Fig. 44-12 Soft tissue recession at tooth 11 observed during the course of active orthodontic treatment.

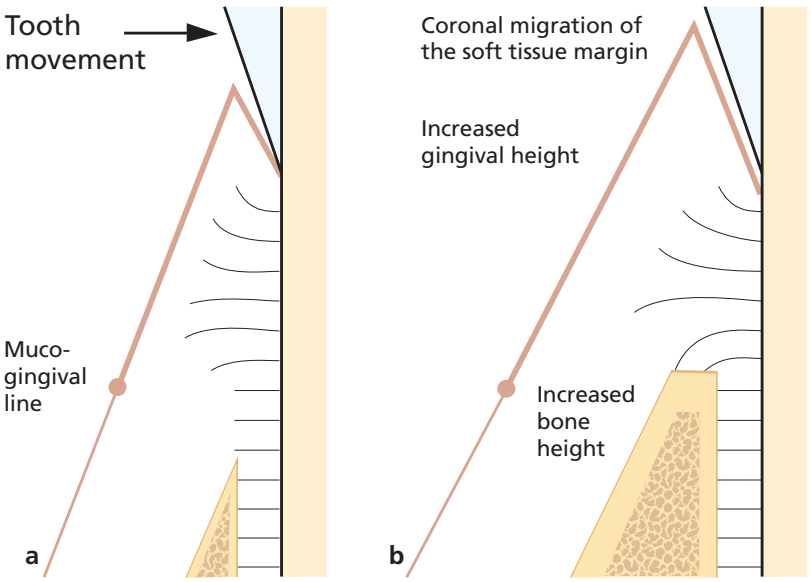

Fig. 44-13 (a) Schematic drawing illustrating alterations occurring in the marginal periodontal tissues following lingual movement of a tooth prominently positioned in the arch and having a bone dehiscence. (b) An increase in bone height and gingival height will be seen as well as a coronal migration of the soft tissue margin following lingual positioning of the tooth.

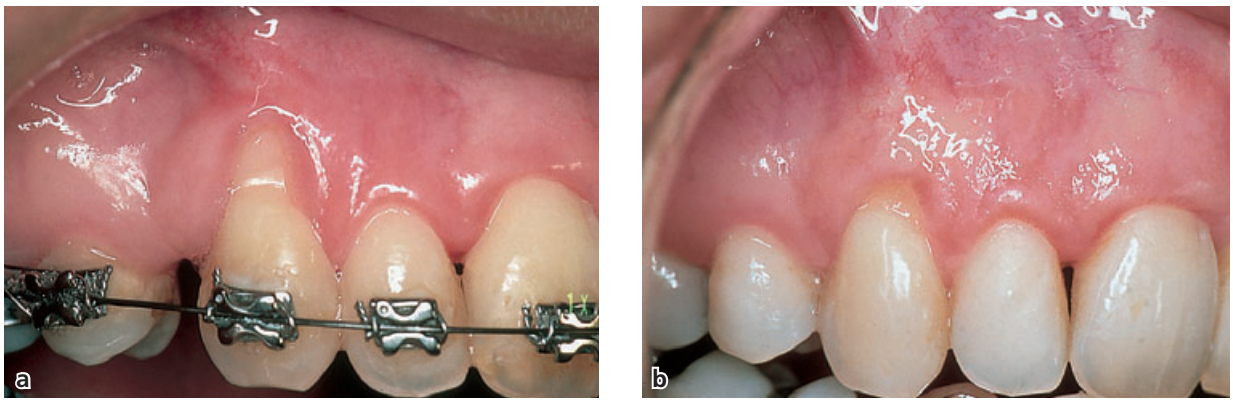

Fig. 44-14 (a) A prominently positioned 13 showing soft tissue recession. (b) The same tooth following the completion of the orthodontic tooth movement. Note the reduction of the recession that has taken place as a consequence of the changed position of the tooth.

sure side, rather than its apico-coronal height, would determine whether or not marginal tissue recession develops during orthodontic therapy.

Support for the hypothesis is obtained from an experimental study in monkeys (Wennström *et al*. 1987) in which teeth were orthodontically moved into areas with varying thickness and quality of the marginal soft tissue. Following extensive bodily movement of incisors in a labial direction through the alveolar bone (Fig. 44-15), most teeth showed a small apical displacement of the soft tissue margin but no loss of connective tissue attachment (Fig. 44-16). In other words, the apical displacement of the gingival margin was the result of a reduced height of the free gingiva (Fig. 44-17), which in turn may be related to tension ("stretching") in the soft tissues during the facial tooth movement and reduced bucco-lingual tissue thickness. Similar to results presented by Foushee *et al*. (1985) from a study in humans, no relationship was found between the initial apico-coronal width (height) of the gingiva and the degree of apical displacement of the soft tissue margin during orthodontic therapy. Thus, the findings do not lend support to the concept of a certain zone of gingiva as essential for the prevention of recession during orthodontic therapy, but rather collaborate observations reported by Coatoam *et al*. (1981) that the integrity of the periodontium can also be maintained during orthodontic therapy in areas which have only a minimal zone of gingiva.

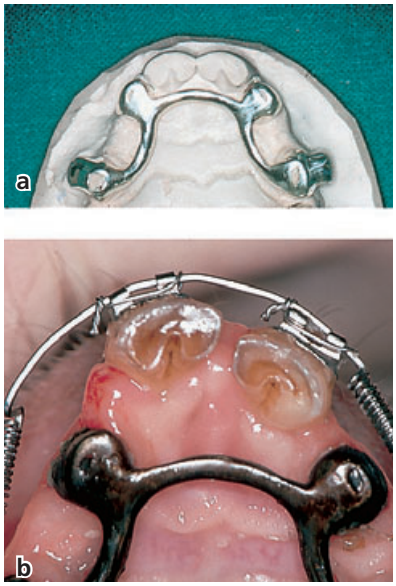

Fig. 44-15 Occlusal view of the maxillary jaw in a monkey showing the position of the central incisors before (a) and after (b) bodily movement in labial direction. The canines and lateral incisors were joined in an individual fabricated silver splint and used as anchorage teeth.

In the experimental studies by Steiner *et al*. (1981) and Wennström *et al*. (1987) it was observed that teeth, which experienced loss of connective tissue attachment when orthodontically moved facially, showed obvious clinical signs of inflammation throughout the experimental period. Since it has been demonstrated that, in presence of plaque-induced suprabony lesions, orthodontic forces generating bodily tooth movement are not capable of causing accelerated destruction of the connective tissue attachment (Ericsson *et al*. 1978), a decreased bucco-lingual dimension of the border tissue due to "stretching" of the facial gingiva may have favored the destructive effect of the plaque-associated inflammatory lesion. This assumption is validated by the observations that, in the presence of plaque-induced gingivitis, a thin marginal soft tissue is more susceptible to complete breakdown than a thick one (Baker & Seymour 1976). Furthermore, no difference in attachment loss was observed at plaque-infected teeth that were bodily moved *within the alveolar bone*, irrespective of the type of bordering soft tissue (gingiva or lining mucosa) (Wennström *et al*. 1987). Hence, the *thickness rather than the quality* of the marginal soft tissue on the pressure side of the tooth may be the determining factor for the development of the recession. The interpretation is supported by findings of recent clinical studies in humans analyzing factors of importance for the development of recessions during labial movement of mandibular incisors. Melsen and Allais (2005) found that gingival inflammation and a "thin gingival

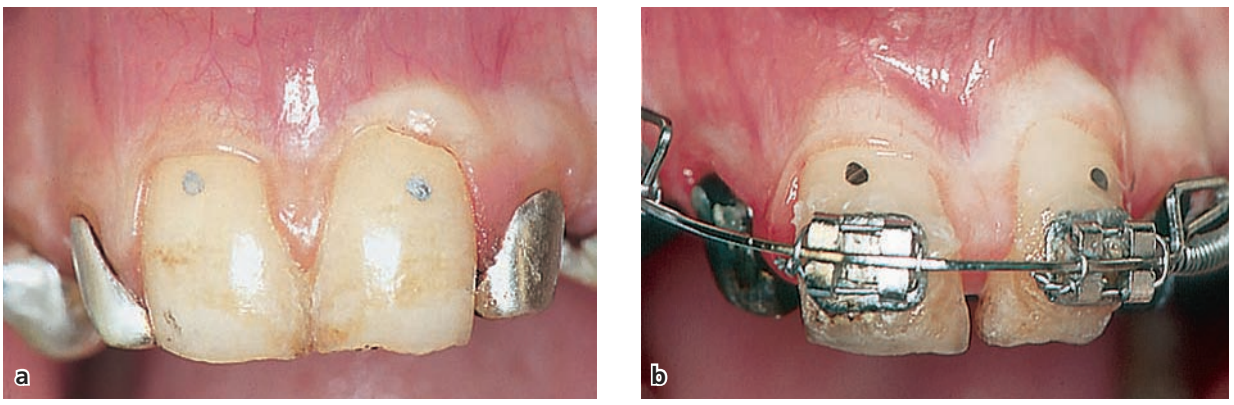

Fig. 44-16 The buccal aspect of the central incisors shown in Fig. 44-15, before (a) and after (b) the labial tooth movement. No obvious change in the location of the gingival margin has occurred despite the pronounced labial displacement of the incisors.

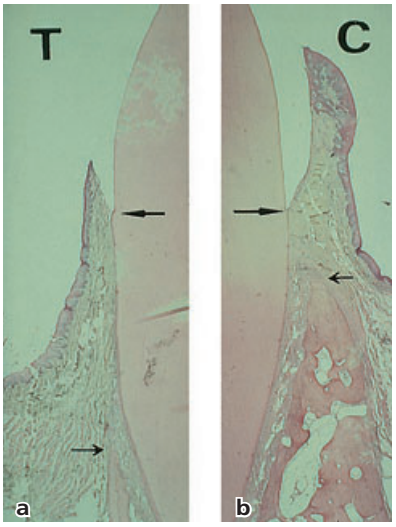

Fig. 44-17 Histologic specimens showing (a) reduced alveolar bone height at an incisor bodily moved in labial direction and (b) normal alveolar bone height at a non-moved control tooth. Note the maintained level of connective tissue attachment and the reduced height of the free gingiva at the labially displaced incisor (a). Large arrows indicate the position of the cemento-enamel junction and small arrows the position of the alveolar bone crest.

biotype" were significant predictors for gingival recession, and Yared *et al*. (2006) reported that 93% of the teeth that developed recession had a gingival thickness less than 0.5 mm. Hence, the observations made in the studies discussed strongly emphasize the importance of adequate infection control during orthodontic treatment.

Conclusion

The clinical implication of the results from the studies discussed is that labial tooth movement should be preceded by careful examination of the dimensions of the tissues covering the facial aspect of the teeth to be moved. As long as the tooth can be moved within the envelope of the alveolar process, the risk of harmful side effects in the marginal tissue is minimal, irrespective of the dimensions and quality of the soft tissue surrounding the tooth. If, however, the tooth movement is expected to result in the establishment of an alveolar bone dehiscence, the volume (thickness) of the covering soft tissue should be considered as a factor that may influence the development of soft tissue recession during, as well as after, the phase of active orthodontic therapy. A thin gingiva may serve as a *locus minorus resistentia* to developing soft tissue defects in the presence of plaque-induced inflammation or toothbrushing trauma.

Gingival dimensions and restorative therapy

The placement of restoration margins subgingivally may not only create a direct operative trauma to the tissues (Donaldson 1974), but may also facilitate subgingival plaque accumulation, with resultant inflammatory alterations in the adjacent gingiva and recession of the soft tissue margin (Parma-Benfenati *et al*. 1985; Lang 1995; Günay *et al*. 2000). Over a 10-year period, Valderhaug (1980) evaluated longitudinally the soft tissue alterations taking place at facial sites of 286 teeth with subgingivally or supragingivally placed crown margins in 82 patients. The re-examination performed 1 year after insertion of the restorations revealed that the gingivae at teeth with subgingival restoration margins were more inflamed than at those with supragingivally placed borders. Of the 150 teeth which had the facial crown margin located subgingivally at the time of cementation, 40% already showed supragingival exposure of the crown margin after 1 year, and at the 10-year examination as many as 71% had become supragingivally positioned due to recession of the soft tissue margin. Compared to teeth with supragingivally placed crown margins the amount of recession and clinical attachment loss was greater at sites with subgingivally placed restoration margins.

Stetler and Bissada (1987) evaluated the periodontal conditions at teeth with subgingivally placed restoration margins on teeth with varying apico-coronal height of gingiva and found that teeth having a narrow (<2 mm) band of gingiva showed more pronounced clinical signs of inflammation than restored teeth with a wide gingival zone, but that there was no difference in loss of probing attachment. However, if subgingivally placed restorations favor plaque accumulation and the adjacent gingiva is thin, there may be a potential risk for the development of soft tissue recession. In fact, an experimental study in the beagle dog (Ericsson & Lindhe 1984), in which metallic strips were inserted subgingivally in areas with varying width of gingiva, showed that in sites with a thin gingival margin, recession was a more likely consequence of the combined tissue trauma caused by the insertion of the strip and subsequent plaque accumulation during a 6-month period than in sites with a broad gingival zone. The authors suggested that the placement of restorations in a subgingival position might favor plaque retention and at sites with a thin gingiva this will lead to loss of tissue height, i.e. an apical displacement of the soft tissue margin. Accordingly, if such an apical displacement as a consequence of plaque-induced inflammation is to be prevented, either the plaque-control standard has to be improved or the *thickness* of the gingival margin has to be increased. However, an increased gingival dimension will not prevent the apical propagation of the plaque-associated lesion and the associated loss of periodontal attachment.

Conclusion

Subgingival placement of the margin of a restoration is likely to result in soft tissue recession over time.

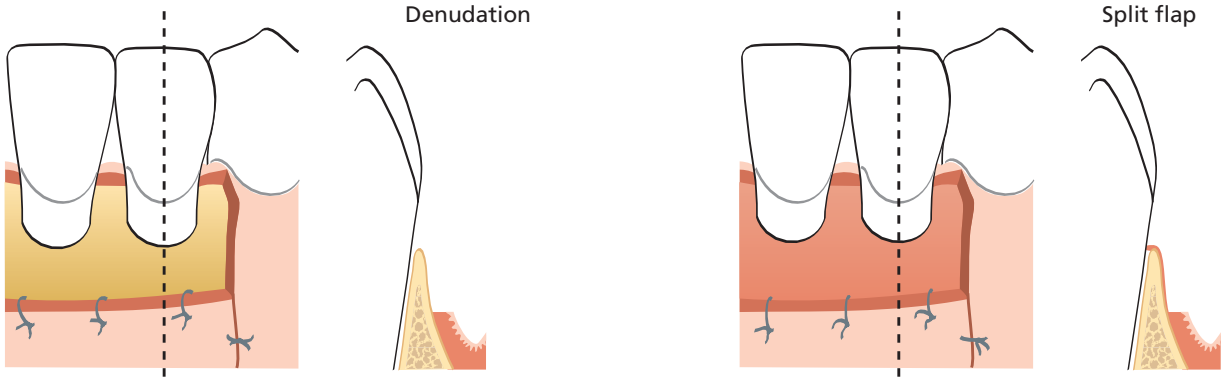

Fig. 44-18 The use of vestibular extension operations for increasing the width of the gingiva involves the production of a wound extending from the gingival margin to a level some millimeters apical to the mucogingival junction. With the "denudation" technique all soft tissue is removed leaving the alveolar bone exposed. With the "split flap" procedure only the superficial portion of the oral mucosa is removed leaving the bone covered with connective tissue.

Experimental and clinical data suggest that the thickness of the marginal gingiva, but not the apico-coronal width of the gingiva, may influence the magnitude of recession taking place as a result of direct mechanical trauma during tooth preparation and bacterial plaque retention.

Indications for gingival augmentation

Scientific data obtained from well controlled clinical and experimental studies have unequivocally demonstrated that the apico-coronal width of gingiva and the presence of an attached portion of gingiva are not of decisive importance for the maintenance of gingival health and the height of the periodontal tissues. Consequently, the presence of a narrow zone of gingiva *per se* cannot justify surgical intervention (Proceedings of the 1st European Workshop on Periodontology 1994; Proceedings of the World Workshop in Periodontics 1996). However, gingival augmentation should be considered in situations where, for example, the patient experiences discomfort during toothbrushing and/or chewing due to an interfering lining mucosa. Furthermore, when orthodontic tooth movement is planned and the final positioning of the tooth can be expected to result in an alveolar bone dehiscence, an increase of the *thickness* of the covering soft tissue may reduce the risk for development of soft tissue recession. An increase of the *thickness* of the gingival margin may also be considered in certain situations when subgingival restorations are placed in areas with a thin marginal tissue.

Gingival augmentation procedures

Gingival augmentation operations comprise a number of surgical techniques, the majority of which have been developed mainly on an empiric basis and without sufficient knowledge about the biology of the involved tissues. The earliest of these techniques are the "vestibular extension operations" which were designed mainly with the objective of extending the depth of the vestibular sulcus (Bohannan 1962a,b). In recent years, however, the use of pedicle or free soft tissue grafts have become the most commonly used techniques in the management of "insufficient" gingival dimensions, because of higher predictability of the healing result.

Vestibular/gingival extension procedures

The "denudation techniques" included the removal of all soft tissue within an area extending from the gingival margin to a level apical to the mucogingival junction leaving the alveolar bone completely exposed (Ochsenbein 1960; Corn 1962; Wilderman 1964) (Fig. 44-18). Healing following this type of treatment resulted often in an increased height of the gingival zone, although in some cases only a very limited effect was observed. However, the exposure of alveolar bone produced severe bone resorption with permanent loss of bone height (Wilderman *et al*. 1961; Costich & Ramfjord 1968). In addition, the recession of marginal gingiva in the surgical area often exceeded the gain of gingiva obtained in the apical portion of the wound (Carranza & Carraro 1963; Carraro *et al*. 1964). Due to these complications and severe postoperative pain for the patient, the use of the "denudation technique" can hardly be justified.

With the "periosteal retention" procedure or "split flap" procedure (Fig. 44-18) only the superficial portion of the oral mucosa within the wound area was removed leaving the bone covered by periosteum (Staffileno *et al*. 1962, 1966; Wilderman 1963; Pfeifer 1965). Although the preservation of the periosteum implies that less severe bone resorption will occur than following the "denudation technique", loss of crestal bone height was also observed following this type of operation unless a relatively thick layer of connective tissue was retained on the bone surface (Costich & Ramfjord 1968). If a thick layer was not secured, the periosteal connective tissue tended to undergo necrosis and the subsequent

healing closely resembled that following the "denudation technique" described above.

Other described gingival extension procedures may be considered as modifications of the "denudation" and "split flap" techniques or combinations of these procedures. The apically repositioned flap procedure (Friedman 1962), for instance, involved the elevation of soft tissue flaps and their displacement during suturing in an apical position, often leaving 3–5 mm of alveolar bone denuded in the coronal part of the surgical area. This resulted in the same risk for extensive bone resorption as other "denudation techniques". It was proposed by Friedman (1962) that a post-surgical increase of the width of the gingiva can be predicted with the "apically repositioned flap", but several studies indicated that the presurgical width most often was retained or became only slightly increased (Donnenfeld *et al*. 1964; Carranza & Carraro 1970).

The vestibular/gingival extension procedures referred to were based on the assumption that it is the frictional forces encountered during mastication that determines the presence of a keratinized tissue adjacent to the teeth (Orban 1957; Pfeifer 1963). Therefore, it was believed that by the displacement of muscle attachments and the extension of vestibular depth, the regenerating tissue in the surgical area would be subjected to physical impacts and adapt to the same functional requirements as those met by "normal" gingiva (Ivancie 1957; Bradley *et al*. 1959; Pfeifer 1963). Later studies, however, showed that the characteristic features of the gingiva are determined by some inherent factors in the tissue rather than being the result of functional adaptation and that the differentiation (keratinization) of the gingival epithelium is controlled by morphogenetic stimuli from the underlying connective tissue (see Chapter 1).

Grafting procedures

The gingival and palatal soft tissues will maintain their original characteristics after transplantation to areas of the alveolar mucosa (see Chapter 1). Hence, the use of transplants offers the potential to predict the post-surgical result. The type of transplants used can be divided into (1) pedicle grafts, which maintain their connection with the donor site after placement at the recipient site (Fig. 44-19), and (2) free grafts that are completely deprived of their connection with the donor area (Fig. 44-20). For gingival augmentation free grafts have been used most commonly (Haggerty 1966; Nabers 1966; Sullivan & Atkins 1968a; Hawley & Staffileno 1970; Edel 1974). Acellular freeze-dried dermal matrix (ADM) allografts may be utilized

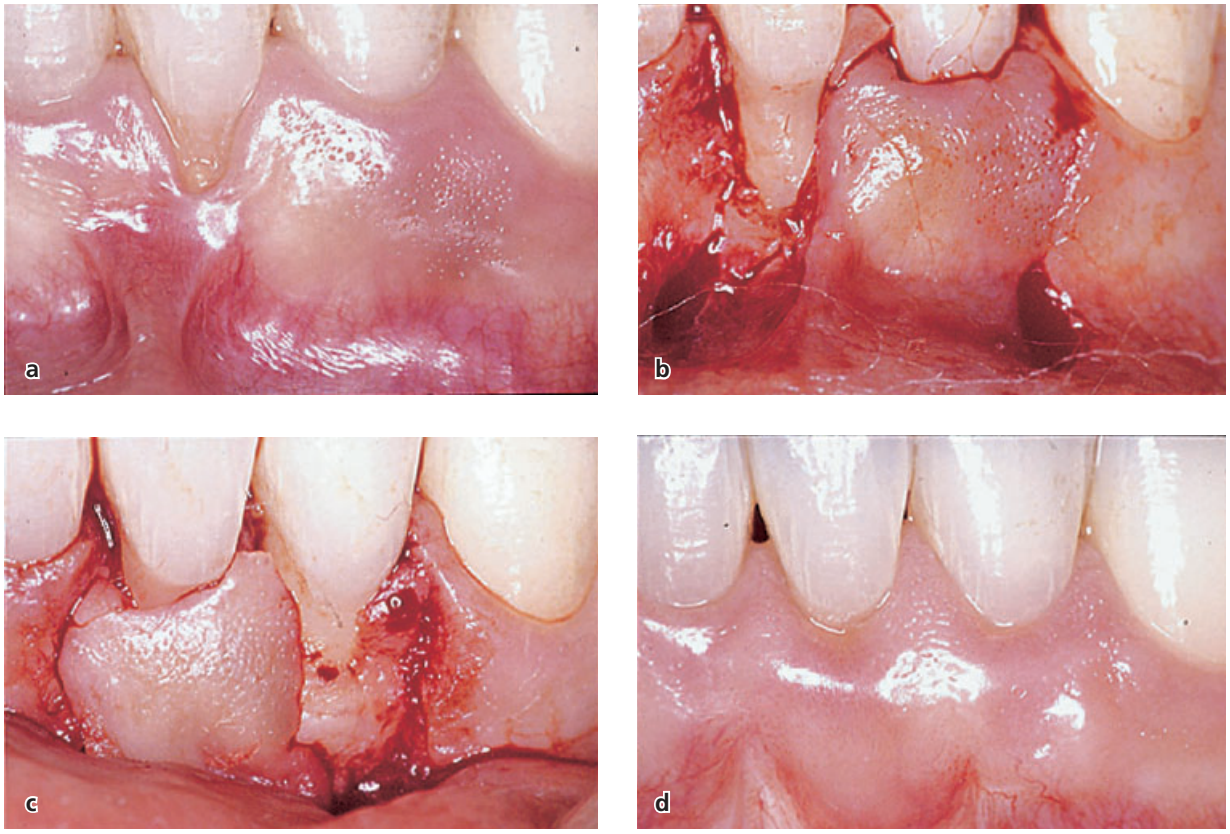

Fig. 44-19 Pedicle graft procedure for gingival augmentation. (a) A lower central incisor with facial soft tissue recession associated with high attachment of a frenulum. (b) The frenulum is released and a split flap of keratinized tissue is dissected from the area of the neighboring tooth. (c) The mobilized soft tissue flap is laterally moved and secured in position at the recipient site. (d) The healing result 1 year post-treatment shows the establishment of a broad zone of keratinized tissue without interfering frenulum.

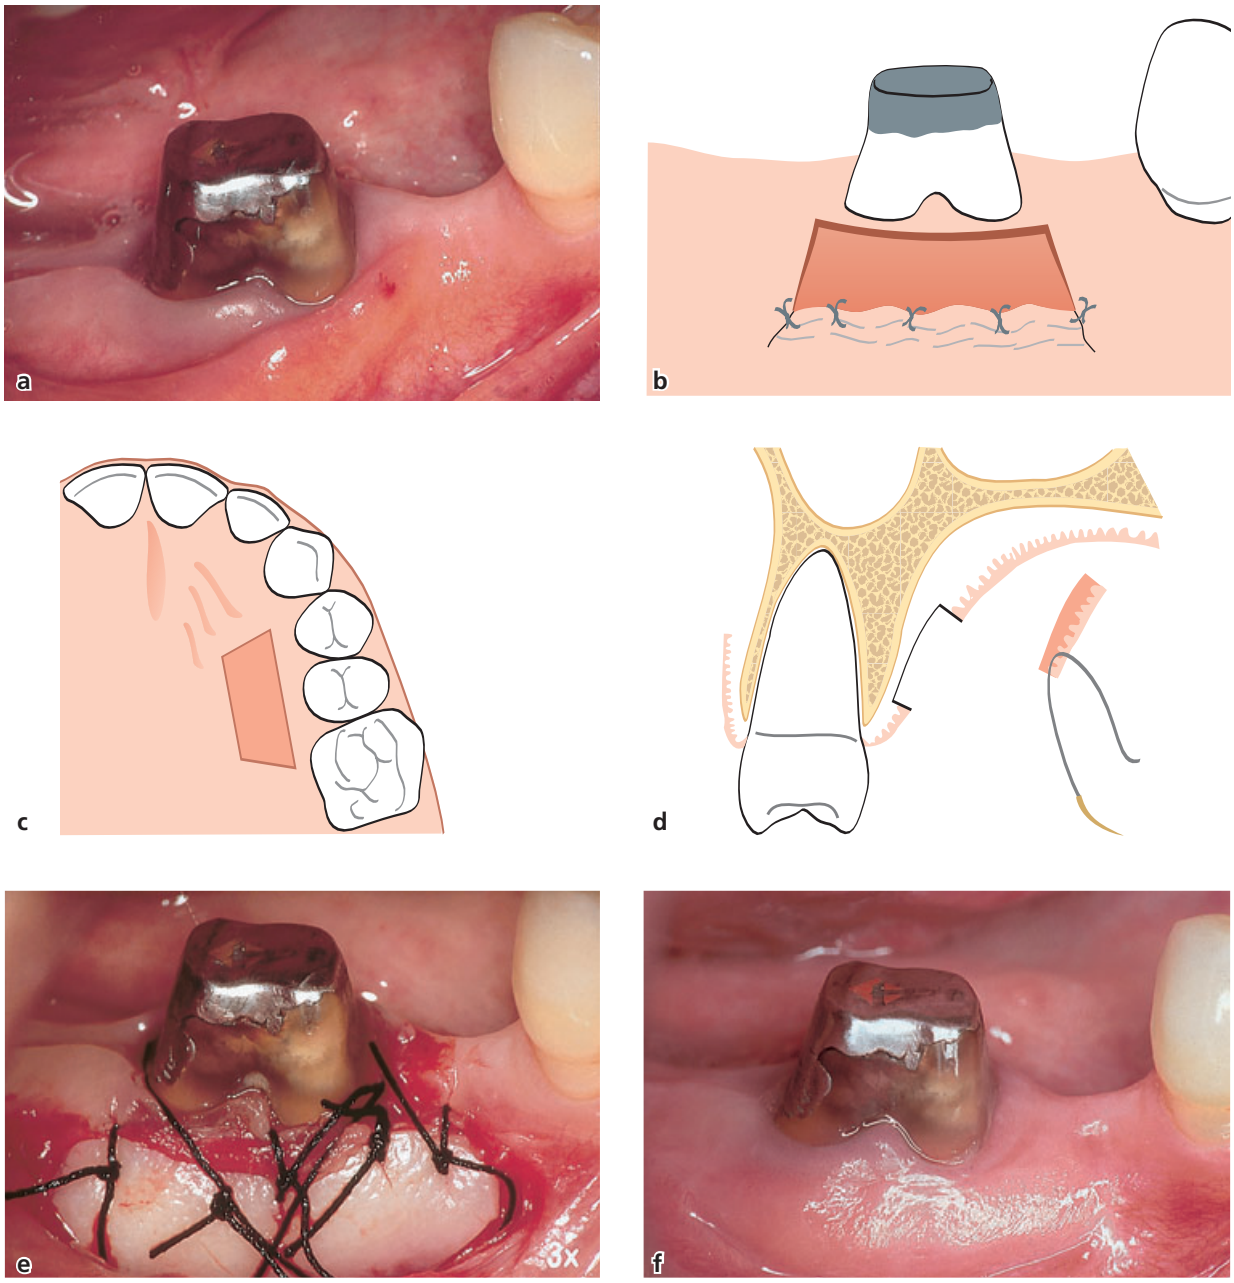

Fig. 44-20 Grafting procedure for gingival augmentation. (a) A lower molar at which the patient experiences discomfort during toothbrushing due to interfering lining mucosa and high attachment of a frenulum. Decision was made to displace the attachment of the frenulum apically and augment the gingival zone through the placement of a free graft. (b) A partial-thickness flap is dissected to prepare a recipient bed. The flap is displaced apically and sutured. (c,d) A graft with a thickness of 1.5–2 mm and of sufficient size and contour (a foil template of the recipient site may be used) is dissected from the palatal mucosa in the region of the premolars. (e) The graft is immediately transferred to the prepared recipient bed and anchored by sutures to secure a close adaptation of the graft to the recipient bed. (f) A periodontal dressing is applied to protect the graft. Following healing a broad zone of keratinized tissue has been established.

as an alternative to the use of an autogenous mucosal graft from the palate (Wei *et al*. 2000; Harris 2001), but the increase in the width of keratinized tissue following the use of these grafts may not be as predictable as with the use of autogenous grafts.

Technique

- The surgical procedure is initiated with the preparation of the recipient site (Fig. 44-20a-b). A periosteal bed free from muscle attachment and of sufficient size is prepared by sharp dissection. The partial-thickness flap is displaced apically and sutured.
- In order to ensure that a graft of sufficient size and proper contour is removed from the donor area, usually the palatal mucosa in the region of the premolars, it is recommended to produce a foil template over the recipient site. The template is transferred to the donor site where it is outlined by a shallow incision (Fig. 44-20c). A graft with a thickness of approximately 1.5–2 mm is then dissected from the donor area (Fig. 44-20d). It is

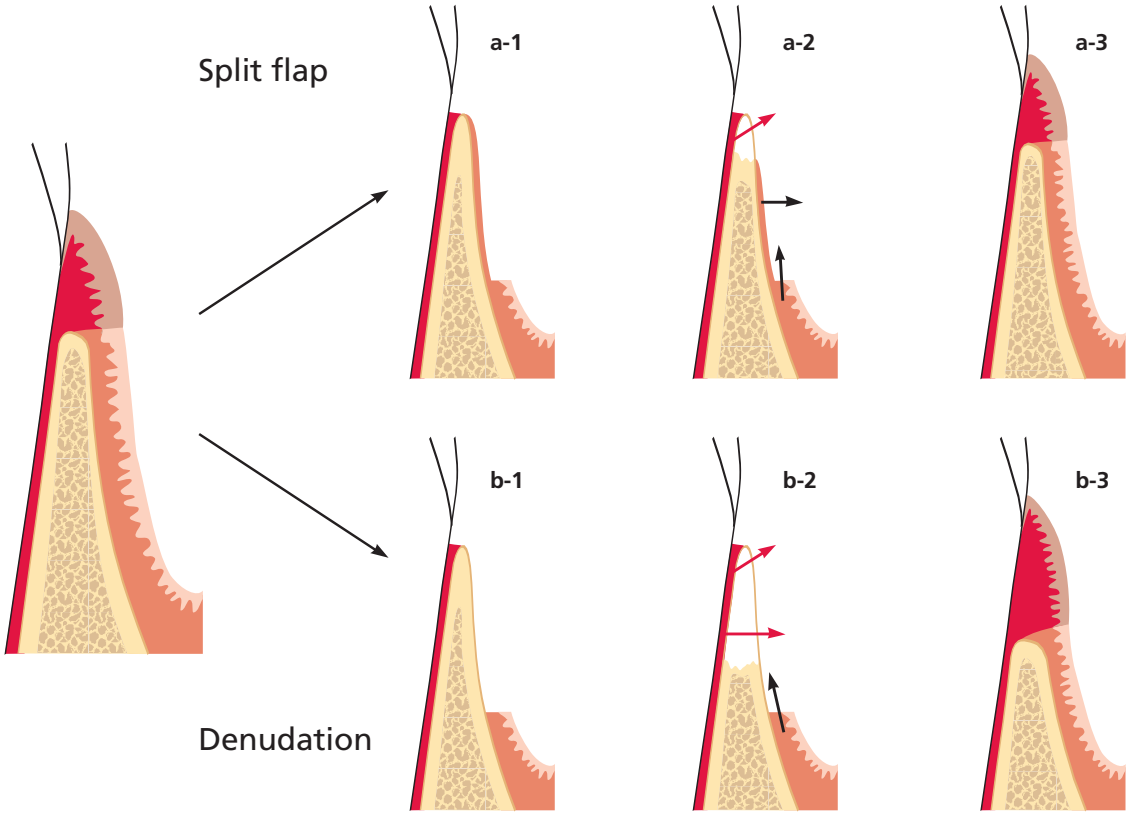

Fig. 44-21 Schematic drawing illustrating different stages of healing following the "split-flap" (a) and "denudation" (b) techniques. Cells from the oral mucosa, bone, and periodontal ligament (arrows) participate in granulation tissue formation. Due to the difference in the degree of bone resorption (a-2, b-2), a larger area of the coronal portion of the wound is filled with granulation tissue from the periodontal ligament following "denudation" than following the "split-flap" technique. Since granulation tissue from the periodontal ligament possesses the ability to induce a keratinized epithelium, "denudation" usually results in a wider zone of keratinized tissue than is the case following the "split-flap" technique (a-3, b-3).

advocated to place the sutures in the graft before it is cut completely free from the donor area since this may facilitate its transfer to the recipient site.

- The graft is immediately transferred to the prepared recipient bed and sutured (Fig. 44-20e). In order to immobilize the graft at the recipient site the sutures must be placed in the periosteum or the adjacent attached gingiva. After suturing, pressure is exerted against the graft for 5 minutes in order to eliminate blood and exudate from between the graft and the recipient bed. The graft and the palatal wound are protected with a periodontal dressing. To retain the dressing in the palatal site, a stent usually has to be used.
- The sutures and periodontal dressing are removed after 1–2 weeks.

For description of the pedicle graft procedure, see "Root coverage procedures".

Healing following gingival augmentation procedures

Vestibular/gingival extension procedures

Since the specificity of the gingiva is determined by some inherent factor in the tissues, the post-operative results of vestibular extension procedures depend on the degree to which the various tissues contribute to the formation of granulation tissue in the wound area (Karring *et al*. 1975). Following the "denudation" or "split flap technique", the wound area is filled with granulation tissue derived from the periodontal ligament, the tissue of the bone marrow spaces, the retained periosteal connective tissue, and the surrounding gingiva and lining mucosa (Fig. 44-21). The degree of bone resorption induced by the surgical trauma influences the relative amount of granulation tissue that grows into the wound from these various tissue sources. The resorption of crestal bone exposes varying amounts of the periodontal ligament tissue in the marginal area allowing granulation tissue from the periodontal ligament to fill out the coronal portion of the wound. The greater the bone loss, the greater is the portion of the wound that becomes filled with granulation tissue from the periodontal ligament. This particular tissue possesses the capability to induce keratinization of the covering epithelium. This means that the widening of the keratinized tissue following "denudation" and "split flap" operations is achieved at the expense of a reduced bone height. The "denudation technique" usually results in more bone loss than the "split flap technique". Therefore, a greater amount of granulation tissue

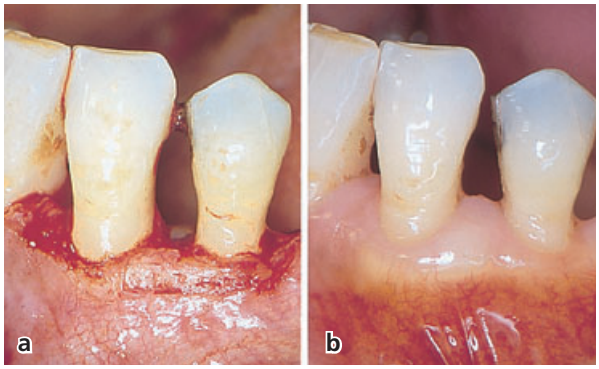

Fig. 44-22 (a) Clinical photograph of the buccal aspect of a canine and a premolar following the removal of the entire zone of gingiva by a gingivectomy procedure. (b) The healing result 9 months after surgery shows the regain of keratinized tissue.

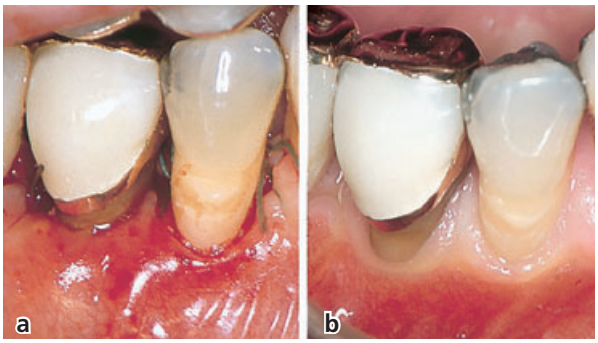

Fig. 44-23 Clinical photographs of a tooth region subjected to excision of the entire zone of gingiva by a flap procedure. (a) The alveolar mucosa has been displaced coronally to achieve complete coverage of the surgically exposed alveolar bone. (b) Healing has resulted in the reformation of a narrow zone of gingiva on the buccal aspect of the teeth, 9 months post surgery.

with the capability of inducing a keratinized epithelium develops in the marginal area following the "denudation technique" than following the "split flap technique". This is in accordance with the clinical observation that the "denudation technique" usually is superior to the "split flap technique" in increasing the width of keratinized tissue (Bohannan 1962a,b).

In a clinical study by Wennström (1983) periodontal pockets were eliminated by the use of a "gingivectomy" or a "flap" procedure which both involved the complete removal of the keratinized tissue. In the "gingivectomy" procedure the wounded area was left to heal by second intention, while in the "flap" procedure the alveolar mucosa was repositioned to achieve complete coverage of the surgically exposed alveolar bone (Figs. 44-22a and 44-23a). Irrespective of the surgical technique used, healing resulted in the reformation of keratinized tissue, the width of which, however, was greater following the "gingivectomy" procedure than following the "flap" procedure (Figs. 44-22b and 44-23b). The gingiva was formed because granulation tissue from the periodontal ligament, with the capacity of inducing a keratinized epithelium, had proliferated coronally along the root surface. This granulation tissue formation was obviously favored by a more pronounced bone resorption during the healing following the "gingivectomy" procedure.

It can be concluded that the success or failure in extending the width of keratinized tissue by the "denudation" or "split flap" techniques rests with the origin of granulation tissue, which is related to the extent of bone loss induced by the surgical trauma. This in turn means that the result with respect to increasing the gingival width by methods involving periosteal exposure or denudation of the alveolar bone is unpredictable. The use of such methods is therefore not justified in periodontal therapy. The procedures discussed merely represent examples on how lack of knowledge about basic biologic principles may lead to the development of inappropriate therapeutic methods.

Grafting procedures

Healing of free soft tissue grafts placed entirely on a connective tissue recipient bed were studied in monkeys by Oliver *et al*. (1968) and Nobuto *et al*. (1988). According to these authors healing can be divided into three phases (Fig. 44-24):

1. *The initial phase (from 0–3 days)*. During these first days of healing a thin layer of exudate is present between the graft and the recipient bed. During this period the grafted tissue survives with an avascular "plasmatic circulation" from the recipient bed. Therefore, it is essential for the survival of the graft that a close contact is established to the underlying recipient bed at the time of operation. A thick layer of exudate or a blood clot may hamper the "plasmatic circulation" and result in rejection of the graft. The epithelium of the free graft degenerates early in the initial healing phase, and subsequently it becomes desquamated. In placing a graft over a recession, part of the recipient bed will be the avascular root surface. Since the graft is dependent on the nature of its bed for diffusion of plasma and subsequent revascularization, the utilization of free grafts in the treatment of gingival recessions involves a great risk of failure. The area of the graft over the avascular root surface must receive nutrients from the connective tissue bed that surrounds the recession. Thus, the amount of tissue that can be maintained over the root surface is limited by the size of the avascular area.
2. *Revascularization phase (from 2–11 days)*. After 4–5 days of healing, anastomoses are established between the blood vessels of the recipient bed and those in the grafted tissue. Thus, the circulation of blood is re-established in the pre-existing blood vessels of the graft. The subsequent time period is

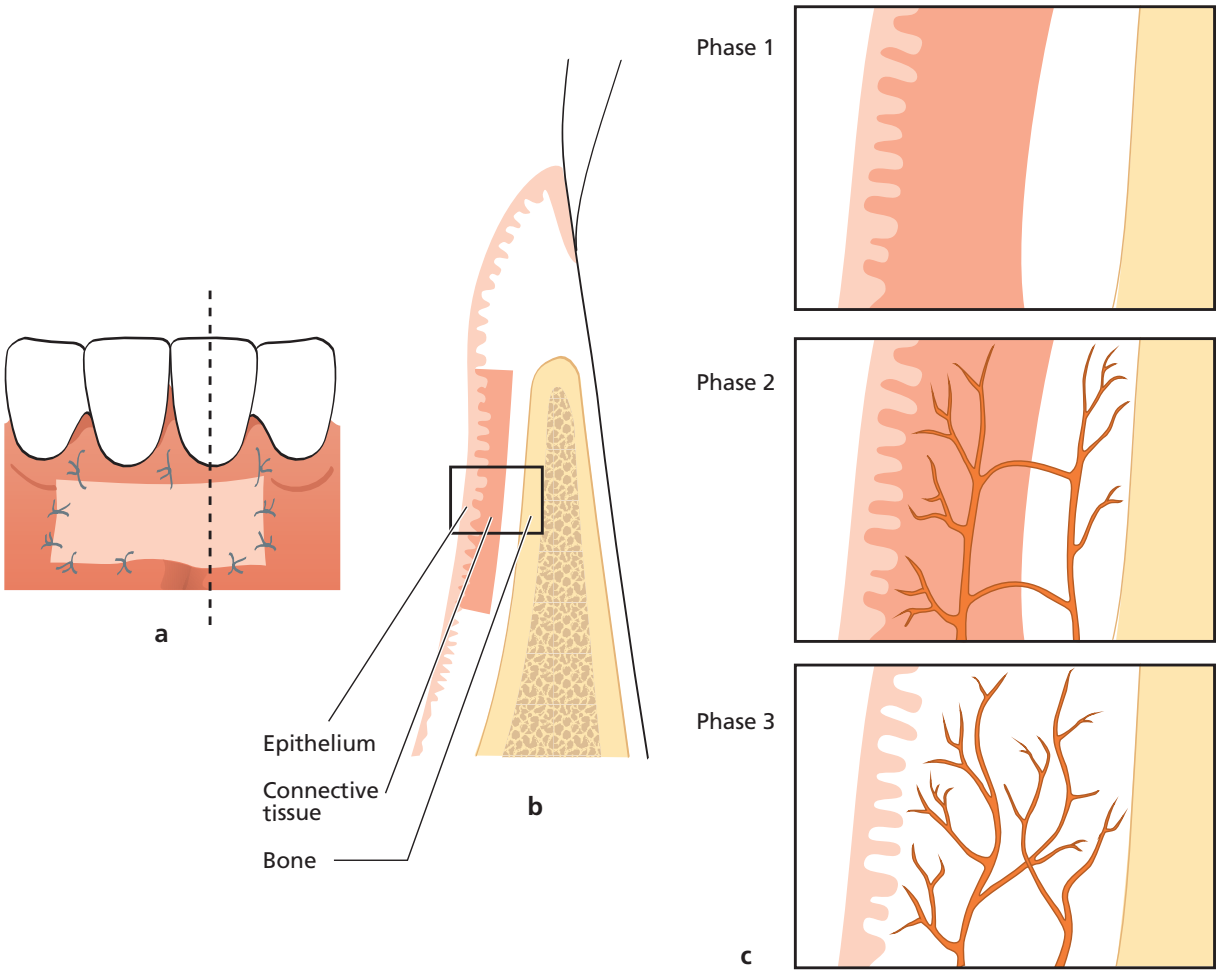

Fig. 44-24 Schematic drawings illustrating healing of a free gingival graft placed entirely on a connective tissue recipient bed (a). A cross-section through the area is shown in (b). The framed areas (c) illustrate the three phases into which the healing process can be divided.

characterized by capillary proliferation, which gradually results in a dense network of blood vessels in the graft. At the same time a fibrous union is established between the graft and the underlying connective tissue bed. The re-epithelialization of the graft occurs mainly by proliferation of epithelium from the adjacent tissues. If a free graft is placed over the denuded root surface, apical migration of epithelium along the tooth-facing surface of the graft may take place at this stage of healing.

3. *Tissue maturation phase (from 11–42 days).* During this period the number of blood vessels in the transplant becomes gradually reduced, and after approximately 14 days the vascular system of the graft appears normal. Also, the epithelium gradually matures with the formation of a keratin layer during this stage of healing.

The establishment and maintenance of a "plasmatic circulation" between the recipient bed and the graft during the initial phase of healing is critical for the result of this kind of therapy. Therefore, in order to ensure ideal conditions for healing, blood between the graft and the recipient site must be removed by exerting pressure against the graft following suturing.

Root coverage

The main indications for root coverage procedures are esthetic/cosmetic demands (Fig. 44-25) and root sensitivity. Changing the topography of the marginal soft tissue in order to facilitate plaque control is also a common indication for root coverage procedures (Fig. 44-26).

It should be recalled that the two major causative factors in the development of marginal tissue recession are trauma caused by toothbrushing and plaque-induced periodontal inflammation. The control of these factors will prevent further progression of the recession in most cases. This means that in tooth regions with a thin covering soft tissue, with or without an incipient recession, the patient should be encouraged to carry out effective but at the same time non-traumatic plaque-control measures. With respect to toothbrushing, the Bass method (Chapter 35) should be avoided and the patient should be

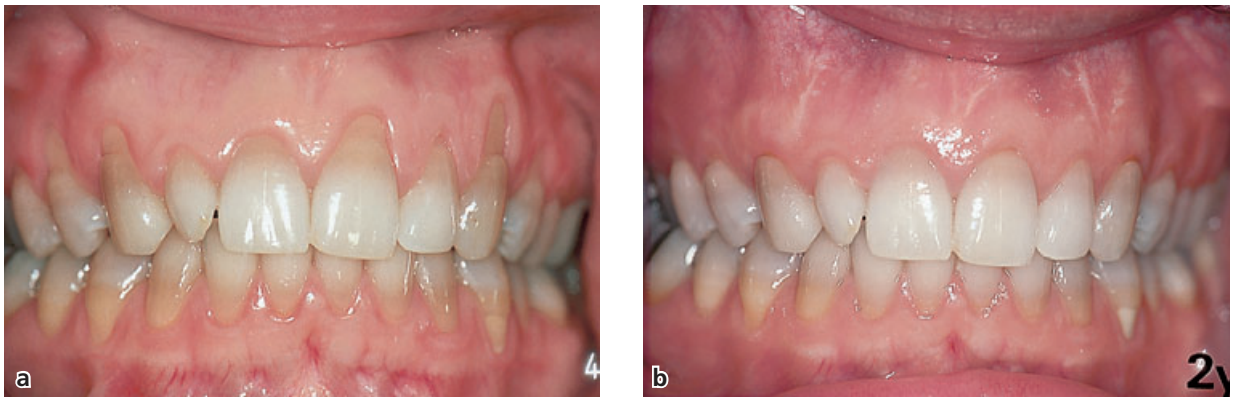

Fig. 44-25 (a) A 25-year-old woman with esthetic concerns due to multiple soft tissue recessions in the maxilla and a high lip line. The gingiva is healthy and several of the exposed root surfaces show abrasion defects, indicating toothbrushing trauma as the causative factor for the development of the recessions. The brushing technique was altered and root coverage was achieved surgically. (b) The 2-year post-treatment view.

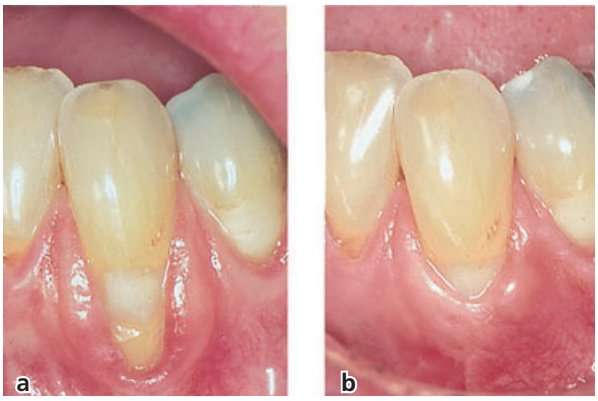

Fig. 44-26 (a) A mandibular canine with a deep recession, which offers problems with respect to self-performed plaque control. (b) To facilitate plaque control the position of the soft tissue margin was altered surgically.

instructed to use a technique creating as little apically directed pressure on the soft tissue margin as possible. A soft toothbrush should, of course, be used.

Miller (1985a) described a useful classification of recession defects taking into consideration the anticipated root coverage that is possible to obtain (Fig. 44-27):

- Class I: marginal tissue recession not extending to the mucogingival junction. No loss of interdental bone or soft tissue.
- Class II: marginal tissue recession extends to or beyond the mucogingival junction. No loss of interdental bone or soft tissue.
- Class III: marginal tissue recession extends to or beyond the mucogingival junction. Loss of interdental bone or soft tissue is apical to the CEJ, but coronal to the apical extent of the marginal tissue recession.
- Class IV: marginal tissue recession extends beyond the mucogingival junction. Loss of interdental bone extends to a level apical to the extent of the marginal tissue recession.

While complete root coverage can be achieved in class I and II defects, only partial coverage may be expected in class III. Class IV recession defects are not amenable to root coverage. Consequently, the critical clinical variable to assess in order to determine the possible outcome of a root coverage procedure is the level of periodontal tissue support at the proximal surfaces of the tooth.

Recession defects in the child need particular attention. In the growing child recession defects may be eliminated spontaneously, provided adequate plaque control is established and maintained (Fig. 44-28). Andlin-Sobocki *et al*. (1991) reported from a 3-year prospective study that 25 out of 35 recession defects with an initial depth of 0.5–3.0 mm healed spontaneously following improvement of the oral hygiene standard. Furthermore, all but three remaining recessions showed a decrease and no site demonstrated an increase in depth. Hence, reparative surgical treatment of soft tissue recessions in the developing dentition may not be necessary and should preferably be postponed until the growth is completed.

In an orthodontic case showing a recession defect and a thin (delicate) gingiva associated with a prominent, facially positioned tooth (Fig. 44-29a), surgical treatment for root coverage should be postponed until the orthodontic therapy is completed. The recession, as well as the dehiscence, will decrease as a consequence of the lingual movement of the tooth into a more proper position within the alveolar bone (Fig. 44-29b), and, if still indicated, the root coverage procedure will show higher predictability if performed after rather than before the tooth movement.

Root coverage procedures

Surgical procedures used in the treatment of recession defects may basically be classified as (1) *pedicle soft tissue graft procedures* and (2) *free soft tissue graft procedures*.

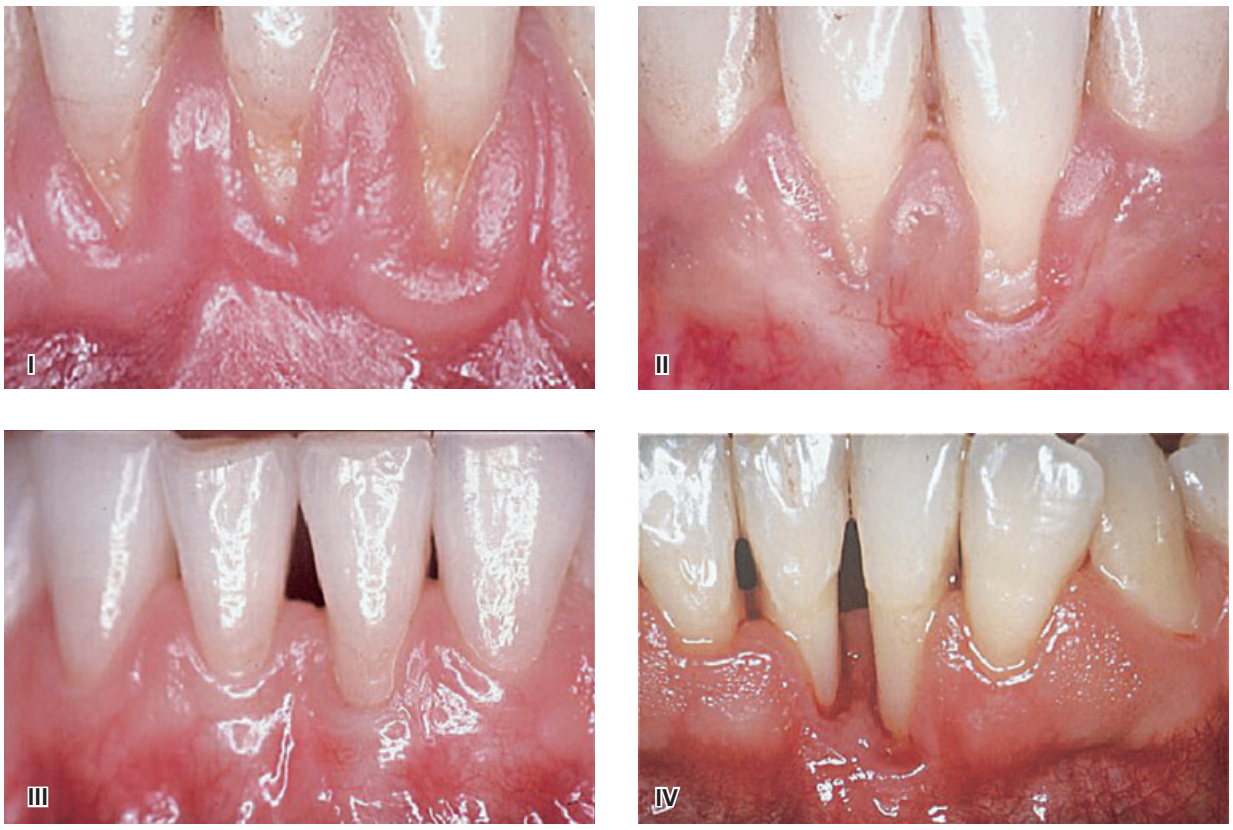

Fig. 44-27 The Miller classification of recession defects (see text).

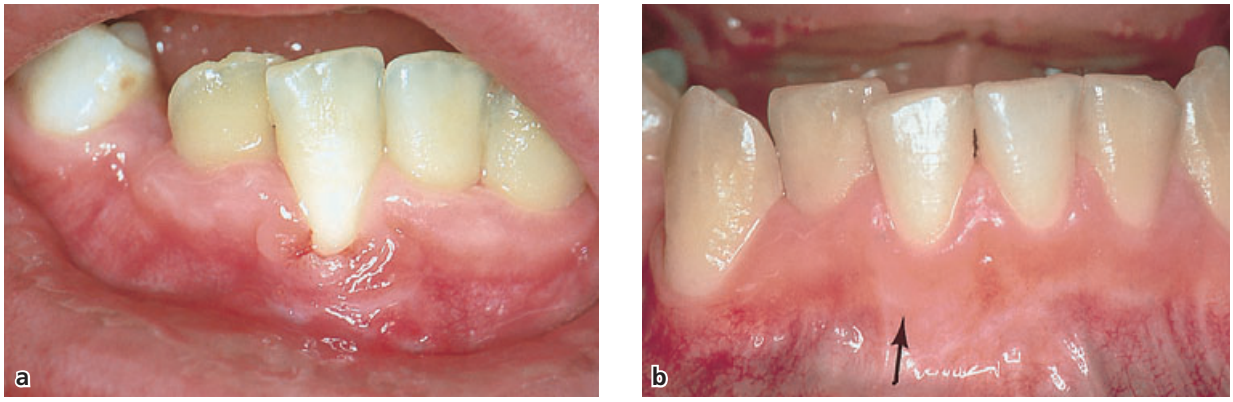

Fig. 44-28 A 9-year-old boy showing recession at tooth 41. (a) The tooth is rotated and buccally positioned. The minimal amount of gingiva found apical to the recession shows pronounced signs of inflammation. The plaque control in the region was improved but surgical intervention was postponed. (b) The same tooth area at the age of 14 years. Note the spontaneous soft tissue repair that has taken place at tooth 41 as a consequence of the improved plaque control and the growth in the alveolar process.

The pedicle graft procedures are, depending on the direction of transfer, grouped as (1) *rotational flap procedures* (e.g. laterally sliding flap, double papilla flap, oblique rotated flap) or (2) *advanced flap procedures* (e.g. coronally repositioned flap, semilunar coronally repositioned flap). The latter procedures do not include rotation or lateral movement of the pedicle graft. Regenerative procedures are also included within the group of pedicle graft procedures, i.e. rotational and advanced flap procedures involving the placement of a barrier membrane between the graft and the root or the application of enamel matrix proteins.

The autogenous free soft tissue graft procedure may be performed as (1) an epithelialized graft or as (2) a subepithelial connective tissue graft (non-epithelialized graft), both usually taken from the area of the masticatory mucosa in the palate.

Factors, such as depth and width of recession, availability of donor tissue, presence of muscle

Fig. 44-29 Spontaneous repair of soft tissue recessions following orthodontic tooth movement. (a) A 22-year-old woman showing recessions and thin marginal tissues at prominently positioned teeth, particularly 23, 33, 41, and 43. (b) Following proper alignment of the teeth, the recessions have spontaneously been resolved and an increased gingival height can be noted.

Fig. 44-30 (a) A canine showing pronounced recession and a composite resin restoration in the exposed root. Following removal of the restoration the exposed root was surgically covered with soft tissue (pedicle graft). (b) 2-year post-operative healing result.

attachments, and esthetics, have to be taken into consideration in the selection of treatment procedure.

Treatment of the exposed root surface

Before root coverage is attempted the exposed portion of the root should be rendered free from bacterial plaque. Preferably, this is achieved by the use of a rubber cup and a polishing paste. Controlled clinical trials have shown no differences in terms of root coverage or residual probing depth between teeth that had been instrumented (root planed) or polished only (Oles *et al*. 1988; Pini Prato *et al*. 1999). Extensive root planing may therefore only be performed in situations where a reduced root prominence would be considered beneficial for graft survival or tissue regeneration, or if a shallow root caries lesion is diagnosed. The presence of a filling in the root does not preclude the possibility for root coverage (Fig. 44-30), but the filling should be removed before the root is covered with soft tissue.

The use of root surface demineralization agents has been advocated as important not only for the removal of the smear layer, but also to facilitate the formation of a new fibrous attachment through exposure of collagen fibrils of the dentine matrix and to allow subsequent interdigitation of these fibrils with those in the covering connective tissue. However, controlled clinical trials comparing the clinical outcome of root coverage procedures with and without root conditioning (Ibbott *et al*. 1985; Oles *et al*. 1985; Bertrand & Dunlap 1988; Laney *et al*. 1992; Bouchard *et al*. 1997; Caffesse *et al*. 2000) failed to demonstrate a beneficial effect from the use of acid root biomodification. Gottlow *et al*. (1986) evaluated the healing following treatment of localized gingival recessions with coronally positioned flaps and citric acid root biomodification in a controlled study in dogs. Histologic analysis after 3 months of healing disclosed no differences in the amount of root coverage or new connective tissue attachment between citric acid-treated sites and saline-treated control sites. Although root resorption was a common finding among the citric acid-treated teeth in this dog model, such a finding has not been reported to be common in humans. In conclusion, the literature clearly indicates that the inclusion of root conditioning does not improve the healing outcome of root coverage procedures.

Pedicle soft tissue graft procedures

Rotational flap procedures

The use of a laterally repositioned flap to cover areas with localized recession was introduced by Grupe and Warren (1956). This technique, which was called *the laterally sliding flap* operation, involved the reflection of a full-thickness flap in a donor area adjacent to the defect and the subsequent lateral displacement of this flap to cover the exposed root surface (Fig. 44-19). In order to reduce the risk for recession on the donor tooth, Grupe (1966) suggested that the marginal soft tissue should not be included in the flap. Staffileno (1964) and Pfeifer and Heller (1971) advocated the use of a split-thickness flap to minimize the potential risk for development of dehiscence at the donor tooth. Other modifications of the procedure presented are *the double papilla flap* (Fig. 44-31) (Cohen & Ross 1968), *the oblique rotational flap* (Pennel *et al*. 1965), *the rotation flap* (Patur 1977), and *the transpositioned flap* (Bahat *et al*. 1990).

The technique is as follows:

- The rotational flap procedure (Fig. 44-32) is initiated with the preparation of the recipient site. A reverse bevel incision is made all along the soft tissue margin of the defect (Fig. 44-32a). After removal of the dissected pocket epithelium, the exposed root surface is thoroughly curetted.
- At a distance of approximately 3 mm from the wound edge, which delineates the defect at the side opposite the donor area, a superficial incision is performed extending from the gingival margin to a level approximately 3 mm apical to the defect (Fig. 44-32b). Another superficial incision is placed horizontally from this incision to the opposite wound edge. The epithelium together with the outer portion of the connective tissue within the area delineated by these incisions and the wound edges is removed by sharp dissection (Fig. 44-32c). In this way a 3 mm wide recipient bed is created at the one side of the defect, as well as apical to the defect.
- A tissue flap to cover the recession is then dissected in the adjacent donor area. The preparation of this flap is initiated by a vertical superficial incision placed parallel to the wound edge of the recession and at a distance that exceeds the width of the recipient bed and the exposed root surface by approximately 3 mm (Fig. 44-32c). This incision is extended beyond the apical level of the recipient bed and is terminated within the lining mucosa with an oblique releasing incision directed towards the recession site. An incision connecting the vertical incision and the incision previously made around the recession is placed approximately 3 mm apical to the gingival margin of the donor site.

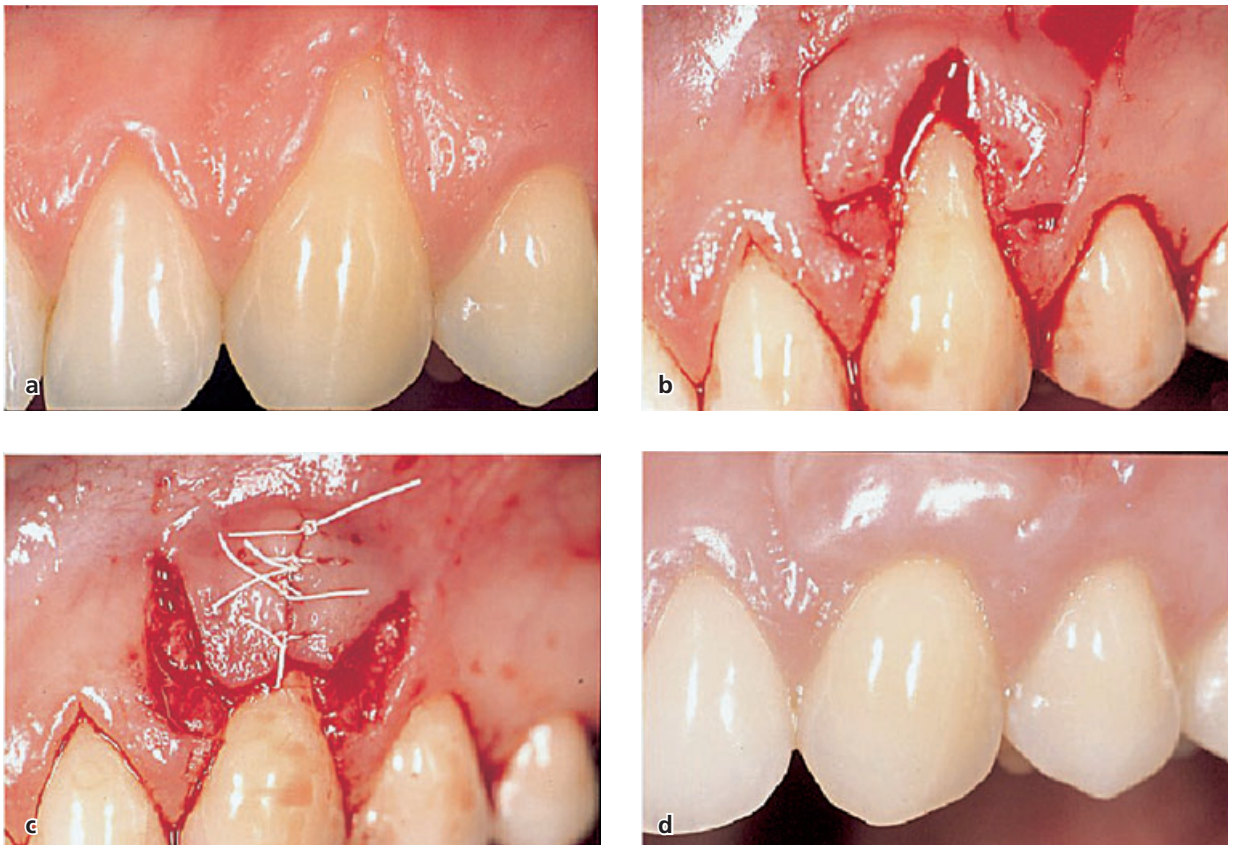

Fig. 44-31 Double papilla flap procedure. (a) Pre-treatment view of a maxillary canine with facial soft tissue recession. Using split incisions, soft tissue flaps are mobilized from both sides of the recession (b) and sutured together for coverage of the exposed root (c). The healing result 6-month post-operatively shows complete root coverage (d).

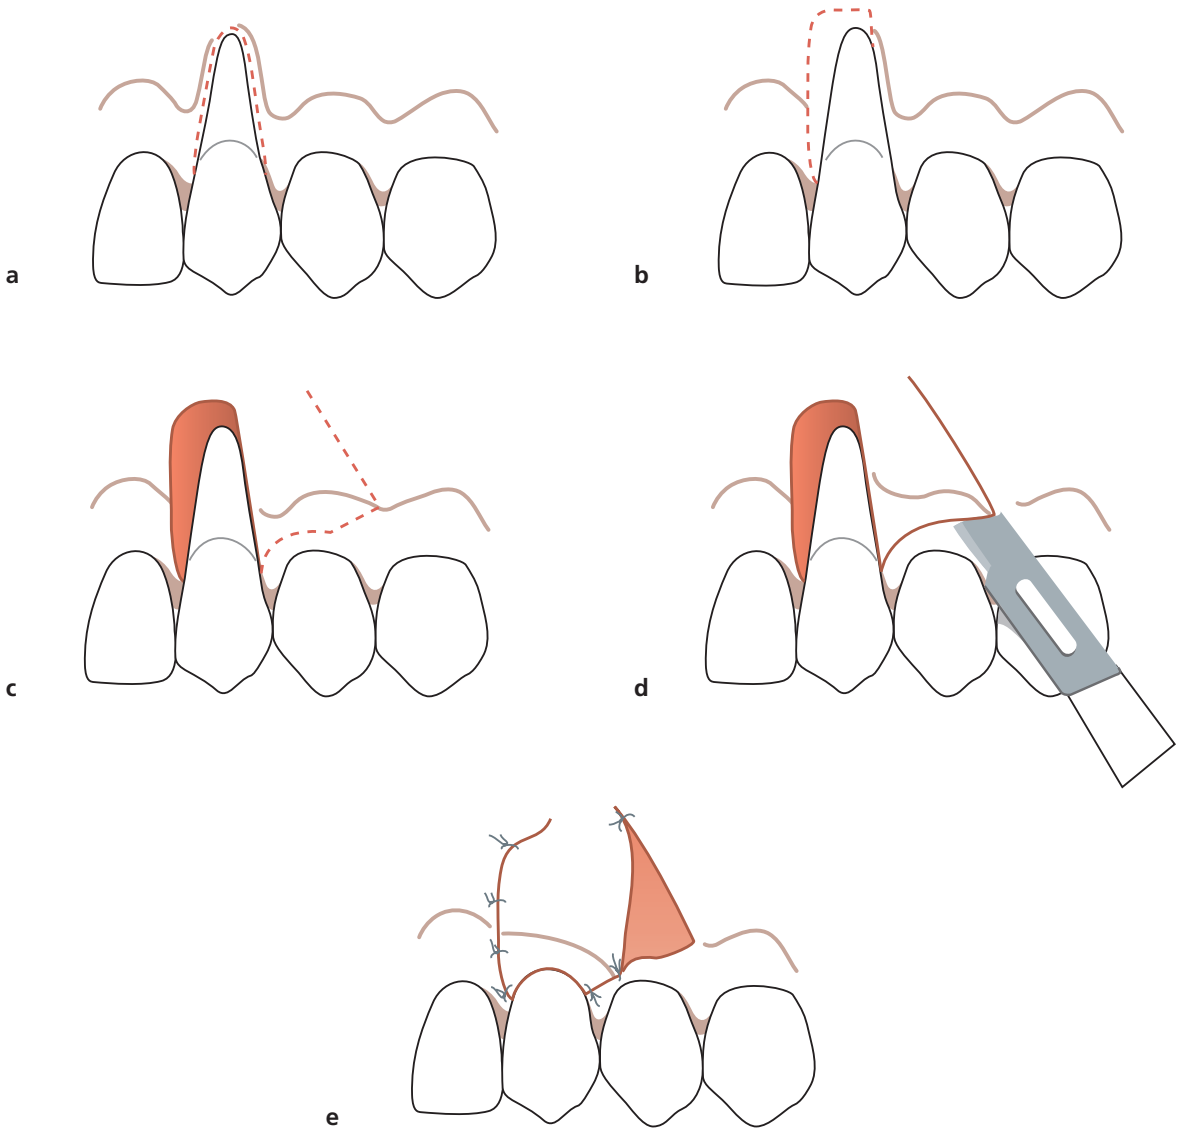

Fig. 44-32 Rotational flap procedure. Schematic drawings illustrating the surgical technique in utilizing rotational pedicle grafts to cover localized recession defects (see the text for explanation).

- A split-thickness flap is then prepared by sharp dissection within the area delineated by these incisions so that a layer of connective tissue is left covering the bone in the donor area when the flap is displaced laterally over the denuded root surface (Fig. 44-32d). It is important that the oblique releasing incision is made so far apically that the tissue flap can be placed on the recipient bed without being subjected to tearing forces when adjacent soft tissues are moved. The prepared tissue flap is rotated about 45° when sutured at the recipient bed (Fig. 44-32e).
- The suturing of the flap should secure a close adaptation of the pedicle graft to the underlying recipient bed. Pressure is applied against the flap for 2–3 minutes in order to further secure a good adaptation. To protect the surgical area during the initial phase of healing, a periodontal dressing may be applied. A light-cured dressing material, e.g. Barricaid™ (Dentsply International Inc., Milford, DE, USA), is preferably used since this can be applied without dislocating the flap and has, in addition, a favorable esthetic appearance.
- Following removal of the dressing and the sutures, usually after 10–14 days, the patient is instructed to avoid mechanical tooth cleaning for further 2 weeks, but to use twice daily rinsing with a chlorhexidine solution as a means of infection control.

Advanced flaps

Since the lining mucosa is elastic, a mucosal flap raised beyond the mucogingival junction can be stretched in coronal direction to cover exposed root surfaces (Harvey 1965; Sumner 1969; Brustein 1979; Allen & Miller 1989; Wennström & Zucchelli 1996; De Sanctis & Zucchelli 2007). The coronally advanced flap can be used for root coverage of a single tooth as well as multiple teeth, provided suitable donor tissue is available. In situations with only shallow

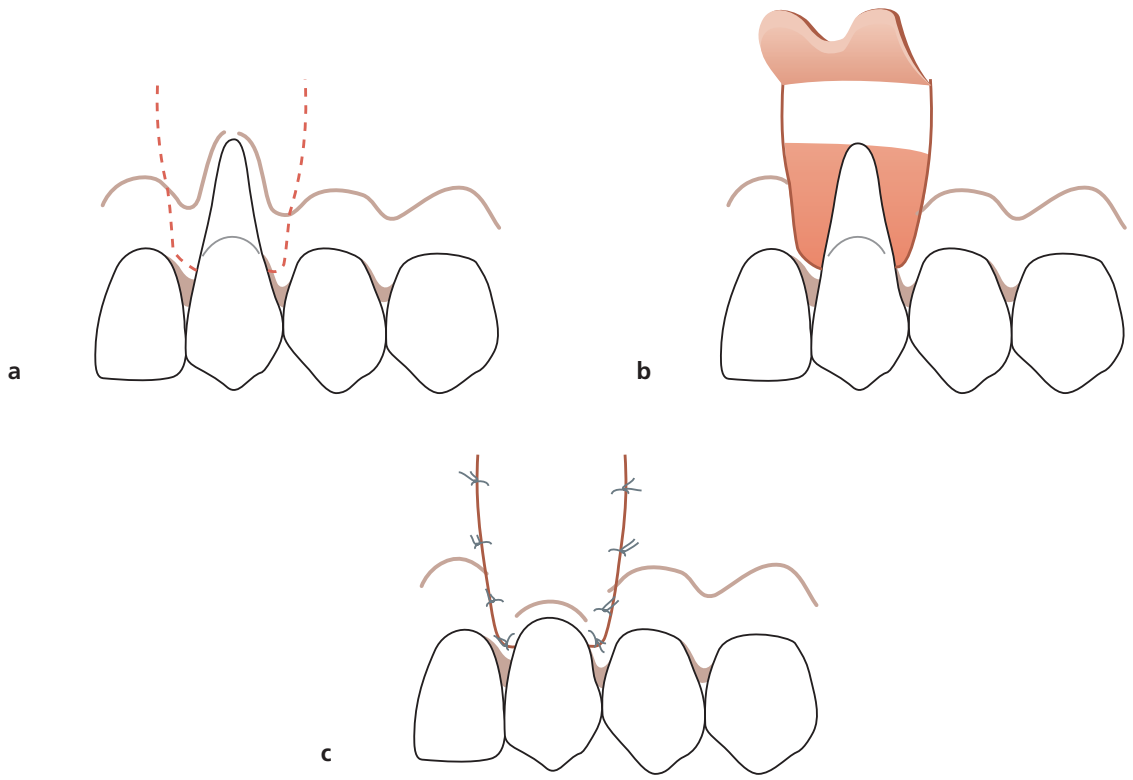

Fig. 44-33 Coronally advanced flap procedure. Schematic drawings illustrating the surgical technique in utilizing coronally advanced pedicle grafts to cover localized recession defects (see the text for explanation).

recession defects and minimal probing pocket depth labially, the *semilunar coronally repositioned flap* may offer an alternative approach (Harlan 1907; Tarnow 1986). For the treatment of an isolated deep gingival recession affecting a lower incisor, or the mesial root of the first maxillary molar, Zucchelli *et al*. (2004) suggested the use of a *laterally moved and coronally advanced flap*.

The technique for a *coronally advanced flap procedure* is as follows (Fig. 44-33):

- The coronally advanced flap procedure is initiated with the placement of two apically divergent vertical releasing incisions, extending from a point coronal to the CEJ at the mesial and distal line axis of the tooth and apically into the lining mucosa (Fig. 44-33a).
- A split-thickness flap is prepared by sharp dissection mesial and distal to the recession and connected with an intracrevicular incision. Apical to the receded soft tissue margin on the facial aspect of the tooth, a full-thickness flap is elevated to maintain maximal thickness of the tissue flap to be used for root coverage (Fig. 44-33b). Approximately 3 mm apical to the bone dehiscence, a horizontal incision is made through the periosteum, followed by blunt dissection into the vestibular lining mucosa to release muscle tension. The blunt dissection is extended buccally and laterally to such an extent that the mucosal graft is tension-free when positioned coronally at the level of the CEJ. The facial portion of the interdental papillae may be de-epithelialized to allow for a final placement of the flap margin coronal to the CEJ.
- The tissue flap is coronally advanced, adjusted for optimal fit to the prepared recipient bed, and secured at the level of the CEJ by suturing the flap to the connective tissue bed in the papilla regions (Fig. 44-33c). Additional lateral sutures are placed to carefully close the wound of the releasing incisions. Mechanical tooth cleaning is avoided during the first 3–4 weeks of healing (rinsing with a chlorhexidine solution is prescribed), and when re-instituted, instructions in the use of a tooth-brushing technique creating minimal apically directed trauma to the soft tissue margin is given.

Figure 44-34 illustrates the treatment of a recession defect with the use of the coronally advanced flap procedure. To allow the positioning of the flap margin coronal to the CEJ at the buccal surface the interdental papillae have to be de-epithelialized before suturing (Fig. 44-35).

The technique for a *laterally moved, coronally advanced flap* is as follows (Fig. 44-36):

- A vertical incision is made approximately 3 mm from the lateral edge of the recession defect at the side opposite the donor area, and parallel to the lateral border of the recession defect. The incision is extended from the level of the CEJ to a point

Fig. 44-34 Coronally advanced flap procedure. (a) A deep and wide recession defect on a canine with a composite resin restoration in the exposed root portion. Before preparation of the pedicle graft, the root is polished with pumice and a rubber cup. (b) A split flap has been dissected mesial and distal to the root, and a full-thickness flap apical to the recession. Approximately 4 mm apical to the bone dehiscence the periosteum has been cut and a blunt dissection performed to facilitate the coronal positioning of the pedicle graft. (c) The composite resin restoration is removed. (d) Close suturing of the pedicle graft to cover the exposed root surface. (e) Healing outcome 1 year post-operatively.

approximately 3 mm apical to the defect. At the marginal end of the vertical incision (at the level of the CEJ), a horizontal incision is made towards the recession defect. A third incision is made parallel to the lateral soft tissue margin of the recession defect on the donor side, from the bottom of the defect to the apical termination of the vertical incision on the recipient side. The area delineated by these incisions is de-epithelialized. In this way a 3 mm wide recipient bed is created lateral as well as apical to the defect.

- A pedicle graft is harvested from the adjacent tooth site by the use of three incisions: (1) a beveled intrasulcular incision along the lateral edge of the recession defect, (2) a horizontal submarginal incision with a 6 mm greater length than the width of the recession defect, and (3) a beveled oblique vertical incision extending into the alveolar mucosa and parallel to the first incision. The outline of the submarginal incision should preserve 3 mm of marginal soft tissue at the donor tooth, and preferably provide at least 2 mm of keratinized tissue

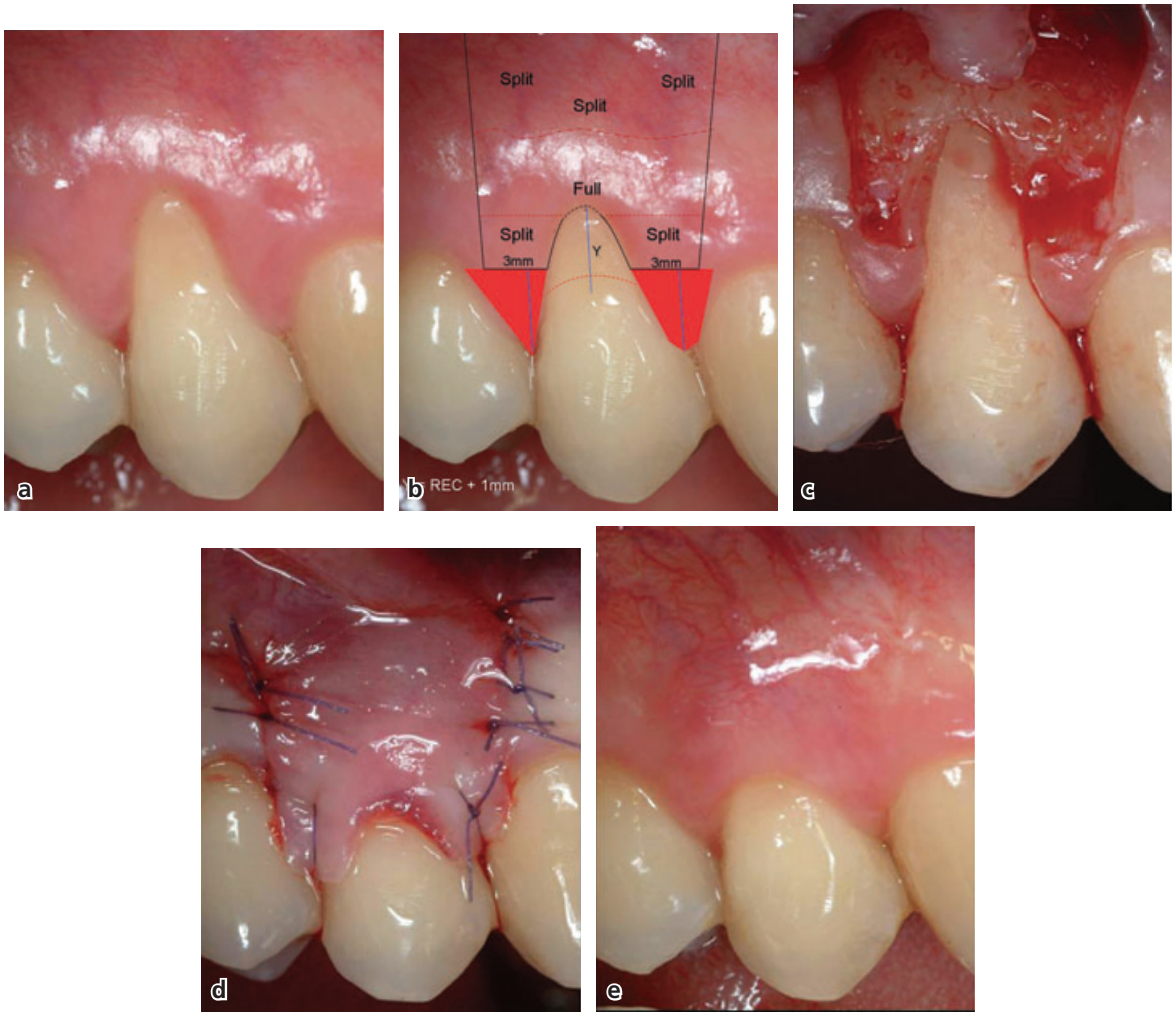

Fig. 44-35 Coronally advanced flap procedure. (a) A recession defect affecting a first premolar. (b) Schematic outline of the flap preparation. Blue line = amount (in mm) of intended coronal advancement of the flap; dotted red area = de-epithelialized papillae; Split = split-thickness elevation; Full = full-thickness elevation. (c) Flap elevated. The papilla areas are then de-epithelialized to allow anchorage of the flap coronal to the cemento-enamel junction (CEJ). (d) The flap is advanced and anchored at a level coronal to the CEJ with a sling suture. (e) Clinical healing at 1 year.

along the entire mesial–distal extension of the flap.

- The flap is mobilized as a split-thickness flap in its lateral parts, while the center part, which will be placed over the exposed root, is elevated as a full-thickness flap. Apical to the mucogingival line, the elevation is continued as split-thickness until it is possible to passively move the mucosal graft laterally to the recipient site.
- Blunt dissection is performed into the vestibular mucosa to release muscle tension to permit coronal advancement and passive adaptation of the flap to a level coronal to the CEJ.
- The facial surface of the interdental papillae is de-epithelized to create connective tissue beds to which the laterally moved, coronally advanced flap can be sutured.
- The suturing of the flap starts with the placement of two interrupted periosteal sutures in the most apical end of the vertical releasing incisions, and continues with a series of interrupted sutures, directed in a apical–coronal direction from the flap to the adjacent wound edge. A horizontal double mattress periosteal suture is placed apical to the vertical incisions to reduce lip tension on the root coverage portion of the flap. The coronal suture is a sling suture, which permits a precise adaptation of the flap against the root surface and the interdental connective tissue beds.

Figure 44-37 illustrates the treatment of a recession defect at a maxillary molar with the use of the *laterally moved, coronally advanced flap* procedure.

Zucchelli and De Sanctis (2000) described a flap design for the treatment of multiple recessions, which allows for optimal adaptation of the flap following its coronal advancement without placement of vertical releasing incisions. The technique for this *coronally advanced flap procedure for multiple recessions* is as follows (Fig. 44-38):

Fig. 44-36 The laterally moved, coronally advanced flap (see text for explanation). (a) A cenral insicor with recession defect. (b) Schematic outline of the preparation of the recipient site and the pedicle graft. Dotted pink area = receiving area for lateral flap; dotted red area = de-epithelialized papillae; x = recession width at the level of the cemento-enamel junction; Split = split-thickness elevation; Full = full-thickness elevation. (c,d) The flap is transpositioned laterally and coronally, and secured in position by sutures. A horizontal double mattress suture is performed to reduce lip tension on the marginal portion of the flap. (e) Clinical healing at 1 year.

- Oblique submarginal incisions are made in the interdental areas and connected with intracrevicular incisions at the recession defects. The incisions are extended to include one tooth on each side of the teeth to be treated to facilitate coronal repositioning of the flap. The oblique incisions over the interdental areas are placed in such a manner that the "surgically created papillae" mesial to the midline of the surgical field are dislocated apically and distally, while the papillae of the flap distal to the midline are shifted in a more apical and mesial position (Fig. 44-37a).
- Starting at the oblique interdental incisions, a split-thickness flap is dissected (Fig. 44-38c). Apical to the level of the root exposures, a full-thickness flap is raised to provide maximum soft tissue thickness of the flap to be positioned coronally over the roots (Fig. 44-38d).
- At the most apical portion of the flap, the periosteum is incised and followed by dissection into the vestibular lining mucosa to eliminate all muscle tension. The mobilized flap should be able to passively reach a level coronal to the CEJ at each single tooth in the surgical field.
- The remaining facial portion of the interdental papillae is de-epithelialized to create connective tissue beds to which the flap can be sutured.
- Sutures are placed to accomplish a precise adaptation of the coronally advanced flap against the teeth and to the interdental connective tissue beds (Fig. 44-38e). In addition, a horizontal double mattress suture is placed to reduce lip tension on the marginal portion of the flap.

The technique for a *semilunar coronally repositioned flap procedure* is as follows (Fig. 44-39):

Fig. 44-37 The laterally moved, coronally advanced flap. (a–c) A recession defect at a first maxillary molar treated because of root sensitivity (see text for explanation). (d) Clinical healing at 1 year.

- A semilunar incision is placed apical to the recession and at a distance from the soft tissue margin, which should be approximately 3 mm greater than the depth of the recession. The outline of the incision should be parallel to the curvature of the gingival margin (Fig. 44-39a). The incision is extended into the papilla region on each side of the tooth, but care should be taken to maintain a broad base of anchorage to secure a collateral blood supply to the pedicle graft.
- A split-thickness dissection of the facially located tissue is then made by an intracrevicular incision extending apically to the level of the semilunar incision (Fig. 44-39b). The mid-facial soft tissue graft is coronally repositioned to the level of the CEJ (Fig. 44-39c) and stabilized by light pressure for 5 minutes.
- No suturing is needed but a light-cured dressing may be applied for wound protection.

Pedicle soft tissue graft procedures combined with a barrier membrane

The use of a barrier membrane, according to the principles of guided tissue regeneration (GTR, see Chapter 25), in conjunction with pedicle soft tissue graft procedures was introduced as a treatment modality for root coverage by Pini Prato *et al*. (1992). In order create space for tissue formation between the facial root surface and the membrane Pini Prato *et al*. (1992) suggested that extensive root planing should be carried out to produce concave root morphology. Specially designed membranes for the treatment of recession type defects are available, such as non-absorbable titanium-reinforced expanded polytetrafluoroethylene (e-PTFE) membranes (Fig. 44-40c). In addition, a variety of bioabsorbable membranes are commercially available, but many of these may not be rigid enough for maintaining required space during healing.

The pedicle graft used in the GTR procedure is generated through the preparation of a coronally advanced flap (Fig. 44-40):

- Apically divergent vertical releasing incisions are made at the mesial and distal line axis of the tooth, extending from a point coronal to the CEJ and apically into the lining mucosa. A trapezium-shaped full-thickness flap is raised beyond the bone dehiscence (Fig. 44-40b). The periosteum at the base of the raised mucoperiosteal flap is incised, followed by a blunt supraperiosteal dissection to such a depth that the trapezoidal flap easily can be advanced coronally to the desired position. Depending on the degree of coronal repositioning, the facial portion of the interdental papillae may need to be de-epithelialized to prepare proper recipient beds for the pedicle graft.
- The root is extensively planed or ground to obtain a concave profile of the root surface, thereby providing space for tissue formation. If a titanium-reinforced membrane is used, the root profile may not need to be changed to establish the required space between the root and the membrane.

Fig. 44-38 Coronally advanced flap procedure for multiple recessions (see text for explanation). (a–e) The oblique incisions over the interdental areas are placed in such a manner that the "surgically created papillae" mesial to the midline of the surgical field are dislocated apically and distally, while the papillae of the flap distal to the midline are shifted in a more apical and mesial position. (f) The 1-year post-treatment view.

- The membrane barrier to be used is trimmed to cover the exposed root and approximately 3 mm of the bone lateral and apical to the dehiscence (Fig. 44-40c) and anchored to the tooth by a sling suture placed at the level of the CEJ.
- The mobilized flap is positioned coronally and secured by interdentally placed interrupted sutures (Fig. 44-40d). The membrane should be completely covered by the flap to reduce the risk for bacterial contamination during healing. Additional sutures are placed to close the lateral wound of the releasing incisions.
- The patient is advised to use a chlorhexidine mouth rinse for infection control and not to use any mechanical cleaning devices for at least 6 weeks in the tooth region subjected to surgery.
- The use of non-biodegradable membrane barriers requires a second surgery for membrane removal, usually after 5–6 weeks (Fig. 44-40e,f). A partial-thickness trapezoidal flap is raised to expose the membrane. Following its removal, the flap is repositioned at the level of the CEJ to completely cover the newly formed tissue. Mechanical plaque control is reinstituted 4 weeks after membrane removal.

Pedicle soft tissue graft procedures combined with enamel matrix proteins

Abbas *et al*. (2003) described a surgical procedure for periodontal regenerative therapy of recession defects utilizing enamel matrix derivative bioactive material (Emdogain®):

- The surgical technique utilized is the coronally advanced flap as described above (Fig. 44-33). The interdental papillae should be de-epithelialized to

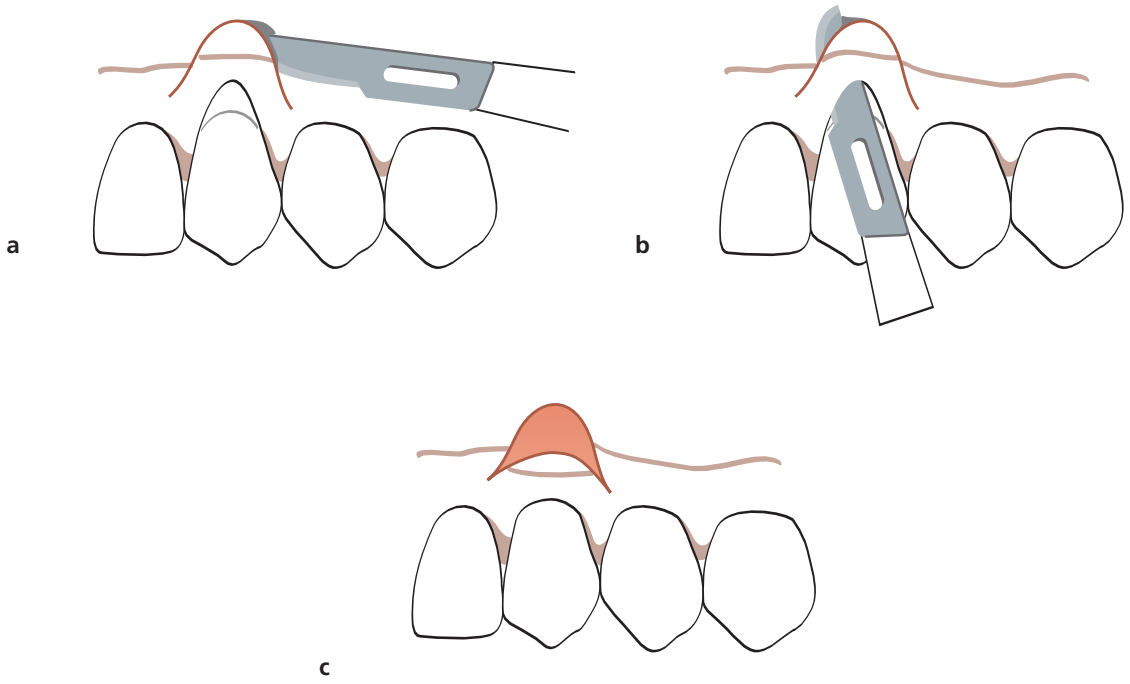

Fig. 44-39 Semilunar coronally repositioned flap procedure. Schematic drawings illustrating the surgical technique in utilizing coronally displaced pedicle grafts to cover shallow localized recession defects (see text for explanation).

allow for maximum coronal positioning of the tissue flap over the exposed root surface at suturing.

- Following preparation of the coronally advanced flap, the exposed root surface is conditioned with PrefGel™ (24% EDTA-gel, pH 6.7; Straumann Biologics, Switzerland) for 2 minutes to remove the smear layer.
- After thorough rinsing with sterile saline, the enamel matrix protein gel (Emdogain®, Straumann Biologics, Switzerland) is applied to the exposed root surface. The pedicle graft is advanced coronally and secured at a level slightly coronal to the CEJ by suturing the flap to the de-epithelialized papilla regions using non-irritating sutures. The vertical incisions are then closed with two to three sutures. Mechanical tooth cleaning is avoided during the first 3–4 weeks of healing (rinsing with a chlorhexidine solution is prescribed), and when re-instituted, a toothbrushing technique creating minimal apically directed trauma to the soft tissue margin is used.

Free soft tissue graft procedures

A free soft tissue graft of masticatory mucosa is usually selected when there is no acceptable donor tissue present in the area adjacent to the recession defect or when a thicker marginal tissue is desirable. The procedure can be used for the treatment of a single tooth as well as for groups of teeth. The graft used may either be (1) an *epithelialized graft* or (2) a *subepithelial connective tissue graft* of palatal masticatory mucosa.

Epithelialized soft tissue graft

The epithelialized free soft tissue graft procedure can be performed either as a two-step surgical technique, where an epithelialized free soft tissue graft is placed apical to the recession and following healing is positioned coronally over the denuded root (Fig. 44-41) (Bernimoulin *et al*. 1975; Guinard & Caffesse 1978), or as a one-step technique by which the graft is placed directly over the root surface (Sullivan & Atkins 1968a,b; Miller 1982) (Fig. 44-42). The latter of the two techniques has been most commonly used.

The principles of utilizing free mucosal grafts were outlined by Sullivan and Atkins (1968a,b) and later modified by Miller (1982):

- Before any incisions the exposed root surface is carefully scaled and root planed (Fig. 44-42a). The convexity of the root may be reduced to minimize the mesio-distal avascular recipient bed.
- As in the treatment with pedicle grafts, the preparation of *the recipient bed* is crucial for the success of free graft procedure. A 3–4 mm wide recipient connective tissue bed should be prepared apical and lateral to the recession defect (Fig. 44-42b). The area is demarcated by first placing a horizontal incision, at the level of the CEJ, in the interdental tissue on each side of the tooth to be treated. Subsequently, two vertical incisions, extending from the incision line placed in the interdental tissue to a level approximately 4–5 mm apical to the recession, are placed. A horizontal incision is then made connecting the two vertical incisions at their apical termination. Starting from an intracrevicular incision, a split incision is made to sharply dissect the

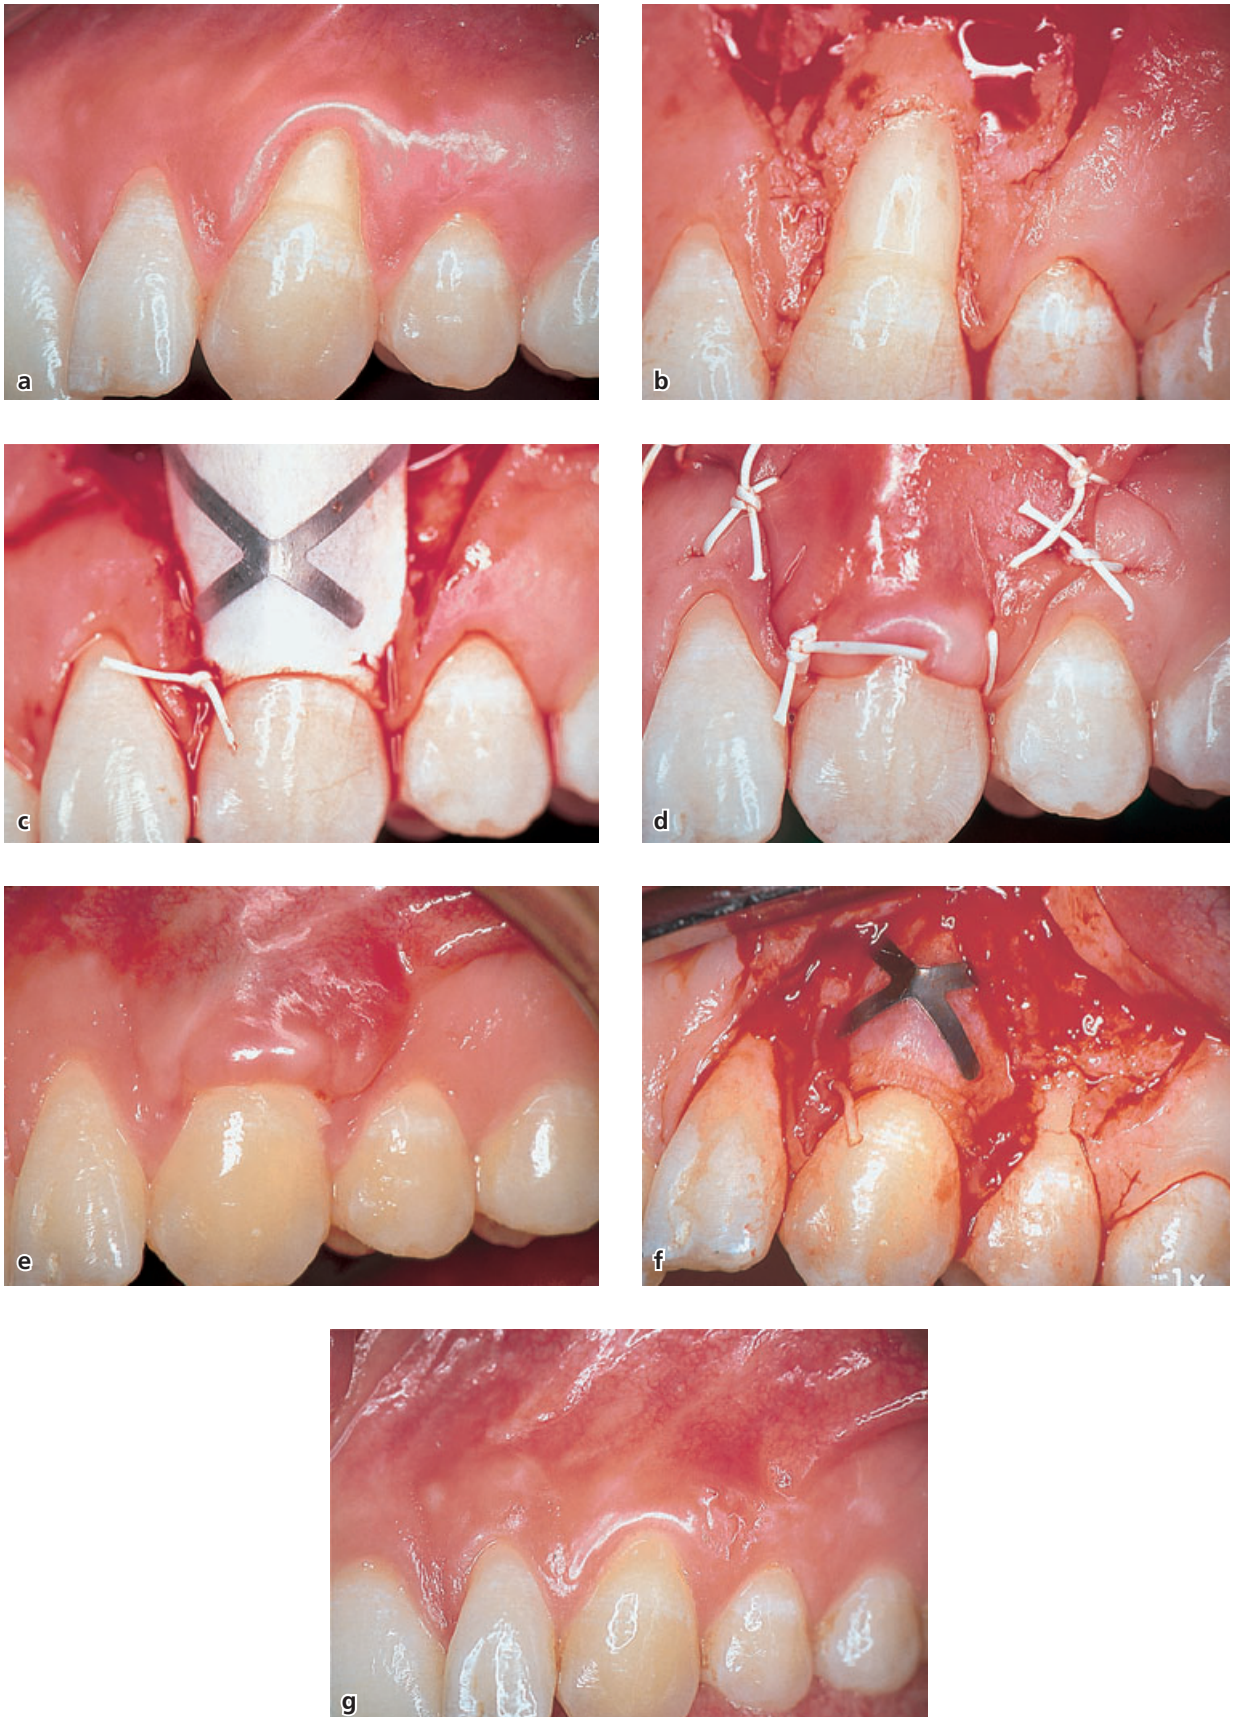

Fig. 44-40 Coronally advanced flap procedure combined with a titanium-reinforced non-biodegradable membrane barrier. (a–f) A recession defect at tooth 23 requiring treatment due to the patient's esthetic demands (see the text for explanation). (g) The 1-year post-operative result.

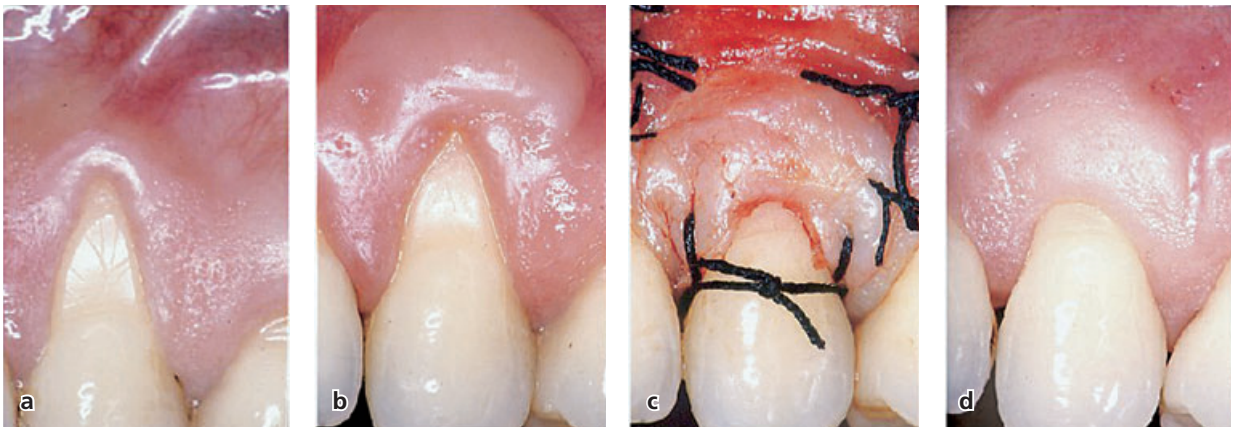

Fig. 44-41 Two-stage epithelialized free soft tissue graft procedure. (a–c) An epithelialized soft tissue graft is placed apical to the recession and allowed to heal. At a second stage surgery, a coronally advanced flap procedure is performed to achieve coverage of the denuded root. (d) The 1-year post-operative result.

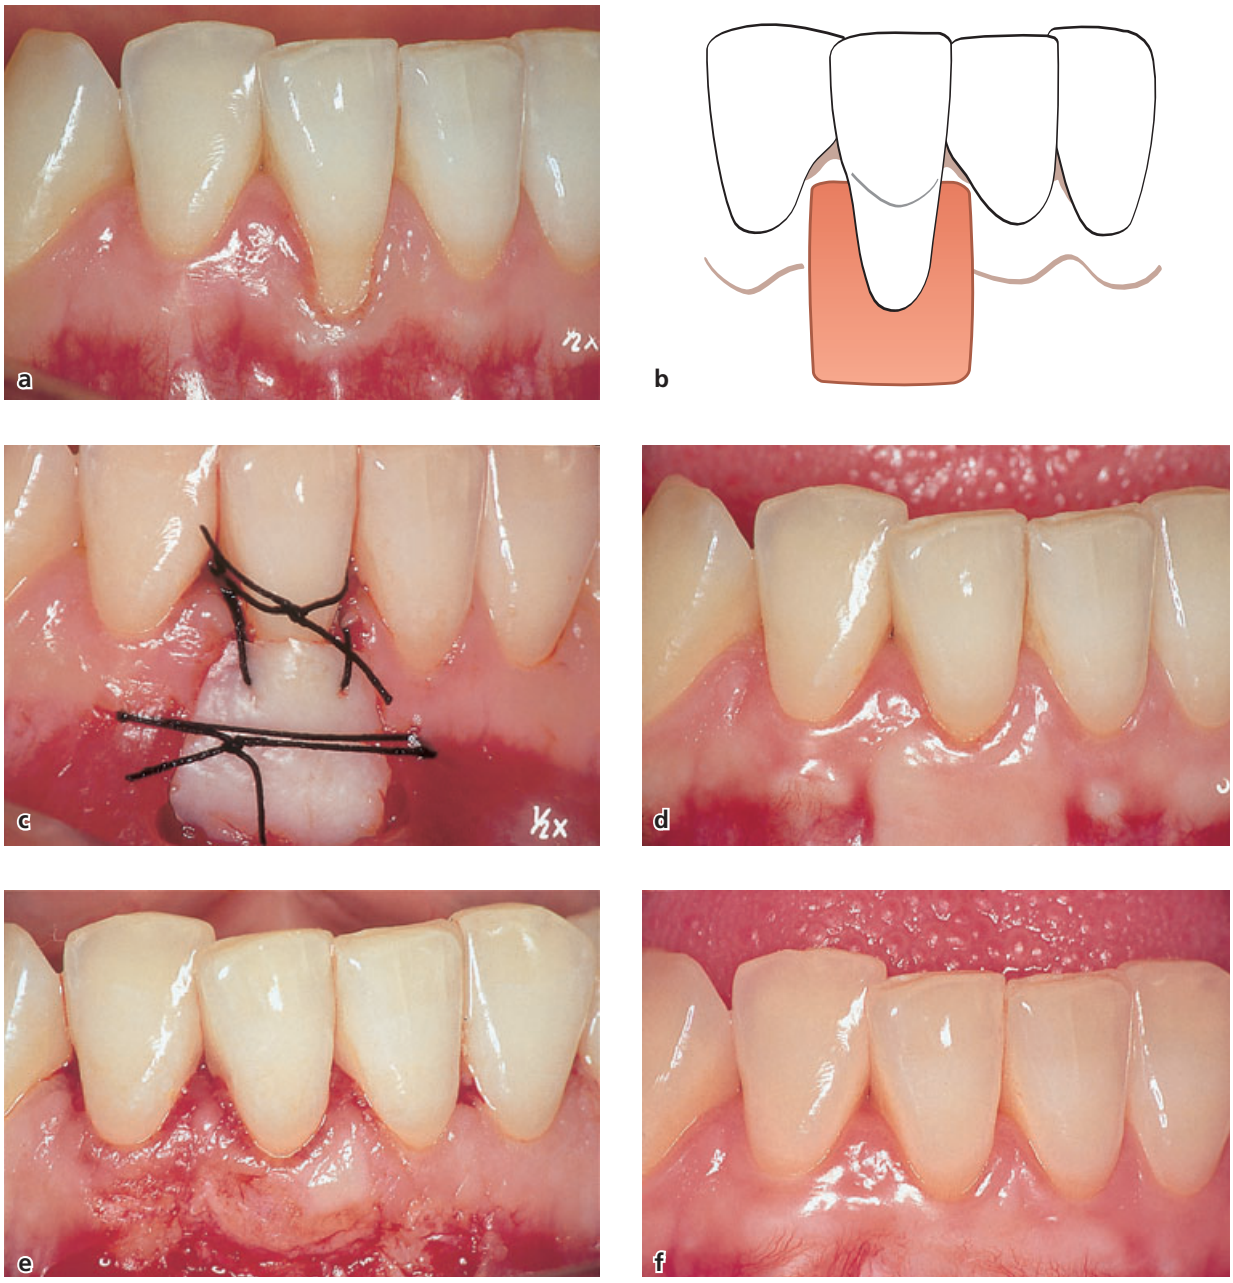

Fig. 44-42 Epithelialized free soft tissue graft procedure. A recession defect at a mandibular central incisor treated with the free graft procedure (see the text for explanation).

epithelium and the outer portion of the connective tissue within the demarcated area.

- To ensure that a graft of sufficient size and proper contour is removed from the donor area, a foil template of the recipient site is prepared. This template is transferred to the donor site, the palatal mucosa in the region of the premolars, and the required size of the graft is outlined by a shallow incision. A graft with a thickness of 2–3 mm is then dissected from the donor area (Fig. 44-20c–d). It is advocated to place sutures in the graft before it is cut completely free from the donor area since this may facilitate its transfer to the recipient site. Following the removal of the graft, pressure is applied to the wound area for control of bleeding.
- The graft is immediately placed on the prepared recipient bed. In order to immobilize the graft at the recipient site, sutures must be anchored in the periosteum or in the adjacent attached gingiva. Adequate numbers of sutures are placed to secure close adaptation of the graft to the underlying connective tissue bed and root surface (Fig. 44-42c). Before the placement of a periodontal dressing, pressure is exerted against the graft for some minutes in order to eliminate blood from between the graft and the recipient bed. Following the control of bleeding, the wound in the donor area in the palate is covered by a periodontal dressing. An acrylic plate may be required to maintain the dressing in place during healing phase.
- The sutures and periodontal dressing are usually maintained for 2 weeks. The appearance of a grafted area after 3 months of healing is shown in Fig. 44-42d. A gingivoplasty may be indicated to achieve a satisfactory esthetic appearance of the grafted area (Fig. 44-42e,f).

Connective tissue graft

The techniques utilizing a subepithelial soft tissue graft, i.e. the connective tissue, involve the placement of the graft directly over the exposed root and the mobilization of a mucosal flap coronally (Fig. 44-43) or laterally (Fig. 44-44) for coverage of the graft (Langer & Langer 1985; Nelson 1987; Harris 1992; Bruno 1994; Zucchelli *et al*. 2003). An alternative technique is to place the base of the connective tissue graft within an "envelope" prepared by an undermining partial-thickness incision from the soft tissue margin, i.e. part of the graft will rest on the root surface coronal to the soft tissue margin (Fig. 44-45) (Raetzke 1985; Allen 1994). For the treatment of multiple adjacent recessions, a multi-envelope recipient bed ("tunnel") may be prepared (Zabalegui *et al*. 1999). The subepithelial connective tissue graft is harvested from the palate or the retromolar pad by the

Fig. 44-43 Free connective tissue graft combined with a coronally advanced flap procedure – single recession (see the text for explanation). (a) Deep gingival recession at a cuspid with minimal height of keratinized tissue apical to the root exposure. (b) The graft has been sutured to leave an area between the cemento-enamel junction and the graft available for the marginal keratinized tissue of the flap. (c) The flap has been advanced coronally and sutured. (d) Clinical healing at 1 year.

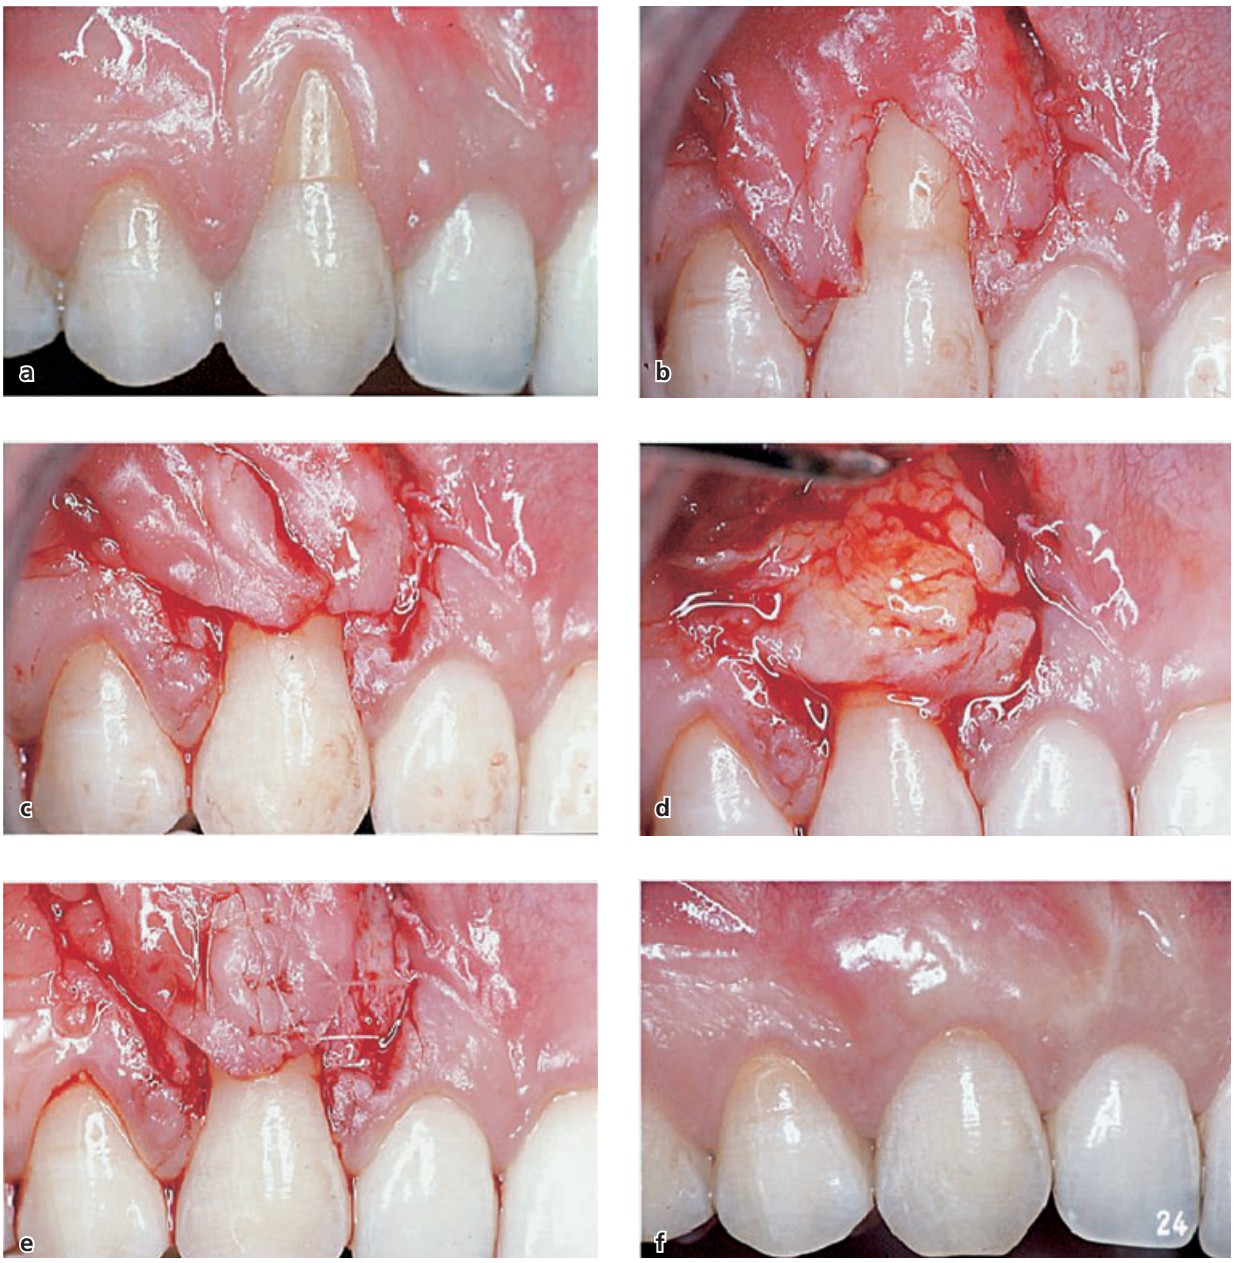

Fig. 44-44 (a–e) Free connective tissue graft combined with a double papilla flap procedure. (f) The 1-year post-treatment result.

use of a "trap door" approach (Fig. 44-46). Compared to the epithelialized graft, the connective tissue graft is preferable due to a less invasive palatal wound and an improved esthetic result.

The technique for the *connective tissue graft combined with a coronally advanced flap* is as follows (Fig. 44-43):

- The surgical technique utilized is the coronally advanced flap as described above, but with the difference that the flap is elevated entirely as a split-thickness flap. The interdental papillae should be de-epithelialized to allow for maximum coronal positioning of the tissue flap over the exposed root surface at suturing (Fig. 44-43b).
- A subepithelial connective tissue graft of masticatory mucosa is harvested on the palatal aspect of the maxillary premolars/first molar (or from the retromolar pad) by the use of a "trap door" approach (Fig. 44-46). Before incisions are placed, the available thickness of the mucosa is estimated by the use of the tip of the syringe. A horizontal incision, perpendicular to the underlying bone surface, is made approximately 3 mm apical to the soft tissue margin (Fig. 44-46a). The mesio-distal extension of the incision is determined by the graft size required, which is 6 mm longer than the width of the dehiscence measured at the level of the CEJ. To facilitate the removal of the graft, a vertical releasing incision may be made at the mesial termination of the primary incision. An incision is then placed from the line of the first incision and directed apically to perform a split incision of the palatal mucosa (Fig. 44-46b–f). A small periosteal

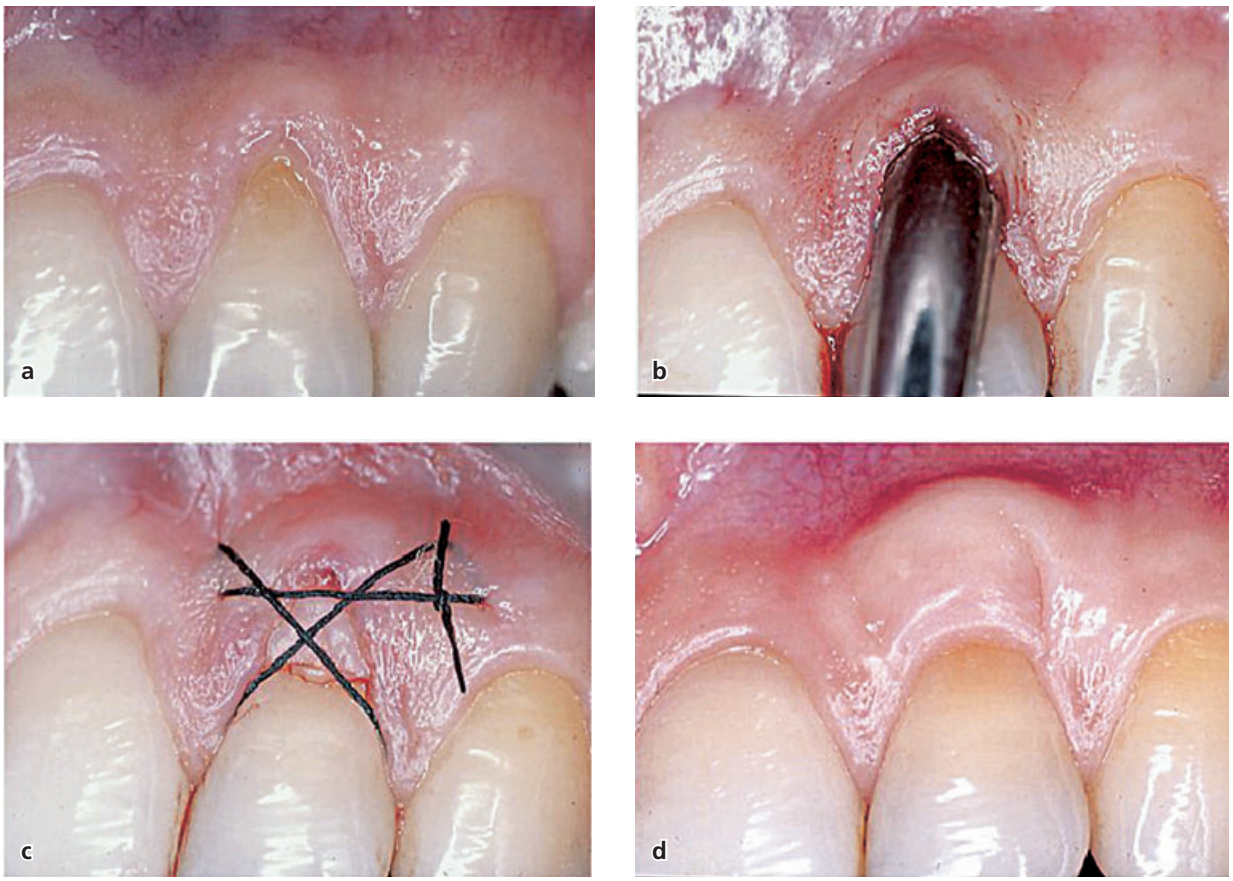

Fig. 44-45 (a–c) Free connective tissue graft procedure – the "envelope technique" (see text for explanation). (d) The 1-year post-treatment result. (Courtesy of Dr. P. Cortellini, Italy.)

elevator or scalpel is used to release the connective tissue graft from the bone.

- The graft is immediately transferred to the recipient site and positioned at a distance from the CEJ equal to the height of keratinized tissue originally present apical to the recession defect. The graft is secured in position with two double vertical mattress sutures to adjacent soft tissue lateral to the dehiscence (Fig. 44-43c). A sling suture is placed in the papilla regions to position the margin of the covering advanced flap about 1 mm coronal to the CEJ. Interrupted sutures are used to close the wound along the vertical incisions (Fig. 44-43d).

Figure 44-47 illustrates the procedure applied to a case with multiple recession sites.

The "envelope" technique (Fig. 44-48) is as follows:

- With the use of the "envelope" technique the recipient site is prepared by first eliminating the sulcular epithelium by an internal beveled incision (Fig. 44-48a). Secondly, an "envelope" is prepared apically and laterally to the recession by split incisions (Fig. 44-48b). The depth of the preparation should be 3–5 mm in all directions. In an apical direction, the preparation of the site should extend beyond the mucogingival junction to facilitate the placement of the connective tissue graft and to allow for coronal advancement of the mucosal flap at time of suturing.
- A foil template may be used for the harvest of an appropriately sized connective tissue graft. The graft, which is obtained by the "trap door" approach described above (Fig. 44-46), is inserted into the prepared "envelope" and positioned to cover the exposed root surface (Fig. 44-48c–d).
- Sutures are placed to secure graft in position (Fig. 44-48d). A crossed sling suture may be placed to advance the mucosal flap coronally. Pressure is applied for 5 minutes to adapt the graft closely to the root surface and covering soft tissue.

Figure 44-45 shows the treatment of a recession defect with the "envelope" technique.

The "tunnel" technique (Fig. 44-49) is as follows:

- In case multiple adjacent recessions are to be treated, "envelopes" are prepared for each tooth as described above. However, the lateral split incisions are extended so that the multi-envelopes are connected mesially and distally to form a mucosal tunnel. Care should be taken to avoid detachment of the papillae.
- The graft is gently positioned inside the tunnel and its mesial and distal extremities are fixed with two interrupted sutures. Sling sutures may be placed

Table 44-1 Summary of the data available in the literature on the amount of root coverage obtainable with various procedures (Miller class I–II defects)

Root coverage procedure	No. of studies	No. of patients/teeth	Root coverage	
			Mean % of initial recession	Range
Rotational flaps	10	222/235	68	41–74
Coronally advanced flap	17	315/527	79	55–99
Guided tissue regeneration	35	589/695	75	48–94
Enamel matrix proteins	10	207/219	86	72–94
Free connective tissue graft	33	683/890	86	53–98
Epithelialized free soft tissue graft	16	335/491	63	11–87

to advance the mucosal flap coronally over the exposed portions of the connective tissue graft. Pressure is applied for 5 minutes to closely adapt the graft to the root surface and covering soft tissue. Application of a periodontal dressing is often not required.

Clinical outcome of root coverage procedures

Independent of the modality of surgical procedure used to obtain soft tissue root coverage, shallow residual probing depths, gain in clinical attachment, and an increase in gingival height are the common characteristics of treatment outcome. Although the major indication for performing root coverage procedures is esthetic/cosmetic demands by the patient, few studies have included assessments of esthetics as an end-point of success. Instead, the common outcome variables used are the amount of root coverage achieved, expressed in percentage of the initial depth of the recession defect, and the proportion of treated sites showing complete root coverage.

Root coverage

An overall comparison of the treatment outcome of various root coverage procedures is hampered by the fact that comparatively few studies have presented well documented clinical data and that there is substantial heterogeneity between studies (Roccuzzo *et al*. 2002; Oates *et al*. 2003). A summary with regard to the average amount of initial Miller class I–II recession defects that was successfully covered following treatment, based on the data published in a systematic review by Pagliaro *et al*. (2003) and relevant data from studies published between 2003 and 2006 (Table 44-1), shows that an average of 63–86% root coverage may be expected. However, the variability in the treatment outcome for the various procedures, both within and between studies, is large. This indicates that the procedures are operator sensitive and/or that various factors influencing the treatment outcome have not been adequately considered.

Complete coverage of the recession defect is the ultimate goal of the therapy. Table 44-2 summarizes

Table 44-2 Summary of the data available in the literature on the predictability of complete root coverage following the use of various procedures (Miller class I–II defects)

Root coverage procedure	No. of studies	No. of patients/teeth	Complete root coverage	
			Mean % of teeth	Range
Rotational flaps	1	30/30	43	–
Coronally advanced flap	15	287/499	48	9–95
Guided tissue regeneration	24	357/453	36	0–75
Enamel matrix proteins	7	138/150	72	53–90
Free connective tissue graft	26	549/732	61	0–93
Epithelialized free soft tissue graft	10	253/380	28	0–90

data on the predictability of this event with the use of the various surgical procedures. The average percentage of complete root coverage following pedicle or free graft procedures varies between 28 and 72%, with large variability between studies irrespective of surgical procedure used. According to the systematic reviews by Roccuzzo *et al*. (2002) and Oates *et al*. (2003), coronally advanced flaps with connective tissue grafts result in significantly greater root coverage compared to guided tissue regeneration. The lower mean predictability of complete root coverage achieved with the GTR procedure has been associated with the problem of membrane exposure during healing (Trombelli *et al*. 1995), but whether a bioabsorbable or a non-biodegradable barrier membrane is used does not seem to affect the treatment outcome (Roccuzzo *et al*. 1996).

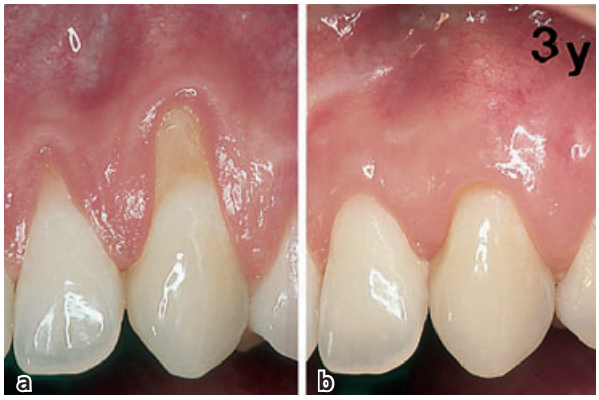

Fig. 44-50 (a) Buccal recession defects but no loss of periodontal support at proximal surfaces. Complete root coverage can be achieved. (b) 3-year follow-up.

Factors influencing the degree of root coverage

Patient-related factors. As with other surgical periodontal treatment procedures, poor oral hygiene is a factor that will negatively influence the success of root coverage procedures (Caffesse *et al*. 1987). Further, the predominant causative factor in the development of gingival recession is toothbrushing trauma, and hence this factor has to be corrected to secure an optimal outcome of any root coverage procedure. Treatment outcome in terms of root coverage is usually less favorable in smokers than in non-smokers (Trombelli & Scabbia 1997; Zucchelli *et al*. 1998; Martins *et al*. 2004; Erley *et al*. 2006; Silva *et al*. 2006), although some studies showed no differences (Tolmie *et al*. 1991; Harris 1994).

Site related factors. Among site-specific factors, the level of interdental periodontal support may be of greatest significance for the outcome of root coverage procedures. From a biological point of view complete root coverage is achievable in class I–II recession defects (Fig. 44-50), while when loss of connective tissue attachment also involves proximal tooth sites (class III–IV recession defects), only partial facial root coverage is obtainable (Miller 1985b) (Fig. 44-51).

An additional factor shown to influence the degree of attainable root coverage is the dimensions of the recession defect. Less favorable treatment outcome has been reported at sites with wide (>3 mm) and deep (≥5 mm) recessions (Holbrook & Ochsenbein 1983; Pini Prato *et al*. 1992; Trombelli *et al*. 1995). In a study comparing the treatment effect of coronally advanced flap and free connective tissue graft procedures, Wennström and Zucchelli (1996) reported that complete root coverage was observed in only 50% of the defects with an initial depth of ≥5 mm compared

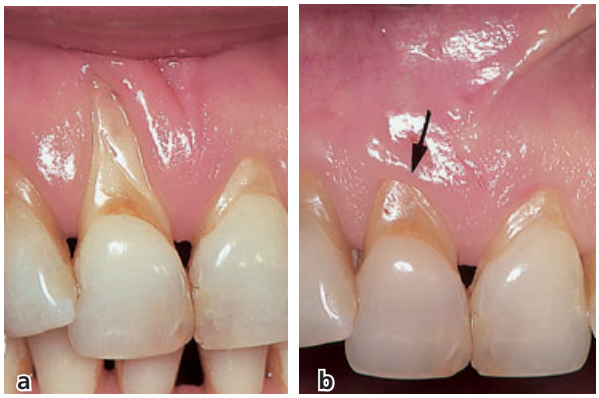

Fig. 44-51 (a) A deep buccal recession at tooth 11. The tooth has loss of support at proximal sites (Miller class III) and complete root coverage is not achievable. Also neighboring teeth show recessions at all tooth surfaces. (b) 2-year healing result following attempted root coverage at the facial aspect of tooth 11. The coronal position of the soft tissue margin is defined by the extension of proximal loss of periodontal support.

to 96% in shallower defects. Pini Prato *et al*. (1992) suggested, based on clinical observations in a controlled clinical trial, that a more favorable result with respect to root coverage might be obtained with the GTR procedure in sites with deep (≥5 mm) recession defects as compared to the coronally advanced flap. At the 18-month examination the average coverage was 77% with and 66% without the inclusion of a membrane barrier. However, data presented from recent systematic reviews and meta-analyses (Roccuzzo *et al*. 2002; Oates *et al*. 2003) showing that the predictability of root coverage is significantly reduced with the use of barrier membranes, limit the justification of using the GTR procedure in the treatment of recession defects. The pre-treatment gingival height apical to the recession defect is not correlated to the amount of root coverage obtained (Romanos *et al*. 1993; Harris 1994).

Technique-related factors. Several technique-related factors may influence the treatment outcome of a pedicle graft procedure. In a systematic review including data from 15 studies (Hwang & Wang 2006) a positive correlation was demonstrated between the thickness of the tissue flap and recession reduction. For complete root coverage the critical threshold thickness was found to be about 1 mm. However, whether a full- or split-thickness pedicle graft is used for root coverage may not influence the treatment outcome (Espinel & Caffesse 1981).

Elimination of flap tension is considered an important factor for the outcome of the coronally advanced flap procedure. Pini Prato *et al*. (2000a) measured the tension in coronally advanced flaps to compare the amount of root coverage in sites with and without residual flap tension. At sites that had residual tension (mean 6.5 g) the root coverage amounted to 78% 3 months post-surgically and 18% of the treated sites showed complete root coverage. Sites without tension demonstrated mean root coverage of 87% and complete root coverage in 45% of the cases. Furthermore, a statistically significant negative association was shown between the magnitude of residual tension in the flap and the amount of recession reduction.

Although the connective tissue areas lateral to the recession defect are considered important for the retention of the advanced flap when positioned over the root surface, the dimension of the interdental papilla is not a prognostic factor for the clinical outcome of the root coverage procedure (Saletta *et al*. 2001). As can be expected, the position of the gingival margin relative to the CEJ after suturing affects the probability of complete root coverage following healing. Pini Prato *et al*. (2005) demonstrated that for 100% predictability of complete root coverage in the treatment of Miller class I recessions with a coronally advanced flap procedure the flap margin has to be positioned at least 2 mm coronal to the CEJ.

With regard to free graft procedures, the thickness of the graft is a factor influencing the success of treatment procedure (Borghetti & Gardella 1990). A thickness of the free graft of about 2 mm is recommended.

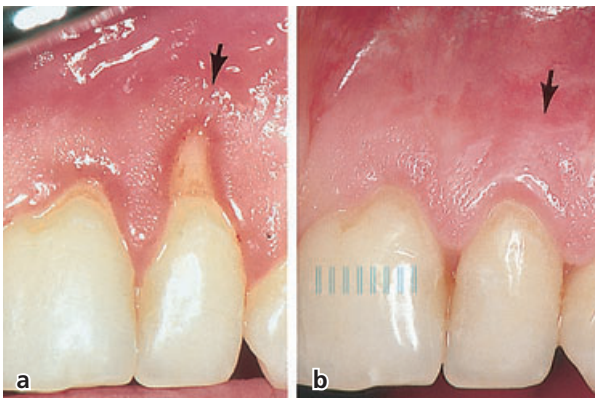

Fig. 44-52 Increased dimension of keratinized tissue 1 year following root coverage with a coronally advanced flap procedure. Before (a) and 1-year post-operatively (b). Arrows indicate the position of the mucogingival line.

Increased gingival height

An increased apico-coronal height of the gingiva is found following all procedures in which pedicle grafts of adjacent gingiva or free grafts from the palate have been placed over the recession defect. It is interesting to note, however, that an increased gingival height is also a common finding following a coronally advanced flap procedure only involving the existing gingiva apical to the recession (Fig. 44-52). This finding may be explained by several events taking place during the healing and maturation of the marginal tissue. Granulation tissue formation derived from the periodontal ligament tissue will form a connective tissue similar to the one of gingiva and with the potential to induce keratinization of the covering epithelium (Karring *et al*. 1971). A second factor to consider is the tendency of the mucogingival line to regain its "genetically" defined position following its coronal "dislocation" with the coronally advanced flap procedure used to achieve root coverage. Support for the concept that the mucogingival line will regain its original position over time is generated from a study by Ainamo *et al*. (1992). The authors performed an apically repositioned flap procedure in the lower anterior tooth region, which resulted in a 3 mm apical displacement of the mucogingival line. Re-examination after 18 years showed no differences in position of the mucogingival line between sites treated with the apically repositioned flap and contralateral control sites treated with a procedure not interfering with the mucogingival line, indicating that the mucogingival line had regained its original position.

Soft tissue healing against the covered root surface

Treatment of gingival recessions by pedicle grafts or free grafts may be clinically successful, but does the

treatment result in a healing characterized by the formation of a connective tissue attachment or an epithelial attachment? Independent of the quality of attachment formed, however, root coverage procedures evidently rarely result in the formation of a deep periodontal pocket.

Healing of pedicle soft tissue grafts

In the areas surrounding the recession defect, i.e. where the recipient bed consists of bone covered by connective tissue, the pattern of healing is similar to that observed following a traditional flap operation. Cells and blood vessels from the recipient bed as well as from the tissue graft invade the fibrin layer, which gradually becomes replaced by connective tissue. After 1 week a fibrous reunion is already established between the graft and the underlying tissue.

Healing in the area where the pedicle graft is in contact with the denuded root surface was studied by Wilderman and Wentz (1965) in dogs. According to these authors the healing process can be divided into four different stages (Fig. 44-53):

1. *The adaptation stage (from 0–4 days).* The laterally repositioned flap is separated from the exposed root surface by a thin fibrin layer. The epithelium covering the transplanted tissue flap starts to proliferate and reaches contact with the tooth surface at the coronal edge of the flap after a few days.
2. *The proliferation stage (from 4–21 days).* In the early phase of this stage the fibrin layer between the root surface and the flap is invaded by connective tissue proliferating from the subsurface of the flap. In contrast to areas where healing occurs between two connective tissue surfaces, growth of connective tissue into the fibrin layer can only take place from one surface. After 6–10 days a layer of fibroblasts is seen in apposition to the root surface. These cells are believed to differentiate into cementoblasts at a later stage of healing. At the end of the proliferation stage, thin collagen fibers are formed adjacent to the root surface, but a fibrous union between the connective tissue and the root has not been observed. From the coronal edge of the wound, epithelium proliferates apically along the root surface. According to Wilderman and Wentz (1965), the apical proliferation of epithelium may stop within the coronal half of the defect although further downgrowth of epithelium was also frequently observed.
3. *The attachment stage (from 27–28 days).* During this stage of healing thin collagen fibers become inserted in a layer of new cementum formed at

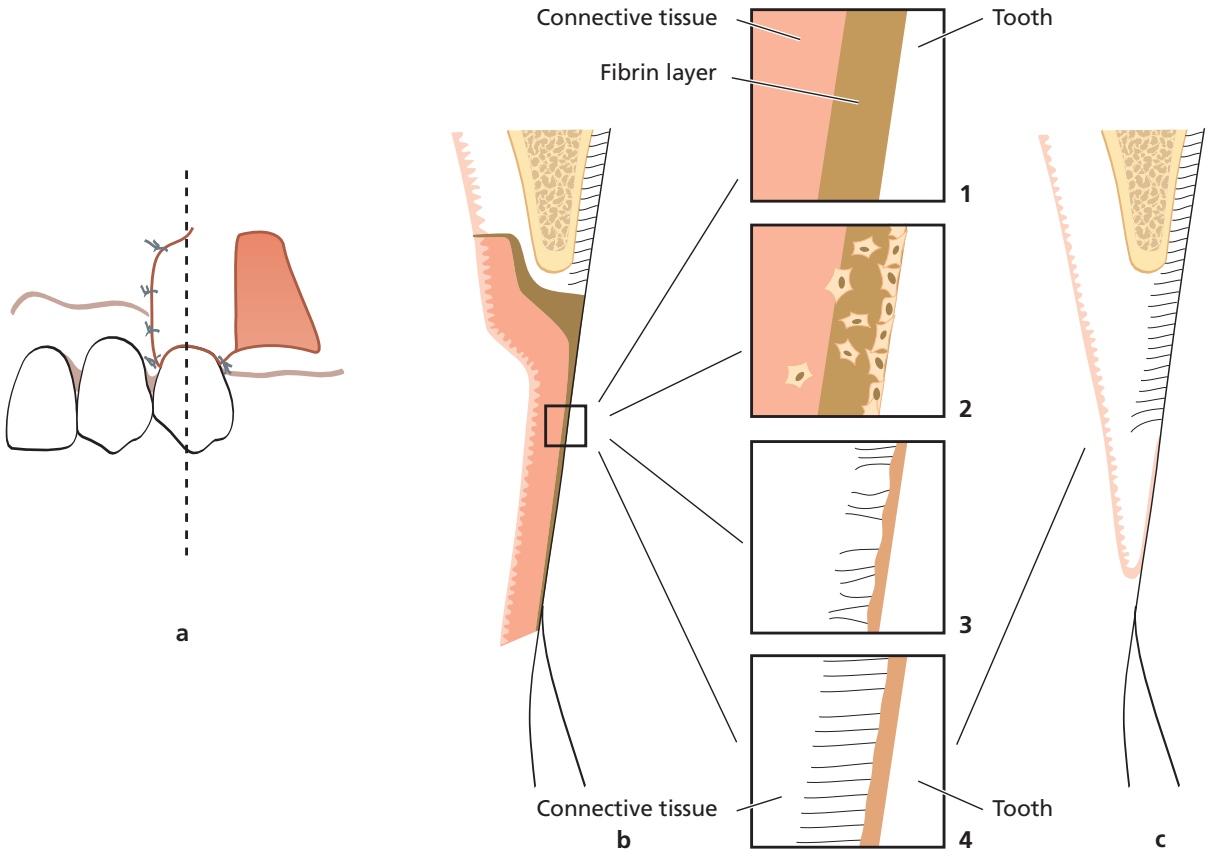

Fig. 44-53 (a) Schematic drawing illustrating healing following treatment of a localized soft tissue recession with a pedicle graft. (b) Cross section through the area immediately after operation. The framed areas (1–4) illustrate the four stages into which the healing process can be divided. (c) Area after healing. Approximately 50% of the successfully covered defect may show new connective tissue attachment.

the root surface in the apical portion of the recession.

4. *The maturation stage.* This last stage of healing is characterized by continuous formation of collagen fibers. After 2–3 months bundles of collagen fibers insert into the cementum layer on the curetted root surface in the apical portion of the recession.

Results of experimental studies in monkeys and dogs on the healing characteristics of the periodontal wound have been interpreted to indicate that gingival connective tissue lacks the ability to form a new connective tissue attachment to the root, but may induce root resorption (see Chapter 25). This finding is of particular interest when considering the rationale for the treatment of recession defects by free or pedicle soft tissue grafts. Since, in these surgical procedures, gingival connective tissue is placed in contact with a denuded root surface, root resorption should be expected to occur. The reason why it is not a common complication following this type of treatment can be explained by two possible events. Either cells from the periodontal ligament form a fibrous attachment to the root surface or epithelial cells proliferate apically, forming a root-protective barrier (long junctional epithelium) towards the gingival connective tissue.

Histologic studies on whether it is the one or the other type of attachment that results following treatment of recessions with pedicle grafts indicate that new connective tissue attachment may be formed in part of the defect. In the study by Wilderman and Wentz (1965) a connective tissue attachment of around 2 mm and an epithelial attachment of the same height had formed in the soft tissue covered portion of the defect, i.e. about 50% of the successfully covered defect showed new connective tissue attachment. Gottlow *et al*. (1986) examined the result of healing following treatment of experimentally produced recession type defects with a coronally advanced flap in dogs (Fig. 44-54). The histologic analysis after 3 months of healing disclosed that, on average, 20% of the apico-coronal length of the original defect had been exposed due to recession during healing (i.e. about 80% root coverage was achieved), 40% was covered by epithelium and 40% demonstrated connective tissue attachment with cementum formation (Fig. 44-55). Determining factors for the type of healing result were the size and the shape of the defect. The possibility of achieving a new connective tissue attachment in the apical portion of the defect seemed to be considerably better in narrow recession defects than in wider ones, most likely because the periodontal ligament at the lateral parts of the defect will serve as a source of granulation

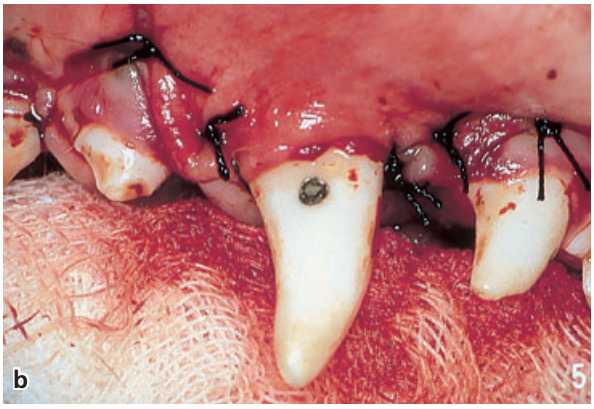

Fig. 44-54 Clinical photographs illustrating the treatment of an experimentally induced localized recession defect in a dog with a coronally displaced flap. (a) Presurgical appearance of the localized recession defect. (b) The site following flap closure of the defect and (c) following 3 months of healing.

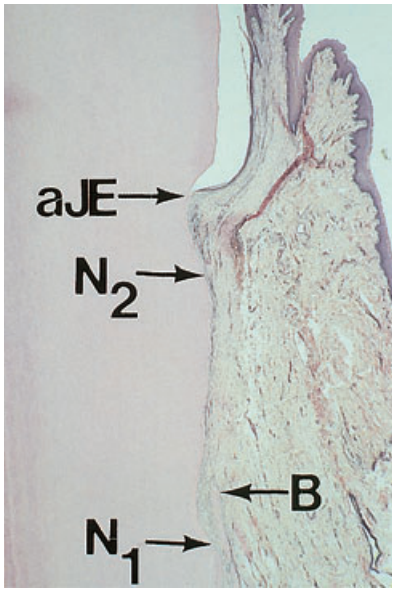

Fig. 44-55 Microphotograph of the healing following a coronally displaced flap in the dog as illustrated in Fig. 44-54. A new connective tissue attachment is formed and extends coronally from the apical border of the notch prepared at the bottom of the bone dehiscence (N_1) to the apical termination of the epithelium (aJE) located within the notch indicating the presurgical level of the soft tissue margin (N_2). B = alveolar bone crest.

tissue from which a new connective tissue attachment can develop.

Healing following pedicle graft procedures has also been histologically studied in monkeys (Caffesse *et al*. 1984; Gottlow *et al*. 1990), and in these studies 38–44% of the successfully covered recession defects demonstrated formation of new connective tissue attachment. The study by Gottlow *et al*. (1990) also showed that the use of a GTR membrane between the root surface and the pedicle graft generated significantly more new connective tissue attachment (79% of the covered part of the recession defect). A significantly increased amount of cementum formation with inserting collagen fibers was also demonstrated following the utilization of enamel matrix proteins in combination with a coronally advanced flap for treatment of experimentally produced recession defects in dogs (Sallum *et al*. 2004).

Some case reports with human block sections provide further evidence that new connective tissue attachment may be formed following pedicle graft procedures. Histologic evaluation of two teeth treated with a laterally positioned flap revealed that connective tissue attachment was re-established in the apical quarter of the successfully covered portion of the root (Sugarman 1969). Cortellini *et al*. (1993) examined histologically a tooth treated with the GTR procedure and showed that connective tissue faced 74% of the length of the recession defect. New cementum with inserting collagen fibers, i.e. new connective tissue attachment, covered 48% of the distance between the apical border of the root instrumentation and the soft tissue margin. In addition, histomorphometric assessments of a tooth treated with enamel matrix proteins revealed that new cementum covered 73% of the original defect (Heijl 1997).

Healing of free soft tissue grafts

Survival of a free soft tissue graft placed over a denuded root surface depends on diffusion of plasma and subsequent revascularization from those parts of the graft that are resting on the connective tissue bed surrounding the dehiscence. The establishment of collateral circulation from adjacent vascular borders of the bed allows the healing phenomenon of "bridging" (Sullivan & Atkins 1968a). Hence, the amount of tissue that can be maintained over the root surface is limited by the size of the avascular area (Oliver *et al*. 1968; Sullivan & Atkins 1968). Other factors considered critical for the survival of the tissue graft placed over the root surface are that a sufficient vascular bed is prepared around the dehiscence and that a thick graft is used (Miller 1985b).

Another healing phenomenon frequently observed following free graft procedures is "creeping attachment", i.e. coronal migration of the soft tissue margin. This occurs as consequence of tissue maturation during a period of about 1 year post treatment.

There are few histologic evaluations of the nature of the attachment established to the root surface following the use of free grafts for root coverage. Sugarman (1969) reported from a histologic evaluation of a human tooth treated with a free soft tissue graft that new connective tissue attachment was found in the apical quarter of the successfully covered recession defect. Harris (1999) and Majzoub *et al*. (2001), each reporting the histologic outcome of free connective tissue grafts in two cases, found only minimal amounts of new cementum formation in the most apical part of the recession defect and that healing resulted in a long junctional epithelium occupying the interface between the covering soft tissue and the root. Carnio *et al*. (2002) performed histologic evaluation of four cases of root coverage with a connective tissue graft combined with application of enamel matrix proteins (Emdogain®). They reported that the healing resulted in connective tissue adhesion to the root surface and that the formation of new cementum was observed only in the most apical end of the grafted area.

Thus, the limited histologic information available from humans on the healing of free soft tissue grafts indicates that a healing pattern similar to the one discussed above following pedicle graft procedures may result, namely that connective tissue attachment may be established in the most apical and lateral parts of the recession defect, but that an epithelial attachment is formed along the major portion of the root. Further, the application of enamel matrix proteins may prevent the apical migration of the epithelium but may not favor the formation of a true

connective tissue attachment between the free graft and the root surface.

Interdental papilla reconstruction

There may be several reasons for loss of papilla height and the establishment of "black triangles" between teeth. The most common reason in the adult individual is loss of periodontal support due to plaque-associated lesions. However, abnormal tooth shape, improper contours of prosthetic restorations, and traumatic oral hygiene procedures may also negatively influence the outline of the interdental soft tissues.

Nordland and Tarnow (1998) proposed a classification system regarding the papillary height adjacent to natural teeth, based on three anatomic landmarks: the interdental contact point, the apical extent of the facial CEJ, and the coronal extent of the proximal CEJ (Fig. 44-56):

- *Normal*: the interdental papilla occupies the entire embrasure space apical to the interdental contact point/area.
- *Class I*: the tip of the interdental papilla is located between the interdental contact point and the level of the CEJ on the proximal surface of the tooth.
- *Class II*: the tip of the interdental papilla is located at or apical to the level of the CEJ on the proximal surface of the tooth but coronal to the level of the CEJ mid-buccally.
- *Class III*: the tip of the interdental papilla is located at or apical to the level of the CEJ mid-buccally.

In an observational study in humans, Tarnow *et al*. (1992) analyzed the correlation between the presence of interproximal papillae and the vertical distance between the contact point and the interproximal bone crest. When the vertical distance from the contact point to the crest of bone was 5 mm or less, the papilla was present almost 100% of the time, whereas if the distance was 6 mm or more only partial papilla fill of the embrasure between the teeth was most commonly found. Considering that a supracrestal connective tissue attachment zone of approximately 1 mm is normally found (Gargiulo 1961), the observation indicates that the biologic height of the interdental papilla may be limited to about 4 mm. This interpretation is supported by the observation that in interdental areas denuded following an apically repositioned flap procedure, an up-growth of around 4 mm of soft tissue had taken place 3 years after surgery (Van der Velden 1982). Hence, before attempts are made to surgically reconstruct an interdental papilla, it is important to carefully assess both (1) the vertical distance between the bone crest and the apical point of the contact area between the crowns and (2) the soft tissue height in the interdental area. If the distance bone crest–contact point is ≤5 mm and the papilla height is less than 4 mm, surgical intervention for increasing the volume of the papilla could be justified in order to solve the problem of an interdental "black triangle". However, if the contact point is located >5 mm from the bone crest, because of loss of periodontal support and/or an inappropriate interdental contact relationship between the crowns, means to lengthen the contact

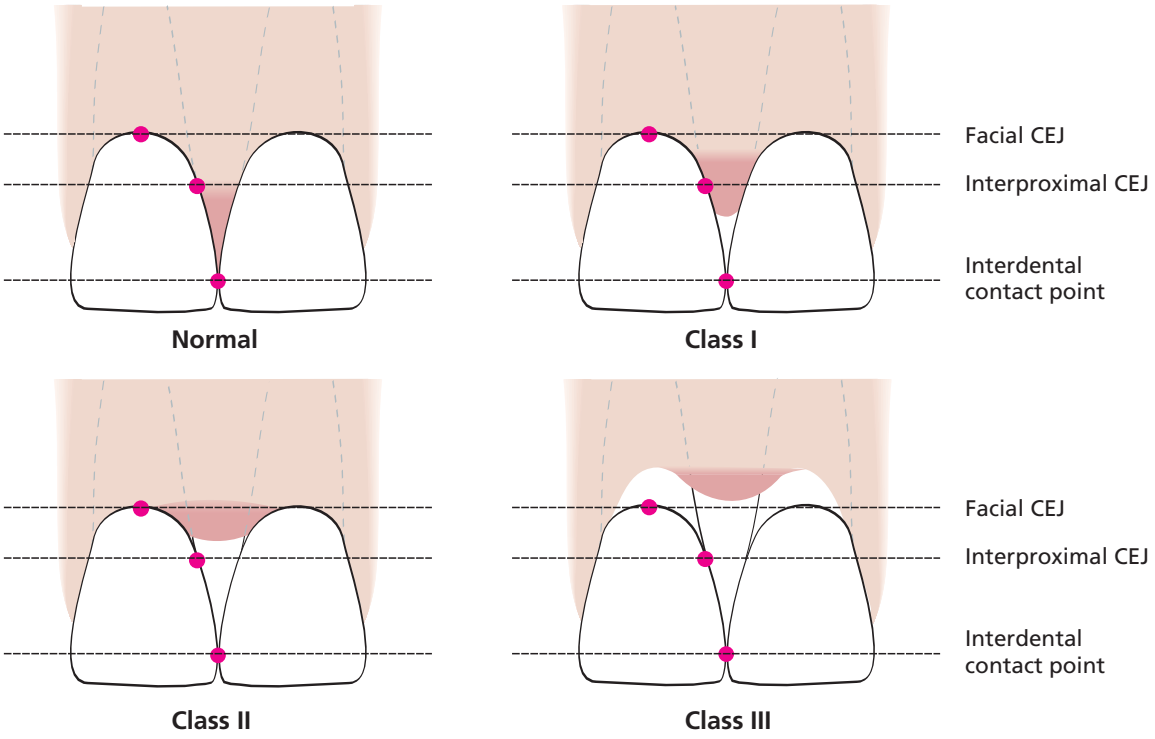

Fig. 44-56 Schematic drawing illustrating the classification system for papilla height (Nordland & Tarnow 1998).

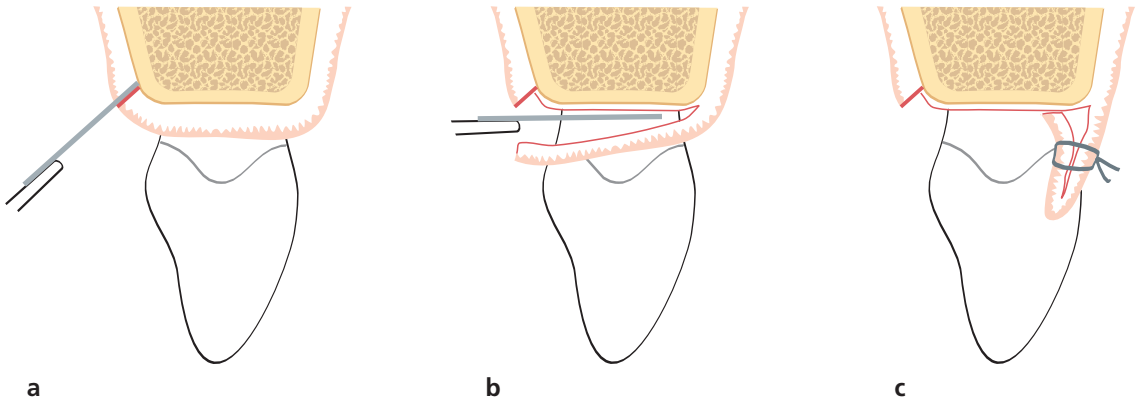

Fig. 44-57 Papilla reconstruction – pedicle graft technique. Schematic drawings illustrating the surgical technique (see the text for explanation).

area apically between the teeth should be selected rather than a surgical attempt to improve the topography of the papilla.

If loss of papilla height is only caused by soft tissue damage from oral hygiene devices, interproximal hygiene procedures must be initially discontinued to allow soft tissue recovery and then successively modified in order to eliminate/minimize traumatic injury to the papillae.

Surgical techniques

Several case reports have been published regarding surgical techniques for reconstruction of deficient papillae (e.g. Beagle 1992; Han & Takei 1996; Azzi *et al*. 1999). However, the predictability of the various procedures has not been documented and no data are available in the literature providing information on the long-term stability of surgically regained interdental papillae.

Beagle (1992) described a pedicle graft procedure utilizing the soft tissues palatal to the interdental area (Fig. 44-57). A split-thickness flap is dissected on the palatal aspect of the interdental area. The flap is elevated labially, folded, and sutured to create the new papilla at the facial part of the interdental area. A periodontal dressing is applied on the palatal aspect only, in order to support the papilla.

Han and Takei (1996) proposed an approach for papilla reconstruction ("semilunar coronally repositioned papilla") based on the use of a free connective tissue graft (Fig. 44-58). A semilunar incision is placed in the alveolar mucosa facial to the interdental area and a pouch-like preparation is performed into the interdental area. Intrasulcular incisions are made around the mesial and distal half of the two adjacent teeth to free the connective tissue from the root surfaces to allow coronal displacement of the gingival–papillary unit. A connective tissue graft, taken from the palate, is placed into the pouch to support the coronally positioned interdental tissue.

Azzi *et al*. (1999) described a technique in which an envelope-type flap is prepared for coverage of a connective tissue graft (Fig. 44-59). An intrasulcular incision is made at the tooth surfaces facing the interdental area to be reconstructed. Subsequently, an incision is placed across the facial aspect of the interdental area and an envelope-type split-thickness flap is elevated into the proximal site as well as apically to a level beyond the mucogingival line. A connective tissue graft is harvested from the tuberosity area, trimmed to adequate size and shape, and placed under the flaps in the interdental papilla area. The flaps are brought together and sutured with the connective tissue graft underneath.

Crown-lengthening procedures

Excessive gingival display

In most patients, the lower edge of the upper lip assumes a "gum-wing" profile which limits the amount of gingiva that is exposed when a person smiles. Patients who have a high lip line expose a broad zone of gingival tissue and may often express concern about their "gummy smile" (Fig. 44-60a). The form of the lips and the position of the lips during speech and smiling cannot be easily changed, but the dentist may, if necessary, modify/control the form of the teeth and interdental papillae as well as the position of the gingival margins and the incisal edges of the teeth. In other words, it is possible by a combination of periodontal and prosthetic treatment measures to improve dentofacial esthetics in this category of patient.

As a base for treatment decisions, a careful analysis of the dentofacial structures and how they may affect esthetics should be performed. It should include the following features:

- Facial symmetry
- Interpupillary line; even or uneven
- Smile line: low, median or high
- Dental midline in relation to facial midline
- Gingival display during speech and during broad, relaxed smile
- Harmony of gingival margins

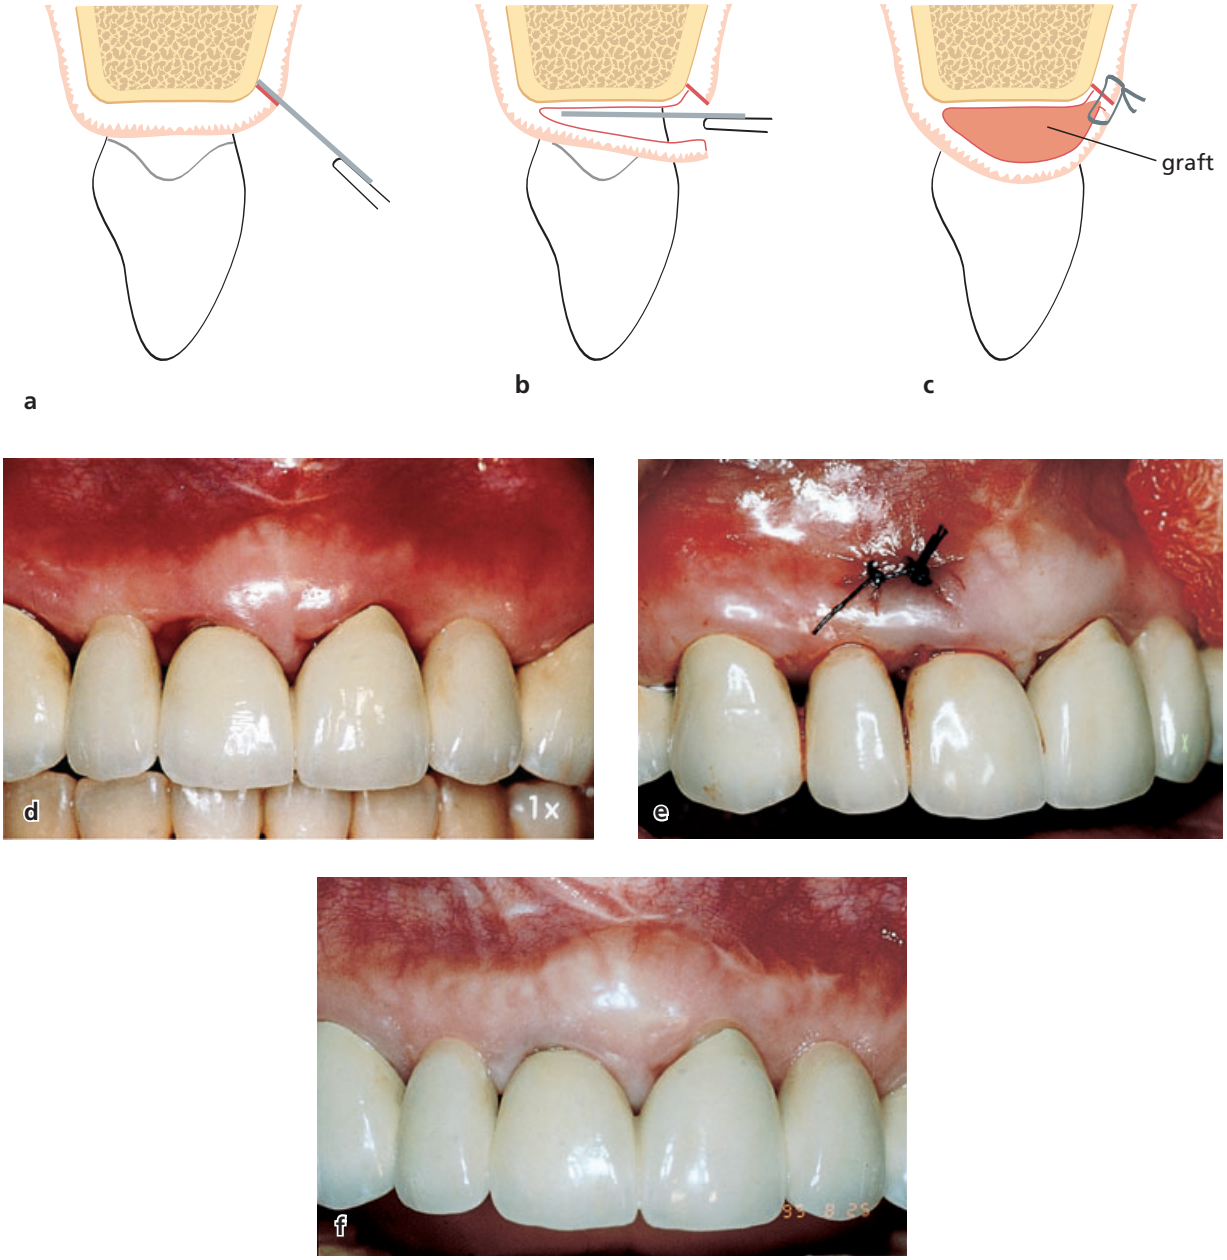

Fig. 44-58 Papilla reconstruction – the "semilunar coronally repositioned papilla" technique. (a–c) Schematic drawings illustrating the surgical technique (see the text for explanation). (d–f) Reconstruction of papillae distal to the central incisors with the use of the semilunar coronally repositioned papilla technique in a patient with a fixed bridge reconstruction.

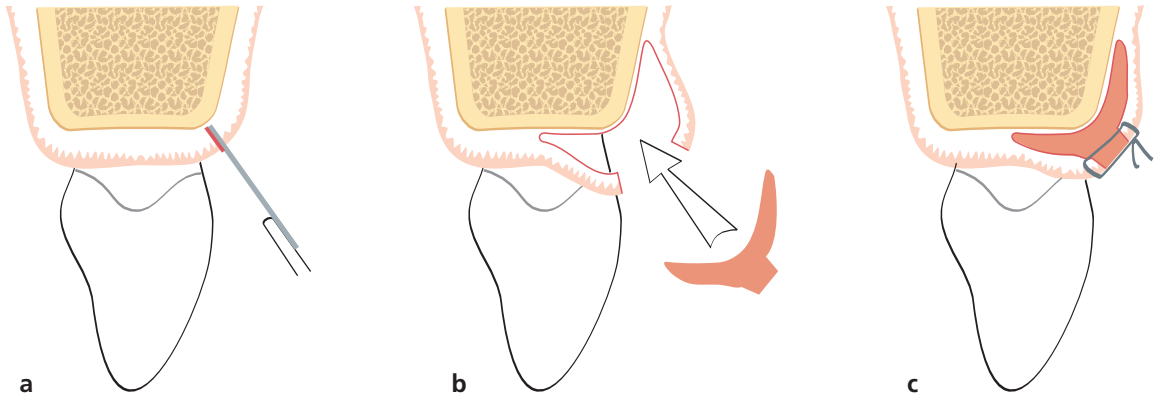

Fig. 44-59 Papilla reconstruction – "envelope" technique. Schematic drawings illustrating the surgical technique (see the text for explanation).

Fig. 44-60 Crown-lengthening procedure. (a,b) Pretreatment views. The clinical crowns are considerably shorter than the anatomic crowns. The lateral incisors were congentially missing and orthodontic treatment had been carried out to move the posterior teeth anteriorly. The canine teeth in the position of the lateral incisors added to the esthetic disharmony. (c) A gingivectomy was performed to expose the anatomic crowns of the teeth. (d) One month post surgery. At this appointment, the canine and first premolar teeth were reshaped and bonded. (e) Tooth form and proportional balance were improved by bonding. (f) At 3 years post-treatment, the gingival tissues exhibited no rebound and retained the architectural form sculpted into the tissue at the time of the surgical procedure.

- Location of gingival margins in relation to the CEJs
- Tooth size and proportions/harmony
- Incisal plane/occlusal plane.

If excessive gingival exposure is due to insufficient length of the clinical crowns, a crown-lengthening procedure is indicated to reduce the amount of gingiva exposed, which in turn will favorably alter the shape and form of the anterior teeth. To select the proper treatment approach for crown lengthening, an analysis of the individual case with regard to crown–root–alveolar bone relationships should also be included.

In the young adult with an intact periodontium the gingival margin normally resides about 1 mm coronal to the CEJ. However, some patients may have a height of free gingiva that is greater than 1 mm, resulting in an disproportional appearance of the clinical crown. If such a patient complains about their "small front teeth" and the periodontium is of a thin biotype, full exposure of the anatomic crown

Fig. 44-61 (a) Pretreatment view. The patient disliked her "small front teeth" and diastema. Radiographs and probing indicated the gingival tissues were covering the cervical one third of the crowns. Crestal bone was thin and in normal relationship to the cemento-enamel junctions. The patient preferred "pink gums" if she could possibly have them. (b) A long externally beveled path of incision was used to accomplish the gingivectomy. (c) This view shows the color changes and pleasing architecture produced in the anterior gingiva at 2 months post surgery. The diastema was partially closed by direct bonding at this time. (d) Post-treatment view showing the enhancement of esthetic values for the patient.

can be accomplished by a gingivectomy/gingivoplasty procedure (Fig. 44-60).

An assessment should also be made regarding the amount and pattern of pigmentation existing within the gingival tissues, and the patient's desire to maintain or lessen the pigmentation contained within the tissues. The externally beveled path of incision that is usually employed in a gingivectomy procedure will remove the pigmentation and produce pink gingival tissue upon initial healing (Fig. 44-61). The surgically induced color change in the tissues comes about rapidly and markedly affects esthetic values. For this reason, an externally beveled gingivectomy procedure should not be terminated at the midline in patients that have pigmented gingival tissues. It should be extended across the midline to the premolar area to avoid a color mismatch in the esthetic zone of the anterior teeth. The color change may be permanent or the pigmentation may slowly return over a period of a year or more. Patients should be informed of the changes in tissue color that will occur and be allowed to make a choice as to the color of the tissue they will have post-surgically. If they wish to maintain their pigmentation, an internally beveled path of incision (internal gingivectomy) should be employed (Fig. 44-62).

If the periodontium is of the thick biotype and there is a bony ledge at the osseous crest, an apically positioned flap procedure (see Chapter 38) should be performed. This will allow for osseous recontouring (Fig. 44-63).

More extensive bone recontouring is required to solve esthetic problems found in patients who do indeed have short anatomic crowns in the anterior section of the dentition. In this category of patients, prosthetic measures must be used after resective periodontal therapy to increase the apico-coronal dimension of the crowns (Fig. 44-64). Patients who are candidates for this kind of resective therapy can be divided into two categories:

1. Subjects who have normal occlusal relationships and incisal guidance. In this category the incisal line of the front teeth must remain unaltered but the clinical crowns can be made longer by surgically exposing root structure and by locating the cervical margins of the restorations apical to the CEJ (Fig. 44-64).
2. Subjects who have abnormal occlusal relationships with excessive interocclusal space in the posterior dentition when the anterior teeth are in edge-to-edge contact. In this category of patients

Fig. 44-62 (a) Pretreatment view. This patient disliked the looks of her "small front teeth"; she sought consultation to have her teeth made longer by crowning them. Probing and radiographs revealed normal osseous morphology and a wide zone of attached gingiva that covered the cervical one third of the incisors. It was explained to the patient that a surgical solution was preferred to restorative procedures to make her teeth longer. The patient made a request that the color of her gingival tissues remain unchanged. (b) An internally beveled path of incision was use to effect an "internal gingivectomy" to maintain the pigmentation in the tissues. This created mini flaps in the areas of the papillae. (c) 5-0 gut sutures were used to stabilize the papillae. (d). The crown lengthening that was achieved with maintenance of color harmony can be seen in this view at 3 months post surgery. (Courtesy of Dr. E. Saacks, Pennsylvania, USA.)

Fig. 44-63 (a) Pretreatment view. The patient, a dentist, requested crown lengthening to lessen his "gummy smile" and give him a more masculine appearance. The patient had a wide zone of attached gingiva and thick crestal bone. Palpation indicated bony exostoses. (b) An apically positioned flap and osseous resective surgery, from second premolar to second premolar, were used to lengthen the teeth. The surgery was confined to the labial surfaces. This view shows one half of the surgery completed. (c) Vertical mattress sutures were utilized to hold the flap apically. (d) Three years post-treatment. Note that the gingival tissues retain the morphology created at the time of surgery.

Fig. 44-64 Crown lengthening by surgical and prosthetic procedures. (a) Pretreatment view. The patient displayed "short front teeth" and a broad exposure of gum tissue. The full anatomic crown is exposed in this case and the surgically induced recession will expose root structure. (b) The patient had an unusually wide zone of attached gingiva. The gingival margins were positioned apically by making an internally beveled flap with a submarginal entrance incision as outlined in red ink. The crest of the bone was reduced in height. (c) After the tissues had matured following surgery, individual crowns were prepared for each of the anterior teeth. Crown lengthening was achieved and the patient no longer exposed a broad expanse of gum tissue. (Courtesy of Dr. D. Garber, Atlanta, GA, USA.)

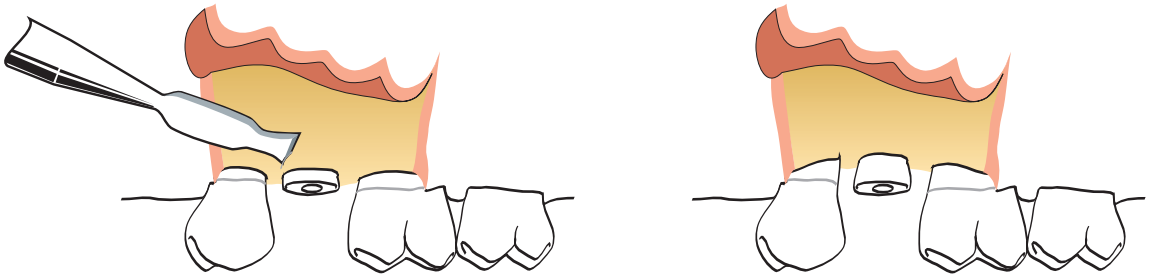
the length of the maxillary front teeth can be reduced without inducing posterior occlusal interferences. In addition, the marginal gingiva can be resected or relocated to an apical position before crown restorations are made.

In some individuals with an excessive display of gingiva, the size and shape of the teeth and the location of the gingival margins may be perfectly normal. The excessive display of gingiva in these cases is often caused by vertical maxillary excess and a long mid-face (Fig. 44-65). Periodontal crown lengthening procedures will not suffice to solve their problems, but rather the maxilla must be altered by a major maxillofacial surgical procedure. The risk–benefit and cost–benefit ratios must be thoroughly evaluated before recommending this type of surgical therapy to correct esthetic problems.

Fig. 44-65 This patient displays a large expanse of gingival tissue when smiling or speaking. The patient has a long mid-face and vertical maxillary excess. The gingival margins reside 1 mm coronal to the cemento-enamel junction and the anatomic and clinical crowns are approximately equal.

Exposure of sound tooth structure

Crown-lengthening procedures may be required to solve problems such as (1) inadequate amount of tooth structure for proper restorative therapy, (2) subgingival location of fracture lines, and (3) subgingival location of carious lesions. The techniques used to accomplish crown lengthening include (1) apically positioned flap procedure including bone resection and (2) forced tooth eruption with or without fiberotomy.



a b

Fig. 44-66 Surgical resective therapy for crown lengthening cannot be confined to the tooth in need of treatment. The principles of osseous resection require that bone be removed from the adjacent teeth to create a gradual rise and fall in the profile of the osseous crest. This causes a loss of attachment apparatus and recession of the adjacent teeth as well.

Apically positioned flap with bone recontouring

The apically positioned flap technique with bone recontouring (resection) may be used to expose sound tooth structure. As a general rule, at least 4 mm of sound tooth structure must be exposed at the time of surgery. During healing the supracrestal soft tissues will proliferate coronally to cover 2–3 mm of the root (Herrero *et al*. 1995; Pontoriero & Carnevale 2001; Lanning *et al*. 2003), thereby leaving only 1–2 mm of supragingivally located sound tooth structure. When this technique is used for crown lengthening it must also be realized that gingival tissues have an inherent tendency to bridge abrupt changes in the contour of the bone crest. Thus, in order to retain the gingival margin at its new and more apical position, bone recontouring must be performed not only at the problem tooth but also at the adjacent teeth to gradually reduce the osseous profile (Fig. 44-66). Consequently, substantial amounts of attachment may have to be sacrificed when crown lengthening is accomplished with an apically positioned flap technique. It is also important to remember that, for esthetic reasons, symmetry of tooth length must be maintained between the right and left sides of the dental arch. This may, in some situations, call for the inclusion of even more teeth in the surgical procedure.

- *Indication:* crown lengthening of multiple teeth in a quadrant or sextant of the dentition.
- *Contraindication:* surgical crown lengthening of single teeth in the esthetic zone (Fig. 44-67).
- *Technique:* The apically positioned flap technique and methods used for bone recontouring are discussed in Chapter 38.

Forced tooth eruption

Orthodontic tooth movement can be used to erupt teeth in adults (Reitan 1967; Ingber 1974, 1976; Potashnick *et al*. 1982). If moderate eruptive forces are used, the entire attachment apparatus will move in unison with the tooth. The tooth must be extruded a distance equal to or slightly longer than the portion of sound tooth structure that will be exposed in the subsequent surgical treatment. After the tooth has reached the intended position and has been stabilized, a full-thickness flap is elevated and bone recontouring is performed to expose sound root structure. For esthetic reasons it is important that the bone and soft tissue levels at adjacent teeth remain unchanged.

Fig. 44-67 A deformity which interfered with dentofacial esthetics was created at the right central incisor by using a surgical crown lengthening procedure at one single tooth to expose sound tooth structure. The soft tissues cannot follow the abrupt and steep changes in the osseous profile. The crown preparation invaded the zone of normal supracrestal connective tissue. This created a chronic periodontal pocket and adversely affected esthetics. (Courtesy of Dr. A. Winnick, Toronto, Canada.)

Forced tooth eruption can also be used to level and align gingival margins and the crowns of teeth to obtain esthetic harmony. Instead of using surgical procedures to position the gingival margins of unaffected normal teeth apically to the level of a tooth with recession or orthodontic malalignment, the tooth that is malpositioned or has sustained recession is erupted to the level of the normally positioned teeth. The entire attachment apparatus and dentogingival junction will follow the root of the tooth as it is moved coronally (Fig. 44-68).

Fig. 44-68 Forced tooth eruption (show method) used to level gingival margins, treat recession on a single tooth and create esthetic harmony. (a,b) Recession on the left central incisor exposed the root surface darkened from root canal treatment. The uneven gingival margins and dark root surface detracted from an otherwise attractive smile. (c) A nitol wire with an offset bracket was used to slowly extrude the incisor. (d) Occlusal adjustment was done on the lingual side of the crown to create room for the tooth to erupt. This view, at 1 month in tooth movement, shows the gingival tissues moving with the root of the tooth. (e) Sufficient eruption had occurred by 3 months to level the gingival margins. The orthodontic brackets were used for temporary stabilization and a new crown was prepared. (f) The new crown masked the show-through of the dark root. The even gingival margins and beautiful crown created esthetic harmony. (Courtesy of Dr. J. Ingber, Philadelphia, PA, USA.)

- *Indication:* crown lengthening at sites where removal of attachment and bone from adjacent teeth must be avoided. The forced eruption technique can also be used as a means of reducing pocket depth at sites with angular bony defects (Brown 1973; Ingber 1974, 1976). The angular bony defect at the problem tooth can be reduced while the attachment level at the adjacent tooth surface remains unchanged (Fig. 44-69).
- *Contraindication:* the forced eruption technique requires the use of fixed orthodontic appliances. Thus, in patients who only have a few teeth remaining, an alternative approach for crown lengthening has to be selected.
- *Technique:* orthodontic brackets are bonded to the problem tooth and to adjacent teeth and are combined with an arch wire. Another type of mechanical system can be utilized by placing a heavy gauge bar or wire in grooves prepared in the adjacent teeth and over the problem tooth. A power elastic is tied from the bracket to the arch wire (or the bar), which pulls the tooth coronally. If most of the

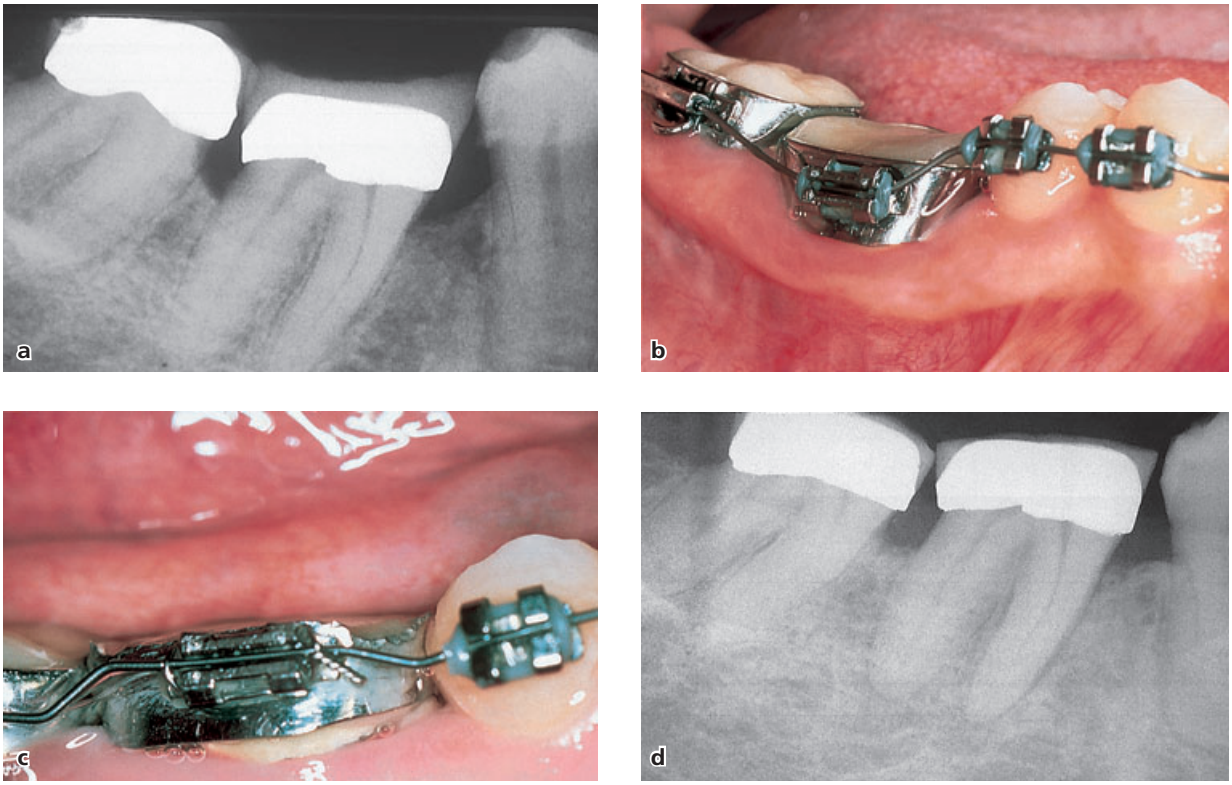


Fig. 44-69 Slow tooth eruption procedure used to level cemento-enamel junctions and angular bone crests. (a) Pretreatment radiograph. (b) A nitol wire was used to erupt the molar. (c) The crown was shortened over a period of 4 months by selective grinding. (d) Radiograph taken 8 months after the start of treatment. The angular bone defects were leveled.

crown structure is lost, root canal therapy is required. A post placed in the root canal is fitted with a power elastic, which is also joined with the arch wire. The direction of the tooth movement must be carefully checked to ensure that the problem tooth is not tilted or moved toward the adjacent tooth surfaces.

Forced tooth eruption with fiberotomy

If fiberotomy is performed during the forced tooth eruption procedure the crestal bone and the gingival margin are retained at their pre-treatment locations, and the tooth–gingiva interface at adjacent teeth is unaltered. Fiberotomy is performed by the use of a scalpel at 7–10-day intervals during the forced eruption to sever the supracrestal connective tissue fibers, thereby preventing the crestal bone from following the root in coronal direction. In the case presented in Fig. 44-70, fiberotomy was performed only at the mesial half of the root. Radiographs obtained after 9 weeks demonstrate that crestal bone migration has occurred at the distal but not at the mesial surface of the erupted tooth (Pontoriero *et al*. 1987).

- *Indication:* crown lengthening at sites where it is important to maintain the location of the gingival margin at adjacent teeth unchanged.
- *Contraindication:* fiberotomy should not be used at teeth associated with angular bone defects.
- *Technique:* similar to the technique described for the forced tooth eruption procedure. Fiberotomy is performed once every 7–10 days during the phase of forced tooth eruption.

Ectopic tooth eruption

Surgical intervention is often indicated for teeth erupting ectopically, i.e. with an eruption position facial to the alveolar ridge (Fig. 44-71). To create a satisfactory width of the gingiva for the permanent tooth, the tissue entrapped between the erupting tooth and the deciduous tooth is usually utilized as donor tissue (Agudio *et al*. 1985; Pini Prato *et al*. 2000b).

Three different techniques have been described for the interceptive mucogingival treatment of buccally erupting teeth, depending on the distance from the donor site (entrapped gingiva) to the recipient site (area located facially–apically to the erupting permanent tooth) (Agudio *et al*. 1985; Pini Prato *et al*. 2000b):

- *Double pedicle graft* (Fig. 44-72). This flap procedure is indicated when the permanent tooth erupts within the zone of keratinized tissue but close to the mucogingival junction. An intrasulcular incision is performed at the deciduous tooth and extended laterally to the gingival crevice of the adjacent teeth and apically to the erupting

Fig. 44-70 Rapid tooth eruption procedure in conjunction with fiberotomy procedure. (a) Buccal view, the fracture on the first premolar extended subgingivally. (b) Soft tooth structure was excavated and a twisted wire with an occlusal hook was temporarily cemented in the root canal. A bar was placed into the amalgam restoration on the premolar and bonded to the lingual surface of the canine. (c,d) Sulcular fiber resection was performed at the mesial half of the tooth to the level of the bone crest. The distal half remained as a control surface. The fiber resection was repeated once a week during the 3-week eruption phase. (e) The tooth was stabilized for 6 weeks, and at that time a full-thickness flap was raised. The bone crest had a "positive" angulation at the distal surface and remained unchanged at the "test" mesial surface. Osseous resection was used to level the bony septum on the distal surface. (f) Ample crown lengthening was obtained and the gingival margins healed to their former shape and location. (g) Pretreatment radiograph enlarged to show the normal shape of the crests of the interdental septae. (h) Enlargement of the post-eruption radiograph (3 weeks of rapid eruption and 6 weeks of stabilization) to show the "positive" angular crest on the "control" distal side and the unchanged crest on the mesial "test" side. permanent tooth. By mobilization of the flap apical to the mucogingival line, the entrapped gingiva can be elevated and transposed for positioning apically to the erupting tooth. Sutures may be placed to secure the position of the gingival tissue facial to the erupting tooth.

- *Apically positioned flap* (Fig. 44-73). When the permanent tooth is erupting apical to the mucogingival junction, vertical releasing incisions have to be placed to allow for apical positioning of the keratinized tissue. Two lateral releasing incisions are made and extended apically beyond the mucogin-

gival junction. An intrasulcular incision is performed at the deciduous tooth and a partial-thickness flap is elevated beyond the ectopically erupting tooth. The mobilized gingival flap is moved apical to the erupting tooth and secured in position by sutures.

- *Free gingival graft* (Fig. 44-74). If the tooth is erupting within the alveolar mucosa distant to the mucogingival junction, a free gingival graft procedure may be selected. The entrapped gingiva is removed by a split incision and used as an epithelialized connective tissue graft. The free gingival graft is placed at a prepared recipient site facial/apical of the erupting tooth. Careful suturing is performed to secure close adaptation of the graft to the underlying connective tissue bed.

All the described procedures have been proven to be effective in establishing a facial zone of gingiva following the alignment of teeth erupting in an ectopic position (Pino Prato *et al*. 2000b,c).

The deformed edentulous ridge

A partially edentulous ridge may retain the general shape of the alveolar process. Such a ridge is traditionally referred to as a normal ridge. Even though this normal ridge has retained the bucco-lingual and apico-coronal dimensions of the alveolar process, it is not normal in many other respects; the eminences that existed in the bone over the roots are no longer present, and the interdental papillae are missing.

The smooth contours of the normal ridge create problems for the restorative dentist. In a fixed bridge the pontics (1) frequently give the impression that they rest on the top of the ridge rather than emerge from within the alveolar process, (2) lack a root eminence, and (3) lack marginal gingivae and interdental papillae. Dark triangles, which almost always inter-

fere with dentofacial esthetics, are present in the embrasure area between the pontics and between the abutments and the pontics. In other words, in the presence of a normal ridge it may be difficult or impossible to produce a fixed prosthesis which truly restores the esthetics and function of the natural dentition.

Prevention of soft tissue collapse following tooth extraction

Following extraction of a tooth, the topography of the surrounding soft and hard tissues will be altered. The soft tissue margin will collapse and the height of the adjacent papillae will be reduced. This soft tissue collapse may be prevented by immediate post-extraction placement of an ovate pontic to support the soft tissues. Figure 44-75 illustrates such a situation where a central incisor had to be extracted due to root fracture. With the immediate placement of the pontic the facial soft tissue margin and the papillae were maintained almost unchanged following the healing of the extraction site. Also, in situations where several adjacent teeth have to be extracted, insertion of ovate pontics may facilitate the preservation of the outline of the soft tissue ridge (Fig. 44-76).

Prevention of ridge collapse due to alveolar bone resorption following tooth extractions must also be considered. Borghetti and Laborde (1996) recommended means for prevention of bone ridge collapse after tooth extraction in any case of:

1. Fracture of the vestibular osseous plate during tooth extraction or due to trauma
2. Resorption of the vestibular osseous plate
3. Presence of a thin vestibular bone plate.

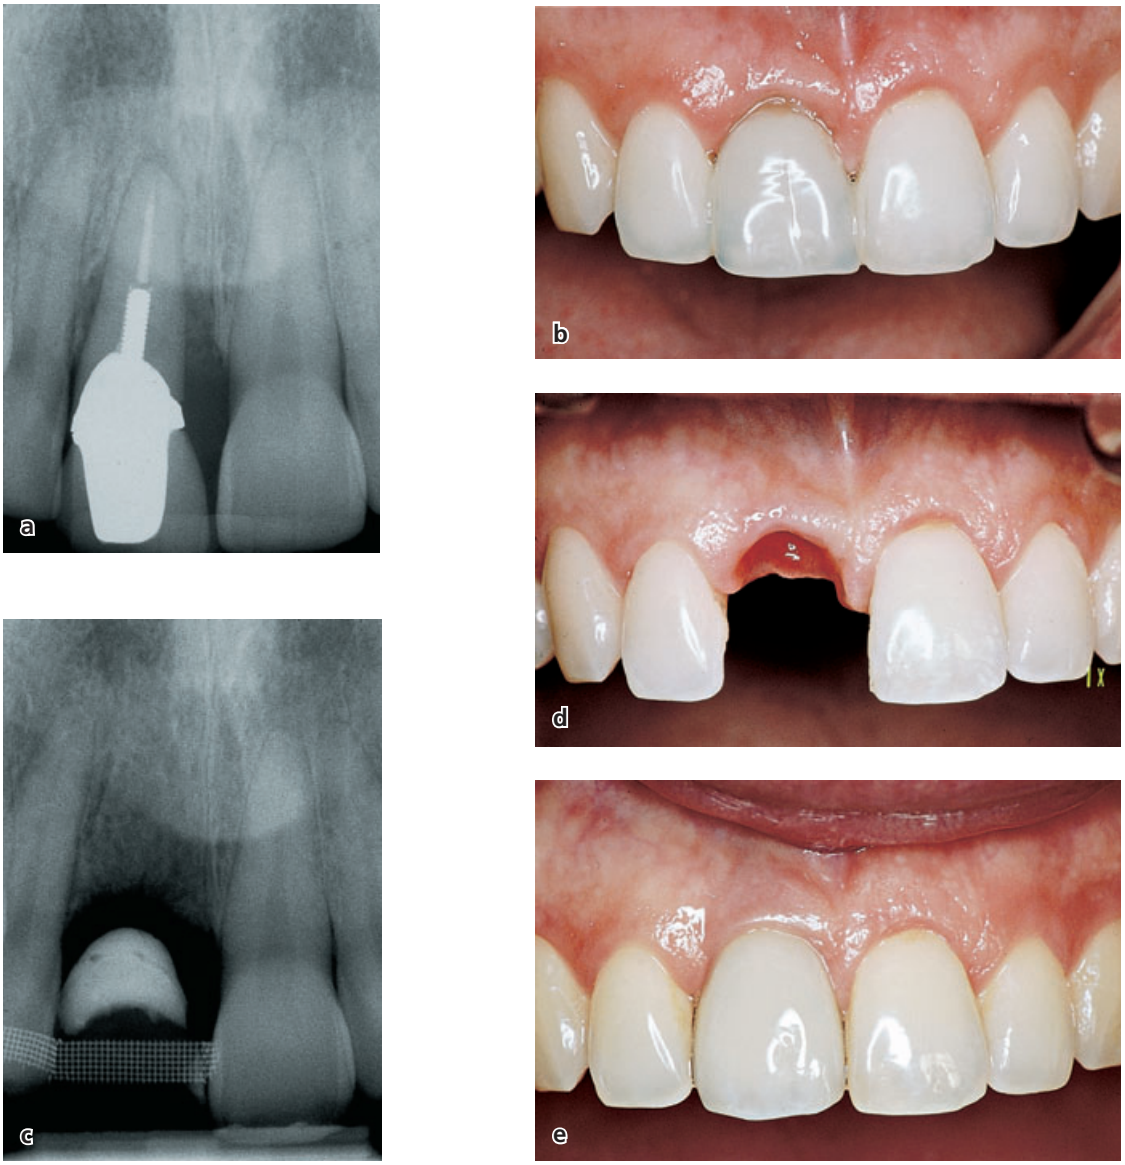

Fig. 44-75 (a) A central incisor that cannot be maintained because of root fracture which also caused pronounced periodontal destruction. (b) Immediately following tooth extraction, an ovate pontic was inserted to support the facial and proximal soft tissues. (c,d) Radiographic and clinical view of the area 6 weeks after tooth extraction. (e) Follow-up 1 year after the placement of permanent prosthetic reconstruction (single implant).

Fig. 44-76 (a) A 26-year-old female patient who had a trauma against the maxillary central incisors. Due to root fracture and endodontic complications both central incisors had to be extracted. (b) A Rochette bridge with ovate pontics was fabricated as a temporary replacement for the incisors. (c) Clinical view if the front tooth region 8 weeks after tooth extraction and placement of the resin bonded temporary bridge.

Among procedures proposed for prevention of ridge collapse in conjunction with tooth extractions are (1) flap elevation for complete soft tissue closure of the extraction sites (Borghetti & Glise 2000), (2) placement of connective tissue grafts over the extraction sites (Nevins & Mellonig 1998), (3) placement of bone grafts (Becker *et al*. 1994), and (4) utilization of barrier membranes (Lekovic *et al*. 1997). Procedures for preservation of the bone dimensions following tooth extraction are discussed in Chapter 49.

Correction of ridge defects by the use of soft tissue grafts

A deformed ridge may result from tooth extractions, advanced periodontal disease, abscess formations, etc. The deformity that exists in the ridge is directly related to the volume of root structure and associated bone that is missing or has been destroyed. According to Siebert (1983) ridge defects can be divided into three classes:

- Class I: loss of bucco-lingual width but normal apico-coronal height
- Class II: loss of apico-coronal height but normal bucco-lingual width
- Class III: a combination of loss of both height and width of the ridge.

Ridge augmentation procedures should be preceded by careful surgical–prosthetic treatment planning with joint consultations involving the surgeon and the restorative dentist in order to attain an optimal esthetic result. The following factors should be determined prior to the initiation of therapy:

- Volume of tissue required to eliminate the ridge deformity
- Type of graft procedure to be used
- Timing of various treatment procedures
- Design of the provisional restoration
- Potential problems with tissue discolorations and matching tissue color.

Ideally, a provisional restoration should be made prior to surgery. The shape of the teeth in the provisional restoration, the axial inclination and emergence profile of the teeth, and embrasure form should be an exact prototype of the final prosthesis that is to be constructed. It is the task of clinician performing the surgery to augment the tissues to meet the provisional prosthesis in the most exact manner possible. If a gingival flange of pink-colored acrylic is used around single or multiple pontics on a temporary removable partial denture, the flange must be cut away in order to avoid pressure on the graft and give the tissues room to swell during the immediate post-surgical phase of healing. The soft tissue at the surgically treated recipient site for a graft will undergo considerable swelling during the early phase of healing and the tissues will conform to the tissue-facing surfaces of the bridge or partial denture. The prosthesis is thus used to help in shaping the outline of the augmented ridge to the desired form. The location and shape of interproximal embrasure areas in the provisional bridge will determine

where the "papillae" created in the ridge will be located.

Surgical procedures for ridge augmentation

Numerous surgical graft and implant procedures attempting to reconstruct a partially edentulous ridge or ridge defect have been described in the literature over the years. The procedures may be grouped according to the means used for ridge augmentation as (1) soft tissue augmentation procedures and (2) hard tissue augmentation procedures. In this chapter only soft tissue augmentation procedures will be addressed, while hard tissue augmentation procedures are covered in Chapter 49. To illustrate various approaches for utilization of soft tissues for ridge augmentation, the following procedures will be discussed:

- Pedicle graft procedure:
  - Roll flap procedure
- Free graft procedures:
  - Pouch graft procedure
  - Interpositional graft procedure
  - Onlay graft procedure.

Studer *et al*. (1997) proposed the use of the pedicle graft procedure for correction of a single-tooth ridge defect with minor horizontal and vertical loss, whereas submerged free connective tissue graft procedures should be selected for larger defects. The onlay full-thickness graft procedure is indicated primarily for ridge augmentation in the presence of additional mucogingival problems such as insufficient gingival width, high frenum, gingival scarring, or tattoo. These recommendations were based on short-term evaluation of the obtained volumetric increase of the edentulous ridge following various augmentation procedures, which demonstrated superior results with the use of submerged connective tissue grafts compared to the use of full-thickness grafts (Studer *et al*. 2000).

The "roll flap procedure"

Surgical concept

The "roll flap procedure" (Abrams 1980) involves the preparation of a de-epithelialized connective tissue pedicle graft, which is subsequently placed in a subepithelial pouch (Fig. 44-77). This procedure is used in the treatment of small to moderate class I ridge defects, primarily in cases with a single-tooth space. The technique enables the surgeon to augment tissue apically and labially to the cervical area of a pontic and to give the recipient site the appearance of a normal tooth–gingiva interface. Hence, a buccolingual ridge concavity can be converted into a ridge convexity resembling the eminence produced by the roots of the adjacent teeth (Fig. 44-78).

Technique

A rectangular pedicle of connective tissue is prepared on the palatal side of the defect (Fig. 44-77). The length of the pedicle must match the amount of

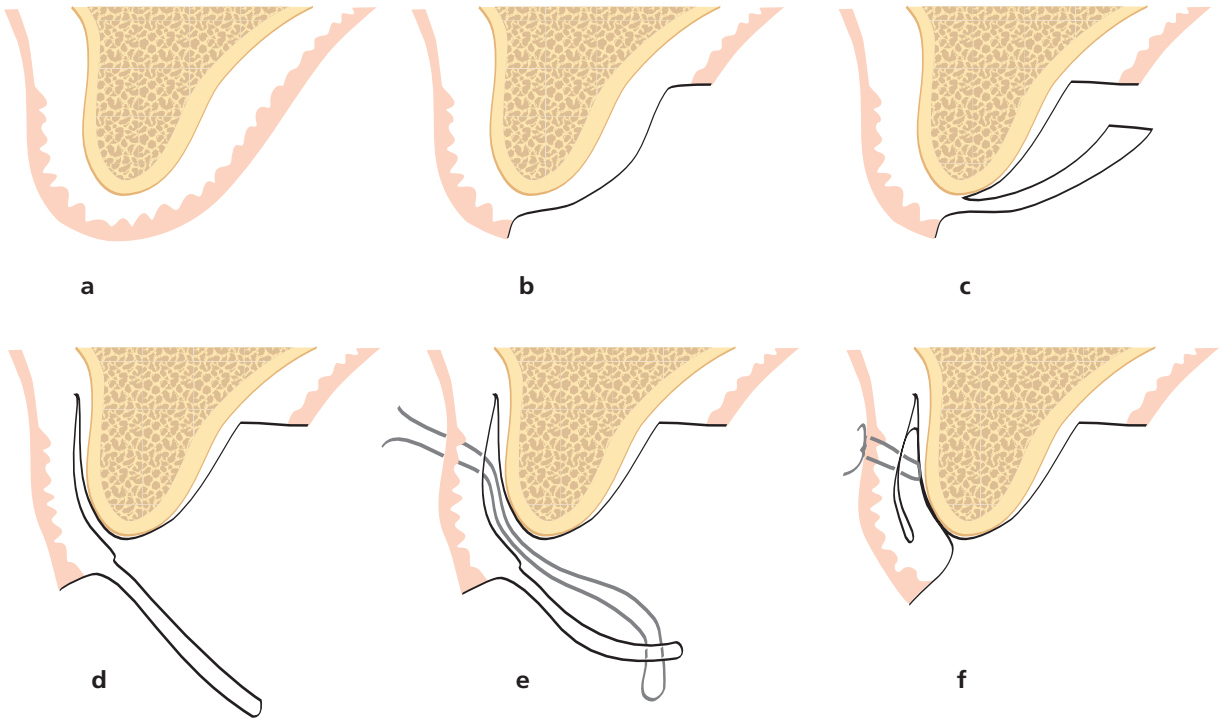

Fig. 44-77 Sequence of steps in the "roll flap procedure". (a) Cross section of the residual edentulous ridge prior to treatment. (b) The removal of the epithelium. (c) The elevation of the pedicle. (d) The pouch is created. (e) Sutures are placed at the mucogingival junction to catch the tip of the pedicle flap and pull it into place in the pouch. (f) The flap is secured. A convexity in the ridge was created.

(b) This view shows the surgical site 1 week after surgery and prior to the removal of the sutures. (c) The tissue surface of the pontic was relined with autopolymerizing resin. (d) Final prosthesis in place. Note the illusion of a root eminence and a free gingival margin apical to the lateral incisor pontic tooth. (Courtesy of Dr. L. Abrams, Philadelphia, PA, USA.)

apico-coronal augmentation that is planned. This, in turn, is related to the amount of root eminence that exists on either side of the defect. If a two- or three-tooth pontic space is treated with the roll technique, two or three separate pedicles are raised. Each of these pedicles will form a new "root–cervical margin".

The epithelium on the palatal surface of the donor site is first removed. A maximum amount of supraperiosteal connective tissue is raised from the palate using sharp dissection. The void that is produced at the donor site will gradually fill in with granulation tissue. Caution must be exercised in dissection of the pedicle flap so that tissue perforation is avoided when the plane of dissection approaches the facial (labial) surface. A pouch is made in the supraperiosteal connective tissue at the facial (labial) surface of the ridge. In order to preserve as much connective tissue and blood supply as possible at the recipient site, the dissection must be made as close as possible to the periosteum of the facial bone.

The pedicle is tucked into the pouch as a try-in procedure. Adjustment of pedicle size should now be made. Once the pedicle fits as desired, it is made ready for the stabilizing suture. The suturing scheme is illustrated in Fig. 44-77. The suture must be positioned close to the mucobuccal fold. This enables the surgeon to pull the pedicle to the apical portion of the pouch. The suture should not be tied tightly, since it only serves as a positioning and stabilizing device. The use of a resorbable suture material is recommended.

Adjustment of pontic contours

Measures used to adapt the tissue surface of the pontic to the contour of the surgically treated ridge are common to all soft tissue ridge augmentation procedures in patients with fixed bridgework. A light contact is maintained between the pedicle graft and the tissue surface of the pontics. The post-operative swelling will cause the tissue to conform to the shape of the pontic. This enables the clinician to shape the soft tissue into a form that is intended for the augmented site. Autopolymerizing resin is added to the tissue surface of the pontics and is allowed to cure until the resin reaches a dough-like state. The bridge is then seated and pressed into the grafted site. When the resin has set to a firm consistency, the bridge is removed and placed in hot water to complete the process of polymerization (Fig. 44-78). The tissue surface of the pontics and the embrasure areas are then carved to the shape that is intended for the final bridge. The surface of the pontic is polished and the

bridge put in place using appropriate temporary cement.

Post-operative care
A periodontal dressing is placed over the donor site. No dressing should be placed over the facial (labial) surface of the grafted area where swelling will occur. The dressing at the donor site should be changed at weekly intervals and maintained until wound healing has progressed to a point where the tissue is no longer tender to touch.

Pouch graft procedures

Surgical concept
A subepithelial pouch is prepared in the area of the ridge deformity, into which a free graft of connective tissue is placed and molded to create the desired contour of the ridge. The entrance incision and the plane of dissection may be made in different ways (Kaldahl *et al*. 1982; Seibert 1983; Allen *et al*. 1985; Miller 1986; Cohen 1994):

- Coronal–apically: the horizontal incision is made on the palatal or lingual side of the defect and the plane of dissection carried in an apical direction (Fig. 44-79).
- Apical–coronally: the horizontal incision is made high in the vestibule near the mucobuccal fold and the plane of dissection is carried coronally to the crest of the ridge.
- Laterally: one or two vertical entrance incisions are started from either side of the defect (Fig. 44-80). The plane of dissection is made laterally across the span of the deformity.

Indication
The technique is used to correct class I defects. Patients with large-volume defects may have thin palatal tissues, which are insufficient to provide the volume of the donor tissue necessary to fill the deformity. In such cases, various procedures for hard tissue augmentation may be selected (see Chapter 49).

Technique
The pouch is prepared as described above. The mesio-distal entrance incision for the edge of the pouch should be made with a long bevel and must be started well to the palatal (lingual) side of the defect (Fig 44-79). After the pouch has been filled with graft, the facial tissue will be stretched. The long bevel of the entrance incision permits the palatal edge of the flap to slide toward the facial surface

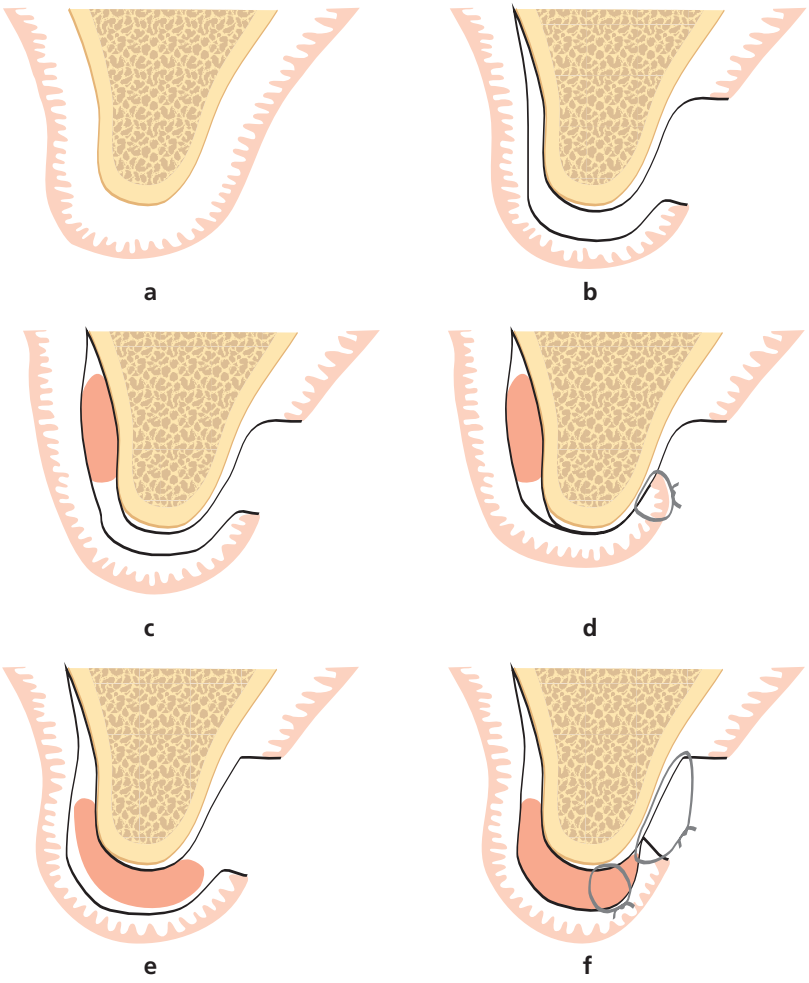

Fig. 44-79 Sequence of steps in the "pouch graft procedure" utilizing a free graft of connective tissue (CT) to expand the ridge. (a) Cross section of the residual edentulous ridge prior to treatment. (b) The horizontal incision to create the pouch is made well to the palatal side of the defect. The incision is started partial-thickness to leave CT to suture to when the flap is closed. The dissection is made supraperiosteal on the labial side of the ridge to (1) ensure an adequate blood supply within the pedicle and (2) permit the flap to expand labially or labially and coronally free of tension. (c,d) The CT graft can be placed as shown for maximal bucco-lingual augmentation. (e,f) If vertical augmentation is desired, the CT implant can be placed closer to the crest of the ridge. As is shown in (d) and (f), the more the flap is stretched or extended to gain augmentation, the more difficult it is to gain primary flap closure.

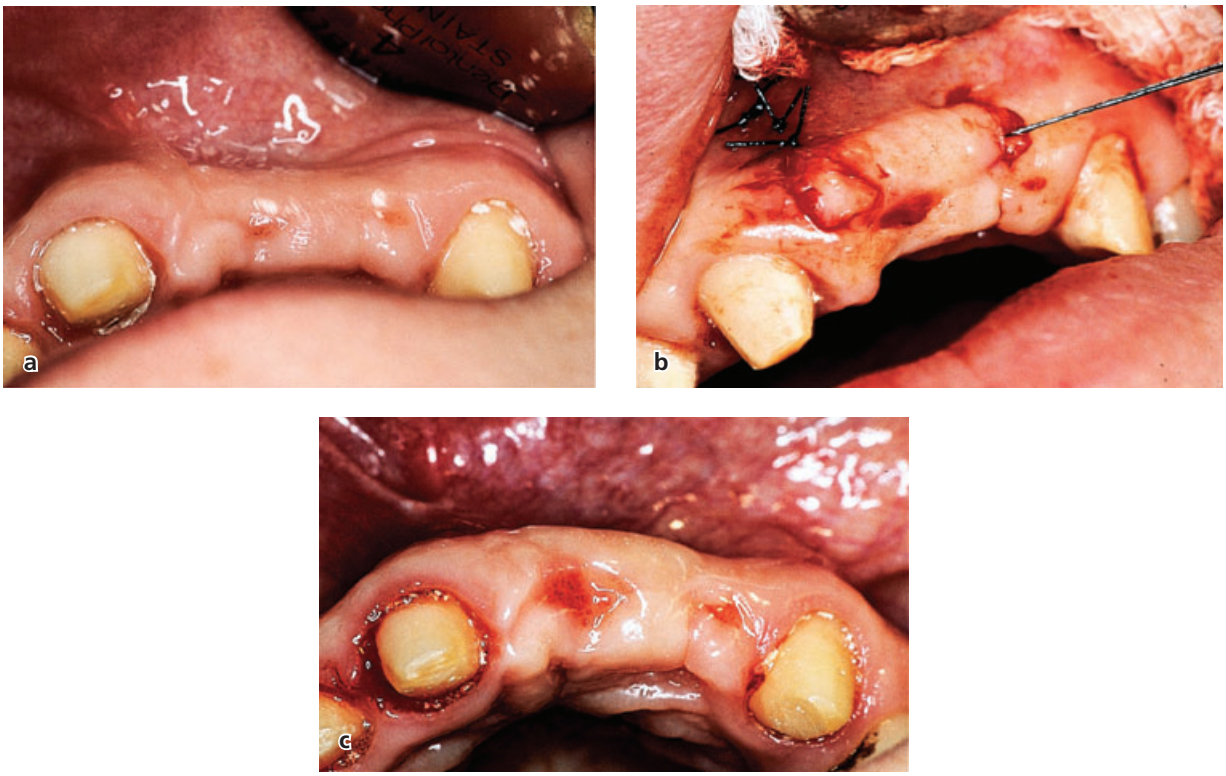

Fig. 44-80 Pouch graft procedure. (a) Pretreatment view of a class I ridge deformity. (b) Placement of the free connective tissue graft in a tunnel prepared by split incision between the two vertical incisions. The graft is brought into position by the use of a suture placed in one end of the free graft. (c) Four months post treatment showing restored facial dimension of the edentulous ridge.

without opening a gap at the incision line. Sometimes vertical releasing incisions have to be made lateral to the border of the defect.

A suitable donor site is selected in the palate, the tuberosity area, or in an edentulous area and a free graft of connective tissue is excised by the use of a "trap-door" approach. The graft is immediately transferred to the recipient site and properly positioned. The palatal entrance incision and the releasing incisions are closed with sutures.

Interpositional graft procedure

Surgical concept

Interpositional grafts are not completely submerged and covered in the manner that a subepithelial connective tissue graft is placed (Fig. 44-81) (Seibert 1991, 1993a,b). Therefore, there is no need to remove the epithelium from the surface of the donor tissue. If augmentation is required not only in the buccolingual but also in the apico-coronal direction, a portion of the graft must be positioned above the surface of the tissue surrounding the recipient site (Fig. 44-82). A certain amount of the grafted connective tissue will thus be exposed in the oral cavity.

Indications

Interpositional graft procedures are used to correct class I as well as small and moderate class II defects.

Technique

An envelope flap, or a split-thickness flap with releasing incisions, is prepared at the facial surface of the defect area. The provisional bridge is placed in position to serve as a reference when estimates are made regarding the amount of tissue that has to be grafted to fill the defect. A periodontal probe may be used to measure the length, width and depth of the void of the pouch. A suitable donor site is selected in the palate or the tuberosity area, and a free graft of epithelium–connective tissue is excised (Fig. 44-81).

The donor tissue is transferred to the recipient site and placed in position. If gain in ridge height is not intended, the epithelial surface for the graft is placed flush with the surrounding epithelium. The graft is sutured along its entire circumference to the tissues of the recipient site. The provisional bridge is placed in position and the pontics are trimmed and adjusted as discussed above. No dressing is used to cover the recipient site.

If gain also in ridge height is intended, a certain portion of the graft has to be kept above the surface of the surrounding tissue (Fig. 44-82d). Granulation tissue formed during healing will eventually make the border between the graft and the adjacent tissue smooth and properly epithelialized. The swelling, which occurs post-operatively, will assist in sculpting the contour of the ridge.

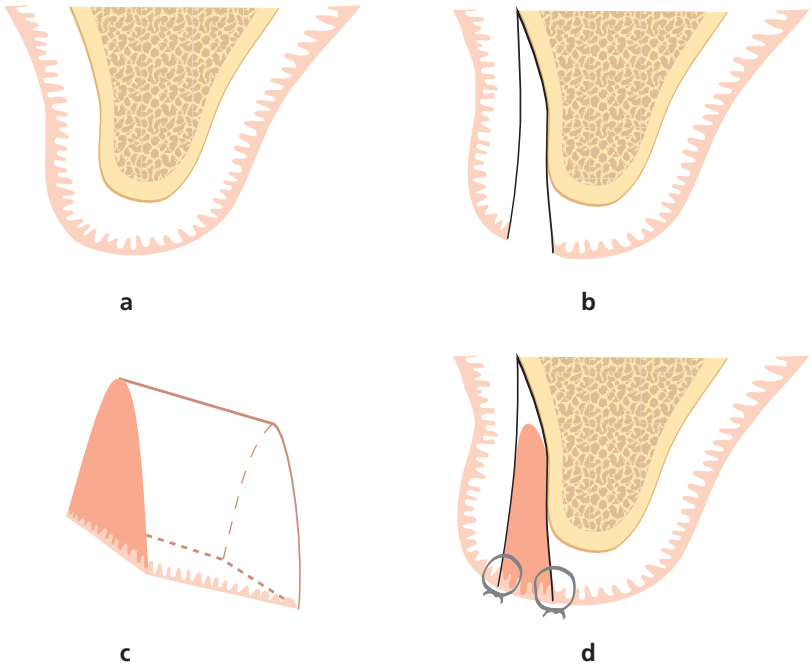

Fig. 44-81 Schematic illustrations of the interpositional graft procedure. (a) Cross section of class I ridge defect. (b) A labial flap (partial-thickness dissection preferred) is used to create the pouch. (c) A wedge-shaped graft is removed from the palate. (d) The epithelial surface of the graft is placed flush with the surface of the tissue surrounding the pouch and sutured around its circumference.

Onlay graft procedures

Surgical concept

The onlay procedure was designed to augment ridge defects in the apico-coronal plane, i.e. to gain ridge height (Meltzer 1979; Seibert 1983). Onlay grafts are epithelialized free grafts which, following placement, receive their nutrition from the de-epithelialized connective tissue of the recipient site. The amount of apico-coronal augmentation that can be obtained is related to the initial thickness of the graft, the events of the wound healing process, and the amount of graft tissue that survives (Figs. 44-82, 44-83, 44-84). If necessary, the grafting procedure can be repeated at 2-month intervals to gradually increase the ridge height.

Indications

Onlay graft procedures are used in the treatment of large class II and III defects. They are not suitable in areas where the blood supply at the recipient site has been compromised by scar tissue formation from previous wound healing.

Technique

An attempt must be made to retain as much of the lamina propria of the recipient site as possible. The anesthetic solution should be placed high in the vestibular fornix and in the palate, thus keeping vasoconstriction in the recipient site to a minimum. A scalpel blade is used to remove the epithelium. The scalpel is moved with short, saw-like strokes across the recipient site at a level approximately 1 mm below the outer surface of the epithelium. The least amount of connective tissue possible should be excised. The margins of the recipient site can be prepared with either a butt joint or a beveled margin. The prepared recipient site should be covered with a surgical gauze moistened with isotonic saline while the donor tissue is dissected (Fig. 44-82g–i).

Selection of donor site

Onlay graft procedures, as well as interpositional graft procedures, require large amounts of donor tissue. As a general rule, the palatal vault region of premolars and first molars, midway between the gingival margin and the midline raphae, is the only area in the maxilla that contains the necessary volume of tissue required to augment large ridge defects. During the presurgical planning phase, the tissue of the palate should be probed with a 30-gauge syringe needle to ensure that an acceptable volume of tissue can be obtained at the time of surgery.

The major palatine artery emerges from the posterior palatine foramen located adjacent to the distal surface of the maxillary second molar, midway between the gingival margin and the midline raphae (Fig. 44-85). The artery passes in an anterior direction close to the surface of the palatal bone. It is important therefore that the second and third molar regions are not used as donor sites for large volume grafts.

Planning in graft preparation

As a rule the graft should be made a few millimeters wider and longer than the dimensions required at the recipient site. The dimensions of the graft are outlined on the palate with the use of a scalpel and light bleeding is provoked to define the surface borders. In order to avoid interference with the palatine artery, the borders of the graft must be planned in such a way that its thinner portions are located high in the palatal vault or in the first molar area. The thicker

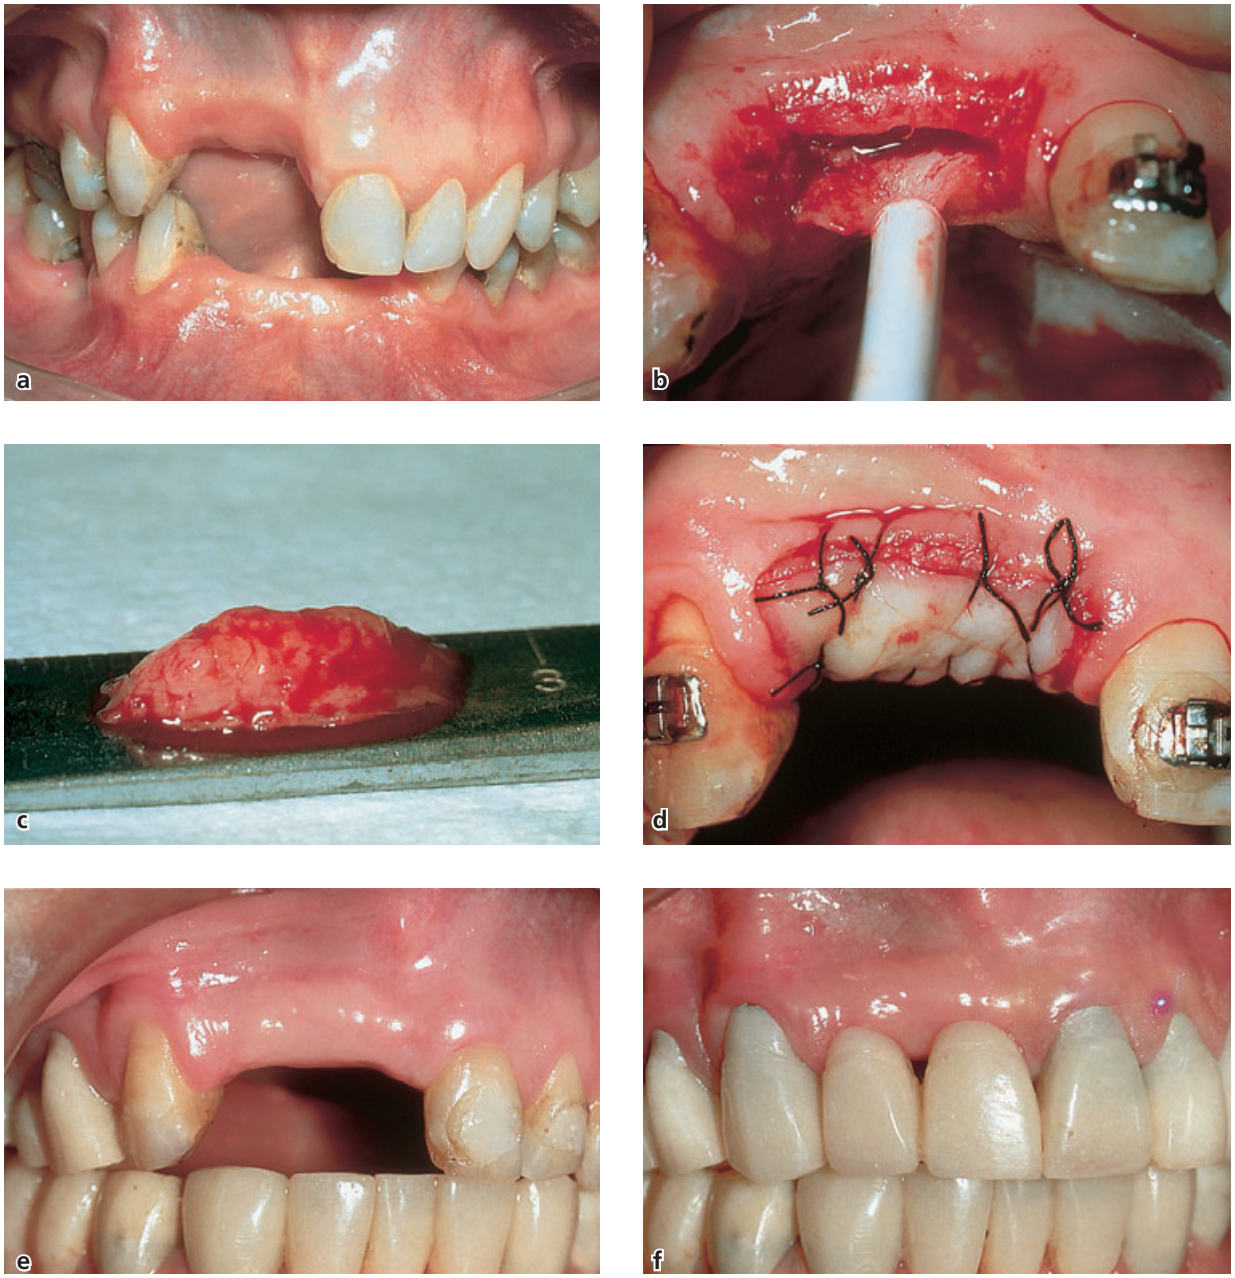

Fig. 44-82 (a) Pretreatment view, class III ridge defect. A two-stage procedure will be used to augment the ridge. (b) A pouch was prepared to receive an interpositional graft. Epithelium was removed from the borders of the recipient site to permit some of the graft to be placed above the level of the surrounding tissue in order to gain apico-coronal augmentation. (c) The wedge-shaped graft was 10 mm thick at its center. (d) The interpositional graft is both displacing the labial surface of the pouch in the labial direction as well as adding height to the ridge. (e) Two months post-treatment. Additional augmentation is needed apico-coronally. (f) A second-stage onlay graft will be used to create a papilla and fill the dark triangle between the pontics. (g) Two months after the first surgical procedure, the ridge was de-epithelialized and cuts were made into the connective tissue prior to placing the second-stage onlay graft into position. (h) The onlay graft was sutured into position. (i) The pontics were adjusted and brought into light contact with the graft. (j) Marked swelling occurred within the graft at 14 days post surgery. (k) Two months following the second surgical procedure, a gingivoplasty was performed to deepen the pontic receptacle sites for the ovate pontics. (l) Post-treatment view 1 year after the final surgical procedure. (Courtesy of Dr. J. Seibert & Dr. P. Malpeso, USA.)

portions should be harvested from the premolar areas.

Dissection of donor tissue

The base of the graft should be V- or U-shaped to match the shape of the defect in the ridge. The different planes of incision prepared in the palate must therefore converge towards an area under the center or toward one edge of the donor site. It is comparatively easy, with the use of a scalpel, to dissect in an antero-posterior or, from an area high in the palate, in a lateral direction towards the teeth. It is, however, difficult to dissect in an anterior direction from the distal edge of the donor site. There is a variety of

Fig. 44-82 *Continued*

blade holders available which permit the scalpel blade to be positioned at different angles to the holder and which enable the surgeon to cut with a back-action. When the donor tissue has been removed, it must be stored in pieces of surgical gauze moistened in isotonic saline at all times.

Treatment of the donor site

Since it is difficult to anchor and maintain a periodontal dressing at the donor site in the palatal vault, an acrylic stent should be fabricated prior to surgery. The stent should be made with wrought wire clasps on each side to add retention and to aid the patient in removing and inserting the device.

The donor site must be inspected carefully for signs of arterial bleeding. If any small vessel bleeding is observed, a circumferential suture must be placed around the vessel distal to the bleeding point. Immediately thereafter, the void at the donor site should be packed with a suitable hemostatic agent and the edges of the wound be brought closer together with sutures. The stent is then put into position.

Try-in and stabilization of graft

The graft is transferred with tissue forceps to the recipient site for a try-in. The graft is trimmed to the proper shape and adjusted to fit the connective tissue surface of the prepared ridge. A series of parallel cuts may be made deep into the exposed lamina propria of the recipient site to sever large blood vessels (Fig. 44-82g) immediately before suturing. A series of interrupted sutures is placed along the borders of the

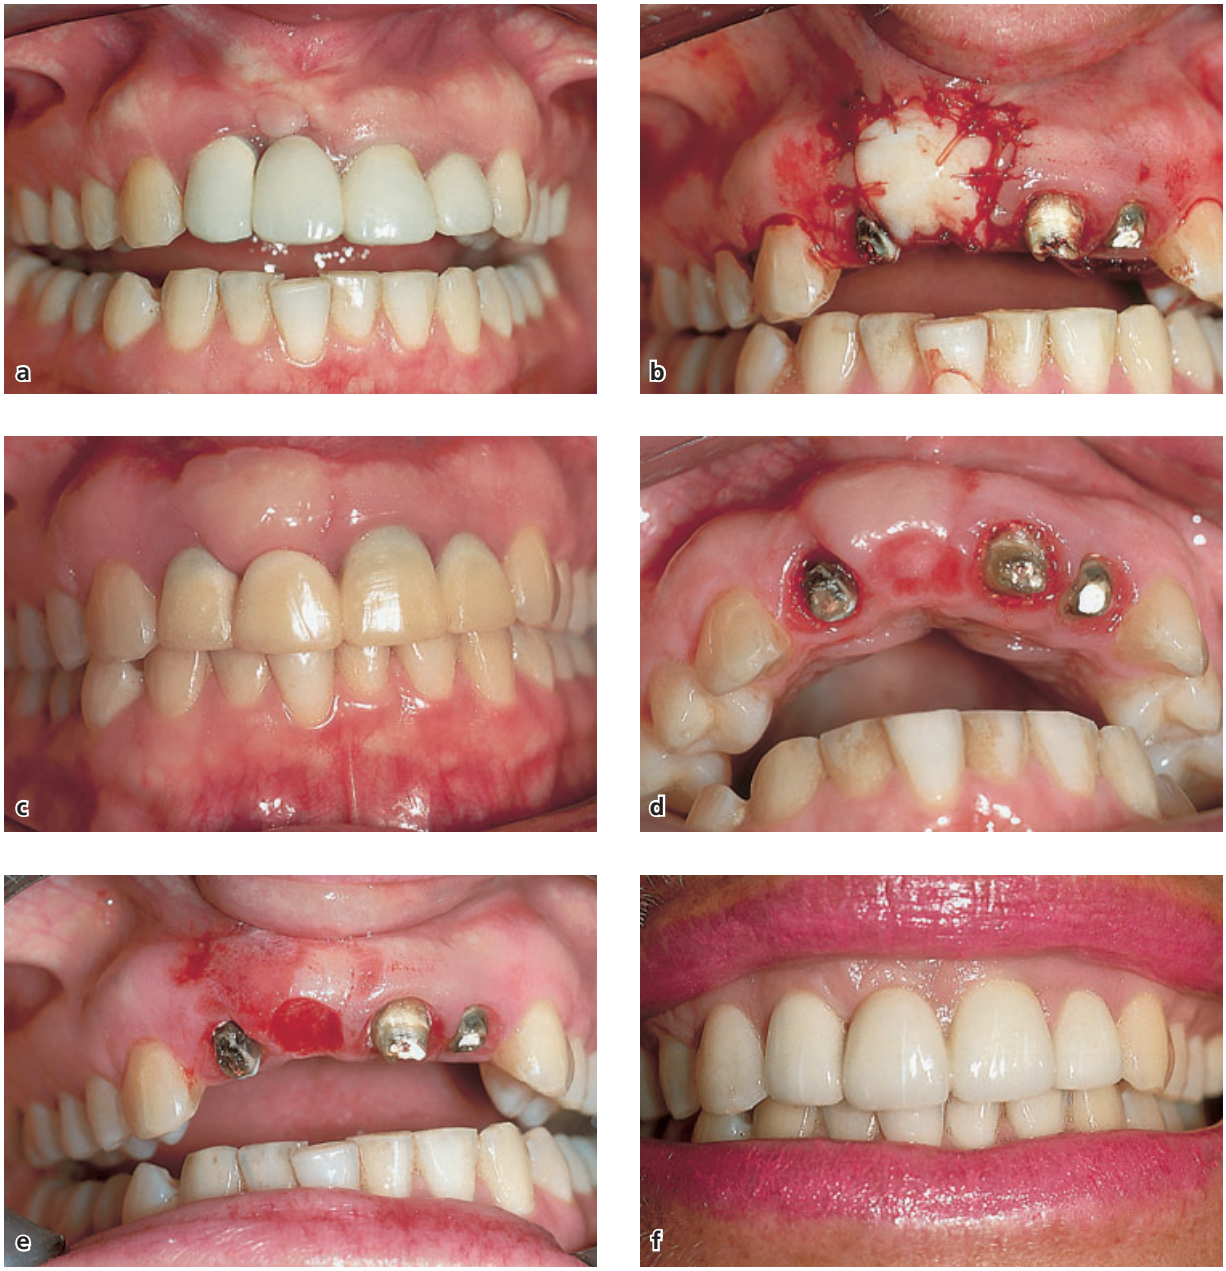

Fig. 44-83 Onlay graft procedure. (a) Pretreatment view. The gingival tissues were distorted from previous attempts at esthetic reconstruction. The patient wished to have a papilla between the right maxillary lateral and central incisor and a natural looking bridge. (b) The pontic area, including the papilla on the mesial of the right lateral incisor, was de-epithelialized and a thick (5 mm) onlay graft was sutured into position. (c) The pontic was shortened at the time of surgery to accommodate the thick graft. At 3 months post surgery the graft had undergone maximum shrinkage and gingivoplasty could now be done. (d) Incisal view at 3 months post surgery. Note the "papilla" that has been created. The indentation in the ridge was naturally created by the tissue swelling against the pontic tooth. (e) Rotary diamond point gingivoplasty was done to reshape the bulky graft to normal contours, deepen the receptacle site for the ovate pontic and level the gingival margins. (f) This view shows the esthetic harmony that was obtained in the soft tissues and tooth form at 2 years post treatment. (Courtesy of Dr. J. Seibert & Dr. C. Williams, USA.)

Fig. 44-84 Onlay graft procedures utilized to augment ridge and create papillae. (a) Pretreatment view. The left lateral incisor was extracted after a traumatic injury. The patient detested the dark triangle on the mesial of the pontic, the poor tooth form in the bridge and the irregular contours in her gingival tissue. (b,c) An onlay graft was used to gain apico-coronal and bucco-lingual ridge augmentation as well as to develop papillae. Note how the graft was extended to the palatal side of the ridge to gain greater blood supply from a larger connective tissue base. (d,e) At 2 months post surgery, a second-stage veneer graft was used to eliminate the surface irregularities on the surface of the gingiva and gain greater bucco-lingual augmentation. (f) At 4 months post second-stage surgery, gingivoplasty was done to prepare the area for an ovate form pontic. (g–h) 1 year post treatment, esthetics have been restored for this patient. graft. The dental assistant should stabilize the onlay graft against the surface of the recipient site, while the surgeon completes the placement of sutures.

Wound healing in the recipient site

Considerable post-operative swelling often occurs during the first week after pouch and onlay augmentation procedures. The epithelium of the graft will slough to form a white film on the surface of the graft. Patients should rinse two to four times per day with an antimicrobial mouthwash during the first week after surgery and refrain from mechanical cleaning measures in the area until a new epithelial covering has formed over the graft, which will not occur until a functional capillary circulation has been re-established in the graft (4–7 days after the surgery). The grafted tissue will assume a normal color as the epithelium thickens via stratification. Tissue form is usually stable after 3 months, but further shrinkage may occur over a period of several months. Final restorative measures should therefore not be initiated until after 6 months.

Wound healing in the donor site

Granulation tissue will gradually fill the donor site. Initial healing is usually complete within 3–4 weeks after the removal of a 4–5 mm thick graft. Patients should wear the surgical stent for about 2 weeks to protect the healing wound. The palate returns to its presurgical contour after about 3 months.

Combined onlay–interpositional graft procedures

Class III ridge defects pose a major challenge to the clinician since the ridge has to be augmented in both vertical and horizontal dimensions. The combined onlay–interpositional graft procedure (Fig. 44-86 and 44-87) may successfully be used in such a situation (Seibert & Louis 1996). The combined graft procedure may offer the following advantages:

- The submerged connective tissue section of the interpositional graft aids in the revascularization of the onlay section of the graft, thereby gaining a greater percentage of take of the overall graft.
- A smaller post-operative open wound in the palate donor site.
- Faster healing in the palate donor site with less patient discomfort.
- Greater latitude or ability to control the degree of bucco-lingual and apico-coronal augmentation within a single procedure.
- Vestibular depth is not decreased and the muco-gingival junction is not moved coronally, thereby eliminating the need for follow-up corrective procedures.

Refinement of pontic contours and gingivoplasty soft tissue sculpting procedures

It is desirable, when reconstructing defects within a partially edentulous ridge, to moderately over-correct the ridge in the area of the deformity. This will compensate for wound contraction and provide the necessary bulk of tissue within the ridge to sculpt the ridge to its final form. Gingivoplasty techniques using rotary coarse diamond stones in an ultraspeed handpiece with copious water spray are used to smooth out incision lines and perfect the fit and shape of the pontic teeth to the crest of the ridge (Figs. 44-83, 44-87). Adjustments are made to shape the cervical contour and emergence profile of the pontic teeth to match that of the contralateral teeth. The tissue-contacting surfaces of the pontic teeth are immediately rebased with autopolymerizing resin and polished. This final tissue sculpting procedure and reshaping of the provisional prosthesis is minor in nature but aids greatly in defining the shape of the papillae and creating the illusion of the presence of a cuff of free gingiva at the pontic–ridge interface.

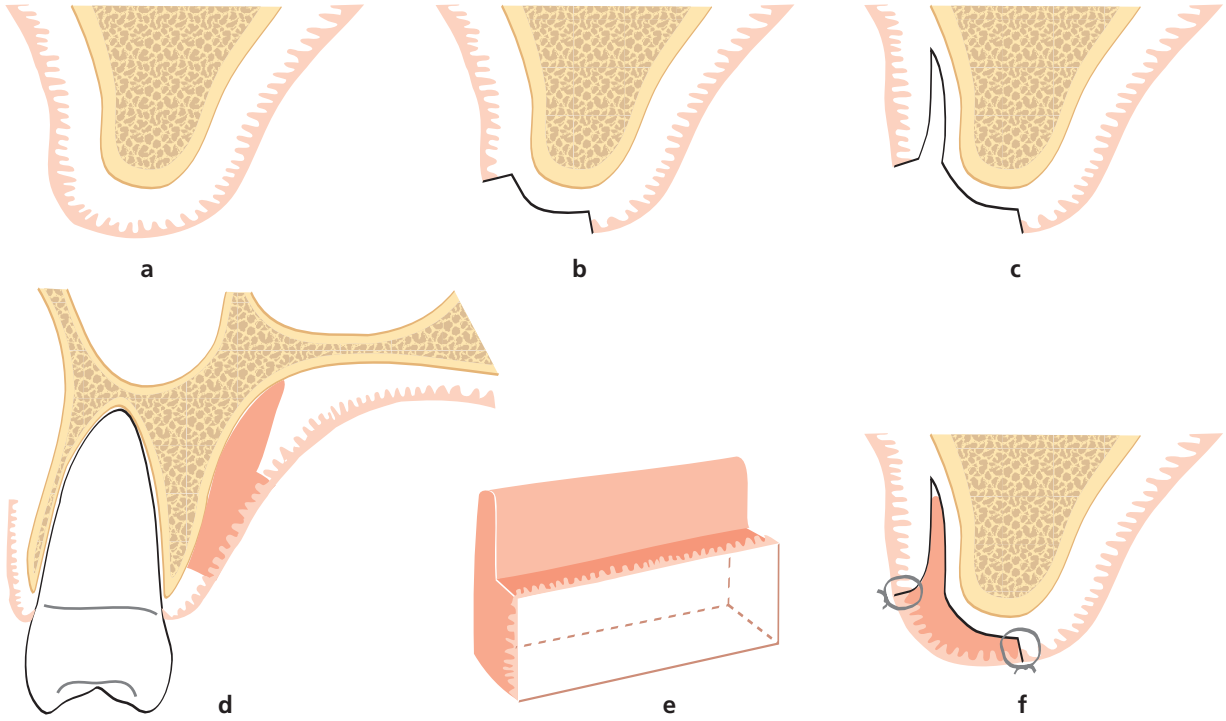

Fig. 44-86 Diagram of the combination onlay-interpositional graft procedure. (a) Cross section of a class III ridge defect. (b) Epithelium is removed on the labial–crestal side of the ridge to prepare the recipient bed for the onlay segment of the graft. (c) Partial-thickness dissection was then used to create a pouch for the interpositional section of the graft. (d) The dissection for the graft is started at right angles to the surface of the palate. The scalpel blade is then angled to remove a long connective tissue segment for the graft. (e) Three-dimensional view of the onlay section of the graft (including epithelium) and the connective tissue segment for buccolingual augmentation. (f) Graft sutured into position. (Reprinted with permission from *The International Journal of Periodontics and Restorative Dentistry*.)

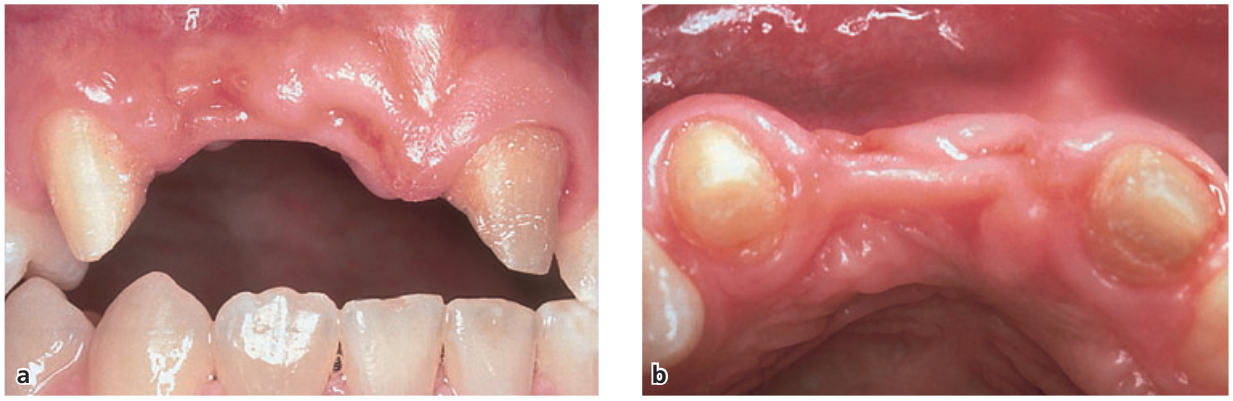

Fig. 44-87 (a,b) The right maxillary lateral and central incisors were lost due to trauma. These views show the horizontal and vertical loss of ridge tissue 10 months after the extractions. (c) A partial-thickness path of incision was extended labially and apically to create a pouch. The amount of space created within the pouch and the degree of relaxation of the flap was then tested with a periosteal elevator. (d) The epithelialized section of the graft can be seen in this view. (e) The premolar area, maxillary right side, was used as a donor area. The area of exposed connective tissue corresponds to the onlay section of the graft. The incisions were extended another 5–7 mm towards the midline on a long bevel to obtain the interpositional segment of the graft. (f) The graft was tucked into the labial pouch and sutured first along its palatal border. The labial flap was then sutured along the epithelial connective border of the graft. The residual labial socket defect in the flap created a soft tissue discontinuity defect along the labial margin of the flap. (g) At 6 weeks post surgery, it can be seen that further augmentation would be required to gain additional soft tissue in both the vertical and horizontal planes. A second-stage procedure was done at this time. (h) An incision 1.5 mm in depth was utilized to de-epithelialize the crestal surface of the ridge. Note that the papillae were not included within the surgical field. The mesial and distal borders of the onlay section of the recipient site were then extended apically to create vertical releasing incisions. The overall recipient site was to be trapezoidal in shape. A labial flap to create the pouch section of the recipient site was made using partial-thickness dissection. (i) The left maxillary premolar area was used as the donor site for the second-stage surgery. (j) This side view clearly shows the epithelialized onlay section of the graft and the de-epithelialized connective tissue section of the graft, as well as tissue thickness. (k) The graft was sutured first along the fixed palatal border to gain initial stabilization. Then the connective tissue interpositional section was sutured along the lateral borders. The flap was then sutured over the interpositional section of the graft at the epithelialized edge of the onlay section of the graft and along the vertical incisions. (l) At 6 weeks post surgery, the provisional prosthesis was modified to bring the tissue surface of the pontics into contact with the healing ridge. (m) At 2 months post surgery, tooth form was further modified on the provisional prosthesis and gingivoplasty was done to sculpt the tissues to final form and smooth out surface irregularities. (n) The final ceramo-metal prosthesis was inserted 4 months later. The life-like reconstruction of the soft tissues and dentition restored dentofacial esthetics for the patient. (Courtesy of Dr. J. Seibert, Dr. J. Louis & Dr. D. Hazzouri, USA. Reprinted with permission from *The International Journal of Periodontics and Restorative Dentistry*.)

Chapter 45

Periodontal Plastic Microsurgery

Rino Burkhardt and Niklaus P. Lang

Microsurgical techniques in dentistry (development of concepts)

In general, the main aim of a surgical intervention is no longer only the survival of the patient or one of his organs, but the effort to preserve a maximum amount of function and to improve patient comfort. In many surgical specialties, these demands are met owing to a minimally invasive surgical approach.

Microsurgery in general is not an independent discipline, but is a technique that can be applied to different surgical disciplines. It is based on the fact that the human hand, by appropriate training, is capable of performing finer movements than the naked eye is able to control. First reports on microsurgery go back to the nineteenth century when a microscope was developed for use in ophthalmology (Tamai 1993). Later, the first surgical operation with a microscope was performed in Sweden to correct otosclerotic deafness (Nylén 1924). Microsurgical technique, however, did not attract the interest of surgeons until the 1950s, when the first surgical microscope, OPMI 1, with a coaxial lighting system and the option for stereoscopic view, was invented and commercialized by the Carl Zeiss company.

The micro vessel surgery that later revolutionized plastic and transplantation surgery was mainly developed by neurosurgeons (Jacobsen & Suarez 1960; Donaghy & Yasargil 1967). Applying microsurgically modified techniques, small vessels of a diameter of less than 1 mm could be successfully anastomosed on a routine basis (Smith 1964). As a consequence, a completely amputated thumb was successfully replanted for the first time in 1965 (Komatsu & Tamai 1968). Between 1966 and 1973, a total of 351 fingers were replanted at the Sixth People's Hospital in Shanghai without magnification, resulting in a healing rate of 51% (Zhong-Wei *et al*. 1981). From 1973, the interventions mentioned were solely performed with surgical microscopes and the corresponding success rates of replanted fingers increased to 91.5%. These results documented the importance of a fast and successful restoration of the blood circulation in replanted extremities and free tissue grafts. Further achievements of the microsurgical technique in plastic reconstructive surgery included transplantation of toes to replace missing thumbs (Cobbett 1969), interfascicular nerve transplantation (Millesi 1979), microvascular transplantation of toe joints (Buncke & Rose 1979), micro neurovascular transplantation of the pulp of a toe to restore the sensitivity of the finger tips (Morrison *et al*. 1980), and microvascular transplantation of the nail complex (Foucher 1991). Positive results of microsurgically modified interventions have led to today's clinical routine applications in orthopedics, gynecology, urology, plastic–reconstructive and pediatric surgery.

After a few early single reports (Baumann 1977; Apotheker & Jako 1981), the surgical microscope was introduced in dentistry in the 1990s. Case reports and the applications of the microscope were described in the prosthetic (Leknius & Geissberger 1995; Friedman & Landesman 1997, 1998; Mora 1998), endodontic (Carr 1992; Pecora & Andreana 1993; Ruddle 1994; Mounce 1995; Rubinstein 1997), and periodontal literature (Shanelec 1991; Shanelec & Tibbetts 1994, 1996; Tibbetts & Shanelec 1994; Burkhardt & Hürzeler 2000).

Treatment outcomes have been statistically analyzed in prospective studies in endodontics, since the

introduction of microendodontic techniques (Rubinstein & Kim 1999, 2002). Within 1 year after apical microsurgery, 96.8% of the cases were considered to be healed. At re-evaluation, 5–7 years after the first post-operative year, a success rate of 91.5% measured by clinical and radiographic parameters was still evident (Rubinstein & Kim 2002). The corresponding percentage of healed cases, treated without a surgical microscope, yielded only 44.1%, 6 months to 8 years after conventional apical surgery (Friedman *et al*. 1991).

Despite the positive results in prospective studies (Rubinstein & Kim 2002; Cortellini & Tonetti 2001; Burkhardt & Lang 2005), the surgical microscope experiences a slow acceptance in prosthodontics, endodontics (Seldon 2002), and periodontal surgery. Possible reasons are the long learning curve, the impaired maneuverability of the devices and the high cost of purchasing the instrument.

Concepts in microsurgery

The continuous development of operating microscopes, refinement of surgical instruments, production of improved suture materials and suitable training laboratories have played a decisive role for the worldwide establishment of the microsurgical technique in many specialties. The three elements, i.e. *magnification*, *illumination*, and *instruments* are called the *microsurgical triad* (Kim *et al*. 2001), the improvement of which is a prerequisite for improved accuracy in surgical interventions. Without any one of these, microsurgery is not possible.

Magnification

An optimal vision is a stringent necessity in periodontal practice. More than 90% of the sensations of the human body are perceived by visual impressions. Vision is a complex process that involves the cooperation of multiple links between the eye, the retina, the optic nerve, and the brain. An important element to assess in human eyesight is visual acuity, measured in angular degrees. If necessary, it may be improved by corrective lenses. It is defined by the ability to perceive two objects separately. Visual acuity is influenced by anatomic and physiologic factors, such as the density of cells packed on the retina and the electrophysiologic process of the image on the retina.

Another important factor influencing visual acuity is the lighting. The relation between visual acuity and light density is well established: a low light density decreases visual acuity. The best eyesight can be achieved at a light density of 1000 cd/m^2. At higher densities, visual acuity decreases. This, in turn, means that claims for optimal lighting conditions have to be implemented.

Visualization of fine details is enhanced by increasing the image size of the object. Image size can be increased in two ways: (1) by getting closer to the objects and (2) by magnification. Using the former method, the ability of the lens of the eye to accommodate becomes important and has a relevant influence on the visual capacity. By changing the form of the lens, the refraction of the optical apparatus increases, allowing it to focus on nearer objects. During ageing, the ability to focus at closer distances is compromised because the lens of the eye loses its flexibility (Burton & Bridgeman 1990). This phenomenon is called presbyopia. Presbyopia affects all people in middle age, and becomes especially noticeable when the nearest point at which the eye can focus accurately exceeds ideal working distances (Burton & Bridgeman 1991). To see small objects accurately, the focal length must be increased. As an example, an older individual reading without glasses must hold the reading matter farther from the eyes to see the print. Increasing the distance enables the person to see the words, but the longer working distance results in a smaller size of the written text. This decrease in image size, resulting from the increased working distance, needs to accommodate the limitations of presbyopia and is especially hindering in clinical practice. In periodontal practice, the tissues to manipulate are usually very fine resulting in a situation in which the natural visual capacity reaches its limits. Therefore, the clinical procedure may only be performed successfully with the use of magnification improving precision and, hence, the quality of work.

Optical principles of loupes

In dentistry, two basic types of magnification systems are commonly used: the surgical microscope and loupes. The latter can further be classified as (1) single-lens magnifiers (clip-on, flip-up, jeweller's glasses) and (2) multi-lens telescopic loupes. Single-lens magnifiers produce the described diopter magnification that simply adjust the working distance to a set length. As diopters increase, the working distances decrease. With a set working distance, there is no range and no opportunity for movement; this can create difficulty in maintaining focus and, therefore, may cause neck and back strain from poor posture (Basset 1983; Diakkow 1984; Shugars *et al*. 1987). Additionally, diopter magnifiers also give poor image quality, which restricts the quality of the work (Kanca & Jordan 1995). These types of glasses cannot be considered to be a true means of magnification.

Telescopic loupes (compound or prism loupes), however, offer improved ergonomic posture as well as significant advancements in optical performance (Shanelec 1992). Instead of increasing the thickness of a single lens to increase magnification, compound loupes use multiple lenses with intervening air spaces (Fig. 45-1). These allow an adjustment of magnification, working distance, and depth of the field without excessive increase in size or weight. Prism loupes are

Fig. 45-1 Fixed compound loupe, adjustable only in the interpupilary distance (Galilean principle).

Fig. 45-2 Prism loupe, sealed to avoid leakage of moisture, front frame mounted and fully adjustable (Prism principle).

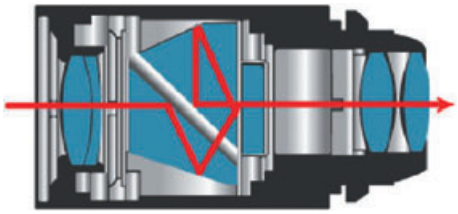

Fig. 45-3 Light path through prism loupe. Even though the distance the light travels has increased, there is no decrease in brightness or image contrast, even at 4× or 5×. This is because the light does not travel through air but instead through the glass of the prism.

the most optically advanced type of loupe magnification available (Fig. 45-2). While compound loupes use multiple refracting surfaces with intervening air spaces to adjust optical properties, prism loupes are actually low-power telescopes. They contain Pechan or Schmidt prisms that lengthen the light path through a series of mirror reflections within the loupes (Fig. 45-3). Prism loupes produce better magnification, larger fields of view, wider depths of field, and longer working distances than do other loupes. To guarantee proper adjustment of loupes, the knowledge of some basic definitions and key optical features of loupes is necessary (Fig. 45-4).

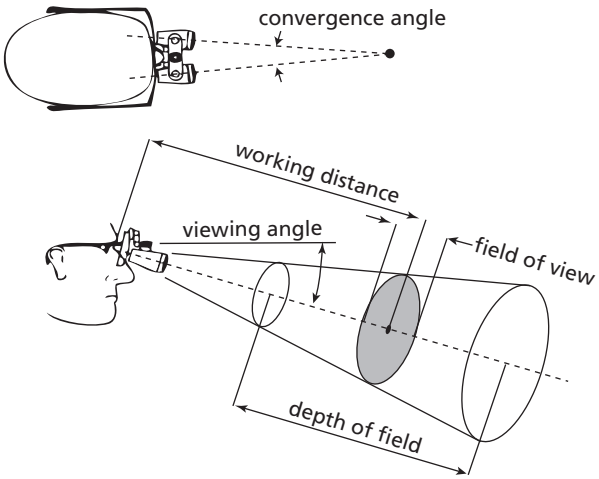

Fig. 45-4 Diagram indicating the principal optical features of loupes.

Working distance

The working distance is the distance measured from the eye lense location to the object in vision. There is no set rule for how much the working distance may be increased. Depending on the height and the resulting length of the arms, the working distance with slightly bended arms usually ranges from 30 to 45 cm. At this distance, postural ergonomics are greatly improved and eye strain reduced due to lessened eye convergence. The multitude of back, neck, shoulder, and eye problems that dentists suffer, working without using loupes, frequently originate from the need to assume a short working distance to increase visual acuity (Coburn 1984; Strassler 1989). By wearing surgical loupes, the head is placed in the centre of its balance over the spine and stabilized against gravity.

Working range

The working range (depth of field) (Fig. 45-4) is the range within which the object remains in focus. The depth of field of normal vision ranges from working distance to infinity. Moving back from a close working distance, the eyes naturally accommodate and refocus to the new distance. Normally, eye position and body posture are not frozen in one place for an extended period, but vary constantly. Wearing loupes changes this geometry. Body posture and position of the extraocular muscles are confined to a range determined by the loupe's characteristics. It is important to understand that each individual's vision is limited to his/her own internal working range, which means that one may only be able to maintain focus on an object within a 15 cm range, even though the loupes have a 23 cm depth of field. With any brand of loupe, the depth of field decreases as the magnification increases.

Convergence angle
The convergence angle (Fig. 45-4) is the pivotal angle aligning the two oculars, such that they are pointing at the identical distance and angle. At a defined working distance, the convergence angle varies with interpupillary distance. Wider-set eyes will have more eye convergence at short working distances. Therefore, the convergence angle defines the position of the extraocular muscles that may result in tension of the internal and external rectus muscles; this may be an important source of eye fatigue.

Field of view
The field of view (Fig. 45-4) is the linear size or angular extent of an object when viewed through the telescopic system. It also varies depending on the design of the optic lens system, the working distance, and the magnification. As with depth of field, when magnification increases, the field of view decreases.

Interpupillary distance
The interpupillary distance (Fig. 45-4) depends on the position of the eyes of each individual and is a key adjustment that allows long-term, routine use of loupes. The ideal setting, as with binoculars, is to create a single image with a slightly oval-shaped viewing area. If the viewing area is adjusted to a full circle, excess eye muscle strain would limit the ability to use loupes for long periods.

Viewing angle
The viewing angle (Fig. 45-4) is the angular position of the optics allowing for comfortable working. The shallower the angle, the greater the need to tilt the neck to view the object being worked at. Therefore, loupes for dental clinicians should have a greater angulation than loupes designed for industrial workers. A slight or no angulation, which results when magnifiers are embedded in the lenses of the eyeglasses, may cause the operator to unduly tilt his or her head to view a particular object. This, again, may lead not only to neck discomfort, but also to pain in the shoulder muscles and possibly to a headache. As the working posture is likely to change over time, the loupes should be adjustable to any posture change.

Illumination
Most of the manufacturers offer collateral lighting systems or suitable fixing options. These systems may be helpful, particularly for higher magnification in the range of 4× and more. Loupes with a large field of view will have better illumination and brighter images than those with narrower fields of view. Important considerations in the selection of an accessory lighting source are total weight, quality, and the brightness of the light, ease of focusing and directing the light within the field of view of the magnifiers, and ease of transport between surgeries (Strassler *et al*. 1998).

It should be realized that each surface refraction in a lens will result in a 4% loss in transmitted light due to reflection. In telescopic loupes, this could amount to as much as 50% reduction in brightness. Anti-reflective coatings have been developed to counteract this effect by allowing lenses to transmit light more efficiently. The quality of lens coatings also varies and should be evaluated when selecting loupes (Shanelec 1992).

Choice of loupes
Before choosing a magnification system, different loupes and appropriate time for a proper adjustment have to be considered. Ill fitting or improperly adjusted loupes and the quality of the optics will influence the performance. For the use in periodontal surgery, an adjustable, sealed prism loupe with high-quality, coated lenses offering a magnification between 4× and 4.5×, either headband- or front frame-mounted, with a suitable working distance and a large field of view, seems to be the instrument of choice. The information in Table 45-1 serves as a basic guide to making an adequate selection.

Optical principles and components of a surgical microscope

The surgical microscope is a complicated system of lenses that allows stereoscopic vision at a magnification of approximately 4–40× with an excellent illumination of the working area. In contrast to loupes, the light beams fall parallel onto the retinas of the observer so that no eye convergence is necessary and the demand on the lateral rectus muscles is minimal (Fig. 45-5). The microscope

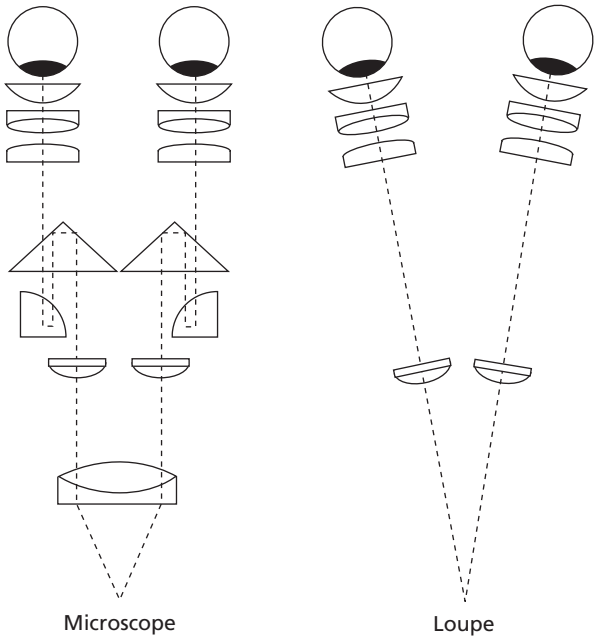

Fig. 45-5 Diagram illustrating the comparison of vision enhancement with loupes and a microscope. The loupes necessitate eye convergence while vision is paralleled through the microscope.

Table 45-1 Features to consider in the selection of a magnifying loupe system

Compound loupes (Galilean)	• Magnification range 2–3.5× • Lighter in weight • Shorter working distance • Shorter loupe barrel
Prism loupes (Keplerian)	• Magnification range 3–5× • Heavier in weight • Longer working distance • Longer loupe barrel
Front-frame mounted	• Allow up to 90% of peripheral vision • No prescription glasses • Require soft and cushioned nose piece • Better weight distribution
Head-band mounted	• Restricted peripheral vision • Allow to use prescription glasses • Better weight distribution • Require adjustment more often
Fixed-lens magnifiers	• No adjustment options when changing posture • Minimum weight
Flip-up capability	• Require removable, sterilizable handle • Allow switch from magnified to regular vision
Quality of the lenses	• Corrected for chromatic and spherical aberration • No drop-off in clarity when approaching the edges • Sealed system to avoid leakage of moisture • Option for disinfection
Adjustment options	• Interpupillary distance • Viewing angle • Vertical adjustment • Lock in adjusted position • Convergence angle (preset angle may be more user-friendly)
Lens coating	• Brighter image • More light
Accessories	• Transportation box • Side and front shields for protection • Mounted light source • Removable cushions

consists of the optical components, the lighting unit, and a mounting system. To avoid an unfavorable vibration of the microscope during use, the latter should be firmly attached to the wall, the ceiling or a floor stand. Mounted on the floor, the position of the microscope in the room must provide quick and easy access.

The optical unit includes the following components (Fig. 45-6): (1) magnification changer, (2) objective lenses, (3) binocular tubes, (4) eyepieces, and (5) lighting unit (Burkhardt & Hürzeler 2000).

Magnification changer

The magnification changer or "Galilean" changer consists of one cylinder, into which two Galilean telescope systems (consisting of a convex and concave lens) with various magnification factors are built. These systems can be used in either direction depending on the position of the magnification changer. A total of four different magnification levels are available. Straight transfer without any optics yields no magnification. The combination of the magnification changer with varying objective lenses and eyepieces yields an increasing magnification line when the control is adjusted.

The stepless motor-driven magnification changer must achieve a magnification of 0.5–2.5× with one optical system, which is operated by either a foot pedal or an electric rotating control, mounted on the microscope. The operator should decide whether to use the manual or motorized magnification changer. If the magnification must be changed frequently, it can be accomplished more quickly with the manual than with the motorized changer, the former not having in-between levels. While the motorized system improves the focus and comfort compared to the manual system, the former is more expensive.

Objective lenses

As processed by a magnification changer, the image is only projected by a single objective. This simultaneously projects light from its source twice for deflection by the prisms into the operation area (i.e. coaxial lighting). The most frequently used objective is 200 mm (f = 200 mm). The focal length of the objective generally corresponds to the working distance of the object.

Binocular tubes

Depending on the area of use, two different binocular tubes are attached (i.e. straight and inclined tubes). With straight tubes, the view direction is parallel to the microscope axis. Using inclined tubes, an angulation to the microscope axis of 45° is achieved. In dentistry, only inclined, swivelling tubes, that permit continuously adjustable viewing, are feasible for ergonomic reasons (Fig. 45-7). The precise adjustment of the interpupillary distance is the basic prerequisite for the stereoscopic view of the operation area.

Eyepieces

The eyepieces magnify the interim image generated in the binocular tubes. Varying magnifications can be achieved (10×, 12.5×, 16×, 20×) using different eyepieces. Eyepiece selection not only determines the magnification, but also the size of the field of view. Corresponding to the loupe spectacles, an indirect relationship exists between the magnification and the field of view. The 10× eyepiece generally provides a sufficient compromise between magnification and field of view. Modern eyepieces allow a correction

Fig. 45-7 Tiltable viewing tube which provides an ergonomic posture during clinical work, a prerequisite for optimal performance using microsurgical technique.

facility within –8 to +8 diopters that is a purely spherical correction.

The majority of surgical microscopes consist of modules and can be equipped with attachments that include integrated video systems, photographic adapters for cameras, units for image storage, colour printers, and powerful lighting sources. Prior to purchasing accessories, inexperienced clinicians should gather information about the needed equipment. The use of magnifying loupes is recommended prior to purchasing a microscope to accustom oneself to working under magnification.

Lighting unit

Optimal illumination is necessary with high magnifications. In recent years, the use of halogen lamps became popular. These lamps provide a whiter light than do lamps using conventional bulbs due to their higher colour temperature. As halogen lamps emit a considerable portion of their radiation within the infrared part of the spectrum, microscopes are equipped with cold-light mirrors to keep this radiation from the operation area. An alternative to the halogen light is the xenon lamp that functions up to ten times longer than the halogen lamp. The light has daylight characteristics with even a whiter colour and delivers a brighter, more authentic image with more contrast.

Advantages and disadvantages of loupes and surgical microscopes

A substantial number of periodontists have already adopted the use of low magnification in their practices and recognize its great benefits. Most of the present results are based on subjective statements of patients or observations of the attending surgeons. At present, it can only be speculated how significantly the selection of magnification influences the result of the operation. The magnification recommended for surgical interventions ranges from 2.5–20× (Apotheker & Jako 1981; Shanelec 1992). In periodontal surgery, magnifications of 4–5× for loupe spectacles and 10–20× for surgical microscopes appear to be ideal depending on the kind of intervention. As the depth of field decreases with increasing magnification, the maximum magnification for a surgical intervention is limited to about 12–15×, when dealing with a localized problem such as the coverage of a single soft tissue recession or interdental wound closure after guided tissue regeneration of an infrabony defect. A magnification range of 6–8× seems appropriate for clinical inspections or surgical interventions when the entire quadrant is under operation. Higher magnifications such as 15–25× are more likely limited to the visual examination of clinical details only, such as in endodontic interventions.

Loupes have the advantage over the microscope in that they reduce technique sensitivity, expense,

and learning phase. The lighting of the operation field is often insufficient, however, and that may limit magnifications more than 4.5×. The surgical microscope guarantees a more ergonomic working posture (Zaugg *et al*. 2004), optimal lighting of the operation area, and freely selectable magnification levels. These advantages are countered by increased expenses of the equipment and an extended learning phase for the surgeon and his assistant. In order to visualize lingual or palatal sites that are difficult to access, the microscope must have sufficient maneuverability. Recent developments have enabled direct viewing of oral operation aspects. By means of these optical devices, it will be possible to perform all periodontal interventions with the surgical microscope.

Instruments

Proper instrumentation is fundamental for microsurgical intervention. While various manufacturers have sets of microsurgical instruments, they are generally conceived for vascular and nerve surgery and, therefore, inappropriate for the use in plastic periodontal surgery. As the instruments are primarily manipulated by the thumb, index and middle finger, their handles should be round, yet provide traction so that finely controlled rotating movements can be executed. The rotating movement of the hand from two o'clock to seven o'clock (for right-handed persons) is the most precise movement the human body is able to perform. The instruments should be approximately 18 cm long and lie on the saddle between the operator's thumb and the index finger; they should be slightly top-heavy to facilitate accurate handling (Fig. 45-8). In order to avoid an unfavorable metallic glare under the light of the microscope, the instruments often have a coloured coating surface. The weight of each instrument should not exceed 15–20 g (0.15–0.20 N) in order to avoid hand and arm muscle fatigue. The needle holder should be equipped with a precise working lock that should not exceed a locking force of 50 g (0.5–N). High locking forces generate tremor, and low locking forces reduce the feeling for movement.

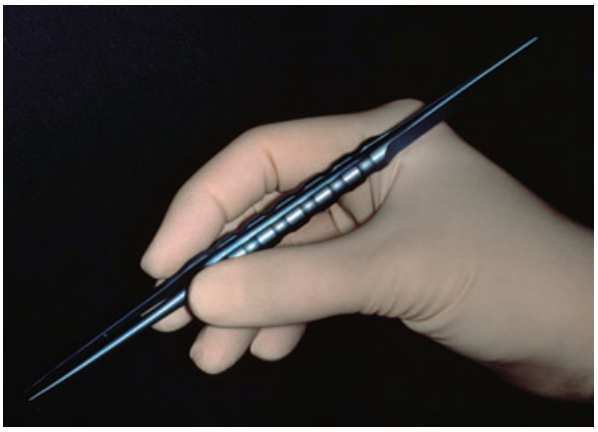

Fig. 45-8 Illustration demonstrating proper hand position for utilization of microsurgical instruments. Fine rotary movements which you get gripping the instrument like a pencil are needed for precise movements.

Appropriate sets of steel or titanium instruments for periodontal surgery are available from different manufacturers. A basic set comprises a needle holder, micro scissors, micro scalpel holder, anatomic and surgical forceps, and a set of various elevators. In order to avoid sliding of the thread when tying the knot, the tips of the forceps have flat surfaces or can be finely coated with a diamond grain that improves the security by which the needle holder holds a surgical needle (Abidin *et al*. 1990). The configuration of the needle holder jaw has considerable influence on needle holding security. The presence of teeth in the tungsten carbide inserts provides the greatest deterrent to either twisting or rotating of the needle between the needle holder jaws. This benefit must be weighed against the potential damaging effects of the teeth on suture material. Smooth jaws without teeth cause no demonstrable damage to 6-0 monofilament nylon sutures, whereas needle holder jaws with teeth ($7000/in^2$) markedly reduce the suture breaking strength (Abidin *et al*. 1990). Additionally, the sharp outer edges of the needle holder jaws must be rounded to avoid breakage of fine suture materials (Abidin *et al*. 1989). When the needle holder jaws are closed, no light must pass through the tips. Locks aid in the execution of controlled rotation movements on the instrument handles without pressure. The tips of the forceps should be approximately 1–2 mm apart, when the instrument lies in the hand idly.

Various shapes and sizes of micro scalpels can be acquired from the discipline of ophthalmology or plastic surgery instrument sets and supplemented with fine instruments (fine chisels, raspatories, elevators, hooks, and suction) from conventional surgery.

In order to prevent damage, micro instruments are stored in a sterile container or tray. The tips of the instruments must not touch each other during sterilization procedures or transportation. The practice staff should be thoroughly instructed about the cleaning and maintenance of such instruments, as cleansing in a thermo disinfector without instrument fixation can irreparably damage the tip of these very expensive micro instruments.

Suture materials

Suture material and technique are essential factors to consider in microsurgery (Mackensen 1968). Wound closure is a key prerequisite for healing following surgical interventions and most important to avoid complications (Schreiber *et al*. 1975; Kamann *et al*. 1997). The most popular technique for wound closure is the use of sutures that stabilize the wound margins sufficiently and ensure proper closure over a defined period of time. However, the penetration of a needle

through the soft tissue in itself causes a trauma, and the presence of foreign materials in a wound may significantly enhance the susceptibility to infection (Blomstedt *et al*. 1977; Österberg & Blomstedt 1979). Hence, it is obvious that needle and thread characteristics influence wound healing and surgical outcome.

Characteristics of the needle

The needle consists of a swage, body, and tip and differs concerning material, length, size, tip configuration, body diameter, and the nature of connection between needle and thread. In *atraumatic* sutures, the thread is firmly connected to the needle through a press-fit swage or stuck in a laser-drilled hole. There is no difference concerning stability between the two attachment modalities (Von Fraunhofer & Johnson 1992). The body of the needle should be flattened to prevent twisting or rotating in the needle holder. The needle tips differ widely depending on the specialty in which they are used. Tips of cutting needles are appropriate for coarse tissues or atraumatic penetration. In order to minimize tissue trauma in periodontal microsurgery, the sharpest needles, reverse cutting needles with precision tips or spatula needle with micro tips (Fig. 45-9), are preferred (Thacker *et al*. 1989).

The shape of the needle can be straight or bent to various degrees. For periodontal microsurgery, the 3/8″ circular needle generally ensures optimum results. There is a wide range of lengths, as measured along the needle curvature from the tip to the proximal end of the needle lock. For papillary sutures in the posterior area, needle lengths of 13–15 mm are appropriate. The same task in the front aspect requires needle lengths of 10–12 mm, and for closing a buccal releasing incision, needle lengths of 5–8 mm are adequate. To guarantee a perpendicular penetration through the soft tissues without tearing, an asymptotic curved needle is advantageous in areas where narrow penetrations are required (e.g. margins of gingivae, bases of papillae). To fulfil these prerequisites for ideal wound closure, at least two different sutures are used in most surgical interventions. Table 45-2 serves as a basic guide to select the appropriate suture material.

Characteristics of the suture material

The suture material may be either *resorbable* or *nonresorbable* material. Within these two categories, the materials can be further divided into *monofilament* and *polyfilament* threads. The bacterial load of the oral cavity demands attention in the choice of the suture material. Generally, in the oral cavity the wound healing process is uneventful, hereby reducing the risk of infection caused by contamination of the thread. As polyfilament threads are characterized by a high capillarity, monofilament materials are to be preferred (Mouzas & Yeadon 1975). *Pseudomonofilaments* are coated polyfilament threads with the aim of reducing mechanical tissue trauma. During suturing the coating will break and the properties of the pseudomonofilament thread then corresponds to that of the polyfilament threads (Macht & Krizek 1978). Additionally, fragments of the coating may invade the surrounding tissues and elicit a foreign body reaction (Chu & Williams 1984).

Resorbable sutures

Resorbable threads may be categorized as *natural* or *synthetic*. Natural threads (i.e. surgical gut) are produced from intestinal mucosa of sheep or cattle. The twisted and polished thread loses its stability within 6–14 days by enzymatic breakdown (Meyer & Antonini 1989). Histologic examinations confirmed the inflammatory tissue reactions with a distinct infiltrate. For that reason, natural resorbable threads are generally obsolete (Bergenholtz & Isaksson 1967; Helpap *et al*. 1973; Levin 1980; Salthouse 1980).

Synthetic materials are advantageous due to their constant physical and biologic properties (Hansen 1986). The materials used belong to the polyamides, the polyolefines or the polyesters and disintegrate by hydration into alcohol and acid. Polyester threads are mechanically stable and, based on their different hydrolytic properties, lose their firmness in different,

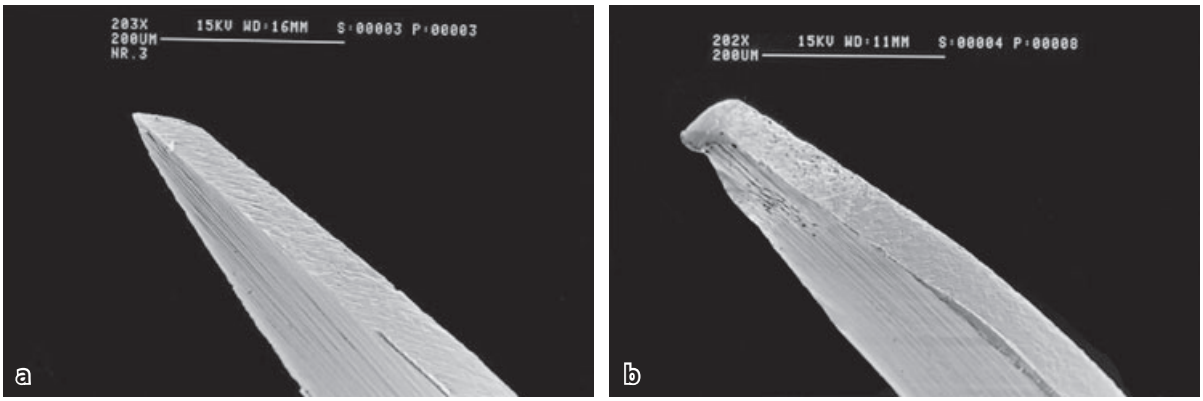

Fig. 45-9 (a) Intact sharp spatula needle. (b) Damaged needle tip after sticking into the enamel surface.

Table 45-2 Ideal needle–thread combinations (non-resorbable) for use in periodontal microsurgery

Indications	Suture gauge	Needle characteristics	Thread materials	Product name
Buccal releasing incisions	7-0 7-0 9-0	3/8 curvature, cutting needle with precision tip, needle length 7.6 mm asymptotic curved needle, cutting needle tip, round body, needle length 8.9 mm 3/8 curvature needle, spatula needle, needle length 5.2 mm	Polypropylene Polypropylene Polyamide	Prolene® Prolene® Ethilon®
Interdental sutures, front area	6-0 7-0	3/8 curvature, cutting needle with precision tip, needle length 11.2 mm 3/8 curvature, cutting needle with precision tip, needle length 11.2 mm	Polypropylene Polyamide	Prolene® Ethilon®

Interdental suture, molar area	6-0	3/8 curvature, cutting needle, needle length 16.2 mm	Polyamide	Ethilon®
Crestal incisions	7-0 6-0	3/8 curvature, cutting needle with precision tip, needle length 11.2 mm 3/8 curvature, cutting needle with precision tip, needle length 12.9 mm	Polyamide Polypropylene	Ethilon® Prolene®
Papilla basis incisions	7-0 9-0	asymptotic curved needle, cutting needle tip, round body, needle length 8.9 mm 1/2 curvature, cutting needle with micro tip, needle length 8.0 mm	Polypropylene Polyamide	Prolene® Ethilon®

but constant times. A 50% reduction of breaking resistance can be expected after 2–3 weeks for polyglycolic acid and polyglactin threads, 4 weeks for polyglyconate, and 5 weeks for polydioxanone threads. The threads are available in twisted, polyfilament forms, and monofilament forms for finer suture materials. The capillary effect is limited and hardly exists for polyglactin sutures (Blomstedt & Österberg 1982).

Non-resorbable sutures

Polyamide is a commonly used material for fine monofilament threads (0.1–0.01 mm) that show adequate tissue properties. Tissue reactions seldom occur except after errors in the polymerization process (Nockemann 1981). Polyolefines, as a variation of choice, are inert materials that remain in the tissues without hydrolytic degradation (Salthouse 1980; Yu & Cavaliere 1983). Polypropylene and its newest development, polyhexafluoropropylene, are materials with excellent tissue properties. After suturing, the thread will be encapsulated in connective tissues and keep its stability for a longer period. In 5-0 and thicker gauges, the monofilament threads are relatively stiff and, for that reason, may impair patient comfort.

A substance with similar biologic, but improved handling properties, is polytetrafluoroethylene. Due to its porous surface structure, the monofilament threads should only be used with restriction in the bacterially loaded oral cavity.

Intraoral tissue reactions around suture materials

The initial tissue reaction after suturing is a result of the penetration trauma, and reaches its culmination at the third post-operative day (Selvig *et al*. 1998). It is quite similar for resorbable and non-resorbable suture threads (Postlethwait & Smith 1975). Histologically, this early response is characterized by three zones of tissue alteration (Selvig *et al*. 1998): (1) an intensive cellular exudation in the immediate vicinity of the entry to the stitch canal, followed by (2) a concentric area, harboring damaged cells as well as intact tissue fragments, and (3) a wide zone of inflammatory cells in the surrounding connective tissues.

If a resorbable suture is left *in situ* for more than 2 weeks after wound closure, an acute inflammatory reaction still exists. This phenomenon is caused by bacteria entering the stitch canal and penetrating along the thread (Chu & Williams 1984; Selvig *et al*. 1998). The bacteriostatic effect of glycolic acid during the resorption process of polyglactin threads (Lilly *et al*. 1972) cannot be established (Thiede *et al*. 1980), and the resorption process of the polyglycolic thread is additionally inhibited by the acid environment caused by the infection (Postlethwait & Smith 1975).

Such studies confirm the increased risk for bacterial migration along the thread in the moist and bacterially loaded oral cavity. Experimental and clinical data indicate that most wound infections begin around suture material left within the wound (Edlich *et al*. 1974; Varma *et al*. 1974). Polyfilament threads additionally facilitate bacterial migration; bacteria can also penetrate into the inner compartment of the thread and evade the immunologic response of the host (Blomstedt *et al*. 1977; Haaf & Breuninger 1988). This is only one reason why monofilament, nonresorbable sutures should be preferred and removed at the earliest biologically acceptable time (Gutmann & Harrison 1991). The infectious potential can be further reduced by using an anti-infective therapy based on a daily rinsing or topical application of chlorhexidine (Leknes *et al*. 2005).

Another promising option to reduce bacterial migration along the suture is coating it with a bacteriostatic substance. Vicryl® Plus (Ethicon®, Norderstedt, Germany) is a resorbable suture material, coated with triclosan that inhibits bacterial growth for up to 6 days by damaging the membrane of the cells (Rothenburger *et al*. 2002; Storch *et al*. 2002).

Training concepts (surgeons and assistants)

The benefits of the operating microscope in periodontal surgery seem to be obvious. What then can be the reasons for the delay in taking advantage of periodontal surgery under the microscope? The main reason is that most surgeons do not adjust to the surgical microscope and those who have been using microscopes successfully, have not made adequate indepth practical recommendations to help other periodontal surgeons overcome their initial problems. Working with magnification changes the clinical settings as the visual direction during the surgical intervention does not meet the working ends of the instruments and the field of view has a smaller diameter. Additionally, the minimal size of tissue structures and suture threads requires a guidance of movement by visual rather than tactile control. This altered clinical situation requires an adjustment of the surgeon.

The three most common errors in the use of the surgical microscope are: (1) using magnification that is too high, (2) inadequate task sharing between surgeon and assistant, and (3) lack of practice.

High magnification

There is a tendency to use magnification which is too high. As described above, this is one of the fundamental optical principles: the higher the magnification, the narrower the field of vision and the smaller its depth. This concept is important because high magnification causes surgery to become more difficult, especially when it involves considerable movement. In these circumstances low magnification of 4–7× should be used. On the other hand, higher magnification of 10–15× may be useful when dissecting within a small area requiring less movement, e.g. in papilla preservation techniques. In general, the magnification should be that which allows the surgeons to operate with ease, and without increasing their usual operating time for a particular surgical procedure. Surgical time does not have to be increased once the surgeon has adapted fully to the microscope. The more experienced and skilled surgeons are with the microscope, the higher the magnification they can use with ease.

It may take 6 months or more for surgeons to be familiar with magnification of 10×, which usually is the maximum used in plastic periodontal surgery. A point of diminishing returns will eventually be reached where the advantages of increased magnification are outweighed by the disadvantages of a narrower field of vision.

Task sharing between surgeon and assistant (teamwork)

In microendodontics, during root canal treatment, the whole procedure is performed with a minimum amount of position changes of the operating persons. Focusing can easily be achieved by moving the mirror towards or away from the objective lenses. In periodontal surgery both hands are used to hold the instruments and position changes are more frequently required which increase the demands on the operating team and require for an ideal cooperation between surgeon and assistant.

In all surgeries at least two operating persons are involved: a surgeon and an assistant, who assists the surgeon in the most rudimentary tasks in the operation. However, the tasks that the assistant constantly repeats in almost all operations with varying levels of skill will be taken into consideration. These tasks include: flap retraction, suction, rinsing, and cutting the sutures. To guarantee a continuous work flow during the surgical intervention, a second assistant who organizes the instruments is frequently desirable.

In periodontal microsurgery, where there is inherently very little access enjoyed by the surgeon, retraction is absolutely vital. Retraction should be done in different positions and must be devoid of all tremor or movement. This is an exceptionally strenuous task as the human assistant is expected to maintain the same posture for up to 1 hour. This is extremely energy consuming and the fatigue experienced by the assistant increases the chances of tremor as time goes by.

For an optimal work flow, magnification is also required for the assistant. An assistant wearing loupes has the advantage of an open peripheral vision to arrange the instruments and to check the patient's facial expression during the operation. On the other hand, co-observer tubes allow the same view for surgeon and assistant, enabling the assistant

to point the suction tube to the right place and keep the view clear. This also becomes an issue during suturing when the air intake of the suction tube can easily suck the fine threads.

Lack of practice

When working with high magnification, the surgeon has to adjust to being a prisoner within a narrow field of view. A new coordination has to be sought between the surgeon's eyes and hands – an adjustment which can come only after much regular practice with simple surgical procedures. The practice unit consists of a microscope, micro instruments, and different suitable models. To start training, a two-dimensional model, such as rubber dam, is appropriate to learn how to manipulate the instruments, how to pick up the needles, and tying knots. After the initial training, working with three-dimensional models (fruits, eggs, chicken) helps the surgeon to get used to the restricted depth of the field.

Another aim of training is the reduction of tremor. Its physiologic basis is uncertain, but it is important to be aware of the causes in order to prevent it. An important factor is the body posture, which must be natural, with the spinal column straight and the forearms and hands fully supported. An adjustable chair, preferably with wheels, is recommended for the surgeon who should place himself in the most comfortable position. Tremor varies with individuals and even in the same individual it varies under different conditions. In some people, intake of coffee, tea or alcohol may increase tremor; in others, emotions, physical exercise, or the carrying of heavy weights can cause it.

After the completion of appropriate training when instrument handling has become automatic, the surgeon has adjusted to the new conditions and can now fully concentrate on the surgical procedure in clinical practice without taking additional time.

Clinical indications and limitations

The clinical benefits of a microsurgical approach in periodontal practice are mainly evaluated by case reports (Shanelec & Tibbetts 1994, 1996; Michaelides 1996; de Campos *et al*. 2006) and case–cohort studies (Cortellini & Tonetti 2001; Wachtel *et al*. 2003; Francetti *et al*. 2004). The different procedures described apply to the surgical coverage of buccal root recessions and flap closure after regenerative interventions. In both interventions, delicate soft tissue structures have to be manipulated during the surgery, which could be refined by selecting a less traumatic surgical approach. All of the studies confirmed the beneficial effects of the microsurgical approach. When covering a root recession, the vascularization of the injured tissues becomes critical as there is no blood supply from the underlying root surface. Frequently, coverage is performed by a connective tissue graft from the palate, which has different vascular characteristics compared to the supracrestal gingiva; supracrestal gingiva is the only tissue, naturally created and specifically designed, to survive and function over avascular root surfaces. As graft survival depends upon early plasmatic diffusion (Oliver *et al*. 1968; Nobutu *et al*. 1988), firm and stable flap or graft adaptation is of crucial importance to minimize the coagulum and facilitate the ingrowth of new vessels. A minimally traumatic approach allows more precise flap preparation and suturing with a reduction in tissue and vessel injuries, resulting in more rapid and more complete anastomosis of new capillary buds from the recipient bed with the existing, but severed, vessels of the graft or the flap.

The interdental gingiva is also a delicate tissue with a limited vascular network. As the gingival plexus does not extend interproximally, the central part of the interdental soft tissue is only supplied by vessels from the periodontal ligament space and arterioles that emerge from the crest of the interdental septa (Folke & Stallard 1967; Nuki & Hock 1974). These anatomic factors influence the wound-healing capacity of the tissues after surgical dissection and the small size of the structures (i.e. papilla or col) complicates a precise adaptation of the flap margins. Wound dehiscences, resulting in healing by secondary intention, are therefore a common finding after suturing the papilla in papilla-preservation techniques (Tonetti *et al*. 2004). Using microsurgery for a modified or simplified papilla preservation flap, primary wound closure could be noted in 92.3% of all treated sites 6 weeks after the intervention (Cortellini & Tonetti 2001).

Historic comparisons with studies performed by the same authors without the use of an operating microscope showed a clear advantage in the use of a microsurgical approach. Complete primary wound closure was observed in only 67% of the cases treated with a simplified (Cortellini *et al*. 1999), and in 73% of the cases treated with a modified papilla preservation flap (Cortellini *et al*. 1995). These results clearly demonstrated the improvement in tissue preservation and handling using a minimally invasive approach in order to achieve primary closure of the interdental space (Fig. 45-10).

A recently published case–cohort study, evaluating a new flap design for regeneration with enamel matrix derivates (MIST, *minimally invasive surgical technique*) combined with microsurgical techniques, confirmed the previous positive results, yielding a primary wound closure of the interdental tissues in all of the treated sites, 6 weeks post-operatively (Cortellini & Tonetti 2007) (Fig. 45-11).

Subjective observations of clinicians have found there is a less traumatic approach in periodontal surgery when magnification aids and fine suture materials are used. This ensures passive wound closure in most surgical interventions. This speculation

was recently substantiated by an *in vitro* experiment, which evaluated the tearing characteristics of mucosal tissue samples for various suture sizes and needle characteristics in relation to the applied tension forces (Burkhardt *et al*. 2006). The pig jaw mucosal tissue samples were attached in a test-tearing apparatus of a Swiss textile company and the tension tearing diagrams were traced for 3-0, 5-0, 6-0, and 7-0 sutures with forces up to 20 N. While the 3-0 sutures almost exclusively led to tissue breakage at an average of 13.4 N, the 7-0 sutures broke before tissues were torn in every instance, at an applied mean force of 3.6 N. With 5-0 and 6-0 sutures both events occured at random, at a mean force of 10 N. This means that a clinician can influence the amount of damage to the tissue by selecting thicker or thinner suture material. Considering this fact, it may be speculated that wound dehiscence can be prevented and passive flap adaptation can be improved by the choice of thinner sutures; this inevitably requires magnification if its benefits are to be fully appreciated.

The opponents of periodontal microsurgery often mention the adverse effect of a prolonged duration of the intervention while working with microscopes. It has been shown that the incidence and severity of complications and pain following periodontal surgery are correlated well with the duration of the surgical procedure (Curtis *et al*. 1985). It may be speculated that an extended operation time may compensate for the beneficial treatment effect of minimally invasive techniques. However, studies comparing micro- and macrosurgical approaches did not support such a hypothesis (Burkhardt & Lang 2005).

Considering all these facts there are no clinical contraindications for the use of magnification in periodontal surgery. From a user's point of view, only few areas in the oral cavity are difficult to access by an operating microscope which may limit its application. In these circumstances and in surgical interventions which require a frequent change of position, the use of loupes may be preferable.

Fig. 45-10 Primary closure of the buccal papillae after a crown-lengthening procedure. Modified mattress sutures (vertically everting) with 7-0 polyamide thread (black) and two single-knot closures with 8-0 polypropylene threads (blue) in each interdental area.

Comparison to conventional mucogingival interventions

Today's *plastic periodontal surgery*, evolving from *mucogingival surgery*, includes all surgical procedures performed to prevent or correct anatomic, developmental, traumatic or disease-induced defects of the gingiva, alveolar mucosa or bone (Proceedings of the World Workshop in Periodontics 1996). To verify the beneficial effects of a microsurgical approach, the results after using a conventional technique in all the different indications have to be evaluated first. The variables to be used as descriptors of the therapeutic end-point of success may vary, depending on the specific goal of the mucogingival therapy. Some results, such as volume changes after ridge augmentation procedures, are clinically difficult to assess due to a lack of a defined end-point and are therefore documented in the literature by qualitative measurements only. Plastic surgical interventions with clearly defined landmarks for measurement, and thus well investigated in the literature, are the guided tissue regeneration procedures (Needleman *et al*. 2006) and the coverage of buccal root recessions (Roccuzzo

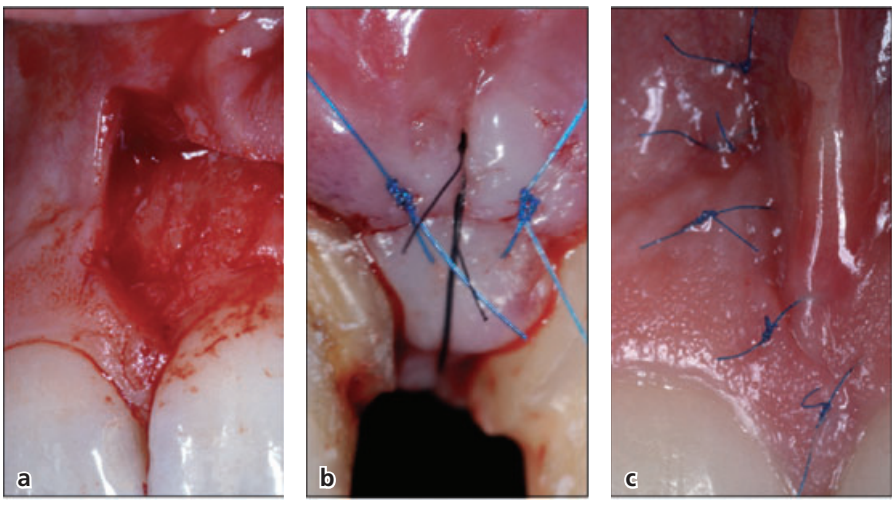

Fig. 45-11 Minimally invasive surgical technique (MIST) (Cortellini & Tonetti 2007). (a) Releasing incision, ending right-angled at the gingival margin. (b) Primary closure of the buccal papilla by a mattress suture (according to Laurell) with 7-0 polyamide thread (black) and two single-knot closures with 8-0 polypropylene threads (blue). (c) Clinical appearance of the releasing incision 4 days post-operatively.

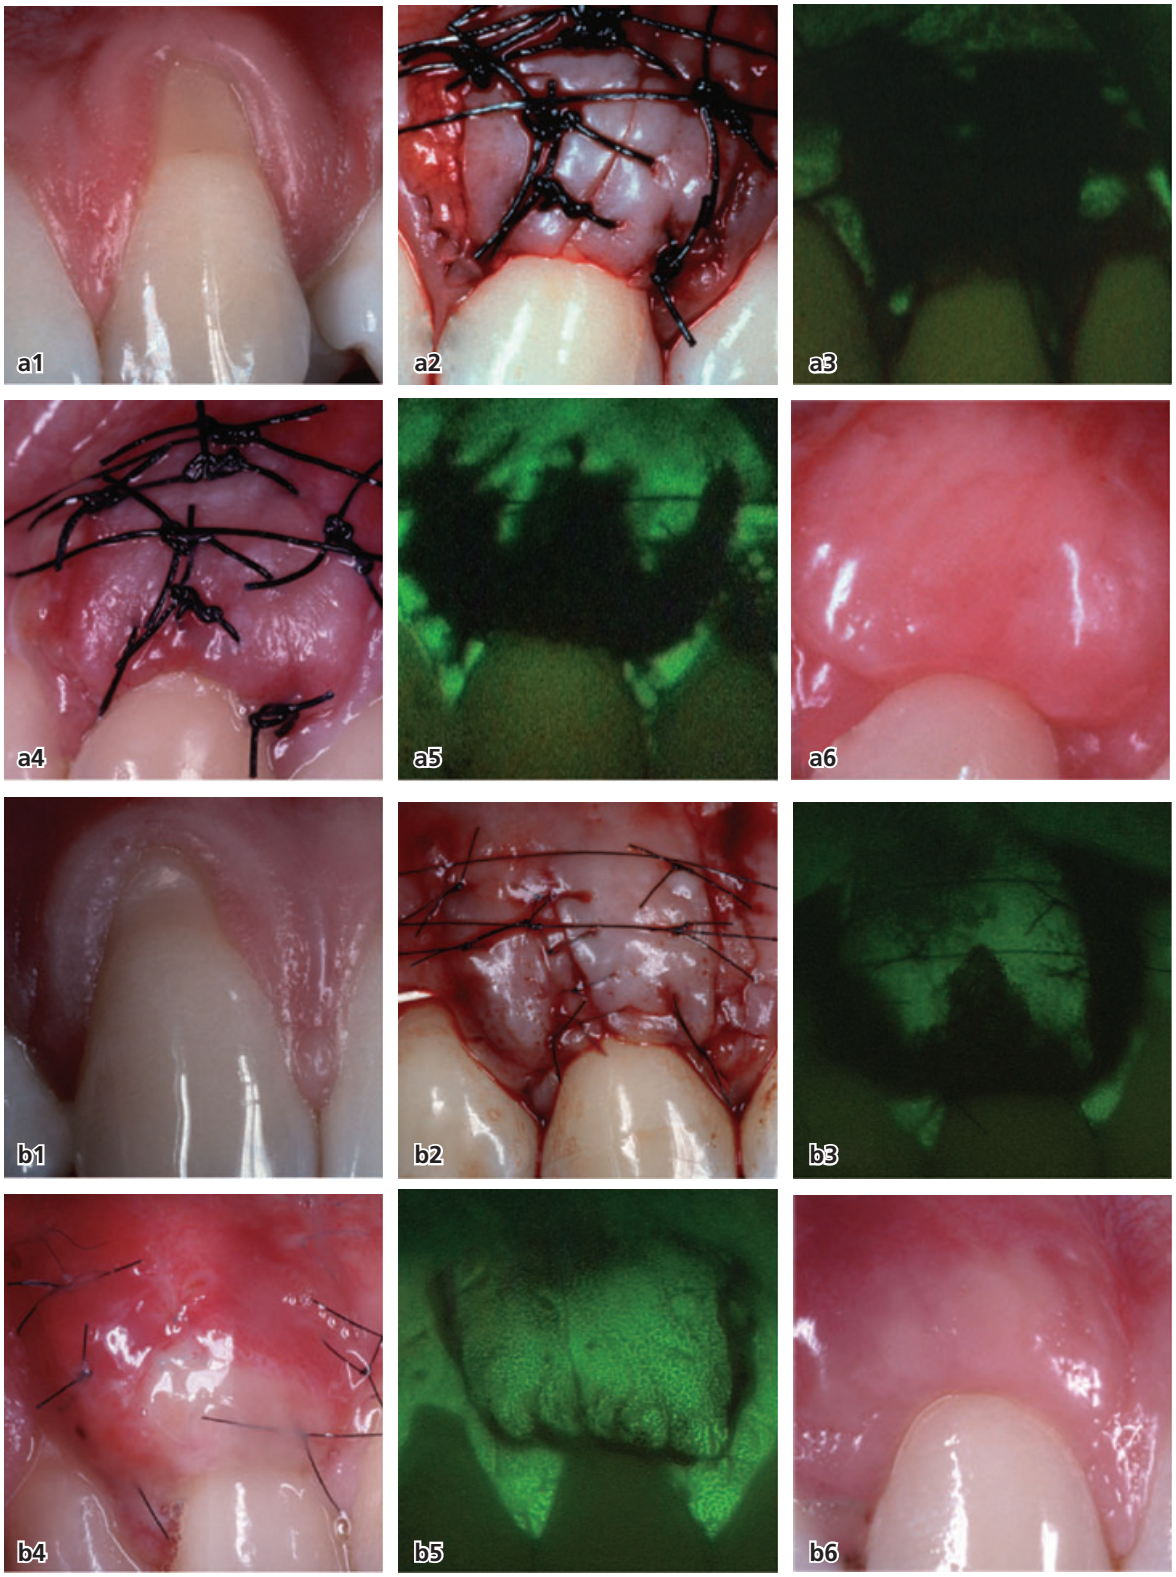

Fig. 45-12 Recession coverage: Macro- and microsurgery in comparison (Burkhardt & Lang 2005). (a) Macrosurgical recession coverage: (a1) pre-operative clinical situation; (a2) immediately after the surgical intervention; (a3) corresponding angiographic evaluation after the intervention; (a4) healing after 7 days; (a5) angiographic evaluation after 7 days; (a6) clinical situation after 3 months (visible contours of incision lines). (b) Microsurgical recession coverage: (b1) pre-operative clinical situation; (b2) immediately after the surgical intervention; (b3) corresponding angiographic evaluation after the intervention; (b4) healing after 7 days; (b5) angiographic evaluation after 7 days; (b6) clinical situation after 3 months (no traces of the intervention visible).

et al. 2002; Oates *et al*. 2003). While the former results in a reduction in probing measures, an improved attachment gain, and less increase in gingival recession compared to open flap debridement, the latter yields a significant reduction in recession depth and also an improvement in clinical attachment level measures. However there is a marked variability between the studies, indicating the influence of case selection, the materials used, the techniques applied, and the surgeons' dexterity. As a result, it is difficult to draw general conclusions because the factors affecting the outcomes are unclear from the literature and these might include study conduct issues such as bias. Among these factors, the dexterity of the surgeon ranks high and seems to influence the results strongly. It is a complicated, proprioceptive reflex involving eye, hand, and brain, and is therefore difficult to assess in clinical settings. To eliminate its influence and to estimate the magnitude of the real benefits of a microsurgical approach, micro- and macrosurgical techniques should be compared in controlled studies.

Concerning the coverage of mucosal recessions, a comparison between the two approaches (micro- and macrosurgery) has been performed in a randomized controlled clinical trial (Burkhardt & Lang 2005). The study population consisted of ten patients with bilateral class I and class II recessions at maxillary canines. In split-mouth design, the defects were randomly selected for recession coverage either by a microsurgical (test) or macrosurgical (control) approach. Immediately after the surgical procedures and after 3 and 7 days of healing, fluorescent angiograms were performed to evaluate graft vascularization. The results at test sites revealed a vascularization of 8.9 ± 1.9% immediately after the procedure. After 3 days and after 7 days, the vascularization rose to 53.3 ± 10.5% and 84.8 ± 13.5%, respectively. The corresponding vascularization at control sites were 7.95 ± 1.8%, 44. 5 ± 5.7%, and 64.0 ± 12.3%, respectively (Fig. 45-12). All the differences between test and control sites were statistically significant.

In addition, the clinical parameters were assessed before the surgical intervention, and 1, 3, 6, and 12 months post-operatively. The clinical measurement revealed a mean recession coverage of 99.4 ± 1.7% for the test and 90.8 ± 12.1% for the control sites after the first month of healing. Again, this difference was statistically significant. The percentage of root coverage in both test and control sites remained stable during the first year, at 98% and 90%, respectively.

The present clinical experiment has clearly demonstrated that mucogingival surgical procedures designed for the coverage of exposed root surfaces, performed using a microsurgical approach, improved the treatment outcomes substantially and to a clinically relevant level when compared with the clinical performance under routine macroscopic conditions. However, the choice of micro- and macrosurgical approaches must be seen in different lights, including treatment outcomes, logistics, cost, and patient-centered parameters. Future comparative studies will produce the evidence whether the use of the surgical microscope will further increase surgical effectiveness and thus become an indispensable part of periodontal surgical practice.

Chapter 46

Re-osseointegration

Tord Berglundh and Jan Lindhe

Introduction

In Chapter 24 (Peri-implant Mucositis and Peri-implantitis) important features of inflammatory lesions in the peri-implant tissues were described. Peri-implantitis is defined as a progressive inflammatory process that involves the mucosa and the bone tissue at an osseointegrated implant in function, and that this process results in loss of osseointegration and supporting bone (Fig. 46-1).

In Chapter 41 (Treatment of Peri-implant Lesions) it is emphasized that peri-implantitis is associated with the presence of submarginal deposits of plaque and calculus and that the successful treatment of the condition must include (1) comprehensive debridement of the implant surface and (2) subsequent interceptive supportive therapy including professional and self-performed plaque removal measures.

An obvious, additional goal in the treatment of peri-implantitis is the regeneration and *de novo* bone formation, i.e. "re-osseointegration", at the portion of the implant that lost its "osseointegration" in the inflammatory process. Furthermore, since the level of the peri-implant mucosa is dependent on the level of the marginal bone, an increase of the height of the osseous tissue will result in a marginal shift of the mucosa. Soft tissue esthetics may also be enhanced, therefore, through re-osseointegration.

Is it possible to resolve a marginal hard tissue defect adjacent to an oral implant?

Non-contaminated, pristine implants at sites with a wide marginal gap (crater)

Peri-implantitis lesions are per definition associated with bone loss and loss of osseointegration. The pattern of bone loss is angular and the ensuing defect often has the shape of a marginally open crater.

Findings from animal experiments and fracture healing suggested that hard tissue bridging, through woven bone formation, may occur in a bone defect provided that the distance between the fracture lines was ≤1 mm (Schenk & Willenegger 1977). This concept was translated to implant dentistry. Thus, it was implied that if a large (>1 mm) marginal defect were present between a newly installed oral implant and the host bone of the alveolar process, osseointegration would become compromised (Wilson *et al.* 1998, 2003).

Results presented by Botticelli *et al.* (2004) challenged this hypothesis. In a human study that included implant placement in fresh extraction sockets, they were able to demonstrate that a large void (gap) between the newly installed implant and the socket walls could become completely resolved

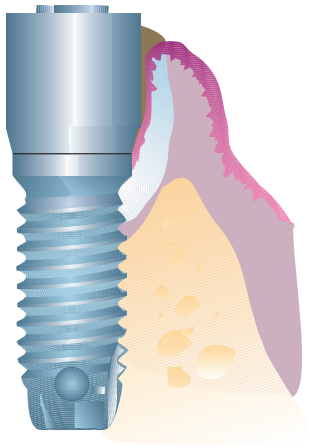

Fig. 46-1 Schematic drawing illustrating characteristics of peri-implantitis including the inflammatory lesion and the associated bone defect.

within a 4-month period. Furthermore, in animal experiments Botticelli *et al*. (2003a,b, 2005, 2006) produced – by mechanical means – large hard tissue defects in the marginal portion of edentulous sites prior to implant installation. The authors reported that (1) the presence of the wide marginal defect *per se* was not an impediment for osseointegration, (2) depending on the surface characteristics of the implant, complete resolution of the defect occurred within a 4-month period, and (3) bone fill in the defect was always the result of appositional osteogenesis.

Contaminated implants and crater-shaped bone defects

Experimental model

In order to study the ability of the tissues in the peri-implant defect to regenerate and to establish *de novo* bone tissue deposition on the contaminated implant surface, a research model was developed. The model was used to induce well defined peri-implantitis lesions in the dog (Lindhe *et al*. 1992) or in the monkey (Lang *et al*. 1993; Schou *et al*. 1993) and is described in detail in Chapter 24.

Re-osseointegration

"Re-osseointegration" can be defined as the establishment of *de novo* bone formation and *de novo* osseointegration to a portion of an implant that during the development of peri-implantitis suffered loss of bone-to-implant contact and became exposed to microbial colonization (alt. the oral environment) (Fig. 46-2). A treatment procedure that aims at re-osseointgration must (1) ensure that substantial regeneration of bone from the walls of the defect can occur and (2) "re-juvenate" the contaminated (exposed) implant surface.

Is re-osseointegration a feasible outcome of regenerative therapy?

Regeneration of bone from the walls of the defect

Persson *et al*. (1999) induced peri-implant tissue breakdown in beagle dogs according to the Lindhe model referred to above (Lindhe *et al*. 1992). Mandibular premolars were extracted, socket healing allowed, and fixtures (Brånemark System®) with a turned surface were placed and submerged. Abutment connection was performed after 3 months. When the mucosa surrounding all implants had attained a clinically normal appearance, plaque accumulation was allowed and ligatures (cotton floss) were placed around the neck of the implants and retained in a position close to the abutment/fixture junction. After 3 months when the soft tissue exhibited signs of severe inflammation and deep crater-like defects had formed in the peri-implant bone compartments, the ligatures were removed (Fig. 46-3a). Treatment was performed and included (1) systemic administration of antibiotics (amoxicillin and metronidazole for 3 weeks), (2) elevation of full-thickness flaps at the experimental sites and curettage of the hard tissue defect, (3) mechanical debridement of the exposed portion of the implants, (4) removal of the abutment portions of the implants and placement of pristine cover screws, and finally (5) flap management and closure of the soft tissue wound. Radiographs and biopsies were obtained after 7 months of submerged healing. The analysis of the radiographs indicated a complete bone fill in the hard tissue defects (Fig. 46-3b). The histologic analysis of the biopsy sections revealed that treatment had resulted in (1) a complete resolution of the soft tissue inflammation and (2) the formation of substantial

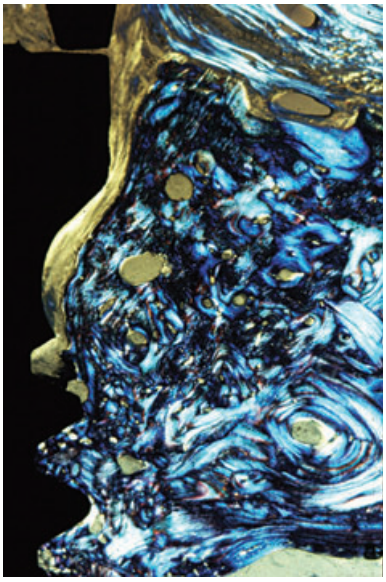

Fig. 46-5 The ground section in Fig. 46-4 in polarized light. Note the connective tissue capsule located between the newly formed bone and the implant surface.

amounts of new bone (appositional osteogenesis) in the previous hard tissue defects (Fig. 46-4). However, only small amounts of "re-osseointegration" to the decontaminated titanium surface could be observed and consistently only at the apical base of the defects. In most sites a thin connective tissue capsule separated the "exposed" implant surface from the newly formed bone (Fig. 46-5). Similar findings were reported by Wetzel *et al*. (1999) from another study in the beagle dog and the use of implants with various surface characteristics (turned, plasma sprayed, and sandblasted–etched surfaces).

Conclusion: Based on the outcome of the above studies it was concluded (1) that the inflammatory lesions in experimentally induced peri-implantitis can be resolved, (2) that *de novo* bone formation (appositional growth) predictably will occur from the hard tissue walls of the defect, and (3) that often the large defects may become more or less completely filled with new bone following a treatment that is based on antimicrobial measures. Hence, the problem inherent in re-osseointegration appears to be the implant surface rather than the host tissues at the site.

"Rejuvenate" the contaminated implant surface

Different techniques have been proposed for a local therapy aimed at "rejuvenating" the once contaminated implant surface. Such techniques have included mechanical brushing of the surface, the use of air–powder abrasives, and the application of chemicals such as citric acid, hydrogen peroxide, chlorhexidine, and delmopinol (Persson *et al*. 1999; Wetzel *et al*. 1999; Kolonidis *et al*. 2003). These local therapies were effective in cleaning the titanium surface and allowing soft tissue healing and bone fill in the bone craters, but only limited amounts of re-osseointegration occurred.

Is the quality of the implant surface important in a healing process that may lead to re-osseointegration?

The surface of the metal device in the compromised implant site

It is well known that pristine implants made of commercially pure titanium are covered with a thin layer of titanium dioxide (Kasemo & Lausmaa 1985, 1986). This dioxide layer gives the implant a high surface energy that facilitates the interaction between the implant and the cells of the host tissues. Contamination of a titanium surface, however, alters its quality and an implant with a low surface energy results. Such a surface may not allow tissue integration to occur but may instead provoke a foreign body reaction (Baier & Meyer 1988; Sennerby & Lekholm 1993).

The problem regarding the implant surface was addressed a dog study (Persson *et al*. 2001a) in which pristine implant parts were placed in crater-like bone defects that had developed during "experimental peri-implantitis" (a.m. Lindhe *et al*. 1992). The test implants used were comprised of two separate parts, one 6 mm long apical and one 4 mm long marginal part, that were joined together via a connector. During surgical therapy following experimental peri-implantitis, the marginal portions of the implants were removed and replaced with pristine analogues. In biopsies obtained after 4 months of healing it was observed that new bone had formed in the crater-like defects and that "re-osseointegration" had occurred to a large area of the pristine implant components.

In an experiment in the dog, Persson *et al*. (2001b) evaluated the potential for "re-osseointegration" to implants designed with either smooth (polished) or roughened (SLA; sandblasted, large grit acid etched) surfaces. Custom-made solid screw implants were placed in the edentulous mandible; in the right side implants with a rough, SLA surface (Fig. 46-6) and in the left side implants with a smooth surface (Fig. 46-7). "Experimental peri-implantitis" was induced and then blocked when about 50% of the peri-implant bone support was lost (Fig. 46-8a). Treatment included (1) systemic antibiotics (amoxicillin and metronidazole for 17 days), (2) flap elevation and curettage of the bone defect, and (3) mechanical debridement of the implant surface (cotton pellets soaked in saline). The implants were submerged and biopsies obtained after 6 months of healing. In all implant sites most of the crater-like defects had been filled with newly formed bone (Fig. 46-9b). However, at sites with smooth surface implants only small amounts of "re-osseointegration" (Fig. 46-10) had occurred. Examination of the histologic sections from sites with rough surface implants, however, revealed that >80% of the previously exposed rough surface exhibited "re-osseointegration" (Fig. 46-11).

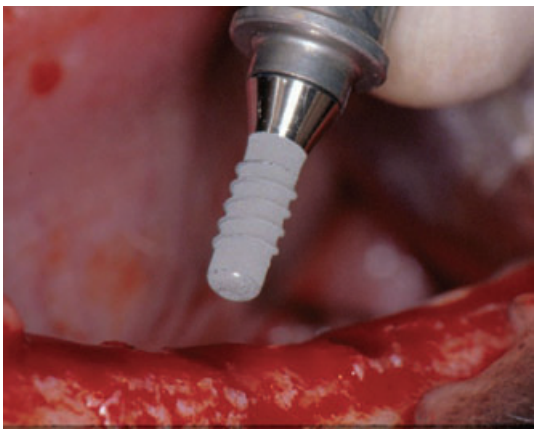

Fig. 46-6 Custom-made implant with a roughened (SLA) surface.

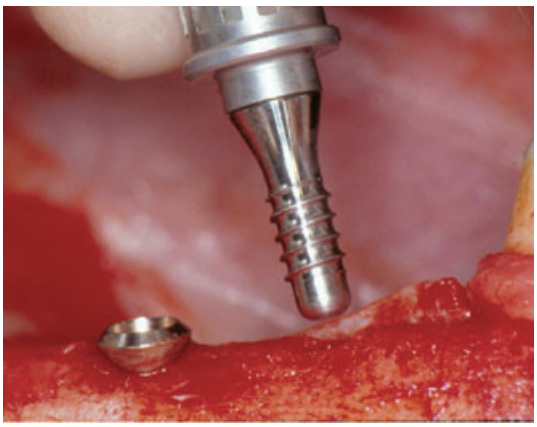

Fig. 46-7 Custom-made implant with a smooth (polished) surface.

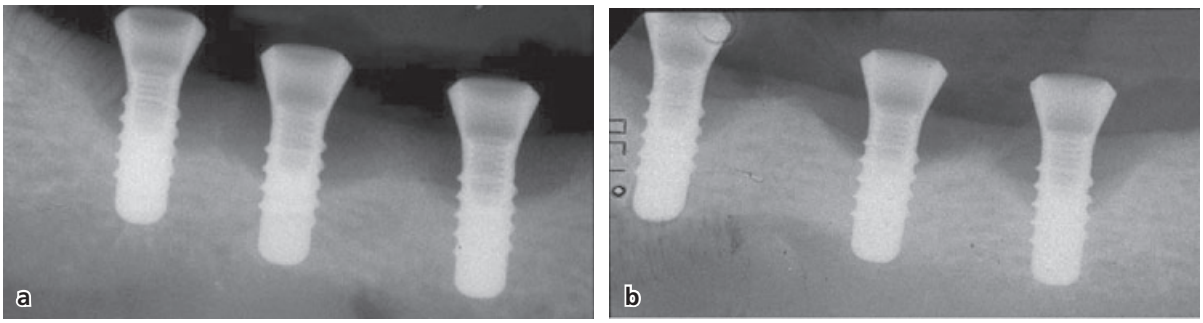

Fig. 46-8 Radiographs illustrating crater-like bone defects following experimental peri-implantitis at implants with a rough (a) and smooth (b) surface.

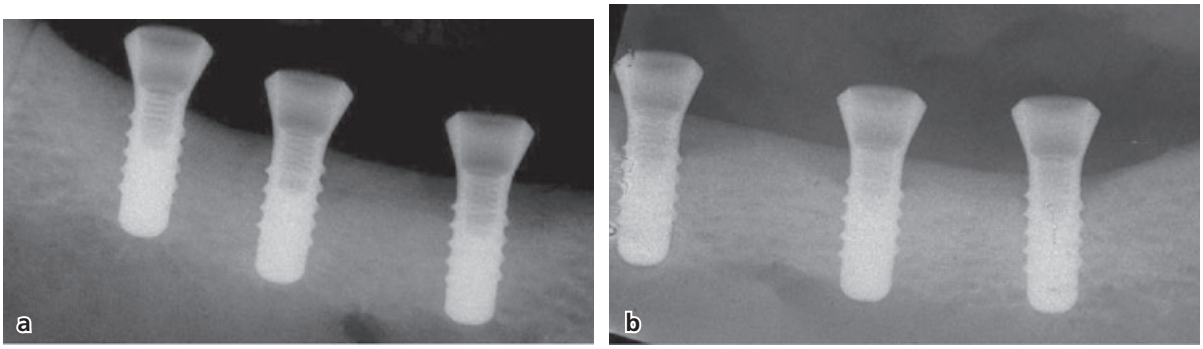

Fig. 46-9 Radiographs illustrating substantial bone-fill in bone defects at 6 months of healing after treatment of experimental peri-implantitis at implants with a rough (a) and smooth (b) surface.

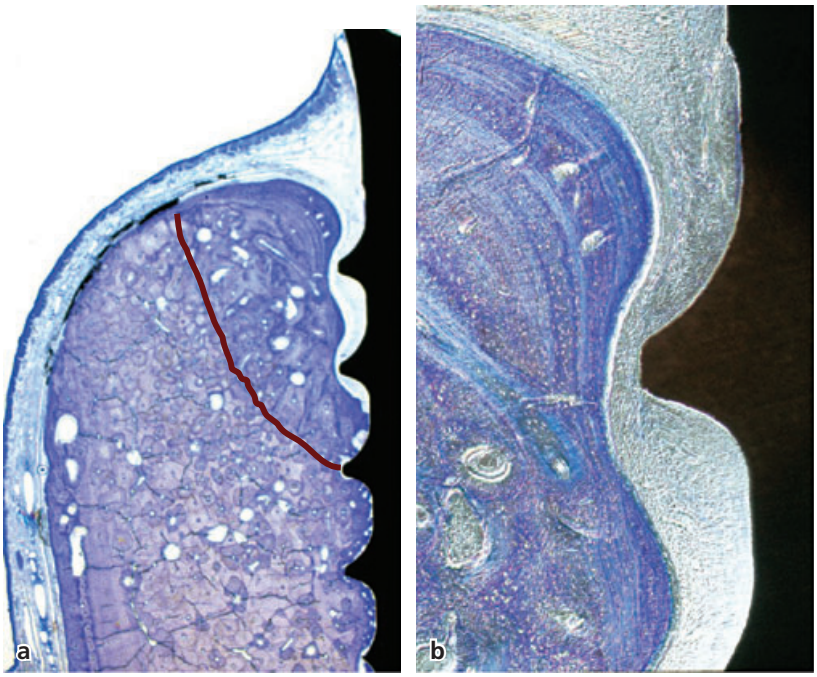

Fig. 46-10 (a) Ground section representing 6 months of healing after treatment of peri-implantitis at sites with smooth surface implants. The red line indicates the outline of the previous hard tissue defect. (b) Note the connective tissue capsule between the newly formed bone and the implant surface.

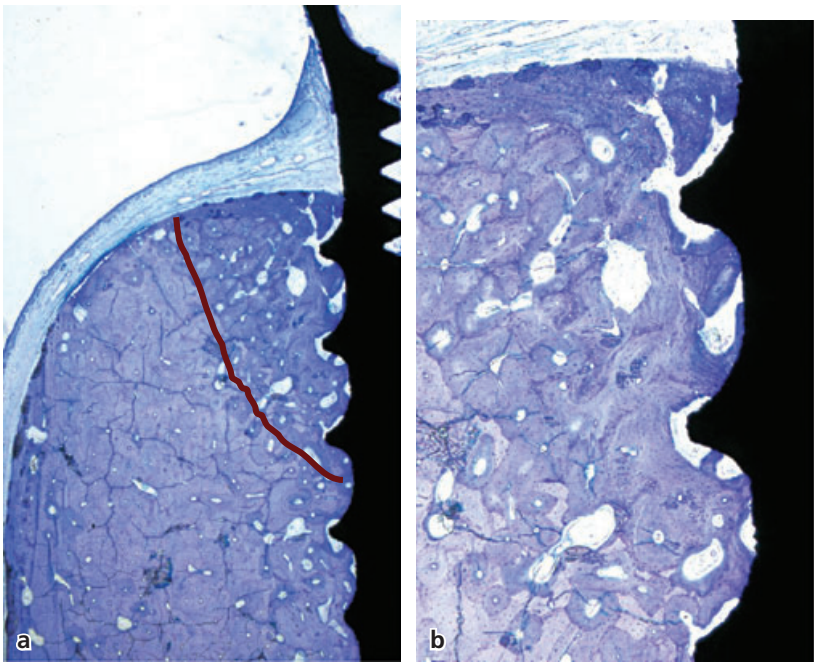

Fig. 46-11 (a) Ground section representing 6 months of healing after treatment of peri-implantitis at sites with rough surface implants. The red line indicates the outline of the previous hard tissue defect. (b) Note the high degree of re-osseointegration to the previously exposed rough implant surface.

Conclusion: Based on the above documentation it is proposed that the rough implant surface may have contributed to a better stability of the blood clot in the bone crater. In addition, during the phase of contraction of the coagulum and formation of granulation tissue, the rough surface may have ensured a continued contact between the newly formed immature tissue and the implant. This upheld contact relationship may, in turn, have facilitated the subsequent formation of a provisional matrix, an osteoid, and eventually woven bone (see Chapter 4). The maintained contact may thus have made possible the bridging of the gap between the walls of the hard tissue crater and the previously exposed implant surface.

In this context it is important to point out that the surface characteristics (smooth vs. rough) of the implant may also influence the risk for a rapid progression of peri-implantitis once initiated (see Chapter 24). Thus, in an experimental study in dogs Berglundh *et al*. (2007) demonstrated that progression of peri-implantitis was more pronounced at implants with a rough (SLA) than with a smooth (polished) surface.

Part 14: Surgery for Implant Installation

Chapter 47

Timing of Implant Placement

Christoph H.F. Hämmerle, Maurício Araújo, and Jan Lindhe

Introduction

Restorative therapy performed on implant(s) placed in a fully healed and non-compromized alveolar ridge, has high clinical success and survival rates (Pjetursson *et al*. 2004). Currently, however, implants are also being placed in (1) sites with ridge defects of various dimensions, (2) fresh extraction sockets, (3) the area of the maxillary sinus, etc. Although some of these clinical procedures were first described many years ago, their application has only recently become common. Accordingly one issue of primary interest in current clinical and animal research in implant dentistry includes the study of tissue alterations that occur following tooth loss and the proper timing thereafter for implant placement.

In the optimal case, the clinician will have time to plan for the restorative therapy (including the use of implants) prior to the extraction of one or several teeth. In this planning, a decision must be made whether the implant(s) should be placed immediately after the tooth extraction(s) or if a certain number of weeks (or months) of healing of the soft and hard tissues of the alveolar ridge should be allowed prior to implant installation. The decision regarding the timing for implant placement, in relation to tooth extraction, must be based on a proper understanding of the structural changes that occur in the alveolar process following the loss of the tooth (teeth). Such adaptive processes were described in Chapter 2.

The removal of single or multiple teeth will result in a series of alterations within the edentulous segment of the alveolar ridge. Hence during socket healing the hard tissue walls of the alveolus will resorb, the center of the socket will become filled with cancellous bone and the overall volume of the site will become markedly reduced. In particular, the buccal wall of the edentulous site will be diminished not only in the bucco-lingual/palatal direction but also with respect to its apico-coronal dimension (Pietrokovski & Massler 1967; Schropp *et al*. 2003). In addition to hard tissue alterations, the soft tissue in the extraction site will undergo marked adaptive changes. Immediately following tooth extraction, there is a lack of mucosa and the socket entrance is thus open. During the first weeks following the removal of a tooth, cell proliferation within the mucosa will result in an increase of its connective tissue volume. Eventually the soft tissue wound will become epithelialized and a keratinized mucosa will cover the extraction site. The contour of the mucosa will subsequently adapt to follow the changes that occur in the external profile of the hard tissue of the alveolar process. Thus, the contraction of the ridge is the net result of bone loss as well as loss of connective tissue. Figure 47-1 presents a schematic drawing illustrating the tissue alterations described above. It is obvious that no ideal time point exists following the removal of a tooth, at which the extraction site presents with (1) maximum bone fill in the socket and (2) voluminous mature covering mucosa.

A consensus report was published in 2004, describing issues related to the timing of implant placement in extraction (Hammerle *et al*. 2004). Attempts had previously been made to identify advantages and disadvantages with early, delayed, and late implant placements. Hämmerle and coworkers considered it

necessary, however, to develop a new concept (classification) that incorporated the growing knowledge in this field of implant dentistry. This new classification took into consideration data describing structural alterations that occur following tooth extraction as well as knowledge derived from clinical observations.

The classification presented in Table 47-1 was introduced in the consensus report. Important aspects of this new classification included the following:

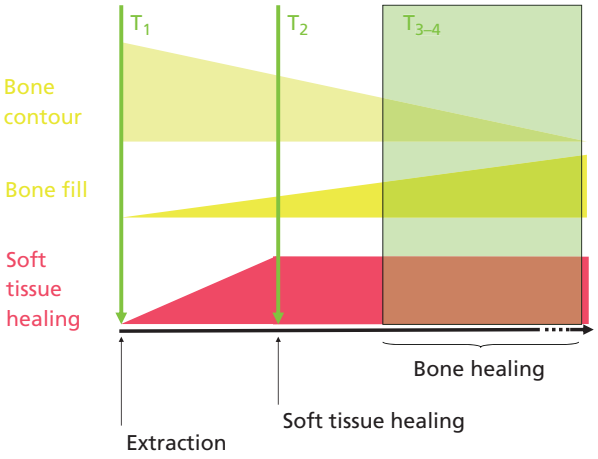

Fig. 47-1 Schematic drawing depicting the changes in the soft and hard tissues following tooth extraction over time. $T_{1–4}$ represent the four different time points regarding timing for implant placement.

- In clinical practice the decision to place an implant following tooth extraction is usually determined by some soft and hard tissue characteristics of the healing socket. Healing does not necessarily follow rigid time frames, and may vary according to site and patient factors.
- To avoid temporal-based descriptions, this new classification used numerical descriptors – types 1, 2, 3, and 4 – that reflect the conditions of the hard and soft tissues:
  - Type 1 placement: the implant is placed immediately following the extraction of a tooth
  - Type 2 placement: the implant is placed in a site where the soft tissues have healed and a mucosa is covering the socket entrance
  - Type 3 placement: the implant is placed in an extraction site at which substantial amounts of new bone have formed in the socket
  - Type 4 placement: the implant is placed in a fully healed ridge
- It was further recognized that there is a clear separation between hard tissue healing and soft tissue healing within and around the extraction socket.

Advantages and disadvantages with the various timings are presented in Table 47-1.

Two methods for flap closure have been described at implant sites. One approach requires primary would closure, whereas the other one allows for a

Table 47-1 Classification types 1–4, descriptive definition as well as advantages and disadvantages of each type

Classification	Definition	Advantages	Disadvantages
Type 1	Implant placement as part of the same surgical procedure and immediately following tooth extraction	Reduced number of surgical procedures Reduce overall treatment time Optimal availability of existing bone	Site morphology may complicate optimal placement and anchorage Thin tissue biotype may compromise optimal outcome Potential lack of keratinized mucosa for flap adaptation Adjunctive surgical procedures may be required Technique-sensitive procedure
Type 2	Complete soft tissue coverage of the socket (typically 4–8 weeks)	Increased soft tissue area and volume facilitates soft tissue flap management Allows resolution of local pathology to be assessed	Site morphology may complicate optimal placement and anchorage Increased treatment time Varying amounts of resorption of the socket walls Adjunctive surgical procedures may be required Technique-sensitive procedure
Type 3	Substantial clinical and/or radiographic bone fill of the socket (typically 12–16 weeks)	Substantial bone fill of the socket facilitates implant placement Mature soft tissues facilitate flap management	Increased treatment time Adjunctive surgical procedures may be required Varying amounts of resorption of the socket walls
Type 4	Healed site (typically >16 weeks)	Clinically healed ridge Mature soft tissues facilitate flap management	Increased treatment time Adjunctive surgical procedures may be required Large variation in available bone volume

transmucosal position of the implant or the healing cap. No differences regarding survival rates and interproximal bone levels were found when these two methods were compared in a split-mouth design (Ericsson *et al*. 1997; Astrand *et al*. 2002; Cecchinato *et al*. 2004). These studies did, however, not analyze in detail the differences between submerged or transmucosal healing in sites of high esthetic importance. Hence, not only the width of the gap but also the width of the alveolar ridge are parameters to be considered during treatment planning.

Type 1: placement of an implant as part of the same surgical procedure and immediately following tooth extraction

Ridge corrections in conjunction with implant placement

It has become common to insert implants immediately after the removal of teeth that were scheduled for extraction for various reasons. Over the years, many claims have been made regarding advantages of immediate implant placement (Chen *et al*. 2004). These advantages include easier definition of the implant position, reduced number of visits in the dental office, reduced overall treatment time and costs, preservation of bone at the site of implantation, optimal soft tissue esthetics, and enhanced patient acceptance (Werbitt & Goldberg 1992; Barzilay 1993; Schwartz-Arad & Chaushu 1997a; Mayfield 1999; Hammerle *et al*. 2004).

It was proposed that placement of an implant in a fresh extraction socket may stimulate bone tissue formation and osseointegration and hence counteract the adaptive alterations that occur following tooth extraction. In other words, type 1 implant installation may allow the preservation of bone tissue of the socket and the surrounding jaw. It was in fact recommended (e.g. Denissen *et al*. 1993; Watzek *et al*. 1995; for review see Chen *et al*. 2004) that implant installation should be performed directly following tooth extraction as a means to avoid bone atrophy.

Clinical studies in man (Botticelli *et al*. 2004; Covani *et al*. 2004) and experiments in dogs (Araujo & Lindhe 2005; Araujo *et al*. 2006a,b) have examined the influence of implant installation in the fresh extraction socket on bone modeling and remodeling in the surgical site.

Botticelli *et al*. (2004) examined hard tissue alterations that occurred in the alveolar ridge during a 4-month period of healing following implant placement in fresh extraction sockets. Eighteen subjects (21 extraction sites) with moderate chronic periodontitis were studied. The treatment planning of all 18 subjects called for extraction of single teeth, and restoration by means of implants in the incisor, canine, and premolar regions of the dentition.

Following sulcus incisions, full-thickness mucosal flaps were raised and the tooth was carefully mobilized and removed with forceps. The site was prepared for implant installation with the use of pilot and twist drills. The apical portion of the socket was pre-tapped. A non-cutting solid screw implant (Straumann®; Basel, Switzerland) with a rough surface topography was installed. The implant was positioned in such a way that the marginal level of its rough surface portion was located apical of the marginal level of the buccal and lingual/palatal walls of the socket (Fig. 47-2a). After implant installation (1) the distance between the implant and the inner and outer surface of the buccal and/or lingual bone plates, and (2) the width of the marginal gap that was present between the implant and the buccal, lingual, mesial, and distal bone walls were determined with the use of sliding calipers.

The soft tissue flaps were replaced and the implants were "semi-submerged" during healing (Fig. 47-2b). After 4 months of healing a surgical re-entry procedure was performed (Fig. 47-2c). The clinical measurements were repeated so that alterations that had occurred during healing regarding (1) the thickness and height of the buccal and lingual/palatal socket walls and (2) the width of the marginal gap could be calculated.

Figure 47-3a presents a photograph of an extraction socket immediately after the removal of a maxillary canine tooth. At re-entry it was realized that the

(c) Clinical occlusal view of the implant site after 4 months of healing. (d) Clinical buccal view of the implant site after 4 months of healing. Note the very thin bone covering the buccal aspect.

marginal gap had completely resolved. Furthermore, the thickness of the buccal as well as the palatal bone walls had become markedly reduced (Fig. 47-3c,d). In Fig. 47-3d the implant surface can be seen through the very thin remaining buccal bone wall.

Another site from this clinical study is presented in Fig. 47-4. The first maxillary premolar (tooth 14) was removed (Fig. 47-4a) and one implant was placed in the palatal socket of the fresh extraction site. A second implant was placed in the healed edentulous ridge and in position 25 (Fig. 47-4b). At re-entry, it was observed that (1) the marginal gap had been entirely resolved and (2) the distance between the implant and the outer surface of the buccal bone plate had become markedly reduced (Fig. 47-4c).

Botticelli *et al*. (2004) reported that during the 4 months of healing following tooth extraction and implant installation practically all marginal gaps had become resolved. At the time of implant placement, the mean distance (18 subjects, 21 sites) between the implant and the outer surface of the buccal bone wall was 3.4 mm while the matching dimension on the lingual/palatal aspect was 3.0 mm. At re-entry after 4 months, the corresponding dimensions were 1.5 mm (buccal) and 2.2 mm (lingual). In other words, the reduction of the buccal dimension was 1.9 mm (or 56%) while the equivalent reduction of the lingual dimension was 0.8 mm (or 27%).

The findings by Botticelli *et al*. (2004) strongly indicate that implant placement in a fresh extraction socket may, in fact, not prevent the physiologic modeling/remodeling that occurs in the ridge following tooth removal.

In order to study bone modeling/remodeling that occurs in the fresh extraction site following implant placement in more detail, Araújo and Lindhe (2005) performed an experiment in the dog. In this study the authors used histologic means to determine the magnitude of the dimensional alterations that occurred in the alveolar ridge following the placement of implants in fresh extraction sockets. Buccal and lingual full-thickness flaps were elevated in both quadrants of the mandible of beagle dogs. The distal roots of the 3rd and 4th premolars were removed (Fig. 47-5a). In the right jaw quadrants, implants (solid screw, Straumann®, Basel) with a rough surface were placed in the sockets so that the marginal border of the rough surface was below the buccal and lingual bone margin (Fig. 47-5b). The flaps were replaced to allow a "semi-submerged" healing (Fig. 47-5c). In the left jaws the corresponding sockets were left without implantation and the extraction sockets were fully submerged under the mobilized flaps (Fig. 47-5d).

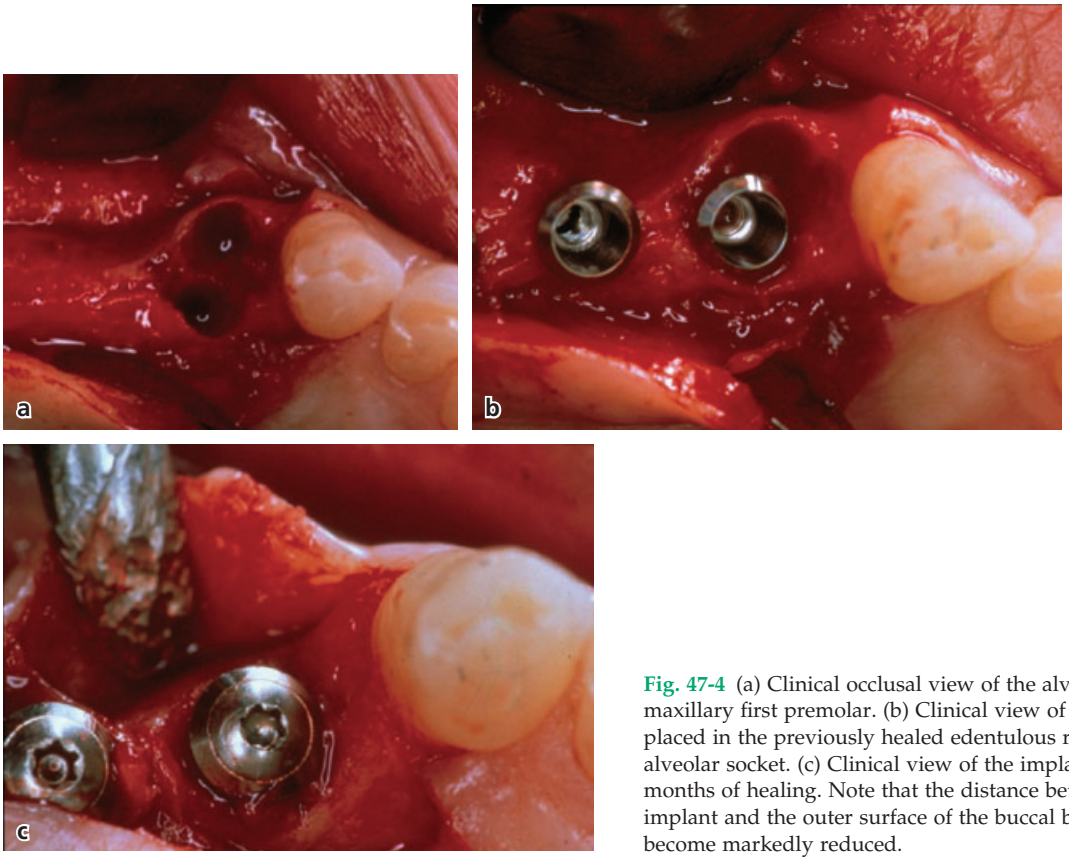

Fig. 47-4 (a) Clinical occlusal view of the alveolar socket of a maxillary first premolar. (b) Clinical view of the implants placed in the previously healed edentulous ridge and in the alveolar socket. (c) Clinical view of the implant sites after 4 months of healing. Note that the distance between the implant and the outer surface of the buccal bone plate had become markedly reduced.

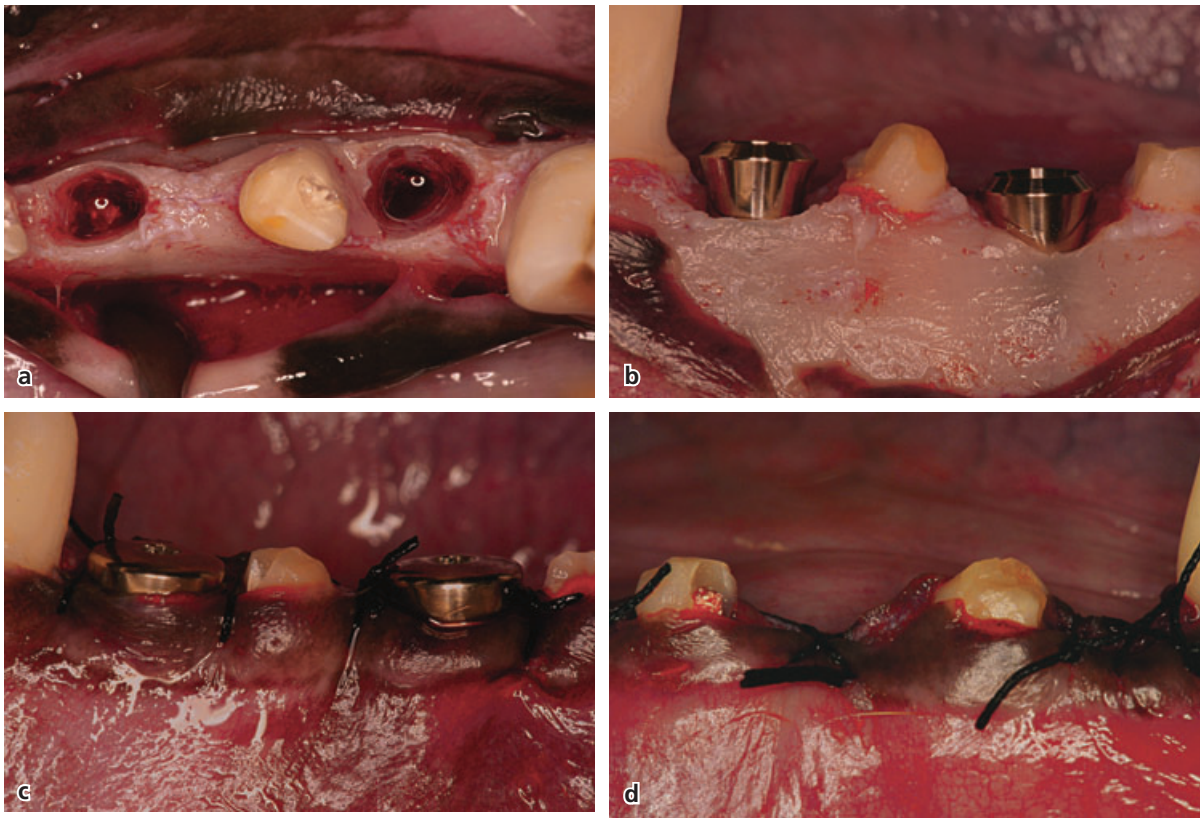

Fig. 47-5 (a) Photograph illustrating a mandibular premolar site (from a dog experiment) from which the distal root of the 4th premolar was removed. (b) In the test side of the mandible, the implant was placed in the socket in such way that the rough surface marginal limit was flush with the bone crest. (c) The mucosal, full-thickness flaps were replaced and sutured to allow a "semi-submerged" healing. (d) In the contralateral side of the mandible, the sockets were left without implantation.

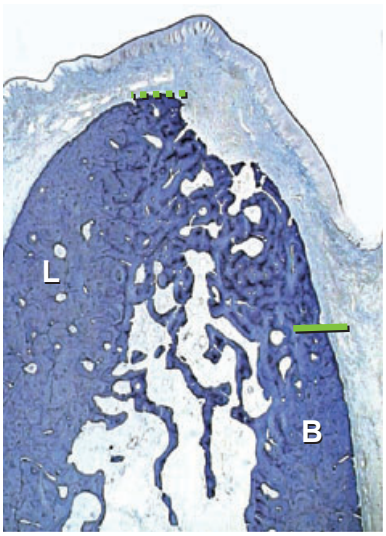

Fig. 47-7 Buccal–lingual section of the edentulous site. Note that the remaining buccal crest (continuous line) is located far below the lingual counterpart (dotted line). B = buccal aspect; L = lingual aspect.

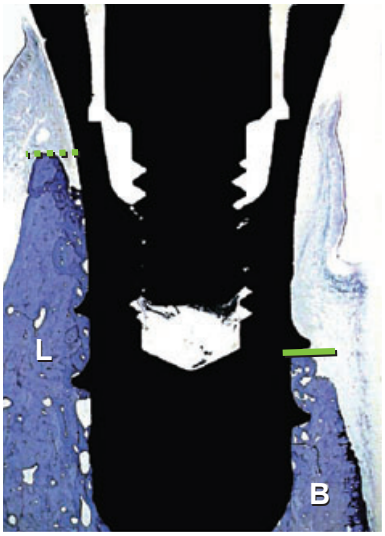

Fig. 47-8 Buccal–lingual section of the implant site. Note that the remaining buccal crest (continuous line) is located far below the lingual counterpart (dotted line). B = buccal aspect; L = lingual aspect.

After 3 months, the mucosa at the experimental sites in the right and left jaw quadrants appeared properly healed (Fig. 47-6). The animals were sacrificed and tissue blocks containing the implant sites and the edentulous socket sites were dissected and prepared for histologic examination.

Figure 47-7 presents a buccal–lingual section of one edentulous site after 3 months of healing. Newly formed bone is covering the entrance of the socket. The lamellar bone of the buccal, cortical plate is located about 2.2 mm apical of its lingual counterpart. Figure 47-8a presents a similar section from an implant site in the same dog. The marginal termination of the buccal bone plate is located about 2.4 mm apical to the lingual crest. In other words, the placement of an implant in the fresh extraction socket failed to influence the process of modeling that occurred in the hard tissue walls of the socket following tooth removal. Thus, after 3 months of healing the amount of reduction of the height of the buccal bone wall (in comparison to lingual bone alteration) was similar at the implant sites and the edentulous sites. At 3 months, the vertical discrepancy between the buccal and lingual bone margins was >2 mm in both categories of sites; edentulous sites = 2.2 mm and implant sites = 2.4 mm.

In a follow-up experiment in the dog, Araújo *et al*. (2006a,b) studied whether osseointegration, once established following implant placement in a fresh extraction socket, could be lost as a result of continued tissue modeling of the bone walls during healing. As was the case in their previous study the distal roots of the 3rd and 4th premolars in both quadrants of the mandible were removed following flap elevation. Implants were installed in the fresh extraction sockets, and initial stability of all implants was secured. The flaps were replaced and "semi-submerged" healing of the implant sites was allowed. Immediately following flap closure, biopsies were obtained from two dogs, while in five dogs healing periods of 1 month and 3 months were permitted prior to biopsy.

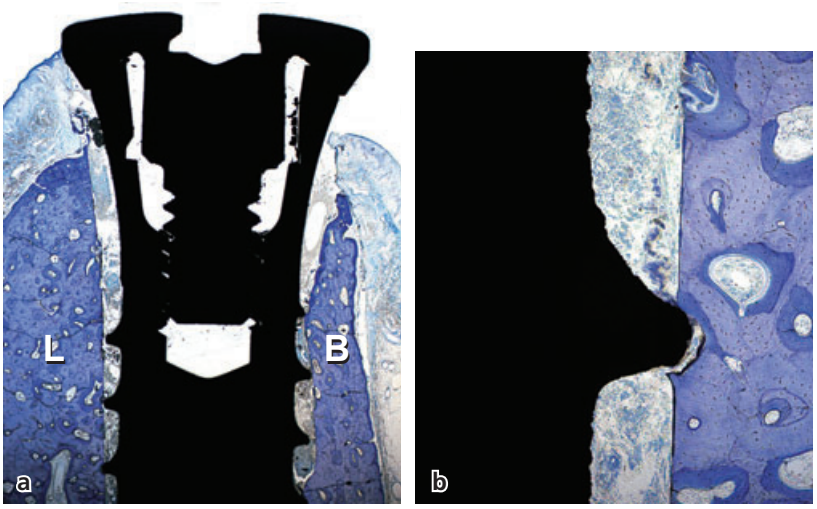

Fig. 47-9 (a) Buccal–lingual section of an extraction site immediately after implant installation. (b) Contact was established between the pitch on the surface of the implant body and the walls of the socket. B = buccal aspect; L = lingual aspect.

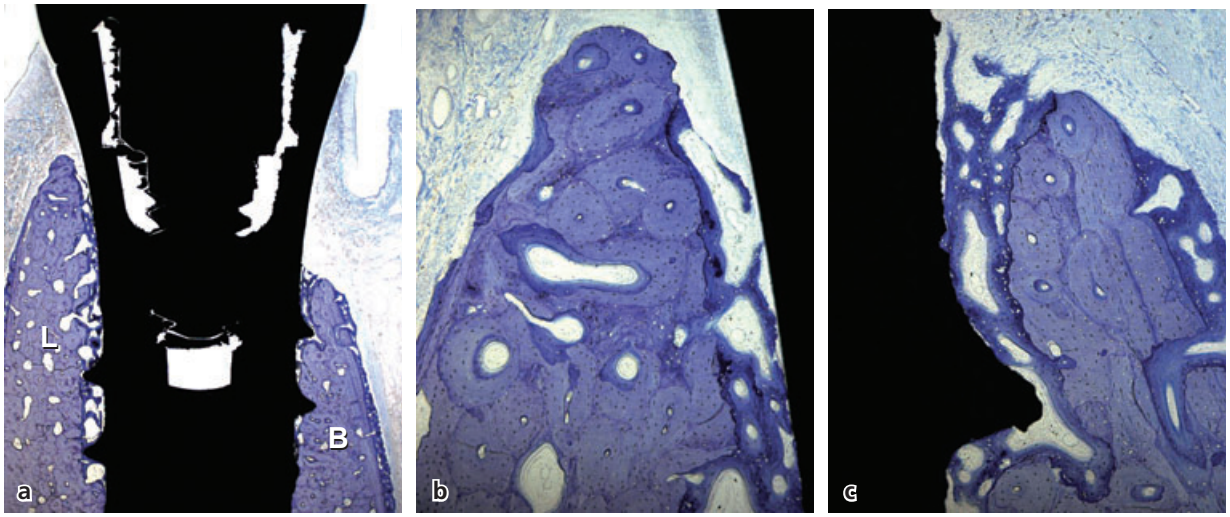

Fig. 47-10 (a) Buccal–lingual section 4 weeks after implant installation. The void between the implant surface and the bone wall was completely filled with newly formed bone in both lingual (b) and buccal (c) aspects. B = buccal aspect; L = lingual aspect.

Figure 47-9a presents a buccal–lingual aspect of an extraction site immediately after implant installation. Contact was established between the pitch on the surface of the implant body and the walls of the socket. A coagulum resided in the void between the contact regions (Fig. 47-9b) and also in the marginal gap. In sections representing 4 weeks of healing, it was observed that this void had become filled with woven bone that made contact with the rough surface part of the implant (Figs. Fig 47-10). In this 4-week interval, (1) the buccal and lingual bone walls had undergone marked surface resorption, and (2) the height of the thin buccal hard tissue wall had been reduced.

In the interval between 4 weeks and 12 weeks of healing the buccal bone crest shifted further in an apical direction (Fig. 47-11). The woven bone at the buccal aspect that in the 4-week sample made contact with the implant in the marginal gap region had modeled and only fragments of this bone remained (Fig. 47-11c). At the end of the study, the buccal bone crest was located >2 mm apical to the marginal border of the rough implant surface.

These findings demonstrate that the bone (woven bone)-to-implant contact that was established during the early phase of socket healing following implant installation, was in part lost when the buccal bone wall underwent continued atrophy.

It is obvious, therefore, that the alveolar process following tooth extraction (loss) will adapt to the altered functional demands by atrophy and that an implant, in this respect is unable to substitute for the tooth. The clinical problem with type 1 placement is that the bone loss will frequently cause the buccal portion of the implant to gradually lose its hard tissue coverage, and that the metal surface may become visible through a thin peri-implant mucosa and cause esthetic concerns (Fig. 47-12).

The question now arises whether it is possible to overcome this problem. This issue was studied in a beagle dog experiment by Araújo *et al*. (2006b). The distal root of the 3rd mandibular premolar and the

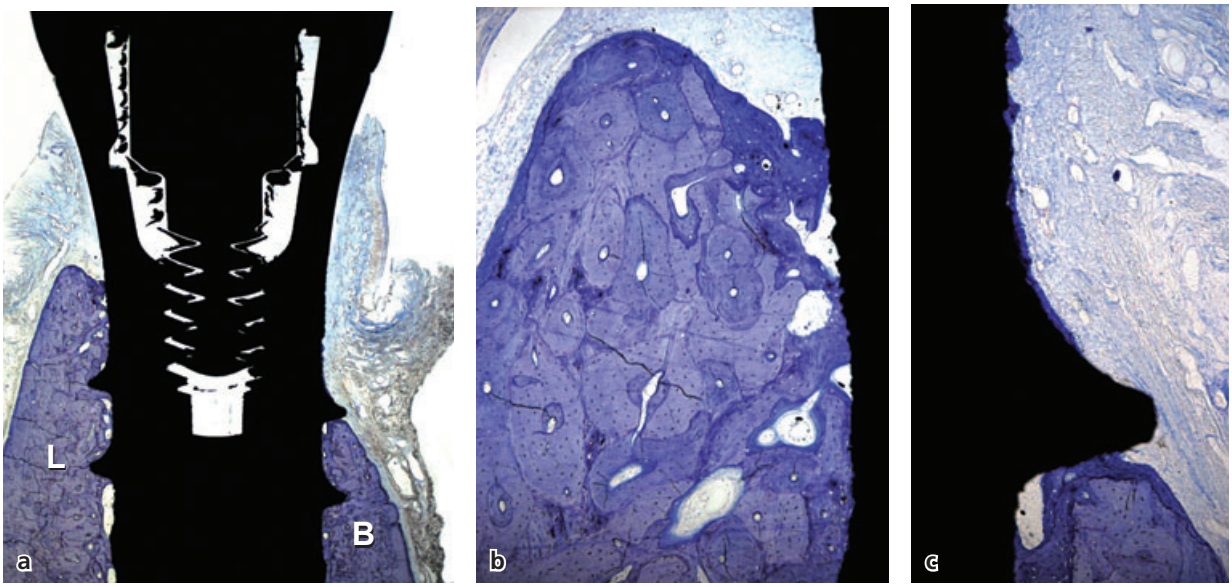

Fig. 47-11 (a) Buccal–lingual section 12 weeks after implant installation. Note that buccal bone crest shifted in an apical direction and fragments of it could be seen on the denuded implant surface (c). The lingual bone crest, however, remained stable (b). B = buccal aspect; L = lingual aspect.

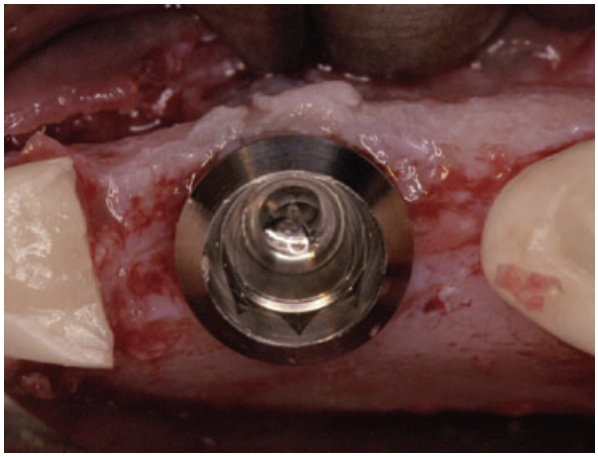

Fig. 47-13 Photograph illustrating implant installation in the narrow, 3rd premolar alveolar socket.

distal root of the 1st mandibular molar were removed and implants placed in the fresh extraction sockets. The 3rd premolar socket in this dog model is comparatively small, and hence the implant inserted (Straumann® Standard Implant, diameter 4.1 mm) occupied most of the hard tissue wound (Fig. 47-13). During healing resorption of the buccal bone wall occurred (Fig. 47-14) and >2 mm of the marginal portion of the implant became exposed to peri-implant mucosa.

The molar socket, on the other hand is very large (Fig. 47-15) and hence after implant (Straumann® Standard Implant, diameter 4.1 mm) placement a >1 mm wide marginal gap occurred between the metal body and the bone walls (Fig. 47-16b). Primary stability of the implant was achieved through contacts between the metal body and the bone in the apical (periapical) portions of the socket. During the early phase of healing this gap in the molar site became filled with woven bone. In the interval when the buccal bone wall underwent programmed atrophy, the newly formed bone in the gap region maintained osseointegration and continued to cover all surfaces of the implant (Fig. 47-16a,b).

Conclusion: The data reported illustrate an important biologic principle. Atrophy of the edentulous ridge will occur following tooth loss. This contraction of the ridge cannot be prevented by placing an implant in the fresh extraction socket. The atrophy includes a marked reduction of the width and the height of both the buccal and lingual bone plates; in particular the buccal bone plate will undergo marked change. To some extent the problem with buccal bone

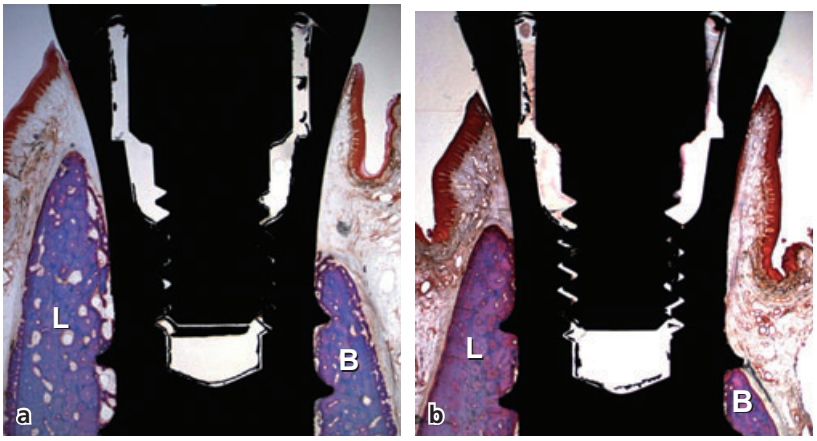

Fig. 47-14 Buccal–lingual section of the healed premolars sites representing (a) 4 and (b) 12 weeks after implant installation. B = buccal aspect; L = lingual aspect.

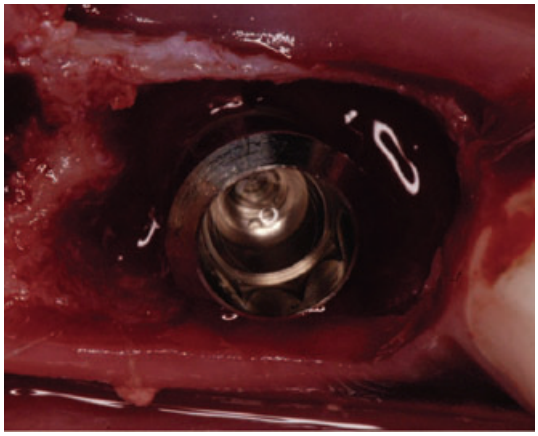

Fig. 47-15 Photograph illustrating implant installation in the wide, 1st molar alveolar socket.

resorption can be overcome by placing the implant deeper into the fresh socket and in the lingual/palatal portion of the socket.

As a consequence of the above described healing, bone regeneration procedures may be required to improve or retain bone volume and the buccal contour at a fresh extraction site. Such bone augmentation is sometimes mandatory in the esthetic area.

Stability of implant

Another issue with type 1 (and also type 2) placement is the anchorage of the implant to obtain primary stability in a position in the jaw that will enable the subsequent restoration to meet high demands regarding esthetics and function. In most cases of type 1 placement, the implants are fixed in native bone apical to the alveolus (Fig. 47-17). Additional retention may be achieved by anchoring the implant in the bony structures of the alveolar walls or inter-radicular septa.

In a recently presented controlled clinical trial (Siegenthaler *et al*. 2007) it was observed that primary stability for some implants in a type 1 procedure could not always be achieved. In this study implants were inserted to replace teeth either exhibiting periapical pathology (test) or presenting healthy periapical conditions (control). In four implant sites in the test group and one in the control group no implants could be placed due to an unfavorable bone morphology, which precluded primary implant stability.

Type 2: completed soft tissue coverage of the tooth socket

There are several reasons why the type 2 approach is often recommended. At this stage of healing the socket entrance is covered with a mucosa. The soft tissue is (1) comparatively mature, (2) has proper volume, and (3) can be easily managed during flap elevation and replacement procedures. Furthermore, the type 2 timing permits an assessment of the resolution of periapical lesions that may have been associated with the extracted tooth. The disadvantages inherent in the type 2 approach include (1) resorption of the socket walls and (2) an extended treatment time (Table 47-1).

Following tooth extraction, the socket becomes filled with a coagulum that is replaced with granulation tissue within a few weeks. In the normal case it takes about 4–8 weeks before the soft tissue (granulation tissue, provisional connective tissue; see Chapter 2) fills the socket and its surface becomes covered with epithelium (Amler 1969; Zitzmann *et al*. 1999; Hämmerle & Lang 2001; Nemcovsky & Artzi 2002). The maturation of the soft tissue (further deposition and orientation of collagen fibers) that may facilitate flap management may require an even longer healing time.

The larger amount of soft tissue that is present at the site of implant placement when the type 2 approach is used will allow for precise management of the mucosal flap and hence optimal soft tissue healing (Fig. 47-18). This advantage with the type 2 timing must be matched against the hard tissue reduction and the change of the ridge contour that results from the resorption of the socket walls and of the buccal bone plate. It must be observed that at

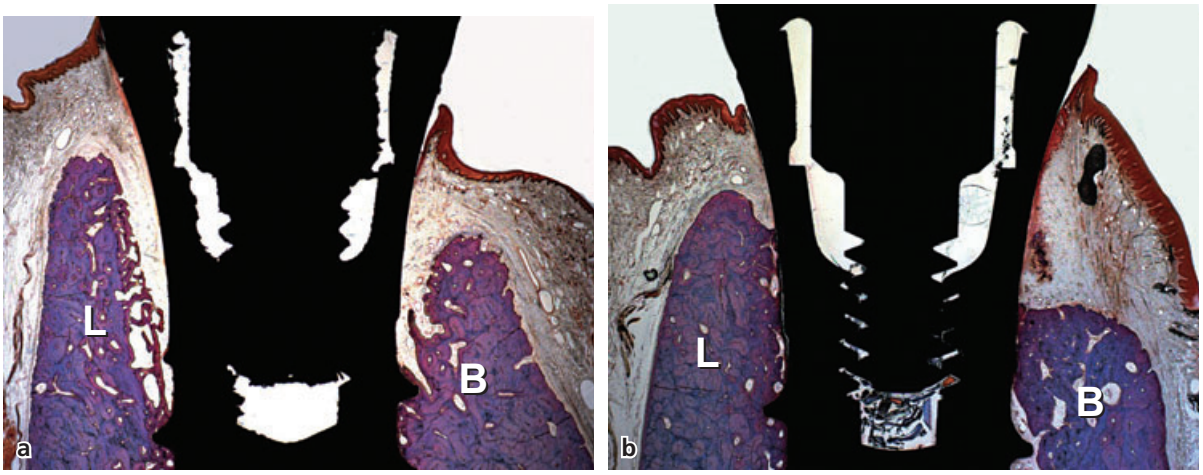

Fig. 47-16 Buccal–lingual section of the healed molars sites representing (a) 4 and (b) 12 weeks after implant installation. B = buccal aspect; L = lingual aspect.

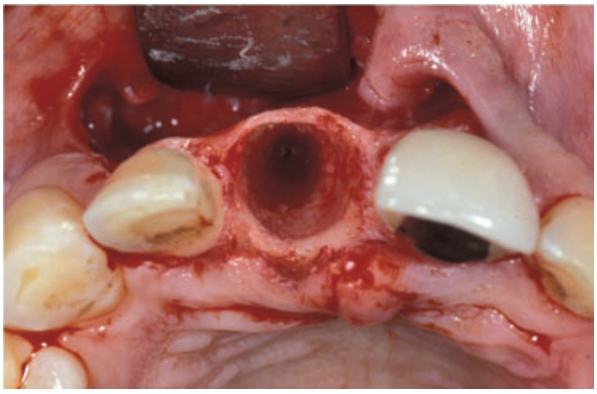

Fig. 47-17 Type 1 implant placement provides optimal availability of existing bone contours. Note the presence of a thin buccal bone plate. Anchorage of an implant can be achieved by engaging the bone apical to the apex of the extracted tooth and the palatal wall of the socket.

Fig. 47-18 The soft tissues have completely healed over the extraction socket 8 weeks after tooth removal (type 2).

some extraction sites the mucosa may remain adherent via scar tissue to the underlying bone or to the provisional connective tissue of the socket. In such cases it may be difficult to separate the soft tissue from the bone and to mobilize the flap. In such a situation, the trauma caused in conjunction with flap elevation may rupture the soft tissue and compromise healing. This in turn may result in soft tissue dehiscence, local infection, and inflammation (Zitzmann *et al*. 1997).

As described in the schematic drawing in Fig. 47-1 the initial gain in mucosa (area and volume) is later followed by an overall loss of soft tissue volume. This is evidenced by the fact that the volume of alveolar ridge – including the bone as well as the mucosal compartments – markedly decreased during the first 12 months following tooth extraction (Schropp *et al*. 2003).

During the 4–8 weeks between tooth extraction and type 2 implant placement only small amounts of new bone (woven bone) will form in the socket. This means that the risk of not achieving primary implant stability is similar in type 1 and type 2 approaches. Thus, in sites where the available bone height apical to the tip of the root is less than 3 mm, it is frequently impossible to obtain primary implant stability in the bone beyond the apex of the extracted tooth. When, in addition, a wide alveolus is precluding the engagement of its bony walls, the type 3 approach may be favored.

Type 3: substantial bone fill has occurred in the extraction socket

The type 3 time frame is chosen for implant installation at sites where, for various reasons, bone fill is required within the extraction socket. Newly formed woven bone will occupy the socket area after healing periods extending from 10–16 weeks (Evian *et al*. 1982). In this period, however, the walls of the socket are frequently completely resorbed and replaced

with woven bone. The entrance to the socket is closed with a cap of woven bone that is in the process of remodeling. The mucosa that covers the extraction site is (1) residing on a mineralized ridge, and (2) mature and more easy to manage during surgical flap elevation and replacement procedures.

The type 3 approach often allows the clinician to place the implant in a position that facilitates the prosthetic phase of the treatment. The disadvantages with the type 3 approach encompass (1) a prolonged treatment time, (2) additional resorption and diminuton of the ridge including a substantial change of its contour, and (3) a concomitant loss of soft tissue volume.

Type 4: the alveolar ridge is healed following tooth loss

In the type 4 approach the implant is placed in a fully healed ridge. Such a ridge can be found after 4 but more likely after 6–12 months of healing following tooth extraction (loss). After 6–12 months of healing following tooth extraction, the clinician will find a ridge that is lined by a mature, often well keratinized mucosa that resides on dense cortical bone. Beneath the cortical bone plate, cancellous bone occupies a varying portion of the alveolar process (for detail see Chapter 2).

In a study including human volunteers it was observed that the rate of formation of new bone within the extraction site started to decrease after 3–4 months of healing. At this stage the newly formed bone and the remaining bone of the socket walls entered into a phase of remodeling (Evian *et al*. 1982). Concomitant with the remodeling of this centrally located bone tissue, extra-alveolar resorptive processes leading to a further contraction of the ridge and change of its contour continued for at least 12 months (Schropp *et al*. 2003).

The advantage of type 4 installation is that healing is more or less complete and that only minor additional change of the ridge may occur. The disadvantages include (1) increased treatment time and (2) further reduction of the overall volume of the ridge and change of its external contour. This pronounced additional loss of ridge volume may at times require complicated bone augmentation procedures (Fig. 47-19). As a consequence type 4 placement is avoided in most cases when the tooth (teeth) to be replaced is (are) present at the time of examination and treatment planning.

Clinical concepts

When implants are to be placed in the edentulous portion of the ridge, factors other than the tissue changes over time must be considered. Thus, in the treatment planning phase aspects, such as (1) the overall objective of the treatment, (2) the location of the tooth within the oral cavity – in the esthetic or non-esthetic zone – and (3) the anatomy of the bone and the soft tissue at the site(s) to be treated, must be evaluated.

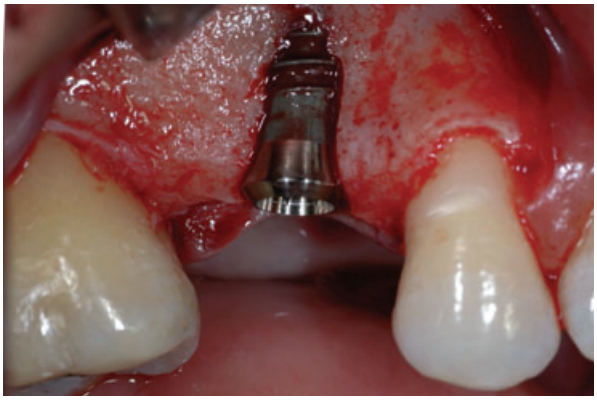

Fig. 47-19 A buccal dehiscence defect is present at an implant placed into a ridge, which has undergone substantial buccal bone resorption since tooth extraction several months ago (type 4).

Aim of therapy

Dental implants are most often used to restore health and function. During the surgical phase of therapy, therefore, ideal conditions must be established for successful bone and soft tissue integration to the implant. In a growing number of cases, however, treatment must also satisfy demands regarding the esthetic outcome. In such cases, the overall surgical and prosthetic treatment protocol may become more demanding, since factors other than osseointegration and soft tissue integration may play an important role.

Restoration of health and function

In cases where the restoration of health and function constitutes the primary goal of the treatment, the location and volume of available hard and soft tissues are the important factors to consider. In such cases the type 1 approach is usually selected (Wichmann 1990).

The replacement of a single-rooted tooth with an implant in a fully healed ridge will, in most cases, ensure proper primary stability with the implant in a correct position (Fig. 47-20). In addition, the soft tissues are sufficient in volume and area. The mucosal flap can be adapted to the neck (or the healing cap) of the implant (one-stage protocol). When primary wound closure is intended (two-stage protocol), mobilization of the soft tissue will allow tension-free adaptation and connection of the flap margins.

When an implant is placed in the fully healed site of a multi-rooted tooth, the surgical procedure becomes more demanding. Often the ideal position for the implant is in the area of the inter-radicular septum. If the septa are delicate, anchorage for

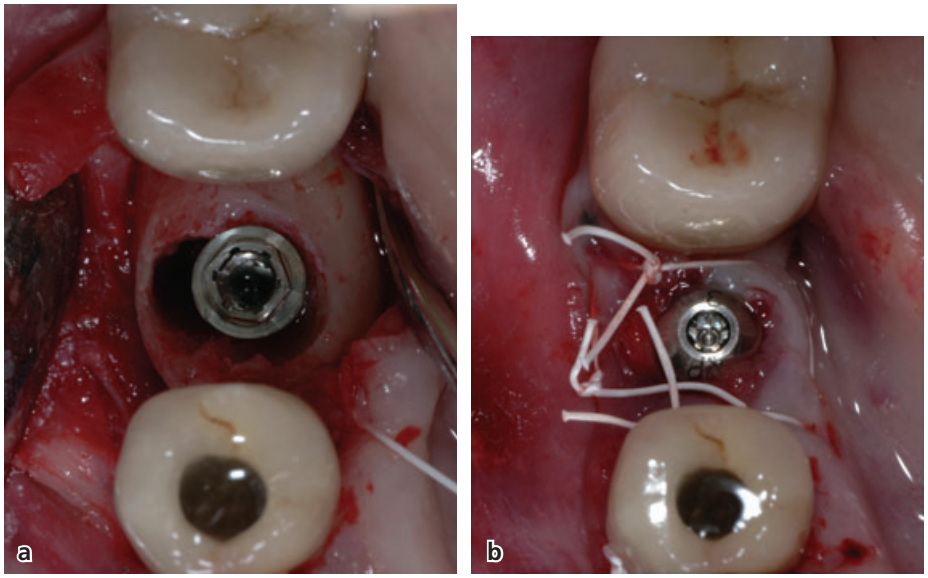

Fig. 47-20 (a) Immediate implant placement (type 1) in a mandibular premolar extraction socket. Note the buccal bone deficiency, where bone will be augmented by guided bone regeneration (GBR). (b) The same site as in (a) following adaptation of the flap around the neck of the implant obtaining a transmucosal mode of healing.

primary implant stability may become difficult to achieve. In addition, in molar sites there is often only a small amount of soft tissue present. This may create a problem with respect to wound closure with a mobilized, tension-free flap. In some molar sites, primary wound closure may not be possible at times following implant installation.

The presence of marginal defects (gaps) between the implant and the fully healed ridge following type 4 placement was regarded in the past as a significant problem that could compromise osseointegration. Recent studies in man and animals have demonstrated, however, that in such a horizontal marginal defect (gap) of ≤2 mm, new bone formation as well as defect resolution and osseointegration of the implant (with a rough titanium surface) will occur (Wilson *et al*. 1998; Botticelli *et al*. 2004; Cornelini *et al*. 2005).

Esthetic importance and tissue biotype

The replacement of missing teeth with implants in the esthetic zone is a demanding procedure. Deficiencies in the bone architecture and in the soft tissue volume and architecture may compromise the esthetic outcome of treatment (Grunder 2000). Hence, when an implant is to be placed in the esthetic zone, not only the anatomy of the hard tissues but also the texture and the appearance of the soft tissues must be considered.

Type 2 installation is often to be preferred when implants are placed in the esthetic zone (Fig. 47-21). The key advantage in type 2 (as opposed to type 1) is the increased amount of soft tissue that has formed during the first weeks of healing following tooth extraction. It must be emphasized, however, that comparative studies analyzing the treatment outcomes in randomly selecting type 1 or type 2 placements have so far not been reported.

In a recent clinical study, implants were placed in fresh extraction sockets (Botticelli *et al*. 2004). During healing, the implants became clinically osseointegrated within the borders of the previous extraction socket. Significant loss of buccal bone height (contour) however also occurred. In esthetically critical situations this loss of contour may lead to a compromised outcome. Hence not infrequently, tissue augmentation procedures must be performed in the esthetic zone.

In this context it is important to realize that when a two-stage implant placement protocol is used, the labial mucosa will recede following abutment connection surgery. Mean values of recession between 0.5 mm and 1.5 mm with large variations have been reported in several clinical studies (Grunder 2000; Oates *et al*. 2002; Ekfeldt *et al*. 2003). These findings additionally stress the necessity for a careful treatment approach when implants are placed in the esthetic zone.

The biotype (see Chapter 3) of the soft and hard tissue tissues may play a role regarding the esthetic outcome of implant therapy. Characteristics of soft and hard tissues at teeth were described and classified into two biotypes: the flat thick or the pronounced scalloped thin biotype (Weisgold *et al*. 1997; Olsson & Lindhe 1991; Olsson *et al*. 1993). The thin tissues in the pronounced scalloped biotype include a thin free gingiva, a narrow zone of attached mucosa, and a pronounced "scalloped" contour of the gingival margin. In addition, the scalloped thin biotype is associated with a delicate bone housing. In a recent study it was found that buccal tissue recession at single-tooth implants was more pronounced in patients exhibiting a thin biotype compared to

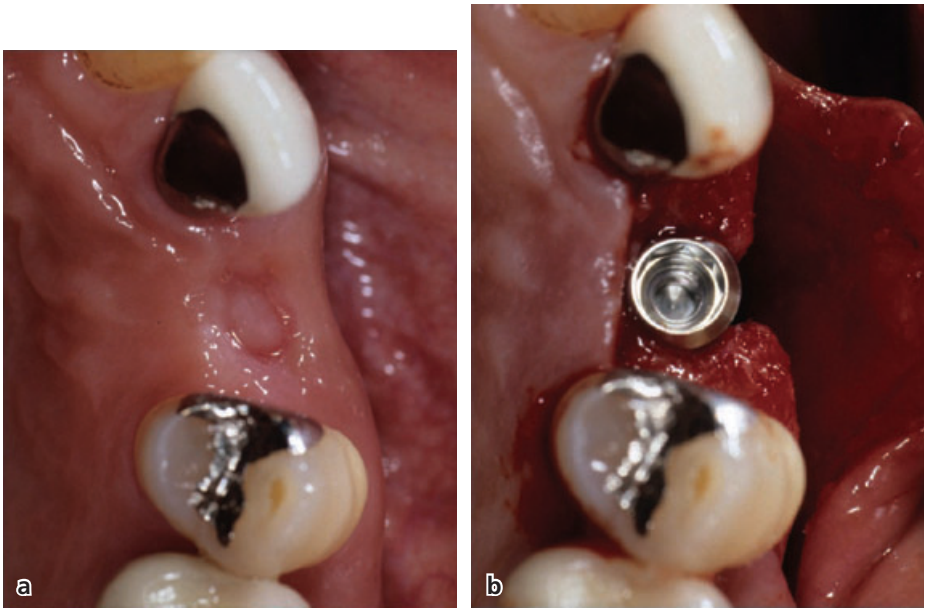

Fig. 47-21 (a) A single tooth gap 8 weeks following tooth extraction. The soft tissues have completely healed over the extraction socket. (b) The same site as in (a). An implant has been placed in the edentulous gap. The resulting buccal dehiscence defect will be augmented with bone by applying GBR.

Fig. 47-22 A patient exhibiting a thin tissue biotype as characterized by a thin free gingiva, a narrow zone of keratinized and of attached mucosa, shallow probing depths, and a pronounced "scalloped" contour of the gingival margin including recessions at some maxillary anterior teeth. Tooth 11 is scheduled for extraction and replacement by an implant using a type 2 or 3 approach.

patients with a thick biotype (Evans & Chen 2007). Based on these findings and on clinical experience it was proposed that patients exhibiting a pronounced scalloped biotype should be treated with a type 2, 3, or 4 rather than with a type 1 implant installation approach (Fig. 47-22). Data collected from properly designed clinical studies regarding this issue are presently lacking.

Success of treatment and long-term outcomes

Numerous clinical studies have demonstrated that type 1 implant placement is a successful and predictable clinical method (Lang *et al*. 1994; Schwartz-Arad & Chaushu 1997b; Hämmerle *et al*. 1998; Covani *et al*. 2004). In addition, success and survival rates for type 1 implants have been reported to be of the same magnitude as implants placed in healed ridges (Gelb 1993; Grunder 2000; Gomez-Roman *et al*. 2001; Gotfredsen 2004; Schwartz-Arad *et al*. 2004). Histologic studies in animals confirmed the viability of type 1 placement. Unloaded titanium implants placed in extraction sockets showed a high degree of osseointegration (Anneroth *et al*. 1985), i.e. similar to the one at implants placed in healed sites. Furthermore, a few studies analyzing survival rates of type 2 and 3 placements have shown similar survival rates as the ones reported for types 1 and 4 (Watzek *et al*. 1995; Nir-Hadar *et al*. 1998; Polizzi *et al*. 2000).

Conclusions

In situations where teeth are to be replaced with implants, various factors govern the decision regarding the optimal time point for implantation following tooth extraction. Of special importance are the overall objective of the treatment, the location of the tooth within the oral cavity, the anatomy of the bone and the soft tissue at the site, and the adaptive changes of the alveolar ridge following tooth extraction. The decision regarding the timing for implant placement needs to be based on a thorough understanding of the structural changes that occur in the alveolar process following tooth extraction, with and without implant placement as presented in this chapter.

Chapter 48

The Surgical Site

Marc Quirynen and Ulf Lekholm

Bone: shape and quality

It is imperative that the conditions of the soft and hard tissues as well as of the shape of the bone in the recipient sites intended for implants are carefully examined. Both clinical and radiographic parameters must be used in this examination.

Clinical examination

The clinical examination should include assessment of (1) colour and texture alterations of the mucosa (indicative of a lesion) and (2) the thickness of the soft tissues. The recipient site should also be palpated in order to estimate the volume of the tissues available in the edentulous region of the jaw. It must be realized, however, that both the mucosa and the bone of the edentulous region are included in this clinical measure. Hence, the clinician must realize that palpation may overestimate the volume of hard tissue present at the site.

The clinical examination must also determine the inter-arch gap and the dimensions of the edentulous area to ascertain that enough space is present (1) to allow optimal maneuvering (access of the hand piece together with the preparation drills) during surgical procedures, (2) to avoid damage of the periodontium of teeth adjacent to the edentulous area during implant insertion, and (3) to allow placement of the prosthetic device. As a rule of thumb, the inter-arch distance should be ≥5 mm, and the distance between a tooth and an implant should be ≥3 mm. If the size of the edentulous region is diminutive, implants with a small diameter must be selected, and eventually a surgical guide (stent) used to assist the surgeon during implant installation. This might help to avoid contact with the neighboring teeth.

The jaw relation (angle class) must also be determined, as this will have an influence on the direction of insertion of the implants (further discussed below). In the final step of the clinical examination impressions of the jaws (dentition) are obtained and stone cast models prepared. Such models can later be used during treatment planning and for the preparation of surgical position and direction stents.

Radiographic examination

The radiographic examination (see Chapter 28) will provide more detailed information on the amount and quality of the bone available at the recipient site. Lekholm and Zarb (1985) proposed that the edentulous jaw (segment of the jaw) should be classified regarding its shape and quality. Thus a grading into five groups was used to describe the shape of the jaw (Fig. 48-1a) while four groups were used to describe the quality of the bone tissue (Fig. 48-1b).

Panoramic and intraoral apical radiographic images give a first impression of the bone, as well as of important anatomic landmarks such as: the floor of sinusal and nasal cavities; the incisive nerve; the inferior alveolar nerve; the roots and apices of neighboring teeth; and the crest of the alveolar ridge. From the two-dimensional images it is also possible to obtain some information about the available height of the bone at the recipient site, while three-dimensional radiographs are essential to determine the width of the alveolar crest. It is important to realize that the definitive evaluation of the dimension

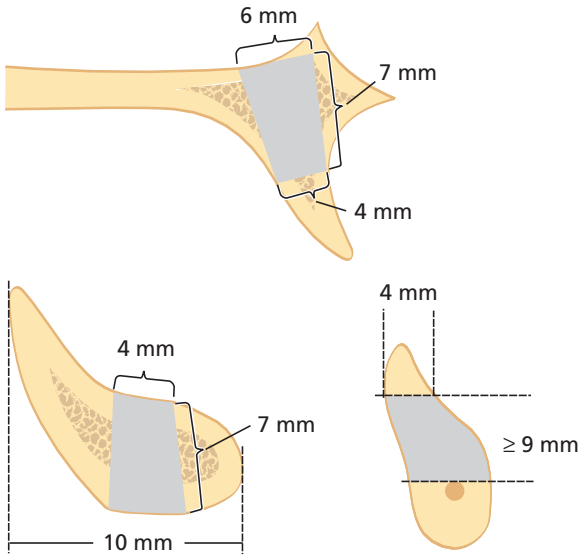

Fig. 48-2 Schematic drawings showing minimum bone volume needed for standard implants of the Brånemark System.

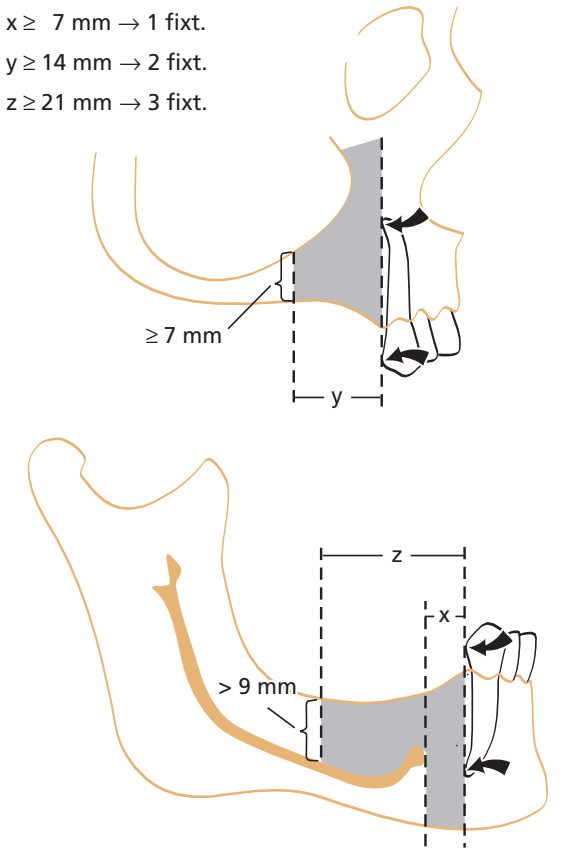

Fig. 48-3 Schematic drawings indicating location of minimum bone volume areas in distal directions, and giving distances needed for various numbers of implants. Arrows indicate prominence and apex of the nearest tooth.

of the recipient site should not be based on observations made in intraoral radiographs or in orthopantomograms. This is especially true in cases where intraoral palpation indicated the presence of a narrow ridge (jaw). Indeed, the precise location of the inferior alveolar nerve must be identified via measurements made in images from conventional or computer-assisted tomography (CT). Correct identification of the mandibular canal may assist the clinician to avoid damaging the nerve during surgery and thereby preventing the occurrence of complications such as impaired sensory function and paresthesia of the lower lip and neighbouring soft tissues (Abarca *et al*. 2006).

The cylinder-shaped cavity prepared in the recipient site to house the endosseous part of the implant is, as a rule, 1–2 mm longer than the titanium device *per se*. Thus, for a 7-mm long implant, the required minimum height of the bone of the recipient site is 8–9 mm (Fig. 48-2). In cases where implants are to be installed in positions above the inferior alveolar nerve, a minimum height of 9–10 mm of bone is required for a 7-mm long implant.

Planning for implant placement

Radiographs are used to make preliminary decisions regarding the position(s) as well as the number and dimensions of implants to be used. The location of the most distal implant is determined first (Fig. 48-3). The number and the position of more mesially located implants are identified thereafter. In this treatment planning process it must be recognized that the inter-implant distance must be ≥3 mm.

The final decision regarding the number and dimension of implants to be inserted, however, is most often made during surgery, i.e. after the soft

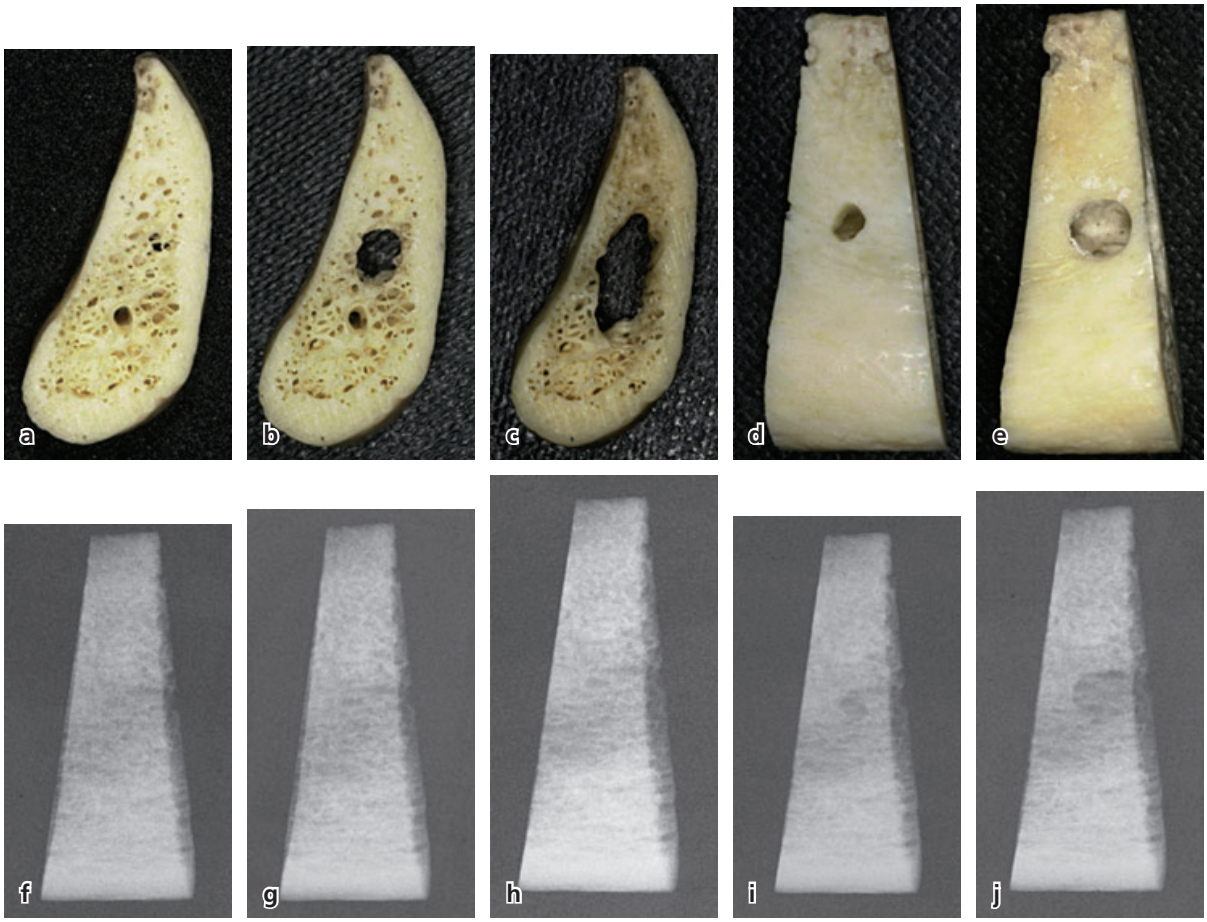

Fig. 48-4 An example (for this illustration without soft tissues) of part of a jawbone in which a progressively larger defect has been created, initially within the spongious bone (a–c), later (d,e) also perforating the cortex. The images (f–j) represent the corresponding radiographs.

tissue flaps have been elevated and the bone of the recipient sites has been exposed.

Defects in the jaw bone

Intraoral (conventional or digital) as well as extraoral radiographic images (conventional tomography, spiral CT) may not necessarily reveal all lesions and defects in the jawbone. In a recent *ex vivo* study (Van Assche *et al*. 2007), intraoral radiographs were taken of progressively larger, artificially created, defects in both the mandible and the maxilla. As illustrated in Fig. 48-4, a defect first became visible in the radiograph when the area (junction) including the cortical plate and cancellous bone was involved. This indicates that the clinician may overlook such intra-ridge lesions (Quirynen *et al*. 2005).

During implant installation surgery, minor fenestrations or marginal dehiscences sometimes occur. Hence some threads of the implants may be exposed (not covered by bone). In most cases such uncovered threads may be left unattended since no adverse reactions have been observed in the mucosa at such locations (Lekholm *et al*. 1996). On the other hand, if the jaws contain defects of such a magnitude that the implants cannot be placed in proper positions without having major parts of their surfaces exposed, ridge augmentation is often recommended. This may include guided bone regeneration (Molly *et al*. 2006) and/or bone grafting (Buser *et al*. 1994; Deporter 2001). A recent systematic review on augmentation techniques (Chiapasco *et al*. 2006) indicated that several different procedures may enhance the bone volume in a predictable manner and establish better conditions for implant insertion. For further details regarding ridge augmentation see Chapter 49.

Summary: the local condition of edentulous areas considered for implants must be properly evaluated, and no pathology in the soft and/or hard tissues of the jaws should be accepted at the time of implant placement. Radiographic evaluations are necessary in order to identify important landmarks in the jaws as well as to study the shape and the quality of the bone tissue in areas considered for implants. Tomography is used when implants are to be placed above the inferior alveolar nerve, and/or when the clinical examination indicates that the recipient site harbors minute amounts of bone. The minimum amount of bone required for implant surgery is related to the size and surface of the implants to be used.

Implant placement

Guiding concept

The main purpose for the use of implants in dentistry is to establish a stable anchorage for a fixed or removable prosthesis (Brånemark *et al*. 1985). In order to allow osseointegration to occur and be maintained, the handling of the bone tissue during surgery must be diligent. It is important to recognize that bone is a living tissue that must not be exposed to undue trauma. The surgical procedure must be performed according to carefully established guidelines (e.g. Adell *et al*. 1985; Lekholm & Jemt 1989). Furthermore, the surgeon must pay maximum attention to basic rules of sterility and asepsis. It is often noticed that sterile drapes are used while the nose, the most infected site of the entire facial area, is left uncovered. The use of a sterile nose cap that allows the patient to breath freely but prevents the contamination of the sterile gloves and instruments (van Steenberghe *et al*. 1997) is recommended.

Flap elevation

The mucosa of the ridge can be incised using either a crestal or a vestibular approach. At present there is no information available to indicate that one of the two approaches is more advantageous than the other. Consequently, the clinician can select the method best suited for the individual situation. Crestal incisions may be preferred at sites where the crest of the ridge is wide. If the crest is high but narrow, a buccal approach might be preferred. Moreover, when ridge augmentation is to become part of the surgical procedure, incisions on top of the area to be augmented should be avoided (to prevent early exposure of bone substitute or membrane). In cases of so-called one-stage installation surgery, a crestal incision is, of course, mandatory.

Implants are often placed in edentulous sites that are bordered by teeth. Whenever possible, and in particular in the "esthetic zones", the gingiva (papillae) of the neighboring teeth should not be included in the flap. Shrinkage of the papillae during healing is therefore avoided and the occurrence of black triangles in the "tooth–implant" region prevented.

At narrow edentulous sites where implants must be placed close to teeth, it is often necessary to include the gingiva in the flap. In such cases, the crestal incision made in the edentulous area is continued mesially and/or distally into the pocket of the adjacent teeth and is sometimes combined with vertical releasing incisions in the gingiva. The flap is hereby increased in dimension, will receive a more adequate vascular support, and may be managed to allow full soft tissue coverage of the bone and the implant(s).

It is important to make sure that, during the soft tissue elevation procedure, the entire periosteum is properly released from the walls of the jaw and included in the flap (full-thickness flap). This is particularly important when a flap is released from the lingual side of the mandible. The exposure of the lingual hard tissue wall of the mandible allows the surgeon to detect an accidental perforation of the lingual cortex during drilling and implant installation. It is also important to release a full-thickness flap on the buccal side of both the maxilla and the mandible. This will make it possible to observe the presence of cavities and/or protrusions of the jaws, contours of tooth roots, and nerve entrances, i.e. structures that may influence the positioning of the implants. Finally flap elevation and exposure of the osseous tissue will facilitate irrigation (cooling) of the site during drilling.

Flapless implant insertion

Implant installation without flap elevation and exposure of the bone tissue was recently introduced. This approach is obviously supported by commercial pressure. Flapless surgery no doubt may offer some advantages including (1) reduction in complications for the patient (less pain and swelling), (2) reduced surgical time and no suturing, and (3) good fit between implant and soft tissues that facilitates the restorative phase of treatment. The success of this implant installation approach depends to a large extent on the quality of the surgical template (stent) that must be used.

The scientific data on flapless implant surgery is sparse (Becker *et al*. 2005; van Steenberghe *et al*. 2005; Fortin *et al*. 2006). Hence, the use of flapless implant insertion as "routine" procedure in daily practice is questioned, due to the absence of long-term data.

Model-based guided surgery

With the use of a plaster model that presents the edentulous area and with additional information on the thickness of the soft tissues, the dental technician can replicate the underlying jaw bone. The implant insertion can be planned and performed on the plaster model and the most convenient position for the permanent restoration can also be determined. In a next step, the model can be used to prepare a surgical template. The template can be fitted with sleeves (canals) to guide the drilling procedure. Since the model also reproduces the soft tissues of the recipient site, fabrication of a provisional restoration can be made even before the implants are actually inserted in the jaw of the patient.

Bone preparation

Bone tissue must not be exposed to adverse heat. Drilling in bone tissue may increase the temperature at the recipient site (Brånemark *et al*. 1985). The threshold level for osteocyte damage lies around 47°C, only about 10°C above body temperature

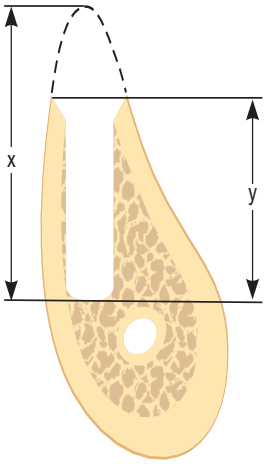

Fig. 48-5 Schematic drawing showing maximum drilling depth (x) without reaching the nerve, as measured from the top of the crest, and implant site length (y), as measured from the lowest bone level in the canal entrance.

(Eriksson & Adell 1986). Consequently, all mechanical preparation of the jaw must be performed with a minimum rise in temperature. This can be achieved via the use of an intermittent drilling technique, together with the use of sharp burs. The preparation of the implant bed should be performed in a sequence of steps, and consistently with profuse saline irrigation (Adell *et al*. 1985). In the presence of particularly dense bone, e.g. in the symphysis region of the mandible, it is also recommended to use an extra wide twist drill, prior to the pretapping procedure and/or insertion the implants (Friberg 1994). When implants are to be placed in soft bone, drilling must be performed with the greatest care, as there is a risk that the entrance of the implant site may be widened too much, and the inserted implant may become unstable. To minimize the risk of initial implant instability, an adjusted surgical technique using either thinner drills or wider diameter implants was recommended (Bahat 1993; Friberg 1994; Watzek & Ulm 2001).

The only structure that can clearly be identified both in radiographs and clinically is the top of the alveolar crest. Consequently, this configuration has to be used as reference for all measurements, both in radiographs and during surgery. During the preparation of the site it is also of particular importance to keep an eye on the depth indicators of the drills and how they relate to the top of the crest. It must be pointed out that during the preparation of the site, the reference point on the crest for the depth measurements may move in an apical direction, particularly if a narrow and drop-shaped alveolar crest is present in the recipient site (Fig. 48-5).

Anatomic landmarks with potential risk

Implant surgery is often regarded/promoted, especially by implant companies, as a safe and minimally invasive procedure. This is not the case, however, especially when implants are placed in the lower jaw (Mraiwa *et al*. 2003a,b). Mechanical compression and/or direct injury during implant insertion may (1) disturb the nerve and initiate a neural degenerative process, or (2) disturb the microcirculation and cause edema and/or a local hematoma.

Neurosensory disorders of the inferior alveolar, mental, or incisive nerves have been reported to occur after implant surgery. Usually the resulting anesthesia, paresthesia, or even dysesthesia are transient phenomena, but certain long-lasting/permanent neuropathies have been reported. An optimal radiographic analysis of the lower jaw is mandatory when planning for implant placement in the neighborhood of the mental foramen or above the inferior alveolar nerve. It still remains a matter of discussion whether injury to the incisive canal in the lower jaw can cause neuropathy.

Several cases of severe hemorrhage in the floor of the mouth, with subsequent life-threatening upper airway obstruction, have been recorded in association with implant placement in both the anterior and posterior portions of the mandible (for review see Kalpidis & Setayesh 2004). Two arteries are responsible for the vascular supply to the mandible (Fig. 48-6a). At the anterior border of the hypoglossus muscle, the lingual artery gives rise to the sublingual artery. This important artery (2 mm in diameter) traverses the floor of the mouth in a frontal direction, near the medial and superior surface of the mylohyoid muscle, medially to the sublingual gland, and inferio-medially to the submandibular duct and the lingual nerve. The sublingual artery gives off several alveolar branches for complementary blood supply to the lingual anterior cortical plate of the mandible. A second small artery, the submental artery (2 mm in diameter), a branch of the facial artery, runs along the inferior plane of the mylohyoid muscle lateral to the anterior belly of the digastric muscle. As illustrated in Fig. 48–6b, the submental artery runs close to the lingual lower border of the mandible. The largest branches of this artery may be seen on a cone-beam or dental CT as they extend into the bone (Fig. 48-6c–e).

The intimate proximity of these arteries, or their vascular plexa, to the lingual cortical plate explains why a lingual perforation in the lower third of the mandible can result in a massive hematoma in the floor of the mouth. Due to the presence of the strong cervical fasciae in the neck region (the *superficial layer*, the *fasciae of the infra-hyoid muscles*, the *pretracheal layer*), the hematoma will displace the tongue and floor of the mouth superiorly and posteriorly, posing a potentially serious threat of obstruction of the upper airway (for review see Kalpidis & Setayesh 2004). Several reports have appeared in the literature describing massive hematoma in the floor of the mouth, where unfortunately a tracheostomy or

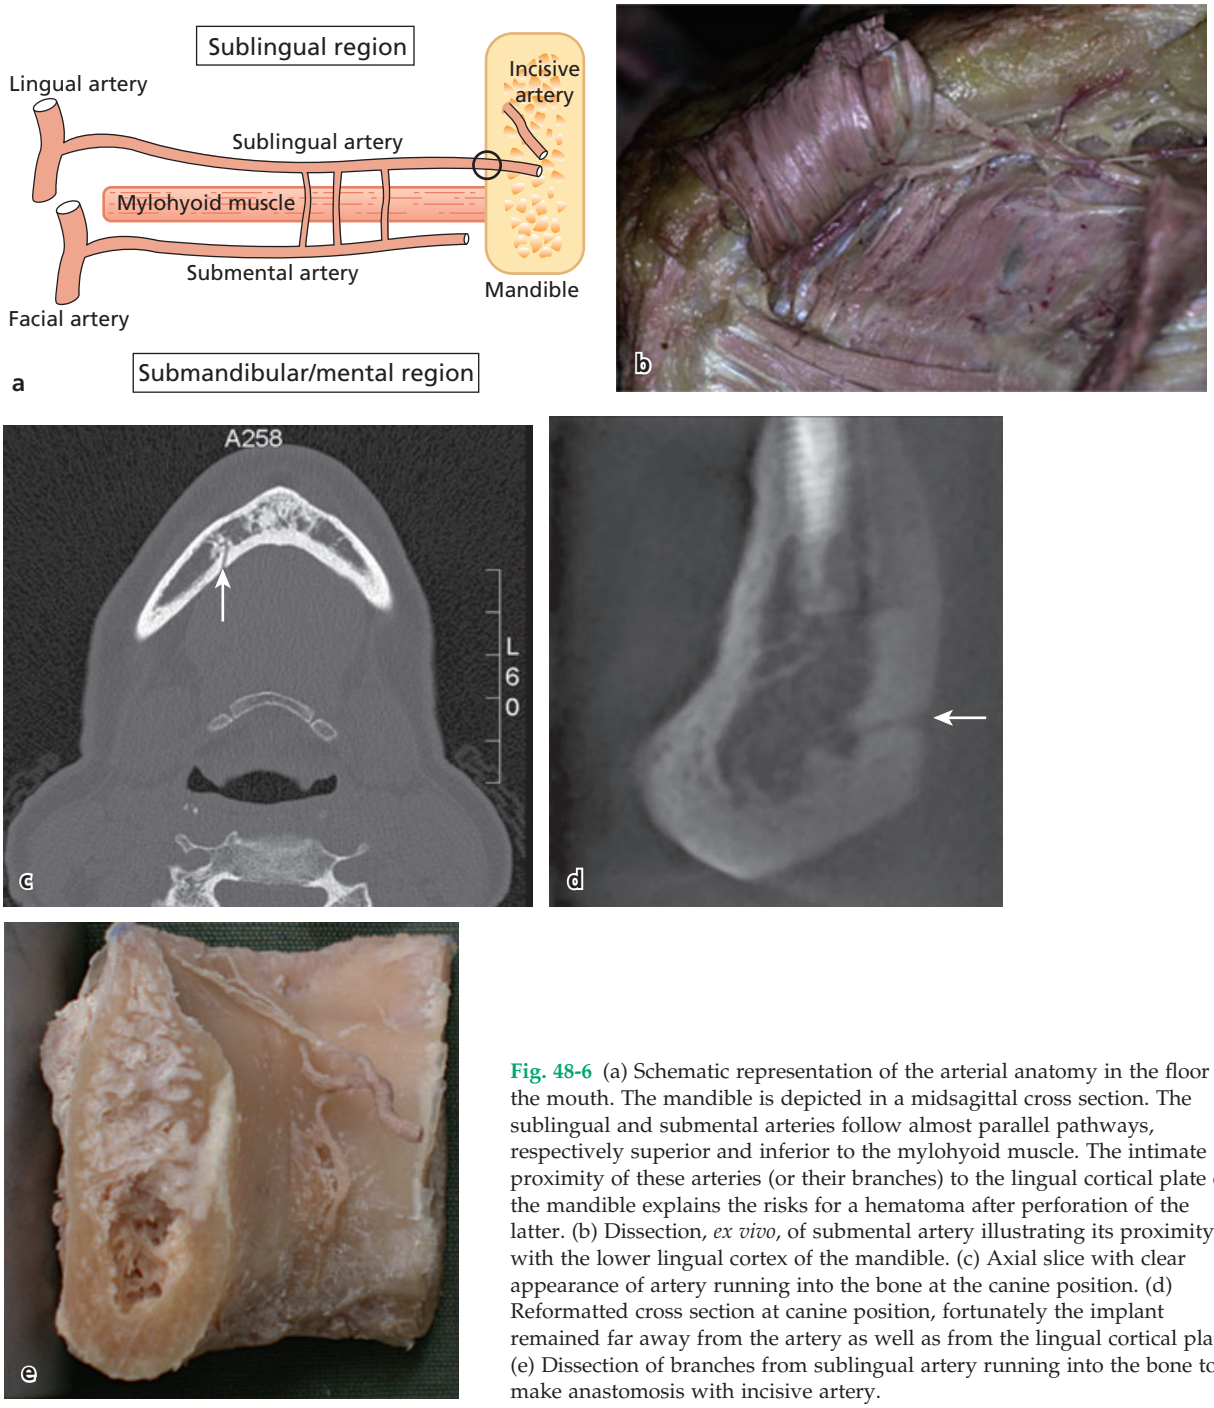

Fig. 48-6 (a) Schematic representation of the arterial anatomy in the floor of the mouth. The mandible is depicted in a midsagittal cross section. The sublingual and submental arteries follow almost parallel pathways, respectively superior and inferior to the mylohyoid muscle. The intimate proximity of these arteries (or their branches) to the lingual cortical plate of the mandible explains the risks for a hematoma after perforation of the latter. (b) Dissection, *ex vivo*, of submental artery illustrating its proximity with the lower lingual cortex of the mandible. (c) Axial slice with clear appearance of artery running into the bone at the canine position. (d) Reformatted cross section at canine position, fortunately the implant remained far away from the artery as well as from the lingual cortical plate. (e) Dissection of branches from sublingual artery running into the bone to make anastomosis with incisive artery.

intubation was the only option to save the life of the patient.

The shape of the lower jaw exhibits large individual variation. A small proportion of jaws (3%) (Quirynen *et al*. 2003) has a distinct lingual depression between lateral incisor and second premolar, superior to the mylohyoid muscle, to house the lingual gland (called the sublingual fovea). Perforation of the bone with a drill in this region must be avoided. As stated previously, deep dissection of the mucoperiosteal flap lingually is strongly recommended in implant installation surgery to expose the cortical plate of the mandible.

Implant position

If possible an implant should be placed in tooth position (Fig. 48-7), both in a mesio-distal and in a bucco-lingual direction. To achieve this, the starting point for the insertion in the bone must, in most instances, be located towards the buccal side of the crest in the mandible, and towards the palate in the maxilla. This is due to the presence of concavities that often exist in the jaws. Depending on the size of such concavities, the starting point (for the instertion) will be located either close to the top of the crest, as in the case of a wide alveolar process, or deeper down

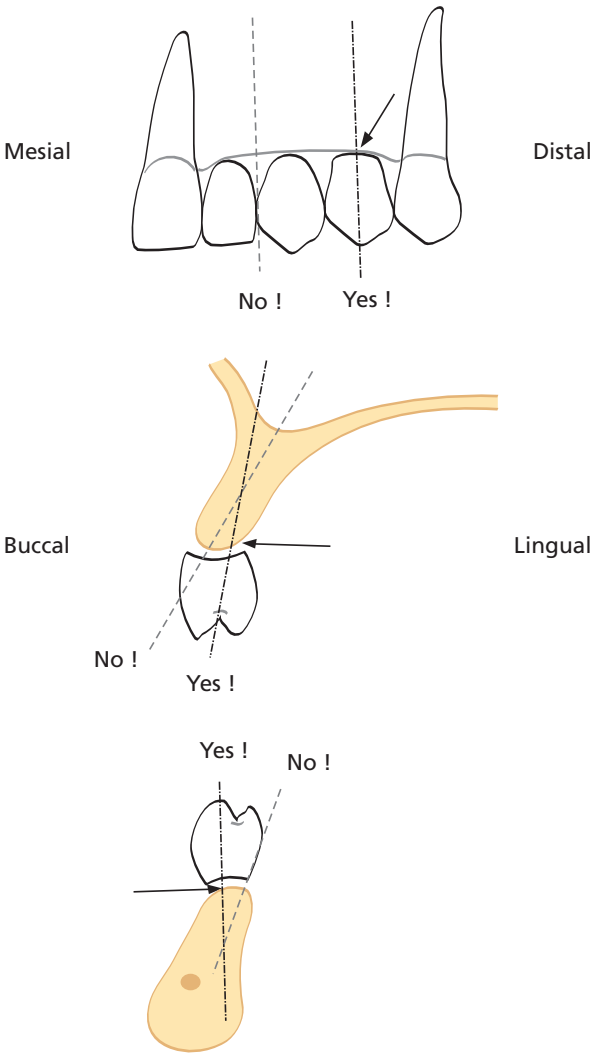

Fig. 48-7 Schematic drawings showing implant positions in mesial–distal and buccal–lingual dimensions. Indicated starting points for drilling are marked with black arrows.

palatally or buccally (Fig. 48-7), if the jaw is thin in its coronal portion.

In cases of partial edentulism, the recipient site closest to a tooth must first be identified. The cylindrical canal in the recipient site is prepared approximately 3.5–4 mm away from the prominence of the tooth. The subsequent implant positions, in a distal direction, are then identified. The minimum amount of bone that must be present in a recipient site is dependent on the dimension of the implants used; as a rule of thumb: the bone tissue of the site should be about 4(5) mm (in a horizontal direction) and about 7(9) mm (in a vertical direction) (Figs. 48-2, 48-3).

In a fully edentulous jaw, it might be preferable to start by placing the most distal implants, so that the position of other implants can be selected accordingly. The longest distance that can be accepted between two implants has not yet been properly defined. As an alternative to a reduced inter-implant distance, and an increased number of implants, it is sometimes possible to use wider diameter implants, as discussed below.

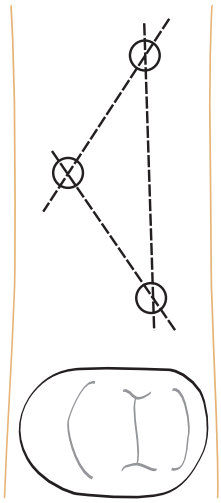

Fig. 48-8 Schematic drawing indicating a tripod placement of the implants in order to minimize individual load distribution onto each implant by creating several rotational axes.

Number of implants

In partially edentulous jaws preferably three implants should be inserted in order to avoid overloading of the anchorage units (Rangert *et al*. 1989). The failure rate has been reported to be higher for reconstorations placed on two than for those on three or more implants (Jemt & Lekholm 1993). Furthermore, the implants should be placed in a tripod position (Fig. 48-8) instead of being inserted in a straight line, thereby minimizing the transmission of bending forces on to each individual implant (Rangert *et al*. 1989). If only one implant can be inserted, then in most cases this anchorage should be used to support a single crown restoration. Implants should never be placed in the midline of the maxilla, not only because they might eventually expand the suture between the two maxillae, but such implants may eventually compromise the esthetics and phonetics after the prosthetic device has been inserted.

Implant direction

After the position of the implant has been identified, the direction/inclination of the implant in the jaw (bucco-lingual and mesio-distal) must be determined. If possible the implants should be placed in tooth position. This means that in the normal case the long axis of the implant should be directed through the occlusal surface of the final restoration. Regarding the bucco-lingual dimension (Fig. 48-9), the long axis of mandibular implants will mainly be directed towards the limbus part of the incisors or the palatal cusps of the teeth in the maxilla. For implants placed in the maxilla, the corresponding inclination should be towards the incisal edges of the frontal teeth or the buccal cusps of the premolars or molars of the mandible. If the starting point of the implant sites in the maxilla is located close to the top of the crest, and if

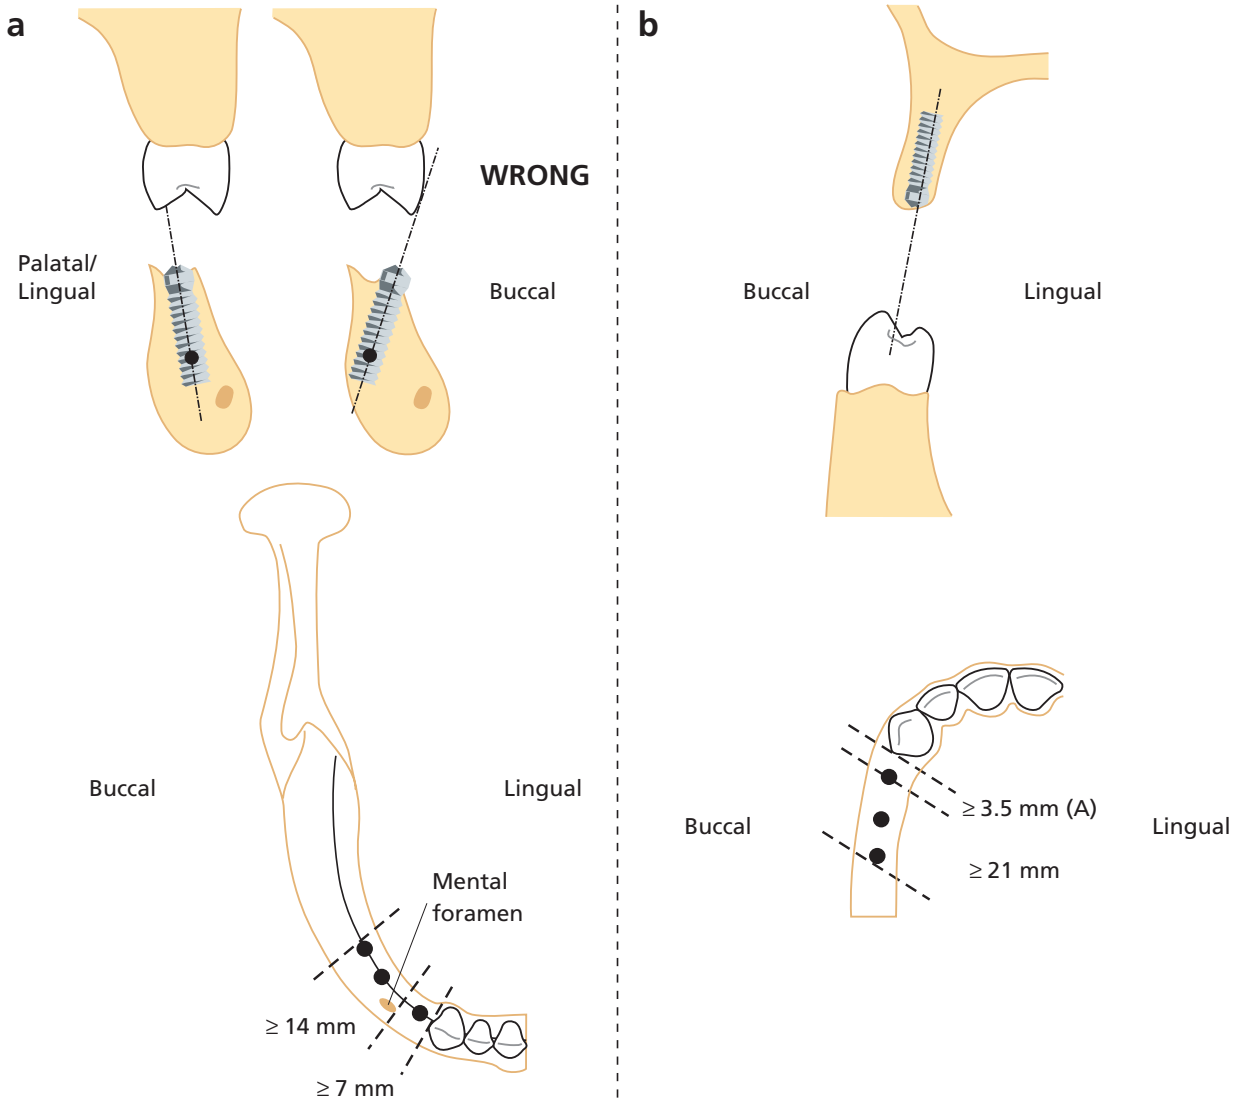

Fig. 48-9 Schematic drawings showing the most favorable starting points and implant directions in a buccal–lingual dimension within (a) the mandible and (b) the maxilla. A = closest distance of a site to a tooth.

a concavity on the buccal side of the ridge is present, there is a risk that the surgeon leans the long axis of the implants too far buccally. The equivalent for the mandible is an implant directed too far lingually owing to the presence of lingual concavities. Such adverse directions can impair the esthetics and function of the future restoration (Fig. 48-7), even though angulated abutments may to some extent compensate for such a surgical shortcoming.

In addition, the inclination of the implants to be inserted will depend on the existing jaw relation. In the case of angle class I jaw relation, the implants should be placed rather vertically in both jaws. In angle class II, the implants should often be placed vertically in the maxilla and slightly buccally in the mandible. In angle class III relations, the implants are inclined buccally in the maxilla and more lingually in the mandible. If the relation between the jaws is markedly adverse, orthognatic surgery may be considered (Clokie 2001) to correct the abnormal jaw relation. Another treatment option in such cases is an overdenture, retained by a bar construction on two implants in the mandible and/or on four implants in the maxilla. The overdenture often offers a favorable outcome to the patient with respect to esthetics, speech, lip and facial support, and function (Naert *et al*. 1998; van Steenberghe *et al*. 2001; Mericske-Stern *et al*. 2002; Eckert & Carr 2004; Kronstrom *et al*. 2006), even though the success rates of the supporting implants might be slightly lower than for implants that support fixed full bridges (Schwartz-Arad *et al*. 2005).

For the mesio-distal orientation of the implant (Fig. 48-10), the rule is that the implant closest to the last tooth is placed parallel with the long axis of the root of this tooth. The further distally the site is located into the molar region, on the other hand, the more inclined are the positions of the implants. In the mandible, for example, it is recommended that the most distal implants be placed in a slightly mesial direction to facilitate the connection of the abutments with the fixed bridge restoration.

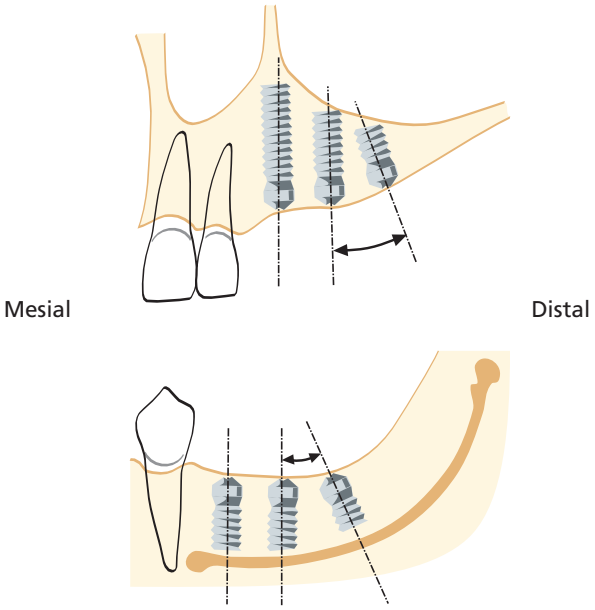

Fig. 48-10 Drawings showing implant directions in the mesial–distal dimension of posterior parts of the jaws. In the maxilla, the most distal implant is directed distally due to the orientation of the sinus wall to engage more bone. In the mandible, the implant is tilted mesially to provide better access for instruments during abutment and prosthetic procedures.

In extremely resorbed mandibles, the most distal implant that is placed immediately in front of the mental foramen, can be tilted distally in order to achieve optimal spreading of the supporting units (Maló *et al*. 2005). Correspondingly, in the resorbed maxilla, the canal prepared for the most distal implant (lateral to the canine) can be directed slightly distally and follow the mesial wall of the maxillary sinus, thereby allowing a longer implant to be placed (Maló *et al*. 2005). An alternative to this procedure would be to use of sinus elevation and grafting techniques (Hochwald & Davis 1992; Neukam & Kloss 2001).

Healing time

According to early protocols the healing time following installation of implants with a turned surface was 3–4 months (Lekholm & Zarb 1985). For the maxilla and occasionally in the posterior areas of the mandible the healing time was 5–6 months, as the bone is normally more cancellous in these portions of the jaws (Adell *et al*. 1985; Watzek & Ulm 2001). Furthermore, for implants placed in quality 4 bone (Lekholm & Zarb 1985), it was recommended that the healing time in the mandible was also extended another 1 or 2 months (Friberg 1994). As variations may exist between different regions of the same jaw, e.g. between frontal and distal segments or even between different sites within the same region (Watzek & Ulm 2001), it is also important to individualize the healing time and to allow the softest bone site to decide the timing.

For implants with a (mechanically or chemically) modified surface, reduced healing times (6 weeks) have been advocated. Such implants have also been recommended for early or even immediate loading protocols (see also Chapter 47). Immediate loading of implants, both with the use of provisional (Balshi & Wolfinger 1997; Schnitman *et al*. 1997) and/or definite reconstructions has been proposed (Brånemark *et al*. 1999; Randow *et al*. 1995; Ericsson *et al*. 2000a; van Steenberghe *et al*. 2005). The current experience with immediate occlusal loading of oral implants was summarized in several consensus reports and systematic reviews (Aparicio *et al*. 2003; Cochran *et al*. 2004; Misch *et al*. 2004a,b; Nkenke & Fenner 2006). Thus, the outcomes of short-term randomized controlled trials have shown that survival and success rates of immediately loaded implants in fully edentulous jaws may be similar to those of conventionally loaded implants (Chiapasco *et al*. 2001; Romeo *et al*. 2002).

The survival rate of immediately restored single-tooth implants was similar to or slightly lower than that of conventionally loaded single-tooth implants (Ericsson *et al*. 2000b; Cannizzaro & Leone 2003). Ericsson *et al*. (2000b) had a restoration placed immediately on the implant, but occlusal contacts were avoided. Some clinicians try to protect "immediately loaded" implants from forces exerted by the tongue or during chewing by using occlusal splints (Lorenzoni *et al*. 2003). To date, there are no controlled studies that enable evidence-based decisions to be made as to whether single-tooth implants can be loaded immediately or should only be restored without occlusal contacts (Nkenke & Fenner 2006).

Currently, it is not possible to draw conclusions concerning exclusion and inclusion criteria for immediate loading, threshold values for implant stability that allow immediate loading, bone quality needed for immediate loading, and the relevance of immediate functional loading and immediate non-functional loading (Nkenke & Fenner 2006). In most of the studies on immediate loading, good bone quality has been mentioned as an important prognostic factor for the success of the procedure (Chiapasco *et al*. 2001; Romeo *et al*. 2002). Although this conclusion seems reasonable, the level of evidence that supports the assumption is low (Nkenke & Fenner 2006). There are, in fact, no controlled studies that have been especially designed to compare immediate loading of oral implants placed in bone of varying density (soft/hard). The same is true for the lengths and diameters of implants that should be used for immediate loading. In one controlled study, moderately rough implant surfaces appeared to improve the survival rate of immediately loaded implants (Rocci *et al*. 2003a,b). In this study, however, the difference between the moderately rough as opposed to the machined-surface implants was not significant.

Review papers on immediate loading have also addressed additional biomechanical aspects of this

procedure (Szmukler-Moncler *et al*. 2000; Gapski *et al*. 2003; Chiapasco 2004; Nkenke & Fenner 2006). Based on different experimental studies, it was stated that a micromotion threshold should not be exceeded; otherwise, osseointegration would be hindered. The critical threshold seems to be 50–150 µm (Pilliar *et al*. 1986; Szmukler-Moncler *et al*. 1998). Therefore, it has been claimed that a high initial stability is necessary for immediate loading of dental implants (Chaushu *et al*. 2001; Calandriello & Tomatis 2005). For this purpose, these authors used modified drilling protocols combined with bone compaction with osteotomes to achieve increased primary stability. Some authors have chosen insertion torque as a measure of implant stability, and arbitrarily selected torque values of ≥32–40 Ncm as thresholds to allow immediate loading (Wöhrle 1998; Hui *et al*. 2001; Lorenzoni *et al*. 2003). With resonance frequency analysis (Meredith *et al*. 1996) it has become possible to measure initial implant stability, i.e. the density of the bone surrounding the implant. The bone quality can thereby be analyzed repeatedly over time and the healing period individualized without using any invasive technique for the tests. An implant stability quotient (ISQ) value of >60 was recommended (Sennerby & Meredith 2002) to allow oral implants to be loaded directly after their insertion. Until now, controlled studies that have compared the relationship between different levels of implant stability and implant survival rate have been lacking. Consequently, there is currently no proven threshold value that indicates that immediate loading will be successful. Besides high initial stability, it has been stressed that immediately loaded implants in multi-unit situations should be rigidly splinted by the use of superstructures (Nikellis *et al*. 2004; van Steenberghe *et al*. 2004). In order to optimize splinting, the use of metal-reinforced superstructures was advocated. High success rates have also been reported for immediate loading of implants connected with superstructures that were not reinforced with metal (Nikellis *et al*. 2004).

Part 15: Reconstructive Ridge Therapy

Chapter 49

Ridge Augmentation Procedures

Christoph H.F. Hämmerle and Ronald E. Jung

Introduction

Successful implant therapy is dependent upon an adequate volume of bone at the site of implant placement, since the long-term prognosis of dental implants is adversely affected by inadequate bone volume (Lekholm *et al*. 1986).

In principle, four methods have been described to increase the rate of bone formation and to augment bone volume: osteoinduction by the use of appropriate growth factors (Reddi 1981; Urist 1965); osteoconduction, where a grafting material serves as a scaffold for new bone growth (Buch *et al*. 1986; Reddi *et al*. 1987); distraction osteogenesis, by which a fracture is surgically induced and the two fragments are then slowly pulled apart (e.g. Ilizarov 1989a,b); and finally, guided tissue regeneration (GTR), which allows spaces maintained by barrier membranes to be filled with new bone (Dahlin *et al*. 1988, 1991a; Kostopoulos & Karring 1994; Nyman & Lang 1994).

Among these methods, guided bone regeneration (GBR) is the best documented for the treatment of localized bone defects in the jaws. GBR has allowed the use of endosseous implants in areas of the jaw with insufficient bone volume. Lack of bone volume may be due to congenital, post-traumatic, or post-surgical defects or result from disease processes. The predictability and success which can now be achieved with GBR procedures enable the clinician to obtain similar rates of treatment success at sites with bone defects compared to sites without defects (Hammerle *et al*. 2002).

Although bone augmentation procedures are an important part of contemporary implant therapy, other factors are also critical in order to obtain treatment success. In this respect a systematic approach to a given patient situation is key to achieving the desired aim. In complex cases with a multitude of problems, several aspects have to be taken into consideration. These include the patient's general health status, behavior of the patient, environmental factors, the presence of any oral diseases, and the situation at the site planned for implantation as well as the regions of the dentition adjacent to and opposing this site.

GBR is frequently part of complex treatments, but this chapter will focus only on the aspects of bone augmentation at localized defects in the alveolar process.

More than two decades have passed since the introduction of GBR into clinical practice. Today, general understanding of the mechanisms leading to regeneration of desired tissues still agrees with the initially published statements (Karring *et al*. 1980; Nyman *et al*. 1980, 1989). In brief, when a space is formed, cells from the adjacent tissues will grow into this space to form their parent tissue, i.e. the tissue they migrated in from. In order to give preference to

cells from desired tissues, membranes are placed to prevent cells from undesired tissues having access to the space.

Patient situation

It is generally agreed that certain general health conditions represent a risk for successful GBR procedures. In a recent consensus conference one group examined the effect of systemic diseases on implant success (Mombelli & Cionca 2006). It was found that the scientific literature is inconclusive on these issues due to a lack of well performed clinical studies. Hence, it was concluded that neither the same rate of success nor an increased rate of failures have been documented in the presence of the specific systemic conditions under investigation. Furthermore, no conclusive data are available with respect to bone augmentation procedures in patients suffering from systemic diseases which cause impaired tissue healing. The same was found for patients who show behaviors (e.g. smoking, poor compliance) which lead to impaired tissue healing or to a higher susceptibility for disease development. Risk–benefit analysis should be performed with these uncertainties in mind, when planning implant therapy in the presence of bone defects.

It has been demonstrated that implant therapy in patients who have lost their teeth due to periodontal disease will be subject to more implant failures and complications regarding the supporting tissues than in patients who have lost their teeth due to other reasons (Mengel *et al*. 2001; Hardt *et al*. 2002; Karoussis *et al*. 2003; Wennstrom *et al*. 2004). Although, there are few well controlled studies available, it may be expected that these problems also exist when implants are supported by regenerated bone.

Bone morphology

Bone defects may be classified into intra-alveolar, horizontal, and vertical defects. Intra-alveolar defects are dealt with in Chapter 43.

When examining a clinical situation regarding bone morphology, the following aspects are of therapeutic importance: the presence of a bone defect; the size of the edentulous gap (single-tooth, double-tooth or multiple-tooth); and the bone level at the teeth adjacent to the defect.

Horizontal bone defects

Horizontal bone defects are the ones most frequently encountered. They include dehiscences and fenestrations.

The treatment of these types of defects has been shown to be highly successful in numerous studies (Balshi *et al*. 1991; Jung *et al*. 2003; Lundgren *et al*. 1994b; Mayfield *et al*. 1997; Simion *et al*. 1997). In addition, both bioresorbable and non-resorbable membranes have been successfully employed (Sandberg *et al*. 1993; Sevor *et al*. 1993; Schliephake *et al*. 1994; Crump *et al*. 1996; Chung *et al*. 1997; Hammerle *et al*. 1997, 1998; Lundgren *et al*. 1997). In a controlled clinical trial 18 implants with exposed surfaces were treated in nine patients (Simion *et al*. 1997). In the test sites bioresorbable membranes of polylactic and polyglycolic acid (PLA/PGA) were used, whereas non-resorbable membranes of expanded polytetrafluoroethylene (e-PTFE) were applied in the control sites. Autogenic bone was additionally placed to cover the exposed implant threads prior to membrane adaptation. The results at re-entry, 6–7 months later, revealed favorable healing and bone regeneration in both test and control sites, with the control sites demonstrating slightly higher amounts of bone regeneration.

In situations with a bone defect at a site where primary stability of an implant cannot be achieved, or when implant placement is not possible in the ideal location for subsequent prosthetic therapy, GBR prior to implantation represents the method of choice.

Experimental research on ridge augmentation using GBR was presented in the early 1990s (Seibert & Nyman 1990). In a dog model, large defects of the alveolar ridge were surgically prepared both in the mandible and in the maxilla. Morphologic and histologic analysis revealed that, in sites treated with membranes, with or without the addition of grafts, the entire space between the membrane and the jawbone was filled with bone. In the absence of membranes, bone formation was lacking.

The conclusions drawn from these and other pioneering experiments were that the method of GBR can indeed be successfully employed in the regeneration of alveolar ridge defects (Seibert & Nyman 1990; Schenk *et al*. 1994; Smukler *et al*. 1995).

Ridge augmentation in a lateral direction has been shown to be a method with predictable success (Nyman *et al*. 1990; Dahlin *et al*. 1991b; Becker *et al*. 1994b; Nevins & Mellonig 1994; Buser *et al*. 1996; von Arx *et al*. 1996). Successful methods regarding augmentation of the alveolar ridge in a vertical direction, however, are not well established.

Vertical bone defects

Data from animal experiments have clearly demonstrated that gain of bone above the external borders of the skeleton were possible using GBR (Lundgren *et al*. 1995; Hämmerle *et al*. 1996, 1997; Schliephake & Kracht 1997; Schmid *et al*. 1997; Lorenzoni *et al*. 1998).

Vertical ridge augmentation represents the most demanding indication in GBR therapy. Established techniques involve the placement of autogenous, particulated or block bone grafts, or bone substitute materials in combination with e-PTFE membranes of various configurations (Simion *et al*. 1994b, 1998;

Tinti *et al*. 1996; Tinti & Parma-Benfenati 1998; Chiapasco *et al*. 2004). The membranes were either supported by the graft alone or additionally supported by the implant protruding vertically from the host bone for various lengths. The results after submerged healing consistently showed bone formation reaching above the previous border of the alveolar crest. In some situations vertical bone formation reached up to 4 mm above the previous border of the alveolar crest. Within the area of the newly formed bone, osseointegration of the implants had occurred as demonstrated by histologic analysis of experimentally retrieved test implants. The amount of vertical bone formation, however, was not predictable and bone growth to the top of the membrane was not consistently reached when several millimeters of new bone formation were attempted. The remainder of the space between the newly formed bone and the membrane was occupied by non-mineralized tissue (Simion *et al*. 1994a).

Soft tissue morphology

The morphology of the soft tissues at the site of bone regeneration has a significant impact on the result of treatment. On the one hand, soft tissue coverage is a prerequisite for successful bone augmentation. On the other hand, in situations with high esthetic importance the soft tissues and the reconstruction determine whether or not a result is esthetically pleasing.

In many situations the availability of the soft tissues will limit the amount of bone formation possible. In other words a lack of soft tissues may prevent large amounts of bone volume gain because it is impossible to cover the area intended for regeneration. In such situations it may be advisable first to augment the volume of the soft tissues and then perform the bone augmentation procedure as a second step.

Critical aspects regarding the soft tissues include: vertical or horizontal soft tissue defects; level of the soft tissues at the teeth neighboring the gap; gingival biotype; and scars, pathologies or discolorations in the soft tissues lining the area of the bone defect.

Augmentation materials

Membranes

A wide range of membrane materials has been used in experimental and clinical studies to achieve GBR, including polytetrafluoroethylene (PTFE), expanded PTFE (e-PTFE), collagen, freeze-dried fascia lata, freeze-dried dura mater allografts, polyglactin 910, polylactic acid, polyglycolic acid, polyorthoester, polyurethane, polyhydroxybutyrate, calcium sulfate, micro titanium mesh, and titanium foils. Devices used for GBR in conjunction with endosseous implants should be safe and effective. Since no life-threatening diseases or deficiencies are treated, possible adverse effects emerging from the implanted devices should be kept to a minimum. At the same time, documentation of the effectiveness of the procedures and materials should be available. Certain critical criteria regarding membranes used for GTR have been formulated (Hardwick *et al*. 1994): biocompatibility, cell occlusiveness, integration by the host tissues, clinical manageability, and the space making function. For bioresorbable and biodegradable membranes additional criteria need to be fulfilled. Tissue reactions resulting from the resorption of the membrane should be minimal, these reactions should be reversible, and they should not negatively influence regeneration of the desired tissues (Gottlow 1993).

Although GBR is quite a successful procedure, a better understanding of the factors critical for success or failure is mandatory. This understanding will lead to more refined clinical protocols and will allow for the manufacturing of membrane materials with improved performance for a given indication. Some of these factors include membrane stability, duration of barrier function, enhanced access of bone and bone marrow-derived cells to the area for regeneration, ample blood fill of the space, prevention of soft tissue dehiscence, *in situ* forming, and delivery of factors influencing tissue formation beneficially.

Non-resorbable membranes

With the presentation of the first successful GBR procedures and the subsequent wide and successful application of e-PTFE membranes, this material soon became a standard for bone regeneration. Expanded PTFE is characterized as a polymer with high stability in biologic systems. It resists breakdown by host tissues and by microbes and does not elicit immunologic reactions.

A frequent complication with membrane application in conjunction with implants is membrane exposure and infection. Wound dehiscence and membrane exposure have been reported to impair the amount of bone regenerated in a number of experimental animal (Gotfredsen *et al*. 1993; Kohal *et al*. 1999a) and clinical investigations (Gher *et al*. 1994; Simion *et al*. 1994a; Hämmerle *et al*. 1998).

In situations where bone formation is desired in large defects or in supracrestal areas, conventional e-PTFE membranes do not adequately maintain space unless supported by grafting materials. The alternative approach involves the use of membranes with a stable form, such as titanium-reinforced membranes. Recent research has demonstrated the successful use of these membranes in vertical ridge augmentation and in the treatment of large defects in the alveolar process (Jovanovic & Nevins 1995; Tinti *et al*. 1996; Simion *et al*. 1998).

Many of the factors critical for successful bone formation were identified in experimental studies

applying e-PTFE membranes. Furthermore, clinical protocols regarding surgical procedures, postoperative care, and healing times required were established using non-resorbable membranes. Today, as evidence of the effectiveness of bioresorbable membranes increases, non-resorbable membranes are losing importance in clinical practice and their use is increasingly limited to specific indications. Since e-PTFE membranes have been documented to allow successful GBR therapy, results obtained using new materials should always be compared with results of e-PTFE membranes.

Bioresorbable membranes

Non-resorbable membranes have to be removed during a second surgical intervention. The removal surgery will impose morbidity and psychologic stress on the patient and represents a risk for tissue damage. Since these disadvantages do not occur when working with bioresorbable membranes, they are increasingly applied in the clinic.

Apart from the fact that there is no need for surgical intervention for removal of the membrane, bioresorbable membranes offer some additional advantages. These include improved soft tissue healing (Lekovic *et al*. 1997, 1998; Zitzmann *et al*. 1997), the incorporation of the membranes by the host tissues (depending on material properties), and quick resorption in case of exposure, thus eliminating open microstructures prone to bacterial contamination (Zitzmann *et al*. 1997; Lorenzoni *et al*. 1998).

Bioresorbable materials that may be used for the fabrication of membranes all belong to the groups of natural or synthetic polymers. The best known groups of polymers used for medical purposes are collagen and aliphatic polyesters. Currently tested and used membranes are made of collagen, or of polyglycolide and/or polylactide or copolymers thereof (Hutmacher & Hürzeler 1995).

A wide range of bioresorbable membranes made of either collagen or polyglycolide and/or polylactic acid has been investigated in experimental and clinical studies (Lundgren *et al*. 1994a; Mayfield *et al*. 1997; Simion *et al*. 1997; Zitzmann *et al*. 1997). Results have generally been good, partly because of the low rate of complications, so bioresorbable membranes have become the standard for most clinical situations and have, thus, largely replaced the non-resorbable e-PTFE membranes.

It should be realized, however, that in a recent systematic review a reasonable comparison between bioresorbable and non-resorbable membranes could not be drawn due to a lack of well designed studies (Chiapasco *et al*. 2006). Only a few studies could be identified which compared the results of bioresorbable and non-resorbable membranes (Zitzmann *et al*. 1997, 2001b; Christensen *et al*. 2003). These studies did not find any difference between the two treatment modalities.

Obviously, choice of material is critical when it comes to bioresorbable membranes for GBR. Inflammatory reactions have been documented in the tissues adjacent to some bioresorbable membranes, ranging from mild (Sandberg *et al*. 1993; Piatelli *et al*. 1995; Aaboe *et al*. 1998; Kohal *et al*. 1999a,b) to severe (Gotfredsen *et al*. 1994). Another study reported on therapeutic failures using polylactic membranes for bone regeneration at peri-implant defects in dogs (Schliephake *et al*. 1997). Soft tissue complications were frequent, and the results did not reveal any improvement over control sites without the use of membranes.

Convincing results of bone regeneration in animal experiments have been reported for collagen membranes (Hürzeler *et al*. 1998; Zahedi *et al*. 1998). Furthermore, reports of human cases or case series (Hämmerle & Lang 2001) as well as controlled clinical studies (Zitzmann *et al*. 1997) have been presented describing the successful use of collagen membranes for GBR at exposed implant surfaces.

Bioresorbable membranes that are commercially available at present are not capable of maintaining adequate space unless the defect morphology is very favorable (Oh *et al*. 2003; Lundgren *et al*. 1994b). Even if the membranes seem able to maintain space initially, they generally lose their mechanical strength soon after implantation into the tissues. Favorable results have been reported only in situations where the bony borders of the defects adequately support the membrane. When defects do not maintain the space by themselves, failure of bone regeneration results (Zellin *et al*. 1995; Mellonig *et al*. 1998). Therefore, they need to be supported in some way.

In summary, animal experiments, human case reports, and initial controlled clinical studies demonstrate that bioresorbable and non-resorbable membranes can successfully be used for bone regeneration at implants with exposed surface areas. It appears, however, that bioresorbable membranes generally show better clinical performance compared with non-resorbable membranes. Hence, unless the defect morphology or other factors prevent the application of bioresorbable membranes their use is to be preferred. The choice of the best material has to be based on the individual patient situation.

Bone grafts and bone graft substitutes

Bone grafts have long been used in reconstructive surgery with the aim of increasing the bone volume in the previous defect area. Bone grafts and bone substitute materials may be classified into two main groups: autogenic and xenogenic materials. The term autogenic graft refers to tissues that are transplanted within one and the same organism. Xenogenic grafts encompass all materials of an origin other than the recipient organism and may further be divided into materials from the same species but different individuals, materials from other species, and finally products of non-organic origin.

Bone grafts or bone graft substitutes in conjunction with GBR need to fulfill a number of requirements. They should adequately support the membrane to provide a predefined volume of the regenerated bone. In addition, they should serve as a guiding structure into which the bone can grow or is even encouraged to grow. As a result capillaries and perivascular cells can easily form and migrate, respectively, within the voids provided by the supporting material. Later bone-forming cells can populate the spaces and produce new bone. Finally, the supporting material should be resorbed and replaced by the patient's own bone (Jensen *et al*. 1996; Fugazzotto 2003a,b).

The successful combination of autogenic corticocancellous bone grafts and GBR has been shown in a clinical study (Buser *et al*. 1990). A group of 40 patients, who had been treated with this method, demonstrated very low frequency of soft tissue complications and successful ridge augmentation in 66 sites. A mean gain in crest width of 3.5 mm was measured allowing implant placement in a proper position in all 66 sites. More recently, studies in humans and animals have lead to further development and refinement of this method with very good clinical success (Buser *et al*. 1996).

The necessity for membranes in conjunction with block grafts was tested in a prospective randomized clinical study involving 13 patients (Antoun *et al*. 2001). Patients were either treated with onlay bone grafts alone or additionally covered by e-PTFE membranes. The width of the ridges was evaluated clinically immediately following graft placement and at the time of membrane removal 6 months later. In the group with membranes significantly less resorption had occurred. This controlled clinical study confirms animal experimental data and is in accordance with case series reporting the occurrence of pronounced resorption of bone grafts (Jensen *et al*. 1995; Widmark *et al*. 1997; von Arx *et al*. 2001; Cochran *et al*. 2002).

Xenogenic bone substitutes have been developed and applied to GBR. Experimental studies have dealt with materials manufactured synthetically, derived from corals or algae, or originated from natural bone mineral (for review see Hammerle & Jung 2003). These materials are regarded to be biocompatible and osteoconductive. Nevertheless, considerable differences have been reported in their behavior based on material properties.

In a recent systematic review it was concluded that the paucity of available scientific data precludes clear recommendations regarding the choice of a specific supporting material for GBR procedures (Chiapasco *et al*. 2006). Comparative data were rarely found (Christensen *et al*. 2003) and no randomized controlled clinical trials were available as a basis for decision making.

The studies evaluating clinical outcomes of lateral ridge augmentation with GBR procedures in staged implantation commonly used autogenous bone as filler materials in combination with non-resorbable membranes (Nevins & Mellonig 1994; Buser *et al*. 1996). Limited data are available reporting on the application of bone substitutes in combination with bioresorbable membranes for ridge augmentation prior to implant placement (Zitzmann *et al*. 2001a; Friedmann *et al*. 2002; Hammerle *et al*. 2008).

In one of these studies 12 patients with 15 sites exhibiting lateral bone defects were treated using blocks of deproteinized bovine bone mineral and bioresorbable collagen membranes (Hammerle *et al*. 2008). The size of the defects precluded implant placement without prior bone augmentation. Initially the average ridge width amounted to 3.2 mm. At the re-entry operation 9–10 months later, the mean crestal bone width had increased to 6.9 mm. In all of the cases but one, the resulting bone volume was adequate to place the implant in a prosthetically optimal position. In one case, no gain of bone volume had occurred during the phase of regeneration for unknown reasons. While in previous clinical studies, small bone defects at implant sites had been augmented by use of DBBM (Hämmerle & Lang 2001; Zitzmann *et al*. 2001a; Friedmann *et al*. 2002; Hellem *et al*. 2003), larger bone defects were predictably augmented in this case series (Hammerle *et al*. 2008).

The technique of applying biomaterials to support bioresorbable membranes avoids the risks associated with harvesting autogenic bone (Nkenke *et al*. 2001; von Arx *et al*. 2005). This is a significant benefit to the patient and represents an important step in the development of GBR procedures. Future research should be focused on such patient-centered outcomes. The development of biomaterials, ideally coupled with the incorporation of bone growth factors and bioactive peptides, represents an important line of research in this direction (Jung *et al*. 2003).

Long-term results

Recent systematic reviews have compiled the literature regarding survival and success rates of implants partly or fully placed into regenerated bone (Hammerle *et al*. 2002; Fiorellini & Nevins 2003; Chiapasco *et al*. 2006). The survival rate of implants placed into sites with regenerated/augmented bone using barrier membranes varied between 79% and 100% with the majority of studies indicating more than 90% after at least 1 year of function. The survival rates obtained in the studies identified by these systematic reviews were similar to those generally reported for implants placed conventionally into sites without the need for bone augmentation. Two studies were identified that provided internal control data (Mayfield *et al*. 1998; Zitzmann *et al*. 2001b). In particular, the data from these two studies provided survival and success rates with no significant differences for implants in regenerated compared to non-regenerated bone. In addition, the loss of crestal bone

was not different between test and control implants in one of these studies (Mayfield *et al*. 1998).

The long-term stability of vertically augmented bone was assessed in a multi-center study involving 123 patients (Simion *et al*. 2001). The results demonstrated marginal bone level changes to be within the range of variations reported for implants placed into intact bony beds.

Long-term analysis of the stability of the regenerated bone is almost exclusively focused on radiographic assessments of the interproximal bone and on implant survival. There is a need for studies to evaluate the fate of the buccal bone plate, regenerated or not, over time. As has been suggested in previous studies, the stability of the regenerated bone may be assessed using various clinical or radiographic measures (Chiapasco *et al*. 1999).

Clinical concepts

Analysis of the bony defect morphology is the basis for deciding which treatment strategy to follow and which materials to apply for GBR. Basically there are two procedures: a one-step (combined approach) and a two-step (staged approach) procedure. Whenever the bone morphology allows anchorage of the implant with primary stability in prosthetically correct position the one-step approach is preferred. In situations where the defect morphology precludes primary implant stability, the two-step procedure is performed, i.e. the bone volume is first augmented to a degree allowing implant placement in a second intervention. The classification of bone defects is intended as a guideline for choosing the best techniques and materials for GBR at implant sites (Fig. 49-1).

Ridge preservation

In situations where there is a substantial lack of soft and/or hard tissues it may be advisable to apply methods for improving hard tissue as well as soft tissue healing. Attempts have been made to maintain the contour of the ridge by placing non-resorbable materials into the fresh extraction socket. Cones of hydroxyapatite were placed into the socket (Denissen & de Groot 1979; Quinn & Kent 1984). Whereas the resorption of the ridge could be somewhat reduced the overall result was not satisfactory. A large number of soft tissue dehiscences occurred and in some situations the cones had to be removed (Kwon *et al*. 1986).

GBR has been used to preserve or augment the alveolar ridge at the time of tooth removal. Supporting materials were placed into fresh extraction sockets and subsequently covered by non-resorbable membranes (Nemcovsky & Serfaty 1996; Lekovic *et al*. 1997; Fowler *et al*. 2000). One of the problems encountered, as described above, is the lack of soft tissue to cover the GBR site completely. In order to solve this problem coronal and lateral sliding flaps or soft tissue grafts were employed. In some studies no attempt was made to contain the filler material with membranes nor was the soft tissue manipulated to allow for primary closure. In these situations and when necrosis of the covering soft tissues occurred, loss of grafting particles was a common finding (Nemcovsky & Serfaty 1996).

Histomorphometric analysis of biopsies revealed that more vital bone had formed at sites treated with GBR compared to sites that were left to spontaneous healing. The investigators attributed this positive finding to the characteristics of the filler materials.

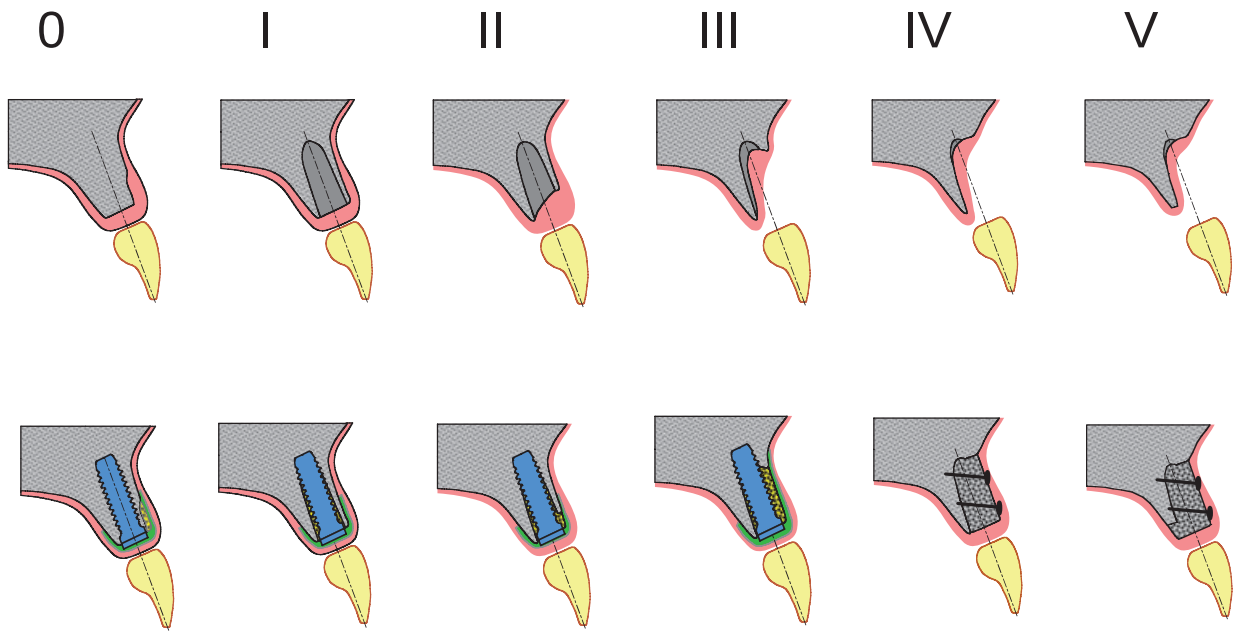

Fig. 49-1 Schematic drawing depicting the defect classification with classes 0–V.

Both osteoconductivity and resorbability of the materials apparently influenced new bone formation in a positive manner (Smukler *et al*. 1999; Artzi *et al*. 2000; Bolouri *et al*. 2001; Froum *et al*. 2002).

When applying GBR procedures it was clinically observed that the rate of resorption of the alveolar process could be reduced compared to untreated control sites (Lekovic *et al*. 1997, 1998; Yilmaz *et al*. 1998; Camargo *et al*. 2000). Complications with soft tissue dehiscences, however, frequently occurred in GBR-treated sites (Fowler *et al*. 2000; Yang *et al*. 2000). Although, the method of using GBR to reduce the loss of ridge volume has been well documented, it is not practical in many clinical situations due to the following shortcomings: it requires a long healing period before the implant therapy can be continued; the method is invasive and technique sensitive; soft tissue coverage is difficult to achieve and may lead a compromized esthetic result; and it is costly.

A different approach to provide optimal conditions for implant therapy regarding the profile of the alveolar ridge has led to the development of techniques aimed at improving the soft tissue conditions. Previous case reports described the use of autogenous soft tissue grafts to seal extraction sites before (Landsberg & Bichacho 1994) or at the time of implant placement (Evian & Cutler 1994; Landsberg 1997; Chen & Dahlin 1996; Tal 1999). Several problems exist with these procedures, including necrosis of the transplanted mucosa and poor color integration at the recipient site. In order to address this issue in a systematic way 20 patients in need of tooth extraction received soft tissue grafts to seal the entrance to the alveolus of the freshly extracted tooth (Jung *et al*. 2004) (Fig. 49-2a). First a grafting material was placed into the socket with the aim of maintaining the contour of the ridge. Subsequently, a soft tissue graft harvested from the palate was carefully sutured to cover the grafting material and thus seal off the alveolus from the oral cavity (Fig. 49-2b). Six weeks later, the vitality of the graft and the color match with respect to the surrounding mucosa were assessed. More than 99% of the grafted tissue area appeared vital. Digital measurement of the color difference between the grafted and the neighboring host tissues generated values below thresholds for normally detectable values in such situations (Fig. 49-2c). This technique, therefore, beneficially influenced the conditions at extraction sites for subsequent implant placement and soft tissue management in comparison to spontaneous healing (Fig. 49-3). Due to the effort and expense necessary to perform this treatment approach, it is primarily recommended for situations with high esthetic priority.

At times the implant is completely inserted into native bone but the buccal contour of the hard and soft tissues is insufficient for an optimal treatment outcome. This may be the case in esthetically highly demanding situations. In order to improve the esthetic result an augmentation procedure is conducted (class 0). A membrane-supporting material and a membrane are placed to promote labial bone formation in order to obtain the desired tissue contours.

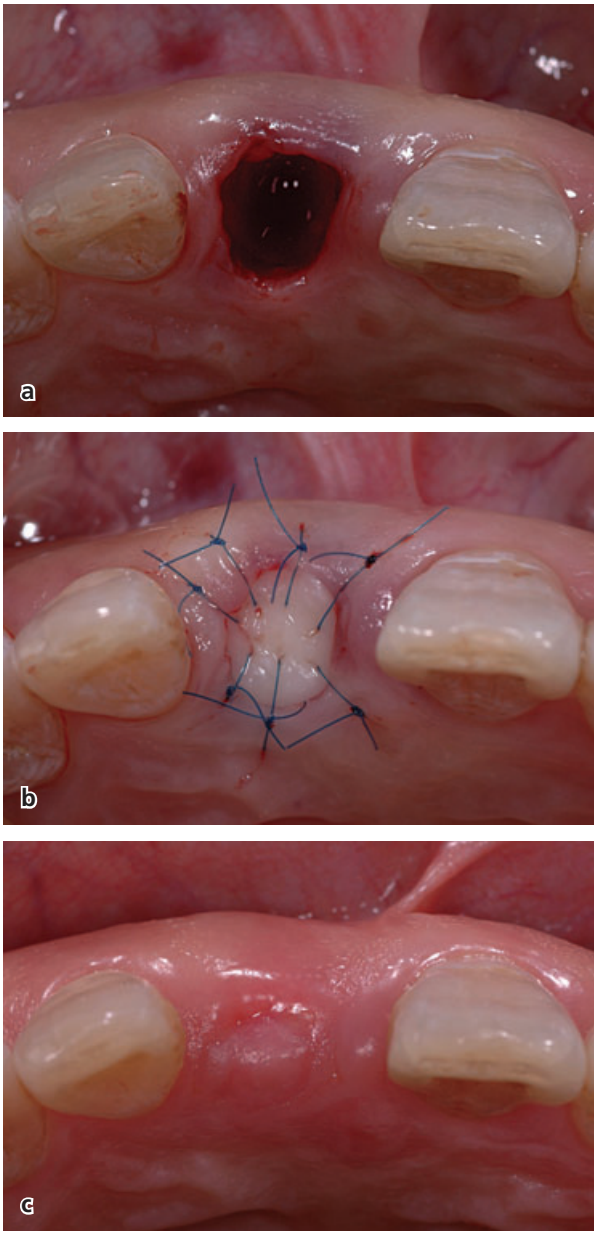

Fig. 49-2 (a) Occlusal view of an extraction site 11 immediately following removal of the tooth. Note the normal appearance of the external ridge contour and the soft tissue deficit over the extraction socket. (b) A soft tissue graft taken from the palate has been placed and sutured to seal the entrance of the alveolus. (c) After 6 weeks of healing, the soft tissue graft is completely integrated at the recipient site and a healthy soft tissue cover of the former entrance of the alveolus is present.

Extraction sockets (class I)

Currently implants are often placed in fresh extraction sockets. Although some of these clinical procedures were first described many years ago, their application has become more common in recent years.

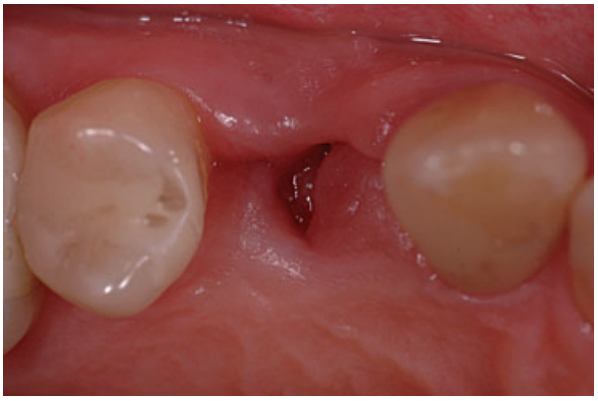

Fig. 49-3 An extraction site after 6 weeks of spontaneous healing. Note the incomplete healing rendering soft tissue management difficult.

In situations where teeth are to be replaced with implants, a decision must be taken during treatment planning whether the implant should be placed immediately after tooth extraction or if a certain number of weeks of healing of the soft and hard tissues of the alveolar ridge should be allowed prior to implant placement. For details regarding timing of implant placement into extraction sockets see Chapter 47.

If bone augmentation is required at implants immediately placed into extraction sockets, the following procedure is recommended. A flap is raised to allow easy access to the site and the implant is inserted. A membrane-supporting material is adapted to support the membrane. Depending on the defect morphology (for details see Chapter 47) this material is placed into the space between the walls of the socket and the implant surface. In addition, in some situations, especially in the esthetic zone, it may be necessary to augment the bone beyond the labial wall of the socket. Thus, the membrane-supporting material is also applied in order to correct the ridge profile to obtain a more prominent labial tissue contour. Subsequently, the membrane is adapted to cover the supporting material and a narrow zone of the adjacent bone and the flap is adapted and sutured. Whenever a partial or complete loss of the buccal wall of the socket is encountered the procedure described for dehiscence defects is applied.

Dehiscence defects (classes II and III)

Dehiscence defects may range from a very small lack of marginal bone to large areas of denuded implant surfaces. As long as the implant can be securely anchored in the existing bone, concomitant implantation and bone regeneration may be performed. When the defect is quite small, it may be questionable whether or not a regeneration procedure will improve the treatment outcome and its long-term stability (Hämmerle 1999). Often the esthetic result, as well as aspects of health and function, is important. In esthetically demanding situations it is generally recommended to perform an augmentation procedure, whereas in other areas of the mouth recommendations are not as strict. It needs to be understood, however, that the presently available scientific data do not allow an evidence-based statement to be made regarding the borderline between a situation requiring bone augmentation and a situation without this requirement (Chiapasco *et al*. 2006).

In situations where it is decided to carry out a GBR procedure, the material of choice should fulfill the following requirements: it should have proven efficacy; be thoroughly researched and scientifically documented; and be re-evaluated at regular intervals. In recent clinical studies, it has been demonstrated that the application of bone substitutes in conjunction with the placement of implants lead to successful coverage of the previously exposed implant surfaces (Zitzmann *et al*. 1997; Hämmerle *et al*. 1998; Moses *et al*. 2005). Hence, harvesting of autogenous bone for the treatment of dehiscence defects may not always be necessary for a successful treatment outcome.

The grafting material should reliably support the area intended for bone augmentation, allow or preferably promote in-growth of bone forming cells, and support bone–implant contact formation. Among other materials deproteinized bovine bone mineral is very well researched and has consistently demonstrated excellent clinical results (Esposito *et al*. 2006).

When choosing an appropriate membrane the same basic documentation as required for the supporting materials needs to be available: i.e. it should have proven efficacy; be thoroughly researched and scientifically documented; and be re-evaluated at regular intervals. Additional parameters regarding selection of a suitable membrane include the mechanical properties, the risk for soft tissue dehiscence, and the ease of clinical handling. In most situations with dehiscence defects a bioresorbable collagen membrane will be optimal regarding the scientifically and clinically required characteristics. In contrast, in situations, where the defect morphology requires improved stability of the area to be regenerated, e-PTFE membranes are most suitable. Apart from the substantial risk for soft tissue dehiscence and subsequent infection of the area, the need for membrane-removal surgery represents the major disadvantage of non-resorbable membranes. As a consequence, bioresorbable membranes are preferred whenever possible for the treatment of small and larger dehiscence defects.

The clinical protocol to promote bone formation for successful coverage of exposed implant surfaces includes the following steps. After a flap is raised, the implant is inserted (Fig. 49-4a). A membrane-supporting material is placed in the area of the buccal dehiscence defect with the aim of promoting bone formation for bone integration of the implant and

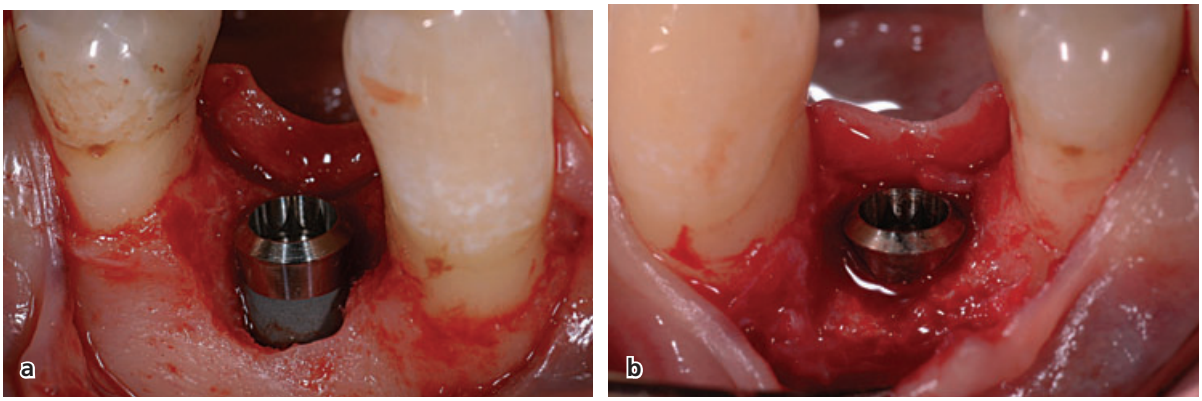

Fig. 49-4 (a) A small labial dehiscence defect at an implant in position of tooth 44. The defect is treated by GBR applying a bioresorbable membrane and a deproteinized bovine bone mineral for membrane support. (b) The same case as in (a) at re-entry surgery. New bone has formed within the previous defect area. A thin layer of non-mineralized tissue covers the regenerated bone.

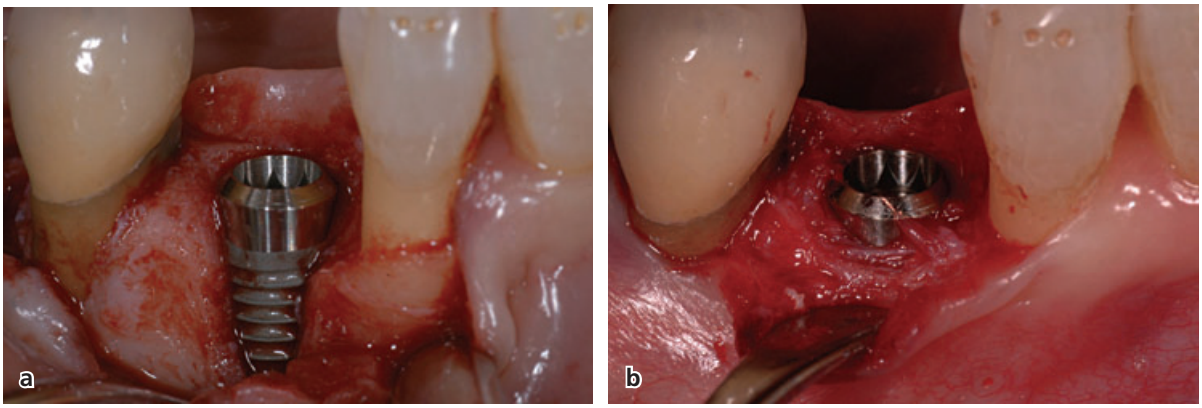

Fig. 49-5 (a) A large labial dehiscence defect at an implant in position of tooth 43. The defect is also treated by GBR applying a bioresorbable membrane and a deproteinized bovine bone mineral for membrane support. (b) The same case as in (a) at re-entry surgery. The dehiscence defect has been augmented with bone, which is covered by a thin layer of non-mineralized tissue.

obtaining a natural appearance of the bone and soft tissue contours of the alveolar ridge. Subsequently a membrane is adapted and placed to cover the supporting material and the defect. A decision has to be taken on how the membrane is fixed in place to provide the stability necessary for bone to form. This fixation may be obtained by simply adapting the membrane to the intact walls of the bone defect, by tacking it with pins, by suturing it to the soft tissues, or by adapting it to the implant. Thereafter, the flap is adapted and sutured to allow for submerged or transmucosal healing of the implant site. Following 4–6 months of healing the former defect is filled with new bone (Fig. 49-4b). The same clinical protocol is applied for the treatment of larger dehiscence defects (Fig. 49-5).

Horizontal defects (class IV)

The autogenous block transplant represents the gold standard for treatment of horizontal ridge defects (Becker *et al*. 1994a; Buser *et al*. 1996; von Arx *et al*. 2001). Both intraoral and extraoral harvesting procedures have been described. Intraoral sites have been preferred, especially for the treatment of localized bone defects in partially edentulous jaws (Joshi & Kostakis 2004). Intraorally, common donor sites include the chin and the area of the retromolar region in the mandible. Intraoral harvesting procedures also have disadvantages, such as limited availability of bone graft volume, complications including altered sensation of teeth, neurosensory disturbances, wound dehiscence, and infection (Nkenke *et al*. 2001; von Arx *et al*. 2005).

The advantages of autogenic block grafts include the large scientific and clinical documentation, handling properties, stabilization of the area intended for regeneration due to the possibility of securing the grafts in place by metal screws, and the optimal biologic properties. The disadvantages include donor site morbidity, technically difficult harvesting procedures, and the impossibility of using the graft as a carrier for growth factors.

Clinical procedures require harvesting of the graft, adaptation to the defect area, fixation by screws, coverage with a membrane, and primary closure with the soft tissue flap. During a second surgical intervention after 4–9 months of healing, the result of the

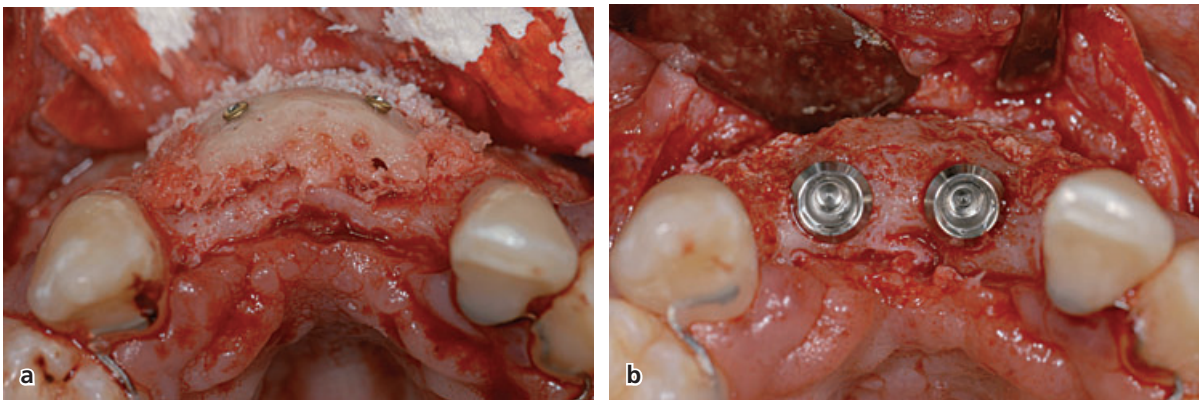

Fig. 49-6 (a) An extensive bone defect in the anterior maxilla. A bone graft harvested from the chin is adapted and secured in place by titanium screws. In the periphery bone chips and deproteinized bovine bone mineral are added to improve contouring of the area. Subsequently, a bioresorbable collagen membrane is placed to cover the area intended for bone augmentation and the flap is closed. (b) The same case as in (a) at the time of implant placement. Note the large volume of bone available for implant placement and as a basis for achieving an optimal esthetic result.

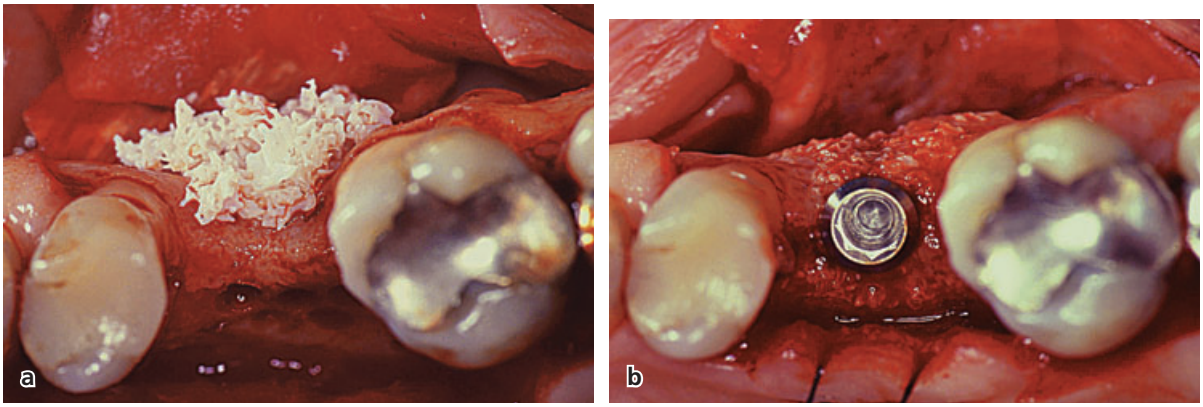

Fig. 49-7 (a) A lateral bone defect at a single tooth gap. A block of deproteinized bovine bone mineral and chips generated from this block are placed to support a bioresorbable collagen membrane before the flap is closed. (b) The same case as in (a) at the time of implant placement. Note the substantial volume of bone available for implant placement as a basis for achieving an optimal result.

augmentation procedure can be seen and implants can be placed (Fig. 49-6).

As described above recent case reports and case series have described the use of deproteinized bovine bone mineral in conjunction with bioresorbable collagen membranes and found successful bone augmentation at lateral ridge defects (Zitzmann *et al*. 2001a; Friedmann *et al*. 2002; Hammerle *et al*. 2008). During the second surgical intervention implants could be placed in a prosthetically optimal position in most situations (Fig. 49-7).

These newer studies indicate that, provided the appropriate protocols are developed, ridge augmentation without the use of autogenous block grafts could become a standard procedure.

Vertical defects (class V)

The indications for vertical ridge augmentation include situations where the remaining bone height is too small for proper anchorage of oral implants, where unfavorable crown:implant ratios will result, and where unfavorable esthetic outcomes are expected from the lack of remaining hard and soft tissues.

The same procedures are recommended for patient treatment as described for the class IV defects with the exception that the bone block is partially or fully placed on to the ridge in order to gain bone in a vertical direction. Other than that the materials and the techniques applied are identical to the ones for lateral bone augmentation using bone grafts. Obviously, flap adaptation is more difficult due to the increased volume intended for regeneration, which needs to be covered by the flap.

It appears that varying amounts of bone height may be gained, depending on the clinical treatment protocol. The factors critical for success or failure have not been elucidated. In addition, no data is presently available indicating whether there is a biologically limited maximum of bone gain, and if so, what parameters influence this maximum.

Future developments

Progress in every medical discipline is largely based on better understanding of the physiologic and pathologic mechanisms governing health, disease, and healing. This understanding is a key step to the development of new strategies and materials in medicine. The aim is to develop more effective techniques that predictably promote the body's natural ability to regenerate lost tissue instead of using external materials to repair lost tissue. The most intriguing method currently being investigated is the application of polypeptide or natural proteins that regulate wound and tissue regeneration.

Growth and differentiation factors

In the past decade a number of basic science experiments and clinical studies have clarified biologic mechanisms of several growth and differentiation factors on the regeneration of oral soft and hard tissue (Howell *et al*. 1997a). Growth and differentiation factors currently believed to contribute to periodontal and alveolar ridge augmentation include platelet-derived growth factor (PDGF), insulin-like growth factor (IGF-I and IGF-II), transforming growth factor beta (TGF-β), fibroblast growth factor (a-FGF and b-FGF), and bone morphogenetic proteins (BMPs 1–15). Among these bone morphogenetic protein is the most widely studied in the dental literature. BMP, by chemotaxis, triggers proliferation and differentiation of mesenchymal progenitor cells (Wozney *et al*. 1988). Recombinant biotechnology has enabled characterization of at least 15 BMPs and production of quantities of purified recombinant protein for therapeutic application (Groeneveld & Burger 2000). Recombinant human BMP-2 (rhBMP-2) has been found to exhibit very high osteogenic activity in experimental (Sigurdsson *et al*. 1996; Hanisch *et al*. 1997; Cochran *et al*. 1999; Higuchi *et al*. 1999; Jung *et al*. 2005) and in clinical studies (Boyne *et al*. 1997; Howell *et al*. 1997a; Jung *et al*. 2003, 2005).

Delivery systems for growth and differentiation factors

The regenerative potential of growth and differentiation factors depends upon the carrier material (Sigurdsson *et al*. 1996; Hunt *et al*. 2001). The effect of such proteins is dependent upon a carrier material, which serves as a delivery system and as a scaffold for cellular in-growth (Ripamonti & Reddi 1994).

Collagen has extensively been studied as a carrier material for growth factors applied to promote bone formation in different kinds of indications (Nevins *et al*. 1996; Boyne *et al*. 1997; Howell *et al*. 1997b). Different studies (Barboza *et al*. 2000) using rhBMP-2 in an absorbable collagen sponge (ACS) for alveolar ridge augmentation gained only small amounts of bone. The investigators concluded that the compromised results were due to the failure of the ACS to adequately support the supra-alveolar wound space. In order to overcome this lack of structural strength rh-BMP-2/ACS has been combined with hydroxyapatite (HA) in an experiment attempting lateral ridge augmentation (Barboza *et al*. 2000). In contrast to rhBMP-2/ACS alone, a significant clinical improvement in ridge width was observed with the addition of HA to rhBMP-2/ACS. However, the HA particles were largely encapsulated by fibrous tissue and they appeared partially to obstruct bone formation. The investigators concluded that space maintenance in BMP-induced bone formation is an important factor (Barboza *et al*. 2000). A recent study demonstrated that the results of GBR procedures in humans could be improved by the addition of rhBMP-2 to a xenogenic bone substitute mineral. This improvement was documented by a higher degree of bone maturation and an increased graft–bone contact fraction at the BMP-treated sites (Jung *et al*. 2003). Synthetic polymers, on the other hand, can reproducibly be fabricated and the growth factors can be incorporated under controlled manufacturing conditions (Weber *et al*. 2002).

In a recent study in dogs implants were placed in the mandible and peri-implant infra-osseous defects were prepared (Jung *et al*. 2007). The defects were grafted with a synthetic polyethylene glycol (PEG) matrix, which was either empty or contained a 35 amino acid peptide of parathyroid hormone (cys-$PTH_{1–34}$). Control defects were grafted with autogenous bone or left empty. One and three months later, the sites with PEG and PTH showed similar amounts of bone formation compared with the sites grafted with autogenous bone. In the two other groups less bone formation was observed. It was concluded that the synthetic PEG hydrogel containing $PTH_{1–34}$ was a suitable matrix-differentiation factor system to obtain bone regeneration.

However, the ideal carrier material, which is easy to apply, able to provide space for regeneration, bioresorbable, and allows controlled release of the bioactive molecules, has not yet been discovered. Further research is needed to determine the ideal combination of factors for regeneration, the best delivery system, and the optimum doses.

Membrane developments

The benefit of using both barrier membranes and BMP for bone augmentation remains controversial (Linde & Hedner 1995; Howell *et al*. 1997b; Cochran *et al*. 1999; Jung *et al*. 2003). It was found that the presence of a non-resorbable e-PTFE membrane initially (4 weeks) inhibited bone formation with rhBMP-2 but did no longer do so at later time points (12 weeks) (Cochran *et al*. 1999). It has been shown that bone induction by rhBMP-2 occurs at early time points and that rhBMP-2 undergoes rapid clearance. Hence, the use of a membrane may potentially reduce

the bone-forming effect of rhBMP-2 due to limited availability of inducible cells. Another animal study in rats reported no difference in bone healing with the combination of rhBMP-2 and an e-PTFE membrane compared to rhBMP-2 alone (Linde & Hedner 1995). From a clinical point of view, the use of a membrane simplifies the handling and stabilization of the bone substitute mineral at the time of bone augmentation, but from a biologic point of view the use of a membrane may block the recruitment of cells from the environment.

The question whether or not bioactive molecules are best used in conjunction with membranes or in the absence of membranes has not yet been answered conclusively. On the one hand, it is reasonable to apply them as adjunctive agents to GBR therapy in order to accelerate membrane-guided bone regeneration. On the other hand, it may be hypothesized that their mode of action is best taken advantage of when membranes are not applied simultaneously, thus allowing all inducible cells from the wound environment access to the area to be regenerated.

Common to all presently used membranes is the fact that their fabrication is completed before they are delivered for patient use. Consequently, they are made available in standard sizes and forms and need to be adapted to the patient's individual situation. Alternatively, a membrane could be custom made directly for an individual defect intra-operatively, using a material different from the ones mentioned above.

Hydrogels made of PEG fulfill a number of criteria required to serve as synthetic membranes which form *in situ*. Polyethylene glycol has been shown to be highly biocompatible (Pang 1993; Working *et al*. 1997). It is presently approved for several pharmaceutical applications (Zalipsky & Harris 1997) and as medical devices, e.g. a sprayable adhesion barrier.

In a recent study in rabbits, four evenly distributed craniotomy defects, 6 mm in diameter, were prepared in the area of the right and left parietal and frontal bones (Jung *et al*. 2006). All sites were grafted with highly porous hydroxyapatite (HA)/tricalciumphosphate (TCP) granules. The sites were covered towards both the internal and external soft tissue either with e-PTFE or PEG membranes or left uncovered as control sites. A similar amount of newly formed bone was observed within the former defect space at e-PTFE- and PEG-treated sites. These findings demonstrated that the PEG membrane formed *in situ* could be successfully applied for bone regeneration.

Future outlook

Further developments in bone augmentation procedures can be related to either the simplification of clinical handling or influencing of biologic processes. In order to simplify clinical handling new materials should be comprised of a matrix with optimal cell in-growth capacities and with good mechanical properties providing space for tissue regeneration. No membrane and no specific procedures for mechanical fixation should be necessary. This would reduce the technique sensitivity and therefore increase the predictability of bone augmentation.

From a biologic point of view the growth and differentiation factors may induce earlier bone growth into the area to be regenerated. Thus, the area of regeneration would be stabilized earlier. Furthermore, the use of such materials would allow treatment of extensive bone defects. At present, large bone defects are regularly augmented with autogenous block grafts and membranes. The use of synthetic materials would result in lower surgical risks and lower morbidity in the augmentation procedure and would represent an important step forward in simplifying bone regeneration techniques.

Acknowledgments

The authors express their special thanks to Dr. Gianandrea Hälg and to Samantha Merki for valuable support in the preparation of this chapter.

Chapter 50

Elevation of the Maxillary Sinus Floor

Bjarni E. Pjetursson and Niklaus P. Lang

Introduction

Elevation of the maxillary sinus floor was first reported by Boyne in the 1960s. Fifteen years later, Boyne and James (1980) reported on elevation of the maxillary sinus floor in patients with large, pneumatized sinus cavities as a preparation for the placement of blade implants. The authors described a two-stage procedure, where the maxillary sinus was grafted using autogenous particulate iliac bone at the first stage of surgery. In the second stage of surgery after approximately 3 months, the blade implants were placed and later used to support fixed or removable reconstructions (Boyne & James 1980).

As implant dentistry developed, it became more evident that the posterior maxillary region was often limited for standard implant placement, since the residual vertical bone height was reduced (Fig. 50-1). An elevation of the maxillary sinus floor was an option in solving this problem. Several surgical techniques have been presented for entering the sinus cavity, elevating the sinus membrane, and placing bone grafts.

A crestal approach for sinus floor elevation with subsequent placement of implants was first suggested (Tatum 1986). Utilizing this crestal approach, a "socket former" for the selected implant size was used to prepare the implant site. A "green-stick fracture" of the sinus floor was accomplished by hand tapping the "socket former" in a vertical direction. After preparation of the implant site, a root- formed implant was placed and allowed to heal in a submerged way.

Summers (1994) later described another crestal approach, using tapered osteotomes with increasing diameters (Fig. 50-2). Bone was conserved by this osteotome technique because drilling was not performed. Adjacent bone was compressed by pushing and tapping as the sinus membrane was elevated. Then, autogenous, allogenic or xenogenic bone grafts were added to increase the volume below the elevated sinus membrane. A follow-up of 173 press-fit submerged implants, placed using this technique, reported a success rate of 96% at 18 months after loading (Rosen *et al*. 1999).

Today, two main procedures of sinus floor elevation for dental implant placement are in use: a two-stage technique using the lateral window approach, and a one-stage technique using a lateral or a crestal approach. The decision to use the one- or the two-stage technique is based on the amount of residual bone available and the possibility of achieving primary stability for the inserted implants.

Treatment options in the posterior maxilla

Implant placement in the posterior maxilla remains a challenge. Reduced bone volume due to alveolar

Fig. 50-1 Radiograph of a posterior maxilla, showing reduced residual bone height which will not allow standard implant placement.

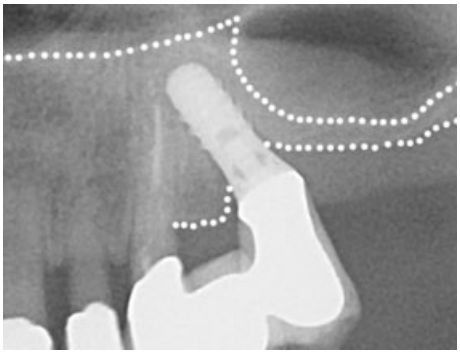

Fig. 50-3 Radiograph showing a tilted implant placed in the position of 25 to avoid entering the sinus cavity. After remodeling, the bone level on the distal aspect of the implant is more apical than at the time of implant placement. This may lead to increased probing pockets depths around tilted implants. (The dotted lines represent the outlines of the residual bone.)

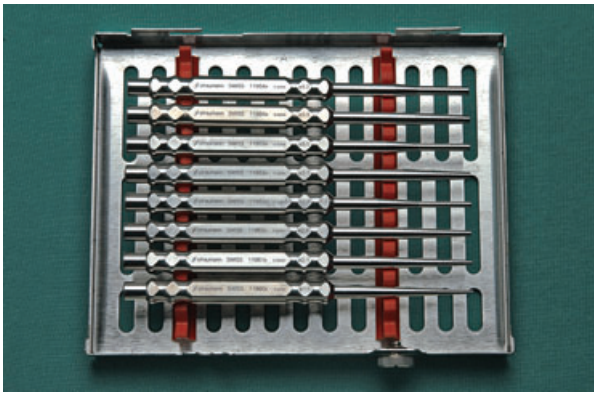

Fig. 50-2 In 1994, Summers introduced a set of tapered osteotomes with different diameters to compress and push the residual bone from the implant preparation into the sinus cavity and to elevate the sinus membrane.

Fig. 50-4 Patient with a shortened dental arch. Three implants were placed in the positions of 15, 14, and 25 without elevating the maxillary sinus floor and, consequently, the patient was restored to the second premolar.

bone resorption and pneumatization of the sinus cavity makes it more difficult to place implants to support a dental prosthesis.

Several treatment options have been used in the posterior maxilla to overcome the problem of inadequate bone quantity. The most conservative treatment option would be to place short implants to avoid entering the sinus cavity. For placement of short implants, there is still a need for at least 6 mm of residual bone height, however. Another way of avoiding grafting the maxillary sinus would be to place tilted implants in a position mesial or distal to the sinus cavity if these areas have adequate bone (Fig. 50-3). Furthermore, extra-long zygomatic implants can be placed in the lateral part of the zygomatic bone.

However, in patients with appropriate residual bone height, minor augmentation of the sinus floor can be accomplished via the crestal approach using the osteotome technique (Summers 1994; Rosen *et al*. 1999; Ferrigno *et al*. 2006). The problem of inadequate bone height may be overcome by elevating the maxillary sinus floor via the closed technique to provide sufficient quantity of bone for dental implant placement.

The most invasive treatment option in the posterior maxilla is the one- or two-stage sinus floor elevation with a lateral approach. By mastering these different methods, most edentulous areas in the maxilla can by restored with implant-supported reconstructions. The concept of a shortened dental arch must also be kept in mind. The work of Käyser (1981) has shown that patients maintained adequate (50–80%) chewing capacity with a premolar occlusion (Fig. 50-4).

Sinus floor elevation with a lateral approach

Anatomy of the maxillary sinus

The maxilla consists of a variety of anatomic structures, including the maxillary sinus, the lateral nasal

walls, the pterygoid plates, associated vasculature structures, and teeth.

The maxillary sinus is pyramidal in shape. The base of the pyramid is the medial wall of the sinus that is also the lateral wall of the nasal cavity, and its apex is pointed towards the zygomatic bone. The roof of the sinus is also the floor of the orbit. The sinus has a non-physiologic drainage port high on the medial wall (maxillary ostium) that opens into the nasal cavity between the middle and lower nasal conchae.

The maxillary sinus maintains its overall size while the posterior teeth remain in function. It is, however, well known, that the sinus expands with age, and especially when posterior teeth are lost. The average volume of a fully developed sinus is about 15 ml but may range between 4.5 and 35.2 ml. The sinus cavity expands both inferiorly and laterally, potentially invading the canine region. This phenomenon is possibly the result of atrophy caused by reduced strain from occlusal function. One or more septa termed "Underwood's septa" may divide the maxillary sinus into several recesses.

The overall prevalence of one or more sinus septa is between 26.5% and 31% (Ulm *et al*. 1995; Kim *et al*. 2006) and is most common in the area between the second premolar and first molar. Edentulous segments have a higher prevalence of sinus septa than dentate maxillary segments.

The sinus is lined with respiratory epithelium (pseudo-stratified ciliated columnar epithelium) that covers a loose, highly vascular connective tissue (Fig. 50-5). Underneath the connective tissue, immediately next to the bony walls of the sinus, is the periosteum. These structures (epithelium, connective tissue, and periosteum) are collectively referred to as the Schneiderian membrane.

The blood supply to the maxillary sinus is derived primarily from the maxillary artery and, to a lesser degree, from the anterior ethmoidal and superior labial arteries. The sinus floor receives blood supply from the greater/lesser palatine and sphenopalatine arteries. These vessels penetrate the bony palate and ramify within the medial, lateral, and inferior walls of the sinus. The posterior superior alveolar artery has tributaries that perfuse the posterior and lateral walls. The posterior superior alveolar and infraorbital arteries anastomose in the bony lateral wall, on average 19 mm from the alveolar bone crest (Solar *et al*. 1999). The dense vascular network of the maxilla reduces after tooth loss and with increased age. The vast majority of the blood vessels in the maxilla (70–100%) come from the periosteum (Chanavaz 1990, 1995). Venous drainage is into the sphenopalatine vein and pterygomaxillary plexus. Neural supply comes from branches of the maxillary nerve.

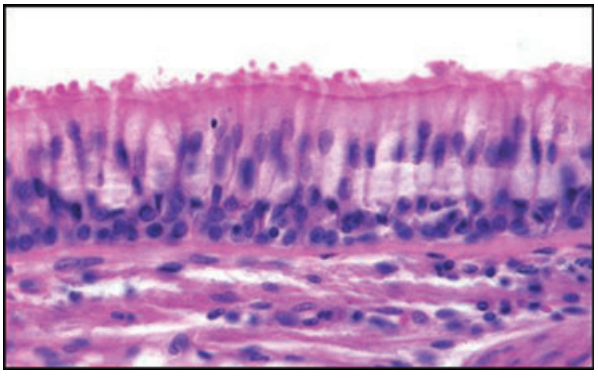

Fig. 50-5 Pseudostratified, ciliated columnar epithelium.

Non-hemolytic and alpha-hemolytic streptococci and *Neisseria* spp. are the normal commensal microbiota of the maxillary sinus. Staphylococci, diphtheroids, *Hemophilus* spp., pneumococci, *Mycoplasma* spp., and *Bacteroides* spp. are also found in varying amounts (Timmenga *et al*. 2003).

The healthy maxillary sinus is self-maintaining by postural drainage and actions of the ciliated epithelial lining, which propels bacteria toward the ostium. The maxillary sinus also produces mucus containing lysozymes and immunoglobulins. The significant vascularity of the Schneiderian membrane helps maintain its healthy state by allowing lymphocytic and immunoglobulin access to both the membrane and the sinus cavity.

The fact that the maxillary sinus opening to the nasal cavity is not in the lower part of the sinus (where a graft may be placed) is important and provides an anatomic rationale to sinus floor elevation, as the grafting procedure does not interfere with normal sinus function. In fact, a maxillary sinus floor elevation may improve symptoms of sinusitis/congestion by bringing the floor of the sinus closer to the drainage port.

Pre-surgical examination

Prior to planning complicated surgical procedures like elevation of the maxillary sinus floor, a thorough examination, including medical and dental history, should be obtained (see Chapters 27, 30, and 33).

The dental and periodontal status are evaluated using clinical and radiologic examination methods. The vitality of the neighbouring teeth has to be tested. The infraorbital, lateral nasal, and superior labial areas of the face must be examined regarding tenderness to palpation, swelling or asymmetry. The patient's history along with findings made during the clinical examination should provide sufficient information for diagnosing acute, allergic, and chronic sinusitis.

Pre-operative screening to assess a potential pathologic condition in the maxillary sinus should include radiographic examination, such as e.g. orthopantomography (OPT), tomography, computerized tomography (CT) scans or aquitomo-scans (see Chapter 28).

Before performing the sinus floor elevation surgery, all dentate patients should receive cause-related therapy (see Chapters 34–37).

Medical or surgical therapy of sinusitis, and removal of polyps and tumors must be completed prior to sinus floor elevation.

Indications and contraindications

The main indication for maxillary sinus floor elevation utilizing a lateral approach is reduced residual bone height, which does not allow standard implant placement or placement of implants in combination with minor sinus floor elevation using the osteotome technique. In cases of reduced bone height due to alveolar bone resorption and pneumatization of the sinus cavity the so-called lateral approach, with or without horizontal bone augmentation, is indicated.

Contraindications for sinus floor elevation can by divided into three groups: intraoral contraindications, medical conditions, and local contraindications.

The *medical* contraindications include: chemotherapy or radiotherapy of the head and neck area at the time of sinus floor elevation or in the preceding 6 months depending on the field of radiation; immunocompromised patients; medical conditions affecting bone metabolism; uncontrolled diabetes; drug or alcohol abuse; patient non-compliance; and psychiatric conditions.

Whether or not smoking is an absolute contraindication for maxillary sinus floor elevation remains controversial. In a case series, Mayfield and coworkers (2001) evaluated survival of implants placed in combination with bone augmentations (horizontal, vertical, and sinus elevations). The survival rate of these implants was 100% for non-smokers compared to only 43% for smokers after 4–6.5 years of functional loading (Mayfield *et al*. 2001). This reduced survival rate has been corroborated by several other authors (Bain & Moy 1993; Jensen *et al*. 1996; Gruica *et al*. 2004). However, a large study evaluating 2132 implants after sinus floor elevation with simultaneous implant placement found conflicting results (Peleg *et al*. 2006). Two hundred and twenty-six sinus floor elevations (627 implants) were performed on smokers, and 505 sinus floor elevations (1505 implants) on non-smokers. After a follow-up time of up to 9 years, the survival rate of the implants was 97.9%, and there were no statistically significant differences between survival rates in smokers and in non-smokers.

Alteration of the nasal–maxillary complex that interferes with normal ventilation as well as the mucociliary clearance of the maxillary sinus, may be a contraindication for sinus floor elevation. However, such abnormal conditions may be clinically asymptomatic or only present with mild clinical symptoms. These conditions include viral, bacterial, and mycotic rhinosinusitis, allergic sinusitis, sinusitis caused by intra-sinus foreign bodies, and odontogenic sinusitis resulting from necrotic pulp tissue. All odontogenic, periapical, and radicular cysts of the maxillary sinus should be treated prior to sinus floor elevation.

A sinus floor elevation under any of the above conditions may disturb the fine mucociliary balance, resulting in mucus stasis, suprainfection or a subacute sinusitis.

Absolute local contraindications for sinus floor elevation are: acute sinusitis; allergic rhinitis and chronic recurrent sinusitis; scarred and hypofunctional mucosae; local aggressive benign tumors; and malignant tumors.

Surgical techniques

The original Caldwell-Luc technique, commonly referred to as the lateral window or lateral approach, describes an osteotomy prepared in a superior position just anterior to the zygomatic buttress. Two other positions have also been described: a mid-maxillary position between the alveolar crest and zygomatic buttress area, and a low anterior position near the level of the existing alveolar ridge (Lazzara 1996; Zitzmann & Scharer 1998). The technique described in this chapter is a modification of these techniques:

- A presurgical rinse with chlorhexidine 0.1% is performed for a period of 1 minute.
- Local anesthesia is delivered buccal and palatal to the surgical area.
- The initial incision is midcrestal extending well beyond the planned extension of the osteotomy. The incision is carried on forward beyond the anterior border of the maxillary sinus. Releasing incisions are made anteriorly extending into the buccal vestibulum to facilitate reflection of a full-thickness mucoperiosteal flap.
- A mucoperiosteal flap is raised slightly superior to the anticipated height of the lateral window.
- After the lateral sinus wall has been exposed, a round carbide bur in a straight hand piece is used to mark the outline of the osteotomy (Fig. 50-6).

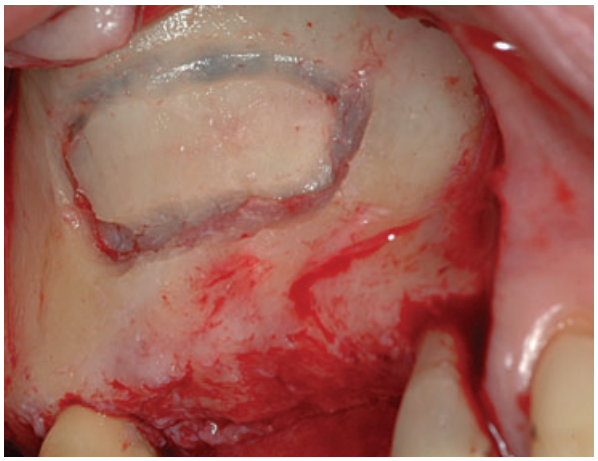

Fig. 50-6 The outline of the lateral window has been marked with a round bur.

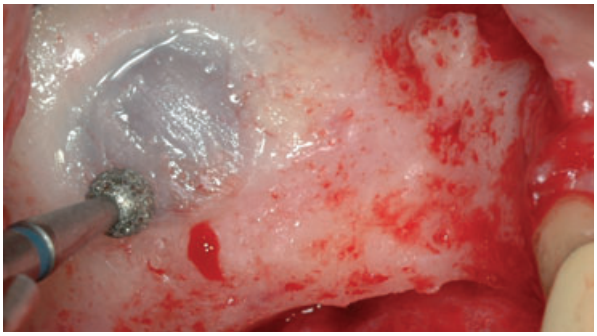

Fig. 50-7 The buccal bony plate is trimmed to a paper-thin lamella with a fine grit round diamond bur, avoiding the perforation of the sinus membrane.

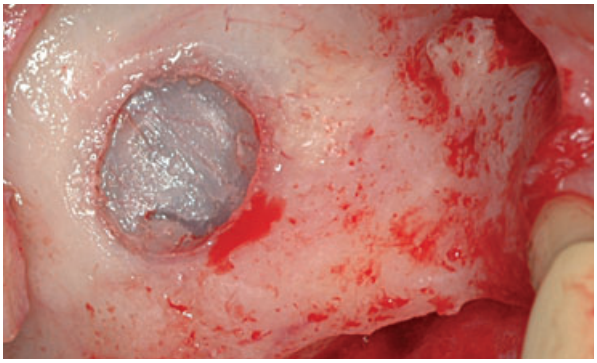

Fig. 50-9 Before elevating the sinus membrane the entire buccal bone is removed to gain access to the membrane.

Fig. 50-8 After removing the buccal bony plate, the bluish hue of the sinus membrane becomes clearly visible.

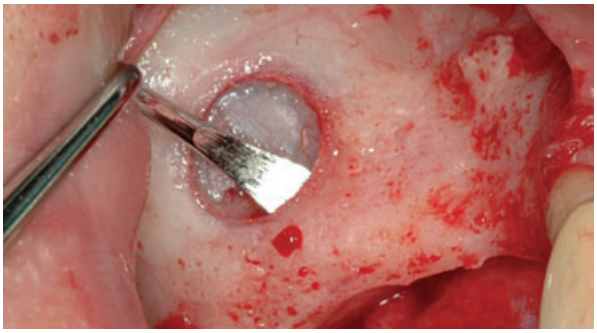

Fig. 50-10 The sinus membrane is carefully elevated using a blunt instrument. To avoid penetration, it is essential to keep contact with the underlying bone at all time during this procedure.

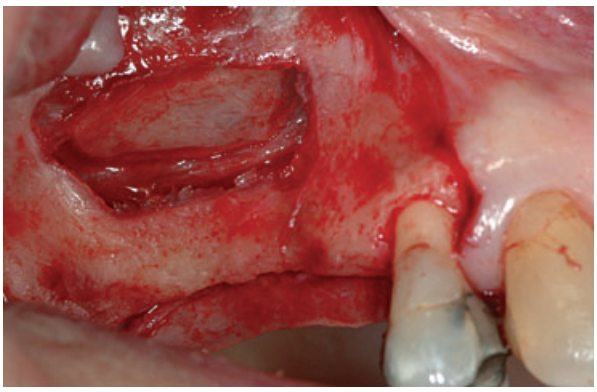

Fig. 50-11 The buccal cortical bony plate was fractured and moved upwards and inwards like a "trap-door". The cortical bony plate is delineating the superior border of the maxillary sinus compartment.

When the bone has been trimmed down to a thin bony plate, the preparation is continued with a round diamond bur (Fig. 50-7) in a straight hand piece until a bluish hue of the sinus membrane is observed (Fig. 50-8). Three methods for handling the buccal cortical bone plate have been proposed. The most common one is the thinning of the buccal bone to a paper-thin bone lamella using a round bur, and removing it prior to the elevation of the sinus membrane (Fig. 50-9). The second method is to fracture the cortical bony plate like a trap-door and use it as the superior border to the sinus compartment, leaving it attached to the underlying mucosa. Since the cortical bony plate is resistant to bone resorption this may protect the graft. The third method proposed is to remove the cortical bony plate during sinus floor elevation and replace it on the lateral aspect of the graft at the end of the grafting procedure. The rationale for this method was the notion that the lateral window would not completely heal without replacement of its cortical plate. However, healing of the lateral window by bone apposition has been demonstrated to occur without replacing the cortical bony plate (Boyne 1993).

- The next step will be chosen according to the technique used. If the buccal wall is eliminated, the sinus membrane is elevated directly with blunt instruments (Fig. 50-10). On the other hand, gentle tapping is continued until movement of the bony plate is observed if the "trap-door" technique is used. Then, in combination with the elevation of the sinus membrane in the inferior part of the sinus, the bony plate is rotated inwards and upwards to provide adequate space for grafting material (Fig. 50-11). Care should be taken not to perforate the sinus membrane.

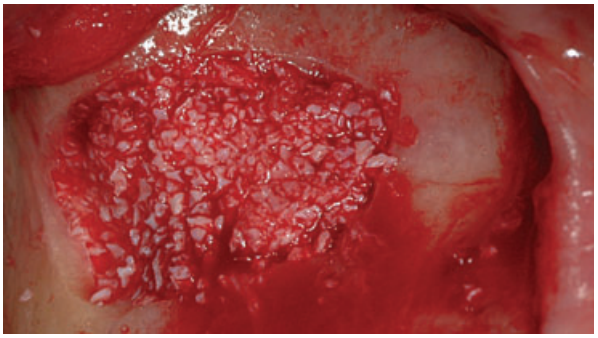

Fig. 50-12 The sinus compartment has been filled with a loosely packed 1 : 1 mixture of particulate autogenous bone and a xenograft.

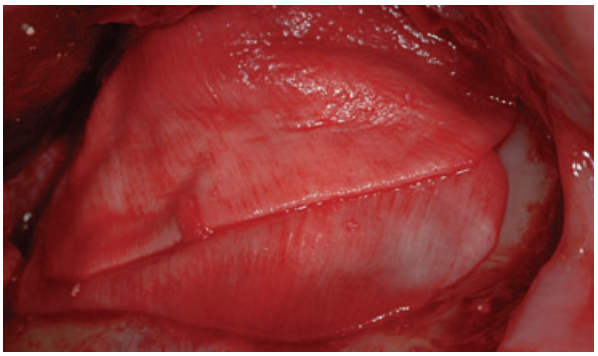

Fig. 50-13 The lateral window has been covered with single or double layer of resorbable barrier membrane.

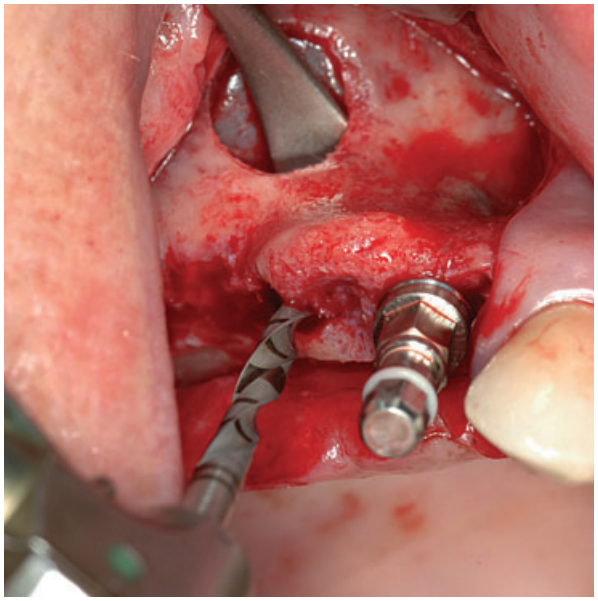

Fig. 50-14 If rotary instruments are used to prepare the implant site, the sinus membrane has to be protected with a periosteal elevator that is placed into the sinus compartment.

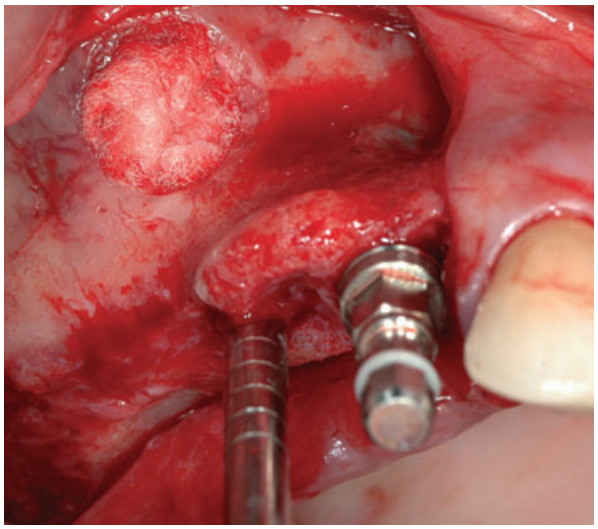

Fig. 50-15 If osteotomes are utilized to prepare the implant site, the sinus membrane can be protected by inserting sterile gauze into the sinus compartment.

Depending on the clinical condition and the surgeon's preference, a delayed (two-stage) or a one-stage sinus floor elevation simultaneously with the implant installation is chosen.

- Two-stage sinus elevation (delayed installation of the implant):
  - Grafting material is placed in the compartment made by the elevation of the sinus membrane. The grafting material should not be densely packed, because this reduces the space needed for ingrowth of newly forming bone. In addition, pressurizing the thin sinus membrane may result in a late perforation.
  - After the compartment has been filled with grafting material (Fig. 50-12), the lateral window is closed by covering it with a resorbable or a non-resorbable barrier membrane (Fig. 50-13). Subsequently, the flap is closed free of tension. In most conditions, there is a need for deep periosteal incisions to achieve tension-free closure.
- One-stage sinus floor elevation with simultaneous implant placement:
  - After the sinus membrane has been elevated, the implant sites are prepared. If rotary instruments are used, the sinus membrane has to be protected using a periosteal elevator (Fig. 50-14). Osteotomes of different diameters may be used to prepare the implant site, and then the membrane can be protected by inserting sterile gauze into the sinus compartment (Fig. 50-15).
  - The appropriate implant length is measured with a blunt depth gauge (Fig. 50-16). Before placing the implant, the grafting material is inserted into the medial part of the sinus compartment (Fig. 50-17). After implant placement (Fig. 50-18), the lateral part of the compartment is filled with grafting material (Fig. 50-19).
  - The subsequent steps coincide with those described for the two-stage procedure.

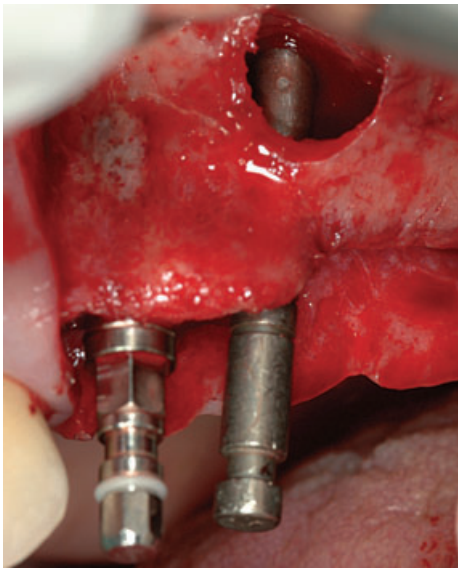

Fig. 50-16 If sinus floor elevation and simultaneous implant placement are performed, the height of the sinus compartment and implant length may be determined by inserting a blunt depth gauge into the implant site. Care must be taken not to apply too much pressure on the sinus membrane.

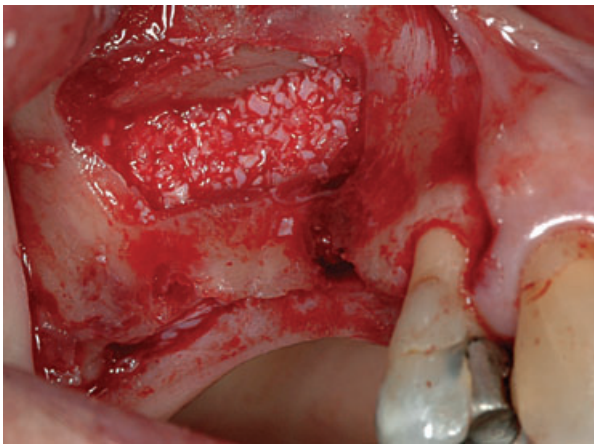

Fig. 50-17 Before placing the implants, grafting material has to be inserted into the medial part of the sinus compartment, because access to the medial part of the sinus compartment is restricted after implant installation.

The main differences between the methods used presently are the position and technique used to prepare the lateral window, the amount of sinus membrane elevation, the type of graft utilized, and the choice of one-stage or two-stage approaches.

Histomorphometric evidence of enhanced bone formation following membrane placement over the lateral window is available. In a randomized controlled clinical trial (Tarnow *et al*. 2000), a split mouth design with bilateral sinus grafts was performed for 12 patients with or without covering the lateral window using a membrane. After 12 months, histologic samples were taken through the lateral window. The mean percentage of vital bone formation was 25.5% with and 11.9% without a covering barrier.

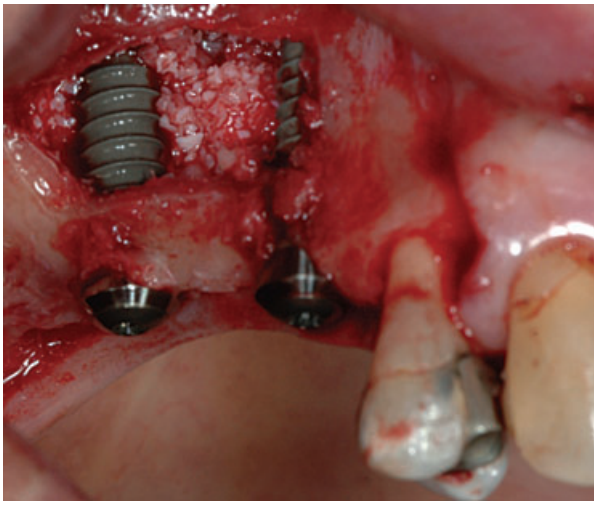

Fig. 50-18 Two implants have been installed after filling the medial part of the sinus compartment.

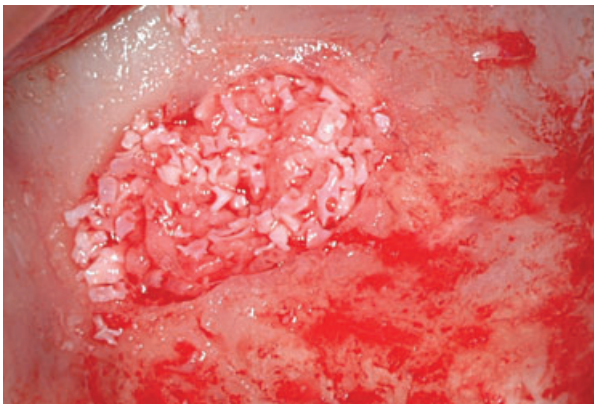

Fig. 50-19 After implant installation the lateral part of the sinus compartment is filled up with loosely packed grafting material.

Similar results were obtained in a controlled clinical trial (Froum *et al*. 1998) measuring bone formation in 113 sinuses grafted either with xenograft alone or a composite of xenograft and autograft. The mean vital bone formation was 27.6% when a membrane was used compared to 16% without.

Post-surgical care

In order to minimize post-operative pain and discomfort for the patient, surgical handling should be as atraumatic as possible. Precautions must be taken to avoid perforation of the flap and the sinus membrane. The bone should be kept moist during the surgery, and a tension-free primary flap closure is essential. The pain experienced by patients is mostly limited to the first days after surgery. Swelling and bruising of the area are usually the chief post-operative sequelae. Often, swelling and bruising extend from the inferior border of the orbit to the lower border of the mandible or even to the neck. In order to reduce swelling, it is important to cool the area

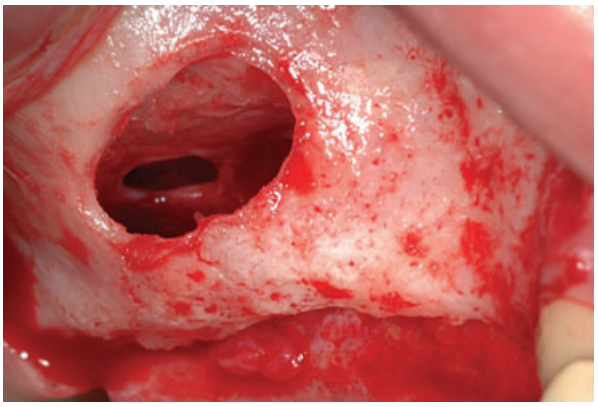

Fig. 50-20 The most frequent complication during maxillary sinus floor elevation is perforation of the sinus membrane. A medium-sized perforation can be detected after elevation of the membrane.

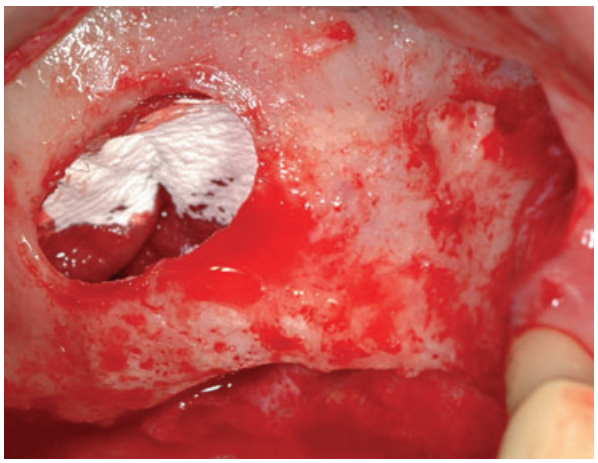

Fig. 50-21 Small- to medium-sized sinus membrane perforations may be closed by applying a resorbable barrier membrane.

with cooling pads at least for the first post-operative hours. Occasionally, minor bleeding may arise from the nose. It is important to inform the patients that some irritation in the nasal area may be expected. In the event of the need for sneezing, the nose should not be covered so that air pressure is allowed to escape. After the surgery, patients are placed on antibiotic therapy. Furthermore, antiseptic rinses with 0.1–0.2% chlorhexidine twice daily are indicated for the first 3 weeks after surgery.

Complications

When performing sinus floor elevation, the risk of complications must be considered and the appropriate treatment foreseen. The most common intra-operative complication is perforation of the sinus membrane (Fig. 50-20). Presence of maxillary sinus septa and root apices penetrating into the sinus may increase the risk of membrane perforation. The risk of perforation has been reported to be between 10 and 40% during surgery (Block & Kent 1997; Timmenga *et al*. 1997; Pikos 1999). In the event of a membrane perforation, it is recommended to elevate the membrane in the opposite direction to prevent further enlargement of the perforation. Smaller perforations (<5 mm) may be closed by using tissue fibrin glue, suturing or by covering them with a resorbable barrier membrane (Fig. 50-21). In cases of larger perforations, larger barrier membranes, lamellar bone plates or suturing may be used either alone or in combination with tissue fibrin glue to provide a superior border for the grafting material. In instances of larger perforations, where a stable superior border cannot be achieved the grafting of the maxillary sinus must by aborted and a second attempt at sinus floor elevation may be performed 6–9 months later (Tatum *et al*. 1993; van den Bergh *et al*. 2000).

Other complications that were reported during surgery included excessive bleeding from the bony window or the sinus membrane, and wound dehiscences. Iatrogenic complications include injury of the infraorbital neurovascular bundle from deep dissection to free the flap from tension or blunt trauma due to the compression of the neurovascular bundle during retraction. Implant migration, hematoma, and adjacent tooth sensitivity have also been reported.

Infection of the grafted sinuses is a rare complication. However, the risk for infection increases with a membrane perforation. Hence, it is recommended to avoid sinus grafting and simultaneous implant placement in situations of membrane perforation (Jensen *et al*. 1996). Infection of the grafted sinuses is usually seen 3–7 days post surgically and may lead to a failure of the graft. Possible complication secondary to infection may involve a parasinusitis with the spread of the infection to the orbita or even to the brain. For these reasons, infected sinus grafts must be treated immediately and aggressively. Surgical removal of the entire graft from the sinus cavity and administration of high doses of antibiotics are essential.

Sinusitis is another complication that may occur after sinus grafting. In a study (Timmenga *et al*. 1997) evaluating the function of the maxillary sinus after sinus floor elevation, 45 patients who had received 85 sinus grafts underwent endoscopic examination. Of these, five were diagnosed with sinusitis. In these five patients, the endoscopic examination revealed oversized turbinates and septal deviation. Hence, the result of this study showed that the incidence of sinusitis was low and mainly found in patients with an anatomic or functional disorder prior to the sinus grafting.

Late failure reports include chronic infection, graft exposure, loss of the entire bone graft, oro-antral fistula, ingrowth of soft tissue through the lateral window, granulation tissue replacing the graft, and sinus cysts.

Grafting materials

There are differences in opinion on the necessity of grafting material when elevating the maxillary sinus floor.

Sinus floor elevation without grafting material

Studies in monkeys (Boyne 1993) showed that implants protruding into the maxillary sinus following elevation of the sinus membrane without grafting material, exhibited spontaneous bone formation over more than half of the implant's height. Hence, protrusion of an implant into the maxillary sinus does not appear to be an indication for bone grafting. In the same study, it was also seen that the design of the implant influenced the amount of spontaneous bone formation. Implants with open apices or deep-threaded configurations did not reveal substantial amounts of new bone formation. On the other hand, implants with rounded apices tended to show spontaneous bone formation extending all around the implants if they only penetrated 2–3 mm into the maxillary sinus. However, when the same implants penetrated 5 mm into the maxillary sinus, only a partial (50%) growth of new bone was seen towards the apex of the implant.

In a clinical study (Ellegaard *et al*. 2006), 131 implants were placed using the lateral approach. The sinus membrane was elevated, implants were inserted and left to protrude into the sinus cavity. The sinus membrane was allowed to settle on to the apex of the implants, thus creating a space to be filled with a blood coagulum. After a mean follow-up time of 5 years, the survival rate of these implants was 90%. It must be kept in mind, however, that the residual bone height in this study was at least 3 mm.

Autogenous bone

Autogenous bone grafts are considered the gold standard for grafting due to their maintenance of cellular viability and presumptive osteogenic capacity. The use of autogenous grafts in sinus floor elevation was first reported by Boyne and James (1980) and Tatum (1986).

Grafts may be harvested intraorally or extraorally. Common intraoral donor sites are the maxillary tuberosity, the zygomatico-maxillary buttress, the zygoma, the mandibular symphysis and the mandibular body and ramus (Fig. 50-22). Bone may be harvested in block section or in particulate form. The extraoral donor sites that have been utilized are the anterior and posterior iliac crest, the tibial plateau, the rib, and the calvaria.

Autologous bone grafts contain bone morphogenic proteins (BMPs) that are capable of inducing osteogenic cells in the surrounding tissues. They also contain other growth factors essential for the process of graft incorporation. Processing of autograft, with grinding or morselizing, does not seem to disturb the viability of the osteogenic cells (Springer *et al*. 2004). The main source of osteogenic cells during graft consolidation is the periosteum that includes mesenchymal progenitor cells and provides a rich source of blood vessels. Osteoclasts are then required for remodeling of the graft–woven bone complex. The consolidation of the graft depends on the properties of the graft material and the osteogenic potential of the recipient bed. Initially, cortical bone grafts act as weight-bearing space fillers and remain a mixture of necrotic and viable bone for a prolonged period of time. The ideal graft material has to allow ingrowth of blood vessels and formation of bone on its surfaces for integration into the recipient bed (osteoconductivity).

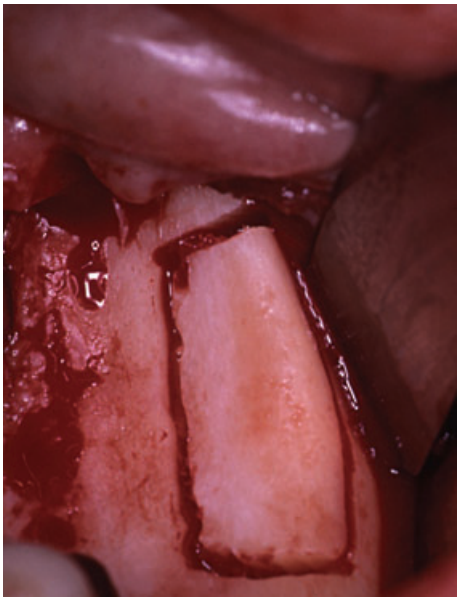

Fig. 50-22 The most suitable sites used to harvest block or particulate bone grafts intraorally are the mandibular body and the mandibular ramus.

In situations of sinus floor elevations that do not eventually receive dental implants, the bone grafts may resorb due to the lack of functional load and strain.

Bone substitutes

Loss of autografts during healing occurs when resorption of the autograft exceeds new bone formation during the consolidation phase. Thus, to overcome excessive resorption of autografts, bone substitutes that are known for their slow resorption process, are added to autografts to increase the stability of grafts during the consolidation phase.

Tricalcium phosphate was the first bone substitute to be applied successfully for sinus floor elevation (Tatum 1986). Over the years, allografts, alloplasts, and xenografts of various types have been used alone or in combination with autografts. Studies in animal models showed that the use of bone substitutes, such

Fig. 50-23 A 1 : 1 mixture of particulate autologous bone and bone substitute. The autologous bone particles include viable osteogenic cells, bone morphogenic proteins, and other growth factors. The bone substitute is supposed to decrease the resorption of the grafting material.

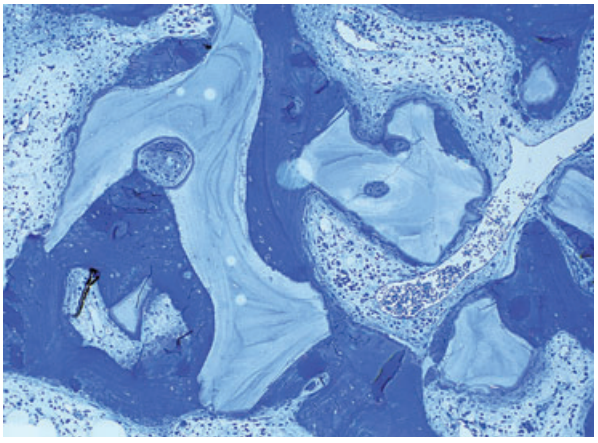

Fig. 50-24 The bovine bone mineral particles (xenograft) are mostly surrounded by new mature compact bone. No gaps can be seen at the interface between the xenograft particles and the newly formed bone. (Courtesy of Dr. Dieter D. Bosshardt, Berne.)

as bovine bone mineral, either alone or in combination with autografts, preserved the vertical height of the graft over time (Fig. 50-23). In a human study, sinus grafts consisting of autografts and demineralized allografts, were observed over a period of time. A graft resorption of up to 25% was seen. Furthermore, a more recent human study (Hatano *et al*. 2004) showed also significant reduction in graft volume, when either autogenous bone alone or a mixture of autogenous bone and xenografts were used. There is a definitive need for good long-term studies that address the stability of the different types of grafting materials in the maxillary sinuses over time.

Histologic analysis of human biopsy specimens from sinuses augmented with xenografts revealed that xenograft particles were mostly surrounded by mature compact bone (Fig. 50-24). In some Haversian canals, it was possible to observe small capillaries, mesenchymal cells, and osteoblasts in conjunction with new bone. No gaps were noted at the interface between the xenograft particles and the newly formed bone (Piattelli *et al*. 1999).

A human study (Froum *et al*. 1998) evaluating bone formation after sinus floor elevation using xenografts alone or in combination with autogenous bone and/or demineralized freeze-dried bone allografts reported statistically significant increase in vital bone formation, when as little as 20% of autologous bone was added to the bone substitutes. The mean vital bone formation was 27.1% after a healing period of 6–9 months. However, comparative studies (Hising *et al*. 2001; Hallman *et al*. 2002a,b; Valentini & Abensur 2003) reported higher survival rates for implants placed into sinuses grafted with 100% xenograft as compared to those placed in sinuses grafted with 100% autogenous bone or composite graft of xenograft and autogenous bone.

Another indication for using bone substitutes is to reduce the volume of bone that must be harvested. When a large sinus cavity is grafted with autologous bone alone, 5–6 ml of bone may be necessary. Using bone substitutes alone or in combination with autografts, the amount of autogenous bone to be harvested is greatly reduced.

Success and implant survival

Jensen and co-workers (1996) published the findings from the Consensus Conference of the Academy of Osseointegration. Retrospective data was collected from 38 clinicians who collectively performed 1007 sinus floor elevations and placed 2997 implants over a 10-year period. The majority of the implants had been followed for 3 years or more. Two hundred and twenty-nine implants were lost resulting in a overall survival rate of 90.0%. However, the database was so variable that no definitive conclusions regarding the grafting material, the type of implants, and the timing for implant placement could be drawn.

Survival of implants cannot be the sole criterion for success of maxillary sinus floor elevation. Factors, such as the pre-operative residual bone height, the long-term stability of the bone graft, and the incidence of failing two-stage sinus grafting due to graft resorption must also be considered.

Of the 900 patient records that were screened for the Consensus Conference in 1996, only 100 had radiographs of adequate quality for analysis of the residual bone height. In total, only 145 sinus grafts in 100 patients, with 349 implants, were analyzed. After a mean follow-up period of 3.2 years, 20 implants were lost. Of the implants lost, 13 were initially placed in residual bone with a height ≤4 mm, seven were placed in residual bone with a height of 5–8 mm. None of the implants placed in residual bone height of more than 8 mm was lost. There was a statistically significant difference in implant loss when residual bone height was 4 mm or less as compared to 5 mm or greater (Jensen *et al*. 1996).

A critical appraisal of the dental literature on maxillary sinus floor elevation shows that the two-stage approach (delayed implant installation) is more likely

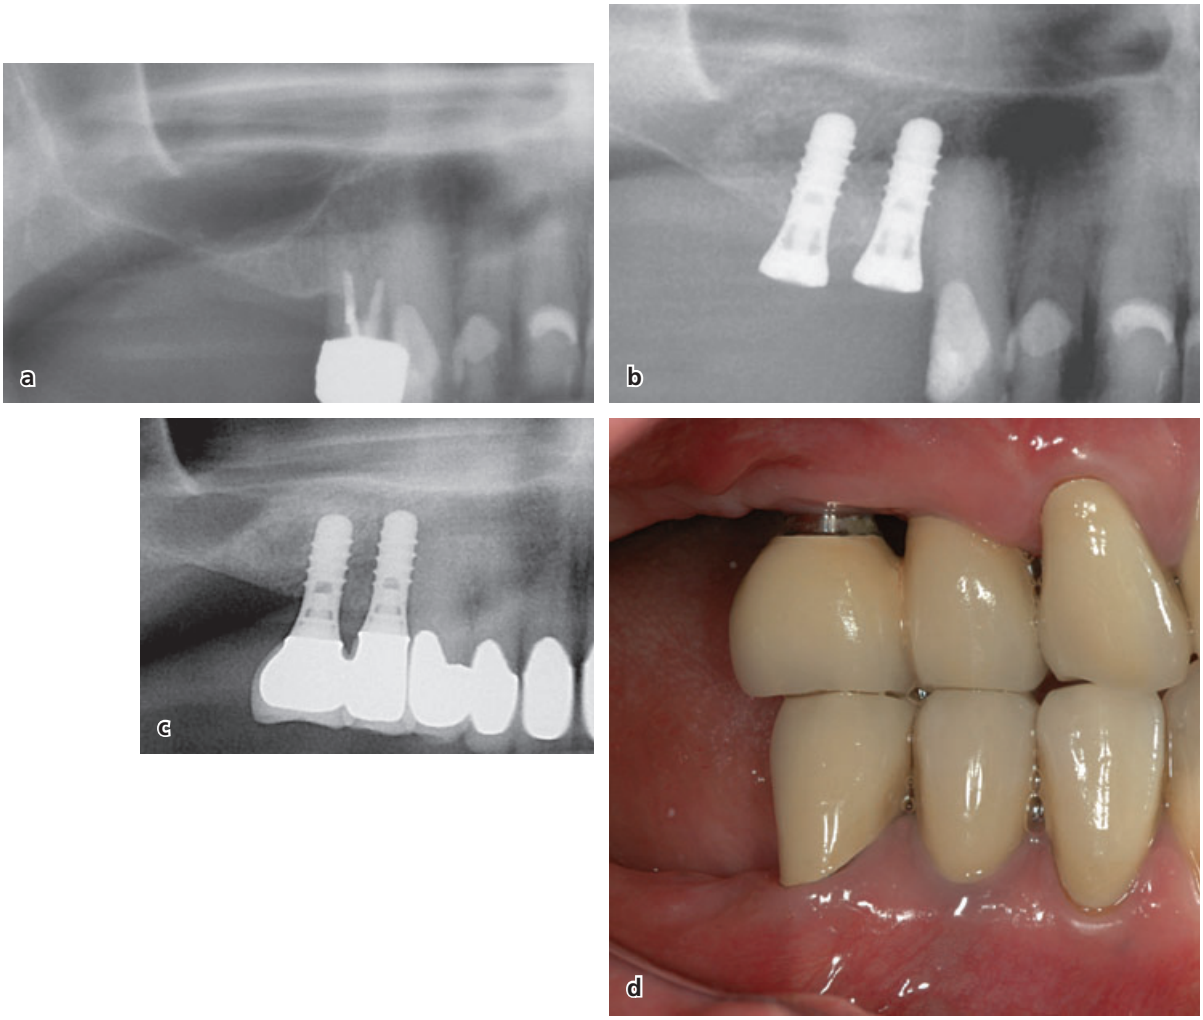

Fig. 50-25 One-stage sinus floor elevation. (a) A panoramic radiograph showing oblique inferior sinus borders and a residual bone height between 2 and 6 mm in the position of 25. (b) Two implants were placed, a standard implant placement in the position of 24 and an implant installed in combination with sinus floor elevation in the position of 25. A 1 : 1 mixture of particulate autologous bone harvested from the maxillary tuberosities and the zygomatic bone combined with bovine bone mineral was used as the grafting material. (c) OPT taken 1 year after functional loading. A new inferior border of the maxillary sinus and a stable graft volume was evident. (d) The clinical situation at the 1-year follow-up visit.

to be used in situations with less residual bone height compared to the one-stage approach (simultaneous implant placement).

The efficacy of performing a one-stage sinus floor elevation in patients whose residual alveolar bone height in the posterior maxilla was between 3 and 5 mm was assessed (Peleg *et al*. 1999). Using the modified Caldwell-Luc technique, the maxillary sinus was elevated with composite grafts of symphysal autograft and demineralized freeze-dried bone allograft in a 1 : 1 ratio. One hundred and sixty implants were placed in 63 elevated sinuses. A 100% survival rate of the implants was reported after 4 years. In a second study (Peleg *et al*. 1998) using a similar protocol on 55 implants placed into 20 elevated sinuses, the residual alveolar bone height was only 1–2 mm. All implants osseointegrated successfully, and no implants were lost after 2 years of functional loading.

Only one randomized controlled clinical trial (Wannfors *et al*. 2000) compared one- and two-stage sinus floor elevation, in 40 patients divided into groups. The residual bone height ranged from 2 to 7 mm. The one-stage protocol (Fig. 50-25) with 75 implants placed reported a survival rate of 85.5% as compared to the two-stage protocol (Fig. 50-26) with 90.5% survival rate for 74 implants placed after 1 year in function. Apparently, the risk of implant failure in grafted areas for the one-stage procedure was greater than for two-stage procedure, although the results did not reach statistical significance.

The stability of the sinus graft height was evaluated on panoramic radiographs for 349 implants. After a mean follow-up period of 3.2 years, the reduction of the graft height varied between 0.8 mm (autograft and alloplast) and 2.1 mm (autograft). This indicated that all of the graft materials appeared to be stable, with only 1–2 mm of the graft height being lost over the 3-year period (Jensen *et al*. 1996). Further studies evaluating the long-term stability of sinus grafts (Block *et al*. 1998; Hatano *et al*. 2004) yielded similar results.

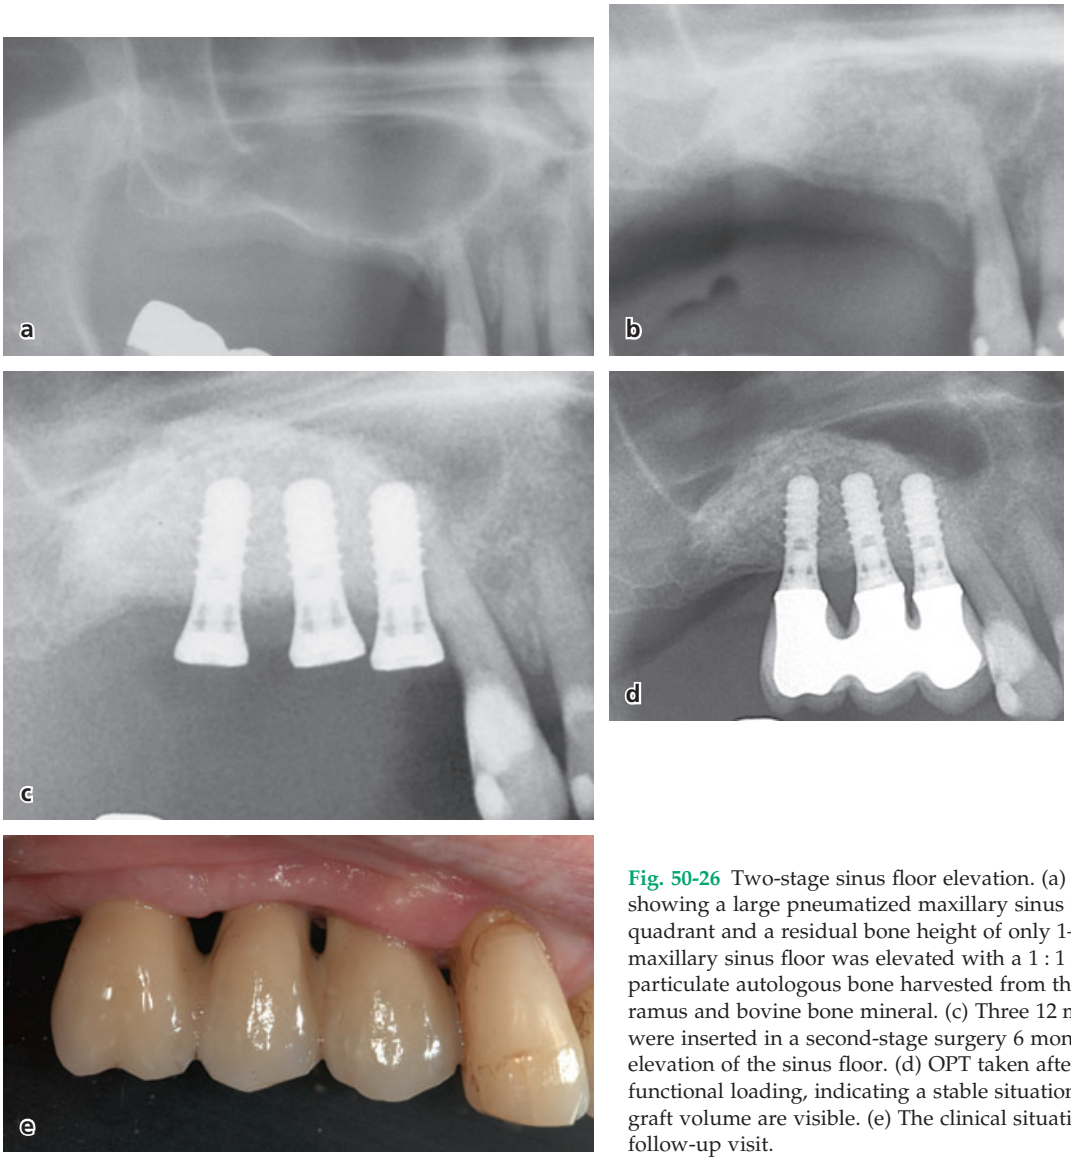

Fig. 50-26 Two-stage sinus floor elevation. (a) An OPT showing a large pneumatized maxillary sinus in the 1st quadrant and a residual bone height of only 1–2 mm. (b) The maxillary sinus floor was elevated with a 1 : 1 mixture of particulate autologous bone harvested from the mandibular ramus and bovine bone mineral. (c) Three 12 mm implants were inserted in a second-stage surgery 6 months after the elevation of the sinus floor. (d) OPT taken after 1 year of functional loading, indicating a stable situation. No changes in graft volume are visible. (e) The clinical situation at the 1-year follow-up visit.

In 2003, Wallace and Froum published a systematic review on the effect of maxillary sinus floor elevation on the survival of dental implants. The inclusion criteria were human studies with a minimum of 20 interventions, a follow-up time of 1 year of functional loading and with an outcome varied of implant survival. The main results indicated:

1. A survival rate of implants placed in conjunction with sinus floor elevation with the lateral approach varied between 61.7 and 100%, with an average of 91.8%.
2. Implant survival rates compared favorably to reported survival rates for implants placed in the non-grafted maxilla.
3. Rough-surfaced implants yielded higher survival rate than machined-surface implants when placed in grafted sinuses.
4. Implants placed into sinuses augmented with particulate autografts showed higher survival rates than those placed in sinuses that had been augmented with block grafts.
5. Implant survival rates were higher when barrier membranes were placed over the lateral window.
6. The utilization of grafts consisting of 100% autogenous bone or the inclusion of autogenous bone as a component of composite grafts did not affect implant survival.

Sinus floor elevation with the crestal approach (osteotome technique)

The osteotome technique was first developed to compress soft, type III and IV maxillary bone. The concept is intended to increase the density of bone in the maxilla leading to better primary stability of inserted dental implants.

In the maxilla, the bone crest in edentulous ridges is often narrow in the bucco-palatal dimension. This

Fig. 50-27 Set of straight and tapered osteotomes used to prepare the implant site and to elevate the maxillary sinus floor.

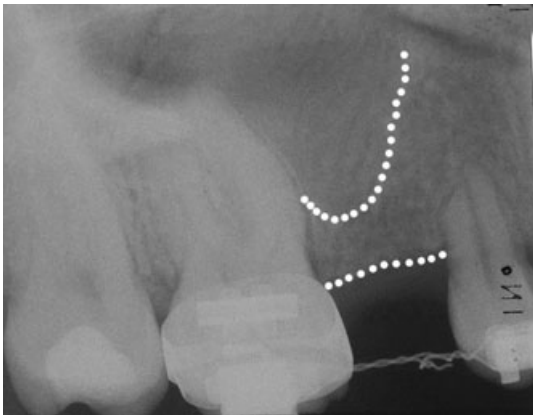

Fig. 50-28 Edentulous space in position 15. The oblique inferior border of the maxillary sinus lies at approximately 60° to the inferior border of the alveolar crest (the dotted lines represent the outlines of the residual bone). In a clinical situation like this, it is difficult to elevate the maxillary sinus floor with osteotomes. The osteotomes will first enter the sinus cavity distally at the lowest level of oblique sinus floor while still having bone resistance on the cranial level of the sinus floor. Hence, the risk of the sharp margin perforating the sinus membrane is high.

limits the possibility of standard drilling in preparing an implant site. Thus, to address this difficult situation, tapered round osteotomes of increasing diameters have been used to expand the compactible cancellous maxillary bone and gently move it in a lateral direction to increase crestal width. This procedure is known as "ridge expansion osteotome technique" and will not be addressed further in this chapter.

Tatum (1986) described the crestal approach to elevate the sinus floor. The osteotome technique for sinus floor elevation, using a set of osteotomes of varying diameters (Fig. 50-27) to prepare the implant site, was first presented by Summers (1994). The bone-added osteotome sinus floor elevation (BAOSFE), today referred to as the *Summers technique*, may be considered to be a more conservative and less invasive approach than the conventional lateral approach of sinus floor elevation. A small osteotomy is made through the crest of the edentulous ridge, at the inferior region of the maxillary sinus. This intrusion osteotomy procedure elevates the sinus membrane, thus creating a "tent". This creates space for bone graft placement. It should be noted that the bone grafts are placed blindly into the space below the sinus membrane. Hence, the main disadvantage of this technique is the uncertainty of possible perforation of the sinus membrane. However, an endoscopic study has shown that the sinus floor can be elevated up to 5 mm without perforating the membrane (Engelke & Deckwer 1997).

Indications and contraindications

Indications for the transalveolar osteotome technique (crestal approach) include a flat sinus floor with a residual bone height of at least 5 mm and adequate crestal bone width for implant installation.

The contraindications for the osteotome technique are similar to those previously described for the lateral approach. In addition, however, patients with a history of inner ear complications and positional vertigo are not suitable for the osteotome technique. As for the local contraindications, an oblique sinus floor (>45° inclination) is not suitable for the osteotome technique either (Fig. 50-28). The reason is the fact that the osteotomes first enter the sinus cavity at the lower level of an oblique sinus floor, while still having bone resistance on the higher level. In this situation, there is a high risk of perforating the sinus membrane with the sharp margin of the osteotome (Fig. 50-29).

Surgical technique

Apart from the original technique (Summers 1994), only minor modifications have been presented (Rosen *et al*. 1999; Fugazotto 2001; Chen & Cha 2005). The technique described in this chapter represents a modification of the original technique:

- Pre-surgical patient preparation includes oral rinsing with 0.1% chlorhexidine for a period of 1 minute.
- Local anesthesia is administered into the buccal and palatal regions of the surgical area.
- A mid-crestal incision with or without releasing incision is made and a full-thickness mucoperiosteal flap is raised.
- With a surgical stent or a distance indicator, the implant positions are marked on the alveolar crest with a small round bur (#1). After exactly locating the implant positions, the opening of the preparations are widened with two sizes of round burs (#2 and #3) to a diameter about half a millimeter smaller than the implant diameter that is chosen (Fig. 50-30).

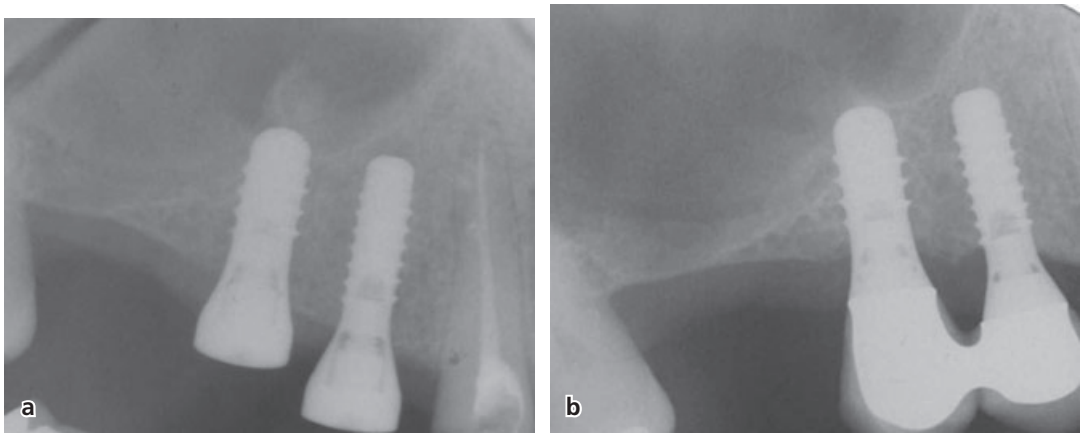

Fig. 50-29 (a) A sinus floor elevation was performed with the osteotome technique in a situation of an oblique sinus floor. The cortical bone of the sinus floor was in-fractured and rolled-up causing a perforation of the sinus membrane. Due to the membrane perforation no grafting material was utilized. (b) The same patient at the 5-year follow-up visit. The implant was stable, but only minor new bone formation is visible at the distal aspect of the implant.

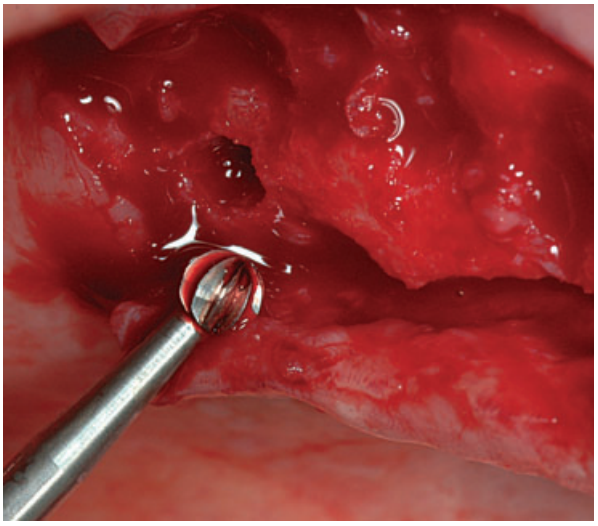

Fig. 50-30 The exact position of the implant site is first marked with a small round bur (#1) and then extended with two sizes of round burs (#2 and #3) to a diameter about 0.5–1 mm smaller than that of the implant to be installed.

- The distance from the crestal floor of the ridge to the floor of the maxillary sinus, measured prior to implant site preparation on the pre-operative radiograph, can in most cases, be confirmed at surgery by penetrating the opening of the preparation with a blunt periodontal probe through the soft trabecular bone (type III or IV bone) to the floor of the maxillary sinus.
- After confirming the distance to the sinus floor, pilot drills with small diameters (1–1.5 mm smaller than the implant diameter) are used to prepare the implant site to a distance of approximately 2 mm below from the sinus floor (Fig. 50-31a). In conditions of soft type IV bone and a residual bone height of 5–6 mm, there is usually no necessity to use the pilot drills. It is sufficient to perforate the cortical bone at the alveolar crest with the round burs.
- The first osteotome used in the implant site is a small diameter tapered osteotome (Fig. 50-32). With light malleting, the osteotome is pushed towards the compact bone of the sinus floor (Fig. 50-31b). After reaching the sinus floor, the osteotome is pushed about 1 mm further with light malleting in order to create a "greenstick" fracture on the compact bone of the sinus floor. A tapered osteotome with small diameter is chosen to minimize the force needed to fracture the compact bone.
- The second tapered osteotome, with a diameter slightly larger then the first one, is used to increase the fracture area of the sinus floor (Fig. 50-33). The second osteotome is applied to the same length as the first one.
- The third osteotome used is a straight osteotome with a diameter about 1–1.5 mm smaller than the implant to be placed (Fig. 50-34).

From this point onwards, the technique utilized in the surgical procedure depends on whether or not bone grafts or bone substitutes will be placed.

Implant placement without grafting material

- Without applying grafting material, the straight osteotome with a diameter about 1–1.5 mm smaller than that of the implant will be pushed further until it penetrates the sinus floor.
- The last osteotome to be used must have a form and diameter suitable for the implant to be placed. For example, for a cylindrical implant with a diameter of 4.1 mm, the last osteotome should be a straight osteotome with a diameter about 0.5 mm smaller than the implant diameter (3.5 mm). It is important that last osteotome only enters the preparation site once (Fig. 50-35). If several attempts have to be made in sites with soft bone (type III or IV), there is a risk of increasing the diameter of the

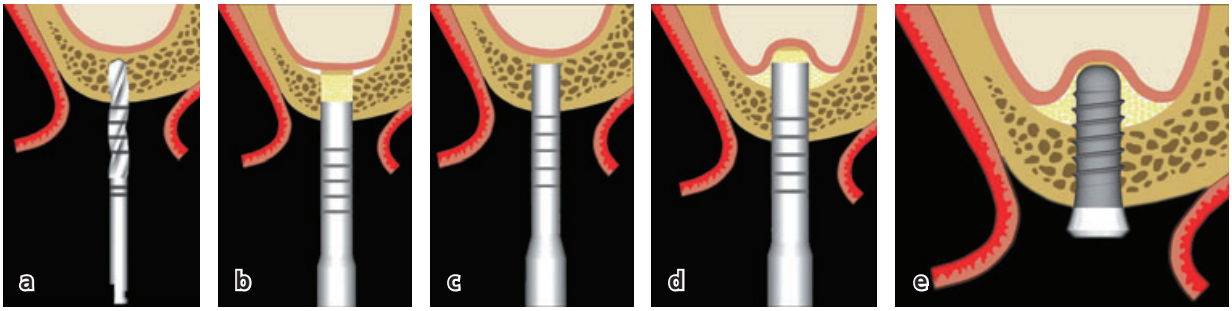

Fig. 50-31 (a) The implant site is prepared to a distance of approximately 2 mm below the sinus floor with a small diameter pilot drill. (b) After reaching the sinus floor, the osteotome is pushed approximately 1 mm further with light malleting in order to create a "greenstick" fracture on the compact bone of the sinus floor. (c) Grafting material is slowly pushed into the sinus cavity with a straight osteotome. This procedure is repeated several times. (d) The tip of the osteotome is only supposed to enter the sinus cavity after some grafting material has been pushed through the preparation site to elevate the sinus membrane. (e) The inserted implant and the grafting material maintain space below the sinus membrane.

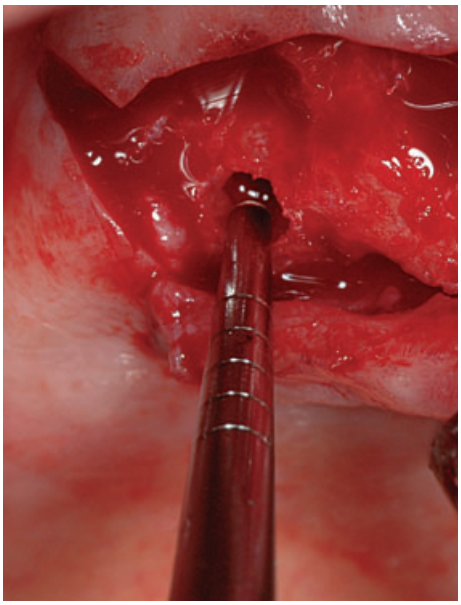

Fig. 50-32 The first osteotome used in the implant site is a small-diameter tapered osteotome. Such an osteotome is chosen to minimize the force needed to fracture the compact bone.

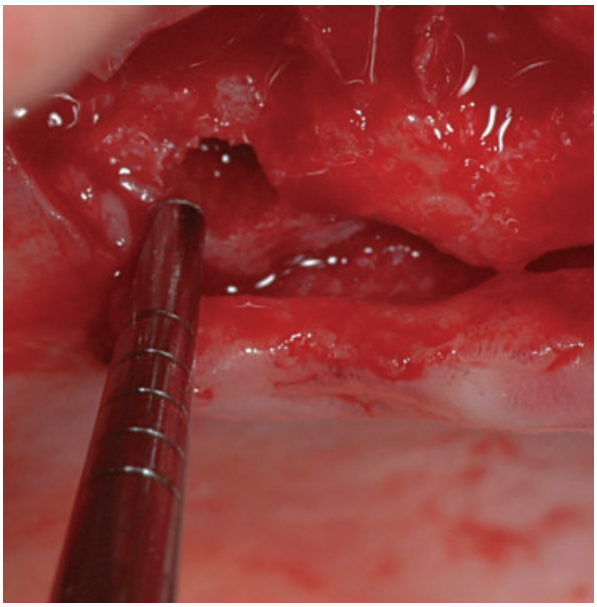

Fig. 50-33 A second osteotome, which is also tapered, but with a diameter slightly larger then the first one, is used to increase the fractured area of the sinus floor.

preparation that might jeopardize achieving good primary stability. On the other hand, if the last osteotome diameter is too small compared to the implant diameter, too much force must be used to insert the implant. By squeezing the bone, more bone trauma and, hence, greater bone resorption will occur, delaying the osseointegration process (Abrahamsson *et al*. 2004). It is thus important, especially when placing implants in sites with reduced bone volume, that the fine balance between good primary stability and traumatizing the bone is respected.

- During the entire preparation, it is crucial to maintain precise control of the penetration length. Regular osteotomes have sharp cutting edges, thus entry into the sinus cavity increases the risk of membrane perforation. The final step before placing the implant is to check that the preparation

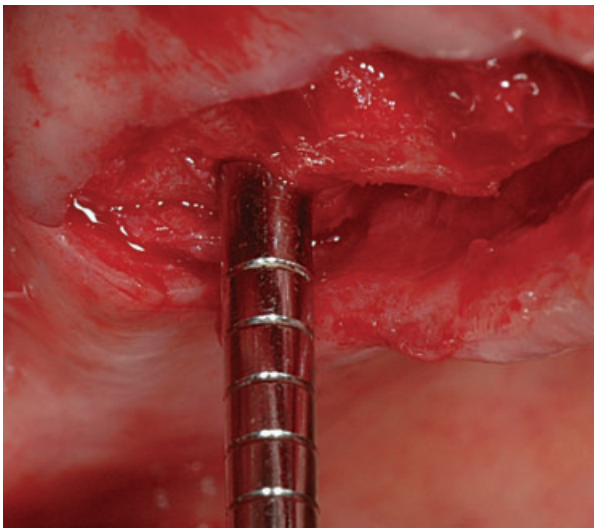

Fig. 50-34 The third osteotome utilized is a straight osteotome with a diameter about 1–1.5 mm smaller than that of the implant to be placed.

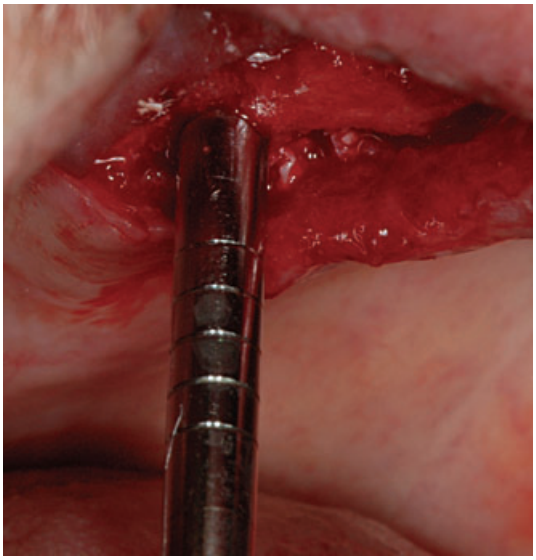

Fig. 50-35 The last osteotome to be used must have a form and diameter suitable for the implant to be placed. For example, for a cylindrical implant with a diameter of 4.1 mm, the last osteotome should be straight with a diameter approximately 0.5 mm smaller than that of the implant (3.5 mm). It is important that the last osteotome is allowed to enter the preparation site only once.

Fig. 50-36 The final step before placing the implant is to check that the preparation is patent to the planned insertion depth. An osteotome with a rounded tip or a depth gauge, for the relevant implant diameter, is pushed to the decided length.

is patent to the planned insertion depth. An osteotome with a rounded tip or a depth gauge, for the relevant implant diameter, is pushed to the decided length (Fig. 50-36).

Implant placement with grafting materials

- When performing the osteotome technique with grafting materials, the osteotomes are not supposed to enter the sinus cavity *per se*. Repositioned bone particles, grafting materials, and the trapped fluid will create a hydraulic effect moving the fractured sinus floor and the sinus membrane upwards. The sinus membrane is less likely to tear under this kind of pressure that has a fluid consistency.
- After pushing the third osteotome up to the sinus floor and before placement of any grafting material, the sinus membrane must by tested for any perforations. This is tested with the Valsalva maneuver (nose blowing). The nostrils of the patients are compressed (Fig. 50-37), and the patient blows against the resistance. If air leaks out of the implant site, the sinus membrane is perforated, and no grafting material should be placed into the sinus cavity.
- If the sinus membrane is judged to be intact, the preparation is filled with grafting material (Fig. 50-38). The grafting material is then slowly pushed into the sinus cavity with the same straight third osteotome (Fig. 50-39). This procedure is repeated four to five times (Fig. 50-31c) until about 0.2–0.3 g of grafting material has been pushed into the sinus cavity below the sinus membrane (Fig. 50-40). In the fourth and fifth time of applying grafting material, the tip of the osteotome may enter about 1 mm into the maxillary sinus cavity to test if there is resistance in the preparation site (Fig. 50-31d).
- Finally, before implant placement (Fig. 50-41), the preparation is checked for patency, as mentioned before, and the Valsalva maneuver is repeated.

Fig. 50-37 To test the sinus membrane, the nostrils of the patients are compressed and the patient is asked to blow against the resistance. If air leaks out of the implant site, the sinus membrane is perforated, and no grafting material should be placed into the sinus cavity.

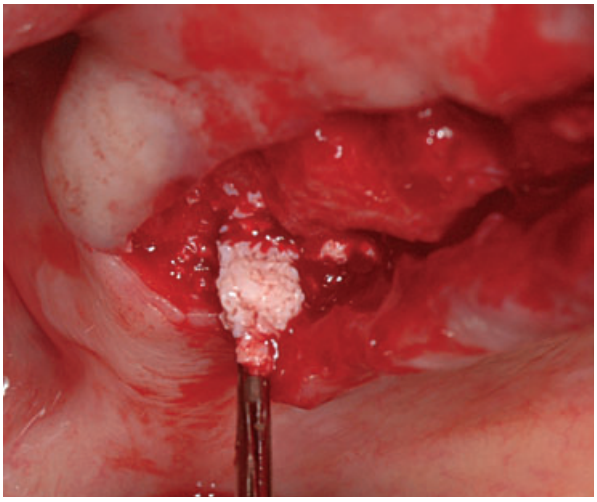

Fig. 50-38 If the sinus membrane is intact, the preparation site is filled four to five times with grafting material.

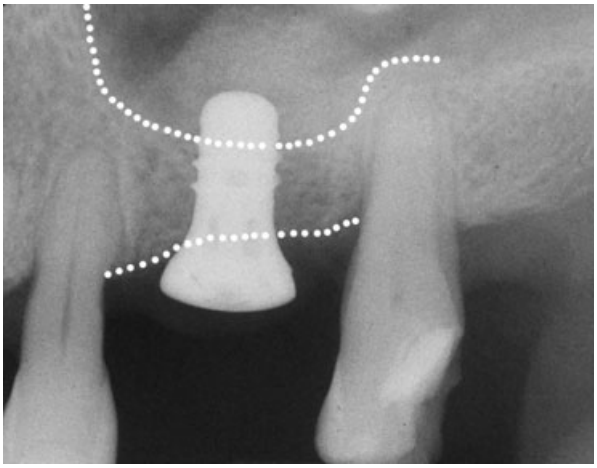

Fig. 50-40 A radiograph, taken after implant placement, showing a dome-shape configuration of the graft. In this instance, 0.25 g of grafting material (xenograft) was used to elevate the sinus membrane (the dotted lines represent the outlines of the residual bone).

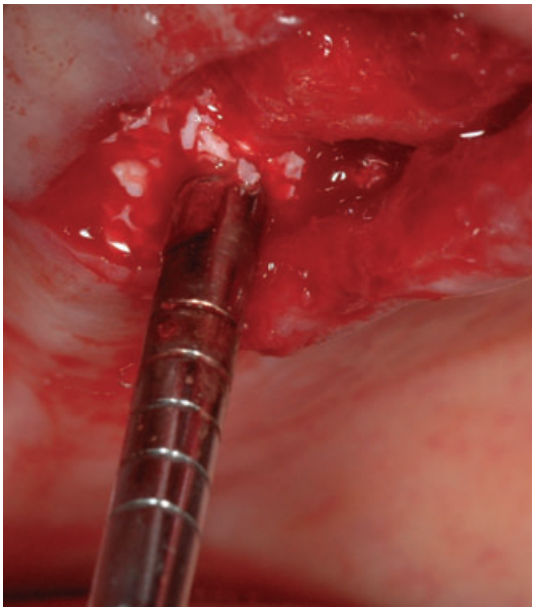

Fig. 50-39 The grafting material is then slowly pushed into the sinus cavity with a straight osteotome with a diameter about 1–1.5 mm smaller than that of the intended implant.

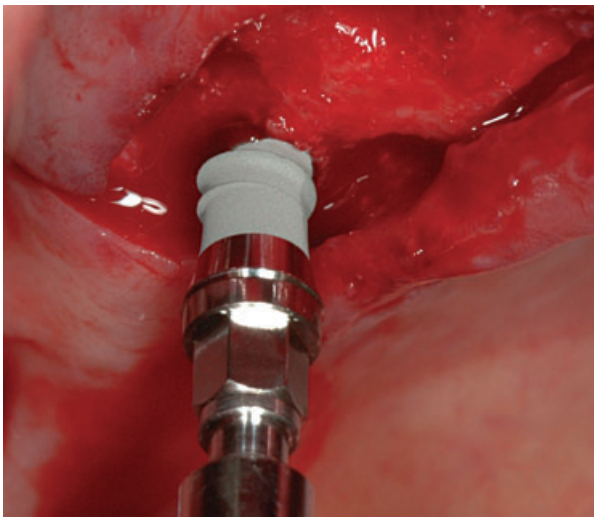

Fig. 50-41 A rough-textured implant was installed after preparing the implant site with the osteotome technique. Good primary stability was achieved.

Post-surgical care

The post-surgical care after placing implants with the osteotome technique is similar to that after standard implant placement. In addition to the standard oral home care, antiseptic rinsing with 0.1–0.2% chlorhexidine twice daily for the first 3 weeks after surgery is highly recommended. However, if bone substitutes were used, the patients are placed on antibiotic prophylaxis for a period of 1 week.

Grafting material

There is still controversy with regards to the necessity of a grafting material to maintain the space for new bone formation after elevating the sinus membrane utilizing the osteotome technique. Shortly after Summers introduced the BAOSFE, a multi-center retrospective study of eight centers was performed. Evaluation was carried out with 174 implants placed in 101 patients. The use of grafting material was decided by the individual clinician. Autografts, allografts, and xenografts were used, alone or in combinations. The authors concluded that the type of grafting material did not influence implant survival (Rosen *et al*. 1999).

When no grafting material is used, some dense structure is often visible apical to the implant, immediately after implant placement. However, after at least 1 year of remodeling, this structure may no longer be detectable and only a moderate amount of bone gain mesially and distally may persist

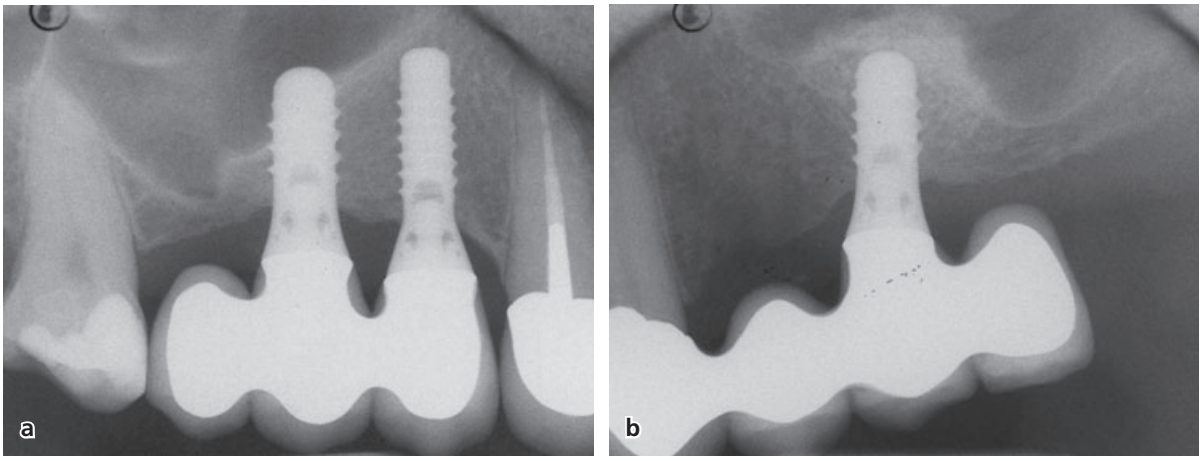

Fig. 50-42 (a) A radiograph, taken at the 5-year follow-up visit, of an implant placed in the 1st quadrant utilizing the osteotome technique without grafting material. A new cortical bony plate at the inferior border of the maxillary sinus is clearly visible, but no bony structure can be detected apical to the implant. (b) A radiograph (same patient) of an implant placed in the 2nd quadrant utilizing the osteotome technique with xenograft grafting material, taken after 5 years in function. A dome-shaped structure is clearly visible documenting a definite increase in bone volume compared to the initial situation. The "dome" is surrounded with a new cortical bony plate.

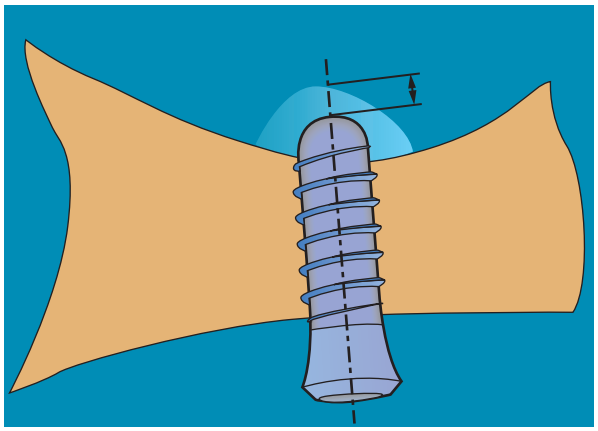

Fig. 50-43 Grafted area apical to the implants undergoes shrinkage and remodeling and the original border of the sinus is eventually consolidated and replaced by a new cortical plate (Brägger *et al*. 2004).

(Pjetursson *et al*. 2008a,b). When grafting material is used, a cloudy dome-shaped structure with a hazy demarcation may be visible after implant placement. The size of this dome is usually reduced after remodeling but still gives a definite increase in bone volume compared to the pre-operative situation (Pjetursson *et al*. 2008a,b) (Fig. 50-42).

Brägger and co-workers (2004) investigated the patterns of tissue remodeling after placement of 25 implants in 19 patients using the osteotome technique with composite xenografts and autografts. Intraoral radiographs were obtained pre-surgically and post-surgically at 3 and 12 months. The mean height of the new bone reaching apical and mesial to the implants was 1.52 mm at surgery, but was reduced significantly to 1.24 mm at 3 months and 0.29 mm after 12 months (Fig. 50-43). It was concluded that the grafted area apical to the implants underwent shrinkage and remodeling (Fig. 50-44) and the original outline of the sinus was eventually consolidated and replaced by a new cortical plate.

Implants installed into the sinuses of 40 patients using an osteotome technique with no graft or cushion materials were recently evaluated (Leblebicioglu *et al*. 2005). The authors reported a mean gain of alveolar bone height in scanned panoramic radiographs of 3.9 ± 1.9 mm.

Success and implant survival

In a multi-center retrospective study (Rosen *et al*. 1999) evaluating the Summers technique applied to the placement of 174 implants in 101 patients, the survival rate was 96%, when residual bone height was 5 mm or more, but dropped down to 85.7% when residual bone height was 4 mm or less (Fig. 50-45).

Survival and success rates of 588 implants placed in 323 consecutive patients with a residual bone height ranging from 6–9 mm after a mean observation period of 5 years were 94.8% and 90.8%, respectively (Ferrigno *et al*. 2006). During the study period, only 13 perforations of the sinus membrane were detected, giving a perforation rate of only 2.2%. The authors also concluded that the installation of short implants in conjunction with osteotome sinus floor elevation is predictable and may reduce the indications for more invasive and complex procedures, such as the sinus floor elevation by the lateral approach.

Moreover, a systematic review (Emmerich *et al*. 2005) evaluated the effectiveness of sinus floor elevation using osteotomes. The inclusion criteria considered studies that had more than ten patients and at least 6 months of functional loading. Eight studies met these inclusion criteria. Within the limits of the small amount of long-term data, the reviewers con-

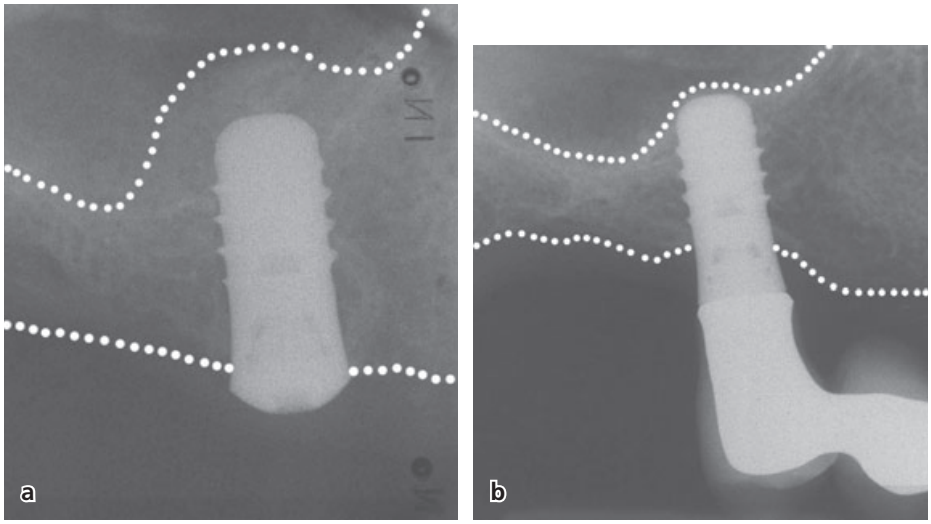

Fig. 50-44 (a) Radiograph taken immediately after implant insertion with the osteotome technique and grafting material, showing a cloudy dome-shaped structure extending 2–3 mm apical to the implant. (b) Radiograph of the same implant taken 1 year later showing significant reduction of the size of the "dome", but the new bony structure is clearly visible apical to the implant (the dotted lines represent the outlines of the grafting material and the residual bone).

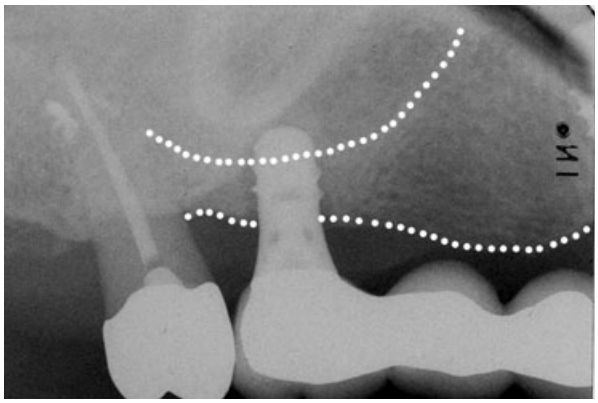

Fig. 50-45 Radiograph of a 6 mm implant that was inserted utilizing the osteotome technique without grafting material. The residual bone height was only 3 mm. After 6 months of functional loading, the implant became loose and had to be removed. After a healing time of 2 months, the maxillary sinus floor was elevated with the lateral approach and two new implants were placed simultaneously (the dotted lines represent the outlines of the residual bone).

cluded that the short-term success rates were similar to success rates of implants conventionally placed in partially edentulous patients (96.0% after 36 months). Long-term outcomes (>5 years) of implants placed with the osteotome technique are still scarse. The database was heterogenous regarding different surgical techniques, implant types, and grafting materials. Hence, no statistical analysis was performed on these parameters.

Short implants

In the light of sinus floor elevation techniques being indicated to facilitate the installation of dental implants in the maxillary posterior region without adequate bone volume, treatment alternatives have to be discussed (see Chapter 31). Since patient-centered outcomes and morbidity associated with these procedures have not been addressed so far, it has to be anticipated that a great number of patients may not choose sinus floor elevation for their treatment. Hence, shortened dental arches (Käyser 1981) may have to be considered in treatment planning.

Another variation to conventional implant installation in the posterior maxilla is the choice of short implants to avoid penetration into the sinus cavity. Jemt and Lekholm (1995) reported that implant failure in edentulous maxilla correlated significantly with bone quality especially for short (7 mm) implants. Other studies (Friberg *et al*. 1991; Jaffin & Berman 1991) had also reported low survival rates of short implants. However, it must be kept in mind that all these studies reported on implants with machined surface geometries. Based on these studies and others, the clinical "dogma" has been followed, that generally only long implants should be inserted in type IV "poor-quality" bone in the posterior maxilla.

A targeted review (Hagi *et al*. 2004) of study outcomes with short (≤7 mm) implants placed in partially edentulous patients, concluded that machined-surface implants experienced greater failure rates than rough-textured implants. The implant surface geometry appeared to be a major determinant in the performance of these short implants.

In a multi-center study (ten Bruggenkate *et al*. 1998) evaluating 6-mm non-submerged rough-surface dental implants, only one of 208 short implants placed in the mandible was lost compared to six of 45 implants placed in the maxilla. Four of these implants were lost during the healing phase

with three remaining in function. The survival rates were 99.5% and 86.7% respectively, after a follow-up time up to 7 years.

In contrast, recent clinical studies (Fugazotto *et al*. 2004; Renouard & Nisand 2005) on short implants with rough surfaces, designed for high initial stability, reported survival rates of about 95% which correlates with the survival rate reported for implants after 5 years in a systematic review (Berglundh *et al*. 2002). Two multi-center studies on rough-surface implants (Buser *et al*. 1997; Brocard *et al*. 2000) analyzed the survival and success rates of implants of different lengths. No significant difference was found between 8, 10, and 12 mm implants with rough-surface geometry after up to 8 years follow-up time.

The most recent review prepared for the Consensus Meeting of the European Association of Osseointegration (EAO) (Renouard & Nisand 2006) concluded on the basis of 12 studies on machined-surface implants meeting the inclusion criteria and 22 studies on rough-textured implants that the survival and success rates of short (<10 mm) implants was comparable to those obtained with longer implants, provided that surgical preparation was related to bone density, rough-textured implants were employed and operators' surgical skills were developed.

The use of short implants may be considered in sites thought unfavorable for implant placement, such as those associated with bone resorption or previous injury and trauma. While in these situations implant failure rates may be increased, outcomes should be compared with those associated with advanced surgical procedures such as bone grafting and sinus floor elevation.

Conclusions and clinical suggestions

In the posterior maxilla, implants with morphometry designed to achieve high initial stability and with rough surface geometry giving high percentage of bone-to-implant contact during initial healing phase (Abrahamsson *et al*. 2004), are to be preferred. Implants with slightly conical morphometry or implants with wider implant neck tend to give better primary stability in cases of reduced residual bone height and soft bone geometry.

The clinical decision on which method (short implants, osteotome technique or lateral approach) should be chosen, depends on the residual bone height of the alveolar crest and surgeons' preferences. The following recommendations are suggested:

1. Residual bone height of 8 mm or more and flat sinus floor: standard implant placement (Fig. 50-46).
2. Residual bone height of 8 mm or more and oblique sinus floor: standard implant placement using short implant or elevation of the maxillary sinus floor using the osteotome technique without grafting material (Fig. 50-47).

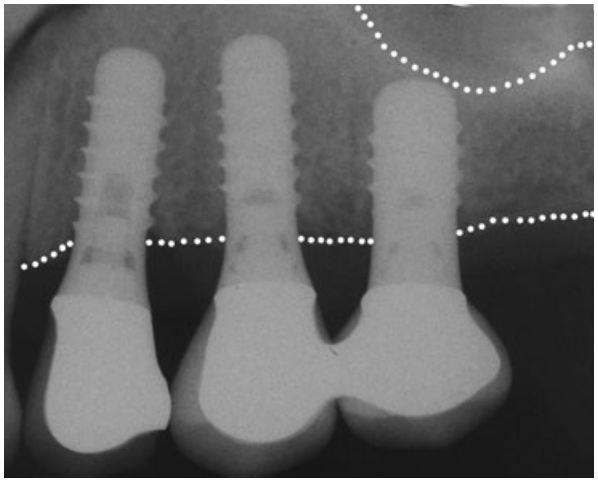

Fig. 50-46 Radiograph of a short (8 mm) implant in the posterior maxilla (the dotted lines represent the outlines of the residual bone).

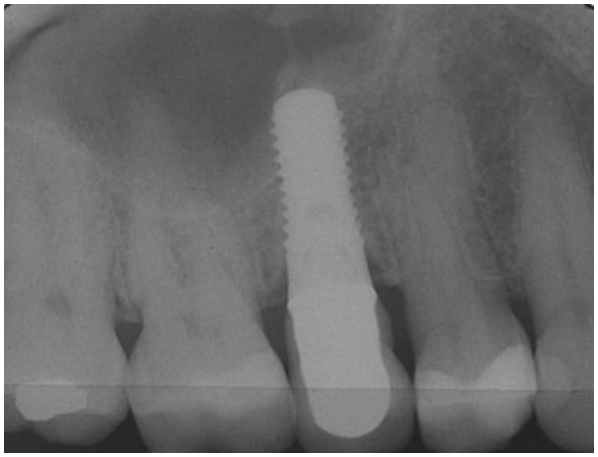

Fig. 50-47 Radiograph of an implant inserted in the posterior maxilla with an oblique sinus floor and a residual bone height of 8–10 mm. The osteotome technique without grafting material was used. The distal aspect of the apex of the implant extends into the sinus cavity, but the mesial aspect is covered with residual bone.

3. Residual bone height of 5–7 mm and flat sinus floor: elevation of the maxillary sinus floor using the osteotome technique with grafting material that is resistant to resorption (Fig. 50-48).
4. Residual bone height of 5–7 mm and oblique sinus floor: elevation of the maxillary sinus floor using lateral approach with grafting material, and simultaneous implant placement (one-stage) (Fig. 50-49).
5. Residual bone height of 3–4 mm and flat or oblique sinus floor: elevation of the maxillary sinus floor using lateral approach with grafting material, and simultaneous implant placement (one-stage) (Fig. 50-50).
6. Residual bone height of 1–2 mm and flat or oblique sinus floor: elevation of the maxillary sinus floor using lateral approach with grafting material and delayed implant placement 4–8 months later (two-stage) (Fig. 50-51).

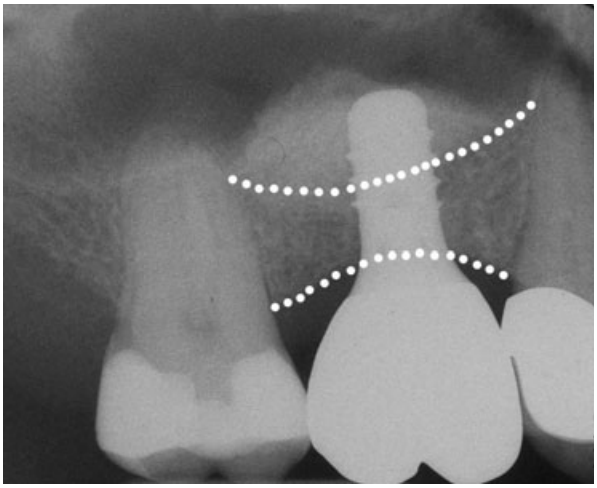

Fig. 50-48 Radiograph of an implant inserted in the posterior maxilla with a flat sinus floor and a residual bone height of 5–6 mm. The osteotome technique with grafting material was used. The radiograph shows a dome-shaped formation covering the entire apex of the implant (the dotted lines represent the outlines of the residual bone).

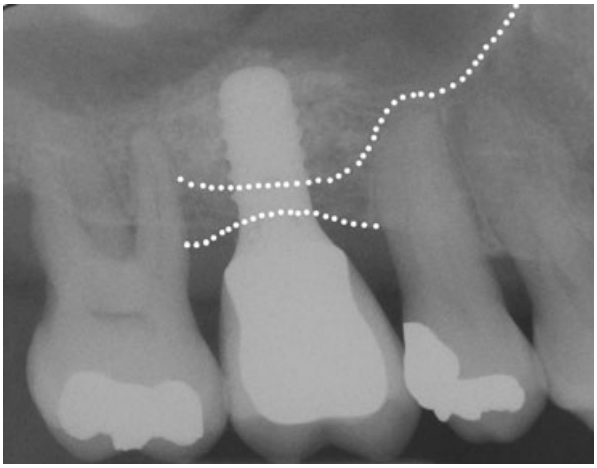

Fig. 50-50 Radiograph of an implant inserted in the posterior maxilla with a flat sinus floor and a residual bone height between 2 and 3 mm. The maxillary sinus floor was elevated using the lateral approach, and one implant was inserted simultaneously (the dotted lines represent the outlines of the residual bone).

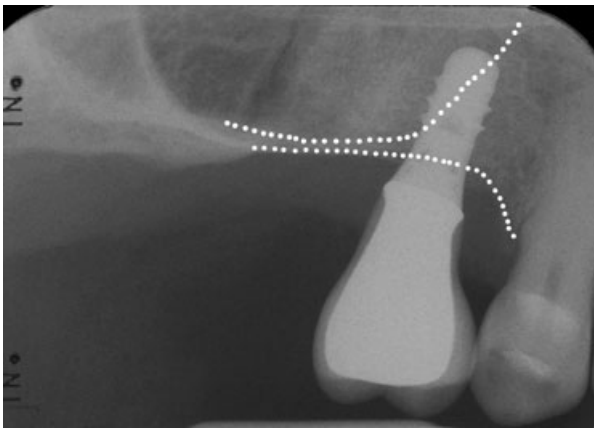

Fig. 50-49 Radiograph of an implant inserted in the posterior maxilla with a oblique sinus floor and a residual bone height between 2 and 8 mm. The maxillary sinus floor was elevated using the lateral approach, and one implant was inserted simultaneously (the dotted lines represent the outlines of the residual bone).

Fig. 50-51 Radiograph showing a large pneumatized maxillary sinus, where a two-stage sinus floor elevation with a delayed implant insertion has to be used.

Part 16: Occlusal and Prosthetic Therapy

Chapter 51

Tooth-Supported Fixed Partial Dentures

Jan Lindhe and Sture Nyman

Clinical symptoms of trauma from occlusion

Angular bony defects

It has been claimed that *angular bony defects* and *increased tooth mobility* are important symptoms of trauma from occlusion (Glickman 1965, 1967). The validity of this suggestion has, however, been questioned (see Chapter 14). Thus, angular bony defects have been found at teeth affected by *trauma from occlusion* as well as at teeth with normal occlusal function (Waerhaug 1979). *This means that the presence of angular bony defects cannot* per se *be regarded as an exclusive symptom of trauma from occlusion*.

Increased tooth mobility

Increased tooth mobility, determined clinically, is expressed in terms of amplitude of displacement of the crown of the tooth. Increased tooth mobility can, indeed, be observed in conjunction with *trauma from occlusion*. It may, however, also be the result of a reduction of the height of the alveolar bone with or without an accompanying angular bony defect caused by plaque-associated periodontal disease (see Chapter 14). Increased tooth mobility resulting from occlusal interferences may further indicate that the periodontal structures have become adapted to an altered functional demand, i.e. a widened periodontal ligament with a normal tissue composition has become the end result of a previous phase of progressive tooth mobility (see Chapter 14) associated with trauma from occlusion.

Progressive (increasing) tooth mobility

In Chapter 14, it was concluded that the diagnosis trauma from occlusion should be used solely in situations where a progressive mobility could be observed. Progressive tooth mobility can be identified only through a series of repeated tooth mobility measurements carried out over a period of several days or weeks.

Tooth mobility crown excursion/root displacement

Initial and secondary tooth mobility

A tooth which is surrounded by a normal periodontium may be moved (displaced) in horizontal and vertical directions and may also be forced to perform limited rotational movements. Clinically, tooth mobility is usually assessed by exposing the crown of the tooth to a certain force and determining the distance the crown can be displaced in buccal and/or lingual direction. The mobility (= movability) of a tooth in a horizontal direction is closely dependent on the height of the surrounding supporting bone, the width of the periodontal ligament, and the shape and number of roots present (Fig. 51-1).

The mechanism of tooth mobility was studied in detail by Mühlemann (1954, 1960) who described a

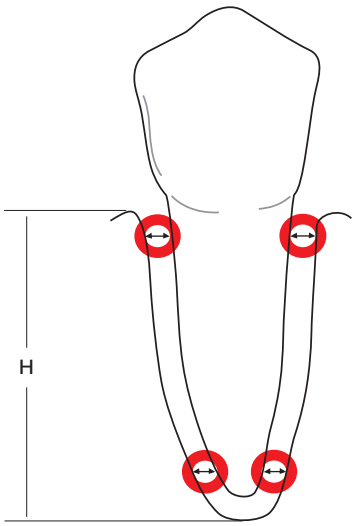

Fig. 51-1 The mobility of a tooth in horizontal direction is dependent on the height of the alveolar bone (H), the width of the periodontal ligament (encircled arrows), and the shape and number of roots.

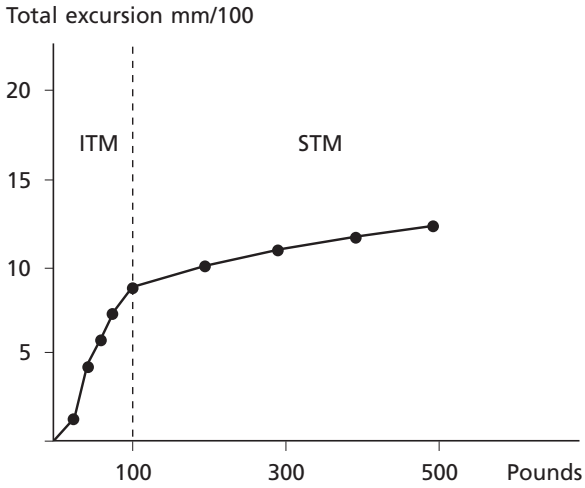

Fig. 51-3 Initial tooth mobility (ITM) means the excursion of the crown of a tooth when a force of 100 pounds is applied to the crown. Secondary tooth mobility (STM) means the excursion of the crown of the tooth when a force of 500 pounds is applied.

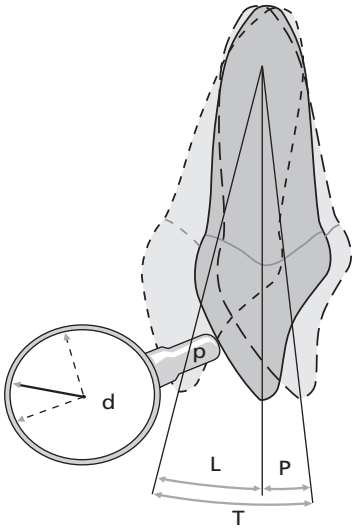

Fig. 51-2 Tooth mobility measurements by means of the Periodontometer. d = dial indicator; p = pointer; L = labial excursion of the crown; P = palatal excursion of the crown; T = L + P = total excursion of the crown.

standardized method for measuring even minor tooth displacements. By means of the "Periodontometer" a small force (~45 kg (100 pounds)) is applied to the crown of a tooth (Fig. 51-2). The crown starts to tip in the direction of the force. The resistance of the tooth-supporting structures against displacement of the root is low in the initial phase of force application and the crown is moved only 5/100–10/100 mm. This movement of the tooth was called "*initial tooth mobility*" (ITM) by Mühlemann (1954) and is the result of an *intra-alveolar* displacement of the root (Fig. 51-3). In the pressure zone (see Chapter 14) there is a 10% reduction in the width of the periodontal ligament and in the tension zone there is a corresponding increase. Mühlemann and Zander (1954) stated that "there are good reasons to assume that the initial displacement of the root (ITM) corresponds to a reorientation of the periodontal membrane fibers into a position of functional readiness towards tensile strength". The magnitude of the ITM varies from individual to individual, from tooth to tooth, and is mainly dependent on the structure and organization of the periodontal ligament. The ITM value of ankylosed teeth is therefore zero.

When a larger force (~225 kg (500 pounds)) is applied to the crown, the fiber bundles on the tension side cannot offer sufficient resistance to further root displacement. The additional displacement of the crown that is observed in "*secondary tooth mobility*" (STM) (Fig. 51-3) is allowed by distortion and compression of the periodontium in the pressure side. According to Mühlemann (1960) the magnitude of STM, i.e. the excursion of the crown of the tooth when a force of 500 pounds is applied, (1) varies between different types of teeth (e.g. incisors 10–12/100 mm, canines 5–9/100 mm, premolars 8–10/100 mm and molars 4–8/100 mm), (2) is larger in children than in adults, and (3) is larger in females than males and increases during, for example, pregnancy. Furthermore, tooth mobility seems to vary during the course of the day; the lowest value is found in the evening and the largest in the morning.

A new method for determining tooth mobility was presented by Schulte and co-workers (Schulte 1987; Schulte *et al*. 1992) when the Periotest® (SiemensAG, Bensheim, Germany) system was introduced. The Periotest device measures the reaction of the periodontium to a defined percussion force which is applied to the tooth and delivered by a tapping instrument. A metal rod is accelerated to a speed of 0.2 m/s with the device and maintained at a constant velocity. Upon impact the tooth is deflected and the

rod decelerated. The contact time between the tapping head and the tooth varies between 0.3 and 2 milliseconds and is shorter for stable than mobile teeth. The Periotest scale (the Periotest values) ranges from –8 to +50 and the following ranges should be considered:

- –8 to +9: clinically firm teeth
- 10–19: first distinguishable sign of movement
- 20–29: crown deviates within 1 mm of its normal position
- 30–50: mobility is readily observed.

The Periotest values correlate well with (1) tooth mobility assessed with a metric system, and (2) degree of periodontal disease and alveolar bone loss. The simple Periotest device is likely to be used in both the clinic and research settings in the future.

Clinical assessment of tooth mobility (physiologic and pathologic tooth mobility)

If, in the traditional clinical measurement of tooth mobility, a comparatively large force is exerted on the crown of a tooth which is surrounded by a normal periodontium, the tooth will tip within its alveolus until a closer contact has been established between the root and the marginal (or apical) bone tissue. The magnitude of this tipping movement, which is normally assessed using the tip of the crown as a reference point, is referred to as the "*physiologic*" tooth mobility. The term "*physiologic*" implies that "*pathologic*" tooth mobility may also occur.

What, then, is "pathologic" tooth mobility?

1. If a similar force is applied to a tooth which is surrounded by a periodontal ligament with an increased width, the excursion of the crown in horizontal direction will become increased; the clinical measurement consequently demonstrates that the tooth has an increased mobility. Should this increased mobility be regarded as *pathologic*?
2. An increased tooth mobility, i.e. an increased displacement of the crown of the tooth after force application, can also be found in situations where the height of the alveolar bone has been reduced but the remaining periodontal ligament has a normal width. At sites where this type of bone loss is extensive, the degree of tooth mobility (i.e. excursion of the crown) may be pronounced. Should this increased tooth mobility be regarded as "pathologic"?

Figure 51-4b illustrates a tooth which is surrounded by alveolar bone of reduced height. The width of the remaining periodontal ligament, however, is within normal limits. A horizontally directed force applied to the crown of the tooth in this case will result in a larger excursion of the crown than if a similar force is applied to a tooth with normal height of the alveolar bone and normal width of the periodontal ligament (Fig. 51-4a). There are reasons to suggest that the *so-called increased mobility* measured in the case of Fig. 51-4b is, indeed, *physiologic*. The validity of this statement can easily be demonstrated if the displacement of the two teeth is assessed not from the crown but from a point on the root at the level of the bone crest. If a horizontal force is directed to the teeth as indicated in Fig. 51-4 the reference points (*) on the root surfaces will be displaced a similar distance in both instances. *Obviously, it is not the length of the excursive movement of the crown that is important from a biologic point of view, but the displacement of the root within its remaining periodontal ligament*.

In plaque-associated periodontal disease, bone loss is a prominent feature. Another so-called classical symptom of periodontitis is "increased tooth mobility". It is important to realize, however, that in many situations with even or "horizontal" bone loss patterns, the increased crown displacement (tooth mobility) assessed in clinical measurements should, according to the above discussion, also be regarded as physiologic; the movement of the root within the space of its remaining "normal" periodontal ligament is normal.

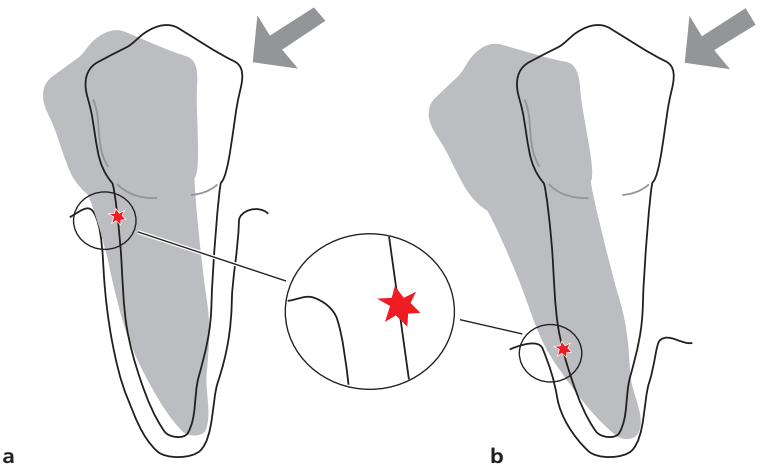

Fig. 51-4 (a) The normal "physiologic" mobility of a tooth with normal height of the alveolar bone and normal width of the periodontal ligament. (b) The mobility of a tooth with reduced height of the alveolar bone. The distance of the horizontal displacement of the reference point (*) on the roots is the same in the two situations (a,b).

3. Increased crown displacement (tooth mobility) may also be detected in a clinical measurement where a "horizontal" force is applied to teeth with angular bony defects and/or increased width of the periodontal ligament. If this mobility does not increase gradually – from one observation interval to the next – the root is surrounded by a periodontal ligament of increased width but normal composition. This mobility should also be considered *physiologic* since the movement is a function of the height of the alveolar bone and the width of the periodontal ligament.
4. Only *progressively increasing tooth mobility*, which may occur in conjunction with trauma from occlusion, is characterized by active bone resorption (see Chapter 14) and which indicates the presence of inflammatory alterations within the periodontal ligament tissue, may be considered *pathologic*.

Treatment of increased tooth mobility

A number of situations will be described below which may call for treatment aimed at reducing an increased tooth mobility.

Situation I

Increased mobility of a tooth with increased width of the periodontal ligament but normal height of the alveolar bone

If a tooth (for instance a maxillary premolar) is fitted with an improper filling or crown restoration, occlusal interferences develop and the surrounding periodontal tissues become the seat of inflammatory reactions, i.e. trauma from occlusion (Fig. 51-5). If the restoration is so designed that the crown of the tooth in occlusion is subjected to undue forces directed in a buccal direction, bone resorption phenomena develop in the buccal–marginal and lingual–apical pressure zones with a resulting increase of the width of the periodontal ligament in these zones. The tooth becomes hypermobile or moves away from the "traumatizing" position. Since such traumatizing forces in teeth with normal periodontium or overt gingivitis cannot result in pocket formation or loss of connective tissue attachment, the resulting increased mobility of the tooth should be regarded as a physiologic adaptation of the periodontal tissues to the altered functional demands. A proper correction of the anatomy of the occlusal surface of such a tooth, i.e. occlusal adjustment, will normalize the relationship between the antagonizing teeth in occlusion, thereby eliminating the excessive forces. As a result, apposition of bone will occur in the zones previously exposed to resorption, the width of the periodontal ligament will become normalized and the tooth stabilized, i.e. it reassumes its normal mobility (Fig. 51-5). In other words, resorption of alveolar bone which is caused by trauma from occlusion is a reversible process which can be treated by the elimination of occlusal interferences.

The capacity for bone regeneration after resorption following trauma from occlusion has been documented in a number of animal experiments (Waerhaug & Randers-Hansen 1966; Polson *et al*. 1976a; Karring *et al*. 1982; Nyman *et al*. 1982). In such experiments, the induced bone resorption not only involved the bone within the alveolus but also the alveolar bone crest. When the traumatizing forces were removed, bone tissue was deposited not only in the walls of the alveolus, thereby normalizing the width of the periodontal ligament, but also on the bone crest area, whereby the height of the alveolar bone was normalized (Fig. 51-6) (Polson *et al*. 1976a). In the presence

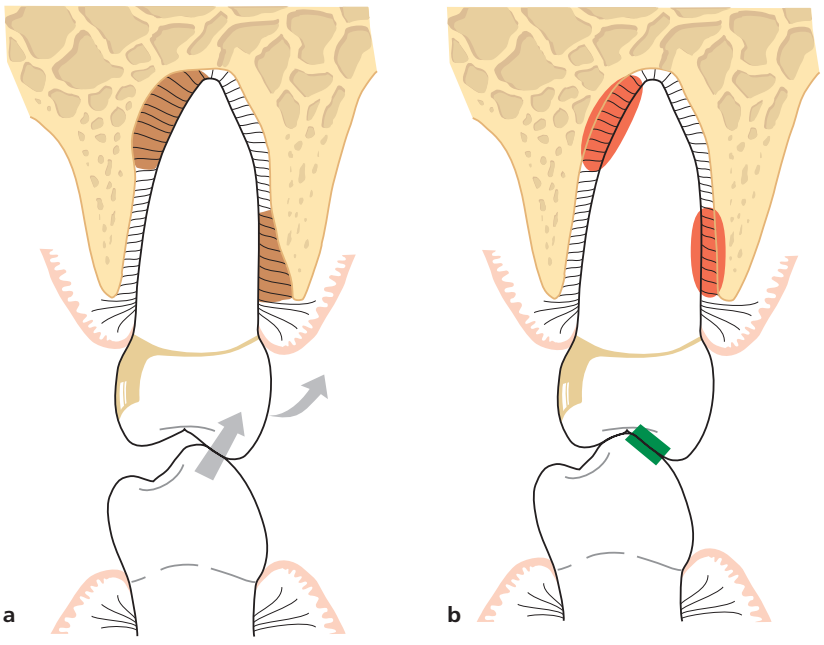

Fig. 51-5 (a) Contact relationship between a mandibular and a maxillary premolar in occlusion. The maxillary premolar is fitted with an artificial restoration with an improperly designed occlusal surface. Occlusion results in horizontally directed forces (arrows) which may produce an undue stress concentration within the "brown" areas of the periodontium of the maxillary tooth. Resorption of the alveolar bone occurs in these areas. A widening of the periodontal ligament can be detected as well as increased mobility of the tooth. (b) Following adjustment of the occlusion, the horizontal forces are reduced. This results in bone apposition ("red areas") and a normalization of the tooth mobility.

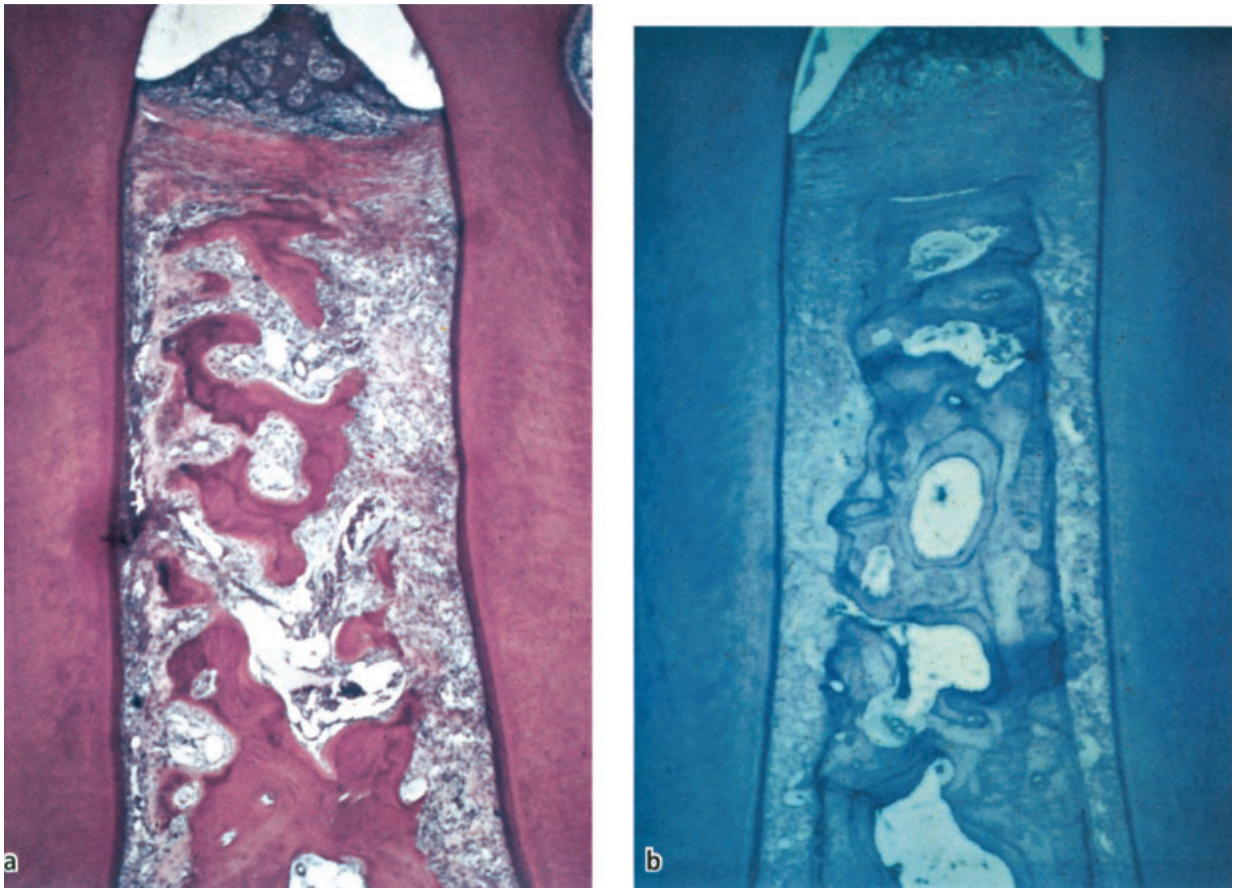

Fig. 51-6 Photomicrographs illustrating the interdental area between two mandibular premolars in the monkey. In (a) the two premolars are exposed to jiggling forces. Note the reduction of alveolar bone in the area and the location of the bone crest. Ten weeks after the elimination of the jiggling forces (b) a considerable regeneration of bone has occurred. Note the increase of the height of the interdental bone and the normalization of the width of the periodontal ligaments. The apical end of the junctional epithelium is located at the cemento-enamel junction. (Courtesy of Dr. A.M. Polson; from Polson *et al*. (1976a).)

of an untreated, plaque-associated lesion in the soft tissue, however, substantial bone regrowth did not always occur (Fig. 51-7) (Polson *et al*. 1976b).

Situation II

Increased mobility of a tooth with increased width of the periodontal ligament and reduced height of the alveolar bone

When a dentition has been properly treated for moderate to advanced periodontal disease, gingival health is established in areas of the dentition where teeth are surrounded by periodontal structures of reduced height. If a tooth with a reduced periodontal tissue support is exposed to excessive horizontal forces (trauma from occlusion), inflammatory reactions develop in the pressure zones of the periodontal ligament with accompanying bone resorption. These alterations are similar to those which occur around a tooth with supporting structures of a normal height; the alveolar bone is resorbed, the width of the periodontal ligament is increased in the pressure/tension zones and the tooth becomes hypermobile (Fig. 51-8a). If the excessive forces are reduced or eliminated by occlusal adjustment, bone apposition to the "pre-trauma" level will occur, the periodontal ligament will regain its normal width and the tooth will become stabilized (Fig. 51-8b).

Conclusion: situations I and II

Occlusal adjustment is an effective therapy against increased tooth mobility when such mobility is caused by an *increased width* of the periodontal ligament.

Situation III

Increased mobility of a tooth with reduced height of the alveolar bone and normal width of the periodontal ligament

The increased tooth mobility which is the result of a reduction in height of the alveolar bone without a concomitant increase in width of the periodontal membrane cannot be reduced or eliminated by occlusal adjustment. In teeth with normal width of the periodontal ligament, no further bone apposition on the walls of the alveoli can occur. If such an increased

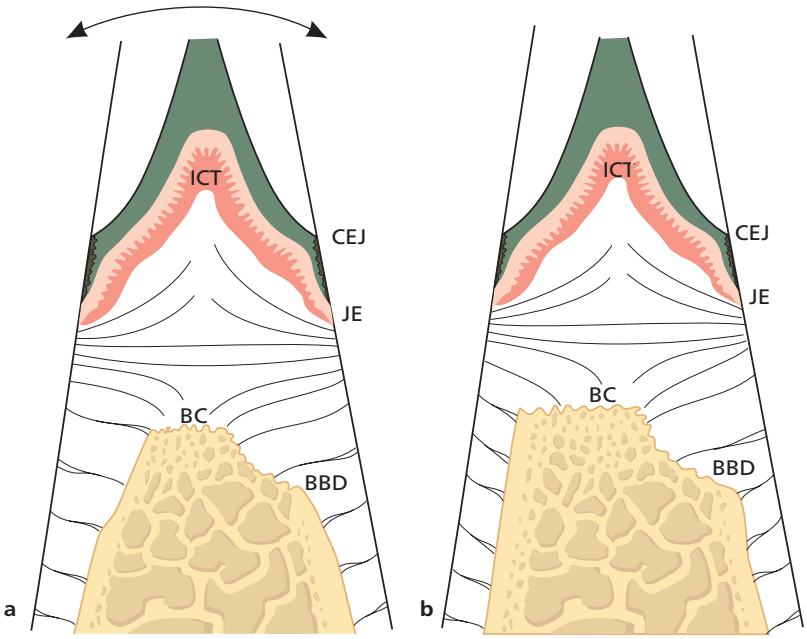

Fig. 51-7 In the presence of an existing marginal inflammation, alveolar bone, lost by jiggling trauma (a), will not always regenerate following elimination of the traumatic forces (b). ICT = infiltrated connective tissue; CEJ = cemento-enamel junction; JE = apical end of junctional epithelium; BC = alveolar bone crest; BBD = bottom of angular bony defect. From Polson *et al.* (1976b).

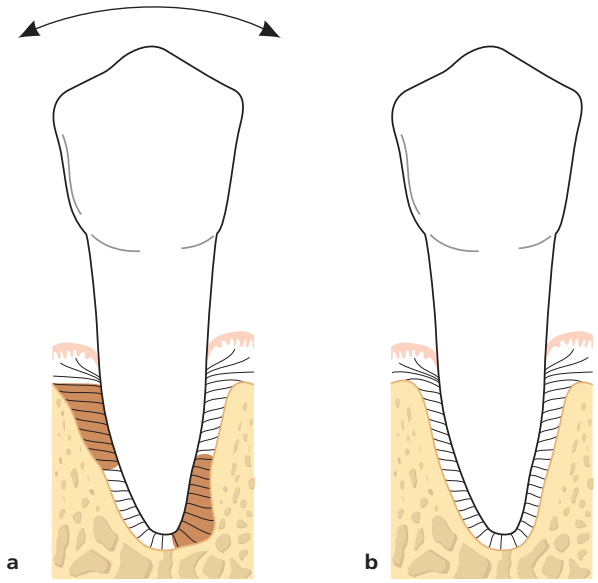

Fig. 51-8 If a tooth with reduced periodontal tissue support (a) has been exposed to excessive horizontal forces, a widened periodontal ligament space ("brown" areas) and increased mobility (arrow) result. (b) Following reduction or elimination of such forces, bone apposition will occur and the tooth will become stabilized.

tooth mobility does not interfere with the patient's chewing function or comfort, no treatment is required. If the patient experiences the tooth mobility as disturbing, however, the mobility can only be reduced in this situation by splinting, i.e. by joining the mobile tooth/teeth together with other teeth in the jaw into a fixed unit – a splint.

A splint, according to the Glossary of Periodontic Terms (1986) is "an appliance designed to stabilize mobile teeth". A splint can be fabricated in the form of joined composite fillings, fixed bridges, removable partial prostheses, etc.

Example: Case A, 64-year-old male

The periodontal condition of this patient is illustrated by the probing depth, furcation involvement and tooth mobility data as well as the radiographs from the initial examination in Fig. 51-9. Periodontal disease has progressed to a level where, around the maxillary teeth, only the apical third or less of the roots is invested in supporting alveolar bone. The following discussion is related to the treatment of the maxillary dentition.

In the treatment planning of this case it was decided that the first premolars (teeth 14 and 24) had to be extracted due to advanced periodontal disease and furcation involvement of degree III. For the same reasons, teeth 17 and 27 were scheduled for extraction. Teeth 16 and 26 were also found to have advanced loss of periodontal tissue support in combination with deep furcation involvements. The most likely *definitive* treatment should include periodontal and adjunctive therapy in the following parts of the dentition: 15 and 25, and 13, 12, 11, 21, 22, 23. For functional and esthetic reasons, 14 and 24 obviously had to be replaced. The question now arose as to whether these two premolars should be replaced by two separate unilateral bridges, using 13, 15 and 23, 25 as abutment teeth, or if the increased mobility of these teeth and also of the anterior teeth (12, 11, 21, 22) (Fig. 51-9) called for a bridge of cross-arch design, with the extension 15–25, to obtain a splinting effect. If 14 and 24 are replaced by two unilateral bridges, each one of these three-unit bridges will exhibit the same degree of mobility in a bucco-lingual direction as the individual abutment teeth (degree 2) (Fig. 51-9), since a unilateral straight bridge will not have a stabilizing effect on the abutment teeth in this force direction.

b

Fig. 51-9 Case A, 64-year-old male. Periodontal status (a) and radiographs (b) prior to therapy.

From the radiographs it can be seen that the increased mobility observed in the maxillary teeth of this patient is associated mainly with reduced height of the alveolar bone and not with increased width of the periodontal ligaments. This means that the mobility of the individual teeth should be regarded as normal or "physiologic" for teeth with such a reduced height of the supporting tissues. This in turn implies that the increased tooth mobility in the present case does not call for treatment unless it interferes with the chewing comfort or jeopardizes the position of the front teeth. This particular patient had not recognized any functional problems related to the increased mobility of his maxillary teeth. Consequently, there was no reason to install a cross-arch bridge in order to splint the teeth, i.e. to reduce tooth mobility.

Following proper treatment of the plaque-associated periodontal lesions, two separate provisional bridges of unilateral design were produced (15, 14, 13; 23, 24, 25, 26 palatal root). The provisional acrylic bridges were used for 6 months during which the occlusion, the mobility of the two bridges and the position of the front teeth were all carefully monitored. When, after 6 months, no change of position of the lateral and central incisors had occurred and no increase of the mobility of the two provisional bridges had been noted, the definitive restorative therapy was performed.

Figure 51-10 presents radiographs obtained 10 years after initial therapy. The position of the front teeth and the mobility of the incisors and the two bridges have not changed during the course of the maintenance period. There has been no further loss of periodontal tissue support during the 10 years of observation, no further spread of the front teeth and no widening of the periodontal ligaments around the individual teeth, including the abutment teeth for the bridgework.

Conclusion: situation III

Increased tooth mobility (or bridge mobility) as a result of reduced height of the alveolar bone can be accepted and splinting avoided, provided the occlusion is stable (no further migration or further increasing mobility of individual teeth), and provided the degree of existing mobility does not disturb the patient's chewing ability or comfort. Consequently, splinting is indicated when the mobility of a tooth or a group of teeth is so increased that chewing ability and/or comfort are disturbed.

Situation IV

Progressive (increasing) mobility of a tooth (teeth) as a result of gradually increasing width of the reduced periodontal ligament

Often in cases of advanced periodontal disease the tissue destruction may have reached a level where extraction of one or several teeth cannot be avoided. In such a dentition, teeth which are still available for periodontal treatment may, after therapy, exhibit such a high degree of mobility, or even signs of progressively increasing mobility, that there is an obvious risk that the forces elicited during function may mechanically disrupt the remaining periodontal ligament components and cause extraction of the teeth.

It will only be possible to maintain such teeth by means of a splint. In such cases a fixed splint has two objectives: (1) to stabilize hypermobile teeth and (2) to replace missing teeth.

Example: Case B, 26-year-old male

Figure 51-11 presents radiographs taken prior to therapy and Fig. 51-12 those obtained after periodon-

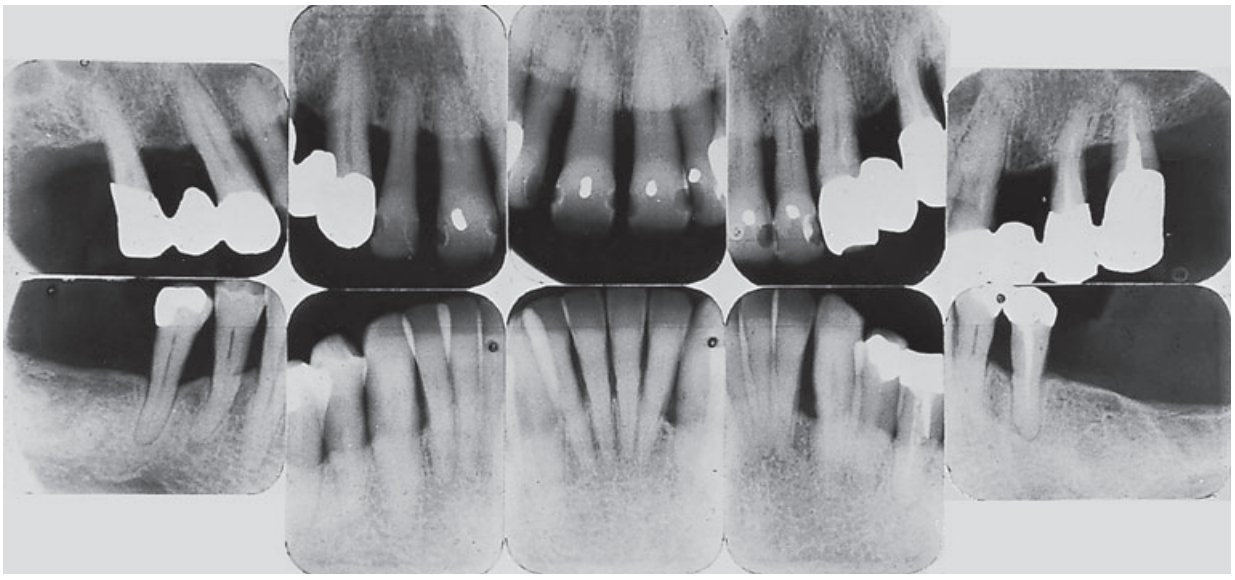

Fig. 51-10 Case A. Radiographs obtained 10 years after periodontal therapy and installation of two unilateral bridges in the maxilla.

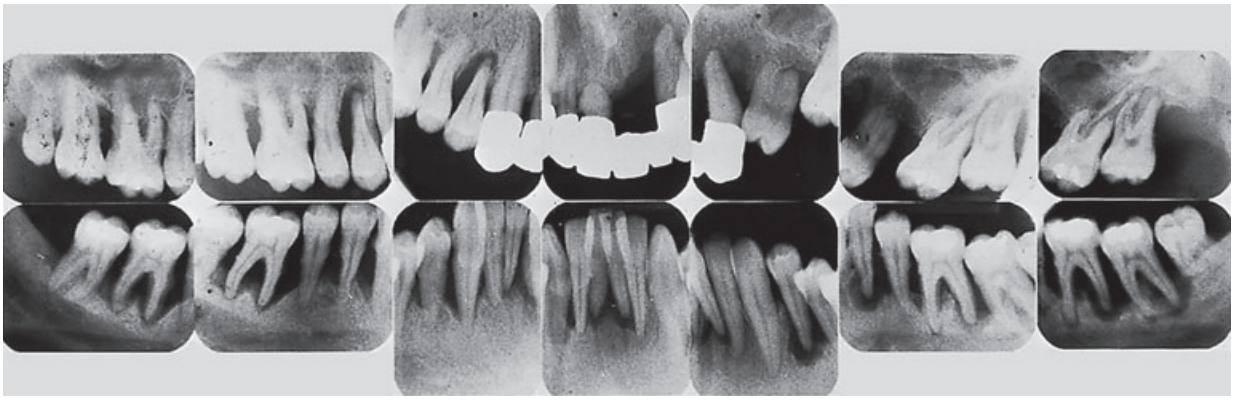

Fig. 51-11 Case B, 26-year-old male. Radiographs illustrating the periodontal conditions prior to therapy.

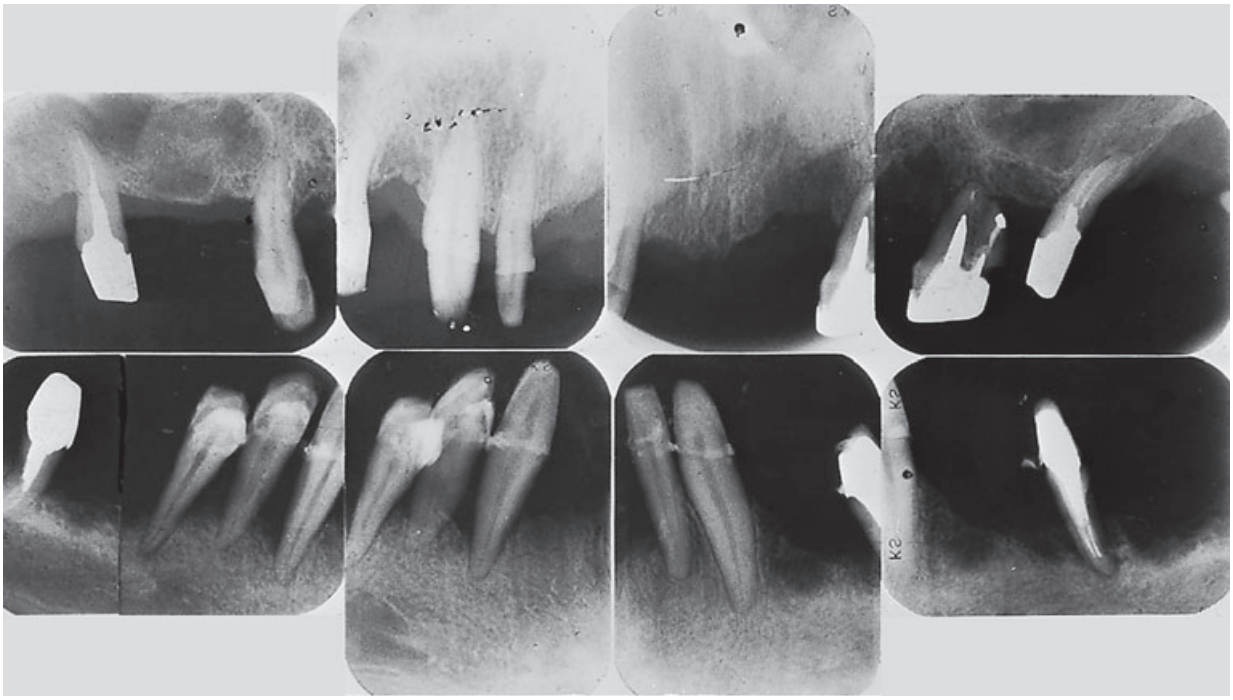

Fig. 51-12 Case B. Radiographs obtained after periodontal treatment and preparation of the abutment teeth for two fixed splints.

tal treatment and preparation of the remaining teeth as abutments for two fixed splints. All teeth except 13, 12, and 33 have lost around 75% or more of the alveolar bone and widened periodontal ligaments are a frequent finding. The four distal abutments for the two splints are root-separated molars, the maintained roots being the following: the palatal root of 17, the mesio-buccal root of 26, and the mesial roots of 36 and 47. It should be observed that tooth 24 is root-separated and the palatal root maintained with only minute amounts of periodontium left. Immediately prior to insertion of the two splints, all teeth except 13, 12, and 33 displayed a mobility varying between degrees 1 and 3. From the radiographs in Fig. 51-12 it can be noted that there is an obvious risk of extraction of a number of teeth such as 24, 26, 47, 45, 44, 43, and 36 if the patient is allowed to bite with a normal chewing force without the splints in position.

Despite the high degree of mobility of the individual teeth, the splints were entirely stable after insertion, and have maintained their stability during a maintenance period of more than 12 years. Figure 51-13 describes the clinical status and Fig. 51-14 presents the radiographs obtained 10 years after therapy. From these radiographs it can be observed (compare with Fig. 51-12) that during the maintenance period there has been no further loss of alveolar bone or widening of the various periodontal ligament spaces.

Conclusion: situation IV

Splinting is indicated when the periodontal support is so reduced that the mobility of the teeth is progressively increasing, i.e. when a tooth or a group of teeth are exposed to extraction forces during function.

Fig. 51-13 Case B. Clinical status 9 years after therapy.

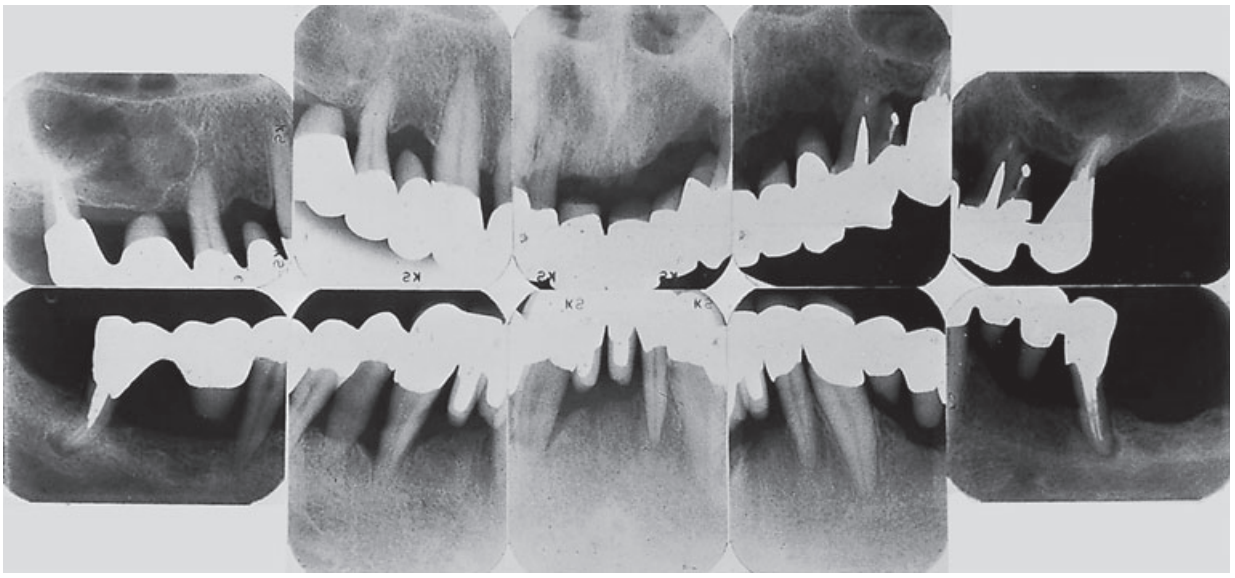

Fig. 51-14 Case B. Radiographs obtained 10 years after therapy.

Situation V

Increased bridge mobility despite splinting

In patients with advanced periodontal disease it can often be observed that the destruction of the periodontium has progressed to varying levels around different teeth and tooth surfaces in the dentition. Proper treatment of the plaque-associated lesions often includes multiple extractions. The remaining teeth may display an extreme reduction of the supporting tissues concomitant with increased or progressive tooth mobility. They may also be distributed in the jaw in such a way as to make it difficult, or impossible, to obtain a proper splinting effect even by means of a cross-arch bridge. The entire bridge/splint may exhibit mobility in frontal and/or lateral directions.

It was stated above (situation III) that a certain mobility of a tooth or a bridge of unilateral design

can be accepted provided this mobility does not interfere with the patient's chewing ability or comfort. This is also valid for a cross-arch bridge/splint. From a biologic point of view there is no difference between increased tooth mobility on the one hand and increased bridge mobility on the other. However, neither progressive tooth mobility nor progressive bridge mobility are acceptable. In cases of extremely advanced periodontal disease, a cross-arch splint with an increased mobility may be regarded as an acceptable result of rehabilitation. The maintenance of status quo of the bridge/splint mobility and the prevention of tipping or orthodontic displacement of the total splint, however, requires particular attention regarding the design of the occlusion. Below, a case is reported which may serve as an interesting illustration of this particular clinical problem.

Example: Case C, 52-year-old female

Figure 51-15 shows radiographs obtained at the initial examination. A 12-unit maxillary bridge was installed 10–15 years prior to the present examination using 18, 15, 14, 13, 12, 11, 21, 22, 23, and 24 as abutments. After a detailed clinical examination it was obvious that 15, 14, 22, and 24 could not be maintained because of severe symptoms of caries and periodontal disease. The remaining teeth were subjected to periodontal therapy and maintained as abutments for a new bridge/splint in the maxilla extending from tooth 18 to the region of 26, i.e. a cross-arch splint was installed which carried three cantilever units, namely 24, 25, and 26. The mobility of the individual abutment teeth immediately prior to insertion of the splint was the following: degree 1 (tooth 18), degree 0 (tooth 13), degree 2 (teeth 12 and 11), degree 3 (tooth 21), and degree 2 (tooth 23).

Radiographs obtained 5 years after therapy are shown in Fig. 51-16. The bridge/splint had a mobility of degree 1 immediately after its insertion and this mobility was unchanged 5 years later. The radiographs demonstrate that no further widening of the periodontal ligament occurred around the individual teeth during the maintenance period.

When a cross-arch bridge/splint exhibits increased mobility, the center (fulcrum) of the movement must be identified. In order to prevent further increase in the mobility and/or to prevent displacement of the bridge, it is essential to design the occlusion in such a way that when the bridge/splint is in contact with the teeth of the opposing jaw, it is subjected to a balanced load, i.e. equal force on each side of the fulcrum. If this can be achieved, the force to which the bridge is exposed in occlusion can be used to retain the fixed prosthesis in proper balance (a further increase of mobility being thereby prevented).

Balanced loading of a mobile bridge/splint has to be established not only in the intercuspal position (IP) and centric occlusion (CP) but also in frontal and lateral excursive movements of the mandible if the bridge shows mobility or a tendency for tipping in the direction of such movements. In other words, a force which tends to displace the bridge in a certain direction has to be counteracted by the introduction of a balancing force on the opposite side of the fulcrum of the movement. If, for instance, a cross-arch splint in the maxilla exhibits mobility in frontal direction in conjunction with protrusive movements of the mandible, the load applied to the bridge in the frontal region has to be counterbalanced by a load in the distal portions of the splint; this means that there must be a simultaneous and equal contact relationship between the occluding teeth in both the frontal and the posterior regions of the splint. If the splint is mobile in a lateral direction, the force acting on the working side of the jaw must be counteracted by a force established by the introduction of balancing contacts in the non-working side of the jaw. The prin-

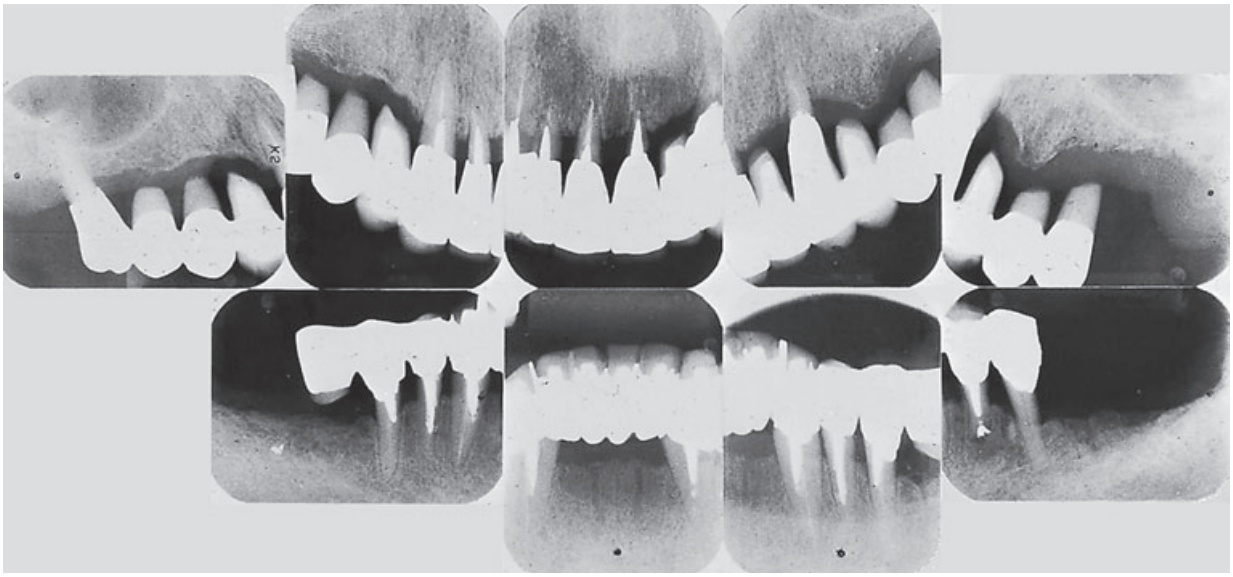

Fig. 51-16 Case C. Radiographs obtained 5 years after therapy.

ciple for establishing stability of a *mobile* cross-arch splint is consequently the same as that used to obtain stability in a complete denture. In situations where distal abutment teeth are missing in a cross-arch bridge/splint with increased mobility, balance and functional stability may be obtained by means of cantilever units. It is important in this context to point out that balancing contacts on the non-working side should not be introduced in a bridge/splint in which no increased mobility can be observed.

The maxillary splint in the patient described in Figs. 51-15 and 51-16 exhibited increased mobility in a frontal direction. Considering the small amount of periodontal support left around the anterior teeth, it is obvious that there would have been a risk of frontal displacement of the total bridge had the bridge terminated at the last abutment tooth (23) on the left side of the jaw. The installation of cantilever units in the 24 and 25 region prevented such a displacement of the bridge/splint by the introduction of a force counteracting frontally directed forces during protrusive movements of the mandible (Fig. 51-17). In addition, the cantilever units provide bilateral contact relationship towards the mandibular teeth in the intercuspal position, i.e. bilateral stability of the bridge.

In cases similar to the one described above, cantilever units can thus be used to prevent increasing mobility or displacement of a bridge/splint. It should, however, be pointed out that the insertion of cantilever units increases the risk of failures of a technical and biophysical character (fracture of the metal frame, fracture of abutment teeth, loss of retention, etc.).

In cases of severely advanced periodontal disease it is often impossible to anticipate in the planning phase whether a bridge/splint will show signs of instability and increasing (progressive) mobility after

Fig. 51-17 Case C. The cantilever section including teeth 24, 25, and 26.

insertion. In such cases, a provisional splint should always be inserted. Any alterations of the mobility of the bridge/splint can be observed over a prolonged period of time and the occlusion continuously adjusted until, after 4–6 months, it is known whether stability (i.e. no further increase of the mobility) can be achieved. The design of the occlusion of the provisional acrylic bridge is then reproduced in the permanent bridge construction. If, on the other hand, stability cannot be obtained, the rehabilitation of the case cannot be achieved with a fixed splint. The alternative treatment then is a complete denture or an implant-supported restoration.

Conclusion: situation V

An increased mobility of a cross-arch bridge/splint can be accepted provided the mobility does not disturb chewing ability or comfort and the mobility of the splint is not progressively increasing.

Chapter 52

Implants in Restorative Dentistry

Niklaus P. Lang and Giovanni E. Salvi

Introduction

Ever since oral titanium implants were shown to yield high predicability (97–98%) for incorporation (Berglundh *et al*. 2002; Pjetursson *et al*. 2007) and satisfactory longevity (survival rates of approximately 89% after 10 years of service) (Pjetursson *et al*. 2007), the choice of oral implants as abutments for reconstructing the dentition has revolutionized restorative dentistry. Without adequate evidence, some clinicians trust an implant abutment even more than a natural tooth, and there is an erroneous belief that oral implants now solve most prosthetic problems with a lot more ease and less risk than traditional reconstructive dentistry did.

Even though there is an increasing body of evidence documenting that implant-supported reconstructions have a three-times higher incidence of technical complications than tooth-supported reconstructions (Lang *et al*. 2004; Pjetursson *et al*. 2004a,b; Tan *et al*. 2004) and that the incidence of biologic complications remains approximately the same for the two alternatives, the trend in dentistry, unfortunately, is to prefer the implant over the tooth abutment.

It has to be clearly stated that the decision to maintain and treat or to extract a compromised tooth has to precede the decision regarding the need for and the modalities of tooth replacement. In this sense, "*implants are here to replace missing teeth, they are not supposed to replace teeth*".

If properly evaluated, the indication for oral implants as abutments in restorative dentistry is complementary to traditional approaches and helps to facilitate treatment planning in many instances.

Treatment concepts

When reconstructing a mutilated dentition, it has to be realized that teeth were usually lost due to the two most frequently encountered oral diseases, caries and periodontitis. Only a small proportion of teeth are lost due to trauma or are not present due to agenesis. Hence, the vast majority of patients in need of reconstructions present with an oral biofilm infection of variable severity and extent. It is evident that such patients need to be treated with a cause-related approach, i.e. systematic periodontal therapy has to precede any type of reconstructive therapy. It is of utmost importance that oral biofilm infections be under control prior to the placement of oral implants, since residual periodontal pockets or untreated ecologic niches within the oral cavity may serve as a source of infection and jeopardize the health of the peri-implant region (Mombelli *et al*. 1995). Hence, implant installation and prosthetic reconstruction is generally not a treatment in itself, but belongs to a systematic approach of comprehensively establishing esthetic and functional demands under healthy conditions (see Chapter 31).

It is obvious that chewing function is affected both by tooth loss and the type of prosthetic reconstruction chosen to replace missing teeth. A quantitative comparison by measuring bite force and chewing efficiency with identical methods in subjects with overdentures, complete full dentures, and natural dentitions was performed (Fontijn-Tekamp *et al*. 2000). In the latter group, chewing efficiency was significantly greater than that of patients with full dentures irrespective of the nature of their mandibular ridge. By installing implants, bite force and

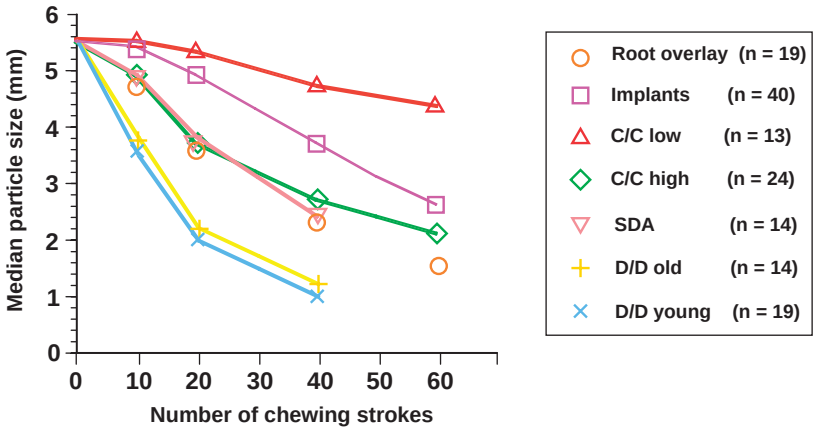

Fig. 52-1 Masticatory chewing efficiency. Number of chewing strokes needed to reach respective particle sizes of the same test food. From Fontijn-Tekamp *et al*. (2000).

chewing efficiency could be significantly improved, although it did not reach that of the dentate patients. Shortened dental arch patients exerted bite forces similar to those of patients with a complete natural dentition, but their chewing efficiency was slightly limited due to the reduced occlusal area. This, in turn, meant that patients with a shortened dental arch would have to perform approximately twice as many chewing strokes to reach the same efficiency as the fully dentate patient (Fig. 52-1).

Limited treatment goals

Generally, efforts are made to completely reconstruct a partially edentulous dentition. The question arises whether or not missing teeth have to be replaced at all and to the full extent. Usually, single teeth are replaced because of predominantly esthetic demands, while multiple missing teeth may also affect functionality and chewing capacity and, hence, are replaced to improve these aspects. However, it is evident from a number of cross-sectional and longitudinal studies (Käyser 1981; Battistuzzi *et al*. 1987; Witter *et al*. 1988, 1990a,b, 1991, 1994) that not all teeth lost are to be replaced. The loss of one or more molars has been thoroughly studied by the Nijmegen group of clinical researchers. No clinically significant differences were found in these studies between subjects with a complete dentition and those with reduced dental arches regarding masticatory capacity, signs and symptoms of temporomandibular disorders, migration of remaining teeth, periodontal support, and oral comfort.

Shortened dental arch concept

Studies on shortened dental arches (SDA) have shown that dentitions comprising anterior and premolar teeth generally fulfil the requirements of a functional dentition, including patient-assessed oral comfort and chewing ability. A review of the literature on SDA concluded that the concept deserves serious consideration in treatment planning for partially edentulous patients. However, with ongoing changes, e.g. in dental health and economy, the concept requires continuing research, evaluation, and discussion (Kanno & Carlsson 2006).

Fig. 52-2 Increasing subjective chewing comfort for completely edentulous patients. Two implants in the canine region united with a bar device (or solely with a retention element without the bar) can dramatically improve masticatory ability and efficacy.

Special attention has to be given to the patient's own needs and desires for increased chewing capacity when considering the SDA as a limited treatment goal. Clinical observation, as well as research findings, indicate that elderly patients can function at an acceptable level with a reduced dentition consisting of ten or even fewer occluding pairs of teeth (Käyser 1990). The WHO goal for the year 2020, namely to maintain a natural dentition of no less than 20 teeth throughout life, is also substantiated by a recent literature review as this proposed dentition will assure oral function (Gotfredsen & Walls 2007).

The choice of implants as abutments to fulfil individual needs may, therefore, become a welcome treatment option within the concept of a shortened dental arch.

Indications for implants

Three major indications can be defined for the use of oral implants:

- To increase subjective chewing comfort
- To preserve natural tooth substance and adequate, existing reconstructions
- To replace strategically important missing teeth.

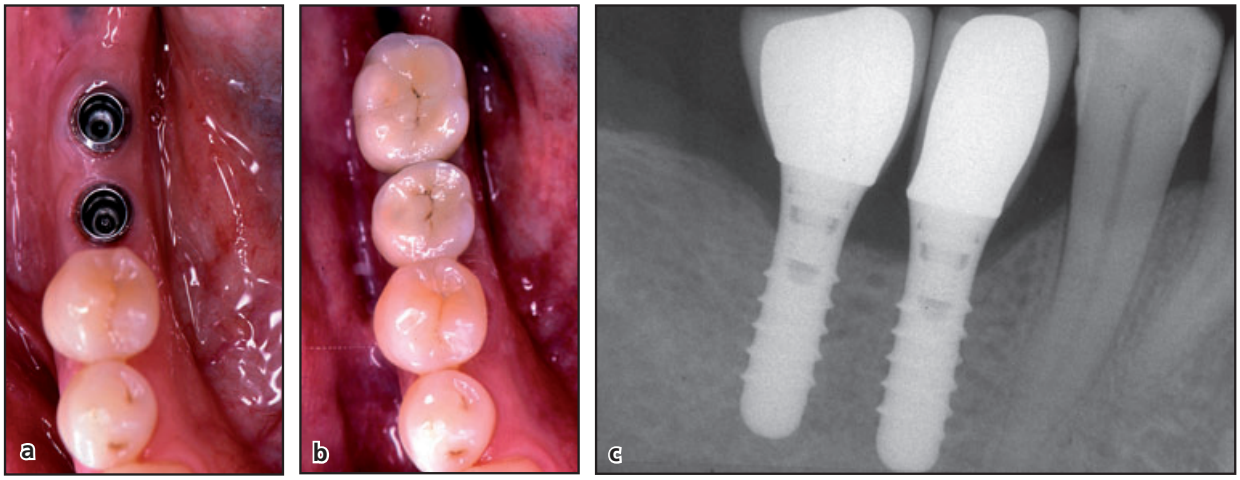

Fig. 52-3 Increasing subjective chewing comfort by replacing missing teeth in a free-end edentulous situation. (a) Installation of two standard size (4.1 mm diameter) Straumann® implants (10 mm), 5 and 11 mm distal to the distal aspect of tooth 45. (b) Chewing units are replaced as a premolar on implant in position 46 and a molar in position 46/47. (c) Radiographic view 5 years after the reconstruction.

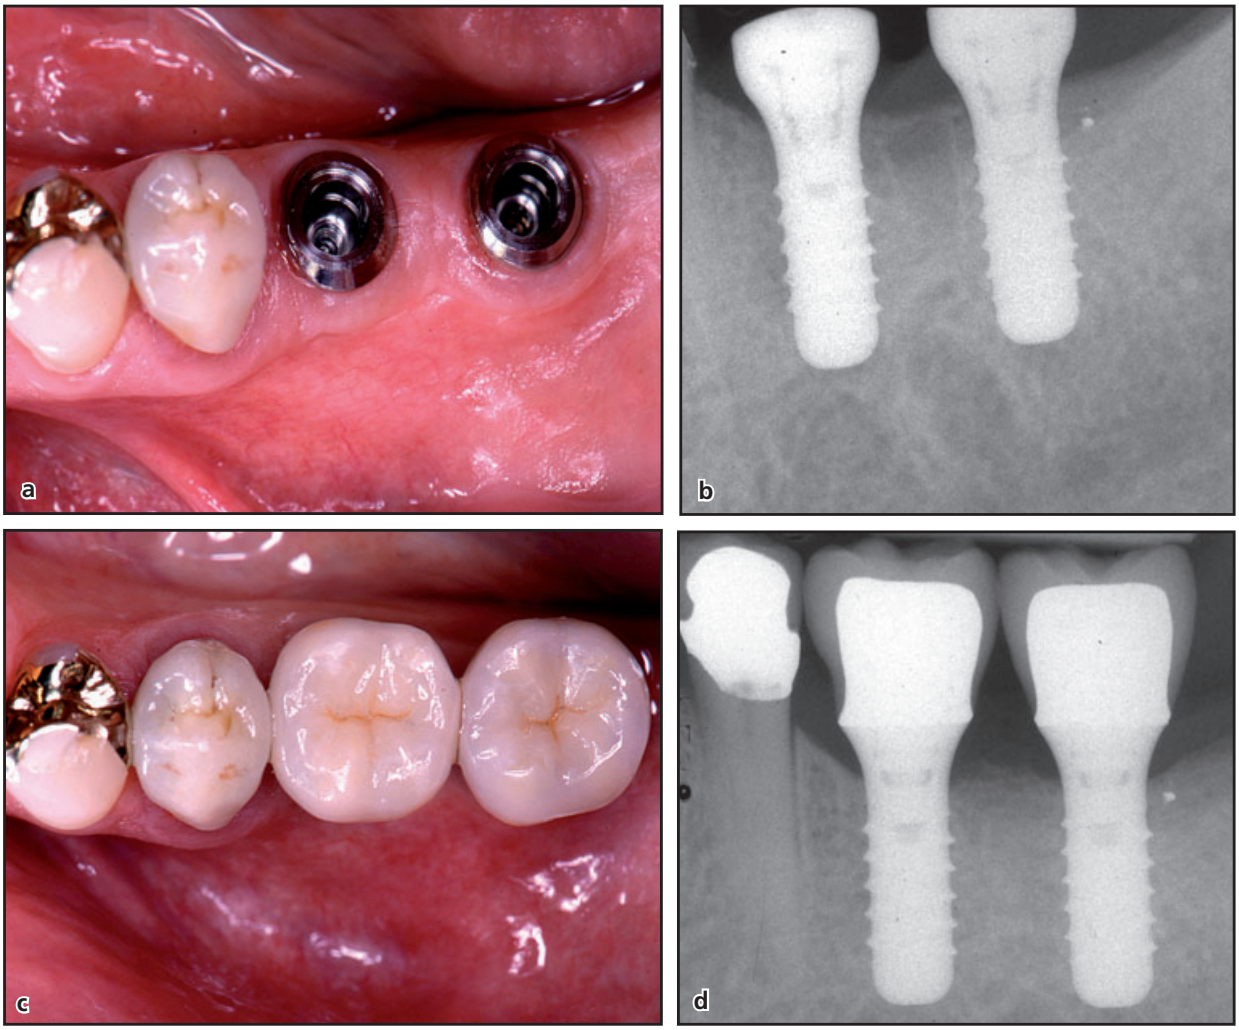

Fig. 52-4 Increasing subjective chewing comfort by replacing missing molars in a mandibular free-end situation. (a) Installation of two standard (4.1 mm diameter) Straumann® implants (8 mm), 6 and 14 mm distal to the distal aspect of tooth 35. (b) Radiographic view at the time of implant installation. (c) Two molar crowns on implants in position 36 and 37, 8 years after installation. (d) Radiographic view, 8 years after loading of the implants.

Increase the subjective chewing comfort

Studies have demonstrated that the installation of a small number of mandibular implants (two to four) may dramatically improve chewing function, especially if the edentulous mandibular ridge showed severe resorption (Fontijn-Tekamp *et al.* 2000, 2004a,b). Hence, it is evident that the completely edentulous patient will benefit from as few as two oral implants installed in the mandibular canine region (Fig. 52-2).

Likewise, subjective chewing comfort may be improved by supplementing single premolar chewing units in the posterior region in order to fulfill individual demands for more chewing capacity under a shortened dental arch concept (Fig. 52-3). It is imperative that the implants be placed in the prosthetically correct location leaving enough space for an interdental (inter-implant) space and observing the dimensions of a premolar width (7 mm).

Instead of adding chewing comfort in premolar units, implant systems with wider necks or platforms may be installed in order to truly mimic the replacement of the missing molars. In these instances, an inter-implant distance of 8 mm has to be observed in order to create enough space for the molars and the inter-implant space (Fig. 52-4).

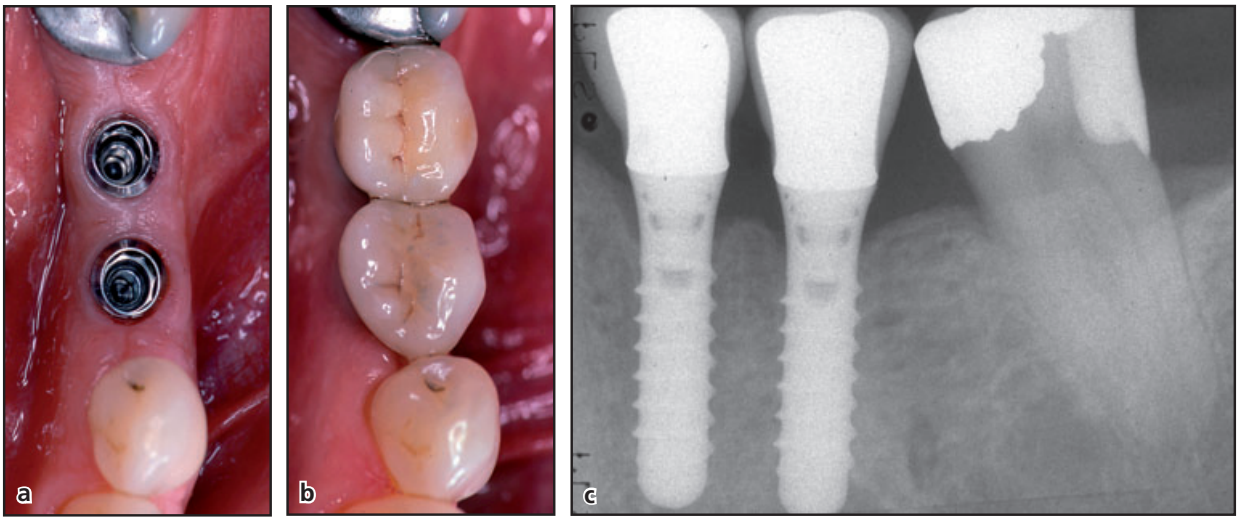

Fig. 52-5 Increasing subjective chewing comfort by closing a mandibular gap. (a) Installation of two standard (4.1 mm diameter) Straumann® implants (10 mm), 5 mm distal to the distal aspect of tooth 34 and 12 mm distal to tooth 34 (= 6 mm mesial to tooth 37). Total extension of the gap: 18 mm. (b) Reconstruction of the implants in premolar units to fit the size of the gap. (c) Radiographic documentation, 6 years after loading. The filling on tooth 37 was satisfactory and did not need replacement.

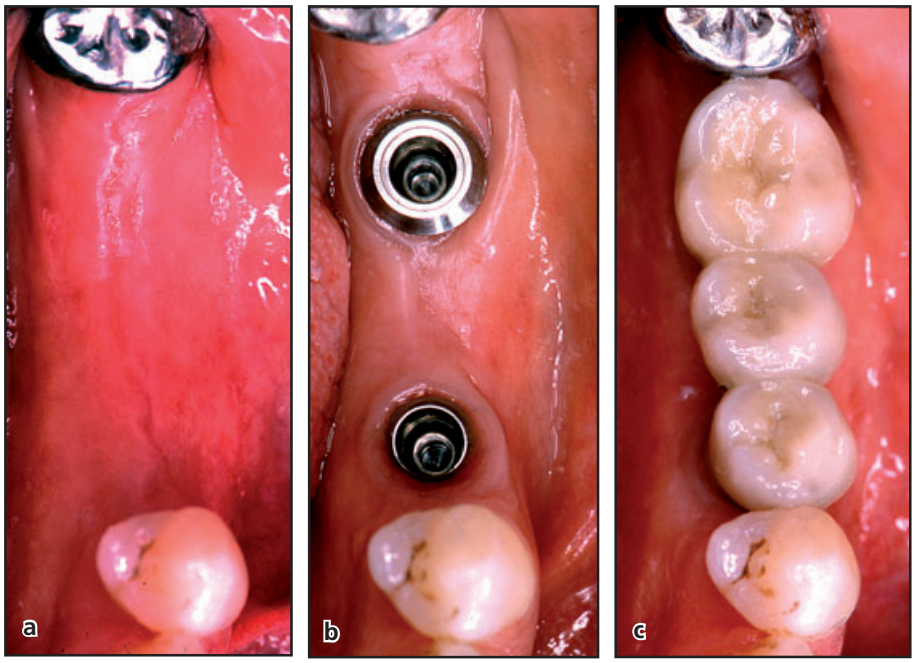

Fig. 52-6 Increasing subjective chewing comfort by filling a large mandibular gap. (a) Edentulous ridge between teeth 34 and 38 is 28 mm. (b) Installation of a standard (4.1 mm diameter) Straumann® implant, 5 mm distal to the distal aspect of tooth 34 and a wide-body (4.8 mm diameter), wide-neck Straumann® implant, 20 mm distal to the distal aspect of tooth 34 and 8 mm mesial to the mesial aspect of tooth 38. (c) Three-unit implant-supported fixed prosthesis filling the gap.

Fig. 52-7 Preservation of natural tooth substance. (a) Deciduous molar 75 has to be replaced owing to the advanced root resorption. (b) Following extraction of tooth 75, the site would be ideal for replacing the missing tooth with a three-unit bridge or a single implant. (c) The single implant is chosen to avoid jeopardizing the integrity and vitality of the two adjacent teeth, 34 and 36. Cutting preparations for full coverage of crowns will result in 10% of the prepared teeth loosing vitality after 10 years. (d) Single tooth replacement of 75, 5 years after reconstruction. (e) Occlusal view of the single implant-supported crown to replace a deciduous molar, 5 years after reconstruction. The adjacent teeth remain unsevered.

Fig. 52-8 Preservation of intact tooth substance. Single tooth replacement of a missing central incisor 21. (a) The teeth 11 and 22 adjacent to the edentulous space 21 are intact teeth with no fillings and with periodontally healthy conditions. Both mesial and distal papillae are intact and reach coronally to the contact area in this juvenile patient. (b) Following the installation of a Standard Plus (4.1 mm diameter) Straumann® implant with a length of 12 mm, the mucosal tissue is conditioned to achieve a perfect emergence profile. (c) Radiographic documentation 2 years after the prosthetic reconstruction of the implant. (d) Tissue conditioning due to a more apical insertion of the implant for esthetic sites. (e) Implant-supported single tooth replacement 21, 2 years after reconstruction.

Considering the dimensions of premolars (7 mm) and molars (8 mm) and adequate space for the interdental/inter-implant space (4–5 mm), edentulous ridges between existing teeth may be reconstructed and chewing comfort increased without involving adjacent teeth (Fig. 52-5). Obviously, risks can be minimized by reducing the length of bridge spans.

In combinations of molar and premolar reconstructions (Fig. 52-6), the surgical positioning of the implants has to be calculated in detail and restoration-driven stents may have to be used in order to create adequate conditions for prosthetic reconstruction.

Preservation of natural tooth substance and existing functional, satisfactory reconstructions

Oral implants are ideal abutments if natural tooth substance can be preserved. The preparation of a tooth to serve as an abutment for a crown or a bridge anchor opens about 40 000 to 70 000 dentinal tubules per mm^2. This, in turn, means that the integrity of a

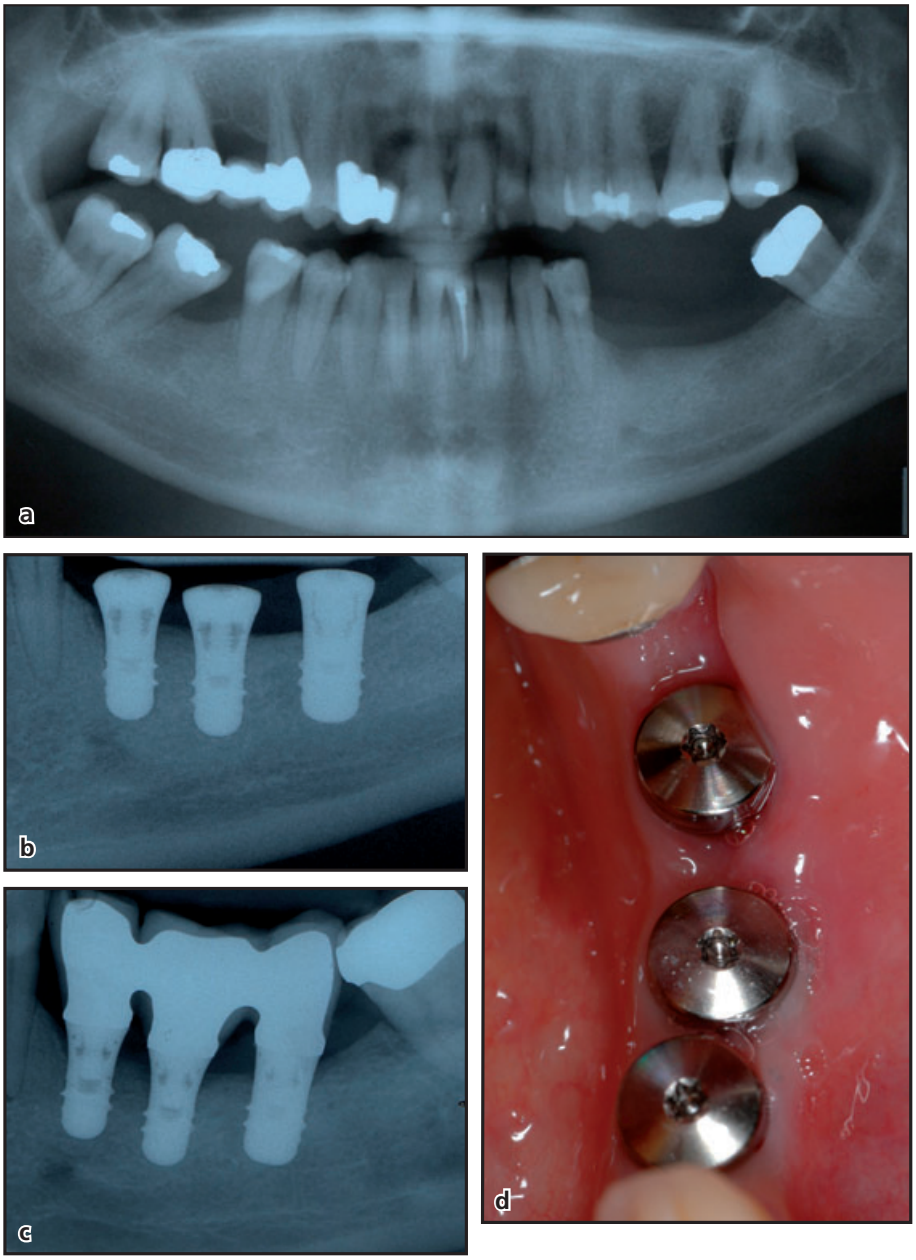

Fig. 52-9 Mandibular edentulous area after the extraction of teeth 35, 36 and 37. (a) Orthopantomogram revealing the neighboring anatomic structures (inferior mandibular nerve) and intact reconstructions on the teeth adjacent to the edentulous ridge. (b) Installation of two standard (4.1 mm diameter) and one wide-body (4.8 mm diameter) Straumann® implants at a distance of 5 mm, 11 mm and 20 mm distal to the distal aspect of tooth 34. (c) Transmucosal implant installation for two premolar and one molar unit. Implants covered with healing caps. The intact crown on tooth 38 is visible. (d) Radiographic documentation after 5 years. Implant crowns are splinted because of the short (6 mm) implants (in the neighborhood of the inferior mandibular nerve).

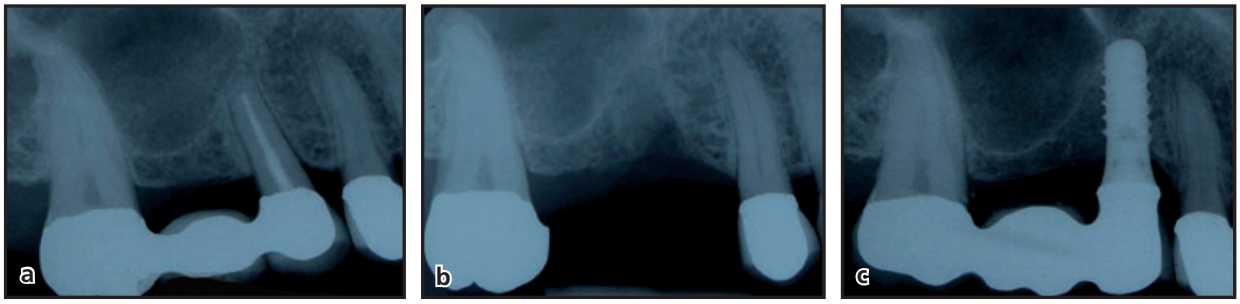

Fig. 52-10 Replacing strategically important teeth. (a) A fixed dental prosthesis is seated on two abutment teeth, 17 and 15. Tooth 15 was root canal treated and suffered from a root fracture jeopardizing the integrity of the entire reconstruction. (b) The bridge is separated between 17 and pontic 16. (c) A new fixed dental prosthesis was seated on the implant 15 and soldered to the existing, still satisfactory crown 17. In this manner, the implant helped to avoid a costly and extensive reconstruction.

vital tooth is severely compromized. Even though a small proportion of abutment teeth will lose their vitality immediately as a sequelae of the preparation procedure, it has been documented that approximately 10% of all vital abutments will have lost vitality after 10 years (Bergenholtz & Nyman 1984; Pjetursson *et al*. 2004b; Tan *et al*. 2004). Hence, it is obvious that an implant installation avoiding tooth preparation represents the most biologically sound way of replacing a missing tooth (Fig. 52-7).

In areas of esthetic priority, the replacement of a missing tooth with a single implant may, beyond any doubt, provide the best and most esthetic treatment option (Fig. 52-8). This is especially true in a periodontally healthy dentition and in situations where the papillae towards the adjacent teeth are still present. By placing the implant in a slightly (1–2 mm) submucosal location, an optimal emergence profile can be achieved.

Instead of preserving natural tooth substance, the clinician may choose to save existing, still satisfactory reconstructions, thereby simplifying the restoration of a mutilated dentition (Fig. 52-9). Occasionally, the reconstruction may have a smaller extent and, hence, have a reduced chance of encountering technical complications during the years of service.

Replacement of strategically important missing teeth

The loss of a strategically important tooth often creates a whole chain reaction of therapeutic measures to be taken. Treatment planning may become highly involved and extensive reconstructions may result from the loss of such a tooth. Especially in dentitions that have received multiple reconstructions, the loss of one strategic abutment may lead to time-consuming and costly therapy (Fig. 52-10). Oral implants provide valuable and indispensable treatment alternatives to redoing existing reconstructions. By the installation of oral implants in strategically correct locations, partial reconstruction of a dentition may be possible. Obviously, such implants have to be installed at locations that are restoration driven, at the proper location for prosthetic reconstruction. In cases with bone dehiscence or lack of adequate bone volume, bone augmentation procedures may have to be performed (Fig. 52-11).

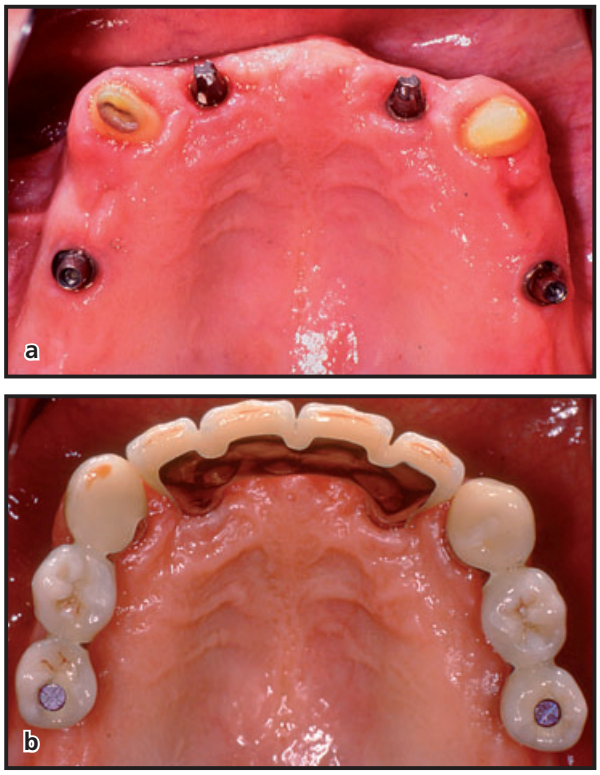

Fig. 52-11 Replacing strategically important abutments. (a) Only the two periodontally healthy maxillary canines 13 and 23 remain. To reconstruct this maxilla with a fixed dental prosthesis requires the installation of oral implants in strategically correct locations. An implant-supported maxillary front reconstruction and two mixed tooth–implant-supported reconstructions in the posterior segments are planned. (b) Eight years following implant installation. The maxillary front reconstruction is cemented on solid abutments that have been installed in the positions of 12 and 22, i.e. 5 mm mesial to the mesial aspects of the canines. The posterior segment reconstructions are cemented on the canines and screw-retained on two implants in the positions of 15 and 25, i.e. the implants are placed 11 mm distal to the distal aspects of the canines allowing the placement of three-unit reconstructions with minimal risks. A shortened dental arch as a limited treatment goal provides satisfactory chewing function.

Conclusions

Oral implants are best used as abutments in restorative dentistry if subjective chewing comfort has to be increased, natural tooth substance or existing satisfactory reconstructions have to be preserved or strategically important missing teeth have to be replaced.

Hence, oral implants have become valuable, indispensable, and welcome treatment alternatives to traditional dental reconstructions. Obviously, oral implants should only be incorporated in oral cavities with healthy conditions, i.e. a thorough periodontal treatment has to precede restorative therapy.

Chapter 53

Implants in the Esthetic Zone

Urs C. Belser, Jean-Pierre Bernard, and Daniel Buser

Basic concepts

The clinical replacement of lost natural teeth by osseointegrated implants has represented one of the most significant advances in restorative dentistry. Numerous studies on various clinical indications have documented high implant survival and success rates with respect to specific application criteria (Ekfeldt *et al*. 1994; Laney *et al*. 1994; Andersson *et al*. 1995, 1998; Brånemark *et al*. 1995; Lewis 1995; Jemt *et al*. 1996; Lindqvist *et al*. 1996; Buser *et al*. 1997, 2002; Ellegaard *et al*. 1997a;b; Levine *et al*. 1997; Bryant & Zarb 1998; Eckert & Wollan 1998; Ellen 1998; Lindh *et al*. 1998; Mericske-Stern 1998; ten Bruggenkate *et al*. 1998; Wyatt & Zarb 1998; Gunne *et al*. 1999; Lekholm *et al*. 1999; Van Steenberghe *et al*. 1999; Wismeijer *et al*. 1999; Behneke *et al*. 2000; Hosny *et al*. 2000; Hultin *et al*. 2000; Weber *et al*. 2000; Boioli *et al*. 2001; Gomez-Roman *et al*. 2001; Kiener *et al*. 2001; Mengel *et al*. 2001; Oetterli *et al*. 2001; Zitzmann *et al*. 2001; Bernard & Belser 2002; Haas *et al*. 2002; Leonhardt *et al*. 2002; Romeo *et al*. 2002). Several recently published studies have focused on treatment outcome of implant therapy in partially edentulous patients in general, and related to maxillary anterior implant restorations in particular. Belser (1999) reviewed selected publications which appear to have impact when it comes to the discussion of esthetic aspects which will be addressed in this chapter. In a prospective longitudinal study involving a total of 94 implants (50 in the anterior maxilla) restored with fixed partial dentures (FPDs), Zarb and Schmitt (1993) published an average success rate of 91.5% for an observation period up to 8 years. The respective data concerning the maxillary implants demonstrated a success rate of 94% (100% for the prosthesis success). It was concluded that implant therapy in anterior partial edentulism can replicate the data established in the literature for fully edentulous patients. The same authors (Schmitt & Zarb 1993) published an 8-year implant survival rate of 97.9% for single-tooth replacement in partially edentulous patients. These results were confirmed by Avivi-Arber and Zarb in 1996.

Andersson *et al*. (1998) published similarly favorable prospective 5-year data on single-tooth restorations, performed either in a specialist clinic or in general practices, while Eckert and Wollan (1998) presented a retrospective evaluation up to 11 years on a total of 1170 implants inserted in partially edentulous patients, and found no differences in survival rates with respect to the anatomic location of the implants. A meta-analysis concerning implants placed for the treatment of partial edentulism was carried out by Lindh *et al*. (1998). The 6–7-year survival rate for single implant crowns corresponded to 97.5%, while the survival rate of implant-supported FPDs was 93.6%. The influence of implant design and surface texture was investigated by Norton (1998) by means of a radiographic follow-up of 33 implants loaded for up to 4 years. A most favorable maintenance of marginal bone around the conical collar was revealed, with a mean marginal bone loss of 0.32 mm mesially and 0.34 mm distally for the whole group.

Soft tissue stability around implant restorations and adjacent teeth is of paramount importance within the appearance zone (Bengazi *et al*. 1996; Chang *et al*. 1999; Ericsson *et al*. 2000; Grunder 2000; Choquet *et al*. 2001; Cooper *et al*. 2001; Mericske-Stern *et al*. 2001; Bernard & Belser 2002; Engquist *et al*. 2002; Haas *et al*. 2002; Krenmair *et al*. 2002). Scheller *et al*. (1998) specifically addressed this parameter in their 5-year prospective multicenter study on 99 implant-supported single-crown restorations. The authors reported overall cumulative success rates of 95.9% for implants and 91.1% for implant crowns. Soft tissue levels around implant restorations and adjacent teeth remained stable over the entire evaluation period. Wyatt and Zarb (1998) published a longitudinal study on 77 partially edentulous patients, involving a total of 230 implants and 97 fixed partial dentures, with an observation period of up to 12 years (mean 5.41 years) after loading. The average implant success rate was 94%, while the continuous stability of the prostheses (fixed partial dentures) corresponded to 97%. This study comprised 70 anterior and 31 posterior maxillary implants. No significant differences with respect to longevity could be detected either between anterior and posterior locations or between maxillary and mandibular implant restorations.

Along with osseointegration and restoration of function, the patient's subjective satisfaction is a key element of the success of implant therapy. Especially when the implant is located in the anterior part of the oral cavity, an essential part of the therapy aims at creating appropriate conditions, so that the implant prosthesis cannot be distinguished from the adjacent natural teeth at the end of treatment. In this context, a variety of specific procedures have been developed, including novel bone augmentation protocols, connective tissue grafting and reconstruction of lost papillary tissue (Bahat *et al*. 1993; Salama & Salama 1993; Bahat & Daftary 1995; Salama *et al*. 1995; Price & Price 1999; Choquet *et al*. 2001).

Being part of a comprehensive textbook about clinical periodontology, this chapter will focus primarily on fixed implant restorations located in the esthetic zone.

General esthetic principles and related guidelines

The basic parameters related to dental and gingival esthetics in general and to the maxillary anterior segment in particular are well established in the dental literature (Goldstein 1976; Belser 1982; Schärer *et al*. 1982; Seibert & Lindhe 1989; Goodacre 1990; Rüfenacht 1990; Nathanson 1991; Magne *et al*. 1993a,b, 1994, 1996; Chiche & Pinault 1994; Kois 1996; Kokich 1996; Kokich & Spear 1997; Jensen *et al*. 1999) and have been recently summarized in the form of an updated integral check-list by Magne and Belser (2002). When it comes to the characteristics of the natural maxillary anterior dentition, a number of fundamental objective criteria, including gingival health and its normal morphology as well as dimension, form, specific structural composition, color, opalescence, translucency, transparency, and surface texture of incisors and canines, have been identified (Table 53-1, Fig. 53-1). This list is completed by an addition of subjective criteria associated with esthetic integration, such as variations in the arrangement and positioning of front teeth, relative crown length and negative space.

Depending on the type of a given initial clinical situation requiring the replacement of one or several teeth, the patient's expectations may vary from the achievement of an almost perfect illusion, i.e. that the untrained eye cannot easily distinguish the restoration from the surrounding natural dentition, to the

Table 53-2 Patient expectations related to maxillary anterior edentulous segments

- Long-lasting esthetic and functional result with a high degree of predictability
- Minimal invasiveness (preservation of tooth structure)
- Maximum subjective comfort
- Minimum risk for complications associated with surgery and healing phase
- Avoidance of removable prostheses
- Optimum cost effectiveness

Table 53-3 Therapeutic modalities for tooth replacement in the esthetic zone

- Conventional fixed partial dentures (FPDs), comprising cantilever units
- Resin-bonded ("adhesive") bridges
- Conventional removable partial dentures (RPDs)
- Tooth-supported overdentures
- Orthodontic therapy (closure of edentulous spaces)
- Implant-supported prostheses (fixed, retrievable or removable suprastructures)
- Combinations of the above

acceptance of various degrees of compromise from a purely esthetic point of view. The latter case is not infrequent after multiple anterior tooth loss in combination with significant hard and soft tissue deficiencies. In relation to maxillary anterior edentulous segments, patients generally expect a long-lasting functional and esthetic result with a high level of predictability (Table 53-2). To this primary objective are normally added a number of secondary goals which include parameters such as minimal invasiveness, low risk associated with eventual surgery, overall simplicity, and cost effectiveness.

Prior to selecting an implant-based solution, one should comprehensively review all of the possible treatment modalities available (Table 53-3) which have the potential to solve a given clinical problem, and carefully ponder their respective advantages and eventual shortcomings, and only then take the decision together with the adequately informed patient. Currently, the restorative spectrum in the case of missing maxillary anterior teeth comprises conventional FPDs, resin-bonded bridges, removable partial dentures (RPDs), tooth-supported overdentures and implant-supported fixed or removable prostheses. Furthermore, one should not forget that occasionally orthodontic therapy, e.g. closure of limited edentulous spaces, can represent an effective and elegant alternative or adjunct to a prosthetic treatment. However, the availability of scientific evidence – when possible at its highest level – for the planned treatment modality, should be the key parameter for the final choice.

Table 53-4 Criteria favoring implant-borne restorations

- Normal wound healing capacity
- Intact neighboring teeth
- Unfavorable ("compromised") potential abutment teeth
- Extended edentulous segments
- Missing strategic abutment teeth
- Presence of diastemas

In this clinical decision-making process certain criteria, for example the compromised structural, periodontal and/or endodontic status of potential natural abutments, or the extended dimension of the edentulous segment, are among the factors favoring an implant-borne restoration rather than a tooth-supported fixed prosthesis (Table 53-4).

Esthetic considerations related to maxillary anterior implant restorations

In the context of the natural dentition, long clinical crowns, the irregular contour of the gingival margin, i.e. any abrupt change in vertical tissue height between neighboring teeth, and the loss of papillary tissue often have an adverse influence on dental–facial esthetics (Seibert & Lindhe 1989). Furthermore, the same authors have underlined that in the case of a *high scalloped gingival morphotype* (in contrast to a rather *low scalloped gingival morphotype*) there is mostly an unpredictable relationship between the underlying bone and the gingival contour, often leading to so called "black hole cases" and presenting a high risk for losing soft tissue (e.g. gingival or mucosal recession at the labial aspect of teeth or implants), particularly in relation to restorative procedures, as for example insertion of retraction cords and impression taking.

Another esthetically relevant concern lies in the fact that under normal conditions a maxillary front tooth extraction leads on average to approximately 2 mm loss in vertical tissue height. The mean length of the clinical crown of a maxillary central incisor is 10.2 mm, the one of a lateral incisor 8.2 mm and that of a canine 10.4 mm. Consequently, any kind of maxillary anterior restoration should aim at staying within reasonable limits of these average morphologic dimensions, if a harmonious and esthetically pleasing result is to be achieved. Ultimately, an anterior implant restoration should correspond closely to an ovate pontic of a conventional FPD with respect to the relevant soft tissue parameters (Kois 1996).

Numerous publications, mostly in the form of textbooks, book chapters, reviews, case reports and descriptions of clinical and laboratory procedures and techniques, have addressed various aspects specifically related to esthetics and osseointegration (Parel & Sullivan 1989; Gelb & Lazzara 1993; Jaggers *et al*. 1993; Vlassis *et al*. 1993; Bichacho & Landsberg

Table 53-5 Evaluation of anterior tooth-bound edentulous sites prior to implant therapy

- Mesio-distal dimension of the edentulous segment, including its comparison with existing contralateral control teeth
- Three-dimensional analysis of the edentulous segment regarding soft tissue configuration and underlying alveolar bone crest (ref. "bone-mapping")
- Neighboring teeth:
  - volume (relative tooth dimensions), basic features of tooth form and three-dimensional position and orientation of the clinical crowns
  - structural integrity and condition
  - surrounding gingival tissues (course/scalloping of the gingival line)
  - periodontal and endodontic status/conditions
  - crown-to-root ratio
  - length of roots and respective inclinations in the frontal plane
  - eventual presence of diastemata
- Interarch relationships:
  - vertical dimension of occlusion
  - anterior guidance
  - interocclusal space
- Esthetic parameters:
  - height of upper smile line ("high lip" versus "low lip")
  - lower lip line
  - course of the gingival-mucosa line
  - orientation of the occlusal plane
  - dental versus facial symmetry
  - lip support

Table 53-6 Optimal three-dimensional implant positioning ("restoration-driven implant placement") in anterior maxillary sites

- Correct vertical position of implant shoulder (sink depth) using the cemento-enamel junction of adjacent teeth as reference:
  - no visible metal
  - gradually developed, flat axial profile
- Correct orofacial position of point of emergence for future suprastructure from the mucosa:
  - similar to adjacent teeth
  - flat emergence profile
- Implant axis compatible with available prosthetic treatment options (ideally: implant axis identical with "prosthetic axis")

Implant = apical extension of the ideal future restoration.

1994; Ghalili 1994; Landsberg & Bichacho 1994; Neale & Chee 1994; Studer *et al*. 1994; Carrick 1995; Corrente *et al*. 1995; De Lange 1995; Garber 1995; Garber & Belser 1995; Jansen & Weisgold 1995; Khayat *et al*. 1995; Touati 1995; Brugnolo *et al*. 1996; Davidoff 1996; Grunder *et al*. 1996; Hess *et al*. 1996; Marchack 1996; Mecall & Rosenfeld 1996; Bain & Weisgold 1997; Bichacho & Landsberg 1997; Chee *et al*. 1997; Garg *et al*. 1997; Spear *et al*. 1997; Salinas & Sadan 1998; Jemt 1999; Price & Price 1999; Belser *et al*. 2000; Tarnow *et al*. 2000).

In view of maxillary anterior implant restorations, the systematic and comprehensive evaluation of edentulous sites, including the surrounding natural dentition, is of paramount importance (Table 53-5). Key parameters comprise the mesio-distal dimension of the edentulous segment, the three-dimensional analysis of the underlying alveolar bone crest, the status of the neighboring teeth, and interarch relationships as well as specific esthetic parameters.

As one should consider the implant as the apical extension of the ideal future restoration and not the opposite, a respective optimal three-dimensional ("restoration-driven") implant position is mandatory (Table 53-6). Consequently, parameters addressing vertical (sink-depth) and oro-facial implant shoulder location, have been defined, as well as guidelines related to the long axis of the implant, as the latter has a significant impact on the subsequent technical procedures during suprastructure conception and fabrication.

Recently, the ITI Consensus Conference has approved the distinctly submucosal implant shoulder location in the maxillary anterior segment in order to respond to natural esthetic demands (Buser & von Arx 2000). As the current implant design – in contrast to the scalloped cemento-enamel junction – features a straight horizontal, "rotation–symmetrical" restorative interface, interproximal implant crown margins are often located several millimeters submucosally, and are thus difficult to reach by the patient's routine oral hygiene efforts (Belser *et al*. 1998). Mainly for this reason a screw-retained implant suprastructure (Sutter *et al*. 1993; Hebel & Gajjar 1997; Keller *et al*. 1998) is preferred to a cemented one, as it benefits from the surface quality and marginal fidelity of prefabricated, machined components, and avoids potential problems associated with cement excess that may be difficult to reach and thoroughly eliminate.

Anterior single-tooth replacement

Favorable 5-year multicenter results for 71 single-tooth replacements in the anterior maxilla (implant success rate of 96.6%) were reported by Henry *et al*. (1996); however, this group mentioned an associated 10% esthetic failure rate. In a retrospective study on 236 patients treated with single-tooth implant restorations in the anterior maxilla (Walther *et al*. 1996), a Kaplan–Meier survival rate of 89% was found for an observation period of 10 years. The failure rate for lateral incisor replacement was lower than that for central incisors. Furthermore, 5% of the related prosthetic suprastructures had to be replaced during the 10 years of observation. Kemppainen *et al*. (1997) prospectively documented 102 implants (ASTRA/ITI) for single-tooth replacement in the anterior maxilla of 82 patients and found survival rates of 97.8% and 100%, respectively, after 1 year. Still related to single-tooth maxillary anterior implants, a prospec-

tive study on 15 patients revealed a 100% implant survival rate after 2 years of function (Palmer *et al*. 1997). At crown insertion (6 months after implant placement) the mean bone level was located 0.47 mm apically to the top of the implants. No significant additional changes in crestal bone level occurred during the remainder of the study.

Today, it is generally accepted that the final implant shoulder sink depth for esthetic fixed single-tooth restorations can be determined primarily by the location of the cemento-enamel junction (CEJ) of the neighboring teeth and by the level of the free gingival margin at the vestibular aspect of these same teeth. This means that the implant shoulder is positioned 1–2 mm more apically to the labial CEJ of the adjacent teeth (Belser *et al*. 1998, 2000). However, the noticeable esthetic progress made in this kind of implant restoration is the result of recent developments in the absence of extensive long-term documentation. Because the exclusive use of clinical signs for establishing peri-implant health or disease may not be sufficient, the evaluation of additional objective parameters is needed. A number of diagnostic tests have been utilized by clinicians to supplement clinical signs with objective methods. These tests include microbiologic monitoring, proteolytic bacterial enzyme markers, markers of tissue destruction, and finally, markers of tissue repair and regeneration. In this context peri-implant crevicular fluid (PICF) analysis has become the focus of intense investigation. It has been observed that the volume of crevicular fluid did not differ between implant sites and natural teeth and that the features of inflammation seem to be the same around teeth and implants. In addition, the histologic arrangement of peri-implant soft tissues resembles basically that observed around natural teeth, although there are also some aspects of scar tissue (Abrahamson *et al*. 1996, 1997; Berglundh & Lindhe 1996; Lindhe & Berglundh 1998).

Giannopoulou *et al*. (2003) investigated the effect of intracrevicular restoration margins on peri-implant health of 61 maxillary anterior implants – mainly single-tooth replacements – in 45 patients for up to 9 years. Results revealed that the only statistically significant differences between baseline and follow-up examination concerned pocket probing depth (PPD) and the distance between the implant shoulder and the mucosal margin (DIM measurements), which increased slightly over time. The remainder of the clinical measurements and almost all of the microbiologic and biochemical parameters analyzed did not change significantly. Probably the most critical parameter from a purely esthetic point of view is the DIM value, particularly on the labial aspect of the maxillary anterior implants investigated in this study. A mean value of –1.5 ± 1.1 mm was found at baseline examination, and a slight increase (–1.7 ± 1.1 mm) at the follow-up. This indicates that the risk for exposure of the implant-to-crown interface or margin can be considered low. These findings corroborate recently published data addressing similar parameters (Grunder 2000). The consistently negative Periotest scores confirmed the stability and osseointegrated status of the implants examined. Furthermore, no associations were observed between the above results and the number of years that the implants had been in function. Based on these clinical, microbiologic, and biochemical data, and on an observation period of 4–9 years (mean 6.8 years), it was concluded that in patients with appropriate oral hygiene, implant-supported maxillary anterior crowns with distinctly intracrevicular margins did not predispose to unfavorable peri-implant host and microbial responses. In particular, overall healthy and stable peri-implant tissue conditions – a paramount criterion when it comes to esthetic implant crowns – were consistently encountered and maintained longitudinally. One of the patients participating in this study and who recently passed the 10-year clinical and radiographic follow-up control, is presented in Figs. 53-2 to 53-6. An adequate esthetic integration of the two single-tooth restorations, replacing the congenitally missing lateral incisors, could be achieved and maintained over time.

Fig. 53-2 Ten-year follow-up of a 28-year-old female patient. Both congenitally missing lateral incisors were replaced by implants, restored with screw-retained porcelain-fused-to-metal crowns.

Fig. 53-3 The frontal view in centric occlusal position documents the harmonious integration of the two implant restorations after 10 years of clinical service.

Fig. 53-4 Ten-year post operative radiograph of the maxillary right lateral single-tooth implant restoration.

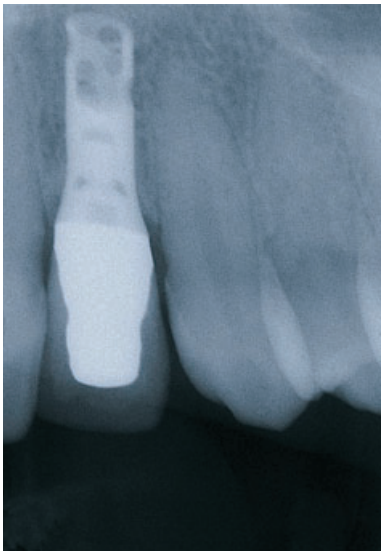

Fig. 53-5 Ten-year post-operative radiograph of the maxillary left lateral single-tooth implant restoration.

Fig. 53-6 During unforced smiling an adequate balance between implant-crowns and natural dentition can be noticed.

Fig. 53-7 Schematic representation of an intact maxillary right anterior segment. The alveolar bone follows the scalloped course of the cemento-enamel junction for a distance of approximately 2 mm (white dotted line), whereas, accordingly, the gingival tissue occupies the interdental area completely.

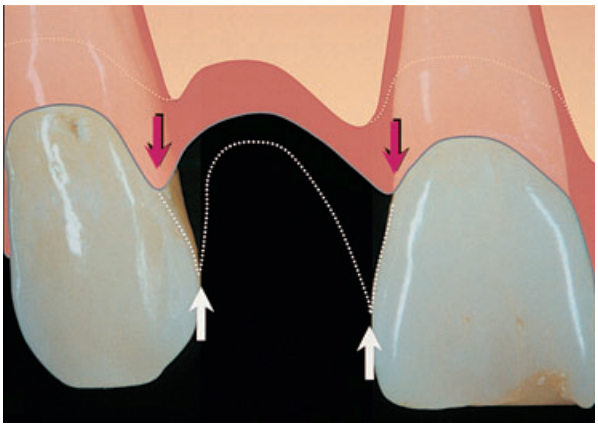

Fig. 53-8 Schematic representation of the same segment after loss of the lateral incisor. While the interproximal bone height has basically been maintained, the corresponding gingival tissue is flattened due to a lack of support originally provided by the now missing tooth.

In a simplistic way, the morphologic and esthetic consequences in the frontal plane of the loss of a single maxillary incisor, when compared to the original intact situation, can be summarized as follows: maintenance of the tooth-sided interproximal bone height at the neighboring teeth, and vertical loss ("flattening") of the corresponding gingival tissue due to a lack of support originally provided by the now missing tooth (Figs. 53-7, 53-8). In case of an anterior single-tooth replacement, the related implant restoration should aim at replicating the clinical crown of the contralateral control tooth from the line of soft tissue emergence to the incisal border. Additionally, a gradually developed, flat emergence profile from the implant shoulder to the peri-implant mucosal margin is mandatory (Figs. 53-9, 53-10).

The basic considerations related to maxillary anterior single-tooth replacement, including the respective general achievements and limitations, and

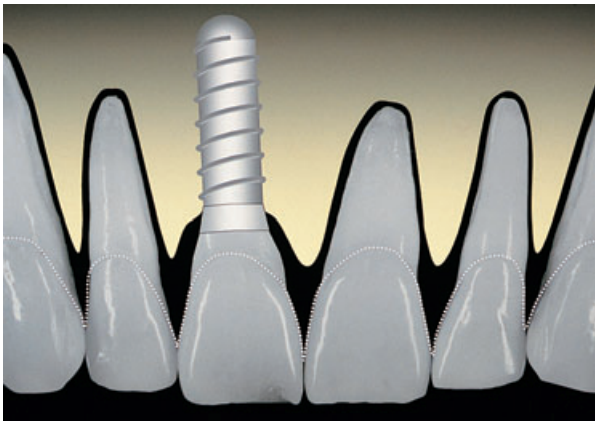

Fig. 53-9 The treatment objective in the case of an anterior single-tooth replacement is an implant restoration with a gradually developed, flat emergence profile from the implant shoulder to the peri-implant mucosal surface. Ideally, the clinical crown of the implant restoration should aim at replicating the clinical crown of the corresponding contralateral tooth.

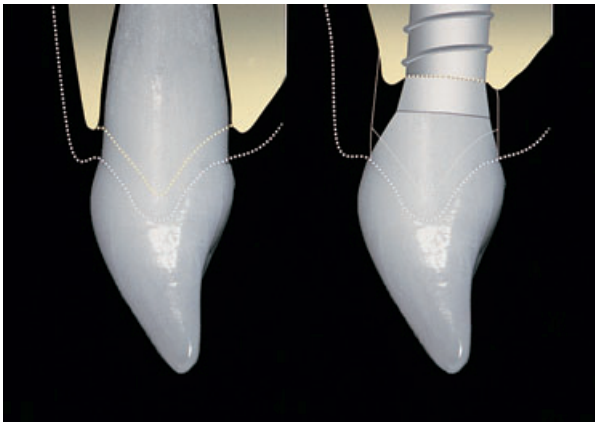

Fig. 53-10 Schematic comparison in the sagittal plane between a natural maxillary incisor and a respective implant borne single-tooth restoration. The decrease of alveolar bone height on the labial and palatal aspect following tooth loss leads to a more palatal implant position when compared to the original root position, which in turn influences the axial profile of the restoration.

addressing edentulous segments with different types of labial bone deficiencies, are presented in Table 53-7.

Sites without significant tissue deficiencies

An increasing body of evidence indicates that the most determinant parameter for achieving an esthetic single-tooth restoration is the interproximal bone height at the level of the teeth confining the edentulous gap. The related bone should be within a physiologic distance, i.e. approximately 2 mm, of the CEJ and thus provide the essential support for the overlaying soft tissue compartments. Consequently, preoperative diagnosis will include interproximal radiographic bone height assessment and periodontal probing of the soft tissue attachment level.

Fig. 53-11 Pre-operative close-up view of the upper right anterior region of a 22-year-old female patient with a missing right central incisor. The scalloped course of the gingiva is maintained, featuring interproximal soft tissue at the level of the cemento-enamel junction.

Table 53-7 Basic considerations related to anterior single-tooth replacement

Achievements	Predictable and reproducible results regarding both esthetic parameters and longevity in sites without significant vertical tissue deficiencies Well defined and well established surgical protocols: • *restoration-driven* implant placement Adequate and versatile restorative protocols and prosthetic components: • occlusal/transverse screw-retention • angulated abutments • high-strength ceramic components
Sites with buccal bone deficienies	Lateral bone augmentation using *autografts* and *barrier membranes*: • technique offers efficacy and predictability • *simultaneous* or *staged approach* depending on defect extension and defect morphology Lateral bone augmentation by means of *alveolar bone crest splitting* and/or various *osteotome techniques*: • limited clinical long-term documentation
Limitations	Combined vertical bone and soft tissue deficiencies: • following removal of ankylosed teeth or failing implants • advanced loss of periodontal tissues, including gingival recession, on neighboring teeth • limited scientific documentation related to *vertical bone augmentation* and *distraction osteogenesis*

If the comprehensive presurgical analysis of a given maxillary anterior single-tooth gap has confirmed a favorable vertical level of both soft tissue and underlying alveolar bone at the interproximal aspect of the two adjacent teeth on the one hand (Figs. 53-11 to 53-13), and no major vestibular bone deficiencies on the other hand, the site can be consid-

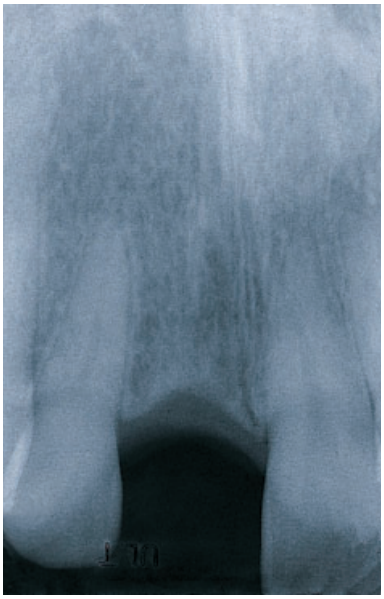

Fig. 53-12 The corresponding radiograph displays favorable bony conditions in view of implant therapy. Note in particular the interproximal bone height, following the cemento-enamel junction for a distance of less than 2 mm.

Fig. 53-13 The oblique close-up view confirms optimal conditions for the insertion of an implant, namely interproximal soft tissue height and no significant loss of the buccal bone plate.

Fig. 53-14 Clinical view of the maxillary anterior implant site 8 weeks after insertion of a solid screw implant according to a one-stage transmucosal surgical protocol. A harmonious peri-implant soft tissue profile has been established by means of a titanium healing cap featuring a respective emergence profile and thus offering adequate interproximal soft tissue support.

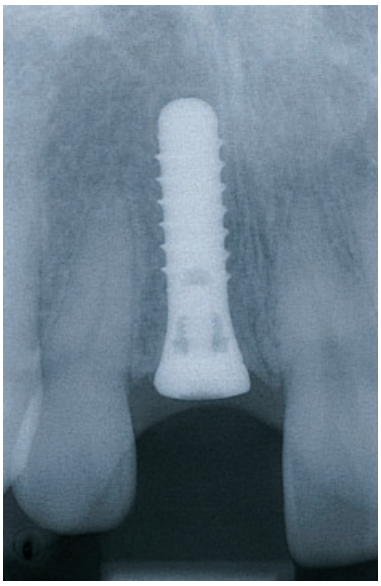

Fig. 53-15 The corresponding radiograph displays a continuous close contact between bone and implant and confirms that the vertical interproximal bone level has been maintained.

ered compatible with a straightforward implant surgical protocol. In order to ensure the best probability of a successful and long-lasting esthetic treatment outcome, the actual implant placement has to be carried out meticulously according to the surgical guidelines defined in Table 53-6. These guidelines include key parameters such as low-trauma surgical principles in general and precise three-dimensional ("restoration-driven") implant positioning in particular. In the case of standard single-tooth sites, most surgeons do not advocate the use of a surgical guide or stent, as the adjacent teeth and associated anatomic structures normally offer sufficient morphologic landmarks to reach the therapeutic objective safely. As far as the detailed surgical protocol is concerned, readers are referred to Chapter 48. Buser and von Arx (2000) have published the surgical step-by-step procedure related to maxillary anterior single-tooth implants, and insisted on a slightly palatal incision technique to preserve a maximum of keratinized mucosa on the labial aspect of the future implant restoration. Another crucial parameter is the maintenance of at least 1 mm of bone plate on the vestibular aspect of the implant in order to minimize the risk for peri-implant soft tissue recessions, a factor parameter when it comes to esthetics. Under such conditions one may consistently achieve post-surgical treatment outcomes featuring unaltered vertical soft tissue and underlying bone levels at the interproximal aspect of the adjacent natural teeth (Figs. 53-14 to 53-16).

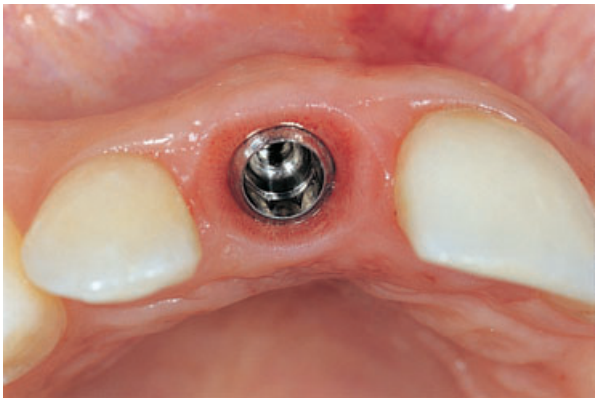

Fig. 53-16 The occlusal view reveals an implant position in the orofacial plane that is in accordance with the adjacent natural roots and thus permits development of a flat emergence profile.

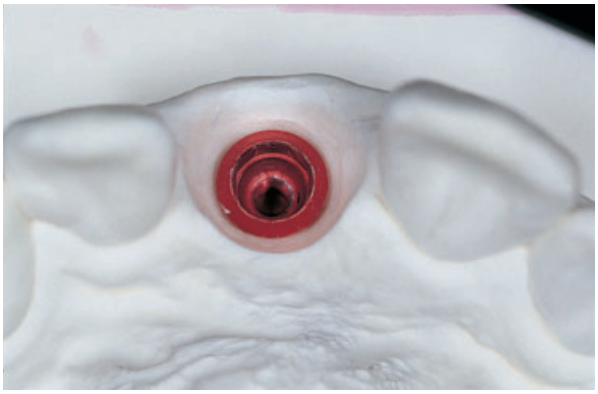

Fig. 53-18 The configuration of the peri-implant soft tissue is subsequently adapted on the stone model according to the diagnostic wax-up. Ultimately, it will be the restoration itself that completes the last phase of soft tissue conditioning by subtle respective physical displacement.

Fig. 53-17 On a stone model derived from the clinical situation, the laboratory technician defines the treatment objective in wax. At this stage priority is given to esthetic principles and maintenance of symmetry rather than to the actual position of the underlying implant.

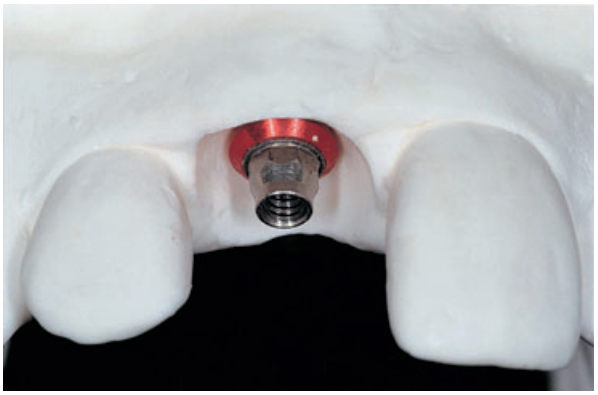

Fig. 53-19 An appropriate secondary titanium component (abutment) is selected as support for the planned screw-retained implant restoration.

Once osseointegration is confirmed radiologically and clinically, the clinical situation is transferred to the master model by means of an impression, normally assisted by auxiliary components in the form of prefabricated impression copings. On the master model, which in turn contains a replica (analogue) of the implant, the laboratory technician defines the final configuration of the single-tooth implant restoration by means of a diagnostic wax-up (Fig. 53-17). Under normal circumstances, i.e. when the natural contralateral control tooth corresponds mostly to the esthetic and functional requirements of an appropriate "target model", the technician basically copies the clinical crown of this control tooth in wax, regardless of the actual underlying implant position. At this stage a close-to-ideal restoration is planned, while its connection to the underlying implant will be addressed later. This approach comprises the minute shaping of the peri-implant soft tissue configuration (on the master model in the form of stone), in view of an identical emergence from the labial and interproximal soft tissue margin, to the one observed on the natural tooth site (Fig. 53-18). Only after having completed this preparatory step, will the ceramist select the most adequate secondary component (i.e. abutment), depending on the three following cardinal criteria (Fig. 53-19):

1. Implant shoulder depth in relation to the labial mucosal margin
2. Oro-facial implant shoulder position with respect to the future line of emergence of the suprastructure
3. Long axis of the implant.

In most instances, preference will be given to a screw-retained implant suprastructure, unless a combination of mesiostructure and cemented restoration is chosen. Screw-retention is primarily preferred due to a marked submucosally located implant shoulder, in particular at the interproximal aspect, which may render the removal of excess cement difficult, and which is mostly not within reach of the patient's routine oral hygiene measures. In addition, screw-retained suprastructures benefit from the close-to-perfect surface quality characteristics and the

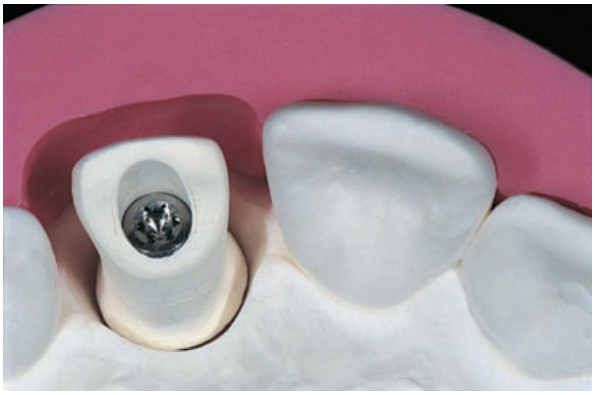

Fig. 53-20 Using a silicon template as guide, a prefabricated ceramic blank is inserted and subsequently reduced to provide adequate space for the external layers of cosmetic porcelain.

Fig. 53-22 In particular, the completed screw-retained all-ceramic restoration displays a high degree of translucency on its incisal third.

Fig. 53-21 Labial view of the completed ceramo-ceramic restoration on the master cast.

Fig. 53-23 A titanium abutment will serve as infrastructure for the transocclusally screw-retained high-strength all-ceramic restoration.

marginal precision of machined, prefabricated components. Nowadays several of the leading implant systems also offer high-strength ceramic tertiary components which may positively contribute to the esthetic treatment outcome, particularly in the case of a rather thin labial peri-implant mucosa (Fig. 53-20). Another parameter which is of primary importance when it comes to esthetic considerations relates to maxillary anterior implant restorations and is associated with the suprastructure design itself at the interproximal aspect. In order to provide optimal conditions for the related soft tissue, a long interdental contact line is established, located slightly more towards the palatal aspect of the restoration (Figs. 53-21, 53-22). This design offers optimal support for the interproximal soft tissue and thereby reduces the potential hazard of a so-called "black triangle" (Figs. 53-23 to 53-25). In this context some studies have indicated that there exists a predictable relationship between the location of the interdental contact point and the associated alveolar bone crest when it comes to presence or absence of interdental papillae fully occupying the interdental space of maxillary anterior teeth (Tarnow *et al*. 1992; Tarnow & Eskow 1995).

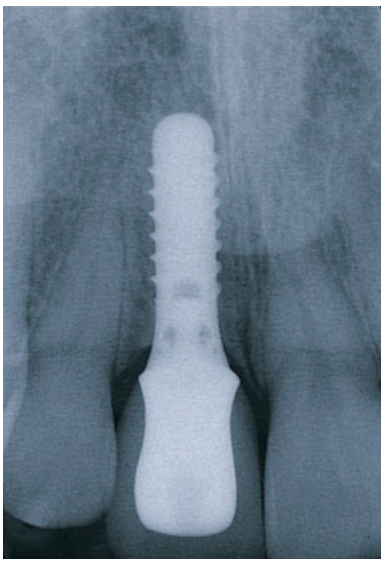

Fig. 53-24 The 1-year post-operative radiograph confirms favorable conditions at the bone-to-implant interface. Note a high degree of radio-opacity of the all-ceramic substrate, permitting the evaluation of the fidelity of the marginal adaptation.

Fig. 53-25 An acceptable overall integration of the metal-free implant-borne restoration on site 11 can be noted.

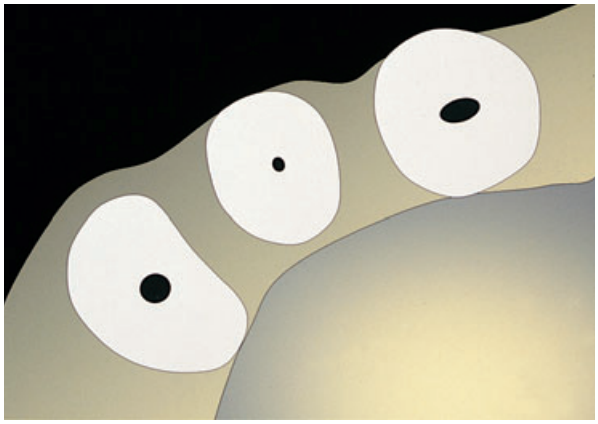

Fig. 53-26 Schematic representation of a horizontal section at the cemento-enamel junction level of the maxillary right anterior segment.

Sites with localized horizontal deficiencies

In a case of a localized (minor) horizontal deficiency, i.e. a confined vestibular alveolar bone crest defect at the vestibular aspect of a maxillary anterior single-tooth gap, one prefers to place the implant and simultaneously undertake a lateral bone augmentation procedure, on condition that several well defined prerequisites are fulfilled. These include an implant placement in accordance with the guidelines presented in Table 53-6 ("restoration-driven" implant placement), the achievement of an adequate primary stability and a resulting cervical dehiscence-type bony defect which is compatible with a predictable bone augmentation procedure. More specifically, the dehiscence should have the form of a two-wall bony defect, and the labial aspect of the inserted implant should not exceed the surrounding bone contours. Under such conditions, the treatment of choice consists of the application of autogenous bone chips, harvested at the site of the implant surgical intervention. The bone chips, which can be combined with one of the numerous available bone substitutes (e.g. BioOss®) if necessary, will provide adequate support for a subsequently adapted barrier membrane. The described grafting material is finally complemented with "bone slurry", constantly collected during the entire procedure. Subsequently, a bioabsorbable membrane is applied prior to repositioning and tension-free suturing of the mucoperiosteal flap. This implicates a rather extended flap design, comprising vertical releasing incisions.

In conclusion, a simultaneous lateral augmentation procedure is recommended if the three following conditions are present:

1. Ideal three-dimensional ("restoration-driven") implant position
2. Adequate primary implant stability
3. Localized two-wall bony defect, exceeding the labial contour of the implant and hereby assuring an appropriate bone regeneration potential and providing the necessary stability to the applied bone graft.

Under these specific conditions, the implant can be functionally loaded after 2–4 months, depending on size and configuration of the respective bone defect.

It is not infrequent in the anterior maxilla, due to its specific alveolar bone crest morphology, that "restoration-driven" rather than "bone-driven" implant positioning leads to a fenestration-type defect in the apical area of the implant. If adequate primary implant stability can be obtained, a similar simultaneous lateral bone augmentation procedure, as described for localized dehiscence-type defects, appears feasible. Under such circumstances the healing time prior to functional implant loading remains the same as advocated for standard implant protocols (i.e. 2 months for SLA-coated screw-type titanium implants).

Sites with extended horizontal deficiencies

In the case of more extended horizontal alveolar bone crest deficiencies, a simultaneous implant placement and lateral bone augmentation procedure becomes technically more difficult and less predictable, as the ultimate goal remains an optimal "restoration-driven" implant positioning (Figs. 53-26, 53-27). The described extended horizontal bone deficiency, on the one hand, may often not permit acceptable primary implant stability to be achieved, and, on the other hand, may lead to a vestibular bone dehiscence that does not have a distinct two-wall morphology. Furthermore, the labial implant contour would be more prominent than the respective surrounding bone (Fig. 53-28). Under these specific circumstances the principal prerequisites for a simultaneous approach are clearly not present, thus leading to the recommendation to proceed according to a staged surgical protocol, which will address the lateral bone augmentation first and the actual implant placement in a second stage.

This may represent a major problem for some patients, as two surgical interventions, normally

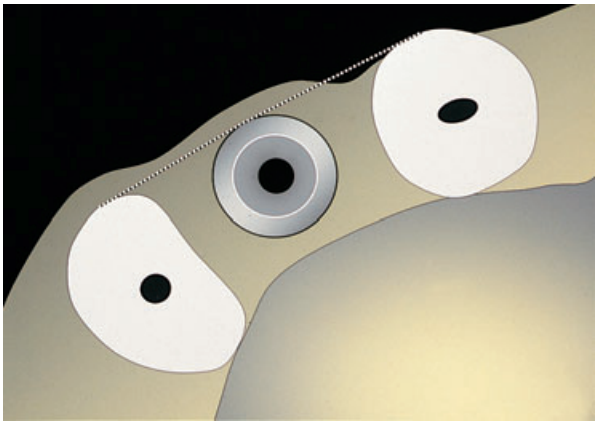

Fig. 53-27 "Restoration-driven" implant placement in the horizontal plane at the site of the maxillary right lateral incisor. In order to maintain at least 1 mm of alveolar bone also on the labial aspect, the implant has to be inserted approximately 1–2 mm more towards the palate when compared to the adjacent roots.

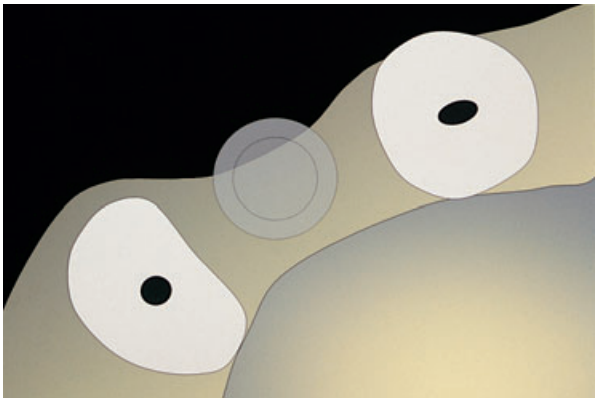

Fig. 53-28 In the case of an extended lateral bone deficiency, where an adequately placed implant would largely exceed the vestibular border of the alveolar bone crest, a lateral bone augmentation procedure (staged approach) is indicated.

separated by approximately 6 months, are necessary, leading to a total treatment time of 8 months or more. It is therefore indispensable to inform the patient thoroughly about both the reasons for the staged approach associated to implant therapy, and the possible conventional prosthodontic alternatives (e.g. a traditional tooth-borne FPD, eventually in combination with a connective tissue grafting procedure to optimize the deficient edentulous ridge in view of an optimal and esthetic pontic). The patient will then be in a position to give his or her informed consent to either of the two therapeutic modalities, according to individual preference.

In the case of implant therapy, the first step consists of the elevation of a rather extended mucoperiosteal flap featuring vertical releasing incisions, as the added site volume (due to the block graft and barrier membrane) will require subsequent splitting of the periosteum prior to flap repositioning and suturing (Fig. 53-29). Numerous studies reporting results of various bone augmentation techniques

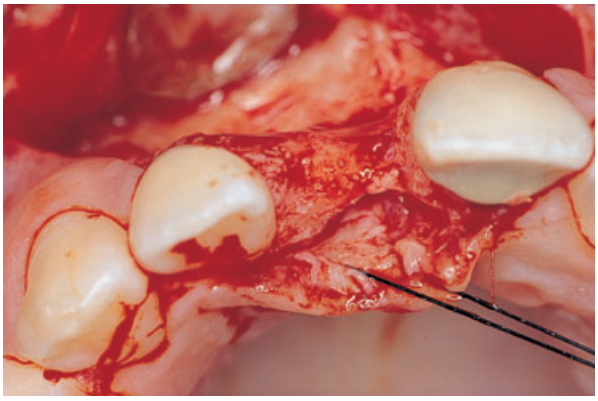

Fig. 53-29 After elevation of a mucoperiosteal flap a severe extended resorption on the vestibular aspect of the edentulous alveolar ridge becomes apparent. Such a morphology is hardly compatible with "restoration-driven" implant placement.

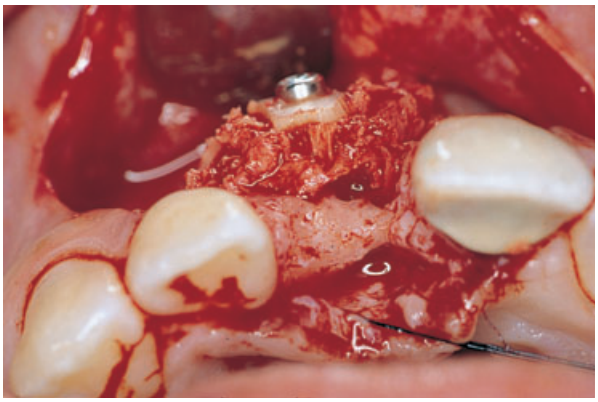

Fig. 53-30 An autogenous bone graft, harvested from the patient's chin region, has been secured with a fixation screw and its periphery filled in with additional bone chips prior to membrane placement.

and related materials have been published (Hürzeler *et al*. 1994; Buser *et al*. 1996; Ellegaard *et al*. 1997b; Chiapasco *et al*. 1999, 2001; von Arx *et al*. 2001a; Zitzmann *et al*. 2001). To date, autogenous bone block grafts, mostly harvested from the chin or the retromolar area, in combination with e-PTFE barrier membranes, still have the best clinical long-term documentation (Buser *et al*. 2002). These authors presented prospectively documented 5-year data of 40 consecutively treated patients, according to a staged protocol. Implants could subsequently be inserted on all laterally augmented sites. It was concluded that the clinical results of implants placed in regenerated bone were comparable to those reported for implants in non-regenerated bone. A clinical example of the described approach is presented in Figs. 53-29 to 53-37.

Sites with major vertical tissue loss

When it comes to maxillary anterior single-tooth gaps with significant vertical tissue loss, the predictable achievement of an esthetically pleasing

Fig. 53-31 Six months after the lateral ridge augmentation procedure the clinical occlusal view documents that uneventful healing has occurred and that the orofacial ridge profile has been improved.

Fig. 53-34 Two weeks after mucosaplasty and exchange of healing caps the initiation of a harmoniously scalloped labial soft tissue course is apparent. Furthermore, the access from the surface to the underlying implant shoulder has been established.

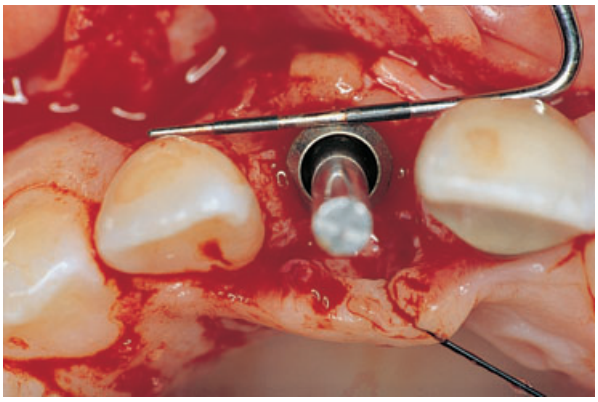

Fig. 53-32 During implant surgery. All key parameters characterizing an optimal implant position (shoulder sink depth, orofacial point of emergence, implant axis) could be satisfied.

Fig. 53-35 The two ceramo-metal crown restorations – one tooth-borne (site 21) and one implant-borne (site 11) – display little difference in appearance since symmetry has been respected from the line of mucosal emergence to the incisal edge.

Fig. 53-33 After 3 months of healing the labial view documents a slight excess of keratinized peri-implant mucosa in a coronal direction, which is a prerequisite for the development of the final esthetic soft tissue contours. The first step of the subsequent procedure will consist of the insertion of a longer titanium healing cap, following a minor mucosaplasty.

Fig. 53-36 The 1-year follow-up radiograph confirms the stability of the osseointegrated 10 mm titanium screw implant.

Fig. 53-37 An esthetically pleasing overall integration of the two maxillary anterior restorations is underlined by a close-up view of the patient's unforced smile.

Fig. 53-38 Pre-operative view of a 35-year-old female patient consulting with a persistant primary tooth in the position of the maxillary left canine. Note the irregular course of the adjacent gingiva in general and the loss in vertical tissue height in particular.

treatment outcome, ideally providing a so-called perfect illusion with respect to its integration in the surrounding natural dentition, gets difficult. As pointed out earlier in this chapter, a close relationship exists between the interproximal bone height and the associated soft tissue level (Figs. 53-7, 53-8). If the coronal border of the alveolar bone is no longer within the physiologic distance of approximately 2 mm from the interproximal CEJ of the teeth confining the edentulous space, there is an increased risk of an altered respective soft tissue course (due to a lack of underlying bony support) and its adverse impact on the appearance. Such situations can be encountered following the removal of ankylosed teeth or failing implants, or in case of advanced periodontal tissue loss – including gingival recession – on neighboring teeth. Under these specific circumstances, the final decision whether or not to use implants will ultimately depend on (1) the careful and comprehensive evaluation of all of the therapeutic modalities available for anterior tooth replacement (Table 53-3), and (2) the patient's individual smile line and expectations. This process includes an objective analysis of the advantages and eventual shortcomings associated with each modality.

To illustrate these clinically relevant aspects, the initial situation and the subsequent implant treatment of a 35-year-old female patient consulting with an ankylosed maxillary deciduous left canine, are presented in Figs. 53-38 to 53-46. The preoperative analysis had led to the conclusion that the fabrication of a conventional tooth-borne three-unit FPD, using the intact lateral incisor and first premolar as abutments and featuring a canine pontic, was not opportune from several points of view. Among these should be particularly mentioned aspects related to the questionable mechanical resistance of the resulting conventional prosthesis, specific occlusal considerations (e.g. canine guidance in a pontic area), lack of esthetic superiority when compared to a virtual implant-borne fixed restoration, and, last but not least, the conflict with the general principle of

Fig. 53-39 One month after removal of the deciduous canine, the root of which was severely resorbed, a mucoperiosteal flap with vertical releasing incisions is elevated and the preparation of a calibrated implant bed performed. One can note an increased distance between the cemento-enamel junction and the coronal border of the alveolar bone and the left lateral incisor.

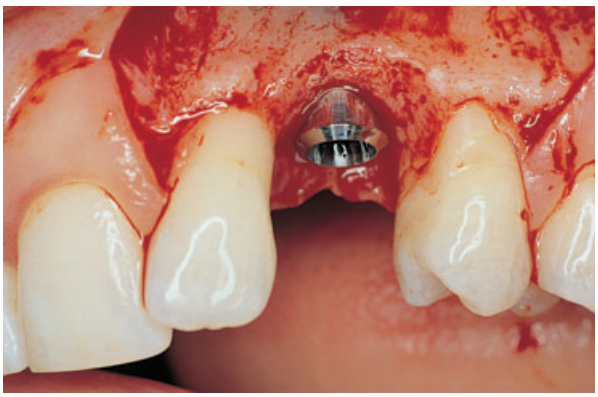

Fig. 53-40 Buccal view after insertion of the implant.

minimal invasiveness (maximum preservation of intact tooth structure).

Once the decision was made, both the implant surgical and the restorative strategies focused on improving or at least optimally exploiting the

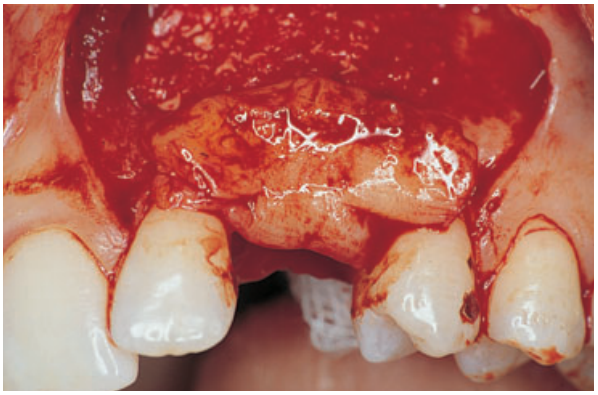

Fig. 53-41 In a case of rather thin mucosa, the utilization of a connective tissue graft, harvested from the palate, may be indicated to create a sufficient thickness of soft tissue at the implant site.

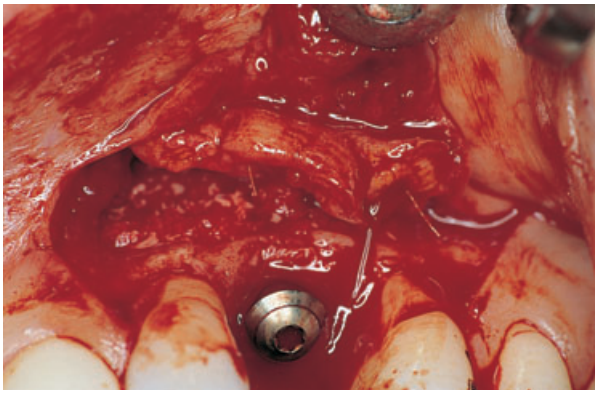

Fig. 53-42 Prior to flap closure, the connective tissue graft is secured to the flap with bioabsorbable sutures.

Fig. 53-43 Coverage of most of the healing cap during suturing is recommended, leading to a submerged or at least to a "semi-submerged" healing mode.

Fig. 53-44 The clinical aspect after insertion of the ceramo-metal implant crown reveals stable and esthetic peri-implant soft tissue contours.

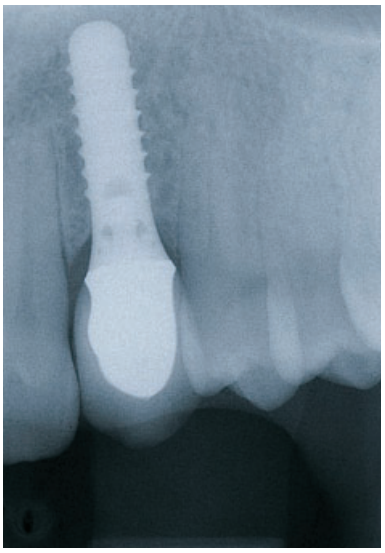

Fig. 53-45 The 2-year follow-up radiograph confirms the stability of the osseointegrated 10 mm solid screw titanium implant.

Fig. 53-46 On a left lateral view, during the patient's forced smiling, one can note that the lack of vertical soft tissue in the interproximal area has been compensated for with an apically extended interdental contact line.

Fig. 53-47 Labial close-up view of the maxillary right anterior region of a 19-year-old female patient. The interdental soft tissue height distal to the central incisor and the corresponding underlying alveolar bone height are markedly reduced, leading to exposure of the cemento-enamel junction.

Fig. 53-48 The contralateral side of the dental arch shows perfectly intact and harmonious conditions with respect to the course of the gingiva.

Fig. 53-49 On the occlusal view of the edentulous site a significant lateral crest deficiency becomes apparent, which calls for both a bone and soft tissue augmentation procedure, particularly if an implant solution is planned.

Fig. 53-50 Six months after combined lateral bone and soft tissue augmentation, the site appears to be compatible with "restoration-driven" implant placement.

pre-existing limited esthetic potential of the site. From the surgical side, this comprised a deeper than normal implant shoulder sink depth (Fig. 53-40), the use of a connective tissue graft on the vestibular aspect (Fig. 53-41), a localized lateral bone augmentation (simultaneous approach) procedure (Fig. 53-42) and a coronally repositioned flap (Fig. 53-43). The metal–ceramic implant restoration featured a transverse screw-retention to provide maximum space for esthetic porcelain stratification and a long contact line on the mesial aspect to compensate for the missing interdental soft tissue height (Figs. 53-44 to 53-46).

A more severe preoperative situation of vertical tissue deficiency, combined with a marked horizontal bone defect, is presented in Figs. 53-47 to 53-49. This 19-year-old female patient lost her maxillary right lateral incisor due to a localized periodontal problem. Again, the comprehensive site analysis concluded that a single-tooth implant restoration was the best compromise in view of major disadvantages associated with all of the conventional prosthodontic options. From a purely esthetic point of view, none of the therapeutic modalities had the potential to predictably lead to a perfect re-establishment of a symmetrical, harmoniously scalloped soft tissue course at its original physiologic level. However, a rather low lip-line during the patient's normal communication and unforced smiling permitted the least invasive approach to be chosen. Following a lateral connective tissue and bone augmentation procedure (Fig. 53-50), an implant could be inserted in an acceptable position and subsequently restored with a screw-retained crown. The final frontal view, allowing a direct comparison between the intact (Fig. 53-51) and the restored side, clearly demonstrates the current esthetic limitations associated with implant therapy in sites with a marked vertical tissue deficiency (Fig. 53-52).

Multiple-unit anterior fixed implant restorations

The normal consequence following loss of two or more adjacent upper anterior teeth comprises a flattening of the edentulous segment. In particular one can observe the disappearance, in an apical direction, of the crestal bone originally located between the

Fig. 53-51 The buccal view in centric occlusion position before therapy summarizes the problems associated with localized vertical tissue deficiencies: lack of a harmoniously scalloped soft tissue course in general and missing interdental papillae in particular.

Fig. 53-52 The corresponding view after lateral bone and soft tissue augmentation and insertion of an implant-borne single-tooth restoration on the site of the right lateral incisor, underlines the resulting shortcomings with respect to esthetic parameters. Vertical tissue deficiencies – which at present cannot be predictably compensated for – clearly compromise the overall integration of an otherwise successful treatment.

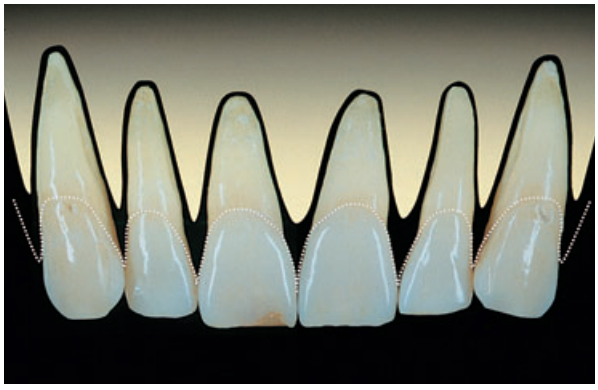

Fig. 53-53 Schematic representation of the six maxillary anterior teeth, including their bony support and the course of the marginal soft tissue, corresponding ideally approximately to the cemento-enamel junction (dotted line).

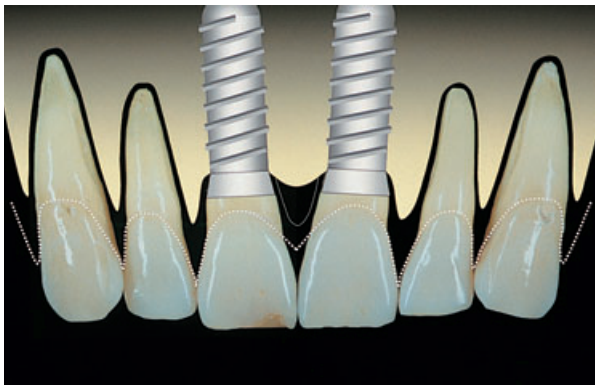

Fig. 53-54 Loss of the two central incisors and their subsequent replacement by implant restorations normally leads to well defined bone loss ("micro-gap", establishment of a "biologic width") around the implant sites. The main consequence from an esthetic point of view consists of vertical soft tissue deficiencies, namely between adjacent implants (dotted lines).

incisor teeth. This phenomenon is not, or only minimally, present at the interproximal aspect of the remaining anterior teeth and thus explains the fundamental difference between a maxillary anterior single-tooth gap and a multi-unit edentulous segment.

If two standard screw-type titanium implants are inserted to replace two missing maxillary central incisors (Figs. 53-53, 53-54), an additional peri-implant bone remodeling process will take place. In the frontal plane, two different characteristic processes, one between the natural tooth and the implant and the other between the two implants, can be distinguished. At the site between tooth and implant, the tooth-sided interproximal bone height should theoretically remain at its original location, i.e. within 2 mm from the CEJ, from where the implant-sided interproximal bone height drops in an oblique manner towards the first implant-to-bone contact, normally located approximately 2 mm apically of the junction ("microgap") between the implant shoulder and the abutment or suprastructure. This phenomenon has been referred to in the literature as "saucerization" or establishment of a "biologic width" (Hermann *et al*. 1997, 2000, 2001a,b). In contrast, the inter-implant bone height normally decreases further in an apical direction, once the respective abutments or suprastructures are connected to the implant shoulder. This process is mostly accompanied by a loss of interimplant soft tissue height and hence may lead to unsightly, so-called "black interdental triangles". The schematic close-up views comparing the original dentate situation with the status after integration of two adjacent implant restorations, clearly demonstrate the negative consequences on the course of the marginal soft tissue line in a case of multiple adjacent maxillary anterior implants (Figs. 53-55, 53-56).

The basic considerations related to the current state of achievements and limitations of maxillary anterior fixed multiple-unit implant restorations in sites with and without horizontal and/or vertical soft

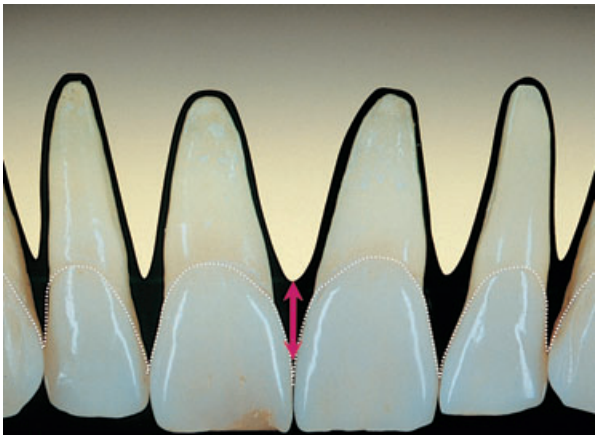

Fig. 53-55 Schematic close-up view of the relationship between cemento-enamel junction, alveolar bone, and course of the gingiva in the maxillary incisor area.

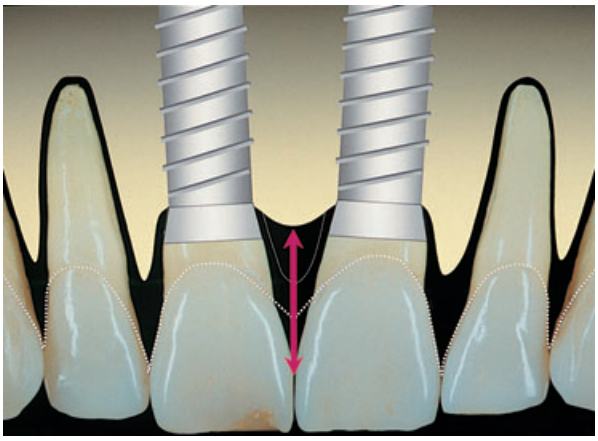

Fig. 53-56 Same area after implant therapy. The red arrow represents the distance between the inter-implant bone crest and the interdental contact point. The lack of bony support for the interdental soft tissue often causes the appearance of black triangles, compromising the esthetic treatment outcome.

and hard tissue deficiencies are summarized in Table 53-8.

Sites without significant tissue deficiencies

Due to the previously described shortcomings inherent in multiple adjacent implant restorations, the clinical decision-making process will thus address both the height of the patient's smile line (low, medium, high) and the individual gingival phenotype (thick and low scalloped or thin and high scalloped). In the presence of a favorable gingival morphotype, some restorative "tricks", including peri-implant soft tissue conditioning and particular interproximal crown design, need to be implemented to predictably achieve an acceptable esthetic compromise (Figs. 53-57 to 53-62). Peri-implant soft tissue conditioning is primarily achieved by using either healing caps featuring an appropriately shaped, continuously increasing (in a coronal direction) axial emergence profile, or by means of plastic components permitting the customization of the best suited axial contour in the region from the implant shoulder or abutment to the mucosal margin (Fig. 53-58). The particular suprastructure design concerns the inter-implant aspect, where, instead of an interdental contact point, a long and slightly palatal contact line is developed in the form of two adjacent "wings",

Table 53-8 Basic considerations related to anterior fixed multiple-unit implant restorations in sites with horizontal and/or vertical soft and hard tissue deficiencies

Achievements	Predictable and reproducible results regarding lateral bone augmentation using barrier membranes supported by autografts: • allows implant placement in patients with a low lip line
Limitations	Vertical bone augmentation is difficult to achieve and related surgical techniques lack prospective clinical long-term documentation Inter-implant papillae cannot predictably be re-established as of yet

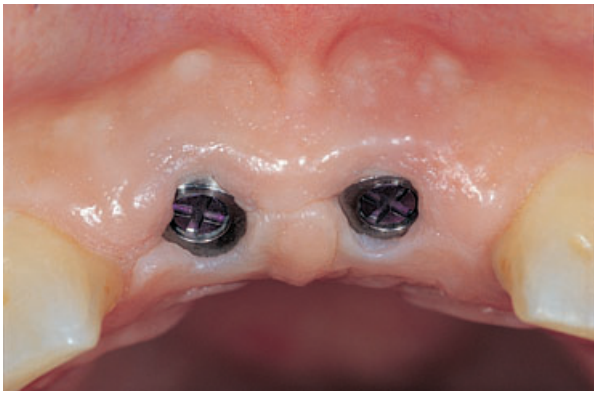

Fig. 53-57 Clinical close-up view of the maxillary anterior segment of a 32-year-old female patient following placement of two 12-mm solid screw implants according to a one-stage transmucosal surgical protocol.

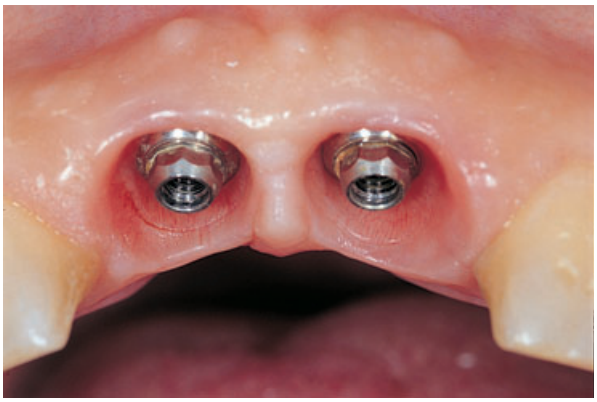

Fig. 53-58 Conditioning of the peri-implant mucosa, in view of the future restorations, has been performed by means of auxiliary plastic components with the possibility of individualizing the emergence profile.

Fig. 53-59 The corresponding clinical close-up view, taken shortly after insertion of the two screw-retained ceramo-metal restorations, documents the effect of a long interdental contact line, the presence of pronounced mesial ridges, and a slight increase of color saturation in the cervico-interdental area. Such technical measures contribute to the compensation of a flat and more apically located labial mucosa line.

Fig. 53-60 Clinically, a slight fill-in of inter-implant mucosa and an overall stable soft tissue situation can be noted after 6 years of clinical service.

which are more color-saturated in order to create a discrete shade transition ("blending-in") at the mucosal margin. If the mesial oblique triangular ridges of the two adjacent implant restorations are located at their normal location, the ceramic crowns will not – despite their increased vestibular diameter – optically appear larger (Fig. 53-61). This design reduced the inter-implant cervical triangle to a minimum at the moment of the crown insertion (Fig. 53-59), and favored a coronal soft tissue increase, clearly visible at the 6-year clinical follow-up (Fig. 53-60).

Sites with extended horizontal deficiencies

If the absence of multiple adjacent teeth in the anterior maxilla is accompanied by a marked, but primarily horizontal, resorption of the edentulous alveolar bone crest towards the palate, one can adopt two different strategies. One consists of a so-called "bone-driven" implant placement which will lead to a distinct palatal implant position. In most instances this strategy calls for an implant assisted overdenture-type prosthesis which can more easily compensate for the discrepancy between the required position of the teeth to be replaced and the actual implant location, when compared to a fixed implant prosthesis. Furthermore, the denture flange can quite efficiently solve shortcomings related to esthetics, phonetics, and/or insufficient labial and facial tissue support. Normally, denture stability and subjective comfort are excellent and – owing to its removable nature – access for oral hygiene is easy (Mericske-Stern 1998; Kiener *et al*. 2001). One should be aware, however, that this approach also has its inherent limits and has to take into account crucial parameters such as phonetics and minimal room required for the tongue. As this chapter focuses primarily on fixed maxillary anterior implant restorations, we refer to the relevant respective literature.

Another approach consists of one of the various lateral bone augmentation procedures reported in

Fig. 53-61 In order to compensate for the reduced height of the inter-implant soft tissue, the ceramist has used an apically prolonged interdental contact line in the form of so-called "mini-wings". These interdental ceramic extensions are made of a more saturated root-like porcelain and are slightly displaced to the palatal aspects of the crowns. This approach results in restorations that integrate successfully, although they are physically larger than the original anatomic crowns.

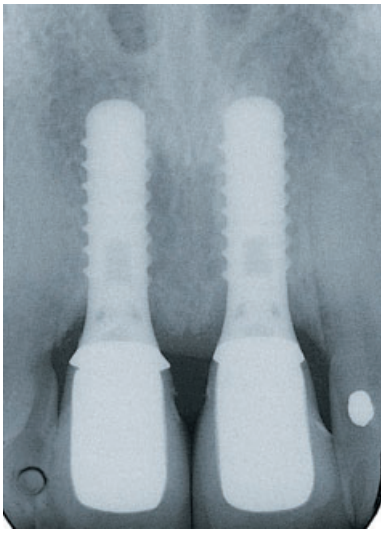

Fig. 53-62 Six years after placement of the 12 mm solid screw titanium implants, the respective radiographs reveal stable conditions at the osseointegrated interface and adequate marginal adaptation.

the literature (Buser *et al*. 1996, 1999, 2002; Chiapasco *et al*. 1999; von Arx *et al*. 2001a,b; Zitzmann *et al*. 2001), which ultimately should lead to a more "restoration-driven" implant placement, ideally compatible with a straightforward fixed implant prosthesis featuring a continuous, flat axial emergence profile. To date a scalloped course of the peri-implant mucosa cannot be predictably achieved around multiple adjacent maxillary anterior fixed implant restorations, and as an increased clinical crown length is normally inherent in this approach as well, the pre-operative assessment of the patient's lip line or smile line (Jensen *et al*. 1999) is of primary importance during the related decision-making process.

Sites with major vertical tissue loss

The replacement of multiple missing adjacent maxillary anterior teeth with a fixed implant prosthesis still represents a major therapeutic challenge in the presence of combined major horizontal and vertical alveolar ridge deficiencies. Vertical bone augmentation techniques, for example the distraction osteogenesis procedure (Chiapasco *et al*. 2001), hold promise for the future but lack clinical long-term documentation at present.

As a consequence, the treatment of choice consists in most instances of an implant-assisted (e.g. spherical attachments, bar devices) removable overdenture.

Conclusions and perspectives

When implants are to be inserted within the esthetic zone in view of a fixed restoration, deep placement – close to or at the alveolar bone crest level – of the shoulder of implants, often specifically designed for this indication, permits the suprastructure margin to be hidden below the mucosa, and the development of a gradual harmonious emergence profile from the implant shoulder to the surface. The resulting clinical crown replicates the profile of the natural control tooth despite a slightly more palatal implant position. This in turn leads to a secondary peri-implant bone loss or bone remodeling – particularly in a case of multiple adjacent implants – due to the reorganization of a biologic width (Hermann *et al*. 1997, 2000, 2001a,b). Under these particular circumstances, screw-retained restorations, based on prefabricated, machined components, will assure a maximum marginal adaptation, favoring the maintenance of the long-term stability of the esthetic result (Belser 1999; Belser *et al*. 1998, 2000). The currently flat, "rotation–symmetrical" design of standard screw-type titanium implants, leading to a marked submucosal implant shoulder position at the interproximal aspect, may not, however, represent the optimal design, in particular in the context of multiple adjacent implants.

Scalloped implant design

As pointed out earlier in this chapter, the traditional implant design may lead to esthetic shortcomings in a case of multiple adjacent maxillary anterior fixed implant restorations. One could hypothesize in this context whether a modified design at the coronal end of the implant, in the sense of a scalloped, more "CEJ-like" configuration, might lead to an improved preservation of peri-implant bone at the interproximal aspect in general, and between adjacent implants in particular. One of the possible design solutions and its anticipated theoretical impact on bone and esthetic parameters are presented in Figs. 53-63, 53-64, and 53-68. More specifically, this approach ultimately aims at creating an inter-implant bone height and resulting soft tissue level situation compatible with generally accepted esthetic criteria. Among these one should primarily mention the establishment and/or maintenance of a harmoniously scalloped course of the marginal peri-implant mucosa. At present, the combination of the following three elements appears important:

Fig. 53-63 Instead of the traditional implant design, featuring a flat rotation–symmetrical coronal aspect, a scalloped connection, inspired by the natural cemento-enamel junction, may lead to a more superficial implant insertion and by this to the preservation of more bone in the interproximal area.

Fig. 53-64 Comparison in the sagittal plane of a natural maxillary central incisor and a titanium implant featuring a scalloped design at its coronal end. The radius corresponds to the amount of bone which might theoretically be preserved.

Fig. 53-65 Vestibular view in centric occlusion position of a 24-year-old male patient. The two maxillary central incisors have been lost due to a traumatic injury.

Fig. 53-66 After 1 year of clinical service, there is a harmoniously scalloped marginal soft tissue course, including the most critical inter-implant area.

1. Screw-type titanium implant body, featuring optimal surface characteristics
2. Tooth-colored transmucosal portion with adequate axial emergence profile and scalloped coronal end
3. Mechanically sound suprastructure connection, permitting both screw retention and cementation.

The clinical potential of such a novel, scalloped implant design is documented in Figs. 53-65 to 53-67, presenting a 24-year-old male patient who had lost his two maxillary central incisors in the course of an accident. The 1-year clinical and radiographic follow-up appears to support – at least short-term – the hypothesis that such an approach may preserve inter-implant crestal bone and overlying soft tissue to a certain extent.

Segmented fixed implant restorations in the edentulous maxilla

Another particular challenge from both a surgical and a prosthodontic point of view represents the

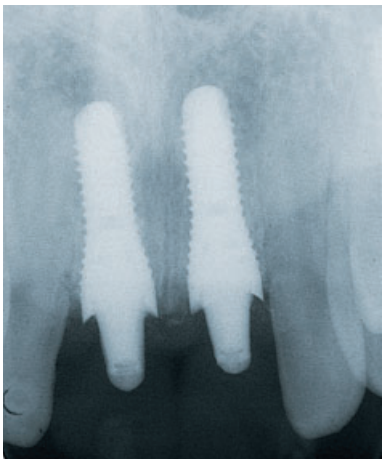

Fig. 53-67 The 1-year follow-up radiograph shows prototype of titanium implants featuring a scalloped design at their coronal end. This design permits a more superficial implant insertion, aiming at a better preservation of inter-implant alveolar bone.

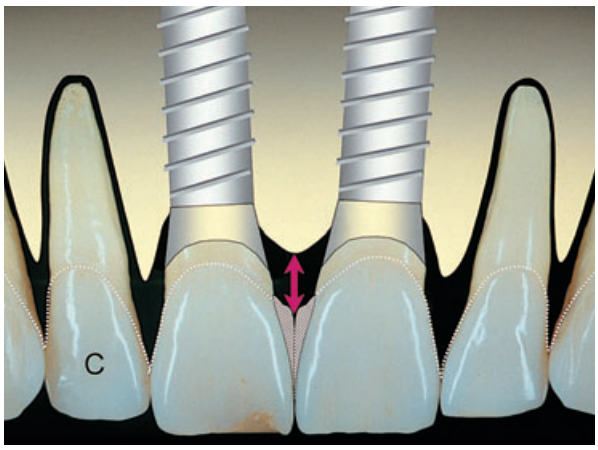

Fig. 53-68 Schematic representation of the theoretical advantages of a scalloped implant design: more superficial implant placement, increased bone and soft tissue preservation particularly in the inter-implant area, and improved esthetics (in combination with interdental "mini-wings").

implant-supported fixed prosthetic rehabilitation of the edentulous maxilla. Undoubtedly esthetic considerations and certain aspects associated with the patient's subjective comfort – both during the actual treatment phase and once the prosthesis is completed – also play a major role in this context. We will limit our reflections to (1) specific aspects of pre-implant diagnosis, (2) the importance of implant number, alignment and spatial distribution, and (3) conception of the suprastructure.

These elements are addressed in the form of a respective clinical case presentation, involving a 67-year-old female patient, edentulous in the maxilla (Figs. 53-69 to 53-89). Besides the traditional clinical and radiologic investigation, an in-mouth try-in of the envisioned treatment objective in the form of a

Fig. 53-69 Vestibular view of a 67-year-old female patient, edentulous in the maxilla for 18 months. The pre-existing fixed prosthetic rehabilitation had to be removed due to periodontal disease and was replaced by an immediate complete upper denture to which she never adapted. In the mandible a natural dentition is present to the premolar area.

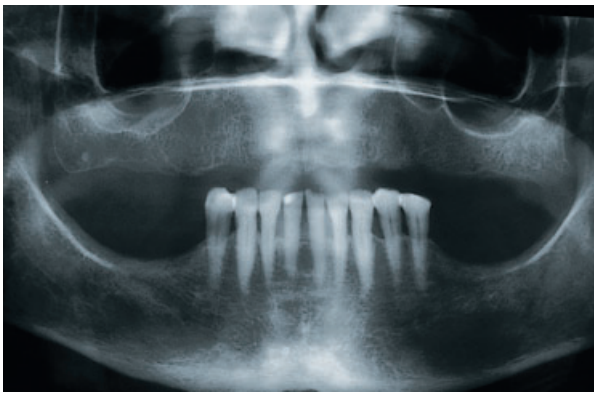

Fig. 53-70 The corresponding panoramic radiograph reveals – at least as far as the vertical bone volume is concerned – favorable conditions in view of implant therapy in both the upper and the lower posterior jaw.

Fig. 53-71 The oblique view confirms the presence of an appropriate intermaxillary relationship which is essential for a fixed implant-supported prosthesis.

Fig. 53-72 On the occlusal view of the edentulous maxilla, one can note overall favorable conditions for implant therapy and the clinical signs of the recently performed tooth extractions.

Fig. 53-73 During an unforced smile, the height of the smile line and the eventual need for additional lip support, are evaluated. Both parameters are decisive for the selection between a fixed implant prosthesis or an implant overdenture.

Fig. 53-74 In order to evaluate the feasibility of a fixed implant prosthesis, the clinical try-in of a diagnostic tooth set-up is of paramount importance. One should perform this tooth set-up without vestibular denture flange, so that the patient can realize how long the clinical crowns will be.

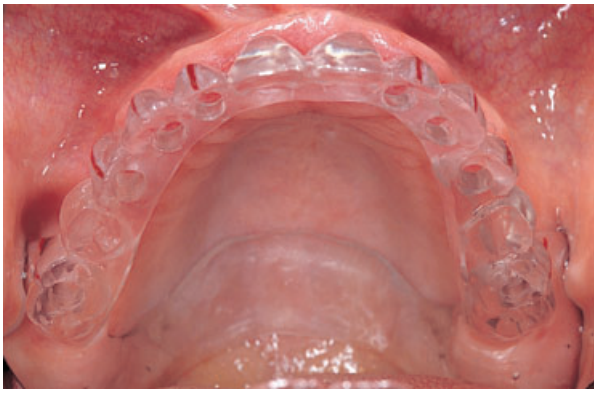

Fig. 53-75 A duplicate of the diagnostic tooth set-up in transparent acrylic will serve as a surgical guide. For optimal stability during surgery, the guide is extended to the posterior palate, an area which will not be concerned by the flap elevation.

Fig. 53-78 Eight weeks after implant surgery, osseointegration is confirmed radiologically and clinically. Screw-retained impression copings are inserted to perform an implant-level impression.

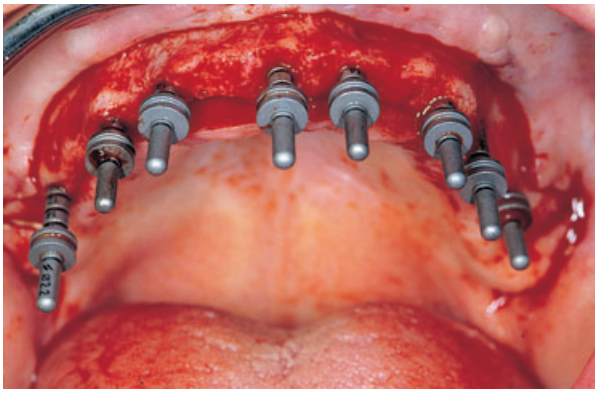

Fig. 53-76 Intrasurgical view of the edentulous maxilla, prepared for the insertion of eight implants to support a fixed prosthesis. Particular attention has been paid to achieving optimal parallelism of the implants by means of a respective surgical guide.

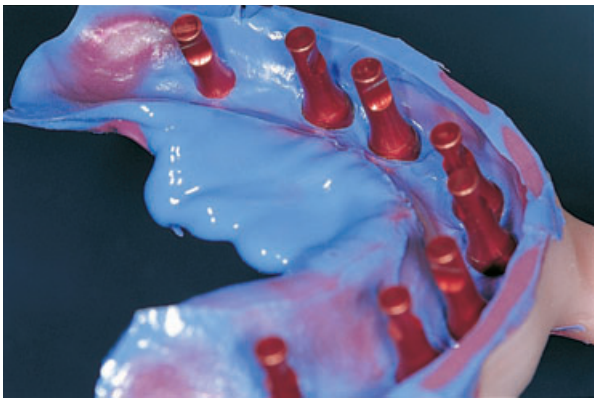

Fig. 53-79 Prior to the master cast fabrication, color-coded implant replicas (analogues) are secured to the respective impression copings.

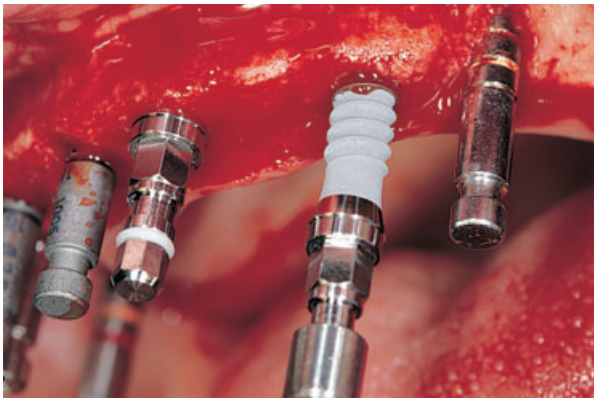

Fig. 53-77 Insertion of a titanium solid screw implant, featuring an SLA surface, in the area of the maxillary left canine.

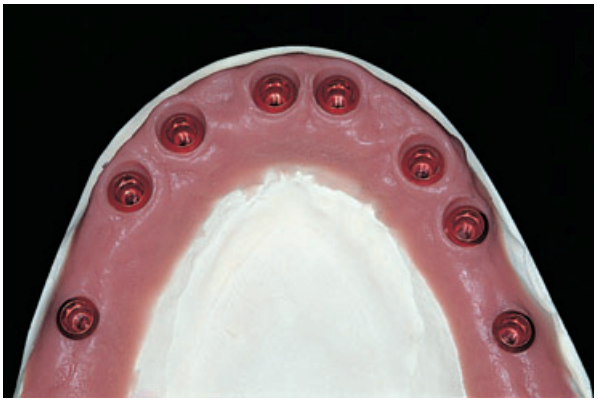

Fig. 53-80 The maxillary master cast features a removable silicon representation of the peri-implant soft tissues.

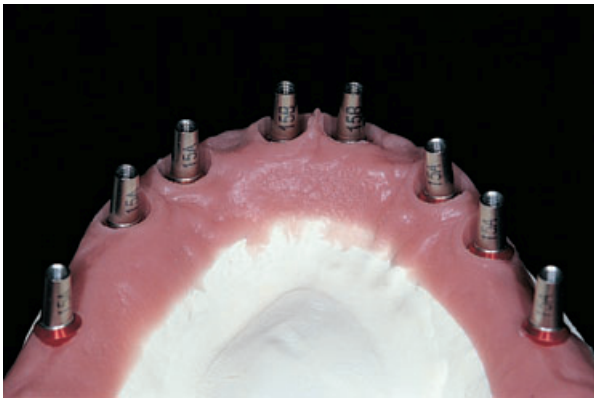

Fig. 53-81 After mounting the master cast in a second-generation, semi-adjustable articulator, the most suitable secondary components (abutments) in view of a cementable fixed implant prosthesis are selected.

Fig. 53-84 Prior to cementation of the described ceramo-metal suprastructure, the secondary implant components (abutments) are tightened to 35 Ncm with a calibrated torque wrench.

Fig. 53-82 Using a silicon key, derived from the diagnostic wax-up, as a guide, the laboratory technician has fabricated the cast metal framework in the form of four independent three-unit segments. Each segment will be supported by two implants.

Fig. 53-85 The corresponding clinical view documents that a design similar to that applied in the natural dentition has been used.

Fig. 53-83 The completed ceramo-metal implant prosthesis on the master cast, ready to be inserted in the patient's mouth.

Fig. 53-86 In the mandible the bilaterally shortened arch has been prolonged to the first molar area by means of two fixed cemented ceramo-metal implant prostheses.

Fig. 53-87 The oblique clinical close-up view of the final implant restoration reveals an acceptable integration both from a functional and an esthetic point of view.

Fig. 53-88 Finally, an esthetically pleasing result could be achieved by means of a fixed implant-supported prosthesis.

Fig. 53-89 The 1-year post-operative panoramic radiograph confirms osseointegration and documents that the maxillary prosthesis has been completed in four independent segments.

set-up of teeth without vestibular denture-type flange is of primary importance (Fig. 53-73). Among other aspects, this approach will allow the visualization of the length of the clinical crowns of the future fixed implant prosthesis, and the evaluation of whether a fixed prosthesis will provide sufficient lip and facial support (Fig. 53-74). A surgical guide, derived from the described tooth set-up, will guarantee that the future implant positions are in accordance with the determined tooth positions. Whenever possible, parallelism of implants is recommended, as it permits an eventual early or immediate loading approach (Szmukler-Moncler *et al*. 2000; Cooper *et al*. 2001; Andersen *et al*. 2002; Cochran *et al*. 2002), and facilitates the subsequent clinical and laboratory procedures. Although little scientific evidence exists to indicate how many implants of which dimension and in what position are required for a predictable and long-lasting fixed implant rehabilitation of an edentulous maxilla, some clinical trends – mostly derived from traditional prosthodontic experience – do exist. If one plans to extend the prosthesis to the first molar area, and if the anatomic conditions allow the use of standard-size (length and diameter) implants, between six and eight implants seem reasonable. However, in order to increase the overall prosthetic versatility and to be able to apply the principle of segmenting, which includes the ease of eventual re-interventions in a case of localized complications (Priest 1996; Goodacre *et al*. 1999; Lang *et al*. 2000; Johnson & Persson 2001), eight implants may be considered adequate. The recommended respective positions are on both sides of the jaw: the sites of the central incisors, the canines, the first premolars, and the first molars (Fig. 53-76). This approach will ultimately allow the fabrication of four independent three-unit FPDs, with all the related technical and clinical advantages (Figs. 53-78 to 53-89). Some of the scientific data available to date and supporting the concept of smaller segments rather than full-arch splinting will be presented and discussed in Chapter 54.

In conclusion, the concepts and therapeutic modalities do exist nowadays to solve – by means of implants – elegantly as well as predictably a majority of clinical situations requiring the replacement of missing teeth in the esthetic zone, and the most promising novel approaches and perspectives can already be identified on a not too distant horizon.

Acknowledgments

The authors wish to acknowledge and thank Drs Jean-Paul Martinet, Nicholas Roehrich, and Dimitri Thiébaud (all of them clinicians at the School of Dental Medicine, University of Geneva, and involved in the treatment of some of the patients presented in this chapter) for their contributions. We would also like to thank the laboratory technicians and ceramists Michel Bertossa, Michel Magne, and Alwin Schönenberger, for their expertise and meticulous execution of the implant suprastructures presented in this chapter. Furthermore, our gratitude is extended to Dr. Pascal Magne (Senior Lecturer, University of Geneva) for his competent assistance in development of the schematic illustrations.

Chapter 54

Implants in the Posterior Dentition

Urs C. Belser, Daniel Buser, and Jean-Pierre Bernard

Basic concepts

General considerations

The overall favorable long-term survival and success rates reported in the recent literature for osseointegrated implants in the treatment of various types of edentulism (Brånemark *et al*. 1995; Jemt *et al*. 1996; Lindqvist *et al*. 1996; Buser *et al*. 1997, 1998b, 2002; Andersson *et al*. 1998; Eckert & Wollan 1998; Lindh *et al*. 1998; Mericske-Stern 1998; ten Bruggenkate *et al*. 1998; Wyatt & Zarb 1998; Gunne *et al*. 1999; Lekholm *et al*. 1999; Van Steenberghe *et al*. 1999; Wismeijer *et al*. 1999; Behneke *et al*. 2000; Hosny *et al*. 2000; Hultin *et al*. 2000; Weber *et al*. 2000; Boioli *et al*. 2001; Gomez-Roman *et al*. 2001; Kiener *et al*. 2001; Mengel *et al*. 2001; Oetterli *et al*. 2001; Zitzmann *et al*. 2001; Bernard & Belser 2002; Haas *et al*. 2002; Leonhardt *et al*. 2002; Romeo *et al*. 2002) permit consideration of dental implants as one of the reliable therapeutic modalities during the establishment of any prosthetic treatment plan. In numerous clinical situations implants can clearly contribute to a notable simplification of therapy, frequently enabling removable prostheses to be avoided, keeping it less invasive with respect to remaining tooth structure or rendering the treatment both more elegant and versatile as well as more predictable (Belser *et al*. 2000).

As part of a textbook focusing essentially on clinical periodontics, this chapter will address primarily implant therapy performed in the posterior segments of partially edentulous patients. In this context, the use of implants may often significantly reduce the inherent risk of a "borderline" conventional tooth-borne fixed prosthesis (e.g. compromised or missing "strategic" abutment teeth, long-span fixed partial dentures, cantilevers) by implementing the principle of segmentation. It is currently widely accepted that – in comparison with extended splinted prosthetic segments – small ones are preferable as they are easier to fabricate, generally provide improved "passive fit" and marginal fidelity, offer better access for the patient's oral hygiene, and ultimately are less complicated to handle where there is need for re-intervention. When it comes to treatment planning in general, and to the choice *implant versus tooth-borne fixed partial denture (FPD) versus tooth* in particular, the related decision-making criteria should be essentially derived from scientific evidence and objective prosthetically oriented risk assessment in the broad

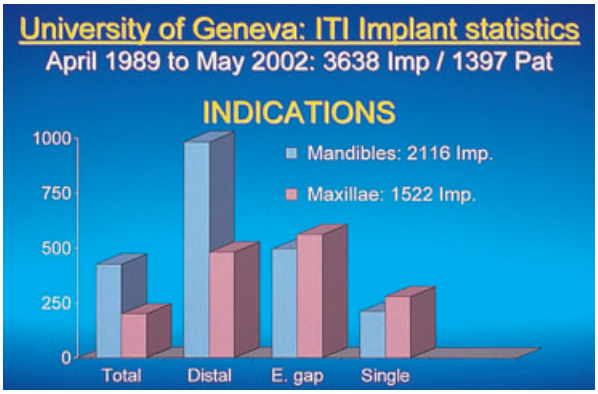

Fig. 54-1 University of Geneva implant statistics, 1989–2002. Indications.

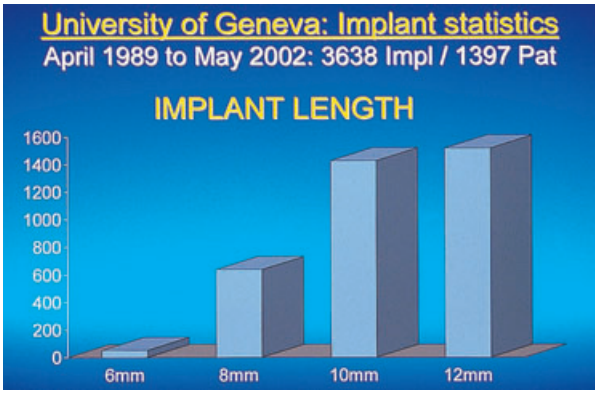

Fig. 54-2 University of Geneva implant statistics, 1989–2002. Implant length distribution.

sense, including additional parameters such as simplicity, cost effectiveness, and quality of life. Beyond any doubt, the advent of osseointegration has had a fundamental impact on the therapeutic approach and strategies implemented today in the field of prosthetic rehabilitation of the compromised posterior dentition. The implant statistics of the University of Geneva School of Dental Medicine, for example, reveal that from April 1989 until May 2002 more than 3600 implants of 6–12 mm length were inserted in about 1400 patients presenting with different types of edentulism (Figs. 54-1, 54-2). This treatment method is increasingly applied worldwide and has had a tremendous influence on traditional prosthodontic attitudes (Beumer *et al*. 1993; Zarb & Schmitt 1995; Tarnow *et al*. 1997; Zitzmann & Marinello 1999; Belser *et al*. 2000; Schwarz-Arad & Dolev 2000; Brägger *et al*. 2001; Deporter *et al*. 2001; Zitzmann & Marinello 2002). Since most of the established dental implant systems today comprise a wide range of mostly screw-type implants with different diameters and dimensions to replace missing premolars and molars (Fig. 54-3), the versatility of implant therapy in the load-carrying part of the dentition of partially edentulous patients has been significantly enhanced.

Numerous other indications have been added to the so-called classical indications for the use of

Fig. 54-3 Different implant diameters are available for the replacement of posterior teeth.

implants, i.e. severely atrophied edentulous jaws, missing teeth in otherwise intact dentitions (congenitally missing teeth; tooth loss due to trauma or due to a localized endodontic/restorative/periodontal complication or failure), and the distally shortened dental arch (particularly when premolars are missing). Among these other indications one should mention all the strategies aiming at either reducing the prosthodontic risk in general or rendering the treatment simpler and more cost effective. Virtually no limits for the placement of implants seem to exist any more owing, for example, to advanced bone augmentation techniques, comprising anterior sinus floor elevation and distraction osteogenesis (Buser *et al*. 1993, 1995, 1996, 1998a, 2002; Chiapasco *et al*. 1999, 2001a; Buser & von Arx 2000; Simion *et al*. 2001; von Arx *et al*. 2001a,b).

When it comes to the technique of placing implants in the posterior segments of the jaws, a one-step non-submerged surgical protocol can be associated with notable advantages. On the one hand, healing of the peri-implant soft tissues occurs simultaneously with osseointegration, and on the other hand the location of the junction between the implant shoulder and the secondary components is normally positioned close to the mucosal surface. It is ultimately the position of this junction which determines the apical migration of the peri-implant epithelium and the crestal bone level, once the so-called biologic width has been established (Abrahamson *et al*. 1997; Hermann *et al*. 1997, 2000, 2001a,b; Lindhe & Berglundh 1998; Engquist *et al*. 2002; Wyatt & Zarb 2002). Positioning of the transition between implant shoulder and secondary components at the level of the mucosa rather than at the crestal bone also represents a biomechanical advantage, as it contributes to the reduction of the lever effect and resulting bending moments acting on the junction between implant and suprastructure. This is clinically relevant, as one should be aware of the existence of an increasing body of evidence reporting technical complications, such as loosening/fracture of screws or fracture of components/veneers, related to implant-supported prosthetic suprastructures (Lundgren & Laurell 1994; Wie 1995;

Fig. 54-4 Occlusal view of the mandible of a 22-year-old male patient. All premolars are congenitally missing, the remainder of the dentition is intact.

Fig. 54-5 Final view after insertion of four implants, restored with cemented metal–ceramic suprastructures.

Hebel & Gajjar 1997; Rangert *et al*. 1997; Bosse & Taylor 1998; Glantz & Nilner 1998; Taylor 1998; Brägger 1999; Goodacre *et al*. 1999; Isidor 1999; Keith 1999; Schwarz 2000; Johnson & Persson 2001). Besides mechanical types of complications, a number of other conditions that are rather biologic in nature, for example peri-implantitis, are reported in the recent literature (Ellegaard *et al*. 1997a,b; Ellen 1998; Lang *et al*. 2000; Brägger *et al*. 2001; Quirynen *et al*. 2001, 2002). As these are addressed in detail in another chapter, we will only focus on aspects related to fixed posterior implant restoration design and maintenance.

It is the aim of this chapter to present clinically oriented guidelines and procedures for implant therapy of various types of edentulism located in the load-carrying part of the dentition, addressing primarily the partially dentate patient and mainly focusing on fixed implant-supported prostheses.

Indications for implant restorations in the load carrying part of the dentition

When it comes to partial edentulism in the posterior segments of the jaws, implants are increasingly used either to preserve sound mineralized tooth structure or to avoid removable partial dentures (RPDs) and high-risk conventional fixed partial dentures (FPDs). This includes situations with missing teeth in otherwise intact dentitions (Figs. 54-4, 54-5), the distally shortened dental arch (Figs. 54-6 to 54-8), extended edentulous segments, missing "strategic" tooth abutments, and structurally, endodontically or periodontally compromised potential abutment teeth (Table 54-1).

The rapid advance in terms of the broad utilization of dental implants is not exclusively based on the associated favorable long-term reports for this treatment modality. Other parameters such as purely "mechanical" advantages and the availability of prefabricated components and auxiliary parts, which in turn contribute notably to the simplification of the treatment, had a significant impact on current con-

Fig. 54-6 Bilaterally distally shortened dental arch in the mandible of a 66-year-old female patient.

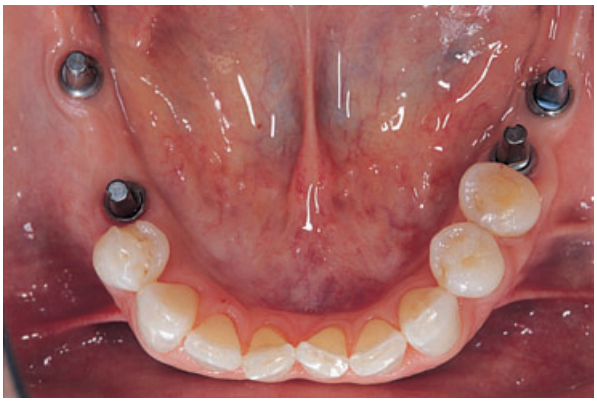

Fig. 54-7 Four implants have been inserted to lengthen the arch bilaterally to the region of the first molars.

cepts and strategies as well (Table 54-2). Furthermore, clinical decision making based on prosthetically oriented risk assessment (Table 54-3), frequently leads to the need for an increased number of abutments. The objective is to reduce the overall risk associated with a given prosthetic solution on the one hand, and to implement the principle of segmenting on the other.

A representative clinical example is given in Figs. 54-9 and 54-10. Instead of a conventional five-unit

Fig. 54-8 Five premolar-sized metal–ceramic elements were used to restore the four implants.

Fig. 54-9 Maxillary occlusal view displaying natural and implant abutments prior to the insertion of an extended porcelain-fused-to-metal restoration. In order to avoid a high-risk long-span FPD, three implants have been added in the left posterior segment.

Table 54-1 Indications for posterior implants

- Replacement of missing teeth in intact dentitions (e.g. congenitally missing premolars), i.e. preservation of tooth structure
- Avoidance of removable partial dentures (RPDs)
- Increase of the number of abutments:
  - Reduction of the prosthetic risk
  - Application of the principle of segmenting
  - Ease of eventual reinterventions
- Maintenance of pre-existing crowns and FPDs
- Following prosthetic complications and failures

Fig. 54-10 A similar restorative design has been chosen for both natural and implant-supported metal–ceramic suprastructures.

Table 54-2 Impact of dental implants related to the treatment of posterior partial edentulism

- Favorable overall long-term results
- Preservation of mineralized tooth structure
- "Mechanical" advantages:
  - Commercially pure (c.p.) titanium (biocompatibility, mechanical properties, no risk for caries)
  - Reproducible, prefabricated ("machined") primary, secondary and tertiary components and auxiliary parts
- Simplified clinical and laboratory protocols

Table 54-3 "High risk" conventional fixed partial dentures (FPDs)

- Long-span fixed partial bridges
- Cantilever units (mainly distal extensions)
- Missing "strategic" tooth abutments
- Structurally/periodontally/endodontically compromised tooth abutments
- Reduced interarch distance
- Presence of occlusal parafunctions/bruxism

FPD, replacing the missing maxillary left first and second premolars as well as the absent first molar, three implants have been inserted. This approach allowed the avoidance of a long-span bridge, a full coverage preparation of the second molar, and an associated surgical crown-lengthening procedure. The additional cost related to the three implants was justified by an overall reduced prosthodontic risk. The question about adequate number, size, and distribution of implants will be addressed later in this chapter. Prosthetically oriented risk assessment comprises the comprehensive evaluation of potential natural abutment teeth, including their structural, restorative, periodontal, and endodontic status. Several well documented treatment modalities are often possible to replace missing posterior teeth, so this objective evaluation is of primary importance and represents an ever increasing challenge to the clinician. This is illustrated by a maxillary posterior segment where both the first premolar and the first molar were missing (Figs. 54-11 to 54-14). The insertion of a five-unit tooth-borne FPD was discarded because of its too invasive nature related to the intact canine, and owing to a slightly questionable status of

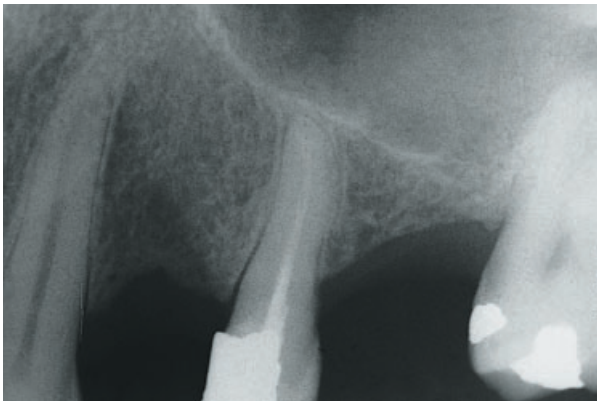

Fig. 54-11 Pre-operative radiograph of the left maxilla, revealing two missing dental elements. One should note in particular an intact canine, a structurally reduced second premolar, and an extended recessus of the sinus in the area of the missing first molar.

Fig. 54-12 Vestibular view of the prosthetic rehabilitation of the maxillary left quadrant: an implant-supported single-tooth restoration on the site of the first premolar, and a three-unit tooth-borne FPD to replace the missing first molar.

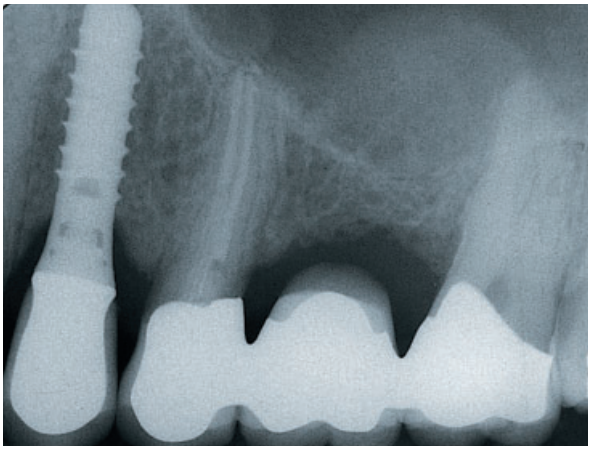

Fig. 54-13 The post-operative radiograph documents that an endodontic revision has been performed on the second premolar prior to its restoration with an adhesive carbon-fibre-post based build-up and a metal–ceramic crown (bridge retainer).

Fig. 54-14 An identical prosthetic design has been applied for both the implant-supported and the tooth-supported restoration.

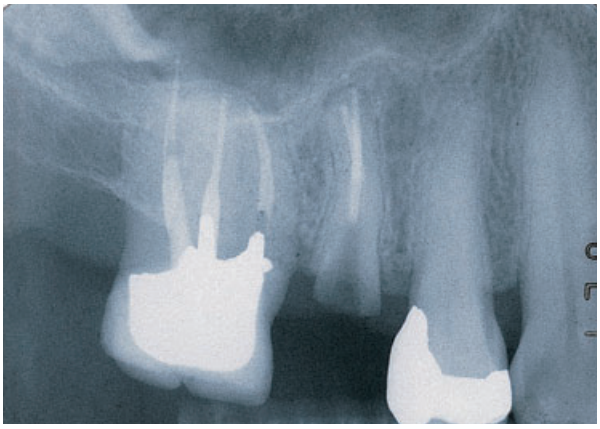

Fig. 54-15 Ad hoc radiograph of the upper right posterior sextant. One notes the presence of a structurally compromised second premolar. The treatment of that particular root would require build-up and crown lengthening (margin exposure, creation of an adequate ferrule) which in turn would negatively affect the adjacent teeth.

the endodontically treated second premolar in view of its eventual use as so-called "peer-abutment". Finally, an implant has been placed at the site of the missing first premolar and subsequently restored with a single-unit restoration. As the proximity of the maxillary sinus at the location of the missing first molar would have required a grafting procedure to make an implant installation possible, a three-unit tooth-supported FPD was ultimately chosen, after having duly discussed the respective advantages and shortcomings with the patient. Having attributed a "strategic value" to the moderately compromised second premolar by using it as abutment of a short-span bridge, there was still a difficulty in consistently establishing clinical treatment plans that were fully based on scientific evidence.

Still under the influence of the high level of predictability and longevity reported for implant therapy, the clinician is currently not only pondering implant-borne restorations versus conventional FPDs, but increasingly implant versus maintaining a compromised tooth (Figs. 54-15, 54-16). In this

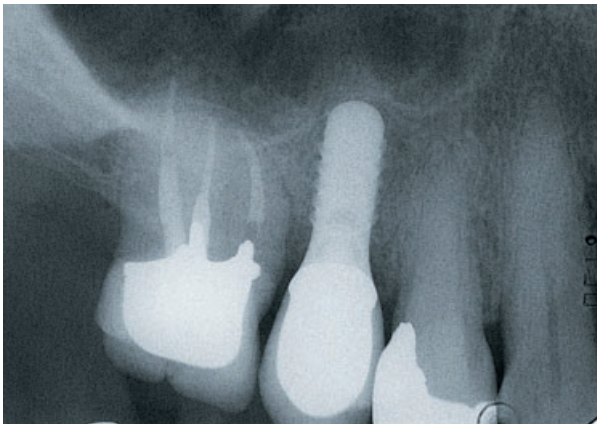

Fig. 54-16 The post-operative radiograph documents that the root of the second premolar has been replaced by a single-tooth implant restoration. In particular, the pre-existing metal–ceramic crown on the first molar could be maintained by this approach.

particular clinical case, the evaluation focused on whether or not it was objectively opportune to restore the structurally compromised root of a maxillary second premolar. This would have required – after elimination of the decayed dentin – a surgical crown-lengthening procedure to create access to the margin, which in turn would have included the risk for an adverse effect (furcation proximity of the adjacent first molar) on the neighboring teeth. Furthermore, a three-unit FPD was out of the question for obvious reasons. Based on this rationale and in the context of a more comprehensive analysis of the situation, it was finally decided to extract a *per se* treatable root and to replace it by an implant. One should never forget, however, that this trend to consider, under certain circumstances, an implant as a better solution than "acrobatically" treating a severely compromised tooth, calls for well defined evidence-based respective criteria and represents a non-negligible ethical responsibility for the clinician.

Controversial issues

Despite the ever-growing body of scientific evidence indicating that implant therapy in the partially edentulous patient is an overall highly predictable treatment modality, several conceptional issues remain controversial to date (Table 54-4). These controversial issues include open questions addressing adequate number, size, and distribution of implants for optimal therapy of a given type and configuration of partial edentulism, as well as parameters related to occlusion and occlusal materials, to implant axis, to the minimal acceptable ratio between suprastructure height and implant length, and – last but not least – related to questions focusing more specifically on the mechanical aspects and requirements of posterior implant prosthodontics. Among these, the kinds of connection between implant and abutment have to be mentioned in particular. Most of these questions will be discussed in the remainder of this chapter, at length where possible and appropriate, or more superficially when solid information is missing or when the topic is more adequately covered by other authors in this book.

Table 54-4 Controversial issues related to posterior implant restorations

- Adequate number, size (length/diameter), configuration and distribution of implants
- Cemented versus screw-retained (transocclusal/transverse screw retention)
- Single units versus splinted adjacent implant restorations
- Longest possible versus shorter implants
- Impact of implant axis
- Optimal implant shoulder sink depth
- Minimal ratio between implant length and suprastructure height
- Combination of natural teeth and implants in the same restoration
- Design of the optimal abutment-to-implant connection
- Implant-specific occlusal concepts, including occluding restorative materials, non-axial loading, type of guidance during mandibular excursions
- Healing times prior to functional loading (immediate/early/delayed)
- Significance of offset/staggered implant positioning

Restoration of the distally shortened arch with fixed implant-supported prostheses

As pointed out earlier in this chapter, from 1989–2002 the distally shortened arch represented the most frequent indication for the use of implants at the University of Geneva School of Dental Medicine. In fact, out of a total of 3638 implants, almost 1500 were placed in distally shortened arches, with close to 1000 implants inserted in the mandible and about 500 in the posterior maxilla (Fig. 54-1). Implants were primarily used when premolars were also missing. Whenever possible, the adopted treatment strategy consisted of restoring the shortened dental arch to the region of the first molars. Occasionally, implant therapy was restricted to the premolar area, according to the principles of the well established premolar occlusion concept, or extended to the second molar area if an antagonistic contact had to be established for an opposing natural second molar.

Number, size, and distribution of implants

It is still unclear to date how many implants of which dimension at which location are required to optimally rehabilitate a given edentulous segment in the load-carrying part of the dentition. Several different respective recommendations and related strategies are currently in use, mostly derived from traditional prosthodontic experience and attitudes, and based on so-called clinical experience and common sense

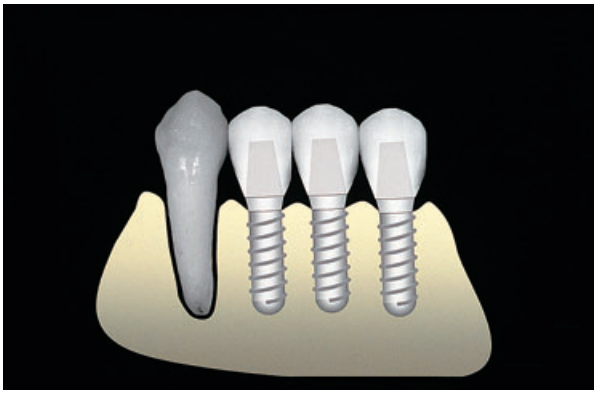

Fig. 54-17 Schematic representation of the distally shortened dental arch. One therapeutic option consists of replacing each missing occlusal unit up to the first molar area with an implant.

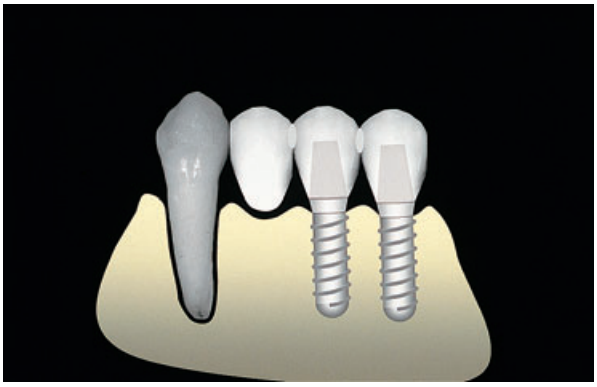

Fig. 54-19 In a case of an inadequate bone volume in the area of the missing first premolar, the placement of two distal implants may be considered, leading to a three-unit suprastructure with a mesial cantilever.

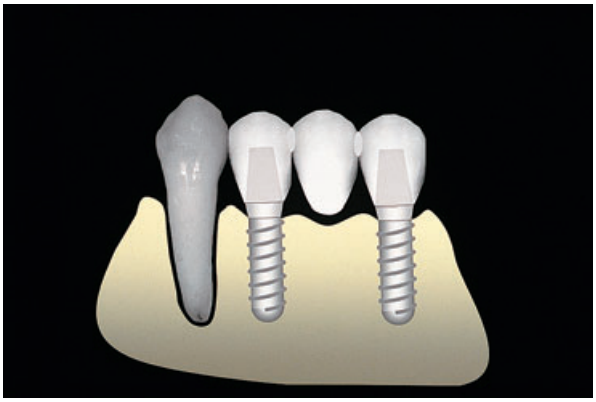

Fig. 54-18 An alternative option would be the replacement of the three missing occlusal units by two implants to support a three-unit suprastructure with a central pontic.

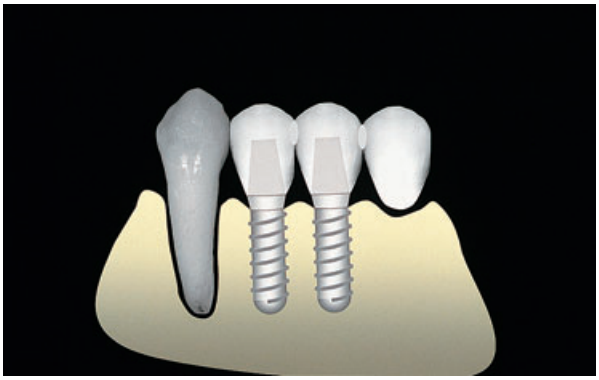

Fig. 54-20 In a case of an inadequate bone volume in the area of the missing first molar, the placement of two mesial implants may be considered, leading to a three-unit suprastructure with a distal cantilever.

rather than on solid scientific evidence. In defense of the situation one should be aware, however, that it is often difficult to design and carry out randomized clinical trials evaluating exclusively and without interference one specific parameter of conceptual relevance.

In a situation where the canine is the most distal remaining tooth of a dental arch, at least five different options can be taken into consideration if one plans to replace the missing teeth up to the first molar area (Figs. 54-17 to 54-21). These include the replacement of each missing occlusal unit by one implant (Fig. 54-17), a mesial and a distal implant to support a three-unit FPD with a central pontic (Fig. 54-18), two distal implants to permit the insertion of a three-unit FPD with a mesial cantilever (Fig. 54-19), two mesial implants to sustain a three-unit FPD with a distal cantilever (Fig. 54-20) and, finally, only one distally inserted implant in view of a four-unit FPD combining implant and natural tooth support (Fig. 54-21).

As far as the recommendation to use premolar-sized units for implant-borne posterior FPDs is concerned, it has proven its practical validity in more than 10 years of clinical experience (Buser *et al*. 1997;

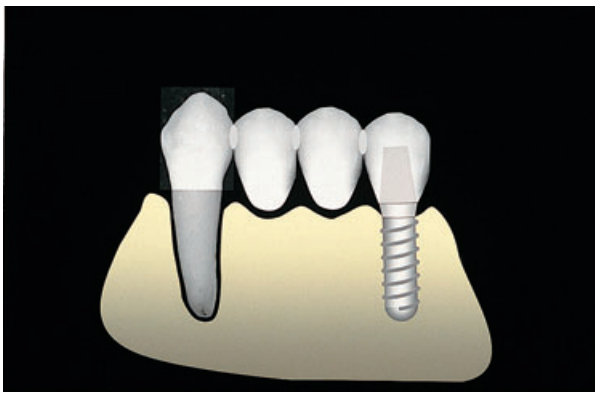

Fig. 54-21 In a case of inadequate bone volume in the area of the two missing premolars, the placement of a distal implant may be considered, leading to a four-unit suprastructure with a mixed (tooth and implant) support.

Bernard & Belser 2002). In fact, a crown featuring a mesio-distal diameter of 7–8 mm at its occlusal surface allows the optimal generation of a harmonious axial profile, gradually emerging from the standard implant shoulder (diameter 4–5 mm on average) to the maximum circumference. In addition, the

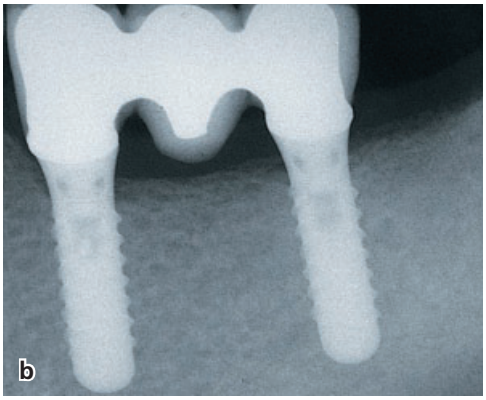

Fig. 54-22 (a) Occlusal view of a cemented three-unit metal–ceramic FPD, supported by a mesial and a distal implant. (b) The corresponding 3-year follow-up radiograph confirms stable conditions at the implant to bone interface of the two 12 mm solid screw implants.

Fig. 54-23 Occlusal view of a cemented four-unit metal–ceramic FPD supported by a mesial and a distal implant.

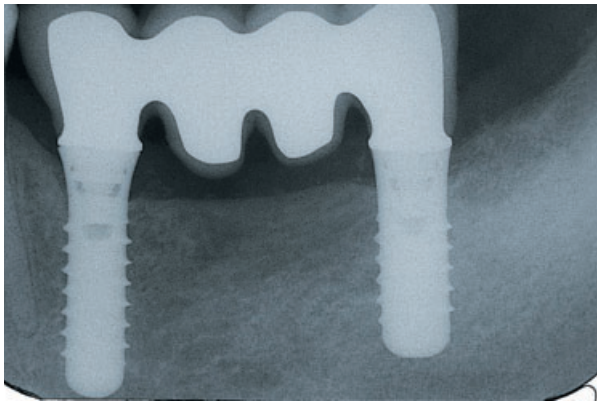

Fig. 54-24 The related 2-year follow-up radiograph documents that at the distal site a 10 mm solid screw implant with an increased diameter ("wide-body implant") has been used.

width of the occlusal table is confined, thereby limiting the risk for unfavorable bending moments to the implant–abutment–suprastructure complex (Belser *et al*. 2000).

Based on an increasing body of scientific evidence, most clinicians' first choice represents the mesial and distal implant and the respective FPD with the central pontic (Fig. 54-22). Prospective long-term multicenter data (Buser *et al*. 1997; Bernard & Belser 2002) have confirmed the efficacy and predictability of this specific modality. In fact, it permits the defined treatment objective with a minimal number of implants and associated costs. Although presently still lacking formal evidence at the level of prospectively documented, randomized clinical trials, it appears from clinical experience that the use of two implants to support a four-unit FPD with two central pontics (Figs. 54-23, 54-24) may be adequate in certain clinical situations. Clinicians tend to use this approach in the presence of favorable bone conditions, permitting standard-size or wide-diameter implants with appropriate length (i.e. 8 mm or more).

If the alveolar bone crest dimension is also sufficient in an oro-facial direction, the utilization of wide-diameter/wide-platform implants is preferred. Due to their increased dimensions a more adapted suprastructure volume and improved axial emergence profile of the implant restoration – when compared to a so-called premolar unit – can be achieved in the molar area (Figs. 54-25 to 54-28). By this token the intercuspation with an opposing natural molar is also facilitated.

Implant restorations with cantilever units

There is strong evidence in the relevant dental literature that cantilever units – in particular distal extensions – of conventional tooth-borne FPDs are associated with a significantly higher complication rate when compared to FPDs featuring a mesial and a distal abutment and a central pontic. Respective failure rates could be attributed to decisive factors such as non-vital abutment teeth as well as specific occlusal conditions such as a reduced interarch distance and/or occlusal parafunctions (Glantz & Nilner 1998). These authors concluded in their review of the current relevant literature that risks were lower for mechanical failures with cantilevered implant-borne reconstructions than with comparable conventional fixed situations. Risks, however, do exist. As loss of

Fig. 54-25 Occlusal view of a bilaterally distally shortened mandibular arch. Two implants have been placed on either side to restore the arch to the area of the first molars. The two distal implants feature an increased diameter, better suited for the replacement of a missing molar.

Fig. 54-26 The master model comprises color-coded aluminum laboratory analogues at the implant sites, facilitating the technician's work in view of the suprastructure fabrication. This is in contrast to the site of the prepared natural abutment.

Fig. 54-27 Once the metal–ceramic restorations are completed, no noticeable design difference between implant-supported and tooth-supported suprastructures is apparent.

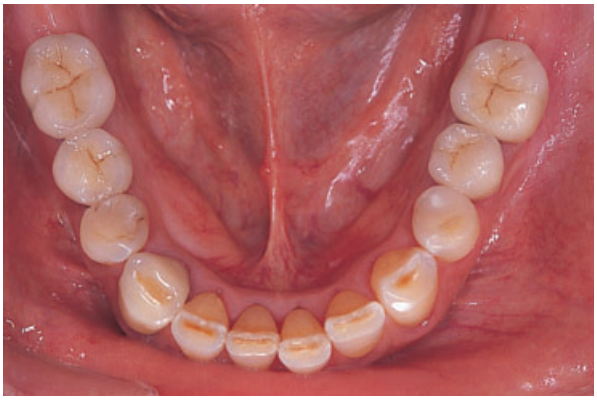

Fig. 54-28 The respective clinical view confirms an acceptable integration of the four implant restorations in the existing natural dentition.

retention, which was one of the frequent complications encountered on conventional cantilevered prostheses, can easily be prevented when it comes to implant-supported restorations of this type, the latter seem to be a viable alternative in cases where the local alveolar bone crest conditions do not allow the insertion of an implant at the most favorable location. In such situations the clinician has to ponder whether a bone augmentation procedure can be objectively justified or if the risk for complications of a more simple, straightforward approach can be considered low.

The 6-year clinical and radiographic follow-up of a three-unit FPD featuring a mesial cantilever is presented in Figs. 54-29 and 54-30.

Combination of implant and natural tooth support

There is general agreement that, from a purely scientific point of view, the combination of implants and natural teeth to support a common FPD is feasible. Clinical studies reporting prospectively documented long-term data did not show adverse effects of splinting teeth to implants (Olsson *et al*. 1995; Gunne *et al*. 1997, 1999; Hosny *et al*. 2000; Lindh *et al*. 2001; Naert *et al*. 2001a,b; Tangerud *et al*. 2002). The issue of connecting implants and teeth by means of rigid or non-rigid connectors, however, remains controversial to date, but intrusion of natural roots has been reported in the literature as a potential hazard of non-rigid connection (Sheets & Earthman 1993). Most of the recently published respective literature reviews conclude with the general clinical recommendation that one should avoid, whenever possible, the direct combination of implants and teeth as it may frequently lead to a more complicated type of prosthesis. If there is no viable alternative available, a rigid type of connection is preferred to prevent an eventual intrusion of the involved abutment teeth (Lundgren & Laurell 1994; Gross & Laufer 1997).

Furthermore, it has been demonstrated that despite the fundamental difference between an osseointe-

Fig. 54-29 Six-year clinical follow-up view of a mandibular three-unit FPD supported by two distal implants.

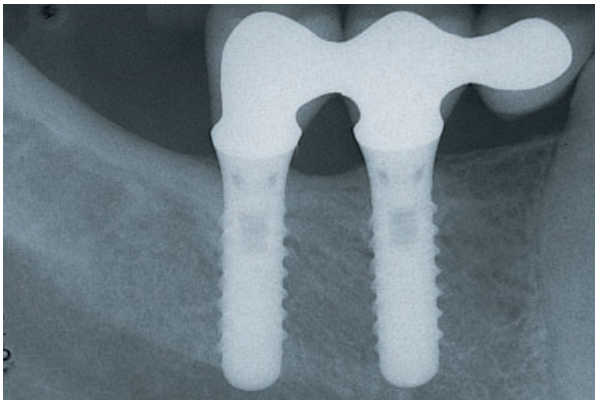

Fig. 54-30 The 6-year radiograph displays stable bony conditions around the two implants supporting a cemented suprastructure with a premolar-sized mesial cantilever unit.

grated implant and a tooth surrounded by a periodontal ligament, the assumption that when these two structures are combined, the entire occlusal load will ultimately go to the implant and hence create an unfavorable "cantilever-type" situation, is not valid from a scientific point of view (Richter, Isidor, Brägger). In fact, under normal function, such as during mastication, the tooth abutment is similarly load-bearing. This may change, however, during severe occlusal parafunctions, like nocturnal bruxism.

Sites with extended horizontal bone volume deficiencies and/or anterior sinus floor proximity

It is not infrequent that distally shortened dental arches do not feature an adequate local bone volume at the prospective implant sites. This may refer to bone height, bone width, alveolar bone crest axis or to the vicinity of noble structures such as the mandibular alveolar nerve canal or the anterior part of the maxillary sinus. Often a combination of several of the mentioned limitations is encountered. As implant insertion is clearly a three-dimensional

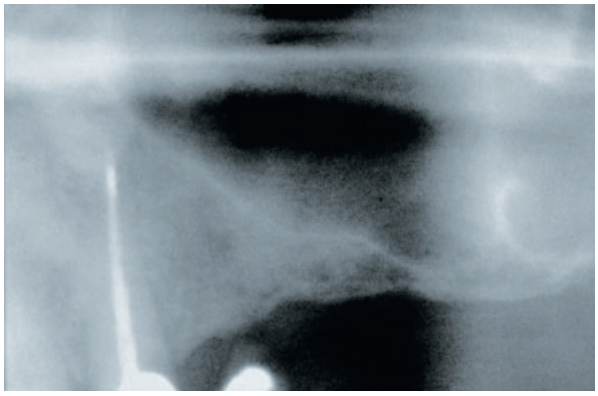

Fig. 54-31 Initial radiograph of the maxillary left posterior segment of a 67-year-old male patient. The canine represents the most distal remaining tooth element. Note the marked extension of the anterior recessus of the sinus.

surgical and restorative procedure on the one hand, and as "restoration-driven" rather than "bone-driven" implant placement is widely recommended on the other hand, a meticulous presurgical site analysis – based on the envisioned treatment objective – is of primary importance. In order to keep the treatment as easy and finally also as cost-effective as possible, one should comprehensively evaluate whether a minor deviation from the ideal implant position could be considered acceptable, i.e. not leading to a compromise which might adversely affect predictability, longevity, and/or subjective comfort. This approach may still permit a professionally defendable result in some cases, but without a complexity of treatment that would be difficult to bear by some patients.

Advanced invasive procedures like lateral bone augmentation, anterior sinus floor elevation, alveolar ridge splitting or distraction osteogenesis, require a high level of skills and respective experience and hence should only be deployed if the relation between benefit and risk/cost is soundly balanced (Buser *et al*. 1993, 1995, 1996, 1999, 2002; Chiapasco *et al*. 1999, 2001a; Simion *et al*. 2001; von Arx *et al*. 2001a,b; Zitzmann *et al*. 2001).

In this specific context, a complex implant treatment of a 67-year-old male patient whose most distal remaining tooth in the left maxilla was an endodontically treated canine, is shown in Figs. 54-31 to 54-44. Pre-operative diagnosis revealed the necessity to perform – according to a staged approach – first a combined lateral bone augmentation procedure and anterior sinus floor elevation and, after a 6 month healing period, the insertion of implants. For the sinus floor elevation the so-called "trap-door" technique was used and the created space grafted with autogenous bone chips and BioOss®. The lateral bone augmentation comprised the fixation of a large block graft in the area of the first premolar. After application of an e-PTFE barrier membrane, primary wound closure was achieved by sectioning of the periosteum of the respective mucoperiosteal flap. This often leads

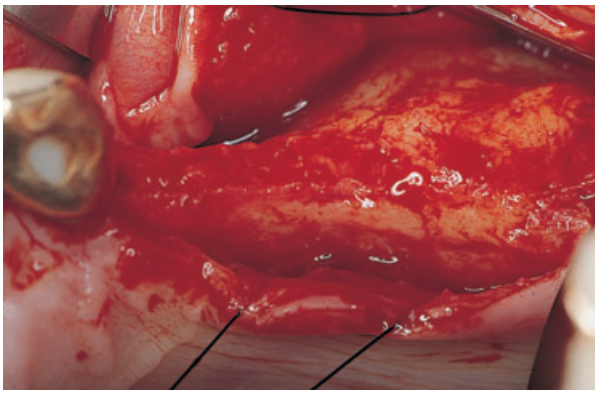

Fig. 54-32 After elevation of a mucoperiosteal flap, an insufficient horizontal bone volume in the region of the premolars becomes apparent.

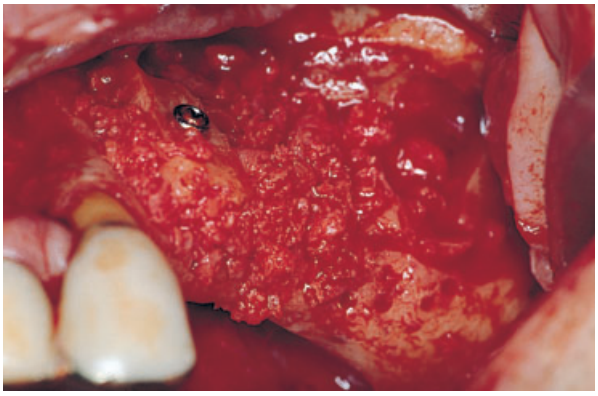

Fig. 54-35 The lateral bone augmentation procedure is completed by adding a combination of autogenous bone chips, bone slurry, and BioOss®.

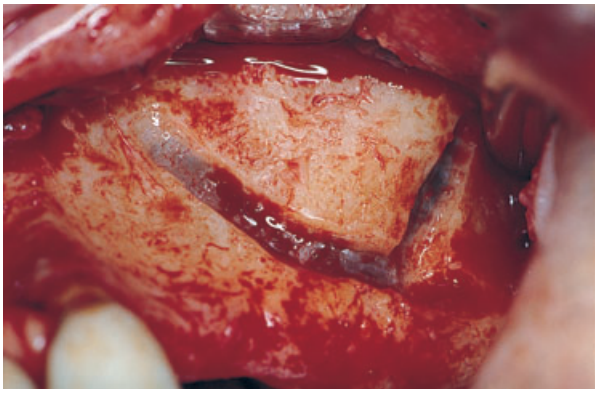

Fig. 54-33 In view of an anterior sinus floor elevation procedure, the first step for a respective osteotomy is performed. Attention is given not to perforate the Schneiderian membrane.

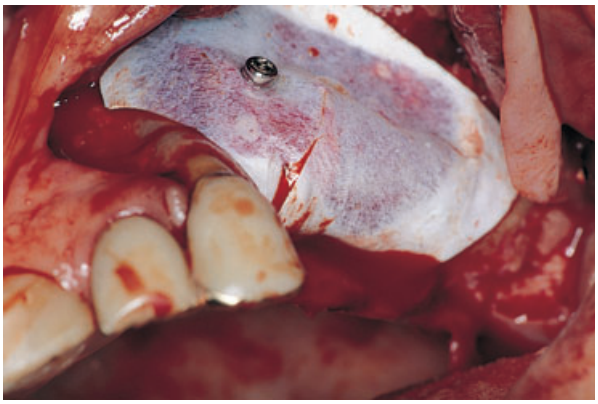

Fig. 54-36 Prior to flap repositioning and suturing, a barrier membrane is applied.

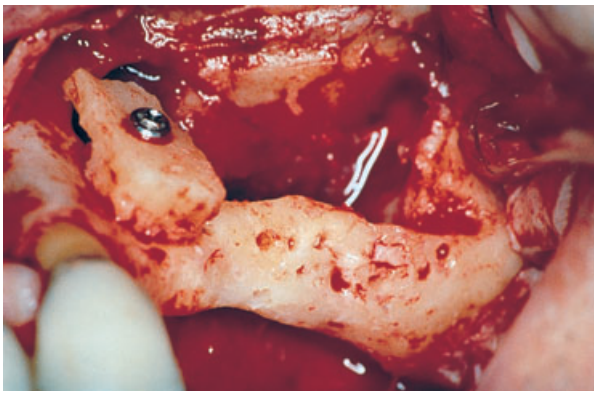

Fig. 54-34 After the so-called "trap-door" procedure in the region of the maxillary sinus, an autogenous bone block graft, harvested from the patient's retromolar area, is positioned and then immobilized by a fixation screw at the location of the missing first premolar.

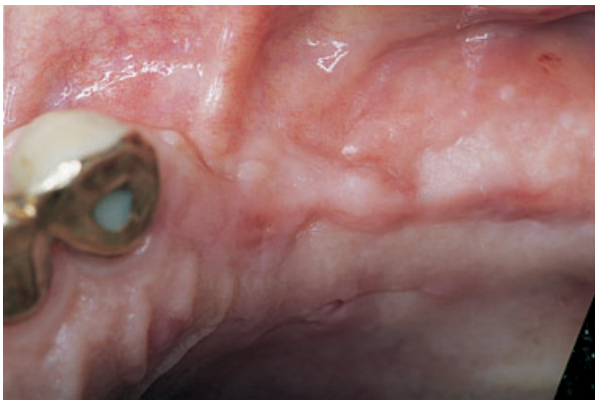

Fig. 54-37 One month after primary wound closure and uneventful healing, the involved soft tissues have recovered their normal appearance.

to a lack of attached keratinized mucosa on the vestibular aspect of the surgical site, which has to be subsequently corrected, most conveniently at the moment of implant placement. When it comes to sites that have been previously grafted, the majority of surgeons advocate inserting one implant per missing occlusal unit. This attitude appears to be based more on the reflection that the overall heaviness of the approach would largely justify this additional security and/or on the hypothesis that augmented bone may not have exactly the same "load-bearing" capacity as the pre-existing bone, than on irrefutable scientific evidence. Accordingly, three adjacent screw-type

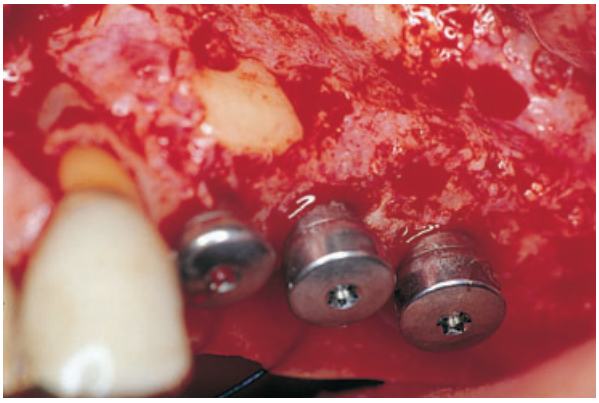

Fig. 54-38 Eight months following the combined anterior sinus floor elevation and lateral bone augmentation procedure, the site is reopened and three implants are inserted.

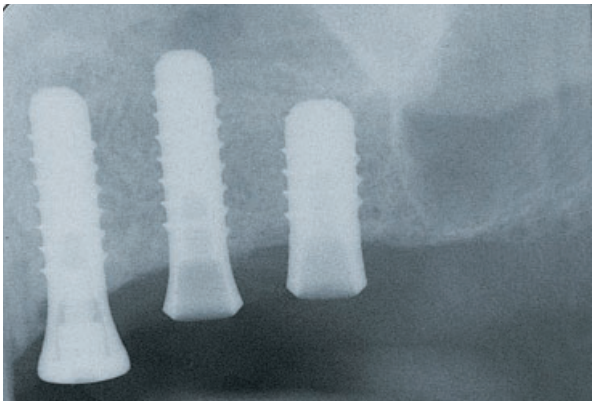

Fig. 54-41 The corresponding radiograph confirms successful osseointegration of the three implants that are mostly located in augmented bone.

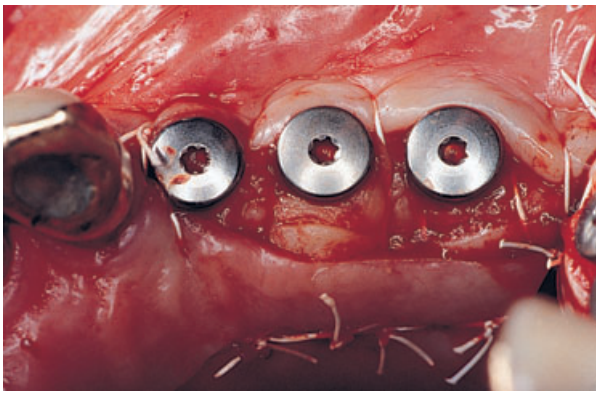

Fig. 54-39 In order to increase the amount of keratinized mucosa on the vestibular aspect of the implants, the flap is repositioned accordingly. The resulting deficiency on the palatal aspect is compensated for by means of a connective tissue being part of the partial-thickness flap.

Fig. 54-42 In a case of implant shoulder location compatible with cementation, respective solid abutments are selected and tightened to 35 Ncm with a calibrated torque wrench.

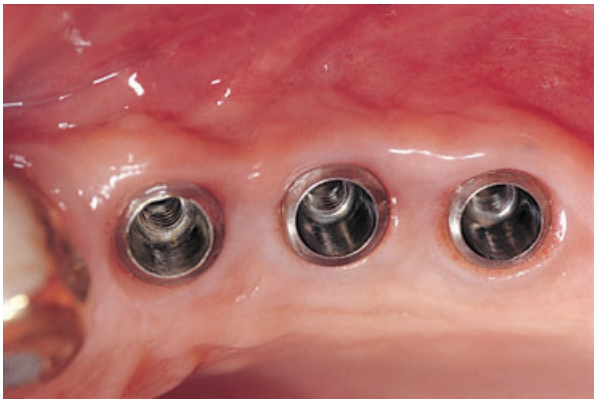

Fig. 54-40 Three months after implant placement, favorable peri-implant soft tissue conditions have been re-established.

Fig. 54-43 Clinical view of the final three-unit metal–ceramic implant suprastructure, featuring a flat and continuous emergence profile and adequate access for inter-implant oral hygiene.

implants – the most distal one an increased-diameter titanium screw – had been placed and subsequently restored by a three-unit splinted metal-ceramic FPD (Figs. 54-38 to 54-44).

Results from a recently published longitudinal clinical study (Buser *et al*. 2002) on 40 consecutively enrolled patients, who were first treated with a lateral bone augmentation procedure and subsequently, in a second stage, received implants inserted in the previously augmented area. Implants could finally be placed as planned in all the treated sites, and a 97% success rate was revealed at the 5-year clinical and

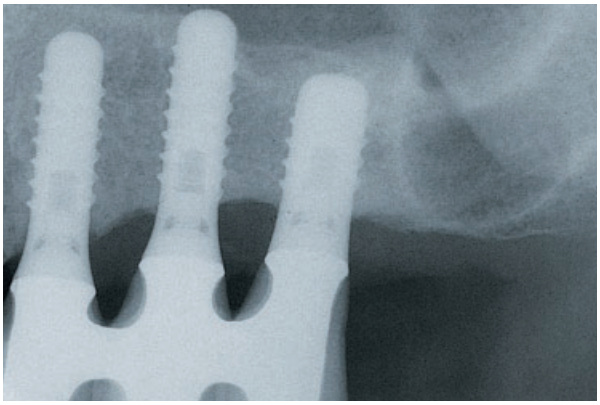

Fig. 54-44 The 4-year follow-up radiograph confirms stable conditions at the osseointegrated interface.

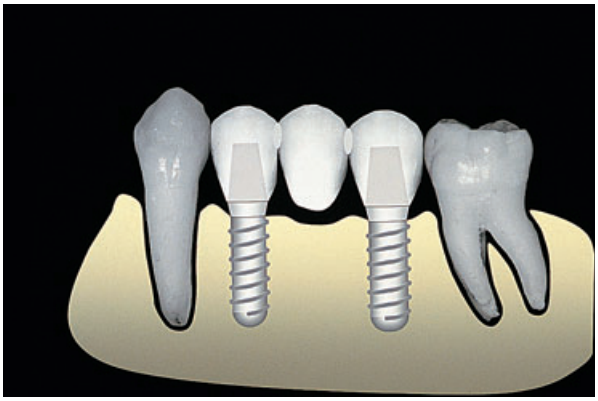

Fig. 54-45 Schematic representation of a tooth-bound posterior edentulous segment, restored by two implants and a three-unit FPD with a central pontic.

radiographic follow-up examination. It was thus concluded that lateral bone augmentation is indeed a predictable procedure and that implants subsequently inserted in augmented sites do have similar success rates to implants placed in comparable non-augmented sites.

Multiple-unit tooth-bound posterior implant restorations

Number, size, and distribution of implants

When it comes to implant therapy in extended posterior edentulous segments confined mesially and distally by remaining teeth, the question about optimal number, size, and distribution of implants has to be raised again. Among the key parameters to be addressed during the decision-making process are the mesio-distal dimension of the edentulous segment, the precise alveolar bone crest volume (including bone height and crest width in an oro-facial direction), the opposing dentition (premolars or molars), interarch distance and specific occlusal parameters, as well as the periodontal, endodontic, and structural conditions of the neighboring teeth.

One feasible approach consists of segmenting the edentulous space in premolar-size units of approximately 7 mm of mesio-distal diameter at the level of the occlusal plane, and of approximately 5 mm at the prospective implant shoulder. On posterior locations, clinicians increasingly prefer a rather superficial implant shoulder location or in many instances even a supramucosal one, so the respective measurements can be carried out at the crest level of study casts. It is important during this process to anticipate a minimal distance between implant shoulders of approximately 2 mm, and between a natural tooth and an implant of about 1.5 mm (to be measured at the interproximal soft tissue level). Again, the treatment objective, i.e. a long-lasting implant-supported FPD, should be predictably reached (1) with optimal efficacy and (2) with a minimum of invasiveness and

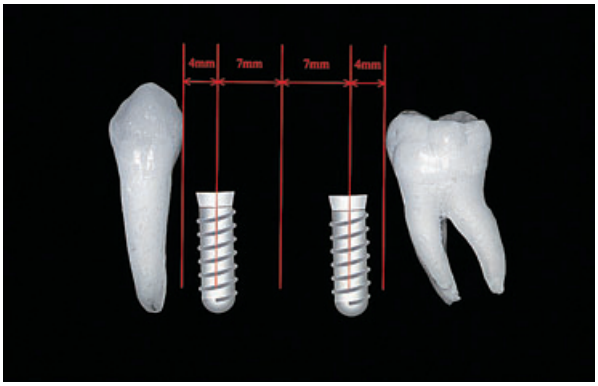

Fig. 54-46 In the case of three missing occlusal units, an implant-supported FPD with a central pontic (approximately 7 mm in width) may be considered as a viable solution.

cost. The still existing controversy of whether each missing occlusal unit should be replaced by one implant or whether a minimal number of implants should be used, has already been addressed earlier in this chapter.

In the case of three missing occlusal units and in the absence of other particular restrictive conditions such as limited local bone volume, the authors recommend the insertion of a mesial and a distal implant to support a three-unit FPD with a central pontic (Fig. 54-45). This approach permits the fabrication of three metal–ceramic elements featuring a mesio-distal diameter of about 7 mm each. Based on an average implant shoulder dimension of approximately 5 mm, one can anticipate a gradually increasing, harmonious emergence profile from the implant shoulder to the occlusal surface. In order to satisfy the remaining important dimensional conditions, i.e. respecting the minimal distance between adjacent implants and in between teeth and implants, one needs to dispose of a minimal total mesio-distal gap distance of 21–22 mm (Fig. 54-46).

In the case of two missing occlusal units, one should try as a general rule to select the largest possible implant diameters with respect to the total mesio-distal distance of the given tooth-bound

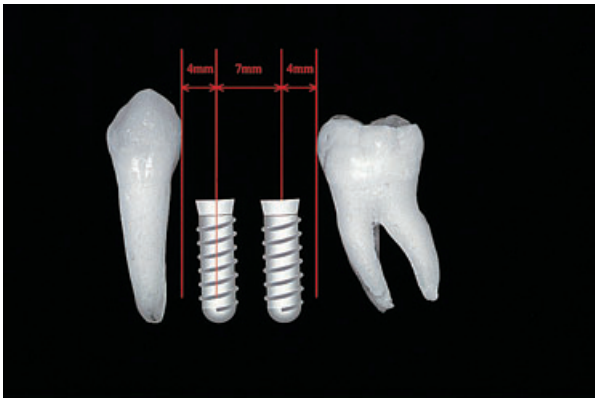

Fig. 54-47 If a given tooth-bound edentulous space only permits the insertion of two adjacent implants, a minimal interimplant distance of 2 mm and a minimal implant-to-tooth distance of 1.5 mm (at the interproximal soft tissue level) should be respected.

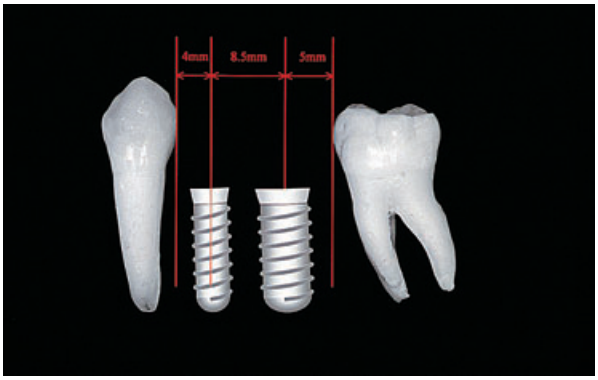

Fig. 54-48 In the presence of a mesio-distal gap width of approximately 17 mm, one may consider the combination of a standard and an increased-diameter ("wide-neck") implant. The same minimal inter-implant and implant-to-tooth distances have to be respected.

edentulous segment. Decisive parameters are again interimplant distance and space between implants and adjacent teeth, as well as oro-facial crest width at the two prospective implant sites. For a total gap diameter of about 14–15 mm, two standard-size implants are most suitable (Fig. 54-47), while for one of 17 to 18 mm the combination of one standard and one wide-diameter/wide-platform implant is considered adequate (Fig. 54-48). It goes without saying that the latter choice also requires the respective oro-facial bone volume.

These are just frequently encountered clinical examples, but in the function of other morphology and dimensions of edentulous tooth-bound segments, additional approaches and implant combinations may be envisioned. Two such clinical situations are presented in Figs. 54-49 to 54-52 and Figs. 54-53 to 54-55. In the first case, the gap diameter required the two adjacent implants to be spaced wider than the normally advocated interproximal 2 mm. The laboratory technician compensated for this excess of space with a root-imitation pontic which in turn

Fig. 54-49 Vestibular aspect of a metal–ceramic restoration supported by two screw-type implants. Due to an excess of mesio-distal space, the implants have been separated by approximately 4 mm. Instead of a traditional pontic, a root imitation has been performed close to the distal implant, providing an adequate guide for an interdental brush in view of an efficient plaque control at the marginal area of the implant restoration.

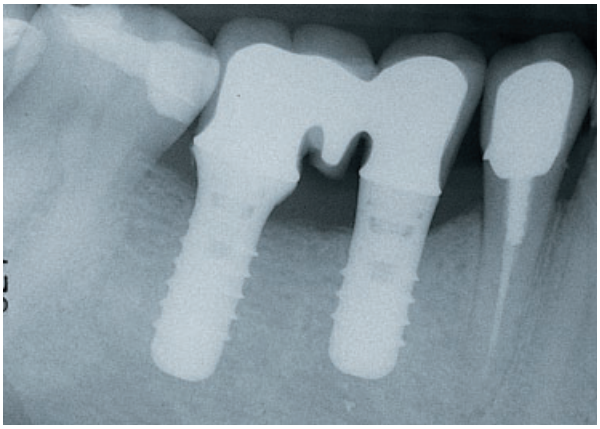

Fig. 54-50 With respect to cleanability, the respective prosthesis design is clearly visible on the post-operative radiograph.

Fig. 54-51 The corresponding master model visualizes the different dimensions and distances involved in this individual case.

Fig. 54-52 On an oblique view the vestibular axial profile of the implant restoration becomes visible. Soft tissue (cheek and tongue) support and harmony with adjacent teeth are of paramount importance.

Fig. 54-53 Buccal view of an extended edentulous right mandibular tooth-bound gap treated with an implant restoration. In the pontic area a design favoring the efficacy of an interdental brush close to the implant margins has been applied.

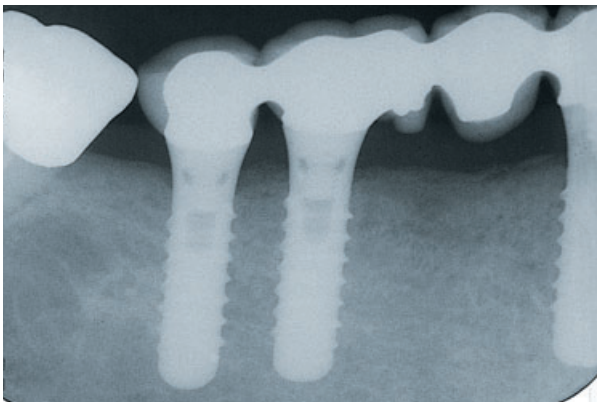

Fig. 54-54 The related radiograph illustrates the chosen design in the pontic area in terms of access to and efficacy of interproximal plaque control.

provided an excellent guide facilitating the use of an interdental brush (Fig. 54-49). In the second case, only the placement of three standard-size implants was possible due to a restricted bone volume in oro-facial direction. Again, the technician could optimally distribute the different restoration volumes but still

Fig. 54-55 Occlusal view of the completed 4-unit implant-borne fixed porcelain-fused-to-metal prosthesis.

Table 54-5 Splinting of multiple adjacent posterior implants

Parameters to consider:
• Access for oral hygiene
• Marginal adaptation/"passive fit"
• Technical simplicity/ease of eventual reinterventions
• "Overload" of the osseointegrated interface
• "Rotational forces" on implant components
• Screw-loosening/fatigue fractures

comply with basic prerequisites such as a flat axial emergence profile and optimal access for the patient's oral hygiene (Figs. 54-53, 54-54).

Splinted versus single-unit restorations of multiple adjacent posterior implants

Another persisting controversial issue relates to the question whether multiple adjacent implants in the load-carrying part of the dentition should support splinted or segmented single-unit restorations (Table 54-5). There still appears to be a confrontation between rather "biological" considerations versus more "mechanical" thinking.

Generally speaking, the biologically oriented considerations, insisting on easy access for oral hygiene and optimal marginal adaptation, represent probably the more scientifically-based point of view. Clinicians advocating splinting of multiple adjacent implants do so primarily for mechanical reasons. They hypothesize that this approach decreases forces and force moments at the level of the suprastructures and the various underlying implant components, and that relatively frequent mechanical complications such as screw-loosening and fractures may be significantly reduced or prevented by this measure. The related literature does not at present provide a clear answer, as randomized long-term clinical trials addressing this particular parameter are still scarce. Some more general reports do exist, however, addressing mainly type and frequency of mechanical complications (Goodacre *et al*. 1999).

Fig. 54-56 The implant shoulder-abutment complex of the three left maxillary posterior implants has been prepared with fine-grain diamond burrs under abundant water cooling in order to facilitate the configuration of the related suprastructure. Particular emphasis was given to margins following closely the scalloped course of the soft tissue.

Fig. 54-57 In a case of reduced-diameter implants, splinting of adjacent units may reduce the risk for technical complications. A metal framework try-in prior to the application of the ceramic veneering may help to detect and eliminate an eventual non-passive fit at an early stage.

Fig. 54-58 The vestibular view of the final metal–ceramic restoration illustrates the impact on esthetics of a metal margin. This aspect should be discussed with the patient before treatment. In case of a high smile line, one may consider an increased sink depth during implant surgery.

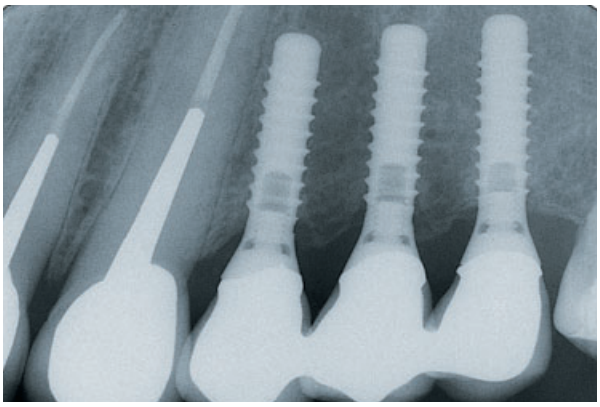

Fig. 54-59 On the 1-year follow-up radiograph an acceptable marginal fidelity can be assessed.

Fig. 54-60 Occlusal view of a right maxillary posterior three-unit implant restoration featuring premolar-sized segments.

Among the frequently forwarded arguments to plead the case of splinting are reduced-diameter (Figs. 54-56 to 54-59) or short (i.e. less than 8 mm) implants, implants inserted in low-density bone, implants placed in augmented or grafted (e.g. after anterior sinus floor elevation) bone, or implant restorations in the posterior segments of patients with verified notable occlusal parafunctions or bruxism. One should be aware, however, that the majority of these arguments are primarily based on clinical opinions and eventually common sense, and that to date they lack formal scientific evidence. In fact, there is increased indication, derived from prospective multicenter studies (although not addressing this parameter in particular), that splinting does not appear to be a prerequisite for preventing excessive crestal bone resorption or even loss of osseointegration. Nowadays, the authors would seriously reconsider their respective choice related to the suprastructure design presented in Figs. 54-60 and 54-61. In the presence of standard-size (i.e. addressing both diameter and length) implants, which are placed in normal density, original (non-augmented or grafted) bone, single-unit restorations are definitely recommended as they comply better with the various parameters that are important from a more biologic point of view, as demonstrated by the clinical example presented in Figs. 54-62 and 54-63.

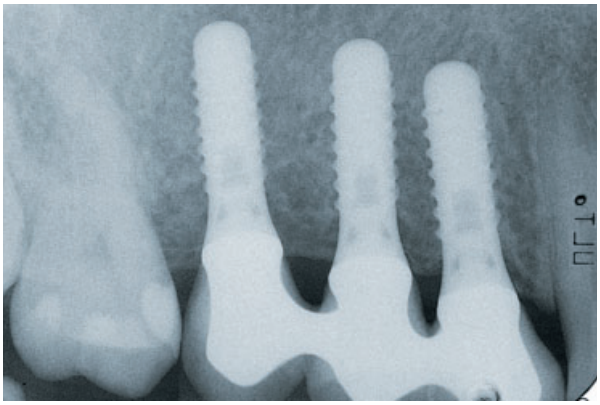

Fig. 54-61 The corresponding follow-up radiograph confirms acceptable peri-implant conditions.

Fig. 54-64 Occlusal view of a single-tooth implant restoration replacing a missing mandibular right second premolar.

Fig. 54-62 Occlusal view of three independent, implant-supported fixed metal–ceramic restorations in the right posterior mandible.

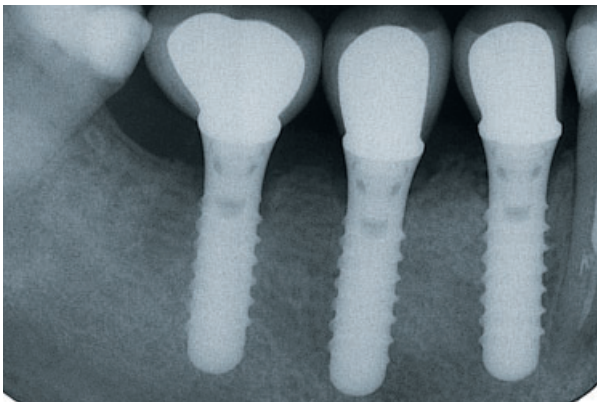

Fig. 54-63 As confirmed by the follow-up radiograph, an increased (more molar-like) dimension has been given to the most distal restoration, despite the fact that a standard-sized implant had to be used for restricted bone volume reasons.

Posterior single-tooth replacement

At the time when most implant systems had basically only one "standard" dimension at disposition, this corresponded to approximately 4–5 mm at the implant shoulder and thus was optimally suited for premolar-size restorations, featuring a continuously increasing (towards coronally) flat axial emergence profile and a mesio-distal diameter of about 7–8 mm at the occlusal surface. Clinicians were not infrequently faced with posterior single-tooth sites, however, that did not comply with these dimensions, for example in the case of missing first molars or after the loss of persisting deciduous (primary) second molars. As a consequence, the resulting implant restorations featured either unfavorable excessive interproximal overcontour or wide open embrasures. The first situation was difficult to clean, while the second led to undesired food retention (impaction). Nowadays most of the leading implant manufacturers offer wide-body/wide-platform implants designed for the replacement of multi-rooted teeth (Fig. 54-3).

Premolar-size single-tooth restorations

When it comes to posterior single-tooth gaps that correspond dimensionally to an average premolar, standard-size screw-form implants are well suited. The respective implant dimensions which include both the intrabony part and the implant shoulder, offer the additional advantage of being mostly compatible with a limited bone volume in an oro-facial direction. Whenever feasible, a straightforward low-maintenance restorative design is advocated, which normally consists of a cementable porcelain-fused-to-metal crown with vestibular and oral axial contours that are in harmony with the adjacent teeth and thus provide adequate guidance for cheek and tongue (Figs. 54-64 to 54-66).

Molar-size single-tooth restorations

If a given posterior single-tooth gap corresponds rather to the mesio-distal dimension of a molar, it is recommended, for the reasons quoted in the previous paragraph, that the insertion of a wide-neck implant is planned (Bahat & Handelsman 1996). This approach, however, also requires the respective bone volume in an oro-facial direction. If this is not the case, presurgical site analysis, eventually in the form

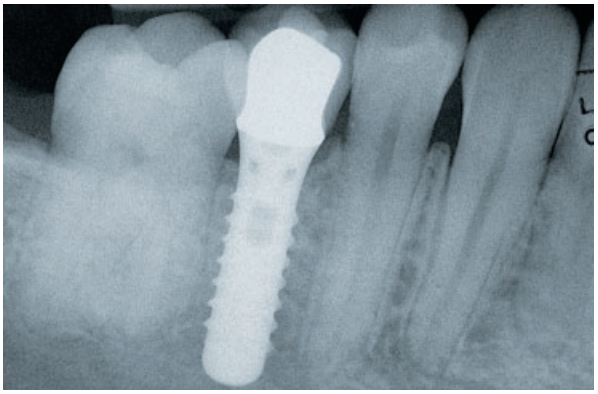

Fig. 54-65 The 5-year radiographic follow-up displays favorable bony conditions around this 12 mm solid screw implant.

Fig. 54-67 In a case of the replacement of a single missing molar, ideally the use of an implant with corresponding dimensions is recommended to permit a restoration featuring optimal subjective comfort and cleansibility.

Fig. 54-66 On the oblique view one can notice that an axial contour similar to that present on the adjacent natural teeth has been applied to facilitate oral hygiene and to assure adequate soft tissue (cheek and tongue) guidance and support.

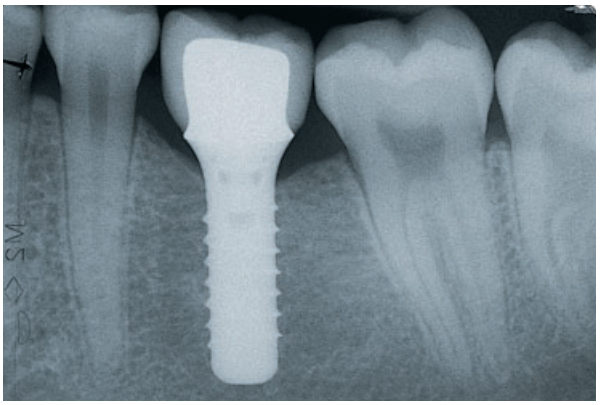

Fig. 54-68 On the 1-year radiographic follow-up a diameter-increased ("wide-neck") implant can be noted which is essential for a suprastructure design without extremely open interdental embrasures, which would be prone to food retention and oral parafunctions.

of a bone-mapping, should identify whether it is possible to have an implant placement in combination with a lateral bone augmentation procedure using a simultaneous approach. If the local bone anatomy requires a bone augmentation according to a staged protocol, one has to carefully ponder and discuss with the patient if this additional effort, risk, and ultimately also cost can be justified by an anticipated implant restoration featuring close-to-ideal axial contours and embrasures.

A clinical example demonstrating the potential of increased-diameter implants for the optimal replacement of a single missing mandibular molar is given in Figs. 54-67 and 54-68.

Sites with limited vertical bone volume

The clinician is quite frequently confronted with posterior single-tooth gaps that present all of the major prerequisites for successful implant therapy listed earlier in this chapter, with the exception of sufficient vertical bone height for the insertion of an implant featuring what is broadly accepted as an adequate length of the implant itself and in relation to the prospective length of the suprastructure. The question that arises is whether there is a minimal implant length required in the context of posterior single-tooth restorations and whether the ratio between implant length and suprastructure length has an influence on crestal bone resorption and ultimately on the longevity of the entire implant–suprastructure complex. The analysis of the respective implant data collected at the University of Geneva School of Dental Medicine in the frame of a prospective multicenter study from 1989 to 2002, permitted the conclusion that shorter implants (6–8 mm) did not show more average crestal bone resorption than longer implants (10–12 mm), and that a so-called unfavorable ratio between implant length and suprastructure height did not lead to more pronounced crestal bone resorption (Bernard *et al*. 1995a; Bernard & Belser 2002). This data is corroborated by other recently published reports (ten Bruggenkate *et al*. 1998; Bischof *et al*. 2001; Deporter *et al*. 2001).

Two examples of respective clinical anecdotal-type evidence, one premolar-size and one molar-size single-tooth restoration, are presented in Figs. 54-69 and 54-70, and Figs. 54-71 and 54-72, respectively.

Fig. 54-69 Clinical aspect of a single-tooth implant restoration in the mandibular right premolar area.

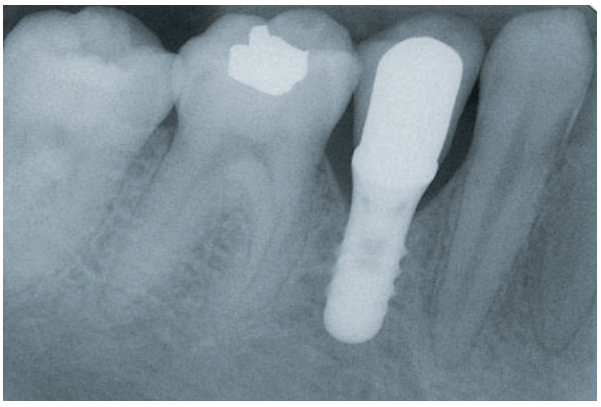

Fig. 54-70 The related 2-year follow-up radiograph shows a so-called unfavorable relationship between the height of the suprastructure and the length of the supporting implant. The placement of a longer implant was not possible due to the limited local bone conditions.

Fig. 54-71 Oblique view of a molar single-tooth implant restoration in the left mandible.

Clinical applications

Screw-retained implant restorations

For many years there was a strong tendency to design most of the fixed implant restorations as screw-retained suprastructures. Retrievability, and by this maintaining the possibility for modification, extension or eventually repair of the prosthesis, was the main rationale for this strategy. One should be aware, however, that this approach also encompasses notable specific inconveniences: colonization of the inner compartments of the implant–abutment–suprastructure complex with mostly anaerobic microorganisms, risk for loosening or fracture of screws, increased technical complexity and related costs, possible interference with structural parameters (weakening of the metal-ceramic design) and esthetics, as well as a "higher maintenance profile" (Sutter *et al*. 1993; Wie 1995; Hebel & Gajjar 1997; Keller *et al*. 1998). As far as the microbial colonization is concerned, it remains unknown to date whether and under which conditions this may have an adverse effect on the longevity of osseointegrated implants.

For these reasons there is currently a distinct trend towards cementable fixed implant restorations in the load-carrying part of the dentition.

The main indications for screw-retention are listed in Table 54-6.

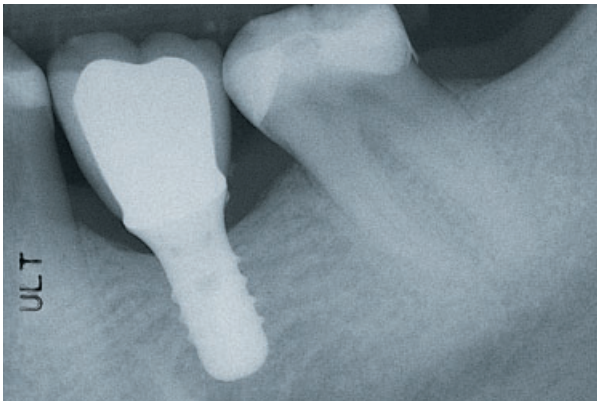

Fig. 54-72 A short diameter-increased screw implant supporting a long molar-sized suprastructure is displayed on the 1-year follow-up radiograph. Note that a normal level of the first bone-to-implant contact has been maintained.

Table 54-6 Indications for screw-retained posterior fixed implant restorations

Parameters to consider:
• Implant shoulder location incompatible with a cemented suprastructure, i.e. inaccessible for meticulous excess cement removal (>2 mm submucosally)
• Reduced intermaxillary distance (<5 mm)
• Foreseeable need for reintervention at the respective implant site
• Extended implant-supported rehabilitations, involving numerous implants
• High overall level of complexity (e.g. non-parallel implants)

Transocclusal screw retention

If for one of the aforementioned reasons a transocclusally screw-retained suprastructure is adopted,

Fig. 54-73 Left lateral view showing the intermaxillary relationship of a young patient in centric occlusion. The missing maxillary second premolar has been replaced by a single-tooth, screw-retained implant restoration. Screw retention was chosen for two reasons: limited interocclusal distance and implant shoulder location incompatible with cementation.

Fig. 54-74 One-year follow-up radiograph of the described 8 mm solid screw implant.

several parameters should be taken into consideration. First, the screw-access channel should be centered on the occlusal surface in order not to interfere too much with the area to be occupied by the cuspids.

A typical clinical example documenting an indication for a screw-retained posterior single-tooth restoration is given in Figs. 54-73 to 54-75. A reduced interarch distance has led to a deeper than usual implant shoulder location which in turn is neither accessible for well controlled excess cement removal nor in reach for the patient's routine oral hygiene. In order to benefit from their superior surface quality characteristics and marginal precision, prefabricated machined cast-on components have been used for the respective suprastructure fabrication. Ideally, the screw-access channel occupies a restricted area in the centre of the occlusal table, and the distance from the head of the screw to the occlusal surface should be sufficient for a subsequent composite cover-restoration (Fig. 54-75).

Furthermore, the principles of the metal–ceramic technology require a well defined space for developing an adequate metal support for a uniform thickness of the overlaying stratification of porcelain. Even in a case of a well centered occlusal perforation, the latter occupies close to half of the mesio-distal and oro-facial diameter of the occlusal table, and thereby significantly weakens the overall mechanical resistance of the structure. If the screw-access channel is not centered, however, additional problems are created in the sense of both weakening the restoration and interfering with esthetic criteria. Under such circumstances one should consider, for example, the use of angled abutments as currently offered by most of the leading implant systems.

Fig. 54-75 Ideally, the screw-access channel should be located in the center of the occlusal surface. This reduces both the risk for interference with an appropriate metal–ceramic design in general, and the risk for porcelain fractures in particular.

Another key parameter represents the interarch distance, or more specifically, the distance between the implant shoulder and the plane of occlusion. According to our experience this distance should be at least equal to 5 mm. This is minimal and does not permit – for esthetic reasons – the occlusal screw to be subsequently covered with a composite resin restoration. In this context 6–7 mm are clearly more adequate.

A combination of several well known problems, which are frequently encountered after implant placement in the posterior mandible, are shown in Figs. 54-76 to 54-78. Two implants have been inserted to restore a distally shortened arch with a three-unit FPD. Owing to the local bone anatomy, the implants were placed in a more lingual position than the original teeth (Fig. 54-76). The implant shoulder location was too superficial for these particular circumstances and did not provide sufficient distance to gradually correct the discrepancy between the actual implant shoulder position and the ideal occlusal location. Furthermore, the necessity of keeping the screw access in the center of the occlusal table, and the insufficient room for composite screw-head coverage, ultimately led to a considerable compromise (Fig. 54-77). The final radiograph (Fig. 54-78) clearly shows that the presurgical bone volume would have permitted a vertical reduction of the edentulous bone

Fig. 54-76 Occlusal view of a mandibular master model comprising two posterior implant analogues and a prepared natural second premolar abutment. Note the proximity of the mesial implant and the second premolar on the one hand, and the distinct lingual position of the two implants on the other.

Fig. 54-77 The clinical view of the completed transocclusally screw-retained three-unit implant-supported FPD demonstrates that the lingual implant position did not allow for a suprastructure that is in line with the adjacent teeth. Furthermore, the screws are reaching the occlusal surface, leaving no space for an esthetic coverage with composite resin.

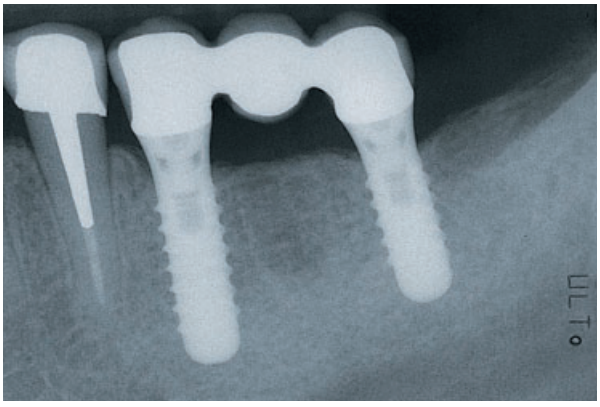

Fig. 54-78 The related 3-year follow-up radiograph documents an only minimal distance between implant shoulder and occlusal surface. Under such conditions, a slight reduction of the alveolar ridge prior to implant placement would have provided more vertical leeway for compensating the lingual implant position and ultimately for covering the occlusal screw.

Fig. 54-79 Occlusal configuration of a three-unit metal–ceramic implant restoration designed for transverse screw retention. Note the absence of any interference due to screws on the occlusal aspect of the restoration.

Fig. 54-80 The oral aspect of that same prosthesis features the decisive elements related to the transverse screw retention: improved esthetics, no weakening of the ceramo-metal design. The screw-access channels are completely protected by the metal framework.

crest to be performed prior to implant insertion. By this token the suboptimal implant position could have been partially corrected by the implant restoration, and the occlusal screw covered by composite resin, or a screw-retained restoration eventually avoided as there would be adequate conditions for a cemented suprastructure.

Transverse screw retention

When it comes to screw-retained posterior implant restorations one should not forget the option of transverse screw retention (Figs. 54-79 to 54-84). This specific technical approach leaves the occlusal surface of the restoration free from any screw and permits the design of a screw-access channel on the oral aspect, featuring a metal protection on the entire circumference of the perforation (Fig. 54-80). These two factors significantly improve both the overall mechanical resistance and the esthetic appearance. Furthermore, the metal protects the surrounding porcelain during removal and tightening of the transverse screw and

Fig. 54-81 Clinical 5-year follow-up of this three-unit implant restoration. No significant changes can be noticed on the occlusal surface.

Fig. 54-82 Palatal view of the transverse screw-retained implant prosthesis after 5 years of clinical service. The screw-access channels are blocked by a temporary material.

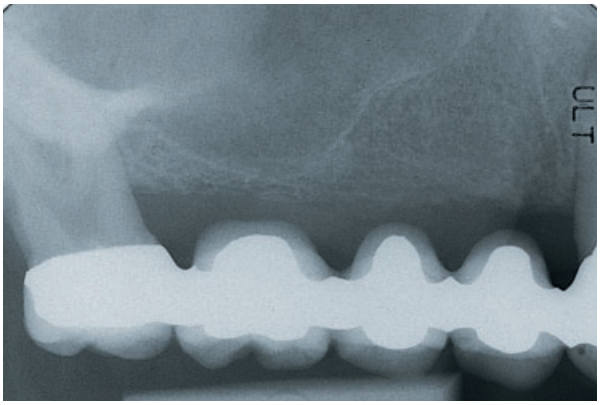

Fig. 54-83 Pre-operative radiograph of the patient's maxillary right posterior segment, revealing a tooth-borne long-span FPD which had failed after 4 years of function due to loss of retention and subsequent damage on the mesial abutment.

thereby prevents the induction of fissures prone to subsequent propagation and ultimately leading to ceramic fractures. One has to be aware, however, that from a purely technical and economic point of view, transverse screw-retained restorations require additional, more complex components and advanced technical skills, and are more expensive. In the long-term, on the other hand, the distinct advantages should clearly outweigh these inconveniences in numerous clinical situations.

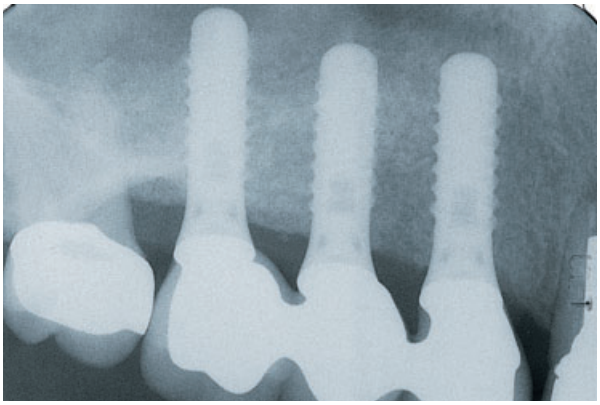

Fig. 54-84 Five-year follow-up radiograph of the same quadrant, now restored with a three-unit transverse screw-retained metal–ceramic implant suprastructure. Note that the distal retainer of the original tooth-borne FPD could be maintained.

Fig. 54-85 Example of a typical mandibular master model, derived from an impression at the abutment level, comprising four colour-coded implant–abutment analogues.

Abutment-level impression versus implant shoulder-level impression

Most of the leading implant systems currently offer the possibility of taking impressions either at the level of a previously inserted abutment or at the level of the implant shoulder itself (Figs. 54-85 and 54-86). The former approach is mostly indicated if the patient does not wear a removable temporary prosthesis and in the case of optimally placed, "restoration-driven" implants, comprising accessibility of the implant shoulder, point of emergence from the soft tissue, implant axis, interarch distance, and overall easy access for use of simple "pop-on" plastic transfer copings. As shown later, a clear preference is given to cemented suprastructures under such simple, straightforward conditions. In fact, the clinician is only required to keep a limited stock of components, i.e. cementable titanium abutments of various heights

Fig. 54-86 Example of a typical mandibular master model, derived from an impression at the implant shoulder level, comprizing three colour-coded implant analogues.

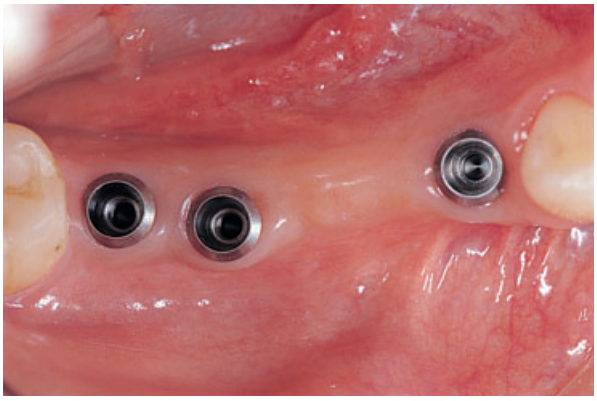

Fig. 54-87 Occlusal view of the mandibular right posterior quadrant with three implants that had been placed according to a single-step transmucosal surgical protocol.

and injection-molded impression copings, in his office. Whenever the clinical situation deviates notably from the previously described conditions, one may consider taking an impression directly at the level of the implant shoulder. For that approach, only transfer copings have to be available in the dental practice. In fact, the patient is leaving the office after the impression session exactly as he came in, i.e. with the same cover screw and with the same unaltered temporary prosthesis. After master model fabrication and articulator mounting, the technician will then select the most appropriate secondary components in the laboratory and ultimately deliver the finished restoration together with the respective supporting abutments.

Fig. 54-88 In accordance with the available interocclusal space, adequately dimensioned solid abutments are selected, inserted and subsequently tightened to 35 Ncm in view of a cemented suprastructure.

Cemented multiple-unit posterior implant prostheses

In recent years, an increasing trend towards cemented posterior implant restorations, using either temporary or permanent luting agents, could be observed. The associated original paradigm, indicating that maintaining "retrievability" was one of the fundamental advantages of implant-borne suprastructures, permitting re-intervention, modification, and/or extension at any time, has been lately challenged by parameters such as increased clinical and technical simplicity, low-maintenance design of the restorations, and superior cost effectiveness. As more implants are utilized in clinical situations where conventional FPDs would also be easily possible, but where the latter have become second choice, the sites are more favorable for this type of therapy and these implants come closer to the characteristics currently termed as "restoration-driven". Parallel to this improved mastering of three-dimensional implant positioning, secondary components such as abutments that are optimally designed for subsequent cemented restorations have been developed, in combination with auxiliary parts such as simplified impression copings, laboratory analogues, and burnout patterns. A typical clinical example of the treatment of an extended tooth-bound posterior segment by means of implants and a subsequently cemented suprastructure is presented in Figs. 54-87 to 54-94. Three screw-type implants have been inserted according to a single-step transmucosal (non-submerged) surgical protocol, leading 8 weeks after implant installation to a clinical situation which is well suited for a restorative procedure similar to the one traditionally used in the context of natural tooth abutments. More particularly, all of the involved implant shoulders are easily accessible (Figs. 54-87 to 54-90) for restorative procedures and later for maintenance, and the surrounding peri-implant mucosa healing and tissue maturation has occurred simultaneously with implant osseointegration, both being key factors in facilitating prosthetic procedures. Furthermore, the superficially located interface between implant shoulder and suprastructure or abutment will reduce the length of suprastructure leverage and by this the resulting bending moments. Under the assumption that presurgical site analysis and, derived from that, prosthetic treatment planning has predictably led to optimal implant positioning, the resulting implant

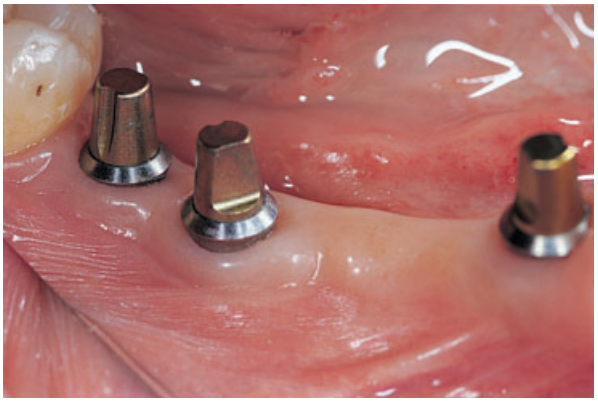

Fig. 54-89 With the solid abutments in place, the inter-implant parallelism is confirmed. Note the easily accessible implant shoulders which will facilitate the following impression and restorative procedures.

Fig. 54-92 Based on prefabricated burn-out patterns, the final metal–ceramic restoration has been completed. Note the continuous flat axial emergence profile of the individual elements.

Fig. 54-90 Prefabricated injection-molded, self-centering impression copings and related color-coded positioning cylinders are inserted prior to impression taking with a stock tray.

Fig. 54-93 The clinical occlusal view of the cemented four-unit implant prosthesis composed of premolar-sized segments.

Fig. 54-91 The completed master model comprises color-coded aluminum implant analogues.

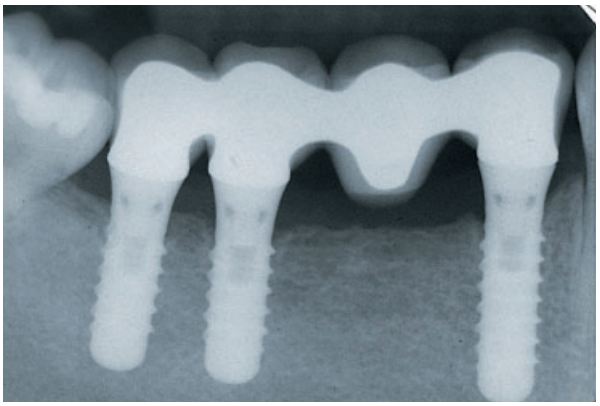

Fig. 54-94 The radiographic control confirms both successful osseointegration of the involved implants and accurate marginal adaptation of the suprastructure.

prosthesis should almost by definition feature a gradually increasing, flat axial emergence profile, adequate embrasures and overall design, and occlusal characteristics similar to those advocated for tooth-borne FPDs (Figs. 54-92 to 54-94).

Angulated abutments

It is not infrequent that all of the parameters defining an optimal three-dimensional implant position cannot be readily reached. Under such conditions the clini-

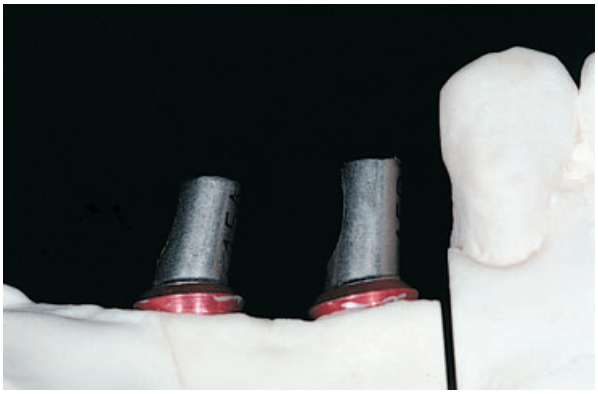

Fig. 54-95 Lateral view of a master model comprising implant level analogues in the right mandibular posterior sextant. Angulated abutments have been selected to correct a too distal implant axis.

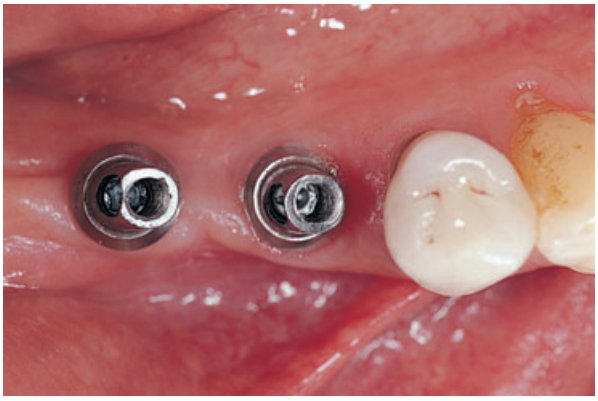

Fig. 54-97 Using an appropriate index, the two angulated abutments are transferred intraorally and subsequently tightened to 35 Ncm with a torque wrench.

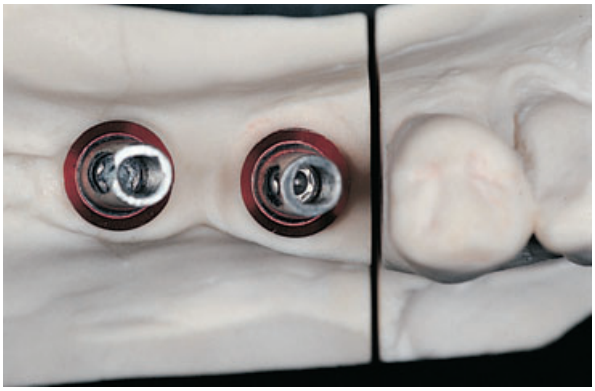

Fig. 54-96 The corresponding occlusal aspect visualizes the amount of axis correction achieved.

Fig. 54-98 Clinical occlusal view of the cemented two-unit metal–ceramic implant restoration.

cian basically has three options. Either a bone augmentation procedure is undertaken, or a conventional tooth-borne prosthesis is chosen, or one evaluates carefully whether a minor positional compromise can be considered acceptable. The related parameters have to be objectively pondered prior to taking the respective decision together with the duly informed patient. The heaviness of a so-called "site-development" procedure (e.g. lateral or vertical bone augmentation or anterior sinus floor elevation) should definitely be put in direct relation with the expected benefit. In some instances this approach allows significantly invasive procedures to be avoided. Particularly in situations where only the implant axis interferes with an otherwise optimal implant positioning, the subsequent use of angled abutments may still lead to a largely acceptable treatment outcome (Figs. 54-95 to 54-98). In other word, there appears to exist limited room for sometimes considering a slightly "bone-driven" instead of a purely "restoration-driven" implant placement in order to render implant therapy bearable for a given individual patient.

Angled abutments, encompassing various inclinations and dimensions, are currently part of the armamentarium of most of the leading implant systems. They are frequently used and compatible with both a cementable or a screw-retained suprastructure design.

High-strength all-ceramic implant restorations

Additional options, such as milled titanium frameworks as infrastructures for metal–ceramic prostheses or high-strength all-ceramic restorations, have also become recently available in the context of posterior implant restorations. Some of these approaches are based on computer-assisted design and computer-assisted machining (CAD/CAM) technology. As implants and their secondary components are mostly industrially produced or machined, and as their related dimensions and tolerances are well defined, they appear particularly well suited to this kind of technology. In this context, and in order to explain the particular interest associated with this type of technology, it has to be underlined that using either the same metal (i.e. c.p. titanium) or no metal at all for the suprastructure fabrication, would be highly preferable. Porcelain-fused-to-metal alloys with high gold content are primarily utilized due to their superior casting ability.

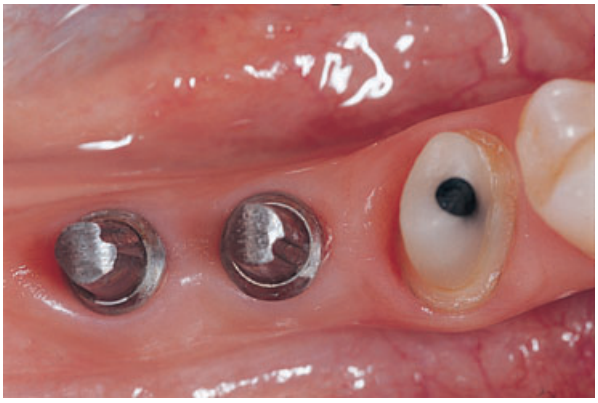

Fig. 54-99 Mandibular right posterior segment, featuring a full-coverage preparation on the non-vital second premolar and two implants equipped with solid abutments in the area of the missing first molar.

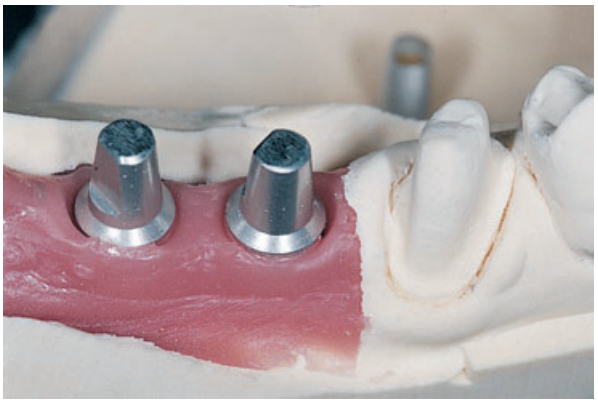

Fig. 54-100 Master model including the stone die of the prepared premolar and the two implant analogues.

Fig. 54-101 Three respective aluminous oxide copings have been fabricated according to the PROCERA® technique.

Fig. 54-102 Clinical try-in of the high-strength porcelain infrastructures.

Fig. 54-103 Vestibular view of the cemented final all-ceramic restorations.

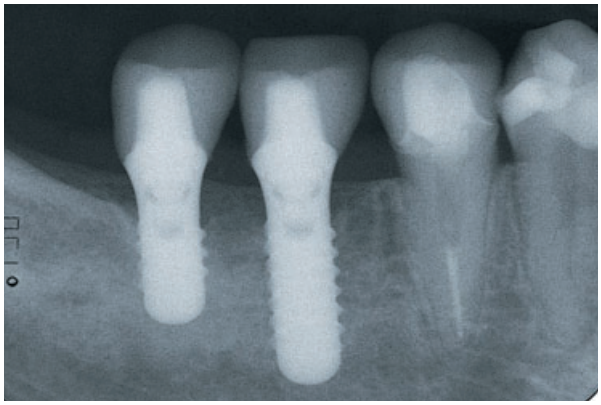

Fig. 54-104 The 1-year radiographic follow-up displays sufficient radio-opacity of the all-ceramic substrate to evaluate the marginal adaptation of the three single-unit restorations.

It would go beyond the scope of this textbook to describe in detail the current evolution in the field of CAD/CAM systems in general and to their impact on implant dentistry in particular. A representative clinical example, however, is given in Figs. 54-99 to 54-105.

All-ceramic implant suprastructures are still preferred as single-unit restorations, primarily for purely technical reasons.

Orthodontic and occlusal considerations related to posterior implant therapy

As one increasingly strives for the best possible biologic, functional and esthetic integration of a given implant restoration in the pre-existing dentition, three-dimensional pre-operative site analysis is of paramount importance. It is not infrequent that this subsequently calls for a pluridisciplinary approach

Fig. 54-105 Occlusal view of the two posterior implant-borne premolar-sized suprastructures and the tooth-supported ceramic restoration on the second premolar.

Fig. 54-106 Right lateral view of a 19-year-old female patient, congenitally missing all four permanent maxillary premolars. One can note both an inadequate mesio-distal gap width and a reduced interarch distance.

Fig. 54-107 A similar situation regarding interarch distance is present on the patient's left side.

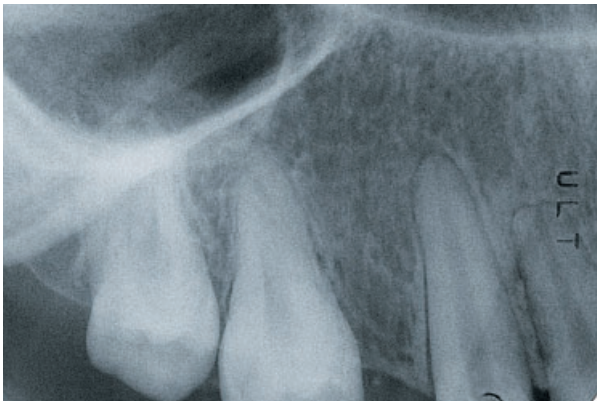

Fig. 54-108 The corresponding radiograph underlines the need for additional orthodontic therapy prior to the insertion of an implant in order to optimize the gap width and the inter-radicular distance.

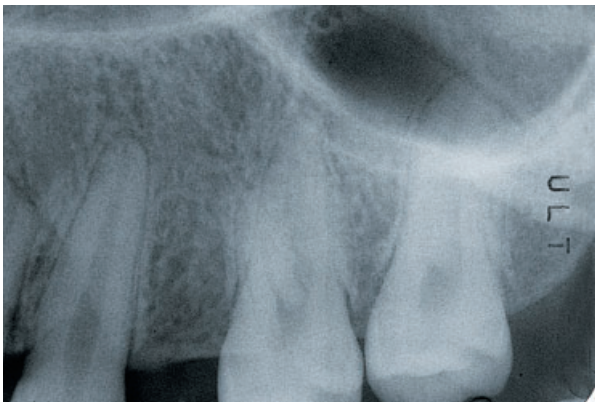

Fig. 54-109 Although to a lesser degree, presurgical orthodontic therapy is also indicated on the maxillary left posterior segment.

Fig. 54-110 The clinical occlusal view displays the bilateral edentulous spaces in the premolar area. Despite previously performed orthodontic therapy, aiming at reducing the edentulous spaces to the size of one premolar, the mesio-distal gap width on the right side is insufficient for the insertion of an implant.

termed "site development", which may also include presurgical orthodontic therapy (Figs. 54-106 to 54-119). The objective is clearly to create local conditions that are best suited for the type of therapy chosen. If implants are to be involved, the local bone and soft tissue anatomy, as well as the mesio-distal and oro-facial distances of a given edentulous segment, have to comply optimally with the respective most appropriate implant dimensions. Quite often mesio-distal gap dimensions have to be optimized orthodontically and neighboring roots aligned, so that they will not interfere with "restoration-driven" implant positioning. Site development in the broad sense of the term

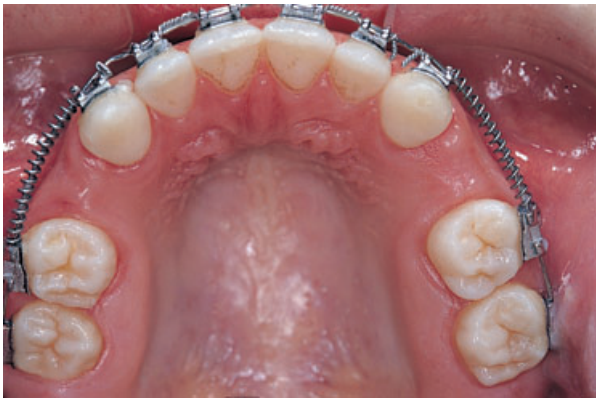

Fig. 54-111 After six months of additional orthodontic treatment using an upper fixed full-arch appliance, the dimensions of the two prospective implant sites appear compatible with this kind of therapy.

Fig. 54-114 The right oblique occlusal view of the implant restoration clearly demonstrates the advantage of the transverse screw-retention design: no occlusal screw access channel interfering with the functional occclusal morphology and esthetics or with structural requirements inherent to the metal–ceramic technology.

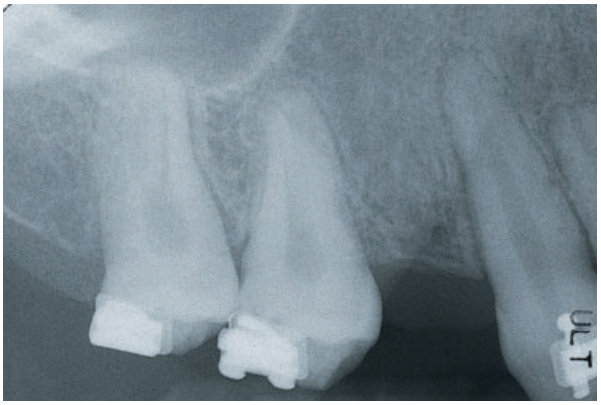

Fig. 54-112 The respective radiograph confirms adequate space in the upper right premolar region for the placement of a standard single-tooth implant.

Fig. 54-115 As described for the patient's right side, the left maxillary fixed single-tooth implant restoration integrates appropriately the existing natural dentition.

Fig. 54-113 A similar presurgical situation is radiographically confirmed for the upper left premolar site.

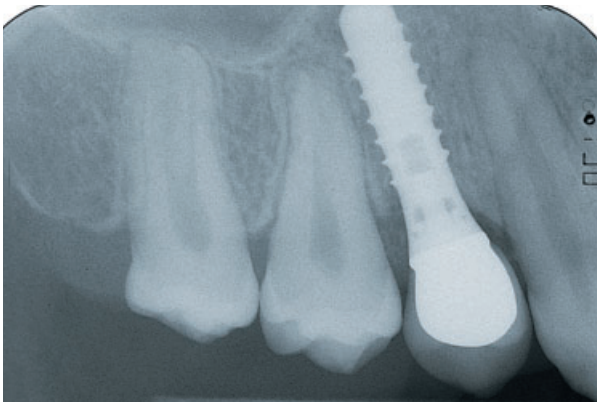

Fig. 54-116 The follow-up radiograph taken 1 year after the insertion of the 12 mm solid screw implant, shows adequate marginal fidelity and stable conditions at the bone-to-implant interface.

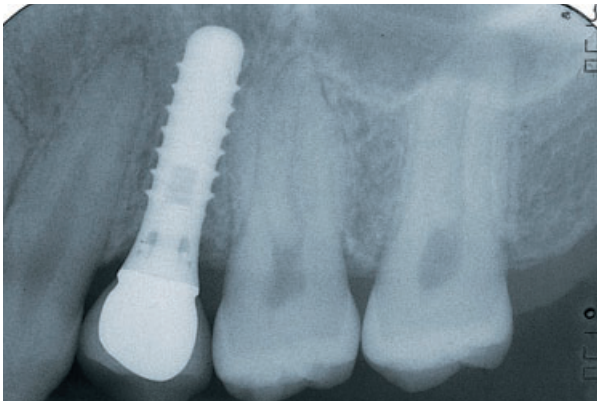

Fig. 54-117 Similar findings are present in the corresponding left-sided follow-up radiograph.

Fig. 54-118 The final right lateral view in centric occlusion features acceptable general interarch conditions and related intercuspation.

Fig. 54-119 During the right lateral excursion of the mandible (working-side movement), a canine guidance could be established.

also comprises parameters associated with intermaxillary relationships such as occlusal plane, interarch space, and occlusal guidance during mandibular excursions. As osseointegrated implants do provide excellent anchorage for orthodontic appliances (Melsen & Lang 2001), and thus can significantly contribute to the efficacy and simplicity of such a treatment, one may also consider implant insertion prior to orthodontic therapy. This, however, requires meticulous pre-operative analysis and precise three-dimensional implant positioning, anticipating perfectly the ideal location with respect to the final treatment objective.

Table 54-7 Hypothetical implant-specific occlusal concept

- "Light infraocclusion" in centric occlusion position (CO) on posterior implant restorations
- "Narrow" occlusal table
- Only "axial" loading on implant restorations
- No or only "minimal contacts" on implant restorations during "mandibular excursions"
  - No canine guidance on implants
  - Eventually "minimal" group function on the working side

When it comes to occlusal considerations related to posterior implant restorations, one should note that most of the relevant literature available to date addresses eventual effects of occlusal loading on the various components of the implant–abutment–suprastructure complex (Brägger 1999, 2001; Bassit *et al*. 2002; Wiskott *et al*. 2002). In fact, various recommendations are derived from such studies, including various occlusal restorative materials, type and mechanical characteristics of different abutment to implant connections, as well as general guidelines for optimal suprastructure design.

Little information is presently available regarding an eventual direct relationship between occlusal loading and maintenance of osseointegration in general and occurrence of peri-implant crestal bone resorption in particular (Wiskott & Belser 1999; Duyck *et al*. 2001; Engel *et al*. 2001; Gotfredsen *et al*. 2001a,b,c; O'Mahony *et al*. 2001; Engquist *et al*. 2002; Wright *et al*. 2002). Attempts have been made to take into account the fundamental differences between a tooth surrounded by a periodontal ligament and an "ankylosed" osseointegrated implant, the latter disposing neither of local mechanoreceptors nor of a so-called "damping" capacity. This led to a hypothetical implant-specific occlusal concept (Table 54-7), featuring parameters such as lighter contacts in centric occlusion when compared with the surrounding natural dentition, and no or only minimal contacts on implant restorations during mandibular excursions. One should clearly note, however, that these guidelines are primarily derived from clinical experience, subjective opinions and eventually common sense, and that there is little or no solid scientific evidence available to date which would support such a concept (Taylor *et al*. 2000).

Concluding remarks and perspectives

Early and immediate fixed implant restorations

Currently, one can observe a strong tendency towards shortened healing delays and ultimately towards

immediate loading or at least "immediate restoration" protocols in association with dental implants (Tarnow *et al*. 1997; Ericsson *et al*. 2000; Gatti *et al*. 2000; Szmuk-ler-Moncler *et al*. 2000; Bernard *et al*. 2001; Chiapasco *et al*. 2001b; Ganeles *et al*. 2001; Gomez-Roman *et al*. 2001; Roccuzzo *et al*. 2001; Romanos *et al*. 2002). Improved implant surface characteristics have contributed to this evolution (Buser *et al*. 1998a; Deporter *et al*. 2001; Gotfredsen *et al*. 2001b; Roccuzzo *et al*. 2001; Cochran *et al*. 2002). Numerous studies have reported that such an approach can be considered predictable under certain well defined conditions. These conditions include four to six implants inserted in the interforaminal part of the edentulous mandible and which are subsequently splinted with a bar device (Gatti *et al*. 2000), as well as multiple implants evenly distributed around an edentulous arch and then immediately restored – according to the principle of "cross-arch stabilization" – with a splinted full-arch FPD (Tarnow *et al*. 1997). Achieving adequate primary stability at the moment of implant installation, and confining, during the crucial first healing period, an eventual mobility below the threshold of approximately 50 microns, appear to be among the decisive parameters for predictably achieving osseointegration (Szmukler *et al*. 2000). With regard to the routine application of immediate loading protocols for posterior single-tooth restorations, it appears advisable to wait for scientific confirmation of its respective potential in the form of randomized controlled clinical trials.

In conclusion, the possibility of performing highly predictable treatments which are more simple, require less time and which can be conducted in a standard dental practice set-up, as well as the associated quality of treatment outcomes, have nowadays made implant therapy in the load-carrying part of the dentition an integral part of the restorative spectrum for any kind of edentulism. This evolution is most dynamic and holds promise for further significant developments.

Acknowledgments

The authors wish to acknowledge and thank Drs Viviana Coto-Hunziker, Stephan Dieth, Thierry Doumas, German Gallucci, Robin Jaquet, Nikolaos Perakis, and Valérie Wouters (all of them clinicians at the School of Dental Medicine, University of Geneva, and involved in the treatment of some of the patients presented in this chapter) for their contributions. We would also like to thank the laboratory technicians and ceramists, Michel Bertossa, Cédric Bertsch, Pierre Martini, Roger Renevey, Alwin Schönenberger, and Gérard Verdel, for their expertise and meticulous execution of the implant suprastructures presented in this chapter. Furthermore, our gratitude is extended to Dr. Pascal Magne (Senior Lecturer, University of Geneva) for his competent assistance in development of the schematic illustrations.

Chapter 55

Implant–Implant and Tooth–Implant Supported Fixed Partial Dentures

Clark M. Stanford and Lyndon F. Cooper

Introduction

The restoration of the fully and partially edentulous situation involves a combination of systematic diagnosis, treatment planning, and careful assessment of the therapy choices and the outcomes. The replacement of a continuous span of teeth creates challenges involving assessment of anatomic, physiologic, cost, time, impact on quality of life (QOL), and patient desires. The clinician is faced with balancing each of these aspects when developing a treatment plan for the patient. Modern dental care assures that tooth replacement therapy is provided in an economical and expedient manner. To this end, dental implants offer advantages for many clinical situations. In certain situations, the restoration of missing teeth using individual free-standing implant-supported crowns is a logical and satisfactory treatment option. At other times use of an implant-supported fixed partial denture (FPD) is a satisfactory approach (Fig. 55-1). Because of functional and esthetic priorities, anterior and posterior multi-tooth implant restorations can present different clinical challenges. This chapter will consider implant-to-implant supported FPD (bridges) separately from tooth-to-implant supported prosthesis since there are unique issues with each type of prosthesis. The use of a fixed complete denture to replace all of the teeth in an arch will be considered as a form of a fixed partial denture.

Initial patient assessment

The predictable esthetic and functional outcomes of implant treatment require comprehensive diagnostic and treatment planning (Stanford 2005a). As a member of the implant team, the prosthodontist needs to collaborate with the surgical specialist, laboratory technician, and allied team members such as radiologists, and dental and surgical assistants. The initial assessment of the patient's medical and dental history assists in the determination of the implant system and devices that will meet the patient's therapeutic needs. The initial patient interview should establish the patient's individual esthetic requirements. This assessment should determine a patient's history of bruxism, periodontal disease, tobacco use, uncontrolled diabetes mellitus, and metabolic bone diseases (Moy *et al.* 2005). Recent literature suggests implant therapy in patients with advanced chronic periodontitis may have an altered prognosis, although stabilized with maintenance therapy (Nevins & Langer 1995; Ellegaard *et al.* 1997; Brocard *et al.* 2000; Pjetursson *et al.* 2004; Wennstrom *et al.* 2004a). Maintenance therapy is vital since longitudinal implant bone loss occurs and can be observed after many years of asymptomatic clinical service (Hardt *et al.* 2002; Fransson *et al.* 2005). In addition, the assessment should educate patients about the etiology of tooth loss, reveal their attitudes about treatment as well as the ability to tolerate it,

Fig. 55-2 Diagnostic wax-up for implant therapy demonstrating desired contours for the planned definitive restorations.

and inform them of estimated treatment costs (Pjetursson *et al.* 2005; Stanford 2005a). Throughout the surgical and prosthetic phases of the implant reconstruction, the dental practitioner should obtain comprehensive written and verbal informed consent for patient treatment. The consent form should document the risks, benefits, and alternatives discussed with the patient. The option for and consequences of no treatment should be included. This initial assessment phase should provide the clinical team with sufficient information to characterize the patient-related risk factors that will influence treatment.

To assure the implant location, number, and implant dimension are congruent with the anticipated prosthesis, it is essential the dentist design and compose the proposed prosthesis during the diagnostic phase. Pre-operative planning gives insights into both technical aspects (number, implant dimension, position, and angulation) as well as potential surgical site development needed prior to or at the time of implant placement. The complete treatment plan then assimilates clinical, radiographic, and psychologic information gathered using the patient interview, clinical examination, and radiographic survey. During the clinical examination, the dentist carefully evaluates the residual ridge for shape and contour, and evaluates alternative intraoral sites for mucosal recession. A careful evaluation of patient's risk factors for soft and hard tissue changes, whatever final restoration is planned, should be made to comply with the informed consent process and encourage realistic patient expectations. However, to move beyond assessing the feasibility of implant treatment, it is essential to utilize articulated diagnostic study casts to fully assess the tissue architecture and relationship of teeth and mucosa with existing edentulous areas.

Thus, the initial clinical examination should conclude only when sufficient materials are available to accurately mount diagnostic casts and interpret the study casts and screening radiographs using recorded clinical information. Based on this diagnostic information, a surgical guide or denture is fabricated using a process of diagnostic waxing of the planned prostheses, evaluation of the desired implant position, angulation, probable abutment dimension and angulation, and, finally, the need for hard or soft tissue augmentation as supportive therapy to implant placement (Fig. 55-2). The diagnostic waxing process is a key step in the assessment of local risk factors affecting fixed partial dentures supported by dental implants and is critical to the process of strategically planning implant placement to limit these risks.

Implant treatment planning for the edentulous arch

The edentulous mandibular arch can be restored using a fixed complete denture, fixed partial dentures or an overdenture. The fixed complete denture can be a gold casting or CAD/CAM milled titanium framework, either with prosthetic acrylic resin teeth or teeth veneered with porcelain (Adell *et al.* 1990) The edentulous arch can also be restored with a series of FPDs that allows the clinic to manage multiple implants without seeking the precision fit of a full-arch prosthesis (Fig. 55-3). This approach also pro-

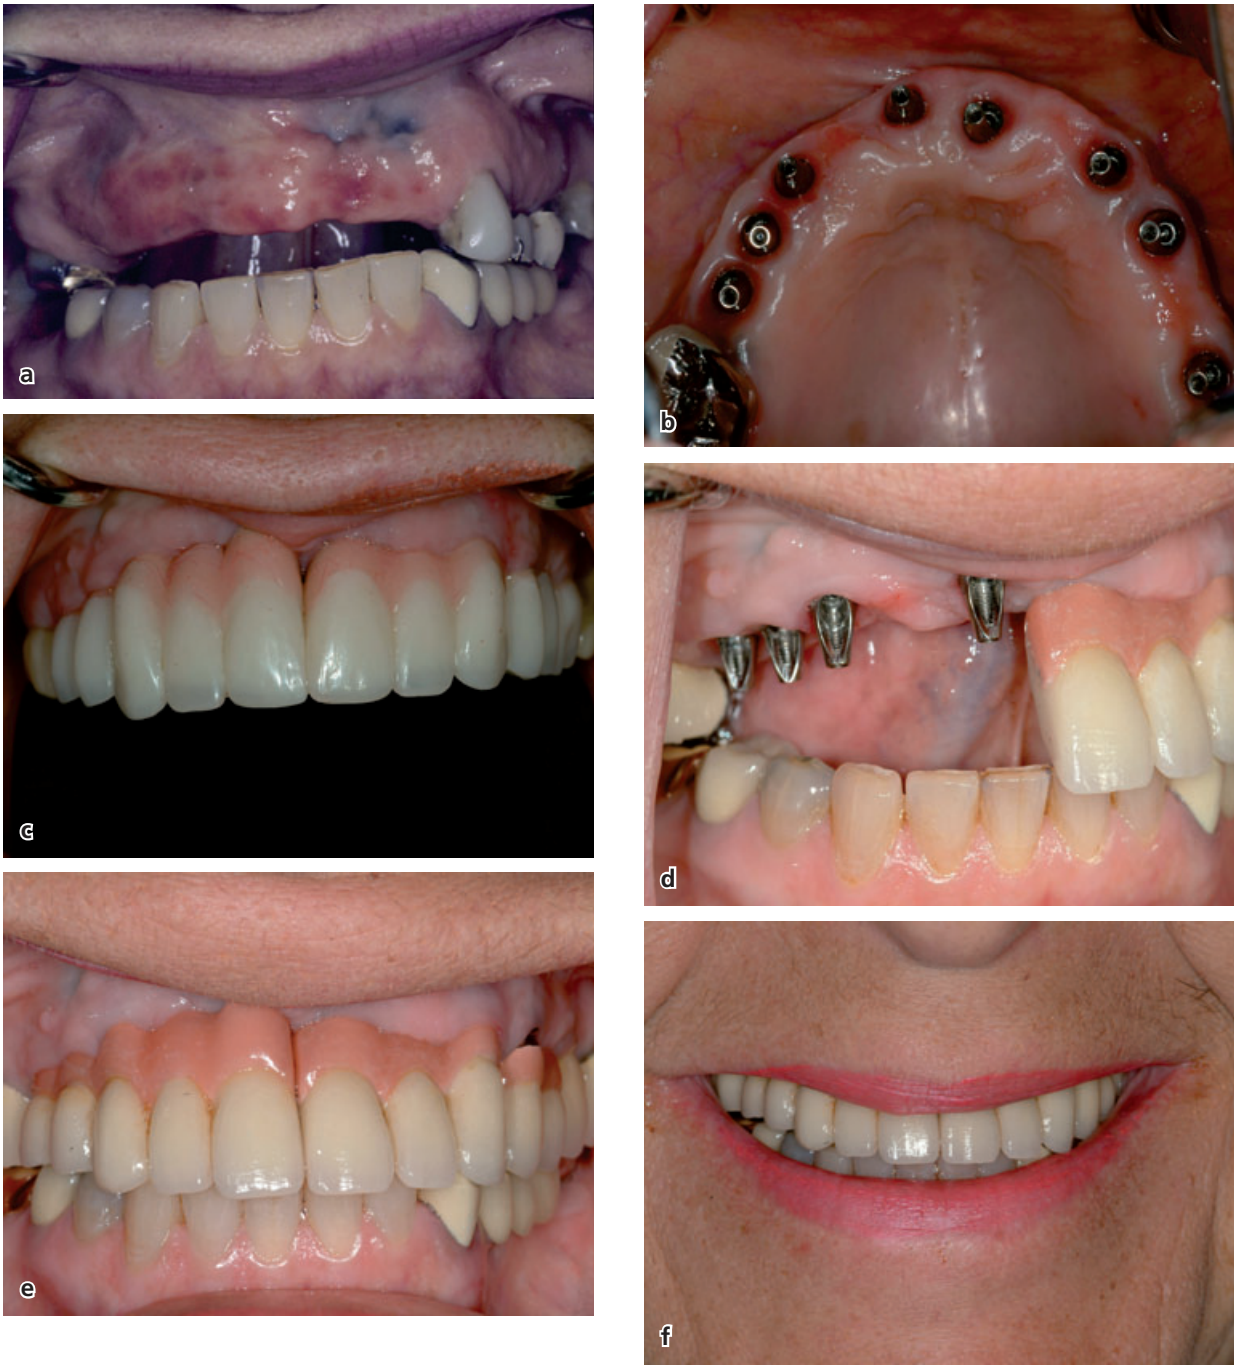

Fig. 55-3 Use of fixed partial dentures to restore missing hard and soft tissue. (a) Patient presented with a 40-year history of an edentulous space in the maxilla. Following placement of eight implants (b), a long-term acrylic resin provisional was fabricated simulating desired tooth and soft tissue dimensions (c). (d) Based on the long-term provisional, a ceramometal fixed prosthesis was fabricated using mucosa-colored ceramic materials on a metal framework. (e,f) Five-year recall demonstrating fixed prosthetic outcomes and anterior esthetics.

vides for greater flexibility in case of complications related to porcelain fracture, recession, wear, etc., and has demonstrated successful long-term outcomes (Bragger *et al.* 2001). An overdenture with attachment to the implant can be fully implant supported and retained or a combination mucosa/implant-borne prosthesis. Clinical studies indicate high patient acceptance of this form of therapy (Feine *et al.* 1994, 2002; Duyck *et al.* 2004; Naert *et al.* 2004a,b; Zitzmann *et al.* 2005).

Prosthesis design and full-arch tooth replacement therapy

If minimal bone resorption exists, restoring the edentulous maxillae with a porcelain-fused-to-metal restoration has a reasonable outcome (Stanford 2005a). The restorative dentist must perform a diagnostic work-up including impressions, jaw relationship records, and an esthetic try-in using prosthetic denture teeth on a trial denture base. The degree of

lip support and smile line (i.e. anterior and posterior occlusal planes) of the diagnostic denture set-up should be evaluated intraorally. It is also useful to evaluate the patient's lip support with and without the anterior facial denture flange (Lewis *et al.* 1992; Stanford 2002). The amount of tooth exposure of the anterior smile line (relaxed and exaggerated), provides clues about the expected crown length, gingival display, and potential need to use gingival tone porcelain for appropriate tooth length and esthetics in a full-arch reconstruction. Communication and discussion with the dental laboratory technician is very helpful at this point prior to finalizing the treatment plan. A fixed maxillary prosthesis has greater incidence of esthetic, phonetic, and oral hygiene problems compared with an overdenture prosthesis, in part associated with excessively long anterior teeth, excessive facial cantilever pontics, and mesial–distal complications with embrasure forms (Lewis *et al.* 1992). Given the clinical and laboratory complexity of these prostheses, a maxillary overdenture on four to six implants may be an alternative (Phillips & Wong 2001; Anon. 2003; Naert *et al.* 2004b).

Complete-arch fixed complete dentures

A complete-arch fixed complete denture (FCD) provides excellent function and patient acceptance (Lewis *et al.* 1992; Feine *et al.* 1994). During the diagnostic phases, the advantages and disadvantages of the FCD compared with those of an overdenture should be discussed with the patient. If using a ceramometal full-arch fixed reconstruction, consider replacing every three teeth with a three-unit fixed partial denture on two implants (e.g. #13–11) using the pontic contours to adjust for implant alignment and esthetic demands (Fig. 55-3) (Stanford 2002). A fixed maxillary reconstruction entails between six and eight implants (first molar, first premolar, canine, and central incisor) with four independent fixed partial dentures (molar to premolar, canine to central incisor, bilaterally) (Stanford 2005a). With care made to limit loading, six implants may be used with distal cantilevers on two fixed partial dentures (cantilever pontics limited to one premolar sized tooth). An overdenture should use a sufficient number of implants for long-term stability, typically four in the maxilla (canine and second premolar region) and two in the lower canine or first premolar region (Mericske-Stern *et al.* 2000). Using the denture set-up, a radiographic guide is fabricated with radio-opaque markers (e.g. gutta-percha or bur shanks) within the denture at the sites of interest. An alternative approach involves duplicating the denture set-up with teeth made using 5% medical grade barium sulfate mixed with clear autopolymerizing resin. This approach allows easy visualization of tooth size, angle, and position on conventional and/or CT-aided treatment planning. In the mandible, the trial set-up evaluates the height and position of the prosthetic teeth relative to the symphyseal cross-sectional anatomy. A conventional fixed complete denture with acrylic teeth requires a minimum of 15 mm from the alveolar crest to the planned incisal edge (Stanford 2005a). If the vertical dimension of occlusion and jaw anatomy is insufficient, one alternative is to perform an aggressive alveoectomy or to rehabilitate with ceramometal restorations (along with treatment planning for the additional cost).

Radiographic information and diagnostic set-up will help determine the type of definitive prosthesis design. Skeletal class I and II relationships with minimal resorption may allow normal contours and lip support with a fixed complete denture. Prognathic class III relationship can increase prosthetic problems, especially if implants cannot be placed distal to the mental foramens. In such cases, an overdenture approach yields a more predictable result (Naert *et al.* 1997).

Prosthesis design and partially edentulous tooth replacement therapy

Clinician or patient preferences for the use of implants for restoration of partial edentulism using FPDs must be carefully weighed against the potential limitations associated with this therapy. Technical complications related to implant components and the suprastructure are more frequently reported than complications related to peri-implant tissues (Berglundh *et al.*, 2002). Also, these complications for implant-supported fixed partial dentures are together more frequent than implant loss or implant fracture. For example, Bragger *et al.* (2001) reported for a 10-year follow-up period that the percentage of reconstructions without any biologic nor technical failure/complication was 66.5% for single-crown implant restorations, 54.4% for implant-supported FPD, and 50% for tooth–implant-supported FPD. Importantly, the authors concluded that prostheses with history of complications were at greater risk of implant failure. It may be possible to infer that complications reflect the functional features of the prosthesis or the patient and, furthermore, that some of these complications are due to limitations in implant and prosthesis planning, placement, construction or the innate limitations of implant components. Complications most frequently observed for FPDs include veneer fracture, opposing restoration fracture, bridge screw loosening or fracture, abutment screw loosening or fracture, and metal framework fractures (Goodacre *et al.* 2003a). The considerations for treatment planning of implant-supported FPDs must include features that affect not only implant success, but also abutment and bridge screw performance, and prosthesis esthetics and longevity.

Primary among clinical considerations for any implant prosthesis is some estimation of the potential forces that will be exerted during function. It is well

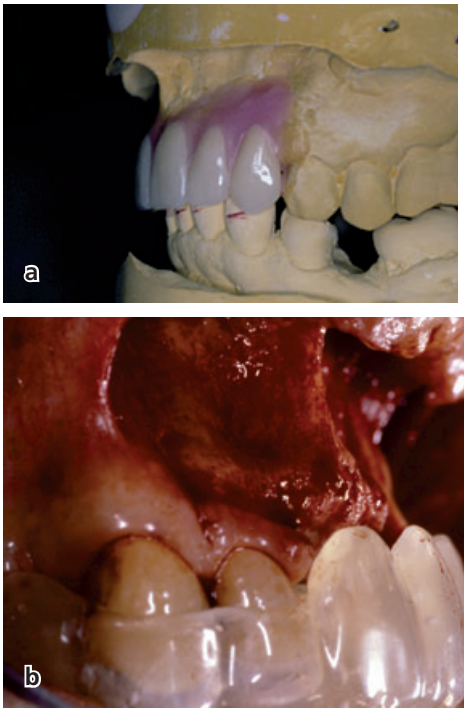

Fig. 55-4 (a) Diagnostic wax-up demonstrating desired tooth position and wax used to demonstrate the amount of planned augmentation needed. (b) At the time of site development, the surgical guide demonstrates the difference between the desired tooth position and the residual ridge.

recognized that masticatory forces increase as the point of interaction moves posterior in the arch. Additionally, damaging bending moments are increased with the acting lever arm length. Greater concern is warranted when implants are planned to support prostheses with large occluso-gingival dimension (extensive resorption) or for prostheses with extensive mesial, buccal or lingual cantilevers or any substantial distal cantilever. Additional immediate considerations typically address the esthetic potential of the prosthesis. This is clearly most relevant for anterior FPDs. Tooth-like restorations are dependent on proper dimensions and, again, greater concern is raised with increasing residual ridge resorption. However, basic features of implant placement such as avoiding encroachment of embrasures are critically important for anterior FPDs. These matters are revealed through the process of evaluating the diagnostic waxing (Fig. 55-4).

The current absence of discrete rules governing the number and dimension of implants (or a particular implant) needed to support a given masticatory function is acknowledged. Krekmanov *et al*. (2002) proposed that support factors can be attributed to implants and that relative risk can be assigned to various clinical scenarios. This approach of recognizing relative risk factors and modifying the clinical approach to therapy – even in a subjective way – merits consideration. At the very least, each clinical scenario should be considered in terms of prosthetic and implant risk both biologically and biomechanically and treatment should be adapted to recognize these risks if possible. Obvious examples would include the use of additional or larger implants to support molar function as opposed to premolar function and the avoidance of distal cantilevers in bruxing patients.

A simple strategy for reducing the biomechanical risks to implants and prostheses of implant-supported FPDs is to plan for implants located beneath the cervical aspect of the terminal mesial and distal FPD retainers whenever possible. This approach reduces the length of bending moments, irrespective of the imposed load, and also assures that the implant and abutment do not encroach on the embrasures to limit oral hygiene or esthetic potential of the restoration (Fig. 55-1).

When multiple implants are placed in an edentulous span, careful treatment planning will indicate mesial and distal width of desired restorative teeth. This plan will in turn indicate proposed sites where implants (e.g. every other tooth) may be placed for stability of the prosthesis. Choice of implant location may depend on available osseous tissues, soft tissue thickness, esthetics, phonetics, and need for ridge development.

Implant per tooth versus an implant-to-implant FPD?

In having a dialog with patients about the desired tooth replacement therapy, clinicians often recommend an implant per tooth approach when replacing multiple contiguous teeth. When this approach is done with individual free-standing crowns, the approach provides potential for a natural tooth-by-tooth replacement. On the other hand, it can create significant issues for the prosthetic restoration if the implants are not placed in exactly the desired location. The use of short-span FPDs therefore has certain general advantages. First, the use of two implants to replace three teeth allows the technician to judiciously use the pontic contours to alter the shape and contour of the prosthesis, compensating for implants that are not optimally positioned. For instance, implants that emerge at the interproximal area can be compensated by the use of angled abutments or custom abutments facilitating the use of the connector dimensions to create an illusion of natural teeth. Another advantage cited by some is the establishment of interproximal contacts between the prosthesis and adjacent teeth.

In order to assess the predictability of these types of restorations, clinical research studies need to be assessed. Randomized, controlled clinical trials of partially edentulous patients with a previous history of periodontal bone loss were evaluated in a 5-year trial by Wennström *et al.* (2004a). This study reported on 149 self-tapping implants (Astra Tech AB, Mölndal, Sweden) placed in the maxilla (n = 83) and mandible (n = 66) in the premolar and molar area. Each patient

received two implants (machined surface versus grit blasted with Ti dioxide) that were allowed to heal for 6 months prior to loading. Screw-retained FPDs were completed and maintenance therapy provided following the CIST program (Lang *et al.* 2004). Implant loss was 5.9% at the subject level. FPDs demonstrated a total 5-year bone loss from implant placement of 0.41 ± 0.78 mm (subject level) (Wennstrom *et al.* 2004a). There was a statistical difference in the frequency of bone loss between those placed in the upper versus those in the lower jaw: 38% of the maxillary implants demonstrated >1 mm bone loss while 9% of the FPD in the lower arch had >1 mm bone loss at 5 years.

Previous studies evaluating bone loss with the implant system used in this study have reported mean marginal bone loss from implant placement to be an average of –0.46 ± 0.38 mm (Olsson *et al.* 1995; Yusuf & Ratra 1996; Karlsson *et al.* 1997, 1998; Makkonen *et al.* 1997; Norton 1997, 2001; Arvidson *et al.* 1998; Astrand *et al.* 1999; Cooper *et al.* 1999, 2001; Palmer *et al.* 2000, 2005; Puchades-Roman *et al.* 2000; van Steenberghe *et al.* 2000; Gotfredsen & Karlsson 2001; Steveling *et al.* 2001; Weibrich *et al.* 2001; Engquist *et al.* 2002; Wennstrom *et al.* 2004a,b, 2005; Rasmusson *et al.* 2005). When implants were placed in the posterior maxilla with the indirect sinus lift technique and restored with FPDs at 6 weeks using a fluoride-modified implant, outcomes demonstrated bone loss –0.19 to –0.4 mm (sd = 0.73) from implant placement with a 98.3% cumulative implant survival rate (CISR) (Stanford 2006). These data support the concept that partially edentulous patients can be restored with FPDs (Gotfredsen & Karlsson 2001). However, post-insertion maintenance is critical. Hardt *et al.* (2002) observed in a population with a history of bone loss associated with periodontitis, that poor oral hygiene and compliance with maintenance therapy resulted in an elevated failure rate of 8% at 5 years; 62% of the implants in patients susceptible to periodontitis vs. 44% in non-perio groups demonstrated more than 2 mm bone loss (Hardt *et al.* 2002). This emphasizes the need for ongoing supportive care for patients undergoing tooth replacement therapy (Lang *et al.* 2004a; Schou *et al.* 2004).

Cantilever pontics

In managing tooth replacement therapy there are times when a mesial or distal extension is needed to the FPD. The use of cantilever extensions increases the mechanical angular moment on the prosthesis and increases the potential for early fatigue and prosthetic complications (Brunski 2003). The use of cantilever extensions were first advocated as a routine prosthetic approach in the Toronto mandibular fixed complete denture designed for the edentulous arch (Zarb 1988; Zarb and Schmitt 1990a,b, 1991). Clinical studies on the use of cantilever extensions suggest greater complications with longer extensions beyond 15 mm, although there are many opinion-based recommendations that range from 10–20 mm (Shackleton *et al.* 1994). Cantilever extensions increase the angular moment on the most distal implant and abutment connection and the complications such as loosening screws, fractured components, etc. are related to a combination of factors including cantilever design, composition, occlusion, jaw relationships, and implant/abutment design (Brunski *et al.* 1986). In a survival analysis though 80 months of fixed complete dentures with an acrylic resin tooth replacement and the external hex Branemark system, Shackleton *et al.* (1994) observed a 100% survival rate for cantilever extension <15 mm but a decline to <30% survival for extension >15 mm.

In the anterior quadrant where esthetics are desired, there are often missing lateral incisors that leave only minimal mesial–distal space for implant placement. One option may be to use narrow diameter implants in such sites but control of occlusion is important (Stanford 2005b). An alternative, especially when there are missing adjacent teeth, is to use cantilever pontics of minimal dimension to replace the missing teeth (Fig. 55-5). This has the potential for more predictable esthetics without excessive site development, expense, and time. The use of cantilever pontics in the posterior quadrants is more controversial. Cantilever pontics in ceramometal FPDs create larger moment arms on the prosthesis and have the potential for increase mechanical complications with the implant–abutment stack (Stanford 1999; Brunski 2000, 2003; Brunski *et al.* 2000; Gratton *et al.* 2001). There are times where posterior cantilever pontics are useful but the clinician should consider these for areas of controlled occlusal forces and primarily for esthetics. Further, in use with ceramometal FPD, their use should be limited with no more than a premolar size pontic (~7 mm mesial-distal dimension) with only light centric occlusal contacts on the pontic (Stanford 2005b).

There are ongoing issues regarding cemented relative to screw-retained FPDs. While the choice of prosthesis is dependent on multiple factors (clinician preference, flexibility, passivity of fit, cost, etc.) there are times when one approach is preferable. For instance, in situations where the patient has multiple clinical signs of recession (thin tissue biotype, recession, lack of keratinized mucosa, etc.) a screw-retained fixed prosthesis may be preferable (Stanford 2005a). This approach will allow the clinician to remove the prosthesis at a later point in time and make repairs which may salvage the prosthesis. Patients with a history of implant loss in the area, difficult implant placement or elevated medical risk are other indications to consider a screw-retained fixed prosthesis. Further, if the prosthesis needs to be routinely removed (e.g. in a research protocol) for accurate measurements of pocket probing depths (PPD) and bleeding on probing (BOP), the clinician may want to chose a screw-retained prosthesis. At times there

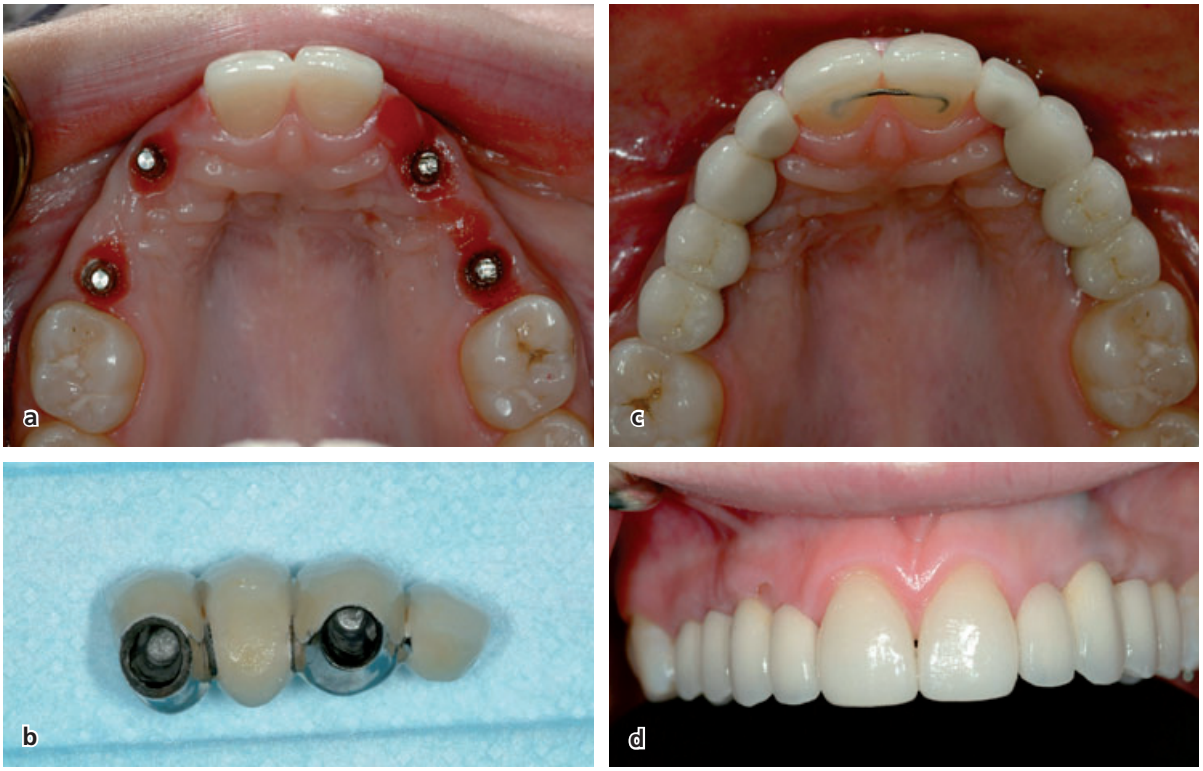

Fig. 55-5 Use of cantilever pontics to replace missing lateral incisors as a part of fixed partial denture (FPD) therapy. (a) Four implants were placed in the maxilla in the second premolar and canine region. (b) A four-unit FPD with cantilever pontics (12 and 22) was fabricated. (c) Restoration of eight missing teeth with four implants allowing establishment of an acceptable esthetic result (d).

Fig. 55-6 Soft and hard tissue prosthetic replacement. (a) Patient presented with soft tissue loss in the area of 21 and 22. (b) Missing mucosal and hard tissue contours were replaced with a combination of gingival and tooth-colored ceramic materials. (c) A prosthetic solution to a difficult esthetic situation. Ceramic reconstruction by Henry Husemann CDT (University of Iowa).

are indications for fabricating a fixed prosthesis that replaces both hard and soft tissues (Garcia & Verrett 2004). In sites where there has been considerable loss of supporting structures, common following trauma or long-term chronic bone loss such as periodontal disease, it may be necessary to replace both dental and osseous supporting structures (Fig. 55-3). If this cannot be accomplished with biological site development, the clinicians may need to reconstruct this area with a combination of porcelain teeth developed with the appropriate mesial-distal and inciso-gingival dimensions to match the adjacent teeth and blend into the esthetic contours of the dentition and face. In doing so, it may become obvious that the gingival tissues need to be replicated in "mucosal" colored porcelain or acrylic. The development of tissue-matched mucosal shades takes significant laboratory skill and dexterity and often means the patient needs to be seen directly by the technician along with the restorative dentist (Malament 2000; Malament & Neeser 2004). Custom mucosal shades often need to be developed and matched chairside. While these approaches can be quite time consuming the end results can be quite satisfactory and surpass what can be accomplished by repeated soft tissue procedures (Fig. 55-6). The restorative dentist needs carefully to assess the patient early in the diagnostic process for implant therapy and determine if they are at elevated risk for unpredictable loss of soft tissue. Key factors to assess are thin tissue biotype, previous history of

recession, mucosal inflammation, tooth loss due to trauma or chronic progressive osseous disease (e.g. periodontitis). All of these conditions influence the stability and position of the mucosal tissues following implant tooth replacement therapy.

Immediate provisionalization

The application of implant-supported FPDs has a unique role especially in early and immediate loading procedures. While the splinting of implants for long-term osseointegration is not considered routinely necessary, the early splinting of multiple implants during the osseous healing process is considered important (Cooper *et al.* 2002, 2005, 2006; Slaets *et al.* 2005; De Kok *et al.* 2006; Duyck *et al.* 2006). Immediate provisionalization procedures have the potential to provide rapid function, esthetics, and patient satisfaction, and the use of implant-supported FPD prosthetic designs plays an intimate role in controlling micromotion and allowing successful outcomes similar to conventional loading procedures (De Kok *et al.* 2006; Duyck *et al.* 2006; Hall *et al.* 2006; Peleg *et al.* 2006).

The immediate provisionalization of implant-supported fixed dentures has a unique role in the retreatment of failing fixed prostheses. When large fixed prostheses are present with only one or two failing abutments, further tooth-supported restoration often requires extensive restoration. This is particularly true if strategic abutments such as a canine or terminal abutment tooth are not salvageable due to caries, fracture or localized periodontitis. In such cases, segmental resection of the failed tooth and supported pontic teeth can be replaced by dental implants. The advantages are obvious in terms of preventing the retreatment of a much larger FPD and providing an esthetic and functional treatment option for an anterior restoration.

Disadvantages of implant–implant fixed partial dentures

The disadvantages of FPDs on implants are associated with increased difficulty of cleaning and maintaining the prosthesis along with the prosthesis complications associated with conventional tooth-supported FPDs. Based on patient expectations, there is the potential that the patient isn't satisfied with the inability to clean between the retainers and pontic contours. FPDs on implants can also be more difficult to fabricate in the laboratory. In this case there may be issues with the path of insertion on the abutments (necessitating customized abutment) or difficulties in obtaining draw and passive fit between multiple abutments. There is also the danger of mechanical wear and material failure with the completed prosthesis such as abutment loosening, prosthesis fracture or veneer material failure. The use of screw-retained prosthesis may be helpful if retrievability is critical but the screw access hole itself may weaken the strength of the veneering material. Lastly, there is the danger that if one of the supporting implants are lost or the abutment demonstrates recession exposing the transmucosal titanium surface, the entire prosthesis may have to be replaced increasing time and expense to the patient.

In assessing the clinical success of implant-supported FPDs, it is difficult to determine outcomes due to incomplete reporting of the specific types of prosthesis in a range of dental implant studies and yet the primary measure of evidence-based care is the systematic assessment of the clinical question of interest. The literature supporting the use of this type of prosthesis is often retrospective in nature with different outcome measures, end points, duration of recall, etc. This makes comparisons between studies difficult and limited. In the assessment of prosthodontic mechanical complications, the pattern of defects often will vary with a time-dependent pattern. In implant-supported FPDs, early failures (before loading) are often associated with implant loss (Goodacre *et al.* 2003b). As discussed by Pjetursson *et al.* (2004), implant loss prior to restoration can be expected on average to be 2.5% of all implants placed with an additional 2–3% lost over the first 5 years of function. In this systematic assessment of the more recent literature from the 1990s though 2004, 21 studies of 176 reviews were considered based on the inclusion and exclusion criteria. The authors summarized the current literature of five implant systems with 1123 patients, 1336 FPDs on 3578 implants followed for at least 5 years. Implant survival, FPD survival, success, and complications were reported (Table 55-1). The authors outlined that this type of assessment has limitations based on the quality of the studies, their duration, drop-outs, and reliability but in this instance, with the limited dataset, the authors outlined that the most common complication was

Table 55-1 Implant supported fixed partial dentures (FPDs) with an average of 5 years' follow-up (Pjetursson *et al.* 2004: in this review, 90% of the FPDs were screw-retained)

	Average	95% confidence interval
Implant survival	95.6%	93.3–97.2%
FPD prosthesis survival*	95%	92.2–96.8%
FPD success†	61.3%	55.3–66.8%
Complications	38.7%	
• Veneer fracture	13.2%	8.3–20.6%
• Lost occlusal restorations	8.2%	
• Loose screws	5.8%	3.8–8.7%
• Fractured abutments/ occlusal screws	1.5%	0.8–2.8%
• Fractured implants	0.4%	0.1–1.2%

* Survival was defined as retained in function within the mouth. Prosthesis may have had multiple repairs.
† Success was defined as in function with no clinical complications.

Table 55-2 Local features considered in risk assessment for implant-supported fixed partial dentures (FPDs)

FPD location	Anterior locations possess higher esthetic risk Posterior locations may possess higher functional risk
Length of span	Long span increases complexity of prosthesis, mechanical loads and prosthetic complications Short span may increase abutment crowding and restrict hygiene
Occluso-gingival dimension	Increased occluso-gingival dimension results in lower bending moments at abutment and bridge screw connections Reduced occluso-gingival dimension (<6 mm) may limit prosthesis construction and integrity
Excessive vertical residual ridge resorption	Excessive vertical residual ridge resorption results in increased occluso-gingival dimensions of the restoration
Implant malposition	Buccal or lingual malposition creates unintended buccal or lingual cantilever of prosthesis Mesial or distal malposition encroaches on embrasure and hygiene access; both reduce esthetic potential Excessive deep placement increases bending moment at abutment screw, may create anaerobic environment, can lead to bone resorption and esthetic complications
Thin mucosal biotype	Risk of mucosal resorption and unesthetic display of abutment material
History of periodontitis	Elevated risk for peri-implantitis if control is absent. May need multiple staged procedures to replace hard and soft tissue contours

loss of veneering material (often acrylic facings) followed by other mechanical complications inherent in screw-retained style prosthesis. Biologic complications such as peri-implantitis (probing pocket depth >5 mm) with bleeding on probing (BOP) have been reported in one study to average 10% of patients (Pjetursson *et al.* 2004). Pjetursson *et al.* (2004) used a random-effects Poisson modeling approach to determine a pooled cumulative rate of 8.6% for biologic complications (95% CI: 5.1–14.1%) based on a assessment of nine studies providing sufficient information for analysis.

A FPD supported by two or more implants provides a valuable treatment option. It has a role in providing rehabilitation for patients with challenging implant positions and angulation, lost hard and soft tissues, reduced cost, and may allow avoidance of some grafting procedures (e.g. sinus grafting). The selection of a FPD supported by implants often represents the alternative to selecting a much larger FPD supported by many teeth (Table 55-2). While recent reviews suggest there may be little difference in the long-term complication rates for FPDs supported by teeth and implants, it is of practical importance that implant-supported FPDs often are smaller prostheses. On balance, the use of FPDs plays a valuable role in providing multiple tooth replacement therapy.

Tooth–implant fixed partial dentures

The use of dental implants combined with teeth as retainers for FPDs has been advocated by a number of clinicians to restore multiple missing teeth. There are multiple case reports in the literature of prosthesis designs that have either a rigid connection between the natural tooth and implant retainers and or that utilize a non-rigid connection to ostensibly allow individual movement of the implant(s) relative to the greater mobility of the natural teeth (Stanford & Brand 1999). The difference in mobility can be of the order of about one magnitude with mobility on teeth with a healthy PDL being 50–200 μm while an integrated implant will have mobility of <10 μm (Brunski & Hipp 1984; Brunski 1988a,b, 1999, 2003; Rangert *et al.* 1997). The use of implant–tooth FPD does have the potential to reduce costs, time, and morbidity especially if the outcome provides a service to the patient that would be equivalent to implant–implant FPD or single-tooth implant restorations (Fig. 55-7). The advantages must be balanced with the potential complication of pathology associated with the dental retainers or the implant(s). The fate of both is tied together.

Lang *et al.* (2004b) performed a systematic review of the clinical studies that evaluated tooth–implant FPDs over at least 5 years and were able to identify 13 studies using the inclusion/exclusion criteria. Of these, nine were prospective and four retrospective in nature addressing outcomes with five different implant systems in 555 patients (538 FPDs on 1002 implants); the majority (91%) were reported as being screw-retained. The authors assessed the thirteen studies by evaluating those with follow-up from 5–6.5 years. In this group, of the 932 implants installed, 25 were lost prior to restoration and 65 during the recall period. This resulted in a 5-year implant survival proportion of 90.1% (CI: 82.4–94.5%) (Lang *et al.* 2004b). In the second group, followed though 10 years, implant survival was estimated at 82.1% (CI: 55.8–93.6%). Following the same theme, a systematic

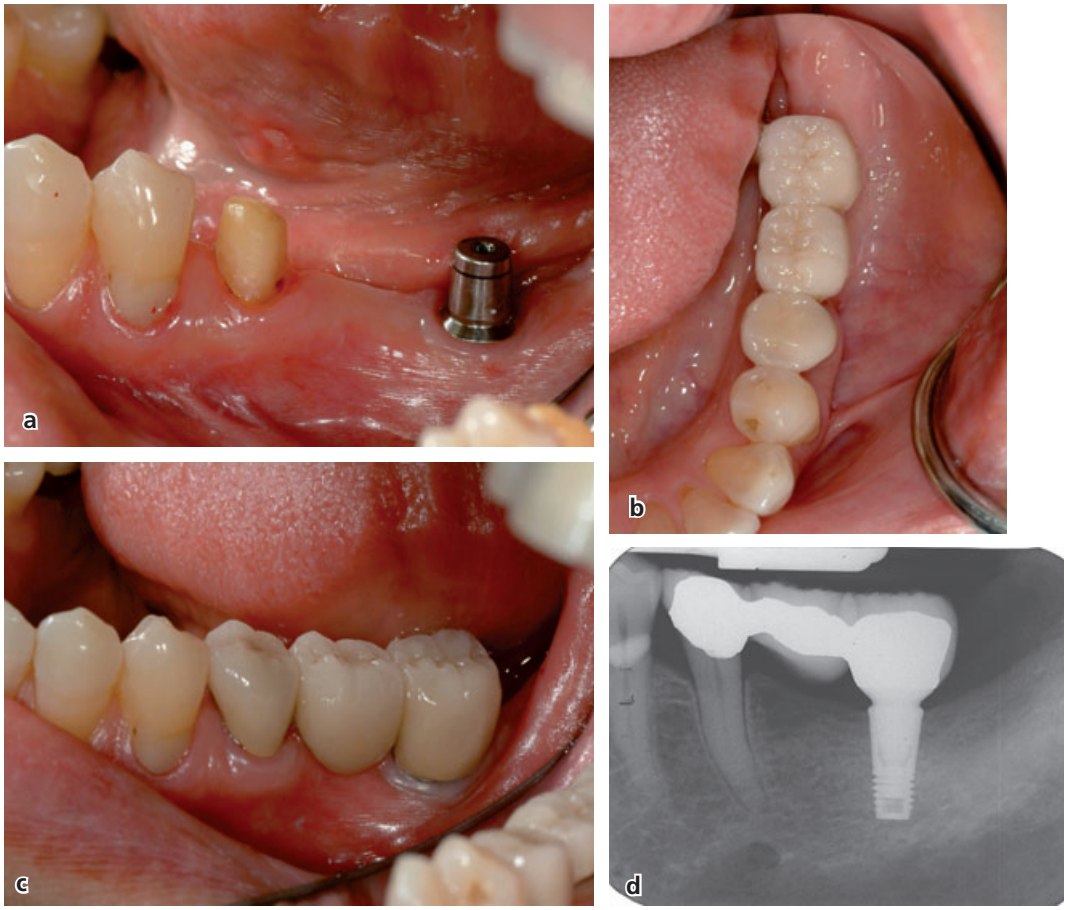

Fig. 55-7 Implant–tooth fixed partial denture. (a) Example demonstrates use of a rigid fixed partial denture (FPD) framework on a three-unit FPD (35–37). (b) A metal–ceramic prosthesis was cemented which has been monitored with frequent recall over 5 years (c). (d) Five-year recall radiograph indicates healthy peri-apical and peri-implant osseous tissues.

review of biologic and technical complications (Berglundh *et al*. 2002) indicated that tooth–implant-borne FPDs were at greater risk for implant loss (irrespective of complications leading to abutment tooth loss) than implant–implant FPDs. In regards to the prosthesis survival, estimates of 94.1% (CI: 90.2–96.5%) at 5 years and 77.8% (CI: 66.4–85.7%) at 10 years were determined (Lang *et al*. 2004). Assessment of dental abutment survival indicated 3.2% were lost by 5 years due to fracture, caries, or endodontic or periodontal complications (Lang 2004) If the patient has the option to restore missing teeth with a conventional removable partial denture combined with implant-fixed prosthodontics it is interesting to assess the long-term outcomes.

There has been a number of concerns raised with connecting teeth to implants with FPDs. Some of these complications are associated with technical complications of the prosthesis. For instance, the prognosis of the FPD can be shortened by veneer fractures and other esthetic issues (Kindberg *et al.* 2001). Loss of retention through fracture of the abutment/prosthetic screws or loss of cement retention are possible. Lang *et al.* (2004b) reported in a systematic review of two studies that assessed lost retention and described an average of 6.2% (CI: 3.7–10.4%) at 5 years (Hosny *et al.* 2000; Naert *et al.* 2001; Lang *et al.* 2004b). Endodontic complications on the abutment teeth can also be a significant concern with a range of 3–28% of teeth needing post-insertion root canal therapy (RCT) (average of 11%) (Goodacre *et al.*). Naert *et al.* (2001) reported on the complications after a mean period of 6.5 (1.5–15) years in a retrospective comparison study of implant–implant to tooth–implant FPDs on 123 patients in each group with tooth-implant FPDs. The authors reported a history of chronic apical periodontitis (3.5%), tooth fracture (0.6%) along with a tooth intrusion (3.4%), and cement failure (8%) (Naert *et al.* 2001).

An interesting and unusual observation is the issue of natural tooth intrusion that has been observed (Pesun 1997). Earlier use of implants combined with teeth advocated the use of non-rigid attachments within the prosthetic design to allow differential movement between the implant and tooth. In some cases, the natural tooth appears to retract away from the prosthesis. This phenomenon has been suggested to be due to the interplay of disuse atrophy, food impaction, rebound memory of the PDL, and/or mechanical binding (Rieder & Parel 1993;

Schlumberger *et al.* 1998; Cordaro *et al.* 2005; Palmer *et al.* 2005). In a multicenter study, Block *et al.* (2002) assessed posterior FPD connected either rigidly or non-rigidly with one type of attachment. Of the 30 subjects followed though 5 years, there was no difference in bone loss between the two types of connections but there was a 66% incidence of measurable intrusion in the non-rigid group versus 44% for the rigid group. The authors concluded that tooth–implant FPD had a higher level of maintenance and post-operative complications. Fugazzotto *et al.* (1999) retrospectively assessed a multi-group practice outcome of 843 patients (1206 implants, 3096 attachments) over a period of 3–14 years and observed nine instances of intrusion (0.3%) associated with fractured or lost lateral set screws (rigid-retention). In a prospective study through 3 years, Palmer *et al.* (2005) evaluated 19 subjects with rigid cemented prostheses between natural teeth and implants. These short-term outcomes at 3 years indicated no greater implant bone loss than would be expected (0.78 ± 0.64 mm) with no signs of intrusion with the rigid tooth–implant FPD designs. These results have led to the clinical recommendation that if the clinician needs to join natural teeth with implants, a rigid connection is advocated with close monitoring for clinical signs of complications (Naert *et al.* 2001; Palmer *et al.* 2005; Stanford 2005a).

Fixed partial dentures joining teeth to implants is a controversial issue. There are times when an assessment of clinical needs, patient desires, costs, time, and risk provide support for the clinician to consider this treatment option. It is critical that the patient be informed of the relative risks associated with this type of prosthesis, the implant, and the abutment tooth in the process of informed consent.

Conclusion

Fixed partial denture therapy for the restoration of multiple missing teeth has a long track record in dental implant care. Connecting two or more implants, or in selected cases, teeth with implants, can provide a stable, esthetic, and predictable outcome. All treatment options need to start with a careful assessment of anatomic, clinical, and patient needs and desires. The patient needs to be informed of the assumptions made and the relative costs and benefits that this treatment approach can provide.

Chapter 56

Complications Related to Implant-Supported Restorations

Y. Joon Ko, Clark M. Stanford, and Lyndon F. Cooper

Introduction

The quality of dental implants and prosthetic outcomes has significantly improved since their introduction. This has been coupled with the steady increase in the clinical success and/or survival rate (Cochran 1996; Esposito *et al.* 1998; Lindh *et al.*, 1998; Jokstad *et al.* 2003). The biologic aspect, namely osseointegration, has been the particular target of intensive investigation and there have been conspicuous advances. As a part of these developments there have been continuous efforts to improve the characteristics, microtopographies and chemistries of the implant surface. A major change in surface topography can be summarized by the evolution from machined surfaces to a production-based moderately roughened surface. Superior biologic response, or osseointegration, to roughened implant surfaces has been widely documented in the literature (Astrand *et al.* 1999; Rocci *et al.* 2003; Schneider *et al.* 2003). The cumulative effect of all these efforts is reflected in the extremely high biologic success rate of dental implants. With the enhanced predictability of the integration process of implants becoming well documented, an ongoing issue is related to restorative complications of therapy. These complications can be related to both biologic and prosthetic issues. This chapter discusses potential complications of dental implant-supported restorations, particularly focusing on complications related to the prosthetic aspects of therapy.

Clinical complications in conventional fixed restorations

Implant dentistry shares many of the long-term mechanical complications shared with conventional dental restorative therapy. Goodacre *et al.* (2003b) presented data regarding the incidence of clinical complications associated with conventional dental fixed restorations/prostheses including single crowns (all-metal, metal ceramic, resin veneered metal) and fixed partial dentures (all-metal, metal ceramic, resin-veneered metal); all-ceramic crowns; resin-bonded prostheses; and posts and cores. Regarding single crowns, the most common complication was post-cementation endodontic therapy (3%), followed by porcelain fracture (3%), loss of retention (2%), periodontal disease (0.6%), and caries (0.4%). Regarding fixed partial dentures, the most common complications were: caries (18% abutments; 8% prostheses), need for endodontic treatment (11% abutments; 7% prostheses), loss of retention (7%), esthetics (6%), periodontal disease (4%), tooth fracture (3%), prosthesis fracture (2%), and porcelain veneer fracture (2%). In this narrative review, the authors concluded that complication incidence with conventional dental fixed partial dentures was significantly higher than single crowns. In addressing issues related to implant restorations, material failure and wear are common occurrences with both dental and implant-supported restorations (Fig. 56-1). It is likely that the higher

Fig. 56-1 Prosthetic challenges related to wear and component fracture. Wear, fracture, and change in esthetics is a common occurrence with acrylic resin teeth (a) as are fractures of acrylic resin prosthetic teeth on fixed complete denture (b). While implant fractures are rare, the consequences are challenging. (c) Case example of implant that was mobile 2 years after delivery; (d) the prosthesis was removed and the head of the implant was fractured. (e) The implant was replaced with a wide diameter implant in order to increase the wall thickness and provide a greater abutment-to-implant interface. (f) Recall at 10 years.

biomechanical complexity of the design of the prosthesis contributes to higher complication incidence. Among these complications, pulpal complications, periodontal disease, and caries will apply to only tooth-supported restorations.

Tan *et al.* (2004) assessed the long-term success/survival rate of conventional fixed partial dentures (FPDs) and evaluated the failure rates of FPDs due to specific biologic and technical complications. The result of the systematic review based meta-analysis indicated a 10-year survival rate of FPDs was 89.1%. The 10-year success rate of FPDs declined to 71.1%. Success suggests no intervention was needed over the recall period, relative to survival which suggests retention with or without intervention during the recall period. In general in the literature, the mean 10-year survival rate of conventional FPDs was 90%, and success rate 80%. In this study, the most common reasons for dental FPD failure include periodontal disease and secondary caries. Regarding the complications related to caries, the 10-year risk for decay on abutments was 9.5%, but only 2.6% of FPDs were lost as a result of this disease process. In this study, it was clear that loss of vitality of abutment teeth occurred at a later date and so could not be attributed to the trauma from the preparation of the teeth. This may either indicate a slow progressive tissue degeneration induced by the procedure or reflect the increased susceptibility of pulpal infection by dentinal tubules in advanced periodontitis (Bergenholtz & Nyman 1984). The presence of cast post and dowels and non-vital abutments, especially in distal abutments, has been shown to be associated with increased loss of retention and fracture of teeth and cores. This

cautions against over-dependence on non-vital teeth as strategic abutments.

The 10-year risk of loss of FPDs due to recurrent periodontitis was only 0.5%. Overall, there seemed to be no adverse changes in FPDs incorporated into periodontally well-maintained patients even if they presented with a history of advanced periodontal disease. Where the recall or maintenance is less stringent, periodontal breakdown may occur, and may be more pronounced when margins were subgingivally located (Valderhaug & Karlsen 1976). Secondary use of the bridge for removable prosthesis has a detrimental effect on the gingival tissue (Libby *et al.* 1997). The 10-year risk for technical complications, such as loss of retention, loss due to abutment fracture and the occurrence of material complications, were also calculated in this study. An issue in any of these studies is the multifactorial nature of the causes of failure. The highest 10-year risk was for loss of retention, amounting to 6.4%. Far lower was the 10-year risk for the loss of FPD due to abutment tooth fracture. Relatively low 10-year risks were obtained for material complications. These included fractures of the framework, veneers and/or cores and amounted to a 10-year risk of 3.2%. A comparison of the difference in survival between FPDs with acrylic facings and metal–ceramic FPDs showed that over an 18-year period, 38% of FPDs with acrylic facings and 4% with metal ceramic FPDs were replaced (Sundh & Odman 1997). Reasons cited for the increase in failures were the greater incidence of discoloration and fracture after extensive wear of the acrylic resin material.

Clinical complications in implant-supported restorations

Biologic complications

Surgical complications

Surgical complications directly related to implant placement are generally rare. However, due to the surgical nature of implant therapy, it is impossible to avoid surgical sequelae. Recent surgical methods propose excluding tissue flap openings (so called "flapless approaches") which seek to minimize surgical trauma but carry their own risks as well. Goodacre *et al.* (2003a) provided data regarding the types of complications that have been reported in conjunction with endosseous root form implants. The most common surgical complications associated with implant surgery were hemorrhage-related complications (24%), neurosensory disturbance (7%), and mandibular fracture (0.3%).

Implant loss

To date, there is no known single factor that contributes to an implant loss. Some of the factors that are generally accepted as the etiology include infection and/or contamination, patients' physical status, trauma from surgical procedure, excessive and/or premature occlusal loading, unfavorable axial loading, etc. Most of the surgery-related implant losses can be managed by maintaining a strict infection control protocol, meticulous patient screening prior to the surgery, and reducing the amount of time/trauma during surgery. Occlusal loading is a more challenging factor since the operator has more limited control. Premature occlusal loading can be detrimental to the osseointegration when it is combined with excessive load and/or off-axis force. This can happen during the stage of early or immediate provisionalization and illustrates that the patient should be closely monitored during this initial healing period. In the literature, it has been stated that overloading at any stage of osseointegration can lead to bone loss or even complete disintegration of the implant (Isidor 1996, 1997; Brunski *et al.* 2000; Steigenga *et al.* 2003). However, the concept of implant "overload" has recently been questioned with a series of studies indicating bone is highly responsive to dynamic loads and is resistant to bone loss even with high levels of occlusal function (Stanford & Brand 1999; Duyck *et al.* 2000, 2001; Stanford 2005b).

According to the literature, implant loss ranges from a high of 19% with maxillary overdentures to a low of 3% that occurred with both mandibular fixed complete dentures and single crowns (Goodacre *et al.* 2003a). Implant loss is greater with implants 10 mm or less in length compared with implants greater than 10 mm long (ten Bruggenkate *et al.* 1998; Lekholm *et al.* 1999; Friberg *et al.* 2000; Palmer *et al.* 2000). The implant loss is more likely to occur in the presence of type IV bone compared with more favorable typed bones (Stanford, 1999, 2005b; Stanford & Brand, 1999). Other risk factors that have been suggested include smoking and a previous history of radiation therapy (Moy *et al.* 2005). If indeed a loss of implant occurs, approximately half or more of the lost implants were lost prior to functional loading. This result is in agreement with the result from a previous systematic review (Berglundh *et al.* 2002).

Peri-implant complications

Possible peri-implant complications include marginal bone loss, peri-implant mucosal inflammation/proliferation, soft/hard tissue fenestration/dehiscence, fistula, etc. It is widely accepted that continuous marginal bone loss around established implants over time jeopardizes the potential success and/or survival of the implant therapy. Factors that potentially induce marginal bone loss include surgical trauma during implant placement, trauma during repeated abutment insertions and removal, functional load transfer and concentration, micromotion at the implant–abutment junction, and peri-implant gingival inflammation. According to the literature, the mean bone loss occurring during the first year is, on average, around 0.9–1.5 mm, and the subsequent

loss per year after the first year is around 0.1 mm (Albrektsson *et al.* 1986).

Peri-implantitis is defined as an inflammatory reaction associated with the loss of supporting bone in the tissues around a functioning implant (Albrektsson *et al.* 1994). Peri-implantitis could be asymptomatic but it often accompanies bleeding and/or suppuration. Clinically, bony defects are detected by increased probing depth. Radiographically, a saucer-shaped radiolucent lesion may be observed around the implant. From a prosthetic perspective, the onset of peri-mucositis or peri-implantitis (associated with bone loss) can lead to soft tissue recession and unesthetic show of abutment or prosthetic components.

Marginal defects on the facial aspect of the implant complex are not only esthetically compromising, but can jeopardize the stability and long-term success of the implant. These defects, dehiscence or fenestration, are typically caused by the resorption of the buccal/labial plate of the alveolar bone. In order to prevent this type of defect it is important to maintain a minimum of 1 mm thickness of buccal/labial plate (Stanford 2005a). However, in certain areas, this may be difficult to achieve. To reduce the risks of facial marginal defects one can utilize bone augmentation procedures, mainly autogenous, around the marginal alveolar bone in order to maintain the thickness around the implants. In this case, autogenous bone particles derived from the drilling of the osteotomy may be enough for the purpose. In terms of the timing of implant placement after tooth extraction, it is generally accepted that immediate placement has a greater risk of facial marginal defects compared to delayed placement (Nemcovsky *et al.* 2002).

Malpositioned implants

The definition of a 'malpositioned implant' is an implant placed in a position that created restorative and biomechanical challenges for an optimal result. A malpositioned implant could be caused by numerous factors, the most common being deficiency of the osseous housing around the proposed implant site. Bone resorption is observed in osseous remodeling following tooth loss, osteoporosis, orthopedic revisions, craniofacial defects, or post oral cancer ablation associated with surgery/radiation. For the best biologic, biomechanical, and esthetic result of implant rehabilitations, proper implant placement is essential. The placement of an implant into a defective osseous site not only prevents adequate positioning of the final prosthetic restoration, but also results in compromised integration and subsequently a poor prognosis for the therapeutic outcome. In order to place an implant in the optimal prosthetic position for a restoration, augmentation procedures are often necessary. Current approaches in bone reconstruction use biomaterials, autografts or allografts, although restrictions on all these techniques exist. Restrictions include donor site morbidity and donor shortage for autografts (Damien & Parson 1991), as well as immunologic barriers for allografts and the risk of transmitting infectious diseases (Meyer *et al.* 2004). Numerous artificial bone substitutes containing metals, ceramics, and polymers have been introduced to maintain bone function. However, each material has specific disadvantages, and none of these can perfectly substitute for autografts in current clinical dentistry.

If the status of the existing, deficient bone were addressed prior to the surgery and the restorative dentist confirms it will be possible to fabricate the final prosthesis with the implant(s) in the proposed location, generally implant placement can be a straightforward procedure. It is a significant complication for the implant team and the patient when the implants are placed only in the available bone ignoring the optimal desired prosthetic position (Fig. 56-2). Communication between the surgical and restorative team is vital. The best way of communication between the two parties is through use of comprehensive treatment planning, diagnostic wax-up on mounted casts, and fabrication of a surgical guide. The standard protocol for placing implants will start with a treatment plan developed by the restorative dentist. The surgical guide represents the ideal position and angle of the implant determined by a series of diagnostic procedures. The surgical guide should ideally indicate the three dimensions of the proposed implant position – horizontal position, vertical position, and angle (Fig. 56-3). Horizontally, the surgical guide should clearly indicate the bucco-lingual and mesio-distal location of the proposed site. In most cases, this is determined by the morphology and location of the diagnostic wax-up of the missing tooth. Vertically, the surgical guide should indicate how deep the surgeon should place the implant relative to the planned cemento-enamel junction (CEJ). This is particularly important for implants placed in the esthetic zone. As a general rule, the restorative margin for an implant-supported restoration should be located at the vertical height slightly deeper than that of the CEJ of the adjacent teeth. Thus, when an implant system in which the head of the implant represents the restorative margin, the implant should be placed 2–3 mm below the planned CEJ or occasionally on a line connecting the CEJ of adjacent teeth. When an implant system is used which is capable of adjusting the height of the restorative margin through a separate abutment(s), the depth of the implant may be more flexible (Fig. 56-4). Whichever system is used, the surgical guide should have a component that could notify the surgeon of the proposed depth of the implant. The angle of the implant should also be correct to prevent facial or lingual fenestration of the implant as well as penetration into the radicular portions of adjacent teeth or other structures. The angle should be correct for the prosthesis as well. Should the angle of the implant be too facial, the restorative dentist could face significant esthetic challenges, for example, screw access hole position, necessity of the

Fig. 56-2 Prosthetic complications with malpositioned implants. (a) Patient had an implant placed in area of 24 with facial angulation. (b) The provisional fixed bridge demonstrated the facial position. Due to the depth and position of the implant, a fixed prosthesis was made that rested on the implant abutment (c) allowing a satisfactory esthetic and functional restoration (d).

Fig. 56-4 The restorative margin may be the head of the implant with certain implant designs necessitating the surgeon placing the implant to have a clear idea of where the final margin will be. Other systems use an abutment for cemented restorations that allows variation in the vertical position of the restorative margin.

use of angled abutments, expensive custom abutments, etc. (Fig. 56-5).

Mechanical complications

Overdenture complications

Numerous studies indicate that the use of an acrylic-based implant overdenture has the highest number of post-operative complications (complication being defined as a need for some form of intervention, the degree of which is not necessarily defined). Complications include loss of attachment retention or fracture of the attachment system, fracture of components of the denture, prosthesis-related adjustments, etc.

Fig. 56-5 Innovative use of abutments. (a) Patient presented with a healing abutment indicating placement within the residual ridge. (b) Soft tissue health was adequate though final impression coping (c) indicates angled position relative to remaining teeth. Patient was restored with a cement retained restoration but using a low profile abutment designed for a conventional screw-retained crown (d,e). (Courtesy of Dr. Michael Scalia DDS, and Mr. Henry Husemann CDT (University of Iowa).)

Goodacre *et al.* (2003a) suggested the most common complication in this category was the need for adjustments due to loss of retention and/or attachment system fracture. O-ring systems, Hader-bar and clip-, IMZ-, Ceka-, ERA-, ZAAG-, Locator-attachments all use various forms of plastic components within the anchorage system. Over time, the plastic component tends to wear and distort. Traditional ball attachment systems utilize metal spring matrices and these, too, tend to deform and lose retention with time. Studies that assessed the difference in frequency of maintenance requirement between bar/clip systems and individual attachment systems indicated that individual attachment systems require more frequent adjustments mainly due to loss of retention of the matrix or patrix (van Kampen *et al.* 2003; Walton 2003; MacEntee *et al.* 2005). However, the simplicity and ease of the repair procedure in some individual attachment systems may reduce frequent maintenance and have lead to increasing popularity of these abutment designs. Systems with exchangeable plastic components have especially become popular due to easy maintenance procedures. Further, the conversion of a complete denture patient who rarely returns for maintenance therapy to a routine recall patient (valuable for early

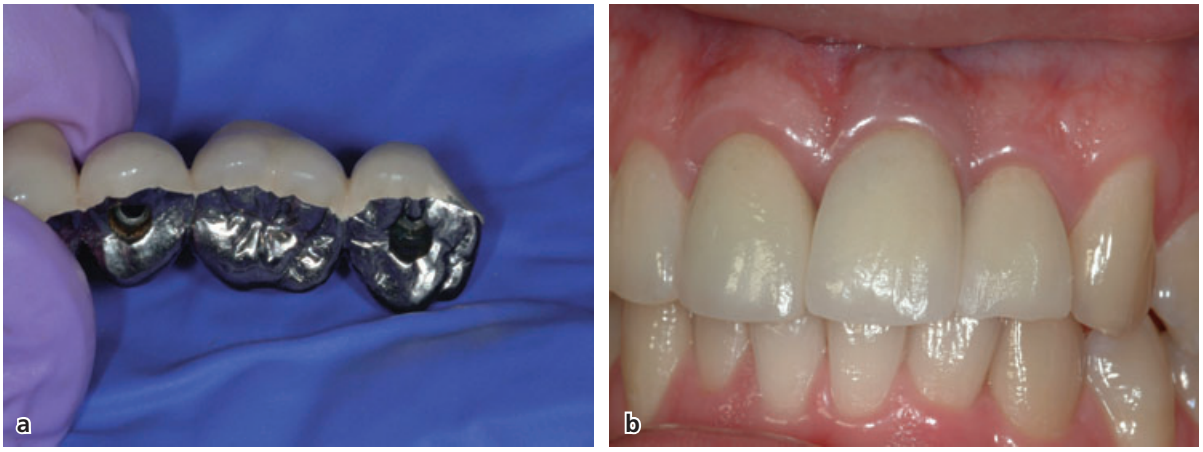

Fig. 56-6 Fractures of veneering ceramic material. (a) Example of facial shear fracture of porcelain on posterior unit. (b) Ceramic shear fracture on facial surface of 22 all-ceramic restoration.

caries detection, oral cancer exams, etc.) by way of their desire to have the attachment system serviced provides a valuable ethical service for the patient.

Because of the housing and attachment components, overdentures typically have a reduced thickness of acrylic resin base in certain areas compared to conventional dentures. It is these thin areas that have a higher risk of fracture. In addition, patients with implant-supported overdentures have a tendency to generate higher masticatory force compared to patients with conventional dentures. The incidence of acrylic base fracture may increase depending on the opposing occlusion. For example, an overdenture opposing an implant-supported fixed complete denture will be at a greater risk of fracture, accelerated wear or prosthetic tooth fracture than one opposing a conventional denture. Overdenture fracture is a relatively common problem according to some studies, and could be as high as 7% of all the mechanical complications related to implant-supported restorations (Carlson & Carlsson 1994; Goodacre *et al.* 2003a).

Prosthesis-related adjustments include reline/rebase of the overdenture, occlusal adjustments, denture adjustment due to soft tissue complications, etc. Normally the hard and soft tissue under the overdenture will remodel with time. Additionally, overdentures only allow limited rotational movements between the abutment and the anchorage system. This means there will be positive vertical and horizontal load on the edentulous ridge, in the area away from the anchorage system. This may increase the rate of resorption and induce the need for denture relines. The change in mucosal adaptation of the prostheses will induce subsequent problems like occlusion changes and soft tissue trauma.

Fracture of fixed restoration veneers/fixed restorations

Without the periodontal ligament (PDL) to provide shock absorption and proprioceptive reflex, dental implants are essentially ankylosed to the surrounding bone. Further, patients tend to generate higher masticatory forces on implant-supported restorations relative to the natural dentition. It has been reported that the maximum bite force generated with conventional dentures is around 50–60 N, whereas implant-supported restorations can generate above 200 N (Carr & Laney 1987; Mericske-Stern *et al.* 1996; Fontijn-Tekamp *et al.* 1998; Morneburg & Proschel 2002; Steigenga *et al.* 2003). As a result, an implant-supported prosthesis is exposed to a risk of higher restorative material failure. Of prosthetic failures, studies suggest the fracture of the restorative veneer material is the most common type of mechanical complication (Fig. 56-6). It includes fracture of the veneering porcelain or resin. Veneer fracture can happen anywhere in the mouth; restorations in the areas of heavy functional forces and higher non-axial forces, such as the occlusal surfaces of mandibular posterior restorations, facial cusps of maxillary posterior restorations, and maxillary anterior restorations, have a greater tendency to shear. To reduce or avoid material failure, especially veneer material fracture, the restoration should have sound supporting structures. The framework that supports the restorative veneer should have sufficient strength and stability to safely support the overlying veneer material. The framework should have minimal flexure even under functional loading – veneer materials usually lack tensile strength and as a result are weak under flexural stress. The framework should be carefully designed so that it will provide maximum support with no unsupported areas of the veneer material (Fig. 56-7). Another important approach to reduce the complication of veneering materials is through control of the occlusion. To reduce or eliminate excessive stress on one particular tooth or restoration, wide distribution of the occlusal force will be better than loads concentrated on a localized area. Also limiting the main occlusal force on to the restoration directly supported by implants may be beneficial: cantilevered restorations may be at higher risk

Fig. 56-7 Fractured all-ceramic implant restoration. Patient had a three-unit fixed partial denture (FPD) (12 to 21) with glass-infused ceramic structure. (a) Restoration demonstrated catastrophic rupture 2 years after delivery. Restoration was removed (b), zirconia abutments cleaned and a new Zirconia reinforced FPD fabricated for enhanced strength (c). (d) Final esthetic appearance for the FPD.

of fracture than those supported by the implant/abutment under an identical amount of occlusal load (Becker 2004; Pjetursson *et al.* 2004).

Occlusal wear is more evident in implant-supported restorations for the same reason. When there is a mismatch of opposing restorative materials, the wear could be especially dramatic. Thus one must be prudent in not only selecting the material for the occlusal surface of the restoration but also the status of polishing to avoid serious maintenance issues. It is known that porcelain can be abrasive when opposed with enamel, metal, resin, or even porcelain, especially when it lacks a highly polished surface (Monasky & Taylor 1971). Exposed opaque layer and use of external characterizations with metal oxides all add to the abrasiveness of porcelain and should be used with care.

A rare but possible complication related to prosthesis fracture is the fracture of mandibular implant-supported fixed complete denture at the midline (Fig. 56-8). It is speculated that the flexure of the mandible during function can cause this type of complication. Repeated extreme mouth opening can accumulate fatigue in the metal framework, and once this accumulated fatigue exceeds the fatigue strength of the material, the prosthesis may facture or veneering material delaminate from the framework. Clinically, patients with this type of restoration may feel tightness of the mandible especially during function, and once the restoration fails, they express "relief" from the tightness. To avoid this problem, fabricating a two-piece fixed restoration has been advocated by some, although this has generated its own problem: because of the lack of the bracing effect and rigidity of the framework, these restorations may

Fig. 56-8 Splitting full-arch ceramometal restoration at the midline to reduce impact of mandibular flexure.

tend to have a higher incidence of screw-related problems.

Implant screw-related complications

Numerous studies indicate that complications related to the screw components of the implant system are very common and require clinical intervention, which could range from simple retightening of the screw(s) to total replacement of the abutment and screw(s). This requires additional time and cost for both dentists and patients. Jemt and Linden (1992) observed with earlier screw abutment designs that screw loosening occurred in 49% of maxillary implant-supported restorations and 20.8% of prostheses in the mandible. They also observed that 57% of the abutment screw loosening occurred within the first year of service and only 37% remained stable over a 3-year period. Goodacre *et al.* (2003a) observed that the frequency of complications related to implant screws like screw loosening or fracture of abutment or prosthetic screws could be as high as 19% of all the potential mechanical complications in implant restorations. Ding *et al.* (2003) reported that the incidence of screw loosening for an external hex system could be as high as 38%. In their systematic review, Pjetursson *et al.* (2004) found that abutment or occlusal screw loosening/fracture was the third most common technical complication, only after restoration veneer fracture and loss of occlusal screw access hole restoration. Its cumulative incidence after 5 years of follow-up was 7.3%.

Theoretically, the lifespan of an abutment or prosthetic screw in an implant restoration needs to last greater than 10^8 cycles of loading or approximately 20 years under the assumption that the system is accurately constructed and the loading conditions are simulating the natural oral environment (Patterson & Johns 1992). However, there are several factors that could drastically reduce the predicted service life resulting in screw loosening and/or fracture. For example, the abutment/implant interface geometry, precision of fit and/or passivity of components, and the amount of preload may lead to reduced service life. In external hexagonal implant system studies, it has been shown that larger implant/abutment contact area provides superior stability of the system and resistance to screw complications and has been one driving force for the use of wider-diameter implant devices (Binon 2000). Additionally, precise anti-rotational features should be present for the joint components to withstand rotational movements that could potentially cause screw loosening (Khraisat 2005). Precise fit of the abutment to the implant interface is highly important. In a study on machining accuracy of several different external hex implant systems, all systems demonstrated rotational movement in excess of four degrees (Binon 1995). Systems that have such "slip-joint" figures such as external hex implant systems are naturally vulnerable to vibration and micromotion during functional loading (Schwarz 2000; Hoyer *et al.* 2001). In the absence of passivity between the implant components, it has been shown that screws accumulate internal stress and this eventually results in metal fatigue failure and screw loosening/fracture (Kano *et al.* 2006). The resulting clamping force exhibited between the abutment and implant generated by the screw is called *preload*. In an external hex system, the preload, along with the frictional force of the abutment/implant joint wall, is the major force resisting functional loads. In most implant systems, a tightening torque is applied and the preload stress in the interface is increased, where this stress should be within the elastic range of the screw material. The screw tightening should result in optimum preload level for the maximum outcome of the implant complex after dynamic loading. Literature indicates that as long as the external loading stress does not exceed the preload stress, the abutment/implant connection can be regarded as safe (Patterson & Johns 1992; Lang *et al.* 2003). Insufficient or excessive preload stress could result in compromised lifespan of the abutment/implant connection.

Chronic problems associated with the external hex or butt-joint interface implant systems have been documented. Because of these inherent problems with external hex design, investigators have presented new concepts in implant design, which aim to improve support and reduce the complications associated with external hex design, by means of additional frictional force between the internal wall of the implant and the external wall of a 1-piece abutment/abutment screw. Sutter and colleagues proposed an 8-degree internal-taper connection between the implant and abutment (ten Bruggenkate *et al.* 1998). The original concept of Morse taper comes from engineering, particularly from the area of machine taper. When connecting exchangeable working bits into the work piece, a popular and very effective method is to use frictional forces between the two components, where the pressure of the spindle against the workpiece drives the tapered shank tightly into the tapered hole. The friction across the entire interface surface area provides a surprisingly large amount of torque transmission. The abutment/implant junction can be designed such that an internal connection is utilized with minimal taper (2–15°), while the screw base portion of the abutment will be connected into the receiving portion of the implant. There are numerous studies reporting on the higher mechanical and enhanced clinical behavior of these internal connection designed implants (Binon 2000). Norton (1997, 1999) verified that the internal conical designed systems significantly enhanced the resistance of connection system against external bending forces. Levine *et al.* (1999) found that the internal connection showed significantly lower incidence (3.6–5.3%) of screw-related complications compared to external hex designed systems. The use of the internal interference fit abutment designs has simplified the

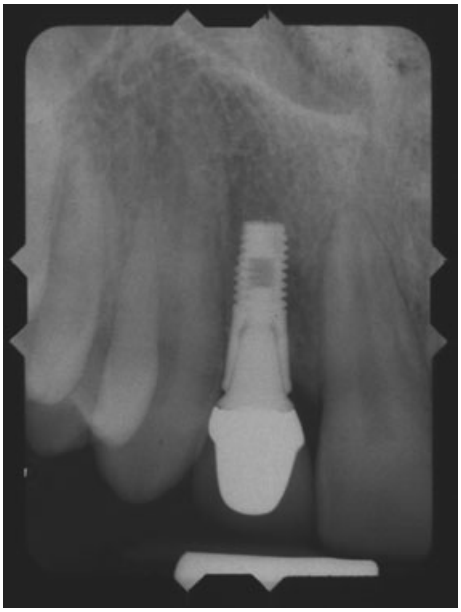

Fig. 56-9 Incomplete seating of abutment in a two-piece implant system. Implant abutment was incompletely seated in implant due to contact on the adjacent osseous contours.

prosthetic phase of therapy and has increased the long-term stability of the screw–joint connections (Stanford & Brand 1999; Brunski 2000, 2003; Jokstad *et al.* 2003).

Abutment-related complications

In positioning an abutment into the implant, there are potential mechanical complications that can arise. One common issue is incomplete seating of the abutment to the implant body (Fig. 56-9). Depending on the implant position and depth, it is also possible that the peri-implant bone may inhibit complete seating of the abutment (giving the dentist the impression that the abutment is fully seated when in fact it is resting on adjacent bone). This may or may not be evident on a radiograph depending on the implant abutment angulation relative to the central beam of the radiographic unit.

Since most prefabricated abutments are produced in standard size and shape, it can be challenging to customize them to individual patients. The modification procedures to a prefabricated abutment may in turn compromise the biomechanical properties of the abutment to achieve an esthetic result. Some systems provide a stock titanium abutment that can be modified by conventional laboratory reshaping or though use of CAD/CAM milling approaches. Depending on the angulation of the implant relative to the prosthesis, the presence of a central abutment screw can sometimes become a complication. This is especially true for narrow-diameter abutments which generally lack sufficient wall thickness for an ideal preparation.

When the head of the implant is placed below the adjacent bone, the architecture of the bone can develop sloped architecture extending from the PDL support of the adjacent teeth down and across to the implant. This often happens in the maxilla area where implants are generally placed deeper to avoid esthetic issues. Periodically this scalloped osseous architecture necessitates the prosthodontist to assess and then modify the abutment and occasionally the implant body in this area (Fig. 56-10). In this case, the mucosal transition zone of the abutment is modified to avoid placing pressure on the bone and soft tissues. It is also helpful to develop a flat or even concave emergence profile of the final restoration to maintain soft tissue dimensions around the restoration (Stanford 2005a).

Other issues related to prosthetic complications

Implant angulation and prosthetic complications

The role of angled implants on clinical outcomes is often of significant concern. Clelland *et al.* (1995) evaluated the stresses and strains generated by an abutment system capable of three angulations (0°, 15°, and 20°). In this study, they observed peak stresses were located in the cortical bone, and the magnitude of these stresses increased with an increase in the abutment angulation. The maximum stress values were generally within the physiologic parameters described for animals, but in one case, the peak compressive stress for the 20° abutment was slightly above this physiologic zone. Peak tensile strains also increased with abutment angulation, but maximum compressive strain values were the same for all three angles. This study suggested that angled abutments were safe to use relative to the bone stability around the implant body.

One approach advocated by some has been to use multiple implants and place a facial–lingual offset between them to enhance the mechanical stability of a connected FPD. Sutpideler *et al.* (2004) evaluated the effect of an offset on the force transmission to bone-supporting implants aligned in either a straight-line configuration or an offset configuration. Also, they addressed the effect of different prosthesis heights and different directions of force application. They observed vertical loading of an implant-supported prosthesis produced the lowest stress to the supporting bone and increasing the angle resulted in greater stress that theoretically simulated surrounding bone. They also observed reducing the height of the prosthesis from 12 mm to 6 mm (crown to implant ratio) or establishing an offset implant location for the middle of three implants can reduce stress, but this reduction did not compensate for the increase in stress found with non-axial loading. This concept has been extended with the recent advocacy for intentionally placing implants at significant

Fig. 56-10 Implant and abutment modification. (a) Patient presented with soft tissue dehiscence on an integrated implant, necessitating placement of an abutment and preparation of the abutment and implant body (b). A fixed partial denture was fabricated using the modified abutment (c) that achieved a reasonable esthetic and functional outcome for this compromised situation (d). Restorative work accomplished by Dr. Manuel Romo DDS (University of Iowa).

angulation relative to each other to avoid vital structures and sinus cavities, and to improve the putative biomechanical position of the implants (Krennmair *et al.* 2005).

Chun *et al.* (2006) investigated the effect of three different abutment types (one-piece, internal-hex, and external-hex) on stress distribution in bone under vertical and inclined loads by finite element analysis. With one-piece implant designs, they observed that the load was transferred evenly into bone as well as within the implant system. However, the maximum stress generated in bone with the one-piece system was always higher than that generated with the internal-hex implant, regardless of load angle inclination. In the case of the internal-hex implant, the contact condition with friction between abutment and implant in the tapered joints and at abutment neck reduced the effect of bending caused by horizontal component of inclined load. The maximum stress in bone was the highest for the external-hex implants.

Erneklint *et al.* (2006) evaluated the load resistance in a conical implant system with two different screw-retained abutment angled designs (20° and 45°) and three different retaining screw materials. They observed that the 20° abutment withstood non-axial forces to a greater extent than a 45° abutment, regardless of retaining screw material. The 45° abutment failed under oblique loads between 450 and 530 N while the 20° abutment failed at 1280–1570 N. Regarding the retaining screw materials, differences were more obvious in a 20° abutment, but not insignificant in the 45° abutment as well. In general, they concluded that abutment taper angles were more important than retaining screw material in determining the assembly strength.

The angulation of the implants can also influence the outcomes of implant overdenture therapy. Gulizio *et al.* (2005) evaluated the retentive capacity of gold and titanium overdenture attachments placed on implants positioned at 0°, 10°, 20°, and 30° from a vertical reference axis. They observed that significant differences in retention of gold matrices were noticed when ball abutments were positioned at 20° and 30°, but not at 0° and 10°. Also they noticed significantly higher variance in retention among the titanium matrices, despite the finding that angle was not a factor affecting retention for titanium matrices. In other words, angle of the implants had an effect on the retention of gold matrices, but not for titanium matrices. This study supports the clinical observation that implant-supported overdentures have higher maintenance needs and may have higher long-term ongoing costs relative to conventional tooth replacement therapies (Naert *et al.* 2004a,b; Krennmair *et al.* 2005; Zitzmann *et al.* 2005; Trakas *et al.* 2006; Visser *et al.* 2006).

Screw-retained vs. cement-retained restorations

The method of attachment of the prosthesis to the implant/abutment can create prosthetic complications. The major advantages of screw-retained implant-supported restorations include their retrievability and freedom from residual cement problems. Thus this type of restoration scheme can be applied when there is a need for future removal, e.g. necessary hygiene maintenance procedures or questionable prognosis of the restoration. It could also be applied when the restorative margin is located too deep for removal of excess cement at the time of restoration delivery. The same advantage applies to provisional restorations as well. However, this type of restoration has inherent disadvantages. Because of the required screw access hole, it not only compromises the esthetics and occlusion, but also has the potential to undermine the strength of the restoration due to the lack of material. The presence of the prosthetic screw also bears the potential of screw complications. Additionally, this type of restoration is more sensitive to the passive fit of the restoration to the supporting implants.

Regarding the clinical performance of each type of restoration, the literature indicates that screw-retained restorations may present more post-operative complications compared to cement-retained restorations. Duncan *et al.* (2003) reported that patients restored with screw-retained restorations had problems with prosthetic screws and screw access hole filling material while no complications were encountered with patients restored with cement-retained restorations after 3 years. Karl *et al.* (2006) found that cement-retained FPDs may result in lower strain levels compared to conventional screw-retained FPDs at the time of either the cementation or screw-tightening procedure. Higher strain level at the time of delivery may reduce the passivity of the fit of the restoration and increase potential future complications. This result is in accordance with other *in vitro* studies (Guichet *et al.* 2000; Taylor *et al.* 2000). However, this study carefully suggests that regardless of the type of restoration, no true passive fit can be achieved. Skalak (1983) theorized that a non-passive fit of the restoration can induce biologic and prosthetic complications. However, Jemt and Book (1996) reported that they could not find a direct association between implant prosthesis misfits with marginal bone loss over 5 years. Vigolo *et al*. (2004) found no evidence of different behavior of the peri-implant marginal bone and soft tissue response around screw-retained or cement-retained single-tooth implant restorations.

Overall, there is no consensus of the superiority of one type over the other – it may be determined by the clinical situation and the operator's preference.

Ceramic abutments

Ceramic implant abutments have recently gained in popularity due to superior esthetic results compared to conventional titanium abutments, especially in thin tissue biotypes (Stanford 2005a). Because of the strength concerns, the current material of choice for ceramic abutments is reinforced ceramic abutment, e.g. alumina (Al_2O_3) or yettria-stabilized Zirconia (ZrO_2) (Fig. 56-7). These abutments were introduced during the 1990s and the first of these abutments consisted of densely sintered aluminum oxide (alumina). Andersson *et al.* (2003) conducted a 5-year multi-center prospective study evaluating the clinical outcome of alumina ceramic abutments. According to this study, the cumulative success rate for alumina ceramic abutments was 98.1% at 5 years compared to 100% for conventional titanium abutments. More recently, zirconia has become popular for ceramic implant abutments. Because ceramic materials are vulnerable to tensile stress, especially around defects or cracks, a ceramic material with higher fracture toughness will be a good material for ceramic abutments. Zirconia is generally known to have higher range of fracture toughness (K_{IC}, ~7–15 $MPam^{-1}$) than that of alumina (K_{IC}, ~4–4.5 $MPam^{-1}$). Its fracture toughness is comparable to that of metal alloys (K_{IC}, ≥20 $MPam^{-1}$) (Piconi & Maccauro 1999; Kelly 2004). Zirconia is known to have the relatively unique property of transformation toughening, where the metastable tetragonal phase can be converted into monoclinic phase with the associated volume expansion (Chevalier 2006). This phenomenon is induced by stress concentration at defect or crack tips, through which the crack is put into compression and its growth retarded. This is the main mechanism for its higher fracture toughness, and it could significantly extend the reliability and lifetime of the restoration. However, there is little evidence if the abutment will still retain this property after being reduced down to less than 1 mm during clinical usage. Further, the hydrolytic properties of water interacting with the material during ageing (hydrolytic ageing) is still an active area of laboratory investigation (Rekow & Thompson 2005). There are outstanding questions relative to the use of this material including long-term fatigue strength, degree of preparation/wall thickness needed, intraoral sites, clinical long-term prognosis, etc. Due to the relatively short period after its introduction, there are few studies that assess the clinical performance of these abutments (Att *et al.* 2006; Denry & Holloway 2006; Deville *et al.* 2006; Itinoche *et al.* 2006; Studart *et al.* 2006).

Esthetic complications

The most frustrating and challenging complication is unacceptable esthetic outcome either at the time of restoration or during long-term follow up. With

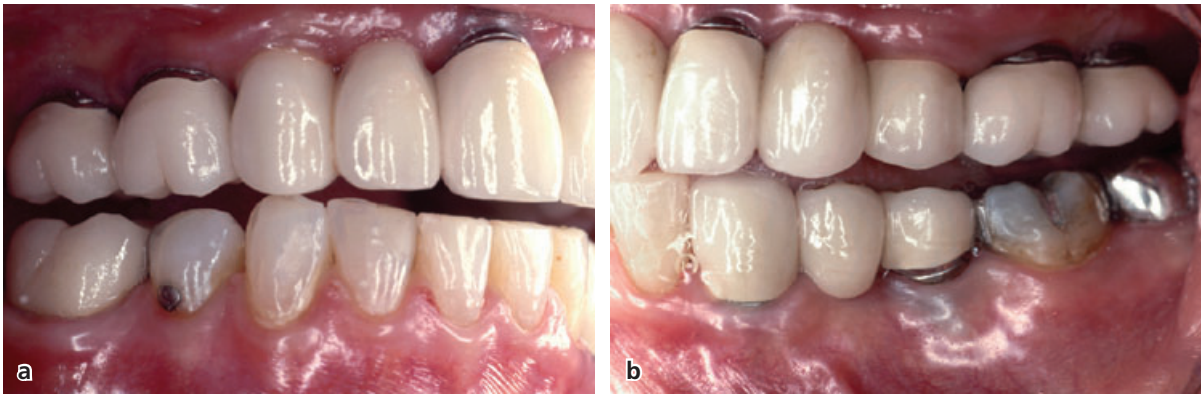

Fig. 56-11 Soft tissue recession on facial aspect of implant supported restoration.

the growing population of esthetically concerned patients, esthetic complications are a serious matter even if the implant team has done its best throughout the procedure. This is an important issue that the implant team and the patient need to be aware of and endeavor to find solutions to prevent or overcome. Common esthetic complications include complications due to malpositioned implants, thin tissue biotypes, and unfavorable soft tissue responses.

The potential cause and impact of malpositioned implants was previously described. A very difficult aspect of implant rehabilitation is that sometimes a slight malpositioning can induce dramatic esthetic compromises which do not become evident until the technician is working with the case. A facially malpositioned implant can become a major challenge for the restorative team (Fig. 56-11). In this case, the restorative dentist may have to address a variety of potential problems, including excessive incisogingival dimensions of the crown, exposed head of the implant, unequal gingival margins, etc. Usually, facially malpositioned implants create greater problems than other malpositioned implants. A 1 mm lingual position to the implant in the maxillary esthetic zone can create a prosthetic challenge to have the final restoration appear even and uniform with the natural dentition. Mesially, or distally malpositioned implants can induce improper anatomy of the restoration as the technician attempts to compensate for implant components in the interproximal space (Fig. 56-12).

Unfavorable soft tissue response can also make the treatment very difficult. It is generally accepted that individuals that have relatively thin attached gingiva, or thin tissue biotype, are more vulnerable to gingival/periodontal disease and subsequent sequelae including gingival recession. Similar findings are reported for the tissue response around implant restorations (Kan *et al.* 2003). Thin biotype tissues tend to show more recessive response to trauma. Restorative procedures, like preparation, impression, repeated abutment/provisional removal, or even toothbrushing, can sometimes cause enough trauma to these thin biotype tissues to result in significant recession and compromise the treatment outcome. It is very important to identify the tissue type early at the treatment planning stage to prevent unfavorable treatment outcome.

Fig. 56-12 Challenges in creating esthetic outcomes when implants are insufficiently placed. Example demonstrates teeth 11 and 21 with compromised contours due to close proximity of the implants.

Success/survival rate of implant-supported prostheses

As previously described, the biologic success/survival rate is extremely high and has become more predictable even in areas that were considered of high risk (e.g. maxillary posterior region). It may be beneficial to know what the literature indicates regarding the success/survival rate of restorations fabricated on the osseointegrated implants. Pjetursson *et al.* (2004) obtained estimates of the long-term survival/success rates of implant-supported FPDs and of the incidence of technical complications in partially edentulous patients with an observation period of more than 5 years. "FPD survival" was defined as "the FPD remaining *in situ* with or without modification for the observation period", as compared to the definition of "FPD success" being "FPD being free of all complications over the entire obser-

vation period" in this study. The cumulative FPD survival rate was 95% after 5 years and 86.7% after 10 years, respectively. In this study, the authors noted an important fact that most of the prosthetic complications occur after 5 years of clinical service. The underlying issue this illustrates is the problem associated with the rapid rate of manufacturing market changes in implant products and components. By the time the restoration needs repair or replacement, the required components may be difficult if not impossible to obtain. Regarding comparison of different implant systems, there is little evidence of superiority of one system over another in terms of mechanical failure. Implant–abutment joint geometry, design of the restoration, and patient factors like parafunctional habits or heavy occlusal forces tend to have more impact on the outcome of implant-supported restoration than implant surface material or topography (Rangert *et al.* 1995; Astrand *et al.* 1999; Naert *et al.* 2002a,b). Some studies indicate that the cumulative complication rate of prosthetic problems can be as high as 43.1% after 5 years (Jemt *et al.* 2003), compared to other studies finding it to be as low as 19.3% after 5 years (Bragger *et al.* 2001; Pjetursson *et al.* 2004). A summary of these studies indicates that one may expect one out of four implant-supported restorations will require some type of repair whether it be minor, such as screw or abutment tightening, or major, such as entire restoration replacement, after 5 years. This implies that significant chair time may be necessary for the maintenance of these restorations (Pjetursson *et al.* 2004).

Berglundh *et al.* (2002) also noticed the higher mechanical/technical complication rate compared to the lower biologic complication rate. This study observed interesting aspects: the incidence of implant loss prior to functional loading was higher by threefold when multiple implants are placed for larger restorations like overdentures or fixed complete restorations than that of single-tooth restorations; implant loss during function occurred in 2–3% of implants supporting fixed reconstructions, while twice as many implants were lost in overdenture therapy during a 5-year period. In this case, the highest frequencies of implant loss during function occurred in the maxilla.

Conclusions

Implant therapy provides many benefits as a form of tooth replacement therapy. As with any form of prosthetic rehabilitation it has limitations including wear, material fatigue and fracture, soft tissue recession and subsequent complications, increased maintenance and costs. The benefits, though, can be enormous with the enhanced patient quality of life that comes with a definitive replacement of teeth. Patients need to be aware during the treatment planning process that the treatment provided may need to be replaced periodically as normal ageing and wear occurs. Specific patient-based risk factors such as parafunctional habits should be discussed and the patient made aware of the risks to the prosthetic reconstructions.

Part 17: Orthodontics and Periodontics

Chapter 57

Tooth Movements in the Periodontally Compromised Patient

Björn U. Zachrisson

Orthodontic treatment may be adjunctive to periodontal therapy. The loss of periodontal support or teeth may result in elongation, spacing, and proclination of incisors, rotation, and tipping of premolars and molars with collapse of the posterior occlusion, and decreasing vertical dimension. But orthodontic tooth movement can also facilitate the management of several restorative and esthetic problems in adults. Such difficulties may be related to subgingivally fractured or lost teeth, tipped abutment teeth, excess spacing, inadequate implant or pontic space, supraerupted teeth, narrow alveolar ridges that prevent implant placement, and other conditions (Ong *et al*. 1998). The purpose of this chapter is to discuss how recent basic and clinical information may be used to improve treatment planning, clinical management, and retention for patients in whom different malocclusions are caused or complicated by moderate to advanced periodontal destruction.

Orthodontic tooth movement in adults with periodontal tissue breakdown

Poorly executed orthodontic treatment in periodontal patients can certainly contribute to further periodontal tissue breakdown. In particular, the combination of inflammation, orthodontic forces, and occlusal trauma may produce a more rapid destruction than would occur with inflammation alone (Kessler 1976). However, with properly performed treatment, extensive orthodontic tooth movement can be made in adults with a reduced but healthy periodontium without further periodontal deterioration. Figures 57-1 to 57-6 show the pretreatment and post-treatment conditions in four different adult orthodontic patients with advanced periodontitis. The findings of no significant further periodontal tissue breakdown in these patients were the result of carefully controlled treatment planning considerations.

Only a few well controlled studies have been published on groups of adults with advanced periodontitis, who have received comprehensive orthodontic fixed-appliance treatment. Boyd *et al*. (1989) described ten adults with generalized periodontitis who received pre-orthodontic periodontal treatment including surgery, and then regular maintenance at 3-month intervals during a 2-year orthodontic treatment period. They were compared with ten control adults who had normal periodontal tissues, and 20 adolescent orthodontic patients. The results demonstrated that:

Fig. 57-1 Adult male patient with advanced periodontitis and marked pathologic migration of the anterior teeth before (left column) and after (right column) periodontal and orthodontic fixed-appliance treatment for 2 years. Clinical appearance of the face and dentition are dramatically improved after the combined periodontic/orthodontic treatment. The dental result is maintained by means of bonded lingual retainer wires. A maxillary two-unit and a mandibular three-unit bridge were constructed. Some interdental recession was unavoidable in the mandibular anterior region (d), but it does not show much clinically (b).

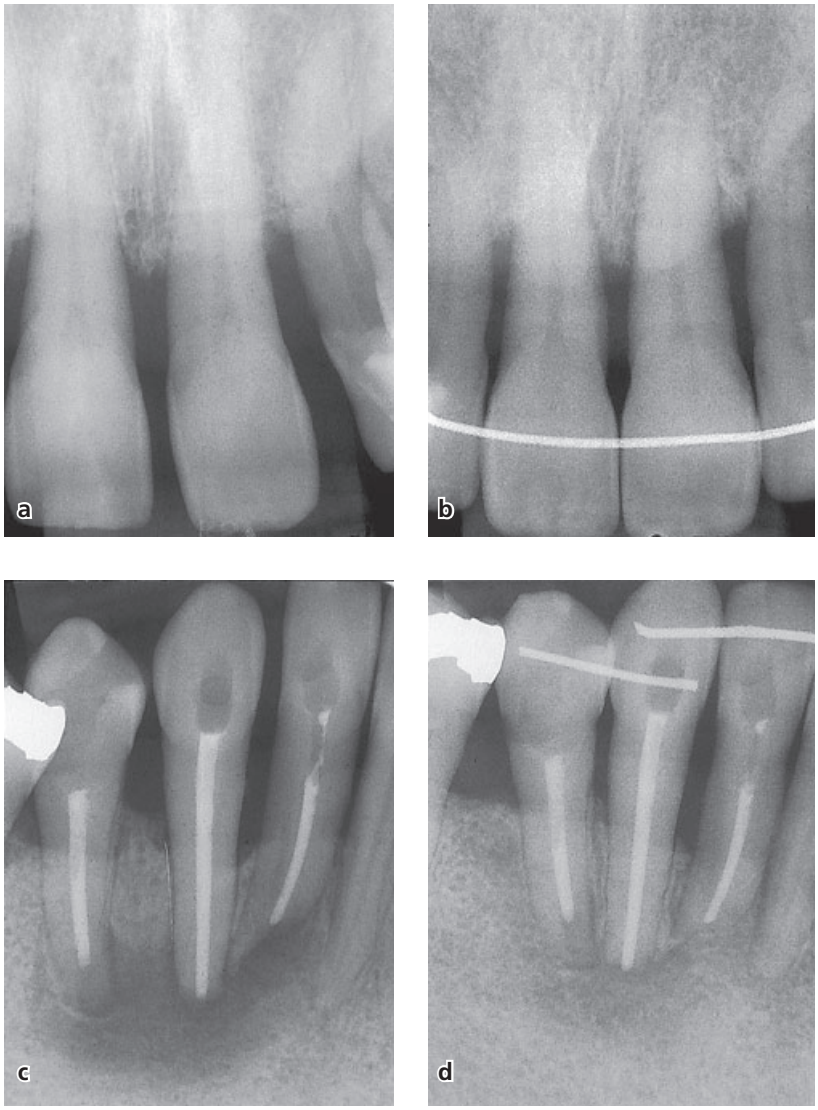

Fig. 57-2 Long-term radiographic follow-up of the same patient as in Fig. 57-1. Radiographs of maxillary and mandibular anterior regions 7 years after the completion of orthodontic therapy (b,d) show reduced but healthy periodontium, with no progression of periodontal tissue destruction compared with the initial situation (a,c).

- Adults were more effective than adolescents in removing plaque, especially late in the orthodontic treatment period.
- Tooth movement in adults with reduced, but healthy, periodontium did not result in significant further loss of attachment (none of the adults had additional mean loss of attachment of more than 0.3 mm).
- Adults with teeth that did *not* have healthy periodontal tissues may experience further breakdown and tooth loss due to abscesses during orthodontic treatment.

In another study by Årtun and Urbye (1988), 24 patients with advanced loss of marginal bone and pathologic tooth migration received active appliance therapy for an average of 7 months, following periodontal treatment. Bone level measurements on radiographs indicated that the majority of sites showed little or no additional loss of bone support. However, a few sites demonstrated pronounced additional bone loss.

More recent studies on much larger groups (350–400 patients) of consecutively treated adult patients from different practices (Nelson & Årtun 1997; Re *et al*. 2000) have confirmed that: (1) pretreatment evidence of periodontal tissue destruction is no contraindication for orthodontics, (2) orthodontic therapy improves the possibilities of saving and restoring a deteriorated dentition, and (3) the risk of recurrence of an active disease process is not increased during appliance therapy. However, these larger samples have indicated that adult orthodontic patients are at a somewhat higher risk than adolescents for tissue breakdown. The mean bone loss on radiographs of the six anterior teeth in the study of Nelson and Årtun (1997) was 0.54 mm (SD 0.62). Only 2.5% of the patients had average bone loss of 2 mm or more, but as many as 36% of these patients had one or more surfaces with bone loss exceeding 2 mm.

Orthodontic treatment considerations

The key element in the orthodontic management of adult patients with periodontal disease is to eliminate, or reduce, plaque accumulation and gingival inflammation. This implies much emphasis on oral hygiene instruction, appliance construction,

Fig. 57-3 Adult female periodontitis patient with pathologic migration of the maxillary incisors before (a,b), during (c–e), and after (f) periodontal and orthodontic treatment. An attempt had been made by the periodontist to grind and splint the overextruded right central incisor with composite resin (b) before orthodontic treatment was started. Due to extensive mesial and distal recontouring of the incisors (stripping) during the treatment (c,d), it was possible to obtain an esthetic final result with almost intact gingival papillae between the incisors in both the maxilla and in the mandible (f).

and periodic check-ups throughout treatment (Zachrisson 1996).

The most appropriate method for tooth movement must be determined in each particular case. Although minor or partial orthodontic treatment with sectional or removable appliances may be possible in some instances, in the majority of cases a fully controlled technique with fixed appliances in both dental arches is preferred in order to carefully control the movement of teeth in three planes.

The orthodontic appliance has to be properly designed. It must provide stable anchorage without causing tissue irritation, and must be esthetically acceptable. For psychologic reasons bonded ceramic brackets are preferred in the most visible regions (Figs. 57-3 to 57-6), generally for the maxillary teeth,

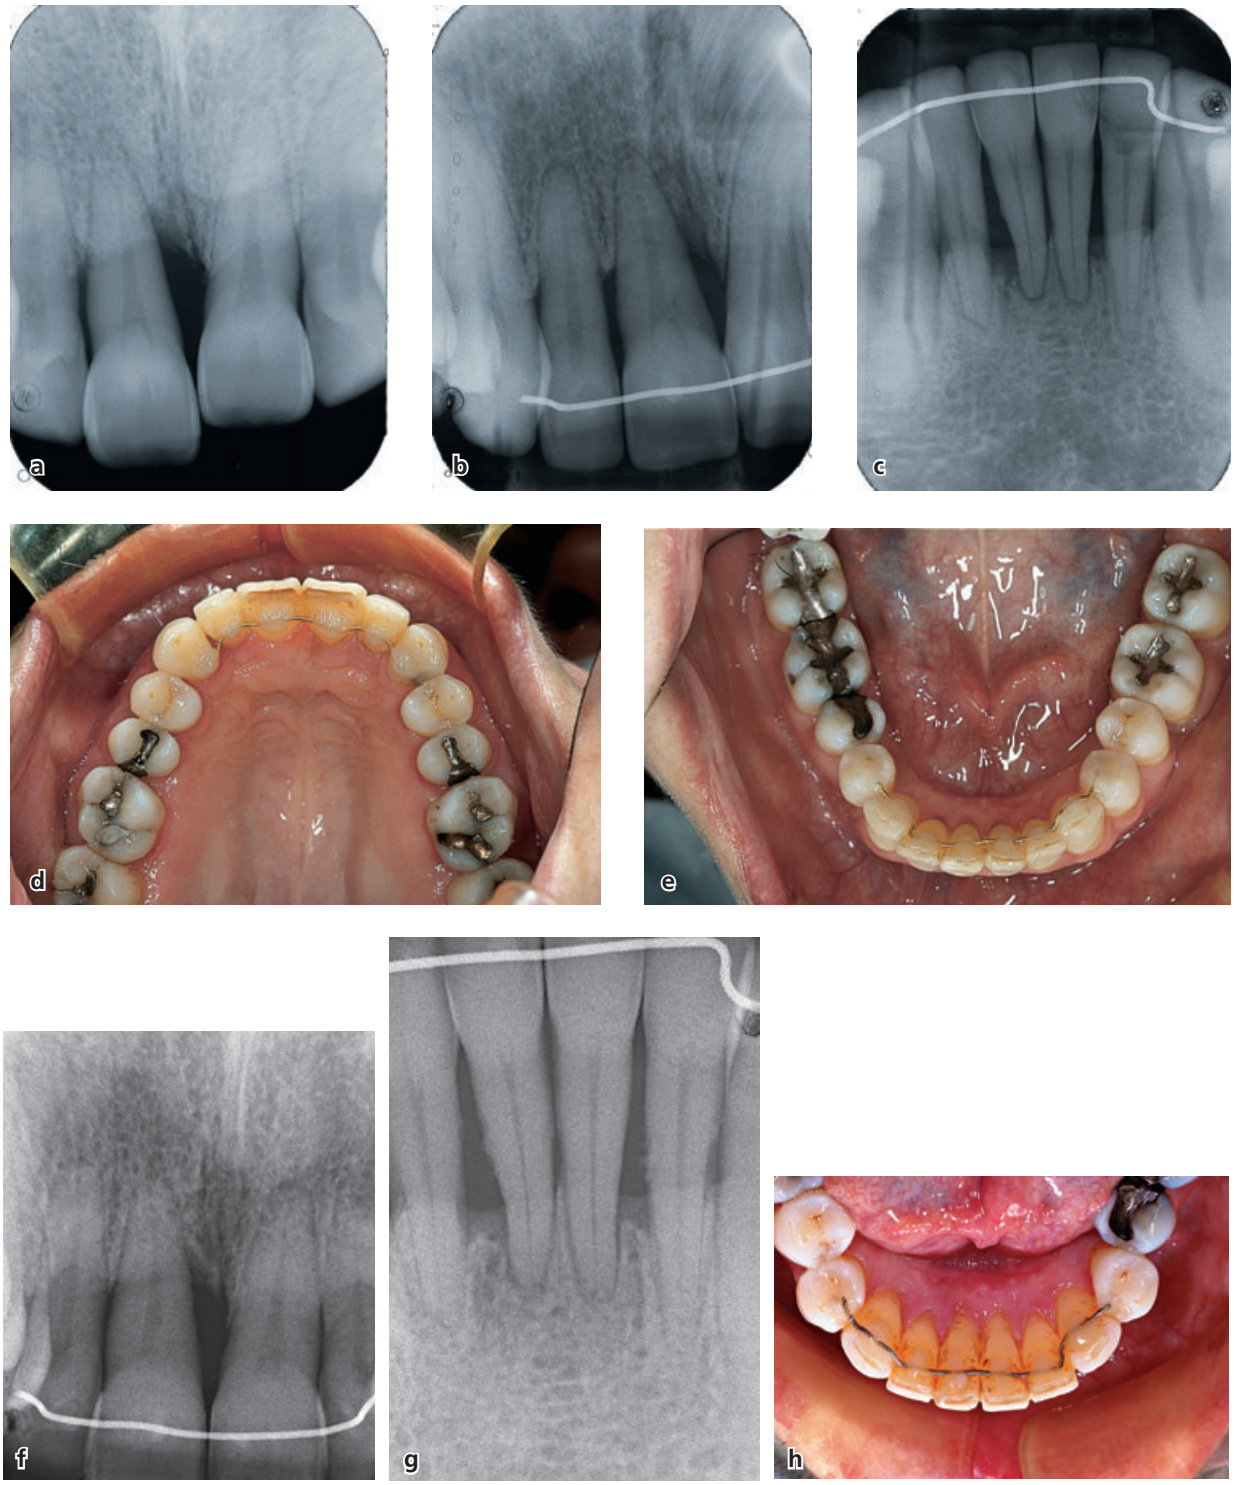

Fig. 57-4 Radiographic and clinical occlusal appearance of the same patient as in Fig. 57-3. No noticeable progression of the periodontal tissue destruction has occurred (compare a and b), and although markedly reduced the periodontium is healthy after the orthodontic therapy (b,c). The treatment result is maintained by means of gold-coated lingual retainers over six maxillary and eight mandibular anterior teeth (d,e).These bonded retainers act as effective orthodontic retainers as well as neat and hygienic periodontal splints. Despite the unfavorable crown–root ratios of particularly the mandibular incisors, the situation is largely unchanged 6 years later (f,g), and the gingival papillae fill in the spaces between the lower anterior teeth nicely (h).

whereas stainless steel or gold-coated attachments are commonly used elsewhere in the mouth (Figs. 57-3, 57-5).

To counteract the tendency of orthodontic appliances to increase the accumulation of plaque on the teeth, attempts should be made to keep the appliances and mechanics simple, and avoid hooks, elastomeric rings, and excess bonding resin outside the bracket bases. The use of steel ligatures is recommended on all brackets (Figs. 57-3 to 57-6), since elastomeric rings have been shown to be significantly more plaque attractive than steel ties (Forsberg *et al*.

Fig. 57-5 Another adult female periodontitis patient with pathologic migration of the maxillary incisors before (a–c), during (d,e), and after (f) periodontal and orthodontic treatment. Despite the advanced periodontal tissue break-down, the case was treated with extraction of two upper first premolars (d). Due to the extensive mesial and distal recontouring of the incisors (stripping) during the treatment (e), it was also possible in this case to obtain an esthetic final result with almost intact gingival papillae between the incisors (h). The clinical and radiographic situation 1.5 years after treatment is shown in g–i. Note gold-coated short labial retainer wires about the closed extraction sites to prevent space reopening (f).

Fig. 57-6 Adult female periodontitis patient with marked loss of the interdental papilla between the maxillary central incisors (a,b). This gap is caused by the "fan-shaped" morphology of the central incisors, which places the interproximal contact too near the incisal edge. To eliminate the unesthetic soft tissue gap, the mesial surfaces of the central incisors were reshaped (c) to lengthen their connector area and move the contact point gingivally (d). After continued orthodontic space closure, a more esthetic final result was achieved (e,f).

1991). Bonds are preferable to bands (Boyd & Baumrind 1992). Bonded molars show less plaque accumulation, gingivitis, and loss of attachment interproximally than banded molars during orthodontic treatment of adults. However, bonding is more complicated in adult patients than in adolescents. Many adults have amalgam restorations and crown-and-bridge restorations made of porcelain or precious metals. Thanks to the introduction of new techniques and materials, it is feasible to bond orthodontic brackets, buccal tubes, and retainer wires to artificial surfaces. Clinical experience with bonding to different artificial tooth surfaces, except gold, is excellent (Zachrisson 2000a,b).

Renewed oral hygiene instruction and motivation is made after placement of the orthodontic appliances. During the treatment period professional tooth cleaning by a dental hygienist or periodontist may be performed at 3-month intervals (Boyd *et al*. 1989; Boyd & Baumrind 1992), or after regular examination updates at 6- and 12-month intervals, depending on the situation. The re-examinations should include recordings of probing depths, mobility, bleeding on probing, suppuration, gingival recessions, bone levels, etc. Professional scaling may be indicated during *active intrusion* of elongated maxillary incisors, since orthodontic intrusion may shift supragingival plaque to a subgingival location (Ericsson *et al*. 1977, 1978). If efforts at maintaining excellent-to-good oral hygiene are unsuccessful, orthodontic treatment should be terminated (Machen 1990).

After appliance removal, reinstruction in oral hygiene measures should be given. Otherwise, subsequent labial gingival recession may be risked due to overzealous toothbrushing, since cleaning is now easier to perform.

Esthetic finishing of treatment results

Adults with a reduced periodontium represent different challenges for orthodontists than adolescents. Worn or abraded teeth, missing papillae and uneven crown lengths are common problems, and it is therefore more difficult to obtain an esthetically optimal appearance of the teeth and gingiva after bracket removal.

Most incisor teeth in adults with malocclusions have more or less worn incisal edges, which represent an adaptation to functional demands. When the axial inclinations and rotations of such incisors are corrected, there is frequently a need for incisal grinding towards a more normal contour. Such grinding can be performed safely as long as the wear is limited, the overbite is adequate, and the patients display enough tooth material in conversation and on smiling. When the abrasion is more significant, however, cooperation with a restorative dentist is generally indicated.

The presence of papillae between the maxillary incisors is a key esthetic factor after orthodontic treatment. Normally, when long-standing crowding with incisor overlap is corrected orthodontically in adults, it is generally not possible to have an intact papilla. This is because the contact point becomes located too far incisally on the triangular crowns that have not had a normal interdental wear pattern. Similarly, in patients with advanced periodontal disease and destruction of the crestal bone between the incisors, the papillae may be absent. This produces unesthetic gaps between the teeth after orthodontics. The best method of correcting this problem is to recontour the mesiodistal surfaces of the incisors during the orthodontic finishing stage (Tuverson 1980). When the diastemata thus created are closed, the roots of the teeth can come closer together. The contact point is lengthened and moved apically, and the papilla can fill out the interdental space more easily (Figs. 57-3, 57-5, 57-6; also see Fig. 57-28).

In patients with high or normal smile lines, the relationship of the gingival margins of the maxillary anterior teeth may be another important factor in the esthetic appearance of the crowns (Kokich 1996a,b). When adult patients have gingival margin discrepancies between adjacent teeth, the orthodontist must determine the proper solution for the problem: orthodontic movement to reposition the gingival margin (see Fig. 57-17) or surgical correction (gingivectomy) to increase the crown length of single or several teeth (see Fig. 57-29).

Retention – problems and solutions; long-term follow-up

Due to the anatomic and biologic differences in tissue reaction between adults and children (Melsen 1991), adults undergoing extensive orthodontic treatment will generally need, at least, a longer period of retention than would an adolescent patient. Also, growth and development no longer take place and cannot aid in changing occlusal levels or in space closure by the eruption of posterior teeth with mesial drift. The space reopening tendency of closed extraction sites in adults can be mitigated by use of labially bonded retainers (Figs. 57-1, 57-5).

The migration of teeth associated with periodontal tissue breakdown around the incisors in adults is usually blamed on inflammatory swelling or the tongue thrust. However, according to Proffit (1978), two major primary factors are involved in the equilibrium which determines the final position of teeth. These are the resting pressures of lip or cheek and tongue, and forces produced by metabolic activity within the periodontal membrane. With an intact periodontium, unbalanced tongue–lip forces are normally counteracted by forces from the periodontal membrane. However, when the periodontium breaks down, its stabilizing function no longer exists and the incisors begin to move. A consequence of this concept would be that persons with advanced periodontal disease and tooth migration would need permanent

retention after the orthodontic correction. For patients with minimum-to-moderate loss of periodontal tissue support, more "normal" retention periods may be sufficient.

The optimal long-term retainer for adults with reduced periodontium is the flexible spiral wire (FSW) retainer bonded lingually on each tooth in a segment. The bonded retainer in the anterior region is generally used together with a maxillary removable plate. The fabrication and long-term evaluation of bonded retainers is described by Dahl and Zachrisson (1991). Figures 57-3, 57-4, 57-5 and 57-20 demonstrate different designs of FSW retainers in the maxilla and the mandible in several patients. At the same time as the FSW retainer works as a reliable, invisible orthodontic retainer, it concomitantly acts as a periodontal splint, which allows the individual teeth within the splint to exert physiologic mobility. As long as the retainer remains intact, small spaces might open up distal to, but not within, the retainer.

Splinting may not be needed for most teeth with increased mobility after periodontal therapy (Ramfjord 1984). However, reduced mobility of teeth after combined periodontal and orthodontic treatment by using a bonded retainer would seem to be of considerable benefit. If a bonded retainer is not used, and instead a removable plate or spring retainer is used at night on a long-term basis, there is a risk for ongoing jiggling of the teeth because of the relapse tendency during the day. Experimental studies in animals indicate that jiggling forces may facilitate the progress of attachment loss in periodontitis, or at least result in more bone resorption. Also, more connective tissue reattachment and bone regeneration may occur around non-jiggled teeth. Monkey experiments have shown that when experimental jiggling of teeth was stopped, a significant gain of alveolar bone occurred (Nyman *et al*. 1982). Similarly, Burgett *et al*. (1992) demonstrated that healing following periodontal therapy may be more advantageous in patients who received occlusal adjustment than in non-adjusted patients.

Long-term follow-up of patients who have received combined periodontal and orthodontic treatment, and have used bonded retainers for several years, demonstrates excellent stability and apparently unchanged, or even improved, periodontal condition (Figs. 57-4, 57-7, 57-8). It should be pointed out, however, that a bonded maxillary retainer must be placed out of occlusion with the mandibular incisors, because biting on a retainer wire will lead to unacceptably high bond failure rates (Årtun & Urbye 1988).

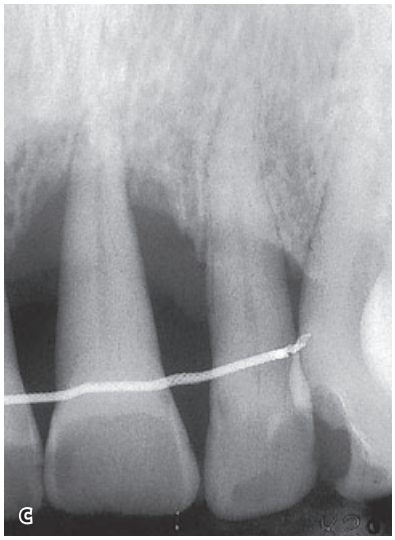
Possibilities and limitations; legal aspects

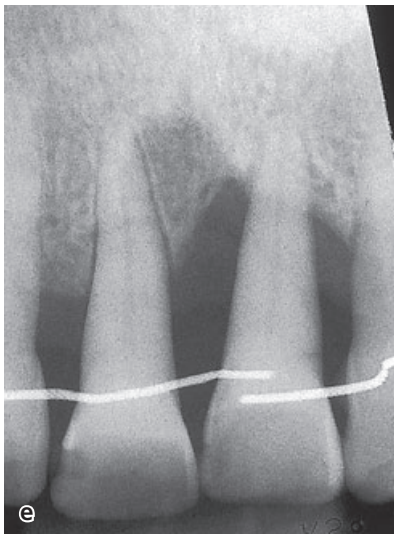
Adult orthodontic patients with marked periodontal destruction may represent potential problems even when optimal treatment is provided. There are, however, no definite metric limits in terms of probing depths or loss of attachment when orthodontic tooth movement can no longer be performed (Diedrich 1999). Each individual treatment plan may depend on a variety of factors and can be limited by biomechanical considerations (force systems, limited anchorage), by periodontal risk factors (tooth/alveolar bone topography, sinus recesses, activity and prognosis of the periodontitis), and by limited patient motivation and poor oral hygiene cooperation.

Single case reports have documented successful periodontal–orthodontic treatment with localized juvenile periodontitis (LJP) after conventional periodontal therapy (Harpenau & Boyd 2000), or with continous antiseptic and short-term systemic (Folio *et al*. 1985) or local (Hoerman *et al*. 1985) antibiotic applications, and microbiologic testing during the orthodontic treatment period to reduce the risk of recurrent disease. However, until more evidence is accumulated, it may seem wise to avoid orthodontic treatment in patients with particularly aggressive forms of periodontal disease. Similarly, multi-rooted teeth with questionable prognosis should be moved orthodontically only in exceptional situations.

"Hopeless teeth": According to old concepts, the retention of teeth diagnosed as periodontally "hopeless" would accelerate the destruction of the adjacent interproximal periodontium. Such teeth were therefore frequently extracted in the past. However, the theoretic rationale for such extractions would seem unsupported, and recent follow-up studies have demonstrated that retained periodontally "hopeless" teeth do not significantly affect the interproximal periodontium of adjacent teeth following periodontal therapy (Chace & Low 1993). The clinical implication is that these teeth can be useful for orthodontic anchorage, if the periodontal inflammation can be controlled (Fig. 57-9). Occasionally, the hopeless tooth may be so improved after orthodontic treatment that it is retained (Mathews & Kokich 1997). Alternatively, a hopeless molar may be hemisectioned after the orthodontic treatment, and the best root may be used as a bridge abutment (Fig. 57-10). Most of the time, however, the hopeless tooth will be extracted, especially if other restorations are planned in the segment.

For improved patient care, stress reduction, and reduction or elimination of law suits, careful examination protocols, documentation and correspondence techniques, and regular progress evaluations are important. The legal implications of orthodontic risk management concepts may be that it is preferable to terminate treatment for patients who fail to improve oral hygiene care, despite the orthodontist's efforts. In the long term, this will be better for both patient and orthodontist, since termination, if properly handled, will be more easily defended than permitting the condition to worsen (Machen 1990). However, if proper procedures are followed, termination of





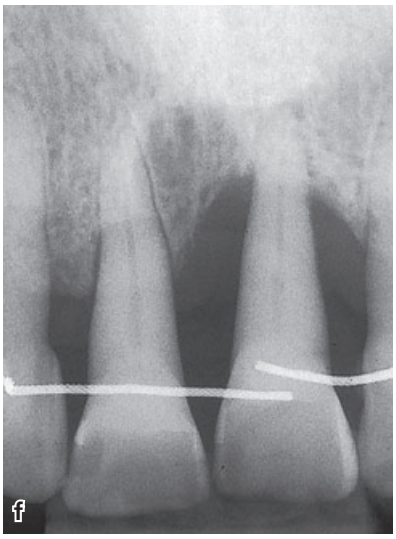


Fig. 57-7 Adult male periodontitis patient after periodontal and orthodontic therapy (a–d). The patient was treated with generalized gingivectomies according to concepts aiming at pocket elimination. The orthodontic result is maintained with a six-unit lingually bonded retainer (d). The bonded wire will act both as an orthodontic retainer and as a periodontal splint, which would appear advantageous in cases where the tissue destruction is as advanced as in this patient. (e) and (f) show the radiographic appearances 7 and 9 years, respectively, after removal of the orthodontic appliances. The left central incisor had so little bone support that if the bonded retainer had not been used, the tooth would probably had been lost over time (see also Fig. 57-8).

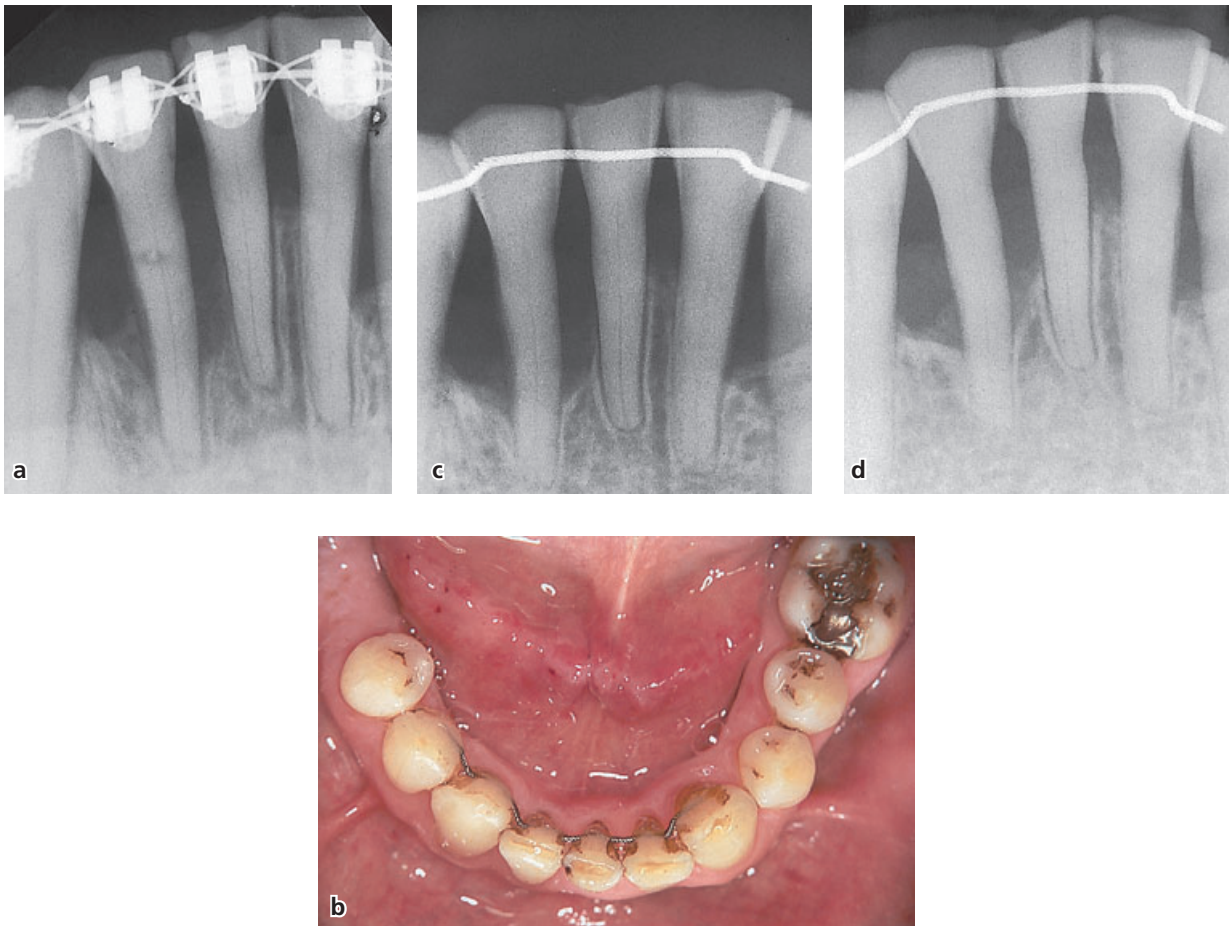

Fig. 57-8 Post-treatment radiographic (a) and clinical (b) appearance of the mandibular dentition in the same patient as in Fig. 57-7 after periodontal and orthodontic treatment. The mandibular six-unit retainer bonded lingual retainer (b) concomitantly acts as a periodontal splint. Note signs of improvement of periodontal condition 7 and 9 years, respectively, after the orthodontic treatment (c,d), with marked crestal lamina dura contours.

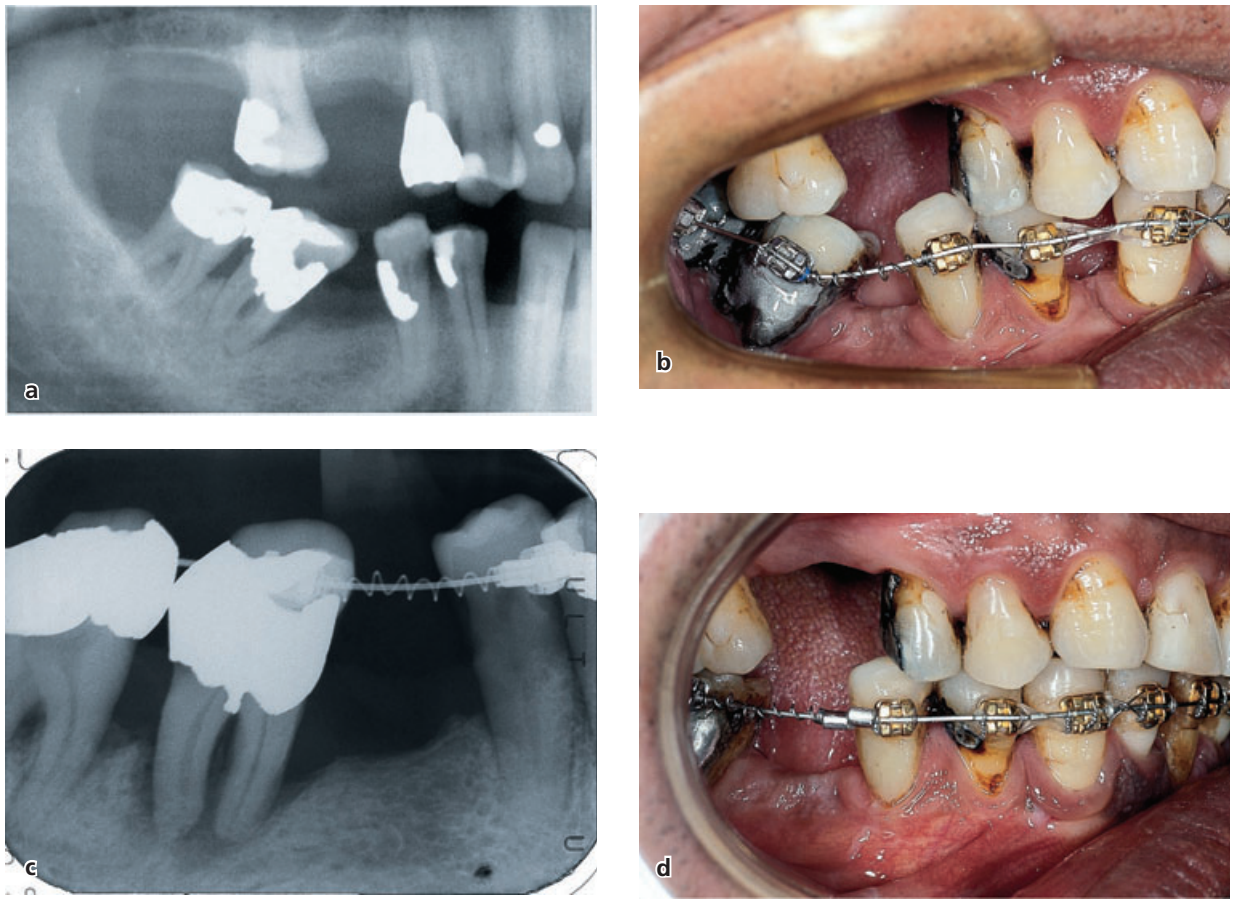

Fig. 57-9 "Hopeless" mandibular right first molar (a) can be used as part of anchorage to move the premolars mesially and upright the second molar (b–d). The first molar may be kept, or extracted, after the orthodontic treatment period.

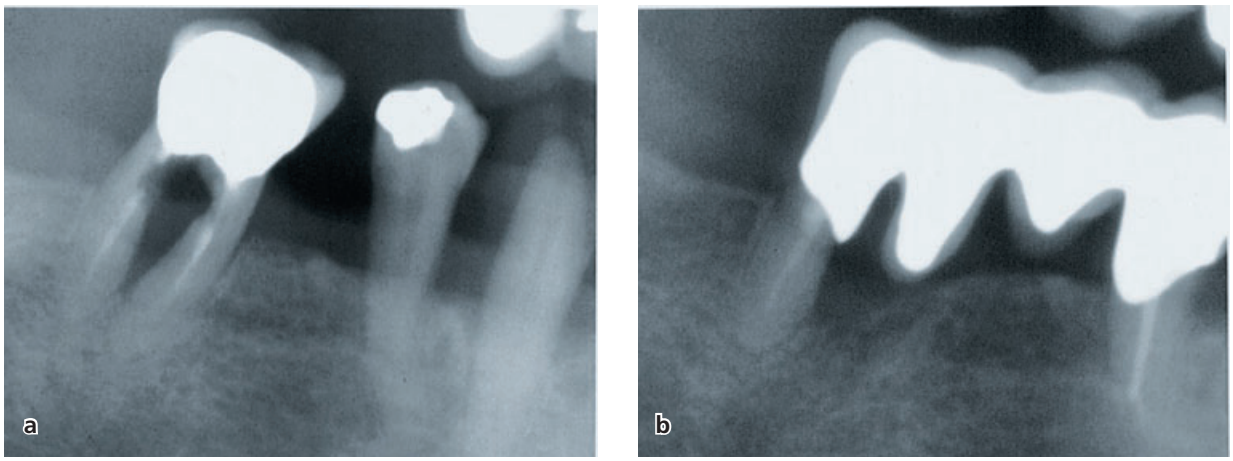

Fig. 57-10 "Hopeless" mandibular right first molar (a) was used as anchorage during orthodontic treatment to close spaces anteriorly, before it was hemisectioned and the distal root employed as a bridge abutment (b).

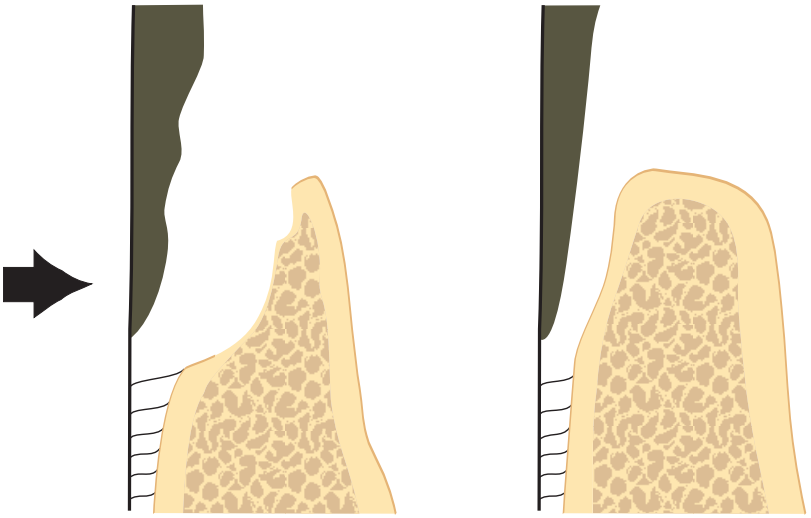

Fig. 57-11 Schematic illustration of persisting junctional epithelium subsequent to orthodontic tooth movement (direction of arrow) into an infrabony pocket.

orthodontic care for periodontal patients will very rarely be needed.

Specific factors associated with orthodontic tooth movement in adults

Tooth movement into infrabony pockets

Orthodontic forces *per se* are unlikely to convert gingivitis into destructive periodontitis. The plaque-induced lesion in gingivitis is confined to the supra-alveolar connective tissue, whereas tissue reactions to orthodontic forces occur in the connective tissue between the root and the alveolar bone. However, infrabony pockets, i.e. angular bony defects with inflamed connective tissue and epithelium apical to the bone crest, may develop as a result of destructive periodontitis. Infrabony pockets may also be created by orthodontic tipping and/or intruding movements of teeth harboring plaque (Ericsson *et al*. 1977). The effect of bodily tooth movement into infrabony defects has been evaluated experimentally in monkeys (Polson *et al*. 1984) and in dogs (Wennström *et al*. 1993). Provided elimination of the subgingival infection was performed before the orthodontic tooth movement was started, no detrimental effects on the attachment level were observed. The angular bony defect was eliminated by the orthodontic treatment, but no coronal gain of attachment was found and a thin epithelial lining covered the root surface corresponding to its pretreatment position (Fig. 57-11). It was therefore concluded that orthodontic tooth movement into infrabony periodontal defects had no favorable effects on the level of connective tissue attachment. However, it was possible to move teeth with reduced *healthy* periodontium without additional attachment loss. If, on the other hand, the orthodontic treatment involved movement of teeth into and through a site with inflammation and angular bone loss, an enhanced rate of periodontal destruction was noted.

Conclusion

Since orthodontic movement of teeth into inflamed infrabony pockets may create a high risk for additional periodontal destruction, and because infrabony pockets are frequently found at teeth that have been tipped and/or elongated as a result of periodontal disease, it is clinically essential that periodontal treatment with elimination of the plaque-induced lesion is performed before orthodontic therapy is begun. It is equally important that excellent oral hygiene is maintained throughout the course of the orthodontic treatment. Following these principles, clinical and radiographic observations confirm that orthodontic treatment can be successfully performed in patients with infrabony pockets resulting from periodontal disease.

Tooth movement into compromised bone areas

Orthodontic tooth movement may sometimes be performed in adults with partially edentulous dentitions (due to agenesis or previous extractions of teeth) and such patients may have a more or less compromised alveolar process. Experimental reports (Lindskog-Stokland *et al*. 1993) and clinical studies (Stepovich 1979; Hom & Turley 1984; Goldberg & Turley 1989; Thilander 1996) have shown that a reduction in vertical bone height is not a contraindication for orthodontic tooth movement towards, or into, the constricted area. Mandibular second molars can be moved mesially through remodeled edentulous first molar areas in adults (Fig. 57-12), with only a limited reduction in vertical bone height, averaging –1.3 mm (Hom & Turley 1984). Space closure is possible also in edentulous maxillary first molar areas, although vertical bone loss and some space reopening can be a complication.

Histologic observations in animal experiments have confirmed that when light forces were applied to move teeth bodily into an area with reduced bone height, a thin bone plate was recreated ahead of the moving tooth (Fig. 57-13) (Lindskog-Stokland *et al*. 1993). The key to moving teeth with bone is direct resorption in the direction of tooth movement, and avoiding hyalinization. Teeth can also be moved with bone into the maxillary sinus (Melsen 1991).

Conclusion

Although the results of clinical experiments and follow-ups are encouraging, provided light forces are used and excellent oral hygiene is maintained, it is probably wise not to stretch the indications for tooth movement into constricted bone areas too far. Marked gingival invaginations are sometimes seen in such areas (Fig. 57-12), and computer tomography analysis and human histologic findings indicate that buccal or lingual bone dehiscences may occur (Diedrich 1996). Such defects are not revealed by conventional radiography. The clinical significance of the gingival clefts and bone dehiscences with regard to relapse tendency and periodontal status is not known. For orthodontic tooth movement into markedly atrophied alveolar ridges, the possibility to acquire new bone by, for example, guided bone regeneration (GBR) procedures should be considered.

Tooth movement through cortical bone

Experimental studies in animals have demonstrated that when a tooth is moved bodily in a labial direction towards and through the cortical plate of the alveolar bone, no bone formation will take place in front of the tooth (Steiner *et al*. 1981; Karring *et al*. 1982). After initial thinning of the bone plate, a labial bone dehiscence is therefore created (Fig. 57-14). Such perforation of the cortical plate can occur during orthodontic treatment either accidentally or because it was considered unavoidable. It may happen, for example, (1) in the mandibular anterior region due to frontal expansion of incisors (Wehrbein *et al*. 1994), (2) in the maxillary posterior region during lateral expansion of cross-bites (Greenbaum & Zachrisson 1982), (3) lingually in the maxilla associated with retraction and lingual root torque of maxillary incisors in patients with large overjets (Ten Hoeve & Mulie 1976), and (4) by pronounced traumatic jiggling of teeth (Nyman *et al*. 1982). The soft tissue reactions accompanying such tooth movements are discussed later in this chapter and in Chapter 51.

Interestingly, however, there is potential for repair when malpositioned teeth are moved back toward their original positions, and bone apposition may take place (Fig. 57-14). Evidently, the soft tissue facial to an orthodontically produced bone dehiscence may contain soft tissue components (vital osteogenic cells) with a capacity for forming bone following repositioning of the tooth into the alveolar process (Nyman *et al*. 1982).

Conclusion

The clinical implication of these observations is encouraging. Bone dehiscences which may occur due to uncontrolled expansion of teeth through the cortical plate may be repaired when the teeth are brought back, or relapse, towards a proper position within the alveolar process, even if this occurs several months later. Similar repair mechanisms may be expected to occur when marked jiggling of teeth is brought under control and stabilized. In the case of buccal cross-bites, the initial discrepancy can apparently be overcorrected with both slow and rapid expansion treatment approaches without causing permanent periodontal injury to the settled occlusion.

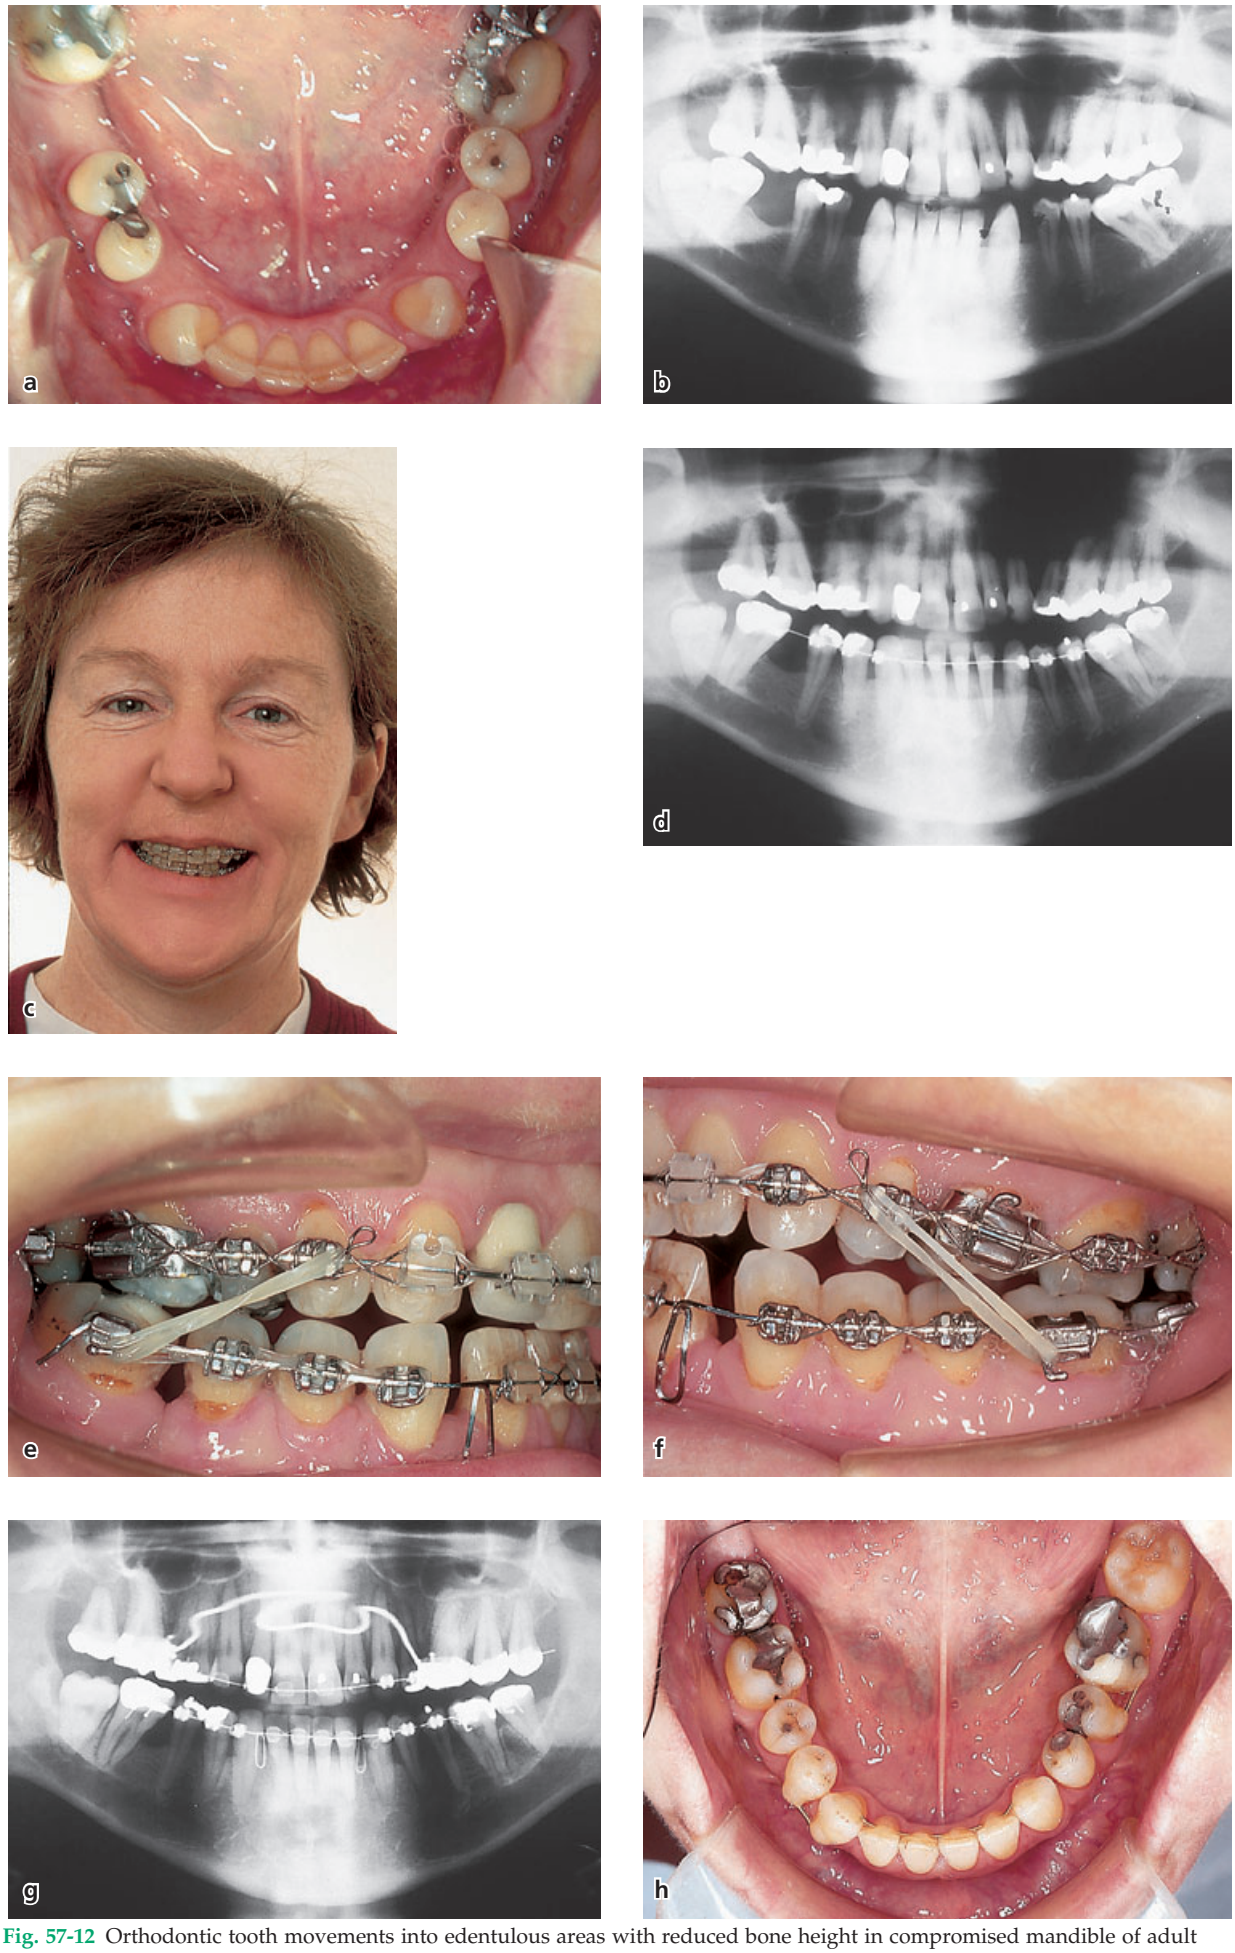

Fig. 57-12 Orthodontic tooth movements into edentulous areas with reduced bone height in compromised mandible of adult female patient. During the orthodontic treatment (c–g), the teeth were moved to close three areas of marked alveolar bone constriction (a,b), most notably in the right first molar area. Note that the impacted third molar erupted spontaneously as the second molar was moved mesially (g). (h) Final result with bonded six-unit lingual and two-unit labial retainers.

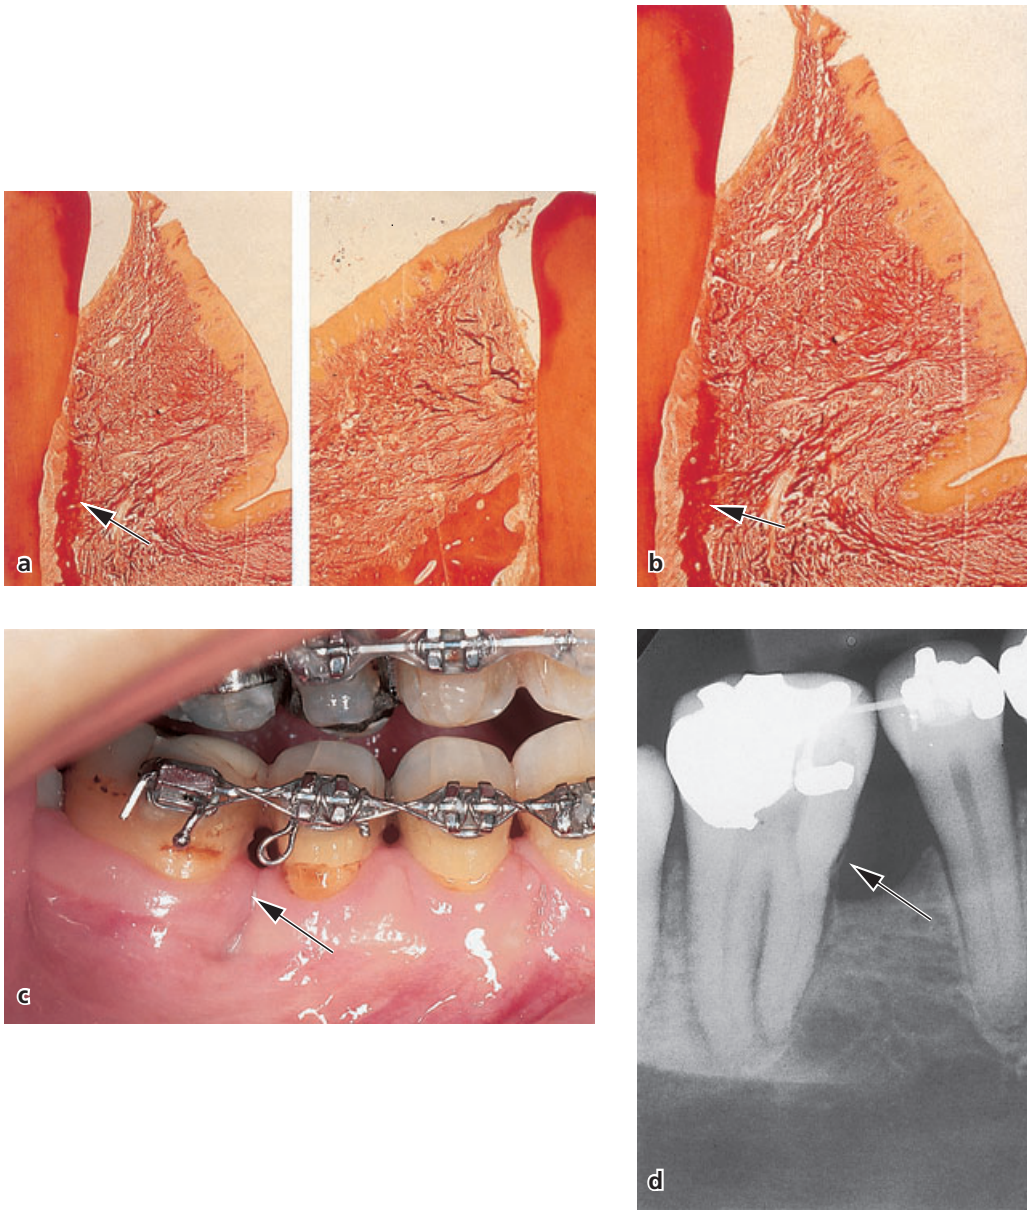

Fig. 57-13 (a,b) Histologic specimens from experimental orthodontic tooth movement into edentulous areas in dogs. The thin bone spicule along the pressure side of the test tooth (b) indicates tooth movement with, and not through, bone. (c,d) The same patient as in Fig. 57-12. Note radiographic visualization of the thin bone spicule on the mesial side of the second molar (arrow in d). Although the molar is moved to contact the second premolar, a marked gingival invagination is present in the area (arrow in c). (a) and (b) from Lindskog-Stokland *et al*. (1993).

Extrusion and intrusion of single teeth – effects on periodontium, clinical crown length, and esthetics

Extrusion

Orthodontic extrusion of teeth, or so-called "forced eruption", may be indicated for (1) shallowing out intraosseous defects and (2) for increasing clinical crown length of single teeth. The forced eruption technique was originally described by Ingber (1974) for treatment of one-wall and two-wall bony pockets that were difficult to handle by conventional therapy alone. The extrusive tooth movement leads to a coronal positioning of intact connective tissue attachment, and the bony defect is shallowed out. This was confirmed in animal experiments (van Venroy & Yukna 1985) and clinical trials. Because of the orthodontic extrusion, the tooth will be in supraocclusion. Hence, the crown of the tooth will need to be shortened, in some cases followed by endodontic treatment.

During the elimination of an intraosseous pocket by means of orthodontic extrusion, the relationship between the CEJ and the bone crest is maintained. This means that the bone follows the tooth during the extrusive movement. This may or may not be beneficial depending on the clinical situation. In other

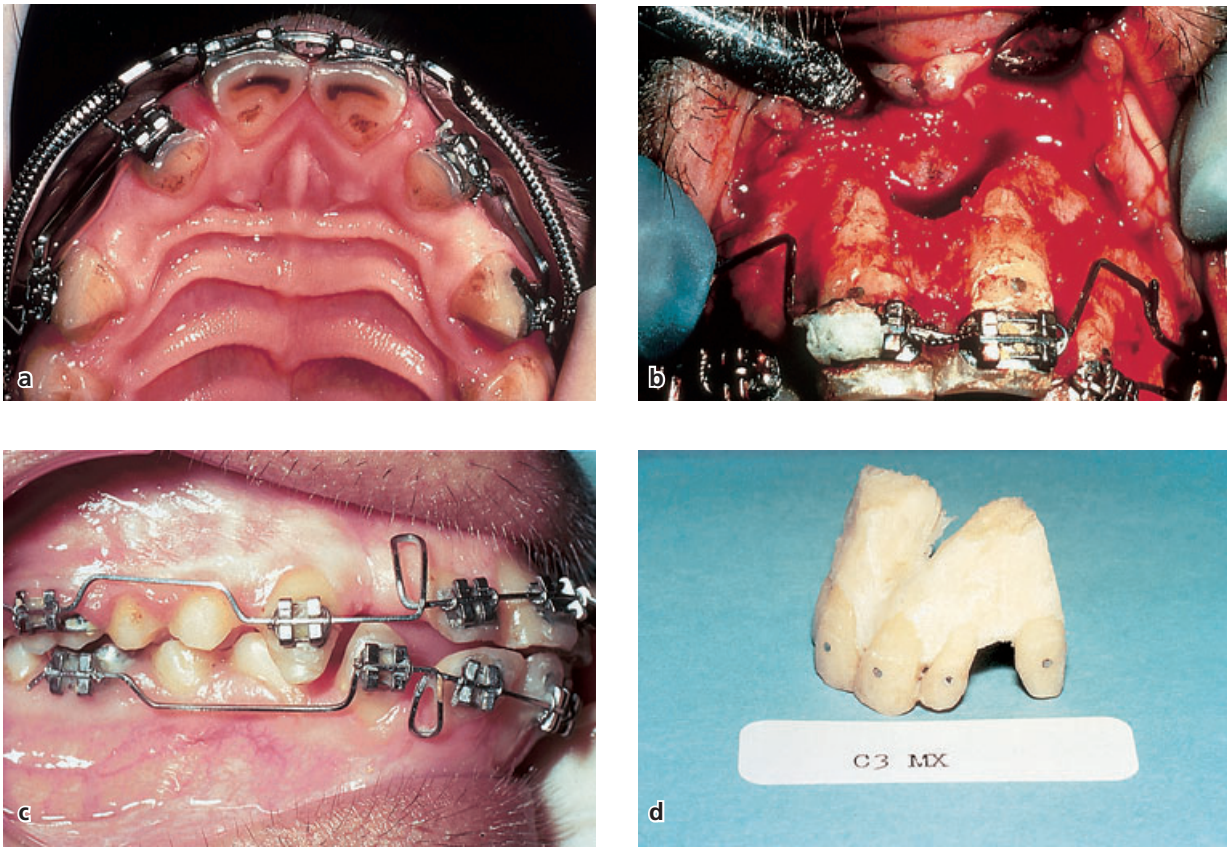

Fig. 57-14 Techniques used by Steiner *et al*. (1981) to advance incisors bodily through the labial bone plate in monkeys (a,b) and by Engelking and Zachrisson (1982) to retract the incisors to their original position (after the teeth had remained in extreme labioversion for 8 months) in a study of periodontal regeneration to such tooth movement. (d) Tissue blocks after tooth repositioning show evident bone regeneration.

words, it is sometimes desirable to have the periodontium follow the tooth and in other situations it is desirable to move a tooth out of the periodontal support. This is further discussed under slow versus rapid eruption of teeth in Chapter 51.

Extrusion with periodontium

Orthodontic extrusion of a single tooth that needs to be extracted is an excellent method for improvement of the marginal bone level before the surgical placement of single implants (Figs. 57-15, 57-21, 57-22). Not only the bone, but also the soft supporting tissues will move vertically with the teeth during orthodontic extrusion. Using tattoo marks in monkeys to indicate the mucogingival junction and clinical sulcus bottom, Kajiyama *et al*. (1993) made a metric evaluation of the gingival movement associated with vertical extrusion of incisors. The results indicated that the free gingiva moved about 90% and the attached gingiva about 80% of the extruded distance. The width of the attached gingiva and the clinical crown length increased significantly, whereas the position of the mucogingival junction was unchanged. Orthodontic extrusion of a "hopeless" incisor is also, therefore, a useful method for esthetic improvement of the marginal gingival level associated with the placement of implants (Fig. 57-22).

Extrusion out of periodontium

In teeth with crown–root fracture, or other subgingival fractures, the goal of treatment may be to extrude the root out of the periodontium (Figs. 57-16, 57-17), and then provide it with an artificial crown. When an increased distance between the CEJ and the alveolar bone crest is aimed at, the forced eruption should be combined with gingival fiberotomy (Pontoriero *et al*. 1987; Kozlowsky *et al*. 1988). In animal experiments, Berglundh *et al*. (1991) showed that when the fiberotomy (i.e. excision of the coronal portion of the fiber attachment around the tooth) was performed frequently (every 2 weeks), the tooth was virtually moved out of the bony periodontium, without affecting the bone heights or level of the marginal gingiva of the neighboring teeth. This procedure is illustrated in Fig. 57-17.

Intrusion

Similar to the indications for extrusion, the orthodontic intrusion of teeth has been recommended (1) for teeth with horizontal bone loss or infrabony pockets, and (2) for increasing the clinical crown length of single teeth. However, the benefits of intrusion for improvement of the periodontal condition around teeth are controversial.

Fig. 57-15 (a,b) Adult female patient with evidence of local severe periodontal tissue breakdown before treatment. The bone loss is particularly pronounced on the mandibular right second premolar (g) and canine (j), whereas the bone support for the first premolar is much better (g,j). The treatment plan included slow orthodontic extrusion of the second premolar and canine to regenerate an improved vertical alveolar bone height prior to the placement of implant-supported restorations. Brackets were placed in a gingival location on the teeth to be extruded (c) and leveling was started with super-elastic rectangular arch-wires. After removal of the pulp, the crowns of the teeth to be extruded were ground with diamond instruments to avoid jiggling with the teeth in the opposing arch (c). A cantilever spring was added for the canine. After 10 months, the leveling was completed (d) and the extruded teeth were extracted with forceps (e). Note the even bone levels (e) and compare with the initial situation (b). A remarkable amount of bone build-up is seen on the radiographs at 10 months of leveling (h,k) before insertion of the implants. A comparison of the final bone heights relative to the cemento-enamel junctions of the neighboring teeth with the initial situation reveals that a significant portion of the bone support for the well integrated implants has been created by the slow vertical tooth movements. The clinical and radiographic situation at the 3-year follow-up is shown in f, i and l.

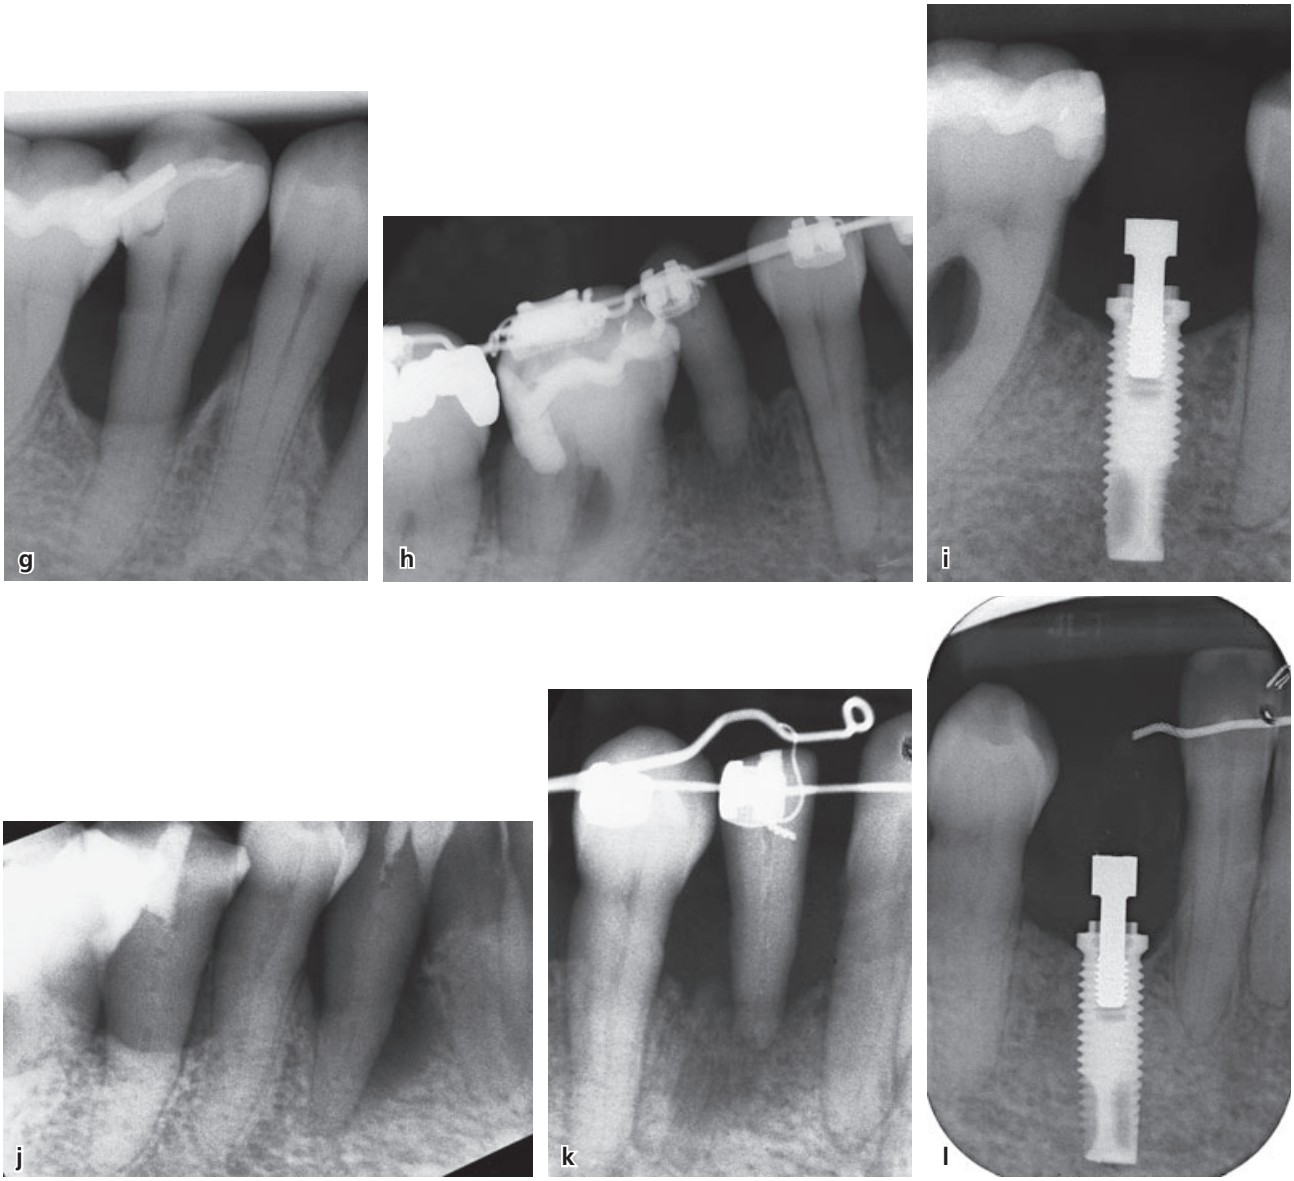

Fig. 57-15 *Continued*

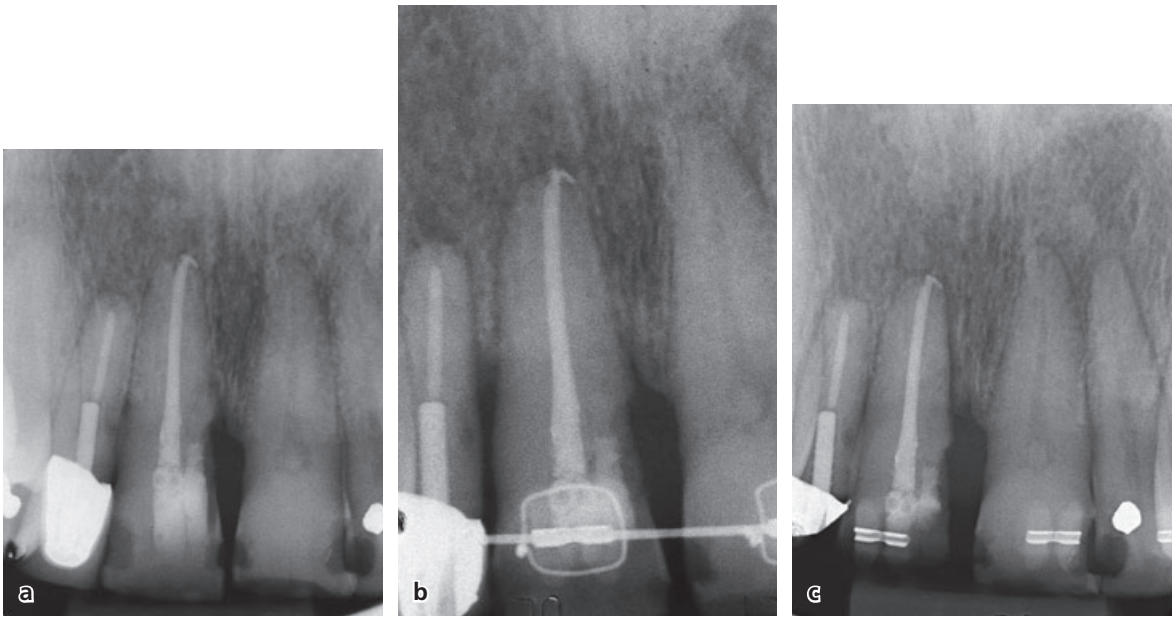

Fig. 57-16 (a) Extrusion out of the periodontium of central incisor with deep crown-root fracture. Rapid extrusion with continuous orthodontic force combined with fiberotomy every 2 weeks. The amount of extrusion can be evaluated by comparing the root ends of the incisors in a–c. (b) The situation after 1.5 months of extrusion. (c) After 4 months, the fracture line was moved from a location below the bone level (a) to a position well above it (c), and the incisor could now be properly restored.

Fig. 57-17 Extrusion out of periodontium. Due to subgingival crown-root fracture on the maxillary right lateral incisor (a,d), this tooth was extruded out of the periodontium with continuous force (a,b) and fiberotomy was performed with 2-week intervals. The amount of extrusion is evident by comparison of the relationship between lateral and central incisor root ends in (e) and (f). Having moved the fracture line to a supragingival position (arrow in c), the tooth could be safely restored. (d) The clinical situation 4 years after treatment.

As mentioned, the intrusion of plaque-infected teeth may lead to the formation of angular bony defects and increased loss of attachment. When oral hygiene is inadequate, tipping and intrusion of the teeth may shift supragingivally located plaque into a subgingival position, resulting in periodontal destruction (Ericsson *et al*. 1977, 1978). This explains why professional subgingival scaling is particularly important during the phase of active intrusion of elongated, tipped, and migrated maxillary incisors commonly occurring in association with advanced periodontal disease. Even in a healthy periodontal environment the question remains as to whether the orthodontic tooth movement intrudes a long epithelial attachment beneath the margin of the alveolar bone or whether the alveolar crest is continously resorbed in front of the intruding tooth.

Histologic (Melsen 1986; Melsen *et al*. 1988) and clinical (Melsen *et al*. 1989) studies indicate that new attachment is possible associated with orthodontic intrusion of teeth. In monkey experiments, periodontal tissue breakdown was induced and intrusion along the axis of the incisors with light forces was initiated following flap surgery. Histologic analysis

showed new cementum formation and connective tissue attachment on the intruded teeth, by an average of 1.5 mm, provided a healthy gingival environment was maintained throughout the tooth movement. The increased activity of periodontal ligament cells and the approximation of formative cells to the tooth surface was suggested to contribute to the new attachment. In the clinical study, the periodontal condition was evaluated following the intrusion of extruded and spaced incisors in patients who had advanced periodontal disease. Judging from clinical probing depths and radiography, there was a beneficial effect on clinical crown lengths and marginal bone levels in many cases, despite large individual variation.

However, the reported clinical and histologic findings associated with a combined orthodontic–periodontal approach must be assessed with great caution, and these findings have not been confirmed by others. Furthermore, new techniques like guided tissue regeneration (GTR) and other regenerative procedures (see below) would appear to be more promising when it comes to creation of new attachment.

Similar to the case with extrusion, metric and histologic studies have been made after experimental intrusion of teeth in monkeys. According to Murakami *et al*. (1989), the gingiva moved only about 60% of the distance when the teeth were intruded with a continuous force of 80–100 g. However, Kokich *et al*. (1984) recommended an interrupted, continuous force for levelling of gingival margins on supraerupted teeth (Fig. 57-18).

The key to understanding why intrusion can be used to increase clinical crown length is related to the subsequent restorative treatment. When orthodontic intrusion is used for levelling of the gingival margins to desired heights, such teeth must then be provided with porcelain laminate veneers or crowns (Fig. 57-18).

Fig. 57-18 (a) Adult female patient in whom the clinical crown length of the maxillary right central incisor was shorter than that of the left central incisor. Because the sulcular depths were normal, the crown lengths were corrected by orthodontic intrusion of the right central incisor (b) and restoring the incisal edge (b) with enamel-bonded ultrathin porcelain laminate veneer (c,d). The alignment and correction of the crown length discrepancy has improved the esthetic appearance of the dentition. Restoration courtesy of Dr. S. Toreskog.

Regenerative procedures and orthodontic tooth movement

The development of barrier membranes to prevent cells of the epithelium and gingival connective tissue from colonizing the decontaminated root surface, as well as the use of Emdogain®, would appear to provide a distinct improvement in orthodontic therapy in the periodontally compromised patient. New supracrestal and periodontal ligament collagen fibers may be gained on the tension side, which can transfer the orthodontic force stimulus to the alveolar bone (Diedrich 1996). In theory, the regenerative techniques would be advantageous associated with both extrusion and intrusion of teeth with infrabony defects, and for uprighting of tipped molars with mesial angular lesions. Moreover, if the epithelium can be prevented from proliferating apically, a bodily tooth movement into or through an intraosseous defect could eliminate the bony pocket more effectively than in the past (Fig. 57-11).

So far, however, relatively little clinical information is available about the use of different regenerative procedures in connection with orthodontic treatment. Diedrich (1996) reported an experiment in dogs in which orthodontic intrusion with flap surgery and GTR were compared with flap surgery alone on periodontally affected teeth. In the presence of minimal or no round cell infiltration, the marking notch was located beneath the alveolar margin indicating that new attachment had formed. The potential of the intrusive/regenerative mechanism was most impressive within the inter-radicular area. Some clinical observations (Nemcovsky *et al*. 1996; Stelzel & Flores-de-Jacoby 1998; Rabie *et al*. 2001) confirm that different regenerative procedures may enrich the therapeutic spectrum in combined periodontal/orthodontic approaches (Fig. 57-19). The combined regenerative and periodontal surgical treatments used together with orthodontic tooth movements create new perspectives and should be an interesting field for further experiments on adults with severe loss of periodontal tissues.

However, other clinical trials have demonstrated that treatment results with barrier membranes in the GTR technique may vary between different patients and that the method is operator and technique sensitive (Leknes 1995). The patient's oral hygiene during the healing phase is critical, and inflammation around the membrane, particularly if it becomes exposed and contaminated, may lead to discouraging clinical results with marked gingival retraction.

Since the membrane is covered in the GBR technique, the risk for inflammation is reduced. The possibility for orthodontic movement of teeth into alveolar processes with deficient bone volume may

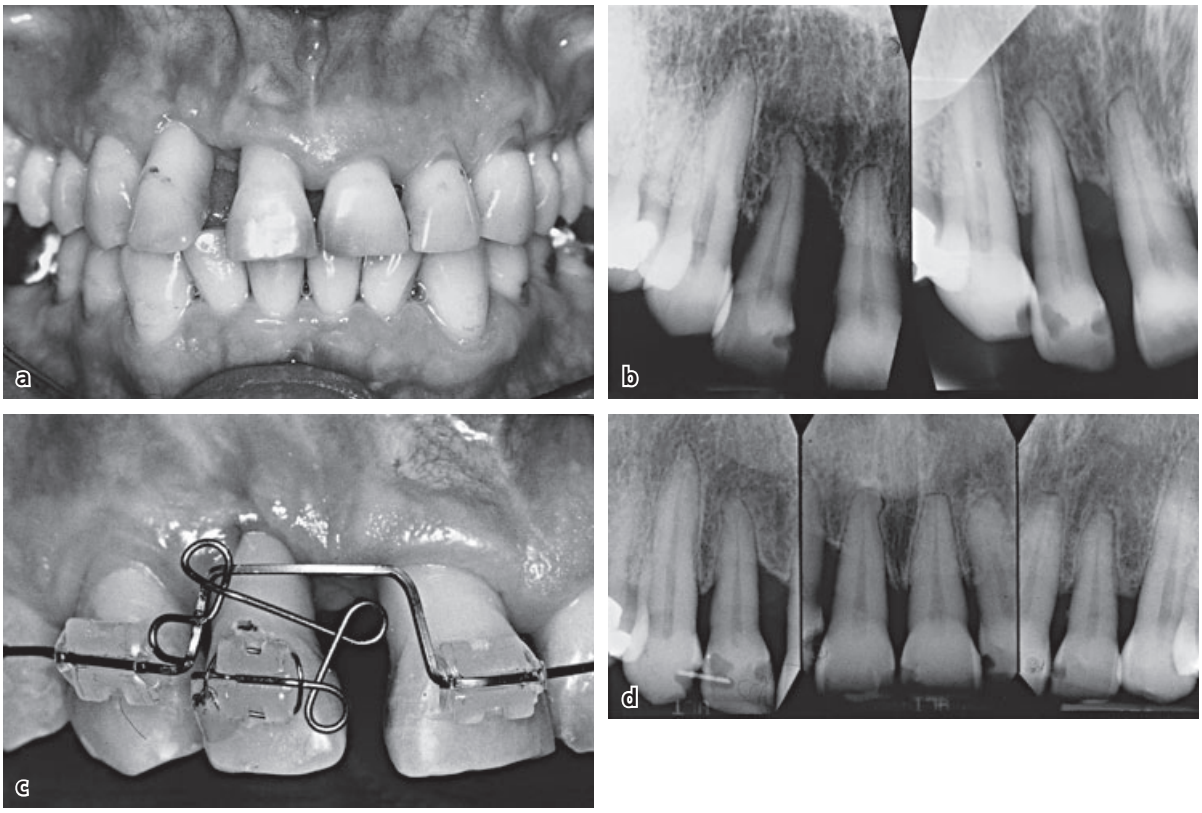

Fig. 57-19 (a) Pathologic tooth migration as a result of an advanced periodontal lesion in adult female patient. (b) Severe intraosseous defect between the right central and lateral incisors. (c) Three months after GTR treatment (GoreTex membrane) partial reossification is evident, possibly with new attachment. (d) Orthodontic leveling with controlled space closure and intrusion of the lateral incisor. (e) Result 6 months after orthodontic tooth movements shows no root resorption and a consolidated alveolar crest. From Diedrich (1996).

thus be improved (Basdra *et al*. 1995). Preorthodontic GBR of markedly constricted alveolar ridges also has the advantage that tooth movement through cancellous bone is easier, and the formation of interfering gingival invaginations can be reduced.

Traumatic occlusion (jiggling) and orthodontic treatment

As discussed in Chapter 14, the role of occlusal trauma in periodontal treatment has not been determined. From an orthodontic perspective, it is of interest that several studies indicate that traumatic occlusion forces (1) do not produce gingival inflammation or loss of attachment in teeth with healthy periodontium, (2) do not aggravate and cause spread of gingivitis or cause loss of attachment in teeth with established gingivitis, (3) may aggravate an active periodontitis lesion, i.e. be a co-destructive factor in an ongoing process of periodontal tissue breakdown (in one way or another favor the apical proliferation of plaque-induced destruction), and (4) may lead to less gain of attachment after periodontal treatment – non-surgical or surgical.

A major problem in this regard is the lack of established and reliable criteria to identify and quantitate different degrees of traumatic occlusion. Various clinical and radiographic indications, such as unfavorable crown/root ratio, increased tooth mobility, widened periodontal ligament space, angular bone loss, alterations in root morphology, etc. are uncertain and insufficient in diagnosis of occlusal trauma, and there have been few scientific clinical reports to evaluate these signs (Jin & Cao 1992).

The extent to which it is necessary to avoid, or reduce, occlusal trauma during orthodontic treatment is controversial and unsupported by scientific evidence. Some orthodontists use bite-planes in virtually every periodontal case with bone deformities, to reduce occlusal trauma and for the purpose of shallowing the bony defects, as teeth supra-erupt. However, independent studies have shown that surgical pocket elimination including bone sculpturing offers no advantage compared with more conservative periodontal treatment (Ramfjord 1984), and apparently there is little need to shallow or eliminate bony deformities. It would still appear sensible to avoid gross interferences, like raising the bite when a maxillary incisor in lingual inversion is moved over the mandibular teeth, and to mitigate evident occlusal interferences on single teeth with markedly increased mobility. However, it may be a futile exercise to try and eliminate all occlusal trauma during active tooth movement, and a more practical solution is to concentrate on controlling the inflammation. After appliance removal, however, occlusal adjustment by selective grinding may be required. Even though good occlusal function is part of the orthodontic treatment goal, correct cusp–fossa relationships cannot always be achieved in adults with orthodontic therapy alone. In general terms, the adjustment should be directed toward obtaining even and stable tooth contacts in centric relation, a straight forward slide from centric relation to centric occlusion without any side shifts or lateral deviation, freedom in centric, smooth gliding contacts in centric and eccentric mandibular motion, and elimination of balancing side interferences (Burgett *et al*. 1992).

The importance of reducing jiggling of teeth *after* orthodontic treatment of patients with moderate to advanced periodontitis may be significant: (1) tooth mobility generally increases with loss of support for the teeth, (2) animal experiments have shown that bone dehiscences produced by jiggling forces will regenerate after elimination of the jiggling trauma, and (3) occlusal adjustment may be a factor in the healing of periodontal defects, especially bony defects, after periodontal treatment. Therefore, the bonded orthodontic retainers, which stabilize the teeth, may secure optimal conditions for improved periodontal healing and bone regeneration after the orthodontic treatment period (Figs. 57-5, 57-7, 57-8). In fact, long-term follow-ups of orthodontic patients with advanced periodontal tissue breakdown may demonstrate better periodontal conditions, with marked crestal lamina dura contours, many years after appliance removal than at the end of the orthodontic treatment (Figs. 57-7, 57-8). If bonded retainers had not been used in many such cases, the most affected teeth would probably have been lost with time.

Molar uprighting, furcation involvement

The problem of mesially tipped mandibular molars because of non-replacement of missing first molars has been the subject of many anecdotal reports over the past 30 years. Tipped molars have been considered a causative or at least an aggravating factor for future periodontal tissue breakdown. However, Lundgren *et al*. (1992) recently observed that 73 molars that had remained in a markedly tipped position for at least 10 years, with most molars having been tipped for as long as 20–30 years, did not constitute an increased risk for initiation or aggravation of moderate periodontal disease at their mesial surface. The study did not consider the potential risk for aggravation of already established advanced periodontitis lesions. This lack of correlation may not exclude other indications for molar uprighting, such as functionally disturbing interferences, paralleling or space problems associated with prosthetic rehabilitation, or traumatic occlusion.

In this context it must be emphasized that the apparent angular bone loss along the mesial surface of tipped molars may be illusive and solely represent an anatomic variation, since lines drawn from the adjacent cemento-enamel junctions appear to parallel the alveolar crest (Ritchey & Orban 1954). While uprighting such a tooth appears to cause a shallow-

ing-out of the angular defect, with new bone forming at the mesial alveolar crest, it may merely reflect the inclination of the molar relative to the alveolar bone, and the attachment level remains unchanged. When there is a definite osseous defect caused by periodontitis on the mesial surface of the inclined molar, uprighting the tooth and tipping it distally will widen the osseous defect. Any coronal position of bone may be due to the extrusion component of the mechanotherapy.

Furcation defects generally remain the same or get worse during orthodontic treatment. For example, if tipped molars have furcation involvement before orthodontic uprighting, simultaneous extrusion may increase the severity of the furcation defects, especially in the presence of inflammation (Burch *et al*. 1992). Hence, initial periodontal therapy and maintenance is essential. The mandibular molar can be split into two roots, one or both of which may be kept and moved orthodontically into new positions. However, this is difficult treatment (Müller *et al*. 1995).

In a thorough study of periodontal conditions around tipped mandibular molars before prosthetic replacement, Lang (1977) reported that after completion of the hygiene phase, significant pocket reduction (mean 1.0 mm) was noted on all surfaces. In addition, a further significant reduction in pocket depth (mean 0.6 mm), associated with a gain of clinical attachment (mean 0.4 mm), was found on the mesial and lingual aspects of the molars as a result of the orthodontic uprighting. He concluded that uprighting of tipped molars is a simple and predictable procedure, provided excellent plaque control is maintained.

Kessler (1976), on the other hand, stated that uprighting of mesially inclined molars is not a panacea, and showed some cases in which evident bone loss and furcation involvement developed during the orthodontic uprighting procedure. Because of the furcation involvement and increased mobility, these teeth were no longer considered suitable as abutments, although they were properly uprighted. Radiographic indications that furcation involvement may develop between the roots at the end of orthodontic molar uprighting is evident also in other studies, even when extrusive movement of the tipped molars has been avoided (Diedrich 1989). However, it is not unlikely that this radiolucent area reflects immature bone.

Conclusion

As risks may be involved in orthodontic uprighting of mesially tipped molars in cases with periodontal lesions along their mesial surface, or with furcation involvement, the indications for molar uprighting must be apparent. Excellent oral hygiene is required during the orthodontic treatment, with careful consideration of the force distribution, and avoiding extrusion as much as possible. The developments of regenerative techniques may make it possible in the future to obtain better outcomes in orthodontic therapy of periodontally compromised patients.

Tooth movement and implant esthetics

Osseointegrated implants may be used (1) to provide anchorage for orthodontic tooth movement and later serve as abutments for restorative treatment, and (2) to replace single missing teeth. The use of implants as anchors for orthodontic treatment is discussed in Chapter 58, and will not be dealt with here.

It is difficult to achieve esthetically satisfactory results with artificial crowns on single-tooth implants, and the orthodontist may play a role in the interdisciplinary treatment planning team of specialists. There are at least three areas where orthodontics may be considered:

- Redistribution of the available space in the dental arch when tooth positions for implant placement are not optimal
- Orthodontic ridge augmentation by vertical tooth movement
- Orthodontic ridge augmentation by horizontal tooth movement.

Redistribution of space

Orthodontic movement of neighboring teeth to optimal positions is often required in association with placement of implants substituting missing maxillary central or lateral incisors (Spear *et al*. 1997). Another common indication is a lack of adequate space for the implant. Figure 57-20 illustrates a typical case with small spaces between the teeth and not enough room to place implants in the maxillary and mandibular first premolar regions.

Ridge augmentation – vertical movement

During selective orthodontic extrusion of one single tooth, both the alveolar bone and the soft periodontal tissues will follow the extruded tooth in an incisal direction, as discussed under forced eruption earlier in this chapter. By this means, it is possible to significantly improve the periodontal tissue esthetics associated with fabrication of prosthetic crowns on single implants (Figs. 57-21, 57-22). The technique of "orthodontic extraction" of a hopeless incisor or molar (Salama & Salama 1993; Zuccati & Bocchieri 2003) may be useful to improve the results for single-tooth implants in patients in whom one or more teeth are to be extracted. Following progressive grinding of the extruded tooth to prevent it from jiggling (Figs. 57-21, 57-22), new periodontal tissues are generated that provide improved conditions for the implant, after extraction of the extruded tooth (Fig. 57-21). Upon extruding a tooth, the periodontal ligaments are pulled away from the bone and thus transfer

Fig. 57-20 Typical orthodontic space reopening before insertion of two implants in the second and third quadrant in an adult female patient (a–f). Note the lingually tipped maxillary and mandibular incisors and the small spaces before treatment (a,b). Continuous force from push-coils (c) was used to open adequate space for the implants in the first premolar regions in both dental arches (d–f).

mechanical strain to cells in the bone. A series of mechano-transduction mediators (Indian hedgehog), are expressed and lead to bone formation (Tang *et al*. 2004). The type of bone formed initially is the "emergency type of bone" with type III collagen (Chayanupatkul *et al*. 2003; Tang *et al*. 2004). This bone is somewhat weak because the cross-links between the collagen fiber matrix are weak. It takes about 6 months to mature to the more stable type I collagen (Chayanupatkul *et al*. 2003). The stable type of bone may accept an implant without showing relapse. The stability of the newly formed bone can thus be influenced by whether the clinician allows the newly formed bone to remodel to the more stable bone. It is conceivable that the time periods for the extrusion and the observation time before implant insertion should be at least 6 months for the newly formed bone to mature into more stable bone (Figs. 57-21, 57-22). To allow for rest periods in between the activations, an interrupted continuous force is recommended, by using small step bends in the arch-wires (Figs. 57-21b,c, 57-22d).

Ridge augmentation – horizontal movement

If an implant cannot be placed because of reduced bucco-lingual ridge thickness after a previous extraction, one option is to move a premolar into the eden-

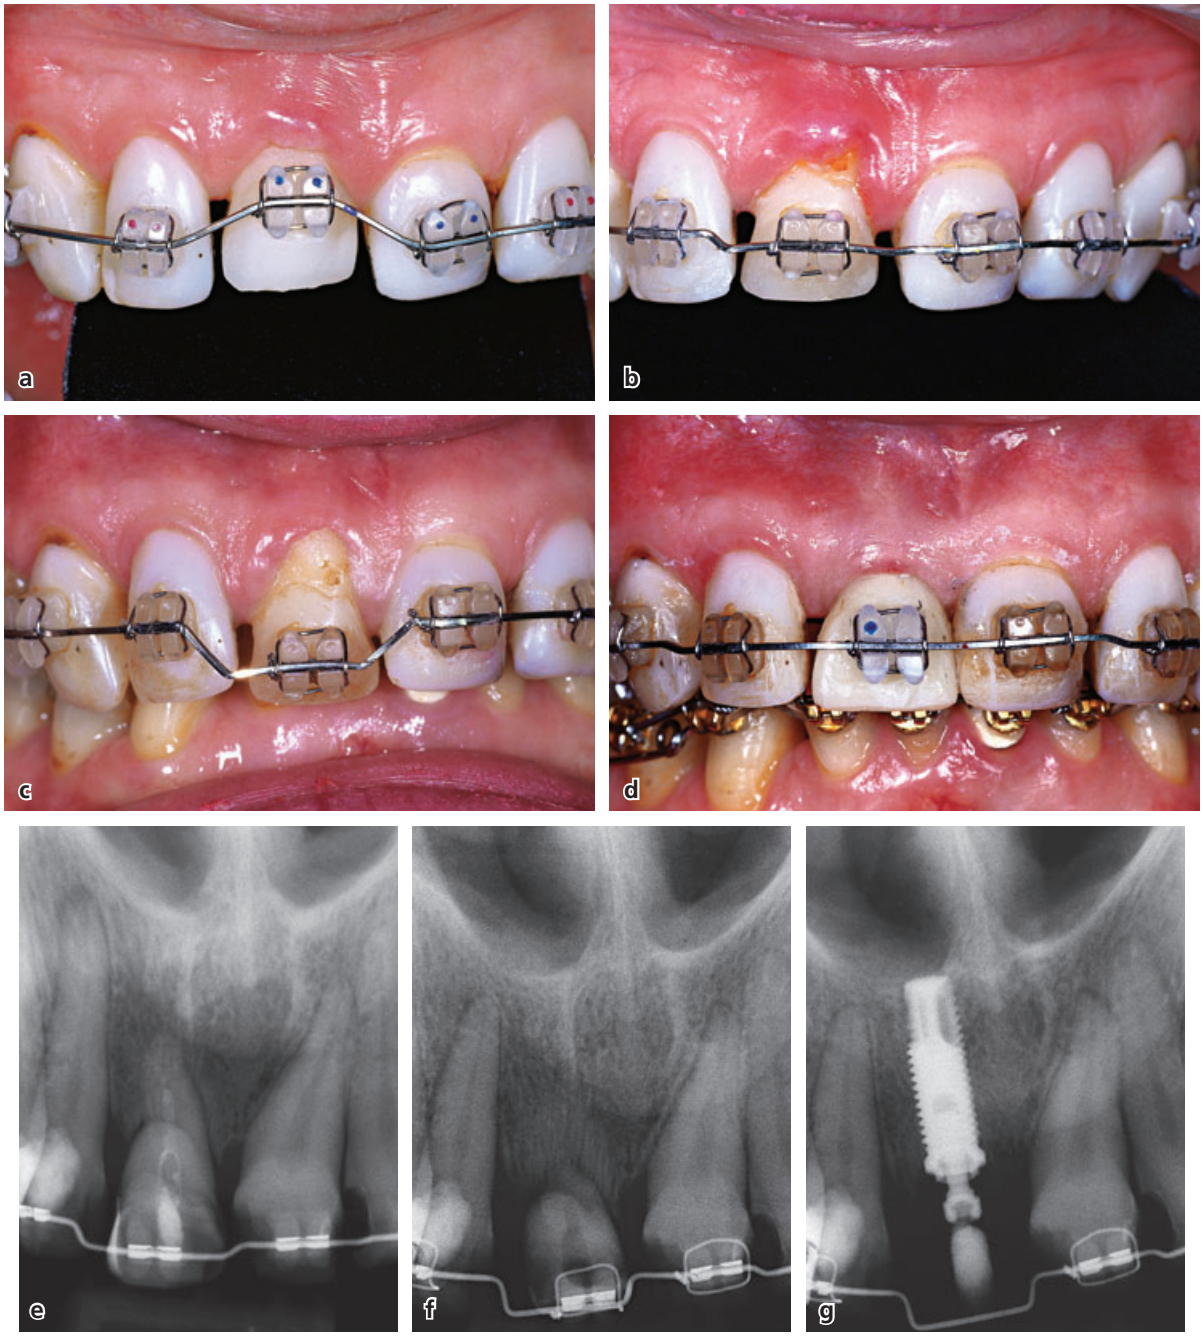

Fig. 57-21 Implant site development by "orthodontic extraction" of maxillary right central incisor with poor prognosis (a,e). The ceramic bracket was positioned in a gingival location on the incisor to be extruded (a), and initial leveling was started with continuous force from a rectangular super-elastic leveling wire. After 1 month, this arch-wire was replaced with a thin rectangular stainless steel wire, using small step-bends for the extrusion (b,e). Such step-bends create an interrupted continuous force which is active for about 2 weeks and then allows 2 weeks of rest before the re-activation at the monthly visits (b,c). The temporary crown on the implant in (d) shows the clinical status at 6 months after implant insertion. The radiographs demonstrate the extensive bone build-up at 10 months (f) and the implant in the regenerated bone at 6 months (g). Note the organization of the bony lamellae reflecting the direction of pull in (f).

tulous space and to place the implant in the position previously occupied by the premolar (Spear *et al*. 1997). The bucco-lingual volume of the new bone on the tension side will be markedly greater than that on the pressure side (Figs. 57-23, 57-24). This is an alternative to surgical ridge augmentation (GBR or bone graft). The situation is similar to that of when a canine is moved distally to open the space for a maxillary lateral incisor implant (Spear *et al*. 1997; Beyer *et al*. 2007). The root of the canine creates an adequate ridge through stretching of the periodontal ligament.

It should be emphasized that there is much less shrinkage of the alveolar bone after horizontal tooth movements than after extractions of teeth. Spear *et al*. (1997) used cast measurements and tomograms through the edentulous ridge to measure the amount of bone loss with time in cases with orthodontic space

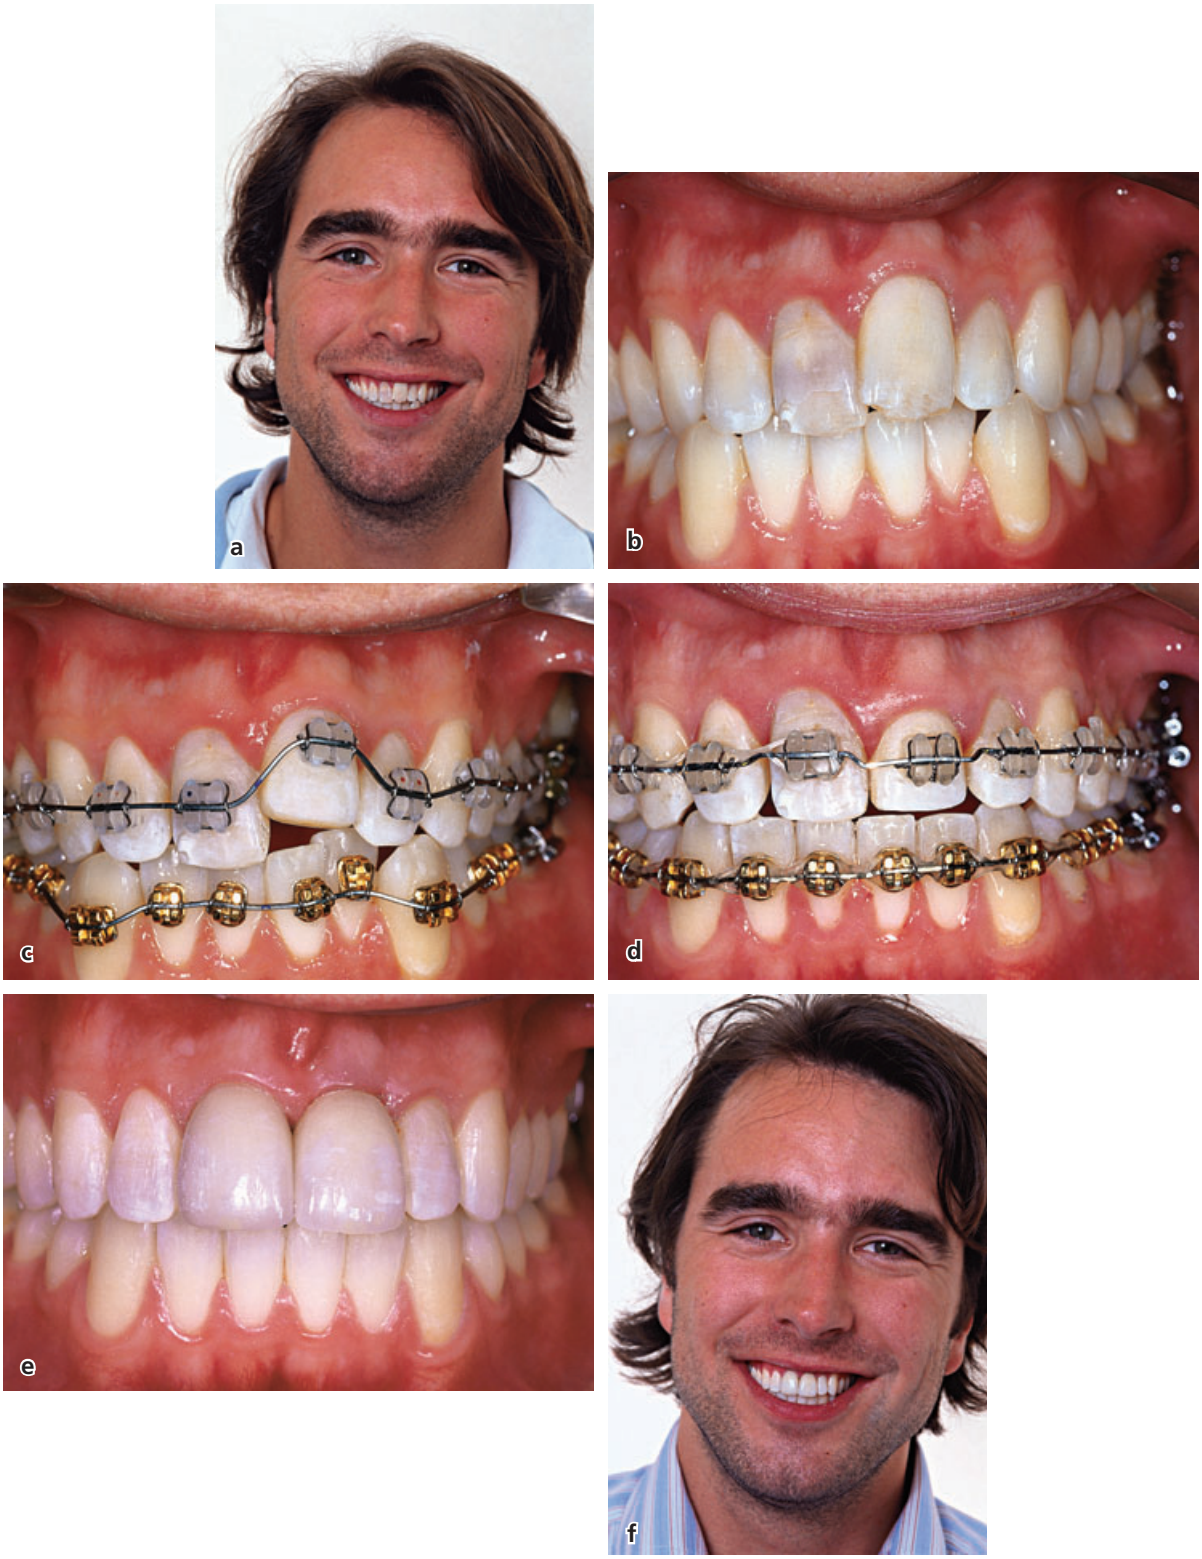

Fig. 57-22 Implant site development in young adult male patient by slow orthodontic extrusion of left central incisor with poor prognosis (a,b). Same procedure as in Fig. 57-21. The ceramic bracket was bonded in a gingival location on the tooth to be extracted. After 1 month of leveling with super-elastic wire, the remaining extrusion for 7 months was made with interrupted continuous force from stainless steel arch-wire, using small step-bends that were reinforced at monthly visits (d). The implant was inserted 4 months after the incisor was extracted. Note the improved gingival margin contour after the orthodontic extrusion (b,d), which permitted an optimal emergence profile of the implant crown (e,f).

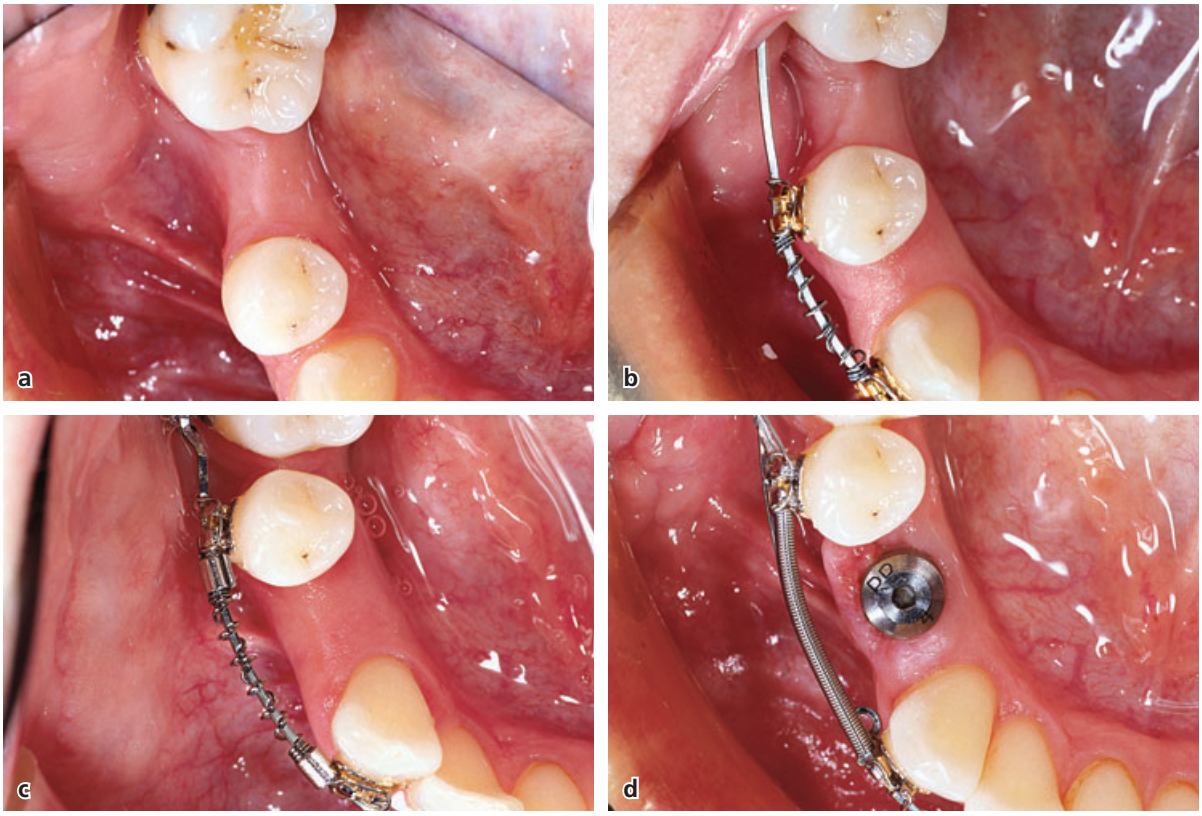

Fig. 57-23 Ridge augmentation by horizontal tooth movement before implant insertion in adult female patient, in whom the alveolar bone in the second premolar area was insufficient to accommodate an implant (a). The first premolar was moved distally with continuous force from a push-coil (b,c). Note wide area of bone regenerated on the tension side of the premolar (b,d) which provided optimal conditions for insertion of the implant (d).

opening for maxillary lateral incisor implants. They found less than 1% alveolar bone shrinkage from the end of treatment up to 4 years later. This contrasts with previous studies showing about 34% reduction of the alveolar ridge over 5 years when anterior teeth are extracted (Carlson 1967).

Figure 57-23 shows a case in which the distal movement of a mandibular first premolar provided new bone of adequate width for implant placement in a previously atrophied alveolar bone area. Similar generation of bone can be obtained in patients who have no molars by moving a terminal premolar distally in the dental arch. Autotransplantation of teeth also represents inherent potential for bone induction and re-establishment of a normal alveolar process after traumatic bone loss (Zachrisson *et al*. 2004).

Gingival recession

Labial recession

"Normal" age changes

Gingival recession, with exposure of cementum on facial surfaces of teeth, may occur on single or multiple teeth. Many factors have been implicated in the etiology, including plaque, position of the tooth in the arch, faulty toothbrushing, traumatic occlusion, high frenum or muscle attachments, lack in dimension of gingiva, lip pressure, etc. (Baker & Seymor 1976). It is difficult to see a single cause of, or a solitary mechanism in the development of, labial gingival recession. Two basic types of recession may occur, one related to periodontal disease, or to factors associated with periodontal disease, and the other relating to mechanical factors, including toothbrushing.

Labial gingival recessions are always accompanied by alveolar bone dehiscences, and there is a direct correlation between the millimetric extension of labial bone dehiscences and the corresponding gingival recessions (Bernimoulin & Curilovic 1977). It has been postulated that a root dehiscence may establish an environment which, for one reason or another, may predispose to gingival recession (Wennström 1990). The position in which a tooth erupts through the alveolar process has a profound influence on the amount of gingiva that will be established around the tooth. When a tooth erupts close to the mucogingival line, only a minimal width, or complete lack, of gingiva may be observed labially, and localized gingival recessions may occur in patients at a young age. Thus the "normal" age changes that will then take place are important. Longitudinal monitoring of labial gingival dimensions during the development of the dentition has shown that provided

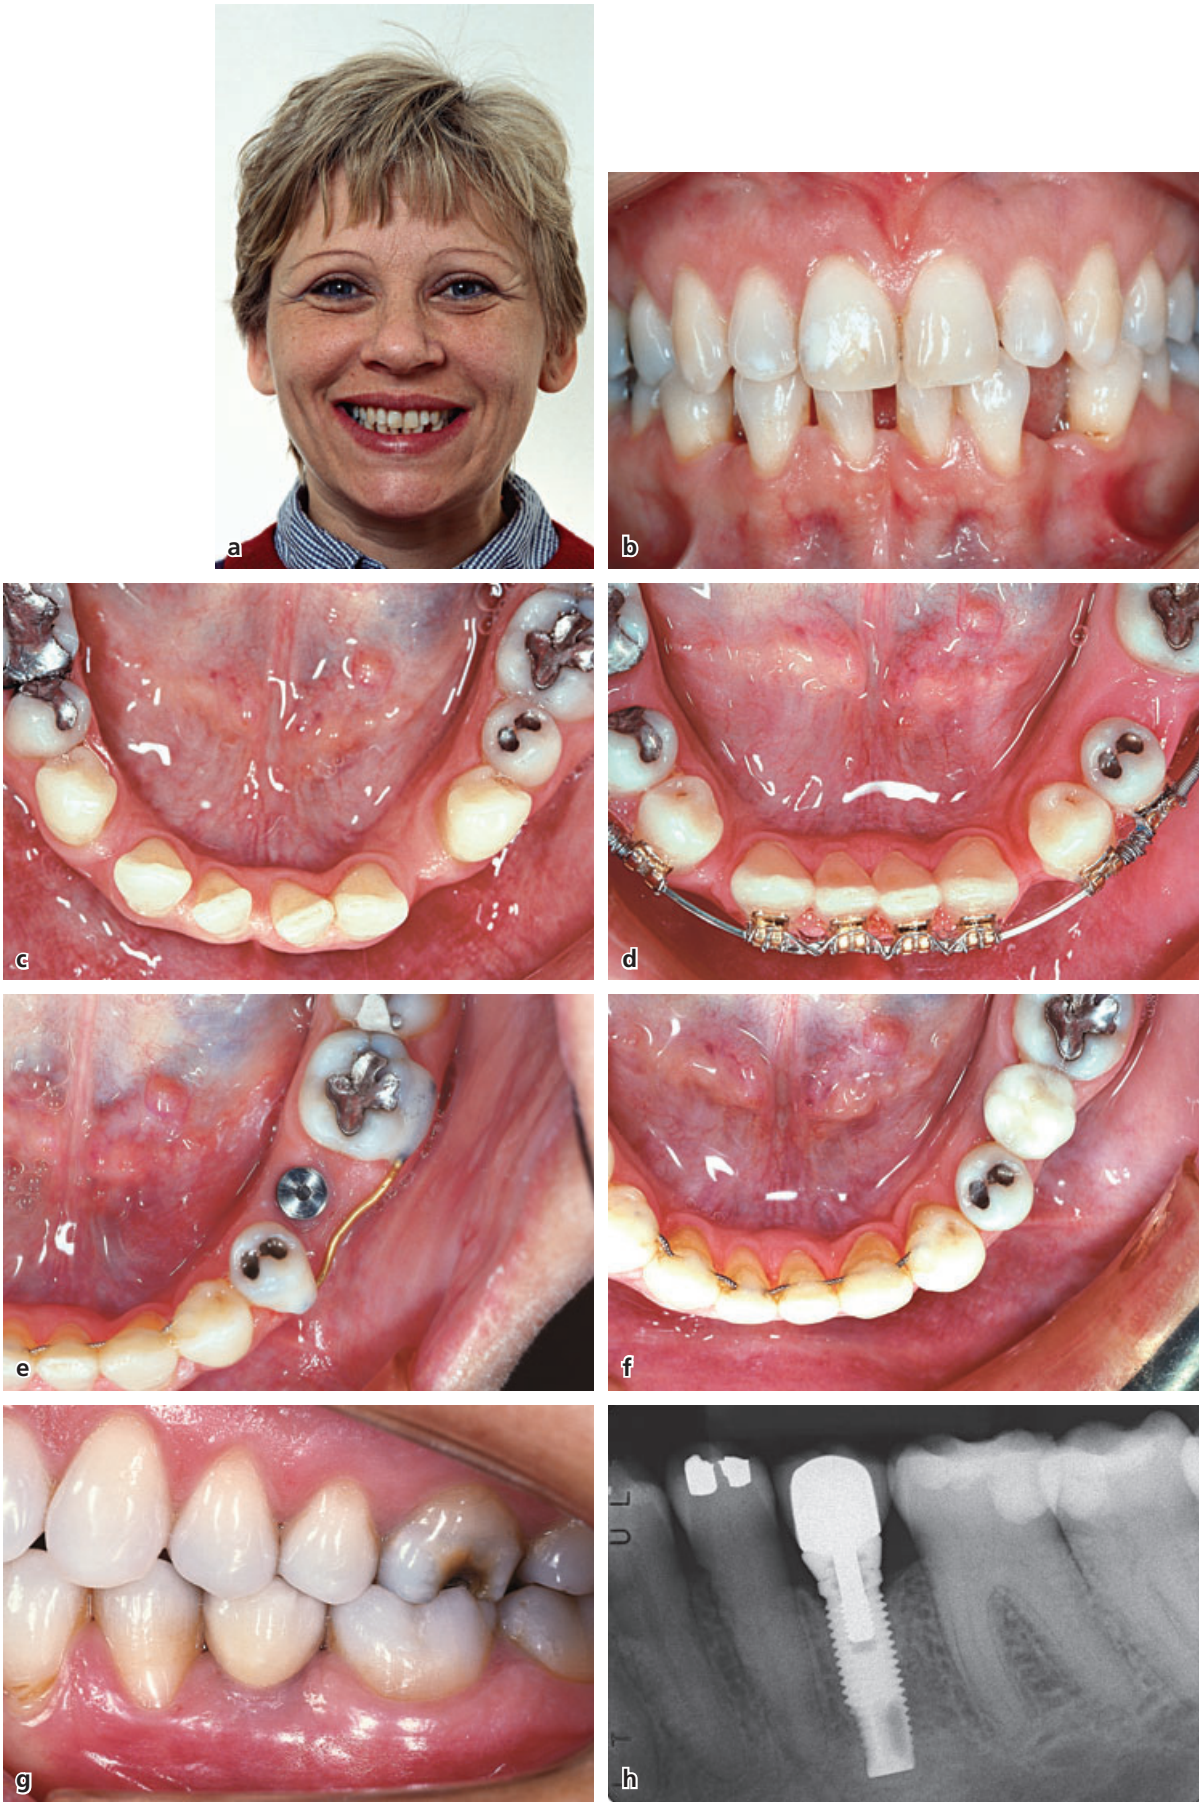

Fig. 57-24 Female patient, 41 years of age, with agenesis of both mandibular central incisors, multiple spacings, thin periodontal tissues, and prominent root topography (a–c). The alveolar bone is too thin labio-lingually to accommodate a titanium implant in the anterior regions (c). The treatment principle was, therefore, to close spaces anteriorly by moving the left first and second premolars mesially (d), and to open up space posteriorly for an implant (e). Note the wide area of alveolar bone on the tension side (d,e), providing ample bucco-lingual space for implant insertion. Permanent implant-supported crown at 3.5 years after treatment (courtesy of Dr. Roy Samuelsson, Oslo, Norway) is shown in f–h.

Fig. 57-25 Thin labial gingiva on prominent mandibular right central incisor (a,b) spontaneously became thicker when the incisor was orthodontically moved lingually and aligned (c) after premolar extractions. (d) Condition after appliance removal.

adequate plaque control is established and maintained, a significant increase of the gingival height will generally occur. Spontaneous improvement of localized mandibular labial recessions is the rule rather than the exception, and in some teeth the recessions were totally eliminated during a 3-year observation period (Andlin-Sobocki *et al*. 1991). Also, spontaneous changes of tooth positions in a bucco-lingual direction will affect the gingival dimension. These alterations in gingival dimensions are similar to, albeit less pronounced than, those observed during orthodontic treatment (see below).

Favorable tooth movements, and tissue factors

Alterations of mucogingival dimensions may occur during orthodontic treatment. Contrary to beliefs in the past, these changes are independent of the apico-coronal width of the keratinized and attached gingiva. Wennström *et al*. (1987) found no relationship between the initial width of keratinized gingiva and the tendency for development of gingival recession during orthodontic tooth movements in monkeys. Instead, it is the bucco-lingual thickness (volume), which may be the determining factor for the development of gingival recession and attachment loss at sites with gingivitis during orthodontic treatment.

A tooth that is positioned facially within the alveolar process may show an alveolar bone dehiscence with a thin covering soft tissue. When such a tooth is moved lingually during orthodontic treatment, the gingival dimensions on the labial aspects will increase in thickness (Figs. 57-25, 57-26). Furthermore, because the mucogingival junction is a stable anatomic landmark and the gingiva is anchored to the supracrestal portion of the root, it will follow the tooth during the movement lingually and will consequently get an increase in gingival height (decreased clinical crown height).

Conclusion: It follows that in cases with a thin (delicate) gingiva caused by a prominent position of the teeth, there is no need for a preorthodontic gingival augmentation procedure. In the case of labial gingival recessions a mucogingival surgical procedure should not be performed before orthodontic therapy, when the position of the tooth is improved by the treatment. The recession, as well as the bone dehiscence, will decrease as a consequence of the lingual movement of the tooth into a more proper position within the alveolar bone. If still indicated at the end of orthodontic therapy, the surgical procedure will have a higher predictability of success than if it had been performed before the tooth movement (Wennström 1996).

Unfavorable tooth movements, and tissue factors

Orthodontic movements of teeth *away* from the genetically determined envelope of the alveolar

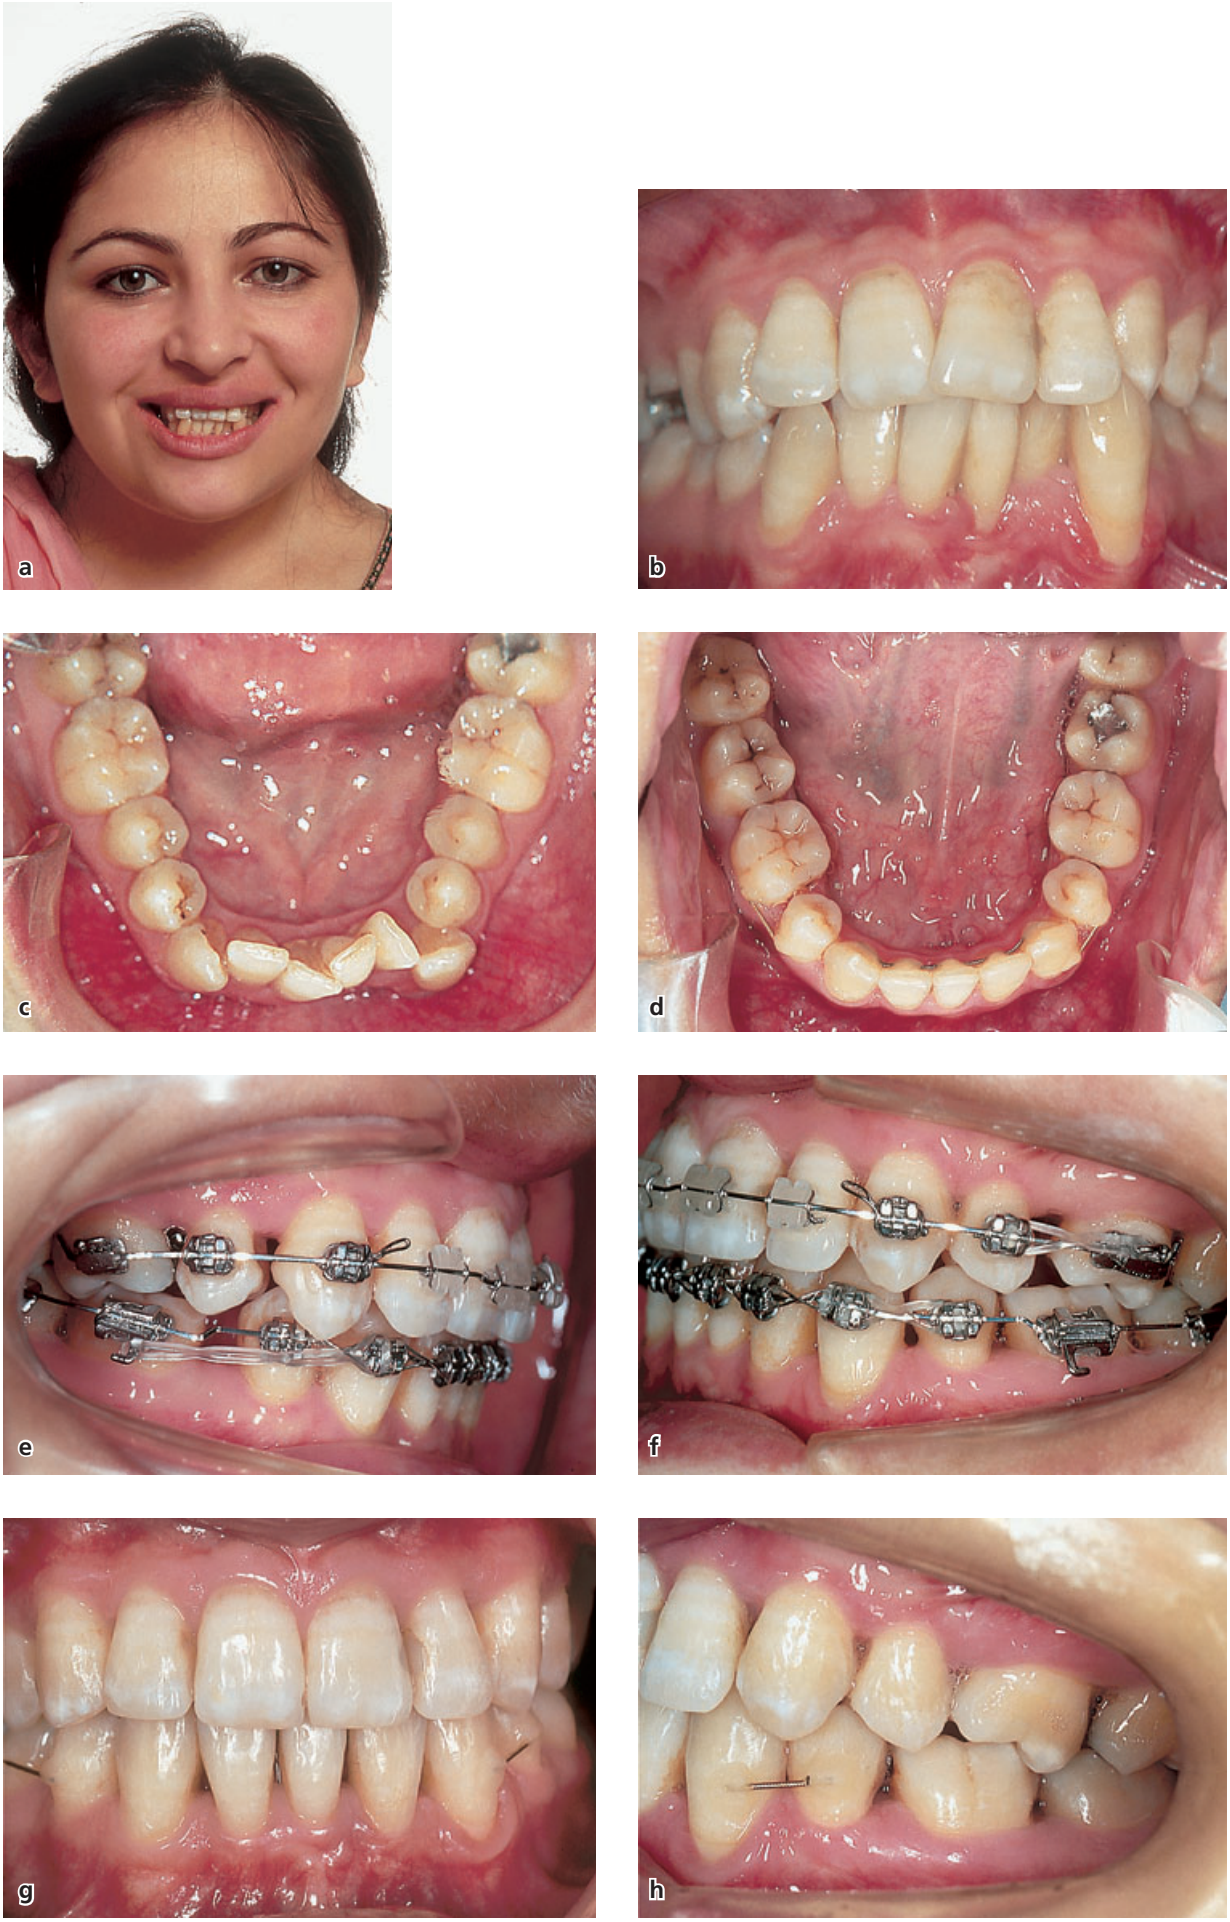

Fig. 57-26 Marked labial gingival recession on prominent left mandibular canine in female young adult patient (a–c). (d) After extraction of two premolars and the left central incisor (sic!), the mandibular arch was leveled orthodontically. (e) and (f) show the clinical condition towards end of orthodontic therapy, and (g,h) at follow-up 1 year after appliance removal. Note spontaneous improvement of gingival recession (f–h).

process are risk movements for development of mucogingival problems, particularly in thin bone and gingival tissues. During frontal and lateral expansion of teeth, tension may develop in the marginal tissues due to the forces applied to the teeth. This stretching may result in thinning of the soft tissues. However, recession-type defects will not develop as long as the tooth is moved within the alveolar bone. If, however, the expansion results in the establishment of a bone dehiscence, the volume (thickness) of the covering soft tissue must be considered as a factor that may influence the development of soft tissue recessions. This may be true both during and after the active orthodontic treatment period. The labial orthodontic tooth movement *per se* will not cause soft tissue recession. However, the thin gingiva that will be the consequence of such movement may serve as a *locus minoris resistentia* to developing soft tissue defects in the presence of bacterial plaque and/or mechanical trauma caused by improper toothbrushing techniques, or orthodontic correction of marked rotations of the incisors.

For stability reasons as well, expansion in the mandibular arch should normally be avoided, if possible. If frontal expansion is still performed in association with orthodontic therapy, the bucco-lingual thickness of the hard and soft tissues should be evaluated. If surgical intervention is considered necessary in order to reduce the risk for development of soft tissue recessions, this should aim at increasing the thickness of the covering tissue (e.g. grafts), and not the apico-coronal width of the gingiva.

Conclusion: Before any kind of orthodontic therapy is started, it is important to check the bucco-lingual thickness of the bone and soft tissues on the pressure side of all teeth, which are to be moved. When tissues are delicate and thin, careful instructions in adequate plaque control measures should be provided, and controlled before and during treatment as well as after removal of the fixed appliances, in order to reduce the risk for development of labial gingival recession.

Interdental recession

Esthetic considerations with regard to defect papillae

Until recently, most clinical emphasis with regard to gingival recession was given to labial defects. If left untreated, most labial gingival recessions will not progress significantly with time, at least if oral hygiene is good, and the main indication for treatment is the esthetic implication for the patient. From an esthetic point of view, however, it would appear that interdental recession, manifest as more or less pronounced empty spaces ("dark triangles") between the teeth, would be equally or more important. Compared with a labial recession, in most patients the loss of interdental papillae would be more visible, both in normal conversation and upon smiling.

Since quality of life (esthetics and lack of pain) has become increasingly important in recent years in selection of periodontal therapies, disfigurement of the gingival papillae during orthodontic treatment of periodontal patients must be avoided, if possible. The development of interdental recession during orthodontic treatment in adults may be caused by one of three factors: (1) advanced periodontal disease, by the tissue destruction or due to pocket elimination by surgery, (2) triangular tooth shape due to abnormal interproximal wear of teeth in crowded positions before the orthodontic treatment, and (3) diverging roots of teeth due to improper bracket placement. To begin with, there is an obvious difference in dental esthetics between patients with advanced periodontitis who have been treated according to "old" and "new" concepts for periodontal therapy. In the past, pocket elimination by gingivectomies frequently resulted in advanced root exposure and complete loss of interdental papillae. However, even with careful non-surgical periodontal therapy in the preparation of patients with advanced periodontal disease for orthodontic treatment, the clinical outcome of the interdisciplinary treatment will normally result in marked interdental recessions, if special precautions are not taken (see below).

Clinical options for treatment

There are only a few options available for the treatment of interdental gingival recession associated with orthodontic treatment in the periodontal patient:

1. Mucogingival surgery, using coronally positioned flaps and GTR techniques (Pini Prato *et al*. 1992)
2. The provision of a gingival prosthesis
3. Orthodontic paralleling of the roots of neighboring teeth
4. Mesio-distal enamel reduction ("stripping").

Of these techniques, the mucogingival surgery aspects are discussed in Chapter 44, and will not be commented on here. A gingival prosthesis may be useful in cases of markedly compromised dentitions, where the psychologic implications of having pronounced retractions are serious. It may be regarded as a last resort. In contrast, the mesio-distal contouring of teeth is a very useful technique to routinely improve the esthetic results achieved by orthodontic treatment in most adult and adolescent patients (Figs. 57-3, 57-5, 57-6, 57-27, 57-28).

Benefits of mesio-distal enamel reduction ("stripping")

Introduced by Tuverson in 1980, mesio-distal recontouring of teeth has now become a routine procedure in orthodontics. It is generally performed on three

Fig. 57-27 Adult female patient with maxillary crowding and large overjet (a,b). After premolar extractions, orthodontic distalization of canines resulted in the development of marked interdental recessions in the anterior region (c). Marked triangular incisor morphology and uneven incisal edges necessitated extensive recontouring (c,d) to allow gingival fill-in after treatment (e,f).

indications: (1) treatment of slight-to-moderate crowding without arch expansion, (2) correction of width discrepancies (so-called TSD, tooth size discrepancies) between maxillary and mandibular teeth, and (3) to prevent interdental recession from developing during orthodontic treatment. The principle involved in stripping is to recontour those teeth which for one reason or another have abnormal morphology, towards an ideal anatomic shape (Figs. 57-6, 57-25). In doing so, the contact points between teeth will be relocated in an apical direction and reduce the contact-to-bone distances (Tarnow *et al*. 1992), and the connector areas (the zone in which two adjacent teeth appear to touch) can be restored towards the optimal 50-40-30 relationships (Morley & Eubank 2001). By this means, normal interdental

Fig. 57-28 Young adult female patient with moderate periodontal tissue breakdown in the anterior region, extruded and irregular maxillary incisors with triangular crown form and incisal wear, and marked interdental gingival recession in the mandibular anterior region (a–c). After 1 month of leveling, the maxillary and mandibular incisors were recontoured by stripping to a more optimal tooth morphology (d). The "new" tooth shapes allowed space closure and leveling and aligning to an esthetic final result (e,f).

gingival papillary contours will be achievable (Figs. 57-3, 57-6, 57-27, 57-28).

In many adult patients with malocclusion, particularly in cases with crowded and overlapping incisors, the crowns of the incisors are much wider at their incisal edges than at the cervical region. As the crowding is unraveled by orthodontic leveling in these instances, the contact point between the incisors will become located in the incisal 1 mm, and a more or less evident space develops above the interproximal contacts of the incisors. Similar, or even more pronounced, loss of the interdental papillae between the maxillary and mandibular incisors, is commonly seen after orthodontic treatment in patients with advanced periodontal destruction.

Short-term (Zachrisson & Mjör 1975) and long-term (>10 years) (Thordarson *et al*. 1991; Zachrisson *et al*. 2007) follow-up studies after extensive grinding of teeth have demonstrated that no harmful side effects are observed subsequent to the procedure, provided adequate cooling is used during the grinding and the prepared surfaces are made smooth and self-cleansing. After the diastema is created, the space between the teeth is closed orthodontically. As this occurs, the roots of neighboring teeth come closer together, the contact area is lengthened, and the reduced papilla can fill out the small space between the teeth (Tarnow *et al*. 1992). In patients with advanced periodontal disease, it is not always possible to restore all papillae in the dentition. Even if it is not possible to eliminate the interdental recession completely after the orthodontic treatment, the esthetic appearance is in most patients substantially improved by stripping, even in cases with extensive periodontal tissue breakdown, such as those in Figs. 57-3 and 57-5.

Minor surgery associated with orthodontic therapy

Several forms of minor periodontal surgery may be used to improve or stabilize the results achieved by orthodontic treatment of malocclusion. More than 30 years ago, Edwards (1970) described clinical techniques to help prevent rotational relapse, reopening of closed extraction spaces (Edwards 1971), and a simple yet effective technique for frenotomy (Edwards 1977). At about the same time, a gingivectomy technique to increase clinical crown length for esthetic improvement of orthodontic results in specific situations was reported (Monefeldt & Zachrisson 1977). Removal of gingival invaginations in extraction sites following orthodontic space closure has also been a subject of considerable interest to orthodontists.

Fiberotomy

The problem of relapse of orthodontically treated teeth in general, and rotated teeth in particular, has been well recognized for years. Methods to reduce the occurrence of rotational relapse may include (1) complete correction, or overcorrection, of rotated teeth, (2) long-term retention with bonded lingual retainers, and (3) the use of fiberotomy.

Two soft-tissue periodontal entities may influence the stability: the principal fibers of the periodontal ligament, and the supra-alveolar fibers. Whereas the fibers of the periodontal ligament and trans-septal groups remodel efficiently and histologically completely in only 2–3 months after orthodontic rotation of teeth, the supra-alveolar fibers are apparently more stable, with a slow turnover. Since the gingival soft tissues are composed primarily of non-elastic collagenous fibers, the exact mechanism by which the gingival soft tissues may apply a force capable of moving the teeth is as yet unknown. From a practical and clinical point of view, however, the supracrestal gingival tissues seemingly do contribute to rotational relapse, as evidenced by the effect of the circumferential supracrestal fiberotomy (CSF) technique.

Basically this technique consists of inserting a scalpel into the gingival sulcus and severing the epithelial attachment surrounding the involved teeth. The blade also transects the trans-septal fibers by interdentally entering the periodontal ligament space. Various modifications of the original CSF technique have been described, in which the scalpel is inserted below the gingival margin, or the cut is reduced to interdental vertical incisions buccally and lingually. In neither case are surgical dressings indicated, and clinical healing is usually complete in 7–10 days. The fiberotomy procedure is not recommended during active tooth movement, or in the presence of gingival inflammation. When performed in healthy tissues after orthodontic therapy, there is negligible loss of attachment (Edwards 1988).

The long-term effectiveness of fiberotomy was evaluated in a prospective follow-up study over a period of 15 years by Edwards (1988). The degree of crowding was examined for CSF and control cases at 4–6 years and at 12–14 years after treatment. A significant effect of the fiberotomy was observed at both time intervals. The surgical procedure was more successful in the maxillary than in the mandibular anterior region; more effective in alleviating rotational than labiolingual relapse; and more useful in reducing relapse in cases with severe rather than mild irregularity of teeth. There was no clinically significant increase in sulcus depth, nor signs of gingival labial recession.

Frenotomy

The contribution of the maxillary labial frenum to the etiology of a persisting midline diastema, and to reopening of diastemas after orthodontic closure, is controversial. The probability for diastema closure in the long run is the same whether or not frenectomy is performed. However, very hyperplastic types of frenum, with a fan-like attachment, may obstruct diastema closure and should be relocated.

In the past, the most common surgical procedure was *frenectomy*, an excision-type operation, which

was often carried over to the palatal aspects. However, a frequently observed complication may be an undesirable loss of the interdental papilla between the maxillary central incisors. For this reason, the *frenotomy*, which represents a more gentle operation, will produce esthetically preferable results. With frenotomy, the attachment of the frenum to gingiva and periosteum is severed, and the insertion of the frenum is relocated several millimeters up on to the alveolar mucosa. If a marked sutural bone cleft is observed in the pretreatment radiographs, the cut is extended to sever the fibers within the coronal part of the midpalatal suture. Tissue healing after a frenotomy procedure is usually uneventful. To further reduce the relapse tendency and/or to increase clinical crown height of single or several teeth, the frenotomy may be combined with fiberotomy and gingivectomy.

Removal of gingival invaginations (clefts)

Incomplete adaptation of supporting structures during orthodontic closure of extraction spaces in adults may result in infolding or invagination of the gingiva. The clinical appearance of such invaginations may range from a minor one-surface crease to deep clefts that extend across the interdental papilla from the buccal to the lingual gingivae. Although gingival invaginations are quite common, the precise cause of the infolding as teeth are moved through an extraction area remains unclear. Since approximated teeth appear to displace the gingival tissue more than move through it, a "piling-up" of gingival tissue is conceivable. There is some resolution of these defects with time, but many invaginations persist for 5 years or more after completion of orthodontic therapy.

Several authors have suggested that compression of trans-septal fibers and alterations of gingival tissue will contribute to extraction-space reopening, but no correlation was found between space reopening and presence and severity of invaginations by Rivera Circuns and Tulloch (1983). They still felt the damage to the gingiva was severe enough to warrant the surgical removal of these defects in selected patients. Edwards (1971) suggested that simple removal of only the excess gingiva in the buccal and lingual area of approximated teeth would be sufficient to alleviate the tendency for the teeth to separate after orthodontic movement. The removal of the gingival papillae in closure sites may enhance the restitution of a more normal connective tissue, although the epithelial hyperplasia, invaginations, and loss of collagen in the underlying gingiva are surprisingly long-standing.

Gingivectomy

The relationship of the gingival margins of the six maxillary anterior teeth plays an important role in the esthetic appearance of the crowns (Kokich 1996a,b). In some instances, it may be necessary to increase clinical crown length of one or several teeth during or after orthodontic treatment. If a gingival margin discrepancy is present, but the patient's lip does not move upward to expose the discrepancy upon smiling, it does not require correction. If the gingival discrepancy is apparent, however, one of four different techniques may be used:

1. Gingivectomy
2. Intrusion + incisal restoration or porcelain laminate veneer (Fig. 57-18)
3. Extrusion + fiberotomy + porcelain crown (Fig. 57-17)
4. Surgical crown lengthening, by flap procedure and ostectomy/ostoplasty of bone (Brägger *et al*. 1992).

Each of these techniques has its specific indications, and whenever gingival margin discrepancies are present, the clinician must determine the proper solution (see also Chapter 44). For example, gingivectomy is not indicated when there is a risk for root exposure, such as when one single incisor has supraerupted (Fig. 57-18).

The gingivectomy technique has proven to be useful in improving orthodontic results, particularly in difficult cases with missing maxillary central or lateral incisors (Fig. 57-29); after premolar autotransplantation to the anterior region; and in some "gummy" smiles. Clinical and histologic examination demonstrated that it was possible to permanently increase clinical crown length after orthodontic treatment by making a labial gingivectomy to the bottom of the clinical pocket. The healing and regeneration of the gingiva was uneventful, provided excellent oral hygiene was maintained in the wound area for 2 months. The result may be explained by one or more of three factors: (1) the effect of the gingivectomy itself, (2) elimination of accumulated hyperplastic gingiva often seen associated with fixed appliance therapy (Fig. 57-29), and (3) elimination of a normally occurring deep pocket. Whatever the reason, the net gain in crown length was close to half the probing depth in all instances (Monefeldt & Zachrisson 1977). The increase in crown length of 1–2 mm may be important to improve the clinical outcome, as shown in Fig. 57-29. Similar long-term results on the position of the marginal soft tissue following periodontal surgery have been reported by others (Lindhe & Nyman 1980). Interestingly, Wennström (1983) demonstrated that even if the gingivectomy is extended into the alveolar mucosa, the regenerated tissue will still be normal gingiva with keratinized epithelium. Thus the human periodontal membrane tissue has the capacity to form a granulation tissue which will prevent the alveolar mucosa from becoming the border tissue against the tooth. When local labial gingivectomies are made in adults, the cut is reduced mesio-distally in order to eliminate the risk for developing interdental recession. Then the incision should not follow the gingival contour all the way, but should be limited by two small vertical cuts towards the interdental papillae.

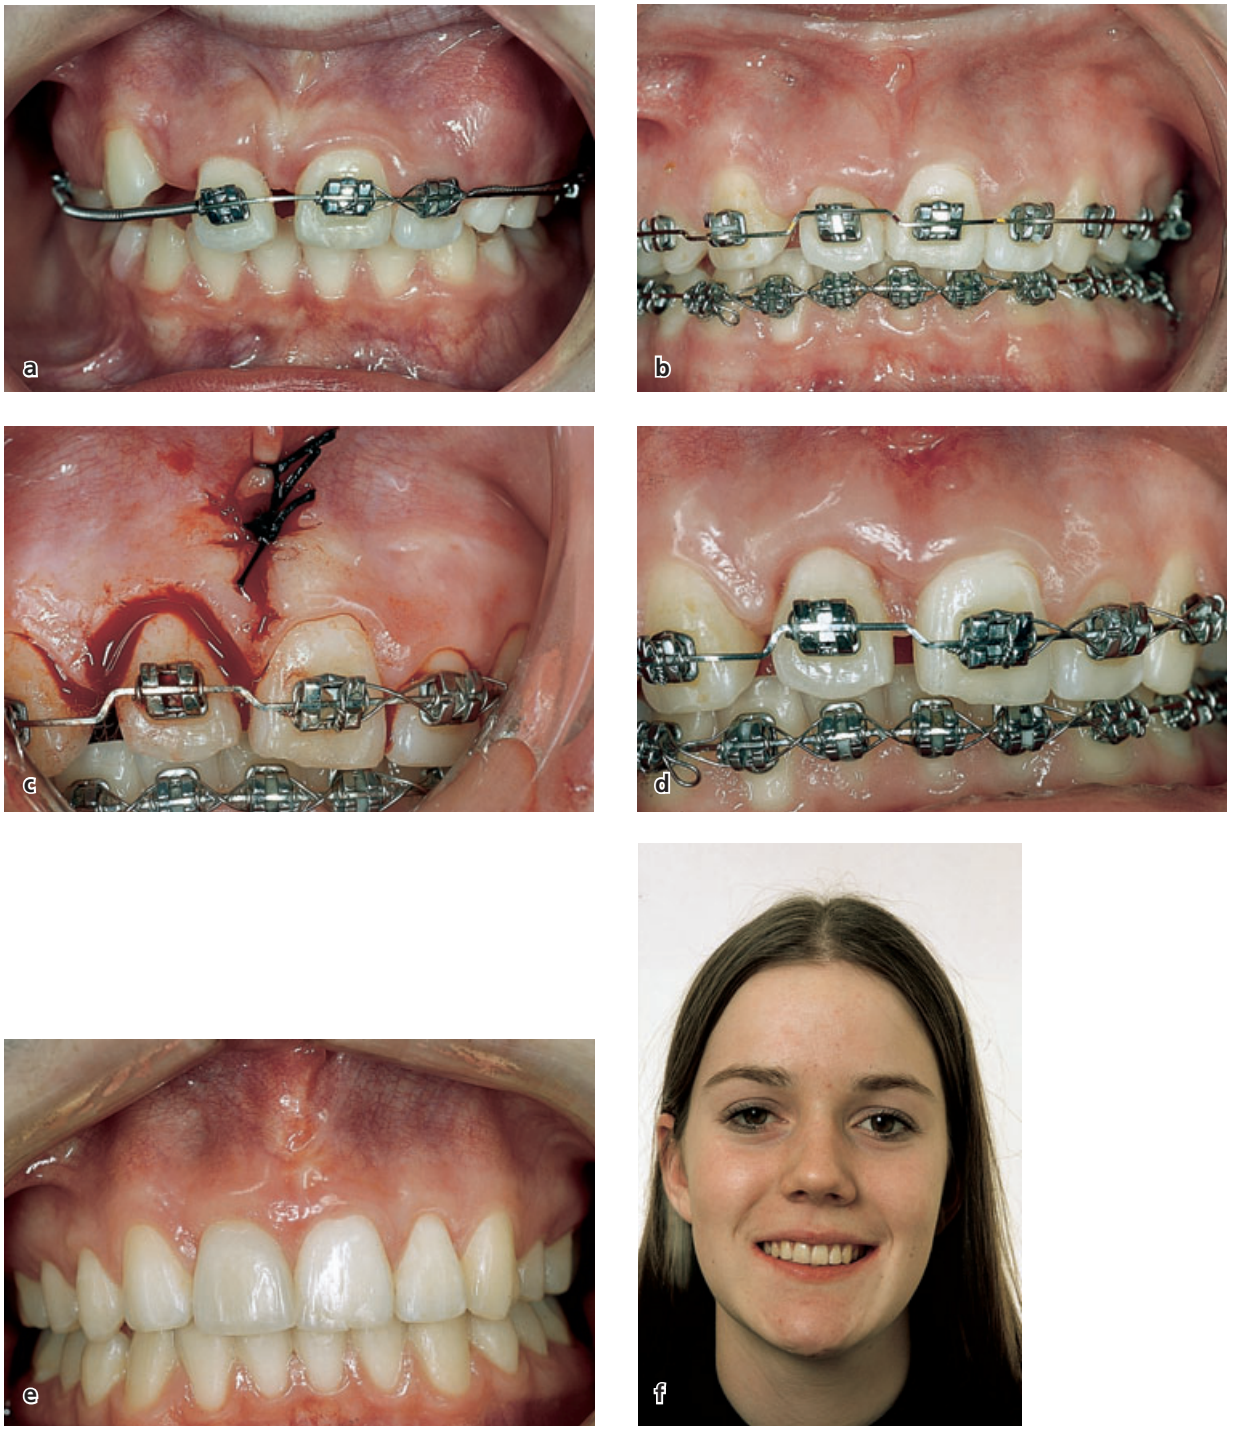

Fig. 57-29 Orthodontic space closure substitution after accidental loss of maxillary right central incisor in young female patient (a). The marginal gingival level on the "new" central incisor was corrected by selective intrusion bends in the arch-wire (b–d) and local gingivectomy and frenotomy (c,d). Local gingivectomies were also performed on the right first premolar in the canine position, and on the left lateral incisor (e). Enamel-bonded ultrathin porcelain veneer on lateral incisor, and vital bleaching of right canine, courtesy of Dr. S. Toreskog. By these means, it was possible to obtain an optimally esthetic result (e,f).

Chapter 58

Implants Used for Orthodontic Anchorage

Marc A. Schätzle and Niklaus P. Lang

Introduction

Anchorage is one of the limiting factors in orthodontics and its control is essential for successful orthodontic treatment. The term orthodontic anchorage was first introduced by Angle (1907) and later defined by Ottofy (1923). Orthodontic anchorage denoted the nature and degree of resistance to displacement of teeth offered by an anatomic unit when used for the purpose of tooth movement. The principle of orthodontic anchorage was implicitly explained in Newton's third law (1687) according to which an applied force can be divided into an *action* component and an equal and opposite *reaction* moment. In orthodontic treatment, reciprocal effects must be evaluated and controlled. The goal is to maximize desired tooth movement and minimize undesirable effects.

Basically, each tooth has its own anchorage potential as well as a tendency to move when force is applied towards the tooth. When teeth are used as anchorage, inappropriate movements of the anchoring units may result in a prolonged treatment time, and unpredictable or less-than-ideal outcomes.

Orthodontic anchorage is oriented to the quality of the biologic anchorage of the teeth. This is influenced by a number of factors such as the size of the root surfaces available for periodontal attachment, the height of the periodontal attachment, the density and structure of the alveolar bone, the turnover rate of the periodontal tissues, the muscular activity, the occlusal forces, the craniofacial morphology, and the nature of the tooth movement planned for the intended correction (Diedrich 1993). To maximize tooth-related anchorage, techniques such as differential torque (Burstone 1982), placing roots into the cortex of the bone (Ricketts 1976), and distal inclination of the molars (Tweed 1941; Begg & Kesling 1977) may be used. If the periodontal anchorage is inadequate with respect to the intended treatment goal, additional intraoral and/or extraoral anchorage may be needed to avoid negative effects. While the teeth are the most frequent anatomic units used for anchorage in orthodontic therapy, other structures, such as the palate, the lingual mandibular alveolar bone, the occiputal bone, and the neck, are also alternatives.

Additional anchorage such as extraoral and intraoral forces are visible and hence, compliance-dependent, and are associated with the risk of undesirable effects such as tipping of the occlusal plane, protrusion of mandibular incisors, and extrusion of teeth.

Implants, miniscrews and ankylosed teeth, as they are in direct contact with bone, do not possess a normal periodontal ligament. As a consequence, they do not move when orthodontic forces are applied (Melsen & Lang 2001) and hence, can be used for "absolute anchorage" that is independent of the patient's compliance.

The aim of this chapter is to present implants to be integrated into orthodontic treatment as "absolute anchorage", thereby avoiding the disadvantages listed above.

Evolution of implants for orthodontic anchorage

The first attempt to achieve skeletal anchorage was made in 1945. Gainsforth and Higley (1945) placed vitallium screws and stainless steel wires into the ramus of dog mandibles and applied elastics that extended from the screw to the hook of a maxillary arch wire to distally tip/retract the canine by immediate orthodontic loading (Fig. 58-1). Even though the authors did not describe the development of infection, failures encountered may be attributed to infection and the lack of antibiotics at that time, as well as the early dynamic loading of the screws. Although minor tooth movement was accomplished using basal bone anchorage in two animals, an effective orthodontic force could not be maintained for more than 31 days.

A generation later, skeletal anchorage systems have evolved from two directions. One such development originated from orthognatic fixation techniques used in maxillofacial surgery. As pioneers, Creekmore and Eklund (1983) used a vitallium bone screw to treat one patient with a deep impinging overbite. The screw was inserted in the anterior nasal spine to intrude and correct the upper incisors using an elastic thread from the screw to the incisors 10 days after the screw had been placed. Subsequently, Kanomi (1997) described a miniscrew specially designed for orthodontic use.

The second development originated from applications in implant dentistry. Linkow (1969) used blade implants for rubber band anchorage to retract teeth, but never presented long-term outcomes. Later, endosseous implants for orthodontic anchorage were suggested (Ödman *et al*. 1988; Saphiro & Kokich 1988). As indicated in various animal studies, osseointegrated titanium implants remained positionally stable under orthodontic loading and thus could be used for orthodontic anchorage (Sherman 1978; Turley *et al*. 1980, 1988; Roberts *et al*. 1984, 1989; Wehrbein & Dietrich 1993; Wehrbein 1994; Wehrbein *et al*. 1998; De Pauw *et al*. 1999; Majzoub *et al*. 1999) (Figs. 58-2, 58-3). This resulted in the development of specially designed implants in the retromolar area (Roberts *et al*. 1990) and the palatal site of the maxilla

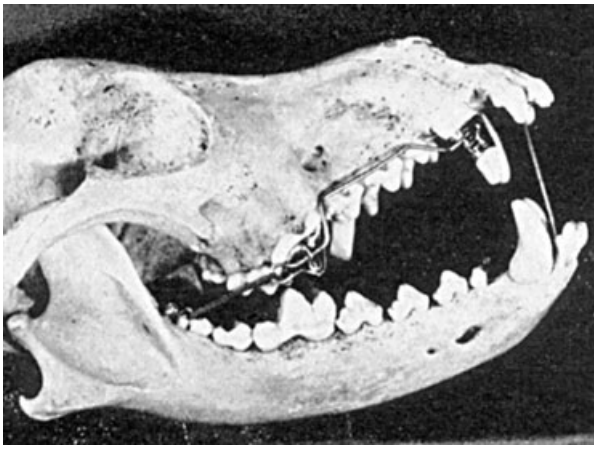

Fig. 58-1 Orthodontic appliance using vitallium screw anchorage. (Courtesy of Gainsforth, B.L. & Higley, L.B. (1945). A study of orthodontic anchorage possibilities in basal bone, *American Journal of Orthodontics and Oral Surgery* **31**, 406–417. Reproduced with permission, copyright © Elsevier.)

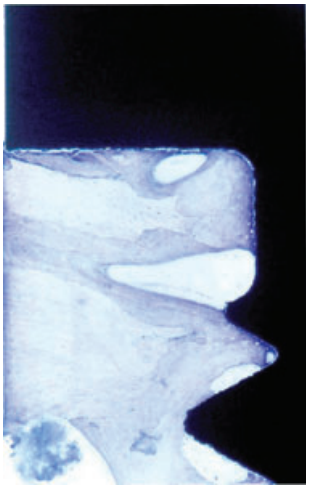

Fig 58-2 Detail of an orthodontic implant 11 months *in situ* in the mandibular retromolar area. Tight contact between the implant shoulder and crestal bone. Signs of remodeling are visible in the peri-implant bone (zones of darker and lighter staining). Toluidine/McNeal stain. Original magnification 20×. From Wehrbein *et al*. (1998) *Clinical Oral Implants Research*.

Fig. 58-3 Longitudinal section of an orthodontic implant after 2 years *in situ*. The implant is well osseointegrated. The shoulder, however, is not in direct contact with the bone surface. Toluidine/McNeal stain. Original magnification 6.6×. From Wehrbein *et al*. (1998) *Clinical Oral Implants Research*.

(Triaca *et al*. 1992). Both applications are used for direct or indirect anchorage (see below).

From a clinical point of view, it is of relevance whether implants are to be used only as temporary anchorage devices (TAD) (Daskalogiannakis 2000) or subsequently to be used as abutment for supporting prosthetic appliances. These aspects determine insertion sites, implant types and dimensions, as well as type of orthodontic anchorage. Moreover, the fact that these devices may have to be placed in a growing patient is of particular importance. Only TADs are suitable for such a purpose.

Prosthetic implants for orthodontic anchorage

The insertion site of prosthetic implants for orthodontic anchorage is determined by the subsequent use of the implant as a prosthetic abutment. The dimensions in length and diameter are dependent on the later prosthetic use. The positions within the alveolar process and the number of implants, however, have to be selected with reference to prospective final tooth position and space after orthodontic treatment.

To determine the location of the prosthetic implants before orthodontic therapy may often be confusing. This is especially true if the teeth are moving towards or away from the implant during orthodontic treatment. In these situations, the presumptive outcomes must be predetermined to achieve the proper implant location and the correct size of the crowns and pontics on the implant-supported prosthesis. In order to use oral implants both for both orthodontic anchorage as well as the subsequent restorative therapy, protocols have been developed for determining the accurate placement of dental implants for prosthetic reconstruction before orthodontic therapy (Smalley 1995; Smalley & Blanco 1995). A plastic placement guide is constructed and used by the clinician to determine proper implant location. The placement guide is based on information derived from a diagnostic wax-up. Therefore, it is necessary to construct the set-up casts from an exact duplicate of the tooth and base portions of the original dental casts. The bases are used as a reference for the proposed position of the implant.

An orthodontic attachment is then either fixed to the provisional crown or to a prefabricated bonding base (Figs. 58-4, 58-5). The orthodontic force acts at the implant suprastructure. The reactive moments and forces are then directly transmitted to the implant and its adjacent bone (direct implant anchorage).

Bone reaction to orthodontic implant loading

Dental implants should not only fulfill prosthetic stability but also withstand the stress and strain applied during orthodontic treatment. There are substantial

Table 58-1 Turnover characteristics of alveolar bone in relation to the magnitude of strain applied (from Melsen & Lang 2001)

Strain values	Bone appositional surface (%)	Resting bone (homeostatic) surface (%)	Bone resorptive surface (%)
>6700 μ strain			
Mean	16.4	21.2	51.5
95% confidence interval	11–22	16–26	42–62
3400–6600 μ strain			
Mean	62.7	16.9	5.0
95% confidence interval	56–70	12–22	1–9
<3300 μ strain			
Mean	20.9	61.9	43.5
95% confidence interval	15–27	56–68	34–53

differences between orthodontic forces and occlusal loading. Orthodontic forces are continuous and horizontal, occlusal loads, in contrast, are discontinuous and mainly in the vertical direction of the implants/teeth.

The effect of orthodontic loading to the adjacent bone of the oral implant is of great interest, because the applied forces should not have a negative impact on the peri-implant bone and therefore, should not impair the long-term prognosis as a prosthetic abutment.

Specially designed oral implants were inserted in monkeys and subjected to well defined continuous loading (Melsen & Lang 2001) (Table 58-1). None of the implants had lost osseointegration after 11 weeks of loading, but loading significantly influenced the turnover of the alveolar bone in the vicinity of the implants. Bone apposition was most frequently found when the calculated strain varied between 3400 and 6600 microstrain. On the other hand, when the strain exceeded 6700 microstrain, the remodeling of the bone resulted in a net loss of bone.

These studies support the theory that apposition of bone around an oral implant is the biologic response to a mechanical stress below a certain threshold, whereas loss of marginal bone or complete loss of osseointegration may be the result of mechanical stress beyond this threshold.

Several other studies where orthodontic forces have been applied confirmed the apposition or increase in bone density rather than loss of bone surrounding an oral implant (Roberts *et al*. 1984; Wehrbein & Diedrich 1993; Asikainen *et al*. 1997; Akin-Nergiz *et al*. 1998).

Indications of prosthetic oral implants for orthodontic anchorage

Orthodontic anchorage provided by prosthetic oral implants may be indicated in partially edentulous adult patients with intra-arch malposition of teeth to correct over-eruption, infra-eruption or tipping of teeth, to retract anteriorly displaced frontal teeth, and intra-arch protraction of teeth that are positioned distally to reduce a multi-tooth gap or improve tooth position in edentulous spaces (Fig. 58-6). Prosthetic oral implants might also be used for the correction of inter-arch malocclusion of single teeth or the whole dentition.

The most important factor of the entire process is interdisciplinary communication and planning. It is critically important for the orthodontist, periodontist, and restorative dentist to work closely as a team during the planning and treatment to achieve the best possible final result (Kokich 1996).

Prosthetic oral implant anchorage in growing orthodontic patients

The use of prosthetic oral implants in growing individuals has been studied in both clinical (Ödman *et al*. 1988; Thilander *et al*. 1994, 1999) and animal studies (Ödman *et al*. 1991; Thilander *et al*. 1992; Sennerby *et al*. 1993). Like ankylosed teeth (Fig. 58-7), oral implants do not follow the developmental changes of the alveolar processes encountered in combination with continuous eruption of adjacent teeth (Fig. 58-8). Moreover, the osseointegrated implants will not be able to be displaced in all dimensions during growth of the jaws (Thilander *et al*. 1994; Iseri & Solow 1996) and hence, would impair the development of the surrounding bony structures and even that of adjacent teeth.

Implant therapy in young individuals with residuous growth potential has been addressed in several studies and yielded major impairment in esthetic outcomes, especially in anterior implant-borne restorations. To assess remaining facial growth potential, hand–wrist radiographs have been proposed for evaluation, but appear not to be specific enough. The best method of evaluating the completion of facial growth is based on the superimposition of sequential cephalometric radiographs. It is, therefore, advisable to await the completion of adolescent body growth in height. At that point, a cephalometric radiograph should be taken. Another radiograph should be taken at least 6 months to a year later. If these radiographs are superimposed with no changes revealed in

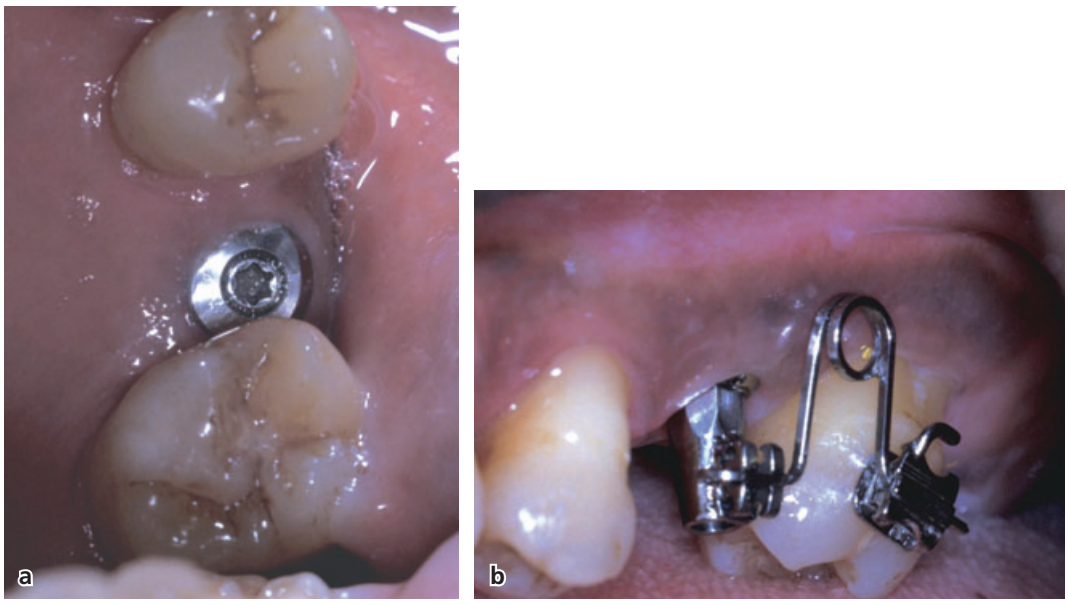

Fig. 58-6 (a) Occlusal view of an oral implant replacing tooth 26, 3 months after installation. Tooth 27 has tipped mesially rendering prosthetic reconstruction of tooth 26 impossible. (b) Following prosthetic abutment connection, the implant is used as anchorage for uprighting tooth 27, hereby providing adequate space for the installation of a single crown.

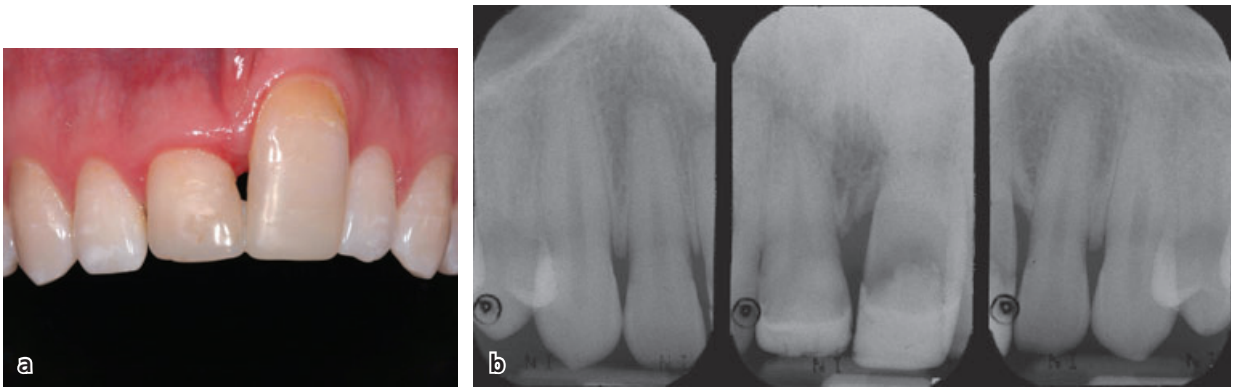

Fig. 58-7 (a) Ankylosed tooth 21 after trauma and on-going composite adaptation over several years. Tooth 21 has not followed the changes associated with alveolar process growth. (b) Radiographic documentation 6 years following trauma of tooth 21 yielding the development of the alveolar process with concomitant ankylosis of tooth 21.

vertical facial height (nasion to menton), the completion of the facial growth may be assumed. The installation of an oral implant at that time may no longer be associated with significant eruption of adjacent teeth (Kokich 2004).

In most adult patients, completion of facial growth is assumed but residual growth and ageing changes affecting the alveolar process may be encountered. This was documented in a retrospective study (Bernard *et al*. 2004) supporting the assumption that mature adults may also exhibit major vertical steps after anterior restorations were inserted on osseointegrated implants.

Orthodontic implants as temporary anchorage devices

Fundamental differences exist with respect to implant dimensions, insertion sites, type of implant anchorage, and intended duration of implant use. The most important difference is that a temporary anchorage device is to be removed after completion of intended orthodontic tooth movement (Daskalogiannakis 2000).

Implant designs and dimensions

As regular orthodontic patients do not display edentulous alveolar bony ridges for the insertion of an implant, implants for orthodontic anchorage must be placed in areas other than the usual topographical locations foreseen for the replacement of missing teeth. Besides the installation of orthodontic anchorage implants into the retromolar area of the mandible (Roberts *et al*. 1990; Higuchi & Slack 1991), the midsagittal palatal region (Triaca *et al*. 1992; Block & Hoffmann 1995; Wehrbein *et al*. 1996a) was initially proposed.

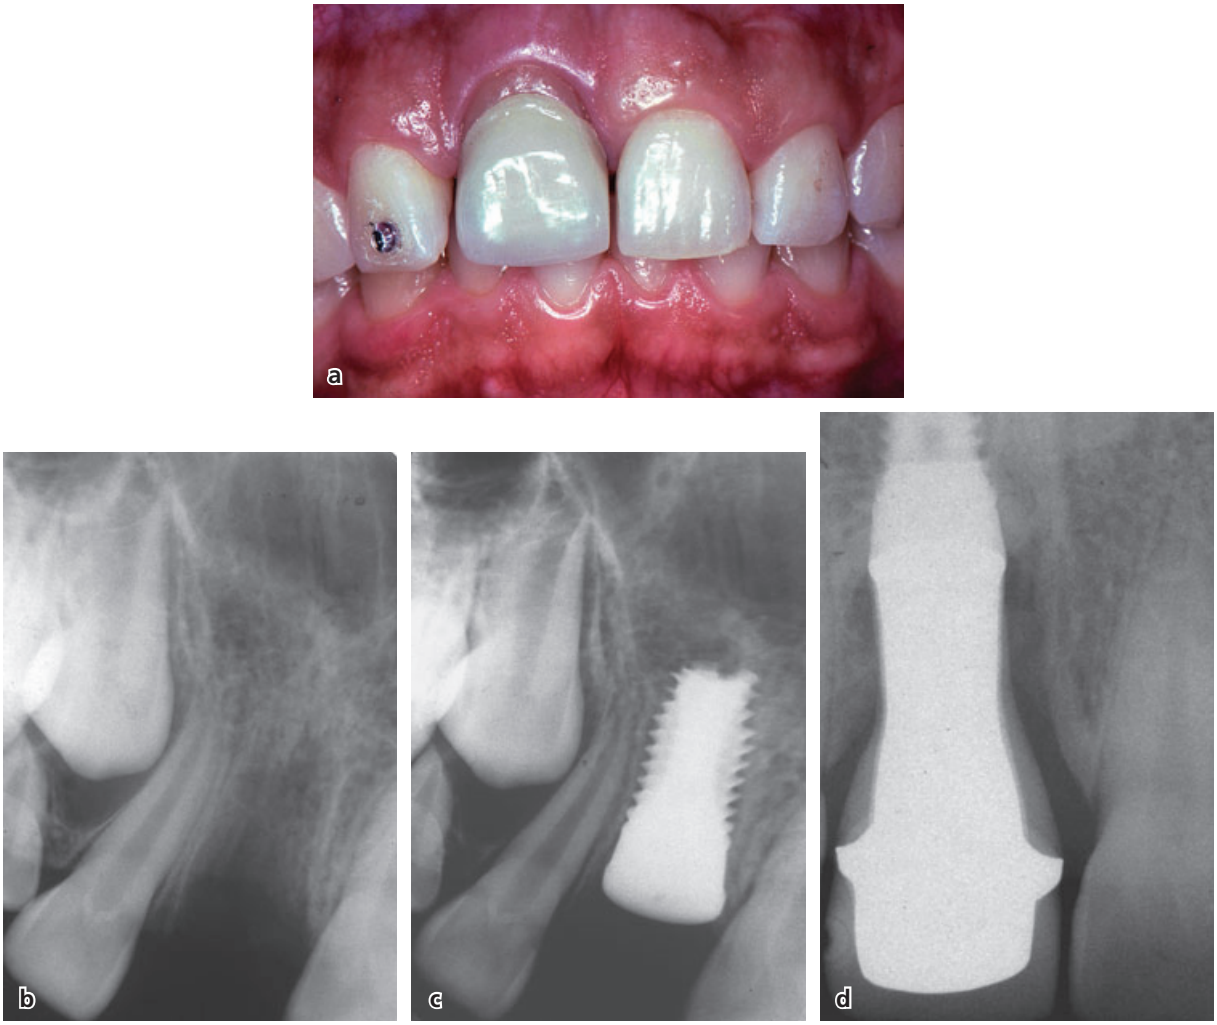

Fig. 58-8 (a) Oral implant placed prematurely (at age 9 years) in a growing patient. The implant did not follow the growth development of the alveolar process resulting in the need for multiple (three times) replacement of the prosthetic reconstruction until adolescence. Unsatisfactory esthetic outcomes persist. Radiographic documentation: (b) Following traumatic loss of tooth 11 at age 9 years. (c) Implant placement in the growing maxilla. (d) Oral implant 9 years after placement and third single tooth crown reconstruction (Courtesy of G.E. Salvi, Berne, Switzerland.)

The introduction of diameter-reduced temporary orthodontic anchorage devices such as miniscrews (<2 mm) in various lengths (Kanomi 1997; Costa *et al*. 1998) and titanium pins (Bousquet *et al*. 1996), as well as L-shaped miniplates with the long arm exposed into the oral cavity (Umemori *et al*. 1999) and the zygomatic anchors (De Clerck *et al*. 2002) both fixed by bone screws, offered new additional insertion sites: (1) the inter-radicular septum (Bousquet *et al*. 1996; Kanomi 1997); (2) the supra-apical and infra-zygomatic area (Kanomi 1997; Costa *et al*. 1998; Umemori *et al*. 1999; De Clerck *et al*. 2002); and (3) the mandibular symphysis (Costa *et al*. 1998). It must be pointed out, however, that the retention of miniscrews and titanium pins constitutes only a mechanical fixation of the devices and, hence, is not based on the principle of osseointegration.

Length-reduced orthodontic anchorage devices, such as titanium flat screws (Triaca *et al*. 1992), resorbable orthodontic implant anchors (Glatzmaier *et al*. 1995), T-shaped orthodontic implants (Wehrbein *et al*. 1996) (Orthosystem®, Institut Straumann, Waldenburg, Switzerland) and the Graz implant-supported pendulum (Byloff *et al*. 2000), were subsequently introduced.

Another device, the Onplant® (Block & Hofmann 1995), placed subperiostally, is a smooth titanium disc with a hydroxyapatite-coated surface that is supposed to connect to the bone. Owing to the submerged installation, monitoring of the healing process of these Onplants® may be troublesome, and their osseointegration may be questioned (Celenza & Hochman 2000).

The most widely used orthodontic anchorage system is the Orthosytem® (Institut Straumann, Basel, Switzerland). This titanium implant consists of three distinct features (Fig. 58-9): (1) the self-tapping endosseous body, 4.2 mm long and either 4.1 mm or 4.8 mm in diameter, designed to be inserted into bone; (2) a smooth neck portion (4.8 mm in diameter and 1.8 mm long) as the transmucosal part; and (3) the trigonal head to serve as the orthodontic appliance fixation.

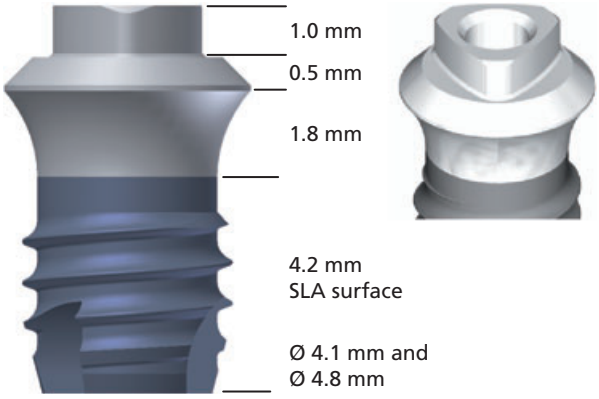

Fig. 58-9 The Orthosystem® (Institut Straumann, Waldenburg, Switzerland) designed for orthodontic anchorage with an intraosseous SLA rough surface, a smooth transmucosal portion, and a trigonal orthodontic fixation base.

Insertion sites of palatal implants

The incomplete closure of the median palatal suture during childhood and early adolescence is a limiting factor for the installation of orthodontic implants in the midsagittal region for fully grown juveniles and adults. Therefore, the paramedian regions of the hard palate (Bernhart *et al*. 2000, 2001) represent a feasible alternative. With respect to the anatomic limitations, sites chosen for palatal orthodontic anchorage device insertion should be carefully evaluated to avoid perforations into the inferior nasal turbinate (Wehrbein *et al*. 1996b). Pre-implantation examinations of the anterior palate have shown that the vertical bone volume decreases from the anterior to the posterior region.

The presence of the palatal suture and the limited bone thickness of the hard palate available may be causes of concern for the achievement of stability of palatal implants. It may be useful to perform imaging diagnosis before palatal implant insertion. Dental computed tomography and/or lateral cephalograms have been recommended for evaluating the vertical bone volume of the hard palate presurgically.

Dental computed tomography of the alveolar process is well established for the evaluation of the alveolar bone volume before implant placement (Lindh *et al*. 1995). It may also be used to assess the vertical bone volume of the hard palate and is currently the most accurate method. The greatest mean thickness was identified to be about 6–9 mm posterior to the incisal foramen in the mid-sagittal plane (Bernhart *et al*. 2000). Avoiding the midpalatal suture, the area suitable for implant placement is, therefore, located 6–9 mm posterior to the incisal foramen and 3–6 mm lateral to the mid-sagittal plane. If the necessary bone volume for an orthodontic implant installation is defined as 4 mm or more (Bernhart *et al*. 2000). In a study, 95% of the patients investigated had adequate vertical bone volume for accommodating palatal implants, 4 mm in length; this is in agreement with other clinical reports (Schiel *et al*. 1996). It must be considered, however, that the patients examined showed a great range of variation of vertical bone volume so a detailed pre-operative diagnostic process is necessary in order to avoid perforation of the lower nasal duct.

Insisting on obtaining precise information for the intended implant sites before placing palatal implants on lateral cephalograms rather than CT examination was proposed (Wehrbein *et al*. 1999). Since the former are used for orthodontic diagnosis and treatment planning, patients are spared from additional radiation exposure. Furthermore, superimposition of structures in CT scans renders this methodology complicated, imprecise, and hazardous for the presurgical assessment of bone volumes for orthodontic anchorage implants.

On wire-marked skulls, the highest bony demarcation of the palatal complex seen radiographically largely coincided with the nasal floor rather than with the mid-sagittal nasal septum, which has additional vertical bone height (Wehrbein *et al*. 1999). Hence, it was suggested that the vertical bone heights in the anterior and middle thirds of the hard palate were at least 2 mm higher vertically than identified on lateral cephalograms. A safety level of at least 2 mm is, therefore, recommended when planning treatment on the basis of lateral cephalograms (Wehrbein *et al*. 1999). It must be realized that even though some implants may project beyond the nasal floor in lateral cephalograms, they may represent false-positive results and may not be related to actual penetrations into the nasal cavity (Crismani *et al*. 2005c). If the palatal complex is perforated, intraoperative probing with a periodontal probe or a sinus probe must be performed for verification.

In addition to the palatal bony morphology, the implant's antero-posterior location and its inclination must also take into account both the pre-treatment and planned final position of the maxillary central incisor, when the implant is placed mid-sagittally (Fig. 58-10).

A distinction has to be made between the vertical bone volume in the mid-sagittal and the paramedian regions, as the indication for implant treatment in the mid-sagittal plane should be limited to adults and fully grown juveniles due to possible developmental disturbances of the palatal suture (Glatzmaier *et al*. 1995; Wehrbein *et al*. 1996b).

Palatal implants and their possible effects in growing patients

During growth, maxillary expansion in a transverse direction is the result of two processes: appositional remodeling of the alveolar process and growth of the palatal suture (Björk & Skieller 1974). While the remodeling process leads to the expansion of the dental arches, the growth in the median suture leads

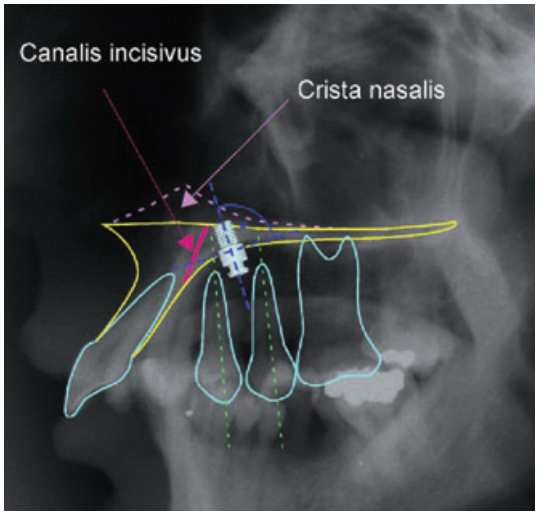

Fig. 58-10 Most palatal implants are installed satisfactorily when the location of entry into the cortical bone is at the antero-posterior level of the maxillary first and second premolars – perpendicular to the palatal surface. From Männchen & Schätzle (2008).

to the expansion of the palate that represents the most important factor in the development of the maxillary width. An average growth in maxillary width of 3 mm was demonstrated between the ages of 10 and 18 years (Björk & Skieller 1977). Since the median or paramedian anterior palate may be chosen as insertion sites for palatal implants, the question arises whether or not the implantation of an orthodontic anchorage device may affect normal transverse palatal growth. Palatal implants affected normal transverse growth in an animal study (Asscherickx *et al*. 2005). It could be shown that implant placement resulted in less transverse sutural growth.

Deficient transverse maxillary width may also cause maxillary arch length discrepancies, as demonstrated for canine impaction (McConnell *et al*. 1996). Therefore, all interventions that might cause a restriction in normal transverse maxillary growth should be avoided. Because it has been shown that the insertion of implants in the median palatal suture in adolescent beagle dogs could cause restriction in normal transverse development of the palate (McConnell *et al*. 1996), the installation of the orthodontic palatal implants is better performed in paramedian areas in growing individuals. Moreover, studies have suggested that the installation of orthodontic implants in the midpalatal suture of growing patients is contraindicated because of the questionable quality of bone to provide adequate primary stability (Bernhart *et al*. 2001; Lioubavina-Hack *et al*. 2006). The paramedian region of the anterior palate is largely stable from a growth point of view (Thilander 1995).

The most important vertical growth changes are the result of the displacement of the maxillary complex and surface remodeling processes. The sutural lowering of the maxillary complex as well as the apposition at the orbital floor and at the infrazygomatic crest will not be affected by implant installation in the palate. The resorptive lowering of the nasal floor, however, and the increase of the maxillary alveolar bone height might be influenced. The mean degree of growth from the age of 4 years to adulthood has been identified (Björk & Skieller 1977). The nasal floor appears to drift 4.6 mm caudally, and the height of the maxillary alveolar bone appears to increase 14.6 mm. Assuming that about one third of these growth changes take place from the age of 12 years to adulthood implies a residual vertical growth of about 1.5 mm in the palate and of about 5 mm in maxillary alveolar bone height (Fig. 58-11).

Osseointegrated implants are in direct contact with bone, do not possess a periodontal ligament and hence, behave like ankylosed teeth. Therefore, an osseointegrated palatal implant would remain 1.5 mm behind its surrounding bone, whereas an implant placed in the alveolar bone would produce an infra-occlusion of 5 mm during the same period. Consequently, palatal implants directly or indirectly attached to teeth would lead to an infra-eruption of a single tooth, several teeth or the whole upper dentition, respectively. By influencing the maxillary vertical growth dimension the horizontal displacement of the mandible will also be affected and would, therefore, cause a closing effect on the mandibular plane angle (anterior mandible rotation). It must be considered, however, that palatal implants as temporary orthodontic anchorage devices usually remain 1–2 years *in situ*. Thus, potential vertical and transversal growth impairment are likely to be limited to values of less than 1 mm.

Clinical procedures and loading time schedule for palatal implant installation

Patient stress during implantation and/or explantation and subsequent wound healing may be minimized by applying a minimally traumatic surgical technique. Under palatal local anesthesia, the palatal mucosa is perforated to the cortical bone using a mucosal punch or a system-compatible trephine during explantation and removed with an elevator or a curette (Fig. 58-12a). After smoothing the exposed bone surface to prevent the profile drill from slipping, the centre of the implant site is marked with a round bur (Fig. 58-12b). The implant bed is then prepared to the required depth using a series of pilot and twist drills (Fig. 58-12c). The drilling axis perpendicular to the bone surface is defined based on the presurgical cephalometric analysis. While preparing the insertion site intermediate drilling and cooling of the drilling channel continuously with pre-cooled physiologic saline or Ringer's solution should be performed. The implant is then hand-installed as far as possible, and a ratchet is used to tighten the implant to its final position (Fig. 58-12d). The implant is covered with the healing cap to prevent the inner screw well of the implant from clogging up and from being covered by hyperplastic mucosal tissue (Fig. 58-12e). After insertion, the palatal Orthosystem® implant is allowed to heal *in situ* for 12 weeks during which it should not be loaded.

In some cases, there may be a premature loss of the implant prior to orthodontic load. This loss may be caused by the lack of adequate primary stability. Such insufficient primary stability, causes inappropriate healing and the possible premature loss of the implant (Friberg *et al*. 1991; Lioubavina-Hack *et al*. 2006). Therefore, it is generally recommended to use the 4.1 mm diameter palatal Orthosystem® implant. The 4.8 mm diameter device should only be used if the prerequisite of primary stability cannot be achieved with the smaller (regular 4.1 mm) diameter implant.

Following the placement of an endosseous implant, primary mechanical stability is gradually replaced by biologic bonding. The transition from primary mechanical stability, provided by the implant design, to biologic stability, provided by the osseointegration process, occurs during the first month of wound healing (Berglundh *et al*. 2003). During this critical time, the orthodontic implant should not be used as anchorage.

The installation of implants as absolute anchorage devices facilitates and accelerates orthodontic therapy (Trisi & Rebaudi 2002), even though an inactive waiting time of at least 3 months after insertion (12 week healing time) remains (Wehrbein *et al*. 1996a, 1998; Keles *et al*. 2003; Crismani *et al*. 2005a,b). Especially in adult patients, there is a growing need to reduce this inactive waiting time and to reduce the risk for implant failure during early loading. There are several studies that have reported a successful outcome of early/immediate loaded conventional dental implants placed in the alveolar ridge (Calandriello *et al*. 2003; Rocci *et al*. 2003; Bischof *et al*. 2004; Gallucci *et al*. 2004; Glauser *et al*. 2004; Jaffin *et al*. 2004). However, as of today there is only one study evaluating early loaded palatal orthodontic implants in humans by means of resonance frequency analysis (RFA). On this basis, the possibility of loading palatal orthodontic implants earlier than recommended in the aforementioned literature was suggested with caution (Crismani *et al*. 2006).

There is still a lack of histologic documentation about adequately termed healing periods before loading orthodontic implants in the palatal region and no attempts have been made to document sequential histologic changes of the transition from primary stability to the process of osseointegration. Further studies are needed to define shorter appropriate healing periods.

After the recommended inactive healing period, an impression is taken for the construction of the transpalatal arch (TPA) connection (Fig. 58-12f,g). After integration of the TPA, the implant-related orthodontic treatment is begun. Depending on the treatment goal, schedule, and TPA design, different palatal arches may be necessary during the course of treatment in the same patient.

Direct or indirect orthodontic implant anchorage

Reliable three-dimensional attachment of orthodontic wires to the orthodontic implant is of crucial importance. There are two principles in using implants for orthodontic anchorage:

- Orthodontic forces are applied at anchorage teeth that are not to be moved and are kept in position through a rigid connection (e.g. transpalatal arch, lingual arch) with the implant (*indirect anchorage*) (Wehrbein *et al*. 1996b). The element connected directly to teeth may limit tooth movements and need adaptation or refabrication of the TPA by a dental technician (Fig. 58-12f).
- If force systems act directly between the teeth to be moved and the implant (*direct anchorage*), then the TPA may be adapted more easily by adjusting the active sectional wires (Männchen 1999). It must be considered, however, that the implant should be placed paramedian on the same side in order to keep the torque moments as low as possible, if a direct unilateral sagittal force is applied to the implant (Fig. 58-12g).

The three-dimensional attachment of the orthodontic wire to the implant may be guaranteed by using a clamping cap, a welding or soldering cap or a post cap with a pre-lased wire.

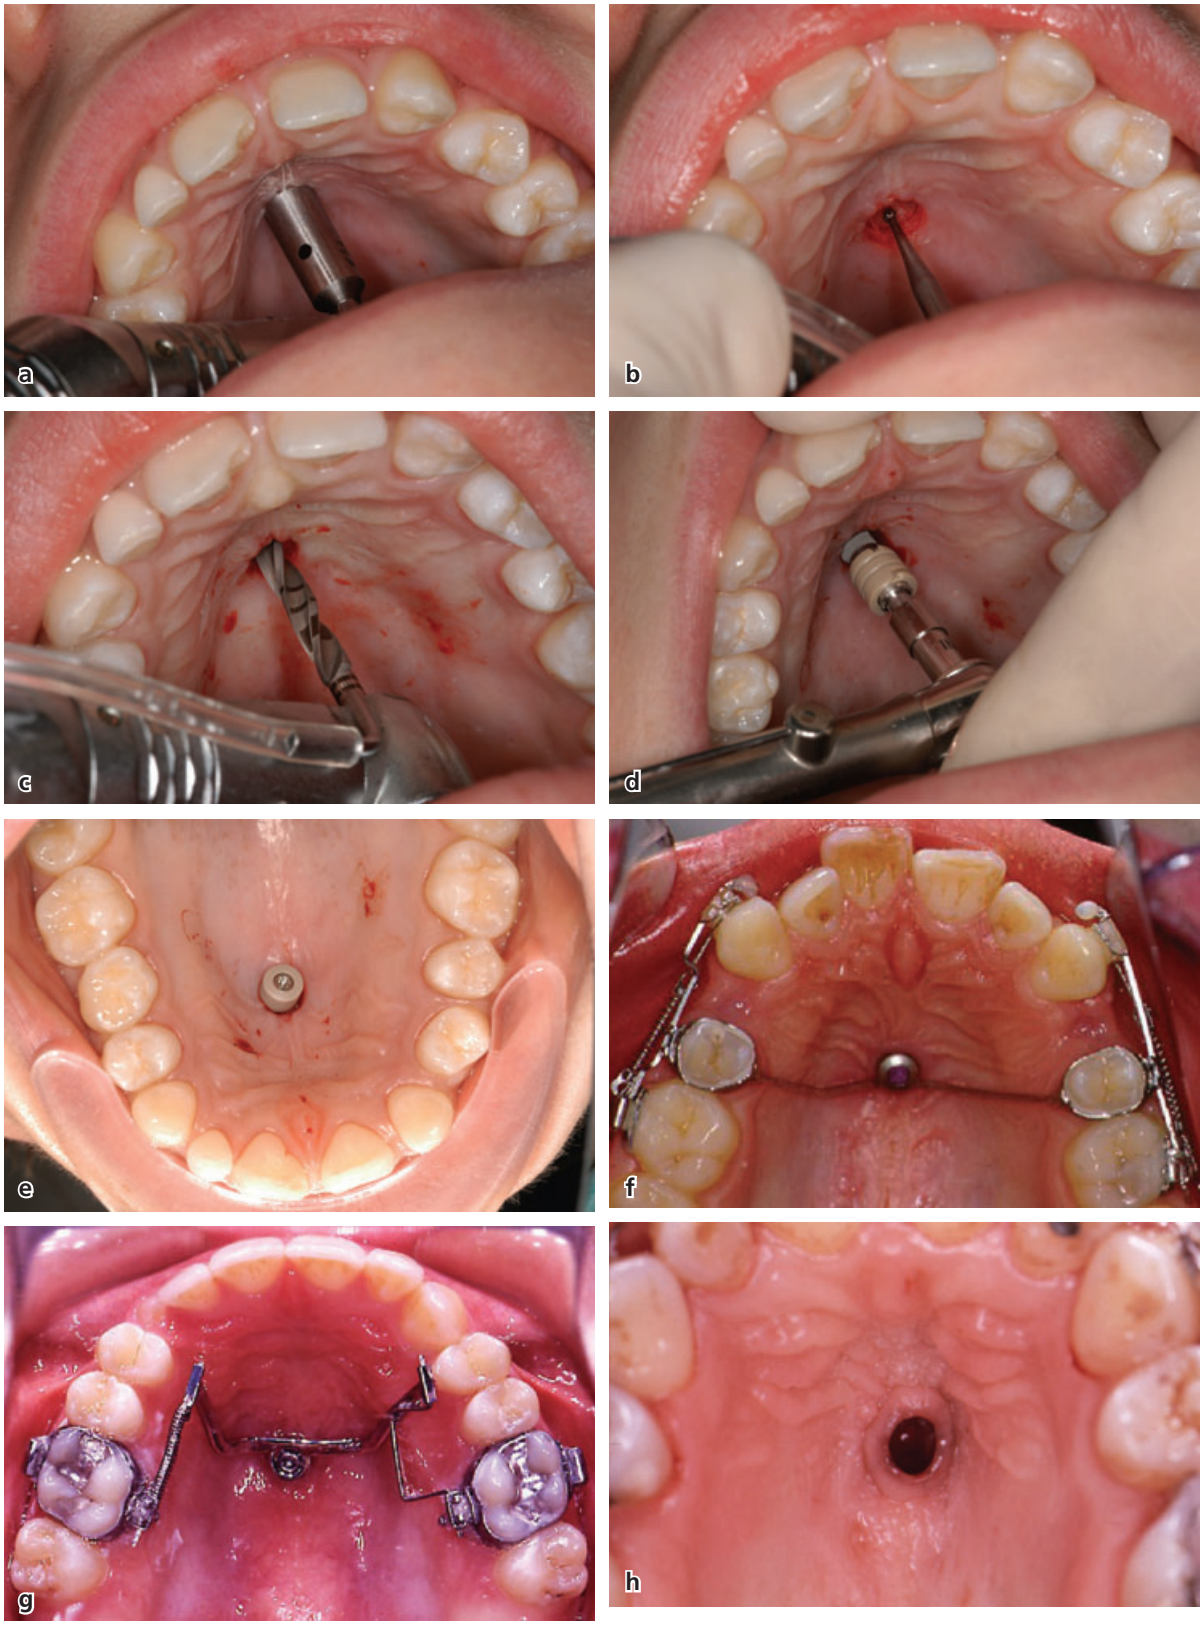

Fig. 58-12 Clinical procedures to install a palatal Orthosystem® (Straumann AG, Basel, Switzerland). (a) Perforation of the palatal mucosa using a system compatible punch or trephine. (b) Marking the center of the intended implant site with a round bur. (c) Preparation of the implant bed at the location determined presurgically and perpendicular to the bone surface. (d) Tightening of the orthodontic implant using a ratchet. (e) Covering the device with a healing cap. (f) Affixation of the transpalatal arch (TPA) for indirect loading (from Wehrbein *et al*. 1998) and (g) for direct loading (according to Männchen 1999). (h) Palatal orthodontic anchorage site after explantation.

Besides offering reliable fixation of the connecting element to the implant abutment, the connecting element must be sufficiently rigid to prevent deflection. A mean loss of anchorage of approximately 1 mm by retracting or torquing of incisors to the buccal segment has been reported (Wehrbein *et al*. 1999a). This contradiction was probably due to deformation of the TPA and/or a slight rotational play of the supraconstruction. Although this anchorage loss might be clinically irrelevant, the pre-activation of the connecting element in the opposite direction may help to avoid this side effect.

It is clear that implant-supported teeth receive continuous loading stimulation. Unfavorable jiggling forces on anchor teeth, as found in compliance-dependent anchorage aids, might be reduced or avoided. This may play a more decisive role in cases with reduced periodontal anchorage.

Stability and success rates

Despite the small dimensions, orthodontic implant anchoring devices must maintain positional stability under orthodontic loading in order to serve as absolute anchorage. As connective tissue encapsulation would initiate implant dislocation, osseointegration is a prerequisite. Histologic examination of explanted human orthodontic implant bone specimens inserted palatally revealed that osseointegration is maintained during long-term orthodontic loading under clinical conditions (Figs. 58-2, 58-3). The percentage of implant-to-bone contact in patients varied between 34% and 93% with an average of 75% (Wehrbein *et al*. 1998), obviously an adequate anchorage to withstand orthodontic loading.

There is only one retrospective cohort study reporting the success rate of a large number of inserted palatal Orthosystem® implants (Männchen & Schätzle 2008). Only three out of 70 inserted palatal implants (4.3%) did not successfully osseointegrate. Of these, two implants were lost due to inadequate primary stability. These were replaced after a short healing period with implants of a greater dimension and osseointegrated successfully thereafter. One implant was placed penetrating the incisal canal and was lost spontaneously. Of the 67 successfully osseointegrated implants loaded actively and/or passively for approximately 19 months, only one implant (1.5%) was lost after 5 months of unilateral heavy active loading (Männchen & Schätzle 2008). This report documented success rates for palatal implants after orthodontic loading comparable to those reported for conventional oral implants (Berglundh *et al*. 2002; Pjetursson *et al*. 2007).

Implant removal

No reports exist on "sleeping orthodontic palatal implants". As a consequence, they have to be removed after completion of the orthodontic treatment. By means of a system-compatible trephine, the peri-implant bone is separated from the device. Then, the implant may be explanted together with the surrounding bone by slow rotations with a extraction forceps. As a variation, the implant–bone contact may be broken by turning the ratchet used for seating the implant counter-clockwise, applying a torque of up to 40 N/cm, and a mechanical torque wrench The implant is then retrieved (Fig. 58-12h). After explantation, possible oro-antral communication must be verified and treated if necessary.

Full recovery at the original anchorage site may be observed 3–4 weeks after implant removal.

Advantages and disadvantages

Even though the orthodontic treatment may be completed faster and with more predictability, patients have to undergo two minor surgical procedures. Additionally, an inactive waiting time after implant installation remains. The extra cost for placing a palatal orthodontic implant must be balanced against other treatment options. Besides cooperation and esthetic aspects to be considered, the costs of orthognathic surgery and/or prosthetic reconstruction may be avoided or reduced by installation of an implant for orthodontic anchorage. In cases in which the palatal implant is directly loaded, bonding of the whole jaw or the entire dentition may not be necessary (Fig. 58-13). The main risks encountered with the use of orthodontic implant anchorage are the development of peri-implant infection, oro-antral connection, and/or implant loss prior to completion of orthodontic treatment.

Conclusions

Osseointegrated implants are providing absolute orthodontic anchorage and hence, are considered to be superior to any orthodontic tooth-borne anchorage device. Indications for orthodontic implant anchorage include: inadequate periodontal anchorage; non-compliant patients for extra- and/or intraoral anchorage aids; prevention of potential side effects of conventional anchorage devices; esthetic aspects; or avoidance of orthognathic surgery after growth completion. Moreover, prosthetic reconstruction may be avoided. The simplicity in use, minimal stress during surgical implant installation and removal, as well as the reliable success rates are prerequisites for the high acceptance of this treatment by orthodontic patients. It must be kept in mind, however, that treatment objectives may be achieved by several treatment plans. Proper orthodontic anchorage should be chosen according to the preceeding diagnosis and to fit the appropriate treatment plan.

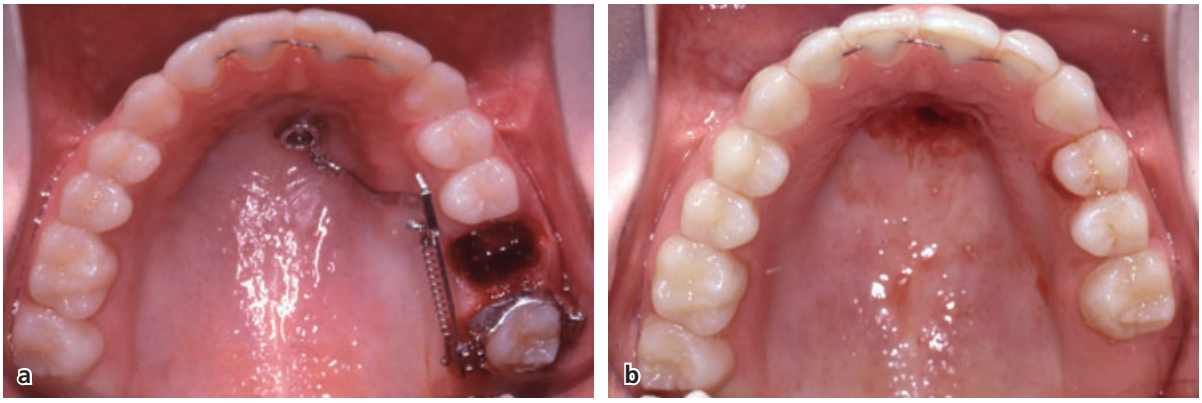

Fig. 58-13 Absolute anchorage by means of a palatal orthodontic implant avoiding the need for bonding the entire maxillary dentition with fixed orthodontic appliances. (a) After the extraction of tooth 26, protraction of tooth 27 was initiated by direct implant loading. (b) At implant and orthodontic appliance removal, the gap between teeth 25 and 27 has been completely closed, thereby avoiding the placement of a fixed partial denture. (Courtesy of R. Männchen, Winterthur, Switzerland.)

Part 18: Supportive Care

Chapter 59

Supportive Periodontal Therapy (SPT)

Niklaus P. Lang, Urs Brägger, Giovanni E. Salvi, and Maurizio S. Tonetti

Clinical trials on the long-term effects of treatment of periodontitis have clearly demonstrated that post-therapeutic professional maintenance care is an integral part of the treatment. This also constitutes the only means of assuring the maintenance of long-term beneficial therapeutic effects. Reinfection could be prevented or kept to a minimum in most patients, mainly through rigid surveillance involving professional visits at regular intervals. However, the maintenance systems presented in various studies do not allow the presentation of a clear concept with general validity for the frequency of professional maintenance visits and the mode of maintenance therapy. A danger for supervised neglect of reinfection and recurrent disease in some patients coexists with a tendency for overtreatment in others.

Objective criteria for assessing the patient's individual risk for recurrent disease have been the focus of attention of recent years. However, the evaluation of the patient's individual risk still has to be based on a probability estimation based on the analysis of patient, tooth or tooth site risk assessments.

The purpose of this chapter is to discuss the basics of continuous patient monitoring following active periodontal therapy in order to prevent reinfection and the continued progression of periodontal disease following therapy. The mode and extent of interceptive therapeutic measures needed to achieve this goal will also be evaluated.

Definitions

Periodontal treatment includes:

1. Systemic evaluation of the patient's health
2. A cause-related therapeutic phase with, in some cases
3. A corrective phase involving periodontal surgical procedures
4. Maintenance phase.

The 3rd World Workshop of the American Academy of Periodontology (1989) renamed this treatment phase "supportive periodontal therapy" (SPT). This term expresses the essential need for therapeutic measures to support the patient's own efforts to control periodontal infections and to avoid reinfection. Regular visits to the therapist should serve as a positive feedback mechanism between the patient and the therapist with the purpose of ensuring that patients have the opportunity to maintain their dentitions in a healthy status for the longest possible time. An integral part of SPT is the continuous diagnostic monitoring of the patient in order to intercept with adequate therapy and to optimize the therapeutic interventions tailored to the patient's needs.

Basic paradigms for the prevention of periodontal disease

Periodontal maintenance care, or SPT, follows the paradigms of the etiology and pathogenesis of

periodontal disease and – at present – must consider the fact that these diseases are coping with the result of the host defense on an opportunistic infection.

Almost 40 years ago, a cause–effect relationship between the accumulation of bacterial plaque on teeth and the development of gingivitis was proven (Löe *et al*. 1965). This relationship was also documented by the restoration of gingival health following plaque removal. Ten years later, a corresponding relationship between plaque accumulation and the development of periodontal disease, characterized by loss of connective tissue attachment and resorption of alveolar bone, was shown in laboratory animals (Lindhe *et al*. 1975). Since some of these animals did not develop periodontal disease despite a persistent plaque accumulation for 48 months, it must be considered that the composition of the microbiota or the host's defense mechanisms or susceptibility for disease may vary from individual to individual. Nevertheless, in the study mentioned, the initiation of periodontal disease was always preceded by obvious signs of gingivitis. Hence, it seems reasonable to predict that the elimination of gingival inflammation and the maintenance of healthy gingival tissues will result in the prevention of both the initiation and the recurrence of periodontal disease. In fact, as early as 1746, Fauchard stated that "little or no care as to the cleaning of teeth is ordinarily the cause of all diseases that destroy them" (Fauchard 1746).

From the clinical point of view, the above-mentioned results must be translated into the necessity for proper and regular personal plaque elimination, at least in patients treated for or susceptible to periodontal disease. This simple principle may be difficult to implement in all patients; however, interceptive professional supportive therapy at regular intervals may, to a certain extent, compensate for the lack of personal compliance with regard to oral hygiene standards.

These aspects have been imitated in a beagle dog model with naturally occurring periodontal disease (Morrison *et al*. 1979). Two groups of animals were used. The test group was subjected to initial scaling and root planing and, subsequently, plaque was eliminated by daily toothbrushing and biweekly polishing with rubber cups for a period of 3 years. In the control group, no initial scaling and no oral hygiene practices were performed during the same period of time. Every 6 months, however, the teeth in two diagonally opposed jaw quadrants in both test and control animals were scaled and root planed. The results showed that the reduction of probing depth and the gain of probing attachment, obtained after the initial scaling and root planing in the test animals, were maintained throughout the entire course of the study irrespective of whether or not repeated scaling and root planing had been performed. The control animals, on the other hand, continued to show increasing probing depths and loss of attachment in all quadrants irrespective of whether or not repeated scaling and root planing had been performed. However, in the jaw quadrants where the teeth were repeatedly instrumented every 6 months, the progression of periodontal destruction was significantly less pronounced (Fig. 59-1). These results indicate that professional supportive therapy, performed at regular intervals, may, at least to a certain extent, compensate for a "suboptimal" personal oral hygiene standard. In this respect, it has been demonstrated that following root instrumentation, the subgingival microbiota is significantly altered in quantity and quality (Listgarten *et al*. 1978), and that the re-establishment of a disease-associated, subgingival microbiota may take several months (Listgarten *et al*. 1978; Slots *et al*. 1979; Mousquès *et al*. 1980; Caton *et al*. 1982; Magnusson *et al*. 1984).

In a number of longitudinal, clinical studies on the outcome of periodontal therapy, the crucial role of SPT in maintaining successful results has been documented (Ramfjord *et al*. 1968, 1975; Lindhe & Nyman 1975, 1984; Rosling *et al*. 1976; Nyman *et al*. 1977; Knowles *et al*. 1979, 1980; Badersten *et al*. 1981, 1987; Hill *et al*. 1981; Lindhe *et al*. 1982a,b; Pihlström *et al*. 1983; Westfelt *et al*. 1983a, 1985; Isidor & Karring 1986; Kaldahl *et al*. 1988). In all these studies, probing depths and clinical attachment levels were maintained as a result of a well organized professional maintenance care program (recall intervals varying between 3 and 6 months) irrespective of the initial treatment modality performed. In one of the studies (Nyman *et al*. 1977) an alarming result was that patients treated for advanced periodontal disease involving surgical techniques, but not incorporated in a supervised maintenance care program, exhibited recurrent periodontitis including loss of attachment at a rate three to five times higher than documented for natural progression of periodontal disease in population groups with high disease susceptibility (Löe *et al*. 1978, 1986). Within this area, the effect of negligence in providing adequate supportive maintenance care following periodontal treatment has been studied over a 6-year period by Axelsson and Lindhe (1981a). Following presurgical root instrumentation and instruction in oral hygiene practices, all study patients were subjected to modified Widman flap procedures. During a 2-month healing period, professional toothcleaning was performed every 2 weeks. Following this time period, baseline clinical data were obtained and one out of every three patients was dismissed from the clinic, while the other two were incorporated in a professionally conducted maintenance program with a recall once every 3 months. These patients maintained excellent oral hygiene and consequently yielded a very low frequency of bleeding sites. In addition, probing depths and probing attachment levels were maintained unchanged over the 6-year period. In contrast, the non-recalled patients demonstrated obvious signs of recurrent periodontitis at the 3-year and 6-year

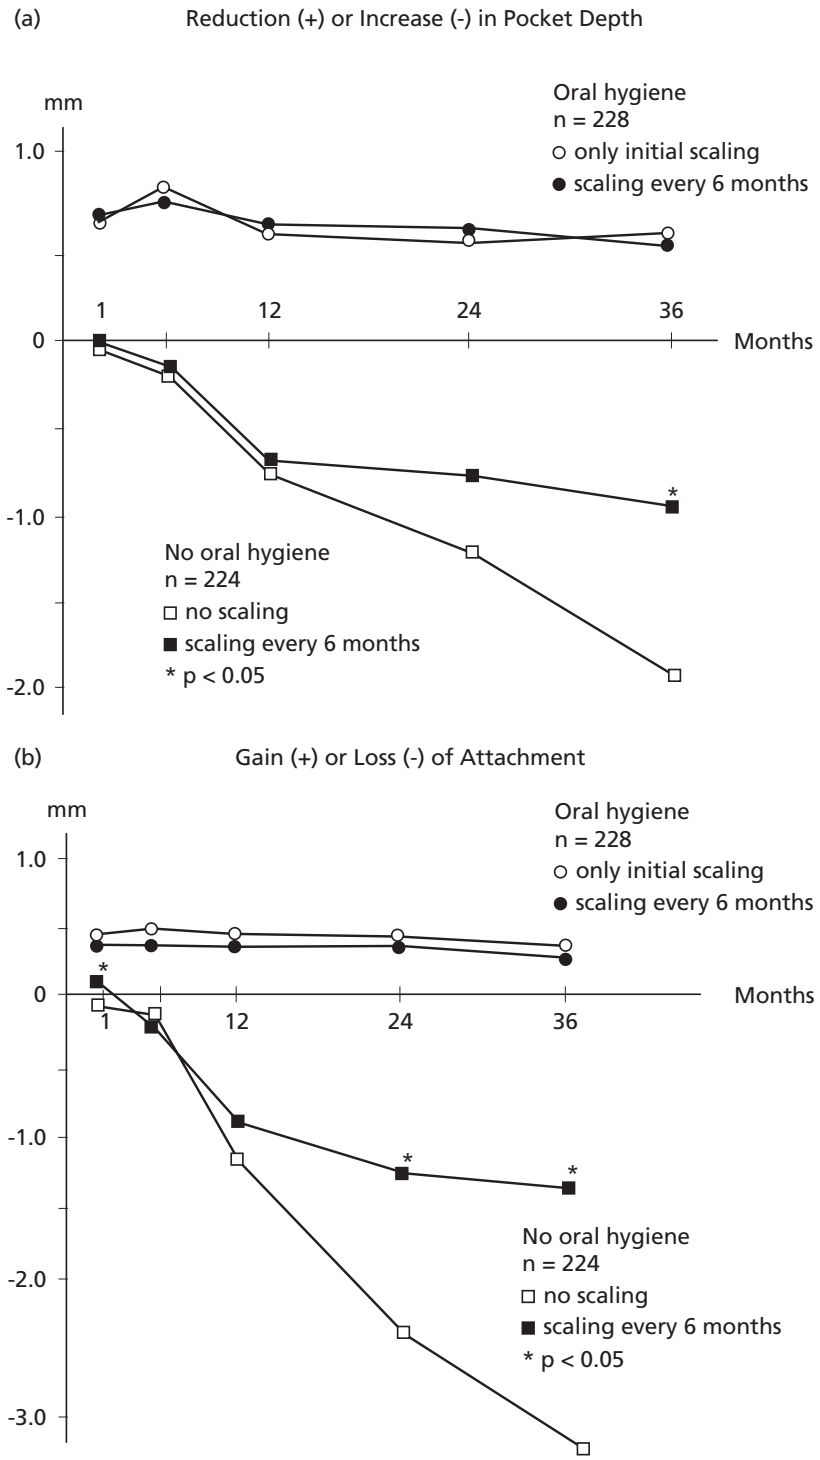

Fig. 59-1 (a) Mean probing depth reduction (+) or increase in probing depth (–) in millimeters with or without repeated scaling and root planing in experimental (oral hygiene) and control (no oral hygiene) animals relative to baseline means. (b) Mean gain (+) or loss (–) of probing attachment with or without repeated scaling and root planing in experimental (oral hygiene) and control (no oral hygiene) animals relative to baseline means. (Data from Morrison *et al*. 1979.)

re-examinations. Further evidence for the likelihood of recurrent disease in patients not subjected to professional maintenance care was presented by Kerr (1981). Five years after successful treatment, 45% of the patients presented with periodontal conditions similar to their status before treatment. Supportive therapy had only been provided at intervals varying between 9 and 18 months.

Similar results have been described for private practice patients who decided not to participate in an organized maintenance care program following active periodontal therapy (Becker *et al*. 1984). Subsequent examinations revealed clear signs of recurrent periodontal disease including increased probing depths and involvements of furcations of multirooted teeth concomitant with tooth loss. Also, loss of alveolar bone observed in radiographs and tooth loss have been reported for a group of patients in whom post-therapeutic supportive maintenance care was provided less frequently than once every 12 months (De Vore *et al*. 1986). From all these studies it is evident that periodontal treatment is ineffective in maintaining periodontal health if supportive maintenance care is neglected, denied or omitted.

Even though the number of well controlled longitudinal clinical trials is rather limited for patients who, in addition to periodontal treatment, have undergone extensive reconstructive therapy, it should be realized that the concept of professional maintenance care has unrestricted validity. In a longitudinal study of combined periodontal and prosthetic treatment of patients with advanced periodontal disease, periodontal health could be maintained over a study period of 5–8 years with regular recall appointments scheduled every 3–6 months (Nyman & Lindhe 1979). Similar results have been presented by Valderhaug and Birkeland (1976) and by Valderhaug (1980) for periods of up to 15 years. Another study of 36 patients who received extensive poly-unit cantilevered bridgework following periodontal therapy, confirmed the maintenance of periodontal health over 5–12 years (Laurell *et al*. 1991). More recent studies on the long-term maintenance over 10 and 11 years of periodontal patients who, following successful treatment of chronic periodontitis, were reconstructed with extensive fixed reconstructions revealed that regularly performed SPT resulted in periodontal stability. Only 1.3% (Hämmerle *et al*. 2000) and 2.0% (Moser *et al*. 2002) of the abutments showed some minor attachment loss during these long periods of observation. In contrast, a report of insurance cases who were not regularly maintained by SPT yielded a recurrence rate for periodontitis of almost 10% after an observation of 6.5 years (Randow *et al*. 1986).

Summary: The etiology of gingivitis and periodontitis is fairly well understood. However, the causative factors, i.e. the microbial challenge which induces and maintains the inflammatory response, may not be completely eliminated from the dentogingival environment for any length of time. This requires the professional removal of all microbial deposits in the supragingival and subgingival areas at regular intervals, since recolonization will occur following the debridement procedures, leading to a reinfection of the ecologic niche and, hence, giving rise to further progression of the disease process. Numerous well controlled clinical trials, however, have documented that such a development can be prevented over very long periods of time only by regular interference with the subgingival environment which aims at removal of the subgingival bacteria.

Patients at risk for periodontitis without SPT

The effect of an omission of SPT in patients with periodontitis may best be studied either in untreated populations or patient groups with poor compliance.

One of the few studies documenting untreated periodontitis-susceptible patients reported on the continuous loss of periodontal attachment as well as teeth in Sri Lankan tea plantation workers receiving no dental therapy (Löe *et al*. 1986). In this – for the western world – rather unique model situation, an average loss of 0.3 mm per tooth surface and year was encountered. Also, the laborers lost between 0.1 and 0.3 teeth per year as a result of periodontitis. In another untreated group in the United States, 0.61 teeth had been lost per year during an observation period of 4 years (Becker *et al*. 1979). This is in dramatic contrast to reports on tooth loss in well maintained patients treated for periodontitis (e.g. Hirschfeld & Wasserman 1978; McFall 1982; Becker *et al*. 1984; Wilson *et al*. 1987). Such patients were either completely stable and lost no teeth during maintenance periods ranging up to 22 years or lost only very little periodontal attachment and only 0.03 teeth (Hirschfeld & Wasserman 1978) or 0.06 teeth (Wilson *et al*. 1987), respectively.

Non-complying, but periodontitis-susceptible patients receiving no SPT following periodontal surgical interventions continued to lose periodontal attachment at a rate of approximately 1 mm per year regardless of the type of surgery chosen (Nyman *et al*. 1977). This is almost three times more than would have to be expected as a result of the "natural" course of periodontal disease progression (Löe *et al*. 1978, 1986).

In a British study of a private practice situation (Kerr 1981) where the patients were referred back to the general dentist after periodontal therapy, 45% of the patients showed complete reinfection after 5 years.

Probably the most impressive documentation of the lack of SPT in disease-susceptible individuals arises from a clinical trial in which one third of the patients had been sent back to the referring general practitioner for maintenance, while two thirds of the patients received SPT in a well organized maintenance system (Axelsson & Lindhe 1981a). The 77 patients were examined before treatment, 2 months after the last surgical procedure and 3 and 6 years later. The 52 patients on the carefully designed SPT system visited the program every 2 months for the first 2 years and every 3 months for the remaining 4 years of the observation period. The results obtained from the second examination (2 months after the last surgery) showed that the effect of the initial treatment was good in both groups. Subsequently, the recall patients were able to maintain proper oral hygiene and unaltered attachment levels. In the non-recall group, plaque scores increased markedly from the baseline values, as did the number of inflamed gingival units (Fig. 59-2a). Concomitantly, there were obvious signs of recurrent periodontitis. The mean values for pocket depth and attachment levels at the 3-year and 6-year examinations were higher than at baseline (Fig. 59-2b). In the recall group, approximately 99% of the tooth surfaces showed either improvement, no change or less than 1 mm loss of attachment, compared to 45% in the non-recall group

(Table 59-1). In the latter patients, 55% of the sites showed a further loss of attachment of 2–5 mm at the 6-year examination, and 20% of the pockets were 4 mm deep or more (Tables 59-1, 59-2).

Summary: Patients susceptible to periodontal disease are at high risk for reinfection and progression of periodontal lesions without meticulously organized and performed SPT. Since all patients who were treated for periodontal diseases belong to this risk category by virtue of their past history, an adequate maintenance care program is of utmost importance for a beneficial long-term treatment outcome. SPT has to be aimed at the regular removal of the subgingival microbiota and must be supplemented by the patient's efforts for optimal supragingival plaque control.

Table 59-1 Percentage of sites showing various changes in probing attachment level between baseline examination, 2 months after completion of active periodontal therapy, and at follow-up examination 6 years later (adapted from Axelsson & Lindhe 1981b)

Change in attachment level	Percentage of surfaces showing change	
	Recall	Non-recall
Attachment level improved	17	1
No change	72	10
Attachment level worse by:		
≥1 mm	10	34
2–5 mm	1	55

Table 59-2 Percentage of various probing depths in recall and non-recall patients at the initial examination, 2 months after active periodontal treatment, and at 3- and 6-year follow-up visits (adapted from Axelsson & Lindhe 1981b)

Examinations	Percentage of pockets of various depths					
	≤3 mm		4–6 mm		≥7 mm	
	Recall	Non-recall	Recall	Non-recall	Recall	Non-recall
Initial	35	50	58	38	8	12
Baseline	99	99	1	1	0	0
3 years	99	91	1	9	0	0
6 years	99	80	1	19	0	1

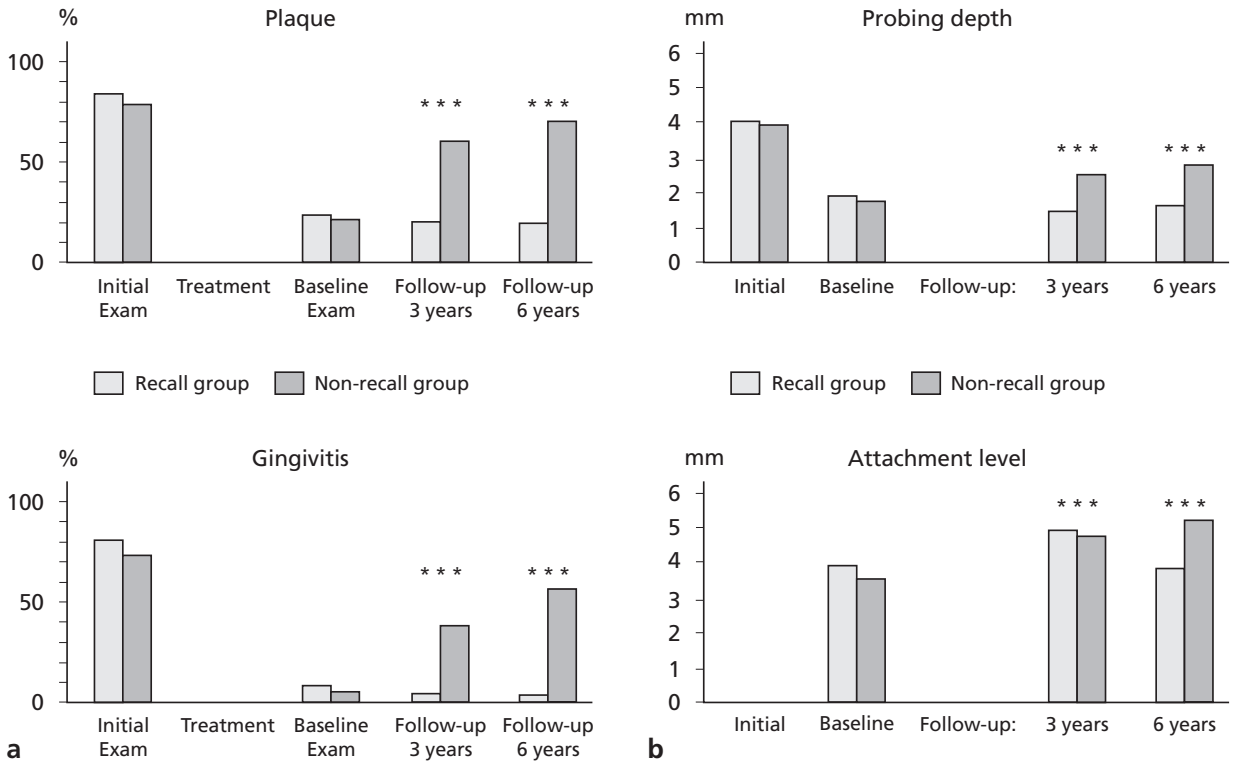

Fig. 59-2 Histograms showing (a) average percentages of tooth surfaces harboring visible plaque (above) and inflamed gingival units (bleeding on probing) (below), and (b) average probing depth (above) and probing attachment levels (below), at initial, baseline and follow-up examinations. (Data from Axelsson & Lindhe 1981b.)

SPT for patients with gingivitis

Several studies, predominantly in children, have documented that periodic professional prophylactic visits in conjunction with reinforcement of personal oral hygiene are effective in controlling gingivitis (Badersten *et al*. 1975; Poulsen *et al*. 1976; Axelsson & Lindhe 1981a,b; Bellini *et al*. 1981). This, however, does not imply that maintenance visits in childhood preclude the development of more severe disease later in life. It is obvious that SPT, therefore, must be a lifelong commitment of both the patient and the profession.

Adults whose effective oral hygiene was combined with periodic professional prophylaxis were clearly healthier periodontally than patients who did not participate in such programs (Lövdal *et al*. 1961; Suomi *et al*. 1971). One particular study of historic significance was performed on 1428 adults from an industrial company in Oslo, Norway (Lövdal *et al*. 1961). Over a 5-year observation period, the subjects were recalled two to four times per year for instruction in oral hygiene and supragingival and subgingival scaling. Gingival conditions improved by approximately 60% and tooth loss was reduced by about 50% of what would be expected without these efforts.

In another study (Suomi *et al*. 1971) loss of periodontal tissue support in young individuals with gingivitis or only loss of small amounts of attachment was followed over 3 years. An experimental group receiving scaling and instruction in oral hygiene every 3 months yielded significantly less plaque and gingival inflammation than the control group in which no special efforts had been made. The mean loss of probing attachment was only 0.08 mm per surface in the experimental as opposed to 0.3 mm in the control group.

When adult patients with gingivitis were treated with scaling and root planing, but did not improve their oral hygiene procedures, the gingival condition did not improve compared with individuals receiving prophylaxes at 6-month intervals (Listgarten & Schifter 1982).

Summary: The available information indicates that the prevention of gingival inflammation and early loss of attachment in patients with gingivitis depends primarily on the level of personal plaque control, but also on further measures to reduce the accumulation of supragingival and subgingival plaque.

SPT for patients with periodontitis

As mentioned previously, a series of longitudinal studies on periodontal therapeutic modalities was performed over the past 25 years, first at the University of Michigan, later at the University of Gothenburg, Sweden, and also at the Universities of Minnesota, Nebraska, and Loma Linda. These studies always incorporated the patients into a well organized maintenance care system with recall visits at regular intervals (generally 3–4 months). Although the patients performed plaque control with various degrees of efficacy, the SPT resulted in excellent maintenance of post-operative attachment levels in most patients (Knowles 1973; Ramfjord *et al*. 1982).

On average, excellent treatment results with maintained reduced probing depths and maintained gains of probing attachment were documented for most of the patients in the longitudinal studies irrespective of the treatment modality chosen (Ramfjord *et al*. 1975; Lindhe & Nyman 1975; Rosling *et al*. 1976; Nyman *et al*. 1977; Knowles *et al*. 1979, 1980; Badersten *et al*. 1981, 1987; Hill *et al*. 1981; Lindhe *et al*. 1982a; Pihlström *et al*. 1983; Westfelt *et al*. 1983a,b, 1985; Isidor & Karring 1986).

In a study on 75 patients with extremely advanced periodontitis, who had been successfully treated for the disease with cause-related therapy and modified Widman flap procedures (Lindhe & Nyman 1984), recurrent infection occurred in only very few sites during a 14-year period of effective SPT. However, it has to be realized that recurrent periodontitis was noticed at completely unpredictable time intervals, but was concentrated in about 25% of the patient population (15 out of 61). This suggests that, in a periodontitis-susceptible risk population, the majority of patients can be "cured" provided an optimally organized SPT is performed, while a relatively small proportion of patients (20–25%) will suffer from occasional episodes of recurrent periodontal reinfection. It is obviously a challenge for the diagnostician to identify such patients with very high disease susceptibility and to monitor the dentitions for recurrent periodontitis on a long-term basis.

As opposed to the study by Lindhe and Nyman (1984) which exclusively involved patients with advanced periodontitis, another study on 52 patients with generalized mild to moderate adult periodontitis addressed the efficacy of SPT 8 years following completion of cause-related periodontal therapy (Brägger *et al*. 1992). Full-mouth intraoral radiographs were used to assess changes in the radiographic alveolar bone height as a percentage of the total tooth length. As a result of cause-related therapy, a gain in probing attachment followed by a loss of 0.5–0.8 mm over the following 8 years was observed. The radiographic loss of alveolar bone height in the same time period was less than 2% and thus clinically insignificant. In this patient group initially presenting with mild to moderate periodontitis, the frequency of SPT rendered per year did not affect the rate of progression of periodontal desease. However, patients seeking SPT less than once per year over 8 years lost further periodontal attachment during the period of observation. From these studies it is evident that patients having experienced periodontitis need some kind of SPT. Obviously, the frequency of SPT visits has to be adapted to the risk of susceptibility for the

disease. Patients with advanced periodontitis may need SPT at a regular and rather short time interval (3–4 months), while for mild to moderate forms of periodontitis, one annual visit may be enough to prevent further loss of attachment.

More recently, the effect of a plaque-control-based maintenance program on tooth mortality, caries, and periodontal disease progression was presented after 30 years of SPT in a private dental office (Axelsson *et al*. 2004). This prospective controlled cohort study initially included 375 test and 180 control patients that received traditional maintenance care (by the referring dentist once to twice a year). After 6 years, the control group was discontinued. The test group was subjected to prophylactic visits every second month for the first 2 years and every 3–12 months (according to their individual needs) during years 3–30. The prophylactic visits to the dental hygienist included plaque disclosure and professional mechanical tooth cleaning, including the use of a fluoride-containing dentifrice. During the 30 years of maintenance, very few teeth were lost (0.4–1.8%), and these were predominately lost because of root fractures. Within 30 years of maintenance, 1.2–2.1 new carious lesions (>80% secondary caries) were found. With the exception of buccal sites, no sites demonstrated any loss of periodontal attachment during this period. On approximal sites, there was even some gain of attachment. This unique study clearly demonstrated that SPT based on plaque control tailored to the individual needs of the patient will result in very low tooth mortality, minimal recurrent caries, and almost complete periodontal stability.

Summary: SPT is an absolute prerequisite to guarantee beneficial treatment outcomes with maintained levels of clinical attachment over long periods of time. The maintenance of treatment results for the majority of patients has been documented up to 14 years, and in a private practice situation even up to 30 years, but it has to be realized that a small proportion of patients will experience recurrent infections with progression of periodontal lesions in a few sites in a completely unpredictable mode. The continuous risk assessment at subject, tooth and tooth site levels, therefore, represents a challenge for the SPT concept.

Continuous multi-level risk assessment

As opposed to an initial periodontal diagnosis which considers the sequelae of the disease process, i.e. documents the net loss of periodontal attachment and the concomitant formation of periodontal pockets and the existence of inflammation, clinical diagnosis during SPT has to be based on the variations of the health status obtained following successful active periodontal treatment. This, in turn, means that a new baseline will have to be established once the treatment goals of active periodontal therapy (i.e. phases 1–3) are reached and periodontal health is restored (Claffey 1991). This baseline includes the level of clinical attachment achieved while the inflammatory parameters are supposed to be under control. Under optimal circumstances, supportive periodontal care would maintain clinical attachment levels obtained after active therapy for the years to come. The relevant question would, therefore, be which clinical parameters may serve as early indicators for a new onset or recurrence of the periodontal disease process, i.e. reinfection and progression of periodontal breakdown of a previously treated periodontal site.

From a clinical point of view the stability of periodontal conditions reflects a dynamic equilibrium between bacterial aggression and effective host response. As such, this homeostasis is prone to sudden changes whenever one of the two factors prevails. Hence, it is evident that the diagnostic process must be based on continuous monitoring of the multi-level risk profile. The intervals between diagnostic assessments must also be chosen based on the overall risk profile and the expected benefit. To schedule patients for supportive periodontal therapy on the basis of an individual risk evaluation for recurrence of disease has been demonstrated to be cost effective (Axelsson & Lindhe 1981a,b; Axelsson *et al*. 1991).

By virtue of their previous disease predisposition, all patients under a periodontal maintenance program represent a population with a moderate to high risk for recurrent periodontal infection. As opposed to the general population without such a history, periodontal patients need to participate in a well organized recall system which should provide both continuous risk assessment and adequate supportive care. Without this, the patients are likely to experience progressive loss of periodontal attachment (Axelsson & Lindhe 1981a; Kerr 1981; Becker *et al*. 1984; Cortellini *et al*. 1994, 1996). On the other hand, it is important to determine the level of risk for progression in each individual patient in order to be able to determine the frequency and extent of professional support necessary to maintain the attachment levels obtained following active therapy. The determination of such risk level would thus prevent undertreatment, and also excessive overtreatment, during SPT (Brägger *et al*. 1992).

Subject risk assessment

The patient's risk assessment for recurrence of periodontitis may be evaluated on the basis of a number of clinical conditions whereby no single parameter displays a more paramount role. The entire spectrum of risk factors and risk indicators ought to be evaluated simultaneously. For this purpose, a functional diagram has been constructed (Fig. 59-3) (Lang & Tonetti 2003) including the following aspects:

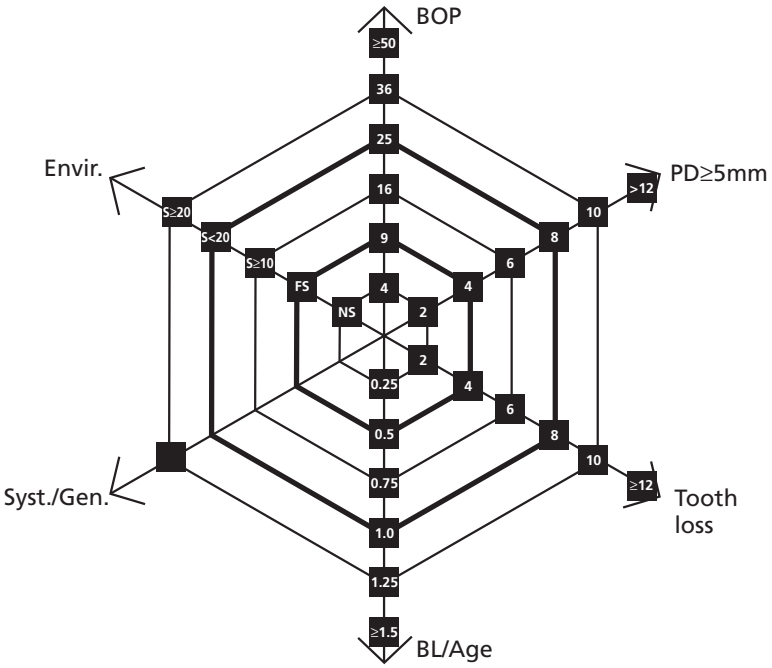

Fig. 59-3a Functional diagram to evaluate the patient's risk for recurrence of periodontitis. Each vector represents one risk factor or indicator with an area of relatively low risk, an area of moderate risk, and an area of high risk for disease progression. All factors have to be evaluated together and hence the area of relatively low risk is found within the center circle of the polygon, while the area of high risk is found outside the periphery of the second polygon in bold. Between the two rings in bold, there is the area of moderate risk.

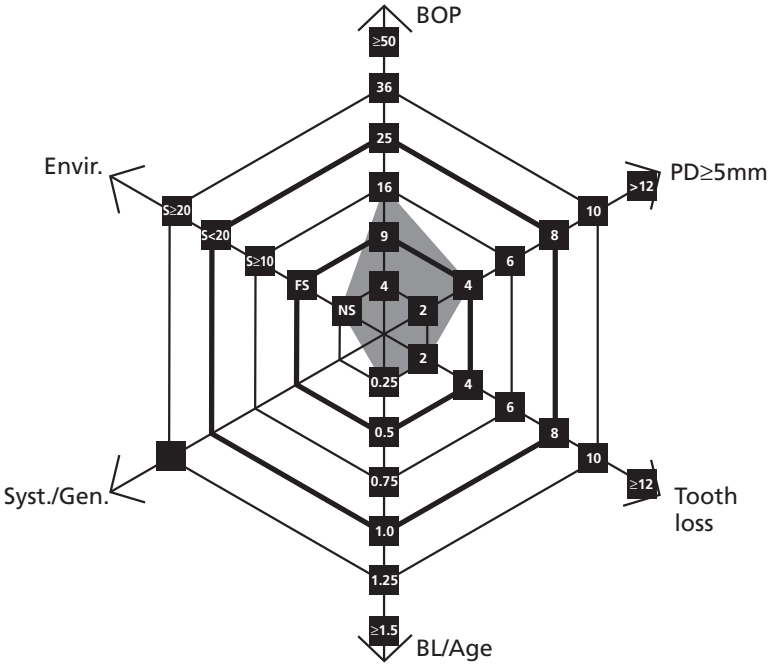

Fig. 59-3b Functional diagram of a low-risk maintenance patient. BOP is 15%, four residual pockets ≥5 mm are diagnosed, two teeth have been lost, the bone factor in relation to the age is 0.25, no systemic factor is known and the patient is a non-smoker.

1. Percentage of bleeding on probing
2. Prevalence of residual pockets greater than 4 mm
3. Loss of teeth from a total of 28 teeth
4. Loss of periodontal support in relation to the patient's age
5. Systemic and genetic conditions
6. Environmental factors such as cigarette smoking.

Each parameter has its own scale for minor, moderate, and high-risk profiles. A comprehensive evaluation, the functional diagram will provide an individualized total risk profile and determine the frequency and complexity of SPT visits. Modifications may be made to the functional diagram if additional factors become important from future evidence.

Compliance with recall system

Several investigations have indicated that only a minority of periodontal patients comply with the prescribed supportive periodontal care (Wilson *et al*. 1984; Mendoza *et al*. 1991; Checchi *et al*. 1994; Demetriou *et al*. 1995). Since it has been clearly established that treated periodontal patients who comply with regular periodontal maintenance appointments have a better prognosis than patients who do not comply (Axelsson & Lindhe 1981a; Becker *et al*. 1984; Cortellini *et al*. 1994, 1996), non-compliant or poorly compliant patients should be considered at higher risk for periodontal disease progression. A report that investigated the personality differences of patients

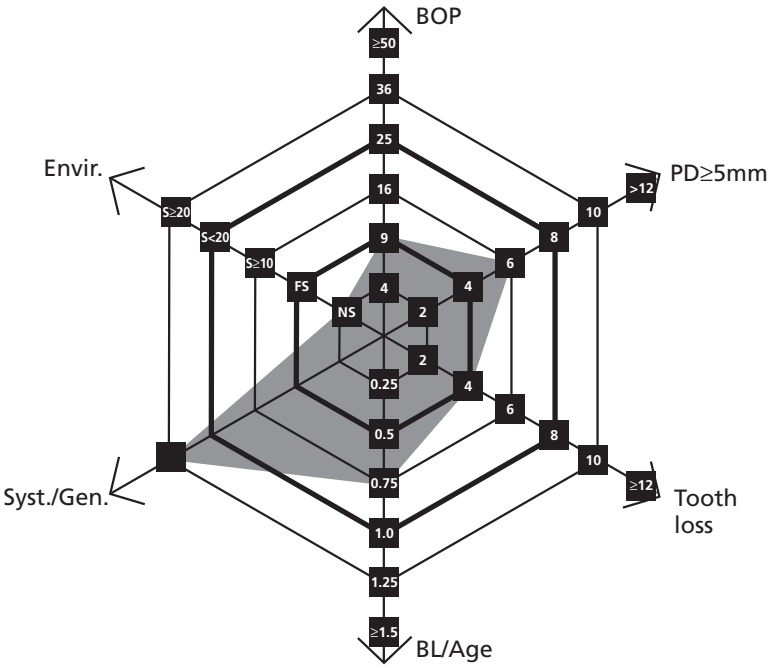

Fig. 59-3c Functional diagram of a medium-risk maintenance patient. BOP is 9%, six residual pockets ≥5 mm are diagnosed, four teeth have been lost, the bone factor in relation to the age is 0.75, the patient is a type I diabetic, but a non-smoker.

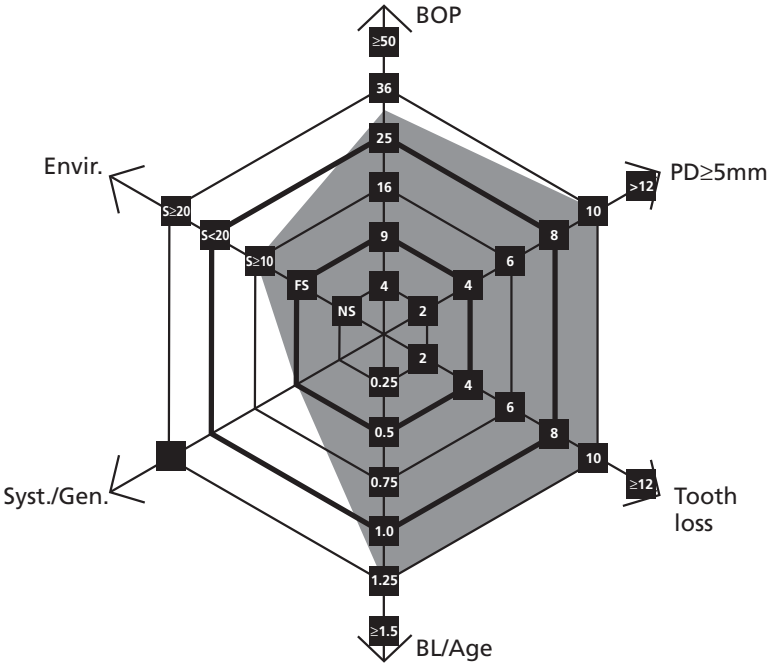

Fig. 59-3d Functional diagram of a high-risk maintenance patient. BOP is 32%, ten residual pockets ≥5 mm are diagnosed, ten teeth have been lost, the bone factor in relation to the age is 1.25, no systemic factor is known, and the patient is an occasional smoker.

participating in a regular recall program as compared to patients who did not, revealed that patients who did not take part in a maintenance program following periodontal therapy had higher incidences of stressful life events and less stable personal relationships in their lives (Becker *et al*. 1988).

Oral hygiene

Since bacterial plaque is by far the most important etiologic agent for the occurrence of periodontal diseases (for review see Kornman and Löe 1993), it is evident that the full-mouth assessment of the bacterial load must have a pivotal impact in the determination of the risk for disease recurrence. It has to be realized, however, that regular interference with the microbial ecosystem during periodontal maintenance will eventually obscure such obvious associations. In patients treated with various surgical and non-surgical modalities, it has been clearly established that plaque-infected dentitions will yield recurrence of periodontal disease in multiple locations, while dentitions under plaque control and regular supportive care maintain periodontal stability for many years (Rosling *et al*. 1976; Axelsson & Lindhe 1981a,b). Studies have thus far not identified a level of plaque infection compatible with maintenance of periodontal health. However, in a clinical set-up, a plaque control record of 20–40% might be tolerable by most patients. It is important to realize that the full-mouth

plaque score has to be related to the host response of the patient, i.e. compared to inflammatory parameters.

Percentage of sites with bleeding on probing

Bleeding on gentle probing represents an objective inflammatory parameter which has been incorporated into index systems for the evaluation of periodontal conditions (Löe & Silness 1963; Mühlemann & Son 1971) and is also used as a parameter by itself. In a patient's risk assessment for recurrence of periodontitis, bleeding on probing (BOP) reflects, at least in part, the patient's compliance and standards of oral hygiene performance. Although there is no established acceptable level of prevalence of BOP in the dentition above which a higher risk for disease recurrence has been established, a BOP prevalence of 25% has been the cut-off point between patients with maintained periodontal stability for 4 years and patients with recurrent disease in the same timeframe in a prospective study in a private practice (Joss *et al*. 1994) (Fig. 59-4). Further evidence of BOP percentages between 20% and 30% determining a higher risk for disease progression originates from studies of Claffey *et al*. (1990) and Badersten *et al*. (1990).

In assessing the patient's risk for disease progression, BOP percentages reflect a summary of the patient's ability to perform proper plaque control, the patient's host response to the bacterial challenge, and the patient's compliance. The percentage of BOP, therefore, is used as the first risk factor in the functional diagram of risk assessment (Fig. 59-3). The scale runs in a quadratic mode with 4, 9, 16, 25, 36, and >49% being the divisions on the vector.

Individuals with low mean BOP percentages (<10% of the surfaces) may be regarded as patients with a low risk for recurrent disease (Lang *et al*. 1990), while patients with mean BOP percentages >25% should be considered to be at high risk for reinfection.

Prevalence of residual pockets greater than 4 mm

The enumeration of the residual pockets with probing depths greater than 4 mm represents, to a certain extent, the degree of success of periodontal treatment rendered. Although this figure *per se* does not make much sense when considered as a sole parameter, the evaluation in conjunction with other parameters, such as BOP and/or suppuration, will reflect existing ecologic niches from and in which reinfection might occur. It is, therefore, conceivable that periodontal stability in a dentition would be reflected in a minimal number of residual pockets. Presence of high fre-

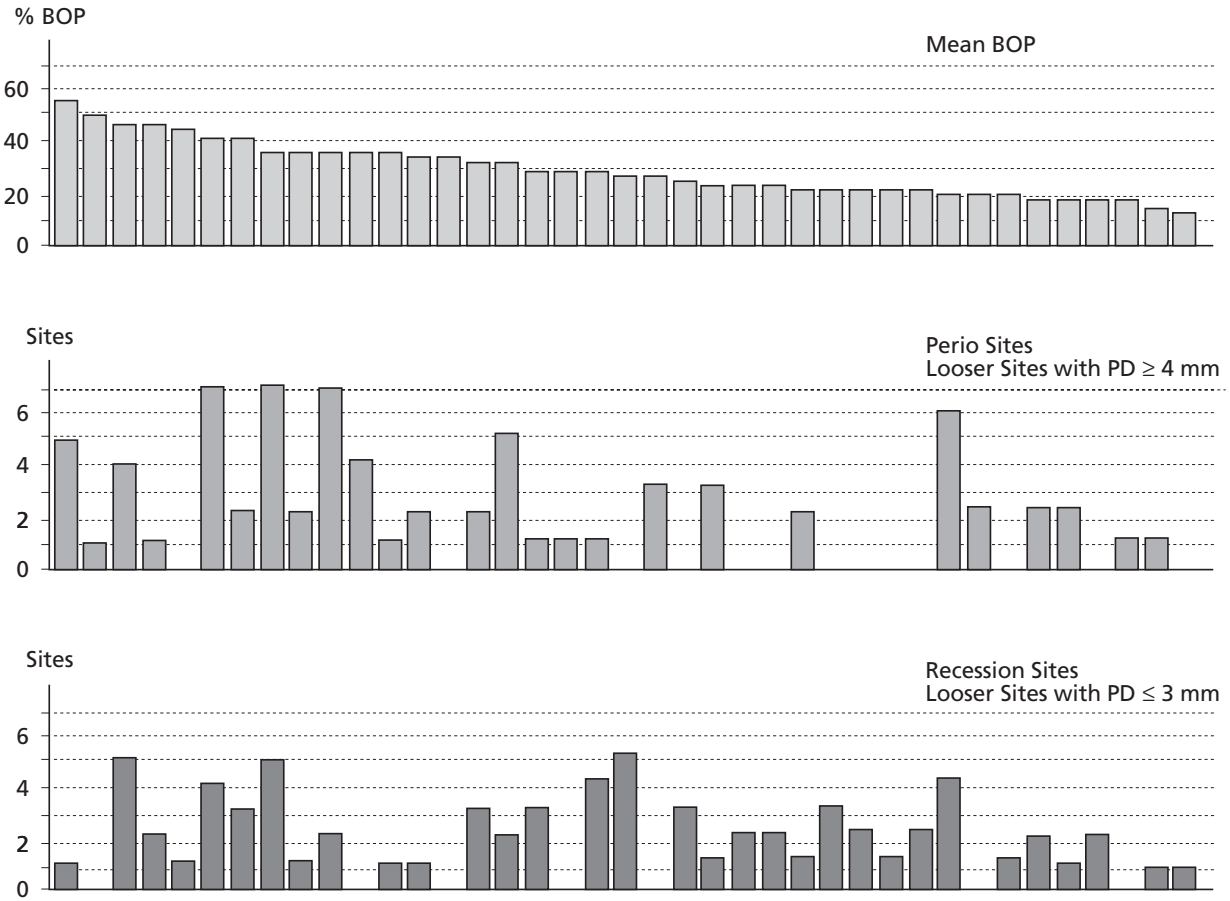

Fig. 59-4 Distribution of "looser" sites (probing depth (PD) ≥4 mm) due to periodontal disease progression with or without concomitant recession, dependent on the mean bleeding on probing (BOP) percentage during an observation period of 4 years. Patients are sorted by decreasing mean BOP percentages. Patients with <20% BOP have a significantly lower risk for disease recurrence. (Data from Joss *et al*. 1994.)

quencies of deep residual pockets and deepening of pockets during supportive periodontal care has, in fact, been associated with high risk for disease progression (Badersten *et al*. 1990; Claffey *et al*. 1990). On the other hand, it has to be realized that an increased number of residual pockets does not necessarily imply an increased risk for reinfection or disease progression, since a number of longitudinal studies have established the fact that, depending on the individual supportive therapy provided, even deeper pockets may be stable without further disease progression for years (e.g. Knowles *et al*. 1979; Lindhe & Nyman 1984).

Nevertheless, in assessing the patient's risk for disease progression, the number of residual pockets with a probing depth of ≥5 mm is assessed as the second risk indicator for recurrent disease in the functional diagram of risk assessment (Fig. 59-3). The scale runs in a linear mode with 2, 4, 6, 8, 10, and ≥12% being the divisions on the vector.

Individuals with up to four residual pockets may be regarded as patients with a relatively low risk, while patients with more than eight residual pockets may be regarded as individuals with high risk for recurrent disease.

Loss of teeth from a total of 28 teeth

Although the reason for tooth loss may not be known, the number of remaining teeth in a dentition reflects the functionality of the dentition. Mandibular stability and individual optimal function may be assured even with a shortened dental arch of premolar to premolar occlusion, i.e. 20 teeth. The shortened dental arch does not seem to predispose the individual to mandibular dysfunction (Witter *et al*. 1990, 1994). However, if more than eight teeth from a total of 28 teeth are lost, oral function is usually impaired (Käyser 1981, 1994, 1996). Since tooth loss also represents a true end-point outcome variable reflecting the patient's history of oral diseases and trauma, it is logical to incorporate this risk indicator as the third parameter in the functional diagram of risk assessment (Fig. 59-3). The number of teeth lost from the dentition without the third molars (28 teeth) is counted, irrespective of their replacement. The scale runs also in a linear mode with 2, 4, 6, 8, 10, and ≥12% being the divisions on the vector.

Individuals with up to four teeth lost may be regarded as patients in low risk, while patients with more than eight teeth lost may be considered as being in high risk.

Loss of periodontal support in relation to the patient's age

The extent and prevalence of periodontal attachment loss (i.e. previous disease experience and susceptibility), as evaluated by the height of the alveolar bone on radiographs, may represent the most obvious indicator of subject risk when related to the patient's age. In light of the present understanding of periodontal disease progression, and the evidence that both onset and rate of progression of periodontitis might vary among individuals and during different timeframes (van der Velden 1991), it has to be realized that previous attachment loss in relation to the patient's age does not rule out the possibility of rapidly progressing lesions. Therefore, the actual risk for further disease progression in a given individual may occasionally be underestimated. Hopefully, the rate of progression of disease has been positively affected by the treatment rendered and, hence, previous attachment loss in relation to patient's age may be a more accurate indicator during SPT than before active periodontal treatment. Given the hypothesis that a dentition may be functional for the most likely life expectancy of the subject in the presence of a reduced height of periodontal support (i.e. 25–50% of the root length), the risk assessment in treated periodontal patients may represent a reliable prognostic indicator for the stability of the overall treatment goal of keeping a functional dentition for a lifetime (Papapanou *et al*. 1988).

The estimation of the loss of alveolar bone is performed in the posterior region on either periapical radiographs, in which the worst site affected is estimated gross as a percentage of the root length, or on bite-wing radiographs in which the worst site affected is estimated in millimeters. One millimeter is equated with 10% bone loss. The percentage is then divided by the patient's age. This results in a factor. As an example, a 40-year-old patient with 20% of bone loss at the worst posterior site affected would be scored BL/Age = 0.5. Another 40-year-old patient with 50% bone loss at the worst posterior site scores BL/Age = 1.25.

In assessing the patient's risk for disease progression, the extent of alveolar bone loss in relation to the patient's age is estimated as the fourth risk indicator for recurrent disease in the functional diagram of risk assessment (Fig. 59-3). The scale runs in increments of 0.25 of the factor BL/Age, with 0.5 being the division between low and moderate risk and 1.0 being the division between moderate and high risk for disease progression. This, in turn, means that a patient who has lost a higher percentage of posterior alveolar bone than his/her own age is at high risk regarding this vector in a multi-factorial assessment of risk.

Systemic conditions

The most substantiated evidence for modification of disease susceptibility and/or progression of periodontal disease arises from studies on type I and type II (insulin-dependent and non-insulin-dependent) diabetes mellitus populations (Gusberti *et al*. 1983; Emrich *et al*. 1991; Genco & Löe 1993).

It has to be realized that the impact of diabetes on periodontal diseases has been documented in patients

with untreated periodontal disease, while, as of today, no clear evidence is available for treated patients. It is reasonable, however, to assume that the influence of systemic conditions may also affect recurrence of disease.

In recent years, genetic markers have become available to determine various genotypes of patients regarding their susceptibility for periodontal diseases. Research on the interleukin-1 (IL-1) polymorphisms has indicated that IL-1 genotype-positive patients show more advanced periodontitis lesions than IL-1 genotype-negative patients of the same age group (Kornman *et al*. 1997). Also, there is a trend to higher tooth loss in the IL-1 genotype-positive subjects (McGuire & Nunn 1999). In a retrospective analysis of over 300 well maintained periodontal patients, the IL-1 genotype-positive patients showed significantly higher BOP percentages and a higher proportion of patients which yielded higher BOP percentages during a 1-year recall period than the IL-1 genotype-negative control patients (Lang *et al*. 2000). Also, the latter group had twice as many patients with improved BOP percentages during the same maintenance period, indicating that IL-1 genotype-positive subjects do indeed represent a group of hyper-reactive subjects even if they are regularly maintained by effective SPT (Lang *et al*. 2000). In a prospective study over 5 years on Australian white collar and blue collar workers on a University campus, the IL-1 genotype-positive age group above 50 years showed significantly deeper probing depth than their IL-1 genotype-negative counterparts, especially when they were non-smokers.

In assessing the patient's risk for disease progression, systemic factors are only considered, if known, as the fifth risk indicator for recurrent disease in the functional diagram of risk assessment (Fig. 59-3). In this case, the area of high risk is marked for this vector. If not known or absent, systemic factors are not taken into account for the overall evaluation of risk.

Research on the association and/or modifying influence in susceptibility and progression of periodontitis of physical or psychologic stress is sparse (Cohen-Cole *et al*. 1981; Green *et al*. 1986; Freeman & Goss 1993). The hormonal changes associated with this condition, however, are well documented (Selye 1950).

Cigarette smoking

Consumption of tobacco, predominantly in the form of smoking or chewing, affects the susceptibility and the treatment outcome of patients with adult periodontitis. Classical explanations for these observations have included the association between smoking habits and poor oral hygiene as well as lack of awareness of general health issues (Pindborg 1949; Rivera-Hidalgo 1986). More recent evidence, however, has established that smoking *per se* represents not only a risk marker, but probably a true risk factor for periodontitis (Ismail *et al*. 1983; Bergström 1989; Bergström *et al*. 1991; Haber *et al*. 1993). In a young population (19–30 years of age), 51–56% of periodontitis was associated with cigarette smoking (Haber *et al*. 1993). The association of smoking and periodontitis has been shown to be dose-dependent (Haber *et al*. 1993). It has also been shown that smoking will affect the treatment outcome after scaling and root planing (Preber & Bergström 1985), modified Widman flap surgery (Preber & Bergström 1990), and regenerative periodontal therapy (Tonetti *et al*. 1995). Furthermore, a high proportion of so-called refractory patients has been identified as consisting of smokers (Bergström & Blomlöf 1992). The impact of cigarette smoking on the long-term effects of periodontal therapy in a population undergoing supportive periodontal care has been reported. Smokers displayed less favorable healing responses both at re-evaluation and during a 6-year period of supportive periodontal care (Baumert-Ah *et al*. 1994). In spite of the paucity of evidence relating cigarette smoking to impaired outcomes during supportive periodontal care, it seems reasonable to incorporate heavy smokers (>20 cigarettes/day) in a higher risk group during maintenance.

In assessing the patient's risk for disease progression, environmental factors such as smoking must be considered as the sixth risk factor for recurrent disease in the functional diagram of risk assessment (Fig. 59-3). While non-smokers (NS) and former smokers (FS) (more than 5 years since cessation) have a relatively low risk for recurrence of periodontitis, the heavy smokers (HS), as defined by smoking more than one pack per day, are definitely at high risk. Occasional (OS; <10 cigarettes a day) and moderate smokers (MS) may be considered at moderate risk for disease progression.

Calculating the patient's individual periodontal risk assessment (PRA)

Based on the six parameters specified above, a multifunctional diagram is constructed for the PRA. In this diagram, the vectors have been constructed on the basis of the scientific evidence available. It is obvious that ongoing validation may result in slight modifications.

- A low periodontal risk (PR) patient has all parameters within the low-risk categories or at the most one parameter in the moderate-risk category (Fig. 59-3b).
- A moderate PR patient has at least two parameters in the moderate category, but at most one parameter in the high-risk category (Fig. 59-3c).
- A high PR patient has at least two parameters in the high-risk category (Fig. 59-3d).

Based on a 4-year prospective cohort study, the application of the multi-functional diagram for the

subject-based PRA was validated (Persson *et al*. 2003) and, indeed, yielded complete periodontal stability after individually tailored recall intervals for all patients with a negative IL-1 gene polymorphism. For the IL-1 genotype-positive patients, however, the PRA resulted only in periodontal stability for 90% of the patients.

Summary: The subject risk assessment may estimate the risk for susceptibility for progression of periodontal disease. It consists of an assessment of the level of infection (full-mouth bleeding scores), the prevalence of residual periodontal pockets, tooth loss, an estimation of the loss of periodontal support in relation to the patient's age, an evaluation of the systemic conditions of the patient, and finally, an evaluation of environmental and behavioral factors such as smoking and stress. All these factors should be contemplated and evaluated together. A functional diagram (Fig. 59-3) may help the clinician in determining the risk for disease progression on the subject level. This may be useful in customizing the frequency and content of SPT visits.

Tooth risk assessment

Tooth position within the dental arch

Early clinical surveys have associated the prevalence and severity of periodontal diseases with malocclusion and irregularities of tooth position (Ditto & Hall 1954; Bilimoria 1963). However, many subsequent studies using clinical evaluation methods could not confirm these conclusions (Beagrie & James 1962; Geiger 1962; Gould & Picton 1966). Although a relationship between crowding and increased plaque retention and gingival inflammation has been established (Ingervall *et al*. 1977; Buckley 1980; Griffith & Addy 1981; Hörup *et al*. 1987), no significant correlation between anterior overjet and overbite (Geiger *et al*. 1973), crowding and spacing (Geiger *et al*. 1974) or axial inclinations and tooth drifts (Geiger & Wasserman 1980) and periodontal destruction, i.e. attachment loss subsequent to gingival inflammation, could be established. It is evident from the literature mentioned that crowding of teeth might eventually affect the amount of plaque mass formed in dentitions with irregular oral hygiene practices, thus contributing to the development of chronic gingivitis, but, as of today, it remains to be demonstrated whether tooth malposition within the dental arch will lead to an increased risk for periodontal attachment loss.

Furcation involvement

It is evident that multi-rooted teeth with periodontal lesions extending into the furcation area have been the subject of intensive therapeutic studies for many years (Kalkwarf & Reinhardt 1988). Retrospective analyses of large patient populations in private periodontal practices of periodontal specialists (Hirschfeld & Wasserman 1978; McFall 1982) have clearly established that multi-rooted teeth appear to be at high risk for tooth loss during the maintenance phase. The most impressive long-term documentation maintained 600 patients for an average duration of 22 years, and 10% of these patients were even maintained for more than 30 years (Hirschfeld & Wasserman 1978). While 83% of the patients could be considered "well maintained" and had lost only 0–3 teeth during the observation period, a patient group of 4% (25) was identified with an extreme risk for disease progression and had lost between 10 and 23 teeth during a regularly scheduled maintenance program. Irrespective of the patient group of low, moderate, and high risk for disease progression during maintenance, the majority of the teeth lost were furcation-involved molars (Hirschfeld & Wasserman 1978). Similar results were obtained in a study on 100 treated periodontal patients maintained for 15 years or longer (McFall 1982).

Prospective studies on periodontal therapy in multi-rooted teeth have also revealed significant differences between non-molar sites and molar flat surfaces on the one hand and molar furcation sites on the other, when looking at the treatment outcomes evaluated as bleeding frequency, probing depth reductions, and levels of attachment (Nordland *et al*. 1987). Again, teeth with furcation involvement and original probing depths >6 mm had reduced treatment outcomes.

The assumption that the prognosis for single-rooted teeth and non-furcation-involved multi-rooted teeth is better than the prognosis for furcation-involved multi-rooted teeth was also confirmed by Ramfjord *et al*. (1987) in a prospective study over 5 years. It has to be realized, however, that these results are not intended to imply that furcation-involved teeth should be extracted, since all the prospective studies have documented a rather good overall prognosis for such teeth if regular supportive care is provided by a well organized maintenance program.

Iatrogenic factors

Overhanging restorations and ill fitting crown margins certainly represent an area for plaque retention, and there is an abundance of association studies documenting increased prevalence of periodontal lesions in the presence of iatrogenic factors (for review see Leon 1977). Depending on the supragingival or subgingival location of such factors, their influence on the risk for disease progression has to be considered. It has been established that slightly subgingivally located overhanging restorations will, indeed, change the ecologic niche, providing more favorable conditions for the establishment of a Gram-negative anaerobic microbiota (Lang *et al*. 1983). There is no doubt that shifts in the subgingival microflora towards a more periodontopathic microbiota, if

unaffected by treatment, represent an increased risk for periodontal breakdown.

Residual periodontal support

Although many clinicians believe that teeth with reduced periodontal support are unable to function alone and should be extracted or splinted, there is clear evidence from longitudinal studies that teeth with severely reduced, but healthy, periodontal support can function either individually or as abutments for many years without any further loss of attachment (Nyman & Lindhe 1979; Nyman & Ericsson 1982; Brägger *et al*. 1990). Hence, successfully periodontally treated teeth can be maintained over decades and function as abutments in fixed bridgework or as individual chewing units irrespective of the amount of residual periodontal support, provided that physiologic masticatory forces do not subject such teeth to a progressive trauma which may lead to spontaneous extraction. Obviously, by virtue of the already reduced support, should disease progression occur in severely compromised teeth, this may lead to spontaneous tooth exfoliation.

Mobility

In light of the discussion of abutment teeth with severely reduced but healthy periodontal support, tooth mobility may be an indicator for progressive traumatic lesions, provided that the mobility is increasing continuously (Nyman & Lang 1994). When assessing tooth mobility, it has to be realized that two factors may contribute to hypermobility: (1) a widening of the periodontal ligament as a result of unidirectional or multidirectional forces to the crown, high and frequent enough to induce resorption of the alveolar bone walls; and (2) the height of the periodontal supporting tissues. If this is reduced due to prior periodontal disease, but the width of the periodontal ligament is unchanged, the amplitude of root mobility within the remaining periodontium is the same as in a tooth with normal height, but the leverage on the tooth following application of forces to the crown is changed. Therefore, it has to be realized that all teeth that have lost periodontal support have increased tooth mobility as defined by crown displacement upon application of a given force. Nevertheless, this hypermobility should be regarded as physiologic (Nyman & Lindhe 1976).

Since tooth mobility is probably more frequently affected by reduced periodontal height rather than unidirectional or multidirectional application of forces on the tooth, its significance for the evaluation of the periodontal conditions has to be questioned. Several studies have indicated that tooth mobility varies greatly before, during, and after periodontal therapy (Persson 1980, 1981a,b). From these studies it can be concluded that periodontally involved teeth show a decrease in mobility following non-surgical and/or surgical periodontal procedures. However, following surgical procedures, tooth mobility may temporarily increase during the healing phase and may resume decreased values later on. Provisional splinting as an adjunct to non-surgical or surgical therapy does not seem to affect the final result of tooth mobility.

Summary: The tooth risk assessment encompasses an estimation of the residual periodontal support, an evaluation of tooth positioning, furcation involvements, presence of iatrogenic factors, and a determination of tooth mobility to evaluate functional stability. A risk assessment at tooth level may be useful in evaluating the prognosis and function of an individual tooth and may indicate the need for specific therapeutic measures during SPT visits.

Site risk assessment

Bleeding on probing

Absence of bleeding on probing (BOP) is a reliable parameter to indicate periodontal stability if the test procedure for assessing BOP has been standardized (Lang *et al*. 1990). Presence of bleeding upon standardized probing will indicate presence of gingival inflammation. Whether or not repeated BOP over time will predict the progression of a lesion is, however, questionable (Lang *et al*. 1986, 1990; Vanooteghem *et al*. 1987). Nevertheless, a 30% probability for attachment loss to occur in the future may be predicted for sites repeatedly positive for BOP (Fig. 59-5) (Badersten *et al*. 1985, 1990; Lang *et al*. 1986; Vanooteghem *et al*. 1987, 1990; Claffey *et al*. 1990).

Obviously, BOP is rather sensitive to different forces applied to the tissues. An almost linear relationship (R = 0.87) existed between the probing force

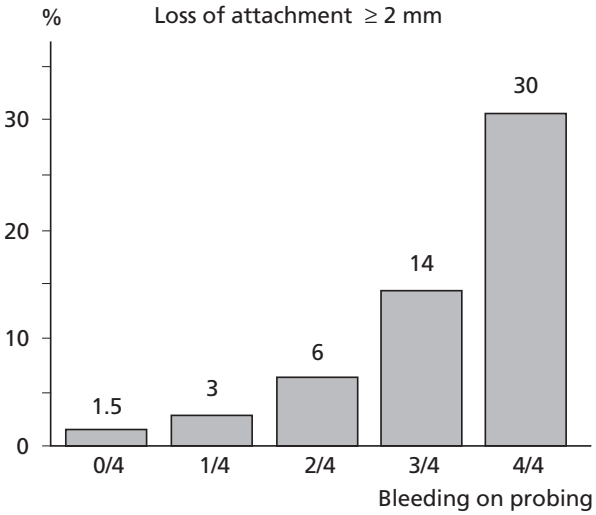

Fig. 59-5 Positive predictive values for loss of probing attachment of ≥2 mm in 2 years in sites which bled on probing 0, 1, 2, 3 or 4 times out of four SPT visits in a total of 48 patients following active periodontal therapy. (Data from Lang *et al*. 1986.)

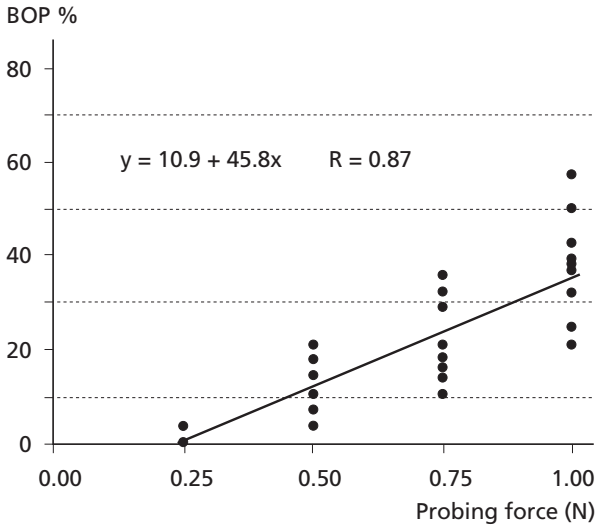

Fig. 59-6 Regression analysis between mean bleeding on probing (BOP) percentage and probing forces applied in young dental hygiene students with a healthy gingiva and normal anatomy. A very high correlation coefficient (R = 0.87) and an almost linear correlation between probing force and BOP percentage was found. (Data from Lang *et al*. 1991.)

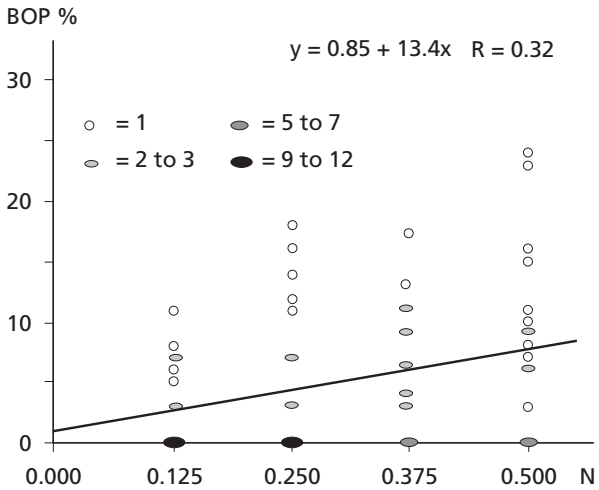

Fig. 59-7 Regression analysis between mean bleeding on probing (BOP) percentage and probing forces applied in subjects with successfully treated periodontitis: a reduced, but healthy, periodontium. (Data from Karayiannis *et al*. 1991.)

applied and the percentage of bleeding sites in a study on healthy young adults (Fig. 59-6) (Lang *et al*. 1991). If the probing force exceeded 0.25 N (25 g), the tissues were traumatized and bleeding was provoked as a result of trauma, rather than as a result of tissue alterations due to inflammation. To assess the "true" percentage of bleeding sites due to inflammation, a probing force of 0.25 N or less should be applied, which clinically means a light probing force. This has also been confirmed for patients who have experienced loss of attachment, i.e. with successfully treated advanced periodontitis (Fig. 59-7) (Karayiannis *et al*. 1991; Lang *et al*. 1991).

Since absence of BOP at 0.25 N indicated periodontal stability with a negative predictive value of 98–99% (Lang *et al*. 1990), this clinical parameter is the most reliable for monitoring patients over time in daily practice. Non-bleeding sites may be considered periodontally stable. On the other hand, bleeding sites seem to have an increased risk for progression of periodontitis, especially when the same site is bleeding at repeated evaluations over time (Lang *et al*. 1986; Claffey *et al*. 1990).

It is, therefore, advisable to register the sites with BOP in a dichotomous way using a constant force of 0.25 N. This allows the calculation of the mean BOP for the patient, and also yields the topographic location of the bleeding site. Repeated scores during maintenance will reveal the surfaces at higher risk for loss of attachment.

Probing depth and loss of attachment

Clinical probing is the most commonly used parameter both to document loss of attachment and to establish a diagnosis of periodontitis. There are, however, some sources of error inherent in this method which contribute to the variability in the measurements. Among these are (1) the dimension of the periodontal probe; (2) the placement of the probe and obtaining a reference point; (3) the crudeness of the measurement scale; (4) the probing force; and (5) the gingival tissue conditions.

In spite of the recognized method errors inherent in clinical probing, this diagnostic procedure has not only been the most commonly used but is also the most reliable parameter for the evaluation of the periodontal tissues. It has to be realized that increased probing depth and loss of probing attachment are parameters which reflect the history of periodontitis rather than its current state of activity. In order to obtain a more realistic assessment of the disease progression or, more commonly, the healing following therapy, multiple evaluations should be performed. Obviously, the first evaluation prior to therapy will yield results confounded by greater measurement error than evaluations following therapy. The reference point (cemento-enamel junction) may be obstructed by calculus or by dental restorations, and the condition of the gingival tissues may allow an easy penetration of the periodontal probe into the tissues, even though the probe position and force applied are standardized. These biologic variables (tissue conditions and calculus) may be minimized following initial periodontal therapy, and hence, repeated periodontal evaluations using probing will improve the metric assessment. The first periodontal evaluation after healing following initial periodontal therapy should, therefore, be taken as the baseline for long-term clinical monitoring (Claffey 1994).

Suppuration

In a proportion of periodontal lesions, pus will develop and may drain through the orifice of a

pocket. This criterion of suppuration may be recognized while clinically probing the lesion, or preferably, by using a ball burnisher (Singh *et al*. 1977). Several longitudinal studies on the results of periodontal therapy have evaluated clinical parameters, including suppuration, for the prediction of future loss of attachment (Badersten *et al*. 1985, 1990; Claffey *et al*. 1990). In all these studies, the presence of suppuration increased the positive predictive value for disease progression in combination with other clinical parameters, such as BOP and increased probing depth. Hence, following therapy a suppurating lesion may provide evidence that the periodontitis site is undergoing a period of exacerbation (Kaldahl *et al*. 1990).

Summary: The tooth site risk assessment includes the registration of BOP, probing depth, loss of attachment, and suppuration. A risk assessment on the site level may be useful in evaluating periodontal disease activity and determining periodontal stability or ongoing inflammation. The site risk assessment is essential for the identification of the sites to be instrumented during SPT.

Radiographic evaluation of periodontal disease progression

As a consequence of the clinical risk assessments the decision may be made to gather radiographic information on the periodontal conditions as well (Hirschmann *et al*. 1994). The task may be related to a generalized pattern of disease progression or a localized monitoring. Not only periodontal aspects, but a comprehensive approach, should influence the choice of the radiographic technique (Rohlin & Akerblom 1992). Periodic radiographic surveys not based on clinical signs and symptoms should not be scheduled simply to confirm health.

Radiographic perception of periodontal changes is characterized by a high specificity, but a low sensitivity, with underestimation of the severity of a periodontal defect (Hämmerle *et al*. 1990; Åkesson *et al*. 1992). Undetectability of minute changes at the alveolar crest is related to overprojections and variations in projection geometry when taking repeated radiographs (Lang & Hill 1977; Goodson *et al*. 1984; Jenkins *et al*. 1992). This may result in mimicked variations in the alveolar bone height, obscured furcation status, etc. In addition, film processing variations may result in unreliable assessments of alveolar bone density changes (Rams *et al*. 1994).

The standard procedure for periodontal evaluations is based on a filmholder system with an alignment for long-cone paralleling technique (Rushton & Horner 1994). With the addition of simple pins to the filmholders as a repositioning reference, the methodologic error was impressively reduced (Carpio *et al*. 1994).

It is a fact that, in general, the standards in oral radiology related to agreement in the choice of a technique, the quality of film processing and the agreement in the diagnosis need to be improved (Brägger 1996).

Clinical implementation

The *three levels* of risk assessment presented represent a logic sequence of clinical evaluation to be performed prior to rendering treatment during maintenance. The information gathered from a stepwise evaluation should not impinge on, but should rather improve, the efficacy of secondary prophylactic periodontal care and treatment. A logical sequence of checks and examinations may be easily obtained in a short period of time and at no extra cost for laboratory tests. The information obtained from clinical monitoring and multi-level risk assessment facilitates an immediate appreciation of the periodontal health status of an individual and the possible risk for further infection and/or disease progression.

Most longitudinal studies published to date have been based on single-level, i.e. site or tooth, risk assessment, rather than accounting for the most evident factor in risk assessment: the patient. Ample evidence indicates that a minority of patients will continue to present problems and hence, differ completely from the maintenance pattern visualized in the majority of the patients. Even in the studies where this fact has been explicitly addressed (Hirschfeld & Wasserman 1978), the factors which determined whether or not a patient belonged to a well maintained group or to a group with continuous loss of periodontal attachment have not been identified.

Summary: It is suggested that patients be evaluated on the *three different levels* mentioned. At the patient level, loss of support in relation to patient age, full mouth plaque and/or bleeding scores, and prevalence of residual pockets are evaluated, together with the presence of systemic conditions or environmental factors, such as smoking, which can influence the prognosis. The clinical utility of this first level of risk assessment influences primarily the determination of the recall frequency and time requirements. It should also provide a perspective for the evaluation of risk assessment conducted at the tooth and site levels.

At the tooth and tooth site levels, residual periodontal support, inflammatory parameters and their persistence, presence of ecologic niches with difficult access such as furcations, and presence of iatrogenic factors have to be put into perspective with the patient overall risk profile (Fig. 59-8). The clinical utility of tooth and site risk assessment relates to rational allocation of the recall time available for therapeutic intervention to the sites with higher risk, and possibly to the selection of different forms of therapeutic intervention.

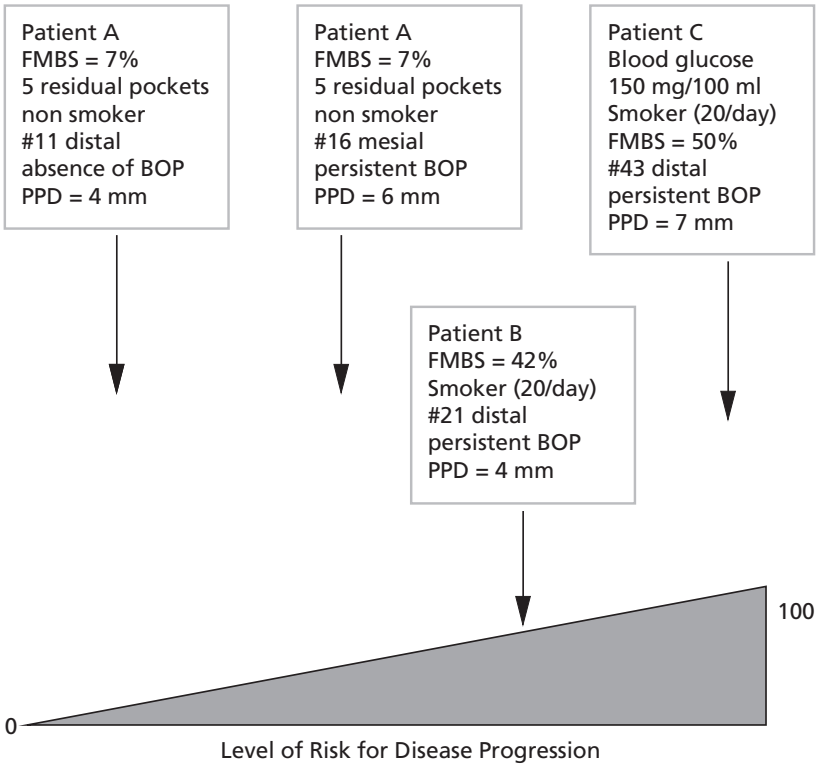

Fig. 59-8 Continuous multiple level risk assessment. Subject, tooth, and site parameters are combined to establish the clinical risk for disease progression. Note that different sites in the same patient may have a different level of risk. Subject-based risk factors are used to put the tooth and/or site risk assessment in perspective.

Objectives for SPT

The objective of maintenance care must be the continued preservation of gingival and periodontal health, obtained as a result of the active periodontal treatment. Irrespective of whether or not additional treatment such as prosthetic reconstructions or placement of implants has been rendered, the regular and adequate removal of supragingival plaque by the patient is, therefore, a prerequisite for a good long-term prognosis. In order to reach these goals, regular clinical re-evaluations with appropriate interceptive treatment, continued psychologic support and encouragement of the patient, and a lifelong commitment by the therapists are required.

General rules regarding frequency of maintenance care visits are difficult to define. However, there are a few aspects to consider in this respect: the patient's individual oral hygiene standard, the prevalence of sites exhibiting bleeding on probing, and the pretherapeutic attachment level and alveolar bone height. This in turn means that patients with suboptimal plaque control and/or concomitant high prevalence of bleeding sites should be recalled more frequently than patients exhibiting excellent plaque control and healthy gingival tissues. Nevertheless, patients with healthy gingival conditions, but with a severely reduced height of periodontal support, should also be recalled with short time intervals (not exceeding 3–4 months) in order to exclude or at least reduce the risk of additional tooth loss. In most of the longitudinal studies referred to above, positive treatment results were maintained with regular maintenance care provided at 3–6-month intervals. It seems reasonable to commence post-therapeutic maintenance with recall visits once every 3–4 months and then shorten or prolong these intervals in accordance with the aspects discussed above.

Since clinical attachment levels are usually stable 6 months following active periodontal therapy, it has been suggested that the first 6 months after completion of therapy be considered a healing phase (Westfelt *et al*. 1983b) during which frequent professional tooth-cleaning has been recommended. Following this healing phase, it is generally agreed to recall patients treated for periodontal disease at intervals of 3–4 months in a well organized system of SPT. It has to be realized that tissue contours may be subjected to remodeling processes despite stable clinical attachment levels and, hence, morphologic changes may still improve the accessibility of all tooth surfaces to oral hygiene practices for months and years. Proper oral hygiene practices appear to be the most important patient factor to guarantee long-term stability of treatment results (Knowles *et al*. 1979; Ramfjord *et al*. 1982, 1987; Lindhe & Nyman 1984). This, in turn, necessitates optimization of the patient's skills and continuous motivation and reinforcement to perform adequate mechanical oral hygiene practices, although chemical agents, such as the potent antiseptic chlorhexidine, may substitute and later complement the patient's efforts during the healing phase, when mechanical practices are difficult (Westfelt *et al*. 1983a). It is obvious that regular recall visits for SPT should be scheduled soon after completion of cause-related therapy, even if periodontal surgical procedures are still to be performed following a careful re-evaluation of the tissue response. To postpone the organization

of a maintenance care program until corrective procedures such as surgery, endodontic, implant, operative or reconstructive therapy have been performed may reinforce a possible misconception of the patient that the professional visits to a therapist or hygienist guarantee positive treatment outcomes and optimal long-term prognosis rather than the patient's own regular performance of individually optimal and adequate oral hygiene practices.

SPT in daily practice

The recall hour should be planned to meet the patient's individual needs. It basically consists of four different sections which may require various amounts of time during a regularly scheduled visit:

1. Examination, re-evaluation, and diagnosis (ERD)
2. Motivation, reinstruction, and instrumentation (MRI)
3. Treatment of reinfected sites (TRS)
4. Polishing of the entire dentition, application of fluorides, and determination of future SPT (PFD).

The SPT recall hour (Fig. 59-9) is generally composed of 10–15 minutes of diagnostic procedures (ERD) followed by 30–40 minutes of motivation, reinstruction, and instrumentation (MRI) during which time the instrumentation is concentrated on the sites diagnosed with persistent inflammation. Treatment of reinfected sites (TRS) may include small surgical corrections, applications of local drug delivery devices or just intensive instrumentation under local anesthesia. Such procedures, if judged necessary, may require an additional appointment. The recall hour is normally concluded with polishing of the entire dentition, application of fluorides and another assessment of the situation, including the determination of future SPT visits (PFD). Approximately 5–10 minutes have to be reserved for this section.

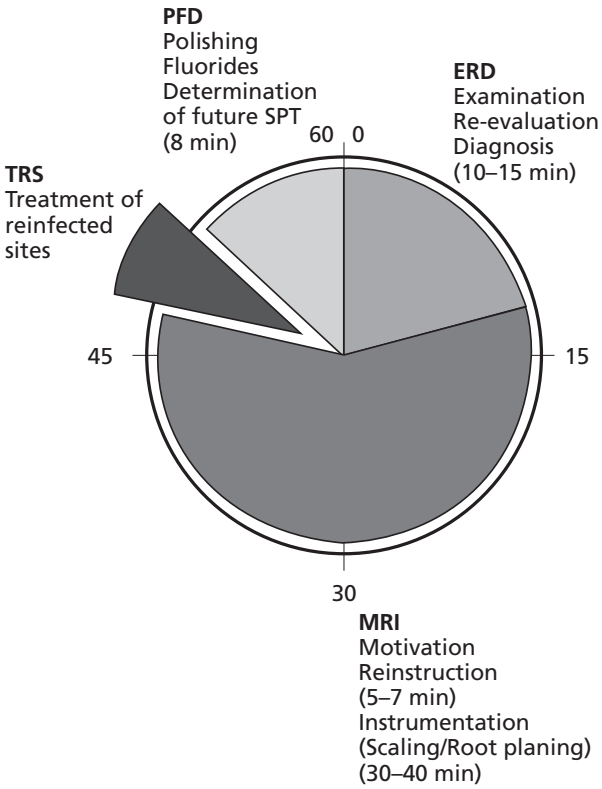

Fig. 59-9 The SPT recall hour is divided into four sections. (1) Examination, re-evaluation and diagnosis (ERD) providing information on stable and inflamed sites. This segment uses 10–15 minutes. (2) Motivation, reinstruction of oral hygiene where indicated, and instrumentation (MRI) will use the bulk of the recall hour (30–40 minutes). Sites which were diagnosed as not stable are instrumented. (3) Treatment of reinfected sites (TRS) may require a second appointment. (4) Polishing all tooth surfaces, application of fluorides and determination of the future recall interval (PFD) conclude the recall hour (5–10 minutes).

Examination, re-evaluation, and diagnosis (ERD)

Since patients on SPT may experience significant changes in their health status and the use of medications, an update of the information on general health issues is appropriate. Changes in health status and medications should be noted. In middle-aged to elderly patients, especially, these aspects might influence the future management of the patient. An extraoral and intraoral soft tissue examination should be performed at any SPT visit to detect any abnormalities and to act as a screening for oral cancer. The lateral borders of the tongue and the floor of the mouth should be inspected in particular. An evaluation of the patient's risk factors will also influence the choice of future SPT and the determination of the recall interval at the end of the maintenance visit. Following the assessment of the subject's risk factors, the tooth site-related risk factors are evaluated. As indicated above, the diagnostic procedure usually includes an assessment of the following:

1. The oral hygiene and plaque situation
2. The determination of sites with bleeding on probing, indicating persistent inflammation
3. The scoring of clinical probing depths and clinical attachment levels. The latter is quite time-consuming and requires the assessment of the location of the cemento-enamel junction as a reference mark on all (six) sites of each root. Therefore, an SPT evaluation usually only includes scoring of clinical probing depths
4. The inspection of reinfected sites with pus formation
5. The evaluation of existing reconstructions, including vitality checks for abutment teeth
6. The exploration for carious lesions.

All these evaluations are performed for both teeth and oral implants. Occasionally, conventional dental radiographs should be obtained at SPT visits. Especially for devitalized teeth, abutment teeth and oral

implants, single periapical films exposed with a parallel and preferably standardized technique are of great value. Bite-wing radiographs are of special interest for caries diagnostic purposes. They also reveal plaque-retentive areas such as overhanging fillings and ill fitting crown margins. Since only approximately 10–15 minutes are available for this section, these assessments have to be performed in a well organized fashion. It is preferable to have a dental assistant available to note all the results of the diagnostic tests unless a voice-activated computer-assisted recording system is used.

Motivation, reinstruction, and instrumentation (MRI)

This aspect uses most of the available time of the SPT visit. When informed about the results of the diagnostic procedures, e.g. the total percentage of the BOP score or the number of pockets exceeding 4 mm, the patient may be motivated either in a confirmatory way in the case of low scores or in a challenging fashion in the case of high scores. Since encouragement usually has a greater impact on future positive developments than negative criticism, every effort should be made to acknowledge the patient's performance.

Patients who have experienced a relapse in their adequate oral hygiene practices need to be further motivated. Especially if the personal life situation has influenced the performance, positive encouragement is appropriate. Standard "lecturing" should be replaced by an individual approach.

Occasionally, patients present with hard tissue lesions (wedge-shaped dental defects) which suggest overzealous and/or faulty mechanical tooth cleaning (Fig. 59-10). Such habits should be broken and the patient reinstructed in toothbrushing techniques which emphasize vibratory rather than scrubbing movements.

Since it appears impossible to instrument 168 tooth sites in a complete dentition in the time allocated, only those sites which exhibit signs of inflammation and/or active disease progression will be re-instrumented during SPT visits. Hence, all the BOP-positive sites and all pockets with a probing depth exceeding 5 mm are carefully rescaled and root planed. Repeated instrumentation of healthy sites will inevitably result in mechanically caused continued loss of attachment (Lindhe *et al*. 1982a).

Similar observations were made in clinical studies by Claffey *et al*. (1988) where loss of clinical attachment levels immediately following instrumentation was observed in 24% of the sites. It is also known from regression analyses of several longitudinal studies (e.g. Lindhe *et al*. 1982b) that probing attachment may be lost following instrumentation of pockets below a "critical probing depth" of approximately 2.9 mm. Instrumentation of shallow sulci is, therefore, not recommended. As it has been shown

Fig. 59-10 Wedge-shaped defects apical to the cemento-enamel junction following recession of the gingival tissues resulting from overzealous or faulty toothbrushing.

in several studies that non-bleeding on probing sites represent stable sites (Lang *et al*. 1986, 1990; Joss *et al*. 1994), it appears reasonable to leave non-bleeding sites for polishing only and concentrate on periodontal sites with a positive BOP test or probing depths exceeding 5 mm. To protect the hard tissues, root planing should be performed with great caution. The deliberate removal of "contaminated" cementum during SPT is no longer justified (Nyman *et al*. 1986, 1988; Mombelli *et al*. 1995). During SPT visits, root surface instrumentation should be aimed especially at the removal of subgingival plaque rather than "diseased" cementum. This may require a more differentiated approach than hitherto recommended. In this respect, the use of ultrasonics may have to be re-evaluated.

Treatment of reinfected sites (TRS)

Single sites, especially furcation sites or sites with difficult access, may occasionally be reinfected and demonstrate suppuration. Such sites require a thorough instrumentation under anesthesia, the local application of antibiotics in controlled-release devices or even open debridement with surgical access. It is evident that such therapeutic procedures may be too time-consuming to be performed during the routine recall hour, and hence, it may be necessary to reschedule the patient for another appointment. Omission of thorough retreatment of such sites or only performing incomplete root instrumentation during SPT may result in continued loss of probing attachment (Kaldahl *et al*. 1988; Kalkwarf *et al*. 1989).

Treatment choices for reinfected sites should be based on an analysis of the causes most likely responsible for the reinfection.

Generalized reinfections are usually the result of inadequate SPT. Although not all sites positive for

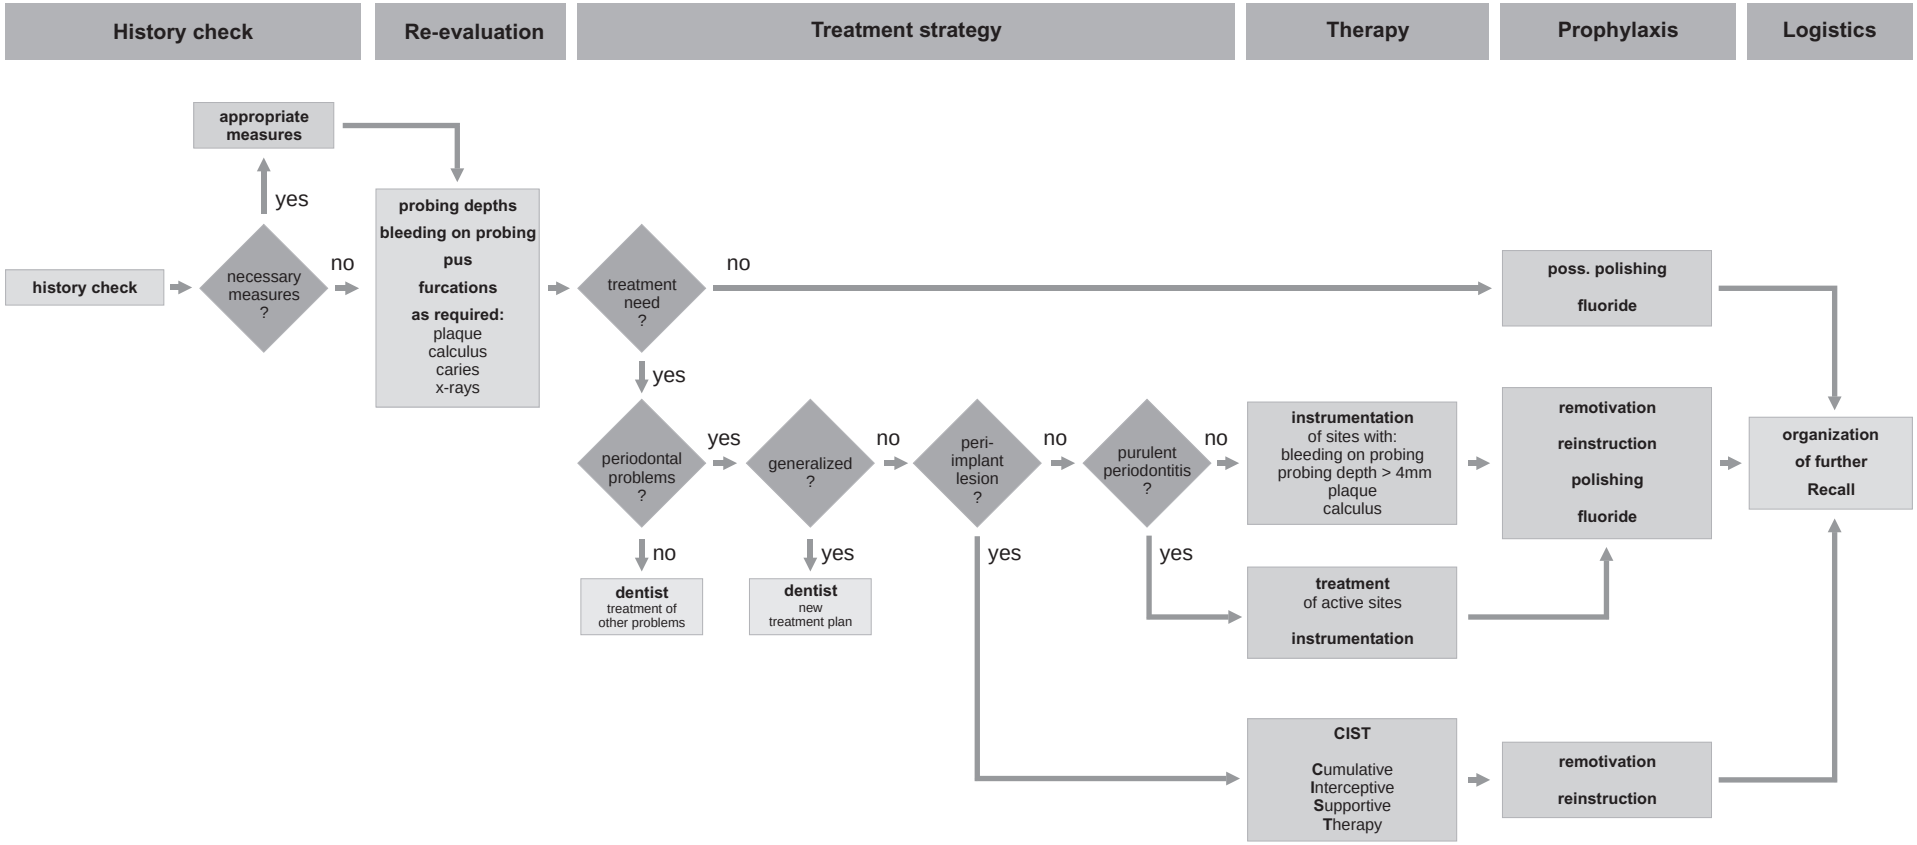

Fig. 59-11 Flow sheet of supportive periodontal therapy (SPT) with strategic decision tree for the recall visit.

BOP may further progress and lose attachment, high BOP percentages call for more intensive care and more frequent SPT visits. Sometimes, a second visit 2–3 weeks after the recall may be indicated to check the patient's performance in oral home care. It is particularly important to supervise patients closely for advanced periodontitis if they have a high subject risk assessment (Westfelt *et al*. 1983b; Ramfjord 1987).

Local reinfections may either be the result of inadequate plaque control in a local area or the formation of ecologic niches conducive to periodontal pathogens. The risk assessment on the tooth level may identify such niches which are inaccessible for regular oral hygiene practices. Furcation involvements often represent special periodontal risk factors which may require additional therapy to be performed following diagnosis in the regular SPT visit.

Polishing, fluorides, determination of recall interval (PFD)

The recall hour is concluded with polishing the entire dentition to remove all remaining soft deposits and stains. This may provide freshness to the patient and facilitates the diagnosis of early carious lesions. Following polishing, fluorides should be applied in high concentration in order to replace the fluorides which might have been removed by instrumentation from the superficial layers of the teeth. Fluoride or chlorhexidine varnishes may also be applied to prevent root surface caries, especially in areas with gingival recession. The determination of future SPT visits must be based on the patient's risk assessment.

Summary: Figure 59-11 provides a flowchart for SPT. The SPT recall hour is divided into four sections. While the first 10–15 minutes are reserved for examination, re-evaluation and diagnosis, the second and most time-consuming section of 30–40 minutes is devoted to reinstruction and instrumentation of sites at risk identified in the diagnostic process. Some reinfected sites may require further treatment, and hence, the patient may have to be rescheduled for an additional appointment. The recall hour is concluded by polishing the dentition, applying fluorides and determining the frequency of future SPT visits.

Part 19: Halitosis

Chapter 60

Halitosis Control

Edwin G. Winkel

Introduction

Offensive body odor is one of the greatest taboos in our society. Conditions that are associated with body odors are bromidrosis, the secretion of foul-smelling sweat, body odor also known as osmidrosis or kakidrosis (Leyden 1981; Lukacs 1991; Guillet *et al*. 2000), flatulence, excessive production of bowel gases (Suarez *et al*. 1999; Bell 2000), and bad breath (Attia & Marshall 1982; Delanghe *et al*. 1997; van Steenberghe 1997). One factor these conditions have in common is that bacteria play an essential role in the etiology.

This chapter will focus on bad breath. Several terms like breath malodor, oral malodor, *fetor ex ore*, *fetor oris*, bad or foul breath, and halitosis are used to prescribe noticeably unpleasant odors exhaled in breathing. Halitosis is a technical term for bad breath and originates from the Latin "halitus" meaning "breath" and the Greek "osis" meaning "abnormal" or "diseased". Knowledge of this condition dates back to ancient cultures. The Talmud, a collection of ancient rabbinical writings dating back more than 2 millennia, states that bad breath is a major disability. The marriage license (the Ketuba) may be legally broken in the case of halitosis of one of the partners (Shifman *et al*. 2002). The theme is also discussed in ancient writings from China, Greek, Roman, early Christian, and Islamic cultures. For example, Islamic theology stresses the importance of the Siwak or Miswak, a stick obtained from a plant called Salvadore Persica, to clean the teeth and the tongue. Prior to the late 1930s, most references pertaining to halitosis consisted mainly of anecdotal statements that have been perpetuated in the literature. In 1934, Fair and Wells developed the osmoscope, an instrument for measuring the intensity of odors. Later, this apparatus was used for breath analysis (Brening *et al*. 1938). During the last 40 years, our scientific knowledge about the source and causes of halitosis has become much greater.

Several non-oral pathologic conditions have been related to oral malodor, including infection of the upper and lower respiratory tracts, the gastrointestinal tract, and some metabolic diseases involving the kidneys and the liver (Manolis 1983). However, clinical surveys have shown that over 90% of all bad breath odors originate in the mouth (Delanghe *et al*. 1997; van Steenberghe 1997).

Epidemiology

Information regarding the prevalence of oral halitosis is scarce due to the lack of epidemiologic studies. An early study from The Netherlands among 11 625 individuals revealed a prevalence of approximately 25% in subjects older than 60 years (de Wit 1966). In subjects under 20 years, the prevalence of oral halitosis was 10%, indicating that the prevalence of this condition increases with age. In Japan the prevalence of individuals with complaints of halitosis is approximately 14% (National Survey 1999). In the USA, it is estimated that 10–30% of the adult population have an appreciable problem with bad breath (Meskin 1996). Recently, in China the incidence of oral halitosis was surveyed in a sample of 2000 individuals aged 15–64 years. Oral halitosis was measured in 27.5% of the subjects with organoleptic measurements

Table 60-1 Breath volatile sulphur compounds and some amines, together with some of their known odor characteristics

Formula	Name	Odor qualification	100% odor recognition concentration (ppb)
H_2S	Hydrogen sulfide	Rotten eggs	1000
CH_3SH	Methyl mercaptan	Pungent, rotten cabbage	35
CH_3SCH_3	Dimethyl sulfide	Unpleasantly sweet	100
CH_3SSCH_3	Dimethyl disulfide	Pungent	7
$CH_2{=}CHCH_2SH$	Allyl mercaptan	Garlic-like	0.05
$CH_2{=}CHCH_2SCH_3$	Allyl methyl sulfide	Garlic-like	Unknown
$CH_3CH_2CH_2SH$	Propyl mercaptan	Unpleasant, pungent	0.7
$CH_3CH_2CH_2SCH_3$	Methyl propyl sulfide		Unknown
CS_2	Carbon disulfide	Slightly pungent	900
NH_3	Ammonia	Pleasantly sweet	55 000
$(CH_3)_2NH$	Dimethylamine	Fishy, ammoniacal	6000
$(CH_3)_3N$	Trimethylamine	Fishy, ammoniacal	4000

24 ppb = 1 nmol/l (at room temperature).
Adapted from Tangerman (2002).

(Liu *et al*. 2006). However, only a few patients visit dental clinics to seek help for this condition.

Odor characteristics

Together with some of their known odor characteristics, the most common odorous volatile sulfur compounds and some amines found in the breath of patients with halitosis of different origin are shown in Table 60-1 (Verschueren 1983; Tangerman 2002). The 100% odor recognition threshold is the concentration at which 100% of the odor panel defined the odor as being representative of the odorant being studied. The unsaturated mercaptans (allyl mercaptan in garlic) and the unsaturated sulfides (allyl methyl sulfide in garlic) are the most odorous, followed by saturated mercaptans (propyl mercaptan in onion, methyl mercaptan in bad breath), disulfides (dimethyl disulfide), and sulfides (methyl propyl sulfide in onion and dimethyl sulfide and hydrogen sulfide in bad breath).

For a proper diagnosis and therapy and/or referral to a physician or specialist, it is important for the general practitioner to clearly differentiate between halitosis from oral and non-oral origin. Therefore, in this chapter the term *intraoral halitosis* (oral malodor) will be used to define halitosis with a cause within the oral cavity, whereas *extraoral halitosis* is used for halitosis of non-oral cause.

Pathogenesis of intraoral halitosis

Intraoral halitosis may be indicative of either oral diseases, such as periodontal diseases, or the presence of excessive bacterial reservoirs on the tongue. The pathogenesis of intraoral halitosis is associated with the bacterial degradation of sulfur-containing amino acids (methionine, cystine, and cysteine) into volatile sulfur compounds (VSCs) of which methyl mercaptan (CH_3SH) and hydrogen sulfide (H_2S) are the major compounds. It appears that methyl mercaptan is the predominant causative factor of malodor (Tangerman 2002; Awano *et al*. 2004; Tangerman & Winkel 2007). Despite the strong evidence that VSCs are the major causative factors in intraoral halitosis, several research groups still suggest that other volatile compounds such as cadaverine, indole, skatole, and butyric acid may influence oral halitosis (Rosenberg & McCulloch 1992; Goldberg *et al*. 1994; Rosenberg 1996; Greenman *et al*. 2004). No data of the presence of smellable concentrations of such volatiles in mouth air have ever been shown. Therefore, no evidence exists of such a relationship. On the contrary, Tonzetich (1977) clearly showed that diamines, such as cadaverine, inhibited odor formation. It was also stated that indole and skatole, although emanating an objectionable odor in pure state, did not impart an odor to saliva under conditions approximating those of the oral cavity. He ascribed this to their extremely low volatility. The same holds for butyric acid. Due to their low volatilities these compounds have a low odor potential. This is in strong contrast with the VSCs which have a very high odor potential (Verschueren *et al*. 1983).

Formation of volatile sulfur compounds

Gram-negative, proteolytic bacteria are believed to play an essential role in the formation of VSCs, although Gram-positive bacteria such as *Peptostreptococcus* species have also shown ability to produce VSCs *in vitro* (McNamara *et al*. 1972; Persson 1989; Claesson 1990; Persson *et al*. 1990). The most active producers of VSCs *in vitro* are shown in Table 60-2. In our clinic we selected over 100 patients with halitosis but without a history of periodontitis. By culturing periodontal pathogens we found meanly *Fusobacterium* species and low levels of *Prevotella intermedia* (unpublished data), which was in accordance with findings of Loesche and Kazor (2002). This

Table 60-2 Microorganisms with a high capability of generating volatile sulfur compounds *in vitro*

H_2S from serum	CH_3SH from serum	H_2S from cysteine	CH_3SH from methionine
Porphyromonas gingivalis	*Porphyromonas gingivalis*	*Bacteroides* spp.	*Bacteroides* spp.
Porphyromonas endodontalis	*Porphyromonas endodontalis*	*Selenomonas* spp.	*Porphyromonas endodontalis*
Prevotella loescheii		*Fusobacterium* spp.	*Fusobacterium* spp.
Treponema denticula		*Peptostreptococcus* spp.	*Eubacterium* spp.
Prevotella intermedia		*Prevotella intermedia*

Adapted from Persson *et al*. (1990).

suggested that the indigenous tongue flora is distinct from the periodontal flora. Therefore, microbiologic information about patients with halitosis should clearly differentiate between patients with or without (a history of) periodontitis.

Periodontium

In patients with periodontal disease, methyl mercaptan was found to be the most abundant VSC (Yaegaki & Sanada 1992c). The role of hydrogen sulfide (H_2S) and methyl mercaptan (MM) in the etiology of periodontitis is unclear. VSCs are potentially capable of altering the permeability of the gingival tissues, including inflammatory responses. By modulating the functions of gingival fibroblasts, VSCs may play a role in the pathogenesis of gingivitis and periodontitis (Ratkay *et al*. 1995; Ratcliff & Johnson 1999; Torresyap *et al*. 2003). In an *in vitro* study, it was shown that MM had a more pronounced effect on the permeability of mucosa than a similar concentration of H_2S (Johnson 1992; Ng 1984). MM has also been shown to act synergistically with both lipopolysaccharide (LPS) and interleukin 1-beta (IL-1β) to increase secretion of prostaglandin E_2 and collagenase, important mediators of inflammation and tissue destruction (Ratkay *et al*. 1995). In fact, increased VSCs in mouth air are related to deep periodontal pockets (Coil & Tonzetich 1992; Yaegaki & Sanada 1992a,c). However, it has also become clear that intraoral halitosis may also occur in individuals with a healthy periodontium (Kaizu *et al*. 1978; Bosy *et al*. 1994; Winkel *et al*. 2003). In patients with periodontitis, Yeagaki and Sanada (1992c) found six times more tongue coating than in those who were periodontally healthy.

Tongue

The tongue has the largest bacterial load of any oral tissue and makes the greatest contribution to bacteria found in the saliva. It is believed that the bacterial mass located at the posterior dorsum of the tongue is the principal site where malodorous compounds are produced (Bosy *et al*. 1994; De Boever *et al*. 1994). Individuals that suffer from intraoral halitosis have a significantly higher bacterial load on the dorsum of the tongue in comparison to individuals without intraoral halitosis (De Boever & Loesche 1995; Yaegaki & Sanada 1992a). In addition, the rough surface of the tongue provides an ideal habitat for anaerobic bacteria, which flourish under a continually forming tongue coating of food debris, dead cells, and hundreds of thousands of bacteria, both living and dead.

Pathogenesis of extraoral halitosis

Approximately 10% of cases of halitosis are caused by extraoral halitosis (Delanghe *et al*. 1998; Tangerman & Winkel 2007).

Examples of extraoral halitosis of the upper respiratory tract are chronic sinusitis, nasal obstruction, nasopharyngeal abscess, and carcinoma of the larynx. Examples of the lower respiratory tract are bronchitis, bronchiectasis, pneumonia, pulmonary abscess, and carcinoma of the lungs (Attia & Marshall 1982; Lu 1982; Durham *et al*. 1993; McDowell & Kassebaum 1993).

Extraoral halitosis might also be a manifestation of a serious systemic disease, such as hiatus hernia, hepatic cirrhosis, or diabetes mellitus. These diseases may produce specific smells (Tangerman 2002) (Table 60-3). For example, *fetor hepaticus* in liver cirrhosis is a type of severe bad breath caused by dimethyl sulfide (Tangerman *et al*. 1994). While intraoral halitosis is largely caused by MM and to a lesser extent by H_2S (Tangerman 2002; Awano *et al*. 2004; Tangerman & Winkel 2007), these components cannot be found in blood-borne halitosis (Tangerman 2002). A new finding is outlined in a study by Tangerman and Winkel (2007) where they found that the majority of extraoral blood-borne halitosis was caused by a hitherto unknown metabolic disorder resulting in elevated odorous levels of dimethyl sulfide in blood and breath. Unpleasant odor from the lower gastrointestinal tract is only detectable during belching or vomiting, because the oesophagus is normally collapsed (Attia & Marshall 1982). The stomach is therefore not considered to contribute to halitosis, except in rare circumstances (Rosenberg 1996).

Table 60-3 Odorous volatiles in the breath of patients with extraoral blood-borne halitosis

Causes of blood-borne halitosis	Odorant
Systemic diseases	
Hepatic failure/liver cirrhosis	Dimethyl sulfide
Uremia/kidney failure	Dimethylamine, trimethylamine
Diabetic ketoacidosis, diabetes mellitus	Acetone
Metabolic disorders	
Isolated persistent hypermethioninemia	Dimethyl sulfide
Fish odor syndrome, trimethylaminuria	Trimethylamine
Medication	
Disulfiram	Carbon disulfide
Dimethylsulfoxide	Dimethyl sulfide
Cysteamine	Dimethyl sulfide
Food	
Garlic	Allyl methyl sulfide
Onion	Methyl propyl sulfide

Adapted from Tangerman (2002).

Table 60-4 Organoleptic scoring scale

Score	Category	Description
0	Absence of halitosis	Odor cannot be detected
1	Questionable halitosis	Odor is detectable, although the examiner could not recognize it as halitosis
2	Slight halitosis	Odor is deemed to exceed the threshold of halitosis recognition
3	Moderate halitosis	Halitosis is definitely detected
4	Strong halitosis	Strong halitosis is detected, but can be tolerated by examiner
5	Severe halitosis	Overwhelming halitosis is detected and cannot be tolerated by examiner (examiner instinctively averts the nose)

Adapted from Yaegaki & Coil (2000).

Diagnosis

Flowchart in a halitosis practice

There are no accepted clinical protocols for the diagnosis of patients with halitosis.

In practice, the flowchart in Fig. 60-1 is suggested for patients with complaints of halitosis. The techniques and strategies for diagnosis and treatment that are described below have been drawn from the research methods and results of important workers in the field of halitosis (Tonzetich 1977; Preti *et al*. 1992; Rosenberg 1995; Richter 1996; van Steenberghe & Rosenberg 1996; Yaegaki & Coil 1999; Sanz *et al*. 2001; Coil *et al*. 2002; Quirynen *et al*. 2002b) and from the experience of the author in treating patients with chief complaints of halitosis for more than 10 years.

Before first consultation

Before the first appointment all patients receive detailed medical and halitosis questionnaires as well as written instructions (Fig. 60-2). The general medical questionnaire, which includes questions about e.g. systemic diseases, allergy, asthma, rhinitis, sinusitis, and medication, has to be filled in before the appointment and can be discussed beforehand with the physician if needed. Additionally a specific halitosis questionnaire is given to the patient (Fig. 60-3).

At the first examination

The questionnaires form the basis for the consultation. The various points and their implications are discussed with the patient. These points include the unreliability of the patient's self assessment. One's own breath odor is often undetectable due to habituation. Many patients link bad breath with bad taste (metallic, sour, fecal, etc.). From the start of the consultation it must be made clear to the patient that you are treating *bad breath* and not *bad taste* and that the presence of a bad taste does not mean that the patient also has bad breath. Nor does a fresh taste imply fresh breath. The opinion of the patient about the level of halitosis is thus unreliable.

It is important to start the examination by firstly carrying out both subjective and objective assessment of the degree of halitosis and then start the intraoral examination. In this way, the severity of the halitosis is assessed before any changes in the degree of halitosis can occur.

Organoleptic measurements

Sniffing of expelled air of the patient by using the nose of the examiner, organoleptic scoring, is the usual technique for halitosis examination in daily practice (Schmidt *et al*. 1978; Rosenberg & McCulloch 1992; van Steenberghe 1997). Differentiation between intraoral and extraoral halitosis can easily be done by comparing mouth breath with nose breath (Durham *et al*. 1993; Richter 1996; Rosenberg 1996).

Examination: For the organoleptic evaluation, participants are instructed to close their mouth for 1 minute, then to slowly exhale air out of the mouth at a distance of approximately 10 cm from the nose of the examiner (Fig. 60-4). For evaluation of extraoral halitosis, patients are also asked to slowly exhale air out of the nose, also at a distance of approximately 10 cm from the nose of the examiner. Full mouth and nose organoleptic odor assessments are used, on a scale of 0 to 5 (Table 60-4) (Rosenberg *et al*. 1991b; Yaegaki & Coil 2000).

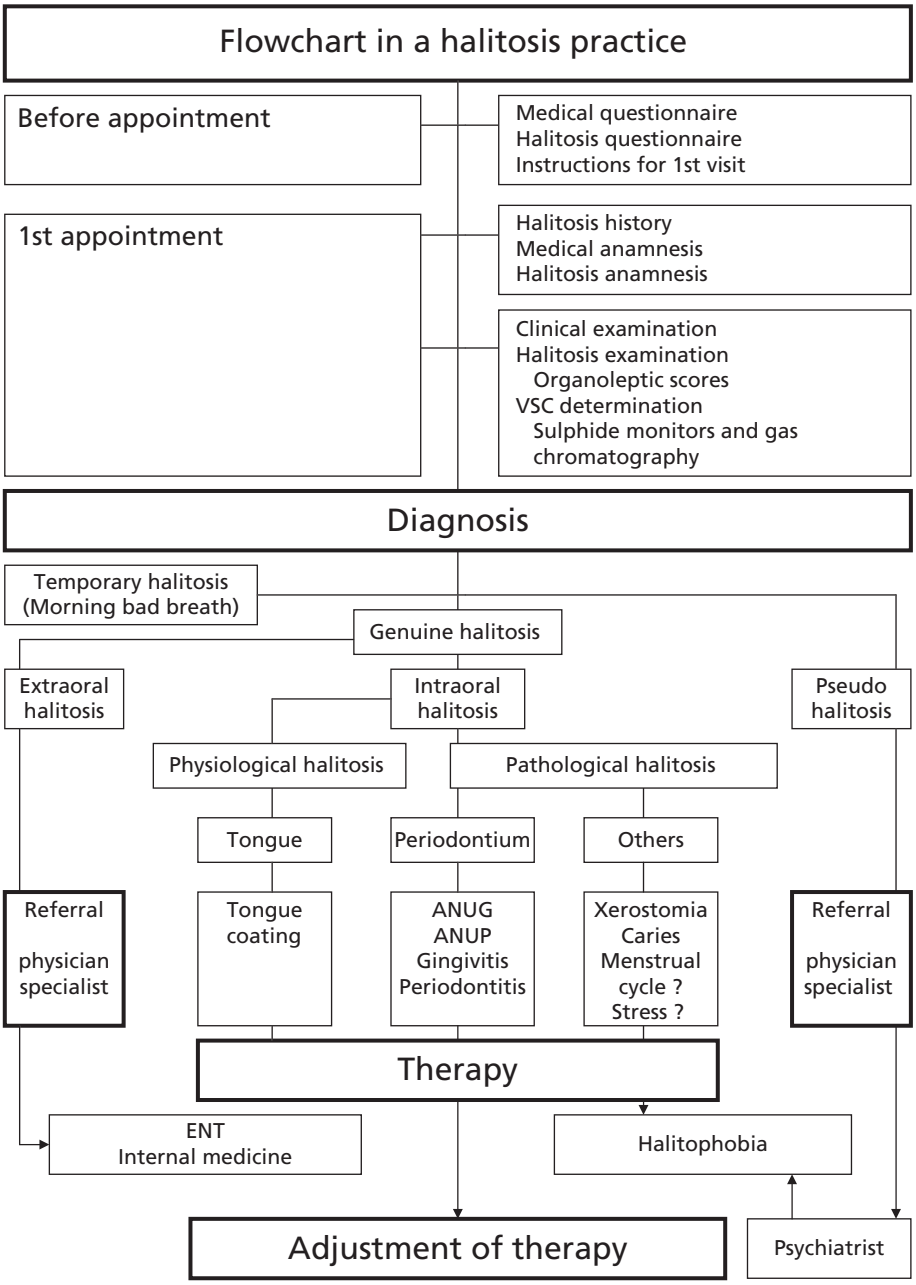

Fig. 60-1 Flowchart in a halitosis practice.

Sulfide monitor

Dental practices and breath clinics now use portable sulfide monitors. For example the Breathtron™ (Sopapornamorn 2006) and the Halimeter™ (Rosenberg *et al*. 1991a) can test the breath air for levels of sulphur emissions. The Halimeter (Fig. 60-5) has a high sensitivity for hydrogen sulfide but a lower sensitivity for methyl mercaptan, which is a significant contributor to halitosis. Certain foods such as garlic and onions produce sulfur in the breath for as long as 48 hours and may result in false readings. The Halimeter is also very sensitive to alcohol, so one should avoid drinking alcohol or using alcohol-containing mouthwashes for at least 12 hours prior to being tested.

The Halimeter is unsuitable for measuring patients with extraoral halitosis from dimethyl sulfide (Tangerman & Winkel 2007).

Examination: The Halimeter needs to be calibrated to zero on ambient air prior to each measurement. First, the disposable straw, connected to the Halimeter, is placed in the opening of the nose of the patient. Then the patient is asked to blow slowly through to the nose. The maximum peak value of VSCs is recorded. Second, the patient is asked to close the mouth for 1 minute. Then the patient is asked to open the mouth and protrude the tongue. The straw is placed at the dorsal posterior mid part of the tongue and fixed until again the maximum peak value of VSCs is recorded. Peak VSC levels are registered in parts per billion (ppb) (Fig. 60-6a). According to

Instructions for 1st visit

In these instructions, subjects are asked **not** to:

1) take antibiotics for 8 weeks before assessment;
2) consume food containing onions, garlic or hot spices for 48 hours before the baseline measurements;
3) drink alcohol or smoke in the previous 12 hours;
4) eat and drink in the previous 8 hours (drinking water up to 3 hours before examinations is allowed);
5) perform oral hygiene, including tooth brushing, interdental and tongue cleaning, and not to use mouthrinses the morning of the examination;
6) use scented cosmetics or after-shave lotions on the morning of the examination.

If the patient has any condition like diabetes, which will be aggravated by fasting for the period of time indicated, please contact the dentist about alternative methods of preparation.

Fig. 60-2 Instructions for first visit.

the manufacturer, human standard ("normal") Halimeter readings range between 80 and 110 ppb (http://www.halimeter.com/halcal.htm). Values over 160 ppb are considered to identify a patient with true halitosis (Fig. 60-6b).

Gas chromatography

Gas chromatography is by far the most appropriate method to detect halitosis of different origins and should be considered as the gold standard. It is an objective means of obtaining exact values for the various odorous volatiles (Tonzetich 1967; Furne *et al*. 2002; Tangerman 2002). New technology is now appearing in the form of portable gas chromatography machines such as the OralChroma™ (Fig. 60-7), which is specifically designed to digitally measure molecular levels of the three major VSCs (hydrogen sulfide, methyl mercaptan, and dimethyl sulfide) in a sample of breath air. It is extremely sensitive and produces visual results in graph form via computer interface (Fig. 60-8a).

Examination: Insert the 1-ml plastic syringe halfway into the oral cavity and ask the patient to hold the syringe between the lips (Fig. 60-8b). Ask the patient not to touch the syringe with the tongue nor the palate. Wait 1 minute, then slowly pull the plunger, push it in again, and pull it for a second time before removing the syringe out of the oral cavity. Avoid saliva in the syringe. If the top of the syringe is wet, wipe it dry with a tissue, attach the needle and eject the air to 0.5 ml and then insert the needle in the injection port of the gas chromatograph (Fig. 60-8c). The apparatus will process the sample in 8 minutes.

Oral inspection

During the first visit, extensive soft tissue, hard tissue, and periodontal examinations are performed in order to determine whether the patient has other oral health problems. Specific attention is paid to the tongue and the presence of tongue debris is noted using a tongue-coating index.

Index systems for tongue coating

A variety of index systems has been developed over the years (Miyazaki *et al*. 1995; Gomez *et al*. 2001; Winkel *et al*. 2003; Lundgren *et al*. 2007). Miyazaki *et al*. (1995) divides the tongue into three sections and the presence or absence of tongue coating is registered as follows: score 0 = none visible; 1 = less than one third of tongue dorsum is covered; 2 = between one and two thirds; 3 = more than two thirds. Gomez *et al*. (2001) divides the tongue into nine different sections, whilst Winkel *et al*. (2003) divides the tongue into six sections, three in the posterior and three in the anterior part of the tongue. Each sextant is categorized as: score 0 = no coating present; 1 = presence of a light coating; 2 = presence of a distinct coating. The resulting Winkel tongue coating index (WTCI) is obtained by adding all six scores (Winkel *et al*. 2003) (Fig. 60-9).

The tongue is normally pink (Fig. 60-10) but a very thin whitish coating can also be considered normal. Having a coating on your tongue does not necessarily mean that you have bad breath (Fig. 60-11), although heavy tongue coatings are usually positively related to halitosis (Fig. 60-12).

Halitosis questionnaire

Do you suffer from a dry mouth?
Do you breathe through your mouth?
How many drinks do you have per day (include **all** beverages)?
How many cups of coffee do you drink per day?
How many units of alcohol do you drink per day?
Do you often have a bad taste in your mouth?
Is this related to your bad breath?
What time of day do you have problems with bad breath?
From who have you heard that you have bad breath?
Over how many years have you had a problem with bad breath?
How would you assess the severity of your bad breath?
How do others assess the severity of your bad breath?
How have you consulted a doctor over this problem?
Do you have problems with phlegm in the back of your throat (post nasal drip)?
Do you think that there is a relationship between your bad breath and stomach troubles?
Do you smoke? If so, how many per day and over how long a period? (pack/years)
Do you ever brush your tongue?
Do you use a tongue scraper?
Do you use a mouthwash? If so, what sort of mouthwash do you use?
Do you move away from other people because of your bad breath? If so what is the minimal distance that you are comfortable with?
Do you use sweets (e.g. mints or chewing gum) to disguise your bad breath?

Classification of halitosis

In 1999, Miyazaki and co-workers classified halitosis as "*genuine*" *halitosis*, *pseudo-halitosis*, and *halitophobia* (see Fig. 60-1). One year later genuine halitosis was subclassified as *physiologic halitosis* or *pathologic halitosis*. In physiologic halitosis there is no apparent disease or pathologic condition, whereas pathologic halitosis occurs as a consequence of an infection of the oral tissues. *Pseudo-halitosis* is a condition in which halitosis is non-existent but the patients are convinced that they have halitosis. *Halitophobia* can occur when there is no physical or social confirmation to suggest that halitosis is present, which can persist after therapy for either genuine halitosis or pseudo-halitosis (Yaegaki & Coil 2000).

Temporary or transient halitosis is a term for a very common temporary condition caused by such things as oral dryness, hunger (ketosis), stress, eating certain foods such as garlic (Suarez *et al*. 1999) and onions, smoking, or poor oral hygiene. "*Morning bad breath*" is a common example of temporary halitosis and is attributed to physiologic causes, such as reduced salivary flow during sleep.

Therapy

Pseudo-halitosis and halitophobia

Pseudo-halitosis must be considered if halitosis cannot be detected organoleptically from the patient complaining of bad breath, if higher than normal VSCs cannot be demonstrated instrumentally and if the patient cannot provide reliable third-party verification (confidant) of an odor problem. If after treatment for genuine halitosis or pseudo-halitosis the patient still believes that he or she has halitosis, the diagnosis should be halitophobia (Yaegaki & Coil 2000) and the patient might be referred to a psychiatrist. The therapeutic recommendation is never to advise the patient to use certain products against halitosis, because the patient will think that this therapist has finally found something and the patient may be a constant problem in your practice. Patients with the experience of tonsilloliths also can develop a halitophobia. A tonsillolith, also called *tonsil stone* or *calculus of the tonsil*, is a calcified structure that develops in the tonsillar crypts (Fletcher & Blair 1988;

Tsuneishi *et al*. 2006). These deposits break away from the tonsils and are coughed up as small stones that have an unpleasant smell. Patients often wrongly assume that they have halitosis based on this experience.

Patients with pseudo-halitosis and halitophobia might be advised to visit a clinical psychologist. However, few of these patients are willing to follow this advice. Again, it is very important that such patients are not treated for halitosis because there are no benefits in this course of action.

Temporary halitosis

Temporary halitosis gradually disappears on its own by eating, by not smoking, and not using garlic, onions or spicy food.

Morning bad breath

Morning bad breath in healthy subjects is a cosmetic problem analogous to body malodor. Morning bad breath develops during sleep when the saliva flow rate and the oxygen availability are at their lowest, promoting anaerobic formation of VSCs. This would explain why halitosis is generally most severe upon arising in the morning.

To reduce morning bad breath one could advise the patient to use a tongue scraper in the evening before sleeping (Tonzetich & Ng 1976; Faveri *et al*. 2006). Mouth rinses (Roldan *et al*. 2003a) are also advocated to reduce morning bad breath (see below). After drinking and eating in the morning the halitosis will most likely disappear.

Extraoral halitosis

Nose and throat

Extraoral halitosis associated with respiratory problems, e.g. rhinitis, sinusitis, tonsillitis, pharyngitis or foreign bodies (unilateral), is characterized by bad breath arising from the nose and not or limited from the mouth, i.e. the organoleptic score for nose breath is higher than that for mouth breath. Halimeter and gas chromatographic scores are usually low. Chronic infection of the nasal cavity and paranasal sinuses leads to changes in the cleansing action of the respiratory epithelium, allowing bacterial overgrowth and stasis of the secretions to occur.

These patients should be sent to an ENT specialist. Post-nasal drip may also give rise to unpleasant odors but seems to be difficult to treat. Dental treatment such as root canal therapy and dental extractions may violate the maxillary sinus and cause infections necessitating further dental intervention.

Systemic conditions

Extraoral halitosis associated with pulmonary problems (blood-borne halitosis) is characterized by bad breath arising from both nose and the mouth, i.e. the organoleptic score for nose breath and mouth breath are about the same. The Halimeter readings are low in both cases because H_2S and MM are not present. Gas chromatography may show high dimethyl sulfide (DMS) values and low or zero H_2S and MM levels (Tangerman & Winkel 2007).

Medication

It is important to note that some medications for allergy and high blood pressure, antidepressants, and sinus medication can give rise to blood-borne halitosis (Table 60-5) (Porter & Scully 2006). Metabolites of many drugs have been found to be excreted via the lungs. A good example is disulfiram (Antabuse), a drug used in treating alcoholism, which is metabolized to carbon disulfide (Manolis 1983). Antineoplastic medications may indirectly contribute to halitosis due to mucosites, ulceration, and increased gingival inflammation. Some drugs may induce xerostomia (see below).

Trimethylaminuria: the fish malodor syndrome

The fish malodor syndrome, also known as the fish odor syndrome and trimethylaminuria, is a metabolic disorder characterized by the presence of abnormal amounts of dietary-derived trimethylamine, in the urine, sweat, expired air, and other bodily secretions. Trimethylamine itself has the powerful aroma of rotten fish, resulting in a highly objectionable body odor, which can be destructive to the personal, social, and work life of the affected individual. Therapy for this syndrome is limited. It appears that dietary management might be most effective in mild to moderate forms of fish odor syndrome but not in all cases (Mitchell 2005). Fortunately, cases of trimethylaminuria are very rare.

Treatment planning

Patients with these forms of extra-oral halitosis are referred to the appropriate specialist. Halitosis associated with medication need to be discussed with the patient's physician.

Intraoral halitosis

In a halitosis practice most patients (±90%) have intraoral halitosis (Delanghe *et al*. 1998; Seemann *et al*. 2006). Intraoral halitosis is characterized by a low or non-existant score for nose breath combined with a high organoleptic score for mouth breath. The Halimeter gives similar results. The gas chromatograph shows high levels of H_2S and MM and low levels of DMS. Occasionally, the levels of VSCs registered by the Halimeter are unusually low due to low levels of H_2S whilst the organoleptic scores are high. This is usually associated with halitosis with high levels of MM.

Pathologic halitosis

Periodontium

According to a majority of authors, halitosis is more closely associated with tongue coating than with the severity of periodontal disease (Tonzetich & Ng 1976; Bosy *et al*. 1994). Causes of halitosis such as periodontitis (Sulsur *et al*. 1939; Sato *et al*. 1980; Delanghe *et al*. 1998), pericoronitis, dry socket, necrotizing periodontitis, necrotizing ulcerative gingivitis (NUG), oral infection, and dental caries (Sulsur *et al*. 1939) should be treated accordingly by the dentist and/or periodontist.

Xerostomia

Xerostomia is defined as a subjective complaint of dry mouth that may result from a decrease in the production of saliva (Guggenheimer 2003). Studies have found this condition in approximately 20% of sampled populations (Nederfors 1997). There seems to be a strong correlation between medication (Table 60-6) and dry mouth (Guggenheimer 2003; Nederfors 1997). Dental caries is a major complication of xerostomia. Patients with symptoms associated with a dry mouth and/or medication require further investigation by the appropriate practitioner/specialist.

Sedative agents
Muscle relaxant agents
Analgesic agents
Antihistamines
Anticonvulsants
Anorexiants
Anti-incontinence agents
Antiparkinsonian agents
Smoking cessation

Adapted from Guggenheimer (2003).

Menstrual cycles

Elevated VSCs were found in mouth air during mid-cycle and around menstruation (Tonzetich *et al*. 1978; Queiroz 2002).

Stress

Stressful situations can be a predisposing factor for the increase of VSCs in mouth air, but the mechanism cannot be simply explained by the reduction of the salivary flow (Queiroz 2002).

Physiologic halitosis

Tongue coating

It has been shown that mechanical tongue cleaning has a significant reducing effect on the VSC levels in mouth air (Yaegaki & Sanada 1992a; Danser *et al*. 2003). Tongue scraping seems to be the most effective hygienic procedure to reduce morning bad breath in periodontally healthy subjects (Faveri *et al*. 2006), even more than interdental flossing. Tongue scrapers seem to be a little bit more effective than toothbrushes (Seemann *et al*. 2001; Outhouse *et al*. 2006). Cleaning the surface of the tongue with a hard toothbrush wetted with chlorhexidine also seems to be effective in reducing halitosis (Bosy *et al*. 1994; De Boever & Loesche 1995; Cicek *et al*. 2003).

Treatment planning

Tongue scraper

Mechanical cleansing is recommended in patients with tongue coating. Both tongue brushing (Gross *et al*. 1975) and tongue scraping (Fig. 60-13) have been advocated as a means of removing the tongue coating (Quirynen 2004). It is important to clean the back of the tongue as far as possible, because the posterior portion of the tongue is loaded with most coating. A recommended regime for patients with severe halito-

Fig. 60-13 Tongue scraping.

sis is to use five strokes of the tongue scraper twice a day. Care must be taken not to irreversibly damage the tongue. Tongue cleaning reduces the substrate for putrefaction (Gross *et al*. 1975; Quirynen 2004), rather than the bacterial load (Menon & Coykendall 1994; Quirynen 2004). Moreover, tongue scraping improved the taste sensation more than tongue brushing (Quirynen 2004).

Dentifrice

It was shown that brushing the dorso-posterior surface of the tongue with a dentifrice was more effective than brushing the teeth in reducing VSCs (Tonzetich & Ng 1976). In volunteers, dentifrices with triclosan have been shown to reduce organoleptic scores significantly (Gerlach *et al*. 1998; Niles *et al*. 1999; Sharma *et al*. 1999; Nogueira-Filho *et al*. 2002; Hu *et al*. 2003; Vazquez *et al*. 2003; Farrell *et al*. 2006). Also dentifrices with baking soda (Brunette *et al*. 1998), essential oils (Olshan *et al*. 2000), and stannous fluoride (Gerlach *et al*. 1998) seem to be effective. The delivery of an antimicrobial agent via a dentifrice may not be as efficient in reducing intraoral halitosis as the same agent delivered in a mouth rinse (Loesche & Kazor 2002).

Mouth rinses

In addition to tongue scraping, the use of mouth rinses has been advocated (Nachnani 1997; Roldan *et al*. 2003a). Active components in these rinses include antibacterial compounds such as: cetylpyridinium chloride (Yaegaki & Sanada 1992b; Rosenberg *et al*. 1992; Kozlovsky *et al*. 1996; Silwood *et al*. 2001; van Steenberghe *et al*. 2001; Borden *et al*. 2002; Quirynen *et al*. 2002a, 2005; Winkel *et al*. 2003; Carvalho *et al*. 2004; Roldan *et al*. 2004, 2005); chlorhexidine (Rosenberg *et al*. 1992; Bosy *et al*. 1994; De Boever & Loesche 1995; Quirynen *et al*. 1998, 2002a, 2005; van Steenberghe *et al*. 2001; Winkel *et al*. 2003; Roldan *et al*. 2003b, 2004, 2005; Carvalho *et al*. 2004); essential oils (Pitts *et al*. 1981, 1983; Rosenberg *et al*. 1992; Yaegaki & Sanada 1992b; Kozlovsky *et al*. 1996; Silwood *et al*. 2001; Borden *et al*. 2002; Carvalho *et al*. 2004); chlorine dioxide (Frascella *et al*. 1998, 2000; Silwood *et al*. 2001; Borden *et al*. 2002); metal ions, such as zinc lactate and zinc chloride (Schmidt & Tarbet 1978; van Steenberghe *et al*. 2001; Young *et al*. 2001; Borden *et al*. 2002; Quirynen *et al*. 2002a; Winkel *et al*. 2003; Codipilly *et al*. 2004; Roldan *et al*. 2004, 2005); triclosan (Carvalho *et al*. 2004); and hydrogen peroxide (Suarez *et al*. 2000). Most of these studies demonstrated that these products are effective in reducing oral malodor.

Despite the recommendations of the various manufacturers of these oral rinses, the efficacy of these products on intraoral halitosis is not clear. The main reason for this is that the duration and the number of controlled clinical trials is limited. The other problem with the studies which are available is that the patient groups in the studies are rarely patients with a definite diagnosis of intraoral halitosis. The mouth rinses are tested in students (Rosenberg *et al*. 1992; van Steenberghe *et al*. 2001; Quirynen *et al*. 2002a; Carvalho *et al*. 2004) and volunteers (Pitts *et al*. 1981, 1983; Yaegaki & Sanada 1992b; Kozlovsky *et al*. 1996; Suarez *et al*. 2000; Silwood *et al*. 2001; Borden *et al*. 2002; Codipilly *et al*. 2004; Roldan *et al*. 2004; Quirynen *et al*. 2005) without any complaints of halitosis. It is questionable if the results of these studies in "normal" patients and/or patients with Halimeter values within the normal range (80–110 ppb) are applicable for the treatment of patients with real halitosis. Only a limited amount of studies were performed in subjects with a complaint of "bad breath" or with high objectionable levels of VSCs. These are case report studies with 0.2% chlorhexidine (Bosy *et al*. 1994), 0.12% chlorhexidine (De Boever & Loesche 1995), and 0.05% chlorhexidine, 0.05% cetylpyridinium chloride and 0.14% zinc lactate (Roldan *et al*. 2005) with a 3-month follow-up. A dual centre, placebo-controlled, double-blind, randomized controlled clinical trial with 0.05% chlorhexidine, 0.05% cetylpyridinium chloride, and 0.14% zinc lactate was performed by Winkel *et al*. (2003) and Roldan *et al*. (2003). The mouth rinse used in this study (Halita) was specifically formulated to treat halitosis. This mouth rinse contains ingredients with low concentrations of the active components without alcohol and has therefore limited side effects for long-term use. The results indicated significant improvements in organoleptic and VSC scores in the test group.

Quirynen *et al*. (1998) found a reduction in organoleptic scores in periodontitis patients with and without complaints of oral halitosis, after scaling and root planing of all pockets within 24 hours together with the application of chlorhexidine. Despite the demonstrated efficacy of 0.2% and 0.12% chlorhexidine, long-term use of these solutions cannot be recommended because of the side effects (Gagari & Kabani 1995). Some of these adverse effects are lost taste and discoloration of the teeth and the tongue. More suitable agents are mouth rinses with low concentrations of active ingredients. Based on the double-blind placebo-controlled study (Winkel *et al*. 2003) a recommended regime for severe halitosis patients is gargling twice a day for 1 minute with 15 ml of Halita with the tongue out. By gargling, instead of rinsing, the cleansing agents can reach the dorsal surface of the back of the tongue.

Antibiotics

Currently, no research data are available about the use of antibiotics in patients with halitosis. In our clinic some patients with halitosis had used systemic antibiotics for other medical reasons. For a limited

Instructions for recall visit

In these instructions, subjects are asked **not** to:

1) consume food containing onions, garlic or hot spices for 48 hours before recall visit;
2) drink alcohol or smoke in the previous 12 hours;
3) use scented cosmetics or after-shave lotions on the morning of the recall visit.

Patient should perform oral hygiene, including tooth brushing, interdental and tongue cleaning, and use mouthrinses according to the treatment protocol.

Fig. 60-14 Instructions for recall visit.

time there was a reduction of intraoral halitosis but after a few weeks, halitosis recurred. A possible explanation is that patients with intraoral halitosis based on tongue coating have commensal bacteria (Van Winkelhoff & Winkel 1997), e.g. *Fusobacterium nucleatum*. These commensal bacteria are suppressed by the antibiotics for a short period of time but re-colonize up to a normal level after some weeks.

Use of a confidant

Previous research has demonstrated that patients with halitosis are generally unable to rate the intensity of their own halitosis (Rosenberg *et al*. 1995). Therefore, patients cannot reliably assess the effectiveness of the prescribed therapy. The recommended course of action is to ask them to use another person as a confidant. A confidant could be a spouse, a family member or close friend, who is willing to smell the patient's breath and provide straightforward feedback.

Adjustment of therapy

All patients with the diagnosis of intraoral halitosis should come back for a recall visit and adjustment of therapy (Fig. 60-14). At the first visit, patients are seen in the "worst" condition to make a proper diagnosis. At the re-examination patients are asked to present themselves in the "best" condition, meaning proper oral hygiene and correctly following the advised treatment protocol for patients with halitosis. The purpose of the recall visit is to adjust the therapy based on the results of this re-examination. Organoleptic scores, measurement with the sulphide monitor and gas chromatography are performed. The first question to the patient is: "Did the therapy work?" Although, most of the time the therapy for intraoral halitosis is very successful, some patients will answer "No". The reason is that most of these patients still have a bad taste and think that the presence of a bad taste means that they have a bad breath, which is not necessarily the case. A confidant is of paramount importance for this group of patients. Another important question is about the "comfort range". The result is compared with the comfort range from the first examination. If the comfort range is the same and the halitosis is well treated, the patient could develop halitophobia and needs to seek professional help.

Future perspectives

In a preliminary study, Burton *et al*. (2005) showed that replacement of bacteria implicated in halitosis by colonization with competitive bacteria (probiotica) such as *S. salivarius* may provide an effective strategy to reduce the severity of halitosis.

Conclusions

Social relationships are one of the pillars of the quality of life (Elias & Ferriani 2006). In that respect, halitosis can be a crippling social problem and therefore needs to be considered a serious problem. Extraoral halitosis might be a manifestation of a serious disease. It is of paramount importance to differentiate between extra- and intraoral halitosis.

Although there is an effective treatment of intraoral halitosis, many physicians, dentists, and dental hygienists do not recognize intraoral halitosis as a manageable condition. Since in most of the cases of halitosis the oral cavity is *the place of origin*, health professionals in medicine and dentistry should be knowledgeable about diagnosis and therapy of this disorder. In most cases intraoral halitosis can be treated by tongue scraping and the use of chemical solutions with low concentrations of zinc ions, chlorhexidine, and cetylpyridinium chloride. The dental hygienist, dentist, and periodontist are the most appropriate professionals to diagnose and to treat this condition.
