The lesions are seldom associated with deep pocket formation, because extensive gingival necrosis often coincides with loss of crestal alveolar bone. The gingival necrosis develops rapidly and within a few days the involved papillae are often separated into one facial and one lingual portion with an interposed necrotic depression, a negative papilla, between them. The central necrosis produces considerable tissue destruction and a regular crater is formed. At this stage of the disease, the disease process usually involves the periodontal ligament and the alveolar bone, and loss of attachment is now established. The diagnosis of the disease process is consequently NP.

Along with the papilla destruction, the necrosis usually extends laterally along the gingival margin at the oral and/or facial surfaces of the teeth. Necrotic areas originating from neighboring interproximal spaces frequently merge to form a continuous necrotic area (Figs. 20-2 and 20-3). Superficial necrotic lesions only rarely cover a substantial part of the attached gingiva, which becomes reduced in width as the result of disease progression. The palatal and lingual marginal gingiva is less frequently involved than the corresponding facial area. Frequently, gingiva of semi-impacted teeth and in the posterior maxillary region are affected (Figs. 20-4 and 20-5). Progression of the interproximal process often results in destruction of most interdental alveolar bone (Fig. 20-6). In more advanced cases, pain is often considerable and may be associated with a markedly increased salivary flow. As a result of pain it is often difficult for

Fig. 20-2 Necrotizing gingivitis progressing along the gingival margin of the right maxilla. The interproximal necrotizing processes have merged.

the patients to eat, and a reduced food intake may be critical to HIV-infected patients because they may already lose weight in association with their HIV infection.

Sequestrum formation

The disease progression may be rapid and result in necrosis of small or large parts of the alveolar bone. Such a development is particularly evident in severely immunocompromised patients including HIV-seropositive individuals. The necrotic bone, denoted a sequestrum, is initially irremovable but after some time becomes loosened, whereafter it may be removed with forceps. Analgesia may not be required. A sequestrum may not only involve interproximal bone but also include adjacent facial and oral cortical bone (Fig. 20-7).

Involvement of alveolar mucosa

When the necrotic process progresses beyond the mucogingival junction, the condition is denoted NS (Figs. 20-8 and 20-9) (Williams *et al*. 1990). The severe tissue destruction characteristic of this disease is related to seriously compromised immune functions typically associated with HIV infection and malnutrition (Fig. 20-10). Importantly, it may be life-threatening. NS may result in extensive denudation of bone, resulting in major sequestration with the development of oro-antral fistula and osteitis (SanGiacomo *et al*. 1990; Felix *et al*. 1991).

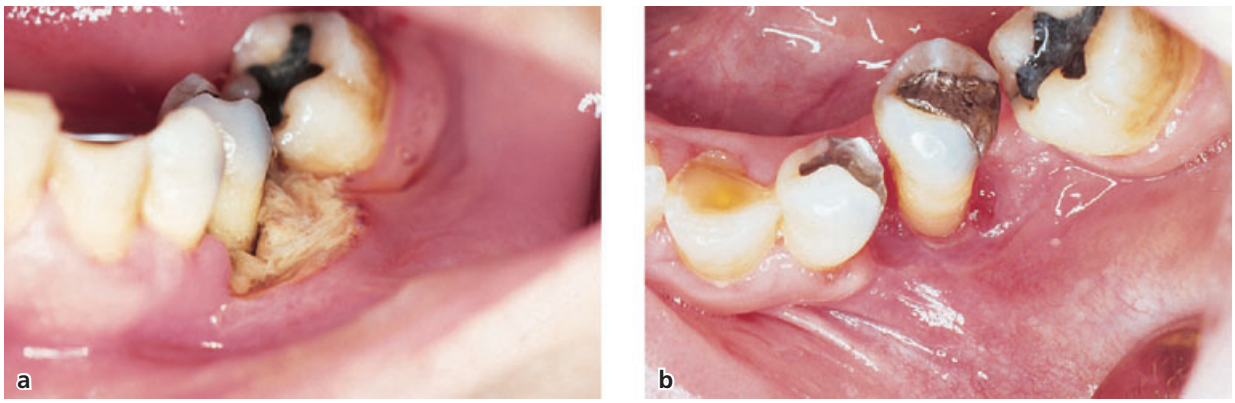

Fig. 20-8 (a) Necrotizing stomatitis affecting periodontium of left mandibular premolar region and adjacent alveolar mucosa. (b) After treatment and healing, no attached gingiva remains.

Fig. 20-9 Necrotizing stomatitis of right maxilla with extensive necrotic ulcer of palatal mucosa.

Swelling of lymph nodes

Swelling of the regional lymph nodes may occur in NPD but is particularly evident in advanced cases. Such symptoms are usually confined to the submandibular lymph nodes, but the cervical lymph nodes may also be involved. In children with NPD, swelling of lymph nodes and increased bleeding tendency are often the most pronounced clinical findings (Jiménez & Baer 1975).

Fever and malaise

Fever and malaise is not a consistent characteristic of NPD. Some investigations indicate that elevated body temperature is not common in NG and that, when present, the elevation of body temperature is usually moderate (Grupe & Wilder 1956; Goldhaber & Giddon 1964; Shields 1977; Stevens *et al*. 1984). A small decrease in body temperature in NG has even been described. The disagreement on this point may, in fact, be due to misdiagnosis of primary herpetic gingivostomatitis as NG (see below).

Oral hygiene

The oral hygiene in patients with NPD is usually poor. Moreover, brushing of teeth and contact with the acutely inflamed gingiva is painful. Therefore, large amounts of plaque on the teeth are common, especially along the gingival margin. A thin, whitish film sometimes covers parts of the attached gingiva (Fig. 20-11). This film is a characteristic finding in patients who have neither eaten nor performed oral hygiene for days. It is composed of desquamated epithelial cells and bacteria in a meshwork of salivary proteins. The film is easily removed.

In general, the clinical characteristics of NPD in HIV-seropositive patients do not essentially differ from those in HIV-seronegative patients. However, the lesions in HIV-seropositive patients may not be associated with large amounts of plaque and calculus. Thus, the disease activity in these patients sometimes shows limited correlation with etiologic factors as determined by the amount of bacterial plaque (Holmstrup & Westergaard 1994). Further, lesions of NPD in HIV-seropositive patients have sometimes been revealed in gingival tissue affected by Kaposi's sarcoma (Fig. 20-12).

Acute and recurrent/chronic forms of necrotizing gingivitis and periodontitis

In most instances the course of the diseases is acute, characterized by the rapid destruction of the periodontal tissue. However, if inadequately treated or left untreated, the acute phase may gradually subside. The symptoms then become less unpleasant to the patient, but the destruction of the periodontal tissues continues, although at a slower rate, and the necrotic tissues do not heal completely. Such a condition has been termed chronic necrotizing gingivitis, or periodontitis in the case of attachment loss (Fig. 20-13).

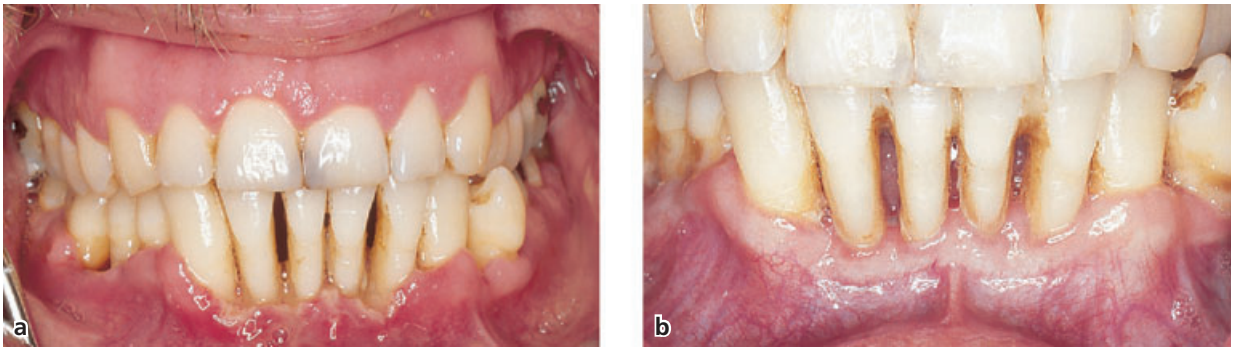

Fig. 20-10 (a) Necrotizing stomatitis affecting the mandible of an HIV-seropositive patient. (b) Two years after treatment the result of treatment is satisfactory, and there has been no recurrence.

Fig. 20-11 A whitish film sometimes covers parts of the attached gingiva in patients with NPD as demonstrated in the maxillary gingiva. The film is composed of desquamated epithelial cells which have accumulated because the patient has not eaten or performed oral hygiene for days.

Fig. 20-12 Necrotizing periodontitis affecting Kaposi's sarcoma of left maxillary central incisor gingiva in an HIV-infected patient. The sarcoma affected almost the entire maxillary gingiva after 9 months.

The necrotizing lesions persist as open craters, frequently with a content of subgingival calculus and bacterial plaque. Although the characteristic ulcerative, necrotic areas of the acute phase usually disappear, acute exacerbations with intervening periods of quiescence may also occur. In recurrent acute phases, subjective symptoms again become more prominent

Fig. 20-13 Chronic necrotizing periodontitis with edematous gingiva particularly of mandible. The slightly active necrotizing processes at the bottom of the negative papillae are not visible.

and necrotic ulcers reappear. Some authors prefer the term recurrent rather than chronic to describe this category of necrotizing disease (Johnson & Engel 1986). Plaque and necrotic debris are often less conspicuous in these phases than in the acute forms, because they are located in pre-existing interdental craters. Several adjoining interdental craters may fuse, resulting in total separation of facial and oral gingivae, which form two distinct flaps. Recurrent forms of NG and NP may produce considerable destruction of supporting tissues. The most pronounced tissue loss usually occurs in relation to the interproximal craters.

Diagnosis

The diagnosis of NG, NP, and NS is based on clinical findings as described above. The patient has usually noticed pain and bleeding from the gingiva, particularly upon touch. The histopathology of the necrotizing diseases is not pathognomonic for NG, and biopsy is certainly not indicated in the heavily infected area.

Differential diagnosis

NPD may be confused with other diseases of the oral mucosa. Primary herpetic gingivostomatitis (PHG) is

Table 20-1 Important characteristics for differential diagnosis between NPD and PHG

	NPD	PHG
Etiology	Bacteria	Herpes simplex virus
Age	15–30 years	Frequently children
Site	Interdental papillae. Rarely outside the gingiva	Gingiva and the entire oral mucosa
Symptoms	Ulcerations and necrotic tissue and a yellowish white plaque	Multiple vesicles which disrupt, leaving small round fibrin-covered ulcerations
	Foetor ex ore	*Foetor ex ore*
	Moderate fever may occur	Fever
Duration	1–2 days if treated	1–2 weeks
Contagious	–	+
Immunity	–	Partial
Healing	Destruction of periodontal tissue remains	No permanent destruction

Fig. 20-14 Primary herpetic gingivostomatitis. Note that the ulcers affect the gingival margin but not primarily interdental papillae. A circular ulcer of the second premolar gingiva is highly suggestive of the diagnosis.

not infrequently mistaken for NPD (Klotz 1973). The important differential diagnostic criteria for the two diseases are listed in Table 20-1. It should be noted that in the USA and in northern Europe, NPD occurs very rarely in children, whereas PHG is most commonly found in children. If the body temperature is markedly raised, to 38°C or more, PHG should be suspected. NG and NP has a marked predilection for the interdental papillae, while PHG shows no such limitation and may occur anywhere on the free or the attached gingiva, or in the alveolar mucosa (Fig. 20-14). In PHG erythema is of a more diffuse character and may cover the entire gingiva and parts of the alveolar mucosa. The vesicular lesions in PHG, which disrupt and produce small ulcers surrounded by diffuse erythema, occur both on the lips and tongue as well as on the buccal mucosa. PHG and NPD may occur simultaneously in the same patient, and in such cases there may be mucosal lesions outside the gingiva, and fever and general malaise tend to occur more frequently than with NPD alone.

Oral mucosal diseases that have been confused with NPD include desquamative gingivitis, benign mucous membrane pemphigoid, erythema multiforme exudativum, streptococcal gingivitis, gonococcal gingivitis, and others. All of these are clinically quite distinct from NPD.

In some forms of leukemia, especially acute leukemia, necrotizing ulcers may occur in the oral mucosa and are not infrequently seen in association with the gingival margin, apparently as an exacerbation of an existing chronic inflammatory condition. The clinical appearance can resemble NPD lesions, and the symptoms they produce may be the ones that first make the patient seek professional consultation. In acute leukemia the gingiva often appears bluish red and edematous with varying degrees of ulceration and necrosis. Generally, the patient has more marked systemic symptoms than with ordinary NPD, but can feel relatively healthy for a while. The dentist should be aware of the possibility that leukemias present such oral manifestations, which require medical examination of the patient, whereas biopsy is usually not indicated.

Histopathology

Histopathologically, NG lesions are characterized by ulceration with necrosis of epithelium and superficial layers of the connective tissue and an acute, nonspecific inflammatory reaction (Fig. 20-15). An important aspect is the role of the microorganisms in the lesions, because they have been demonstrated not only in the necrotic tissue components but also in vital epithelium and connective tissue.

Sometimes the histologic findings demonstrate the formation of regular layers with certain characteristics (Listgarten 1965) but there may be variations in regularity. The surface cover of yellowish white or grayish slough can be observed clinically; under the light microscope it appears to be a meshwork of fibrin with degenerated epithelial cells, leukocytes and erythrocytes, bacteria, and cellular debris. At the ultrastructural level, bacteria of varying sizes and forms including small, medium-sized, and large spirochetes have been revealed between the inflammatory cells, the majority of which are neutrophilic granulocytes. Moreover, in presumably vital parts of the surface epithelium, compact masses of spirochetes and short, fusiform rods have been found intercellularly.

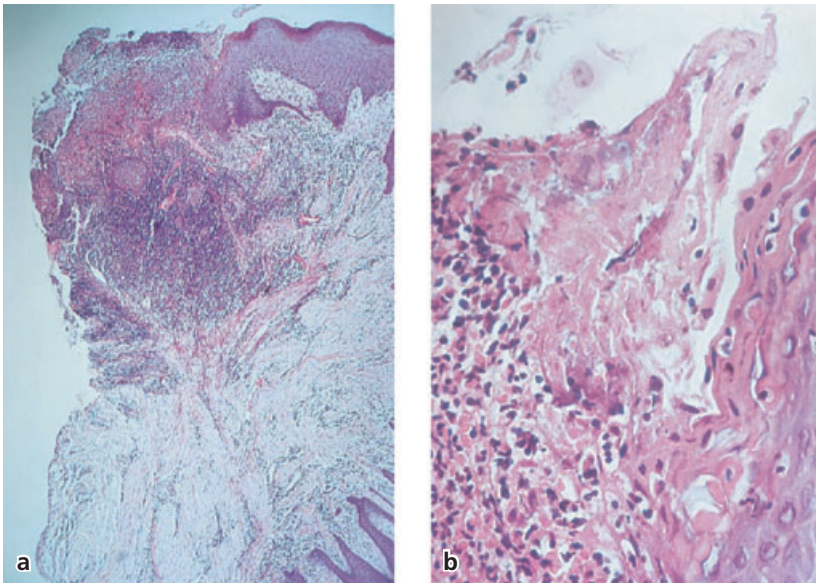

Fig. 20-15 Photomicrograph of gingival tissue affected by necrotizing gingivitis. (a) Upper right part of gingival biopsy shows gingival oral epithelium whereas upper left is ulcerated surface. Underneath the ulcer the connective tissue is heavily infiltrated by inflammatory cells. (b) Higher magnification of margin of ulcer shows necrotic tissue infiltrated with neutrophils. Right border is covered by epithelium. Courtesy of Dr. Finn Prætorius.

The vital connective tissue in the bottom of the lesion is covered by necrotic tissue, characterized by disintegrated cells, many large and medium-sized spirochetes, and other bacteria which, judging from their size and shape, may be fusobacteria. In the superior part of the vital connective tissue, characterized by intact tissue components, the tissue is infiltrated by large and medium-sized spirochetes, but no other microorganisms have been seen. In the vital connective tissue the vessels are dilated. They also proliferate to form granulation tissue, and the tissue is heavily infiltrated by leukocytes. As always in acute processes the inflammatory infiltrate is dominated by neutrophils (Figs. 20-15b and 20-16). In the deeper tissue, the inflammatory process also comprises large numbers of monocytes and plasma cells (Listgarten 1965; Heylings 1967).

Microbiology

Microorganisms isolated from necrotizing lesions

Microbial samples from NPD lesions have demonstrated a constant and a variable part of the flora. The "constant flora" primarily contained *Treponema* sp., *Selenomonas* sp., *Fusobacterium* sp., and *B. melaninogenicus* ss *intermedius* (*Prevotella intermedia*), and the "variable flora" consisted of a heterogeneous array of bacterial types (Loesche *et al*. 1982). Although the characteristic bacterial flora of spirochetes and fusobacteria has been isolated in large numbers from the necrotic lesions in several studies, their presence is not evidence of a primary etiologic importance. Their presence could equally well result from secondary overgrowth. Moreover, the microorganisms associated with NG are also harbored by healthy mouths and mouths with gingivitis or periodontitis (Johnson & Engel 1986). An important role for *Treponema* sp. and *B. intermedius* (*P. intermedia*) has been suggested by studies of antibodies in NPD patients to such bacteria, compared to levels in age- and sex-matched controls with healthy gingiva or simple gingivitis (Chung *et al*. 1983).

There is little available information about the microbiology of HIV-associated NPD. *Borrelia*, Gram-positive cocci, β-hemolytic streptococci and *Candida albicans* have been isolated from the lesions (Reichart & Schiødt 1989). It has also been proposed that human cytomegalovirus (HCMV) may play a role in the pathogenesis of NPD (Sabiston 1986). This virus has been found in the digestive tract of HIV-patients (Kanas *et al*. 1987; Langford *et al*. 1990), and a case of oral HCMV infection with similarities to necrotizing periodontitis has been reported (Dodd *et al*. 1993). An increased frequency of HCMV and other herpes viruses found in necrotizing lesions among Nigerian children supports a contributory role of the viruses (Contreras *et al*. 1997), although it remains to be demonstrated in future studies whether cytomegalovirus does play a causal role.

Pathogenic potential of microorganisms

Our knowledge of the pathogenic mechanisms by which the bacterial flora produces the tissue changes characteristic of NPD is limited. One reason is that it has been difficult to establish an acceptable animal experimental model. However, several of the pathogenic mechanisms which have been associated with chronic gingivitis and periodontitis may also be of etiologic importance in the necrotizing forms of the diseases.

An important aspect in the pathogenesis of periodontitis is the capacity of the microorganisms to invade the host tissues. Among the bacteria isolated from necrotizing lesions, spirochetes and fusiform bacteria can, in fact, invade the epithelium (Heylings 1967). The spirochetes can also invade the vital

Fig. 20-16 Electronmicrograph demonstrating phagocytosing neutrophil (N) close to the surface of a sequestrum (C), covered by numerous microorganisms including spirochetes (S) and rods (R). Bar = 1 µm.

connective tissue (Listgarten 1965). The pathogenic potential is further substantiated by the fact that both fusobacteria and spirochetes can liberate endotoxins (Mergenhagen *et al*. 1961; Kristoffersen & Hofstad 1970).

A number of observations indicate that the effects of endotoxins are more prominent in NPD than in chronic gingivitis and periodontitis. The large masses of Gram-negative bacteria liberate endotoxins in close contact with connective tissue. Endotoxins may produce tissue destruction both by direct toxic effects and indirectly, by activating and modifying tissue responses of the host (Wilton & Lehner 1980). Through a direct toxic effect, endotoxins may lead to damage of cells and vessels. Necrosis is a prominent feature in the so-called "Shwartzman reaction", which is caused by endotoxins. Indirectly, endotoxins can contribute to tissue damage in several ways: they can function as antigens and elicit immune reactions; they can activate complement directly through the alternative pathway and thereby liberate chemotoxins; but they can also activate macrophages, B and T lymphocytes, and influence the host's immune reactions by interfering with cytokines produced by these cells. Studies have shown that endotoxins can stimulate catabolic processes with degradation of both connective tissue and bone induced by the released cytokines. The extent to which such reactions contribute to host defense or to tissue damage is not yet known.

An aspect which has been of major concern, especially in wartime, is the communicability of the disease. Several reports have considered this aspect but it has been concluded that the necrotizing diseases are not transmissible by ordinary means of contact (Johnson & Engel 1986). Attempts to transmit the disease from one animal to another, or to produce necrotic lesions in experimental animals, have failed to yield conclusive results (MacDonald *et al*. 1963). Several suspect microorganisms and several combinations of microorganisms can produce similar lesions in experimental animals. A combination of four different bacteria, none of them fusobacteria or spirochetes, has been found to possess such properties and there are indications that among the four bacterial species, *Bacteroides melaninogenicus* was the true pathogen (MacDonald *et al*. 1956, 1963). *B. melaninogenicus* may, under certain conditions, produce an enzyme which degrades native collagen (Gibbons & MacDonald 1961). It is still not clear, however, whether this microorganism is of particular importance in the pathogenesis of NPD. NG lesions have

also been induced in dogs pretreated with steroids and inoculated with a fusiform–spirochete culture from dogs which had gingival lesions similar to the NG lesions seen in humans (Mikx & van Campen 1982). The lesions produced in experimental animals may not be identical to those which occur in humans. It is also important to note that even if necrotic lesions can be transmitted by transmission of infectious material or bacterial cultures, this does not necessarily mean that the disease is truly contagious.

It is obvious from the above observations and assumptions that a fundamental question remains to be answered, and at this point it may be stated that the necrotizing periodontal diseases belong to those diseases to which Pasteur referred when he said: "there are some bacteria that cause a disease, but there are some diseases that bring about a condition that is ideal for the growth of some bacteria" (Wilson 1952). If the microorganisms mentioned above play a role in the etiology of the disease, then, presumably, the disease is an opportunistic infection. Consequently, the pathogenic characteristics of the microorganisms are normally overcome by the host defenses, and disease occurs when the host defenses are impaired. The isolated microorganisms do possess biologic activities which may contribute to the pathogenesis, but the exact role of the various microorganisms has not yet been clarified (Johnson & Engel 1986).

Host response and predisposing factors

It is particularly evident for HIV-infected patients that the disease is associated with diminished host resistance; among other predisposing factors, the basic mechanism may include altered host immunity. Changes in leukocyte function and the immune system have been observed in some studies, although the biologic reason for, and significance of, these findings are unclear (Johnson & Engel 1986).

Significantly increased IgG and IgM antibody titers to intermediate-sized spirochetes and higher IgG titers to *B. melaninogenicus* ssp *intermedius* have been found in NG patients as compared to age- and sex-matched healthy and gingivitis control groups (Chung *et al*. 1983). These results, however, are in disagreement with other data showing no differences in serum antibody levels to bacterial antigens (Wilton *et al*. 1971).

Total leukocyte counts have been found to be similar for patients and controls. NG patients, however, displayed marked depression in polymorphonuclear leukocyte chemotaxis and phagocytosis as compared with control individuals. Reduced mitogen-induced proliferation of peripheral blood lymphocytes has also been found in NG patients. It was suggested that elevated blood steroids may account for the reduced chemotactic and phagocytic responses (Cogen *et al*. 1983).

For many years it has been known that a number of predisposing factors may interact with the host defense systems and render the patient susceptible to NPD. Usually, a single one of these factors is not sufficient to establish disease. The various factors, which have been focused upon, comprise systemic diseases, including HIV infection and malnutrition, poor oral hygiene, pre-existing gingivitis and history of previous NPD, psychologic stress and inadequate sleep, smoking and alcohol use, Caucasian background, and young age.

A recent analysis of suspected predisposing factors among American patients with NPD has shown that HIV seropositivity overwhelmed all other factors in importance when present (Horning & Cohen 1995). Among the HIV-seronegative patients the ranked importance of the predisposing factors was: history of previous NPD; poor oral hygiene; inadequate sleep; unusual psychologic stress; poor diet; recent illness; social or greater alcohol use; smoking; Caucasian background; and age under 21 years. The various predisposing factors mentioned below are obviously not equally important in industrialized and developing countries, but many of these factors are known to relate to impaired immunity.

Systemic diseases

Systemic diseases which impair immunity predispose to NPD. This is why NPD occurs more frequently in HIV-infected individuals and in patients with other leukocyte diseases including leukemia (Melnick *et al*. 1988). Examples of other diseases predisposing to NPD are measles, chicken pox, tuberculosis, herpetic gingivostomatitis, and malaria, but malnutrition is also important. Whereas these examples of predisposing factors are rare in western patients, they are evident in developing countries, where they often predispose to NPD and noma in children (Emslie 1963; Pindborg *et al*. 1966, 1967; Sheiham 1966; Enwonwu 1972, 1985). It is important to note that NPD is sometimes an early signal of impending serious illness (Enwonwu 1972).

HIV infection

In Africa, the general population shows a high HIV-seropositive prevalence rate, ranging up to 33% in some populations. In Europe, prevalence figures have been established for areas in the UK, where the prevalence figures were 0.1–0.2% (Nicoll *et al*. 2000). In South Africa NPD in otherwise systemically healthy individuals was correlated with HIV infection, with a predictive value of 69.6% (Shangase *et al*. 2004). In industrialized countries, a significant portion of patients with NPD are HIV-infected patients, and no characteristics have been revealed that distinguish NPD in HIV-seropositive from that in HIV-seronegative patients. A history of frequent relapses and poor response to traditional or drug therapy may

be suggestive (Greenspan *et al*. 1986; Horning & Cohen 1995). Suspicion of HIV infection is also supported by the simultaneous presence of oral candidosis, "hairy leukoplakia", or Kaposi's tumor, but these lesions are far from always present in HIV-infected patients.

HIV infection attacks the T-helper cells of the body, causing a drastic change in the T-helper(CD4+)/T-suppressor(CD8+) ratio with severe impairment of the host's resistance to infection. Depleted peripheral T-helper lymphocyte counts correlate closely with the occurrence of NG as demonstrated in a study of 390 US HIV-seropositive soldiers (Thompson *et al*. 1992). Furthermore, a complete absence of T cells in gingival tissue of HIV-infected patients with periodontitis has been reported (Steidley *et al*. 1992). The lack of local immune effector and regulatory cells in HIV-seropositive patients could in fact explain the characteristic and rapidly progressive nature of periodontitis in these patients. Moreover, a protective effect has been encountered with antiviral treatment of the HIV infection against NPD (Tappuni & Fleming 2001) as well as against HIV-associated gingivitis and periodontitis (Masouredis *et al*. 1992). NP has been revealed as a marker for immune deterioration, with a 95% predictive value that CD4+ cell counts were below 200 cells/mm^3, and, if untreated, a cumulative probability of death within 24 months (Glick *et al*. 1994). As a consequence of this finding, if possible all NPD patients should be recommended to have a test for HIV infection.

Malnutrition

In developing countries malnutrition has often been mentioned as a predisposing factor to NPD (Enwonwu 1972; Osuji 1990). Malnutrition results in lowered resistance to infection and protein malnutrition has been emphasized as the most common public health problem affecting underprivileged Nigerian children who are most often affected by NPD (Enwonwu 1985, 1994). In response to periodontal pathogens, phagocytes elaborate destructive oxidants, proteinases, and other factors. Periodontal damage may occur as the result of the balance between these factors, the antioxidants and host-derived antiproteinases. Malnutrition is characterized by marked tissue depletion of the key antioxidant nutrients, and impaired acute-phase protein response to infections. This is due to impairment in the production and cellular action of the cytokines. Other features of malnutrition include inverted helper/suppressor T lymphocyte ratio, histaminemia, hormonal imbalance with increased blood and saliva levels of free cortisol, and defective mucosal integrity. Malnutrition usually involves concomitant deficiencies of several essential macro- and micronutrients, and therefore has the potential to adversely influence the prognosis of periodontal infections (Enwonwu 1994).

Poor oral hygiene, pre-existing gingivitis, and history of previous NPD

Many of the early studies of NPD showed that a low standard of oral hygiene contributed to the establishment of the disease (Johnson & Engel 1986). This has been supported by recent studies in the USA and Nigeria (Taiwo 1993; Horning & Cohen 1995). Consequently, NPD is usually established on the basis of preexisting chronic gingivitis (Pindborg 1951b). It should be emphasized, however, that plaque accumulation as seen in NPD patients may also be enhanced by the discomfort experienced with oral hygiene practices due to the disease. Based on questionnaires and personal interviews, 28% of NPD patients have been found with a history of previous painful gingival infection and 21% had gingival scars suggestive of previous NPD (Horning & Cohen 1995).

Psychologic stress and inadequate sleep

Just as other ulcerative gastrointestinal conditions have been shown to have psychogenic origins, psychologic stress has often and for many years been mentioned as a predisposing factor (Johnson & Engel 1986). Epidemiologic investigations seem to indicate a more frequent occurrence of necrotizing diseases in periods when the individuals are exposed to psychologic stress (Pindborg 1951a,b; Giddon *et al*. 1963; Goldhaber & Giddon 1964). New recruits and deploying military personnel, college students during examination periods, patients with depression or other emotional disorders, and patients feeling inadequate at handling life situations are more susceptible to NPD (Pindborg 1951a,b; Moulton *et al*. 1952; Giddon *et al*. 1963; Cohen-Cole *et al*. 1983). Urine levels of corticosteroids have been used as a physiologic measure of stress, and increased free cortisol levels have been encountered in the urine of NPD patients as compared with controls. The NPD patients showed significantly higher levels of trait anxiety, depression, and emotional disturbance than did control individuals (Cohen-Cole *et al*. 1983). The role of anxiety and psychologic stress in the pathogenesis of NG has been borne out by both psychiatric and biochemical investigations (Moulton *et al*. 1952; Shannon *et al*. 1969; Maupin & Bell 1975). There are several ways by which psychologic stress factors may interfere with host susceptibility. Host tissue resistance may be changed by mechanisms acting through the autonomic nervous system and endocrine glands resulting in elevation of corticosteroid and catecholamine levels. This may reduce gingival microcirculation and salivary flow and enhance nutrition of *Prevotella intermedia*, but also depress neutrophil and lymphocyte functions which facilitate bacterial invasion and damage (Johnson & Engel 1986; Horning & Cohen 1995).

Inadequate sleep, often as the result of lifestyle choices or job requirements, has been mentioned

by many patients with NPD (Horning & Cohen 1995).

Smoking and alcohol use

Smoking has been listed as a predisposing factor to NPD for many years and presumably predisposes to other types of periodontitis as well (The American Academy of Periodontology 1996). Two studies from the 1950s found that 98% of the patients were smokers (Pindborg 1951a; Goldhaber 1957). More recent data have confirmed this by finding only 6% non-smokers among NPD patients in contrast to 63% in a matched control group (Stevens *et al*. 1984). The amount smoked also appears important since 41% of subjects with NG smoked more than 20 cigarettes daily whereas only 5% of controls smoked that much (Goldhaber & Giddon 1964).

The relationship between tobacco usage and NPD appears to be complex. It has often been stated that smokers in general have poorer oral hygiene than non-smokers but studies have shown that there is little difference in the level of plaque accumulation in smokers versus non-smokers. Also, there have been no conclusive studies to show that smoking adversely affects periodontal tissues by altering the microbial composition of plaque (The American Academy of Periodontology 1996). Smoking could lead to increased disease activity by influencing host response and tissue reactions. As examples, smokers have depressed numbers of T-helper lymphocytes, and tobacco smoke can also impair chemotaxis and phagocytosis of oral and peripheral phagocytes (Eichel & Shahrik 1969; Kenney *et al*. 1977; Ginns *et al*. 1982; Costabel *et al*. 1986; Lannan *et al*. 1992; Selby *et al*. 1992). Nicotine-induced secretion of epinephrine resulting in gingival vasoconstriction has been proposed as one possible mechanism by which smoking may influence tissue susceptibility (Schwartz & Baumhammers 1972; Kardachi & Clarke 1974; Bergström & Preber 1986). The exact mechanism of tobacco smoking predisposing to NPD, however, remains to be determined.

Social or heavy drinking has been admitted by NPD patients and its role as a predisposing factor has been accounted for by its numerous physiologic effects which add to other factors as general sources of debilitation (Horning & Cohen 1995).

Caucasian background

A number of American studies have demonstrated a 95% preponderance of Caucasian patients with NPD including a study in which the referring population was 41% African American (Barnes *et al*. 1973; Stevens *et al*. 1984; Horning & Cohen 1995), but a proportion of 49% of African Americans in another study casts doubt on race as a predisposing factor alone, and the mechanism for this factor is unknown.

Young age

In industrialized countries, young adults appear to be the most predisposed to NPD. The disease can occur at any age, the reported mean age for NPD being between 22 and 24 years. This may reflect a number of factors such as military population age, wartime stress, and probably is related to the involvement of other factors such as smoking (Horning & Cohen 1995).

Treatment

The treatment of the necrotizing periodontal diseases is divided into two phases: acute and maintenance phase treatment.

Acute phase treatment

The aim of the acute phase treatment is to eliminate disease activity as manifest by ongoing tissue necrosis developing laterally and apically. A further aim is to avoid pain and general discomfort which may severely compromise food intake. Among patients suffering from systemic diseases resulting in loss of weight, further weight loss due to reduced food intake should be avoided by rapid therapeutic intervention.

At the first consultation scaling should be attempted, as thoroughly as the condition allows. Ultrasonic scaling may be preferable to the use of hand instruments. With minimal pressure against the soft tissues, ultrasonic cleaning may accomplish the removal of soft and mineralized deposits. The continuous water spray combined with adequate suction usually allows good visibility. How far it is possible to proceed with debridement at the first visit usually depends on the patient's tolerance of pain during instrumentation. Obviously toothbrushing in areas with open wounds does not promote wound healing. Therefore, patients should be instructed in substituting toothbrushing with chemical plaque control in such areas until healing is accomplished.

Hydrogen peroxide and other oxygen-releasing agents also have a long-standing tradition in the initial treatment of NPD. Hydrogen peroxide (3%) is still used for debridement in necrotic areas and as a mouth rinse (equal portions 3% H_2O_2 and warm water). It has been thought that the apparently favorable effects of hydrogen peroxide may be due to mechanical cleaning, and the influence on anaerobic bacterial flora of the liberated oxygen (Wennström & Lindhe 1979; MacPhee & Cowley 1981). Further adjunctive local oxygen therapy of NDP showed a more rapid clinical restitution with less periodontal destruction than in a group without oxygen therapy (Gaggl *et al*. 2006).

Twice daily rinsing with a 0.2% chlorhexidine solution is a very effective adjunct to reduce plaque formation, particularly when toothbrushing is not

performed. It also assists self-performed oral hygiene during the first weeks of treatment. Its effect is discussed elsewhere in this book. For an optimal effect of this medicament, it should be used only in conjunction with and in addition to systematic scaling and root planing. The chlorhexidine solution does not penetrate subgingivally and the preparation is readily inactivated by exudates, necrotic tissues, and masses of bacteria (Gjermo 1974). The effectiveness of chlorhexidine mouth rinses is therefore dependent upon a simultaneous, thorough mechanical, debridement.

In some cases of NPD the patient's response to debridement is minimal or the general health is affected to such an extent that the supplementary use of systemic antibiotics or chemotherapeutics is indicated. This also applies to patients with malaise, fever, and lassitude. The choice of drug aims at a direct action on bacteria which are the cause of the inflammatory process in NPD. Supplementary treatment with metronidazole 250 mg three times daily has been found effective against spirochetes and appears to be the first choice in the treatment of NPD (Proctor & Baker 1971; Shinn 1976; Loesche *et al*. 1982). The adjunctive use of metronidazole in HIV-associated NPD is reported to be extremely effective in reducing acute pain and promoting rapid healing (Scully *et al*. 1991). Acute pain usually disappears after a few hours (Fig. 20-17).

Antibiotics such as penicillins and tetracyclines are also effective. Penicillin (1 million i.u. three times daily) should be used as an adjunct to scaling as for metronidazole until the ulcers are healed. Topical application of antibiotics is not indicated in the treatment of NPD, because intralesional bacteria are frequent, and topical application does not result in sufficient intralesional concentration of antibiotics.

It is important to emphasize that many HIV-seropositive patients with NPD at their initial visit are not aware of their serostatus. If HIV infection is a suspected predisposing factor, the patient can be referred to her or his physician for further examination. Some patients may prefer referral to a hospital department. Information on HIV-serostatus is frequently not available at initiation of therapy, but the lack of information has no serious implications for the choice of treatment or for the handling of the patient. As a consequence of a lack of information on HIV-serostatus of patients seeking dental treatment in general, all procedures in the dental office must always include precautions to protect against transmission of the virus to the dentist, to the dental auxiliaries, and to other patients.

If the dentist asks the patient about his or her possible chance of having contracted HIV infection this should be done with great care, because HIV infection has serious implications for the patient. Consequently, a successful outcome depends on a

Fig. 20-17 Necrotizing periodontitis with severe pain. The entire gingival margin is the seat of a necrotic ulcer. (a) Facial aspect. (b) Palatal aspect. (c,d) The patient was treated with scaling supplemented with metronidazole and the next day the patient was free of symptoms and the clinical features were significantly improved.

confidential relationship between patient and dentist. In the case of a new patient, such a relationship is first established after at least a couple of appointments in the clinic.

In HIV-infected patients antibiotic prophylaxis in relation to scaling does not usually appear to be necessary. Bacteria recovered from venipuncture 15 minutes after scaling were not detectable in samples obtained at 30 minutes (Lucartoto *et al*. 1992). Neither does removal of sequestra always appear to require antibiotic cover (Robinson 1991). HIV-infected patients are susceptible to candidal infections (Holmstrup & Samaranayake 1990) and if oral candidosis is present or occurs throughout the period of antibiotic treatment, treatment with appropriate antimycotic drugs such as miconazole may be necessary.

Patients with NPD should be seen almost daily as long as the acute symptoms persist. Appropriate treatment alleviates symptoms within a few days. Thereafter the patient should return in approximately 5 days. Systematic subgingival scaling should be continued with increasing intensity as the symptoms subside. Correction of restoration margins and polishing of restorations and root surfaces should be completed after healing of ulcers. When the ulcerated areas are healed, local treatment is supplemented with oral hygiene instruction and patient motivation. Instruction in gentle but effective toothbrushing and approximal cleaning is mandatory. In many cases the extensive tissue destruction results in residual soft tissue defects that are difficult for the patient to keep clean. Oral hygiene in these areas often requires the use of interproximal devices and soft, smaller brushes. Sometimes healing is delayed in HIV-infected patients and intensive professional control may be necessary for prolonged periods of time.

Patients with NPD are not always easily motivated to carry out a proper program of oral hygiene. They frequently have poor oral hygiene habits and possibly a negative attitude to dental treatment in general. As a result, some patients discontinue treatment as soon as pain and other acute symptoms are alleviated. Motivation and instruction should be planned to prevent this happening, and should be reinforced during later visits. Patients with severely impaired immune function, for instance due to HIV infection, may suffer from other infections or diseases during the period of treatment. This may complicate the treatment, because patients may be hospitalized.

Maintenance phase treatment

When the acute phase treatment has been completed, necrosis and acute symptoms in NPD have disappeared. The formerly necrotic areas are healed and the gingival craters are reduced in size, although some defects usually persist. Bacterial plaque readily accumulates in such areas, and the craters, therefore, predispose to recurrence of NPD or to further destruction because of a persisting chronic inflammatory process, or both. These sites, therefore, may require surgical correction. Shallow craters can be removed by simple gingivectomy, while the elimination of deep defects may require flap surgery. Treatment of necrotizing gingivitis has not been completed until all gingival defects have been eliminated and optimal conditions for future plaque control have been established. If possible, elimination of predisposing factors is also very important to prevent recurrence. Due to delayed healing in HIV-infected patients, periodontal surgery is not recommended in these patients. Instead, intensive approximal cleaning is necessary to prevent recurrence of disease.

Chapter 21

Periodontal Disease as a Risk for Systemic Disease

Ray C. Williams and David W. Paquette

Throughout the history of mankind, there has been the belief that diseases which affect the mouth, such as periodontal disease, can have an effect on the rest of the body. Over the centuries, writings from the ancient Egyptians, Hebrews, Assyrians, Greeks, and Romans, to name a few, have all noted the importance of the mouth in overall health and wellbeing. Thus, one could say that the concept linking systemic disease and periodontitis can be traced back to the beginning of recorded history and medicine (O'Reilly & Claffey 2000).

This chapter examines the evidence which has emerged since the early 1990s implicating periodontal disease as a risk factor for several systemic conditions such as cardiovascular disease, adverse pregnancy outcomes, diabetes, and pulmonary disease. But first, it is helpful for the student of dentistry to understand the historical perspective under which this relationship emerged. The concept of "focal infection" which emerged around 1900 has resurfaced and has stimulated much new interest and research into the role of periodontitis as a risk for systemic disease.

Early twentieth century concepts

At the beginning of the twentieth century, medicine and dentistry were searching for reasons to explain why people became afflicted with a wide range of systemic diseases. Medicine at that time had very little insight into what caused diseases such as arthritis, pneumonia, and pancreatitis. Through the writings and lectures of principally two individuals, Willoughby D. Miller, a microbiologist in Philadelphia, and William Hunter, a London physician, the concept that oral bacteria and infection were likely causes of most systemic illnesses suddenly became very popular (O'Reilly & Claffey 2000). For the next 40 years, physicians and dentists would embrace the idea that infections, especially those originating in the mouth, caused most human suffering and illness. This era, which came to be known as the "era of focal infection", can be attributed primarily to Willoughby D. Miller and William Hunter (O'Reilly & Claffey 2000).

Willoughby Miller was an instructor at the University of Pennsylvania School of Dental Medicine around the turn of the twentieth century. Miller had earlier trained in microbiology in Berlin in Robert Koch's institute. Koch was a pioneer in microbiology and the father of the modern "germ theory" of disease. While under the influence of Robert Koch, Miller too became intensely interested in the role of "germs" or bacteria in causing diseases. Miller returned to the US following his training, convinced that the bacteria residing in the mouth could cause or be attributed to most systemic diseases in patients. In a paper published in 1891, entitled "The human mouth as a focus of infection", Miller argued that the oral flora caused ostitis, osteomyelitis, septicemia, pyemia, disturbances of the alimentary tract, noma, dyptheria, tuberculosis, syphilis, and thrush (Miller 1891). Clearly from this one publication, one can appreciate just how extensively the mouth and oral infection were blamed for causing systemic disease (O'Reilly & Claffey 2000).

While attending one of Miller's lectures at the International Congress of Hygiene in London, William Hunter, a physician from the London Fever Hospital, noted that he and Miller were in strong agreement about the systemic impact of oral infections or oral sepsis. Shortly after, Hunter was invited to speak at the opening of the Strathcona Medical Building at McGill University in Montreal in 1910. In

his address to the audience, he blamed poor dentistry and the resulting oral sepsis for causing most of mankind's systemic disease. Hunter remarked that the crowns, bridges and partial dentures he saw in his patients in London were built on teeth surrounded by a "mass of sepsis". Indeed, this oral sepsis could explain why most individuals developed chronic diseases (Hunter 1900; O'Reilly & Claffey 2000). It is likely that Hunter was referring to the untreated periodontal diseases, caries, and defective restorations he was noting in his adult patients at the London Fever Hospital. But whatever Hunter thought he observed in the mouths of his sick patients, his speech at McGill University and his subsequent publication on the role of sepsis and antisepsis in medicine (Hunter 1910) ushered in an era of belief that periodontitis, caries, and poor oral hygiene were the primary cause of systemic illness. The term "oral sepsis" used by Hunter was replaced with the term "focal infection" in 1911 (Billings 1912). Focal infection implied that there was a nidus of infection somewhere in the body, such as periodontitis, which could affect distant sites and organs via the bloodstream. Throughout the 1920s and 1930s, dentists and physicians believed that the bacteria on the teeth and the resultant infectious diseases, such as caries, gingivitis, and periodontitis, were a focus of infection that led to a wide variety of systemic problems. It became popular during this period to extract teeth as a means of ridding the body of oral bacteria and preventing and/or treating diseases affecting the joints, as well as diseases of the heart, liver, kidneys, and pancreas (Cecil & Angevine 1938; O'Reilly & Claffey 2000).

However, by 1940, medicine and dentistry were realizing that there was much more to explain a patient's general systemic condition than bacteria in the mouth. Dentists and physicians realized that (1) extracting a person's teeth did not necessarily make the person better or make their disease go away, (2) people with very healthy mouths and no obvious oral infection developed systemic disease, and (3) people who had no teeth and thus no apparent oral infection still developed systemic diseases (Galloway 1931; Cecil & Angevine 1938).

By 1950, it was apparent to medicine and dentistry that oral infections, such as dental caries, gingivitis, and periodontitis, could not explain why individuals developed a wide range of systemic diseases. By this time medicine was making strides in discovering the true etiologies of many diseases, and dentistry was making great strides in the prevention as well as the treatment of caries and periodontal disease. Thus, the era of focal infection as a primary cause of systemic diseases came to an end (O'Reilly & Claffey 2000).

Throughout the second half of the twentieth century, several researchers and clinicians continued to question whether oral infection (and inflammation) might in some way contribute to a person's overall health, but the reasons given were mostly speculative. Clinicians continued to propose that bacteria and bacterial products within the periodontal pocket, and which could enter the bloodstream from the mouth, could surely in some way be harmful to the body as a whole (Thoden van Velzen *et al*. 1984). However, it was not until the last decade of the twentieth century that dentistry and medicine again began to examine the relationship of periodontitis as a risk for systemic disease. The student of dentistry thus needs to appreciate the intense focus on oral infection as a "likely" cause of many systemic diseases from 1900–1950, then the era of retreat from the focal infection theories of disease causation from 1950 to around 1989, and now the new look at emerging science that suggests periodontitis as a possible risk factor for several systemic diseases, including cardiovascular disease, adverse pregnancy outcomes, diabetes mellitus, and bacterial pneumonia.

Periodontitis as a risk for cardiovascular disease

In 1989 Kimmo Mattila and co-workers in Finland conducted a case–control study on patients who had experienced an acute myocardial infarction and compared these patients to control subjects selected from the community. A dental examination was performed on all of the subjects studied and a dental index computed. The dental index used by Mattila was the sum of scores from the number of carious lesions, missing teeth and periapical lesions, and probing depth measures to indicate periodontitis and the presence or absence of pericoronitis. Mattila and his group reported a highly significant association between poor dental health, as measured by the dental index, and acute myocardial infarction. The association was independent of other risk factors for heart attack such as age, total cholesterol, high density lipoprotein (HDL) triglycerides, C peptide, hypertension, diabetes, and smoking (Mattila *et al*. 1989).

Mattila's findings initiated a great deal of interest in the scientific community. Might it be possible that there was a significant association between periodontitis and cardiovascular disease? Physicians and dentists noted the following commonalities. Patients with periodontal disease share many of the same risk factors as patients with cardiovascular disease, including age, gender (predominantly male), lower socioeconomic status, stress, and smoking (Beck *et al*. 1998). Additionally, a large proportion of patients with periodontal disease also exhibit cardiovascular disease (Umino & Nagao 1993). These observations suggest that periodontal disease and atherosclerosis share similar or common etiologic pathways. Scannapieco and colleagues (2003a) conducted a systematic review of the evidence supporting or refuting any relationship. In response to the focused questions, "Does periodontal disease influence the initiation/progression of atherosclerosis and therefore cardiovascular disease, stroke and peripheral vascular disease?" the investigators identified 31 human

Table 21-1 Summary of select case–control and cohort observational studies supporting an association between periodontal disease and cardiovascular disease

Reference	Study design	Population	Periodontal outcome or exposure	Cardiovascular outcome	Findings and conclusions
Matilla *et al*. 1989	Case–control	Finland; 100 cases and 102 controls	Dental Severity Index (sum of scores for caries, periodontal disease, periapical pathosis and pericoronitis)	Evidence of myocardial infarction (MI) from EKG and elevated enzyme levels (creatinine phosphokinase isoenzyme MB)	Dental health significantly worse in patients with MI versus controls after adjusting for smoking, social class, smoking, serum lipids, and diabetes
Beck *et al*. 2001	Cohort	United States; 6017 subjects (ARIC Study)	Severe periodontitis defined as clinical attachment loss ≥3 mm at ≥30% of sites	Carotid artery intima media wall thickness (IMT) ≥1 mm	Periodontitis may influence atheroma formation (OR = 1.3)
Beck *et al*. 2005	Cohort	United States; 15 792 subjects (ARIC Study)	Serum antibodies to periodontal pathogens	Carotid artery IMT ≥1 mm	Presence of antibody to *C. rectus* was associated with carotid atherosclerosis (OR = 2.3)
Hung *et al*. 2004	Cohort	United States; 41 407 males from the HPFS and 58 974 females from the NHS	Self-reported tooth loss at baseline	Incident fatal and non-fatal MI or stroke	For males with tooth loss, the relative risk for coronary heart disease was 1.36. For females with tooth loss, the relative risk was 1.6
Engebretson *et al*. 2005	Cohort	United States; 203 subjects from INVEST	Radiographic alveolar bone loss	Carotid plaque thickness via ultrasonography	Severe periodontal bone loss was independently associated with carotid atherosclerosis (OR = 3.64)
Desvarieux *et al*. 2005	Cohort	United States; 1056 subjects from INVEST	Subgingival bacterial burden	Carotid artery IMT ≥1 mm	Severe periodontal bone loss was independently associated with carotid atherosclerosis (OR = 3.64)
Pussinen *et al*. 2004	Cohort	Finland; 6950 subjects in the Mobile Clinic Health Survey	Serum antibodies to *P. gingivalis* or *A. actinomycetemcomitans*	Incident fatal or non-fatal stroke	Seropositive subjects had an OR of 2.6 for stroke
Abnet *et al*. 2005	Cohort	China; 29 584 rural subjects	Tooth loss	Incidence of fatal MI or stroke	Tooth loss was associated with an increased odds for death from MI (RR = 1.29) and stroke (RR = 1.1)

studies. Table 21-1 lists selected influential studies identified in the review plus additional recent observational studies discussed below. Although the authors did not perform a meta-analysis due to differences in reported outcomes, the authors noted relative (not absolute) consistency and concluded, "Periodontal disease may be modestly associated with atherosclerosis, myocardial infarction and cardiovascular events." An accompanying consensus report approved by the American Academy of Periodontology recommends, "Patients and health care providers should be informed that periodontal intervention may prevent the onset or progression of atherosclerosis-induced diseases."

Since Scannapieco's review and consensus report, other meta-analyses on the cardiovascular–periodontal disease association have been conducted and published. Meurman and co-workers (2004) reported a 20% increase in the risk for cardiovascular disease among patients with periodontal disease (95% CI

1.08–1.32), and an even higher risk ratio for stroke varying from 2.85 (95% CI 1.78–4.56) to 1.74 (CI 1.08–2.81). Similarly, Vettore and co-workers reported relative risk estimates of 1.19 (95% CI 1.08–1.32) and 1.15 (95% CI 1.06–1.25) respectively (Khader *et al*. 2004; Vettore 2004). These meta-analyses of the available observational human data suggest a modest but statistically significant increase in the risk for cardiovascular disease with periodontal disease.

Recent findings from several worldwide population studies also should be noted. These studies include the Atherosclerosis Risk in Communities Study (ARIC), the Health Professional Follow-up Study (HPFS), the Nurses Health Study (NHS), and the Oral Infections and Vascular Disease Epidemiology Study (INVEST) conducted in the United States. Other studies have involved populations from Sweden, Finland, and China.

Periodontal probing data were collected on 6017 persons, 52–75 years of age, participating in the ARIC study (Beck *et al*. 2001, 2005; Elter *et al*. 2004). The investigators assessed both the presence of clinical cardiovascular disease (MI or revascularization procedure) and subclinical atherosclerosis (carotid artery intima media wall thickness (IMT) using B-mode ultrasound) as dependent variables in the population. Individuals with both high attachment loss (≥10% of sites with attachment loss >3 mm) and high tooth loss exhibited elevated odds of prevalent cardiovascular disease as compared to individuals with low attachment loss and low tooth loss (OR = 1.5, 95% CI 1.1–2.0 and OR = 1.8, CI 1.4–2.4 respectively) (Elter *et al*. 2004). A second logistic regression analysis indicated a significant association between severe periodontitis and thickened carotid arteries after adjusting for covariates like age, gender, diabetes, lipids, hypertension, and smoking (Beck *et al*. 2001). Accordingly, the odds ratio for severe periodontitis (i.e. 30% or more of sites with ≥3 mm clinical attachment loss) and subclinical carotid atherosclerosis was 1.31 (95% CI 1.03–1.66). In a third report, these investigators quantified serum IgG antibody levels specific for 17 periodontal organisms using a whole bacterial checkerboard immunoblotting technique (Beck *et al*. 2005). Analyzing mean carotid IMT (≥1 mm) as the outcome and serum antibody levels specific as exposures for this same population, the investigators noted the presence of antibody to *Campylobacter rectus* increased the risk for subclinical atherosclerosis two-fold (OR = 2.3, 95% CI 1.83–2.84). In particular, individuals with both high *C. rectus* and *Peptostreptococcus micros* antibody titers had almost twice the prevalence of carotid atherosclerosis as compared to those with only a high *C. rectus* antibody (8.3% versus 16.3%). Stratification by smoking indicated that all microbial models significant for smokers were also significant for never smokers except for *Porphyromonas gingivalis*. Thus, clinical signs of periodontitis are associated with cardiovascular disease and subclinical atherosclerosis in the ARIC population, and exposures to specific periodontal pathogens significantly increase the risk for atherosclerosis in smoking and non-smoking subjects.

Self-reported periodontal disease outcomes and incident cardiovascular disease were assessed in two extant databases, HPFS (n = 41 407 males followed for 12 years) and NHS (n = 58 974 females followed for 6 years) (Hung *et al*. 2004). After controlling for important cardiovascular risk factors, males with a low number of teeth (≤10 at baseline) had a significantly higher risk of cardiovascular disease (RR = 1.36; 95% CI 1.11–1.67) as compared to males with a higher number of teeth (25 or more). For females with the same reported extent of tooth loss, the relative risk for cardiovascular disease was 1.64 (95% CI 1.31–2.05) as compared to women with at least 25 teeth. The relative risks for fatal cardiovascular disease events increased to 1.79 (95% CI 1.34–2.40) for males and 1.65 (95% CI 1.11–2.46) for females with tooth loss respectively. In a second report, the investigators evaluated the association between self-reported periodontal disease and serum elevations in cardiovascular disease biomarkers cross-sectionally in a subset of HPFS participants (n = 468 males) (Joshipura *et al*. 2004). Serum biomarkers included C-reactive protein (CRP), fibrinogen, factor VII, tissue plasminogen activator (t-PA), LDL cholesterol, von Willebrand factor, and soluble TNF receptors 1 and 2. In multi-variate regression models controlling for age, cigarette smoking, alcohol intake, physical activity, and aspirin intake, self-reported periodontal disease was associated with significantly higher levels of CRP (30% higher among periodontal cases compared with non-cases), t-PA (11% higher), and LDL cholesterol (11% higher). These analyses reveal significant associations between self-reported number of teeth at baseline and risk of cardiovascular disease and between self-reported periodontal disease and serum biomarkers of endothelial dysfunction and dyslipidemia.

One population study called INVEST has been planned *a priori* and conducted exclusively to evaluate the association between cardiovascular disease and periodontal outcomes in a cohort population. It was reported that for a group of 203 stroke-free subjects (ages 54–94) at baseline, mean carotid plaque thickness (measured with B-mode ultrasound) was significantly greater among dentate subjects with severe periodontal bone loss (≥50% measured radiographically) as compared to those with less bone loss (<50%) (Engebretson *et al*. 2005). These investigators noted a clear dose–response relationship when they graphed subject tertiles of periodontal bone loss versus carotid plaque thickness. The investigators next collected subgingival plaque from 1056 subjects and tested for the presence of 11 known periodontal bacteria using DNA techniques (Desvarieux *et al*. 2005). The investigators found that cumulative periodontal bacterial burden was significantly related to carotid IMT after adjusting for cardiovascular disease risk factors. Whereas mean IMT values were similar

across burden tertiles for putative (orange complex) and health-associated bacteria, IMT values rose with each tertile of etiologic bacterial burden (*Actinobacillus acinomycetemcomitans* (recently renamed *Aggregatibacter acinomycetemcomitans*), *P. gingivalis, Treponema denticola* and *Tannerella forsythia*). Similarly, white blood cell values (but not serum CRP) increased across these burden tertiles. These data from INVEST provide evidence of a direct relationship between periodontal microbiology and subclinical atherosclerosis independent of CRP.

Consistent associations between periodontal outcomes and atherosclerosis have been recently demonstrated among populations in Europe and Asia. For 131 adult Swedes, mean carotid IMT values were significantly higher in subjects with clinical and/or radiographic evidence of periodontal disease compared to periodontally healthy controls (Soder *et al*. 2005). Multiple logistic regression analysis identified periodontal disease as a principal independent predictor of carotid atherosclerosis with an odds ratio of 4.64 (95% CI 1.64–13.10). Pussinen *et al*. (2004) monitored antibody responses for *A. actinomycetemcomitans* and *P. gingivalis* among 6950 Finnish subjects for whom cardiovascular disease outcomes over 13 years were available (Mobile Clinic Health Survey). Compared with the subjects who were seronegative for these pathogens, seropositive subjects had an odds ratio of 2.6 (95% CI 1.0–7.0) for a secondary stroke. In a second report on 1023 males (Kuopio Ischemic Heart Disease Study), Pussinen and co-workers (2005) observed that cases with myocardial infarction or cardiovascular disease death were more often seropositive for *A. actinomycetemcomitans* than those controls who remained healthy (15.5% versus 10.2%). In the highest tertile of *A. actinomycetemcomitans* antibodies, the relative risk for MI or coronary heart disease death was 2.0 (95% CI 1.2–3.3) compared with the lowest tertile. For *P. gingivalis* antibody responses, the relative risk was of 2.1 (95% CI 1.3–3.4). Abnet and co-workers (2005) recently published findings from a cohort study of 29 584 healthy, rural Chinese adults monitored for up to 15 years. Tooth loss was evaluated as an exposure outcome for periodontal disease, and mortality from heart disease or stroke were modeled as dependent variables. Individuals with greater than the age-specific median number of teeth lost exhibited a significantly increased risk of death from MI (RR = 1.28, 95% CI 1.17–1.40) and stroke (RR = 1.2, 95% CI 1.02–1.23). These elevated risks were present in male and females irrespective of smoking status. Collectively, these findings indicate consistent associations for periodontal disease and pathogenic exposures with cardiovascular disease for European and Asian populations.

Biologic rationale

Many investigators have asked the question: what is the biologic rationale to explain how periodontitis may be related to cardiovascular disease? Scientists have noted that a patient who has, for example, 28 teeth with pocket depths of 6–7 mm and bone loss, has a large overall surface area of infection and inflammation (Waite & Bradley 1965). In patients with moderate periodontitis, the surface area could be the size of the palm of the hand or larger. In addition, the subgingival bacteria in periodontal pockets exists in a highly organized biofilm. Since periodontal infections result in low-grade bacteremias and endotoxemias in affected patients (Sconyers *et al*. 1973; Silver *et al*. 1980), systemic effects on vascular physiology via these exposures appear biologically plausible. Four specific pathways have been proposed to explain the plausibility of a link between cardiovascular disease and periodontitis (Fig. 21-1). These pathways (acting independently or collectively) include: (1) direct bacterial effects on platelets, (2) autoimmune responses, (3) invasion and/or uptake of bacteria in endothelial cells and macrophages, and (4) endocrine-like effects of pro-inflammatory mediators. In support of the first pathway, two oral bacteria, *P. gingivalis* and *Streptococcus sanguis* express virulence factors called "collagen-like platelet aggregation associated proteins" (PAAP) that induce platelet aggregation *in vitro* and *in vivo* (Hertzberg & Meyer 1996, 1998). Secondly, autoimmune mechanisms may play a role since antibodies that cross react with periodontal bacteria and human heat shock proteins have been identified (Hinode *et al*. 1998; Sims *et al*. 2002). Deshpande *et al*. (1998) have thirdly demonstrated that *P. gingivalis* can invade aortic and heart endothelial cells via fimbriae. Several investigative groups have independently identified specific oral pathogens in atheromatous tissues (Chui 1999; Haraszthy *et al*. 2000). In addition, macrophages incubated *in vitro* with *P. gingivalis* and LDL uptake the bacteria intracellularly and transform into foam cells (Giacona *et al*. 2004). In the last potential pathway, systemic pro-inflammatory mediators are up-regulated for endocrine-like effects in vascular tissues, and studies consistently demonstrate elevations in CRP and fibrinogen among periodontally diseased subjects (Slade *et al*. 2000; Wu *et al*. 2000a,b).

Experiments with animal models demonstrate that specific infections with periodontal pathogens accelerate atherogenesis. For example, inbred heterozygous and homozygous apoE-deficient mice exhibit increased aortic atherosclerosis when challenged orally or intravenously with invasive strains of *P. gingivalis* (Li *et al*. 2002; Lalla *et al*. 2003; Chi *et al*. 2004; Gibson *et al*. 2004). While *P. gingivalis* challenges increased aortic atherosclerosis in apoE-deficient mice in a hypercholesterolemic background only, normocholesterolemic pigs were recently shown to develop both coronary and aortic lesions with *P. gingivalis* challenges (Brodala *et al*. 2005). This finding suggests that *P. gingivalis* bacteremia may exert an atherogenic stimulus independent of high cholesterol

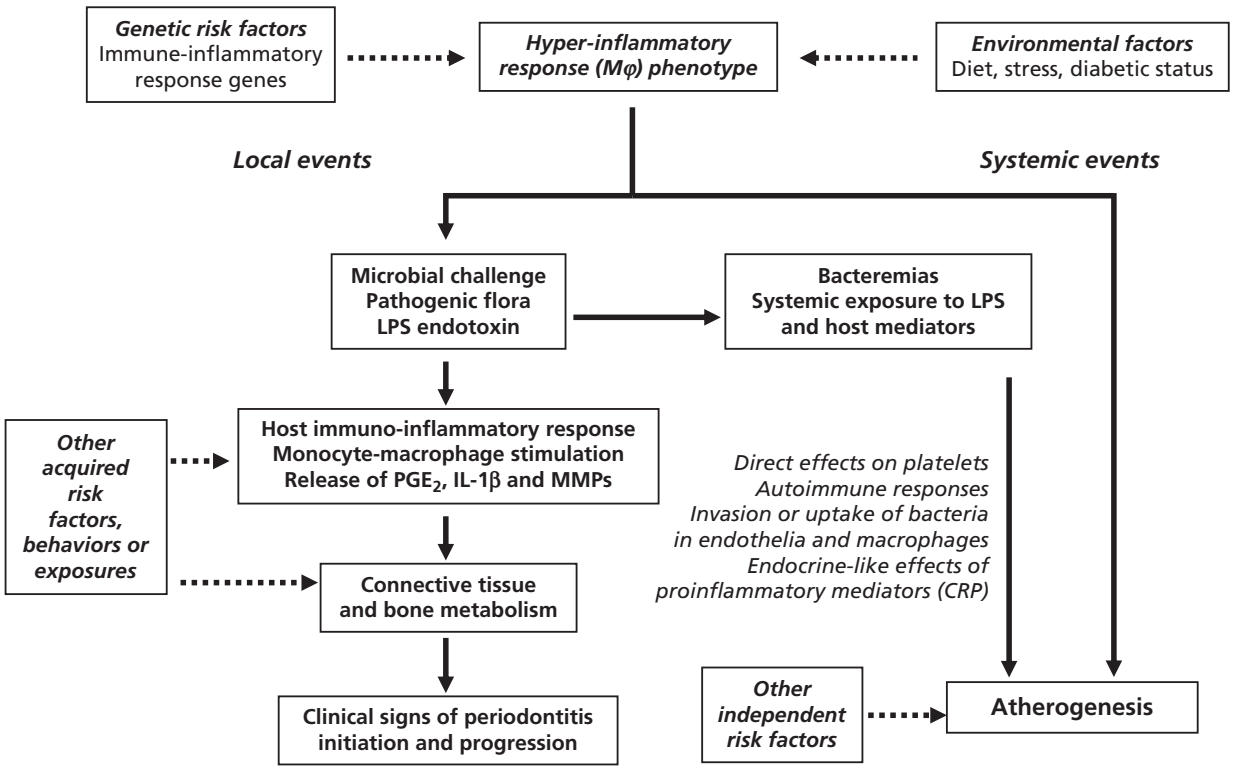

Fig. 21-1 Proposed model and mechanisms linking periodontal disease and cardiovascular disease.

levels in pigs. It is worth noting that a wide range of *P. gingivalis* doses was used in these animal studies. While the clinically relevant dose for human subjects is unknown at present, it probably varies greatly (Daly *et al*. 2001; Haynes & Stanford 2003; Ide *et al*. 2004). Importantly, *P. gingivalis* challenges enhance atherosclerosis despite these different routes of administration and dosing regimens in both species. *P. gingivalis* 16 ribosomal DNA was detected by polymerase chain reaction (PCR) in atheromas from some but not all of these mutant mice and the pigs. These experiments suggest that both the host response and the virulence of the specific *P. gingivalis* strains appear to be important variables in these infection–atherogenesis models. Collectively, when one looks at the body of evidence gathered so far since 1989, there appears to be a compelling association between periodontitis and coronary heart disease.

Periodontitis as a risk for adverse pregnancy outcomes

In 1996, following a landmark report by Offenbacher and colleagues (1996), there has been much interest and research into whether periodontitis may be a possible risk factor for adverse pregnancy outcomes. Adverse pregnancy outcomes that have been linked to periodontal disease include preterm birth, low birthweight, miscarriage or early pregnancy loss, and pre-eclampsia. Pre-eclampsia and preterm births are major causes of maternal and prenatal morbidity and mortality.

Preterm infants who are born with low birthweights represent a major social and economic public health problem, even in industrialized nations. Although there has been an overall decline in infant mortality in the US over the past 40 years, preterm low birthweight remains a significant cause of perinatal mortality and morbidity. A 47% decrease in the infant mortality rate to a level of 13.1 per 1000 live births occurred between 1965 and 1980. But from 1980 to 2000, the percentage of low birthweight infants increased by 11.8% and that of very low birthweight infants increased by 24.3% in the US; among survivors, low birthweight is a major contributor to long-term disability.

Preterm low birthweight deliveries represent approximately 10% of annual births in industrialized nations and account for two-thirds of overall infant mortality. Approximately one-third of these births are elective while two-thirds are spontaneous preterm births. About a half of the spontaneous preterm births are due to premature rupture of membranes and the other half are due to preterm labor. For the spontaneous preterm births, 10–15% occur before 32 weeks gestation, result in very low birthweight (<1500 g) and often cause long-term disability, such as chronic respiratory diseases and cerebral palsy (Offenbacher *et al*. 1996, 1998; Champagne *et al*. 2000; Scannapieco *et al*. 2003c; Xiong *et al*. 2006).

Among the known risk factors for preterm low birthweight deliveries are young maternal age (<18 years), drug, alcohol and tobacco use, maternal stress, genetic background, and genitourinary tract infec-

tions. Although 25–50% of preterm low birthweight deliveries occur without any known etiology, there is increasing evidence that infection may play a significant role in preterm delivery (Hill 1998; Goldenberg *et al*. 2000; Sobel 2000; Williams *et al*. 2000; Scannapieco *et al*. 2003c; Xiong *et al*. 2006).

One of the more important acute exposures that has been implicated in preterm birth is an acute maternal genitourinary tract infection at some point during the pregnancy. Bacterial vaginosis (BV) is a Gram-negative, predominantly anaerobic infection of the vagina, usually diagnosed from clinical signs and symptoms. It is associated with a decrease in the normal lactobacillus-dominated flora and an increase in anaerobes and facultative species including *Gardenerella vaginalis*, *Mobiluncus curtsii*, *Prevotella bivia*, and *Bacteroides ureolyticus.* Bacterial vaginosis is a relatively common condition that occurs in about 10% of all pregnancies. It may ascend from the vagina to the cervix and even result in inflammation of the maternal fetal membranes (chorioamnionitis). Extending beyond the membranes, the organisms may appear in the amniotic fluid compartment that is shared with the fetal lungs and/or involve placental tissues and result in exposure to the fetus via the bloodstream. Despite the observed epidemiologic linkage of bacterial vaginosis with preterm birth, the results from randomized clinical trials to determine the effects of treating bacterial vaginosis with systemic antibiotics on incident preterm birth are equivocal (Goldenberg *et al*. 2000). Still, there are compelling data linking maternal infection and the subsequent inflammation to preterm birth. It appears that inflammation of the uterus and membranes represents a common effector mechanism that results in preterm birth, and, thus, either clinical infection or subclinical infection is a likely stimulus for increased inflammation.

In the early 1990s, it was hypothesized that oral infections, such as periodontitis, could represent a significant source of both infection and inflammation during pregnancy. It was noted that periodontal disease is a Gram-negative anaerobic infection with the potential to cause Gram-negative bacteremias in persons with periodontal disease. It was hypothesized that periodontal infections, which serve as reservoirs for Gram-negative anaerobic organisms, lipopolysaccharide (LPS, endotoxin), and inflammatory mediators including prostaglandin E_2 (PGE_2) and tumor necrosis factor-α (TNF-α), may be a potential threat to the fetal–placental unit (Fig. 21-2) (Collins *et al*. 1994a,b).

As a first step in testing this hypothesis, Greg Collins in Offenbacher's laboratory conducted a series of experiments in the pregnant hamster animal model. It had been noted earlier by Lanning *et al*. (1983) that pregnant hamsters challenged with *Escherichia coli* LPS had malformation of fetuses, spontaneous abortions, and low fetal weight. The work by Lanning and co-workers clearly demonstrated that

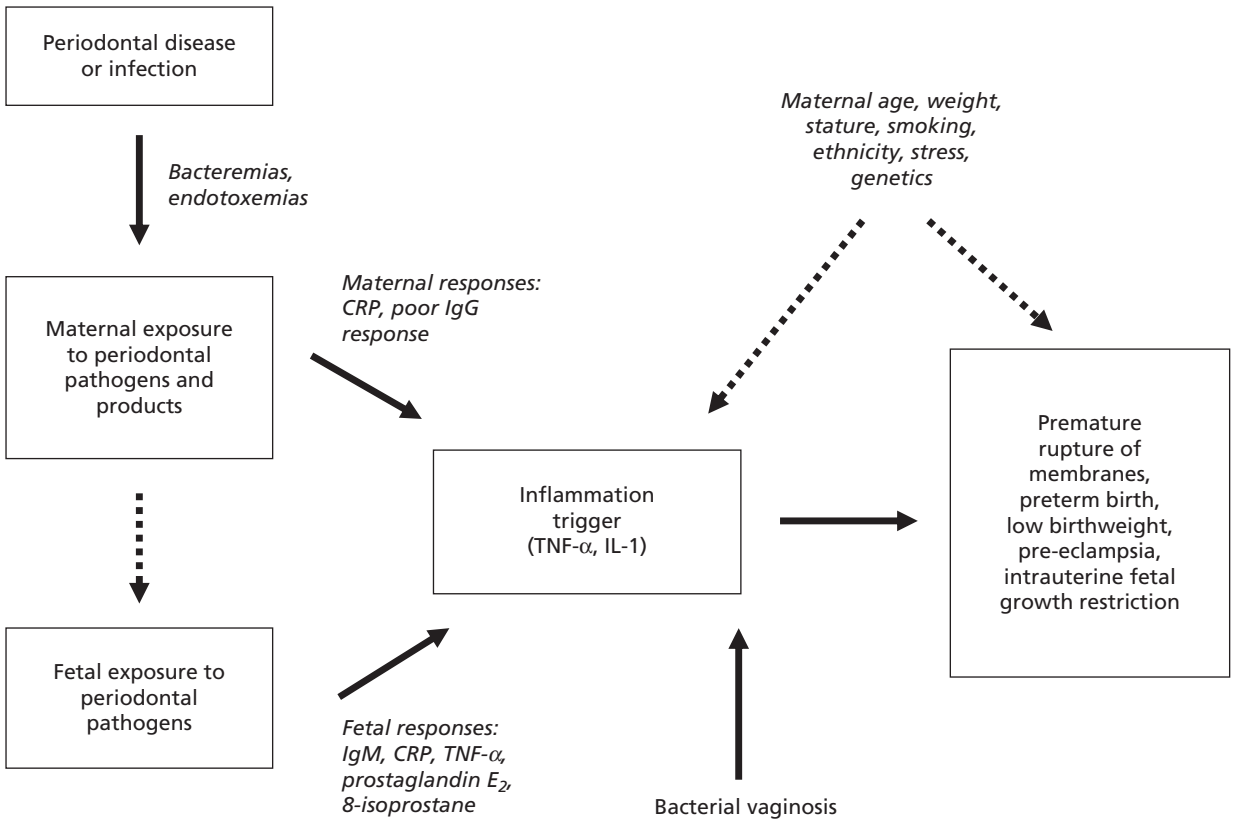

Fig. 21-2 Proposed model for relationship between periodontal disease and adverse pregnancy outcomes.

infections in pregnant animals could elicit many pregnancy complications including spontaneous abortion, preterm labor, low birthweight, fetal growth restriction, and skeletal abnormalities. It was not clear, however, if these findings from *E. coli* would be similar if endotoxin from oral anaerobes was studied. First of all, LPS from Gram-negative enteric organisms differs in structure and biological activity from oral LPS. Thus, Collins needed to demonstrate that LPS from oral organisms had similar effects on fetal outcomes when administered to pregnant animals. Secondly, the oral cavity represents a distant site of infection. Although pneumonia has been a recognized example of a distant site of infection triggering maternal obstetric complications, it was important to demonstrate that distant, non-disseminating infections with oral pathogens could elicit pregnancy complications in animal models. Thirdly, oral infections are chronic in nature. Increased obstetric risk is generally associated with acute infections that occur during pregnancy. Thus, in concept, maternal adaptation to a chronic infectious challenge was assumed to afford protection to the fetus, even during acute flare-ups that may occur during pregnancy.

Collins' landmark hamster studies (Collins *et al*. 1994a,b) demonstrated that chronic exposure to oral pathogens like *P. gingivalis* in a chamber model (Genco & Arko 1994) does not in fact afford protection, but actually enhances the fetal–placental toxicity of exposure during pregnancy. Thus during pregnancy the mother does not become "tolerant" of infectious challenge from oral organisms. Collins and Offenbacher also wanted to demonstrate that the low-grade infections with low numbers of oral pathogens were not of sufficient magnitude to induce maternal malaise or fever. They noted however a measurable local increase of PGE_2 and TNF-α in chamber fluid with *P. gingivalis* as well as a 15–18% decrease in fetal weight. Further, the magnitude of the PGE_2 and TNF-α response was inversely related to the weight of the fetuses, mimicking the intra-amniotic changes seen in humans with preterm low birthweight. LPS dosing experiments demonstrated that higher levels of LPS could induce fever and weight loss in pregnant animals and resulted in more severe pregnancy outcomes including spontaneous abortions and malformations. These more noteworthy outcomes were not seen in the low-challenge oral infection models, but rather resulted in a consistent decrease in fetal weight. Previous sensitization or exposures to these pathogens prior to pregnancy enhanced the severity of the fetal growth restriction when a secondary exposure occurred during pregnancy.

Collins and colleagues (1994b) next studied infection and pregnancy in the hamster by experimentally inducing periodontal disease in the animal model. Four groups of animals were fed either control chow or plaque-promoting chow for an 8-week period to induce experimental periodontitis prior to mating. Two additional groups of animals (i.e. one control chow and one plaque-promoting chow) received exogenous *P. gingivalis* via oral gavage. Animals fed the plaque-promoting diet beginning 8 weeks prior to mating developed periodontitis. These animals also had litters with a mean fetal weight of 1.25 ± 0.07 g that was 81% of the weight of the control groups. Animals receiving both plaque-promoting diet and *P. gingivalis* gavage also had significantly smaller fetuses. The mean fetal weight for this group was 1.20 ± 0.19 g which represented a significant 22.5% reduction in fetal weight compared to controls. Exogenous *P. gingivalis* challenge by gastric gavage did not appear to promote either more severe periodontal disease or more severe fetal growth restriction. This experiment indicated that experimentally induced periodontitis in the hamster could also alter fetal weight in the hamster.

More recently this group has focused on a possible role for *Campylobacter rectus* in contributing to adverse pregnancy outcomes (Madianos *et al*. 2001). In recent animal studies utilizing the BALB/C mouse model, Yeo *et al*. (2005) have reported that maternal *Campylobacter rectus* infection mediates fetal growth restriction in pregnant mice. More recently, Bobetsis and colleagues (Offenbacher *et al*. 2005) found that maternal *C. rectus* infection induced placental inflammation and decidual hyperplasia as well as a concomitant increase in fetal brain IFN-γ. Maternal infection with *C. rectus* increased mouse pup mortality and also affected the hippocampal region of the neonatal brain, suggesting that maternal infection with *C. rectus* may also affect perinatal neurological growth and development (Offenbacher *et al*., 2005).

In what is now viewed as a landmark human study, Offenbacher and colleagues (1996) conducted a case–control study on 124 pregnant or postpartum women (Table 21-2). Preterm low birthweight cases were defined as a mother whose infant had a birthweight of less than 2500 g and also had one or more of the following: gestational age <37 weeks, preterm labor or preterm premature rupture of membranes. Controls were all mothers whose infant had a normal birthweight. Assessments included a broad range of known obstetric risk factors such as tobacco usage, drug use, and alcohol consumption, level of prenatal care, parity, genitourinary tract infections, and weight gain during pregnancy. Each subject received a full-mouth periodontal examination to determine clinical attachment levels. Mothers of preterm low birthweight (PLBW) cases and first birth PLBW cases had significantly more advanced periodontal disease as measured with attachment loss than the respective mothers of normal birthweight controls. Multi-variate logistic regression models, controlling for other known risk factors and co-variates, demonstrated that periodontitis was a statistically significant risk factor for preterm low birthweight, with adjusted odds ratios of 7.9 and 7.5 for all PLBW cases and primiparous PLBW cases respectively. This research

Table 21-2 Summary of case–control observational studies on periodontal disease and adverse pregnancy outcomes

Reference	Population	Periodontal outcome or exposure	Adverse pregnancy outcome	Findings and conclusions
Offenbacher *et al*. 1996	United States; 93 cases and 31 controls	≥60% of sites with clinical attachment levels ≥3 mm	Birthweight <2500 g, gestational age <37 weeks, preterm labor and/or premature rupture of membranes	Significant association between periodontal disease and preterm low birthweight (LBW) (OR = 7.5)
Davenport *et al*. 2002	United Kingdom; 236 cases and 507 controls	Mean pocket depth (mm)	Preterm delivery <37 weeks and birthweight <2499 g	No association detected for periodontal disease and preterm LBW (OR = 0.83)
Goepfert *et al*. 2004	United States; 59 cases and 44 controls	Clinical attachment levels ≥5 mm	Spontaneous preterm birth <32 weeks	Significantly higher risk for preterm birth for mothers with periodontal disease (OR = 3.4)
Radnai *et al*. 2004	Hungary; 41 cases and 44 controls	One or more sites with probing depth ≥4 mm and bleeding on probing ≥50%	Premature labor, spontaneous rupture of membranes and/or the birthweight of the newborn ≤2499 g	Significant association between periodontal disease and preterm LBW (OR = 5.4)
Jarjoura *et al*. 2005	United States; 83 cases and 120 controls	Five or more sites with clinical attachment levels ≥3 mm	Preterm delivery <37 weeks	Significant association between periodontal disease and preterm delivery (OR = 2.75, 95% CI 1.01–7.54)
Moliterno *et al*. 2005	Brazil; 76 cases and 75 controls	Four or more sites with pocket depth >4 mm and clinical attachment levels ≥3 mm	Preterm delivery <37 weeks and birthweight <2500 g	Significantly higher risk for preterm LBW for mothers with periodontal disease (OR = 3.48)
Buduneli *et al*. 2005	Turkey; 53 cases and 128 controls	Mean pocket depth (mm)	Preterm delivery <37 weeks or birthweight <2500 g	No statistically significant differences between the cases and controls with regard clinical periodontal parameters
Moore *et al*. 2005	United Kingdom; 61 cases and 93 controls	Number of sites with pocket depth ≥5 mm	Preterm delivery <37 weeks	No association between periodontal disease and preterm birth
Bosnjak *et al*. 2006	Croatia; 17 cases and 64 controls	>60% of sites with clinical attachment levels ≥4 mm	Spontaneous preterm birth <37 weeks	Significant association between periodontal disease and preterm birth (OR = 8.13)
Skuldbol *et al*. 2006	Denmark; 21 cases and 33 controls	Pocket depth ≥4 mm and bleeding on probing	Preterm delivery <35 weeks	No difference in mean periodontal parameters between the two groups; no association between periodontal disease and preterm birth
Radnai *et al*. 2006	Hungary; 77 cases and 84 controls	One or more sites with probing depth ≥4 mm and bleeding on probing ≥50%	Preterm delivery <37 weeks and birthweight <2500 g	Significant association between periodontal disease and preterm LBW (OR = 3.32)
Contreras *et al*. 2006	Colombia; 130 cases and 243 controls	Pocket depth and clinical attachment loss ≥4 mm and bleeding on probing	Pre-eclampsia: blood pressure ≥140/90 mmHg and ≥2+ proteinuria	Significant association for periodontal disease and pre-eclampsia (OR = 3.0)

was the first to demonstrate an association between periodontal infection and adverse pregnancy outcomes in humans (Offenbacher *et al*. 1996).

Offenbacher and co-workers proceeded to conduct a prospective cohort study, entitled Oral Conditions and Pregnancy (OCAP), which was designed to determine whether maternal periodontal disease was predictive of preterm (<37 weeks) or very preterm (<32 weeks) birth. One thousand and twenty pregnant women were periodontally examined antepartum (<26 weeks gestation) and postpartum. Again, logistic regression models were developed using maternal exposure to either periodontal disease at enrollment or disease progression during pregnancy (clinical attachment loss ≥2 mm at one or more sites) as independent variables and adjusting for known risk factors (e.g. previous preterm delivery, race, smoking, social domain variables, and other infections). Overall, the incidence of preterm was 11.2% among periodontally healthy women, compared with 28.6% in women with moderate–severe periodontal disease (adjusted risk ratio or RR = 1.6, 95% CI 1.1–2.3). Antepartum moderate–severe periodontal disease was associated with an increased incidence of spontaneous preterm births (15.2% versus 24.9%, adjusted RR = 2.0, 95% CI 1.2–3.2). Similarly, the unadjusted rate of very preterm delivery was 6.4% among women with periodontal disease progression, significantly higher than the 1.8% rate among women without disease progression (adjusted RR = 2.4, 95% CI 1.1–5.2). This second study by the Offenbacher group implicated maternal periodontal disease exposure and progression as independent risk factors for PTB outcomes (Offenbacher *et al*. 2001, 2006; Lieff *et al*. 2004).

A subsequent analysis of OCAP data further indicates that maternal periodontal disease is associated with small-for-gestational-age births (Boggess *et al*. 2006). Defining "small-for-gestational-age" as birthweight less than the tenth percentile for gestational age, Boggess *et al*. (2006) reported that its prevalence was significantly higher among women with moderate or severe periodontal disease, compared with those with health or mild disease (13.8% versus 3.2%). Indeed, mothers with moderate or advanced periodontal disease were 2.3 times (RR, 95% CI 1.1–4.7) more likely to have small-for-gestational-age infants as compared to mothers with periodontal health even after adjusting for age, smoking, drugs, marital/insurance status, and pre-eclampsia (i.e. pregnancy-related hypertension with proteinuria or edema).

Jeffcoat and co-workers (2001a,b) also found a positive association between maternal periodontal disease and preterm birth in a comparable US cohort study involving 1313 pregnant subjects. Complete periodontal, medical, and behavioral assessments were made between 21 and 24 weeks gestation for each subject. Gestational ages of the infants were determined following delivery, and logistic regression modeling was performed to assess any relationship between periodontal disease and preterm birth while making adjustments for other known risk factors. Notably, subjects with severe or generalized periodontal disease had an adjusted OR of 4.45 (95% CI 2.16–9.18) for preterm delivery (<37 weeks) as compared with periodontally healthy subjects. The adjusted OR increased with advancing prematurity to 5.28 (95% CI 2.05–13.60) before 35 weeks gestational age and to 7.07 (95% CI 1.70–27.4) before 32 weeks gestational age. Hence, mothers with severe periodontal disease were four to seven times more likely to deliver a preterm infant relative to mothers with periodontal health.

Two other observational studies involving US populations report a consistent association for maternal periodontal disease and preterm low birthweight. One case–control study, involved 59 women with early spontaneous preterm births (<32 weeks of gestation), 36 women with early indicated preterm births (<32 weeks of gestation), and 44 controls with uncomplicated births at term (≥37 weeks) (Goepfert *et al*. 2004). Severe periodontal disease (clinical attachment loss ≥5 mm) was more common in the spontaneous preterm birth group (49%) as compared to the indicated preterm and term control groups (25% and 30% respectively). The odds for severe periodontal disease and spontaneous preterm birth were 3.4 (95% CI 1.5–7.7). For the second observational study involving 83 preterm cases (<37 weeks gestation) and 120 term delivery controls, preterm birth was associated with severe periodontitis, i.e. five or more sites with clinical attachment loss ≥3 mm, adjusted OR = 2.75, (95% CI 1.1–7.54) (Jarjoura *et al*. 2005).

This relationship has been explored in other cross-sectional and cohort populations around the globe (Tables 21-2 and 21-3). Bosnjak *et al*. (2006) reported an adjusted OR of 8.13 (95% CI 2.73–45.9) for maternal periodontal disease and preterm birth for a Croatian population (17 preterm cases and 64 controls). Similarly, a Finnish study (Oittinen *et al*. 2005) involving 130 consecutively enrolled pregnant mothers found that those with periodontal disease were 5.5 times (95% CI 1.4–21.2) more likely to have preterm deliveries or adverse pregnancy outcomes. Two case–control studies involving Hungarian subjects found positive associations between maternal early localized periodontitis (more than one site with probing depth ≥4 mm and bleeding on probing ≥50%) and preterm low birth weight (OR = 5.4, 95% CI 1.7–17.3; OR = 3.32, 95% CI 1.64–6.69) (Radnai *et al*. 2004, 2006). Another observational study with 96 Spanish pregnant women found a higher severity of periodontal disease (percentage of sites with probing depths ≥4 mm) among those having low birthweight infants relative to those with normal weight infants (Moreu *et al*. 2005). Moliterno and co-workers (2005) measured periodontal disease and birth outcomes for 150 Brazilian mothers and reported a significant association between periodontitis and low birthweight with an OR of 3.48 (95% CI 1.17–10.36). Chilean

Table 21-3 Summary of cohort observational studies on periodontal disease and adverse pregnancy outcomes

Reference	Population	Periodontal outcome or exposure	Adverse pregnancy outcome	Findings and conclusions
Offenbacher *et al*. 2001, 2006; Lieff *et al*. 2004	United States; 1020 subjects	Moderate–severe disease: four or more sites with pocket depths ≥5 mm and clinical attachment levels ≥2 mm; progressive disease: one or more sites with clinical attachment loss ≥2 mm	Preterm delivery <37 weeks; very preterm <32 weeks	Moderate–severe periodontal disease (RR = 1.6) and progressive disease (RR = 2.4) are significant risk factors for preterm delivery
Jeffcoat *et al*. 2001	United States; 1313 subjects	Severe or generalized disease: ≥90 sites with clinical attachment levels ≥3 mm	Preterm delivery <37 weeks	Severe or generalized periodontal disease is associated with preterm delivery (OR = 4.5)
Lopez *et al*. 2002b	Chile; 639 subjects	Four or more teeth showing one or more sites with pocket depth ≥4 mm and with clinical attachment level ≥3 mm	Preterm delivery <37 weeks and birthweight <2500 g	Significant association between periodontal disease and preterm LBW (RR = 3.5)
Boggess *et al*. 2003	United States; 763 subjects	Severe disease: ≥15 sites with pocket depths ≥4 mm; progressive disease: four or more sites with increases in pocket depth ≥2 mm and resulting in pockets ≥4 mm in depth	Pre-eclampsia: blood pressure >140/90 mm Hg and ≥1+ proteinuria	Significantly higher risk for pre-eclampsia among women with severe (OR = 2.4) or progressive (OR = 2.1) periodontal disease
Holbrook *et al*. 2004	Iceland; 96 subjects	Pocket depth ≥4 mm	Preterm delivery <37 weeks or birthweight <2500 g	No association between periodontal disease and preterm LBW
Moore *et al*. 2004	United Kingdom; 3738 subjects	Percentage of sites with pocket depth >4 or 5 mm	Preterm delivery <37 weeks or birthweight <2500 g	No association between periodontal disease case definitions and preterm delivery or LBW
Moreu *et al*. 2005	Spain; 96 subjects	Percentage sites with pocket depths ≥3 mm	Preterm delivery <37 weeks and birthweight <2500 g	Higher severity of periodontal disease among those having LBW infants
Rajapakse *et al*. 2005	Sri Lanka; 227 subjects	Pocket depth, bleeding and plaque scores > median value in the total cohort	Preterm delivery < 37 weeks and birthweight <2500 g	No association between periodontal disease and preterm delivery (OR = 2.3)
Boggess *et al*. 2006	United States; 1017 subjects	Moderate–severe disease: ≥15 sites with pocket depths ≥4 mm	Small-for-gestational-age births: birthweight <10% for gestational age	Association between periodontal disease and small-for-gestational-age births (RR = 2.3)
Meurman *et al*. 2006	Finland; 207 subjects	Community Periodontal Index for Treatment Needs	Preterm delivery <37 weeks, birthweight <2500 g, caesarean section, gestational diabetes or hypertension, pre-eclampsia or infant Apgar score <7	No association between poor periodontal health and pregnancy or delivery complications

mothers with periodontal disease appear to be 3.5 times (RR, 95% CI 1.5–7.9) more likely to have a preterm low birthweight infant versus mothers with periodontal health (Lopez *et al*. 2002a).

A smaller number of observational studies involving populations in Europe and Asia have failed to detect any significant association between maternal periodontal disease and adverse pregnancy outcomes (Davenport *et al*. 2002; Holbrook *et al*. 2004; Buduneli *et al*. 2005; Moore *et al*. 2005; Rajapakse *et al*. 2005; Skuldbol *et al*. 2006; Meurman *et al*. 2006). One prospective study finding no association was conducted at Guy's and St. Thomas' Hospital Trust in London and involved a large cohort of 3738 pregnant subjects (Moore *et al*. 2004). Regression analysis indicated no significant relationships between the severity of periodontal disease (periodontal pocketing or clinical attachment loss) and either preterm birth or low birthweight. The investigators did note a correlation between poorer periodontal health and mothers who experienced a late miscarriage. A subsequent analysis on non-smokers within this same population confirmed no associations between poor periodontal health and either preterm birth or low birthweight (Farrell *et al*. 2006). Again, non-smoking mothers who experienced late miscarriages exhibited a higher mean probing depth as compared with the subjects with term births. This same group of investigators performed genetic testing (restriction fragment length polymerase techniques) on a sub-cohort of 48 preterm cases and 82 control subjects (Moore *et al*. 2004). There were no significant associations reported for the tested cytokine polymorphisms (interleukin-1β+3953 and TNF-α-308 allelic variants), prematurity, and the severity of periodontal disease. In addition, the combination of genotype and periodontal disease did not increase the risk of preterm delivery in this subcohort. These studies reporting no association are a small proportion of the total available evidence collected to date and suggest that differences in the susceptibility to periodontal disease-associated prematurity may occur in certain global populations.

Association of periodontal disease and pre-eclampsia

Pre-eclampsia is a common hypertensive disorder of pregnancy that independently contributes to maternal and infant morbidity and mortality. Accordingly, atherosclerotic-like changes in placental tissues involving oxidative and inflammatory events are thought to initiate the development of pre-eclampsia (Ramos *et al*. 1995). Boggess and co-workers (2003) hypothesized that maternal exposure to periodontal disease or infection may be associated with the development of pre-eclampsia. Using data collected as part of the OCAP study, the investigators conducted logistic regression analyses on outcomes collected from 763 women who were enrolled at less than 26 weeks gestation and who delivered live infants. Pre-eclampsia (defined here as blood pressure >140/90 mmHg on two separate occasions, and ≥1+ proteinuria on catheterized urine specimen) affected 5.1% of subjects. The adjusted OR for severe periodontal disease at delivery (≥15 sites with pocket depths ≥4 mm in depth) and pre-eclampsia was 2.4 (95% CI 1.1–5.3). For women exhibiting periodontal disease progression during pregnancy (four or more sites with increases in pocket depth ≥2 mm and resulting in pockets ≥4 mm in depth) the adjusted OR was 2.1 (95% CI 1.0–4.4). After adjusting for other risk factors, such as maternal age, race, smoking, gestational age at delivery, and insurance status, the results from this cohort study indicate that severe and progressive maternal periodontal disease during pregnancy is associated with an increased risk for pre-eclampsia.

This same hypothesis was tested in a case–control study conducted in Colombia and including 130 pre-eclamptic (blood pressure ≥149/90 mmHg and ≥2+ proteinuria) and 243 non-pre-eclamptic women recruited between 26 and 36 weeks of pregnancy (Contreras *et al*. 2006). In addition to sociodemographic data, obstetric risk factors, and clinical periodontal outcomes, Contreras and co-workers examined the maternal subgingival microbial flora with sampling and anaerobic culture techniques. Sixty-four percent of pre-eclamptic women had chronic periodontitis (pocket depth and clinical attachment loss ≥4 mm and bleeding on probing) (OR = 3.0, 95% CI 1.91–4.87) versus 37% of controls. Notably, a higher proportion of pre-eclamptic women were infected subgingivally with periodontal pathogens including *P. gingivalis* (OR = 1.77, 95% CI 1.12–2–8), *T. forsythia* (OR = 1.8, 95% CI 1.06–3.00), and *Eikenella corrodens* (OR = 1.8, 95% CI 1.14–2.84). This case–control report demonstrates a consistent relationship between exposure to periodontal disease or subgingival pathogens and pre-eclampsia in pregnant women.

Xiong and co-workers (2006) have recently reviewed all of the existing evidence to date that examines the influence of periodontitis on adverse pregnancy outcomes. Twenty-two studies (13 case–control and 9 cohort) focused on preterm low birthweight, low birthweight, preterm birth, birthweight by gestational age, miscarriage or pregnancy loss, and pre-eclampsia. Fifteen studies suggested an association between periodontal disease and increased risk of adverse pregnancy outcome (odds ratio ranging from 1.10 to 20.0) while seven found no evidence of an association (odds ratio ranging from 0.78 to 2.54). This report concludes that more methodologically vigorous studies are needed and those studies are currently being conducted.

Periodontitis as a risk for diabetic complications

Similar to cardiovascular disease, diabetes mellitus is a common, multifactorial disease process involving

genetic, environmental, and behavioral risk factors. Affecting up to 5% of the general population and over 124 million persons worldwide (King *et al*. 1998), this chronic condition is marked by defects in glucose metabolism that produce hyperglycemia in patients. Diabetes mellitus is broadly classified under two major types (American Diabetes Association Expert Committee on the Diagnosis and Classification of Diabetes Mellitus 1997). In patients with type I diabetes, (formerly called insulin-dependent diabetes mellitus), the defect occurs at the level of the pancreatic beta cells that are destroyed. Consequently type 1 diabetics produce insufficient levels of the hormone insulin for homeostasis. In contrast, patients with type 2 diabetes (formerly called non-insulin-dependent diabetes mellitus), exhibit the defect at the level of the insulin molecule or receptor. Cells in type 2 diabetics cannot respond or are resistant to insulin stimulation.

Diabetes mellitus is usually diagnosed via laboratory fasting blood glucose levels that are greater than 7 mmol/L (126 mg/dL). Additionally, casual or non-fasting blood glucose values are elevated above 11.1 mmol/L (200 mg/dL). Thirdly, diabetic patients exhibit abnormal glucose tolerance tests (i.e. blood glucose levels greater than 8.3 mmol/L (150 mg/dL) at 2 hours following a 100 g glucose load). Elevated glycated hemoglobin levels (HbA1 and HbA1c) comprise a fourth laboratory parameter and one that provides a 30–90-day record of the patient's glycemic status. Classic signs and symptoms of diabetes include polyuria, polydipsia, polyphagia, pruritis, weakness, and fatigue. End-stage diabetes mellitus is characterized by problems with several organ systems including micro- and macrovascular disease (atherosclerosis), retinopathy, nephropathy, neuropathy, and periodontal disease.

Although environmental exposures, viral infection, autoimmunity, and insulin resistance are currently considered to play principal roles in the etiology of diabetes mellitus (Yoon 1990; Atkinson & Maclaren 1990), pathogenesis of the disease and end-organ damage relies heavily on the formation and accumulation of advanced glycation end-products (AGEs) (Brownlee 1994). Accordingly, the chronic hyperglycemia in diabetes results in the non-enzymatic and irreversible glycation of body proteins. These AGEs, in turn, bind to specific receptors for advanced glycation end-products (RAGEs) on monocytes, macrophages, and endothelial cells, and alter intracellular signaling (transduction) pathways (Esposito *et al*. 1992; Kirstein *et al*. 1992). With AGE–RAGE binding, monocytes and macrophages are stimulated to proliferate, up-regulate pro-inflammatory cytokines, and produce oxygen free radicals (Vlassara *et al*. 1988; Yan *et al*. 1994; Yui *et al*. 1994). While oxygen free radicals directly damage host tissues, pro-inflammatory cytokines like IL-1, IL-6 and TNF-α exacerbate this damage via a cascade of catabolic events and the recruitment of other immune cells (T and B lymphocytes). Patients with diabetes exhibit elevated levels of AGEs in tissues including those of the periodontium (Brownlee 1994; Schmidt *et al*. 1996). Diabetics also present with elevated serum and gingival crevicular fluid levels of pro-inflammatory cytokines (Nishimura *et al*. 1998; Salvi *et al*. 1998). Furthermore, monocytes isolated from diabetics and stimulated with LPS secrete higher concentrations of pro-inflammatory cytokines and prostaglandins (Salvi *et al*. 1998). Chronic hyperglycemia, the accumulation of AGEs and the hyper-inflammatory response may promote vascular injury and altered wound healing via increased collagen cross-linking and friability, thickening of basement membranes, and altered tissue turnover rates (Weringer & Arquilla 1981; Lien *et al*. 1984; Salmela *et al*. 1989; Cagliero *et al*. 1991). Lastly, diabetic patients exhibit impairments in neutrophil chemotaxis, adherence, and phagocytosis (Bagdade *et al*. 1978; Manouchehr-Pour *et al*. 1981; Kjersem *et al*. 1988), and thus are at high risk for infections like periodontitis.

Numerous epidemiologic surveys demonstrate an increased prevalence of periodontitis among patients with uncontrolled or poorly controlled diabetes mellitus. For example, Cianciola *et al*. (1982) reported that 13.6% and 39% of type 1 diabetics, 13–18 and 19–32 years of age respectively, had periodontal disease. In contrast, none of the non-diabetic sibling controls and 2.5% of the non-diabetic, unrelated controls exhibited clinical evidence of periodontitis. In a classic study, Thorstensson and Hugoson (1993) examined the severity of periodontitis in patients with diabetes mellitus and compared severity of periodontitis with the duration a patient had been diagnosed with diabetes. In looking at three age cohorts, 40–49 years, 50–59 years, and 60–69 years, the 40–49 years age group diabetics had more periodontal pockets ≥6 mm and more extensive alveolar bone loss than non-diabetics. In this same age group, there were also more subjects with severe periodontal disease experience among the diabetics than among the non-diabetics. In noting that the younger age diabetics had more periodontitis than the older age diabetics, these authors reported that early onset of diabetes is a much greater risk factor for periodontal bone loss than mere disease duration.

Safkan-Seppala and Ainamo (1992) conducted a cross-sectional study of 71 type 1 diabetics diagnosed with the condition for an average of 16.5 years. Diabetics identified with poor glycemic control demonstrated significantly more clinical attachment loss and radiographic alveolar bone resorption as compared to well controlled diabetics with the same level of plaque control. Two longitudinal cohort studies monitoring type 1 diabetics for 5 and 2 years respectively documented significantly more periodontitis progression among diabetics overall and among those whose diabetes was poorly controlled (Seppala *et al*. 1993; Firatli 1997).

Investigators from the State University of New York at Buffalo have published a number of papers documenting the periodontal status of Pima Indians,

a population with a high prevalence of type 2 diabetes mellitus. Shlossman *et al*. (1990) first documented the periodontal status of 3219 subjects from this unique population. Diagnosing type 2 diabetes with glucose tolerance tests, the investigators found a higher prevalence of clinical and radiographic periodontitis for diabetics versus non-diabetics independent of age. This investigative group next focused on a cross-sectional analysis of 1342 dental subjects (Emrich *et al*. 1991). A logistic regression analysis indicated that type 2 diabetics were 2.8 times more likely to exhibit clinical attachment loss and 3.4 times more likely to exhibit radiographic alveolar bone loss indicative of periodontitis relative to non-diabetic controls. In a larger study of 2273 Pima subjects, 60% of type 2 diabetics were affected with periodontitis versus 36% of non-diabetic controls (Nelson *et al*. 1990). When a cohort of 701 subjects with little or no evidence of periodontitis at baseline were followed for approximately 3 years, diabetics were 2.6 times more likely to present with incident alveolar bone resorption as compared to non-diabetics. Taylor *et al*. (1998a,b) similarly reported higher odds ratios of 4.2 and 11.4 for the risk of progressive periodontitis among diabetic Pima Indians in general and poorly controlled diabetics (i.e. with glycated hemoglobin levels >9%) respectively.

The studies cited above review the evidence that diabetes is a modifier or risk factor for periodontitis. Of tremendous importance also are the data that have emerged indicating that the presence of periodontitis or periodontal inflammation can increase the risk for diabetic complications, principally poor glycemic control. Taylor *et al*. (1996) tested this hypothesis using longitudinal data on 88 Pima subjects. Severe periodontitis at baseline as defined clinically or radiographically was significantly associated with the risk of worsening glycemic control (glycated hemoglobin >9%) by six-fold over a 2-year period. Other significant co-variates in the regression modeling included subject age, smoking, and baseline severity and duration of type 2 diabetes. Collin and co-workers (1998) studied older adults in Finland and found that people with advanced periodontitis were more likely to have higher HbAlc levels than those who had no or moderate periodontitis at follow-up.

With the emerging evidence reviewed earlier in this chapter that periodontal disease is a significant risk factor for cardiovascular disease, Saremi *et al*. (2005) conducted a longitudinal trial to examine the effect of periodontal disease on overall mortality and cardiovascular disease-related mortality in 600 subjects with type 2 diabetes. In subjects with severe periodontitis, the death rate from ischemic heart disease was 2.3 times as high as the rate in subjects with no or mild periodontitis after accounting for other known risk factors. The death rate from diabetic nephropathy was 8.5 times higher in those with severe periodontitis. When deaths from renal and cardiac causes were analyzed together, the mortality rate from cardiorenal disease was 3.5 times higher in patients with severe periodontitis. These findings further suggest that periodontal disease is a risk for cardiovascular and renal mortality in people with diabetes (Janket *et al*. 2003; Scanniapieco *et al*. 2003a; Mealey & Rose 2005; Saremi *et al*. 2005; Mealey & Oates 2006).

Periodontitis as a risk for respiratory infections

There is emerging evidence that in certain at risk populations, periodontitis and poor oral health may be associated with several respiratory conditions. Respiratory diseases contribute considerably to morbidity and mortality in human populations. Lower respiratory infections were ranked as the third most common cause of death worldwide in 1990, and chronic obstructive pulmonary disease (COPD) was ranked sixth (Scannapieco 1999; Scannapieco *et al*. 2003).

Bacterial pneumonia is either community-acquired or hospital-acquired (nosocomial). Community-acquired pneumonia is usually caused by bacteria that reside on the oropharyngeal mucosa, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. Hospital-acquired pneumonia is often caused by bacteria within the hospital or health care environment, such as Gram-negative bacilli, *Pseudomonas aeruginosa*, and *Staphylococcus aureus* (Scannapieco 1999; Mealey & Klokkvold 2006). As many as 250 000 to 300 000 hospital-acquired respiratory infections occur in the US each year with an estimated mortality rate of about 30%. Pneumonia also contributes to a significant number of other deaths by acting as a complicating or secondary factor with other diseases or conditions.

COPD is another common severe respiratory disease characterized by chronic obstruction to airflow with excess production of sputum resulting from chronic bronchitis and/or emphysema. Chronic bronchitis is the result of irritation to the bronchial airway causing an expansion of the propagation of mucus-secreting cells within the airway epithelium. These cells secrete excessive tracheobronchial mucus sufficient to cause cough with expectoration for at least 3 months of the year over 2 consecutive years. Emphysema is the distention of the air spaces distal to the terminal bronchiole with destruction of the alveolar septa (Scannapieco 1999).

Beginning in 1992 with a report by Scannapieco's group at SUNY-Buffalo (Scannapieco *et al*. 1992), several investigators have hypothesized that oral and/or periodontal infection may increase the risk for bacterial pneumonia or COPD. It seems plausible from all the evidence reviewed in this chapter that the oral cavity may have a critical role in respiratory infections. For example, oral bacteria from the periodontal pocket can be aspirated into the lung to cause

aspiration pneumonia. The teeth may also serve as a reservoir for respiratory pathogen colonization and subsequent nosocomial pneumonia. Typical respiratory pathogens have been shown to colonize the dental plaque of hospitalized intensive care and nursing home patients. Once established in the mouth, these pathogens may be aspirated into the lung to cause infection. Also, periodontal disease-associated enzymes in saliva may modify mucosal surfaces to promote adhesion and colonization by respiratory pathogens, which are then aspirated into the lungs. These same enzymes may also destroy salivary pellicles on pathogenic bacteria to hinder their clearance from the mucosal surface. Lastly, cytokines originating from periodontal tissues may alter respiratory epithelium to promote infection by respiratory pathogens (Scannapieco 1999).

Data from a longitudinal study of more than 1100 men revealed that alveolar bone loss was associated with the risk of COPD. Over a 25-year period, 23% of subjects were diagnosed with COPD. Subjects who had more severe bone loss at the baseline dental examination had a significantly increased risk of subsequently developing COPD compared with subjects with less bone loss (Hayes *et al*. 1998). Scannapieco and co-workers (1998) found that individuals with poor oral hygiene were at increased risk for chronic respiratory diseases such as bronchitis and emphysema. Scannapieco and Ho (2001) reported that patients with a history of COPD had significantly more periodontal attachment loss (1.48 ± 1.35 mm) than subjects without COPD (1.17 ± 1.09 mm). However, two recent systematic reviews of all of the current evidence indicate that at present there is not sufficient evidence to say that there is an association between periodontal disease and COPD (Scannapieco *et al*. 2003; Azarpazhooh & Leake 2006). There is emerging evidence for an association between hospital-acquired (nosocomial) bacterial pneumonia and periodontal disease. It is thought that potential respiratory pathogens, usually from the gastrointestinal tract, can colonize the oral cavity, where they are subsequently aspirated, leading to pneumonia (Mealey & Klokkevold 2006).

Effects of treatment of periodontitis on systemic diseases

This chapter has examined the evidence, gathered by many investigators since the early 1990s, which suggests that periodontitis may be a risk for certain systemic conditions such as cardiovascular disease, adverse pregnancy outcomes, diabetes mellitus, and pulmonary disease. Collectively, the findings gathered from investigators world-wide are very compelling. It would certainly appear that periodontal disease is strongly associated with systemic conditions.

Students of dentistry will next ask, "If you treat periodontitis, do you prevent the onset or reduce the severity of these systemic complications?" It is clear that dentistry must now focus on intervention studies to determine whether treating periodontitis will have a beneficial effect on systemic diseases. This is not an easy task and some studies will take considerable time before we know the answer. However, there are initial data which examine intervention and the impact of periodontal treatment on several systemic conditions and the results are promising.

Regarding cardiovascular disease, evidence in human subjects demonstrating the beneficial effects of periodontal therapy on cardiovascular disease outcomes is limited and indirect at present. D'Aiuto and co-workers (2004) demonstrated that periodontitis patients treated with scaling and root planing exhibited significant serum reductions in the cardiovascular disease biomarker, CRP, and IL-6. In particular, patients who clinically responded to periodontal therapy in terms of pocket depth reductions were four times more likely to exhibit serum decreases in CRP relative to patients with a poor clinical periodontal response. Elter and colleagues (2006) also reported decreases in these serum biomarkers plus improved endothelial functions (i.e. flow-mediated dilation of the brachial artery) for 22 periodontitis patients treated with "complete mouth disinfection" (i.e. scaling and root planing, periodontal flap surgery, and extraction of hopeless teeth within a 2-week interval). Similarly, Seinost and co-workers (2005) tested endothelial function in 30 patients with severe periodontitis versus 31 periodontally healthy control subjects. Prior to interventions, flow-mediated dilation was significantly lower in patients with periodontitis than in control subjects. Periodontitis patients with favorable clinical responses to non-surgical periodontal therapy (i.e. scaling and root planing, topical and peroral antimicrobials plus mechanical retreatment) exhibited concomitant improvements in flow-mediated dilatation of the brachial artery and serum CRP concentrations. While the effects of periodontal therapy on cardiovascular disease events in patients have yet to be determined, the available pilot data suggest that periodontal therapies can improve surrogate cardiovascular disease outcomes like serum biomarkers and endothelial dysfunction.

In considering adverse pregnancy outcomes, four published intervention studies provide early evidence that preventive and treatment interventions aimed at reducing maternal periodontal infection and inflammation may reduce the likelihood of preterm low birthweight infants, while one study did not find an effect. Mitchell-Lewis and co-workers (2000) conducted a non-randomized pilot trial involving 164 US inner-city minority pregnant women. One group received full mouth debridement (scaling with hand and/or ultrasonic instruments) plus tooth polishing and oral hygiene instructions. The second group received no periodontal intervention. No differences in clinical periodontal status were observed

between preterm low birthweight cases and women with normal birth outcomes, but preterm low birthweight mothers had significantly higher levels of subgingival pathogens like *T. forsythia* and *C. rectus.* Strikingly, while 18.9% of women receiving no periodontal intervention delivered preterm low birthweight infants, only 13.5% of the treated women had preterm low birthweight infants.

A second pilot trial conducted in the US involved 366 women with periodontitis recruited between 21 and 25 weeks gestation (Jeffcoat *et al*. 2003). Subjects were stratified for risk factors (previous spontaneous PTB at <35 weeks, body mass index <19.8 or bacterial vaginosis as assessed by Gram stain) and randomized to one of three treatment groups as follows: (1) dental prophylaxis plus placebo capsule; (2) scaling and root planing plus placebo capsule; or (3) scaling and root planing plus metronidazole capsule (250 mg tid for 1 week). An additional group of 723 pregnant women meeting the same criteria for periodontitis but receiving no intervention served as the negative control. Women treated with scaling and root planing plus placebo capsules exhibited the lowest incidence rate for PTB <35 weeks (0.8%). Those treated with dental prophylaxis plus placebo capsules or scaling and root planing plus metronidazole capsules exhibited intermediate incidence rates for preterm deliveries (4.9% and 3.3% respectively). In contrast, the rate of PTB for the untreated reference group was 6.3%. This trial supported the hypothesis that mechanical periodontal therapy alone may reduce PTB in pregnant women with periodontitis.

Lopez and co-workers (2002a, 2005) have reported results from two intervention studies conducted in Chile demonstrating consistent, significant, and beneficial effects of mechanical periodontal therapy on preterm low birthweight outcomes. In the first trial, the investigators enrolled 351 pregnant women with clinical evidence of periodontitis (four or more teeth with one or more site exhibiting pocket depth ≥4 mm and clinical attachment loss ≥3 mm) and randomized them to immediate mechanical periodontal therapy (scaling and root planing) versus delayed (postpartum) treatment. The total incidence of PLBW in this cohort of periodontitis subjects was 6.26%. For women treated for periodontal disease, the incidence of PLBW was only 1.84%, while the incidence was 10.11% in untreated women. When a multivariate logistic regression analysis was performed controlling for other risk factors, delayed periodontal disease treatment was the strongest factor related to PLBW with an OR of 4.70 (95% CI 1.29–17.13). In the second trial, 870 pregnant women with gingivitis (≥25% of sites bleeding on probing but no clinical attachment loss ≥2 mm) were randomly assigned to immediate versus postpartum periodontal treatment (supra- and subgingival scaling, tooth polishing, and daily rinsing with 0.12% chlorhexidine gluconate). Those receiving immediate periodontal treatment also received maintenance therapy plus oral hygiene instructions every 2–3 weeks until delivery. Accordingly, the incidence of preterm low birthweight in the immediate treatment group was 2.14% versus 6.71% for the control group (OR = 3.26, 95% CI 1.56–6.83). After adjusting for other known risk factors, women with gingivitis receiving delayed intervention were almost three times more likely to deliver preterm as compared to women who received periodontal treatment (OR = 2.76, 95% CI 1.29–5.88). One trial did not find an effect of scaling and root planing on adverse pregnancy outcomes (Michalowicz *et al*. 2006). Overall, these clinical trials suggest that mechanical intervention in pregnant mothers with gingivitis or periodontitis can reduce the incidence of preterm low birthweight.

Clinicians and investigators working with patients who have diabetes mellitus have studied whether periodontal treatment can improve glycemic control. Several investigators have sought to answer this question using periodontal mechanical treatment as the intervention (Seppala & Ainamo 1994; Aldridge *et al*. 1995; Smith *et al*. 1996; Christgau *et al*. 1998; Stewart *et al*. 2001). Some of these studies have failed to detect an improvement in glycated hemoglobin level with scaling and root planing alone, while others have shown an improvement.

Kiran and co-workers conducted a study of patients with well controlled type 2 diabetes who had gingivitis or mild periodontitis. Prophylaxis and scaling and root planing, without systemic antibiotic therapy, was examined for the effect on periodontal disease and glycemic control. Control diabetic subjects with periodontal disease received no treatment. The treated subjects had a 50% reduction in the prevalence of gingival bleeding 3 months after treatment. In addition these subjects had a significant improvement in glycemic control, with a reduction in the mean HbAlc value of 0.8%. The control subjects who were not treated had no change in periodontal status or glycemic control (Kiran *et al*. 2005).

Grossi *et al*. (1997) reported positive findings from an intervention trial featuring 113 Pima Indians with type 2 diabetes and periodontitis who received both mechanical and antimicrobial treatment. At baseline, participants were treated with scaling and root planing plus one of five antimicrobial regimens: (1) water (placebo) rinse and peroral doxycycline (100 mg qid for 2 weeks), (2) 0.12% chlorhexidine rinse and peroral doxycycline, (3) povidone–iodine rinse and peroral doxycycline, (4) 0.12% chlorhexidine rinse and peroral placebo, or (5) povidone–iodine rinse and peroral placebo. Subjects were evaluated using clinical, microbiologic, and laboratory parameters prior to therapy and at 3 and 6 months. All treatment groups on average demonstrated clinical and microbiological improvements; however, those groups treated with adjunctive peroral tetracycline exhibited significant and greater reductions in pocket depth and subgingival detection rates for *P. gingivalis* as compared to the groups receiving peroral placebo.

Most strikingly, diabetic subjects receiving mechanical therapy plus peroral tetracycline demonstrated significant, 10% reductions in their glycated hemoglobin levels. Two small, uncontrolled cohort studies with type 1 diabetic–periodontitis patients each similarly reported improvements in glycemic control with combination mechanical–antimicrobial therapy (Williams & Mahan 1960; Miller *et al*. 1992).

At present it is still not clear what can be expected from treating or reducing periodontal disease in diabetic subjects on glycemic control. There are enough available data to at least say that the effect of periodontal disease treatment on reducing HbAlc levels in subjects with diabetes has promise. There is such great variability among patients in the studies to date that it appears that some diabetic subjects had little change in glycemic control while others had major improvement. Nonetheless, it is very clear that periodontal health is a major goal for subjects with diabetes (Mealey & Oates 2006).

Last, the evidence for the effect of periodontal intervention on bacterial pneumonia shows promise. There are a number of studies which examine the effect of treating oral infection in reducing the risk of pneumonia in high-risk populations. DeRiso and colleagues (1996) studied subjects admitted to a surgical intensive care unit. When subjects received a chlorhexidine rinse twice a day compared to control subjects receiving a placebo rinse, the incidence of pneumonia was reduced 60% in the chlorhexidine treated group compared to the control group. Fourrier and colleagues (2000) found a similar 60% reduction in pneumonia with the use of a 0.2% chlorhexidine gel.

In a landmark study, Yoneyama and co-workers (2002) examined the role of supervised toothbrushing plus providone–iodine on the incidence of pneumonia in a group of elders living in nursing homes in Japan. When these subjects had their mouths cleaned, with supervision, there was a 39% reduction in pneumonia over a 2-year period compared to the control group. Recent reviews of the evidence clearly indicate that when bacterial plaque is reduced in the mouth in at-risk subjects, the risk of pneumonia is reduced. These findings are limited at present to special-care populations. Little evidence exists that poor oral hygiene and periodontal disease increase the risk for community-acquired pneumonia (Azarpazhooh & Leake 2006; Scannapieco *et al*. 2003b).

Dentistry has come a long way since 1900 when Willoughby Miller and William Hunter proclaimed that oral disease caused most systemic disease. A century later we are developing a scientifically based understanding of how in fact periodontitis may be a risk for certain systemic diseases. As these more recent observations are confirmed and clarified, dentistry will have a new responsibility in caring for patients who may develop or who have periodontitis. It is no longer just teeth that are at risk.

Chapter 22

The Periodontal Abscess

Mariano Sanz, David Herrera, and Arie J. van Winkelhoff

Introduction

Odontogenic abscesses include a broad group of acute infections that originate from the tooth and/or the periodontium. Such abscesses are associated with an array of symptoms, including a localized purulent inflammation in the periodontal tissues that causes pain and swelling. Abscesses are one of the main causes for patients to seek emergency care in the dental clinic. Depending on the origin of the infection the lesions can be classified as periapical, periodontal, and pericoronary abscesses.

Classification

Different classifications have been suggested for periodontal abscesses: chronic or acute; single or multiple; gingival or periodontal; occurring in the supporting periodontal tissues or in the gingiva. A classification has been proposed (Meng 1999) and includes *gingival abscesses* (in previously healthy sites and caused by impactation of foreign bodies), *periodontal abscesses* (either acute or chronic, in relation to a periodontal pocket), and *pericoronal abscesses* (at incompletely erupted teeth). This classification was included at the revised classification system for periodontal diseases developed at *The International Workshop for a Classification of Periodontal Diseases and Conditions* organized by the American Academy of Periodontology in 1999, and for the first time, periodontal abscesses were included as an independent entity.

The most rational classification of periodontal abscesses is, however, the one based on its aetiology. Depending on the cause of the acute infectious process, two types of abscesses may occur:

- *Periodontitis-related abscess*, when the acute infection originates from bacteria present at the subgingival biofilm in a deepened periodontal pocket
- *Non-periodontitis-related abscess*, when the acute infection originates from bacteria originating from another local source, such as a foreign body impaction or from alterations in the integrity of the root leading to bacteria colonization.

In a periodontitis patient a periodontal abscess represents a period of active tissue breakdown and is the result of an extension of the infection into the still intact periodontal tissues. This abscess formation is usually due to the marginal closure of a deep periodontal pocket and lack of proper drainage. Therefore, the existence of deep, tortuous pockets and deep concavities associated with furcation lesions favors the development of these acute conditions. Once the acute inflammatory process is started, there is a local accumulation of neutrophils, formation of pus, and tissue breakdown. The retention of pus in the pocket may further compromise the drainage and the lesion may progress rapidly.

There are different mechanisms behind the formation of a *periodontitis-related abscess*:

- *Exacerbation of a chronic lesion*. Such abscesses may develop in a deepened periodontal pocket without any obvious external influence, and may occur in: (a) an untreated periodontitis patient, or (b) as a recurrent infection during supportive periodontal therapy.
- *Post-therapy periodontal abscesses*. There are various reasons why an abscess may occur during the course of active therapy:
  - Post-scaling periodontal abscess (Dello Russo 1985). When these lesions occur immediately after scaling or after a routine professional prophylaxis they are usually related to the presence of small fragments of remaining calculus that obstruct the pocket entrance once the oedema in the gingiva has disappeared (Dello Russo 1985; Carranza 1990). This type of

abscess formation can also occur when small fragments of calculus have been forced into the deep, previously uninflamed portion of the periodontal tissues (Dello Russo 1985).

- Post-surgery periodontal abscess. When an abscess occurs immediately following periodontal surgery, it is often the result of an incomplete removal of subgingival calculus or to the presence of foreign bodies in the periodontal tissues, such as sutures, regenerative devices, or periodontal pack (Garrett *et al.* 1997).
- Post-antibiotic periodontal abscess. Treatment with systemic antibiotics without subgingival debridement in patients with advanced periodontitis may also cause abscess formation (Helovuo & Paunio 1989; Helovuo *et al.* 1993; Topoll *et al.* 1990). In such patients, the subgingival biofilm may protect the residing bacteria from the action of the antibiotic, resulting in a super-infection leading to an acute process with the ensuing inflammation and tissue destruction. Helovuo *et al.* (1993) followed patients with untreated periodontitis who were given broad-spectrum antibiotics (penicillin, erythromycin) for non-oral reasons. They showed that 42% of these patients developed marginal abscesses within 4 weeks of antibiotic therapy.

Non-periodontitis-related abscess formation may also occur in relation to a periodontal pocket, but in such cases, there is always an external local factor that explains the acute inflammatory process. Such factors may include:

- Impaction of foreign body in the gingival sulcus or periodontal pocket (Gillette & Van House 1980; Abrams & Kopczyk 1983). It may be related to oral hygiene practices (toothbrush, toothpicks, etc.) (Gillette & Van House 1980; Abrams & Kopczyk 1983), orthodontic devices, food particles, etc.
- Root morphology alterations. In this instance local anatomic factors, such as an invaginated root (Chen *et al.* 1990), a fissured root (Goose 1981), an external root resorption, root tears (Haney *et al.* 1992; Ishikawa *et al.* 1996) or iatrogenic endodontic perforations (Abrams *et al.* 1992), may be the cause of the abscess formation.

Prevalence

The prevalence of periodontal abscesses was studied in emergency dental clinics (Ahl *et al.* 1986; Galego-Feal *et al.* 1996), in general dental clinics (Lewis *et al.* 1990), in periodontitis patients before treatment (Gray *et al.* 1994), and in periodontitis patients during supportive periodontal therapy (SPT) (Kaldahl *et al.* 1996; McLeod *et al.* 1997).

Among all dental conditions in need of emergency treatment, periodontal abscesses represent between 8% and 14% (Ahl *et al.* 1986; Galego-Feal *et al.* 1996). Gray *et al.* (1994) monitored periodontal patients in a military clinic and found that periodontal abscesses had a prevalence of 27.5%. In this population, 13.5% of the patients undergoing active periodontal treatment had experienced abscess formation, while untreated patients showed a higher figure, 59.7%. McLeod *et al.* (1997) followed 114 patients in SPT and identified 42 patients (27.5%) that had suffered from acute episodes of periodontal abscess.

In a prospective longitudinal treatment study, by Kaldahl *et al.* (1996), the occurrence of periodontal abscesses during 7 years of periodontal maintenance was also studied. From the 51 patients included, 27 abscesses were detected. Twenty-three of the abscesses occurred at teeth in quadrants treated only by coronal scaling, three in areas treated by root planing, and only one in areas treated by surgical therapy. Sixteen out of 27 abscess sites had an initial probing pocket depth >6 mm, while in eight sites the probing depth was 5–6 mm.

Abscesses often occur in molar sites, representing more than 50% of all sites affected by abscess formation (Smith & Davies 1986; McLeod *et al.* 1997; Herrera *et al.* 2000a). The most likely reason for this high prevalence of abscesses in molars could be presence of pockets involving the furcation and the complex anatomy and root morphology of such teeth. However, in a recently published study in Colombian patients, the lower anterior incisors were the most frequently affected teeth (Jaramillo *et al.* 2005).

The occurrence of a periodontal abscess may be important not only due to its relatively high prevalence, but also on how these acute infections may influence the prognosis of the affected teeth. Since abscesses sometimes develop during SPT in teeth with remaining deep periodontal pockets and a reduced periodontal support, the additional periodontal destruction occurring during the acute periodontal process may be the main indication for its extraction (Chace & Low 1993; McLeod *et al.* 1997).

Pathogenesis and histopathology

The periodontal abscess lesion contains bacteria, bacterial products, inflammatory cells, tissue breakdown products, and serum. The precise pathogenesis of this lesion is still obscure. It is hypothesized that the occlusion of the periodontal pocket lumen, due to trauma or tissue tightening, will prevent drainage and result in extension of the infection from the pocket into the soft tissues of the pocket wall, resulting in the formation of the abscess. The entry of bacteria into the soft tissue pocket wall could be the event that initiates the formation of a periodontal abscess, however it is the accumulation of leukocytes and the formation of an acute inflammatory infiltrate what will be the main cause of the connective tissue

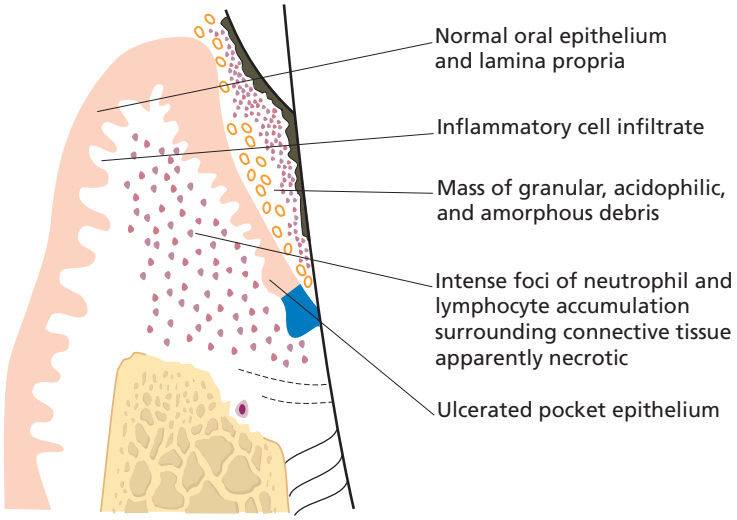

Fig. 22-1 Schematic drawing showing the histopathology of a periodontal abscess.

destruction, encapsulation of the bacterial mass, and formation of pus. The inflammatory cells and their extracellular enzymes are, therefore, the main cause of this destruction of connective tissue. Both the lowered tissue resistance and the virulence and number of bacteria will determine the course of this acute infection.

The histopathology of this lesion demonstrates, in its first phases, the central area of the abscess filled with neutrophils, in close vicinity with remains of tissue destruction and soft tissue debris. At a later stage, a pyogenic membrane, composed of macrophages and neutrophils, is organized. The rate of tissue destruction within the lesion will depend on the growth of bacteria inside the foci and their virulence, as well as on the local pH. An acidic environment will favor the activity of lysosomal enzymes and promote tissue destruction (DeWitt *et al.* 1985).

De Witt *et al*. (1985) studied biopsies sampled from 12 abscesses. The biopsies were taken immediately apical to the centre of the abscess and processed for histologic examination. They observed that the sites examined had a normal oral epithelium and lamina propria, but an inflammatory cell infiltrate resided lateral to the pocket epithelium. There were foci of neutrophil and lymphocyte accumulations in areas characterized by massive tissue destruction and a mass of granular, acidophilic, and amorphous debris present in the pocket (Fig. 22-1). Gram-negative bacteria were seen invading both the pocket epithelium and the compromised connective tissue in seven out of nine biopsies evaluated by electron microscopy.

Microbiology

In review articles and textbooks it is usually cited that that purulent oral infections are polymicrobial, and mainly caused by endogenous bacteria (Tabaqhali 1988). However, very few studies have investigated the specific microbiota of periodontal abscesses. Newman & Sims (1979) studied nine abscesses and found that 63.1% of the microbiota was comprised of strict anaerobes. Topoll *et al.* (1990) analysed 20 abscesses in 10 patients who had taken antibiotics prior to the study. They reported that 59.5% of the microbiota was made up of strict anaerobes. Herrera *et al*. (2000a) reported that 45.1% of the bacteria in the abscess material included anaerobes.

These studies have shown that the microbiota of periodontal abscess is not different from the microbiota of chronic periodontitis lesions. This microflora is polymicrobial and dominated by non-motile, Gram-negative, strict anaerobic, rod-shaped species. From this group, *Porphyromonas gingivalis* is probably the most virulent and relevant microorganism. The occurrence of *P. gingivalis* in periodontal abscesses ranges from 50–100% (Newman & Sims 1979; van Winkelhoff *et al.* 1985; Topoll *et al.* 1990; Hafström *et al.* 1994; Herrera *et al.* 2000a; Jaramillo *et al.* 2005). Using a polymerase chain reaction technique, Ashimoto *et al*. (1998) found *P. gingivalis* in all of the seven cases of abscesses they investigated. Other anaerobic species that are usually found include *Prevotella intermedia*, *Prevotella melaninogenica*, *Fusobacterium nucleatum*, and *Tannerella forsythia*. Spirochetes (*Treponema* species) are also found in most cases (Ashimoto *et al.* 1998). The majority of the Gram-negative anaerobic species are non-fermentative and display moderate to strong proteolytic activity. Strict anaerobic, Gram-positive bacterial species in periodontal abscesses include *Micromonas micros*, *Actinomyces* spp., and *Bifidobacterium* spp. Facultative anaerobic Gram-negative bacteria that can be isolated from periodontal abscesses include *Campylobacter* spp., *Capnocytophaga* spp., and *Aggregatibacter actinomycetemcomitans* (Hafström *et al.* 1994). The presence of Gram-negative enteric rods has also been reported (Jaramillo *et al.* 2005).

Diagnosis

The diagnosis of a periodontal abscess should be based on the overall evaluation and interpretation of

Fig. 22-2 Periodontal abscess associated with a lower right first molar. Observe the association between the abscess formation and the furcation lesion in this molar.

Fig. 22-4 Periodontal abscess associated with a lower right first molar. Observe the spontaneous suppuration expressed through the gingival margin.

Fig. 22-3 Periodontal abscess associated with a mandibular second molar. There is diffuse swelling affecting all the buccal surface of the molar.

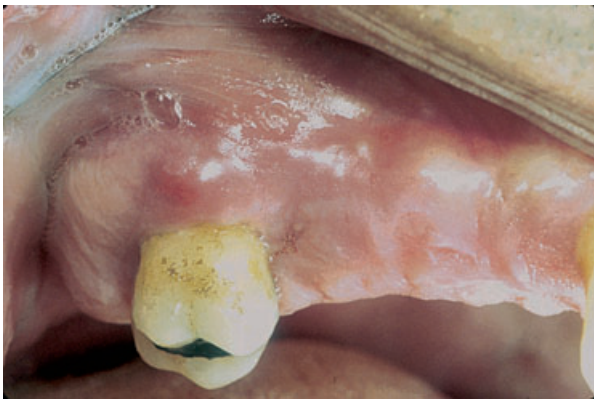

Fig. 22-5 Periodontal abscess associated with an upper right third molar. This lesion is associated with tooth extrusion and mobility.

the patient´s chief complaint, together with the clinical and radiological signs found during the oral examination (Corbet 2004).

The most prominent symptom of a periodontal abscess is the presence of an ovoid elevation of the gingival tissues along the lateral side of the root (Fig. 22-2). Abscesses located deep in the periodontium may be more difficult to identify by this swelling of the soft tissue, and may present as diffuse swellings or simply as a red area (Fig. 22-3). Another common finding is suppuration, either from a fistula or, most commonly, from the pocket (Fig. 22-4). This suppuration may be spontaneous or occur after applying pressure on the outer surface of the gingiva.

The clinical symptoms usually include pain (from light discomfort to severe pain), tenderness of the gingiva, swelling, and sensitivity to percussion of the affected tooth. Other related symptoms are tooth elevation and increased tooth mobility (Fig. 22-5).

During the periodontal examination, the abscess is usually found at a site with a deep periodontal pocket. Signs associated with periodontitis such as bleeding on probing, suppuration and sometimes increased tooth mobility are also present (Smith & Davies 1986; Hafström *et al.* 1994; Herrera *et al.* 2000a). The radiographic examination may reveal either a normal appearance of the interdental bone or evident bone loss, ranging from just a widening of the periodontal ligament space to pronounced bone loss involving most of the affected root (Fig. 22-6).

In some patients the occurrence of a periodontal abscess may be associated with elevated body temperature, malaise, and regional lymphadenopathy (Smith & Davies 1986; Carranza 1990; Ibbott *et al.* 1993; Herrera *et al.* 2000a). Herrera *et al.* (2000a) reported laboratory data from blood and urine in patients immediately after the diagnosis of a periodontal abscess and reported that in 30% of the patients there was an elevated number of blood leukocytes. The absolute number of blood neutrophils and monocytes was also increased in 20–40% of the patients.

Differential diagnosis

The differential diagnosis of periodontal abscesses should always be made with other abscesses that can occur in the oral cavity. Acute infections, such as periapical abscesses, lateral periapical cysts, vertical root fractures, endo-periodontal abscesses, may have a similar appearance and symptomatology as a periodontal abscess, although with a clearly different

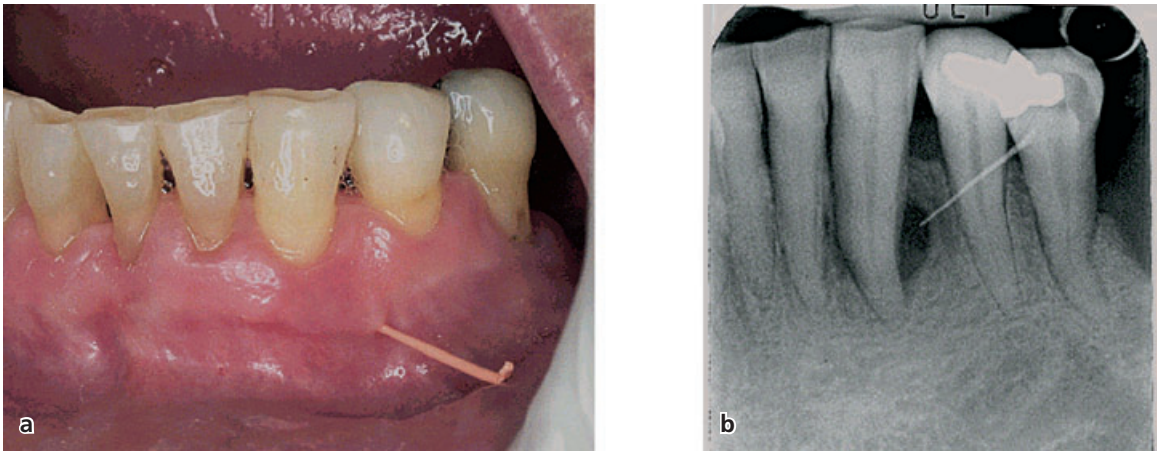

Fig. 22-6 (a) Periodontal abscess associated with a lower left canine. The fistulous tract opening is demonstrated with a gutta-percha point. (b) Radiologic image of the lower canine from (a). The differentiation from a periapical abscess was by the positive tooth vitality and absence of caries or restoration in the canine and the presence of a deep periodontal pocket in the lingual aspect of this tooth.

aetiology. Signs and symptoms indicating a more likely periodontal origin include: a history of periodontal disease or previous periodontal therapy; clinical signs of deep periodontal pockets releasing pus; frequently a vital pulp response; and radiographic findings of crestal bone loss, frequently associated with angular bone defects and furcations. On the contrary signs and symptoms indicating a more likely periapical (endodontal) origin will include: a history of caries, restorative or endodontic therapy; clinical signs of questionable or lack of response to pulp tests; presence of advanced caries lesions or restorations and the presence of a sinus tract; the radiographic findings will usually evidence the presence of a periapical radiolucency associated with either a carious or restored tooth or an endodontically treated tooth showing more or less endodontic filling or endodontic or post perforations.

Other lesions may appear in the oral cavity with a similar appearance as a periodontal abscess. Parrish *et al.* (1989) described three cases of osteomyelitis in periodontitis patients, initially diagnosed as periodontal abscesses. Different tumors may also have the appearance of a periodontal abscess. Such tumors include gingival squamous cell carcinoma (Torabinejad & Rick 1980; Kirkham *et al.* 1985), a metastatic carcinoma from pancreatic origin (Selden *et al.* 1998), a metastatic head and neck cancer (Elkhoury *et al.* 2004), and an eosinophilic granuloma diagnosed by rapid bone destruction after periodontal therapy (Girdler 1991). In cases where the abscess does not respond to conventional therapy, a biopsy and pathologic diagnosis are recommended (see also Chapter 16).

Treatment

The treatment of the periodontal abscess usually includes two stages: (1) the management of the acute lesion, and (2) the appropriate treatment of the original and/or residual lesion, once the emergency situation has been controlled.

For the treatment of the acute lesion, different alternatives have been proposed ranging from: (1) incision and drainage, (2) scaling and root planing, (3) periodontal surgery, and (4) the use of different systemically administered antibiotics. Some authors have recommended a pure mechanical treatment with either surgical drainage through the pocket, or scaling and planing of the root surface and compression and debridement of the soft tissue wall (Ahl *et al.* 1986; Ammons 1996). This mechanical therapy may cause irreversible damage to healthy periodontal tissues adjacent to the lesion. Such damage may particularly occur when the swelling is diffuse or is associated with marked tissue tension. In order to avoid this damage to healthy periodontal tissue other authors recommend the use of systemically administered antibiotics as the only initial treatment in abscesses with marked swelling, tension, and pain. In such instances, once the acute condition has receded, mechanical debridement, including root planing, should be performed.

The clinical evidence of the efficacy of these different therapeutic approaches is scarce, since only few clinical studies have assessed the efficacy of abscess therapy. Smith and Davies (1986) studied 62 abscesses in 55 patients. Their proposed treatment included incision, drainage, and systemic metronidazole (200 mg, tid for 5 days) and after the acute phase, regular periodontal treatment. Hafström *et al.* (1994) recommended supragingival debridement, together with systemic tetracycline therapy for 2 weeks, and reported good clinical outcomes when drainage and irrigation were added to the protocol. Similar good results were obtained in a controlled parallel study in which two systemic antibiotic regimes (amoxicillin/clavulanate, 500 + 125 mg, tid for 8 days; and azithromycin, 500 mg, once per day for 3 days) were used as the only treatment during the phase of initial

Fig. 22-7 (a) Treatment of a periodontal abscess with systemic antibiotics (azithromycin, 500 mg for 3 days) without any mechanical therapy. Baseline situation. (b) 5 days after antibiotic therapy. (c) 12 days after antibiotic therapy, just before the final periodontal instrumentation.

therapy. This was followed by regular periodontal treatment once the acute phase was resolved (Herrera *et al.* 2000b). The study showed that the short-term clinical outcome with the use of both antibiotics regimens was successful and the infectious process and abscess symptomatology was controlled just by using systemic antibiotics without concomitant or prior debridement (Fig. 22-7). There was a rapid reduction of the pain, significant resolution of the oedema, redness, and swelling, and the suppuration almost entirely disappeared. Periodontal outcome measurements, such as bleeding and periodontal probing depth, were also significantly reduced. Short-term microbiological results demonstrated a reduction of the microbiota in the abscess, as well as the number of selected periodontal pathogens (Herrera *et al.* 2000b). However, none of the antibiotic therapies were able to resolve the infection entirely. This implies that mechanical debridement, sometimes including a surgical approach, is an essential measure in the definitive treatment of this lesion. Moreover, two different studies have provided information on the antibiotic susceptibility profiles of periodontal pathogens isolated from periodontal abscesses and have reported the presence of resistant strains (Herrera *et al.* 2000b; Jaramillo *et al.* 2005).

Table 22-1 shows a number of different antibiotics that may be used in the treatment of a periodontal abscess. Doses and regimes recommended may differ between different countries. In principle, a high dose of the antibiotic delivered during a short period of time, is recommended. If the patient is recovering properly, the antibiotic should not be given for more than a 5-day period.

Complications

Tooth loss

Periodontal abscesses have been suggested as the main cause for tooth extraction during the phase of supportive periodontal therapy (SPT) (Chace & Low 1993). A tooth with a history of repeated abscess formation is considered to be a tooth with a questionable prognosis (Becker *et al.* 1984). In a retrospective study, 45% of teeth with periodontal abscesses in a SPT population were extracted (McLeod *et al.* 1997). Another retrospective study including 455 of teeth with a questionable prognosis showed that 55 (12%) were lost after a mean of 8.8 years, and that the main reason for tooth extraction was periodontal abscess formation (Chace & Low 1993). Smith and Davies (1986) evaluated 62 teeth with abscesses; 14 (22.6%) teeth were extracted as initial therapy, and 9 (14.5%) after the acute phase. Out of the 22 teeth treated and subsequently monitored, 14 had to be extracted during the following 3 years.

Table 22-1 Antimicrobial agents that may be used in the treatment of periodontal abscesses

Antimicrobial agent	Effective against	Properties
Penicillin V	Streptococci, some strict anaerobes	Poorly absorbed, affected by β-lactamases, bactericidal
Amoxicillin	Most Gram-positive oral species, many Gram-negative	Well absorbed, affected by β-lactamases but can be protected by clavulanic acid, bactericidal
Cephalexin	Anaerobes, streptococci, strict anaerobes, facultative	Well absorbed, affected by β-lactamases, not against methicillin-resistant staphylococci, bactericidal
Ceftibuten	Gram-negative rods, broad-spectrum against Gram-negative and Gram-positive bacteria	Resistant to most β-lactamases, bactericidal, not effective against staphylococci, pseudomonads
Clindamycin	Gram-positive cocci including staphylococci	Bacteriostatic or bactericidal depending on local concentration and susceptibility of the pathogen, drug of choice in case of rapid local spread
Metronidazole	Gram-positive and Gram-negative anaerobes	Well absorbed, not effective against facultative bacteria, bactericidal
Azithromycin	Most anaerobes, Gram-positive and negative bacteria, many strict anaerobes	Good tissue concentration, bacteriostatic for most pathogens

Dissemination of the infection

A number of publications, mainly case reports, have described different systemic infections in different parts of the body, in which the suspected source of infection was a periodontal abscess. Two possible sources of dissemination have been described:

- Dissemination of the bacteria inside the tissues during therapy. A case of pulmonary actinomycosis was related to the treatment of a periodontal abscess, which was ultrasonically scaled 1 month earlier (Suzuki & Delisle 1984). A case of brain abscess was observed in a healthy patient with a periodontal abscess who was treated with drainage and curettage without systemic antibiotic 2 weeks earlier. The microbiology of the lesions demonstrated, among other bacteria, *Prevotella melaninogenica* and other *Bacteroides* sp. (Gallaguer *et al.* 1981). A retrospective study on total knee arthroplasty infections (Waldman *et al.* 1997) discovered that 9 out of 74 infections had been previously treated for an oral infection, including the drainage of a periodontal abscess.
- Bacterial dissemination through the blood stream due to bacteremia from an untreated abscess. Cellulitis in breast cancer patients have been reported following gingivitis or an abscess (Manian 1997), due to transient bacteremia and reduced host defenses (radiation therapy and axillary dissection). A periodontal abscess was associated with the development of a cervical necrotizing fasciitis (Chan & McGurk 1997). A necrotizing cavernositis was thought to be related to a severe periodontal infection, including three periodontal abscesses (Pearle & Wendel 1993).

Chapter 23

Lesions of Endodontic Origin

Gunnar Bergenholtz and Domenico Ricucci

Introduction

In the study of pathogenesis and causality of periodontal disease processes, lesions of endodontic origin are significant as they frequently extend and manifest themselves in the attachment apparatus. Not only do these lesions produce signs and symptoms of inflammation in apical areas of teeth, they may also induce tissue destruction along the lateral aspects of roots and in furcations of two- and multirooted teeth. In either instance, the lesions are maintained by noxious elements that derive from the pulpal space along openings to the periodontal tissues. Channels connecting the two tissue compartments include foramina at the apex and lateral ramifications termed accessory canals.

Microorganisms residing in necrotic areas of a more or less broken down pulp usually maintain these lesions. Lesions of endodontic origin may also appear or prevail following endodontic treatment. In these cases, treatment measures, aimed at either preventing the establishment of a root canal infection or getting rid of an already manifest infection, have been unsuccessful. As root canal infections have been assumed to have an impact on both the progression of periodontitis and the potential to achieve optimal results of periodontal therapy, the first part of this chapter describes the specific features and dynamic events that are associated with lesions of the pulp and the manner by which they may interfere with the periodontium.

The fact that the periodontium and the dental pulp are anatomically interconnected also implies that exchange of noxious agents may also occur in the opposite direction, that is from the external environment to the pulp. A prerequisite for this is that those communication pathways that are normally secured by healthy periodontal tissue have been uncovered. This will occur as periodontal disease advances. The lesion of the pulp that may follow may involve both pain and tissue destruction. Resorptive processes and treatment measures aimed at managing periodontal disease enhance this potential as the accompanying exposure of dentinal tubules, by loss of cementum, establishes yet another passage across the body of the tooth structure. In fact, a common complication to periodontitis and periodontal therapy is an ailment commonly termed root dentin hypersensitivity, a condition associated with the direct exposure of root dentin to the oral environment (Gillam & Orchardson 2006).

The second part of this chapter is concerned with the consequences for the vital pulp of root surface exposure by periodontal disease and periodontal therapy. It also covers aspects of the mechanisms and management of root dentin hypersensitivity.

Disease processes of the dental pulp

Causes

The dental pulp is normally well protected from injurious influences by an intact hard tissue encasement and by a healthy periodontium. The healthy condition of the pulp, however, is regularly challenged under clinical conditions. While some adverse influences are of minor significance and cause only negligible tissue injury and minimal discomfort to the

patient, others threaten the pulp's vital functions and can result in infectious complications, with effects both locally and systemically. Lesions of the pulp may have either a direct infectious background or may be induced by non-infectious injury. Both causes will be covered here in some detail.

Of non-infectious impairments, accidental trauma causing rupture of the neurovascular supply at the apex and major internal bleeding represents a distinct threat to the vitality of the pulp. Hence, concussions, sub-luxations, and various forms of tooth displacements may result in widespread ischemia leading to complete necrosis of the tissue. As the potential for tissue regeneration is slim in the fully developed tooth (Kristerson & Andreasen 1984), such pulp tissue necrosis, although not primarily infected, acts as a target for microbial invasion. The infecting microorganisms usually originate from the oral cavity. Following their penetration of cracks in the enamel and the dentinal tubules, multiplication in the necrotic pulp results in the development of inflammatory lesions of the periodontal tissues (Bergenholtz 1974; Sundqvist 1976).

Most pulpal conditions are initiated and maintained by infectious elements that access the pulp following loss of hard tissue integrity. Tooth destruction by caries is by far the most common source of bacterial exposure and is especially threatening when the lesion has reached the vicinity of the pulp tissue proper (see further below). Also fractures of teeth and dental restorative work bring an inherent risk for detrimental bacterial effects, should a restoration fail to seal completely the defect in the tooth substance (see review by Bergenholtz 2000). Most risky are extensive restorative works like full coverage crowns, which often require substantial sacrifice of healthy tooth tissue. Clearly in the short term, before the permanent restoration is cemented, the tissue exposure is subject to bacterial leakage along the margins of the temporary restoration, especially if it is poorly adapted to the remaining tooth substance. Yet, even though the pulp may have survived the initial stress of the cutting trauma and the leakage of bacterial elements, the injury induced usually results in considerable repair phenomena (scars). Such tissue changes involve hard tissue depositions and soft tissue fibrosis, which occur at the expense of vascularity and nerve tissue support (Bender & Seltzer 1972). Tissue alterations of this nature logically result in impaired immune defense function and, thus, reduce the potential for the pulp to resist future bacterial challenges.

Clinical follow-ups of teeth supplied with single crowns or included as abutments in bridge works have indeed demonstrated that pulp tissue necrosis is not a rare complication and may affect 10–20% of the observed teeth over a 10–15-year period (Bergenholtz & Nyman 1984; Karlsson 1986; Saunders & Saunders 1998; Cheung *et al*. 2005). In fact, the incidence of loss of pulpal vitality has been reported to increase over the course of time (Bergenholtz & Nyman 1984; Cheung *et al*. 2005). A similar increasing rate of pulpal infections has also been reported for young permanent teeth suffering traumatic ischemic injuries where pulps have been partly or completely replaced by hard tissue repair (Jacobsen & Kerekes 1977; Robertson *et al*. 1998).

Conclusion

Injurious elements that may put the vital functions of the pulp at risk include deep caries, accidental trauma, and dental restorative procedures. A single insult, such as a traumatic injury, may cause an immediate breakdown of the tissue by severing the neurovascular supply. In other instances tissue breakdown is preceded by a direct bacterial exposure or following tissue repair to non-infectious and infectious insults.

Progression and dynamic events

Although any injury may have serious implications for the vitality of the pulp, its ability to withstand insults, especially of a microbial nature, is far better if an intervening layer of dentin remains than if the tissue is directly exposed through the hard tissue barrier. In the former case even a thin dentin wall, although permeable, usually allows the pulp to mount an appropriate inflammatory response to offset bacterial threats. The common observation that the pulp rarely suffers breakdown underneath a caries lesion confined to dentin is strong evidence of the pulp's defense potential (Reeves & Stanley 1966; Massler 1967; Kamal *et al*. 1997; see also review by Björndal & Mjör 2001). The mechanisms involved relate both to innate and adaptive immune responses (Hahn *et al*. 2003; Dommisch *et al*. 2005; Durand *et al*. 2006; for a review see also Jontell *et al*. 1997) as well as to changes in dentin that constrict its permeability (for reviews see Pashley 1996; Bergenholtz 2000).

Experimental evidence to this effect derives from observations in both humans (Lundy & Stanley 1969; Warfvinge & Bergenholtz 1986) and animals (Lervik & Mjör 1977; Warfvinge & Bergenholtz 1986; Taylor *et al*. 1988). In some of these studies test cavities were prepared deep into dentin and were left unrestored to the oral environment (Lundy & Stanley 1969; Taylor *et al*. 1988). In other experimental series, similar cavities were challenged with soft carious dentin (Mjör & Tronstad 1972; Lervik & Mjör 1977) or components of dental plaque bacteria (Bergenholtz & Lindhe 1975; Warfvinge & Bergenholtz 1986). Reflecting the permeability of dentin to microbial elements, inflammatory sequels consisting of increased vascular permeability, migration of polymorphonuclear leukocytes (PMNs) (Bergenholtz & Lindhe 1975; Warfvinge & Bergenholtz 1986), and nerve fiber sproutings (Taylor *et al*. 1988) rapidly emerged in the pulp adjacent to the exposed dentinal tubules. The

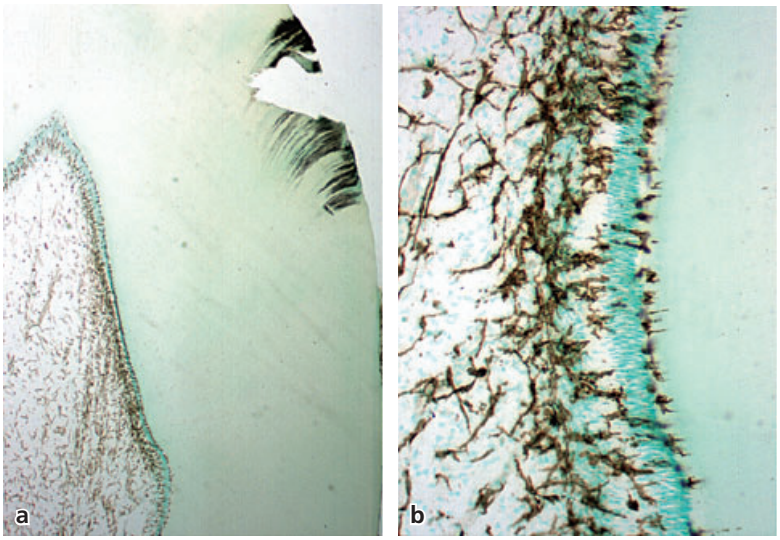

Fig. 23-1 (a) Defense response of a human dental pulp to superficial caries in dentin (defect and dark stain at upper right hand corner) as represented by increased accumulation of Class II molecule-expressing cells of a dendritic morphology. (b) Extensions of cytoplasmatic processes into the dentinal tubules are numerous. Images kindly provided by Dr. Takashi Okiji.

adapative immune defense is also activated at very early stages as indicated by an increased presence of antigen-presenting cells (Jontell *et al*. 1997). Indeed, dendritic cells appear soon in an area of the pulp next to both cavity preparations (Ohshima *et al*. 1995) and superficial caries (Kamal *et al*. 1997) (Fig. 23-1). Yet, over the course of time, these responses subside and reparative dentin and soft tissue repair emerge, along with a reduction of immunocompetent cells, at the site of the previous inflammatory event (Lundy & Stanley 1969; Lervik & Mjör 1977; Warfvinge & Bergenholtz 1986; Kamal *et al* 1997). In the experiments involving unrestored human teeth (Lundy & Stanley 1969), patients experienced pain and increased sensitivity of the exposed dentin along with the initial inflammatory episode. As repair and healing progressed the pain symptoms disappeared.

An important point is that although inflammatory responses develop rapidly and early to bacterial challenges, microorganisms *per se* are rarely able to penetrate the dentinal barrier and enter the pulp tissue, so long as it retains vital functions. Staining for bacteria in the histologic analysis of Lundy and Stanley (1969), for example, revealed that in no case, observed after 2–240 days, were organisms traced in the pulp tissue proper, while the exposed dentinal tubules were invaded to a varying extent. This finding once again demonstrates that dentin and pulp in concert are able to oppose bacterial threats.

By contrast, direct exposure of the pulp to the oral environment puts its vital functions at risk as bacteria in the oral cavity now may gain direct access to the tissue. Even a minuscule exposure is critical, unless properly treated, as there is little self-healing capacity by virtue of epithelium that can bridge the defect. Defense mechanisms may therefore prevent bacterial invasion of the pulpal space for only a limited period of time.

Three clinical cases, displayed in Figs. 23-2 to 23-4, demonstrate how pulpal inflammatory processes may typically develop and progress to the adjoining periodontal tissues. In these cases, caries has advanced to expose the tissue at an earlier point in time.

In the first example (Fig. 23-2) an inflammatory lesion is present at the site where caries has exposed the pulpal tissue. A rather thick layer of reparative dentine has formed at the roof of the pulp chamber next to the exposure indicating a repair response to previous irritation (Fig. 23-2a). Note that, except for the lesion area, the pulp displays normal tissue morphology with intact odontoblast layers lining the periphery of the tissue. Bacteria have accumulated (blue stains in dentin) near the exposure site (Fig. 23-2c). The high magnification in Fig. 23-2d reveals numerous bacterial profiles in the pulp as well, where they are opposed by infiltrating PMNs in the lesion area. In this particular case the inflammatory process was clearly localized and both radiographic (Fig. 23-2a) and histologic examination gave no indication of interference with the periodontium.

A more advanced pulpal lesion is demonstrated in Fig. 23-3, where the inflammatory response to the distally located caries process in the lower molar has extended to the furcation area along a wide accessory canal (23-3b). Intrafurcal alveolar bone is resorbed and has been replaced by inflammatory tissue displaying proliferating epithelium (23-3c). There is also an apical radiolucency at the distal root, while the apical region of the mesial root seems unaffected (23-3a).

A third case (Fig. 23-4) shows necrosis of the coronal pulp following what has obviously been a rather long-standing caries process in a lower first molar. There are radiographic signs of apical periodontitis on both the distal and the mesial roots and a widened periodontal ligament space in the furcation (Fig. 23-4A). At the mesial aspect of the tooth, gingival tissue has proliferated into the pulp chamber (Fig. 23-4B). Figure 23-4C displays an area of the pulpal space at the entrance of the distal root canal,

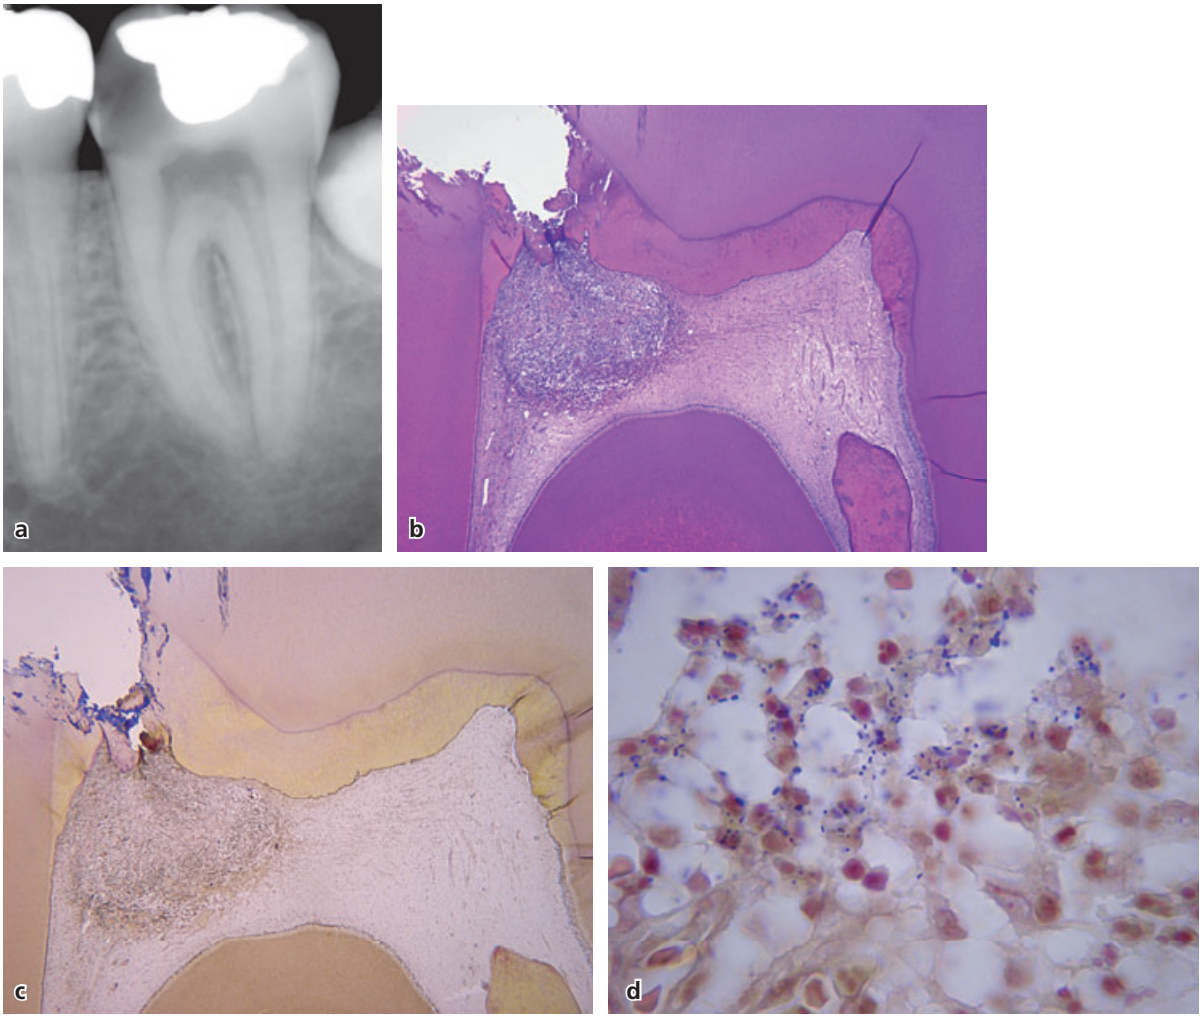

Fig. 23-2 (a) Second lower molar from a 30-year-old man with deep caries at the mesial aspect. Before extraction of the tooth the patient had presented with typical signs of pulpitis including percussion sensitivity and radiating pain. (b) A localized inflammatory response is present in the pulp adjacent to the site of caries penetration without spreading. In a section stained for bacteria (c) organisms are seen at the exposure site (blue stain) as well as in the inflammatory tissue lesion *per se* (d) (see also text).

where the pulp is necrotic and where bacterial organisms have aggregated on the canal walls in a biofilm structure. Further down in the middle portion of the root, numerous PMNs meet the bacterial front and are engaged in phagocytic activities (Fig. 23-4D and inset). In more apical portions of the canal, numerous widened blood vessels are seen along with an infiltrated pulp connective tissue (Fig. 23-4E). The most apical portion of the pulp shows normal tissue structure (Fig. 23-4G), which also applies to the soft tissue attached to the root tip (Fig. 23-4F and inset) representing the apical radiolucency at the distal root in Fig. 23-4A.

Conclusion

The cases selected demonstrate an important function of the inflammatory defense in general that also applies to the dental pulp, which is to confine infectious elements and limit spread to other body compartments. The cases also demonstrate that a pulpal lesion has its prime focus at the source of the bacterial exposure. Hence, it is only following extension due to breakdown of the pulp and advancement of the bacterial front that periodontal tissue involvement is imminent. In some cases this may occur at a rather early stage of the pulp tissue lesion if an accessory canal is open to the marginal periodontium such as in the case in Fig. 23-3. In the absence of accessory canals extensive breakdown of the pulp is first required before the periodontal tissues may become engaged.

Accessory canals

Accessory canals are lateral ramifications off the root canal system that connect the neurovascular system of the pulp with that of the periodontal ligament. Such anastomoses are formed during the early phases of tooth development, but may become blocked or reduced in width during the completion of root formation. Patent communications of varying sizes, numbers and locations, however, may remain in the fully developed tooth and serve as additional

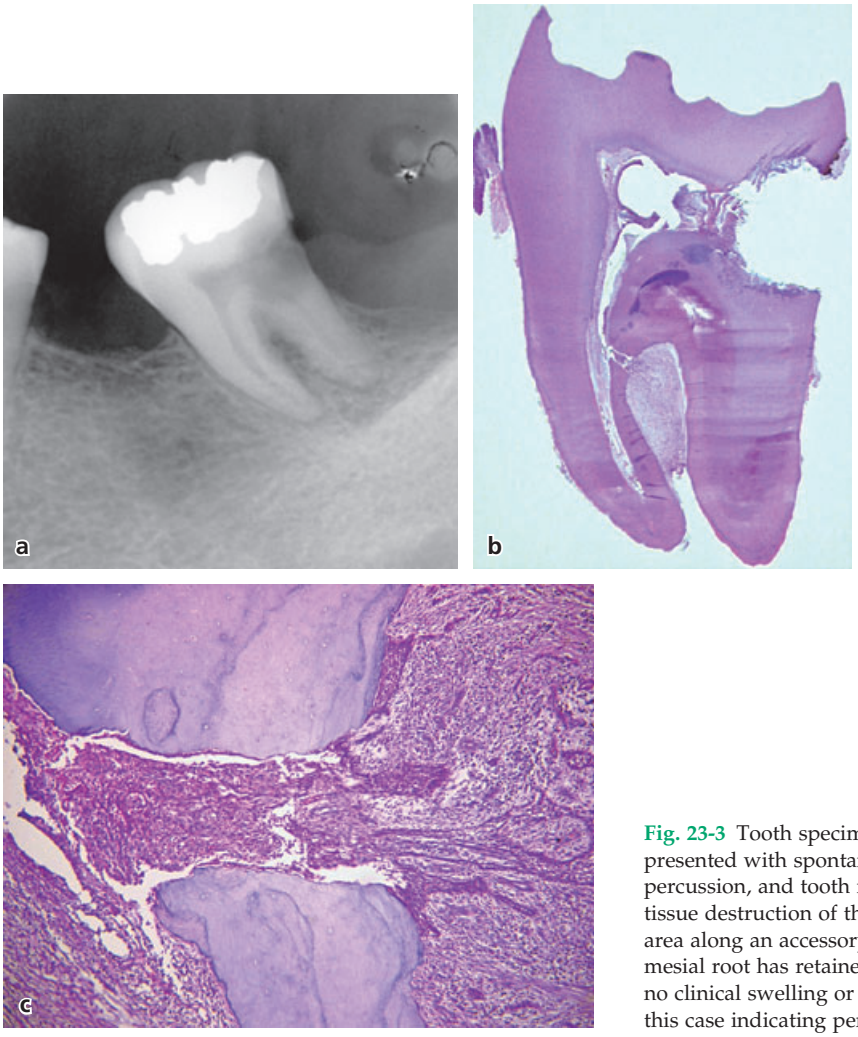

Fig. 23-3 Tooth specimen of a 48-year-old man, who presented with spontaneous pain, pain on mastication, percussion, and tooth mobility. An extensive inflammatory tissue destruction of the coronal pulp extends into the furcal area along an accessory canal. More apically, the pulp of the mesial root has retained normal tissue structures. There was no clinical swelling or remarkable pocket probing depth in this case indicating periodontal involvement (see text).

pathways for the neurovascular supply of the pulp beyond that of the main apical foramen.

Accessory canals can be observed in all groups of teeth. In fact, careful examinations of large numbers of extracted teeth, rendered transparent and injected with contrasting medium in the pulp chamber to allow three-dimensional visualizations, have revealed accessory canals in cervical and middle-root areas as well as in the apical root portions (DeDeus 1975; Vertucci 1984). Clearly the majority is found apically, whereas the prevalence tapers off in the middle and cervical root segments (DeDeus 1975; Vertucci 1984). In a study of 1140 extracted human teeth from adult subjects, De Deus (1975) reported accessory canals in 27% of the examined teeth. These canals were distributed at various levels of the root as depicted in Fig. 23-5.

Molars harbor accessory canals more frequently than premolars and anterior teeth. Patent canals are especially common in the furcation areas, where they have been found in between 20% and 60% of examined teeth (Lowman *et al*. 1973; Vertucci & Williams 1974; Gutmann 1978; Vertucci 1984). Vertucci (2005) has distinguished between different directions of entry by which accessory canals go into the furcation of mandibular molars. In some cases they run more or less vertically from the pulpal chamber. They may also extend off either root canal in a horizontal direction of which 80% derive from the distal root canal (Vertucci 2005) (Fig. 23-6).

When accessory canals do occur, the potential dissemination of inflammatogenic elements from a diseased pulp to the periodontium is obvious. There is no documentation yet available to indicate how often such lesions develop. Although clinical observations demonstrate occurrence (Figs. 23-3, 23-7, 23-8), the rate at which endodontic lesions appear in the marginal periodontium from accessory and furcation canals seems to be low, as indicated by lack of reports of this being a significant clinical problem. It is to be expected that the wider accessory canals are, the greater is the likelihood for overt lesions to develop. Diameters of furcation canals in mandibular molars for example have been reported to vary from just a few microns to 720 microns (Vertucci 2005). Consequently, thin accessory canals, with the potential to mediate some release of infectious substances, may not cause more than a minor periodontal reaction that goes clinically undetected.

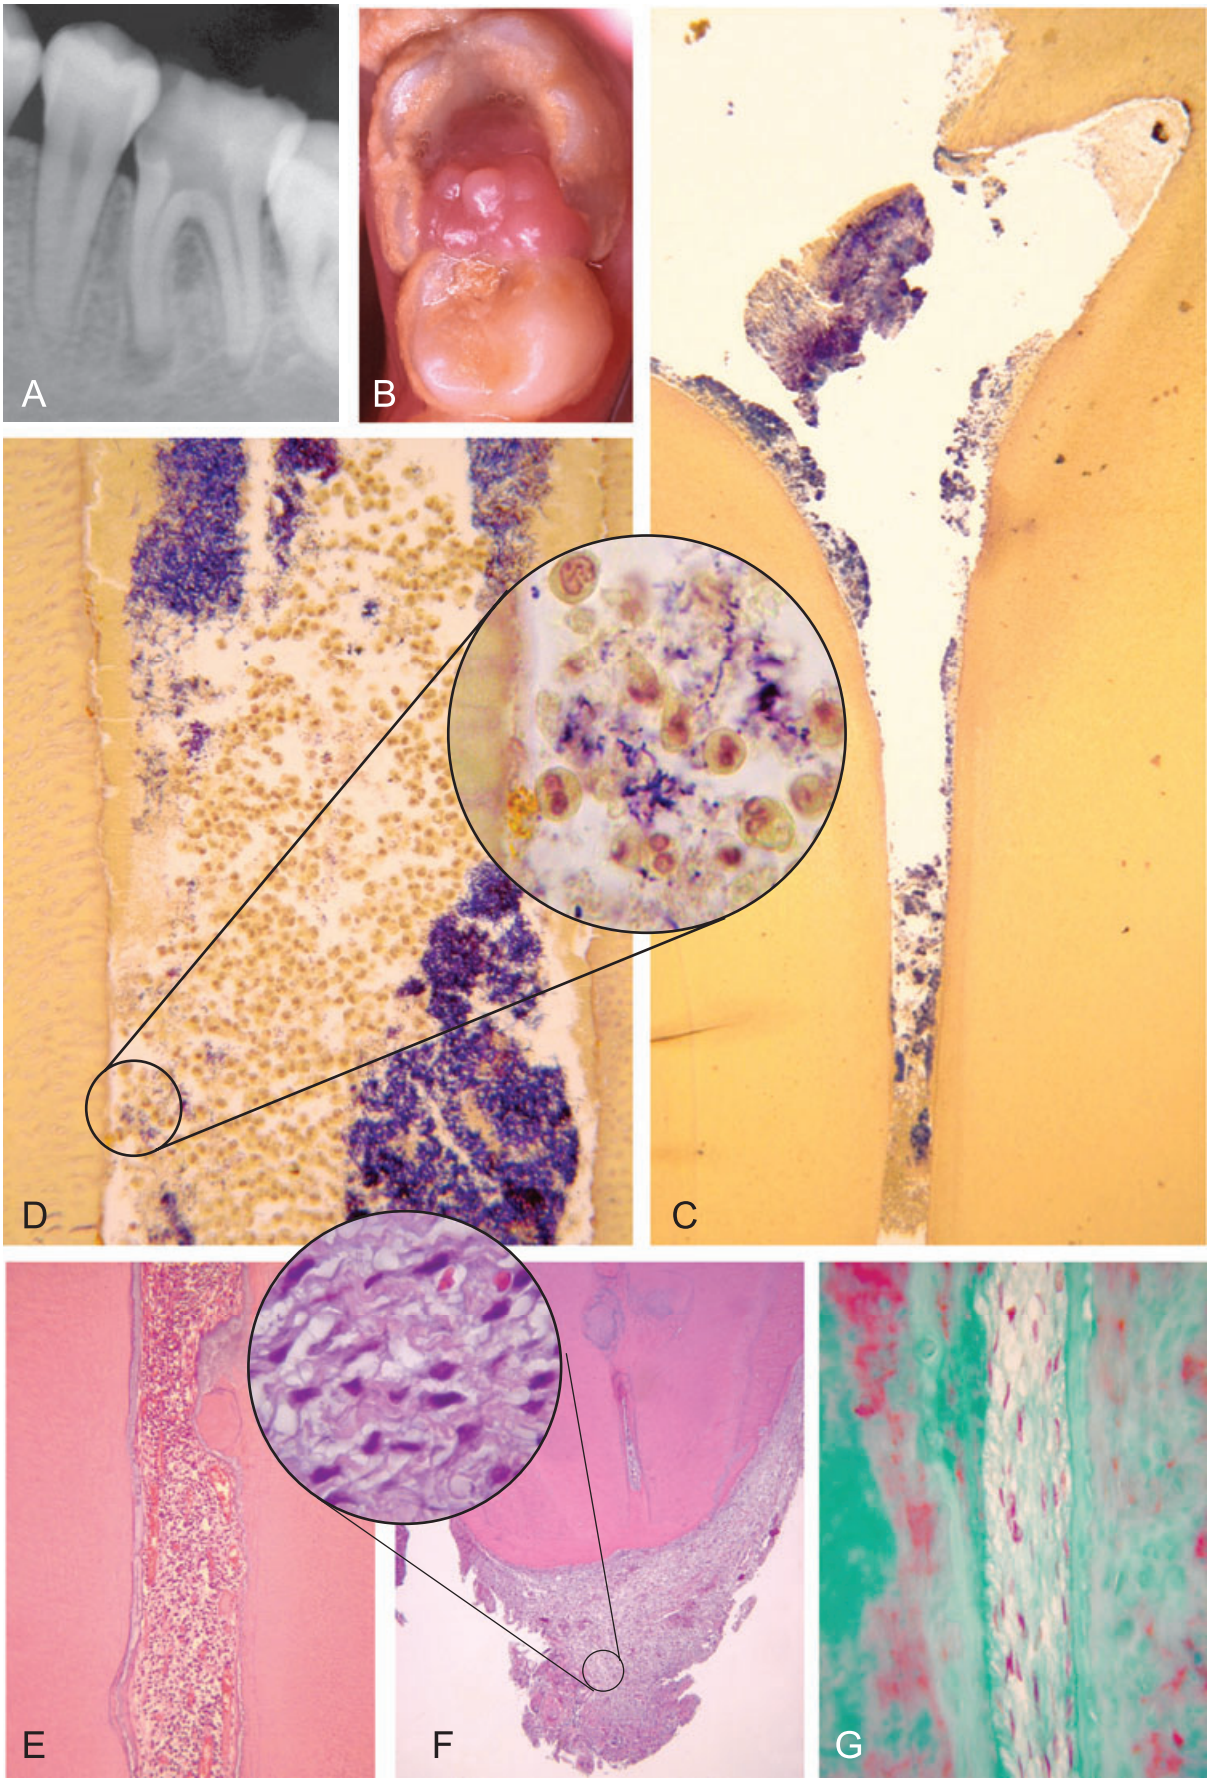

Fig. 23-4 Tooth specimen of a 19-year-old female with extensive caries in a 1st lower molar that has led to partial pulp tissue breakdown, bacterial invasion, and establishment of an inflammatory defense line inside the pulpal space (see text). Fig. 23-5 Frequency of accessory canals at different levels of the root. The data are average values obtained from DeDeus (1975). Observations were made after teeth had been rendered transparent and the root canal system filled with India ink. The figures given for the coronal portion include those of bi- and trifurcations of two- and multi-rooted teeth.

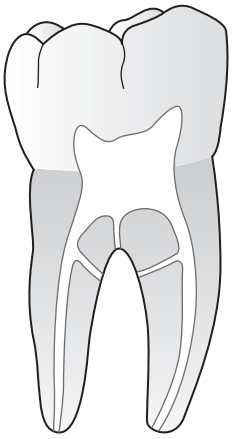

Fig. 23-6 Furcal canals of two- and multirooted teeth, when present, may extend into the periodontium from the pulpal space either in a horizontal or vertical direction or both. Drawing adapted from Vertucci (2005).

Conclusion

Although they occur, the large majority of teeth lack accessory canals in their cervical and middle root regions. This fact may explain why pulpal inflammatory lesions rarely are seen extended to the marginal periodontium. Most often they become centered around root apices only. When present with a diameter similar to that of the apical foramen, accessory canals can certainly mediate lesions of endodontic origin in the marginal periodontium. In endodontically treated teeth iatrogenic root perforations, carried out in conjunction with root canal instrumentation or post preparations, may serve as yet another pathway for dissemination of noxious elements to the periodontium (see Chapter 40).

Periodontal tissue lesions to root canal infection

The ultimate outcome of an inflammatory breakdown of the pulp is microbial take over of the pulpal space (Fig. 23-9). As host defense mechanisms are unable to reach far into root canals of necrotic pulps in order to combat the infection and pave the way for regeneration of pulpal tissue, an inflammatory defense zone is established in the periodontal tissues at exits of accessory canals and apical foramina. Hence, lesions of this nature remain as chronic processes unless subjected to treatment. Because the inflammatory process most frequently becomes positioned near root apices, the term apical periodontitis is commonly employed. As lesions may also develop along the lateral aspects of roots, the expression endodontic lesion will be used throughout this text to denote a periodontal lesion in any position that is sustained by noxious elements of endodontic origin.

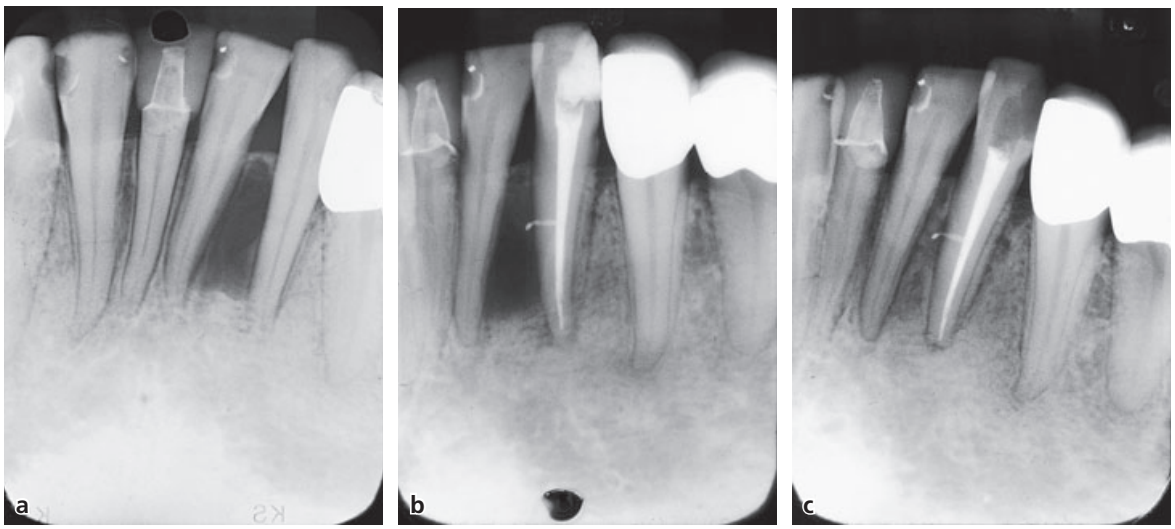

Fig. 23-7 (a) A lateral, alveolar bone destruction is observed between the roots of teeth #31 and #32. (b) The lesion in this case turned out to be associated with an accessory canal (filled in conjunction with the root filling procedure) emanating from an infected root canal in tooth #32. Fig. 23-8 Radiographs of a lower premolar molar; (a) prior to endodontic treatment, (b) prior to extraction due to extensive caries 11 years after endodontic treatment. (c, d) Cleared specimens show numerous accessory canals filled with root filling material. (e) Histologic examination shows that accessory canals are only partially filled (black material interspersed with inflammatory tissue).

The bacterial organisms that are able to initiate and maintain endodontic lesions have been studied in great detail over the years, primarily by sampling infected root canals followed by laboratory processing and phenotypic identification. The purpose of such studies has been to identify organisms that are prevalent and which can be linked to more or less aggressive forms of apical periodontitis (see below). In recent years molecular identification methods, including the polymerase chain reaction (PCR), have been used to supplement the picture (for reviews see Siqueira & Rocas 2005a; Spratt 2004). Indeed it has

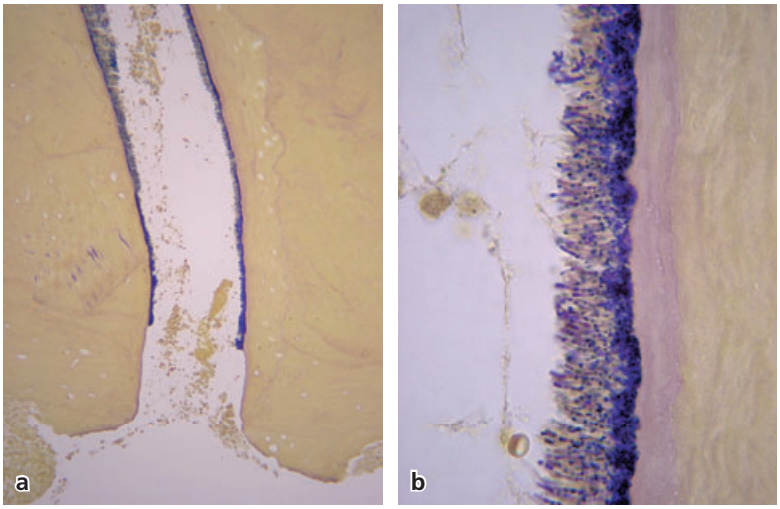

Fig. 23-9 (a) Tooth specimen with complete absence of pulp tissue. (b) Filaments and coccoid organisms are seen attached in a biofilm to the root canal walls. From Dr Ricucci's collection, images previously published by Svensäter & Bergenholtz (2004).

been demonstrated that many more species are involved than previously anticipated and the concept that only a limited group of 20–30 common isolates are associated with these lesions is currently being reassessed (Siqueria & Rocas 2005a,b; Siqueria *et al.* 2005). Yet, the microbiota in primary endodontic infections show features similar to that of deep periodontal pockets (Kerekes & Olsen 1990) and anaerobes usually have a dominant role. Spirochetes (Dahle *et al*. 1996; Rocas & Siqueria 2005; Foschi *et al*. 2005) and fungi (Waltimo *et al*. 1997; Peciuliene *et al*. 2001; Egan *et al*. 2002) may also reside in infected root canals and may contribute to the maintenance of these lesions. By contrast persistent infections subsequent to endodontic treatments seem less dominated by anaerobes and cultivation studies have demonstrated high prevalences of Gram-positive facultatives (Molander *et al*. 1998; Sundqvist *et al*. 1998; Chavez de Paz *et al*. 2003; Gomes *et al*. 2004; Forschi *et al*. 2005).

Although not comprehensively studied, root canal infections most likely involve attachment of bacterial organisms to the root canal walls and the development of microbial communities in biofilms (Fig. 23-9) (Svensäter & Bergenholtz 2004). Organization in biofilms affords these organisms better protection against host defense mechanisms in comparison to their planktonic counterparts, but they are detached from such sites and dispersed for colonization at other body sites. Root canal bacteria usually have limited potential to survive in the periodontal tissue lesion *per se* although bacterial organisms can be found in acute abscesses (Oguntebi *et al*. 1982; Williams *et al*. 1983; Lewis *et al*. 1986). It should also be mentioned that case reports have indicated that *Actinomyces*-related species occasionally may invade the tissue lesion and aggregate in clusters or nests that elude host tissue elimination (Sundqvist & Reuterving 1980; Happonen *et al*. 1986). Yet in most instances bacteria are confined to the root canal space (Nair 1987). While the front line may be established at the orifice of the canal (Fig. 23-10), the host tissue–bacterial interface zone usually becomes localized well inside the root canal exits (Nair 1987) (Fig. 23-11). In what may be a rare situation (Siqueira & Lopes 2001), bacterial organisms in primary endodontic infections may overcome the host defense and aggregate as a biofilm on the outer root surface (Lomcali *et al*. 1996) (Fig. 23-12). Such structures have also been observed on root ends of teeth which have not responded favorably to endodontic treatment (Tronstad *et al*. 1990).

The shape and character of the periodontal tissue response to a root canal infection may vary. Often lesions assume a limited and stable extension around root apices and/or at orifices of accessory canals. The inflammatory process may then remain unchanged in size for years, although cyst transformation can result in substantial destruction of alveolar bone (Fig. 23-13). However, the initial expansion of an emerging lesion or acute exacerbation of a chronic lesion, can result in rapid and extensive destruction of the attachment apparatus. In certain cases the periodontal tissue support can be lost to an extent that the gingival sulcus is involved, from where drainage of pus occurs to the oral environment (Fig. 23-14). Such an apical marginal communication along the root surface may later become a permanent pathway for pus that will be released periodically along what is simply a fistulous tract.

The character of the infecting microbiota, its metabolic activity, and the virulence factors it produces, together with the capacity of the host defense to confine and neutralize the bacterial elements, are important parameters that decide the course of the inflammatory process. Hence, growing and multiplying organisms with capacities to invade the periodontal tissues and evade host defense mechanisms mediate acute manifestations of endodontic lesions. Single organisms are normally unable to cause these lesions, which are maintained by groups of organisms; virulent strains of *Porphyromonas*, *Prevotella*, *Fusobacterium* and *Peptostreptococcus* spp. have been implicated by culture studies (Dahlén 2002). Recent

reports utilizing PCR methodology have inferred that a variety of other species, unrecognized by culture, may be of prime importance (Rocas & Siqueria 2005; Sakamoto *et al*. 2006). Given the recent surge in use of molecular methods to map the structure of the endodontic microbiota, it is likely that, in the future, a clearer understanding will be gained of the key organisms which cause acute manifestations of endodontic infections.

The endodontic microbiota associated with asymptomatic lesions is apparently less aggressive. This condition is likely to be linked to the harsh nutritional supply that usually prevails in root canals and which puts the organisms in a low state of metabolic activity. Nutrients are available primarily from tissue components of the necrotic pulp. In the absence of inflammatory exudate entering the root canal along apical foramina and accessory canals, organisms will consequently have little drive to grow, multiply, and invade the periodontal tissue compartment. When this condition of relative starvation is broken by increase of the nutritional supply, an acute endodontic lesion may occur. Suppressed virulent strains can then be revived and become the dominant organisms

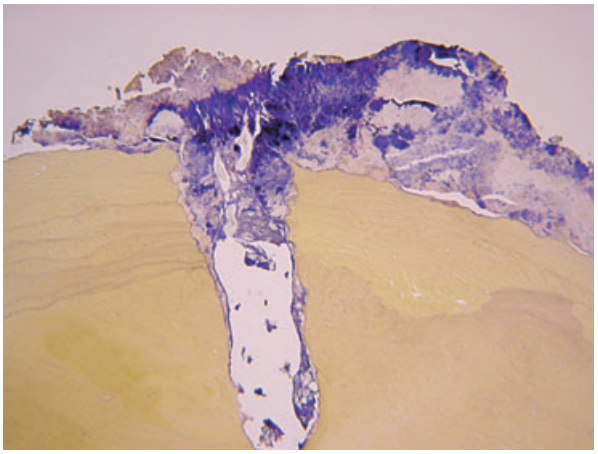

Fig. 23-12 Accumulation of bacterial mass (blue stain) at the external root surface of a tooth with an infected necrotic pulp. From Ricucci & Bergenholtz (2004).

at the expense of the less virulent members of the microbial community. Consequently, acute exacerbations of asymptomatic endodontic lesions may occur, for example, when saliva and gingival exudates gain access to the root canal space following a direct exposure of root canals to the oral environment. Similarly during endodontic treatment, inadvertent enlargement of the apical foramen increases the passageway for protein-rich inflammatory exudate into the root canal space.

While acute manifestations of endodontic lesions are characterized by expanding bone resorption, exudation and influx of phagocytic cells, a balanced host–parasite relationship will be established sooner or later (Stashenko 1990; Nair 1997; Stashenko *et al*. 1998). Microscopically, the established lesion is characterized by a richly vascularized granulation tissue, which is infiltrated, to a varying degree, by inflammatory cells (Fig. 23-15). PMNs play a most

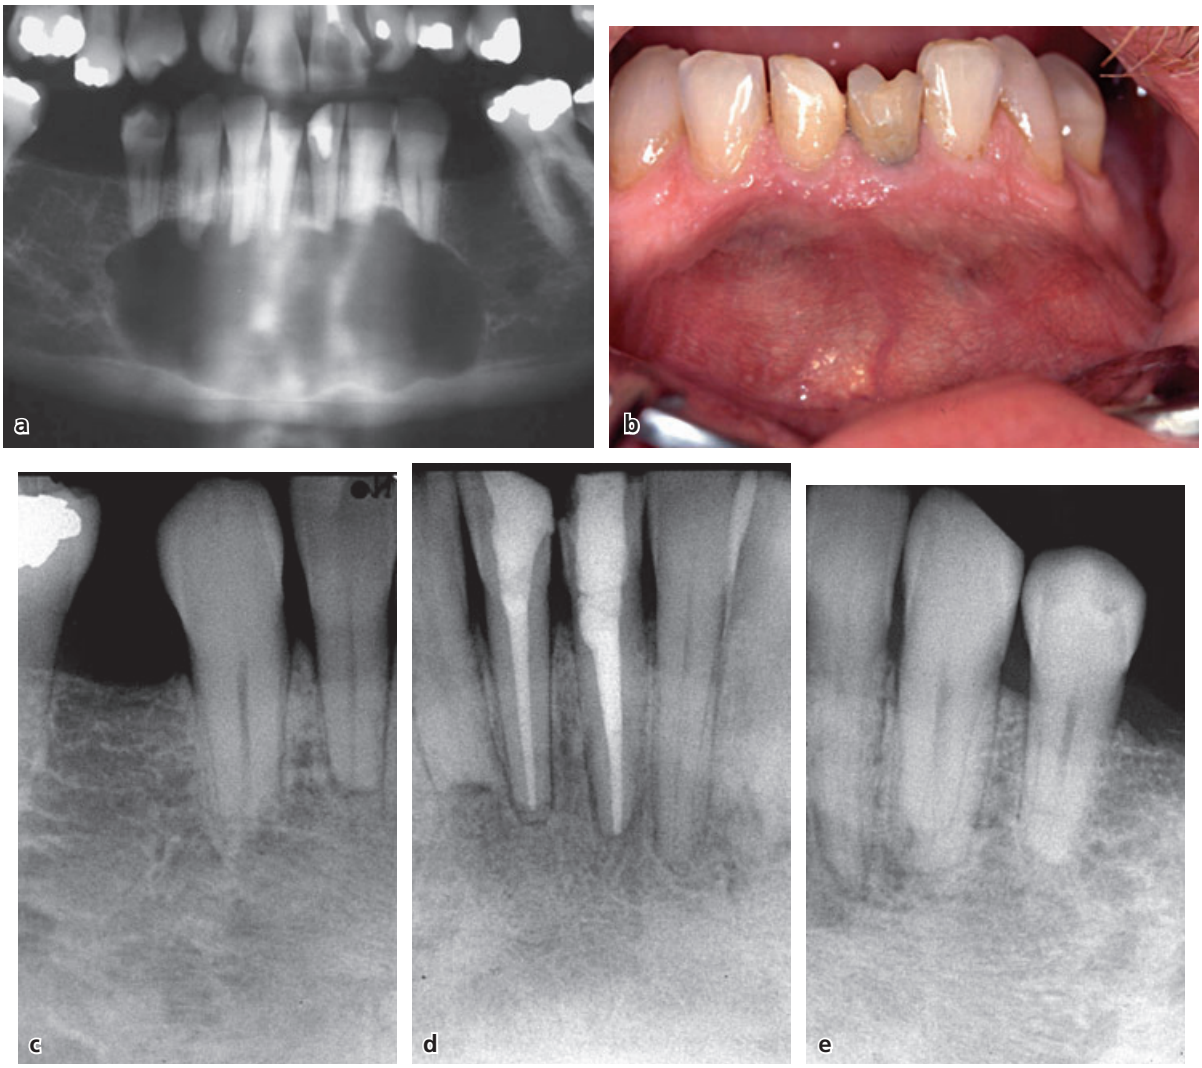

Fig. 23-13 Extensive destruction of alveolar bone as a result of cyst transformation of a periapical lesion emanating from tooth #31. (a) Note root resorption of neighboring teeth. (b) Buccal protrusion of the process was non-painful to palpation. All teeth responded vital to pulp testing except for the root filled teeth #31 and #41. The latter tooth, however, had a vital pulp as revealed on accessing the root canal. Treatment, carried out in collaboration with Dr. Ulf Lekholm, included placement of an oburator for drainage, decompression, and saline irrigation of the cyst cavity over 6 months. Following its reduction, teeth #31 and #41 received completion of endodontic treatment and a residue of the process was excised surgically. (c–e) Complete resolution of the process 10 months post surgery.

Fig. 23-14 Drainage of pus upon periodontal probing from a lesion of endodontic origin associated with an upper molar.

important role in confining the infection to the pulpal space (Stashenko *et al*. 1995) and constitute an important cellular front line (Fig. 23-11). The remainder of the lesion will be composed of a mixed cellular response (Fig. 23-15c) typical of a longstanding infectious process where various immunocompetent cells (*viz.* dendritic cells, macrophages, T and B cells) are prevalent (Torabinejad & Kettering 1985; Babal *et al*. 1987; Okiji *et al*. 1994; Stashenko *et al*. 1998; Marton & Kiss 2000). With increasing distances from the root canal apertures, the established lesion harbors a decreasing number of inflammatory cells and an increasing amount of fibrovascular elements representing attempts at repair. More peripherally there is a much stronger expression of fibroblastic activity and formation of new vessels. In the most peripheral portions of the lesion, a collagen-rich connective tissue normally separates it from the surrounding bone tissue (Bergenholtz *et al*. 1983) (Fig. 23-15a,d).

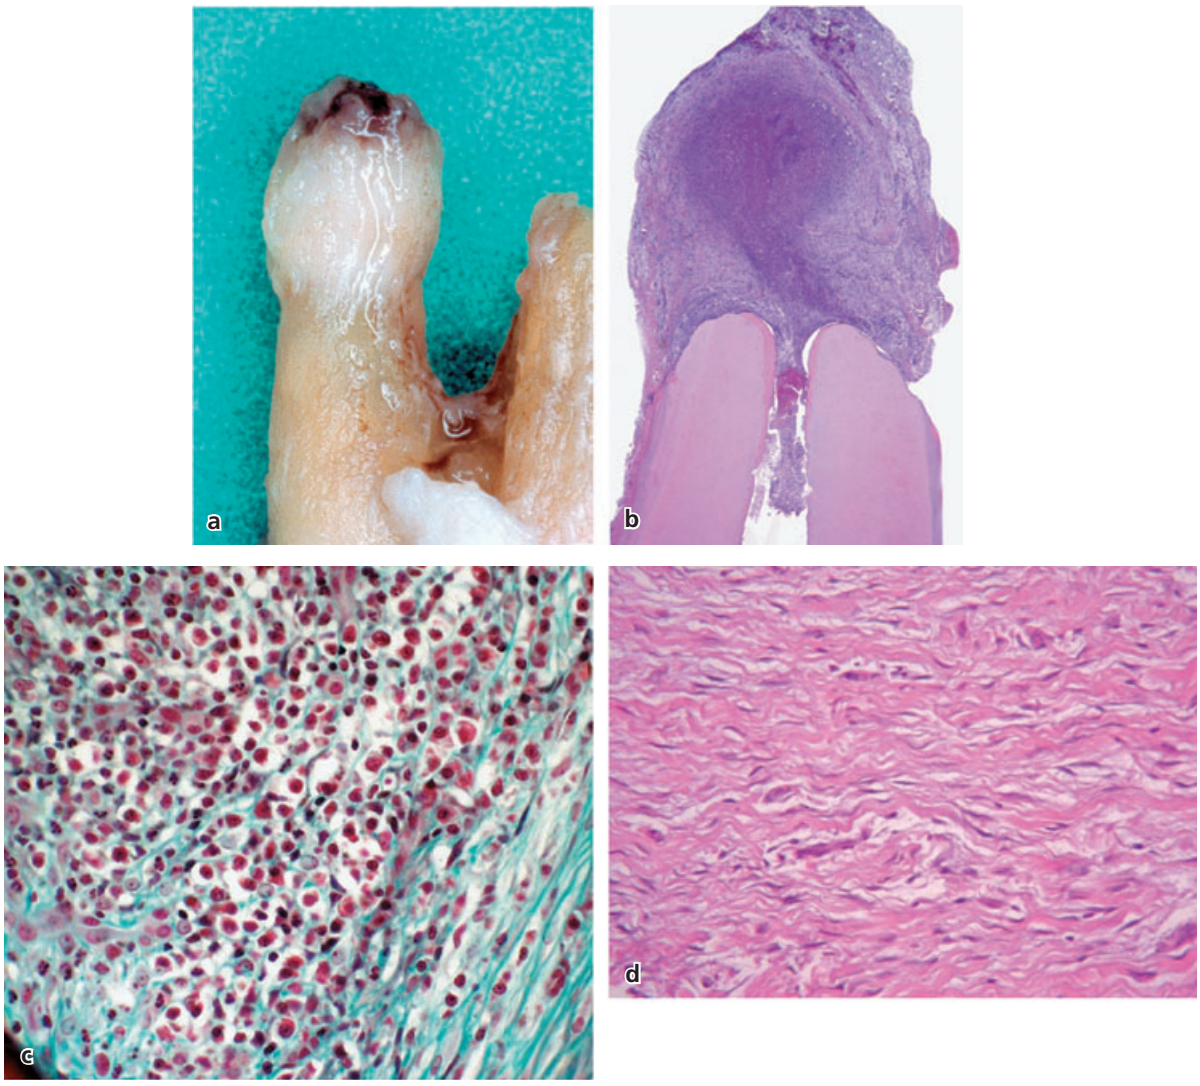

Fig. 23-15 Series of images demonstrating features of apical inflammatory lesions caused by root canal infection. (a) A soft lesion attached to the tip of the palatal root of an extracted upper molar. (b) The longitudinally cut tissue section through the root tip shows an overview of the lesion. The outer collagen-rich connective tissue confines the soft tissue lesion and attaches it to the root surface. (c) A typical mixed inflammatory cell infiltrate at the center of a lesion. (d) In the most peripheral portion the connective of an established lesion is rich in collagen and devoid of inflammatory cells. Microphotograph in (c) is from an apical lesion in a monkey.

In non-symptomatic endodontic lesions, the relative distribution of cellular and tissue elements may show great variation and some, but far from every lesion, may also contain proliferating epithelial cells (Nair 1997). The origin of epithelial strands is thought to be the epithelial rests of Malassez (Ten Cate 1972) that are stimulated to divide and proliferate by the release of pro-inflammatory cytokines and growth factors during the process of inflammation (Thesleff 1987; Lin *et al*. 1996; Suzuki *et al*. 2002). In the lesion, they appear to take a random course, but sometimes they may also attach to the root surface (Fig. 23-16) and eventually block the root canal exit for bacterial advancement into the periapical tissue compartment (Nair & Schroeder 1985). Their contribution to periodontal pocket formation upon an endodontic lesion, developing in close proximity to the epithelial sulcus of the marginal periodontium, remains obscure.

Conclusion

Inflammatory processes of the periodontium associated with necrotic dental pulps have an infectious etiology similar to periodontal disease. An essential difference between the two disease entities is their different source of infection. While periodontal disease is maintained by bacterial accumulations in the dentogingival region, endodontic lesions are directed towards infectious elements released from the pulpal space. The bacterial organisms in endodontic infections are usually confined to the root canal space. They may also be found in the soft tissue lesion *per se* either as clusters or as bacterial aggregations on the external root surface. Endodontic lesions rarely involve the marginal periodontium, unless abscessed. Cyst transformation may occur but even then marginal involvement is not common. In its established form, the endodontic lesion is clearly localized and constitutes an immunologically active protection zone which is important in preventing the dissemination of endodontic pathogens to the surrounding tissues (Stashenko 1990).

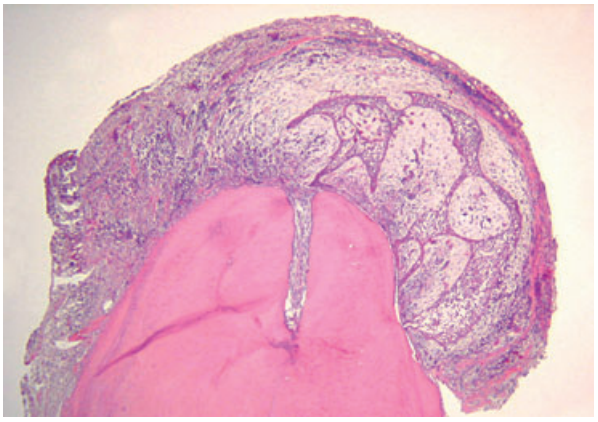

Fig. 23-16 Display of a periapical inflammatory process with proliferating epithelium partially attached to the root surface.

Effects of periodontal disease and periodontal therapy on the condition of the pulp

Influences of periodontal disease

The formation of bacterial plaque on detached root surfaces following periodontal disease has the potential to induce inflammation in the pulp along the very same pathways as an endodontic infection can affect the periodontium in the opposite direction. Thus, bacterial products and substances released by the inflammatory process in the periodontium may gain access to the pulp via exposed accessory canals and apical foramina, as well as dentinal tubules.

A clear association between progressive periodontal disease and pulpal involvement, however, does not exist. While inflammatory alterations as well as localized inflammatory cell infiltrates and necrosis of pulp tissue have been observed adjacent to accessory canals in teeth exposed by periodontal disease (Seltzer *et al*. 1963; Rubach & Mitchell 1965), a number of clinical studies has failed to confirm a direct relationship between progression of periodontitis and pulp tissue changes (Mazur & Massler 1964; Czarnecki & Schilder 1979; Torabinejad & Kiger 1985). In the cases in these studies, the pulp was observed to remain fully functional without overt inflammatory changes even though the periodontal tissue breakdown was severe. As already pointed out, an important reason for the lack of pulp tissue involvement, is that patent accessory canals are not invariably present and especially not in the cervical root portions. Another is that cementum obviously exerts protection. It is only when the cementum layer has been damaged, by, for example, instrumentation in periodontal therapy, wear from tooth cleaning, external root resorption, and root surface caries, that dentinal tubules can serve as pathways for microbial elements to the pulp (Figs. 23-17 to 23-19).

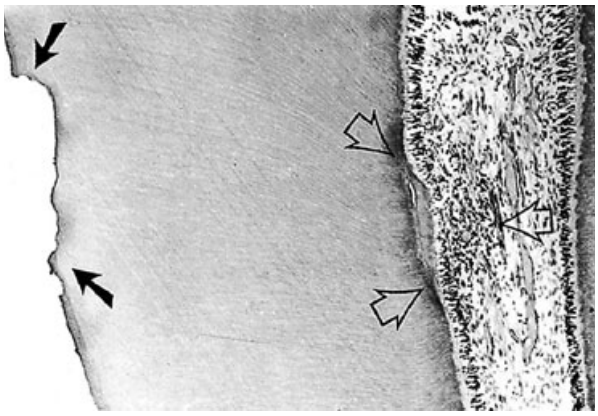

Fig. 23-17 Histologic section of a monkey tooth exposed to experimental periodontal tissue breakdown. Beneath resorptive defects in the external root surface a minor inflammatory cell infiltrate and a small rim of reparative dentin have been formed in the pulp. From Bergenholtz & Lindhe (1978).

Fig. 23-18 Histologic section of a human tooth with bacterial accumulations on the external root surface. There are obvious defects in the root surface. Pulp tissue is minimally affected, however, except for numerous mineralization processes both in the tissue proper and at the inner root canal wall.

The fact that tissue changes develop infrequently and even so only locally in the pulp of teeth subjected to periodontitis was underscored by an experimental study in monkeys (Bergenholtz & Lindhe 1978). Following a ligature-induced breakdown of the attachment apparatus, it was found that the majority of the root specimens examined (70%) exhibited no inflammatory changes, despite the fact that approximately 30–40% of the periodontal attachment was lost. The remaining roots (30%) displayed only small inflammatory cell infiltrates and/or formations of reparative dentin in the pulp subjacent to root areas exposed by the periodontal tissue destruction. These tissue changes were associated with root surface resorption (Fig. 23-17), supporting the view that dentinal tubules have to be uncovered before external irritants can be transmitted to the pulp. Consequently, the lack of correlation found in clinical observations between periodontal disease and pulp tissue alterations, may simply depend on the fact that few open pathways exist to the pulp in many periodontally involved teeth. Furthermore, as described above, once the dentin/pulp complex has been exposed to bacterial elements, repair and healing will often be instituted

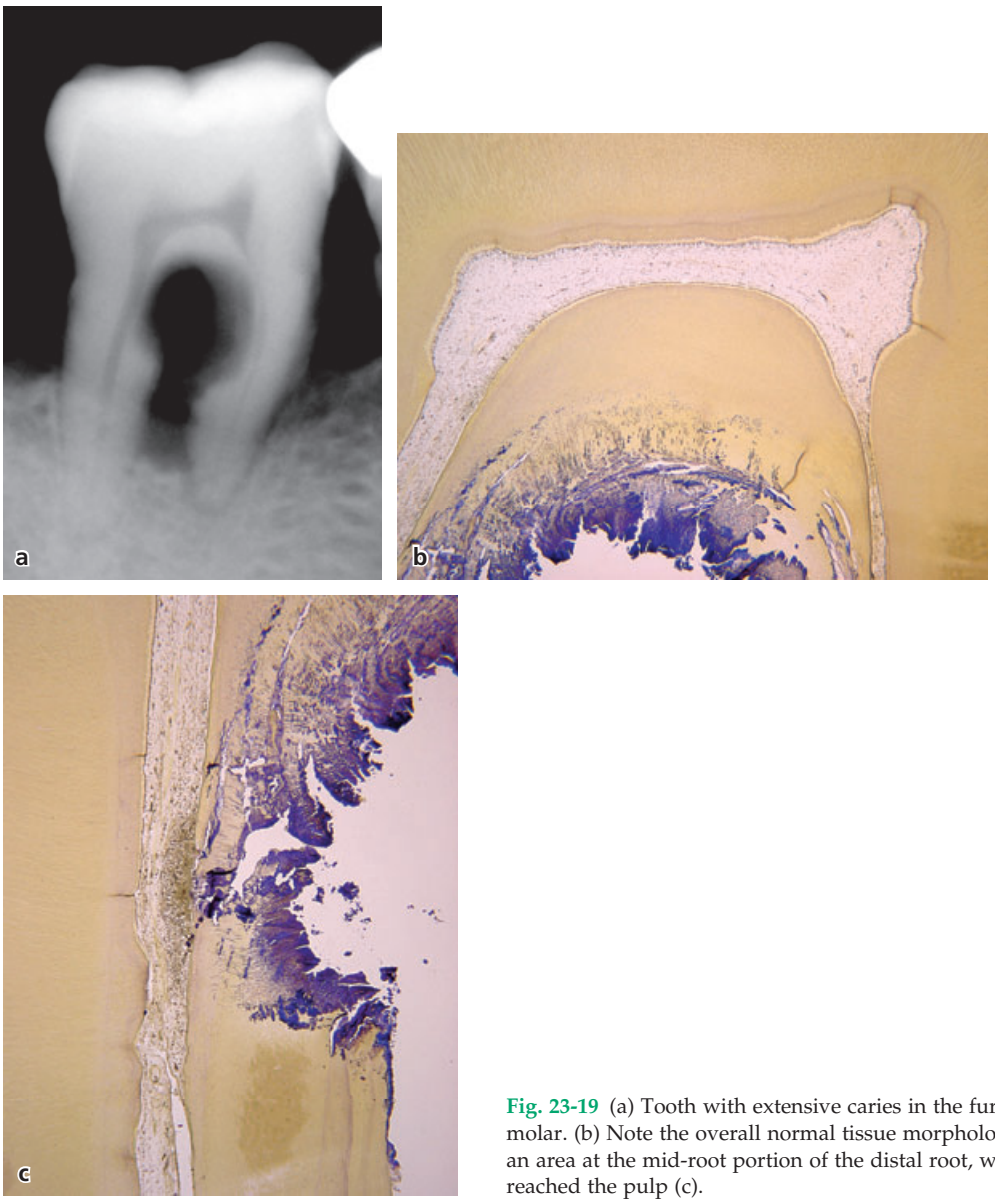

Fig. 23-19 (a) Tooth with extensive caries in the furcation region of a lower molar. (b) Note the overall normal tissue morphology of the pulp except for an area at the mid-root portion of the distal root, where caries process has reached the pulp (c).

soon after the initial inflammatory events, leaving the remaining tissue unaffected.

In the study by Bergenholtz and Lindhe (1978), destructive periodontal disease was produced experimentally during a comparatively short period (5–7 months), while in humans a similar degree of destruction of periodontal tissue normally requires several years. It has been reported that the pulp of teeth with longstanding periodontal disease develops fibrosis and various forms of intra-pulpal mineralizations (Bender & Seltzer 1972; Lantelme *et al*. 1976) (Fig. 23-18). If there is an association, it seems reasonable to assume that tissue changes of this nature represent the accumulated response of the pulp to the relatively weak, but repeatedly occurring, insults to the tissue over time, for example by microbial elements reaching the pulp over root surface exposures. Nonetheless the pulp can obviously remain healthy for as long as periodontal disease has not arrived at a terminal stage, when plaque accumulation and associated inflammatory lesions interfere with the neurovascular supply of the tissue through the main apical foramen (Fig. 23-20).

Conclusion

Available documentation suggests that the vital functions of the pulp are rarely threatened by periodontal disease influences. In teeth with moderate breakdown of the attachment apparatus, the pulp usually remains healthy. Breakdown of the pulp presumably does not occur until the periodontal disease process has reached a terminal stage, i.e. when plaque and the periodontal inflammatory process have progressed to the main apical foramina, whereby a retrograde destructive inflammatory pulpal lesion is initiated (Langeland *et al*. 1974) (Fig. 23-20). Consequently, as long as the blood supply through the apical foramen remains intact, the pulp is usually capable of withstanding injurious elements released by the lesion in the periodontium.

Influence of periodontal treatment measures on the pulp

Pocket/root debridement in periodontal therapy by hand instrumentation (scaling and root planing, S/RP) or ultrasonics is indispensable in the treatment of periodontal disease. However, this treatment is associated with a number of undesired side effects. Except for recession of gingival tissues resulting in exposures of root surfaces, the instrumentation *per se* may also inadvertently remove root cementum and the superficial parts of dentin. Thereby a large number of dentinal tubules will become exposed to the oral environment as treated root surfaces are normally left unprotected. Subsequent contact with microbial elements in the oral cavity is potentially harmful to the pulp as bacterial invasion of the exposed dentinal tubules may occur (Adriaens *et al*. 1988). While localized inflammatory lesions may be initiated in the pulp, the experimental study by Bergenholtz and Lindhe (1978) did not observe increased incidence of pulpal lesions in teeth subjected to S/RP in comparison to non-treated teeth subjected to periodontal tissue breakdown alone. In the study, root surfaces denuded of root cementum were left open to the oral environment for up to 30 days. The finding that plaque accumulation on root dentin exposed by one session of S/RP does not seriously threaten the vitality of the pulp has been confirmed in similarly designed experimental studies (Nilvéus & Selvig 1983; Hattler & Listgarten 1984). Yet, root dentin hypersensitivity may follow such treatment measures, causing an uncomfortable problem which is difficult to manage (see below).

During the maintenance phase of periodontal therapy, there are reasons to restrict repeated instrumentations, as some additional dentin always will be removed. Such therapy can result in weakening of the tooth structure and also in extensive reparative dentin formation in the pulp (Fig. 23-21).

Conclusion

Results of clinical observations and animal experiments support the view that pocket/root debridement procedures normally do not threaten the vitality of the pulp. Localized inflammatory alterations may occur adjacent to instrumented root surfaces followed by tissue repair in the form of hard tissue depositions on the root canal walls.

Root dentin hypersensitivity

Symptoms and incidence

Patients who have received pocket/root debridement in periodontal therapy may frequently experience sensitivity of the treated teeth to evaporative, tactile, thermal, and osmotic stimuli (Fischer *et al*. 1991; Kontturi-Närhi 1993; Chabanski *et al*. 1996; Tammaro *et al*. 2000; for review see Gillam & Orchardson 2006). Usually, the symptoms, when they occur, develop and peak during the first week, and then subside or disappear within the subsequent weeks; they are, although uncomfortable, most often a temporary and sustainable problem (Schuurs *et al*. 1995; Chabanski *et al* 1996; Gillam *et al*. 1999; Fardal *et al*. 2002). Occasionally, the condition may become a chronic pain problem and may persist for months or years. Patients appear to be especially at risk after periodontal surgery. In a comprehensive questionnaire survey, severe painful symptoms were reported to prevail in 26% of the subjects 6 months to 5 years after the completion of treatment, while 16%, treated non-surgically, reported pain symptoms (Kontturi-Närhi 1993). In a clinical trial comprising 35 patients, Tammaro *et al*. (2000) observed that the incidence of sensitive teeth increased following non-surgical

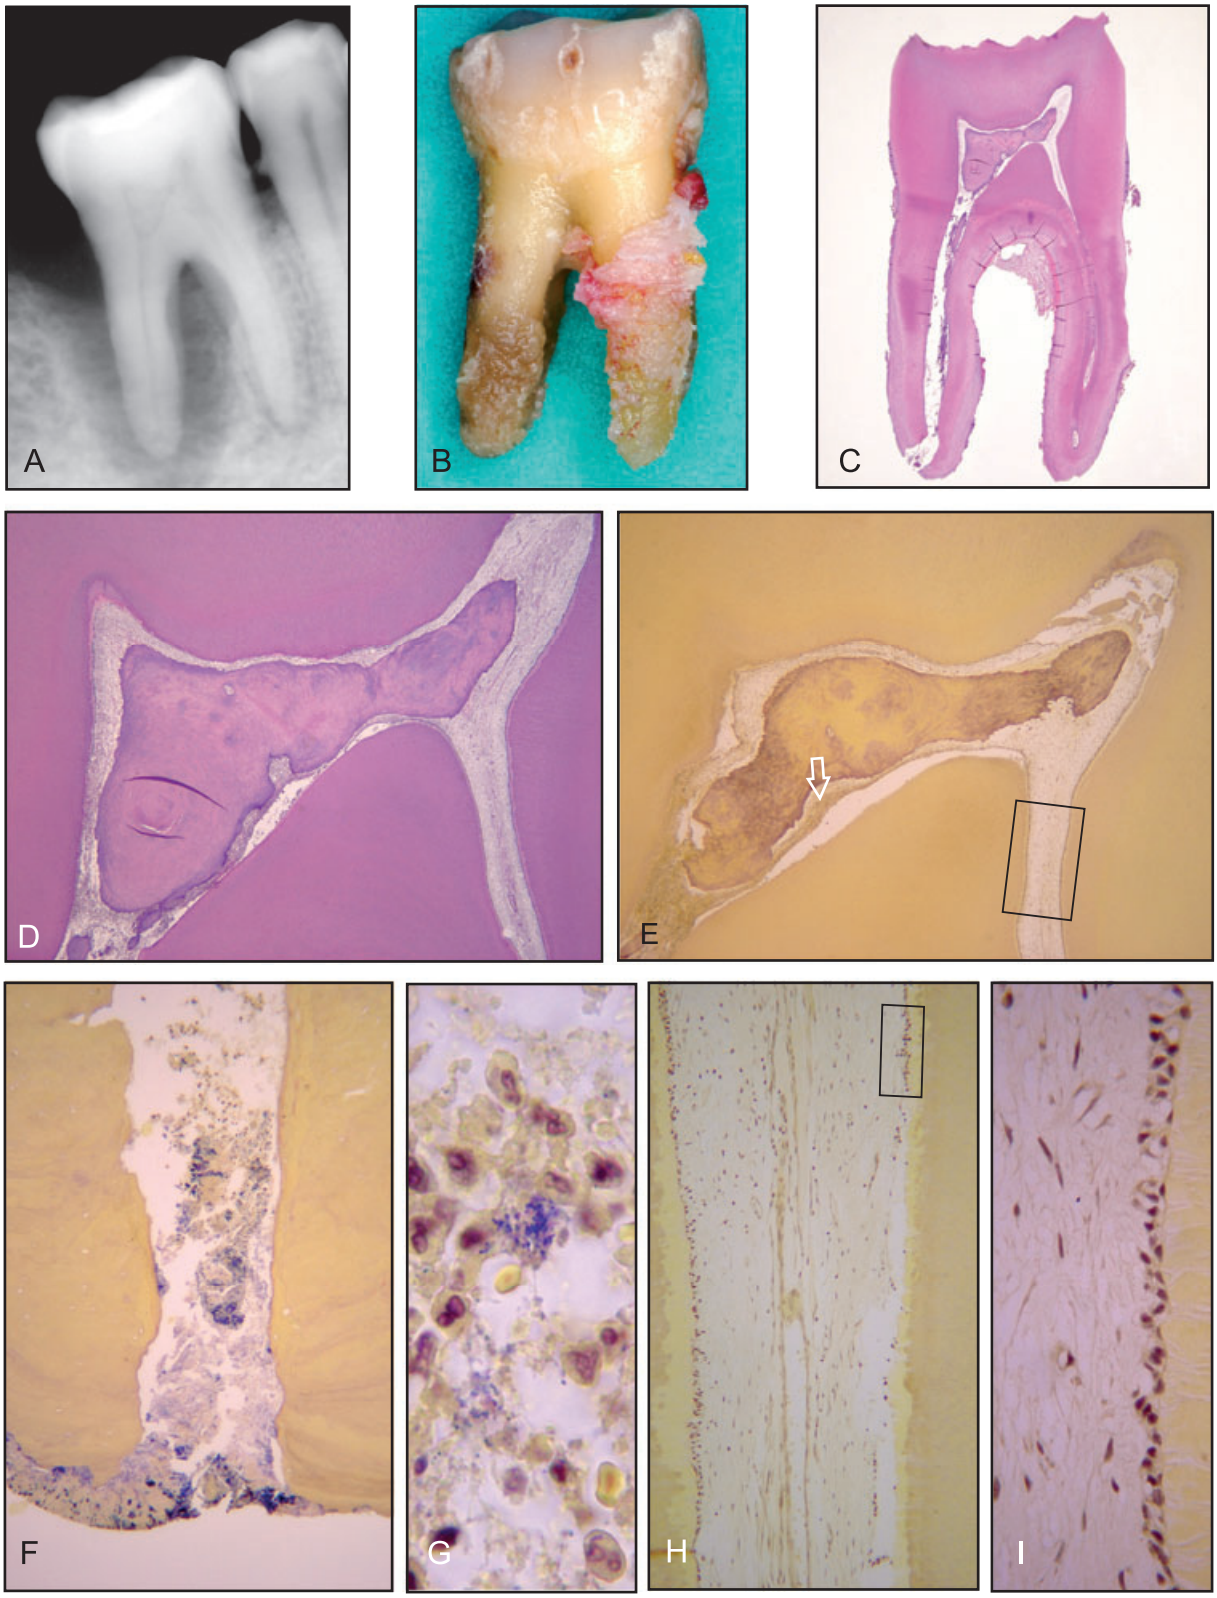

Fig. 23-20 (A) Extensive periodontal tissue breakdown circumscribing the distal root of a lower molar. (B, F) Plaque and calculus cover the root surface to the apical foramen. (C–G) The pulp is necrotic and infected all the way to the extensive hard tissue deposition in the coronal pulp (to arrow in E). Microphotographs enlarging marked area in (E) (H, I) indicate that the pulp tissue of the mesial root is completely unaffected and displays normal tissue morphology. Tooth responded vital to pulp testing.

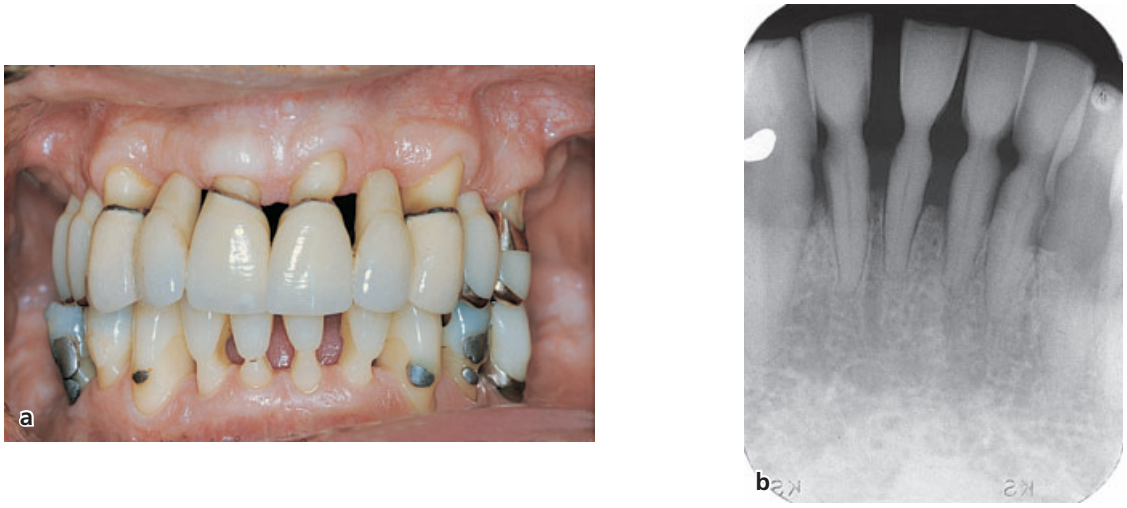

Fig. 23-21 (a) Clinical photograph of a patient, who has been in the maintenance phase for periodontal disease. While there are excellent gingival conditions and no pocket probing depths, there is substantial loss of cervical root dentin. (b) One of the lower incisors later had a horizontal fracture, but without a pulpal exposure due to fill of reparative dentin in the coronal portion of the pulp chamber. Courtesy of Dr. Sture Nyman.

periodontal instrumentation in comparison to non-instrumented teeth after initiating a self-performed oral hygiene program in patients with moderate to advanced periodontal disease. While affecting a majority of the patients, pain was generally reported to be minor. Only a few teeth in a small number of the patients developed highly sensitive root surfaces.

The main initial symptom is sharp pain of rapid onset that disappears once the stimulus is removed. In more severe, long-standing cases, shorter or longer periods of lingering, dull or aching pain may be provoked. These symptoms of a pulpitis character may not only be localized to the tooth (teeth) in question but to both quadrants of the jaw. Even a minimal contact with a toothbrush may elicit intense pain – a condition which is not only uncomfortable but one that is likely to hinder proper oral hygiene measures.

Mechanisms

The painful condition has been given many names, including dentine sensitivity, cervical dentine hypersensitivity, root dentine sensitivity, and root dentine hypersensitivity, reflecting some of the confusion that still exists regarding its etiologic background (Gillam & Orchardson 2006). The fact that root surfaces become sensitive to a variety of externally derived stimuli after periodontal instrumentation is not surprising as dentinal tubules become uncovered to the oral environment and subject to hydrodynamic forces. Hence, a variety of pain-evoking stimuli including evaporative, tactile, thermal, and osmotic stimuli may elicit sudden fluid shifts in the exposed tubules, thereby inducing a painful sensation according to the hydrodynamic theory of dentin sensitivity (Brännström 1966; Pashley 1996). This mechanism alone can certainly explain the sensitivity patients experience immediately after the instrumentation procedure and during a short period afterwards, while it does not make clear why the symptoms increase over time and why pain may prevail in certain patients and in certain teeth.

The increase in pain intensity may have one or both of the following two explanations. Firstly, the smear layer formed on the root surface by the S/RP procedure will be dissolved within a few days (Kerns *et al*. 1991). This in turn will increase the hydraulic conductance of the involved dentinal tubules (Pashley 1996) and thus decrease the peripheral resistance to fluid flow across dentin. Thereby pain sensations are more readily evoked. Secondly, open dentinal tubules serve as pathways for diffusive transport of bacterial elements in the oral cavity to the pulp, which may cause a localized inflammatory pulpal response (Bergenholtz & Lindhe 1975, 1978). Indeed, experiments in dogs have shown that dentin exposures left unprotected greatly enhance the sensitivity of responding nerve fibers (Närhi *et al*. 1994). A large number of intradental A-delta fibers, normally inactive, then become able to respond (Närhi *et al*. 1996). It has furthermore been shown that the receptive field of each individual fiber gets wider (Närhi *et al*. 1996). In addition, sprouting of new terminal branches from pulpal axons may occur in the area subjacent to the root surface defect (Taylor *et al*. 1988). As already stated, sprouting of nerves is a temporary event and will subside if inflammation disappears; a feature which is consistent with their involvement in root dentin hypersensitivity (Byers & Närhi 1999). In other words, an essential component of the increasing root sensitivity patients experience after an instrumentation procedure is likely to be related to a peripheral sensitization of pulpal nociceptors leading to what is termed primary hyperalgesia.

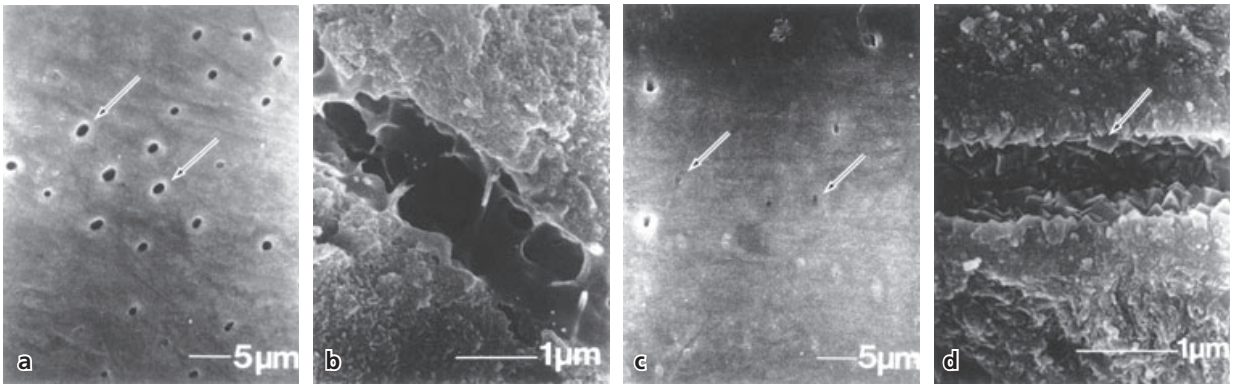

Fig. 23-22 Scanning electron microscopic images of root surface biopsies of hypersensitive (a, b) and of non-sensitive root dentin areas of human teeth (c, d). Numerous wide tubular apertures are seen in (a). These tubules show no evidence of hard tissue deposition after being opened longitudinally (b). By contrast, most tubules are occluded in (c) and below the surface rhombohedral crystals of from 0.1–0.3 µm are present. Images kindly provided by Dr. Masahiro Yoshiyama and published with permission of the *Journal of Dental Research*.

The fact that root dentin hypersensitivity often disappears a few weeks after the instrumentation procedure is best explained by the development of a natural occlusion of the exposed dentinal tubules. The deposition of mineral crystals in the tubular lumen may play an important role (Yoshiyama *et al*. 1989, 1990) (Fig. 23-22), firstly by inactivating the hydrodynamic mechanism for dentinal pain and secondly, by restricting the potential for an inward diffusion of bacterial elements to the pulp. The observation of few open tubules in non-sensitive root dentin (Hiatt & Johansen 1972; Absi *et al*. 1987; Yoshiyama *et al*. 1989; Cuenin *et al*. 1991; Oyama & Matsumoto 1991; Kontturi-Närhi 1993), while hypersensitive root areas show large numbers of tubular apertures on their surfaces (Absi *et al*. 1987; Yoshiyama *et al*. 1989; Cuenin *et al*. 1991; Oyama & Matsumoto 1991; Kontturi-Närhi 1993), supports this view.

The fact that only certain individuals become seriously affected may be related to local factors in the oral cavity, as well as to the level of the subjects' pain perception. Certain dietary factors, in particular fruit juices, yoghurt, and wines, have been implicated in the causation of root dentin hypersensitivity (Addy *et al*. 1987). By their acidity and ability to etch dentin these substances may dissolve the occlusions of the dentinal tubules or prevent them from forming. It needs be recognized that pain is not only an expression of injury and noxious stimuli, but also a psychobiologic phenomenon having both a physiologic and psychologic basis for its perception and reaction to it. Indeed, a variety of emotional elements may influence the subjective interpretation of pain. Anxiety, fear, and depression are factors that are known to affect pain perception as well as the subject's ability to identify coping methods (Eli 2003).

An important consideration in the deliberation of the mechanisms behind enhanced and lingering pain symptoms of root dentin hypersensitivity is the potential of central nervous system sensitization (for review see Sessle 2006). It is now well documented that frequent and repeated pain stimulations result in structural and functional changes that allow the brain to respond more rapidly and more effectively to the same stimuli. Such an increase of the excitability of central neurons has a downside in that pain may continue as a memory function even if the peripheral cause has been eliminated. Thus, it is possible that central sensitization phenomena explain failure of treatment attempts in some patients.

Principles for management

In patients suffering from severe root dentin hypersensitivity, active treatment is urgent. However, the methods presently available provide an unpredictable remedy and at best only temporary relief is attained (Ikola 2001; Gillam & Orchardson 2006). Since tubular patency of the exposed dentin seems to play a crucial role in the pathogenesis of root dentin hypersensitivity most procedures hitherto attempted are logically aimed at inducing blockage of the peripheral openings. Some agents commonly employed, primarily for dentist-applied treatment, act by causing an astringent or coagulating effect on the tubular content. Such chemicals include strontium chloride, sodium monofluorophosphate, sodium fluoride, calcium hypophosphate, calcium hydroxide, potassium nitrate, potassium oxalates, glutaraldehyde, ferric oxalate, and stannous fluoride. Other methods aim to produce a physical block for example by the use of grafting procedures and laser applications (for reviews see Zappa 1994; Gangarosa 1994; Ikola 2001; Gillam & Orchardson 2006).

There may be several explanations why such treatments sometimes fail to remedy the problem. One is likely to be of a technical nature in that it is often difficult to attain a completely dry dentin surface during the application of, for example, an astringent solution. Hence, the release of gingival fluid from the sulcus is not easily restrained by compressed air or other methods. Consequently, upon application of

the agent, protein from the gingival exudate might primarily be brought to coagulation rather than the tubular content. The precipitate is then easily removed upon subsequent tooth cleaning measures leaving the tubules unoccluded. Most agents furthermore may only cause a superficial block that may be dissolved over the course of time. Also topical applications do not address the pain mechanisms associated with either peripheral or central sensitization of nociceptors. Agents able to decrease the excitability of intradental nerves have, therefore, been proposed based on the assumption that potassium ions released from formulations containing potassium salts (e.g. chlorides, nitrates, citrate, and oxalates) may penetrate dentinal tubules and temper intradental nerve activity (Markowitz & Kim 1992; Orchardson & Peacock 1994). Toothpastes with potassium-containing preparations as active ingredients have indeed shown promise in clinical trials by giving better relief of pain in selected teeth in comparison to toothpastes without active substance (Sowinski *et al*. 2001; Wara-Aswapati *et al*. 2005). Experiments employing electrophysiological recordings in dogs, however, have shown that the effect of topical application of potassium salt is weak and becomes abolished after irrigation (Ikola 2001). More research appears necessary to confirm a clear treatment effect of potassium salts in gels, mouthwashes, and toothpastes (Orchardson & Gillam 2000). This also applies to any other treatment mode. It needs be recognized that demonstrating a significant treatment effect of a given compound in clinical trials is fraught with several difficulties. One is to assemble a sufficient number of patients that are reasonably identical in terms of duration and level of pain. Another is that the pain condition may go into natural remission at any time. A large placebo effect also operates in studies of this nature (Holland *et al.* 1997; Yates *et al*. 1998; Orchardson & Gillam 2000).

Any treatment approach to root dentin hypersensitivity should be preceded by a careful analysis of conditions that may be the cause of, or contributory to, the symptoms. Cracked teeth including cusp fractures, fractured or leaky restorations, caries, as well as a variety of other exposures of dentin to the oral environment may cause pulpal pain sensations to the very same stimuli which elicit root dentin hypersensitivity. An area of exposed dentin may be more sensitive if there is irritation of the pulp from other areas of the tooth, for example from the margin of a restoration that is not sealed from the oral environment (Närhi *et al*. 1994). Particular care should be taken to eliminate traumatic occlusion to alleviate any activation of pulpal nociceptors. Furthermore, dietary counseling should be given to patients who admit excessive consumption of citrus fruits, apples, or any other food or drinks that are acidic in nature.

Self-performed plaque control is important for the prevention and treatment of root dentin hypersensitivity. It has been observed clinically that, with time, teeth in patients with excellent oral hygiene habits develop hard, smooth, and insensitive root surfaces. Electron microscopic examination of the dentin of such root surfaces has revealed that mineral deposits obliterate the tubular openings (Hiatt & Johansen 1972). However, when severe symptoms of root hypersensitivity have emerged, it is difficult to motivate the patient to maintain the degree of plaque control that is necessary to allow for a natural occlusion of the dentinal tubules. In such situations, an agent which has a capacity to block the tubular openings, may be beneficial at least temporarily, so that proper oral hygiene measures can be reinforced. In severe cases, where no remedy is achieved with any advice or treatment approach, pulpectomy and root filling are a last resort.

Any pain treatment should take into consideration the potential of preventing the condition from emerging in the first place. However, no well proven protocol has as yet been established whereby root dentine hypersensitivity can be effectively prevented. Attempts to block the exposed dentinal tubules immediately following S/RP should be an obvious approach. In fact a couple of placebo-controlled studies have shown promise in that significantly fewer sensitive teeth were attained subsequent to instrumentation when 6% ferric oxalate (Wang *et al*. 1993) and 3% potassium oxalate (Pillon *et al*. 2004) were applied topically. The long-term outcome of such procedures awaits confirmation.

Conclusion

Root dentin hypersensitivity frequently develops as an uncomfortable and sometimes difficult ailment to treat subsequent to scaling and root planing procedures in periodontal therapy. Although the exact mechanism is not well established, the condition is clearly related to open dentinal tubules that allow hydrodynamic mechanisms to elicit painful sensations upon external stimulation. Both peripheral and central sensitizations are likely to contribute to the more intense and lingering pain symptoms some patients experience after root dentin exposure.

Diagnosis and treatment planning should consider contributory etiologic factors including over-consumption of acidic food items. Root dentin hypersensitivity should also be checked against other conditions causing similar pain symptoms and rule out cracked teeth, leaky restoration margins, caries in the tooth or in neighboring teeth, as well as trauma from occlusion. A large number of treatment methods are available for both in-office and over-the-counter applications. Some aim to block tubular patency of the exposed root dentin and others attempt to decrease excitability of intradental nerves for reduced pain transmission. Unpredictable treatment results are to be expected and only temporary relief may be attained.

Part 7: Peri-implant Pathology

Chapter 24

Peri-implant Mucositis and Peri-implantitis

Tord Berglundh, Jan Lindhe, and Niklaus P. Lang

Definitions

Peri-implant disease

Inflammatory processes in the tissues surrounding an implant (Albrektsson & Isidor 1994).

Peri-implant mucositis

Reversible inflammatory process in the soft tissues surrounding a functioning implant.

Peri-implantitis

Inflammatory process additionally characterized by loss of peri-implant bone.

See Fig. 24-1.

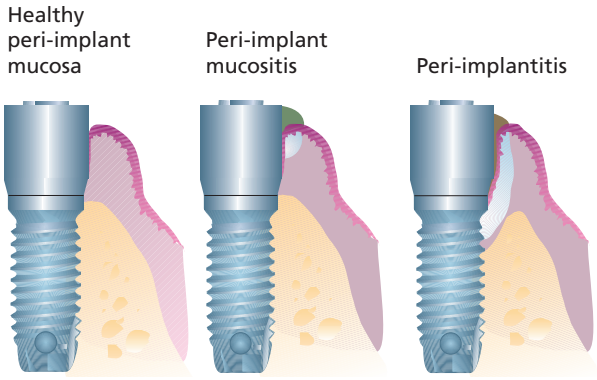

Fig. 24-1 Schematic drawing illustrating healthy peri-implant mucosa, peri-implant mucositis, and peri-implantitis.

Ridge mucosa

The edentulous, hard tissue portion of the alveolar process is covered by a mucosa that is about 2–4 mm thick (see also Chapter 3). The mucosa is lined by a keratinized epithelium and is comprised of a connective tissue that is rich in fibroblasts, collagen fibers, and vascular structures (e.g. Türk 1965; Krajicek *et al*. 1984; Liljenberg *et al*. 1996). The connective tissue is continuous with the cortical bone crest via the periosteum. A few scattered inflammatory cells can be observed adjacent to the basement membrane in the connective tissue papillae between the rete pegs of the epithelium.

Peri-implant mucosa

Following implant installation, a transmucosal passage is formed around the abutment portion of the device. The ridge mucosa at such sites adapts to the new functional demands and a peri-implant mucosa becomes established. The mucosa surrounding implants and the gingiva surrounding teeth have many features in common. Both types of tissues are lined with a keratinized oral epithelium; at clinically healthy sites this is continuous with a thin non-keratinized barrier or junctional epithelium that faces the implant or the tooth surface. In the connective tissue immediately lateral to these thin epithelial linings small infiltrates of inflammatory cells (neutrophils, macrophages, T cells, B cells) are frequently seen (Liljenberg *et al*. 1997). The inflammatory cells represent the host's defense against bacterial products and hence they may be considered as one important component of the biological seal that separates the peri-implant and periodontal attachment tissues from the oral cavity (see also Chapters 3 and 11).

Peri-implant mucositis

Clinical features

The clinical features of peri-implant mucositis are in many respects similar to those of in gingivitis at teeth and include classical symptoms of inflammation, such as swelling and redness (see Chapter 17). Differences in the morphology of the peri-implant mucosa and the lack of light transmission through the metal of the device, however, may mask visible signs of inflammation. Assessment of peri-implant mucositis must therefore always include assessment of bleeding following probing (Fig. 24-2).

Prevalence

Bleeding on probing (BoP) is a good discriminating indicator of peri-implant mucositis. The prevalence of this disease remains difficult to estimate since data on BoP at implants are infrequently reported (Berglundh *et al*. 2002). In a study on 25 subjects treated with implant-supported fixed prosthesis, Lekholm *et al*. (1986) reported that BoP occurred at 80% of the implants. Roos-Jansåker *et al*. (2006a,b,c) examined 987 implants in 216 patients and reported that more than 73% of all implants exhibited BoP. Higher frequencies of BoP at implants were presented by Fransson *et al*. (2007) in a study on 82 subjects. It was reported that BoP occurred in more than 90% of implant sites.

Histopathology

Response to early plaque formation

The response of the gingiva and the peri-implant mucosa to early and more long-standing periods of plaque formation was analyzed both in studies in man and in experiments in animals. Pontoriero *et al*. (1994) engaged 20 partially edentulous human subjects in a clinical "Experimental gingivitis in man" (Löe *et al*. 1965) study. All subjects had been treated for advanced periodontal disease and thereafter had been restored with implants in one or several segments of the dentition. During a 6-month period following the prosthetic rehabilitation, the subjects were enrolled in a meticulous maintenance program that included regularly repeated supportive measures. A baseline examination was subsequently performed including assessment of plaque, soft tissue inflammation, probing pocket depth (PPD), soft tissue recession, and composition of oral biofilms. The participants refrained from all oral hygiene measures for 3 weeks. It was observed that during this interval plaque build-up (amount and composition) and the soft tissue response to the microbial challenge, e.g. inflammation and PPD change, developed in a similar manner in the tooth and implant segments of the dentition.

Zitzmann *et al*. (2001) studied the response to plaque formation in the soft tissues at implant and tooth sites in humans. Twelve subjects with healthy periodontal and peri-implant conditions were asked to refrain from tooth/implant cleaning for a period of 3 weeks (Fig. 24-3). Clinical examinations were performed and soft tissue biopsies were harvested prior to and at the end of the plaque accumulation period. The tissues were examined using histologic techniques. It was demonstrated that plaque build-up was associated with clinical signs of soft tissue inflammation. Furthermore, the initially minute lesions in the gingiva and in the peri-implant mucosa markedly increased in size after 3 weeks of plaque build-up: from 0.03 mm^2 at baseline to 0.3 mm^2 (gingiva) and 0.2 mm^2 (peri-implant mucosa). In addition, the proportion of B cells and neutrophils increased more in the lesion in the gingiva than in its counterpart in the peri-implant mucosa.

Experimental model

In a carefully supervised experiment in the dog, Berglundh *et al*. (1992) compared the reaction of the gingiva and the peri-implant mucosa to 3 weeks of *de novo* plaque formation. The mandibular premolars in one side of the mandible were extracted, leaving the premolars on the contralateral side as controls. After 3 months of socket healing, implants were inserted in the edentulous ridge. The animals were placed in a plaque-control program to allow for ideal healing of the mucosa at the implants and to prevent

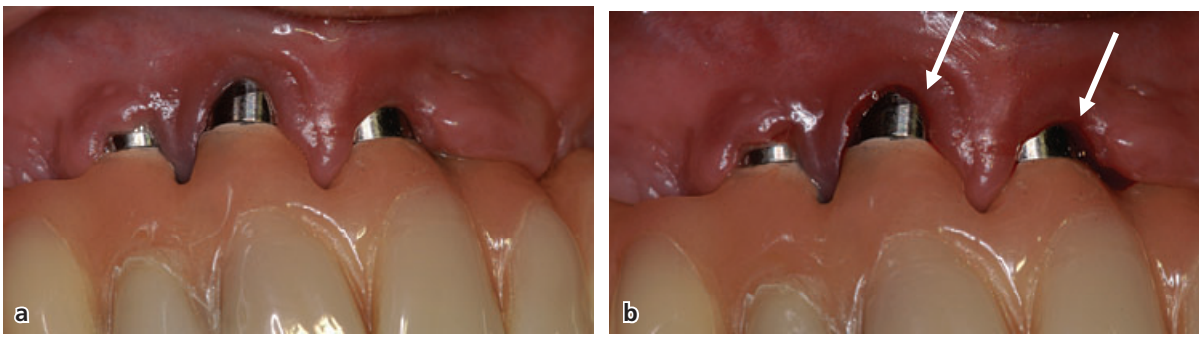

Fig. 24-2 (a) Clinical symptoms of peri-implant mucositis including varying signs of redness and swelling. (b) Probing resulted in bleeding from the margin of the mucosa.

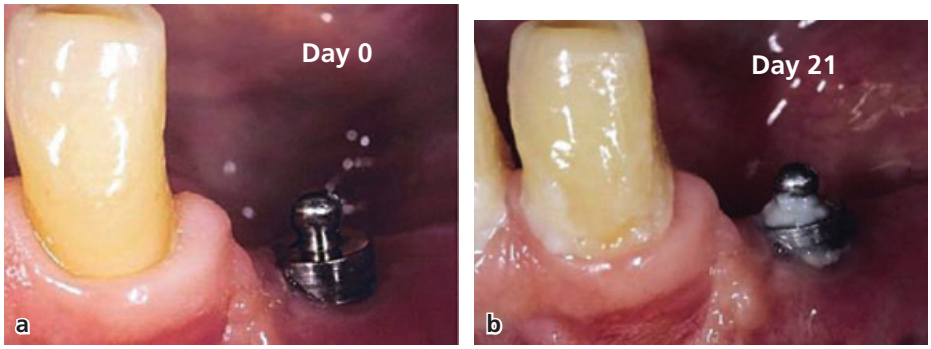

Fig. 24-3 (a) Clinical photograph from sites with healthy gingiva and peri-implant mucosa. (b) The sites illustrated in (a) following 3 weeks of plaque formation.

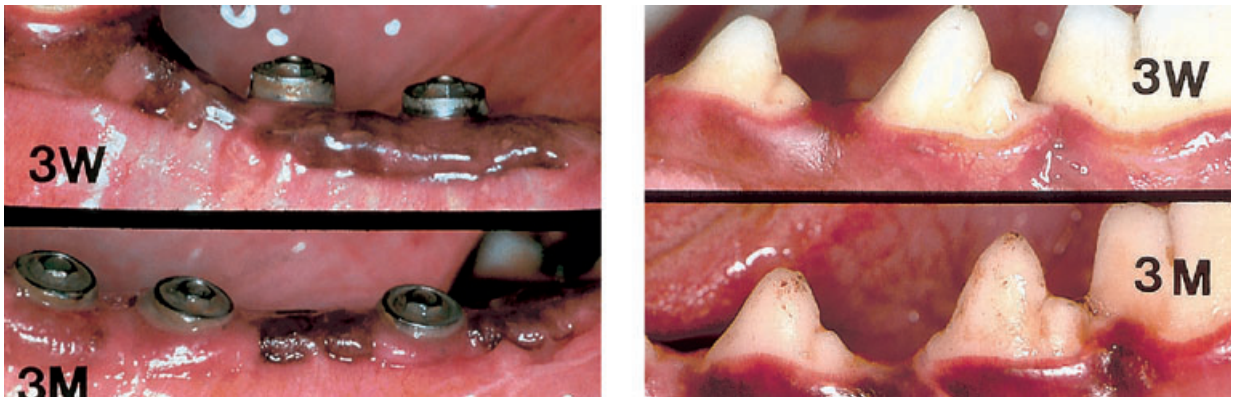

Fig. 24-4 A clinical view illustrating 3 weeks (3 W) and 3 months (3 M) of undisturbed plaque formation on the implants and the teeth of a beagle dog.

gingivitis from occurring in the tooth segments of the dentition. After this healing period, the dogs were examined and samples from the minute biofilms that were present on the implant and the tooth surfaces were harvested. The plaque-control program was terminated and the animals given a soft diet, that allowed gross plaque formation. Re-examinations, including clinical assessment (Fig. 24-4), sampling of plaque from teeth and implants as well as biopsy, were performed after 3 weeks.

During the course of the study, it was observed that similar amounts of plaque formed on the tooth and implant segments of the dentition. The composition of the two developing plaques was also similar. It was therefore concluded that early microbial colonization on titanium implants followed the same pattern as that on teeth (Leonhardt *et al.* 1992).

Both the gingiva and the peri-implant mucosa responded to this microbial colonization with the establishment of overt inflammatory lesions, i.e. infiltrates of leukocytes in the connective tissue. The lesions in the gingiva and in the peri-implant mucosa were matched both with respect to size and location. Hence, both lesions were consistently found in the marginal portion of the soft tissues and between the keratinized oral epithelium and the junctional or barrier epithelium (Fig. 24-2).

Response to long-standing plaque formation

With increasing duration of plaque build-up (3 months) in the dog model described above, the lesions in the peri-implant mucosa seemed to have expanded and to have progressed further "apically" while the gingival lesions remained unchanged (Ericsson *et al.* 1992) (Fig. 24-5). Furthermore, the lesion in the peri-implant mucosa contained a much smaller number of fibroblasts than the corresponding infiltrate in the gingiva. In any inflammatory lesion of long standing, periods of breakdown and periods of repair interchange. It was suggested, therefore, that in the gingival lesion, the amount of tissue breakdown that occurred during the 3 month interval was more or less fully compensated by tissue build-up that took place during a subsequent phase of repair. In the lesion within the peri-implant mucosa, the tissue breakdown was not fully recovered by reparative events. This reduced build-up may have been the reason for the resulting additional propagation and spread of the lesion in the peri-implant mucosa.

In a similar dog experiment Abrahamsson *et al.* (1998) studied soft tissue lesions after 5 months of plaque formation at three different implant systems. They observed that the response of the peri-implant mucosa to long-standing plaque formation appeared

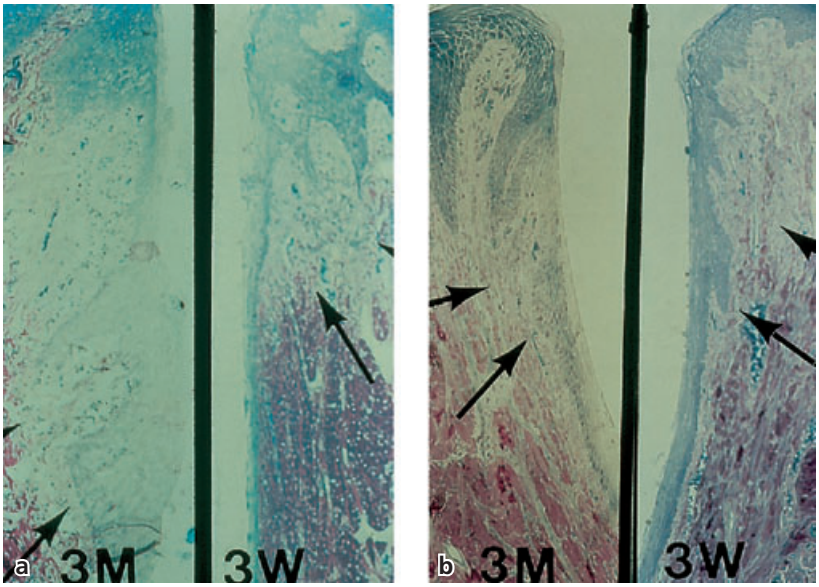

Fig. 24-5 Microphotographs illustrating the establishment of inflammatory cell infiltrates (ICT) in the peri-implant mucosa (a) and the gingiva (b) (3 W = 3 weeks; 3 M = 3 months). Note, in the microphotographs representing 3 months, the infiltrate in the peri-implant mucosa extends much deeper into the tissue than is the case in the gingiva.

to be independent of the implant system that harbored the biofilm.

Peri-implantitis

Clinical features

Peri-implantitis represents a clinical condition that includes the presence of (1) an inflammatory lesion in the peri-implant mucosa and (2) loss of peri-implant bone. The assessment of the diagnosis *peri-implantitis* must consequently require detection of both bleeding on probing (BoP) as well as bone loss in radiographs. Peri-implantitis initially affects the marginal part of the peri-implant tissues and the implant may remain stable and in function for varying periods of time. Implant mobility is therefore not an essential symptom for peri-implantitis but may occur in a final stage of disease progression and indicates complete loss of integration.

As pointed out for the clinical characteristics of peri-implant mucositis, various factors such as the morphology of the peri-implant mucosa and position of the implant may also influence the clinical appearance of inflammation in peri-implantitis. Probing is therefore a prerequisite in the examination of peri-implant tissues and should include assessment of both BoP and probing pocket depth (PPD).

The clinical appearance of peri-implantitis may, hence, vary and may not always be associated with overt signs of pathology. Two different cases are illustrated in Figs. 24-6 and 24-7. While plaque and calculus together with clinical signs of inflammation are present in the case in Fig. 24-6, the case in Fig. 24-7a does not reveal such symptoms. Probing the site in Fig. 24-7a, however, resulted in a PPD of about 10 mm and BoP (Fig. 24-7b).

Crater-formed defects around implants are frequently found in radiographs obtained from sites with peri-implantitis (Fig. 24-8). Bone loss in such

Fig. 24-6 Clinical symptoms of peri-implantitis. Note the large amounts of plaque and calculus and visible signs of inflammation in the peri-implant mucosa.

sites appears also to be symmetric, i.e. similar amount of bone loss occur at mesial, distal, buccal, and lingual aspects of the implants. On the other hand, the morphology of the osseous defect may vary depending on the horizontal dimension of the alveolar ridge. Thus, in sites where the buccal–lingual width of the ridge exceeds that of the peri-implantitis lesion, a buccal and lingual bone wall may remain. Conversely, in sites with a narrow ridge the buccal and lingual bone will be resorbed and lost during progression of peri-implantitis.

Conclusion

Symptoms of peri-implantitis relate to the infectious/inflammatory nature of the lesion. Thus, there is radiographic evidence of bone loss and the bone loss often has the shape of a crater. Swelling and redness of the mucosa as well as bleeding on gentle probing occur. Suppuration is also a frequent finding. The implant may remain stable over long periods.

Prevalence

Previous estimates of the prevalence of peri-implantitis were based on reports describing varying

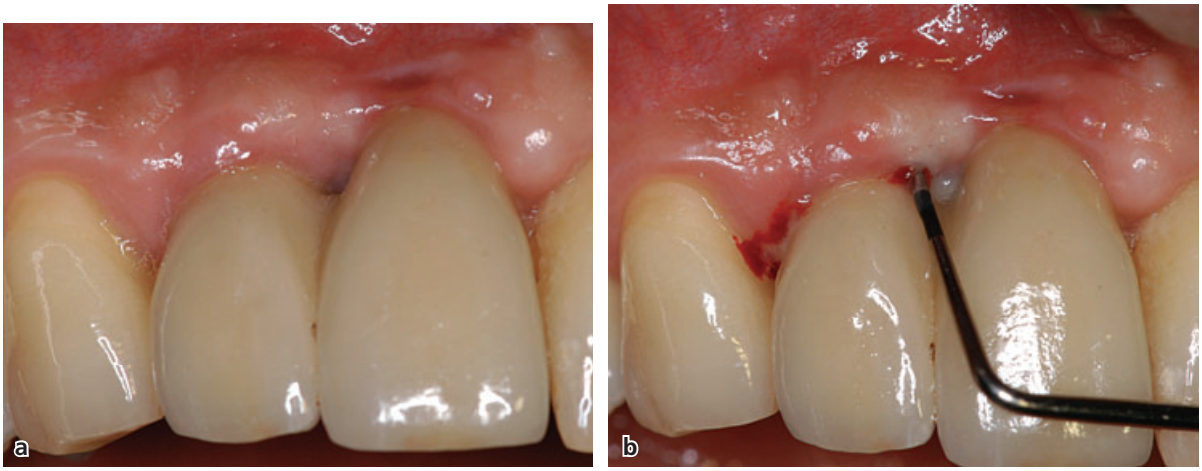

Fig. 24-7 Clinical photograph from two implant-supported crowns in the lateral (12) and central (11) incisor positions. (a) No or minor signs of inflammation in the surrounding mucosa. (b) Probing resulted in bleeding and suppuration from the implant site in the lateral incisor position.

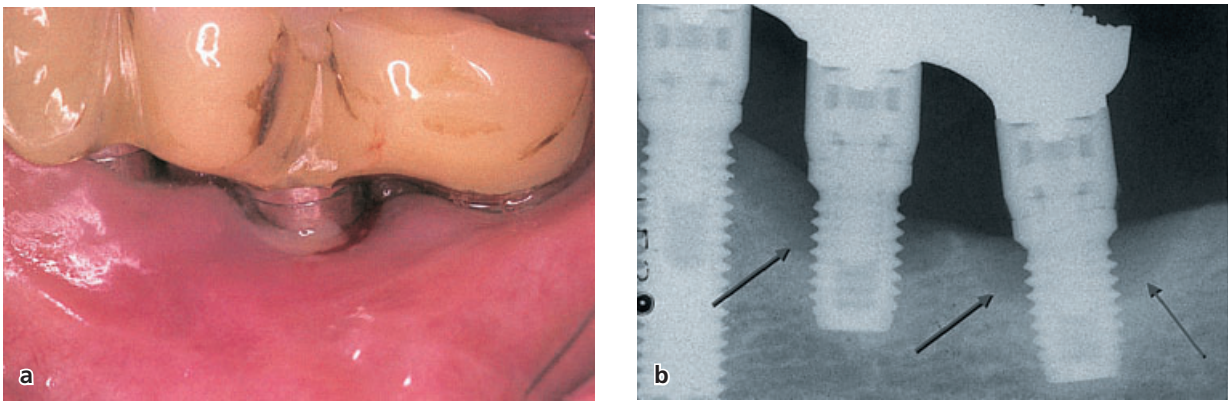

Fig. 24-8 Clinical (a) and radiographic (b) characteristics of two implant sites with peri-implantitis in the left side of the mandible. Note the presence of swelling and suppuration in the peri-implant mucosa (a) and the crater-formed bone destruction around the implants in the radiograph (arrows) (b).

frequencies of implant failures that were associated with high plaque scores or severe signs of inflammation (van Steenberge *et al*. 1993; Weyant & Burt 1993; Weyant 1994; Esposito *et al*. 1998). Other criteria were used by Mombelli and Lang (1998) and Brägger *et al*. (2001) and it was suggested that the prevalence of peri-implantitis may vary between 5 and 10% among implants.

The difficulty of retrieving information on the prevalence of peri-implantitis was confirmed in a systematic review by Berglundh *et al*. (2002). They evaluated the incidence of biologic and technical complications in implant therapy reported in prospective longitudinal studies of at least 5 years. From the 1310 titles and abstracts provided by the search in databases, 159 studies were selected for full-text analysis, out of which 51 studies were used for meta-analysis. Implant loss was the most frequently reported type of complication, while information regarding peri-implantitis and pronounced bone loss was only provided in 40–50% of the studies. The limited information on the incidence of peri-implantitis was explained by the fact that the term peri-implantitis, with the definition by Albrektsson and Isidor (1994) referred to above, was included in only a few studies. The inability to use information on the incidence of peri-implantitis and the occurrence of pronounced bone loss at implants was also due to the lack of data describing frequency distributions of various probing depths and amount of radiographic bone loss.

It is important to use appropriate terms in clinical reports to avoid confusion. Peri-implantitis is a clinical condition and should not be mistaken for implant failure. If left untreated, however, peri-implantitis may progress and lead to implant loss. The term failure should thus be avoided and terms referring to peri-implant disease (peri-implant mucositis and peri-implantitis) should be used for implants in function. Implant loss is consequently the term to use for implants that were lost or removed. In a consensus report from the 4th European Workshop on Periodontology, Lang *et al*. (2002) suggested that authors should avoid the terms implant success and failure

and report data on implant survival in combination with incidence of complications. It was also recommended that data should be provided on a subject basis. The majority of publications in implant dentistry, however, describe results based on number or proportions of implants. This information is of limited value for the clinician and, hence, data that relate the outcome of treatment for the patient under examination should be required.

Recently subject-based data on peri-implantitis were presented. Fransson *et al*. (2005) evaluated the prevalence of subjects with progressive bone loss at implants with a function time of at least 5 years. Radiographs of 1346 patients who had attended annual follow-up visits at the Brånemark Clinic, Göteborg, Sweden were retrieved. 662 subjects fulfilled the inclusion criteria. Implants that had suffered bone loss amounting to three or more threads of an implant were identified. Progressive bone loss at implants in the study was defined as bone loss occurring between the 1-year examination and the 5 or more years of follow-up examination. It was reported that 27.8% (184) of the 662 included subjects had one or more implants with "progressive" bone loss. A logistic regression analysis revealed that the individuals in this group carried a significantly larger number of implants than the subjects in whom no implants with progressive loss were detected (6 vs. 4.8). Furthermore, >30% of the subjects in the group with progressive bone loss had three or more identified implants and about 33% of all such implants in this group exhibited extensive bone loss. Out of the total 3413 implants included in the study, 423 implants (12.4%) demonstrated progressive bone loss. Fransson *et al*. (2005) concluded that the prevalence of progressive bone loss at implants assessed from subject-based data is higher than that evaluated from implant-based data. In a subsequent clinical study Fransson *et al*. (2007) reported that about 94% of the implants with "progressive" bone loss exhibited BoP. Thus, according to the definition of peri-implantitis presented in this chapter, the findings in the study by Fransson *et al*. (2005) suggest that the prevalence of subjects with peri-implantitis within this implant population was about 28%.

Roos-Jansåker *et al*. (2006b) examined 216 implant-treated patients (Brånemark System®) after 9–14 years of function and reported that 16% of the subjects and 6.6% of the implants had peri-implantitis. Roos-Jansåker *et al*. (2006b), however, used a modified definition of peri-implantitis and suggested that a certain amount of bone loss (≥1.8 mm compared with the 1-year data) together with the finding of BoP was required for the diagnosis *peri-implantitis*. It should be pointed out, however, that the prevalence of implants with peri-implantitis in the study by Roos-Jansåker *et al*. (2006b) would be >43% if normal criteria for peri-implantitis, i.e. bone loss and BoP, were applied.

Conclusion

The majority of clinical studies reported in the literature did not provide sufficient data on the prevalence of peri-implant mucositis and peri-implantitis. Results from recent publications, however, indicate that both peri-implant mucositis and peri-implantitis are common disorders. The prevalence of subjects with peri-implantitis in more recent studies varied between 25 and 45%.

Histopathology

Microscopic examinations of tissues harvested from peri-implantitis sites in humans consistently revealed that the mucosa contained large inflammatory cell infiltrates. Sanz *et al*. (1991) analyzed soft tissue biopsies from six patients with peri-implantitis and reported that 65% of the connective tissue portion was occupied by an inflammatory lesion. Piattelli *et al*. (1998) described some pathological features of tissues harvested from 230 retrieved implants. It was reported that at sites where implants were removed due to peri-implantitis, "an inflammatory infiltrate, composed of macrophages, lymphocytes and plasma cells, was found in the connective tissue around the implants". In a study including 12 human peri-implantitis lesions, Berglundh *et al*. (2004) found that the mucosa contained very large lesions in which numerous plasma cells, lymphocytes, and macrophages were present (Fig. 24-9). It was furthermore observed that the inflammatory cell infiltrate consistently extended to an area apical to the pocket epithelium and that the apical part of the soft tissue lesion frequently reached the bone tissue. Berglundh *et al*. (2004) also reported that numerous neutrophil granulocytes (PMN cells) were present in the lesions. Such cells occurred not only in the pocket epithelium and associated areas of the lesions, but also in perivascular compartments in the center of the infiltrate, i.e. distant from the implant surface. In the apical part of the lesion the inflamed connective tissue appeared to be in direct contact with the biofilm on the implant surface. Gualini and Berglundh (2003) included six subjects in a study and used immunohistochemical techniques to analyze the composition of peri-implantitis. PMN cells were found in large numbers in the central portions of the infiltrate. This finding was in agreement with observations made by Hultin *et al*. (2002). They analyzed the exudate that could be harvested from implant sites in 17 patients with peri-implantitis and reported the presence of large numbers of PMN cells.

Experimental models

In order to study the ability of the peri-implant mucosa to respond to long-standing plaque exposure and to manage the associated inflammatory lesions, an experimental periodontitis/peri-implantitis model was developed in the dog (Lindhe *et al*. 1992) and in

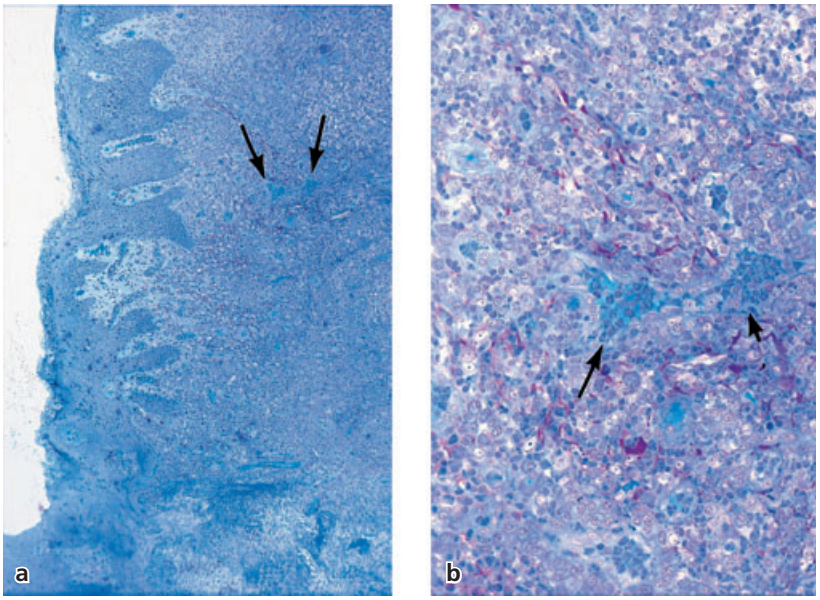

Fig. 24-9 (a) Microphotograph illustrating a human peri-implantitis lesion. Note the large inflammatory infiltrate lateral to the pocket epithelium. The implant was positioned to the left. (b) Arrows indicate vascular units illustrated in a larger magnification.

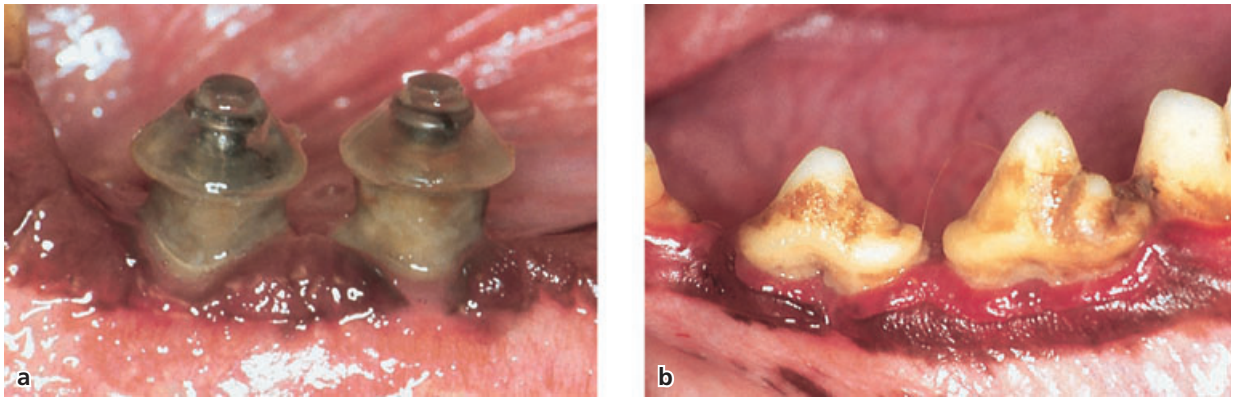

Fig. 24-10 (a) A clinical view describing features of experimental peri-implantitis in the beagle dog. (b) A clinical view describing features of experimental periodontitis in the beagle dog.

the monkey (Lang *et al*. 1993; Schou *et al*. 1993). Although the experiments had somewhat varying design, the outcome of the studies was almost identical and, hence, only the result from the dog model will be reported.

In the *dog model*, the premolars were extracted in one side of the mandible, fixtures (Brånemark system®) were inserted and abutment connection performed 3 months later as described above (Berglundh *et al*. 1991). During the healing phase a strict plaque control regimen was maintained and healthy tissue conditions were thereby established in all tooth and implant sites to be monitored. On a given day, the periodontitis and peri-implantitis lesions were induced. This was accomplished by (1) terminating the plaque control regimen and (2) placing cotton floss ligatures around the neck of both the premolar teeth and the implants. The ligatures were forced into a position apical to the soft tissue margins. A "pocket" between the tooth/gingiva and implant/mucosa was thereby created, a submarginal microbiota rapidly formed, and inflammatory lesions developed in the neighboring tissues. Radiographs obtained after 6 weeks of the experiment revealed that a substantial amount of bone tissue had been lost at both teeth and implant sites. The ligatures were removed. After another 4 weeks, the animals were re-examined (Fig. 24-10), radiographs obtained, bacteria sampled, and biopsies of tooth and implant sites harvested.

It was observed that the plaque that had formed in the deep "pockets" was similar at tooth and implant sites and was dominated by Gram-negative and anaerobic species (Leonhardt *et al*. 1992). This observation is consistent with findings indicating that, in humans, the microbiota at teeth and implants has many features in common but also that the microbiota at healthy and diseased sites – tooth sites as well as implant sites – is very different. Thus, implants and teeth that are surrounded by healthy soft tissues are associated with biofilms including small amounts of Gram-positive coccoid cells and rods. Sites with extensive periodontal and peri-implant inflammation harbor biofilms with large numbers of

Gram-negative anaerobic bacteria (for review see Mombelli 1999).

The histopathologic examination of the biopsy samples from the dog study (Lindhe *et al*. 1992) revealed that there were marked differences in the size and location of the inflammatory lesions of the two sites. Thus, while the lesions in the periodontal sites (Fig. 24-11) were consistently separated from the alveolar bone by a zone, about 1 mm high, of uninflamed connective tissue, the lesion in the peri-implant tissue in most situations extended into and involved the marrow spaces of the alveolar bone. It was concluded that the pattern of spread of inflammation was different in periodontal and peri-implant tissues. The lesions in plaque-associated periodontitis were limited to the connective tissue, while in the peri-implant tissues the lesions extended to the alveolar bone (Fig. 24-12).

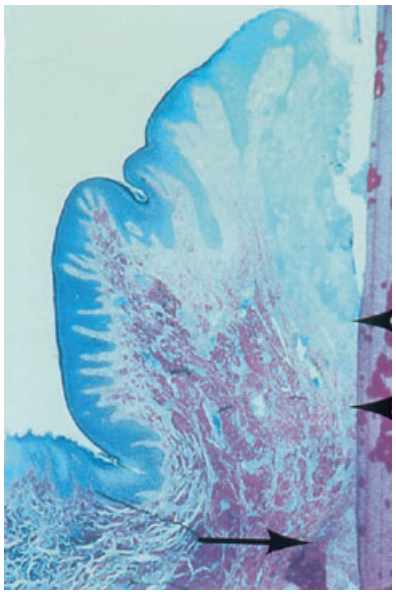

Fig. 24-11 Microphotograph (buccal–lingual section) illustrating a periodontitis lesion. Note the apical extension of the infiltrate (arrow) but also the presence of a zone of normal connective tissue between the infiltrate and the bone crest (arrow).

It was suggested that the peri-implant tissues, in variance with the periodontal tissues, are poorly organized to resolve progressive, plaque-associated lesions. The validity of this conclusion was substantiated in subsequent studies (Marinello *et al*. 1995; Ericsson *et al*. 1996; Persson *et al*. 1996; Gotfredsen *et al*. 2002), using similar models but allowing for different periods of tissue breakdown.

It was also reported that peri-implantitis lesions, which initially were experimentally induced by ligatures as reported above, could spontaneously progress after the removal of the ligatures. Thus, Zitzmann *et al*. (2004) prepared 21 sites with ligature-induced experimental peri-implantitis in five Labrador dogs. After the lesions had become established, the ligatures were removed and the sites were monitored for an additional 12-month interval. It was observed that in 16 sites the aggressive peri-implantitis conditions persisted and caused continuous bone loss. In the remaining five sites, however, the lesions became encapsulated and no further breakdown of peri-implant bone took place. Using a similar model, Berglundh *et al*. (2007) evaluated progression of peri-implantitis at implants with different surface roughness. Experimental peri-implantitis was induced at implants with either a sandblasted acid-etched surface (SLA) or a polished surface. The ligatures were removed when about 40% of the height of the supporting bone had been lost and plaque accumulation continued during an additional 5 months. It was reported that following ligature removal the progression of bone loss was larger at SLA than at

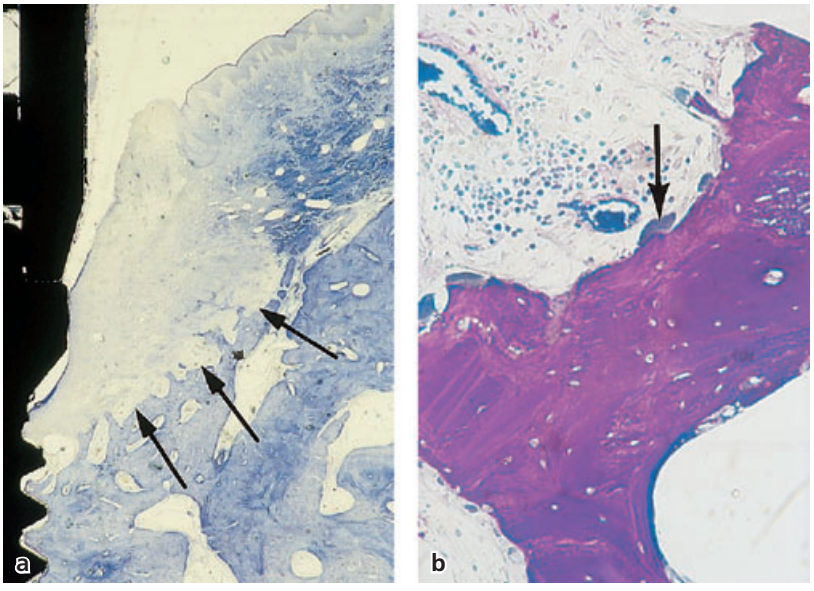

Fig. 24-12 (a) Ground section illustrating a peri-implantitis lesion. The implant is positioned to the left and the apical portions of the infiltrate (arrows) extend into contact with the bone. (b) Close-up of (a) illustrating the presence of inflammatory cells and osteoclasts (arrow) on the bone surface.

polished sites. The histologic examination revealed that both bone loss and the size of the inflammatory lesion in the connective tissue were larger in SLA than in polished implant sites. The area of plaque was also larger at implants with a SLA surface than at implants with a polished surface. It was concluded that the progression of peri-implantitis, if left untreated, is more pronounced at implants with a moderately rough surface than at implants with a polished surface.

Conclusion

Peri-implantitis lesions are poorly encapsulated, extend to the marginal bone tissue and may, if they are allowed to progress, lead to the loss of the implant. The large numbers of neutrophils in the peri-implantitis lesion and the absence of an epithelial lining between the lesion and the biofilm, indicate that the peri-implantitis lesions have features that are different from those of periodontitis lesions. Progression of peri-implantitis is more pronounced at implants with rough than at smooth surfaces.

Summary

Studies in man and experiments in animals have documented that *de novo* formation of a biofilm on the implant surface initiates a host response that involves the establishment of an inflammatory lesion in the peri-implant mucosa (peri-implant mucositis). This lesion is initially located in the connective tissue immediately lateral to the barrier epithelium and is, in many respects, similar to that which develops in the gingiva when plaque forms on adjacent tooth surfaces. In the continued presence of a submarginal biofilm, the lesion in the marginal mucosa around implants may occasionally spread in an "apical" direction to involve the hard tissue, compromise osseointegration, cause varying degrees of marginal bone loss (peri-implantitis), and eventually the loss of the implant.

Part 8: Tissue Regeneration

Chapter 25

Concepts in Periodontal Tissue Regeneration

Thorkild Karring and Jan Lindhe

Introduction

At risk assessment in periodontal patients, the presence of sites with a residual pocket depth ≥6 mm after active treatment plays a significant role in predicting future periodontal destruction (Haffajee *et al*. 1991; Grbic & Lamster 1992; Claffey & Egelberg 1995). Thus, an important goal of periodontal therapy is to obtain a reduced pocket depth after treatment in order to prevent further disease progression. Usually, this goal can be accomplished by non-surgical therapy in patients with moderate periodontitis, whereas in severe cases, particularly in the presence of intrabony defects and furcations, the treatment must be supplemented with periodontal surgery. A fundamental objective of periodontal surgery is to provide access for proper instrumentation and cleaning of the root surface; in addition, most surgical procedures result in the elimination or the reduction of the soft tissue component of the periodontal pocket. Generally, the elimination of deep pockets is achieved by gingivectomy or apical displacement of raised tissue flaps, sometimes associated with bone contouring. In recent years, however, the use of regenerative procedures aimed at restoring the lost periodontal support has become more common.

Periodontal treatment, both surgical and non-surgical, results in recession of the gingival margin after healing (Isidor *et al*. 1984). In severe cases of periodontitis, this may lead to poor esthetics in the front areas of the dentition, in particular when applying surgical procedures including bone contouring for the eradication of bone defects. Treatment of such cases without bone contouring, on the other hand, may result in residual pockets inaccessible to proper cleaning during post-treatment maintenance. These problems can be avoided or reduced by applying regenerative surgical procedures by which the lost periodontal attachment in the bone defects can be restored. Thus, the indication of applying regenerative periodontal therapy is often based on esthetic considerations, besides the fact that the function or long-term prognosis of the treated teeth may be improved.

Localized gingival recession and root exposure may represent an esthetic problem to the patient, and it is often associated with root sensitivity. Such a situation is an indication to apply regenerative periodontal therapy to obtain root coverage in order to improve esthetics and reduce root sensitivity. Successful root coverage implies regeneration of the attachment apparatus on the exposed root surface including cementum with inserting collagen fibers, as well as an esthetically acceptable restoration of the anatomy of the mucogingival complex.

Another indication for regenerative periodontal therapy is furcation-involved teeth. The furcation area is often inaccessible to adequate instrumentation and frequently the roots present concavities and furrows which make proper cleaning of the area after resective surgery impossible. Considering the long-term results and complications reported following

treatment of furcation involvements by traditional resective therapy (Hamp *et al*. 1975; Bühler 1988), it is reasonable to anticipate that the long-term prognosis of furcation-involved teeth can be improved considerably by successful regenerative periodontal therapy.

Case reports also exist demonstrating that "hopeless" teeth with deep vertical defects, increased tooth mobility or through-and-through furcations can be successfully treated with regenerative periodontal therapy (Gottlow *et al*. 1986). However, controlled clinical trials or serial case reports presenting a reasonable predictability of treating such advanced cases are not available.

Regenerative periodontal surgery

Regenerative periodontal therapy comprises procedures which are specially designed to restore those parts of the tooth-supporting apparatus which have been lost due to periodontitis. Regeneration is defined as a reproduction or reconstruction of a lost or injured part in such a way that the architecture and function of the lost or injured tissues are completely restored (Glossary of Periodontal Terms, 1992). This means that the attachment of the tooth has been regenerated when new cementum with inserting collagen fibers has formed on the detached root surface, while regeneration of the periodontal supporting apparatus (periodontium) also includes re-growth of the alveolar bone. Procedures aimed at restoring lost periodontal support have also been described as "reattachment" or "new attachment" procedures.

The term "reattachment" was used to describe the regeneration of a fibrous attachment to a root surface surgically or mechanically deprived of its periodontal ligament tissue, whereas the term "new attachment" was preferred in the situation where the fibrous attachment was restored on a root surface deprived of its connective tissue attachment due to the progression of periodontitis. Research findings, however, indicate that there is no difference regarding the possibility of restoring a connective tissue attachment, whether this has been lost because of periodontal disease or mechanically removed (Nyman *et al*. 1982; Isidor *et al*. 1985). Therefore, it was suggested that the term "new attachment" should be used to describe the formation of new cementum with inserting collagen fibers on a root surface deprived of its periodontal ligament tissue, whether or not this has occurred because of periodontal disease or by mechanical means, and that the term "reattachment" should be confined to describing the reunion of surrounding soft tissue and a root surface with preserved periodontal ligament tissue (Isidor *et al*. 1985).

Periodontal regeneration has been reported following a variety of surgical approaches involving root surface biomodification, often combined with coronally advanced flap procedures, the placement of bone grafts or bone substitute implants, or the use of organic or synthetic barrier membranes (guided tissue regeneration). However, many cases that clinically are considered successful, including cases with significant regrowth of alveolar bone, may histologically show an epithelial lining along the treated root surface instead of deposition of new cementum (Listgarten & Rosenberg 1979).

Successful regeneration is assessed by periodontal probing, radiographic analysis, direct measurements of new bone, and histology. Although histology remains the ultimative standard in assessing true periodontal regeneration, periodontal probing, direct bone measurements, and radiographic measurements of osseous changes are used in the majority of studies of regenerative therapy (Reddy & Jeffcoat 1999).

At the American Academy of Periodontology World Workshop in Periodontics in 1996, the fulfillment of the following criteria was required in order for a periodontal regenerative procedure to be considered as a therapy which can encourage regeneration:

- Human histologic specimens demonstrating formation of new cementum, periodontal ligament, and bone coronal to a notch indicating the apical extension of the periodontitis-affected root surface.
- Controlled human clinical trials demonstrating improved clinical probing attachment and bone.
- Controlled animal histologic studies demonstrating formation of new cementum, periodontal ligament, and bone.

In addition, however, it seems reasonable to require that a regenerative procedure is based on a biological concept which can explain why the treatment results in periodontal regeneration on the basis of current knowledge about periodontal wound healing.

Periodontal wound healing

Regeneration of the periodontium must include the formation of new cementum with inserting collagen fibers on the previously periodontitis-involved root surfaces and the regrowth of the alveolar bone. However, whether regrowth of alveolar bone should always be considered a requirement for success following regenerative periodontal surgery is a matter of discussion. The basis for this discussion is that a fibrous attachment may exist without opposing bone in a normal dentition, not affected by periodontitis, in the presence of bone dehiscenses and fenestrations (see Fig. 1-74).

In 1976, Melcher suggested in a review paper that the type of cell which repopulates the root surface after periodontal surgery determines the nature of the attachment that will form. After flap surgery the

curetted root surface may be repopulated by four different types of cell (Fig. 25-1):

1. Epithelial cells
2. Cells derived from the gingival connective tissue
3. Cells derived from the bone
4. Cells derived from the periodontal ligament.

Previously, in most attempts to restore lost tooth support, particular attention was directed towards the regeneration of the alveolar bone. An investigation was carried out in dogs in order to examine the relationship between the re-establishment of a connective tissue attachment to the root surface and the regrowth of alveolar bone (Nyman & Karring 1979). After elevation of mucoperiostal flaps, the marginal 5–7 mm of the buccal alveolar bone of each experimental tooth was removed (Fig. 25-2). During this procedure, care was taken to minimize the mechanical injury to the connective tissue attachment on the root surface. Prior to flap closure, a notch, serving as a landmark for the histologic measurements, was prepared in the root surface at the level of the surgically reduced bone crest. After 8 months of healing, the animals were sacrificed. Histologic analysis demonstrated that although a connective tissue attachment was re-established consistently on the roots, the amount of bone regeneration varied widely. In some roots, bone regrowth was negligible (Fig. 25-3), whereas in others the bone had regenerated to its normal level. These results demonstrated that the amount of bone regrowth is unrelated to the re-establishment of a connective tissue attachment.

Another experiment was carried out in monkeys (Lindhe *et al*. 1984), in order to examine whether the presence of bone may stimulate the formation of a new connective tissue attachment. Mandibular and maxillary incisors were extracted and re-implanted

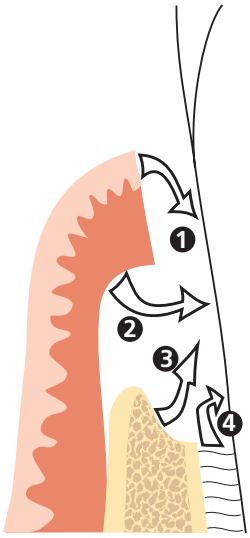

Fig. 25-1 Following flap surgery, the curetted root surface may be repopulated by (1) epithelial cells, (2) gingival connective tissue cells, (3) bone cells, or (4) periodontal ligament cells.

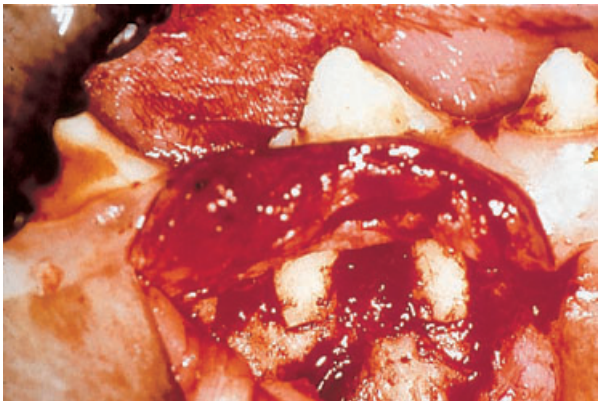

Fig. 25-2 Following flap elevation, the buccal bone, including a part of the inter-radicular and interproximal alveolar bone, is removed without injuring the connective tissue attachment on the root surface.

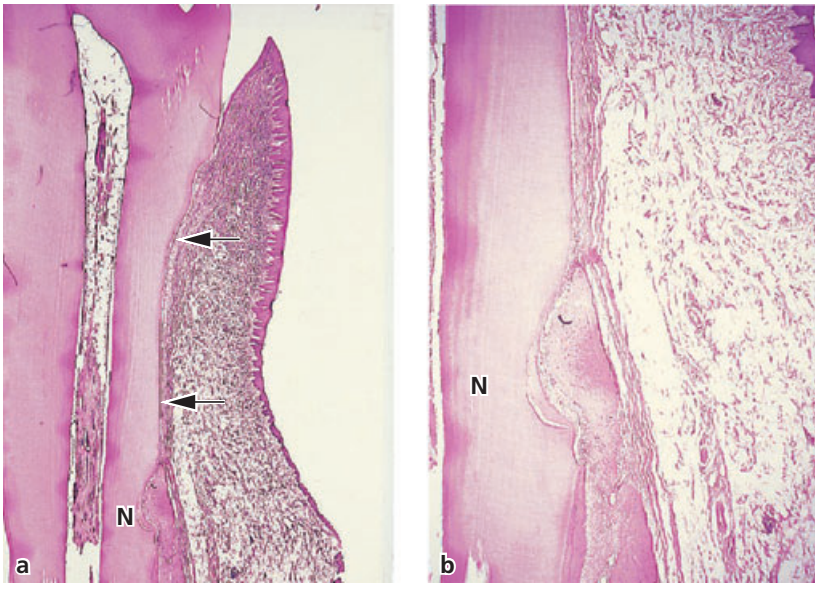

Fig. 25-3 (a) Microphotograph of specimen 8 months following bone removal. A connective tissue attachment is re-established (arrows). Bone regeneration is negligible and is confined to the notch (N) in the root surface. (b) Higher magnification of the newly formed bone in the notch area (N).

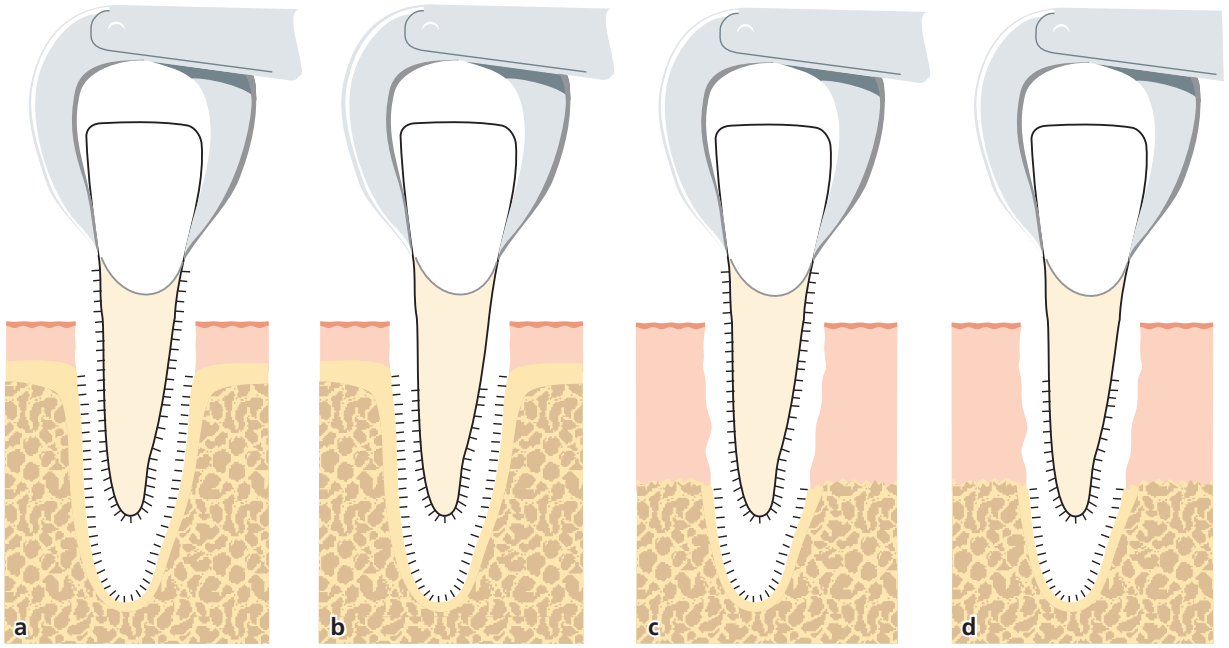

Fig. 25-4 Schematic drawing showing the four experimental conditions (a–d) under which experimental teeth were extracted and re-implanted in their own sockets.

in their own sockets under the following four experimental conditions (Fig. 25-4):

1. Non-root-planed teeth were re-implanted into sockets with normal bone height.
2. Teeth, root planed in their coronal portion, were re-implanted into sockets with normal bone height.
3. Non-root-planed teeth were re-implanted into sockets with a reduced bone height.
4. Teeth, root planed in their coronal portion, were re-implanted into sockets with reduced bone height.

Histologic examination after 6 months of healing revealed that a fibrous reunion was established in areas where the periodontal connective tissue attachment was retained at the time of re-implantation. However, in areas, where the periodontal ligament tissue was removed, the epithelium had always migrated to the apical extension of root instrumentation (Fig. 25-5). These results of healing occurred irrespective of the presence or absence of bone, indicating that the establishment of a connective tissue attachment is unrelated to the presence of alveolar bone.

Using orthodontic appliances, Karring *et al*. (1982) tilted maxillary second and third incisors in labial direction in dogs. Subsequently, these teeth were moved back to their original position. During the same period the contralateral incisors were moved to a labially deviated position. The orthodontic appliances were then used to retain the teeth in these positions for a period of 5 months before sacrifice of the animals. Histologic analysis demonstrated that in all experimental teeth, the apical termination of the junctional epithelium was at the cemento-enamel junction. In the teeth which were retained in their labially displaced position, the level of the alveolar bone was reduced to a position about 4.5 mm apical to the cemento-enamel junction (Fig. 25-6a), while in the teeth which were moved back to their original position, the alveolar bone crest was located at a normal level relative to the cemento-enamel junction (Fig. 25-6b). This experiment demonstrated that bone resorption or bone regeneration may be induced by orthodontic forces on teeth with a pristine connective tissue attachment. The experiments described above indicate that the re-establishment of a connective tissue attachment to the root surface and the regeneration of the alveolar bone are not related to each other.

The use of bone grafts in regenerative periodontal therapy is based on the assumption that the promotion of bone regrowth may also induce cells in the bone to produce a new cementum layer with inserting collagen fibers on previously periodontitis-involved root surfaces. However, histologic studies in both humans and animals have demonstrated that grafting procedures often result in healing with a long junctional epithelium rather than a new connective tissue attachment (Caton & Zander 1976; Listgarten & Rosenberg 1979; Moscow *et al*. 1979).

Ellegaard *et al*. (1973, 1974, 1975, 1976) and Nielsen *et al*. (1980) reported that grafting materials in periodontal bony defects may be:

1. Osteoproliferative (osteogenetic), which means that new bone is formed by bone-forming cells contained in the grafted material.
2. Osteoconductive, which means that the grafted material does not contribute to new bone forma-

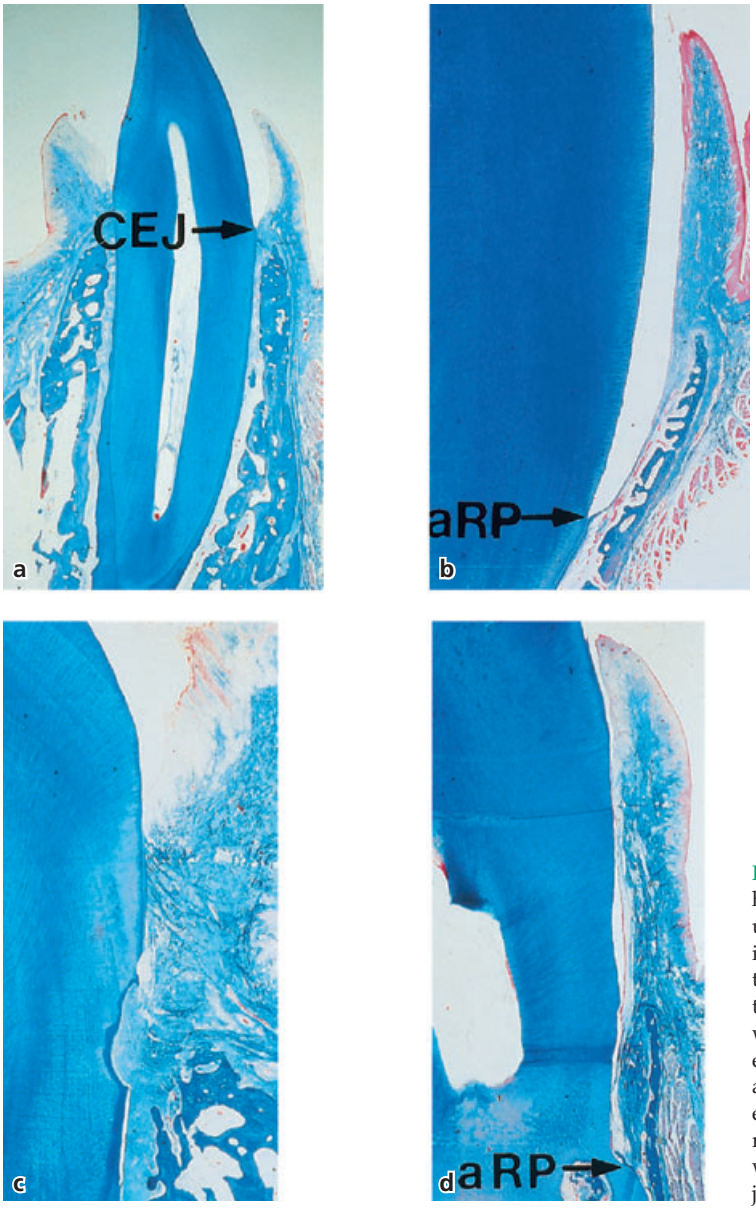

Fig. 25-5 Microphotographs showing the histological features after 6 months of healing, under the four experimental conditions (a–d) illustrated in Fig. 25-4. The teeth in (b) and (d) are those root planed in their coronal portion, and the teeth (a) and (b) are those re-implanted in sockets with normal bone height. A fibrous reunion was established in areas where the connective tissue attachment was retained (a and c) while the epithelium has migrated to the apical extension of root instrumentation (a RP) where the attachment was removed (b and d). CEJ = cemento-enamel junction.

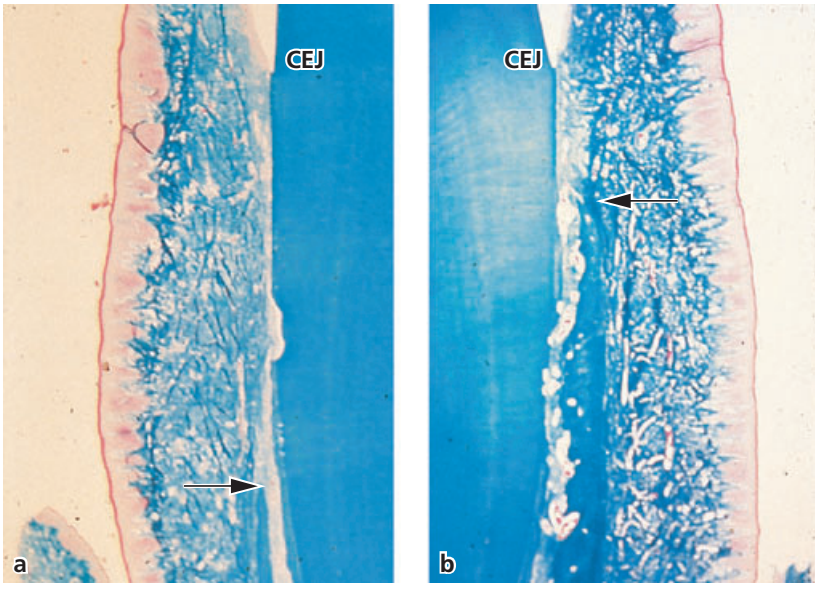

Fig. 25-6 Microphotograph of a tooth retained in its labially displaced position (a) and a tooth (b) moved back to its original position. The level of alveolar bone (arrow) is reduced in (a) while it has regenerated to its normal level (arrow) in (b). The apical termination of the junctional epithelium is at the cemento-enamel junction (CEJ) in both situations.

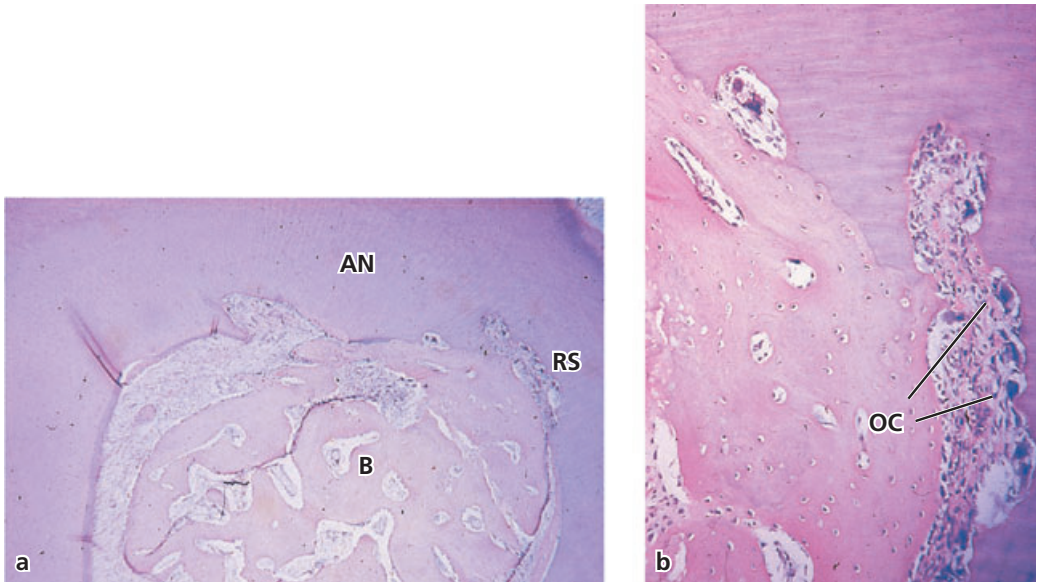

Fig. 25-7 (a) Microphotograph of furcation 6 weeks after grafting with iliac crest marrow. The furcation is completely filled with bone (B), but ankylosis (AN) and root resorption (RS) can be seen. (b) Higher magnification of the area in (a) showing ankylosis and resorption. OC = osteoclasts.

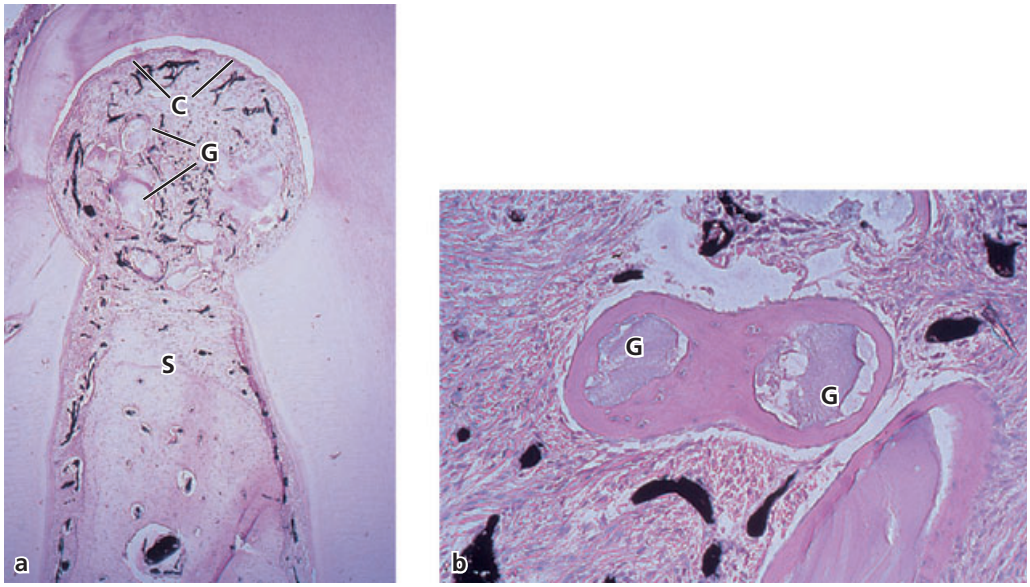

Fig. 25-8 (a) Microphotograph of a healed bifurcation defect following transplantation of non-vital bone grafts. The grafts (G) have not been reached by bone formation from the interradicular septum (S), but occur as isolated particles surrounded by "cementum". Cementum (C) and new connective tissue attachment formation have taken place along the entire circumference of the bifurcation. (b) High magnification of isolated bone grafts (G) with newly formed "cementum" on the surface.

tion *per se* but serves as scaffold for bone formation originating from adjacent host bone.

3. Osteoinductive, which means that bone formation is induced in the surrounding soft tissue immediately adjacent to the grafted material.

These studies, where various types of bone graft were placed in intrabony defects or inter-radicular lesions, revealed that cells survived transplantation only in iliac bone marrow grafts. Transplantation of iliac bone marrow grafts almost consistently resulted in bone fill in the experimental defects, but healing was frequently accompanied by ankylosis and root resorption (Fig. 25-7). The iliac bone marrow grafts exerted an osteogeneic effect, and it was suggested that this was responsible for the induction of root resorption (Ellegaard *et al*. 1973, 1974). Jaw bone grafts and xenografts did not actively contribute to bone formation but served as a scaffold for bone regeneration (i.e. osteoconductive effect). Often, however, these bone grafts were not reached by the new bone growing out from the host bone, but occurred as isolated particles surrounded by a bone-like or cementum-like substance (Fig. 25-8). It was

found that the treated bifurcation defects became filled mainly with granulation tissue derived from the periodontal ligament (Fig. 25-9). The authors (Nielsen *et al*. 1980) suggested that this invasion of ligament tissue inhibited bone formation and that the new cementum on the root surface in the bifurcation defects, including the cementum-like substance observed around the implanted bone particles, was formed by periodontal ligament cells (Fig. 25-8). Thus, it appeared from these studies that the key cells in periodontal regeneration are periodontal ligament cells rather than bone cells.

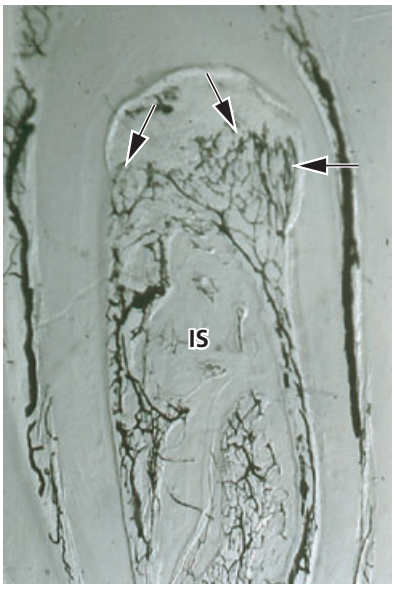

Fig. 25-9 Cleared specimen from a 1-week-old bifurcation defect treated with bone grafts. Judged from the course of the blood vessels, the granulation tissue in the defect has developed mainly from the periodontal ligament (arrows) and only to a minor extent from the inter-radicular septum (IS).

Regenerative capacity of bone cells

The ability of newly formed tissue originating from bone to produce a new connective tissue attachment was examined in a study by Karring *et al*. (1980). Roots of periodontitis-affected teeth were extracted and placed in surgically created sockets in edentulous areas of dogs. The implanted roots were covered with tissue flaps (submerged) and the results of healing were examined histologically after 3 months. A periodontal ligament was re-established in the apical portion of the re-implanted roots where, at the time of implantation, remnants of periodontal ligament tissue were preserved. In the coronal portion of the roots which were previously exposed to periodontitis and then scaled and planed, healing had consistently resulted in ankylosis and root resorption (Fig. 25-10). On the basis of this finding, it was concluded that tissue derived from bone lacks cells with the potential to produce a new connective tissue attachment.

Regenerative capacity of gingival connective tissue cells

Another experiment (Nyman *et al*. 1980) was carried out in order to examine the potential of gingival connective tissue to produce a new connective tissue attachment. The teeth were treated as described in the experiment above but were not transplanted into sockets. Instead they were placed in bone concavities prepared on the buccal aspect of the jaw and subsequently covered by tissue flaps. Thus, half the circumference of the roots was in contact with bone while the remaining part was facing the gingival connective tissue at the subsurface of the flaps. Histologic examination after 3 months of healing showed areas with periodontal ligament in the apical portion of the roots where, at the time of implantation,

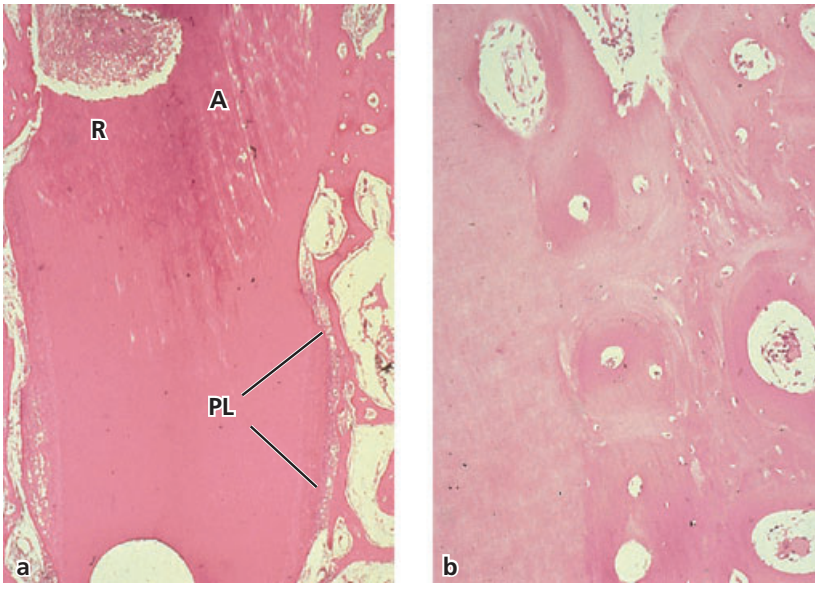

Fig. 25-10 (a) Microphotograph of a re-implanted root after 3 months of healing. A periodontal ligament (PL) has become re-established in the apical portion of the root whereas ankylosis (A) and root resorption (R) is the predominant feature in the coronal portion. (b) High magnification of the ankylosis seen in (a).

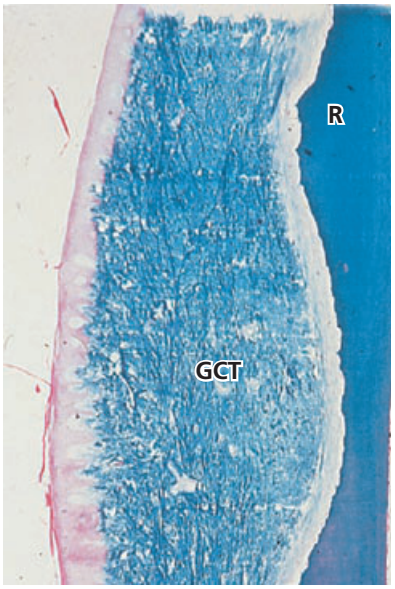

Fig. 25-11 Microphotograph of root (R) which has been re-implanted with its surface facing the gingival connective tissue (GCT). The surface exhibits extensive resorption.

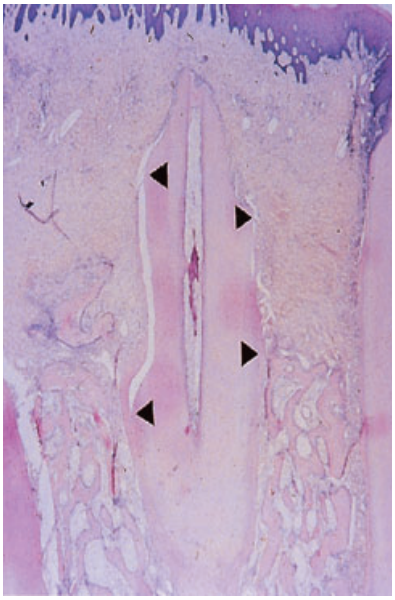

Fig. 25-12 Microphotograph showing new attachment formation (between the arrows) on a submerged root with a non-impaired periodontal ligament. Coronal to the cementum, root resorption is the predominant feature.

periodontal ligament tissue was preserved. In the coronal, previously exposed part of the roots, no signs of new connective tissue attachment were present. The root portion located in contact with gingival connective tissue demonstrated a connective tissue with fibers oriented parallel to the root surface and without attachment to the root. However, root resorption occurred at the majority of the surfaces (Fig. 25-11). On the basis of this result it was concluded that gingival connective tissue also lacks cells with the potential to produce a new connective tissue attachment.

Regenerative capacity of periodontal ligament cells

In the experiments described above, root resorption was also observed occasionally in the apical portion of the extracted and re-implanted roots (Karring *et al*. 1980; Nyman *et al*. 1980). It was suggested that this occurred because the periodontal ligament tissue retained on this part of the root had become injured during extraction, thereby allowing bone or gingival connective tissue to contact the root surface during healing and induce resorption. It was assumed that this damage of the retained periodontal ligament tissue had also restricted its potential of proliferating in the coronal direction along the root surface. Indeed, in a later study (Karring *et al*. 1985), where periodontitis-involved roots were retained in their sockets and subsequently submerged, significant amounts of new connective tissue attachment formed on the coronal portion of the roots (Fig. 25-12). The finding of new attachment only on the roots with a non-impaired periodontal ligament, but never on the extracted and re-implanted roots with an impaired ligament, indicates that periodontal ligament tissue contains cells with the potential to form a new connective tissue attachment on a detached root surface.

Active root resorption occurred consistently at the root surfaces above the coronal extension of new attachment (Fig. 25-12). It was suggested that this resorption was induced by gingival connective tissue which had proliferated apically from the covering tissue flap. Thus, only cells in the periodontal ligament seem capable of regenerating lost periodontal attachment.

The final evidence that the progenitor cells for new attachment formation reside in the periodontal ligament was provided in studies in which titanium dental implants were placed in contact with retained root tips whose periodontal ligament served as a source for cells which could populate the implant surface during healing (Buser *et al*. 1990a,b; Warrer *et al*. 1993). Microscopic analysis revealed that a distinct layer of cementum with inserting collagen fibers had formed on the surfaces of the implants (Fig. 25-13a), and that these fibers, often oriented perpendicularly to the surface, were embedded in the opposite bone (Fig. 25-13b). Control implants (Fig. 25-14) placed without contact with retained roots healed with the characteristic features of osseointegration (i.e. direct contact between bone and the implant surface).

Further proof of the ability of periodontal ligament cells to produce a new connective tissue attachment was recently provided by Parlar *et al*. (2005) using a novel and unique experimental model in dogs. After resection of the crowns of the canine teeth in the dogs, the roots were hollowed to a depth of 5 mm. leaving a thin dentinal wall. Slits were then

Fig. 25-13 (a) Microphotograph of a titanium implant placed in contact with retained root tips. A distinct cementum layer (arrows) and periodontal ligament (PL) in continuity with that on the roots (R) is visible on the implant surface. (b) High magnification in polarized light of the periodontal ligament formed around the implant seen in (a). A cementum layer (arrows) with Sharpey's fibers is present at the implant surface. Principal fibers, oriented perpendicular to the surface, are running across the ligament space (LS) and are inserting in the opposing bone (B) as in natural teeth (see Fig. 1-71).

Fig. 25-14 Microphotograph of a titanium implant placed without contact with retained roots (control). This implant has healed with a direct contact between the bone and the implant surface (osseointegration).

prepared in the cavity wall to create passages from this chamber to the surrounding periodontal ligament. A titanium implant was placed into the center of each chamber, and finally a collagen barrier was placed over the chamber before the roots were submerged. Histologic analysis after 4 months of healing revealed that a periodontal ligament, bone, and root cementum had formed between the implant and the dentinal wall of the chamber. Due to the invasion of periodontal ligament tissue through the slits into the chamber, cementum had formed on the implant as well as the dentinal wall, and a periodontal ligament was consistently interposed between the implant and the bone and between the bone and the dentinal wall. Thus, there is strong evidence that the progenitor cells for periodontal attachment formation reside in the periodontal ligament and not in the alveolar bone as previously assumed (Melcher *et al*. 1987).

Role of epithelium in periodontal wound healing

Some of the roots in the experiment described above (Karring *et al*. 1985) penetrated the covering mucosa at early stages of healing, thereby allowing the epithelium to grow apically along the root surface. The amount of new connective tissue attachment on these roots was considerably smaller than that formed on the roots which remained submerged throughout the study. This finding and those of other investigators (Moscow 1964; Kon *et al*. 1969; Proye & Polson 1982) indicate that the apical migration of epithelium reduces the coronal gain of attachment, evidently by preventing periodontal ligament cells from repopulating the root surface (Fig. 25-15).

Downgrowth of epithelium into the periodontal lesion has most likely occurred to a varying extent during healing following most flap and grafting procedures applied in regenerative periodontal therapy, which may explain the varying results reported. This view is supported by the results of the monkey study by Caton *et al*. (1980). These investigators examined healing in ligature-induced periodontal lesions following treatment with four different modalities of regenerative surgical procedures:

1. Root planing and soft tissue curettage
2. Widman flap surgery without bone grafting

Fig. 25-15 Microphotograph illustrating an intrabony defect after regenerative treatment. New bone (NB) has formed in the defect but epithelium has migrated apically along the root surface to the notch (arrow) in the root surface indicating the bottom of the defect before treatment.

Fig. 25-16 Microphotograph of an implanted root (R) where epithelium was allowed to migrate into the wound after 2 weeks. The epithelium has migrated along the coronal, previously periodontitis-involved root surfaces down to the level indicated by the arrows. In the areas covered by epithelium, there are no signs of resorption. Apical to this level the root surfaces demonstrate root resorption.

3. Widman flap surgery with the placement of frozen autogeneous red bone marrow and cancellous bone
4. Beta-tricalcium phosphate in intrabony defects.

Healing following all treatment modalities resulted in the formation of a long junctional epithelium extending to or close to the same level as before treatment.

Root resorption

In the experimental studies described previously, granulation tissue, derived from gingival connective tissue or bone, produced root resorption when contacting the curetted root surface during healing following surgery (Karring *et al*. 1980, 1985; Nyman *et al*. 1980). It should be expected, therefore, that this phenomenon would occur as a frequent complication to periodontal surgery, particularly following those procedures which include the placement of grafting materials to stimulate bone formation. The reason why root resorption is rarely seen is most likely that post-operatively, the dentogingival epithelium migrates apically along the root surface, forming a protective barrier towards the root surface (Fig. 25-15). This view is supported by the results of an experimental study in monkeys (Karring *et al*. 1984) in which roots, which previously had been subjected to ligature-induced periodontitis, were extracted and re-implanted in contact with bone and connective tissue and covered with a tissue flap (submerged). After varying time intervals the submerged roots were exposed to the oral cavity by a second incision (wounding) through the covering mucosa, thereby permitting the epithelium to migrate into the wound. In specimens where the wounding occurred within 2 weeks (Fig. 25-16), the previously diseased part of the roots was covered by epithelium and showed no signs of resorption. With increasing intervals between implantation of the roots and the wounding, a steadily diminishing part of the diseased root surface was covered by epithelium, and root resorption and ankylosis became progressively pronounced (Fig. 25-17). This observation concurs with results presented by Björn *et al*. (1965) who treated 11 periodontally diseased teeth in seven human volunteers, using the submerging technique which prevented apical migration of the dentogingival epithelium. The authors reported that root resorption was indeed a common complication following this kind of therapy.

Regenerative concepts

One of the first methods used in attempts to obtain new attachment was scaling and root planing combined with soft tissue curettage (i.e. mechanical removal of the diseased root cementum and the pocket epithelium). Studies in humans (e.g. McCall 1926; Orban 1948; Beube 1952; Waerhaug 1952;

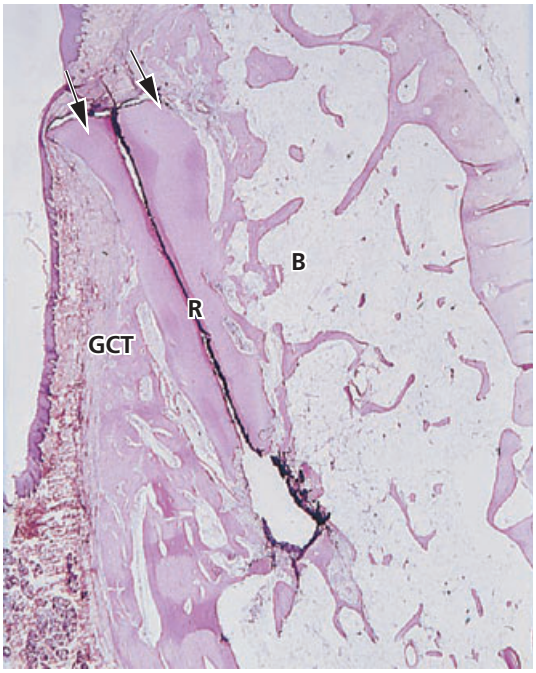

Fig. 25-17 Microphotograph of an implanted root (R) where epithelium was allowed to migrate into the wound after 4 weeks. The epithelium (arrows) covers only the coronal cut root surface. Extensive resorption is seen on the surface facing the gingival connective tissue (GCT) and resorption and ankylosis are seen on the surface facing the bone tissue (B).

Schaffer & Zander 1953; Carranza 1954, 1960) and in animals (e.g. Beube 1947; Ramfjord 1951; Kon *et al*. 1969) showed that this type of periodontal therapy resulted not only in the establishment of gingival health but also in a reduction of the initially recorded pocket depth. This decrease in the depth of the periodontal pocket was assumed to be partly the result of shrinkage of the initially inflamed gingiva, but partly also the effect of the formation of a new connective tissue attachment in the apical part of the pocket.

The possibility of obtaining new attachment became widely accepted with the work of Prichard (1957a,b), in which new attachment formation in intrabony periodontal lesions was reported as a predictable outcome of treatment. Seventeen cases were presented out of which four were subjected to a re-entry surgical procedure, revealing that these defects were filled with bone. The technique of Prichard (1957b, 1960) was only used for the treatment of three-wall intrabony defects, and the results obtained suggested that the morphology of the periodontal bony defect was essential for the establishment of a predictable prognosis. Goldman and Cohen (1958) introduced a classification of periodontal intrabony defects which was based on the number of osseous walls surrounding the defect, being either three-wall, two-wall or one-wall defects or a combination of such situations (Fig. 25-18).

The technique of Prichard (1957a,b, 1960) included the elevation of tissue flaps in order to get access to the defect. All granulation tissue in the defect was removed and the root surface was scaled and planed. In order to enhance regeneration of bone, small perforations were made with a bur at several sites of the bone walls. The flaps were sutured to accomplish complete coverage of the defect. Many clinical investigators have claimed that new attachment resulted following this type of treatment but there is little quantitative or qualitative documentation (Patur & Glickmann 1962; Wade 1962, 1966; Ellegaard & Löe 1971). Patur and Glickmann (1962) reported a clinical study including 24 intrabony defects treated according to the Prichard technique (1957a,b). The outcome was evaluated by comparing pre-operative and post-operative radiographs, measurements of the alveolar bone level adjacent to the root and study casts taken during operation and post-operatively after reflecting buccal and lingual flaps. The authors reported that new attachment had occurred in two-wall and three-wall intrabony defects but not in one-wall defects. Results from a study by Ellegaard and Löe (1971) comprising 191 defects in 24 patients with periodontal disease indicated that complete regeneration, determined radiographically and by periodontal probing, had occurred in around 70% of the three-wall defects, in 40% of the combined two-wall and three-wall defects, and in 45% of the two-wall defects.

In a later study by Rosling *et al*. (1976), 124 intrabony defects in 12 patients were treated by means of the modified Widman flap procedure (Ramfjord & Nissle 1974). Following treatment the patients were recalled twice per month for professional tooth cleaning. Re-examination performed clinically and on radiographs 2 years after therapy demonstrated bone fill-in of two-wall as well as three-wall defects. The authors suggested that this regrowth of bone was also associated with the formation of new connective tissue attachment and ascribed the successful healing mainly to the optimal standard of oral hygiene which was maintained in all patients during healing. A clinical study with almost identical results was presented by Polson & Heijl (1978). The results of several histologic studies in animals and humans, on the other hand, indicate that formation of new periodontal attachment is by no means predictable following subgingival curettage or flap surgery (Listgarten & Rosenberg 1979; Caton & Nyman 1980; Caton *et al*. 1980; Steiner *et al*. 1981; Stahl *et al*. 1983; Bowers *et al*. 1989a).

Grafting procedures

In a number of clinical trials and animal experiments, the flap approach was combined with the placement of bone grafts or implant materials into the curetted bony defects with the aim of stimulating periodontal regeneration. The various graft and

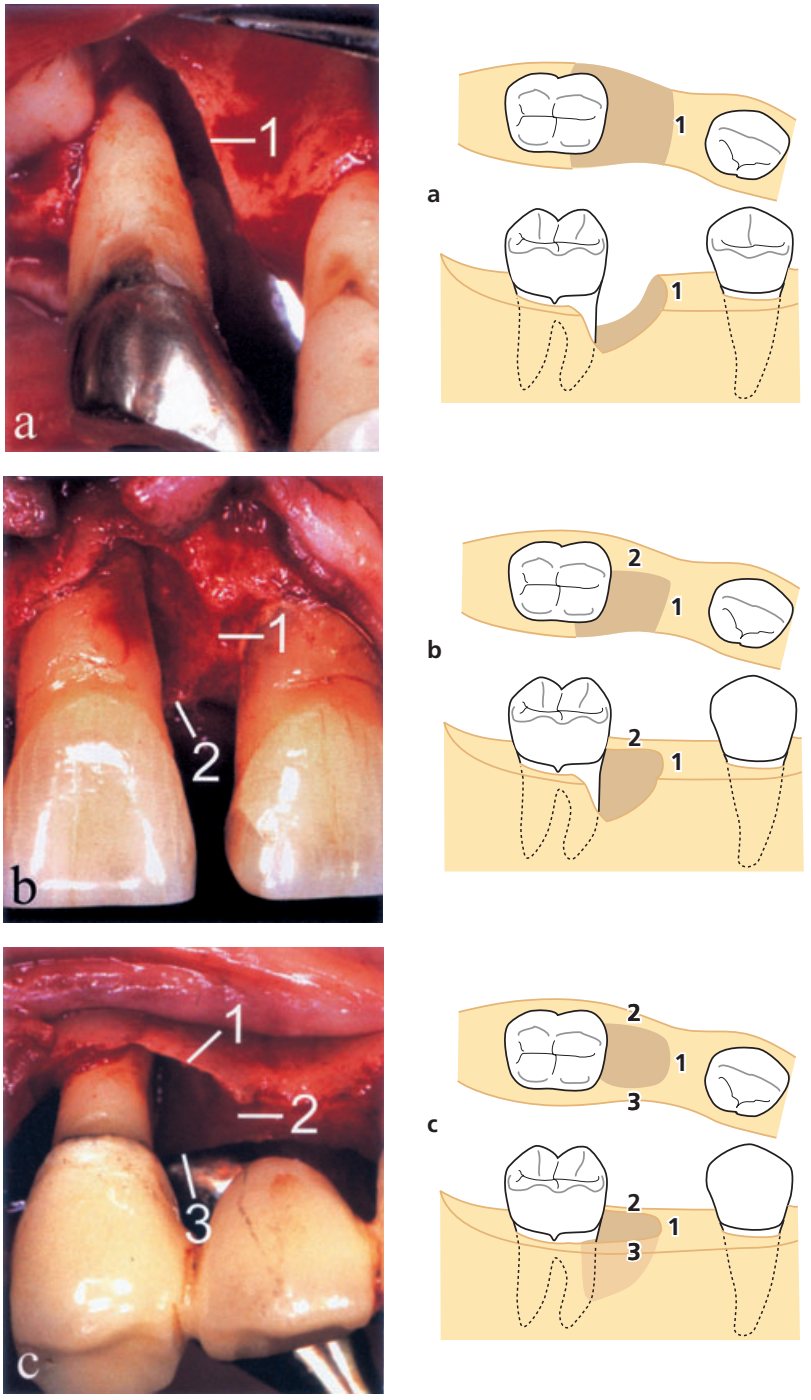

Fig. 25-18 Progression of periodontitis at a different rate on neighboring tooth surfaces results in the development of intrabony defects. Based on the number of surrounding bone walls such defects are classified as one-wall (a), two-wall (b) or three-wall (c) defects.

implant materials used so far can be placed into four categories:

1. *Autogenous grafts*: grafts transferred from one position to another within the same individual. This type of graft comprises (i) cortical bone or (ii) cancellous bone and marrow, and is harvested either from intraoral or extraoral donor sites.
2. *Allogeneic grafts*: grafts transferred between genetically dissimilar members of the same species. (i) Frozen cancellous bone and marrow, and (ii) freeze-dried bone have been used.
3. *Xenogeneic grafts*: grafts taken from a donor of another species.
4. *Alloplastic materials*: synthetic or inorganic implant materials which are used as substitutes for bone grafts.

The rationale behind the use of bone grafts or alloplastic materials is the assumption that both the regrowth of alveolar bone and the formation of new attachment would be stimulated because these materials may either (1) contain bone-forming cells (osteogenesis), or (2) serve as a scaffold for bone formation (osteoconduction), or because (3) the matrix of the bone grafts contains bone-inducing substances (osteoinduction) (Urist 1980; Brunsvold & Mellonig 1993). Such complete regeneration of the periodontal attach-

ment apparatus following grafting procedures would imply, however, that cells derived from bone possess the ability to form new cementum with inserting collagen fibers on a previously periodontitis-involved root surface (Melcher *et al*. 1987). This assumption is in conflict with current knowledge about the biology of periodontal wound healing, that repopulation of the detached root surface with cells from the periodontal ligament is the prerequisite for new attachment formation. This means that all therapeutic procedures involving the placement of bone grafts or bone substitute implants are based on a biologic concept which cannot explain how such treatment should result in regeneration of the periodontium.

The effect of using bone grafts or alloplastic materials for periodontal regeneration has mainly been examined in case reports, while histologic evidence of new attachment and controlled clinical studies is limited. The results from such reports vary and the documentation presented usually consists of pre-operative and post-operative probing attachment levels, radiographic interpretations or re-entry procedures.

Autogenous grafts

Autogenous grafts (autografts) may retain some cell viability and are considered to promote bone healing mainly through osteogenesis and/or osteoconduction. They are gradually resorbed and replaced by new viable bone. In addition, potential problems of histocompatibility and disease transmission are eliminated with autogenous grafts. Autogenous grafts can be harvested from intraoral or extraoral sites.

Intraoral autogenous grafts

Intraoral autogenous grafts obtained from edentulous areas of the jaw, healing extraction sites, maxillary tuberosities or the mandibular retromolar area were commonly used in periodontal regenerative surgery (Mann 1964; Ellegaard & Löe 1971; Rosenberg 1971a,b; Dragoo & Sullivan 1973a,b; Hiatt & Schallhorn 1973; Froum *et al*. 1983; Stahl *et al*. 1983). Generally cancellous bone is preferred as graft material but cortical bone, applied as small chips (Rosenberg *et al*. 1979), or mixed with blood prior to the placement in the defects (Robinson 1969; Froum *et al*. 1976), was also reported to be effective in producing regeneration in periodontal intrabony defects.

The effect of intraoral autogenous grafts has been evaluated in both animals and humans. In a study in monkeys, Rivault *et al*. (1971) observed that intrabony defects filled with intraoral autogenous bone chips mixed with blood (osseous coagulum) healed with new bone formation, but no more bone was found in such experimental defects than was observed in similar control defects treated with surgical curettage. Other studies in monkeys and dogs also failed to demonstrate significant differences in bone formation between grafted and non-grafted intrabony or furcation defects (Ellegaard *et al*. 1974; Coverly *et al*. 1975; Nilveus *et al*. 1978).

In clinical case series where intraoral autogenous grafts were used for the treatment of intrabony periodontal defects, a mean bone fill ranging from 3.0–3.5 mm was reported (Nabers & O'Leary 1965; Robinson 1969; Hiatt & Schallhorn 1973; Froum *et al*. 1975). Hiatt and Schallhorn (1973) treated 166 intrabony lesions with intraoral autogenous cancellous bone. They reported a mean increase in bone height of 3.5 mm, evaluated by clinical measurements. One-wall, two-wall, and three-wall defects were included, and the largest bone fill was observed in defects with the highest number of bone walls. A block section obtained from a patient treated in this study presented histologic evidence of new cementum, bone, and periodontal ligament formation. In controlled clinical studies, intraoral autogenous grafts were found superior to surgical debridement alone in terms of bone fill (Froum *et al*. 1976), or probing attachment (PAL) gain (Carraro *et al*. 1976) in two-wall defects. However, there are controlled studies that demonstrate more modest results regarding bone fill or PAL gain after intraoral grafting when compared to ungrafted controls (Ellegaard & Löe 1971; Renvert *et al*. 1985).

Ross and Cohen (1968) reported new bone and cementum formation in a human histologic specimen from an intrabony defect retrieved 8 months following debridement and placement of intraoral autogenous grafts. They also found that the grafts were without osteocytes and that the deposition of new alveolar bone had taken place around the grafts. Nabers *et al*. (1972) observed that new cementum and functionally oriented periodontal ligament fibers were present in half the length of a defect which was biopsied about 4.5 years after treatment with intraoral autogenous bone grafts. In other human histologic reports, bone fill and new attachment were observed coronal to reference notches placed on the treated roots at the apical termination of root planing (Hiatt *et al*. 1978) or at the most apical level of previously existing calculus (Froum *et al*. 1983; Stahl *et al*. 1983). Other investigators, however, observed an epithelial lining which occupied a varying portion of the previously diseased part of the root (Hawley & Miller 1975; Listgarten & Rosenberg 1979; Moscow *et al*. 1979). The results from these studies and those from a recent meta-analysis (Trombelli 2005) indicate that the treatment of periodontal osseous defects with intraoral bone grafts may result in periodontal regeneration, but not predictably.

Extraoral autogenous grafts

Schallhorn (1967, 1968) introduced the use of autogeneous hip marrow grafts (iliac crest marrow) in the treatment of furcation and intrabony defects. Later several studies were published demonstrating the osteogenic potentials of this material (Schallhorn *et al*. 1970; Schallhorn & Hiatt 1972; Patur 1974; Froum

et al. 1975), and as much as 3–4 mm gain in crestal bone was reported following the treatment of intrabony defects with hip marrow grafts. The effect of iliac crest marrow and of intraoral cancellous bone grafts in one-wall, two-wall, and three-wall bony defects in humans was evaluated by Patur (1974). He reported that bone fill occurred to a varying extent with both types of graft. The amount of bone fill in one-wall bony defects was larger with iliac crest marrow than with cancellous bone or when no grafts were used. Some defects within all three groups showed bone fill, and no difference was observed between the control defects and those treated with intraoral cancellous bone grafts. The author stated that even with fresh iliac crest marrow, bone regeneration is variable and unpredictable.

Healing of inter-radicular and intrabony lesions following placement of iliac crest marrow was evaluated in monkeys by Ellegaard *et al*. (1973, 1974). Regeneration occurred more frequently with the use of grafts, but iliac crest marrow frequently resulted in ankylosis and root resorption (Fig. 25-19).

Histologic evidence of periodontal regeneration in humans following the use of iliac crest marrow grafts was provided by Dragoo and Sullivan (1973a,b). At 8 months following therapy a mature periodontal ligament was present at the grafted sites and about 2 mm supracrestal new attachment had also formed. Clinical evidence of root resorption was noted in seven of the 250 grafted sites.

Due to the morbidity associated with the donor site and the fact that root resorption sometimes results, iliac crest marrow grafts are not used in regenerative periodontal therapy today.

Fig. 25-19 Photomicrograph illustrating an intrabony defect 2 months following grafting with iliac crest marrow. The defect is completely filled with bone, but new cementum (c) is lacking on the root surface except for the most apical part (n) of the defect. Note that ankylosis and root resorption (arrows) are occurring in the coronal part of the defect.

Allogeneic grafts

Allogeneic grafts (allografts) were utilized in attempts to stimulate bone formation in intrabony defects in order to avoid the additional surgical insult associated with the use of autogenous grafts. However, the use of allogeneic grafts involves a certain risk regarding antigenicity, although the grafts are usually pretreated by freezing, radiation or chemicals in order to suppress foreign body reactions.

The types of allogeneic grafts used are frozen iliac cancellous bone and marrow, mineralized freeze-dried bone allogeneic grafts (FDBA), and decalcified freeze-dried alogeneic bone grafts (DFDBA). The need for cross matching to decrease the likelihood of graft rejection as well as the risk of disease transmission virtually eliminated the use of frozen iliac allogeneic grafts in periodontics.

FDBA is a mineralized bone graft, which loses cell viability through the manufacturing process and, therefore, is supposed to promote bone regeneration through osteoconduction/osteoinduction (Goldberg & Stevenson 1987). The freeze drying also markedly reduces the antigenicity of the material (Turner & Mellonig 1981; Quattlebaum *et al*. 1988). The efficacy of FDBA was evaluated in a study which included 89 clinicians (Mellonig 1991). At re-entry surgery it was found that 67% of the sites treated with FDBA alone and 78% of the sites treated with FDBA plus autogenous bone grafts demonstrated complete or more than 50% bone fill. Thus, FDBA plus autogenous bone appeared more effective than FDBA alone. In split-mouth studies where FDBA was combined with autogenous grafts or tetracycline powder (Sanders *et al*. 1983; Mabry *et al*. 1985), a defect fill of 60% and 80% of the initial lesion was reported. In a split-mouth study it was also shown that FDBA implantation had a similar effect on defect resolution as that achieved by DFDBA (Rummelhart *et al*. 1989) or granular porous hydroxyapatite (Barnett *et al*. 1989). However, the only controlled clinical trial comparing treatment of intrabony defects with FDBA implantation versus flap surgery failed to demonstrate any difference in terms of clinical attachment gain and bone fill between test and control sites at 1 year re-entry examination (Altiere *et al*. 1979). In addition, human histologic specimens demonstrated that implantation of FDBA in intrabony defects yielded no periodontal regeneration but resulted in a long epithelial attachment on the previously diseased root surface (Dragoo & Kaldahl 1983).

Several animal studies suggested that demineralization of a cortical bone allograft (DFDBA) enhances its osteogenic potential by exposing bone morphogenic proteins (BMPs) which presumably have the ability to induce host cells to differentiate into osteoblasts (Urist & Strates 1970; Mellonig *et al*. 1981). Several case reports presented clinical improvements and bone fill after implantation of DFDBA into intrabony defects (Quintero *et al*. 1982; Werbitt 1987; Fucini *et al*. 1993; Francis *et al*. 1995), and controlled clinical studies documented considerable gain of attachment and bone fill in sites treated with DFDBA as compared with non-grafted sites (Pearson *et al*. 1981; Mellonig 1984; Meadows *et al*. 1993). However, no statistical differences regarding attachment level changes and bone fill were found when comparing sites treated with FDBA and sites treated with DFDBA (Rummelhart *et al*. 1989).

Histologic evidence of regeneration following grafting with DFDBA was provided by Bowers *et al*. (1989b,c). Complete regeneration with new cementum, periodontal ligament, and bone amounting to 80% of the original defect depth was reported at sites treated with DFDBA, which was considerably more than that observed in defects treated with surgical debridement alone. However, animal experiments failed to confirm the regenerative potential of DFDBA grafting (Sonis *et al*. 1985; Caplanis *et al*. 1998).

The controversial results regarding the effect of DFDBA on the regeneration of periodontal intraosseous defects along with great differences in the osteoinductive potential (ranging from high to no osteoinductive effect) of commercially available DFDBA (Becker *et al*. 1994, 1995; Shigeyama *et al*. 1995; Schwartz *et al*. 1996; Garraway *et al*. 1998), and the (although minute) risk for disease transmission have raised concern about the clinical applicability of DFDBA. In EU countries, commercially available DFDBA is not granted a CE mark permitting distribution of the material within the community.

Xenogeneic grafts

The use of xenogeneic bone grafts (xenografts) in regenerative periodontal surgery was examined several years ago. Nielsen *et al*. (1981) treated 46 intrabony defects with Kielbone® (i.e. defatted and deproteinized ox bone) and another 46 defects with intraoral autogenous bone grafts. The results, which were evaluated by periodontal probing and radiographically, showed no difference between the amount of clinical gain of attachment and bone fill obtained in the two categories of defect. A study in monkeys also demonstrated that the two types of bone graft displayed similar histologic features and were frequently seen in the connective tissue of the healed defects as isolated bone particles surrounded by a cementum-like substance (Nielsen *et al*. 1980).

Recently, new processing and purification methods have been utilized which make it possible to remove all organic components from a bovine bone source and leave a non-organic bone matrix in an unchanged inorganic form (e.g. Bio-Oss®, Geistlich AG, Switzerland; Lubboc®/Laddec®, Ost Development SA, France; Endobone®, Biomet Inc. Dordrecht, The Netherlands; OsteoGraf®/N, DENTSPLY, Friadent CeraMed, Lakewood, CO, USA; Cerabone®, aap Implantate AG, Berlin, Germany). However, differences in the purification and manipulation methods of the bovine bone have lead to commercially available products with different chemical properties and possibly different biologic behavior. These materials are available in different particle sizes or as block grafts.

To date, no controlled human study has compared the effect of such graft materials in periodontal defects with flap surgery alone, but a clinical study has demonstrated that implantation of Bio-Oss® resulted in pocket reduction, gain of attachment, and bone fill in periodontal defects to the same extent as that of DFDBA (Richardson *et al*. 1999). There are, on the other hand, several controlled clinical studies reporting about the outcome of treatment of periodontal intrabony defects with Bio-Oss used as an adjunct to guided tissue regeneration (GTR). In one of these studies, including 124 patients, the combined treatment had an added benefit of 0.8 mm PAL gain over that with flap surgery alone (Tonetti *et al*. 2004). However, conflicting results have been reported following the combined Bio-Oss and GTR treatment of intrabony defects versus GTR alone. In a recent study, significantly more PAL gain was found after the combined treatment than after GTR treatment with a collagen membrane (5.1 mm versus 4.0 mm) (Paolantonio 2002), while in another study, the clinical improvements obtained following the two treatments were similar (Stavropoulos *et al*. 2003b). This latter finding is in agreement with the results of a recent systematic review evaluating various bone grafts and bone graft substitutes as adjuncts to GTR (Murphy & Gunsolley 2003). Studies in experimental animals have also failed to show an added effect of Bio-Oss combined with GTR (Carmagnola *et al*. 2002, 2003). However, human histology (Camelo *et al*. 1998; Nevins *et al*. 2003; Sculean *et al*. 2003) and a study in dogs (Clergeau *et al*. 1996) have suggested that the placement of bovine bone-derived biomaterials in periodontal bone defects may enhance both the regeneration of a new connective tissue attachment and bone. The results of several experimental studies in animals, on the other hand, have questioned whether Bio-Oss encourages bone formation (Stavropoulos *et al*. 2001, 2003a, 2004; Aghaloo *et al*. 2004; Cardaropoli *et al*. 2005). In fact, the results of some of these studies suggest that grafting of Bio-Oss may compromise bone formation.

The use of coral skeleton as a bone graft substitute was proposed some decades ago (Holmes 1979; Guillemin *et al*. 1987). Depending on the pretreatment procedure, the natural coral turns into

non-resorbable porous hydroxyapatite (e.g. Interpore 200, Interpore International, Irvine, US) or to a resorbable calcium carbonate (e.g. Biocoral, Inoteb, St Gonnery, France) skeleton (Nasr *et al*. 1999). Implantation of coralline porous hydroxyapatite in intrabony periodontal defects in humans produced more probing pocket depth reduction, clinical attachment gain, and defect fill than non-grafting (Kenney *et al*. 1985; Krejci *et al*. 1987; Yukna 1994; Mora & Ouhayoun 1995; Yukna & Yukna 1998), and similar results were found when compared with grafting of FDBA (Barnett *et al*. 1989). When porous hydroxyapatite was compared with DFDBA for the treatment of intraosseous defects, similar results were also obtained (Bowen *et al*. 1989), but another study reported clinical results in favor of this material (Oreamuno *et al*. 1990). However, both animal (West & Brustein 1985; Ettel *et al*. 1989) and human studies (Carranza *et al*. 1987; Stahl & Froum 1987) have provided only vague histologic evidence that grafting of natural coral may enhance the formation of true new attachment. In most cases, the graft particles were embedded in connective tissue with minimal bone formation.

Alloplastic materials

Alloplastic materials are synthetic, inorganic, biocompatible and/or bioactive bone graft substitutes which are claimed to promote bone healing through osteoconduction. There are four kinds of alloplastic materials, which are frequently used in regenerative periodontal surgery: hydroxyapatite (HA), beta-tricalcium phosphate (β-TCP), polymers, and bioactive glasses (bio-glasses).

Hydroxyapatite

The HA products used in periodontology are of two forms: a particulate non-resorbable ceramic form (e.g. Periograf®, Miter Inc., Warsaw, IN, US; Calcitite®, Calcitek Inc., San Diego, US) and a particulate, resorbable non-ceramic form (e.g. OsteoGraf/LD®, CeraMed Dental, Lakewood, CO, US). In controlled clinical studies, grafting of intrabony periodontal lesions with HA resulted in a PAL gain of 1.1–3.3 mm and also in a greater bone defect fill as compared with non-grafted surgically debrided controls (Meffert *et al*. 1985; Yukna *et al*. 1985, 1986, 1989; Galgut *et al*. 1992). In these studies, improvement of clinical parameters (i.e. PPD reduction and PAL gain) was more evident in the grafted sites than in the sites treated only with debridement, especially for initially deep defects. However, animal studies (Barney *et al*. 1986; Minabe *et al*. 1988; Wilson & Low 1992) and human histologic data (Froum *et al*. 1982; Moskow & Lubarr 1983; Ganeles *et al*. 1986; Sapkos 1986) showed that bone formation was limited and that a true new attachment was not formed consistently after grafting of intrabony periodontal defects with HA. The majority of the HA particles were embedded in connective tissue and new bone was only observed occasionally around particles in close proximity to host bone. A junctional epithelium lined the major part of the roots.

Beta-tricalcium phosphate (β-TCP)

β-TCP ($Ca_3(PO_4)_2$) (e.g. Synthograft®, Johnson and Johnson, New Brunswick, NJ, US) has been used in a series of case reports for the treatment of periodontal osseous lesions (Nery & Lynch 1978; Strub *et al*. 1979; Snyder *et al*. 1984; Baldock *et al*. 1985). After variable time intervals, a significant gain of bone was observed by means of re-entry or radiographs. However, there is no controlled study comparing the result of β-TCP grafting with that of open-flap debridement, and histologic data from animal (Levin *et al*. 1974; Barney *et al*. 1986) and human studies (Dragoo & Kaldahl 1983; Baldock *et al*. 1985; Bowers *et al*. 1986; Stahl & Froum 1986; Froum & Stahl 1987; Saffar *et al*. 1990) showed that β-TCP is rapidly resorbed or encapsulated by connective tissue, with minimal bone formation and no periodontal regeneration.

Polymers

There are two polymer materials that have been used as bone graft substitutes in the treatment of periodontal defects: a non-resorbable, calcium hydroxide coated co-polymer of polymethylmethacrylate (PMMA) and polyhydroxylethylmethacrylate (PHEMA), which is often referred to as HTR (hard tissue replacement) (e.g. HTR™, Bioplant Inc., New York, NY, US), and a resorbable polylactic acid (PLA) polymer (Driloc®, Osmed Corp., Costa Mesa, CA, US).

In controlled clinical studies, implantation of HTR polymer grafts in intrabony defects resulted in a defect fill of approximately 2 mm, representing about 60% of the initial defect depth, but the improved clinical response with grafting was not significantly better than that following solely flap operation (Yukna 1990; Shahmiri *et al*. 1992). Human histologic data from an experimental study (Plotzke *et al*. 1993), and from two case reports (Stahl *et al*. 1990b; Froum 1996) also revealed that grafting of osseous periodontal defects with HTR does not promote periodontal regeneration. The HTR particles were most frequently encapsulated by connective tissue with only scarce evidence of bone formation. Healing resulted in a long junctional epithelium along the root surface, and true new attachment formation was not observed.

When PLA particles were implanted into intrabony defects in humans and compared with DFDBA or surgically debrided controls, it was found that the healing results were less favorable than after flap operation alone, both in terms of clinical parameters (PPD and PAL gain), and in terms of bone fill (Meadows *et al*. 1993).

Bioactive glasses (bio-glasses)

Bio-glasses are composed of SiO_2, Na_2O, P_2O_5 and are resorbable or not resorbable depending on the relative proportion of these components. When bio-glasses are exposed to tissue fluids, a double layer of silica gel and calcium phosphate is formed on their surface. Through this layer the material promotes absorption and concentration of proteins used by osteoblasts to form extracellular bone matrix which theoretically may promote bone formation (Hench *et al*. 1972). Commercially available bio-glasses in particulate form, and theoretically resorbable, have been proposed for periodontal treatment (e.g. PerioGlass®, US Biomaterials Corp., Alachua, FL, US; BioGran®, Orthovita, Malvern, PA, US).

A human case report demonstrated that implantation of bio-glass in periodontal osseous defects resulted in a gain of clinical attachment of 2.0–5.3 mm and a radiographic bone fill of 3.5 mm, and in a controlled study, the treatment of intrabony defects with bio-glass also resulted in greater clinical improvements than surgical debridement alone (Froum *et al*. 1998). However, other controlled studies (Zamet *et al*. 1997) and split-mouth studies on grafting of intrabony defects with bio-glass (Ong *et al*. 1998) failed to demonstrate statistically significant better clinical results than surgery alone or DFDBA grafting (Lovelace *et al*. 1998). Although experimental studies in monkeys have suggested that bio-glass grafting of periodontal intrabony defects (Karatzas *et al*. 1999) may favor new cementum formation and inhibit epithelial downgrowth, there is no histologic evidence in humans that bio-glass may promote true periodontal regeneration. In a histologic evaluation of bio-glass implanted in intrabony defects in humans it was observed that, although clinically satisfactory results were produced, healing had most frequently occurred with a junctional epithelium along the previously diseased part of the root, and new cementum with inserting collagen fibers was found in only one out of five treated teeth. Bone formation was limited in all specimens (Nevins *et al*. 2000).

Evaluation of alloplastic materials

There are no controlled clinical studies demonstrating that grafting with tricalcium phosphate or polymers results in significant clinical improvements beyond that of flap surgery, whereas several reports have indicated that grafting with hydroxyapatite or bioactive glasses may produce more gain of attachment than open-flap debridement (Galgut *et al*. 1992; Zamet *et al*. 1997; Froum *et al*. 1998) or a gain similar to that obtained following grafting with DFDBA (Lovelace *et al*. 1998). Histologic evidence that the use of alloplastic or synthetic graft materials may lead to periodontal regeneration in humans is lacking, and animal experiments have failed to demonstrate regeneration of a functional periodontium following implantation of hydroxyapatite, tricalcium phosphate or polymers in periodontal lesions (Barney *et al*. 1986; Shahmiri *et al*. 1992). It was reported, however, that treatment with bioactive glasses in experimental animals produced significantly more bone fill and new attachment compared with that in non-grafted controls (Fetner *et al*. 1994; Karatzas *et al*. 1999) or in sites grafted with hydroxyapatite or tricalcium phosphate (Wilson & Low 1992). Although some bone formation has been reported following the use of alloplastic materials, there is no evidence that these materials may stimulate the formation of new cementum with inserting collagen fibers. At the 1996 American Academy of Periodontology World Workshop, it was concluded that synthetic graft materials function primarily as defect fillers.

Root surface biomodification

Much research has been directed to altering the periodontitis-involved root surface in a manner that will promote the formation of a new connective tissue attachment. Removal of bacterial deposits, calculus, and endotoxins from the cementum is generally considered essential for the formation of a new connective attachment (Garrett 1977). However, it was suggested by Stahl *et al*. (1972) that demineralization of the root surface, exposing the collagen of the dentin, would facilitate the deposition of cementum by inducing mesenchymal cells in the adjacent tissue to differentiate into cementoblasts. The biologic concept is that exposure of collagen fibers of the dentin matrix may facilitate adhesion of the blood clot to the root surface and thereby favor migration of the fibroblasts. However, it is doubtful whether this concept is in accordance with current knowledge about periodontal wound healing since there is no evidence that the exposure of collagen fibers of the dentin matrix may facilitate repopulation of the root surface with cells derived from the periodontal ligament. As mentioned previously, periodontal ligament cells are required for the accomplishment of a new connective tissue attachment.

Several studies using various animal models demonstrated an improved healing response histologically following citric acid and tetracycline root surface demineralization (Register & Burdick 1976; Crigger *et al*. 1978; Polson & Proye 1982; Claffey *et al*. 1987). However, in a study in dogs where naturally occurring furcations were treated with citric acid, several specimens demonstrated ankylosis and root resorption (Bogle *et al*. 1981). This finding corroborates that of Magnusson *et al*. (1985) in monkeys, where citric acid conditioning was evaluated in combination with coronally displaced tissue flaps after 6 months. These investigators found root resorption on 28 out of 40 surfaces examined and 21 of these also presented ankylosis.

New connective tissue attachment following citric acid demineralization of root surfaces has been demonstrated histologically in humans (Cole *et al*. 1980; Frank *et al*. 1983; Stahl *et al*. 1983; Stahl & Froum

1991a). Cole *et al*. (1980) showed histologic evidence of a new connective tissue attachment and bone formation coronal to reference notches placed in the apical extent of calculus identified on the root surface at the time of surgery. However, despite histologic evidence of regeneration following root surface biomodification with citric acid, results of controlled clinical trials failed to show any improvements in clinical conditions compared to controls not treated with acid (Moore *et al*. 1987; Fuentes *et al*. 1993).

In recent years, biomodification of the root surface with enamel matrix proteins (Emdogain®) during surgery and following demineralization with EDTA has been introduced to encourage periodontal regeneration. The biologic concept is that the application of enamel matrix proteins (amelogenins) may promote periodontal regeneration because it mimics events that took place during the development of the periodontal tissues (Hammarström 1997; Gestrelius *et al*. 2000). This view is based on the finding that the cells of the Hertwigs epithelial root sheath deposit enamel matrix proteins on the root surface prior to cementum formation and that these proteins are the initiating factor for the formation of cementum. The commercially available product, Emdogain®, a purified acid extract of porcine origin, contains enamel matrix derivatives (EMD), supposed to be able to promote periodontal regeneration. However, it is not quite clear how this concept is in accordance with current knowledge about periodontal wound healing since no evidence has been provided that it is cells derived from the periodontal ligament that are encouraged to repopulate the root surface after treatment. In fact, a study in dogs (Araùjo *et al*. 2003) where re-implanted roots that had been extracted and deprived of vital cementoblasts and subsequently treated with EMD failed to prevent ankylosis and root resorption, indicating that the root surfaces did not become repopulated with cells with the capacity to form cementum. A recent study in vitro has also failed to confirm that EMD has any significant effect on periodontal ligament cell proliferation (Chong *et al*. 2006).

In case series reports, 4–4.5 mm gain of clinical attachment, and about 70% bone fill in intrabony defects were reported following treatment with EMD (Heden *et al*. 1999; Heden 2000). In a multicenter clinical study involving 33 subjects with 34 paired intrabony defects, application of EMD resulted in larger amounts of PAL gain (2.2 mm) and statistically significantly more bone gain (2.6 mm) than open-flap debridement after 36 months, evaluated clinically and radiographically (Heijl *et al*. 1997). Similar results were reported in another split-mouth clinical trial (23 patients) published more recently (Froum *et al*. 2001). In that study a PPD reduction of 4.9 mm, a PAL gain of 4.3, and a bone gain of 3.8 mm (evaluated by re-entry surgery) were observed after EMD application in 53 intrabony defects. These values were statistically significantly larger than those obtained by flap surgery (2.2 mm, 2.7 mm, and 1.5 mm, respectively, in 31 defects).

In a more recent prospective multicenter randomized controlled clinical trial, the clinical outcomes of papilla preservation flap surgery (simplified papilla preservation flap, SPPF) with or without the application of enamel matrix proteins, were compared (Tonetti *et al*. 2002). A total of 83 test and 83 control patients with similar baseline periodontal conditions and defect characteristics were treated with either SPPF and Emdogain® or with SPPF alone. The test defects exhibited significantly more clinical attachment level (CAL) gain than the controls (3.1 ± 1.5 mm and 2.5 ± 1.5 mm, respectively).

When application of EMD was compared with GTR treatment, it was found that similar clinical improvements were obtained. In a randomized controlled clinical study, Pontoriero *et al*. (1999) compared EMD application with GTR with resorbable (two kinds: Guidor and Resolut) and non-resorbable (e-PTFE) membranes in intrabony defects. After 12 months, there were no significant differences among the groups, and EMD application resulted in a PPD reduction of 4.4 mm and a PAL gain of 2.9 mm, while the corresponding values from the membrane-treated sites (both GTR groups combined) were 4.5 mm and 3.1 mm, respectively. Silvestri *et al*. (2000) reported a PPD reduction of 4.8 mm and a PAL gain of 4.5 mm after EMD application in intrabony defects versus 5.9 mm and 4.8 mm, respectively, after GTR with non-resorbable membranes. Similar results were reported by other investigators (Sculean *et al*. 1999a,b; Silvestri *et al*. 2003; Sanz *et al*. 2004). There are studies indicating that following the application EMD in intrabony defects, clinical improvements can be achieved by the additional use of some bone graft materials (Zucchelli *et al*. 2003; Gurinsky *et al*. 2004; Trombelli *et al*. 2006), although others have failed to demonstrate a beneficial effect of this combined treatment (Sculean *et al*. 2005).

Histologic evidence of new cementum formation with inserting collagen fibers on a previously periodontitis-affected root surface and the formation of new alveolar bone in human specimens have been demonstrated following EMD treatment (Mellonig 1999; Sculean *et al*. 1999b). However, while in the study of Mellonig (1999) healing had occurred with acellular cementum on the root surface, the newly formed cementum in the study of Sculean *et al*. (1999b) displayed a predominantly cellular character. The ability of EMD to produce regeneration has been confirmed in controlled animal experiments (Fig. 25-20), following the treatment of intrabony, furcation, and dehiscence defects (Hammarström *et al*. 1997; Araújo & Lindhe 1998; Sculean *et al*. 2000). In a later study it was shown in monkeys that the combined application of EMD and autogenous bone grafts may improve periodontal regeneration in periodontal defects compared to flap surgery alone (Cochran *et al*. 2003).

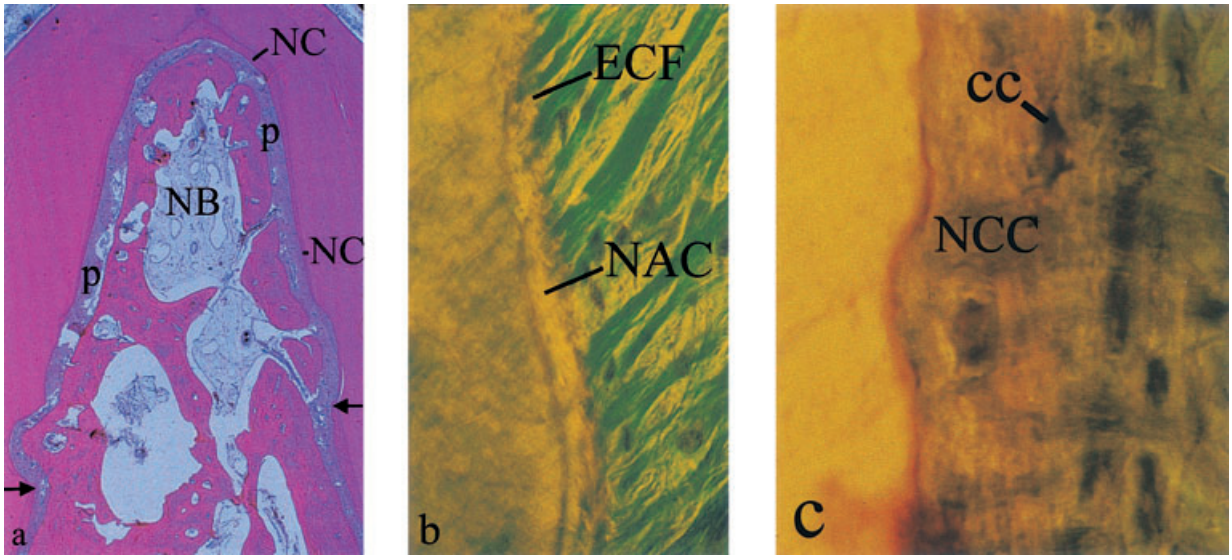

Fig. 25-20 (a) Photomicrograph of a grade III furcation defect in a dog following root surface biomodification with enamel matrix proteins and subsequently covered with a resorbable membrane. The defect has healed completely with bone (NB), a periodontal ligament (p) and new cementum (NC). The arrows indicate the apical extension of the lesion. (b) The cementum (NAC) formed on the root surface in the apical portion of the defect was acellular with inserting extrinsic collagen fibers (ECF) while (c) new cellular cementum (NCC) had formed in the coronal portion. cc = cells.

Growth regulatory factors for periodontal regeneration

Growth factor is a general term to denote a class of polypeptide hormones that stimulate a wide variety of cellular events such as proliferation, chemotaxis, differentiation, and production of extracellular matrix proteins (Terranova & Wikesjö 1987). Proliferation and migration of periodontal ligament cells and synthesis of extracellular matrix as well as differentiation of cementoblasts and osteoblasts is a prerequisite for obtaining periodontal regeneration. Therefore, it is conceivable that growth factors may represent a potential aid in attempts to encourage regeneration of the periodontium.

The effects of various growth factors were studied *in vitro*, and a significant regeneration potential of growth factors was also demonstrated in animal models. Lynch *et al*. (1989, 1991) examined the effect of placing a combination of platelet-derived growth factors (PDGF) and insulin-like growth factors (IGF) in naturally occurring periodontal defects in dogs. The control sites treated without growth factors healed with a long junctional epithelium and no new cementum or bone formation, while regeneration of a periodontal attachment apparatus occurred at the sites treated with growth factors. Similar results were reported by other investigators following application of a combination of PDGF and IGF in experimentally induced periodontal lesions in monkeys (Rutherford *et al*. 1992; Giannobile *et al*. 1994, 1996). One study examined the effect of PDGF and IGF in periodontal intrabony defects and grade II furcations in humans (Howell *et al*. 1997). At re-entry after 9 months, significantly increased bone fill was only observed at the furcation sites treated with growth factors. Considerable clinical improvements were also observed following a combined treatment of grade II furcations with GTR, a bone graft substitute and PDGF compared to open-flap debridement (Lekovic *et al*. 2003). It can be concluded that growth factors seem to have a positive effect on periodontal regeneration, but several important questions need to be resolved before this type of regenerative treatment can be used in humans (Graves & Cochran 1994).

Bone morphogenetic proteins (BMPs) are osteoinductive factors that may have the potential to stimulate mesenchymal cells to differentiate into bone-forming cells (Wozney *et al*. 1988). Sigurdsson *et al*. (1995) evaluated bone and cementum formation following regenerative periodontal surgery using recombinant human BMP in surgically created supraalveolar defects in dogs. Following application of BMP the flaps were advanced to submerge the teeth and sutured. Histologic analysis showed significantly more cementum formation and regrowth of alveolar bone on BMP-treated sites as compared to the controls. Significant amounts of bone regeneration in periodontal defects have also been reported by other investigators following application of BMPs combined with various carrier systems or space-providing devices in different animal models (Ripamonti *et al*. 1994; Selvig *et al*. 2002; Wikesjö *et al*. 2003a,b). Further experimentation is needed to evaluate a possible role of BMP in periodontal regeneration.

Guided tissue regeneration (GTR)

The experimental studies (Karring *et al*. 1980; Nyman *et al*. 1980; Buser *et al*. 1990a,b; Warrer *et al*. 1993) described previously have documented that the

progenitor cells for the formation of a new connective tissue attachment reside in the periodontal ligament. Consequently, it should be expected that a new connective tissue attachment would be predictably achieved if such cells populate the root surface during healing. This view was confirmed in a study in monkeys in which both gingival connective tissue and gingival epithelium were prevented from contacting the root surface during healing by the use of a barrier membrane (Gottlow *et al*. 1984). After reduction of the supporting tissues around selected experimental teeth, the root surfaces were exposed to plaque accumulation for 6 months. Soft tissue flaps were then raised and the exposed root surfaces were curetted. The crowns of the teeth were resected and the roots were submerged. However, prior to complete closure of the wound, a membrane was placed over the curetted root surfaces on one side of the jaws in order (1) to prevent gingival connective tissue contacting the root surface during healing, and (2) to provide a space for in-growth of periodontal ligament tissue. No membranes were placed over the contralateral roots. The histologic analysis after 3 months of healing demonstrated that the roots covered with membranes exhibited considerably more new attachment than the non-covered roots (Fig. 25-21). In four of the nine test roots, new cementum covered the entire length of the root. In all control specimens, the surface coronal to the newly formed cementum presented multinucleated cells and resorption cavities. In one control specimen virtually half the root was resorbed. Coronal regrowth of alveolar bone had occurred to a varying extent in test and control roots, and no relationship was found between the amount of new cementum formation and the degree of bone regrowth. The results of this study strongly suggested that the exclusion of epithelial and gingival connective tissue cells from the healing area by the use of a physical barrier may allow (guide) periodontal ligament cells to repopulate the detached root surface. This observation provided the basis for the clinical application of the treatment principle termed "guided tissue regeneration" (GTR). Thus. GTR treatment involves the placement of a physical barrier to ensure that the previous periodontitis-affected root surface becomes repopulated with cells from the periodontal ligament (Fig. 25-22).

Treatment of the first human tooth with GTR was reported by Nyman *et al*. (1982). Due to extensive periodontal destruction, the tooth was scheduled for extraction. This offered the possibility of obtaining histologic documentation of the result of the treatment. Following elevation of full thickness flaps, scaling of the root surface, and removal of all granulation tissue, an 11 mm deep periodontal lesion was ascertained. Prior to flap closure, a membrane was adjusted to cover parts of the detached root surfaces, the osseous defect, and parts of the surrounding bone. Histologic analysis after 3 months of healing revealed that new cementum with inserting collagen fibers had formed on the previously exposed root surface (Fig. 25-23). In a later study (Gottlow *et al*. 1986), 12 cases treated with GTR were evaluated clinically, and in five of these cases histologic documentation was also presented. The results showed that considerable but varying amounts of new connective tissue attachment had formed on the treated

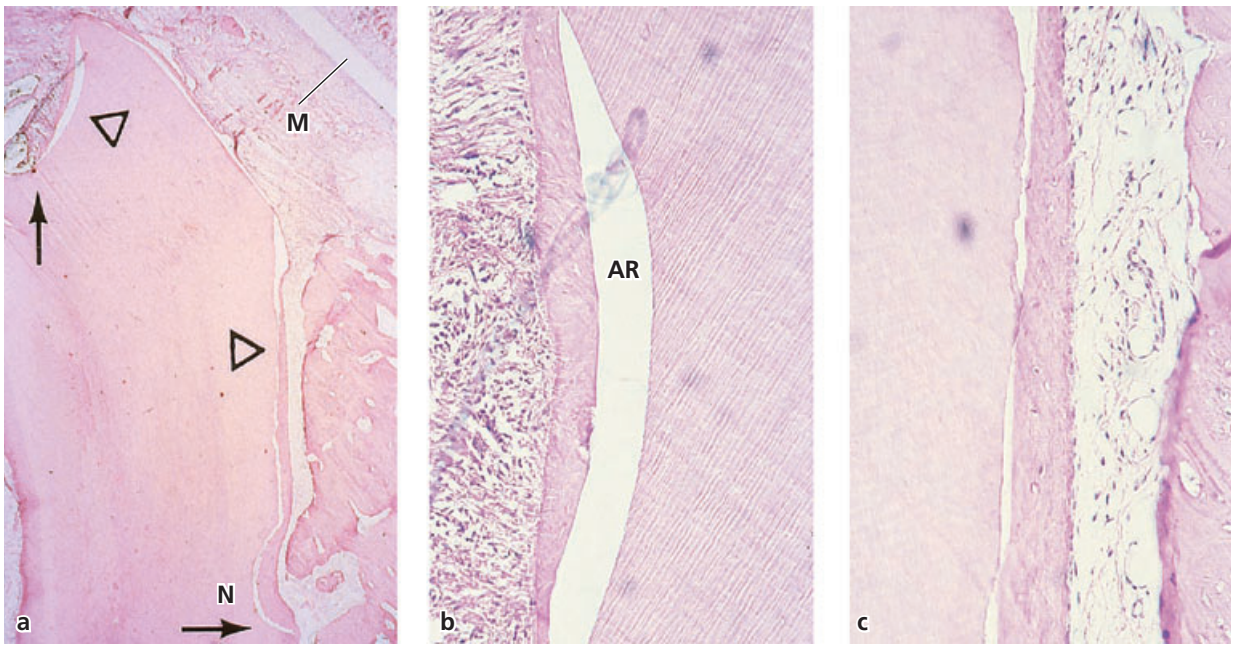

Fig. 25-21 (a) Microphotograph of membrane (M) covered root. Newly formed cementum is visible on the entire length of the buccal root surface coronal to the notch (N) and also on part of the coronal cut surface (arrow). (b, c) Higher magnifications of the areas at the upper and lower triangles in (a), showing that collagen fibers are inserted into the newly formed cementum. AR = artifact.

teeth. Frequently, however, bone formation was incomplete. The varying results were ascribed to factors such as the amount of remaining periodontal ligament, the morphology of the treated defect, technical difficulties regarding membrane placement, gingival recession, and bacterial contamination of the membrane and the wound during healing.

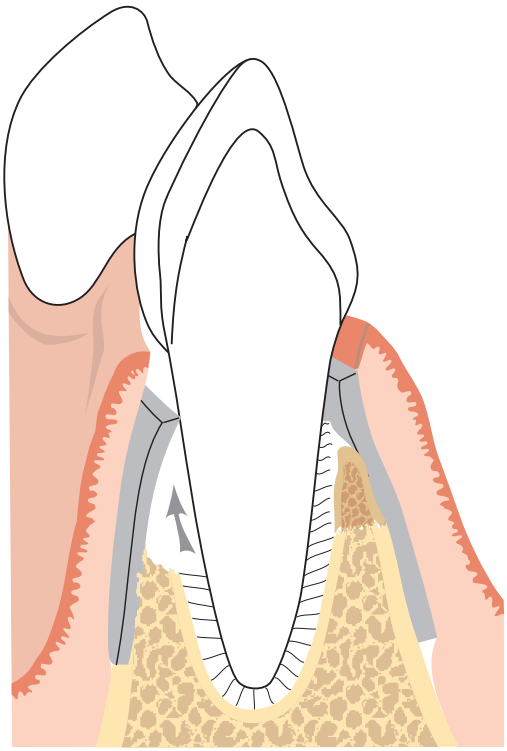

Fig. 25-22 Drawing illustrating the placement of the physical barrier which prevents the epithelium and gingival connective tissue from contacting the root surface during healing. At the same time the membrane allows cells from the periodontal ligament (arrow) to repopulate the previously periodontitis-involved root surface.

In the last decades, GTR has been applied in a number of clinical trials for the treatment of various periodontal defects such as intrabony defects (for review see Cortellini & Bowers 1995), furcation involvements (for review see Machtei & Schallhorn 1995; Karring & Cortellini 1999), and localized gingival recession defects (Pini-Prato *et al*. 1996). The efficiency of GTR in producing periodontal regeneration in these defects has been documented in animal studies (Gottlow *et al*. 1990; Araùjo *et al*. 1998; Laurell *et al*. 2006) and in several controlled clinical trials (see Chapter 43).

The clinical outcomes of GTR are most frequently evaluated by changes in clinical attachment levels (CAL), bone levels (BL), probing pocket depths (PPD), and the position of the gingival margin. In some of the studies on grade II and III furcations, horizontal changes in clinical attachment, bone level, and pocket depth were also measured. However, evidence of true regeneration of periodontal attachment can only be provided by histologic means.

Assessment of periodontal regeneration

In most studies on the effect of regenerative periodontal surgery, the outcomes are evaluated by probing attachment level measurements, radiographic analysis or re-entry operations. However, such methods do not provide proof of a true gain of attachment (i.e. formation of cementum with inserting collagen fibers coronal to the attachment level before treatment).

Periodontal probing

The inability of periodontal probing to determine accurately the coronal level of the connective tissue

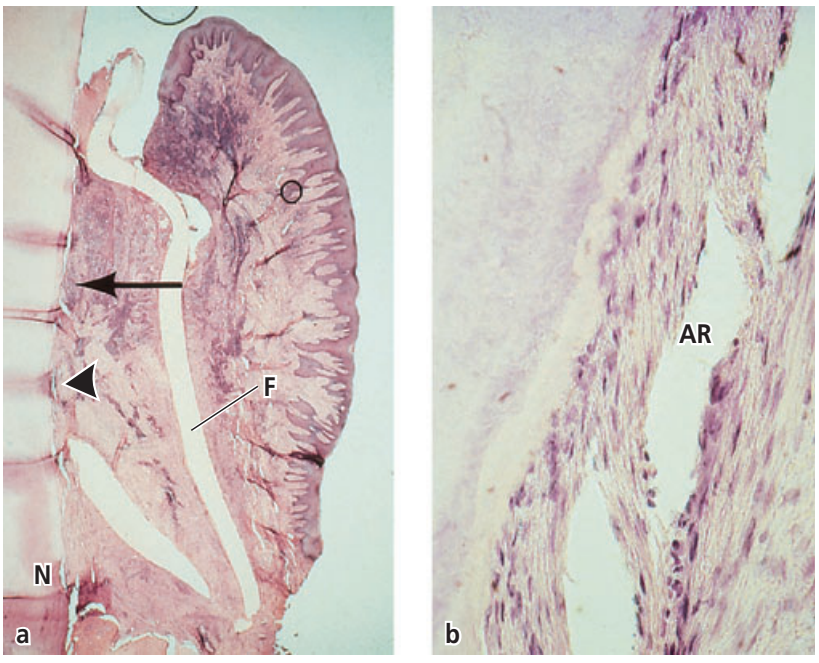

Fig. 25-23 (a) Microphotograph of a human tooth 3 months following GTR treatment using a Millipore filter (F). New cementum with inserting collagen fibers (about 5 mm) has formed from the notch (N) to the level of the arrow. Bone formation underneath the filter is lacking, probably due to the inflammatory infiltrate seen in the tissues adjacent to the filter. (b) Higher magnification of the area indicated by the arrowhead in (a) showing newly formed cementum with inserting collagen fibers. AR = artifact.

attachment has been demonstrated by several investigators (Listgarten *et al*. 1976; Armitage *et al*. 1977; Van der Velden & de Vries 1978). It is known from these studies that, in the inflamed periodontium, the probe does not stop precisely at the coronal level of the connective tissue attachment. Usually it penetrates 0.5 mm or more into the connective tissue, surpassing the transition between the apical extension of the dentogingival epithelium and the coronal level of connective tissue attachment. After therapy, when the inflammatory lesion is resolved, the probe tip tends to stop coronal to the apical termination of the epithelium. Following treatment of intrabony defects, new bone may form so close to the tooth surface that the probe cannot penetrate (Caton & Zander 1976). Thus, a gain of probing attachment level (PAL) following therapy does not necessarily mean that a true gain of connective tissue attachment was accomplished. More likely it is a reflection of improved health of the surrounding soft tissues which offer increased resistance to probe penetration.

Radiographic analysis and re-entry operations

Healing of intrabony defects following regenerative surgery is often documented by measurements made on radiographs obtained in a standardized and reproducible manner and/or assessed in conjunction with a re-entry operation. Analysis of radiographs before and after therapy and inspection of the treated area during a re-entry operation can certainly provide evidence of new bone formation. However, such "bone fill" does not prove formation of new root cementum with inserting collagen fibers (i.e. a new periodontal ligament). In fact, it was demonstrated by Caton and-Zander (1976) and Moscow *et al*. (1979) that despite the fact that bone regeneration had occurred adjacent to the root in intrabony defects, a junctional epithelium was interposed between the newly formed bone and the curetted root surface. This means that radiographic analysis and assessments of bone formation by re-entry operations are unreliable methods for the documentation of new attachment formation.

Histologic methods

In several studies healing is analyzed in histologic sections of block biopsies obtained after various forms of regenerative periodontal therapy. Histologic analysis is the only valid method to assess the formation of a true new attachment, but it requires that the location of the attachment level prior to therapy can be assessed with a reasonable accuracy. In a few studies histologic reference notches were placed in the apical extent of calculus deposits, identified on the root surface at the time of surgery (Cole *et al*. 1980; Bowers *et al*. 1989b,c). Usually, however, a reference is obtained by producing a notch in the root surface at the level of the reduced bone height. Although such a notch may not reflect the exact extent of the periodontitis-involved root surface prior to treatment, it is considered an adequate landmark for the assessment of new attachment (Isidor *et al*. 1985). It was also suggested that clinical signs of probing attachment gain and bone fill can be accepted as evidence of periodontal regeneration in the evaluation of GTR procedures (Lindhe & Echeverria 1994). This suggestion was based on evidence of a new attachment apparatus in histologic specimens from human biopsies harvested following GTR treatment (Nyman *et al*. 1982; Gottlow *et al*. 1986; Becker *et al*. 1987; Stahl *et al*. 1990a; Cortellini *et al*. 1993) and on the biologic concept of GTR (Karring *et al*. 1980, 1985, 1993; Nyman *et al*. 1980; Gottlow *et al*. 1984).

Conclusions

There is evidence that the progenitor cells for reformation of lost periodontal attachment are present in the periodontal ligament. Consequently, a periodontal regenerative procedure needs to encourage repopulation of the previous periodontitis-affected root surface with cells from the periodontal ligament.

GTR and conditioning of the root surface with enamel matrix proteins represent the best documented regenerative procedures for obtaining periodontal regeneration in periodontal lesions, although there is some uncertainty whether enamel matrix proteins in fact stimulate the proliferation of periodontal ligament cells.

Placement of bone grafts or bone substitute implants are based on a biologic concept which cannot explain how such treatment should result in regeneration of the periodontium. There are some studies indicating that bone grafting in periodontal intrabony defects may produce clinical improvements beyond that achieved with only flap surgery, but generally bone grafts or bone substitute implants are considered as primarily defect filler materials.

Part 9: Examination Protocols

Chapter 26

Examination of Patients with Periodontal Diseases

Giovanni E. Salvi, Jan Lindhe, and Niklaus P. Lang

History of periodontal patients

The history of the patient is a revealing document as a basis for comprehensive treatment planning and understanding of the patient's needs, social and economic situation, as well as general medical conditions. In order to expedite history taking, a health questionnaire may be filled out by the patient prior to the initial examination. Such a questionnaire should be constructed in a way that the professional immediately realizes compromising or risk factors that may modify the treatment plan and, hence, may have to be discussed in detail with the patient during the initial visit. The assessment of the patient's history requires an evaluation of the following six aspects: (1) chief complaint, (2) social and family history, (3) dental history, (4) oral hygiene habits, (5) smoking history, and (6) medical history and medications.

Chief complaint and expectations

It is essential to realize the patient's needs and desires for treatment. If a patient has been referred for specific treatment, the extent of the desired treatment has to be defined and the referring dentist should be informed of the intentions for treatment.

Patients reporting independently, however, usually have specific desires and expectations regarding treatment outcomes. These may not be congruent with the true assessment of a professional with respect to the clinical situation. Optimal treatment results may only be achieved if the patient's demands are in balance with the objective evaluation of the disease and the projected treatment outcomes. Therefore, the patient's expectations have to be taken seriously and must be incorporated in the evaluation in harmony with the clinical situation.

Social and family history

Before assessing the clinical condition in detail, it is advantageous to elucidate the patient's social environment and to get a feeling for his/her priorities in life, including the attitude to dental care. Likewise, a family history may be important, especially with respect to aggressive forms of periodontitis.

Dental history

These aspects include an assessment of previous dental care and maintenance visits if not stated by a referring dentist. In this context, information regarding signs and symptoms of periodontitis noted by the patient, such as migration and increasing mobility of teeth, bleeding gums, food impaction, and difficulties in chewing have to be explored. Chewing comfort and the possible need for tooth replacement is determined.

Oral hygiene habits

In addition to the exploration of the patient's routine dental care, including frequency and duration of daily tooth brushing, knowledge about interdental cleansing devices and additional chemical supportive agents, and regular use of fluorides should be assessed.

Smoking history

Since cigarette smoking has been documented to be the second most important risk factor after inadequate plaque control (Kinane *et al*. 2006) in the etiology and pathogenesis of periodontal diseases, the importance of smoking counseling cannot be overestimated. Hence, determination of smoking status, including detailed information about exposure time and quantity, has to be gathered. Further aspects of smoking cessation programs are presented in Chapter 33.

Medical history and medications

General medical aspects may be extracted from the health questionnaire constructed to highlight the medical risk factors encountered for routine periodontal and/or implant therapy. The four major complexes of complications encountered in patients may be prevented by checking the medical history with respect to: (1) cardiovascular and circulatory risks, (2) bleeding disorders, (2) infective risks, and (4) allergic reactions. Further aspects are presented in Chapters 30 and 33.

In light of the increasing consumption of medications in the aging population, an accurate assessment of the patient's prescribed medications and their potential interactions and effects on therapeutic procedures has to be made. It may be necessary to contact the patient's physician for detailed information relevant to the planned dental treatment.

Signs and symptoms of periodontal diseases

Periodontal diseases are characterized by color and texture alterations of the gingiva, e.g. redness and swelling, as well as an increased tendency to bleeding upon probing in the gingival sulcus/pocket area (Fig. 26-1). In addition, the periodontal tissues may exhibit reduced resistance to probing perceived as increased probing depth and/or tissue recession. Advanced stages of periodontitis may also be associated with increased tooth mobility as well as drifting or flaring of teeth (Fig. 26-2).

In radiographs, periodontitis may be recognized by moderate to advanced loss of alveolar bone (Fig. 26-3). Bone loss is defined either as "horizontal" or "angular". If bone loss has progressed at similar rates in the dentition, the crestal contour of the remaining bone in the radiograph is even and defined as being "horizontal". In contrast, angular bony defects are the result of bone loss that developed at different rates around teeth/tooth surfaces and, hence, that type is defined as being "vertical" or "angular".

In a histological section, periodontitis is characterized by the presence of an inflammatory cell infiltrate within a 1–2 mm wide zone of the gingival connective tissue adjacent to the biofilm on the tooth (Fig. 26-4). Within the infiltrated area there is a pronounced loss of collagen. In more advanced forms of periodontitis, marked loss of connective tissue attachment to the root and apical downgrowth of the dentogingival epithelium along the root are important characteristics.

Results from clinical and animal research have demonstrated that chronic and aggressive forms of periodontal disease:

1. Affect individuals with various susceptibility at different rates (Löe *et al*. 1986)
2. Affect different parts of the dentition to a varying degree (Papapanou *et al*. 1988)
3. Are site specific in nature for a given area (Socransky *et al*. 1984)
4. Are sometimes progressive in character and, if left untreated, may result in tooth loss (Löe *et al*. 1986)
5. Can be arrested following proper therapy (Rosling *et al*. 2001).

For effective treatment planning, the location, topography, and extent of periodontal lesions must be recognized in all parts of the dentition. It is, therefore, mandatory to examine all sites of all teeth for the presence or absence of periodontal lesions. This, in turn, means that single-rooted teeth will have to be examined at least at four sites (e.g. mesial, buccal, distal, and oral) and multi-rooted teeth at least at six sites (e.g. mesio-buccal, buccal, disto-buccal, disto-oral, oral, and mesio-oral) with special attention to the furcation areas.

Since periodontitis includes inflammatory alterations of the gingiva and a progressive loss of periodontal attachment and alveolar bone, the comprehensive examination must include assessments describing such pathologic alterations. Figure 26-1 illustrates the clinical status of a 59-year-old patient diagnosed with advanced generalized chronic periodontitis. The examination procedures used to assess the location and extension of periodontal disease will be demonstrated by using this case as an example.

The gingiva

Clinical signs of gingivitis include changes in color and texture of the soft marginal gingival tissue and bleeding on probing.

Various index systems have been developed to describe gingivitis in epidemiologic and clinical research. They are discussed in Chapter 7. Even though the composition of the inflammatory infiltrate can only be identified in histologic sections, the correct clinical diagnosis for inflamed gingival tissue is made on the basis of the tendency to bleed on probing. The symptom "bleeding on probing" (BoP) to the bottom of the gingival sulcus/pocket is associ-

Fig. 26-1 (a–g) Buccal–labial and palatal–lingual views of a 59-year-old male patient diagnosed with advanced generalized chronic periodontitis with furcation involvement.

ated with the presence of an inflammatory cell infiltrate. The occurrence of such bleeding, especially in repeated examinations, is indicative for disease progression (Lang *et al*. 1986), although the predictive value of this single parameter remains rather low (i.e. 30%). On the other hand, the absence of bleeding on probing yields a high negative predictive value (i.e. 98.5%) and, hence, is an important indicator of periodontal stability (Lang *et al*. 1990; Joss *et al*. 1994).

Since trauma to the tissues provoked by probing should be avoided to assess the true vascular permeability changes associated with inflammation, a probing pressure of 0.25 N should be applied for assessing "bleeding on probing" (Lang *et al*. 1991; Karayiannis *et al*. 1992). The identification of the apical extent of the gingival lesion is made in conjunction with pocket probing depth (PPD) measurements. In sites where "shallow" pockets are present,

inflammatory lesions in the overt portion of the gingiva are distinguished by probing in the superficial marginal tissue. When the infiltrate is in sites with attachment loss, the inflammatory lesion in the apical part of the pocket must be identified by probing to the bottom of the deepened pocket.

Fig. 26-2 Buccal migration of tooth 13 as a sign of advanced periodontitis.

Bleeding on probing (BoP)

A periodontal probe is inserted to the "bottom" of the gingival/periodontal pocket applying light force and is moved gently along the tooth (root) surface (Fig. 26-5). If bleeding is provoked by this instrumentation upon retrieval of the probe, the site examined is considered "bleeding on probing" (BoP)-positive and, hence, inflamed.

Figure 26-6 illustrates the chart used to identify BoP-positive sites in a dichotomous way at the initial examination. Each tooth in the chart is represented and each tooth surface is indicated by a triangle. The inner segments represent the palatal/lingual gingival units, the outer segments the buccal/labial units and the remaining fields the two approximal gingival units. The fields of the chart corresponding to the

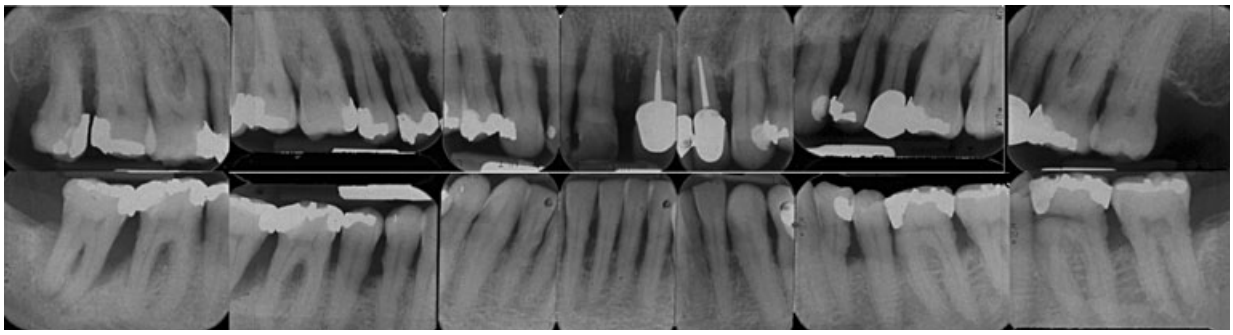

Fig. 26-3 Periapical radiographs of the patient presented in Fig. 26-1.

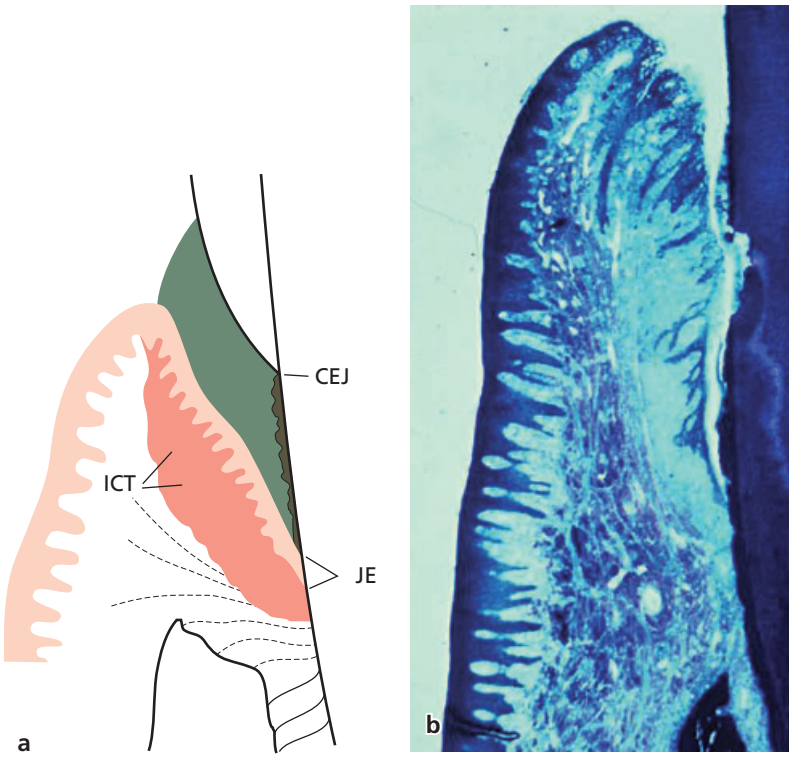

Fig. 26-4 Schematic drawing (a) and histologic section (b) illustrating the characteristics of periodontal disease. Note the zone of infiltrated connective tissue (ICT) lateral to the junctional epithelium (JE). CEJ = cemento-enamel junction; JE = junctional epithelium.

inflamed gingival units are marked in red. The mean BoP score (i.e. gingivitis) is given as a percentage. In the present example, 104 out of a total number of 116 gingival units bled on probing, amounting to a BoP percentage of 89%. This method of charting not only serves as a means of documenting areas of health and disease in the dentition but similar charting during the course of therapy or maintenance will disclose sites which become healthy or remain inflamed. The topographical pattern will also identify sites with consistent or repeated BoP at various observation periods.

The periodontal ligament and the root cementum

In order to evaluate the amount of tissue lost in periodontitis and also to identify the apical extension of the inflammatory lesion, the following parameters should be recorded:

1. Probing pocket depth (PPD)
2. Probing attachment level (PAL)
3. Furcation involvement (FI)
4. Tooth mobility (TM).

Assessment of probing pocket depth

The probing depth, i.e. the distance from the gingival margin to the bottom of the gingival sulcus/pocket, is measured to the nearest millimeter by means of a graduated periodontal probe with a standardized tip diameter of approximately 0.4–0.5 mm (Fig. 26-7). The pocket depth should be assessed at each surface of all teeth in the dentition. In the periodontal chart (Fig. 26-8), PPD <4 mm are indicated in black figures, while deeper PPD (i.e. ≥4 mm) are marked in red. This allows an immediate evaluation of diseased sites (i.e. red figures) both from an extent and severity point of view. The chart may be used for case presentation and discussion with the patient.

Fig. 26-5 Probing pocket depth (PPD) in conjunction with bleeding on probing (BoP). A graduated periodontal probe is inserted to the "bottom" of the gingival/periodontal pocket applying light force and is moved gently along the tooth (root) surface.

Results from pocket depth measurements will only give proper information regarding the extent of loss of probing attachment in rare situations (when the gingival margin coincides with the cemento-enamel junction, CEJ). For example, an inflammatory edema may cause swelling of the free gingiva resulting in coronal displacement of the gingival margin without a concomitant migration of the dentogingival epithelium to a level apical to the CEJ. In such a situation, a pocket depth exceeding 3–4 mm represents a "pseudopocket". In other situations, an obvious loss of periodontal attachment may have occurred without a concomitant increase of probing pocket depth. A situation of this kind is illustrated in Fig. 26-9, where multiple recessions of the gingiva can be seen. Hence, the assessment of the probing depth in relation to the CEJ is an indispensable parameter for the evaluation of the periodontal condition (i.e. PAL).

Assessment of probing attachment level

PAL may be assessed to the nearest millimeter by means of a graduated probe and expressed as the distance in millimeters from the CEJ to the bottom of the probeable gingival/periodontal pocket. The clinical assessment requires the measurement of the distance from the free gingival margin (FGM) to the CEJ for each tooth surface. After this recording, PAL may be calculated from the periodontal chart (i.e. PPD – distance CEJ to FGM). In cases with gingival recession, the distance FGM–CEJ turns negative and, hence, will be added to the PPD to determine PAL.

Errors inherent in periodontal probing

The distances recorded in a periodontal examination using a periodontal probe have generally been assumed to represent a fairly accurate estimate of the PPD or PAL at a given site. In other words, the tip of the periodontal probe has been assumed to identify the level of the most apical cells of the dentogingival (junctional epithelium) epithelium. Results from research, however, indicated that this is seldom the

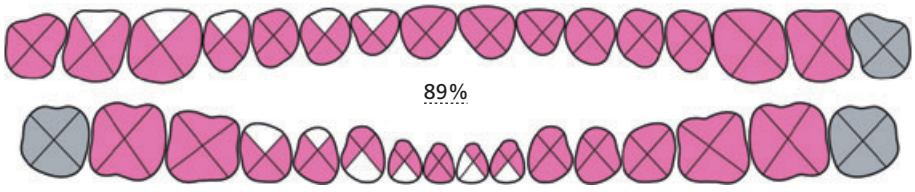

Fig. 26-6 Chart used to identify BoP-positive sites in a dichotomous way at the initial examination and during maintenance care.

Fig. 26-7 Examples of graduated periodontal probes with a standardized tip diameter of approximately 0.4–0.5 mm.

case (Saglie *et al*. 1975; Listgarten *et al*. 1976; Armitage *et al*. 1977; Ezis & Burgett 1978; Spray *et al*. 1978; Robinson & Vitek 1979; van der Velden 1979; Magnusson & Listgarten 1980; Polson *et al*. 1980). A variety of factors influencing measurements made with periodontal probes include: (1) the thickness of the probe used, (2) angulation and positioning of the probe due to anatomic features such as the contour of the tooth surface, (3) the graduation scale of the periodontal probe, (4) the pressure applied on the instrument during probing, and (5) the degree of

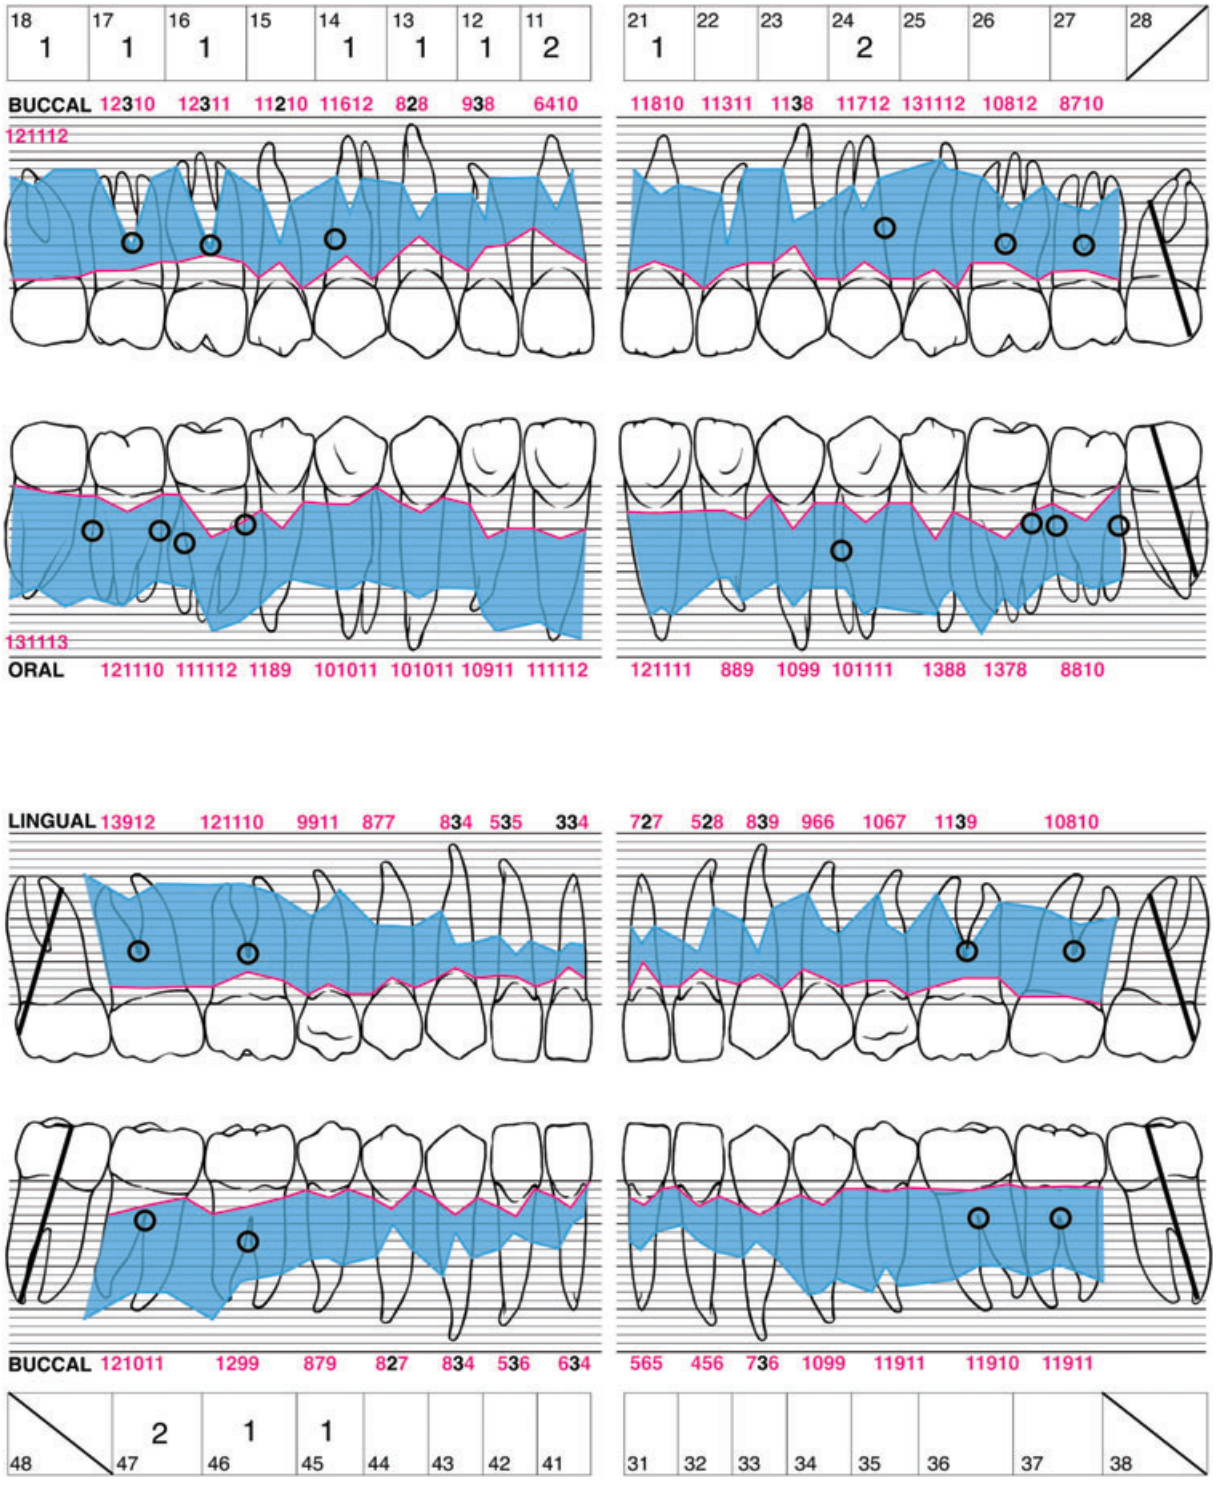

Fig. 26-8 Periodontal chart indicating PPD <4 mm in black figures and PPD ≥4 mm in red figures. This allows an immediate evaluation of diseased sites (i.e. red figures) both from an extent and severity point of view.

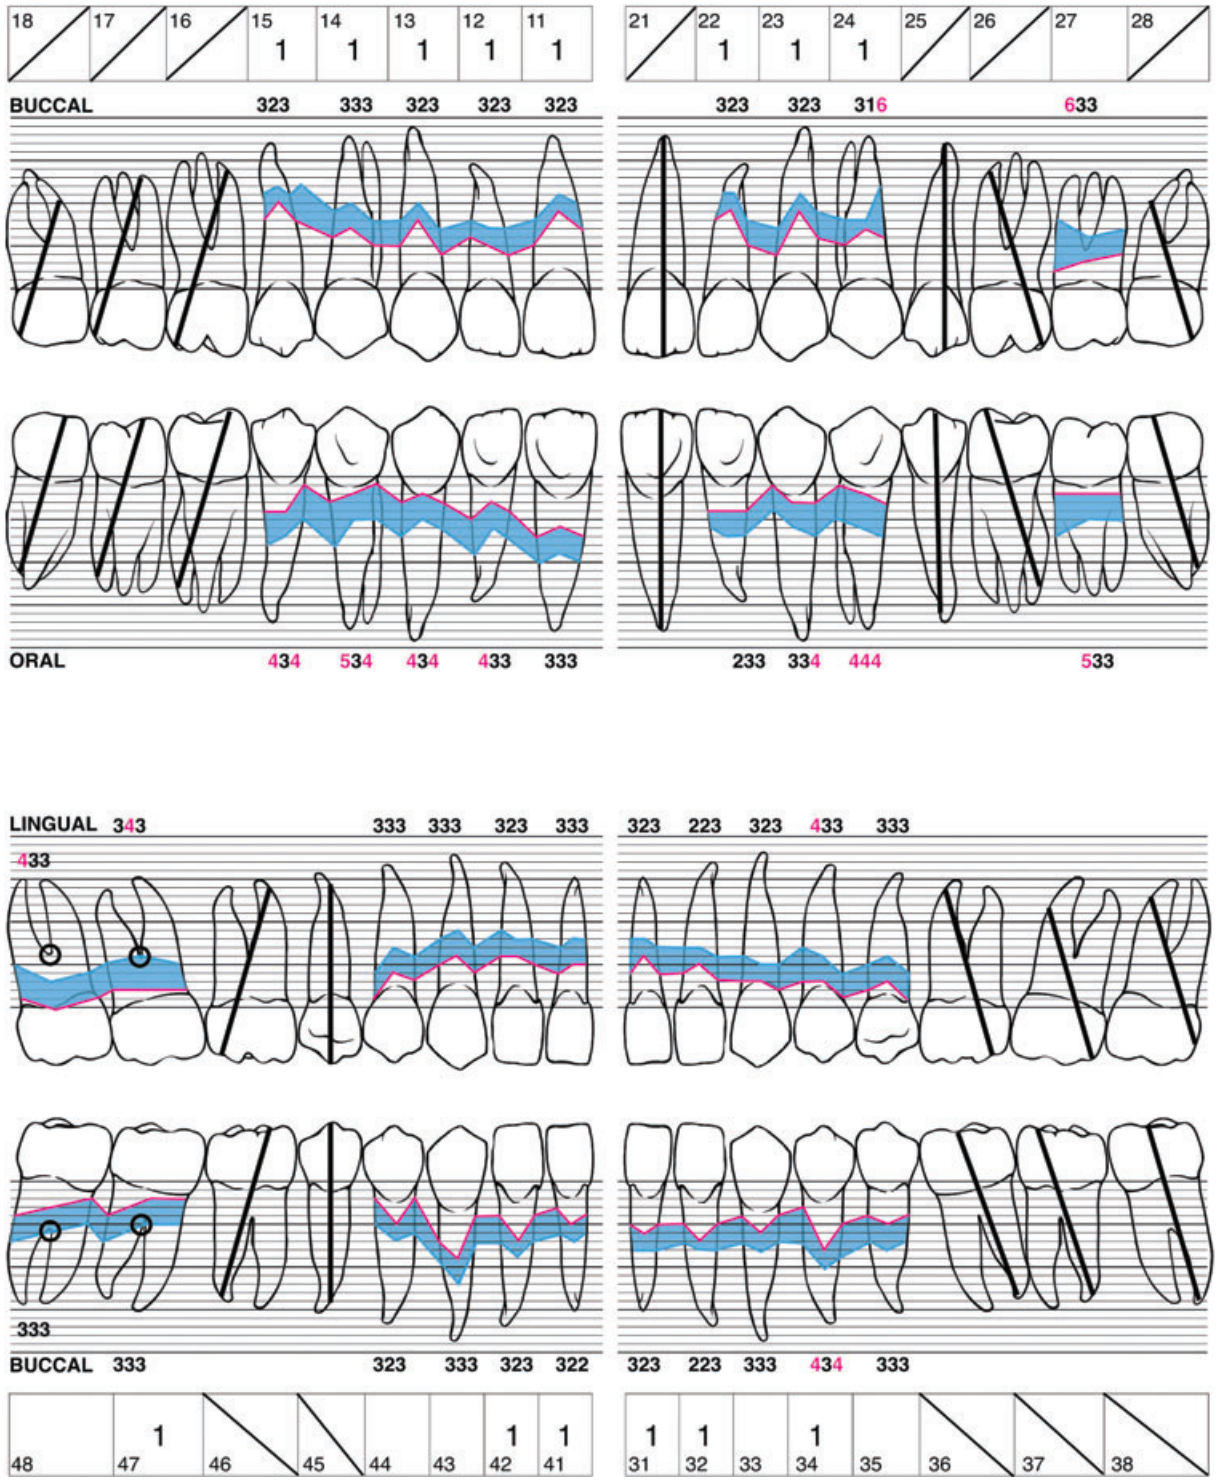

Fig. 26-9 Periodontal attachment loss has occurred without a concomitant increase of probing pocket depth. Multiple buccal/labial as well as palatal/lingual gingival recessions can be seen.

inflammatory cell infiltration in the soft tissue and accompanying loss of collagen. Therefore, a distinction should be made between the histologic and the clinical PPD to differentiate between the depth of the actual anatomic defect and the measurement recorded by the probe (Listgarten 1980).

Measurement errors depending on factors such as the thickness of the probe, the contour of the tooth surface, incorrect angulation, and the graduation scale of the probe can be reduced or avoided by the selection of a standardized instrument and careful management of the examination procedure. More difficult to avoid, however, are errors resulting from variations in probing force and the extent of inflammatory alterations of the periodontal tissues. As a rule, the greater the probing pressure applied, the deeper the penetration of the probe into the tissue. In this context, it should be realized that in investigations designed to disclose the pressure (force) used by different clinicians, the probing pressure was found to range from 0.03–1.3 N (Gabathuler & Hassell 1971; Hassell *et al*. 1973), and also, to differ by as

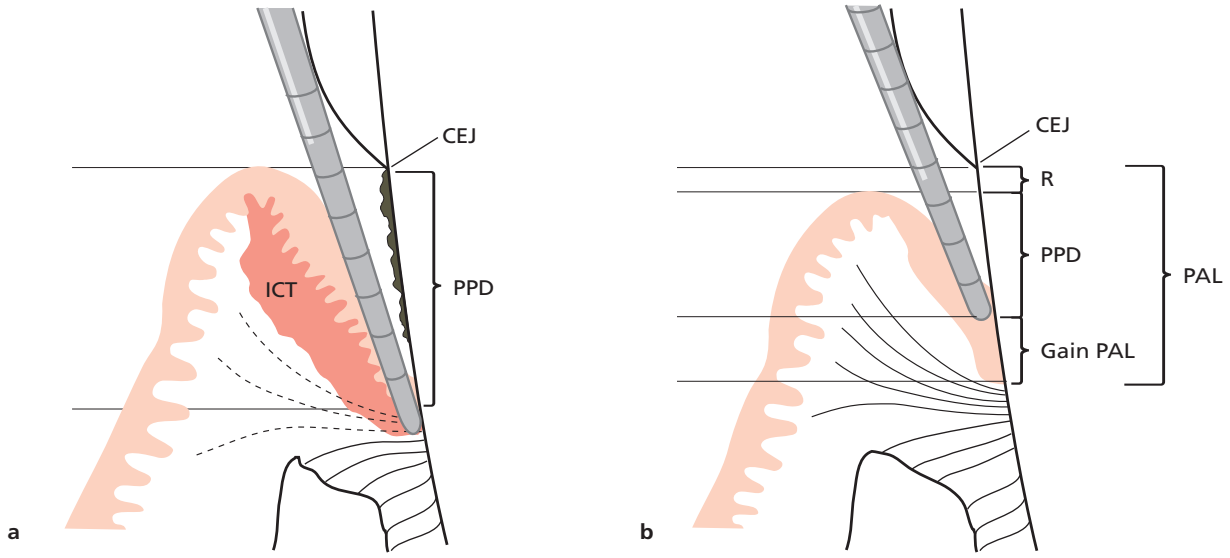

Fig. 26-10 (a) In the presence of an inflammatory cell infiltrate (ICT) in the connective tissue of the gingiva, the periodontal probe penetrates apically to the bottom of the histologic pocket. (b) Following successful periodontal therapy, the swelling is reduced and the connective tissue cell infiltrate is replaced by collagen. The periodontal probe fails to reach the apical part of the dentogingival epithelium. CEJ = cemento-enamel junction; PPD = probing pocket depth; PAL = probing attachment level; R = recession; Gain PAL = recorded false gain of attachment ("clinical attachment").

much as 2:1 for the same dentist from one examination to another. In order to exclude measurement errors related to the effect of variations in probing pressure, so-called pressure-sensitive probes have been developed. Such probes will enable the examiner to probe with a predetermined pressure (van der Velden & de Vries 1978; Vitek *et al*. 1979; Polson *et al*. 1980). However, over- and underestimation of the "true" PPD or PAL may also occur when this type of probing device is employed (Armitage *et al*. 1977; Robinson & Vitek 1979; Polson *et al*. 1980). Thus, when the connective tissue subjacent to the pocket epithelium is infiltrated by inflammatory cells (Fig. 26-10), the periodontal probe will most certainly penetrate beyond the apical termination of the dentogingival epithelium. This results in an overestimation of the "true" depth of the pocket. Conversely, when the inflammatory infiltrate decreases in size following successful periodontal treatment, and a concomitant deposition of new collagen occurs within the previously inflamed tissue area, the dentogingival tissue will become more resistant to penetration by the probe. The probe may now fail to reach the apical termination of the epithelium using the same probing pressure. This, in turn, results in an underestimation of the "true" PPD or PAL. The magnitude of the difference between the probing measurement and the histologic "true" pocket depth (Fig. 26-10) may range from fractions of a millimeter to a couple of millimeters (Listgarten 1980).

From this discussion it should be understood that reductions in PPD following periodontal treatment and/or gain of PAL, assessed by periodontal probing, do not necessarily indicate the formation of a new connective tissue attachment at the bottom of the previous lesion. Rather, such a change may merely represent a resolution of the inflammatory process and may thus occur without an accompanying histologic gain of attachment (Fig. 26-10). In this context it should be realized that the terms "probing pocket depth" (PPD) and "probing attachment level" (PAL) have replaced the previously used terms "pocket depth" and "gain and loss of attachment". Likewise, PAL is used in conjunction with "gain" and/or "loss" to indicate that changes in PAL have been assessed by clinical probing.

Current knowledge of the histopathology of periodontal lesions and healing thereof has thus resulted in an altered concept regarding the validity of periodontal probing. However, despite difficulties in interpreting the significance of PPD and PAL measurements, such determinations still give the clinician a useful estimate of the degree of disease involvement, and particularly so, when the information obtained is related to other findings of the examination procedure such as BoP and changes in alveolar bone height.

In recent years, periodontal probing procedures have been standardized to the extent that automated probing systems such as, e.g. the Florida Probe™, have been developed, yielding periodontal charts with PPD, PAL, BoP, furcation involvement (FI) and tooth mobility (TM) at one glance (Gibbs *et al*. 1988). Also, repeated examinations allow the comparison of parameters, and, hence, an assessment of the healing process (Fig. 26-11).

Assessment of furcation involvement

In the progression of periodontitis around multirooted teeth, the destructive process may involve the supporting structures of the furcation area (Fig.

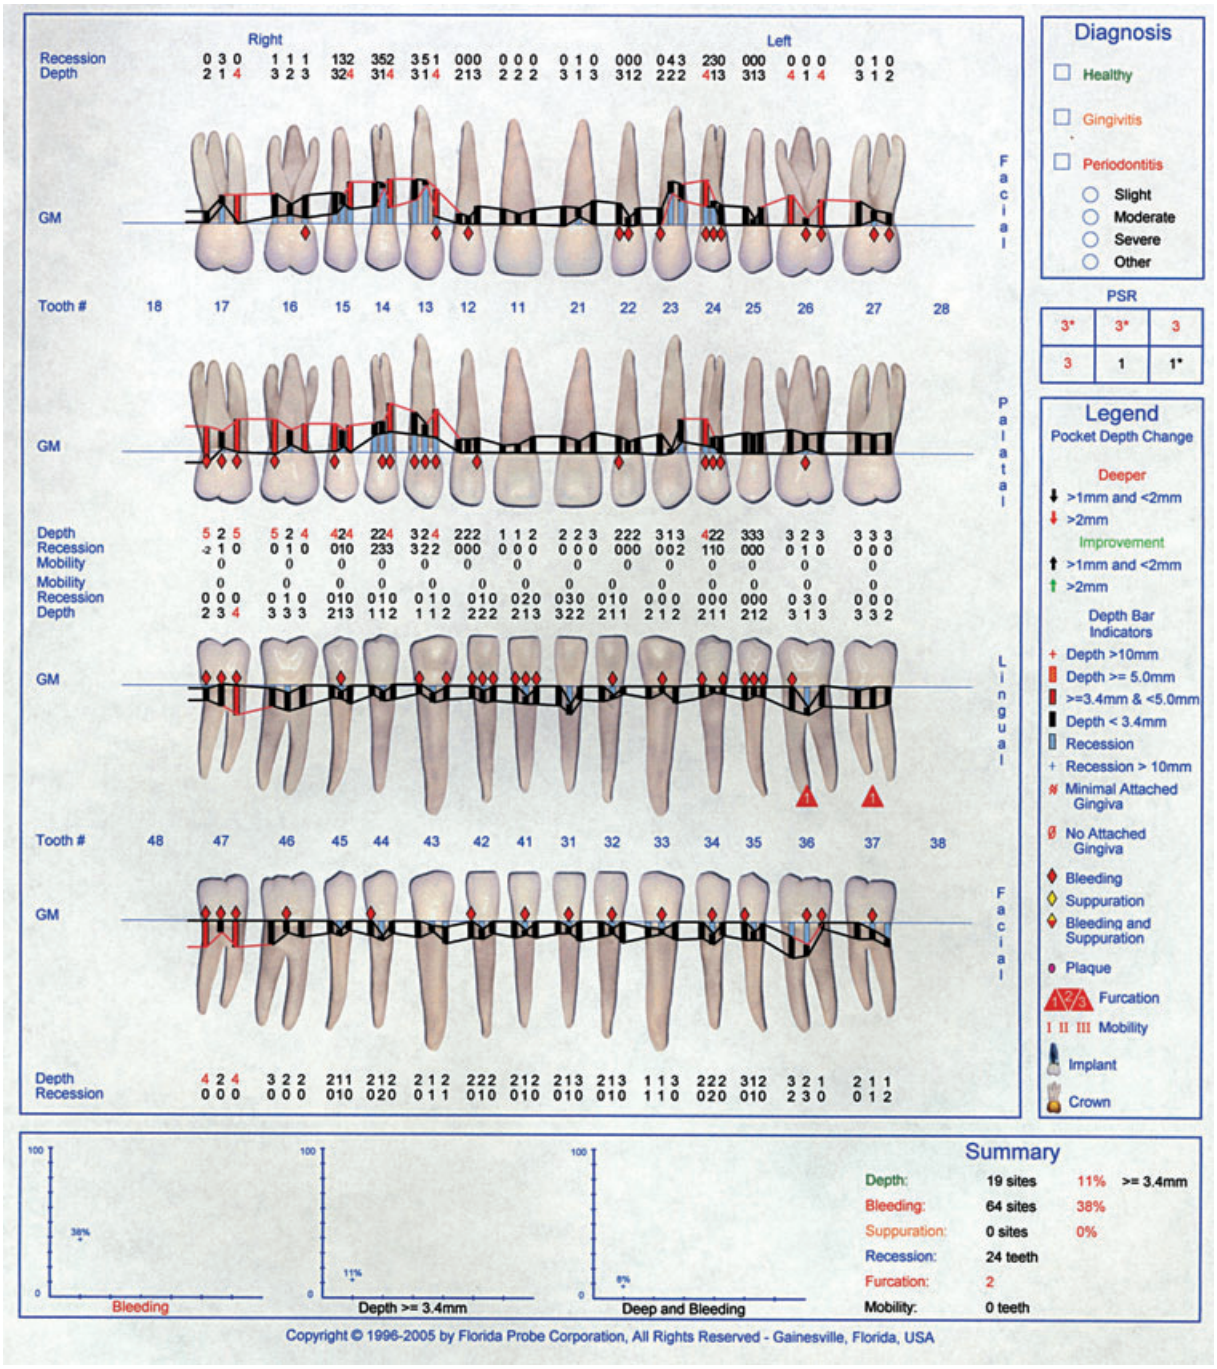

Fig. 26-11 Periodontal chart using an automated probing system (Florida Probe™). Reproduced with permission, © Copyright 1996–2005 Florida Probe Corporation.

26-12). In order to plan treatment for such involvement, a detailed and precise identification of the presence and extension of periodontal tissue breakdown within the furcation area is of importance for proper diagnosis.

Furcation involvement is assessed from all the entrances of possible periodontal lesions of multirooted teeth, i.e. buccal and/or lingual entrances of the mandibular molars. Maxillary molars and premolars are examined from the buccal, disto-palatal, and mesio-palatal entrances. Owing to the position of the first maxillary molars within the alveolar process, the furcation between the mesio-buccal and the palatal

Fig. 26-12 Superficial (tooth 46) and deep (tooth 16) periodontal tissue destruction in the buccal furcation areas.

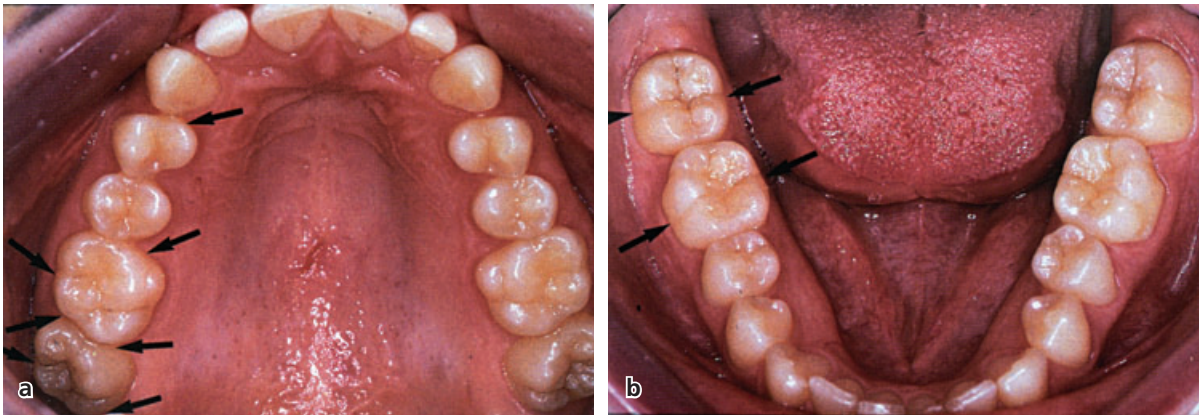

Fig. 26-13 (a,b) Anatomic locations for the assessment of furcation involvement (FI) in the maxilla and in the mandible.

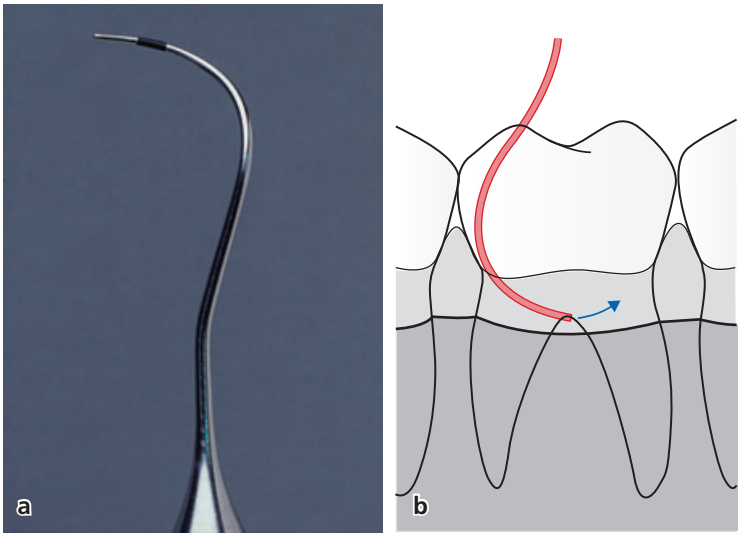

Fig. 26-14 (a,b) Furcation involvement (FI) is explored using a curved periodontal probe graduated at 3 mm (Nabers furcation probe).

roots is best explored from the palatal aspect (Fig. 26-13).

Furcation involvement is explored using a curved periodontal probe graduated at 3 mm (Nabers furcation probe) (Fig. 26-14). Depending on the penetration depth, the FI is classified as "superficial" or "deep":

- Horizontal probing depth ≤3 mm from one or two entrances is classified as a degree I FI.
- Horizontal probing depth >3 mm in at the most one furcation entrance and/or in combination with a degree I FI is classified as degree II FI.
- Horizontal probing depth >3 mm in two or more furcation entrances usually represents a "through-and-through" destruction of the supporting tissues in the furcation and is classified as degree III FI.

The FI degree is presented in the periodontal chart (Fig. 26-15) together with a description of which tooth surface the involvement has been identified on. A detailed discussion regarding the management

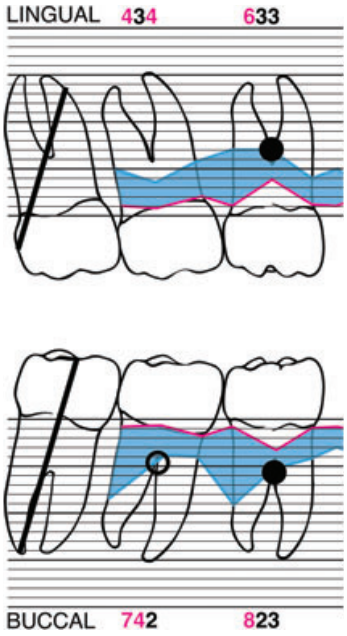

Fig. 26-15 The FI degree is illustrated in the periodontal chart. Open circles represent a superficial FI (i.e horizontal probe penetration ≤3 mm) whereas filled black circles represent a deep FI (i.e. horizontal probe penetration >3 mm).

of furcation-involved teeth is presented in Chapter 39.

Assessment of tooth mobility

The continuous loss of the supporting tissues during periodontal disease progression may result in increased tooth mobility. However, trauma from occlusion may also lead to increased tooth mobility. Therefore, the reason for increased tooth mobility as being the result of a widened periodontal ligament or a reduced height of the supporting tissues or a combination thereof should be elaborated. Increased tooth mobility may be classified according to Miller (1950).

- Degree 0: "physiological" mobility measured at the crown level. The tooth is mobile within the alveolus to approximately 0.1–0.2 mm in a horizontal direction.
- Degree 1: increased mobility of the crown of the tooth to at the most 1 mm in a horizontal direction.
- Degree 2: visually increased mobility of the crown of the tooth exceeding 1 mm in a horizontal direction.
- Degree 3: severe mobility of the crown of the tooth both in horizontal and vertical directions impinging on the function of the tooth.

It must be understood that plaque-associated periodontal disease is not the only cause of increased tooth mobility. For instance, overloading of teeth and trauma may result in tooth hypermobility. Increased tooth mobility can frequently also be observed in conjunction with periapical lesions or immediately following periodontal surgery. From a therapeutic point of view it is important, therefore, to assess not only the degree of increased tooth mobility but also the cause of the observed hypermobility (see Chapters 14 and 57).

All data collected in conjunction with measurements of PPD, PAL, as well as from the assessments of FI and tooth mobility are included in the periodontal chart (Fig. 26-8). The various teeth in this chart are denoted according to the two-digit system adopted by the FDI in 1970.

The alveolar bone

The height of the alveolar bone and the outline of the bony crest are examined in radiographs (Fig. 26-3). Radiographs provide information on the height and configuration of the interproximal alveolar bone. Obscuring structures such as roots of the teeth often make it difficult to identify the outline of the buccal and lingual alveolar bony crest. Analysis of radiographs must, therefore, be combined with a detailed evaluation of the periodontal chart in order to come up with a correct estimate concerning "horizontal" and "angular" bony defects.

Fig. 26-16 The use of a Rinn filmholder and a long-cone paralleling technique yield reproducible radiographs.

As opposed to the periodontal chart that represents a sensitive diagnostic estimate of the lesions, the radiographic analysis is a specific diagnostic test yielding few false-negative results and, hence, is confirmatory to the periodontal chart (Lang & Hill 1977).

To enable meaningful comparative analysis, a radiographic technique should be used which yields reproducible radiographs. In this context, a long-cone paralleling technique (Updegrave 1951) is recommended (Fig. 26-16).

Diagnosis of periodontal lesions

Based on the information regarding the condition of the various periodontal structures (i.e. the gingiva, the periodontal ligament, and the alveolar bone) which has been obtained through the comprehensive examination presented above, a classification of the patient as well as a diagnosis for each tooth regarding the periodontal conditions may be given (Table 26-1). Four different tooth-based diagnoses may be used:

- *Gingivitis*. This diagnosis is applied to teeth displaying bleeding on probing. The sulcus depth usually remains at levels of 1–3 mm irrespective of the level of clinical attachment. "Pseudopockets" may be present in cases of slightly increased probing depth without concomitant attachment and alveolar bone loss and presence/absence of bleeding on probing. The diagnosis of gingivitis usually characterizes lesions confined to the gingival margin.
- *Parodontitis superficialis* (mild–moderate periodontitis). Gingivitis in combination with attachment loss is termed "periodontitis". If the PPD does not exceed 6 mm, a diagnosis of mild–moderate

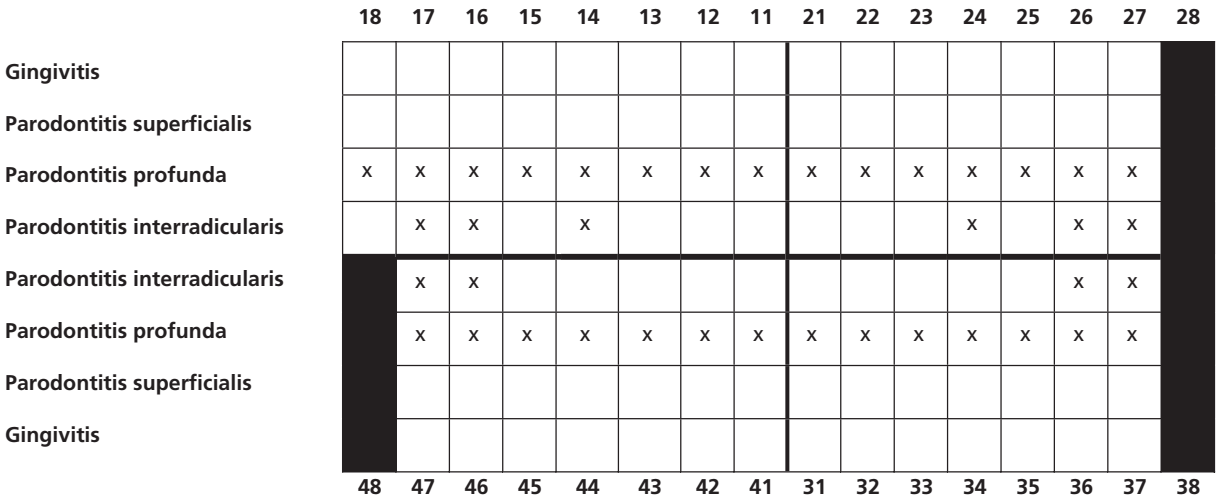

Fig. 26-17 Chart of the individual tooth diagnosis of the patient presented in Fig. 26-1.

Table 26-1 The diagnosis of the periodontal tissue conditions around each tooth in the dentition is given using main criteria (i.e. periodontal chart and radiographic analysis) and additional criteria (i.e. bleeding on probing)

Diagnosis	Main criteria	Additional criteria
Gingivitis	Bleeding on probing (BoP) No loss of PAL and alveolar bone PPD ≤3 mm Pseudopockets	
Parodontitis superficialis	PPD ≤5 mm, irrespective of the morphology of the periodontal lesion Angular and/or horizontal alveolar bone loss	Bleeding on probing (BoP)
Parodontitis profunda	PPD ≥6 mm, irrespective of the morphology of the periodontal lesion Angular and/or horizontal alveolar bone loss	Bleeding on probing (BoP)
Parodontitis interradicularis	Horizontal PPD ≤3 mm: superficial FI Horizontal PPD >3 mm: deep FI	Bleeding on probing (BoP)

periodontitis is given irrespective of the morphology of periodontal lesions. This diagnosis may, therefore, be applied to teeth with "horizontal" loss of supporting tissues, representing suprabony lesions, and/or to teeth with "angular" or "vertical" loss of supporting tissues, representing infrabony lesions. "Infrabony" lesions include "intrabony one-, two- and three-wall defects" as well as "craters" between two adjacent teeth.

- *Parodontitis profunda* (advanced periodontitis). If the PPD does exceeds 6 mm, a diagnosis of advanced periodontitis is given irrespective of the morphology of periodontal lesions. As for mild–moderate periodontitis, angular as well as horizontal alveolar bone loss are included in this diagnosis. The distinction between mild–moderate and advanced periodontitis is only based on increased PPD.
- *Parodontitis interradicularis* (periodontitis in the furcation area). Adjunctive diagnoses may be attributed to multi-rooted teeth with FI (see above): superficial FI if horizontal PPD ≤3 mm (parodontitis interradicularis superficialis) and deep FI for horizontal PPD >3 mm (parodontitis interradicularis profunda).

In the presence of necrotizing and/or ulcerative lesions, these terms may be added to tooth-related diagnoses of both gingivitis and periodontitis (Chapter 20). Acute lesions including gingival and periodontal abscesses are diagnosed as indicated in Chapter 22.

The various teeth of the patient whose clinical status is shown in Fig. 26-1, the radiographs in Fig. 26-3 and the periodontal chart in Fig. 26-8 have received the diagnoses described in Fig. 26-17.

Oral hygiene status

In conjunction with the examination of the periodontal tissues, the patient's oral hygiene practices must also be evaluated. Absence or presence of plaque on each tooth surface in the dentition is recorded in a dichotomous manner (O'Leary *et al*. 1972). The bacterial deposits may be stained with a disclosing solution to facilitate their detection. The presence of plaque is marked in appropriate fields in the plaque chart shown in Fig. 26-18. The mean plaque score for the dentition is given as a percentage in correspondence with the system used for BoP (Fig. 26-6).

Alterations with respect to the presence of plaque and gingival inflammation are illustrated in a simple

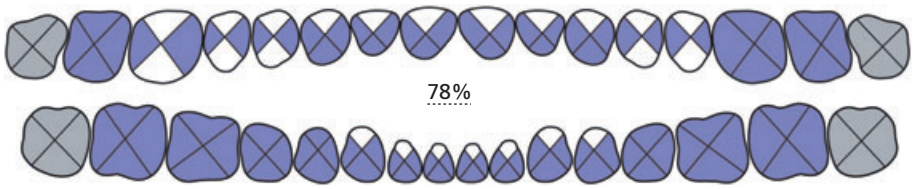

Fig. 26-18 The presence of bacterial deposits is marked in the appropriate fields in the plaque chart.

way by the repeated use of the combined BoP (Fig. 26-6) and plaque (Fig. 26-18) charts during the course of treatment. Repeated plaque recordings alone (Fig. 26-18) are predominantly indicated during the initial phase of periodontal therapy (i.e. infection control) and are used for improving self-performed plaque control. Repeated BoP charts alone (Fig. 26-6), on the other hand, are predominantly recommended during maintenance care.

Additional dental examinations

In addition to the assessment of plaque, retentive factors for plaque, such as supra- and subgingival calculus and defective margins of dental restorations, should also be identified. Furthermore, the assessment of tooth sensitivity is essential for comprehensive treatment planning. Sensitivity to percussion may indicate acute changes in pulp vitality and lead to emergency treatment prior to systematic periodontal therapy. It is obvious that a complete examination and assessment of the patient will have to include the search for carious lesions both clinically as well as radiographically.

Screening for functional disturbances may be performed using a short (i.e. 1/2 minute) test according to Shore (1963). In this test, harmonious function of the jaws with simultaneous palpation of the temporomandibular joints during opening, closing, and excursive movements is verified. Maximal mouth opening is assessed and finally, the lodge of the lateral pterygoid muscles is palpated for muscle tenderness. Further morphologic characteristics of the dentition as well as occlusal and articulating contacts may be identified.

Conclusion

The methods described above for the examination of patients with respect to periodontal disease provide a thorough analysis of the presence, extent and severity of the disease in the dentition. The classification of the patient and the correct diagnosis for each individual tooth should form the basis for a pretherapeutic prognosis and the treatment planning of the individual patient (see Chapter 31).

Chapter 27

Examination of the Candidate for Implant Therapy

Hans-Peter Weber, Daniel Buser, and Urs C. Belser

Dental implants in periodontally compromised patients

Modern comprehensive dental care for patients with periodontally compromised dentitions has to include the consideration of dental implants. Since the initial description of osseointegration experimentally (Branemark *et al*. 1969; Schroeder *et al*. 1976, 1981), scientific evidence has been established through human clinical studies that dental implants will serve as long-term predictable anchors for fixed and removable prostheses in fully and partially edentulous patients and that patient satisfaction with dental implant therapy is high (Adell *et al*. 1990; Fritz 1996; Buser *et al*. 1997; Lindh *et al*. 1998; Moy *et al*. 2005; Pjetursson *et al*. 2005). Furthermore, substantial scientific and clinical evidence has become available to help the understanding of factors enhancing or compromising treatment success with regard to esthetic concerns (Belser *et al*. 2004a,b; Buser *et al*. 2004, 2006; Higginbottom *et al*. 2004; Martin *et al*. 2006). Overall, the pool of information on contributing factors enhancing or compromising treatment success with dental implants continues to grow and is becoming more and more valuable despite its diversity and scientific inconsistency. This is possible through a focused interpretation of the published information via systematic reviews.

The decision whether to use remaining natural teeth as abutments for conventional fixed prostheses or to add dental implants for the replacement of diseased natural teeth is influenced by a number of factors, such as location in the dental arches, strategic value and treatment prognosis for such teeth, subjective and objective need for tooth replacement, dimensions of the alveolar process, esthetic impact, as well as access for treatment. Indications for dental implants in the periodontally compromised dentition include the replacement of single or multiple "hopeless" or missing teeth within or as distal extensions to partially dentate maxillary and mandibular arches (Fig. 27-1).

In the edentulous jaw, implants supporting fixed or removable prostheses will more frequently be inserted in the anterior regions where there are more favorable alveolar bone dimensions and quality. In partially edentulous patients, implants are more likely indicated in posterior regions with less favorable anatomic conditions. The volume of the alveolar process may be substantially reduced, especially in dentitions where teeth have been lost due to periodontal disease (Fig. 27-2). This introduces a number of concerns related to the longevity of implant anchorage, function, and esthetics.

In the posterior areas of the jaw, such concerns may primarily be of biomechanical nature due to the resulting unfavorable "crown–root ratios" in the region of the greatest masticatory forces. Treatment alternatives include the use of multiple short implants splinted together with the fixed partial denture they support (Fig. 27-3), external or internal sinus floor elevation (Fig. 27-4), vertical ridge augmentation with various bone grafting techniques or distraction osteogenesis, nerve repositioning, distal extension

Fig. 27-1 (a) Intraoral image of a 77-year-old female patient with multiple dental problems including severe adult periodontitis after several years of neglect. At the initial examination on 12/6/06, the patient states that she does not want removable prostheses and asks for dental implants to replace the teeth, which may require extraction. (b) Full-mouth set of periapical radiographs of the same patient.

Fig. 27-2 Typical example of patient with reduced alveolar bone volume in the posterior areas of the upper right and lower left quadrant due to preceding severe periodontal bone loss. The lower left quadrant reveals a failed *alio loco* attempt for implant restoration of the lower left quadrant. According to the patient, one of the two short implants originally placed failed shortly after delivery of the fixed partial denture.

fixed prostheses anchored on remaining natural teeth or premolar occlusion without replacement of the failed molars (shortened dental arch concept) (Fig. 27-5).

Prior to the availability of dental implants and bone augmentation techniques for the replacement of posterior teeth lost to periodontal disease, cantilevered fixed partial dentures were a widely used alternative to extend dental arches distally where indicated and to spare the patient from removable partial dentures (Nyman and Lindhe 1976). Whereas this type of periodontal prosthesis performed admirably when designed and maintained properly (Fig. 27-5), the biological and biomechanical risks associated with such reconstructions have been shown to be considerable (Hammerle *et al*. 2000; Pjetursson *et al*. 2004). In the patient with advanced *generalized* periodontal disease and a lack of sufficient posterior bone volume for dental implants, the extraction of the remaining compromised anterior dentition for the purpose of placing implants in combination with cantilevered full-arch prostheses as originally described by Brånemark *et al*. (1985) may prognostically be the most favorable treatment approach (Adell *et al*. 1990).

This generally supportive evidence for implant therapy has to be weighed against the long-term performance of dental implants in patients with a history of periodontal disease. This issue has recently received increased attention in the peer-reviewed dental literature (Ellegaard *et al*. 1997; Baelum &

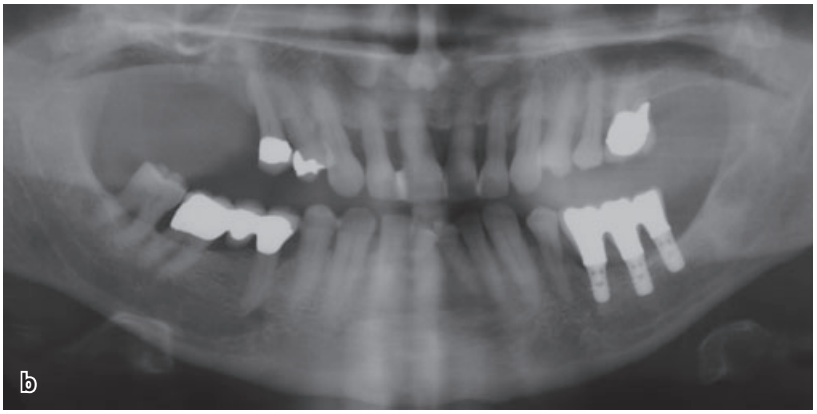

Fig. 27-3 (a) Intraoral clinical image of the same patient after prosthodontic reconstruction of the lower left quadrant with three short implants and a three-unit fixed partial denture. Note the resulting extensive crown heights. (b) Panoramic radiographic image of the implant restoration in the lower left quadrant using three 6 mm long implants. Five-year follow-up. The patient decided to wait with any prosthodontic treatment of the upper right quadrant, where a vertical ridge augmentation combined with external sinus elevation is required.

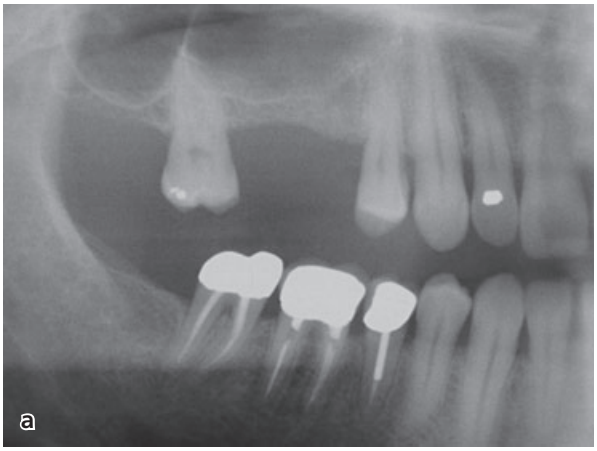

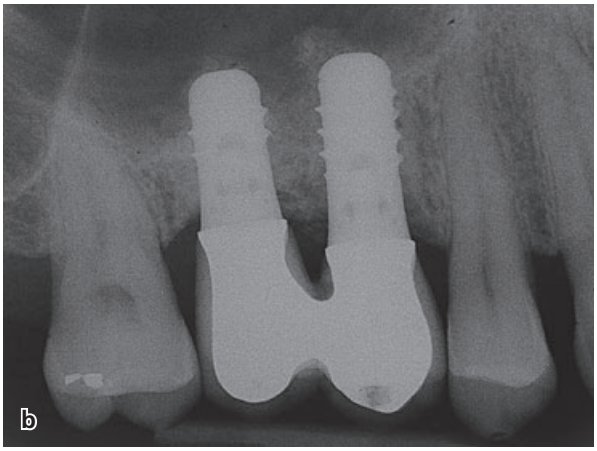

Fig. 27-4 (a) Reduced alveolar bone height in area of second premolar and first molar in the upper right quadrant. Teeth lost due to endodontic complications and periodontal disease combined. (b) Area restored with implant-supported, splinted restorations after internal sinus augmentation procedure at time of implant placement. Four-year follow-up.

Ellegaard 2004). Whereas after 5 years of function no difference was observed between implants in patients free of periodontal disease versus those with disease, a somewhat increased risk for peri-implantitis with bone loss and subsequent implant failure was found for certain implants after 10 years of follow-up. Despite this finding, the authors concluded that dental implants remain a good treatment alternative for patients with periodontal disease. In this context, the outcome with implants placed in sinus grafts in periodontitis patients was not different from subjects free of periodontal disease (Ellegaard *et al*. 2006).

A potential correlation of interleukin-1 (IL-1) gene polymorphism and susceptibility to severe periodontal disease has been reported by Kornman *et al*. (1997). Furthermore, the risk associated with IL-1 polymorphism, smoking and peri-implant bone loss was assessed in a study by Feloutzis *et al*. (2003). The results suggested that in heavy cigarette smokers, the presence of a functionally significant IL-1 gene complex polymorphism is associated with an increased risk for peri-implant bone loss following prosthetic reconstruction and during the supportive periodontal care phase of the treatment. More

Fig. 27-5 Radiographic documentation of periodontal prostheses with distal cantilevers in all four quadrants as used prior to the availability of dental implants. The patient tolerated the shortened dental arches without difficulty.

recently, Laine *et al*. (2006) found that IL-1 gene polymorphism is associated with peri-implantitis (odds ratio = 2.6!). The authors conclude that this has to be considered a long-term risk factor for implant therapy.

In the anterior region, the loss of periodontal hard and soft tissues and the subsequent 'lengthening' of teeth brings along esthetic concerns, which can become complex, especially in patients with high expectations and smile lines as will be discussed later in this chapter. It is important to envision such problems and analyze local conditions carefully at the time of examination so that expected outcomes can be appropriately discussed with the patient prior to the initiation of therapy.

Patient history

Implant therapy is part of a comprehensive treatment plan. This is especially true for patients with a history of periodontal disease and tooth loss. An understanding of the patient's needs, social and economic background, general medical condition, etc., is a prerequisite for successful therapy. In order to expedite history taking, the patient should fill out a health questionnaire prior to the initial examination visit. As discussed in Chapter 26, such questionnaires are best constructed in a way that the professional immediately realizes compromising factors that may modify the treatment plan and may have to be discussed in detail with the patient during the initial visit or may require medical consultations to enable proper treatment planning. The assessment of the patient's history should include (1) chief complaint and expectations, (2) social and family history, (3) dental history, (4) motivation and compliance (e.g. oral hygiene), (5) habits (smoking, recreational drugs, bruxism), and (6) medical history and medications.

Chief complaint and expectations

To facilitate a successful treatment outcome, it is of critical importance to recognize and understand the patient's needs and desires for treatment. Patients usually have specific desires and expectations regarding treatment procedures and results. These may not be in tune with the attainable outcome projected by the clinician after assessment of the specific clinical situation. Optimal individual treatment results may only be achieved if the patient's demands are in balance with the objective evaluation of the condition and the projected treatment outcomes. Therefore, the patient's expectations have to be taken seriously and must be incorporated in the evaluation. A clear understanding of the patient's views is essential, especially in regard to dentofacial esthetics. Esthetic compromises need to be made often when implant restorations are performed in the periodontally compromised dentition because of the loss of hard and soft tissues. If a patient has been referred for specific treatment, the extent of the desired treatment has to be defined and the referring dentist informed of the intentions for treatment and the expectations regarding outcomes.

Social and family history

Before assessing the clinical condition in detail, it is helpful to interview the patient on her/his professional and social environment and on his/her priorities in life, especially when extensive, time-consuming, and costly dental treatment is envisioned as it is often the case with dental implant treatment. Likewise, a family history may reveal important clues with respect to time and cause of tooth loss, systemic or local diseases such as aggressive forms of periodontitis or other genetic predispositions, habits, compliance, and other behavioral aspects.

Dental history

It is important that previous dental care, including prophylaxis and maintenance, is explored with the patient if not stated by a referring dentist. As described in Chapter 26, information regarding cause of tooth loss, signs and symptoms of periodontitis noted by the patient such as migration and increasing mobility of teeth, bleeding gums, food impaction,

and difficulties in chewing have to be explored in this context. Patient comfort with regard to function and esthetics and the subjective need for tooth replacement is assessed at this time.

Motivation and compliance

In this part of the communication, an assessment is made of the patient's interest and motivation for extended and costly therapy. The patient's view on oral health, her/his last visit to a dentist and/or hygienist, frequency and regularity of visits to the dentist, and detailed information on home care procedures are helpful pieces of information in this regard.

Habits

Cigarette smoking has been shown to be a risk factor for implant failure (Bain & Moy 1993; Chuang *et al*. 2002; McDermott *et al*. 2003). In the patient with (severe) periodontal disease, smoking has to be of even greater concern when combined with IL-1 gene polymorphism as discussed earlier in this chapter (Feloutzis *et al*. 2003; Laine *et al*. 2006). The patient's smoking status including details on exposure time and quantity should be assessed as part of a comprehensive examination of the implant candidate. Furthermore, testing for IL-1 gene polymorphism is strongly recommended. In this context, the importance of smoking counseling cannot be overestimated. Further aspects of smoking cessation programs are presented in Chapter 33.

Whereas the scientific evidence for a correlation of bruxism and implant failure is lacking, prosthetic complications, such as fractures of the veneering material, appear to be more frequent. Reports in the literature support the value of including precautionary measures in the implant treatment plan such as the use of implants of sufficient length and diameter, splinting of multiple implants, and use of retrievable restorations and occlusal guards. Whereas early recognition of bruxism or clenching is beneficial for appropriate treatment planning (Lobbezoo *et al*. 2006), it often cannot be diagnosed at the outset of treatment.

Medical history and medications

A thorough review of the patient's medical history is important. Certain medical conditions may contraindicate dental implant therapy. Any condition which has the potential to negatively affect wound healing has to be considered at least a conditional contraindication. This includes chemotherapy and radiation therapy for the treatment of cancers, bisphosphonate therapy, antimetabolic therapy for the treatment of arthritis, uncontrolled diabetes, seriously impaired cardiovascular function, bleeding disorders including medication-induced anticoagulation, active drug addiction including alcohol, and heavy smoking. Patients with psychiatric conditions may not be good candidates for implant therapy. Such conditions are often difficult to identify at time of initial examination. If identified, these patients should be thoroughly examined by medical specialists before they are accepted for implant treatment (Hollender *et al*. 2003).

In light of the increasing need for medications in the aging population, an accurate assessment has to be made of the patient's prescribed and over-the-counter medications with their potential interactions and effects on therapeutic procedures. Most frequent in this context are anticoagulants, such as coumadin and aspirin. Also the need for antibiotic prophylaxis for dental surgical procedures should be recognized. Recently, the occurrence of ostoenecrosis of the jaw in patients on current long-term bisphosphonate therapy or a history thereof has been described. The occurrence of osteonecrosis has primarily been observed after oral surgical procedures in patients on long-term intravenous bisphosphonate therapy as used in the treatment of cancers, but has also been observed in patients taking oral drugs of this kind (Marx *et al*. 2005). According to the American Dental Association (online member information), the risk for osteonecrosis translates into about seven cases per year for every million people taking oral bisphosphonates. In the most recent article addressing this issue, Mortensen *et al*. (2007) conclude that the increasing number of reports about bisphosphonate-associated osteomyelitis and the difficulty in treating these patients require further investigation to identify those patients who are at increased risk. Also, the optimal and safe duration of treatment with bisphosphonates remains to be determined. Due to the existing uncertainty in this area, recognition of patients on bisphosphonate therapy, communication with the treating physician(s), and a risk:benefit assessment have to be made for such patients who are being considered for implant therapy.

In summary, while most of this medical information can be extracted from a health questionnaire as mentioned earlier (see example in Chapter 26), it is important for the clinician to ask specific questions related to the patient's answers in the questionnaire to clarify their potential impact on treatment with dental implants. In many instances it will be necessary to contact the patient's physician for detailed information relevant to the planned treatment. Further aspects are presented in Chapters 30 and 33.

Local examination

Extraoral

An extraoral examination should form part of any initial patient examination. The clinician should look for asymmetries, lesions or swellings of the head and

Fig. 27-6 Examination of patient's mouth-opening ability. The width of at least two of the patient's fingers placed vertically between upper and lower incisors is necessary to allow proper access for implant placement in posterior sites.

Fig. 27-7 Smile characteristics of patient introduced in Fig. 27-1.

neck areas. Observation of function and palpation of the head and neck musculature and temporomandibular joints are performed. Assessment of the opening amplitude of the mandible is especially important, since instrumentation involved with dental implant therapy requires that the patient is able to open sufficiently wide (Fig. 27-6). This is also the perfect time to take note of esthetic characteristics such as smile line, lip line, gingival line, and facial and dental midline (Fig. 27-7).

General intraoral examination

The general intraoral examination includes the assessment of the condition of soft and hard tissues of the oral cavity. This also entails a careful cancer screening. Soft or hard tissue lesions will most likely require treatment prior to the placement of dental implants. Pathological soft tissue conditions include herpetic stomatitis, candidiasis, prosthesis-induced stomatitis, tumors, hyperplasia, etc. Hard tissue pathologies, which most likely require treatment prior to implant therapy, include tooth impactions, bone cysts, root fragments, residual infections in the alveolar bone, e.g. caused by failed endodontic treatment, or tumors.

Dental hard tissues are equally carefully examined to determine the need for restorative treatment in the remaining dentition, most importantly those teeth directly adjacent to edentulous spaces. The need for restoration of the latter may influence the treatment plan in terms of choosing a conventional fixed partial denture over an implant-supported restoration to replace a missing tooth. Pathologies such as caries, fractures, attrition, abrasion, abfraction, tooth mobility, or tooth misalignment are noted. Existing restorations are recorded and deficiencies such as open margins, open contacts, or fractures identified. Testing for vitality of teeth, especially of those adjacent to potential implant sites, will point to possible endodontic pathologies, which should be treated prior to implant placement. The examination of periodontal tissues including the assessment of the patient's oral hygiene is described in detail in Chapter 26.

Finally, static and dynamic aspects of the patient's occlusion are determined, including the adequacy of the patient's vertical dimension of occlusion, maxillomandibular relationship (angle classification), overbite, overjet, stability in habitual occlusion, centric relation, slide in centric, and lateral and anterior excursive contacts (canine guidance, group function, anterior guidance).

Radiographic examination

The initial patient evaluation will include a radiographic survey. For the implant candidate with a history of periodontal disease and, hence, comprehensive treatment needs, a full-mouth set of periapical radiographs is needed to supplement the intraoral examination (Fig. 27-1b). A panoramic view will often be required as well, to reveal structures apical to the remaining teeth such as the infra-alveolar nerve canal, the mental foramina, the floor of the maxillary and nasal sinuses, and pathologic findings in the jaws (Fig. 27-8). Minimal radiographic bone height requirements for implant placement depend on a number of factors such as recommended implant length for a single implant restoration, single vs. multiple adjacent implants, jaw location, and ease and predictability of ridge augmentation in that location. For detailed planning of implant placement, additional radiographs such as occlusal views, cephalometric images, conventional or computer tomograms may be indicated. Implant-specific radiographic studies and their indications are described in Chapter 28, and treatment planning details are discussed in Chapter 32.

Implant-specific intraoral examination

Sites without esthetic implications

An implant-specific intraoral examination, emphasizing the local characteristics of potential implant

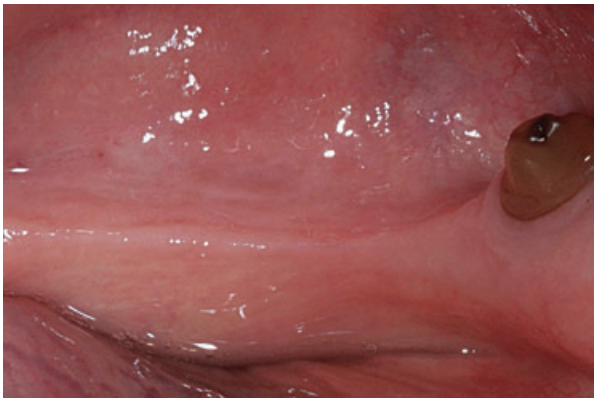

Fig. 27-9 Examination of alveolar ridge in lower left edentulous area. The ridge appears narrow in the area of the missing second premolar. Further radiographic information (lateral tomograms, computer tomograms) are recommended if dental implants are being considered.

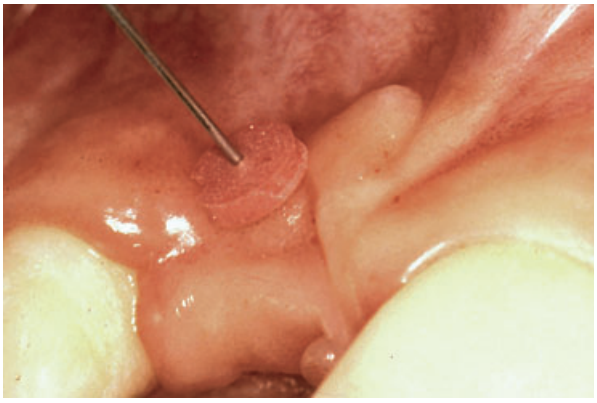

Fig. 27-10 Area of local soft tissue hyperplasia. Bone mapping is applied to explore the soft tissue thickness and the location of the underlying bone.

sites, is important. Different locations in the oral cavity have varying requirements in this regard, primarily due to differing esthetic impacts of implant treatment. They are, therefore, addressed separately in this text.

Although esthetic concerns are overall of lesser importance in mandibular and posterior maxillary sites, the evaluation of the condition of the local mucosa needs to be part of the examination in these areas as well. The clinical width and height of the alveolar process in potential implant areas is examined (Fig. 27-9). At the same time, pathologic changes are noted including mucosal hyperplasia or hypertrophy (Fig. 27-10). Probing of the local tissues may be indicated to assess tissue thickness and confirm the presence of sufficient alveolar bone. This can be done with a bone mapping procedure using a fine needle or explorer after local anesthesia has been applied (Fig. 27-10).

Besides the above, local assessment of sites with low esthetic impact consists primarily of a three-dimensional space assessment and evaluation of the condition of the adjacent teeth and their surrounding hard and soft tissues. A detailed and accurate space assessment is often difficult intraorally. Thus, it is strongly recommended to obtain diagnostic impressions and adequate bite records to produce articulator-mounted casts, on which these critical diagnostic steps can be properly performed, including a diagnostic tooth set-up or wax-up. This is especially important when multiple teeth need to be replaced (Fig. 27-11).

From a comprehensive restorative point of view, edentulous spaces to be restored with implant restorations should ideally have the mesio-distal width of the natural tooth (teeth) that would normally be there. In the patient with a history of periodontal disease, tooth movements occur frequently and space assessment becomes important. Orthodontic pretreatment may be desirable or even required (Fig. 27-12).

From the perspective of implant placement, a mesio-distal width of 7 mm will allow the insertion of a regular-platform or regular-neck implant (3.75–5 mm). For spaces only 5–6 mm wide, narrow-platform or narrow-neck implants of approximately 3.5 mm diameter are available. For single-tooth spaces larger than 7 mm, wide-platform or wide-neck implants with a platform diameter of 6–7 mm may be the choice.

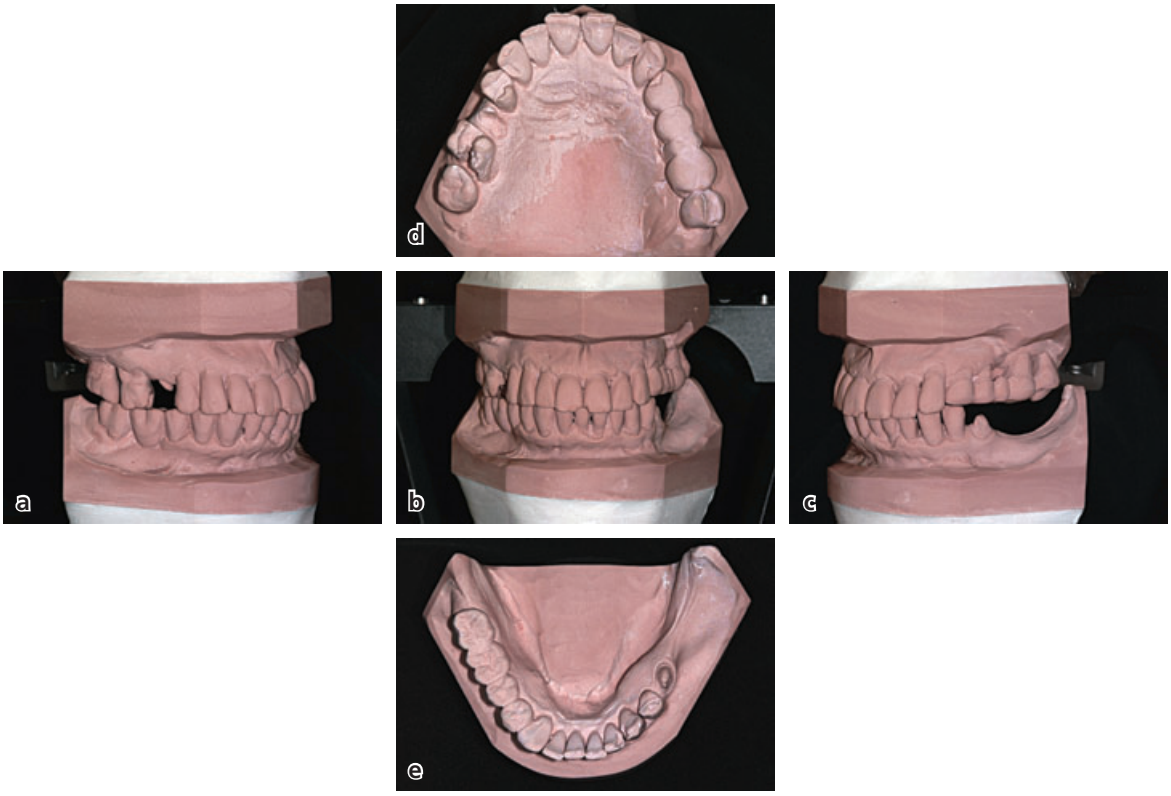

Fig. 27-11 Mounted diagnostic casts of patient introduced in Fig. 27-1: (a) right lateral view; (b) frontal view; (c) left lateral view; (d) maxillary occlusal view; (e) mandibular occlusal view.

Fig. 27-12 Patient with severe periodontitis and resulting tooth movement in addition to pre-existing malocclusion.

It is important to note that wide-neck or -platform implants generally will also have a wider screw diameter. Thus, sufficient buccal–lingual bone width for the placement of a wider diameter implant is important so as to avoid perforation of the alveolar bone buccal or lingual to the implant. The buccolingual width of the alveolar process at an implant site is assessed either by bone mapping or cross-sectional radiographs (see Chapter 28).

A minimum vertical distance from the crestal mucosa of the potential implant site(s) to the opposing dentition is needed for implant restorations. This space requirement may vary depending on the design of the restoration, including the choice of abutments. As a general guideline, a vertical distance of at least 4 mm from the top of the mucosa to the opposing tooth (teeth) is required for straightforward implant placement and restoration. In the patient with tooth loss due to periodontal disease, this usually does not pose a problem. In contrast, due to concomitant bone loss, the distance is generally greater than the original height of a natural tooth (teeth) so that the potential esthetic and biomechanical impacts of the resulting overlong implant restoration have to be taken in consideration as documented earlier (Fig. 27-3).

Sites with esthetic implications

Definition of the problem

In the specific context of implant therapy in the *periodontally* compromised dentition with esthetic implications, which is primarily the anterior (maxillary) dentition, the local, implant-related examination will have to focus particularly on the esthetic consequences of periodontal disease in this area of the jaw. The most common visible sequels of generalized periodontal disease which may have a direct impact on esthetic appearance, depending on the patient's smile line, comprise (over-)long clinical crowns and flattening of the originally scalloped course of the gingival line, including loss of papillary tissue

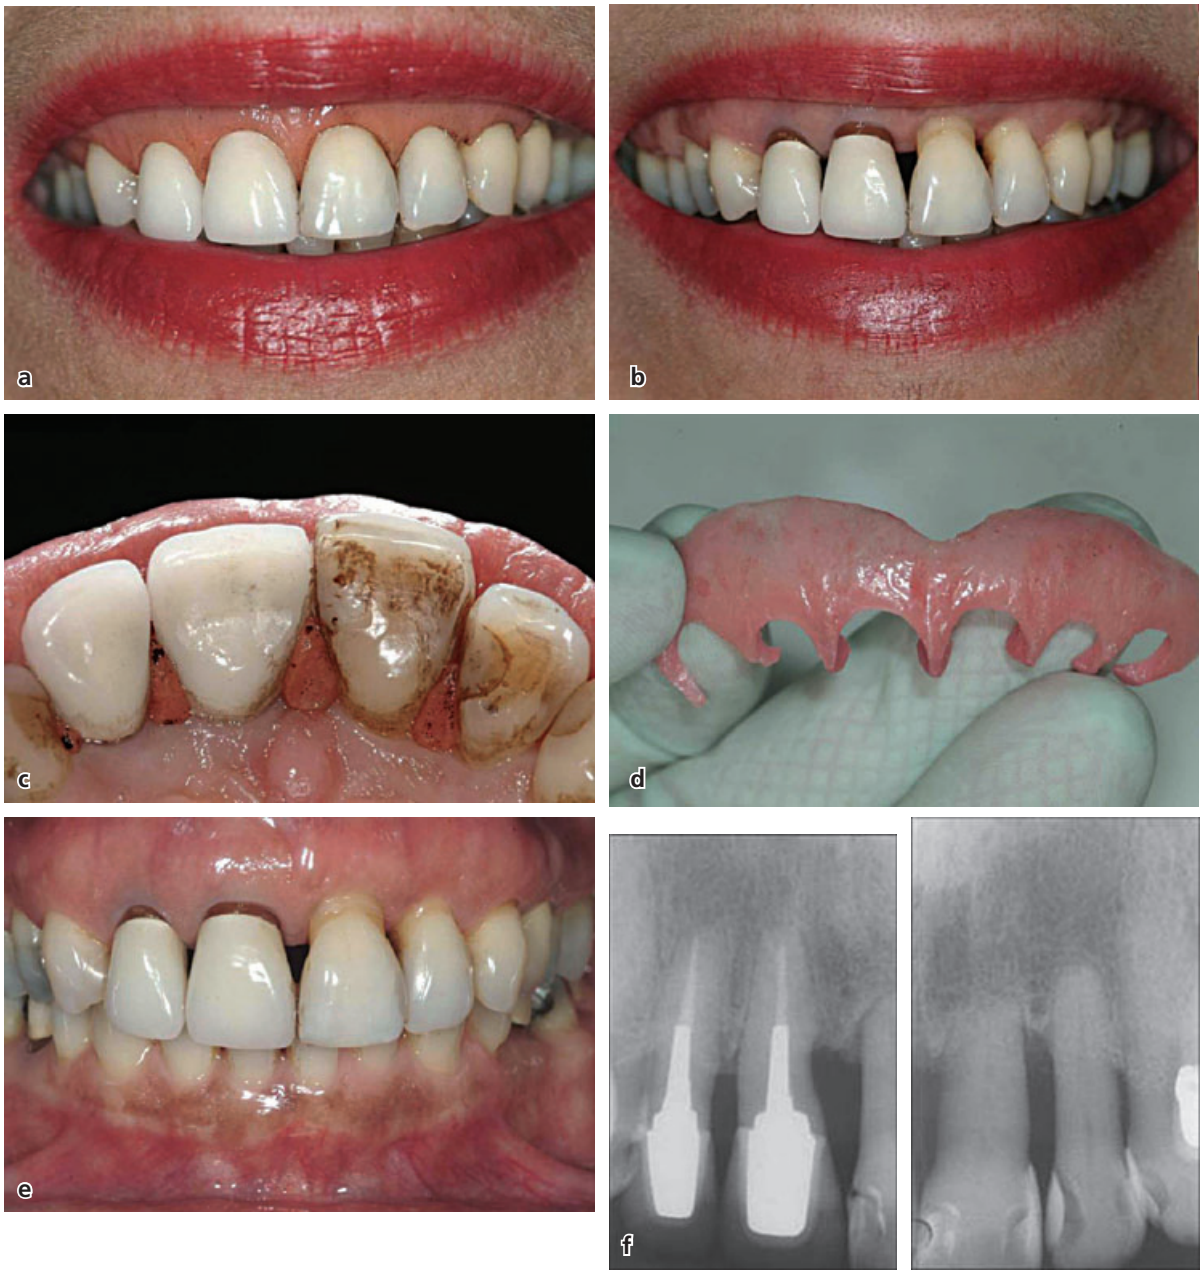

Fig. 27-13 (a) Frontal view of a 60-year-old female patient. During unforced smiling the transition between the clinical crowns and the artificial gingival epithesis is completely exposed. (b) The view without gingival epithesis displays long clinical crowns and open embrasures, both affecting the esthetic appearance. (c) The occlusal close-up view of the maxillary incisor region highlights the anchorage mechanism of the epithesis in the region of the open embrasures. (d) The gingival epithesis made of pink silicone is characterized by its regular scalloped occlusal course, compensating for the missing interproximal soft tissue. (e) The clinical view in centric occlusal reveals an average inter-arch relationship, but an altered length-to-width ratio of the clinical crowns of the four maxillary incisors as a consequence of periodontal tissue loss. (f) The corresponding radiographs document the advanced interproximal bone loss, indicating in particular that tooth #21 cannot be maintained.

leading to unsightly, "black interdental triangles". This is particularly pronounced in patients with an originally "*scalloped thin*" *gingival morphotype*, in contrast to a rather "*flat thick*" *phenotype* (Seibert & Lindhe 1989; Olsson & Lindhe 1991; Olsson *et al*. 1993). Not infrequently, vertical and/or lateral migration of teeth may also have occurred which, in turn, can significantly affect esthetic parameters. Furthermore, in case of more localized periodontal disease and loss of attachment, abrupt changes in vertical tissue height between neighboring teeth can be present.

The resulting major shortcomings from an esthetic point of view mainly consist of an altered length-to-width ratio of the involved clinical crowns (*long teeth syndrome*) on the one hand and of interdental spaces that are not completely filled-out with gingival tissue on the other hand (Fig. 27-13). The latter may not only affect esthetics, but also lead to food retention and phonetic disturbances. As a consequence,

reconstructive measures generally, and in implant therapy in particular, have not only to aim at a predictable and long-lasting functional rehabilitation, but need also to re-establish harmony from an esthetics and phonetics perspective. In general, fixed prosthodontic measures have somewhat limited potential of correcting length-to-width discrepancies of clinical crowns and to diminish open inter-proximal embrasures. Furthermore, the clinician should be aware of the additional specific limitations associated with current implant therapy (as described in Chapter 53), particularly when it comes to esthetic parameters, and therefore include this notion while proceeding to the local examination. In this context, the importance of assessing the height of the patient's smile line and his individual treatment expectations, should be once more underlined.

In the scope of this chapter and specifically addressing the local, pre-implant examination, two distinct clinical conditions can be theoretically encountered:

- One or several elements (teeth) of the anterior maxillary segment are periodontally compromised to such an extent (degree) that they can not be maintained and thus require replacement.
- One or several elements (teeth) of the anterior maxillary segment have already been lost due to periodontal disease.

This distinction is of importance, as the removal of a tooth consistently leads to horizontal and vertical tissue loss which includes soft and underlying bone tissue and which has been reported to vary between 2 and 3 mm vertically (Kois 1996; Araujo & Lindhe 2005; Araujo *et al*. 2005, 2006). This means that in the case of teeth still being present, but considered *irrational to treat*, an additional esthetic aggravation has to be expected. In this context, the beneficial potential of a slow orthodontic *"forced eruption"* procedure prior to tooth extraction, has to be mentioned (Salama & Salama 1993). Furthermore, as described in more detail in Chapter 53, one has to keep in mind that single-tooth replacement is significantly more predictable when it comes to long-term esthetic treatment outcome, than multiple adjacent implant restorations in the anterior maxilla (Belser *et al*. 2004a,b; Buser *et al*. 2004, 2006; Higginbottom *et al*. 2004). Clearly, single-tooth implant restorations benefit from tissue support provided by the adjacent natural teeth. As a consequence, the currently recommended *extraction strategy* for this area of the jaw should try to avoid, whenever feasible, ending up with *two-unit* tooth gaps. In other terms, one should either aim for *single-tooth gaps* or, if this is not possible, for *more extended edentulous segments* (three or more missing adjacent teeth). The latter concept, on the one hand, permits one to replace part of the missing teeth with pontics and thus benefit from their inherent superior esthetics (eventually enhanced by connective tissue grafting procedures), and, on the other hand, to avoid adjacent implant restorations.

Table 27-1 Elements of the local, implant-specific examination of the periodontally compromised dentition in the esthetic zone

- Patient's smile line (high, medium, low)
- Periodontal examination (including gingival index, plaque index, probing pocket depth, clinical attachment level, bleeding on probing, width of the keratinized mucosa, gingival recessions, tooth mobility, tooth migrations)
- Inter-proximal bone height (as assessed on radiographs)
- Bone anatomy of the existing and/or anticipated (in case of inevitable tooth extractions) edentulous ridge
- Soft tissue anatomy (course of the gingival line in relation to the cemento-enamel junction of existing teeth and/or the osseous ridge)
- Gingival phenotype ("flat thick" vs. "scalloped thin")
- Shape of anatomic tooth crowns ("square" vs. "triangular")
- Length-to-width ratio of clinical crowns
- Overbite, overjet, malposition of teeth, occlusal parafunctions (wear facets, bruxism)
- Restorative/endodontic status of remaining teeth
- Width of existing and/or prospective edentulous spaces (single-tooth vs. multiple-unit gaps; identification of edentulous spaces that do not correspond to the volume of the respective missing teeth)

Clinical and radiographic examination

A structured comprehensive examination of the periodontally compromised anterior maxillary dentition (Table 27-1) should logically start with the assessment of the height of the patient's smile line. This will immediately indicate if the major esthetic shortcomings associated with an implant rehabilitation under such conditions, i.e. *long clinical crowns and open embrasures*, will become visible during unforced smiling. The examination will then focus on the detailed periodontal status, aiming at determining the prognosis of each individual unit of the respective dentition from a primarily periodontal perspective. As it is anticipated in the scope of this chapter that either one or several teeth cannot be maintained for periodontal reasons, or that one or several teeth have already been lost due to periodontal disease, the examination will have to assess whether implant therapy represents the adequate treatment solution or not. This means that additional parameters, directly related to implant therapy, have to be included in the examination process. These parameters comprise the localization of interproximal bone height assessed on radiographs, the bone anatomy of the existing or prospective (after additional tooth extractions) edentulous ridge, the course of the gingival (mucosal) line in relation to the cemento-enamel junction, as well as the width of the edentulous spaces. Furthermore, the general shape of the anatomic crowns (square or triangular) and the length-

to-width ratio of the clinical crowns have to be assessed. Finally, the restorative and endodontic status of the remaining teeth and the overall occlusal conditions such as overbite, overjet, and the presence of occlusal parafunctions (wear facets, bruxism) have to be registered. In other words, all additional information which refers directly to implant therapy (e.g. bone volume) is a prerequisite for the decision-making process, to determine if implant therapy is feasible under these specific circumstances.

Patient-specific risk assessment

Summarizing the above mentioned aspects of a comprehensive preoperative examination, an individual risk profile is recommended for every candidate for implant therapy. Two different risk assessment forms are routinely used by the authors when examining potential implant patients, one for implant sites without esthetic priority, generally those in the mandible or in the posterior maxilla depending on the patient's smile profile, and a more detailed version for sites where esthetic aspects play a dominant role, primarily those in the (anterior) maxilla.

Risk assessment for sites without esthetic implications

The risk assessment in partially edentulous patients without or with low objective and subjective esthetic concerns is less complex. It should include the patient's health status, periodontal disease susceptibility, smoking history, interleukin-1 phenotype, history of bruxism, patient compliance including oral hygiene, and presence and type of alveolar bone deficiencies at potential implants sites (Table 27-2). In most patients, it takes less than 5 minutes to complete the proposed risk assessment form. Utilizing the obtained information, each implant candidate is categorized as low, medium or high risk. In patients with a 'high risk' mark in multiple areas, the appropriateness of implant therapy must be questioned. For example, heavy smokers with advanced or refractory periodontal disease and a positive IL-1 test have to be considered overall high risk when extended bone augmentation procedures are needed to enable sufficient bony implant anchorage. It is important to discuss the individual risk situation with the patient prior to therapy and obtain the patient's consent based on the given circumstances.

Risk assessment for sites with esthetic implications

Risk assessment for implant sites with esthetic importance is much more detailed and complex. The risk assessment form contains additional surgical and prosthetic parameters, which are critical for an esthetic treatment outcome (Table 27-3). These parameters have been outlined in detail by Martin *et al*. (2006) in the first ITI Treatment Guide. In periodontally compromised patients, clinicians are often confronted with medium- to high-risk situations, since vertical bone and soft tissue deficiencies are a frequent clinical finding.

Conclusion

Modern comprehensive dental care for patients with a periodontally compromised dentition has to include the consideration of dental implants. Implant-assisted replacement of teeth that are missing or need to be extracted due to periodontal disease is an overall predictable treatment alternative in this type patient. A meticulous comprehensive examination of implant candidates is crucial and should include a patient and indication-specific risk assessment to achieve favorable short- and long-term treatment outcomes with regard to function and esthetics.

Table 27-2 Risk assessment for patients/sites without esthetic treatment implications

	Low risk	Medium risk	High risk
Health status (see Medical history and medications)	Normal wound healing		Conditions with potential for impaired wound healing
Periodontal disease susceptibility	Gingivitis	Mild to moderate chronic periodontitis	Severe or refractory periodontitis
Smoking	Non-smoking	<10 cigarettes per day	≥10 cigarettes per day
IL-1 gene phenotype	Negative		Positive
Bruxism	No		Yes
Compliance including oral hygiene	Good	Fair	Poor
Bone deficiency at implant site	None	Horizontal deficiency	Vertical deficiency

Table 27-3 Risk assessment for patients/sites with esthetic treatment implications

	Low risk	Medium risk	High risk
Health status (see Medical history and medications)	Normal wound healing		Conditions with potential for impaired wound healing
Periodontal disease susceptibility	Gingivitis	Mild to moderate chronic periodontitis	Severe or refractory periodontitis
Smoking	Non-smoking	<10 cigarettes per day	≥10 cigarettes per day
IL-1 gene phenotype	Negative		Positive
Bruxism	No		Yes
Patient's esthetic demand	Low	Medium	High
Lip line	Low	Medium	High
Gingival biotype	Thick, low scalloped	Medium thick, medium scalloped	Thin, highly scalloped
Shape of tooth crown	Rectangular		Triangular
Bone level at adjacent teeth	≤5 mm to contact point	5.5–6.5 mm to contact point	≥7 mm to contact point
Local infection at implant site	None	Chronic	Acute
Restorative status of neighboring teeth	Virgin		Restored
Width of edentulous space	One tooth ≥7 mm* One tooth ≥5.5 mm**	One tooth <7 mm* One tooth <5.5 mm**	Two teeth and more
Soft tissue anatomy	Intact soft tissues		Soft tissue defect
Bone deficiency at implant site	No bone deficiency	Horizontal bone deficiency	Vertical bone deficiency

* For regular neck/regular platform implants.
** For narrow neck/narrow platform implants.

Chapter 28

Radiographic Examination of the Implant Patient

Hans-Göran Gröndahl and Kerstin Gröndahl

Introduction

In 1965, Brånemark installed the first dental implants made of titanium in the mandible of a 35-year-old male who, due to a cleft palate and loss of most of his teeth, could neither speak nor eat properly (Brånemark *et al*. 2005). The era of osseointegration, as a means to restore oral function compromised as a result of missing teeth, had begun.

The foundation for the use of titanium as the metal of choice for prostheses placed in the bone was laid many years earlier. In 1940, Bothe, Beaton and Davenport published the results of a study in which they had inserted pegs of different metals, among them titanium, in cat femurs. They found that "... the response to titanium was as good as, if not better, than that to the non-corrosive alloys in that there was more tendency for the bone to fuse with it". In 1951, Leventhal inserted screws made of titanium into the femurs of rats. He describes that "At the end of six weeks, the screws were slightly tighter than when originally put in; at twelve weeks the screws were more difficult to remove; and at the end of sixteen weeks, the screws were so tight that in one specimen the femur was fractured when an attempt was made to remove the screw". He continues: "In the past, the use of some prostheses has not become popular because it has been felt that these would remain separate from the bone and eventually loosen. Since titanium adheres to bone, it may prove to be an ideal metal for such prostheses".

Brånemark realized that screw-shaped titanium implants placed in the human jawbone could serve as substitutes for teeth that had been lost or never developed. In 1977, results from a 10-year study period were published (Brånemark *et al*. 1977) that demonstrated the clinical usefulness of what would become known as osseointegrated implants.

In the beginning of the osseointegration era limited numbers of people, and practically only those with no teeth left, were treated with dental implants. Gradually the indications were widened until partially edentulous and the patient missing just a single tooth also became candidates for implant treatment. From having been a treatment modality offered by a small number of specialists, it has emerged as a treatment mode provided by more and more dentists worldwide. It seems to grow exponentially and many more years probably remain before the vertex of its diffusion curve has been reached (Fig. 28-1a).

From a radiological point of view this must give us pause because it means that more people will undergo more extensive radiographic examination than people who receive conventional prosthetic treatment do. Consequently, we must try to use radiographic methods that do not unnecessarily increase the radiation burden to the population whilst providing us with all the information that is necessary for successful long-term treatment results.

In this chapter we will show how radiographic examinations for implant treatment purposes can be made so that they yield all necessary information at a reasonable cost both in terms of radiation dosage and economical resources. We will, in other words, adhere to the very important principle in radiography, the ALARA principle. This states that all radiographic information should be obtained with radiation doses that are As Low As Reasonably

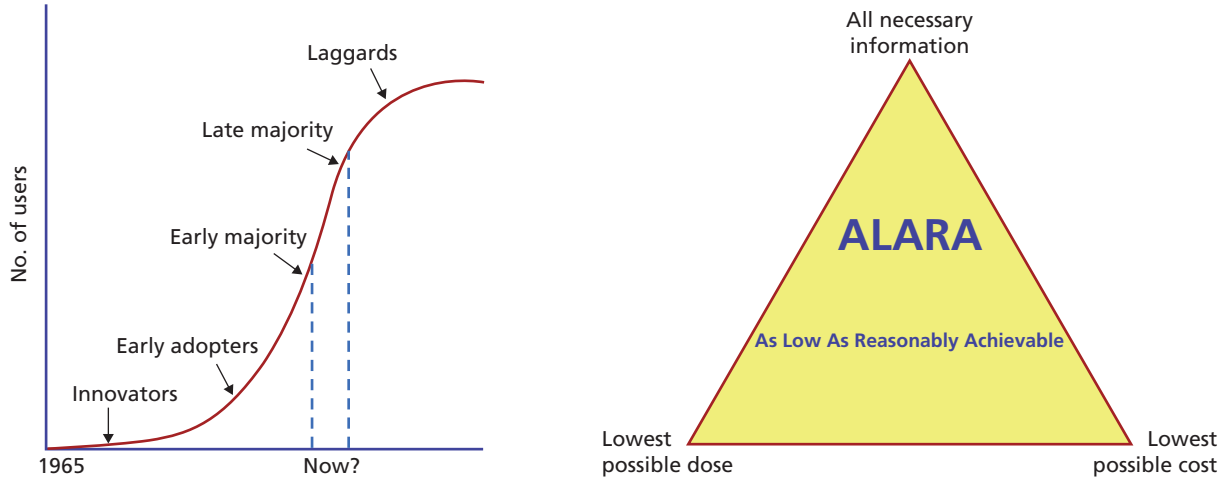

Fig. 28-1 (a, b) With the increasing use of implant treatment, it becomes increasingly important to adhere to the ALARA principle and keep radiation doses and monetary costs as low as possible.

Achievable. This principle may well be broadened so that it is also understood as stating that the monetary costs should be as low as reasonably achievable (Fig. 28-1b).

Radiographic examination for implant planning purposes – general aspects

The clinical vs. the radiologic examination

Too often a distinction is made between the clinical and the radiographic examination. The latter depends on the former and a meticulous clinical examination, including a thorough patient history, is the foundation upon which any radiologic examination must be based. Without it one can neither decide whether radiographic information is necessary, nor where and how it must be sought. The clinical examiner, whether or not he or she plans to make the radiographic examination her/himself, or refer the patient to a radiologist, thereby plays a decisive role when it comes to keeping radiation doses as low as reasonably achievable whilst obtaining the radiographic information that is necessary for a successful treatment planning. According to the International Commission on Radiation Protection, ICRP 60 (1991) all radiographic examinations should be justified and optimized. It is the clinical need of radiographic information that can make the radiographic examination justified. It is then the responsibility of the person, who will plan and perform the latter, to make certain that it will be made optimally.

What is the necessary radiographic information?

Before any radiographic technique can be chosen for any type of clinical problem one needs to clarify what radiographic information that is needed to enable a proper diagnosis and treatment plan. As regards the prospective implant patient, the necessary radiographic information is that which allows the clinician to determine:

- Whether implant treatment is the treatment option that offers the best long-term prognosis
- Whether pathological conditions are present in the jaws or remaining teeth that must be taken into account before implant treatment can be contemplated
- Where and how implants can be placed so that they have the best possibilities to become integrated with the surrounding bone and the associated crown/bridge can come into best clinical use
- How to place the implant(s) so that the surgical procedure becomes as safe as possible and the risk for post-operative failures as small as possible

A pre-operative radiographic examination is essential for all implant patients but how much of the jawbones that need to be examined and in what way will vary from patient to patient. Therefore, different radiographic techniques have to be used for different patients.

The pre-operative radiographic examination has several roles to play in respect to the clinician's needs. More specifically, the clinician needs to know the height of the bone that can be used for implant placement. One must then bear in mind that the bone height that can be used for implant placement is not necessarily the same as the total bone height (Fig. 28-2). The bone must also preferably be of a width which allows the implant to be surrounded by bone around its entire circumference. It is not only the available height that is of interest. When planning for implants to be placed adjacent to teeth or other implants one should try to ensure that they do not become positioned too close to each other (Fig. 28-3). Hence, the horizontal dimension of a potential implant site also needs to be assessed. When an

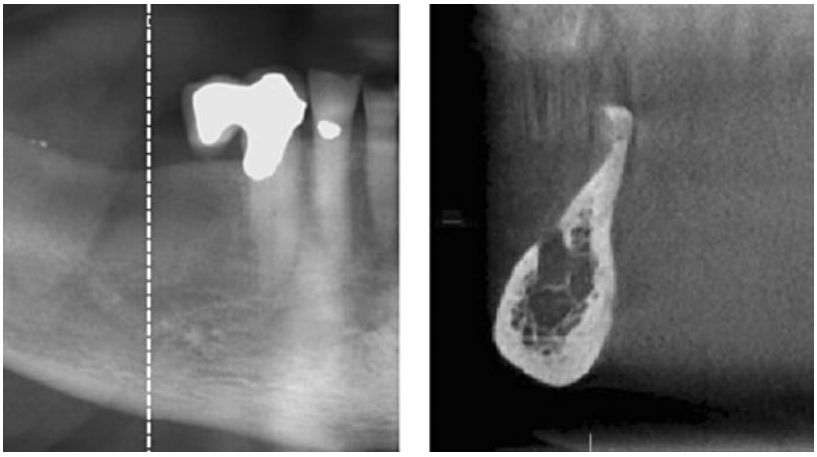

Fig. 28-2 An apparent height, as seen in the cropped panoramic image to the left, does not necessarily correspond to a bone volume useful for implant placement, as revealed by a tomogram (right image) representing a layer indicated by the dotted line.

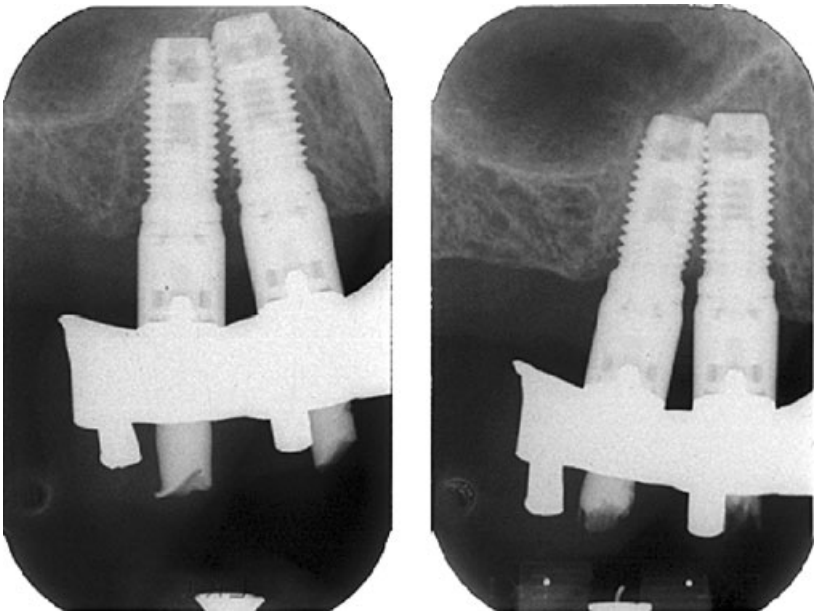

Fig. 28-3 Two implants placed very close to each other. A control radiograph taken 1 year after bridge connection (on right) demonstrates, by the thin radiolucent lines around the implants, that they have not become integrated with the surrounding bone.

implant will be placed adjacent to a tooth one should make certain that it does not become inserted too close to the tooth. Should this happen there is an increased risk of bone loss at the adjacent tooth or implant at least in the immediate period after implant surgery (Esposito *et al*. 1993; Andersson *et al*. 1995; Cardaropoli *et al*. 2003).

It is of great importance that the implant can be placed so that it will remain stable during the healing phase. The marginal bone crest may be used as a supporting bone cuff and a bony border in which the "apical" part of the implant can be placed will render some support. This can also be provided by the lingual and/or buccal cortical bone plate(s). The lower borders of the nasal cavity and the maxillary sinuses can give support to an implant (Fig. 28-4), but the upper border of the mandibular canal must not be used as anchorage of the implant tip (Worthington 2004).

A crucial aspect is that which concerns the location of anatomic structures that must not be damaged during implant surgery. In the lower jaw the mandibular canal, with its nerve bundle and blood vessels, is the most important. In the upper jaw placement of the implants so that they come in conflict with the nasopalatine canals should be avoided.

To make the placing of the implant(s) as safe a procedure as possible the radiographic examination must also enable a description of the outer contours of the jawbones so that, for example, tilting of the alveolar bone as well as the presence and depth of bony fossae will be observed and accounted for.

From the above it can be concluded that it is important to evaluate different aspects of the bone in which one intends to place an implant and that accurate and precise measurements of different distances are essential.

The pre-operative radiographic examination serves more purposes than those described above. When implants are to be placed in jaws with remaining teeth, the condition of those and their surrounding bone must be thoroughly evaluated. Inflammatory lesions in the vicinity of an implant site may compromise the implant treatment result. Careful assessment of the remaining teeth may also lead to the choice of an alternative treatment modality. The pre-operative radiographic examination thus serves to:

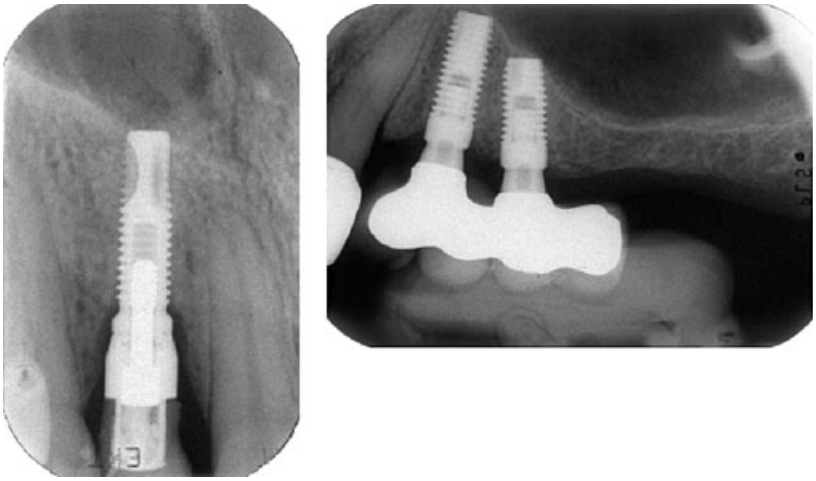

Fig. 28-4 The lower border of the nasal cavity and the maxillary sinus can provide support to an implant.

Fig. 28-5 A panoramic image of poor quality can give rise to serious problems. In this one it was not noticed that the bone in the upper right anterior region was not suitable for implant placement. Nevertheless, implants were placed (see inlay in upper left corner), soon to be lost.

- Ascertain that implant treatment is an appropriate treatment given the condition of the remaining teeth
- Make certain that bone height and width are sufficient for implant placement
- Provide measurements so that implants can be inserted without damaging neighboring structures
- Make implant insertion a safe procedure.

Needless to say, none of these objectives can be obtained without a radiographic examination of the best possible quality.

Radiographic methods for obtaining the information required for implant planning

In this chapter we will not discuss the examination of totally edentulous patients, only of those who have lost one or several teeth in jaws where some teeth still remain. As already mentioned one must then take into account the conditions of the remaining teeth in order not to jeopardize the implant treatment. A comprehensive examination, clinical as well as radiologic, of the dentition should therefore be made prior to a decision about where and how to insert implants. Depending upon the result of the clinical examination, the primary radiographic examination can be made with a combination of panoramic and intraoral radiography or by one or the other. One should not hesitate to take intraoral radiographs in regions where the panoramic radiograph has not been able to provide a clear view of the anatomic structures.

An adage well worth remembering, when determining whether an image is good enough for diagnosis and treatment planning, is that optimal diagnostic quality is only present when all diagnostically important structures are clearly visualized. Figure 28-5 illustrates a case when a panoramic radiograph was considered of good enough quality to be used for implant planning purposes. However, implants were lost, even before being subjected to

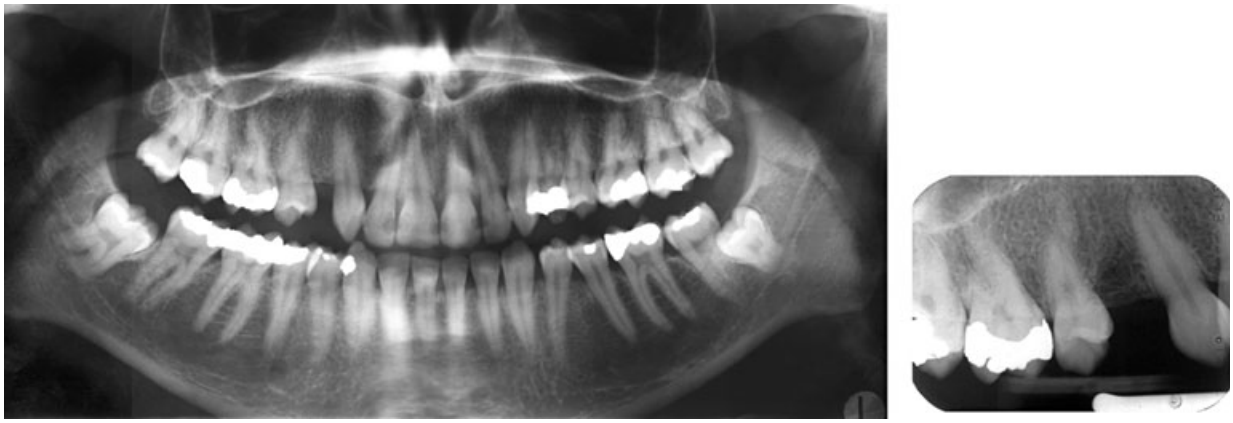

Fig. 28-6 Horizontal distortions are common in panoramic radiographs, especially in the upper premolar area, and give a false impression of available horizontal bone dimensions. Compare the distance between the second premolar and the cuspid in the two images.

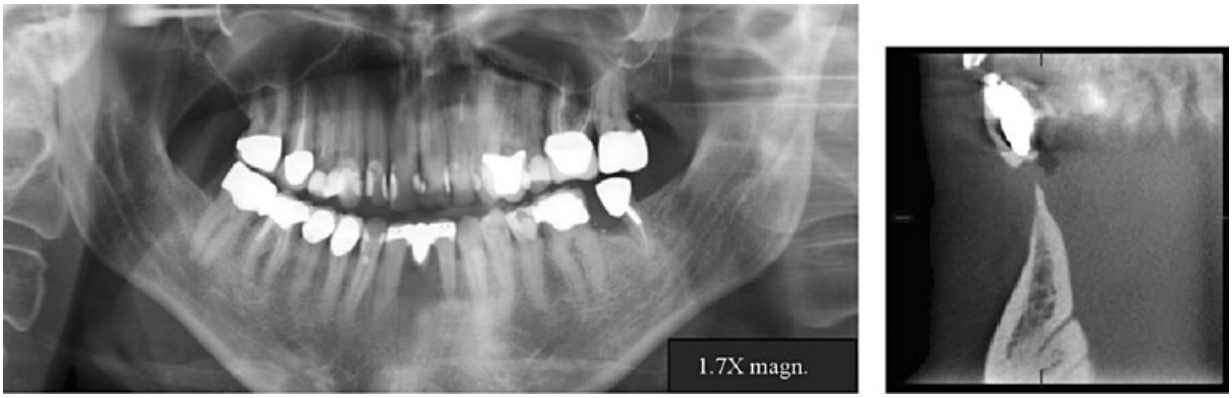

Fig. 28-7 The panoramic radiograph does not provide information about the width of the alveolar bone. A sagittal tomographic image reveals the true conditions in the lower anterior region.

occlusal loads, due to the poor bone conditions in the region that could have been observed had a better pre-operative radiographic examination been made.

Intraoral radiography should be performed according to the paralleling technique and radiographs taken so that there will be some overlapping between adjacent image fields. Most teeth will then be seen from two different angulations allowing for a better appreciation of the location of different structures.

Panoramic radiography may seem easy to perform but is a technique where many mistakes are made, not least in patient positioning. Panoramic radiographs taken on incorrectly positioned patients may provide a severely distorted view of the patient's jaws (Tronje 1982). This can cause large overlapping of neighboring teeth that can prevent a proper diagnosis. In regions where teeth are present the distortions are evident due to the overlapping of tooth surfaces (Fig. 28-6). In edentulous areas, however, distortions may not be that apparent which can lead to misjudgement of distances within the jaws. The panoramic technique can be used to provide a quick estimate of the bone height. A tomographic examination needs to be carried out in many cases to determine whether it is sufficient for implant placement (Fig. 28-7). The magnification in panoramic images varies between different types of panoramic machines. Some units also permit various types of radiographic images to be taken, that differ in magnification. It is thus important that one makes certain what magnification is indicated in the image to be evaluated.

Tomography can be used to obtain cross-sectional images, that is, images that are perpendicular to the curvature of the jawbones in the intended implant site. This is the best way in which to assess the width of the jawbone, and thereby the height available for implant placement, as well as other important aspects of the jawbone anatomy. Equipment for tomographic examinations shows much more variation than does that for panoramic and intraoral radiography. Widely different imaging principles are used resulting in different types of images.

The implant treatment spectrum varies from the single implant case to that where large parts of the facial skeleton are missing, and making an implant-anchored facial prosthesis necessary. Ideally, a clinic for oral and maxillofacial radiology is therefore equipped with a spectrum of X-ray machines for tomography capable of satisfying different demands

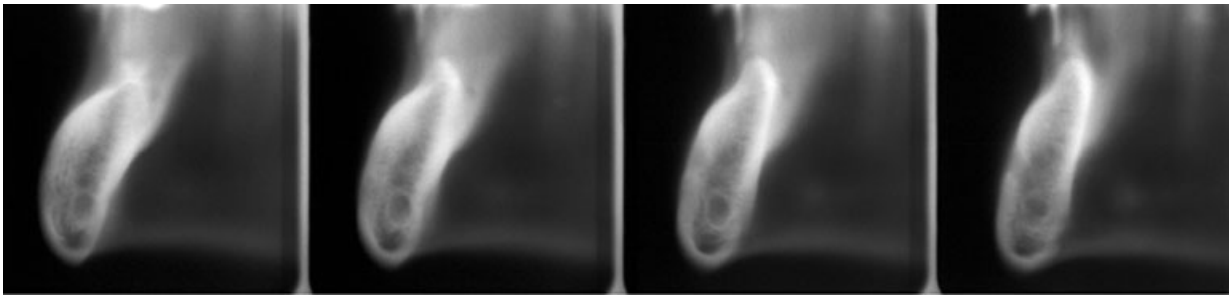

Fig. 28-8 Conventional spiral tomography of the lower jaw. Contiguous, 4 mm wide slices with the most anterior one taken in the region of the mental foramen (image to far right) that serves as an anatomic landmark.

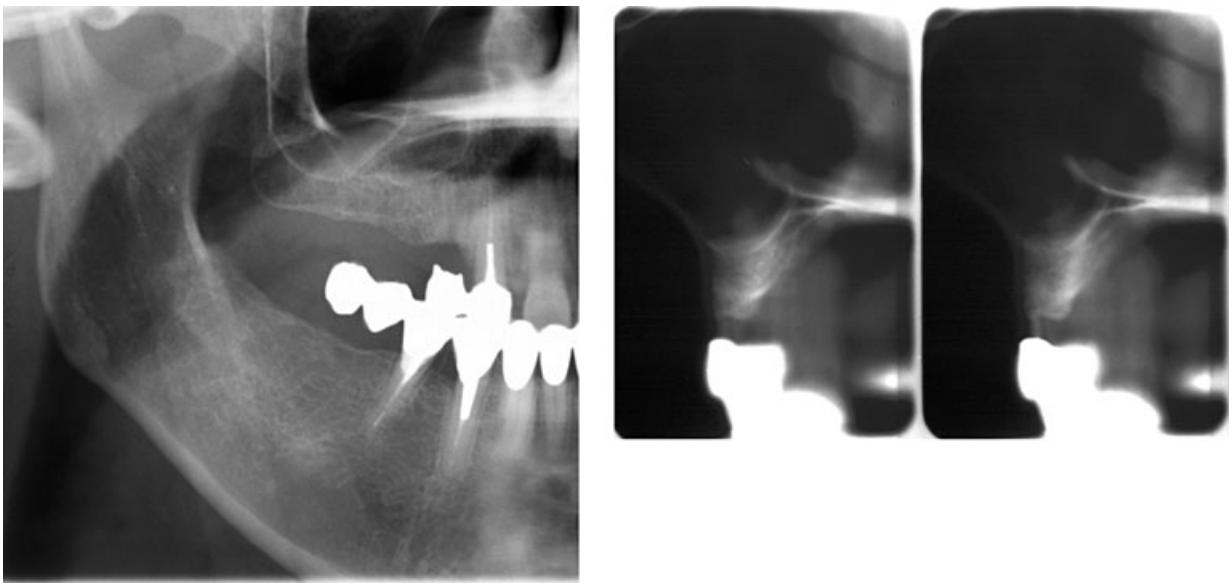

Fig. 28-9 By selecting just a few tomographic layers the dose can be minimized. Images taken distal to the upper right cuspid (see cropped) panoramic image.

and providing high-quality tomographic examinations. There is a difference between what different machines are best suited for. Three main groups of tomographic techniques are used for pre-implant tomography: motion (conventional) tomography, computed tomography (CT), and digital volume tomography (DVT), also known as cone beam CT. This is not the place to present these techniques in any detail but a little will be said about each of them as it relates to the examination of the implant patient.

Conventional tomography as applied for dental purposes underwent a profound development in the end of the 1980s when tomographic X-ray machines dedicated for the examination of the jawbones entered the market. Units such as the Scanora (Soredex Co, Helsinki, Finland) later to be followed by Cranex Tome from the same company meant that, most of the time, a comprehensive pre-implant examination of the patient could be made in the same unit and with the patient in the same position (Gröndahl *et al*. 1996, 2003). From a panoramic image one determines where in the jaw(s) one needs information that can only be found in cross-sectional, tomographic images. The tomographic examination of the selected region is then accomplished by means of a synchronized, spiral, movement of the X-ray tube and the detector (film or image plate) permitting image layers of 2–4 mm width to be obtained containing a minimum of spurious contours from adjacent structures.

One to four images of contiguous tomographic layers can be taken during the same examination, that is, without changing patient position or detector. They will then appear on the same film, or within the same digital image frame (Fig. 28-8). By selecting just a few layers to be exposed, radiation doses can be minimized (Fig. 28-9).

By means of multimodality units, conventional spiral tomography provides the possibility of tomographic examinations of limited regions selected from a panoramic view of the entire jaw or a part of it. It has the advantage of being done with a small unit that can also be used for many other radiographic examinations of the oromaxillofacial regions. Spiral tomography can be made with film or image plates but not with CCD or CMOS solid-state detectors: these are not yet available for use with the dental multimodality-type of X-ray machines.

Computed tomography is widely used for pre-implant tomography, often because other techniques are not available (Ekestubbe *et al*. 1997). In the overwhelming majority of cases a stack of axial tomographic layer images is first taken. The height of the stack should be such that it covers a distance from just outside the marginal bone crest down to and including the base of the mandible or, for the upper jaw, up to and including the hard palate. In the upper jaw the slices should be parallel to the hard palate, in the lower jaw to the base of the mandible (Fig. 28-10). The information in the axial slices can be used for image reformatting so that cross-sectional views of the jawbone will be displayed (Fig. 28-11). These are perpendicular to a curve corresponding to the shape of the jaw as seen in a representative axial view.

Computed tomography is easily performed but can also be associated with high radiation doses (Dula *et al*. 1996, 1997; Frederiksen *et al*. 1995; BouSerhal *et al*. 2001). Doses can, however, be significantly reduced by adhering to so-called low-dose protocols which are well suited for studies where the primary interest lies in examining bony structures (Ekestubbe *et al*. 1996, 1999). When using computed tomography it is also important that the height of the examined volume is kept as small as possible. Computed tomography is not ideal for tomographic examinations of partially dentate patients. This is because the volume of diagnostic interest, even when the height of the exposed volume is small, constitutes only a small fraction of the latter. Exposing as small a volume as diagnostically feasible is one of the best ways of adhering to the ALARA principle. Should several edentulous regions within the same jaw need to be tomographically examined, computed tomography may be justified (Buser *et al*. 2002).

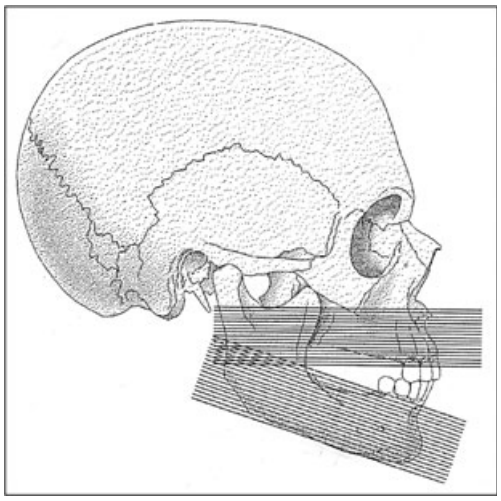

Fig. 28-10 Orientation of the axial tomographic slices differs between jaws. The height of the stack should be kept to a minimum.

Digital volume tomography (*DVT*) is becoming exceedingly popular as a tool for maxillofacial imaging not least for pre-implant planning purposes. With the midpoint of the region of interest as a centre, the X-ray tube moves along the periphery of a circle, on the other side of which is positioned the detector. During this movement a cone-shaped X-ray beam, the diameter of which differs between different types of equipment, exposes the region of interest either continuously or in short bursts. From the X-ray detector a signal is sent to a computer where the electronic signal is converted into a digital one. Based on this information images can be reconstructed so that layer images (axial, sagittal, and coronal) of the exposed volume will appear on the screen. It is possible to travel in either direction within the volume so that the entire volume can be easily searched. Many DVT units make it possible to display curved layers of varying width so that something similar to a conventional panoramic view, although with thinner layer thickness, is obtained.

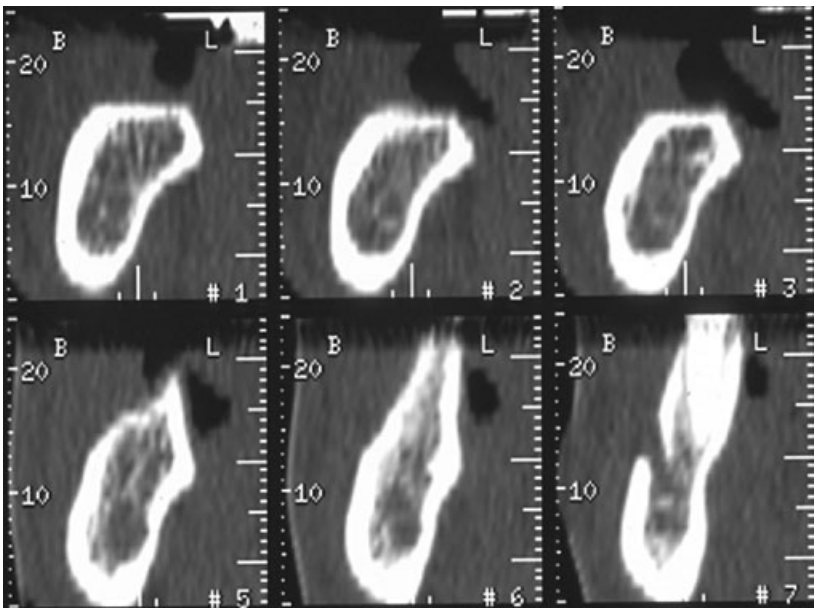

Fig. 28-11 Some reformatted cross-sectional images from the right side of the mandible.

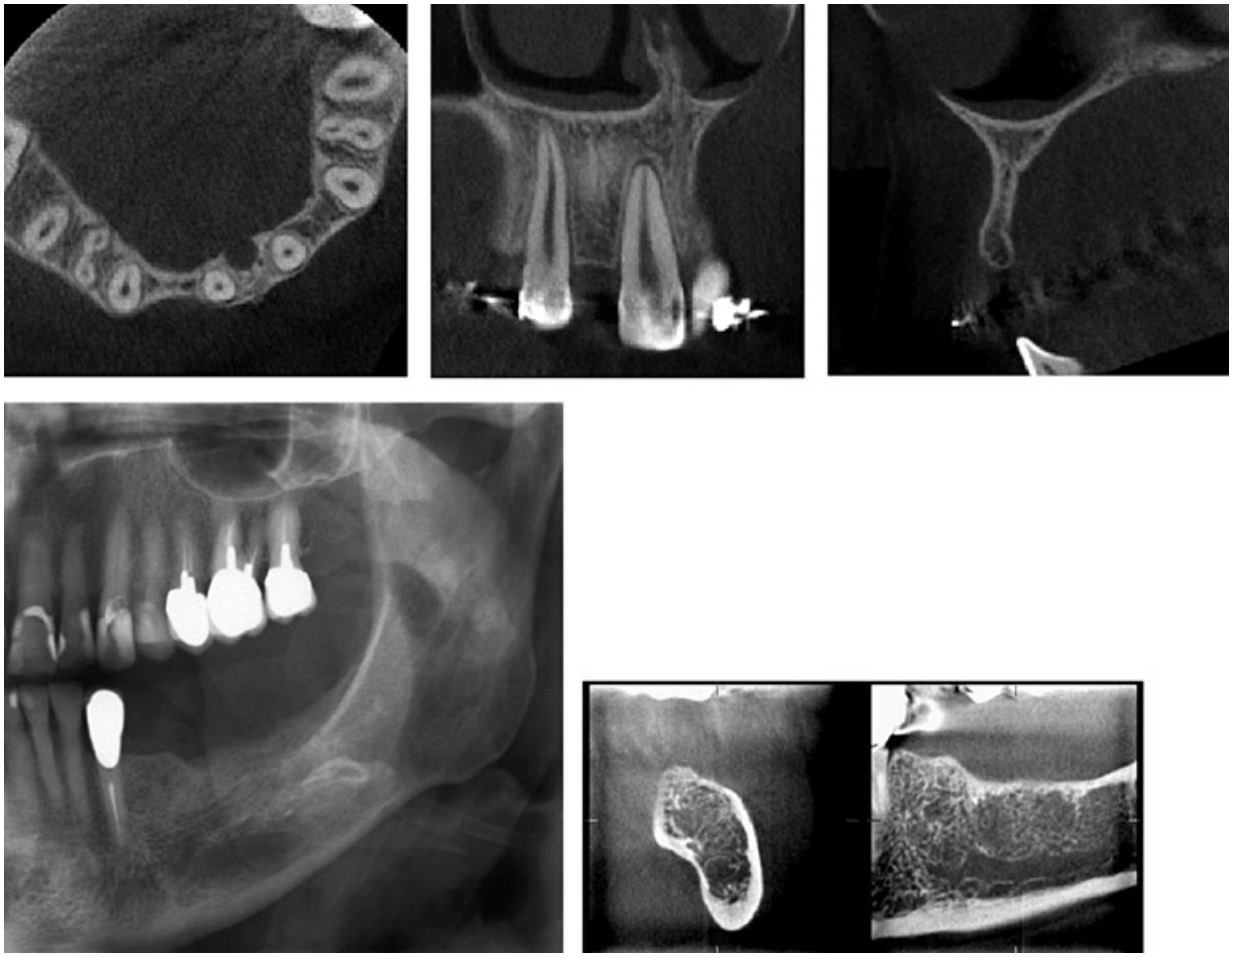

Fig. 28-12 Images (except the panoramic view) taken with 3DX Accuitomo DVT unit (J. Morita Co., Kyoto, Japan). The upper row images show the conditions in the right upper lateral incisor region. In the lower row the coronal and the sagittal tomographic images show the mandibular canal that is barely visible in the panoramic image.

Equipment for digital volume tomography comes in many different shapes (Frederiksen 2004), and they vary with regard to size of the volume that can be examined, geometric resolution, ease of use etc. They also differ as regards the radiation dose to the patient due to, above all, differences in volume size, resolution, and type of detector (Ludlow *et al*. 2006). Digital volume tomography could very well become the technique with which most partially dentate patients in need of implant treatment will be examined. The examination is easily done and radiation doses can be kept low, especially when machines that permit different sized volumes are used. An excellent way of reducing radiation dose is to expose the smallest possible volume. An advantage with digital volume tomography is its applicability in many areas of clinical dentistry. Figures 28-12 and 28-13 provide examples of images taken with DVT units.

Realizing that far from everybody has access to a wide spectrum of X-ray machines we will present various types of commonly seen cases. We will describe how they can be radiographically examined by means of different techniques but not include the totally edentulous patient or the patient in need of facial prosthetic constructions.

Radiographic examination for implant planning purposes – upper jaw examination

Depending upon where in the upper jaw implant treatment is to be planned one must take different anatomic factors into account. A common denominator is of course that the width and height of the bone must be evaluated. The available height depends on the bucco-palatal width of the bone because, ideally, the implant should be covered by bone both on its buccal and palatal aspects. The length of implants that can be used thus depends on the distance between the inferior border of the nasal cavity, or the maxillary sinus, and that part of the alveolar bone where it is sufficiently wide for implant placement (Fig. 28-14). When implants are to be placed in the vicinity of the midline one must evaluate the width of the incisive foramen and the nasopalatine canal. One must assess the height and width of the alveolar bone on the buccal and distal side of these structures to determine whether and where an implant can be placed (Fig. 28-15).

In the upper frontal region it is not uncommon for a single tooth be missing as a result of previous

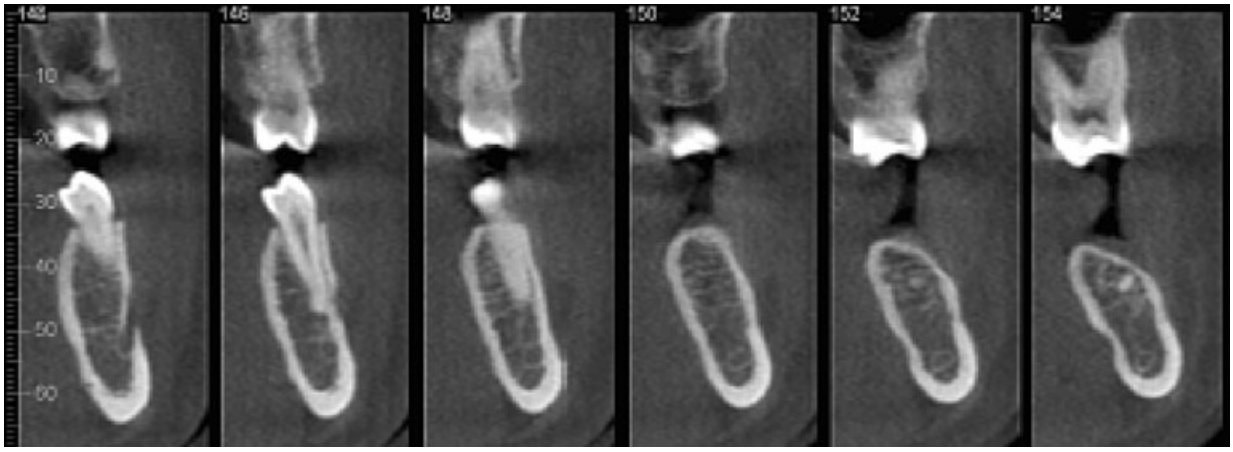

Fig. 28-13 Lower jaw tomography performed by i-CAT cone beam CT machine (Imaging Sciences International, Hatfield, PA, USA). Courtesy of Dr. Allan Farman, University of Louisville, Kentucky, USA.

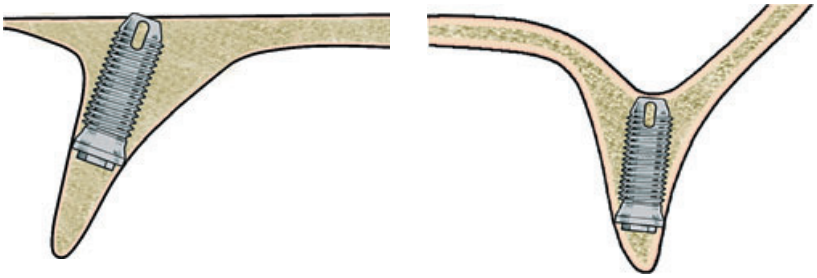

Fig. 28-14 The height of the bone available for implant placement depends on its width. It may therefore be less than the height as it appears in e.g. intraoral or panoramic radiographs.

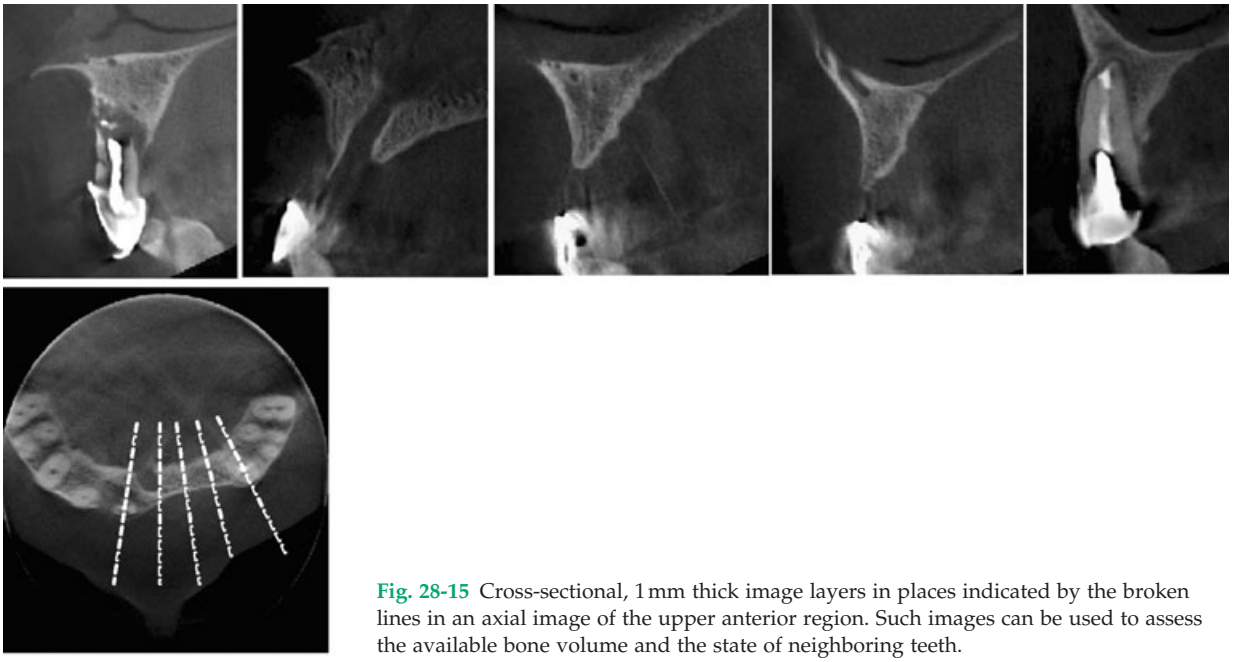

Fig. 28-15 Cross-sectional, 1 mm thick image layers in places indicated by the broken lines in an axial image of the upper anterior region. Such images can be used to assess the available bone volume and the state of neighboring teeth.

trauma. In these cases the radiographic examination can be done in a simple, yet comprehensive, way by one or two intraoral radiographs and a single tomographic image (Fig. 28-16).

Should the available bone lack the dimensions needed for the placement of an implant, the patient may be willing to accept that bone augmentation is performed to provide for sufficient height and width of the bone. In the latter case tomographic images will be of help when determining exactly where the bone is of less than sufficient width or height and the extent to which it needs to be augmented. Tomographic images can also be used to observe the results after healing (Figs. 28-17 and 28-18).

In areas where teeth have been extracted and it is uncertain how much of the alveolus has become

Fig. 28-16 Two cases of missing upper incisors in which the pre-operative radiographic examination was made by intraoral radiographs and conventional spiral tomography. In the lower row case an implant could be placed buccal to the nasopalatine canal.

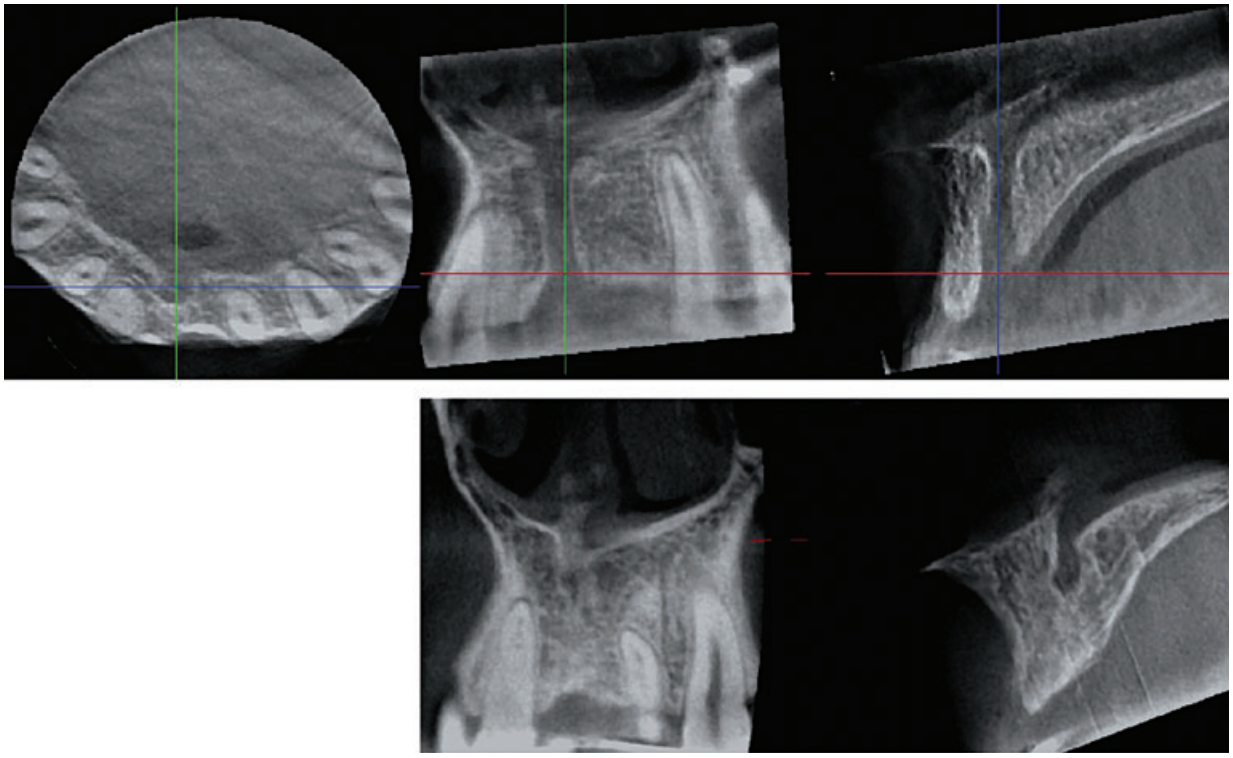

Fig. 28-17 Pre-operative (upper row) and post-operative images of a patient in whom a bone substitute was placed both buccally and in the nasopalatine canal to enable insertion of an implant in an optimal position.

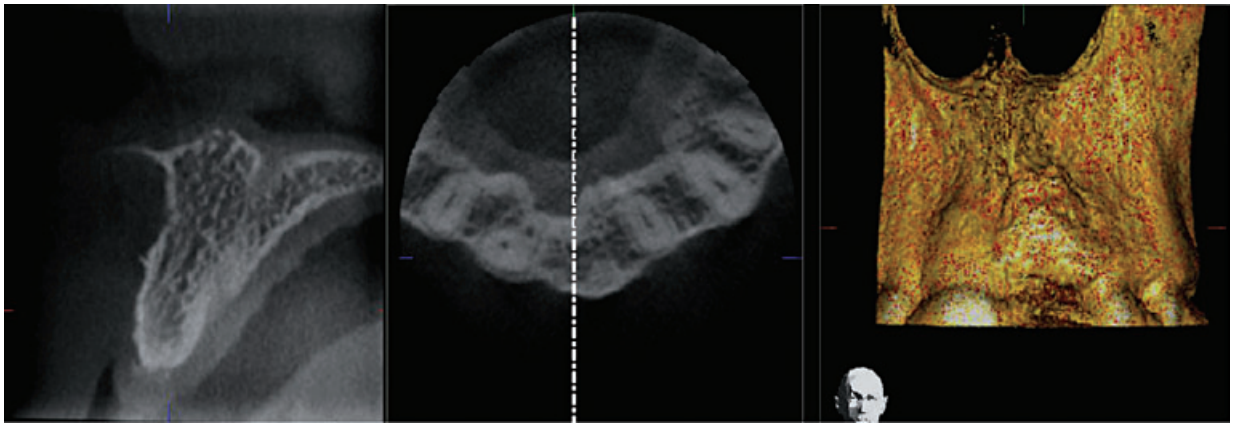

Fig. 28-18 A sagittal (left) and an axial tomographic image (middle) after a bone substitute has been placed on the buccal surface. The dotted line indicates the position of the sagittal slice. To the right is a three-dimensional image reconstructed from the volume data.

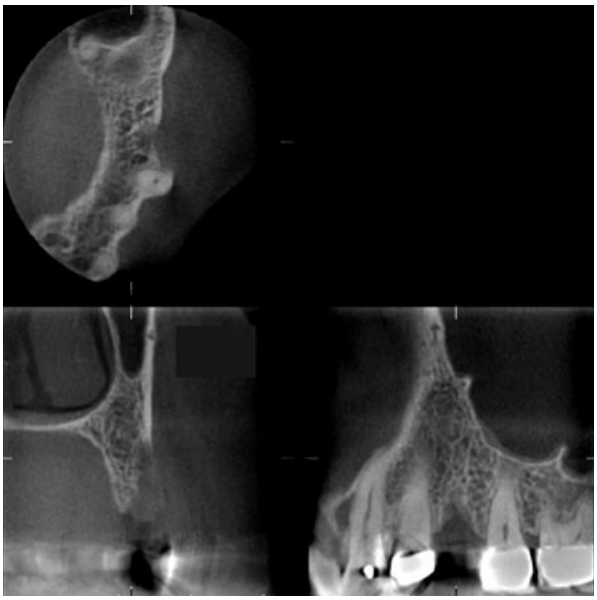

Fig. 28-19 Digital volume tomography in the upper first premolar area. Notice the lack of complete bone filling of the extraction socket and the relation of the alveolar bone to the nasal and maxillary sinus cavity.

filled with new bone, digital volume tomography is a helpful tool. This is illustrated in Fig. 28-19, where it is also apparent how well this technique is able to demonstrate the conditions anterior and inferior to the frontal border of the maxillary sinus.

In some patients in whom the available bone height below the maxillary sinus is too small one can occasionally find bone suitable for implant placement on the palatal side of the sinus. Tomography must be performed so that this can be determined (Fig. 28-20).

In the posterior parts of the upper jaw the maxillary sinus may extend so far down into the alveolar bone that there is not enough bone available in which to insert an implant. By entering the sinus through a buccal window, bone substitutes can be placed under the mucosal lining. Digital volume tomography is an ideal method to evaluate how the bone substitute is positioned and its relation to the adjacent bone (Fig. 28-21).

When implants are intended to be placed in more than one region, the use of computed tomography may be justified (Buser *et al*. 2002) provided that low-dose protocols are applied (Rustemeyer *et al*. 2004). A panoramic radiograph and, when remaining teeth are not well displayed in it, complementary intraoral radiographs are nevertheless important. Figure 28-22 describes how the results of such an examination can look. From the stack of axial images a representative image is chosen in which the curvature of the jaw is drawn. A dedicated computer program then makes new tomographic images at chosen distances. These images describe layers that are perpendicular to the curve and in which measurements of bone height and width can be made.

Computed tomography is mostly performed in medical radiology departments and images considered relevant for the purpose are sent to the clinician. Sometimes these are limited to the axial image describing the curvature of the jaw and the reconstructed cross-sectional images. We recommend that the referring dentist should also receive the scout image and the stack of axial images. In the scout image it is possible to see what reference plane that was used and, if needed, make the appropriate adjustment of the measurements taken in the cross-sectional views. In the axial images one may be able to pick up information about the remaining teeth not displayed in the panoramic or intraoral radiographs (Huumonen *et al*. 2006).

Radiographic examination for implant planning purposes – lower jaw examination

In the lower jaw there is a distinction between implant placement in the region anterior to the mental foramina and in regions posterior to the foramina. The height of the anterior region is usually well preserved

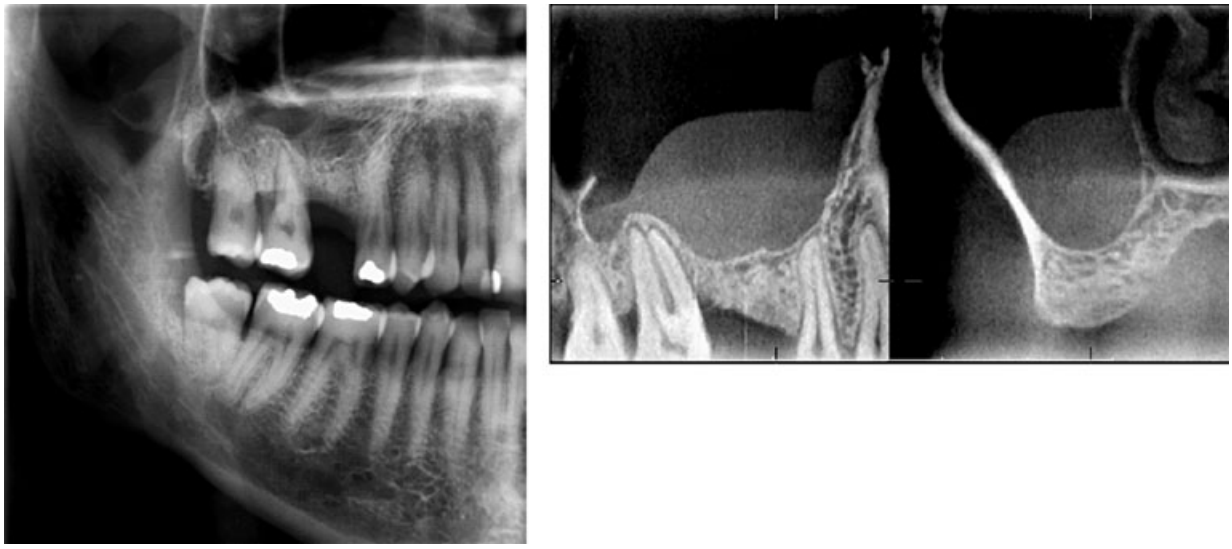

Fig. 28-20 From the panoramic image (left) it is not possible to determine that bone for implant placement is available on the palatal side of the maxillary sinus, as is clearly seen in the tomographic image (right). Notice the soft tissue swelling in the sinus.

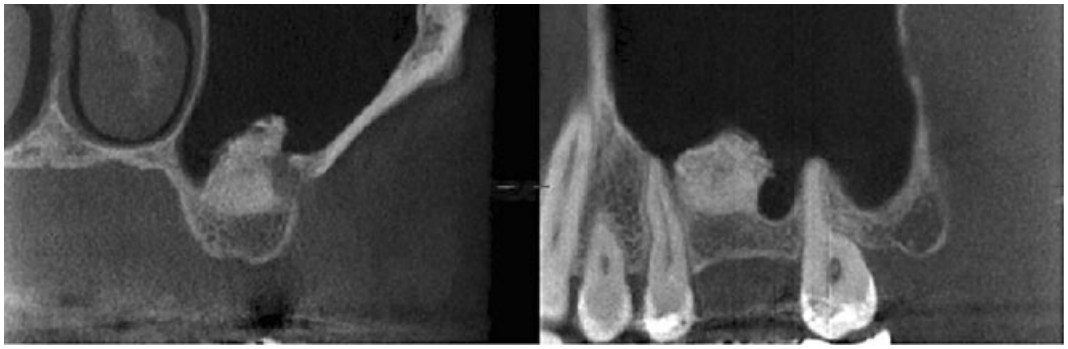

Fig. 28-21 A coronal and a sagittal tomographic layer of the lower part of the maxillary sinus in which a bone substitute has been placed.

if teeth have not been missing for a long time. This is rarely the case in the partially dentate patient. Its width, however, may be a limiting factor. One can get an indication that the alveolar bone is thinner than normal from periapical radiographs or from panoramic images, provided that the anterior region is well reproduced. This is often the case when one can see vertically running radiolucent structures corresponding to the blood vessel canals in the inner walls of the cortex. They become visible when the bone is thin or has fewer and thinner bone trabeculae than normal. In such cases a tomographic examination may be advisable so that one can determine beforehand whether a thin upper ridge will be removed or a bone augmentation procedure applied.

When implants are to be placed posterior to the mental foramina one must not only take into account the factors one had to consider in the frontal regions. One must also be able to identify the path of the mandibular canal and accurately assess the distance between the upper level of the alveolar bone, where it is sufficiently wide, to the upper border of the canal. To do this before surgery requires that tomography is performed, so that the jawbone anatomy can be evaluated in image layers that correspond to cross sections of the mandible. Estimating this distance in panoramic radiographs, as many seem to do (Worthington 2004), requires so many assumptions of unknown variables that mistakes can easily be made (Fig. 28-23). These can result in temporary or permanent damage to the inferior alveolar nerve. These problems "are more frequent than expected" (Worthington 2004). We are convinced that careful presurgical planning, including the use of tomography, will keep the incidence of nerve damage to an absolute minimum.

The entire distance from where sufficient width of the mandible is found to the upper border of the mandibular canal cannot be used for implant surgery. One reason is that the drill used for preparing the implant site will go deeper than the implant itself. Another is that one cannot always measure distances in radiographs with absolute accuracy and precision. Therefore, prudent clinicians make use of at least a 2 mm safety zone between the upper border of the

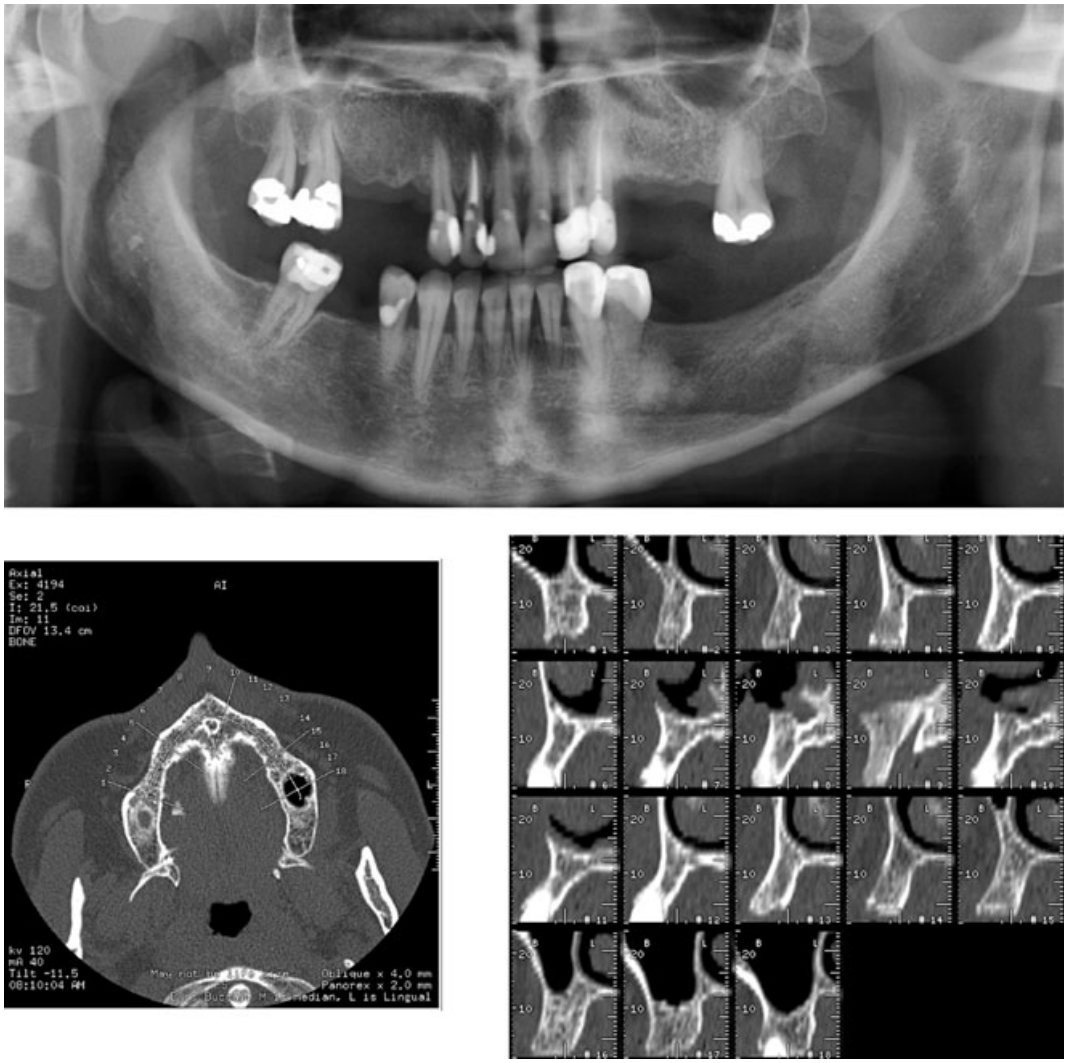

Fig. 28-22 Computed tomography of the upper jaw where implants are planned to be installed on both sides. To the lower right are cross-sectional views from one side to the other, perpendicular to the curve seen in the axial view to the left.

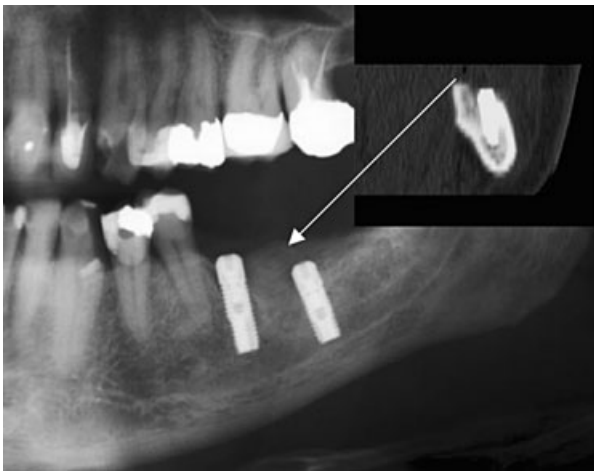

Fig. 28-23 In this case implant treatment planning was based on a panoramic radiograph only. One of the implants was placed with its tip into the mandibular canal as seen in a subsequent CT image. The positioning of the implant into the canal may have been caused by a misinterpretation of the panoramic radiograph. It is the lingual part of the upper alveolar bone that gives rise to the upper contour in the panoramic image.

mandibular canal, as seen in the radiograph, and the planned level of the tip of the implant (Fig. 28-24).

Among other factors that must be considered in the planning process is the outer shape of the mandible. Both concavities and the lingual tilt differ in extension between patients and between different parts of the jaw (Figs. 28-25 and 28-26). Accidental penetration of the lingual wall of the mandible can more easily occur under those conditions than when they are not present. Severing of arteries in the underlying soft tissues can cause severe, even fatal, bleeding (Darriba & Mendonca-Caridad 1977; Niamtu 2001).

Sometimes the mandibular canal, before it ends at the mental foramen, continues a little bit in an anterior direction before going upwards and distally toward the foramen making a so-called anterior loop (Arzouman *et al*. 1993). Therefore it is recommended not to place an implant immediately anterior to the foramen. In other cases there can be a relatively wide anterior continuation of the canal, as indicated by Fig. 28-27. It is then recommended that a radiographic

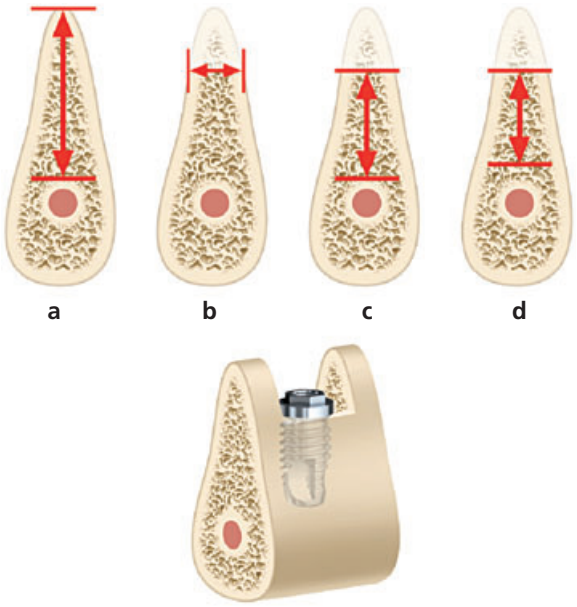

Fig. 28-24 How measurements can be made in tomographic images to ensure that the tip of the implant will not enter the mandibular canal. (a) Measure the entire height from the upper border of the canal to the marginal bone crest. (This value can be used as a reference during surgery.) (b) Assess where the bone is wide enough for the implant. (c) Measure from this level to the canal. (d) Subtract 2 mm from the latter value. From Gröndahl *et al*. (2003).

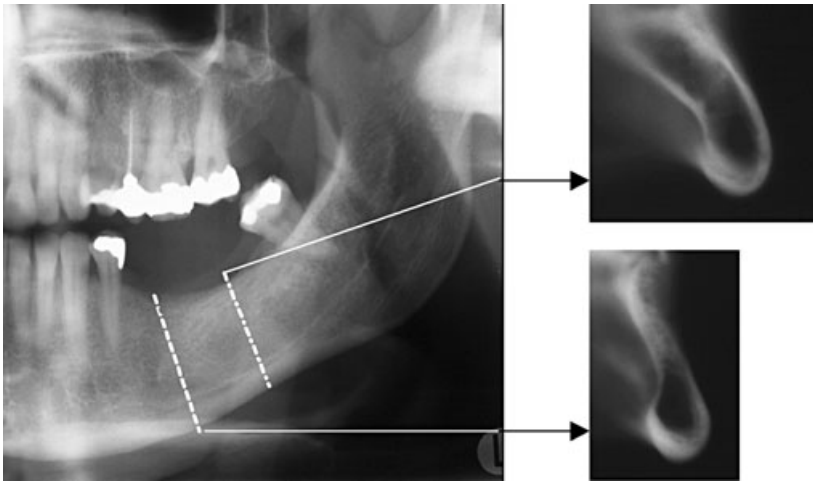

Fig. 28-25 Lingual concavity and a small bucco-lingual width just distal to the mental foramen and a different shape and width in a more distal position.

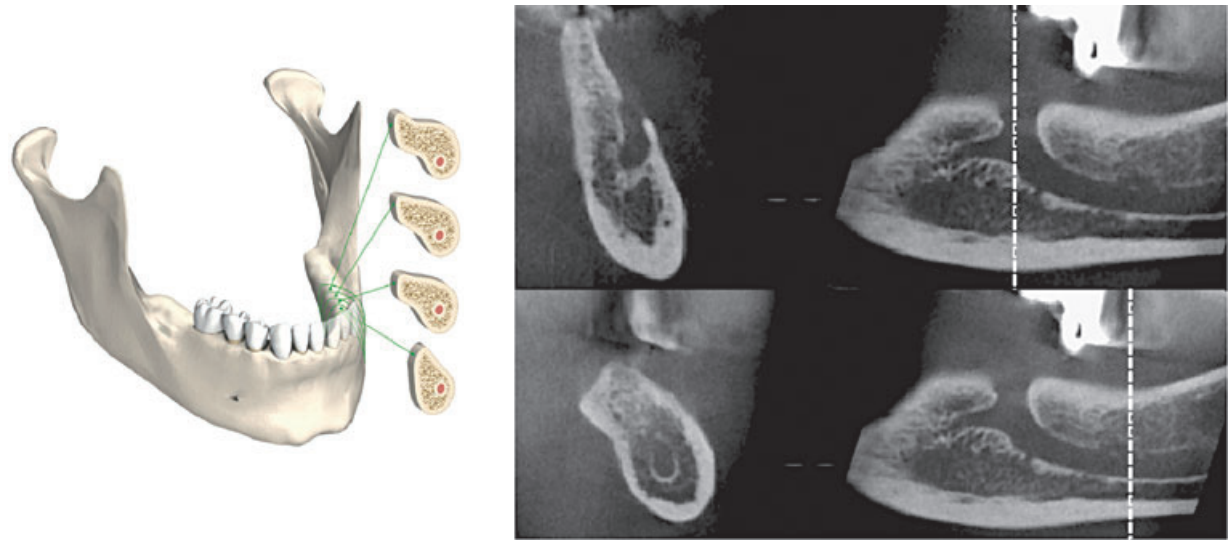

Fig. 28-26 The shape and angulation of the mandibular jawbone can be very different just a short distance apart. The dotted lines in the sagittal tomograms indicate the positions of the cross-sectional tomographic layers. This information can only be obtained pre-operatively by means of tomography.

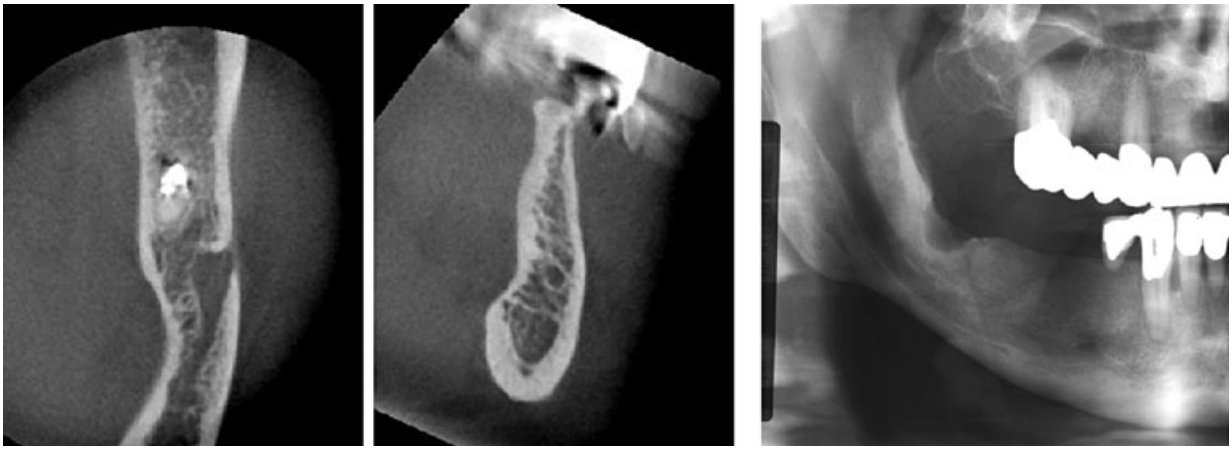

Fig. 28-27 An anterior continuation of the mandibular canal from the mental foramen as seen in tomographic images (same patient as in Fig. 28-26) and as it may appear in a panoramic view (different patient).

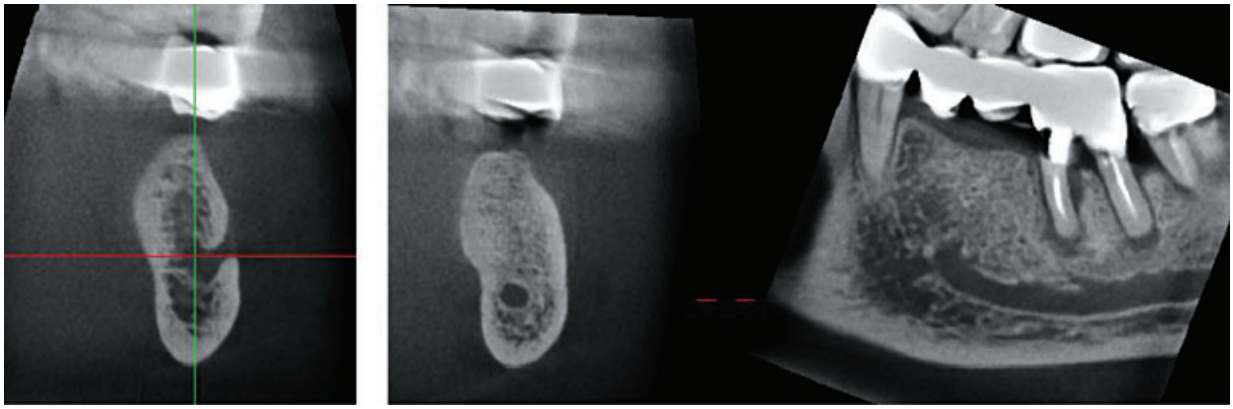

Fig. 28-28 Large local differences in bone density and architecture. The much denser bone in the most distal tomographic layer most probably is due to the inflammatory conditions at the adjacent molar.

evaluation is performed to determine its position relative to potential implant positions.

This is not the place to discuss factors related to general health that may have an influence on bone structure and architecture. In can be noted however, that in tomographic images, given that their resolution is sufficiently high, the cancellous bone pattern in intended implant sites can be studied and the thickness of the cortical bone evaluated. Local factors can contribute to local variations in bone density. In Fig. 28-28 large differences in bone density can be seen in tomographic images less than 1 cm apart. The higher density in the more distal region is most likely a reaction to the inflammatory conditions seen at an adjacent tooth.

Radiographic monitoring of implant treatment

Meticulous planning of the implant treatment together with gentle surgical technique for the insertion of the implants make immediate post-operative radiographic examination superfluous unless something unexpected occurs during surgery. Under normal conditions, however, there is simply nothing, apart from the expected, to be found. Should the patient experience symptoms before the first post-operative radiographic examination is scheduled, one should of course not hesitate in taking radiographs if information from them is considered essential for a proper diagnosis.

The radiographs in Fig. 28-29 are from a patient who presented with severe pain very soon after implants were inserted. The images show unevenly demarcated radiolucent areas around the implants, especially the most distally and the most mesially placed. This is a strong indication of bone infection. In addition, the most mesially placed implant appears to have its tip in close proximity to the anterior loop of the mandibular canal. This is confirmed by a tomographic examination. The affected implants were removed and the symptoms soon subsided.

When implants are inserted in dense bone heat necrosis can occur around the "apical" part of the implants, particularly when the implants are long and effective cooling during their insertion has not been applied. Usually this is accompanied by pain. In the radiograph one can see a radiolucent area surrounding the apical part of the implant. A radiolucent area just beneath the apical part and caused by

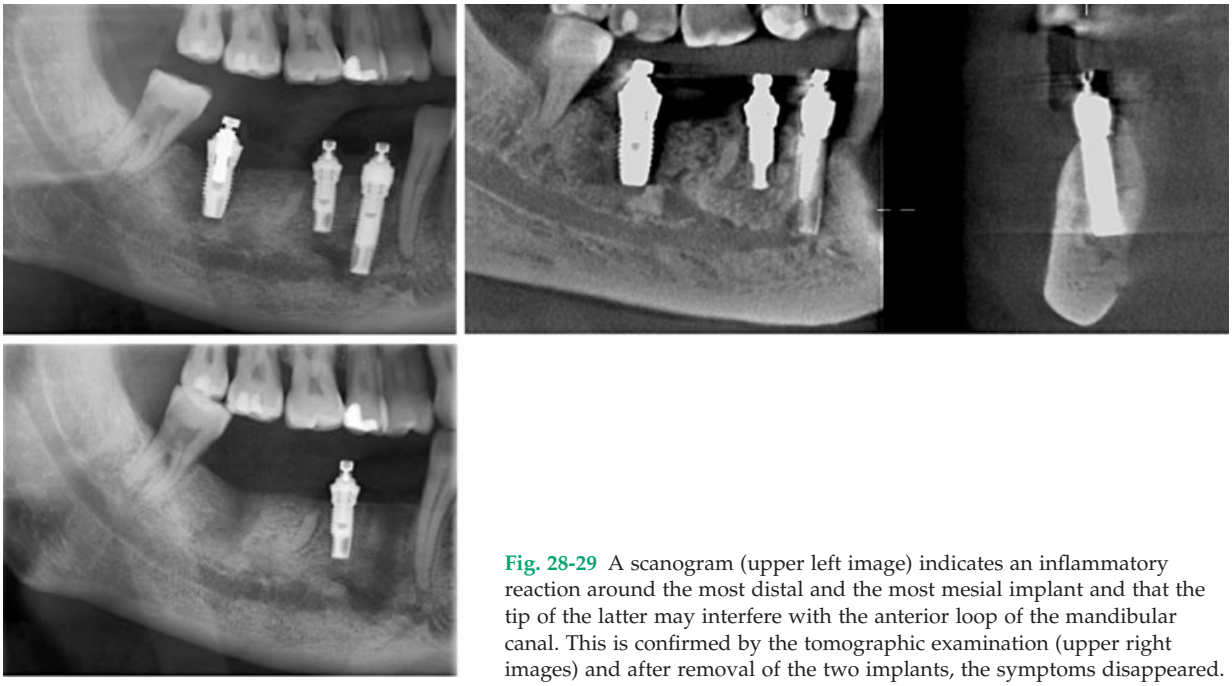

Fig. 28-29 A scanogram (upper left image) indicates an inflammatory reaction around the most distal and the most mesial implant and that the tip of the latter may interfere with the anterior loop of the mandibular canal. This is confirmed by the tomographic examination (upper right images) and after removal of the two implants, the symptoms disappeared.

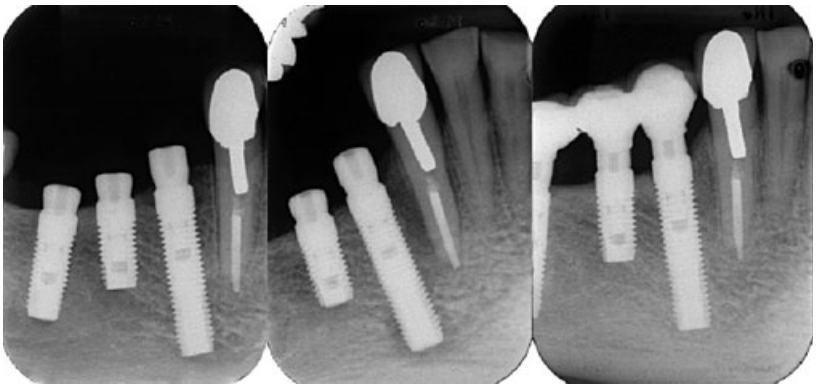

Fig. 28-30 Soon after implant insertion the patient presented with slight pain. A radiograph (left image) was interpreted as showing normal conditions. Two weeks later the pain had increased in intensity and a radiolucency could now be seen around the tip of the most mesial implant (middle image). The right image, taken some months later shows completely normal conditions.

the drill should not be confused with the radiolucency that is a result of heat necrosis. Heat necrosis is most commonly seen in the lower jaw (Fig. 28-30).

Often it is not possible to take radiographs of implants using standard intraoral techniques. One either has to take radiographs more from below or use panoramic radiography or, better yet, so-called scanograms (Fig. 28-31).

Implants that have not been correctly placed in the bone may cause symptoms as well. Should an intraoral examination fail to show the cause of the problem a tomographic examination may be needed (Fig. 28-32). It should preferably be performed with digital volume tomography, as it is less prone to cause artifacts from the implants than computed tomography.

Depending upon the implant system used there may or may not be a need for a radiographic examination when abutments are placed. To examine

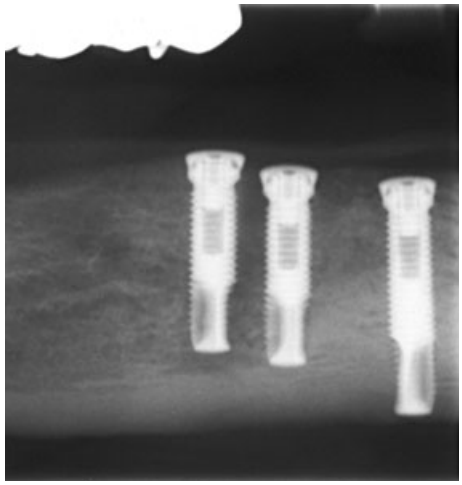

Fig. 28-31 A so-called scanogram by which even deeply seated implants can be displayed in their entirety.

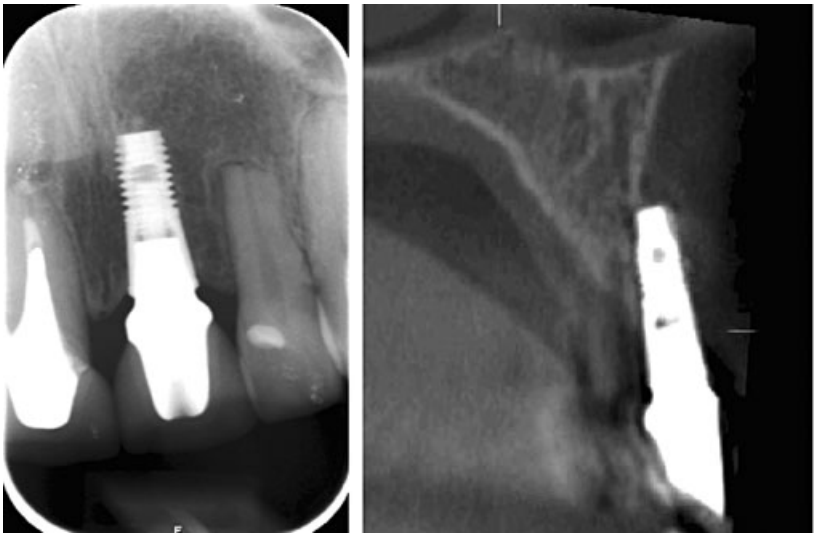

Fig. 28-32 An intraoral radiograph (left) failed to reveal the cause of the problem in a patient with pain in the region of a newly placed implant A DVT image demonstrated that most of the implant was not placed in the bone.

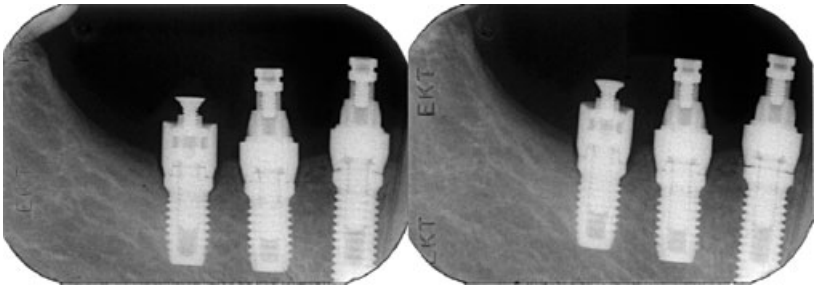

Fig. 28-33 Small gaps between abutment and implant pillar (most mesial implant) may go unnoticed in radiographs taken with less than perfect geometry (left image).

whether abutments are correctly positioned on top of the implant pillar the X-rays need to pass at right angles to the implant. If not, gaps between the abutment and implant pillar may go unnoticed and uncorrected for (Fig. 28-33). The occlusal load will then not be optimally distributed which can later cause component fractures. Marginal bone loss has also been attributed to gaps between the abutment and the implant pillar (Hermann *et al*. 2001; King *et al*. 2002).

Reference radiographs, with which later radiographs can be compared to monitor the interaction between implant and bone, are preferably taken when crowns or bridges are placed. Little can come out of such comparisons if the quality of the radiographs is not high. It must be possible to notice small marginal bone level differences over time as well as the condition of the bone–implant interface. This requires radiographs to be taken with the X-rays being directed perpendicular to the longitudinal axis of the implant and the surface of the detector. When threaded implants are used the radiographic appearance of the threads provides useful information about the irradiation geometry used and how to change it should it not be correct to start with. One must be able to get a clear picture of the inner parts of the threads on either side of the implant (Fig. 28-34).

Intraoral radiography is the method of choice for monitoring of implant treatment. Irradiation geometry and exposure can be individualized for different implants or group of implants. Panoramic radiography cannot provide the same detailed information and should be reserved for the few cases when intraoral radiography cannot be tolerated. A better alternative can be used by those who have access to multimodality units able to provide multiple exposures of selected small areas using slightly different irradiation geometry.

With high-quality intraoral radiography it is possible to follow the course of events in the marginal and peri-implant bone over time. A fairly typical course of events for lower jaw implants, from abutment placement via bridge installation to a 5-year follow-up examination, can be seen in Fig. 28-35. With well trained and motivated personnel it is possible to get high-quality and comparable radiographs over long periods of time even without going to the effort of using particular film-holding devices. The images in Fig. 28-36 are taken over a 5-year period by different radiographers.

High-quality radiographs make it possible to detect, observe, and quantify bone level changes over time. In the majority of patients the bone level remains at the position it had after the post-surgical remodeling over as long periods that it has been hitherto possible to cover in longitudinal studies (Adell *et al*. 1990; Snauwert *et al*. 2000; Ekelund *et al*. 2003). In other patients one can find loss of bone at the marginal bone crest that affects all implants or, more often, one or a few. It is important to detect those so that the cause of the bone loss can be identified (Figs. 28-37 and 28-38).

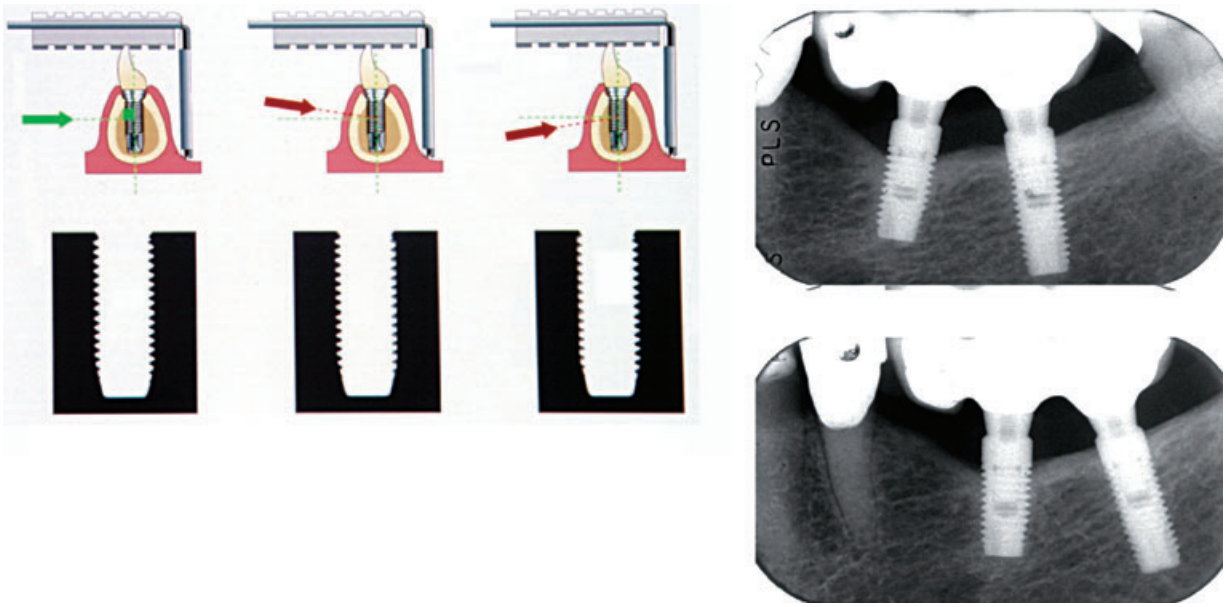

Fig. 28-34 The appearance of the threads of an implant provides useful information about how to change the direction of the X-ray beam so that it can become directed perpendicular to the implant. From Gröndahl *et al*. (1996).

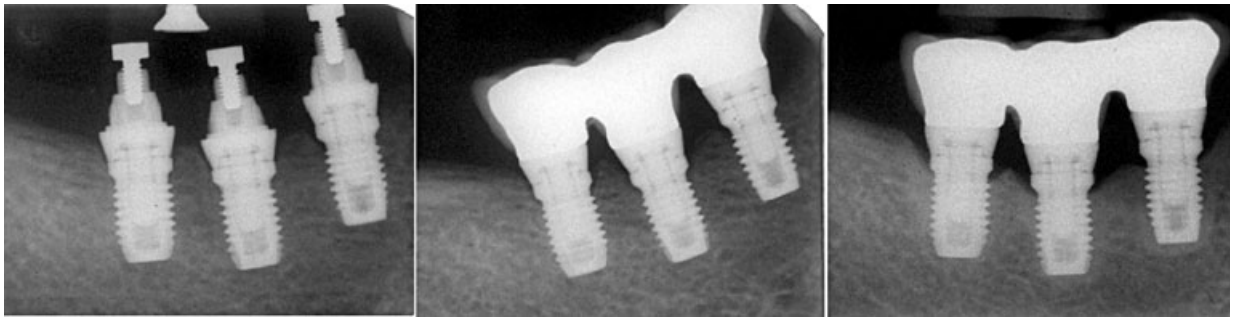

Fig. 28-35 From abutment connection via bridge installation to a 5-year follow-up examination.

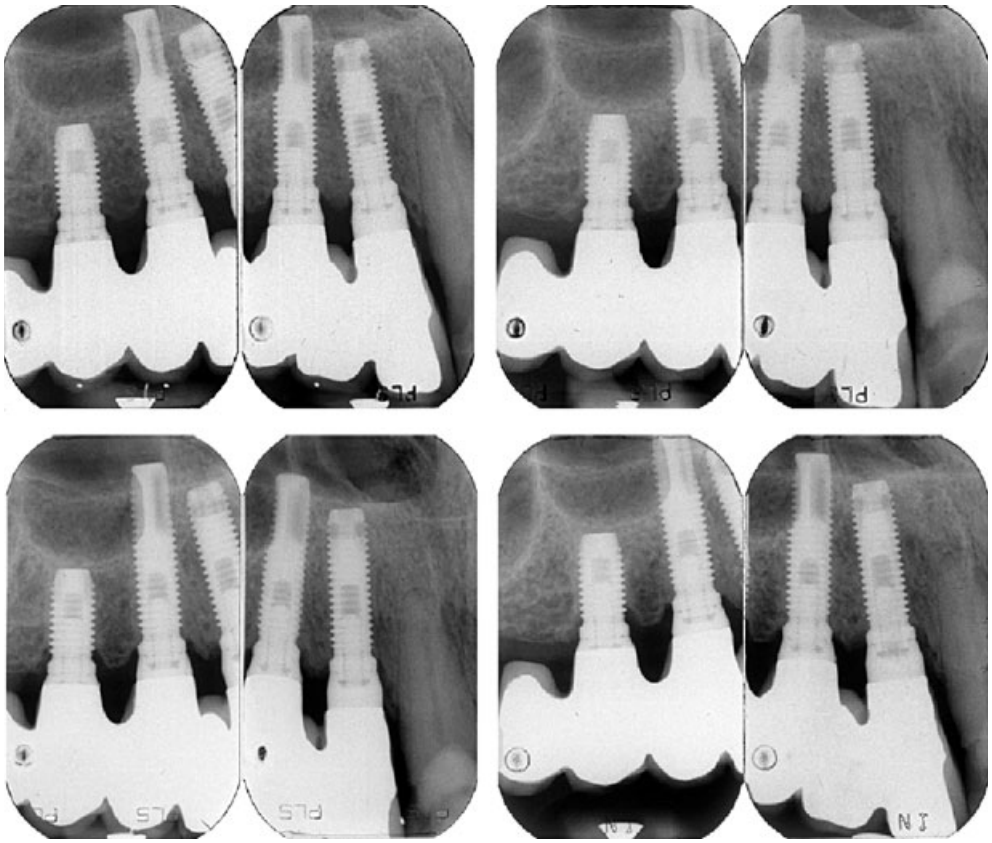

Fig. 28-36 Intraoral radiographs taken with a free-hand technique and by different radiographers at bridge installation (upper left corner) and at follow-up examinations (1, 3, and 5 years later) demonstrate excellent possibilities of monitoring the post-operative course of events.

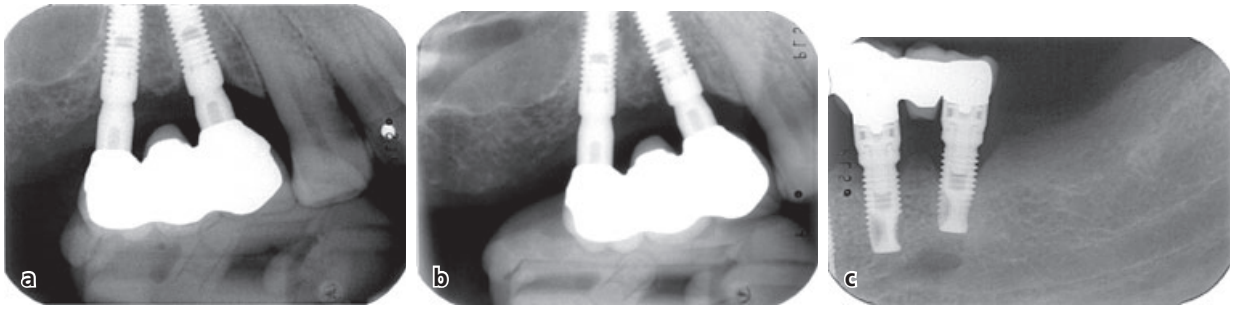

Fig. 28-37 In radiograph (b), the mesial implant has marginal bone loss that was not evident a year before. In radiograph (c), the most distal implant has marginal bone loss involving about a third of the implant length.

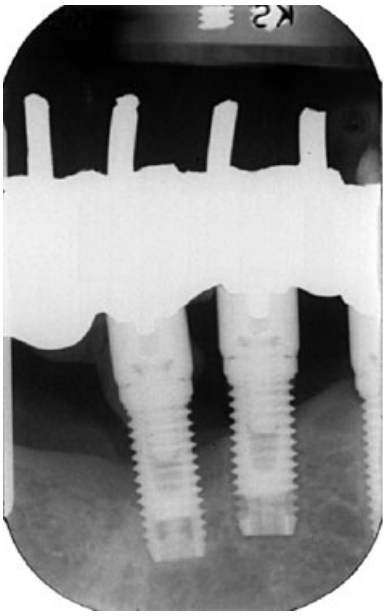

Fig. 28-38 Both implants show marginal bone loss exceeding one third of the implant length. The implant to the right is also surrounded by a thin radiolucent zone. This indicates that the implant is not osseointegrated. At a clinical examination it was found to be mobile and consequently removed.

In high-quality radiographs it is possible to identify implants that are not osseointegrated with an accuracy that is on a par with what one can find when radiography is used for other dental diagnostic purposes (Sundén *et al*. 1995; Gröndahl & Lekholm 1997). Since the first radiographic signs are very subtle, as seen in the radiographs in Fig. 28-39, it is very helpful if one is able to compare radiographs with ones taken previously. Most implants that have not become integrated are found during the first year after bridge installation, or even before that. This stresses the importance that radiographs taken at abutment connection and at bridge installation are of the highest possible quality. Radiographs should be of a quality so that it is possible to evaluate not only the conditions in the surrounding bone and the marginal bone level but also the conditions of all the technical implant components. Such conditions are, for example, fractures of the centre screw or of the implant pillar itself and gaps between abutment and implant pillar, or between bridgework and abutment (Figs. 28-40, 28-41 and 28-42).

Radiation detectors for intraoral radiography

Although a correctly exposed and optimally processed film, in our opinion, provides the best quality images for implant monitoring we have to accept that digital imaging techniques are gaining wider and wider acceptance among dentists. There are some advantages of digital images over film-based ones, in that they can be subjected to image processing algorithms that can enhance their diagnostic quality and adapt them to various diagnostic tasks (Analoui 2001a,b). This can of course be of value when the diagnostic tasks are so varied as they are in implant monitoring when one must be able to evaluate both thin marginal bone and the metal components of the implant construction.

As we have pointed out several times in this chapter the irradiation geometry is essential when implants are to be monitored. The X-rays should come perpendicular to the longitudinal axis of the implant and to the detector plane. Therefore one must have a digital detector that can be placed in the mouth, and relative to the implants, as easily as can film. When the X-ray beam has passed through a jaw in which implants have been inserted, the transmitted radiation consists of a wide spectrum of X-rays of different intensity. Thus, the detector has to be able to respond to a wide range of exposure differences; its exposure latitude must be wide. Image plate systems possess a wider exposure latitude than most solid-state systems (Farman & Farman 2005). With solid-state systems it is therefore easier that thin bone structures become over-exposed and not visible in the radiograph (Fig. 28-43). For this reason, and because image plates are as easy to use as films, we have chosen image plate systems for implant monitoring purposes. Image plates are, however, not without problems. They can easily get scratched if not handled with extreme care.

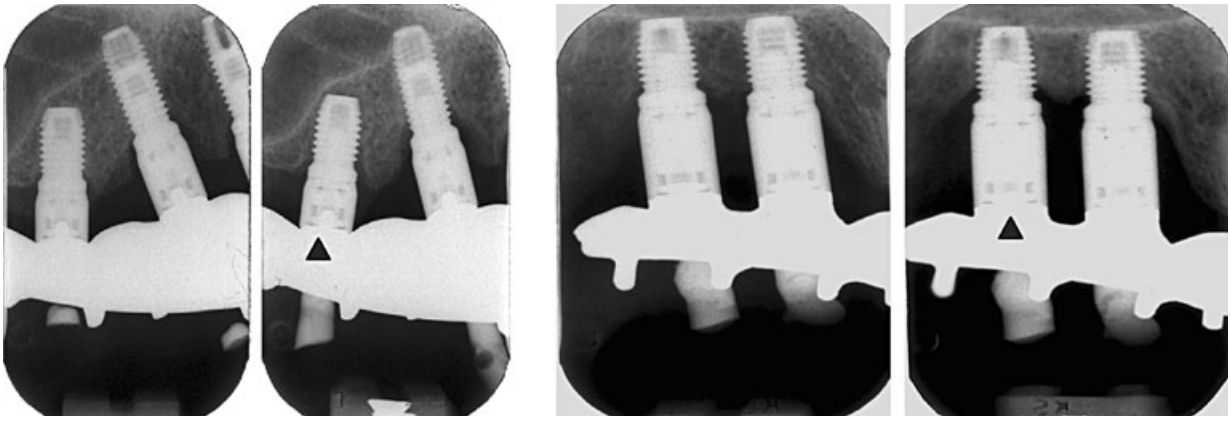

Fig. 28-39 Notice the very subtle sign, a thin radiolucent zone around the implants, indicating that the implants marked by arrows are not osseointegrated. Comparison of the radiographs with those taken earlier, the ones to the left in each image pair, makes the detection of subtle signs much easier.

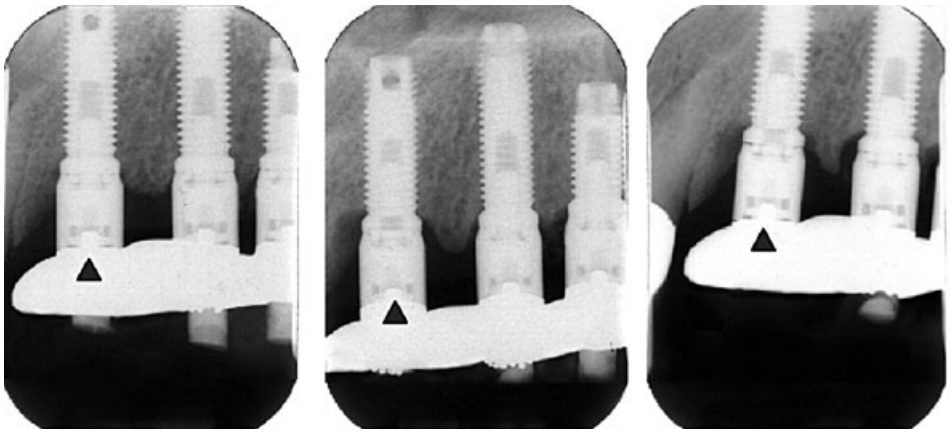

Fig. 28-40 In the implant marked by an arrow normal conditions were found at bridge installation (left image). One year later, a fracture of the centre screw went unnoticed (middle image) resulting in a gap between abutment and implant pillar seen in an image taken another year later. Notice that the irradiation geometry was not optimal at the second occasion.

Fig. 28-41 In this case the conical abutment was not correctly placed (left image). After correction for this, the crown was remade but a later control then found a gap between crown and abutment. Notice the difference in marginal bone height on the distal side.

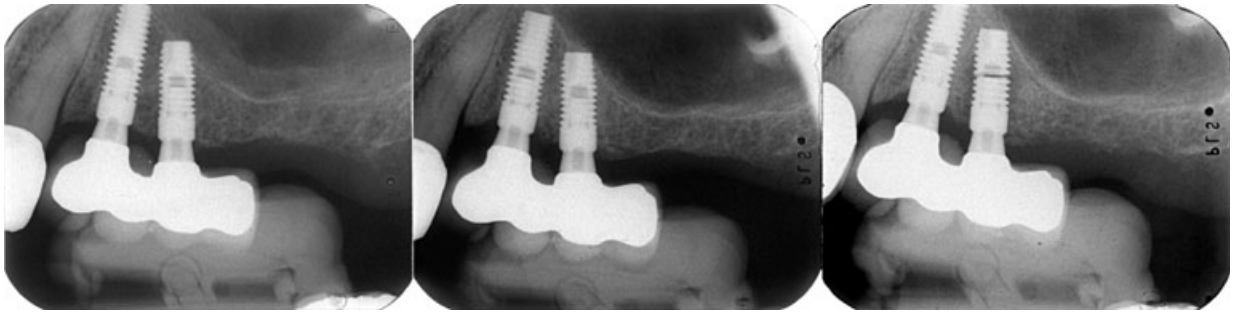

Fig. 28-42 Fracture of the implant pillar seen in radiographs taken 2 years after bridge installation. Neither the image from the latter occasion, nor the one taken at a 1-year control examination show any sign of fracture. Notice the inflammatory reaction along both sides of the implant.

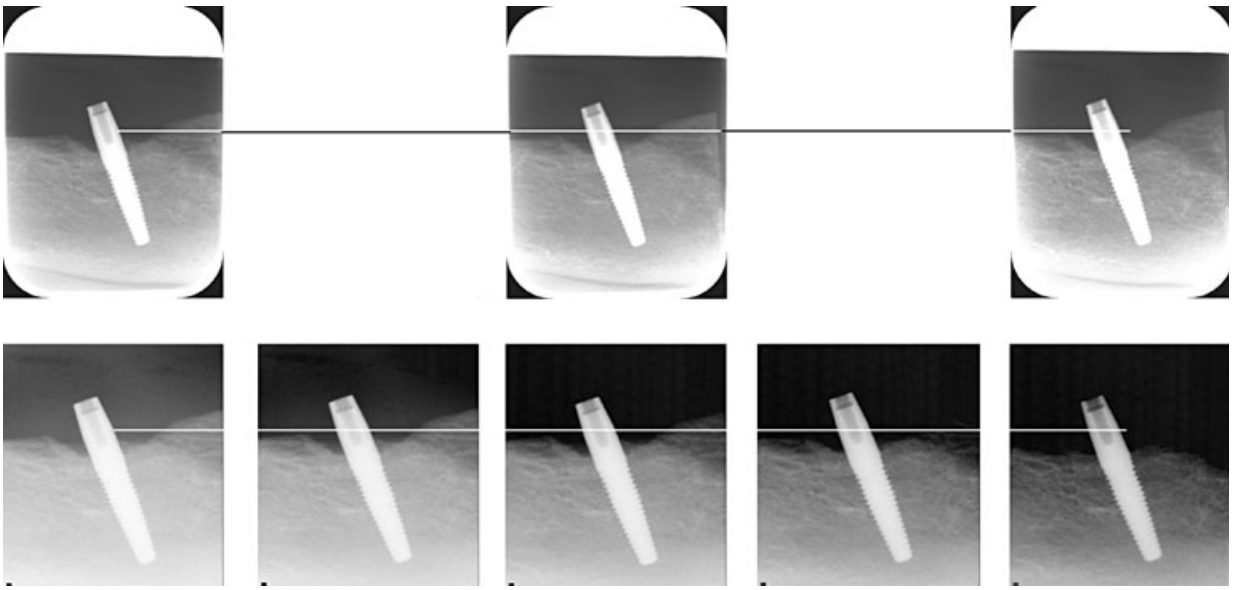

Fig. 28-43 Images taken with an image plate system, exposure times: 0.25 sec, 0.40 sec and 0.63 sec (upper row) and a CMOS system, exposure times: 0.25 sec, 0.32 sec, 0.40 sec, 0.50 sec and 0.63 sec (lower row). In the upper images the marginal bone is seen at the same level. In the lower ones it seems lower with increasing exposure. Compare with the horizontal reference line.

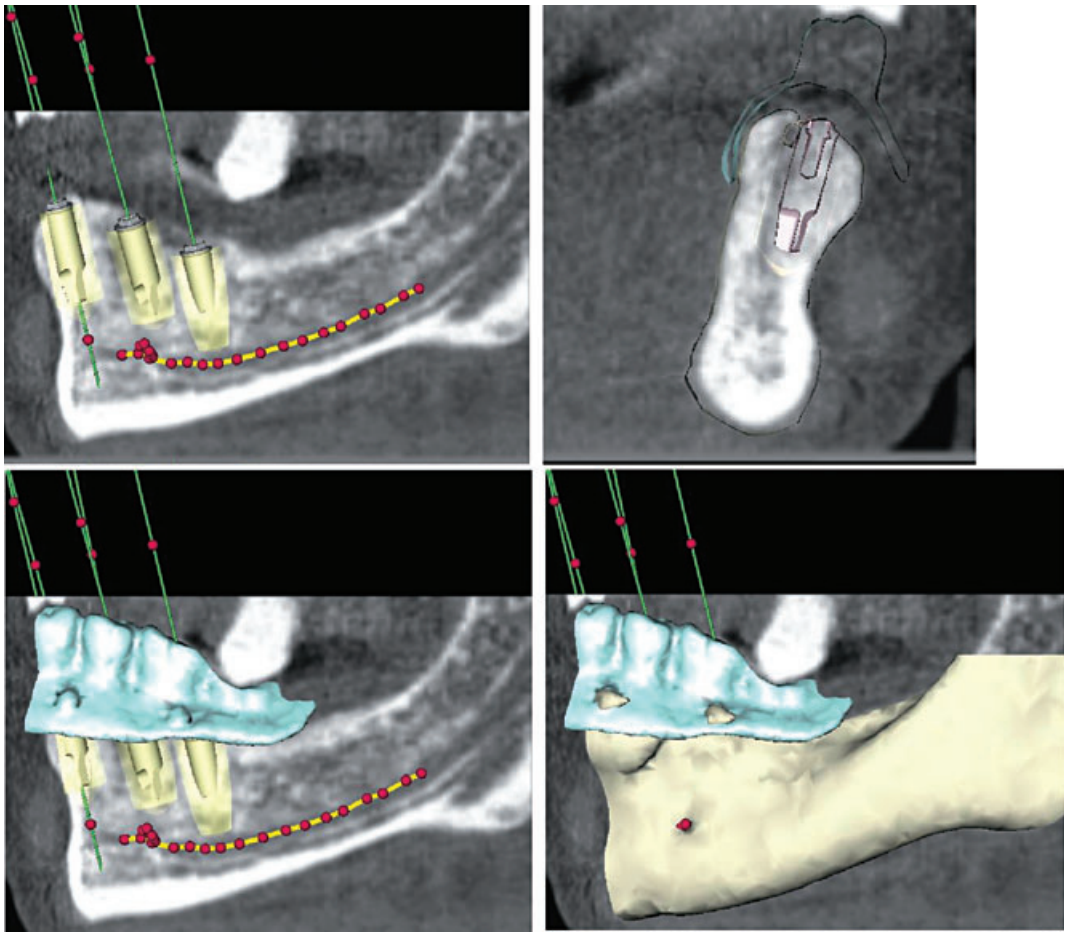

Fig. 28-44 Images describing the use of a system for surgical planning and image-guided surgery. Courtesy of Matts Andersson and Andreas Pettersson, Nobel Biocare, Göteborg, Sweden.

Image-guided surgery

Due to the three-dimensional information offered by computed tomography and digital volume tomography it is possible to use those techniques to play a more direct role in the surgical placement of the implants (BouSerhal 2001; Guerrero 2005). The exact placement and angulation of implants are determined by means of the radiographs. Guiding templates are then constructed and applied during surgery so that the implants will be positioned as intended, so-called image-guided surgery. It is also possible to build up images in which the result of the treatment, with specific implants and the final prosthesis "in place". Development in this area is rapid with implant companies, manufacturers of radiographic equipment, and software companies all working to develop and refine these techniques. For that reason we will do no more than mention the possibility and show just a few images that can shed some light on how these techniques can be used (Fig. 28-44). We strongly recommend that radiographic techniques that limit the radiation dose to the patient as much as possible are used. We also recommend that a careful scrutiny for diagnostic purposes is made of all radiographs before they are used for surgical implant planning and guiding.

Chapter 29

Examination of Patients with Implant-Supported Restorations

Urs Brägger

Identification of the presence of implants and implant systems

Screening

With the growing use of dental implants, the number of patients with implant-supported restorations seeking dental care will soon affect most dentists on a regular basis (Österberg *et al*. 2000; Berge 2000; Zitzmann & Hagmann 2007). Cohorts with fixed or removable implant-supported restorations demonstrated considerable amounts of technical and biological failures and complications over 5- and 10-year observation periods (Berglund *et al*. 2002; Pjetursson *et al*. 2004; Brägger *et al*. 2005; Widbom *et al*. 2005; Fransson *et al*. 2005; Roos-Jansaker *et al*. 2006). In the coming decades, the profession will be challenged to prevent, diagnose, and treat technical and biological problems of implant-supported restorations. Screening of all new patients, identification of the implants, and assessment of the condition of the implants, the restoration, and the surrounding structures are therefore mandatory. Aspects related to general health, smoking, etc, which may affect the quality of implant integration and function, are discussed in Chapters 27 and 30.

Implant pass

Information gathered by means of questionnaires can often be incorrect or incomplete. After a few years, patients may not be aware of how many implants were placed or even where exactly they are located. In addition, patients cannot be expected to remember and list brand names, names of biomaterials or complex interventions.

Several professional associations and manufacturers of implant systems have therefore developed an implant pass for patients (Fig. 29-1). All implant-related information can be filled out on the pass, avoiding the loss of important data. Furthermore, tracking of components back to their origin is possible applying the corresponding lot numbers in the patient chart as well as in an implant pass. Patients with implant-supported restorations would benefit from this document whenever a dental service needs to be provided, including emergency situations, maintenance, repairs or even a new restoration. Just a simple tightening of a screw-retained implant-supported prosthesis might be tedious if the dental team is unable to identify the components and if no corresponding screwdriver is available.

CERTIFICATE FOR DENTAL IMPLANTS

This certificate is issued to patients who have received dental implants.
This certificate gives information about the implant type, implant localisation and suprastructure components.
The patient is advised to show this document at any dental examination or treatment.
This certificate must be updated at any surgical or prosthodontic treatment.

Questionnaire for new patients

The most straightforward way to obtain information on the presence of implants and implant-supported restorations in new patients is to ask questions related to any past implant experiences. The following comprehensive list of questions can be added to currently used questionnaires in educational programs, clinics, and private practices:

- Do you carry an implant pass?
- Did your dentist ever place implants into your jaw bones (name, address of the dentist, surgeon)?
- How many implants were placed?
- When were these implants placed (if remembered)? (How old were you when implants were placed?)
- Where are they located?
- Why were these implants placed or what were the reasons for the loss of teeth?
- Do you wear a prosthesis/crown supported by an implant (name of the dentist, prosthodontist, technician)?
- Did you have enough bone to have the implant placed?
- Were there additional treatments performed before implants could be placed?
- Did the surgeon perform a bone augmentation, sinus lift procedure?
- What was the brand name of the implants (if remembered)?
- Were bone graft particles used (if remembered)?
- What was the brand name of the biomaterials used (if remembered)?
- Have you ever experienced failures/complications with the implants?
- Have you ever experienced failures/complications with the prostheses/crowns?
- How often has this occurred?
- Are you satisfied with the way you can function with the implant-supported prosthesis/crown?
- Are you satisfied with the esthetic situation?
- Did you have to pay for the implants and prosthesis or was there insurance involved?
- How do you clean the neck portion of the implant/abutment?
- How do you clean the prosthesis/crowns?
- Do you use any special aids/disinfectants to carry out the cleaning?
- Does the mucosa/do the gums around your implant bleed?
- Do you notice a bad taste coming from underneath the prosthesis/crown?
- Is your implant mobile?
- Have you recently noticed a change with the implant-supported restorations?

Anamnestic information from patients on maintenance

Before starting to examine the oral conditions at maintenance visits, questions related to implant-supported restorations should include:

- Have you noticed a change with your implant-supported restorations?
- Are your implants stable?
- Do the gums around your implant(s) bleed?
- Are you able to clean the area around the neck portion of the implant(s) easily?
- Do you still have enough cleaning aids/disinfectants to perform daily plaque control?

In addition, general questions related to patient's satisfaction with the implant-supported reconstruction should be part of a quality management concept (Vermylen *et al*. 2003; Pjetursson *et al*. 2005).

The development of implant recognition software

Sahiwal *et al*. (2002a,b,c) collected implants from more than 50 manufacturers and divided them into threaded and non-threaded, as well as tapered and non-tapered categories. Radiographs were then taken at different angulations. Using tables and flow charts, test implants could be correctly identified in radiographs taken within ±10 degrees, according to their identifying features.

A very recent method to assist in identifying unknown implant systems applies an implant recognition software (IRS) (Michelinakis *et al*. 2006). The internet was searched for implant manufacturing companies worldwide in all languages. Relevant information on the implant designs was collected. A program was devised using key design factors for the identification of specific implants. The search revealed 87 implant manufacturers with 231 different designs. A valuable adjunct to the identification of implant systems was thus introduced for both general dental practice use and forensic identification.

Clinical inspection and examination

Characteristics of implant-supported restorations

Following the conventional extraoral and intraoral examination, the distribution of implants in the dental arch is marked in a dental record. A detailed description of the implant-borne restoration, the prosthetic components, and the components of the respective implant system may include material and design aspects.

- Restorations:
  - Crown
  - FDP, number of units
  - Extension prosthesis
  - Telescopic restoration
  - Removable partial denture
  - Bar device
  - Overdenture

- Defect prosthesis
- Other

- Material of:
  - Veneer
  - Framework
  - Denture teeth
- Fixation:
  - Cemented
  - Removable by the patient/dentist
  - Screw retained: transocclusal, transversal, access closed, access free, type of screw head, component of what system
  - Friction
  - Via attachments
  - Connection to teeth: one piece, detachable, attachments
  - Material.

Characteristics of prosthetic components and components of implant systems

- Prosthetic components:
  - Telescopic or conus crowns
  - Bar device
  - Riders
  - Matrices, patrices
  - Mesostructures
  - Individualized components
  - Material
- Components of implant systems:
  - Abutments for cementation
  - Abutments for transocclusal screw retention
  - Abutments for transversal screw retention
  - Angulated abutment
  - Anchors: ball anchor, magnets, locator system
  - Mesostructures
  - Material
  - CAD/CAM components
- Connection of abutments to the implants:
  - Localization of microgaps
  - How many gaps
  - Platform
  - Internal, external
  - Morse taper, butt joint
  - Geometry
  - Abutment screw: access free, closed, type of screwhead, components of what system.

Technical failures/complications

Until the first European Workshop on evidence-based reconstructive dentistry, held in Hünigen, Switzerland, 4–7 November 2006, there was no generally accepted definition for success and survival for reconstructions. Zöllner and Belser (2007) therefore suggested the following definitions:

- Success of abutment-reconstruction complex ("reconstruction"): survival without any biologic and/or technical complication
- Survival of abutment-reconstruction complex ("reconstruction"):
  - On abutment level: abutment is still *in situ*
  - On reconstruction level: reconstruction remaining *in situ* with or without modification
  - Alternatively: reconstruction remaining *in situ* in its original extension with or without modification.

In addition, factors regarded as biological or technical failures were listed but not further defined:

- Biological complications of abutment-reconstruction complex ("reconstruction"):
  - Natural abutment tooth: caries, loss of sensitivity, apical periodontitis, periodontitis
  - Implant: peri-implant diseases, implant mobility, loss of sensitivity of adjacent tooth
- Technical complications of abutment-reconstruction complex ("reconstruction"):
  - Tooth supported reconstruction: loss of retention, fracture of abutment, fracture of framework, fracture of veneering material
  - Implant supported reconstruction: loss of retention/screw loosening/abutment loosening, loss of access hole restoration, fracture of implant, fracture of abutment, screws, fracture of framework, fracture of veneering material.

While describing the above-mentioned detailed characteristics of the implant-supported restorations, any defects and irregular observations are marked.

The suprastructures are inspected for signs of loosening, loss of retention, loss of friction, wear, attrition, fractures of frame work, of denture teeth, of porcelain, of veneers, discolorations, bacterial deposits, precision or misfit at margins, cement rests (Figs. 29-2 and 29-3).

Fig. 29-2 Fractures of porcelain veneer at the distal aspects 35 and 46 as well as a porcelain chip off at 33. The patient was restored with three screw-retained porcelain fused to metal FDPs (I46 × I44/I43xxxxI33/I35I35). Three repairs within 3 years were needed. In the opposing jaw, the patient still had all his natural teeth. At night the patient wears an occlusal protective splint on an irregular basis.

The torque of occlusal screws can be checked where corresponding equipment is available. Obviously, loose screw-retained suprastructures are removed for further inspection, cleaning and retightening. Stable fixed restorations do not need to be disassembled if there were no complications reported by the patient and if the clinical examination did not reveal any technical problems.

Defective screw heads might complicate the removal of the suprastructure since screw drivers might not catch anymore. Occlusal screws that were tightened together with cementation might as well be very difficult to be removed with the regular instruments. In such cases, repair sets are needed to remove defective screws in a controllable standardized manner (Fig. 29-4). Repair sets might also be very helpful in cases with fractured abutment screws that are completely blocked in the implant (Luterbacher *et al*. 2000a) (Fig. 29-5). Abutments are also checked for their torque, the presence of bacterial deposits, corrosion products, cement rests, fractures, and deformations.

If replacement of a component is needed, the corresponding brand name and ordering number should be identified; a task that can be very tedious in the light of numerous implant producers and, in addition, a long list of copycat products (Jokstad *et al*. 2003).

Some manufacturers of implant components offer a complaint system to protect their customers from

Fig. 29-3 Fracture of the denture tooth 13 as well as part of the veneer from a screw-retained extension prosthesis on five implants. In the lower jaw, the patient was restored with a fixed partial denture with bilateral distal extensions. The prosthesis could be removed and repaired.

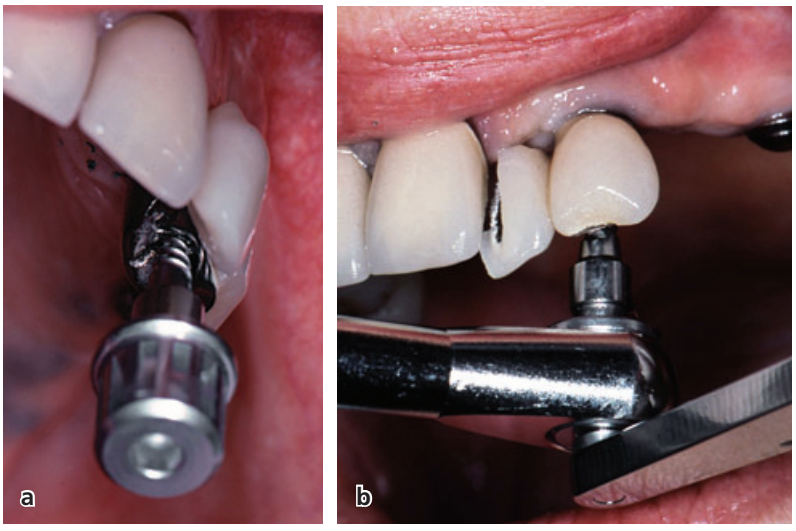

Fig. 29-4 (a) Removal of a screw-retained FDP using a screwdriver was impossible since the head of the occlusal screw was completely worn down due to attrition. The components of the repair set developed for the Straumann Dental Implant System® include an extraction bolt which can be tightened into a hole prepared with drills into the head of the occlusal screw. (b) Applying sufficient torque, the segmented part of the FDP is being removed together with the occlusal screw, the abutment, and the abutment screw. The implant was then used again for the support and fixation of a new extension prosthesis shown in Fig. 29-3.

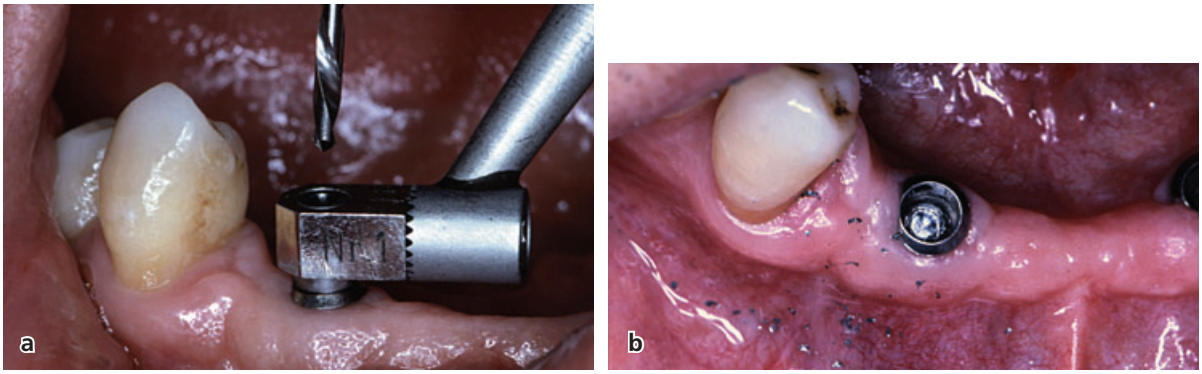

Fig. 29-5 (a) Application of the assembled components of the repair system developed for the Straumann Dental Implant System® for the removal of fractured abutment screws. The conical insert at the end of the handle secures the centered guidance of the drill. (b) After counter-clockwise drilling with ample cooling, the fractured portion of the abutment screw is removed. The threads are then recut by hand instruments with conical and cylindrical configurations.

Fig. 29-6 (a,b) Screw-retained defect prosthesis on three implants in a fibula graft after excision of a malignant tumor. Function and phonetics are acceptable considering the severity of the defect. (c,d) After 5 years, some of the grafted bone has been resorbed. The soft tissues receded, leaving a large space underneath the pontics. Articulation and phonetics became more and more difficult. In addition, loss of saliva during speaking became intolerable. The FDP was removed and reshaped to fill out the missing soft tissues.

undue costs arising because of a potential error in production. Forms are completed with all the relevant information related to the loss of implants or a damaged component of the respective implant system. The defective components are sent in and exposed to a metallurgic evaluation and other tests. If the components were applied for the correct indications and a possible production error has been confirmed, the manufacturer will replace components and may even help to finance part of a new restoration as decided case by case.

If the abutment was individualized, it may also be impossible to just replace the component and use the existing suprastructure. In such cases, a new impression at the implant level will be needed to replace the abutment; a remake of the entire restoration may be necessary.

Function

Functional analysis

A functional analysis of the dentition with fixed and/or removable dental prostheses on implants needs to be carried out according to standard protocols in prosthodontics and includes parameters assessing articulation, occlusion, phonetics, denture stability, etc.

Articulation, phonetics

Disturbed articulation after placement of implant supported restorations may be very difficult to assess without the use of objective parameters (Fig 29-6). Heydecke *et al*. (2004) recorded test words articulated by 30 patients having adjusted to different implant-supported maxillary restorations for 2 months. Lay judges were asked to rate the quality of the articulation. This within-subjects crossover trial demonstrated that overdentures with or without palate enabled patients to produce better speech quality than with fixed prostheses on the implants.

Implant

Cases with removable implant-borne restorations allow direct access for clinical inspection and examination of the implant components and the peri-implant soft tissue conditions. Cemented or screw-retained crowns or fixed dental prostheses may complicate the access for visual inspection and probing.

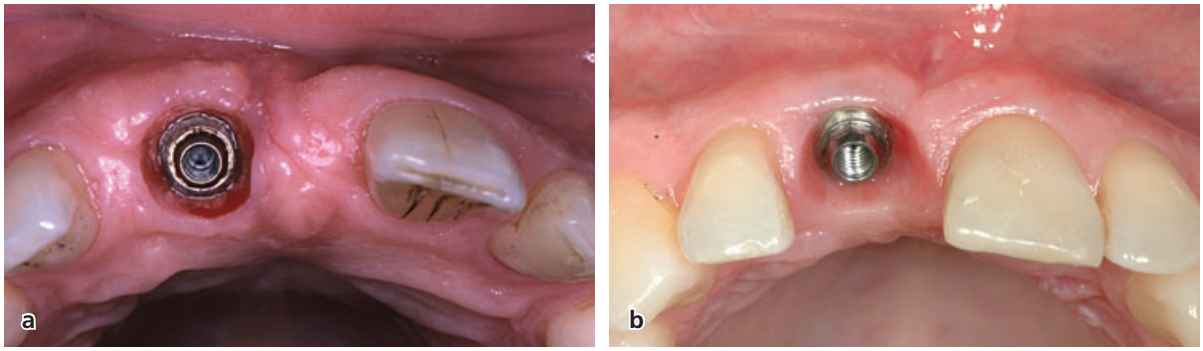

Fig. 29-7 (a) After removal of a screw-retained crown on an octa abutment, the amount of submucosal biofilm was impressive (3 years after placement of the crown). The epithetical lining of the emergence profile was ulcerated which led to bleeding after removal of the crown. (b) In a similar case, there were no obvious bacterial deposits detectable. The peri-implant soft tissues appeared epithelialized with few signs of inflammation.

Clinical test of mobility

Presence or absence of mobility is checked manually/digitally or with the help of instruments trying to move the implants. A perceived mobility of the restoration *per se* does not necessarily mean that the implant is loose. The connection suprastructure/abutment and/or abutment/implant might be loose leading to the mobility. Implant mobility can only be confirmed after disassembling all the components.

In the case of a multi-unit fixed restoration, the absence of mobility does not necessarily mean that the implants are all well integrated. Actual mobility might be obscured by the splinting effect.

Electronic tools to assess the quality of osseointegration

Resonance frequency analyses and Periotest® readings were part of numerous study protocols to quantitate the stability of implants. Changes in the readings were interpreted to reflect biological processes such as bone apposition, bone remodeling, bone maturation or, in a negative sense, deterioriation of the firmness of the bone to implant connection. Recent evidence from the literature was condensed to the following consensus statements (Hobkirk & Wiskott 2006): stability may be confirmed by performing repeated Periotest® measurements of the same implant over time. Increases of these measurements, however, became evident, when the implants are clinically obviously loose. Implants with high implant stability quotient (ISQ) values during maintenance appear to stay firmly integrated, while decreasing ISQ values may be indicative of developing instability. For both biomechanical testing methods, however, the lack of normative values and the wide range of reported values for stable implants and potentially failing implants would not justify their routine clinical use.

Bacterial deposits

The amount and distribution of visual bacterial deposits are evaluated at the emerging portion of the implant-borne restorations (implant neck, abutment, mesostructures, patrices) (Fig. 29-7). A *yes* or *no* for presence of bacterial deposits may be noted or marked in a scheme. In clinical studies, a gradual index such as the mPl (by Mombelli *et al*. 1987) has often been used.

Soft tissues

Mucosa

The inspection of the soft tissues will include the detection and description of visual signs of infection and/or other pathologic conditions, such as swelling, edema, redness, irregular keratinization, tattoos, pigmentation, hyperplasia, ulceration, soft tissue dehiscencies, or fistula. All soft tissues of the oral cavity, not only the peri-implant tissues, need to be examined (Fig. 29-8).

Palpation/sensitivity

Palpation at the buccal aspects of the implants may assist in the detection of loose implants (osseo-disintegration). Palpation furthermore reveals pus, swelling and pain, and the exudation of grafting particles. During palpation and sensitivity testing any morbidity due to, for example, grafting procedures (Clavero & Lundgren 2003) or side effects of implant placement, e.g. close to the mandibular nerve, may be detected.

Recession, pocket probing depth, probing attachment level, bleeding on probing

Measuring the localization of the margin of the mucosa in relation to a fixed reference point such as the connection suprastructure/abutment, abutment/

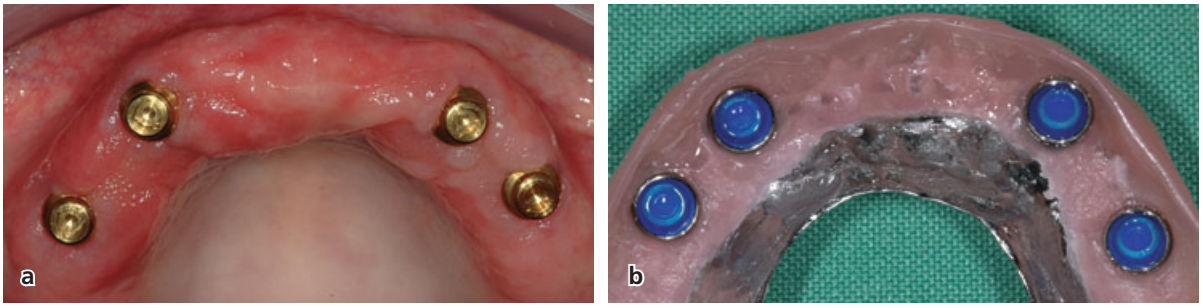

Fig. 29-8 (a) This 55-year-old female patient is wearing a palate free overdenture. Signs of denture stomatitis are an alarming signal to reinforce plaque control using chlorhexidine gel and rinses. (b) The base of the overdenture as well as the locator® matrices appear to be kept clean.

implant, suprastructure/implant, suprastructure/mesostructure as well as the pocket probing depth (PPD) reflects the anatomic situation after implant placement and reconstructive rehabilitation. Clinical parameters assessed by means of probing were first described around the neck of a one-piece transmucosal implant and included the distance between the implant shoulder and the mucosal margin (DIM), and the pocket probing depth (PPD). By adding PPD and DIM, the probing attachment level was calculated (PAL) (Buser *et al*. 1990).

Applying similar force, the insertion depth of a periodontal probe is usually deeper at implants compared to contralateral natural teeth. In addition, it seems to be easier to provoke bleeding after probing at implants compared to teeth (Brägger *et al*. 1997; Karoussis *et al*. 2004). Repeated probing using similar direction, localization, force, and the same references reveals stable conditions or increasing probing depths and/or increasing recession as signs of continuous loss of tissue or osseointegration.

With increasing PPD, the accuracy of repeated probing will decrease (Christensen *et al*. 1997). Precise readings of tissue destruction in deeper lesions are hindered by blocked access for probing and the lack of a continuous smooth surface to guide the probe tip apically. This occurs mostly at screw threads no longer covered by bone or horizontal steps between implants and abutments (Mombelli *et al*. 1997).

Similarly to periodontal disease, the absence of bleeding on probing (BoP) may reflect a stable condition, while repeated BoP may be indicative of a higher chance to develop tissue disintegration. Clinical and microbiological tests for monitoring tissue conditions during supportive periodontal therapy were performed in 19 patients, and the results indicated statistically significant better diagnostic characteristics of both tests at implants compared to teeth. The inclusion of an additional microbiologic test significantly enhanced the diagnostic characteristics of BoP alone at teeth as well as at implants (Luterbacher *et al*. 2000b).

Increased PPD combined with BoP and/or pus secretion may indicate various stages of mucositis or peri-implantitis.

According to one of the proposed concepts for the prevention and treatment of mucositis and peri-implantitis (cumulative interceptive supportive therapy), a cascade of anti-infective and corrective treatment modalities is applied depending on the severity of the findings (Lang *et al*. 2000). The treatment decisions are based on the clinical findings described above. In case of a suspected peri-implantitis, radiographic evaluation may be required to visualize bone levels or changes in bone levels in relation to reference points. If antibiotics are considered, information on the microbiologic composition of plaque samples as well as resistance testing will assist in decision making.

Esthetics

Papillae, interdental space and type of mucosa

A comprehensive assessment and documentation of the soft tissue condition may be of importance, especially for fixed restorations in esthetically critical areas (Fig. 29-9). The appearance of papillae and interdental spaces can be evaluated objectively using various indices, possibly including metric measurement (Jemt 1997). When linear measurements and stable reference points were used, valuable parameters for the long-term observation of changes in the papilla characteristics could be obtained (Jemt & Lekholm 2005). This also required that no changes to the crown contour were made (Klinge & Meyle 2006).

Some factors, such as the thickness of the peri-implant soft tissues, the amount of the available keratinized mucosa, the space between implants or between teeth and implants, and the underlying bone levels, may influence the esthetic appearance of the papilla/interdental space complex (Tarnow *et al*. 2000; Choquet *et al*. 2001; Gastaldo *et al*. 2004; Lee *et al*. 2005). In some cohorts reformation of papillae was also described (Jemt 1997; Chang *et al*. 1999). Metallic markers can be used to indicate the tip of the papilla in a radiograph in order to assess the distance between the underlying bone level and a papilla (Tarnow *et al*.

Fig. 29-9 A porcelain fused to metal crown was cemented on an implant of the Straumann Dental Implant System®. The clinical slides document the situation after cementation and after 1, 5, and 10 years. After 1 year, soft tissue seems to cover the implant shoulder and fill the interdental space: a result that was completely maintained over 5 and 10 years.

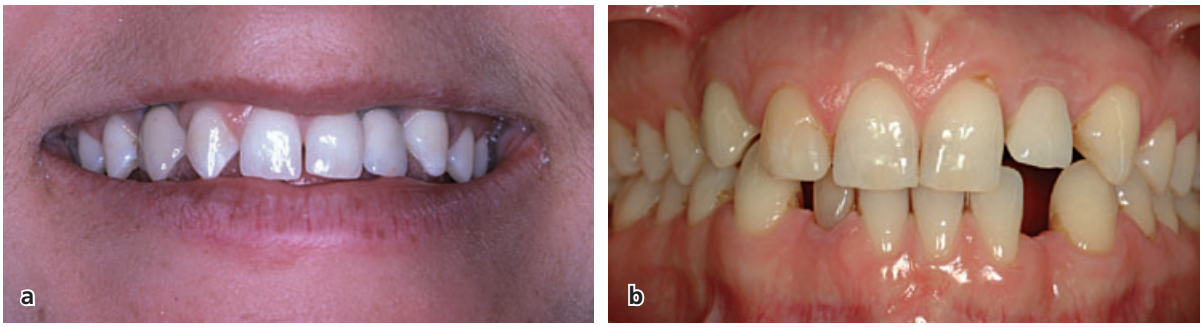

Fig. 29-10 Fifteen years ago, implants were sometimes not correctly placed to fulfill today's esthetic expectations. As a disappointing result, implant margins as well as the implant body were shining through the thin mucosa of this 20-year-old female patient. Due to the continuous eruption of the neighboring teeth, soft tissues now cover the dark implants. The crowns on I13 and I22, however, are no longer in occlusion.

1992). Assessment of the width of the keratinized mucosa can be facilitated by staining the lining non-keratinized mucosa with Schiller's (IKI) solution (Fasske & Morgenroth 1958; Brägger *et al*. 1997).

Condition of adjacent teeth

Implants placed too closely to adjacent teeth might lead to unfavorable periodontal conditions. In some studies, alveolar bone loss was observed if distances were chosen below a minimum distance (Krennmair *et al*. 2003). Adjacent teeth might have been damaged while preparing the implant bed. Delayed loss of sensitivity (vitality) may lead to endodontic interventions.

Long-term vertical changes of anterior maxillary teeth adjacent to implants in 14 young and 14 mature adults were measured in radiographs. In both groups, the tooth eruption process resulted in considerable changes ranging between 0.1 mm and 1.65 mm and 0.12 mm to 1.86 mm (Bernard *et al*. 2004) after an average observation period of about 4 years.

The lack of an implant eruption may result in the formation of steps related to adjacent teeth, incisal edges, etc. Occlusal contacts may still be present, however, due to the different eruption in the opposing jaw; step formation can also be observed (Zachrisson 2006) (Fig. 29-10).

Fig. 29-11 In this 25-year-old female patient, a full ceramic crown and mesostructure were placed on an implant of the Straumann Dental Implant System®. After only 3 years, a step appeared in relation to the adjacent incisal edges. In addition, the color shade of the full ceramic crown appears to be too dark due to the fact that the patient had been bleaching her teeth.

Color shades

For a complete documentation of implant-supported restoration, a set of intraoral images of the area of interest may be desirable. In addition, an assessment of color shades based on visual or digital/electronic measurements are helpful. Of special concern are changes in color shade due to aging or bleaching of the adjacent natural teeth leading to noticeable unpleasant shade differences (Fig. 29-11).

Receding margins of the peri-implant mucosa result in visible implant components, potentially interfering with esthetics in visible zones. Even white ceramic components may result in an esthetically unfavorable situation if color matching over a wider range is not possible (Zachrisson 2006). Coverage of recessions or enlargement of the thickness of the mucosa can technically be achieved by means of free mucosa transplants. The predictability and the long-term success of such interventions remains to be assessed.

Chapter 30

Risk Assessment of the Implant Patient

Gary C. Armitage and Tord Lundgren

In the past few decades the widespread availability and successful use of dental implants have greatly expanded the treatment options for replacement of missing teeth. Data from numerous follow-up studies of the retention rates of implants indicate that well over 90% of the fixtures are functional for 5–10 years after insertion (Lindh *et al*. 1998; Berglundh *et al*. 2002; Weng *et al*. 2003; Fugazzotto *et al*. 2004; Pjetursson *et al*. 2004; Romeo *et al*. 2004). It is clear, however, that some implants fail. In addition, the risk for implant failures and complications is not evenly distributed among all people in a given population since implant problems tend to cluster in certain subsets of patients (Weyant & Burt 1993). There are many possible reasons for failure but it is generally acknowledged that biological, mechanical, or behavioral causes can be important. In general, any factor that increases the risk of developing periodontitis also increases the risk of implant failure. Therefore, in clinical practice it is essential that practitioners understand the possible reasons for implant failures so these threats to implant survival can be minimized. Risk assessment for endosseous implants is an evolving field and it is essential that clinicians have a working knowledge of the current literature dealing with risk factors for the development of implant complications and failure. Without this knowledge an intelligent assessment of risk cannot be conducted.

Principles of risk assessment

Risk assessment is the deliberate and thoughtful evaluation of all circumstances that can affect the outcome of a therapeutic intervention. In the case of dental implants the assessment is intended to identify variables that increase the risk of complications leading to implant loss. In many cases, early identification of these variables makes it possible to avoid or eliminate them. At the very least, knowledge of the risk-altering variables allows the clinician to discuss with the patient circumstances that might affect implant survival. Risk assessment should be performed: (1) before placement of implants (designed to avoid high failure rates by identifying suitable candidates for implant treatment), (2) during the phase of implant placement and osseointegration (designed to identify and avoid technical issues that can affect implant survival), (3) during the phase of implant maintenance (designed to minimize failure by heading off problems), and (4) after an implant has failed and been removed. This "post-mortem" analysis tries to identify the causes of failure and incorporates the experience into future risk-assessment analyses of other patients.

In the literature the therapeutic outcomes of implant placement are usually described in terms of the fixture's survival, success, or its failure. A detailed

Table 30-1 Criteria for implant success, as suggested by Albrektsson *et al*. (1986)

1. That an individual, unattached implant is immobile when tested clinically
2. That a radiograph does not demonstrate any evidence of peri-implant radiolucency
3. That vertical bone loss be less than 0.2 mm annually following the implant's first year of service
4. That individual implant performance be characterized by an absence of persistent and/or irreversible signs and symptoms such as pain, infections, neuropathies, paresthesia, or violation of the mandibular canal
5. That, in the context of the above, a successful rate of 85% at the end of a 5-year observation period and 80% at the end of a 10-year period be a minimum criterion for success

discussion of these terms has been reviewed by others and will not be repeated here (Mombelli 1994; Esposito *et al*. 1998a). Criteria for these outcomes have not been consistently used in the literature. Success is often difficult to define since it implies that a large number of criteria have been met, such as stability, functionality, little or no change in bone support, radiographic evidence of osseointegration, absence of infection, lack of paresthesia, comfort, acceptable esthetics, and overall patient satisfaction. However, the criteria for "success" as presented by Albrektsson *et al*. (1986) over 20 years ago are still useful (Table 30-1).

Many authors simply use the outcome of implant "survival" which implies that at least some criteria for overall success have been met. An implant can, of course, survive and meet all of the criteria for success except those dealing with patient satisfaction. If the patient regards the implant as a failure, it is a failure since a major criterion for success has not been met (i.e. patient satisfaction). Since implant failure is often the end result of a gradual accumulation of unwanted events, most studies use surrogates for failure such as the development of implant mobility, abscess formation, and loss of function. Therefore in many papers, failure is defined as the appearance of failure-associated complications such as the development of peri-implantitis.

There are very few *absolute* or unequivocal contraindications to the placement of dental implants. Depending on a number of patient-centered circumstances, dental implants can be considered even in individuals who are at an elevated risk for implant failure. Like most situations in clinical practice, the potential benefits of an intervention need to be weighed against the morbidity of potential adverse outcomes.

A *risk factor* is an environmental, behavioral, or biological factor that, if present directly increases the probability of a disease (or adverse event) occurring and, if absent or removed, reduces that probability. Risk factors are part of the causal chain, or expose the host to the causal chain (Genco *et al*. 1996). In the case of risk assessment for implant failure, risk factors can be broadly categorized as local, systemic, or behavioral factors (Table 30-2). In general, risk factors for implant failure make outcomes of implant treatment less predictable. A *risk indicator* is a probable risk

Table 30-2 Potential risk factors for peri-implantitis and implant failure that should be considered in the risk-assessment process

Local risk factors

Presence of ongoing (or incompletely treated) oral infections
- Periodontal infections
- Oral hygiene
- Probing depths around remaining teeth (deep pockets are habitats or reservoirs of microorganisms that can lead to implant failure)
- Endodontic infections

Parafunctional habits (e.g. bruxism, clenching, grinding)

Dentoalveolar conditions
- Ridge anatomy (e.g. width, height)
- Bone quality
- Existing prosthetic restorations in region

Maxillary sinus location

Systemic risk factors

Age

Smoking

Medication history
- Bisphosphonate therapy
- Phenytoin, calcium-channel antagonists
- Cancer chemotherapy
- Anticoagulants
- Immunosuppressive agents (e.g. corticosteroids)

Immunosuppression
- HIV infection/AIDS

History of radiation therapy to the jaws

Diabetes mellitus

Bone disorders
- Osteoporosis

Connective tissue and autoimmune disorders
- Scleroderma
- Lupus erythematosus

Xerostomia
- Sjögren syndrome

Hematological and lymphoreticular disorders
- Neutrophil defects or insufficiency
- Aplastic anemia

Genetic traits and disorders
- Polymorphisms (e.g. proinflammatory genotype)
- Down syndrome
- Papillon-Lefèvre syndrome
- Crohn's disease
- Ectodermal dysplasia
- Vitamin D-resistant rickets

Behavioral risk factors

History of poor compliance

Substance use/abuse

Psychiatric/psychological issues

Lack of understanding or communication

factor that has not been confirmed by carefully conducted longitudinal studies. A *risk predictor* is a characteristic that is associated with an elevated risk for a disease (or adverse event), but may not be part of the causal chain (Genco *et al*. 1996). In the case of dental implants, a good risk predictor might be a documented history of the failure of previously inserted implants. In the risk assessment process for multifactorial conditions, such as implant failure, it is important to remember that the presence of several risk factors is required to result in implant loss. One or two risk factors are rarely sufficient to cause implant failure.

Clinical information required for risk assessment

The process of risk assessment begins with taking thorough medical/dental histories and conducting a complete examination of the prospective candidate for dental implants. Details of these procedures are discussed in Chapters 27–29 and will not be repeated here. However, items that are required for risk assessment include anything that helps identify individuals who might be at an increased risk of implant complications and failure.

A comprehensive evaluation of the patient should contain a review of past dental history including earlier periodontal treatment, reasons for tooth loss, how extraction sockets were treated at the time of extraction, history of increased susceptibility to infection, and awareness of parafunctional habits such as clenching and grinding. It should also include an evaluation of the patient's socioeconomic status and willingness to adjust to an often long treatment process. Dissatisfaction with earlier dental treatment may indicate an increased risk for complications during implant therapy.

The comprehensive medical history should include past and present medications and any substance use or abuse. A standard medical history form filled out and signed by the patient is an efficient way to collect basic information. This should always be followed by a verbal interview to explore in more depth any potential medical risks of implant therapy. If any uncertainties remain regarding the patient's health after the interview, a written medical consultation should be obtained from the patient's physician.

Components of a complete examination

A complete intraoral examination should be performed to determine the feasibility of placing implants in desired locations. This examination includes oral hygiene status, periodontal status, jaw relationships, occlusion, signs of bruxism, temporomandibular joint conditions, endodontic lesions, status of existing restorations, presence of non-restored caries, crown–root ratio, interocclusal space, available space for implants, ridge morphology, soft and hard tissue conditions, phonetics, and prosthetic restorability.

An appropriate radiographic evaluation of the quality and quantity of available bone is required in order to determine the optimal site(s) for implant placement. Assessments from periapical radiographs, panoramic projections, and tomographic cross-sectional imaging can individually or in combination be helpful diagnostic tools. It is important to understand that accurate estimations of bone height and width cannot be made without a comprehensive clinical examination followed by cross-sectional tomographic images. A comprehensive radiographic evaluation minimizes the risk of injuring vital anatomic structures during the surgical procedure and is also helpful in determining which cases require bone augmentation surgery before implants can be placed. A custom-made stent with radiopaque markers worn by the patient during the radiographic imaging can help locate the proper position for implant placement and also help in evaluation of the relationship between the planned implant location and available bone.

An evaluation of the quality and quantity of peri-implant soft tissues at the proposed implant site will help determine how closely this tissue will mimic the appearance of gingival tissue once the implant has been inserted. The presence of keratinized mucosa around a dental implant is an important part of an esthetically successful dental implant. It is important to evaluate the patient's perception of esthetics prior to implant placement. This is especially true in situations with compromised hard and soft tissues where esthetics can be a real challenge. Diagnostic casts and intraoral photographs can be helpful in evaluating potential esthetic outcomes as well as in the overall treatment-planning process. In general, to minimize the risk of implant complications and failure, any diseases of the soft or hard oral tissues should be treated before implant therapy.

Technical procedures to help minimize risk

Minimizing post-surgical infection

Post-operative infections increase the risk of early implant failure. It is important to perform implant surgeries with a strict hygiene protocol to minimize bacterial contamination of the surgical site. Although the incidence of post-operative infection associated with implant placement is only about 1% (Powell *et al*. 2005), some clinicians attempt to reduce this risk by prescribing pre-operative systemic antibiotics (Dent *et al*. 1997; Laskin *et al*. 2000). However, the value of pre-operative antimicrobial treatment has not been established in randomized placebo-controlled clinical trials (Lawler *et al*. 2005). In addition, the results of several case–control studies indicate that there is no advantage in using antibiotics in conjunction with implant placement (Gynther *et al*. 1998; Morris *et al*. 2004; Powell *et al*. 2005).

Minimizing tissue damage

Surgical techniques that are designed to avoid unnecessary tissue damage should be used whenever possible. Thermal damage to bone can be caused during the drilling sequence if dull drills are used or if osteotomy is performed without using enough liquid coolant. It is important to follow the manufacturer's guidelines and change the drills in the surgical kit accordingly.

Achieving early stability of implant

An important goal of the osteotomy is to prepare a site for the implant that will allow good stability of the implant during the healing process (Sennerby *et al*. 1992). Post-insertion stability lowers the risk of implant complications or failure. The presence of good-quality bone with a sufficient amount of cortical bone at the implant site is desirable to achieve this objective. In situations where there are less than optimal bone conditions (i.e. thin cortex, low trabecular density), increased initial stability can still be established by using implants with rough surfaces, parallel walls, and optimal height and width. In a study of implants placed in rabbit tibias it was found that good initial stability could be achieved by bicortical placement of an implant that engages two cortical layers of bone (Ivanoff *et al*. 1996). However, the same authors found that in a 15-year retrospective study in humans, bicortically anchored implants failed nearly four times more often than the monocortical ones (Ivanoff *et al*. 2000). They speculated that the overambitious fixation of the bicortical anchorage increased the likelihood of implant fractures that accounted for 80% of the failures in the study.

Avoiding anatomic structures

Anatomic structures that are at risk of serious collateral or accidental damage during the placement of implants include: nerves, blood vessels, floor of the mouth, nasal cavity, maxillary sinuses, and adjacent teeth. The risks to these structures can be minimized by careful assessment of radiographs and meticulous treatment planning. It is important to remember that the drills used for osteotomies penetrate further than the depth indicators on the drills. In certain situations radiographic indicator methods should be performed during surgery to help determine direction of the implant and its proximity to vital structures.

For implants that are to be placed in the mandible, the distance from the edentulous alveolar crest to the upper border of the inferior alveolar canal should be assessed from cross-sectional tomographic radiographs. The safety zone between the tip of the implant and the border of the canal should be at least 1–2 mm. Patients with compromised vertical bone dimension can sometimes be treated by placing multiple shorter implants of optimal width followed by splinting the prosthetic crowns together during the restorative phase of therapy.

The position of the mental foramen should be identified and located when implant surgeries in the premolar and molar areas of the mandible are performed. In some situations a loop of the nerve can be found to extend mesially. In one report the anterior loop of the mental neurovascular bundle extended mesially from 1.1–3.3 mm and a safety zone of 4 mm was recommended to avoid damaging the nerve during implant placement (Kuzmanovic *et al*. 2003). When placing an implant in the anterior part of the maxilla the size and location of the incisive papilla need to be determined. In addition, it must be established if there is enough bone in the area to place an implant or if the area needs to be grafted.

Anatomic concavities are frequently found on the lingual side of the mandible. It is important to avoid perforating the lingual plate during preparation of the implant site since perforations in this location can result in extensive and even life-threatening bleeding (Bruggenkate *et al*. 1993). A safe way of performing surgery in this area is to reflect a lingual flap at least to a level corresponding to the length of the implant to be placed. If this precaution is taken, any perforation that might occur is detected before any extensive damage and serious bleeding occur.

Some of the challenges of treating the partially edentulous patient are related to biological and functional differences between teeth and implants. If these differences are ignored there is an increased risk for complications. For example, in cases where there are compromised hard and soft tissues a few implants may not be able to withstand heavy occlusal forces associated with extensive posterior reconstructions (Albrektsson *et al*. 1988). Differences in morphology between implants and teeth can present another challenge. In the anterior part of the mouth an implant should blend in with the neighboring natural teeth. To accomplish this, an implant with the correct diameter must be selected and then placed in the optimal position in order to mimic a tooth esthetically and functionally.

After tooth extractions in the maxillary anterior region the alveolar ridge resorbs in a palatal direction. This will affect the position in which the anterior implants need to be placed since the relation of the implants to the lip and opposing dentition is critically important for a successful outcome (Jansen & Weisgold 1995). Where to place anterior implants in patients with a high smile line and thin periodontal tissues should be carefully evaluated to achieve acceptable esthetic and functional results.

Local risk factors and conditions

Presence of ongoing oral infections

There are abundant data showing that poor oral hygiene and microbial biofilms are important

etiologic factors leading to the development of peri-implant infections and implant loss (Mombelli *et al*. 1987; Jepsen *et al*. 1996; Salcetti *et al*. 1997; Esposito *et al*. 1998a,b; Lindquist *et al*. 1988; Listgarten & Lai 1999; van Winkelhoff *et al*. 2000; Heydenrijk *et al*. 2002; Quirynen & Teughels 2003; Fugazzotto *et al*. 2004). Therefore any risk assessment for implant survival should include an evaluation of the patient's ability to perform oral hygiene procedures (Salvi & Lang 2004).

Periodontitis

There are several reasons to believe that untreated or incompletely treated periodontitis increases the risk for implant failure. First, there are case reports that suggest an association (Malmstrom *et al*. 1990; Fardal *et al*. 1999). Second, a similar subgingival microbiota has been found in pockets around teeth and implants with similar probing depths (Papaioannou *et al*. 1996; Sbordone *et al*. 1999; Hultin *et al*. 2000; Agerbaek *et al*. 2006). Third, evidence exists that periodontal pockets might serve as reservoirs of pathogens (Apse *et al*. 1989; Quirynen & Listgarten 1990; Papaioannou *et al*. 1996) that hypothetically can be transmitted from teeth to implants (Quirynen *et al*. 1996; Sumida *et al*. 2002).

Studies dealing with the microbiota of failing or failed implants clearly indicate the presence of multiple periodontal pathogens (Table 30-3). However, one of the striking features of the microbiota associated with implant failures is its extensive diversity. It would be naïve to assume that infections around implants are due to a narrow range of microorganisms. A more realistic view is that peri-implant infections are caused by a consortium of multiple

microorganisms living on the implant surface in a biofilm. Contrary to the view of some (Heydenrijk *et al*. 2002), peri-implant infections are not simply caused by Gram-negative anaerobic bacteria. Certainly this group of bacteria is important, but yeasts and Gram-positive bacteria such as *Micromonas micros* and *Staphylococcus* species are often implicated in peri-implant infections (Table 30-3). Furthermore, in the implant literature the methods used to examine subgingival biofilms have primarily relied on microscopic (morphologic), cultural, and DNA probe analyses to characterize the microbiota. Culture-independent molecular analyses (e.g. studies of 16S ribosomal RNA gene sequences) have not been used to characterize the microbiota associated with implant failures. Application of such techniques to the subgingival microbiota associated with periodontitis has revealed the existence of a more diverse and complex microbial community than can be detected by conventional methods (Paster *et al*. 2001; Brinig *et al*. 2003; Lepp *et al*. 2004). In the case of periodontitis it is estimated that only about 50% of the subgingival flora can be characterized using conventional methods (Wilson *et al*. 1997) and therefore culture-independent analyses are required to get a more complete picture. This will probably also be true of the peri-implant subgingival microbiota once culture-independent molecular methods of analyses are applied to this ecosystem. Based on the documented diversity of the microbiota associated with failing implants, it is unlikely that testing for the presence of a small number of suspect bacteria for risk assessment purposes would have any clinical value.

Subgingival sites are micro-ecosystems that are preferentially colonized by oral bacteria well adapted to thriving in such environments. Indeed, subgingival sites are the natural or preferred habitat of a diverse group of oral microorganisms. In an interesting study of 15 patients, Devides and Franco (2006) sampled mucosa-associated biofilms of edentulous sites with paper points and analyzed the specimens using polymerase chain reaction (PCR) methods to detect certain periodontal pathogens. At the edentulous sites *Aggregatibacter actinomycetemcomitans* was detected in 13.3% of subjects, *Prevotella intermedia* was detected in 46.7% of subjects, and *Porphyromonas gingivalis* was not detected. Six months after placement of endosteal implants at the same sites, subgingival plaque samples taken from around the implants were positive for *A. actinomycetemcomitans* in 73.3% of subjects, *Pr. intermedia* in 53.3% of subjects, and *P. gingivalis* in 53.3% of subjects. None of the implants showed any clinical signs of either failure or peri-implantitis. These results indicate that healthy subgingival sites around implants are readily colonized by periodontal pathogens without any concomitant development of clinically detectable disease. The mere presence of PCR-detected pathogens is not a valid surrogate for peri-implant disease.

It is important to remember that the microbiota adjacent to failing implants will differ depending on the cause of the failure. For example, Rosenberg *et al*. (1991) demonstrated that the microbiota associated with implants failing because of traumatic loads was different to that found around implants failing because of infection.

There are several reports that the survival rate of implants is decreased when the patient has a history of periodontitis (Hardt *et al*. 2001; Evian *et al*. 2004; Karoussis *et al*. 2004; Wagenberg & Froum 2006). One implication of these observations is that patients who have had periodontitis might also be more susceptible to peri-implant infections. However, this is clearly not always the case since it has also been demonstrated that periodontally compromised patients who have lost a considerable amount of alveolar bone can be successfully treated with dental implants (Nevins & Langer 1995; Ellegaard *et al*. 1997; Sbordone *et al*. 1999). Since there is no clear-cut consensus in the literature on this topic, in risk-assessment discussions with patients it is a good idea to emphasize that based on their history of periodontitis they might be at an increased risk of developing peri-implantitis and therefore should be extra diligent in adhering to a rigorous post-insertion implant maintenance program.

Endodontic infections

The presence of untreated or insufficiently treated endodontic infections adjacent to the site of implant placement can adversely affect the outcome (Sussman & Moss 1993; Shaffer *et al*. 1998). There are numerous reports of retrograde peri-implantitis in which it is hypothesized that a periapical infection on a tooth spreads to an adjacent implant (Ayangco & Sheridan 2001; Chaffee *et al*. 2001; Jalbout & Tarnow 2001; Quirynen *et al*. 2005b). However, successful retention of implants has been reported when implants were inserted immediately after extraction of endodontically infected teeth (Villa & Rangert 2005).

Based on the strength of existing data discussed above, it is highly recommended that any existing periodontal or endodontic infections should be controlled before dental implants are placed. Although the presence of ongoing oral infections does not guarantee that implants will fail, such infections appear to increase the risk of failure. Finally, since it has been documented that some peri-implant infections may be associated with *Candida* spp. (Table 30-3) it is probably wise to control and treat any existing candidiasis before implants are inserted.

Systemic risk factors

Age

In adult patients, age is usually not considered an important risk factor for implant loss. Indeed, most

longitudinal studies of survival rates of implants include some subjects who are well over 75 years of age (Dao *et al*. 1993; Hutton *et al*. 1995; Nevins & Langer 1995; Davarpanah *et al*. 2002; Becktor *et al*. 2004; Fugazzotto *et al*. 2004; Karoussis *et al*. 2004; Fransson *et al*. 2005; Herrmann *et al*. 2005; Quirynen *et al*. 2005a; Mundt *et al*. 2006; Wagenberg & Froum 2006). An upper age limit is usually not listed as an exclusion criterion in such studies. It is clear that implants can be quite successful when placed in patients who are in their eighth and ninth decades of life. Several reports indicate that there is not a statistically significant relationship between age of the patient and implant failure (Dao *et al*. 1993; Hutton *et al*. 1995; Bryant & Zarb 1999; Fransson *et al*. 2005; Herrmann *et al*. 2005; Mundt *et al*. 2006; Wagenberg & Froum 2006). However, a thorough risk-assessment process involves evaluation of multiple possible risk factors. It is possible that there may have been some selection bias in the above studies since some older patients might have been excluded for medical reasons. Older individuals included in the above studies may be atypical in that they were healthy enough to be good candidates for implant placement.

In one retrospective study of the success of 4680 dental implants placed by a single surgeon over a 21-year period in 1140 patients, it was reported that increasing age was strongly associated with implant failure (Moy *et al*. 2005). A univariate analysis of the data indicated that compared to patients younger than 40 years (n = 181), patients in the 60–79-years age group (n = 499) had a significantly higher risk of implant failure (relative risk = 2.24; $P < 0.05$). However, in a multivariate analysis of the data from the entire study population, age was not a significant predictor of implant failure (Moy *et al*. 2005).

At the other end of the spectrum, a potential problem associated with the placement of dental implants in still-growing children and adolescents is the possibility of interfering with growth patterns of the jaws (Op Heij *et al*. 2003). Osseointegrated implants in growing jaws behave like ankylosed teeth in that they do not erupt and the surrounding alveolar housing remains underdeveloped. Dental implants can be a superb service to young people who have lost teeth due to trauma or have congenitally missing permanent teeth. However, because of the potential deleterious effects of implants on growing jaws it is highly recommended that implants not be placed until craniofacial growth has ceased or is almost complete (Thilander *et al*. 2001).

Smoking

Based on data generated by several follow-up studies of implant survival, cigarette smoking is often identified as a statistically significant risk factor for implant failure (Bain & Moy 1993; Lindquist *et al*. 1997; Wilson & Nunn 1999; Feloutzis *et al*. 2003; Gruica *et al*. 2004; Karoussis *et al*. 2004; Levin *et al*. 2004; Galindo-Moreno *et al*. 2005; Moy *et al*. 2005; Nitzan *et al*. 2005; Mundt *et al*. 2006). In addition, smoking has been associated with increased post-operative complications after sinus-lift operations and placement of onlay bone grafts (Levin *et al*. 2004).

Smoking is now generally accepted as an important modifiable risk factor for the development and progression of periodontitis (Johnson & Hill 2004). The reasons that smokers are more susceptible to both periodontitis and peri-implantitis are complex, but usually involve impairment of innate and adaptive immune responses (Kinane & Chestnutt 2000; Johnson & Hill 2004) and interference with wound healing (Johnson & Hill 2004; Labriola *et al*. 2005). Smoking is such a strong risk factor for implant failure that some clinicians highly recommend smoking-cessation protocols as part of the treatment plan for implant patients (Bain 1996; Johnson & Hill 2004).

Nevertheless, it should be emphasized that smoking is not an absolute contraindication for the placement of dental implants. Indeed, there are reports indicating that smoking did not adversely affect the rate of implant survival (Peleg *et al*. 2006; Wagenberg & Froum 2006). For multifactorial problems such as peri-implantitis and implant failure, the presence of one risk factor alone is usually insufficient to cause the adverse outcome.

Medication history

Bisphosphonates

Bisphosphonates are a widely prescribed class of drugs used for the treatment of osteoporosis and to reduce the bone-lytic effects of certain malignancies such as multiple myeloma and metastatic breast cancer (Woo *et al*. 2006). These pyrophosphate drugs are potent inhibitors of osteoclast activity that also have anti-angiogenic effects. The drugs have a high affinity for hydroxyapatite and are rapidly incorporated into all parts of the skeleton and have a very long half-life (i.e. decades). Relative potencies of the agents depend on their formulation (Table 30-4). An uncommon complication associated with the use of bisphosphonates is the increased risk of developing osteochemonecrosis or osteonecrosis of the jaws (ONJ) (Ruggiero *et al*. 2004; Marx *et al*. 2005; Braun & Iacono 2006). The vast majority of cases of ONJ occur in cancer patients who have received high-potency aminobisphosphonates (e.g. zoledronate, pamidronate) given intravenously to decrease the osteolytic effects of multiple myeloma or malignancies that have metastasized to bone (e.g. breast or prostate cancer).

Of major concern to the prospective implant patient who has been taking an oral bisphosphonate for osteoporosis is the possible risk of developing ONJ after implant placement. Oral bisphosphonates

Table 30-4 Relative potency for inhibition of osteoclast activity of various bisphosphonates, adapted from Braun & Iacono (2006)

Drug	Manufacturer	Potency factor
Etidronate (Didronel®)	Procter & Gamble	1
Tiludronate (Skelid®)	Sanofi	10
Clodronate (Bonefos®)	Schering	10
Clodronate (Loron®)	Roche	10
Neridronate (Nerixia®)	Abiogen	100
Pamidronate (Aredia®)	Novartis	100
Alendronate (Fosamax®)	Merck	500
Ibandronate (Bondronat®)	Roche	1 000
Risedronate (Actonel®)	Procter & Gamble	2 000
Zoledronate (Zometa®)	Novartis	10 000

have been reported to be associated with implant failure (Starck & Epker 1995) and ONJ (Ruggiero *et al*. 2004; Marx *et al*. 2005). Although rare, the risk is real. Since bisphosphonates tightly bind to hydroxyapatite and have a very long half-life, it is likely that the length of time a patient has been taking oral bisphosphonates is important in determining the level of risk. Since oral bisphosphonates slowly accumulate in bone with time, an osteoporosis patient who has been taking the drug for 1 year is at a lower risk of developing ONJ or implant failure than someone who has been on the drug for many years. In general, it is not recommended that implants be placed in patients who have been on the drug for more than 3 years. It has been suggested by some that prolonged use of bisphosphonates is a contraindication to implant placement (Scully *et al*. 2006).

It is important to remember that bone-remodeling processes are severely inhibited in patients who have been chronically taking oral bisphosphonates for osteoporosis. Because of this such patients are poor candidates for bone-grafting procedures and sinus-lift operations. Therefore, many ridge-augmentation procedures that often make implant placement possible are ill advised in these individuals.

Drug-influenced gingival enlargement

It is well known that one of the side effects of phenytoin, calcium-channel antagonists, and cyclosporin is gingival enlargement in about 25–50% of the individuals who take one or more of these drugs (Peñarrocha-Diago *et al*. 1990; Hassell & Hefti 1991). Gingival enlargement has also been reported around dental implants in individuals taking either phenytoin (Chee & Jansen 1994) or a calcium-channel antagonist (Silverstein *et al*. 1995). When there is significant gingival enlargement around teeth or implants, oral hygiene and maintenance procedures can become quite difficult. Therefore, medications associated with gingival enlargement should be considered in the overall risk assessment prior to implant placement.

Cancer chemotherapy

Oral cancer patients are frequently candidates for the placement of endosteal dental implants since prostheses designed to replace missing portions of the jaws need to be anchored to implants. Since antimitotic drugs used as chemotherapy for cancer might affect wound healing and suppress certain components of the immune system, it is important to know if these drugs interfere with osseointegration and success of dental implants. In a retrospective study, implant success was compared in 16 oral cancer patients who had no chemotherapy with the success in 20 patients who received postsurgical adjuvant chemotherapy with either cis- or carboplatin and 5-fluorouracil (Kovács 2001). It was found that these drugs did not have any detrimental effects on the survival and success of implants placed in the mandible.

It has also been reported that some cancer patients who received cytotoxic antineoplastic drugs experienced infections around existing transmucosal or endosteal dental implants (Karr *et al*. 1992). Therefore, it is important to recognize that many anticancer drugs suppress or kill cells necessary for optimal innate and adaptive immunity. Patients who are receiving cancer chemotherapy should have thorough periodontal and implant maintenance care to minimize the development of adverse events.

Anticoagulants

Patients who have blood-coagulation disorders or are taking high doses of anticoagulants are at an elevated risk of experiencing post-operative bleeding problems after implant surgery. Some patients with coagulation disorders may be at an elevated risk of implant failure (van Steenberghe *et al*. 2003) whereas other patients who chronically take oral anticoagulants can safely receive dental implants (Weischer *et al*. 2005). Patients who are on continuous oral anticoagulant therapy (e.g. coumarin derivatives) to reduce the risk of thromboembolic events and require dental implants for optimal restorative care should be evaluated on a case-by-case basis. Most of these patients can safely continue their warfarin or other anticoagulant therapy when they have their dental implant surgery (Wahl 1998, 2000). In such patients, local bleeding after the placement of dental implants can usually be well controlled by conventional hemostatic methods. The risk of developing life-threatening bleeding or bleeding that cannot be controlled using local measures following placement of dental implants is so low that there is no need to stop oral anticoagulant therapy (Beirne 2005).

Therapeutic levels of an anticoagulant drug such as warfarin are measured by the international normalized ratio (INR) which is the patient's prothrombin time (PT) divided by the mean normal PT for the laboratory (i.e. PTR). The PTR is then adjusted for the reagents used to arrive at a standardized INR value that will be comparable anywhere in the world. A higher INR reflects a higher level of anticoagulation with an attendant increased risk of hemorrhage (Herman *et al*. 1997). Although there are insufficient data to draw any evidence-based conclusions, placement of single implants is regarded as safe when the INR target values are 2.0–2.4 (Herman *et al*. 1997).

Immunosuppressive agents

Any medication that interferes with wound healing or suppresses components of innate and adaptive immunity can theoretically increase the risk of implant failure. Corticosteroids are a good example. They are potent anti-inflammatory agents that are widely used for the management of a wide variety of ailments. These drugs can interfere with wound healing by blocking key inflammatory events needed for satisfactory repair. In addition, through their immunosuppressive effects on lymphocytes, they can increase the rate of post-operative infections. In general, these undesirable effects are greatest in patients who take high doses of the drugs for long periods of time.

Immunosuppression

In the early years of the AIDS epidemic placement of dental implants was ill advised since affected patients developed major life-threatening oral infections. With the advent of effective HAART (highly active anti-retroviral therapy) regimens, most HIV-positive patients who take their medications live for many years without developing severe opportunistic infections. There have been no controlled studies dealing with the risk of dental implant failures in HIV-positive individuals. However, several case reports suggest that placement of dental implants in HIV-positive patients is not associated with elevated failure rates (Rajnay & Hochstetter 1998; Baron *et al*. 2004; Shetty & Achong 2005; Achong *et al*. 2006). Low T-helper (CD4) cell counts (i.e. <200/μL) do not appear to predict increased susceptibility to intraoral wound infections or elevated failure rates of dental implants (Achong *et al*. 2006). Although more studies are needed, it appears that it is safe to place dental implants if the patient's HIV disease is under medical control.

History of radiation therapy to the jaws

Patients who have received radiation (i.e. absorbed dose of ≥60 Gy) to the head and neck as part of the treatment for malignancies are at an increased risk of developing osteoradionecrosis (ORN). Most cases of this complication of cancer treatment are triggered by the extraction of teeth or other oral surgery procedures such as insertion of implants. Implant failure rates of up to 40% have been reported in patients who have had a history of radiation therapy (Granström *et al*. 1993, 1999; Beumer *et al*. 1995; Esposito *et al*. 1998a,b; Lindquist *et al*. 1988). At one time it was believed that ORN was due to vascular derangement and hypoxia of bone cells caused by the tissue-damaging effects of radiation (Teng & Futran 2005). Based on this hypothesis, it has been recommended that oral surgical procedures in patients at risk of ORN be performed in conjunction with hyperbaric oxygen (HBO) therapy. Indeed, Granström *et al*. (1999) reported that use of HBO therapy improved implant survival rates. However, the value of HBO therapy for the management of ORN has been called into question partly based on a placebo-controlled, randomized clinical trial (Annane *et al*. 2004) and other reports showing no advantage to HBO interventions (Maier *et al*. 2000; Gal *et al*. 2003). In addition, a systematic review by Coulthard *et al*. (2003) indicated that there is no high-quality evidence that HBO therapy improves implant survival in irradiated patients.

It is now believed that the pathogenesis of ONR is much more complex than a simple hypoxia-related phenomenon related to poor vascularity of irradiated tissues. Current evidence supports the view that ONR is a fibroatrophic process (Teng & Futran 2005). From the perspective of risk-assessment procedures for implant placement, patients who have a history of irradiation to the jaws should be considered at high risk for implant failure and HBO interventions will probably not lower that risk.

Diabetes mellitus

Although there is a slight tendency for more failures of implants in a diabetic compared to a non-diabetic population, the increased risk is not substantial in patients who are under good metabolic control (Shernoff *et al*. 1994; Kapur *et al*. 1998; Balshi & Wolfinger 1999; Fiorellini *et al*. 2000; Morris *et al*. 2000; Olson *et al*. 2000). In the general population the 5-year overall success rate for implants is approximately 95% (Buser *et al*. 1997; Weber *et al*. 2000; Davarpanah *et al*. 2002; Fugazzotto 2005), whereas in a diabetic population the rate is approximately 86% (Fiorellini *et al*. 2000).

Diabetics under suboptimal metabolic control often experience wound-healing difficulties and have an increased susceptibility to infections due to a variety of problems associated with immune dysfunctions (Geerlings & Hoepelman 1999). In the risk evaluation of diabetics it is important to establish the level of metabolic control of the disease. A useful test to determine the level of control over the last 90 days is a blood test for glycosylated hemoglobin (HbA_{1c}). This is a test for the percentage of hemoglobin to

which glucose is bound. Normal values for a non-diabetic or a diabetic under good metabolic control are HbA_{1c} <6–6.5% and fasting blood glucose <6.1 mmol/L (110 mg/dL). Diabetics with HbA_{1c} values of ≥8% are under poor control and have an elevated risk of encountering wound healing problems and infection if dental implants are placed.

Metabolic bone disease

Osteoporosis

Osteoporosis is a complex group of systemic skeletal conditions characterized by low bone mass and microarchitectural deterioration of bone tissue. Osteoporotic bone is fragile and has an increased susceptibility to fracture. Primary osteoporosis is a common condition and is diagnosed when other disorders known to cause osteoporosis are not present. Secondary osteoporosis is diagnosed when the condition is related to, or occurs as a consequence of, osteoporosis-inducing circumstances. These might include diet (e.g. starvation, calcium deficiency), congenital conditions (e.g. hypophosphatasia, osteogenesis imperfecta), drugs (e.g. alcohol abuse, glucocorticoids), endocrine disorders (e.g. Cushing's syndrome), and certain systemic diseases (e.g. diabetes mellitus, rheumatoid arthritis). Osteoporosis is assessed using bone densitometry in which a patient's bone mass or bone mineral density (BMD) is determined. BMD refers to grams of bone mineral per square centimeter of bone cross-section and is expressed in units of g/cm^2.

There are multiple case reports that conclude that osteoporosis alone is not a significant risk factor for implant failure (Dao *et al*. 1993; Friberg 1994; Fujimoto *et al*. 1996; Friberg *et al*. 2001). Implants placed in individuals with osteoporosis appear to successfully osseointegrate and can be retained for years. However, in cases of secondary osteoporosis there are often accompanying illnesses or conditions that increase the risk of implant failure (e.g. poorly controlled diabetes mellitus, corticosteroid medications). Therefore, in the risk-evaluation process the presence of osteoporosis should alert the clinician to the possible presence of osteoporosis-associated circumstances that are known to increase the risk of implant failure.

In the implant literature the concept of "poor bone quality" was introduced by Lekholm and Zarb (1985). This is something quite different to osteoporosis. Poor bone quality refers to the subjective appraisal of the presence and amount of compact and trabecular bone as visualized in radiographs. The radiographic appraisal of bone quality is reassessed during explorative drilling at the fixture-preparation site. The assessment system uses the following four groups:

- Type 1 = almost the entire jaw is comprised of homogenous compact bone
- Type 2 = a thick layer of compact bone surrounds a core of dense trabecular bone
- Type 3 = a thin layer of cortical bone surrounds a core of dense trabecular bone of favorable strength
- Type 4 = a thin layer of cortical bone surrounds a core of low density trabecular bone.

The system has serious reproducibility problems that limit its usefulness in the risk-assessment process. Nevertheless, there are reports indicating that jaw bone quality is significantly related to implant failure especially when there is type 4 bone (Jaffin & Berman 1991; Hutton *et al*. 1995; Herrmann *et al*. 2005).

Connective tissue and autoimmune disorders

Scleroderma

Systemic sclerososis or scleroderma is a chronic autoimmune disease that targets the skin, lungs, heart, gastrointestinal tract, kidneys, and musculoskeletal system. The disease is characterized by widespread tissue fibrosis, endothelial dysfunction of small blood vessels, and formation of auto-antibodies against a number of tissue components. The skin loses much of its flexibility and becomes leatherlike. Patients often experience stiffening of the finger joints making it almost impossible to grasp items such as a toothbrush and other oral hygiene devices. The lips become so stiff and taut that opening the mouth is restricted to only a few centimeters. As a result of these access problems, all types of dental care (i.e. self-administered and professionally delivered) become extraordinarily difficult. The overall effect is long-standing poor oral hygiene leading to the inevitable loss of multiple teeth due to caries and periodontal disease.

There are no well controlled studies on the success rates of dental implants in patients with scleroderma. However, there are some case reports showing that patients with this disease can have implants successfully placed and maintained for several years (Jensen & Sindet-Pedersen 1990; Patel *et al*. 1998; Hodgson *et al*. 2006). If the decision is made to place dental implants in patients with scleroderma, it is critical that a rigorous maintenance program be incorporated into the treatment plan.

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is an autoimmune disease that affects many organ systems, with the joints, kidneys, heart, and lungs being the most commonly affected. It is well established that SLE patients have increased susceptibility to many opportunistic infections (Zandman-Goddard & Shoenfeld 2003; Bosch *et al*. 2006). The reasons for this increased susceptibility are not well understood but SLE-

associated abnormalities of both humoral and cellular immunological responses and use of immunosuppressive therapy (e.g. corticosteroids) are undoubtedly important. If implants are absolutely required for a patient with SLE, it should be emphasized that bacteremias from oral surgery procedures increase the risk of developing infections of SLE-affected joints. In such cases it is recommended that antibiotic coverage be considered to minimize this potential problem (Fitzgerald *et al*. 2003). There are no well controlled studies, or even a well documented case series, of the success rates of implants placed in patients with SLE.

Xerostomia

Xerostomia or dry mouth can be caused by a wide range of factors, including certain medications, aging, and damage to salivary glands (Beikler & Flemmig 2003). Sjögren syndrome (SS) is a group of autoimmune diseases that may be limited to lacrimal and salivary glands leading to xerostomia and keratoconjunctivitis (primary SS). In secondary SS the xerostomia and keratoconjunctivitis occur along with a number of connective tissue disorders such as rheumatoid arthritis and scleroderma. One of the main oral problems associated with SS is severe xerostomia that often leads to severe dental caries, burning sensations of the oral mucosa, oral candidiasis, and difficulty in swallowing. In many cases all of the teeth are lost because of rampant root and coronal caries. Patients with severe xerostomia find wearing artificial dentures to be a difficult and very unpleasant experience because of the lack of lubrication ordinarily supplied by saliva. Based on a few case reports it appears that dental implants can be successfully used in patients with SS (Payne *et al*. 1997; Isidor *et al*. 1999; Binon 2005). However, since SS often accompanies other conditions that increase the risk of implant failure (e.g. scleroderma, lupus erythematosus), it is important that implant candidates with SS be carefully evaluated for numerous other risk factors that might be present.

Hematologic and lymphoreticular disorders

A number of hematologic and lymphoreticular disorders carry with them an increased susceptibility to periodontitis and other infections (Kinane 1999). Among these disorders are: agranulocytosis, acquired neutropenias, cyclic neutropenias, leukocyte adherence deficiency, and aplastic anemia (e.g. Fanconi's syndrome). Since patients with these diseases frequently lose teeth early in life they often have extensive prosthetic needs that can be met by the placement of dental implants. In the risk-assessment process prior to implant placement the major concern to be considered is the increased susceptibility to infections that could occur around any implants that might be placed. There are no well controlled studies of the success rates of implants placed in patients with these disorders. However, implants can be placed if the patient's disease is under control or in remission and a rigorous post-insertion implant maintenance program is an integral part of the overall treatment plan.

Genetic traits and disorders

Polymorphisms (IL-1 and MMP)

Polymorphisms are small variations in base-pair components of DNA that occur with a frequency of approximately 1–2% in the general population (Kornman & Newman 2000). These small variations in genes are biologically normal and do not cause disease. However, gene polymorphisms can affect in subtle ways how different people respond to environmental challenges. Within the context of risk assessment for implant failure, they affect how people respond to a microbial challenge and how efficiently their wounds heal.

Polymorphisms in the interleukin-1 (IL-1) gene cluster on chromosome 2q 13 have been associated with a hyper-responsive inflammatory reaction to a microbial challenge. A specific composite genotype of *IL-1A* and *IL-1B* polymorphisms, consisting of allele 2 of both IL-1A –889 (or the concordant +4845) and *IL-1B* +3954 has been associated with an increased risk of severe chronic periodontitis in non-smokers (Kornman *et al*. 1997). Several investigators have attempted to determine if this composite IL-1 genotype can serve as a risk factor for complications associated with implants such as bone loss or their eventual failure (Wilson & Nunn 1999; Rogers *et al*. 2002; Feloutzis *et al*. 2003; Gruica *et al*. 2004; Jansson *et al*. 2005). All of these reports found that being positive for the composite IL-1 genotype was not associated with an increased risk of bone loss or other implant-related problems. However, in some populations there appears to be a synergistic effect between a positive IL-1 genotype and smoking that puts dental implants at a higher risk of developing peri-implant bone loss (Feloutzis *et al*. 2003; Gruica *et al*. 2004).

Matrix metalloproteinases (MMPs) are a family of at least 15 zinc-dependent endopeptidases that function extracellularly. They are important in both normal and pathologic remodeling of tissues and differ in some of their substrate specificities. For example, MMP-1 is an interstitial collagenase capable of cleaving collagen types I, II, III, VII, and X. While another enzyme called MMP-9 or gelatinase B cleaves collagen types IV, V, VII, and XIV. In a pilot study of 46 patients it was found that a polymorphism in the promoter region of the *MMP-1* gene was associated with early implant failure, whereas a polymorphism

in the promoter region of the *MMP-9* gene had no relationship with implant loss (Santos *et al*. 2004). Further studies in this general area are warranted since a validated genetic risk factor for implant failure would have immense clinical utility.

Genetic disorders

A number of genetic disorders such as those associated with chromosomal defects (e.g. Down syndrome) or those transmitted as Mendelian traits (e.g. Papillon-Lefèvre syndrome) often lead to tooth loss due to increased susceptibility to infections. An important question in the restorative care of these individuals is, will the increased susceptibility to periodontal infections also increase the risk of implant failure? In the risk-evaluation process it is probably best to assume that the answer to this question is "yes". However, with good post-operative and effective long-term maintenance care, implants can be successfully placed and retained in high-risk patients. For example, Papillon-Lefèvre syndrome is due to loss-of-function mutations in the cathepsin C gene that impairs innate immune responses (Toomes *et al*. 1999). Even in patients with this genetic disorder dental implants can be successful (Ullbro *et al*. 2000).

Importance of behavioral considerations in risk assessment

In the examination and evaluation of a candidate for dental implants, one of the most difficult tasks is to analyze the behavioral aspects of risk assessment. This area has not been well studied and falls within the realm of the art, rather than the science, of clinical practice. Important behavioral issues that need to be assessed include compliance history, substance use/abuse habits, psychiatric/psychological issues, practitioner–patient communications, and expectations of the patient.

Dental history of compliance behaviors

Long-term success of dental implants requires that the patient is able and willing to comply with the recommended post-insertion maintenance procedures required for long-term survival and success of implants. Since poor oral hygiene is a documented risk factor associated with failure of implants, it is critically important that patients understand this and are taught the skills necessary to perform plaque removal on a daily basis (Mombelli *et al*. 1987; Lindquist *et al*. 1988; Jepsen *et al*. 1996; Salcetti *et al*. 1997; Esposito *et al*. 1998a,b; Listgarten & Lai 1999; van Winkelhoff *et al*. 2000; Heydenrijk *et al*. 2002; Fugazzotto *et al*. 2004; Quirynen & Teughels 2003). The teaching of oral hygiene is not a trivial task and often requires a considerable investment of time over multiple visits. In addition, since patient-performed oral hygiene does not adequately remove or disrupt dental plaque biofilms at subgingival locations, periodic maintenance visits are needed so the oral healthcare provider can deliver this care. It is recommended that these visits be at 3-month intervals until it can be established that a less intense schedule is sufficient. The patient's compliance with the recommended maintenance schedule is a major key to long-term success.

Substance use/abuse

Cigarette smoking as a risk factor for peri-implantitis and implant loss has been discussed earlier in this chapter. Smoking is a well documented risk factor that has both local and systemic effects on implant success. In addition, smoking is a powerful addiction with many complex behavioral components. In the consultation visit with the patient it is important that the clinician explain that smoking can contribute to complications after implant insertion. Referral to experts who conduct smoking-cessation programs is often helpful.

Patients who have addictions to alcohol and drugs are usually poor candidates for dental implants. Since the success of implant therapy requires a considerable amount of patient cooperation at all stages of care, individuals with substance-abuse problems should receive prosthetic care that does not depend on implants.

Psychiatric/psychological issues

In general, patients who have severe mental health problems or exhibit psychotic behavior are not good candidates for dental implants. As in the case of individuals with substance-abuse problems, the cooperation needed for successful implant therapy is missing. However, people with medically controlled mental health problems, such as depression, can be successfully treated with implants. In cases where there is uncertainty regarding how well the problem is under medical control, a consultation with the patient's physician is advisable.

Lack of understanding or communication

Most practitioners explain to their patients what the proposed dental care involves. However, in many cases patients do not understand what has been explained to them. It is important that the practitioner determine if the information they tried to convey was understood. One of the best ways to do this is to convey the information in easily understood (non-technical) language and in small increments. A common mistake is to rapidly present too much

information. It is highly recommended that the patient be encouraged to give some feedback showing that they actually understand what they have been told. Patients who understand what is being done are usually quite cooperative and this cooperation leads to the increased probability of successful therapeutic outcomes.

Patient's expectations

It is important to remember that the practitioner's and patient's perspectives may be somewhat different regarding the primary criteria used to measure implant success. From the patient's point of view the successful implant should be esthetically acceptable, comfortable, low-cost, and functional. Practitioners usually discuss implant success in terms of extent of osseointegration, level of alveolar bone, probing depths, and stability. Although the two sets of criteria are not in conflict, they emphasize different things. During the consultation visit, before any care is delivered, the practitioner should discuss, using patient-centered outcomes, what can be expected from placement of the implant.

A final comprehensive treatment plan should be presented to the patient that includes all recommended dental therapy and alternative treatment options. The patient should also be informed about the sequencing of the clinical procedures, risks and costs involved, and the anticipated total treatment time. This discussion between practitioner and patient is critically important in lowering the overall risk of treatment problems. Patients who understand what will be done, and why, are more likely to cooperate with the recommended treatment.

Interest and commitment to post-treatment care and maintenance program

As discussed above, daily self-care (oral hygiene) and adherence to a maintenance-recall schedule is absolutely required for long-term success. This is best discussed and conveyed to the patient at the consultation visit. Long-term success of both periodontal and implant therapy depends on an effective partnership between the patient and practitioner. Many patients play a passive role when it comes to oral care. They place themselves in the hands of the therapist and expect most of the care to be done for them. An effective way to reduce the risk of implant complications and failure is to stress the importance of the patient's role as an active participant in the overall therapeutic program.

Summary and conclusions

A key part of implant therapy is the risk-assessment process in which an attempt is made to identify variables that increase the risk of complications leading to implant failure. In many cases, early identification of these variables makes it possible to avoid or eliminate them, thereby increasing the chances of long-term implant survival. Risk factors for implant failure are environmental, biologic, or behavioral factors that are part of the causal chain leading to implant complications. For multifactorial problems, such as peri-implantitis and implant failure, the presence of one risk factor alone is usually insufficient to cause the adverse outcome. It is the combination of multiple risk factors that has clinical importance.

To minimize the risk of implant complications clinicians can use a number of technical procedures, such as adhering to a strict hygienic surgical protocol, performing the osteotomies with sharp drills, achieving early implant stability, and avoiding damage to vital anatomic structures during surgery. Since ongoing oral infections can lead to implant complications it is highly recommended that any endodontic, periodontal, and other oral infections be treated prior to implant placement. Conventional microbiologic methods have revealed that a large number of microorganisms are associated with peri-implant infections. Because of this microbial diversity, it is unlikely that testing for the presence of a small number of suspect bacteria for risk-assessment purposes will have any clinical value. Existing evidence does not support the routine use of pre-operative systemic antibiotics in implant therapy.

Most of the systemic risk factors for implant complications are those that increase the patient's susceptibility to infections or those that interfere with wound healing. Particularly important risk factors that suppress or alter neutrophil function are cigarette smoking, poor metabolic control of diabetes mellitus, and certain hematologic disorders. Factors that can significantly suppress adaptive immune functions are chronic use of corticosteroid medications and the presence of systemic lupus erythematosus. Important risk factors that can interfere with healing around implants are long-term use of bisphosphonates, history of radiation therapy to the jaws, and poor metabolic control of diabetes mellitus.

An effective risk-assessment process includes thorough medical and dental histories, a complete clinical examination, and an appropriate radiographic survey. Important behavioral issues that need to be assessed include compliance history, substance use/abuse habits, psychiatric/psychologic issues, effectiveness of practitioner–patient communication, and expectations of the patient. Depending on a number of circumstances, dental implants can be considered even in individuals who are at an elevated risk for implant complications. Risk assessment of the implant patient is a critically important preamble to treatment planning and if properly done can minimize the complications associated with endosseous implants.

Part 10: Treatment Planning Protocols

Chapter 31

Treatment Planning of Patients with Periodontal Diseases

Giovanni E. Salvi, Jan Lindhe, and Niklaus P. Lang

Caries and periodontal diseases represent opportunistic infections associated with biofilm formation on the surfaces of teeth. Factors such as bacterial specificity and pathogenicity as well as the disposition of the individual for disease, e.g. local and general resistance, may influence the onset, the rate of progression, and clinical characteristics of plaque-associated dental disorders. Findings from animal experiments and longitudinal studies in humans, however, have demonstrated that treatment, including the elimination or the control of the biofilm infection and the introduction of careful plaque control measures, in most, if not all, cases results in dental and periodontal health. Even if health cannot always be achieved and maintained, the arrest of disease progression following treatment must be the goal of modern dental care.

The treatment of patients affected by caries and periodontal disease, including symptoms of associated pathologic conditions such as pulpitis, periapical periodontitis, marginal abscesses, tooth migration, etc., may from a didactic point of view be divided into four different phases:

1. Systemic phase of therapy including smoking counseling
2. Initial (or hygiene) phase of periodontal therapy, i.e. cause-related therapy
3. Corrective phase of therapy, i.e. additional measures such as periodontal surgery, and/or endodontic therapy, implant surgery, restorative, orthodontic and/or prosthetic treatment
4. Maintenance phase (care), i.e. supportive periodontal therapy (SPT).

Treatment goals

In every patient diagnosed with periodontitis, a treatment strategy, including the elimination of the opportunistic infection, must be defined and followed. This treatment strategy must also define the clinical outcome parameters to be reached through therapy. Such clinical parameters include:

- Reduction or resolution of gingivitis (bleeding on probing; BoP). A patient full mouth mean BoP ≤25% should be reached.
- Reduction in probing pocket depth (PPD). No residual pockets with PPD >5 mm should be present.
- Elimination of (through-and-through) open furcations in multi-rooted teeth. Initial furcation involvement should not exceed 3 mm.
- Absence of pain.
- Individually satisfactory esthetics and function.

In this context it must be emphasized that risk factors for periodontitis that can be controlled must be addressed as well. The three main risk factors for chronic periodontitis are (1) improper plaque control, (2) cigarette smoking, and (3) uncontrolled diabetes mellitus (Kinane *et al.* 2006).

Systemic phase

The goal of this phase is to eliminate or decrease the influence of systemic conditions on the outcomes of therapy and to protect the patient and the dental care

providers against infectious hazards. Contact with a physician or specialist should enable appropriate preventive measures to be taken, if necessary. Efforts must be undertaken to stimulate a smoker to enroll in a smoking cessation program. Additional aspects are discussed in Chapter 33.

Initial (hygiene) phase

This phase represents the cause-related therapy. The objective of this phase is the achievement of clean and infection-free conditions in the oral cavity through complete removal of all soft and hard deposits and their retentive factors. Furthermore, this phase should aim at motivating the patient to perform optimal plaque control. The initial phase of periodontal therapy is concluded by re-evaluation and planning of both additional and supportive therapies.

Corrective phase (additional therapeutic measures)

This phase addresses the sequelae of the oportunistic infections and includes therapeutic measures, such as periodontal and implant surgery, endodontic therapy, restorative and/or prosthetic treatment. The amount of corrective therapy required and the selection of the type of restorative and prosthetic therapy can be determined only when the degree of success of the cause-related therapy can be properly evaluated. The patient's willingness and ability to cooperate in the overall therapy must determine the type of corrective treatment. If this cooperation is inadequate, it may not be worth initiating treatment procedures: permanent improvement of oral health, function and esthetics may therefore not be achieved. The validity of this statement can be exemplified by the results of studies aimed at assessing the relative value of different types of surgical methods in the treatment of periodontal disease. A number of clinical trials (Lindhe & Nyman 1975; Nyman *et al.* 1975, 1977; Rosling *et al.* 1976a,b; Nyman & Lindhe 1979) have demonstrated that gingivectomy and flap procedures performed in patients with proper plaque control levels often result in gain of alveolar bone and clinical attachment, while surgery in plaque-contaminated dentitions may cause additional destruction of the periodontium.

Maintenance phase (supportive periodontal therapy)

The aim of this treatment is the prevention of reinfection and disease recurrence. For each individual patient a recall system must be designed that includes (1) assessment of deepened sites with bleeding on probing, (2) instrumentation of such sites, and (3) fluoride application for the prevention of dental caries. In addition, this treatment involves the regular control of prosthetic restorations incorporated during the corrective phase of therapy. Tooth sensitivity testing should be applied to abutment teeth as loss of vitality is a frequently encountered complication (Bergenholtz & Nyman 1984; Lang *et al.* 2004; Lulic *et al.* 2007). Based upon the individual caries activity, bitewing radiographs should be incorporated into SPT at regular intervals.

Screening for periodontal disease

A patient seeking dental care is usually screened for the presence of carious lesions by means of clinical and radiographic tools. Likewise, it is imperative that such a patient is screened for the presence of periodontitis as well, using a procedure termed the basic periodontal examination (BPE) (or periodontal screening record; PSR).

Basic periodontal examination

The goal of the BPE is to screen the periodontal conditions of a new patient and to facilitate treatment planning. BPE scoring will allow the therapist to identify:

- A patient with reasonably healthy periodontal conditions, but in need of long-term preventive measures
- A patient with periodontitis and in need of periodontal therapy.

In the BPE the screening of each tooth or implant is evaluated. For this purpose, the use of a thin graduated periodontal probe is recommended. At least two sites per tooth/implant (i.e. mesio-buccal and disto-buccal) should be probed using a light force (i.e. 0.2 N). Each dentate sextant within the dentition is given a BPE code or score, whereby the *highest* individual site score is used.

BPE system code

- Code 0 = probing pocket depth (PPD) ≤3 mm, BoP negative, no calculus or overhanging fillings (Fig. 31-1a)
- Code 1 = PPD ≤3 mm, BoP positive, no calculus or overhanging fillings (Fig. 31-1b)
- Code 2 = PPD ≤3 mm, BoP positive, presence of supra- and/or subgingival calculus and/or overhanging fillings (Fig. 31-1c)
- Code 3 = PPD >3 mm but ≤5 mm, BoP positive (Fig. 31-1d)
- Code 4 = PPD >5 mm (Fig. 31-1e).

If an examiner identifies a single site with a PPD >5 mm within a sextant, the sextant will receive a code of 4, and no further assessments are needed in this particular sextant. Patients with sextants given codes of 0, 1 or 2 belong to the relatively periodontally healthy category. A patient exhibiting a sextant with codes of 3 or 4 must undergo a more comprehensive periodontal examination (for details see Chapter 26).

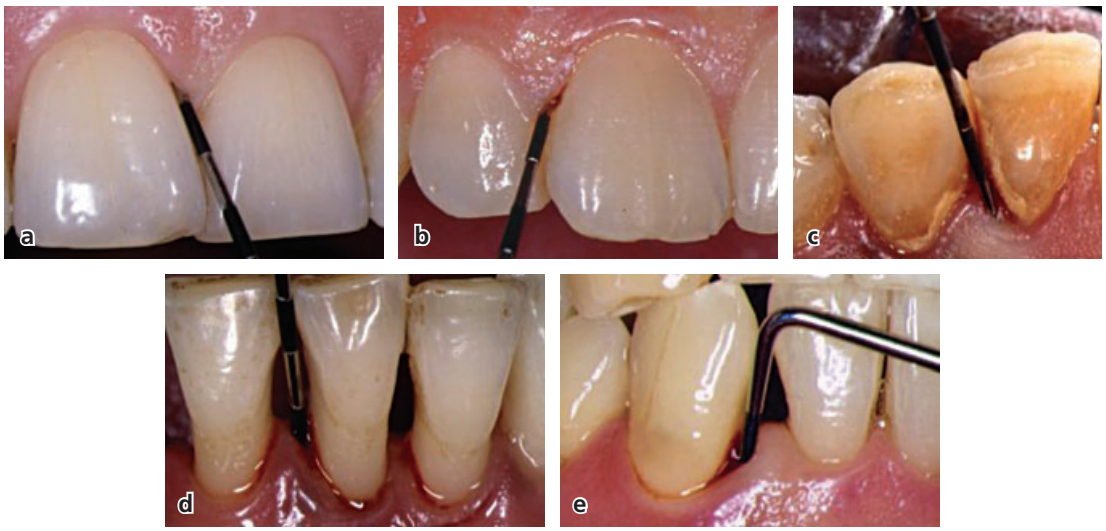

Fig. 31-1 Clinical illustration of the basic periodontal examination scores. (a) BPE code 0. (b) BPE code 1. (c) BPE code 2. (d) BPE code 3. (e) BPE code 4.

Fig. 31-2 (a–d) Clinical status of a 27-year-old female patient (S.B.) diagnosed with generalized aggressive periodontitis with furcation involvement.

The aim of the following text is to explain the overall objectives of the treatment planning of patients with BPE codes of 3 and 4 undergoing a comprehensive diagnostic process.

Diagnosis

The basis for the treatment planning described in this chapter is established by the clinical data collected from the patient's examination (see Chapter 26). This patient (Ms. S.B., 27 years of age) was systemically healthy and a non-smoker. She was examined with respect to her periodontal conditions, i.e. gingival sites displaying signs of *bleeding on probing* were identified, *probing pocket depths* were measured, the *periodontal attachment level* was calculated, *furcation involvements* were graded, *tooth mobility* was assessed, and the radiographs were analyzed to determine the *height* and *outline* of the *alveolar bone crest*.

The clinical characteristics of the dentition of this patient are shown in Fig. 31-2. The periodontal chart

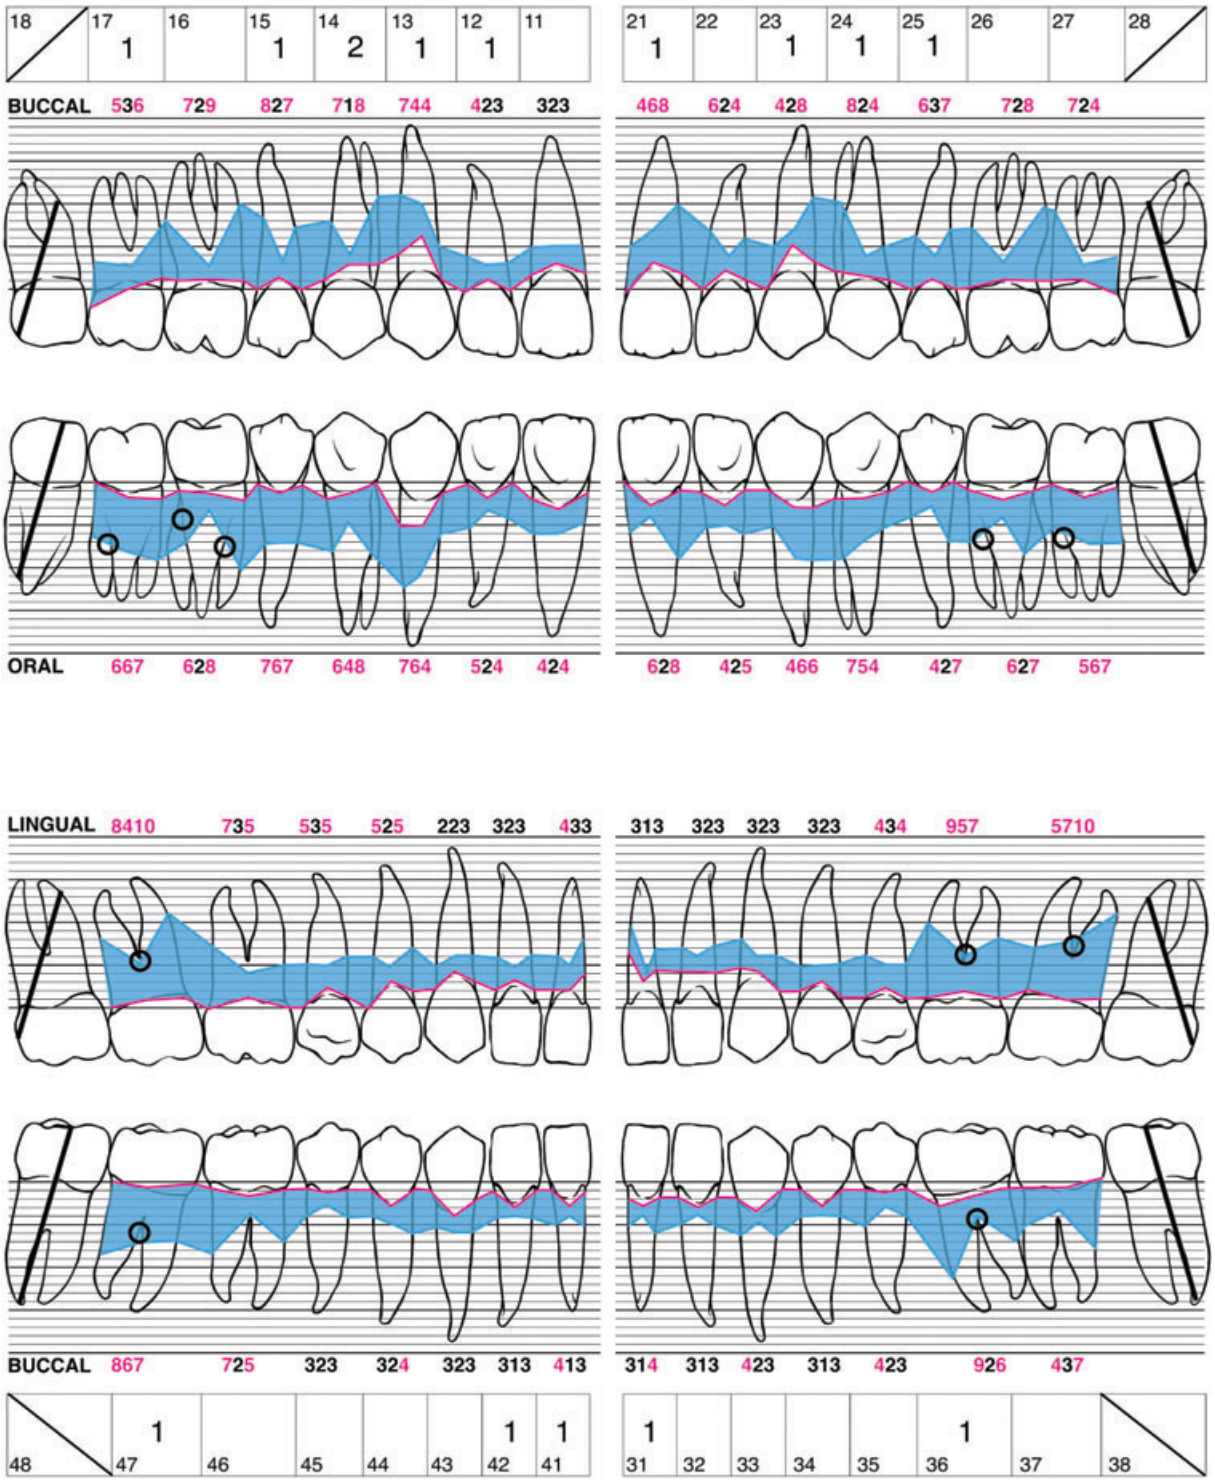

Fig. 31-3 Periodontal chart of the patient presented in Fig. 31-2.

and the radiographs are presented in Figs. 31-3 and 31-4, respectively. Based on these findings, each tooth in the dentition was given a diagnosis (Fig. 31-5) and a pre-therapeutic prognosis (Fig. 31-6). In addition to the examination of the periodontal condition, detailed assessments of primary and recurrent caries were made for all tooth surfaces in the dentition. Furthermore, the patient was examined with respect to endodontic and occlusal problems as well as temporomandibular joint dysfunction.

Treatment planning

Initial treatment plan

Provided that the patient's examination has been completed (see Chapter 26) and a diagnosis of all pathologic conditions has been made, an initial treatment plan can been established. At this early stage in the management of a patient, it is, in most instances,

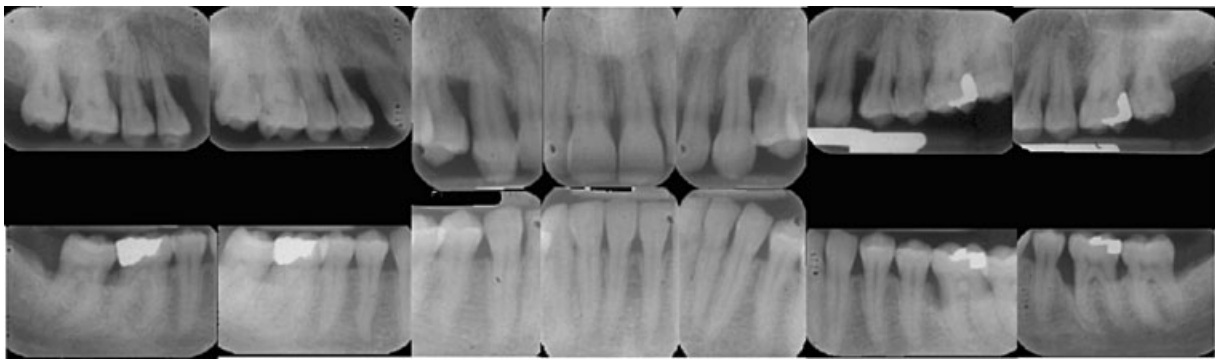

Fig. 31-4 Radiographs of the patient presented in Fig. 31-2.

impossible to make definite decisions regarding all aspects of the treatment sequence, because:

1. *The degree of success of initial therapy is unknown*. The re-evaluation after initial, cause-related therapy forms the basis for the selection of means for additional therapy. The degree of disease elimination that can be reached depends on the outcome of subgingival instrumentation, but also on the patient's ability and willingness to exercise proper plaque control and to adopt adequate dietary habits.
2. *The patient's "subjective" need for additional (periodontal and/or restorative) therapy is unknown*. When the dentist has completed the examination of the patient and an inventory has been made regarding periodontal disease, caries, pulpal disease, and temporomandibular joint disorders, the observations are presented to the patient (i.e. "the case presentation"). During the case presentation

session it is important to find out if the patient's subjective need for dental therapy coincides with the dentist's professional appreciation of the type and amount of therapy that is required. It is important that the dentist understands that the main objective of dental therapy, besides *elimination of pain*, is *to satisfy the patient's demands regarding chewing function (comfort) and esthetics*, demands that certainly vary considerably from one individual to another.

3. *The result of some treatment steps cannot be predicted.* In patients exhibiting advanced forms of caries and periodontal disease it is often impossible to anticipate whether or not all teeth that are present at the initial examination can be successfully treated, or to predict the result of certain parts of the intended therapy. In other words, critical and difficult parts of the treatment must be performed first, and the outcome of this treatment must be evaluated before all aspects of the definitive corrective treatment can be properly anticipated and described.

Pre-therapeutic single tooth prognosis

Based on the results of the comprehensive examination, including assessments of periodontitis, caries, tooth sensitivity, and the resulting diagnosis, as well as considering the patient's needs regarding esthetics and function, a pre-therapeutic prognosis for each individual tooth (root) is made. Three major questions are addressed:

1. Which tooth/root has a "*good*" (secure) prognosis?
2. Which tooth/root is "*irrational-to-treat*"?
3. Which tooth/root has a "*doubtful*" (unsecure) prognosis?

Teeth with a *good* prognosis will require relatively simple therapy and may be regarded as secure abutments for function.

Teeth that are considered "irrational-to-treat" should be extracted during initial, cause-related therapy. Such teeth may be identified on the basis of the following criteria:

- Periodontal:
  - Recurrent periodontal abscesses
  - Combined periodontal–endodontic lesions
  - Attachment loss to the apex
- Endodontal:
  - Root perforation in the apical half of the root
- Dental:
  - Vertical fracture of the root
  - Oblique fracture in the middle third of the root
  - Caries lesions that extend into the root canal
- Functional:
  - Third molars without antagonists and with periodontitis/caries.

Teeth with a *doubtful* prognosis are usually in need of comprehensive therapy and must be brought into the category of teeth with a *good* prognosis by means of additional therapy. Such teeth may be identified on the basis of the following criteria:

- Periodontal:
  - Furcation involvement
  - Angular (i.e. vertical) bony defects
  - "Horizontal" bone loss involving more than two thirds of the root
- Endodontal:
  - Incomplete root canal therapy
  - Periapical pathology
  - Presence of voluminous posts/screws
- Dental:
  - Extensive root caries.

Case presentation

The "case presentation" is an essential component of the initial treatment plan and must include a description for the patient of different therapeutic goals and the modalities by which these may be reached. At the case presentation for Ms. S.B. the following treatment plan was described:

- The teeth in the dentition from 12 to 22 and from 45 to 35 will probably not confront the dentist with any major therapeutic challenges. For the remaining teeth in the dentition, however, the treatment plan may involve several additional measures.

Expected benefits inherent to a certain treatment plan versus obvious disadvantages should always be explained to and discussed with the patient. His/her attitude to the alternatives presented must guide the dentist in the design of the overall treatment plan.

Based on the pre-therapeutic single tooth prognosis (Fig. 31-6), the following detailed treatment plan was presented to the patient.

Systemic phase

Owing to the fact that the patient was systemically healthy and a non-smoker, no medical examination and smoking cessation counseling were required.

Initial phase (cause-related therapy)

The treatment was initiated and included the following measures to eliminate or control the bacterial infection:

1. *Motivation* of the patient and *instruction* in oral hygiene measures with subsequent check-ups and re-instruction
2. *Scaling and root planing* under local anesthesia in combination with removal of plaque-retentive factors

Fig. 31-7 (a–c) Clinical front and lateral views of the patient presented in Fig. 31-2 at re-evaluation after initial periodontal therapy.

3. *Excavation and restoration* of carious lesions (16 and 26)
4. *Endodontic treatment* of tooth 46.

Re-evaluation after initial phase

The initial phase of therapy is completed with a thorough analysis of the results obtained with respect to the elimination or degree of control of the dental infections. This implies that a re-evaluation of the patient's periodontal conditions and caries activity must be performed. The results of this re-evaluation (Figs. 31-7 and 31-8) form the basis for the selection, if necessary, of additional corrective measures to be performed in the phase of definitive treatment (i.e. corrective phase). In order to provide time for the tissues to heal, the re-evaluation should be performed no earlier than 6–8 weeks following the last session of instrumentation.

Planning of the corrective phase (i.e. additional definitive therapy)

If the results from the re-evaluation, made 6–8 weeks after the termination of the initial treatment phase, show that periodontal disease and caries have been brought under control, the additional treatment may be carried out. The main goal of this phase is to correct the sequelae caused by oral infections (i.e. periodontal disease and caries). The following procedures may be performed:

- *Additional endodontic treatment with/without post-and-core build-ups*
- *Periodontal surgery*. The type (i.e. open-flap debridement, regenerative or resective surgery) and extent of surgical treatment should be based on probing depth measurements, degree of furcation involvement and BoP score assessed at re-evaluation. Periodontal surgery is often confined to those areas of the dentition where the inflammatory lesions were not resolved by root instrumentation and in areas with angular bony defects or in furcation-involved molars.
- *Installation of oral implants*. In regions of the dentition where tooth abutments are missing, implant therapy for esthetic and functional reasons may be considered. It is essential to realize that implant therapy must be initiated once all dental infections are under control, i.e. after successful periodontal therapy.
- *Definitive restorative and prosthetic treatment* including fixed or removable dental prostheses.

Corrective phase (additional therapy)

After initial therapy the patient (Ms. S.B.) exhibited low plaque and gingivitis scores (i.e. 5–10%) and no active carious lesions. The corrective phase therefore included the following components:

1. *Periodontal surgery* (i.e. open-flap debridement) in the maxillary left and right quadrants as well as in the mandibular molar regions (Fig. 31-9)
2. *Guided tissue regeneration* (GTR) for tooth 36
3. *Re-evaluation* after periodontal surgery (Figs. 31-10 and 31-11)

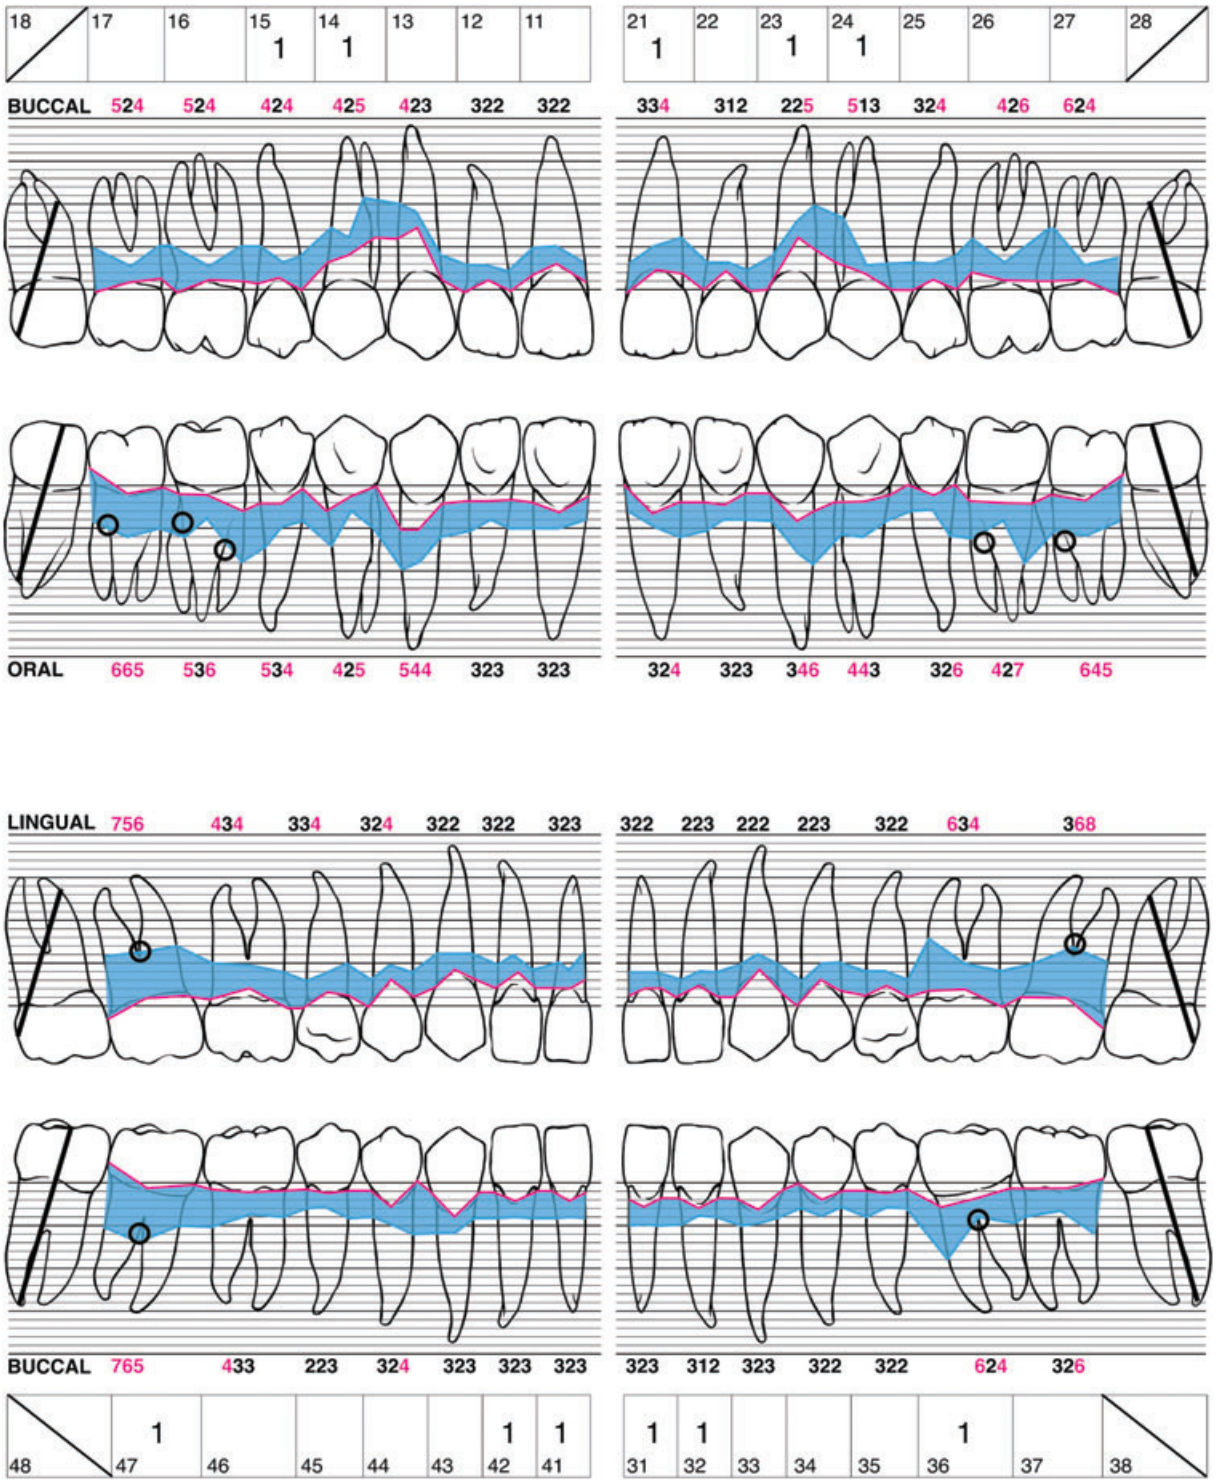

Fig. 31-8 Periodontal chart of the patient presented in Fig. 31-2 at re-evaluation after initial periodontal therapy.

4. *Orthodontic therapy* in the maxillary front area (Fig. 31-12)
5. *Restorative therapy* in the maxillary front area for esthetic reasons (Fig. 31-13).

Re-evaluation after corrective phase

The corrective phase of therapy is completed with a thorough analysis of the results obtained with respect to the elimination of the sequelae of periodontal tissue destruction (Figs. 31-14, 31-15 and 31-16). This implies that a re-evaluation of the patient's periodontal and peri-implant conditions must be performed. The results of this re-evaluation form the basis for the assessment of the residual periodontal risk. The outcomes of the periodontal risk assessment (PRA), in turn, will determine the recall frequency of the patient during maintenance phase.

Maintenance phase (care)

Following completion of cause-related therapy, the patient must be enrolled in a recall system aiming at

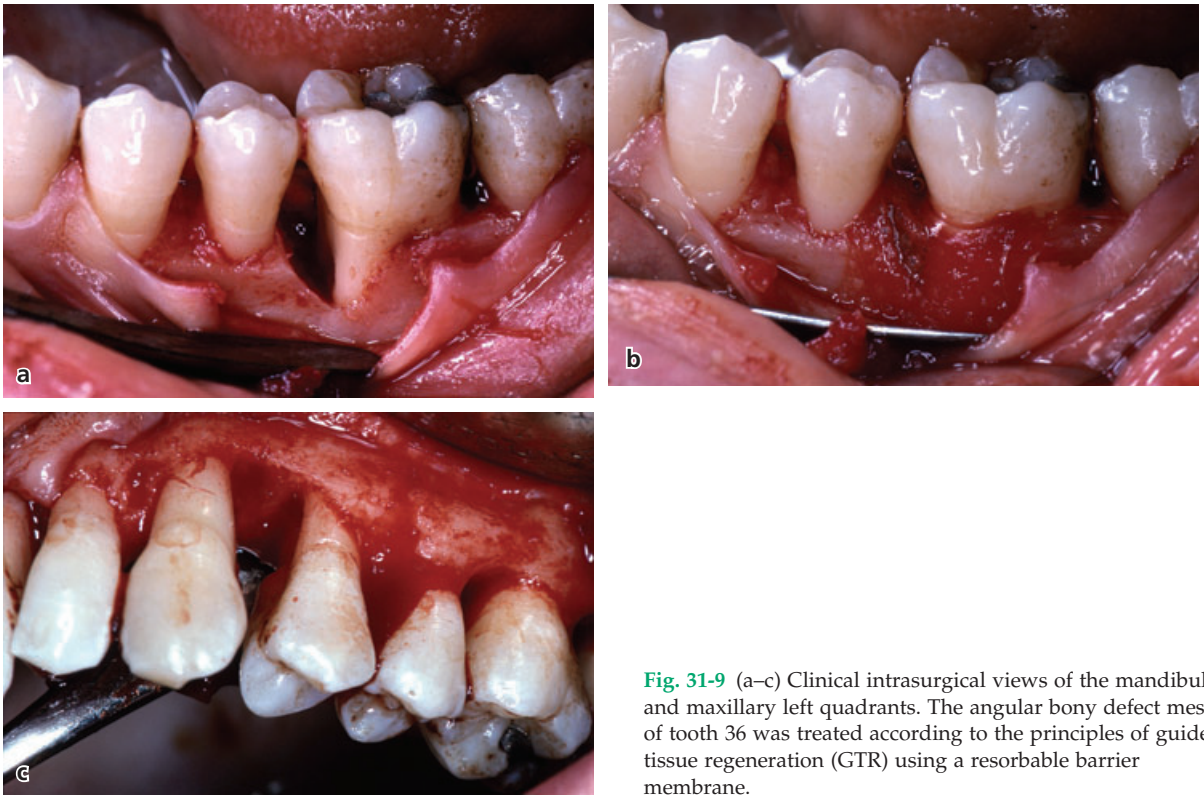

Fig. 31-9 (a–c) Clinical intrasurgical views of the mandibular and maxillary left quadrants. The angular bony defect mesial of tooth 36 was treated according to the principles of guided tissue regeneration (GTR) using a resorbable barrier membrane.

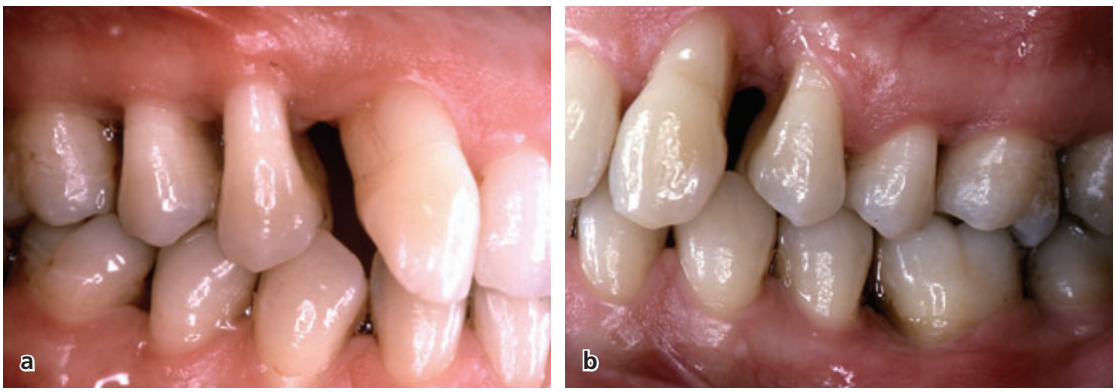

Fig. 31-10 (a,b) Clinical lateral views of the patient presented in Fig. 31-2 at re-evaluation after periodontal surgery.

preventing the recurrence of oral infections (i.e. periodontitis, caries, and peri-implantitis). Supportive periodontal therapy (SPT) should be scheduled at the re-evaluation after initial therapy and independently of the need for additional therapy. The time interval between the recall appointments should be based on a periodontal risk assessment established at the re-evaluation after the corrective phase. It is well established that self-performed plaque control combined with regular maintenance care visits following active periodontal treatment represents an effective means of controlling gingivitis and periodontitis and limiting tooth mortality over a 30-year period (Axelsson *et al.* 2004). It is important to emphasize, however, that the recall program must be designed to meet the individual needs of the patient. According to a PRA performed after completion of active therapy, some patients should be recalled every 3 months, while others may have to be checked only once a year (Lang & Tonetti 2003).

At the various recall visits the following procedures should be carried out:

1. Update of the medical and smoking history
2. Soft tissue examination as cancer screening
3. Recording of the full-mouth PPD ≥5 mm with concomitant BoP
4. Re-instrumentation of bleeding sites with PPD ≥5 mm
5. Polishing and fluoridation for the prevention of dental caries.

The patient (Ms. S.B.), presented to describe the guiding principles of treatment planning, was recalled twice during the first 6 months after active treatment (i.e. every 3 months) and subsequently only once every 6 months based on the individual PRA.

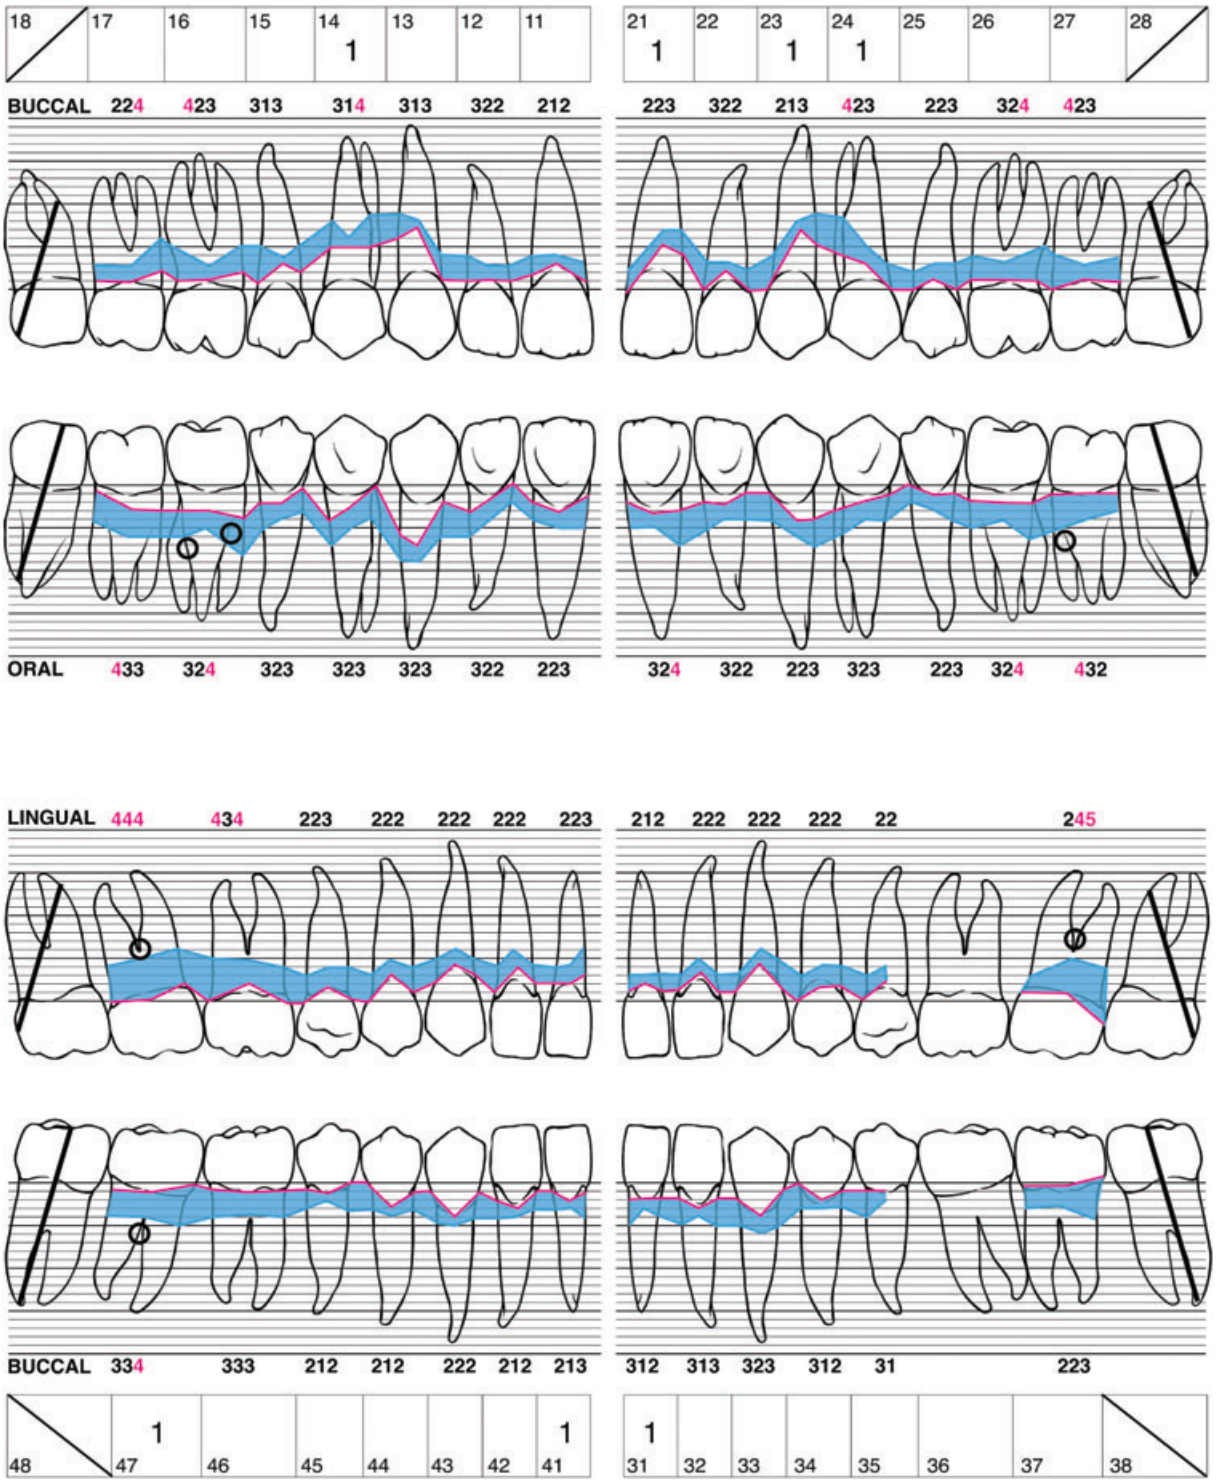

Fig. 31-11 Periodontal chart of the patient presented in Fig. 31-2 at re-evaluation after periodontal surgery.

Concluding remarks

The overall treatment plan and the sequence of the different treatment procedures used in this case were selected for presentation in order to illustrate the following principle: *in patients exhibiting a generalized advanced breakdown of the periodontal tissues, but with an intact number of teeth, considerable efforts should be made to maintain all teeth*. Extraction of a single tooth in such a dentition will frequently also call for the extraction of several others for "prosthetic reasons". The end result of such an approach thus includes a prosthetic rehabilitation that, if the treatment planning had been properly done, would have been unnecessary.

The large variety of treatment problems that different patients present may obviously require deviations from the sequence of treatment phases (i.e. systemic phase, initial cause-related therapy, corrective therapy, and maintenance care) discussed above.

Such deviations may be accepted as long as the fundamental principles characterizing the treatment phases are understood.

Case report

A patient will be presented below together with a brief description of his specific dental problems and the treatment delivered in order to demonstrate the rationale behind such treatment phases.

Patient S.K. (male, 35 years old)

Initial examination

The chief complaint of the patient was the slightly increased mobility of tooth 21. The periodontal conditions (i.e. probing pocket depths, furcation involvements, tooth mobility, and periapical radiographs) from the initial examination are shown in Figs. 31-17, 31-18, and 31-19.

The data obtained from the initial examination disclosed the presence of an advanced destruction of the supporting tissues in most parts of the dentition (Fig. 31-18) and the presence of several angular bony defects (Fig. 31-19). The full-mouth plaque score (FMPS) and full-mouth bleeding score (FMBS) were 32% and 86%, respectively. The patient was systemically healthy and a former smoker.

Diagnosis

The patient was diagnosed with generalized chronic periodontitis with furcation involvement.

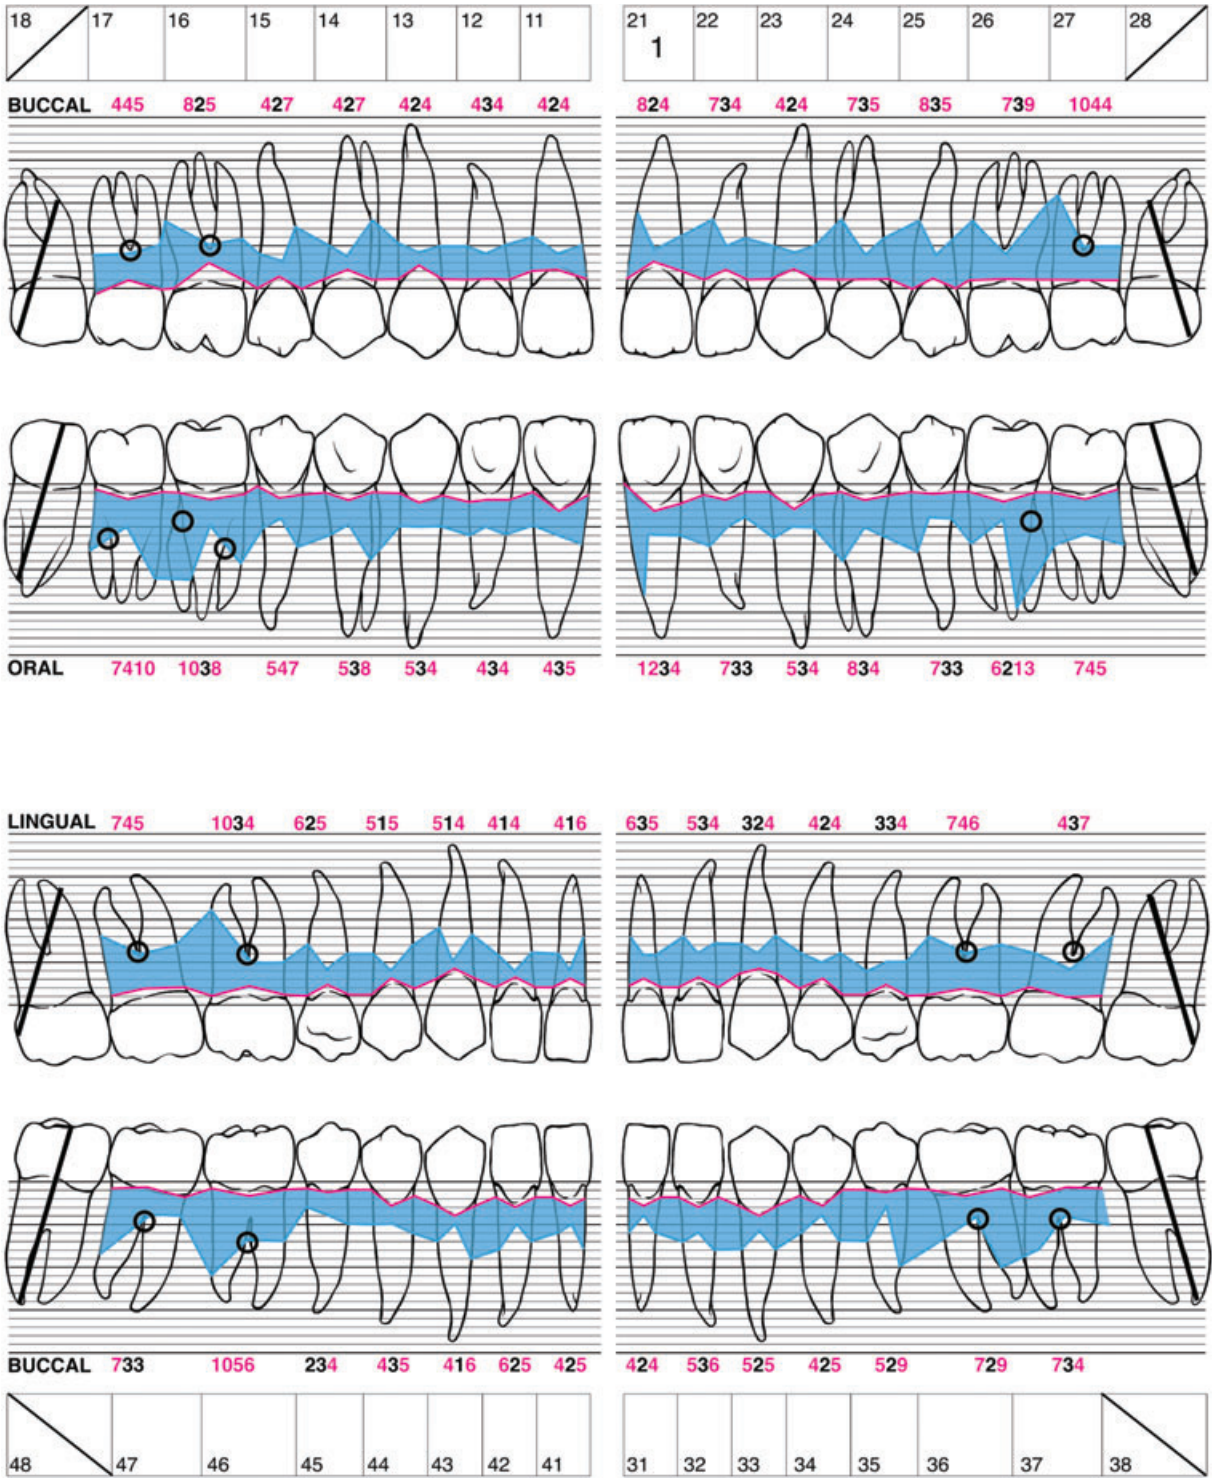

Fig. 31-18 Periodontal chart of the patient presented in Fig. 31-17.

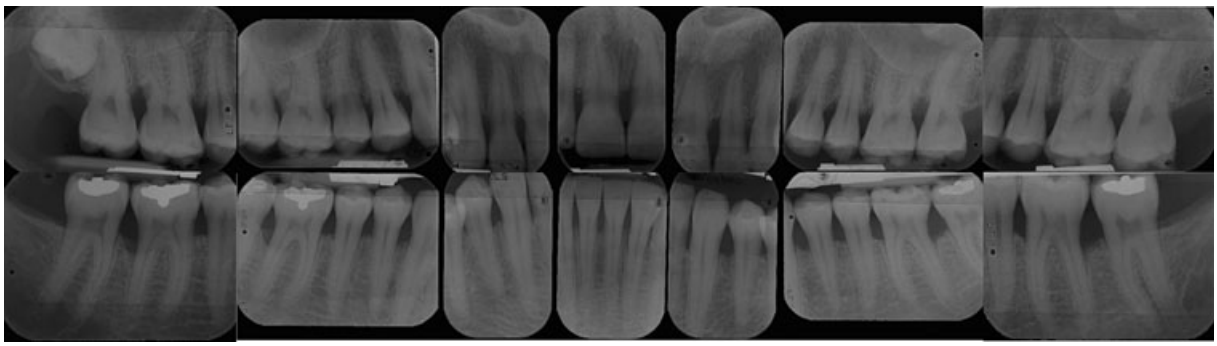

Fig. 31-19 Radiographs of the patient presented in Fig. 31-17.

Etiology

The supra- and subgingival bacterial deposits were identified as the main etiologic factors. Past cigarette smoking was considered a modifying factor.

Pre-therapeutic single tooth prognosis

Teeth 28, 38, and 48 were missing. Tooth 18 was impacted and considered irrational-to-treat. Teeth 13, 12, 11, and 23 in the maxilla and from 45 to 35 in the mandible were classified as secure. A doubtful prognosis was assigned to 17, 16, 15, 14, 21, 22, 24, 25, 26, and 27 in the maxilla and to 36, 37, 46, and 47 in the mandible (Fig. 31-20).

Treatment planning

In the treatment planning of this young patient, it seemed reasonable to anticipate the retention of all teeth of his periodontally compromised dentition. The prerequisites for a good long-term prognosis after therapy included (1) optimal self-performed plaque control, (2) proper healing of the periodontal tissues following non-surgical and surgical therapy, and (3) a carefully monitored maintenance care program. As stated above, tooth 21 displayed increased mobility. This mobility, however, did not disturb the chewing comfort of the patient.

In such a young patient, extensive efforts were made to treat inflammatory periodontal disease pro-

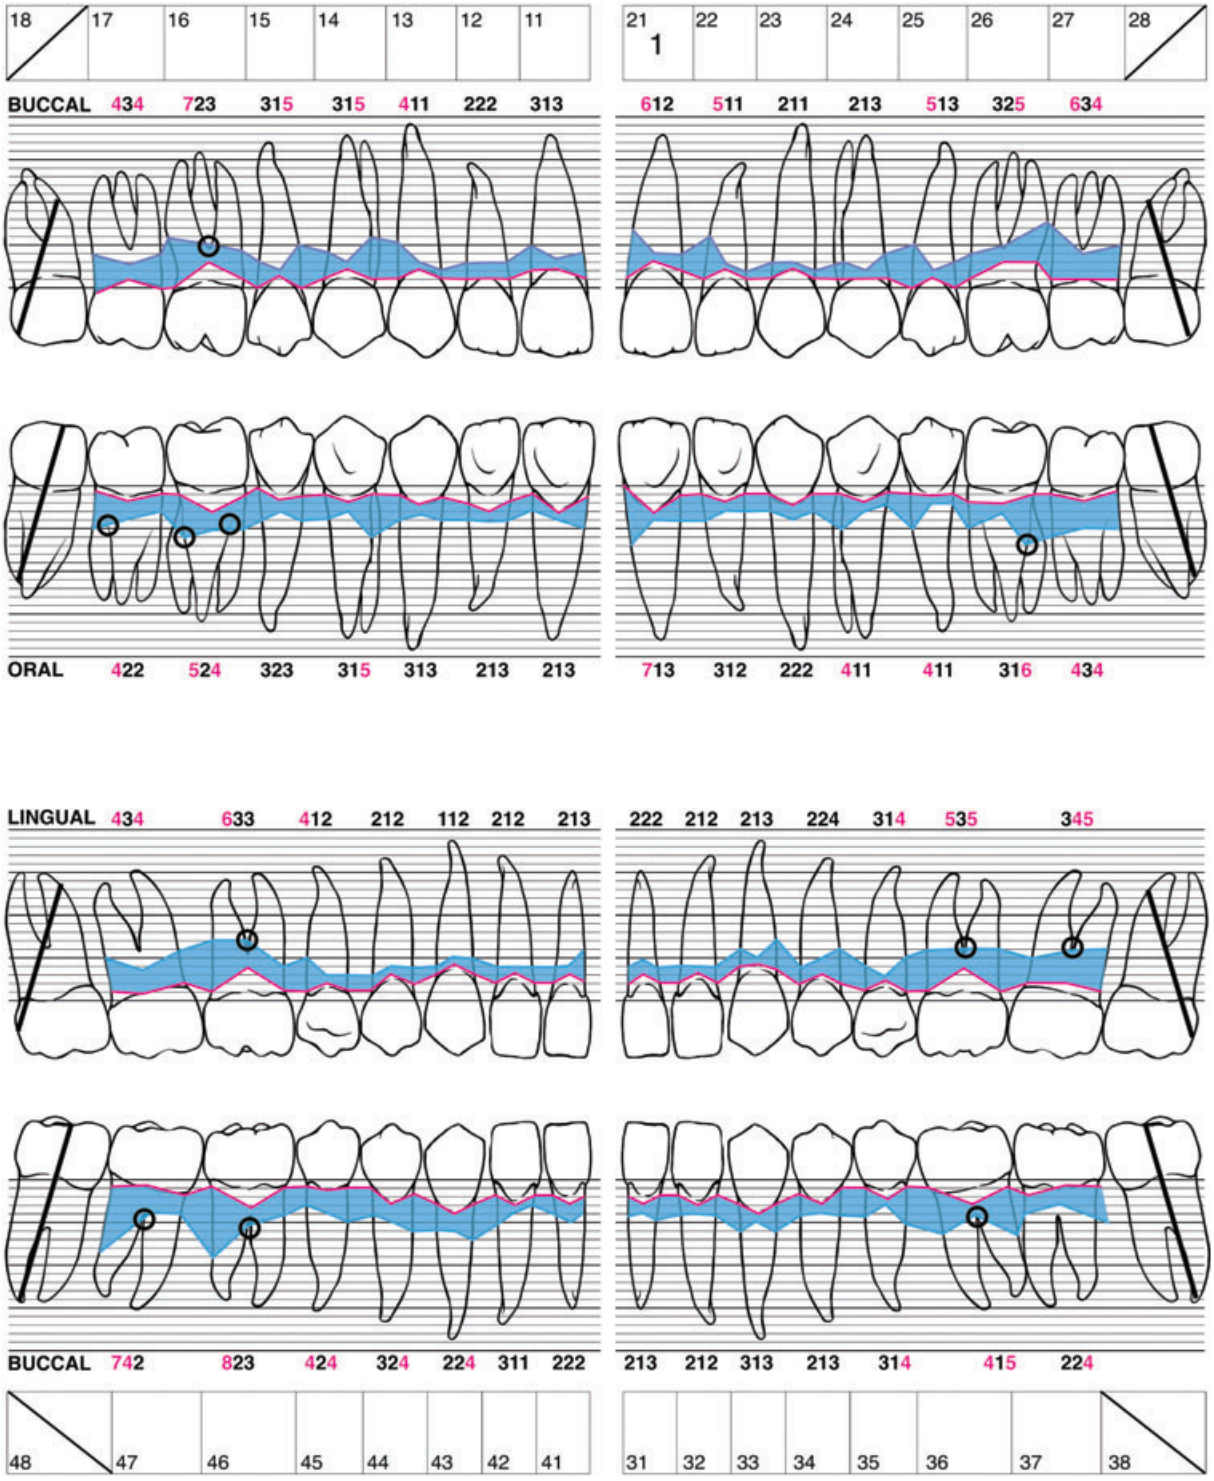

Fig. 31-22 Periodontal chart of the patient presented in Fig. 31-17 at re-evaluation after initial therapy.

perly in the entire dentition, in order to avoid tooth extraction and subsequent prosthetic rehabilitation.

Treatment

Subsequent to initial examination, the patient was given a detailed "case presentation" and information regarding alternative goals of and prerequisites for the overall treatment. This information included a description of the role of dental biofilms in the etiology of periodontal disease and the significance of optimal plaque control for a successful outcome of therapy. A treatment program was subsequently planned which aimed at maintaining all teeth. The overall treatment was performed in the sequence described below.

Initial cause-related therapy

The patient was counseled not to start smoking again. After thorough motivation, the patient was instructed

Fig. 31-23 (a-c) Intra- and postsurgical views of the upper front area of the patient presented in Fig. 31-17.

Fig. 31-24 (a–c) Clinical front and lateral views of the patient presented in Fig. 31-17 at the final examination.

in the toothbrushing technique according to Bass and in the use of interdental brushes. Scaling and root planing of all teeth were performed under local anesthesia. The front and lateral views as well as the periodontal chart at re-evaluation after initial therapy are presented in Figs. 31-21 and 31-22, respectively.

Additional therapy

The need for additional therapy was based on the re-evaluation after initial therapy (Fig. 31-22). Periodontal surgery in conjunction with regenerative procedures was deemed necessary in all quadrants. During access flap surgery in the first quadrant extending from 13 to 17, tooth 18 was extracted.

Between the upper front teeth 11 and 21, the modified papilla preservation technique (Cortellini *et al.* 1995) was incorporated in the surgical procedure to gain access to the angular bony defect of tooth 21 (Fig. 31-23). In this area, the application of enamel matrix derivatives (i.e. Emdogain®) aimed at regenerating the lost periodontal tissues on the mesial aspect of 21.

In the third quadrant, the surgical access flap extended from 35 to 37. In the fourth quadrant, flap surgery in conjunction with the simplified papilla preservation technique (Cortellini *et al.* 1999) was used to gain access to the angular bony defect on the distal aspect of 46. In this area, the application of enamel matrix derivatives (i.e. Emdogain®) aimed at regenerating the lost periodontal tissues. Six months after completion of the corrective phase (Fig. 31-24), a re-evaluation of the periodontal conditions (Fig. 31-25), including radiographs (Figs. 31-26 and 31-27) followed by a PRA, were performed.

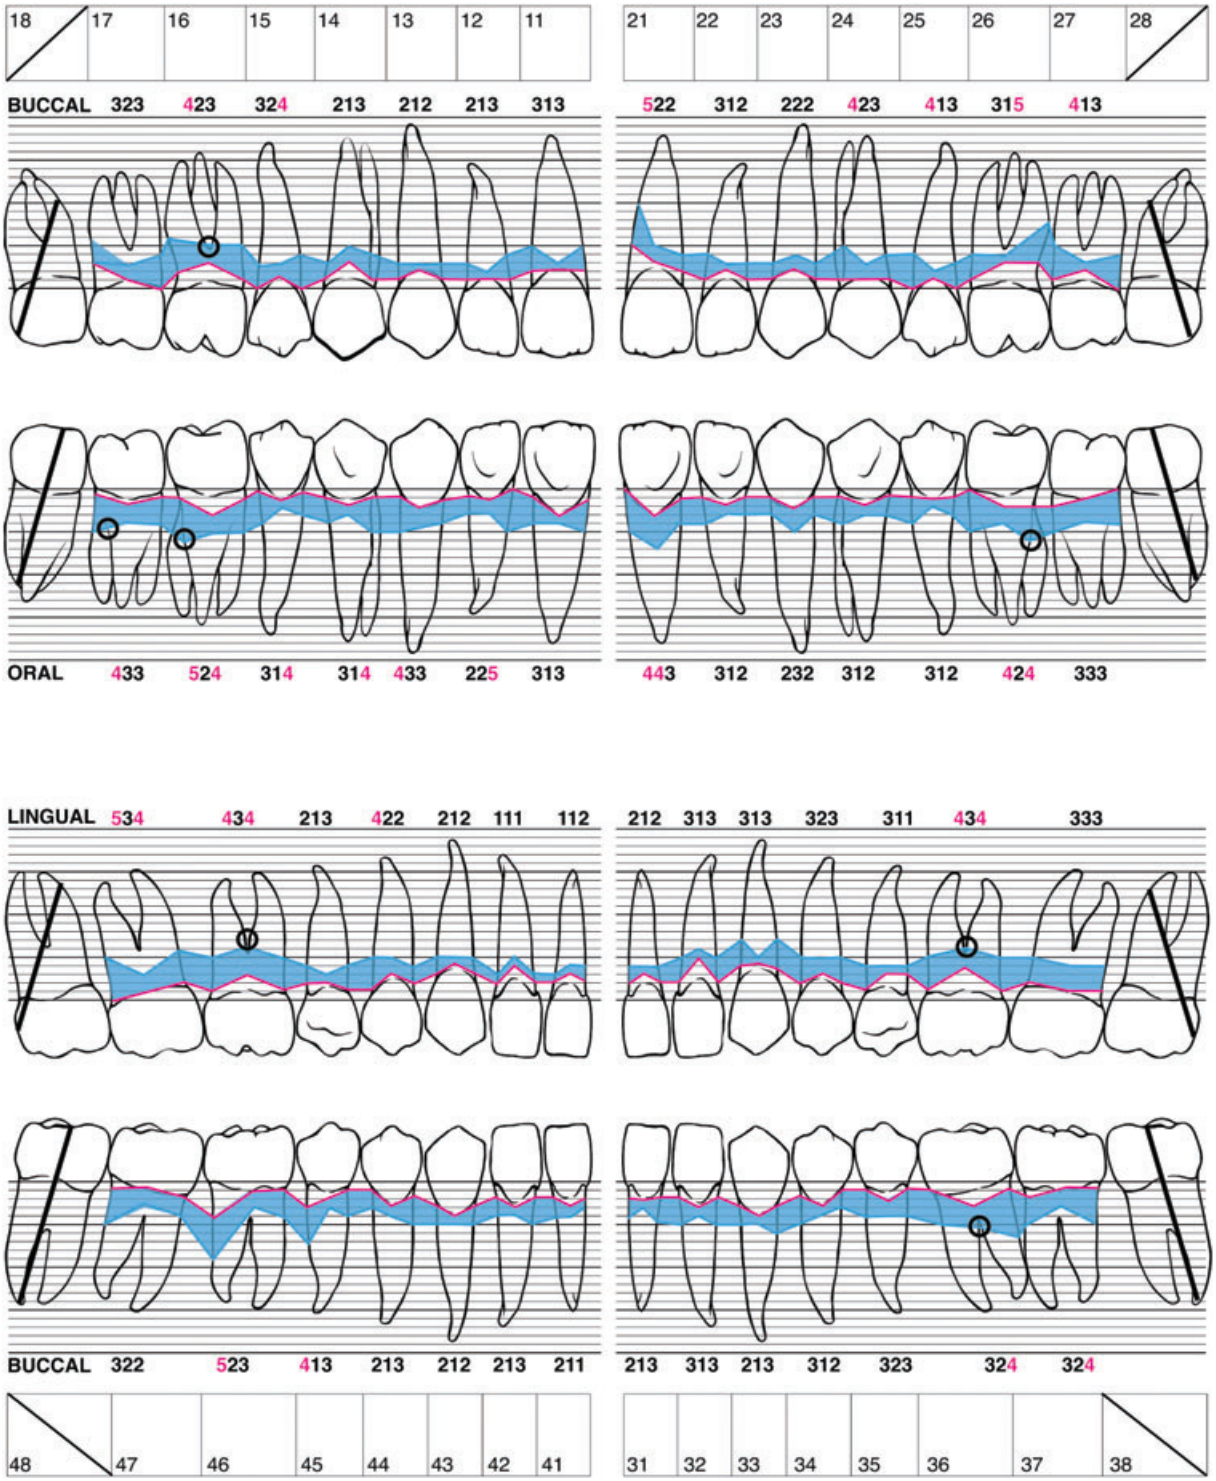

Fig. 31-25 Periodontal chart of the patient presented in Fig. 31-17 at the final examination.

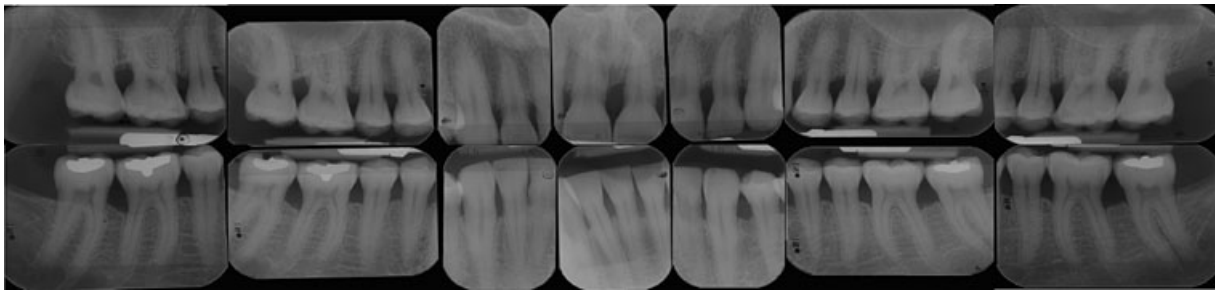

Fig. 31-26 Radiographs of the patient presented in Fig. 31-17 at the final examination.

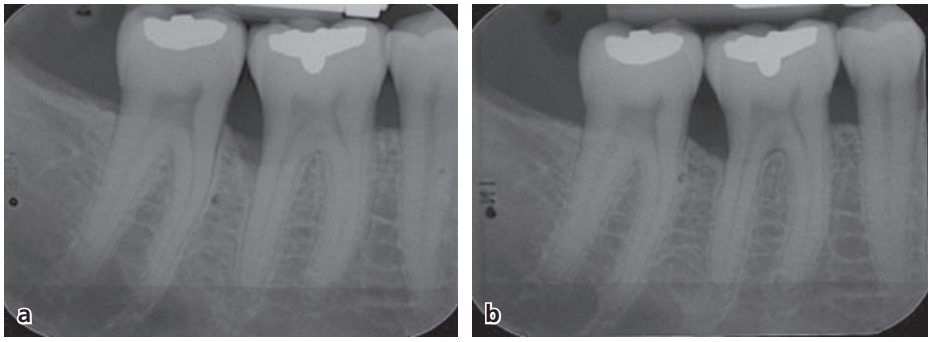

Fig. 31-27 Radiographs before (a) and after (b) periodontal regeneration of the angular bony defect on the distal aspect of tooth 46.

Supportive periodontal therapy

After completion of initial and corrective therapy, the patient was recalled for maintenance care every 3 months. During recall appointments, sites bleeding on probing and with a PPD ≥5 mm were re-instrumented. If necessary, the patient was remotivated and re-instructed in oral hygiene procedures. Fluoride was regularly applied in order to prevent the onset of dental caries.

Chapter 32

Treatment Planning for Implant Therapy in the Periodontally Compromised Patient

Jan L. Wennström and Niklaus P. Lang

The use of dental implants for replacement of missing teeth is a viable option in the rehabilitation of the periodontally compromised patient, and certainly the availability of this treatment option may also influence our decisions regarding the preservation of teeth with varying degrees of periodontal tissue destruction.

Prognosis of implant therapy in the periodontally compromised patient

Global data on survival rates of dental implants indicate a rather low incidence of implant loss. The question is, however, whether the long-term prognosis for implants is better than that for teeth. In a systematic review by Berglundh *et al.* (2002), including 16 studies reporting data on implant-supporting fixed partial dentures (FPDs), the overall 5-year failure rate was calculated as about 5%. In the few studies that included a follow-up of 10 years the figure for implant loss was about 10%. It should be noted, however, that these studies did not specifically address the prognosis of implant therapy in periodontally compromised patients. Hardt *et al.* (2002) reported from a 5-year study that 8% of the implants were lost in patients who at time of implant placement presented advanced loss of periodontal support at their natural teeth. The corresponding figure in patients without periodontal tissue destruction was only 3% (Table 32-1). In the periodontally compromised patients most of the implants that were lost were so-called late failures. Furthermore, after 5 years 64% of the periodontally compromised patients showed a mean bone loss at the implants of >2 mm compared to only 24% among the non-compromised patients. Karoussis *et al.* (2003) found a failure rate of 10% after 10 years in patients that had been treated for periodontitis before implant placement, compared to 4% in patients who had received implant therapy because of tooth loss for reasons other than periodontal disease. The data reported above indicate that there is an increased risk for implant failure in individuals susceptible to periodontitis.

A question of concern in relation to treatment decisions in a periodontally compromised patient is whether the failure rate of implants is different from that of teeth. In order to give an answer to this

Table 32-1 Proportion (%) of implants lost in relation to experience of destructive periodontal disease

König *et al.* (2002)	12	3.1	2.6
Karoussis *et al.* (2004)	10	5	5

question we have to know the incidence of tooth loss in periodontally treated patients. Based on data from studies involving patients that have been treated for advanced periodontal disease and thereafter been provided with regular supportive periodontal therapy (SPT), the average incidence of tooth loss during a 10-year period can be estimated to be between 2 and 5% (Table 32-2). These figures, in comparison with the data for implant loss presented above, indicate that the prognosis for long-term survival of implants is not better than that of properly treated periodontitis-affected teeth. Furthermore, evidence is accumulating that suggests that longitudinal bone loss at implants is positively correlated with periodontal disease susceptibility and that implant therapy in the periodontally compromised patient may not be as successful as the global data for implant therapy in general has indicated.

Strategies in treatment planning

A comprehensive clinical and radiographic examination forms the basis for the treatment planning of the periodontally compromised patient. In relation to implant therapy, careful risk assessments should also be made (see Chapter 30) and additional radiographic examinations may be required (see Chapter 28). The goal of the treatment is to satisfy the patient's demands regarding chewing comfort and esthetics, with a favorable long-term prognosis of the restoration. The use of implants as a means to restore chewing function and esthetics in the periodontitis-susceptible patient has to be carefully evaluated in relation to the patient's standard of infection control. In partially dentate patients with remaining periodontal lesions, implants are rapidly colonized by periodontal pathogens, which indicates that periodontal pockets may act as reservoirs for microbial colonization of implants (see Chapter 10). Since there is no evidence that the host response to the microbial challenge is altered when a tooth is substituted with an implant, it should be anticipated that a periodontitis-susceptible individual with improper infection control will face similar risk for disease-induced bone loss at implants and teeth.

Elimination of periodontitis lesions before implant placement and the establishment of a high standard of infection control are consequently decisive factors for the success of implant therapy. Regular recalls for supportive care should be scheduled after the completion of the therapy (see Chapter 59). Provided such a treatment program is adhered to, the long-term success of implant therapy in the periodontally compromised patient may not deviate from that in a non-susceptible patient (Baelum & Ellegaard 2004; Wennström *et al.* 2004).

Treatment decisions – case reports

Posterior segments

In the periodontally compromised patient the posterior segments of the dentition are usually those that are most severely affected by the disease and tooth loss. Figure 32-1 shows the clinical and radiographic status of a 53-year-old male following the completion of basic periodontal therapy for the establishment of infection control. Following periodontal treatment, the patient, originally diagnosed with severe chronic periodontitis, demonstrated a high standard of self-performed infection control and all lesions in the periodontal tissues have now been resolved. Because of the severity of the periodontal destruction, remaining teeth posterior to the canines in the maxilla as well as one remaining mandibular molar had to be removed. Hence, the dentition is markedly reduced, not only with regard to the number of teeth but also in terms of the amount of remaining periodontal support. From a chewing comfort point of view the patient is in need of prosthetic rehabilitation, particularly in the posterior segments of the maxilla. The treatment options available include (1) a removable prosthesis or (2) implant-supported FPDs. Considering that the remaining teeth show slightly increased mobility, the treatment alternative involving implant-supported FPDs seems most appropriate. In addition, the patient would if possible prefer to have fixed prosthetic reconstructions.

Clinical and radiographic evaluation of the posterior jaw segments of the maxilla revealed that two implants might be placed in quadrant 1 between the canine and the anterior border of the maxillary sinus, while the dimension of the bone inferior of the sinus was judged inadequate for placement of implants (Fig. 32-1b,c). If the implant in position 15 was placed along the anterior wall of the sinus cavity and was angulated slightly distally, space might be available to insert a pontic between the two implants and to provide the patient with a three-unit FPD. In the quadrant 2, the bone dimensions were more

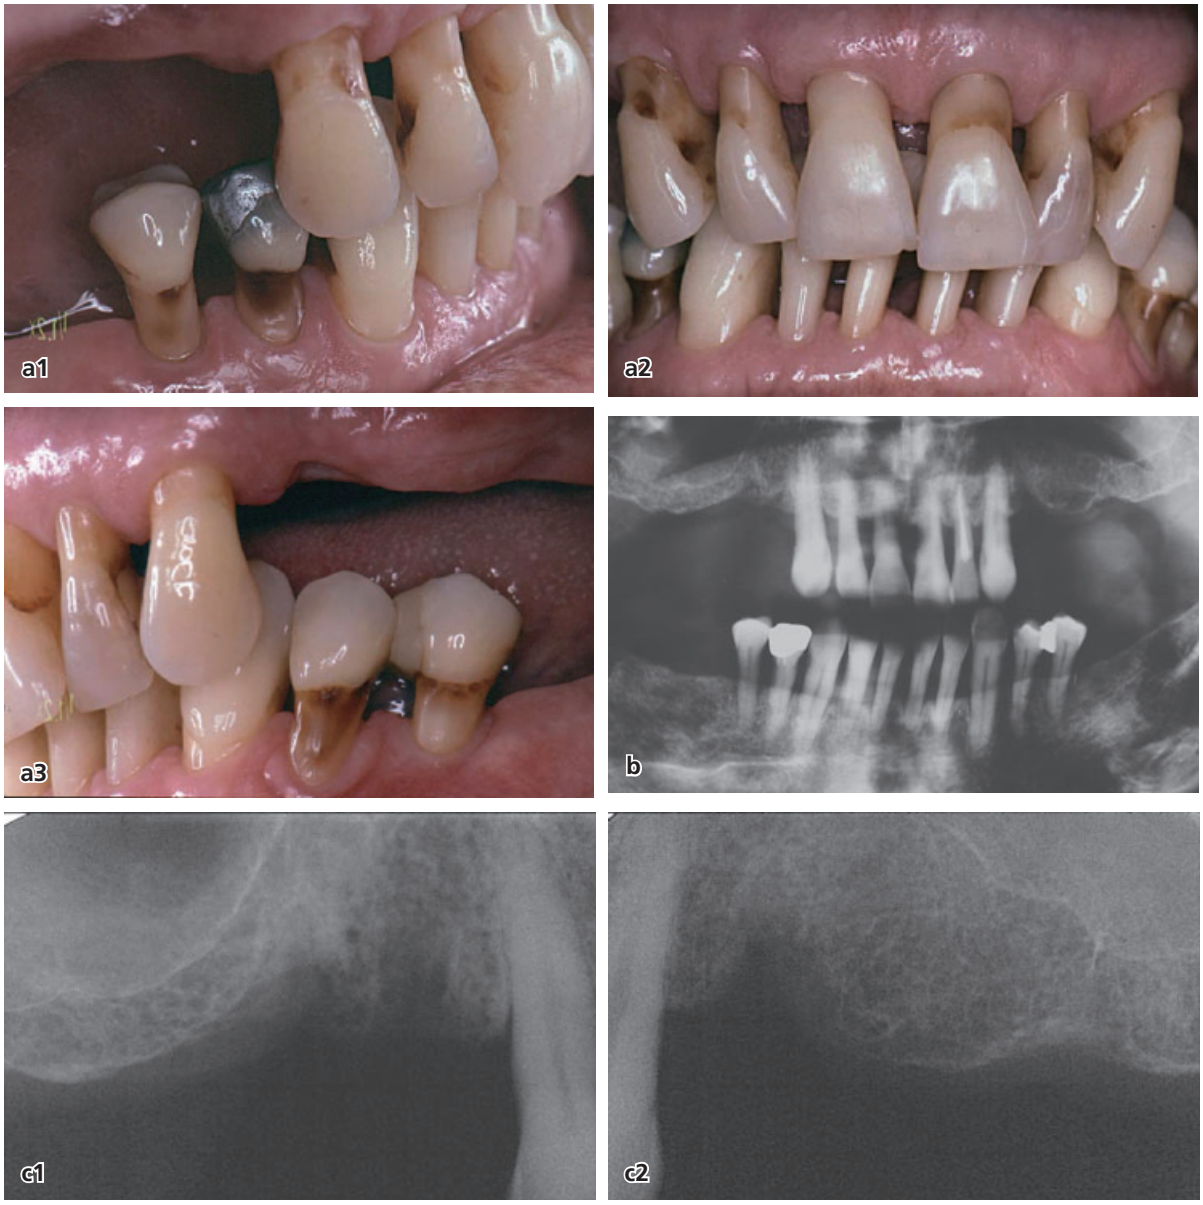

Fig. 32-1 (a–c) A 53-year-old male patient (H.L.) with periodontally compromised dentition. Clinical and radiographic status after periodontal treatment and establishment of infection control.

favorable and it was judged feasible to install three implants. Hence, by providing the patient with two three-unit implant-supported FPDs in the posterior segments of the maxilla a premolar occlusion could be established. The patient considered this treatment solution to be satisfactory with regard to his demands for improved chewing function. He had no requests for improved esthetics in the anterior segments, most likely because of a low lip line and because he only exposed the incisial half of the crown when smiling.

Figure 32-1d–f shows the outcome of the restorative treatment. In order to further improve the patient's chewing comfort a single implant was inserted in the left side of the mandible, after the second premolar had been tilted mesially. After completion of the restorative treatment the patient was enrolled in a maintenance care program, including recalls once every 6 months to secure a high standard of infection control and to provide preventive means to reduce the risk for development of root caries. The 10-year follow-up status (Fig. 32-1g–h) reveals healthy marginal tissues and no loss of supporting structures, neither at the implants nor at the teeth. The standard of self-performed infection control has been excellent throughout the follow-up period.

In conclusion: The treatment outcome in this case clearly illustrates that the periodontitis-susceptible patient can be successfully treated with the use of implants and without signs of peri-implant bone loss over time, provided proper infection control is established and maintained. The recall visits for supportive therapy must include careful evaluation of both the periodontal and the peri-implant tissues for detection of signs of pathology, and proper decisions regarding indicated treatment (see Chapter 59).

Tooth versus implant

Our treatment decisions regarding implant therapy or advanced periodontal therapy often relate to a single tooth. Figure 32-2(a,b) illustrates such a case. A 67-year-old woman presents with a localized advanced periodontal lesion at an abutment tooth in a three-unit FPD. The FPD is about 15 years old and the patient has no esthetic or functional complaints with regard to the FPD. Tooth 15 has a 10 mm deep pocket at the mesial aspect. The pocket is associated with a wide angular bone defect, and the tooth is positioned with its root in close proximity to the anterior wall of the maxillary sinus. If the tooth is extracted one may anticipate a marked remodeling of the ridge in the area, and the amount of bone available in the region might become insufficient for implant placement to support a new FPD, unless sinus elevation and bone grafting procedures are performed.

The question in the treatment planning with regard to tooth 15 is whether there is a reasonable chance to save 15 and maintain the FPD with periodontal therapy, or should the tooth be extracted and implants placed to support a new FPD? Considering the great functional value of the tooth, it was decided to perform flap elevation and to evaluate the potential for tissue regeneration. Following debridement (Fig. 32-2c), it was observed that the defect was wide and had the morphology of a combined one-/two-/three-wall defect. A regenerative approach (application of enamel matrix proteins; see Chapter 43) was selected. The healing resulted in 6 mm gain in clinical attachment level and radiographic bone fill. The amount of

soft tissue recession was minimal as seen from the 6-year follow-up documentation (Fig. 32-2d, e).

In conclusion, considering that implant therapy in this case most likely would have required sinus elevation and bone grafting to satisfy the patient's demands for esthetics and chewing function, the maintenance of 15 through proper periodontal therapy was of great benefit for the patient.

Aggressive periodontitis

Figure 32-3 shows a 22-year-old female patient diagnosed as a case of aggressive periodontitis. The first molar in the maxillary right quadrant and in the mandibular left quadrant have already been lost due to advanced periodontal destruction. The patient is asking for prosthetic replacement of the missing

Fig. 32-3 *Continued*

teeth. The clinical examination also disclosed the presence of deep angular defects at the first molar in the mandibular right quadrant and at the second premolar in the maxillary right quadrant. It seems reasonable to plan for implant-supported restorations to replace the missing 16 and 36. The more difficult question, however, is related to the treatment of the periodontally compromised 15 and 46 (Fig. 32-3c,d). Is it possible to successfully eliminate the periodontal lesions at 15 and 46 with a good long-term prognosis for the teeth? Or should the teeth be removed and replaced with implant-supported restorations? For tooth 15 extraction may be seen as a rational decision since implant therapy is planned in the region of 16. However, from an esthetic perspective it would be preferable to maintain 15 because the crown is intact

and there is no loss of attachment or soft tissue height at the mesial aspect of the tooth (Fig. 32-3b).

Patients with aggressive periodontitis can be successfully treated, and this is well documented in the literature. Further, by applying a regenerative method in the surgical treatment of deep angular defects like those at 15 and 46, the chance of attachment gain of a magnitude of >4 mm is markedly increased (Giannobile *et al.* 2003; Murphy & Gunsolley 2003). Hence, the treatment decisions made in this case were to first establish proper infection control and then to apply a regenerative surgical approach (guided tissue regeneration) in the periodontal treatment of the lesions at 15 and 46.

Evaluation of the periodontal healing revealed closure of the pockets and *de novo* bone tissue formation. Single implant-supported restorations were subsequently performed to restore for the loss of teeth 16 and 36 (Fig. 32-3e). After completion of the active treatment the patient was assigned to a supportive care program with recall appointments once every 6 months. Fig. 32-3f–i illustrates the outcome at 12 years post treatment. The regained height of the periodontal tissue support at 15 and 46 following the active treatment was maintained over the years, and optimal bone height is seen around the single implants. The good long-term prognosis in this case is attributed to a high quality of infection control and careful monitoring during the maintenance period.

Furcation problems

Even if the goal of the treatment of patients with periodontitis should be to preserve the teeth, there may be situations when this goal seems less meaningful in relation to the patient's need for prosthetic rehabilitation. Such a situation is illustrated in Fig. 32-4(a–d). The patient is missing the two premolars in the first quadrant and the molars present with advanced periodontal destruction and through-and-through furcation involvement (grade III). The patient requests a fixed restoration to substitute for the missing premolars. A possible treatment solution following periodontal therapy could include root sepa-

Fig. 32-4 A 52-year-old male patient with advanced periodontal destruction at remaining molars in the maxillary right quadrant. (a–d) Clinical and radiographic status at the initial examination. (e,f) Clinical and radiographic status 2 years after active treatment.

ration of the molars, after proper endodontic therapy, and the maintenance of, for example, the palatal roots of the molars to be used as posterior abutments in a fixed tooth-supported prosthesis 17 . . . 13. However, advanced inter-radicular periodontal destruction was identified by furcation probing, indicating that the palatal roots might not have enough remaining periodontal support in order to provide functional stability of a straight FPD (17 . . . 13). The clinical and radiographic examination reveals that the alveolar process in the premolar–molar region has proper dimensions for implant placement. An alternative treatment solution to satisfy the patient's demands for improved function and esthetics could therefore include implant placement to support a FPD.

The decision made in this case was to extract the two molars and, following proper periodontal treatment of the remaining dentition and establishment of adequate infection control, provide the patient with a three-unit implant-supported FPD and a single-crown restoration on tooth 13 (Fig. 32-4e,f). After completion of active treatment this patient was enrolled in a maintenance care program including recall appointments once every 4 months.

Single-tooth problem in the esthetic zone

Figure 32-5(a–e) illustrates the maxillary front tooth region of a 45-year-old female patient diagnosed with generalized chronic periodontitis. The right central incisor has severe periodontal destruction with probing pocket depths of 10–11 mm and obvious signs of inflammation at its distal and palatal surfaces. The tooth responded positively to sensibility testing. Interdental black triangles can be seen in the entire anterior tooth region because of approximal loss of periodontal attachment and soft tissue recession. Based on the results of the comprehensive examination, tooth 11 was judged to have a questionable prognosis, whereas it would be possible to resolve the periodontal lesions at the other anterior teeth by non-surgical means and improved self-performed infection control. Since the patient had a high lip line, potential recession of the soft tissue margins as a consequence of the treatment was a factor that had to be considered, particularly in relation to the treatment decision for the severely affected right central incisor. By regenerative therapy it might be possible to maintain the tooth, but will the treatment result in acceptable esthetics? The fact that the defect had a wide extension (buccally–lingually) and that the adjacent teeth presented with approximal attachment loss indicated that there was an obvious risk for loss of tissue height during healing following a surgical intervention. An alternative treatment approach could include the extraction of tooth 11 and to perform installation of a single implant. This alternative solution would also offer the possibility of correcting the position of the crown of 11. In discussing the different treatment alternatives and their consequences with the patient, it was apparent that she preferred to have the position of the tooth corrected as part of the treatment. Hence, based on the careful analysis of the esthetic problems associated with the treatment of the tooth, the decision made was to extract the tooth and make an implant-supported restoration. By the use of the crown together with a portion of the root as a pontic, support to the surrounding soft tissues during initial healing of the extraction socket was provided (Fig. 32-5f).

Evaluation of the outcome of the cause-related phase of therapy, which included oral hygiene instructions, plaque control evaluations, and full-mouth pocket/root debridement, disclosed no remaining pathologically deepened pockets in the front tooth region (Fig. 32-5g). The radiographic evaluation of the extraction site 2 months after the removal of 11 (Fig. 32-5h) showed a preserved bone height at the neighboring approximal tooth sites and gain of bone in the extraction socket. Clinically only minor changes had taken place in the position of the soft tissue margin at the extraction site. A single implant was installed and after 3 months the prosthetic therapy was completed.

Following the completion of the active treatment, the patient was scheduled for supportive care every 6 months. Figure 32-5(i–k) shows the clinical and radiographic status at the 1-year follow-up examination. The position of the soft tissue margin is located at a similar level at the implant-supported crown and the contralateral incisor. Compared to the pre-treatment conditions (Fig. 32-5a), only minimal changes in the position of the soft tissue margins at the implant-borne restoration are evident. Overall some recession of the soft tissue margin has occurred as a consequence of the establishment of healthy marginal tissues.

In conclusion: Although it may be possible to maintain a tooth with severe local periodontal destruction by regenerative periodontal surgery, soft tissue recession as a consequence of the treatment may render the treatment outcome unsatisfactory from an esthetic perspective. Selection of a treatment approach involving tooth extraction and implant therapy instead of periodontal therapy should be based on a careful evaluation of the potential of the various treatment approaches to satisfy the patient's demands for esthetics.

Conclusions

- The prognosis for the properly treated periodontitis-affected tooth is at least as good as that for the implant.
- An increased risk of failure of implant therapy has been reported for periodontitis-susceptible patients.
- Proper infection control is a critical factor for the long-term success of implant therapy in the periodontally compromised patient.

Chapter 33

Systemic Phase of Therapy

Niklaus P. Lang and Hans-Rudolf Baur

Introduction

The systemic phase of periodontal therapy should be concerned with general health implications of periodontal diseases and periodontal treatment. While the former aspects are described in Chapters 12, 13, 16, and 21, the latter aspects are presented in this chapter.

The systemic phase of periodontal therapy is designed to protect the patient against unforeseen systemic reactions, to prevent complications affecting the general health of the patient and to protect the health care providers from (predominantly infectious) hazards in conjunction with the treatment of risk patients.

In order to adequately plan the systemic phase, results from a health questionnaire (Chapter 26) filled in by the patient in the waiting area, the family and social history, the general medical and, in particular, the smoking history have to be evaluated. Also, any extra- and intraoral findings pertinent to the patient's systemic health have to be considered.

The systemic phase of periodontal therapy encompasses:

- Precautions for protecting the general health of the dental team and other patients against infectious and contagious diseases
- Protection against potentially harmful systemic effects of routine therapy
- Making allowances for systemic diseases or disorders that may influence the etiology of the patient's periodontal conditions, the healing potential, and the systemic response to therapy
- Controlling anxiety and low pain threshold
- Risk assessment and considerations of systemic supportive therapy
- Smoking counseling and instituting tobacco use cessation programs.

Protection of the dental team and other patients against infectious diseases

As a rule, routine periodontal therapy should be postponed in a patient with an active contagious state of a disease until the patient has received adequate medical treatment. Given the fact that patients may not always be aware of such a state or that all manifestations of disease may have abated, but the patient may still be carrier of infectious agents, routine dental treatment should be carried out under special precautions against transmission of the most serious diseases being transmitted orally. These include infectious hepatitis (Levin *et al*. 1974), HIV infection, and venereal diseases (Chue 1975). Hygiene in the dental office, therefore, has to address the most contagious level of infective agents, the hepatitis virus, and cope with the prevention of the transmission of these infections. As a minimal precaution, the wearing of rubber gloves and mouth masks is strongly recommended for all dental therapy in all patients. Also protective glasses for both the therapist and the patient should be worn during procedures generating aerosols.

Herpes simplex virus (Nahmias & Roizman 1973) and tuberculosis are other infectious diseases with a high transmission potential. Special precautions should be observed in patients with a recent history (2–3 years) of infectious hepatitis, although the dental team may be vaccinated against hepatitis. If the medical history and the oral examination reveal that the patient may have overt or hidden systemic

disease, she/he should be referred for medical examination prior to enrolling the patient into comprehensive periodontal therapy.

Protection of the patient's health

A number of systemic conditions may affect treatment planning, although there may be no direct relevance in the pathogenesis and healing potential of periodontal lesions. Since over 50% of all patients over 40 years of age may have systemic conditions or take medications affecting periodontal therapy, these aspects have to be carefully appraised prior to instituting therapy.

For patients with life-threatening systemic conditions, such as coronary insufficiency or hypertensive heart disease, the patient's physician should be consulted about appropriate patient management and whether treatment should be performed in a hospital or clinic rather than a private practice setting. If the dental office is considered to be the adequate environment for treating these patients, short appointments should be planned and treatment performed with complete pain control using local anesthesia without any or with minimal vasoconstrictive drugs.

Prevention of complications

The complications most commonly encountered in the dental office are:

- Infection
- Bleeding
- Cardiovascular incidents
- Allergic reactions.

These may be prevented if appropriate precautions are taken. Hence, gaining awareness of possible complications from a medical history is an important step for treatment planning and total patient care.

Infection, specifically bacterial endocarditis

Patients with cardiac disease or disorders involving the endocardium are susceptible to endocarditis as a result of blood-borne infection. Such conditions include rheumatic heart disease, congenital valvular heart defects, aortic valvular diseases, and collagen diseases involving the endocardium. In addition, patients wearing prosthetic heart appliances belong to this risk group.

The major procedures thought to be the cause of bacterial endocarditis are extractions and scaling and/or root planing leading to significant bleeding and possible bacteremia (Durack 1995). Hence, it is not surprising that national societies have issued guidelines for antibiotic prophylaxis against bacterial endocarditis (USA: Dajani *et al*. 1997; UK: Gould *et al*. 2006; FDI, 1987). The common belief is that a bacteremia occurs only when dental procedures cause bleeding and does not occur when there is no bleeding. Hence, procedures such as extractions, root instrumentation, and periodontal and implant surgical procedures would require antibiotic prophylaxis, while for example the placement of fillings does not. This hypothesis was addressed in a study in children in which 14 various dentogingival manipulative procedures were evaluated (Roberts *et al*. 1997). It was clearly demonstrated that no relationship existed between the existence of bleeding and bacteremia. However, the number of oral organisms isolated from the blood where bleeding was present was statistically significantly higher than when there was no bleeding. It was concluded that the cumulative exposure to bacteremia is significantly greater from "everyday" procedures, when compared to dental procedures and hence, the cause of bacterial endocarditis may be attributable to such cumulative everyday exposures that are often thousands to millions of times greater than that occurring following surgical procedures, such as extractions of teeth (Roberts 1999).

Antibiotic prophylaxis to prevent bacterial endocarditis is predominantly based on anecdotal and circumstantial evidence suggesting a causal association between various procedures and bacteremia (Baltch *et al*. 1982). A case study, however, did not identify a link between endocarditis and dental treatment (Guntheroth 1984; Strom *et al*. 1998). Moreover, accumulating evidence suggests that bacteremia may easily be produced, e.g. by toothbrushing or chewing, rather than by single procedures causing bleeding. Hence, endocarditis causation has shifted from procedure-related bacteremia to cumulative or "everyday" bacteremia (Gould *et al*. 2006).

Indeed, a recent systematic review of the Cochrane Collaboration (Oliver *et al*. 2004) concluded that there was no conclusive evidence to support the use of prophylactic penicillin to prevent bacterial endocarditis in invasive dental procedures. This review did not find any randomized controlled clinical trials, any controlled clinical trials or any cohort studies. From a total of three case–control studies (Imperiale & Horowitz 1990; Van der Meer *et al*. 1992; Lacassin *et al*. 1995), only one study (Van der Meer *et al*. 1992) complied with the inclusion criteria. Details of 349 individuals who developed definite native-valve endocarditis in the Netherlands within a 2-year period were collected. Controls had not been diagnosed with endocarditis, but had one of the cardiac conditions and were outpatients of one of five hospitals. Controls were matched for age and had undergone dental procedure within 180 days of their interview. No significant protective effect of antibiotic prophylaxis was seen against endocarditis.

It has to be realized, however, that clinicians feel bound by guidelines and medico-legal considerations to provide antibiotic prophylaxis rather than by the best scientific evidence available. Ethically, practitio-

Table 33-1 Recommendations of the British Society for Antimicrobial Chemotherapy (BSAC) for prophylaxis of bacterial endocarditis

Where a course of treatment involves several visits, the antibiotic regimen should alternate between amoxicillin and clindamycin.
Pre-operative mouth rinse with chlorhexidine gluconate 0.2% (10 ml for 1 minute).

Table 33-2 British Society for Antimicrobial Chemotherapy (BSAC) Prevention of Infective Endocarditis Guidelines Information for Patients and Parents February 2006

A BSAC group of experts has spent a lot of time carefully looking at whether dental treatment procedures are a possible cause of infective endocarditis (IE) (sometimes called bacterial endocarditis (BE)), which is infection of the heart valve.

After a very detailed analysis of all the available evidence they have concluded that there is no evidence that dental treatment procedures increase the risk of these infections.

Therefore, it is recommended that the current practice of giving patients antibiotics before dental treatment be stopped for all patients with cardiac abnormalities, except for those who have a history of healed IE, prosthetic heart valves and surgically constructed conduits.

The main reasons for this are the lack of any supporting evidence that dental treatment leads to IE and the increasing worry that administration of antibiotics may lead to other serious complications such as anaphylaxis (severe allergy) or antibiotic resistance.

The advice from the BSAC is that patients should concentrate on achieving and keeping a high standard of oral and dental health, as this does reduce the risk of endocarditis. Help for this will be provided by your Dental Professional.

British Society for Antimicrobial Chemotherapy (BSAC), 2 February 2006

ners need to discuss the potential benefits and harms of antibiotic prophylaxis with the patients and their cardiologists before the decision is made about administration (Oliver *et al*. 2004). Considering the change in paradigms regarding bacterial endocarditis, a task force of the British Society for Antimicrobial Chemotherapy has recently published new guidelines (Gould *et al*. 2006) (Table 33-1). According to these, the practice of giving patients antibiotics is reserved for those patients with a history of healed bacterial endocarditis, prosthetic heart valves, and surgically constructed conduits, while patients with cardiac abnormalities should no longer receive antibiotic prophylaxis before dental procedures. A patient information form has also been published (Table 33-2).

Bleeding

Due consideration must be given to patient on anticoagulant medication or patients on preventive anticoagulant drugs such as salicylates. For the first group of patients, a consultation with the patient's physician is indispensable. Especially prior to periodontal or implant surgical procedures, temporary adjustment of the intake of anticoagulant medication may have to be initiated in cooperation with the physician. Careful planning and timing of these procedures is mandatory.

Preventive anticoagulant therapy does not generally create problems for routine dental therapy, including surgical procedures, although consultation with the patient's physician still is advisable.

Individuals with known cirrhosis of the liver, or even patients with high alcohol consumption over many years without diagnosed cirrhosis, are at a potential risk for bleeding complications during periodontal and/or implant surgery, as their clotting mechanisms may be affected (Nichols *et al*. 1974). Again, medical consultation is recommended prior to periodontal treatment of such patients.

Extra precautions against bleeding should be taken when treating patients with any kind of blood dyscrasia or hemophilia. Following mandatory consultation with the patient's physician, it is recommended to render treatment in small segments (only a few teeth being instrumented at each visit) and to apply periodontal dressings over the treated area, even if the treatment only consisted of root instrumentation. With systematic periodontal treatment and institution of efficacious oral hygiene measures, the annoying symptom of oral bleeding can often be controlled irrespective of the patient's bleeding disorder.

Cardiovascular incidents

Cardiac patients are often treated with anticoagulants and, hence, may develop bleeding problems (as indicated above), especially if given drugs (e.g. aspirin, indomethacin, sulfonamide, tetracycline) that interact with coagulation. Other cardiovascular drugs (antihypertensive, anti-arrhythmic, diuretic) are often used in these patients which may increase the danger of hypotensive episodes during dental treatment.

Stress associated with dental procedures may precipitate anginal pain or congestive heart failure in patients with cardiovascular disease. Therefore, every effort should be made to keep procedures short and control anxiety and pain in this patient population.

Allergic reactions and drug interactions

Full knowledge of the patient's known allergies and the medications administered is essential before any drug is prescribed, administered or used during treatment. The most common allergic reactions encountered in the dental office are allergies to some local anesthetics (Novocain®), penicillins, sulfa derivatives, and disinfectants, such as iodine. In case of known allergies, such drugs have to be avoided. A consultation with the patient's physician is advisable to discuss the possible administration of replacement drugs.

Many patients – over 90% over the age of 60 years – regularly take medications for various systemic conditions, special attention has to be devoted to possible drug interactions, especially in the elderly. Drugs prescribed as part of periodontal therapy or used during treatment may interfere with the effectiveness of drugs the patient is already taking or create hazardous or synergistic action with such drugs. Hence, no new drugs should be prescribed without fully understanding their possible interaction with drugs already in use. Dentists should never change an existing drug therapy without prior discussion and preferably written consent of the physician.

Many patients regularly take tranquilizers and antidepressant drugs that have the potential for summation and synergistic effects with drugs that may be used during periodontal therapy. Moreover, the interaction with and potentiation of these drugs with alcohol should be discussed with the patient.

Systemic diseases, disorders or conditions influencing pathogenesis and healing potential

All possible attempts should be made to alleviate the effects of systemic diseases, such as blood disorders and diabetes mellitus, as much as possible before definitive periodontal treatment is initiated. However, cause-related therapy may easily be carried out and generally results in remarkable success even during active stages of these systemic conditions. How far the treatment plan should progress with respect to pocket reduction and/or regenerative procedures depends on the seriousness of the patient's systemic involvement and likewise, to a great extent, on the potential threat to the patient's health from incomplete periodontal therapy.

Diabetes control, as an example, may be facilitated by successful control of the periodontal infection (Grossi *et al*. 1997; Genco *et al*. 2005). Thus, periodontal treatment may have a beneficial effect on the systemic health of the patient (see Chapter 21). Palliative treatment of advanced periodontitis with furcation involvement and residual deep pockets that cannot be reduced should not be undertaken for such patients. Rather the involved teeth with repeated abscesses and pus formation should be extracted if needed to accomplish infection control.

Clinical experience indicates that the healing response of the periodontal tissues is as good in diabetic as in non-diabetic patients provided that the diabetes is fairly well controlled. However, juvenile diabetics may have angiopathic changes associated with a lowered resistance to infection that may require the use of antibiotics following periodontal or implant surgery. With controlled diabetes, premedication with antibiotics is not indicated. Hypoglycemia may become aggravated by the stress of periodontal surgery and, hence, precautions have to be taken to avoid hypoglycemic reactions in such patients.

Patients taking therapeutic doses of cortisone over a long period of time may yield considerable metabolic effects with systemic manifestations of a reduced rate of fibroblastic activity and hence, a lowered resistance to infection during wound healing. Nevertheless, such patients can be treated successfully by regular cause-related therapy with no significant delay in healing. The use of antibiotics is not recommended for these patients, unless there is a serious infectious condition in the mouth associated with the development of fever.

Control of anxiety and pain

Many patients interested in maintaining a healthy dentition do not regularly seek dental care because of anxiety and apprehension related to such treatment. Since modern dentistry offers a variety of effective means for controlling pain and apprehension, patients should no longer suffer from dental treatment. During history taking and the oral examination, the patient's profile regarding anxiety and pain thresholds should be explored.

Prior to therapy, it may be advisable to premedicate an apprehensive patient using diazepams (Benzodiazepine, Valium®, 2–5 mg) to be taken the night before, in the morning and half an hour before an

extensive and/or surgical procedure. Painless dental care can be achieved by carefully applying local anesthetics.

Post-operative analgesic medication, such as non-steroidal anti-inflammatory drugs (NSAIDs) with analgesic and antipyretic properties are recommended. Diclofenac potassium, the active ingredient of Voltaren® Rapide, inhibits prostaglandin synthesis by interfering with the action of prostaglandin synthetase. Following any kind of periodontal and implant surgery, 50 mg twice daily of Voltaren® Rapide is administered for 3 days. In addition, further adjunctive pain killers (Mefenaminic acid, e.g. Ponstan®, 500 mg not more than every 6–8 hours) may be prescribed depending on the individual patient's need and pain threshold.

Favorable personality interactions between the patient, the therapist, and the entire office staff may contribute to the control of anxiety, but may require more time and consideration than that allocated to the routine patient.

Smoking counseling

Cigarette smoking constitutes the second most important risk factor in the etiology and pathogenesis of periodontal diseases after poor oral hygiene standards. A careful assessment of the patient's smoking history is therefore indispensable. Depending on the duration of the exposure to tobacco smoking, daily consumption, and the patient's periodontal status, smoking counseling has to be undertaken as one of the primary measures. In all patients that smoke, the contributory role of tobacco consumption to the pathogenesis of periodontitis has to be addressed. Depending on the patient's response, smoking cessation programs may be instituted. Short-term interventions lasting 3–5 minutes using motivational interviewing techniques (Chapter 34) may be included during the initial phase of periodontal therapy. If a heavy smoker is ready to quit the habit, professional cessation programs may be the appropriate measures to take. Smoking counseling is further discussed in Chapter 34.

Conclusions

The goals of the systemic phase of periodontal therapy are to appraise the aspects that may require protection of both the dental team and the systemic health of the patient. Infection control in the dental office plays a central role. Protecting the patient against presumptive complications, such as infection, especially bacterial endocarditis, bleeding, cardiovascular incidences, and allergies, requires in-depth knowledge of the patient's medical history and oral examination.

Bacterial endocarditis prophylaxis is nowadays reserved for those patients with a history of a healed bacterial endocarditis, prosthetic heart valves or surgically constructed conduits, while the use of antibiotics before dental treatment is not necessary for patients with cardiac abnormalities. Patients with systemic diseases such as diabetes mellitus or cardiovascular diseases usually are treated with a number of medications that may interact with drugs prescribed during periodontal therapy. Precautions should be taken, and consultation with the patient's physician prior to systematic periodontal therapy is recommended.

It has to be realized that periodontal treatment may have a beneficial effect on the systemic health of the patient as well. Glycemic control may be facilitated in diabetics if proper periodontal therapy is rendered.

Finally, smoking counseling is part of modern periodontal treatment owing to the fact that, after inadequate oral hygiene standards, cigarette smoking constitutes the second most important risk factor for periodontitis.

Part 11: Initial Periodontal Therapy (Infection Control)

Chapter 34

Motivational Interviewing

Christoph A. Ramseier, Delwyn Catley, Susan Krigel, and Robert A. Bagramian

The importance of behavioral change counseling in periodontal care

Periodontal health is supported by appropriate behaviors such as regularly self-performed plaque control, avoidance of tobacco, and consumption of a healthy diet. Inadequate oral hygiene, tobacco use, and uncontrolled diet in type 2 diabetes mellitus, on the other hand, are shown to have a destructive impact on periodontal tissues. The prevention and control of periodontal disease needs to be addressed on both the population and the individual level. Efficient public health approaches consider the entire population and focus on health issues that present the largest burden within a community. The dental community involved with oral health care should gain an understanding of the health effects of inappropriate behaviors in order to successfully target prevention and disease control. As a consequence, services for primary and secondary prevention on an individual level oriented towards the change of inappropriate behavior become a professional responsibility for all oral health care providers.

Data from epidemiologic studies consistently reveal the prevalence of periodontal disease in more than 50% of the adult population (Albandar *et al*. 1999; Albandar 2002). In addition to the causal relationship with dental biofilms, a positive association with tobacco use has been documented (Bergstrom 1989; Haber *et al*. 1993; Tomar & Asma 2000). Tobacco use contributes to the global burden of public health with almost one third of the adult population using various forms of tobacco and an increasing number of annual deaths from tobacco-related diseases. Moreover, dietary excess has been shown to significantly impact chronic diseases including obesity, cardiovascular diseases, type 2 diabetes, cancer, osteoporosis, and oral diseases (Petersen 2003).

There is growing evidence that the patient's individual behavior is seen to be influential or even critical for the success of periodontal therapy; since the results of periodontal therapy appear to be limited in patients who especially lack appropriate behavior. In a recent literature review by Ramseier (2005) it was shown that second to plaque control, smoking cessation was the most important measure for the management of chronic periodontitis. Therefore, it appears to be reasonable in clinical concepts for periodontal care to (1) include assessments of patient behavior, and (2) if necessary apply effective behavior change counseling methods.

Traditional periodontal care includes the instruction of proper oral hygiene methods. In practice, as an example, a demonstration of a suitable toothbrushing method is given to the patient, followed by recommendations of both the frequency and the time spent per brushing. Past and recent studies on the effectiveness of oral hygiene instructions consistently revealed that the patient adherence to a proper daily oral hygiene regime generally remains poor (Johansson *et al*. 1984; Schuz *et al*. 2006). The reinforcement of oral hygiene habits through additional appointments can compensate somewhat for the ineffectiveness of one-time or repeated oral hygiene instructions. However, due to weak patient adherence, visits for supportive periodontal care are often cancelled,

resulting in a lack of professional maintenance care and the potential recurrence of periodontal disease (Wilson *et al*. 1984; Demetriou *et al*. 1995; Schuz *et al*. 2006).

Unfortunately, many health education approaches seem to be inefficient in accomplishing long-term change, potentially leading to frustration of both the patient and the clinician. The following hypothetical dialogue between a clinician (Dr) and a patient (P) illustrates how using a directive advice-oriented method for behavior change counseling can lead to an unproductive conversation and little likelihood of change by the patient:

Dr Are you flossing regularly?
P Yes, but not as often as I should.
Dr I strongly recommend that you floss every day. There are serious consequences if you don't floss frequently enough.
P I know I should do it more often, but . . .
Dr It is really important!
P I know . . . . . but I don't have the time!

Since the clinician doesn't offer the patient a chance to discuss the reasons to floss as well as the patient's perceived barriers to flossing, the conversation reaches an impasse and behavior change will be unlikely. In certain cases, the patient may even be blamed for poor compliance and further oral health education may be seen to be pointless.

There is a shortage of evidence in both the dental and behavioral literature on effective methods for behavior counseling in periodontal care, in particular regarding:

- Individual oral hygiene instructions for optimal oral hygiene
- Effective tobacco use prevention and cessation counseling to help abstain from tobacco
- Appropriate dietary counseling for a healthy diet.

In order to get reliably effective outcomes in periodontal care, it may be necessary to apply different behavior change counseling methods for each individual behavior. According to the best available evidence for oral hygiene instructions, the repeated demonstration of a cleaning device may be applied, while for tobacco use cessation, in addition to pharmacotherapy, the method of the five As (ask, advise, assess, assist, arrange) may be used (Fiore 2000). Additionally, type 2 diabetic patients or patients with a high carbohydrate diet may be referred to nutritionists for dietary counseling. From a practical point of view, however, it may be complicated and even discouraging to approach the periodontal patient with a variety of different methods targeting the same purpose: establishing appropriate behavior to improve the outcomes of both periodontal therapy and long-term supportive periodontal care.

Hence, aiming for simplicity, it may be preferable to apply one single method for behavior change counseling in periodontal care that is shown to be effective in both primary and secondary prevention of oral diseases. This method should be:

- Based on the best available evidence
- Applicable to oral hygiene behavior, tobacco use prevention and cessation, and dietary counseling
- Suitable for implementation by the dental practice team in a cost-effective way.

Development of motivational interviewing

As discussed, health *education* efforts provided by practitioners are frequently ineffective in changing patient behavior. Considerable behavioral research suggests that the root of this common problem can be traced back to a false assumption inherent in the health education approach. Specifically, that behavior change is simply a function of a patient having the requisite knowledge or understanding, and that it is up to the practitioner to provide the relevant information. Motivational interviewing (MI), in contrast, is based on a different assumption of human behavior change. It assumes that the knowledge is insufficient to bring about behavior change and that, instead, sustained behavior change is much more likely when change is connected to something the individual values. In other words, motivation is elicited "from within the patient" rather than externally imposed upon the patient by a practitioner. In MI, the assumption is that individuals have "within them" their own reasons for changing and that the role of the practitioner is to elicit and reinforce these reasons.

MI originated in the field of addictive behavior but has increasingly been applied to a wide variety of other behavior change problems, including health behaviors such as tobacco use and diet and exercise (Burke *et al*. 2004; Hettema *et al*. 2005). MI principles and methods have also been specifically adapted for brief interventions in medical settings (Butler *et al*. 1999; Rollnick *et al*. 1999) and have recently been tested in a dental setting (Weinstein *et al*. 2006).

History of motivational interviewing

William Richard Miller, the originator of MI, developed the method in response to his observations regarding the treatment of patients with alcohol problems in the 1970s. The standard approach to the treatment of alcoholic patients was confrontational, and failure of treatment was attributed either to "denial", seen as a personality deficit on the part of the client, or the failure of the client to engage with the program (Miller 1983). In contrast, he observed that the research literature suggested that positive outcomes were mostly related to a strong bond or "therapeutic alliance" between the counselor and the patient. Miller began to test his empathy-centered treatments on problem drinkers and found that change was occurring more quickly than with traditional methods (Moyers 2004). This brief treatment which used the *therapeutic alliance* and *empathy* to engender the client's inherent motivation to change was first described in an article by Miller in Behavioural Psychotherapy (1983). Subsequently Miller met Stephen Rollnick, the co-founder of the MI method, who had been concentrating on ambivalence, or the extent to which the client envisioned the pros and cons of changing. Miller and Rollnick began to explore the use of language during MI, concentrating on the elicitation of client "change talk" to promote behavior change. In 1991, Miller and Rollnick published the first edition of "*Motivational Interviewing: Preparing People to Change Addictive Behaviors*" in which they provided a detailed description of the approach. Since then there has been an explosion in the research and application of MI with many researchers addressing the applicability of the method to addressing health behavior change (Resnicow *et al*. 2002).

What is motivational interviewing?

MI has been defined as "a client-centered, directive method for enhancing intrinsic motivation to change by exploring and resolving ambivalence" (Miller & Rollnick 2002). The client-centered element refers to the emphasis that is placed on understanding and working from the perspective of the patient and their view of what it means to make a behavior change. For example, rather than a clinician simply telling a patient about the benefits of quitting smoking (from the practitioner perspective), the practitioner invites the patient to describe *his or her own view* of the advantages and disadvantages of quitting continuing to smoke. Although the patient's perspective is central, because MI is also directive, the practitioner takes deliberate steps to facilitate a particular behavioral outcome. For example, without ignoring patient concerns about changing, the practitioner selectively reinforces and encourages elaboration of any patient statements that are oriented toward the possibility or benefits of making a change. By eliciting and elaborating upon the patient's own reasons for change the motivation for change that is fostered is intrinsic or internal, rather than externally imposed. This approach rests on the assumption that individuals are almost always ambivalent about changing their behavior (i.e., it is almost always the case that individuals can identify both pros and cons of changing). MI practitioners therefore attempt to enhance intrinsic reasons for change by facilitating an exploration and resolution of the patient's underlying ambivalence.

Evidence for motivational interviewing

Because MI was initially developed for the treatment of addictive behavior, particularly alcohol addiction, the bulk of empirical studies has been conducted in this area. Nevertheless, the explosion in the application (Hettema *et al*. 2005) of MI to other areas of behavior change has been sufficient that there are now four published meta-analyses (Burke *et al*. 2003, 2004; Hettema *et al*. 2005; Rubak *et al*. 2005), the more recent of which include more than 70 clinical trials. Generally, the meta-analyses indicate that MI-based interventions are at least equivalent to other active treatments and superior to no-treatment or placebo controls for problems involving addictive behavior (drugs, alcohol, and gambling), adoption of water purification/safety technology, diet and exercise, and treatment engagement, retention, and adherence. Effect sizes are on average in the small to medium range but are highly variable (Hettema *et al*. 2005). Of particular relevance to dental settings where only brief counseling is feasible, is that MI-based interventions are just as efficacious as alternative active interventions despite involving significantly less contact time, suggesting that MI may be a particularly efficient method of counseling (Burke *et al*. 2004). Rubak *et al*. (2005) report that in brief encounters of 15 minutes, 64% of studies showed an effect. In addition, when the intervention was delivered by physicians an effect was observed in approximately 80% of studies suggesting that it is feasible for professionals who are not counseling experts to deliver effectively MI in brief encounters.

Studies of MI for tobacco use cessation are also of particular relevance. Although fewer studies were available, the meta-analyses cited above did not find

MI to be efficacious for smoking cessation. Nevertheless, most of the smoking cessation studies can be criticized for various reasons, including not having procedures to ensure and document fidelity to MI principles by the interventionists (Colby *et al*. 1998; Butler *et al*. 1999; Stotts *et al*. 2002; Wakefield *et al*. 2004), testing the intervention with smokers who are already motivated to quit which may be counterproductive (Smith *et al*. 2001; Ahluwalia *et al*. 2006), and not providing sufficient guidance on *how* to quit once participants were motivated by MI (Butler *et al*. 1999; Okuyemi *et al*. 2007). On the positive side, these studies also show that MI leads to significantly more quit attempts (Wakefield *et al*. 2004; Borrelli *et al*. 2005); greater reductions in smoking level (Borrelli *et al*. 2005); greater advances in readiness to quit (Butler *et al*. 1999); greater self-reported abstinence in the previous 24 hours (Butler *et al*. 1999); and a lower rate of increased smoking among pregnant women who were smoking early in pregnancy (Tappin *et al*. 2005). Importantly, a recent study (published subsequent to the meta-analyses) of primary care patients has shown that three 20-minute sessions of MI delivered by family physicians can increase smoking cessation more than five-fold compared to brief advice (Soria *et al*. 2006). This study addressed many of the limitations of prior studies by recruiting a large proportion of smokers not necessarily ready to quit, and incorporating procedures to ensure fidelity to MI principles.

Another particularly relevant target behavior for oral health is dietary habits. As indicated, meta-analyses have found significant effects of MI for changing diet. Specifically, these studies have documented changes due to MI in overall dietary intake (Mhurchu *et al*. 1998), fat intake (Mhurchu *et al*. 1998; Bowen *et al*. 2002), carbohydrate consumption (Mhurchu *et al*. 1998), cholesterol intake (Mhurchu *et al*. 1998), body mass index (BMI) (Mhurchu *et al*. 1998), weight (Woollard *et al*. 1995), salt intake (Woollard *et al*. 1995), alcohol consumption (Woollard *et al*. 1995), and consumption of fruits and vegetables (Resnicow *et al*. 2001; Richards *et al*. 2006).

At the time of writing, there was only one published study focused on oral health. This study examined the effect of using MI compared to traditional health education for motivating 240 mothers of young children with high risk for developing dental caries to use dietary and non-dietary behaviors for caries prevention (Weinstein *et al*. 2004, 2006). An MI session and six follow-up phone calls over a year in addition to an educational pamphlet and video was more effective than the pamphlet and video alone in preventing new dental caries among the children after 2 years. This result is consistent with the results of the meta-analyses that have found MI to be efficacious for dietary change (Burke *et al*. 2003; Hettema *et al*. 2005).

In summary, there is generally a wealth of support for MI as an effective method of counseling for behavior change. MI has also been shown to be relatively efficient and has been successfully delivered by medical practitioners. In areas of specific relevance to oral health practitioners, MI has either already been shown to be efficacious or offers significant promise. Given the extraordinary explosion in the application of MI we anticipate that it will not be long before there will be many more studies specific to dental settings.

Implementation of motivational interviewing into the periodontal treatment plan

Key principles of motivational interviewing

Although MI methods and techniques provide a wealth of guidance of what to do and what not to do when counseling patients, Miller and Rollnick have emphasized that to be an effective MI practitioner it is more important to embody the underlying philosophy than to be able to apply the collection of techniques. They have identified four general principles that capture the underlying philosophy of the method. First, a practitioner should *express empathy* for the patient's behavior change dilemma. In other words, the practitioner should communicate acceptance of the patient's perspective, providing and *expressing* full acknowledgement of the patient's feelings and concerns. The second principle is to *develop discrepancy* between the patient's current behavior and how they would ideally like to behave to be consistent with their broader goals and values. For example, the goal of being strong or responsible, or a good spouse or parent, can often be linked to being healthy and suggest the need for improved health behaviors. The third principle is to *roll with resistance*. When patients argue against change there is a strong tendency to fall into the trap of providing counter arguments. As a result the patient expends all of their energy arguing against change which is precisely the opposite of what is desired, perhaps making them even less likely to change. MI practitioners therefore avoid arguing and instead use MI methods to "roll with resistance". The fourth principle is to *support self-efficacy* or the patient's confidence in their ability to make a change. Patients are unlikely to succeed in making a change even if they are motivated, when they don't know how or don't believe they can. MI practitioners therefore make efforts to enhance their patients' confidence through such means as expressing their belief in the patient's ability to change or pointing out past successes or steps in the right direction.

Basic communication skills

Implementing MI in a dental setting requires consideration of how to ensure the collaborative and

Fig. 34-1 Appropriate position for a conversation: the clinician is facing the patient on the same seating level.

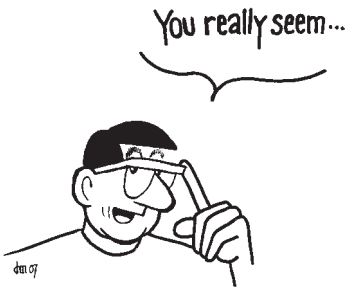
Fig. 34-2 Inappropriate position for a conversation: the clinician is wearing a face mask and is at a higher level than the supine patient.

empathic spirit of the method. Even such basic matters as how the patient and practitioner are seated can contribute to the patient feeling like they are truly being invited to engage in a dialogue as a partner (Fig. 34-1), rather than feeling they are simply to be the recipient of expert advice (Fig. 34-2).

There are four primary activities for the beginning stages of a brief MI session. These can be summarized with the acronym OARS, for **o**pen-ended questions, **a**ffirm the patient, **r**eflect, and **s**ummarize.

- *Ask open-ended questions*. Approaching the patient with multiple closed-ended questions (question that will be answered with "yes" or "no") sets the patient's role to be a rather passive one. In contrast, open-ended questions invite thought, collaboration, and effort on the part of the patient. Example: "How do you feel about your smoking?"

- *Affirm the patient*. It is human nature to presume a negative attitude, particularly when one's own behavior is coming under scrutiny. Acknowledging the patient's strengths and appreciation of his or her honesty will decrease defensiveness, increase openness, and the likelihood of change. Example: "You're telling me clearly why you're not very concerned about your toothbrushing and I appreciate that honesty."



- *Reflect what the patient is communicating*. Reflection is the primary way to demonstrate empathy (ability to understand another person's perspective). Appropriate reflection includes the genuine effort to understand the patient's perspective. It (1) captures the underlying meaning of the patient's words, (2) is concise, (3) is spoken as an observation or a comment, and (4) conveys understanding rather than judgment. Example: "You really seem to have lost hope that you can ever really quit smoking."

- *Summarize*. Summarizing the patient demonstrates interest, organizes the interview, and gets things back on track if necessary. It involves the compilation of the patient's thoughts on change mentioned during the counseling. Example: "So there's a big part of you that doesn't feel ready to change right now. You really enjoy smoking, but you have been a little worried by the way some people react when they find out that you smoke. Is that about right?"

Giving advice

Although we have highlighted the distinction between advice-oriented health education and MI in this chapter, it is important to recognize that at times it is appropriate to provide information to address patient's questions, misapprehensions, or lack of knowledge. The Motivational Interviewing Skill Code (Moyers *et al*. 2003), which is used to assess practitioner's adherence to principles of MI distinguishes between giving advice *without* permission, which is proscribed, and giving advice *with* permission, which is consistent with MI principles. In essence, it is consistent with MI to provide information when the patient is willing and interested in receiving it. Practitioners commonly err by providing advice too soon in an encounter with a patient, resulting in patients perceiving the practitioner as having an agenda that they are trying to "push". In contrast, it is common in MI practice to find that the process of eliciting the patient's perspective reveals gaps in knowledge, questions and concerns, and misapprehensions that the patient would appreciate receiving more information about. The practitioner can then provide particularly relevant information that is much more likely to be well received. Rollnick *et al*. (1999) have outlined a three-step process that serves as a useful framework for providing advice in an MI consistent style:

- Step 1: *elicit* the patient's readiness and interest in hearing the information. For example a practitioner might say to a patient "I have some information related to (that topic) that you may be interested in. Would you be interested in hearing more about that?"
- Step 2: *provide* the information in as neutral a fashion as possible. For example, a practitioner might say "Research indicates that. . . ." or "Many of my patients tell me that . . ." This allows factual information to be presented in a manner that supports the patient's autonomy.
- Step 3: *elicit* the patient's reaction to the information presented. Following up will often facilitate the patient to integrate the new information in a way that brings about a new perspective and increases motivation to change. Alternatively, following up may reveal further gaps in knowledge or misunderstandings that can be addressed. If a patient "rejects" the information it is important not to get into a debate. It is generally better to simply acknowledge the patient's perspective with statements such as "This information doesn't fit with your experience" or "This information doesn't seem relevant to your situation" and then move on to a more productive area of conversation.

Case examples for oral hygiene motivation

Oral hygiene motivation 1

Using the following case example, MI is demonstrated in a dialogue for oral hygiene motivation between a periodontist (Dr) and a patient (P) diagnosed with chronic periodontitis at the beginning of periodontal therapy.

Dr Would you mind if we talk about methods to improve your oral hygiene during and after your gum treatment?
P No, I don't mind.
Dr Good. Let me know a little bit about how you usually clean your teeth.
P I usually brush once or twice a day.
Dr So you brush your teeth regularly. What are you using when you clean your teeth?
P I use a toothbrush and toothpaste.
Dr Very good. Could you let me know how you use your toothbrush?
P I brush all upper and lower teeth on the outside and the inside as I was shown a long time ago.
Dr And how do you feel about brushing your teeth that way?
P I generally feel quite good about it. But since I have been told I have gum disease, I'm wondering if I haven't been brushing enough?
Dr So you have been making efforts to keeping your teeth clean but you're worried that maybe you haven't been brushing enough.
It can be difficult to get to all the areas of your teeth and gums to remove the plaque that causes gum disease. I have some information related to prevention of gum disease that you might be interested in. Would you like to hear about it?
P Yes.
Dr The chronic gum or periodontal disease you are diagnosed with was caused by bacterial plaque attached to your teeth over time.
Plaque has to be entirely removed from all the tooth surfaces on a daily basis in order to prevent and control this disease.
How confident are you that you were cleaning all the surfaces on a regular basis?
P Not very, although I thought that I was doing enough.

Dr Well actually, research indicates that using a toothbrush alone is not sufficient to clean between the teeth. In order to clean these areas, an interdental device is needed such as a dental floss, a toothpick, or an interdental brush. Are you using any one of these devices?
P Yes, I've tried using dental floss.
Dr How did you find the use of dental floss?
P I had some trouble getting to some of the spaces between my teeth. In other areas, the floss used to rip up too, so I quit using it.
Dr I am sorry to hear that you had trouble using the dental floss. The floss can rip up at the edges of dental fillings or crowns. In spaces with extensive tartar built-up, the gap between your teeth may even be blocked out with tartar. Are you using anything else for cleaning?
P Yes, I use a toothpick whenever I have something stuck between my teeth.
Dr So in addition to your regular brushing with toothpaste you are also using a toothpick from time to time to clean your teeth?
P That's right.
Dr Good. During gum treatment, fillings and crowns with rough edges will be smoothed over and tartar can be removed which should make it easier to use things like dental floss or a toothpick between your teeth. Thinking of a 10-point scale where 0 is not at all important and 10 is extremely important, how important is it to you to floss or use a toothpick every day to clean the gaps between your teeth?
P Probably a 7.
Dr That sounds quite important. What makes this so important to you?
P I want to do everything needed to keep my teeth. However, I am not quite sure if I will be able to keep doing it over time.
Dr So you are quite motivated now because you want to look after your teeth, but you are worried about the long term. If you were to use the same 10-point scale to rate how confident you are that you can do it over the long-term, where would rate yourself?
P I would be at a 6.
Dr That sounds fairly confident. What gives you that level of confidence?
P Well, taking care of my teeth and gums is part of my routine already so this would just need to be added to it. But it does take extra effort, so it's a matter of realizing that it's really that important for my gums.
Dr So the fact that it can be part of your existing routine will help. But perhaps I can help you remain motivated in the long run by showing you at your follow-up visits the benefits you are achieving with your treatment by doing it regularly. How do you think that might help you to stick with it over time?
P Well, yes I think that would probably help a lot to see or learn from you that it really is making a difference to the success of my treatment.
Dr Great! So let me summarize what we have discussed. You plan to keep brushing on a regular basis with toothbrush and toothpaste and you will start to use a device for cleaning the gaps between your teeth after the issues with the rough filling and crown margins have been resolved. Then, each time you visit we'll see how you are progressing with your cleaning at home and see if we need to find any other ways to help. Does that sound like it would work for you?
P Yes, that sounds like it would work.

Oral hygiene motivation 2

In this second case example dialogue, MI is used in a conversation about oral hygiene at a visit for supportive periodontal therapy (SPT).

Dr From looking at your plaque index, I noticed today that compared to your visit 3 months ago there is more plaque around the areas between your teeth. I was wondering if you could tell me a little bit about how you find the cleaning between your teeth.
P Oh . . . I guess that I don't do it as often as I should. I barely have time now to do it every day, you know.
Dr I understand. It takes time to clean all the areas between your teeth, you are right. May I ask you a few questions about your current oral hygiene habits so I could understand your situation better?
P Sure you can.
Dr Good. So what do you use to clean your teeth currently?
P I am using an electric toothbrush and the interdental brushes you showed me.
Dr OK. How often do you use these?
P I use the electric toothbrush every day and I use the interdental brushes from time to time.
Dr So you are using the toothbrush on a regular basis, but only occasionally using the interdental brushes. What is prompting you when you do decide to use the interdental brushes?
P Well, sometimes I just feel guilty that I haven't been using them and sometimes I can see the tartar on my teeth and am reminded to use them again.
Dr So you sometimes worry that you are not using them enough and sometimes you can see on your teeth that you are not using them enough.
P Right, I suppose I should be doing better.

Dr Well let me ask you this. If you had to rate how important it is for you to use the interdental brushes every day on a scale from 0 to 10, 0 being not important at all and 10 being very important, where would you place yourself?
P I guess the use of these brushes is pretty important. I'd say an 8.
Dr Well that sounds very motivated. What makes it that important for you?
P Well I don't want to have a lot of problems with my teeth – I hate having fillings and of course I don't want to lose any teeth in the long run.
Dr So avoiding pain and discomfort and keeping your teeth is important to you. So how confident are you that you can use the brushes on a daily basis? Where would you rate yourself on that 0 to 10 scale?
P As I said, I know that I should use them more often, but finding the time is hard and I even just forget sometimes. I'd give it a 3.
Dr Using them daily seems quite hard for you. Out of curiosity, though, it seems you do have a little bit of confidence in doing this – may I ask you why a 3 instead of a 0 or a 1?
P Well, I just think that I would use them more often if they would become a part of my routine tooth cleaning, you know? I used to have toothpicks on my dinner table too and so I used them whenever I saw them sitting there. I could think about putting my interdental brushes on my sink next to my toothbrush. So I would be reminded to use them after brushing my teeth with the electric toothbrush.
Dr That sounds like a really good plan. Can you see any problems with doing that?
P No, not really. Once I have that reminder in place it's just a matter of staying committed to doing it.
Dr Very good. So if I can summarize, it sounds like you feel quite motivated to use the interdental brushes everyday, and that you think that if you put your interdental brushes on your sink next to your electric toothbrush that would help you remember to actually do it.
P Yes, that's right.
Dr Well does that sound like something you want to do?
P Yes, I'll do that tonight.

Case example for tobacco use cessation

A brief intervention for tobacco use cessation using MI is presented in a clinical case example dialogue between a periodontist (Dr) and a patient (P) at the beginning of periodontal therapy.

Dr According to your tobacco use history, you are currently smoking cigarettes. May I ask you a few questions about your smoking?
P Yes.
Dr Tell me how you feel about your smoking.
P Well I know I should quit. I know it's not good for my health. But I don't want to quit right now.
Dr So you don't feel that you want to quit right now, but you do have some concern about the health effects.
P Yes.
Dr Well, tell me more about what concerns you?
P Well, mainly that I would get lung cancer or something.
Dr So you worry a bit about getting cancer because of smoking. Is there anything else that you don't like about smoking?
P Well if I quit my clothes would stop smelling.
Dr So the smell of tobacco smoke is something you would like to be rid of?
P Yes, but I've smoked for many years, you know and I tried to quit once before.
Dr So even though you would like to be a non-smoker for health and other reasons you haven't had much success quitting.
P Yes, and right now I'm enjoying smoking so there's not much motivation to try.
Dr Well it sounds like even though you have some important reasons to quit, you're not very confident you could succeed and you don't feel ready to take on this challenge right now. I wonder if it would be OK for us to talk about this again next time to see where you are with it and whether I could help?
P Yes that sounds fine.

Conclusion

Chronic damaging behaviors not only affect general and oral health that individuals face but also impact the burden of disease on a community level. Hence, the services for primary and secondary prevention on an individual level oriented towards the change of inappropriate behavior become a professional responsibility for all oral health care providers. Motivational interviewing, encouraging the modification of all common risk factors for periodontal diseases such as insufficient oral hygiene, tobacco use, unhealthy dietary habits, and alcohol abuse, appears to be suitable for implementation into the periodontal treatment plan.

Acknowledgment

We are grateful to Dr. Dieter Müller, Bremgarten, Berne, Switzerland, for providing the cartoons of this chapter.

Chapter 35

Mechanical Supragingival Plaque Control

Fridus Van der Weijden, José J. Echeverría, Mariano Sanz, and Jan Lindhe

Importance of supragingival plaque removal

Dental plaque is a bacterial biofilm that is not easily removed from the surface of teeth. Biofilms consist of complex communities of bacterial species that reside on tooth surfaces or soft tissues. It has been estimated that between 400 and 1000 species may, at some time, colonize oral biofilms. In these microbial communities, there are observable associations between specific bacteria due in part to synergistic or antagonistic relationships and in part to the nature of the available surfaces for colonization or nutrient availability (Chapter 9). The products of biofilm bacteria are known to initiate a chain of reactions leading to host protection but also to tissue destruction (Chapter 11).

The dental biofilm is a complex configuration leading many to speculate that traditional plaque indices are inadequate because they fail to evaluate qualitative features. Furthermore, the term *plaque* is not precise. Plaque may be supragingival or subgingival and may be adherent or non-adherent to tooth or tissue. In addition the microbial composition of plaque varies from person to person and from site to site within the same mouth (Thomas 2004).

Supragingival plaque is exposed to saliva and to the natural self-cleansing mechanisms existing in the oral cavity. Friction through mastication may have a limiting effect on occlusal and incisal extensions of plaque. However, in most populations natural cleaning of the human dentition appears unimportant (Löe 2000). Therefore, in order to maintain oral health, regular personal plaque removal measures must be undertaken. The most widespread means of actively removing plaque at home is toothbrushing. There is substantial evidence which shows that plaque and gingivitis/periodontitis can be controlled most reliably through toothbrushing supported by other mechanical cleansing procedures. Thus, evidence stemming from large cohort studies demonstrated that high standards of oral hygiene will ensure the stability of periodontal tissue support (Hujoel *et al*. 1998; Axelsson *et al*. 2004).

As meaningful as oral hygiene measures are for disease prevention, they are relatively ineffective when used *alone* for treatment of moderate and severe forms of periodontitis (Loos *et al*. 1988; Lindhe *et al*. 1989). On the other hand, without an adequate level of oral hygiene in periodontitis-susceptible subjects, periodontal health tends to deteriorate once periodontitis is established and further loss of attachment may occur (Lindhe & Nyman 1984).

Meticulous, self-performed plaque removal measures can modify both the quantity and composition of subgingival plaque (Dahlén *et al*. 1992). The Socransky group (Haffajee 2001) confirmed this finding and reported that a permanent optimal supragingival plaque control regimen can alter the composition of the pocket microbiota and lower the percentage of periodontopathic bacteria.

At present both primary prevention of gingivitis and primary and secondary prevention of periodontitis are based on the achievement of sufficient plaque removal. Almost 50 years of experimental research, clinical trials in different geographical and social settings, have confirmed that effective removal of dental plaque is essential to dental and periodontal health (Löe 2000). The concept of the primary prevention of gingivitis derives from the assumption that gingivitis is the precursor of periodontitis and that maintenance of a healthy gingiva will prevent periodontitis.

Consequently, preventing gingivitis could have a major impact on expenditure for periodontal care (Baehni & Takeuchi 2003). Primary prevention of periodontal diseases includes educational interventions on periodontal diseases and related risk factors as well as regular self-performed plaque removal and professional mechanical removal of plaque and calculus. Optimal oral hygiene requires appropriate motivation of the patient, adequate tools, and professional oral hygiene instruction.

Self-performed plaque control

Personal oral hygiene refers to the effort of the patient to remove supragingival plaque. Procedures used to remove supragingival plaque are as old as recorded history. The earliest record of the chewstick which has been considered the primitive toothbrush dates back in the Chinese literature to about 1600 BC (Carranza & Shklar 2003). In his writings, Hippocrates (460–377 BC) included commentaries on the importance of removing deposits from the tooth surfaces. The observation that self-performed plaque removal is one of the foundations of periodontal health was clearly described by Antonie van Leeuwenhoek in 1683, who wrote (Carranza & Shklar 2003):

"Tis my wont of a morning to rub my teeth with salt and then swill my mouth out with water; and often, after eating, to clean my back teeth with a toothpick, as well as rubbing them hard with a cloth; wherefore my teeth, back and front, remain as clean and white as falleth to the lot of few men of my years, **and my gums never start bleeding**."

The Chinese are given credit for developing the first bristle toothbrush which was introduced in the Western world in the sixteenth century. Currently, toothbrushes of various kinds are important aids for mechanical plaque removal. Furthermore, a fluoridated dentifrice is an integral component of daily home care. The use of toothbrush and dentifrices is almost universal. The use of interdental cleaning devices, mouthrinses, and other oral hygiene aids is less well documented, but available evidence tends to suggest that only a small percentage of the population use such additional measures on a regular basis (Bakdash 1995).

There is an increasing public awareness of the value of good oral health practices. This fact is proven by a recorded increase in both public spending on oral hygiene products (over $3.2 billion a year in the US) and industry spending on consumer-related advertising (over $272 million a year in the US) (Bakdash 1995).

Brushing

Different cleaning devices have been used in different cultures (toothbrushes, chewing sticks, chewing sponges, etc.). Toothbrushing is currently the most commonly used measure in oral hygiene practice. Toothbrushing alone, however, does not provide adequate interdental cleaning since a toothbrush may only reach the facial, oral, and occlusal tooth surfaces. It was suggested (Frandsen 1986) that the outcome of toothbrushing is dependent on: (1) the design of the brush, (2) the skill of the individual using the brush, and (3) the frequency and (4) duration of brushing.

Dental professionals must become familiar with the variety in shapes, sizes, textures, and other characteristics of available toothbrushes in order to provide their patients with proper advice. From the numerous products present on the market only a few should be selected for the individual patient. It is important that the dental care provider understands the advantages and disadvantages of the various toothbrushes (and other aids) to provide the patient with proper information during the oral hygiene instruction session.

For the most part, studies that have compared the effectiveness of different manual brushes have found relatively little difference among designs (see below). It is quite possible that a given patient may obtain better results with one particular toothbrush than with another. Providing oral hygiene information should therefore be tailored to the individual.

Motivation

Oral hygiene education is essential in primary prevention of gingivitis. Improvement in a patient's oral hygiene is often accomplished through cooperative interaction between the patient and the dental professional. The role of the patient is to seek education regarding efficient self-performed plaque removal and accept regular check-ups to ensure a high level of oral hygiene. The patient must be interested in maintaining the health of the tissues, interested in a proposed treatment plan, and motivated to participate. Without compliance, which has been described as the degree to which a patient follows a regimen prescribed by a dental professional, a good treatment outcome will not be achieved. In this context it should be realized that compliance with treatment recommendations is generally poor, particularly in patients with chronic diseases in which the risk of complications is not immediate or life threatening. Also compliance with oral hygiene recommendations is generally poor (Thomas 2004).

So, however effective any toothbrushing method is, it will only be of any real value if the patient is prepared to use the technique on a regular basis (Warren & Chater 1996a). Merely the patient's positive attitude to treatment may have a positive long-term effect on her/his tooth cleaning efforts. Thus, well motivated patients who are compliant with professional advice and instruction are likely to achieve and sustain ideal levels of plaque control.

There is an increasing public awareness of the value of personal oral hygiene. Good oral hygiene should form an integral part of overall health practices, such as regular exercise, stress management, diet and weight control, smoking cessation, and moderation in alcohol consumption. If the clinician can establish the link between oral health and general health for the patient, this individual may be more willing to establish proper oral hygiene measures as part of her/his lifestyle.

The issue of changing a patient's lifestyle is the more difficult part of motivational sessions (Chapter 34). The principles of brushing and flossing are easy to learn. Integrating them into one's daily routine is far more difficult. This can form a source of frustration for the clinician who has provided a patient with information about the necessity of personal oral hygiene measures.

Toothbrush (see Procedure 1)

It is believed that the first toothbrush made of hog's bristles was mentioned in the early Chinese literature. In 1698 Cornelis van Solingen, a doctor from The Hague, published a book in which he presented the first illustration of a toothbrush in Europe (Fig. 35-1). Nylon filaments were introduced in 1938 since complications of World War II prevented the Chinese export of wild boar bristles. Nearly all current toothbrushes are made exclusively of synthetic materials (Wilkins, 1999). Such nylon filaments and plastic handle are easy to manufacture, and therefore more affordable. This has made toothbrushing a common practice in most societies.

During toothbrushing the removal of dental plaque is achieved primarily through direct contact between the filaments of the toothbrush and the surfaces of teeth and soft tissues. At the European Workshop on Mechanical Plaque Control, it was agreed that the features of an ideal manual toothbrush should include (Egelberg & Claffey 1998):

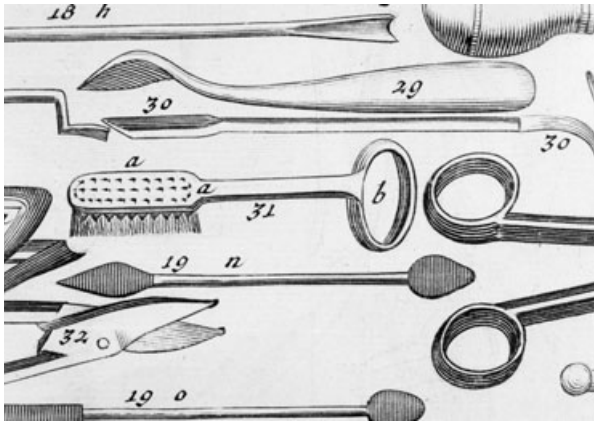

Fig. 35-1 Illustration of a toothbrush and tongue scraper from the book of Cornelis van Solingen with special thanks to the University Museum of Dentistry in Utrecht, The Netherlands.

1. Handle size appropriate to user age and dexterity so that the brush can easily and efficiently be manipulated
2. Head size appropriate to the size of the individual patient's requirements
3. Use of end-rounded nylon or polyester filaments not larger than 0.23 mm (0.009 inches) in diameter
4. Use of soft filament configurations as defined by the acceptable international industry standards (ISO)
5. Filament patterns which enhance plaque removal in the approximal spaces and along the gum line.

Additional characteristics could be: inexpensive, durable, impervious to moisture, and easily cleaned.

Modern toothbrushes have filament patterns designed to enhance plaque removal from hard-to-reach areas of the dentition, in particular from proximal areas. Cross-placed filaments, crimped, and tapered filaments are the most recent improvements. Such designs are based on the premise that the majority of subjects in any population use a simple horizontal brushing action. In order to improve patient comfort brush head shape, filament shape, and placement of filaments into the handles also have been subject to change over time. Multiple tufts of filaments, sometimes angled in different directions, are currently used (Jepsen 1998). Thus, when the head of the toothbrush is located horizontal to the tooth surface, there are filaments angled in the direction of the approximal tooth surfaces. Toothbrushes with this design facilitate more plaque removal in such difficult-to-reach areas when compared with flat-headed brushes (Cugini & Warren 2006).

Double- and triple-headed toothbrushes have been proposed in order to reach lingual surfaces more easily, especially in molar areas, which are normally the tooth surfaces hardest to reach with a regular toothbrush. Although some studies have indicated that the use of such multi-headed toothbrushes may improve plaque control in lingual areas (Agerholm 1991; Yankell *et al*. 1996), their use is not widespread.

Where handles used to be straight and flat, nowadays round and curved handles are more common. Today, a modern toothbrush has a handle size that is appropriate to the hand size of the prospective user, and much emphasis has been placed on new ergonomic designs (Löe 2002). Several studies have investigated differences in plaque removal between brushes with different handle design. In such studies brushes with long and contoured handles appeared to remove more plaque than brushes with traditional handles (Saxer & Yankell 1997).

When brushes with hard, soft, multi-tufted, and space-tufted filaments were compared, no significant clinical differences were found with respect to plaque removal. It is worth considering that most of such

toothbrush studies involved highly motivated participants such as dental students, who do not represent the general population. Most studies on manual brushes are 'single-use' tests. Although such short-term trials may be useful as pilot experiments, they need to be supplemented with studies of longer duration. Numerous manual toothbrushes are available on the market. There is still, however, insufficient evidence that one specific toothbrush design is superior to another. In 1994, two well performed clinical trials which assessed the efficacy of two toothbrushes came to entirely different conclusions (Grossman *et al*. 1994; Sharma *et al*. 1994). In the one trial toothbrush A was more effective than brush B while in the other trial brush B was superior to brush A. The trial which proved that brush A was most effective was sponsored by the manufacturer of brush A. The finances of the other trial which proved that brush B was more effective came from the manufacturer of brush B. As with many other aspects of oral hygiene aids, there is insufficient information to make evidence-based recommendations. Thus, in absence of this evidence, the best toothbrush continues to be the one that is (properly) used by the patient (Cancro & Fischman 1995; Jepsen 1998).

Efficacy of toothbrushing

The enthusiastic use of the toothbrush is not synonymous with a high standard of oral hygiene. Adults, despite their apparent efforts, appear not to be as effective in their plaque removal as might be expected. Most individuals only remove about 50% of plaque by toothbrushing (Jepsen 1998). De la Rosa and coworkers (1979) studied the pattern of plaque accumulation and removal with daily toothbrushing during a 28-day period following a dental prophylaxis. On average about 60% of the plaque was left after the self-performed brushing. Morris *et al*. (2001) reported on the 1998 UK Adult Dental Health survey and observed that the mean proportion of teeth with plaque deposits was 30% in the 25–34-year age group and 44% in those aged 65 years and above. At the Academic Centre for Dentistry Amsterdam (ACTA) a study was conducted which assessed the efficacy of a single 1-minute brushing exercise in subjects adhering to their customary brushing method (Van der Weijden *et al*. 1998a). It was observed that after 1 minute of brushing, approximately 39% of the plaque had been removed. The results of the studies described above indicate that most subjects are not effective brushers and that they probably live with large amounts of plaque on their teeth, even though they brush once every day.

Methods of toothbrushing

There is no single oral hygiene method that is correct for all patients. The morphology of the dentition (crowding, spacing, gingival phenotype etc.), the type and severity of the periodontal tissue destruction, as well as the patient's own manual dexterity determine what kind of hygiene aids and cleaning techniques are to be recommended. It should also be realized that during the course of periodontitis therapy, the techniques may have to be changed or adapted to the morphologic situation (longer teeth, open interdental spaces, exposed dentin).

The ideal brushing technique is the one that allows complete plaque removal in the least possible time, without causing any damage to the tissues (Hansen & Gjermo 1971). Different toothbrushing methods have been recommended over time, but also been abandoned. Such methods can be classified based on the position and motion of the brush.

Horizontal brushing is probably the most commonly used toothbrushing method. It is most frequently used by individuals who never had instruction in oral hygiene techniques. Despite the efforts of the dental profession to instruct patients to adopt other more efficient brushing techniques, most individuals use horizontal brushing since it is simple. The head of the brush is positioned perpendicular to the tooth surface and then a horizontal back and forth movement is applied. The occlusal, lingual, and palatal surfaces of the teeth are brushed with open mouth. In order to reduce pressure of the cheek on the brush head the vestibular surfaces are cleaned with the mouth closed.

Vertical brushing (Leonard (1939) technique) is similar to the horizontal brushing technique, but the movement is applied in vertical direction using up and down strokes.

Circular brushing (Fones (1934) method): with the teeth closed the brush is placed inside the cheek and a fast circular motion is applied that extends from the maxillary gingiva to the mandibular gingiva using light pressure. Back and forth strokes are used on the lingual and palatal tooth surfaces. The *scrubbing method* includes a combination of horizontal, vertical, and circular strokes.

Sulcular brushing (Bass (1948) technique): this method emphasizes cleaning of the area directly beneath the gingival margin. The head of the brush is positioned in an oblique direction towards the apex. Filament tips are directed into the sulcus at approximately 45° to the long axis of the tooth. The brush is moved in a back and forth direction using short strokes without disengaging the tips of the filaments from the sulci. On the lingual surfaces in the anterior tooth regions the brush head is kept in the vertical direction. The Bass technique is widely accepted as an effective method for removing plaque not only at the gingival margin, but also subgingivally. A few studies have been carried out on teeth affected with periodontal disease and scheduled for extraction, where the gingival margin was marked with a groove and the depth of subgingival cleaning was measured. These studies showed that with the use of this brushing method the plaque removal could reach a depth of approximately 1 mm subgingivally (Waerhaug 1981a).

Vibratory technique (Stillman (1932) method): as originally described by Stillman the method was designed for massage and stimulation of the gingiva as well as for cleaning the cervical areas of the teeth. The head of the brush is positioned in an oblique direction toward the apex, with the filaments placed partly in the gingival margin and partly on the tooth surface. Light pressure together with a vibratory (slight rotary) movement is then applied to the handle, while the filament tips are maintained in position on the tooth surface.

Vibratory technique (Charters (1948) method): this method was originally developed to increase cleansing effectiveness and gingival stimulation in the interproximal areas. It uses a reverse position of the brushhead as compared to the Stillman technique. The head of the brush is positioned in an oblique direction with the filament tips directed towards the occlusal or incisal surfaces. Light pressure is used to flex the filaments and gently force the tips into the interproximal embrassures. A vibratory (slight rotary) movement is then applied to the handle while the filament tips are maintained in position on the tooth surface. This method is particularly effective in cases with receded interdental papillae because the filament tips can easily penetrate the interdental space (Fig. 35-2).

Roll technique: the head of the brush is positioned in an oblique direction toward the apex of the teeth, with the filaments placed partly in the gingival margin and partly on the tooth surface. The sides of the filaments are pressed lightly against the gingiva. Next the head of the brush is rolled over the gingiva and tooth in occlusal direction.

Modified Bass/Stillman technique: the Bass and Stillman methods were designed to concentrate on the cervical portion of the teeth and adjacent gingival tissues. Each of these methods can be modified to add a roll stroke. The brush is positioned similarly to the Bass/Stillman technique. After activation of the brushhead in a back and forth direction, the head of the brush is rolled over the gingiva and tooth in occlusal direction making it possible for some of the filaments to reach interdentally.

In the 1970s several investigators compared various methods of brushing. Because of varying experimental conditions the outcomes of such studies are difficult to compare. To date no methods of toothbrushing have been shown to be clearly superior to others. As early as 1986, Frandsen commented on this issue by stating: "Researchers have realized that improvement in oral hygiene is not as dependent upon the development of better brushing methods as upon improved performance by the persons using any one of the accepted methods." Therefore, since no particular toothbrushing method has been found to be clearly superior to another, there is no reason to introduce a specific toothbrushing technique in each new periodontal patient. In most cases, small changes in the patient's own method of toothbrushing will suffice, always bearing in mind that more important than the selection of a certain method of

Fig. 35-2 (a) The Charters method of toothbrushing. The head of the toothbrush is placed in the left maxilla. Note the angulation of the bristles against the buccal tooth surfaces. The bristles are forced into the interproximal areas. (b) The palatal aspect of the incisor region in the maxilla illustrating the penetration of the bristles through the interproximal spaces (arrows).

toothbrushing is the willingness and thoroughness on the part of the patients to effectively clean their teeth. Implementation of the toothbrushing methods described above must be made according to patient´s needs. For example, since the Bass method has been associated with gingival recession (O'Leary 1980), it would be hardly indicated in individuals with energetic toothbrushing habits who have a thin gingival biotype.

Frequency of toothbrushing

There is no consensus as to the optimum frequency of toothbrushing. How often and how much plaque has to be removed in order to prevent dental disease from developing is not known. The majority of individuals, including periodontal patients, are usually not able to remove dental plaque completely as a result of daily brushing. However complete plaque removal does not seem to be necessary. A proper level of oral hygiene theoretically is the extent of plaque removal that prevents gingivitis/periodontal disease and tooth decay in the individual patient. Prevention of gingival inflammation is important because the inflammatory condition of soft tissues also favors plaque accumulation (Ramberg *et al*. 1994; Rowshani *et al*. 2004).

Results in cross-sectional studies have been equivocal when the self-reported frequency of tooth cleaning has been related to caries and periodontal disease. Disease appears to be more related to quality of cleaning than to its frequency (Bjertness 1991). Kressin and co-workers (2003) evaluated the effect of oral hygiene practices on tooth retention in a longitudinal study with a 26-year follow-up. They observed that consistent brushing (at least once a day) resulted in a 49% reduction of the risk of tooth loss compared to a lack of consistent oral hygiene habits.

If plaque is allowed to accumulate freely in the dentogingival region, subclinical signs of gingival inflammation (gingival fluid) appear within 4 days (Egelberg 1964). The minimum frequency of tooth cleaning to reverse experimentally induced gingivitis is once every day or every second day. Bosman and Powell (1977) induced experimental gingivitis in a group of students. The signs of gingival inflammation persisted in those students who removed plaque only every third or fifth day. In groups who properly cleaned their teeth once a day or every second day, the gingivae healed within 7–10 days.

Based on the observation that the onset of gingivitis appears to be more related to the maturation and age of the plaque than to its amount, the minimum frequency needed to prevent the development of gingivitis has been investigated in a prospective study. Dental students and young dental faculty members with healthy periodontal conditions were assigned to study groups with different cleaning frequencies over periods of 4–6 weeks. The results showed that that students who thoroughly removed plaque once daily or even every second day, did not develop clinical signs of gingival inflammation over a 6-week period. This tooth cleaning included the use of interproximal aids (dental floss and woodsticks) as well as the toothbrush (Lang *et al*. 1973). Caution should be excercised in extrapolating the results obtained from studies including dentally aware subjects to the average patient.

From a practical standpoint, it is generally recommended that patients brush their teeth at least twice daily, not only to remove plaque but also to apply fluoride through the use of dentifrice in order to prevent caries. This advice is also conceivable based on reasons of practibility and feeling of oral freshness. For most patients, it may be desirable to perform all necessary procedures (e.g. brushing and interdental cleaning) at the same time and in the same manner each day. Unfortunately, with subjects who live busy, stressful lives, this may be difficult to achive (Thomas 2004). Despite the fact that most individuals claim to brush their teeth at least twice a day, it is clear from both epidemiologic and clinical studies that mechanical oral hygiene procedures as performed by most subjects are insufficient to control supragingival plaque formation and to prevent gingivitis and more severe forms of periodontal disease (Sheiham & Netuveli 2002).

Brushing duration

Patients usually believe that they spend more time on toothbrushing than they actually do (Saxer *et al*. 1998). The least time spent on brushing was observed in a study carried out on English schoolchildren; in the 13 years age group, the children spent approximately 33 seconds on brushing (Macgregor & Rugg-Gunn 1985). About one third of the studies that were reviewed reported an average brushing time of less than 56 seconds whereas two thirds of the studies reported a brushing time of ≥56 seconds and <70 seconds. One investigation which used dental students as study population reported an average of 90 seconds (Ayer *et al*. 1965). The best estimate of actual manual brushing time seems to range between 30 and 60 seconds (Van der Weijden *et al*. 1993).

In reviewing the literature for studies that addressed the question whether in adult patients the duration of toothbrushing is correlated with efficacy of plaque removal five studies were identified. Three of these evaluated the use of electric toothbrushes (Van der Weijden *et al*. 1996a; McCracken *et al*. 2003, 2005). One study compared a manual toothbrush with an electric toothbrush (Preber *et al*. 1991), while one study included only manual toothbrushes (Hawkins *et al*. 1986). Results from all five studies indicate that duration of brushing is consistently correlated with the amount of plaque that is removed. In one study, toothbrushing was delivered by a dentist/dental hygienist. This study compared the effect of brushing time on plaque removal using manual and electric toothbrushes utilizing five different brushing times (30, 60, 120, 180, and 360 seconds).

This study showed that 2 minutes of electric toothbrushing can be as effective as 6 minutes of manual toothbrushing. The authors furthermore observed that at 2 minutes an optimum in plaque-removing efficacy was reached with both a manual and electric toothbrushes (Van der Weijden *et al*. 1993). Based on these observations the duration of toothbrushing should also be stressed during the toothbrushing instruction session.

Brushing filaments

Most current toothbrushes have nylon filaments. The degree of hardness and stiffness of a toothbrush depends on the filament characteristics, such as material, diameter, and length. Also the density of filaments in a tuft influences stiffness, since each filament gives support to the adjacent fiaments and each tuft gives support to adjacent tufts. Toothbrushes with thinner filaments are softer while thicker filament diameters are stiffer and less flexible. This increased stiffness will prevent the filament ends from bending back during brushing, avoiding the potential risk of damaging the gums. However, the filament must be sufficiently stiff so that during brushing enough pressure is exerted to allow proper plaque removal. Consider that a rod represents a filament of a toothbrush. Whilst brushing, a vertical upward load is exerted, which in turn exerts an effect of the same order of magnitude on the oral mucosa. The force of the brush, acting on the individual filament, is thus always as great as the load exercised by the filament on the mucosa. If the load is increased then the load on the mucosa increases to the same extent. Consequently the risk of soft tissue damage increases in that the filament's tip can penetrate into the mucosa. However, elastic rods demonstrate a peculiarity in their behavior. They suddenly fold back laterally when a certain limit load is reached. When folding back, the rod suddenly gives way elastically (without breaking) and the load on the oral mucosa diminishes abruptly. A load higher than this fold-back limit can thus not be transferred to the mucosa by the rod, via its tip. Tapered filaments (Fig. 35-3) have endings with the shape of an extreme rotational ellipsoid instead of a hemisphere. This is suggested to give the filaments very soft endings combined with a good stability of the filament corpus. Curved filaments may be more flexible and less stiff than straight filaments of equal length and diameter.

As late as 1967, most people were buying hard brushes (Fanning & Henning 1967). The shift in preference to soft brushes of specific design paralleled the change that occurred in oral health care when calculus was the prime etiologic agent in periodontal disease (Mandell 1990). The concentration on plaque, especially in the crevicular area and the attention to intrasulcular brushing strongly influenced the change from hard to soft filaments, primarily because of the concern of trauma to the gingival tissues (Niemi *et al*. 1984). The cleaning performance of a toothbrush is influenced by its degree of hardness. The toothbrush must not be too hard, to avoid damaging the gums when positioning the toothbrush. The harder the toothbrush filaments are the greater is risk of gingival abrasion (Khocht *et al*. 1993). But there is no point in using a brush with very thin filaments that merely strokes across the tooth and, as a result of the lack of load, no longer cleans the tooth surface.

Filament end-rounding

The end of a toothbrush filament can be cut bluntly or rounded. End-rounding has become increasingly common in the manufacturing process to reduce gingival abrasion (Fig. 35-4). The logic that smooth filament tips would cause less trauma than filament tips with sharp edges or jagged projections has been validated with both animal and clinical studies (Breitenmoser *et al*. 1979). Danser *et al*. (1998) evaluated two types of end-rounding, and saw an effect of end-rounding on the incidence of abrasion. The form to which the ends were rounded, however, had no effect on the level of plaque removal.

Toothbrush wear and replacement

It is generally recommended that toothbrushes be replaced before the first signs of the filaments

Fig. 35-3 Tapered toothbrush filaments.

Fig. 35-4 Filament end-rounding.

becoming worn. The useful life of an average toothbrush has been estimated to be 2–3 months. Not all patients take this advice, and evidence indicates that the average age at which a toothbrush is replaced ranges from 2.5–6 months (Bergström 1973). Common sense would suggest that a worn toothbrush with splayed or frayed filaments loses resilience and is less likely to be as effective in removing plaque than a new brush. This is why dental professionals often recommend that toothbrushes are used for a maximum of 3 months before they are they are replaced. Whilst this advice would seem reasonable, there is little actual clinical proof that this recommendation is correct. Because of variability in subjects' brushing techniques and the force applied to the teeth whilst brushing, the degree of wear varies significantly from subject to subject. It is also likely that different brushes, made from various materials, would exhibit differences in longevity. Some commercially available brushes have filaments that change color after a certain amount of use. This serves as a reminder to the patients that it is time to replace the brush.

Kreifeldt and co-workers (1980) showed that new brushes were more efficient in removing dental plaque than old brushes. They examined worn toothbrushes and observed that, as a result of wear, the filaments showed a taper, proceeding from the insertion to the free end. For example filaments were seen which tapered from 0.28 mm at one end to 0.020–0.015 mm at the free end. They concluded that among other wear factors, tapering contributed the most to loss of effectiveness. Their explanation for this observation was that as the tapering will result in a reduction of filament diameter, the brush will become softer and remove less plaque.

Since many patients use a brush for periods significantly longer than the recommended time of 3 months, it is important to know whether excessive wear is of clinical relevance. Several studies have examined this question but there is inconclusive evidence about the relationship between toothbrush wear and plaque removal. Studies with laboratory-worn toothbrushes reported that such used toothbrushes had inferior plaque removal efficacy as compared to new brushes (Kreifeldt *et al*. 1980; Warren *et al*. 2002). However, artificially worn toothbrushes may not mimic the characteristics of a naturally worn brush. In a laboratory study of the wear of toothbrushes, wear will inevitably be highly uniform and not reflect the variation in wear seen in normal toothbrush use. Most studies in which naturally worn toothbrushes were used reported no statistically significant decrease in reduction of whole-mouth plaque scores after brushing when compared to using new toothbrushes (Daly *et al*. 1996; Sforza *et al*. 2000; Tan & Daly 2002; Conforti *et al*. 2003; Van Palenstein Helderman *et al*. 2006). From this brief review of the literature it may be concluded that in contrast to what is generally thought, the wear status of a toothbrush might be less critical for maintaining good plaque control.

Electric toothbrushes (see Procedure 2)

In well motivated and properly instructed individuals who are willing to invest the necessary time and effort, mechanical measures, using traditional toothbrushes and adjunctive manual (interdental) devices, are effective in removing plaque. Maintaining a dentition close to plaque-free is, however, not easy. The electric toothbrush represents an advance that has the potential to both enhance plaque removal and patient motivation. Electric toothbrushes were introduced to the market more than 50 years ago. The first toothbrush powered by electricity was developed by Bemann & Woog in Switzerland and was introduced in the United States in 1960 as the Broxodent. In 1961 a cordless rechargeable model was introduced by General Electric (Darby & Walsh 2003). Studies of the use of these early electric tootbrushes showed that there was no difference in plaque removal when compared with a manual toothbrush and they had mixed effects on gingivitis. The consensus of the research reports on toothbrushing of the World Workshop in Periodontics in 1966 states: "*in non-dentally oriented persons, in persons not high motivated to oral health care, or in those who have difficulty in mastering suitable hand brushing technique the use of an electric brush with its standard movements may result in more frequent and better cleansing of the teeth*".

Since the 1980s, tremendous advances have been made in the technology of electrically powered toothbrushes. Various electric toothbrushes have been developed to improve the efficiency of plaque removal using increased filament velocity, brush stroke frequency, and various filament patterns and motions. Where old electric toothbrushes were using a combination of horizontal and vertical movements mimicking closely the back-and-forth motion of the traditional brushing methods, the more recent designs apply rotary motion or oscillating/rotating motion with pulsation, or have brush heads which move at high frequencies.

After reviewing many of the published reports over the past decades, it may be concluded that certain newer types of rechargeable electric toothbrushes have become more effective in removing supragingival plaque and controlling gingivitis. It is also clear that the effectiveness of particularly the low-cost battery-operated brushes are not well documented. To some extent, power brushes have overcome the limitations of the manual dexterity and skill of the user. Modern design features appear to be responsible for this (Fig. 35-5). These newer designed toothbrushes remove plaque in a shorter time than a standard manual brush (Van der Weijden *et al*. 1993, 1996a). The new generation of electric brushes have better plaque removal efficacy and gingival inflammation control in the approximal tooth surfaces

Fig. 35-5 Overview of the development of electric toothbrushes from brushes mimicking a manual toothbrush to high-frequency brushhead movement. From left to right: the Braun D3®, Rotadent®, Interplak®, Braun/Oral-B Triumph®, Sonicare Elite®.

(Egelberg & Claffey 1998). This superiority was clearly demonstrated in a study carried out on extracted teeth (Rapley & Killoy 1994). The electric toothbrush should not be considered a substitute for a specific interdental cleaning method, such as flossing, but it may offer advantages in terms of an overall approach to improved oral hygiene.

Two independent systematic reviews confirmed that oscillating rotating toothbrushes have superior efficacy over manual toothbrushes in reducing plaque and gingivitis (Sicilia *et al*. 2002; Robinson *et al*. 2005). Toothbrushes with this mode of action reduced plaque by 7% and gingival bleeding by 17% when compared with manual brushes (Robinson *et al*. 2005).

One electric toothbrush that has consistently been shown to be more effective than a manual toothbrush, both with respect to plaque removal and improvement of the gingival condition, is the original Braun Oral-B Plaque Remover (D7) (Warren & Chater 1996b). This toothbrush features a small round brush head that makes rotating and oscillating movements at a speed of 2800 oscillating rotations per minute. A further development of this brush, the Braun Oral-B Ultra Plaque Remover (D9) maintained the oscillating rotating action but at an increased speed (3600 rotations per minute). A clinical study with the D9 demonstrated equivalence in safety and a trend towards greater plaque removal when compared with the D7 (Van der Weijden *et al*. 1996b). Newer developments in the oscillating rotating brush technology add the additional high-frequency vibrations in the direction of the bristles creating three-dimensional movements during brushing. This modification was developed to enhance penetration and removal of plaque from approximal spaces of the dentition. Studies have shown the three-dimensional movements carried out by the brush are safe to use and more efficient regarding plaque removal (Danser *et al*. 1998).

Another approach in this technology was the development of sonic toothbrushes that have a high frequency of filament movement in excess of approximately 30 000 strokes per minute. Two recently introduced sonic toothbrushes are the Oral-B Sonic Complete® (SC; Oral-B Laboratories, Boston, MA, USA) rechargeable toothbrush with a side-to-side filament operating at 260 Hz, and the Philips Sonicare® Elite (SE; Philips Oral Healthcare, Snoqualmie, WA, US) based on a different technology, with a side-to-side motion also operating at a frequency of 260 Hz. Some clinical studies have shown sonic technology to be comparable or more effective than a manual toothbrush in removing plaque and reducing gingival inflammation (Johnson & McInnes 1994; Tritten & Armitage 1996; Zimmer *et al*. 2000; Moritis *et al*. 2002). Two studies using the same experimental gingivitis model compared an earlier Sonicare device and the Oral-B oscillating rotating toothbrush. In both studies the oscillating rotating brush was more effective in improving the level of gingival health (Putt *et al*. 2001; Van der Weijden *et al*. 2002a,b). This confirmed the findings of an earlier 6-week crossover study (Isaacs *et al*. 1998) where improvement in gingival condition was 8.6% greater with the oscillating rotating brush. Rosema and co-workers (2005) compared the Sonicare Elite to the Oral-B Professional Care 7000 and again found the oscillating rotating pulsation brush to be more effective. On the other hand, Tritten & Armitage (1996) compared the Sonicare advance to a traditional manual toothbrush in a 12-week parallel group study and concluded that both brushes were equally effective in reducing gingival inflammation.

Modern power toothbrushes are known to enhance long-term compliance. In a study involving periodontitis patients with persistent poor compliance, Hellstadius and co-workers (1993) found that switching from a manual to a power toothbrush reduced plaque levels and that the reduced levels were maintained over a period of between 12 and 36 months. The power brush significantly improved compliance, and patients expressed a positive attitude to the new brush. In a survey carried out in Germany most dentists stated that the time their patients spent on toothbrushing was too small (Warren 1998). Approximately half of the dentists stated that they recommend their patients to use a power toothbrush, and the vast majority of the dentists believed that changing to a power toothbrush would improve the condition of their patients' teeth and gums. Findings from a recent US practice-based study, involving a large number of subjects who switched from a manual toothbrush to the Braun Oral-B Ultra Plaque Remover (D9), confirmed the findings from the German study (Warren *et al*. 2000).

Electrically active (ionic) toothbrush

Several toothbrushes have been marketed over the years, which are designed to send a small

imperceptible electronic current through the brush head, presumedly to enhance the efficacy of the brush in plaque elimination. The electrons should reduce the H^+ ions from the organic acid in the plaque which may result in a decomposition of the bacterial plaque (Hoover *et al*. 1992). The first record of a charged toothbrush, the "Dr. Scott's Electric Toothbrush" was found in the February 1886 issue of Harper's weekly magazine. The handle of Dr. Scott's toothbrush was purportedly "charged with an electromagnetic current which acts without any shock, immediately upon the nerves and tissues of the teeth and gums . . . arresting decay . . . and restoring the natural whiteness of the enamel."

Short-term clinical studies with the use of these kinds of brushes documented a beneficial effect in terms of plaque reduction and gingivitis resolution (Hoover *et al*. 1992; Weiger 1998). Hotta and Aono (1992) studied an electrically active manual toothbrush that was designed with a piezo-electric element in the handle. This brush generates a voltage potential corresponding to the bending motion of the handle as the teeth are brushed. In this study no difference in the amount of remaining plaque after brushing was observed between the placebo and the electrically active brush. Other toothbrushes, which have a claimed 'electrochemical' effect on dental plaque, have a semiconductor of TiO_2 incorporated in the brush handle. In the presence of light, saturated low energy electrons in the wet semiconductor are transformed into high-energy electrons. An electron current of approximately 10 nA was measured to run from the semiconductor to the tooth (Weiger 1988).

Interdental cleaning

There is confusion in the literature with respect to the definitions of approximal, interproximal, interdental, and proximal sites. Commonly used indices are not suitable for assessing interdental plaque (directly under the contact area), and thereby limit interpretation of interdental plaque removal. The European Workshop on Mechanical Plaque Control in 1999 proposed the following definitions: *approximal* (proximal) areas are the visible spaces between teeth that are not under the contact area. In health these areas are small, although they may increase after periodontal attachment loss. The terms *interproximal* and *interdental* may be used interchangeably and refer to the area under and related to the contact point.

As stated above, the toothbrush does not reach the approximal surfaces of teeth as efficiently as it does for the facial, lingual, and ooclusal aspects nor does it reach into the interproximal area between adjacent teeth. Therefore measures for interdental plaque control should be selected to complement plaque control by toothbrushing (Lang *et al*. 1977; Hugoson & Koch 1979).

The interdental gingiva fills the embrasure between two teeth apical to their contact point. This is a 'sheltered' area, difficult to access, when teeth are in normal position. In populations that use a toothbrush, the interproximal surfaces of the molars and premolars are the predominant sites of residual plaque. The removal of plaque from these surfaces remains a valid objective, since in patients susceptible to periodontal diseases, gingivitis and periodontitis are usually more pronounced in this interdental area than on oral or facial aspects (Löe 1979). Dental caries also occurs more frequently in the interdental region than on oral or facial smooth surfaces. A fundamental principle of prevention is that the effect is greatest where the risk of disease is greatest. Therefore, interdental plaque removal, which cannot be achieved with the toothbrush, is of critical importance for most patients. A number of interdental cleaning methods have been developed, ranging from floss to the more recently introduced electrically powered cleaning aids. Flossing is the most universally applicable method, since it may be used effectively in nearly all clinical situations. However, not all interdental cleaning devices suit all patients or all types of dentitions. Factors such as the contour and consistency of gingival tissues, the size of the interproximal embrasure, tooth position and alignment, and the ability and motivation of the patient should be taken into consideration when recommending an interdental cleaning method. The most appropriate interdental hygiene aids must be selected for each individual patient. The selection made from the numerous commercially available devices is dependent for the most part on the size and shape of the interdental space as well as on the morphology of the proximal tooth surface. In subjects with normal gingival contours and embrasures, dental floss or tape should be recommended. At sites where soft tissue recession has become pronounced, flossing becomes progressively less effective. Then an alternative method (either woodsticks or interdental brushes) should be recommended. A review on interdental cleaning methods (Warren & Chater 1996a) concluded that all conventional devices are effective, but each method should be suited to a particular patient but also to a particular situation in the mouth (Table 35-1).

The use of dental floss, interproximal brushes, and woodsticks may also induce soft tissue damage. In most cases, however, this damage is limited to acute lesions, such as lacerations and gingival erosions (Gillette & Van House 1980). Gingival bleeding during interdental cleaning can be a result of trauma or an indication of inflammation. Patients must be aware that bleeding *per se* is not a sign that interdental cleaning should be avoided but more likely an indicator of inflammation that needs to be treated.

Dental floss and tape (see Procedure 3)

Of all the methods used for removing interproximal plaque, dental flossing is the most frequently recom-

Table 35-1 Interdental cleaning methods recommended for particular situations in the mouth

Situation	Interdental cleaning method
Intact interdental papillae; narrow interdental space	Dental floss or small woodstick
Moderate papillary recession; slightly open interdental space	Dental floss, woodstick or small interdental brush
Complete loss of papilla; wide open interdental space	Interdental brush
Wide embrasure space; diastema, extraction diastema, furcation or posterior surface of most distal molar, root concavities or grooves	Single-tufted/end-tufted brush or gauze strip

mended technique. Levi Spear Parmly, a dentist based in New Orleans, is credited as being the inventor of modern dental floss. As early as 1815 Parmly recommended teeth flossing with a piece of silk thread. Clinical studies clearly show that, when toothbrushing is used together with flossing, more plaque is removed from the proximal surfaces than by toothbrushing alone (Reitman *et al*. 1980; Kinane *et al*. 1992). Dental floss and tape – a type of broader dental floss – are most useful where the interdental papillae completely fill the embrasure space. When properly used, flossing effectively removes up to 80% of proximal plaque. Even subgingival plaque can be removed, since dental floss can be introduced 2–3.5 mm below the tip of the papilla (Waerhaug 1981b). Several types of floss (waxed, unwaxed) are available. Studies have shown no difference in the effectiveness of unwaxed versus waxed dental floss. Unwaxed dental floss is generally recommended for patients with normal tooth contacts because it slides through the contact area easily. It is the thinnest type of floss available, yet when it separates during use it covers a larger surface area of the tooth than waxed floss. Waxed floss is recommended for patients with tight proximal tooth contacts. *Ease of use* is the most important factor that influences whether patients will use floss on a daily basis. Recently, powered flossing devices have been introduced. In comparison with manual flossing no differences have been found in terms of plaque removal and gingivitis reduction, although patients preferred flossing with the automated device (Gordon *et al*. 1996).

Frequent reinstruction and reinforcement in the use of floss are necessary because flossing is a difficult skill to master. Flossing is also time-consuming. When a patient is unwilling to use dental floss alternative interdental hygiene aids should be recommended even if these are less efficient. If a patient finds a particular method or device more appealing to use, long-term compliance becomes an achievable goal. Although it is clear that flossing, when properly used, removes plaque in a very efficient manner, there is no evidence that flossing in adult patients with preserved interproximal periodontal tissues should be routinely indicated (Burt & Eklund 1999).

To facilitate flossing a special floss holder may be used. The holder may be re-used and is normally made of plastic material, durable, lightweight, and easily cleaned. Research reveals that reductions in bacterial plaque biofilm and gingivitis are equivalent with either the use of a hand flossing or flossholder. A Swedish national dental survey showed that approximately 46% of adults use woodsticks sporadically and only 12% use woodsticks daily. On the other hand, dental floss is used occasionally by 12% of adults and daily by only 2%. In other words, adults use woodsticks as an oral hygiene aid four to six times more frequently than dental floss (Axelsson 1994).

Woodsticks (see Procedure 4)

Picking our teeth may well be one of humanity's oldest habits and the toothpick one of the earliest tools. The evolution of the primitive toothpick took a second pathway in the more acquisitive societies. It became part of a personal care kit along with a depilatory tweezer and a ear wax scoop (Mandel 1990). In 1872, Silas Noble and J.P. Cooley patented the first toothpick-manufacturing machine.

The key difference between a toothpick and a woodstick (wooden stimulator/cleaner) relates to the triangular (wedge-like) design. Woodsticks should not be confused with toothpicks which are simply meant for removing food debris after a meal (Warren & Chater 1996a). Woodsticks are inserted interdentally with the base of the triangle resting on the gingival side. The tip should point occlusally or incisally and the triangles against the adjacent tooth surfaces. Triangular wedge-like woodsticks have been found to be superior in plaque removal when compared with round or rectangluar woodsticks since they fit the interdental area more snugly (Bergenholtz *et al*. 1980; Mandel 1990). Woodsticks are usually made of soft wood to prevent injury to the gingiva. The tapered form makes it possible for the patient to angle the woodstick interdentally and even clean the lingually localized interdental surfaces. Unlike floss they can be used on the concave surfaces of the tooth root. Some are hand held, while others are designed to be mounted in a handle, which helps gain access to the interdental areas in the posterior region of the mouth (Axelsson 2004).

The wood can store fluoride crystals both on the surface and in the porosities. These crystals readily dissolve when the woodstick is moistened with saliva (Axelsson 2004). During use the soft wood may become splayed. As soon as the first signs of splaying are evident the woodstick should be discarded. As stated above most patients prefer to use woodsticks

for the removal of interdental plaque. Woodsticks have the advantage that they are easy to use, and can be used throughout the day without the need for special facilities such as a bathroom or a mirror. Woodsticks may also be used in primary prevention, even in cases of poor manual dexterity, including posterior areas. To use woodsticks there must be sufficient interdental space available and in these cases woodsticks are an excellent substitute to dental floss. Although woodsticks have a good cleansing capacity in the center part of the interproximal surfaces of teeth in contact, their effect is reduced on the lingual side of these surfaces. The woodstick is somewhat difficult to use in the far posterior regions of the jaws because of the lack of accessibility and since the triangular cross section must pass into the embrassure space at a specific angle (Bassiouny & Grant 1981).

When used in healthy dentitions, woodsticks may depress the gingival margin and clean the toothsurface up to 2–3 mm subgingivally (Morch & Waerhaug 1956). Long-term use may cause a permanent loss of the papilla and opening of the embrasure which may have important esthetic implications in the anterior dentition. Woodsticks can clearly be recommended in patients with open interdental spaces as secondary prevention for periodontal diseases.

A review of the literature for studies that have addressed the question whether woodsticks used as adjunct to toothbrushing in adult patients have an effect on plaque and periodontal inflammation identified eight publications. In only one study a significant reduction in plaque scores was reported as result of the use of woodsticks (Schmid *et al*. 1976). In three studies the use of woodsticks resulted in reduction of gingival bleeding (Anaise 1976; Bassiouny & Grant 1981; Bouwsma *et al*. 1992).

Interdental brushes (see Procedure 5)

Interdental brushes were introduced in the 1960s as an alternative to woodsticks. They are effective in the removal of plaque from the proximal tooth surfaces (Bergenholtz & Olsson 1984). The interdental brush consists of soft nylon filaments twisted into a fine stainless steel wire. This 'metal' wire can prove uncomfortable for patients with sensitive root surfaces. For such patients the use of plastic-coated metal wires may be recommended. The support wire is continuous or inserted into a metal/plastic handle. Interdental brushes are manufactured in different sizes and forms The most common forms are cylindrical or conical/tapered (like a Christmas tree). The length of the bristles in cross section should be tailored to the interdental space. Appropriate interdental brushes are currently available for the smallest to the largest interdental space (Fig. 35-6). Although unconfirmed with scientific documentation, it is believed that the most effcient cleaning is achieved if the brush selected is slightly larger than the embrasure space. The brush is inserted obliquely into the interdental space, from an apical direction. Cleaning is performed with a back-and-forth motion. The interdental brush is the aid of choice when root surfaces with concavities or grooves have been exposed. The interdental brush is also the most suitable cleaning device in "through-and-through" furcation defects. Like woodsticks, interdental brushes are easy to use, although they may have some drawbacks, including the fact that different types may be needed to fit differently sized open interproximal spaces. When not properly used, interdental brushes may elicit dentin hypersensitivity. In order to minimize the risk of hard tissue abrasion interdental brushes should be used without dentifrice except in special cases and then only short-term. They can also be regularly used as a carrier to apply fluoride or antimicrobial agents, e.g. chlorhexidine gel into the interdental space to prevent caries or the recolonization of residual pockets. The brush should be discarded when the filaments become loose or deformed.

Fig. 35-6 With interdental brushes the diameter of the metal wire core is a detemining factor with respect to access. A close fit of the brushing filaments influences the cleaning ability.

Interdental brushes represent the ideal interdental cleaning tool, especially for periodontitis patients. Waerhaug (1976) showed that individuals who habitually used an interdental brush were able to maintain supragingival proximal surfaces free of plaque and to remove some subgingival plaque below the gingival margin. In a more recent study in patients with moderate to severe periodontitis Christou and coworkers (1998) showed the interdental brush to be more effective than dental floss in the removal of plaque and in promoting pocket reduction. Patients reported that the use of interdental brushes was easier than the use of dental floss. This is in agreement with previous studies (e.g. Wolffe 1976). Also the perception of efficacy was better for the interdental brushes. Significantly less patients reported problems with the use of interdental brushes. Even if efficacy of interdental brushes were not better than that of floss, the long-term use of interdental brushes

might be more easily implemented in a patient's routine than that of floss.

Single-tufted/end-tufted brush (see Procedure 6)

Single-tufted brushes are designed with smaller brush heads that have a small group of tufts or a single tuft. The tuft may be 3–6 mm in diameter and can be flat or tapered. The handle can be straight or contra-angled. Angulated handles permit easier access to lingual and palatal aspects. The filaments are directed into the area to be cleaned and activated with a rotating motion. Single-tufted toothbrushes are designed to improve access to distal surfaces of posterior molars, tipped, rotated or displaced teeth, to clean around and under fixed partial dentures, pontic, orthodontic appliances, or precission attachment, and to clean teeth affected by gingival recession and irregular gingival margin or furcation involvement.

Adjunctive aids

Dental water jet

The dental water jet was introduced in 1962. This device, also called an oral irrigator, has been demonstrated to be safe and effective. Oral irrigation has been a source of controversy within the field of periodontology. The daily use of oral irrigation has been shown to reduce dental plaque, calculus, gingivitis, bleeding, probing depth, periodontal pathogens, and host inflammatory mediators (Cutler *et al*. 2000). The strongest and most consistent evidence for the benefit of daily use of a dental water jet is the ability of the device to reduce gingivitis and bleeding. It has been reported that a pulsating stream of water is better than a continuous flow. The pulsating, hydrodynamic forces produced by irrigators can rinse away food debris from interdental spaces and plaque-retentive areas. Irrigation is not, however, a monotherapy but an adjunct designed to supplement or enhance other home care methods (brushing and flossing) intended for mechanical plaque removal (Hugoson 1978; Cutler *et al*. 2000).

Irrigation devices may be used with water or with disinfective ingredients (Lang & Raber 1982). In a study by Flemmig and co-workers (1990) it was observed that the addition of water irrigation to regular oral hygiene reduced bleeding on probing by 50% over a 6-month timeframe. The use of chlorhexidine in suboptimum concentrations (e.g. 0.06%) led to improved plaque inhibition and had an anti-inflammatory effect (Lang & Räber 1982; Flemmig *et al*. 1990). The success of pulsating irrigators with regular tips is limited in the subgingival area, and in periodontal pockets (Wennström *et al*. 1987). With specially designed tips (PikPocket: Waterpik Technologies, Inc.; Newport Beach, CA, USA), the pulsating stream of fluid may penetrate more deeply into the pocket areas (Cobb *et al*. 1988).

Tongue cleaners (see Procedure 7)

The dorsum of the tongue, with its papillary structure and furrows, harbors a great number of microorganisms (Chapter 60). It forms a unique ecologic oral site with a large surface area (Danser *et al*. 2003). The tongue is said to act as a reservoir which permits the accumulation and stagnation of bacteria and food residues (Outhouse *et al*. 2006). The tongue bacteria may serve as a source of bacterial dissemination to other parts of the oral cavity, e.g. the tooth surfaces and may contribute to dental plaque formation. Therefore, tongue brushing has been advocated as part of daily home oral hygiene together with toothbrushing and flossing (Christen & Swanson 1978). Tongue brushing has also been advocated as a component of the so-called "full-mouth disinfection" approach in the treatment of periodontitis, with the aim of reducing possible reservoirs of pathogenic bacteria (Quirynen *et al*. 2000).

Regular tongue cleaning has been used since ancient times and is still used by natives of Africa, Arabic countries, India, and South America. Many ancient religions emphasized cleanliness of the entire mouth, including the tongue. Indian people's daily ritual of oral hygiene was not only confined to brushing of the teeth but also the tongue was scraped and the mouth was rinsed with concoctions of betel leaves, cardamom, camphor or other herbs.

A large variety of tongue cleaners is commercially available. A modern tongue-scraping instrument may consist of a long strip of plastic ribbon. This is held in both hands and bent so that the edge can be pulled down over the dorsal surface of the tongue. Brushing also appears to be an easy method of cleaning the tongue providing that the gagging reflex can be controlled. In a recent systematic review it was concluded that scrapers or cleaners are more effective than toothbrushes for tongue cleaning (Outhouse *et al*. 2006). Patients should be informed that it is most important to clean the posterior portion of the tongue dorsum.

Tongue cleaning is a simple and fast procedure that helps to remove microorganisms and debris from the tongue. When tongue cleaning is practiced on a daily basis, the process becomes easier. Eventually, the patient may indeed feel "unclean" when tongue debris is not removed on a regular basis. In a study by Gross and co-workers (1975) the test group was instructed to brush their tongues as an adjunct to their normal oral hygiene measures. The members of a control group were not instructed to clean the tongue. A reduction in the presence of tongue coating was found of 40% in the test group as compared to the control group.

Some studies have shown that tongue brushing in combination with other methods of oral hygiene is

an effective method in reducing the formation of dental plaque. In contrast, Badersten and co-workers (1975) found no difference in *de novo* plaque accumulation between a 4-day period of tongue brushing and a 4-day period of no oral hygiene procedures. The authors suggested that the majority of the important plaque-forming bacteria might not originate from the tongue. Another reason for not finding an effect of tongue brushing on plaque formation may be that brushing of the posterior part of the dorsum of the tongue is difficult due to inaccesibility and discomfort.

Dentifrices

The use of a toothbrush is usually combined with a dentifrice (sold as *toothpaste*) with the purpose of facilitating plaque removal and applying agents to the tooth surfaces for therapeutic or preventive reasons (Chapter 36). In 1824, a dentist named Peabody was the first person to add soap to toothpaste. John Harris first added chalk as an ingredient to toothpaste in the 1850s. Colgate mass-produced the first toothpaste in a jar. In 1892, Dr. Washington Sheffield of Connecticut manufactured toothpaste into a collapsible tube. The traditional role of dentifrice is primarily cosmetic, in aiding the cleaning of teeth and producing fresh breath. It also makes toothbrushing more pleasant.

The studies by de la Rosa and co-workers (1979) and Stean and Forward (1980) validated the use of dentifrice since they found that there was a reduction in plaque growth after brushing with a dentifrice as opposed to brushing with water. In the course of the years many dentifrice formulations were tested and became well established because of their anti-plaque and/or anti-gingivitis properties. For additional information see Chapter 36.

Foam brushes, swabs or tooth towelettes

Tooth towelettes are being marketed as a method of plaque removal when toothbrushing is not possible. Their use is not meant to replace a daily toothbrushing regimen. Recently the I-Brush® has been introduced. This swab is mounted on the index finger of the brushing hand. It uses the agility and sensitivity of the finger. Consequently it could permit a better control over the finger pressure because the finger can actually feel the tooth and gingival surfaces and help positioning the brush for more effective scrubbing. During a 3-week clinical trial, no adverse effects were found. The results show that the finger brush removed less plaque than a regular manual toothbrush. In particular approximal plaque reduction was poor in comparison with the manual toothbrush. Based on these results, it is concluded that there is no beneficial effect of the finger brush in comparison with a regular manual toothbrush (Graveland *et al*. 2004).

Foam brushes resemble a disposable soft sponge on a stick and have been dispensed to hospital patients for intraoral cleansing and refreshing as early as the 1970s. They are particularly used for oral care in medically compromised and immunocompromised patients, to reduce the risk of oral and systemic infection (Pearson & Hutton 2002). Lefkoff and co-workers (1995) studied the effectiveness of such a disposable foam brush on plaque. In this study the regular manual toothbrush was found to be significantly more effective in retarding the accumulation of plaque from a plaque-free baseline on both facial and lingual surfaces. The foam brush did, however, show some plaque-preventive capabilities by maintaining plaque formation below 2 mm at the cervical margin of the tooth. Nevertheless, according to most authors, foam brushes should not be considered as a substitute for a regular toothbrush. In a study by Ransier and co-workers (1995) foam brushes were saturated with a chlorhexidine solution. They found the foam brush which had been soaked in chlorhexidine to be as effective as a regular toothbrush in controlling plaque and gingivitis levels. Therefore, if a toothbrush cannot be used in hospitalized patients, an alternative may be the use of chlorhexidine applied with a foam brush.

Side effects

Brushing force

Studies have shown brushing force with powered toothbrushes to be lower than that of a manual toothbrush (Van der Weijden *et al*. 1996c). This appears to be a consistent finding. There is an approximately 1.0 N difference between manual and powered toothbrushes. Recently McCracken and co-workers (2003) observed, in a range from 0.75–3.0 N, that the improvement in plaque removal, using a power toothbrush with forces in excess of 1.5 N was negligible. In a feedback study a professional brusher was asked to brush at 1.0 N, 1.5 N, 2.0 N, 2.5 N, and 3.0 N, during which the efficacy in relation of brushing force to brushing was determined. An increase in efficacy was observed with raising brushing force from 1.0 N to 3.0 N (Van der Weijden *et al*. 1996c). Hasegawa and co-workers (1992) evaluated the effect of different toothbrushing forces on plaque reduction by brushing with 100 g intervals on a scale from 100–500 g. The results of their study corroborate the findings of earlier studies that with increasing force more plaque is removed. In addition they observed that 300 g seems to be the most effective brushing force when using a manual toothbrush for both children and adults. Forces exceeding 300 g caused pain and gingival bleeding in the test patients. As shown in a manual brushing study in which efficacy was plotted against brushing force the relationship between force and efficacy appears not to be linear (Van der Weijden *et al*. 1998a). Using this particular manual toothbrush a positive correlation between efficacy and force up to 4.0 N was found. The more force was used, the more effective was the plaque removal. However

efficacy was reduced when forces above 4.0 N were used. Indeed there appeared to be a negative correlation. The hypothesis is that this negative correlation had to do with distortion of the brushing filaments. Above 4.0 N the brushing was no longer performed with the tip of the filament, but due to bending, with its side. This indicates that brushing force is not the sole factor which determines efficacy. Other factors such as action of the brush, size of the brushhead, brushing time, and manual dexterity may be of greater importance.

Excessive brushing force has been mentioned as a factor which is partly responsible for the origin of toothbrush trauma (gingival abrasion). In response to patients that use excessive force, manual and electric toothbrush manufacturers have introduced toothbrush designs, which can limit the amount of force used and thus reduce the chance of damage to soft and hard tissues. However there is no linear correlation between brushing force and abrasion. Mierau and Spindler (1989) performed a quantitative assessment of habit patterns of toothbrushing in 28 subjects and nine sessions. Least variations within each individual were observed with regard to brushing force. Brushing force ranged from 1.0–7.4 N between individuals. They did not observe any (visual) lesions from brushing in those individuals using a brushing force <2 N. If the brushing force was >2 N, co-factors such as brushing time, brushing method, and frequency of brushing appeared to be associated with acute brushing lesions. Burgett & Ash (1974) argued that the potential detrimental effect of brushing is related to the force applied at a particular point, i.e. pressure. it must be recognized that the head of a manual brush is larger than the head of the electric brush. Since the forces are given as a total of the force over the entire brush it may be that the unit pressure was less for the manual than for the electric brushes. They observed no difference in pressure between a soft manual (11.32 g/mm^2) and an electric toothbrush (11.29 g/mm^2). These data which show that the pressure for the electric and the manual brush are similar are also in agreement with findings presented by Van der Weijden and co-workers (1996c).

Toothbrush abrasion

Since various mechanical products are used in personal control of supragingival plaque, the possibility exists that some deleterious effects may appear as a consequence of these oral hygiene practices (Echeverría 1998). It has already been known for a long time that toothbrushing may have some unwanted effects on the gingiva and hard tooth tissues (Kitchin 1941). Trauma to hard tissues leads to cervical abrasion of the tooth surface. These lesions have been associated with toothbrush stiffness, the method of brushing, and brushing frequency. Cervical tooth abrasion has a multifactorial etiology, but in most cases it is the consequence of toothbrushing due to an excessive pressure of the brush and an excessive number of toothbrushing episodes/time. Both situations are probably linked to personality traits (*compulsive brushers*). Tooth wear has also been associated with toothbrush characteristics, especially related to the finishing and hardness of the filaments (Fishman 1997). It has been stated that hard tissue damage is mainly caused by the abrasives in the dentifrice, whereas lesions of the gingival tissues are caused by the toothbrush (Axelsson *et al*. 1997; Meyers *et al*. 2000).

In many instances, *tooth abrasion* is found in combination with *gingival recession*. Whereas gingival recession is associated with different etiologic/risk factors, e.g. periodontal inflammation, smoking, gingival biotype or repeated periodontal instrumentation, inadequate toothbrushing is probably the most significant one (Björn *et al*. 1981). Clinical experience does support the idea that, with improper use, toothbrushing can cause superficial damage to the gingival tissues. Patients with good oral hygiene have been found to have more gingival recession and more dental abrasion than those with poor oral hygiene. Unfortunately there are few studies in the dental literature concerning gingival lesions resulting from toothbrushing. Thus, to what extent oral hygiene procedures may traumatize the gingival tissues is not clear. Gingival abrasions as a result of brushing are often reversible localized superficial lesions. It is unlikely that gingival abrasion is induced by a single factor. One factor which has already been mentioned to be related to gingival abrasion is brushing force. In the literature, other factors have been suggested such as brushing method (e.g. Bass method), abusive toothbrush use, manual or powered toothbrushing, toothbrush grip, brush head shape, stiffness of filaments, end-rounding of toothbrush filaments, and toothbrushing frequency (Van der Weijden & Danser 2000).

Interestingly, there has been little debate on the role of dentifrice in the abrasion of soft tissues. This is somewhat surprising when abrasion of dental hard tissues is almost entirely a function of dentifrice. Detergents in dentifrice, agitated over a mucosal surface, could enhance the removal of the protective salivary glycoprotein layer and exert cytotoxic action on the overlying epithelial cells (Addy & Hunter 2003). No statistically significant difference in the incidence of gingival abrasion was found between brushing with dentifrice or without dentifrice (Versteeg *et al*. 2005) (Fig. 35-7).

Importance of instruction and motivation in mechanical plaque control

A fundamental principle for all preventive action is that the effect is greatest where the risk of development of disease is greatest. Needs-related instruction in oral hygiene should therefore intensify mechanical plaque removal on those individual teeth and surfaces that are at risk. A prerequisite for establishing needs-related toothcleaning habits is a well

Fig. 35-7 (a) Soft tissue damage as a result of extensive toothbrushing. Note gingival recession on the buccal gingival surface of tooth 13. (b) Note multiple ulcerations of the buccal gingival margin in the right maxilla. (c,d) Hard tissue damage has resulted after extensive use of interdental brushes.

motivated, well informed, and well instructed patient (Axelsson 2004). Mechanical plaque control demands active participation of the individual subject, and therefore the establishment of proper oral home care habits is a process that involves and depends on behavioral changes to a great extent. When implementing behavioral changes, dental professionals should try to ensure that the patient recognizes his/her oral health status and the role of his/her personal oral hygiene procedures in the prevention of caries and periodontal diseases. The patient should be informed about the casual relationship that led to the disease process and should be encouraged to take responsibility for his/her own oral health. The dental team has numerous possibilities to demonstrate soft tissue alterations elicited by inflammation to the patient, and the responsible etiologic factors. Most commonly, as with sports coaching, a one-to-one professional–patient approach should be employed.

Many patients spend too little time brushing or they brush haphazardly. The importance of thorough plaque removal should be stressed. Toothbrushing instruction for a patient involves teaching what, when, where, and how. In addition, instruction should also involve a description of specific toothbrushing methods, the grasp of the brush, the sequence and amount of brushing, the areas of limited access, supplementary brushing for occlusal surfaces and the tongue. The possible detrimental effects from improper toothbrushing and variations for special condition are described (Wilkins 1999). The design of toothbrushes or a specific toothbrushing method are of secondary importance to the skills of the individual in using the brush (Frandsen 1986). The simplest, least time-consuming procedures that will effectively remove bacterial plaque and maintain oral health should be recommended. If a patient prefers a specific oral hygiene strategy the clinician can evaluate this and modify the technique to maximize effectiveness, rather than changing it. Although it is necessary to give all patients honest feedback on their plaque removal efforts, it is also important to reward a positive performance and not entertain unrealistic expectations, so that the patient will not dread each maintenance visit.

Oral hygiene instruction should also include components such as self-assessment, self-examination, self-monitoring, and self-instruction. With this purpose, several devices and chemical agents have been used in order to make dental plaque more evident to the patient. The interested patient can be informed and motivated, for example, through use of disclosing agents to visualize plaque at the gingival margin or in the interdental spaces. Disclosing agents are chemical compounds such as erythrosine, fuchsin or a fluorescein-containing dye that stains dental plaque and thus makes it fully evident to the patient, either with regular or ultraviolet light. Erythrosine

Fig. 35-8 (a) Disclosing solution is often used to identify plaque. (b) Note remaining plaque on the buccal tooth surfaces after staining. (c) After self-performed tooth cleaning, remaining plaque can be identified by the patient following rinsing with a disclosing solution.

has already been used for many years and has received an FDA approval (Arnim 1963) (Fig. 35-8).

When applied immediately before toothbrushing, the patient can identify the amount of plaque formed after the last toothbrushing episode, thus receiving an immediate feedback about his/her cleaning performance. This procedure is useful during the early phase of plaque control. Later on, the disclosing agent should be applied after toothbrushing, which allows the patient to identify those areas needing additional cleaning efforts. Disclosing solution is available in either liquid or tablet form. The liquid may offer some advantages in that the operator can ensure that all surfaces are adequately covered. The red disclosing solution remains in the mouth for some time and may temporarily stain the lips and gingiva.

Disclosing of plaque in the patient's mouth is usually not enough to establish good oral hygiene habits, however. Other factors might influence the individual to modify or determine his or her behavior. These factors may be more or less beyond the control of the dental personnel (such as social and personal factors, environmental setting, and past dental experiences) or may lie within the control of dental personnel (such as conditions of treatment, instruction, and education of the patient). All of these should be considered in the design of an individualized oral hygiene program.

A variety of methods can be used to deliver advice and instruction. The effect of various oral hygiene instruction programs, administered individually or in groups, has been evaluated in a number of clinical studies. These studies have evaluated whether instruction given during one visit only is similar to step-by-step instruction provided during several visits, or whether the use of pamphlets or video tapes is superior to self-instruction manuals and to personal instruction given by a dental professional. In a study by Renton-Harper and co-workers (1999) an instructional video for an oscillating rotating electric toothbrush was evaluated. The subjects that followed the instructional video benefited significantly and considerably in terms of plaque removal compared to subjects receiving only written instructions. Different types and amounts of feedback to the patients using disclosed plaque scores and phase contrast demonstrations have also been investigated. These studies have usually reported similar improvements in plaque and gingivitis scores, irrespective of the mode of instruction. However, these results should be interpreted with caution since the subjects participating in these studies were examined at regular intervals, and therefore it is difficult to separate the effect of repeated examinations from the effect of the instructions (Renvert & Glavind 1998).

If oral hygiene motivation, information, and instruction are combined with professional tooth cleaning the effect in terms of reduction of plaque levels and levels of gingival inflammation may persist even after 6 months. A recent systematic review concluded, based on studies ≥6 months of duration, that a single oral hygiene instruction, describing the use of a mechanical toothbrush, in addition to a single

professional "oral prophylaxis" provided at baseline, had a significant, albeit small, positive effect on the reduction of gingivitis (Van der Weijden & Hioe 2005).

Rylander and Lindhe (1997) have recommended that oral hygiene instruction be given during a series of visits allowing the possibility of giving the patient immediate feedback and reinforcing the patient in his/her home care activities. The protocol below is based on the one used in several clinical trials by Lindhe and Nyman (1975), Rosling and co-workers (1976), and Lindhe and co-workers (1982), where the role of plaque control in preventing and arresting periodontal diseases was clearly proven.

First session

1. Apply a plaque-disclosing solution to the teeth and, with aid of a hand mirror, demonstrate all sites with plaque to the patient (Fig. 35-8b). The plaque score should be recorded using a plaque control record (Fig. 35-9).
2. Ask the patient to clean the teeth using his/her traditional technique. With the aid of a hand mirror, demonstrate the results of the toothbrushing to the patient, again identifying all sites with plaque (Fig. 35-8c).
3. Without changing the technique, ask the patient to clean the surfaces with plaque.

Depending on the plaque remaining after this second toothbrushing, the dental professional should either improve the technique or introduce an alternative system of toothbrushing. In order not to overload the patient with too much information during the first session, the use of adjunctive devices for interproximal cleaning can be introduced or improved in the second session.

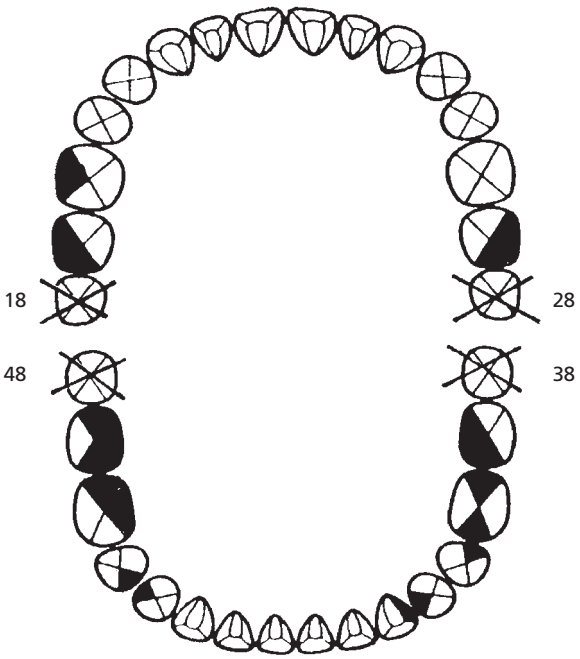

Fig. 35-9 A chart illustrating the teeth and tooth surfaces in the maxilla and mandible. The distribution of tooth surfaces with dental plaque (shadowed areas) is identified. In this case the plaque score is 17%.

Second session

1. A few days after the previous session, the disclosing solution is again applied. The results, in terms of plaque deposits, are identified in the mouth, recorded in the plaque control record, and discussed with the patient.
2. The patient is then invited to clean the teeth, according to the directions previously given in the first session, until all staining is removed. In many cases, toothbrushing instructions will need to be reinforced. Reinforcement and positive recognition should be given to the patient at the same time.

If necessary, the use of interproximal cleaning aids can now be introduced or improved.

Third and following sessions

1. One or two weeks later the same procedure used in the second session is repeated. However, the efficacy of self-performed plaque control should be evaluated and presented to the patient at each appointment. This repeated instruction, supervision, and evaluation aims to reinforce the necessary behavioral changes.

The long-term result of oral hygiene instruction is dependent on behavioral changes. Patients may fail to comply with given instructions for many reasons, ranging from unwillingness to perform oral self-care, poor understanding, lack of motivation, poor dental health beliefs, and unfavorable dental health values, to stressful life events or low socioeconomic status. Although the use of behavior-modification techniques may offer an advantage over traditional instruction techniques, there is limited research in this area to clarify the relationship between health beliefs and compliance.

Conclusion

- Oral hygiene instruction should be tailored to each individual patient on the basis of his/her personal needs and other factors.
- The patient should be involved in the instructional process.
- An individualized maintenance program should follow the basic oral hygiene instruction.

All the illustrations for the following procedures are used with permission from *Paro Praktijk Utrecht*.

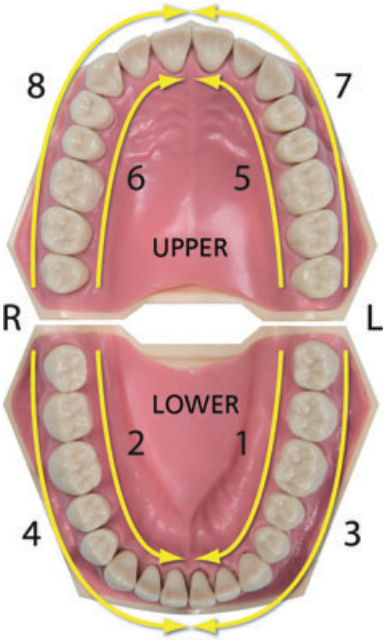
Procedure 1: Instruction for Manual Toothbrush

It is of utmost importance that in addition to using the correct toothpaste and also brushing for at least 2 minutes to brush the teeth in a set sequence. This prevents missing out certain areas. Areas untouched by the brush allow plaque to continue to grow. Try to choose a brush with medium or soft bristles and a small head.

Instruction

- Hold the brush firmly and place the bristles at an angle against the edge of your gums (use a 45° angle). Take care to ensure that the bristles are in contact with a small part of the gum margin.
- Place the brush against the molar or tooth at the back of the mouth and make short back and forth scrubbing movements. Brush from the back to the front of the mouth and try to overlap the strokes. Do not brush more than two teeth simultaneously. Always start at the back and work slowly forwards.
- Always hold the brush head horizontal when cleaning the outside surfaces of the teeth. It is easier to hold the head vertically when brushing the inside surfaces of the top and bottom teeth.
- Avoid too much pressure and fast movements and be aware of feeling contact with the gum margin. Also avoid brushing too vigorously thereby preventing damage to the gums.

When cleaning the teeth keep using the same sequence of brushing. For example, inside of bottom jaw left (15 seconds) inside right (15 seconds). Then left on the outside (15 seconds), followed by right on the outside (15 seconds). Repeat the same sequence in the top jaw. Finally, brush the chewing surfaces with small scrubbing movements. Replace the brush when the bristles start to splay.



Procedure 2: Instruction for the Electric Toothbrush

The importance of using a set sequence of brushing movements is also applicable when using an electric toothbrush. The question as to whether an electric brush is better than a manual one has been asked many times. Both allow to one achieve a high level of oral hygiene. However research has shown that electric toothbrushes are more efficient and many people report that they are easier to use.

Instruction

- Place the brush firmly on the hand piece. Grip the brush in the palm so that the bristles of the head are somewhat angled toward the gums (at an angle of approximately 70°). Try to allow the longer bristles to penetrate between the teeth and take care that the bristles contact your gums.
- Switch on the brush and place the head on the last tooth in the mouth (check the angle) and move the head gradually (in about 2 seconds) from the back to the front of this tooth.
- Try to follow the contour of both the tooth and the gums. Place the brush head on the next tooth and repeat this process.
- Allow the electric toothbrush to do the work. It is not necessary to press hard or make brushing movements.
- Use a timer! Many brushes will give some form of signal after 30 seconds (the apparatus stops for a moment). This is the point at which to move on to a new part of the mouth.

Remember to thoroughly clean the brush and its head when finished.

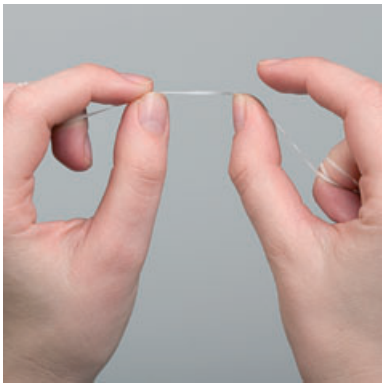
Procedure 3: Use of Dental Floss

The use of dental floss has become part of oral care in addition to correct, more frequent and longer tooth brushing. Floss can be purchased in a variety of thicknesses and types and with or without a layer of wax. If there is sufficient space between the front and back teeth is it advisable to use the somewhat thicker tape than the thinner floss.

Instruction

- Take approximately 40 cm of floss and wind the ends loosely around the middle finger. Allow for 10 cm between the middle fingers. Then hold the floss between the thumb and first finger so that about 3 cm remains between the thumbs.
- Using a sawing movement, allow the tightly stretched piece of floss to pass between the front and back teeth. This may be difficult where teeth are so close that the space between them is limited. Avoid allowing the floss to slip so fast between the teeth that the gums become damaged.
- Stretch the floss around one of the teeth and carefully allow it to pass just under the gum, once again with a sawing movement.
- Draw the floss up to the contact point with a sawing movement and then repeat the process on the other tooth bordering the space filled with gum tissue.
- Remove the floss from between the teeth, once again with a sawing movement and repeat this process for all the other spaces in the mouth.
- Use a clean piece of floss for each separate space by unwinding part of it from around one middle finger whilst winding it around the other middle finger.

Do not worry if at first your gums bleed slightly. This will stop after using the floss a number of times. Don't give up!



Procedure 4: Woodsticks

Most adults have sufficient space available between the incisors and molars to allow woodsticks to be used. These come in differing thicknesses and are made from wood and have a triangular cross section, mimicking the shape of the space between the teeth. Woodsticks can only be used once and are ideal when you have a few spare moments – for example when sitting in a traffic queue!

Instruction

- Hold the woodstick firmly between the thumb and first finger about halfway along its length. When possible place the other fingers for support on the chin. Moisten the tip of the woodstick by sucking on the point of it, thus making it softer and more flexible.
- Place the flat side of the woodstick (i.e. not the sharp side) against the gum. In the upper jaw the flat surface will face upwards and in the lower jaw downwards.
- Push the woodstick firmly from the outer side of the space into it until it becomes just wedged. Then pull it back slightly and push it back once again, using a light sawing motion at right angles to the outer surfaces of the teeth. Light pressure can also be applied simultaneously to the gums. Repeat this a few times, angling the woodstick so as to contact the surfaces of the teeth enclosing the space.
- When using a woodstick between the premolars and molars, close the mouth slightly to reduce tension in the cheeks making the movements easier.

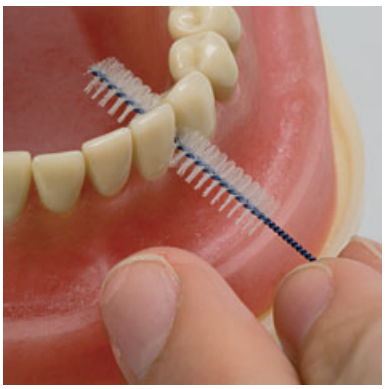
With this method, all spaces between the teeth throughout the mouth can be cleaned. Should the woodstick prick the surface of the gums with the point, angle it a little differently – in the upper jaw the point will face downwards and in the lower jaw upwards. Do not be concerned if your gums bleed a little at first – this will disappear after using the woodsticks repeatedly for a period of time.

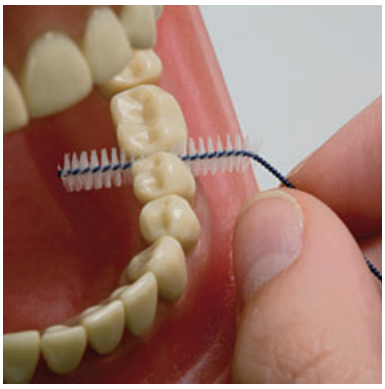
Procedure 5: Interproximal Brushes

Interdental brushes are purchasable in a variety of sizes varying from small to very large. It is of importance to choose the correct diameter of the bristle part of the brush. The size of the space between the teeth determines the size of the diameter of the bristles on the brush. It is often necessary to use different size of brush within one mouth for optimal cleansing. In order to effectively remove dental plaque there should be a slight degree of resistance when the brush is moved back and forth between the teeth.

Instruction

- Always use the interdental brush *without* toothpaste
- Hold the interdental brush between the thumb and first finger just behind the bristles. Support can be achieved when necessary by placing your other fingers on your chin. Push, from the outer side of the space, the interdental brush carefully between the teeth, taking care that the brush remains at right angles to the teeth.
- Avoid scraping the centre (metal spiral part) of the brush against the teeth.
- Slide the brush in and out of the space using the full length of the bristle part of the brush. This will remove the dental plaque.
- The area of contact between the brush and the teeth can be somewhat increased by using differing angles of insertion.
- Slight pressure of the brush against the gums should be used as this will allow the bristles to penetrate a little underneath the gum margin.
- By slightly closing the mouth it will be easier to manipulate the brush as the tension in the cheeks is lessened. It may also be of help to slightly bend the brush to ease insertion.
- Cleanse all areas between the teeth where an interdental brush will fit. Rinse the interdental brushes thoroughly after use and allow them to dry out. It is often a good idea to combine the use if interdental brushes and woodsticks.



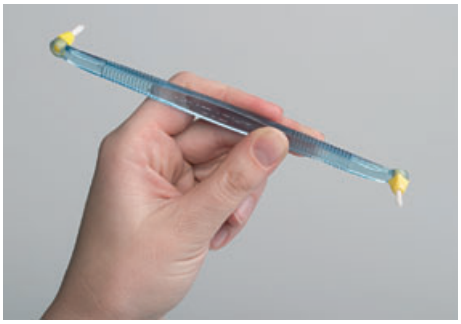


Procedure 6: Instruction for Single-Tufted/End-Tufted Brush

The single-tufted toothbrush is a small brush with a small, single tuft of short bristles attached to the end. The end-tufted brush has a number of small tufts attached in a similar manner. These brushes are ideal for cleansing areas of the dentition which cannot be reached with other oral hygiene aids. For example a lone standing tooth, the back surface of the last molar or tooth in the arch, wires and locks of orthodontic braces, grooves or the entrance to areas where roots split apart.

Instruction

- Hold the single-tufted brush in the same way as a pen. This prevents too much force being applied to the gums.
- Place the single-tufted brush at an angle directed toward the gums (about 45°) – this allows the bristles to reach just under the gum margin.
- Use small, rotational pencil movements.
- The bristles of the brush will then rotate under and along the gum margin. The brush should then be slowly moved along the tooth surface to cover all areas.



Procedure 7: Use of Tongue Cleaners

Tongue cleaning is a useful addition to the daily oral hygiene routine. Many bacteria can be found within the grooves on the back of the tongue which can cause bad breath. By brushing or scraping the tongue this problem can be markedly helped or prevented entirely. One of the problems associated with tongue cleaning is that it can stimulate a gag reflex, especially when first using this procedure. This occurs more frequently with brushing than when using a scraper. Some people find it less of a problem if they clean their tongue in the evening.

Instruction

- There are various types of tongue cleaners: the most effective seems to be one having the form of a loop.
- Extend the tongue as far as possible out of your mouth.
- Breathe calmly through your nose.
- Place the tongue cleaner as far as possible on the back of the tongue and press lightly with it so that the tongue becomes flattened.
- Ensure full contact of the tongue cleaner with the tongue.
- Pull the tongue cleaner slowly forward.
- Clean the middle part of the tongue first using the raised edge on one side of the instrument.
- Use the smooth surface of the tongue cleaner on the sides of the tongue.
- Repeat these scraping movements a number of times.
- Rinse the mouth several times.

Remember to clean the tongue cleaner thoroughly after use.

Chapter 36

Chemical Supragingival Plaque Control

Martin Addy and John Moran

This chapter will consider the past and present status and success of chemical supragingival plaque control in the prevention of gingivitis and thereby the occurrence or recurrence of chronic periodontal diseases. Chlorhexidine, arguably the most studied agent, will be used to consider the possible applications of chemical plaque control in periodontal practice.

Classification and terminology of agents

Agents that could inhibit the development or maturation of supragingival plaque have been classified according to possible mechanisms of action (for review see Addy & Moran 1997): (1) anti-adhesive; (2) antimicrobial; (3) plaque removal; and (4) antipathogenic. The majority of agents used to control supragingival plaque are contained in "oral hygiene" products and available to the general public either directly "over the counter" or following recommendation/prescription by a dental or medical professional. Manufacturers of these products and, for that matter, published literature use a variety of terms to describe the action of these chemical agents, often interchangeably, which has tended to cause confusion. In an attempt to clarify the various descriptive terms used the European Federation of Periodontology in the 1996 European Workshop on Periodontology recommended definitions for the terminology employed for agents in chemical supragingival plaque control (Lang & Newman, 1997) as follows:

- Antimicrobial agents: chemicals that have a bacteriostatic or bactericidal effect *in vitro* that alone cannot be extrapolated to a proven efficacy *in vivo* against plaque.
- Plaque reducing/inhibitory agents: chemicals that have only been shown to reduce the quantity and/or affect the quality of plaque, which may or may not be sufficient to influence gingivitis and/or caries.
- Antiplaque agents: chemicals that have an effect on plaque sufficient to benefit gingivitis and/or caries (Addy *et al*. 1983).
- Antigingivitis agents: chemicals which reduce gingival inflammation without necessarily influencing bacterial plaque (includes anti-inflammatory agents).

The classification, terminology, and definitions are presented here because of their fundamental importance to understanding the concept of chemical

supragingival plaque control. They will be considered in greater detail however under the headings of "Approaches to chemical supragingival plaque control" and "Evaluation of chemical agents and products" and, particularly for the latter, in respect of implied and inferred claims made by manufacturers.

The concept of chemical supragingival plaque control

Epidemiologic studies revealed a peculiarly high correlation between supragingival plaque levels and chronic gingivitis (Ash *et al*. 1964), and clinical research (Löe *et al*. 1965) led to the proof that plaque was the primary etiologic factor in gingival inflammation. Subgingival plaque, derived from supragingival plaque, is also intimately associated with the advancing lesions of chronic periodontal diseases. On the basis that plaque-induced gingivitis always precedes the occurrence and recurrence of periodontitis (Lindhe 1986; Löe 1986), the mainstay of primary and secondary prevention of periodontal diseases is the control of supragingival plaque (for review see Hancock 1996). Periodontal diseases appear to occur when a pathogenic microbial plaque acts on a susceptible host (for review see Haffajee & Socransky 1994). What constitutes a pathogenic subgingival plaque has been, and continues to be, a much researched area in periodontology. In the 1996 World Workshop on Periodontology a small number of bacteria were confirmed as true pathogens with a longer list considered as putative pathogens (for reviews see Zambon 1996). Much has been learned in the intervening decade, not the least of which is the bacterial diversity of subgingival plaque in health and disease, highlighted in a number of reviews (for review see Socransky & Haffajee 2005). The possibility that viruses may be involved has also been postulated (for review see Slots 2003). If the latter postulate becomes proven an extension of the classification of chemical agents, to include antiviral, will be necessary. Interestingly, and alluded to later in this chapter, some of the antimicrobial agents used in chemical plaque control do have antiviral activity.

Susceptibility to periodontal disease is less well understood and, at this time, certainly difficult to predict and quantify, although risk factors have been identified including genetic markers (for reviews see Kinane *et al*. 2005) (see Chapters 11 and 18). The relationship of plaque levels to pathogenicity and susceptibility is also poorly understood and therefore, for any one individual, what constitutes a satisfactory level of oral hygiene cannot be stated. This aside, there is evidence which demonstrates that improving oral hygiene and gingival health, over several decades, noted in developed countries (Hugoson *et al*. 1998a), has been associated with a decreasing incidence of periodontal disease (Hugoson *et al*. 1998b). Additionally, long-term follow-up of treated periodontal disease patients has shown that success is dependent on maintaining plaque levels compatible with gingival health (Axelsson & Lindhe 1981). Supragingival plaque control is thus fundamental to the prevention and management of periodontal diseases and, with appropriate advice and instruction from professionals, is primarily the responsibility of the individual.

It could be argued that the heavy reliance on mechanical methods to prevent what are microbially associated diseases is outdated. Very few hygiene practices against microorganisms used by humans on themselves, in the home, at the workplace or in the environment rely on mechanical methods alone and some methods are only chemical. The contrary argument must be that the prevention of periodontitis, through the control of gingivitis, would require the discovery of a safe and effective agent. Also, such a preventive agent would have to be applied from an early age to a large proportion of all populations, many of whom would have low or no susceptibility to periodontal disease (for review see Papapanou 1994).

These discussions aside, chemical preventive agents, aimed at the microbial plaque, have been a feature of periodontal disease management for almost a century (for review see Fischman 1997). The consensus appears to be that the use of preventive agents should be as adjuncts and not replacements for the more conventional and accepted effective mechanical methods and only then when these appear partially or totally ineffective alone.

Mechanical tooth cleaning through toothbrushing with toothpaste is arguably the most common and potentially effective form of oral hygiene practiced by peoples in developed countries (for reviews see Frandsen 1986; Jepsen 1998); although, *per capita* in the world, wood sticks are probably more commonly used. Interdental cleaning is a secondary adjunct and would seem particularly important in individuals who, through the presence of disease, can be retrospectively assessed as susceptible (for reviews see Hancock 1996; Kinane 1998). Unfortunately, it is a fact of life that a significant proportion of all individuals fail to practice a high enough standard of plaque removal such that gingivitis is highly prevalent and from an early age (Lavstedt *et al*. 1982; Addy *et al*. 1986). This, presumably, arises either or both from a failure to comply with the recommendation to regularly clean teeth or lack of dexterity with tooth cleaning habits (Frandsen 1986). Certainly, many individuals remove only around half of the plaque from their teeth even when brushing for 2 minutes (de la Rosa *et al*. 1979). Presumably this occurs because certain tooth surfaces receive little or no attention during the brushing cycle (Rugg-Gunn & MacGregor 1978; MacGregor & Rugg-Gunn 1979). The adjunctive use of chemicals would therefore appear a way of overcoming deficiencies in mechanical tooth cleaning habits as practiced by many individuals.

Supragingival plaque control

The formation of plaque on a tooth surface is a dynamic and ordered process, commencing with the attachment of primary plaque-forming bacteria. The attachment of these organisms appears essential for initiating the sequence of attachment of other organisms such that, with time, the mass and complexity of the plaque increases (see Chapter 8). Left undisturbed, supragingival plaque reaches a quantitative and qualitative level of bacterial complexity that is incompatible with gingival health, and gingivitis ensues. Even though, as yet, the microbiology of gingivitis is poorly understood, the sequencing of plaque formation highlights how interventions may prevent the development of gingivitis. Thus, any method of plaque control, which prevents plaque achieving the critical point where gingival health deteriorates, will stop gingivitis. Unfortunately, the lack of knowledge of bacterial specificity for gingivitis does not allow targeting or the control of particular organisms except for perhaps the primary plaque formers. Plaque inhibition has, therefore, targeted plaque formation at particular points – bacterial attachment, bacterial proliferation, and plaque maturation – and these will be discussed in more detail in the later section "Approaches to chemical supragingival plaque control".

The mainstay of supragingival plaque control has been regular plaque removal using mechanical methods which, in developed countries, means the toothbrush, manual or electric, and in less well developed countries the use of wood or chewing sticks (for review see Frandsen 1986, Hancock 1996). These devices primarily access smooth surface plaque and not interdental deposits. Interdental cleaning devices include wood sticks, floss, tape, interdental brushes, and, more recently, electric interdental devices (for reviews see Egelberg & Claffey 1998; Kinane 1998). Regular mechanical tooth cleaning is directed towards maintaining a level of plaque, quantitatively and/or qualitatively, which is compatible with gingival health, and not rendering the tooth surface bacteria free. Theoretically, mechanical cleaning of teeth could prevent caries but workshops have concluded that tooth brushing *per se* and interdental cleaning as performed by the individual do not prevent caries (for review see Frandsen 1986). Clearly, but outside the scope of this chapter, the toothbrush and other mechanical devices do provide a vehicle whereby anticaries agents, such as fluoride, can be delivered to the tooth surface. Under the conditions of clinical experimentation, tooth cleaning performed once every 2 days was shown to prevent gingivitis (Lang *et al*. 1973). The professional recommendation however, has been to brush twice per day, for which there is evidence of a benefit to gingival health over less frequent cleaning with no additional benefit for more frequent brushing (for review see Frandsen 1986). Indeed, recommendations to increase the frequency of brushing more than twice daily may result in more damage to hard and soft tissues (for review see Addy & Hunter 2003). The duration of brushing is somewhat controversial given that most surveys or studies reveal an average brushing time of 60 seconds or less (Rugg-Gunn & MacGregor 1978; MacGregor & Rugg-Gunn 1979). It is worth noting that one study showed less than 50% plaque removal after 2 minutes' brushing (de la Rosa *et al.* 1979). This perhaps highlights that many individuals spend little or no time during the brushing cycle at some tooth surfaces, notably lingually (Rugg-Gunn & MacGregor 1978; MacGregor & Rugg-Gunn 1979).

Oral hygiene, oral hygiene instruction, and the effect of supragingival plaque control alone on subgingival plaque and therefore periodontal disease is the subject of other chapters. Nevertheless, some further comments on mechanical tooth cleaning are pertinent in this chapter, particularly in respect of comparative efficacy of devices. The manual toothbrush as known today, man-made filaments in a plastic head, was invented as recently as the 1930s. Evidence for such devices dates back to China, approximately 1000 years ago, re-emerging in the 1800s in Europe, but too expensive for common usage (for reviews see Fischman 1997). Numerous changes in manual toothbrush design have occurred, particularly recently, and similarly numerous claims have been made for the efficacy of individual designs. Despite this, researchers, workshop reports, and consensus views have repeatedly concluded that there is no best design of manual toothbrush nor an optimal method of tooth cleaning: the major variable being the person using the brush (for reviews see Frandsen 1986; Jepsen 1998). Limited evidence is available comparing the modern toothbrush with chewing sticks but what is available suggests similar efficacy (Norton & Addy 1989), perhaps not surprisingly if indeed the user is the important factor. Interdental cleaning is considered important particularly for those individuals who are known to be susceptible to or have periodontal disease (for reviews see Egelberg & Claffey 1998; Kinane 1998). Here again, there is little evidence supporting one interdental cleaning method over another, leaving patients and professionals to hold subjectively related preferences (for review see Kinane 1998). Electric toothbrushes of the counter-rotation type found prominence for a short time in the 1960s and 1970s but were unreliable and proven of no greater efficacy over manual brushes, except for handicapped individuals (for reviews see Frandsen 1986). More recently, ranges of new electric brushes have appeared with a variety of head, tuft, and filament actions. For these, consensus reports conclude that there is evidence for greater efficacy over manual brushes particularly when professional advice in their use is provided (for reviews see Hancock 1996; Egelberg & Claffey 1998; van der Weijden *et al*. 1998). More recently, a Cochrane systematic review concluded that only oscillating

rotating electric toothbrushes could be proven significantly more effective than manual toothbrushes in reducing plaque and gingivitis (Heanue *et al*. 2004). Despite this, there is no clear evidence that any one electric design or head motion is superior and, again, the user appears the major variable. As with manual brushes advice and instruction in the use of electric brushes can result in very high levels of plaque control (Renton Harper *et al*. 2001). Given the speed of head movement for electric versus manual brushes, there must be concerns over potential harmful effect to hard and soft tissues. In this respect, Phaneuf and co-workers (1962) hypothesized that electric brushes would produce the same or less harm, postulating that the users would apply less force. Many years later the application of less pressure to electric compared to manual brushes was proven (for review see van der Weijden *et al*. 1998). Overall, therefore, it has been concluded that the benefits of normal toothbrushing alone and as a vehicle for toothpaste with a variety of active ingredients far outweigh the potential for harm to hard and soft tissues (for review see Addy & Hunter 2003).

Chemical supragingival plaque control

History of oral hygiene products

The terminology "oral hygiene products" is recent but there is evidence dating back at least 6000 years that formulations and recipes existed to benefit oral and dental health (for reviews see Fischman 1997). This includes the written Ebers Papyrus 1500 BC containing recipes for tooth powders and mouth rinses dating back to 4000 BC. A considerable number of formulations can be attributed to the writer and scientist Hippocrates (circa 480 BC). By today's standards the early formulations appear strange if not disgusting but they were not always without logic. Thus, bodies or body parts of animals perceived to have good or continuously erupting teeth were used in the belief that they would impart health and strength to the teeth of the user. Hippocrates, for example, recommended the head of one hare and three whole mice, after taking out the intestines of two, mixing the powder derived from burning the animals with greasy wool, honey, aniseeds, myrrh, and white wine. This early toothpaste was to be rubbed on the teeth frequently.

Mouth rinses similarly contained ingredients which would have had some stimulating effect on salivary flow, breath odor masking and antimicrobial actions, albeit not necessarily formulated with all these activities in mind. Alcohol-based mouth rinses were particularly popular with the Romans and included white wine and beer. Urine, as a mouth rinse, appeared to be popular with many peoples and over many centuries. There even appeared differences in opinion, with the Cantabri and other peoples of Spain preferring stale urine, whereas Fauchard (1690–1761) in France recommended fresh urine. The Arab nations were purported to prefer children's urine and the Romans to prefer Arab urine. Anecdotal reports suggest the use of urine as a mouth rinse to this very day with individuals rinsing with their own urine. There could, indeed, be benefits to oral health from rinsing with urine by virtue of the urea content; however this has never been evaluated, and given today's Guidelines for Good Clinical Practice, it is unlikely that study protocols would receive ethical approval.

Throughout the centuries, most tooth powders, toothpastes, and mouth rinses appear to have been formulated for cosmetic reasons including tooth cleaning and breath freshening rather than the control of dental and periodontal diseases. Many formulations contained very abrasive ingredients and/or acidic substances. However, ingredients with antimicrobial properties were used, perhaps not intentionally, and included arsenic and herbal materials. Herbal extracts are, perhaps, increasingly being used in toothpastes and mouth rinses, although there are little data to support efficacy for gingivitis and none for caries. Many agents prescribed well into the twentieth century, usually as rinses, had the potential to cause local damage to tissues, if not systemic toxicity, including aromatic sulfuric acid, mercuric perchloride, carbolic acid, and formaldehyde (Dilling & Hallam 1936).

Perhaps the biggest change to toothpastes came with the chemoparasitic theory of tooth decay of W.D. Miller in 1890. The theory that organic acids were produced by oral bacteria acting on fermentable carbohydrates in contact with enamel led to both the introduction of agents into toothpaste which might influence this process, and the production of alkaline products. Shortly after, and at the beginning of the twentieth century, various potassium and sodium salts were added to toothpaste as a therapy for periodontal disease. The first half of the twentieth century saw numerous claims for toothpastes for oral health benefits, including tooth decay and periodontal disease. For example, with the early recognition that periodontal diseases were associated with microorganisms, emetin hydrochloride was added to toothpaste to treat possible amoebic infections. Perhaps with the exception of the well known essential oil mouth rinse marketed at the end of the nineteenth century, the addition of antimicrobial and/or antiseptic agents to toothpastes and mouth rinses is a relatively recent practice by manufacturers. During the nineteenth and twentieth centuries, toothpastes also became less abrasive. Interestingly, the importance of a level of abrasivity in toothpastes to the prevention of extrinsic dental stain became apparent when one manufacturer marketed a non-abrasive liquid dentifrice. The unsightly brown tooth staining that developed in many users resulted in the early removal of this product from the marketplace. Standard organizations, notably the British Standards

Institute (BSI) and the International Standards Organisation (ISO), have written standards for toothpaste (BS5136:1981, ISO11609:1995). The ISO standard for toothpaste is, at this time, under review although, as for the original standard, it is safety rather than efficacy, which is the key issue. Toxicity and abrasivity (see later under Vehicles) are important sections of the toothpaste standard although evaluations for fluoride availability are likely to feature in the next finalized toothpaste standard. An ISO standard for mouth rinses is also under preparation where the hard tissue safety issue of low pH mouth rinses is under consideration. Throughout the ages, and until relatively recently, scientific evaluations of agents and formulations for gum health were not performed and claims for efficacy appear based on anecdotal reports at best. Indeed, given the nature of many ingredients and the recipes recommended in the past for oral hygiene benefits, it is unlikely that efficacy will ever be tested. In the 6000 years history of oral hygiene products, scientific evaluation must be seen as an extremely recent event: an observation which can, of course, be applied to almost all aspects of chemoprevention and chemotherapy of human diseases. Indeed, perhaps the first ever, double-blind, randomized cross-over design clinical trial in dentistry was less than 50 years ago (Cooke & Armitage 1960).

Rationale for chemical supragingival plaque control

The epidemiologic data and clinical research (Ash *et al*. 1964; Löe *et al*. 1965) directly associating plaque with gingivitis perhaps, unfortunately, led to a rather simplistic view that regular tooth cleaning would prevent gingivitis and thereby periodontal disease. Theoretically correct, this concept did not appear to consider the multiplicity of factors which influence the ability of individuals to clean their teeth sufficiently well to prevent disease, not the least of which are those factors which affect individual compliance with advice, and dexterity in performing such tasks. The need for research into those psychosocial factors which might influence attitude to and performance in oral hygiene, was stated in a workshop report on plaque control and oral hygiene practices (Frandsen 1986) but appears not to have been heeded to this day. Moreover, and as described in other chapters, epidemiologic data suggest that not all individuals are particularly susceptible to periodontal disease. The most severe disease is accounted for by a relatively small proportion of any population and then by only a proportion of sites in their dentition (Baelum *et al*. 1986). Even accepting that a considerable proportion of middle-aged adults will have one or more sites in the dentition with moderate periodontal disease, this will be of the chronic type and a minimal threat to the longevity of their dentition (Papapanou 1994) (see Chapter 7). The prevention of chronic periodontal diseases, through improved oral hygiene practices, will therefore be grossly over-prescribed as the early identification of susceptible individuals is impossible at present.

Host susceptibility is described retrospectively in the already diseased individual but, even here, an explanation for their susceptibility, except for a few risk factors, cannot be made. These risk factors include smoking, diabetes, and polymorph defects, and possibly stress (for review see Chapters 11 and 12). Genetic markers for periodontal disease have been identified but, at present, appear to be applied retrospectively rather than prospectively (Kornman *et al*. 1997; Kinane *et al*. 2005) and the value to early onset disease has been questioned (Hodge *et al*. 2001).

One definition of periodontal disease is chronic gingivitis with loss of attachment. This is a particularly useful definition, since not only does it describe the pathogenic processes occurring but also alludes to the approach to prevent, treat or prevent recurrence of the disease. Therefore prevention through supragingival plaque control still remains the mainstay of controling gingivitis and therefore the occurrence or recurrence of periodontitis. The importance of oral hygiene to outcome and long-term success of therapy for periodontal disease is hampered by the frequent ineffectiveness of mechanical cleaning of specific sites using a toothbrush, and the limited or lack of use of interdental cleaning by many individuals. Despite the encouraging improvements in oral hygiene, gingivitis and, to some extent, periodontitis in developed countries, gingival inflammation is still highly prevalent (see Chapter 7). Taken with the microbial etiology of both gingivitis and periodontitis, this supports the concept of employing agents to control plaque which require minimal compliance and skill in their use. This is the concept that underlies chemical supragingival plaque control, but as with oral hygiene instruction in mechanical methods, it will have to be vastly over-prescribed if periodontal disease prevention is to be achieved in susceptible individuals. Chemical supragingival plaque control has thus been the subject of extensive research using scientific methodologies for 40 years. The question to be addressed here is whether a chemical or chemicals have been discovered and proven efficacious in, firstly, the prevention of gingivitis and, secondly, periodontitis.

Conclusions

- Gingivitis and periodontitis are highly prevalent diseases and prevention of occurrence or recurrence is dependent on supragingival plaque control.
- Tooth cleaning is largely influenced by the compliance and dexterity of the individual and little by design features of oral hygiene appliances and aids.

- The concept of chemical plaque control may be justified as a means of overcoming inadequacies of mechanical cleaning.
- Gingivitis is highly prevalent and from a young age in all populations, but the proportion of individuals susceptible to tooth loss through periodontal disease is small.
- Prediction of susceptibility to periodontal disease from an early age is at present impossible.
- Mechanical and/or chemical supragingival plaque control measures for prevention of periodontitis will have to be greatly over-prescribed.
- In those individuals with chronic periodontal disease, and therefore considered susceptible, a daily form of interdental cleaning must be essential to long-term treatment success.

Approaches to chemical supragingival plaque control

The well ordered and dynamic process of plaque formation is summarized in Fig. 36-1. It is apparent that this process can be interrupted, interfered with, reversed or modified at several points and before the plaque mass and/or complexity reach a level whereby gingival health deteriorates. Mechanical cleaning aims to regularly remove sufficient microorganisms to leave a "healthy plaque" present, which cannot induce gingival inflammation. Chemical agents, on the other hand, could influence plaque quantitatively and qualitatively via a number of processes and these are summarized in Fig. 36-1. The action of the chemicals could fit into four categories:

1. Antiadhesive
2. Antimicrobial
3. Plaque removal
4. Antipathogenic.

Antiadhesive agents

Antiadhesive agents would act at the pellicle surface to prevent the initial attachment of the primary plaque-forming bacteria. Such antiadhesive agents would probably have to be totally preventive in their effects, acting most effectively on an initially clean tooth surface. Antiadhesive agents do exist and are used in industry, domestically, and in the environment. Such chemicals prevent the attachment and development of a variety of biofilms and are usually described as antifouling agents. Unfortunately the chemicals found in such applications are either too toxic for oral use or ineffective against dental bacteria plaques. Nevertheless, the concept of antiadhesives continues to attract research interest (for review see Wade & Slayne 1997). To date, effective formulations or products with antiadhesive properties are not available to the general public, although the amine alcohol, delmopinol, which appears to interfere with bacterial matrix formation and therefore fits somewhere between the concepts of antiadhesion and plaque removal, has been shown effective against plaque and gingivitis (Collaert *et al*. 1992; Claydon *et al*. 1996). Were antiadhesive agents to be discovered, a secondary benefit of extrinsic stain prevention of teeth may be expected.

Antimicrobial agents

The bacterial nature of dental plaque, not surprisingly, attracted interest in prevention of plaque formation through the use of antimicrobial agents. Antimicrobial agents could inhibit plaque formation through one of two mechanisms alone or combined. The first would be the inhibition of bacterial proliferation and would be directed, as with antiadhesive agents, at the primary plaque-forming bacteria. Antimicrobial agents therefore could exert their effects either at the pellicle-coated tooth surface before the primary plaque formers attach or after attachment but before division of these bacteria. This plaque inhibitory effect would be bacteriostatic in type, with the result that the lack of bacterial proliferation would not allow attachment of subsequent bacterial types on to the primary plaque-forming bacteria. The second effect could be bactericidal, whereby the antimicrobial agent destroys all of the microorganisms either attaching or already attached to the tooth surface. Many antimicrobial agents exist which could produce this effect; however, as will be discussed, to be effective in inhibiting plaque, the bactericidal effect would have to be absolute and/or persistent.

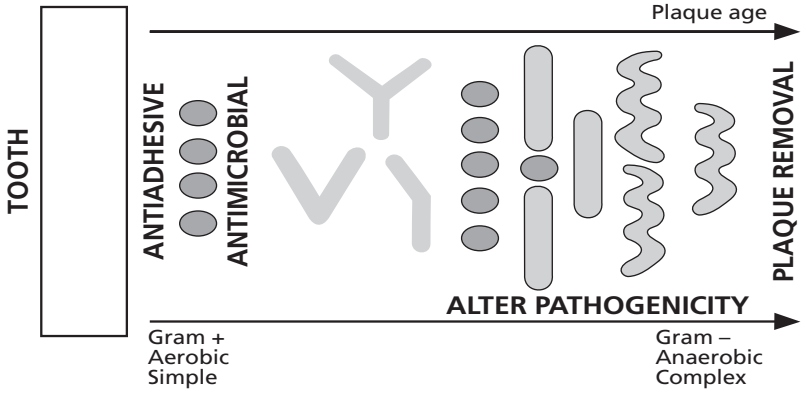

Fig. 36-1 Bacterial succession plaque formation. There is increasing mass and bacterial complexity as plaque bacteria attach and proliferate. Ideal sites of action for chemicals which might influence plaque accumulation are shown. Acknowledgment to Dr. William Wade for permission to publish this diagram.

If not, other bacteria within the oral environment would colonize the tooth surface immediately following the loss of the bactericidal effect and the biofilm would be re-established. For the most part biofilms in themselves are fairly resistant to total bactericidal effects of antimicrobial agents and, thus far, there does not appear to have been any agent discovered which effectively would sterilize the tooth surface after each application. If such an agent were found it could, of course, have potentially dangerous implications for the oral cavity since it would almost certainly destroy most of the commensal bacteria which normally colonize the oral cavity. This would open up the potential for exogenous microorganisms, with dangerous pathogenic potential, colonizing the oral cavity. In the event, it is probable that antimicrobial agents exert both a bactericidal effect followed by a bacteriostatic action of variable duration. The bactericidal effect will occur when the antimicrobial agent is at high concentration within the oral cavity and usually this will represent the time when the formulation is actually within the oral cavity. This bactericidal effect would be expected to be lost very soon after expectoration.

As will be discussed in respect of chlorhexidine, it is almost certainly the persistence of the bacteriostatic action of antimicrobial agents which accounts for their plaque-inhibitory activity. Calculations by Stralfors (1961) indicated that plaque inhibition through a bactericidal effect would require the immediate killing of 99.9% of the oral bacteria to effect a plaque-inhibitory action of significant duration. Antimicrobial agents for plaque inhibition, to date, are the only agents that have found common usage in oral hygiene products. The efficacy of these agents and products varies at the extremes (for reviews see Addy 1986; Kornman 1986; Mandel 1988; Addy *et al*. 1994; Addy & Renton-Harper 1996; Rolla *et al*. 1997; Eley 1999).

Plaque removal agents

The idea of employing a chemical agent which would act in an identical manner to a toothbrush and remove bacteria from the tooth surface, is an attractive proposition. Such an agent, contained in a mouth rinse, would be expected to reach all tooth surfaces and thereby be totally effective. For this reason, the idea of chemical plaque removal agents has attracted the terminology of "the chemical toothbrush". As with antiadhesives, there are agents, such as the hypochlorites, which might be expected to remove bacterial deposits and are commonly employed within the domestic environment. Again, such chemicals would likely be toxic were they to be applied within the oral cavity. Perhaps, the nearest success was with enzymes, directed at both pellicle, e.g. proteases, or bacterial matrices, e.g. dextranase and mutanase (for review see Kornman 1986). Again, as will be discussed, these enzymes, albeit potentially effective, lacked substantivity within the oral cavity and had local side effects.

Antipathogenic agents

It is theoretically possible that an agent could have an effect on plaque microorganisms, which might inhibit the expression of their pathogenicity without necessarily destroying the microorganisms. In some respects antimicrobial agents, which exert a bacteriostatic effect, achieve such results. At present the understanding of the pathogenesis of gingivitis is so poor that this approach has received no attention. Were our knowledge on the microbial etiology of gingivitis to improve, there exists the possibility of an alternative, but related, approach: the introduction into the oral cavity of organisms which have been modified to remove their pathogenic potential to the gingival tissues. This is not a new concept and was an approach experimented with to replace pathogenic staphylococci within the nasal cavities of surgeons with the idea of reducing the potential for wound infection caused by the operator. At present such an approach within the oral cavity for either gingivitis or caries is perhaps within the realms of science fiction.

Conclusions

- At present most antiplaque agents are antimicrobial and prevent the bacterial proliferation phase of plaque development.
- Plaque formation could be controlled by antiadhesive or plaque removal agents, but these are not, as yet, available or safe for oral use.
- Alteration of bacterial plaque pathogenicity through chemical agents or bacterial modification would require a greater understanding of the bacterial etiology of gingivitis.

Vehicles for the delivery of chemical agents

The carriage of chemical agents into the mouth for supragingival plaque control has involved a small but varied range of vehicles (for reviews see Addy 1994; Cummins 1997).

Toothpaste

By virtue of common usage the ideal vehicle for the carriage of plaque-control agents is toothpaste. A number of ingredients go to make up toothpaste and each has a role in either influencing the consistency and stability of the product or its function (for review see Forward *et al*. 1997).

The major ingredients may be classified under the following headings:

1. *Abrasives*, such as silica, alumina, dicalcium phosphate, and calcium carbonate either alone, or more usually today, in combination. Abrasives affect

the consistency of the toothpaste and assist in the control of extrinsic dental staining. The range of abrasivity of toothpaste against dental hard tissues is defined in the BSI and ISO toothpaste standards (presently under review) in an attempt to minimize tooth wear from normal toothbrushing with toothpaste. Dentine abrasion is of prime importance as the majority of abrasives used in toothpastes produce little or no wear to enamel: non-hydrated alumina being the exception. Also, toothpaste detergents produce wear to dentine (Moore & Addy 2005). Abrasivity is calculated by relating the wear of dentine (enamel) by toothpaste to a standard formulation: the relative dentine abrasivity (RDA) value (relative enamel abrasivity (REA)). For the BSI standard a calcium carbonate based abrasive formulation is used whereas for the ISO standard it is calcium pyrophosphate based. The wear of dentine, measured directly by profilometry or release of P^{52}, by the standard is considered as 100. Toothpastes, according to the two standards, can be up to twice the standard for BSI (RDA range 0–200) and two and a half times for ISO (RDA range 0–250).

2. *Detergents*: the most common detergent used in toothpaste is sodium lauryl sulfate, which imparts the foaming and "feel" properties to the product. Additionally, detergents may help dissolve active ingredients and the anionic detergent sodium lauryl sulfate has both antimicrobial and plaque inhibitory properties (Jenkins *et al*. 1991a,b). Certain toothpaste products cannot employ anionic detergents as they interact with cationic substances that may be added to the product, such as chlorhexidine, or polyvalent metal salts, such as strontium, used in the treatment of dentine hypersensitivity.
3. *Thickeners*, such as silica and gums, primarily influence the viscosity of the product.
4. *Sweeteners*, including saccharine.
5. *Humectants*, notably glycerine and sorbitol to prevent drying out of the paste once the tube has been opened.
6. *Flavors*, of which there are many but mint or peppermint are popular in the western world although rarely found in toothpaste in the Indian subcontinent where herbal flavors are more popular.
7. *Actives*, notably fluorides for caries prevention; for plaque control triclosan and stannous fluoride and, to a lesser extent, chlorhexidine have been the most studied examples. Other actives relate to different aspects of oral care including anticalculus agents (pyrophosphates), whitening agents (polyphosphates), and desensitizing agents (strontium and potassium salts).

As stated, the addition of cationic antiseptics to toothpastes is difficult but chlorhexidine has been formulated into toothpastes and shown to be effective (Yates *et al*. 1993; Sanz *et al*. 1994), although few products have reached or lasted in the marketplace.

Mouth rinses

Despite the ideal nature of the toothpaste vehicle, most chemical plaque-control agents have been evaluated and later formulated in the mouth rinse vehicle. Mouth rinses vary in their constituents but are usually considerably less complex than toothpastes. They can be simple aqueous solutions, but the need for products, purchased by the general public, to be stable and acceptable in taste usually requires the addition of flavoring, coloring, and preservatives such as sodium benzoate. Anionic detergents are included in some products but, again, cannot be formulated with cationic antiseptics such as cetylpyridinium chloride or chlorhexidine (Barkvoll *et al*. 1989). Ethyl alcohol is commonly used both to stabilize certain active ingredients and to improve the shelf-life of the product. Several concerns, not always well substantiated, have been expressed over alcohol-containing mouth rinses (for review see Eley 1999). The possible association of alcohol intake with oropharyngeal cancer, has been extended to include alcohol-containing mouth rinses. Whether these concerns are scientifically valid has not been established and separating out the well established role of smoking in these cancers is difficult, if not impossible, as is other sources of alcohol. Also, since at present there seems little support for the long-term use of mouth rinses for gingival health benefits, when mouth rinses are correctly prescribed the risk from contained alcohol is probably minuscule. This, however, does not obviate the possible risk from self-prescription, the chronic use of mouth rinses, or the ingestion of alcoholic mouth rinses by children. In the latter case, toxicity has been reported. Additionally, alcohol may adversely affect the physical properties of some esthetic restoration materials. Sensibly the prescription or recommendation of alcohol-containing mouth rinses would seem inappropriate to known alcoholics or to those individuals whose religion or culture forbids the intake of alcohol. The proportion of alcohol is usually less than 10% but some rinses have in excess of 20% alcohol. Some manufacturers are now producing alcohol-free mouth rinses.

Spray

Spray delivery of chemical plaque-control agents has attracted both research interest and the development of products by some manufacturers in some countries. Sprays have the advantage of focusing delivery on the required site. The dose is clearly reduced and for antiseptics such as chlorhexidine this has taste advantages. When correctly applied, chlorhexidine sprays were as effective as mouth rinses for plaque inhibition, although there was no reduction in staining (Francis *et al*. 1987a; Kalaga *et al*. 1989a). Chlorhexidine sprays were found particularly useful for plaque

control in physically and mentally handicapped groups (Francis *et al*. 1987a,b; Kalaga *et al*. 1989b).

Irrigators

Irrigators were designed to spray water, under pressure, around the teeth. As such they only removed debris, with little effect on plaque deposits (for review see Frandsen 1986). Antiseptics and other chemical plaque-control agents, such as chlorhexidine, have been added to the reservoir of such devices. A variety of dilutions of chlorhexidine has been employed to good effect (Lang & Raber 1981) but again with the incumbent local side effects of this agent.

Chewing gum

Over a relatively short period there has been interest in employing chewing gum to deliver a variety of agents for oral health benefits. Also, there appear to be significant benefits to dental health through the use of sugar-free chewing gum. Unfortunately, chewing gums alone appear to have little in the way of plaque-control benefits particularly at sites prone to gingivitis (Hanham & Addy 2001). They can reduce occlusal plaque deposits (Addy *et al*. 1998), but whether this is directly relevant to the prevention of fissure caries has not been proven, indeed is unlikely. Nonetheless, the vehicle has been used to deliver chemical agents such as chlorhexidine and, when used as an adjunct to normal toothbrushing, reduced plaque and gingivitis levels have been shown (Ainamo & Etemadzadeh 1987; Smith *et al*. 1996).

Varnishes

Varnishes have been employed to deliver antiseptics including chlorhexidine, but the purpose has been to prevent root caries rather than as a reservoir for plaque control throughout the mouth.

Conclusions

- Many vehicles may be used to deliver antiplaque agents but most information relates to mouth rinses and toothpaste.
- Toothpaste appears the most practical and cost-effective method for chemical plaque control for most individuals.
- In formulating antiplaque agents into toothpaste, potential inactivation by other ingredients must be considered.
- Minority groups, such as the handicapped, may benefit from other delivery systems.

Chemical plaque control agents

Over a period of nearly four decades there has been quite intense interest in the use of chemical agents to control supragingival plaque and thereby gingivitis. The number and variation of chemical agents evaluated are quite large but most have antiseptic or antimicrobial actions and success has been extremely variable. It is important to emphasize that formulations based on antimicrobial agents provide a considerably greater preventive than therapeutic action. The most effective agents inhibit the development of plaque and gingivitis but are limited or slow to affect established plaque and gingivitis. Were they available, antiadhesive agents would similarly be expected to provide preventive rather than therapeutic effects. Plaque removal agents, on the other hand, would almost certainly provide both preventive and therapeutic actions. Chemical plaque-control agents have been the subject of many detailed reviews since 1980 (Hull 1980; Addy 1986; Kornman 1986; Mandel 1988; Gjermo 1989; Addy *et al*. 1994; Heasman & Seymour 1994; Jackson 1997; Eley 1999). Based on knowledge derived from chlorhexidine (for review see Jones 1997), the most effective plaque-inhibitory agents in the antiseptic or antimicrobial group are those showing persistence of action in the mouth measured in hours. Such persistence of action, sometimes termed substantivity (Kornman 1986), appears dependent on several factors:

1. Adsorption and prolonged retention on oral surfaces including, importantly, pellicle-coated teeth
2. Maintenance of antimicrobial activity once adsorbed primarily through a bacteriostatic action against the primary plaque-forming bacteria
3. Minimal or slow neutralization of antimicrobial activity within the oral environment or slow desorption from surfaces.

The latter concepts will be discussed later under chlorhexidine.

Antimicrobial activity of antiseptics *in vitro* is not a reliable predictor of plaque-inhibitory activity *in vivo* (Gjermo *et al*. 1970, 1973). Early studies on a number of antiseptics revealed similar antimicrobial profiles but a large variation in clinical effects. For example, compared to chlorhexidine, the cationic quaternary ammonium compound, cetylpyridinium chloride, has a similar antimicrobial profile *in vitro* (Gjermo *et al*. 1970, 1973; Roberts & Addy 1981) and is initially adsorbed in the mouth to a considerably greater extent (Bonesvoll & Gjermo 1978). The persistence of action of cetylpyridinium chloride is, however, much shorter than chlorhexidine (Schiott *et al*. 1970; Roberts & Addy, 1981), and plaque inhibition is considerably less (for review see Mandel 1988). Several reasons may explain these apparent anomalies, including poor retention of cetylpyridinium chloride within the oral cavity (Bonesvoll & Gjermo 1978), reduced activity once adsorbed, and neutralization in the oral environment (Moran & Addy 1984), or a combination of these factors. Attempts to improve efficacy of cetylpyridinium chloride can, of course, include increasing the frequency of use, but this is likely to incur compliance problems and side effects (Bonesvoll & Gjermo 1978). Alternatively,

Table 36-1 Groups of agents used in the control of dental plaque and/or gingivitis

Group	Example of agents	Action	Used now/product
Antibiotics	Penicillin Vancomycin Kanamycin Niddamycin Spiromycin	Antimicrobial	No
Enzymes	Protease Lipase Nuclease Dextranase Mutanase	Plaque removal	No
	*Glucose oxidase *Amyloglucosidase	Antimicrobial	*Yes Toothpaste
Bisbiguanide antiseptics	*Chlorhexidine Alexidine Octenidine	Antimicrobial	*Yes Mouthrinse Spray Gel Toothpaste Chewing gum Varnish
Quaternary ammonium compounds	*Cetylpyridinium chloride *Benzalconium chloride	Antimicrobial	*Yes Mouthrinse
Phenols and essential oils	*Thymol *Hexylresorcinol *Ecalyptol *Triclosan+	*Antimicrobial +Anti-inflammatory	*Yes Mouthrinse Toothpaste
Natural products	*Sanguinarine	Antimicrobial	No
Fluorides	(*)Sodium fluoride (*)Sodium monofluoro-phosphate *Stannous fluoride+ +Amine fluoride	*Antimicrobial () minimal + ?	+*Yes Toothpaste Mouthrinse +Gel
Metal salts	*Tin+ *Zinc Copper	Antimicrobial	*Yes Toothpaste Mouthrinse +Gel
Oxygenating agents	*Hydrogen peroxide *Sodium peroxyborate *Sodium peroxycarbonate	Antimicrobial ? plaque removal	*Yes Mouthrinse
Detergents	*Sodium lauryl sulfate	Antimicrobial ? plaque removal	*Yes Toothpaste Mouthrinse
Amine alcohols	Octapinol Delmopinol	Plaque matrix Inhibition	No Yes Toothpaste Mouthrinse
Salicylanide	Salifluor	Antimicrobial and anti-inflammatory	No

substantivity could be improved by combining antimicrobials or using agents to increase the retention of antimicrobials (Gaffar *et al*. 1992). Individual groups of compounds, together with the specific agents within the group, are listed in Table 36-1 and discussed below.

Systemic antimicrobials including antibiotics

(For reviews see Addy 1986; Kornman 1986)

Despite evidence for efficacy in preventing caries and gingivitis or resolving gingivitis, the opinion today is

that systemic antimicrobials should not be used either topically or systemically as preventive agents against these diseases. The risk-to-benefit ratio is high and even systemic antimicrobial use in the treatment of adult periodontitis is open to debate (for reviews see Slots & Rams 1990; Addy & Martin 2003) (see Chapter 42). Thus, systemic antimicrobials have their own specific side effects not all of which can be avoided by topical application. Perhaps of greatest importance is the development of bacterial resistance within human populations, for example methicillin-resistant *Staphylococcus aureus* (MRSA), which causes serious and life-threatening wound infections, particularly within hospitalized patients.

Enzymes

(For reviews see Addy 1986)

Enzymes fall into two groups. Those in the first group are not truly antimicrobial agents but more plaque removal agents in that they have the potential to disrupt the early plaque matrix, thereby dislodging bacteria from the tooth surface. In the late 1960s and early 1970s enzymes such as dextranase, mutanase and various proteases were thought to be a major breakthrough in dental plaque control that might prevent the development of both caries and gingivitis. Such agents, unfortunately, had poor substantivity and were not without unpleasant local side effects, notably mucosal erosion. The second group of enzymes employed glucose oxidase and amyloglucosidase to enhance the host defense mechanism. The aim was to catalyse the conversion of endogenous and exogenous thiocyanate to hypothiocyanite via the salivary lactoperoxydase system. Hypothiocycanite produces inhibitory effects upon oral bacteria, particularly streptococci, by interfering with their metabolism. This approach is a theoretical possibility and the chemical processes can be produced in the laboratory. A toothpaste product containing the enzymes and thiocyanate was produced but equivocal results for benefits to gingivitis were obtained and there are no convincing long-term studies of efficacy.

Bisbiguanide antiseptics

(For reviews see Addy 1986; Addy *et al*. 1994; Kornman 1986; Gjermo 1989; Jones 1997; Eley 1999)

Chlorhexidine is thus far the most studied and effective antiseptic for plaque inhibition and the prevention of gingivitis. Consequent upon the original publication (Löe & Schiott 1970), chlorhexidine arguably represents the nearest that research has come to identifying a chemical agent that could be used as a replacement for, rather than an adjunct to, mechanical oral hygiene practices. Other bisbiguanides such as alexidine and octenidine have less or similar activity, respectively, to chlorhexidine but bring with them no improvement in local side effects and have less toxicity data available. Chlorhexidine has thus remained the only bisbiguanide used in a number of vehicles and available in commercial products. In view of the importance of this antiseptic within preventive dentistry, a separate section later in the chapter will be devoted to considering its activity and usage in the mouth.

Quaternary ammonium compounds

(For reviews see Mandel 1988; Eley 1999)

Benzalconium chloride and, more particularly, cetylpyridinium chloride are the most studied of this family of antiseptics. Cetylpyridinium chloride is used in a wide variety of antiseptic mouth rinse products, usually at a concentration of 0.05%. At oral pH these antiseptics are monocationic and adsorb readily and quantitatively, to a greater extent, than chlorhexidine to oral surfaces (Bonesvoll & Gjermo 1978). The substantivity of cetylpyridinium chloride however appears to be only 3–5 hours (Roberts & Addy 1981) due either to loss of activity once adsorbed or rapid desorption. Cetylpyridinium chloride in mouth rinses has some chemical plaque-inhibitory action but evidence for gingivitis benefits is equivocal, particularly when formulations are used alongside toothbrushing with toothpaste. Home use studies, given the large number of rinse products containing this antiseptic, are surprisingly few. Those available, with one exception, failed to demonstrate any adjunctive benefits to toothbrushing with toothpaste. The one exception (Allen *et al*. 1998) was peculiar in that there was a lack of the expected Hawthorne effect in the control group (see section "Evaluation of chemical agents and products" later in this chapter) and the plaque reduction in the active group, 28%, was as great as seen in no brushing chemical plaque inhibition studies. As will be discussed, it is not unusual to find chemicals that provide modest, even moderate, plaque inhibition in no brushing studies but fail to show effects in adjunctive home use studies. This occurs because the range over which to show a benefit of the chemical is limited by the mechanical oral hygiene practices of the study subjects. Additionally, the plaque-inhibitory properties of cetylpyridinium chloride are reduced by toothpaste used before or after the rinse (Sheen *et al*. 2001, 2003). This may explain why a pre-brushing cetylpyridinium mouth rinse offered no adjunctive benefit to mechanical plaque control (Moran & Addy 1991). The efficacy of cetylpyridinium chloride can be increased by doubling the frequency of rinsing to four times per day (Bonsvoll & Gjermo 1978), but this increases local side effects, including tooth staining, and would probably affect compliance. Mouth rinses combining cetylpyridinium chloride with chlorhexidine are available and compare well with established chlorhexidine products (Quirynen *et al*. 2001, 2005). Whether the cetylpyridinium chloride actually contributes to the

activity of the chlorhexidine cannot be assessed. A slow-release system and lozenges have been used to deliver cetylpyridinium chloride but provided no greater plaque inhibition than the cetylpyridinium mouth rinse and significantly less than a chlorhexidine rinse (Vandekerchove *et al*. 1995). Interestingly, in this study, the lozenges produced the most dental staining. There is limited information on quaternary ammonium compounds in toothpastes and very few products are available.

Phenols and essential oils

(For reviews see Mandel 1988; Jackson 1997; Eley 1999)

Phenols and essential oils have been used in mouth rinses and lozenges for many years. One mouth rinse formulation dates back more than 100 years and, although not as efficacious as chlorhexidine, has antiplaque activity supported by a number of short- and long-term home use studies. This mouth rinse product may reduce gingivitis via both a plaque-inhibitory action and an anti-inflammatory action possibly due to an anti-oxidative activity (Firalti *et al*. 1994). The data from home use studies led the American Dental Association to accept the product as an aid to home oral hygiene measures (for review see Eley 1999). When compared directly with chlorhexidine one 6-month study has demonstrated equivalent effects on plaque and gingivitis but without the inherent side effects of chlorhexidine (Charles *et al*. 2004). Nevertheless, the pH of the product is low (pH 4.3) and has been shown *in vitro* and *in situ* to cause erosion of dentine and enamel respectively, albeit to a considerably less degree than orange juice (Addy *et al*. 1991; Pontefract *et al*. 2001). Combining essential oils with cetylpyridinium chloride has been attempted and with promising results from initial studies (Hunter *et al*. 1994).

The non-ionic antimicrobial triclosan, a trichlora-2-hydroxy phenyl ether, is usually considered to belong to the phenol group and has been widely used over many years in a number of medicated products including antiperspirants and soaps. More recently, it has been formulated into toothpaste and mouth rinses and, for the former, has accumulated an impressive amount of literature, some of which is conflicting. In simple solutions, at relatively high concentrations (0.2%) and dose (20 mg twice per day), triclosan has moderate plaque-inhibitory action and antimicrobial substantivity of around 5 hours (Jenkins *et al*. 1991a,b). The dose response against plaque of triclosan alone is relatively flat (Jenkins *et al*. 1993), although significantly greater benefits are obtained at 20 mg doses twice daily compared to 10 mg doses. In terms of plaque inhibition, a 0.1% triclosan concentration (10 mg dose twice per day) was considerably less effective than a 0.01% chlorhexidine mouth rinse (1 mg twice per day) (Jenkins *et al*. 1994).

The activity of triclosan appears to be enhanced by the addition of zinc citrate or the co-polymer, polyvinylmethyl ether maleic acid (for review see Gaffar *et al*. 1992). The co-polymer appears to enhance the retention of triclosan whereas the zinc is thought to increase the antimicrobial activity. Only triclosan toothpastes with the co-polymer or zinc citrate have shown antiplaque activity in long-term home use studies (for review see Jackson 1997). Some home use studies showed little or no effect for one or other of the products on plaque alone, gingivitis alone or both compared to the control paste or conventional fluoride toothpaste (Palomo *et al*. 1994; Kanchanakamol *et al*. 1995; Renvert & Birkhed 1995; Binney *et al*. 1996; Owens *et al*. 1997a). Triclosan toothpastes appear to provide greater gingivitis benefits in some studies than plaque reductions and this could be explained by a possible anti-inflammatory action for this agent (Barkvoll & Rolla 1994).

More recently, long-term studies have suggested that triclosan-containing toothpaste can reduce the progress of periodontitis, although the effects have been considered small (Rosling *et al*. 1997; Ellwood *et al*. 1998). Mouth rinses containing triclosan and the co-polymer are available, with some evidence of adjunctive benefits to oral hygiene and gingival health when used alongside normal tooth cleaning (Worthington *et al*. 1993). This latter study was again interesting with, unusually, no clear Hawthorne effect in the control group. Other studies on the plaque inhibitory properties of a triclosan/co-polymer mouth rinse showed effects significantly less than those of an essential oil mouth rinse product (Moran *et al*. 1997).

Natural products

(For review see Mandel 1988; Eley 1999)

Herb and plant extracts have been used in oral hygiene products for many years if not centuries. Unfortunately, there are few data available and such toothpaste products provide no greater benefits to oral hygiene and gingival health than do conventional fluoride toothpaste (Moran *et al*. 1991). The plant extract sanguinarine has been used in a number of formulations. Zinc salts are also incorporated, which makes it difficult to evaluate the efficacy of sanguinarine alone. Even when it is combined with zinc, however, data are equivocal for benefits (Moran *et al*. 1988, 1992a; Quirynen *et al*. 1990). Some positive findings were reported for the combined use of sanguinarine/zinc toothpaste and mouth rinses (Kopczyk *et al*. 1991), but the benefit-to-cost ratio must be low. Importantly and very recently, sanguinarine-containing mouth rinses have been shown to increase the likelihood of oral precancerous lesions almost ten-fold even after cessation of mouth rinse use. The manufacturer of the most well known product has replaced sanguinarine in the mouth rinses with an alternative agent. More recently, tea tree oil

has been suggested to be of value when topically delivered with positive effects at reducing gingival inflammation (Sookoulis & Hirsch 2004) but as yet no conclusive evidence for effects on plaque accumulation.

Fluorides

The caries-preventive benefits for a number of fluoride salts are well established but the fluoride ion has no effect against the development of plaque and gingivitis. Amine fluoride and stannous fluoride provide some plaque-inhibitory activity, particularly when combined; however, the effects appear to be derived from the non-fluoride portion of the molecules. A mouth rinse product containing amine fluoride and stannous fluoride is available and there is some evidence from home use studies of efficacy against plaque and gingivitis (Brecx *et al*. 1990, 1992), but less so than chlorhexidine.

Metal salts

(For reviews see Addy *et al*. 1994; Jackson 1997)

Antimicrobial actions including plaque inhibition by metal salts have been appreciated for many years, with most research interest centered on copper, tin, and zinc. Results have been somewhat contradictory but appear dependent on the metal salt used, its concentration, and frequency of use. Essentially, polyvalent metal salts alone are effective plaque inhibitors at relatively high concentration when taste and toxicity problems may arise. Stannous fluoride is an exception but is difficult to formulate into oral hygiene products because of stability problems, with hydrolysis occurring in the presence of water. Stable anhydrous gel and toothpaste products are available with evidence of efficacy against plaque and gingivitis (Beiswanger *et al*. 1995; Perlich *et al*. 1995). Stannous pyrophosphate at 1% has been added to some stannous fluoride toothpaste to good effect (Svatun 1978). Indeed, it appears that the concentration of available stannous ions is the most significant factor in determining efficacy (Addy *et al*. 1997). Dental staining, however, occurs with stannous formulations and appears to occur by the same mechanism as for chlorhexidine and other cationic antiseptics, involving interaction with dietary chromogens (for reviews see Addy & Moran 1995; Watts & Addy 2001). Combining metal salts with other antiseptics produces added plaque and gingivitis inhibitory effects, for example zinc and hexetidine (Saxer & Muhlemann 1983) and, as already described, zinc and triclosan. Copper also causes dental staining but is not available in oral hygiene products. Zinc, at low concentration, has no side effects and is used in a number of toothpastes and mouth rinses; however, alone it has little effect on plaque (Addy *et al*. 1980) except at higher concentrations. Zinc salts nevertheless, may be of value at reducing volatile sulfur compounds associated with oral malodor (Rosing *et al*. 2002).

Oxygenating agents

(For review see Addy *et al*. 1994)

Oxygenating agents have been used as disinfectants in various disciplines of dentistry, including endodontics and periodontics. Hydrogen peroxide has been employed for supragingival plaque control and more recently has become important as bleach in tooth whitening. Similarly, peroxyborate may be used in the treatment of acute ulcerative gingivitis (Wade *et al*. 1966). Products containing peroxyborate and peroxycarbonate were, until recently, available in Britain and Europe with evidence of antimicrobial and plaque-inhibitory activity (Moran *et al*. 1995). There are little data from long-term home use studies and such evaluations would seem warranted before conclusions about true antiplaque activity can be drawn.

Detergents

Detergents, such as sodium lauryl sulfate, are common ingredients in toothpaste and mouth rinse products. Besides other qualities and, for that matter, side effects, detergents such as sodium lauryl sulfate have antimicrobial activity (Jenkins *et al*. 1991b) and probably provide most of the modest plaque-inhibitory action of toothpaste (Addy *et al*. 1983). Alone, sodium lauryl sulfate was shown to have moderate substantivity, measured at between 5 and 7 hours, and plaque-inhibitory action similar to triclosan (Jenkins *et al*. 1991a,b). Detergent-only formulations are not available and no long-term evaluations have been performed.

Amine alcohols

This group of compounds does not truly fit into an antimicrobial or antiseptic category; indeed they exhibit minimal effects against microbes. Of these morpholinoethenol derivatives, octopinol was the first to be shown effective as an antiplaque agent but was withdrawn for toxicologic reasons. Delmopinol followed and at 0.1% and 0.2% in mouth rinses was shown to be effective against plaque and gingivitis in short-term no oral hygiene and long-term home use studies (Collaert *et al*. 1992; Moran *et al*. 1992b; Claydon *et al*. 1996; Hase *et al*. 1998; Lang *et al*. 1998). Arguably, the short-term no oral hygiene studies showed plaque inhibition closer to chlorhexidine than any other previous agent (Moran *et al*. 1992b). Recently, the data from eight studies from seven independent research groups in five European countries using a 0.2% delmopinol mouth rinse as an adjunct to normal oral hygiene practices were subjected to a meta-analysis. Delmopinol, one of the very few chemical plaque-control agents to be subjected to

such analyses, was shown to be a significantly effective adjunct for reducing the plaque burden and severity of gingivitis (Addy *et al*. 2007). The data for gingivitis in several studies met the efficacy criteria for gingivitis reduction of the American Dental Association. The mode of action of delmopinol can be debated but appears to be an interference with plaque matrix formation, reducing the adherence of the primary plaque-forming bacteria of the successional bacteria (Simonsson *et al*. 1991a,b). If correct, delmopinol would closest fit classification as an antiadhesive agent. Side effects include tooth discoloration, transient numbness of the tongue, and burning sensations in the mouth (Claydon *et al*. 1996; Hase *et al*. 1998; Lang *et al*. 1998). Interestingly, the staining was considerably less than with chlorhexidine, rarely reported by study participants and easily removed. In these adjunctive studies discontinuations were considerably less with delmopinol than chlorhexidine. Rinses containing 0.2% delmopinol are available in some countries.

Salifluor

(For review see Eley 1999)

Salifluor, a salicylanide with both antibacterial and anti-inflammatory properties, has been studied for its effects of plaque inhibition and retardation of onset of gingivitis (Furuichi *et al*. 1996). To improve oral retention and to maximize adsorption, Gantrez (PVM/MA) has been incorporated in salifluor toothpaste and mouth rinse formulations. Perhaps surprisingly, salifluor has not been extensively evaluated, since initial 4-day plaque regrowth studies and 14-day gingivitis studies have suggested equivalent efficacy to a 0.12% chlorhexidine mouth rinse (Furuichi *et al*. 1996). In spite of this evidence to suggest the potential value of the chemical as an antiplaque agent, further long-term studies have yet to be carried out.

Acidified sodium chlorite

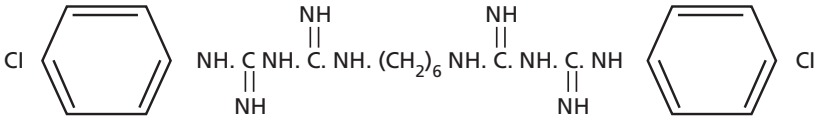
(For review see Yates *et al*. 1997)

This agent does not sit well with any particular group listed in Table 36-1; however, depending on the acid chosen and the conditions of the reaction between the acid and the sodium chlorite, a varied and complex range of reaction products can ensue. Under ideal conditions for antimicrobial benefits sodium chlorite is reacted with a protic acid to produce chlorous acid, which then liberates a range of higher oxidant species but contains minimal amounts of chlorine dioxide. These higher oxidant species have a broad range of antimicrobial action against bacteria, fungi, yeast, and viruses, and products are available in the US within the veterinary and food industry, both as a preventive for mastitis in cows and for the preservation of frozen poultry. Experimental mouth rinses have been tested in short-term plaque regrowth studies and salivary bacterial count investigations (Yates *et al*. 1997). Surprisingly, given that the acid and sodium chlorite are mixed immediately before rinsing, and that the duration of the chemical reaction would be limited to the rinsing time, three experimental formulations were shown to be as good as chlorhexidine against plaque regrowth and showed the same substantivity as chlorhexidine. Although not tested in longer-term studies, side effects, particularly staining and alteration of taste, would appear unlikely with the acidified sodium chlorite mouth rinses. Unfortunately, the low pH of the formulations would be expected to cause some dental erosion and this has been proven in studies *in situ* (Pontefract *et al*. 2001). Such erosion, which was found comparable to that of orange juice *in situ*, would tend to obviate the long-term continuous use of such agents. Acidified sodium chlorite mouth rinses, however, could find application in preventive dentistry similar to those to be described for chlorhexidine (see later in this chapter). The erosive effects would not, in short- to medium-term use, reach clinically significant levels. To date no commercial products are available.

Other antiseptics

(For review see Addy 1986)

A number of antiseptics/antimicrobial agents have been studied for plaque inhibition. Most have been found to have little or no effect *in vivo*; a few have been formulated in mouth rinse products including povidone iodine and hexetidine. Povidone iodine at 1% has a substantivity of only 60 minutes (Addy & Wright 1978) and lacks appreciable plaque-inhibitory activity (Addy *et al*. 1977) or action in acute infections such as acute ulcerative gingivitis (Addy & Llewelyn 1978), for which it is recommended. Povidone iodine is largely without side effects but as a rinse has potential to affect thyroid function adversely (Wray *et al*. 1978). Hexetidine, a saturated pyrimidine, at 0.1% was shown to have limited plaque-inhibitory action (Bergenholtz & Hanstrom 1974) and no evidence for antiplaque activity when used as an adjunct for oral hygiene (Chadwick *et al*. 1991). The action of hexetidine against plaque appears enhanced by zinc salts (Saxer & Muhlemann 1983) but data are derived only from short-term studies. Side effects for hexetidine include tooth staining and mucosal erosion, although both are uncommon (Bergenholtz & Hanstrom 1974). Nevertheless, mucosal erosion is markedly increased in incidence if the concentration is raised to 0.14% (Bergenholtz & Hanstrom 1974). A mouth rinse product containing 0.1% hexetidine is available in some European countries. Recent studies have shown favorable effects on plaque and gingivitis (Sharma *et al*. 2003; Ernst *et al*. 2005) and when compared to 0.1% chlorhexidine, less tendency for stain production (Ernst *et al*. 2005).



1,6–di (4–chlorophenyldiguanido) hexane

Fig. 36-2 Chlorhexidine molecule.

Conclusions

- Effective antimicrobial antiplaque agents show prolonged persistence of action in the mouth (substantivity). Chlorhexidine is the most effective antiplaque agent to date. Stannous fluoride and triclosan oral hygiene products are available with proven antiplaque activity. The long established mouth rinse, based on essential oils, has some evidence for adjunctive antiplaque activity.
- The limited information on natural products, for example herbal formulations, is not encouraging and the root extract sanguinarine has been withdrawn because of the potential to cause precancerous oral lesions.
- The amine alcohol, delmopinol, is an effective antiplaque agent and products are becoming available.
- Acidified sodium chlorite appears as effective as chlorhexidine against plaque but the acidic nature of the rinse may obviate oral hygiene products ever coming to the marketplace.
- Combinations of agents sometimes provide additive or synergistic action, but with the exception of triclosan, few products are available.

Chlorhexidine

Chlorhexidine is available in three forms, the digluconate, acetate, and hydrochloride salts. Most studies and most oral formulations and products have used the digluconate salt, which is manufactured as a 20% V/V concentrate. Digluconate and acetate salts are water soluble but hydrochloride is very sparingly soluble in water. Chlorhexidine was developed in the 1940s by Imperial Chemical Industries, England, and marketed in 1954 as an antiseptic for skin wounds. Later, the antiseptic was more widely used in medicine and surgery including obstetrics, gynecology, urology, and presurgical skin preparation for both patient and surgeon. Use in dentistry was initially for presurgical disinfection of the mouth and in endodontics. The first definitive study on chlorhexidine was performed by Löe and Schiott (1970). This study showed that rinsing for 60 seconds twice per day with 10 ml of a 0.2% (20 mg dose) chlorhexidine gluconate solution in the absence of normal tooth cleaning, inhibited plaque regrowth and the development of gingivitis. Numerous studies followed, such that chlorhexidine is one of the most investigated compounds in dentistry (for reviews see Jones 1997; Eley 1998). Chlorhexidine is a bisbiguanide antiseptic, being a symmetrical molecule consisting of four chlorophenyl rings and two biguanide groups connected by a central hexamethylene bridge (Fig. 36-2). The compound is a strong base and dicationic at pH levels above 3.5, with two positive charges on either side of a hexamethylene bridge. Indeed, it is the dicationic nature of chlorhexidine, making it extremely interactive with anions, which is relevant to its efficacy, safety, local side effects, and difficulties with formulation in products.

Toxicology, safety, and side effects

The cationic nature of chlorhexidine minimizes absorption through the skin and mucosa, including from the gastrointestinal tract. Systemic toxicity from topical application or ingestion is therefore not reported, nor is there evidence of teratogenicity in the animal model. Even in intravenous infusion in animals, chlorhexidine is well tolerated and this has occurred accidentally in humans without serious consequences. Hypersensitivity reactions including anaphylaxis have been reported in fewer than 10 people in Japan and resulted from the application of non-proprietary chlorhexidine products to sites other than the mouth. There was insufficient information to confirm that the reactions were actually due to chlorhexidine. Neurosensory deafness can occur if chlorhexidine is introduced into the middle ear and the antiseptic should not be placed in the outer ear in case the eardrum is perforated. The antiseptic has a broad antimicrobial action, including a wide range of Gram-positive and Gram-negative bacteria (Wade & Addy 1989). It is also effective against some fungi and yeasts including *Candida*, and some viruses including HBV and HIV. Bacterial resistance has not been reported with long-term, oral use or evidence of super-infection by fungi, yeasts or viruses. Long-term oral use resulted in a small shift in the flora towards the less sensitive organisms but this was rapidly reversible at the end of the 2-year study (Schiott *et al*. 1976).

In oral use as a mouth rinse, chlorhexidine has been reported to have a number of local side effects (Flotra *et al*. 1971). These side effects are:

1. Brown discoloration of the teeth and some restorative materials and the dorsum of the tongue (Figs. 36-3 and 36-4).
2. Taste perturbation where the salt taste appears to be preferentially affected (Lang *et al*. 1988) to leave food and drinks with a rather bland taste.
3. Oral mucosal erosion (Fig. 36-5). This appears to be an idiosyncratic reaction and concentration

Fig. 36-3 Brown discoloration of the teeth of an individual rinsing twice a day for 3 weeks with a 0.2% chlorhexidine mouth rinse.

Fig. 36-4 Brown discoloration of the tongue of an individual rinsing twice a day for 2 weeks with a 0.2% chlorhexidine mouth rinse.

Fig. 36-5 Mucosal erosion occurring following a few days of rinsing twice a day with a 0.2% chlorhexidine mouth rinse.

dependent. Dilution of the 0.2% formulation to 0.1%, but rinsing with the whole volume to maintain dose, usually alleviates the problem. Erosions are rarely seen with 0.12% rinse products used at 15 ml volume.

4. Unilateral or bilateral parotid swelling (Fig. 36-6). This is an extremely rare occurrence and an explanation is not available.
5. Enhanced supragingival calculus formation. This effect may be due to the precipitation of salivary proteins on to the tooth surface, thereby increasing pellicle thickness and/or precipitation of inorganic salts on to or into the pellicle layer.

Fig. 36-6 Bilateral parotid swelling following a few days of rinsing with a 0.2% chlorhexidine mouth rinse.

Chlorhexidine also has a bitter taste, which is difficult to mask completely.

Chlorhexidine staining

The mechanisms proposed for chlorhexidine staining can be debated (Eriksen *et al*. 1985; for reviews see Addy & Moran 1995; Watts & Addy 2001) but have been proposed as:

1. Degradation of the chlorhexidine molecule to release parachloraniline
2. Catalysis of Maillard reactions
3. Protein denaturation with metal sulfide formation
4. Precipitation of anionic dietary chromogens.

Degradation of chlorhexidine to release parachloraniline appears not to occur on storage or as a result of metabolic processes. Also, alexidine, a related bisbiguanide, does not have parachloraniline groups, yet causes staining identical to that of chlorhexidine. Non-enzymatic browning reactions (Maillard reactions) catalyzed by chlorhexidine are a theoretical possibility; however, evidence is indirect, circumstantial or inconclusive (Eriksen *et al*. 1985). The theory does not consider the fact that other antiseptics and metals such as tin, iron, and copper also produce dental staining. Protein denaturation produced by chlorhexidine with the interaction of exposed sulfide radicals with metal ions is also theoretically possible but there is no direct evidence to support this concept. Again, the theory does not take into account similar staining by other antiseptics and metal ions. Laboratory and clinical studies also could

not reproduce this process (for reviews see Addy & Moran 1985; Watts & Addy 2001). Precipitation of anionic dietary chromogens by cationic antiseptics, including chlorhexidine and polyvalent metal ions as an explanation for the phenomenon of staining by these substances, is supported by a number of well controlled laboratory and clinical studies (for reviews see Addy & Moran 1995; Watts & Addy 2001). Thus, the locally bound antiseptics or metal ions on mucosa or teeth can react with polyphenols in dietary substances to produce staining. Beverages such as tea, coffee, and red wine are particularly chromogenic, but other foods and beverages will interact to produce various colored stains. These reactions between chlorhexidine and other cationic antiseptics and polyvalent metal ions with chromogenic beverages can be performed within the test tube. Interestingly, most of the precipitates formed between polyvalent metal ions and chromogens have the same color as their sulfide salts. It is for this reason that original theories considered that staining, seen in individuals exposed to these polyvalent metal ions, usually in the workplace, was due to metal sulfide formation. Again, laboratory and clinical experiments have failed to produce such interactions.

It is perhaps the staining side effect that limits long-term use of chlorhexidine in preventive dentistry (Flotra *et al*. 1971) and occurs with all correctly formulated products including gels, toothpastes, and sprays. Indeed, the staining side effect can be used to assess patient compliance in the use and activity of formulations. In the latter case laboratory and clinical studies on staining have revealed a proprietary chlorhexidine mouth rinse product to be inactive (Renton-Harper *et al*. 1995). Interestingly, this particular chlorhexidine product was reformulated in the UK to produce an active formulation (Addy *et al*. 1991), but the manufacturers maintained the original formulation within France when both laboratory and clinical studies confirmed markedly reduced potential of the product to cause staining in the laboratory, and plaque inhibition in the clinic (Renton-Harper *et al*. 1995). Recently, a chlorhexidine product with an anti-discoloration system (ADS) was launched in Europe. A clinical study purporting to show reduced staining had significant drawbacks in design and presentation (Bernadi *et al*. 2004). A laboratory study found no difference in staining potential (Addy *et al*. 2005) and a plaque regrowth study showed significantly reduced plaque inhibition for the ADS rinse (Arweiler *et al*. 2006). The old adage concerning chlorhexidine products appears to still hold true: "If it does not stain it does not work".

Mechanism of action

(For reviews see Addy 1986; Jenkins *et al*. 1988)

Chlorhexidine is a potent antibacterial substance but this alone does not explain its antiplaque action. The antiseptic binds strongly to bacterial cell membranes. At low concentration this results in increased permeability with leakage of intracellular components including potassium. At high concentration, chlorhexidine causes precipitation of bacterial cytoplasm and cell death. In the mouth chlorhexidine readily adsorbs to surfaces including pellicle-coated teeth. Once adsorbed, and unlike some other antiseptics, chlorhexidine shows a persistent bacteriostatic action lasting in excess of 12 hours (Schiott *et al*. 1970). Radio-labelled chlorhexidine studies suggest a slow release of the antiseptic from surfaces (Bonesvoll *et al*. 1974a,b) and this was suggested to produce a prolonged antibacterial milieu in the mouth (Gjermo *et al*. 1974). The methods used, however, could not determine the activity of the chlorhexidine, which was almost certainly attached to the salivary proteins and desquamating epithelial cells and therefore unavailable for action. Consistent with the original work and conclusions (Davies *et al*. 1970), a more recent study and review suggested that plaque inhibition is derived only from the chlorhexidine adsorbed to the tooth surface (Jenkins *et al*. 1988). It is possible that the molecule attaches to pellicle by one cation leaving the other free to interact with bacteria attempting to colonize the tooth surface. This mechanism would, therefore, be similar to that associated with tooth staining. It would also explain why anionic substances, such as sodium lauryl sulfate based toothpastes, reduce the plaque inhibition of chlorhexidine if used shortly after rinses with the antiseptic (Barkvoll *et al*. 1989). Indeed, a more recent study has demonstrated that plaque inhibition by chlorhexidine mouth rinses is reduced if toothpaste is used immediately before or immediately after the rinse (Owens *et al*. 1997b). These inhibitory effects on chlorhexidine activity by substances such as toothpastes can be modeled using the chlorhexidine tea staining method, which shows reduced staining activity by the chlorhexidine solutions resulting from an interaction with toothpaste (Sheen *et al*. 2001).

Plaque inhibition by chlorhexidine mouth rinses appears to be dose related (Jenkins *et al*. 1994) such that similar effects to that seen with the more usual 10 ml, 0.2% solution (20 mg) can be achieved with high volumes of low-concentration solutions (Lang & Ramseier-Grossman 1981). It is worth noting, however, that not inconsiderable plaque inhibition is obtained with doses as low as 1–5 mg twice daily (Jenkins *et al*. 1994). Also, and relevant to the probable mechanism of action, topically applying 0.2% solutions of chlorhexidine only to the tooth surface, including by the use of sprays, produces the same level of plaque inhibition as rinsing with the full 20 mg dose (Addy & Moran 1983; Francis *et al*. 1987a; Jenkins *et al*. 1988; Kalaga *et al*. 1989a).

Chlorhexidine products

Chlorhexidine has been formulated into a number of products.

Mouth rinses

Aqueous alcohol solutions of 0.2% chlorhexidine were first made available for mouth rinse products for twice daily use in Europe in the 1970s. A 0.1% mouth rinse product also became available; however questions were raised over the activity of the 0.1% product and in some countries the efficacy of this product is less than would be expected from a 0.1% solution (Jenkins *et al*. 1989). Later, in the US, a 0.12% mouth rinse was manufactured but to maintain the almost optimum 20 mg doses derived from 10 ml of 0.2% rinses, the product was recommended as a 15 ml rinse (18 mg dose). The studies revealed equal efficacy for 0.2% and 0.12% rinses when used at appropriate similar doses (Segreto *et al*. 1986). More recently alcohol-free chlorhexidine rinses have become available, some formulated with the inclusion of 0.05% CPC. Such formulations have been shown to possess equivalent effects at inhibiting plaque and gingivitis compared to alcohol-containing chlorhexidine rinses but with better taste acceptability with the non-alcoholic rinse (Quirynen *et al*. 2001; Van Strydonck *et al*. 2005)

Gel

A 1% chlorhexidine gel product is available and can be delivered on a toothbrush or in trays. The distribution of the gel by toothbrush around the mouth appears to be poor and preparations must be delivered to all tooth surfaces to be effective (Saxen *et al*. 1976).

In trays the chlorhexidine gel was found to be particularly effective against plaque and gingivitis in handicapped individuals (Francis *et al*. 1987a). The acceptability of this tray delivery system to the recipients and the carers was found to be poor (Francis *et al*. 1987b). More recently, 0.2% and 0.12% chlorhexidine gels have become available.

Sprays

Sprays containing 0.1% and 0.2% chlorhexidine are commercially available in some countries. Studies with the 0.2% spray have revealed that small doses of approximately 1–2 mg delivered to all tooth surfaces produces similar plaque inhibition to a rinse with 0.2% mouth rinses (Kalaga *et al*. 1989a). Sprays appear particularly useful for the physically and mentally handicapped groups, being well received by individuals and their carers (Francis *et al*. 1987a,b; Kalaga *et al*. 1989b).

Toothpaste

(For review see Yates *et al*. 1993)

Chlorhexidine is difficult to formulate into toothpaste for reasons already given and early studies produced variable outcomes for benefits to plaque and gingivitis. More recently, a 1% chlorhexidine toothpaste with and without fluoride was found to be superior to the control product for the prevention of plaque and gingivitis in a 6-month home use study (Yates *et al*. 1993). Stain scores however, were markedly increased as was supragingival calculus formation, and the manufacturer did not produce a commercial product. For a short time a commercial product was available, having been shown to be efficacious for both plaque and gingivitis (Sanz *et al*. 1994). Although effective, chlorhexidine products based on toothpaste and sprays produce similar tooth staining to mouth rinses and gels; taste disturbance, mucosal erosion, and parotid swellings tend to be less or have never been reported.

Varnishes

Chlorhexidine varnishes have been used mainly for prophylaxis against root caries rather than an antiplaque depot for chlorhexidine in the mouth.

Slow-release vehicles

A chlorhexidine chip has been produced commercially for placement into periodontal pockets as an adjunct to scaling and root planning. This will be discussed in Chapter 42.

Conclusions

- Chlorhexidine to date is the proven most effective antiplaque agent, for which commercial products are available to the public.
- Chlorhexidine is free from systemic toxicity in oral use, and microbial resistance and super-infection do not occur.
- Local side effects are reported which are mainly cosmetic problems.
- The antiplaque action of chlorhexidine appears dependent on prolonged persistence of antimicrobial action in the mouth (substantivity).
- A number of vehicles for delivering chlorhexidine are available, but mouth rinses are most commonly recommended.
- Extrinsic dental staining and perturbation of taste are variably the two side effects of chlorhexidine mouth rinse usage, which limit acceptability to users and the long-term employment of this antiseptic in preventive dentistry.

Clinical uses of chlorhexidine

Despite the excellent plaque inhibitory properties of chlorhexidine, widespread and prolonged use of the agent is limited by local side effects. Moreover, because of the cationic nature of the chlorhexidine and therefore its poor penetrability, the antiseptic is of limited value in the therapy of established oral conditions including gingivitis, and is much more valuable in the preventive mode. A number of

clinical uses, some well researched, have been recommended for chlorhexidine (for reviews see Gjermo 1974; Addy 1986; Addy & Renton-Harper 1996; Addy & Moran 1997; Eley 1999).

As an adjunct to oral hygiene and professional prophylaxis

Oral hygiene instruction is a key factor in the treatment plan for patients with periodontal disease and as part of the maintenance program following treatment. Adequate plaque control by periodontal patients is therefore essential to successful treatment and the prevention of recurrence of the disease. Chlorhexidine should therefore increase the improvement in gingival health through plaque control, particularly following professional prophylaxis to remove existing supra- and immediately subgingival plaque. There is, however, a potential disadvantage of using such an effective chemical plaque-control agent at this stage of the periodontal treatment plan. Thus, following oral hygiene instruction, it is normal, usually by the use of indices, to quantify the improvement in plaque control by patients so instructed and, in particular, the improvement at specific sites, which previously had been missed by individual patients. By virtue of the excellent plaque-control effects of chlorhexidine, the response to oral hygiene instruction cannot be accurately assessed since the antiseptic will overshadow any deficiencies in mechanical cleaning. Indeed, as the original research demonstrated, with chlorhexidine mouth rinse patients could maintain close to zero levels of plaque following a professional prophylaxis without using any form of mechanical oral hygiene (Löe & Schiott 1970). Nevertheless, chlorhexidine mouth rinse may be of value in maintaining oral hygiene following scaling and root planing when adequate tooth brushing may be compromised by post-treatment soreness or sensitivity.

Post oral surgery including periodontal surgery or root planing

Chlorhexidine may be used post-operatively since it offers the advantage of reducing the bacterial load in the oral cavity and preventing plaque formation at a time when mechanical cleaning may be difficult because of discomfort. In periodontal surgery, periodontal dressings have largely been replaced by the use of chlorhexidine preparations, in particular mouth rinses, since healing is improved and discomfort reduced (Newman & Addy 1978, 1982). Regimens vary but chlorhexidine should be used immediately post treatment and for periods of time until the patient can re-institute normal oral hygiene. Depending on the appointment schedule, chlorhexidine could be used throughout the treatment phase and for periods of weeks after completion of the treatment plan. If dressings are used, chlorhexidine is of limited value to the post-operative site since it does not penetrate beneath the periodontal dressings (Pluss *et al*. 1975). Although chlorhexidine rinses are probably used after root planing by many clinicians, evidence of therapeutic benefit has only recently been published (Faveri *et al*. 2006).

The idea of full-mouth disinfection using chlorhexidine both supra- and subgingivally as an adjunct to scaling and root planing has been assessed by one group in a number of papers since 1995 (for review see Quirynen *et al*. 2006). In the event, few adjunctive benefits could be shown (for review see Apatzidou 2006). It appeared that the more dominant factor was the time over which the non-surgical treatment plan was completed. Thus, root planing performed totally within 24 hours was more effective than root planing completed over more conventional periods of several weeks (Quirynen *et al*. 2006). Similar clinical research however, showed no difference between root planing completed within 24 hours compared to within several weeks (Apatzidou & Kinane 2004).

For patients with jaw fixation

Oral hygiene is particularly difficult when jaws are immobilized by such methods as intermaxillary fixation. Chlorhexidine mouth rinses have been shown markedly to reduce the bacterial load, which tends to increase during jaw immobilization, and to improve plaque control (Nash & Addy 1979). The more recent trend to use sub-dermal or sub-mucosal plates to stabilize bony fragments probably impedes oral hygiene procedures to a lesser degree, providing there are no oral mucosal lacerations. The influence of these factors on oral hygiene and therefore the role of chlorhexidine formulation has never been investigated.

For oral hygiene and gingival health benefits in the mentally and physically handicapped

Chlorhexidine has been found particularly useful in institutionalized mentally and physically handicapped groups, improving both oral hygiene and gingival health (Storhaug 1977). Spray delivery of 0.2% solutions was found particularly useful and acceptable to patients and care workers (Francis *et al*. 1987a,b; Kalaga *et al*. 1989b).

Medically compromised individuals predisposed to oral infections

A number of medical conditions predispose individuals to oral infections, notably candidiasis. Chlorhexidine is effective as an anticandidal agent but is most useful when combined with specific anticandidal drugs, such as nystatin or amphotericin B (Simonetti *et al*. 1988). Indications for chlorhexidine use combined with anticandidal drugs have been for the prevention of oral and systemic infections in the

immunocompromised, including those with blood dyscrasias, those receiving chemotherapy and/or radiotherapy, and notably bone marrow transplant patients (Ferretti *et al*. 1987, 1988; Toth *et al*. 1990). The value of chlorhexidine appears greatest when initiated before oral or systemic complications arise. A chlorhexidine spray was also found to produce symptomatic/psychologic oral care benefits in the terminally ill (Jobbins *et al*. 1992).

High-risk caries patients

Chlorhexidine rinses or gels can reduce considerably the *Streptococcus mutans* counts in individuals who are caries prone. Additionally, and interestingly, chlorhexidine appears synergistic with sodium fluoride and combining chlorhexidine and fluoride rinses appears beneficial to such at-risk individuals (Dolles & Gjermo 1980). Sodium monofluorophosphate on the other hand, reduces the effect of chlorhexidine and probably *vice versa* (Barkvoll *et al*. 1988). A chlorhexidine rinse product with sodium fluoride has recently become available.

Recurrent oral ulceration

Several studies have shown that chlorhexidine mouth rinses and chlorhexidine gels reduce the incidence, duration, and severity of recurrent minor aphthous ulceration (for review see Hunter & Addy 1987). The mechanism of action is unclear but may relate to a reduction in contamination of ulcers by oral bacteria, thereby reducing the natural history of the ulceration. Regimens have included three times daily use of chlorhexidine products for several weeks. Interestingly, one study showed that triclosan rinses reduce the incidence of recurrent mouth ulcers (Skaare *et al*. 1996). There have been no controlled studies of chlorhexidine in the management of major aphthous ulceration or other oral erosive or ulcerative conditions, although anecdotally chlorhexidine appears ineffective. Again, this may reflect the low therapeutic potential of this and other antiseptics, and the considerable amount of proteinacious material associated with these lesions which would both tend to inactivate chlorhexidine and block access to underlying microorganisms (Roberts & Addy 1981). A similar explanation may be propounded for the failure of chlorhexidine mouth rinses in treatment of acute necrotizing ulcerative gingivitis (periodontitis) (Addy & Llewelyn 1978): further evidence for the lack of absorption into tissues and biofilms of this cationic antiseptic.

Removable and fixed orthodontic appliance wearers

Plaque control in the early stages of orthodontic appliance therapy may be compromised and chlorhexidine can be prescribed for the first 4–8 weeks. Additionally, chlorhexidine has been shown to reduce the number and severity of traumatic ulcers during the first 4 weeks of fixed orthodontic therapy (Shaw *et al*. 1984).

Denture stomatitis

Chlorhexidine has been recommended in the treatment of *Candida*-associated infections; however, in practice even applying chlorhexidine gel to the fitting surfaces of dentures produces, in many cases, slow and incomplete resolution of the condition. Again, chlorhexidine is less effective in the therapeutic mode and it is more advantageous to treat denture stomatitis with specific anticandidal drugs and then employ chlorhexidine to prevent recurrence. The denture itself can be usefully sterilized from *Candida* by soaking in chlorhexidine solutions (Olsen 1975).

Oral malodor

Rinsing with chlorhexidine as with other antiseptic mouth rinses containing CPC, triclosan, and essential oils, has been suggested to be of value in reducing halitosis. Reductions in volatile sulphur compounds and morning malodor have been noted with all these chemicals (Carvalho *et al*. 2004).

Immediate pre-operative chlorhexidine rinsing and irrigation

This technique can be used immediately prior to operative treatment, particularly when air polishing, ultrasonic scaling or high-speed instruments are to be used. Such pre-operative rinsing markedly reduces the bacterial load and contamination of the operative area, operator, and staff (Worral *et al*. 1987). Additionally, in susceptible patients, irrigation of chlorhexidine around the gingival margin reduces the incidence of bacteremia (MacFarlane *et al*. 1984). This should be seen, however, only as an adjunct to appropriate systemic antimicrobial prophylaxis. Chlorhexidine mouth rinsing now features as an adjunct to antibiotic prophylaxis in the new UK guidelines.

Subgingival irrigation

Numerous antimicrobial agents have been used as subgingival irrigants in the management and treatment of periodontal diseases (for reviews see Wennstrom 1992, 1997). Alone, irrigation with antimicrobial agents produces effects little different from using saline, and they are of short duration, suggesting that the action is a washing-out effect. Irrigation combined with root planing appears to provide no adjunctive benefits.

Conclusions

- There is a significant number of indications for the use of chlorhexidine in preventive dentistry, most

of which rely on the antimicrobial properties of the antiseptic and its duration of action.
- The most valuable chemical plaque-control uses of chlorhexidine are in the short to medium term when mechanical tooth cleaning is not possible, difficult or inadequate and during which time local side effects are likely to be minimized.
- Chlorhexidine is more effective as a preventive rather than a therapeutic agent and therefore must be of questionable value as a subgingival adjunct in the treatment of periodontitis (see Chapter 42).

Evaluation of chemical agents and products

(For reviews see Addy *et al*. 1992; Addy 1995; Moss *et al*. 1995; Addy & Moran 1997)

The number and use of oral hygiene products has grown enormously in recent years and, as an example, hundreds of millions of pounds per year are spent on oral hygiene products in the UK and presumably billions worldwide. There can be no doubt that the oral hygiene industries, through their collaboration and research with the dental profession and their promotion of their products have, in no small way, contributed to the improvement in dental health seen in many countries. Claims for efficacy of oral hygiene products, however, are frequently made and it is essential that these are supported by scientific evidence. Without such evidence the profession and the public may be confused or misled. The dental profession is, however, faced with a large number of oral hygiene products supported by huge quantities of varied promotional literature and media advertising, which makes impossible, in many cases, any valid judgment or assessment of the efficacy or value of individual products to specific patient groups or the public as a whole. Even those with specialized interest, and research experience in specific aspects of oral hygiene product evaluation, must find validation, based on published literature, a daunting task. This is made all the more difficult since what constitutes proof of efficacy is not generally agreed even amongst so-called experts. Few countries of the world have central control over what evidence is required before efficacy claims can be made and there are very few guidelines suggesting requirements for proof of efficacy for oral hygiene products.

The scientific evaluation of dental products, and for that matter, preventive and therapeutic agents in medicine as a whole, is a relatively modern concept but today must be the backbone on which to base claims of efficacy. Anecdotal and case reports, uncontrolled studies and data listed as "held on file" by manufacturers, whilst interesting, should not be used as the basis for efficacy claims. Blind, randomized, controlled clinical and laboratory studies must be the methods used today to obtain data on the activity of agents, formulations, and products. Terminology and phraseology in product claims also needs to be carefully reviewed and assessed. Perhaps the greatest area for criticism must be the implied claim by the manufacturer and/or the inferences left to be drawn, from promotional material, by the dental profession or public. A classic scenario for which there is precedence can be stated as follows: A is the cause of B, C reduces A, leaving the inference to be drawn that C can control B. Perhaps nowhere is this more apparent than in the use of agents which are known to control plaque, and therefore it can be implied, without evidence, they must control gingivitis. The now familiar claim would be "this product reduces plaque, the major cause of gum disease". Similarly, creative arithmetic is not infrequently used to give inflated impressions of efficacy. Proportional differences, rather than actual differences, are not infrequently quoted, as are percentages of percentages giving hundreds of percent improvements over another product or control, yet the actual benefit is a fraction of the scoring index used. Finally, "piggy back" claims are not uncommon, when a known active ingredient is formulated into a new product and equivalent efficacy to established products is assumed. It would seem reasonable here to repeat the definitions for the terminology for oral hygiene products, agreed at the European Workshop on Periodontology in 1996 which defined certain terms (Lang & Newman 1997):

- *Antimicrobial agents*: chemicals that have a bacteriostatic or bactericidal effect *in vitro* that alone cannot be extrapolated to a proven efficacy *in vivo* against plaque.
- *Plaque reducing/inhibitory agents*: chemicals that have only been shown to reduce the quantity and/or affect quality of plaque, which may or may not be sufficient to influence gingivitis and/or caries.
- *Antiplaque agents*: chemicals that have an effect on plaque sufficient to benefit gingivitis and/or caries.
- *Antigingivitis agents*: chemicals which reduce gingival inflammation without necessarily influencing bacterial plaque (includes anti-inflammatory agents).

Thus, the fact that antimicrobial agents such as antiseptics kill or inhibit the growth of bacteria does not necessarily mean they will be effective plaque inhibitors (Gjermo *et al*. 1970). Also, the mere incorporation of a known antiplaque agent into a formulation is not a guarantee of efficacy because inactivation by other ingredients may occur.

This section looks at methods that have been used to test oral hygiene products both in the laboratory and the clinic. No one protocol can provide all the answers, and research and development of agents into products is a step-by-step process, hopefully culminating in a body of evidence proving efficacy, beyond doubt, of a final product. Methods *in vitro* and *in vivo* will be summarized but animal testing

will not be discussed except to acknowledge that the use of animals is still necessary in drug development, in understanding the mode of action of drugs and, particularly, in evaluating safety from a toxicologic point of view. The evaluation of oral hygiene products on animals, however, particularly for efficacy, must be questioned on a number of scientific and moral grounds.

Most laboratory and clinical methods have been developed to test antimicrobial agents but methodologies are available, or present ones could be modified, to study potential antiadhesive and plaque removal chemicals (for reviews see Addy *et al*. 1992; Addy 1995; Addy & Moran 1997).

Studies *in vitro*

Bacterial tests

Antimicrobial tests, including minimum inhibitory concentration (MIC), minimum bactericidal concentration (MBC), and kill curves, can be determined. These tests indicate the antibacterial activity and antimicrobial spectrum of agents and formulations against a range of oral bacteria. Continuous culture techniques can also be used but they may not provide more meaningful data. It is likely that, with technologic advances, laboratory models to accurately replicate the plaque biofilm will become available to test chemical plaque-control agents. At present, antimicrobial tests *in vitro* primarily only indicate activity, or lack of it, and they are very poor predictors *per se* of effects on plaque *in vivo*. This is because, so far, methods do not provide particularly reliable information on the substantivity of the antimicrobial agent. Nevertheless, antimicrobial tests are valuable for a variety of reasons. With few exceptions, agents without activity *in vitro* will not provide activity *in vivo*. The additive or negative effects of ingredient mixtures can be determined. The availability of active ingredients incorporated in the product can be assessed. The adverse influence of the oral environment can be modeled; for example, the influence of saliva or proteins on the antibacterial activity of agents can be tested.

Uptake measurements

One aspect of substantivity is adsorption of antimicrobials and other potential plaque-inhibitory agents on to surfaces. This can be quantified using a variety of substrates such as hydroxyapatite, dentine, enamel, acrylic, and other polymers. The influence of other factors or agents on the uptake of a particular agent can also be assessed. Such data are of interest but must be interpreted with caution since they only measure uptake, not activity once adsorbed. Nevertheless, desorption of an agent from such surfaces can be measured by a variety of analytical techniques, thereby giving some indication of both the adsorption profile and the subsequent substantivity of the agent to the substrate surface.

Other methods

Activity or availability of an ingredient in a formulation can be measured or assessed. Methods include chemical analyses; however, some methods chemically extract the agent from the formulation in its entirety and therefore do not necessarily demonstrate that it is freely available and active within the formulation. For the cationic antiseptics and polyvalent metal salts, their potential to bind dietary chromogens from beverages such as tea can be used to assess the possibility that they may cause staining *in vivo*. More usefully, the test method can be employed to determine and compare the availability of the same ingredient in different formulations. Such methods have shown considerable differences in availability of chlorhexidine and cetylpyridinium chloride in apparently similar mouth rinses (Addy *et al*. 1995). Moreover, how other oral hygiene products might interfere with the activity of chemical plaque-control agents, such as toothpaste with chlorhexidine and cetylpyridinium chloride, has given surprisingly accurate predictions of clinical outcome (Owens *et al*. 1997b; Sheen *et al*. 2001, 2003). Again, these methods give little indication of substantivity and therefore the staining method *in vitro* cannot be used to compare different agents for propensities to cause staining *in vivo*. For example, a 0.05% cetylpyridinium chloride mouth rinse produces comparable tea staining on a substrate surface to a 0.2% chlorhexidine mouth rinse, yet clinically the amount of staining reported for chlorhexidine is considerably greater than that for cetylpyridinium chloride and this can be explained by the fact that the substantivity of the former is greater than that of the latter.

Study methods *in vivo*

A considerable number of protocols have been developed to evaluate potential antiplaque agents and products. Ideally, because of the number of ingredients and more particularly formulations, a step-by-step pyramid approach is taken. Thus initially, study designs are used which permit, if necessary, the screening of relatively large numbers of agents and formulations and on relatively small numbers of subjects.

Depot studies

Retention of agents in the mouth may be measured by determining the amount expectorated versus the known dose (the buccal retention test) or by measuring plaque and saliva levels of the agent over time. Such retention assessments can be misleading because retention is only one aspect of substantivity and the measurement techniques do not provide information

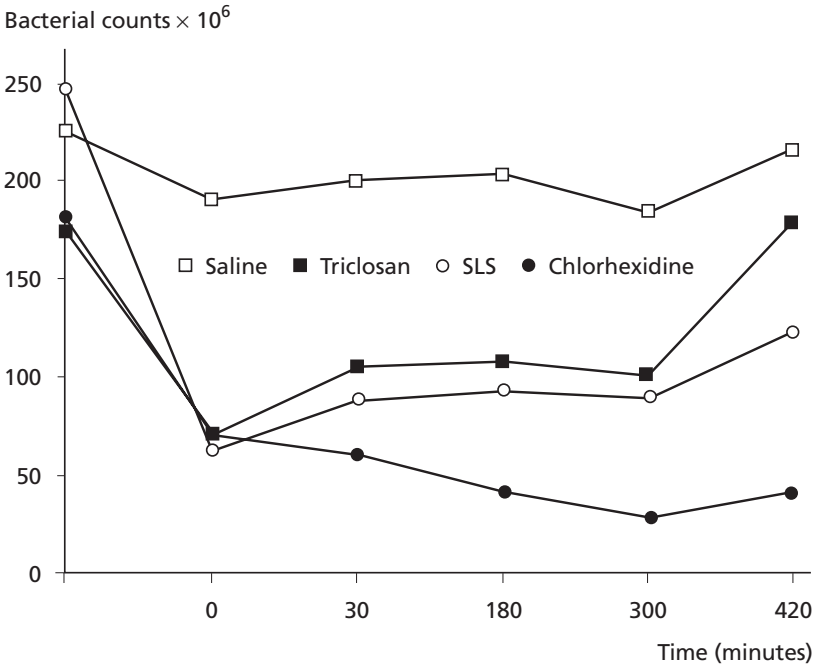


Fig. 36-7 Salivary bacterial counts over time following mouth rinsing with chlorhexidine, saline, sodium lauryl sulfate, and triclosan. Following a single rinse with chlorhexidine, sodium lauryl sulfate, and triclosan there is an immediate large reduction in bacterial counts. This continues and persists to the 420-minute endpoint of the study for chlorhexidine (positive control) with a tendency for counts to revert towards baseline for triclosan and sodium lauryl sulfate. With saline (placebo control), there is little change in counts over time.

on the activity of the retained agents. Moreover, the buccal retention test does not distinguish drug absorption from adsorption nor determine how much is swallowed. Thus, for example, studies using radiolabeled chlorhexidine purported to demonstrate slow release from oral surfaces and this occurred over a protracted period of time (Bonesvoll *et al*. 1974a,b). However, saliva derived from subjects following rinsing with chlorhexidine only provided antimicrobial activity for up to 3 hours following rinsing (Addy & Wright 1978). This is clearly markedly less than the known substantivity or persistence of action of chlorhexidine in the mouth of at least 12 hours (Schiott *et al*. 1970). It is likely, therefore, that the initial desorption studies using a radiolabel were merely detecting chlorhexidine adsorbed to desquamating oral surfaces, particularly the mucosa.

Antimicrobial tests

For antimicrobial agents only, salivary bacterial count assessments are much more indicative of substantivity and are predictive of antiplaque action for the same agents. The method involves measuring salivary bacterial counts before, and at time points, after a single rinse with the agent (Fig. 36-7) and was first described for chlorhexidine (Schiott *et al*. 1970). In the case of toothpaste, the product can be either brushed or rinsed as an aqueous slurry (Addy *et al*. 1983; Jenkins *et al*. 1990). Agents and products produce variable reductions in counts ranging from none, as with water, to greater than 90%, as with chlorhexidine. More importantly, the duration of reduction from baseline varies from minutes to hours. Thus, povidone iodine only reduces counts for approximately 1 hour, cetylpyridinium chloride for 3 hours (Roberts & Addy 1981), whereas chlorhexidine produces such effects for over 12 hours (Schiott *et al*. 1970). Toothpastes generally show reductions in counts between 3 and 5 hours, probably largely due to contained detergents and/or specific ingredients such as triclosan (Addy *et al*. 1989).

Experimental plaque studies

Short-term plaque regrowth studies are perhaps the most commonly used clinical experiments to screen chemical oral hygiene products. They have the advantage of assessing the chemical action of the formulation divorced from the indeterminate variable of toothbrushing. Typically, plaque regrowth from a zero baseline and the influence of the test agent is recorded. Originally used for mouth rinses, the method has been modified for toothpaste by delivering the formulation in a tray applied to the teeth (Etemadzadeh *et al*. 1985) or as a slurry rinse (Addy *et al*. 1983). Studies are usually cross-over, allowing many formulations to be evaluated against suitable controls. Study periods range from 24 hours to several days, usually 4–5 days (Harrap 1974; Addy *et al*. 1983). A negative control such as water and a positive control such as chlorhexidine may be used (Fig. 36-8). These help to position the activity of the test formulations between the extremes. Also, because the results from these controls can be predicted, their use tends to confirm or otherwise the conduct of these blind, randomized study designs.

Experimental gingivitis studies

Experimental gingivitis studies (Löe & Schiott 1970) are based on the original experimental gingivitis in man protocol first used to demonstrate the direct etiologic relationship between plaque and gingivitis

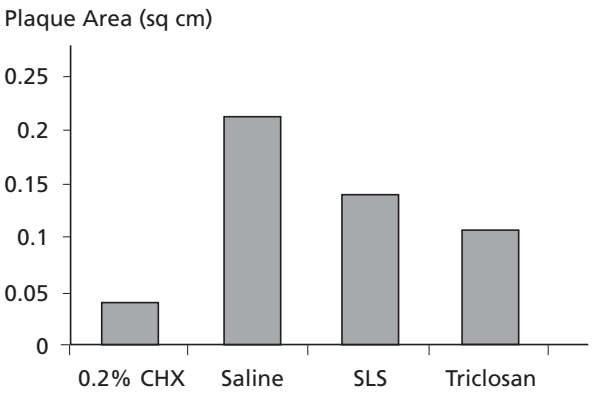

Fig. 36-8 Plaque area following the use of chlorhexidine, saline, sodium lauryl sulfate, and triclosan mouth rinses after 4-day periods. Considerable plaque inhibition was afforded by chlorhexidine (positive control) when toothcleaning was suspended. Both sodium lauryl sulfate and triclosan show significant plaque-inhibitory action compared to saline (placebo control) albeit significantly less than chlorhexidine.

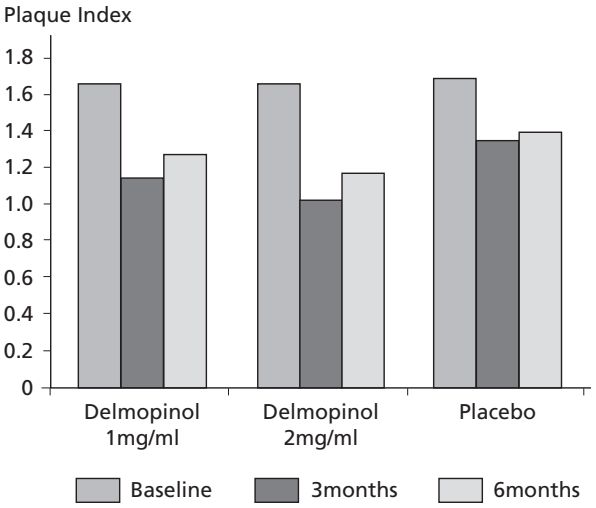

Fig. 36-9 A 6-month study of delmopinol rinses as adjuncts to oral hygiene. Significant improvements in plaque scores are seen in the delmopinol mouth rinse groups at 3 and 6 months compared to placebo. A Hawthorne effect of improved toothcleaning irrespective of the treatment is apparent in the placebo group, particularly at 3 months, although this is still present at 6 months.

(Löe *et al*. 1965). This latter original study did not return subjects to zero baseline plaque scores or gingival health, whereas most subsequent methods, to evaluate oral hygiene products, have taken this approach with baseline parameters. Study periods usually range from 12, but more particularly 19–28 days. In the absence of normal tooth cleaning, the development of plaque and gingivitis are recorded under the influence of test and control formulations. Studies may be either cross-over or parallel.

Home use studies

For chemical oral hygiene products and usually toothpastes and mouth rinses, the final evaluation requires that they are shown to be effective against plaque and, more particularly, gingivitis, when used along with normal mechanical tooth cleaning. Studies can be over days or weeks but usually, in accordance with guidelines such as those for the American Dental Association (Council of Dental Therapeutics 1985), they need to be 6 months or longer, particularly since safety needs to be assessed (Fig. 36-9). Most studies are parallel in design. Protocols have used two approaches. One is perhaps more therapeutic in concept whereby subjects have to exhibit a certain level of plaque and/or gingivitis before entry (Johansen *et al*. 1975). The other is more preventive in concept and there is a pre-study period in which subjects with gingivitis receive prophylaxis and instruction to improve their gingival health. Those satisfactorily responding are entered, and change in gingival health is monitored in the test and control groups (Stephen *et al*. 1990).

Several factors tend to confound home use studies of oral hygiene products and may mask a proven chemical antiplaque action determined from short-term plaque and experimental gingivitis studies. Most important is the so-called Hawthorne effect where subjects knowingly involved in oral hygiene studies improve their tooth cleaning (Fig. 36-9). Secondly, baseline prophylaxes are commonly given and the influence of this on the subsequent gingivitis levels is not known. In mouth rinse studies used as adjuncts to tooth cleaning, there is the potential of interaction between toothpaste and mouth rinse, which could be additive but in most cases is more likely negative for effects on mouth rinse ingredients (Owens *et al*. 1997b; Sheen *et al*. 2001, 2003). Compliance in home use studies can also be a problem and difficult to determine accurately. In short-term studies compliance can be guaranteed through supervision but this is difficult in home use studies although was achieved, in part, in a series of delmopinol studies (for review see Addy *et al*. 2007). Finally, particularly in toothpaste studies, the control product will have some inherent plaque-inhibitory action consequent upon ingredients such as detergents (Addy *et al*. 1983). If the appropriate control products have been used in the screening plaque inhibitory and experimental gingivitis models this should not pose a problem. However, there is no doubt, and this will be discussed, that the choice of control toothpaste, used to compare an active toothpaste, could considerably influence the outcome and therefore the conclusions concerning a potential antiplaque toothpaste.

Clinical trial design considerations

Clinical trials involving human patients, subjects or healthy volunteers in many countries must now conform to the Guidelines for Good Clinical Practice (ICH 1996) including the Declaration of Helsinki (World Medical Association 1996). The Declaration of

Helsinki was introduced primarily to protect the well-being of the participants. The Guidelines for Good Clinical Practice are broadly concerned with all aspects of a clinical trial and, in particular, the ethical requirements, the design and conduct of the trial, data collection and record keeping, data analysis, and reporting of the findings. As a result, the Guidelines not only also protect the interests of the participants but of those organizing, supporting, and conducting the trials. An important additional purpose of the Guidelines is to limit the possibility of falsification of data. Requirements of ethical committees will vary locally, nationally, and internationally; however, common to all is a need for a detailed protocol covering all aspects of the clinical trial, subject or patient information, and consent. Written indemnification and/or insurance cover from the appropriate source or sources for the subjects or patients is required, although the details may vary both nationally and internationally. For example, in the UK most ethical committees would adopt the indemnification principles as set out by the Association of British Pharmaceutical Industries.

The basic requirements of a clinical trial are that it should be blind, randomized, and suitably controlled. These three aspects of clinical trial design are intimately related and are there to remove, limit or allow adjustment for possible influences that might confound the outcome of a clinical trial and thereby reduce or completely obviate the scientific value of any particular study. These three design features will be discussed individually.

Blindness

The term "blindness" is for obvious reasons not universally accepted and alternatives include "masking" or "masked". All clinical studies must be, at least, single, examiner blind. Single blindness requires that any investigator collecting data from the patients or subjects should not know the identity of the treatments used by any particular individual. Single blindness should eliminate bias in data collection. Examiner blindness, however, can be compromised to a variable degree if a particular treatment produces changes within the oral cavity, which can be perceived by the examiner. Such an example could be extrinsic staining of the teeth and/or oral mucosa by chlorhexidine formulations. The use of objective measures, which reduce or remove the requirement for subjective judgment, by the examiner, can improve the likelihood of single blindness. Unfortunately, such objective methods are not common to the recording of plaque, gingivitis, and periodontal disease parameters.

Double blindness is the ideal when neither the examiner nor subject or patient is aware of the treatment being used by the individual. Numerous factors will influence whether the subjects or patients can be maintained totally blind to their treatment(s), including whether the study is parallel or cross-over (to be discussed later), prior experience with treatments, and the presentation, taste, and appearance of the treatments, particularly controls. Subject blindness, although ideal, is less important where the treatment outcome measures are out of the immediate control of the subject, e.g. plaque accumulation and gingivitis; assuming, that is, that lack of subject blindness does not influence compliance. Subject blindness becomes highly important where the subject is required to make a valid judgment of the effects of the treatment, for example the effects of treatments on symptoms such as pain. The term "triple blindness" is used by some investigators and relates to the blindness of the individual analyzing the data to the identity of the treatments. Thus, the data are analyzed using the treatment codes e.g. treatments A, B, and C. The identities of A, B, and C are only revealed once the statistical tests have been completed.

Randomization

The order in which treatments are received by each subject in a cross-over study, or into which treatment group subjects are placed in a parallel study, should be according to a randomized schedule. Randomization provides several important safety aspects to the study design in that firstly it is an essential part of examiner blindness. Secondly, in a cross-over study randomization should remove the potential confounding effects of the order of product use, the so-called period effects. Thirdly, the use of balanced randomization designs allows for potential carry-over effects of treatments in cross-over design studies (Newcombe *et al*. 1995). Finally, where the effects of a treatment on a disease state are to be assessed, randomization improves the chances that parallel treatment groups should be as similar as possible in baseline disease levels and, if relevant, demographic data. Randomization schedules, which use subject matching for demographic and disease status or stratification for level of disease, can be employed to improve balancing of parallel groups.

Controls

The use of appropriate control treatments is essential to the evaluation of the benefits of a particular agent or product. Without such controls, studies essentially become no more than case report data at best and anecdotal at worst, particularly when specific treatment is evaluated alone for effects on various parameters. The choice of controls, however, can vary depending on the aim of the study and the level of evaluation of an agent or product within a program of research. The choice of controls could therefore be one or more of the following:

- *Placebo control*. Here the control is a substance without any expected pharmacologic action, e.g. water. This is useful when assessing a new agent or positioning an agent or formulation between a positive or benchmark control. Placebo controls are particularly valuable where a condition or symptom

may be perceived by the subject or patient to have improved, so-called placebo response, or where a condition appears to improve naturally over time, the so-called regression to the mode. Both of these phenomena are common to studies of the treatment of dentine hypersensitivity where pain is a primary outcome measure, but they are, of course, unlikely to occur in studies where the outcome measure are levels of plaque and gingivitis.

- *Minus active control (negative control)*. This type of control is commonly employed to determine whether an agent provides activity over and above its vehicle. It is particularly useful in the initial assessment of formulations such as toothpastes which have included a new active. In the later stages of development, perhaps at the product level, the use of minus active controls in home use studies is of less value since minus active controls are not normally used by the general public.
- *Bench mark control*. This term is usually used to define a control which is a commercially available product commonly used by the general public. Such controls would appear more sensible for home use studies rather than minus active products when, for example, a new toothpaste product is formulated to promote gingival health benefits. In this case it would seem reasonable to determine whether efficacy is superior to conventional fluoride toothpaste rather than the minus active toothpaste.
- *Positive control*. Positive control is an agent or formulation presently considered the most effective agent available. In this case chlorhexidine mouth rinse is arguably considered the "gold" standard antiplaque agent and is frequently used as the positive control by which to compare and position the efficacy of agents and formulations. Usually a chlorhexidine mouth rinse is used as the positive control in the early no oral hygiene study protocols.

Depending on the aims and constraints of a clinical study, more than one of the aforementioned controls may be used; for example, in the short-term studies it is not unusual to position an agent or formulation for plaque and gingivitis efficacy between a positive control, chlorhexidine, and a placebo, water.

Study groups

Study designs for oral hygiene products are usually either parallel or cross-over. Parallel group studies require that each individual uses only one of the formulations (active or control) throughout the duration of the study. Parallel designs can be used for any of the previously described oral hygiene study methods; however they are more commonly used when the study duration is protracted to weeks or months. Parallel designs require that the study groups are large in number to provide sufficient power for statistical analysis. Indeed, the power of any particular study to demonstrate a statistically significant difference between treatments should be calculated prior to the study, although this may be compromised by lack of data as to the likely outcome or by difficulty in deciding the clinical relevance of any difference found. Advice from a statistician is important and group sizes can be calculated based on expected differences between test and control formulations. It must be remembered that small differences can be found statistically significant merely by using large group sizes.

Cross-over studies randomly allocate subjects to use all of the agents or formulations under test. Since each individual acts as their own control, paired statistical analytical techniques mean that the power to detect differences is markedly increased compared to parallel designs, and thereby the total study cohort of subjects can be relatively small. Furthermore, a considerable number of formulations can be compared, although this will be limited by the duration of each study period which, in itself, will have a knock-on effect on acceptability to and compliance of the subjects. Cross-over studies require a wash-out period between each treatment period and this will depend on the known, or expected, carry-over effect of a treatment or a condition into the next period. Random incomplete block designs can be used, in which each subject only uses so many of the agents under test.

The relationship between statistical significance and clinical significance is always difficult to resolve (for review see Addy & Newcombe 2005). Statistical significance is a mathematical concept which, with varying levels of probability, supports the idea that any difference between treatments is not due to chance. Clinical significance, on the other hand, is conceptual and attempts to define the benefit to the patient of any particular treatment. Unlike some branches of medicine and surgery, in periodontology, clinical significance is particularly difficult to define because the usual outcome variables are not absolute. Thus, treatment effects on plaque and/or gingivitis indices, unless approaching 100%, cannot be translated with any certainty to the initiation or progress of periodontitis and certainly not to tooth loss. Clinical significance could be:

1. *Bench mark equivalent*: when a formulation performs as well as an established formulation or product.
2. *Bench mark superior*: when a formulation performs significantly better than an established formulation.
3. *Disease related*: when a formulation has an effect on an etiologic factor such that the related signs or symptoms of the associated disease are reduced to a significantly greater extent than the control, e.g. plaque reduction which reduced gingivitis to a greater extent than control.
4. *Positive*: when a formulation produced the effect significantly greater than the most effective agent

today, e.g. the antiplaque effect is greater than chlorhexidine.

5. *Proportional superiority*: when from the outset of a study a minimum percentage improvement over the control group is set down as clinically significant.

Conclusions

- Terminology concerning oral hygiene products needs to be standardized and defined.
- Efficacy claims, which are implied, or rely on inferences to be drawn, should be avoided.
- Studies *in vitro* can provide supportive data to clinical investigations but cannot stand alone as proof of efficacy *in vivo*.
- Research and development of oral hygiene products needs to be step-by-step processed, making available a body of knowledge supporting the efficacy of a final formulation.
- Clinical proof should be largely dependent on data from blind, randomized, controlled clinical trials conducted to the Guideline for Good Clinical Practice (GCP).
- In reporting clinical trials the clinical significance of the finding should be considered.
- Statistical significance should not necessarily be taken as proof *per se* of the benefit of an oral hygiene product to the general public.
- Clinical outcome, when possible, should be evaluated against side effects and the cost–benefit ratio should be determined.
- Where possible, systematic reviews with meta-analyses need to be conducted to prove the efficacy of agents and products for the control of supragingival plaque.

Chapter 37

Non-surgical Therapy

Noel Claffey and Ioannis Polyzois

Introduction

It is generally accepted that the goal of the initial periodontal treatment is to restore the biological compatibility of periodontally diseased root surfaces, thus halting the process of the disease. Figure 37-1 illustrates the role and sequencing of non-surgical therapy in the management of most periodontitis patients.

Non-surgical therapy aims to eliminate both living bacteria in the microbial biofilm and calcified biofilm microorganisms from the tooth surface and adjacent soft tissues. Complete elimination of such pathogenic microorganisms is perhaps over-ambitious. However a reduction in inflammation of the periodontium due to a lesser bacterial load leads to beneficial clinical changes. In addition, non-surgical therapy aims to create an environment in which the host can more effectively prevent pathogenic microbial recolonization using personal oral hygiene methods.

This chapter outlines the various methods used in non-surgical therapy, such as hand instrumentation, ultrasonic and sonic scalers, and ablative laser therapy. Their respective merits and shortcomings and their clinical efficacy will be discussed. The chapter will attempt to identify realistic prognostic outcomes of therapy when taking into consideration factors such as different methods of instrumentation, different root surfaces, and varying degrees of periodontitis.

Re-evaluation of the initial clinical response to non-surgical therapy as well as consideration of modifiable risk factors allows the clinician to formulate an ongoing treatment plan tailored to the individual.

Detection and removal of dental calculus

Periodontitis is strongly associated with the presence of dental calculus on root surfaces. It has been suggested that the rough surface of calculus does not in itself induce inflammation but that the deleterious effect of calculus relates to its ability to provide an ideal surface for microbial colonization (Waerhaug 1952). It has also been demonstrated that epithelial adherence to subgingival calculus can occur following its disinfection with chlorhexidine (Lisgarten & Ellegaard 1973). Thus, a rationale for the removal of calculus relates to eliminating, as far as possible, surface irregularities harboring pathogenic bacteria.

Microbes giving rise to and colonizing the surface of dental calculus have been shown to produce lipopolysaccharides (LPS). These potent triggers of host response mechanisms were thought to be present within calculus and underlying cementum. For this reason it was thought necessary to remove not only calculus but also underlying cementum. However later evidence suggested that removal of tooth substance was not necessary. Ground sections of extracted periodontally involved teeth were examined. LPS was detected on cementum which had been previously exposed to the periodontal pocket. LPS also extended 1 mm into the surrounding connective tissue attachment. On no occasion was LPS seen penetrating into sub-surface cementum (Hughes & Smales 1986). These conclusions were further supported by animal and human studies which demonstrated that removal of superficial plaque on subgingival calculus resulted in the healing of periodontal lesions and the maintenance of health,

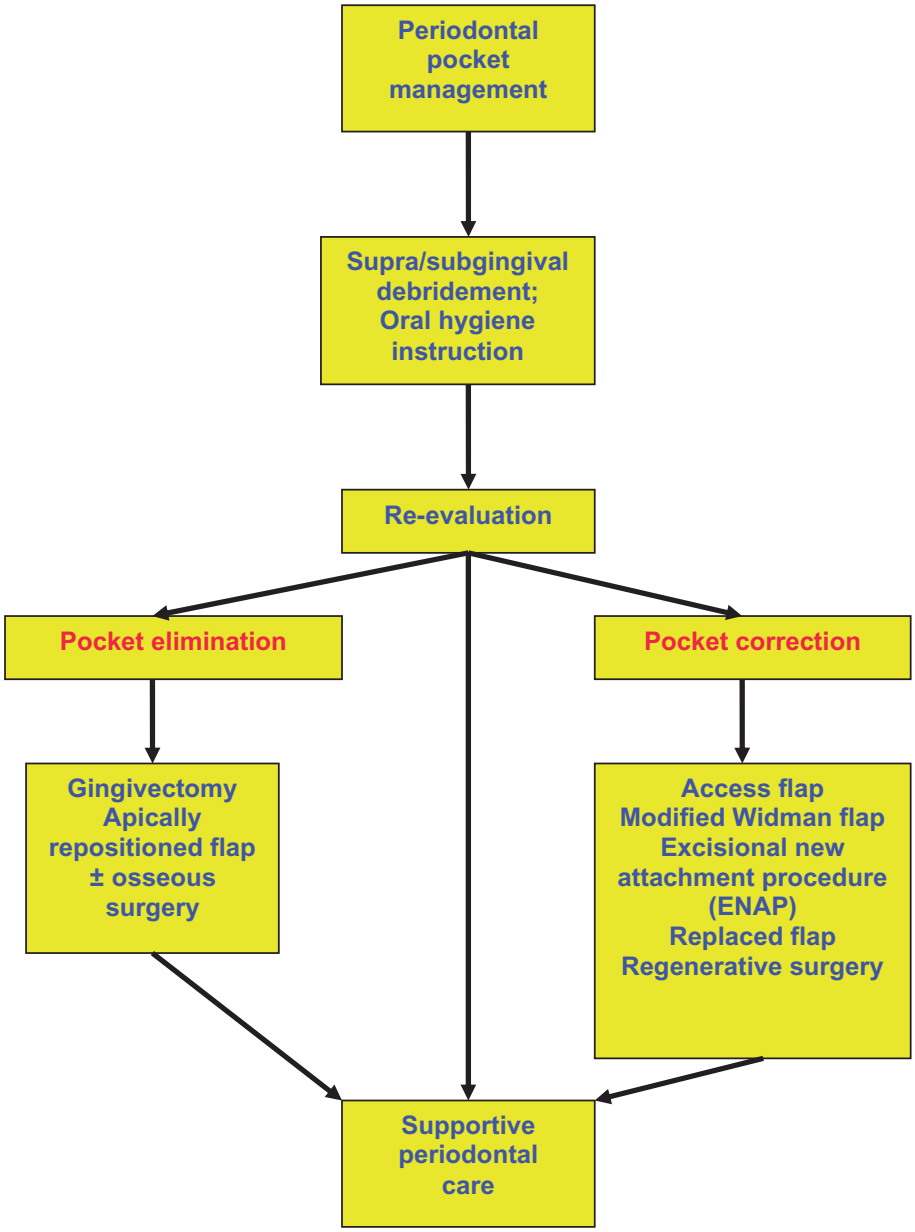

Fig. 37-1 Schematic representation of a typical treatment regimen for periodontitis patient management.

provided supragingival hygiene was meticulous (Nyman *et al*. 1986, 1988; Mombelli *et al*. 1995). From a clinical standpoint, minimizing the total volume of dental calculus present seems to be desirable. However, aggressive tooth substance removal does not seem warranted.

Factors that may influence complete calculus removal include the extent of disease, anatomic factors, the skill of the operator, and the instruments used. Waerhaug (1978) suggested that in more than 90% of cases, deposits of plaque and calculus remained in sites with pocket depths (PD) >5 mm following scaling and root planing. Similar conclusions were reported by Rabbani *et al*. (1981) and Magnusson *et al*. (1984). Brayer *et al*. (1989) investigated inter-operator variability performing non-surgical root debridement, comparing operators of two different levels of experience. It was found that the more experienced clinician achieved a superior level of calculus removal.

Although Caffesse *et al*. (1986) found more residual calculus following non-surgical root debridement compared to root debridement as part of a surgical procedure, 50% or more of surfaces with PD >7 mm showed residual calculus irrespective of methodology. Buchanan and Robertson (1987) found more residual calculus following non-surgical treatment on molar and premolar tooth surfaces than non-molar teeth. They also demonstrated that over 60% of molar sites had residual calculus following closed root debridement. These findings may reflect increased difficulty in achieving successful root debridement in posterior areas in the mouth in addition to the more complicated anatomy of multi-rooted teeth.

Matia *et al*. (1986) noted no difference in the quality of root debridement following evaluation of ultra-

sonic, sonic or hand instrumentation. However none of the sites treated were totally free of calculus.

The agreement between clinicians in the detection of residual subgingival calculus has been found to be low. Furthermore microscopic studies have demonstrated that even if calculus is not detected clinically it may yet be present on a microscopic level. Nonetheless from a practical standpoint if calculus is detected clinically the site is more likely to display ongoing inflammation (Sherman *et al*. 1990).

Methods used for non-surgical root surface debridement

Scaling is a procedure which aims at the removal of plaque and calculus from the tooth surface. Depending on the location of deposits, scaling is performed by supragingival and/or subgingival instrumentation. Root planing denotes a technique of instrumentation by which the "softened cementum" is removed and the root surface is made "hard" and "smooth". However, on the basis of evidence already discussed, excessive tooth substance removal is not warranted and so perhaps the term root debridement is more appropriate. Root debridement may therefore be defined as the removal of plaque and/or calculus from the root surface without the intentional removal of tooth structure.

Non-surgical periodontal treatment may be carried out using a variety of methods including hand instruments, sonic and ultrasonic scalers reciprocating instruments, and ablative laser therapy.

Hand instrumentation

Hand instrumentation allows good tactile sensation while minimizing the risk of contaminated aerosol production. However, it tends to be more time consuming than other methods and, if aggressively performed, hand instrumentation can lead to excessive tooth substance removal. In addition, hand instrumentation is more technique sensitive and requires correct and frequent instrument sharpening.

Access to furcations and the base of deep pockets is limited compared to some machine-driven instruments which have been designed to access narrow apertures and relatively inaccessible areas (Leon *et al*. 1987; Oda & Ishikawa 1989; Dragoo *et al*. 1992; Takacs *et al*. 1993; Yukna *et al*. 1997; Kocher *et al*. 1998, 2001; Beuchat *et al*. 2001). Recently however, modified curettes with extended shanks for deep pockets and mini-bladed curettes for narrow pockets have been developed to improve efficacy of scaling and root planing in difficult areas (Singer *et al*. 1992; Landry *et al*. 1999).

Hand instruments

A hand instrument is composed of three parts: the working part (the blade), the shank, and the handle (Fig. 37-2). The cutting edges of the blade are centered over the long axis of the handle in order to give the instrument proper balance. The blade is often made of carbon steel, stainless steel or tungsten carbide.

Curettes are instruments used for both scaling and root debridement (Fig. 37-3). The working part of the curette is the spoon-shaped blade which has two curved cutting edges. The two edges are united by the rounded toe. The curettes are usually made "double-ended" with mirror-turned blades. The length and angulation of the shank as well as the dimensions of the blade differ between different brands of instruments.

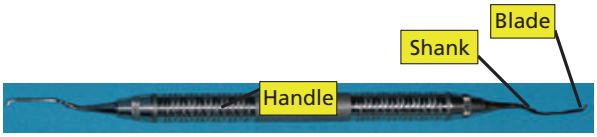

Fig. 37-2 A curette demonstrating the handle, shank, and blade.

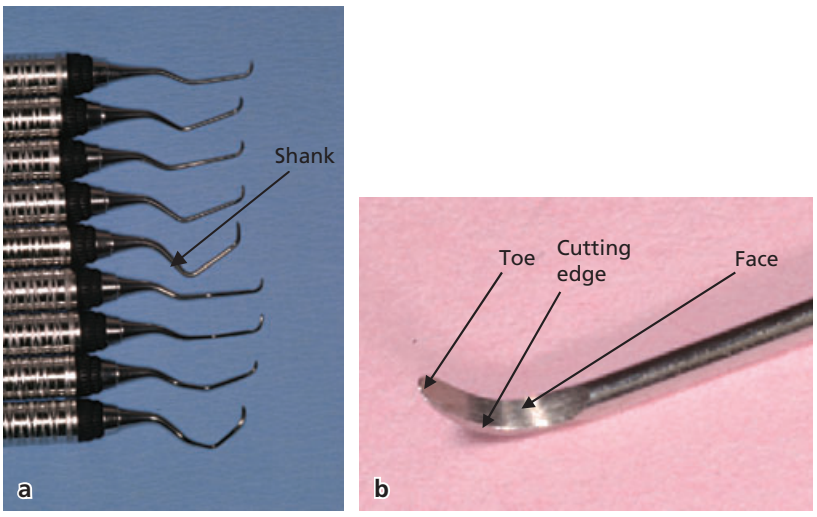

Fig. 37-3 (a) Selections of curettes with varying shank configurations to facilitate debridement of different areas of the dentition. (b) The working end of a curette demonstrating rounded toe, face, and cutting edge.

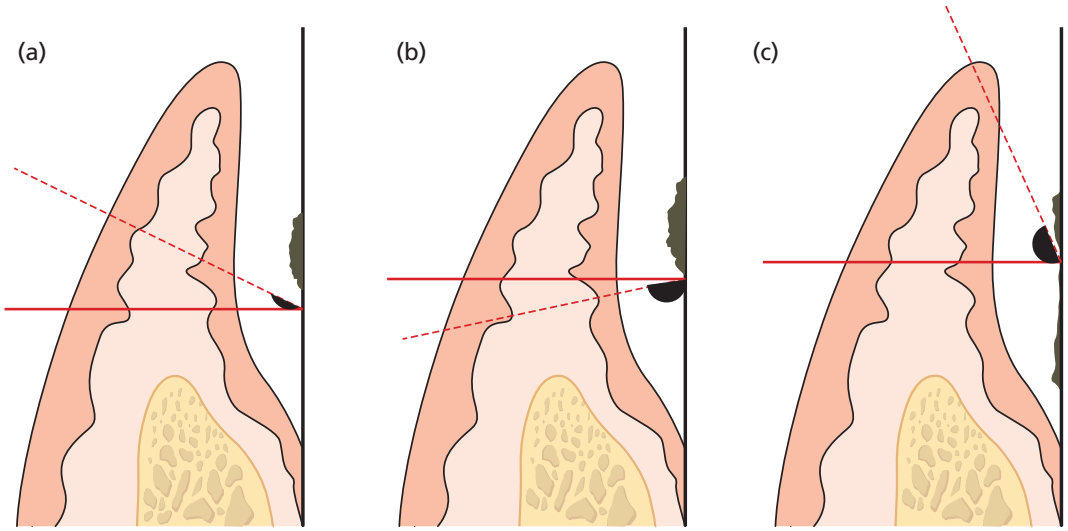

Fig. 37-5 The effect of different angulations of the cutting edge of the curette to the tooth surface. (a) Correct angle of application. (b) Too obtuse angulation resulting in ineffective calculus removal and the possibility of cratering the surface. (c) Too acute angulation resulting in ineffective calculus removal and burnishing of the calculus deposits.

The sickle is manufactured with either a curved or a straight blade which has a triangular cross section and two cutting edges. The "facial" surface between the two cutting edges is flat in the lateral direction but may be curved in the direction of its long axis. The "facial" surface converges with the two lateral surfaces of the blade. Sickles are mainly used for supragingival debridement or scaling in shallow pockets (Fig. 37-4a).

The hoe has only one cutting edge. The blade is turned at a 100° angle to the shank with the cutting edge bevelled at a 45° angle. The blade can be positioned at four different inclinations in relation to the shank: facial, lingual, distal, and mesial. The hoe is mainly used for supragingival scaling (Fig. 37-4b). Periodontal files can be useful for smoothing roots in areas of stubborn deposits (Fig. 37-4c).

Principles of curette use

Perhaps the most widely used instrument type for subgingival debridement is the curette. The angulation of the cutting edge of the curette to the tooth surface influences the efficiency of debridement. The optimal angle between the cutting edge and the tooth is approximately 80° (Fig. 37-5a). Too obtuse an angle, as shown in Fig. 37-5b, will result in cratering and consequent roughening of the root surface. Too acute an angle, as shown in Fig. 37-5c, will result in ineffective removal and burnishing of subgingival calculus deposits.

Subgingival instrumentation should preferably be performed under local anesthesia. The root surface of the diseased site is explored with a probe to identify (1) the probing depth, (2) the anatomy of the root surface (irregularities, root furrows, open furcation, etc.), and (3) the location of the calcified deposits.

The instrument is held in a modified pen grasp and the blade inserted into the periodontal pocket with the face of the blade parallel to and in light contact with the root surface. It is important that all root surface instrumentation is performed with a proper finger rest. This implies that one finger – the third or the fourth – must act as a fulcrum for the movement of the blade of the instrument. A proper finger rest serves to (1) provide a stable fulcrum, (2) permit optimal angulation of the blade, and (3) enable the use of wrist–forearm motion. The finger rest must

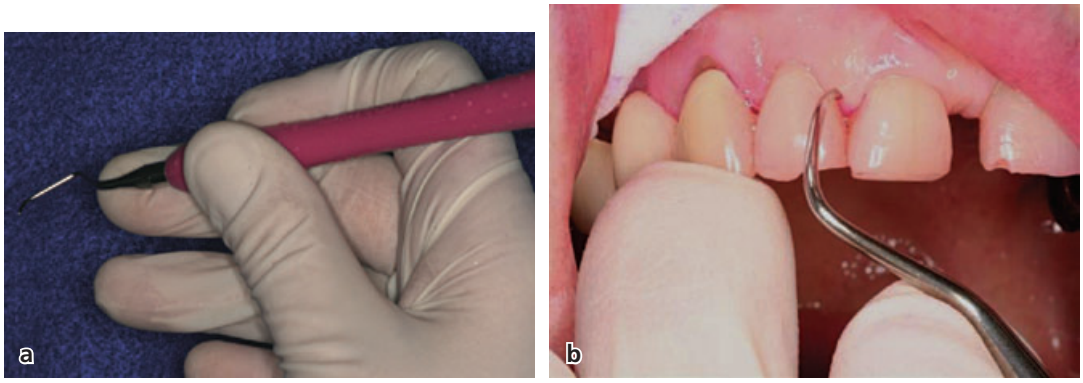

Fig. 37-6 Illustrations of (a) a modified pen grasp and (b) a finger rest in close proximity to the area of instrumentation.

Fig. 37-7 Illustration of the shank of the curette held parallel to the long axis of the tooth during instrumentation of a posterior site.

be secured as close as possible to the site of instrumentation to facilitate controlled use of the instrument (Fig. 37-6).

After the base of the periodontal pocket has been identified with the lower edge of the blade, the instrument is turned into a proper "cutting" position: i.e. the shank is parallel to the long axis of the tooth (Fig. 37-7). The grasp of the instrument is tightened somewhat, the force between the cutting edge and the root surface is increased, and the blade is moved in a coronal direction. Strokes must be made in different directions to cover all aspects of the root surface (crosswise, back and forth) but, as stated above, strokes should always start from an apical position and be guided in a coronal direction. The probe is inserted in the pocket again and the surface of the root assessed anew for the presence of calculus.

Frequent sharpening of the cutting edge of the instrument is necessary to obtain efficient calculus removal (Fig. 37-8a). The angle between the face and the back of curettes must be maintained at approximately 70° during sharpening (Fig. 37-8b). Any greater angle will result in dulling of the cutting edge. A more acute angle results in a fragile and easily worn cutting edge.

Sonic and ultrasonic scalers

A common alternative to hand instrumention for non-surgical periodontal therapy is the use of sonic and ultrasonic scalers. Sonic scalers use air pressure to create mechanical vibration that in turn causes the instrument tip to vibrate; the frequencies of vibration ranging from 2000–6000 Hz (Gankerseer & Walmsley 1987; Shah *et al*. 1994). Ultrasonic scalers convert electrical current to mechanical energy in the form of high-frequency vibrations at the instrument tip; the vibration frequencies ranging from 18 000–45 000 Hz. There are two types of ultrasonic scalers, magnetostrictive and piezoelectric. In piezoelectric scalers the alternating electrical current causes a dimensional change in the hand piece which is transmitted to the working tip as vibrations. The pattern of vibration at the tip is primarily linear. In magnetostrictive scalers the generated electrical current produces a magnetic field in the handpiece that causes the insert to expand and contract along its length and in turn causes the insert to vibrate. The pattern of vibration at the tip is elliptical. Modified sonic and ultrasonic scaler tips, e.g. tiny, thin, periodontal probe type, and diamond coated, have been developed for use in deep pockets (Drisko *et al*. 2000).

Recently, ultrasonic instruments using a working frequency of 25 kHz and a coupling at the head of the handpiece to transfer energy indirectly to the working tip have been developed. These instruments are cooled by a water-based medium containing polishing particles of various sizes dependent on therapeutic indication. The amount of contaminated aerosol is said to be reduced compared to other ultrasonic or sonic scalers. This system has been advocated for the treatment of periodontitis and peri-implantitis, as well as minimal invasive preparation of tooth structures. This development has been shown to be equally effective as conventional methods (Sculean *et al*. 2004).

Reciprocating instruments

Few studies have been carried out to investigate the efficacy of reciprocating instruments. Results demon-

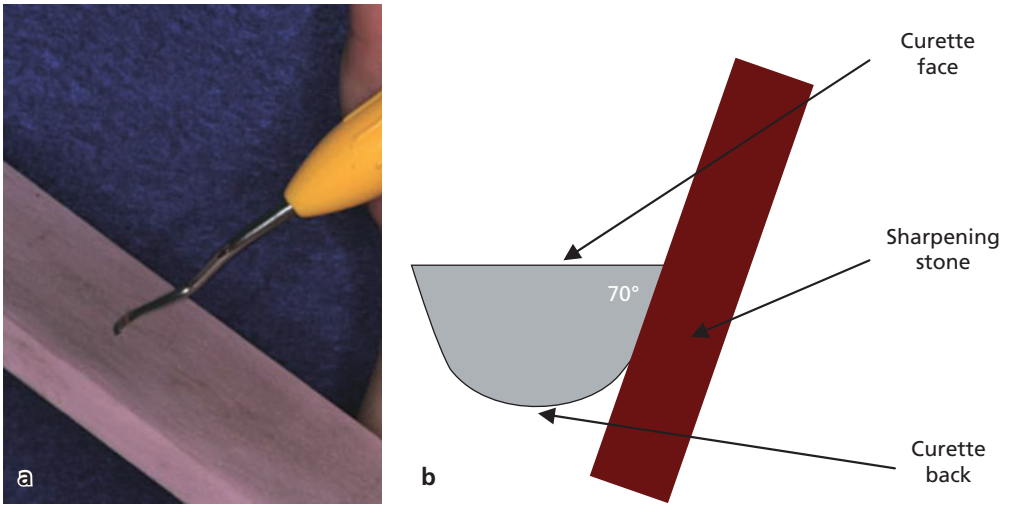

Fig. 37-8 (a) The angulation of the sharpening stone in relation to the curette shank. (b) The angle between the flat surface of the sharpening stone and the cutting edge of the curette.

strated that they produce an equivalent clinical outcome compared to hand, sonic or ultrasonic scalers. The use of reciprocating instruments is less time consuming than hand instrumentation and results in less root surface loss (Obeid *et al*. 2004; Obeid & Bercy 2005). Further evidence is awaited to support their widespread use.

Ablative laser therapy

Ablative laser therapy targets both the soft and hard tissues of the periodontium. It has bacteriocidal and detoxification effects and can remove the epithelium lining and granulation tissue within the periodontal pocket which may potentially improve healing. Considering the possibility of bacterial invasion into the soft tissues of pockets, this effect could be an important factor in the treatment of moderate to deep pockets. However, studies have shown that curettage of granulation tissues had no added benefit over scaling and root planing (Lindhe & Nyman 1985; Ramfjord *et al*. 1987). Laser therapy is capable of removing plaque and calculus with extremely low mechanical stress and no formation of a smear layer on root surfaces. In addition the use of lasers may allow access to sites that conventional mechanical instruments cannot reach.

Various types of lasers such as carbon dioxide lasers, Er:YAG lasers, and Nd:YAG lasers are currently in use. Carbon dioxide lasers, when used with relatively low energy output in a pulsed and/or defocused mode, have root conditioning, detoxification, and bacteriocidal effects on contaminated root surfaces. However, at low energy outputs they are unable to remove calculus. Er:YAG lasers are capable of effectively removing calculus from the root surface. Er:YAG laser irradiation energy is absorbed by water and organic components of the biological tissues which causes their evaporation resulting in heat generation, water vapour production, and thus an increase in internal pressure within the calculus deposits. The resulting expansion within the calculus causes its separation from the root surface.

Choice of debridement method

It has been demonstrated that hand, sonic, and ultrasonic scalers produce similar periodontal healing response with respect to probing pocket depths, bleeding on probing, and clinical attachment level (Badersten *et al*. 1981, 1984; Lindhe & Nyman 1985; Kalkwarf *et al*. 1989; Loos *et al*. 1987; Copulos *et al*. 1993; Yukna *et al*. 1997; Kocher *et al*. 2001; Obeid *et al*. 2004; Wennstrom *et al*. 2005; Christgau *et al*. 2006). With respect to time spent, several studies have shown that debridement time spent per tooth may be reduced when ultrasonic or sonic scalers used compared to hand scalers (Copulos *et al*. 1993; Boretti *et al*. 1995; Tunkel *et al*. 2002; Wennstrom *et al*. 2005; Christgau *et al*. 2006). Regarding root surface loss, sonic and ultrasonic scalers have been shown to produce less tooth surface loss compared to hand scalers (Ritz *et al*. 1991; Schmidlin *et al*. 2001).

In contrast to hand instrumentation, the use of sonic and ultrasonic scalers is less technique sensitive, requires less time to complete, and removes less root surface cementum. It has been shown to provide better access to deep pockets and furcation areas (Kocher *et al*. 1998; Beuchat *et al*. 2001). In addition the flushing action of water used in sonic and ultrasonic scalers removes, to a certain extent, debris and bacteria from the pocket area. However, tactile sensation is reduced, and there is production of contaminated aerosols (Harrel *et al*. 1998; Barnes *et al*. 1998; Rivera-Hidalgo *et al*. 1999; Timmerman *et al*. 2004). Some patients may find the vibration, sound, and water spray uncomfortable.

It has been demonstrated that the use of lasers produces results comparable to scaling and root planing (Schwarz *et al*. 2001). However, no adjunctive

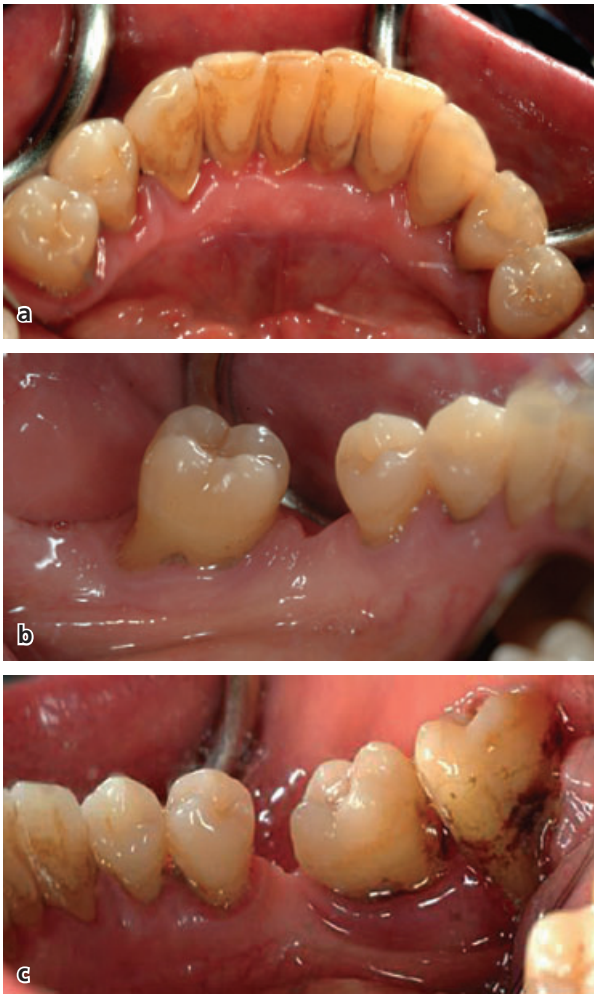

Fig. 37-9 Lingual view of mandibular teeth of patient with untreated periodontitis prior to periodontal therapy.

Fig. 37-10 Lingual view of mandibular teeth of patient 3 months following initial non-surgical therapy.

benefit of the use of lasers over scaling and root planing alone has been demonstrated (Schwarz *et al*. 2003; Ambrosini *et al*. 2005). Inadvertent irradiation and reflection from shiny metal surfaces may cause damage to patient's eyes, throat, and oral tissues other than the targeted area. In addition there is also a risk of excessive tissue destruction by direct ablation and thermal side effects. Also the high cost of the laser apparatus is a drawback for many clinicians.

Figures 37-9 and 37-10 demonstrate the effects of non-surgical therapy.

The influence of mechanical debridement on subgingival biofilms

Supra- and subgingival debridement results in the mechanical disruption of the plaque biofilm and remains the "gold standard" modality for periodontal treatment. Removal of subgingival plaque and calculus deposits through subgingival debridement exposes the cementum, root dentine, and pocket epithelium for novel colonization. Species which may have thrived in the subgingival environment of the diseased pocket may find the new habitat less hospitable. A decreased concentration of microbial products and tissue breakdown products, and a decrease in the flow of gingival crevicular fluid, along with a more neutral subgingival biofilm pH may encourage the growth of less pathogenic bacterial species. Also a decrease in pocket depth as a result of a resolution of inflammation, decreased oedema, and a re-adaptation of apical junctional epithelium favors the recolonization of more aerobic species.

Following treatment the subgingival habitat may be repopulated by microorganisms which originate from: residual subgingival plaque deposits (Ramberg *et al*. 1994; Dahan *et al*. 2004); radicular dentinal tubules or cementum (Daly *et al*. 1982; Adriaens *et al*. 1988; Giuliana *et al*. 1997); pocket epithelium and connective tissues (Slots & Rosling 1983); supragingival plaque deposits (Magnusson *et al*. 1984; Ximenez-Fyvie *et al*. 2000); subgingival deposits of adjacent teeth and from other intraoral soft tissue sites (von Troil-Linden *et al*. 1996).

Subgingival debridement has been observed to result in a decrease in the total number of micro-

organisms present in subgingival sites and a shift in the relative proportion of different microbial species within the subgingival plaque biofilm. A decrease in the total bacterial count for sites of 3 mm or greater depth, from $91 \pm 11 \times 10^5$ to $23 \pm 6 \times 10^5$, has been observed immediately following subgingival debridement (Teles *et al*. 2006). Although pre-debridement subgingival microbial counts are restored in 4–7 days post debridement (Sharawy *et al*. 1966), the impact of subgingival debridement on the composition of subgingival plaque biofilms, although often transient, is more long lasting.

Subgingival debridement has been observed to result in a decrease in the mean counts and number of sites colonized by *P. gingivalis*, *A. actinomycetemcomitans*, *Pr. intermedia* (Shiloah & Patters 1994), *T. forsythia*, and *Tr. denticola* (Darby *et al*. 2005) several weeks following subgingival debridement. The persistence of *A. actinomycetemcomitans* and *P. gingivalis* following subgingival debridement is attributed to the ability of these microorganisms to invade the pocket epithelium and connective tissues (Slots & Rosling 1983; Renvert *et al*. 1990; Shiloah & Patters 1994). Haffajee *et al*. (1997) found that the only species to be significantly affected in prevalence and mean counts 3 months following non-surgical periodontal therapy were *B. forsythus*, *P. gingivalis*, and *Tr. denticola*.

An increase in the proportions of Gram-positive aerobic cocci and rods following subgingival debridement is associated with health (Cobb 2002). Haffajee *et al*. (2006) reported an increase in proportion of streptococci (including *S. gordonni*, *S. mitis*, *S. oralis*, and *S. sanguinis*) and *Actinomyces* spp., *E. corrodens*, and *G. morbillarum* post subgingival debridement.

Microorganisms do not exist in isolation in the subgingival environment, but rather as members of communities. Socransky *et al*. (1998) identified groups of organisms which were commonly found together and subdivided microorganisms into complexes accordingly. Members of the red and orange complexes are most commonly identified at sites displaying signs of periodontitis. A re-emergence of species of the red and orange complex 3–12 months post debridement may be associated with ongoing attachment loss at these sites (Haffajee *et al*. 2006).

In the absence of appropriate home care, the re-establishment of the pretreatment microflora as well as the rebound of clinical improvements due to treatment will occur in a matter of weeks (Magnusson *et al*. 1984; Loos *et al*. 1988; Sbordone *et al*. 1990). In the absence of professional maintenance an increase in the prevalence and counts of periodontopathogens is to be expected (Renvert *et al*. 1990; Shiloah & Patters 1994). Following supra- and subgingival debridement and appropriate home care the re-establishment of a pathogenic subgingival microflora and an associated rebound in clinical parameters may occur in localized sites (Beikler *et al*. 2004).

Implication of furcation involvement

Once attachment loss has progressed to the furcation area of multi-rooted teeth, patient-performed home care and professionally performed subgingival debridement become more difficult (Wylam *et al*. 1993). Microbial communities may develop relatively undisturbed in this sheltered anatomic site and increasingly anaerobic and virulent microbes may thrive.

Loos *et al*. (1988) observed that while subgingival debridement resulted in improvements in clinical and microbiologic parameters over a 1-year period post debridement, sites with furcation involvement consistently demonstrated higher microbial counts and greater proportions of suspected periodontopathogens. Generally clinical improvement was found to be less pronounced in furcation sites than in other locations (Loos *et al*. 1989). Nordland *et al*. (1987) and Claffey and Egelberg (1994) observed that the frequency of continued probing attachment loss was considerably greater in furcation-involved sites compared with all other sites. Consequently, teeth with furcation involvement may be viewed with some caution with respect to long-term prognosis.

Pain and discomfort following non-surgical therapy

It has been demonstrated that tissue trauma occurs during non-surgical periodontal therapy (Claffey *et al*. 1988). This trauma can trigger local mechanoreceptors and polymodal nociceptors, the activation of which leads to the release of chemicals, such as prostaglandins, bradykinin, and histamine, and ultimately to the perception of pain in the central nervous system.

Clinical studies referring to pain experience after non-surgical therapy are limited. Quantifying pain is difficult as it cannot be measured directly. Pain perception to a similar stimulus is highly variable from individual to individual. Pain may be measured using visual analogue scales whereby the patient is asked to indicate their level of pain by a mark on a gradated scale from no pain to the most severe pain imaginable.

Pihlstrom *et al*. (1999) reported that patients experienced pain of significant duration and magnitude following scaling and root planning. Pain was reported to peak in intensity between 2 and 8 hours post therapy and on average lasted for 6 hours. Almost 25% of patients self-medicated to relieve pain after treatment.

In addition to pain resulting from soft tissue trauma, patients may also experience root sensitivity following non-surgical therapy. Good oral hygiene measures resulting in low plaque scores prior to commencement of non-surgical periodontal therapy have been shown to decrease root dentin sensitivity.

Despite this, root dentin sensitivity can be a side effect of thorough root planing. Tammaro *et al*. (2000) demonstrated only moderate increases in root dentin sensitivity in most patients with only a small portion of patients experiencing more extreme sensitivity. Patients with sensitive teeth prior to treatment had higher levels of sensitivity following treatment. Although a reduction in the intensity of root dentin sensitivity over 4 weeks was noted, the number of sensitive teeth remained unchanged.

Clinical trials have shown anxiety, depression, and stress to be related to pain perception. Kloostra *et al*. (2006) investigated these factors with regard to non-surgical as well as surgical periodontal therapy and concluded that psychosocial factors may influence pain experience and the need for medication after therapy.

In a further clinical trial concerned with patients' experience of pain during diagnosis and non-surgical treatment of periodontitis it was demonstrated that pain experience during diagnostic instrumentation correlated significantly with pain experience during root instrumentation (van Steenberghe *et al*. 2004). One third of patients took analgesic medication after non-surgical treatment. However approximately half of the total number of patients complained of gingival soreness and pain and two thirds even experienced problems while eating.

Pain during and after periodontal diagnosis and non-surgical therapy seems to be on average mild to moderate and transient in nature. Nevertheless, some patients experience significant pain during treatment. Patients' psychosocial factors such as anxiety may influence the intensity of the pain experienced. Moreover recognition of this anxiety may be the first step in the management of pain in such patients (Chung *et al*. 2003). There is some first evidence that preemptive analgesics (ibruprofen arginine) may have some beneficial effect and help the patient to have a much more positive experience during periodontal treatment (Ettlin *et al*. 2006).

Re-evaluation

Healing following non-surgical therapy is almost complete at 3 months. However a slower ongoing but limited healing can continue for up to 9 or more months following the treatment (Badersten *et al*. 1984). Re-evaluation is a vital stage in a periodontal treatment plan. At re-evaluation the effectiveness of treatment previously carried out is evaluated and the nature of further therapy, if needed, is established.

Measurements are made at baseline and again at 3 months as a method of evaluation of periodontal status and effectiveness of therapy. Measurements include plaque scores, bleeding on probing, suppuration on probing, probing pocket depth, recession, probing attachment level, and assessment of mobility. These are usually recorded at four to six sites around each tooth.

Interpretation of probing measurements at re-evaluation

Probing depth is defined as the distance from the gingival margin to the base of the periodontal pocket measured in millimeters using a periodontal probe. Probing attachment level change is utilized to assess events occurring at the base of the periodontal pocket. Measurements are made at different times from a fixed point, such as from a stent margin or cemento-enamel junction to the base of the pocket. It is generally accepted that any improvement in probing attachment level is not a result of connective tissue reattachment but due to a re-adaptation of the junctional epithelium at the base of the pocket (Fig. 37-11). Probing depth change is a combination of recession and the change in probing attachment level

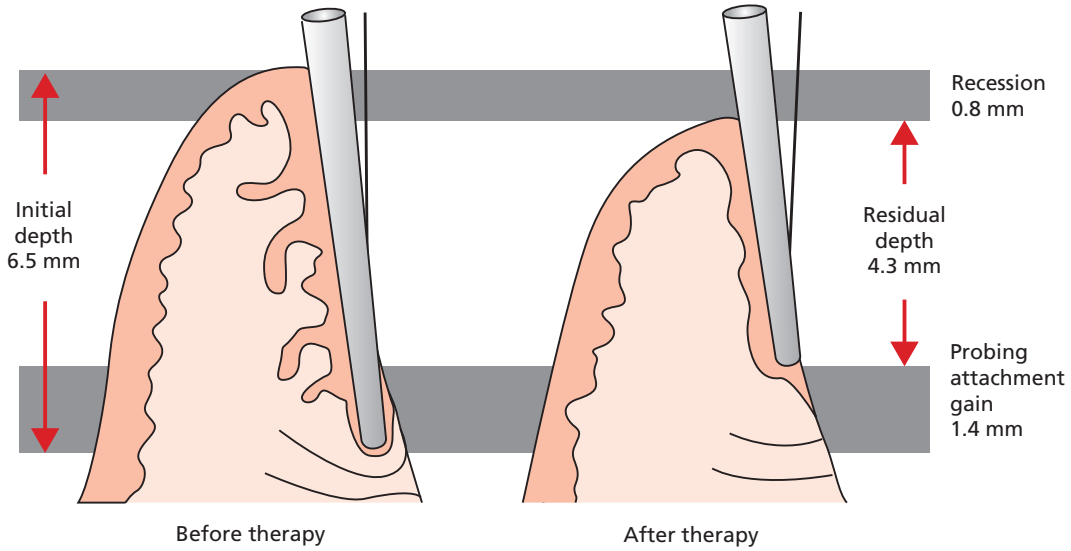

Fig. 37-11 Schematic illustration of the healing occurring in deep pockets following initial therapy (adapted from Fowler *et al*. 1982).

due to events occurring at the base of the periodontal pocket.

On average the change in pocket depth seen following treatment for deeper pockets is a combination of recession at the gingival margin due to resolution of inflammation and a tightening of the junctional epithelium at the base of the pocket. Moreover the reduced bleeding on probing scores found after treatment may reflect the increased resistance to probe penetration into the connective tissue.

Average changes in measurements due to non-surgical therapy

Tables 37-1 and 37-2 present mean changes in plaque scores, bleeding scores, probing depths, and probing attachment levels which were generally observed in studies of mean changes from baseline to re-evaluation. However the use of mean results of pooled sites can mask deterioration or improvement at individual sites.

It is important to appreciate that the extent of the initial probing depth has a marked influence on probing depth changes due to treatment. For example, for shallow pockets, non-surgical treatment results in loss of probing attachment, whereas in deep pockets there is a marked gain of probing attachment. It has been shown that there is an initial loss of probing attachment due to instrumentation trauma for pockets of all initial probing depths. However in the deeper sites this loss is reversed upon resolution of inflammation (Claffey *et al*. 1988).

Interpretation of longitudinal changes at individual sites

Difficulties arise in detecting individual sites with ongoing destruction due to the following reasons:

Table 37-1 Estimations generally observed in studies, of improvements in plaque and bleeding scores for sites of different initial probing depths after a single episode of supra- and subgingival instrumentation

Initial probing depth (mm)	Plaque	Bleeding
≤3.5	≈ 50% → 10%	≈ 55% → 15%
4–6.5	≈ 80% → 15%	≈ 80% → 25%
≥7	≈ 90% → 25%	≈ 90% → 30%

Table 37-2 Mean changes (mm) generally observed in studies in probing depth, probing attachment levels, and gingival recession after a single episode of supra- and subgingival instrumentation

Initial probing depth (mm)	Probing depth	Probing attachment level	Recession
≤3.5	0	–0.5	0.5
4–6.5	1–2	0–1	0–1
≥7	2–3	1–2	1–2

- Lack of reproducibility of probing measurements. Factors influencing the reproducibility of probing measurements include: probing force, probe tip diameter, angulation of probe, position in the mouth, probing depth itself and the inflammatory status of the tissues. A similar lack of reproducibility has been reported following recordings made by the same examiner at different time points (intra-examiner) and recordings taken by different examiners at the same time points (inter-examiner). Badersten *et al*. (1984) demonstrated that duplicate probing measurements were exactly the same in only 30–40% of cases when looking at both inter-examiner and intra-examiner reproducibility. Differences of 2 mm or more were noted in 5–7% of recordings. Therefore, such probing attachment level changes at individual sites cannot be relied upon to indicate true disease progression.
- As discussed above variations in probing attachment levels may simply reflect changes in the inflammatory status at the base of the pocket rather than true connective tissue loss or gain.

With these points in mind, in order to identify sites with ongoing connective tissue loss, probing measurements should be interpreted with caution. Various methods have been reported in the literature to address this problem. One method is to demand a high threshold of change before indicating a site as deteriorating. Others include the application of statistical methods, such as regression analysis, to a series of longitudinal measurements.

Prediction of outcome and evaluation of treatment

It would be of great benefit to the clinician to be able to predict the outcome of treatment prior to therapy and also to identify at re-evaluation the sites likely to continue to deteriorate. Prediction and evaluation must be considered both at a patient level and a site level. On a patient level, the extent of baseline bleeding scores, probing attachment loss, and probing depths have been found to relate to future probing attachment loss in untreated patients (Halazonetis *et al*. 1989; Lindhe *et al*. 1989; Haffajee *et al*. 1991). In patients treated with non-surgical therapy without the use of local anesthetic, baseline scores of attachment loss were also seen to relate to the risk of further loss of attachment (Grbic *et al*. 1991; Grbic & Lamster 1992). On a patient level, the number of sites greater then 6 mm at re-evaluation bears a direct relationship to future periodontal breakdown (Claffey & Egelberg 1995).

On a site level, bleeding on probing is, at best, a moderate predictor of future attachment loss (Badersten *et al*. 1990; Claffey *et al*. 1990). On the other hand, absence of bleeding on probing has been demonstrated as a useful indicator of health (Lang *et al*. 1990). Claffey *et al*. (1990) found that deep residual

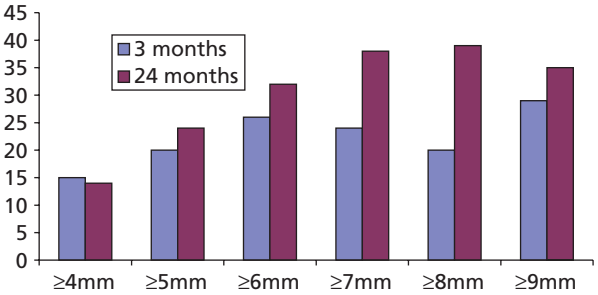

Fig. 37-12 Diagnostic predictability of residual probing depths at 3 months and 12 months following non-surgical treatment of advanced periodontitis. Diagnostic predictability is the percentage of sites with a certain feature, for instance with a deep probing depth at 3 or 6 months, which show attachment loss at a later time point.

probing depth was of limited predictive value when observed over short periods (Fig. 37-12). However, over the longer term, deep residual sites appeared to be more indicative of further attachment loss, particularly if combined with bleeding on probing. This emphasizes the need for ongoing monitoring to identify such sites and instigate appropriate intervention.

Full-mouth disinfection

Traditionally non-surgical treatment of periodontitis involves a series of appointments separated by perhaps a week or more. Each appointment typically involves root debridement of a quadrant depending on disease severity. In 1995 Quirynen *et al*. introduced the concept of total mouth disinfection as a new treatment strategy. It involved full-mouth scaling and root debridement within a 24-hour treatment period, subgingival irrigation (repeated three times within 10 minutes) with 1% chlorhexidine gel, tongue brushing with 1% chlorhexidine gel, and mouth rinsing with 0.2% chlorhexidine. This full-mouth disinfection protocol aimed to reduce the bacterial load in pockets and intraoral niches to minimize the risk of reinfection of the treated pockets from areas harboring pathogenic bacteria. Quirynen *et al*. (1995) showed that full-mouth disinfection yielded better periodontal treatment results on a short-term basis compared to conventional treatment.

Subsequent studies (Bollen *et al*. 1996, 1998; Vandekerckhove *et al*. 1996; Mongardini *et al*. 1999; Quirynen *et al*. 1999, 2000; De Soete *et al*. 2001) concluded that the full-mouth disinfection protocol resulted in clinical and microbiologic improvements comparable to the traditional technique of treatment in patients with advanced chronic periodontitis.

Many recent studies report varying degrees of efficacy of full-mouth disinfection protocol (Apatzidou & Kinane 2004). However, the full-mouth disinfection treatment approach has been promoted as a more efficient way of treating chronic periodontitis patients (Koshy *et al*. 2004; Wennstrom *et al*. 2005).

Part 12: Additional Therapy

Chapter 38

Periodontal Surgery: Access Therapy

Jan L. Wennström, Lars Heijl, and Jan Lindhe

Introduction

Since most forms of periodontal disease are plaque-associated disorders, it is obvious that surgical access therapy can only be considered as adjunctive to cause-related therapy (see Chapters 34 to 37). Therefore, the various surgical methods described below should be evaluated on the basis of their potential to facilitate removal of subgingival deposits and self-performed plaque control and thereby enhance the long-term preservation of the periodontium.

The decision concerning what type of periodontal surgery should be performed and how many sites should be included is usually made after the effect of initial cause-related measures has been evaluated. The time lapse between termination of the initial cause-related phase of therapy and this evaluation may vary from 1 to 6 months. This routine has the following advantages:

- Removal of calculus and bacterial plaque will eliminate or markedly reduce the inflammatory cell infiltrate in the gingiva (edema, hyperemia, flabby tissue consistency), thereby making assessment of the "true" gingival contours and pocket depths possible.
- Reduction of gingival inflammation makes the soft tissues more fibrous and thus firmer, which facilitates surgical handling of the soft tissues. The propensity for bleeding is reduced, making inspection of the surgical field easier.
- A better basis for a proper assessment of the prognosis has been established. The effectiveness of the patient's home care, which is of decisive importance for the long-term prognosis, can be properly evaluated. Lack of effective self-performed infection control will often mean that the patient should be excluded from surgical treatment.

Techniques in periodontal pocket surgery

Over the years, several different surgical techniques have been described and used in periodontal therapy. A superficial review of the literature in this area may give the reader a somewhat confusing picture of the specific objectives and indications relevant for various surgical techniques. It is a matter of historic interest that the first surgical techniques used in periodontal therapy were described as means of gaining access to diseased root surfaces. Such access could be accomplished without excision of the soft tissue pocket ("open-view operations"). Later, procedures were described by which the "diseased gingiva" was excised (gingivectomy procedures).

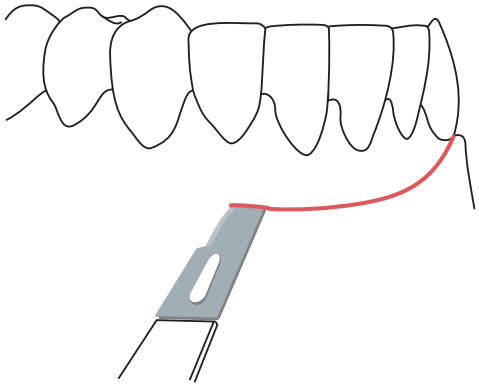

Fig. 38-1 Gingivectomy. The straight incision technique (Robicsek 1884).

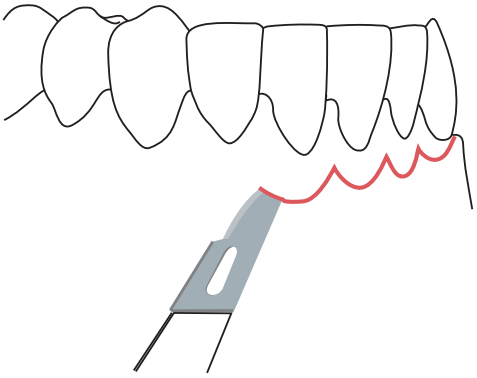

Fig. 38-2 Gingivectomy. The scalloped incision technique (Zentler 1918).

The concept that not only inflamed soft tissue but also "infected and necrotic bone" had to be eliminated called for the development of surgical techniques by which the alveolar bone could be exposed and resected (flap procedures). Other concepts such as (1) the importance of maintaining the mucogingival complex (i.e. a wide zone of gingiva) and (2) the possibility for regeneration of periodontal tissues have also prompted the introduction of "tailor-made" surgical techniques.

In the following, surgical procedures will be described which represent important steps in the development of the surgical component of periodontal therapy.

Gingivectomy procedures

The surgical approach as an alternative to subgingival scaling for pocket therapy was already recognized in the latter part of the nineteenth century, when Robicsek (1884) pioneered the so-called *gingivectomy* procedure. Gingivectomy was later defined by Grant *et al*. (1979) as being "the excision of the soft tissue wall of a pathologic periodontal pocket". The surgical procedure, which aimed at "pocket elimination", was usually combined with recontouring of the diseased gingiva to restore physiologic form.

Robicsek (1884) and, later, Zentler (1918) described the gingivectomy procedure in the following way. The line to which the gum is to be resected is determined first. Following a straight (Robicsek) (Fig. 38-1) or scalloped (Zentler) (Fig. 38-2) incision, first on the labial and then on the lingual surface of each tooth, the diseased tissue should be loosened and lifted out by means of a hook-shaped instrument. After elimination of the soft tissue, the exposed alveolar bone should be scraped. The area should then be covered with some kind of antibacterial gauze or be painted with disinfecting solutions. The result obtained should include eradication of the deepened periodontal pocket and formation of an area which can be kept clean more easily.

Technique

The gingivectomy procedure as it is employed today was described in 1951 by Goldman.

- When the dentition in the area scheduled for surgery has been properly anesthetized, the depths of the pathological pockets are identified with a conventional periodontal probe (Fig. 38-3a). At the level of the bottom of the pocket, the gingiva is pierced with the probe and a bleeding point is produced on the outer surface of the soft tissue (Fig. 38-3b). The pockets are probed and bleeding points produced at several location points around each tooth in the area. The series of bleeding points produced describes the depth of the pockets in the area scheduled for treatment and is used as a guideline for the incision.
- The primary incision (Fig. 38-4), which may be made by a scalpel (blade No. 12B or 15; Bard-Parker®) in either a Bard-Parker handle or an angulated handle (e.g. a Blake's handle), or a Kirkland knife No. 15/16, should be planned to give a thin and properly festooned margin of the remaining gingiva. Thus, in areas where the gingiva is bulky, the incision must be placed at a level more apical to the level of the bleeding points than in areas with a thin gingiva, where a less accentuated bevel is needed. The beveled incision is directed towards the base of the pocket or to a level slightly apical to the apical extension of the junctional epithelium. In areas where the interdental pockets are deeper than the buccal or lingual pockets, additional amounts of buccal and/or lingual (palatal) gingiva must be removed in order to establish a "physiologic" contour of the gingival margin. This is often accomplished by initiating the incision at a more apical level.
- Once the primary incision is completed on the buccal and lingual aspects of the teeth, the interproximal soft tissue is separated from the interdental periodontium by a secondary incision using an Orban knife (No. 1 or 2) or a Waerhaug knife (No. 1 or 2; a saw-toothed modification of the Orban knife) (Fig. 38-5).

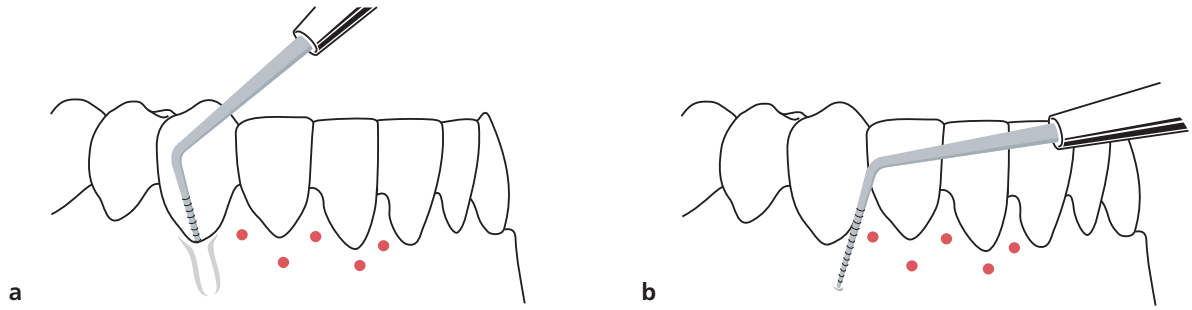

Fig. 38-3 Gingivectomy. Pocket marking. (a) An ordinary periodontal probe is used to identify the bottom of the deepened pocket. (b) When the depth of the pocket has been assessed an equivalent distance is delineated on the outer aspect of the gingiva. The tip of the probe is then turned horizontally and used to produce a bleeding point at the level of the bottom of the probeable pocket.

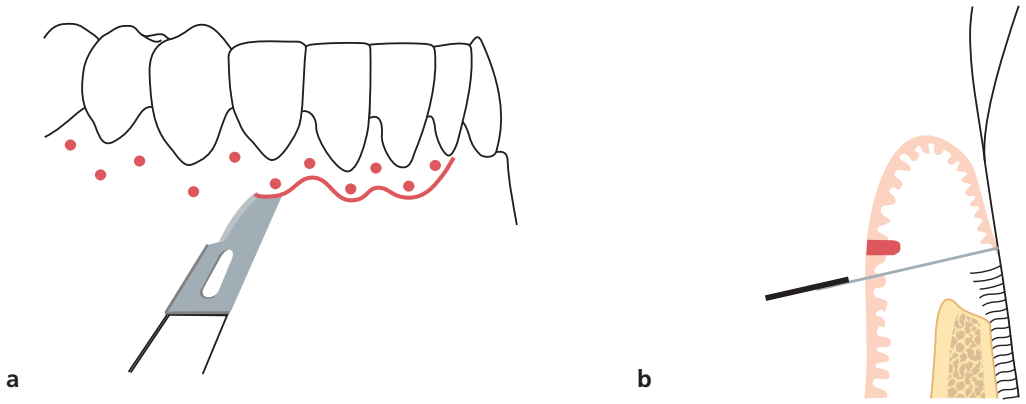

Fig. 38-4 Gingivectomy. (a) The primary incision. (b) The incision is terminated at a level apical to the "bottom" of the pocket and is angulated to give the cut surface a distinct bevel.

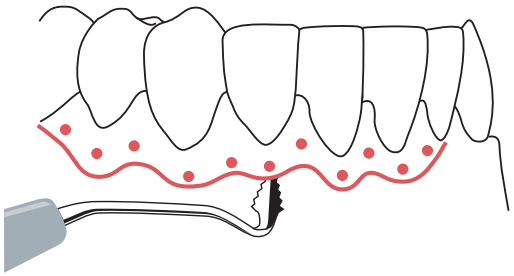

Fig. 38-5 Gingivectomy. The secondary incision through the interdental area is performed with the use of a Waerhaug knife.

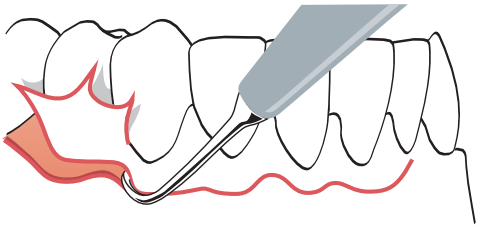

Fig. 38-6 Gingivectomy. The detached gingiva is removed with a scaler.

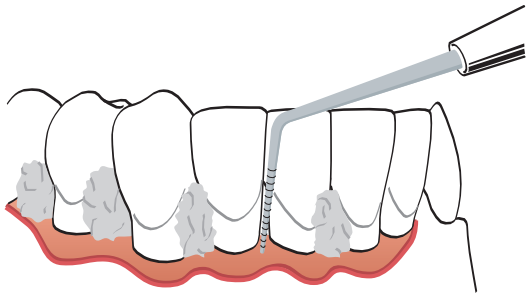

Fig. 38-7 Gingivectomy. Probing for residual pockets. Gauze packs have been placed in the interdental spaces to control bleeding.

- The incised tissues are carefully removed by means of a curette or a scaler (Fig. 38-6). Remaining tissue tabs are removed with a curette or a pair of scissors. Pieces of gauze packs often have to be placed in the interdental areas to control bleeding. When the field of operation is properly prepared, the exposed root surfaces are carefully scaled and planed.
- Following meticulous debridement, the dentogingival regions are probed again to detect any remaining pockets (Fig. 38-7). The gingival contour is checked and, if necessary, corrected by means of knives or rotating diamond burs.
- To protect the incised area during the period of healing, the wound surface must be covered by a periodontal dressing (Fig. 38-8). The dressing should be closely adapted to the buccal and lingual wound surfaces as well as to the interproximal spaces. Care should be taken not to allow the

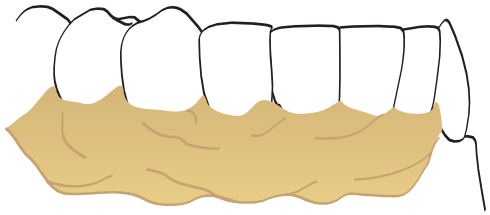

Fig. 38-8 Gingivectomy. The periodontal dressing has been applied and properly secured.

dressing to become too bulky, since this is not only uncomfortable for the patient, but also facilitates dislodgement of the dressing.

- The dressing should remain in position for 10–14 days. After removal of the dressing, the teeth must be cleaned and polished. The root surfaces are carefully checked and remaining calculus removed with a curette. Excessive granulation tissue is eliminated with a curette. The patient is instructed to clean properly the operated segments of the dentition, which now have a different morphology compared to the pre-operative situation.

Flap procedures

The original Widman flap

In 1918 Leonard Widman published one of the first detailed descriptions of the use of a flap procedure for pocket elimination. In his article "The operative treatment of pyorrhea alveolaris" Widman described a mucoperiosteal flap design aimed at removing the pocket epithelium and the inflamed connective tissue, thereby facilitating optimal cleaning of the root surfaces.

Technique

- Sectional releasing incisions were first made to demarcate the area scheduled for surgery (Fig. 38-9). These incisions were made from the mid-buccal gingival margins of the two peripheral teeth of the treatment area and were continued several millimeters out into the alveolar mucosa. The two releasing incisions were connected by a gingival incision, which followed the outline of the gingival margin and *separated the pocket epithelium and the inflamed connective tissue from the non-inflamed gingiva*. Similar releasing and gingival incisions, if needed, were made on the lingual aspect of the teeth.
- A mucoperiosteal flap was elevated to expose at least 2–3 mm of the marginal alveolar bone. The collar of inflamed tissue around the neck of the teeth was removed with curettes (Fig. 38-10) and the exposed root surfaces were carefully scaled. Bone recontouring was recommended in order to achieve an ideal anatomic form of the underlying alveolar bone (Fig. 38-11).

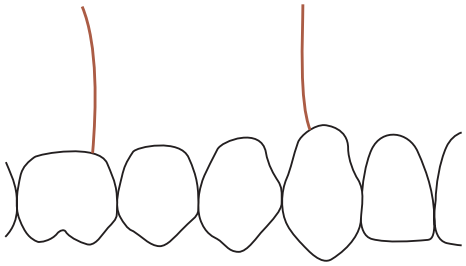

Fig. 38-9 Original Widman flap. Two releasing incisions demarcate the area scheduled for surgical therapy. A scalloped reverse bevel incision is made in the gingival margin to connect the two releasing incisions.

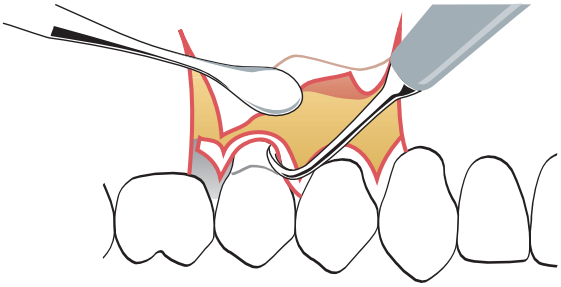

Fig. 38-10 Original Widman flap. The collar of inflamed gingival tissue is removed following the elevation of a mucoperiosteal flap.

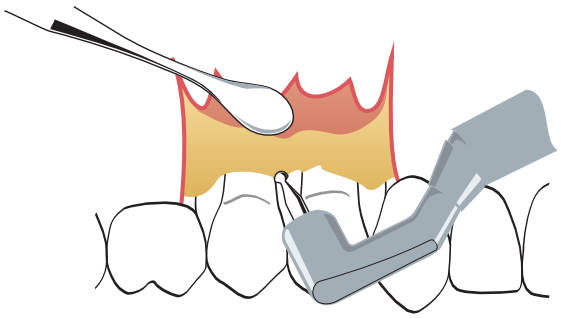

Fig. 38-11 Original Widman flap. By bone recontouring, a "physiologic" contour of the alveolar bone may be re-established.

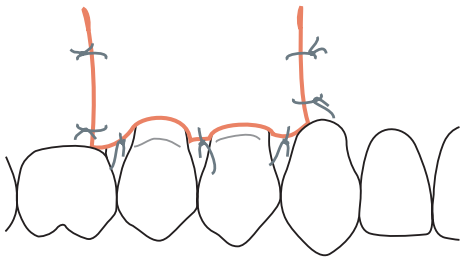

Fig. 38-12 Original Widman flap. The coronal ends of the buccal and lingual flaps are placed at the alveolar bone crest and secured in this position by interdentally placed sutures.

- Following careful debridement of the teeth in the surgical area, the buccal and lingual flaps were laid back over the alveolar bone and secured in this position with interproximal sutures (Fig. 38-12). Widman pointed out the importance of placing

the soft tissue margin at the level of the alveolar bone crest, so that no pockets would remain. The surgical procedure resulted in the exposure of root surfaces. Often the interproximal areas were left without soft tissue coverage of the alveolar bone.

The main advantages of the "*original Widman flap*" procedure in comparison to the gingivectomy procedure included, according to Widman (1918):

- Less discomfort for the patient, since healing occurred by primary intention
- It was possible to re-establish a proper contour of the alveolar bone in sites with angular bony defects.

The Neumann flap

Only a few years later, Neumann (1920) suggested the use of a flap procedure, which in some respects was different from that originally described by Widman.

Technique

- According to the technique suggested by Neumann, an intracrevicular incision was made through the base of the gingival pockets and the entire gingiva (and part of the alveolar mucosa) was elevated in a mucoperiosteal flap. Sectional releasing incisions were made to demarcate the area of surgery.
- Following flap elevation, the inside of the flap was curetted to remove the pocket epithelium and the granulation tissue. The root surfaces were subsequently carefully "cleaned". Any irregularities of the alveolar bone were corrected to give the bone crest a horizontal outline.
- The flaps were then trimmed to allow both an optimal adaptation to the teeth and a proper coverage of the alveolar bone on both the buccal/lingual (palatal) and the interproximal sites. With regard to pocket elimination, Neumann (1920) pointed out the importance of removing the soft tissue pockets, i.e. replacing the flap at the crest of the alveolar bone.

The modified flap operation

In a publication from 1931 Kirkland described a surgical procedure to be used in the treatment of "periodontal pus pockets". The procedure was called the *modified flap operation*, and is basically an access flap for proper root debridement.

Technique

- In this procedure incisions were made intracrevicularly through the bottom of the pocket (Fig. 38-13) on both the labial and the lingual aspects of the interdental area. The incisions were extended in a mesial and distal direction.

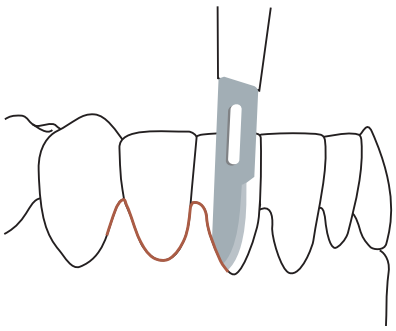

Fig. 38-13 Modified flap operation (the Kirkland flap). Intracrevicular incision.

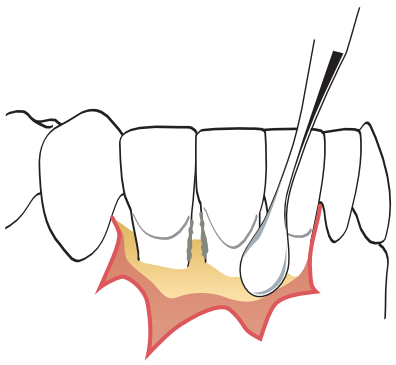

Fig. 38-14 Modified flap operation (the Kirkland flap). The gingiva is retracted to expose the "diseased" root surface.

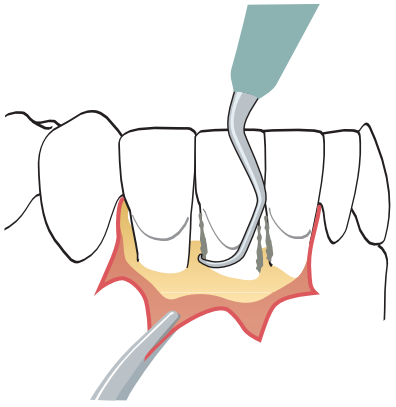

Fig. 38-15 Modified flap operation (the Kirkland flap). The exposed root surfaces are subjected to mechanical debridement.

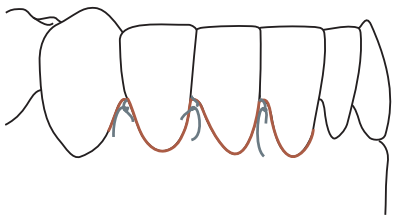

Fig. 38-16 Modified flap operation (the Kirkland flap). The flaps are replaced to their original position and sutured.

- The gingiva was retracted labially and lingually to expose the diseased root surfaces (Fig. 38-14) which were carefully debrided (Fig. 38-15). Angular bony defects were curetted.
- Following the elimination of the pocket epithelium and granulation tissue from the inner surface of the flaps, these were *replaced* to their original position and secured with interproximal sutures (Fig. 38-16). Thus, no attempt was made to reduce the pre-operative depth of the pockets.

In contrast to the *original Widman flap* as well as the *Neumann flap*, the *modified flap operation* did not include (1) extensive sacrifice of non-inflamed tissues and (2) apical displacement of the gingival margin. The method could be useful in the anterior regions of the dentition for esthetic reasons, since the root surfaces were not markedly exposed. Another advantage of the *modified flap operation* was the potential for bone regeneration in intrabony defects which frequently occurred according to Kirkland (1931).

The main objectives of the flap procedures so far described were to:

- Facilitate the debridement of the root surfaces as well as the removal of the pocket epithelium and the inflamed connective tissue
- Eliminate the deepened pockets (the *original Widman flap* and the *Neumann flap*)
- Cause a minimal amount of trauma to the periodontal tissues and discomfort to the patient.

The apically repositioned flap

In the 1950s and 1960s new surgical techniques for the removal of soft and, when indicated, hard tissue periodontal pockets were described in the literature. The importance of maintaining *an adequate zone of attached gingiva* after surgery was now emphasized. One of the first authors to describe a technique for the preservation of the gingiva following surgery was Nabers (1954). The surgical technique developed by Nabers was originally denoted "repositioning of attached gingiva" and was later modified by Ariaudo and Tyrrell (1957). In 1962 Friedman proposed the term *apically repositioned flap* to describe more appropriately the surgical technique introduced by Nabers. Friedman emphasized the fact that, at the end of the surgical procedure, the entire complex of the soft tissues (gingiva and alveolar mucosa) rather than the gingiva alone was displaced in an apical direction. Thus, rather than excising the amount of gingiva which would be in excess after osseous surgery (if performed), the whole muco-gingival complex was maintained and repositioned apically. This surgical technique was used on buccal surfaces in both upper and lower jaws and on lingual surfaces in the lower jaw, while an excisional technique had to be used on the palatal aspect of maxillary teeth where the lack of alveolar mucosa made it impossible to reposition the flap in an apical direction.

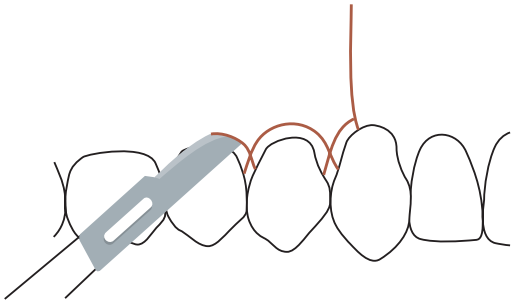

Fig. 38-17 Apically repositioned flap. Following a vertical releasing incision, the reverse bevel incision is made through the gingiva and the periosteum to separate the inflamed tissue adjacent to the tooth from the flap.

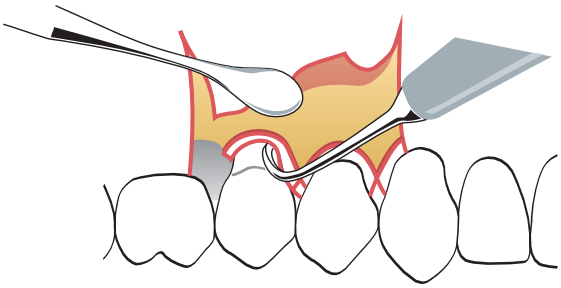

Fig. 38-18 Apically repositioned flap. A mucoperiosteal flap is raised and the tissue collar remaining around the teeth, including the pocket epithelium and the inflamed connective tissue, is removed with a currette.

Technique

According to Friedman (1962) the technique should be performed in the following way:

- A reverse bevel incision is made using a scalpel with a Bard-Parker blade (No. 12B or No. 15). How far from the buccal/lingual gingival margin the incision should be made is dependent on the pocket depth as well as the thickness and the width of the gingiva (Fig. 38-17). If pre-operatively the gingiva is thin and only a narrow zone of keratinized tissue is present, the incision should be made close to the tooth. The beveling incision should be given a scalloped outline, to ensure maximal interproximal coverage of the alveolar bone when the flap subsequently is repositioned. Vertical releasing incisions extending out into the alveolar mucosa (i.e. past the muco-gingival junction) are made at each of the end points of the reverse incision, thereby making apical repositioning of the flap possible.
- A full-thickness mucoperiosteal flap including buccal/lingual gingiva and alveolar mucosa is raised by means of a mucoperiosteal elevator. The flap has to be elevated beyond the muco-gingival line in order to be able later to reposition the soft tissue apically. The marginal collar of tissue, including pocket epithelium and granulation tissue, is removed with curettes (Fig. 38-18), and

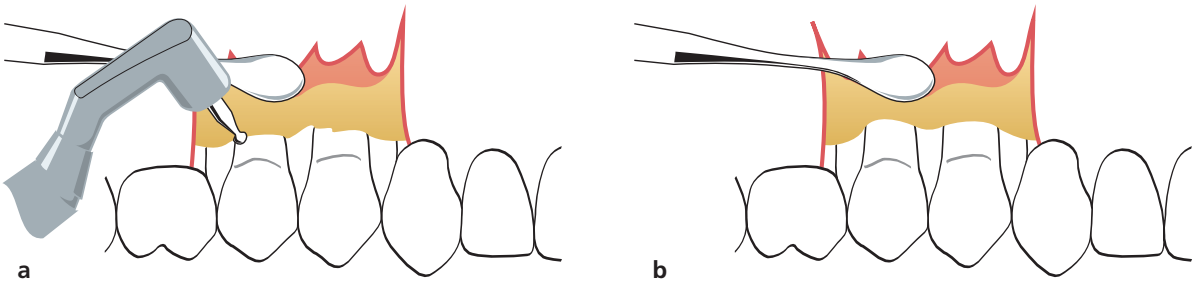

Fig. 38-19 Apically repositioned flap. Osseous surgery is performed with the use of a rotating bur (a) to recapture the physiologic contour of the alveolar bone (b).

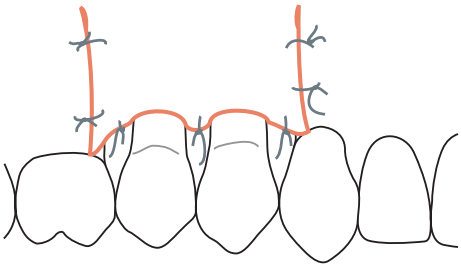

Fig. 38-20 Apically repositioned flap. The flaps are repositioned in an apical direction to the level of the recontoured alveolar bone crest and retained in this position by sutures.

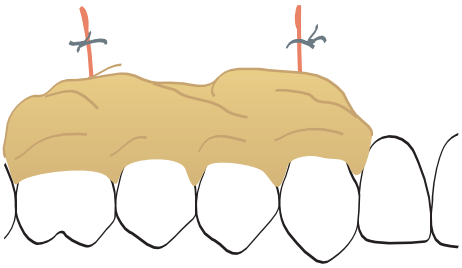

Fig. 38-21 Apically repositioned flap. A periodontal dressing is placed over the surgical area to ensure that the flaps remain in the correct position during healing.

the exposed root surfaces are carefully scaled and planed.

- The alveolar bone crest is recontoured with the objective of recapturing the normal form of the alveolar process but at a more apical level (Fig. 38-19). The osseous surgery is performed using burs and/or bone chisels.
- Following careful adjustment, the buccal/lingual flap is repositioned to the level of the newly recontoured alveolar bone crest and secured in this position (Fig. 38-20). The incisional and excisional technique used means that it is not always possible to obtain proper soft tissue coverage of the denuded interproximal alveolar bone. A periodontal dressing should therefore be applied to protect the exposed bone and to retain the soft tissue at the level of the bone crest (Fig. 38-21). After healing, an "adequate" zone of gingiva is preserved and no residual pockets should remain.

To handle periodontal pockets on the palatal aspect of the maxillary teeth, Friedman described a modification of the "apically repositioned flap", which he termed the *beveled flap*:

- In order to prepare the tissue at the gingival margin to follow the outline of the alveolar bone crest properly, a conventional mucoperiosteal flap is first resected (Fig. 38-22).
- The tooth surfaces are debrided and osseous recontouring is performed (Fig. 38-23).
- The palatal flap is subsequently replaced and the gingival margin is prepared and adjusted to the alveolar bone crest by a secondary scalloped and beveled incision (Fig. 38-24). The flap is secured in this position with interproximal sutures (Fig. 38-25).

Among a number of suggested advantages of the *apically repositioned flap* procedure, the following have been emphasized:

- Minimum pocket depth post-operatively
- If optimal soft tissue coverage of the alveolar bone is obtained, the post-surgical bone loss is minimal
- The post-operative position of the gingival margin may be controlled and the entire muco-gingival complex may be maintained.

The sacrifice of periodontal tissues by bone resection and the subsequent exposure of root surfaces (which may cause esthetic and root sensitivity problems) were regarded as the main disadvantages of this technique.

The modified Widman flap

Ramfjord and Nissle (1974) described the *modified Widman flap* technique that is also recognized as the *open flap curettage* technique. It should be noted that, while the *original Widman flap* technique included both apical displacement of the flaps and osseous recontouring (elimination of bony defects) to obtain proper pocket elimination, the *modified Widman flap* technique is not intended to meet these objectives.

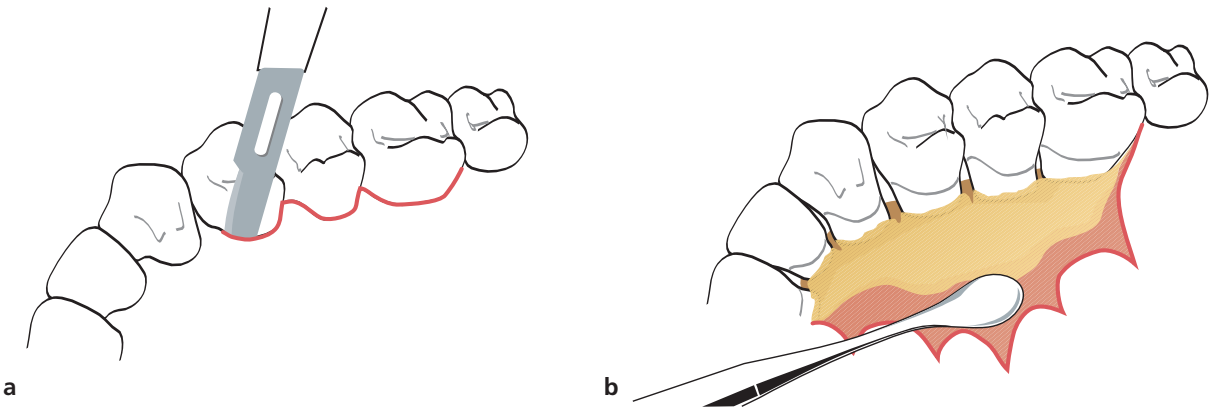

Fig. 38-22 Bevelled flap. A primary incision is made intracrevicularly through the bottom of the periodontal pocket (a) and a conventional mucoperiosteal flap is elevated (b).

Fig. 38-23 Bevelled flap. Scaling, root planing, and osseous recontouring are performed in the surgical area.

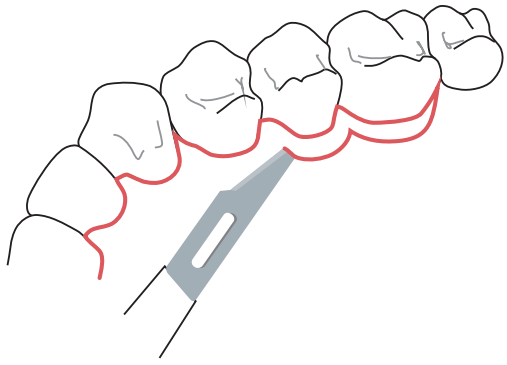

Fig. 38-24 Bevelled flap. The palatal flap is replaced and a secondary, scalloped, reverse bevel incision is made to adjust the length of the flap to the height of the remaining alveolar bone.

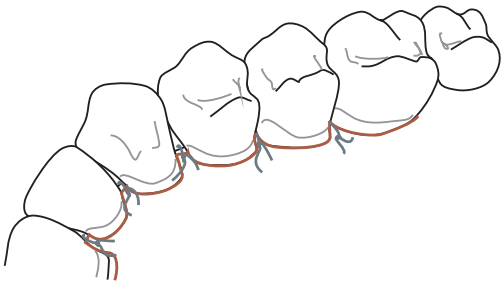

Fig. 38-25 Bevelled flap. The shortened and thinned flap is replaced over the alveolar bone and in close contact with the root surfaces.

Technique

- According to the description by Ramfjord and Nissle (1974) the *initial incision* (Fig. 38-26), which may be performed with a Bard-Parker knife (No. 11), should be parallel to the long axis of the tooth and placed approximately 1 mm from the buccal gingival margin in order to properly separate the pocket epithelium from the flap. If the pockets on the buccal aspects of the teeth are less than 2 mm deep or if esthetic considerations are important, an intracrevicular incision may be made. Furthermore, the scalloped incision should be extended as far as possible in between the teeth, to allow maximum amounts of the interdental gingiva to be included in the flap. A similar incision technique is used on the palatal aspect. Often, however, the scalloped outline of the initial incision may be accentuated by placing the knife at a distance of 1–2 mm from the mid-palatal surface of the teeth. By extending the incision as far as possible in between the teeth, sufficient amounts of tissue can be included in the palatal flap to allow for proper coverage of the interproximal bone when the flap is sutured. Vertical releasing incisions are not usually required.
- Buccal and palatal full-thickness flaps are carefully elevated with a mucoperiosteal elevator. The flap elevation should be limited and allow only a few millimeters of the alveolar bone crest to become exposed. To facilitate the gentle separation of the collar of pocket epithelium and granulation tissue from the root surfaces, an intracrevicular incision is made around the teeth (*second incision*) to the alveolar crest (Fig. 38-27).
- A *third incision* (Fig. 38-28) made in a horizontal direction and in a position close to the surface of

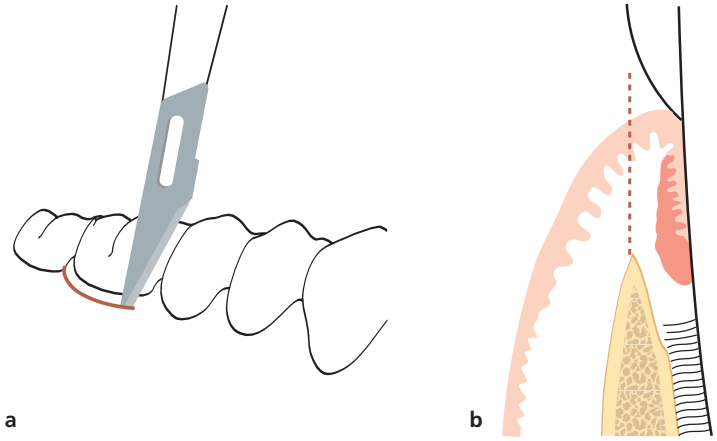

Fig. 38-26 Modified Widman flap. The initial incision is placed 0.5–1 mm from the gingival margin (a) and parallel to the long axis of the tooth (b).

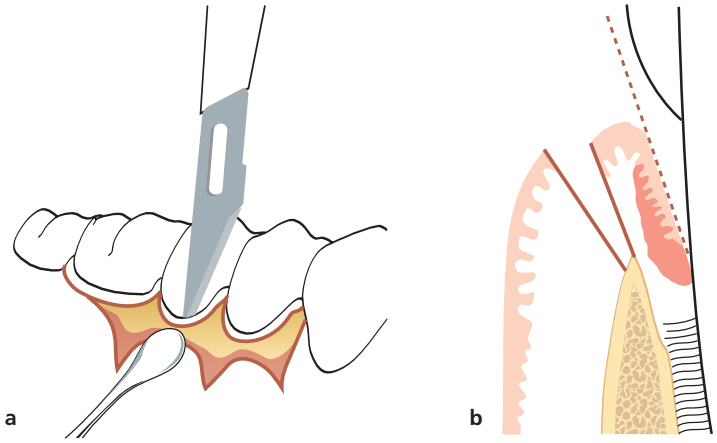

Fig. 38-27 Modified Widman flap. Following careful elevation of the flaps, a second intracrevicular incision (a) is made to the alveolar bone crest (b) to separate the tissue collar from the root surface.

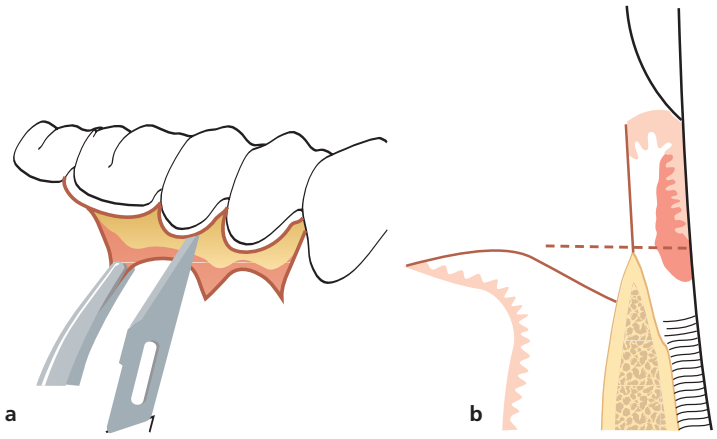

Fig. 38-28 Modified Widman flap. A third incision is made perpendicular to the root surface (a) and as close as possible to the bone crest (b), thereby separating the tissue collar from the alveolar bone.

the alveolar bone crest separates the soft tissue collar of the root surfaces from the bone.

- The pocket epithelium and the granulation tissues are removed by means of curettes. The exposed roots are carefully scaled and planed, except for a narrow area close to the alveolar bone crest in which remnants of attachment fibers may be preserved. Angular bony defects are carefully curetted.
- Following the curettage, the flaps are trimmed and adjusted to the alveolar bone to obtain complete coverage of the interproximal bone (Fig. 38-29). If this adaptation cannot be achieved by soft tissue recontouring, some bone may be removed from the outer aspects of the alveolar process in order to facilitate the all-important flap adaptation. The flaps are sutured together with individual interproximal sutures. Surgical dressing may be placed over the area to ensure close adaptation of the flaps to the alveolar bone and root surfaces. The dressing, as well as the sutures, is removed after 1 week.

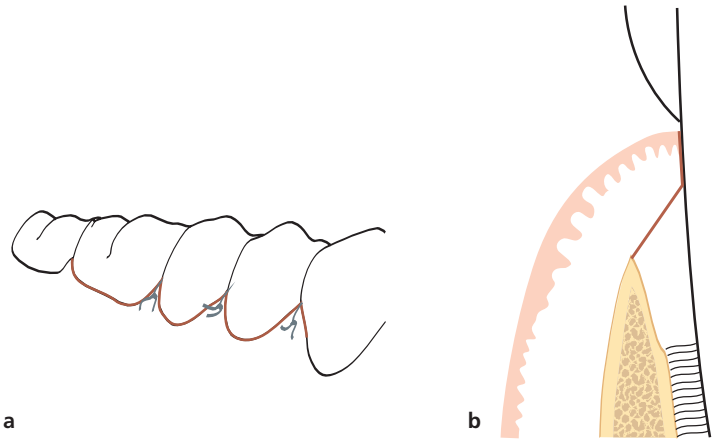

Fig. 38-29 Modified Widman flap. (a) Following proper debridement and currettage of angular bone defects, the flaps are carefully adjusted to cover the alveolar bone and sutured. (b) Complete coverage of the interdental bone as well as close adaptation of the flaps to the tooth surfaces should be accomplished.

The main advantages of the *modified Widman flap* technique in comparison to other procedures previously described are, according to Ramfjord and Nissle (1974):

- The possibility of obtaining a close adaptation of the soft tissues to the root surfaces
- The minimum of trauma to which the alveolar bone and the soft connective tissues are exposed
- Less exposure of the root surfaces, which from an esthetic point of view is an advantage in the treatment of anterior segments of the dentition.

The papilla preservation flap

In order to preserve the interdental soft tissues for maximum soft tissue coverage following surgical intervention involving treatment of proximal osseous defects, Takei *et al*. (1985) proposed a surgical approach called *papilla preservation technique*. Later, Cortellini *et al*. (1995b, 1999) described modifications of the flap design to be used in combination with regenerative procedures. For esthetic reasons, the papilla preservation technique is often utilized in the surgical treatment of anterior tooth regions.

Technique

- According to the description by Takei *et al*. (1985) the *papilla preservation flap technique* is initiated by an intra-sulcular incision at the facial and proximal aspects of the teeth without making incisions through the interdental papillae (Fig. 38-30a). Subsequently, an intra-sulcular incision is made along the lingual/palatal aspect of the teeth with a semilunar incision made across each interdental area. The semilunar incision should dip apically at least 5 mm from the line angles of the teeth, which will allow the interdental tissue to be dissected from the lingual/palatal aspect so that it can be elevated intact with the facial flap. In situations where an osseous defect has a wide extension into the lingual/palatal area, the semilunar incision may be placed on the facial aspect of the interdental area to have the papillae included with the lingual/palatal flap.
- A curette or interproximal knife is used to free the interdental papilla carefully from the underlying hard tissue. The detached interdental tissue is pushed through the embrasure with a blunt instrument (Fig. 38-30b).
- A full-thickness flap is reflected with a periosteal elevator on both facial and lingual/palatal surfaces. The exposed root surfaces are thoroughly scaled and root planed and bone defects carefully curetted (Fig. 38-31).
- While holding the reflected flap, the margins of the flap and the interdental tissue are scraped to remove pocket epithelium and excessive granulation tissue. In anterior areas, the trimming of granulation tissue should be limited in order to maintain the maximum thickness of tissue.
- The flaps are repositioned and sutured using cross mattress sutures (Fig. 38-32). Alternatively, a direct suture of the semilunar incisions can be done as the only means of flap closure. A surgical dressing may be placed to protect the surgical

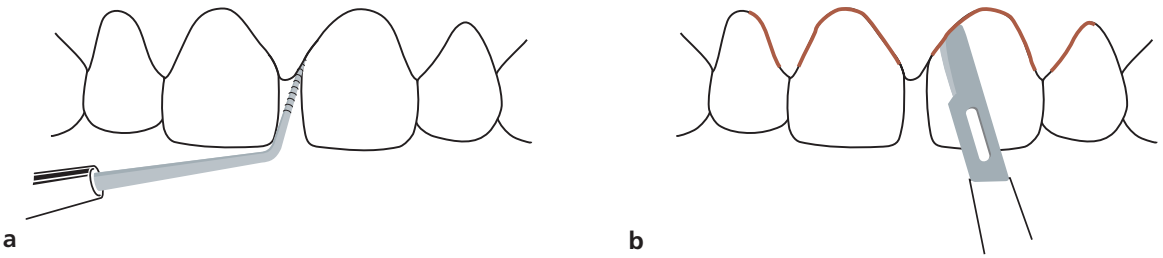

Fig. 38-30 Papilla preservation flap. Intracrevicular incisions are made at the facial and proximal aspects of the teeth.

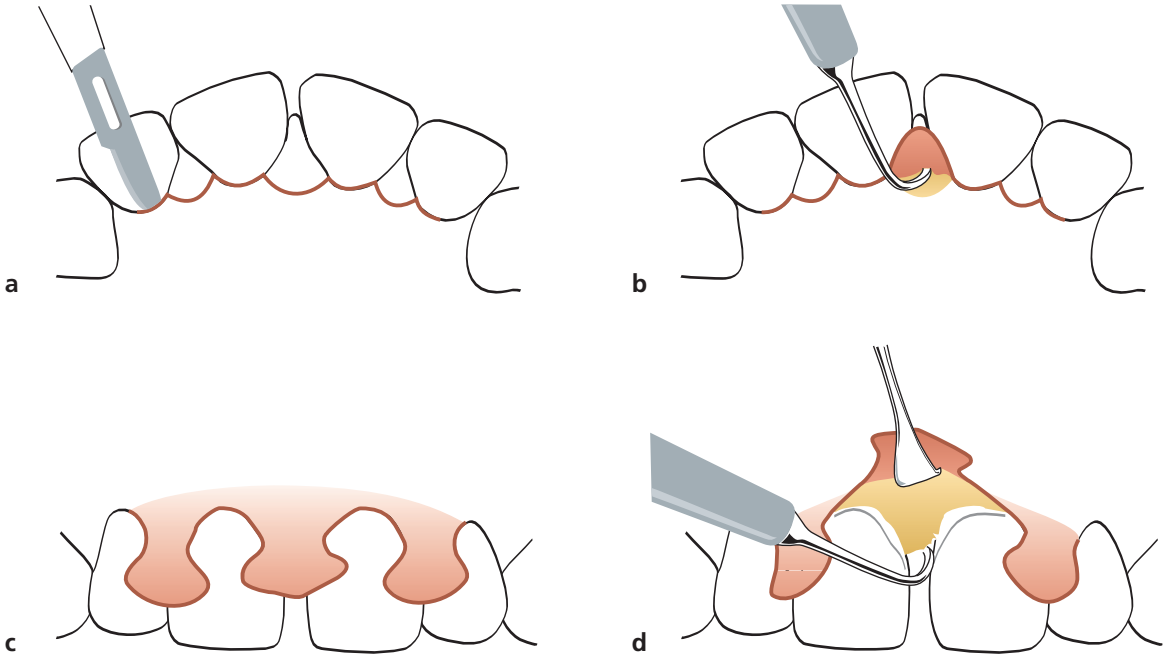

Fig. 38-31 Papilla preservation flap. (a) An intracrevicular incision is made along the lingual/palatal aspect of the teeth with a semilunar incision made across each interdental area. (b) A curette or a papilla elevator is used to carefully free the interdental papilla from the underlying hard tissue. area. The dressing and sutures are removed after 1 week.

Regenerative procedures

In the 1980s treatment of periodontal pockets was given a new dimension when it was shown that, with specific surgical handling of the periodontal wound, a significant amount of new connective tissue attachment is achievable following surgical treatment (Nyman *et al*. 1982; Bowers *et al*. 1989).

Obtaining periodontal regeneration has always been a major challenge to the periodontist and several approaches to periodontal regeneration have been used throughout the years. The earliest attempts involved various bone-grafting procedures, such as the use of autogenous grafts from both extraoral and intraoral donor sites, allogenic marrow grafts, and non-decalcified/decalcified lyophilized bone grafts, or "implant" procedures utilizing slowly resorbable tricalcium phosphate and non-resorbable, non-porous hydroxyapatite. Other approaches to periodontal regeneration involved the use of citric acid for root surface demineralization or the use of methods for improved root surface biocompatibility or to enhance cellular responses.

The use of physical barriers, such as membranes (non-biodegradable or biodegradable), to retard or prevent apical migration of epithelium as well as exclude gingival connective tissue from the healing wound, formed the basis for the concept known as "guided tissue regeneration" (Gottlow *et al*. 1986). The procedure can be described as a coronally repositioned flap procedure without bone recontouring, with the adjunctive use of a membrane tightened to the tooth to cover the exposed root surface and adjacent intrabony defect before repositioning the soft tissue flaps.

In the late 1990s a new approach to periodontal regeneration was presented, which involves the use of a derivative of enamel matrix proteins (Hammarström 1997; Heijl *et al*. 1997). These proteins are involved in the embryogenesis of cementum, periodontal ligament, and supporting bone, and when applied to the exposed root surface facing an intrabony periodontal defect they mediate regeneration of a new attachment apparatus. The surgical procedure is performed as a coronally repositioned flap procedure without bone recontouring. Before repositioning of the soft tissue flaps, the exposed roots are treated with EDTA for removal of the "smear layer", followed by the application of the derivative of enamel matrix proteins.

Various regenerative procedures for surgical treatment of periodontal lesions, as well as the biologic

basis for periodontal regeneration, are discussed in detail in Chapters 25 and 43.

Distal wedge procedures

In many cases the treatment of periodontal pockets on the distal surface of distal molars is complicated by the presence of bulbous tissues over the tuberosity or by a prominent retromolar pad. The most direct approach to pocket elimination in such cases in the maxillary jaw is the gingivectomy procedure. The incision is started on the distal surface of the tuberosity and carried forward to the base of the pocket of the distal surface of the molar (Fig. 38-33).

However, when only limited amounts of keratinized gingiva are present, or none at all, or if a distal angular bony defect has been diagnosed, the bulbous tissue should be reduced in size rather than being removed *in toto*. This may be accomplished by the *distal wedge procedure* (Robinson 1966). This technique facilitates access to the osseous defect and makes it possible to preserve sufficient amounts of gingiva and mucosa to achieve soft tissue coverage.

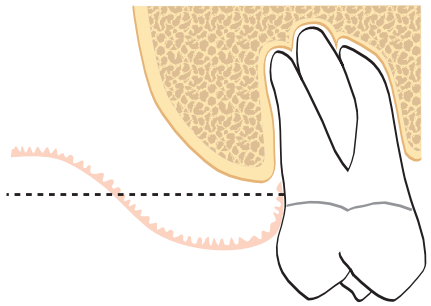

Fig. 38-33 Distal wedge procedure. Simple gingivectomy incision (broken line) can be used to eliminate a soft tissue pocket and adjacent fibrous tissue pad behind a maxillary molar.

Technique

- Buccal and lingual incisions are made in a vertical direction through the tuberosity or retromolar pad to form a triangular wedge (Fig. 38-34a). The facial and lingual incisions should be extended in a mesial direction along the buccal and lingual surfaces of the distal molar to facilitate flap elevation.
- The facial and lingual walls of the tuberosity or retromolar pad are deflected and the incised wedge of tissue is dissected and separated from the bone (Fig. 38-34b).
- The walls of the facial and lingual flaps are then reduced in thickness by undermining incisions (Fig. 38-34c). Loose tags of tissue are removed and the root surfaces are scaled and planed. If necessary, the bone is recontoured.
- The buccal and lingual flaps are replaced over the exposed alveolar bone, and the edges trimmed to avoid overlapping wound margins. The flaps are secured in this position with interrupted sutures (Fig. 38-34d). The sutures are removed after approximately 1 week.

The original distal wedge procedure may be modified according to individual requirements. Some commonly used modifications of the incision

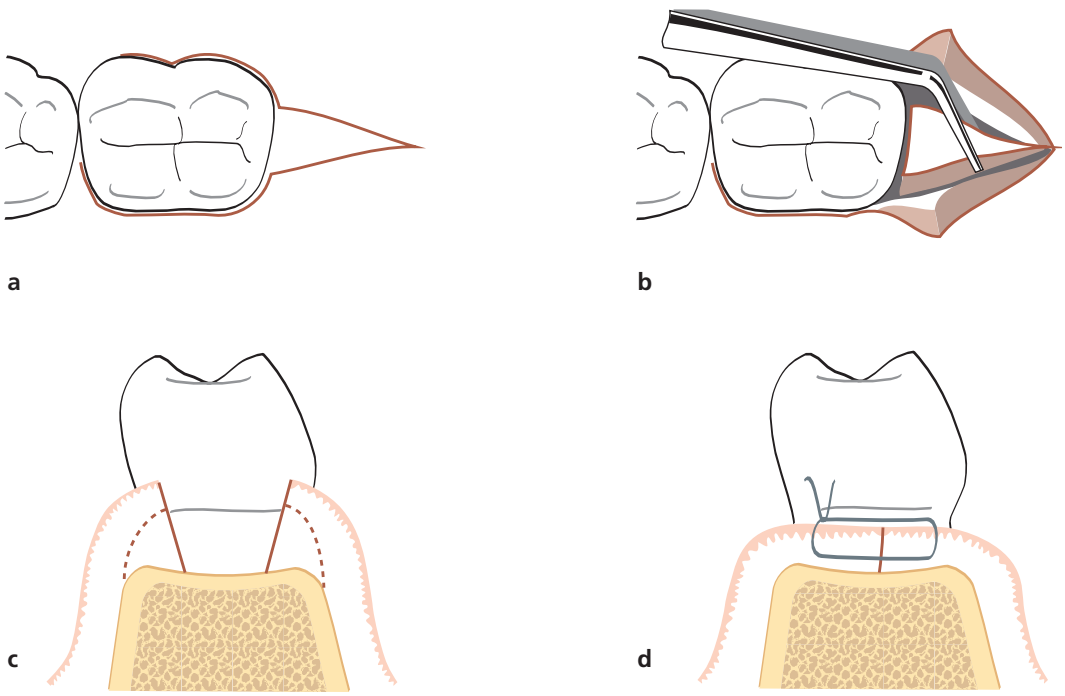

Fig. 38-34 Distal wedge procedure. (a) Buccal and lingual vertical incisions are made through the retromolar pad to form a triangle behind a manibular molar. (b) The triangular-shaped wedge of tissue is dissected from the underlying bone and removed. (c) The walls of the buccal and lingual flaps are reduced in thickness by undermining incisions (broken lines). (d) The flaps, which have been trimmed and shortened to avoid overlapping wound margins, are sutured.

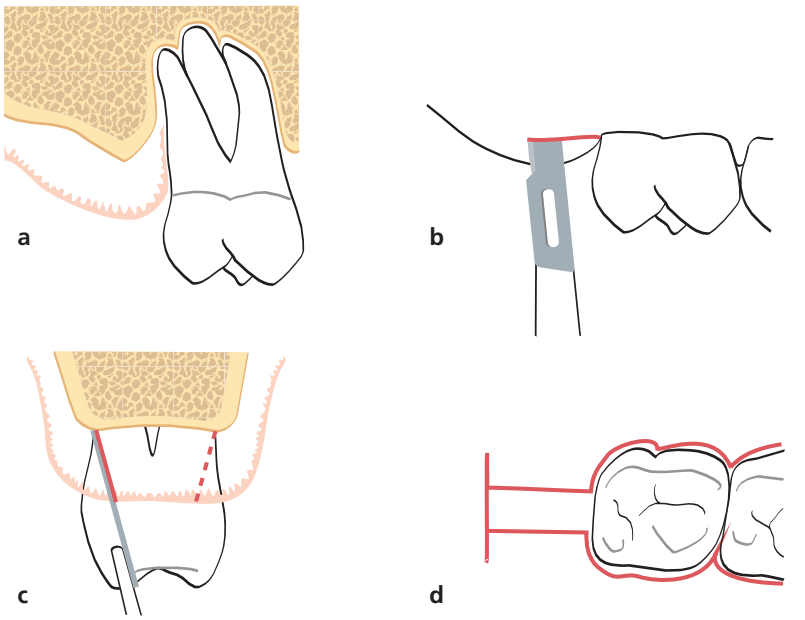

Fig. 38-35 Modified distal wedge procedure. A deep periodontal pocket combined with an angular bone defect at the distal aspect of a maxillary molar (a). Two parallel reverse bevel incisions, one buccal and one palatal, are made from the distal surface of the molar to the posterior part of the tuberosity (b–d), where they are connected with a bucco-lingual incision (d). The buccal and palatal incisions are extended in a mesial direction along the buccal and palatal surfaces of the molar to facilitate flap elevation.

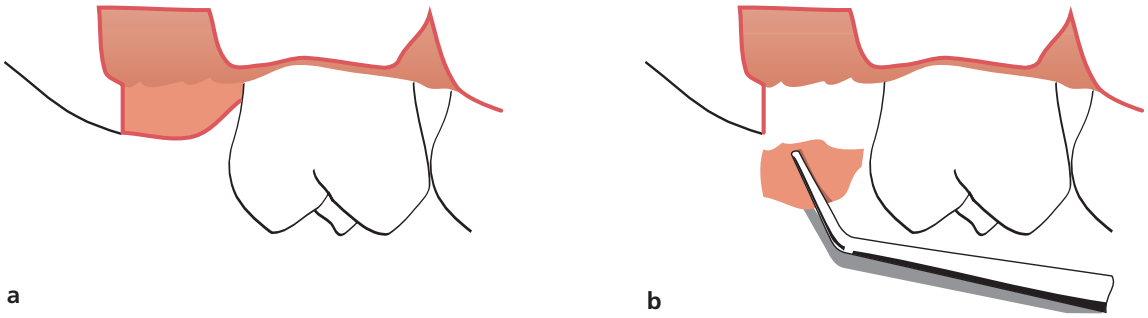

Fig. 38-36 Modified distal wedge procedure. Buccal and palatal flaps are elevated (a) and the rectangular wedge is released from the tooth and underlying bone by sharp dissection and then removed (b).

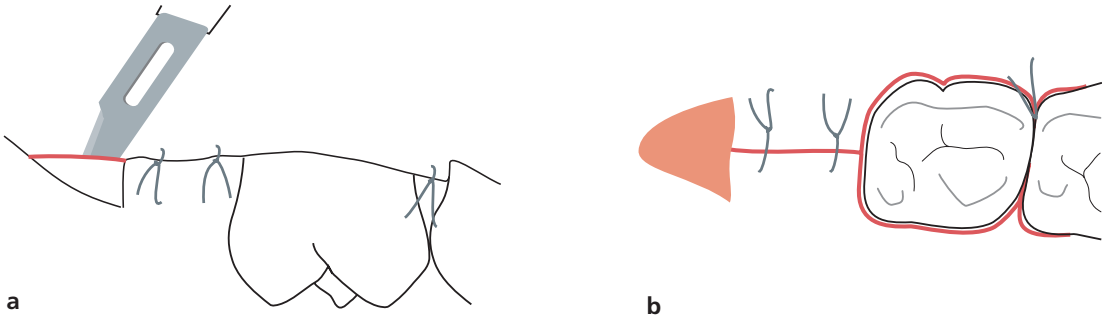

Fig. 38-37 Modified distal wedge procedure. Following bone recontouring and root debridement, the flaps are trimmed and shortened to avoid overlapping wound margins and sutured (a,b). A close soft tissue adaptation should be accomplished to the distal surface of the molar. The remaining fibrous tissue pad distal to the bucco-lingual incision line is "levelled" by the use of a gingivectomy incision.

technique are illustrated in Figs. 38-35 to 38-38, all having the goals of eliminating the deep pocket and achieving mucosal coverage of the remaining periodontium.

Osseous surgery

The principles of osseous surgery in periodontal therapy were outlined by Schluger (1949) and Goldman (1950). They pointed out that alveolar bone loss caused by inflammatory periodontal disease often results in an uneven outline of the bone crest. Since, according to these authors, the gingival contour is closely dependent on the contour of the underlying bone as well as the proximity and anatomy of adjacent tooth surfaces, the elimination of soft tissue pockets often has to be combined with osseous reshaping and the elimination of osseous craters and

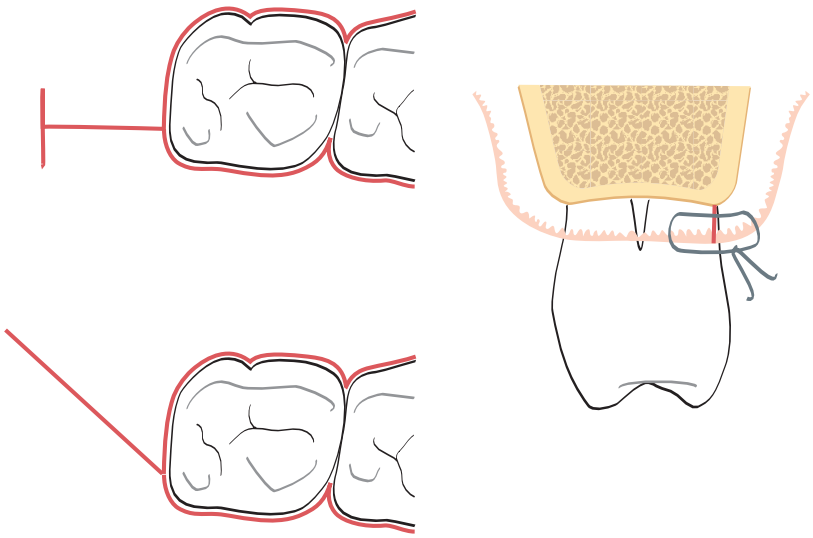

Fig. 38-38 Modified incision techniques in distal wedge procedures. To ensure optimal flap adaptation at the furcation site the incision technique may be modified. The amount of attached keratinized tissue present as well as the accessibility to the retromolar area has to be considered when placing the incision.

angular bony defects to establish and maintain shallow pockets and optimal gingival contour after surgery.

Osteoplasty

The term *osteoplasty* was introduced by Friedman in 1955. The purpose of osteoplasty is to create a physiologic form of the alveolar bone *without* removing any "supporting" bone. Osteoplasty therefore is a technique analogous to gingivoplasty. Examples of osteoplasty are the thinning of thick osseous ledges and the establishment of a scalloped contour of the buccal (lingual and palatal) bone crest (Fig. 38-39). In flap surgery without bone recontouring, interdental morphology may sometimes preclude optimal mucosal coverage of the bone post-surgically, even if pronounced scalloping of soft tissue flaps is performed. In such a situation removal of non-supporting bone by vertical grooving to reduce the facio-lingual dimension of the bone in the interdental areas may facilitate flap adaptation, thereby reducing the risk of bone denudation as well as reducing the risk of ischemic necrosis of unsupported mucosal flaps due to flap margin deficiencies.

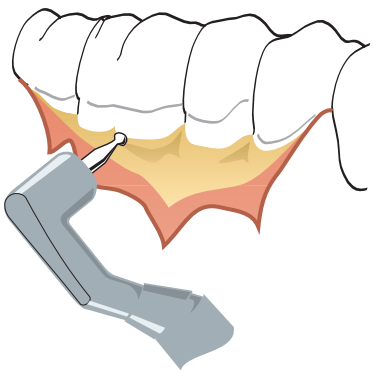

Fig. 38-39 Osteoplasty. Thick osseous ledges in a mandibular molar region area are eliminated with the use of a round bur to facilitate optimal flap adaptation.

Removal of non-supporting bone may sometimes also be required to gain access for intrabony root surface debridement. The leveling of interproximal craters and the elimination (or reduction) of bony walls of circumferential osseous defects are often referred to as "osteoplasty" since usually no resection of supporting bone is required (Fig. 38-40).

Ostectomy

In *ostectomy* supporting bone, i.e. bone directly involved in the attachment of the tooth, is removed to reshape deformities caused by periodontitis in the marginal and interdental bone. Ostectomy is considered to be an important part of surgical techniques aimed at pocket elimination. As a general rule, however, care must be exercised when supporting bone is to be removed.

After exposing the alveolar bone by elevation of a flap, buccal and/or lingual crater walls are reduced to the base of the osseous defect using bone chisels and bone rongeurs (Fig. 38-41). A round bur or a diamond stone under continuous saline irrigation

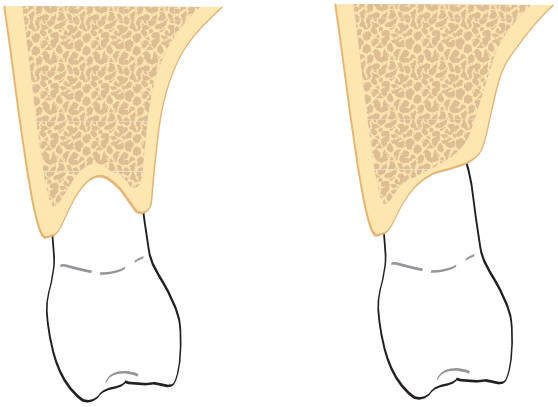

Fig. 38-40 Osteoplasty. Levelling of an interproximal bone crater through the removal of the palatal bone wall. For esthetic reasons the buccal bone wall is maintained to support the height of the soft tissue.

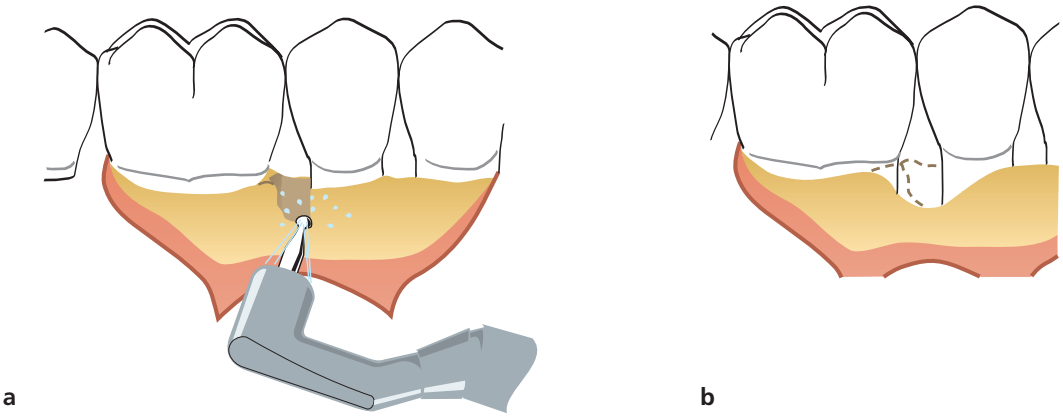

Fig. 38-41 Ostectomy. (a) A combined one- and two-wall osseous defect on the distal aspect of a mandibular bicuspid has been exposed following reflection of mucoperiosteal flaps. Since esthetics is not a critical factor to consider in the posterior tooth region of the mandible, the bone walls are reduced to a level close to the base of the defect using rotating round burs under continuous saline irrigation. (b) The osseous recontouring completed. Note that some supporting bone has to be removed from the buccal and lingual aspect of both the second bicuspid and the first molar in order to provide a hard tissue topography which allows a close adaptation of the covering soft tissue flap.

can also be used. If bone resection has been carried out in the interdental area, the buccal and lingual/palatal bone margins may subsequently have to be recontoured to compensate for discrepancies in bone height resulting from the interdental bone resection (Fig. 38-41b). It is considered important to remove the small peaks of bone, which often remain in the area of the line angles. The objective of bone surgery is thus to establish a "physiologic" anatomy of the alveolar bone, but at a more apical level.

General guidelines for periodontal surgery

Objectives of surgical treatment

Traditionally, *pocket elimination* has been the main objective of periodontal therapy. The removal of the pocket by surgical means served two purposes: (1) the pocket, which established an environment conducive to progression of periodontal disease, was eliminated and (2) the root surface was made accessible for scaling and for self-performed tooth cleaning after healing.

While these objectives cannot be entirely discarded today, the necessity for pocket elimination in periodontal therapy has been challenged. During recent years our understanding of the biology of the periodontium, the pathogenesis of periodontal disease and the healing capacity of the periodontium has markedly increased. This new information has thus formed the basis for a more differentiated understanding of the role played by periodontal surgery in the preservation of teeth.

In the past, *increased pocket depth* was the main indication for periodontal surgery. However, pocket depth is no longer as unequivocal a concept as it used to be. The *probeable depth*, i.e. the distance from the gingival margin to the point where tissue resistance stops further periodontal probe penetration, may only rarely correspond to the "true" depth of the pocket (see Chapter 26). Furthermore, regardless of the accuracy with which pockets can be measured, there is no established correlation between probeable pocket depths and the presence or absence of active disease. This means that symptoms other than increased probing depth should be present to justify surgical therapy. These include clinical signs of inflammation, especially exudation and bleeding on probing (to the bottom of the pockets), as well as aberrations of gingival morphology. Finally, the fact that proper infection control, maintained by the patient, is a decisive factor for a good prognosis (Rosling *et al*. 1976a; Nyman *et al*. 1977; Axelsson & Lindhe 1981) must be considered prior to the initiation of surgery.

In conclusion, the main objective of periodontal surgery is to contribute to the long-term preservation of the periodontium by facilitating plaque removal and infection control, and periodontal surgery can serve this purpose by:

- Creating accessibility for proper professional scaling and root planing
- Establishing a gingival morphology which facilitates the patient's self-performed infection control.

In addition to this, periodontal surgery may aim at regeneration of periodontal attachment lost due to destructive disease. (New attachment procedures in periodontal therapy are discussed in Chapter 43.)

Indications for surgical treatment

Impaired access for scaling and root planing

Scaling and root planing are methods of therapy that are difficult to master. The difficulties in

accomplishing proper debridement increase with (1) increasing depth of the periodontal pockets, (2) increasing width of the tooth surfaces, and (3) the presence of root fissures, root concavities, furcations, and defective margins of dental restorations in the subgingival area.

Provided a correct technique and suitable instruments are used, it is usually possible properly to debride pockets up to 5 mm deep (Waerhaug 1978; Caffesse *et al*. 1986). However, this 5 mm limit cannot be used as a universal rule of thumb. Reduced accessibility and the presence of one or several of the above-mentioned impeding conditions may prevent proper debridement of shallow pockets, whereas at sites with good accessibility and favorable root morphology, proper debridement can be accomplished even in deeper pockets (Badersten *et al*. 1981; Lindhe *et al*. 1982a).

It is often difficult to ascertain by clinical means whether subgingival instrumentation has been properly performed. Following scaling, the root surface should be smooth – roughness will often indicate the presence of remaining subgingival calculus. It is also important to monitor carefully the gingival reaction to subgingival debridement. If inflammation persists and if bleeding is elicited by gentle probing in the subgingival area, the presence of subgingival deposits should be suspected (Fig. 38-42). If such symptoms are not resolved by repeated subgingival instrumentation, surgical treatment should be performed to expose the root surfaces for proper cleaning.

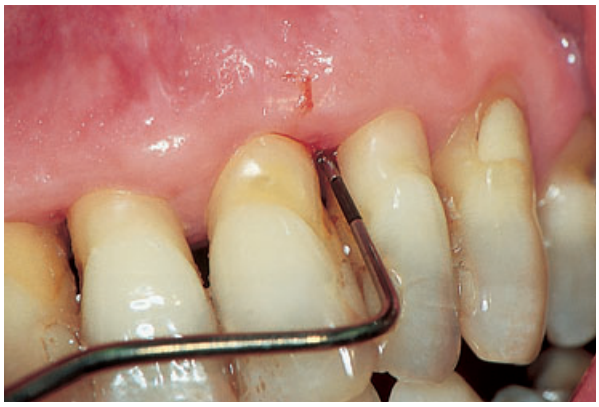

Fig. 38-42 Evaluation following non-surgical instrumentation reveals persistent signs of inflammation, bleeding following pocket probing and probing depth ≥6 mm. Flap elevation to expose the root surface for proper cleaning should be considered.

Impaired access for self-performed plaque control

The level of infection control that can be maintained by the patient is determined not only by his/her interest and dexterity but also, to some extent, by the morphology of the dentogingival area. The patient's responsibility in an infection-control program must obviously include the cleansing of the supragingival tooth surfaces and the marginal part of the gingival sulcus. This means that the tooth area coronal to the gingival margin and at the entrance to the gingival sulcus should be the target for the patient's home care efforts.

Pronounced gingival hyperplasia and gingival craters (Fig. 38-43) are examples of morphologic aberrations, which may impede proper home care. Likewise, the presence of restorations with defective marginal fit or adverse contour and surface characteristics at the gingival margin may seriously compromise plaque removal.

By the professional treatment of periodontal disease, the dentist prepares the dentition in such a way that home care can be effectively managed. At the completion of treatment, the following objectives should have been met:

- No sub- or supragingival dental deposits
- No pathologic pockets (no bleeding on probing to the bottom of the pockets)
- No plaque-retaining aberrations of gingival morphology

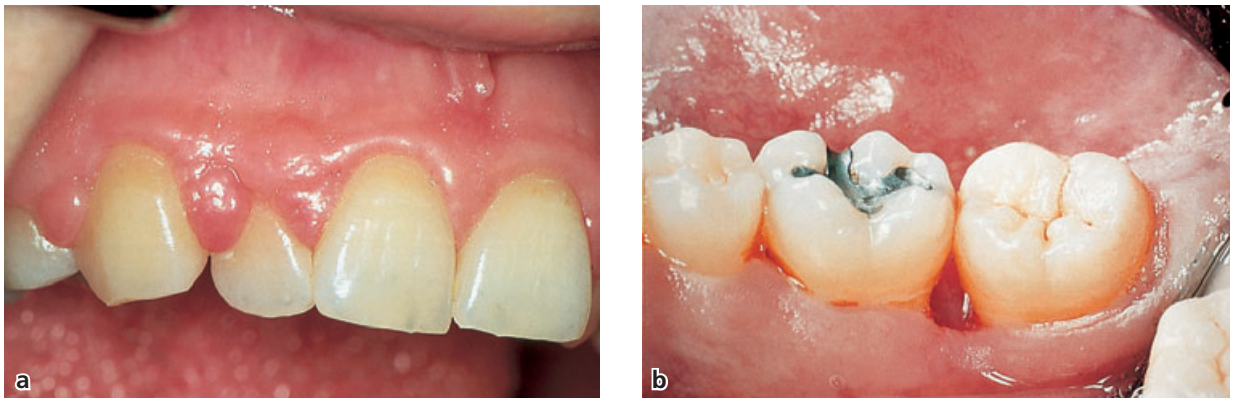

Fig. 38-43 Examples of gingival aberrations, (a) gingival enlargement and (b) proximal soft tissue crater, which favor plaque retention and thereby impede the patient's plaque control.

- No plaque-retaining parts of restorations in relation to the gingival margin.

These requirements lead to the following indications for periodontal surgery:

- Accessibility for proper scaling and root planing
- Establishment of a morphology of the dentogingival area conducive to infection control
- Pocket depth reduction
- Correction of gross gingival aberrations
- Shift of the gingival margin to a position apical to plaque-retaining restorations
- Facilitate proper restorative therapy.

Contraindications for periodontal surgery

Patient cooperation

Since optimal post-operative infection control is decisive for the success of periodontal treatment (Axelsson & Lindhe 1981), a patient who fails to cooperate during the cause-related phase of therapy should not be exposed to surgical treatment. Even though short-term post-operative infection control entails frequent professional treatments, the long-term responsibility for maintaining good oral hygiene must rest with the patient. Theoretically, even the poorest oral hygiene performance by a patient may be compensated for by frequent recall visits for supportive therapy (e.g. once a week), but it is unrealistic to consider larger groups of patients being maintained in this manner. A typical recall schedule for periodontal patients involves professional consultations for supportive periodontal therapy once every 3–6 months. Patients who cannot maintain satisfactory oral hygiene over such a period should normally be considered unsuited for periodontal surgery.

Cardiovascular disease

Arterial hypertension does not normally preclude periodontal surgery. The patient's medical history should be checked for previous untoward reactions to local anesthesia. Local anesthetics free from or low in adrenaline may be used and an aspirating syringe should be adopted to safeguard against intravascular injection.

Angina pectoris does not normally preclude periodontal surgery. The drugs used and the number of episodes of angina may indicate the severity of the disease. Premedication with sedatives and the use of local anesthesia low in adrenaline are often recommended. Safeguards should be adopted against intravascular injection.

Myocardial infarction patients should not be subjected to periodontal surgery within 6 months following hospitalization, and thereafter only in cooperation with the physician responsible for the patient.

Anticoagulant treatment implies increased propensity for bleeding. Periodontal surgery should be scheduled first after consultation with the patient's physician to determine whether modification of the anticoagulant therapy is indicated. In patients on moderate levels of anticoagulation and only requiring minor surgical treatment, no alteration of their anticoagulant therapy may be required. To keep the prothrombin time within a safety level for hemorrhage control during surgery in patients with higher levels of anticoagulation, adjustments of the anticoagulant drug therapy usually needs to be initiated 2–3 days prior to the dental appointment. Anticoagulation may be safely resumed immediately after the periodontal surgical procedure since several days are needed for full anticoagulation to return. Aspirin and other non-steroidal anti-inflammatory drugs should not be used for post-operative pain control since they increase bleeding tendency. Furthermore, tetracyclines are contraindicated in patients on anticoagulant drugs due to interference with prothrombin formation (Fay & O'Neil 1984).

Rheumatic endocarditis, *congenital heart lesions*, and *heart/vascular implants* involve risk for transmission of bacteria to heart tissues and heart implants during the transient bacteremia that follows manipulation of infected periodontal pockets. In patients with these conditions, as well as in patients at risk of hematogenous total prosthetic joint infection (for the first 2 years following joint placement), probing, scaling and root planing (including placement of antimocribial devices and prophylactic cleaning of implants and teeth where bleeding is anticipated), surgery and tooth extraction should be preceded by prescription and administration of an appropriate antibiotic at a high dose (American Dental Association – Position Statement on Antibiotic Prophylaxis 2003) and antiseptic mouth rinsing (0.2% chlorhexidine). According to the recommendations by the American Heart Association (Advisory Statement 1997), 2 grams of amoxicillin administrated orally 1 hour before the treatment is an adequate regimen. If the patient is allergic to penicillin, clindamycin (600 mg) orally 1 hour before the treatment is recommended as alternative. No second doses are recommended for any of the above dosing regimens. Tetracyclines and erythromycin are not recommended for prophylactic cardiovascular antibiotic coverage.

Organ transplantation

In organ transplantation medications are used to prevent transplant rejection. The drug of choice today is cyclosporine A, a potent immunosuppressant drug. The adverse effects seen following cyclosporine A treatment include an increased risk for gingival enlargement as well as hypertension. In addition, hypertension seen in renal transplant recipients is often treated with calcium channel blockers. These

antihypertensive agents have also been associated with gingival enlargement. As in patients on phenytoin therapy, gingival enlargement in patients on cyclosporine A therapy or on antihypertensive therapy with calcium blockers may be corrected by means of periodontal surgery. However, due to the strong propensity for recurrence, the use of intensified conservative periodontal therapy to prevent gingival enlargement in susceptible patients should be encouraged.

Prophylactic antibiotics are recommended in transplant patients taking immunosuppressive drugs, and the patient's physician should be consulted before any periodontal therapy is performed. In addition, antiseptic mouth rinsing (0.2% chlorhexidine) should precede the surgical treatment.

Blood disorders

If the medical history includes blood disorders, the exact nature of these should be ascertained. Patients suffering from *acute leukemias*, *agranulocytosis*, and *lymphogranulomatosis* must *not* be subjected to periodontal surgery. *Anemias* in mild and compensated forms do not preclude surgical treatment. More severe and less compensated forms may entail lowered resistance to infection and increased propensity for bleeding. In such cases, periodontal surgery should only be performed after consultation with the patient's physician.

Hormonal disorders

Diabetes mellitus entails lowered resistance to infection, propensity for delayed wound healing, and predisposition for arteriosclerosis. Well compensated patients may be subjected to periodontal surgery provided precautions are taken not to disturb dietary and insulin routines.

Adrenal function may be impeded in patients receiving large doses of corticosteroids over an extended period. These conditions involve reduced resistance to physical and mental stress, and the doses of corticosteroid may have to be altered during the period of periodontal surgery. The patient's physician should be consulted.

Neurologic disorders

Multiple sclerosis and *Parkinson's disease* may, in severe cases, make ambulatory periodontal surgery impossible. Paresis, impaired muscular function, tremor, and uncontrollable reflexes may necessitate treatment under general anesthesia.

Epilepsy is often treated with *phenytoin* that, in approximately 50% of cases, may mediate the formation of gingival enlargement. These patients may, without special restrictions, be subjected to periodontal surgery for correction of the enlargement. There is, however, a strong propensity for recurrence of the enlargement, which in many cases can be countered by intensifying plaque control.

Smoking

Although smoking negatively affects wound healing (Siana *et al*. 1989), it may not be considered as a contraindication for surgical periodontal treatment. The clinician should be aware, however, that less resolution of probing pocket depth and smaller improvement in clinical attachment may be observed in smokers than in non-smokers (Preber & Bergström 1990; Ah *et al*. 1994; Scabbia *et al*. 2001; Labriola *et al*. 2005).

Local anesthesia in periodontal surgery

Traditional views of pain and discomfort as an inevitable consequence of dental procedures, in particular surgical procedures (including scaling and root planing) and extractions, are no longer accepted by patients. Pain management is an ethical obligation and will improve patient satisfaction in general (e.g. increased confidence and improved cooperation) as well as patient recovery and short-term functioning after oral/periodontal surgical procedures. In order to prevent pain during the performance of a periodontal surgical procedure, the entire area of the dentition scheduled for surgery, the teeth as well as the periodontal tissues, require proper local anesthesia.

Mechanism of action

Local anesthesia is defined as a loss of feeling or sensation that is confined to a certain area of the body. All local anesthetics have a common mechanism of action. To produce their effect they block the generation and propagation of impulses along nerve fibers. Such impulses are transmitted by rapid depolarization and repolarization within the nerve axons. These changes in polarity are due to the passage of sodium and potassium ions across the nerve membrane through ionic channels within the membrane. Local anesthetics prevent the inward movement of sodium ions, which initiate depolarization, and as a consequence the nerve fiber cannot propagate any impulse. The potassium efflux, on the other hand, is influenced very little and there is no change in the resting potential. The mechanisms behind the activity of the local anesthetics are not fully understood, but the most plausible theory is that the lipid-soluble free base form of the local anesthetic, which is the form that penetrates biologic membranes most easily, penetrates the connective tissue to reach the axons and diffuses across the lipid membrane into the axon. Inside the axon the drug interacts with specific receptor sites on or within the sodium channels to exert an inhibitory effect on sodium influx and, consequently, on impulse conduction.

Dental local anesthetics

Anesthetics from the chemical group amino-amides, for example lidocaine, mepivacaine, prilocaine, and articaine, are more potent and significantly less allergenic than amino-esters (e.g. procaine and tetracaine) and have therefore replaced esters as the "gold standard" for dental local anesthetics.

Due to the specific need for bone penetration, dental local anesthetics contain high concentrations of the active agent. Although most amide local anesthetics may cause local vasoconstriction in low concentrations, the clinically used concentrations in dental solutions will cause an increase in the local blood flow. Significant clinical effects of this induced vasodilatation are an increased rate of absorption, thus decreasing the duration of anesthesia. Major benefits can therefore be obtained by adding relatively high concentrations of vasoconstrictors (e.g. epinephrine >1 : 200 000 or >5 mg/ml) to dental local anesthetic solutions; the duration is considerably prolonged, the depth of anesthesia may be enhanced, and the peak concentrations of the local anesthetic in blood can be reduced. Furthermore, in periodontal surgery incorporation of adrenergic vasoconstrictors into the local anesthetic is of considerable value to allow for only minimal bleeding during surgery (to avoid considerable blood loss, to visualize the surgical site, and shorten the time spent on the procedure maintaining surgical quality). As a matter of fact, the use of a dental local anesthetic without a vasoconstrictor during a periodontal surgical procedure is counterproductive because the vasodilating properties of such a local anesthetic will increase bleeding in the area of surgery.

Vasoconstrictors and local hemostasis

Epinephrine is the vasoconstrictor of choice for local hemostasis and is most commonly used in a concentration of 1 : 80 000 (12.5 mg/ml). However, 1 : 100 000 epinephrine also provides excellent hemostasis and most periodontists are unable to detect a clinical difference between the two concentrations. It therefore seems prudent to use the least concentrated form of epinephrine that provides clinically effective hemostasis (i.e. the 1 : 100 000 concentration).

Although the cardiovascular effects of the usually small amounts of epinehrine used during a periodontal surgical procedure are of little practical concern in most individuals, accidental intravascular injections, unusual patient sensitivity and unanticipated drug interactions (or excessive doses), can result in potentially serious outcomes. It must also be understood that the use of epinephrine for hemostasis during periodontal surgery has some potential drawbacks. Epinephrine will produce a rebound vasodilatation after the vasoconstriction has worn off leading to increased risk for bleeding in the immediate postoperative period. There is a greater potential for such undesirable delayed hemorrhage following the use of 1 : 80 000 epinephrine than after the use of 1 : 100 000.

Post-operative pain may increase and wound healing may be delayed when adrenergic vasoconstrictors are used because of local ischemia with subsequent tissue acidosis and accumulation of inflammatory mediators. Furthermore, the possibility of an ischemic necrosis of surgical flaps infiltrated with an adrenergic vasoconstrictor (especially if norepinephrine is used instead of epinephrine) cannot be discounted. For these reasons as well as for the possibility of systemic reactions eluded to above, dental local anesthetics containing adrenergic vasoconstrictors for hemostasis should be infiltrated *only* as needed and *not* merely by habit.

Felypressin, another commonly used vasoconstrictor, appears to act preferentially on the venous side of the microcirculation and is not very active in constricting the arteriolar circulation. Felypressin is therefore not nearly as effective as adrenergic vasoconstrictors in limiting hemorrhage during a surgical procedure.

Individual variability in response to dental local anesthetics

Although it is possible for the periodontist to choose from a broad spectrum of dental local anesthetics to achieve the expected clinical action, there is a number of other factors (i.e. not related to the drug) that can affect the drug action in a single patient. During clinical conditions the variability in response to dental local anesthetics administered can be expected to be great, for example with regard to depth and duration of anesthesia. The reasons for the great variation have not been adequately explained but have to be accepted as the variation may have significant implications in periodontal surgical procedures. A list of possible factors that may cause anesthetic failures include:

- Accuracy in administration of the drug
- Anatomic variation between patients (e.g. in elderly patients with bone resorption)
- Status of the tissues at the site of injection (vascularity, inflammation)
- General condition of patient
- Psychologic factors.

Inaccuracy in administration is a major factor causing anesthetic failures. Although not particularly significant in infiltration anesthesia, the mandibular block is a prime example of a technique in which duration of anesthesia is greatly influenced by accuracy of injection.

The general condition of the patient as well as psychologic factors may also affect the anticipated duration of action. Infection, stress or pain will usually lead to decreased duration of anesthesia,

while an increase in the patient's own defense mechanisms against pain perception by, for example, release of endogenous endorphins, may provide for improved depth and/or duration of anesthesia.

Techniques for anesthesia in periodontal surgery

Injections of dental local anesthetics prior to a periodontal surgical procedure may be routine for the dentist, but is often a most unpleasant experience for the patient. Reassurance and psychologic support are essential and will increase the patient's confidence in his dentist. To create a relaxed atmosphere and to decrease the patient's fear in an unusual situation is of course also a useful way of increasing the patient's own defense mechanisms against pain perception (e.g. release of endogenous endorphins).

Anesthesia for periodontal surgery is obtained by nerve block and/or by local infiltration. In cases of flap surgery, complete anesthesia must be attained before commencing the operation, as it may be difficult to supplement the anesthesia after the bone surface has been exposed. In addition, the pain elicited by needle insertion can be significantly reduced if the mucosa at the puncture site is anesthetized in advance by the use of a suitable topical ointment or spray.

Local infiltration may have a greatly decreased rate of success in areas where inflammation remains in the periodontal tissues, in spite of optimal conservative periodontal therapy and good oral hygiene. The suggested reason being that tissue pH tends to be low in inflamed areas and anesthetic solutions are less potent at low pH because there is a greater proportion of charged cation molecules than of the uncharged base molecules. Because of this, diffusion of the local anesthetic into the axoplasm is slower with subsequent delayed onset and decreased efficacy. Another more recent hypothesis suggests that NGF (nerve growth factor) released during tissue inflammation will induce sprouting or proliferation of sensory nerve endings expressing a different (sub-) type of sodium channel than is expressed in normal tissues. Our presently used dental local anesthetics may not be selective enough for proper interaction with these sodium channel subtypes to induce anticipated anesthesia.

Local anesthesia in the mandible

As a rule, analgesia of the teeth and the soft and hard tissues of the mandible should be obtained by a mandibular block and/or a mental block. In the anterior region of the mandible, canines and incisors can often be anesthetized by infiltration, but there are often anastomoses over the midline. These anastomoses must be anaesthetized by bilateral infiltration, or by bilateral mental blocks. The buccal soft tissues of the mandible are anesthetized by local infiltration or by blocking the buccal nerve. Local infiltration, performed as a series of injections in the buccal fold of the treatment area, has of course the added advantage of providing a local ischemic effect if a suitable anesthetic is used.

The lingual periodontal tissues must also be anesthetized. This is accomplished by blocking the lingual nerve and/or by infiltration in the floor of the mouth close to the site of operation. If necessary to obtain proper ischemia, and only then, supplementary injections may be made in the interdental papillae (intraseptal injections).

Local anesthesia in the maxilla

Local anesthesia of the teeth and buccal periodontal tissues of the maxilla can easily be obtained by injections in the muco-gingival fold of the treatment area. If larger areas of the maxillary dentition are scheduled for surgery, repeated injections (in the muco-gingival fold) have to be performed, e.g. at the central incisor, canine, second premolar, and second molar. In the posterior maxillary region a tuberosity injection can be used to block the superior alveolar branches of the maxillary nerve. However, because of the vicinity to the pterygoid venous plexus, this type of block anesthesia is not recommended due to the risk of intravenous injection and/or hematoma formation.

The palatal nerves are most easily anesthetized by injections made at right angles to the mucosa and placed around 10 mm apical to the gingival margin adjacent to teeth included in the operation. In cases of advanced bone loss, the pain produced by injecting into the non-resilient palatal mucosa can be minimized if the injections are performed from the buccal aspect, i.e. through the interdental gingiva. Sometimes blocks of the nasopalatine nerves and/or the greater palatine nerves can be applied. Supplementary blocking of the greater palatine nerve should be considered, especially for periodontal surgery involving molars.

Instruments used in periodontal surgery

General considerations

Surgical procedures used in periodontal therapy often involve the following measures (instruments):

- Incision and excision (periodontal knives)
- Deflection and re-adaptation of mucosal flaps (periosteal elevators)
- Removal of adherent fibrous and granulomatous tissue (soft tissue rongeurs and tissue scissors)
- Scaling and root planing (scalers and curettes)
- Removal of bone tissue (bone rongeurs, chisels, and files)
- Root sectioning (burs)

Fig. 38-44 Set of instruments used for periodontal surgery and included in a standard tray.

- Suturing (sutures and needle holders, suture scissors)
- Application of wound dressing (plastic instruments).

The set of instruments used for the various periodontal surgical procedures should have a comparatively simple design. As a general rule, the number and varieties of instruments should be kept to a minimum. In addition to particular instruments used for periodontal treatment modalities, equipment and instruments generally used in oral surgery are often needed. Within each category of surgical instruments used for periodontal therapy there are usually several brands available, varying in form and quality, leaving ample room for individual preferences.

The instruments should be stored in sterile "ready-to-use" packs or trays. Handling, storing, and labeling of surgical instruments and equipment must be managed in such a way that interchanging of sterile and non-sterile items is prevented.

It is also important that the instruments are kept in good working condition. The maintenance routine should ensure that scalers, curettes, knives with fixed blades, etc., are sharp and the hinges of scissors, rongeurs, and needle holders are properly lubricated. Spare instruments (sterile) should always be available to replace instruments found to be defective or accidentally contaminated.

The instrument tray

Instrument trays for periodontal surgery may be arranged in several ways. Different trays can be used for different procedures or a standard tray can be used for all procedures supplemented with the particular instruments that are needed for a specific procedure.

A commonly used standard tray combines the basic set of instruments used in oral surgery and a few periodontal instruments. The instruments listed below are often found on such a standard tray (Fig. 38-44):

- Mouth mirrors
- Graduated periodontal probe/explorer
- Handles for disposable surgical blades (e.g. Bard-Parker handle)
- Mucoperiosteal elevator and tissue retractor
- Scalers and curettes
- Cotton pliers
- Tissue pliers (*ad modum* Ewald)
- Tissue scissors
- Needle holder
- Suture scissors
- Plastic instrument
- Hemostat
- Burs.

Additional equipment may include:

- Syringe for local anesthesia
- Syringe for irrigation
- Aspirator tip
- Physiologic saline
- Drapings for the patient
- Surgical gloves, surgical mask, surgeon's hood.

Surgical instruments

Knives

Knives are available with fixed or replaceable blades. The advantage of the fixed blade versions is that the blade can be given any desired shape and orientation in relation to the handle. A disadvantage is that such instruments need frequent resharpening. Figure 38-45 shows examples of knives with fixed blades.

New disposable blades are always sharp. They can be rapidly replaced if found defective. The cutting edge of the blades normally follows the long axis of

Fig. 38-45 Examples of gingivectomy knives with fixed blades. From left to right: Kirkland 15/16, Orban 1/2, and Waerhaug 1/2.

Fig. 38-47 A universal 360° handle for disposable blades, which allows the mounting of the blade in any angulated position of choice.

Fig. 38-46 Disposable blades which can be mounted in various types of handles. The shape of the blades are from left to right: No. 11, No. 12, No. 12D, No. 15, and No. 15C.

Fig. 38-48 Examples of double-ended sickle scalers and curettes useful for root debridement in conjunction with periodontal surgery. From left to right: Curette SG 215/16C Syntette, Sickle 215-216 Syntette, and mini-curette SG 215/16MC.

the handle, which limits their use. However, knives with disposable blades fitted at an angle to the handle are also available. Disposable blades are manufactured in different shapes (Fig. 38-46). When mounted in ordinary handles (Bard-Parker®), they are used for releasing incisions in flap operations and mucogingival surgery and for reverse bevel incisions where access is obtainable. Special handles (Fig. 38-47) make it possible to mount blades in angulated positions, which facilitate the use of such knives for both gingivectomy excisions and reverse bevel incisions.

Scalers and curettes

Scaling and root planing in conjunction with periodontal surgery take place on exposed root surfaces. Access to the root surfaces for debridement may therefore be obtained with the use of comparatively sturdy instruments (Fig. 38-48). Tungsten carbide curettes and scalers with durable cutting edges are often used when "access" is not a problem. Rotating fine-grained diamond stones (Fig. 38-49) may be used

Fig. 38-49 A set of burs useful in periodontal surgery. The rotating fine-grained diamond stones may be used for debridement of infrabony defects. The round burs are used for bone recontouring.

Fig. 38-50 Examples of instruments used for bone recontouring. From left to right: Bone chisels Ochsenbein no. 1 and 2 (Kirkland 13K/13KL), Bone chisel Ochsenbein no. 3, and Schluger curved file no. 9/10.

within infrabony pockets, root concavities, and entrances to furcations.

Instruments for bone removal

Sharp bone chisels or bone rongeurs (Fig. 38-50) cause the least tissue damage and should be employed whenever access permits. With reduced access, surgical burs or files may be used. The burs should operate at low speed and ample rinsing with sterile physiologic saline should ensure cooling and removal of tissue remnants.

Instruments for handling flaps

The proper healing of the periodontal wound is critical for the success of the operation. It is therefore important that the manipulations of soft tissue flaps are performed with the minimum of tissue damage. Care should be exercised in the use of periosteal elevators when flaps are deflected and retracted for optimal visibility. Surgical pliers and tissue retractors that pierce the tissues should not be used in the marginal area of the flaps. Needle holders with small beaks and atraumatic sutures should be used.

Additional equipment

Hemorrhage is rarely a problem in periodontal surgery. The characteristic oozing type of bleeding can normally be controlled by a pressure pack (sterile gauze moistened with saline). Bleeding from small vessels can be stopped by clamping and tying using a hemostat and resorbable sutures. If the vessel is surrounded by bone, bleeding may be stopped by crushing the nutrient canal in which the vessel runs with a blunt instrument.

Sterile physiologic saline is used for rinsing and moistening the field of operation and for cooling when burs are employed. The saline solution may be kept in a sterile metal cup on the instrument tray and may be applied to the wound by means of a sterile disposable plastic syringe and a needle with a blunt tip.

Visibility in the field of operation is secured by using effective suction. The lumen of the aspirator tip should have a smaller diameter than the rest of the tube, in order to prevent clogging.

The patient's head may be covered by autoclaved cotton drapings or sterile disposable plastic/paper drapings. The surgeon and all assistants should wear sterile surgical gloves, surgical mask, and surgeon's hood.

Selection of surgical technique

Many of the technical problems experienced in periodontal surgery stem from the difficulties in accurately assessing the degree and type of breakdown that has occurred prior to surgery. Furthermore, at the time of surgery, previously undiagnosed defects may be recognized or some defects may have a more complex outline than initially anticipated. Since each of the surgical procedures described above is designed to deal with a specific situation or to meet a certain objective, it must be understood that in most patients no single standardized technique alone can be applied when periodontal surgery is undertaken. Therefore, in each surgical field, different techniques are often used and combined in such a way that the overall objectives of the surgical part of the periodontal therapy are met. As a general rule, surgical modalities of therapy that preserve or induce the formation of periodontal tissue should be preferred over those that resect or eliminate tissue.

General indications for various surgical techniques

Gingivectomy

The obvious indication for gingivectomy is the presence of deep supra-alveolar pockets. In addition, the gingivectomy technique can be used to reshape abnormal gingival contours such as gingival craters and gingival hyperplasias (Fig. 38-43). In such cases the technique is often termed *gingivoplasty*.

Gingivectomy is usually not considered suitable in situations where the incision will lead to the removal of the entire zone of gingiva. This is the case when the bottom of the probeable pocket to be excised is located at or below the mucogingival junction. As an alternative in such a situation, an *internal beveled gingivectomy* may be performed (Fig. 38-51). Furthermore, since the gingivectomy procedure is aimed at the complete elimination of the periodontal pocket, the procedure cannot be used in periodontal sites where infrabony lesions or bony craters are present.

These limitations, combined with the development in recent years of surgical methods which have a broader field of application, have led to less frequent use of gingivectomy in the treatment of periodontal disease.

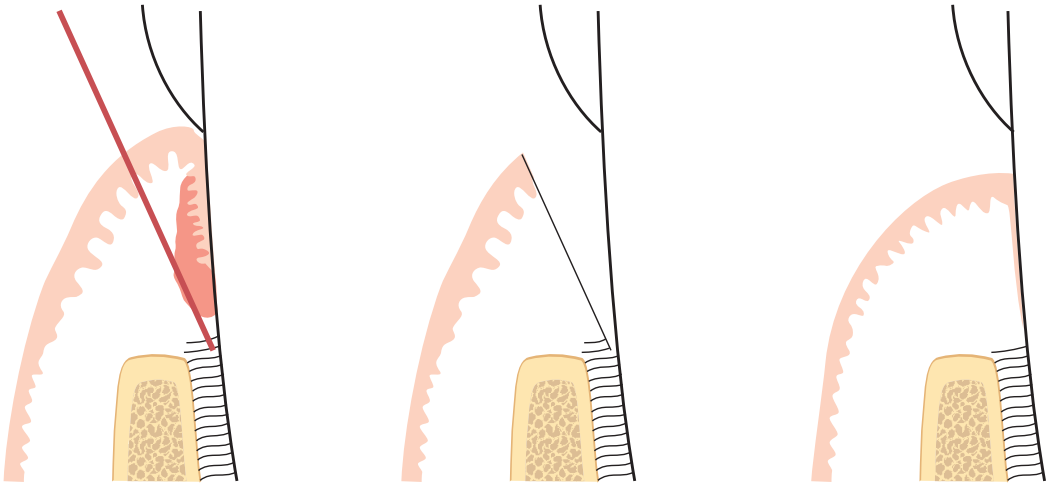

Fig. 38-51 Internal beveled gingivectomy. Schematic illustration of the incision technique in case of the presence of only a minimal zone of gingiva.

Flap operation with or without osseous surgery

Flap operations can be used in all cases where surgical treatment of periodontal disease is indicated. Flap procedures are particularly useful at sites where pockets extend beyond the muco-gingival border and/or where treatment of bony lesions and furcation involvements is required.

The advantages of flap operations include:

- Existing gingiva is preserved
- The marginal alveolar bone is exposed whereby the morphology of bony defects can be identified and the proper treatment rendered
- Furcation areas are exposed, the degree of involvement and the "tooth–bone" relationship can be identified
- The flap can be repositioned at its original level or shifted apically, thereby making it possible to adjust the gingival margin to the local conditions
- The flap procedure preserves the oral epithelium and often makes the use of surgical dressing superfluous
- The post-operative period is usually less unpleasant to the patient when compared to gingivectomy.

Treatment decisions for soft and hard tissue pockets in flap surgery

Classifications of different flap modalities used in the treatment of periodontal disease often make distinctions between methods involving the marginal tissues and those involving the muco-gingival area and, further, between tissue-eliminating/resective varieties and tissue-preserving/reconstructive types (access flaps for debridement). Such classifications appear less than precise since several techniques are often combined in the treatment of individual cases, and since there is no clear-cut relationship between disease characteristics and selection of surgical methods. From a didactic point of view it seems more appropriate to discuss surgical therapy with regard to how to deal with (1) the soft tissue component and (2) the hard tissue component of the periodontal pocket at a specific tooth site (Fig. 38-52).

Soft tissue pockets

The description of the various flap procedures reveals that, depending on the surgical technique used, the soft tissue flap should either be apically positioned at the level of the bone crest (original Widman flap, Neumann flap, and apically repositioned flap) or maintained in a coronal position (Kirkland flap, modified Widman flap, and papilla preservation flap) at the completion of the surgical intervention. The maintenance of the pre-surgical soft tissue height is of importance from an esthetic point of view, particularly in the anterior tooth region. However, long-term results from clinical trials have shown that major differences in the final position of the soft tissue margin are not evident between surgical procedures involving coronal and apical positioning of the flap margin. The reported difference in final positioning of the gingival margin between surgical techniques is attributed to osseous recontouring (Townsend-Olsen *et al*. 1985; Lindhe *et al*. 1987; Kaldahl *et al*. 1996; Becker *et al*. 2001). In many patients it may be of significance to position the flap coronally in the anterior tooth region in order to give the patient a prolonged time of adaptation to the inevitable soft tissue recession. In the posterior tooth region, however, an apical position should be the standard.

Independent of flap position, the goal should be to achieve complete soft tissue coverage of the alveolar bone, not only at buccal/lingual sites but also in proximal sites. It is therefore of utmost importance to carefully plan the incisions in such a way that this goal can be achieved at the termination of the surgical intervention.

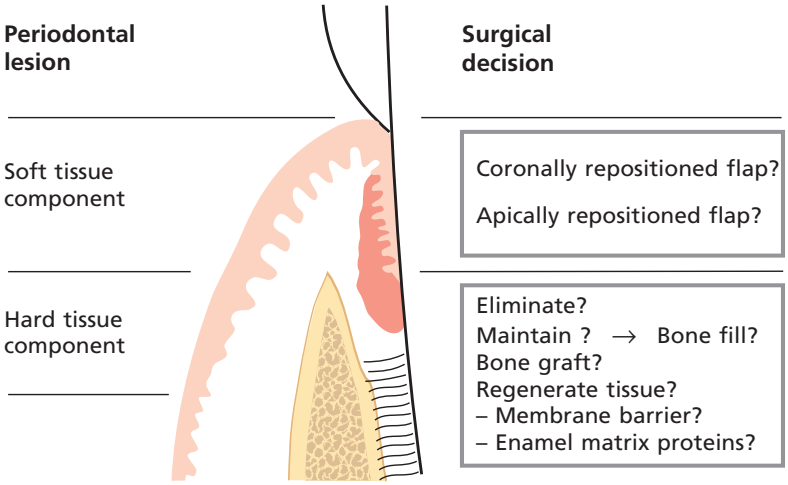

Fig. 38-52 Surgical decisions. Treatment decisions with respect to the soft and the hard tissue component of a periodontal pocket.

Hard tissue pockets

During conventional periodontal surgery one would usually opt for the conversion of an intrabony defect into a suprabony defect, which then is eliminated by apical repositioning of the soft tissues. Osseous recontouring of angular bony defects and craters are excisional techniques, which should be used with caution and discrimination. However, the therapist is often faced with the dilemma of deciding whether or not to eliminate an angular bony defect. There are a number of factors that should be considered in the treatment decision, such as:

- Esthetics
- Tooth/tooth site involved
- Defect morphology
- Amount of remaining periodontium.

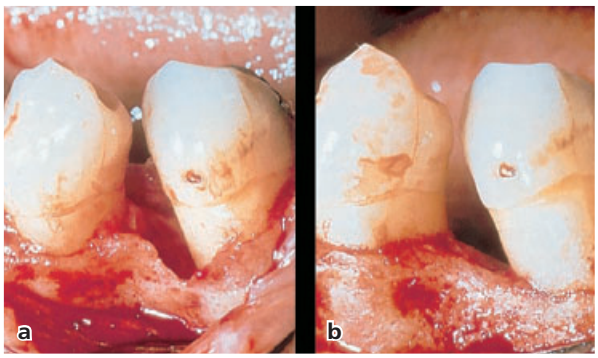

Fig. 38-53 Illustration of the amount of crestal bone resorption that may take place following a modified Widman flap procedure without bone recontouring. (a) View of the area at time of initial surgical treatment. (b) At the re-entry operation performed after 6 months of healing.

Since alveolar bone supports the soft tissue, an altered bone level through recontouring will result in recession of the soft tissue margin. For esthetic reasons one may therefore be restrictive in eliminating proximal bony defects in the anterior tooth region. For example, in the case of an approximal crater it may often be sufficient to reduce/eliminate the bone wall on the lingual side of the crater, thereby maintaining the bone support for the soft tissue on the facial aspect (Fig. 38-40). In favor of esthetics one may even have to compromise the amount of bone removal and accept that some pocket depth will remain in certain situations. In addition to esthetics, the presence of furcations may limit the extent to which bone recontouring can be performed.

Defect morphology is a variable of significance for repair/regeneration during healing (Rosling *et al*. 1976a; Cortellini *et al*. 1993, 1995a). While two- and, especially, three-wall defects may show great potential for repair/regeneration, one-wall defects and approximal craters will rarely result in such good healing. Further, the removal of intrabony connective tissue/granulation tissue during a surgical procedure will always lead to crestal resorption of bone, especially in sites with thin bony walls. This results in reduction of the vertical dimensions of the bone tissue at the site (Fig. 38-53). Thus, the potential for bone fill following a compromise in regard to osseous surgery is greater in areas with thick, non-supporting bone.

The various treatment options available for the hard tissue defect may include:

- Elimination of the osseous defect by resection of bone (osteoplasty and/or ostectomy)
- Maintenance of the area without osseous resection (hoping for some type of periodontal repair, e.g. bone fill leading to gain of clinical attachment)
- Compromising the amount of bone removal and accepting that a certain pocket depth will remain
- An attempt to improve healing through the use of a regenerative procedure
- Extract the involved tooth if the bony defect is considered too advanced.

After careful consideration, indications for osseous surgery in conjunction with apical repositioning of flaps may also include subgingival caries,

perforations or root fractures in the coronal third of the root as well as inadequate retention for fixed prosthetic restorations due to a short clinical crown (crown-lengthening procedures). The "crown lengthening" needed in such cases is performed by removing often significant amounts of supporting bone and by recontouring. A "biologic width" of approximately 3 mm between the alveolar bone crest to be established and the anticipated restoration margin must be ensured for successful results (Brägger *et al*. 1992; Herrero *et al*. 1995; Pontoriero & Carnevale 2001).

Root surface instrumentation

Before incisions are made to excise or elevate the soft tissue, a careful examination should be carried out to identify at which tooth sites periodontal lesions remain. Only tooth sites with signs of pathology (bleeding following pocket probing) should be subjected to root instrumentation following surgical exposure. Further, at these sites root surface instrumentation should be limited to that part of the root that will be covered by the soft tissue following flap replacement and suturing. This is an important consideration since instrumentation of the supragingival portion of the root may lead to post-surgical root hypersensitivity, which in turn may impede proper oral hygiene measures. Before root instrumentation is executed, therefore, remaining granulation tissue must be removed, bone recontouring is carried out, if indicated, and the post-surgical soft tissue level is determined. If the intention is to reposition the flap apically at the level of the bone crest, only approximately 3 mm of the root surface coronal to the bone crest has to be carefully scaled and root planed, whereas if the flap is to be positioned coronally the entire exposed root has to be instrumented.

The root instrumentation can be performed with hand or ultrasonic instruments according to the operator's preferences. Ultrasonic (sonic) instrumentation offers the additional benefits of improved visibility due to the irrigating effect of the cooling water. For root instrumentation within intrabony defects, root concavities, and entrances to furcations, the use of rotating fine-grained diamond stones may be used.

Root surface conditioning/biomodification

An important consideration in periodontal surgery is to make the exposed root surface biologically compatible with a healthy periodontium. This so-called conditioning includes removing bacteria, endotoxins, and other antigens found within the cementum–dentin of a pathologically exposed root. In addition to scaling and root planing, agents such as citric acid/orthophosphoric acid, tetracycline, and EDTA are used for root surface conditioning. Root surface conditioning/biomodification by means of an etching procedure may serve several purposes:

- Removal of the smear layer following mechanical debridement
- Demineralization of the root surface (citric acid)
- Selective removal of hydroxyapatite and exposure of the collagenous matrix of the root surface (EDTA)
- Local delivery of antimicrobial compound (tetracycline HCL)
- Inhibition of collagenolytic activity (tetracycline HCL)
- Enhancing cellular responses
- Preventing of epithelial down-growth
- Improving retention of different biomolecules to exposed collagen
- To express a cementoblast phenotype for colonizing cells.

It should be noted that etching of a root surface with an agent operating at a low pH, e.g. citric acid or orthophosphoric acid, might exert immediate necrotizing effects on the surrounding periodontal ligament and other periodontal tissues, whereas agents operating at a neutral pH (e.g. EDTA) do not seem to have this negative effect (Blomlöf & Lindskog 1995a,b).

Although *in vitro* results have indicated possible benefits of the use of root surface conditioning/biomodification agents through enhanced cellular responses during wound healing, the usefulness of acids as well as other chemical agents for conditioning of root surfaces in conjunction with conventional periodontal surgery has been questioned (Blomlöf *et al*. 2000). Histologic evidence indicates that healing following root surface conditioning with acids or other chemical agents is generally dominated by a long junctional epithelium or connective tissue attachment without evidence of new cementum formation. However, root surface biomodification must still be regarded as an important method to facilitate regeneration. Thus, in this treatment the root represents one of the wound margins and must provide an appropriate surface for cell attachment, colonization, and proliferation.

Suturing

When a flap procedure has been employed it is important to ensure that, at the end of surgery, the flaps are placed in the intended position and that the flaps are properly adapted to each other and to the tooth surfaces. Preferably, full coverage of the buccal/lingual (palatal) and interdental alveolar bone should be obtained by full (primary) closure of the soft tissue flaps. If this can be achieved, healing by first intention results and post-operative bone resorption is minimal. Therefore, prior to suturing, the flap margins should be trimmed to properly fit the buccal and lingual (palatal) bone margin as well as the interproximal areas; excessive soft tissue must be removed. If the amount of flap tissue present is insufficient to

cover the interproximal bone, the flaps at the buccal or lingual aspects of the teeth must be recontoured and, in some cases, even displaced coronally.

Following proper trimming, the flaps are secured in the correct position by sutures. Sutures should not interfere with incision lines and must not pass through the tissues near the flap margins or too close to a papilla, because this may result in tearing of the tissues. The use of non-irritating, mono-filamentous materials is recommended. These materials are non-resorbable and extremely inert, do not adhere to tissues, and are therefore easy to pull out. "Wicking", the phenomenon of bacteria moving along or within multi-stranded suture materials, particularly silk, is also avoided. The dimensions usually preferred are 4/0 to 5/0, but even finer suture material (6/0 or 7/0) may be used, particularly in conjunction with periodontal micro- and plastic surgical procedures. Sutures are removed after 7–14 days.

Since the flap tissue following the final preparation is thin, either curved or straight non-traumatic needles (eyeless), with a small diameter, should be used. Such needles are available as rounded (non-cutting) or with different cutting edges. In the latter case, a reverse-cutting needle should be selected.

Suturing technique

The three most frequently used sutures in periodontal flap surgery are:

- Interrupted interdental sutures
- Suspensory sutures
- Continuous sutures.

The *interrupted interdental suture* (Fig. 38-54) provides a close interdental adaptation between the buccal and lingual flaps with equal tension on both units. This type of suture is therefore not recommended when the buccal and lingual flaps are repositioned at different levels. When this technique of suturing is employed, the needle is passed through the buccal flap from the external surface, across the interdental area and through the lingual flap from the internal surface, or vice versa. When closing the suture, care must be taken to avoid tearing the flap tissues.

In order to avoid having the suture material between the mucosa and the alveolar bone in the interdental area, an alternative technique in the use of the interrupted interdental suture can be used if the flaps have not been elevated beyond the mucogingival line (Fig. 38-55). With the use of a curved needle the suture is anchored in the attached tissue on the buccal aspect of the proximal site, the suture brought to the lingual side through the proximal sites, and anchored in the attached tissue on the lingual side. The suture is then brought back to the starting point and tied (Fig. 38-55b). Hence, the suture will be lying on the surface of the interdental tissue,

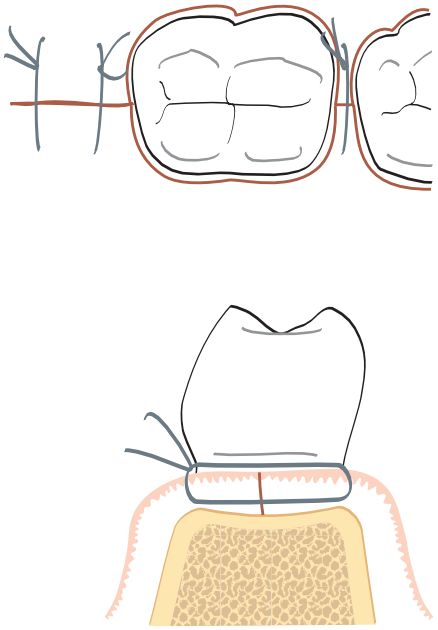

Fig. 38-54 Suturing. Interrupted interdental suture.

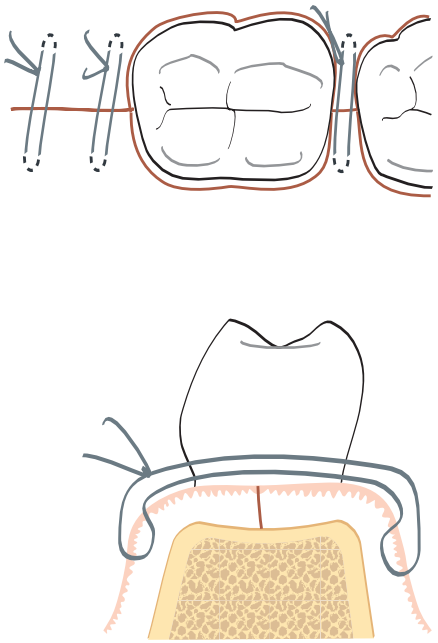

Fig. 38-55 Suturing. Modified interrupted interdental suture. Note that with this suturing technique the suture is laying on the surface of the interdental tissue keeping the soft tissue flaps in close contact with the underlying bone.

keeping the soft tissue flaps in close contact with the underlying bone.

In regenerative procedures, which usually require a coronal advancement of the flap, a *modified mattress suture* may be used to secure close flap adaptation (Fig. 38-56). The needle is passed through the buccal flap from the external surface, across the interdental area and through the lingual flap from the internal surface. The suture is run back to the buccal side by passing the needle through the lingual and buccal flaps. Thereafter, the suture is brought through the approximal site coronally to the tissue, passed

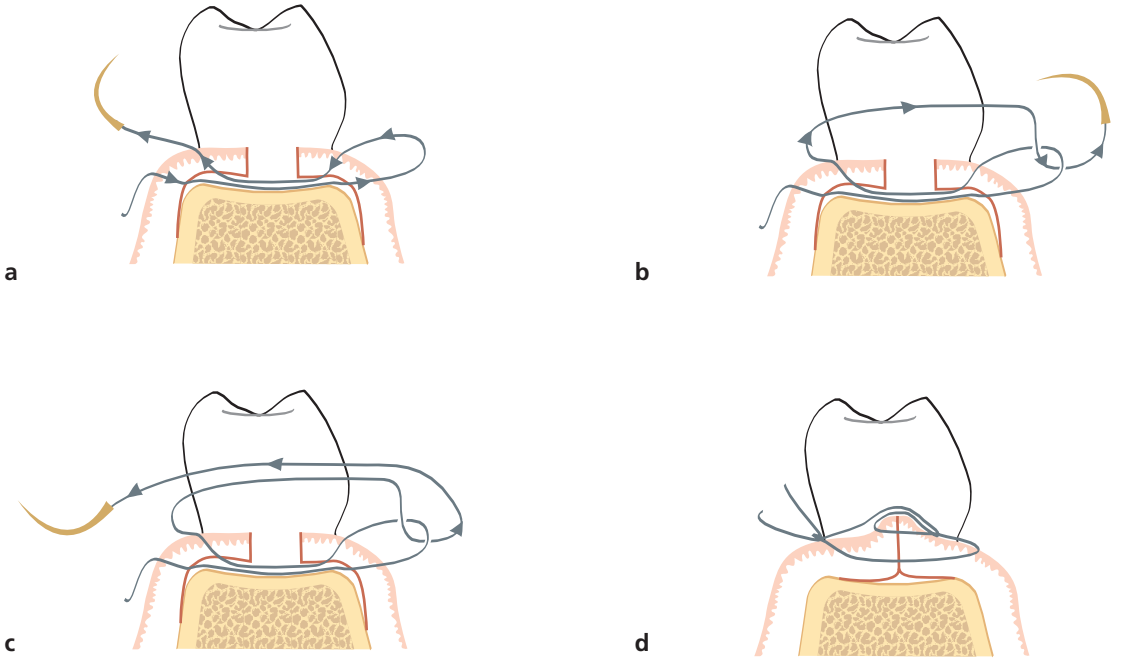

Fig. 38-56 Suturing. Modified mattress suture.

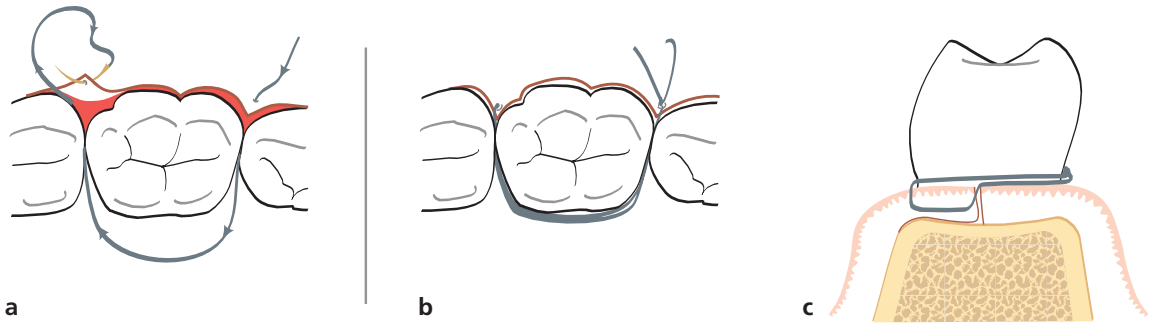

Fig. 38-57 Suturing. Suspensory suture.

through the loop of the suture on the lingual aspect, and then brought back to the starting point on the buccal side and tied.

The *suspensory suture* (Fig. 38-57) is used primarily when the surgical procedure is of limited extent and involves only the tissue of the buccal or lingual aspect of the teeth. It is also the suture of choice when the buccal and lingual flaps are repositioned at different levels. The needle is passed through the buccal flap from its external surface at the mesial side of the tooth, the suture is placed around the lingual surface of the tooth and the needle is passed through the buccal flap on the distal side of the tooth (Fig. 38-57a). The suture is brought back to the starting point via the lingual surface of the tooth and tied (Figs. 38-57b,c). If a lingual flap has been elevated as well, this is secured in the intended position using the same technique.

The *continuous suture* (Fig. 38-58) is commonly used when flaps involving several teeth are to be repositioned apically. When flaps have been elevated on both sides of the teeth, one flap at a time is secured

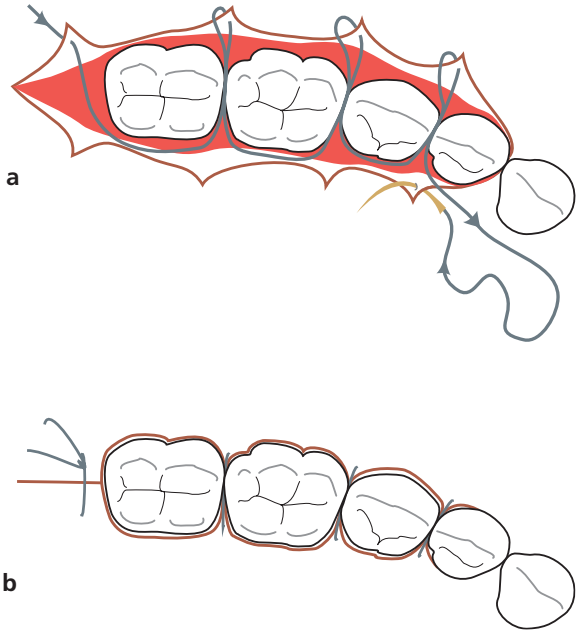

Fig. 38-58 Suturing. Continuous suture.

in its correct position. The suturing procedure is started at the mesial/distal aspect of the buccal flap by passing the needle through the flap and across the interdental area. The suture is laid around the lingual surface of the tooth and returned to the buccal side through the next interdental space. The procedure is repeated tooth by tooth until the distal/mesial end of the flap is reached. Thereafter, the needle is passed through the lingual flap (Fig. 38-58a), with the suture laid around the buccal aspect of each tooth and through each interproximal space. When the suturing of the lingual flap is completed and the needle has been brought back to the first interdental area, the positions of the flaps are adjusted and secured in their proper positions by closing the suture (Fig. 38-58b). Thus, only one knot is needed.

Periodontal dressings

Periodontal dressings are mainly used:

- To protect the wound post-surgically
- To obtain and maintain a close adaptation of the mucosal flaps to the underlying bone (especially when a flap has been repositioned apically)
- For the comfort of the patient.

In addition, periodontal dressings can prevent post-operative bleeding during the initial phase of healing and, if properly placed in the operated segment (especially interproximally), prevent the formation of excessive granulation tissue.

Periodontal dressings should have the following properties:

- The dressing should be soft, but still have enough plasticity and flexibility to facilitate its placement in the operated area and to allow proper adaptation.
- The dressing should harden within a reasonable time.
- After setting, the dressing should be sufficiently rigid to prevent fracture and dislocation.
- The dressing should have a smooth surface after setting to prevent irritation to the cheeks and lips.
- The dressing should preferably have bacteriocidal properties to prevent excessive plaque formation.
- The dressing must not detrimentally interfere with healing.

It has been suggested that antibacterial agents should be incorporated in periodontal dressings to prevent bacterial growth in the wound area during healing. Results from clinical studies and *in vitro* evaluation of the antibacterial properties of various periodontal dressings, however, suggest that the antibacterial activity of most commercial dressings probably is exhausted long before the end of the 7–14-day period during which the dressing is frequently maintained in the operated segment (O'Neil 1975; Haugen *et al*. 1977).

Mouth rinsing with antibacterial agents such as chlorhexidine does not prevent the formation of plaque *under* the dressing (Plüss *et al*. 1975) and should therefore not be regarded as a means to improve or shorten the period of wound healing. On the other hand, results from clinical studies as well as clinical experience suggest that a periodontal dressing may often be unnecessary or even undesirable after periodontal flap procedures and may be usefully replaced by rinsing with chlorhexidine only (Sanz *et al*. 1989; Vaughan & Garnick 1989).

A commonly used periodontal dressing is Coe-Pak™ (Coe Laboratories Inc., Chicago, IL, USA), which is supplied in two tubes. One tube contains oxides of various metals (mainly zinc oxide) and lorothidol (a fungicide). The second tube contains non-ionizing carboxylic acids and chlorothymol (a bacteriostatic agent). Equal parts from both tubes are mixed together immediately prior to insertion. Adding a retarder can prolong the setting time of the dressing.

A light-cured dressing, e.g. Barricaid™ (Dentsply International Inc., Milford, DE, USA), is useful in the anterior tooth region and particularly following muco-gingival surgery, because it has a favorable esthetic appearance and it can be applied without dislocating the soft tissue. However, the light-cured dressing is not the choice of dressing for situations where the flap has to be retained apically, due to its soft state before curing.

Cyanoacrylates have also been used as periodontal dressings with varying success. Dressings of the cyanoacrylate type are applied in a liquid directly on to the wound, or sprayed over the wound surface. Although the application of this kind of dressing is simple, its properties often do not meet clinical demands, which is why its use is rather limited at present.

Application technique

- Ensure that bleeding from the operated tissues has ceased before the dressing material is inserted.
- Carefully dry teeth and soft tissue before the application for optimal adherence of the dressing.
- Moisten the surgical gloves to avoid the material sticking to the fingertips.
- When using the Coe-Pak™ dressing material, the interproximal areas are filled first. Thin rolls of the dressing, adjusted in length to cover the entire field of operation, are then placed against the buccal and lingual surfaces of the teeth. The rolls are pressed against the tooth surfaces and the dressing material is forced into the interproximal areas. Coe-Pak™ may also be applied to the wound surfaces by means of a plastic syringe. It is important to ensure that dressing material is never introduced between the flap and the underlying bone or root surface.

- The surface of the dressing is subsequently smoothened and excess material is removed with a suitable instrument. The dressing should not cover more than the apical third of the tooth surfaces. Furthermore, interference of the dressing with muco-gingival structures (e.g. vestibular fold, frenula) should be carefully checked to avoid displacement of the dressing during normal function.

The light-cured dressing (Barricaid™) is preferably applied with the supplied syringe, adjusted and then cured by light. It is important to dry teeth and soft tissue carefully before application for optimal adherence. Excess of dressing material can easily be removed following curing with a knife or finishing burs in a low-speed handpiece.

Post-operative pain control

In order to minimize post-operative pain and discomfort for the patient, surgical handling of the tissues should be as atraumatic as possible. Care should be taken during surgery to avoid unnecessary tearing of the flaps, to keep the bone moistened, and to secure complete soft tissue coverage of the alveolar bone at suturing. With a carefully performed surgical procedure most patients will normally experience only minimal post-operative problems. The pain experience is usually limited to the first days following surgery and of a level that in most patients can be adequately controlled with normally used drugs for pain control. However, it is important to recognize that pain threshold level is subjective and may vary between individuals. It is also important to give the patient information about the post-surgical sequence and that uncomplicated healing is the common event. Further, during the early phase of healing, the patient should be instructed to avoid chewing in the area subjected to surgical treatment.

Post-surgical care

Post-operative plaque control is the most important variable in determining the long-term result of periodontal surgery. Provided proper post-operative infection control levels are established, most surgical treatment techniques will result in conditions that favor the maintenance of a healthy periodontium. Although there are other factors of a more general nature affecting surgical outcome (e.g. the systemic status of the patient at time of surgery and during healing), disease recurrence is an inevitable complication, regardless of surgical technique used, in patients not given proper post-surgical and maintenance care.

Since self-performed oral hygiene is often associated with pain and discomfort during the immediate post-surgical phase, regularly performed professional tooth cleaning is a more effective means of mechanical infection control following periodontal surgery. In the immediate post-surgical period self-performed rinsing with a suitable antiplaque agent, e.g. twice daily rinsing with 0.1–0.2% chlorhexidine solution, is recommended. Although an obvious disadvantage with the use of chlorhexidine is the staining of teeth and tongue, this is usually not a deterrent for compliance. Nevertheless, it is important to return to and maintain good mechanical oral hygiene measures as soon as possible. This is especially important since rinsing with chlorhexidine, in contrast to properly performed mechanical oral hygiene, is not likely to have any influence on subgingival recolonization of plaque.

Maintaining good post-surgical wound stability is another important factor affecting the outcome of some types of periodontal flap surgery. If wound stability is judged an important part of a specific procedure, the procedure itself as well as the post-surgical care must include measures to stabilize the healing wound (e.g. adequate suturing technique, protection from mechanical trauma to the marginal tissues during the initial healing phase). If a muco-periosteal flap is replaced rather than repositioned apically, early apical migration of gingival epithelial cells will occur as a consequence of a break between root surface and healing connective tissue. Hence, maintenance of a tight adaptation of the flap to the root surface is essential and one may therefore consider keeping the sutures in place for longer than the 7–10 days usually prescribed following standard flap surgery.

Following suture removal, the surgically treated area is thoroughly irrigated with a dental spray and the teeth are carefully cleaned with a rubber cup and polishing paste. If the healing is satisfactory for starting mechanical tooth cleaning, the patient is instructed in gentle brushing of the operated area using a toothbrush that has been softened in hot water. Toothpicks are prescribed for cleaning the interdental area. In this early phase following surgical treatment the use of interdental brushes is abandoned due to the risk of traumatizing the interdental tissues. Visits are scheduled for supportive care at 2-week intervals to monitor the patient's plaque control closely. During this post-operative maintenance phase, adjustments of the methods for optimal self-performed mechanical cleaning are made depending on the healing status of the tissues. The time interval between visits for supportive care may gradually be increased, depending on the patient's plaque control standard.

Outcome of surgical periodontal therapy

Healing following surgical pocket therapy

Gingivectomy

Within a few days following excision of the inflamed gingival soft tissues coronal to the base of the peri-

odontal pocket, epithelial cells start to migrate over the wound surface. The epithelialization of the gingivectomy wound is usually complete within 7–14 days following surgery (Engler *et al*. 1966; Stahl *et al*. 1968). During the following weeks a new dentogingival unit is formed (Fig. 38-59). The fibroblasts in the supra-alveolar tissue adjacent the tooth surface proliferate (Waerhaug 1955) and new connective tissue is laid down. If the wound healing occurs in the vicinity of a plaque-free tooth surface, a free gingival unit will form which has all the characteristics of a normal free gingiva (Hamp *et al*. 1975). The height of the newly formed free gingival unit may vary not only between different parts of the dentition but also from one tooth surface to another due to primarily anatomic factors.

The re-establishment of a new, free gingival unit by coronal regrowth of tissue from the line of the "gingivectomy" incision implies that sites with so-called "zero pockets" only occasionally occur following gingivectomy. Complete healing of the gingivectomy wound takes 4–5 weeks, although by clinical inspection the surface of the gingiva may appear to be healed already after approximately 14 days (Ramfjord *et al*. 1966). Minor remodeling of the alveolar bone crest may also occur post-operatively.

The apically repositioned flap

Following osseous surgery for elimination of bony defects and the establishment of "physiologic contours" and repositioning of the soft tissue flaps to the level of the alveolar bone, healing will occur primarily by first intention, especially in areas where proper soft tissue coverage of the alveolar bone has been obtained. During the initial phase of healing, bone resorption of varying degrees almost always occurs in the crestal area of the alveolar bone (Fig. 38-60)

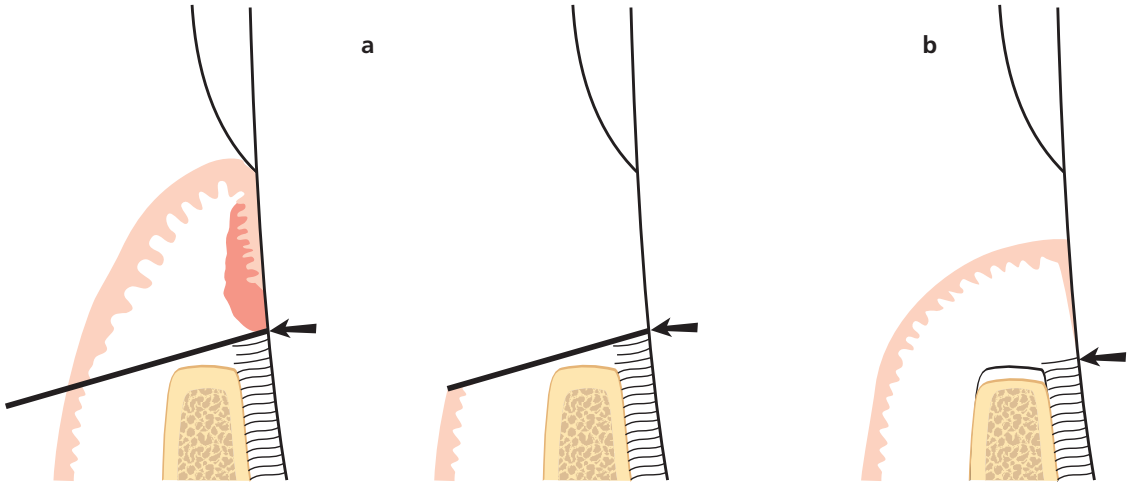

Fig. 38-59 Gingivectomy. Dimensional changes as a result of therapy. (a) The pre-operative dimensions. The black line indicates the location of the primary incision, i.e. the suprabony pocket is eliminated with the gingivectomy technique. (b) Dimensions following proper healing. Minor resorption of the alveolar bone crest as well as some loss of connective tissue attachment may occur during the healing.

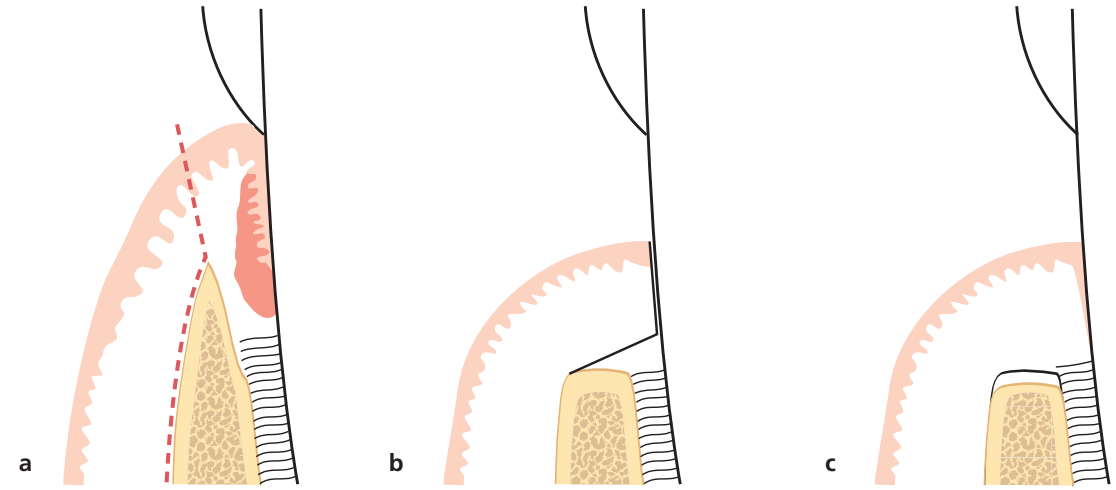

Fig. 38-60 Apically repositioned flap. Dimensional changes. (a) The pre-operative dimensions. The broken line indicates the border of the elevated mucoperiosteal flap. (b) Bone recontouring has been completed and the flap repositioned to cover the alveolar bone. (c) Dimensions following healing. Minor resorption of the marginal alveolar bone has occurred as well as some loss of connective tissue attachment.

(Ramfjord & Costich 1968). The extent of the reduction of the alveolar bone height resulting from this resorption is related to the thickness of the bone in each specific site (Wood *et al*. 1972; Karring *et al*. 1975).

During the phase of tissue regeneration and maturation a new dentogingival unit will form by coronal growth of the connective tissue. This regrowth occurs in a manner similar to that which characterized healing following gingivectomy.

The modified Widman flap

If a "modified Widman flap" procedure is carried out in an area with a deep infrabony lesion, bone repair may occur within the boundaries of the lesion (Rosling *et al*. 1976a; Polson & Heijl 1978). However, crestal bone resorption is also seen. The amount of bone fill obtained is dependent upon (1) the anatomy of the osseous defect (e.g. a three-walled infrabony defect often provides a better mould for bone repair than two- or one-walled defects), (2) the amount of crestal bone resorption, and (3) the extent of chronic inflammation, which may occupy the area of healing. Interposed between the regenerated bone tissue and the root surface, a long junctional epithelium is always found (Fig. 38-61) (Caton & Zander 1976; Caton *et al*. 1980). The apical cells of the newly formed junctional epithelium are found at a level on the root that closely coincides with the presurgical attachment level.

Soft tissue recession will take place during the healing phase following a modified Widman flap procedure. Although the major apical shift in the position of the soft tissue margin will occur during the first 6 months following the surgical treatment (Lindhe *et al*. 1987), the soft tissue recession may often continue for a time period of more than 1 year. Among factors influencing the degree of soft tissue recession as well as the time period for soft tissue remodeling are the initial height and thickness of the supracrestal flap tissue and the amount of crestal bone resorption.

Clinical outcome of surgical access therapy in comparison to non-surgical therapy

Surgical treatment of periodontal lesions mainly serves the purpose of (1) creating accessibility for proper professional debridement of the infected root surfaces and (2) establishing a gingival morphology that facilitates the patient's self-performed plaque control, in order to enhance the long-term preservation of the dentition. Hence, the amount of tooth loss would be the most relevant criterion in an evaluation of the relative importance of surgical access therapy in the overall treatment of periodontal disease. However, this would require studies with extremely long follow-up periods and, therefore, other criteria are commonly used to evaluate the efficacy of periodontal therapy, even if these may only be considered as surrogate end-points. The most commonly used outcome criteria in clinical research have been resolution of gingivitis (bleeding on probing), probing pocket depth reduction, and clinical attachment level change. An additional variable often of concern is gingival recession, since this outcome variable may affect the patient's overall appreciation of the treatment result. With regard to changes in probing attachment levels, it should be recalled that healing following conventional surgical access therapy consistently results in the formation of a junctional epithelium to a level on the root that closely coincides with the presurgical attachment level. Hence, when

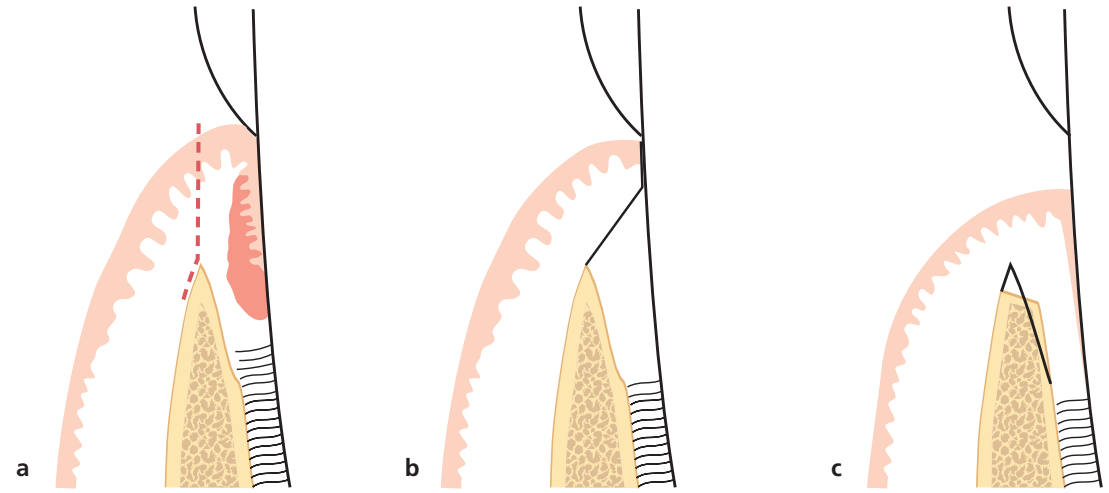

Fig. 38-61 Modified Widman flap. Dimensional changes. (a) The pre-operative dimensions. The broken line indicates the border of the elevated mucoperiosteal flap. (b) Surgery (including currettage of the angular bone defect) is completed with the mucoperiosteal flap repositioned as close as possible to its presurgical position. (c) Dimensions following healing. Osseous repair as well as some crestal bone resorption can be expected during healing with the establishment of a "long" junctional epithetium interposed between the regenerated bone tissue and the root surface. An apical displacement of the soft tissue margin has occurred.

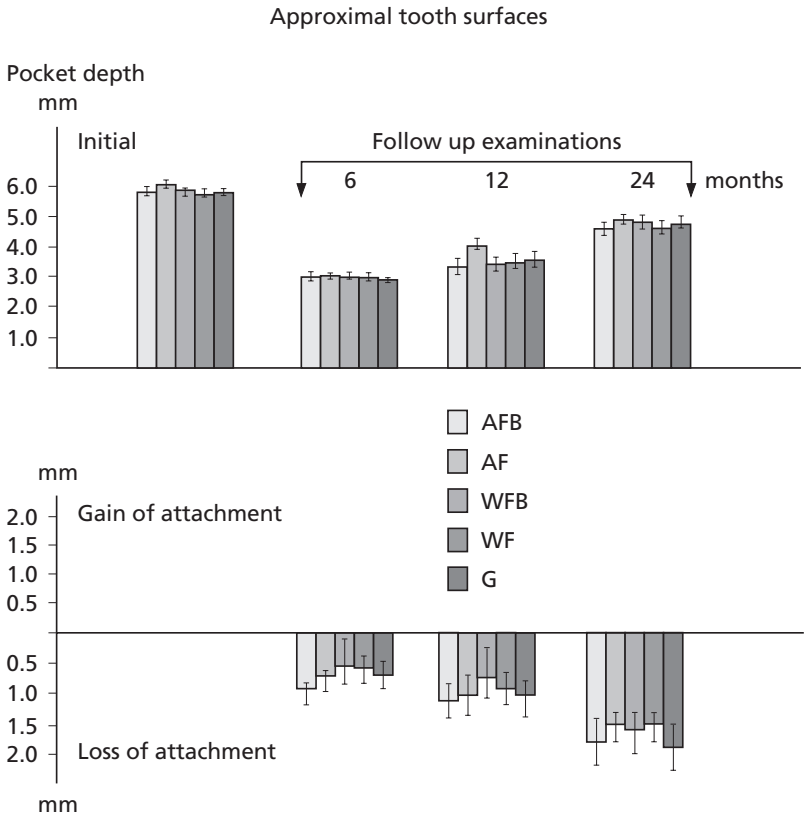

Fig. 38-62 Average approximal pocket depth at the initial examination and 6, 12, and 24 months after surgery (top) and alterations in approximal attachment levels from the initial examination immediately prior to surgery to the re-examinations 6, 12, and 24 months post-operatively (bottom). Note that only areas with pockets that at the initial examination had a depth of 3 mm or more are included in the analysis. I = standard error; AFB = apically repositioned flap with bone recontouring; AF = apically repositioned flap; WFB = modified Widman flap with bone recontouring; WF = modified Widman flap; G = gingivectomy including curettage of bone defects. (Data from Nyman *et al.* 1977.)

evaluating the outcome of various therapeutic approaches the magnitude of *gain* of clinical attachment may be of less importance since it mainly is a measure of "pocket closure". Instead maintained probing attachment levels or further loss should be focused on as the pertinent outcome variable.

Pioneering contributions to the understanding of the relative importance of the surgical component of periodontal therapy were generated by the classical longitudinal studies by the Michigan group (Ramfjord and co-workers) and the Gothenburg group (Lindhe and co-workers). Subsequently, several other clinical research centers contributed with important data regarding the efficacy of surgical access therapy in comparison to non-surgical periodontal therapy. The topic has been extensively reviewed in several recent publications (e.g. Kaldahl *et al*. 1993; Palcanis 1996) and some of the general conclusions from these reviews will be highlighted below.

Plaque accumulation

An important factor to consider in the evaluation of the relative effect of the surgical component of periodontal therapy is the standard of post-operative infection control. Nyman *et al*. (1977) reported on a clinical study in which the patients received only a single episode of oral hygiene instruction before the surgical treatment and no specific post-operative supportive care. As a consequence both plaque and gingival indices remained relatively high during the 2 years of post-operative follow-up. Independent of surgical technique used, the patients showed a rebound of pocket depths to more or less pre-treatment levels and further deterioration of clinical attachment levels at both proximal and lingual tooth sites (Fig. 38-62). In contrast, in a parallel study in which the patients received repeated oral hygiene instructions and professional tooth-cleaning once every 2 weeks during the post-operative period (Rosling *et al*. 1976b), the patients maintained the surgically reduced pocket depth throughout the 2-year follow-up period and clinical attachment level gains were observed for most of the surgical procedures evaluated (Fig. 38-63). The fact that the standard of post-operative oral hygiene is decisive for the outcome of surgical pocket therapy is further underlined by data from a 5-year longitudinal study by Lindhe *et al*. (1984), which showed that patients with a high standard of infection control maintained clinical attachment levels and probing depth reductions following treatment more consistently than patients with poor plaque control. On the other hand, professional tooth cleaning, including subgingival scaling every 3 months, may partly compensate for the negative effects of variations in self-performed plaque control (Ramfjord *et al*. 1982; Isidor & Karring 1986).

With regard to post-treatment plaque accumulation, there is no evidence to suggest that differences exist between non-surgical or surgical treatment or between various surgical procedures. In addition, most studies have shown that the magnitude of gingivitis resolution is not influenced by the treatment modality.

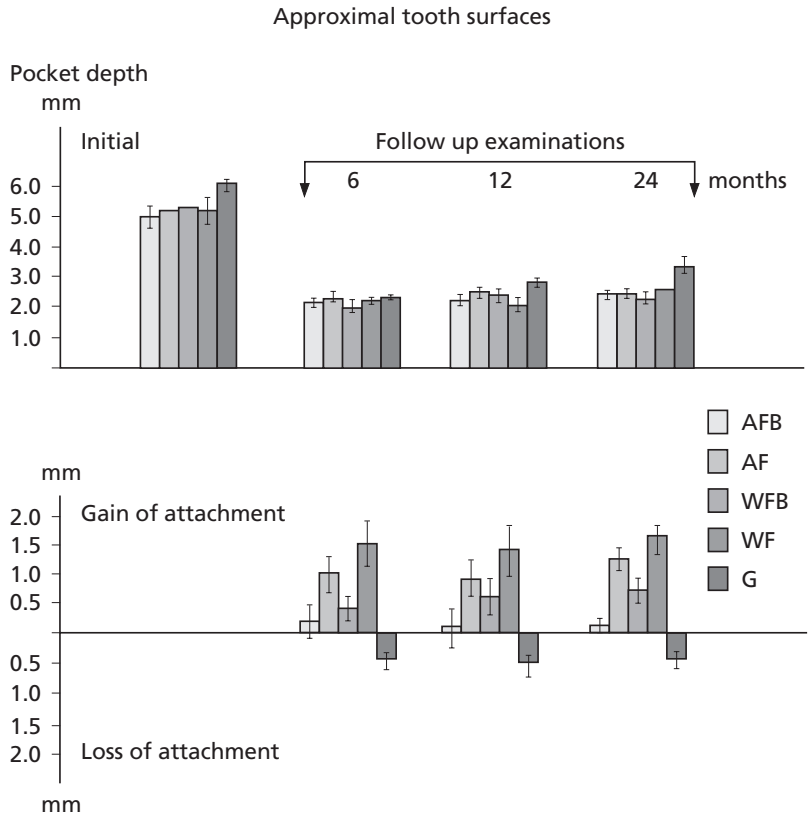

Fig. 38-63 Average approximal pocket depth at the initial examination and 6, 12, and 24 months after surgery (top) and alterations in approximal attachment levels from the initial examination immediately prior to surgery to the re-examinations 6, 12, and 24 months post-operatively (bottom). Note that only areas with pockets that at the initial examination had a depth of 3 mm or more are included in the analysis. I = standard error; AFB = apically repositioned flap with bone recontouring; AF = apically repositioned flap; WFB = modified Widman flap with bone recontouring; WF = modified Widman flap; G = gingivectomy including curettage of bone defects. (Data from Rosling *et al.* 1976b.)

Probing pocket depth reduction

All surgical procedures result in a decrease in probing pocket depths with greater reduction occurring at initially deeper sites (Knowles *et al.* 1979; Lindhe *et al.* 1984; Ramfjord *et al.* 1987; Kaldahl *et al.* 1996; Becker *et al.* 2001). Furthermore, surgical therapy generally creates greater short-term reduction of probing depth than non-surgically performed scaling and root planing. Flap surgery with bone recontouring (pocket elimination surgery) usually results in the most pronounced short-term pocket reduction. Long-term (5–8 years) results show various outcomes. Some studies reported greater probing depth reduction following surgery while others reported no differences in relation to non-surgical therapy. Also, the magnitude of the initial probing depth reduction shows a tendency to decrease with time, independent of treatment modality.

Clinical attachment level change

In sites with shallow initial probing depth, both short- and long-term data demonstrate that surgery creates a greater loss of clinical attachment than non-surgical treatment, whereas in sites with initially deep pockets (≥7 mm), a greater gain of clinical attachment is generally obtained (Knowles *et al.* 1979; Lindhe *et al.* 1984; Ramfjord *et al.* 1987; Kaldahl *et al.* 1996; Becker *et al.* 2001) (Fig. 38-64). When clinical attachment levels following surgery with and without osseous resection were compared, either no difference was found between therapies, or flap surgery without osseous resection produced a greater gain. In addition, there was no difference in the longitudinal maintenance of clinical attachment levels between sites treated non-surgically and those treated surgically, with or without osseous resection.

Based on data generated from a clinical trial comparing non-surgical and surgical (modified Widman flap) approaches to root debridement, Lindhe *et al.* (1982b) developed the concept of *critical probing depth* in relation to clinical attachment level change. For each treatment approach, the clinical attachment change was plotted against the initial pocket depth and regression lines were calculated (Fig. 38-65). The point where the regression line crossed the horizontal axis (initial probing depth) was defined as the *critical probing depth* (CPD), i.e. the level of pocket depth below which clinical attachment loss would occur as the result of the treatment procedure performed. The CPD was consistently found to be greater for the surgical approach than for the non-surgical treatment. Furthermore, at incisors and premolars the surgical therapy showed superior outcome only when the initial probing depth was greater than 6–7 mm, while at molars the corresponding cut-off point was 4.5 mm. The interpretation of the latter finding would be that, in the molar tooth regions, the surgical approach to root debridement offers advantages over the non-surgical approach. This interpretation is supported by the observation that inferior results are obtained by non-surgical therapy in molars compared to single-rooted teeth (Nordland *et al.*

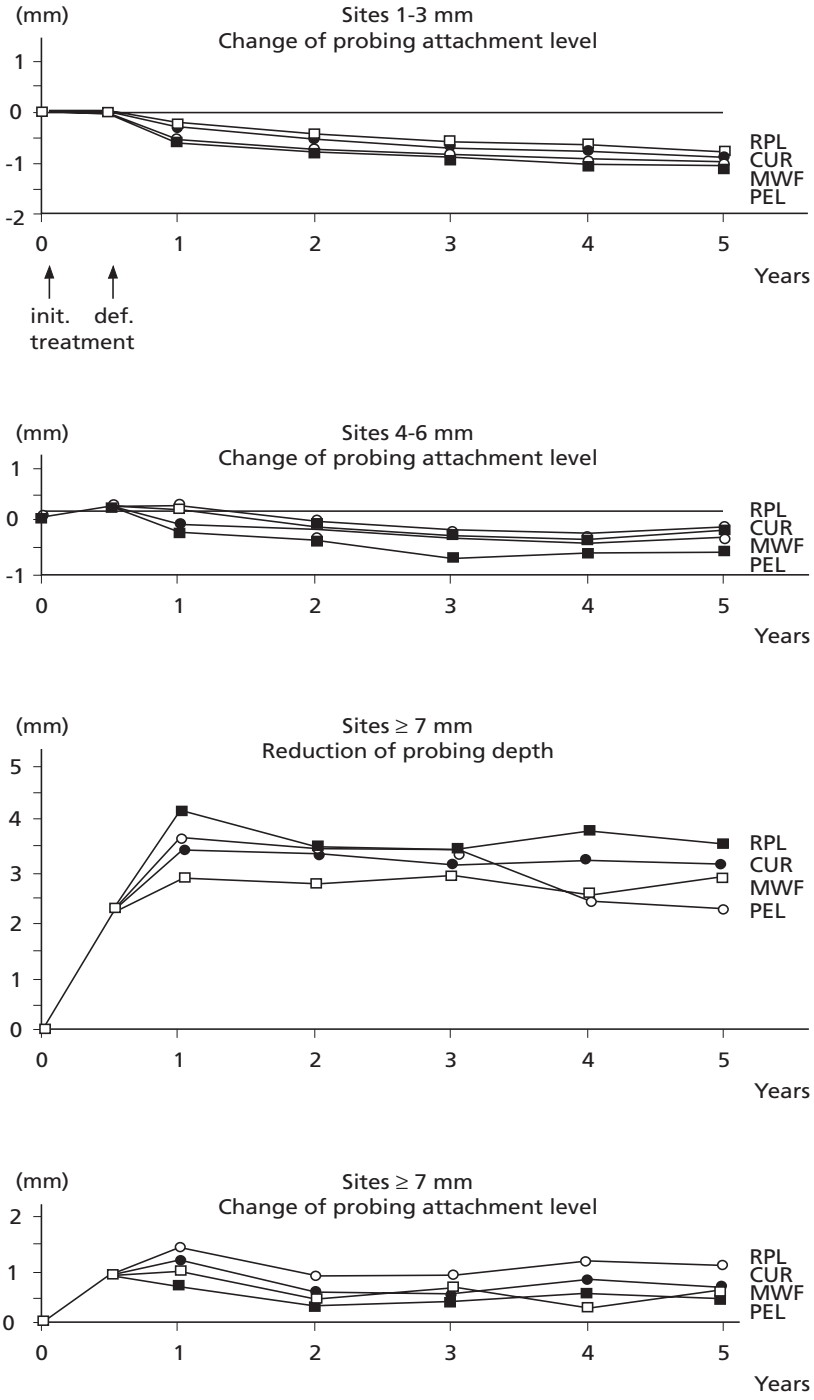

Fig. 38-64 Longitudinal evaluation of four treatment modalities in the three categories of initial probing depth; 1–3 mm, 4–6 mm and ≥7 mm. RPL = scaling and root planning; CUR = subgingival curettage; MWF = modified Widman flap; PEL = pocket elimination surgery. (Data from Ramfjord *et al*. 1987, presented by Egelberg 1995.)

1987; Loos *et al*. 1988). Also data generated from studies comparing closed and open root debridement in furcation sites favor surgical access therapy in the treatment of molar tooth regions (Matia *et al*. 1986).

The removal of the pocket epithelium and the soft tissue lesion by curettage (Echeverria & Caffesse 1983; Ramfjord *et al*. 1987) or surgical excision (Lindhe & Nyman 1985) is not a prerequisite for proper healing of the treated periodontal site. In the study by Lindhe and Nyman (1985) three treatment modalities were used, i.e. excision of the soft tissue lesion during flap surgery (modified Widman flap procedure), surgery without removal of the soft tissue lesion (Kirkland flap), and non-surgical scaling and root planing. The 1-year follow-up examination revealed about 1 mm of gain in clinical attachment level for all three procedures. Thus, deliberate excision of the soft tissue lesion did not improve the healing result.

Gingival recession

Gingival recession is an inevitable consequence of periodontal therapy. Since it occurs primarily as a result of resolution of the inflammation in the periodontal tissues, it is seen both following non-surgical and surgical therapy. Irrespective of treatment modality used, initially deeper pocket sites will experience

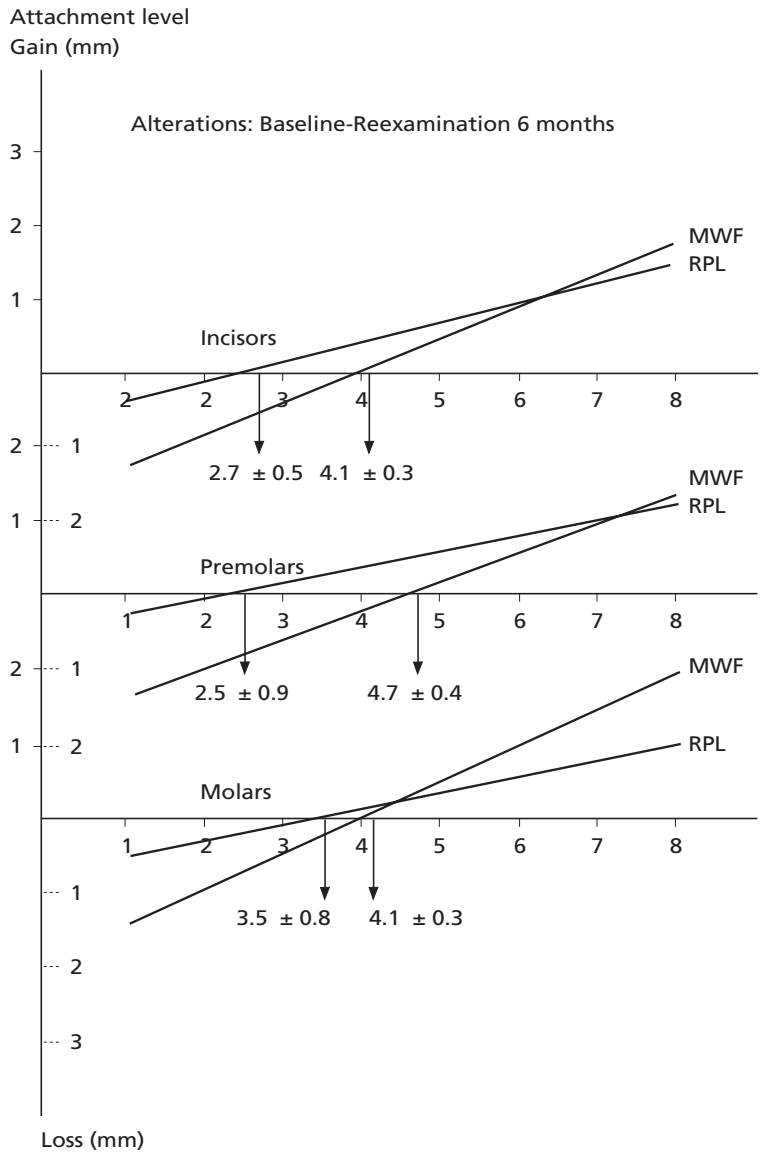

Fig. 38-65 Diagram illustrating the gain and loss of clinical attachment (Y-axis) at incisors, premolars, and molars, calculated from measurements taken prior to and 6 months after treatment. RPL = scaling and root planning; MWF = modified Widman flap surgery. The non-surgical approach (RPL) consistently yielded lower critical probing depth (CPD) values than the surgical approach. (Data from Lindhe *et al*. 1982b.)

more pronounced signs of recession of the gingival margin than sites with shallow initial probing depths (Badersten *et al*. 1984; Lindhe *et al*. 1987; Becker *et al*. 2001).

A general finding in short-term follow-up studies of periodontal therapy is that non-surgically performed scaling and root planing causes less gingival recession than surgical therapy, and that surgical treatment involving osseous resection results in the most pronounced recession. However, data obtained from long-term studies reveal that the initial differences seen in amount of recession between various treatment modalities diminish over time due to a coronal rebound of the soft tissue margin following surgical treatment (Kaldahl *et al*. 1996; Becker *et al*. 2001) (Fig. 38-66). Lindhe and Nyman (1980) found that after an apically repositioned flap procedure the buccal gingival margin shifted to a more coronal position (about 1 mm) during 10–11 years of maintenance. In interdental areas denuded following surgery, van der Velden (1982) found an upgrowth of around 4 mm of gingival tissue 3 years after surgery, while no significant change in attachment levels was observed. A similar finding was reported by Pontoriero and Carnevale (2001) 1 year after an apically positioned flap procedure for crown lengthening.

Bone fill in angular bone defects

The potential for bone formation in angular defects following surgical access therapy has been demonstrated in a number of studies. Rosling *et al*. (1976a) studied the healing of two- and three-wall angular bone defects following a modified Widman flap procedure, including careful curettage of the bone defect and proper root debridement, in 24 patients with multiple osseous defects. Following active treatment, patients assigned to the test group received supportive periodontal care once every 2 weeks for a 2-year period, while the patients in the control group were only recalled once a year for prophylaxis. Re-examination carried out 2 years after therapy demonstrated that the patients who had been subjected to the inten-

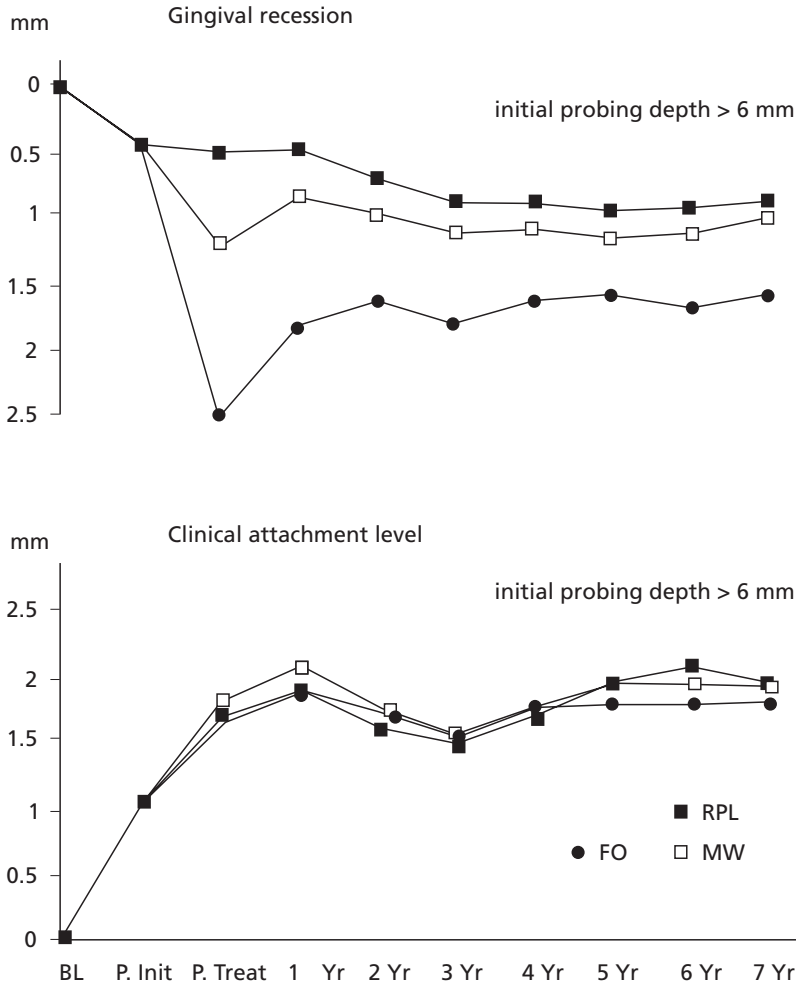

Fig. 38-66 Longitudinal changes over 7 years in recession (top diagram) and clinical attachment levels (bottom diagram) at sites with initial probing pocket depth of >6 mm following three different periodontal treatment modalities. RPL = scaling and root planning; MWF = modified Widman flap procedure; FO = flap and osseous surgery. (Data from Kaldahl *et al*. 1996.)

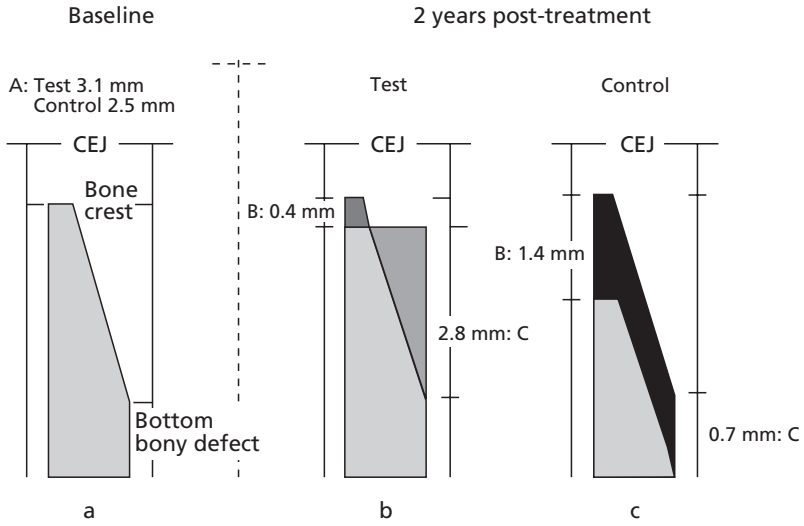

Fig. 38-67 Schematic drawing illustrating alterations in the level of the marginal bone crest and the level of the bottom of the bone defects in the test and control groups of the study by Rosling *et al*. (1976a). Distance A denotes the depth of the bone defects at the initial examination; test group 3.1 mm, control 2.5 mm. Distance B denotes resorption of the alveolar crest (b,c), which amounted to 0.4 mm in the test patients (b) and 1.4 mm in the controls (c). Distance C denotes gain or loss of bone in the apical portion of the defect. There was a refill of bone in the test patients (b) amounting to 2.8 mm, whereas a further 0.7 mm loss of bone occurred in the control patients (c).

sive professional tooth-cleaning regimen had experienced a mean gain of clinical attachment in the angular bone defects amounting to 3.5 mm. Measurements performed on radiographs revealed a marginal bone loss of 0.4 mm, but the remaining portion of the original bone defect (2.8 mm) was refilled with bone (Fig. 38-67). All the 124 bone defects treated were completely resolved. In the control group most of the sites treated showed signs of recurrent periodontitis, including further loss of clinical attachment and alveolar bone. Similar healing results were reported by Polson and Heijl (1978). They treated 15 defects (two- and three-wall) in nine patients using a modified Widman flap procedure. Following curettage of the bone defect and root planing, the flaps were closed to achieve complete soft tissue coverage of the defect area. All patients were enrolled in a professional tooth-cleaning program. The healing was evaluated

at a re-entry operation 6–8 months after the initial surgery. Eleven of the 15 defects had resolved completely. The healing was characterized by a combination of coronal bone regeneration (77% of the initial depth of the defects) and marginal bone resorption (18%). The authors concluded that intrabony defects might predictably remodel after surgical debridement and establishment of optimal plaque control.

The results from the studies referred to demonstrate that a significant bone fill may be obtained in two- and three-wall intrabony defects at single-rooted teeth, provided the post-operative supportive care is of very high quality. Two recent reviews (Laurell *et al*. 1998; Lang 2000), focusing on the outcome of surgical access therapy in angular bone defects, give additional information regarding expected bone regeneration in angular defects following open-flap debridement (modified Widman flap). In the review by Laurell *et al*. (1998) 13 studies were included representing a total of 278 treated defects with a mean depth of 4.1 mm. The weighted mean bone fill in the angular defects amounted to 1.1 mm. Lang (2000) reported an analysis of 15 studies providing data generated from radiographic assessments of the healing of 523 angular bone defects. The analysis yielded a weighted mean of 1.5 mm of bone gain. Since the included studies in these reviews showed great variability in bone fill, one may assume that the standard of post-surgical plaque control varied between the studies. As shown in the study by Rosling *et al*. (1976a), meticulous post-surgical plaque control and close professional supervision of the patients are critical for optimal healing conditions. One also has to consider that the potential for bone fill may differ depending on the morphology of the angular bone defect. Most angular defects appear as combinations of one-, two- and three-wall defects and whereas the two- and three-wall component of an angular bone defect may show great potential for bone fill during healing, the one-wall component will rarely demonstrate this type of healing.

Chapter 39

Treatment of Furcation-Involved Teeth

Gianfranco Carnevale, Roberto Pontoriero, and Jan Lindhe

Detailed knowledge of the morphology of the multi-rooted teeth and their position in the dental arch is a fundamental prerequisite for a proper understanding of problems which may occur when such teeth become involved in destructive periodontal disease. The first part of this chapter therefore includes a brief description of some important anatomic features of the root complexes and related structures of premolars and molars.

Terminology

Root complex is the portion of a tooth that is located apical to the cemento-enamel junction (CEJ), i.e. the portion that normally is covered with a root cementum. The root complex may be divided into two parts: the *root trunk* and the *root cone(s)* (Fig. 39-1).

The *root trunk* represents the *undivided region* of the root. The height of the root trunk is defined as the distance between the CEJ and the separation line (furcation) between two root cones (roots). Depending on the position of the separation line the height of the root trunk may vary from one surface to the next in one given molar or premolar.

The *root cone* is included in the *divided region* of the root complex. The root cone (root) may vary in size and position and may at certain levels be connected to or separated from other root cones. Two or more root cones make up the *furcated region* of the root complex (Fig. 39-2a). The *furcation* is the area located between individual root cones.

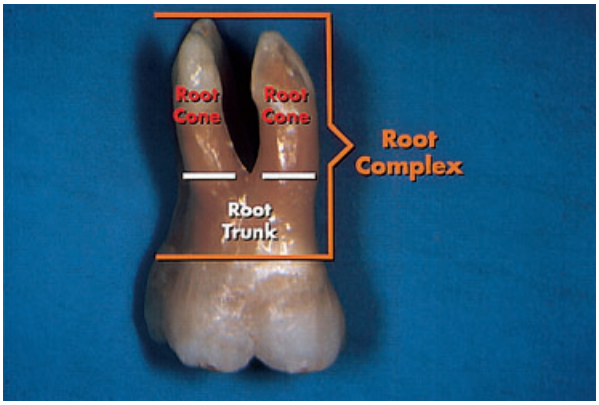

Fig. 39-1 Root complex of a maxillary molar. The root complex is separated into one undivided region: the root trunk, and one divided region: the (three) root cones.

The *furcation entrance* is the transitional area between the undivided and the divided part of the root (Fig. 39-2a,b). The *furcation fornix* is the roof of the furcation (Fig. 39-2b).

The d*egree of separation* is the angle of separation between two roots (cones) (Fig. 39-3a). *Divergence* is the distance between two roots; this distance normally increases in apical direction (Fig. 39-3a). The *coefficient of separation* is the length of the root cones in relation to the length of the root complex (Fig. 39-3b).

Fusion between divergent root cones may occur. The fusion may be complete or incomplete. In the

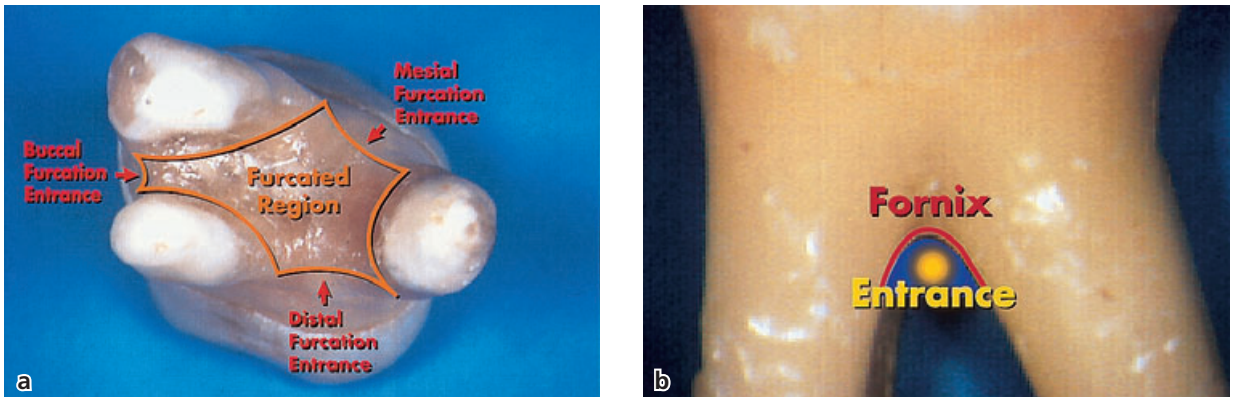

Fig. 39-2 (a) Apical-occlusal view of a maxillary molar where the three root cones make up the furcated region and the three furcation entrances. (b) A buccal view of the furcation entrance and of its roof.

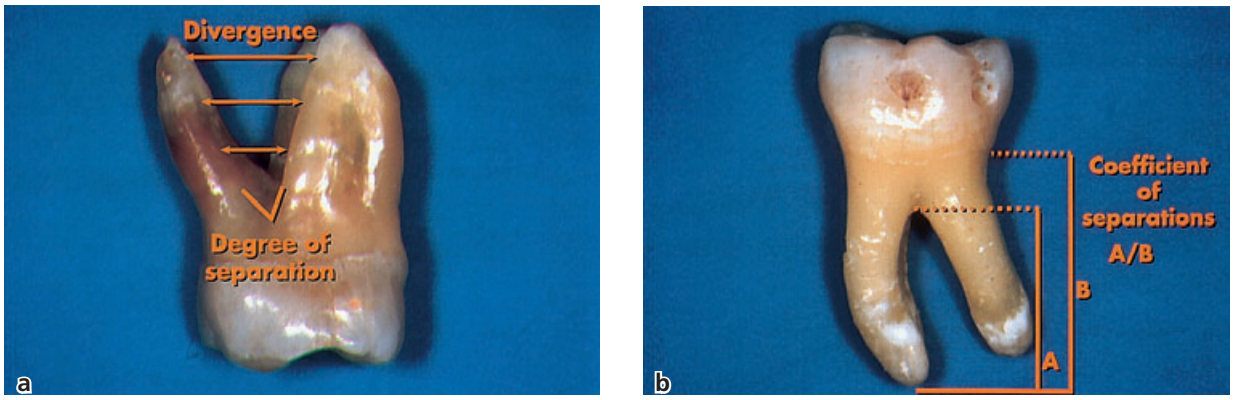

Fig. 39-3 (a) Photograph illustrating the angle (degree) of separation and the divergence between the mesio-buccal and the palatal roots of a maxillary molar. (b) The coefficient of separation (A/B) of the illustrated mandibular molar is 0.8 (A = 8 mm; B = 10 mm).

case of an incomplete fusion, the root cones may be fused in the area close to the CEJ but separated in a more apical region of the root complex.

Anatomy

Maxillary molars

As a general rule the maxillary first molar, in all respects – crown and individual roots – is larger than the second molar, which in turn is larger than the third molar.

The first and second molars most often have three roots; one mesio-buccal, one disto-buccal, and one palatal. The mesio-buccal root is normally vertically positioned while the disto-buccal and the palatal roots are inclined. The disto-buccal root projects distally and the palatal root projects in palatal direction (Fig. 39-4). The cross sections of the distobuccal and the palatal roots are generally circular. The palatal root is generally wider in the mesio-distal than in the bucco-palatal direction. The distal surface of the mesio-buccal root has a concavity which is about 0.3 mm deep (Bower 1979a,b). This concavity gives the cross section of the mesio-buccal root an "hour-glass" configuration (Fig. 39-5).

The three furcation entrances of the maxillary first and second molars vary in width and are positioned at varying distances apical to the CEJ. As a rule, the first molar has a shorter root trunk than the second molar. In the first molar the mesial furcation entrance is located about 3 mm from the CEJ, while the buccal is 3.5 mm and the distal entrance about 5 mm apical to the CEJ (Abrams & Trachtenberg 1974; Rosenberg 1988). This implies that the furcation fornix is inclined; in the mesiodistal plane the fornix is comparatively close to the CEJ at the mesial but closer to the apex at the distal surface. The buccal furcation entrance is narrower than its distal and mesial counterparts.

The degree of separation between the roots and their divergence decreases from the first to the second, and from the second to the third maxillary molar.

The mesio-buccal root of the first molar is frequently located more buccally in the arch than the disto-buccal root. If the buccal bone plate is thin, the mesio-buccal root frequently projects through the outer surface of the alveolar bone and bone fenestrations and/or dehiscences may occur.

Fig. 39-4 Furcation entrances (a, mesial; b, buccal; c, distal) and the position of the roots of a maxillary first molar.

Fig. 39-5 Root-shape of a maxillary first molar in a horizontal cut at the level of the coronal third of the cones. Note the circular shape of the palatal root in comparison with the mesio-distally compressed shape of the mesio-buccal root, which also exhibits a concavity in the distal aspect.

Maxillary premolars

In about 40% of cases the maxillary first premolars have two root cones, one buccal and one palatal, and hence have a mesiodistal furcation. A concavity (about 0.5 mm deep) is often present in the furcation aspect of the buccal root. In many cases the furcation is located in the middle or in the apical third of the root complex (Fig. 39-6). The mean distance between CEJ and the furcation entrance is about 8 mm. The width of the furcation entrance is about 0.7 mm.

Fig. 39-6 A maxillary first premolar with the furcation located in the apical third of the root complex.

Mandibular molars

The mandibular first molar is larger than the second molar, which in turn is larger than the third molar. In the first and second molars the root complex almost always includes two root cones, one mesial and one distal. The mesial root is larger than the distal. The mesial root has a position which is mainly vertical while the distal root projects distally. The mesial root is wider in the bucco-lingual direction and has a larger cross-sectional area than the distal root. The cross section of the distal root is circular while the mesial root has an "hour-glass" shape. In addition, furrows and concavities often occur on the distal surface of the mesial root (Fig. 39-7). The distal concavity of the mesial root is more pronounced than that of the distal root (Bower 1979a,b; Svärdström & Wennström 1988).

The root trunk of the first molar is often shorter than the trunk of the second molar. The furcation entrances of the mandibular first molar, similar to

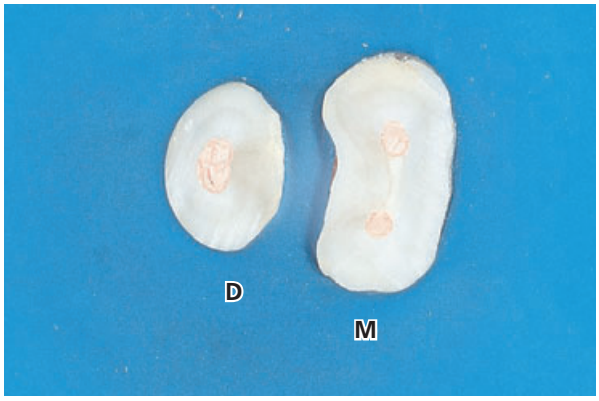

Fig. 39-7 "Hour-glass" shape of the mesial root – with a concavity in the distal aspect – and the circular shape of the distal root (horizontal section at the level of the coronal third of the cones).

Fig. 39-8 From left to right, differences in degree of separation and in divergence between the root cones from the first to the mandibular third molar.

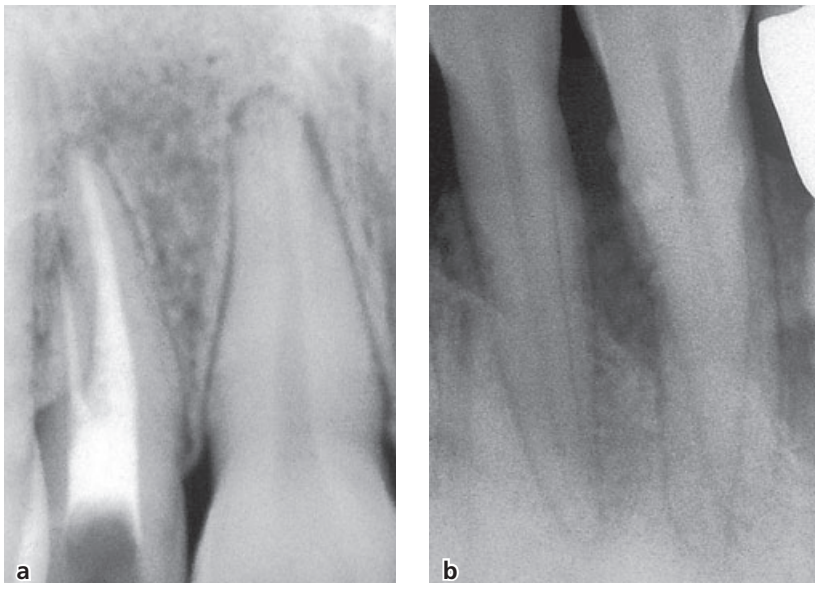

Fig. 39-9 Radiographs illustrating morphologic variations represented by two-rooted (a) maxillary lateral incisor and (b) mandibular canine.

those of the maxillary first molar, are located at different distances from the CEJ. Thus, the lingual entrance is frequently found more apical to the CEJ (>4 mm) than the buccal entrance (>3 mm). Thus, the furcation fornix is inclined in the bucco-lingual direction. The buccal furcation entrance is often <0.75 mm wide while the lingual entrance is >0.75 mm in most cases (Bower 1979a,b). The degree of separation and divergence between the roots decreases from the first to the third molar (Fig. 39-8).

It should also be observed that the buccal bone plate is thinner outside the roots of the first than of the second molar. Bone fenestrations and dehiscences are, as a consequence, more frequent in the first than in the second molar region.

Other teeth

Furcations may be present also in teeth which normally have only one root. In fact, two-rooted incisors (Fig. 39-9a), canines (Fig. 39-9b), and mandibular premolars may exist. Occasionally three-rooted maxillary premolars (Fig. 39-10a) and three-rooted mandibular molars can be found (Fig. 39-10b).

Diagnosis

The presence of furcation-involved teeth in a periodontal patient will influence the treatment plan (see Chapter 31). The selection of procedures to be used in the treatment of periodontal disease at multirooted teeth can first be made when the presence and depth of furcation lesions have been assessed. In this examination traditional measures of periodontal disease are used (see Chapter 26) but special attention is paid to findings from clinical *probing* and analysis of *radiographs* from the premolar–molar regions.

The classification description of the involved furcation is based on the amount of periodontal tissue destruction that has occurred in the inter-radicular area, i.e. degree of "horizontal root exposure" or

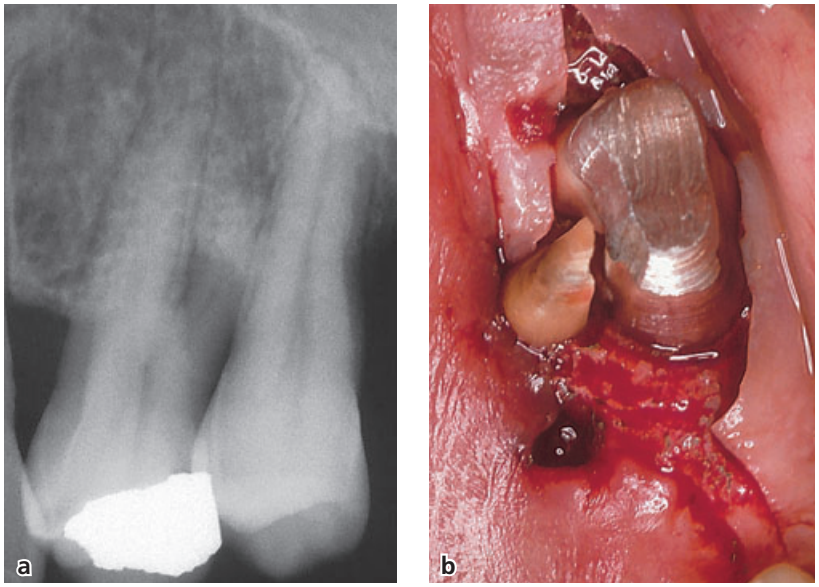

Fig. 39-10 (a) Anatomic variation represented in a radiograph of a three-rooted mandibular first premolar. (b) Clinical photograph illustrating, during surgery, the separation – before extraction – of an "abnormal" second mesial root of a mandibular molar.

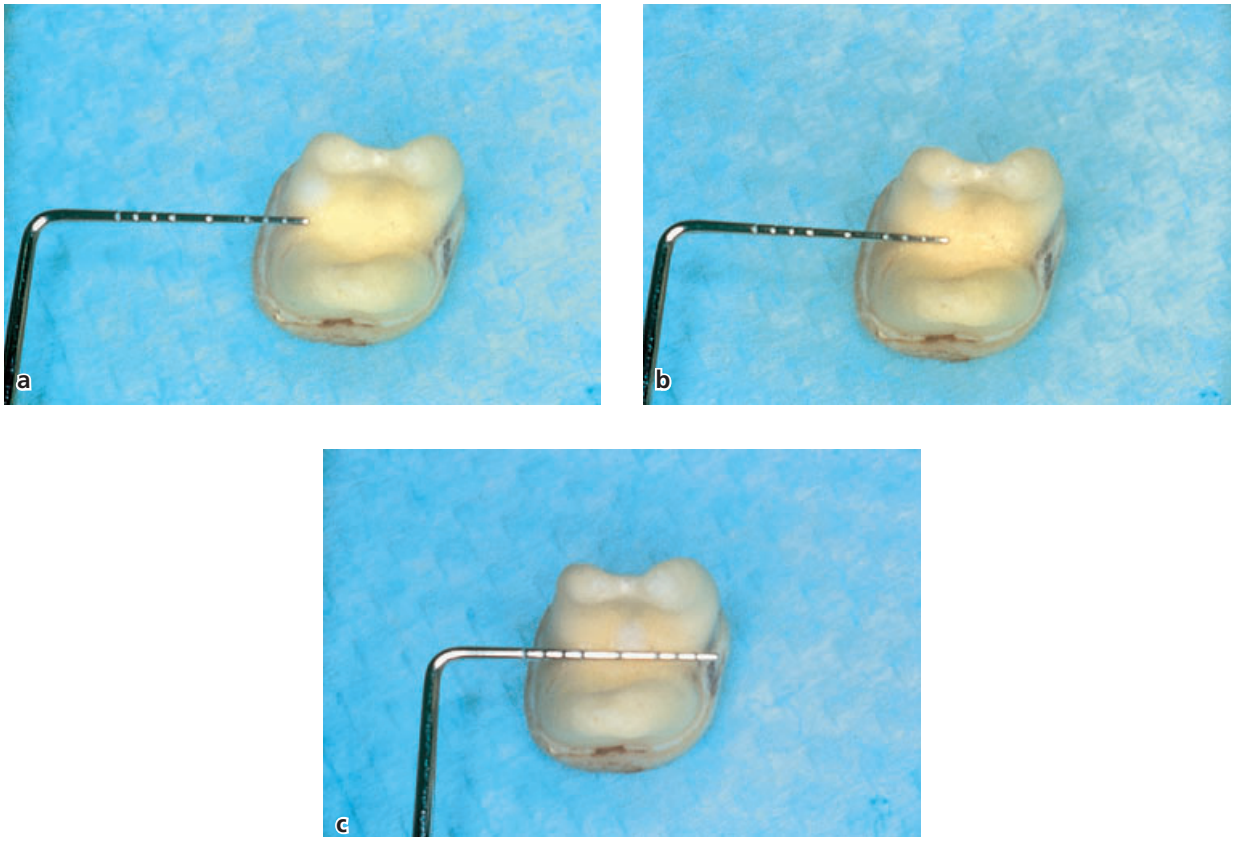

Fig. 39-11 Different degrees of furcation involvement in relation to the probe (penetration/superimposition) in the interradicular space of a mandibular molar. (a) Degree I. (b) Degree II. (c) Degree III.

attachment loss that exists within the root complex. Hamp *et al*. (1975) has suggested the following classification of the involved furcation:

- Degree I: horizontal loss of periodontal support not exceeding one third of the width of the tooth (Fig. 39-11a).
- Degree II: horizontal loss of periodontal support exceeding one third of the width of the tooth, but not encompassing the total width of the furcation area (Fig. 39-11b).
- Degree III: horizontal "through-and-through" destruction of the periodontal tissues in the furcation area (Fig. 39-11c).

It is important to understand that each furcation entrance must be examined and each entrance must be classified according to the above criteria.

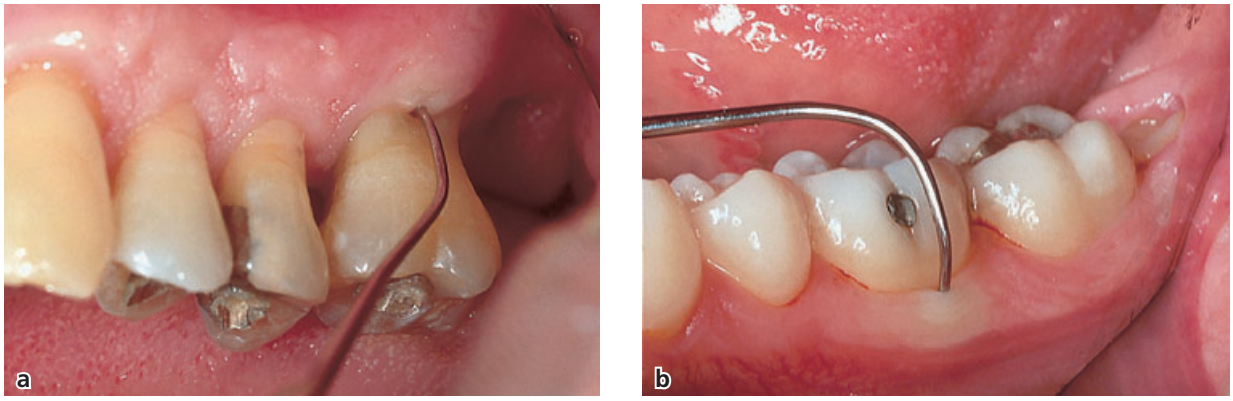

Fig. 39-12 Easily accessible vestibular furcation entrances for probing of a (a) maxillary molar and (b) mandibular molar.

Fig. 39-13 Common access for probing of a mesial furcation entrance of a maxillary molar. The mesial furcation entrance is generally located at the palatal aspect of the tooth, while the distal entrance is located midway between the buccal and the palatal surface.

Fig. 39-14 Radiograph showing the location of the interdental bone level in relation to the furcation entrances of the maxillary first and second molar.

Probing

The buccal furcation entrance of the *maxillary molars* and the buccal and lingual furcation entrances of the *mandibular molars* are normally accessible for examination using a curved graduated periodontal probe (Fig. 39-12), an explorer or a small curette. The examination of approximal furcations is more difficult, in particular when neighboring teeth are present. Large contact areas between the teeth further impair access to approximal furcation entrances.

In maxillary molars the mesial furcation entrance is located much closer to the palatal than to the buccal tooth surface. Thus, the mesial furcation should be probed from the palatal aspect of the tooth (Fig. 39-13). The distal furcation entrance of a *maxillary molar* is generally located midway between the buccal and palatal surfaces and, as a consequence, this furcation could be probed from either the buccal or the palatal aspect of the tooth.

In *maxillary premolars* the root anatomy often varies considerably. The roots may also harbor irregularities such as longitudinal furrows, invaginations or true furcations, which may open at varying distances from the CEJ. Due to the above variations and limited access, the clinical assessment of a furcation involvement in maxillary premolars is often difficult. In some patients, a furcation involvement may, in such teeth, first be identified after the elevation of a soft tissue flap.

Radiographs

Radiographs must always be obtained to confirm findings made during probing of a furcation-involved tooth. The radiographic examination should include both paralleling "periapical" and vertical "bite-wing" radiographs. In the radiographs the location of the interdental bone as well as the bone level within the root complex should be examined (Fig. 39-14). Situations may occur when findings from clinical probing and from the radiographs are inconsistent. Thus, the localized but extensive attachment loss which may be detected within the root complex of a maxillary molar with the use of a probe, will not always appear in the radiograph. This may be due to the superimposition in the radiograph of the palatal root and of remaining bone structures (Fig. 39-15a). In such a case, additional radiographs with different angles of orientation of the central beam should be used to identify bone loss within the root complex (Fig. 39-15b).

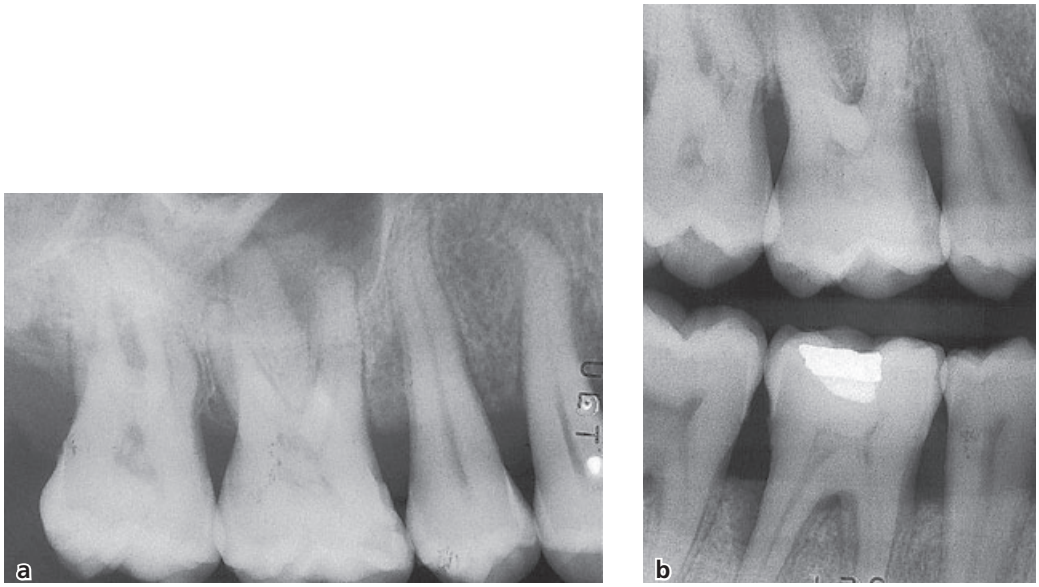

Fig. 39-15 (a) Radiographs of the right maxillary molar region where, with a normal bisecting projection, the furcation defect of the first molar is not evident. (b) It is, however, easily identified in a bitewing radiograph.

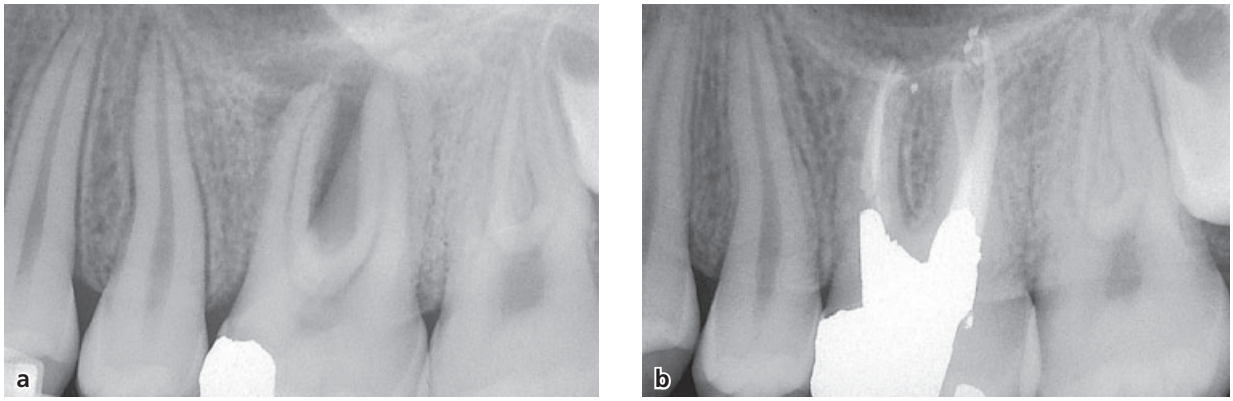

Fig. 39-16 (a) Radiograph demonstrating a destruction of inter-radicular bone and the presence of periapical defects at the mesial and distal roots of a maxillary first molar. (b) Radiographic appearance of complete healing of the inter-radicular and periapical lesions after endodontic treatment.

Differential diagnosis

A lesion in the inter-radicular space of a multi-rooted tooth may be associated with problems originating from the root canal or be the result of occlusal overload. The treatment of a furcation-involved tooth, therefore, should not be initiated until a proper differential diagnosis of the lesion has been made.

Pulpal pathosis may sometimes cause a lesion in the periodontal tissues of the furcation (see Chapter 23). The radiographic appearance of such a defect may have some features in common with a plaque-associated furcation lesion. In order to differentiate between the two lesions the vitality of the affected tooth must *always* be tested. If the tooth is vital, a plaque-associated lesion should be suspected. If the tooth is non-vital, the furcation involvement may have an endodontic origin. In such a case, proper endodontic treatment must *always* precede periodontal therapy. In fact, endodontic therapy may resolve the inflammatory lesion, soft and hard tissue healing may occur and the furcation defect will disappear (Fig. 39-16). If signs of healing of a furcation defect fail to appear within 2 months of endodontic treatment, the furcation involvement is probably associated with marginal periodontitis.

Trauma from occlusion

Forces elicited by occlusal interferences, e.g. bruxers and clenchers (see Chapters 14 and 51), may cause inflammation and tissue destruction or adaptation within the inter-radicular area of a multi-rooted tooth. In such a tooth a radiolucency may be seen in the radiograph of the root complex. The tooth may exhibit increased mobility. Probing, however, fails to detect an involvement of the furcation. In this particular situation, occlusal adjustment must always precede periodontal therapy. If the defects seen

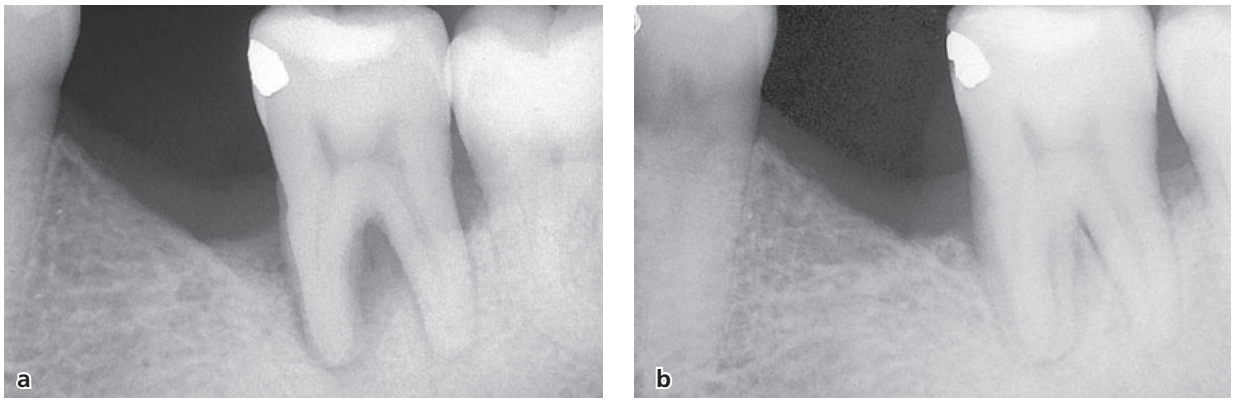

Fig. 39-17 (a) Radiographic appearance of a defect in the furcation area caused by occlusal overload. After occlusal adjustment the interradicular defect spontaneously healed, as documented 6 months after therapy in a radiograph (b). (Courtesy of M. Cattabriga.)

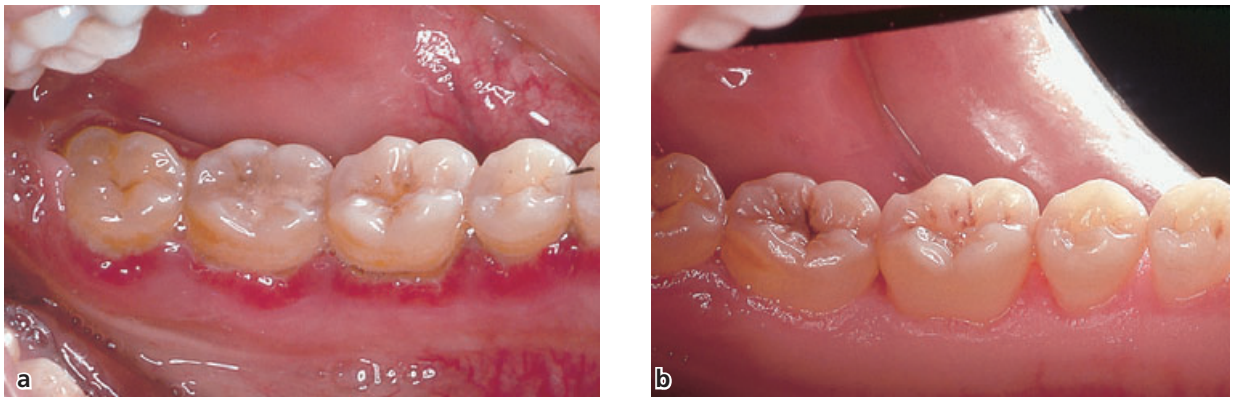

Fig. 39-18 Resolution of inflammatory lesions in the gingiva achieved by scaling, root planing and the re-establishment of a correct tissue morphology in the inter-radicular area of degree I furcation-involved mandibular molars. (a) Before therapy. (b) 6 months after therapy.

within the root complex are of "occlusal" origin, the tooth will become stabilized and the defects disappear within weeks following correction of the occlusal overload (Fig. 39-17).

Therapy

Treatment of a defect in the furcation region of a multi-rooted tooth is intended to meet two objectives:

1. The elimination of the microbial plaque from the exposed surfaces of the root complex.
2. The establishment of an anatomy of the affected surfaces that facilitates proper self-performed plaque control.

Different methods of therapy are recommended:

- Degree I furcation involvement. Recommended therapy: scaling and root planing; furcation plasty.
- Degree II furcation involvement. Recommended therapy: furcation plasty; tunnel preparation; root resection; tooth extraction; guided tissue regeneration at mandibular molars.
- Degree III furcation involvement. Recommended therapy: tunnel preparation; root resection; tooth extraction.

Scaling and root planing

Scaling and planing of the root surfaces in the furcation entrance of a degree I involvement in most situations result in the resolution of the inflammatory lesion in the gingiva. Healing will re-establish a normal gingival anatomy with the soft tissue properly adapted to the hard tissue walls of the furcation entrance (Fig. 39-18).

Furcation plasty

Furcation plasty (Fig 39-19) is a resective treatment modality which should lead to the elimination of the inter-radicular defect. Tooth substance is removed (odontoplasty) and the alveolar bone crest is remodeled (osteoplasty) at the level of the furcation entrance.

Furcation plasty is used mainly at buccal and lingual furcations. At approximal surfaces access is

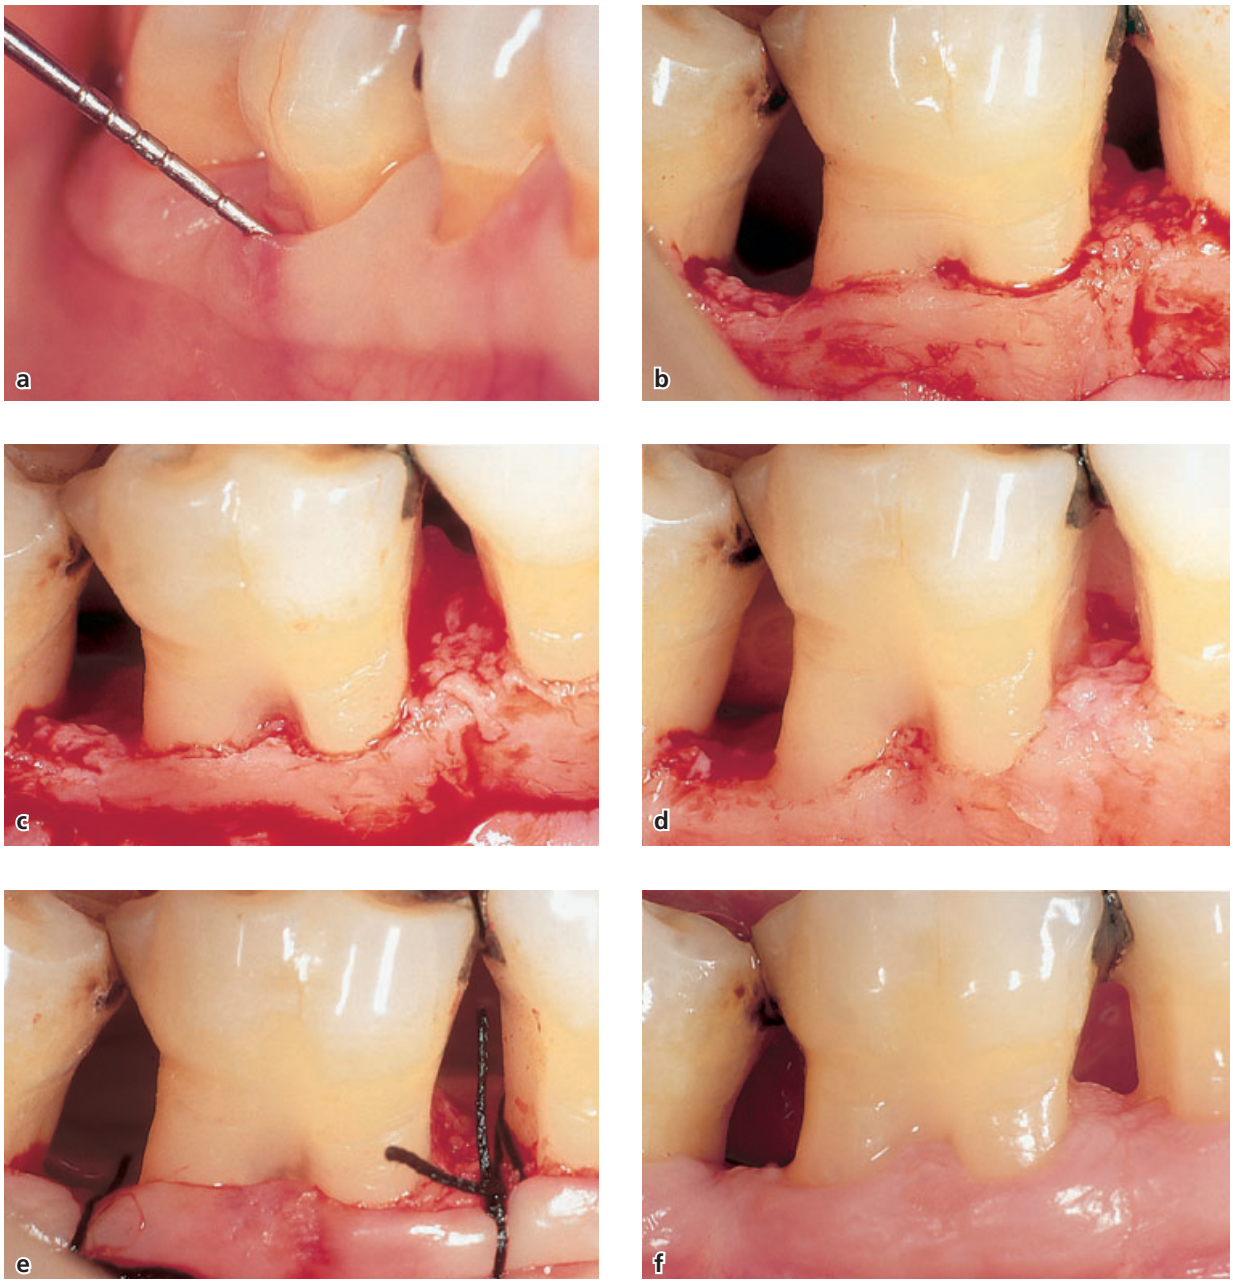

Fig. 39-19 Furcation plasty performed at the buccal aspect of a mandibular molar. (a) Initial degree II furcation involvement. (b) After flap elevation, removal of the granulation tissue and scaling of the exposed root surfaces. (c) After odontoplasty. (d) After osteoplasty. (e) Apical position of the flap managed by periosteal sutures. (f) Healing resulting in the elimination of the furcation defect and in the establishment of a proper soft tissue morphology.

often too limited for this treatment. Furcation plasty involves the following procedures:

- The dissection and reflection of a soft tissue flap to obtain access to the inter-radicular area and the surrounding bone structures.
- The removal of the inflammatory soft tissue from the furcation area followed by careful scaling and root planing of the exposed root surfaces.
- The removal of crown and root substance in the furcation area (odontoplasty) to eliminate or reduce the horizontal component of the defect and to widen the furcation entrance.
- The recontouring of the alveolar bone crest in order to reduce the buccal–lingual dimension of a bone defect in the furcation area.
- The positioning and the suturing of the mucosal flaps at the level of the alveolar crest in order to cover the furcation entrance with soft tissue. Following healing a "papilla-like" tissue should close the entrance of the furcation.

Care must be exercised when odontoplasty is performed on vital teeth. Excessive removal of tooth structure will enhance the risk for increased root sensitivity.

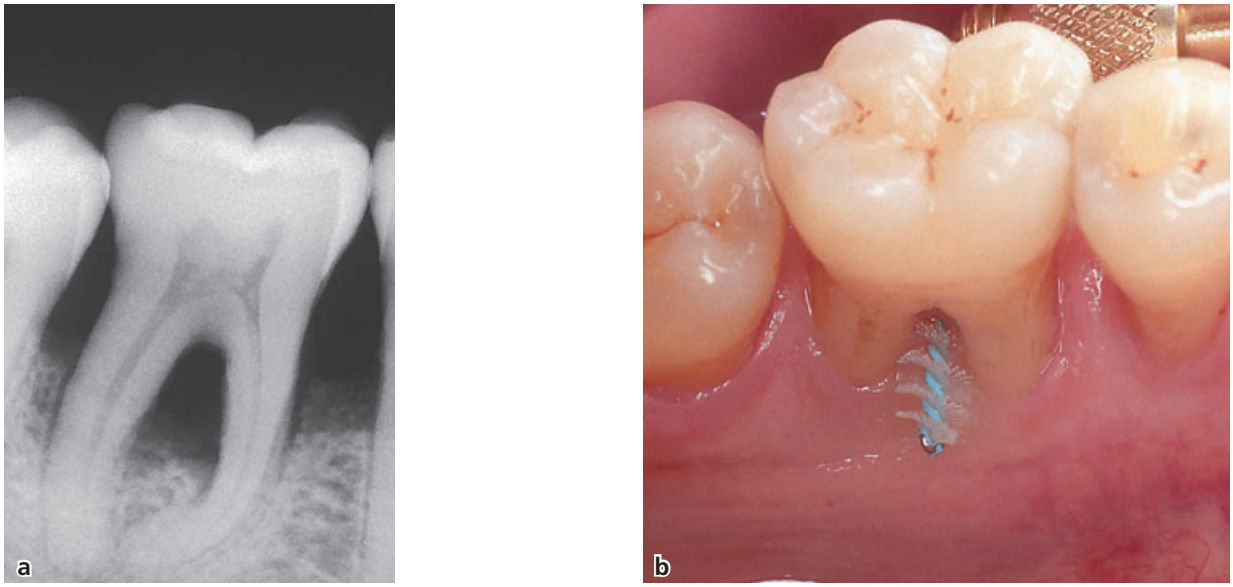

Fig. 39-20 Tunnel preparation of a degree III-involved mandibular molar. Radiograph (a) and photograph (b) showing a wide inter-radicular space where self-performed plaque control can be obtained by the use of an interproximal brush.

Tunnel preparation

Tunnel preparation is a technique used to treat deep degree II and degree III furcation defects in mandibular molars. This type of resective therapy can be offered at mandibular molars which have a short root trunk, a wide separation angle, and long divergence between the mesial and distal root. The procedure includes the surgical exposure and management of the entire furcation area of the affected molar.

Following the reflection of buccal and lingual mucosal flaps, the granulation tissue in the defect is removed and the root surfaces are scaled and planed. The furcation area is widened by the removal of some of the inter-radicular bone. The alveolar bone crest is recontoured; some of the interdental bone, mesial and distal to the tooth in the region, is also removed to obtain a flat outline of the bone. Following hard tissue resection enough space has been established in the furcation region to allow access for cleaning devices to be used during self-performed plaque-control measures (Fig. 39-20). The flaps are apically positioned to the surgically established inter-radicular and interproximal bone level.

During maintenance the exposed root surfaces should be treated by topical application of chlorhexidine digluconate and fluoride varnish. This surgical procedure should be used with caution, because there is a pronounced risk for root sensitivity and for carious lesions developing on the denuded root surfaces within artificially prepared tunnels (Hamp *et al*. 1975).

Root separation and resection (RSR)

Root separation involves the sectioning of the root complex and the maintenance of all roots. *Root resection* involves the sectioning and the removal of one or two roots of a multi-rooted tooth. RSR is frequently used in cases of deep degree II and degree III furcation-involved molars.

Before RSR is performed the following factors must be considered:

- *The length of the root trunk*. In a patient with progressive periodontal disease a tooth with a *short* root trunk may have an early involvement of the furcation (Larato 1975; Gher & Vernino 1980). A tooth with a short root trunk is a good candidate for RSR; the amount of remaining periodontal tissue support following separation and resection is often sufficient to ensure the stability of the remaining root cone. If the root trunk is *long*, the furcation involvement occurs later in the disease process, but, once established, the amount of periodontal tissue support left apical to the furcation may be insufficient to allow RSR.
- *The divergence between the root cones.* The distance between the root cones must be considered. Roots with a short divergence are technically more difficult to separate than roots which are wide apart. In addition, the smaller the divergence is, the smaller also is the inter-radicular (furcation) space. In cases where the divergence between two roots is small, the possibility of increasing the inter-radicular distance with an orthodontic root movement may be considered (Fig. 39-21). The furcation space may also be increased by odontoplasty performed during surgery. Figure 39-22 illustrates that *odontoplasty* was performed on (1) the distal part of the mesial root and (2) the mesial part of the distal root and deep finishing lines prepared for the subsequent restoration (Di Febo *et al*. 1985).
- *The length and the shape of the root cones*. Following separation, short and small root cones (Fig. 39-23)

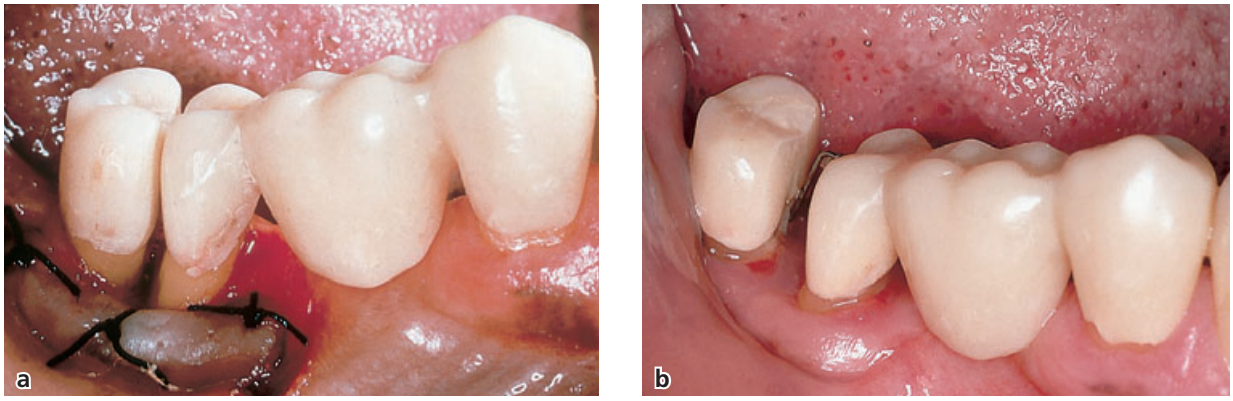

Fig. 39-21 Effect of orthodontic treatment of a separated mandibular molar with a small root divergence. (a) After root separation. (b) 3 months after completion of orthodontic therapy.

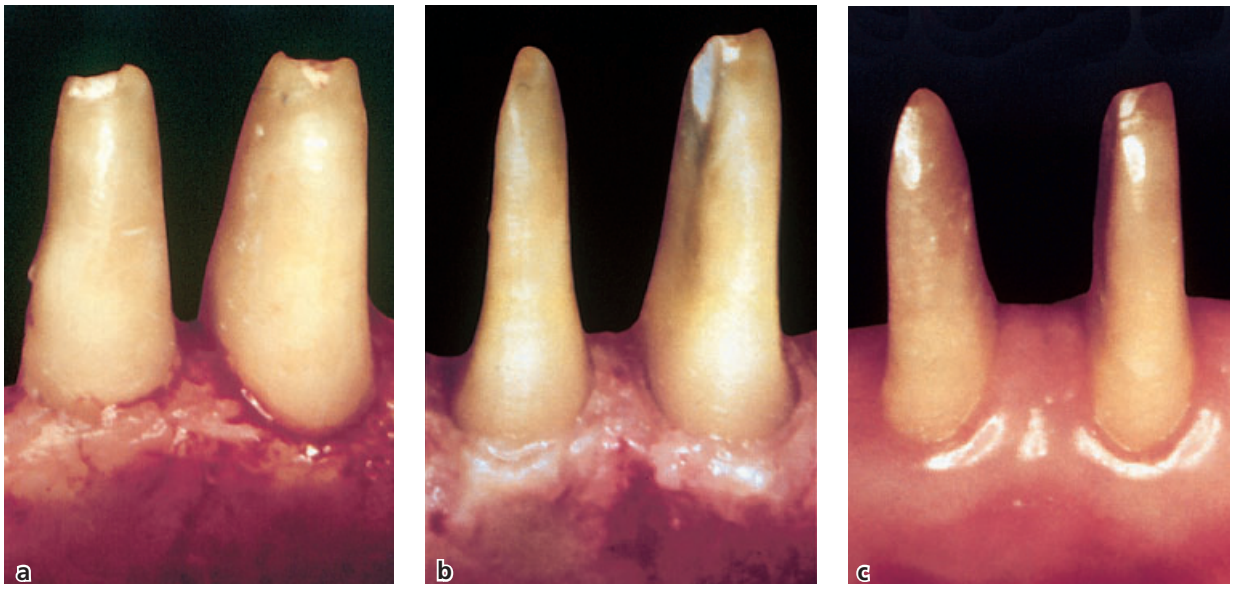

Fig. 39-22 Odontoplasty of a separated mandibular molar performed during surgery to increase the furcation space. After flap elevation and exposure of the alveolar bone, it is evident that the distance between the two roots is small (a). By preparing the inter-radicular surfaces during surgery (b) the furcation space is increased and is sufficient for self-performed plaque control measures (c).

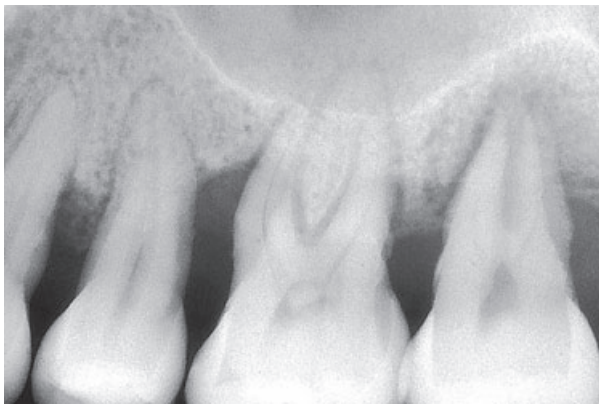

Fig. 39-23 Radiograph showing maxillary molars with thin, short, and conical roots.

tend to exhibit an increased mobility. Such roots, in addition, have narrow root canals which are difficult to ream. Short and small roots consequently should be regarded as poor abutments for prosthetic restorations.

- *Fusion between root cones*. When a decision has been made to perform RSR, it is important that the clinician first determines that the cones within the root complex are not fused. This is generally an uncomplicated diagnostic problem for mandibular molars or for the buccal furcation of maxillary molars (Fig. 39-24). At such teeth the separation area between the roots can easily be identified both with the probe and in a radiograph. It is more difficult to identify a separation line between mesio-buccal (or disto-buccal) and palatal roots of a maxillary molar or maxillary first premolar with a narrow root complex. In such situations, a soft tissue flap must often be raised to allow the operator to get proper

access to the approximal tooth surfaces. The mesial (or distal) entrance of the furcation must be probed to a depth of 3–5 mm to ascertain that a fusion does *not* exist between the roots scheduled for RSR.

- *Amount of remaining support around individual roots.* This should be determined by probing the entire circumference of the separated roots. It should be observed that a localized deep attachment loss at one surface of one particular root (e.g. on the buccal surface of the palatal root, or the distal surface of the mesio-buccal root of a maxillary molar) may compromise the long-term prognosis for an otherwise ideal root.
- *Stability of individual roots*. This must be examined following root separation. Rule of thumb: the more mobile the root cone is, the less periodontal tissue support remains.
- *Access for oral hygiene devices*. After completion of therapy the site must have an anatomy which facilitates proper self-performed tooth cleaning.

Maxillary molars

General example

Several decisions must be made when RSR is planned for a furcation-involved maxillary molar. Since such teeth have three root cones, one or two cones may be retained after separation. Different treatment alternatives exist. They are listed in Table 39-1.

Prior to RSR, the morphology of the individual roots as well as the surface area of each root must be carefully analyzed.

The *disto-buccal root* of a maxillary molar (1) is the shortest of the three roots; (2) the root trunk is comparatively long. Thus, the distal root has a small quantity of bone support and once separated, the cone may exhibit increased mobility. The disto-buccal root is, therefore, often removed as part of RSR (Rosenberg 1978; Ross & Thompson 1980).

The *mesio-buccal root* has (1) a wide buccopalatal dimension, (2) an hour-glass cross section, and therefore a large root surface area. In fact, the mesio-buccal cone often has a total root surface area that is equal to or greater than that of the palatal root cone. The mesio-buccal root (1) is located centrally in the alveolar process, (2) is properly aligned with the maxillary premolars and is in an ideal position to function as a separate unit (Fig. 39-25). For these reasons, the mesio-buccal root may be preferred for retention when the clinician is selecting between the mesio-buccal or palatal root. It should be remembered, however, that the root canals of the mesio-buccal root are narrow and more difficult to treat than the single and wide canal of the palatal root.

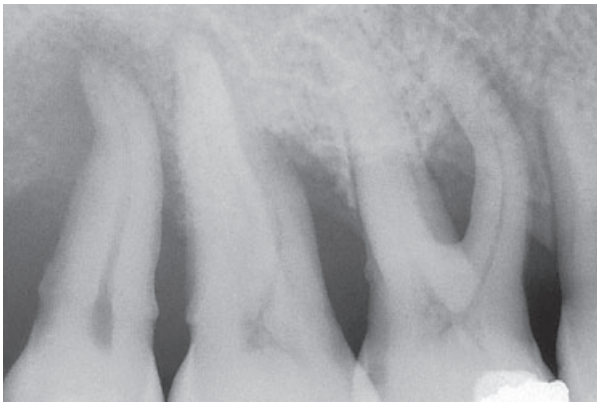

Fig. 39-24 Radiograph indicating the presence of a degree III involvement of the buccal furcation of the maxillary first molar. This tooth is a candidate for root resection.

Fig. 39-25 Occlusal view of a restoration using the mesial root of a maxillary first molar as abutment. Note the alignment of the mesial root and the adjacent premolars.

Table 39-1 Root resective treatment possibilities in molars with furcation involvement

Furcation involvement	Root resection	Root resection plus separation of the remaining roots
1 Buccal	Mesio-buccal, disto-buccal	
Mesial	Mesio-buccal, palatal	
Distal	Disto-buccal, palatal	
2 Buccal & distal	Disto-buccal, mesio-buccal & palatal	Palatal
Buccal & mesial	Mesio-buccal, disto-buccal & palatal	Palatal, disto-buccal
Mesial & distal	Palatal, mesial & disto-buccal	Distobuccal

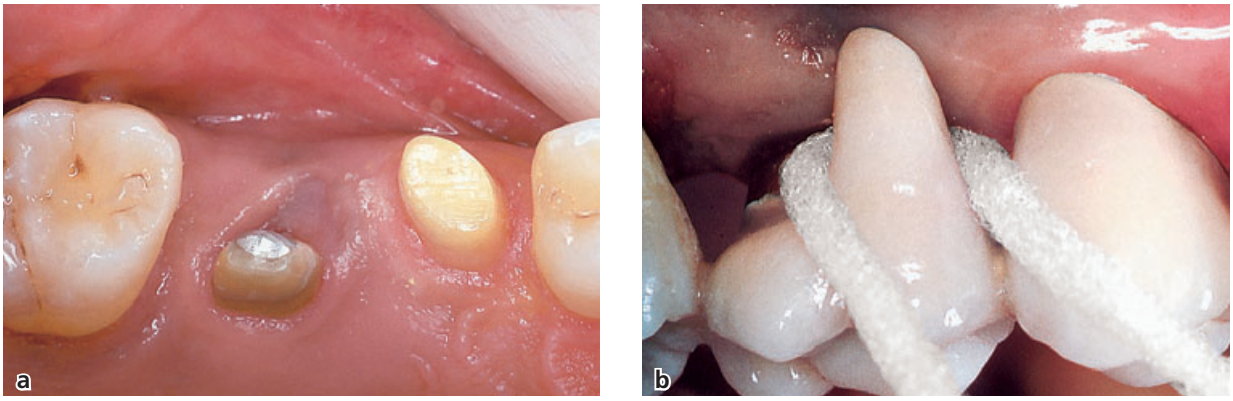

Fig. 39-26 (a) Palatal root of a root-resected maxillary molar serving as a single abutment for a crown restoration. (b) A mesio-buccal root was included in the restoration for esthetic reasons.

The tissue destruction in the furcation area often causes deep attachment and bone loss at the distal palatal surface of the mesio-buccal root. In such situations the palatal root remains as the only candidate for retention (Fig. 39-26).

The series of illustrations presented in Fig. 39-27 demonstrates two left maxillary molars (teeth 26 and 27) with degree III involvement of all six furcation entrances. Both teeth were, following a detailed examination and diagnosis, scheduled for treatment with RSR. Note that in this case the second premolar was missing. In cases of advanced periodontal disease at maxillary molars, it is often necessary to separate all three roots of the individual tooth to obtain access to the inter-radicular area for assessment of the height of the remaining bone at (1) the buccal surface of the palatal root and (2) the palatal surfaces of the buccal roots. Figure 39-27b illustrates the two maxillary molars with all six roots separated. Because of anatomic considerations and increased mobility, the distobuccal roots of 26 and 27 were extracted (Fig. 39-27c). The palatal root of the first molar had a deep area of localized attachment loss on its buccal surface, was considered to be a poor candidate for a bridge abutment, and was extracted. The mesio-buccal root of the first molar as well as the mesio-buccal and palatal roots of the second molar (27) were stable and exhibited moderate probing depth. It was anticipated that at all three roots the anatomy would allow proper plaque control following healing after treatment. The three roots were maintained (Fig. 39-27d). Figure 39-27e shows the area after 3 months' healing and Fig. 39-27f illustrates the segment properly restored. Since in this segment one premolar was missing, the mesio-buccal root of the first molar was used as second premolar in the prosthetic reconstruction and the two roots of the second molar served as abutments for a crown restoration in the position of a molar.

Maxillary premolars

Root resection of maxillary first premolars is possible only in rare instances due to the anatomy of the root complex (Joseph *et al*. 1996) (Fig. 39-28). The furcation of this premolar is often located at such an apical level that the maintenance of one root serves no meaningful purpose. In most cases, therefore, the presence of a deep furcation involvement of degree II or degree III in a maxillary first premolar calls for tooth extraction.

Mandibular molars

If RSR must be applied in a furcation-involved mandibular molar, three treatment alternatives exist:

1. Separate the two roots, but maintain both roots (premolarization)
2. Separate and extract the mesial root
3. Separate and extract the distal root.

In some situations, both roots may be maintained following separation. If one root is to be removed, the following facts must be considered:

- The *mesial* root has a significantly greater root surface area than the distal root. The mesial root, however, has an hour-glass-shaped cross section which may be difficult to manage (1) in the self-performed plaque control and (2) in the restorative procedure. In addition, the mesial root frequently has two narrow root canals. The root canals are often close to the external root surface. This may complicate root preparation during the subsequent restorative treatment.
- The *distal* root has an oval cross section and, as a rule, only one, wide root canal. The distal root is: (1) comparatively large, providing a greater mass of dentin to resist root fracture (Langer *et al*. 1981); and (2) a good candidate for pin or post placement. Further, when the resected mandibular molar is a terminal abutment for a bridge, the retention of the distal root will result in a longer dental arch than would be the case had the mesial root been retained (Fig. 39-29).

Fig. 39-27 The sequential stages of root resection of two maxillary molars with degree III involvement. (a) Radiograph showing the pre-RSR situation. (b)The roots were separated before flap elevation. (c,d) The distal roots of both molars and the palatal root of the first molar were extracted and the teeth prepared. (e) After 3 months of healing. (f) The final prosthetic restoration of the site.

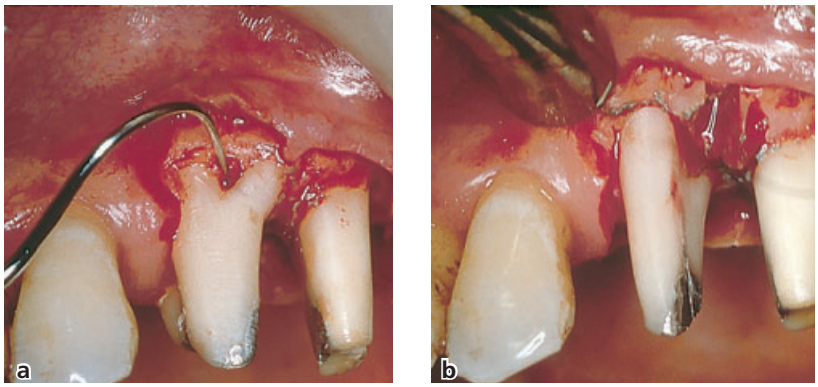

Fig. 39-28 Resection of the disto-buccal root of a three-rooted maxillary first premolar.

Sequence of treatment at RSR

Once anatomic and pathologic characteristics of the root complex(es) of multi-rooted teeth have been documented, treatment should follow a logical plan (see also Chapter 31).

Endodontic treatment

If the tooth to be resected is vital or if an improper root canal filling was placed in a non-vital tooth, RSR starts with endodontic therapy. Rubber dam can be placed, and optimal conditions thus be established for the important management (cleaning and shaping) of the root canal. The structural integrity of the root must be maintained and minimal amounts of root dentin should be removed (Fig. 39-30a,b). Direct filling with amalgam or chemically cured composite of the endodontically treated tooth should be performed before RSR (Fig. 39-30c). Each root should have individual retention for a restoration which should not break or detach during RSR, removal and relining of the provisional restorations, impressions, and prosthetic try-in. Endocanal posts or endodontic screws are used only if natural retention needs improvement.

Fig. 39-29 Results of the root resection of a mandibular first molar of which the distal root was retained.

Occasionally, a furcation involvement may first be identified during periodontal surgery. In this emergency situation RSR may be completed but the root canal entrance(s) of the remaining root(s) must be properly sealed. Definitive root canal therapy must be completed within 2 weeks (Smukler & Tagger 1976).

Provisional restoration

Alginate impressions of the area to be treated are taken and sent to the laboratory together with a wax record of the intercuspal position. A provisional restoration is prepared.

Root separation and resection

Root separation and root resection may be performed as part of the preparation of the segment for prosthetic rehabilitation ("prosthetic preparation"), i.e. prior to periodontal surgery (Carnevale *et al*. 1981). During the prosthetic preparation it is important to *avoid*

- Exposing the interradicular bone to undue mechanical trauma (Fig. 39-31)
- Leaving behind parts of the furcation fornix (Fig. 39-32)
- Perforating the root canals
- Preparing the vertical surfaces of the remaining roots with sharp angles (Fig. 39-33).

Situation 1: *mandibular molar*. Following separation, both roots are maintained. The distal surface of the distal root and the mesial surface of the mesial root must be prepared parallel to each other to increase the retention for a subsequent restoration. The mesial surface of the distal root and the distal surface of the mesial root should be prepared with diverging angles to increase the space available between the separated roots (Fig. 39-34).

Situation 2: *maxillary molar*. Following separation, the disto-buccal root was extracted. The distal surface of the crown is prepared with a bevel cut and in such

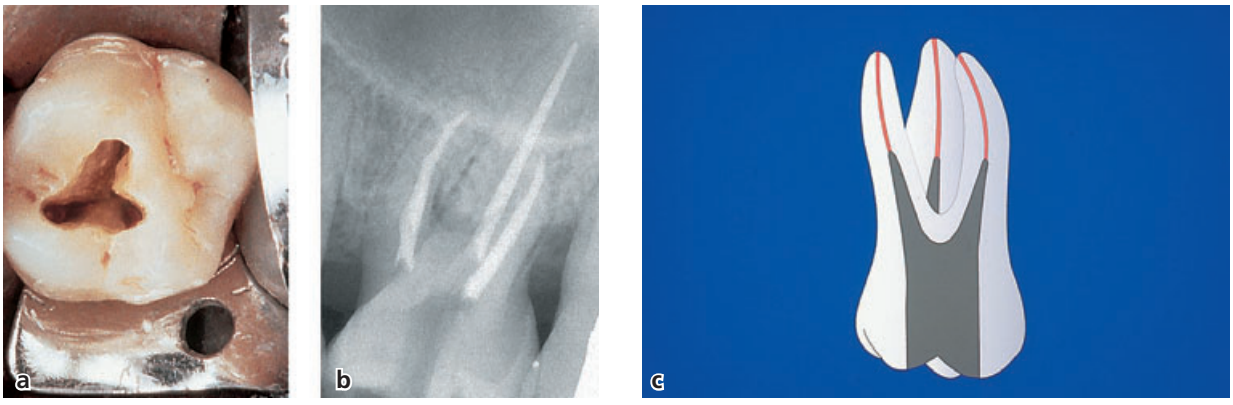

Fig. 39-30 Combined photograph and radiograph showing the "conservative" approach both regarding the access to the pulp chamber (a) and the shaping and filling of the root canal system (b). (c) Schematic illustration showing the temporary restoration of the endodontically treated tooth.

a way that the concave curvature (in apicocoronal direction) is eliminated (Fig. 39-35). If the mesio-buccal and the palatal roots of this molar must be separated but maintained, it is important that the buccal surface of the mesio-buccal root and the palatal surface of the palatal root are prepared parallel to each other. This will enhance the retention of the subsequent restoration. The palatal surface of the mesio-buccal root and the buccal surface of the palatal root must be prepared at diverging angles to increase the space available between the separated roots (Fig. 39-36). At this stage the provisional restoration is relined with cold cured acrylic and cemented after RSR.

Fig. 39-31 Radiograph illustrating the damage which occurred to the inter-radicular septum during root separation.

Periodontal surgery

Following flap elevation, osseous resective techniques are used to eliminate angular bone defects that may exist around the maintained roots. Bone resection may also be performed to reduce the buccolingual dimension of the alveolar process of the extraction site. The remaining root(s) may be prepared with a bevel cut to the level of the supporting bone (Levine 1972; Ramfjord & Nissle 1974; Carnevale *et al*. 1983). This additional preparation may serve the purpose of (1) eliminating residual soft and hard deposits and (2) eliminating existing undercuts to facilitate the final impression (Fig. 39-37). The provisional restoration is relined. The margins of the provisional restoration must end ≥3 mm coronal of the bone crest. The soft tissue flaps are secured with sutures at the level of the bone crest. The relined provisional restoration is cemented and a periodontal dressing is applied to cover the surgical area. The dressing and the sutures are removed 1 week later. The roots are debrided and a new dressing applied. After another week, the dressing is finally removed

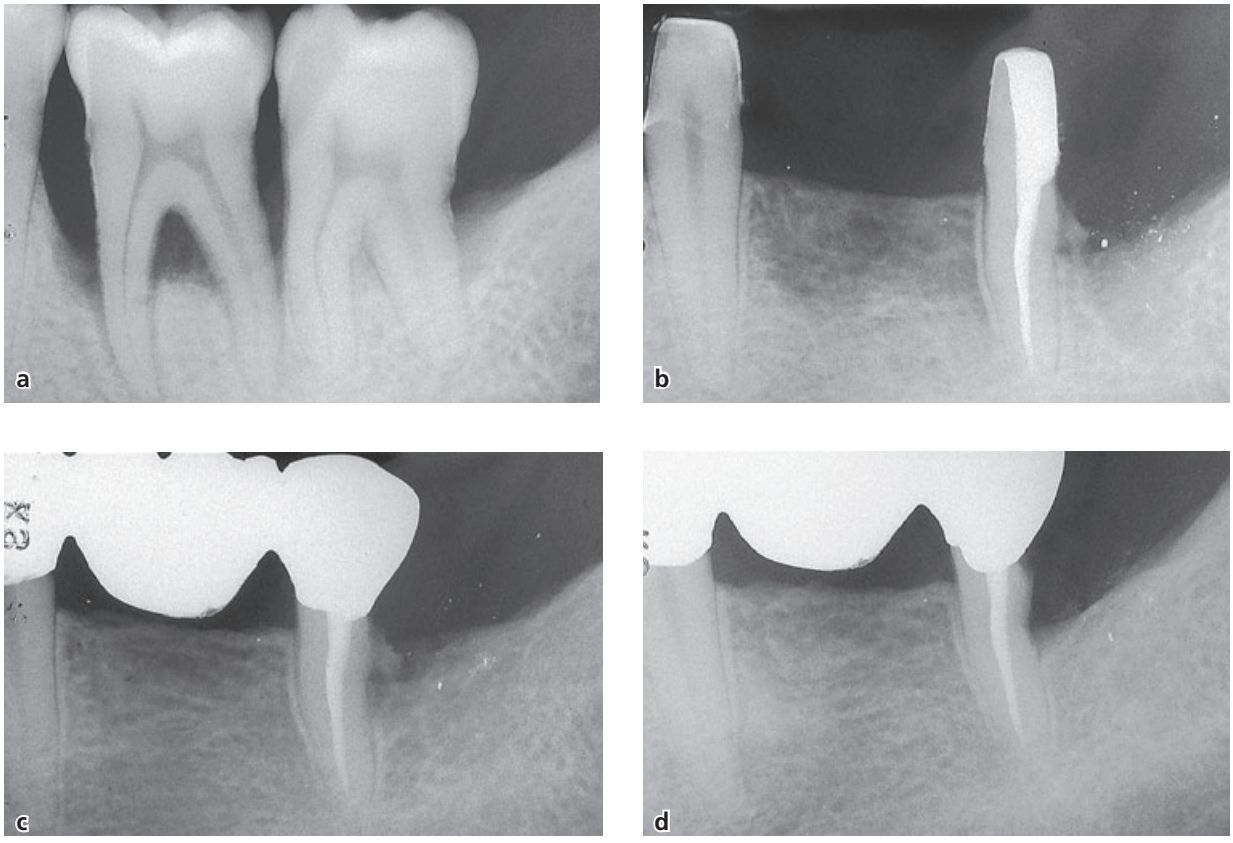

Fig. 39-32 (a) Radiographs of a mandibular first molar to be extracted and of a second molar to be root resected. (b) During hemisection an overhang is left behind as a result of an oblique sectioning of the tooth distal to the furcation. (c) In a radiograph obtained 2 years later, the presence of an angular bony defect can be seen adjacent to the "overhang". The lesion was resolved and the angular defect disappeared following removal of the "overhang". (d) Radiograph after 2 years.

Fig. 39-33 Maintenance of the two fused buccal roots of a maxillary first molar. The buccal roots were separated from the palatal root. Note the rounded line angles and the wide space created between the separated roots.

Fig. 39-34 Mandibular molar after root separation. Note the diverging angle of preparation performed to increase the inter-radicular space between the mesial and distal roots and the parallel approximal surfaces.

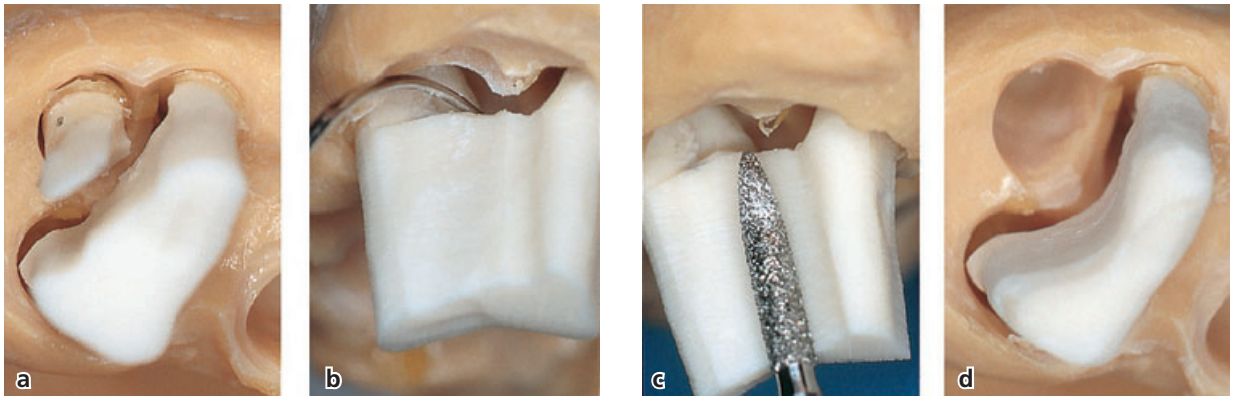

Fig. 39-35 (a,b) The sequential stages of root resection and extraction of the distal root of a maxillary molar. In order to minimize the concave outline of the cut surfaces, the sectioning should be performed with a straight line cut. (c, d) After extraction of the distal root, the furcation area of the remaining roots must be re-prepared to eliminate undercuts.

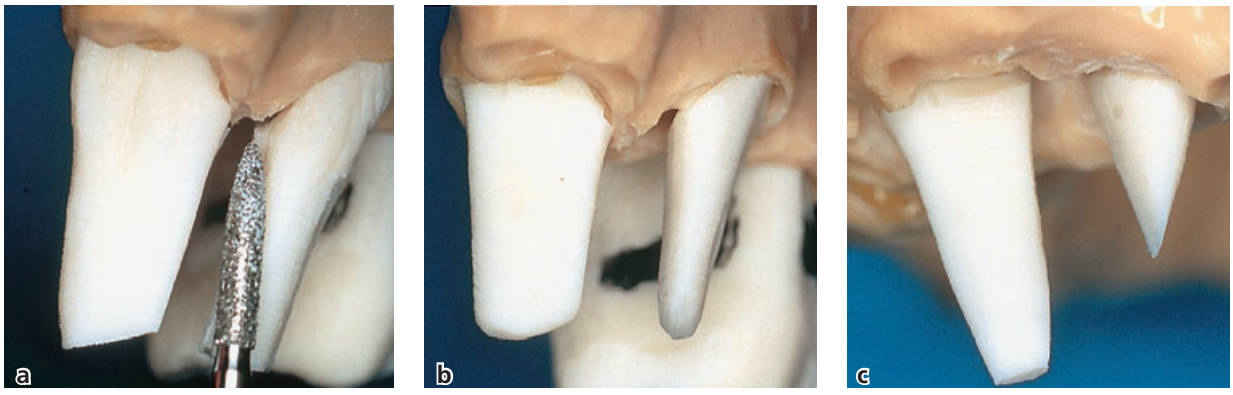

Fig. 39-36 (a,b) Preparation, during separation, of the mesio-buccal and palatal roots after the disto-buccal root of a maxillary molar had been extracted. The internal (furcation) surfaces of the two roots should be prepared with diverging angles to increase the inter-radicular space, while the external surfaces of the two roots should be prepared parallel to each other to increase the subsequent retention of the restoration. (c) When the palatal surface of the palatal root is not prepared parallel to the buccal surface, the palatal abutment will become shortened and not self-retentive.

Fig. 39-37 (a,b) Sequential stages of root resection at maxillary first and second molars. The extraction of the distal root of the first molar was performed during tooth preparation and prior to the insertion of the provisional restoration. (c,d,e) During the surgical procedure, after flap elevation, the furcation-involved second molar was separated, the mesial and palatal roots were extracted and the osseous defects were eliminated. (f) Healing with the definitive prosthetic restoration in place.

and the patient instructed in proper plaque-control techniques.

Final prosthetic restoration

Since the prosthetic preparation of the roots was completed during surgery, the clinician concerns him-/herself only with minor adjustments. The preparation margins are located supragingivally, which improves the precision of the definitive crown restoration. The framework of the restoration must be rigid to compensate for the compromised abutments (roots) with a compromised periodontal tissue support. The occlusion should be designed to minimize the infliction of lateral deflective forces (see Chapter 51) (Fig. 39-38).

Regeneration of furcation defects

The possibility of regenerating and closing a furcation defect has been investigated (see Chapter 43). Following an early case report publication (Gottlow *et al*. 1986), where histologic documentation of new attachment formation in human furcation defects (Fig. 39-39) treated by "guided tissue regeneration" (GTR) therapy was provided, the results of several investigations on this form of treatment in furcation-

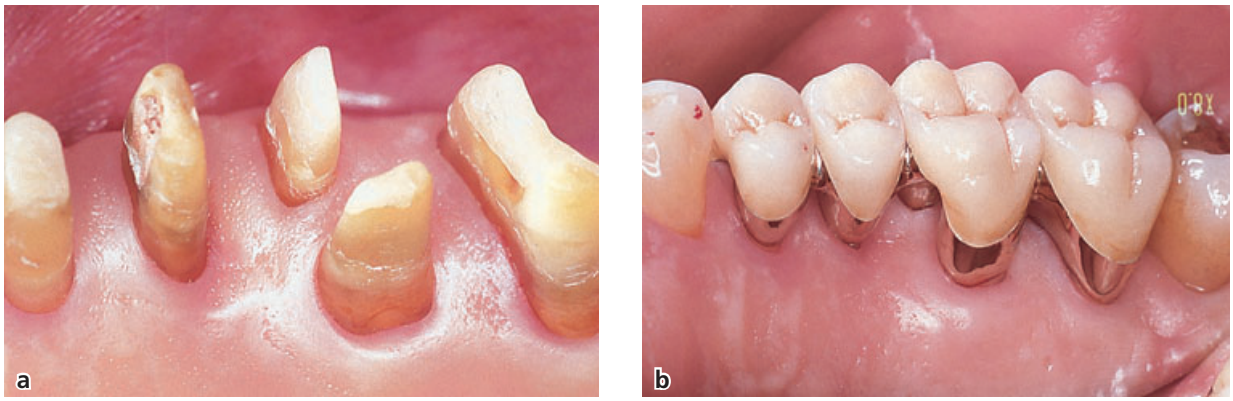

Fig. 39-38 (a) Soft tissue healing at a separated maxillary first molar and at a root-resected second molar. (b) The final prosthetic restoration in place with the occlusion designed to minimize the lateral stresses on the roots left as abutments.

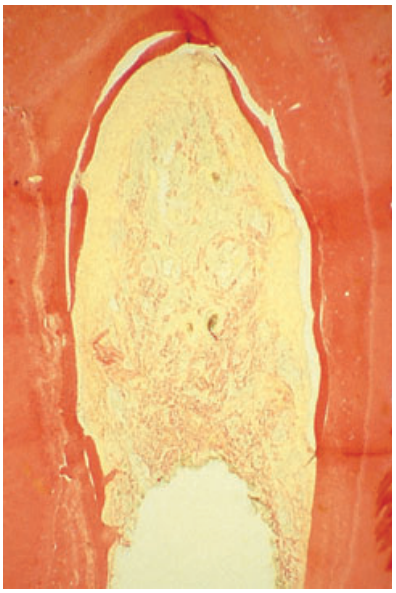

Fig. 39-39 Histologic mesiodistal section of a previous degree II furcation involvement of a human mandibular molar, treated with GTR. The section demonstrates that the newly formed cementum covers the entire circumference of the furcation defect.

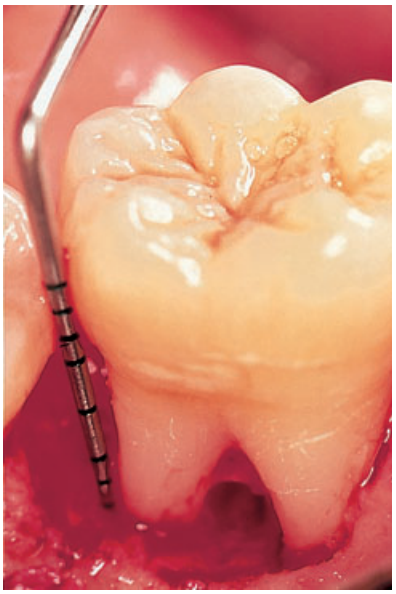

Fig. 39-40 Position of the furcation fornix in relation to the level of the supporting bone and attachment apparatus in a lingual degree II furcation-involved mandibular molar.

involved teeth have been presented. In these reports, a reasonably predictable outcome of GTR therapy was demonstrated only in degree II furcation-involved mandibular molars, where a clinical soft tissue closure or a decreased probing depth of the furcation defect was recorded (Pontoriero *et al*. 1988; Lekovic *et al*. 1989; Caffesse *et al*. 1990).

Less favorable results have been reported when GTR therapy was used in other types of furcation defects such as degree III furcation-involved mandibular and maxillary molars (Pontoriero *et al*. 1989; Pontoriero & Lindhe 1995a) and degree II furcations in maxillary molars (Metzeler *et al*. 1991; Pontoriero & Lindhe 1995b).

The reason for the limited predictability of GTR therapy in furcation-involved teeth may be related to several factors:

- The morphology of the periodontal defect, which in the root complex often has the character of a "horizontal lesion". New attachment formation is hence dependent on coronal upgrowth of periodontal ligament tissue (Fig. 39-40).
- The anatomy of the furcation, with its complex internal morphology, may prevent proper instrumentation and debridement of the exposed root surface (Fig. 39-41).
- The varying and changing location of the soft tissue margins during the early phase of healing with a possible recession of the flap margin and early exposure of both the membrane material and the fornix of the furcation (Fig. 39-42).

GTR treatment could be considered in dentitions with isolated degree II furcation defects in mandibular molars. The predictability of this treatment outcome improves following GTR therapy if:

- The *interproximal* bone is located at a level which is close to the CEJ of the approximal surface. This "key-hole" type of degree II involvement allows for an effective retention of the membrane material and retention also of the position of the coronally placed flap margins (Fig. 39-43).
- The debridement of the exposed root surfaces in the furcation area is comprehensive. Since the width of the furcation entrance and the internal morphology of the inter-radicular area may limit the access of curettes for proper debridement, the removal of hard and soft bacterial deposits from the root surfaces must frequently be made with ultrasonic instruments, rotating, flame-shaped fine diamond burs, and endodontic files (Fig. 39-44).
- The membrane material is properly placed and a "space" between the tooth and the material

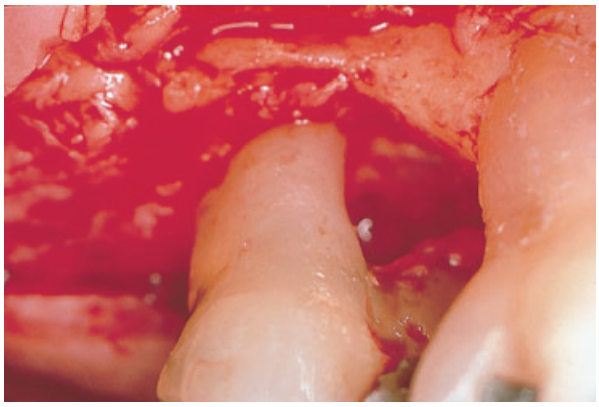

Fig. 39-41 Internal morphology of the furcation of a maxillary molar. Note the invagination of the palatal root.

Fig. 39-42 Exposure of the membrane and of the furcation entrance as a consequence of recession of the flap margin. The photograph is taken at 3 weeks of healing after GTR treatment of a degree II buccal furcation of a mandibular molar.

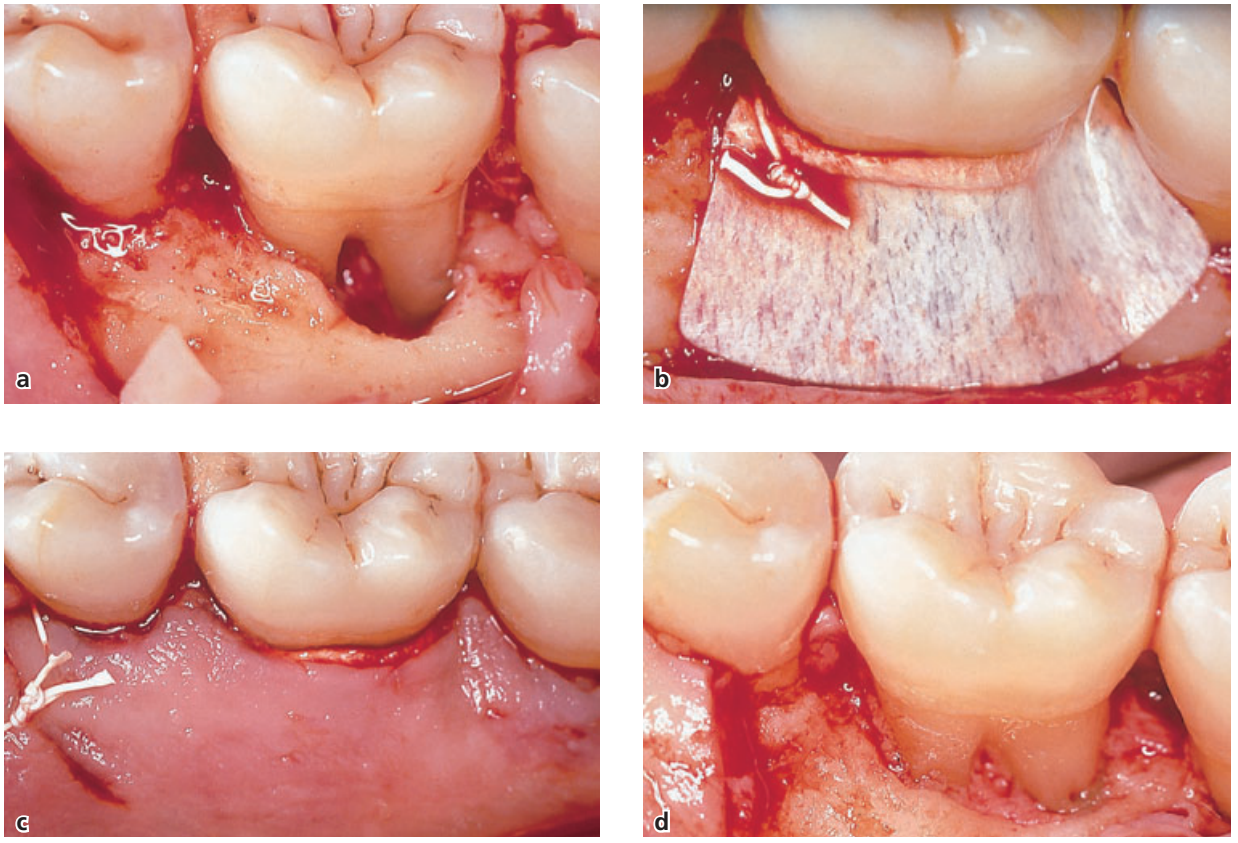

Fig. 39-43 Aspect of a lingual degree II furcation involvement in a mandibular first molar. (a) Note the infrabony component of the defect and the level of the approximal supporting bone in relation to the furcation fornix. (b) The Teflon membrane sutured in position and supported by the interproximal alveolar bone. (c) The flap positioned and sutured over the membrane. (d) At re-entry, after 6 months of healing, the previously exposed furcation defect was closed and filled with bone tissue.

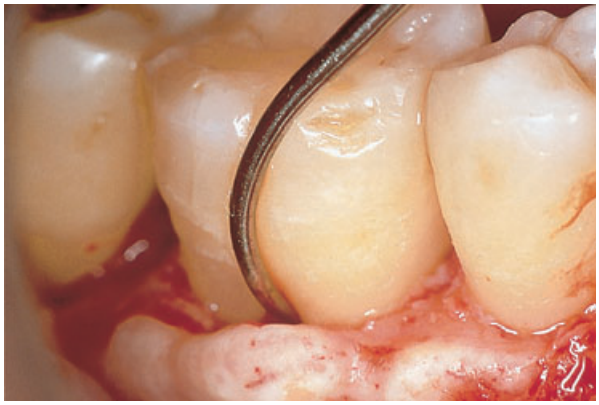

Fig. 39-44 Phase of debridment of a buccal degree II furcation defect by the use of an "extra-fine" ultrasonic tip.

established. A "primary" wound closure is thereby obtained, blood clot protection will occur, and recession of the soft tissue margin during the early phase of healing will be minimized (Fig. 39-45).

- A plaque-control program is put in place. This should include daily rinsing with a chlorhexidine solution and professional tooth cleaning once a week for the first month, and once every 2–3 weeks for at least another 6 months of healing following the surgical procedure.

Enamel matrix proteins included in a commercially available product (Emdogain®; Straumann, Basel, Switzerland) were used in the treatment of furcation defects in experimental studies in animals (Araùjo & Lindhe 1998) and in clinical trials in humans (Jepsen *et al*. 2004; Meyle *et al*. 2004). The ability of Emdogain® (EMD), applied to the root surfaces in the furcation area, to stimulate periodontal regeneration in surgically created degree III furcation defects in dogs was documented histologically by Araùjo and Lindhe (1998). In a multicenter randomized controlled clinical trial, including 45 subjects with 45 paired mandibular molars with buccal degree II furcation involvements, Jepsen *et al*. (2004) compared the EMD with GTR therapy. After 14 months of healing, the subjects were re-examined. The authors reported a mean reduction in the open horizontal furcation depth of 2.8 mm for EMD-treated sites and of 1.8 mm for GTR-treated defects. In addition the frequency of complete closed furcation defects was higher for EMD sites (8/45) than for GTR sites (3/45). It was concluded that both treatment modalities resulted in significant clinical improvements although the EMD method provided (1) greater reduction of the furcation depths, (2) a smaller incidence of post-operative pain/swelling, and (3) less gingival recession (Meyle *et al*. 2004) as compared to GTR therapy.

The outcome of the regenerative procedures at furcation-involved molars should result in the complete elimination of the defect within the interradicular space in order to establish anatomic conditions which facilitate optimal self-performed plaque-control measures. In fact, partial gain of clinical attachment levels within the furcation defect, although statistically significant, will not necessarily improve the site's accessibility for plaque-control measures.

Extraction

The extraction of a furcation-involved tooth must be considered when the attachment loss is so extensive that no root can be maintained or when the treatment will not result in a tooth/gingival anatomy which allows proper self-performed plaque-control measures. Moreover, extraction can be considered as an alternative form of therapy when the maintenance of the affected tooth will not improve the overall treatment plan or when, due to endodontic or caries-related lesions, the preservation of the tooth will represent a risk factor for the long-term prognosis of the overall treatment.

The possibility of substituting a furcation-involved tooth with an osseointegrated implant should be considered with extreme caution and only if implant therapy will improve the prognosis of the overall treatment (see Chapter 32). In fact, the implant alternative has obvious anatomic limitations in the maxillary and mandibular molar regions.

Prognosis

Several studies have evaluated the long-term prognosis of multi-rooted teeth with furcation involvement that were treated in accordance with the principles described in this chapter (Table 39-2). In a 5-year study, Hamp *et al*. (1975) observed the outcome of treatment of 175 teeth with various degrees of furcation involvement in 100 patients. Of the 175 teeth, 32 (18%) were treated by scaling and root planing alone, 49 (28%) were subjected, in addition to scaling and root planing, to furcation plasty which included odonto- and/or osteoplasty. In 87 teeth (50%) root resection had been carried out and in seven teeth (4%) a tunnel had been prepared. At the completion of the active phase of therapy the patients were enrolled in a maintenance program which included a recall visit every 3–6 months. The plaque and gingivitis scores assessed immediately after treatment and once a year during maintenance indicated that the patients' oral hygiene was of high quality. None of the teeth treated was lost during the 5 years of study. Only 16 furcation sites exhibited probing depths exceeding 3 mm. During the observation period carious lesions were detected in 12 surfaces of the 32 teeth which had been treated by scaling and root planing, in three surfaces of the 49 teeth subjected to furcation plasty, in five surfaces of the

78 root-resected teeth, and in four surfaces of the seven teeth where a tunnel was prepared.

The results of this study were basically confirmed in a more recent investigation (Hamp *et al*. 1992). In this 7-year study, the authors followed 100 patients with 182 furcation-involved teeth. Out of the 182 furcation-involved teeth, 57 had been treated by scaling and root planing only, 101 were treated by furcation plasty, and 24 were subjected to root resection or hemisection. No tunnel preparation was performed. After the active phase of therapy, the patients were enrolled in a meticulous maintenance care program including recall appointments once every 3–6 months. During the course of the study, more than 85% of the furcations treated with scaling root planing alone, or in conjunction with furcation plasty, maintained stable conditions or showed signs of improvement. Only one tooth and one mesial root of a mandibular molar were extracted among the root-resected or hemisected teeth.

Carnevale *et al*. (1998), in a 10-year prospective controlled clinical trial, demonstrated a 93% survival rate of root resected furcation-involved teeth and a 99% survival rate of non-furcation-involved teeth.

More recently, Svärdström (2001) presented the results of a retrospective analysis on factors influencing the decision-making process regarding the treatment for 1313 molars with furcation involvement in 222 patients and the outcome of the treatment decisions after 8–12 years (mean 9.5 years) of regular maintenance care. The treatment options included were: tooth extraction, root separation/resection, and maintenance of the tooth with non-surgically/surgically performed scaling and root planing with or without furcation plasty. Of the 1313 furcation-involved molars, 366 (28%) were extracted during the active phase of therapy. The decision for tooth extraction was primarily influenced by factors such as tooth mobility, tooth position, absence of occlusal antagonism, the degree of furcation involvement, probing depth, and the amount of remaining periodontal support. Out of the 685 molars with furcation involvement and the 160 patients that were available for the follow-up examination 8–12 years after treatment, 47 teeth were root separated/resected and 638 teeth were considered to be maintainable after a non-surgical or conservative surgical therapy.

The factor found to have the strongest influence for the decision to perform root separation/resection was the degree of furcation involvement (degree II and III). Tooth position, probing depth, and tooth mobility were also factors of statistical significance. The author explained that other factors such as endodontic conditions, root anatomy, and overall treatment strategy may also have influenced the choice of treatment. The long-term outcome of the treatment decisions made for furcation-involved molars showed a favorable survival rate for both root resective (89%)

Table 39-3 Factors to consider in treatment of furcation-involved molars

Tooth-related factors
Degree of furcation involvement
Amount of remaining periodontal support
Probing depth
Tooth mobility
Endodontic conditions and root/root-canal anatomy
Available sound tooth substance
Tooth position and occlusal antagonisms
Patient-related factors
Strategic value of the tooth in relation to the overall plan
Patient's functional and esthetic demands
Patient's age and health conditions
Oral hygiene capacity

and non-resective (96%) therapy options in patients included in a proper maintenance care program. Of the 47 root separated/resected teeth, only five (11%) were lost during the 9.5 years of follow-up. Of the 638 molars initially considered to be maintainable by a non-resective treatment, 21 teeth (3.5%) were extracted and three teeth were root resected.

Conclusion

In treatment decisions for furcation-involved molars, it must be realized that there is no scientific evidence that a given treatment modality is superior to the others (Table 39-3).

Chapter 40

Endodontics and Periodontics

Gunnar Bergenholtz and Gunnar Hasselgren

Introduction

Inflammatory lesions of the attachment apparatus of teeth involve a variety of etiologies other than plaque accumulations in the dentogingival region; these require attention in diagnosis and treatment planning processes. In fact, signs and symptoms, seen as typical of periodontitis, such as pocket probing depths, loss of attachment, increased tooth mobility, pain, swellings and suppurations, may reflect several tooth-associated infections including infections of endodontic origin (here termed endodontic lesion), infections initiated and maintained by iatrogenic root perforations, vertical root fractures, and external root resorption.

Differentiating between inflammatory disease conditions of the periodontium is not normally a thorny exercise. This is because symptoms of periodontitis usually affect several teeth in the dentition and are confined to the marginal periodontium. Other tooth-associated infections, by contrast, are usually isolated to a single tooth and display rather typical clinical and radiographic signs. These conditions can nevertheless produce confusing clinical expressions and lead to misinterpretation of their cause, especially when affecting teeth in dentitions diseased by periodontitis. Diagnostic difficulties particularly arise when lesions appear deep down the lateral aspects of roots in what can be designated a marginal–apical communication. These so-called "endo–perio lesions" present the clinician with exceptional challenges in that the origin and thus the proper course of treatment are not readily revealed. An "endo–perio lesion", as the term implies, involves a condition where both the pulp and the periodontium are diseased simultaneously in what appears to be a single periodontal lesion. However, a complicating factor is that the process may be of periodontal origin in its entirety and may have caused the death of the pulp in the process or the lesion may just be a representation of a root canal infection alone. Hence, determination of causality is crucial in these cases not only to avoid unnecessary and possibly detrimental treatment, but also to assess whether the disease condition stands a reasonable chance of being successfully treated.

To guide clinical decision making on diagnosis and treatment of inflammatory lesions in the periodontium, the focus of this chapter is on various tooth-associated disorders that display similar signs and symptoms to periodontitis. Specifically addressed are the clinical presentations and the means by which endodontic infections and infections associated with root perforations, root fractures, and root resorptions can be identified and distinguished from manifestations of periodontitis. Management principles will be given where appropriate. Non-infectious processes *viz.* developmental cysts and tumors, which also can interfere with the supporting tissues, will not be discussed in this chapter.

Infectious processes in the periodontium of endodontic origin

General features

Disease conditions of the dental pulp are for the most part infectious in nature and involve inflammatory processes. Caries, restorative procedures, and traumatic injuries are common etiologies (see Chapter 23). In fact, any loss of hard tissue integrity of teeth, exposing dentin or the pulp directly to the oral environment, may allow bacteria and bacterial elements to adversely affect the normally healthy condition of the pulp. The resulting inflammatory lesion will then be directed towards the source of irritation and be confined for as long as the inflammatory defense does not collapse and convert into a major destructive breakdown of the pulpal tissue. Consequently, inflammatory alterations in the vital pulp will not normally produce lesions in the adjoining periodontium that can be detected by clinical means. Yet, disruption of the apical lamina dura or widening of the periodontal ligament space can occasionally be observed radiographically (Fig. 40-1a). Teeth, particularly in young individuals with large pulp chambers, may also display minor radiolucent areas either apically or laterally along the root surface at exits of accessory canals and apical foramina or both, in spite of the fact that vital pulp functions prevail (Langeland 1987; Gesi *et al*. 2006). In such cases, typical clinical signs of pulpitis, including spontaneous pain, thermal sensitivity or tenderness to percussion, may or may not be present.

Overt lesions in the periodontium, on the other hand, are common in teeth where the pulp has lost its vitality. In these cases the process is associated either with a non-treated necrotic pulp or a tooth that has been the subject of endodontic treatment. In the latter case, the cause of the lesion is usually to be found in an existing, although not successfully managed, root canal infection (Fig. 40-1b). Extrusion of toxic medicaments and root-filling materials into the periodontium in conjunction with endodontic treatments may also cause periodontal lesions. While severe damage of the periodontal tissue support formerly was a rather common complication following the use of arsenic- or formaldehyde-based preparations to devitalize pulps, medicate, and fill root canals (Fig. 40-2), modern day medicaments for canal irrigation and disinfection as well as materials for root canal filling are comparatively well tolerated (Geurtsen & Leyhausen 1997). However, acute toxic and allergic reactions may be encountered from the use of highly concentrated sodium hypochlorite (Pashley *et al*. 1985) and adverse components of root-filling material (Hensten-Pettersen *et al*. 1985).

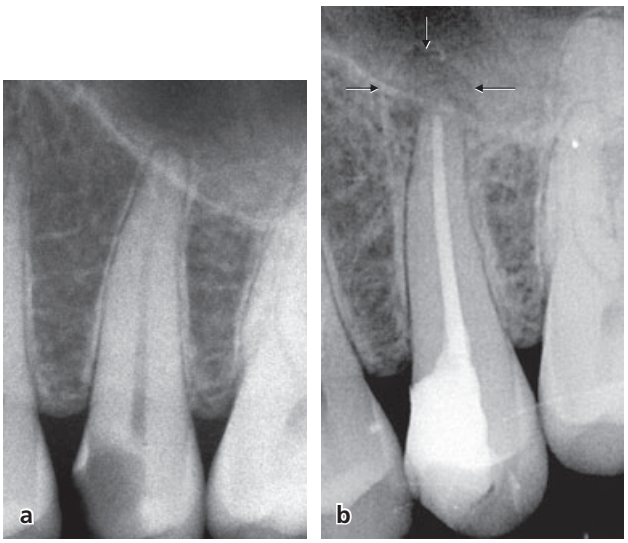

Fig. 40-1 (a) Radiograph of an upper second premolar with caries extending to the vicinity of the pulp. There is loss of lamina dura at the root tip. (b) The 3-year recall radiograph after pulpectomy of the vital pulp and root filling shows a periapical radiolucency suggesting existence of a persistent root canal infection in this case.

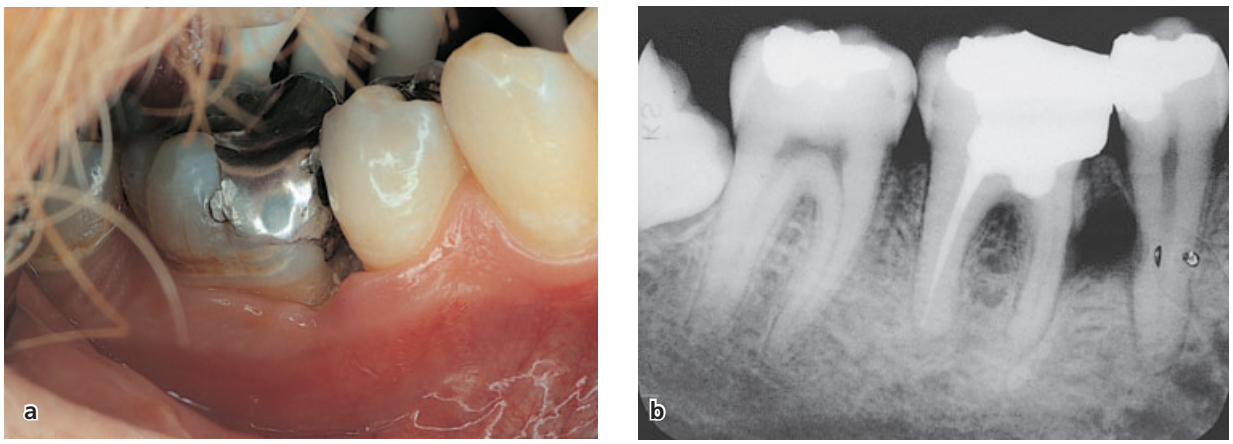

Fig. 40-2 (a) Clinical photograph showing a periodontal defect at the mesial aspect of tooth #46. The pulp had been subjected to devitalization by the use of a paraformaldehyde-containing paste. (b) Leakage of the agent along the temporary filling margins obviously occurred as suggested by the subsequent loss of proximal bone and the emergence of a bone sequestrum.

Conclusion

It is important to realize that as long as the pulp maintains vital functions, although inflamed or scarred, it is unlikely to produce irritants that cause overt periodontal tissue lesions. For clinically significant lesions to occur the pulp must have lost its vitality. Consequently no benefit will normally be gained from extirpation of vital pulps (pulpectomy) as an adjunct or alternative to the treatment of teeth for periodontal disease.

Clinical presentations

Inflammatory lesions in the periodontal tissues, induced and maintained by root canal infection, typically expand around the apex of teeth, where the root canal space interconnects with the periodontium along apical foramina. Lesions develop more seldom in a juxtaposition that is at the lateral aspects of roots (Fig. 40-3) and in furcations of multi-rooted teeth (Fig. 40-4). An important reason is that accessory canals that can mediate the release of bacterial elements from the pulpal chamber are relatively uncommon in cervical and mid-root portions (see Chapter 23). Another important factor is that an intact layer of root cementum blocks potential dissemination of bacteria and their products along the dentinal tubules.

The clinical presentation varies. Lesions can either be in a silent, non-symptomatic state or appear with more or less salient signs of acute infection. In the former case a balanced host–parasite interrelationship has usually been established. The only means to diagnose the condition is then by radiography (Fig. 40-1b). Unless transformed to a cyst, the extension of such non-symptomatic lesions may remain limited and stable over many years. This applies in particular to lesions associated with root-filled teeth, where the persisting root canal infection has assumed a relatively low grade of metabolic activity (see Chapter 23).

Lesions associated with untreated infections of a necrotic pulp or with inadequately treated root canals may any time, either soon after pulp tissue breakdown or after a period of silence, turn into an exacerbating, acute inflammatory process. Exacerbating lesions may also be induced in conjunction with endodontic treatment from over-instrumentation along with extrusion of bacterial organisms and tissue-irritating medicaments. Exudation and pus production dictate the clinical course. Typical symptoms

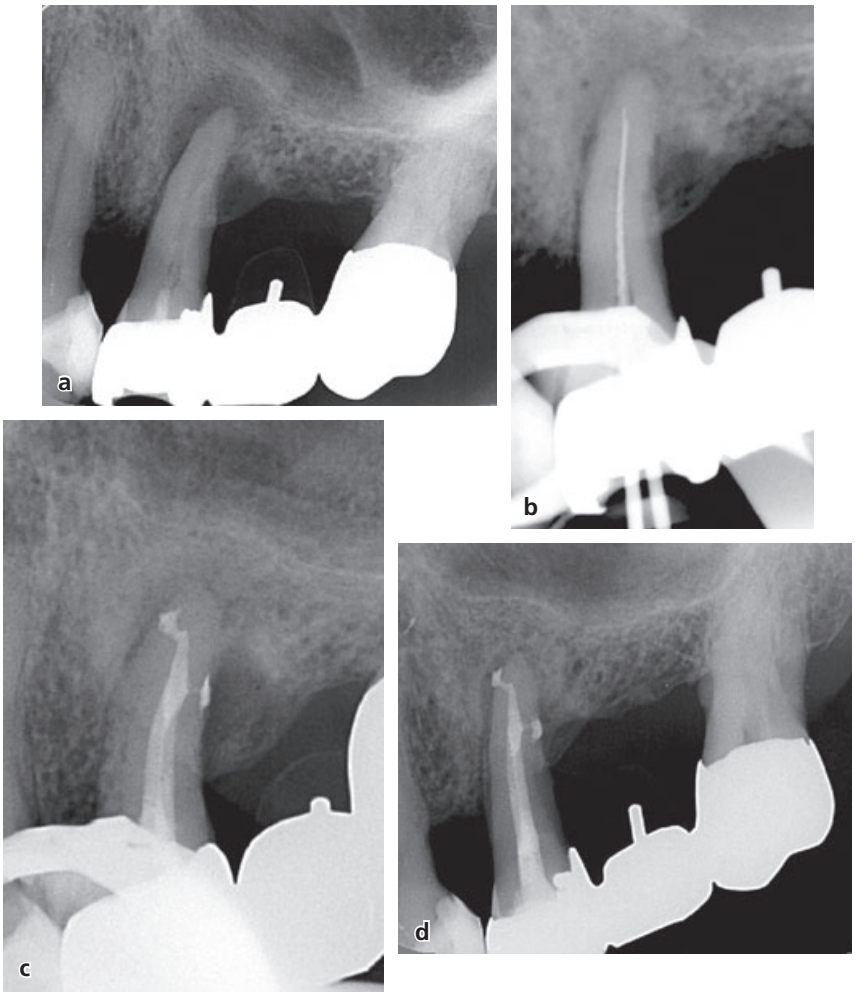

Fig. 40-3 Series of radiographs showing endodontic treatment of an upper premolar included as an abutment in a three-unit bridge. The patient, a 78-year-old male, had been treated and maintained for periodontal disease. (a) There are bone lesions both at the apical and at the distal aspect of the tooth. Following endodontic treatment of the necrotic pulp (b) and root filling (c), an accessory canal communicating with the lateral lesion became evident. (d) The 6-month recall radiograph shows substantial reduction of both bone lesions. Case kindly provided by Dr. Peter Jonasson.

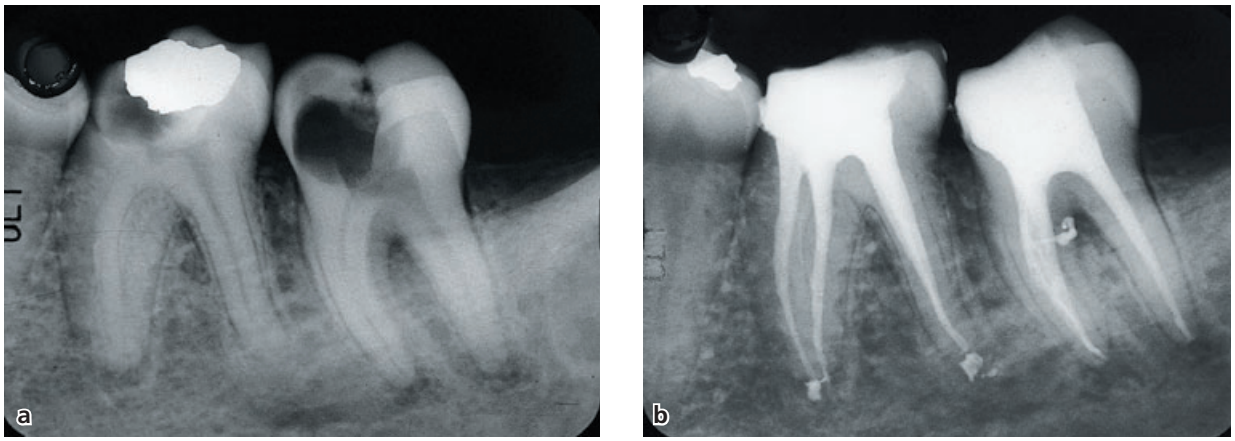

Fig. 40-4 (a) Bone loss of the furcal region in a second left molar in addition to apical bone lesions at both the mesial and the distal roots. (b) Upon endodontic treatment an accessory canal became filled, suggesting that the furcal lesion was of endodontic origin. Case kindly provided by Dr. Pierre Machtou.

include throbbing pain, pain on percussion, tenderness to palpation, increased tooth mobility, and apical as well as marginal swellings. The severity of these symptoms may have escalated successively over a period of time, although a single sign may be the only presenting symptom. It should be noted that the very same symptoms occur with some forms of aggressive periodontitis, iatrogenic root perforation, root fracture, and external root resorption (see below).

The pressure the exudative process exerts results in tissue destruction as a path for drainage is sought. This expansion of the lesion may take a variety of directions. Significant in the context of differential diagnosis to periodontitis are those lesions that drain at or near the gingival margin. The character of the accompanying bone lesion may add to the risk of misdiagnosis, as it may look similar to that of aggressive periodontitis (Fig. 40-5).

Several routes of drainage from an acute endodontic lesion should be recognized (Fig. 40-6):

1. The suppurative process may drain off along the periodontal ligament space and exit at the bottom of the sulcus (Fig. 40-6a). This usually results in only a narrow opening of the fistula into the gingival sulcus/pocket and may not be detected unless careful probing of the sulcus is carried out at multiple sites. Such a sinus tract may readily be probed down to the apex of the tooth, where no increased probing depth otherwise may exist around the tooth. In multi-rooted teeth a sinus tract along the periodontal ligament can drain into the furcation area as it exits along the root surface. The resulting bone lesion may then resemble a "through-and-through" furcation defect from periodontal disease (Figs. 40-7 and 40-8).
2. A periapical abscess can also perforate the cortical bone close to the apex. In this acute stage the soft tissue including the periosteum may be elevated from the bone surface to the extent that a wide opening for drainage of pus is created in the gingival sulcus/pocket area (extraosseous drainage; Fig. 40-6b). Later this route of drainage may develop into in a chronic sinus tract that may remain in or near the sulcus, often at the buccal aspect of the involved tooth. Such a fistula may also emerge following a less aggressive process. It is important to note that this type of drainage is not associated with loss of bone tissue at the inner walls of the alveolus, and that a periodontal probe cannot penetrate into the periodontal ligament space.

Conclusion

Endodontic lesions either do not have overt clinical signs or may present with various acute manifestations of root canal infection. The asymptomatic lesions usually assume a limited extension around the apex, while rapid and extensive destruction that may extend marginally along the attachment apparatus may follow acute exacerbations. Exudation and pus formed in the process may drain off in different directions; pathways along the periodontal ligament space or following penetration of the alveolar bone at the apical region with drainage in or near the gingival sulcus/pocket warrant particular attention from a differential diagnostic point of view. In addition to deep pocket probing depths, the accompanying bone lesion may mimic that of periodontitis.

Distinguishing lesions of endodontic origin from periodontitis

Pulp vitality testing

Differential diagnosis is important because at times endodontic lesions may produce clinical signs and symptoms similar to those of periodontitis. Tools to distinguish the two disease conditions from each

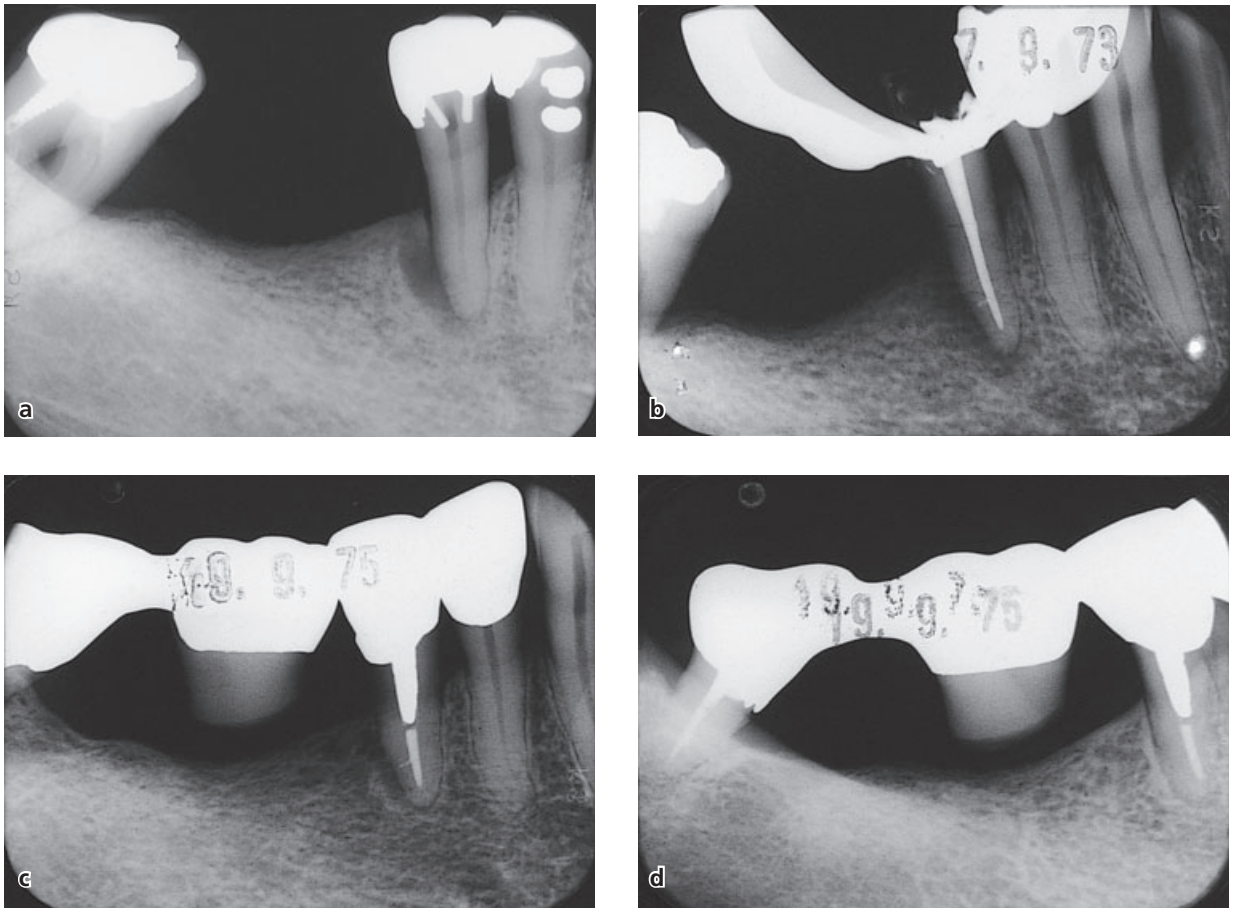

Fig. 40-5 (a) A radiolucent area along the distal root surface of tooth #45 is combined with horizontal loss of marginal bone. (b) As the pulp was non-vital it was subjected to endodontic treatment. After prosthodontic treatment (c) the 2-year recall radiograph (d) shows bone fill in the previous angular defect. Careful examination of the radiographs in (b) and (c) reveals a filled accessory canal communicating with the lateral bone defect.

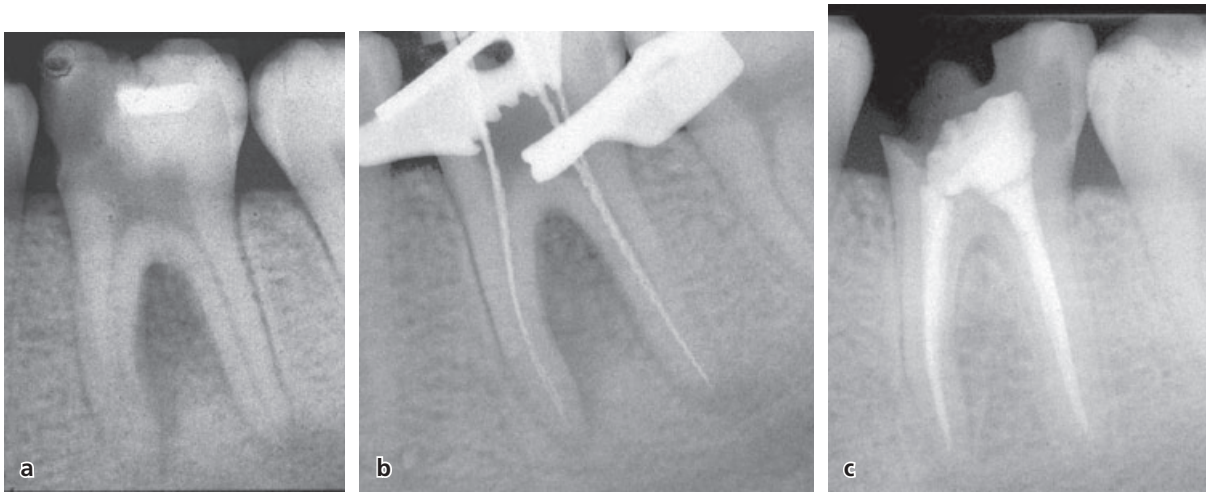

Fig. 40-7 (a) A large radiolucent area is present in the furcal region of a lower left first molar mimicking a furcation involvement caused by periodontal disease. In this case the lesion was of endodontic origin as indicated by the large caries lesion and necrosis of the pulp. (b) Endodontic treatment resulted in complete resolution of the bone lesion as demonstrated by the 18-month follow-up radiograph (c). Case kindly provided by Dr. Kevin Martin.

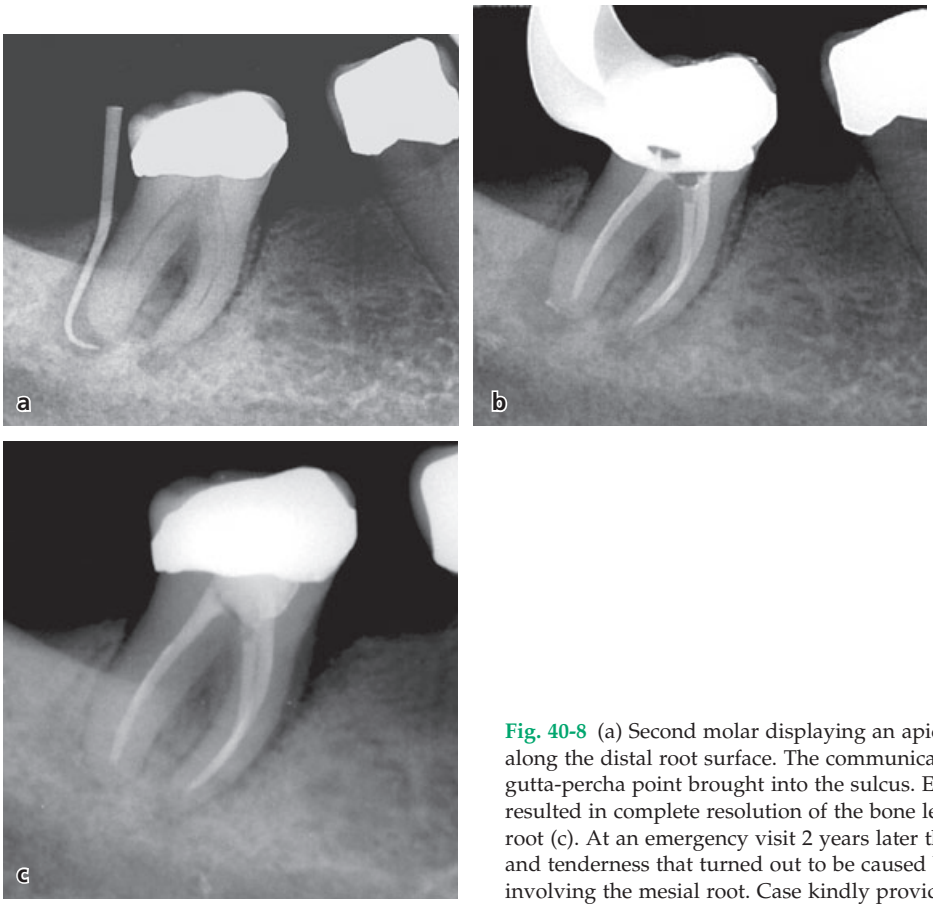

Fig. 40-8 (a) Second molar displaying an apical–marginal communication along the distal root surface. The communication was made visible by a gutta-percha point brought into the sulcus. Endodontic treatment (b) resulted in complete resolution of the bone lesions associated with the distal root (c). At an emergency visit 2 years later the patient complained of pain and tenderness that turned out to be caused by a longitudinal root fracture involving the mesial root. Case kindly provided by Dr. Peter Jonasson.

other, however, are limited as neither the patient's disease history, the clinical presentation nor the character of the radiographic signs invariably are clear-cut. As an endodontic lesion of clinical significance in this context cannot emerge unless the tissue has turned necrotic and become infected, determination of pulp vitality is a most important measure in cases where an endodontic etiology is suspected. Endodontic lesions associated with root-filled teeth are discussed separately, below.

Pulp vitality implies that the tissue has an intact neurovascular supply to support cell and tissue functions. Although a vital pulp may be inflamed or display a variety of degenerative changes, the vasculature is still functioning in a vital pulp. Most methods of determining pulp vitality act by stimulating the

pulp's sensory nerve function and presume that the provocation of a sharp pain sensation indicates a vital pulp. This means that in reality the *sensibility* of the pulp is tested rather than the *vitality* of it. However, there is ample documentation to support the concept that a tooth which responds to sensory stimuli has vital pulp functions. Conversely, if a tooth does not respond, the pulp may be non-vital (Petersson *et al*. 1999; Peters *et al*. 1994; Pitt Ford & Patel 2004). Means to detect blood flow within the pulp by non-invasive methods, for example by laser light scattering, have been developed and tested, but have so far gained limited clinical application (see review by Pitt Ford & Patel 2004).

Caution should be exercised in interpreting sensibility tests as findings can reflect both false-positive and false-negative readings (Mumford 1964; Petersson *et al*. 1989; Peters *et al*. 1994; Pitt Ford & Patel 2004). A combination of different test methods should be employed to ensure correct diagnosis, especially in doubtful cases. Also the equipment and the results should be tested for reliability by comparing results from tests of neighboring and contralateral teeth. No test has so far been advanced, which can identify the disease status of the pulp in other terms than vital or non-vital.

Testing non-restored or minimally restored teeth in dentitions affected by periodontitis can usually be successfully conducted by mechanical, thermal, and electric stimulation. Common methods utilize hydrodynamic forces to stimulate nociceptive mechanoreceptors at the pulp–dentin border, primarily the fast conducting A-delta fibers. Useful techniques include direction of a jet of compressed air against an exposed root surface, scratching such surfaces, use of a rubber wheel to generate frictional heat, and various cold tests; all intended to elicit movement of dentinal fluid. Highly effective and reliable are carbon dioxide snow (Fulling & Andreasen 1976) and dichlorodifluoro-methane sprayed on a cotton pledge. Boiling points of these two agents are at –72°C and –50°C, respectively. For this reason patients should be cautioned prior to application that an intense pain response might be elicited. Clues can also be obtained with less potent means such as ice sticks and ethyl chloride as well as heated gutta-percha sticks (for review see Pitt Ford & Patel 2004).

In dubious cases, mechanical and thermal provocation should be supplemented with electric pulp testing. Units are available which provide a read-out value of the voltage or micro-current being applied to generate the pain response. This function is important so that the test result can be repeated and compared for assessment of patient reliability. Electric pulp testing is technique sensitive and therefore warrants extra precaution to avoid leakage of current to the gingiva and neighboring teeth. To avoid this problem, the test should only be carried out on cleaned and dry teeth isolated from saliva and adjacent teeth with pieces of rubber dam placed in the tooth contacts (Fig. 40-9). The test further requires that the tooth electrode be provided with proper conducting medium and applied directly on to enamel or dentin.

Fig. 40-9 Demonstration of proper tooth isolation to avoid leakage of current during pulp sensibility testing with an electric pulp tester.

Cases with extensive restorations and crowned teeth present special challenges as none of the normal test procedures are useful. Unless tooth substance can be reached underneath the restoration with a good margin to the gingiva, the restoration must be pierced to the extent that the test procedure can be conducted in a so-called test cavity. Even then a false-negative response can be obtained as extensive hard tissue repair may have developed in the pulp from previous disease and cutting traumas thus attenuating the stimulus.

Three cases are described below to illustrate the significance of pulp vitality testing in the process of distinguishing endodontic lesion from periodontitis. The cases demonstrate, in addition, that diagnostic entities such as location, form, and extension of radiolucencies, clinical symptoms of pain or swelling, and increased probing depths may not serve as precise diagnostic signs.

The clinical photograph in Fig. 40-10a shows swelling of the marginal gingiva on the buccal aspect of tooth #11. The swelling had been preceded by severe throbbing pain for a few days. Radiographic examination (Fig. 40-10b) disclosed the presence of an angular bone defect that involved the apical portions of the tooth. In this case the pulp clearly responded sensible on testing, indicating that the pathologic condition was not of endodontic origin. Pocket debridement was combined with irrigation with 0.2% chlorhexidine digluconate solution and systemic administration of an antibiotic. The lesion healed rapidly. Seven months following treatment new bone had formed around the apex and in the defect along the mesial root surface (Fig. 40-10c). In this case, therefore, the periodontal lesion was a manifestation of periodontal disease.

In Fig. 40-11a the radiograph taken of the lower front teeth demonstrates bone loss associated with

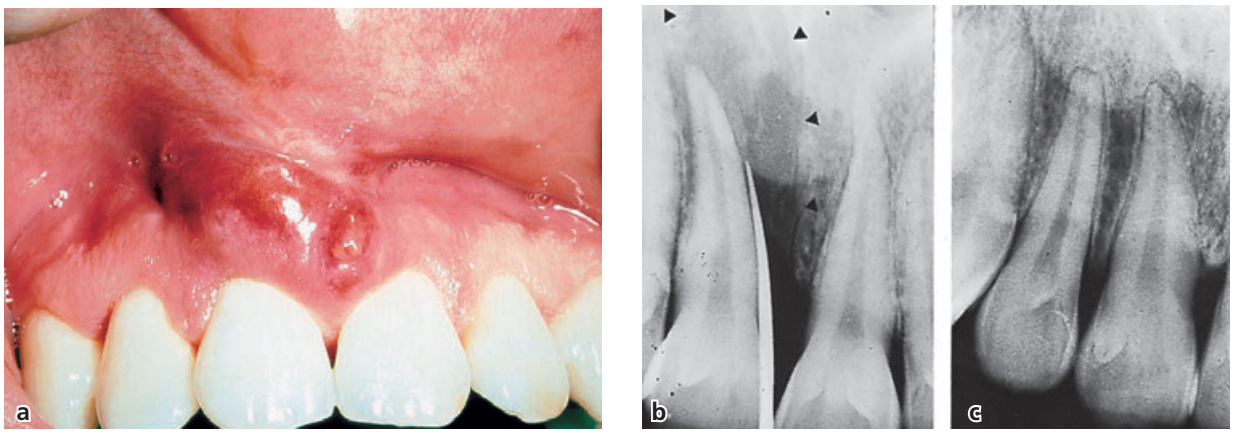

Fig. 40-10 (a) Gingival swelling at the buccal aspect of tooth #11. (b) There is advanced destruction of alveolar bone along the mesial aspect of the root (arrowheads). Following periodontal treatment bone lesion resolved. Case kindly provided by Dr. Harald Rylander.

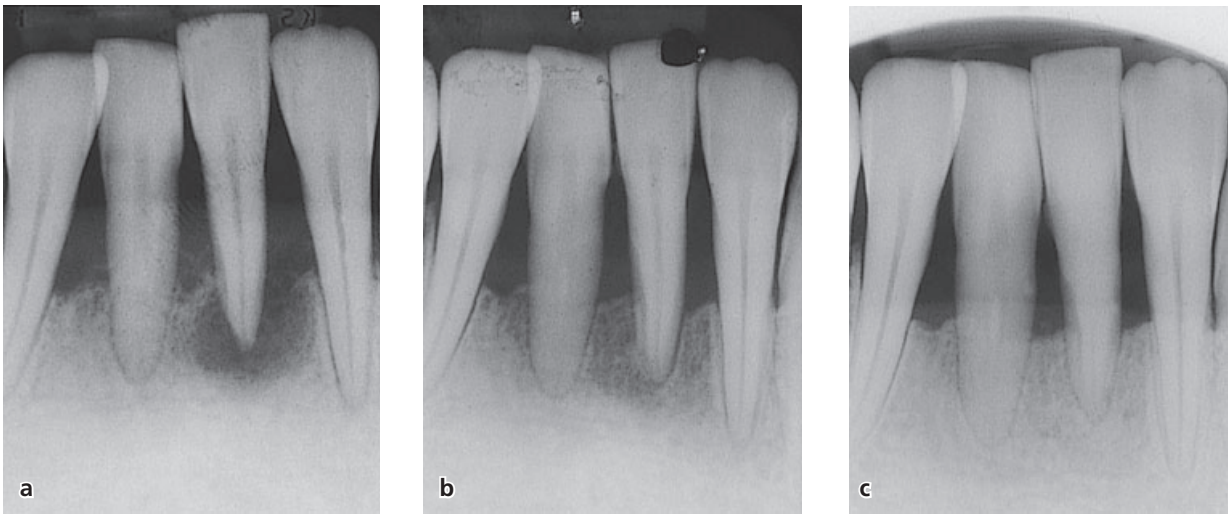

Fig. 40-11 Advanced bone destruction of alveolar bone including an angular bone defect simulating an endodontic periapical lesion around the root tip of tooth #31. The pulp responded vital on testing and the tooth was therefore not subjected to endodontic therapy but to periodontal treatment only. For further case history see the text. Case kindly provided by Dr. Ingvar Magnusson.

the apex of tooth #31 in addition to a generalized horizontal loss of alveolar bone in this young individual. The form and extension of the apical radiolucency around tooth #31 suggests an endodontic lesion. Clinically, a deep periodontal pocket could be probed along the disto-buccal aspect of the root. The patient had been on a recall program after treatment for periodontal disease and had previously shown excellent gingival conditions. Sensibility tests by cold and electricity indicated vital pulp. Therefore, endodontic treatment was not performed. On elevating a mucoperiosteal flap an angular bone defect was found at the buccal aspect of the root without involvement of the root tip. The wound area was debrided along with scaling of the root surface. Rapid bone fill followed surgery without undertaking any adjunctive measures to support tissue regeneration (Fig. 40-11b). The pulp maintained its vitality, although later the root canal became obliterated by hard tissue, most likely as a consequence of the surgical trauma (Fig. 40-11c). The apically positioned radiolucency in Fig. 40-11a is explained by superimposition of the buccal loss of alveolar bone on the root tip of tooth #31, which went beyond its most apical level (Fig. 40-12) without interfering with the neurovascular supply of the pulp.

Figure 40-13 demonstrates a clinical case where pulp vitality testing was difficult to carry out and which gave inconclusive findings even upon the preparation of a test cavity. A swelling had appeared at the buccal aspect of tooth #46 (Fig. 40-13a) after the patient had experienced pain and tenderness in the area for approximately 1 week. Periodontal probing disclosed a deep facial pocket along the mesial root (Fig. 40-13b). Radiographic examination indicated a lesion that seemed to circumscribe the mesial root with a marginal extension into the furcation (Fig. 40-13c). Frictional heat by drilling, as well as cold and

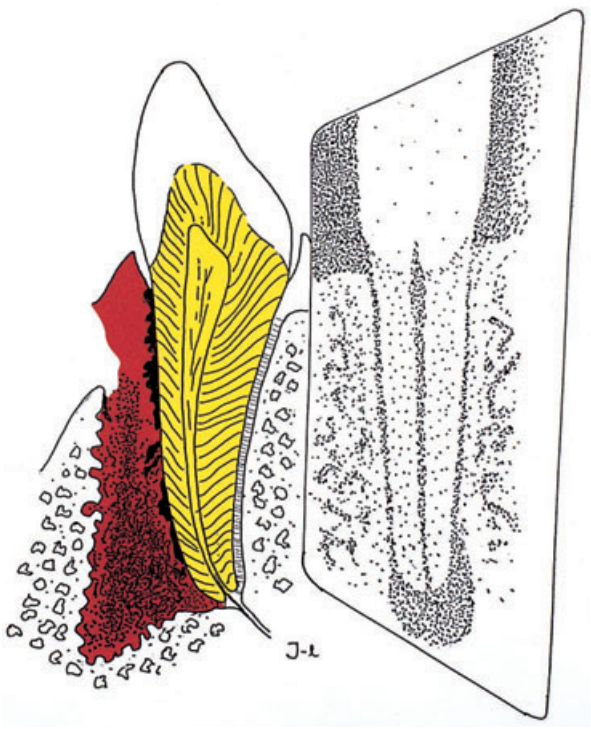

Fig. 40-12 Drawing depicting a potential mechanism for the radiographic lesion in tooth #31, Fig. 40-11. While there was substantial breakdown of alveolar bone there was no interference of the inflammatory lesion with the neurovascular supply of the pulp. The fact that the bone lesion appeared as an apical radiolucency is explained by the superimposition of the bone loss on the root tip. Courtesy of Dr. Mats Joatell.

electric tests, failed to give a positive response even in a test cavity preparation. After finding a sensitive and bleeding pulp in the distal root, a necrotic pulp with pus drainage was detected in the mesial root canals confirming an endodontic cause of the lesion. Endodontic treatment with a temporary intracanal dressing with calcium hydroxide over 3 months resulted in an obvious reduction of the bone lesion (Fig. 40-13d). The gingival lesion resolved with no abnormal pocket-probing depth (Fig. 40-13e), although a small bone defect remained in the furcation area (Fig. 40-13d). Treatment was then completed with root canal fillings. The 12-month recall radiograph demonstrates complete resolution of the bone defect (Fig. 40-13f).

Other indications of endodontic lesion

Except for a negative pulp test response, single-tooth lesions in a dentition otherwise free from periodontal disease strongly suggest an endodontic cause, provided other tooth-associated disorders such as external root resorption and root fracture can be excluded. An endodontic etiology should be explored particularly in cases with extensive restoration or a crowned tooth (Figs. 40-8 and 40-13), bridge abutment (Fig. 40-3), caries (Fig. 40-7), a root-filled tooth, and in patients with a history of a previous dental trauma. The character of the pocket probing depth should also be taken into consideration. Endodontic lesions, when extending marginally, usually do not follow more than one root surface and then exit in a rather narrow area of the sulcus. Pocket probing depth may also be in an area uncharacteristic of periodontitis, for example at the buccal aspect, when all other sites display normal probing depths.

Conclusion

The clinical presentation and the character of radiographic findings may lead to erroneous diagnosis in cases, where an endodontic lesion emerges in a patient with periodontal disease. The recognition of pulp vitality is crucial because clinically significant lesions of endodontic origin rarely develop in teeth with vital but inflamed pulps. The clinician should always be watchful for false leads and consider features which normally are associated with diseased pulps, such as extensive restoration, previous pulp capping, history of dental trauma, and endodontic treatment.

Endo–perio lesions – diagnosis and treatment aspects

The potential for an infected, necrotic pulp to cause breakdown of the attachment apparatus with extension into the marginal periodontium has been addressed above, along with the measures to establish the diagnosis. Once confirmed, the mode of treatment in this type of case is simple and should involve only conservative root canal therapy. Following adequate treatment, directed to elimination of the root canal infection, the lesion should be expected to heal without a persistent periodontal defect (Figs. 40-3, 40-5, 40-8, and 40-13). Adjunctive periodontal therapy would have no treatment effect and would be inappropriate.

A more complex situation arises when a periodontal lesion is sustained by both plaque infection and a root canal infection concurrently. This kind of lesion is associated with a deep pocket probing depth and a lateral bone defect that extends to the apex (Fig. 40-8). The problem here is that it is not normally possible to determine how much of the lesion is sustained by one or the other infection. In fact there are three scenarios. Firstly, the entire lesion may be a manifestation of a root canal infection alone. Secondly, the entire lesion may be the result of plaque infection. Thirdly, there are, in fact, two disease processes, one marginal associated with a plaque infection and one apical associated with a root canal infection. It is just that the two soft tissue lesions have merged and there is no longer a clear demarcation zone between the two as a probe can penetrate both soft tissue lesions. This latter condition has been termed a “true endo–perio lesion”.

Pulp vitality testing only partly settles the diagnostic quandary in this kind of case. Yet, if distinctly

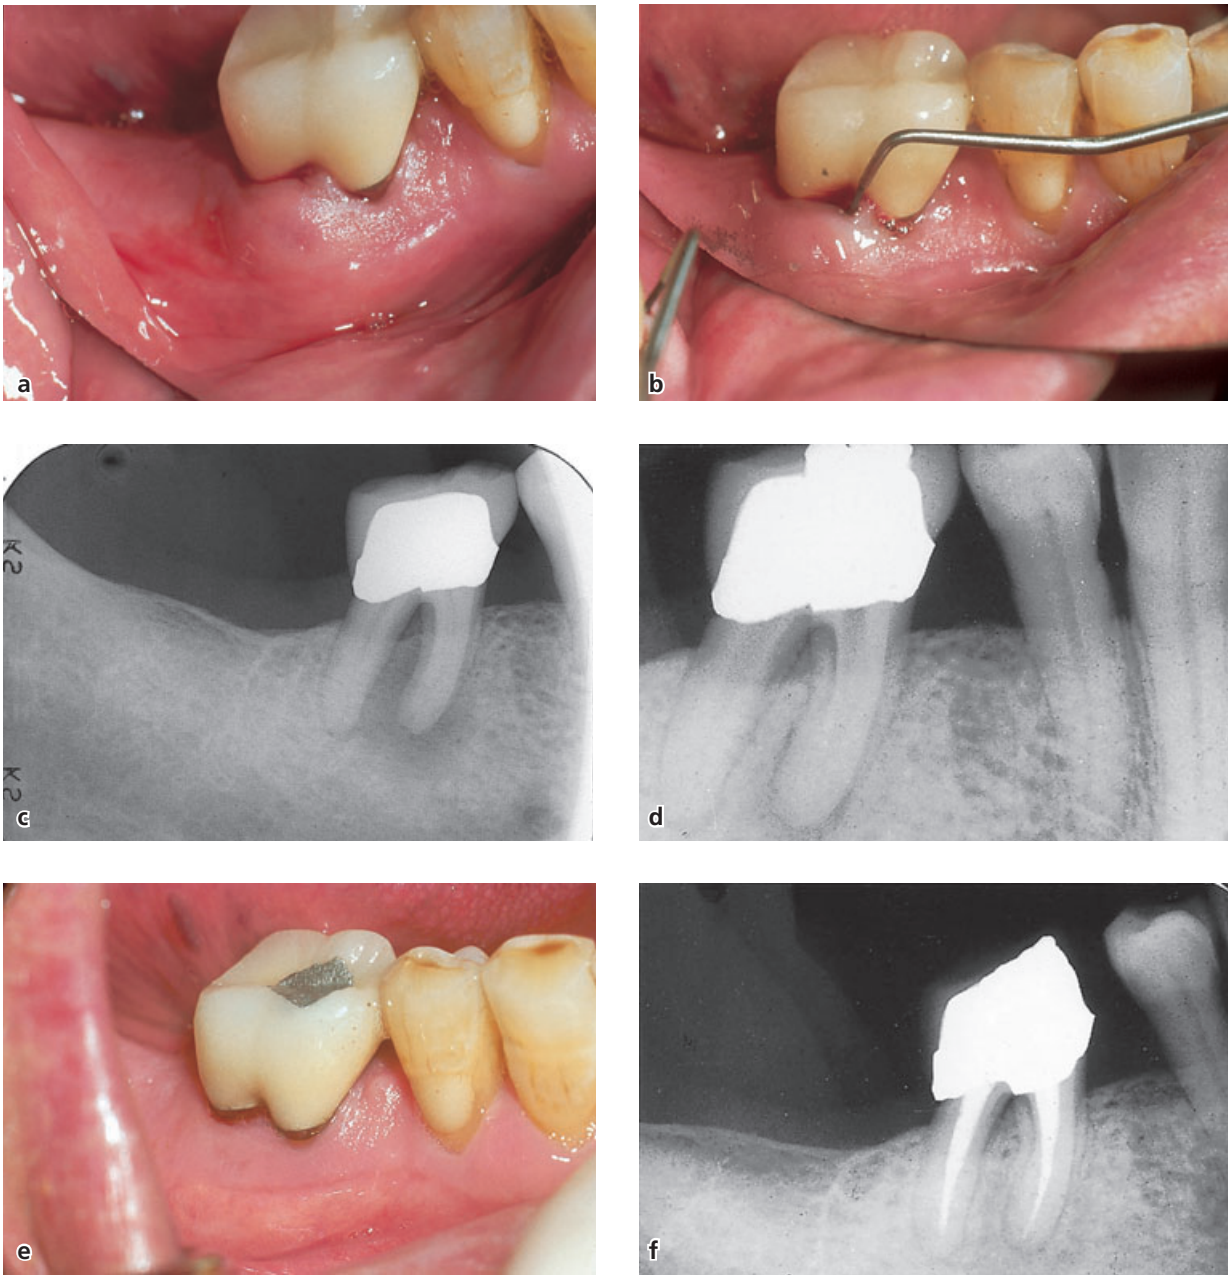

Fig. 40-13 Case with an initial unclear etiology of a facial swelling and deep pocket probing depth that turned out to have an endodontic etiology. The case history is given in the text. Diagnosis and treatment of this case was carried out by one of the authors (G.B.) in collaboration with Dr. David Simpson.

positive, one can exclude contribution of an endodontic infection and the process should be subject to periodontal therapy. Taking the pulp out and replacing it with a root filling is then a meaningless and unnecessary treatment effort. In the case of a negative pulp test, death of the pulp may have occurred as a direct result of the periodontal disease process or it may have developed independently as a separate condition. In the former case, prognosis for any other treatment than extraction must be regarded as bleak. A major reason is that not only may a substantial portion of the attachment apparatus be lost, but the root surface may be bacterially infected close to the root tip as well. In addition, the infection may have entered the root canal after necrosis of the pulp (see Chapter 23). Accessing this kind of infection for treatment is therefore a very challenging task with a questionable outcome.

If a portion of the lesion is sustained by a root canal infection independent of periodontal disease, the potential for periodontal tissue regeneration is much increased. Because it is not possible to know beforehand how far the endodontic lesion has extended along the root, root canal treatment should be attempted first and periodontal treatment postponed until the result of the endodontic treatment can be evaluated. The part of the lesion sustained by root canal infection can usually be expected to heal rapidly (Fig. 40-3). Periodontal attachment along with bone healing can then be expected within a few

Table 40-1 Outline of treatment strategies

Cause	Condition of the pulp	Treatment
Endodontic	Non-vital	Endodontic
Periodontal	Vital	Periodontal
Endodontic/periodontal	Non-vital	Endodontic – first observe the result of this therapy and institute periodontal therapy later if necessary

months. The part of the lesion caused by plaque infection may also heal following adequate periodontal therapy. Yet little or no regeneration of the attachment apparatus should be anticipated. Table 40-1 outlines the strategy to be taken for treatment of "endo–perio lesions".

Conclusion

Deep pocket probing depths associated with angular bone defects may reflect a combined endodontic and periodontal lesion. Yet, the extent to which an endodontic infection has contributed to the attachment loss cannot normally be determined upon a negative sensibility test, as the entire loss might be caused by plaque infection. Therefore, a treatment strategy should be applied which includes endodontics in the first place, but only in cases where an endodontic etiology is reasonably plausible, that is in teeth with large restorations, full-coverage crowns or history of dental trauma. If the tooth is completely intact without major restoration, caries or history of trauma, the potential of an endodontic etiology of the process is remote.

Endodontic treatments and periodontal lesions

Periodontal lesions, as already stated, may be maintained by infectious elements released from endodontically treated teeth. The lesion may have never resolved or may have developed after the completion of treatment. Several routes for dissemination of bacterial products are possible. Except for apical foramina and accessory canals, another possible pathway is inadvertently produced communication by root perforation (see below). The clinical presentation is no different to the one described above and consequently may involve acute exacerbations with quite extensive breakdowns of the attachment apparatus as well as localized, non-symptomatic lesions, only apparent in radiographs.

A persistent infection in root-filled teeth may also impact on the periodontium along dentinal tubules in areas where cementum has been damaged or lost (Hammarström *et al*. 1986; Blomlöf *et al*. 1988). The potential significance of such an avenue has been highlighted in clinical studies. Comparing teeth with healthy pulps, endodontically treated teeth with periapical pathology, indicating presence of persistent root canal infection, showed increased pocket probing depths (Jansson *et al*. 1993a), more marginal bone loss (Jansson *et al*. 1993b), and retarded or impaired periodontal tissue healing subsequent to periodontal therapy (Ehnevid *et al*. 1993a, b). Although the differences in probing depths and attachment losses in these studies were rather small, the observations suggest that endodontic re-treatment should be considered as an adjunct to periodontal therapy when a root canal filling is defective and/or displays signs of periapical inflammation. In individuals with no or minor evidence of periodontal disease, the root canal condition, whether root filled or not or infected or not, did not seem to affect the periodontal status in a controlled study (Miyashita *et al*. 1998).

Conclusion

Unfilled spaces in endodontically treated root canals can sustain bacterial growth, and infectious products from these may reach the periodontium along the very same pathways as in an untreated tooth with infected pulp. Endodontic re-treatment may be considered as an adjunct to periodontal therapy when a root canal filling is of poor quality and/or displays signs of periapical inflammation because of the potential that bacterial elements may become disseminated to the periodontium along dentinal tubules exposed by periodontal instrumentation.

Iatrogenic root perforations

During endodontic treatment, and in conjunction with preparation of root canals for insertion of posts, instrumentation can accidentally result in perforation of the root and wounding of the periodontal ligament (Sinai 1977; Kvinnsland *et al*. 1989; Eleftheriadis & Lambrianidis 2005). Perforations can be made through the lateral walls of the root or through the pulpal floor in multi-rooted teeth. The clinical course from then on depends largely on the extent the wound site becomes infected (Beavers *et al*. 1986). If made in the crestal bone area, a typical feature is epithelial proliferation and periodontal pocket formation (Lantz & Persson 1967; Petersson *et al*. 1985). If the perforation is more apical along the root, a wound site infection process may first lead to an acute pain condition, including abscess formation and drainage of pus, followed by further loss of fibrous attachment and periodontal pocketing (Fig. 40-14).

Early detection is critical for a successful outcome of treatment as long-standing perforations with a manifest infection have poor potential for repair.

Fig. 40-14 Angular bone defect at the distal root surface of a mandibular molar (arrows). The root is perforated as indicated by the misaligned post. Clinical symptoms included drainage of pus from the pocket and increased tooth mobility. The tooth was extracted.

Successful treatments have, however, been attained in such cases (Tsesis & Fuss 2006).

Diagnosis is based on the occurrence of sudden pain and bleeding during preparation of root canals coronal to the working length. Such signs are likely to be less distinct, however, if the perforation occurs during a procedure conducted under local anesthesia. A perforation may also go undetected as bleeding may not invariably be provoked. For example, when post preparations are carried out by means of a machine-driven instrument, a smear layer is formed that may clog up the blood vessels. Thus, in many instances no bleeding will be noticed until the following visit, when granulation tissue has proliferated into the root canal space along the perforation defect. Granulation tissue usually bleeds profusely on attempts to remove it. Electronic apex locators are helpful in the confirmation of a root perforation, when readings obtained are substantially shorter than the root canal length (Fuss *et al*. 1996).

Over the years many therapeutic agents and methods have been proposed for the management of root perforations (reviewed by Tsesis & Fuss 2006). Materials proposed for sealing from the inside of the root canal space include amalgam, zinc oxide and eugenol cements, both chemically cured and light-cured calcium hydroxide-containing pastes, and plaster of Paris. More recently, mineral trioxide aggregate (MTA) based on Portland cement has shown great promise by its ability to permit cementum repair (Arens & Torabinejad 1996; Schwartz *et al*. 1999).

Regardless of the material used, healing of the lesion in the periodontium depends on whether bacterial infection can be excluded from the wound site by a tight seal of the perforation (Beavers *et al*. 1986) (Fig. 40-15). This may be difficult to achieve, particularly if the perforation is made deep into the root canal at an oblique angle giving it an oval-shaped orifice into the periodontium. Nevertheless, for mid-root and cervical perforations, non-surgical approaches, including placement of an internal seal, are preferable to a surgical approach, as the latter often results in persistent pocket formation and furcation involvement. Furthermore, surgical treatment is not always feasible because of the inherent difficulty of accessing many perforation sites. As a last resort, extraction followed by repair and reimplantation of the tooth may be attempted (Tsesis & Fuss 2006). In multi-rooted teeth, hemisection and extraction of one or two roots may be a treatment of choice.

Conclusion

Inflammatory lesions in the marginal periodontium, as manifested by increased probing depth, suppuration, increased tooth mobility, and loss of fibrous attachment, may result from an undetected or unsuccessfully treated root perforation. If an iatrogenic root perforation occurs during instrumentation of root canals, filling of the artificial canal to the periodontium should be carried out without delay to prevent granulation tissue formation and wound site infection. Outcome of treatment depends on how well the wound site can be sealed. The closer the perforation is to the bone margin, the greater the likelihood is for proliferation of epithelium at the perforation site with a deep, potentially suppurating pocket as a result.

Vertical root fractures

Clinical symptoms that are typical of tooth-associated infections such as endondontic lesions and plaque-induced periodontitis may also appear at teeth with vertical root fractures. A vertical root fracture is defined as a fracture of a root that is longitudinally oriented at a more or less oblique angle relative to the long axis of the tooth (Fig. 40-16). It can traverse the root in different directions mesially/distally or facially/lingually; it may, but does not always, engage the root canal space. A vertical root fracture can extend the entire length of a root and then involve the gingival sulcus/pocket area. It may also be incomplete and confined to either coronal or apical ends. It should be noted that vertical root fractures although expanding in opposite directions may extend to one root surface only.

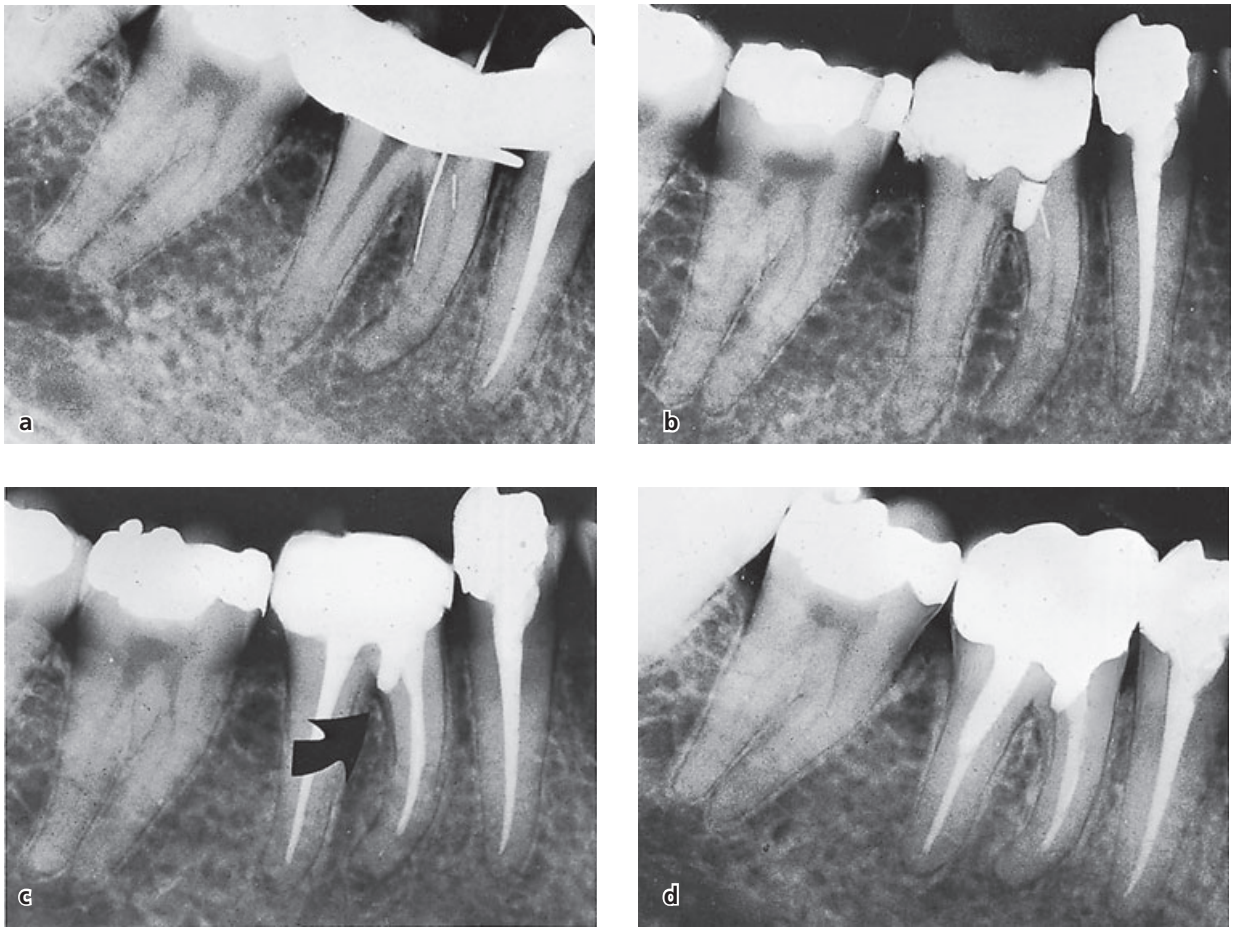

Fig. 40-15 (a) Perforation of the pulpal floor of the mandibular first molar occurred in conjunction with a search for root canal openings. There is also a file fragment in one of the mesial canals. (b) The perforation was immediately sealed with gutta-percha. (c) In a radiograph taken 1 month after treatment a slight radiolucency is seen at the site of the perforation (arrow). (d) Follow-up after 2 years showed normal periodontal conditions both clinically and radiographically. Case kindly provided by Dr. Gunnar Heden.

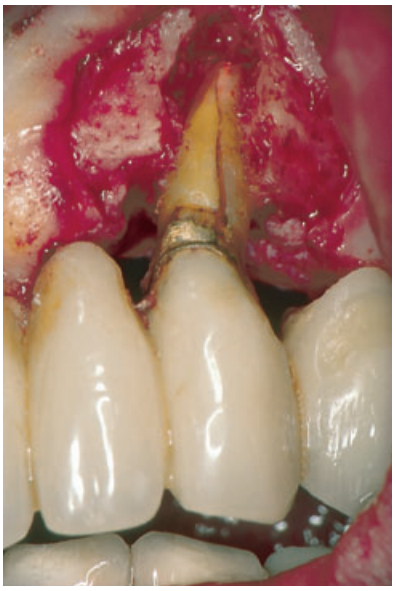

Fig. 40-16 Vertical root fracture of a root-filled upper canine included as an abutment in a prosthetic reconstruction. Due to inflammatory breakdown of the buccal plate a typical bone dehiscence is seen.

Mechanisms

Endodontically treated teeth appear over-represented among teeth with vertical root fracture in comparison to teeth with vital pulps (Meister *et al*. 1980; Gher *et al*. 1987; Patel *et al*. 1995). Generally the increased fracture propensity of root-filled teeth has been attributed to loss of tooth structure as a result of endodontic instrumentation and subsequent restorative procedures (Reeh *et al*. 1989; Sedgley & Messer 1992). Loss of fracture resistance increases especially after overzealous root canal preparation leaving thin dentin walls to the periodontium (Tjan & Whang 1985). Notches, ledges, and cracks induced by root canal preparation, root canal filling procedures, and seating of threaded pins and posts also contribute to sites of stress concentration during mastication that eventually may lead to fracture (Kishen 2006). Decrease of moisture content following root canal treatment is another claimed cause of increased fracture susceptibility of root-filled teeth; insignificant moisture differences were found, however, when dentin of teeth with vital pulps and dentin of root-filled teeth were compared (Papa *et al*. 1994). More recent observations have nevertheless demonstrated

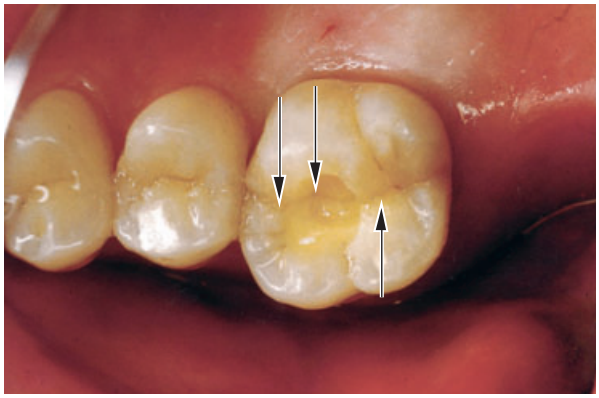

Fig. 40-17 Crack in an unrestored maxillay molar causing symptoms of pulpitis. The patient, a 47-year-old male, had thought the pain problem originated from the temporomandibular joint. Following the preparation of a test cavity, a clear split line was observed at the bottom of the cavity (arrows), confirming the cause of the pain condition. Case kindly provided by Dr. Hideaki Suda.

that biomechanical effects occur in dehydrated dentin that may render endodontically treated teeth prone to fracture (Kishen 2006). Dehydrated dentin *in vitro* was observed to assume increased stiffness as well as a decrease in toughness (e.g. the total energy a material can absorb before fracturing) in comparison to hydrated dentin (Jameson *et al*. 1994; Kahler *et al*. 2003; Kishen & Asundi 2005). Hence, fluid-filled dentinal tubules as well as a water-rich pulp tissue may give normal teeth better resistance to occlusal loading forces than root-filled teeth. It has also been speculated that, along with loss of vital pulp tissue, mechanoreceptive functions are lost concomitantly, allowing larger loads to be placed during mastication than the patient normally would feel tolerable (Löwenstein & Rathkamp 1955; Randow & Glantz 1986).

Vertical root fracture may also occur in clinically intact teeth with no or minor restoration (Fig. 40-17). As posterior teeth are exposed to more heavy occlusal forces, mandibular molars appear to be especially at risk for fracture (Yang *et al*. 1995; Chan *et al*. 1999). Subsequent to fracture of teeth with vital pulps, typical pulpitis symptoms may be initiated, together with pain on percussion and mastication.

Incidence

Data on the incidence of vertical root fractures are scarce in the literature. While it appears to be low, vertical root fractures probably occur more often than clinicians are able to diagnose (Tamse *et al*. 1999b). Molars and premolars appear more often affected than incisors and canines (Meister *et al*. 1980; Testori *et al*. 1993). In longitudinal clinical follow-up studies of patients treated with fixed prostheses, vertical root fractures were frequent in root-filled teeth with posts and especially so in teeth serving as terminal abutments in cantilever bridges (Randow *et al*. 1986).

It is important to recognize that root fracture of endodontically treated teeth may occur several years after the completion of endodontic therapy and final restoration of the tooth (Fig. 40-18). In a study comprising 32 vertical root fractures, the average time between the completion of endodontic treatment and diagnosis of fracture was 3.25 years, with a range varying between 3 days and 14 years (Meister *et al*. 1980). In another study comprising 36 teeth, symptoms of root fracture developed on average more than 10 years after completion of treatment (Testori *et al*. 1993).

Clinical expressions

Clinical signs and symptoms associated with vertical root fractures vary hugely. Occasionally, there may be pronounced pain symptoms and abscess formation because of active bacterial growth in the fracture space (Fig. 40-18). In other instances clinical symptoms may be limited to tenderness on mastication, mild pain, and dull discomfort. Sinus tracts may emerge near the gingival margin (Fig. 40-19). A strong indication of a vertical root fracture is sinus tracts occurring at both buccal and lingual/palatal sites (Tamse 2006). In other instances, a narrow, local deepening of a periodontal pocket in an area not typical for periodontal disease may be the only clinical finding (Fig. 40-20).

The osseous defect emanating from the periodontal tissue lesion may take different shapes depending on how the fracture extends. If there is a buccal extension, the thin alveolar bone plate readily resorbs and a typical bone cleft can be seen upon raising a mucoperiosteal flap (Fig. 40-16). At palatal or lingual extensions, the lesion may not resorb the entire bone wall. Therefore, the osseous defect may take a U-form shape with the height of the bone margin preserved. On fractures that are limited to the apical portion of the root, the bone defect may center on the root apex, similar to that of a periapical lesion associated with an infected root canal.

In conventional intraoral periapical radiographs these bone lesions may not be readily visible, depending on the location, character, and shape of the bone destruction (Fig. 40-20). Absence of lesion, even when taken at different angles, can also be explained by superimposition of roots and bone structures over the bone dehiscence. In yet other cases radiographic signs may be limited to widening of the periodontal ligament space. Lateral radiolucency along one or both of the lateral root surfaces may be discerned with more pronounced bone lesions. A thin halo-like apical radiolucency is another example of a radiographic lesion suggestive of a vertical root fracture (Pitts & Natkin 1983; Testori *et al*. 1993; Tamse *et al*. 1999a). Recent developments of tomographic techniques have brought valuable new diagnostic tools as they can remove interfering anatomic structures and thereby help to visualize presence, location, and

Fig. 40-18 A typical case of a root fracture. (a) The first maxillary premolar had been asymptomatic for 20 years after completion of endodontic treatment and bridge-work. Patient sought treatment because of suddenly appearing pain, tenderness and facial swelling. (b) A deep periodontal pocket could be probed at the buccal aspect of the tooth, while all other sites displayed normal pocket probing depths. (c) Radiographs revealed a radiolucent area along the mesial aspect of the root system. (d) A set of radiographs taken 6 months earlier showed no such lesion. (e) Elevation of a mucoperiosteal flap revealed substantial loss of marginal bone at the buccal aspect of the root. A fracture going in a mesio-distal direction was subsequently confirmed. (f) Following removal of bone tissue, the roots were separated from the crown and extracted.

extension of bone lesions (Gröndahl & Hummonen 2004) (Fig. 40-20e,f).

Diagnosis

The diagnosis of a vertical root fracture is often difficult to ascertain because the fracture is usually not readily detectable by clinical inspection unless there is a clear separation of the root fragments. To give a radiographic appearance of the fracture in the absence of separation, the central X-ray beam has to be parallel to the fracture plane (Fig. 40-21). This is rarely achieved. The suspicion of a vertical root fracture is often inferred from a pocket probing depth in an

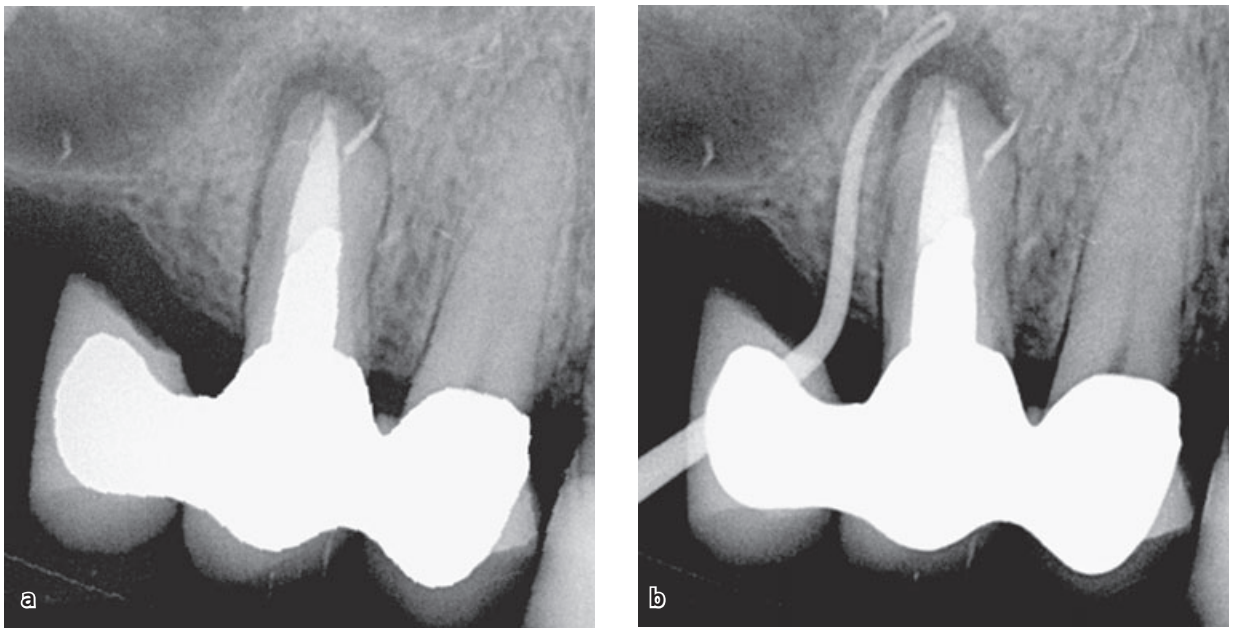

Fig. 40-19 (a) Periapical radiolucency associated with an upper second premolar that turned out to be caused by a vertical root fracture. There was a buccal, deep pocket-probing depth and a sinus tract near the gingival margin. (b) A gutta-percha point inserted in the fistulous tract points to the root apex but provided no additional clue in this case. The widely prepared root canal and the use of the tooth as an abutment in a cantilever bridge provided likely contributors to the fracture in this case kindly provided by Dr. Thomas Kvist.

aberrant position, for example at a buccal or lingual aspect of a tooth, in a dentition which otherwise is free from symptoms of periodontal disease. Another strong indication is the sudden appearance of clinical symptoms and/or radiographic lesion on a root-filled tooth that has remained asymptomatic and without lesion for years (Fig. 40-18).

A number of diagnostic procedures can be undertaken to confirm the diagnosis. Application of various dye solutions, e.g. methylene blue or iodine tincture, on to the crown and the root surface can sometimes be indicative. As the dye enters the fracture space, it will show up as a distinct line against the surrounding tooth substance. Indirect illumination of the root, using fiber-optic light, can also be of value. The fiber-optic probe should then be placed at various positions on the crown or the root, whereby the fracture line may clearly present itself. A surgical microscope or an endoscope, providing both enlargement and directed light, are other valuable tools to disclose vertical root fractures.

In premolars and molars the diagnosis may be supported from observation of varying pain sensations elicited by loading facial and lingual cusps. The procedure includes asking the patient to bite down on a rubber wheel or a specially designed plastic stick (FracFinder). Separate loading of either buccal or lingual cusps eliciting pain sensation from one, but not the other loaded cusp indicates the potential of a fracture. Often the diagnosis of a vertical root fracture has to be confirmed by surgical exposure of the root for direct visual examination (Walton *et al*. 1984) at which one may also discover a typical bone dehiscence (Fig. 40-16).

Treatment considerations

Vertical root fractures that involve the gingival sulcus/pocket area usually have a hopeless prognosis due to continuous bacterial invasion of the fracture space from the oral environment. While there are reports of successful management of fractured teeth by re-attaching the fragments with bonding resin or laser fusing after extraction followed by re-implantation, fractured teeth are normally candidates for extraction. In multi-rooted teeth a treatment alternative is hemisection and extraction of the fractured root.

Conclusion

Symptoms and signs associated with vertical root fractures vary and may be difficult to distinguish from those prevalent with other tooth-associated infections. A variety of diagnostic procedures should therefore be considered. Except for the leads obtained from anamnestic findings and pocket probing depths in buccal or lingual positions or both, clinical examination should include measures to make fracture lines visible *viz.* application of disclosing solutions, the use of fiber-optic light, inspection by a surgical microscope or endoscope, or by raising a surgical flap. Pain on selective loading of cusps may indicate root fracture. A vertical root fracture should be anticipated in root-filled teeth, which, after a long history of being asymptomatic and without signs of infection, suddenly present with tenderness, pain, and radiographic bone lesion (Fig. 40-18). Roots with vertical root fracture usually have a hopeless prognosis and are clear candidates for extraction.

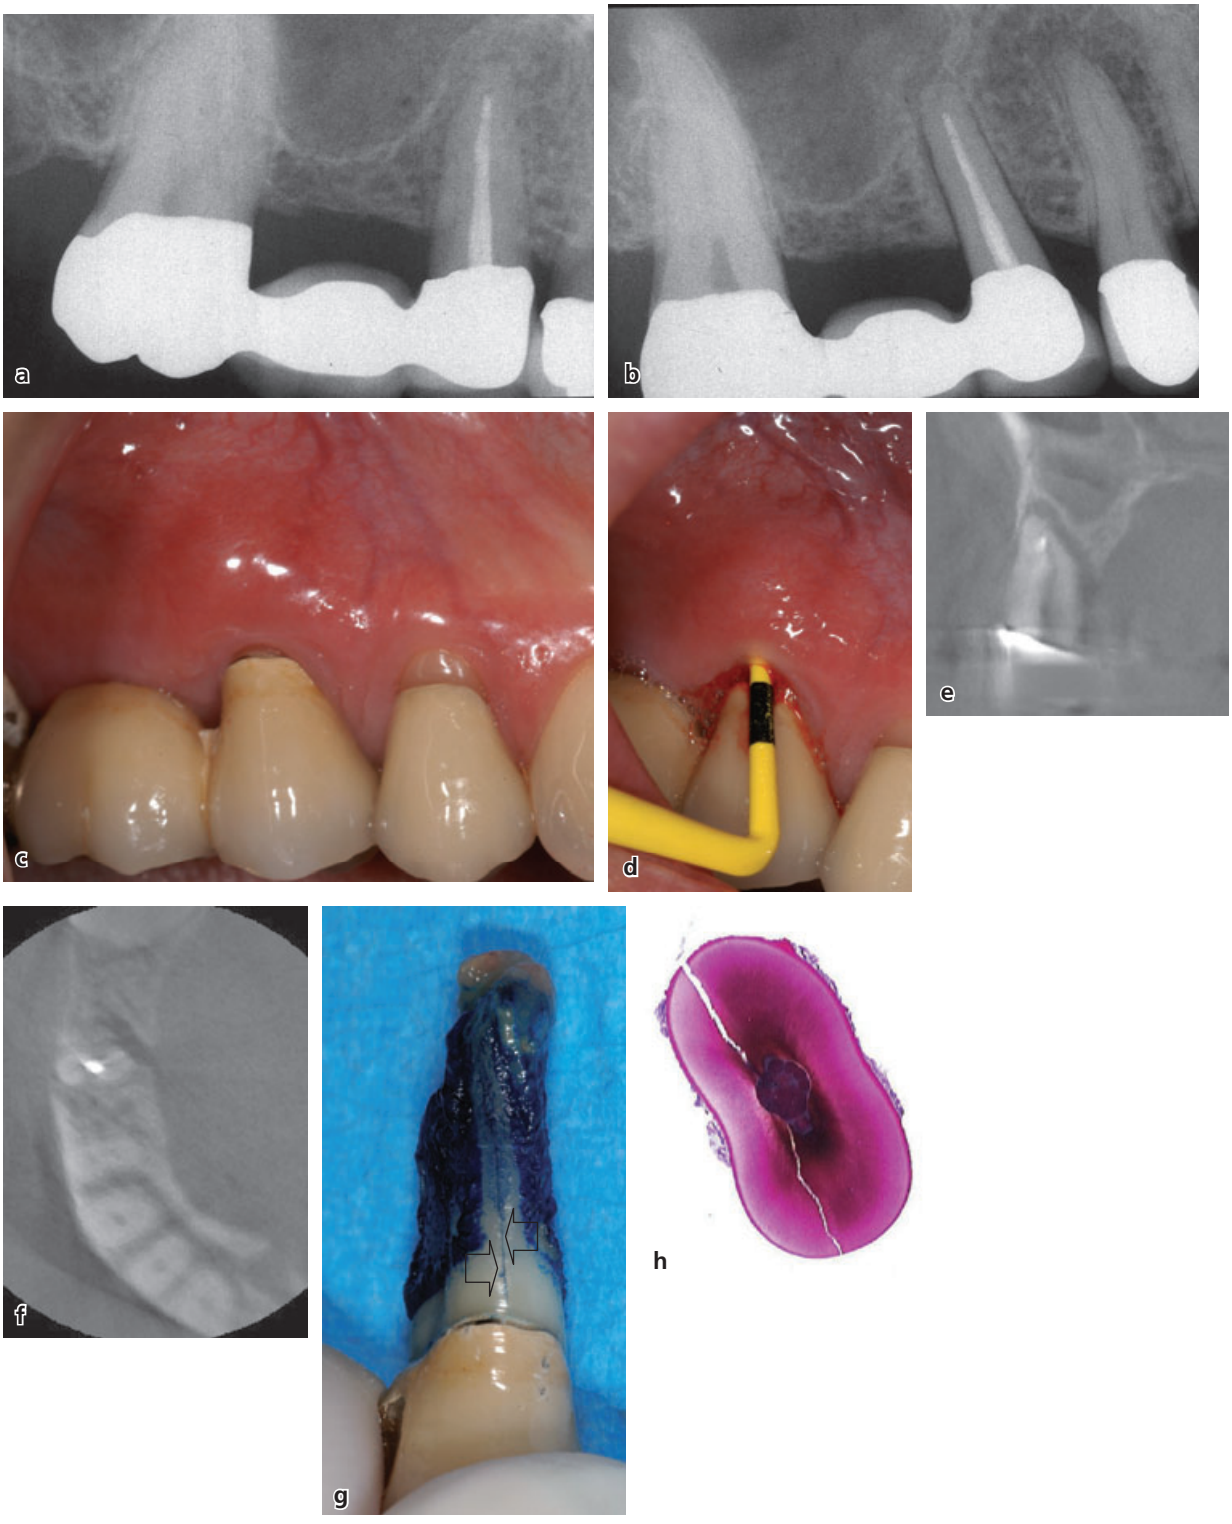

Fig. 40-20 Case of vertical root fracture, where ordinary intraoral radiographs failed to provide evidence of the associated bone lesion. (a) Radiograph shows normal periodontal contours. (b) A second radiograph indicates a widened periodontal ligament space. (c) The patient had complained of recurrent pain on occlusal load for several weeks and presented at the clinic with a light swelling on the buccal aspect that had appeared several weeks before. (d) Clinically there was an isolated 9 mm pocket probing depth mid-buccally, suggesting root fracture. (e,f) Limited cone beam computed tomography was helpful to reveal a bone lesion in this case along the palatal aspect of the tooth. (g) After extraction methylene blue staining visualized the fracture line (arrows) that turned out to extend to both the lingual and the buccal root surface (h). Case kindly provided by Dr. Thomas von Arx.

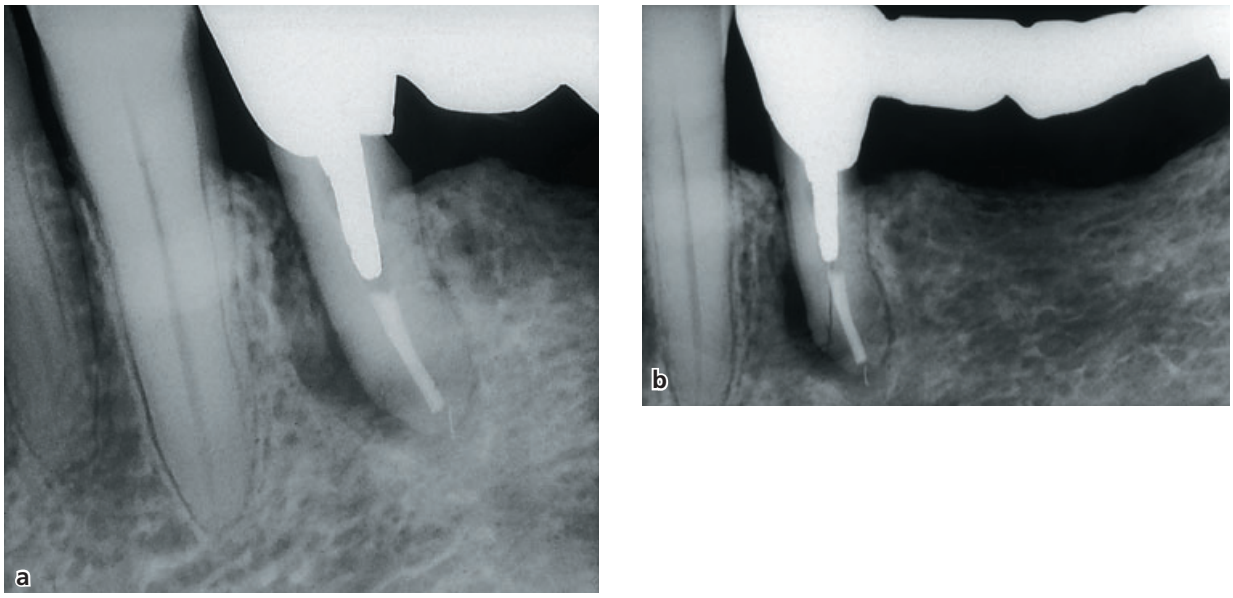

Fig. 40-21 (a) Mandibular premolar included in a four-unit bridge showing a bone lesion at the mesial aspect of the root. In this projection there is no sign of fracture, while in a radiograph (b) taken with a slight shift of angle, a fracture line is clearly visible. Case kindly provided by Dr. K-G. Olsson.

External root resorptions

Root surface resorptions, here termed external root resorptions, usually progress without producing clinical symptoms and may therefore go undetected unless observed radiographically. However, in advanced stages, the surface defect may interfere with the gingival sulcus and thereby initiate an infectious process. As such lesions can be associated with increased pocket probing depths as well as drainage of pus upon probing, this section of the chapter addresses various forms of external root resorptions, their mechanism, clinical features, and management.

Mechanisms of hard tissue resorption in general

The hard tissues of the body consist of two major components, mineral and matrix. While the ratio of these two components varies between bone, cementum, and dentin, the same tools – acids and enzymes – are used by nature to perform the degradation of these tissues. Bone is normally remodeled to adapt to functional changes. Resorption of dental hard tissues of permanent teeth, on the other hand, should be seen as an expression of a pathological process. Clast cells carry out resorption of bone as well as cementum, dentin, and enamel (Hammarström & Lindskog 1992; Suda *et al*. 1996). These cells are large, multinucleated, motile cells emanating from hematopoietic precursor cells in the bone marrow (Marks 1983; Vaes 1988; Pierce *et al*. 1991; Suda *et al*. 1996) and termed osteoclasts when involved in bone remodeling processes. Phenotypically the very same kind of clast cells conduct resorption of the hard tissues of the tooth. Mononucleated cells are also involved in the later phase of the resorption process by eliminating the organic matrix that became released following dissolution of the mineral components (Wedenberg & Lindskog 1985; Lindskog *et al*. 1987; Brudvik & Rygh 1993; Lerner 2006).

Under normal, physiologic conditions, hard tissues are protected from resorption by their respective surface layers of blast cells; in the case of cementum by cementoblasts. As long as these blast cell layers remain intact with the unmineralized layer of osteoid or cementoid at the surface of the mineralized tissue, resorption will not occur. It is known that bone resorption is under hormonal regulation and is mediated by osteoblasts (Lerner 2006). Stimulation by parathyroid hormone makes the osteoblasts first degrade the osteoid and then contract to expose the bone surface for osteoclastic demineralization (Jones & Boyde 1976; Rodan & Martin 1981; Lerner 2006). However, parathyroid hormone exerts no influence on cementoblasts (Lindskog *et al*. 1987), which may explain why bone, but not teeth, is remodeled to adapt to functional changes. However, dental trauma, excessive orthodontic forces and aggressive scaling and root planing during periodontal therapy are examples of injuries that can initiate root resorption (Andreasen 1981; Rygh 1977). Subsequent to the injury, the denuded hard tissue surface, without its blast cell layer and cementoid, attracts motile clast cells (Chambers 1981), which seal themselves to the hard tissue surface and excrete acids for demineralization. Concomitantly an acid environment is created that is essential for the degradation of tissue matrix by lysosomal enzymes at low pH optima (Vaes 1988; Kremer *et al*. 1995; Pascoe & Oursler 2001; Czupalla *et al*. 2006; Henriksen *et al*. 2006).

Consequently, a trigger mechanism is required to set off root resorption. For the resorption process to continue, a lasting osteoclast stimulus is required, for example an infection or a continuous mechanical force such as the one elicited by orthodontic

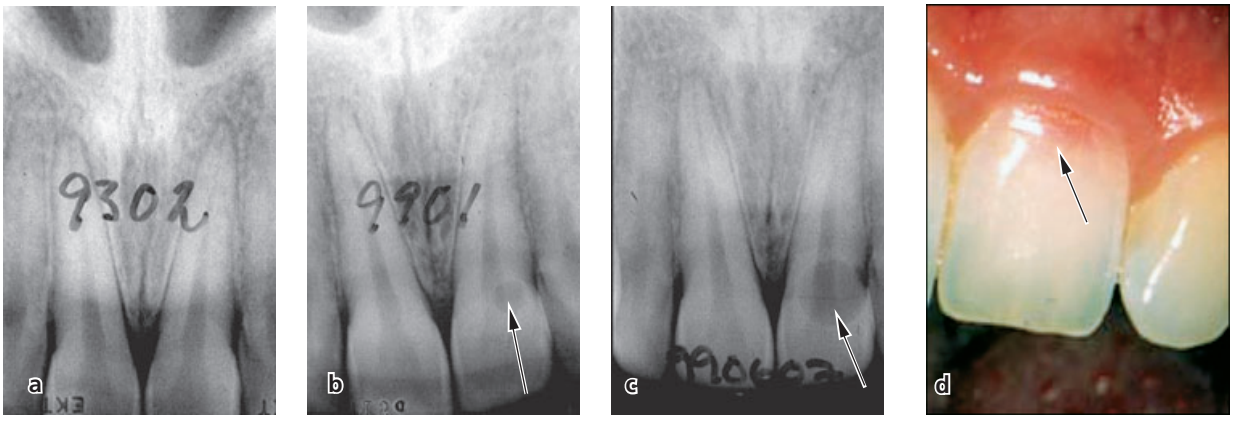

Fig. 40-22 Series of radiographs taken at different time intervals showing the appearance of an external root resorption in a young adult patient. (a) At the age of 15 years there is no sign of resorption. (b) Six years later a small radiolucency is seen (arrow). (c) In just 6 months the lesion expanded considerably (arrow). (d) The lesion appeared clinically as a pink spot in the cervical area of the tooth (arrow). Case kindly provided by Dr. Anders Molander.

treatment. In both instances the resorptive process may be halted if the cause for prolongation can be curbed; in the case of orthodontic tooth movement, by releasing the forces, and in the case of a root canal infection, by root canal therapy.

Conclusion

Two mechanisms are involved in resorption of a hard tissue: (1) a trigger mechanism and (2) a reason for the resorption to continue. Thus, treatment of active root resorption should be directed to eliminate the cause for its continuance.

Clinical presentations and identification

Root resorptions *per se* do not cause painful symptoms. Unless a resorptive process is located coronally and is undermining the enamel, giving it a pinkish appearance (Fig. 40-22), the only way to detect and diagnose dental resorption is by means of radiography (Fig. 40-22b,c). Only in very late stages, as the resorptive process engages the gingival sulcus, may an infectious process emerge with typical features of a periodontal abscess (Fig. 40-23).

A single radiograph is usually not sufficient to define a radiolucent area within the confines of a root as an external resorption. A radiolucency may portray a variety of conditions including a resorptive process inside the root canal (internal root resorption), or a resorptive defect located buccally or lingually as the image of the root is superimposed. It may also be an artifact and reflect a radiolucent bone area superimposed on the root. Therefore, one should always take more than one radiograph and use different angulations to observe whether the radiolucent area belongs to the root or not (Fig. 40-23). New tomographic techniques can be of great benefit to distinguish external from internal root resorptions.

The initial stage of a resorptive process usually passes undetected as radiographs can only present a resorptive cavity after a certain size has been reached (Andreasen *et al*. 1987) (Fig. 40-23). The location of the lesion is also important for detection. A facial or lingual root resorption defect is more difficult to visualize radiographically than a proximal cavity, unless tomography is used. Be aware that in the cervical region it may be difficult to differentiate radiographically between cavities caused by caries and those caused by resorption. To distinguish caries from resorption it is useful to recognize that bacterial acids that demineralize dentin leave a soft cavity surface. By contrast, clastic resorption removes both the mineral and the organic phases of the hard tissues resulting in a cavity floor that is hard to probing.

Different forms

There are different forms of external root resorption. The underlying mechanism is understood only for some of them. A genetic link can be seen in certain cases as external root resorptions run in families. There are also instances when only the enamel of an unerupted tooth is resorbed. Furthermore, external resorptions can be caused by precipitation of oxalate crystals in the hard tissues of patients as a result of increased concentration of oxalates in the blood due to kidney failure (Moskow 1989). Malignant tumors close to a tooth can also cause root resorption (Fig. 40-24).

Andreasen (1981) has published a classification of those external root resorptions that have a known etiology:

- Surface resorption
- Replacement resorption associated with ankylosis
- Inflammatory resorption associated with persistent inflammation in the periodontium adjacent to the resorption site.

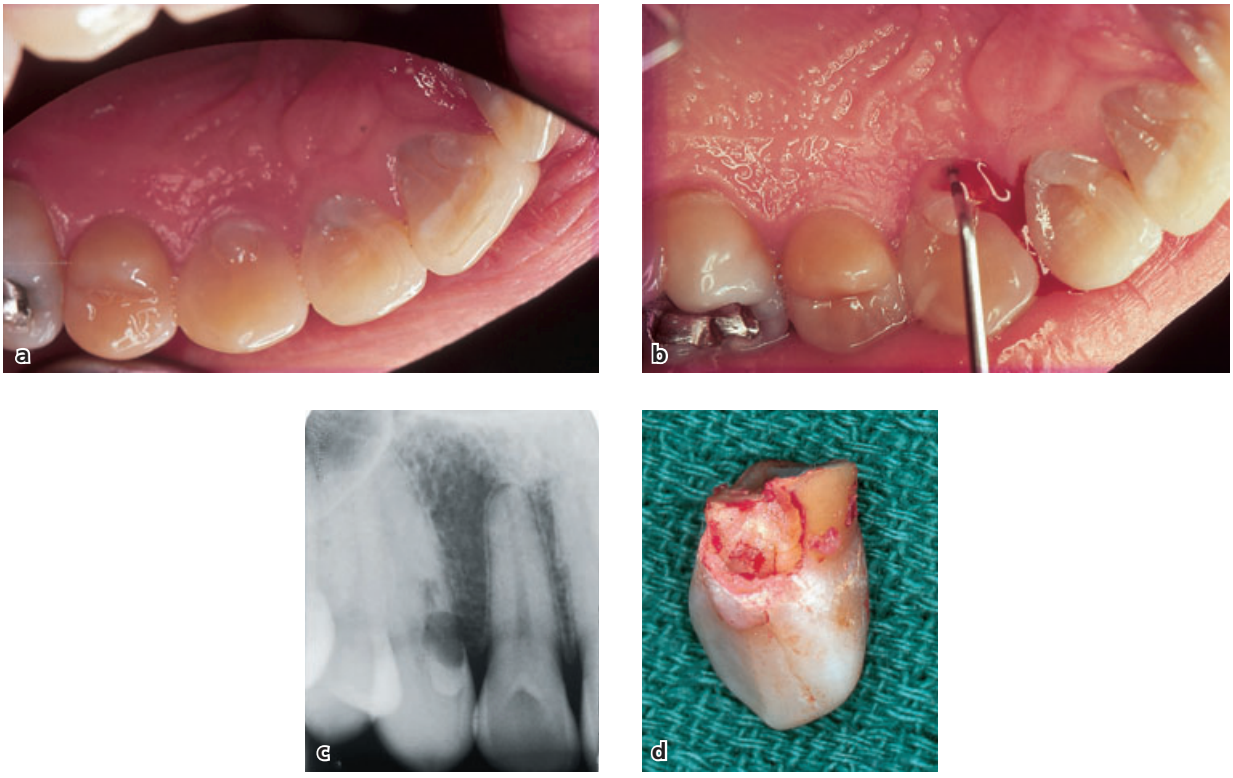

Fig. 40-23 Case of peripheral inflammatory root resorption (PIRR). Pain and tenderness of the right maxilla for several weeks prompted the 30-year-old male patient to seek treatment. (a) Clinical inspection revealed no obvious pathology. (b) Periodontal probing, however, released pus drainage from the lingual aspect of tooth #13. Pulp-vitality test of the tooth as well as neighboring teeth gave clear positive responses. (c) An angulated radiograph disclosed the presence of a resorptive defect. (d) The tooth was extracted as successful treatment was deemed unlikely. An extensive resorptive defect had undermined the clinical crown.

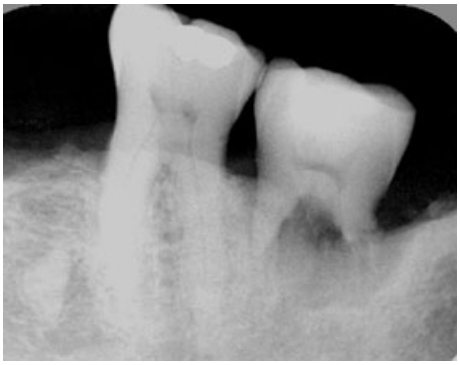

Fig. 40-24 External root resorption of a lower second molar caused by breast cancer metastasis. Case kindly provided by Dr. John Kuo-Hung Yu.

Subforms are:

- Peripheral inflammatory root resorption (PIRR)
- External inflammatory root resorption (EIRR).

Surface resorption

This type of resorption is common, self-limiting, and reversible (Harding 1878; Andreasen 1981). In a histologic study of human teeth from individuals varying in age from 16–58 years, only 10% of the teeth showed absence of active resorption or signs of healed resorptions (Henry & Weinman 1951). Resorptions were noted twice as often in older than in young subjects. Another study demonstrated up to 88% of teeth with active or, in most instances, healed resorptions (Hötz 1967).

The mechanisms behind surface resorptions are only partly understood. These resorptions are normally initiated in conjunction with a localized injury to the cementoblast cell layer, for example by external trauma (Andreasen 1981) or by trauma from occlusion. As clast cells are attracted to the denuded root surface, hard tissue is resorbed for as long as the activating factors are released at the site of injury (Hammarström & Lindskog 1992). The resorptive process then stops within a few days following the disappearance of clast cells along with the defect becoming populated with hard tissue repairing cells leading to cementum repair (Lindskog *et al*. 1983, 1987). The regulating factors governing this process are virtually unknown.

Surface resorption may also result from orthodontic forces. Light forces produce insignificant cemental cratering (root resorption) with rapid tooth movement. On the other hand, intermediate and heavy forces produce substantial cemental cratering and slower tooth movement (Rygh 1977). Following

application of an orthodontic force three main stages for the tooth movement can be identified:

1. *Initial minor movement due to the compression of pliable tissues*. During the initial stage of tooth movement, osteoclasts, macrophages, fibroblasts, and resorption lacunae in bone increase on the pressure side (Kurihara 1977; Brudvik & Rygh 1993, 1995).
2. *Delay period with no movement*. The induced tissue damage to the periodontal ligament is resolved by macrophages and osteoclasts during a delay period (Rygh 1977; Brudvik & Rygh 1993, 1995). If excessive forces are placed on teeth, there is increased damage to the surrounding tissues, which prolongs the delay period (Storey 1973). In this phase, the tissues show signs of hyalinization, i.e. development of a cell-free, structureless zone (Sandstedt 1904; Reitan 1951; Kvam 1967; Brudvik & Rygh 1993) as compressed collagen fibers gradually unite to a more or less cell-free mass (Rygh 1972, 1977).
3. *Rapid tooth movement and extensive bone remodeling*. Elimination of the hyalinized tissue leads to removal of the mature collagen and cementoid layer leaving a raw root surface lacking a protective blast cell barrier. The denuded root surface subsequently attracts clast cells and root resorption continues for as long as the force is present (Storey 1973; Rygh 1977; Brudvik & Rygh 1993, 1995). Major loss of dental hard tissue may follow this kind of iatrogenic injury.

Conclusion

Signs of active or healed surface resorptions or both are common in the large majority of teeth of the adult dentition. It is conceivable that minor traumata caused by unintentional biting on hard objects, bruxism, high fillings, etc., cause localized damage to the periodontal ligament and trigger the initiation of this type of resorption. The process is self-limiting and self-healing and no active treatment is required. During orthodontic treatment caution should be exercised and the forces moderated so that the risk of root foreshortening is minimized. When heavy forces are used the involved teeth should be monitored radiographically.

Replacement resorption

This type of resorptive process involves replacement of the dental hard tissues by bone, hence the name (Andreasen 1981). When a surface resorption stops, cells from the periodontal ligament will proliferate and populate the resorbed area (Lindskog *et al*. 1983, 1987). If the surface resorption defect is large, it will take some time before periodontal ligament cells have covered the entire surface. In the interim period osteoblasts from the nearby bone tissue may then arrive first and establish themselves at the resorbed surface (Andreasen & Kristerson 1981; Gottlow *et al*. 1986). Bone is thus being formed directly upon the dental hard tissue. This results in a fusion between the bone and the tooth substance, which is known as ankylosis. Note that replacement resorption and ankylosis are often erroneously used as synonyms. While replacement resorption describes the active process during which the tooth is resorbed and replaced by bone tissue, ankylosis is the Greek word for immobile. Thus, it describes the situation of a tooth lacking normal mobility due to the fusion between tooth and bone.

The fusion can be permanent or transient and appears to depend on the size of the resorbed area. If the ankylotic area is small, the bone on the tooth surface can resorb and be replaced with reparative cementum (Andreasen & Skougaard 1972; Andreasen & Kristerson 1981; Andersson *et al*. 1985; Hammarström *et al*. 1986). If the ankylotic area is large, a sufficient amount of bone will be formed on the root surface to make the fusion between bone and tooth permanent (Andreasen 1981; Andreasen & Kristersson 1981; Hammarström *et al*. 1986). It has been shown that long-term rigid splinting following external trauma results in a higher incidence of dento-alveolar ankylosis than with a short-term, less rigid fixation (Andreasen 1975).

Clinically, ankylosis is diagnosed by absence of tooth mobility and by a percussion tone that is higher than in a normal tooth (Andreasen 1975; Andersson *et al*. 1985). Radiographically, a local disappearance of the periodontal ligament contour may show an initial stage of fusion. However, even in non-ankylosed teeth it is not always possible to observe the entire contour of the periodontal ligament. Percussion and tooth mobility testing are therefore more sensitive diagnostic tools than radiography in the early stages of replacement resorption (Andersson *et al*. 1985). When dento-alveolar ankylosis occurs at a young age, the tooth will not erupt resulting in infra-occlusion (Andreasen & Hjörting-Hansen 1966; Malmgren *et al*. 1984; Kürol 1984).

The formation of bone on a dentin surface is not a pathologic process, but one to be regarded as a form of repair. The bone has accepted the dental hard tissue as a part of itself and the tooth becomes involved in the normal skeletal turnover (Löe & Waerhaug 1961; Hammarström *et al*. 1986). The turnover phase is fast in a growing child, but slower in an adult. Hence, the rate of bone replacement follows the pattern of bone remodeling. The detailed mechanism directing the resorptive process is not understood.

Conclusion

Ankylosis caused by apposition of bone to a root surface is a prerequisite for replacement resorption. The condition may be seen as a form of repair of root surface resorptions, albeit not desirable from a

clinical standpoint as the root structure will become successively destroyed. No treatment is available for this condition.

External inflammatory resorption

The term external inflammatory resorption describes the presence of an inflammatory lesion in the periodontal tissues adjacent to a resorptive process (Andreasen 1985). There are two main forms – peripheral inflammatory root resorption (PIRR) and external inflammatory root resorption (EIRR). Both forms are triggered by destruction of cementoblasts and the cementoid. In PIRR the factor maintaining osteoclast activation is thought to be provided by an inflammatory lesion in the adjacent periodontal tissue (Andreasen 1985; Gold & Hasselgren 1992). EIRR, on the other hand, receives its stimulus from an infected necrotic pulp (Andreasen 1985; Andreasen & Andreasen 1992).

Peripheral inflammatory root resorption

The major feature of this type of resorption is its location close to the gingival margin and its invasive nature. In teeth with a normal height of bone crest it usually becomes localized cervically, whereas in cases where the periodontal tissue has receded it can develop more apically. Different names have been proposed, including subosseous resorption (Antrim *et al*. 1982) and (the complete opposite) supraosseous extra-canal invasive resorption (Frank & Bakland 1987) reflecting the confusion that has surrounded the cause of this type of resorptive lesion. As it extends into the peripheral dentin towards the pulp, and as clast-activating factors seem to emanate from an inflammatory lesion in the periodontium, the term peripheral inflammatory root resorption (PIRR) was proposed to reflect the potential etiology of this phenomenon (Gold & Hasselgren 1992).

The clinical features of PIRR include a granulation tissue that bleeds freely on probing. Occasionally, a periodontal abscess may develop due to marginal infection, which may mimic a periodontal or endodontic condition (Fig. 40-23). When the lesion is located more apically or proximally, probing is usually difficult. Radiographically, the lesion may only be seen after a certain size has been reached (Fig. 40-22c). Sometimes the appearance is mottled due to the proliferation of bone tissue into the resorptive defect (Seward 1963) (Fig. 40-25). The outline of the root canal can often be seen within the radiolucent area (Figs. 40-22, 40-25 and 40-26) and this is a diagnostic feature for external root resorption in general. The presence of profuse bleeding upon probing and

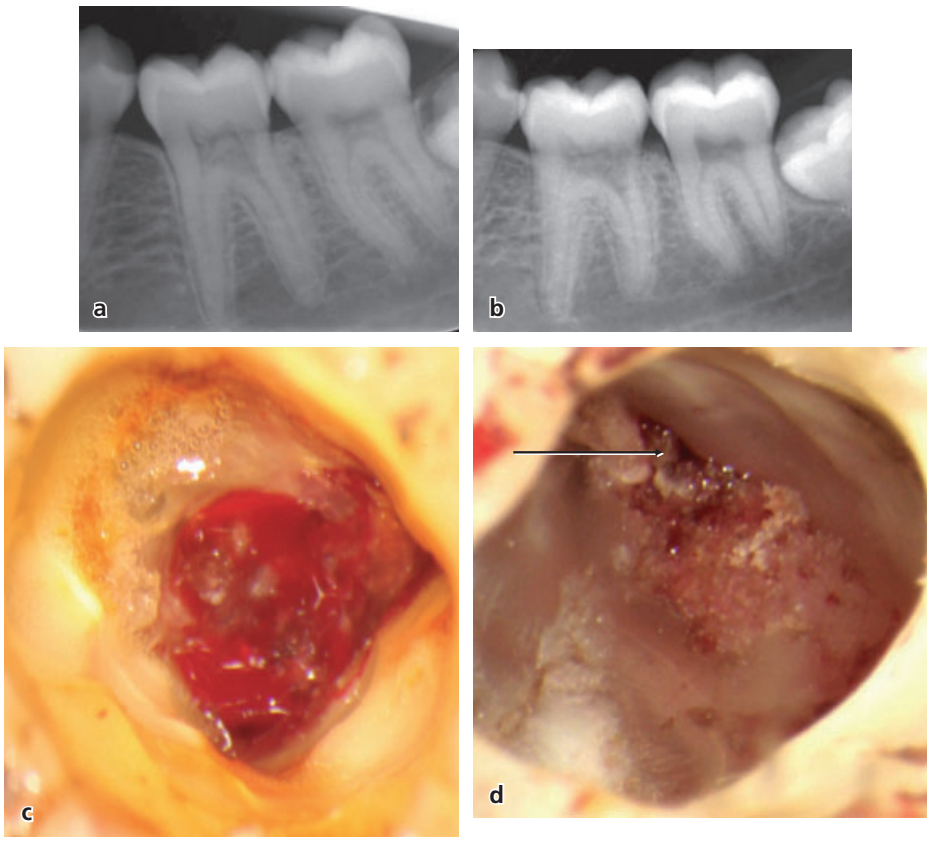

Fig. 40-25 (a,b) Peripheral inflammatory root resorption in a first lower molar showing a mottled appearance. There are pulp stones within the pulp tissue and bone tissue formation within the resorptive defect superimposed on the pulpal space. Following accessing both the pulp and the resorptive process (c) and removing the bleeding tissue, bone tissue appeared at the lingual wall of the cavity, where the resorptive process had entered the tooth (d). Arrow in (d) indicates the orifice of the root canal in the distal root. Case kindly provided by Dr. Magnus Fridjon Ragnarsson.

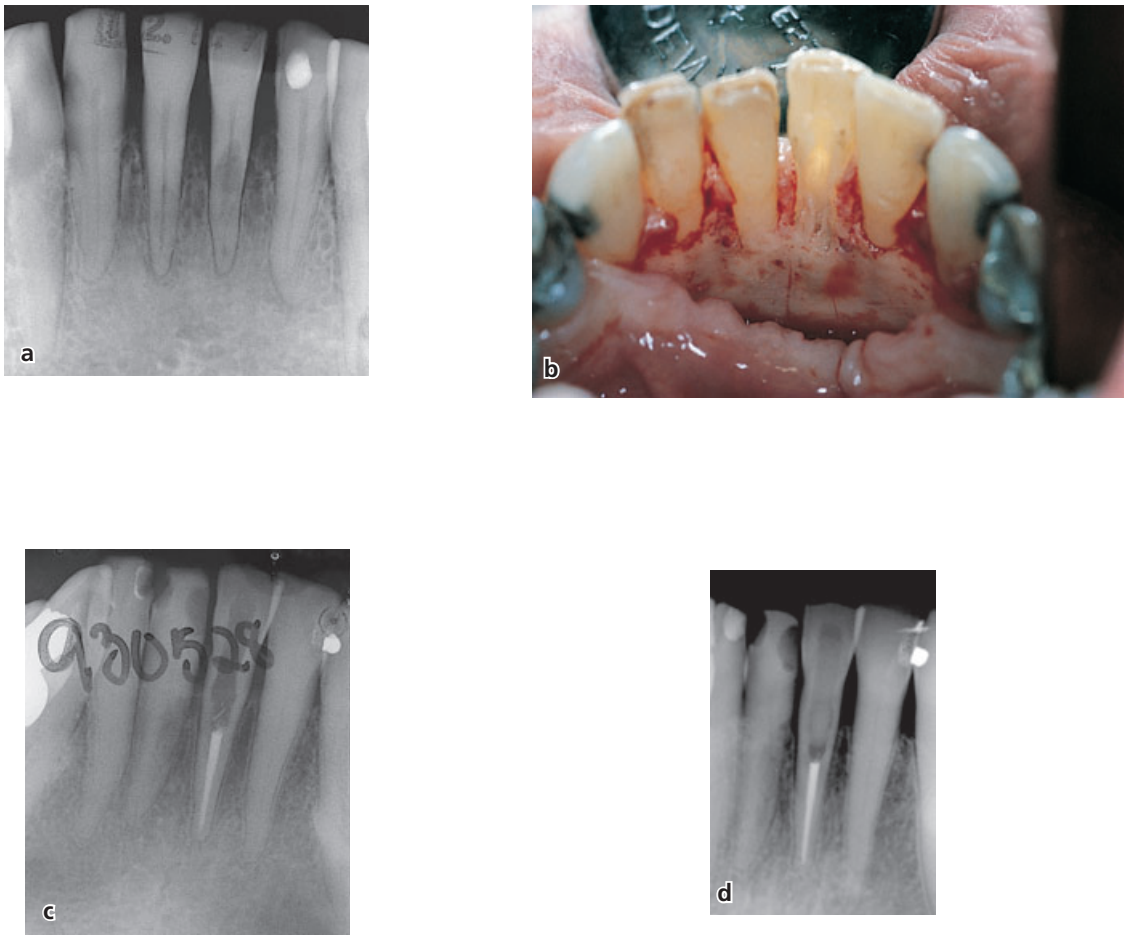

Fig. 40-26 Case with external root resorption on the lingual aspect of both central incisors. (a) The patient, a 78-year-old lady, had presented herself to the clinic after an episode of severe pain and development of a lingual periodontal abscess. The medical history was unremarkable. The patient was initially managed by antibiotic treatment. (b) Later, upon flap elevation and accessing the resorbing area and removal of the granulation tissue, exposure to a necrotic pulp of tooth #31 was noted. (c) Endodontic treatment was carried out during the surgery procedure. Tooth #41 was left without any further treatment and the case was followed clinically and radiographically. No recurrence of resorption occurred on either tooth and the patient remained comfortable. (d) Radiograph of the last follow-up is 8 years after treatment. Note that there is no progression of the resorptive process associated with tooth #41.

granulation tissue formation, in combination with a hard cavity bottom confirm the diagnosis of PIRR. Electric pulp test and cold tests are usually positive, but will not distinguish this condition from caries or internal resorption, the two major differential diagnostic options (Frank & Bakland 1987).

The mechanism for this form of resorption is far from completely understood. Predisposing factors seem to be orthodontic treatment, trauma, and intracoronal bleaching, while periodontal therapy had a low incidence among 222 analyzed cases (Heithersay 1999). The reason for the low incidence following periodontal treatment could be that, even upon excessive scaling and root planing, the damaged area of the root surface usually becomes covered by junctional epithelium. If a resorptive process is triggered it seems that its continuance has an infectious cause (Brosjö *et al*. 1990; Gold & Hasselgren 1992).

Unmineralized, newly formed tissue in cementum (Gottlieb 1942) and in predentin (Stenvik & Mjör 1970) appears resistant to resorption and explains why PIRR expands laterally without invading the pulp. Yet, this peripheral extension can markedly undermine the tooth structure (Fig. 40-23). If there is a non-vital pulp and thus no resorption inhibition in the form of odontoblast-supported predentin, PIRR may extend to the pulpal space. In root-filled teeth, which have been subjected to intracoronal bleaching, tissue toxic bleaching agents such as hydrogen peroxide have been found to be capable of penetrating through dentin and cementum (Fuss *et al*. 1989). If this occurs during the bleaching process, periodontal tissue injury will be inflicted and a resorptive processs may be initiated (Harrington & Natkin 1979; Montgomery 1984). The ensuing progression is thought to be a function of persisting inflammation as bacteria have colonized the chemically emptied dentinal tubules (Cvek & Lindvall 1985).

Obviously there are also different forms of this kind of resorption, some of which may be associated with a broad opening to the periodontium, as in the

cases initiated by bleaching agents. Others may have smaller openings through the cementum layer along which the resorptive process continues inside the tooth structure without causing major peripheral breakdown. The two patterns dictate the choice of treatment attempt. Surgical exposure of the area including removal of the granulation tissue is the only reasonable option in the former case; a dental filling, e.g. a resin composite, is placed in the defect followed by resuturing the flap. Other treatment options include repositioning of the flap apical to the restoration or orthodontic extrusion of the tooth (Gold & Hasselgren 1992). Guided tissue regeneration has also been advocated after surgical removal of the granulation tissue, to promote ingrowth of periodontal ligament cells into the resorbed area (Rankow & Krasner 1996)

External inflammatory root resorption

This type of resorption usually occurs as a complication to luxation injuries in conjunction with dental traumata. It begins as a surface resorption due to damage of the periodontal ligament and the cementum layer. There is good support for the view that the stimulus for continuance is infectious in nature and that the source is an infected pulp that succumbed as a result of the traumatic injury (Bergenholtz 1974; Andreasen 1985; Andreasen & Andreasen 1992). Following the initial surface resorption the often rapid progression is then due to the release of bacterial elements into the periodontal tissue by way of the exposed dentinal tubules. While the inflammatory process is maintained, the resorptive process, aimed at eliminating the irritants in the dentin tubules, moves in the direction of the infected pulp. As dentin is further resorbed, more infectious products are released thus perpetuating the inflammatory reaction with acceleration of the resorptive process as a result (Andreasen 1985).

The earliest stages are not radiographically visible due to the small size of the resorptive cavity and the first radiographic signs following trauma cannot usually be seen for several weeks (Andreasen *et al*. 1987). Treatment is directed towards the cause of the resorption, that is, the root canal infection (Cvek 1993), and the procedure to be carried out is no different to the one applied in normal cases. While a successful halt of the resorption can be anticipated (Cvek 1973) there is always risk of ankylosis after the initial healing phase. The greater the resorbed area, the greater is the risk for this complication (Andreasen & Kristerson 1981; Andersson *et al*. 1985; Gottlow *et al*. 1986).

Conclusion

Peripheral inflammatory root resorption (PIRR) and external inflammatory root resorption (EIRR) are two forms of progressive external root resorption associated with persistent inflammation in the periodontal tissues. While the direct cause for progression is not well understood, infectious elements maintaining periodontal inflammation close to a root surface that is not covered by periodontal ligament or epithelium appear to drive PIRR. To remedy the condition it is necessary to remove all resorbing granulation tissue surgically and fill the resorption cavity. In certain cases it may be possible to carry out the treatment from the pulpal side (Fig. 40-25). Regardless of approach, periodontal tissue complications may ensue, including deep pockets and suppuration from such pockets. Treated cases should therefore be monitored by regular clinical/radiographic follow-ups to

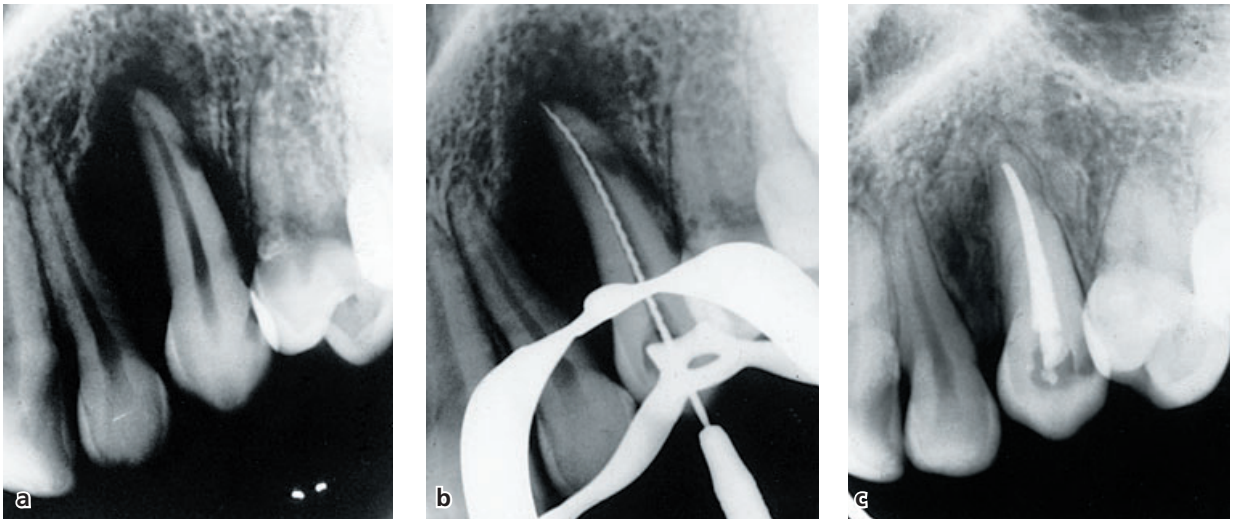

Fig. 40-27 Radiographs from a 27-year-old woman showing the emergence of external inflammatory root resorptions on the left maxillary canine, which had been autotransplanted into a surgically prepared socket 2 months earlier (a). Endodontic treatment of the necrotic pulp (b) halted the resorptive process. (c) Radiograph following root filling shows that the external resorption cavity is rounded. A normal contour of the periodontal ligament space can be seen between the root and bone, which has filled the prepared socket.

observe any signs of recurrence and how the periodontal tissue copes. In advanced cases extraction is the only reasonable treatment option. EIRR is usually seen as a complication to luxation injuries in conjunction with dental traumata. The primary impetus for its progression is an infected pulp that releases bacterial elements to the resorbing area along exposed dentinal tubules by which an inflammatory lesion is also maintained in the periodontium. EIRR can usually be stopped by focusing the treatment on the endodontic infection (Fig. 40-27) although ankylosis and replacement resorption may appear as complications that may not be detected until years later.

Chapter 41

Treatment of Peri-implant Lesions

Tord Berglundh, Niklaus P. Lang, and Jan Lindhe

Introduction

Inflammatory lesions occurring in the peri-implant tissues were described in Chapter 24. Such processes are the result of opportunistic infections (see Chapter 10) and may, if left untreated, progress deep into the supporting bone and lead to implant loss. It is, therefore, imperative that the tissues around implants be monitored at regular intervals to discover arising biologic complications and to interfere with the disease process at an early stage. The appropriate therapy instituted following diagnosis must be aimed towards the reduction of the submucosal biofilm and the alteration of the ecologic conditions for the bacterial habitat.

The diagnostic process

The examination of the tissues around implants has many features in common with the periodontal examination and must include parameters relevant to the pathogenic process of the peri-implant lesion. It should be understood that, while advanced peri-implant lesions are easily recognized on radiographs, early alterations in the mucosa are often discrete (see also Chapter 24). Hence, a systematic examination for their detection is required that should include assessments of:

- Bleeding on probing (BoP)
- Suppuration
- Probing depth (PPD)
- Radiographic bone loss
- Implant mobility.

Assessments of BoP, suppuration, and PPD must be made at four surfaces (mesial, buccal, distal, and lingual) of each implant, while radiographic evaluation is limited to mesial and distal aspects.

Treatment strategies

The decision on treatment strategies is based on the diagnosis and the severity of the peri-implant lesion. Peri-implant mucositis and incipient forms of peri-implantitis require less extensive measures than advanced peri-implantitis lesions with severe bone loss. In all situations of peri-implant disease, however, the treatment strategies must include mechanical cleaning (infection control) procedures. Thus, information and instruction on the use of oral hygiene measures must be provided to the patient in combination with professional mechanical cleaning, including removal of plaque and calculus on implant surfaces. In this context it is important that the design of the implant-supported prosthesis allows access for oral hygiene. Thus, in cases where access for implant cleaning is obstructed, the prosthesis has to be modified to promote self-performed and professional mechanical infection control.

Two cases that illustrate the outcome of self-performed and professional mechanical cleaning are presented in Figs. 41-1 and 41-2. While plaque, calculus, and signs of inflammation are evident at implants in the initial examination, the follow-up visit at 3 months of infection control demonstrates improved oral hygiene and soft tissue conditions.

There are obvious similarities between teeth and implants regarding the strategies in treatment of

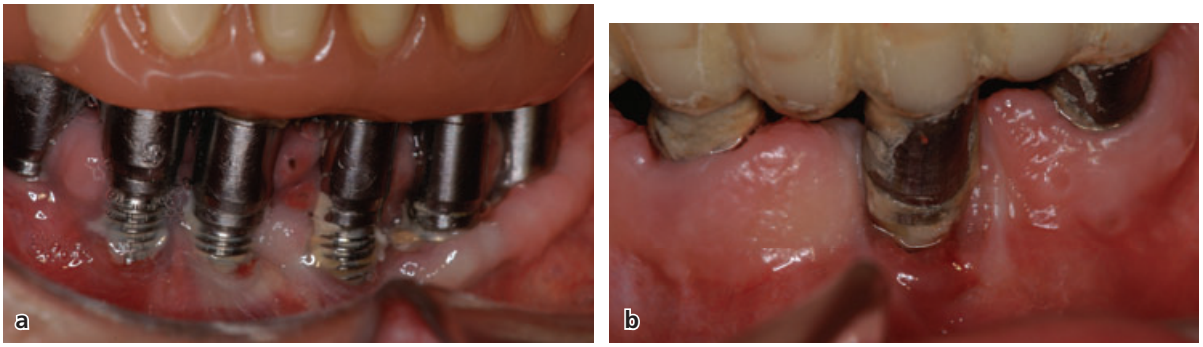

Fig. 41-1 Clinical photograph from implant sites in the mandible of a 75-year-old male (a) and a 62-year-old woman (b). Note the large amounts of plaque and calculus and the overt signs of inflammation in the peri-implant mucosa (a).

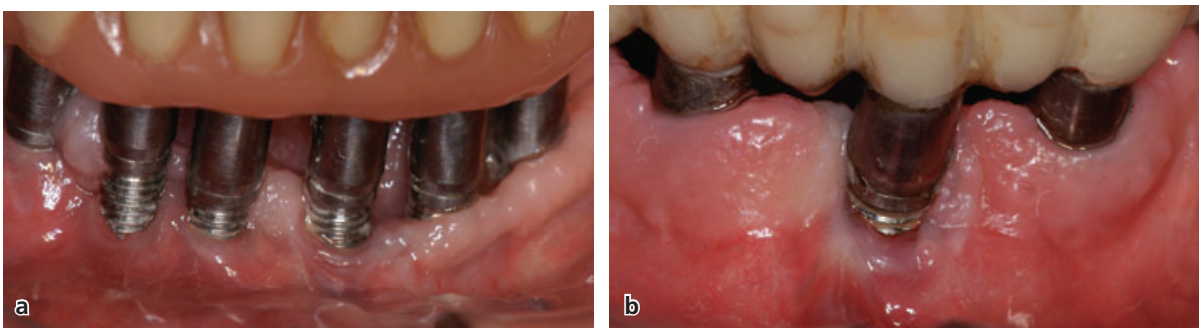

Fig. 41-2 Implant sites in Fig. 41-1 after 3 months of self-performed mechanical infection control combined with professional cleaning. Improved oral hygiene and soft tissue conditions.

periodontal and peri-implant infections. One important difference, however, relates to difficulties with instrumentation of the implant surface below the margin of the mucosa. Thus, subgingival scaling and root planing are well known procedures in the treatment of periodontitis, while in peri-implantitis the geometry of the implant with threads of different designs may impede the ability of the clinician to detect and remove calculus located below the mucosal margin. During such "blind" instrumentation at implants there is also a risk that deposits may be dislodged and become displaced into the mucosa. It is thus recommended that non-surgical debridement of implant surfaces, i.e. procedures that aim to remove calculus and plaque, should be restricted the portion of the implant located coronal to or at the level of the mucosal margin. While calculus may be chipped off using carbon fiber (Fig. 41-3) or plastic curettes, plaque is removed by polishing the implant surface with rubber cups and a polishing paste. Carbon fiber curettes do not damage the implant surface. They may be sharpened and are strong enough to remove most accumulations of calculus. Conventional steel curettes or ultrasonic instruments with metal tips should not be used because they may cause severe damage to the implant surface (Matarasso *et al.* 1996).

Peri-implant mucositis and incipient peri-implantitis lesions may be resolved using the cause-related measures described above. A re-examination

Fig. 41-3 Calculus deposits may be chipped off using carbon fiber curettes with the aim of not scratching the implant surface.

of peri-implant tissues following initial therapy that reveals absence of BoP and pocket closure indicates resolution of peri-implant lesions. On the other hand, if signs of pathology, i.e. BoP/suppuration in combination with deep pockets remain at the re-examination, additional therapy is required. Surgical procedures are one treatment option which provides access to the implant surfaces harboring biofilms. A prerequisite for surgical therapy in treatment of peri-implantitis is appropriate standards of self-performed infection control.

Surgical therapy of peri-implantitis lesions is illustrated in Figs. 41-4, 41-5, and 41-6. Clinical signs

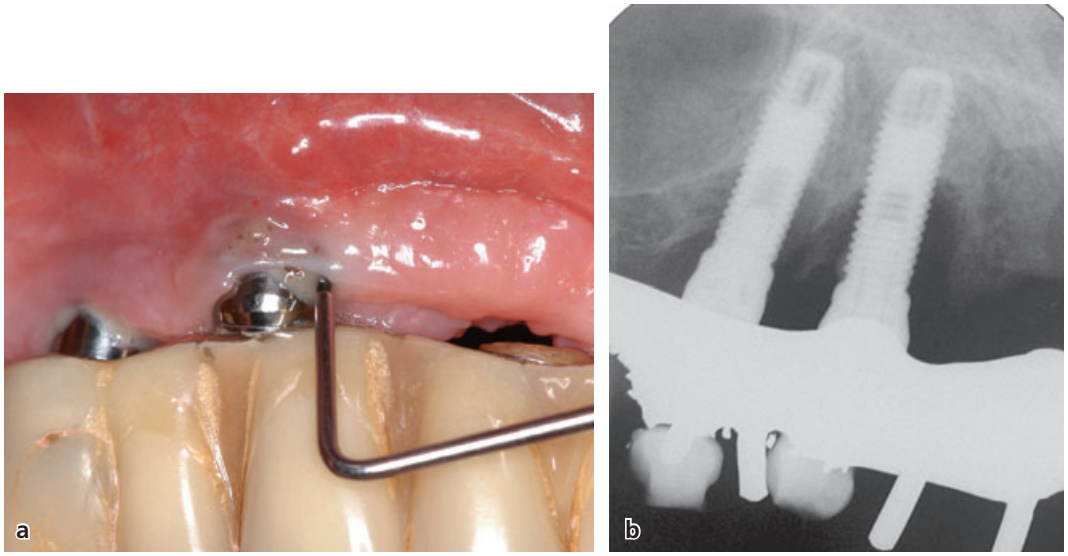

Fig. 41-4 Clinical photograph from implant sites with peri-implantitis. Note the PPD of 10 mm and suppuration (a) and the crater-formed defects in the radiograph (b).

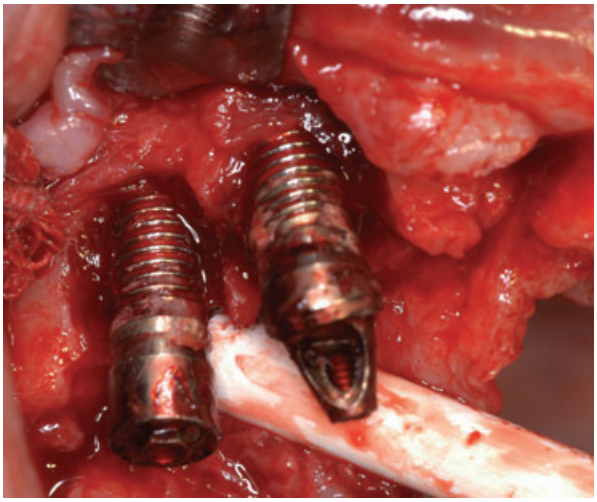

Fig. 41-5 Implant sites in Fig. 41-3 after flap elevation and removal of granulation tissue. Note the absence of buccal bone walls of the osseous defects. The implant surfaces are accessible for mechanical debridement.

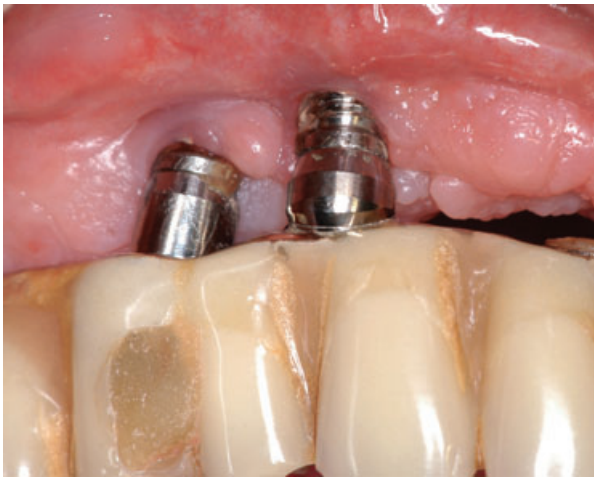

Fig. 41-6 Implant sites in Fig. 41-3 at 6 months after surgical therapy. Maintenance therapy with supervised infection control is provided. Note the soft tissue recession following the pocket elimination procedure.

of inflammation, PPD of about 10 mm in combination with BoP and suppuration were detected at the initial examination (Fig. 41-4). The radiograph revealed crater-formed defects around the two implants. Flap elevation allowed access to the area and granulation tissue in the defects was removed using steel curettes (Fig. 41-5). Mechanical debridement of the implant surface was performed using carbon fiber curettes and small pieces of gauze or pellets soaked in saline. The peri-implantitis associated bone defect may be treated using either resective or regenerative procedures (see also Chapter 46). In this case the morphology of the osseous defect was not suitable for regenerative techniques and, hence, resective procedures were performed to adjust the morphology of the interproximal bone walls. At the 6-month follow-up after surgery, PPD was reduced and clinical signs of inflammation were absent (Fig. 41-6).

Recent reviews on treatment of peri-implant mucositis and peri-implantitis indicated that most articles in the literature consist mainly of case reports (Klinge *et al*. 2002; Roos-Jansåker *et al*. 2003). In addition to mechanical debridement a vast number of different treatment procedures have been suggested including antiseptic agents and local and/or systemic antibiotics. Klinge *et al*. (2002) concluded that there is insufficient evidence to support a specific treatment protocol.

Resolution of peri-implantitis lesions

In dog experiments by Ericsson *et al*. (1996) and Persson *et al*. (1996, 1999), peri-implantitis lesions

were first produced according to the technique previously described (Lindhe *et al*. 1992). The peri-implantitis lesions were subsequently exposed to therapy. Antibiotics (amoxicillin and metronidazole) were administered to the animals via the systemic route but local treatment was provided to only some of the diseased implant sites. Following several months of healing, it was observed that in implant sites also given local therapy, i.e. submarginal debridement, the inflammatory lesions were resolved. In implant sites not exposed to local debridement, however, the inflammatory infiltrate persisted in the mucosa as well as in locations immediately adjacent to the bone tissue.

These observations clearly demonstrate that a treatment regimen that is restricted to systemic administration of antibiotics is not effective in the management of peri-implantitis, but must always be combined with meticulous removal of the biofilm from the contaminated implant surface. In this context it must be remembered that in the treatment of chronic periodontitis administration of systemic antibiotics without local therapy (i.e. scaling and root planing) will not resolve the inflammatory lesion in the gingiva and will also fail to arrest further progression of tissue breakdown (Lindhe *et al*. 1983a,b; Berglundh *et al*. 1998).

Cumulative Interceptive Supportive Therapy (CIST)

Preventive and therapeutic strategies

Depending on the clinical, and eventually the radiographic, diagnosis, protocols for preventive and therapeutic measures were designed to intercept the development of peri-implant lesions. This system of supportive therapy is cumulative in nature and includes four steps, which should not be used as single procedures, but rather as a sequence of therapeutic procedures with increasing anti-infective potential depending on the severity and extent of the lesion. Diagnosis, therefore, represents a key feature of this supportive therapy program (Lang *et al*. 2004).

The major clinical parameters to be used have been discussed above and include:

- Presence of a biofilm
- Presence or absence of BoP
- Presence or absence of suppuration
- Increased peri-implant probing depth
- Evidence and extent of radiographic alveolar bone loss.

Oral implants without plaque and calculus and surrounded by healthy peri-implant tissues, as evidenced by (1) absence of BoP, (2) absence of suppuration, and (3) probing depth usually not exceeding 3 mm, should be considered clinically stable. Such sites should not be exposed to therapeutic measures (Fig. 41-7).

Fig. 41-7 Clinically stable implant with VMK crown (region 21) characterized by absence of bleeding on probing, suppuration, and a peri-implant probing depth not exceeding 3 mm.

Fig. 41-8 Peri-implant mucositis characterized by presence of bleeding on probing, absence of suppuration, and a peri-implant probing depth of 4 mm.

Mechanical debridement; CIST protocol A

Implants with plaque and calculus deposits and surrounded by a mucosa that is BoP positive but suppuration negative and with a PPD ≤4 mm are to be subjected to mechanical debridement as described above (Fig. 41-8).

Antiseptic therapy; CIST protocol A+B

At implant sites which are BoP positive, exhibit an increased probing depth (4–5 mm) and may or may not demonstrate suppuration, antiseptic therapy is delivered in addition to mechanical debridement. A 0.2% solution of chlorhexidine digluconate is prescribed for daily rinsing, or a 0.2% gel of the same antiseptic is recommended for application to the affected site (Fig. 41-9). Generally, 3–4 weeks of antiseptic therapy are necessary to achieve positive treatment results.

Antibiotic therapy; CIST protocol A+B+C

At BoP-positive implant sites with deep pockets (PPD ≥6 mm) (suppuration may or may not be present), there are frequently also radiographic signs of bone loss. Such pockets represent an ecologic habitat which is conducive for the colonization of Gram-negative and anaerobic putative periodontal pathogens (Mombelli *et al*. 1987). Anti-infective treatment must include the use of antibiotics to eliminate or reduce the pathogens in this habitat. This, in turn, will allow soft tissue healing as demonstrated in a clinical study by Mombelli and Lang (1992). Prior to administering antibiotics the mechanical (CIST A) and the antiseptic (CIST B) protocols have to be applied. During the last 10 days of the antiseptic treatment regimen, an antibiotic directed against anaerobic bacteria (e.g. metronidazole or ornidazole) is used. Thus for instance, 350 mg tid of Flagyl® (Rhone-Poulenc) or 500 mg bid of Tiberal® (Roche) is administered via the systemic route. A site treated according to the above protocol is depicted in Fig. 41-10. A fistula can be seen in the buccal aspect of implant site 45 (Fig. 41-10a). The site exhibited BoP and had a probing depth of 7 mm. After therapy the inflammation is resolved (Fig. 41-10b) and some recession of the mucosal margin has occurred. In Fig. 41-10c the bone fill that took place in the angular defect is illustrated in a subtraction radiography image using contrast enhancing. Figure 41-10d presents the site 8 years after active therapy.

An alternative to systemic administration is the controlled, local delivery of antibiotics. It must be realized, however, that only devices with proper release kinetics must be used to assure successful

Fig. 41-9 Mechanical and antiseptic cleansing. Application of chlorhexidine gel (Plakout®, 0.2%) to a site with peri-implant mucositis.

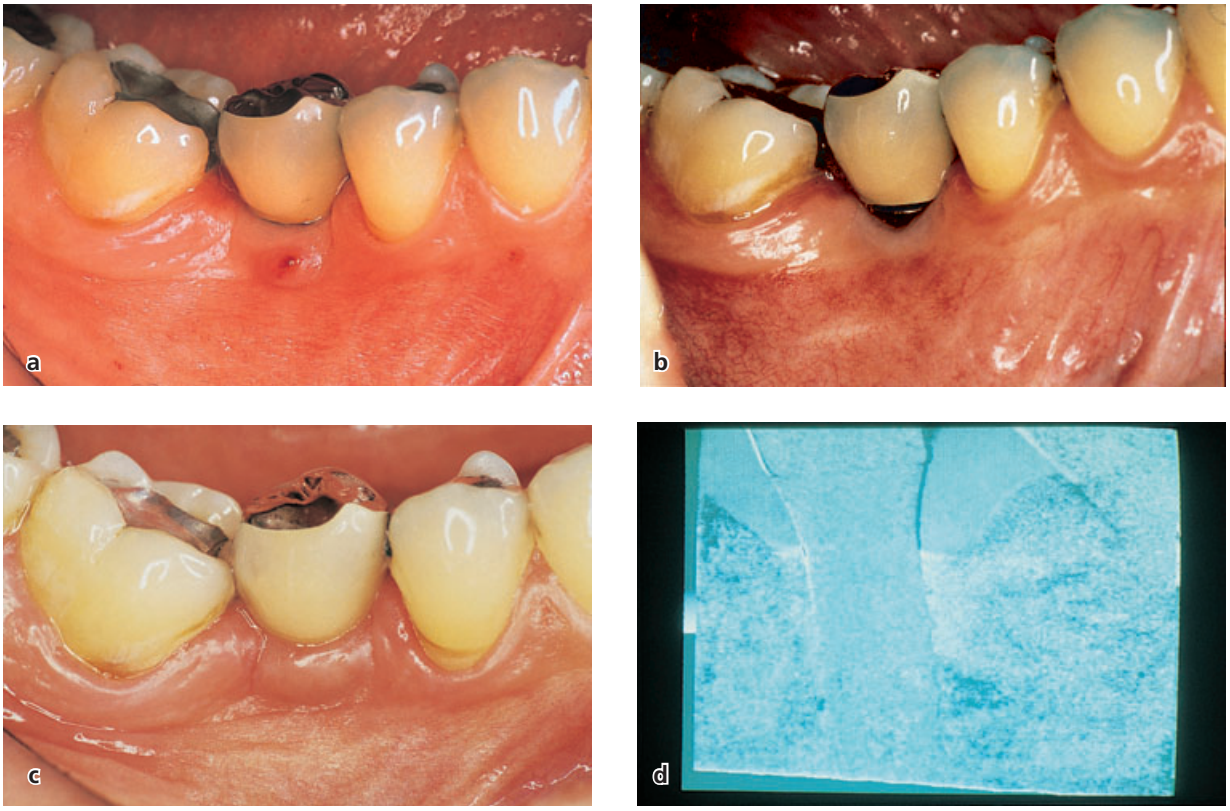

Fig. 41-10 Treatment of peri-implantitis according to the protocol of CIST (cumulative interceptive supportive therapy). (a) Clinical diagnosis of peri-implantitis: presence of bleeding on probing, suppuration, development of a fistula, loss of alveolar bone. Peri-implant probing depth 7 mm. (b) Clinical resolution of the peri-implant infection 1 year after mechanical and antiseptic cleansing, followed by the systemic application of antibiotics (500 mg Tiberal® bid for 10 days). Some recession is visible. (c) Absence of mucositis, reduced peri-implant probing depth to 3 mm, and bone fill of the lesion. (d) Documentation of the healed peri-implant infection by contrast-enhanced subtraction radiography. The intrabony crater has been completely filled 1 year after therapy.

clinical results. The antibiotic must thus remain at the site of action for at least 7–10 days and in a concentration high enough to penetrate the submucosal biofilm (Mombelli *et al*. 2001). An example of such a controlled-release device is the tetracycline-containing periodontal fiber (Actisite®; Alza). The therapeutic effect of this controlled-release device appears to be identical to the effect obtained by the systemic use of antibiotics (Mombelli *et al*. 2001).

In a more recent development, minocycline microspheres (1 mg Arestin®; Orapharma, Johnson & Johnson) have been used as a controlled-release device in a similar manner to the application of tetracycline fibers (Mombelli *et al*. 2001). These microspheres are easily applied into the peri-implant pocket by means of a syringe. The antibiotic is contained in very small beads that stick to the lateral walls of the pocket and to the implant surface providing enough substantivity (high enough concentration for up to 14 days) to penetrate the biofilm. The principle has been tested in a randomized controlled clinical trial with a 1% chlorhexidine gel as a control (Renvert *et al*. 2006) and a prospective cohort study in patients with peri-implantitis (Persson *et al*. 2006; Salvi *et al*. 2007). Both studies demonstrated reduction in bleeding on probing, pocket depth reduction, and slight recession. Significantly lower bacterial loads were seen after 10 days and up to 180 days for some presumptive pathogens (Persson *et al*. 2006). This indicates that the application of minocycline microspheres adjunctive to the CIST protocols A+B represents a valuable alternative to the administration of systemic antibiotics for the treatment of incipient peri-implant infections.

Regenerative or resective therapy; CIST protocol A+B+C+D

It is imperative to understand that regenerative or resective therapy is not instituted until the peri-implant infection is under control. Thus, before surgical intervention is planned, the previously diseased site should have become BoP negative, exhibit no suppuration, and have a reduced probing depth. Depending on the extent and severity of the local bone loss, a decision is made whether regenerative or resective measures are to be applied. In this context it must be realized that the goal of regenerative therapy, including the use of barrier membranes, is new bone formation in the crater-like defect around the implant, although *de novo* osseointegration may occur to a limited extent (Persson *et al*. 1999; Wetzel *et al*. 1999).

Conclusions

An implant patient must always be enrolled in a supportive therapy program that involves recall visits at regular intervals. Each recall visit must start with an examination to assess whether the implant sites are healthy or exhibit signs of inflammation. Cumulative Interceptive Supportive Therapy (CIST) includes a series of four protocols to be used when the examination and the diagnostic process are completed.

Figure 41-11 outlines (1) the decision process to be used for the peri-implant tissue diagnosis (Lang *et al*. 2004) and (2) the different therapeutic measures that are available to treat and/or prevent peri-implant infections.

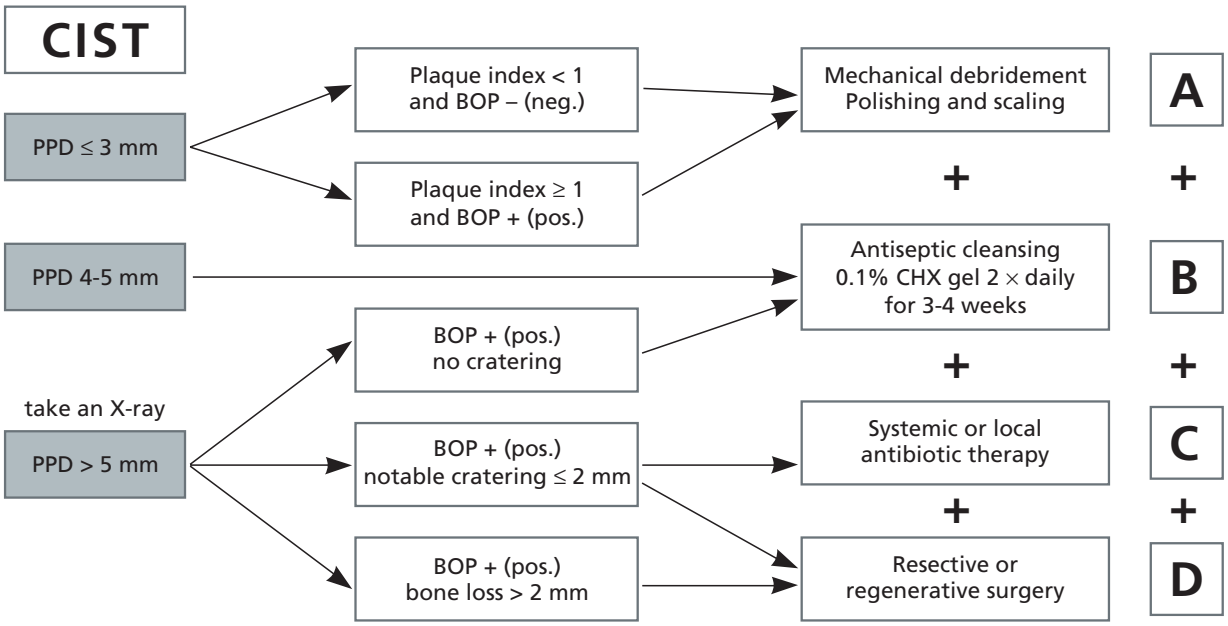

Fig. 41-11 Decision tree for cumulative interceptive supportive therapy (CIST). Depending on the mucosal condition and probing depth, either regime A or regime A+B, regime A+B+C or regime A+B+C+D are performed. A = Mechanical debridement; B = Antiseptic cleansing; C = Antibiotic therapy; D = Resective or regenerative surgery.

Chapter 42

Antibiotics in Periodontal Therapy

Andrea Mombelli

Principles of antibiotic therapy

Antibiotics are drugs that can kill or stop the multiplication of bacterial cells, at concentrations that are relatively harmless to host tissues, and therefore can be used to treat infections caused by bacteria. The capacity of the drug to reach the infected site, and the ability of targeted bacteria to resist or inactivate the agent determine the effectiveness of therapy. Based on their effect at concentrations tolerated by the host, antibiotics can be categorized as "bactericidal" or "bacteriostatic", and, depending on the range of susceptible bacteria, "narrow-spectrum" or "wide-spectrum". Antibiotics are just one group of antimicrobial agents, which also comprise antiviral, antifungal, and antiparasitic chemicals. The term was originally applied to substances extracted from fungus or other living organisms, but today also includes synthetic products.

As antibiotics can kill or suppress bacteria, the recognition of periodontitis as an infection – caused or sustained by certain bacteria living and multiplying in diseased sites – is a fundamental issue for any antimicrobial treatment concept. Antibiotics do not remove calculus and bacterial residues, and this is traditionally perceived to be an essential part of periodontal therapy.

The limitations of mechanical therapy: can antimicrobial agents help?

The continued presence of large masses of bacteria on hard oral surfaces induces inflammation in adjacent soft tissues such as gingiva or mucosa, and the importance of removing bacterial plaque for resolution of gingivitis or mucositis is undisputed. The propensity of sites to undergo further periodontal destruction is felt to be more specific in nature, since not all sites with gingivitis invariably progress to periodontitis, and since increased proportions and detection frequencies of suspected oral pathogens are found in periodontitis lesions. Nevertheless, thorough mechanical cleaning of the root surfaces has also proven to be beneficial in the case of periodontitis, of whatever class, and under whatever clinical circumstances. Furthermore, it has been shown that the ability of the patient to prevent the re-formation of structured bacterial deposits by toothbrushing is crucial for long-term stability (for review see Chapter 59). However, this way of dealing with periodontal disease is time consuming, requires high levels of motivation and manual skills – of both the clinician and the patient – and has unwanted effects. It would be irrational to believe that mechanical instruments are able to completely remove periodontal pathogens from all infected sites (Mombelli *et al*. 2000). Bacteria may be inaccessible to mechanical instruments in concavities, lacunae, and dentin tubules, not to mention invaded soft tissues. Substantial hard tissue trauma may arise from repeated attempts at instrumentation in locally unresponsive sites, or sites with recurrent disease (Fig. 42-1). In addition, successfully treated sites may be recolonized by pathogens persisting in non-dental areas. Although we know that mechanical therapy can be clinically successful in many patients even if all putative pathogens are not completely eradicated, persistence or regrowth of certain microorganisms in treated sites should be

Fig. 42-1 Conventional periodontal therapy and maintenance imply repeated treatment of sites with localized unresponsive or recurrent disease, resulting in sometimes substantial hard tissue trauma.

considered as a cause of unsatisfactory treatment outcomes.

A closer look at the composition of the subgingival microbiota reveals that mechanical treatment is targeted at a variable mixture of different bacteria. The number of different species and subspecies occasionally identified in samples from human plaque by far exceeds 100, but only relatively few show a distinctive pattern of association with disease. While most frequently identified organisms are thought to harm tissues significantly only if present in high numbers over prolonged periods of time, in susceptible individuals certain species may have a negative effect even at relatively low numbers. On the basis of their pathogenicity, demonstrated in animal experiments, and the identification of virulence factors, a few organisms have been suggested to be specific periodontal pathogens (for review see Chapter 9). *Aggregatibacter actinomycetemcomitans* (formerly known as *Actinobacillus actinomycetemcomitans*) (Norskov-Lauritsen & Kilian 2006) and *Porphyromonas gingivalis* have attracted particular attention because longitudinal and retrospective studies have indicated an increased risk for periodontal breakdown in positive sites and because results of treatment have been better if the organisms could no longer be detected at follow-up (Bragd *et al*. 1987; Wennström *et al*. 1987; Carlos *et al*. 1988; Haffajee *et al*. 1991; Grossi *et al*. 1994; Haffajee & Socransky 1994; Dahlén *et al*. 1996; Rams *et al*. 1996; Chaves *et al*. 2000). If periodontal disease is in fact caused by a limited number of bacterial species, then non-specific continuous plaque removal is not the only possibility for prevention and therapy. Specific suppression of pathogenic bacteria becomes a valid alternative, and antibiotic approaches to regain and maintain periodontal health may have a better efficiency ratio.

In the late 1930s and early 1940s, the appearance of powerful agents selectively active against bacteria – sulfonamides, penicillin, and streptomycin – revolutionized the treatment of bacterial infections. The phenomenal success of these agents in the treatment of formerly life-threatening diseases led many to believe that bacterial infections would never again be a major medical concern. More than six decades of experience with these, and hundreds of additionally developed antimicrobial drugs have shown that, despite all the success, this view was too optimistic. Emerging problems, resulting from the widespread use of antibiotics have modified the general perception of the capabilities of antimicrobial agents. Over the years, many bacteria have developed a remarkable ability to withstand or repel antibiotic agents and are increasingly resistant to formerly potent agents. It has been noted that the use of antibiotics may disturb the delicate ecologic equilibrium of the body, allowing the proliferation of resistant bacteria or non-bacterial organisms. Sometimes this may initiate new infections that are worse than the ones originally treated. In addition, no antibacterial drug is absolutely non-toxic and the use of any antimicrobial agent carries with it accompanying risks. Thus, before we can start to administer antibiotics routinely to our periodontal patients we need to be sure about the specific benefit in comparison to standard treatment approaches. To limit the development of microbial antibiotic resistance in general, and to avoid the risk of unwanted systemic effects of antibiotics for the treated individual, a precautionary, restrictive attitude towards using antibiotics is recommended.

Specific characteristics of the periodontal infection

The term infection refers to the presence and multiplication of microorganisms in or on body tissues. The uniqueness of plaque-associated dental diseases as infections relates to the lack of massive bacterial invasion of tissues. Although there is evidence for bacterial penetration in severely diseased periodontal tissues, notably in periodontal abscesses and in acute necrotizing ulcerative lesions (Listgarten 1965; Saglie *et al*. 1982a,b; Allenspach-Petrzilka & Guggenheim 1983; Carranza *et al*. 1983), it has not been generally accepted that true bacterial invasion (including multiplication of bacteria within tissues) is crucial for periodontal disease progression. Bacteria in the subgingival plaque obviously interact with host tissues even without direct tissue penetration. Thus, to have an effect, any antimicrobial agent used in periodontal therapy needs to be available at a sufficiently high concentration not only within the periodontal tissues, but also in the environment of the periodontal pocket (Fig. 42-2). Antibiotic resistance always occurs first in sites where penetration of the agent is restricted, and

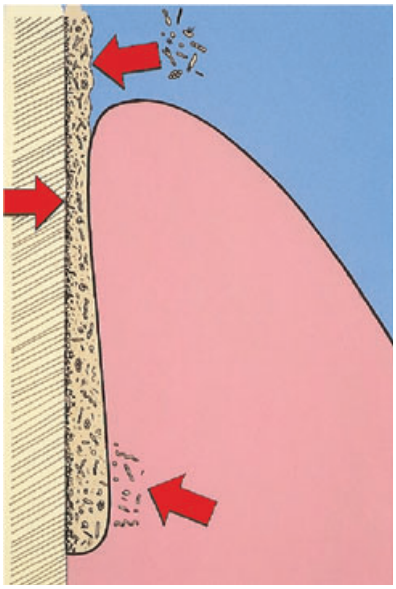

Fig. 42-2 Specific conditions for the use of antimicrobial agents in periodontal therapy. The periodontal pocket as an open site is subject to recolonization after therapy (top arrow). The subgingival bacteria are protected from antimicrobial agents in a biofilm (middle arrow). The agent must be available at a sufficiently high concentration not only within, but also in the subgingival environment, outside the periodontal tissues (bottom arrow).

therapeutic concentrations are difficult to achieve. A periodontal pocket may contain very large amounts of bacteria, and the antimicrobial agent may be inhibited, inactivated or degraded by non-target microorganisms.

The subgingival microbiota accumulate on the root surface to form an adherent layer of plaque. Accumulation of bacteria on solid surfaces can be observed on virtually all surfaces immersed in natural aqueous environments and is called "biofilm" formation. Extensive bacterial growth, accompanied by excretion of copious amounts of extracellular polymers, is a typical phenomenon in biofilms. Biofilms effectively protect bacteria from antimicrobial agents (Anwar *et al*. 1990, 1992). Bacteria involved in adhesion-mediated infections that develop on permanently or temporarily implanted materials, such as intravascular catheters, vascular prostheses or heart valves, are notoriously resistant to systemic antimicrobial therapy and tend to persist until the device is removed (Gristina 1987; Marshall 1992). Several mechanisms leading to this increased resistance of bacteria in biofilms have been proposed. Due to limited diffusion, antimicrobial agents may simply not reach deeper parts of a biofilm at sufficiently high levels during a given time of exposure. Within biofilms an unequal distribution of electrical charge may develop. Intrusion may thus be further complicated in certain areas of the biofilm depending on the charge of the penetrating molecule. Because of a limited availability of nutrients within the biofilm, bacteria may also reduce their metabolism, rendering them less susceptible to killing by agents interfering with protein, DNA or cell wall synthesis. *In vitro* experiments indicate that the attachment of bacteria to surfaces can trigger genes, which activate specific resistance mechanisms. Since these mechanisms are switched on upon contact, they may occur already in newly forming, very thin biofilms (Costerton *et al*. 1995).

Recognizing the above described problems there is currently a general consensus that mechanical instrumentation must always precede antimicrobial therapy. First, we should quantitatively reduce the large mass of bacteria, which otherwise may inhibit or degrade the antimicrobial agent. Second, we should mechanically disrupt the structured bacterial aggregates that can protect the bacteria from the agent.

Since the periodontal flora never consists of one single species, synergistic, but also antagonistic, relationships between microorganisms could occur. Based on the concept that the presence of beneficial bacterial species may suppress the activity of pathogens, one can speculate that it may be advantageous specifically to eliminate target bacteria only and to allow the growth of potentially beneficial microorganisms. Such contemplations have been used as an argument to propagate narrow-spectrum antibiotics for periodontal therapy.

Drug delivery routes

Oral antibiotics (*per os*, by mouth, abbreviated "p.o.") are the most common approach for treating bacterial infections. Administration by means other than through the alimentary tract (as by intramuscular or intravenous injection) is usually reserved for serious medical conditions if the oral route is proven ineffective. Some local infections can be treated with topically administered antibiotics, as with eyedrops or ointments. In the therapy of periodontal diseases antibiotics may be delivered via the systemic route or by direct placement into the periodontal pocket. Each method of delivery has specific advantages and disadvantages (Table 42-1). Local therapy may allow the application of antimicrobial agents at levels that cannot be reached by the systemic route and may be suitable for agents, i.e. antiseptics, that are too toxic to be delivered by the systemic route. This form of application seems to be particularly promising if the presence of target organisms is confined to the clinically visible lesions. Systemic administration of antibiotics may be better if the targeted bacteria are distributed wider. Studies have shown that periodontal bacteria may in fact be distributed throughout the whole mouth in some patients (Mombelli *et al*. 1991a, 1994), including non-dental sites, such as the dorsum of the tongue or tonsillary crypts (Zambon *et al*. 1981; van Winkelhoff *et al*. 1988; Müller *et al*. 1993, 1995; Pavicic *et al*. 1994). Disadvantages of systemic antibiotic therapy relate to the fact that the

Table 42-1 Comparison of local and systemic antimicrobial therapy

Issue	Systemic administration	Local administration
Drug distribution	Wide distribution	Narrow effective range
Drug concentration	Variable levels in different body compartments	High dose at treated site, low levels elsewhere
Therapeutic potential	May reach widely distributed microorganisms better	May act locally on biofilm associated bacteria better
Problems	Systemic side effects	Re-infection from non-treated sites
Clinical limitations	Requires good patient compliance	Infection limited to the treated site
Diagnostic problems	Identification of pathogens, choice of drug	Distribution pattern of lesions and pathogens, identification of sites to be treated

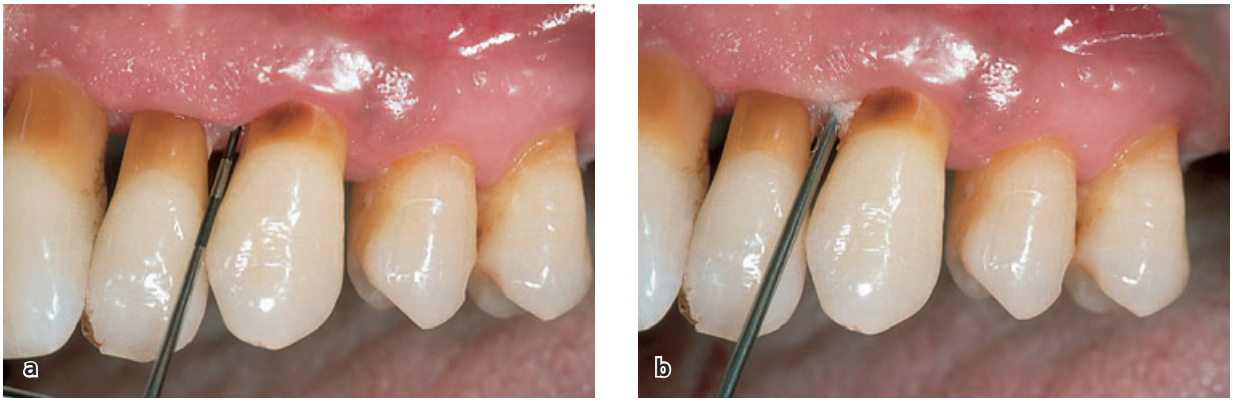

Fig. 42-3 (a) An antimicrobial gel is applied with a syringe inserted into a residual pocket. (b) For retention of the agent in the site, the viscosity of the carrier should change immediately. A large portion of the product may otherwise be expelled from the pocket quickly.

drug is dissolved by dispersal over the whole body, and only a small portion of the total dose actually reaches the subgingival microflora in the periodontal pocket. Adverse drug reactions are a greater concern and more likely to occur if drugs are distributed via the systemic route. Even mild forms of unwanted effects may severely decrease patient compliance (Loesche *et al*. 1993). Local delivery is independent of patient compliance.

Local drug delivery systems are means of drug application to confined areas. For the treatment of periodontal disease, local delivery of antimicrobial drugs ranges from simple pocket irrigation, over the placement of drug-containing ointments and gels, to sophisticated devices for sustained release of antibacterial agents. In order to be effective, the drug should not only reach the entire area affected by the disease, including especially the base of the pocket, but should also be maintained there at a sufficiently high local concentration for some time. With a mouth rinse or supragingival irrigation it is not possible to deliver an agent predictably to the deeper parts of a periodontal defect (Eakle *et al*. 1986; Pitcher *et al*. 1980). The crevicular fluid rapidly washes out agents brought into periodontal pockets by subgingival irrigation. Based on an assumed pocket volume of 0.5 ml and a crevicular fluid flow rate of 20 µl/hr, Goodson (1989) estimated that the half-time of a non-binding drug placed into a pocket is about 1 minute. Even a highly concentrated, highly potent agent would thus be diluted below a minimal inhibitory concentration (MIC) for oral microorganisms within minutes. If an agent can bind to surfaces and be released in active form, a prolonged time of antibacterial activity could be expected. Such an effect has in fact been noted for salivary concentrations of chlorhexidine after use of chlorhexidine mouth rinse (Bonesvoll & Gjermo 1978). Although there are indications that this may also occur to a certain extent within the periodontal pocket, for instance after prolonged subgingival irrigation with tetracycline (Tonetti *et al*. 1990), the potential to create a drug reservoir of significant size on the small surface area available in a periodontal pocket is limited. To maintain a high concentration over a prolonged period, the flushing action of the crevicular fluid flow has to be counteracted by a steady release of the drug from a larger reservoir. Considering the small volume of a periodontal pocket and the pressure exerted by the tonus of the periodontal tissues on anything inserted, it appears unlikely that this task can be completed by a carrier that does not maintain its physical stability for some time and that cannot be secured against premature loss. Gels, for instance, rapidly disappear after instillation into periodontal pockets (Fig. 42-3), unless they change their viscosity immediately after

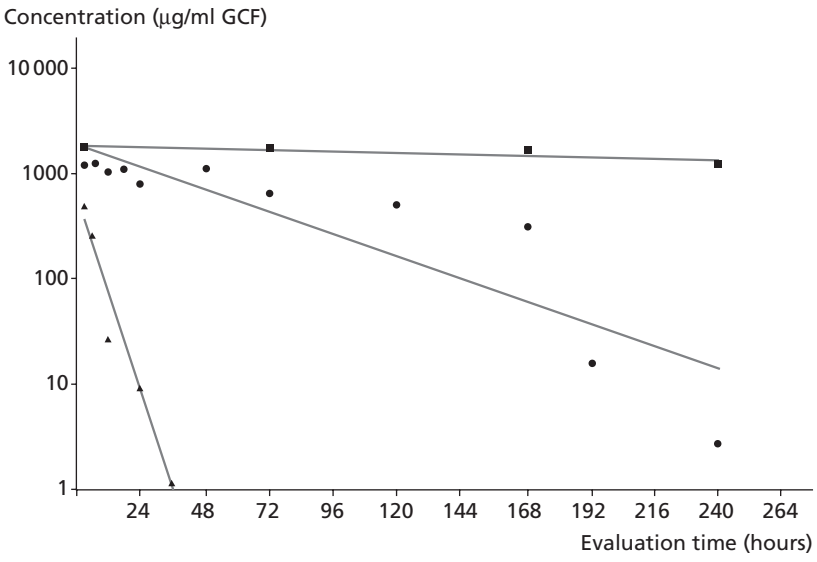

Fig. 42-4 Mean concentration of tetracycline (■) in gingival crevicular fluid (GCF) during tetracycline fiber treatment (Tonetti *et al*. 1990), of doxycycline hyclate (•) after application in a biodegradable polymer (Stoller *et al*. 1998), and of metronidazole (▲) after application of 25% metronidazole dental gel (Stoltze 1992).

placement (Oostervaal *et al*. 1990; Stoltze 1995). Viscous and/or biodegradable devices show an exponential decrease of their concentration in gingival fluid. In order to have sustained control over drug release it is necessary to have a matrix that lasts longer than the drug load. Controlled delivery of an antimicrobial agent over several days has been shown for tetracycline released from non-degradable monolithic ethylene vinyl acetate fibers (Fig. 42-4).

Evaluation of antibiotics for periodontal therapy

In the large range of antimicrobial agents, a limited number have been tested thoroughly for use in periodontal therapy. The drugs more extensively investigated for systemic use include tetracycline, minocycline and doxycycline, erythromycin, clindamycin, ampicillin, amoxicillin, and the nitroimidazole compounds metronidazole and ornidazole. The drugs investigated for local application include tetracycline, minocycline, doxycycline, metronidazole, and chlorhexidine.

The first antibiotics used in periodontal therapy were mainly systemically administered penicillins. The choice was initially based exclusively on empiric evidence. Penicillins and cephalosporins act by inhibition of cell wall synthesis. They are narrow-spectrum and bactericidal. Among the penicillins, amoxicillin has been favored for treatment of periodontal disease because of its considerable activity against several periodontal pathogens at levels available in gingival fluid. The molecular structure of penicillins includes a β-lactam ring that may be cleaved by bacterial enzymes. Some bacterial β-lactamases have a high affinity for clavulanic acid, a β-lactam molecule without antimicrobial activity. To inhibit bacterial β-lactamase activity, clavulanic acid has been added successfully to amoxicillin. This combination (Augmentin®) has been tested for periodontal therapy in clinical studies.

Tetracycline-HCl became popular in the 1970s due to its broad-spectrum antimicrobial activity and low toxicity. The tetracyclines, clindamycin, and erythromycin are inhibitors of protein synthesis. They have a broad spectrum of activity and are bacteriostatic. In addition to their antimicrobial effect, tetracyclines are capable of inhibiting collagenase (Golub *et al*. 1985). This inhibition may interfere with tissue breakdown in periodontal disease. Furthermore they bind to tooth surfaces, from where they may be released slowly over time (Stabholz *et al*. 1993).

The nitro-imidazoles were introduced into the periodontal field in 1962 when *The Lancet* published the report of a female patient, who after a week of treatment for trichomonal vaginitis with metronidazole (200 mg tid) declared she had undergone "a double cure". The vaginitis was cured and the "acute marginal gingivitis" she was also suffering from was relieved (Shinn 1962). The nitro-imidazoles (metronidazole and ornidazole) and the quinolone antibiotics (e.g. ciprofloxacin) act by inhibiting DNA synthesis. Metronidazole is known to convert into several short-lived intermediates after diffusion into an anaerobic organism. These products react with the DNA and other bacterial macromolecules, resulting in cell death. The process involves reductive pathways characteristic of strictly anaerobic bacteria and protozoa, but not aerobic or microaerophilic organisms. Thus, metronidazole affects specifically the obligately anaerobic part of the oral flora, including *P. gingivalis* and other black-pigmenting Gram-negative organisms, but not *A. actinomycetemcomitans*, a facultative anaerobe.

The concentrations following systemic administration of the most common antimicrobial agents used in the treatment of periodontal disease are listed in Table 42-2. The *in vitro* susceptibility of *A. actinomycetemcomitans* to selected antimicrobial agents is given in Table 42-3 and the susceptibility of *P. gingivalis* is listed in Table 42-4. The data given in these tables may serve as a base for the choice of an

Table 42-2 Characteristics of antimicrobial agents used in the treatment of periodontal disease (adapted from Lorian 1986; Slots & Rams 1990)

Antibiotic	Dose (mg)	c serum (μg/ml)	c crevicular fluid (μg/ml)	t_{max} serum (h)	Half-life (h)
Penicillin	500	3	ND	1	0.5
Amoxicillin	500	8	3–4	1.5–2	0.8–2
Doxycycline	200	2–3	2–8	2	12–22
Tetracycline	500	3–4	5–12	2–3	2–3
Clindamycin	150	2–3	1–2	1	2–4
Metronidazole	500	6–12	8–10	1–2	6–12
Ciprofloxacin	500	1.9–2.9	ND	1–2	3–6

c = concentration; t_{max} = hours to reach peak serum concentration; ND = not determined.

appropriate agent. However, it is important to remember that *in vitro* tests do not reflect the true conditions found in periodontal pockets. In particular, they do not account for the biofilm effect. One should add that MIC values depend on technical details that may vary between laboratories. As a consequence, demonstration of *in vitro* susceptibility is no proof that an agent will work in treatment of periodontal disease.

Since the subgingival microbiota in periodontitis often harbors several putative periodontopathic species with different antimicrobial susceptibility, combination drug therapy may be useful. A combination of antimicrobial drugs may have a wider spectrum of activity than a single agent. Overlaps of the antimicrobial spectrum may reduce the possible development of bacterial resistance. For some combinations of drugs there may be synergy in action against target organisms, allowing a lower dose of the single agents. A synergistic effect against *A. actinomycetemcomitans* has been noted *in vitro* between metronidazole and its hydroxy metabolite (Jousimies-Somer *et al*. 1988; Pavicic *et al*. 1991) and between these two compounds and amoxicillin (Pavicic *et al*. 1992). With some drug combinations there may, however, also be antagonistic drug interaction. For instance, bacteriostatic agents such as tetracyclines, which suppress cell division, may decrease the antimicrobial effect of bactericidal antibiotics such as β-lactam drugs or metronidazole, which act during bacterial cell division. Combination drug therapy may also lead to increased adverse reactions.

Table 42-5 lists common adverse reactions to systemic antibiotic therapy (for a detailed overview the reader is referred to Walker 1996). The penicillins are among the least toxic antibiotics. Hypersensitivity reactions are by far the most important and most common adverse effects of these drugs. Most reactions are mild and limited to a rash or skin lesion in the head or neck region. More severe reactions may induce swelling and tenderness of joints. In highly sensitized patients a life-threatening anaphylactic reaction may develop. The systemic use of tetracyclines may lead to epigastric pain, vomiting or

Table 42-5 Adverse effects of antibiotics used in the treatment of periodontal diseases

Antibiotic	Frequent effects	Infrequent effects
Penicillins	Hypersensitivity (mainly rashes), nausea, diarrhea	Hematologic toxicity, encephalopathy, pseudomembranous colitis (ampicillin)
Tetracyclines	Gastrointestinal intolerance, candidiasis, dental staining and hypoplasia in childhood, nausea, diarrhea, interaction with oral contraceptives	Photosensitivity, nephrotoxicity, intracranial hypertension
Metronidazole	Gastrointestinal intolerance, nausea, antabus effect, diarrhea, unpleasant metallic taste	Peripheral neuropathy, furred tongue
Clindamycin	Rashes, nausea, diarrhea	Pseudomembranous colitis, hepatitis

diarrhea. Tetracyclines can induce changes in the intestinal flora, and superinfections with non-bacterial microorganisms (i.e. *Candida albicans*) may emerge. Tetracyclines are deposited in calcifying areas of teeth and bones where they cause yellow discoloration. Systemic administration of clindamycin may be accompanied by gastrointestinal disturbances, leading to diarrhea or cramps, and may cause mild skin rashes. The suppression of the normal intestinal flora increases the risk for colonization of *Clostridium difficile*, which may cause a severe colon infection (antibiotic-associated colitis). Although not related to *C. difficile*, gastrointestinal problems are also the most frequent adverse event of systemic metronidazole therapy. Nausea, headache, anorexia, and vomiting may be experienced. Symptoms may be more pronounced with alcohol consumption, because imidazoles affect the activity of liver enzymes. Because some cases have developed permanent peripheral neuropathies (numbness or paresthesia), patients should be advised to stop therapy immediately if such symptoms occur.

Systemic antimicrobial therapy in clinical trials

Although clinical efficacy is not an absolute proof for bacteriologic efficacy (Marchant *et al*. 1992), the ultimate evidence to advocate the use of systemic antibiotics must come from clinical trials in humans with periodontitis. A large number of reports suggesting beneficial effects in various clinical situations have been published. However, many of them score low when evaluated by established study quality criteria, e.g. those proposed by the Oxford Centre for Evidence-based Medicine (http://www.cebm.net/levels_of_evidence.asp). Studies may be difficult to interpret due to an unclear status of patients at baseline (treatment history, disease activity, composition of subgingival microbiota), insufficient or non-standardized maintenance after therapy, short observation periods, or lack of randomization and controls. Comparisons may be possible because studies not only vary with regard to the treatment provided, but also in the selection of subjects, sample size, range of study parameters, outcome variables, the duration of the study, and the control to which the test procedure is compared. In most trials, systemic antibiotics have been used as an adjunct to scaling and root planing. Typically, the effect of mechanical therapy plus the antimicrobial agent has been compared to mechanical treatment alone. In studies evaluating the effect of antimicrobial therapy in patients with refractory periodontitis or with recurrent abscess formation, placebo control is often lacking for ethical reasons.

In recent years systematic reviews have become the preferred method of analyzing the medical literature. They use explicit procedures to perform a thorough literature search, critically appraise individual reports, and try to combine valid studies by applying appropriate statistical techniques. Two systematic reviews have been conducted to determine whether systemically administered antibiotics improve the clinical outcome of periodontal therapy (Herrera *et al*. 2002; Haffajee *et al*. 2003). Both have been prepared in the context of structured consensus conferences, where the findings have been translated into consensus statements on periodontal therapy.

Herrera *et al*. (2002) sought studies of at least 6 months' duration, designed as controlled clinical trials, in which systemically healthy subjects with either chronic or aggressive periodontitis had been treated with scaling and root planing, with or without systemic antibiotics. Main outcome variables were changes in clinical attachment level and pocket probing depth. Twenty-five papers were eligible for inclusion, but due to difficulties encountered when pooling the data, only limited meta-analyses could be performed. Overall, antibiotic groups showed better results than control groups. A specific benefit in change of attachment level was found in deep pockets for the combination of metronidazole plus amoxicillin.

Haffajee *et al*. (2003) sought clinical trials in periodontitis patients of more than 1 month duration, comparing systemic antibiotic therapy with non-antibiotic therapy, and using mean attachment level change as primary outcome. A meta-analysis included the data from 27 eligible studies. The authors noted that by and large therapeutic procedures were diverse, although metronidazole, alone or in combination with amoxicillin, was the most frequently

used drug. In all studies the antibiotic groups showed significantly better mean attachment level changes than the control groups, and this benefit averaged 0.45 mm. Although tests of heterogeneity were not significant, indicating that the outcomes were consistent, differences in the magnitude of the effect were noted in some patient populations: aggressive periodontitis groups had a larger adjunctive benefit than patients with chronic periodontitis. Results varied more between trials in which antibiotics had been used adjunctively to surgery than in trials where antibiotics had been tested adjunctively to scaling and root planing. Where it was possible to discriminate, sites with deep pockets seemed to show the greatest improvements. The reviews were unable to clarify which agents should be used for which infection, and what the optimal dosage and duration of antibiotic therapy should be. Furthermore it remained open how long the benefit would persist, and to what extent the antibiotics induced resistance or other changes in the oral microbiota. The low level of evidence with regards to the dosing regimen is very regrettable since the amount of drug administered is known to be a critical determinant of antimicrobial efficacy (Craig 1998).

In many trials the antibiotic has not been chosen based on a microbiologic analysis. This approach does not consider the possibility that some pathogens may be resistant to the tested drugs. We have mentioned *A. actinomycetemcomitans*, which is not susceptible to metronidazole when used as a monotherapy. Therefore, clinical studies including patients for an antibiotic therapy irrespective of their microbiologic status may underestimate the potential of the tested drug. Some studies have in fact indicated that systemic antibiotics were only effective in patients with a specific microbial profile (Flemmig *et al*. 1998; Winkel *et al*. 2001). Others, however, have demonstrated considerable adjunctive benefits to mechanical treatment even in the absence of specific target organisms (e.g. Rooney *et al*. 2002), and one could argue that nobody has ever shown certain patients to be better off, if treated *without* antibiotics.

In recent years the combination of metronidazole and amoxicillin has become the favorite treatment modality for many practitioners and clinical researchers. Studies corroborating the benefit of this regime, for example in non-surgical treatment of generalized aggressive periodontitis (Guerrero *et al*. 2005), continue to be published. Its remarkable ability to suppress or even eliminate *A. actinomycetemcomitans* and other subgingival organisms from periodontitis lesions and other oral sites (Christersson *et al*. 1989; Kornman *et al*. 1989; van Winkelhoff *et al*. 1989, 1992; Goené *et al*. 1990; Pavicic *et al*. 1992, 1994) has made it the first choice especially for the treatment of advanced periodontitis associated with *A. actinomycetemcomitans*. Gastrointestinal disturbances (diarrhea, nausea, and vomiting) have been noted as the most frequent side effects.

Systemic antibiotics in clinical practice

Overall, it can be stated that systemic antibiotic therapy can improve the clinical conditions and microbiologic status of periodontal patients. There is evidence to support the use of systemic antibiotics in cases of aggressive forms of periodontitis associated with *P. gingivalis* and/or *A. actinomycetemcomitans*. Systemic antibiotics are also indicated in generalized refractory periodontitis patients with evidence of ongoing disease despite previous mechanical therapy. Although some studies have shown a certain benefit of antibiotics even when administered without thorough subgingival debridement (Berglundh *et al*. 1998; Lopez & Gamonal 1998; Lopez *et al*. 2000, 2006) there is a general consensus that whenever possible antibiotics should not be administered before completion of root surface debridement (Mombelli 2006). Patients with acute signs of disease such as periodontal abscesses, or acute necrotizing gingivitis, with fever and malaise, may be the exception. Systemic antibiotics, given after scaling and root planing, provide an additional treatment benefit especially in deep pockets, and can reduce the need for further, surgical therapy (Loesche *et al*. 1992). In most cases however, mechanical therapy is initially carried out without antibiotics and evaluated after an appropriate period of time. The original treatment plan is then adapted, to account for the degree of clinical improvement already obtained. Immediately before starting the antibiotic regime the subgingival area should be re-instrumented once more to reduce the bacterial mass as much as possible and to disrupt the subgingival biofilm. This may be accomplished during a surgical intervention but is indicated also if no further mechanical therapy seems necessary from a clinical point of view.

Table 42-6 lists adjunctive systemic antibiotic regimens currently recommended for the therapy of periodontal diseases. Metronidazole alone has proven to be effective against *P. gingivalis*, *Tannerella forsythia*, spirochetes, and other strictly anaerobic Gram-negative bacteria. Clindamycin and tetracyclines have also been shown to act on a broad range of periodontal bacteria. Monotherapy with one antibiotic as an adjunct to mechanical instrumentation can change the composition of the subgingival microbiota significantly, but certain periodontal organisms cannot be eliminated predictably. For maximal suppression of subgingival *A. actinomycetemcomitans* the combination of metronidazole and amoxicillin is recommended. For patients who cannot tolerate amoxicillin it has been suggested to combine metronidazole with cefuroximaxetil or ciprofloxacin (Rams *et al*. 1992; van Winkelhoff & Winkel 2005).

Microbiologic tests can help to choose the appropriate antibiotic regimen. A microbial analysis should be comprehensive and sensitive enough to quantitatively identify the most important periodontal organisms. From the discussion above it follows that data

Table 42-6 Adjunctive systemic antibiotic regimens currently recommended for the therapy of periodontal diseases (adapted from van Winkelhoff & Winkel 2005)

Antibiotic	Usual dosage	Microbiology
Metronidazole	250–500 mg, tid 7–10 days	*P. gingivalis* *T. forsythia* *Treponema* spp.
Clindamycin	300 mg, qid 7–8 days	Gram-negative anaerobes Absence of *A. actinomycetemcomitans*
Doxycycline	100–200 mg, sid 7–14 days	Non-specific infection
Metronidazole + Amoxicillin	250–500 mg, tid 375–500 mg, tid 7 days	*A. actinomycetemcomitans* or *P. gingivalis* with high numbers of Gram-positive pathogens
Metronidazole + Cefuroximaxetil	250–500 mg, tid 250–500 mg, bid 7 days	*A. actinomycetemcomitans* Hypersensitivity towards amoxicillin
Metronidazole + Ciprofloxacin	250–500 mg, tid 500 mg, bid 7 days	*A. actinomycetemcomitans* Hypersensitivity towards β-lactams or presence of susceptible enteric microorganisms

indicating the involvement of *A. actinomycetemcomitans* and *P. gingivalis* have the highest practical utility. Microbial samples from the deepest pocket in each quadrant can give a good picture of the presence and relative proportion of these pathogens in the oral flora (Mombelli *et al*. 1991b, 1994). Since the antimicrobial profiles of most putative periodontal pathogens are quite predictable, susceptibility testing is not routinely performed. One should keep in mind, however, that some important microorganisms might demonstrate resistance to tetracyclines, β-lactam drugs or metronidazole.

As mentioned already, suboptimal dosage of antibiotics, caused by either inadequate prescribing or poor patient compliance, favors the spread of antibiotic-resistant bacterial clones. The classical oral dosage for metronidazole, used in most studies, has been 250 mg, three times a day, for 7–10 days. This dosage might not be sufficient in subjects with a high body mass. In addition, it has been proposed to prolong medication in smokers (van Winkelhoff & Winkel 2005), because smoking decreases the gingival blood flow and the amount of crevicular fluid, and hereby the availability of the drug in the subgingival environment (Morozumi *et al*. 2004). The specific conditions of smokers have become the subject of clinical research in recent time. The utilization of azithromycin, a macrolide antibiotic derived from erythromycin, has been advocated specifically for smokers (Mascarenhas *et al*. 2005). More research is however needed to substantiate the specific benefit of particular regimes for distinct groups of patients.

After resolution of the periodontal infection, the patient should be placed on an individually tailored maintenance care program. Optimal plaque control by the patient is of paramount importance for a favorable clinical response (Kornman *et al*. 1994) and long-term stability. Systemic antibiotics should never be applied as a means to compensate for inadequate oral hygiene.

Local antimicrobial therapy in clinical trials

Various methods to deliver antimicrobial agents into periodontal pockets have been devised and subjected to numerous kinds of experiments. The shortcomings of rinsing, irrigating, and similar forms of drug placement – rapid clearance resulting in inadequate exposure of subgingival bacteria to the drug and lack of significant clinical effects – have already been discussed. This section will deal with clinically tested drug delivery systems that fulfill at least the basic pharmacokinetic requirements of sustained drug release. Much of what has been stated about difficulties in the interpretation of studies dealing with the systemic use of antibiotics applies to the studies conducted with local delivery devices. Again, comparisons are complicated because studies vary with regard to sample size, selection of subjects, range of parameters, controls, duration of the study, and the inclusion of only one form of local drug delivery. Most of the evidence for a therapeutic effect of local delivery devices comes from trials involving patients with previously untreated adult periodontitis. Only few studies have addressed the use of local drug delivery in recurrent or persistent periodontal lesions – the potentially most valuable area for their application. Some protocols compare local drug delivery to a negative control, such as the application of only the carrier without the drug. These studies may be able to show a net effect of the drug, but they are not able to demonstrate a benefit over the most obvious

alternative – scaling and root planing – and the question remains as to how much value the procedure has in addition to mechanical treatment. If a study is unable to demonstrate a significant difference between local drug delivery and scaling and root planing, this is not automatically a proof of equivalence of the two treatments (equivalence testing requires statistical testing of the power of the data, taking into account the size of the study sample).

The following paragraphs focus on minocycline ointment and microspheres, doxycycline hyclate in a biodegradable polymer, metronidazole gel, tetracycline in a non-resorbable plastic co-polymer, and chlorhexidine gluconate in a gelatin chip. These are the predominant commercial formulations adequately tested for local antimicrobial periodontal therapy. Unfortunately some of them are currently unavailable in certain regions of the world, or have disappeared completely, while other products without properly evaluated clinical efficacy continue to be introduced and utilized on an empiric basis.

Minocycline ointment and microspheres

The subgingival delivery of minocycline has been investigated in different forms. The efficacy of a 2% minocycline ointment (Dentomycin; Cyanamid, Lederle Division, Wayne, NJ, US) has been evaluated in a randomized, controlled trial of 103 adults with moderate to severe periodontitis (van Steenberghe *et al*. 1993). All patients were treated by conventional scaling and root planing. In addition, the patients received either the test or a control ointment in four consecutive sessions at baseline and weeks 2, 4, and 6. A significantly greater reduction of probing depths was noted in the test group at week 12. An additional study evaluating the repeated application of minocycline ointment as an adjunct to subgingival debridement in chronic periodontitis, demonstrated better clinical and microbiologic conditions over a 15-month period (van Steenberghe *et al*. 1999). One study assessed the effect of a weekly repeated local application of minocycline ointment for 8 weeks after placement of teflon membranes to guide regeneration of periodontal tissue. Although bacterial colonization of treated sites could not be prevented, the mean clinical attachment gain of the test group was significantly greater than that of the control group (Yoshinari *et al*. 2001).

Currently the major device for local minocycline application is a product with the physical properties of a powder, consisting of resorbable polymer microspheres (Arestin; OraPharma, Warminster, PA, US). The efficacy and safety of locally administered microencapsulated minocycline was shown in a multicenter trial including 748 patients with moderate to advanced periodontitis. Minocycline microspheres plus scaling and root planing provided substantially more probing depth reduction than either scaling and root planing alone or scaling and root planing plus vehicle. The difference reached statistical significance after the first month and was maintained throughout the 9 months of the trial (Williams *et al*. 2001; Paquette *et al*. 2004).

Doxycycline hyclate in a biodegradable polymer

A two-syringe mixing system for the controlled release of doxycycline (Atridox; Block Drug, Jersey City, NJ, US) has been evaluated in a number of investigations, and has been commercially available for a few years. One syringe contained the delivery vehicle, flowable bioabsorbable poly (DL-lactide) dissolved in *N*-methyl-2-pyrrolidone, and the other syringe contained doxycycline hyclate powder. The clinical efficacy and safety of Atridox was assessed in two multicenter studies. Each study entered 411 patients who demonstrated moderate to severe adult periodontitis. The treatment was statistically superior to placebo control and oral hygiene, and equally effective as scaling and root planing in reducing the clinical signs of adult periodontitis over a 9-month period (Garrett *et al*. 1999). In a group of patients undergoing supportive periodontal therapy, attachment level gains and probing depth reductions were similar at 9 months after local treatment with doxycycline or traditional scaling and root planing (Garrett *et al*. 2000).

The effect of Atridox, applied after no more than 45 minutes of debridement without analgesia in subjects with moderately advanced chronic periodontitis, was compared to 4 hours of thorough deep scaling and root planing in a study involving 105 patients at three centers. Interestingly, clinical parameters indicated a better result for the pharmacomechanical treatment approach after 3 months, although considerably less time had been invested than for conventional mechanical therapy (Wennström *et al*. 2001).

Metronidazole gel

Dialysis tubing, acrylic strips, and poly-OH-butyric acid strips have been tested as solid devices for delivery of metronidazole. The most extensively used device for metronidazole application is a gel consisting of a semi-solid suspension of 25% metronidazole benzoate in a mixture of glyceryl mono-oleate and sesame oil (Elyzol Dental Gel; Dumex, Copenhagen, Denmark). The gel is applied with a syringe into the pocket, and should increase its viscosity after placement. The clinical response to subgingival application of the metronidazole gel twice within 1 week was compared to the effect of subgingival scaling in several studies including subjects with untreated adult periodontitis (Ainamo *et al*. 1992; Pedrazzoli *et al*. 1992; Grossi *et al*. 1995). The results indicated no significant difference between metronidazole gel application and scaling and root planing. The fact that no significant difference between the two

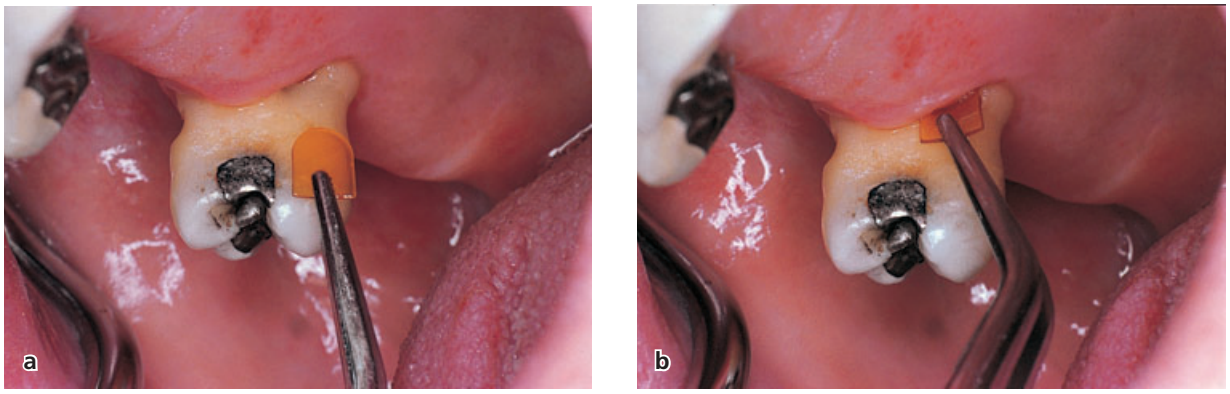

Fig. 42-5 Insertion of a chlorhexidine chip into a residual pocket mesial to an upper molar with a furcation involvement.

treatments was observed opened the question of equivalence between the two treatment modalities. Equivalence between scaling and root planing and metronidazole gel therapy has been evaluated using the lower bounds of confidence intervals in a parallel arm, multicenter, controlled clinical trial including 84 subjects (Pihlstrom *et al*. 1995). The estimates provided by this study indicated that metronidazole gel therapy is 82% as good as mechanical debridement at the 95% confidence level.

Tetracycline in a non-resorbable plastic co-polymer

Hollow devices, such as dialysis tubing, and solid devices, such as acrylic strips, collagen, or poly-OH-butyric acid strips, have been tested for tetracycline delivery in several experiments. Semi-solid viscous media include white petrolatum and poloxamer or carbopol gels. The most extensively tested tetracycline-releasing device is the Actisite periodontal fiber (ALZA, Palo Alto, CA, US). This currently unavailable product consists of a monolithic thread of a biologically inert, non-resorbable plastic co-polymer (ethylene and vinyl-acetate) containing 25% tetracycline hydrochloride powder. The fiber is packed into the periodontal pocket, secured with a thin layer of cyanoacrylate adhesive, and left in place for 7–12 days (Goodson *et al*. 1991a, 1983). By continuous delivery of tetracycline, a local concentration of the active drug in excess of 1000 mg/l can be maintained throughout that period (Fig. 42-4). Many clinical studies have been performed with Actisite, among them the following three large multicenter trials. The first showed better clinical results in deep pockets of 107 periodontitis patients 60 days after fiber therapy than control procedures (Goodson *et al*. 1991b). The second, conducted in periodontal maintenance patients needing treatment of localized recurrent periodontitis, demonstrated superiority after 6 months for scaling and root planing plus tetracycline fiber over scaling and root planing alone (Newman *et al*. 1994). The third indicated that the results obtained within 3 months after therapy were maintained over 1 year and that the combined treatment with fiber and scaling had a significantly lower incidence of disease recurrence than any of the other tested treatment modalities (Michalowicz *et al*. 1995).

Chlorhexidine gluconate in a gelatin chip

Several attempts have been made to develop local delivery devices for the subgingival application of antiseptic, rather than antibiotic agents. Acrylic strips and ethyl-cellulose compounds have been tested for this purpose. PerioChip (Perio Products, Jerusalem, Israel), a degradable gelatin chip containing 2.5 mg chlorhexidine, is the most extensively tested delivery device of this category (Fig. 42-5). Safety and efficacy of PerioChip were evaluated in a multicenter study of 118 patients with moderate periodontitis (Soskolne *et al*. 1997). The average pocket depth reduction in the treated sites with the chip was significantly greater than in the sites receiving mechanical treatment only. The efficacy of the chlorhexidine chip when used as an adjunct to scaling and root planing on reducing probing depth and improving clinical attachment level in adult periodontitis was evaluated in two double-blind, randomized, placebo-controlled multicenter clinical trials. At 9 months significant reductions from baseline were shown with the chlorhexidine chip compared with mechanical control treatments (Jeffcoat *et al*. 1998).

Comparison of treatment methods

Most studies have tested a single form of local drug delivery or systemic administration, instead of comparing various forms of therapy. Understandably, developers and distributors have the primary interest to register and promote their own product for the broadest possible usage, and not to differentiate specific benefits or shortcomings of various applications. The efficacy of three commercially available local delivery systems as adjuncts to scaling and root planing was tested in two trials including patients with persistent periodontal lesions: Actisite,

Dentomycin, Elyzol Dental Gel (Radvar *et al*. 1996; Kinane & Radvar 1999); Atridox, Elyzol Dental Gel, PerioChip (Salvi *et al*. 2002). One systematic review has tried to evaluate the combined literature-based evidence to determine the relative effect of local controlled release anti-infective drug therapy in patients with chronic periodontitis (Hanes & Purvis 2003). A meta-analysis including 19 studies, comparing scaling and root planing plus local sustained-release agents with scaling and root planing alone, confirmed the clinical advantages of minocycline gel, microencapsulated minocycline, doxycycline gel, and chlorhexidine chips over scaling and root planing alone. Due to the heterogeneity of the material the authors could not make any firm statements regarding the superiority of one system. A further systematic review looked at the relative adjunctive benefits of various locally applied agents (Bonito *et al*. 2005). Unfortunately data were combined from studies exploring various modes of local treatment, including irrigation, impregnated strips or pastes. Nonetheless, a statistically significant mean advantage resulted for four agents in terms of additional attachment gain, best for minocycline, followed by tetracycline, chlorhexidine, and metronidazole. One cannot exclude, however, that the differences noted between the drugs primarily reflect differences in modes of application and study populations, not the potency of the agent.

Few studies have addressed the problem of incorporating local or systemic antimicrobial therapy into an overall treatment strategy. As little direct evidence for a comparison of various methods of treatment is available so far, well founded decision algorithms to choose specific methods of intervention for distinct clinical situations are not yet available. A key issue requiring clarification refers to the selection of a local or a systemic delivery approach whenever the use of an antibiotic is indicated. One investigation addressed this question in patients with rapidly progressing periodontitis (Bernimoulin *et al*. 1995). Overall, no significant differences were noted between systemic administration of amoxicillin–clavulanic acid and tetracycline fibers as an adjunct to mechanical therapy. For patients with adult periodontitis, two studies reported better results of scaling and root planing supplemented with locally applied metronidazole than adjunctive systemic metronidazole (Paquette *et al*. 1994; Noyan *et al*. 1997).

As different oral distribution patterns can be recognized in periodontitis patients for microorganisms such as *P. gingivalis* (Mombelli *et al*. 1991a,b), local therapy may be less successful in patients where these organisms are widespread than in patients where the presence of pathogens is confined to isolated areas. This hypothesis was tested in a study comparing two extremes of local therapy. In one group of patients, a combination of measures including full mouth scaling and root planing, application of tetracycline fibers, and chlorhexidine rinse, was applied. In the other group, only two teeth were treated locally and no attempt was made to interfere with the overall conditions of the oral environment. Major clinical differences were found in the local healing response, depending on whether the rest of the dentition was left untreated or was also subjected to therapy (Mombelli *et al*. 1997). How can a clinician be sure that the areas he treats coincide with the sites harboring the pathogens? No diagnostic tool is available presently at a reasonable cost that could give the dentist a detailed distribution map of periodontal pathogens. Provided that such a tool would exist, could *P. gingivalis* and *A. actinomycetemcomitans* be eradicated from an infected dentition by microbiologically guided local antimicrobial therapy? A study evaluating the effect of local antibiotic therapy, given to every tooth with cultural evidence of *P. gingivalis* or *A. actinomycetemcomitans* after completion of conventional mechanical periodontal therapy demonstrated the limits of this approach (Mombelli *et al*. 2002). Even if a detailed microbiologic assessment provided information about the distribution pattern within the dentition, and all positive teeth were treated, the target organisms could be detected again after therapy in some sites in a considerable number of subjects.

Local antibiotics in clinical practice

To treat periodontal disease successfully, local delivery devices must provide therapeutic levels of antimicrobial agents in the subgingival area over several days. Clinical trials show the efficacy of local antibiotic therapy under these conditions. The current evidence suggests that local delivery may be most beneficial in the control of localized ongoing disease in otherwise stable patients. Maintenance patients with a few non-responding sites may therefore benefit most from local antimicrobial therapy. Local antibiotic therapy adds flexibility and improves efficacy of periodontal care by providing a non-surgical local treatment alternative with more powerful antibacterial effects than scaling and root planing. Potential uses for locally delivered antibiotics also include the treatment of peri-implant infections (Mombelli *et al*. 2001; Renvert *et al*. 2006). A comment made in the context of systemic antibiotics needs to be reiterated here with regards to local therapy: antibiotics are not a means to compensate for inadequate oral hygiene. For a maximal benefit, and a sustained local effect, patients should receive specific instructions on how to keep the treated sites plaque free with appropriate home care procedures.

Overall conclusion

Although mechanical periodontal treatment alone improves clinical conditions sufficiently in most cases, adjunctive antibiotics, delivered either

systemically or locally, can enhance the effect of therapy. Systemic antibiotics may be a useful adjunct to the mechanical treatment of aggressive forms of periodontitis and for cases with evidence of ongoing disease despite previous mechanical therapy. By providing an additional treatment benefit especially in deep pockets, systemic antibiotics can reduce the need for further, surgical therapy. Localized non-responding sites and localized recurrent disease may be treated with locally delivered antibiotics. Mechanical debridement before the application of antimicrobial agents, and mechanical plaque control after therapy, are essential for treatment success. To limit the development of microbial antibiotic resistance in general, and to avoid the risk of unwanted systemic effects of antibiotics for the treated individual, a precautionary, restrictive attitude towards using antibiotics is recommended.

Part 13: Reconstructive Therapy

Chapter 43

Regenerative Periodontal Therapy

Pierpaolo Cortellini and Maurizio S. Tonetti

Introduction

The advances in the understanding of the biology of wound healing and periodontal regenerative technologies are applied to improve long-term clinical outcomes of teeth which are periodontally compromised by intrabony or inter-radicular defects. The treatment objective is to obtain shallow, maintainable pockets by reconstruction of the destroyed attachment apparatus and thereby also limiting recession of the gingival margin. In general periodontal regeneration is selected to obtain: (1) an increase in the periodontal attachment of a severely compromised tooth; (2) a decrease in deep pockets to a more maintainable range; (3) a reduction of the vertical and horizontal component of furcation defects. Current approaches, however, remain technique sensitive and clinical success requires application of meticulous diagnostic and treatment strategies.

Classification and diagnosis of periodontal osseous defects

Site-specific periodontal breakdown compromises the long-term prognosis of teeth by producing three types of defects: suprabony (or horizontal) defects, infrabony (or vertical) defects, and inter-radicular (or furcation) defects.

According to the classification by Goldman and Cohen (1958), suprabony defects are those where the base of the pocket is located coronal to the alveolar crest. Infrabony defects, on the other hand, are defined by the apical location of the base of the pocket with respect to the residual alveolar crest. This chapter does not deal with suprabony defects. With regard to infrabony defects, two types of defects can be recognized: intrabony defects and craters. Intrabony defects are bony defects whose infrabony component affects primarily one tooth, while in craters the defect affects two adjacent root surfaces to a similar extent. Intrabony defects (Fig. 43-1) have been classified according to their morphology in terms of residual bony walls, width of the defect (or radiographic angle), and in terms of their topographic extension around the tooth. Three-wall, two-wall, and one-wall defects have been defined on the basis of the number of residual alveolar bone walls. This represents the primary classification system. Frequently, intrabony defects present a complex anatomy consisting of a three-wall component in the most apical portion of the defect, and two- and/or one-wall components in the more superficial portions. Hemiseptal defects, that is, vertical defects in the presence of adjacent roots and where half of a septum remains on one tooth, represent a special case of one-wall defects. Several authors have also used

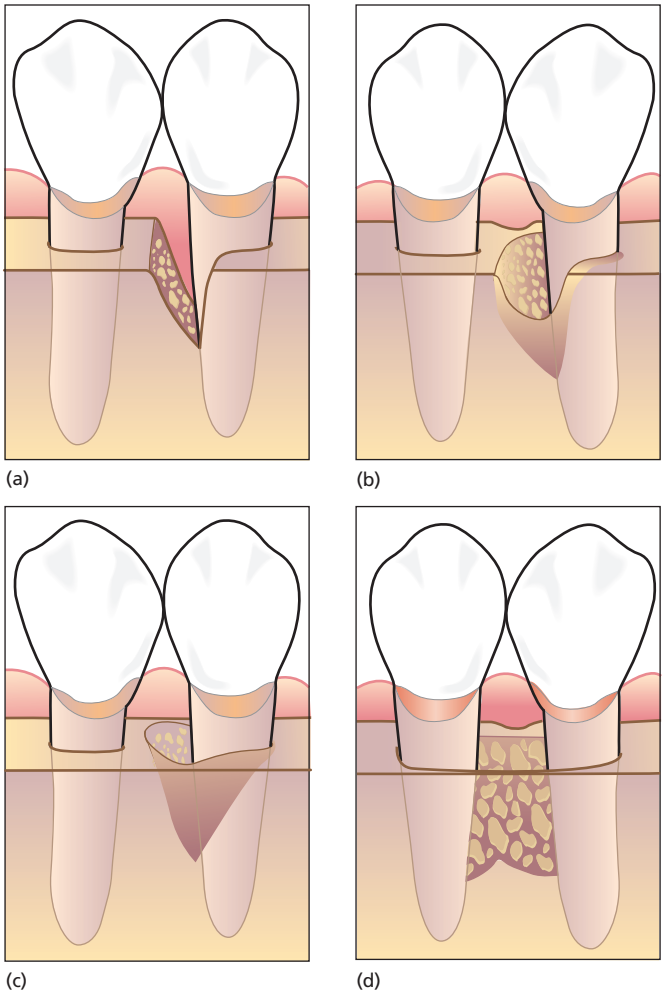

Fig. 43-1 Infrabony defects. (a) One-wall intrabony defect. (b) Two-wall intrabony defect. (c) Three-wall intrabony defect. (d) Interproximal crater. From Papapanou & Tonetti (2000).

descriptive terms to define special morphological characteristics: funnel-shaped defects, moat-like defects, trenches, etc. Of particular interest is a special morphology: the crater (Fig. 43-1). It is defined as a cup- or bowl-shaped defect in the interdental alveolar bone with bone loss nearly equal on the roots of two contiguous teeth and more coronal position of the buccal and lingual alveolar crest; the facial and lingual/palatal walls may be of unequal height. This defect can be considered as the result of the apical spread of periodontitis along two adjacent roots in a relatively narrow (mesiodistally) interproximal area. Notably, all the definitions above are not based on radiographic assessments but on the actual morphology of the defects after flap elevation. Conditions entailing pathologic resorption of bone within the furcation of a multi-rooted tooth, defined as furcation invasions, are also included in the group of periodontal bony defects; the reader however is referred to Chapter 39 for a discussion of the anatomy and classification of furcations.

The diagnosis of the presence and the morphology of periodontal osseous lesions represents a major clinical challenge. It is primarily performed combining clinical information derived from the evaluation of the attachment level with information derived from diagnostic-quality parallel-technique intraoral radiographs. A precise knowledge of root anatomy and its variations is also an important component for the diagnosis of periodontal osseous defects, and inter-radicular defects in particular. Diagnostic-quality radiographs provide additional information on the morphology of the alveolar bone resorption. In this context, interpretation of the radiographic image of the interdental septum is complicated, since the radiograph provides a two-dimensional illustration of a three-dimensional anatomy consisting of superimposed structures including alveolar bone, hard tooth substances, and soft tissue. This complexity of the visualized structures means that a certain amount of tissue destruction must occur before its radiographic detection becomes possible, often rendering incipient bone lesions obscure. Furthermore, even advanced lesions may be masked by the presence of superimposed structures. It is therefore generally stated that radiographic diagnosis has a high positive predictability (that is, the visualized lesions are indeed there) but a low negative predictability (that is, absence of radiographically detectable bone loss does not exclude the presence of an osseous lesion).

Clinical attachment level, on the other hand, is a highly sensitive diagnostic tool; its combination with radiographs, therefore, confers a higher degree of

accuracy to the diagnostic approach (Tonetti *et al.* 1993b). In particular, the site-specific comparison of radiographic bone loss with clinical attachment loss allows the clinician to make a qualified guess of the true osseous architecture, whose exact morphology, however, can only be established after flap elevation. Detection of the defect, its location and extension, along with its major morphologic features, should be performed before flap elevation. A further aid to this end is the use of transgingival probing or bone sounding.

Clinical indications

Periodontal treatment, either surgical or non-surgical, results in recession of the gingival margin after healing (Isidor *et al*. 1984). In advanced cases of periodontitis, this may lead to poor esthetics in the front areas of the dentition, in particular when applying surgical procedures, including bone contouring, for the eradication of bone defects. Treatment of such cases without bone contouring, on the other hand, may result in residual pockets inaccessible to proper cleaning during post-treatment maintenance. These problems can be avoided or reduced by applying regenerative surgical procedures by which the lost periodontal attachment in the bone defects can be restored. Thus, the indication of applying regenerative periodontal therapy is often based on esthetic considerations, besides the fact that the function or long-term prognosis of the treated teeth may be improved.

Another indication for regenerative periodontal therapy are furcation-involved teeth. The furcation area is often inaccessible to adequate instrumentation and frequently the roots present concavities and furrows that make proper cleaning of the area after resective surgery impossible. Considering the long-term results and complications reported following treatment of furcation involvements by traditional resective therapy (Hamp *et al*. 1975; Bühler 1988), the long-term prognosis of furcation-involved teeth can be improved considerably by successful regenerative periodontal therapy.

Case reports also exist demonstrating that "hopeless" teeth with deep vertical defects, increased tooth mobility or through-and-through furcations can be successfully treated with regenerative periodontal therapy (Gottlow *et al*. 1986). However, controlled clinical trials or serial case reports presenting a reasonable predictability of treating such advanced cases are not available.

Long-term effects and benefits of regeneration

A pertinent question with respect to regenerative treatment is whether the achieved attachment level gains can be maintained over an extended period of time. In a long-term follow-up study, Gottlow *et al*. (1992) assessed the stability of new attachment gained through guided tissue regeneration (GTR) procedures. Eighty sites in 39 patients, which 6 months after surgery exhibited a gain of clinical attachment of ≥2 mm (2–7 mm), were monitored during additional periods of 1–5 years. Of the 80 sites, 65 were monitored for 2 years, 40 for 3 years, 17 for 4 years, and 9 sites for 5 years. The results of this study and those of other trials indicate that attachment gain obtained following GTR treatment can be maintained on a long-term basis (Becker & Becker 1993; McClain & Schallhorn 1993).

An investigation on intrabony defects demonstrated that the stability of sites treated with GTR was dependent on participation of the patients in a recall program, and on the absence of bacterial plaque, bleeding on probing, and re-infection of the treated sites with periodontal pathogens (Cortellini *et al*. 1994). The susceptibility to disease recurrence at sites treated with non-bioabsorbable barrier membranes was assessed in a study comparing long-term changes in attachment levels at regenerated and non-regenerated sites in the same patient (Cortellini *et al*. 1996a). Results indicated that there was a high degree of concordance in the clinical outcomes (stability vs. recurrence of attachment loss) within the same patient suggesting that patient factors, rather than the site factors, including the specifics of the histologic type of expected wound healing, are associated with disease recurrence. Among patient factors, compliance with oral hygiene, smoking habits, and susceptibility to disease progression were the major determinants of stability of the treated sites, rather than the employed treatment modality.

Support for a limited impact of the histologic type of healing comes from an experimental study. In a study in monkeys (Kostopoulos & Karring 1994), periodontal breakdown was produced by the placement and retention of orthodontic elastics on experimental teeth until 50% bone loss was recorded. The experimental teeth were endodontically treated and subjected to a flap operation, and all granulation tissue was removed. The crowns of the teeth were resected at the level of the cemento-enamel junction and a barrier membrane was placed to cover the roots before they were submerged. Following 4 weeks of healing, the membranes were removed. At the same time the contralateral teeth that served as controls were endodontically treated and subjected to a sham operation during which the crowns were resected at the level of the cemento-enamel junction. Artificial composite crowns were then placed on both the experimental and the control roots. The sites were allowed to heal for 3 months during which period careful plaque control was performed. At the end of this period cotton-floss ligatures were placed on both experimental and control teeth to induce periodontal tissue breakdown. After another 6 months, the animals were sacrificed. With respect to attachment level, bone level, pocket depth, and gingival recession, similar results were recorded in histologic

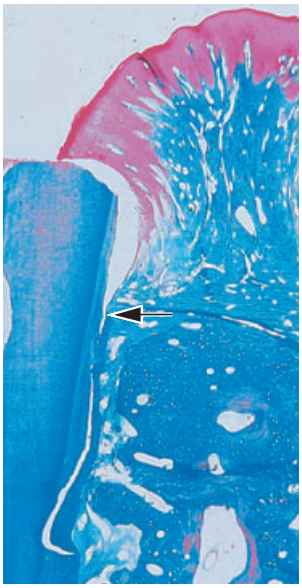

Fig. 43-2 Microphotograph of test specimen with a reformed connective tissue attachment. After 6 months of ligature-induced periodontitis, loss of attachment has occurred from the coronal cut root surface to the level indicated by the arrow.

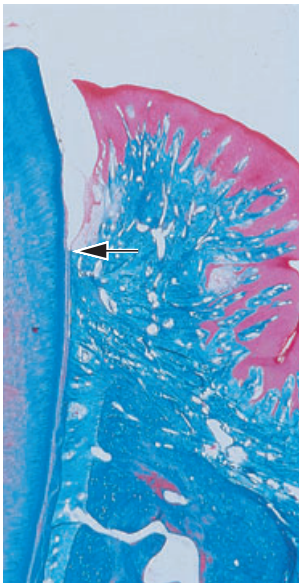

Fig. 43-3 Microphotograph of control specimen with a naturally existing periodontium. After 6 months of ligature-induced periodontitis, loss of attachment has occurred from the coronal cut tooth surface to the level indicated by the arrow.

specimens of experimental (Fig. 43-2) and control (Fig. 43-3) teeth. This indicates that the new connective tissue attachment formed with GTR is not more susceptible to periodontitis than the naturally existing periodontium.

A few studies have evaluated the long-term prognosis for furcation defects treated with regenerative therapy. Sixteen mandibular degree II furcation defects, following coronal flap positioning and citric acid root biomodification with and without implantation of demineralized freeze-dried bone allografts (DFDBA), were determined as completely resolved with bone fill assessed by re-entry surgery. They were re-evaluated after 4–5 years (Haney *et al*. 1997), when 12 of the 16 sites exhibited recurrent degree II furcations and all 16 sites demonstrated probable buccal furcation defects. The investigators concluded that these findings question the long-term stability of bone regeneration in furcations following coronally advanced flap procedures.

The long-term stability of mandibular furcation defects regenerated following GTR alone or in combination with root surface biomodification with citric acid and bone grafting, was also evaluated by McClain and Schallhorn (1993). Out of the 57% of the furcation defects that were assessed as completely filled at 6 and 12 months, only 29% were completely filled after 4–6 years. However, 74% of the furcations treated with GTR in combination with the placement of DFDBA were completely filled at both the short and long-term evaluation, suggesting that the results obtained with the combined procedure were more stable over time. Long-term results of GTR treatment of mandibular degree II furcations with e-PTFE membranes were also reported by Machtei *et al*. (1996). The teeth were followed up to 4 years and compared with non-furcated molars. Improvements assessed in vertical (V-CAL) and horizontal (H-CAL) clinical attachment levels after treatment were also maintained after 4 years, suggesting that changes obtained in degree II furcation defects by GTR are stable. Only 9% of the treated defects were unstable, which was similar to that observed for non-furcated molars. Good oral hygiene, as reflected in low plaque scores and elimination of periodontal pathogens, was closely related to the long-term stability. On the basis of these results, it was concluded that furcation defects treated with membrane barriers can be maintained in health for at least 4 years, provided good oral hygiene and frequent recall visits are established.

In summary, several clinical studies addressing the long-term effects of periodontal regeneration show that, if the patient participates in a professionally delivered supportive periodontal care program and maintains good oral hygiene, the regenerated attachment can be maintained long term (Gottlow *et al.* 1992; MacClain & Schallhorn 1993; Cortellini *et al.* 1994, 1996a; Machtei *et al.* 1996; Christgau *et al.* 1997; Eickholz *et al*. 1997; Sculean *et al.* 2006). Risk factors for attachment loss are those associated with disease recurrence: poor compliance with supportive periodontal care, poor oral hygiene, and cigarette smoking (Cortellini *et al.* 1996a; Cortellini & Tonetti 2004).

Few investigations have looked at the long-term effects of periodontal regeneration on tooth survival. Cortellini and Tonetti (2004) performed a Kaplan Mayer analysis of tooth survival following periodontal regenerative treatment in a sample of 175 patients followed up for 2–16 years (average 8 ± 3.4 years) in a specialist environment. In this study, 96% of teeth

Table 43-1 Survival analysis of regenerated periodontal attachment over a 16-year follow-up period in 175 subjects treated with periodontal regeneration. In this survival analysis, the event is represented by clinical attachment level (CAL) loss of 2 mm or more from the level of attachment obtained at completion of healing 1 year after regeneration. No substantial recurrence of periodontitis (CAL loss) was observed in 92% of treated cases who participated in a secondary prevention program. (From Cortellini & Tonetti (2004) with permission)

Time at risk (years)	N CAL loss ≥2 mm	Censored	Effective sample size	Conditional probability CAL loss (%)	Survival (%)
0–2	2	0	175	1.1	100
2–4	3	0	166	1.7	98.9
4–6	2	0	155	1.2	97.1
6–8	1	55	119	0.7	96
8–10	0	47	70.5	0	95.3
10–12	2	16	41	3.5	95.3
12–14	0	25	24.5	0	92
14–16	0	21	8	0	92
16	0	1	0.5	0	92

treated by periodontal regeneration survived. Of interest was the observation that tooth loss was observed only among the 32% of the population that were smokers (tooth survival was 89% among smokers and 100% among non-smokers). Clinical attachment levels were located at the same level or coronal to the pre-treatment levels in 92% of cases up to 15 years after treatment (Table 43-1, Fig. 43-4).

The potential clinical benefits of periodontal regeneration can be best illustrated in a consecutive case series of strategic abutments severely compromised by the presence of deep intrabony defects with associated deep pockets with up to 8 years' follow-up following regenerative treatment (Tonetti *et al*. 1996a; Cortellini *et al*. 1998). At baseline, the periodontal defect rendered these teeth unsuitable as abutments to be included in a reconstruction. In all cases, periodontal regeneration with barrier membranes was able to change the clinical prognosis by providing both a 30% increase in radiographic bone support and shallow, maintainable probing depths. These outcomes remained stable during the follow-up period (Fig. 43-5). A similar benefit has been recently reported following use of combination therapy (barrier membranes and demineralized freeze-dried bone allograft) in teeth compromised by class II furcation defects (Bowers *et al*. 2003): 92% of class II defects were either closed or transformed into class I and thus at lower risk of tooth loss 1 year after therapy (McGuire & Nunn 1996a,b).

The limitation of recession of the gingival margin observed in controlled clinical trials when comparing a regenerative treatment with a non-regenerative surgical procedure is also an important benefit.

Evidence for clinical efficacy and effectiveness

Questions of efficacy relate to the added benefit of a treatment modality under ideal experimental conditions (such as those of a highly controlled research center environment). Effectiveness, on the other hand, relates to the benefit that can be achieved in a regular clinical setting where the procedure is likely to be performed in relation to morbidity and adverse events. Besides efficiency considerations, both evidence for efficacy and effectiveness need to be available in order to provide support for adoption of a novel approach in clinical practice.

The clinical efficacy of periodontal regenerative procedures has been extensively evaluated in randomized controlled clinical trials that have compared the regenerative procedure with a standard approach.

To limit sample size and study duration, these trials have utilized surrogate outcomes – clinical attachment level changes, decrease in pocket depths, furcation closure or radiographic measurements – rather than changes in tooth survival. These surrogate outcomes, however, are considered to be adequate proxies of the true outcome represented by tooth survival: persistence of deep pockets or furcation involvement are associated with higher risk of periodontal breakdown and tooth extraction.

The majority of clinical trials were small single-center studies. The evidence of these studies has been recently summarized in meta-analyses performed on data retrieved by systematic reviews of the published literature. In 2002 and 2003, the European Workshop on Periodontology and the Workshop on Emerging Technologies in Periodontics provided much of the systematic assessment of the evidence for currently available technologies. These include the use of barrier membranes (guided tissue regeneration, GTR), the use of bone replacement grafts, and the use of biologically active regenerative materials. The clinical evidence must be interpreted in the context of the biologic mechanisms and evidence for regeneration discussed in Chapter 25.

The evidence of clinical efficacy of barrier membranes has been assessed in the systematic reviews and meta-analyses performed by Needleman *et al*.

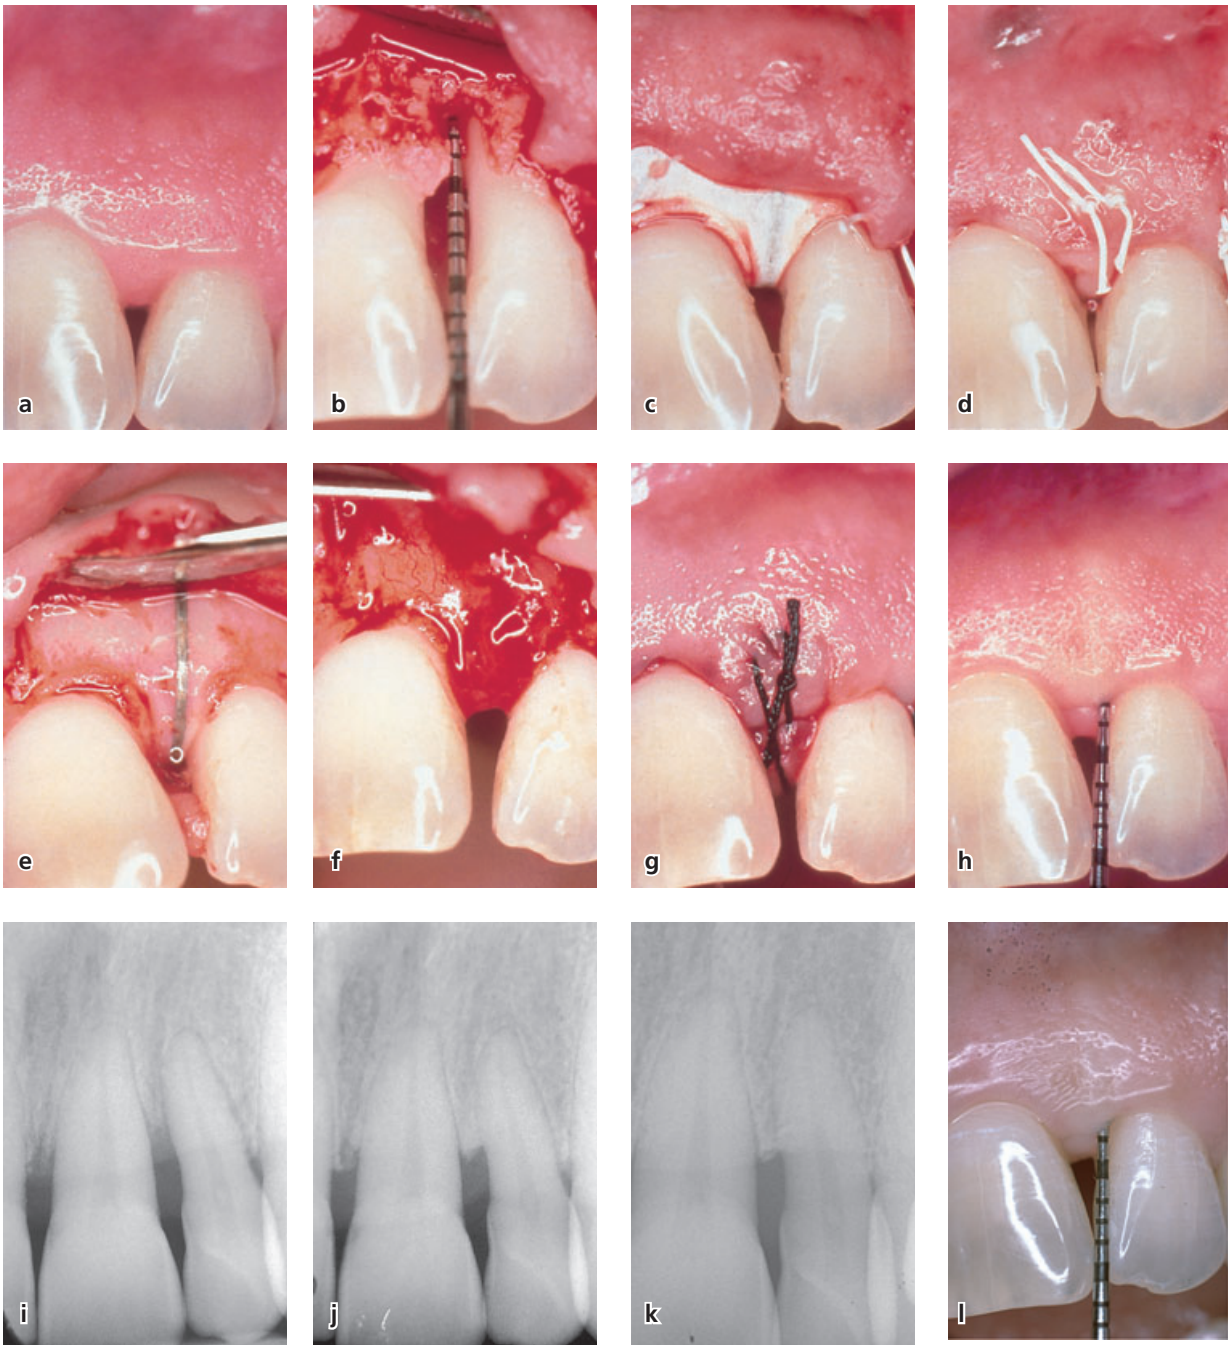

Fig. 43-4 (a,b) Left maxillary lateral incisor with a deep interproximal intrabony defect on the mesial surface. (c) Flaps are raised according to the modified papilla preservation technique, and a titanium-reinforced barrier membrane is placed over the defect. (d) By coronal displacement of the flap and preservation of the interdental papilla, the membrane is completely covered. (e,f) After 6 weeks of uneventful post-operative healing the membrane was removed, (g) and the newly formed tissue was completely covered. (h) At 1 year, residual probing pocket depth was 2 mm and no buccal or interdental recession had occurred. (i) The baseline radiograph shows radiolucency approaching the apex of the tooth, but after 1 year the intrabony defect is resolved and some supracrestal bone apposition seems to have occurred (j). The radiograph taken at 6 years confirms the supracrestal bone regeneration (k) and the clinical image shows the integrity of the interdental papilla with optimal preservation of the esthetic appearance (l).

(2002), Jepsen *et al*. (2002), and Murphy and Gunsolley (2003).

For intrabony defects, 26 controlled trials with 867 intrabony defects were included (Murphy & Gunsolley 2003). The application of barrier membranes resulted in an additional clinical attachment level gain of more than 1 mm compared to an access flap approach control (Fig. 43-6).

For class II furcation defects, 15 controlled trials with 376 involved teeth were included (Murphy & Gunsolley 2003). Membrane application resulted in additional vertical and horizontal (depth of the furcation involvement) clinical attachment level gains (Fig. 43-7).

These data alone, however, did not present conclusive evidence of efficacy as the possibility of bias

Fig. 43-5 Clinical benefits of periodontal regeneration. Patient presented with periodontally compromised mesial abutment of bridge: a 10-mm pocket was associated with a 10-mm intrabony defect extending on three of the four surfaces of the tooth (a–d). A barrier membrane was positioned and secured around the root of the tooth (e). Primary closure with internal mattress sutures was achieved (f) and maintained during the healing period. At 1 year, periodontal probing shows a shallow maintainable pocket (3 mm) (g) and the complete resolution of the defect (h). Clinical and radiographic stability of the outcome is illustrated 8 years following regenerative therapy (i,j): stability of the gingival margin, shallow pockets, good esthetics, and good periodontal support for the abutment are evident.

arising from a possible tendency to report studies with positive results could not be ruled out. Multicenter studies were designed to assess efficacy conclusively. These were performed in a private practice environment in order to assess also the generalizability of the benefit to this specific setting (effectiveness). The results of large prospective multi-center studies in private practice settings (Tonetti *et al*. 1998, 2004b; Cortellini *et al*. 2001) conclusively support the additional benefit of membranes in improving clinical attachment levels in intrabony defects and thus their efficacy and effectiveness. More limited evidence is also available for combination therapy (bone replacement grafts and barrier membranes) in furcation defects (Bowers *et al*. 2003).

The efficacy of bone replacement graft materials has been assessed in two systematic reviews (Trombelli *et al*. 2002; Reynolds *et al*. 2003). As these two

systematic reviews used significantly different criteria for study inclusion, results did not fully overlap. Trombelli *et al*. (2002), who included only controlled studies that reported changes in clinical attachment level as the primary outcome, concluded that there was insufficient evidence to support clinical use of bone replacement graft materials in intrabony defects, since: (1) there was significant heterogeneity among included studies; (2) the size of the adjunctive effect was small; and (3) there were differences that did not allow pooling of results obtained with different materials. In the other meta-analysis for intrabony defects, 27 controlled trials with 797 intrabony defects were included (Reynolds *et al*. 2003). The application of bone replacement grafts resulted in an additional clinical attachment level gain of 0.5 mm compared to an access flap approach control (Fig. 43-8). Greater additional benefits from the application of bone replacement grafts were observed whenever hard tissue measurements (bone fill or defect resolution) were utilized as outcome measures.

For furcation defects, the lack of consistent comparisons did not allow a meaningful assessment of the potential benefits of the use of bone replacement grafts alone (Reynolds *et al.* 2003). No large multicenter trials have provided definitive support for efficacy and/or effectiveness of the use of bone replacement grafts.

The evidence of clinical efficacy of biologically active regenerative materials has been summarized in meta-analyses only for enamel matrix derivative (Trombelli *et al*. 2002; Giannobile & Somerman 2003) and only for the application to intrabony defects. The outcomes of eight studies including 444 defects have indicated that enamel matrix derivative provides additional benefits of a magnitude of 0.75 mm in terms of clinical attachment level gains (Fig. 43-9). These data have been in accordance with those of a

large practice-based multi-center trial that demonstrated both efficacy and effectiveness of enamel matrix derivative in intrabony defects (Tonetti *et al*. 2002).

Patient and defect prognostic factors

The results reported in Table 43-2 indicate that clinical improvements beyond that of flap surgery can be obtained by treating intrabony defects with GTR, but they also suggest a great variability in clinical outcomes among the different studies. In addition, it is apparent from the results that the complete resolution of the intrabony component of the defect is observed in only a minority of sites. A series of prognostic factors associated with the clinical outcomes were identified using multi-variate approaches (Tonetti *et al*. 1993a, 1995, 1996a; Cortellini *et al*. 1994; Machtei *et al*. 1994; Falk *et al*. 1997). Attention has focused on some important patient and defect factors.

Patient factors

Periodontal infection

Periodontal regeneration does not treat periodontitis, but rather is an approach for regenerating defects that have developed as a result of periodontitis. Therefore, appropriate periodontal treatment should always be completed before periodontal regeneration is initiated. In this context – i.e. in patients who underwent a cycle of cause-related periodontal therapy to the satisfaction of the treating clinician – evidence suggests that the level of control of periodontitis, achieved before a periodontal regenerative procedure is initiated, is associated with outcomes: the persistence of poor plaque control, high levels of bleeding upon probing in the dentition, as well as the persistence of high loads of total bacteria or of specific microbial pathogens (or complexes of pathogens) have all been associated in a dose-dependent manner with poor clinical outcomes (Tonetti *et al*. 1993a, 1995; Cortellini *et al*. 1994; Machtei *et al*. 1994; Heitz-Mayfield *et al.* 2006).

The level of self-performed plaque control has a great and dose-dependent effect on the outcome of periodontal regeneration. Better clinical attachment level gains were observed in patients with optimal levels of plaque control as compared with those in patients with less ideal oral hygiene (Cortellini *et al*. 1994; Tonetti *et al*. 1995, 1996a). Patients with plaque on <10% of the tooth surfaces (full mouth plaque score, FMPS) had a gain of clinical attachment which was 1.89 mm greater than that observed in patients with FMPS >20% (Tonetti *et al*. 1995).

Although not formally tested for efficacy in randomized trials, achieving high levels of plaque control and suppression of the pathogenic microflora through behavioral intervention and intensive anti-infective periodontal therapy are generally advocated before proceeding with periodontal regeneration. Furthermore, some proof of principle investigations have assessed the adjunctive effect of using an antibiotic locally delivered within the wound area or in the regenerative material (Yukna & Sepe 1982; Sanders *et al*. 1983; Stavropoulos *et al*. 2003). Results showed consistently better outcomes in the groups that received the antibiotic. At present, however, no regenerative device with enhanced antimicrobial activity is commercially available.

Smoking

A retrospective study found that cigarette smokers displayed significantly impaired regenerative outcomes compared to non-smokers (Tonetti *et al*. 1995). Data showed that cigarette smoking was associated with reduced attachment level gains. The attachment gain in subjects smoking more than ten cigarettes/day was 2.1 ± 1.2 mm versus 5.2 ± 1.9 mm observed in non-smokers (Tonetti *et al*. 1995). Thereafter a series of investigations has confirmed that cigarette smoking displays a dose-dependent detrimental effect on clinical attachment level gains.

Although no formal evidence is available, it is generally suggested that smoking cessation counseling should be initiated in the context of cause-related periodontal therapy and that patients who have been unable to quit the habit should be informed of the possibility of reduced outcomes and of the need to abstain from smoking during the peri-operative and early healing period.

Other patient factors

It has been suggested that other patient factors, such as age, genetics, systemic conditions or stress levels, may be associated with sub-optimal regenerative outcomes. In the light of the lack of evidence, however, no action is required with the exception of considering the patient characteristics that represent a contraindication to surgery (e.g. uncontrolled diabetes or unstable, severe diseases).

Clinical relevance of patient factors

The data discussed above indicates that patient factors play an important role in regenerative periodontal therapy (Fig. 43-10). Some of these factors can be modified by appropriate interventions in some patients. These interventions should be performed before periodontal regenerative therapy. Whenever modification is not possible, reduced outcomes in terms of extent and predictability should be considered.

Defect factors

Type of defect

With the currently available periodontal regenerative technologies, there is no evidence that suprabony (horizontal) defects, supracrestal components of intrabony defects or class III furcation involvements can be predictably treated with regenerative approaches. This limitation is also true for interdental craters, thus limiting the type of defects that can be treated to intrabony defects and class II furcation defects.

Morphology of the defect

Defect morphology plays a major role in healing following periodontal regenerative treatment of intrabony defects. This was demonstrated in studies showing that the depth and width of the intrabony component of the defect influence the amount of clinical attachment and bone gained at 1 year. The deeper the defect, the greater was the amount of clinical improvements, while the wider the defect, the

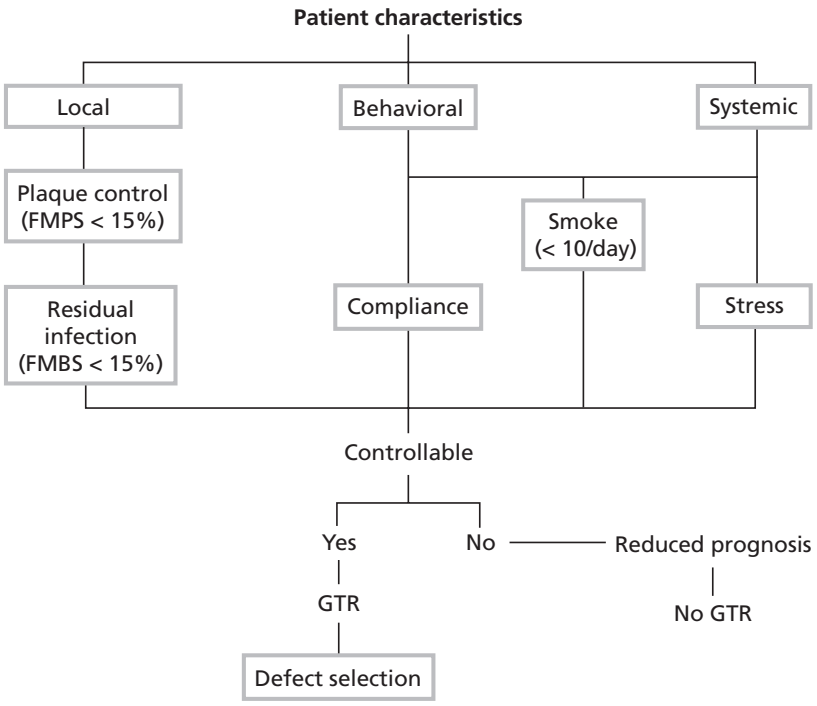

Fig. 43-10 Diagram illustrating patient selection criteria. It can be seen that control of local, behavioral, and systemic patient characteristics may improve the treatment outcomes. FMPS = full mouth plaque score; FMBS = full mouth bleeding score. Modified from Cortellini & Bowers (1995).

lower were the attachment and bone gains (Garrett *et al*. 1988; Tonetti *et al*. 1993a, 1996a).

In a controlled study, however, it was demonstrated that deep and shallow defects have the "same potential" for regeneration. In this study, deep defects (deeper than 3 mm) resulted in larger linear amounts of CAL gains than shallow defects (3.7 ± 1.7 mm versus 2.2 ± 1.3 mm), but the percentage of CAL gains as related to baseline defect depth was similar in deep (76.7 ± 27.7%) and in shallow (75.8 ± 45%) defects. The width of the intrabony component of the defects is measured as the angle that the bony wall of the defect forms with the long axis of the tooth. In a study on 242 intrabony defects treated with membranes, Cortellini and Tonetti (1999) demonstrated that defects with a radiographic angle of 25° or less gained consistently more attachment (1.6 mm on average) than defects of 37° or more.

Two recent follow-up studies have addressed the significance of the baseline radiographic angle of the intrabony defect following the use of either enamel matrix derivative (Tsitoura *et al*. 2004) or of a combination of bone replacement graft with a barrier membrane (Linares *et al*. 2006). The impact of the width of the baseline radiographic angle was confirmed for the non-space-making biological mediator but not for the more stable combination therapy. These data are consistent with the notion that choice of the regenerative technology may partially overcome negative morphologic characteristics of intrabony defects. An earlier secondary analysis of a controlled clinical trial using titanium-reinforced membranes (Tonetti *et al*. 1996a) indicated that the relevance of defect morphology parameters may be diminished with the use of supported membranes.

It was also shown that the number of residual bony walls was related to the outcomes of various regenerative approaches (Goldman & Cohen 1958; Schallhorn *et al*. 1970). This issue as related to GTR therapy was addressed in three investigations (Selvig *et al*. 1993; Tonetti *et al*. 1993a, 1996a). In one study, the reported 1-year mean clinical attachment level gain was 0.8 ± 1.3 mm. This gain corresponded to the depth of the three-wall intrabony component of the defect (Selvig *et al*. 1993). In the other two investigations, on the contrary, gains in attachment were not related to the defect configuration in terms of one-wall, two-wall, and three-wall subcomponents (Tonetti *et al*. 1993a, 1996a). A total of 70 defects were examined in these two latter studies, utilizing a multi-variate approach. The treatment resulted in mean attachment gains of 4.1 ± 2.5 mm and 5.3 ± 2.2 mm, and it was observed that the most coronal portion of the defects which is most susceptible to negative influences from the oral environment were often incompletely filled with bone, irrespective of whether these were one-wall, two-wall or three-wall defects. Thus, these studies questioned the impact of the number of residual bony walls of the defect on the clinical outcomes of periodontal regeneration with membranes and suggested that location of the one-wall subcomponent (the one most likely to be the most superficial one) may have acted as confounder in other studies and be an important predictor of the outcomes.

Tooth factors

The endodontic status of the tooth has been suggested as a potential relevant factor in periodontal

therapy. Emerging evidence (see Chapter 40) indicates that root canal treated teeth may respond differently to periodontal therapy. A clinical study on 208 consecutive patients with one intrabony defect each demonstrated that properly performed root canal treatment does not negatively affect the healing response and the long-term stability of results of deep intrabony defects treated with membranes (Cortellini & Tonetti 2000b).

Tooth mobility has long been considered an important factor for periodontal regeneration (Sanders *et al*. 1983). Recently, a multi-variate analysis of a multi-center controlled clinical trial demonstrated that tooth hypermobility was negatively and dose-dependently associated with the clinical outcomes of regeneration (Cortellini *et al*. 2001). Though significant, the size of the effect was small within the range of physiologic mobility. Another recent secondary analysis of three previously reported trials assessed the regenerative outcomes of hypermobile teeth (Trejo & Weltman 2004). This report indicated that teeth with baseline mobility amounting to less than 1 mm horizontally could be successfully treated by periodontal regeneration. Although no intervention trial has been performed to date, these results are generally considered supportive of an approach that does not set the prognosis of the tooth or the regenerative procedure based on tooth mobility but rather considers splinting hypermobile teeth before periodontal regenerative surgery.

Based on these results, it can be concluded that deep and narrow intrabony defects at either vital or endodontically treated teeth are the ones in which the most significant and predictable outcomes can be achieved by GTR treatment. Severe, uncontrolled dental hypermobility (Miller class II or higher) may impair the regenerative outcomes.

Factors affecting the clinical outcomes of GTR in furcations

Significant evidence has demonstrated that treatment of maxillary degree II furcations and maxillary and mandibular degree III furcation involvements with GTR is unpredictable, while clinical improvements can be expected treating mandibular degree II furcations. The great variability in clinical outcomes, following treatment of mandibular degree II furcations with GTR, is probably related to the factors discussed relative to intrabony defects.

Regarding defect factors, it was shown that first and second mandibular molars and buccal and lingual furcations respond equally well to GTR treatment (Pontoriero *et al*. 1988; Machtei *et al*. 1994). It was also demonstrated that the pre-operative horizontal pocket depth is directly correlated with the magnitude of attachment gain and bone formation in the furcation area (Machtei *et al*. 1993, 1994). The deeper the baseline horizontal pocket, the greater was the H-CAL and bone gain. The anatomy of the furcations in terms of height, width, depth, and volume, however, did not correlate with the clinical outcome (Machtei *et al*. 1994). Anderegg *et al*. (1995) demonstrated that sites with a gingival thickness of >1 mm exhibited less gingival recession post surgery than sites with a gingival thickness of <1 mm. The authors concluded that the thickness of the gingival tissue covering a barrier material must be considered if post-treatment recession is to be minimized or avoided.

The relevance of the surgical approach

At the beginning of the 1980s the need to modify standard periodontal surgical procedures to favor periodontal regeneration became apparent. In particular, the need to preserve soft tissues in order to attempt primary closure of the interdental space to contain grafts or coronally advanced flaps to cover furcation entrances led to the development of specific flap designs for periodontal regeneration (Takei *et al*. 1985; Gantes & Garret 1991).

In fact, graft exfoliation and membrane exposure with consequent bacterial contamination during healing represented the major complications of periodontal regenerative procedures at the time. Membrane exposure was reported to be a major complication with prevalence in the range of 50–100% (Becker *et al*. 1988; Cortellini *et al*. 1990, 1993b; Selvig *et al*. 1992, 1993; Murphy 1995a; DeSanctis *et al*. 1996a,b; Falk *et al*. 1997; Trombelli *et al*. 1997; Mayfield *et al*. 1998). Cortellini *et al*. (1995c,d) reported that the prevalence of membrane exposure could be greatly reduced with the use of access flaps, specifically designed to preserve the interdental tissues (modified papilla preservation technique) (Fig. 43-11).

Many studies have shown that the exposed membranes are contaminated with bacteria (Selvig *et al*. 1990, 1992; Grevstad & Leknes 1992; Machtei *et al*. 1993; Mombelli *et al*. 1993; Tempro & Nalbandian 1993; Nowzari & Slots 1994; Novaes *et al*. 1995; Nowzari *et al*. 1995; DeSanctis *et al*. 1996a,b). Contamination of exposed non-bioabsorbable as well as bioabsorbable membranes was associated with lower probing attachment level gains in intrabony defects (Selvig *et al*. 1992; Nowzari & Slots 1994; Nowzari *et al*. 1995; DeSanctis *et al*. 1996a,b). The impaired clinical results in some studies were associated with high counts of bacteria and with the presence of *P. gingivalis* and *A. actinomycetemcomitans* (Machtei *et al*. 1994; Nowzari & Slots 1994; Nowzari *et al*. 1995).

Bacterial contamination of the membrane may occur during surgery, but also during the post-operative healing phase. After placement, bacteria from the oral cavity may colonize the coronal part of the membrane. Frequently, this results in recession of the gingival tissues, which allows colonization of the membrane material further apically. In addition,

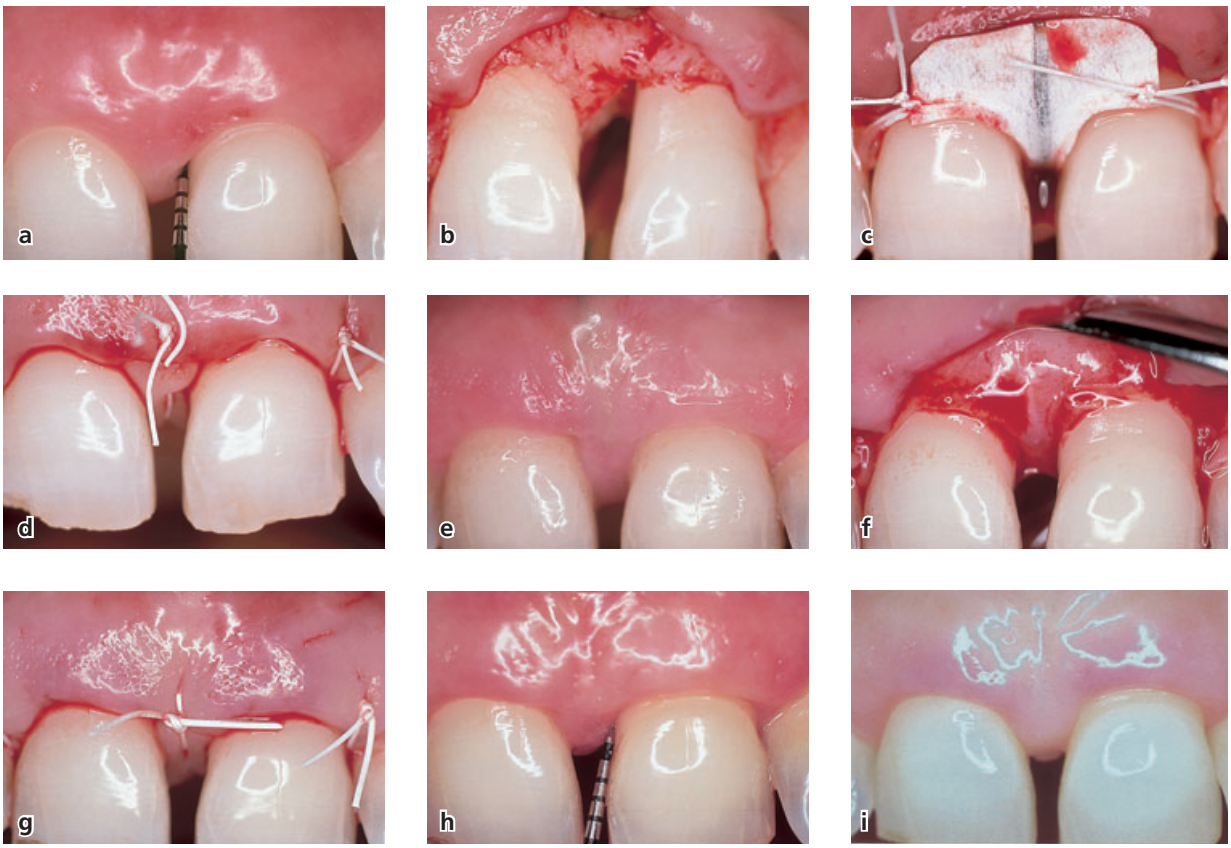

Fig. 43-11 (a) Left maxillary central incisor with a 10-mm pocket depth and 11 mm of clinical attachment loss on the mesial surface. A diastema is present between the two central incisors. (b) Full thickness buccal and palatal flaps have been raised and an intrabony defect can be seen. The interdental papilla has been incised on the buccal aspect and elevated with the palatal flap (modified papilla preservation technique). (c) A titanium-reinforced e-PTFE barrier membrane has been placed and fixed close to the level of the cemento-enamel junction. (d) The membrane is completely covered. This primary closure has been obtained by preserving the interdental papilla and by coronal displacement of the buccal tissue flap. (e) At 6 weeks, the membrane is completely covered with healthy tissue. (f) After membrane removal at 6 weeks, dense newly formed tissue is evident in the defect and in the supracrestal space maintained by the titanium-reinforced membrane. (g) The newly formed tissue is completely covered by the raised and well preserved tissue flaps. (h) The photograph after 1 year shows a 4 mm residual pocket depth. A gain of clinical attachment of 6 mm was recorded, and no recession has occurred compared to baseline. (i) Ten year photograph showing the optimal preservation of the interdental tissues.

"pocket" formation may occur on the outer surface of the membrane due to apical migration of the epithelium on the inner surface of the covering gingival tissue. This may allow bacteria from the oral cavity to colonize the subgingival area. The significance of bacterial contamination was addressed in an investigation in monkeys (Sander & Karring 1995). The findings of this study showed that new attachment and bone formation occurred consistently when bacteria were prevented from invading the membrane and the wound during healing.

In order to prevent wound infection, some investigators have administered systemic antibiotics to patients before and during the first weeks after membrane application (Demolon *et al*. 1993; Nowzari & Slots 1994). However, despite the application of systemic antibiotics, occurrence of post-operative wound infection related to implanted barrier membranes was noticed. This indicates that either the drug administered is not directed against the microorganisms responsible for the wound infection, or that the drug does not reach the infected site at a concentration sufficiently high to inhibit the target microorganisms. An improved effect on periodontal healing after GTR in association with local application of metronidazole was reported by Sander *et al*. (1994). Twelve patients with one pair of intrabony defects participated in the study. Metronidazole in a gel form was placed in the defects and on the membrane prior to wound closure, while the controls were treated with a membrane alone. Six months following membrane removal the medium gain in probing attachment level, presented as a percentage of the initial defect depth, was 92% for test defects versus 50% for the control defects. Other clinical parameters, like plaque index, bleeding on probing, pocket depth reduction or recession of the gingival margin, were similar in the test and control sites. Although the use of local or systemic antibiotics may reduce the bacterial load on exposed membranes, it seems ineffective in preventing the formation of a microbial biofilm (Frandsen *et al*. 1994; Nowzari *et al*. 1995). Apart from the erythema and swelling related to such infection of the wound, more severe post-operative complica-

tions such as suppuration, sloughing or perforation of the flap, membrane exfoliation, and post-operative pain have been reported (Murphy 1995a,b).

Another important issue associated with the clinical results is the coverage of the regenerated tissue after removal of a non-bioabsorbable membrane. Many authors have reported that the frequent occurrence of a gingival dehiscence over the membrane is likely to result in insufficient protection of the interdental regenerated tissue (Becker *et al*. 1988; Selvig *et al*. 1992; Cortellini *et al*. 1993b; Tonetti *et al*. 1993a). Exposure of the regenerated tissue to the oral environment entails the risks of mechanical and infectious insults that in turn may prevent complete maturation of the regenerated tissue into a new connective tissue attachment. In fact, incomplete coverage of the regenerated tissue was associated with reduced attachment and bone gain at 1 year (Tonetti *et al*. 1993a). Recently, the positioning of a saddle-shaped free gingival graft over the regenerated interdental tissue (Fig. 43-12) was suggested to offer better coverage and protection than a dehiscent gingival flap (Cortellini *et al*. 1995a). In this randomized controlled study, more gain of attachment was observed in the 14 sites where a free gingival graft was positioned after membrane removal (5.0 ± 2.1 mm), than in the 14 sites where conventional protection of the regenerated tissue was accomplished (3.7 ± 2.1 mm).

The systematic assessment of the relevant factors associated with variability of periodontal regenerative outcomes performed at the beginning of the 1990s (Tonetti *et al*. 1993a, 1995, 1996a; Machtei *et al*. 1994; Falk *et al*. 1997) provided further evidence that

Fig. 43-12 Clinical case illustrating the management of the most common complication following application of non-resorbable barrier membrane: membrane exposure and consequent loss of interdental soft tissue. Upon completion of cause-related periodontal therapy, regenerative periodontal surgery was performed to resolve a deep pocket associated with a deep intrabony defect (a,b). The 7-mm intrabony defect was accessed with a modified papilla preservation flap (c) and a non-resorbable barrier membrane was placed (d). Primary closure with multilayered sutures was obtained, but 5 weeks after surgery, the membrane became exposed to the oral cavity (e). Upon membrane removal (f), a newly regenerated tissue completely filled the space below the membrane but inadequate amounts of soft tissue were available to completely cover the regenerated tissue in the interdental space. In order to protect the maturation of this tissue, a saddle-shaped interdental free gingival graft was harvested from the palate and shaped to precisely fit the interdental area (g). The graft healed well on the highly vascularized recipient bed and allowed good healing of the interdental tissues. Six years after completion of therapy, the clinical and radiographic outcomes show healing with shallow probing depths and elimination of the defect (h,i).

surgical factors had a great impact on regeneration and led the way to the development of procedures specifically designed for periodontal regeneration.

In general the development of new procedures was aimed at complete tissue preservation of the marginal tissue in order to achieve and maintain primary closure on top of the applied regenerative material during the critical stages of healing. Specifically, flap designs attempted to achieve passive primary closure of the flap combined with optimal wound stability.

Papilla preservation flaps

The modified papilla preservation technique (MPPT) was developed in order to increase the space for regeneration, and in order to achieve and maintain primary closure of the flap in the interdental area (Cortellini *et al*. 1995c,d). This approach combines special soft tissue management with use of a self-supporting titanium-reinforced membrane capable of maintaining a supra-alveolar space for regeneration. The MPPT allows primary closure of the interdental space, resulting in better protection of the membrane from the oral environment (Cortellini *et al*. 1995d). The technique involves the elevation of a full-thickness palatal flap which includes the entire interdental papilla. The buccal flap is mobilized with vertical and periosteal incisions, coronally positioned to cover the membrane, and sutured to the palatal flap through a horizontal internal crossed mattress suture over the membrane. A second internal mattress suture warrants primary closure between the flap and the interdental papilla. A representative case is shown in Figs. 43-4 and 43-11. In a randomized controlled clinical study on 45 patients (Cortellini *et al*. 1995c), significantly greater amounts of attachment gain were obtained with the MPPT (5.3 ± 2.2 mm), in comparison with either conventional GTR (4.1 ± 1.9 mm) or flap surgery (2.5 ± 0.8 mm), demonstrating that a modified surgical approach can result in improved clinical outcomes.

In this study 100% of the sites were closed on top of a titanium-reinforced membrane and 73% remained closed for up to 6 weeks, when the barrier membrane was removed. This study provided proof of principle of the benefit of specific flap designs for periodontal regeneration.

A recent meta-analysis (Murphy & Gunsolley 2003) showed the existence of a trend associating better clinical outcomes in studies using flap designs and closing techniques considered conducive to the achievement and maintenance of primary closure of the flap (Figs. 43-13, 43-14). The reported procedure can be successfully applied in sites where the interdental space width is at least 2 mm at the most coronal portion of the papilla.

When interdental sites are narrower, the reported technique is difficult to apply. In order to overcome this problem, a different papilla preservation procedure (the simplified papilla preservation flap) has been proposed for narrower interdental spaces (Cortellini *et al*. 1999). This approach includes an oblique incision across the defect-associated papilla, starting from the buccal angle of the defect-associated tooth to reach the mid-interdental part of the papilla at the adjacent tooth under the contact point. In this way, the papilla is cut into two equal parts of which the buccal is elevated with the buccal flap and the lingual with the lingual flap. In the cited study, 100% of the narrow interdental papillae could be closed on top of bioresorbable barriers, and 67% maintained primary closure over time, resulting in 4.9 ± 1.8 mm of clinical attachment level gains. This approach has been successfully applied in different multi-center randomized clinical trials designed to test the generalizability of the added benefits of using barrier membranes on deep intrabony defects (Tonetti *et al*. 1998; Cortellini *et al*. 2001).

In the cited studies, GTR therapy of deep intrabony defects performed by different clinicians on various patient populations resulted in both greater amounts and improved predictability of CAL gains than access flap alone. The issue of soft tissue manipulation to obtain stable protection of the regeneration site has been further explored, applying a microsurgical approach in the regenerative therapy of deep intrabony defects (Fig. 43-15). In a patient cohort study on 26 patients with 26 intrabony defects treated with papilla preservation techniques, primary closure on the barrier was obtained in 100% of the cases and maintained over time in 92.3% of the sites (Cortellini & Tonetti 2001). Treatment resulted in large amounts of CAL gains (5.4 ± 1.2 mm) and minimal gingival

recession (0.4 ± 0.7 mm). Thus, the improved vision and better soft tissue handling improved the predictability of periodontal regeneration.

Today, the use of papilla preservation flap designs and closure techniques has become the standard approach for regenerative periodontal surgery.

Modified papilla preservation technique

The rationale for developing this technique was to achieve and maintain primary closure of the flap in the interdental space over the membrane (Cortellini *et al.* 1995d) (Figs. 43-16 to 43-18). Access to the interdental defect consists of a horizontal incision traced in the buccal keratinized gingiva at the base of the papilla, connected with mesio-distal buccal intrasulcular incisions. After elevation of a full-thickness buccal flap, the residual interdental tissues are dissected from the neighboring teeth and the underlying bone and elevated towards the palatal aspect. A full-thickness palatal flap, including the interdental papilla, is elevated and the interdental defect exposed. Following debridement of the defect, the buccal flap is mobilized with vertical and periosteal incisions, when needed.

This technique was originally designed for use in combination with self-supporting barrier membranes. In fact, the suturing technique requires a supportive (or supported) membrane to be effective (Figs. 43-16, 43-17). To obtain primary closure of the interdental space over the membrane, a first suture (horizontal internal crossed mattress suture) is placed beneath the mucoperiosteal flaps between the base of the palatal papilla and the buccal flap. The interdental portion of this suture hangs on top of the membrane allowing the coronal displacement of the buccal flap. This suture relieves all the tension of the flaps. To ensure primary passive closure of the interdental tissues over the membrane, a second suture (vertical internal mattress suture) is placed between the buccal aspect of the interdental papilla (i.e. the most coronal portion of the palatal flap which includes the interdental papilla) and the most coronal portion of the buccal flap. This suture is free of tension.

An alternative type of suture to close the interdental tissues has been proposed by Dr Lars Laurell. This modified internal mattress suture (see Fig. 38-56) starts from the external surface of the buccal flap, crosses the interdental area and gets through the lingual flap at the base of the papilla. The suture runs back through the external surface of the lingual flap and the internal surface of the buccal flap, about 3 mm apart from the first two bites. Finally, the suture is passed through the interdental area above the papillary tissues, passed through the loop of the suture on the lingual side, and brought back to the buccal side, where it is tied. This suture is very effective in ensuring stability and primary closure of the interdental tissues.

In a randomized controlled clinical study on 45 patients (Cortellini *et al.* 1995c), significantly greater amounts of PAL were gained with the MPPT (5.3 ± 2.2 mm), in comparison with either conventional GTR (4.1 ± 1.9 mm) or access flap surgery (2.5 ± 0.8 mm), demonstrating that a modified surgical approach can result in improved clinical outcomes. The sites accessed with the MPPT showed primary closure of the flap in all but one case, and no gingival dehiscence until membrane removal, in 73% of the cases.

This surgical approach has also been used in combination with non-supported bioresorbable barrier membranes (Cortellini *et al.* 1996c), with positive results. Clinical attachment level gains at 1 year were

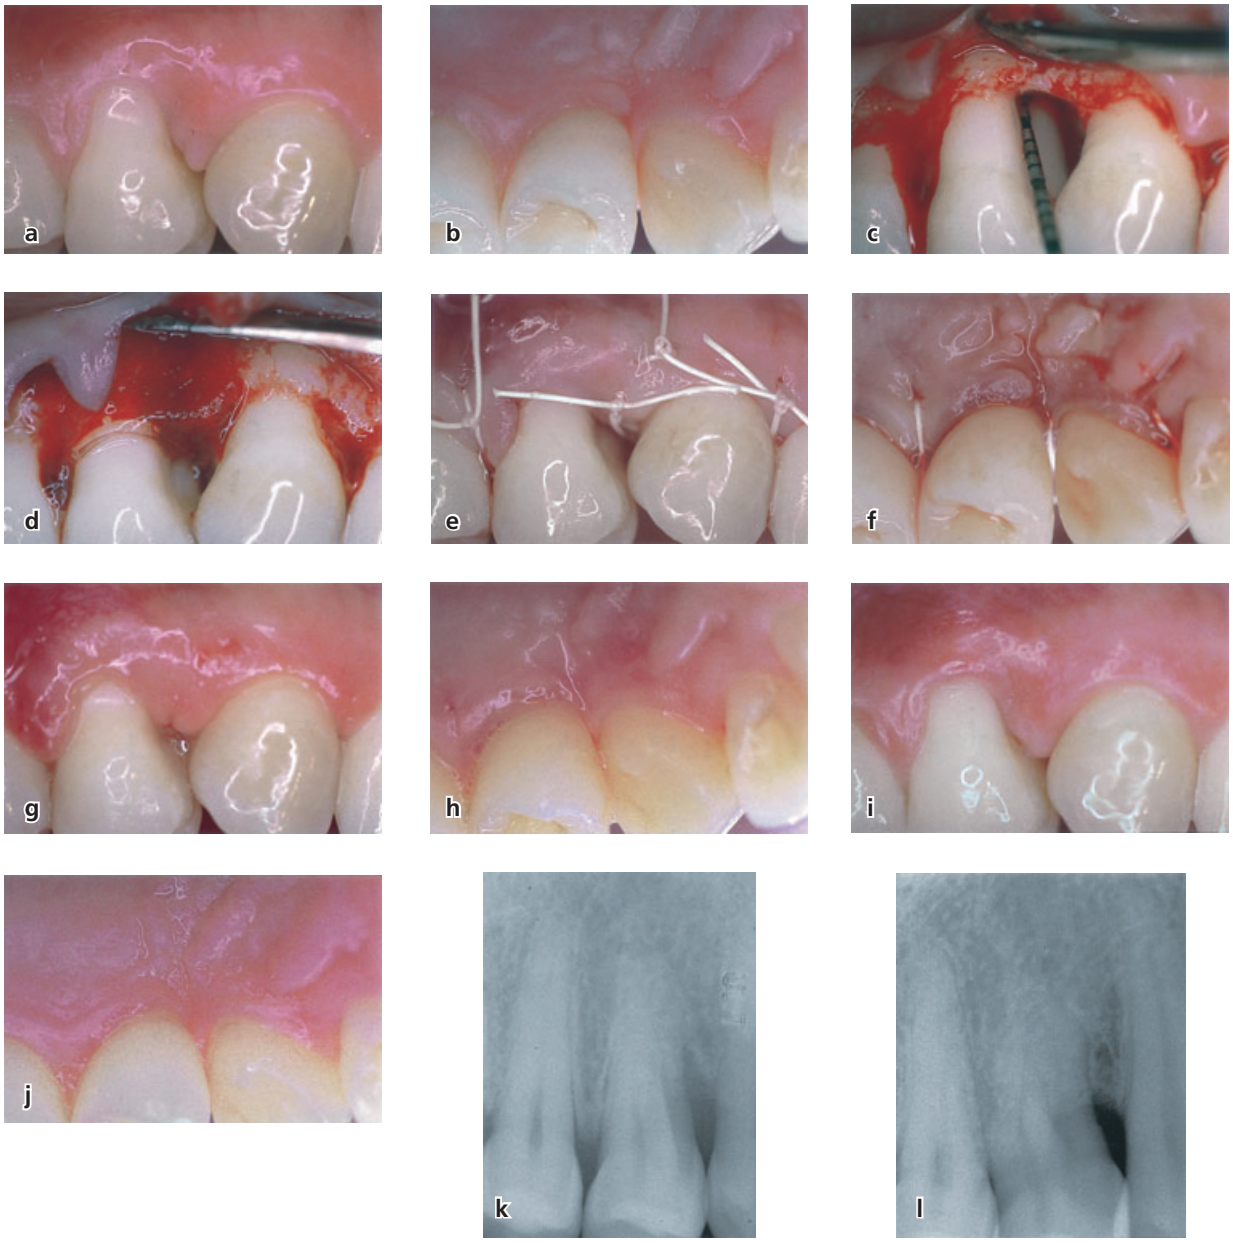

Fig. 43-15 (a) Right first maxillary premolar with a 7-mm pocket on the mesial surface. The interdental space (b) is very narrow (>2 mm), and is accessed with a simplified papilla preservation flap. The 5-mm deep intrabony defect (c) is covered with a bioresorbable barrier membrane (d). Primary closure of the flap over the membrane (e,f) is maintained over time (g,h). After 1 year, the interdental papilla is completely preserved and the residual pocket depth is 3 mm (i,j). The radiograph taken at baseline (k) compared with that taken 1 year after treatment (l) shows that the intrabony defect has healed completely.

4.5 ± 1.2 mm. In all the cases primary closure of the flap was achieved and about 80% of the sites maintained primary closure over time (Fig. 43-19). It should be underlined, however, that the horizontal internal crossed mattress suture most probably caused an apical displacement of the interdental portion of the membrane, thereby reducing the space for regeneration.

The MPPT can be successfully applied in conjunction with a variety of regenerative materials including biologically active materials such as enamel matrix derivative (EMD) (Tonetti *et al*. 2002) (Fig. 43-20) or growth factors and bone replacement grafts (Fig. 43-21) (Tonetti *et al*. 2004b; Cortellini & Tonetti 2005).

The surgical access of the interdental space with the MPPT is technically very demanding, but it has been reported to be very effective and applicable in wide interdental spaces (wider than 2 mm at interdental tissue level), especially in the anterior dentition. In properly selected cases, large amounts of attachment gain, and consistent reduction of pocket depths associated with no or minimal recession of the interdental papilla are consistently expected. It is, therefore, indicated in cases in which esthetics are particularly important.

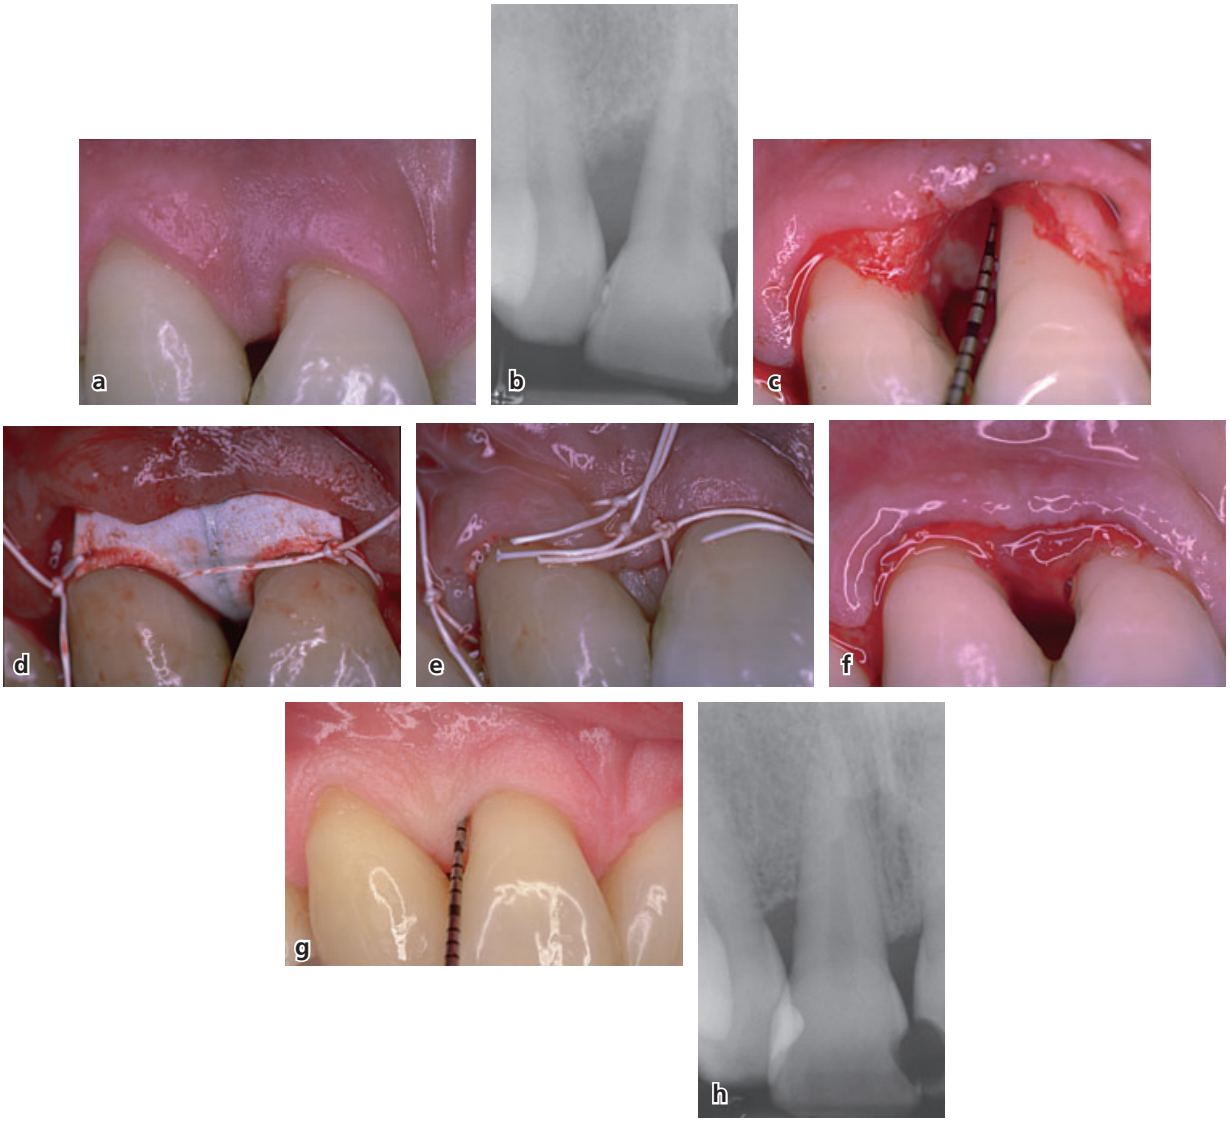

Fig. 43-18 Clinical case illustrating the operative procedure of the modified papilla preservation technique used to completely close the interdental space above a barrier membrane. Following completion of initial cause-related therapy, an 8-mm pocket associated with 2 mm of recession of the gingival margin was present on the distal of the central incisor (a). A wide intrabony defect was detectable on the radiograph (b). The defect was accessed with the modified papilla preservation technique keeping the whole interdental tissue connected with the palatal flap. A 7-mm intrabony defect was uncovered (c). Following root debridement, a titanium-reinforced barrier membrane was positioned (d). Primary closure of the interdental space was obtained by suturing back the papilla preservation flap using a multilayered suturing technique aimed at coronal advancement of the flap, complete relief of wound tension, and good flap stability (e). Six weeks thereafter, the same flap was elevated in order to remove the membrane that had remained completely submerged for the whole time. New tissue formed below the membrane was obtained with a shape that filled the space maintained under the membrane (f). Following completion of healing (1 year) a 3-mm probing depth and fill of the intrabony defect were observed. The results were maintained over time as indicated by the clinical and radiographic appearance 6 years after regeneration (g,h).

Fig. 43-19 Clinical case illustrating the application of the modified papilla preservation technique to a case treated with a resorbable barrier membrane. An 8-mm pocket associated with an intrabony defect persisted on the mesial aspect of the lower first molar following completion of initial cause-related therapy (a,b). The defect was accessed with the modified papilla preservation flap. Please note the papilla preserved attached to the lingual flap (c) as well as the presence of a 7-mm intrabony defect (d). Following root debridement, a bioresorbable barrier membrane was positioned and secured around the root of the tooth with bioresorbable sutures (e). Primary closure of the interdental space was obtained with multilayered sutures (f) and was fully maintained at the 1-week suture removal appointment (g). At 6 years, probing depths were 2–3 mm, the soft tissue profile was conducive to optimal self-performed oral hygiene measures and the radiograph showed elimination of the defect (h–j).

Simplified papilla preservation flap

To overcome some of the technical problems encountered with the MPPT (difficult application in narrow interdental spaces and in posterior areas, suturing technique not appropriate for use with non-supportive barriers) a different approach (simplified papilla preservation flap, SPPF) (Figs. 43-15, 43-22) was subsequently developed (Cortellini *et al*. 1999).

This different and simplified approach to the interdental papilla includes a first incision across the defect-associated papilla, starting from the gingival margin at the buccal-line angle of the involved tooth to reach the mid-interdental portion of the papilla under the contact point of the adjacent tooth. This oblique incision is carried out keeping the blade parallel to the long axis of the teeth in order to avoid excessive thinning of the remaining interdental tissues. The first oblique interdental incision is continued intrasulcularly in the buccal aspect of the teeth neighboring the defect. After elevation of a full-thickness buccal flap, the remaining tissues of the papilla are carefully dissected from the neighboring teeth and the underlying bone crest. The interdental papillary tissues at the defect site are gently elevated along with the lingual/palatal flap to fully expose the interdental defect. Following defect debridement and root planing, vertical releasing incisions and/or periosteal incisions are performed, when needed, to improve the mobility of the buccal flap. After

Fig. 43-20 Clinical case illustrating the application of the papilla preservation technique in conjunction with the application of enamel matrix derivative in gel form. A 10-mm pocket was detectable on the distal aspect of the lower lateral incisor following successful completion of initial cause-related therapy (a). The radiograph showed the presence of a deep intrabony defect extending to the apical third of the root (b). The defect was accessed with the modified papilla preservation technique (c) with limited mesial and distal extension of the flap. Following careful debridement, the root is conditioned with an EDTA gel according to the manufacturer's instructions for the application of enamel matrix derivative (d). After rinsing and drying of the defect and root surface, the enamel matrix derivative gel is applied on the root surface and to fill the defect (e), and flaps are sutured with a multilayer technique to achieve primary closure in the absence of tension (f). One year following regenerative surgery, shallow pockets and radiographic resolution of the defect are apparent (g,h).

application of a barrier membrane, primary closure of the interdental tissues above the membrane is attempted in the absence of tension, with the following sutures:

1. A first horizontal internal mattress suture (offset mattress suture) is positioned in the defect-associated interdental space running from the base (near to the mucogingival junction) of the keratinized tissue at the mid-buccal aspect of the tooth not involved with the defect to a symmetrical location at the base of the lingual/palatal flap. This suture frictions against the interdental root surface, hangs on the residual interdental bone crest and is anchored to the lingual/palatal flap. When tied, it allows the coronal positioning of the buccal flap. A relevant notation is that this suture, lying on the interdental bone crest, does not cause any compression at the mid-portion of the membrane, therefore preventing its collapse into the defect.
2. The interdental tissues above the membrane are then sutured to obtain primary closure with one of the following approaches: (a) one interrupted suture whenever the interdental space is narrow and the interdental tissues thin; (b) two interrupted sutures, when the interdental space is wider and the interdental tissues thicker; (c) an internal vertical/oblique mattress suture, when the interdental space is wide and the interdental tissues are thick.

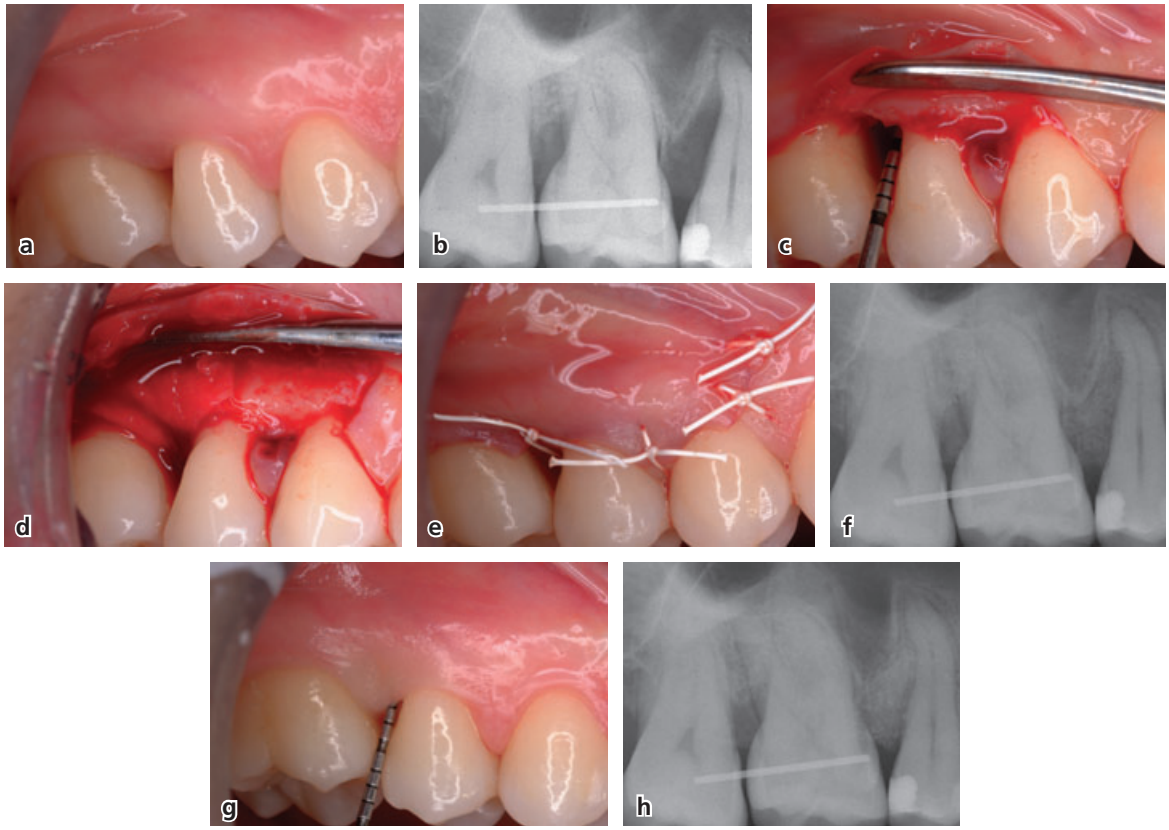

Fig. 43-21 Clinical case illustrating the application of the modified papilla preservation technique in conjunction with a bone replacement graft in combination with a bioresorbable membrane. After completion of initial cause-related therapy, a 9-mm pocket associated with an intrabony defect was present on the distal aspect of the upper second premolar (a,b). The defect reached the apical portion of the root and had a 9-mm intrabony component (c). Following careful root debridement, a bioresorbable membrane was adapted to the local anatomy and was positioned to contain the defect. A bone replacement graft was subsequently inserted under the membrane to provide additional support for the membrane and for the soft tissues (d). Primary closure was achieved with a single internal mattress suture (e). The control radiograph taken upon completion of the surgery shows the presence of the radio-opaque bone replacement graft in the defect (f). At 1-year follow-up, a 3-mm probing depth associated with resolution of the intrabony component of the defect is apparent (g,h). Please note that the radio-opaque bone replacement graft particles are still detectable but appear embedded in newly formed mineralized tissue.

Special care has to be paid to ensure that the first horizontal mattress suture would relieve all the tension of the flaps, and to obtain primary passive closure of the interdental tissues over the membrane with the last suture. When tension is observed, the sutures should be removed and the primary passive closure attempted a second time.

This approach has been preliminarily tested in a case series of 18 deep intrabony defects in combination with bioresorbable barrier membranes (Cortellini *et al*. 1999). The average clinical attachment level gain observed at 1 year was 4.9 ± 1.8 mm. In all the cases it was possible to obtain primary closure of the flap over the membrane, and 67% of the sites maintained primary closure over time. The same approach was then tested in a multi-center controlled randomized clinical trial involving 11 clinicians from seven different countries and a total of 136 defects (Tonetti *et al*. 1998). The average clinical attachment gain observed at 1 year in the 69 defects treated with the SPPF and a resorbable barrier membrane was 3 ± 1.6 mm. More than 60% of the treated sites maintained primary closure over time. It is important to underline that these results were obtained by different clinicians treating different populations of patients and defects, also involving narrow spaces and posterior areas of the mouth. The SPPF was successfully applied in conjunction with a variety of regenerative materials including biologically active materials such as EMD (Tonetti *et al.* 2002) (Fig. 43-23) and bone replacement grafts (Fig. 43-24) (Tonetti *et al*. 2004b; Cortellini & Tonetti 2004).

Minimally invasive surgical technique

In order to provide even greater wound stability and to further limit patient morbidity, a papilla preservation flap can be used in the context of a minimally invasive, high-power magnification-assisted surgical technique (Cortellini & Tonetti 2007a). Such a minimally invasive approach is particularly suited for treatment in conjunction with biologically active agents such as EMD or growth factors.

The defect-associated interdental papilla is accessed either with the simplified papilla preservation flap (SPPF) (Cortellini *et al*. 1999) or the modified

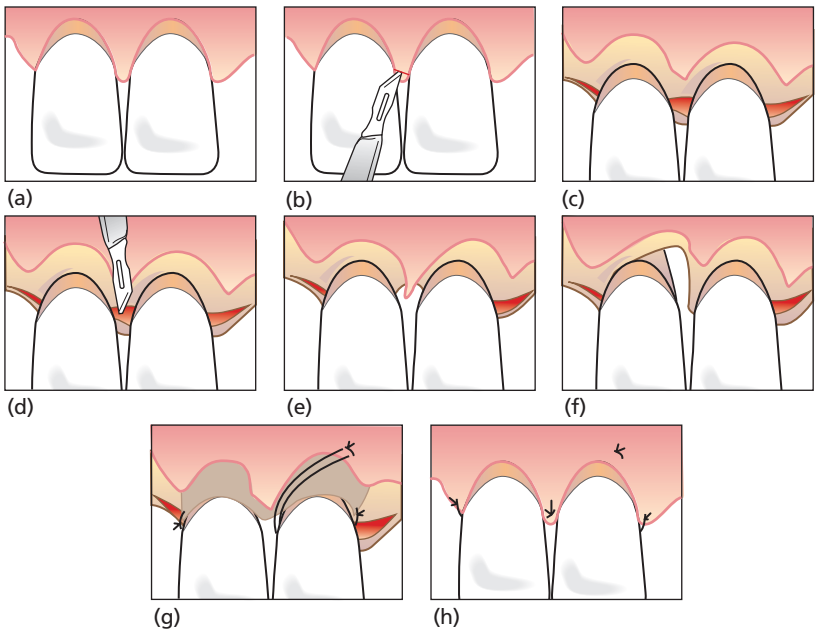

Fig. 43-22 (a) Pre-surgical appearance of the area that will be accessed with a simplified papilla preservation flap (SPPF). The defect is located on the mesial aspect of the maxillary right lateral incisor. (b) First oblique incision in the defect-associated papilla begins at the gingival margin of the mesio-buccal line angle of the lateral incisor. The blade is kept parallel to the long axis of the tooth and reaches the midpoint of the distal surface of the central incisor just below the contact point. (c) First oblique incision continues intrasulcularly in the buccal aspect of the lateral and central incisors, extending until the adjacent papillae, and a buccal full-thickness flap is elevated to expose 2–3 mm of bone. Note the defect-associated papilla still in place. (d) Bucco-lingual horizontal incision at the base of the papilla is as close as possible to the interproximal bone crest. Care is taken to avoid a lingual/palatal perforation. (e) Intrasulcular interdental incisions continue in the palatal aspect of the incisors until the adjacent partially dissected papillae. A full-thickness palatal flap including the interdental papilla is elevated. (f) Intrabony defect following debridement. Note the position of the bone crest on the distal aspect of the central incisor. (g) Membrane is positioned to cover the defect and 2–3 mm of remaining bone and secured to neighboring teeth. A horizontal internal mattress suture runs from the base of the keratinized tissue at the midbuccal side of the central incisor to a symmetric location at the base of the palatal flap. This suture causes no direct compression of the midportion of the membrane, preventing its collapse into the defect. (h) Primary closure and complete coverage of the membrane are obtained. From Cortellini *et al*. (1999) with permission from Quintessence Publishing Co. Inc.

papilla preservation technique (MPPT) (Cortellini *et al*. 1995d). The SPPF is performed whenever the width of the interdental space is 2 mm or narrower, while the MPPT is applied at interdental sites wider than 2 mm. The interdental incision (SPPF or MPPT) is extended to the buccal and lingual aspects of the two teeth adjacent to the defect. These incisions are strictly intrasulcular to preserve all the height and width of the gingiva, and their mesio-distal extension is kept at a minimum to allow the corono-apical elevation of a very small full-thickness flap with the objective of exposing just 1–2 mm of the defect-associated residual bone crest. When possible, only the defect-associated papilla is accessed and vertical releasing incisions are avoided. With these general rules in mind, different clinical pictures can be encountered in different defects.

The shortest mesio-distal extension of the incision and the minimal flap reflection occurs when the intrabony defect is a pure three-wall, or has shallow two- and/or one-wall subcomponents allocated entirely in the interdental area. In these instances the mesio-distal incision involves only the defect-associated papilla and part of the buccal and lingual aspects of the two teeth neighboring the defect. The full-thickness flap is elevated minimally, just to expose the buccal and lingual bone crest delineating the defect in the interdental area (Fig. 43-25).

A larger corono-apical elevation of the full-thickness flap is necessary when the coronal portion of the intrabony defect has a deep two-wall component. The corono-apical extension of the flap is kept to a minimum at the aspect where the bony wall is preserved (either buccal or lingual), and extends more apically at the site where the bony wall is missing (lingual or buccal), the objective being to reach and expose 1–2 mm of the residual bone crest (Fig. 43-26).

When a deep one-wall defect is approached, the full-thickness flap is elevated to the same extent on both the buccal and the lingual aspects.

When the position of the residual buccal/lingual bony wall(s) is very deep and difficult or impossible to reach with the above described minimal incision of the defect-associated interdental space, the flap(s) is(are) further extended mesially or distally involving one extra interdental space to obtain a larger flap reflection. The same approach is used when the bony

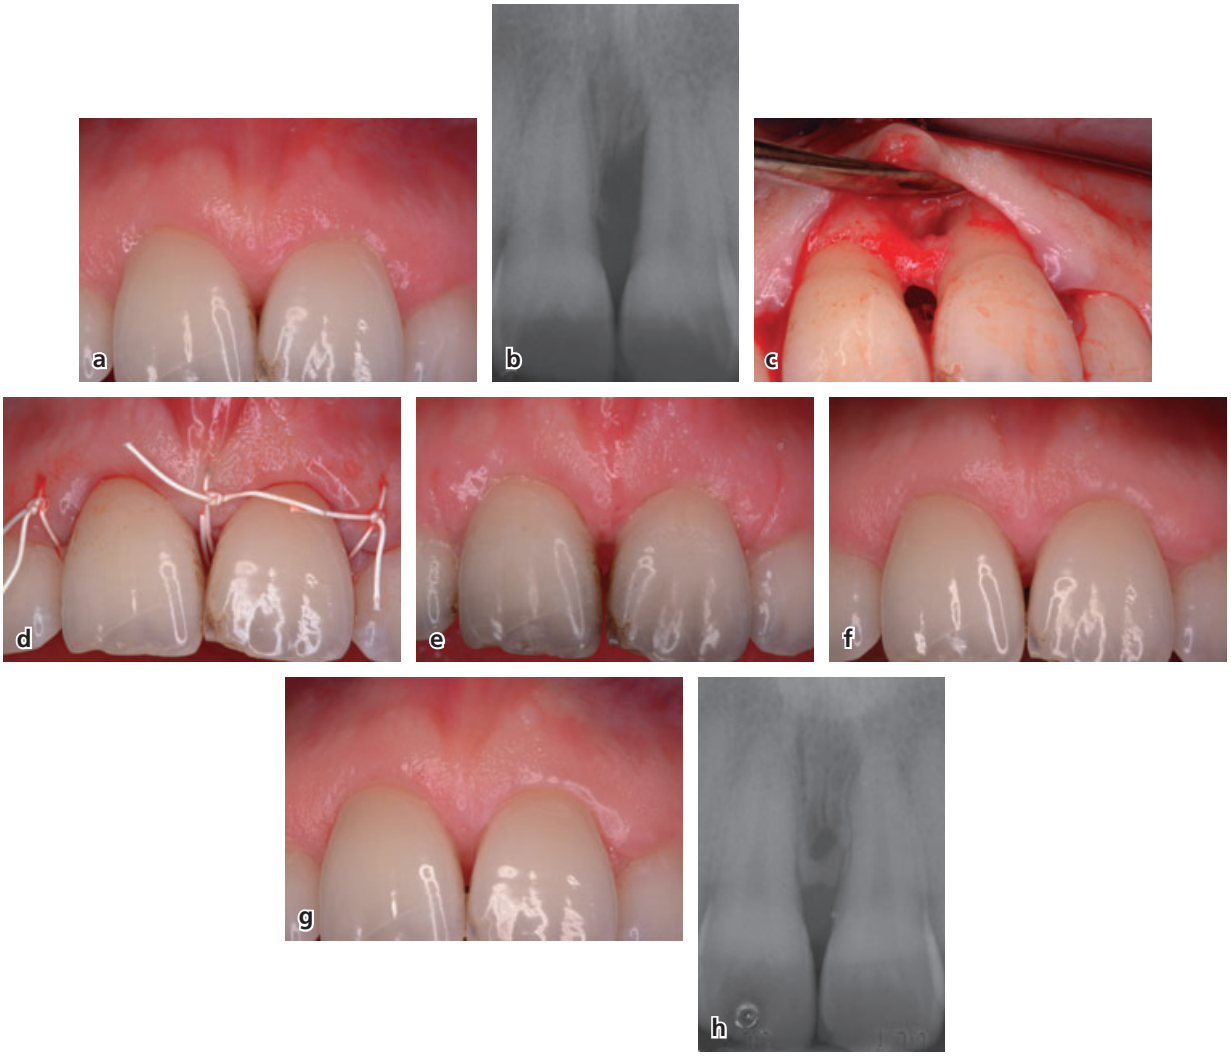

Fig. 43-23 Clinical case illustrating the clinical application of the simplified papilla preservation flap in conjunction with the application of a biologically active regenerative material (enamel matrix derivative in gel form). At re-evaluation following completion of successful initial cause-related therapy, an 8-mm pocket was detected on the mesial palatal aspect of the left central incisor (a). An angular defect was evidenced on a peri-apical radiograph (b). The complex anatomy of the defect is apparent following access to the defect with the modified papilla preservation technique: a buccal fenestration is apparent with the majority of the defect extending palatally to the apical third of the root (c). Following application of the enamel matrix derivative, primary closure of the flap was achieved with a multilayered suture (d). At the 1-week suture removal appointment, excellent maturation of the soft tissue healing is apparent (e). At 6 months, a well represented interdental papilla is present thanks to both the papilla preservation approach and the presence of a bony bridge that assisted in soft tissue support, in spite of the gel formulation of the enamel matrix derivative (f). Clinical and radiographic outcomes at 1 year show preservation of excellent esthetics and elimination of the defect (g,h). Probing depths were in the 2 to 3 mm range.

defect also extends to the buccal or the palatal side of the involved tooth, or when it involves the two interdental spaces of the same tooth (Fig. 43-27) or two approximal teeth (Fig. 43-28). In the latter instance a second interdental papilla is accessed, either with a SPPF or a MPPT, according to indications. Vertical releasing incisions are performed when flap reflection causes tension at the extremities of the flap(s). The vertical releasing incisions are always kept very short and within the attached gingiva (never involving the mucogingival junction). The overall aim of this approach is to avoid using vertical incisions whenever possible or to reduce their number and extent to a minimum when there is a clear indication for them. Periosteal incisions are never performed.

The defects are debrided with a combined use of mini curettes and power-driven instruments and the roots carefully planed. During the instrumentation the flaps are slightly reflected, carefully protected with periosteal elevators and frequent saline irrigations. At the end of instrumentation the biologically active agent is applied. Then the flaps are repositioned.

The suturing approach in most of the instances consists of a single modified internal mattress suture at the defect-associated interdental area to achieve primary closure of the papilla in the absence of any

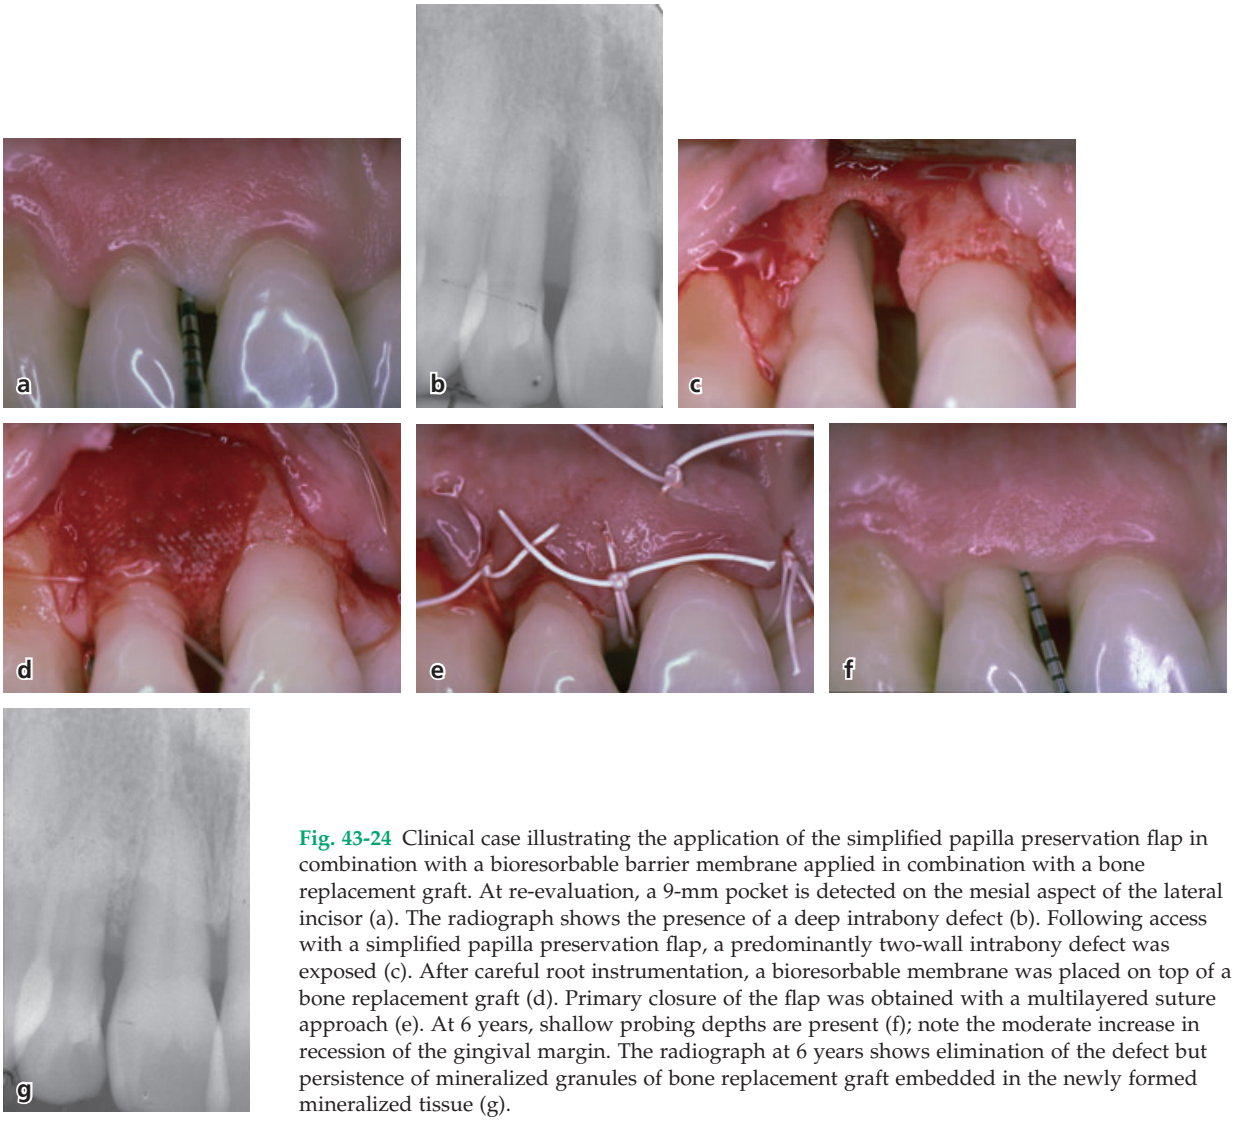

Fig. 43-24 Clinical case illustrating the application of the simplified papilla preservation flap in combination with a bioresorbable barrier membrane applied in combination with a bone replacement graft. At re-evaluation, a 9-mm pocket is detected on the mesial aspect of the lateral incisor (a). The radiograph shows the presence of a deep intrabony defect (b). Following access with a simplified papilla preservation flap, a predominantly two-wall intrabony defect was exposed (c). After careful root instrumentation, a bioresorbable membrane was placed on top of a bone replacement graft (d). Primary closure of the flap was obtained with a multilayered suture approach (e). At 6 years, shallow probing depths are present (f); note the moderate increase in recession of the gingival margin. The radiograph at 6 years shows elimination of the defect but persistence of mineralized granules of bone replacement graft embedded in the newly formed mineralized tissue (g).

tension (Cortellini & Tonetti 2001, 2005). When a second interdental space has been accessed, the same suturing technique is used to obtain primary closure in this area. Vertical releasing incisions are sutured with simple passing sutures. The buccal and lingual flaps are re-positioned at their original level, without any coronal displacement to avoid any additional tension in the healing area.

All the surgical procedures can be performed with the aid of an operating microscope or magnifying loops at a magnification of 4× to 16× (Cortellini & Tonetti 2001, 2005). Microsurgical instruments are utilized, whenever needed, as a complement to the normal set of periodontal instruments.

This approach has been preliminarly tested in two case series with a total of 53 deep intrabony defects (Cortellini & Tonetti 2007a,b). One-year results have shown clinically significant improvements (clinical attachment level gains of 4.8 ± 1.9 mm and 88.7 ± 20.7% clinical resolution of the defect) accompanied by greatly reduced morbidity.

Post-operative regime

The post-operative regime prescribed to the patients is aimed at controlling wound infection or contamination as well as mechanical trauma to the treated sites. A recent meta-analysis indicated that differences in regenerative outcomes are expected based on the post-operative care protocol: more frequent, intensive regimens were associated with better clinical attachment level gains in intrabony defects (Murphy *et al*. 2003) (Fig. 43-29). It generally includes the prescription of systemic antibiotics (doxycycline or amoxicillin) in the immediate post-operative period (1 week), 0.2 or 0.12% chlorhexidine mouthrinsing two or three times per day, and weekly professional tooth cleaning until the membrane is in place. Professional tooth cleaning consists of supragingival prophylaxis with a rubber cup and chlorhexidine gel. Patients are generally advised not to perform mechanical oral hygiene and not to chew in the treated area.

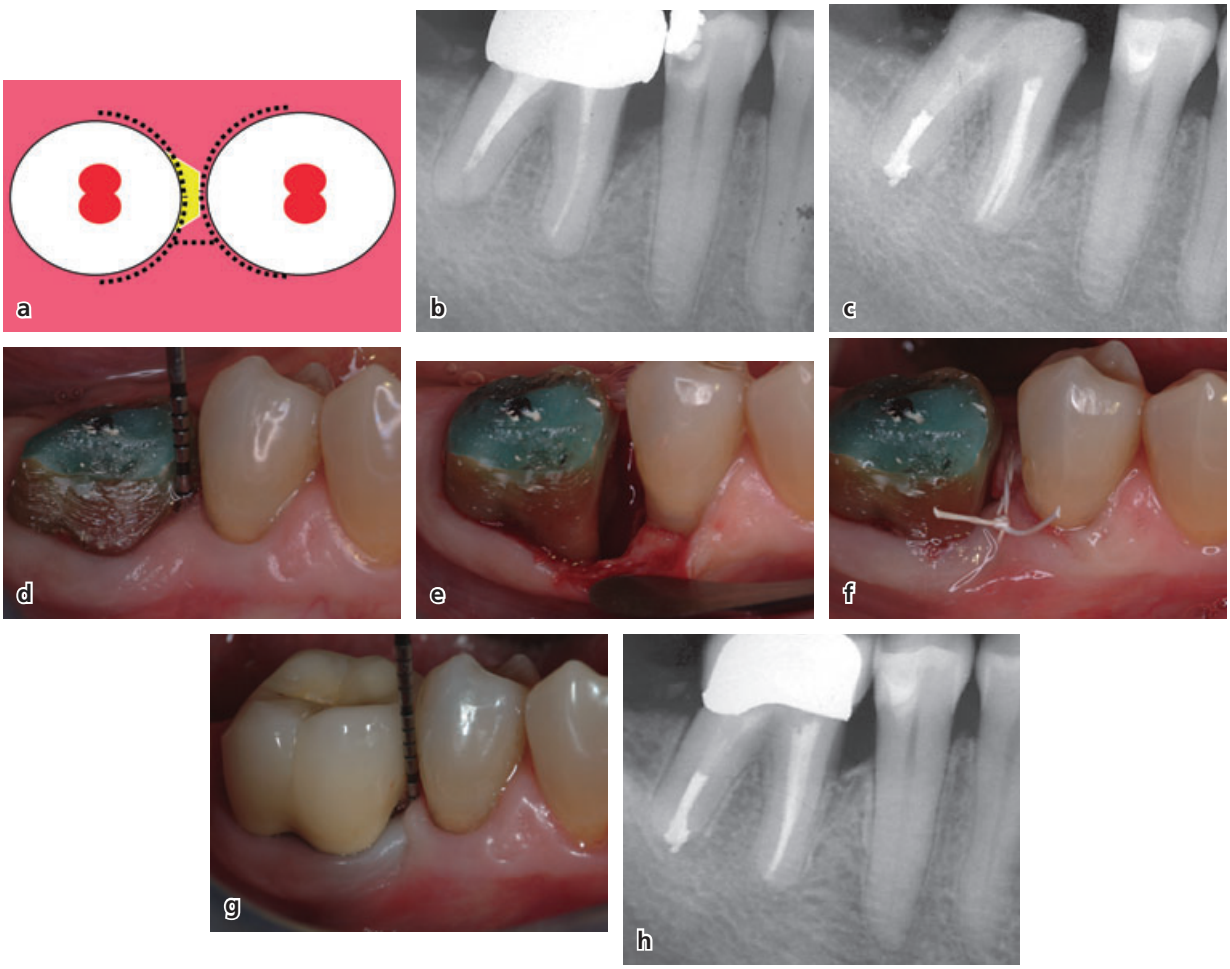

Fig. 43-25 Clinical illustration of the use of the minimally invasive surgical technique (MIST) in an isolated interdental three-wall defect. The diagram shows the extent of the incision performed according to the principles of the modified papilla preservation technique in the interdental space associated with the defect. Mesio-distal extension of the flap is limited to the buccal aspect of the teeth adjacent to the defect in order to optimize wound stability (a). The baseline radiograph shows the presence of dental diseases (peri-apical infection and caries) that need to be controlled during the initial cause-related phase of therapy (b). At re-evaluation, an 8-mm pocket associated with the presence of a deep intrabony defect was detected on the mesial aspect of the first molar (c,d). The defect was accessed in a minimally invasive fashion using a modified papilla preservation flap. The three-wall intrabony defect was exposed and carefully debrided (e). After application of enamel matrix derivative, primary closure was obtained with a single modified internal mattress suture (f). The 1-year outcomes show shallow probing depths and almost complete resolution of the defect (g,h).

Non-resorbable membranes are removed 4–6 weeks after placement, following elevation of partial-thickness flaps. Patients are re-instructed to rinse two or three times per day with chlorhexidine, not to perform mechanical oral hygiene and not to chew in the treated area for 3–4 weeks. In this period weekly professional control and prophylaxis are recommended. When bioresorbable membrane, bone replacement grafts or biologically active regenerative materials are used, the period of tight infection control regime is extended for 6–8 weeks. After this period, patients are re-instructed to resume mechanical oral hygiene gradually, including interdental cleaning, and to discontinue chlorhexidine. Patients are then enrolled in a periodontal care program on a monthly basis until 1 year. Probing or deep scaling in the treated area is generally avoided before the 1-year follow-up visit.

Post-operative morbidity

To date, little consideration has been given to critical elements that could contribute to the patient's assessment of the cost-benefit ratio of GTR procedures. These include post-operative pain, discomfort, complications, and the perceived benefits from the treatment. A parallel group, randomized, multicenter and controlled clinical trial designed to test the efficacy of GTR and flap surgery alone assessed these patient issues (Cortellini *et al*. 2001). During the procedure, 30.4% of the test and 28.6% of the controls reported moderate pain and subjects estimated the hardship of the procedure as 24 ± 25 units on a visual analog scale (VAS in a scale from 0 to 100) in the test group and 22 ± 23 VAS in the controls. Test surgery with membranes required longer chair time than flap surgery (on average 20 minutes longer). Among the

Fig. 43-26 Clinical illustration of the use of the minimally invasive surgical technique (MIST) in an isolated interdental defect extending towards the buccal aspect of the tooth. The diagram shows the extent of the incision performed according to the principles of the modified papilla preservation technique in the interdental space associated with the defect. Mesio-distal extension of the flap is limited to the buccal aspect of the teeth adjacent to the defect and to the interdental aspect adjacent to the buccal extension of the defect in order to optimize wound stability (a). Following completion of successful initial cause-related therapy, a 6-mm pocket associated with an intrabony defect was detected on the distal aspect of the lateral incisor (b,c). The attachment loss extended to the buccal aspect of the lateral incisor, suggesting the need to obtain access to the buccal aspect of this tooth. The defect was therefore accessed with a minimally invasive approach using the modified papilla preservation technique to access the interdental area and extending the incision to the papilla between the lateral and central incisors to ensure adequate access to the defect (d). Primary closure was obtained with a modified internal mattress suture and a simple passing suture (e). The 1-year outcomes show shallow probing depths, good preservation of the soft tissue heights, and resolution of the defect (f,g).

post-operative complications, edema was most prevalent at week 1 and most frequently associated with the GTR treatment, while post-operative pain was reported by fewer than 50% of both test and control patients. Pain intensity was described as mild and lasted on average 14.1 ± 15.6 hours in the test patients and 24.7 ± 39.1 hours in the controls. Post-operative morbidity was limited to a minority of subjects: 35.7% of the test and 32.1% of the controls reported that the procedures interfered with daily activities for an average of 2.7 ± 2.3 days in the test group and 2.4 ± 1.3 days in the control group. These data indicate that GTR adds almost 30 minutes to a flap procedure and is followed by a greater prevalence of post-surgical edema, while no difference could be observed between GTR and flap surgery alone in terms of post-operative pain, discomfort, and interference with daily activities.

To date, no comparative study has reported the morbidity associated with various regenerative approaches. Reports of multi-center trials on application of enamel matrix derivative or barrier membranes using the same methodology, however, show similar results for the application of these two regenerative materials (Tonetti *et al*. 1998, 2004a; Cortellini *et al*. 2001).

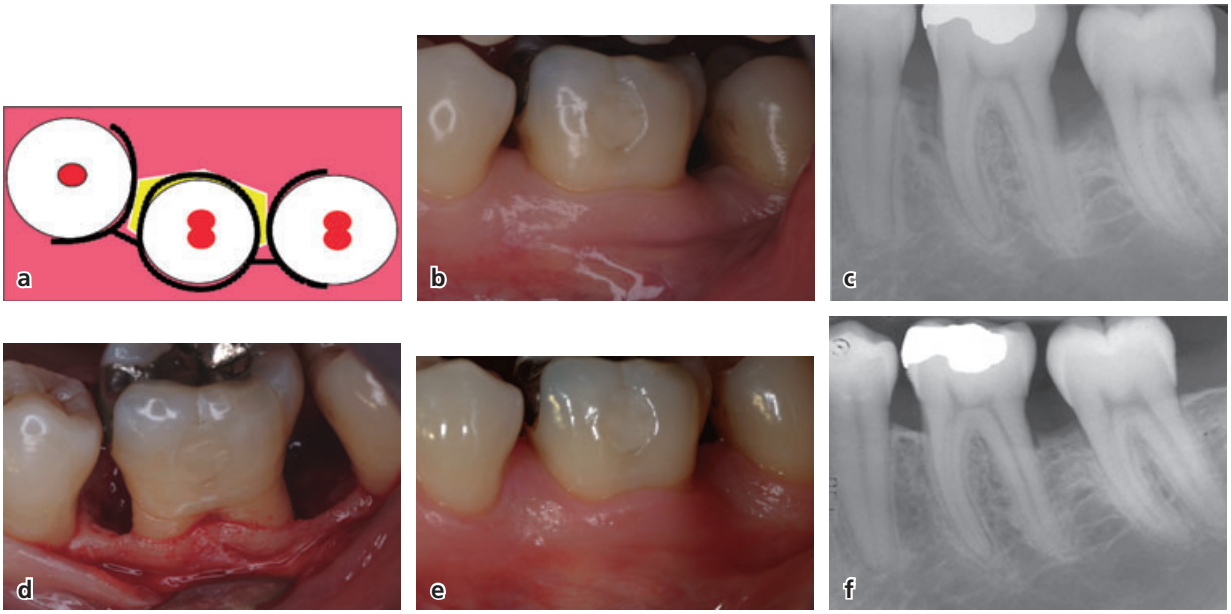

Fig. 43-27 Clinical illustration of the use of the minimally invasive surgical technique (MIST) in intrabony defects involving both interdental spaces of the same tooth. The diagram shows the extent of the incision performed according to the principles of the modified papilla preservation technique in the two interdental spaces associated with the defects. Mesio-distal extension of the flap is limited to the two interdental papillae associated with the defects (a) and reaches the line angle of the two adjacent teeth in order to limit the loss of wound stability while allowing adequate access to the defects. The clinical and radiographic appearance at baseline highlight the good control of inflammation obtained following completion of initial cause-related therapy and the presence of deep mesial and distal pockets with associated intrabony defects (b,c). Both the mesial and distal defects are accessed with papilla preservation flaps, the defects are debrided, and the root surfaces are carefully instrumented (d). Following application of enamel matrix derivative in the well contained defects, primary closure of the flap is achieved by modified internal mattress sutures. At 1-year follow-up, shallow pockets, preservation of soft tissues, and elimination of the defects are apparent (e,f).

Another important issue that has been addressed in a large multi-center trial has been the comparison of surgical complications (such as membrane exposure, flap dehiscence, or occurrence of suppuration) using resorbable barrier membranes or biologically active regenerative materials (EMD in gel form). Sanz *et al*. (2004) showed that all sites treated with membranes presented at least a surgical complication during healing, while this was observed in only 6% of sites treated with EMD. This study indicates that some regenerative materials/procedures may be less technique sensitive than others.

Barrier materials for regenerative surgery

In the first GTR attempts, a bacterial filter produced from cellulose acetate (Millipore®) was used as an occlusive membrane (Nyman *et al*. 1982; Gottlow *et al*. 1984; Magnusson *et al*. 1985b). Although this type of membrane served its purpose, it was not ideal for clinical application.

Non-absorbable materials

Later studies have utilized membranes of expanded polytetrafluoroethylene (e-PTFE) specially designed for periodontal regeneration (Gore Tex Periodontal Material®). The basic molecule of this material consists of a carbon–carbon bond with four attached fluorine atoms to form a polymer. It is inert and does not result in any tissue reaction when implanted in the body. This type of membrane persists after healing and must be removed in a second operation. Membranes of e-PTFE have been used successfully in animal experiments and in several clinical studies. From such studies it was found that for a barrier material to function optimally, it has to meet certain essential design criteria:

1. To allow for good tissue acceptance it is important that the material is biocompatible. The material should not elicit an immune response, sensitization or chronic inflammation that may interfere with healing and present a hazard to the patient. Biocompatibility, however, is a relative term since practically no materials are completely inert.
2. The material should act as a barrier to exclude undesirable cell types from entering the secluded space adjacent to the root surface. It is also considered an advantage that the material would allow the passage of nutrients and gases.
3. Tissue integration is another important property of a barrier material. Thus, tissue may grow into the material without penetrating all the way through. The goal of tissue integration is to prevent rapid epithelial downgrowth on the outer surface of the material or encapsulation of the material,

Fig. 43-28 Clinical illustration of the use of the minimally invasive surgical technique (MIST) in intrabony defects involving two adjacent teeth. The diagram shows the extent of the incision performed according to the principles of the papilla preservation flaps in the two interdental spaces associated with the defects. Mesio-distal extension of the flap is limited to the two interdental papillae associated with the defects (a) and reaches the line angle of the two adjacent teeth in order to limit the loss of wound stability and limit flap extension. After successful initial cause-related therapy, two defects are present on the mesial aspect of the first molar and second premolar (b,c). Simplified papilla preservation flaps are used to access the defects (d). Incisions are stopped at the distal line angle of the first premolar and on the buccal aspect of the first molar. Root debridement and application of enamel matrix proteins in gel form are performed before primary closure of the flap that was obtained by using two modified internal vertical mattress sutures (e). Excellent early healing in the absence of pain or discomfort is evident at the 1-week suture removal (f). At 1-year follow-up, absence of inflammation, shallow probing depths and resolution of the defects are evident (g,h).

Group 3 is statistically different from groups 1 and 2. From Murphy & Gunsolley (2003) with permission from the American Academy of Periodontology.

and to provide stability to the overlying flap. The importance of tissue integration was demonstrated in a study in monkeys (Warrer *et al*. 1992) in which bioabsorbable membranes of polylactic acid, a synthetic polymer, were used for treatment of circumferential periodontal defects. Due to the lack of tissue integration, the membranes in this study became surrounded by an epithelial layer and were often encapsulated and exfoliated.

4. It is also essential that the barrier material is capable of creating and maintaining a space adjacent to the root surface. This will allow the ingrowth of tissue from the periodontal ligament. Some materials may be so soft and flexible that they collapse into the defect. Other materials are too stiff and may perforate the overlying tissue.
5. Finally, there are clinical needs in the design of a barrier. It should be provided in configurations which are easy to trim and to place.

Bioabsorbable materials

In recent years, natural or synthetic bioabsorbable barrier materials for GTR have been introduced in order to avoid a second surgery for membrane removal. Barrier materials of collagen from different species and from different anatomic sites have been tested in animals and in humans (Blumenthal 1988, 1993; Pitaru *et al*. 1988; Tanner *et al*. 1988; Paul *et al*. 1992; Wang *et al*. 1994; Camelo *et al*. 1998; Mellonig 2000). Often the collagen used is a cross-linked variety of porcine or bovine origin. When a collagen membrane is implanted in the human body it is resorbed by the enzymatic activity of macrophages and polymorphnuclear leucocytes (Tatakis *et al*. 1999). Successful treatment following the use of such barrier materials has been demonstrated, but the results of the studies vary. Several complications, such as early degradation, epithelial downgrowth along the material, and premature loss of the material, were reported following the use of collagen materials. The varying results are probably due to differences in the properties of the material and the handling of the material at the time of implantation. Although probably very minimal, there is a risk that infectious agents from animal products can be transmitted to humans, and autoimmunization has also been mentioned as a risk.

Barrier materials of polylactic acid or copolymers of polylactic acid and polyglycolic acid were evaluated in animal and human studies and are commonly used (Magnusson *et al*. 1988; Caffesse *et al*. 1994; Caton *et al*. 1994; Gottlow *et al*. 1994; Laurell *et al*. 1994; Hugoson *et al*. 1995; Polson *et al*. 1995a; Hürzeler *et al*. 1997; Sculean *et al*. 1999a). These materials are biocompatible, but by definition they are not inert since some tissue reaction may be expected during degradation. The materials are degraded by hydrolysis and eliminated from the organism through the Krebs cycle as carbon dioxide and water (Tatakis *et al*. 1999).

The types of barrier materials tested in the studies differ regarding configuration and design. It appears that a number of bioabsorbable materials meet to a varying extent the requirements of a good barrier listed above. Indeed, there are several studies (Hugoson *et al*. 1995; Cortellini *et al*. 1996b; Smith *et al*. 1998; Tonetti *et al*. 1998; Cortellini & Tonetti 2000a) indicating that similar satisfactory results can be obtained with bioabsorbable barrier materials of polylactic and polyglycolic acid as with non-bioabsorbable materials.

Membranes in intrabony defects

Early evidence that GTR treatment of deep intrabony defects may produce clinical improvements in terms of clinical attachment gain was presented in several case reports (Nyman *et al*. 1982; Gottlow *et al*. 1986; Becker *et al*. 1988; Schallhorn & McClain 1988; Cortellini *et al*. 1990). In recent years, a number of clinical investigations have reported on a total of 1283 intrabony defects treated with GTR (Table 43-2). In these studies, the issue of evaluating the predictability of the clinical outcomes following application of GTR procedures was addressed. The weighted mean of the reported results indicates a mean gain in clinical attachment of 3.8 ± 1.7 mm, with a 95% confidence interval ranging from 3.7–4.0 mm (Cortellini & Tonetti 2000a). The reported clinical attachment gains following GTR treatment were significantly larger than the ones obtained from conventional flap surgery. A recent review (Lang 2000) on flap surgery reported a weighted mean of 1172 defects in 40 studies. CAL gains were 1.8 ± 1.4 mm, with a 95% confidence interval ranging from 1.6–1.9 mm.

Different types of non-bioabsorbable (Fig. 43-30) and bioabsorbable (Fig. 43-31) barrier materials were used in the studies summarized in Table 43-2. A subset analysis indicated that cases treated with non-bioabsorbable barrier materials (351 defects) showed a mean gain in clinical attachment of 3.7 ± 1.7 mm which did not differ from that obtained with bioabsorbable barrier materials of 3.6 ± 1.5 mm (592 defects).

Analysis of the results reported in some of the studies in Table 43-2 (i.e. 211 defects in 9 investigations: Proestakis *et al*. 1992; Cortellini *et al*. 1993b, 1995c, 1996b; Cortellini & Pini-Prato 1994; Laurell *et al*. 1994; Mattson *et al*. 1995; Mellado *et al*. 1995; Tonetti *et al*. 1996b) provides important information regarding the predictability of GTR in intrabony defects. Gains of 2–3 mm were observed in 29.2% of the defects, gains of 4–5 mm in 35.4% of the defects, and gains of 6 mm or more in 24.9% of the defects. Only in 10.5% of the treated defects was the gain less than 2 mm, while no change or attachment loss was observed in two cases.

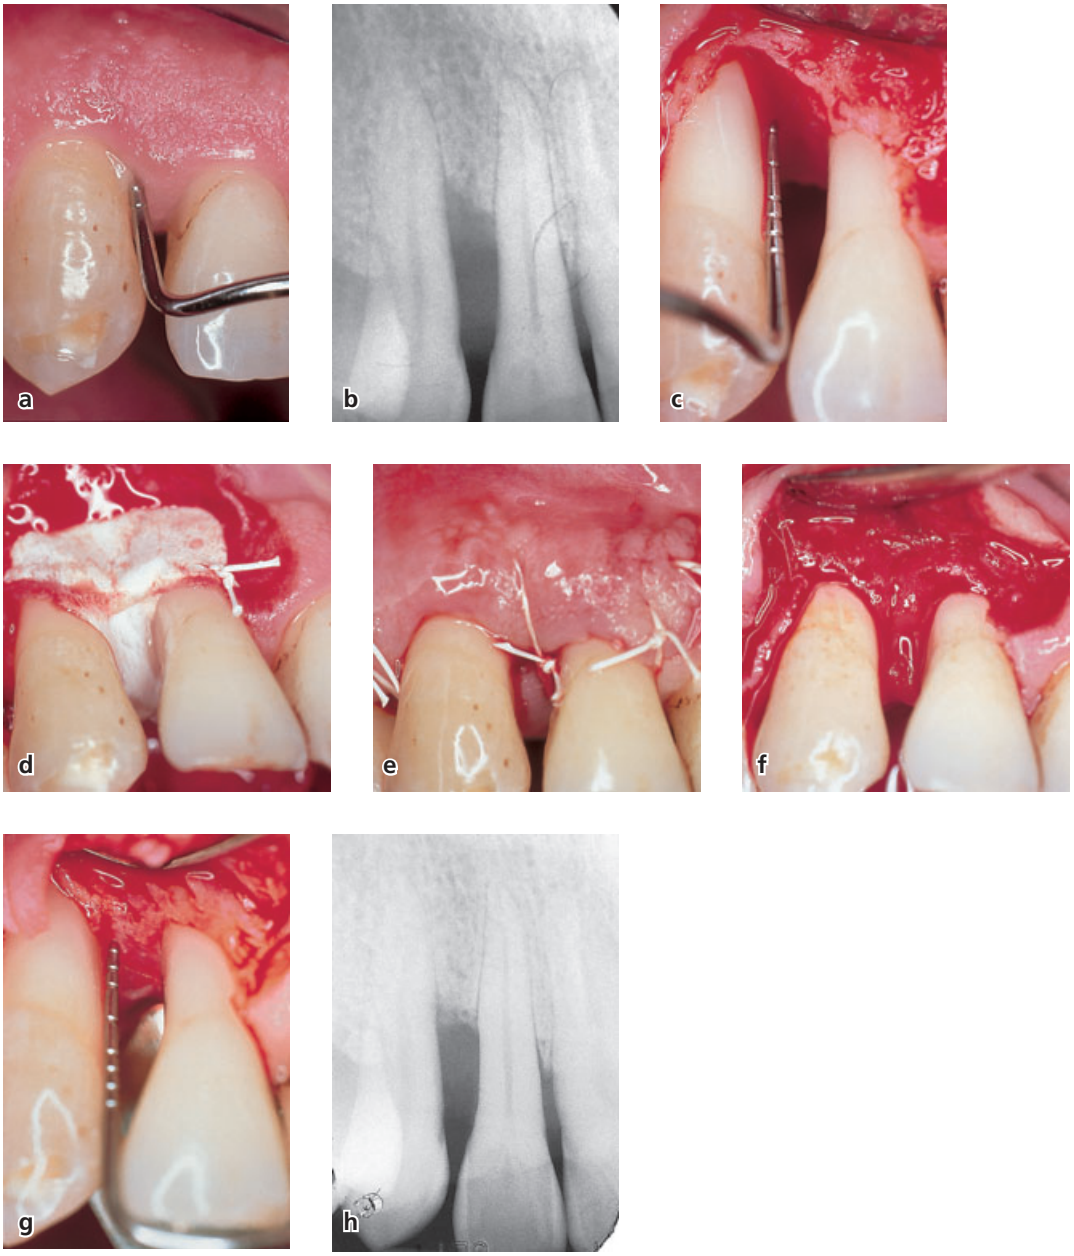

Fig. 43-30 Intrabony defect on the mesial aspect of a right maxillary canine treated with a non-bioabsorbable barrier membrane. (a) The pocket depth is 9 mm and the loss of clinical attachment is 10 mm. (b) Radiograph showing the presence of an interproximal intrabony defect. (c) After full-thickness flap elevation, defect debridement, and root planing, a 4-mm intrabony defect is evident. (d) An e-PTFE non-bioabsorbable barrier membrane has been tailored, positioned and tightly sutured around the teeth adjacent to the defect. (e) The flap has been repositioned and sutured to cover the membrane. Optimal preservation of the soft tissues has been accomplished with an intrasulcular incision. (f) After removal of the membrane at 5 weeks, the defect appears to be completely filled with newly formed tissue. (g) The treated site has been surgically re-entered after 1 year. The intrabony defect is completely filled with bone. (h) The 1-year radiograph confirms the complete resolution of the intrabony defect.

In some of the investigations, changes in bone levels were also reported (Becker *et al*. 1988; Handelsman *et al*. 1991; Kersten *et al*. 1992; Cortellini *et al*. 1993b,c; Selvig *et al*. 1993). Bone gains ranged between 1.1 and 4.3 mm and correlated with the reported gains in clinical attachment. In a study by Tonetti *et al*. (1993b), 1 year after GTR the bone was found to be located 1.5 mm apically to the position of the attained clinical attachment level.

Another important parameter related to the outcome of regenerative procedures is the residual pocket depth. In the studies reported in Table 43-2, shallow pockets were consistently found at 1 year. The weighted mean of residual pocket depth was 3.4 ± 1.2 mm, with a 95% CI ranging from 2.3–3.5 mm.

The reported outcomes indicate that GTR procedures predictably result in clinical improvements in intrabony defects beyond that of flap surgery. This was further confirmed in 11 controlled randomized clinical trials in which guided tissue regeneration was compared with conventional flap surgery (Table 43-3). A total of 267 defects were treated with flap

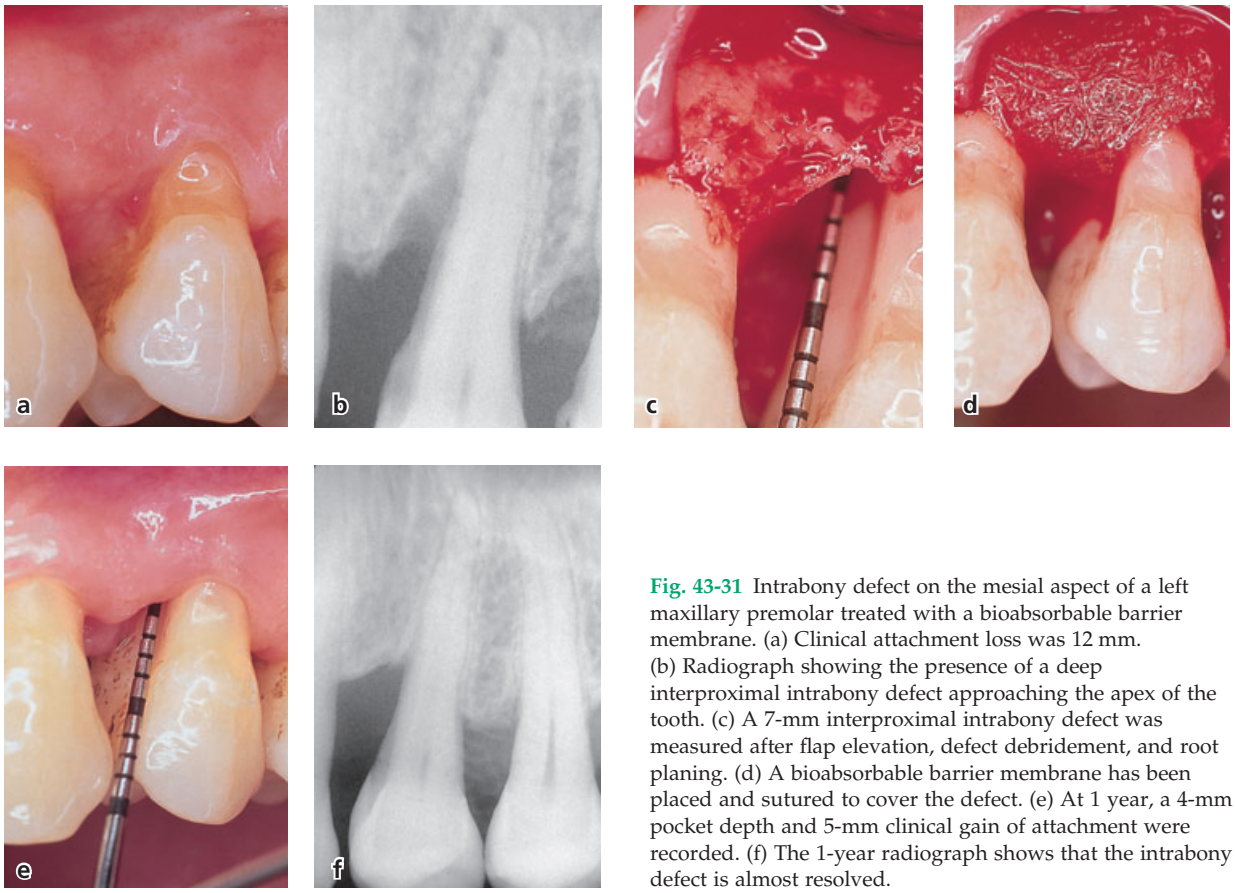

Fig. 43-31 Intrabony defect on the mesial aspect of a left maxillary premolar treated with a bioabsorbable barrier membrane. (a) Clinical attachment loss was 12 mm. (b) Radiograph showing the presence of a deep interproximal intrabony defect approaching the apex of the tooth. (c) A 7-mm interproximal intrabony defect was measured after flap elevation, defect debridement, and root planing. (d) A bioabsorbable barrier membrane has been placed and sutured to cover the defect. (e) At 1 year, a 4-mm pocket depth and 5-mm clinical gain of attachment were recorded. (f) The 1-year radiograph shows that the intrabony defect is almost resolved.

surgery and 317 with GTR. In 9 of the 11 investigations, GTR resulted in statistically significantly greater probing attachment level gains when compared to flap surgery. Similar results were also observed for residual pocket depth. It should be emphasized that one of the investigations reporting no significant differences between GTR and flap surgery was carried out in only nine pairs of defects (18 defects) located on maxillary premolars (Proestakis *et al*. 1992). In this study the intrabony component of the defects was shallow and 10 of the 18 defects had a furcation involvement. The weighted mean of the results reported in the 11 studies listed in Table 43-3 (Cortellini & Tonetti 2000a) indicated that the gain in clinical attachment in sites treated with GTR was 3.3 ± 1.8 mm (95% CI 2.8–3.6 mm), while the flap surgery resulted in a mean gain of 2.1 ± 1.5 mm (95% CI 1.8–2.4 mm). These clinical results strongly indicate that there is an added beneficial effect of placing a barrier material over an intrabony defect in conjunction with surgery.

Membranes for furcation involvement

The invasion of the furcation area of multi-rooted teeth by periodontitis represents a serious complication in periodontal therapy. The furcation area is often inaccessible to adequate instrumentation, and the roots frequently present concavities and furrows which make proper cleaning of the area impossible (see Chapter 39). As long as the pathologic process only extends a small distance (<5 mm; degree I and II involvements) into the furcation area, further progress of the disease can usually be prevented by scaling and root planing, provided a proper oral hygiene program is established after treatment. In more advanced cases (5–6 mm; degree II involvements), the initial cause-related treatment is frequently supplemented with surgery involving contouring of the inter-radicular bone (osteoplasty) or reduction of the tooth prominence at the furcation entrance by grinding (odontoplasty), in order to reduce the horizontal extension of the furcation involvement. In cases where the involvement extends deeper into the furcation area (>5 mm; degree II involvements), or a through-and-through defect (degree III involvements) has developed, tunnel preparation or root resection have been advocated as the choice of treatment. However, both of these latter treatments involve a risk of complications on a long-term basis. Following tunnel preparation, caries frequently develops in the furcation area and root-resected teeth often present complications of non-periodontal nature, although controversial reports exist regarding the long-term results of these treatment modalities (Hamp *et al*. 1975; Langer *et al*. 1981; Erpenstein 1983; Bühler 1988; Little *et al*. 1995; Carnevale *et al*. 1998).

of the long-term results and complications reported following treatment of advanced furcation involvements by traditional resective therapy, predictable regeneration of the periodontium at furcation-involved sites would represent a considerable progress in periodontics.

Mandibular degree II furcations

Pontoriero *et al*. (1988) reported a controlled randomized clinical trial in which significantly greater amounts of horizontal clinical attachment (H-CAL) gain (3.8 ± 1.2 mm) were obtained in 21 mandibular degree II furcations treated with e-PTFE membranes compared to those in a control group treated with open flap debridement alone (H-CAL gains of 2.0 ± 1.2 mm). Complete closure of the furcation was observed in 67% of the test sites and in only 10% of the control sites. Other studies, however, have failed to confirm these promising results to the same extent (Becker *et al*. 1988; Lekovic *et al*. 1989; Caffesse *et al*. 1990). Analysis of a series of studies published between 1988 and 1996 demonstrates a great variability in the clinical outcomes (Figs. 43-32, 43-33). Table 43-4 summarizes the outcomes of 21 clinical trials in which a total of 423 mandibular degree II furcations were treated with different types of non-bioabsorbable and bioabsorbable barrier membranes. The weighted mean of the reported results shows a H-CAL gain of 2.3 ± 1.4 mm with a 95% confidence interval ranging from 2.0–2.5 mm in defects with a baseline horizontal probing depth of 5.4 ± 1.3 mm. The reported number of complete furcation closures after GTR range from 0–67%. In three studies none of the treated furcations were closed (Becker *et al*. 1988; Yukna 1992; Polson *et al*. 1995b), in seven studies fewer than 50% were closed (Schallhorn & McClain 1988; Blumenthal 1993; Bouchard *et al*. 1993; Parashis & Mitsis 1993; Laurell *et al*. 1994; Mellonig *et al*. 1994; Hugoson *et al*. 1995), and in only one study were more than 50% of the treated furcations completely resolved (Pontoriero *et al*. 1988).

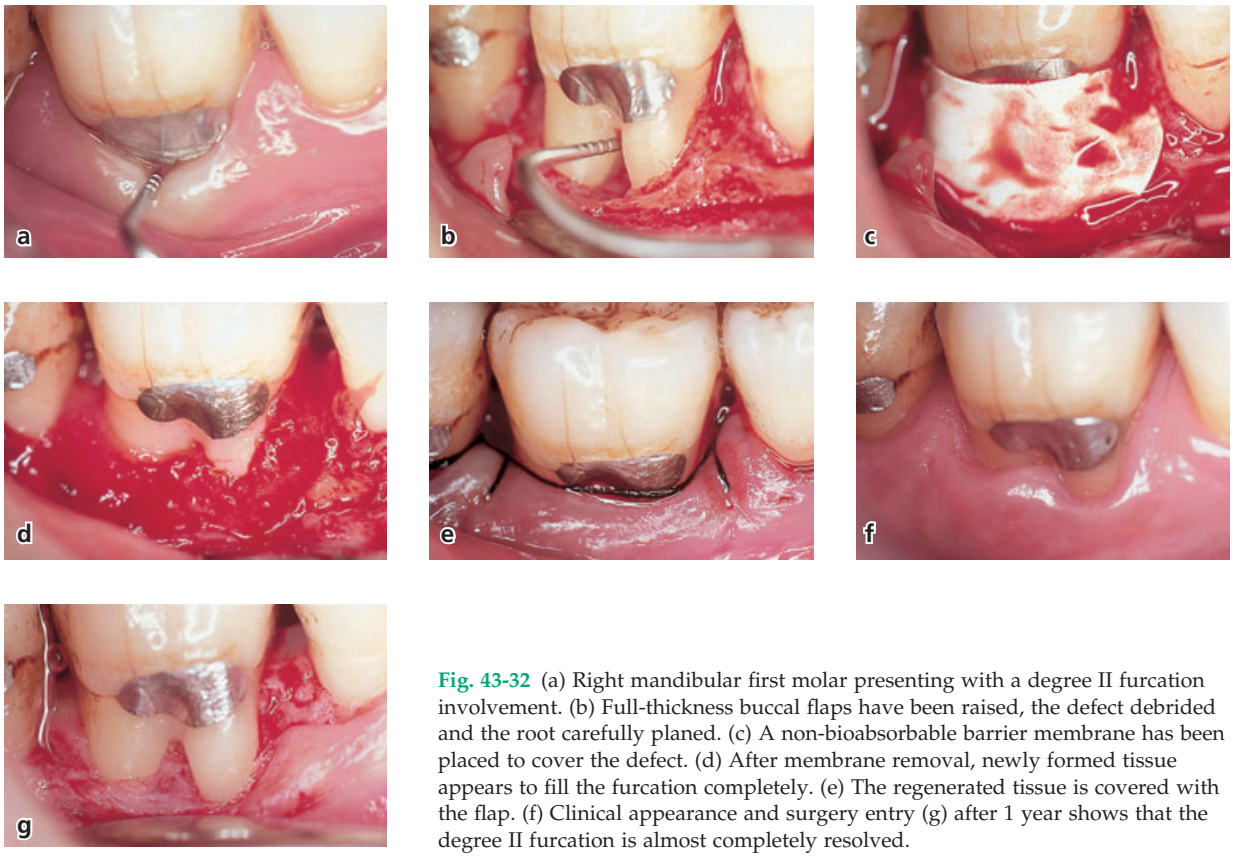

Fig. 43-32 (a) Right mandibular first molar presenting with a degree II furcation involvement. (b) Full-thickness buccal flaps have been raised, the defect debrided and the root carefully planed. (c) A non-bioabsorbable barrier membrane has been placed to cover the defect. (d) After membrane removal, newly formed tissue appears to fill the furcation completely. (e) The regenerated tissue is covered with the flap. (f) Clinical appearance and surgery entry (g) after 1 year shows that the degree II furcation is almost completely resolved.

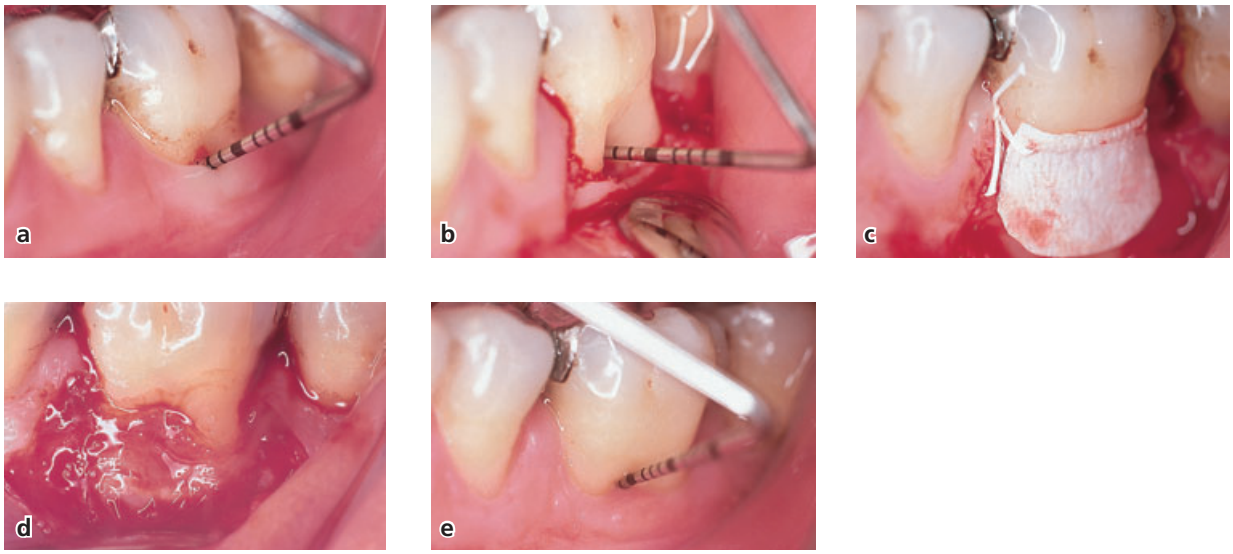

Fig. 43-33 (a) Left mandibular first molar presenting with a deep degree II furcation involvement. (b) Horizontal loss of tooth support of 7 mm was probed. (c) An e-PTFE barrier membrane has been trimmed and sutured to cover the furcation. (d) At membrane removal after 5 weeks, newly formed tissue fills the furcation completely. (e) At 1 year, a 3-mm gain of tooth support was measured, but a residual 4-mm degree II furcation involvement was still present.

A subset analysis of the studies reported in Table 43-4 indicated that furcations treated with non-bioabsorbable barrier membranes (287) showed a gain in horizontal clinical attachment of 1.8 ± 1.4 mm (95% CI 1.5–2.1 mm) as compared with 2.3 ± 1.2 mm H-CAL gain (95% CI 2–2.6 mm) in 174 defects treated with bioabsorbable barrier membranes. Five controlled clinical trials compared treatment with non-resorbable e-PTFE membranes and treatment with different types of bioabsorbable membranes (Table 43-5). In particular, one investigation reported significantly greater H-CAL gain in the non-bioabsorbable group (Bouchard *et al*. 1993), while another one (Hugoson *et al*. 1995) showed a significantly greater H-CAL gain in the bioabsorbable group. The remaining three investigations failed to

detect any significant differences between the outcomes of treatment with bioabsorbable or non-bioabsorbable membranes. Generally the results indicate that the predictability of GTR in the treatment of mandibular degree II furcations is questionable, if the treatment objective is the complete resolution of the furcation involvement.

Significant gain in vertical attachment level (VCAL) and reduction in pocket depth (PPD) was also reported by several investigators following treat-

ment of mandibular degree II furcation defects (Pontoriero *et al*. 1988; Lekovic *et al*. 1989, 1990; Blumenthal 1993; Machtei *et al*. 1993, 1994; Black *et al*. 1994; Laurell *et al*. 1994; Mellonig *et al*. 1994; Wang *et al*. 1994; Hugoson *et al*. 1995; Polson *et al*. 1995b). The reported mean values ranged from 0.1 mm to 3.5 mm for V-CAL gain and from 1 mm to 4 mm for PPD reduction.

The effect of using barrier membranes for the treatment of mandibular degree II furcations was investigated in six controlled randomized clinical trials in which GTR procedures were directly compared to flap surgery (Table 43-6). Sixty-six furcations treated with flap surgery and 87 treated with GTR were included. Three of the four studies reporting H-CAL gains concluded that GTR resulted in statistically significantly greater horizontal attachment level gains than flap surgery (Pontoriero *et al*. 1988; Van Swol *et al*. 1993; Wang *et al*. 1994). The weighted mean of the results reported in Table 43-6 indicated that the H-CAL in furcations treated with GTR was 2.5 ± 1 mm (95% CI 2.1–2.9 mm) while the flap surgery resulted in a mean H-CAL gain of 1.3 ± 1 mm (95% CI 0.8–1.8 mm). These results indicate an added benefit from GTR in the treatment of mandibular degree II furcations.

Maxillary degree II furcations

Results reported in three controlled studies (Metzeler *et al*. 1991; Mellonig *et al*. 1994; Pontoriero & Lindhe 1995a) comparing GTR treatment of maxillary degree II furcations with non-bioabsorbable e-PTFE membranes and with open-flap debridement, indicate that GTR treatment of such defects is generally unpredictable. In a study including 17 pairs of degree II furcations Metzeler *et al*. (1991) measured CAL gains of 1.0 ± 0.9 mm in the GTR-treated sites versus 0.2 ± 0.6 mm in the control sites. Following re-entry, horizontal probing attachment gains (H-OPAL) of 0.9 ± 0.4 mm and 0.3 ± 0.6 mm were detected in the GTR- and flap-treated furcations, respectively. No differences were found and none of the furcations of the two groups were completely resolved. Similarly, Mellonig *et al*. (1994) treated eight pairs of maxillary degree II furcations which resulted in H-OPAL gains of 1.0 mm (GTR sites) and 0.3 mm (flap-treated sites). No differences were found and none of the treated furcations were completely closed. On the other hand, in a study on 28 maxillary degree II furcations Pontoriero and Lindhe (1995a) found a significant gain in CAL (1.5 mm) and horizontal bone (1.1 mm) in buccal degree II furcations.

Although these three investigations show a slight clinical improvement following treatment of degree II maxillary furcations with GTR, the results are generally inconsistent.

Degree III furcations

Four investigations on the treatment of mandibular degree III furcations (Becker *et al*. 1988; Pontoriero *et al*. 1989; Cortellini *et al*. 1990; Pontoriero & Lindhe 1995b) indicate that the treatment of such defects with GTR is unpredictable. A controlled study of Pontoriero *et al*. (1989) showed that only eight out of 21 "through-and-through" mandibular furcations treated with non-bioabsorbable barrier membranes healed with complete closure of the defect. Another ten defects were partially filled, and three remained open. In the control group, treated with open flap debridement, 10 were partially filled and 11 remained open. Similar results were reported by Cortellini *et al*. (1990) who, in a case cohort of 15 degree III mandibular furcations, found that 33% of the defects had healed completely, 33% were partially closed, and 33% were still through-and-through following treatment. Becker *et al*. (1988) did not observe complete closure of any of 11 treated degree III mandibular furcations. Similarly, in a controlled clinical trial by Pontoriero and Lindhe (1995b) on 11 pairs of maxillary degree III furcations randomly assigned to GTR

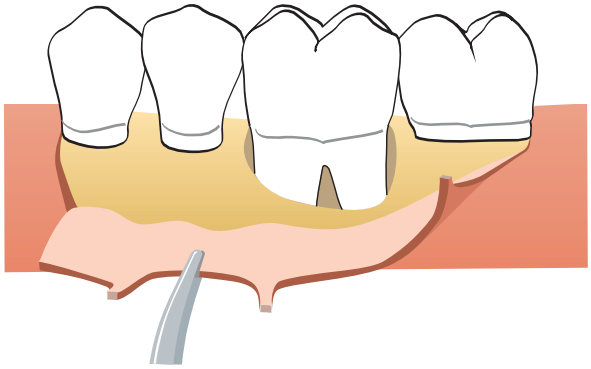

Fig. 43-34 Following marginal incisions and vertical releasing incisions on the buccal aspect of the jaw, buccal and lingual full-thickness flaps are elevated.

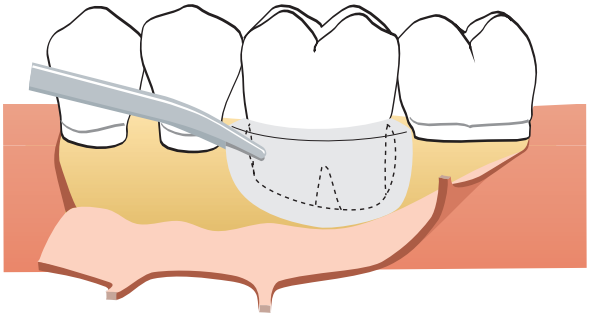

Fig. 43-35 The barrier material is placed in such a way that it completely covers the defect and extends at least 3 mm on the bone beyond the defect margin.

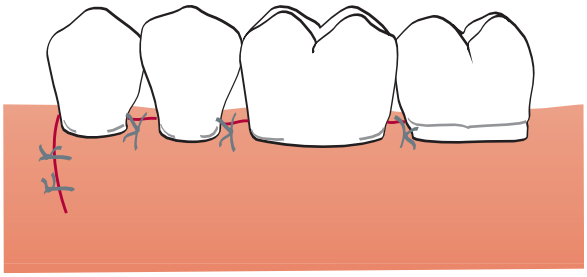

Fig. 43-36 The elevated tissue flaps are coronally displaced and sutured in such a way that the border of the barrier material is at least 2 mm below the flap margin.

or flap surgery, none of the furcation defects were closed.

Based on present evidence, it seems that mandibular degree II furcations in the first or second molars, either buccal or lingual, with deep pockets at baseline and a gingival thickness of >1 mm, may benefit from GTR treatment.

Surgical issues with barrier membranes

Surgery is initiated by sulcular incisions at both the buccal and lingual aspect of the jaw, followed by buccal and vertical releasing incisions, if necessary. For intrabony defects, the releasing incisions must be placed a minimum of one tooth anterior and/or posterior to the tooth that is being treated (Fig. 43-34). Care should be taken during this procedure to preserve the interdental papillae. All pocket epithelium is excised so that fresh connective tissue is left on the full-thickness flaps following reflection. After elevation of the tissue flaps, all granulation tissue is removed and thorough debridement of the accessed root surfaces is carried out using curettes, burs, etc.

Various types of bioabsorbable and non-bioabsorbable barrier materials are available in a variety of configurations designed for specific applications. The configuration most suitable for covering the defect is selected and additional adaptation of the material to the shape and extent of the defect is performed. The shaping of the material is carried out in such a way that it adapts closely to the tooth and completely covers the defect, extending at least 3 mm on the bone beyond the defect margins after placement (Fig. 43-35). This assures good stability of the material and protects the underlying blood clot during healing. At placement it is essential to ensure good adaptation of the barrier material to the alveolar bone surrounding the defect and to avoid overlaps or folds of the material.

Although exceptions exist, the barrier materials available are fixed to the tooth with a suture using a sling technique. For optimal performance, the barrier should be placed with its margin 2–3 mm apical to the flap margin. To maximize coverage of the barrier, a horizontal releasing incision in the periosteum may assist in the coronal displacement of the flap at the suturing of the wound. However, care should be taken not to compromise the blood supply to the flap. The interdental space near the barrier should be closed first. In order to achieve good closure, an internal vertical mattress suturing technique is advocated (Fig. 43-36).

To reduce the risk of infection and to assure optimal healing, the patient should be instructed to brush the area gently post-operatively with a soft bristle toothbrush and to rinse with chlorhexidine (0.2%) for a period of 4–6 weeks. In addition, systemic antibiotics are frequently administered immediately prior to surgery and for 1–2 weeks after surgery. When a non-bioabsorbable barrier is used, it should be removed after 4–6 weeks. However, if complications develop it may be necessary to remove it earlier.

Removal of the material requires a minor surgical procedure (Fig. 43-37). To obtain access to the barrier material, a small incision is made extending one tooth mesial and distal to the border of the barrier. The soft tissue flap is gently reflected and the barrier material dissected free from the flap using a sharp blade. During this procedure it is essential not to compromise the newly regenerated tissue. At removal of the barrier material there will usually be some pocket formation on the outer surface of the material. It is important that this epithelium is removed so

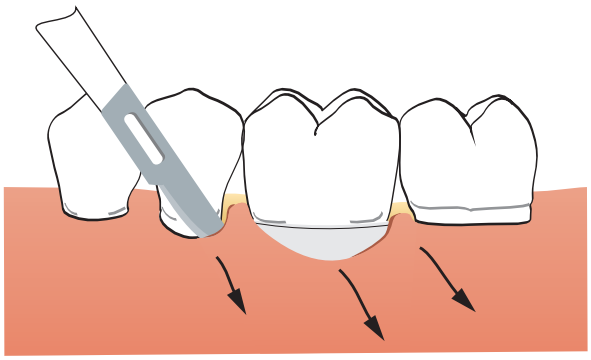

Fig. 43-37 In order to remove the barrier material an incision is made extending one tooth mesially and distally to the border of the barrier. After reflecting the covering tissue flaps, the barrier can be removed without compromising the newly regenerated tissue.

that fresh connective tissue is in contact with the newly regenerated tissue after wound closure. It is essential that the newly regenerated tissue is completely covered after suturing. The patient is instructed to rinse with chlorhexidine for 2–3 weeks during which period frequent visits for professional tooth cleaning are recommended. After this period, brushing and interdental cleaning can be resumed, chlorhexidine rinsing discontinued, and the patient enrolled in a regular periodontal maintenance program.

If the flap is excessively traumatized during surgery either part or all of it may slough during healing. Perforations may also occur, particularly in sites with sharp bony ledges. A minor osteoplasty during placement may help to allow the barrier to better follow the contours of the ridge. Abscess formation may also occur in the wound, probably due to severe bacterial contamination of the barrier. Dependent on the severity of such complications, early removal of the barrier may be indicated.

Bone replacement grafts

Bone replacement grafts (BRG) comprise a heterogeneous group of materials of human (autologous or allogeneic), animal or synthetic origin. Some consist of bone or exoskeletal mineral; others contain mainly bone matrix. Only few materials present evidence of periodontal regeneration. A randomized controlled clinical trial provided histologic support that the healing outcome following application of demineralized freeze-dried bone allograft (DFDBA) in intrabony defects has a regenerative component in the apical to middle portion of the depth of the defect (Bowers *et al*. 1989a,b,c). Isolated evidence also supports the fact that allograft and bovine bone mineral may yield a regenerative outcome when used alone (i.e. without other regenerative materials such as barrier membranes or biologically active regenerative materials (BARG) – see also Chapter 25) (Nevins *et al*. 2000).

Bone replacement grafts were the first periodontal regenerative materials to be applied clinically. Today they are widely used in North America as demineralized freeze-dried allografts and are frequently used in combination with other regenerative materials (GTR and/or BARG).

The clinical efficacy of allografts in terms of bone fill and clinical attachment level gains is supported by a meta-analysis indicating that an additional bone fill of 1 mm and additional clinical attachment level gains of 0.4 mm were observed (Reynolds *et al*. 2003). The total number of defects contributing to this meta-analysis however is relatively small (136 for clinical attachment level gain and 154 for bone fill). Furthermore no large-scale multi-center trial has ever been performed and hence the applicability of these results to clinical practice settings remains to be established.

As to their use, BRG can be applied alone following elevation of a papilla preservation flap for the treatment of intrabony defects. The graft is applied to overfill the defect to compensate for a degree of shedding of the graft expected in cases of imperfect containment of the graft by the closed flap. A study has suggested using BRG in combination with an antibiotic powder to enhance control of the bacterial contamination of the surgical wound (Yukna & Sepe 1982). This study reported improved outcomes from mixing the graft with tetracycline powder.

Biologically active regenerative materials

Preclinical and clinical evidence for the use of biologically active regenerative materials has been reviewed (see also Chapter 25). Currently, two preparations consisting of growth and/or differentiation factors are available for use in periodontal regeneration: enamel matrix derivative (EMD) in a gel form and platelet-derived growth factor (PDGF) mixed in a beta tricalcium phosphate bone replacement graft.

Significant preclinical evidence supports the positive effect of PDGF on periodontal wound healing and regeneration (Howell *et al*. 1997). Clinically, support for use of PDGF comes from a single multicenter trial performed in North America (Nevins *et al*. 2005). In that study 180 defects comprising both intrabony and furcation defects were treated with one of two concentrations of PDGF (0.3 mg/ml and 1.0 mg/ml) combined with the beta tricalcium phosphate delivery device or tricalcium phosphate alone. Results were assessed at 3 and 6 months and included both clinical and radiographic assessments. Clinical attachment level gains at 6 months failed to demonstrate a significant benefit of either concentration of PDGF compared to the bone replacement graft alone. With regards to radiographic assessments, however, the lower tested concentration of PDGF resulted in significantly higher percentages of radiographic bone

Fig. 43-38 Clinical case illustrating the use of enamel matrix derivative to regenerate defects located on two adjacent teeth. At re-evaluation, deep pockets associated with deep intrabony defects are evident on the distal aspect of the first and second molars (a,b). Defects were accessed with the modified papilla preservation technique on the distal aspect of the first molar and with the use of a crestal incision in the retromolar area (c,d). Deep defects were exposed following debridement and root instrumentation (c,d). Following application of enamel matrix derivative in gel form, primary closure was obtained with multilayered sutures. At 1-year follow-up, shallow probing depths associated with the elimination of the defects were observed (e,f).

fill of the defect (57% vs. 18%) and linear radiographic bone growth (2.6 mm vs. 0.9 mm). The results of this study led to the approval by the US Food and Drug Administration of this material. The authors interpreted the dichotomy represented by the significance of the added benefit in terms of radiographic parameters without the presence of significant changes in CAL as the result of biologic action of the growth factor formulation in shortening the healing time of the hard tissues. As of today, however, the results of this study have not been independently confirmed.

The benefit of use of EMD gel in the treatment of intrabony defects is supported by human histologic evidence, case report studies, meta-analysis of randomized controlled clinical trials, and a large multicenter trial (Heijl *et al*. 1997; Heden *et al*. 1999; Sculean *et al*. 1999b; Silvestri *et al*. 2000; Heden 2000; Tonetti *et al*. 2002; Giannobile & Somerman 2003; Heden & Wennstrom 2006) (Fig. 43-38).

Given their hydrophobic nature, enamel matrix proteins are mixed in a gel carrier at low pH for clinical use. Following an increase in pH in the periodontal wound and rapid elimination of the gel, EMD proteins (consisting mainly of amelogenins) are deposited in the wound environment and the root surface. While the mechanism(s) of action of EMD are

not fully understood, significant evidence suggests that periodontal ligament cells exposed to EMD switch their phenotype by increasing expression of a host of growth and differentiation factor related genes (Brett *et al*. 2002; Parkar & Tonetti 2004), including transforming growth factor beta (Lyngstadaas *et al*. 2001).

A secondary analysis of a multi-center trial has shown that, in intrabony defects, the added benefit of EMD was greater in three-wall defects than in one-wall defects (Tonetti *et al*. 2002). Furthermore, another secondary analysis of the same material assessing the effect of the radiographic defect angle on the outcome (Tsitoura *et al*. 2004) has uncovered a negative association between the ragiographic angle of the defect and the clinical attachment level gains observed at 1 year. These data have questioned the suitability of the gel formulation of the EMD for the treatment of defects with a non-supporting anatomy (wide defects with missing bony walls).

These observations have spurred considerable research interest in the incorporation of EMD in a variety of bone replacement grafts in order to enhance wound stability and space maintenance. At this stage, however, no systematic evidence is available to support the use of such combinations.

Clinically, the rate of wound healing following application of EMD seems to be enhanced. A study looking at soft tissue density in the surgical site by using underexposed radiographs (Tonetti *et al*. 2004b) has found that the rate of increase in soft tissue density following application of EMD may be faster than in the access flap control. Such modulation has been interpreted as the outcome of the local release of growth and differentiation factors by the cells involved in local wound healing.

Membranes combined with other regenerative procedures

Compromised results after GTR may be obtained in cases where the membrane collapses/falls (partially or totally) into the defect and/or towards the root surface, thereby reducing the space available for invasion of new tissue capable of forming periodontal ligament and bone in particular. Reduced amounts of regenerated bone due to membrane collapse were noticed in early studies of GTR. In the study of Gottlow *et al*. (1984), it was observed that collapse of the membrane towards the root surface resulted in new cementum formation on the entire exposed root surfaces, whereas bone regeneration was minimal. Although the authors reported that the degree of coronal regrowth of bone was unrelated to the amount of new cementum formation, they did not comment on what effect membrane collapse might have had. Experimental studies, however, recognized the negative effect of membrane collapse on periodontal regeneration generally and on bone formation in particular (Caton *et al*. 1992; Haney *et al*. 1993; Sigurdsson *et al*. 1994; Sallum *et al*. 1998). Haney *et al*. (1993) observed a highly significant correlation between the space provided by the membrane and the amount of regenerated alveolar bone using a supra-alveolar defect model in dogs. This finding corroborates that of Cortellini *et al*. (1995c) who reported that clinical application of self-supporting (reinforced with titanium) e-PTFE membranes, which could be positioned more coronally than ordinary e-PTFE membranes, yielded a statistically significant increase in PAL gain in intrabony defects. A particular risk for membrane collapse exists in cases where the configuration of the defect is incapable of supporting/preserving the membrane at the position where it was originally placed.

As already discussed, membrane materials must possess certain characteristics in order to be efficient. Among those it is important that the membrane is capable of keeping its shape and integral features, thereby maintaining the space created adjacent to the root surface. The e-PTFE membranes reinforced with titanium are the closest in meeting these requirements but they have the disadvantage that they are non-resorbable. At present there are no resorbable membranes available that fulfill this requirement sufficiently, which means that the placement of a resorbable membrane on, for instance, a wide one-wall defect involves the risk of membrane collapse. The collapse may be prevented by means of implantation of a biomaterial into the defect to support the membrane so that it maintains its original position (Fig. 43-39). However, the biomaterial to be used for this purpose must not interfere with the process of periodontal regeneration and ideally it may also promote bone regeneration.

As previously described, periodontal regeneration has been attempted with a variety of grafting materials, among which demineralized freeze-dried bone allografts (DFDBA) apparently facilitated regeneration in humans (Ouhayoun 1996). Schallhorn and McClain (1988) reported on improved clinical results in intrabony defects and degree II furcations, following a combination therapy including barrier membranes plus DFDBA and citric acid root conditioning.

In three controlled clinical trials, the treatment of a total of 45 pairs of intrabony defects with DFDBA grafting and GTR were compared to GTR alone (Table 43-7). The weighted mean of the results of the reported investigations showed similar gain in CAL in the GTR group (2.1 ± 1.1 mm, 95% CI 1.6–2.6 mm) and in the GTR plus DFDBA group (2.3 ± 1.4 mm, 95% CI 1.7–2.9 mm). The differences between the two treatments did not reach statistical significance, thus indicating no added effect of combining DFDBA with barrier materials in the treatment of intrabony defects. Guillemin *et al*. (1993) compared the effect of DFDBA alone with a combination of barrier materials and DFDBA in 15 pairs of intrabony defects. Both treatments resulted in significant amounts of CAL gains

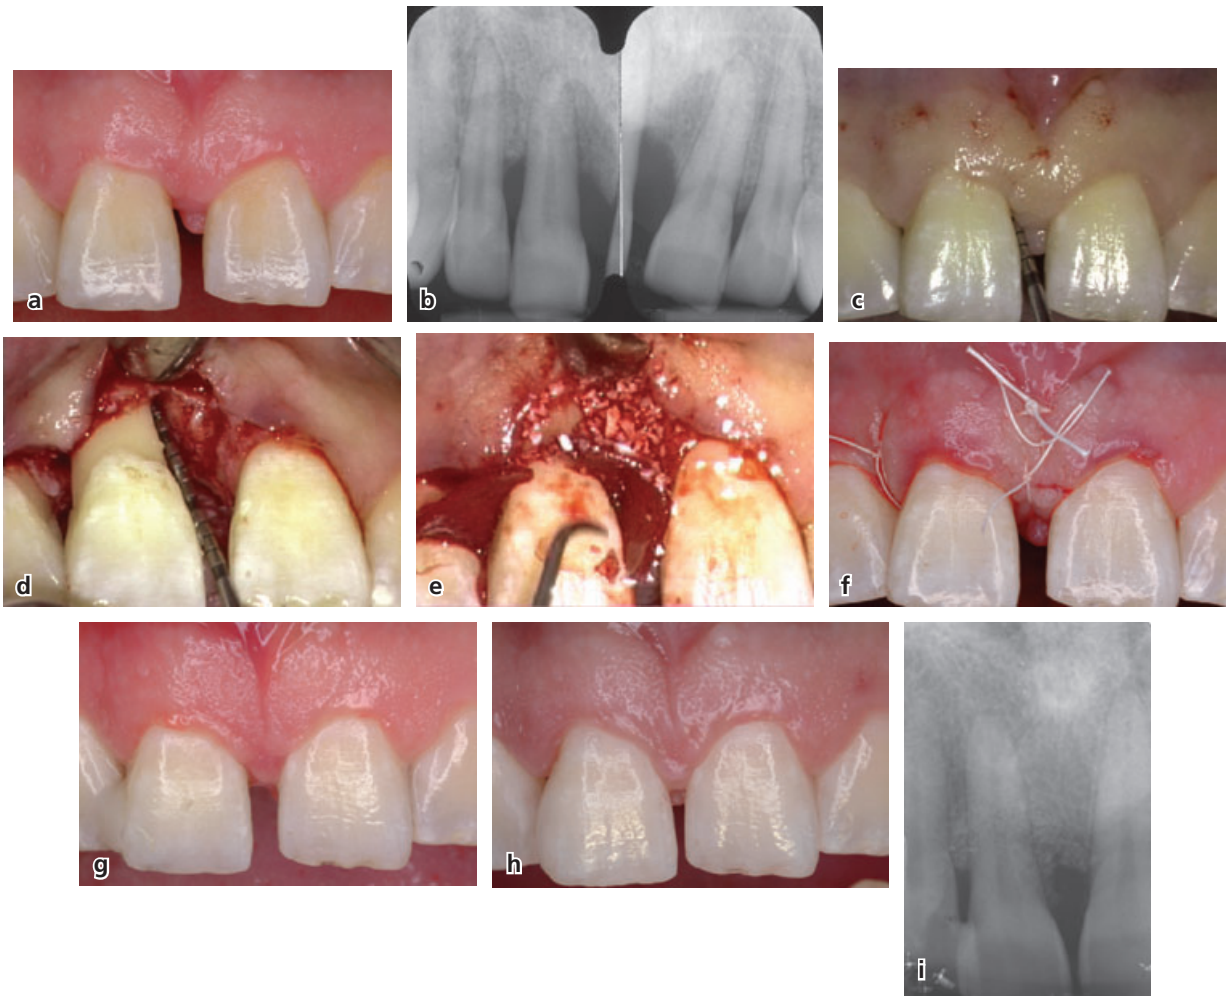

Fig. 43-39 Clinical case illustrating the application of bone replacement graft to support a bioresorbable membrane in a defect with poor space maintaining anatomy. Following control of periodontitis and risk factors, the upper right contral incisor presented with a 12-mm deep pocket associated with a defect extending close to the apex of the tooth (a–c). The defect was accessed with the modified papilla preservation flap to reveal an 8-mm intrabony component (d). A bone replacement graft was placed under a bioresorbable collagen membrane (e). Primary closure was achieved with a multilayered suture technique (f). Excellent early healing was observed already at the 2-week follow-up (g). At 1 year, periodontal regeneration resulted in shallow probing depths and good resolution of the intrabony defect (h,i). Radio-opaque bone replacement graft particles are visible within the newly formed mineralized tissue.

and bone fill at 6 months, but no difference was found between the treatments.

In three studies on mandibular degree II furcations, GTR treatment alone was compared with GTR treatment combined with hydroxyapatite or DFDBA (Table 43-8). In one of these investigations, a statistically significant improvement was found in terms of horizontal open probing attachment levels (H-OPAL) in the group of furcations treated with the combination therapy (Anderegg *et al*. 1991). In another of these three studies the difference between the two treatments was not statistically significant, but the combination therapy resulted in a greater extent of furcation fill (Lekovic *et al*. 1990). In the third investigation (Wallace *et al*. 1994), the two treatments were equivalent in terms of H-OPAL gains. The weighted mean of the cited studies showed greater H-OPAL gains in the cases treated with the combination therapy (2.1 ± 0.9 mm, 95% CI 1.6–2.6 mm) when compared to GTR treatment alone (0.9 ± 0.5 mm, 95% CI 0.6–1.1 mm), indicating a possible added benefit from the use of grafting materials in combination with non-bioabsorbable barrier membranes for the treatment of mandibular degree II furcations.

Promising clinical results with a PAL-gain of 1.0–5.5 mm were obtained in human case reports, in which the GTR technique was combined with grafting of Bio-Oss® for the treatment of intrabony periodontal defects (Lundgren & Slotte 1999; Mellonig 2000; Paolantonio *et al*. 2001). The combined Bio-Oss® and GTR treatment resulted in greater PPD reduction, PAL gain and defect fill than the mere implantation of Bio-Oss® in case series (Camelo *et al*. 1998) and than flap surgery alone in a split-mouth study (Camargo *et al*. 2000).

In a recent randomized controlled clinical study including 60 patients (Stavropoulos *et al*. 2003), Bio-Oss® alone or impregnated with gentamicin was used as an adjunct to GTR in the treatment of one-wall or two-wall intrabony defects, and the outcomes were compared to those obtained following GTR alone or flap surgery. Treatment with a membrane alone (Fig. 43-40) resulted in a mean PAL gain of 2.9 mm, while it was 3.8 and 2.5 mm, respectively, when Bio-Oss® grafts with or without gentamicin were placed in the defects prior to membrane coverage (Fig. 43-41). The control defects treated with flap surgery demonstrated a gain of PAL of only 1.5 mm. The clinical improvements in defects treated with GTR alone or in combination with Bio-Oss® grafting were significantly better than those obtained with flap surgery, whereas the differences between the groups treated with membranes were not statistically significant.

In a controlled study (Pietruska 2001), similar clinical improvements were obtained when Bio-Oss® combined with GTR was compared with biomodification of the root surface with enamel matrix protein (Emdogain®).

Camelo *et al*. (1998) and Mellonig (2000) presented histologic data indicating that the use of Bio-Oss® under a membrane may result in partial regeneration of the periodontal apparatus, but in all the cases, most of the defect was still occupied by deproteinized bone particles. Bone was not observed near the root, and the connective tissue fibers of the "new" periodontal ligament were mostly oriented parallel to the root surface. These results corroborate findings reported by Paolantonio *et al*. (2001), who observed only limited bone formation in the vicinity of the pre-existing bone in a biopsy, taken from a site treated 8 months earlier with Bio-Oss® and a collagen membrane. Most of the space in the defect was occupied by Bio-Oss® particles embedded in connective tissue. However, in a case report where intrabony defects were treated with Bio-Oss® combined with intraoral autogenous bone and GTR, new attachment formation had occurred consistently, but a major portion of the regenerated osseous tissue consisted of deproteinized bone particles (Camelo *et al*. 2001). The effect of combining citric acid root biomodification with GTR treatment was evaluated in two randomized controlled clinical trials in intrabony defects. The first investigation (Handelsman *et al*. 1991) demonstrated significant amounts of CAL gains in both the test (e-PTFE membranes and citric acid; CAL gain 3.5 ± 1.6 mm) and control sites (e-PTFE membranes alone; CAL gain 4.0 ±

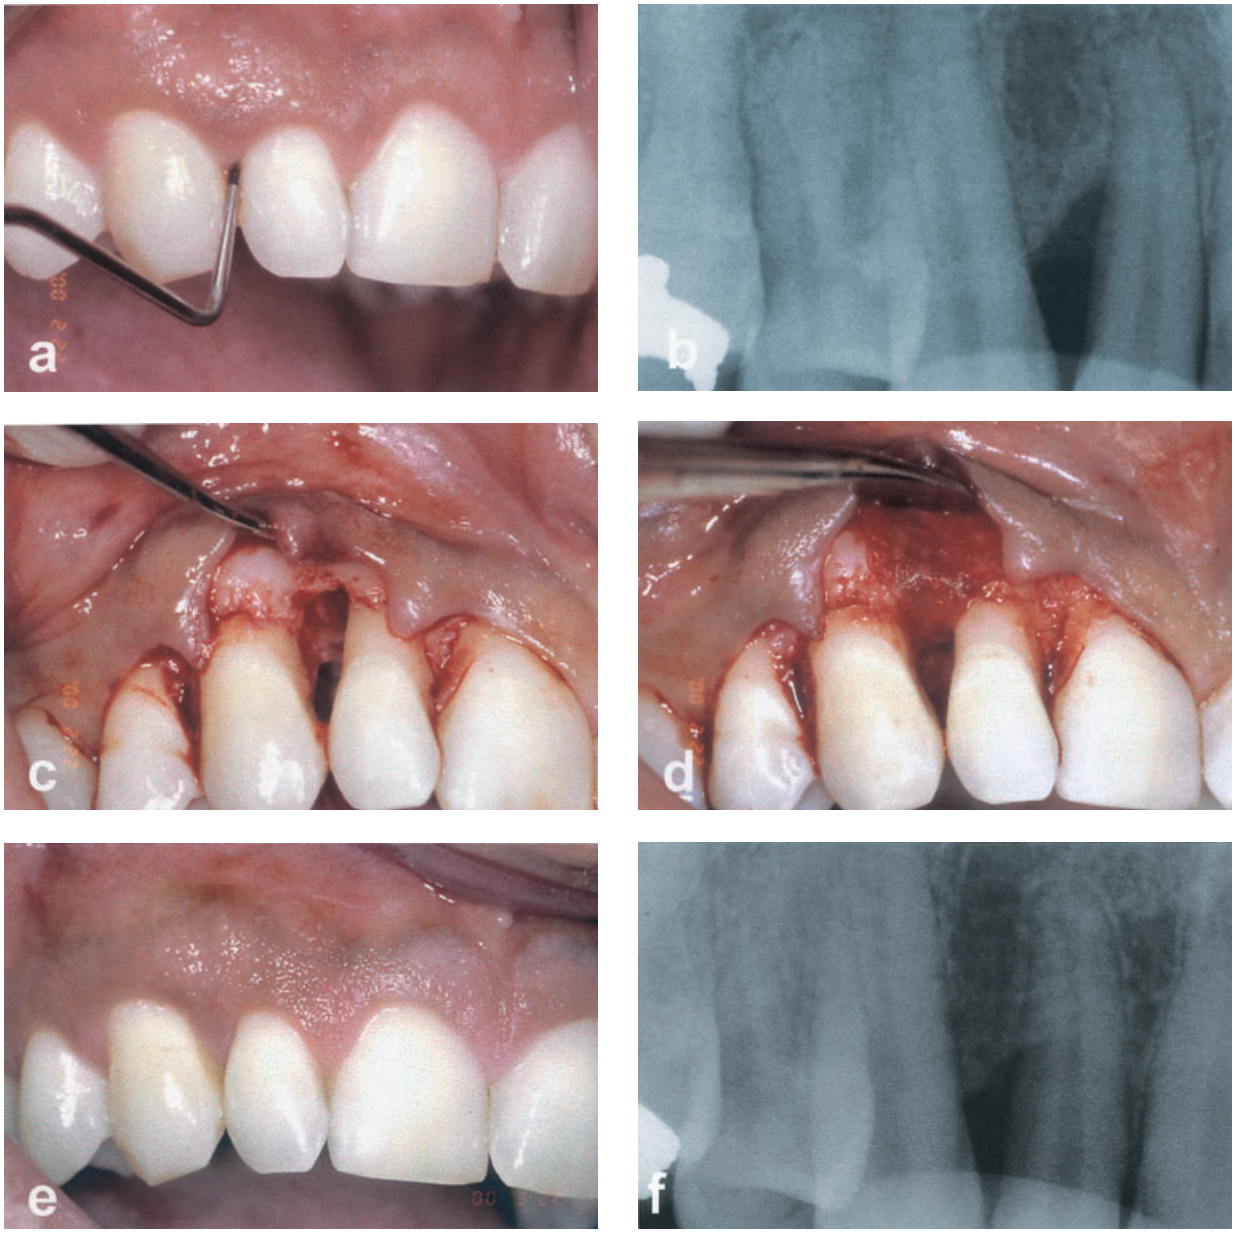

Fig. 43-40 Right lateral maxillary incisor with an 8-mm deep pocket associated with an intrabony defect on the distal aspect (a), as seen on the radiograph (b). Full-thickness buccal and palatal flaps have been raised and the defect has been debrided (c). A bioabsorbable membrane has been adopted over the defect (d). The level of the interdental gingiva is maintained after 1 year (e) and the intrabony defect (f) is resolved.

1.4 mm). Less favorable results following these two treatment modalities were reported by Kersten *et al*. (1992) who found CAL gains of 1.0 ± 1.1 mm in the test group, and CAL gains of 0.7 ± 1.5 mm in the control group. Both studies, however, failed to demonstrate any added effect of the use of citric acid in combination with non-bioabsorbable barrier membranes.

Root surface biomodification with tetracycline alone and in combination with GTR was evaluated in two controlled studies on degree II furcations (Machtei *et al*. 1993; Parashis & Mitsis 1993). Both investigations failed to show significant differences between sites treated with non-bioabsorbable barrier membranes alone or in combination with tetracycline root surface biomodification. Similarly, the use of other surface active chemicals like EDTA also failed to provide a significant added effect to GTR treatment in humans (Lindhe & Cortellini 1996).

Root surface biomodification

The suggested role of root surface biomodification for improving periodontal regeneration has been recently assessed in a systematic review (Mariotti *et al*. 2003). The results of that exhaustive review of the evidence indicated that there was no evidence of a measurable improvement following root conditioning with agents like citric acid, tetracycline HCl, phosphoric acid, fibronectin or EDTA.

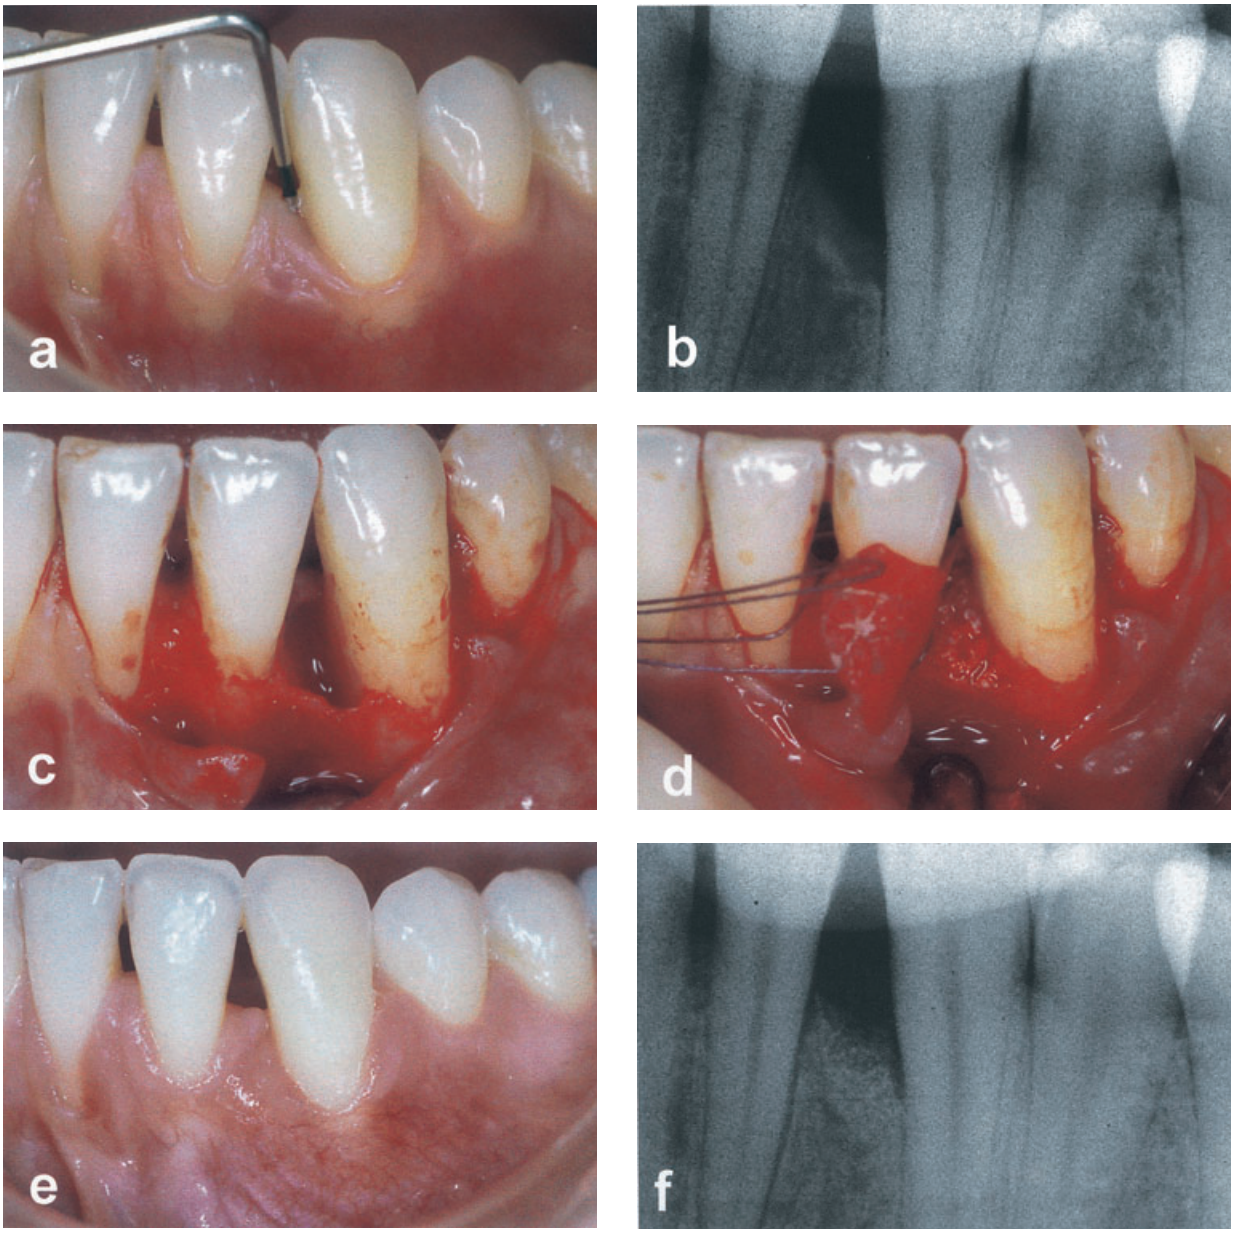

Fig. 43-41 Left mandibular canine with an 8-mm deep pocket (a) associated with an intrabony defect on its mesial aspect (b). The defect is debrided after flap elevation (c) and Bio-Oss® particles are placed in the defect (d) prior to placement of a bioabsorbable membrane. After 1 year (e), no gingival recession has occurred and the intrabony defect is almost resolved (f).

Clinical strategies

Periodontal regeneration in intrabony defects has been successfully attempted with a variety of different approaches. As discussed, meta-analyses of randomized controlled clinical trials as well as human and animal histologic findings support the potential of barrier membranes (Nyman *et al*. 1982; Gottlow *et al*. 1986), demineralized freeze dried bone allograft (DFDBA) (Bowers *et al*. 1989a,b,c), combination of barrier membranes and grafts (Camelo *et al*. 1998; Mellonig 2000), and the use of enamel matrix derivative (Mellonig 1999; Yukna & Mellonig 2000) to induce periodontal regeneration. Controlled clinical trials report that the above-mentioned approaches provide added benefits in terms of clinical attachment level (CAL) gain as compared to open-flap debridement alone (Needleman *et al*. 2002; Murphy *et al*. 2003; Trombelli *et al*. 2002; Giannobile & Somerman 2003; Tonetti *et al*. 2004a). Comparisons among some of the cited regenerative approaches failed to demonstrate a clear superiority of one of the tested materials (Murphy *et al*. 2003; Giannobile & Somerman 2003; Reynolds *et al*. 2003).

The existing evidence, therefore, does not support the choice of a single approach among the different regenerative possibilities. In addition, all the cited studies have shown a substantial degree of variability, in terms of CAL gains, reporting failures or unsatisfactory outcomes in part of the treated population.

Research conducted mostly in the past decade has clearly established that the variability observed in

outcomes of periodontal regenerative procedures is dependent on a variety of patient, defect, and surgical associated factors.

While relevant patient factors include cigarette smoking, residual periodontal infection, and oral hygiene, factors associated with the morphology of the defect are consistently found to be of relevance for the final outcome (Tonetti *et al*. 1998; Cortellini *et al*. 2001). Interestingly, however, the number of residual bony walls defining the defect seems to impact the outcomes of different periodontal regenerative materials in a divergent way. Non-resorbable (e-PTFE and titanium-reinforced e-PTFE) barrier membranes, and bioresorbable barriers supported by a graft do not seem to be affected by the number of residual bony walls of the defect (Tonetti *et al*. 1993a, 1996a, 2004b), while EMD results in better outcomes in three-wall defects (Tonetti *et al*. 2002). Furthermore, healing following application of bioresorbable barriers and non-resorbable e-PTFE barriers as well as EMD is associated with the radiographic width of the intrabony defect (Tonetti *et al*. 1993a; Falk *et al*. 1997; Tsitoura *et al*. 2004). No such association has been found for the use of a xenogenic bone replacement graft and resorbable barrier graft combination (Tonetti *et al*. 2004b).

Among the technical/surgical factors, membrane exposure and contamination have been associated with reduced outcomes (Selvig *et al*. 1992; Nowzari & Slots 1994; Nowzari *et al*. 1995; De Sanctis *et al*. 1996a,b). Similar problems were also encountered with bone grafting (Sanders *et al*. 1983). Reduced outcomes were also observed when the regenerated tissue was not properly protected with the flap at removal of non-resorbable barrier membranes (Tonetti *et al*. 1993a; Cortellini *et al*. 1995c).

A controlled clinical trial demonstrated that the combination of a papilla preservation flap and titanium-reinforced e-PTFE membrane resulted in greater amounts of clinical attachment level gains as compared to a conventional flap approach associated with an e-PTFE membrane (Cortellini *et al*. 1995c). This evidence, also partly supported by a systematic review (Murphy *et al*. 2003), strongly suggests that optimization of the surgical approach and control of surgical variables, particularly in relation to flap design and management and selection of the regenerative material, could improve outcomes. In the context of GTR, several specific flap designs aimed at the full preservation of the soft tissues during access to the defect have been described (Cortellini *et al*. 1995c,d, 1996c, 1999; Murphy 1996). Experimental testing of these regenerative flaps reported great improvements in achieving primary closure during the surgical session with optimal interdental closure being obtained in virtually all cases (Tonetti *et al*. 2004b; Cortellini *et al*. 1995c,d, 1999, 2001). During the subsequent healing, however, dehiscence of the interdental tissue and membrane exposure was observed in up to a third of the cases. The ability to accomplish and maintain primary closure of the tissues over a GTR membrane was further improved by the use of a microsurgical approach that resulted in maintenance of primary wound closure in 92.3% of the treated sites for the whole healing period (Cortellini & Tonetti 2001, 2007a,b).

This body of evidence can be utilized together with a degree of clinical experience to develop an "evidence-based regenerative strategy" to guide clinicians through a decision-making process aimed at the optimization of the clinical outcomes of periodontal regeneration in intrabony defects (Cortellini & Tonetti 2000a, 2005). Key steps of this process are the careful evaluation of the patient and of the defect, the access of the defect with a papilla preservation flap, the possibility of choosing the most appropriate regenerative technology/material, and the ability to seal the regenerating wound from the contaminated oral environment with optimal suturing techniques.

Two to three months after completion of periodontal therapy, baseline clinical measurements are recorded. The regenerative strategy is selected according to a decision-making process. Surgical procedures, according to the principles of periodontal regeneration, are performed. Patients are then enrolled in a stringent periodontal supportive care program for 1 year followed by regular supportive periodontal care.

The appropriate regenerative strategy for the individual case is selected according to a recently modified, evidence-based operative decision tree (Cortellini & Tonetti 2000a, 2005) (Figs. 43-42, 43-43, 43-44).

The surgical access to the intrabony defects is selected from among three different surgical approaches: the simplified papilla preservation flap (SPPF) (Cortellini *et al*. 1999), the modified papilla preservation technique (MPPT) (Cortellini *et al*. 1995d), and the crestal incision (Cortellini & Tonetti 2000a). The SPPF is chosen whenever the width of the interdental space is 2 mm or less, as measured at the level of the papilla; the MPPT is used at sites with an interdental width greater than 2 mm (Fig. 43-42); the crestal incision is applied next to an edentulous area.

Selection of the regenerative material is based on the defect anatomy (Figs. 43-43, 43-44). A non-resorbable titanium-reinforced e-PTFE membrane is used when the defect anatomy is not "supportive", such as in wide and one- or two-wall defects. Alternatively, a bioresorbable membrane supported with a bone replacement graft material can be used in these instances. The latter is preferred to titanium-reinforced e-PTFE when the non-supportive defects are associated with narrow interdental spaces. A bioresorbable membrane is applied alone in "supportive" defects, like the narrow and the two-to-three-wall ones. EMD is preferred in defects with a prevalent three-wall morphology or in well supported two-wall defects.

The suturing approach is chosen according to the defect anatomy and to the type of

Fig. 43-42 Decision-making algorithm illustrating the parameters to take into account when deciding how to access an interdental intrabony defect: the simplified papilla preservation flap (SPPF) is used for narrow interdental spaces (2 mm or narrower), while the modified papilla preservation technique (MPPT) is used to access defect associated with wider interdental spaces (3 mm or wider).

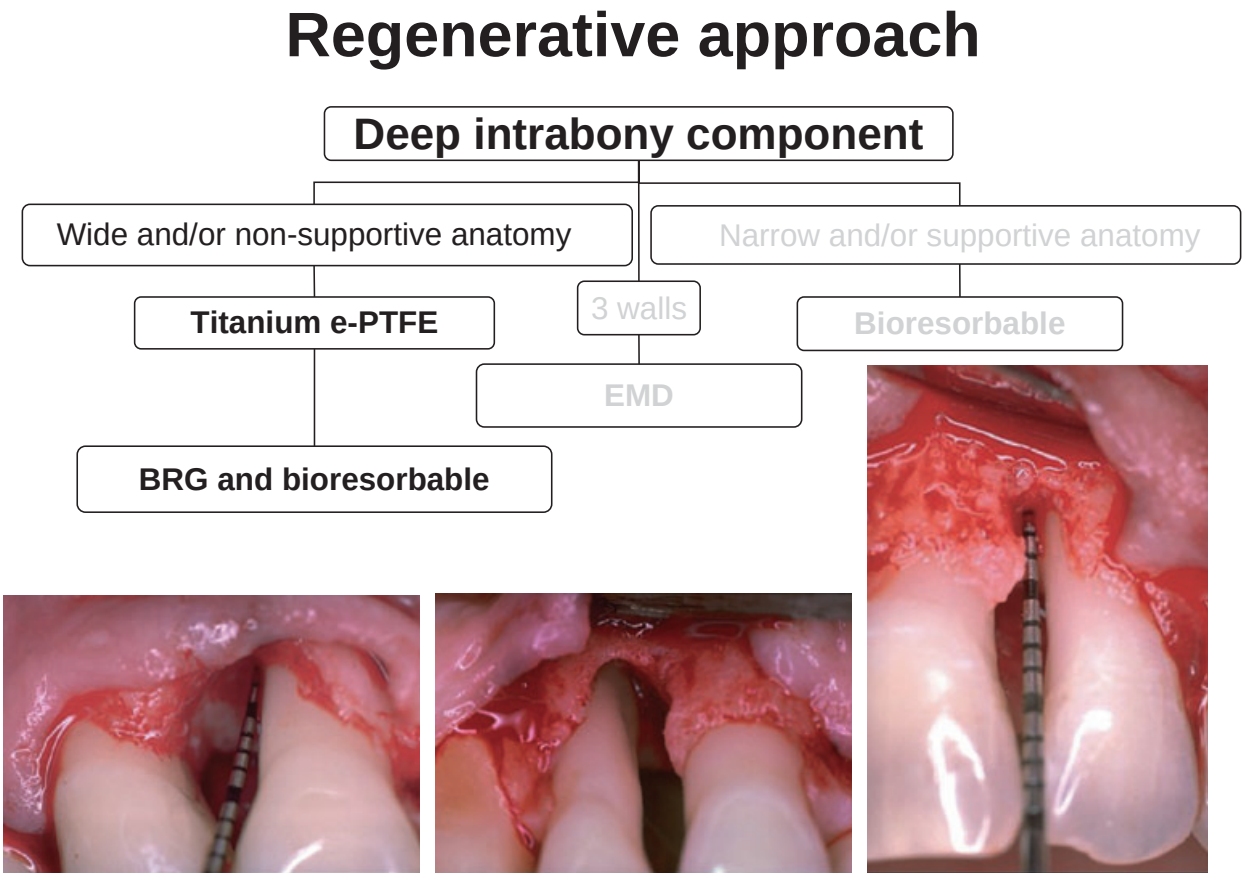

Fig. 43-43 Decision-making algorithm discussing the choice of currently available technologies for application in the treatment of intrabony defects with wide, non-space supporting anatomy. Either titanium-reinforced membranes or bioresorbable membranes are used to obtain a stable regenerative environment, provide space, and support the soft tissues.

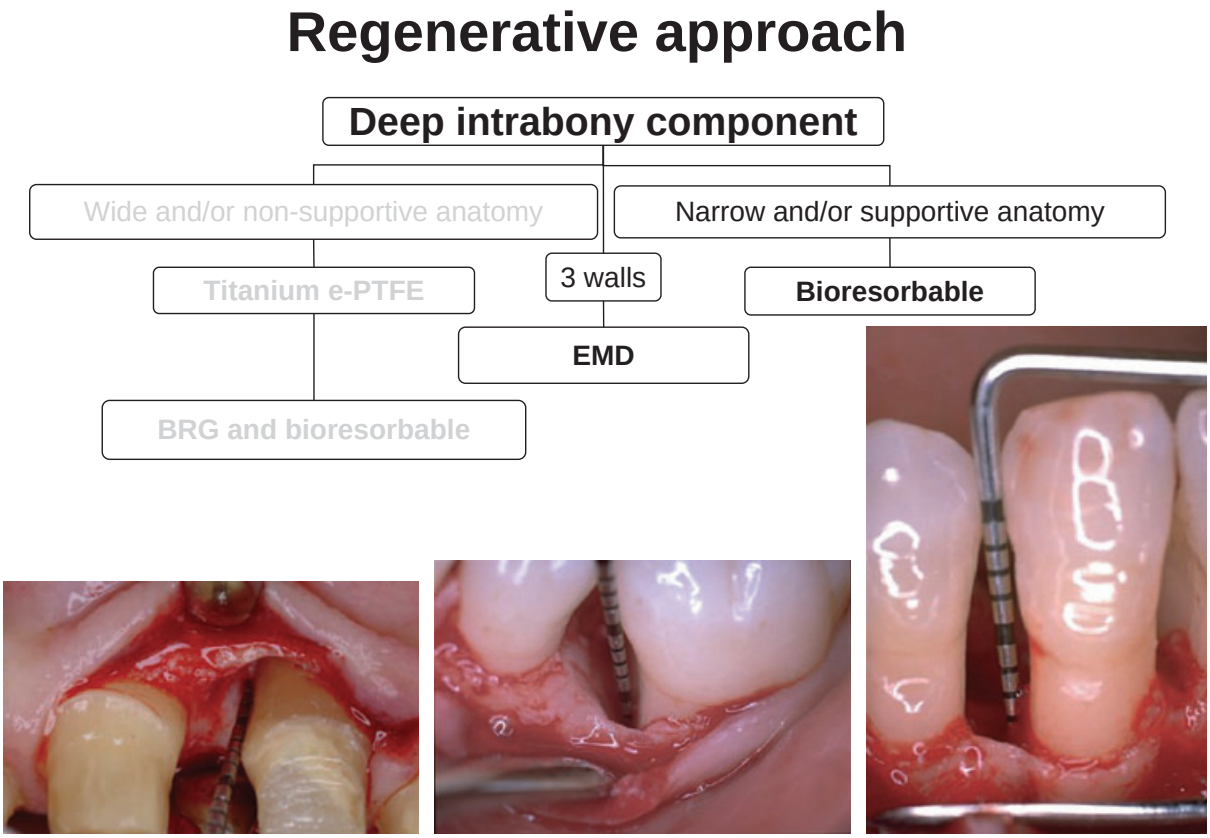

Fig. 43-44 Decision-making algorithm discussing the choice of currently available technologies for application in the treatment of intrabony defects with narrow, space-supporting anatomy. Enamel matrix derivative in gel form is preferred for three-wall defects, while bioresorbable membranes are used for the other narrow type of defects.

regenerative strategy used in each case. It consists of the combination of two sutures applied in the defect-associated interdental area to reach primary closure of the papilla in the absence of any tension. The first interdental suture is positioned between the apical part of the buccal gingiva, near the mucogingival junction, and an apical area of the lingual/palatal flap. In supportive defects (three-wall defects) or in the presence of a supportive membrane (titanium e-PTFE membrane), or a supported membrane (bioresorbable and bone replacement graft), an internal horizontal crossed mattress suture is used. In non-supportive defects and in the presence of bioresorbable membranes or EMD, an offset internal mattress suture is preferred. When a crestal incision is performed, internal horizontal mattress sutures can be conveniently applied. The aims of this first suture are to relieve the residual tension of the flaps in the defect-associated area and to displace the buccal flap coronally. A second, more coronal internal mattress suture is placed to close the interdental papilla passively over the regenerative material.

The surgical procedures can be performed with the aid of magnification such as loupes or an operating microscope. Microsurgical instruments can be utilized to complement the normal periodontal set of instruments.

An empirical protocol for the control of bacterial contamination consisting of doxycycline (100 mg bid for 1 week), 0.12% chlorhexidine mouth rinsing three times per day, and weekly prophylaxis is prescribed. Patients are requested to avoid brushing, flossing, and chewing in the treated area for 6–10 weeks. Non-resorbable membranes are removed after 6 weeks. Patients can resume full oral hygiene and chewing function in the treated area 2–4 weeks after membrane removal or when bioresorbable membranes are fully resorbed. Patients treated with EMD resume full oral hygiene after a period of 4–5 weeks. At the end of the "early healing phase", patients are placed on monthly recall for 1 year.

The performance of this clinical strategy has been recently assessed in a 40-patient consecutive case series (Cortellini & Tonetti 2005). Following completion of initial, cause-related periodontal therapy, subjects presented full-mouth plaque scores of 10.2 ± 2.7% and full-mouth bleeding scores at baseline of 7.9 ± 2.8%. At the intrabony defects, clinical attachment levels (CAL) were 10.2 ± 2.4 mm and probing depths (PD) amounted to 8.9 ± 1.8 mm. The radiographic defect angle was 29° ± 5.9°. Distance from the cemento-enamel junction to the bottom of the defect (CEJ-BD) was 11.2 ± 2.7 mm and the intrabony component of the defects (INFRA) was 6.6 ± 1.7 mm.

In this population the simplified papilla preservation flap could be used in 37.5% of sites, while the modified papilla preservation technique was selected in 45% of cases. The remaining sites, presenting with defects adjacent to edentulous areas, were accessed with a crestal incision.

Based on defect anatomy, non-resorbable titanium-reinforced e-PTFE barrier membranes were used in 30% of cases. In these cases defect angles ranged from 27–42° (average 32.4° ± 4.3°), and two out of three of the selected defects had a one-wall intrabony sub-component of 1–3 mm (average one-wall component of the 12 sites was 1.4 ± 1.2 mm).

Ten of the 11 defects treated with bioresorbable membranes supported with a bone replacement graft, presented a one-wall sub-component of 1–5 mm (average one-wall component of the 11 sites 1.8 ± 1.3 mm); defect angles in this group ranged from 21–45° (average 31.4° ± 7°).

Bioresorbable barriers alone were used in seven sites presenting with a prevalent two- and three-wall morphology and narrow defect angles, ranging from 20–28° (average 24.1° ± 3.7°). EMD was applied to ten defects with a prevalent three-wall component. The defect angle in this group ranged from 19–31° (average 26.5° ± 4.3°).

In all treated sites primary closure was obtained at completion of the surgical procedure. At the 1-week follow-up, when sutures were removed, two sites, both accessed with a SPPF, presented with a small interdental wound dehiscence: one had been treated with a bioresorbable membrane and bone replacement graft, the other with EMD. At week 2, two additional small wound dehiscences were detected: one accessed with MPPT and treated with a bioresorbable membrane and bone replacement graft, the other accessed with SPPF and treated with a bioresorbable barrier alone. All the other sites (90%) remained closed during the whole early healing phase.

The 40 patients presented at the 1-year follow-up visit with excellent levels of plaque control and low levels of bleeding on probing. The 1-year CAL clinical attachment gain was 6 ± 1.8 mm (range 4–11 mm). No sites gained less then 4 mm of CAL; 77.5% gained 5 mm or more and 40% more then 6 mm. Residual probing depths were 2.7 ± 0.6 mm, with an average pocket depth reduction of 6.1 ± 1.9 mm. Only four sites showed a residual probing depth of 4 mm; all the other sites resulted with a 1-year PPD of 3 mm or less. A minimal increase of 0.1 ± 0.7 mm in gingival recession between baseline and 1 year was recorded.

The performance of each of the four treatments was described in the study and it indicated that, whenever the choices were made according to the protocol (i.e. based on: width of the interdental space to chose the papilla preservation surgery; morphology of the defect to choose the regenerative material; and choice of the material and local anatomy to select the suturing approach) all four approaches gave excellent results with clinical attachment level gains equal to 88–95% resolution of the original depth of the intrabony component of the defect (Cortellini & Tonetti 2005).

The use of this decision-making protocol in the reported case series resulted in 6 ± 1.8 mm of CAL gain at 1 year. These results were obtained in defects with an intrabony component of 6.6 ± 1.7 mm. The percentage clinical attachment gain therefore was 92.1 ± 12%. This indicates that a large part of the intrabony component of the defects was resolved. Using the Ellegaard criteria (Ellegaard *et al*. 1971), resolution of the intrabony component of the defect was either satisfactory or complete in all treated cases. In particular 40.5% of defects had attachment level gains equal to or greater then the baseline depth of the intrabony component, while the defect with the worst response showed a 71.4% CAL gain. Historical comparison with clinical experiments using bone grafting or GTR clearly indicates that the results of this trial approach were in the top percentiles in terms of clinical attachment level gains and defect resolution (Cortellini & Tonetti 2000a; Rosen *et al*. 2000).

Conclusions

GTR represents the best documented regenerative procedure for obtaining periodontal regeneration in intrabony defects and in degree II furcations. GTR has demonstrated significant clinical improvement beyond that achieved with only debridement in such defects. Regarding degree II maxillary furcations, the results following GTR treatment are inconsistent, and the treatment of degree III furcation defects is unpredictable. An added benefit may be obtained by the use of grafting materials in combination with GTR in some situations: in particular in furcation defects or to support bioresorbable membranes.

DFDBA alone gives documented improvements in some type of intrabony defects, in particular three-wall and two-wall defects.

EMD in gel formulation gives significant benefits in the treatment of intrabony defects, particularly those with a supportive anatomy (three-wall defects and narrow two-wall defects).

Differences between individuals and studies regarding the results of treating intrabony defects and class II furcations are related to patient compliance, maintenance procedures, selection of defects, surgical management, etc.

Periodontal regeneration obtained following GTR is stable on a long-term basis, provided good oral hygiene is maintained and a proper recall program is established. Current data indicate that, in patients participating in a supportive periodontal care program, 96% of teeth with severe intrabony defects and treated with a periodontal regenerative procedure could be retained for a period up to 15 years.

Chapter 44

Mucogingival Therapy – Periodontal Plastic Surgery

Jan L. Wennström, Giovanni Zucchelli, and Giovan P. Pini Prato

Introduction

Mucogingival therapy is a general term used to describe periodontal treatment involving procedures for correction of defects in morphology, position, and/or amount of soft tissue and underlying bone support at teeth and implants (*Glossary of Terms in Periodontology* 2001).

A more specific term, *mucogingival surgery*, was introduced in the 1950s by Friedman (1957) and was defined as "surgical procedures designed to preserve gingiva, remove aberrant frenulum or muscle attachments, and increase the depth of the vestibule". Frequently, however, the term "mucogingival surgery" was used to describe all surgical procedures that involved both the gingiva and the alveolar mucosa. Consequently, not only were techniques designed (1) to enhance the width of the gingiva and (2) to correct particular soft tissue defects regarded as mucogingival procedures but (3) certain pocket elimination approaches were also included in this group of periodontal treatment modalities. In 1993 Miller proposed the term *periodontal plastic surgery*, considering that mucogingival surgery had moved beyond the traditional treatment of problems associated with the amount of gingivae and recession type defects to also include correction of ridge form and soft tissue esthetics. Periodontal plastic surgery would accordingly be defined as "surgical procedures performed to prevent or correct anatomic, developmental, traumatic or disease-induced defects of the gingiva, alveolar mucosa or bone" (Proceedings of the World Workshop in Periodontics 1996). Among treatment procedures that may fall within this definition are various soft and hard tissue procedures aimed at:

- Gingival augmentation
- Root coverage
- Correction of mucosal defects at implants
- Crown lengthening
- Gingival preservation at ectopic tooth eruption
- Removal of aberrant frenulum
- Prevention of ridge collapse associated with tooth extraction
- Augmentation of the edentulous ridge.

The focus of this chapter is mainly on treatment procedures for corrections of soft tissue defects in relation to the tooth and the edentulous ridge, while bone augmentation procedures are covered in Chapter 49.

Gingival augmentation

A review of the literature on gingival augmentation reveals that the rationale for increasing the width of gingiva as a means of promoting gingival health and

improving attachment levels is poorly supported by scientific evidence. Usually clinical impressions, case reports, and anecdotal information have been used as the main reference to justify surgical intervention. In this perspective a discussion of the scientific evidence forming the basis for our current understanding of the role played by the gingiva in the protection of the periodontium proper seems appropriate.

Gingival dimensions and periodontal health

For many years the presence of an "adequate" zone of gingiva was considered critical for the maintenance of marginal tissue health and for the prevention of continuous loss of connective tissue attachment (Nabers 1954; Ochsenbein 1960; Friedman & Levine 1964; Hall 1981; Matter 1982). Clinicians had the "impression" that sites with a narrow zone of gingiva (Fig. 44-1) were often inflamed while the wide zone of gingiva found at neighboring teeth remained healthy. The prevailing concept was thus that a narrow zone of gingiva was insufficient (1) to protect the periodontium from injury caused by friction forces encountered during mastication and (2) to dissipate the pull on the gingival margin created by the muscles of the adjacent alveolar mucosa (Friedman 1957; Ochsenbein 1960). Moreover it was believed that an "inadequate" zone of gingiva would (1) facilitate subgingival plaque formation because of improper pocket closure resulting from the movability of the marginal tissue (Friedman 1962) and (2) favor attachment loss and soft tissue recession because of less tissue resistance to apical spread of plaque-associated gingival lesions (Stern 1976; Ruben 1979). It was also considered that a narrow gingiva in combination with a shallow vestibular fornix might (1) favor the accumulation of food particles during mastication, and (2) impede proper oral hygiene measures (Gottsegen 1954; Rosenberg 1960; Corn 1962; Carranza & Carraro 1970).

Fig. 44-1 A clinical photograph of a mandibular front tooth region. The gingiva on the buccal aspect of tooth 41 has a narrow width and shows more pronounced signs of inflammation than adjacent gingival units with a wider zone of gingiva.

The opinions expressed concerning what could be regarded as being an "adequate" or "sufficient" dimension of the gingiva varied. While some authors suggested that less than 1 mm of gingiva may be sufficient (Bowers 1963), others claimed that the apico-coronal height of keratinized tissue ought to exceed 3 mm (Corn 1962). A third category of authors had a more biologic approach to the question and stated that an adequate amount of gingiva is any dimension of gingiva which (1) is compatible with gingival health or (2) prevents retraction of the gingival margin during movements of the alveolar mucosa (Friedman 1962; De Trey & Bernimoulin 1980).

One of the first studies in which attempts were made to evaluate the significance of the gingival zone for the maintenance of periodontal health was carried out by Lang and Löe (1972) on dental students who had their teeth professionally cleaned once a day for 6 weeks. All buccal and lingual sites were examined for plaque, gingival conditions, and apico-coronal height of gingiva. The results showed that despite the fact that the tooth surfaces were free from plaque, all sites with less than 2 mm of gingiva exhibited persisting clinical signs of inflammation. Based on this observation the authors suggested that 2 mm of gingiva is an adequate width for maintaining gingival health. Subsequent clinical trials (Miyasato *et al*. 1977; Grevers 1977), however, failed to substantiate this concept of a required minimum dimension of gingiva. In fact, these clinical trials demonstrated that it is possible to maintain clinically healthy marginal tissues even in areas with less than 1 mm of gingiva.

The question whether a firmly attached portion of gingiva is critical for the protection of the periodontium proper was addressed by Wennström and Lindhe (1983a,b) utilizing the beagle dog model. In these studies dentogingival units with different clinical characteristics were experimentally established; (1) units with only a narrow and mobile zone of keratinized tissue and (2) units with a wide, firmly attached gingiva (Fig. 44-2). With daily performed mechanical plaque-control measures, the gingival units could be maintained free from clinical as well as histologic signs of inflammation irrespective of the presence or absence of an attached portion of gingiva. When bacterial plaque was allowed to accumulate (for 40 days), clinical signs of inflammation (redness and swelling) developed that were more pronounced in tooth regions with mobile gingiva (Fig. 44-3a) than in areas with presence of a wide and firmly attached gingival zone (Fig. 44-3b). However, histologic analysis revealed that the size of the inflammatory cell infiltrate and its extension in an apical direction (an assessment which indirectly may be used as an estimate of the apical migration of the bacterial plaque) were similar in the two categories of dentogingival units. The finding that the clinical signs of gingival inflammation did not correspond with the size of the inflammatory cell infiltrate illustrates the difficulties

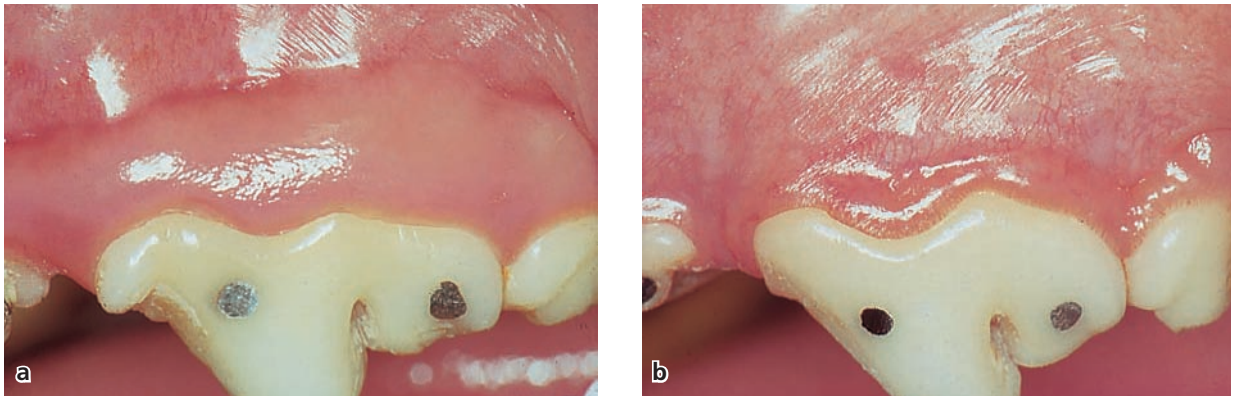

Fig. 44-2 Two teeth in a dog with varying dimensions of the marginal gingiva. (a) A buccal tooth site with a wide zone of attached gingiva. (b) A site with an unattached, narrow band of gingiva.

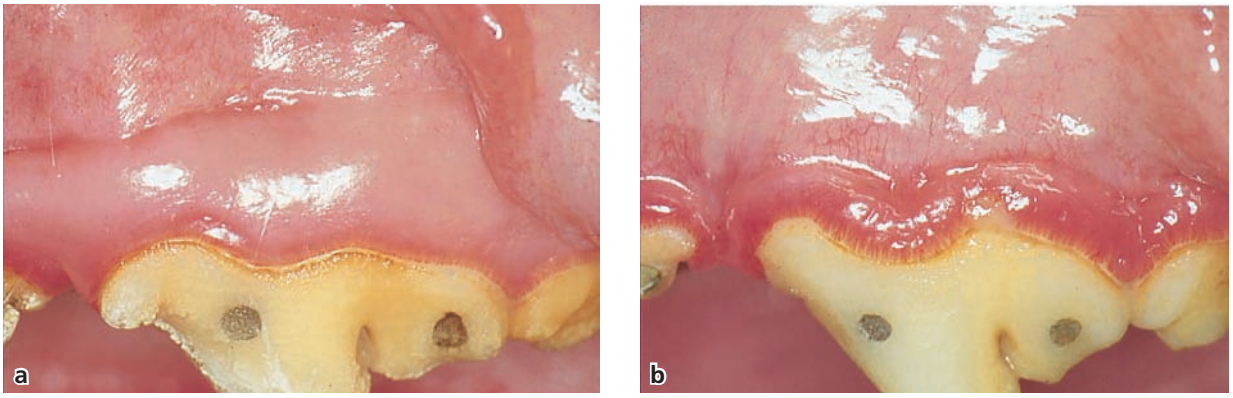

Fig. 44-3 The same teeth as in Fig. 44-2 after 40 days of plaque accumulation. The clinical signs of inflammation are more pronounced at the site with the narrow band of gingiva (b) than at the site with the wide zone of attached gingiva (a).

inherent in the interpretation of data from clinical examinations made in areas with varying width of gingiva. This should be kept in mind when interpreting the data by Lang and Löe (1972) showing that clinically visible signs of inflammation, such as redness and swelling, were more frequent in areas with less than 2 mm of gingiva than in areas with a wider zone of gingiva.

The necessity for and effectiveness of gingival augmentation in maintaining periodontal attachment was examined by Dorfman *et al*. (1980). Ninety-two patients with bilateral facial tooth surfaces exhibiting minimal keratinized tissue (i.e. less than 2 mm) had a free gingival graft placed on one side, while the contralateral side served as the untreated control. Prior to and after surgery the patients were subjected to scaling and root planing and instruction in oral hygiene measures. Not surprisingly, the investigators found a significant increase (approximately 4 mm) in the width of keratinized tissue at the grafted sites. This increased width of gingiva, as well as the clinical attachment level, was maintained throughout the 2 years of follow-up. In the control sites the width of gingiva was less than 2 mm and did not vary significantly during the observation period. However, the attachment level was also maintained unchanged in the non-grafted areas. Thus, the resistance to continuous attachment loss was not linked to the height (width) of gingiva, a conclusion that was further substantiated by subsequent 4- and 6-year follow-up reports of this patient material (Dorfman *et al*. 1982; Kennedy *et al*. 1985).

Further support for the conclusion that a minimal zone of gingiva may not compromise periodontal health is available in a number of other longitudinal clinical studies (e.g. Hangorsky & Bissada 1980; De Trey & Bernimoulin 1980; Lindhe & Nyman 1980; Schoo & van der Velden 1985; Kisch *et al*. 1986; Wennström 1987; Freedman *et al*. 1999). Hence, Hangorsky and Bissada (1980), who evaluated the long-term clinical effect of free soft tissue grafts, concluded that while the free gingival graft is an effective means to widen the zone of the gingiva, there is no indication that this increase has direct influence upon periodontal health.

Conclusion

Gingival health can be maintained independent of its dimensions. Furthermore, there is evidence from both experimental and clinical studies that, in the presence of plaque, areas with a narrow zone of

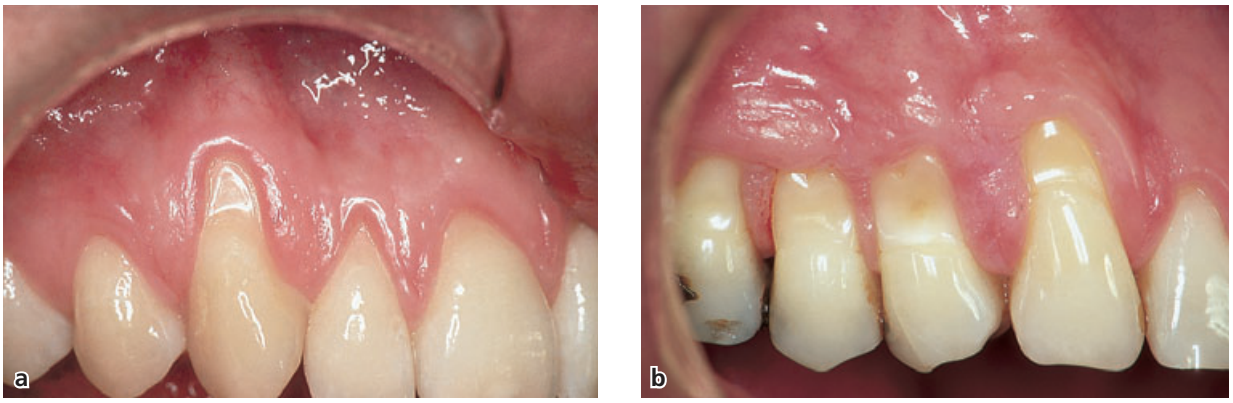

Fig. 44-4 Recessions associated with toothbrushing trauma. The marginal gingiva is clinically healthy and abrasion defects of various extension can be noted in the exposed roots.

gingiva possess the same "resistance" to continuous attachment loss as teeth with a wide zone of gingiva. Hence, the traditional dogma of the need of an "adequate" width (in millimeters) of gingiva, or attached portion of gingiva, for prevention of attachment loss is not scientifically supported.

Marginal tissue recession

Marginal tissue recession, i.e. displacement of the soft tissue margin apical to the cemento-enamel junction (CEJ) with exposure of the root surface, is a common feature in populations with high standards of oral hygiene (e.g. Sangnes & Gjermo 1976; Murtomaa *et al*. 1987; Löe *et al*. 1992; Serino *et al*. 1994), as well as in populations with poor oral hygiene (e.g. Baelum *et al*. 1986; Yoneyama *et al*. 1988; Löe *et al*. 1992; Susin *et al*. 2004). In populations maintaining high standards of oral hygiene, loss of attachment and marginal tissue recession are predominantly found at buccal surfaces (Löe *et al*. 1992; Serino *et al*. 1994), and are frequently associated with the presence of a "wedge-shaped defect in the crevicular area of one or several teeth" (Sangnes & Gjermo 1976). In contrast, all tooth surfaces are usually affected with soft tissue recession in periodontally untreated populations, although the prevalence and severity is more pronounced at single-rooted teeth than at molars (Löe *et al*. 1978; 1992; Miller *et al*. 1987; Yoneyama *et al*. 1988).

Tissue trauma caused by vigorous toothbrushing is considered to be a predominant causative factor for the development of recessions, particularly in young individuals. Traumatizing toothbrushing and tooth malposition are the factors most frequently found to be associated with marginal tissue recession (Sangnes 1976; Vekalahti 1989; Checchi *et al*. 1999). In addition, Khocht *et al*. (1993) showed that recessions are related to the use of hard toothbrushes. Other local factors that have been associated with marginal tissue recession are (1) alveolar bone dehiscences (Bernimoulin & Curilivic 1977; Löst 1984), (2) high muscle attachment and frenal pull (Trott & Love 1966), (3) plaque and calculus (van Palenstein Helderman *et al*. 1998; Susin *et al*. 2004), and (4) iatrogenic factors related to restorative and periodontal treatment procedures (Lindhe & Nyman 1980; Valderhaug 1980).

Fig. 44-5 A recession associated with localized plaque-induced inflammatory lesion.

At least three different types of marginal tissue recessions may exist:

- *Recessions associated with mechanical factors, predominately toothbrushing trauma* (Fig. 44-4). Recessions resulting from improper toothbrushing techniques are often found at sites with clinically healthy gingiva and where the exposed root has a wedge-shaped defect, the surface of which is clean, smooth and polished.
- *Recessions associated with localized plaque-induced inflammatory lesions* (Fig. 44-5). Such recessions may be found at teeth that are prominently positioned, i.e. the alveolar bone is thin or absent (bone dehiscence), and where in addition the gingival tissue is thin (delicate). An inflammatory lesion that develops in response to subgingival plaque occupies the connective tissue adjacent to the dentogingival epithelium. Measurements made by Waerhaug (1952) suggest that the distance between the periphery of microbial plaque on the tooth surface and the lateral and apical extension of the

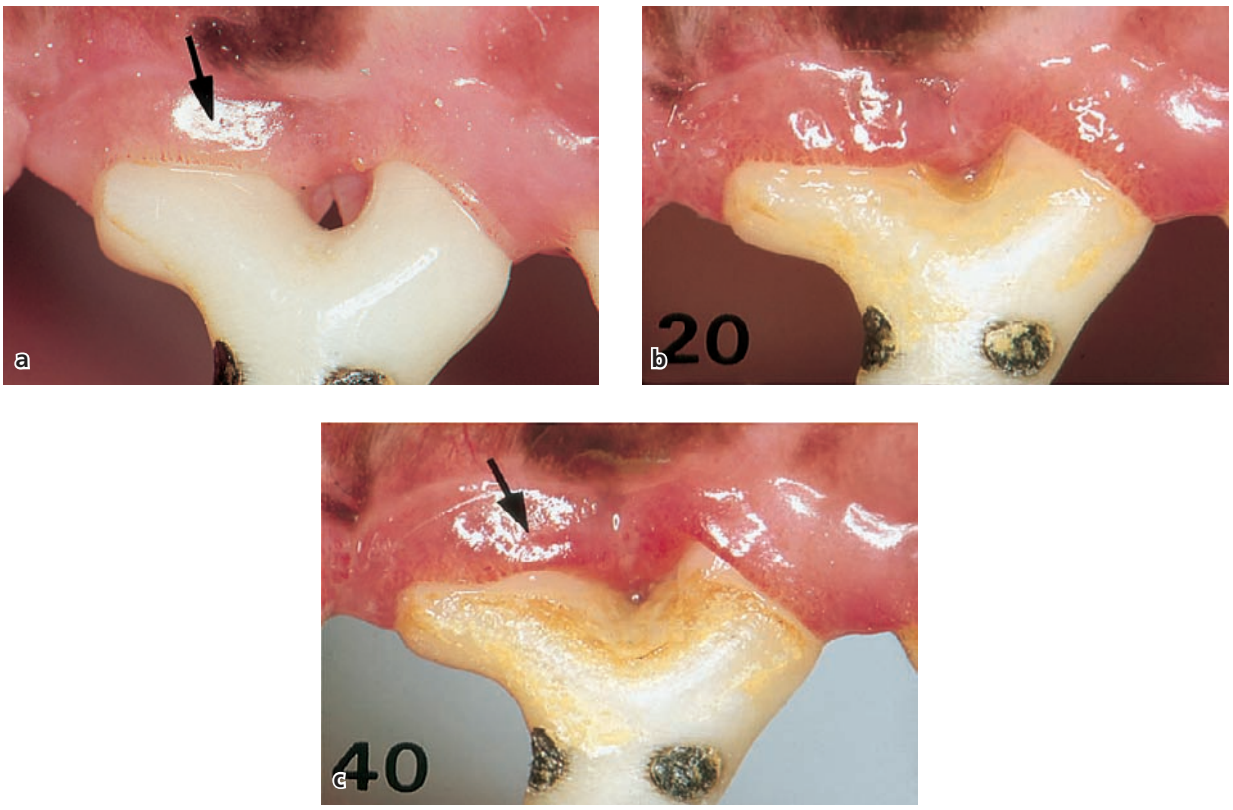

Fig. 44-6 Clinical photographs illustrating the development of a soft tissue recession as a result of plaque-induced inflammation in a beagle dog. (a) Note the thin but healthy gingiva (arrow) at the start of the plaque accumulation period. (b) Pronounced clinical signs of inflammation are seen after 20 days. (c) After 40 days of no tooth cleaning, the gingival margin has receded.

inflammatory cell infiltrate seldom exceeds 1–2 mm. Thus, if the free gingiva is voluminous the infiltrate will occupy only a small portion of the connective tissue. In a thin and delicate gingiva, on the other hand, the entire connective tissue portion may be engaged. Proliferation of epithelial cells from the oral as well as the dentogingival epithelium into the thin and degraded connective tissue may bring about a subsidence of the epithelial surface which clinically becomes manifest as recession of the tissue margin (Baker & Seymour 1976) (Fig. 44-6).

- *Recessions associated with generalized forms of destructive periodontal disease* (Fig. 44-7). The loss of periodontal support at proximal sites may result in compensatory remodeling of the support at the buccal/lingual aspect of the teeth leading to an apical shift of the soft tissue margin (Serino *et al*. 1994).

Fig. 44-7 Recessions associated with generalized forms of destructive periodontal disease. Recession of the soft tissue is found not only at the facial aspect of the teeth but also at proximal sites.

Cross-sectional studies showing that a correlation exists between the presence of recession defects and the height (width) of the gingiva (e.g. Stoner & Mazdyasna 1980; Tenenbaum 1982) have often been interpreted as an evidence that a narrow zone of gingiva is a contributing factor in the development of soft tissue recessions (Fig. 44-8). It should be realized, however, that data derived from cross-sectional studies can neither prove nor disprove a cause–effect relationship. Consequently, the data reported from such studies may equally well be interpreted to demonstrate that the formation of a recession defect results in a reduced height of the gingiva. Fig. 44-1 illustrates a lower incisor tooth region with a localized gingival recession at the buccal aspect of tooth 41. The gingiva apical to the recession defect is narrow ("insufficient") while at neighboring teeth the gingival height may be considered "adequate". It is reasonable to assume that the gingiva at tooth 41, *before*

Fig. 44-8 A mandibular tooth segment with multiple buccal recessions illustrating the association proposed between recession depth and height of gingiva.

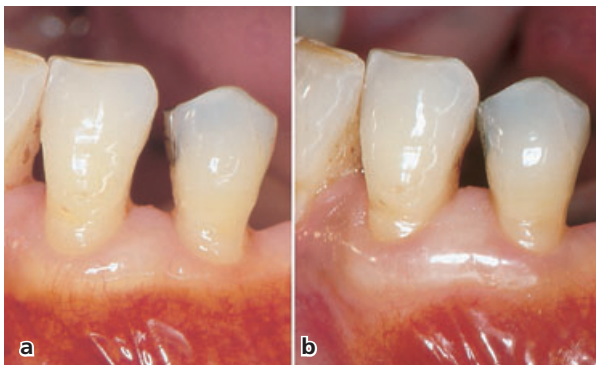

Fig. 44-9 (a) Clinical photographs of a canine and a first premolar in the mandibular jaw with <1 mm of attached portion of gingiva 6 months after surgical treatment. (b) Note the increase of the width of the gingiva at the facial aspect of the teeth and the more coronally positioned gingival margin 5 years later.

the recession defect developed, had a height that was similar to that found at tooth 31 and tooth 42. In other words, the narrow zone of gingiva found at tooth 41 may be the result of *loss of gingival tissue during the period of recession development*, rather than being the cause of the formation of the defect. If this interpretation is valid, the rationale for increasing the height of the gingiva in an area *apical to the existing defect* as a means of preventing further recession may appear somewhat obscure. In fact, data obtained from prospective, longitudinal studies of patients showing areas with only a minimal zone of gingiva favor the conclusion that a certain quantity of gingiva is not essential for the preclusion of soft tissue recessions.

Lindhe and Nyman (1980) examined the alterations of the position of the gingival margin following periodontal surgery in 43 patients with advanced periodontal breakdown. Following active treatment, all patients were recalled once every 3–6 months for maintenance care. The position of the soft tissue margin in relation to the CEJ was assessed on the facial aspect of all teeth after initial healing and after 10–11 years of maintenance. The presence or absence of keratinized tissue after surgical treatment was also determined. The results showed that both in areas with and without visible keratinized tissue after healing, a small coronal regrowth (≈1 mm) of the soft tissue margin had occurred during the period of maintenance. In other words, no recession was observed in this group of patients maintained on a careful prophylaxis program.

Dorfman *et al*. (1982) reported a 4-year follow-up study including 22 patients with bilateral tooth areas exhibiting gingival recession and lack of firmly attached marginal soft tissue. In conjunction with scaling and root planing a free gingival graft was placed on one side, while the contralateral control side was treated by scaling and root planing only. All patients were recalled for prophylaxis once every 3–6 months during a 4-year period. The data obtained from the examinations of the non-grafted control areas revealed that no further recession of the soft tissue margin or loss of probing attachment had occurred despite the lack of attached marginal tissue. In fact, there was a slight gain of probing attachment. The authors concluded that recession sites without attached gingiva might not experience further attachment loss and recession if the inflammation is controlled. In a subsequent report (Kennedy *et al*. 1985), the authors reported data on 10 patients who had not participated in the maintenance program for a period of 5 years. In these patients plaque and clinical signs of inflammation as well as some further recession were noted at the 5-year examination as compared with the data obtained after termination of active treatment. However, except for the clinical signs of inflammation, which were more pronounced in non-grafted sites, no differences were observed between control sites with <1 mm or complete lack of attached gingiva and grafted sites.

The lack of relationship between the height of gingiva and the development of soft tissue recession is further validated by results from longitudinal clinical studies (Schoo & van der Velden 1985; Kisch *et al*. 1986; Wennström 1987; Freedman *et al*. 1999). The study by Wennström (1987) reports observations made at 26 buccal sites surgically deprived of all keratinized tissue. A baseline examination carried out 6 months after treatment revealed that these sites had regained a zone of gingiva which was, however, not attached or had only a minimal (<1 mm) portion attached to the underlying hard tissues (Figs. 44-9a and 44-10a). Adjacent teeth with a broad zone of attached gingiva were also included in the examinations. In most sites the position of the soft tissue margin had been maintained unchanged over 5 years (Figs. 44-9b and 44-10b). A further apical displacement of the soft tissue margin had occurred at two out of 26 sites with no/minimal attached portion of gingiva and at three out of 12 adjacent control sites with a wide attached zone of gingiva. Since four of these five sites were found in one patient (Fig. 44-11), and all sites were free from clinical signs of inflam-

mation, excessive toothbrushing was considered to be the causative factor, and following correction of the brushing technique no further progression was observed. Furthermore, the development of soft tissue recession at the control sites resulted in a decreased width of the gingiva, an observation that supports the concept that a narrow zone of gingiva apical to a localized recession is a consequence rather than a cause of the recession.

Conclusion

Marginal soft tissue recession is a common feature in populations with good as well as poor standards of oral hygiene. There is evidence to suggest that the predominant cause for localized recessions in young individuals is toothbrushing trauma, while periodontal disease may be the primary cause in older adults. Evidence from prospective longitudinal studies shows that the gingival height is not a critical factor for the prevention of marginal tissue recession, but that the development of a recession will result in loss of gingival height.

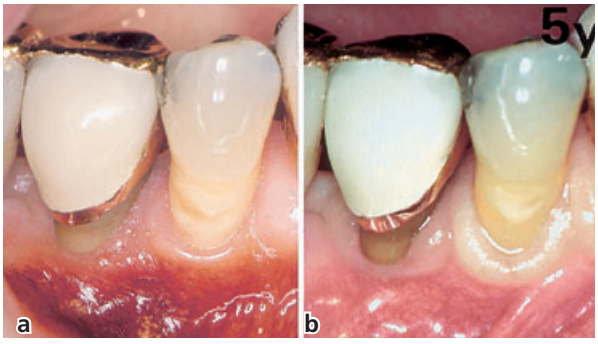

Fig. 44-10 (a) A mandibular canine and first premolar tooth region showing a very narrow zone of gingiva 6 months after surgical therapy. (b) No major change in the position of the soft tissue margin has occurred during a 5-year period despite the lack of attached gingiva.

Marginal tissue recession and orthodontic treatment

Results from clinical and experimental research have documented that most forms of orthodontic therapy are innocuous to the periodontium (see Chapter 57). The clinician may experience, however, that some patients respond to frontal movements of incisors and lateral movements of posterior teeth by gingival recession and loss of attachment (Maynard & Ochsenbein 1975; Coatoam *et al*. 1981; Foushee *et al*. 1985) (Fig. 44-12). Based on the clinical observation that recession may occur during orthodontic therapy involving sites that have an "insufficient" zone of gingiva, it was suggested that a grafting procedure to increase the gingival dimensions should precede the initiation of orthodontic therapy in such areas (Boyd 1978; Hall 1981; Maynard 1987).

As discussed previously, the presence of an alveolar bone dehiscence is considered to be a prerequisite for the development of a marginal tissue recession, i.e. a root dehiscence may establish an environment that is conducive for loss of gingival tissue. With respect to orthodontic therapy, this would imply that as long as a tooth is moved exclusively within the alveolar bone, soft tissue recession will not develop (Wennström *et al*. 1987). On the other hand, predisposing alveolar bone dehiscences may be induced by uncontrolled facial expansion of a tooth through the cortical plate, thereby rendering the tooth liable to development of soft tissue recession. In this context it is interesting to note that experimental studies have shown that labial bone will reform in the area of a dehiscence when the tooth is retracted towards a proper positioning of the root within the alveolar process (Engelking & Zachrisson 1982; Karring *et al*. 1982) (Fig. 44-13). It is therefore likely that the reduction in recession seen at a previously prominently positioned tooth that has been moved into a more proper position within the alveolar process (Fig. 44-14) is also accompanied by bone formation.

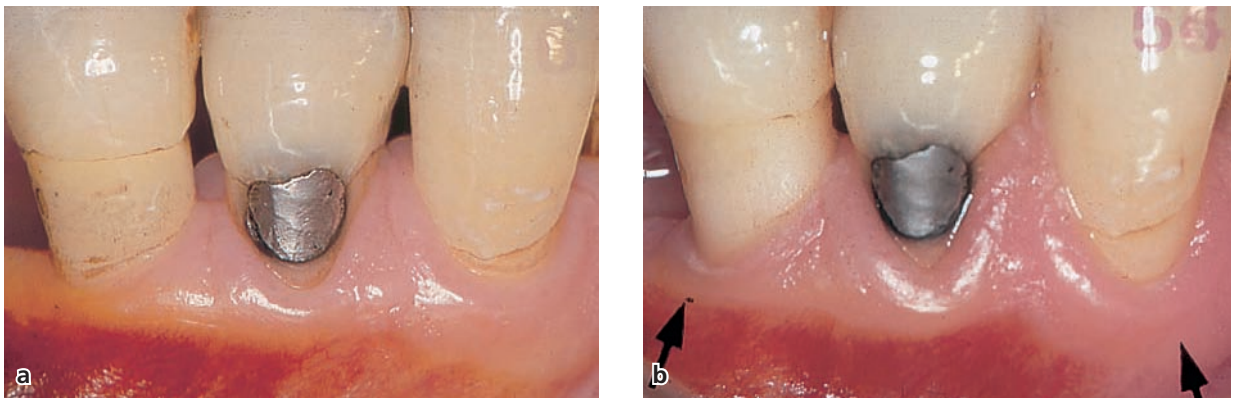

Fig. 44-11 Clinical photographs of the mandibular right canine–premolar tooth region in a patient showing several sites with apical displacement of the soft tissue margin during the 5 years of observation. (a) At the initial examination the two premolars had <1 mm and the canine >1 mm of attached portion of gingiva. (b) After 5 years, recession and loss of keratinized tissue can be seen on the buccal aspect of the canine, which initially had a broad zone of gingiva (black arrow). The second premolar also showed further apical displacement of the soft tissue margin (white arrow).

Alterations occurring in gingival dimensions and marginal tissue position in conjunction with orthodontic therapy are related to the *direction of tooth movement*. Facial movement results in reduced facial gingival dimensions, while an increase is observed following lingual movement (Coatoam *et al*. 1981; Andlin-Sobocki & Bodin 1993). Recession of the labial gingival margin and loss of attachment was demonstrated in experimental studies in the monkey following either tipping and extrusion movements or bodily movements of incisors (Batenhorst *et al*. 1974; Steiner *et al*. 1981). However, similarly designed studies carried out in dogs (Karring *et al*. 1982; Nyman *et al*. 1982) and humans (Rateitschak *et al*. 1968) failed to demonstrate that labial tooth movement is accompanied by marginal tissue recession and attachment loss. The conflicting results may be related to differences with respect to e.g. (1) the amount of labial tooth displacement, (2) the presence/absence of plaque and gingival inflammation in the regions subjected to tooth movement, and/or (3) differences in gingival dimensions. Steiner *et al*. (1981) speculated on mechanisms by which gingival tissue could be lost as a result of labial tooth movement and suggested that tension in the marginal tissue created by the forces applied to the teeth could be an important factor. If this hypothesis were valid, obviously the volume (thickness) of the gingival tissue at the pres-
