FOUNDATIONS IN MICROBIOLOGY

KATHLEEN PARK
TALARO

BARRY
CHESS

A microscopic image of various bacteria. In the center, there are two prominent, reddish, textured structures that appear to be spore-bearing bacteria, possibly Bacillus or Clostridium species. Surrounding these are several blue, filamentous structures that look like long, thin bacteria, possibly Gram-negative bacilli or spirochetes. The background is dark with a blueish tint, suggesting a microscopic field of view.

About the Authors

Kathleen Park Talaro is a microbiologist, educator, author, and artist. She has been nurturing her love of microbiology since her youth growing up on an Idaho farm where she was first fascinated by tiny creatures she could just barely see swimming in a pond. This interest in the microbial world led to a biology major at Idaho State University, where she worked as a teaching assistant and scientific illustrator for one of her professors. This was the beginning of an avocation that she continues today—that of lending her artistic hand to interpretation of scientific concepts. She continued her education at Arizona State University, Occidental College, California Institute of Technology, and California State University.

She taught microbiology and major's biology courses at Pasadena City College for 30 years, during which time she developed

new curricula and refined laboratory experiments. She has been an author of, and contributor to, several publications of the William C. Brown Company and McGraw-Hill Publishers since the early 1980s, first illustrating and writing for laboratory manuals and later developing this textbook. She has also served as a co-author with Kelly Cowan on the first two editions of *Microbiology: A Systems Approach*.

Barry Chess has been teaching microbiology at Pasadena City College for 20 years. He received his Bachelor's and Master's degrees from the California State University and did postgraduate work at the University of California, where his research focused on the expression of eukaryotic genes involved in the development of muscle and bone.

At Pasadena City College, Barry developed a new course in human genetics and helped to institute a biotechnology program. He regularly teaches courses in microbiology, general

biology, and genetics, and works with students completing independent research projects in biology and microbiology. Over the past several years, Barry's interests have begun to focus on innovative methods of teaching that increase student success. He has written cases for the National Center for Case Study Teaching in Science and given talks at national meetings on the effectiveness of case studies in the classroom. His laboratory manual, *Laboratory Applications in Microbiology: A Case Study Approach*, is currently in its third edition. He feels very fortunate to be collaborating with Kathy Talaro, with whom he has worked in the classroom for more than a decade, on this tenth edition. Barry is a member of the American Society for Microbiology and the American Association for the Advancement of Science and regularly attends meetings in his fields of interest, both to keep current of changes in the discipline and to exchange teaching and learning strategies with others in the field.

She lives in Altadena, California, with husband Dave Bedrosian and son David. Whenever she can, she visits her family in Idaho. In her spare time, she enjoys photography, reading true crime books, music, crossword puzzles, and playing with her rescued kitties.

A major intent of this textbook has always been to promote an understanding of microbes and their intimate involvement in the lives of humans, but our other aim is to stimulate an appreciation that goes far beyond that. We want you to be awed by these tiniest creatures and the tremendous impact they have on all of the earth's natural activities. We hope you are inspired enough to embrace that knowledge throughout your lives.

McGraw-Hill Connect[®] Learn Without Limits

Connect is a teaching and learning platform that is proven to deliver better results for students and instructors.

Connect empowers students by continually adapting to deliver precisely what they need, when they need it, and how they need it, so your class time is more engaging and effective.

73% of instructors who use **Connect** require it; instructor satisfaction **increases** by 28% when **Connect** is required.

Connect's Impact on Retention Rates, Pass Rates, and Average Exam Scores

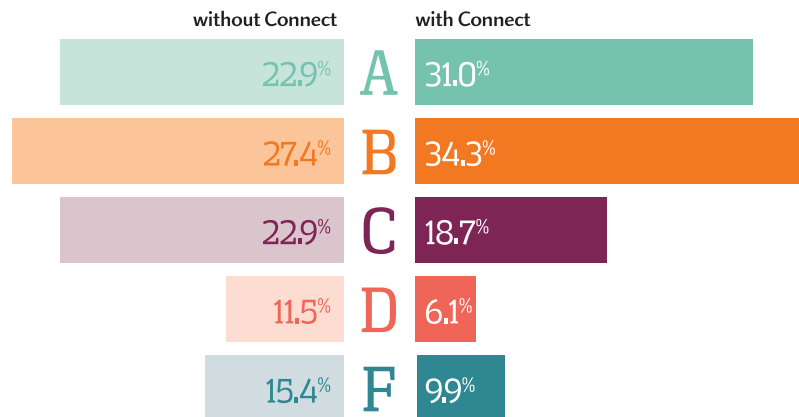

Using **Connect** improves retention rates by **19.8%**, passing rates by **12.7%**, and exam scores by **9.1%**.

Analytics

Connect Insight[®]

Connect Insight is Connect's new one-of-a-kind visual analytics dashboard that provides at-a-glance information regarding student performance, which is immediately actionable. By presenting assignment, assessment, and topical performance results together with a time metric that is easily visible for aggregate or individual results, Connect Insight gives the user the ability to take a just-in-time approach to teaching and learning, which was never before available. Connect Insight presents data that helps instructors improve class performance in a way that is efficient and effective.

Impact on Final Course Grade Distribution

Adaptive

THE ADAPTIVE READING EXPERIENCE DESIGNED TO TRANSFORM THE WAY STUDENTS READ

More students earn **A's** and **B's** when they use McGraw-Hill Education **Adaptive** products.

SmartBook®

Proven to help students improve grades and study more efficiently, SmartBook contains the same content within the print book, but actively tailors that content to the needs of the individual. SmartBook's adaptive technology provides precise, personalized instruction on what the student should do next, guiding the student to master and remember key concepts, targeting gaps in knowledge and offering customized feedback, and driving the student toward comprehension and retention of the subject matter. Available on tablets, SmartBook puts learning at the student's fingertips—anywhere, anytime.

Over **8 billion questions** have been answered, making McGraw-Hill Education products more intelligent, reliable, and precise.

www.mheducation.com

of students reported **SmartBook** to be a more effective way of reading material.

of students want to use the Practice Quiz feature available within **SmartBook** to help them study.

of students reported having reliable access to off-campus wifi.

of students say they would purchase **SmartBook** over print alone.

of students reported that **SmartBook** would impact their study skills in a positive way.

Connecting Instructors to Students— Digital Tools for Your Success

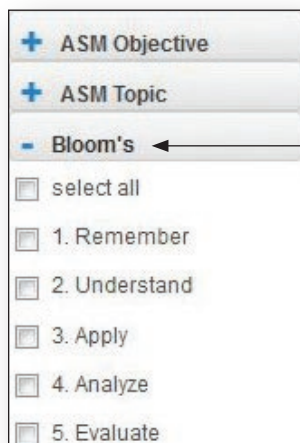

connect®

Save time with auto-graded assessments.
Gather powerful performance data.

McGraw-Hill Connect for Prescott's **Microbiology** provides online presentation, assignment, and assessment solutions, connecting your students with the tools and resources they'll need to achieve success.

Homework and Assessment

With **Connect for Talaro's Foundations in Microbiology**, you can deliver auto-graded assignments, quizzes, and tests online. Choose from a robust set of interactive questions and activities using high-quality art from the textbook and animations. Assignable content is available for every Learning Outcome in the book and is categorized according to the **ASM Curriculum Guidelines**. As an instructor, you can edit existing questions and author entirely new ones.

Significant faculty demand for content at higher Bloom's levels led us to examine assessment quality and consistency of our Connect content, to develop a scientific approach to systemically increase critical-thinking levels, and develop balanced digital assessments that promote student learning. The increased challenge at higher Bloom's levels will help the student grow intellectually and be better prepared to contribute to society.

Instructor Resources

Customize your lecture with tools such as PowerPoint® presentations, animations, and editable art from the textbook. An instructor's manual for the text saves you time in developing your course.

Learn more at connect.mheducation.com.

Detailed Reports

Track individual student performance—by question, by assignment, or in relation to the class overall—with detailed grade reports. Integrate grade reports easily with your Learning Management Systems (LMS).

Lecture Capture

McGraw-Hill **Tegrity**® records and distributes your class lecture with just a click of a button. Students can view anytime, anywhere via computer or mobile device. Indexed as you record, students can use keywords to find exactly what they want to study.

Integrated and Adaptive Laboratory Tools

LearnSmart Labs® is an adaptive simulated lab experience that brings meaningful scientific exploration to students. Through a series of adaptive questions, LearnSmart Labs identifies a student's knowledge gaps and provides resources to quickly and efficiently close those gaps. Once students have mastered the necessary basic skills and concepts, they engage in a highly realistic simulated lab experience that allows for mistakes and the execution of the scientific method.

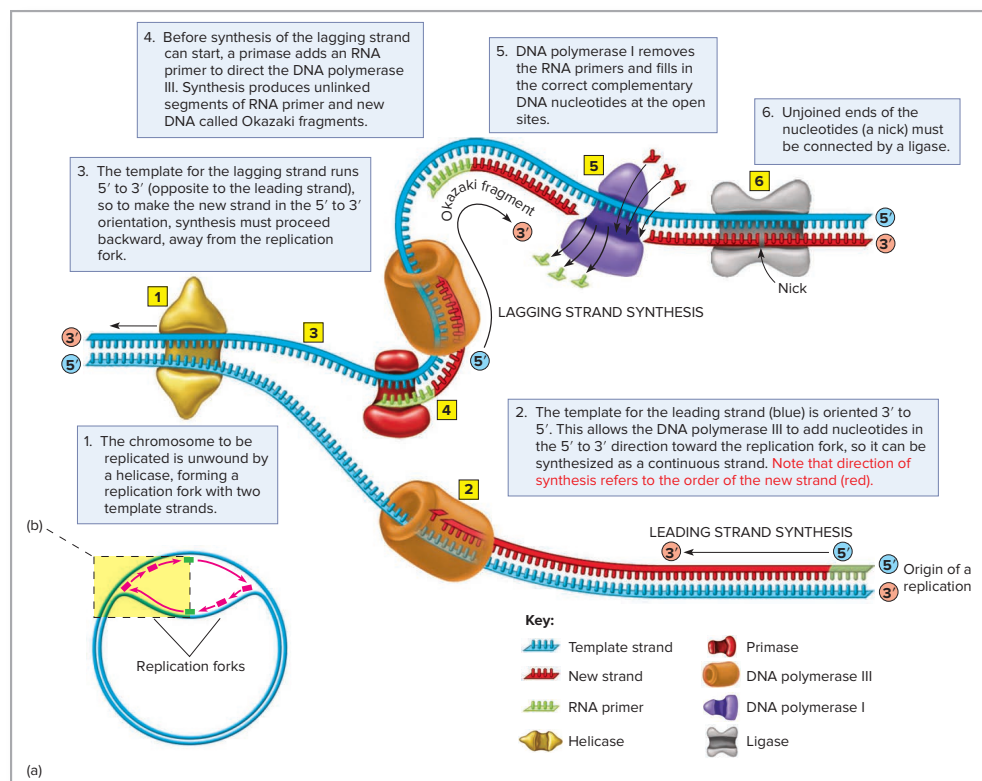

LearnSmart® Prep is an adaptive learning tool that prepares students for college-level work in Microbiology. LearnSmart Prep individually identifies concepts the student does not fully understand and provides learning resources to teach essential concepts so he or she enters the classroom prepared. Data-driven reports highlight areas where students are struggling, helping to accurately identify weak areas.

The Profile of a Student Success Learning Tool

Art and organization of content make this book unique

Carefully crafting a textbook to be a truly useful learning tool for students takes time and dedication. Every line of text and every piece of art in this book is scrutinized for instructional usefulness, placement, and pedagogy, and then reexamined with each revision. In this tenth edition, the authors have gone through the book page by page, with more depth than ever before, to make sure it maintains its instructional quality, fantastic art program, relevant and current material, and engaging, user-friendly writing style. Since the first edition, the goals of this book have been to explain complex topics clearly and vividly, and to present the material in a straightforward way that students can understand. The tenth edition continues to meet these goals with the most digitally integrated, up-to-date, and pedagogically important revision yet.

Like a great masterpiece hanging in a museum, *Foundations in Microbiology* is not only beautiful but also tells a story, composed of many pieces. A great textbook must be carefully constructed to place art where it makes the most sense in the flow of the narrative; create process figures that break down complex processes into their simplest parts; provide explanations at the correct level for the student audience; and offer pedagogical tools that help all types of learners. Many textbook authors write the narrative of their book and call it a day. It is the rare author team, indeed, that examines each page and makes changes based on what will help the students the most, so that when the pieces come together, the result is an expertly crafted learning tool—a story of the microbial world.

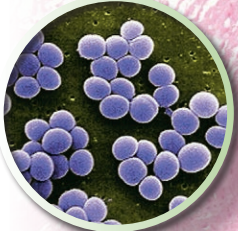

Kathy Talaro introduces new art to a revision by carefully sketching out what she envisions in precise detail, with accompanying instructions to the illustrator. The result is accurate, beautifully rendered art that helps difficult concepts come to life.

The Structure of a Student Success Learning Tool

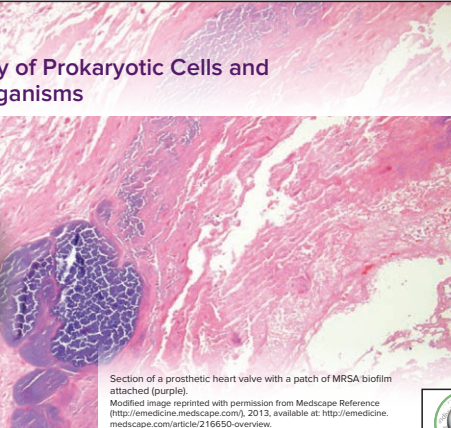

Chapter-Opening Case Studies

Each chapter opens with a Case Study Part 1, which helps the students appreciate and understand how microbiology impacts their lives. Appropriate line art, micrographs, and quotes have been added to the chapter-opening page to help the students pull together the big picture and grasp the relevance of the material they're about to learn. The questions that directly follow Parts 1 and 2 of the Case Study challenge students to begin to think critically about relevant text references that will help them answer the questions as they work through the chapter. The Case Study Perspective wraps up the case and can be found on the Connect website.

CHAPTER 4 A Survey of Prokaryotic Cells and Microorganisms

Looking as harmless as clusters of tiny purple grapes, the gram-positive pathogen *Staphylococcus aureus* is anything but. (inset). Source: Janice Carr/CDC.

Section of a prosthetic heart valve with a patch of MRSA biofilm attached (purple). Modified image reprinted with permission from Medscape Reference (<http://emedicine.medscape.com>), 2013, available at: <http://emedicine.medscape.com/article/216650-overview>.

CASE STUDY Part 1 Heart Valves and Biofilms

On a summer morning in 2008, Maxwell Jones, a 65-year-old man, woke up complaining of abnormal **fatigue** and a **scratchy throat**. His wife said he felt hot and took his temperature. It was slightly elevated at 100°F. He dismissed his condition, saying he was probably tired from working in his garden and suffering one of his regular allergy attacks. Over the next few days, his list of symptoms grew. He lost his appetite, his **joints and muscles were sore**, and he woke up wringing wet from **night sweats**. He continued to have a **fever**, and his wife was worried over how pale he looked. She insisted he see a physician, who performed a physical and took a **throat culture**. Mr. Jones was sent home with instructions to take **oral penicillin** and acetaminophen (Tylenol), and to come back in a week.

At the next appointment the patient reported that he still had some of the same symptoms, including the fever, and that now he had begun to have **headaches, rapid breathing, and coughing**. The physician recorded a **rapid heart rate** and slight **heart murmur**. When the lab report indicated that the throat culture was **negative** for bacterial pathogens, he had to look for other causes.

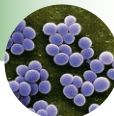

He began to wonder if the patient had a prior medical history of possible **risk factors**. From interviewing Mr. Jones, he learned that an **artificial valve** had been implanted in his heart 10 years before, a fact that had been omitted from his medical chart. This finding immediately caused alarm, and Mr. Jones was admitted to the intensive care unit and placed on a mixture of **intravenous antibiotics**. Tests for **blood cultures** and a **white blood cell count** were ordered as backup. By that evening, Mr. Jones had become confused and lost consciousness. He was rushed to the operating room but died during open heart surgery.

“At least 65% of chronic infections are caused by microbial biofilms.”

- What appear to be the most important facts in this case?
- Explain why Mr. Jones's throat culture was negative for infection.

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

CASE STUDY Part 2

During an autopsy of Mr. Jones's body, the pathologist observed that the prosthetic valve was covered with small patches he called vegetations. The later blood cultures grew a strain of *Staphylococcus aureus** known as MRSA. Microscopic examination of the valve revealed a thick biofilm coating containing that same bacterium. The pathologist concluded that the patient had infective endocarditis,* and that vegetations on the valve lesions had broken loose and entered the circulation. This event created emboli that blocked arteries in his brain and gave rise to a massive stroke. Upon closer review of Mr. Jones's case, the physician discovered that he had suffered from a skin infection the previous spring that had been treated and cured by a different physician. It turned out to be caused by the MRSA type of *Staphylococcus aureus*.

Most bacteria can form structured multicellular communities, or biofilms, on objects in a moist environment. This is even true of bacterial pathogens in the body. The CDC estimates that at least 65% of chronic infections are caused by microbial biofilms. In this case, the MRSA bacteria in the patient's skin infection must have entered the circulation and colonized the artificial valve over several weeks to months. Most cases of chronic endocarditis are caused by biofilms on valves. When the biofilm grows into larger vegetations, portions of it break loose into the circulation. These infect the blood and are spread into organs, causing fever and other signs and symptoms, including the ones that were fatal. MRSA is an emerging pathogen that started as a problem in the hospital but is now prominent in nonhospital settings as well.

- What does the acronym MRSA mean, and what is its significance?

The Art of a Student Success Learning Tool

Author's experience and talent transforms difficult concepts

Truly instructional artwork has always been a hallmark feature of *Foundations in Microbiology*. Kathy Talaro's experiences as a teacher, microbiologist, and illustrator have given her a unique perspective and the ability to transform abstract concepts into scientifically accurate and educational illustrations. Powerful artwork that paints a conceptual picture for students is more important than ever for today's visual learners. *Foundations in Microbiology's* art program combines vivid colors, multidimensionality, and self-contained narrative to help students study the challenging concepts of microbiology.

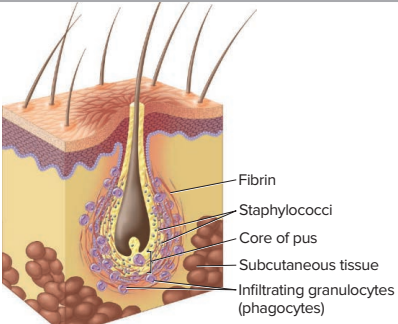

Process Figures

Many difficult microbiological concepts are best portrayed by breaking them down into stages that students will find easy to follow. These process figures show each step clearly numbered within a yellow circle and correlated to accompanying narrative to benefit all types of learners. A distinctive process icon precedes the figure number. The accompanying legend provides additional explanation.

The Relevance of a Student Success Learning Tool

Real clinical photos help students visualize

resolved with no complications, they can lead to infections of subcutaneous tissues. A **furuncle*** (boil) results when the inflammation of a single hair follicle or sebaceous gland progresses into a

* *furuncle* (fur'-unkl) *L. furunculus*, little thief.

(a) Sectional view of a boil or furuncle, a single pustule that develops in a hair follicle or gland and is the classic lesion of the species. The inflamed infection site becomes abscessed when masses of phagocytes, bacteria, and fluid are walled off by fibrin.

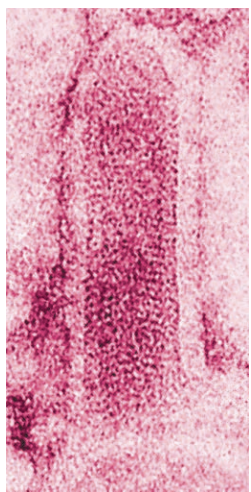

(b) Appearance of folliculitis caused by *S. aureus*. Note the clusters of inflamed papules and pustules.

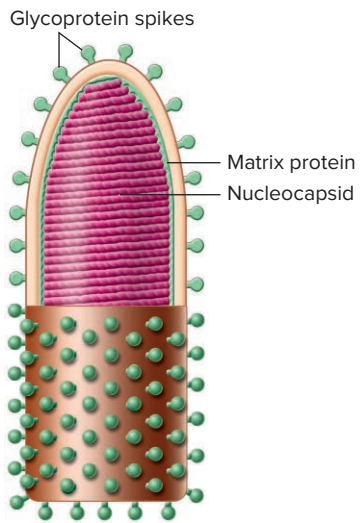

(c) An abscess on the knee caused by methicillin-resistant *Staphylococcus aureus* (MRSA).

Clinical Photos

Color photos of individuals affected by disease provide students with a real-life, clinical view of how microorganisms manifest themselves in the human body.

(a)

(b)

Combination Figures

Line drawings combined with photos give students two perspectives: the realism of photos and the explanatory clarity of illustrations. The authors chose this method of presentation often to help students comprehend difficult concepts.

The Purpose of a Student Success Learning Tool

Secret World of Microbes

The living world abounds with incredible, fascinating microbes that have yet to be discovered or completely understood. This feature enriches our coverage of the latest research discoveries and applications in the field of microbiology. Almost like reading a mystery novel, *The Secret World of Microbes* reveals little-known and surprising facts about this hidden realm.

6.1 Secret World of Microbes Seeking Your Inner Viruses

Would you be alarmed to be told that your cells carry around bits and pieces of fossil viruses? Well, we now know that they do. A fascinating aspect of the virus-host relationship is the extent to which viral genetic material becomes affixed to host chromosomes and is passed on, possibly even for millions of years. We know this from data obtained by the Human Genome Project, which sequenced all of the genetic codes on the 46 human chromosomes. While searching through the genome sequences, virologists began to find DNA they identified as viral in origin. So far they have found about 100,000 different fragments of viral DNA. In fact, over 8% of the DNA in human chromosomes comes from viruses!

These researchers are doing the work of molecular fossil hunters, locating and identifying these ancient viruses. Many of them are retroviruses that converted their RNA codes to DNA codes, inserted the DNA into a site in a host chromosome, and then became dormant and did not kill the cell. When this happened in an egg or sperm cell, the virus could be transmitted basically unchanged for hundreds of generations. One of the most tantalizing questions is what effect, if any, such retroviruses might have on modern humans. Some virologists contend that these virus genes would not have been maintained for thousands and even millions of years if they did not serve some function. Others argue that they are just genetic "garbage" that has accumulated over a long human history.

So far, we have only small glimpses of the possible roles of these viruses. One type of endogenous retrovirus has been shown to be intri-

Does this virus make us look fat?
Source: CDC

mately involved in forming the human placenta, leading microbiologists to conclude that some viruses have become an essential factor in evolution and development. Other retroviruses may be involved in diseases such as prostate cancer and chronic fatigue syndrome.

Evidence is mounting that certain viruses may contribute to human obesity. Several studies with animals revealed that chickens and mice infected with a human adenovirus (see figure) had larger fat deposits and were heavier than uninfected animals. Studies in humans show a similar association between infection with the strain of virus—called Ad-36—and an increase in adipose (fat) tissue. Although adenoviruses have usually been involved in respiratory and eye infections, they can also infect adipose cells. One of the possible explanations for this association suggests that a chronic infection with the virus allows its DNA to regulate cellular differentiation of stem cells into adipocytes (fat cells). This increase in both the number and the size of fat cells adds adipose tissue, more fat production and storage, and more body fat. Simultaneously, the adipocytes may also store more sugar, helping to keep blood sugar levels under control and maintaining insulin sensitivity to glucose. In general, such an association does not prove causation, but it certainly warrants additional research.

Using information you have learned about viruses, explain how viruses could become a permanent component of an organism's genetic material. Answer available on Connect.

Check Your Progress SECTION 13.1

1. Describe the significant relationships that humans have with microbes.
2. Explain what is meant by *microbiota* and *microbiome* and summarize their importance to humans.
3. Differentiate between contamination, colonization, infection, and disease, and explain some possible outcomes in each.
4. How are infectious diseases different from other diseases?
5. Outline the general body areas that are sterile and those regions that harbor normal resident microbiota.
6. Differentiate between...
7. Explain the factors...

6.1 Overview of Viruses

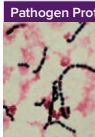

Expected Learning Outcomes

1. Indicate how viruses were discovered and characterized.
2. Describe the unique characteristics of viruses.
3. Discuss the origin and importance of viruses.

Learning Outcomes and Check Your Progress

Every numbered section in the book opens with Expected Learning Outcomes and closes with assessment questions (Check Your Progress). The Learning Outcomes are tightly correlated to digital material. Instructors can easily measure student learning in relation to the specific learning outcomes used in their course. You can also assign Check Your Progress questions to students through McGraw-Hill Connect.

Pathogen Profile #2 *Streptococcus pyogenes*

Microscopic Morphology Gram-positive cocci arranged in chains and pairs; very rarely motile; non-spore-forming.

Identified by Results of a catalase test are used to distinguish *Streptococcus* (negative) from *Staphylococcus* (positive). Beta-hemolysis and sensitivity to bacitracin are hallmarks of *S. pyogenes*. Rapid methods of identification use monoclonal antibodies to detect the C-carbohydrate found on the cell surface of *S. pyogenes*. Such tests provide accurate identification in as little as 10 minutes.

Habitat A fairly strict parasite, *S. pyogenes* is found in the throat, nasopharynx, and occasionally the skin of humans. From 5% to 15% of persons are asymptomatic carriers.

Virulence Factors *S. pyogenes* possesses several cell surface antigens that serve as virulence factors. C-carbohydrate helps prevent the bacterium from being dissolved by the lysozyme of the host; fibriniae on the outer surface of the cell enhance adherence of the bacterium; M-protein helps the cell resist phagocytosis while also improving adherence; and C5a protease catalyzes the cleavage of the C5a protein of the complement system, inhibiting the actions of complement. Most strains of *S. pyogenes* are covered with a capsule composed of hyaluronic acid

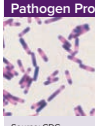

(HA) identical to the HA found in host cells, preventing an immune response by the host. Two different hemolysins, streptolysin O (SLO) and streptolysin S (SLS), cause damage to leukocytes, and liver and heart muscle, whereas erythrogenic toxin produces fever and the bright red rash characteristic of *S. pyogenes* disease. Invasion of the body is aided by several enzymes that digest fibrin clots (streptokinase), connective tissue (hyaluronidase), or DNA (streptodornase).

Primary Infections/Disease Local cutaneous infections include pyoderma (impetigo) or the more invasive erysipelas. Infection of the tonsils or pharyngeal mucous membranes can lead to streptococcal pharyngitis (strep throat), which, if left untreated, may lead to scarlet fever. Rarer infections include streptococcal toxic shock syndrome, *S. pyogenes* pneumonia, and necrotizing fasciitis. Long-term complications of *S. pyogenes* infections include rheumatic fever and acute glomerulonephritis.

Control and Treatment Control of *S. pyogenes* infection involves limiting contact between carriers of the bacterium and immunocompromised potential hosts. Patients should be isolated, and care must be taken when handling infectious secretions. As the bacterium shows little drug resistance, treatment is generally a simple course of penicillin.

Pathogen Profile #3 *Clostridium difficile*

Microscopic Morphology Gram-positive bacilli, present singly or in short chains. Endospores are subterminal and distend the cell, altering its shape.

Identified by Gram reaction and endospore formation. *Clostridium* is differentiated from *Bacillus* as the former is typically a strict anaerobe and the latter is not. ELISA is often used to detect toxins of *C. difficile* in fecal samples.

Habitat Found in small numbers as part of the normal microbiota of the intestine.

Virulence Factors Enterotoxins that cause epithelial necrosis of the colon.

Primary Infections/Disease *Clostridium difficile* infection (CDI) refers to disease caused by the overgrowth of *C. difficile*. Symptoms may range from diarrhea to inflammation of the colon, cecal perforation, and, rarely, death. Although *C. difficile* is ordinarily present in low numbers, treatment with broad-spectrum antibiotics may disrupt the normal microbiota of the colon, leading to a *C. difficile* superinfection.

Control and Treatment Mild cases generally respond to withdrawal of the antibiotic. Severe cases are treated with oral vancomycin or metronidazole, along with probiotics or fecal microbiota transplants to restore the normal microbiota.

Pathogen Profiles

Pathogen Profiles are abbreviated snapshots of the major pathogens in each disease chapter. The pathogen is featured in a micrograph, along with a description of the microscopic morphology, identification descriptions, habitat information, and virulence factors. Artwork displays the primary infections/disease, as well as the organs and systems primarily impacted.

The Framework of a Student Success Learning Tool

Pedagogy created to promote active learning

CLINICAL CONNECTIONS

An Outbreak of Fungal Meningitis

Most fungi are not invasive and do not ordinarily cause serious infections unless a patient's immune system is compromised or the fungus is accidentally introduced into sterile tissues. In 2012 we witnessed how a simple medical procedure could turn into a medical nightmare because a common, mostly harmless fungus got into the wrong place at the wrong time. It all started when a small compounding pharmacy in Massachusetts unknowingly sent out hundreds of mold-contaminated vials of medication to medical facilities for injections to control pain. These vials were sent to 23 states and used to inject the drug into the spinal columns or joints of around 14,000 patients. By the time any problems were reported, several hundred cases of infection had occurred, half of which settled in the meninges. The most drastic outcome was the deaths of 39 patients from complications of meningitis. After months of investigation, the CDC isolated a black mold, *Exserohilum rostratum*, from both the patients and the drug vials.

This mold resides in plants and soil, from which it spreads into the air and many human habitats. But it is not considered a human pathogen, and infections with it are very rare. Examination of the compounding facility uncovered negligence and poor quality controls, along with dirty preparation rooms. Mold spores were introduced during filling of the vials, and because the medication lacked preservatives, they survived and grew. The owner of the compounding pharmacy and the head pharmacist were each charged with 25 counts of second-degree murder, their trial is expected to start in late 2016.

This case drives home several important facts about fungi: (1) They can grow rapidly even in low nutrient environments; (2) just a single spore introduced into a sterile environment, whether it is a vial of medicine or the human body, can easily multiply into millions of fungal cells; and (3) even supposedly "harmless" fungi are often opportunistic, meaning that they will infect tissues "if given an opportunity." This case also emphasizes the need for zero tolerance for microbes of any kind in a drug that is being injected—such a procedure demands sterility. When you think of it, the patients were actually being inoculated in a way that assured the development of serious mycoses.

Explain how a supposedly harmless, airborne mold could get all the way into the brain and cause meningitis. Answer available on Connect.

5. A mnemonic device to keep track of this is *LEO* says *GER*: Lose Electrons Oxidized; Gain Electrons Reduced.

Footnotes

Footnotes provide the reader with additional information about the text content.

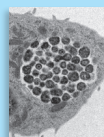

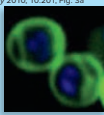

Quick Search

This feature reminds students that videos, animation, and pictorial displays that provide further information on the topic are just a "click" away using their smart-phone, tablet, or computer. This integration of learning via technology helps students become more engaged and empowered in their study of the featured topic.

Tables

This edition contains numerous illustrated tables. Horizontal contrasting lines set off each entry, making them easy to read.

TABLE 4.3 (continued)	
<p>Volume 3 Phylum Firmicutes This collection of mostly gram-positive bacteria is characterized by having a low G + C content (less than 50%). The three classes in the phylum display significant diversity, and a number of the members are pathogenic. Endospore-forming genera include <i>Bacillus</i> and <i>Clostridium</i>. Other important pathogens are found in genera <i>Staphylococcus</i> and <i>Streptococcus</i>. Although they lack a cell wall entirely, mycoplasmas (see figure 4.17) have been placed with the Firmicutes because of their genetic relatedness. (See figures H and I.)</p>	 <p>H. <i>Bacillus anthracis</i>—SEM micrograph showing the rod-shaped cells next to a red blood cell. Source: Arthur Friedlander</p>  <p>I. <i>Streptococcus pneumoniae</i>—image displays the diplococcus arrangement of this species. Source: Janice Carr/CDC</p>
<p>Volume 4 Phylum Actinobacteria This taxonomic category includes the high G + C (over 50%) gram-positive bacteria. Members of this small group differ considerably in life cycles and morphology. Prominent members include the branching filamentous Actinomycetes, the spore-bearing Streptomycetes, <i>Corynebacterium</i> (see figure 4.24), <i>Mycobacterium</i>, and <i>Micrococcus</i> (see figure 4.23a). (See figures J and K.)</p>	 <p>J. <i>Streptomyces</i> species—common soil bacteria; often the source of antibiotics. Source: Dr. David Berdi/CDC</p>  <p>K. <i>Mycobacterium tuberculosis</i>—the bacillus that causes tuberculosis. Source: Janice Carr/CDC</p>
<p>Volume 5 This represents a mixed assemblage of nine phyla, all of which are gram-negative but otherwise widely varied. The following is a selected array of examples.</p> <p>Phylum Chlamydiae Another group of obligate intracellular parasites that reproduce inside host cells. These are among the smallest of bacteria, with a unique mode of reproduction. Several species cause diseases of the eyes, reproductive tract, and lungs. An example is <i>Chlamydia</i> (figure L).</p> <p>Phylum Spirochetes These bacteria are distinguished by their shape and mode of locomotion. They move their slender, twisted cells by means of periplasmic flagella. Members live in a variety of habitats, including the bodies of animals and protozoans, fresh and marine water, and even muddy swamps. Important genera are <i>Treponema</i> (figure M) and <i>Borrelia</i> (see figure 4.23e).</p> <p>Phylum Planctomycetes This group lives in fresh and marine water habitats and reproduces by budding. Many have a stalk that they use to attach to substrates. A unique feature is having a membrane around their DNA and special compartments enclosed in membranes. This has led to the speculation that they are similar to an ancestral form that gave rise to eukaryotes. An example is <i>Gemmatimonas</i> (figure N).</p> <p>Phylum Bacteroidetes These are widely distributed gram-negative anaerobic rods inhabiting soil, sediments, and water habitats, and frequently found as normal residents of the intestinal tracts of animals. They may be grouped with related Phyla Fibrobacteres and Chlorobi. Several members play an important role in the function of the human gut and some are involved in oral and intestinal infections. An example is <i>Bacteroides</i> (figure O).</p>	 <p>L. View of an infected host cell revealing a vacuole containing <i>Chlamydia</i> cells in various stages of development. Source: N. Borel et al., "Mixed infections with <i>Chlamydia</i> and porcine epidemic diarrhea virus—a new <i>in vitro</i> model of chlamydial persistence," BMC Microbiology 2010, 10:201, Fig. 3a</p>  <p>M. <i>Treponema pallidum</i>—spirochetes that cause syphilis. Source: Joyce Ayers/CDC</p>  <p>N. <i>Gemmatimonas</i>—view of a budding cell through a fluorescent microscope (note the large blue nucleoid). Source: K.C. Lee, R. Webb, J.A. Fuerst, "The cell cycle of the planctomycete <i>Gemmatimonas obscuriglobus</i> with respect to cell compartmentalization," BMC Cell Biol. 2005, 104, Fig. 3i, NCBI</p>  <p>O. <i>Bacteroides</i> species—may cause intestinal infections. Source: V.B. Dornell/CDC</p>

*G + C base composition: The overall percentage of guanine and cytosine in DNA is a general indicator of relatedness because it is a trait that does not change rapidly. Bacteria with a significant difference in G + C percentage are less likely to be genetically related. This classification scheme is partly based on this percentage.

Scoping Out The Chapter

This new feature follows the opening case study in Chapters 1-17 and 26-27. Students are provided with a descriptive pictorial guide for the main topics covered within these respective chapters.

SCOPING OUT THE CHAPTER

Modern antimicrobial drugs have revolutionized medical treatment. Literally billions of lives have been saved since they were first introduced 80 years ago. Having an effective drug to treat most infectious diseases is now expected, whether bacterial, viral, fungal, protozoan, or helminth. Though we may take this availability for granted, there are numerous factors that complicate their use. In this chapter we will explore “the good, the bad, and the ugly” elements of antimicrobial drug therapy.

Drug Discovery Antimicrobial drugs come from many sources. Most of them, called antibiotics, are produced by certain bacteria or fungi; others are synthesized through chemical reactions alone, and some are made by combining the two methods.

Do No Harm: Selective Toxicity Antibiotic literally means “against life”, but the actual intention of these drugs is to target only microbial life. This is a very important guiding principle—that drugs do not harm humans while they are getting rid of the infectious agent.

How Antimicrobial Drugs Stop Infections Drugs are chemicals that can interfere with some specific microbial structure or function such as the cell wall, cell membrane, proteins, DNA, RNA, ribosomes, or metabolic pathways. While in contact with the drug, the microbes are either destroyed or severely inhibited and can no longer grow.

Toxicity and Other Side Effects The promise of antimicrobial therapy is spoiled by the numerous possibilities of adverse side effects. Drugs can harm body tissues and organs, disrupt the normal microbiota that help keep a balance in the body's organs, and induce allergies and hypersensitivities.

The Global Race Against Drug Resistance Microbes are very adept at rapidly altering their physiology and genetics to adapt to drugs, making them less effective. They may develop enzyme systems that dismantle the drugs, block the drug's entrance, expel the drugs, or use an alternate pathway that bypasses the drug's effects.

Choosing an Appropriate Drug Selection of an effective drug is guided by several factors. Among the most important considerations are the nature of the infectious agent, knowing which is sensitive to, the possible side effect, and the medical condition of the patient.

SCOPING OUT THE CHAPTER

We don't need to take a course in ornithology to be able to recognize the structure of a bird's wing and describe how it functions. And even when they're too far away for us to see them clearly, we can instantly know that a group of animals flying in a “V” formation is a flock of birds, not butterflies or bats. And though they are about as different as two animals could be, we all understand intuitively that a hummingbird and a turkey are related and should be grouped together. In this chapter we will gain the same type of familiarity with bacterial cells, by studying their structure, function, and evolutionary history.

Cellular Structure The chapter opens with a discussion of what makes up a prokaryotic cell. Beginning with external structures like flagella, moving to the fluid-mosaic barrier of the cell membrane, and finally to internal structures like inclusion bodies. Understanding the anatomy of a cell is key to understanding its biology.

Bacterial Shapes and Arrangements The cell wall and cytoskeleton of a bacterial cell are responsible for its shape, and correctly recognizing the shape of a cell is one of the first steps in determining its identity. The grouping of individual cells into more complex arrangements reveals a great deal about the manner in which a cell multiplies.

Classification and Unusual Bacteria The chapter continues by explaining the ways in which prokaryotic cells may be organized based on their evolutionary relationships. Finally, we introduce several examples of novel bacteria that thrive in boiling water (top left), extraordinarily high concentrations of salt (top right), or are so big that they threaten to redefine what it means to be a bacterium (bottom).

The Planning of a Student Success Learning Tool

Pedagogy designed for varied learning styles

The end-of-chapter material for the tenth edition has been carefully planned and updated to promote active learning and provide review for different learning styles and levels of Bloom's Taxonomy. Questions are divided into two levels:

Level I. Knowledge and Comprehension

Level II. Application, Analysis, Evaluation, and Synthesis

The consistent layout of each chapter allows students to develop a learning strategy and gain confidence in their ability to master the concepts, leading to success in the class!

Case Study Review

These questions provide a quick check of concepts covered by the Case Study and allow instructors to assess students on the case study material.

Writing Challenge

Writing Challenge questions are suggested as a writing experience. Students are asked to compose a one- or two-paragraph response using the factual information learned in the chapter.

End-of-Chapter Questions

Questions are divided into two levels.

Level I. Knowledge and Comprehension

These questions require a working knowledge of and the ability to recall and understand the information.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Chapter Summary with Key Terms

A brief outline of the chapter's main concepts is provided for students, with important terms highlighted. Key terms are also included in the glossary at the end of the book.

Chapter Summary with Key Terms

5.1 The History of Eukaryotes

5.2 Form and Function of the Eukaryotic Cell: External Structures

- A. The exterior configuration of eukaryotic cells is complex and displays numerous structures not found in prokaryotic cells. Biologists have accumulated much evidence that eukaryotic cells evolved through **endosymbiosis** between early prokaryotic cells.
- B. Major external structural features include: appendages (**cilia**, **flagella**), **glycocalyx**, cell wall, and cytoplasmic (or cell) membrane.

5.3 Form and Function of the Eukaryotic Cell: Internal Structures

- A. The internal structure of eukaryotic cells is compartmentalized into individual organelles.
- B. Major **organelles** and internal structural features include: **nucleus**, **nucleolus**, **endoplasmic reticulum**, **Golgi complex**, **mitochondria**, **chloroplasts**, **ribosomes**, **cytoskeleton** (**microfilaments**, **microtubules**).

5.4 Eukaryotic-Prokaryotic Comparisons and Taxonomy of

Case Study Review

1. Which of these is/are an example(s) of neglected tropical protozoan diseases?
- | | |
|-------------------|-----------------|
| a. hookworm | d. a and b |
| b. Chagas disease | e. b and c |
| c. leishmaniasis | f. all of these |

Writing Challenge

For each question, compose a one- or two-paragraph answer. Check Your Progress questions can also be used for writing.

- Describe the anatomy and functions of each of the major organelles.
- Trace the synthesis of cell products, their processing, and packaging through the organelle network.
- a. What is the reproductive potential of molds in terms of

Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with a statement.

- Both flagella and cilia are found primarily in
 - algae
 - protozoa
 - fungi
 - both b and c
- Features of the nuclear envelope include
 - ribosomes

Multiple-Choice Questions

Students can assess their knowledge of basic concepts by answering these questions and looking up the correct answers in appendix D. In addition, SmartBook allows for students to quiz themselves interactively using these questions.

The Innovation of a Student Success Learning Tool

Concept Mapping

An Introduction to Concept Mapping can be found on Connect.

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps along with concept-mapping activities for this chapter.

Critical Thinking

Using the facts and concepts they just studied, students must reason and problem solve to answer these specially developed questions. Questions do not have a single correct answer and thus open doors to discussion and application.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

1. Explain the ways that mitochondria resemble rickettsias and chloroplasts resemble cyanobacteria.
2. Give the common name of a eukaryotic microbe that is unicellular, walled, nonphotosynthetic, nonmotile, and bud-forming.
3. How are the eukaryotic ribosomes and cell membranes different from those of prokaryotes?
4. What general type of multicellular parasite is composed primarily of thin sacs of reproductive organs?
 - a. Name two parasites that are transmitted in the cyst form.
 - b. How must a non-cyst-forming pathogenic protozoan be transmitted? Why?
5. a. Name two parasites that are transmitted in the cyst form.
b. How must a non-cyst-forming pathogenic protozoan be transmitted? Why?
6. Explain what factors could cause opportunistic mycoses to be a growing medical problem.
7. a. How are bacterial endospores and cysts of protozoa alike?
b. How do they differ?
8. For what reasons would a eukaryotic cell evolve an endoplasmic reticulum and a Golgi apparatus?
9. Can you think of a simple test to determine if a child is suffering from pinworms? Hint: Clear adhesive tape is involved.

Visual Challenge

1. What term is used to describe a single species exhibiting both cell types shown below, and which types of organisms would most likely have this trait?

Visual Challenge

Visual Challenge questions take images and concepts learned in other chapters and ask students to apply that knowledge to concepts covered in the current chapter.

The Revision of a Student Success Learning Tool

Changes to Foundations in Microbiology, Tenth Edition

Overall Changes:

- A new feature “Scoping Out The Chapter” has been placed after the opening case studies. This page will give readers a descriptive pictorial guide for the main topics covered in chapters 1–17 and 26–27.
- Ten chapters (6, 7, 13, 19, 21, 22, 24, 25, 26, and 27) contain new case studies chosen for their relevance to major themes in the chapter.
- Approximately 175 new and replacement photographs have been included in the revision.
- Numerous images and figures have been revised and corrected.
- Clinical Connections boxes and side notes have a tinted screen added to set them off from the regular text. Several new Clinical Corrections boxes have been added.
- Coverage of diseases, statistics, and graphic data has been updated.
- Most chapters contain new links and quick searches for exploring topics on the internet.
- Special effort has been directed towards clarifying terms, wording, and definitions to improve understanding of more difficult concepts.

Chapter-Specific Changes:

Chapter 1

- The chapter opens with a new case study featuring microorganisms living in extreme habitats
- Epidemiology statistics have been updated throughout the chapter
- New information on the spread of chikungunya virus and Zika virus has been added
- Information concerning the ongoing pertussis epidemic has been updated
- Information on the link between microorganisms and chronic disease has been updated
- The topic of microbial evolution and classification has been updated

Chapter 2

- Discussions of the manner in which electron shells are filled and the importance of valence electrons to the formation of covalent bonds have been clarified
- The section on polymeric biomolecules (DNA, RNA, lipids, proteins, starches) has been clarified

Chapter 3

- New photos have been added to illustrate differences in resolution between light microscopes and electron microscopes
- New photos have been added to the discussions of fluorescence microscopy, electron microscopy, and selective and differential media

Chapter 4

- A new discussion and figure concerning bacterial microcompartments has been added.
- New photographs for a hyperthermophile and bacterial inclusion bodies

Chapter 5

- The case study concerning neglected tropical diseases (NTDs) has been updated to include the awarding of the 2015 Nobel Prize in Physiology or Medicine to scientists working in this area
- New tables summarize the function of structures within the eukaryotic cell
- New photos of the nucleus and mitochondria emphasize the importance of these organelles
- Update on *Pseudogymnoascus destructans*, the fungus responsible for white nose syndrome in bats

Chapter 6

- The chapter opens with a new case study focused on highly pathogenic avian influenza.
- The role of Adenovirus Ad-36 in weight gain and regulation of blood sugar levels has been updated.
- New photomicrograph of an Ebola virus budding from an infected cell

Chapter 7

- A new case study “A Creature of Habitat” describes the serious problem of cystic fibrosis and its connection with recurring *Pseudomonas* infections.
- New photographs for satellitism and an anaerobic growth chamber
- New information on biofilm formation

Chapter 8

- Addition of coenzymes to table on cofactors.
- Clarification of how the term fermentation is used under different contexts

Chapter 9

- Improved figure showing input by regulatory RNA
- Revised table on types of mutations.
- Updated box on regulatory, noncoding RNA, and riboswitches

- Improved consistency of figures for conjugation and transduction

Chapter 10

- Added details of newer DNA sequencing technologies
- Updated box on the human genome
- Revised tables on genetically-engineered animals
- New graph on genetically engineered crops
- Revised and updated Clinical Connections covering gene therapy
- The term DNA fingerprinting has been replaced with DNA profiling
- Figure on standardized DNA profiling has been revised
- Reorganized section on different uses of DNA profiling
- A note describing the gene editing technology of CRISPR has been added.

Chapter 11

- Updated case study on an outbreak of hepatitis C in a colonoscopy clinic
- Integrated historical aspects of microbial control into main text and removed Making Connections box 11.1.
- New Clinical Connections box discusses the sterilization of reusable medical devices
- Revised the box on use of triclosan, including new FDA ruling

Chapter 12

- Integrated Making connections 12.2 on discovery of drugs into main chapter
- Added a new figure on the chemical synthesis of penicillin drugs
- Included new categories of antibacterial and antiviral drugs
- Updated drug resistance box and added a new figure showing carbapenem-resistant enterobacteriaceae (CRE)

Chapter 13

- New case study “Fatal Filaments from Far Away Africa” that covers the Ebola epidemic in Africa and its spread to the United States.
- Introduced new information on the importance of the microbiome to general human physiology
- Coverage of the relationship of the placental microbiome to infant development and the development of the intestinal microbiome in newborns.
- New surveillance figures for HIV infection, pertussis, and Ebola fever.
- Updated figure on healthcare associated infections (HAI); replacing use of nosocomial infections with the more commonly used HAI

The Effort of a Student Success Learning Tool

- New visual challenge figures to differentiate among different epidemiological patterns for diseases

Chapter 14

- Added new information on the hygiene hypothesis
- Clarified figure on the actions of complement
- Removed discussion of fever from Clinical Connections box and integrated it into text

Chapter 15

- Reorganized the order of introduction of T cell and B cell actions and functions; T cells now are covered first, followed by B cells.
- Revised figure 15.1 to align with new order of coverage.
- Added side note to focus on the functions of T regulatory cells with new information on biologic drugs based on this type of T cell
- Updated the list of monoclonal antibody-based drugs and currently-approved vaccine schedules.
- Coverage of the breast microbiome and the role breast milk has in the development of the immune systems of infants.

Chapter 16

- Revised allergen count figure
- New photographs of atopic and contact dermatitis
- New photograph of blood typing
- New photograph of rheumatoid arthritis
- Illustration of child with velocardiofacial (DiGeorge) syndrome

Chapter 17

- Updated box on point-of-care testing
- New example of the direct fluorescent antibody test
- Replacement figure for rapid identification testing
- New examples of serological test results

Chapter 18

- New electron photomicrograph of methicillin-resistant *Staphylococcus aureus* has been added
- New photos of erysipelas and limb necrosis due to meningococemia
- Updated recommendations for treatment of bacterial infections
- Updated statistics on the prevalence of sexually transmitted diseases
- The discussion of meningococemia and meningitis has been clarified

Chapter 19

- The chapter opens with a new case study concerning *Listeria monocytogenes*

- New photomicrographs of *Bacillus anthracis*, *Corynebacterium diphtheriae*, and fluorescently labeled *Mycobacterium tuberculosis* have been added
- New photographs for myonecrosis, erysipeloid, the Mantoux skin test for tuberculosis, paucibacillary leprosy, multibacillary leprosy, fish tank granuloma, and actinomycosis
- Expanded and updated discussion of the use of fecal microbiota transplants as a treatment of *C-difficile* infection
- New electron micrograph of *Mycobacterium tuberculosis*, updated worldwide statistics for tuberculosis, and updated treatment recommendations for both active and latent tuberculosis
- Updated classification of leprosy to match WHO standards

Chapter 20

- New photomicrograph of *Pseudomonas aeruginosa* and new photo of cutaneous *Pseudomonas* infection
- Updated treatment recommendations for *Pseudomonas* infection, *Brucellosis*, and *Tularemia*
- New information on pertactin-deficient strains of *Bordetella pertussis*
- Updated discussion of *E. coli* pathotypes
- New section on Carbapenem-resistant Enterobacteriaceae infections
- New section on naming conventions in *Salmonella*

Chapter 21

- Chapter opens with a new case study on Q fever and live cell transplantation
- New photographs of *Coxiella burnetii*, *Treponema pallidum*, *Borrelia burgdorferi*, *Vibrio cholera*, *Campylobacter jejuni*, *Orientia tsutsugamushi*, and *Ixodes scapularis*
- Updated statistics on syphilis
- New treatment recommendations for cholera
- New photos of dental caries and oral bacteria

Chapter 22

- Case study has been updated to include the latest facts concerning the fungal meningitis outbreak connected to the New England Compounding Center
- Updates on antifungal drugs and epidemiological statistics
- New photographs of cutaneous blastomycosis, *Tinea pedis*, *Aspergillus*, and aspergillosis
- Reclassification of zygomycosis as mucormycosis

Chapter 23

- Updated drug recommendations for parasitic diseases
- New discussion on genetically engineered mosquitoes resistant to *Plasmodium sp.*
- New feature on Carlos Chagas and his importance to the field of parasitology
- The latest information about phase 3/4 trials of malaria vaccine RTS,S

Chapter 24

- The chapter begins with a new case study concerning unusual varicella zoster virus transmission
- New photos of herpes simplex type 1, neonatal herpes, and lymphocytes infected with Epstein-Barr virus
- Updated recommendations for treatment of neonatal herpes
- Update on treatment and prevention of HPV

Chapter 25

- New case study on measles and subacute sclerosing panencephalitis
- Updates include information on the Ebola outbreak of 2014–2016, the ongoing Zika virus outbreak, and widespread outbreaks of chikungunya virus
- Updated information on influenza vaccines and new chemotherapeutic treatments for influenza
- New information on the measles outbreak of 2015 along with discussion and references to online documentaries about vaccine skepticism
- Distribution maps for *Aedes* mosquitoes, the vector of dengue, chikungunya, and Zika viruses
- Feature on the *Aedes* mosquito
- Information about the recently approved vaccine to prevent dengue fever
- Updates on treatment strategies for HIV, including the use of pre-exposure prophylaxis (PrEP)

Chapter 26

- New case study on drinking water contamination as a result of harmful algae blooms
- New photos of *Rhizobium* root nodules and mycorrhizae
- New discussion concerning fracking as a potential contaminant of groundwater

Chapter 27

- New case study concerning three separate outbreaks of food poisoning

Acknowledgments

This edition marks the 24th anniversary of the first publication of *Foundations* in 1993. Looking back over the previous nine editions, the authors are struck by the extensive discoveries and new developments in the science of microbiology that are reflected in the changing content and character of this book. This 10th edition is no exception. The one thing that has remained constant and unchanging over these years is the outstanding collaboration we enjoy with the editorial and production staff at McGraw-Hill Education. This time around, we have been fortunate to have the able assistance and expertise of product developer Mandy Clark, keeping us on track and providing much needed moral support. We also appreciate the insights and contributions of brand manager Marija Magner and marketing manager Jessica Cannavo. Our project manager Jayne Klein has been an experienced and knowledgeable guide through the intricacies of a digital-style revision.

Other valued members of our team who have been instrumental in developing the text's visual elements are Carrie Burger, the content licensing specialist, Danny Meldung at Photo Affairs, and the designer Tara McDermott, who has produced another striking book and cover design. Some of the unsung heroes of authors are the

readers who must sift through the text with a fine-tooth comb, checking for errors, grammatical usage, and consistency in style. This tedious job fell this time to copy editor Wendy Nelson. After poring over 800 plus pages of text in a few months, she may feel like she has taken a crash course in microbiology.

It takes about a year and a half to complete a textbook revision—a process that involves editing manuscript, writing new text, illustration, research, and much more. During this time, the entire text and art program are inspected at least six times by the authors and team members. Even with the keenest eyes and spell checks, some typos, errors, oversights, and other mistakes may end up on the printed page. If you find any of these or wish to make other comments, feel free to contact the publisher, sales representative, or authors (ktalaro@aol.com and bxchess@Pasadena.edu.)

We hope that you enjoy your explorations in the microbial world and that this fascinating science will leave a lasting impression on you.

—*Kathy Talaro and Barry Chess*

A Note to the Student

How to Maximize Your Learning Curve

Most of you are probably taking this course as a prerequisite to nursing, dental hygiene, medicine, pharmacy, optometry, physician assistant, or other health science programs. Because you are preparing for professions that involve interactions with patients, you will be concerned with infection control and precautions, which in turn requires you to think about microbes and how to manage them. This means you must not only be knowledgeable about the characteristics of bacteria, viruses, and other microbes, and their physiology and primary niches in the world, but you must also have a grasp of disease transmission, the infectious process, disinfection procedures, and drug treatments. You will need to understand how the immune system interacts with microorganisms and the effects of immunization. All of these areas bring their own vocabulary and language—much of it new to you—and mastering it will require time, motivation, and preparation. A valid question students often ask is: “How can I learn this information to increase my success in the course as well as retain it for the future?”

Right from the first, you need to be guided by how your instructor has organized your course. Because there is more information than could be covered in one semester or quarter, your instructor will select what he or she wants to emphasize and will construct reading assignments and a study outline that corresponds to lectures and discussion sessions. Many instructors have a detailed syllabus or study guide that directs the class to specific content areas and vocabulary words. Others may have their own website to distribute assignments and even sample exams. Whatever materials are provided, this should be your primary guide in preparing to study.

The next consideration involves your own learning style and what works best for you. To be successful, you must commit essential concepts and terminology to memory. A list of how we retain information called the “pyramid of learning” has been proposed by Edgar Dale: We remember about 10% of what we read; 20% of what we hear; 50% of what we see and hear; 70% of what we discuss with others; 80% of what we experience personally; and 95% of what we teach to someone else.

There are clearly many ways to go about assimilating information. Mainly, you will want to focus on more than just reading alone to gather the most important points from a chapter. Try to incorporate writing, drawing simple diagrams, and discussion or study with others. You must attend lecture and laboratory sessions to listen to your instructors or teaching assistants explain the material. You can rewrite the notes you’ve taken during lecture, or outline them to organize the main points. This begins the process of laying down memory. You should go over concepts with others—perhaps a tutor or study group—and even take on the role of the teacher-presenter part of the time. With these kinds of interactions, you will move beyond simple rote memorization of words and will come to *understand* the ideas and be able to apply them later.

A way to assess your understanding and level of learning is to test yourself. You may use the exam questions in the text, on the Connect website, or make up your own. LearnSmart, available within the Connect site, is an excellent way to map your own, individualized learning program. It helps to track what you know, pinpoint what you don’t know, and creates personalized questions based on your progress.

Another big factor in learning is the frequency of studying. It is far more effective to spend an hour or so each day for two weeks than a marathon cramming session on one weekend. If you approach the subject in small bites and remain connected with the terminology and topics, over time it will become yours and you will find that the pieces begin to fit together. Just remember that repetition and experience are the most effective ways to acquire knowledge.

In the final analysis, the process of learning comes down to self-motivation and attitude. There is a big difference between forcing yourself to memorize something to get by and really wanting to know and understand it. Therein is the key to most success and achievement, no matter what your final goals. And though it is true that mastering the subject matter in this textbook requires time and effort, millions of students will affirm how worthwhile such knowledge has been in their professions and everyday life.

Contents

CHAPTER 1

The Main Themes of Microbiology 1

 - Formulas, Models, and Equations 38
 - Solutions: Homogeneous Mixtures of Molecules 39
 - Acidity, Alkalinity, and the pH Scale 40
- 2.4 The Chemistry of Carbon and Organic Compounds 41
 - Functional Groups of Organic Compounds 42
 - Organic Macromolecules: Superstructures of Life 43
- 2.5 Molecules of Life: Carbohydrates 43
 - The Nature of Carbohydrate Bonds 45
 - The Functions of Carbohydrates in Cells 47

- 2.6 Molecules of Life: Lipids 47
 - Membrane Lipids 47
 - Miscellaneous Lipids 48
- 2.7 Molecules of Life: Proteins 49
 - Protein Structure and Diversity 50
- 2.8 Nucleic Acids: A Program for Genetics 52
 - The Double Helix of DNA 52
 - Making New DNA: Passing on the Genetic Message 53
 - RNA: Organizers of Protein Synthesis 54
 - ATP: The Energy Molecule of Cells 54

CHAPTER 3

Tools of the Laboratory: Methods of Studying Microorganisms 60

- 3.1 Methods of Microbial Investigation 62
- 3.2 The Microscope: Window on an Invisible Realm 63
 - Magnification and Microscope Design 66
 - Variations on the Optical Microscope 66
 - Electron Microscopy 68
- 3.3 Preparing Specimens for Optical Microscopes 70
 - Fresh, Living Preparations 71
 - Fixed, Stained Smears 71
- 3.4 Additional Features of the Six "I's" 73
 - Inoculation, Growth, and Identification of Cultures 74
 - Isolation Techniques 75
 - Identification Techniques 76
- 3.5 Media: The Foundations of Culturing 78
 - Types of Media 79
 - Physical States of Media 79
 - Chemical Content of Media 80
 - Media to Suit Every Function 81

CHAPTER 4

A Survey of Prokaryotic Cells and Microorganisms 89

- 4.1 Basic Characteristics of Cells and Life Forms 90
 - What Is Life? 91
- 4.2 Prokaryotic Profiles: The Bacteria and Archaea 92
 - The Structure of a Generalized Bacterial Cell 92
 - Cell Extensions and Surface Structures 92

- 4.3 The Cell Envelope: The Outer Boundary Layer of Bacteria 99**
 Basic Types of Cell Envelopes 99
 Structure of Cell Walls 100
 Mycoplasmas and Other Cell-Wall-Deficient Bacteria 102
 Cell Membrane Structure 102
- 4.4 Bacterial Internal Structure 103**
 Contents of the Cell Cytoplasm 103
 Bacterial Endospores: An Extremely Resistant Life Form 105
- 4.5 Bacterial Shapes, Arrangements, and Sizes 107**
- 4.6 Classification Systems of Prokaryotic Domains: Archaea and Bacteria 110**
 Bacterial Taxonomy: A Work in Progress 111
- 4.7 Survey of Prokaryotic Groups with Unusual Characteristics 115**
 Free-Living Nonpathogenic Bacteria 115
 Unusual Forms of Medically Significant Bacteria 117
 Archaea: The Other Prokaryotes 118

CHAPTER 5

A Survey of Eukaryotic Cells and Microorganisms 124

- 5.1 The History of Eukaryotes 126**
- 5.2 Form and Function of the Eukaryotic Cell: External Structures 127**
 Locomotor Appendages: Cilia and Flagella 127
 The Glycocalyx 129
 Form and Function of the Eukaryotic Cell: Boundary Structures 129
- 5.3 Form and Function of the Eukaryotic Cell: Internal Structures 130**
 The Nucleus: The Control Center 130
 Endoplasmic Reticulum: A Passageway and Production System for Eukaryotes 131
 Golgi Apparatus: A Packaging Machine 132
 Mitochondria: Energy Generators of the Cell 133
 Chloroplasts: Photosynthesis Machines 133
 Ribosomes: Protein Synthesizers 134
 The Cytoskeleton: A Support Network 135
- 5.4 Eukaryotic-Prokaryotic Comparisons and Taxonomy of Eukaryotes 136**
 Overview of Taxonomy 137
- 5.5 The Kingdom of the Fungi 138**
 Fungal Nutrition 139
 Organization of Microscopic Fungi 140
 Reproductive Strategies and Spore Formation 141
 Fungal Classification 143
 Fungal Identification and Cultivation 145
 Fungi in Medicine, Nature, and Industry 145
- 5.6 Survey of Protists: Algae 146**
 The Algae: Photosynthetic Protists 146

- 5.7 Survey of Protists: Protozoa 148**
 Protozoan Form and Function 148
 Protozoan Identification and Cultivation 148
 Important Protozoan Pathogens 152
- 5.8 The Parasitic Helminths 154**
 General Worm Morphology 154
 Life Cycles and Reproduction 154
 A Helminth Cycle: The Pinworm 155
 Helminth Classification and Identification 155
 Distribution and Importance of Parasitic Worms 155

CHAPTER 6

An Introduction to Viruses 160

- 6.1 Overview of Viruses 161**
 Early Searches for the Tiniest Microbes 161
 The Position of Viruses in the Biological Spectrum 162
- 6.2 The General Structure of Viruses 163**
 Size Range 163
 Viral Components: Capsids, Nucleic Acids, and Envelopes 165
- 6.3 How Viruses Are Classified and Named 170**
- 6.4 Modes of Viral Multiplication 172**
 Multiplication Cycles in Animal Viruses 172
- 6.5 The Multiplication Cycle in Bacteriophages 177**
 Lysogeny: The Silent Virus Infection 177
- 6.6 Techniques in Cultivating and Identifying Animal Viruses 179**
 Using Cell (Tissue) Culture Techniques 180
 Using Bird Embryos 181
 Using Live Animal Inoculation 181
- 6.7 Viral Infection, Detection, and Treatment 181**
- 6.8 Prions and Other Nonviral Infectious Particles 183**

CHAPTER 7

Microbial Nutrition, Ecology, and Growth 188

- 7.1 Microbial Nutrition 190**
 Chemical Analysis of Cell Contents 190
 Forms, Sources, and Functions of Essential Nutrients 190
- 7.2 Classification of Nutritional Types 193**
 Autotrophs and Their Energy Sources 193
 Heterotrophs and Their Energy Sources 195
- 7.3 Transport: Movement of Substances Across the Cell Membrane 196**
 Diffusion and Molecular Motion 196
 The Diffusion of Water: Osmosis 197
 Adaptations to Osmotic Variations in the Environment 197
 The Movement of Solutes Across Membranes 198
 Active Transport: Bringing in Molecules Against a Gradient 199
 Endocytosis: Eating and Drinking by Cells 201

- 7.4 Environmental Factors That Influence Microbes 201**
 - Adaptations to Temperature 202
 - Gas Requirements 204
 - Effects of pH 206
 - Osmotic Pressure 206
 - Miscellaneous Environmental Factors 206
- 7.5 Ecological Associations Among Microorganisms 206**
- 7.6 The Study of Microbial Growth 212**
 - The Basis of Population Growth: Binary Fission and the Bacterial Cell Cycle 212
 - The Rate of Population Growth 212
 - Determinants of Population Growth 214
 - Other Methods of Analyzing Population Growth 216

CHAPTER 8

An Introduction to Microbial Metabolism: The Chemical Crossroads of Life 222

- 8.1 An Introduction to Metabolism and Enzymes 223**
 - Enzymes: Catalyzing the Chemical Reactions of Life 224
 - Regulation of Enzymatic Activity and Metabolic Pathways 230
- 8.2 The Pursuit and Utilization of Energy 233**
 - Cell Energetics 233
- 8.3 Pathways of Bioenergetics 236**
 - Catabolism: An Overview of Nutrient Breakdown and Energy Release 237
 - Energy Strategies in Microorganisms 237
 - Aerobic Respiration 237
 - Pyruvic Acid—A Central Metabolite 240
 - The Krebs Cycle—A Carbon and Energy Wheel 242
 - The Respiratory Chain: Electron Transport and Oxidative Phosphorylation 242
 - Summary of Aerobic Respiration 245
 - Anaerobic Respiration 245
- 8.4 The Importance of Fermentation 246**
- 8.5 Biosynthesis and the Crossing Pathways of Metabolism 249**
 - The Frugality of the Cell—Waste Not, Want Not 249
 - Assembly of the Cell 251
- 8.6 Photosynthesis: The Earth's Lifeline 251**
 - Light-Dependent Reactions 252
 - Light-Independent Reactions 253
 - Other Mechanisms of Photosynthesis 254

CHAPTER 9

An Introduction to Microbial Genetics 260

- 9.1 Introduction to Genetics and Genes: Unlocking the Secrets of Heredity 262**
 - The Nature of the Genetic Material 262
 - The Structure of DNA: A Double Helix with Its Own Language 264
 - DNA Replication: Preserving the Code and Passing It On 265

- 9.2 Applications of the DNA Code: Transcription and Translation 269**
 - The Gene-Protein Connection 270
 - The Major Participants in Transcription and Translation 271
 - Transcription: The First Stage of Gene Expression 272
 - Translation: The Second Stage of Gene Expression 273
 - Eukaryotic Transcription and Translation: Similar yet Different 275
- 9.3 Genetic Regulation of Protein Synthesis and Metabolism 278**
 - The Lactose Operon: A Model for Inducible Gene Regulation in Bacteria 278
 - A Repressible Operon 281
 - Non-Operon Control Mechanisms 282
- 9.4 Mutations: Changes in the Genetic Code 283**
 - Causes of Mutations 284
 - Categories of Mutations 284
 - Repair of Mutations 285
 - The Ames Test 285
 - Positive and Negative Effects of Mutations 286
- 9.5 DNA Recombination Events 287**
 - Transmission of Genetic Material in Bacteria 287
- 9.6 The Genetics of Animal Viruses 292**
 - Replication Strategies in Animal Viruses 292

CHAPTER 10

Genetic Engineering: A Revolution in Molecular Biology 298

- 10.1 Basic Elements and Applications of Genetic Engineering 300**
 - Tools and Techniques of DNA Technology 300
- 10.2 Recombinant DNA Technology: How to Imitate Nature 308**
 - Technical Aspects of Recombinant DNA and Gene Cloning 309
 - Construction of a Recombinant, Insertion into a Cloning Host, and Genetic Expression 310
 - Protein Products of Recombinant DNA Technology 312
- 10.3 Genetically Modified Organisms and Other Applications 313**
 - Recombinant Microbes: Modified Bacteria and Viruses 313
 - Recombination in Multicellular Organisms 315
 - Medical Treatments Based on DNA Technology 317
- 10.4 Genome Analysis: DNA Profiling and Genetic Testing 319**
 - DNA Profiling: A Unique Picture of a Genome 320

CHAPTER 11

Physical and Chemical Agents for Microbial Control 327

- 11.1 Controlling Microorganisms 329**
 - General Considerations in Microbial Control 329
 - Relative Resistance of Microbial Forms 329

- Terminology and Methods of Microbial Control 331
- What Is Microbial Death? 332
- How Antimicrobial Agents Work: Their Modes of Action 334

- 11.2 Physical Methods of Control: Heat 335**
 - Effects of Temperature on Microbial Activities 335
 - The Effects of Cold and Desiccation 338
- 11.3 Physical Methods of Control: Radiation and Filtration 340**
 - Radiation as a Microbial Control Agent 340
 - Modes of Action of Ionizing Versus Nonionizing Radiation 340
 - Ionizing Radiation: Gamma Rays, X Rays, and Cathode Rays 340
 - Nonionizing Radiation: Ultraviolet Rays 342
 - Filtration—A Physical Removal Process 342
- 11.4 Chemical Agents in Microbial Control 344**
 - Choosing a Microbicidal Chemical 344
 - Factors That Affect the Germicidal Activities of Chemical Agents 344
 - Categories of Chemical Agents 345

CHAPTER 12

Drugs, Microbes, Host—The Elements of Chemotherapy 360

- 12.1 Principles of Antimicrobial Therapy 361**
 - The Origins of Antimicrobial Drugs 361
 - Interactions Between Drugs and Microbes 364
- 12.2 Survey of Major Antimicrobial Drug Groups 370**
 - Antibacterial Drugs That Act on the Cell Wall 371
 - Antibiotics That Damage Bacterial Cell Membranes 372
 - Drugs That Act on DNA or RNA 372
 - Drugs That Interfere with Protein Synthesis 373
 - Drugs That Block Metabolic Pathways 374
- 12.3 Drugs to Treat Fungal, Parasitic, and Viral Infections 375**
 - Antifungal Drugs 375
 - Antiparasitic Chemotherapy 376
 - Antiviral Chemotherapeutic Agents 377
- 12.4 Interactions Between Microbes and Drugs: The Acquisition of Drug Resistance 381**
 - How Does Drug Resistance Develop? 381
 - Specific Mechanisms of Drug Resistance 381
 - Natural Selection and Drug Resistance 383
- 12.5 Interactions Between Drugs and Hosts 386**
 - Toxicity to Organs 386
 - Allergic Responses to Drugs 387
 - Suppression and Alteration of the Microbiota by Antimicrobials 387
- 12.6 The Process of Selecting an Antimicrobial Drug 388**
 - Identifying the Agent 388
 - Testing for the Drug Susceptibility of Microorganisms 389
 - The MIC and the Therapeutic Index 390
 - Patient Factors in Choosing an Antimicrobial Drug 391

CHAPTER 13

Microbe-Human Interactions: Infection, Disease, and Epidemiology 397

- 13.1 We Are Not Alone 399**
 - Contact, Colonization, Infection, Disease 399
 - Resident Microbiota: The Human as a Habitat 399
 - Indigenous Microbiota of Specific Regions 401
 - Colonizers of the Human Skin 403
 - Microbial Residents of the Gastrointestinal Tract 405
 - Inhabitants of the Respiratory Tract 406
 - Microbiota of the Genitourinary Tract 406
- 13.2 Major Factors in the Development of an Infection 407**
 - Becoming Established: Phase 1—Portals of Entry 409
 - The Requirement for an Infectious Dose 412
 - Attaching to the Host: Phase 412
 - Invading the Host and Becoming Established: Phase Three 412
- 13.3 The Outcomes of Infection and Disease 417**
 - The Stages of Clinical Infections 417
 - Patterns of Infection 417
 - Signs and Symptoms: Warning Signals of Disease 419
 - The Portal of Exit: Vacating the Host 420
 - The Persistence of Microbes and Pathologic Conditions 421
- 13.4 Epidemiology: The Study of Disease in Populations 421**
 - Origins and Transmission Patterns of Infectious Microbes 421
 - The Acquisition and Transmission of Infectious Agents 424
- 13.5 The Work of Epidemiologists: Investigation and Surveillance 426**
 - Epidemiological Statistics: Frequency of Cases 426
 - Investigative Strategies of the Epidemiologist 428
 - Hospital Epidemiology and Health-Care-Associated Infections 429
 - Universal Blood and Body Fluid Precautions 432

CHAPTER 14

An Introduction to Host Defenses and Innate Immunities 437

- 14.1 Overview of Host Defense Mechanisms 438**
 - Barriers at the Portal of Entry: An Inborn First Line of Defense 439
- 14.2 Structure and Function of the Organs of Defense and Immunity 441**
 - How Do White Blood Cells Carry Out Recognition and Surveillance? 441
 - Compartments and Connections of the Immune System 442
- 14.3 Second-Line Defenses: Inflammation 451**
 - The Inflammatory Response: A Complex Concert of Reactions to Injury 451
 - The Stages of Inflammation 451

- 14.4 Second-Line Defenses: Phagocytosis, Interferon, and Complement 456**
 Phagocytosis: Ingestion and Destruction by White Blood Cells 456
 Interferon: Antiviral Cytokines and Immune Stimulants 458
 Complement: A Versatile Backup System 459
 An Outline of Major Host Defenses 461

CHAPTER 15

Adaptive, Specific Immunity and Immunization 456

- 15.1 Specific Immunities: The Adaptive Line of Defense 468**
 An Overview of Specific Immune Responses 468
 Development of the Immune Response System 468
 Specific Events in T-Cell Maturation 473
 Specific Events in B-Cell Maturation 474
- 15.2 The Nature of Antigens and Antigenicity 474**
 Characteristics of Antigens and Immunogens 474
- 15.3 Immune Reactions to Antigens and the Activities of T Cells 476**
 The Role of Antigen Processing and Presentation 476
 T-Cell Responses and Cell-Mediated Immunity (CMI) 477
- 15.4 Immune Activities of B Cells 480**
 Events in B-Cell Responses 481
 Monoclonal Antibodies: Useful Products from Cancer Cells 486
- 15.5 A Classification Scheme for Specific, Acquired Immunities 486**
 Defining Categories by Mode of Acquisition 486
- 15.6 Immunization: Providing Immune Protection Through Therapy 489**
 Artificial Passive Immunization 490
 Artificial Active Immunity: Vaccination 490
 Development of New Vaccines 491
 Routes of Administration and Side Effects of Vaccines 494
 To Vaccinate: Why, Whom, and When? 495

CHAPTER 16

Disorders in Immunity 501

- 16.1 The Immune Response: A Two-Sided Coin 503**
 Overreactions to Antigens: Allergy/Hypersensitivity 503
- 16.2 Allergic Reactions: Atopy and Anaphylaxis 504**
 Modes of Contact with Allergens 504
 The Nature of Allergens and Their Portals of Entry 505
 Mechanisms of Allergy: Sensitization and Provocation 505
 Cytokines, Target Organs, and Allergic Symptoms 507
 Specific Diseases Associated with IgE- and Mast-Cell-Mediated Allergy 509
 Anaphylaxis: A Powerful Systemic Reaction to Allergens 510
 Diagnosis of Allergy 511
 Treatment and Prevention of Allergy 512

- 16.3 Type II Hypersensitivities: Reactions That Lyse Foreign Cells 513**
 The Basis of Human ABO Antigens and Blood Types 513
 Antibodies Against A and B Antigens 514
 The Rh Factor and Its Clinical Importance 515
- 16.4 Type III Hypersensitivities: Immune Complex Reactions 517**
 Mechanisms of Immune Complex Diseases 517
 Types of Immune Complex Disease 517
- 16.5 Immunopathologies Involving T Cells 518**
 Type IV Delayed-Type Hypersensitivity 518
 T Cells and Their Role in Organ Transplantation 518
 Practical Examples in Transplantation 521
- 16.6 Autoimmune Diseases: An Attack on Self 522**
 Genetic and Gender Correlation in Autoimmune Disease 522
 The Origins of Autoimmune Disease 523
 Examples of Autoimmune Disease 523
- 16.7 Immunodeficiency Diseases and Cancer: Compromised Immune Responses 524**
 Primary Immunodeficiency Diseases 525
 Secondary Immunodeficiency Diseases 527
 The Role of the Immune System 527

CHAPTER 17

Procedures for Identifying Pathogens and Diagnosing Infections 533

- 17.1 An Overview of Clinical Microbiology 535**
 Phenotypic Methods 535
 Genotypic Methods 535
 Immunologic Methods 535
 On the Track of the Infectious Agent: Specimen Collection 535
- 17.2 Phenotypic Methods 539**
 Immediate Direct Examination of Specimen 539
 Cultivation of Specimen 541
- 17.3 Genotypic Methods 541**
 DNA Analysis Using Genetic Probes 541
 Roles of the Polymerase Chain Reaction and Ribosomal RNA in Identification 542
- 17.4 Immunologic Methods 543**
 General Features of Immune Testing 543
 Agglutination and Precipitation Reactions 545
 The Western Blot for Detecting Proteins 546
 Complement Fixation 547
 Miscellaneous Serological Tests 547
 Fluorescent Antibody and Immunofluorescent Testing 548
- 17.5 Immunoassays: Tests of Great Sensitivity 549**
 Radioimmunoassay (RIA) 549
 Enzyme-Linked Immunosorbent Assay (ELISA) 550
- 17.6 Viruses as a Special Diagnostic Case 551**

CHAPTER 18

The Gram-Positive and Gram-Negative Cocci of Medical Importance 556

- 18.1 General Characteristics of the Staphylococci 557**
 Growth and Physiological Characteristics of *Staphylococcus aureus* 558
 The Scope of Staphylococcal Disease 559
 Host Defenses Against *S. aureus* 560
 Other Important Staphylococci 561
 Identification of *Staphylococcus* Isolates in Clinical Samples 562
 Clinical Concerns in Staphylococcal Infections 563
- 18.2 General Characteristics of the Streptococci and Related Genera 565**
 Beta-Hemolytic Streptococci: *Streptococcus pyogenes* 565
 Group B: *Streptococcus agalactiae* 570
 Group D Enterococci and Groups C and G Streptococci 570
 Laboratory Identification Techniques 571
 Treatment and Prevention of Group A, B, and D Streptococcal Infections 571
 Alpha-Hemolytic Streptococci: The Viridans Group 572
Streptococcus pneumoniae: The Pneumococcus 572
- 18.3 The Family Neisseriaceae: Gram-Negative Cocci 575**
Neisseria gonorrhoeae: The Gonococcus 575
Neisseria meningitidis: The Meningococcus 578
 Differentiating Pathogenic from Nonpathogenic *Neisseria* 581
 Other Genera of Gram-Negative Cocci and Coccobacilli 582

CHAPTER 19

The Gram-Positive Bacilli of Medical Importance 587

- 19.1 Medically Important Gram-Positive Bacilli 588**
- 19.2 Gram-Positive Spore-Forming Bacilli 588**
 General Characteristics of the Genus *Bacillus* 588
 The Genus *Clostridium* 592
- 19.3 Gram-Positive Regular Non-Spore-Forming Bacilli 599**
 An Emerging Food-Borne Pathogen: *Listeria monocytogenes* 599
Erysipelothrix rhusiopathiae: A Zoonotic Pathogen 600
- 19.4 Gram-Positive Irregular Non-Spore-Forming Bacilli 601**
Corynebacterium diphtheriae 601
 The Genus *Propionibacterium* 602
- 19.5 Mycobacteria: Acid-Fast Bacilli 602**
Mycobacterium tuberculosis: The Tubercle Bacillus 603
Mycobacterium leprae: The Leprosy Bacillus 608
 Infections by Nontuberculous Mycobacteria (NTM) 610
- 19.6 Actinomycetes: Filamentous Bacilli 612**
 Actinomycosis 612
 Nocardiosis 612

CHAPTER 20

The Gram-Negative Bacilli of Medical Importance 618

- 20.1 Aerobic Gram-Negative Nonenteric Bacilli 619**
Pseudomonas: The Pseudomonads 619
- 20.2 Related Gram-Negative Aerobic Rods 622**
Brucella and Brucellosis 623
Francisella tularensis and Tularemia 624
Bordetella pertussis and Relatives 624
Legionella and Legionellosis 626
- 20.3 Identification and Differential Characteristics of Family Enterobacteriaceae 627**
 Antigenic Structures and Virulence Factors 629
- 20.4 Coliform Organisms and Diseases 631**
Escherichia coli: The Most Prevalent Enteric Bacillus 631
 Miscellaneous Infections 632
 Other Coliforms 632
 Carbapenem-Resistant Enterobacteriaceae 634
- 20.5 Noncoliform Enterics 634**
 Opportunists: *Proteus* and Its Relatives 634
 True Enteric Pathogens: *Salmonella* and *Shigella* ...
Yersinia pestis and Plague 639
 Oxidase-Positive Nonenteric Pathogens in Family Pasteurellaceae 641
Haemophilus: The Blood-Loving Bacilli 642

CHAPTER 21

Miscellaneous Bacterial Agents of Disease 648

- 21.1 The Spirochetes 649**
 Treponemes: Members of the Genus *Treponema* 649
Leptospira and Leptospirosis 654
Borrelia: Arthropod-Borne Spirochetes 655
- 21.2 Curviform Gram-Negative Bacteria and Enteric Diseases 658**
 The Biology of *Vibrio cholerae* 659
Vibrio parahaemolyticus and *Vibrio vulnificus*: Pathogens Carried by Seafood 660
 Diseases of the *Campylobacter* Vibrios 661
Helicobacter pylori: Gastric Pathogen 661
- 21.3 Medically Important Bacteria of Unique Morphology and Biology 663**
 Order Rickettsiales 663
 Specific Rickettsioses 664
 Emerging Rickettsioses 666
Coxiella and *Bartonella*: Other Vector-Borne Pathogens 667
 Other Obligate Parasitic Bacteria: The Chlamydiaceae 668
- 21.4 Mollicutes and Other Cell-Wall-Deficient Bacteria 671**
 Biological Characteristics of the Mycoplasmas 671
 Bacteria That Have Lost Their Cell Walls 672

- 21.5 Bacteria in Dental Disease 672**
 The Structure of Teeth and Associated Tissues 672
 Hard-Tissue Disease: Dental Caries 673
 Plaque and Dental Caries Formation 673
 Soft-Tissue and Periodontal Disease 675
 Factors in Dental Disease 675

CHAPTER 22

The Fungi of Medical Importance 681

- 22.1 Fungi as Infectious Agents 682**
 Primary/True Fungal Pathogens 682
 Emerging Fungal Pathogens 683
 Epidemiology of the Mycoses 684
 Pathogenesis of the Fungi 684
 Diagnosis of Mycotic Infections 685
 Control of Mycotic Infections 687
- 22.2 Organization of Fungal Diseases 688**
 Systemic Infections by True Pathogens 688
- 22.3 Subcutaneous Mycoses 694**
 The Natural History of Sporotrichosis: Rose-Gardener's Disease 694
 Chromoblastomycosis and Phaeohiphomycosis: Diseases of Pigmented Fungi 694
 Mycetoma: A Complex Disfiguring Syndrome 695
- 22.4 Cutaneous Mycoses 695**
 Characteristics of Dermatophytes 696
- 22.5 Superficial Mycoses 698**
- 22.6 Opportunistic Mycoses 699**
 Infections by *Candida*: Candidiasis 699
Cryptococcus neoformans and Cryptococcosis 700
Pneumocystis jirovecii and *Pneumocystis* Pneumonia 702
 Aspergillosis: Diseases of the Genus *Aspergillus* 702
 Mucormycosis 703
 Miscellaneous Opportunists 704
- 22.7 Fungal Allergies and Intoxications 705**

CHAPTER 23

The Parasites of Medical Importance 710

- 23.1 The Parasites of Humans 711**
- 23.2 Major Protozoan Pathogens 711**
 Infective Amoebas 712
 An Intestinal Ciliate: *Balantidium coli* 715
- 23.3 The Flagellates (Mastigophorans) 716**
 Trichomonads: *Trichomonas* Species 716
Giardia intestinalis and Giardiasis 717
 Hemoflagellates: Vector-Borne Blood Parasites 717
- 23.4 Apicomplexan Parasites 722**
Plasmodium: The Agent of Malaria 722
 Coccidian Parasites 726

- 23.5 A Survey of Helminth Parasites 728**
 General Life and Transmission Cycles 728
 General Epidemiology of Helminth Diseases 729
 Pathology of Helminth Infestation 730
 Elements of Diagnosis and Control 730

- 23.6 Nematode (Roundworm) Infestations 732**
 Intestinal Nematodes (Cycle A) 732
 Intestinal Nematodes (Cycle B) 733
 Tissue Nematodes 735

- 23.7 Flatworms: The Trematodes and Cestodes 737**
 Blood Flukes: Schistosomes (Cycle D) 738
 Liver and Lung Flukes (Cycle D) 738
 Cestode (Tapeworm) Infections (Cycle C) 739

- 23.8 The Arthropod Vectors of Infectious Disease 741**

CHAPTER 24

Introduction to Viruses That Infect Humans: The DNA Viruses 749

- 24.1 Viruses in Human Infections and Diseases 750**
 Important Medical Considerations in Viral Diseases 751
 Overview of DNA Viruses 752
- 24.2 Enveloped DNA Viruses: Poxviruses 752**
 Classification and Structure of Poxviruses 752
 Other Poxvirus Diseases 754
- 24.3 Enveloped DNA Viruses: The Herpesviruses 754**
 General Properties of Herpes Simplex Viruses 755
 Epidemiology of Herpes Simplex 755
 The Spectrum of Herpes Infection and Disease 755
 The Biology of Varicella-Zoster Virus 758
 The Cytomegalovirus Group 760
 Epstein-Barr Virus 760
 Diseases of Herpesviruses 6, 7, and 8 762
- 24.4 The Viral Agents of Hepatitis 763**
 Hepatitis B Virus and Disease 764
- 24.5 Nonenveloped DNA Viruses 766**
 The Adenoviruses 766
 Papilloma- and Polyomaviruses 767
 Nonenveloped Single-Stranded DNA Viruses: The Parvoviruses 769

CHAPTER 25

The RNA Viruses That Infect Humans 774

- 25.1 Enveloped Segmented Single-Stranded RNA Viruses 775**
 The Biology of Orthomyxoviruses: Influenza 775
 Other Viruses with a Segmented Genome: Bunyaviruses and Arenaviruses 781
- 25.2 Enveloped Nonsegmented Single-Stranded RNA Viruses 781**
 Paramyxoviruses 781
 Mumps: Epidemic Parotitis 782

Measles: *Morbillivirus* Infection 783
 Respiratory Syncytial Virus: RSV Infections 785
 Rhabdoviruses 785

CASE STUDY Part 1 Microbes Find A Way

A frozen white wasteland, a toxic soup, a lunar landscape. Three fairly common descriptions of an environment so harsh—cold, toxic, or lacking nutrients—that no life can survive. Lake Whillans, a small, shallow lake trapped beneath half a mile of ice, certainly fits that description. Located 640 kilometers from the South Pole, Lake Whillans is completely encased in ice and sits at a slant, pressed against the side of a hill far below the icy surface. As heat from the core of the Earth melts the bottom of the Antarctic ice sheet, a few milliliters of liquid water are added to the lake each year.

Subglacial lakes like Lake Whillans were discovered only in the late 1990s when ice-penetrating radar and satellite measurements allowed researchers to see through the dense ice sheets that cover the polar regions of the planet. The next phase of the project was—as has been the case as long as humans have been exploring their environments—to determine what, if anything, lived in the newly discovered area. Although the immediate instinct would be to drill through the ice and sample the water in the lake, **microbial ecologists** realized that sampling Lake Whillans was not terribly different from performing surgery on a human patient; **aseptic techniques** would have to be followed so that external microbes were not allowed to contaminate the lake. Drilling equipment was **sterilized** using a combination of ultraviolet light and hydrogen peroxide, the same techniques routinely used in hospitals and laboratories, and the water used to bore through the ice was filtered to remove even the smallest microorganisms. When the drill penetrated the last of the ice, it entered the lake, which at -0.5°C was several degrees warmer than the Antarctic surface.

Over the next few days, until the drilling hole froze shut, scientists and graduate students collected 30 liters of water and several

sediment samples from the lake. Study of those samples, which continues today, reveals that Lake Whillans hosts a vibrant ecosystem. **DNA analysis** revealed nearly 4,000 different **microbial species**, and each milliliter of lake water contained more than 130,000 cells,

comparable to what one finds in the deepest oceans. The biggest difference between life in Lake Whillans and ecosystems found on the surface of the planet is the lack of sunlight. In terrestrial lakes **photosynthetic microorganisms** use the energy in sunlight to convert dissolved carbon dioxide into sugars. Because sunlight can't penetrate the half mile of ice covering Lake Whillans,

many of the microbes in the lake derive energy from the oxidation of iron, sulfur, or ammonium compounds, a strategy used by some deep-sea bacteria. If it turns out, as many scientists believe, that the microorganisms in Lake Whillans supply minerals and nutrients to the surrounding ocean, then this small, dark, cold, invisible lake may have a tremendous effect on the ecosystem surrounding it. Not bad for a frozen wasteland.

- *One of the environmental pressures microorganisms from Lake Whillans had to adapt to was the ability to grow in very cold temperatures. What were several other environmental challenges these microbes faced?*
- *What fields of microbiology were used to initially study these microbes, and what fields could be involved in the further study of the isolated cells?*

“It’s the first time we’ve gotten a real insight into what organisms might live beneath the Antarctic continent.”

David Pearce, a microbiologist at Northumbria University, UK

To continue this Case Study, go to Case Study Part 2 at the end of the chapter.

SCOPING OUT THE CHAPTER

Microbiology is sometimes regarded as an esoteric science, concerned primarily with keeping the milk fresh and getting everyone to wash their hands. In fact, microbiology encompasses a number of interrelated disciplines, a rich history, and more organisms than any other branch of biology. In this chapter you'll get a quick tour of the field.

The Fields of Microbiology

Not every microbiologist works in a lab. Making cheese, wine and bread all rely on a knowledge of microbiology.

The Power of Microbiology

The vats here contain algae that are producing oil through photosynthesis, a potentially endless source of clean energy.

The Evolution of Microorganisms

All life on Earth has evolved from simple microbial cells. Evolutionary trees display the relationship between simpler and more complex organisms.

The Organisms of Microbiology

The vast majority of microorganisms pose no risk to humans. Some however, like certain strains of the bacterium *Staphylococcus aureus*, not only cause severe disease, but are resistant to almost all the drugs commonly used to fight them.

The History of Microbiology

The period from 1850 to 1950 is sometimes known as the **Golden Age of Microbiology**, when people like Louis Pasteur invented the very science of microbiology itself. The recent advent of powerful molecular biology techniques has caused many scientists to view the current era as a second Golden Age.

1.1 The Scope of Microbiology

Expected Learning Outcomes

1. Define *microbiology* and *microorganisms*, and identify the major organisms included in the science of microbiology.
2. Name and define the primary fields included in microbiological studies.

As we observe the natural world, teeming with life, we cannot help but be struck by its beauty and complexity. But for every feature that is visible to the naked eye, there are millions of other features that are concealed from our sight by their small size. This alternate microscopic universe is populated by a vast microbial menagerie that is equally beautiful and complex. To sum up the presence of microbes in one word, they are **ubiquitous**.^{*} They are found in all

^{*} *ubiquitous* (yoo-bik'-wih-tis) L. *ubique*, everywhere and *ous*, having. Being, or seeming to be, everywhere at the same time.

natural habitats and most of those that have been created by humans. As scientists continue to explore remote and unusual environments, the one kind of entity they always find is microbes. These exist deep beneath the polar ice caps, in the ocean to a depth of 7 miles, in hot springs and thermal vents, in toxic waste dumps, and even in the clouds.

Microbiology is a specialized area of biology that deals with tiny life forms that are not readily observed without magnification, which is to say they are **microscopic**.^{*} These microscopic organisms are collectively referred to as **microorganisms, microbes**,^{*} or several other terms, depending upon the purpose. Some people call them “germs” or “bugs” in reference to their role in infection and disease, but those terms have other biological meanings and perhaps place undue emphasis on the disagreeable reputation of microorganisms. The major groups of microorganisms included in this study are **bacteria, viruses, fungi, protozoa, algae, and helminths** (parasitic worms). As we will see in subsequent chapters, each group exhibits a distinct collection of biological characteristics. The nature of microorganisms makes them both easy and difficult to study. Easy, because they reproduce so rapidly and can usually be grown in large numbers in the laboratory. Difficult, because we can't observe or analyze them without special techniques, especially the use of microscopes (see chapter 3).

Microbiology is one of the largest and most complex of the biological sciences because it integrates subject matter from many diverse disciplines. Microbiologists study every aspect of microbes—their genetics, their physiology, characteristics that may be harmful or beneficial, the ways they interact with the environment, the ways they interact with other organisms, and their uses in industry and agriculture.

See **table 1.1** for an overview of some fields and occupations that involve basic study or applications in microbiology. Each major discipline in microbiology contains numerous subdivisions or specialties that deal with a specific subject area or field (table 1.1). In fact, many areas of this science have become so specialized that it is not uncommon for a microbiologist to spend an entire career concentrating on a single group or type of microbe, biochemical process, or disease.

The specialty professions of microbiology include:

- geomicrobiologists, who focus on the roles of microbes in the development of earth's crust (table 1.1B);
- marine microbiologists, who study the oceans and its smallest inhabitants;
- medical technologists, who do the tests that help diagnose pathogenic microbes and diseases associated with them;
- nurse epidemiologists, who analyze the occurrence of infectious diseases in hospitals; and
- astrobiologists, who study the possibilities of organisms in space (see the Case Study for chapter 2).

Studies in microbiology have led to greater understanding of many general biological principles. For example, the study of microorganisms established universal concepts concerning the chemistry of life (see chapters 2 and 8), systems of inheritance (see

chapter 9), and the global cycles of nutrients, minerals, and gases (see chapter 26).

1.2 General Characteristics of Microorganisms and Their Roles in the Earth's Environments

Expected Learning Outcomes

3. Describe the basic characteristics of prokaryotic cells and eukaryotic cells and their evolutionary origins.
4. State several ways that microbes are involved in the earth's ecosystems.
5. Describe the cellular makeup of microorganisms and their size range, and indicate how viruses differ from cellular microbes.

The Origins and Dominance of Microorganisms

For billions of years, microbes have extensively shaped the development of the earth's habitats and influenced the evolution of other life forms. It is understandable that scientists searching for life on other planets first look for signs of microorganisms.

The fossil record uncovered in ancient rocks and sediments points to bacteria-like cells having existed on earth for at least 3.5 billion years (**figure 1.1**). Early microorganisms of this type dominated the earth's life forms for the first 2 billion years. These ancient cells were small and simple, and lacked specialized internal structures to carry out their functions. It is apparent that genetic material of these cells was not bound into a separate compartment called a nucleus or “karyon.” The term assigned to cells and microbes of this type is **prokaryotic**,^{*} meaning “before the nucleus.” About 1.8 billion years ago, there appeared in the fossil record a more complex cell, which had developed a nucleus and various specialized internal structures called **organelles**.^{*} These types of cells and organisms are defined as **eukaryotic**^{*} in reference to their “true” nucleus. **Figure 1.2** compares the two cell types and includes some examples of viruses for comparison. In chapter 5 we will learn more about the origins of eukaryotic cells—they didn't arise suddenly out of nowhere; they evolved over millennia from prokaryotic cells through an intriguing process called endosymbiosis. The early eukaryotes, probably similar to algae and protozoa, started lines of evolution that eventually gave rise to fungi, plants, and multicellular animals such as worms and insects. You can see from figure 1.1 how long that took! The bacteria preceded even the earliest animals by about 3 billion years. This is a good indication that humans are not likely to, nor should we try to, eliminate microorganisms from our environment. Having existed for eons, they are absolutely essential for maintaining the planet's life-giving characteristics.

^{*} *prokaryotic* (proh'-kar-ee-ah'-tik) Gr. *pro*, before, and *karyon*, nucleus. Sometimes spelled procaryotic.

^{*} *organelles* (or-gan'-elz) Gr. *organa*, tool, and *ella*, little.

^{*} *eukaryotic* (yoo'-kar-ee-ah'-tik) Gr. *eu*, true or good, and *karyon*, nucleus. Sometimes spelled eucaryotic.

^{*} *microscopic* (my'-kroh-skaw'-pik) Gr. *mikros*, small, and *scopein*, to see.

^{*} *microbe* (my'-krohbb) Gr. *mikros*, small, and *bios*, life.

TABLE 1.1 A Sampling of Fields and Occupations in Microbiology**A. Public Health Microbiology and Epidemiology**

These branches monitor and control the spread of diseases in communities. Some of the institutions charged with this task are the U.S. Public Health Service (USPHS) and the Centers for Disease Control and Prevention (CDC). The CDC collects information and statistics on diseases from around the United States and publishes it in a newsletter, *The Morbidity and Mortality Weekly Report* (see chapter 13).

C. Biotechnology and Industrial Microbiology

This branch is defined by any process that harnesses the actions of living things to derive a desired product, ranging from beer to stem cells. It includes industrial microbiology, which uses microbes to produce and harvest large quantities of such substances as vaccines, vitamins, drugs, and enzymes (see chapters 10 and 27).

A technician tests the effectiveness of microorganisms in the production of new sources of energy.

E. Genetic Engineering and Recombinant DNA Technology

These interrelated fields involve deliberate alterations of the genetic makeup of organisms to create novel microbes, plants, and animals with unique behavior and physiology. This is a rapidly expanding field that often complements biotechnology (see chapter 10).

H. Branches of Microbiology

Branch	Chapter	Involved in the Study of:
Bacteriology	4	The bacteria—small single-celled prokaryotic organisms
Mycology	5, 22	The fungi, a group of eukaryotes that includes both microscopic eukaryotes (molds and yeasts) and larger organisms (mushrooms, puffballs)
Protozoology	5, 23	The protozoa—animal-like and mostly single-celled eukaryotes
Virology	6, 24, 25	Viruses—minute, noncellular particles that parasitize cells
Parasitology	5, 23	Parasitism and parasitic organisms—traditionally including pathogenic protozoa, helminth worms, and certain insects
Phycology or Algology	5	Simple photosynthetic eukaryotes, the algae, ranging from single-celled forms to large seaweeds
Morphology	4, 5, 6	The detailed structure of microorganisms
Physiology	7, 8	Microbial function (metabolism) at the cellular and molecular levels
Taxonomy	1, 4, 5, 17	Classification, naming, and identification of microorganisms
Microbial Genetics, Molecular Biology	9, 10	The function of genetic material and biochemical reactions that make up a cell's metabolism
Microbial Ecology	7, 26	Interrelationships between microbes and the environment; the roles of microorganisms in the nutrient cycles and natural ecosystems

A medical microbiologist tests specimens for evidence of antibodies to the human immunodeficiency virus (HIV).

Source: James Gathany/CDC

Figure 1.1 Evolutionary time line. The first simple prokaryotes appeared on earth approximately 3.5 billion years ago, and the first eukaryotes arose about 2 billion years ago. Although these appearances seem abrupt, hundreds of millions of years of earth's history passed while they were evolving to these stages. The fossil record for these periods is incomplete because many of the earliest microbes were too delicate to fossilize.

Source: NASA

The Cellular Organization of Microorganisms

As a general rule, prokaryotic cells are smaller than eukaryotic cells, and in addition to lacking a nucleus, they lack organelles, which are structures in cells bound by one or more membranes. Examples of organelles include the mitochondria and Golgi

complexes, and several others, which perform specific functions such as transport, feeding, energy release and use, and synthesis. Prokaryotes perform similar functions, but they lack dedicated organelles to carry them out (figure 1.2).

The body plan of most microorganisms consists of a single cell or clusters of cells (**figure 1.3**). All prokaryotes are microorganisms,

(a) Basic cell types

(b) Examples of viruses

Figure 1.2 Basic structure of cells and viruses. (a) Comparison of a prokaryotic cell and a eukaryotic cell. (b) Two examples of viruses. These cell types and viruses are discussed in more detail in chapters 4, 5, and 6.

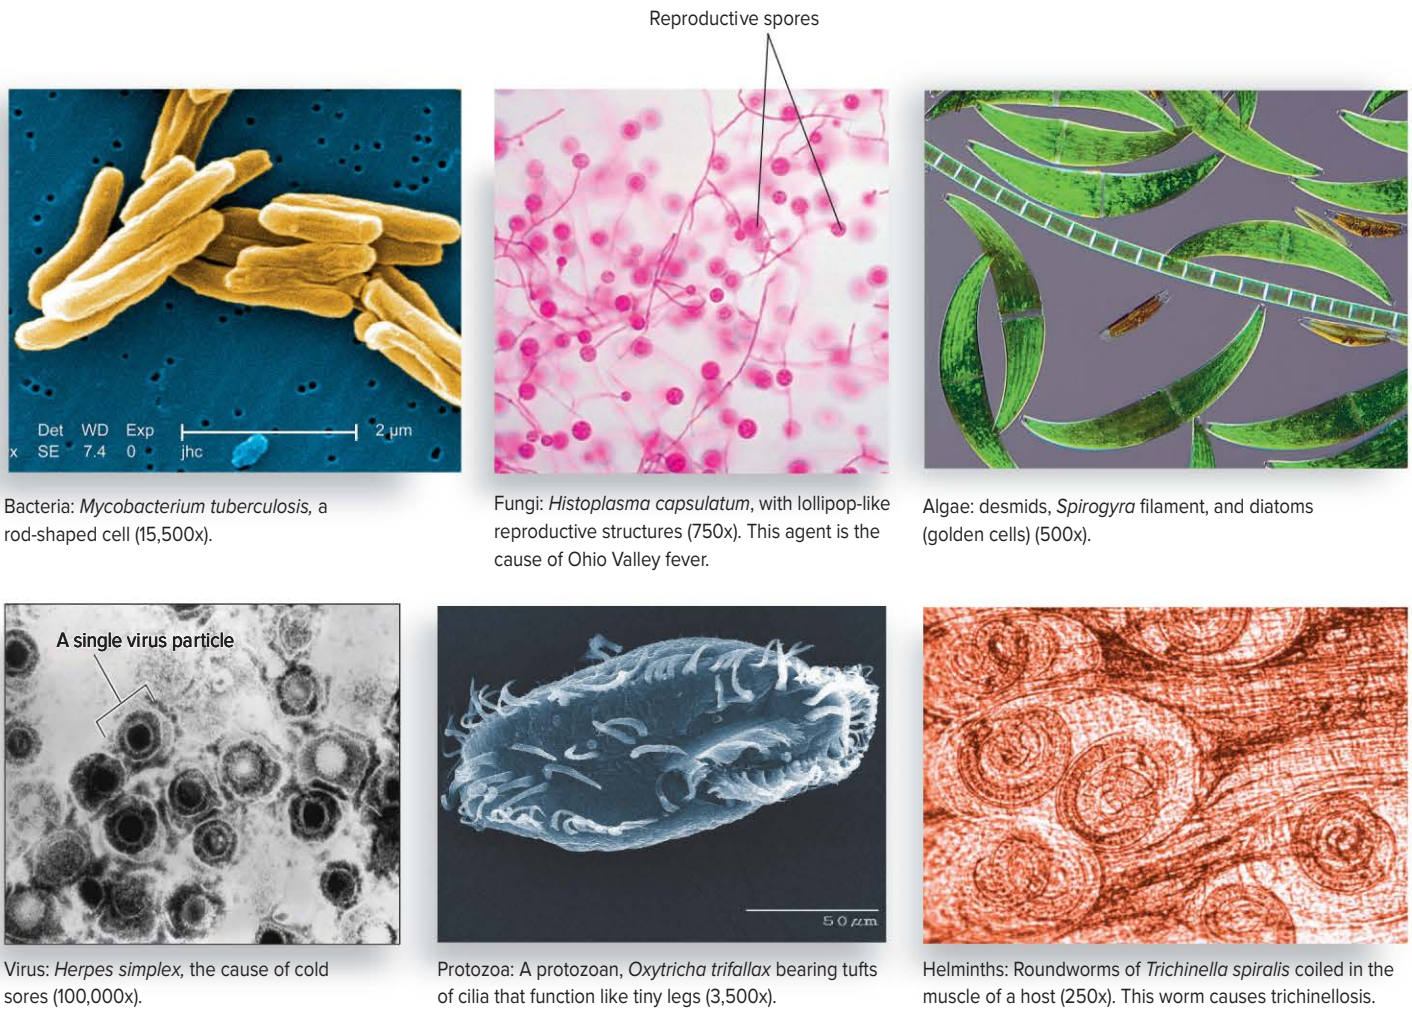

Figure 1.3 The six basic types of microorganisms. Organisms are not shown at the same magnifications; approximate magnification is provided. To see these microorganisms arrayed more accurately to scale, look for them in figure 1.4. (bacteria): Source: Janice Carr/CDC; (fungi): Source: Dr. Libero Ajello/CDC; (algae): © Charles Krebs Photography; (virus): Source: CDC; (protozoa): Source: National Human Genome Research Institute; (helminths): Source: CDC

and they include the bacteria and archaea (see figure 1.14). Only some of the eukaryotes are microorganisms: primarily algae, protozoa, molds and yeasts (types of fungi), and certain animals such as worms and arthropods. Not all members of these last two groups are microscopic, but certain members are still included in the study of microbiology because worms can be involved in infections and may require a microscope to identify them. Some arthropods such as fleas and ticks may also be carriers of infectious diseases. Additional coverage on cell types and microorganisms appears in chapters 4 and 5.

Where Do the Viruses Fit?

Viruses are considered one type of microbe because they are microscopic and can cause infections and disease, but they are not cells. They are small particles that exist at a level of complexity somewhere between large molecules and cells (see figure 1.4). Viruses are much simpler than cells; they are

composed essentially of a small amount of hereditary material wrapped up in a protein covering. Some biologists refer to viruses as parasitic particles; others consider them to be very primitive organisms. Despite this slight disagreement, the impact of viruses is undeniable. Not only are they the most common microbes on earth, but they invade their hosts' cells and can inflict serious damage and death.

An adenovirus

Microbial Dimensions: How Small Is Small?

When we say that microbes are too small to be seen with the unaided eye, what sorts of dimensions are we talking about? This concept is best visualized by comparing microbial groups with some organisms of the macroscopic world and also with the molecules and atoms of the molecular world (**figure 1.4**). The dimensions

Figure 1.4 The sizes of the smallest organisms and objects. Even though they are all very small, they still display extensive variations in size. This illustration organizes the common measurements used in microbiology along with examples of organisms or items that fall into these measurement ranges. The scale includes macroscopic, microscopic, ultramicroscopic, and atomic dimensions. Most microbes we study measure somewhere between 100 micrometers (μm) and 10 nanometers (nm) overall. The examples are more or less to scale within a size zone but not between size zones. (roundworm): Source: CDC; (fungus): © Dennis Kunkel Microscopy, Inc./Phototake; (protozoan): Source: National Human Genome Research Institute; (algae): © Charles Krebs Photography; (mold spores): Dr. Libero Ajello/CDC; (spirochete): Source: CDC; (rods, cocci): Source: Janice Carr/CDC; (herpesvirus): Source: CDC; (range of eye): Source: Berkeley Lab - Roy Kaltschmidt, photographer; (range of light microscope): Source: Rhoda Baer (photographer)/National Cancer Institute; (range of electromicroscope): Source: Pacific Northwest National Laboratory

of macroscopic organisms are usually given in centimeters (cm) and meters (m), whereas those of most microorganisms fall within the range of micrometers (μm) and, sometimes, nanometers (nm) and millimeters (mm). The size range of most microbes extends from the smallest viruses, measuring around 10 nm and actually not much bigger than a large molecule, to protozoans measuring 3 to 4 mm and visible with the naked eye.

Microbial Involvement in Energy and Nutrient Flow

The microbes in all natural environments have lived and evolved there for billions of years. We do not yet know all of their roles, but it is likely they are vital components of the structure and function of these ecosystems.

Microbes are deeply involved in the flow of energy and food through the earth's ecosystems.¹ Most people are aware that plants carry out **photosynthesis**, which is the light-fueled conversion of carbon dioxide to organic material, accompanied by the formation of oxygen. But microorganisms were photosynthesizing long before the first plants appeared. In fact, they were responsible for changing the atmosphere of the earth from one without oxygen to one with oxygen. Today photosynthetic microorganisms (including algae) account for more than 50% of the earth's photosynthesis, contributing the majority of the oxygen to the atmosphere (**figure 1.5a**).

Another process that helps keep the earth in balance is the process of biological **decomposition** and nutrient recycling. Decomposition involves the breakdown of dead matter and wastes into simple compounds that can be directed back into the natural cycles of living things (**figure 1.5b**). If it were not for multitudes of bacteria and fungi, many chemical elements would become locked up and unavailable to organisms. In the long-term scheme of things, microorganisms are the main forces that drive the structure and content of the soil, water, and atmosphere. For example:

- Earth's temperature is regulated by "greenhouse gases," such as carbon dioxide and methane, that create an insulation layer in the atmosphere and help retain heat. A significant proportion of these gases is produced by microbes living in the environment and in the digestive tracts of animals.
- Recent estimates propose that, based on weight and numbers, up to 50% of all organisms exist within and beneath the earth's crust in soil, rocks, and even the frozen Antarctic (**figure 1.5c**). It is increasingly evident that this enormous underground community of microbes is a major force in weathering, mineral extraction, and soil formation.
- Bacteria and fungi live in complex associations with plants. They assist the plants in obtaining nutrients and water and may protect them against disease. Microbes form similar interrelationships with animals, notably as residents of numerous bodily sites.

(a)

(b)

(c)

Figure 1.5 A microscopic wonderland. (a) A summer pond is heavily laden with surface scum that reveals several different types of green algae called desmids (600 \times). (b) A rotting tomato being invaded by a fuzzy forest of mold. The fungus is *Botrytis*, a common decomposer of tomatoes and grapes (250 \times). (c) Even a dry lake in Antarctica, one of the coldest places on earth (-35°C), can harbor microbes under its icy sheet. Here we see a red cyanobacterium, *Nostoc* (3,000 \times), that has probably been frozen in suspended animation there for 3,000 years. Like the example discussed in the chapter-opening case study, this environment may serve as a model for what may one day be discovered on other planets. 1. Ecosystems are communities of living organisms and their surrounding environment.

Check Your Progress SECTIONS 1.1–1.2

1. Define what is meant by the term *microorganism* and outline the important contributions microorganisms make to the earth's ecosystems.
2. Describe five different ways in which humans exploit microorganisms for our benefit.
3. Identify the groups of microorganisms included in the scope of microbiology, and explain the criteria for including these groups in the field of microbiology.
4. Observe figure 1.3 and place the microbes pictured there in a size ranking, going from smallest to largest. Use the magnification as your gauge.
5. Construct a table that displays all microbial groups based on what kind of cells they have or do not have.
6. Explain this statement: Microorganisms—we need to live with them because we can't live without them.

(a)

(b)

Figure 1.6 Microbes at work. (a) A scientist from the National Oceanic and Atmospheric Agency (NOAA) demonstrates a series of biodiesel reactors that culture single-celled algae (inset 750x) as a source of oil. This new “green” renewable energy source looks very promising. (b) Biotechnology meets bioremediation. Scientists at Pacific Northwest National Laboratories (PNNL) test the capacity of two newly discovered bacteria—*Shewanella* (green) and *Synechococcus* (yellow) (1,000x)—to reduce and detoxify radioactive waste. The process, carried out in large bioreactors, could speed the cleanup of hazardous nuclear waste deposits. (a): Source: Christopher Botnick/NOAA; (a, inset): © Yuuji Tsukii, Protist Information Server; (b & b, inset): Source: Pacific Northwest National Laboratory

techniques have also paved the way for characterizing human genetic material and diseases.

Another way of tapping into the unlimited potential of microorganisms is the relatively new science of **bioremediation**.* This process introduces microbes into the environment to restore stability or to clean up toxic pollutants. Bioremediation is required to control

1.3 Human Use of Microorganisms

Expected Learning Outcome

6. Discuss the ways microorganisms can be used to create solutions for environmental problems and industrial products.

The incredible diversity and versatility seen in microbes make them excellent candidates for solving human problems. By accident or choice, humans have been using microorganisms for thousands of years to improve life and even to further human progress. Yeasts, a type of microscopic fungi, cause bread to rise and ferment sugar to make alcoholic beverages. Historical records show that households in ancient Egypt kept moldy loaves of bread to apply directly to wounds and lesions, which was probably the first use of penicillin! The manipulation of microorganisms to make products in an industrial setting is called **biotechnology**.* One newer application of this process uses farmed algae to extract a form of oil (biodiesel) to be used in place of petroleum products (**figure 1.6a**).

Genetic engineering is a newer area of biotechnology that manipulates the genetics of microbes, plants, and animals for the purpose of creating new products and genetically modified organisms. One powerful technique for designing new organisms is termed **recombinant DNA**. This technology makes it possible to deliberately alter DNA² and to switch genetic material from one organism to another. Bacteria and fungi were some of the first organisms to be genetically engineered, because their relatively simple genetic material is readily manipulated in the laboratory. Recombinant DNA technology has unlimited potential in terms of medical, industrial, and agricultural uses. Microbes can be engineered to synthesize desirable proteins such as drugs, hormones, and enzymes (see table 1.1C).

Among the genetically unique organisms that have been designed by bioengineers are bacteria that contain a natural pesticide, yeasts that produce human hormones, pigs that produce hemoglobin, and plants that are resistant to disease (see table 1.1E). The

* **biotechnology** (by'-oh-tek-nol''-oh-gee) The use of microbes or their products in the commercial or industrial realm.

2. DNA, or deoxyribonucleic acid, the chemical substance that comprises the genetic material of organisms.

* **bioremediation** (by'-oh-ree-mee-dee-ay''-shun) *bios*, life; *re*, again; *mederi*, to heal. The use of biological agents to remedy environmental problems.

the massive levels of pollution that result from human activities. Microbes have a surprising capacity to break down chemicals that would be harmful to other organisms. Agencies and companies have developed microbes to handle oil spills and detoxify sites contaminated with heavy metals, pesticides, and even radioactive wastes (**figure 1.6b**). The solid waste disposal industry is focusing on methods for degrading the tons of garbage in landfills, especially plastics and paper products. One form of bioremediation that has been in use for some time is the treatment of water and sewage. With clean freshwater supplies dwindling worldwide, it will become even more important to find ways to reclaim polluted water.

1.4 Microbial Roles in Infectious Diseases

Expected Learning Outcomes

- Review the roles of microorganisms as parasites and pathogens that cause infection and disease.
- Define what is meant by emerging and reemerging diseases.

It is important to remember that the large majority of microorganisms are relatively harmless, have quantifiable benefits to humans and the environment, and in many cases are essential to life as we know it. They are free living, and derive everything they need to survive from the surrounding environment. Much of the time they form cohesive communities with other organisms, sharing habitat and nutrients. Examples include the natural partnerships that are found in symbioses and biofilms.³

Some microbes have adapted to a non-free-living lifestyle called parasitism. A **parasite** lives in or on the body of a larger organism called the **host** and derives most of its sustenance from that host. A parasite's actions generally damage the host through infection and disease. Another term that can be used to specify this type of microbe is **pathogen**.*

Humanity is plagued by nearly 2,000 different pathogens that can cause various types of disease. Infectious diseases still devastate human populations worldwide, despite significant strides in understanding and treating them. The most recent estimates from the World Health Organization (WHO) point to around 10 billion infections of all types across the world every year. There are more infections than people because many people acquire more than one infection. Infectious diseases are also among the most common causes of death in much of humanity, and they still kill a significant percentage of the U.S. population. The worldwide death toll from infections is about 13 million people per year, and 90% of the deaths are caused by just six infectious agents. **Table 1.2** illustrates the toll of some common infectious diseases, while **figure 1.7** compares the death rate among four groups from around the world that differ significantly in socioeconomic levels. It is quite evident which world inhabitants suffer the most from infectious diseases. **Table 1.3** displays the number of people affected by what are commonly known as neglected tropical diseases (NTDs), a collection of conditions that thrive among the worlds

3. A biofilm is a complex network of microbes and their secretions that form in most natural environments, discussed further in chapter 4.

* **pathogen** (path'-oh-jen) Gr. *pathos*, disease, and *gennan*, to produce. Disease-causing agents.

TABLE 1.2 Worldwide Morbidity and Mortality of Common Diseases*

Disease	New Cases per Year	Deaths per Year
Influenza	3–5 million cases of severe illness	250,000–500,000
Typhoid fever	21,000,000	200,000
Measles	20,000,000	145,700
HIV/AIDS	2,300,000	1,500,000
Dengue fever	96,000,000	22,000
Shigellosis	80,000,000–165,000,000	600,000
Viral hepatitis (A and B)	380,000,000	1,280,000
Malaria	200,000,000	627,000
Tuberculosis	9,000,000**	1,500,000

*Estimates from most recent CDC and World Health Organization statistics.

**As many as 2,000,000,000 people are believed to carry the tuberculosis bacterium, most as long-term carriers.

Source: Data from World Health Organization

Figure 1.7 Chart comparing the major causes of death, by world socioeconomic levels. The relationship between income and rate of death from infectious diseases is most evident in this comparison. What other correlations can we make from these data?

TABLE 1.3 Neglected Tropical Diseases

Disease	Number of Cases
Ascariasis	1,000,000,000
Hookworm infection	700,000,000
Onchocerciasis (river blindness)	26,000,000
Lymphatic filariasis	120,000,000
Schistosomiasis	240,000,000
Trachoma	41,000,000
Trichuriasis	800,000,000

1.1 MAKING CONNECTIONS

The Changing Spectacle of Infectious Diseases

The middle of the last century was a time of great confidence in science and medicine. The introduction of antibiotics in the 1940s and a lengthening list of vaccines for preventing numerous diseases caused many medical experts to declare victory. For a short time there was a sense that infectious diseases were going to be completely manageable. But this optimistic viewpoint was on a collision course with a vast army of very tiny invaders that are everywhere—namely, microorganisms. Because humans are constantly interacting with microbes, we serve as a handy incubator for infectious diseases, both those newly recognized and older ones previously identified.

Altogether, government agencies are keeping track of more than 100 emerging and reemerging infectious diseases. The newer or emerging diseases usually erupt suddenly with no warning (Middle East respiratory syndrome). Older or reemerging diseases demonstrate just how difficult it is to eradicate microbes and the diseases they cause, even though we are very aware of them and often have drugs and vaccines to combat them. Only smallpox has been completely eliminated, although we are very close to eradicating polio. In fact, we continue to experience epidemics of childhood diseases that are usually preventable with vaccines. Starting in 2010, pertussis (whooping cough) cases began to increase dramatically over the next 2 years, and even though the increase subsided, the number of cases remained nearly double their pre-2010 levels. Some communities recorded the highest rates of pertussis in decades, even though children were being vaccinated. It now appears that the vaccine's effectiveness wears off and may require additional inoculations to create adequate protection.

What are some of the reasons for this dilemma with our microbial cohabitants? A major contributing factor is our increased mobility and travel, especially by air—an infected person can travel around the world before showing any symptoms of infection, carrying the infectious agent to many far-flung locations and exposing populations along the way, who in turn can infect their contacts. A second factor is the spread of diseases by vectors, living organisms such as fleas, ticks, or mosquitoes. Emerging viruses like chikungunya, dengue, and Zika are all spread by the *Aedes* mosquito, which is so aggressive it routinely follows people indoors to partake of a blood meal (see figure).

Other significant effects involve our expanding population and global food-growing practices. As we continue to encroach into new territory and wild habitats, there is potential for contact with emerging pathogens, as we saw with Ebola fever, Lyme disease, and hantavirus pulmonary syndrome. Our agricultural practices can unearth microbes that were lying dormant or hidden. A bacterium carried in the intestine of domestic cattle, *Escherichia coli* O157:H7, the agent of a serious kidney disease, has been associated with hundreds of thousands of infections from food and water contami-

nated with cattle feces. Much mass-produced fresh food can also travel around the world, infecting people along the way. Several large outbreaks of salmonellosis, shigellosis, and listeriosis have been traced to contaminated dairy and poultry products, and vegetables. In some areas of the world, farmers knowingly or unknowingly use fecally contaminated water and fertilizer on fresh produce that will be on your table the next week.

Then there is the matter of the incredible resistance of microbes. You know about their capacity to live where no other living things could—volcanoes, salt lakes, radioactive waste pits—so it has not been a surprise to discover how readily they can adapt to drugs we use to treat them. The emergence of drug-resistant “superbugs” has become a massive problem in medicine. Some forms of *Staphylococcus aureus* (MRSA) and *Mycobacterium tuberculosis* are resistant to so many drugs that there are few, and sometimes no, treatment choices left.

As hard as we may try to manage microbes, we keep coming up against a potent reality, a sentiment summed up by the renowned microbiologist Louis Pasteur over 130 years ago when he declared: “Microbes will have the last word.”

Why is it unlikely that infectious diseases can ever be completely eradicated? Answer available on Connect.

The *Aedes aegypticus* mosquito is the vector for several emerging viral diseases. In this female mosquito, feeding on her photographer, blood can clearly be seen within the fascicle (feeding apparatus) and filling the distended abdomen of the mosquito. Because this species is found throughout the Americas, it is thought to be only a matter of time before the Zika, dengue, and chikungunya viruses are well established in the United States.

Source: James Gathany/Prof. Frank Hadley Collins, Dir., Cntr. for Global Health and Infectious Diseases, Univ. of Notre Dame/CDC

poorest populations and receive far too little attention. Most NTDs are easily treatable with drugs or preventable with vaccines.

Those hardest hit are residents in countries where access to adequate medical care is lacking. One-third of the earth's 7 billion inhabitants live on less than \$1 per day, are malnourished, are not fully immunized, and have no access to drugs. Take the case of malaria, caused by a microorganism transmitted by mosquitoes, which kills 1 to 2 million people every year worldwide. Currently the most effective way for citizens of developing countries to avoid infection is to sleep under a bed net, because the mosquitoes are

most active in the evening. Yet even this inexpensive solution is beyond the reach of people in many developing countries who cannot afford the \$3 to \$5 for nets to protect their family. Fortunately for many countries in the malaria zone, several international organizations have collaborated to provide special insecticide-treated nets that can help lower the rate of infections.

Emerging and Reemerging Diseases Among the more significant factors in the overall picture of infectious diseases are emerging and reemerging diseases (**1.1 Making Connections**). **Emerging**

diseases are newly identified conditions that are being reported in increasing numbers. Since 1980 at least 87 novel infectious agents have arisen within the human population. Some of them have been associated with a specific location (Ebola fever virus), whereas others have become pandemics, meaning they spread across continents (human immunodeficiency virus—HIV). A number of them cause **zoonoses**,* which are infectious diseases native to animals that can be transmitted to humans. One recent example is chikungunya virus spread by mosquitoes to humans and other mammals. This virus traveled from the Caribbean to Florida in 2014. It is unclear how fast the virus will spread throughout the United States, as conditions become less favorable to the life cycle of mosquitoes as one moves north.

Reemerging diseases are older, well-known diseases that are increasing in occurrence for reasons outlined in 1.1 Making Connections. Among the most common reemerging infectious diseases are tuberculosis (TB), influenza, malaria, cholera, and hepatitis B. Tuberculosis, which has been known since ancient times, still causes 8 million new infections and kills 1 million to 2 million people every year. As you will see, numerous factors play a part in the tenaciousness of infectious diseases, but fundamental to all of them is the formidable capacity of microbes to adapt to alterations in the individual, community, and environment.

CLINICAL CONNECTIONS

Are Microbes a Hidden Cause of Diseases?

One of the most eye-opening discoveries has been that many diseases once considered noninfectious probably do involve microbial infection. Most scientists expect that, in time, a majority of chronic conditions will be linked to microbial agents. The most famous of these is gastric ulcers, now known to be caused by a bacterium called *Helicobacter* (see chapter 21). But there are more. Diseases as disparate as type 1 diabetes, obsessive compulsive disorder, and coronary artery disease have been linked to chronic infections with microorganisms. Even the microbiome, the collection of microorganisms we all carry with us even when healthy, has been shown to have a much greater effect on our health than was previously thought. Recent studies have linked changes in the microbiome population to metabolic syndrome, a collection of health conditions including high cholesterol, hypertension, high blood sugar levels, and excess fat, all of which can raise the risk of heart disease, stroke, and diabetes. It seems that the golden age of microbiological discovery, during which all of the “obvious” diseases were characterized and cures or preventions were devised for them, should more accurately be referred to as the *first* golden age. We’re now discovering the roles of microorganisms in hidden but slowly destructive diseases. These include female infertility caused by *Chlamydia* infection and malignancies such as liver cancer (hepatitis viruses) and cervical cancer (human papillomavirus). In fact, epidemiologists analyzing statistics on world cancer have estimated that one in six cancers can be associated with an infectious agent.

Another important development in infectious disease trends is the increasing number of patients with weakened defenses who are kept alive for extended periods. We are becoming more susceptible to infectious disease precisely because of advances in medicine.

* **zoonoses** (zoh'-uh-noh'-seez) Gr. *zoion*, animal and *nosos*, disease. Any disease indigenous to animals transmissible to humans.

People are living longer. Sicker people are staying alive much longer than in the past. Older and sicker people have heightened susceptibility to what we might call “garden-variety” microbes.

Why would chronic infections be more likely to be associated with diseases like cancer? Answer available on Connect.

Check Your Progress SECTIONS 1.3–1.4

- Describe several ways the beneficial qualities of microbes greatly outweigh microbes’ roles as infectious agents.
- Look up in the index some of the diseases shown in table 1.2 and determine which ones could be prevented by vaccines or cured with drugs. Are there other ways (besides vaccines) to prevent any of these?
- Distinguish between emerging and reemerging infectious diseases and explain what factors contribute to their development.

1.5 The Historical Foundations of Microbiology

Expected Learning Outcomes

- Outline the major events in the history of microbiology, including the major contributors to the early development of microscopy, medical advances, aseptic techniques, and the germ theory of disease.
- Explain the main features of the scientific method, and differentiate between inductive and deductive reasoning and between hypothesis and theory.

If not for the extensive interest, curiosity, and devotion of thousands of microbiologists over the last 300 years, we would know little about the microscopic realm that surrounds us. Many of the discoveries in this science have resulted from the prior work of men and women who toiled long hours in dimly lit laboratories with the crudest of tools. Each additional insight, whether large or small, has added to our current knowledge of life forms and processes. This section summarizes the prominent discoveries made in the past 300 years: microscopy, the rise of the scientific method, and the development of medical microbiology, including the germ theory and the origins of modern microbiological techniques. The table “Significant Events in Microbiology,” found in Online Appendix 2, summarizes some of the pivotal events in microbiology from its earliest beginnings to the present.

The Development of the Microscope: “Seeing Is Believing”

It is likely that from the very earliest history, humans noticed that when certain foods spoiled, they became inedible or caused illness and yet other “spoiled” foods did no harm and even had enhanced flavor. Even several centuries ago, there was already a sense that diseases such as the black plague and smallpox were caused by some sort of transmissible matter. But the causes of such phenomena were obscure because the technology to study them was lacking. Consequently, they remained cloaked in mystery and regarded with superstition—a trend that led even well-educated scientists to believe in spontaneous generation (**1.2 Making Connections**).

1.2 MAKING CONNECTIONS

The Fall of Superstition and the Rise of Microbiology

For thousands of years, people believed that certain living things arose from vital forces present in nonliving or decomposing matter. This ancient idea, known as **spontaneous generation**, was continually reinforced as people observed that meat left out in the open soon “produced” maggots, that mushrooms appeared on rotting wood, that rats and mice emerged from piles of litter, and that other magical phenomena occurred. Though some of these early ideas seem quaint and ridiculous in light of modern knowledge, we must remember that, at the time, mysteries in life were accepted and the scientific method was not widely practiced.

Even after single-celled organisms were discovered during the mid-1600s, the idea of spontaneous generation persisted. Some scientists assumed that microscopic beings were an early stage in the development of more complex ones.

Over the subsequent 200 years, scientists waged an experimental battle over the two hypotheses that could explain the origin of simple life forms. Some tenaciously clung to the idea of **abiogenesis*** which embraced spontaneous generation. On the other side were advocates of **biogenesis**,* saying that living things arise only from others of their same kind. There were serious proponents on both sides, and each side put forth what appeared on the surface to be plausible explanations of why their evidence was more correct. Gradually the abiogenesis hypothesis was abandoned as convincing evidence for biogenesis continued to mount. The following series of experiments were among the most important in finally tipping the balance.

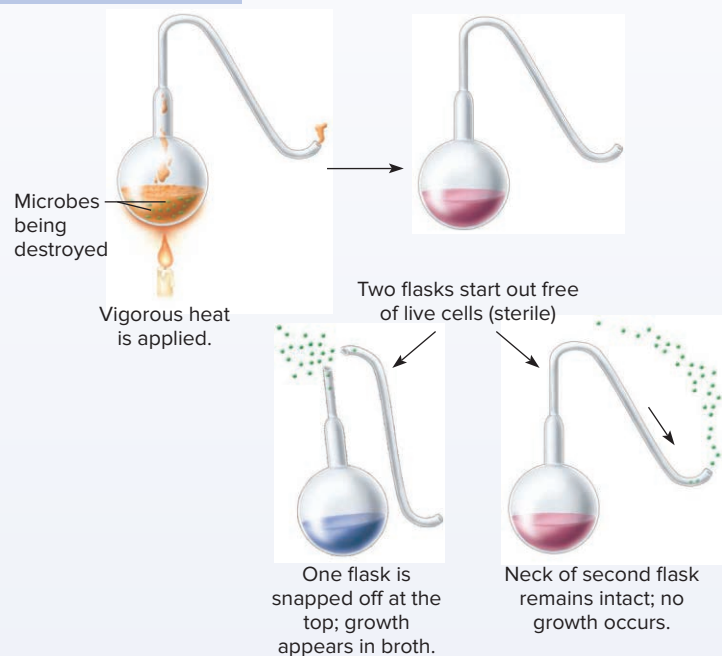

Some of the important variables to be considered in testing the hypotheses were the effects of nutrients, air, and heat, and the presence of preexisting life forms in the environment. One of the first people to test the spontaneous generation theory was **Francesco Redi** of Italy. He conducted a simple experiment in which he placed meat in a jar and covered the jar with fine gauze. Flies gathering at the jar were blocked from entering and thus laid their eggs on the outside of the gauze. The maggots subsequently developed without access to the meat, indicating that maggots were the offspring of flies and did not arise from some “vital force” in the meat. This and related experiments laid to rest the idea that more complex animals such as insects and mice developed through abiogenesis, but it did not convince many scientists of the day that simpler organisms could not arise in that way.

The Frenchman **Louis Jablot** reasoned that even microscopic organisms must have parents, and his experiments with infusions (dried hay steeped in water) supported that hypothesis. He divided an infusion that had been boiled to destroy any living things into two containers: a heated container that was closed to the air and a heated container that was freely open to the air. Only the open vessel developed microorganisms, which he presumed had entered in air laden with dust. Regrettably, the validation of biogenesis was temporarily set back by **John Needham**, an Englishman who did similar experiments using mutton gravy. His results were in conflict with Jablot’s because both his heated and unheated test containers teemed with microbes. Unfortunately, his experiments were done before the realization that heat-resistant microbes are not usually

killed by mere boiling. Apparently Jablot had been lucky; his infusions were sterile.

Then, in the mid-1800s, the acclaimed microbiologist **Louis Pasteur** entered the arena. He had recently been studying the roles of microorganisms in the fermentation of beer and wine, and it was clear to him that these processes were brought about by the activities of microbes introduced into the beverage from air, fruits, and grains. The methods he used to discount abiogenesis were simple yet brilliant.

Pasteur’s Experiment

To further clarify that air and dust were the source of microbes, Pasteur filled flasks with broth and fashioned their openings into elongate, swan-neck-shaped tubes. The flasks’ openings were freely open to the air but were curved so that gravity would cause any airborne dust particles to deposit in the lower part of the necks. He heated the flasks to sterilize the broth and then incubated them. As long as the flask remained intact, the broth remained sterile, but if the neck was broken off so that dust fell directly down into the container, microbial growth immediately commenced.

Pasteur summed up his findings, “For I have kept from them, and am still keeping from them, that one thing which is above the power of man to make; I have kept from them the germs that float in the air, I have kept from them life.”

What type of microorganisms were likely responsible for the misleading results of John Needham’s experiment and were absent in Jablot’s and Pasteur’s experiments? *Answer available on Connect.*

* *abiogenesis* (ah-bee’-oh-jen’-uh-sis) L. *a*, without, *bios*, life, and *genesis*, beginning.

* *biogenesis* (by-oh-gen’-uh-sis) to begin with life.

Figure 1.8 An oil painting of Antonie van Leeuwenhoek (1632–1723) sitting in his laboratory. How astonishing to realize that this curious and original man was the first human being on earth ever to glimpse the “cavorting wee beasties” (his description) of the microbial world! © Bettmann/Corbis

True awareness of the widespread distribution of microorganisms and some of their characteristics was finally made possible by the development of the first microscopes. These devices revealed microbes as discrete entities sharing many of the characteristics of larger, visible plants and animals. Several early scientists fashioned magnifying lenses and microscopes, but these lacked the optical clarity needed for examining bacteria and other small, single-celled organisms. The most careful and exacting observations awaited the simple single-lens microscope hand-fashioned by **Antonie van Leeuwenhoek**, a Dutch linen merchant and self-made microbiologist (**figure 1.8**).

During the late 1600s in Holland, Leeuwenhoek used his early lenses to examine the thread patterns of the draperies and upholstery he sold in his shop. Between customers, he retired to the workbench in the back of his shop, grinding glass lenses to ever-finer specifications. He could see with increasing clarity, but after a few years he became interested in things other than thread counts. He took rainwater from a clay pot, smeared it on his specimen holder, and peered at it through his finest lens. He found “animals appearing to me ten thousand times more than those which may be perceived in the water with the naked eye.”

He didn’t stop there. He scraped plaque from his teeth, and from the teeth of volunteers who had never cleaned their teeth in their lives, and took a close look at that. He recorded: “In the said matter there were many very little living animalcules, very prettily a-moving . . . Moreover, the other animalcules were in such enormous numbers, that all the water . . . seemed to be alive.” Leeuwenhoek started sending his observations to the Royal Society of London, and eventually he was recognized as a scientist of great merit.

(b)

Figure 1.9 Leeuwenhoek’s microscope. (a) A brass replica of a Leeuwenhoek microscope and how it is held (inset). (b) Early illustrations of bacterial cells from a sample of milk, magnified about 300X. These drawings closely resemble those Leeuwenhoek made of his animalcules. (a & a, inset): © Kathy Park Talaro; (b): Source: Trouessart, E.L., *Microbes Ferments and Moulds*. © 1895 D. Appleton and Company.

Leeuwenhoek constructed more than 250 small, powerful microscopes that could magnify up to 300 times (**figure 1.9**). Considering that he had no formal training in science and that he was the first person ever to faithfully record this strange new world, his descriptions of bacteria and protozoa (which he called “animalcules”) were astute and precise. Because of Leeuwenhoek’s extraordinary contributions to microbiology, he is sometimes considered the father of bacteriology and protozoology.

From the time of Leeuwenhoek, microscopes became more complex and improved, with the addition of refined lenses, a condenser, finer focusing devices, and built-in light sources. The prototype of the modern compound microscope, in use from about the mid-1800s, was capable of magnifications of 1,000 times or more, largely because it had two sets of lenses for magnification. Even our modern laboratory microscopes are not greatly different in basic structure and function from those early microscopes. The technical characteristics of microscopes and microscopy are a major focus of chapter 3.

The Scientific Method and the Search for Knowledge

The research that led to acceptance of biogenesis provides us with one example of the early development of science-based thought. Over the next few sections we will glimpse other important milestones in the development of the scientific method, such as vaccination, germ theory, asepsis, and Koch's postulates. The impact of science is so pervasive that you may not realize how much of our everyday life is built upon applications of the scientific method. Vaccines, antibiotics, space travel, computers, medical diagnosis, and DNA testing exist primarily because of the work of thousands of scientists doing objective observations and collecting evidence that is measurable, can be expressed quantitatively, and is subject to critical analysis.

The information obtained through the scientific method is explanatory and predictive. It aims to explain how and why phenomena occur and to predict what is expected to happen under known conditions. Two very recent events dramatically contrast the differences between scientific versus nonscientific reasoning. In 2012, NASA sent the *Curiosity* spacecraft on a 225-million-mile journey to Mars and landed it at a very precise time and place—an incredible achievement that brought to bear vast knowledge of physics, engineering, and mathematics. That same year, rumors started about doomsday predictions supposedly found in interpretations of an ancient Mayan calendar. A surprisingly large number of people all over the world were convinced that the world would come to an end on December 21, 2012. The fact that you are reading this textbook absolutely verifies which of these approaches is more reliable and predictive.

How do scientists apply the scientific method? In the **deductive reasoning** approach, a scientist uses general observations of some phenomenon to develop a set of facts to explain that phenomenon—that is, they *deduce* the facts that can account for what they have observed. This early explanation is considered a **hypothesis**, and however tentative it may start out, it is still based on scientific thought rather than subjective beliefs that come from superstition or myth. A valid hypothesis will allow for experimentation and testing and can be shown to be false. An example of a workable hypothesis based on deduction might be the speculation that a disease such as hemophilia is an inheritable condition. This would pave the way for specific experiments that test for the influence of genetics. A nonworkable hypothesis would be that hemophilia is caused by a curse placed on the royal family of England. Because supernatural beliefs offer no basis for experimentation and must be taken on faith, they can never be subjected to the rigors of the scientific method.

With **inductive reasoning**, one applies specific observations to develop a general explanation. This method is often used in the early phases of evaluation and can formulate a generalization to be tested deductively. In the previous example, induction might begin with the observation of a family in which several people have hemophilia, and this may lead to the general idea that it is inheritable.

A lengthy process of experimentation, analysis, and testing eventually leads to conclusions that either support or refute the hypothesis. If experiments do not uphold the hypothesis—that is, if it is found to be flawed—the hypothesis or some part of it is reconsidered. This does not mean the results are invalid; it means the hypothesis may require reworking or additional tests. Eventually it is either discarded or modified to fit the results of the experiment. If the hypothesis is supported by the experiment, it is not (or should not be) immediately accepted as fact. It then must be tested and retested. Indeed, this is an important guideline in the acceptance of a hypothesis. The results of the experiment must be published and repeated by other investigators.

In time, as each hypothesis is supported by a growing body of data and survives rigorous scrutiny, it moves to the next level of acceptance—the **theory**. A theory is a collection of statements, propositions, or concepts that explains or accounts for a natural event. A theory is not the result of a single experiment repeated over and over again but is an entire body of ideas that expresses or interprets many aspects of a phenomenon. When an unsupported idea is dismissed as being “just a theory,” this is an incorrect use of the term as far as science is concerned. A theory is far from a weak notion or wild guess. It is a viable explanation that has stood the test of time and has yet to be disproved by serious scientific inquiries. Often theories develop and progress through decades of research and are added to and modified by new findings. At some point, evidence of the accuracy and predictability of a theory is so compelling that the next level of confidence is reached, and the theory becomes a **law**, or principle. For example, the **germ theory of disease** has been so thoroughly tested that it has clearly passed into the realm of law.

Science and its hypotheses and theories must progress along with technology. As advances in instrumentation allow new, more detailed views of living phenomena, old theories may be reexamined and altered and new ones proposed. Scientific knowledge is accumulative, and it must have built-in flexibility to accommodate new findings. It is for these reasons that scientists do not take a stance that theories or even laws are absolutely proved.

Figure 1.10 provides a summary of the scientific method in action using Edward Jenner's monumental discovery of vaccines. What is remarkable about Jenner's work is that he was the first to use scientific thought to construct a rigorous experimental model to inoculate people against disease, and he carried it through to its completion. It is also remarkable that he did this knowing nothing about viruses or even microbes. He worked out the concept of safely conferring artificial immunity long before there was any understanding of the immune system (see 15.2 Making Connections).

The Development of Medical Microbiology

Early experiments on the sources of microorganisms led to the profound realization that microbes are everywhere: Not only are air and

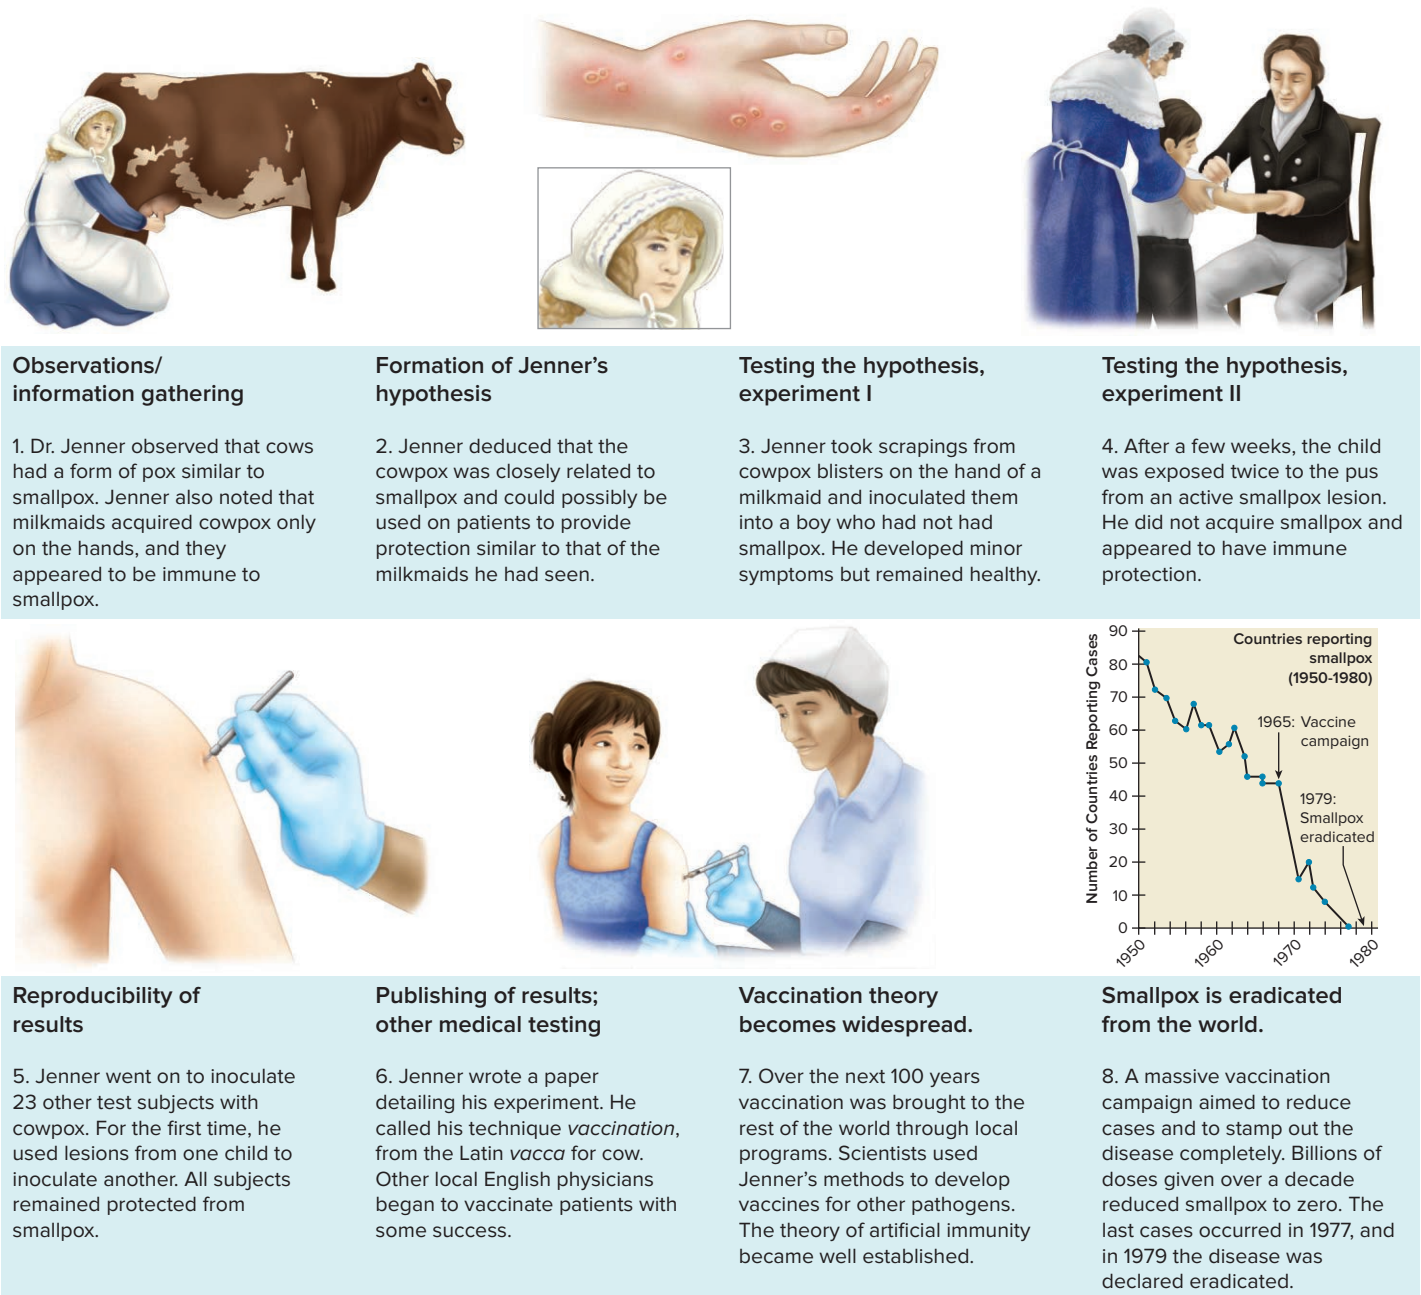

Figure 1.10 Edward Jenner and the saga of the smallpox vaccine. Jenner's work documents the first attempt based on the scientific method to control an infectious disease—smallpox. This disease was characterized by raised skin blisters called pox, and it often caused severe damage to organs. Throughout its long history this deadly disease decimated many populations worldwide, until 1977 when the last case was reported.

dust full of them, but the entire surface of the earth, its waters, and all objects are inhabited by them. This discovery led to immediate applications in medicine. Thus the seeds of medical microbiology were sown in the middle to latter half of the nineteenth century with the introduction of the first practical vaccine, the germ theory of disease, and the resulting use of sterile, aseptic, and pure culture techniques.

Jenner and the Introduction of Vaccination

We saw in figure 1.10 how the English physician and scientist **Edward Jenner** modeled the scientific method. His experiments ultimately gave rise to the first viable method to control smallpox

by inoculating patients with a closely related disease agent. His contributions to medical science so changed the practice of medicine that he is considered the “Father of Immunology.” It is often said of Jenner that his discovery saved more lives than any other in history. His work marked the beginning of an era of great scientific achievement—one that produced some of the most far-reaching developments in microbiology and medicine.

The Discovery of Spores and Sterilization

Following Pasteur's inventive work with infusions (1.2 Making Connections), it was not long before English physicist **John Tyndall**

provided the initial evidence that some of the microbes in dust and air have very high heat resistance and that particularly vigorous treatment is required to destroy them. Later, the discovery and detailed description of heat-resistant bacterial endospores by **Ferdinand Cohn**, a German botanist, clarified why heat would sometimes fail to completely eliminate all microorganisms. The modern sense of the word **sterile**, meaning completely free of all infectious agents, including endospores, viruses, and prions, had its beginnings here (see chapter 11). The capacity to sterilize objects and materials is an absolutely essential part of microbiology, medicine, dentistry, and some industries.

The Development of Aseptic Techniques

From earliest history, humans experienced a vague sense that “unseen forces” or “poisonous vapors” emanating from decomposing matter could cause disease. As the study of microbiology became more scientific and the invisible was made visible, the fear of such mysterious vapors was replaced by the knowledge, and sometimes even the fear, of “germs.” About 130 years ago, the first studies by **Robert Koch** clearly linked a microscopic organism with a specific disease. Since that time, microbiologists have conducted a continuous search for disease-causing agents.

At the same time that abiogenesis was being hotly debated, a few budding microbiologists began to suspect that microorganisms could cause not only spoilage and decay but also infectious diseases. It occurred to these rugged individualists that even the human body itself was a source of infection. **Dr. Oliver Wendell Holmes**, an American physician, observed that mothers who gave birth at home experienced fewer infections than did mothers who gave birth in the hospital, and the Hungarian **Dr. Ignaz Semmelweis** showed quite clearly that women became infected in the maternity ward after examinations by physicians coming directly from the autopsy room.

The English surgeon **Joseph Lister** took notice of these observations and was the first to introduce **aseptic* techniques** aimed at reducing microbes in a medical setting and preventing wound infections. Lister’s concept of asepsis was much more limited than our modern precautions. It mainly involved disinfecting the hands and the air with strong antiseptic chemicals, such as phenol, prior to surgery. It is hard for us to believe, but as recently as the late 1800s surgeons wore street clothes in the operating room and had little idea that hand washing was important. Lister’s techniques and the application of heat for sterilization became the bases for microbial control by physical and chemical methods, which are still in use today.

The Discovery of Pathogens and the Germ Theory of Disease

Two ingenious founders of microbiology, **Louis Pasteur** of France (**figure 1.11**) and **Robert Koch** of Germany (**figure 1.12**), introduced techniques that are still used today. Pasteur made enormous contributions to our understanding of the roles of microorganisms in many aspects of medicine and industry. He developed two vaccines

Figure 1.11 Photograph of Louis Pasteur (1822–1895), the father of microbiology. Few microbiologists can match the scope and impact of Pasteur’s contributions to the science of microbiology.

(rabies and anthrax) and clarified the actions of microbes in wine and beer fermentation. He invented pasteurization and completed some of the first studies showing that human diseases could arise from infection. These studies, supported by the work of other scientists, became known as the **germ theory of disease**. Pasteur’s contemporary, Koch, established *Koch’s postulates*, a series of proofs that verified the germ theory and could establish whether an organism was pathogenic and which disease it caused (see chapter 13). Around 1875 Koch used this experimental system to show that anthrax is caused by a bacterium called *Bacillus anthracis*. So useful were his postulates that the causative agents of 20 other diseases were discovered

* **aseptic** (ay-sep’-tik) Gr. *a*, no, and *sepsis*, decay or infection. These techniques are aimed at reducing pathogens and do not necessarily sterilize.

between 1875 and 1900, and even today they serve as a basic premise for establishing a link between pathogens and diseases.

Numerous exciting technologies emerged from Koch's prolific and probing laboratory work. During this golden age of microbiology, he realized that study of the microbial world would require separating microbes from each other and growing them in culture. It is not an overstatement to say that he and his colleagues invented many of the techniques that are described in chapter 3: inoculation, isolation, media, maintenance of pure cultures, and preparation of specimens for microscopic examination. Other highlights in this era of discovery are presented in later chapters on microbial control (see chapter 11) and vaccination (see chapter 15).

Check Your Progress SECTION 1.5

10. Outline the most significant discoveries and events in microscopy, culture techniques, and other methods of handling or controlling microbes.
11. Differentiate between a hypothesis and a theory. If someone says a scientific explanation is “only a theory,” what do they really mean?
12. Is the germ theory of disease actually a law, and why?
13. Why was the abandonment of the spontaneous generation theory so significant?

1.6 Taxonomy: Organizing, Classifying, and Naming Microorganisms

Expected Learning Outcomes

11. Define *taxonomy* and its supporting terms *classification*, *nomenclature*, and *identification*.
12. Explain how the levels of a taxonomic scheme relate to each other. Give the names of the levels, and place them in a hierarchy.
13. Describe the goals of nomenclature and how the binomial system is structured. Know how to correctly write a scientific name.

Students just beginning their microbiology studies are often dismayed by the seemingly endless array of new, unusual, and sometimes confusing names for microorganisms. Learning microbial **nomenclature*** is very much like learning a new language, and occasionally its demands may be a bit overwhelming. But paying attention to proper microbial names is just like following a baseball game or a theater production: You cannot tell the players apart without a program! Your understanding and appreciation of microorganisms will be greatly improved by learning a few general rules about how they are named.

The formal system for organizing, classifying, and naming living things is **taxonomy**.* This science originated more than

250 years ago when **Carl von Linné** (also known as Linnaeus; 1701–1778), a Swedish botanist, laid down the basic rules for taxonomic categories, or **taxa**. Von Linné realized early on that a system for recognizing and defining the properties of living things would prevent chaos in scientific studies by providing each organism with a unique name and an exact “slot” in which to catalog it. This classification would then serve as a means for future identification of that same organism and permit workers in many biological fields to know if they were indeed discussing the same organism. The von Linné system has served well in categorizing the 2 million or more different types of organisms that have been discovered since that time.

The primary concerns of taxonomy are classification, nomenclature, and identification. These three areas are interrelated and play a vital role in keeping a dynamic inventory of the extensive array of living things. **Classification** is an orderly arrangement of organisms into groups that indicate evolutionary relationships and history. **Nomenclature** is the system of assigning names to the various taxonomic rankings of each microbial species. **Identification** is the process of using the specific characteristics and capabilities of an organism to determine its exact identity and placement in taxonomy. A survey of some general methods of identification appears in chapter 3.

The Levels of Classification

The main taxa, or groups, in a classification scheme are organized into several descending ranks called a **hierarchy**. It begins with **domain**, which is a giant, all-inclusive category based on a unique cell type, and ends with **species**,* the smallest and most specific taxon. All the members of a domain share only one or few general characteristics, whereas members of a species are essentially the same kind of organism—that is, they share the majority of their characteristics. The order of taxa between the top and bottom levels is, in descending order: **domain, kingdom, phylum*** or **division**,⁴ **class, order, family, genus**,* and **species**. Thus, each domain may be subdivided into a series of kingdoms, each kingdom is made up of several phyla, each phylum contains several classes, and so on. Because taxonomic schemes are to some extent artificial, certain groups of organisms cannot be arranged in an exact eight-part taxonomic scheme. In those cases, additional levels can be imposed immediately above (super) or below (sub) a taxon, giving us such categories as superphylum and subclass.

To illustrate how this hierarchy works, we compare the taxonomic breakdowns of a human and a common pond protozoan (**figure 1.13**). Humans and protozoa belong to the same domain (Eukarya) but are placed in different kingdoms. To emphasize just how broad the category kingdom is, ponder the fact that humans belong to the same kingdom as jellyfish. Of the several

* *species* (spee'-sheez) L. *specere*, kind. In biology, this term is always in the plural form.

* *phylum* (fy'-lum) pl. phyla (fye'-luh) Gr. *phylon*, race.

4. The term *phylum* is used for protozoa, animals, bacteria, and fungi. Division is for algae and plants.

* *genus* (jee'-nus) pl. genera (jen'-er-uh) L. birth, kind.

* *nomenclature* (noh'-men-klay"-chur) L. *nomen*, name, and *clare*, to call. A system of naming.

* *taxonomy* (tacks-on"-uh-mee) Gr. *taxis*, arrangement, and *nomos*, name.

Domain: Eukarya (All eukaryotic organisms)

Kingdom: Animalia

Phylum: Chordata

Class: Mammalia

Order: Primates

Family: Hominoidea

Genus: *Homo*

Species: *sapiens*
Scientific name: *Homo sapiens*

(a)

Domain: Eukarya (All eukaryotic organisms)

Kingdom: Protista
Includes protozoa and algae

Phylum: Ciliophora

Protozoa with cilia
Covered by flexible pellicle
Contain two types of nuclei

Class: Oligohymenophora

Single, rapidly swimming cells
Regular rows of cilia
Distinct ciliated oral groove

Order: Peniculida

Uniform dense cilia dispersed over cell
Oral cilia are peniculae
Trichocysts in outer membrane

Family: Parameciidae

Cells round to elongate
Rotate while swimming
Deep oral grooves

Genus: *Paramecium*

Ovoid, cigar- and foot-shaped cells

Species: *caudatum*

Cells elongate, cylindrical
Blunt at one end and tapered to a point at the other

Scientific name: *Paramecium caudatum*

(b)

Figure 1.13 Sample taxonomy. Two organisms belonging to Domain Eukarya, traced through their taxonomic series. (a) Modern humans, *Homo sapiens*. (b) A common protozoan, *Paramecium caudatum*.

phyla within this kingdom, humans are in the Phylum Chordata, but even a phylum is rather all-inclusive, considering that humans share it with other vertebrates as well as with creatures called sea squirts. The next level, Class Mammalia, narrows the field considerably by grouping only those vertebrates that have hair and suckle their young. Humans belong to the Order Primates, a group that also includes apes, monkeys, and lemurs. Next comes the Family Hominoidea, containing only humans and apes. The final levels are our genus, *Homo* (all races of modern and ancient humans), and our species, *sapiens* (meaning wise). Notice that for both the human and the protozoan, the

categories become less inclusive and the individual members more closely related and similar in overall appearance. Other examples of classification schemes are provided in sections of chapters 4 and 5 and in several later chapters. A superior source for the taxonomic breakdown of microbes is Wikipedia. Go there to search the scientific name of any species, and its taxonomy will be shown in a box on the upper-right portion of the first page.

We need to remember that all taxonomic hierarchies are based on the judgment of scientists with certain expertise in a particular group of organisms and that not all other experts may agree with

the system being used. Consequently, no taxa are permanent to any degree; they are constantly being revised and refined as new information becomes available or new viewpoints become prevalent. Our primary aim in introducing taxonomy is to present an organizational tool that helps you keep track of the various microbial groups and recognize their major categories. For the most part our emphasis will remain on the higher-level taxa (phylum, class) and genus and species.

Assigning Scientific Names

Many larger organisms are known by a common name suggested by certain dominant features. For example, a bird species may be called a yellow-bellied sapsucker, or a flowering plant, a sunflower. Some species of microorganisms (especially pathogens) are also sometimes designated by informal names, such as the gonococcus (*Neisseria gonorrhoeae*) or the TB bacillus (*Mycobacterium tuberculosis*), but this is not the usual practice. If we were to adopt common names such as the “little yellow coccus” (for *Micrococcus luteus**) or the “club-shaped diphtheria bacterium” (for *Corynebacterium diphtheriae**), the terminology would become even more cumbersome and challenging than scientific names. Even worse, common names are notorious for varying from region to region, even within the same country. A decided advantage of standardized nomenclature is that it provides a universal language that enables scientists from all countries on the earth to freely exchange information.

The **scientific name**, also known as the **specific epithet**, is assigned by using a **binomial** (two-name) **system** of nomenclature. The scientific name is always a combination of the generic (genus) name followed by the species name. The generic part of the scientific name is capitalized, and the species part begins with a lower-case letter. Both should be italicized (or underlined if italics are not available), as follows:

Histoplasma capsulatum or Histoplasma capsulatum

Because other taxonomic levels are not italicized and consist of only one word, one can always recognize a scientific name. An organism’s scientific name is sometimes abbreviated to save space, as in *H. capsulatum*, but only if the genus name has already been stated. The source for nomenclature is usually Latin or Greek. If other languages such as English or French are used, the endings of these words are revised to have Latin endings. In general, the name first applied to a species will be the one that takes precedence over all others.

An international group oversees the naming of every new organism discovered, making sure that standard procedures have been followed and that there is not already an earlier name for the organism or another organism with that same name. The inspiration for names is extremely varied and often rather imaginative. Some species have been named in honor of a microbiologist who originally

discovered the microbe or who has made outstanding contributions to the field. Other names may designate a characteristic of the microbe (shape, color), a location where it was found, or a disease or symptom that it causes. Some examples of scientific names, pronunciations, and origins are:

1. ***Histoplasma capsulatum*** (hiss"-toh-plaz'-mah cap"-soo-lay'-tum) Gr. *histo*, tissue, *plasm*, to form, and L. *capsula*, small sheath. A fungus that causes Ohio Valley fever.
2. ***Trichinella spiralis*** (trik'-ih-nel'-uh spyr-al'-iss) Gr. *trichos*, hair, *ella*, little, and L. *spira*, coiled. The nematode worm that causes the food-borne infection, trichinellosis.
3. ***Shewanella oneidensis*** (shee"-wan-el'-uh oh-ny"-den'-siss). Named for British bacteriologist J. M. Shewan and Lake Oneida, New York, where it was discovered. This is a remarkable species that can bioremediate radioactive metals in contaminated waste sites.
4. ***Bordetella pertussis*** (bor"-duh-tel'-uh pur-tuss'-iss) After Jules Bordet, a Belgian microbiologist who discovered this bacterium, and L. *per*, severe, and *tussis*, cough. This is the cause of pertussis, or whooping cough.

When you encounter the name of a microorganism in the chapters ahead, it is helpful to take the time to sound it out one syllable at a time and repeat until it seems familiar. You are much more likely to remember the names that way—and they will become part of the new language you will be learning.

Check Your Progress SECTION 1.6

14. Differentiate between taxonomy, classification, and nomenclature.
15. What is the basis for a phylogenetic system of classification?
16. Explain the binomial system of nomenclature and give the correct order of taxa, going from most general to most specific.
17. Explain some of the benefits of using scientific names for organisms.

* *micrococcus luteus* (my"-kroh-kok'-us loo'-tee-us) Gr. *micros*, small, and *kokkus*, berry; L. *luteus*, yellow.

* *corynebacterium diphtheriae* (kor-eye"-nee-bak-ter'-ee-yum dif'-theer-ee-eye) Gr. *coryne*, club, *bacterion*, little rod, and *diphtheriae*, the causative agent of the disease diphtheria.

1.7 The Origin and Evolution of Microorganisms

Expected Learning Outcomes

14. Discuss the fundamentals of evolution, evidence used to verify evolutionary trends, and the use of evolutionary theory in the study of organisms.
15. Explain the concepts behind the organization of the two main trees of life, and indicate where the major groups of microorganisms fall on these trees.
16. Explain the bases for classification, taxonomy, and nomenclature.
17. Recall the order of taxa and the system of notation used in creating scientific names.

All Life Is Related and Connected Through Evolution

As we indicated earlier, *taxonomy*, the classification of biological species, is a system used to organize all of the forms of life. In biology today, there are different methods for deciding on taxonomic categories, but they all rely on the history and relatedness of organisms. The natural relatedness between groups of living things is called their **phylogeny**. Biologists can apply their knowledge of phylogenetic relationships to develop a system of taxonomy.

To understand how organisms originate, we must understand some fundamentals of **evolution**. You have no doubt heard comments that dismiss evolution as “only a theory” as though there remain significant problems with its acceptance. But you have also learned that a scientific theory is a highly documented and well-established concept. The body of knowledge that has accumulated over hundreds of years regarding the process of evolution is so significant that scientists from all disciplines consider evolution to be a fact. It is an important theme that underlies all of biology, including microbiology. Put simply, the scientific principle of evolution states that living things change gradually through billions of years and that these changes result in various types of structural and functional adaptations through many generations. The process of evolution is selective: Those changes that most favor the survival of a particular organism or group of organisms tend to be retained, and those that are less beneficial to survival tend to be lost. The great naturalist Charles Darwin labeled this process natural selection. We do not have the space here to present a detailed analysis of evolutionary theories, but the occurrence of evolution is supported by a tremendous amount of evidence from the fossil record and from the study of **morphology** (structure), **physiology** (function), and **genetics** (inheritance). Evolution accounts for the millions of different species on the earth and their adaptation to its many and diverse habitats.

Evolution is founded on two premises: (1) that all new species originate from preexisting species through inheritance of traits, and (2) that closely related organisms have similar features because they evolved from common ancestral forms. Usually evolution progresses toward greater complexity, and

evolutionary stages range from simple, less evolved forms that are close to an ancestral organism to more complex, evolved forms that have advanced beyond the ancestral forms. Regardless of their evolutionary history, all species presently residing on the earth are modern, but some have arisen more recently in evolutionary history than others.

Traditionally we present the history of life, or phylogeny, in the form of branching trees that are designed to show the origins of various life forms (**figures 1.14** and **1.15**). At the base are the oldest ancestral forms (somewhat like roots), and the trunk indicates the progression of major lines that emerge through selection. Branches split off the main trunk as further selection and modification occurs. With this arrangement, more closely related organisms appear nearer each other on the tree. Any tree of life is nothing more than a system for classifying organisms, and the characteristics used for the process are specified by the person or group creating the tree. Classifying organisms alphabetically (aardvark, acinetobacter, aloe, antelope) or by size (giant redwood, blue whale . . .) are equally valid strategies. However, the most scientifically useful classification schemes group organisms according to their biological characteristics, using the tree to display the evolutionary relationships between organisms.

Systems for Presenting a Universal Tree of Life

The earliest classification schemes assigned every living thing to either the Plant Kingdom or the Animal Kingdom, even though most organisms were a poor fit for either. As knowledge grew concerning cellular structure, means of acquiring nutrients, and how organisms moved about, Robert Whittaker developed a five-kingdom system (figure 1.14) in the 1960s that remained the standard for many years. Individual members of the five kingdoms—the **monera**, **fungi**, **protists**, **plants**, and **animals**—were easily distinguished from one another using techniques common to most laboratories during the mid-twentieth century.

By the late twentieth century, the manner in which organisms were studied was undergoing a dramatic change. The techniques of molecular biology allowed scientists to examine the structure and function of individual genes and to clarify the relationships between organisms based on similarities in their genetic material, rather than simply shared characteristics. Using these new molecular methods, Carl Woese and George Fox proposed a classification system that some have likened to a shrub of life rather than a tree (figure 1.15). In this system, organisms are most broadly classified as belonging to one of three domains. The members of the **Domain Bacteria** have prokaryotic cells and are what most people think of as traditional bacterial species. The **Domain Eukarya** contains all of the organisms that display a eukaryotic cell structure, and includes the Kingdom Protista, Kingdom Fungi, Kingdom Plantae, and Kingdom Animalia. Members of the **Domain Archaea** also possess prokaryotic cells, but these cells are so distinct from those found in the Bacteria and the Eukarya that they have been placed in a domain of their own. Most members of the Domain Archaea are characterized by their ability to live in extreme environments or produce novel metabolic byproducts. Some species thrive in water

Figure 1.14 Traditional Whittaker system of classification. In this system, kingdoms are based on cell structure and type, the nature of body organization, and nutritional type. Bacteria and Archaea (monerans) have prokaryotic cells and are unicellular. Protists have eukaryotic cells and are simple unicellular and colonial organisms. They can be photosynthetic (algae), or they can feed on other organisms (protozoa). Fungi are eukaryotic cells with unicellular or multicellular bodies; they have cell walls and are not photosynthetic. Plants have eukaryotic cells, are multicellular, have cell walls, and are photosynthetic. Animals have eukaryotic cells, are multicellular, do not have cell walls, and derive nutrients from other organisms.

near undersea volcanic vents that has been heated to near boiling or in concentrations of salt as high as 35%, while others produce methane gas as a byproduct of their metabolism.

Although the Woese-Fox system represents the most accurate relationship between organisms, which classification scheme is ultimately used does not affect the presentation of most microbes because we tend to discuss them at the genus and species level. But be aware that biological taxonomy—and more

important, our understanding of the early evolution of organisms—is in a period of transition. It is essential that any methods of classification reflect our current understanding and can be altered as new information is uncovered (see figure 4.27). Also, please note that viruses are *not* included in any of the classification or evolutionary schemes, because they are not cells and their position cannot be given with any confidence. Their special taxonomy is discussed in chapter 6.

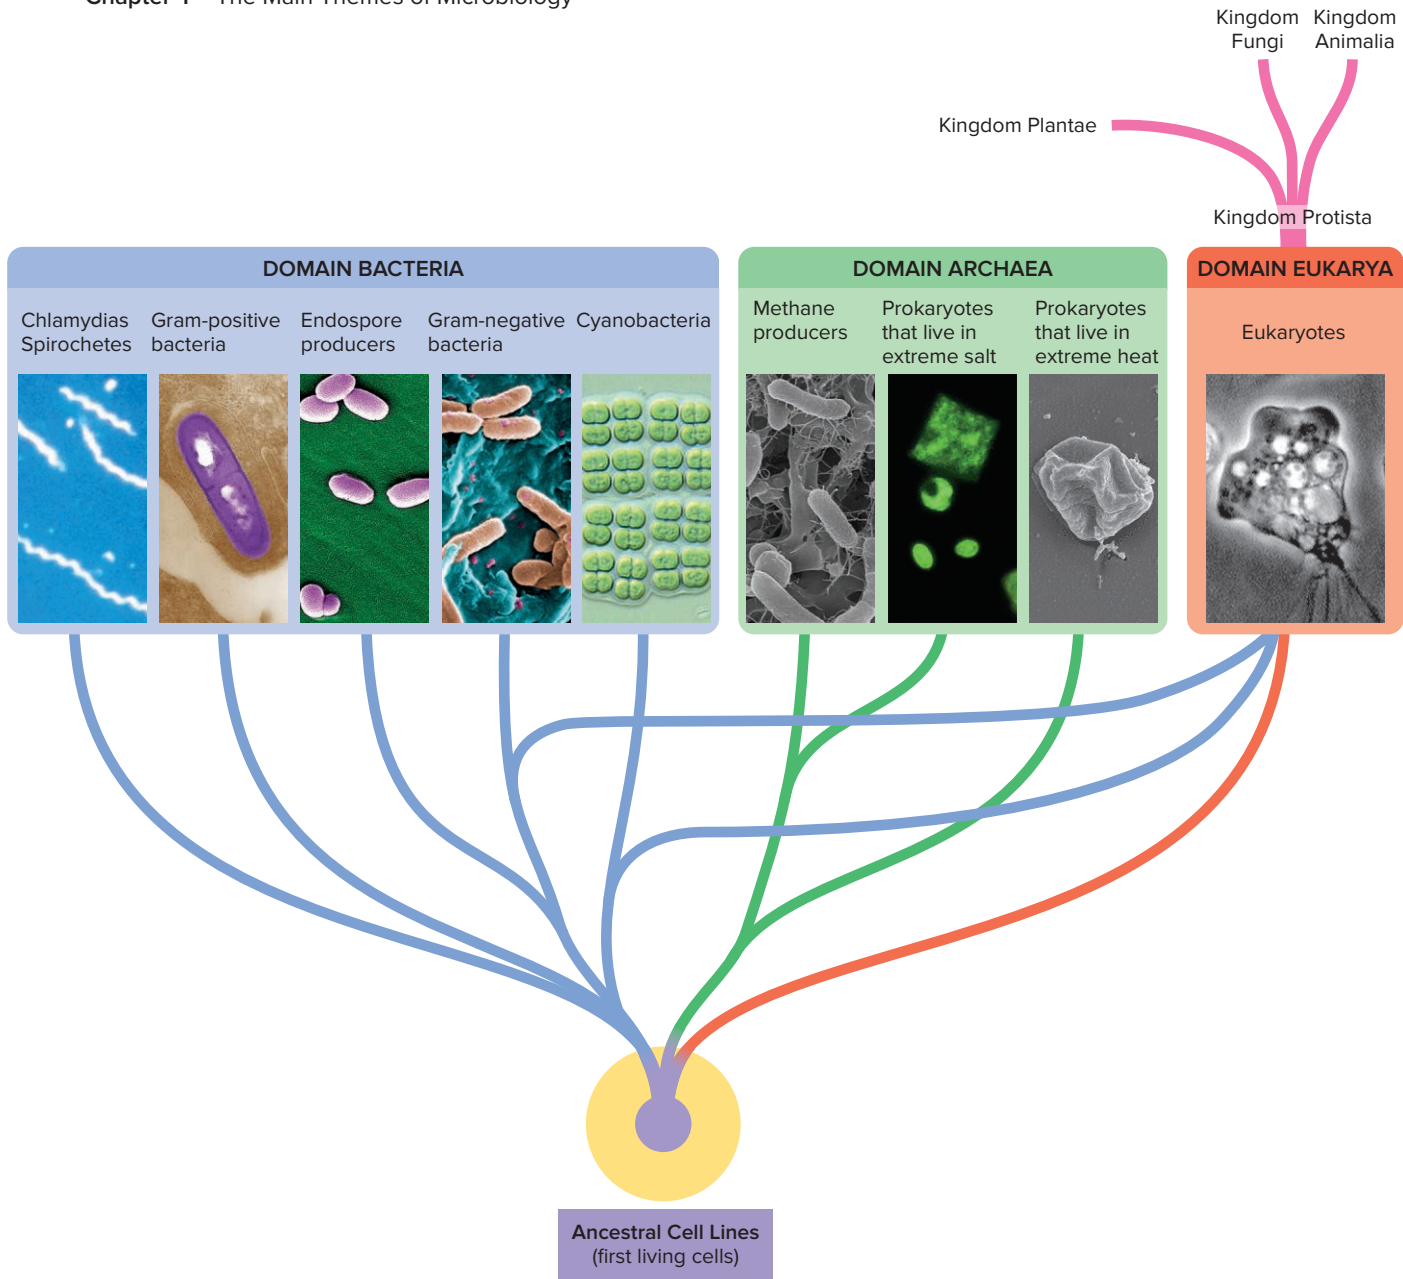

Figure 1.15 Weese-Fox system. A system for representing the origins of cell lines and major taxonomic groups as proposed by Carl Woese and colleagues. They propose three distinct cell lines placed in superkingdoms called domains. We know little about the earliest cells, called progenotes, except that they were prokaryotic. Lines of these early primitive cells gave rise to the Domains Bacteria and Archaea. Molecular evidence indicates that the Archaea started the branch that would eventually become the Domain Eukarya. Notice that two early bacterial lines contributed to the evolution of the Eukarya. Selected representatives of the Domains are included. The traditional eukaryotic kingdoms are still present with this system (see figure 1.14). Further details of classification systems are covered in chapters 4 and 5. Check Your Progress SECTION 1.7

18. Define what is meant by the term *evolution*.
19. Explain how the process of evolution is responsible for the millions of different species on the earth and their adaptation to its many and diverse habitats. Cite examples in your answer.
20. Looking at the tree of life (figure 1.14), determine which kingdom or kingdoms humans are most closely related to.
21. Archaea are often found living in extreme conditions of heat, salt, and acidity, which are similar to those found in early earth. Speculate on the origin of life, especially as it relates to the archaea.
22. Compare the domain system with the five-kingdom system. Does the newer system change the basic idea of prokaryotes and eukaryotes? What is the third cell type?

CASE STUDY Part 2

If Lake Whillans is a frozen wasteland, then Pitch Lake is a toxic soup. Located in Trinidad and Tobago, Pitch Lake is the world's largest asphalt lake—a hot, toxic pool of oily tar, teeming with poisonous hydrocarbons and carbon dioxide—and another environment seemingly too hostile for life to exist. So it was surprising when scientists studying tiny water droplets trapped in the oil discovered vibrant communities of microorganisms, many of which were adapted to life in extreme conditions. Furthermore, chemical analysis of the oil surrounding the water droplets indicated that the microorganisms inside were degrading the oil, using it as a source of energy and producing methane

gas as an end product, a process known as methanogenesis.

- *The organisms found in Pitch Lake degrade oil as a way to supply themselves with energy. How could humans use this same biodegradation to benefit our own environment?*
- *Methane is the most predominant component of natural gas. How could methanogenesis be of value to humans?*

Quick Search

To view videos of expeditions to Lake Whillans or Pitch Lake, search the Internet for the videos “Antarctica’s Secret Garden” and “Pitch lake, are we alone?”

These topics are further explored in chapter 7.

Chapter Summary with Key Terms

1.1 The Scope of Microbiology

- A. **Microbiology** is the study of **bacteria**, **viruses**, **fungi**, **protozoa**, and **algae**, which are collectively called **microorganisms**, or microbes. In general, microorganisms are **microscopic** and, unlike **macroscopic** organisms, which are readily visible, they require magnification to be adequately observed or studied.
- B. The science of microbiology is diverse and has branched out into many subspecialties and applications. Important subspecialties include **immunology**, **epidemiology**, and public health, food, dairy, aquatic, and industrial microbiology.

1.2 General Characteristics of Microorganisms and Their Roles in the Earth’s Environments

Microbes live in most of the world’s habitats and are indispensable for normal, balanced life on earth. They play many roles in the functioning of the earth’s ecosystems.

- A. Microbes are **ubiquitous**.
- B. There are many kinds of relationships between microorganisms and humans; most are beneficial, but a few are harmful.
- C. Microbes are involved in nutrient production and energy flow. Algae and certain bacteria trap the sun’s energy to produce food through **photosynthesis**.
- D. Other microbes are responsible for the breakdown and recycling of nutrients through **decomposition**. Microbes are essential to the maintenance of the air, soil, and water.
- E. Microbial cells are either the small, relatively simple, nonnucleated **prokaryotic** variety or the larger, more complex **eukaryotic** type that contain a **nucleus** and **organelles**.
- F. **Viruses** are microbes but not cells. They are smaller in size and infect their prokaryotic or eukaryotic hosts in order to reproduce themselves.
- G. **Parasites** and **pathogens** are microorganisms that invade the bodies of **hosts**, often causing damage through infection and disease.

1.3 Human Use of Microorganisms

Microbes have been called upon to solve environmental, agricultural, and medical problems.

- A. **Biotechnology** applies the power of microbes to the manufacture of industrial products, foods, and drugs.

- B. Microbes form the basis of **genetic engineering** and **recombinant DNA** technology, which alter genetic material to produce new products and modified life forms.
- C. In **bioremediation**, microbes are used to clean up pollutants and wastes in natural environments.

1.4 Microbial Roles in Infectious Diseases

- A. Nearly 2,000 microbes are **pathogens** that cause infectious diseases that result in high levels of mortality and morbidity (illness). Many infections are **emerging**, meaning that they are newly identified pathogens gaining greater prominence. Many older diseases are reemerging.
- B. Some diseases previously thought to be noninfectious may involve microbial infections (e.g., *Helicobacter*, causing gastric ulcers, and coxsackieviruses, causing diabetes).
- C. An increasing number of individuals have weak immune systems, which makes them more susceptible to infectious diseases.

1.5 The Historical Foundations of Microbiology

- A. Microbiology as a science is about 300 years old. Hundreds of contributors have provided discoveries and knowledge to enrich our understanding.
- B. With his simple microscope, van Leeuwenhoek discovered organisms he called animalcules. As a consequence of his findings and the rise of the **scientific method**, the notion of **spontaneous generation**, or **abiogenesis**, was eventually abandoned for **biogenesis**. The scientific method develops rational **hypotheses** and **theories** that can be tested. Theories that withstand repeated scrutiny become **laws** in time.
- C. Early microbiology blossomed with the conceptual developments of **sterilization**, **aseptic techniques**, and the **germ theory of disease**. Prominent scientists from this period include Robert Koch, Louis Pasteur, and Joseph Lister.

1.6 Taxonomy: Organizing, Classifying, and Naming Microorganisms

- A. **Taxonomy** is a hierarchical scheme for the **classification**, **identification**, and **nomenclature** of organisms, which are grouped in categories called **taxa**, based on features ranging from general to specific.

- B. Starting with the broadest category, the taxa are **domain, kingdom, phylum (or division), class, order, family, genus,** and **species**. Organisms are assigned **binomial scientific names** consisting of their genus and species names.

1.7 The Origin and Evolution of Microorganisms

- A. All life on earth **evolved** from simple cells appearing in ancient oceans about 3.5 billion years ago.
- B. Evolutionary change occurs when the environment places pressure on organisms that selects for the survival of those with more adaptive inheritable traits.
- C. All new species are the products of preexisting species, and their ancestry may be traced by examining fossils, morphology, physiology, genetics, and other scientific forms of investigation.
- D. The records of **phylogeny** are displayed in the form of a tree of life that shows organisms' relatedness.
- E. One classification scheme is based on a five-kingdom organization developed by Whittaker that includes:
1. Kingdom Prokaryotae (Monera), containing eubacteria and archaea;
 2. Kingdom Protista, containing primitive unicellular microbes such as algae and protozoa;
 3. Kingdom Myceteae, containing the fungi;
 4. Kingdom Animalia, containing animals; and
 5. Kingdom Plantae, containing plants.
- F. A newer classification scheme for living things is based on the genetic structure of their ribosomes. This Woese-Fox system recognizes three **Domains: Archaea**, simple prokaryotes that often live in extreme environments; **Bacteria**, typical prokaryotes; and **Eukarya**, all types of eukaryotic organisms.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

1. Which of the following is not considered a microorganism?
 - a. archaeon
 - b. bacterium
 - c. protozoan
 - d. mushroom
2. An area of microbiology that is concerned with the occurrence of disease in human populations is
 - a. immunology
 - b. parasitology
 - c. epidemiology
 - d. bioremediation
3. Which process involves the deliberate alteration of an organism's genetic material?
 - a. bioremediation
 - b. biotechnology
 - c. decomposition
 - d. recombinant DNA
4. A prominent difference between prokaryotic and eukaryotic cells is the
 - a. larger size of prokaryotes
 - b. lack of pigmentation in eukaryotes
 - c. presence of a nucleus in eukaryotes
 - d. presence of a cell wall in prokaryotes
5. Which of the following parts was absent from Leeuwenhoek's microscopes?
 - a. focusing screw
 - b. lens
 - c. specimen holder
 - d. condenser
6. Abiogenesis refers to the
 - a. spontaneous generation of organisms from nonliving matter
 - b. development of life forms from preexisting life forms
 - c. development of aseptic technique
 - d. germ theory of disease
7. A hypothesis can be defined as
 - a. a belief based on knowledge
 - b. knowledge based on belief
 - c. a scientific explanation that is subject to testing
 - d. a theory that has been thoroughly tested
8. Which early microbiologist was most responsible for developing standard microbiology laboratory techniques?
 - a. Louis Pasteur
 - b. Robert Koch
 - c. Carl von Linné
 - d. John Tyndall
9. Which scientist is most responsible for finally laying the theory of spontaneous generation to rest?
 - a. Joseph Lister
 - b. Robert Koch
 - c. Francesco Redi
 - d. Louis Pasteur
10. When a hypothesis has been thoroughly supported by long-term study and data, it is considered
 - a. a law
 - b. a speculation
 - c. a theory
 - d. proved

11. Which is the correct order of the taxonomic categories, going from most specific to most general?
 - a. domain, kingdom, phylum, class, order, family, genus, species
 - b. division, domain, kingdom, class, family, genus, species
 - c. species, genus, family, order, class, phylum, kingdom, domain
 - d. species, family, class, order, phylum, kingdom
12. By definition, organisms in the same _____ are more closely related than are those in the same _____.
 - a. order, family
 - b. class, phylum
 - c. family, genus
 - d. phylum, division
13. Which of the following are prokaryotic?
 - a. bacteria
 - b. archaea
 - c. protists
 - d. both a and b
14. Order the following items by size, using numbers: 1 = smallest and 8 = largest.
 - _____ human immunodeficiency virus HIV
 - _____ protozoan
 - _____ rickettsia
 - _____ protein
 - _____ worm
 - _____ coccus-shaped bacterium
 - _____ spirochete
 - _____ atom
15. Which of the following is not an emerging infectious disease?
 - a. avian influenza
 - b. Lyme disease
 - c. common cold
 - d. West Nile fever
16. How would you categorize a virus?
 - a. as prokaryotic
 - b. as eukaryotic
 - c. as an archaeon
 - d. none of these choices

Explain your choice for question 16.

Case Study Review

1. Many of the bacteria in Lake Whillans derive energy from the oxidation of chemical compounds. What might have made this necessary?
 - a. exceedingly low temperatures
 - b. a lack of sunlight
 - c. the size of the bacterial populations they found
 - d. a lack of fresh water
2. How was the number of different species in Lake Whillans determined?
 - a. counting individual cells
 - b. analyzing the DNA recovered from the samples
 - c. growing the cells and then classifying them according to their structural characteristics
 - d. measuring the concentration of cells in each milliliter of lake water
3. Do you think scientists working at Pitch Lake were at a great risk of infection from the organisms growing in the lake? Explain.

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

1. What does it mean to say microbes are ubiquitous?
2. What is meant by diversity with respect to organisms?
3. What events, discoveries, or inventions were probably the most significant in the development of microbiology and why?
4. Explain how microbiologists use the scientific method to develop theories and explanations for microbial phenomena.
5. Explain how microbes are classified into groups according to evolutionary relationships, provided with standard scientific names, and identified by specific characteristics.
6.
 - a. What are some of the sources for “new” infectious diseases?
 - b. Comment on the sensational ways in which some tabloid media portray the dangers of infectious diseases.

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps along with concept-mapping activities for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

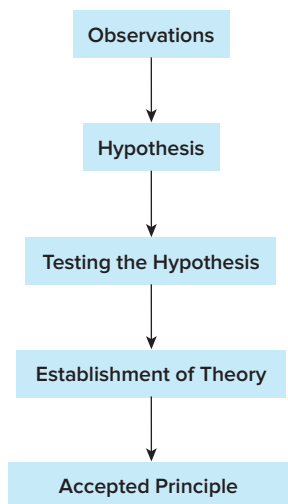

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases they do not have a single correct answer.

1. What do you suppose the world would be like if there were cures for all infectious diseases and a means to destroy all microbes? What characteristics of microbes would prevent this from happening?
2. How would you describe the types of scientific reasoning in the various experiments for supporting and denying spontaneous generation?
3. Give the technical name of a microbiologist who researches or works with protozoa in a termite's gut, bacteria that live in volcanoes, the tapeworms of dogs, molds that cause food poisoning, emerging viral diseases, the metabolism of bacteria that live in acid swamps, the classification of *Paramecium*.
4. Name the six most common infectious agents on earth and the four microbes that cause the highest rates of cancer.
5. What is the ultimate way that microbes will, as Pasteur said, have the "last word"?
6. Can you develop a scientific hypothesis and means of testing the cause of stomach ulcers? (Are they caused by an infection? by too much acid? by a genetic disorder?)
7. Construct the scientific name of a newly discovered species of bacterium using your name or the name of a pet, a place, or a unique characteristic. Be sure to use proper notation and endings.

Visual Challenge

Use the following pattern to construct an outline of the scientific reasoning that was involved in developing the germ theory of disease similar to figure 1.10.

A highly magnified view of a 4-billion-year-old Martian meteorite uncovers tiny rods that resemble earthly prokaryotes, but are they?

Source: Photo by David McKay/NASA

Brown streaks radiating down the slopes of the Hale Crater are flowing streams of water—the first indisputable evidence that liquid water exists on Mars.

CASE STUDY Part 1 Following the Water and Carbon on Mars

Throughout history, humans have gazed at the night sky and pondered the possible existence of other life forms in the universe. Telescopes have allowed closer glimpses of celestial bodies, but they have never been able to show the details needed to verify the presence of **life**. As technology advanced in the 1970s, the National Aeronautics and Space Administration (**NASA**) began a series of voyages to directly explore our own solar system. Astronomers knew from sophisticated **chemical** and **physical** analyses that most of the planets in our solar system had far too extreme conditions to **support life** as we know it, with the possible exception of Mars. Mars has a profile somewhat similar to earth's and is one of the closer planets, orbiting an average of 225 million miles away from earth. It is known to be very dry and cold (the temperature range is 80°F to −225°F), but there was a reasonable possibility that at least **simple organisms** could have developed there.

Starting in 1976, a series of space explorations was launched to find evidence that could point to signs of life on Mars. From these studies sprang a new science—**astrobiology**—which applies principles from biology, chemistry, and geology to investigate the possibilities of extraterrestrial life. One conclusion of NASA scientists that has driven many of their searches is that the only life forms that could possibly survive the extreme conditions of the planet in the past or present are microorganisms.

The significant questions being tackled by astrobiologists include these: What are the basic requirements of life? What would signs of life

look like? As is commonly done for many ideas of a biological nature, they turned to **chemistry** for answers. One of their assumptions was that because some of the same chemical substances on earth would likely exist on Mars, Martian life forms would have a similar profile, at least chemically. Attention was turned to substances that are part of all life on earth: mainly **water** and **carbon-based chemicals**.

The main goals of one of the first Mars space vehicles, *Viking Explorer*, were to sample for **water**, **carbon dioxide**, and **organic compounds**, and to **culture microbes** from Martian soil. The results were mostly negative or inconclusive, except for one—that the atmosphere contained high levels of carbon dioxide gas. Not surprisingly, the samples yielded no Martian microbes.

A discovery in 1996 of tiny rod-shaped objects in a 4-billion-year-old **Martian meteorite** from the Antarctic has been, and continues to be, the subject of much scientific scrutiny. This tantalizing image bears a resemblance to prokaryotic cells, but there is still a controversy about whether these are **ancient microbes** or geologic artifacts.

- *What chemical properties of water make it essential for living processes?*
- *What characteristics of carbon make it the central building block of life?*

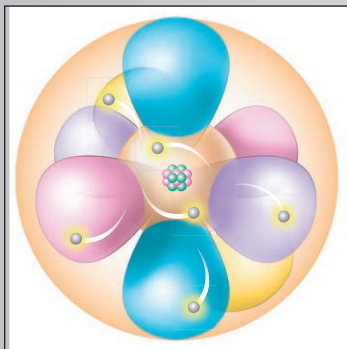

“The only life forms that could possibly survive the extreme conditions of the planet in the past or present are microorganisms.”

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

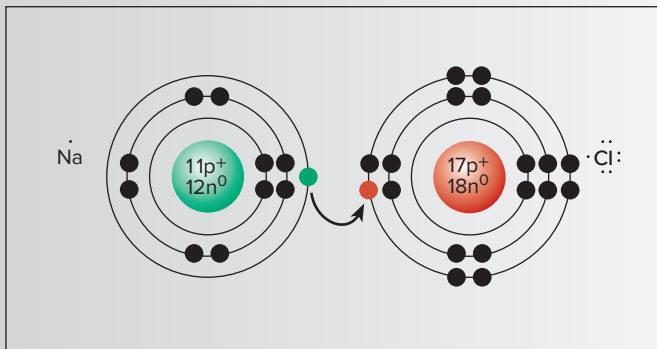

SCOPING OUT THE CHAPTER

It's not surprising that a search for life on other planets always begins by deciding whether conditions for life are possible; after all, life is chemistry. Without a basic understanding of the rules of chemistry, the study of biology is a hopeless endeavor. Why chemical bonds form, how proteins assume a specific shape, and the chemical characteristics of macromolecules important to living systems are just a few of the topics we touch on in this chapter.

Atomic Structure

All matter is composed of atoms, and the number of protons, neutrons, and electrons ultimately determines the characteristics of each element.

Chemical Properties

Atoms react with one another, making or breaking chemical bonds, to create complex molecules and compounds.

Carbohydrates

Simple carbohydrates are used as a source of energy, while more complex carbohydrates provide structure to the walls of plants, algae, and bacterial cells.

Lipids

An important energy source because of their high energy to weight ratio, lipids serve as a major component of cell membranes.

Proteins

The three-dimensional shape of proteins is essential to their function, whether as structural parts of the cell or as enzymes, catalyzing biochemical reactions.

Nucleic acids

The genetic information of cells and viruses is carried in the nucleic acids DNA and RNA.

(proteins): Image from the RCSB PDB (www.rcsb.org) of PDB ID 1R4Q (Fraser, M.E., Fujinaga, M., Cherney, M.M., Melton-Celsa, A.R., Twiddy, E.M., O'Brien, A.D., James, M.N.G. (2004) Structure of shiga toxin type 2 (Stx2) from *Escherichia coli* O157:H7.)

2.1 Atoms: Fundamental Building Blocks of All Matter in the Universe

Expected Learning Outcomes

1. Describe the properties of atoms and identify the relationships of the particles they contain.
2. Characterize elements and their isotopes.

3. Explain the differences between atomic number, mass number, and atomic weight.
4. List the major elements associated with life.
5. Describe electron orbitals and energy shells and how they are filled.

The universe is composed of an infinite variety of substances existing in gaseous, liquid, and solid states. All such tangible materials that occupy space and have mass are called **matter**.

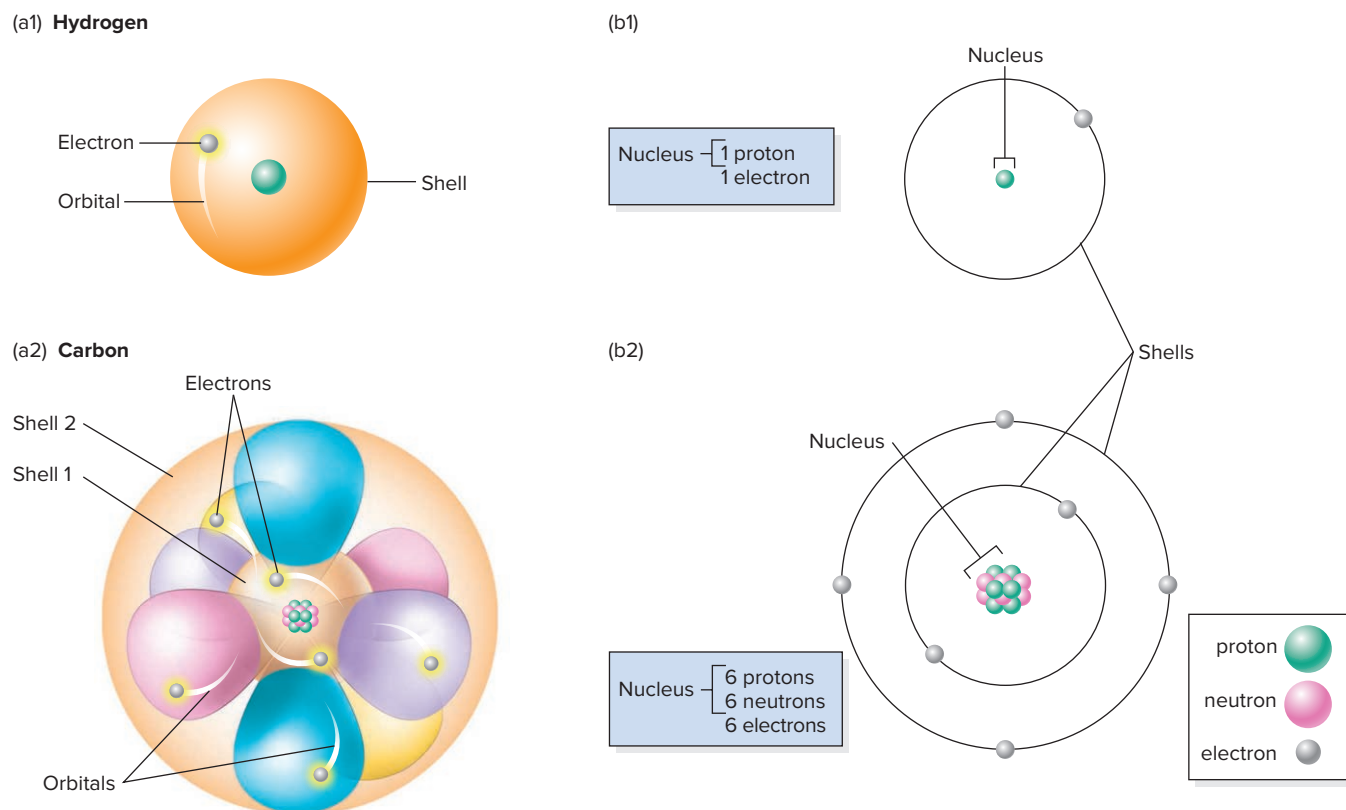

Figure 2.1 Models of atomic structure. Three-dimensional models of hydrogen and carbon that approximate their actual structure. The atomic nucleus is surrounded by electrons that travel within orbitals and occur in energy levels called shells. **(a1)** Hydrogen has just one orbital and one shell. **(a2)** Carbon has four orbitals and two shells. The outermost orbitals are most accurately portrayed as sets of lobe-shaped pairs rather than circles or spheres. **(b1, 2)** Simple models of hydrogen and carbon are not strictly accurate representations of atomic structure but are designed as a quick reference to the numbers and arrangements of shells and electrons, and the numbers of protons and neutrons in the nucleus. (Not to accurate scale.)

The organization of matter—whether air, rocks, or bacteria—begins with individual building blocks called atoms. An **atom** is defined as the smallest particle that cannot be subdivided into smaller substances without losing its properties. Even in a science dealing with very small things, an atom’s minute size is striking; for example, an oxygen atom is only 0.0000000013 mm (0.0013 nm) in diameter, and 1 million of them in a cluster would barely be visible to the naked eye.

Although scientists have not directly observed the detailed structure of an atom, the exact composition of atoms has been well established by extensive physical analysis using sophisticated instruments. In general, an atom derives its properties from a combination of subatomic particles called **protons** (p^+), which are positively charged; **neutrons** (n^0), which have no charge (are neutral); and **electrons** (e^-), which are negatively charged. Protons and neutrons are similar to one another in both mass and volume, while each is about 2,000 times as heavy as an electron. The protons and neutrons make up a central core, or atomic **nucleus**¹, that is surrounded by 1 or more electrons (**figure 2.1**). The nucleus makes up the larger mass (weight) of the atom, whereas the electron region, sometimes called the “electron cloud,” accounts for the greater volume. To get a perspective on proportions, consider this: If an atom

were the size of a football stadium, the nucleus would be about the size of a marble! The stability of atomic structure is largely maintained by

- the mutual attraction of the protons and electrons (opposite charges attract each other), and
- the exact balance of proton number and electron number, which causes the opposing charges to cancel each other out.

At least in theory, then, isolated intact atoms do not carry a charge.

Different Types of Atoms: Elements and Their Properties

All atoms share the same fundamental structure. All protons are identical, all neutrons are identical, and all electrons are identical. But when these subatomic particles come together in specific, varied combinations, unique types of atoms called **elements** result. Each element is a pure substance that has a characteristic atomic structure and predictable chemical behavior. To date, 118 elements have been described. Ninety-four of them are naturally occurring, and the rest were artificially produced by manipulating the particles in the nucleus. By convention, an element is assigned a distinctive name with an abbreviated shorthand symbol. The elements essential to life, often called **bioelements**, are outlined in

1. Be careful not to confuse the nucleus of an atom with the nucleus of a cell.

The Major Elements of Life and Their Primary Characteristics

The unique properties of each element result from the numbers of protons, neutrons, and electrons it contains, and each element can be identified by certain physical measurements.

Each element is assigned an **atomic number (AN)** based on the number of protons it has. The atomic number is a valuable measurement because an element's proton number does not vary, and knowing it automatically tells you the usual number of electrons (recall that a neutral atom has an equal number of protons and electrons). Another useful measurement is the **mass number (MN)**, equal to the number of protons and neutrons. If one knows the mass number and the atomic number, it is possible to determine the number of neutrons by subtraction. Hydrogen is a unique element because its common form has only one proton, one electron, and no neutron, making it the only element with the same atomic and mass number.

Isotopes are variant forms of the same element that differ in the number of neutrons and thus have different mass numbers. These multiple forms occur naturally in certain proportions. Carbon, for example, exists primarily as carbon 12 with 6 neutrons (MN = 12); but a small amount (about 1%) consists of carbon 13 with 7 neutrons and carbon 14 with 8 neutrons. Although isotopes have virtually the same chemical properties, some of them have unstable nuclei that spontaneously release energy in the form of radiation. Such *radioactive isotopes* play a role in a number of research and medical applications. Because they emit detectable energy, they can be used to trace the position of key atoms or molecules in chemical reactions, they are tools in diagnosis and treatment, and they are even applied in sterilization procedures (see chapter 11).

Clarifying Mass, Weight, and Related Terms

Mass refers to the quantity of matter that an atomic particle contains. The proton and neutron have almost exactly the same mass, which is about 1.66×10^{-24} grams, a unit of measurement known as a Dalton (Da) or unified atomic mass unit (U). All elements can be measured in these units. The terms *mass* and *weight* are often used interchangeably in biology, even though they apply to two different but related aspects of matter. *Weight* is a measurement of the gravitational pull on the mass of a particle, atom, or object. Consequently, it is possible for something with the same mass to have different weights. For example, an astronaut on the earth (normal gravity) would weigh more than the same astronaut on the moon (weak gravity). Atomic weight has been the traditional usage for biologists, because most chemical reactions and biological activities occur within the normal gravitational conditions on earth. This permits use of atomic weight as a standard of comparison. You will also see the terms *formula weight* and *molecular weight* used interchangeably, and they are indeed synonyms. They both mean the sum of atomic weights of all atoms in a molecule.

Another important measurement of an element is its **atomic mass** or **atomic weight**. This is given as the average mass numbers of all isotopic forms (table 2.1). You will notice that this number may not come out even, because most elements have several isotopes and differing proportions of them.

TABLE 2.1 Chemical Characteristics of Major Elements of Life

Element	Atomic Symbol*	Atomic Number	Atomic Mass**	Ionized Forms (see section 2.3)
Calcium	Ca	20	40.08	Ca ²⁺
Carbon	C	6	12.01	CO ₃ ²⁻
Carbon*	C-14	6	14.0	
Chlorine	Cl	17	35.45	Cl ⁻
Cobalt	Co	27	58.93	Co ²⁺ , Co ³⁺
Copper	Cu	29	63.54	Cu ⁺ , Cu ²⁺
Hydrogen	H	1	1.00	H ⁺
Hydrogen*	H-3	1	3.01	
Iodine	I	53	126.9	I ⁻
Iodine*	I-131	53	131.0	
Iron	Fe	26	55.84	Fe ²⁺ , Fe ³⁺
Magnesium	Mg	12	24.30	Mg ²⁺
Manganese	Mn	25	54.93	Mn ²⁺ , Mn ³⁺
Nitrogen	N	7	14.0	NO ₃ ⁻ (nitrate)
Oxygen	O	8	15.99	
Phosphorus	P	15	31.97	PO ₄ ³⁻ (phosphate)
Phosphorus*	P-32	15	32	
Potassium	K	19	39.10	K ⁺
Sodium	Na	11	22.99	Na ⁺
Sulfur	S	16	32.06	SO ₄ ²⁻ (sulfate)
Zinc	Zn	30	65.38	Zn ²⁺

*Based on the Latin name of the element. The first letter is always capitalized; if there is a second letter, it is always lowercased.

**The atomic mass or weight is equal to the average mass number for the isotopes of that element.

*An isotope of the element.

table 2.1. In some form or another, they make up the matter of all earth's organisms and viruses. Microorganisms have a particularly important relationship with most of these elements. This is due to the roles microbes play in the cycling processes that maintain the elements in forms usable by other organisms.

The vast majority of life forms require only about 20 of the 94 naturally occurring elements. The other 70 or so elements are not critical to life, and a number of them, such as arsenic and uranium, can be highly toxic to cells. As we will see in chapter 7, microbes have some incredible "survival skills" that enable them to occupy extreme habitats containing large amounts of these elements. The word that describes such a microbe is *extremophile*. * For additional information on the functions of elements and the involvement of microbes in their recycling, look ahead to table 7.1.

* An *extremophile* (ex-tree'-moh-fyl') is a microbe that can live in very severe conditions that would be harmful to other organisms.

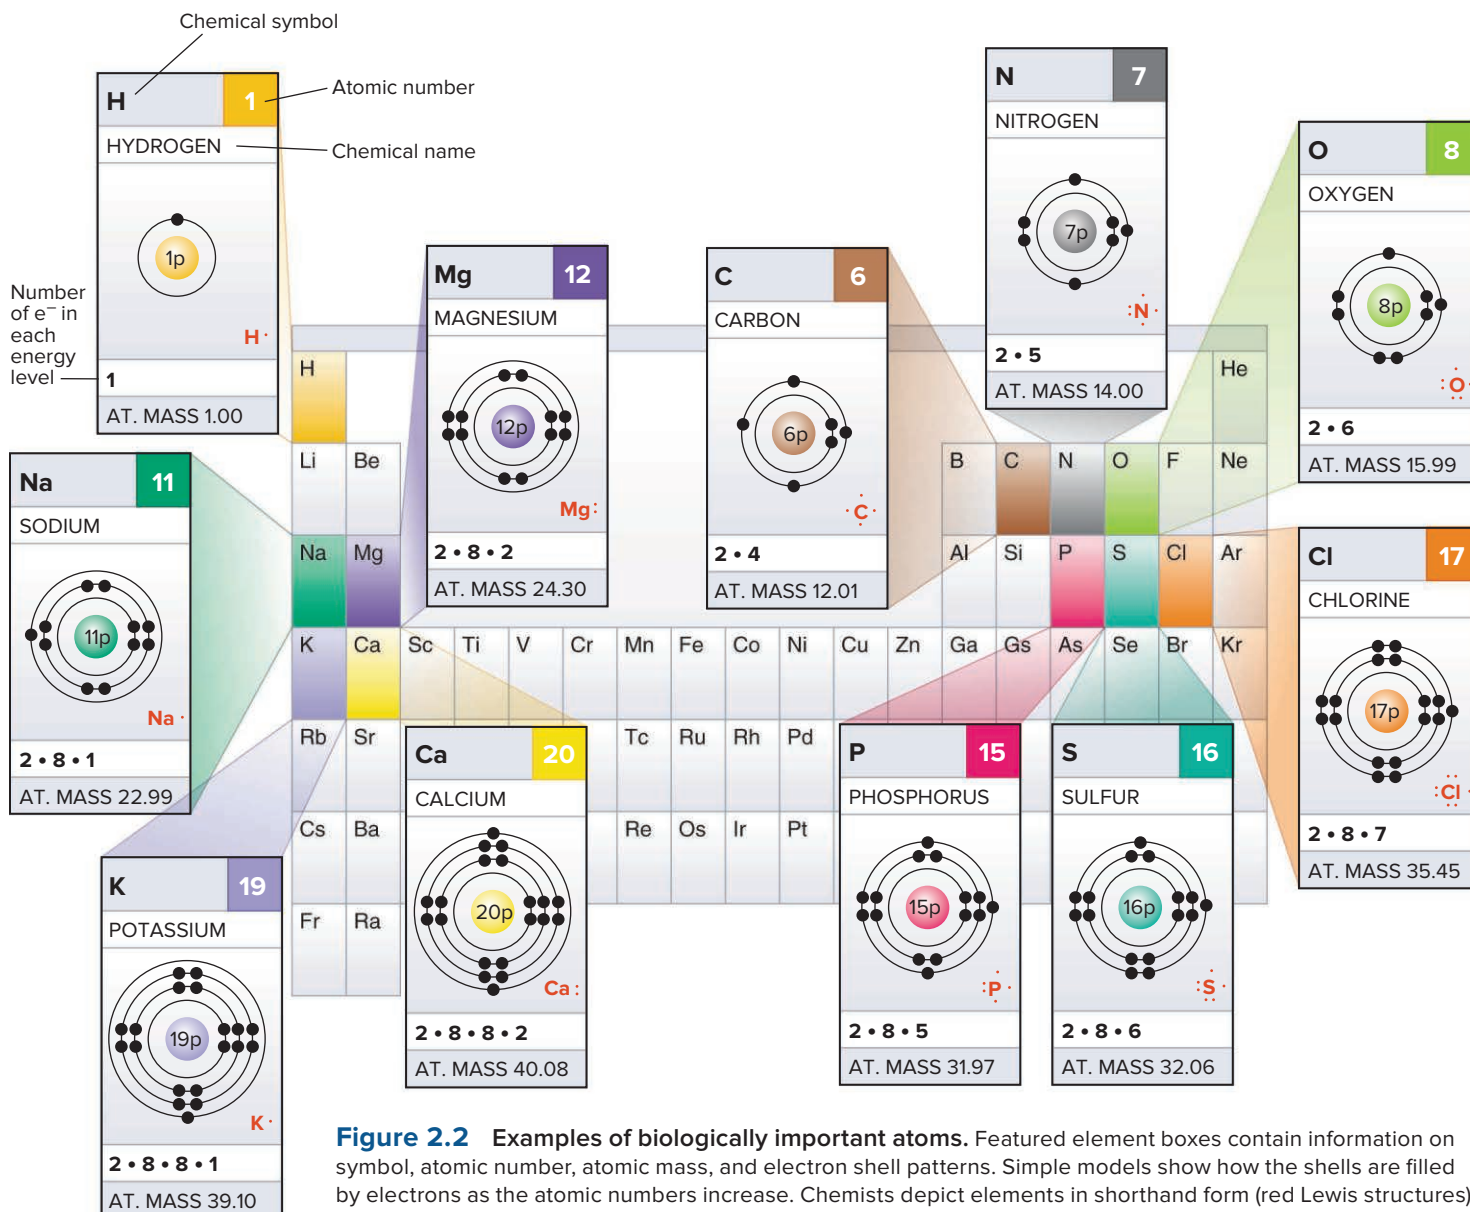

Figure 2.2 Examples of biologically important atoms. Featured element boxes contain information on symbol, atomic number, atomic mass, and electron shell patterns. Simple models show how the shells are filled by electrons as the atomic numbers increase. Chemists depict elements in shorthand form (red Lewis structures) that indicate only the valence electrons, because these are the electrons involved in chemical bonds. In the background is a partial display of the periodic table of elements showing the position of these elements in the periodic table.

Electron Orbitals and Shells

The structure of an atom can be envisioned as a central nucleus surrounded by a cloud of electrons that constantly spin at exceedingly high speed within confined pathways surrounding the nucleus (see figure 2.1). The pathways taken by electrons are called **orbitals**, which are not actual objects or exact locations but represent volumes of three-dimensional space in which an electron is likely to be found. The position of an electron at any one instant is dictated by its energy level or **shell**, proceeding from the lower-level energy electrons nearest the nucleus to the higher-energy electrons in the outer shells.

Electrons fill the orbitals and shells in *pairs*, starting with the shell nearest the nucleus:

- The first shell contains one orbital and a maximum of 2 electrons.
- The second shell has four orbitals and up to 8 electrons.

- The third shell with nine orbitals can hold up to 18 electrons.
- The fourth shell with 16 orbitals contains up to 32 electrons.

The number of orbitals and shells and how completely they are filled depend on the numbers of electrons, so that each element will have a unique pattern. For example:

- Helium (AN = 2) has only a filled first shell of 2 electrons.
- Oxygen (AN = 8) has a filled first shell and a partially filled second shell of 6 electrons.
- Magnesium (AN = 12) has a filled first shell, a filled second shell, and a third shell that has only one orbital, so is nearly empty.

As we will see, the chemical properties of an element are controlled mainly by the distribution of electrons in the outermost shell. **Figure 2.2** presents various simplified models of atomic structure and electron maps, superimposed over a partial display of the periodic table of elements.

Check Your Progress SECTION 2.1

1. How are the concepts of an atom and an element related? What causes elements to differ?
2. What are the subatomic particles and how do they contribute to the structure and character of atoms?
3. How are mass number and atomic number derived? What is the atomic mass or weight?
4. What is distinctive about isotopes of elements, and why are they important?
5. Why is an isolated atom neutral?
6. Describe the concept of the atomic nucleus, electron orbitals, and shells.

2.2 Bonds and Molecules

Expected Learning Outcomes

6. Explain how elements make chemical bonds to form molecules and compounds.
7. State the relationship among an atom, a molecule, and a compound.
8. Identify the differences between covalent, ionic, and hydrogen bonds.
9. Summarize the concepts of valence, polarity, and diatomic elements.
10. Describe ionization and distinguish between anions and cations.
11. Compare oxidation and reduction and their effects.

Most elements do not exist naturally in pure, uncombined form but are bound together as molecules and compounds. A **molecule*** is a distinct chemical substance that results from the combination of two or more atoms. Molecules come in a great variety. A few of them such as oxygen (O_2) consist of the same element (see “The Nature of Diatomic Elements”). But most molecules—for example, carbon dioxide (CO_2) and water (H_2O)—contain two or more different elements and are more appropriately termed **compounds**. So compounds are one major type of molecule. Other examples of compounds are biological molecules such as proteins, sugars, and fats.

The Nature of Diatomic Elements

You will notice that hydrogen, oxygen, nitrogen, chlorine, and iodine are often shown in notation with a subscript 2— H_2 or O_2 . These elements are *diatomic* (two atoms), meaning that in their pure elemental state, they exist in pairs, rather than as a single atom. In every case, these elements are more stable as a pair of atoms joined by a covalent bond than as a single atom. The reason for this

* *molecule* (mol'-ih-kyool) L. *molecula*, little mass.

phenomenon can be explained by their valences. The electrons in the outer shell are configured so as to complete a full outer shell for both atoms when they bind. You can see this for yourself by observing figure 2.4. It is interesting that most of the diatomic elements are gases.

When atoms bind together in molecules, they lose the properties of the atom and take on the properties of the combined substance. In the same way that an atom has an atomic weight, a molecule has a **formula mass** or **molecular weight²** (MW), which is calculated from the sum of all of the atomic masses of the atoms it contains.

Chemical bonds of molecules are created when two or more atoms share, donate (lose), or accept (gain) electrons (**figure 2.3**). This capacity for making bonds, termed **valence***, is determined by the number of electrons that an atom has to lose or share with other atoms during bond formation. The valence electrons determine the degree of reactivity and the types of bonds an element can make. Elements with a filled outer orbital are relatively nonreactive because they have no extra electrons to share with or donate to other atoms. For example, helium has one filled shell, with no tendency either to give up electrons or to take them from other elements, making it a stable, inert (nonreactive) gas. Elements with partially filled outer orbitals are less stable and are more apt to form some sort of bond.

2. Biologists prefer to use this term.

* *valence* (vay'-lents) L. *valentia*, strength. The binding qualities of an atom dictated by the number of electrons in its outermost shell.

Figure 2.3 General representation of three types of bonding. (a) Covalent bonds, both single and double. (b) Ionic bond. (c) Hydrogen bond. Note that hydrogen bonds are represented in models and formulas by dotted lines, as shown in (c).

Figure 2.4 Examples of molecules with covalent bonding.

(a) A hydrogen molecule is formed when two hydrogen atoms share their electrons and form a single bond. (b) In a double bond, the outer orbitals of two oxygen atoms overlap and permit the sharing of 4 electrons (one pair from each) and the saturation of the outer orbital for both. (c) Simple, three-dimensional, and working models of methane. Note that carbon has 4 electrons to share and hydrogens each have one, thereby completing the shells for all atoms in the compound and creating 4 single bonds. Note that (a) and (b) also show the formation of diatomic molecules.

Many chemical reactions are based on the tendency of atoms with unfilled outer shells to gain greater stability by achieving, or at least approximating, a filled outer shell. For example, an atom (such as oxygen) that can accept two additional electrons will bond readily with atoms (such as hydrogen) that can share or donate electrons. We explore some additional examples of the basic types of bonding in the following section.

In addition to reactivity, the number of electrons in the outer shell also dictates the number of chemical bonds an atom can make. For instance, hydrogen can bind with one other atom, oxygen can bind with up to two other atoms, and carbon can bind with four.

Covalent Bonds: Molecules with Shared Electrons

Covalent (cooperative valence) **bonds** form between atoms with valences that suit them to sharing electrons rather than to donating or receiving them. A simple example is hydrogen gas (H_2), which consists of two hydrogen atoms. A hydrogen atom has only a single electron, but when two of them combine, each will bring its electron to orbit about both nuclei, thereby approaching a filled orbital (2 electrons) for both atoms and thus creating a single covalent bond (**figure 2.4a**). Covalent bonding also occurs in oxygen gas (O_2), but with a difference. Because each atom has 2 electrons to share in this molecule, the combination creates two pairs of shared electrons, also known as a double covalent bond (**figure 2.4b**). The majority of the molecules associated with living things are composed of single and double covalent bonds between the most common biological elements (carbon, hydrogen, oxygen, nitrogen, sulfur, and phosphorus), which are discussed in more depth in chapter 7. A slightly more complex pattern of covalent bonding is shown for methane gas (CH_4) in **figure 2.4c**.

Polarity in Molecules

Electronegativity refers to the tendency of an atom or molecule to attract electrons. When atoms of different electronegativity form covalent bonds, the electrons will not be shared equally and will be pulled toward the more electronegative atom. This force causes one end of a molecule to assume a partial negative charge and the other end to assume a partial positive charge. A molecule with such an unequal distribution of charges is termed **polar** and shows polarity—meaning it has positive and negative poles.

Observe the water molecule shown in **figure 2.5** and note that, because the oxygen atom is larger and has more protons than the hydrogen atoms, it will have a stronger attraction for the shared electrons than the hydrogen atoms have. Because the electrons will spend more time near the oxygen, it will express a partial negative charge. The electrons are less attracted to the hydrogen orbitals, causing the positive charge of the hydrogen's single proton to

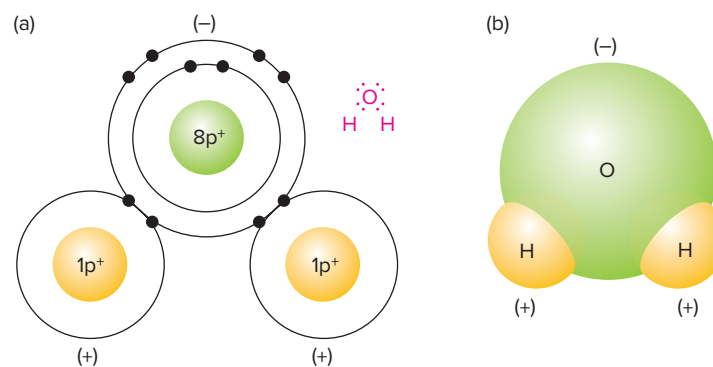

Figure 2.5 Polar molecule. (a) A simple model and (b) a three-dimensional model of a water molecule indicate the polarity, or unequal distribution, of electrical charge, which is caused by the pull of the shared electrons toward the oxygen side of the molecule.

dominate. The polar nature of water plays an important role in a number of biological reactions, which are discussed later. Polarity is a significant property of many large molecules in living systems and greatly influences both their reactivity and their structure.

When covalent bonds are formed between atoms that have the same or similar electronegativity, the electrons are shared equally between the two atoms. Because of this balanced distribution, no part of the molecule has a greater attraction for the electrons. This sort of electrically neutral molecule is termed **nonpolar**. Examples of nonpolar molecules are oxygen, methane (see figure 2.4), and lipids (see figure 2.18).

Ionic Bonds: Electron Transfer Among Atoms

In reactions that form **ionic bonds**, electrons are transferred completely from one atom to another and are not shared. These reactions invariably occur between atoms with complementary valences. This means that one atom has an unfilled outer shell that can readily accept electrons and the other atom has an unfilled outer shell that will readily give up electrons. A striking example is the reaction that occurs between sodium (Na) and chlorine (Cl). Elemental sodium is a soft, lustrous metal so reactive that it can burn flesh, and molecular chlorine is a very poisonous yellow gas. But when the two are combined, they form sodium chloride⁴ (NaCl)—the familiar nontoxic table salt—a compound with properties quite different from either parent element (**figure 2.6**).

How does this transformation occur? Sodium has 11 electrons (2 in shell one, 8 in shell two, and only 1 in shell three), so it is 7 short of having a complete outer shell. Chlorine has 17 electrons (2 in shell one, 8 in shell two, and 7 in shell three), making it 1 short of a complete outer shell. When these two atoms come together, the sodium atom will readily donate its single valence electron and the chlorine atom will avidly receive it. The reaction is slightly more involved than a single sodium atom's combining with a single chloride atom, but the details do not negate the fundamental reaction as described here. The outcome of this reaction is a solid crystal complex that interlinks millions of sodium and chloride atoms (**figure 2.6c, d**). The binding of Na^+ and Cl^- exists in three dimensions. Each Na is surrounded by 6 Cls and vice versa. Their charges balance out, and no single molecule of NaCl is present.

Ionization: Formation of Charged Particles

Compounds with intact ionic bonds are electrically neutral, but they can produce charged particles when dissolved in a liquid called a solvent. This phenomenon, called **ionization**, occurs when the ionic bond is broken and the atoms dissociate (separate) into unattached, charged particles called **ions** (**figure 2.7**). To illustrate what imparts a charge to ions, let us look again at the reaction between sodium and chlorine. When a sodium atom reacts with chlorine and loses 1 electron, the sodium is left with 1 more proton than electrons. This imbalance produces a positively charged sodium ion (Na^+). Chlorine, on the other hand, has gained 1 electron and now has 1 more electron than protons, producing a negatively charged ion (Cl^-). Positively

Figure 2.6 Ionic bonding between sodium and chlorine.

(a) During the reaction, sodium loses its single outer orbital electron to chlorine, thereby filling chlorine's outer shell. (b) Simple model of ionic bonding. (c) Sodium and chloride ions form large molecules, or crystals, in which the two atoms alternate in a definite, regular, geometric pattern. (d) Note the cubic nature of NaCl crystals at the macroscopic level.

© Kathy Park Talaro

charged ions are termed **cations**,* and negatively charged ions are termed **anions**.* Substances such as salts, acids, and bases that release ions when dissolved in water are termed **electrolytes** because their charges enable them to conduct an electrical current.

Owing to the general rule that particles of like charge repel each other and those of opposite charge attract each other, we can

* **cation** (kat'-eye-on) A positively charged ion that migrates toward the negative pole, or cathode, of an electrical field.

* **anion** (an'-eye-on) A negatively charged ion that migrates toward the positive pole, or anode.

4. In general, when a salt is formed, the ending of the name of the negatively charged ion is changed to *-ide*.

Figure 2.7 Ionization. When NaCl in the crystalline form is added to water, the ions are released from the crystal as separate charged particles (cations and anions) into solution. (See also figure 2.12.) In this solution, Cl^- ions are attracted to the hydrogen component of water, and Na^+ ions are attracted to the oxygen (box).

expect ions to interact electrostatically with other ions and polar molecules. Such interactions are important in many cellular chemical reactions, in the formation of solutions, and in the reactions microorganisms have with dyes.

Hydrogen Bonding

Some types of bonding do not involve sharing, losing, or gaining electrons but instead are due to attractive forces between nearby molecules or atoms. One such bond is a **hydrogen bond**, a weak electrostatic force that forms between a hydrogen covalently bonded to one molecule and an oxygen or nitrogen atom on the same molecule or on a different molecule. This phenomenon occurs because a hydrogen atom in a covalent bond tends to be positively charged. Thus, it can attract a nearby negatively charged atom and form an easily disrupted bridge with it. This type of bonding is usually represented in molecular models with a dotted line. A simple example of hydrogen bonding occurs between water molecules (**figure 2.8**). More extensive hydrogen bonding is partly responsible for the structure and stability of proteins and nucleic acids, as you will see later on.

Figure 2.8 Hydrogen bonding in water. Because of the polarity of water molecules, the negatively charged oxygen end of one water molecule is weakly attracted to the positively charged hydrogen end of an adjacent water molecule.

Weak molecular interactions similar to hydrogen bonds that play major roles in the shape and function of biological molecules are **van der Waals forces**. The basis for these interactions is also an attraction of two regions on atoms or molecules that are opposite in charge, but van der Waals forces can occur between nearly any types of molecules and not just those containing hydrogen, oxygen, and nitrogen. These forces come into play whenever the electrons in molecules move about their orbits and become unevenly distributed. This unevenness leads to short-term “sticky spots” in the molecule—some positively charged and others negatively charged. When such regions are located close together, their opposite charges pull them together. These forces can hold even large molecules together because of the cumulative effects of numerous sites of interaction. They not only function between molecules but may occur within different regions of the same large molecule. Van der Waals forces are a significant factor in protein folding and stability (see figure 2.23, steps 3 and 4).

Electron Transfer and Oxidation-Reduction Reactions

The metabolic work of cells, such as synthesis, movement, and digestion, revolves around energy exchanges and transfers. The management of energy in cells is almost exclusively dependent on chemical rather than physical reactions, because most cells are far too delicate to operate with heat, radiation, and other more potent forms of energy. The outer-shell electrons are readily portable and easily manipulated sources of energy. It is in fact the movement of electrons from molecule to molecule that accounts for most energy exchanges in cells. Fundamentally, then, cells must have a supply of atoms that can gain or lose electrons if they are to carry out life processes.

The phenomenon in which electrons are transferred from one atom or molecule to another is termed an **oxidation-reduction** (shortened to **redox**) **reaction**. The term *oxidation* was originally adopted for reactions involving the addition of oxygen, but this is no longer the case. In current usage, *oxidation* includes any reaction that causes an atom to lose electrons. Because all redox reactions occur in pairs, it follows that *reduction* is the result of a different atom gaining

these same electrons. Keep in mind that because electrons are being added during reduction, the atom that receives them will become more negative; and that is the meaning of *reduction* in this context. It does not imply that an atom is getting smaller. In fact, reduction often results in a greater complexity of the molecule.

To analyze the phenomenon, let us again review the production of NaCl but from a different standpoint. When these two atoms, called the redox pair, react to form sodium chloride, a sodium atom gives up an electron to a chlorine atom. During this reaction, sodium is oxidized because it loses an electron, and chlorine is reduced because it gains an electron (**figure 2.9**). With this system, an atom such as sodium that can donate electrons and thereby reduce another atom is a **reducing agent**. An atom that can receive extra electrons and thereby oxidize another molecule is an **oxidizing agent**. You may find this concept easier to keep straight if you think of redox agents as partners: The reducing partner gives its electrons away and is oxidized; the oxidizing partner receives the electrons and is reduced.⁵

Redox reactions are essential to many of the biochemical processes discussed in chapter 8. In cellular metabolism, electrons are frequently transferred from one molecule to another as described here. In other reactions, oxidation and reduction occur with the transfer of a hydrogen atom (a proton and an electron) from one compound to another.

Check Your Progress SECTION 2.2

- Explain how the concepts of molecules and compounds are related.
- Distinguish between the general reactions in covalent, ionic, and hydrogen bonds.
- Which kinds of elements tend to make covalent bonds?
- Distinguish between a single and a double bond.
- Define polarity and explain what causes it.
- Which kinds of elements tend to make ionic bonds?
- Differentiate between an anion and a cation, using examples.
- Differentiate between oxidation and reduction, and between an oxidizing agent and a reducing agent, using examples.

2.3 Chemical Reactions, Solutions, and pH

Expected Learning Outcomes

- Classify different forms of chemical shorthand and types of reactions.
- Explain solutes, solvents, and hydration.
- Differentiate between hydrophilic and hydrophobic.
- Describe the pH scale and how it was derived; define *acid*, *base*, and *neutral levels*.

Figure 2.9 Simplified diagram of the exchange of electrons during an oxidation-reduction reaction. Numbers indicate the total electrons in that shell.

Formulas, Models, and Equations

The atomic content of molecules can be represented by a few convenient formulas. We have already been using the molecular formula, which concisely gives the atomic symbols and the number of the atoms involved in subscripts (CO_2 , H_2O). More complex molecules such as glucose ($\text{C}_6\text{H}_{12}\text{O}_6$) can also be symbolized this way, but this formula is not unique, because fructose and galactose also share it. Molecular formulas are useful, but they only summarize the atoms in a compound; they do not show the position of bonds between atoms. For this purpose, chemists use structural formulas illustrating the relationships of the atoms and the number and types of bonds (**figure 2.10**). Other structural models present the three-dimensional appearance of a molecule, illustrating the orientation of atoms (differentiated by color codes) and the molecule's overall shape (**figure 2.11**). Many complex molecules such as proteins are now represented by computer-generated images (see figure 2.23, step 4).

Molecules, including those in cells, are constantly involved in **chemical reactions**, leading to changes in the composition of the matter they contain. These changes generally involve the breaking and making of bonds and the rearrangement of atoms. The chemical substances that start a reaction and that are changed by the reaction are called the **reactants**. The substances that result from the reaction are called the **products**. Keep in mind that all of the matter in any reaction is retained in some form, and the same types and numbers of atoms going into the reaction will be present in the products. Chemists and biologists use shorthand to summarize the content of a reaction by means of a **chemical equation**. In an equation, the reactant(s) are on the left of an arrow and the product(s) are on the right. The number of atoms of each element must be balanced on either side of the arrow. Note that the numbers of reactants and products are indicated by a coefficient in front of the formula (no coefficient means 1). We have already reviewed the reaction with sodium and chloride, which would be shown with this equation:

Most equations do not give the details or even exact order of the reaction but are meant to keep the expression a simple overview of the process being shown. Some of the common reactions in organisms are syntheses, decompositions, and exchanges.

5. A mnemonic device to keep track of this is *LEO says GER*: Lose Electrons Oxidized; Gain Electrons Reduced.

Figure 2.10 Comparison of molecular and structural formulas. (a) Molecular formulas provide a brief summary of the elements in a compound. (b1) Structural formulas clarify the exact relationships of the atoms in the molecule, depicting single bonds by a single line and double bonds by two lines. (b2) In structural formulas of organic compounds, cyclic or ringed compounds may be completely labeled, or (b3) they may be presented in a shorthand form in which carbons are assumed to be at the angles and attached to hydrogens. See figure 2.16 for structural formulas of three sugars with the same molecular formula, $C_6H_{12}O_6$.

In a **synthesis* reaction**, the reactants bond together in a manner that produces an entirely new molecule (reactant A plus reactant B yields product AB). An example is the production of sulfur dioxide, a by-product of burning sulfur fuels and an important component of smog:

Some synthesis reactions are not such simple combinations. When water is synthesized, for example, the reaction does not really involve one oxygen atom combining with two hydrogen atoms, because elemental oxygen exists as O_2 and elemental hydrogen exists as H_2 . A more accurate equation for this reaction is:

In **decomposition reactions**, the bonds on a single reactant molecule are permanently broken to release two or more product molecules. A simple example can be shown for the common chemical hydrogen peroxide:

* *synthesis* (sin'-thuh-sis) Gr. *synthesis*, putting together.

Figure 2.11 Three-dimensional, or space-filling, models of (a) water, and (b) carbon dioxide. The red atoms are oxygen, the white ones hydrogen, and the black ones carbon. (a and b): © John W. Hole

During **exchange reactions**, the reactants trade portions between each other and release products that are combinations of the two:

This type of reaction occurs between an acid and a base when they react to form water and a salt:

The reactions in biological systems can be reversible, meaning that reactants and products can be converted back and forth. These reversible reactions are symbolized with a double arrow, each pointing in opposite directions, as in the exchange reaction shown earlier. Whether a reaction is reversible depends on the proportions of these compounds, the difference in energy state of the reactants and products, and the presence of **catalysts** (substances that increase the rate of a reaction). Additional reactants coming from another reaction can also be indicated by arrows that enter or leave at the main arrow:

Solutions: Homogeneous Mixtures of Molecules

A **solution** is a mixture of one or more substances called **solutes** uniformly dispersed in a dissolving medium called a **solvent**. An important characteristic of a solution is that the solute cannot be separated by filtration or ordinary settling. The solute can be gaseous, liquid, or solid, and the solvent is usually a liquid. Examples of solutions are salt or sugar dissolved in water and iodine dissolved in alcohol. In general, a solvent will dissolve a solute only if it has similar electrical characteristics as indicated by the rule of solubility, expressed simply as “like dissolves like.” For example, water is a polar molecule and will readily dissolve an ionic solute such as NaCl, yet a nonpolar solvent such as benzene will not dissolve NaCl.

Water is the most common solvent in natural systems, having several characteristics that suit it to this role. The polarity of the water molecule causes it to form hydrogen bonds with other water molecules, but it can also interact readily with charged or polar molecules.

When ionic solutes such as NaCl crystals are added to water, the Na^+ and Cl^- are released into solution. Dissolution occurs because Na^+ is attracted to the negative pole of the water molecule and Cl^- is attracted to the positive poles. In this way, they are drawn

Figure 2.12 Hydration spheres formed around ions in solution. In this example, a sodium cation attracts the negatively charged region of water molecules, and a chloride anion attracts the positively charged region of water molecules. In both cases, the ions become surrounded by spherical layers of specific numbers and arrangements of water molecules.

away from the crystal separately into solution. As it leaves, each ion becomes **hydrated**, which means that it is surrounded by a sphere of water molecules (**figure 2.12**). Molecules such as salt or sugar that attract water to their surface are termed **hydrophilic**.^{*} Nonpolar molecules, such as benzene, that repel water are considered **hydrophobic**.^{*} A third class of molecules, such as the phospholipids in cell membranes, are considered **amphipathic**^{*} because they have both hydrophilic and hydrophobic properties.

Because most biological activities take place in aqueous (water-based) solutions, the concentration of these solutions can be very important (see chapter 7). The **concentration** of a solution expresses the amount of solute dissolved in a certain amount of solvent. It can be figured by percentage or molarity. Percentage is the ratio of solute in solution expressed as some combination of weight or volume.

A common way to calculate concentration by percentage is to use the weight of the solute, measured in grams (g), dissolved in a specified volume of solvent, measured in milliliters (ml). For example, dissolving 3 g of NaCl in the amount of water to produce 100 ml of solution is a 3% solution; dissolving 30 g in water up to

100 ml of solution produces a 30% solution; and dissolving 3 g in 1,000 ml (1 liter) produces a 0.3% solution.

A frequent way to express concentration of biological solutions is by its molar concentration, or **molarity (M)**. A standard molar solution is obtained by dissolving 1 *mole*, defined as the molecular weight of the compound in grams, in 1 L (1,000 ml) of solution. To make a 1 M solution of sodium chloride, we would dissolve 58 g of NaCl to give 1 L of solution; a 0.1 M solution would require 5.8 g of NaCl in 1 L of solution.

Acidity, Alkalinity, and the pH Scale

Another factor with far-reaching impact on living things is the concentration of acidic or basic solutions in their environment. To understand how solutions become acidic or basic, we must look again at the behavior of water molecules. Hydrogens and oxygen tend to remain bonded by covalent bonds, but under certain conditions, a water molecule may dissociate. This occurs when a single hydrogen atom breaks away as an ionic H^+ , or **hydrogen ion**, leaving the remainder of the molecule in the form of an OH^- , or **hydroxide ion**. The H^+ ion is positively charged because it is essentially a hydrogen that has lost its electron; the OH^- is negatively charged because it remains in possession of that electron. Ionization of water is constantly occurring, but in pure water containing no other ions, H^+ and OH^- are produced in equal amounts, and the solution remains neutral. By one definition, a solution is considered **acidic** when one of its components (an acid) releases excess hydrogen ions.⁶ A solution is **basic** when a component (a base) releases excess hydroxide ions, so that there is no longer a balance between the two ions. Another term used interchangeably with basic is **alkaline**.

To measure the acid and base concentrations of solutions, scientists use the **pH** scale, a graduated numerical scale that ranges from 0 (the most acidic) to 14 (the most basic). This scale is a useful standard for rating the relative acid or base content of a substance. Use **figure 2.13** to familiarize yourself with the pH readings of some common substances. It is not an arbitrary scale but actually a mathematical derivation based on the negative logarithm (reviewed in “Exponents” found in Connect) of the concentration of H^+ ions in moles per liter (symbolized as $[H^+]$) in a solution, represented as:

$$pH = -\log[H^+]$$

6. Actually, it forms a hydronium ion (H_3O^+), but for simplicity's sake we will use the notation H^+ .

Figure 2.13 The pH scale. Shown are the relative degrees of acidity and alkalinity and the approximate pH readings for various substances.

^{*} **hydrophilic** (hy-droh-fil'-ik) Gr. *hydros*, water, and *philos*, to love.

^{*} **hydrophobic** (hy-droh-fob'-ik) Gr. *phobos*, fear.

^{*} **amphipathic** (am'-fy-path'-ik) Gr. *amphi*, both.

TABLE 2.2 Hydrogen Ion and Hydroxide Ion Concentrations at a Given pH

Moles/L of Hydrogen Ions	Logarithm	pH	Moles/L of OH ⁻
1.0	10 ⁰	0	10 ⁻¹⁴
0.1	10 ⁻¹	1	10 ⁻¹³
0.01	10 ⁻²	2	10 ⁻¹²
0.001	10 ⁻³	3	10 ⁻¹¹
0.0001	10 ⁻⁴	4	10 ⁻¹⁰
0.00001	10 ⁻⁵	5	10 ⁻⁹
0.000001	10 ⁻⁶	6	10 ⁻⁸
0.0000001	10 ⁻⁷	7	10 ⁻⁷
0.00000001	10 ⁻⁸	8	10 ⁻⁶
0.000000001	10 ⁻⁹	9	10 ⁻⁵
0.0000000001	10 ⁻¹⁰	10	10 ⁻⁴
0.00000000001	10 ⁻¹¹	11	10 ⁻³
0.000000000001	10 ⁻¹²	12	10 ⁻²
0.0000000000001	10 ⁻¹³	13	10 ⁻¹
0.00000000000001	10 ⁻¹⁴	14	10 ⁰

Acidic solutions have a greater concentration of H⁺ than OH⁻, starting with: pH 0, which contains 1.0 moles H⁺/liter. Each of the subsequent whole-number readings in the scale reduces the [H⁺] by tenfold:

- pH 1 contains [0.1 moles H⁺/L].
- pH 2 contains [0.01 moles H⁺/L].
- Continuing in the same manner up to pH 14, which contains [0.00000000000001 moles H⁺/L].

These same concentrations can be represented more manageably by exponents:

- pH 2 has an [H⁺] of 10⁻² moles.
- pH 14 has an [H⁺] of 10⁻¹⁴ moles (**table 2.2**).

It is evident that the pH units are derived from the exponent itself. Even though the basis for the pH scale is [H⁺], it is important to note that as the [H⁺] in a solution decreases, the [OH⁻] increases in direct proportion. At midpoint—pH 7 or **neutrality**—the concentrations are exactly equal and neither predominates, this being the pH of pure water previously mentioned.

In summary, the pH scale can be used to rate or determine the degree of acidity or alkalinity of a solution. On this scale, a pH below 7 is acidic, and the lower the pH, the greater the acidity; a pH above 7 is basic, and the higher the pH, the greater the alkalinity. Incidentally, although pHs are given here in even whole numbers, more often pH readings are given in decimal form; for example, pH 4.5 or 6.8 (acidic) and pH 7.4 or 10.2 (basic). Because of the damaging effects of very concentrated acids or bases, most cells operate best under neutral, weakly acidic, or weakly basic conditions (see chapter 7).

Aqueous solutions containing both acids and bases may be involved in **neutralization** reactions, which give rise to water and other neutral by-products. For example, when equal molar solutions of hydrochloric acid (HCl) and sodium hydroxide (NaOH, a base) are mixed, the reaction proceeds as follows:

Here the acid and base ionize to H⁺ and OH⁻ ions, which form water, and other ions, Na⁺ and Cl⁻, which form sodium chloride. Any product other than water that arises when acids and bases react is called a salt. Many of the organic acids (such as lactic and succinic acids) that function in **metabolism*** are available as the acid and the salt form (such as lactate, succinate), depending on the conditions in the cell (see chapter 8).

- Review the types of chemical reactions and the general ways they can be expressed in equations.
- Define *solution*, *solvent*, and *solute*.
- What properties of water make it an effective biological solvent, and how does a molecule like NaCl become dissolved in it?
- What is molarity? Tell how to make a 1 M solution of Mg₃(PO₄)₂ and a 0.1 M solution of CaSO₄.
- What determines whether a substance is an acid or a base? Briefly outline the pH scale.

2.4 The Chemistry of Carbon and Organic Compounds

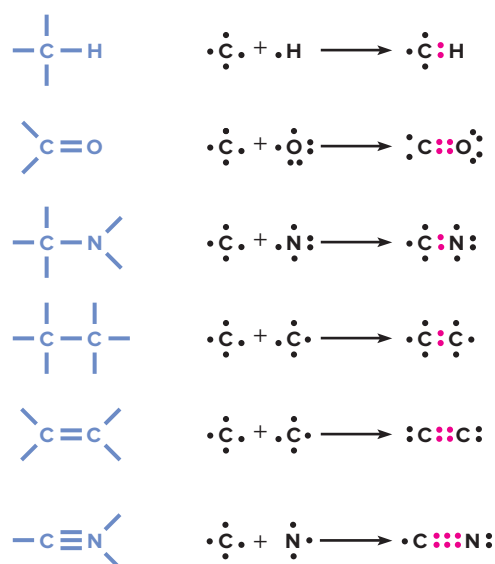

Expected Learning Outcomes

- Describe the chemistry of carbon and the difference between inorganic and organic compounds.
- Identify functional groups and give some examples.
- Define *macromolecule*, *polymer*, and *monomer*.

So far our main focus has been on the characteristics of atoms, ions, and small, simple substances that play diverse roles in the structure and function of living things. These substances are often lumped together in a category called **inorganic chemicals**. A chemical is usually inorganic if it does not contain *both* carbon and hydrogen. Examples of inorganic chemicals include H₂O, O₂, NaCl (sodium chloride), Mg₃(PO₄)₂ (magnesium phosphate), CaCO₃ (calcium carbonate), and CO₂ (carbon dioxide). In reality, however, most of the chemical reactions and structures of living things occur at the level of more complex molecules, termed **organic chemicals**. The minimum requirement for a compound to be considered organic is that it contains a basic framework of carbon bonded to hydrogens. Organic molecules vary in complexity from the simplest, methane (CH₄; see figure 2.4c), which has a molecular weight of 16, to certain antibody molecules (produced by an immune reaction) that have a molecular weight of nearly 1 million and are among the most complex molecules on earth. Most organic chemicals in cells contain other elements such as oxygen, nitrogen, and phosphorus in addition to the carbon and hydrogen.

The role of carbon as the fundamental element of life can best be understood if we look at its chemistry and bonding patterns. The valence of carbon makes it an ideal atomic building block to form the backbone of organic molecules; it has 4 electrons in its outer orbital to be shared with other atoms (including other carbons) through

* *metabolism* (muh-tab'-oh-lizm) A general term referring to the totality of chemical and physical processes occurring in the cell.

(a)

Linear

Branched

Ringed

(b)

Figure 2.14 The versatility of bonding in carbon. In most compounds, each carbon makes a total of four bonds. (a) Single, double, and triple bonds can be made with other carbons, oxygen, and nitrogen; single bonds are made with hydrogen. Simple electron models show how the electrons are shared in these bonds. (b) Multiple bonding of carbons can give rise to long chains, branched compounds, and ringed compounds, many of which are extraordinarily large and complex.

covalent bonding. As a result, it can form stable chains containing thousands of carbon atoms and still has bonding sites available for forming covalent bonds with numerous other atoms. Carbon forms bonds that are linear, branched, or ringed, and it can form four single bonds, two double bonds, or one triple bond (**figure 2.14**). Several unique kinds of molecules are made of pure carbon alone. You may be familiar with diamonds and graphite. A relatively new discovery, fullerene, is made by carbon atoms double-bonding with each other

to produce a hollow sphere. Look ahead to the discussion of nanoparticles in **Clinical Connections** to see a type of this molecule, which is considered one of the most common molecules in the universe, and one that may have many earthly uses.

Functional Groups of Organic Compounds

One important advantage of carbon's serving as the molecular skeleton for living things is that it is free to bind with a variety of special molecular groups or accessory molecules called **functional groups**. Functional groups help define the chemical class of certain groups of organic compounds and confer unique reactive properties on the whole molecule (**table 2.3**). Because each type of functional group behaves in a distinctive manner, reactions of an organic

TABLE 2.3 Representative Functional Groups and Organic Compounds That Contain Them

Formula of Functional Group	Name	Can Be Found In
$\text{R}^* - \text{O} - \text{H}$	Hydroxyl	Alcohols, carbohydrates

*The R designation on a molecule is shorthand for remainder, and its placement in a formula indicates that what is attached at that site varies from one compound to another.

TABLE 2.4 Macromolecules and Their Functions

Macromolecule	Description/Basic Structure	Examples/Notes
Carbohydrates		
Monosaccharides	3- to 7-carbon sugars	Glucose, fructose / Sugars involved in metabolic reactions; building block of disaccharides and polysaccharides
Disaccharides	Two monosaccharides	Maltose (malt sugar) / Composed of two glucoses; an important breakdown product of starch Lactose (milk sugar) / Composed of glucose and galactose Sucrose (table sugar) / Composed of glucose and fructose
Polysaccharides	Chains of monosaccharides	Starch, cellulose, glycogen / Cell wall, food storage
Lipids		
Triglycerides	Fatty acids + glycerol	Fats, oils / Major component of cell membranes; storage
Phospholipids	Fatty acids + glycerol + phosphate	Membranes
Waxes	Fatty acids, alcohols	Mycolic acid / Cell wall of mycobacteria
Steroids	Ringed structure	Cholesterol, ergosterol / Membranes of eukaryotes and some bacteria
Proteins		
Polypeptides	Amino acids in a chain bound by peptide bonds	Enzymes; part of cell membrane, cell wall, ribosomes, antibodies / Metabolic reactions; structural components
Nucleic acids		
	Nucleotides, composed of pentose sugar + phosphate + nitrogenous base	Purines: adenine, guanine; Pyrimidines: cytosine, thymine, uracil
Deoxyribonucleic acid (DNA)	Contains deoxyribose sugar and thymine, not uracil	Chromosomes; genetic material of viruses / Inheritance
Ribonucleic acid (RNA)	Contains ribose sugar and uracil, not thymine	Ribosomes; mRNA, tRNA / Expression of genetic traits
Adenosine triphosphate (ATP)	Contains adenine, ribose sugar, and 3 phosphate groups	A high-energy compound that gives off energy to power reactions in cells

compound can be predicted by knowing the kind of functional group or groups it carries. Many synthesis, decomposition, and transfer reactions rely upon functional groups such as R—OH or R—NH₂. The R designation on a molecule is shorthand for remainder, and its placement in a formula indicates that the group attached at that site varies from one compound to another.

Organic Macromolecules: Superstructures of Life

The compounds of life fall into the realm of **biochemistry**. Biochemicals are organic compounds produced by (or that are components of) living things, and they include four main families: carbohydrates, lipids, proteins, and nucleic acids (**table 2.4**). The compounds in these groups are assembled from smaller molecular subunits, or building blocks, and because they are often very large compounds, they are termed **macromolecules**. All macromolecules except lipids are formed by polymerization, a process in which repeating subunits termed **monomers*** are bound into chains of various lengths termed **polymers**.* For example, amino acids (monomers), when arranged in a chain, form proteins (polymers). The large size and complex, three-dimensional shapes of macromolecules enable them to function as structural components, molecular messengers, energy sources, enzymes (biochemical

catalysts), nutrient stores, and sources of genetic information. In section 2.5 and in later chapters, we consider numerous concepts relating to the roles of macromolecules in cells. Table 2.4 will also be a useful reference when you study metabolism in chapter 8.

Check Your Progress SECTION 2.4

20. What atoms must be present in a molecule for it to be considered organic?
21. Name several inorganic compounds.
22. What characteristics of carbon make it ideal for the formation of organic compounds?

24. Differentiate between a monomer and a polymer. How are polymers formed?

2.5 Molecules of Life: Carbohydrates

Expected Learning Outcomes

19. Define *carbohydrate* and know the functional groups that characterize carbohydrates.
20. Distinguish among mono-, di-, and polysaccharides, and describe how their bonds are made.
21. Discuss the functions of carbohydrates in cells.

* *monomer* (mahn'-oh-mur) Gr. *mono*, one, and *meros*, part.

* *polymer* (pahl'-ee-mur) Gr. *poly*, many; also the root for polysaccharide, polypeptide, and polynucleotide.

CLINICAL CONNECTIONS

Nanoparticles—Molecule-Sized “Smart” Pills

In the near future, it may be possible to treat an infection or cancer by taking a single tiny dose of medicine by nose, mouth, or skin. This is just one of the revolutionary possibilities being explored by the science of **chemotherapy**, defined as the use of chemical compounds (drugs) to treat or prevent diseases. Traditionally drugs have been swallowed in pill form or injected, but often these methods leave a great deal to be desired. For example, a drug being swallowed may be absorbed in unpredictable amounts, and it may not reliably reach the site of action; or it may not be specific to the target cells and may cause harm to healthy tissues.

For several years pharmaceutical researchers have been exploring alternate ways to administer drugs using tiny delivery systems called **nanoparticles**.^{*} This idea comes from the science of **nanotechnology**, defined as the study and application of molecule-sized devices or structures (look ahead to 3.1 Making Connections). Of several molecule-sized systems under development, two that look very promising are liposomes and fullerenes. The structure of these two types of nanoparticles suits them well for carrying drugs to a precise location and controlling their release. In both cases, they display a spherical, hollow structure that provides spaces for holding drugs, and both have surfaces that could be manipulated to bind to a specific organ or cell type.

^{*}*nano* for nanometer, which is one-billionth of a meter in length, about 1/80,000 the diameter of a human hair.

(a) Diagram of a liposome is shown carrying drugs and displaying specific surface molecules to help in homing to the target and drug delivery.

Liposomes are lipid-based molecules with the lipids arranged in a bilayer similar to a cell membrane (**figure a**). They are soluble in water, could carry a variety of drugs in their core, and readily fuse with the membrane of the cell they are targeting, immediately delivering their contents directly into the cytoplasm. Note also that liposomes can also display molecules that improve recognition and entry of the drug. Liposomes are being considered for treating tumors and viral infections, delivering antibiotics to infected tissues and organs, vaccine delivery, and even some types of genetic therapies.

Fullerenes are an unusual group of molecules that consist only of carbon double-bonded to other carbons, forming a lattice network that can assume a number of configurations. The most adaptable configuration is the spheroid form called a buckyball,^{*} composed of 60 carbons (**figure b**). These molecules can also have drugs loaded into their cores and be directed toward specific cells or organs, but they are not broken down in the body and can remain in place significantly longer than traditional drug carriers. They are being tested as a means of treating cancers with radioactive isotopes and delivering antiviral drugs into infected cells.

Nanomedicine is one of the most rapidly growing areas of research. What other applications could grow out of this use of such tiny delivery systems? *Answer available on Connect.*

^{*}This term and fullerene were chosen in honor of Buckminster Fuller, who designed the geodesic dome, an architectural structure that is constructed on the same plan as these tiny molecules.

(b) Structure of a buckyball indicates its “soccer ball” appearance of hexagonal carbons. Courtesy of Pete Marenfeld/NOAO/AURA/NSF

The term **carbohydrate** originates from the way that most members of this chemical class resemble combinations of carbon and water. Carbohydrates can be generally represented by the formula $(\text{CH}_2\text{O})_n$, in which n indicates the number of units that combine to make the finished carbohydrate. The basic structure of a simple

carbohydrate monomer is a backbone of carbon bound to two or more hydroxyl groups. Because they also have either an aldehyde or a ketone group, they are often designated as *polyhydroxy aldehydes* or *ketones* (**figure 2.15**). In simple terms, a sugar such as glucose is an aldehyde with a terminal carbonyl group bonded to a

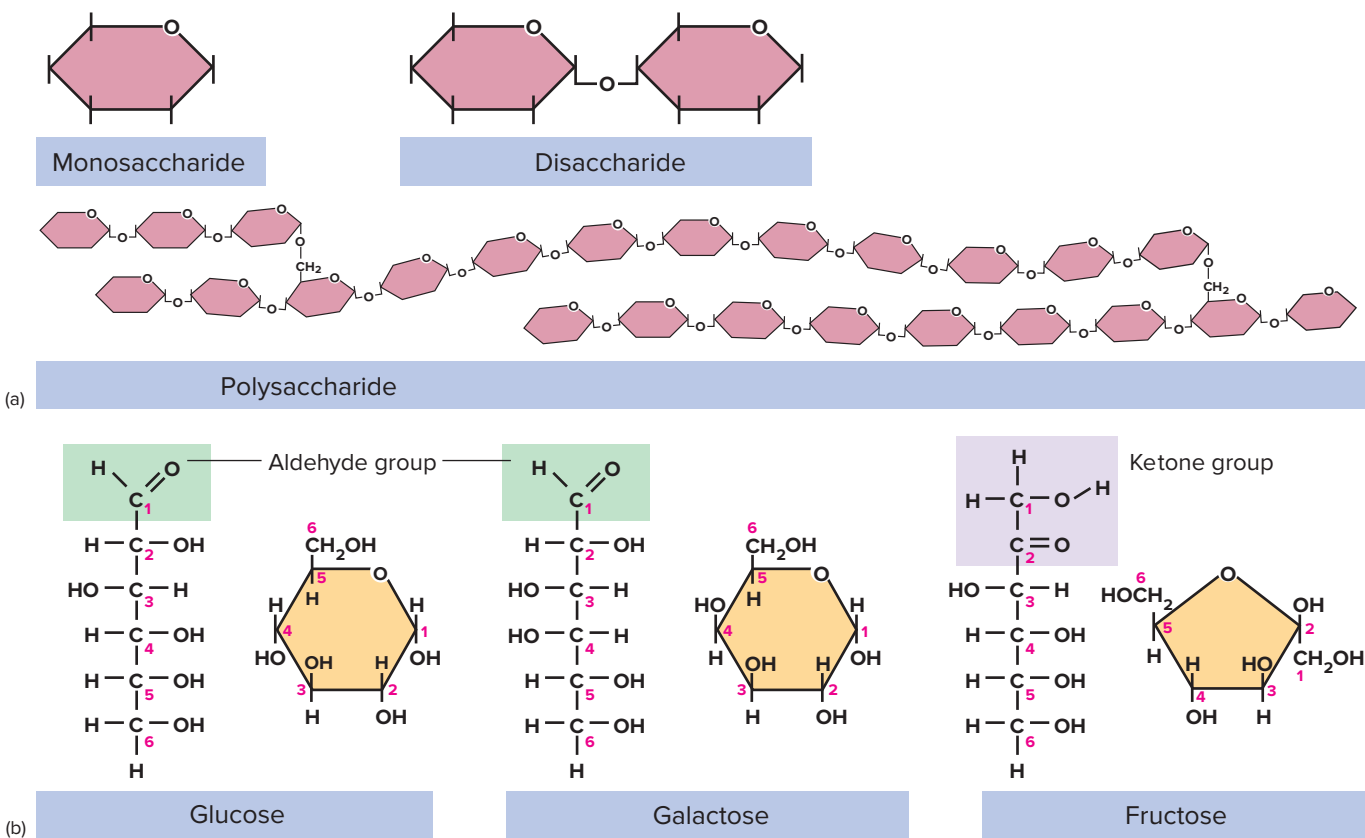

Figure 2.15 Common classes of carbohydrates. (a) Major saccharide groups, named for the number of sugar units each contains. (b) Three hexoses with the same molecular formula ($C_6H_{12}O_6$) and different structural formulas. Both linear and ring models are given. The linear form emphasizes aldehyde and ketone groups, although in solution the sugars exist in the ring form. Note that the carbons are numbered in red so as to keep track of reactions within and between monosaccharides.

hydrogen and another carbon. Fructose sugar is a ketone with a carbonyl group bonded between two carbons.

Carbohydrates exist in a great variety of configurations. The common term **sugar (saccharide*)** refers to a simple carbohydrate, such as a monosaccharide or a disaccharide, that has a sweet taste. A **monosaccharide** is a simple polyhydroxy aldehyde or ketone molecule containing from 3 to 7 carbons; a **disaccharide** is a combination of two monosaccharides; and a **polysaccharide** is a polymer of five or more monosaccharides bound in linear or branched chain patterns (figure 2.15). Monosaccharides and disaccharides are specified by combining a prefix that describes some characteristic of the sugar with the suffix **-ose**. For example, **hexoses** are composed of 6 carbons, and **pentoses** contain 5 carbons. **Glucose** (Greek for sweet) is the most common and universally important hexose; **fructose** is named for fruit (one of its sources); and xylose, a pentose, derives its name from the Greek word for wood. Disaccharides are named similarly: **lactose** (Latin for milk) is an important component of milk; **maltose** means malt sugar; and **sucrose** (French for sugar) is common table sugar or cane sugar.

* *saccharide* (sak'-uh-ryd) Gr. *sakcharon*, sweet.

The Nature of Carbohydrate Bonds

The subunits of disaccharides and polysaccharides are linked by means of **glycosidic bonds**, in which carbons (each is assigned a number) on adjacent sugar units are bonded to the same oxygen atom like links in a chain (figure 2.16). For example:

- Maltose is formed when the number 1 carbon on a glucose bonds to the oxygen on the number 4 carbon on a second glucose.
- Sucrose is formed when glucose and fructose bind oxygen between their number 1 and number 2 carbons.
- Lactose is formed when glucose and galactose connect by their number 1 and number 4 carbons.

This bond is formed by one carbon giving up its OH group and the other (the one contributing the oxygen to the bond) losing the H from its OH group. Because a water molecule is produced, this reaction is known as **dehydration synthesis**, a process common to most polymerization reactions (see proteins, section 2.7). Three polysaccharides (starch, cellulose, and glycogen) are structurally and biochemically distinct, even though all are polymers of the same monosaccharide—glucose. The basis for their differences lies primarily in the exact way the glucose molecules are bound together, which greatly affects the characteristics of the end product (figure 2.17). The

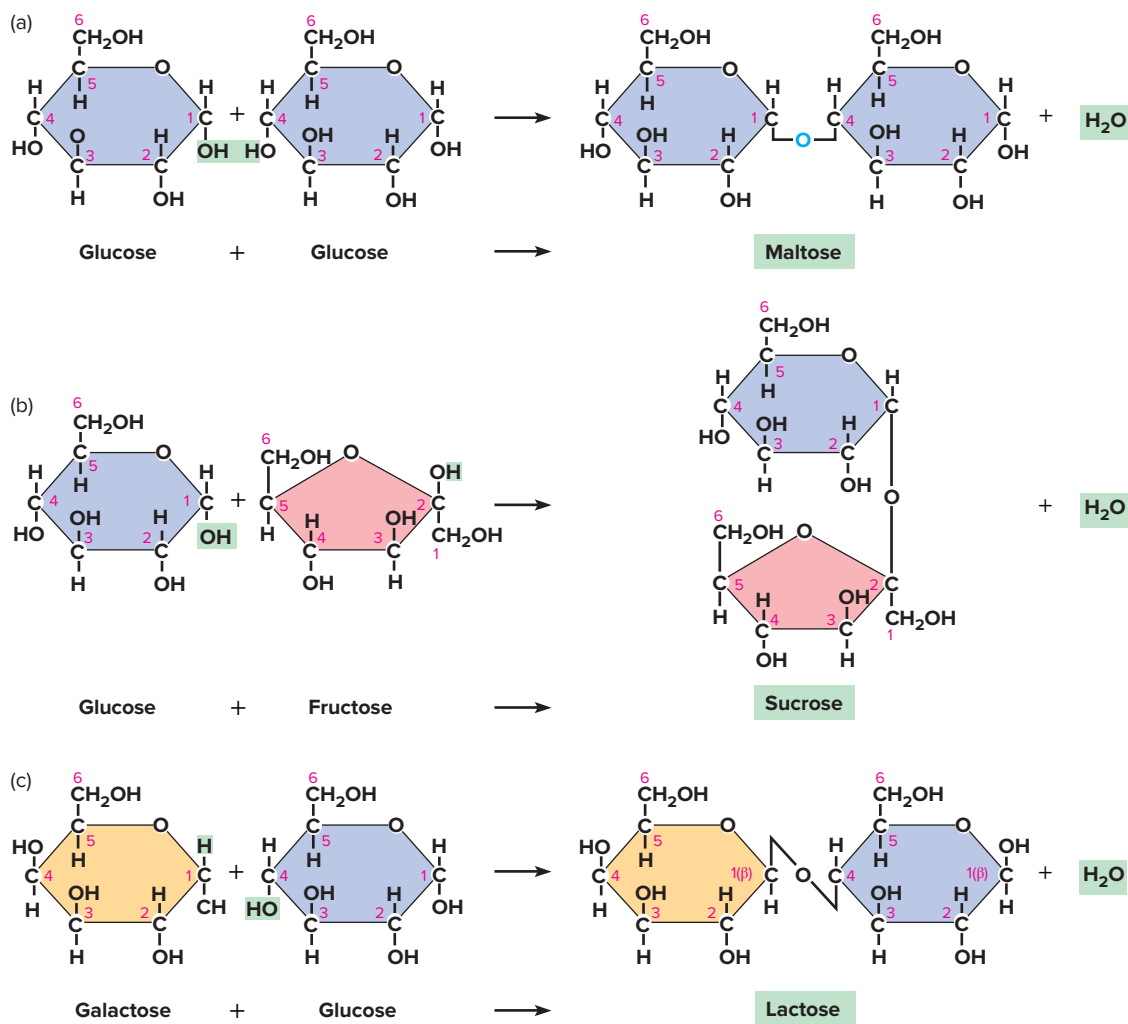

Figure 2.16 Glycosidic bond in three common disaccharides. (a) Formation of the 1,4 bond between two α glucoses to produce maltose. (b) Formation of the 1,2 bond between glucose and fructose to produce sucrose. (c) A 1,4 bond between a galactose and glucose produces lactose. Note that all three dehydration synthesis reactions release water.

Figure 2.17 Polysaccharides. (a) Cellulose is composed of β -glucose bonded in 1,4 bonds that produce linear, lengthy chains of polysaccharides that are H-bonded along their length. This accounts for fibrous support structures of plants. (b) Starch is also composed of glucose polymers, in this case α glucose. The main structure is amylose bonded in a 1,4 pattern, with side branches of amylopectin bonded by 1,6 bonds. The entire molecule is compact and granular.

synthesis and breakage of each type of bond require a specialized catalyst called an enzyme (see chapter 8).

The Functions of Carbohydrates in Cells

Carbohydrates are the most abundant biological molecules in nature. They play numerous roles in cell structure, adhesion, and metabolism.

Polysaccharides typically contribute to structural support and protection and serve as nutrient and energy stores. The cell walls in plants and many microscopic algae derive their strength and rigidity from **cellulose**, a long, fibrous polymer (figure 2.17a). Because of this role, cellulose is probably one of the most common organic substances on the earth, yet it is digestible only by certain bacteria, fungi, and protozoa that produce the enzyme cellulase. These microbes, called decomposers, play an essential role in breaking down and recycling plant materials (see figure 7.2). Some bacteria secrete slime layers of a glucose polymer called *dextran*. This substance causes a sticky layer to develop on teeth that leads to plaque, described later in chapter 21.

Other structural polysaccharides can be conjugated (chemically bonded) to amino acids, nitrogen bases, lipids, or proteins. **Agar**, a polysaccharide indispensable for preparing solid culture media, is a natural component of certain seaweeds. It is a complex polymer of galactose and sulfur-containing carbohydrates. **Chitin** (ky-tun), a polymer of glucosamine (a sugar with an amino functional group), is a major compound in the cell walls of fungi and the exoskeletons of insects. **Peptidoglycan*** is one special class of compounds in which polysaccharides (glycans) are linked to peptide fragments (a short chain of amino acids). This molecule provides the main source of structural support to the bacterial cell wall. The cell wall of gram-negative bacteria also contains **lipopolysaccharide**, a complex of lipid and polysaccharide responsible for symptoms such as fever and shock (see chapters 4 and 13).

The outer surface of many cells has a delicate “sugar coating” composed of polysaccharides bound in various ways to proteins (the combination is called mucoprotein or glycoprotein). This structure, called the **glycocalyx**,* functions in attachment to other cells or as a site for *receptors*—surface molecules that receive and respond to external stimuli. Small sugar molecules account for the differences in human blood types, and carbohydrates are a component of large protein molecules called antibodies. Some viruses have glycoproteins on their surface for binding to and invading their host cells.

Polysaccharides are usually stored by cells in the form of glucose polymers, such as **starch** (figure 2.17b) or **glycogen**, that are readily tapped as a source of energy and other metabolic needs. Because a water molecule is required for breaking the bond between two glucose molecules, digestion is also termed **hydrolysis**.* Starch is the primary storage food of green plants, microscopic algae, and some fungi; glycogen (animal starch) is a stored carbohydrate for animals and certain groups of bacteria and protozoa.

* *peptidoglycan* (pep-tih-doh-gly'-kan).

* *glycocalyx* (gly'-koh-kay'-lix) Gr. *glycos*, sweet and *calyx*, covering.

2.6 Molecules of Life: Lipids

Expected Learning Outcomes

22. Define *lipid*, *triglyceride*, *phospholipid*, *fatty acid*, and *cholesterol*.
23. Describe how an ester bond is formed.
24. Discuss major functions of lipids in cells.

The term **lipid**, derived from the Greek word *lipos*, meaning fat, is not a chemical designation but an operational term for a variety of substances that are not soluble in polar solvents such as water (recall that oil and water do not mix) but will dissolve in nonpolar solvents such as benzene and chloroform. This property occurs because the substances we call lipids contain relatively long or complex C—H (hydrocarbon) chains that are nonpolar and thus hydrophobic. The main groups of compounds classified as lipids are triglycerides, phospholipids, steroids, and waxes.

Important storage lipids are the **triglycerides**, a category that includes fats and oils. Triglycerides are composed of a single molecule of glycerol bound to three **fatty acids** (figure 2.18). **Glycerol** is a 3-carbon alcohol⁷ with three OH groups that serve as binding sites. Fatty acids are long-chain unbranched hydrocarbon molecules with a carboxyl group (COOH) at one end that is free to bind to the glycerol. The bond that forms between the —OH group and the —COOH is defined as an **ester bond** (figure 2.18a). The hydrocarbon portion of a fatty acid can vary in length from 4 to 24 carbons and, depending on the fat, it may be *saturated* or *unsaturated*. A saturated fatty acid has all of the carbons in the chain bonded to hydrogens with single bonds. Fatty acids having at least one carbon—carbon double bond are considered unsaturated (figure 2.18b). Fats that contain such fatty acids are described with these terms as well. The structure of fatty acids is what gives fats and oils (liquid fats) their greasy, insoluble nature. In general, solid fats (such as beef tallow) are more saturated, and oils (or liquid fats) are more unsaturated.

In most cells, triglycerides are stored in long-term concentrated form as droplets or globules. When the ester linkage is acted on by digestive enzymes called lipases, the fatty acids and glycerol are freed to be used in metabolism. Fatty acids are a superior source of energy, yielding twice as much per gram as other storage molecules (starch). Soaps are K⁺ or Na⁺ salts of fatty acids whose qualities make them excellent grease removers and cleaners (see chapter 11).

Membrane Lipids

The **phospholipids** serve as a major structural component of cell membranes. Although phospholipids also contain glycerol and fatty acids, they differ significantly from triglycerides. Phospholipids contain only two fatty acids attached to the glycerol, and the third glycerol binding site holds a phosphate group. The phosphate is in turn bonded to an alcohol, which varies from one phospholipid to another (figure 2.19a). This class of lipids has a hydrophilic region from the charge on the phosphoric acid—alcohol “head” of the molecule and a hydrophobic region that corresponds to the

7. Alcohols are hydrocarbons containing an —OH functional group.

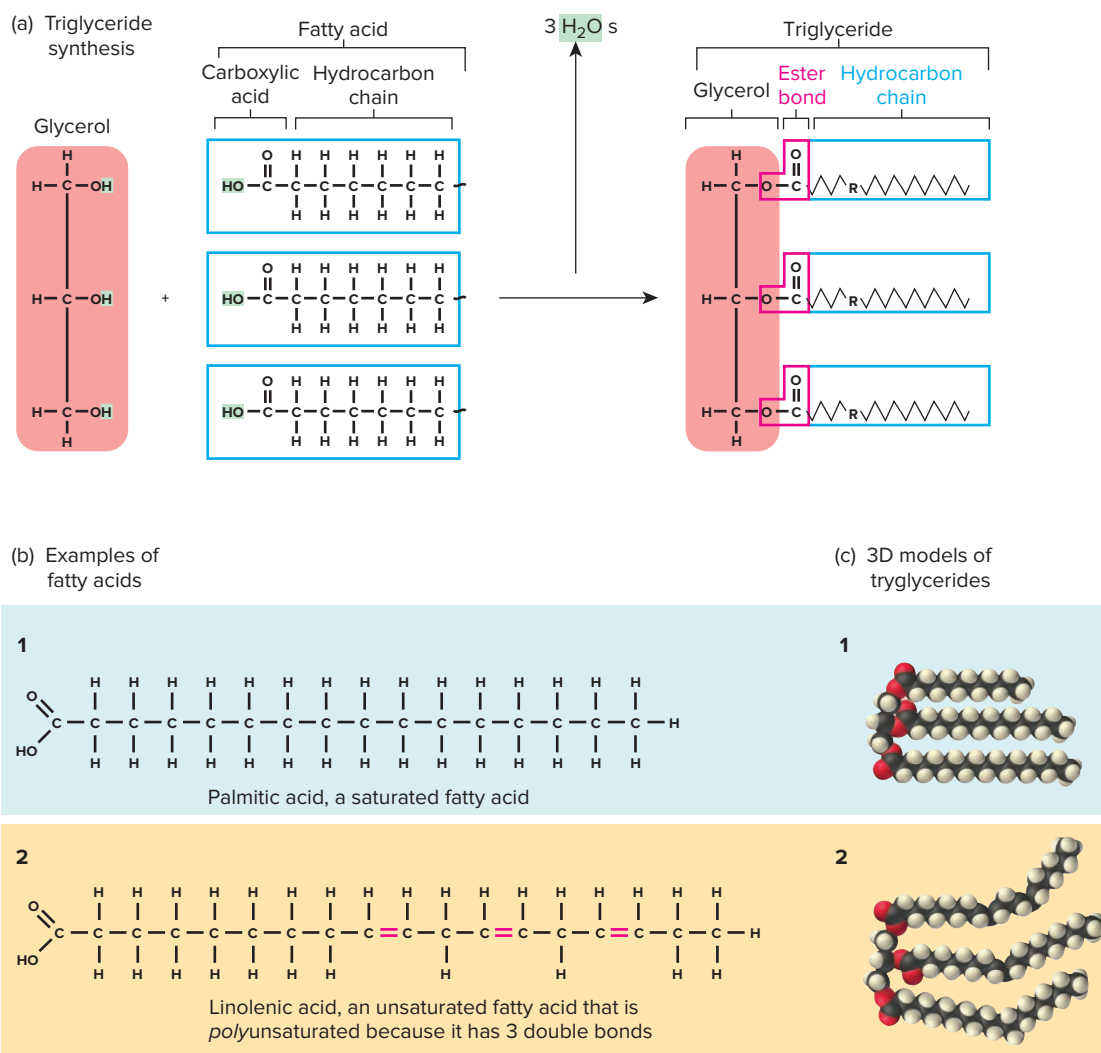

Figure 2.18 Synthesis and structure of a triglyceride. (a) Because a water molecule is released at each ester bond, this is another form of dehydration synthesis. The jagged lines and R symbol represent the hydrocarbon chains of the fatty acids, which are commonly very long. (b) Structural models of two kinds of fatty acids. (1) A saturated fatty acid has long, straight chains that readily pack together. (2) An unsaturated fatty acid has at least one double bond and cannot pack densely due to the bends in the long chain caused by the double bonds. (c) Three-dimensional models of triglycerides containing saturated (1) and unsaturated fatty acids (2). Which of these two fats is an oil and which one is solid?

long, uncharged “tail” (formed by the fatty acids). When exposed to an aqueous solution, the charged heads are attracted to the water phase, and the nonpolar tails are repelled from the water phase (**figure 2.19b**). This property causes lipids to naturally assume single and double layers (bilayers), which contribute to their biological significance in membranes. When two single layers of polar lipids come together to form a double layer, the outer hydrophilic face of each single layer will orient itself toward the solution, and the hydrophobic portions will become immersed in the core of the bilayer. The structure of lipid bilayers confers characteristics on membranes such as selective permeability and fluid nature.

Miscellaneous Lipids

Steroids are complex ringed compounds commonly found in cell membranes and animal hormones. The best known of these is the sterol (meaning a steroid with an OH group) called **cholesterol** (**figure 2.20**). Cholesterol reinforces the structure of the cell mem-

brane in animal cells and in an unusual group of cell-wall-deficient bacteria called the mycoplasmas (see chapter 4).

The cell membranes of fungi also contain a unique sterol, called ergosterol. *Prostaglandins* are fatty acid derivatives found in trace amounts that function in inflammatory and allergic reactions, blood clotting, and smooth muscle contraction. Chemically, a *wax* is an ester formed between a long-chain alcohol and a saturated fatty acid. The resulting material is typically pliable and soft when warmed but hard and water-resistant when cold (paraffin, for example). Among living things, fur, feathers, fruits, leaves, human skin, and insect exoskeletons are naturally waterproofed with a coating of wax. Bacteria that cause tuberculosis and leprosy produce a wax (wax D) that contributes to their pathogenicity.

The Structure and Functions of Membranes

The word **membrane** appears frequently in descriptions of cells in chapters 4 and 5. The word itself can be used to indicate a lining or

Figure 2.19 Phospholipids—membrane molecules.

(a) A model of a single molecule of a phospholipid. The phosphate-alcohol head lends a charge to one end of the molecule; its long, trailing hydrocarbon chain is uncharged. (b) Phospholipids in water-based solutions become arranged (1) in single layers called micelles, with the charged head oriented toward the water phase and the hydrophobic nonpolar tail buried away from the water phase, or (2) in double-layered systems with the hydrophobic tails sandwiched between two hydrophilic layers.

covering including such multicellular structures as the mucous membranes of the body. At the cellular level, however, a membrane is a thin sheet of molecules composed of phospholipids and sterols (averaging about 40% of membrane content) and proteins (averaging about 60%). All cells have a membrane that completely encases the cytoplasm. Membranes are also components of eukaryotic organelles such as nuclei, mitochondria, and chloroplasts, and they appear in internal pockets of certain prokaryotic cells. Even some viruses, which are not cells, can have a membranous envelope.

A standard model of membrane structure has the lipids forming a continuous bilayer. The polar lipid heads face toward the aqueous phases, and the nonpolar tails orient toward the center of the membrane. Embedded at numerous sites in this bilayer are various-sized globular proteins (figure 2.20). Some proteins are situated only at the surface; others extend fully through the entire membrane.

Membranes are dynamic and constantly changing because the lipid phase is in motion and many proteins can migrate freely about. This fluidity is essential to such activities as engulfment of food and discharge or secretion by cells. The structure of the lipid phase provides an impenetrable barrier that accounts for the selective permeability and transport of molecules. Membrane

Figure 2.20 Cutaway view of a membrane with its bilayer of lipids. The primary lipid is phospholipid; however, cholesterol is inserted in some membranes. Other structures are protein and glycolipid molecules. Cholesterol can become esterified with fatty acids at its OH⁻ group, imparting a polar quality similar to that of phospholipids.

proteins function in receiving molecular signals (receptors), in binding and transporting nutrients, and as enzymes, topics to be discussed in chapters 7 and 8.

28. Draw simple structural molecules of triglycerides and phospholipids to compare their differences and similarities. What is an ester bond?

2.7 Molecules of Life: Proteins

Expected Learning Outcomes

25. Describe the structures of peptides and polypeptides and how their bonds form.
26. Characterize the four levels of protein structure and describe the pattern of folding.
27. Summarize some of the essential functions of proteins.

Figure 2.21 Structural formulas of selected amino acids. The basic structure common to all amino acids is shown in blue type; and the variable group, or R group, is placed in a colored box. Note the variations in structure of this reactive component.

The predominant organic molecules in cells are **proteins**, a fitting term adopted from the Greek word *proteios*, meaning first or prime. To a large extent, the structure, behavior, and unique qualities of each living thing are a consequence of the proteins they contain. To best explain the origin of the special properties and versatility of proteins, we must examine their general structure.

The building blocks of proteins are **amino acids**, which exist in 20 different naturally occurring forms. **Figure 2.21** provides examples of several common amino acids. See Appendix A for a table that shows all 20. Various combinations of these amino acids account for the nearly infinite variety of proteins. Amino acids have a basic skeleton consisting of a carbon (called the α

Figure 2.22 The formation of peptide bonds in a tetrapeptide.

carbon) linked to an amino group (NH_2), a carboxyl group (COOH), a hydrogen atom (H), and a variable R group. The variations among the amino acids occur at the R group, which is different in each amino acid and imparts the unique characteristics to the molecule and to the proteins that contain it. A covalent bond called a **peptide bond** forms between the amino group on one amino acid and the carboxyl group on another amino acid. As a result of peptide bond formation, it is possible to produce molecules varying in length from two amino acids to chains containing thousands of them.

Various terms are used to denote the nature of compounds containing peptide bonds. **Peptide*** usually refers to a molecule composed of short chains of amino acids, such as a dipeptide (two amino acids), a tripeptide (three), and a tetrapeptide (four) (**figure 2.22**). A **polypeptide** contains an unspecified number of amino acids but usually has more than 20 and is often a smaller subunit of a protein. A protein is the largest of this class of compounds and usually contains a minimum of 50 amino acids. It is common for the terms *polypeptide* and *protein* to be used interchangeably, though not all polypeptides are large enough to be considered proteins. In chapter 9 we will see that protein synthesis is not just a random connection of amino acids; it is directed by information provided in DNA.

Protein Structure and Diversity

The reason proteins are so varied and specific is that they do not function in the form of a simple straight chain of amino acids (called the primary structure). A protein has a natural tendency to assume more complex levels of organization, called the secondary, tertiary, and quaternary structures (**figure 2.23**).

The **primary (1°) structure** of a protein is simply the sequence of each amino acids in the polypeptide chain. Proteins vary extensively in the exact order, type, and number of amino acids, and it is this quality that gives rise to the unlimited diversity in protein form and function.

* *peptide* (pep'-tyd) Gr. *pepsis*, digestion.

A polypeptide does not remain in its primary state, but instead spontaneously arranges itself into a higher level of complexity called its **secondary (2°) structure**. The secondary structure arises from numerous hydrogen bonds occurring between the C=O and N—H groups of amino acids located near

one another in the primary sequence. This bonding causes the whole chain to coil or fold into regular patterns. The coiled spiral form is called the α helix, and the folded, accordion form is called the β -pleated sheet. Polypeptides ordinarily will contain both types of configurations.

Once a chain has assumed the secondary structure, it goes on to form yet another level of folding and compacting—the **tertiary (3°) structure**. This structure arises through additional intrachain⁸ forces and bonds between various parts of the α helix and β -pleated sheets. The chief actions in creating the tertiary structure are additional hydrogen bonds between charged functional groups, van der Waals forces between various parts of the polypeptide, and covalent disulfide bonds. The disulfide bonds occur between sulfur atoms on the amino acid **cysteine**,* and these bonds confer a high degree of stability to the overall protein structure. The result is a complex, three-dimensional protein that is now the completed functional state in many cases.

The most complex proteins assume a **quaternary (4°) structure**, in which two or more polypeptides interact to form a large, multiunit protein. The polypeptide units form loose associations based on weak van der Waals and other forces. The polypeptides in proteins with quaternary structure can be the same or different. The arrangement of these individual polypeptides tends to be symmetrical and will dictate the exact form of the finished protein (figure 2.23, step 4).

The most important outcome of bonding and folding is that each different type of protein develops a unique shape, and its surface displays a distinctive pattern of pockets and bumps. As a result, a protein can react only with molecules that complement or fit its particular surface features. Such a degree of specificity can provide the functional diversity required for many thousands of different cellular activities. **Enzymes** serve as the catalysts for all chemical reactions in cells, and nearly every reaction requires a different enzyme (see chapter 8). **Antibodies** are complex glycoproteins with specific regions of attachment for bacteria, viruses, and other microorganisms. Certain bacterial toxins (poisonous proteins) react with only one specific organ or tissue. Proteins embedded in the cell membrane have reactive sites restricted to a certain nutrient. Some proteins function as *receptors* to receive stimuli from the environment.

The functional, three-dimensional form of a protein is termed the *native state*, and if it is disrupted by some means, the protein is said to be *denatured*. Such agents as heat, acid, alcohol, and some disinfectants disrupt (and thus denature) the stabilizing intrachain bonds and cause the molecule to become nonfunctional, as described in chapter 11.

2.8 Nucleic Acids: A Program for Genetics

Expected Learning Outcomes

28. Identify a nucleic acid and differentiate between DNA and RNA.
29. Describe the structures of nucleotides and list the nitrogen bases.
30. Explain how the DNA code may be copied, and describe the basic functions of RNA.

The nucleic acids, **deoxyribonucleic acid (DNA)*** and **ribonucleic acid (RNA)***, were originally isolated from the cell nucleus. Shortly thereafter, they were also found in other parts of nucleated cells, in cells with no nuclei (bacteria), and in viruses. The universal occurrence of nucleic acids in all known cells and viruses emphasizes their important roles as informational molecules. DNA, the master instruction manual of cells, contains a coded genetic program with detailed and specific instructions for each organism's heredity. It transfers the details of its program to RNA, "helper" molecules responsible for carrying out DNA's instructions and translating the DNA program into proteins that can perform life functions. For now, let us briefly consider the structure and some functions of DNA, RNA, and a close relative, adenosine triphosphate (ATP).

Both nucleic acids are polymers of repeating units called **nucleotides**,* each of which is composed of three smaller units: a **nitrogenous base**, a pentose (5-carbon) sugar, and a **phosphate** (figure 2.24a). The nitrogenous base is a cyclic compound that comes in two forms: *purines* (two rings) and *pyrimidines* (one ring). There are two types of purines—**adenine (A)** and **guanine (G)**—and three types of pyrimidines—**thymine (T)**, **cytosine (C)**, and **uracil (U)** (figure 2.25). A characteristic that differentiates DNA from RNA is that DNA contains all of the nitrogenous bases except uracil, and RNA contains all of the nitrogenous bases except thymine. The nitrogenous base is covalently bonded to the sugar *ribose* in RNA and *deoxyribose* (because it has one fewer oxygen than ribose) in DNA. Phosphate (PO_4^{3-}), a derivative of phosphoric acid (H_3PO_4), provides the final covalent bridge that connects sugars in series. Thus, the backbone of a nucleic acid strand is a chain of alternating phosphate-sugar-phosphate-sugar molecules, and the nitrogenous bases branch off the side of this backbone (figure 2.24b, c).

The Double Helix of DNA

DNA is a huge molecule formed by two very long polynucleotide (meaning that it consists of many nucleotides joined together) strands linked along their length by hydrogen bonds between complementary pairs of nitrogenous bases. The term *complementary* means that the nitrogenous bases pair in matched sets according to this

Quick Search

* **nucleotide** (noo'-klee-oh-tyd) From *nucleus* and *acid*.

(a) A nucleotide, composed of a phosphate, a pentose sugar, and a nitrogenous base (either A,T,C,G, or U) is the monomer of both DNA and RNA.

(b) In DNA, the polymer is composed of alternating deoxyribose (D) and phosphate (P) with nitrogenous bases (A,T,C,G) attached to the deoxyribose. DNA almost always exists in pairs of strands, oriented so that the bases are paired across the central axis of the molecule.

(c) In RNA, the polymer is composed of alternating ribose (R) and phosphate (P) attached to nitrogenous bases (A,U,C,G), but it is usually a single strand.

Figure 2.24 The general structure of nucleic acids.

pattern: Adenine ordinarily pairs with thymine, and cytosine with guanine. The bases are attracted in this way because each pair has oxygen, nitrogen, and hydrogen atoms positioned precisely to favor the formation of hydrogen bonds between them (**figure 2.26**).

For ease in understanding the structure of DNA, it is sometimes compared to a ladder, with the sugar-phosphate backbone representing the rails and the paired nitrogenous bases representing the steps. The flat ladder is useful for understanding basic components and orientation, but in reality DNA exists in a three-dimensional arrangement called a *double helix*. A better analogy may be a spiral staircase. In this model, the two strands (helices or helices) coil together, with the sugar-phosphate forming outer ribbons, and the paired bases sandwiched between them (**figure 2.26**). As is true of protein, the structure of DNA is intimately related to its function. DNA molecules are usually extremely long, a feature that satisfies a requirement for storing genetic information in the sequence of base pairs the molecule contains. The hydrogen bonds between pairs can be disrupted when DNA is being copied, and the fixed complementary base pairing is essential to maintain the genetic code.

Making New DNA: Passing on the Genetic Message

The biological properties of cells and viruses are ultimately programmed by a master code composed of nucleic acids. This code is in the form of DNA in all cells and many viruses; a number of viruses are based on RNA alone. Regardless of the exact genetic makeup, both cells and viruses can continue to exist only if they can duplicate their genetic material and pass it on to subsequent generations. **Figure 2.27** summarizes the main steps in this process in cells.

During its division cycle, the cell has a mechanism for making a copy of its DNA by **replication**,* using the original strand as a pattern. Note that replication is guided by the double-stranded nature of DNA and the precise pairing of bases that create the master code. Replication requires the separation of the double strand into two single strands by an enzyme that helps to split the

* *replication* (reh"-plih-kay'-shun) A process that makes an exact copy.

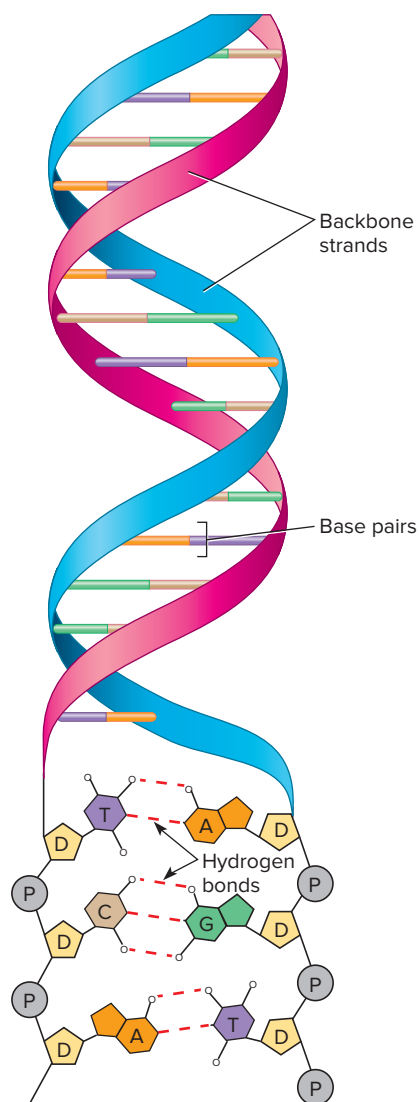

Figure 2.26 A structural representation of the double helix of DNA. At the bottom are the details of hydrogen bonds between the nitrogenous bases of the two strands.

hydrogen bonds along the length of the molecule. This event exposes the base code and makes it available for copying. Complementary nucleotides are used to synthesize new strands of DNA that adhere to the pairing requirements of A—T and C—G. The end result is two separate double strands with the same order of bases as the original molecule. With this type of replication, each new double strand contains one of the original single strands from the starting DNA.

RNA: Organizers of Protein Synthesis

Like DNA, RNA is a polynucleotide that consists of a long chain of nucleotides. However, RNA is a single strand containing ribose sugar instead of deoxyribose and uracil instead of thymine (see figure 2.24). Several functional types of RNA are formed using the DNA template through a replication-like process. Three major types of RNA are important for protein synthesis. Messenger RNA

Figure 2.27 Simplified view of DNA replication in cells. The DNA in the cell's chromosome must be duplicated as the cell is dividing. This duplication is accomplished through the separation of the double DNA strand into two single strands. New strands are then synthesized using the original strands as guides to assemble the correct new complementary bases.

(mRNA) is a copy of a gene from DNA that provides instructions for the order of amino acids; transfer RNA (tRNA) is a carrier that delivers the correct amino acids during protein synthesis; and ribosomal RNA (rRNA) is a major component of ribosomes, which are the sites of protein synthesis. More information on these important processes is presented in chapter 9.

ATP: The Energy Molecule of Cells

A relative of RNA involved in an entirely different cell activity is **adenosine triphosphate (ATP)**. ATP is a nucleotide containing adenine, ribose, and three phosphates rather than just one (**figure 2.28**). It belongs to a category of high-energy compounds (also including guanosine triphosphate, GTP) that give off energy when the bond is broken between the second and third (outermost) phosphate. The presence of these high-energy bonds makes it possible for ATP to release and store energy for cellular chemical reactions. Breakage of the bond of the terminal phosphate releases energy to do cellular work and also generates adenosine diphosphate (ADP). ADP can be converted back to ATP when the

Figure 2.28 Model of an ATP molecule, the chemical form of energy transfer in cells. (a) Structural formula: The wavy lines connecting the phosphates represent bonds that release large amounts of energy when broken. (b) Ball-and-stick model shows the arrangement of atoms in three dimensions.

third phosphate is restored, thereby serving as an energy depot. Carriers for oxidation-reduction activities (nicotinamide adenine dinucleotide [NAD], for instance) are also derivatives of nucleotides (see chapter 8).

36. What is ATP, and how does it function in cells?

Chapter Summary with Key Terms

2.1 Atoms: Fundamental Building Blocks of All Matter in the Universe

A. Atomic Structure and Elements

1. All **matter** in the universe is composed of minute particles called **atoms**—the simplest form of matter not divisible into a simpler substance by chemical means.

CASE STUDY Part 2

Needing to move from speculation to scientific facts, NASA started a series of missions in 2002 that could perform more detailed investigations.

The most recent projects were the *Phoenix* probe in 2008 and the *Curiosity* probe in 2012. Each spacecraft was equipped with a one-ton roving science lab to analyze the Martian surface geology and soil. An important component of rover design was to explore more thoroughly whether conditions conducive to life exist on Mars now or did in the past. Rather than trying to isolate microorganisms, the Mars rover's instruments serve like remote senses—the mouth, nose, and eyes to “taste, sniff, and observe” the Martian soil and ice by measuring and assaying pH, salts, and the basic chemical makeup of its geology and atmosphere. The rover's robotic arms are able to excavate soil, rock, and ice. Other equipment can break up and vaporize rocks and perform detailed chemical analyses on the contents.

Initial results show that the soil is salty and slightly acidic. Past NASA probes had previously detected significant deposits of ice lying just below the surface. Then in September 2015 the *Mars Reconnaissance Orbiter* registered signs of liquid water and photographed streaks of water flowing downhill on craters during the warm season. This liquid is very salty, containing dissolved mixtures of common minerals.

A significant amount of methane also turned up in the samples, but more complex organic compounds have not yet been evident. Methane is formed by certain primitive prokaryotes but can also be the result of geologic activity. *Curiosity** is designed to monitor the methane content and possibly determine if it is from a biological or nonbiological source. A future mission to Mars is planned that will return samples to earth for more detailed analysis.

Quick Search

- For what reasons are complex organic carbon compounds considered strong evidence of living activities?

To conclude this Case Study, go to Connect.

*To learn more about the findings of the *Curiosity* rover, go to <http://mars.jpl.nasa.gov/msl/>.

Atoms are composed of smaller particles called **protons**, **neutrons**, and **electrons**.

2. a. Protons are positively (+) charged, neutrons are without charge, and electrons are negatively (–) charged.
- b. Protons and neutrons form the **nucleus** of the atom.
- c. Electrons orbit the nucleus in energy shells.

3. Atoms that differ in numbers of the protons, neutrons, and electrons are elements. **Elements** can be described by **mass number (MN)**, equal to the number of protons and neutrons it has, and **atomic number (AN)**, the number of protons in the nucleus, and each is known by a distinct name and symbol. Elements may exist in variant forms called **isotopes**. The **atomic mass or atomic weight** is equal to the average of the isotope mass numbers.

2.2 Bonds and Molecules

- A. Atoms interact to form **chemical bonds** and **molecules**. If the atoms combining to make a molecule are different elements, then the substance is termed a **compound**.
 1. The type of bond is dictated by the electron makeup of the outer orbitals (**valence**) of the atoms. Bond types include:
 - a. **Covalent bonds**, with shared electrons. The molecule is formed by one atom sharing its electrons with another atom; the balance of charge will be **polar** if unequal or **nonpolar** if equally shared/ electrically neutral.
 - b. **Ionic bonds**, where one atom transfers its electron(s) to another atom that can come closer to filling up its outer orbital. Dissociation of these compounds leads to the formation of charged **cations** and **anions**.
 - c. **Hydrogen bonds** involve weak attractive forces between hydrogen (+ charge) and nearby oxygens and nitrogens (– charge).
 - d. **Van der Waals forces** are also weak interactions between polarized zones of molecules such as proteins.
- B. An **oxidation** is a loss of electrons and a **reduction** is a gain electrons. A substance that causes an oxidation by taking electrons is called an **oxidizing agent**, and a substance that causes a reduction by giving electrons is called a **reducing agent**.

2.3 Chemical Reactions, Solutions, and pH

- A. Chemicals termed **reactants** can interact in a way to form different compounds termed **products**. Examples of reactions are synthesis and decomposition.
- B. A **solution** is a combination of a solid, liquid, or gaseous chemical (the **solute**) dissolved in a liquid medium (the **solvent**). Water is the most common solvent in natural systems.
- C. Ionization of water leads to the release of hydrogen ions (H^+) and hydroxyl (OH^-) ions. The **pH** scale expresses the concentration of H^+ such that a pH of less than 7.0 is considered **acidic**, and a pH of more than that, indicating fewer H^+ , is considered **basic (alkaline)**.

2.4 The Chemistry of Carbon and Organic Compounds

- A. **Biochemistry** is the study of molecules that are found in living things. Most of these substances are **organic** compounds, which consist of carbon and hydrogen covalently bonded in various combinations. Some are **inorganic** compounds are composed of elements other than C and H.
- B. Functional groups are small accessory molecules bonded to many organic compounds that impart unique characteristics.
- C. **Macromolecules** are very large organic compounds and are generally assembled from single units called **monomers** by

polymerization. Molecules of life fall into basic categories of carbohydrates, lipids, proteins, and nucleic acids.

2.5 Molecules of Life: Carbohydrates

- A. **Carbohydrates** are composed of carbon, hydrogen, and oxygen and contain aldehyde or ketone groups.
 1. **Monosaccharides** such as glucose are the simplest carbohydrates with 3 to 7 carbons; these are the monomers of carbohydrates.
 2. **Disaccharides** such as lactose consist of two monosaccharides joined by **glycosidic bonds**.
 3. **Polysaccharides** such as **starch** and **peptidoglycan** are chains of five or more monosaccharides.

2.6 Molecules of Life: Lipids

- A. **Lipids** contain long hydrocarbon chains and are not soluble in polar solvents such as water due to their nonpolar, hydrophobic character. Common components of fats are **fatty acids**, elongate molecules with a carboxylic acid group. Examples are **triglycerides**, **phospholipids**, sterols, and waxes.

2.7 Molecules of Life: Proteins

- A. **Proteins** are highly complex macromolecules that are crucial in most, if not all, life processes.
 1. **Amino acids** are the basic building blocks of proteins. They all share a basic structure of an amino group, a carboxyl group, an R group, and hydrogen bonded to a carbon atom. There are 20 different R groups, which define the basic set of 20 amino acids, found in all life forms.
 2. A **peptide** is a short chain of amino acids bound by **peptide bonds**: a **protein** contains at least 50 amino acids.
 3. The structure of a protein is very important to its function. This is described by the **primary structure** (the chain of amino acids), the **secondary structure** (formation of α helices and β -sheets due to hydrogen bonding within the chain), **tertiary structure** (cross-links, especially disulfide bonds, between secondary structures), and **quaternary structure** (formation of multisubunit proteins). The incredible variation in shapes is the basis for the diverse roles proteins play as **enzymes**, **antibodies**, receptors, and structural components.

2.8 The Nucleic Acids: A Program for Genetics

- A. **Nucleotides** are the building blocks of nucleic acids. They are composed of a **nitrogen base**, a pentose sugar, and a phosphate. Nitrogen bases are ringed compounds: **adenine (A)**, **guanine (G)**, **cytosine (C)**, **thymine (T)**, and **uracil (U)**. Pentose sugars may be deoxyribose or ribose, depending on the type of nucleic acid.
- B. **Deoxyribonucleic acid (DNA)** is a polymer of nucleotides that occurs as a double-stranded helix with hydrogen bonding between pairs of bases on the helices. It has all of the bases except uracil, and the pentose sugar is deoxyribose. DNA is the master code for a cell's life processes and must be transmitted to the offspring through **replication**.
- C. **Ribonucleic acid (RNA)** is a polymer of nucleotides where the sugar is ribose and **uracil** is the replacement base for thymine. It is almost always found single-stranded and is used to express the DNA code into proteins.
- D. **Adenosine triphosphate (ATP)** is a nucleotide with 3 phosphates that serves as the energy molecule in cells.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

- The smallest unit of matter with unique characteristics is
 - an electron
 - a molecule
 - an atom
 - a proton
- The _____ charge of a proton is exactly balanced by the _____ charge of a (an) _____.
 - negative, positive, electron
 - positive, neutral, neutron
 - positive, negative, electron
 - neutral, negative, electron
- Electrons move around the nucleus of an atom in pathways called
 - shells
 - orbitals
 - circles
 - rings
- Which parts of an element do not vary in number?
 - electrons
 - neutrons
 - protons
 - All of these vary.
- If a substance contains two or more elements of different types, it is considered
 - a compound
 - a monomer
 - a molecule
 - organic
- Bonds in which atoms share electrons are defined as _____ bonds.
 - hydrogen
 - ionic
 - double
 - covalent
- A hydrogen bond can form between _____ adjacent to each other.
 - two hydrogen atoms
 - two oxygen atoms
 - a hydrogen atom and an oxygen atom
 - negative charges
- An atom that can donate electrons during a reaction is called
 - an oxidizing agent
 - a reducing agent
 - an ionic agent
 - an electrolyte
- In a solution of NaCl and water, NaCl is the _____ and water is the _____.
 - acid, base
 - base, acid
 - solute, solvent
 - solvent, solute
- A solution with a pH of 2 _____ than a solution with a pH of 8.
 - has less H^+
 - has more H^+
 - has more OH^-
 - is less concentrated
- Fructose is a type of
 - disaccharide
 - monosaccharide
 - polysaccharide
 - amino acid
- Bond formation in polysaccharides and polypeptides is accompanied by the removal of a
 - hydrogen atom
 - hydroxyl ion
 - carbon atom
 - water molecule
- The monomer unit of polysaccharides such as starch and cellulose is
 - fructose
 - glucose
 - ribose
 - lactose
- A phospholipid contains
 - three fatty acids bound to glycerol
 - three fatty acids, a glycerol, and a phosphate
 - two fatty acids and a phosphate bound to glycerol
 - three cholesterol molecules bound to glycerol
- Proteins are synthesized by linking amino acids with _____ bonds.
 - disulfide
 - glycosidic
 - peptide
 - ester
- The amino acid that accounts for disulfide bonds in the tertiary structure of proteins is
 - tyrosine
 - glycine
 - cysteine
 - serine
- DNA is a hereditary molecule that is composed of
 - deoxyribose, phosphate, and nitrogen bases
 - deoxyribose, a pentose, and nucleic acids
 - sugar, proteins, and thymine
 - adenine, phosphate, and ribose

18. What is meant by the term *DNA replication*?
- synthesis of nucleotides
 - cell division
 - interpretation of the genetic code
 - the exact copying of the DNA code into two new molecules
19. Proteins can function as
- enzymes
 - receptors
 - antibodies
 - all of these
20. RNA plays an important role in what biological process?
- replication
 - protein synthesis
 - lipid metabolism
 - water transport
-

Case Study Review

- Which of the following has not been a major objective of Mars exploration?
 - to analyze elements in soil
 - to discover fossils
 - to detect organic compounds
 - to detect CO₂
 - What was a significant result of the Mars *Phoenix* project?
 - culturing bacteria
 - verifying water
 - finding organic matter
 - discovering precious metals
 - What other elements present in earth microorganisms would one expect to find on Mars?
-

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

- Explain this statement: “All compounds are molecules, but not all molecules are compounds.” Give an example.
 - What causes atoms to form chemical bonds? Why do some elements not bond readily?
 - Why are some covalent molecules polar and others nonpolar?
 - Explain why some elements are diatomic.
 - Exactly what causes the charges to form on atoms in ionic bonds?
 - Why are hydrogen bonds relatively weak?
 - What kind of substances will be expected to be hydrophilic and hydrophobic, and what makes them so?
 - How can a neutral salt be formed from acids and bases?
 - What characteristic of phospholipids makes them essential components of cell membranes?
 - How are saturated and unsaturated fatty acids different?
 - Why is the hydrophilic end of phospholipids attracted to water?
 - What makes the amino acids distinctive, and how many of them are there?
 - Why is DNA called a double helix?
 - Describe what occurs in a dehydration synthesis reaction.
 - How is our understanding of microbiology enhanced by a knowledge of chemistry?
-

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps along with concept-mapping activities for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

- The “octet rule” in chemistry helps predict the types of bonds that atoms will form. In general, an atom will be most stable if it fills its outer shell of 8 electrons. Atoms with fewer than 4 valence electrons tend to donate electrons and those with more than 4 valence electrons tend to accept additional electrons; those with exactly 4 can do both. Using this rule, determine what category each of the following elements falls into: N, S, C, P, O, H, Ca, Fe, and Mg. (You will need to work out the valence of the atoms.)
- Predict the kinds of bonds that occur in ammonium (NH_3), phosphate (PO_4), disulfide (S—S), and magnesium chloride (MgCl_2). (Use simple models, such as those in figure 2.4.)
- Work out the following problems:
 - Will an H bond form between $\text{H}_3\text{C—CH=O}$ and H_2O ? Draw a simple figure to support your answer.
 - Draw the following molecules and determine which are polar: Cl_2 , NH_3 , CH_4 .
 - What is the pH of a solution with a concentration of 0.00001 moles/ml (M) of H^+ ?
- What is the pH of a solution with a concentration of 0.00001 moles/ml (M) of OH^- ?
- Draw the atomic structure of magnesium and predict what kinds of bonds it will make.
- What kind of ion would you expect magnesium to make on the basis of its valence?
- Distinguish between polar and ionic compounds.
- Is galactose an aldehyde or a ketone sugar?
 - How many water molecules are released when a triglyceride is formed?
 - How many peptide bonds are in a hexapeptide?
- Observe figure 2.26 and explain why adenine forms hydrogen bonds only with thymine and why cytosine forms them only with guanine.
- For a and b, explain your choice.
 - Is butter an example of a saturated or an unsaturated fat?
 - Is olive oil an example of a saturated or an unsaturated fat?
 - Explain why sterols like cholesterol can add “stiffness” to membranes that contain them.

Visual Challenge

- Figures 1 and 2 are both highly magnified views of biological substances. Using figure 2.17 as your basis for comparison, speculate which molecules are shown and give the reasons for them having the microscopic appearance we see here.

A clinical “picture of meningitis” would show meningococci (arrow) being engulfed by white blood cells in a sample of spinal fluid. These tiny cells can devastate a healthy person in a few hours. (photo): Source: CDC

CASE STUDY Part 1 Battling a Brain Infection

One Saturday evening in 2007, a 50-year-old woman named Kay Peterson began to suffer **flulike symptoms**, with **fever**, aching joints, sore throat, and a headache. Feeling miserable but not terribly concerned, she took some ibuprofen and went to bed. By the following morning, she began to feel increasingly ill and was unstable on her feet, **confused**, and complaining of **light-headedness**. Realizing this was more than just the flu, her husband rushed her immediately to the nearest emergency room.

An initial examination showed that most of Kay’s vital signs were normal. Conditions that may provide some clues were rapid pulse and respiration, an **inflamed throat**, and a **stiff neck**. A **chest X ray** revealed no sign of **pneumonia**, and a blood test indicated an elevated **white blood cell** count. To rule out a possible brain infection, a puncture of the spinal canal was performed. As it turned out, the **cerebrospinal fluid (CSF)** the technician extracted appeared normal, microscopically and macroscopically.

Within an hour, Kay began to drift in and out of consciousness and was extremely lethargic. At one point, the medical team could

not find a pulse and noticed **dark brown spots** developing on her legs. When her condition appeared to be deteriorating rapidly, she was immediately taken to the intensive care unit and placed on **intravenous antibiotics**. One of the emergency room doctors later reported, “Her medical situation was so critical that our intervention was truly a matter of life or death.”

Because Kay’s symptoms pointed to a possible infection of the **central nervous system**, a second spinal puncture was performed. This time the spinal fluid looked cloudy. A **Gram stain** was performed right away, and cultures were started.

“Intervention was truly a matter of life or death.”

- *What are signs and symptoms of disease? Give examples from the case that appear to be the most diagnostically significant.*
- *What is the importance of a Gram stain in diagnosis of an infection like this?*

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

SCOPING OUT THE CHAPTER

Studying microorganisms in the laboratory is very different from studying elephants, trees, or insects. Microorganisms are invisible to the naked eye, are found everywhere, and typically must be raised in conditions quite different from their natural surroundings. In this chapter you'll get a brief overview of some general laboratory techniques carried out by microbiologists, oftentimes referred to as the six "I's". Procedures start at the central hub of specimen collection and flow from there to inoculation, incubation, and so on. But not all steps are always performed, nor do they necessarily proceed exactly in this order. Some investigators go right from sampling to microscopic inspection or from sampling to DNA testing. Others may require only inoculation and incubation on special media or test systems.

Identification

One goal of these procedures is to attach a name or identity to the microbe, using information gathered from inspection and investigation. Identification is accomplished through the use of keys, charts, and computer programs that analyze the data and arrive at a final conclusion.

Inoculation

The sample is placed into a container of medium that will support its growth. The medium may be solid or liquid, and held in tubes, plates, flasks, and even eggs. The delivery tool is usually a loop, needle, swab, or syringe.

Information Gathering

Additional tests for microbial function and characteristics may include inoculations into specialized media that determine biochemical traits, immunological testing, and genetic typing. Such tests will provide specific information unique to a certain microbe.

Specimen Collection

Microbiologists begin by sampling the object of their interest. It could be nearly any thing or place on earth. Very common sources are body fluids, foods, water, soil, plants, and animals, but even places like icebergs, volcanoes, and rocks can be sampled.

Incubation

Inoculated media are placed in a controlled environment (incubator) to promote growth. During the hours or days of this process, a culture develops as the visible growth of the microbes in the container of medium.

Inspection

Cultures are observed for the macroscopic appearance of growth characteristics. Cultures are examined under the microscope for basic details such as cell type and shape. This may be enhanced through staining and use of special microscopes.

Isolation

Some inoculation techniques can separate microbes to create isolated colonies that each contain a single type of microbe. This is invaluable for identifying the exact species of microbes in the sample, and it paves the way for making pure cultures.

3.1 Methods of Microbial Investigation

Expected Learning Outcomes

1. Explain what unique characteristics of microorganisms make them challenging subjects for study.
2. Briefly outline the processes and purposes of the six types of procedures that are used in handling, maintaining, and studying microorganisms.

Biologists studying large organisms such as animals and plants can, for the most part, immediately see and differentiate their experimental subjects from the surrounding environment and from one another. In fact, they can use their senses of sight, smell, hearing, and even touch to detect and evaluate identifying characteristics and to keep track of growth and developmental changes.

Because microbiologists cannot rely as much as other scientists on senses other than sight, they are confronted by some unique problems. First, most habitats (such as the soil and the human mouth) harbor microbes in complex associations. It is often necessary to separate the organisms from one another so they can be identified and studied. Second, to maintain and keep track of such small research subjects, microbiologists usually will need to grow them under artificial conditions. A third difficulty in working with microbes is that they are not visible to the naked eye. This, coupled with their wide distribution, means that undesirable ones can be inconspicuously introduced into an experiment, where they may cause misleading results.

To deal with the challenges of their tiny and sometimes elusive targets, microbiologists have developed several types of procedures for investigating and characterizing microorganisms. These

techniques can be summed up succinctly as the **six “I’s”**: **inoculation, incubation, isolation, inspection, information gathering, and identification (table 3.1)**. Depending on the purposes of the particular investigator, these may be performed in several combinations and orders, but together they serve as the major tools of the microbiologist’s trade. As novice microbiologists, most of you will be learning some basic microscope, inoculation, culturing, and identification techniques. Many professional researchers use more advanced investigation and identification techniques that may not even require growth or absolute isolation of the microbe in culture (see 3.1 Secret World of Microbes). If you examine the example from the **Case Study** in chapter 1, you will notice that the researchers used only some of the 6 “I’s,” whereas the case study in this chapter includes all of them in some form.

The first four sections of this chapter cover some of the essential concepts that revolve around the six “I’s,” but not necessarily in the exact order presented in table 3.1. Microscopes are so important to microbiological inquiry that we start out with the subject of microscopes, magnification, and staining techniques. This is followed by culturing procedures and media.

Quick Search

Watch “A Tour of the Microbiology Lab” on YouTube to see the daily work performed there.

Check Your Progress SECTION 3.1

1. Name the notable features of microorganisms that have created a need for the specialized tools of microbiology.
2. In one sentence each, define what is involved in each of the six “I’s.”

TABLE 3.1 An Overview of Microbiology Techniques

Technique	Process Involves	Purpose and Outcome
Inoculation	Placing a sample into a container of medium that supplies nutrients for growth and is the first stage in culturing	To increase visibility; makes it possible to handle and manage microbes in an artificial environment and begin to analyze what the sample may contain
Incubation	Exposing the inoculated medium to optimal growth conditions, generally for a few hours to days	To promote multiplication and produce the actual culture. An increase in microbe numbers will provide the higher quantities needed for further testing.
Isolation	Methods for separating individual microbes and achieving isolated colonies that can be readily distinguished from one another macroscopically*	To make additional cultures from single colonies to ensure they are pure; that is, containing only a single species of microbe for further observation and testing
Inspection	Observing cultures macroscopically for appearance of growth and microscopically for appearance of cells	To analyze initial characteristics of microbes in samples. Stains of cells may reveal information on cell type and morphology.
Information gathering	Testing of cultures using procedures that analyze biochemical and enzyme characteristics, immunologic reactions, drug sensitivity, and genetic makeup	To provide specific data and generate an overall profile of the microbes. These test results and descriptions will become key determinants in the last category, identification.
Identification	Analysis of collected data to help support a final determination of the types of microbes present in the original sample; this is accomplished by a variety of schemes	This lays the groundwork for further research into the nature and roles of these microbes; it can also provide numerous applications in infection diagnosis, food safety, biotechnology, and microbial ecology.

*Observable to the unaided or naked eye. This term usually applies to the cultural level of study.

3.2 The Microscope: Window on an Invisible Realm

Expected Learning Outcomes

3. Describe the basic plan of an optical microscope, and differentiate between magnification and resolution.
4. Explain how the images are formed, along with the role of light and the different powers of lenses.
5. Indicate how the resolving power is determined and how resolution affects image visibility.
6. Differentiate between the major types of optical microscopes, their illumination sources, image appearance, and uses.
7. Describe the operating features of electron microscopes and how they differ from optical microscopes in illumination source, magnification, resolution, and image appearance.
8. Differentiate between transmission and scanning electron microscopes in image formation and appearance.

Imagine **Leeuwenhoek's** excitement and wonder when he first viewed a drop of rainwater and glimpsed an amazing microscopic world teeming with unearthly creatures. Beginning microbiology students still experience this sensation, and even experienced microbiologists remember their first view. The microbial existence is indeed another world, but it would remain largely uncharted without an essential tool: the microscope. Your efforts in exploring microbes will be more meaningful if you understand some essentials of **microscopy*** and specimen preparation.

Magnification and Microscope Design

The two key characteristics of a reliable microscope are **magnification,*** the ability to make objects appear enlarged, and **resolving power,** the ability to show detail.

A discovery by early microscopists that spurred the advancement of microbiology was that a clear glass sphere could act as a lens to magnify small objects. Magnification in most microscopes results from a complex interaction between visible light waves and the curvature of the lens. When a beam or ray of light transmitted through air strikes and passes through the convex surface of glass, it experiences some degree of **refraction,*** defined as the bending or change in the angle of the light ray as it passes through a medium such as a lens. The greater the difference in the composition of the two substances the light passes between, the more pronounced is the refraction. When an object is placed a certain distance from the spherical lens and illuminated with light, an optical replica, or **image,** of it is formed by the refracted light. Depending upon the size and curvature of the lens, the image appears enlarged to a particular degree, which is called its power of magnification and is usually identified with a number combined with \times (read “times”). This behavior of light is evident if one looks through an everyday object such as a glass ball or a magnifying glass (**figure 3.1**). It is basic to the function of all

Figure 3.1 Effects of magnification. Demonstration of the magnification and image-forming capacity of clear glass “lenses.” Given a proper source of illumination, a magnifying glass can deliver 2 to 10 times magnification. © Kathy Park Talaro

optical, or light, microscopes, though many of them have additional features that define, refine, and increase the size of the image.

The first microscopes were **simple,** meaning they contained just a single magnifying lens and a few working parts. Examples of this type of microscope are a magnifying glass, a hand lens, and Leeuwenhoek’s basic little tool shown earlier in figure 1.8a. Among the refinements that led to the development of today’s **compound** (two-lens) **microscope** were the addition of a second magnifying lens system, a lamp in the base to give off visible light and **illuminate*** the specimen, and a special lens called the **condenser** that converges or focuses the rays of light to a single point on the object. The fundamental parts of a modern compound light microscope are illustrated in **figure 3.2a**.

Principles of Light Microscopy

To be most effective, a microscope should provide adequate magnification, resolution, and clarity of image. Magnification of the object or specimen by a compound microscope occurs in two phases. The first lens in this system (the one closest to the specimen) is the objective lens, and the second (the one closest to the eye) is the ocular lens, or eyepiece (**figure 3.2b**). The objective forms the initial image of the specimen, called the **real image**. When the real image is projected to the plane of the eyepiece, the ocular lens magnifies it to produce a second image, the **virtual image**. The virtual image is the one that will be received by the eye and converted to a retinal and visual image. The magnifying power

* **microscopy** (mye-kraw/-skuh-pee) Gr. The science that studies microscope techniques.

* **magnification** (mag'-nih-fih-kay/-shun) L. *magnus*, great, and *ficere*, to make.

* **refraction** (ree-frakt', ree-frak'-shun) L. *refringere*, to break apart.

* **illuminate** (ill-oo'-mih-nayt) L. *illuminatus*, to light up.

of the objective alone usually ranges from 4× to 100×, and the power of the ocular alone ranges from 10× to 20×. The total power of magnification of the final image formed by the combined lenses is a product of the separate powers of the two lenses:

<i>Power of Objective ×</i>	<i>Usual Power of Ocular</i>	<i>=</i>	<i>Total Magnification</i>
4× scanning objective	10×	=	40×
10× low-power objective	10×	=	100×
40× high dry objective	10×	=	400×
100× oil immersion objective	10×	=	1,000×

(a)

(b)

Figure 3.2 (a) The main parts of a microscope. This is a compound light microscope with two oculars (binocular) for viewing. Such microscopes usually have four objective lenses, a mechanical stage to move the specimen, a condenser, an iris diaphragm, and a built-in light source (lamp). (b) Light pathway and image formation in light microscopes. Light formed by the lamp is directed through the lamp filter and into the opening of the iris diaphragm; the condenser gathers the light rays and focuses them into a single point on the specimen; an enlarged image of the specimen—the real image—is next formed by the objective lens. This image is not seen but is projected into the ocular lens, which forms a final level of magnification called the virtual image. This image is observed in the field of view by the eye and perceived by the brain. Note that the lenses reverse the image and flip it upside down. (a) Courtesy of Nikon Instruments Inc., Melville, New York, USA, www.nikoninstruments.com

Microscopes are equipped with a nosepiece holding three or more objectives that can be rotated into position as needed. The power of the ocular usually remains constant for a given microscope. Depending on the power of the ocular, the total magnification of standard light microscopes can vary from 40 \times with the lowest-power objective (called the scanning objective) to 2,000 \times ¹ with the highest-power objective (the oil immersion objective).

Resolution: Distinguishing Magnified Objects Clearly In addition to magnification, a microscope must also have adequate **resolution**, or **resolving power**. Resolution defines the capacity of an optical system to distinguish two adjacent objects or points from one another. For example, at a distance of 25 cm (10 in), the lens in the human eye can resolve two small objects as separate points just as long as the two objects are no closer than 0.2 mm apart. The eye examination given by optometrists is in fact a test of the resolving power of the human eye for various-size letters read at a distance of 20 feet. Because microorganisms are extremely small and usually very close together, they will not be seen with clarity or any degree of detail unless the microscope's lenses can resolve them.

A simple equation in the form of a fraction expresses the main mathematical factors that influence the expression of resolving power.

$$\text{Resolving power (RP)} = \frac{\text{Wavelength of light in nm}}{2 \times \text{Numerical aperture of objective lens}}$$

From this equation, it is evident that the resolving power is a function of the wavelength of light that forms the image, along with certain characteristics of the objective. The light source for optical microscopes consists of a band of colored wavelengths in the visible spectrum. The shortest visible wavelengths are in the violet-blue portion of the spectrum (400 nm), and the longest are in the red portion (750 nm). Because the wavelength must pass between the objects that are being resolved, shorter wavelengths (in the 400–500 nm range) will provide better resolution (**figure 3.3**).

The other factor influencing resolution is the **numerical aperture (NA)**, a mathematical constant derived from the physical structure of the lens. This number represents the angle of light produced by refraction and is a measure of the quantity of light gathered by the lens. Each objective has a fixed numerical aperture value ranging from 0.1 in the lowest-power lens to approximately 1.25 in the highest-power (oil immersion) lens. Lenses with higher NAs provide better resolving power because they increase the angle of refraction and widen the cone of light entering the lens. For the oil immersion lens to arrive at its maximum resolving capacity, a drop of oil must be inserted between the tip of the lens and the specimen on the glass slide. Because immersion oil has the same optical qualities as glass, it prevents refractive loss that normally occurs as peripheral light passes from the slide into the air; this property effectively increases the numerical aperture (**figure 3.4**). There is an absolute limitation to resolution in optical microscopes, which can be demonstrated by calculating

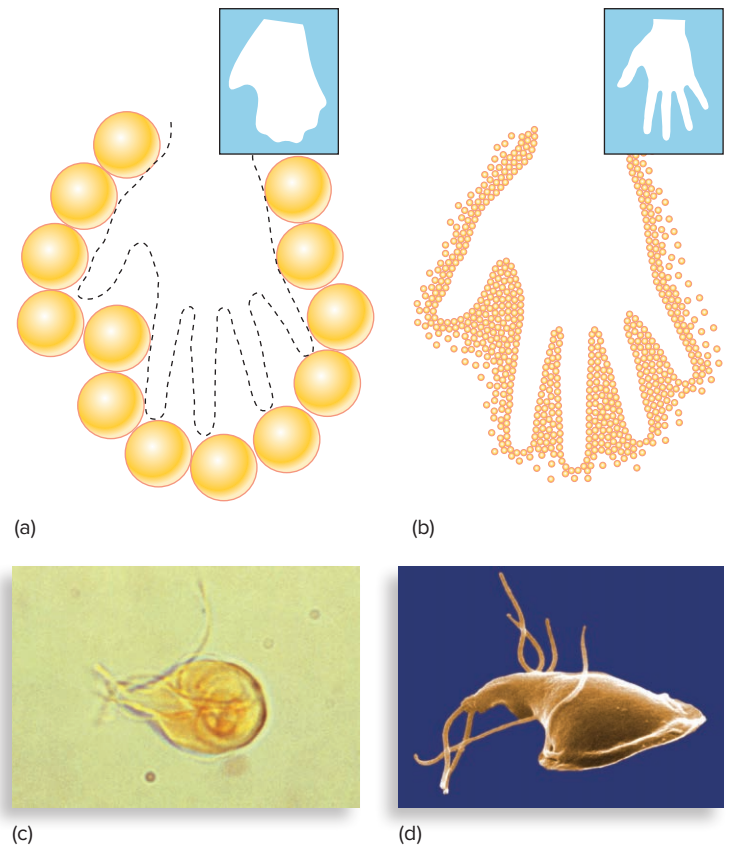

Figure 3.3 Effect of wavelength on resolution. A simple model demonstrates how the wavelength influences the resolving power of a microscope. Here an outline of a hand represents the object being illuminated, and two different sizes of beads represent the wavelengths of light. (a) The longer waves are too large to penetrate between the finer spaces, and they produce a fuzzy, undetailed image. (b) Shorter waves are small enough to enter small spaces and produce a much more detailed image that is recognizable as a hand. (c) The longer waves used by the light microscope produce an indistinct image of the protozoan parasite *Giardia*. (d) The much shorter waves of electrons used by the scanning electron microscope produces an image of the same organism with far greater detail. (c): Source: Dr. Mae Melvin/CDC; (d): Source: Dr. Stan Erlandsen; Dr. Dennis Feely/CDC

the resolution of the oil immersion lens using a blue-green wavelength of light:

$$\begin{aligned} \text{RP} &= \frac{500 \text{ nm}}{2 \times 1.25} \\ &= 200 \text{ nm (or } 0.2 \mu\text{m)} \end{aligned}$$

In practical terms, this calculation means that the oil immersion lens can resolve any cell or cell part as long as it is at least 0.2 μm in diameter and that it can resolve two adjacent objects as long as they are no closer than 0.2 μm (**figure 3.5**). In general, organisms that are 0.5 μm or more in diameter are readily seen. This includes fungi and protozoa and some of their internal structures, and most bacteria. However, a few bacteria and most viruses are far too small to be resolved by the optical microscope and require electron microscopy. The factor that most limits the clarity of a microscope's image is its resolving power. Even if a light microscope were designed to magnify several thousand times, its resolving power

1. Some microscopes are equipped with 20 \times oculars or special annuli that can double their magnification.

Figure 3.4 Workings of an oil immersion lens. To maximize its resolving power, an oil immersion lens (the one with highest magnification) must have a drop of oil placed at its tip. This transmits a continuous cone of light from the condenser to the objective, thereby increasing the amount of light and, consequently, the numerical aperture. Without oil, some of the peripheral light that passes through the specimen is scattered into the air or onto the glass slide; this scattering decreases resolution.

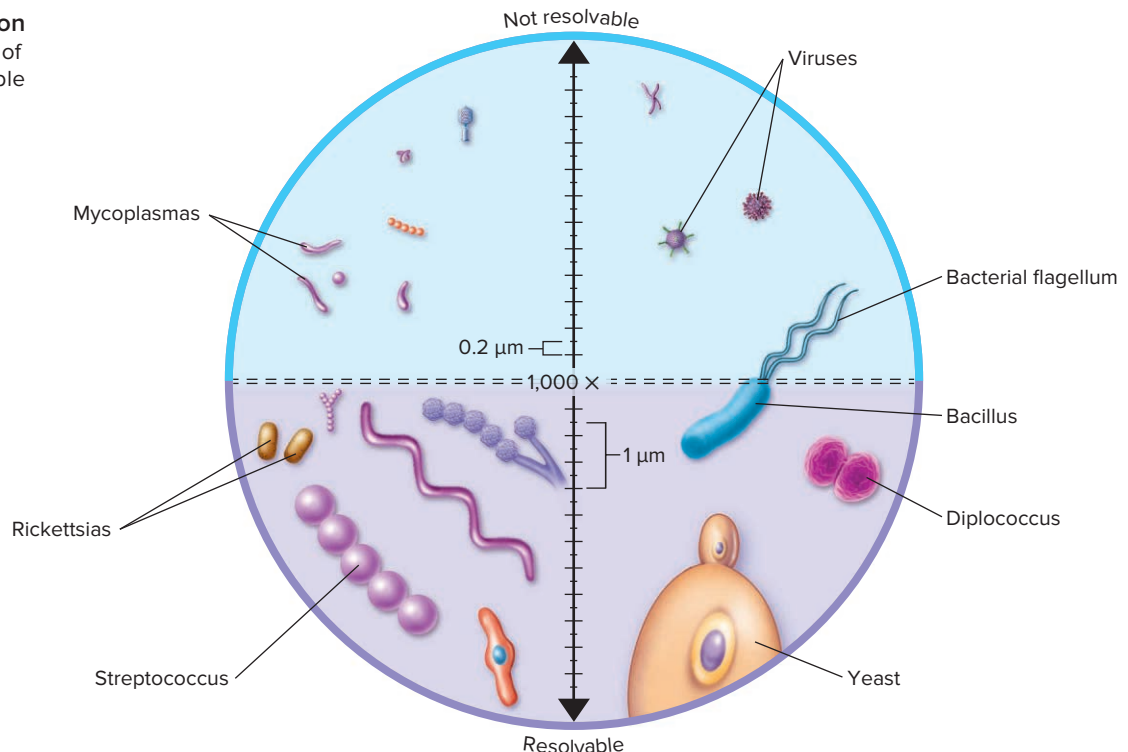

could not be increased, and the image it produced would be enlarged but blurry.

Despite this limit, small improvements to resolution are possible. One is to place a blue filter over the microscope lamp, keeping the wavelength at the shortest possible value. Another comes from maximizing the numerical aperture. That is the effect of adding oil to the immersion lens, which effectively increases the NA from 1.25 to 1.4 and improves the resolving power to $0.17 \mu\text{m}$.

Variations on the Optical Microscope

Optical microscopes that use visible light can be described by the nature of their **field of view**, or **field**, which is the circular area

Figure 3.5 Effect of resolution on image visibility. Comparison of objects that would not be resolvable versus those that would be resolvable under oil immersion at 1,000X magnification. Note that in addition to differentiating two adjacent things, good resolution also means being able to observe an object with clarity.

observed through the ocular lens. With special adaptations in lenses, condensers, and light sources, four special types of microscopes can be described: bright-field, dark-field, phase-contrast, and interference. A fifth type of optical microscope, the fluorescence microscope, uses ultraviolet radiation as the illuminating source, and a sixth, the confocal microscope, uses a laser beam. Each of these microscopes is adapted for viewing specimens in a particular way, as described in the next sections and summarized in **table 3.2**. Refer back to figure 1.4 for size comparisons of microbes and molecules.

Bright-Field Microscopy

The bright-field microscope is the most widely used type of light microscope. A bright-field microscope forms its image when light is transmitted through the specimen. The specimen, being denser and more opaque than its surroundings, absorbs some of this light, and the rest of the light is transmitted directly up through the ocular into the field. As a result, the specimen will produce an image that is darker than the surrounding brightly illuminated field. The bright-field microscope is a multipurpose instrument that can be used for both live, unstained material and preserved, stained material. The bright-field image is compared with that of other microscopes in table 3.2.

Dark-Field Microscopy

A bright-field microscope can be adapted as a dark-field microscope by adding a special disc called a *stop* to the condenser. The stop blocks all light from entering the objective lens except peripheral light that is reflected off the sides of the specimen itself. The resulting image is brightly illuminated specimens surrounded by a dark (black) field (table 3.2). The most effective use of dark-field microscopy is to visualize living cells that would be distorted by

TABLE 3.2

Comparisons of Types of Microscopy

I. Microscopes with visible light illumination

Maximum effective magnification = 1,000X to 2,000X*.
Maximum resolution = 0.2 μm .

A. Comparative Images from Optical Microscopes

The subject here is yeast cells examined at 1,000X with four types of microscopes. Notice the differences in the appearance of the field and the degree of detail shown in the four methods.

Bright-field microscope
Common multipurpose microscope for live and preserved stained specimens; specimen is dark, field is white; provides fair cellular detail.

Dark-field microscope
Best for observing live, unstained specimens; specimen is bright, field is black; provides outline of specimen with reduced internal cellular detail.

Phase-contrast microscope
Used for live specimens; specimen is contrasted against light gray background; excellent for internal cellular detail.

Differential interference contrast microscope
Provides very detailed, highly contrasting, three-dimensional images of live specimens.

II. Microscopes with ultraviolet or laser beam illumination

Maximum effective magnification = 1,000X to 2,000X*.
Maximum resolution = 0.2 μm **.

B. Modifications of Optical Microscopes with Specialized Functions

Fluorescent Microscope
Cells of Yersinia pestis, the bacterium responsible for plague, viewed at 200X. Ultraviolet light is used to illuminate the specimen. Antibodies labeled with fluorescent dyes emit visible light only if the antibody recognizes and binds to the cell. The specificity of this technique makes it a superior diagnostic tool.

Confocal Microscope
Two views of Paramecium 1,500X, stained by fluorescent dyes, and scanned by a laser beam, form multiple images that are combined into a three-dimensional image. Confocal microscopes may utilize visible or ultraviolet light. Note the fine detail of cilia and organelles.

III. Microscopes use a beam of electrons

Maximum effective magnification TEM = 1,000,000X.
Maximum effective magnification SEM = 650,000X.
Maximum resolution TEM = 0.5 nm.
Maximum resolution SEM = 10 nm.

C. Electron Microscopes Image Objects with a Beam of Electrons

Transmission electron microscope (TEM)
Influenza virus particle viewed with a transmission electron microscope (TEM). This type of microscope provides the best resolution and can be used to view the internal structure of cells and viruses.

Colorized transmission electron microscope image
Colorized version of the same TEM image. Electron microscopes produce only black and white images, but these are often artificially colored, with the aid of a computer.

Scanning electron microscope (SEM)
Artificially colorized scanning electron microscope (SEM) image of Middle East respiratory syndrome Coronavirus (MERS CoV) viral particles (colored yellow) on the surface of a eukaryotic cell (colored blue). The electron beam scans over the surface of the cell to produce a three-dimensional image.

*The 2,000X maximum is achieved through the use of a 20X ocular or 2X annulus.

**Three chemists recently developed a super-resolved fluorescent microscope that can resolve to 50 nm (0.05 μm).

drying or heat, or cannot be stained with the usual methods. It can outline the organism's shape and permit rapid recognition of swimming cells that may appear in fresh specimens, but it does not reveal fine internal details.

Phase-Contrast and Interference Microscopy

If similar objects made of clear glass, ice, and transparent plastic are immersed in the same container of water, an observer would have difficulty telling them apart because they have similar optical properties. In the same way, internal components of a live, unstained cell also lack sufficient contrast to be distinguished readily. The phase-contrast microscope contains devices that transform the subtle changes in light waves passing through the specimen into differences in light intensity. For example, thicker cell parts such as organelles alter the pathway of light to a greater extent than thinner regions such as the cytoplasm, creating contrast. The amount of internal detail visible by this method is greater than by either bright-field or dark-field methods (table 3.2). The phase-contrast microscope is most useful for observing intracellular structures such as bacterial spores, granules, and organelles, as well as the locomotor structures of eukaryotic cells.

Like the phase-contrast microscope, the **differential interference contrast (DIC)** microscope provides a detailed view of unstained, live specimens by manipulating the light. But this microscope has additional refinements that can add contrasting colors to the image. DIC microscopes produce extremely well-defined images that are often vividly colored and appear three-dimensional (table 3.2).

Scanning Confocal Microscopes

Simple optical microscopes may be unable to form a clear image at higher magnifications, because samples are often too thick for conventional lenses to focus all levels of cells simultaneously. This is especially true of larger cells with complex internal structures. Instead of using traditional illumination *scanning confocal microscopes* use a laser beam of light to scan various depths in the specimen and deliver a sharp image focusing on just a single plane. This produces an image that is a high-definition “slice” of a sample. A computer is then used to assemble the slices into a high-resolution, three-dimensional image. It is most often used on fluorescently stained specimens, but it can also be used to visualize live unstained cells and tissues (table 3.2).

Fluorescence Microscopy

The fluorescence microscope is a specially modified compound microscope furnished with an ultraviolet (UV) radiation source and filters that protect the viewer's eye from injury by these dangerous rays. The name for this type of microscopy is based on the use of certain dyes (acridine, fluorescein) and minerals that show **fluorescence**. This means that the dyes give off visible light when bombarded by shorter ultraviolet rays. For an image to be formed, the specimen must first be coated or placed in contact with a source of fluorescence. Subsequent illumination by ultraviolet radiation causes the specimen to emit visible light, producing an intense blue, yellow, orange, or red image against a black field.

CLINICAL CONNECTIONS

Fluorescent Techniques in Identification

Fluorescence microscopy has its most useful applications in diagnosing infections caused by specific bacteria, protozoans, and viruses. A staining technique with fluorescent dyes is commonly used to detect *Mycobacterium tuberculosis* (the agent of tuberculosis) in patients' specimens (see figure 19.19). In a number of diagnostic procedures, fluorescent dyes are bound to specific antibodies—immunological proteins that recognize and tightly bind to a specific cells. These *fluorescent antibodies* can be used to identify the causative agents in such diseases as syphilis, chlamydia, trichomoniasis, herpes, and influenza. **Figure 3.6** displays the results of a fluorescent antibody technique used to highlight the spirochete of syphilis. A related technology uses fluorescent nucleic acid probes to differentiate between live and dead cells in mixtures or detect uncultured cells (see 3.1 Secret World of Microbes). A fluorescence microscope can be handy for locating specific microbes in complex mixtures because only those cells targeted by the technique will fluoresce.

Explain why fluorescent microscopic techniques can produce more specific results than other light microscopes. Answer available on Connect.

Figure 3.6 Fluorescent staining of a sample of *Treponema pallidum*, the causative agent of syphilis. The specific fluorescent antibodies that attach only to the pathogen and fluoresce a bright green make it a valuable diagnostic stain. Note the spiral nature of the cells (1,000X). Electron Microscopy

If conventional light microscopes are our windows on the microscopic world, then the electron microscope (EM) is our window on the tiniest details of that world. Unlike light microscopes, the electron microscope forms an image with a beam of electrons that can be made to travel in wavelike patterns when accelerated to high speeds. These waves are 100,000 times shorter than the waves of visible light. Knowing that resolving power is a function of wavelength makes it

TABLE 3.3 Comparison of Light Microscopes and Electron Microscopes

Characteristic	Light or Optical	Electron (Transmission)
Useful magnification	2,000×*	1,000,000× or more
Maximum resolution	200 nm (0.2 μm)	0.5 nm
Image produced by	Light rays	Electron beam

Specimen may be alive	Yes	Usually not
Specimen requires special stains or treatment	Depends on technique	Yes
Shows natural color	Yes	No

*This maximum requires a 20× ocular.

evident that the RP fraction and number will become very small. Indeed, it is possible to resolve atoms with an electron microscope, even though the practical resolution for most biological applications is approximately 0.5 nm. The degree of resolution allows magnification to be extremely high—usually between 5,000× and 1,000,000× for biological specimens and up to 5,000,000× in some applications. Its capacity for magnification and resolution makes the EM an invaluable tool for studying the finest structure of cells and viruses. If not for electron microscopes, our understanding of biological structure and function would still be in its early theoretical stages.

In fundamental ways, the electron microscope is similar to the optical microscope. It employs components analogous to, but not necessarily the same as, those in light microscopy (table 3.3). For instance, it magnifies in stages by means of two lens systems, and it has a condensing lens, a specimen holder, and a focusing apparatus. Otherwise the two types have numerous differences (table 3.3). An electron gun aims its beam through a vacuum to ring-shaped electromagnets that focus this beam on the specimen. Specimens must be pretreated with chemicals or dyes to increase contrast and usually cannot be observed in a live state. The enlarged image is displayed on a viewing screen or photographed for further study rather than being observed directly through an eyepiece. Because images produced by electrons lack color, electron micrographs (a micrograph is a photograph of a microscopic object) are always shades

of black, gray, and white. The color-enhanced micrographs seen in this and other textbooks have computer-added color.

Two general forms of EM are the **transmission electron microscope (TEM)** and the **scanning electron microscope (SEM)** (see table 3.2). Transmission electron microscopes are the method of choice for viewing the detailed structure of cells and viruses. This microscope produces its image by transmitting electrons through the specimen. Because electrons cannot readily penetrate thick preparations, the specimen must be stained or coated with metals that will increase image contrast and sectioned into extremely thin slices (20–100 nm thick). The electrons passing through the specimen travel to the fluorescent screen and display a pattern or image. The darker and lighter areas of the image correspond to more and less dense parts on the specimen (figure 3.7a). The TEM can also be used to produce negative images and shadow casts of whole microbes (see figure 6.3).

The scanning electron microscope provides some of the most dramatic and realistic images in existence. This instrument can create an extremely detailed three-dimensional view of all things biological—from dental plaque to tapeworm heads. To produce its images, the SEM bombards the surface of a whole, metal-coated specimen with electrons while scanning back and forth over it. A shower of electrons deflected from the surface is picked up with great accuracy by a sophisticated detector, and the electron pattern is displayed as an image on a monitor screen. The contours of the specimens resolved with scanning electron micrography are very revealing and often surprising. Areas that look smooth and flat with the light microscope display intriguing surface features with the SEM (figure 3.7b). Improved technology has continued to refine electron microscopes and to develop variations on the basic plan.

3.1 MAKING CONNECTIONS

The Evolution in Resolution: Probing Microscopes

In the past, chemists, physicists, and biologists had to rely on indirect methods to gain information on the structures of the smallest molecules. But technological advances have created a new generation of microscopes that “see” atomic structure by actually feeling it. *Scanning probe microscopes* operate with a minute needle tapered to a tip that can be as narrow as a single atom! This probe scans over the exposed surface of a material and records an image of its outer texture. These revolutionary microscopes have such profound resolution that they have the potential to image single atoms and to magnify 100 million times. The scanning tunneling microscope (STM) was the first of these microscopes. It uses a tungsten probe that hovers near the surface of an object and follows its topography while simultaneously giving off an electrical signal of its pathway, which is then imaged on a screen. The STM is used primarily for detecting defects on the surfaces of electrical conductors and computer chips, but it has also provided the first incredible close-up views of DNA, the genetic material.

Another variety, the atomic force microscope (AFM), gently forces a diamond and metal probe down onto the surface of a specimen like a needle on a record. As it moves along the surface, any deflection of the metal probe is detected by a sensitive device that relays the information to an imager. The AFM is very useful in viewing the detailed functions of biological molecules such as antibodies and enzymes.

The latest versions of these microscopes have increased the resolving power to around 0.5 \AA , which allowed technicians to image a pair of electrons! Such powerful tools for observing and positioning atoms have spawned a field called *nanotechnology*—the science of the “small.” Scientists in this area use physics, chemistry, biology, and engineering to manipulate small molecules and atoms.

A section of graphene recently analyzed by the atomic force microscope, which clearly shows the carbon atoms that make up its structure. This image was so detailed that the bonds between the carbon atoms could be visualized and measured for the first time.

© IBM Research-Zurich

Working at these dimensions, researchers are currently creating tiny molecular tools to miniaturize computers and other electronic devices. A great deal of new research is also being devoted to the development of nanoparticles to deliver drugs, analyze DNA, and treat disease (look back at Clinical Connections, “Nanoparticles—Molecule Sized ‘Smart’ Pills,” in chapter 2).

Looking back at figure 2.1, name some other chemical features that may become visible using these high-power microscopes. *Answer available on Connect.*

Some inventive relatives of the EM are the scanning probe microscope and atomic force microscope (3.1 Making Connections).

Check Your Progress SECTION 3.2

- Differentiate between the concepts of magnification, refraction, and resolution and explain how they contribute to the clarity of an image.
- Briefly explain how an image is made and magnified.
- On the basis of the formula for resolving power, explain why a smaller RP value is preferred to a larger one and explain what it means in practical terms if the resolving power is $1.0 \mu\text{m}$.
- What adjustments can improve a microscope's resolution?
- Compare bright-field, dark-field, phase-contrast, confocal, and fluorescence microscopy as to field appearance, specimen appearance, light source, and uses.
- Compare and contrast the optical compound microscope with the electron microscope.
- Why is the resolution so superior in the electron microscope?
- Compare the way that the image is formed in the TEM and the SEM.

3.3 Preparing Specimens for Optical Microscopes

Expected Learning Outcomes

- Explain the basic differences between fresh and fixed preparations for microscopy and how they are used.
- Define dyes and describe the basic chemistry behind the process of staining.
- Differentiate between negative and positive staining, giving examples.
- Distinguish between simple, differential, and structural stains, including their applications.
- Describe the process of Gram staining and how its results can aid the identification process.

A specimen for optical microscopy is generally prepared by mounting a sample on a suitable glass slide that sits on the stage between the condenser and the objective lens. The manner in which a slide

specimen, or mount is prepared depends upon: (1) the condition of the specimen, either in a living or preserved state; (2) the aims of the examiner, whether to observe overall structure, identify the microorganisms, or see movement; and (3) the type of microscopy available, whether it is bright-field, dark-field, phase-contrast, or fluorescence.

Fresh, Living Preparations

Live samples of microorganisms are used to prepare **wet mounts** so that they can be observed as near to their natural state as possible. The cells are suspended in a suitable fluid (water, broth, saline) that temporarily maintains viability and provides space and a medium for locomotion. A wet mount consists of a drop or two of the culture placed on a slide and overlaid with a cover glass. Although this preparation is quick and easy to make, it has certain disadvantages. The cover glass can damage larger cells, and the slide is very susceptible to drying and can contaminate the handler's fingers.

A more satisfactory alternative is the **hanging drop slide** (below) made with a special concave (depression) slide, an adhesive or sealant, and a coverslip from which a small drop of sample is suspended. These types of short-term mounts provide a true assessment of the size, shape, arrangement, color, and motility of cells. Even greater cellular detail can be observed with phase-contrast or interference microscopy.

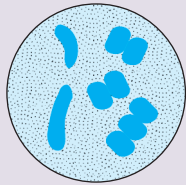

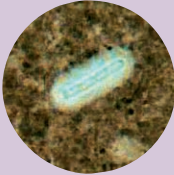

Fixed, Stained Smears

A more permanent mount for long-term study can be obtained by preparing fixed, stained specimens. The smear technique, developed by Robert Koch more than 100 years ago, consists of spreading onto a slide a thin film made from a liquid suspension of cells and air-drying it. Next, the air-dried **smear** is usually heated gently by a process called **heat fixation** that simultaneously kills the specimen and secures it to the slide. Fixation also preserves various cellular components in a natural state with minimal distortion. Some types of fixation are performed with chemicals such as alcohol and formalin.

Like images on undeveloped photographic film, the unstained cells of a fixed smear are quite indistinct, no matter how great the magnification or how fine the resolving power of the microscope. The process of “developing” a smear to create contrast and make inconspicuous features stand out requires staining. Staining is any procedure that applies colored chemicals called dyes to specimens. Dyes impart a color to cells or cell parts by becoming affixed to them through a chemical reaction. In general, they are classified as **basic** (cationic) **dyes**, which have a positive charge, or **acidic** (anionic) **dyes**, which have a negative charge.

TABLE 3.4 Comparison of Positive and Negative Stains

	Positive Staining	Negative Staining
Appearance of cell	Colored by dye	Clear and colorless
		
Background	Not stained (generally white)	Stained (dark gray or black)
Dyes employed	Basic dyes: Crystal violet Methylene blue Safranin Malachite green	Acidic dyes: Nigrosin India ink
Subtypes of stains	Several types: Simple stain Differential stains Gram stain Acid-fast stain Spore stain Structural stains One type of capsule stain Flagella stain Spore stain Granules stain Nucleic acid stain	Few types: Capsule Spore Negative stain of <i>Bacillus anthracis</i> , showing its capsule
		

(bottom): Source: Larry Stauffer, Oregon State Public Health Laboratory/CDC

Negative Versus Positive Staining

Two basic types of staining technique are used, depending upon how a dye reacts with the specimen (summarized in **table 3.4**). Most procedures involve a **positive stain**, in which the dye actually sticks to cells and gives them color. A **negative stain**, on the other hand, is just the reverse (like a photographic negative). The dye does not color the specimens but dries around its outer boundary, forming a silhouette. Nigrosin (a blue-black dye) and India ink (a black suspension of carbon particles) are the dyes most commonly used for negative staining. The cells themselves do not stain because these dyes are negatively charged and are repelled by the negatively charged surface of the cells. The value of negative staining is its relative simplicity and the reduced shrinkage or distortion of cells, as the smear is not heat fixed. A quick assessment can thus be made regarding cellular size, shape, and arrangement. Negative staining is also used to accentuate the capsule that surrounds certain bacteria and yeasts (**figure 3.8**).

Staining Reactions of Dyes

Because many microbial cells lack contrast, it is necessary to use dyes to observe their detailed structure and identify them. Dyes are

colored compounds carrying double-bonded groups such as $C=O$, $C=N$, and $N=N$. When these groups are illuminated, they emit specific colors. Most dyes form ions when dissolved in a compatible solvent. The color-bearing ion, termed a **chromophore**, has a charge that attracts it to certain cell parts bearing the opposite charge.

Basic dyes carry a positively charged chromophore and are attracted to negatively charged cell components (nucleic acids and

proteins). Because bacteria contain large amounts of negatively charged substances, they stain readily with basic dyes such as methylene blue, crystal violet, fuchsin, and safranin.

The chromophores of acidic dyes have a negative charge and therefore bind to areas of a cell carrying a positive charge. One example is eosin, a red dye used to stain blood cells. Because bacterial cells have numerous acidic substances and carry a slightly negative charge on their surface, they tend to repel acidic dyes.

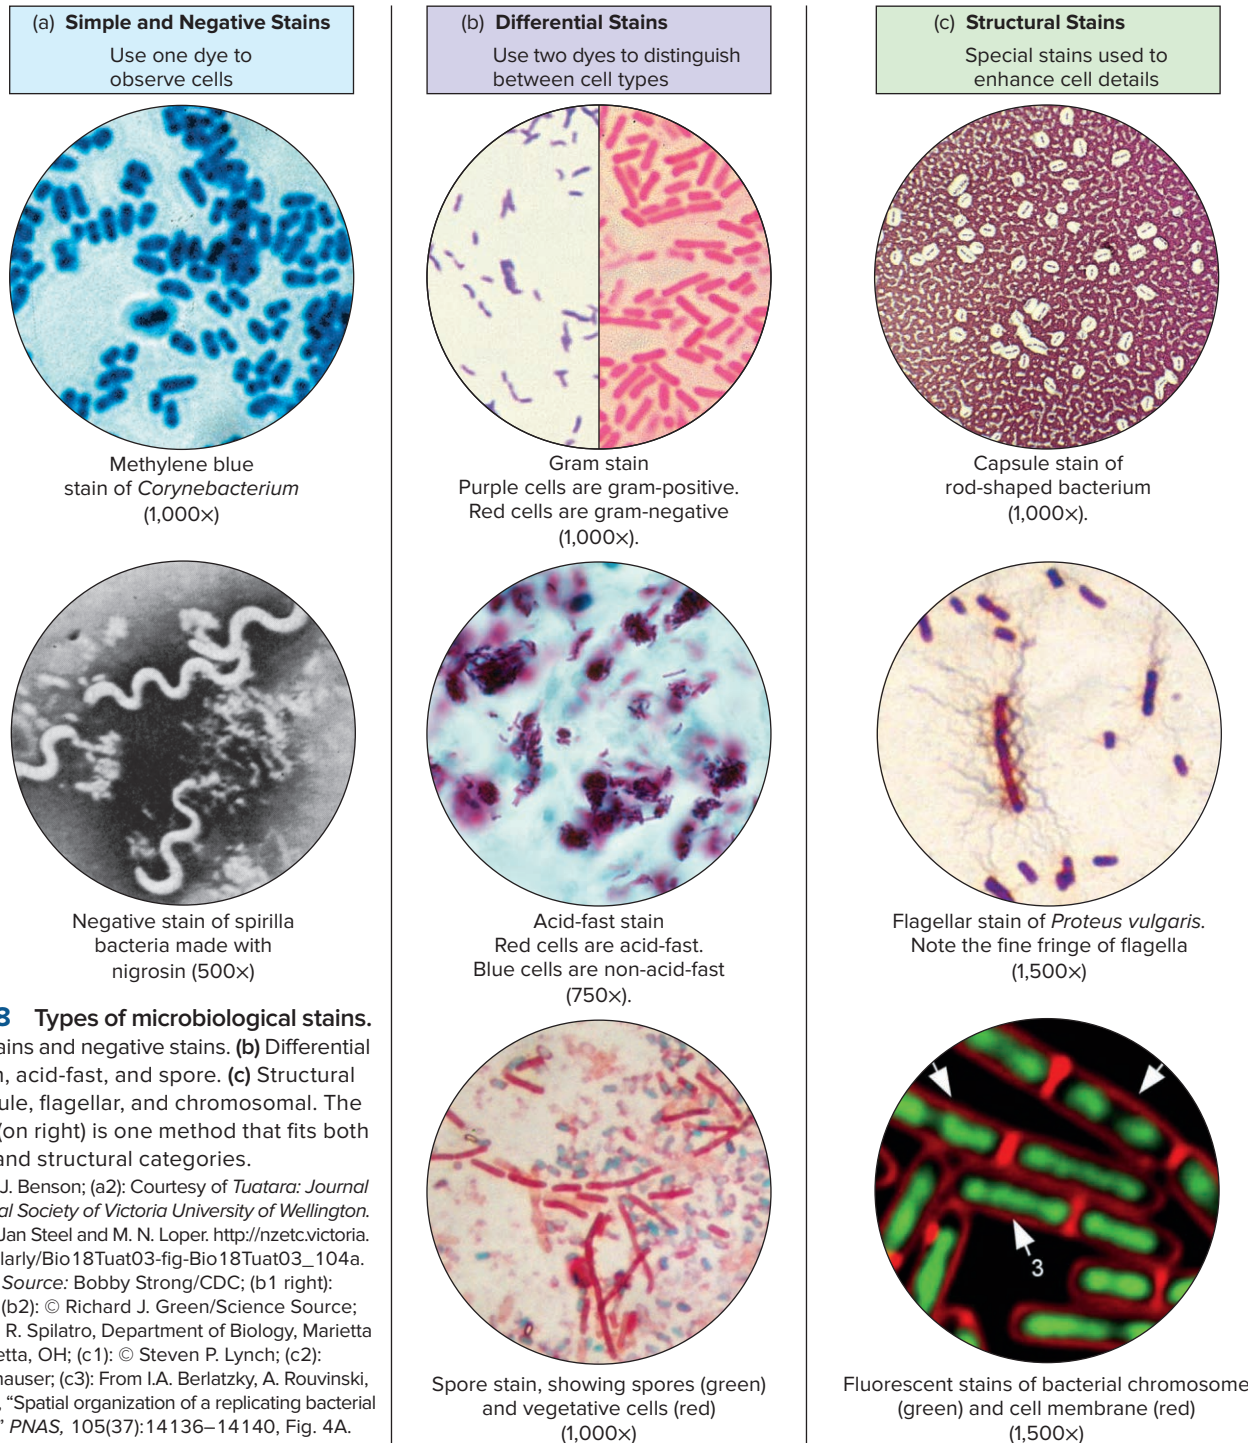

Figure 3.8 Types of microbiological stains.

(a) Simple stains and negative stains. (b) Differential stains: Gram, acid-fast, and spore. (c) Structural stains: capsule, flagellar, and chromosomal. The spore stain (on right) is one method that fits both differential and structural categories.

Ben-Yehuda, "Spatial organization of a replicating bacterial chromosome," *PNAS*, 105(37):14136–14140, Fig. 4A. © 2008 by The National Academy of Sciences of the USA

Acidic dyes such as nigrosin and India ink can still be used successfully on bacteria using the negative stain method (table 3.4). With this technique, the dye settles around the cell and creates a dark background.

Simple Versus Differential Staining Positive staining methods are classified as simple, differential, or structural (see figure 3.8). **Simple stains** require only a single dye and an uncomplicated procedure, while **differential stains** use two different-colored dyes, called the *primary dye* and the *counterstain*, to distinguish between cell types or parts. These staining techniques tend to be more complex, sometimes requiring additional chemical reagents to produce the desired reaction.

Most simple staining techniques take advantage of the ready binding of bacterial cells to dyes like malachite green, crystal violet, basic fuchsin, and safranin. Simple stains cause all cells in a smear to appear more or less the same color, regardless of type, but they can still reveal characteristics such as shape, size, and arrangement. A simple stain with methylene blue is often used to stain granules in bacteria such as *Corynebacterium* (figure 3.8a), which can be a factor in identification.

Types of Differential Stains An effective differential stain uses dyes of contrasting color to clearly emphasize differences between two cell types or cell parts. Common combinations are red and purple, red and green, or pink and blue. Differential stains can also pinpoint other characteristics, such as the size, shape, and arrangement of cells. Typical examples include Gram, acid-fast, and endospore stains. Some staining techniques (spore, capsule) fall into more than one category.

Gram staining is a 130-year-old method named for its developer, **Hans Christian Gram**. Even today, it is an important diagnostic staining technique for bacteria. It permits ready differentiation of major categories based upon the color reaction of the cells: **gram-positive**, which are stained purple, and **gram-negative**, which are stained red (figure 3.8b). This difference in staining quality is due to structural variations found in the cell walls of bacteria (look ahead to chapter 4). The Gram stain is the basis of several important bacteriologic topics, including bacterial taxonomy, cell wall structure, identification, and drug therapy. As we will see in the second part of the case file for this chapter, it is a critical step in diagnosing meningitis. Gram staining is discussed in greater detail in **3.2 Making Connections**.

The **acid-fast stain** is another commonly used differential stain. This stain originated as a specific method to detect *Mycobacterium tuberculosis* in specimens. These bacterial cells have compounds in their outer wall that hold fast (tightly) to the dye (carbol fuchsin) used in the acid-fast stain, even when washed with a solution containing a combination of acid and alcohol (figure 3.8b). After staining, acid-fast bacteria appear pink, while non-acid-fast bacteria are blue in color. This stain is used for other medically important mycobacteria such as the Hansen’s disease (leprosy) bacillus and for *Nocardia*, an agent of lung or skin infections (see chapter 19).

The **endospore stain** (spore stain) is similar to the acid-fast method in that a dye is forced by heat into resistant survival cells called spores or endospores formed in response to adverse conditions (see chapter 4). This stain is designed to distinguish between spores and the vegetative cells that make them (figure 3.8b). Of significance in medical microbiology are the gram-positive, spore-forming members of the genus *Bacillus* (the cause of anthrax) and *Clostridium* (the cause of botulism and tetanus)—dramatic diseases of universal fascination that we consider in later chapters.

Structural stains are used to emphasize special cell parts such as capsules, endospores, and flagella that are not revealed by conventional staining methods. Capsule staining is a method of observing the microbial capsule, an unstructured protective layer surrounding the cells of some bacteria and fungi. Because the capsule does not react with most stains, it is often negatively stained with India ink, or it may be demonstrated by special positive stains. The fact that not all microbes exhibit capsules is a useful feature for identifying pathogens. One example is *Cryptococcus*, which causes a serious fungal meningitis in AIDS patients (figure 3.8c).

Flagellar staining is a method of revealing flagella, the tiny, slender filaments used by bacteria for locomotion. Because the width of bacterial flagella lies beyond the resolving power of the light microscope, in order to be seen, they must be enlarged by depositing a coating on the outside of the filament and then staining it. The presence, number, and arrangement of flagella can be helpful in identification of bacteria (figure 4.4).

Check Your Progress SECTION 3.3

11. List the various staining methods, and briefly characterize each.
12. Explain what happens in positive staining to cause the reaction in the cell.
13. Explain what happens in negative staining that causes the final result.
14. For a stain to be considered differential, what must it do?
15. Outline the main differential stains and how they are used.

3.4 Additional Features of the Six “I’s”

Expected Learning Outcomes

14. Define *inoculation*, *media*, and *culture*, and describe sampling methods and instruments, and what aspects must be controlled.
15. Describe three basic techniques for isolation, including tools, media, incubation, and outcome.
16. Explain what an isolated colony is and indicate how it forms.
17. Differentiate between a pure culture, subculture, mixed culture, and contaminated culture. Define *contaminant*.
18. What kinds of data are collected during information gathering?
19. Describe some of the processes involved in identifying microbes from samples.

3.2 MAKING CONNECTIONS

The Gram Stain: A Grand Stain

In 1884, Hans Christian Gram discovered a staining technique that could be used to make bacteria in infectious specimens more visible. His technique consisted of timed, sequential applications of crystal violet (the primary dye), Gram's iodine (IKI, the mordant), an alcohol rinse (decolorizer), and a contrasting counterstain—usually, the red dye, safranin. This color choice provides differentiation between bacteria that stain purple, called gram-positive, and those that stain red, called gram-negative.

Although these staining reactions involve an attraction of the cell to a charged dye, it is important to note that the terms *gram-positive* and *gram-negative* are used to indicate not the electrical charge of cells or dyes but whether or not a cell retains the primary dye-iodine complex after decolorization. There is nothing specific in the reaction of gram-positive cells to the primary dye or in the reaction of gram-negative cells to the counterstain. The different results in the Gram stain are due to differences in the structure of the cell wall and how it reacts to the series of reagents applied to the cells.

In the first step, crystal violet stains cells in a smear all the same purple color. The second and key differentiating step is the mordant—Gram's iodine. The mordant causes the dye to form large crystals that get trapped by the meshwork of the cell wall. Because this layer in gram-positive cells is thicker, the entrapment of the dye is far more extensive in them than in gram-negative cells. Application of alcohol in the third step dissolves lipids in the outer membrane of the gram-negative cells, which removes the dye from them. By contrast, the crystals of dye tightly embedded in the gram-positive bacteria are relatively inaccessible and resistant to removal. Because gram-negative bacteria are colorless after decolorization, their presence is demonstrated by applying the counterstain safranin in the final step.

This staining method remains an important basis for bacterial classification and identification. It permits differentiation of four major

Step	Microscopic Appearance of Cell		Chemical Reaction in Cell (very magnified view)	
	Gram (+)	Gram (-)	Gram (+)	Gram (-)
1 Crystal violet (primary dye)				
2 Gram's iodine (mordant)				
3 Alcohol (decolorizer)				
4 Safranin (red dye counterstain)				

categories based upon color reaction and shape: gram-positive rods, gram-positive cocci, gram-negative rods, and gram-negative cocci (see table 4.4). The Gram stain can also be a practical aid in diagnosing infection and in guiding drug treatment. For example, Gram staining a fresh urine or throat specimen can point to a preliminary cause of infection, and in some cases it is possible to begin drug therapy on the basis of this stain. Even in this day of elaborate and expensive medical technology, the Gram stain remains an important and unbeatable first tool in diagnosis.

Could the Gram stain be used to diagnose the flu? Why or why not?

Answer available on Connect.

Inoculation, Growth, and Identification of Cultures

To cultivate, or **culture**,* microorganisms, one introduces a tiny sample (the inoculum) into a container of **medium*** (pl. media), which provides an environment in which they multiply. This process is called **inoculation**.* The observable growth that later appears in or on the medium is known as a culture. The nature of the

sample being cultured depends on the objectives of the analysis. Clinical specimens for determining the cause of an infectious disease are obtained from body fluids (blood, cerebrospinal fluid), discharges (sputum, urine, feces), or diseased tissue. Samples subject to microbiological analysis can include nearly any natural material. Some common ones are soil, water, sewage, foods, air, and inanimate objects. The important concept of media will be covered in more detail in section 3.5.

A past assumption has been that most microbes could be teased out of samples and cultured, given the proper media. But this view has had to be greatly revised (see **3.1 Secret World of Microbes**).

* **culture** (kul'-chur) Gr. *cultus*, to tend or cultivate. It can be used as a verb or a noun.

* **medium** (mee'-dee-um) pl. media; L. middle.

* **inoculation** (in-ok''-yoo-lay'-shun) L. *in*, and *oculus*, eye.

3.1 Secret World of Microbes

The Uncultured

For some time, microbiologists have had abundant evidence that culture-based methods are unable to identify many kinds of bacteria. This was first confirmed by environmental researchers, who came to believe that only about 1% (and in some environments, it was 0.001%) of microbes present in lakes, soil, and saltwater environments could be grown in laboratories by the usual methods and that, therefore, these were unknown and unstudied. These microbes are termed **viable but nonculturable**, or **VBNC**.

Microbiologists have spent several decades concocting recipes for media and having great success in growing many kinds of bacteria from many kinds of environments. Just identifying and studying those kept them very occupied. But the rise of specific, nonculturing tools based on genetic testing have led many researchers to identify microbes by analyzing their DNA alone. When these methods were used to sample various environments, they revealed a vast “jungle” of new species that had never before been cultured. These were the techniques that were used to study the bacteria isolated from Lake Whillans (see Case Study in chapter 1). This discovery seemed reasonable, because it may not yet be possible to exactly re-create the many correct media and conditions to grow such organisms in the lab.

Medical microbiologists have also missed a large proportion of microbes that are normal residents of the body. Stanford University scientists applied these techniques to subgingival plaque harvested from one of their own mouths. They used small, known fragments of DNA or probes that can highlight microbes in specimens. Oral biologists had previously recovered about 500 bacterial strains from this site; the Stanford scientists found 30 species that had never before been cultured or described. This discovery energized the medical world and spurred the use of non-culture-based methods to find VBNCs in the human body.

The new realization that our bodies are hosts to a wide variety of unknown microbes has several implications. As evolutionary microbiologist Paul Ewald has asked, “What are all those microbes doing in there?”

A fluorescent micrograph of a biofilm of *Vibrio cholerae* (orange cells) taken from a water sample in India. After an attempt to culture these bacteria over 495 days, a few cells enlarged, but most remained inactive. This pathogen appears to remain dormant in water, where it can be a source of cholera infection for people drinking the water.

© Dr. Rita Colwell & Dr. Munirul Alam

He points out that many oral microbes previously assumed to be innocuous are now associated with cancer and heart disease. Many of the diseases that we currently think of as noninfectious will likely be found to have an infectious cause once we continue to look for VBNCs.

In chapter 13 we will explore some of the findings from the Human Microbiome Project, which recently did a comprehensive study of the microbial content of several body sites. One important finding was the numerous roles many residents have in developing and maintaining the immune system.

Do you think that all of the VBNCs are really not culturable? Suggest some other possibilities. *Answer available on Connect.*

Some Special Requirements of Culturing

Inherent in these practices are the implementation of **sterile**, **aseptic**, and **pure culture**² techniques. Contamination during inoculation is a constant problem, so sterile techniques (media, transfer equipment) help ensure that only microbes that came from the sample are present. Another concern is the possible release of infectious agents from cultures into the environment, which is prevented by aseptic techniques. Many of these techniques revolve around keeping species in the pure culture form for further study, identification, or biotechnology applications.

Isolation Techniques

Certain **isolation** techniques are based on the concept that if an individual bacterial cell is separated from other cells and provided adequate space on a nutrient surface, it will grow into a discrete

mound of cells called a **colony** (figure 3.9). Because it arises from a single cell or cluster of cells, an isolated colony consists of just one species. Proper isolation requires that a small number of cells be inoculated into a relatively large volume or over an expansive area of medium. It generally requires the following materials: a medium that has a relatively firm surface (see the description of agar in section 3.5) contained in a clear, flat covered plate called a *Petri dish*, and inoculating tools.

In the **streak plate method**, a small droplet of sample is spread with a tool called an **inoculating loop** over the surface of the medium according to a pattern that gradually thins out the sample and separates the cells spatially over several sections of the plate (figure 3.10a, b). Because of its ease and effectiveness, the streak plate is the method of choice for most applications.

In the **loop dilution**, or **pour plate technique**, the sample is inoculated, also with a loop, into a series of cooled but still liquid agar tubes so as to dilute the number of cells in each successive tube in the series (figure 3.10c, d). Inoculated tubes are then plated out (poured) into sterile Petri dishes and are allowed to solidify

2. *Sterile* means the complete absence of viable microbes; *aseptic* refers to prevention of infection; *pure culture* refers to growth of a single species of microbe.

Figure 3.9 Isolation technique. Stages in the formation of an isolated colony, showing the microscopic events and the macroscopic result. Separation techniques such as streaking can be used to isolate single cells. After numerous cell divisions, a macroscopic mound of cells, or a colony, will be formed. This is a relatively simple yet successful way to separate different types of bacteria in a mixed sample.

(harden). The number of cells per volume is so decreased that cells have ample space to form separate colonies in the second or third plate. One difference between this and the streak plate method is that in this technique, some of the colonies will develop deep in the medium itself and not just on the surface.

With the **spread plate technique**, a small volume of liquid from a diluted sample is pipetted onto the surface of the medium and spread around evenly by a sterile spreading tool (sometimes called a “hockey stick”). As with the streak plate, cells are spread over separate areas on the surface so that they can form individual colonies (**figure 3.10e, f**).

Once a container of medium has been inoculated, it is **incubated** in a temperature-controlled chamber (incubator) to encourage microbial growth. Although microbes have adapted to growth at temperatures ranging from freezing to boiling, the usual temperatures used in laboratory propagation fall between 20°C and 40°C. Incubators can also control the content of atmospheric gases such as oxygen and carbon dioxide that may be required for the growth of certain microbes. During the incubation period (ranging from a few hours to several weeks), the microbe multiplies and produces a culture with macroscopically observable growth. Microbial growth in a liquid medium materializes as cloudiness, sediment, a surface scum, or colored pigment. Growth on solid media may take the form of a spreading mat or separate colonies.

In some ways, culturing microbes is analogous to gardening. Cultures are formed by “seeding” tiny plots (media) with microbial cells. Extreme care is taken to exclude weeds (contaminants). A pure culture is a container of medium that grows only a single known species or type of microorganism (**figure 3.11c**). This type of culture is most frequently used for laboratory study, because it

allows the precise examination and control of one microorganism by itself. (Instead of the term *pure culture*, some microbiologists prefer the synonymous term *axenic culture*.) A standard method for preparing a pure culture is based on the **subculture** technique for making a second-level culture. A tiny sample of cells from a well-isolated colony is transferred into a separate container of media and incubated.

A **mixed culture** (**figure 3.11a**) is a container that holds two or more easily differentiated species of microorganisms, not unlike a garden plot containing both carrots and onions. A **contaminated culture** (**figure 3.11b**) has had **contaminants** (unwanted microbes of uncertain identity) introduced into it, like weeds into a garden. Because contaminants have the potential for disrupting experiments and tests, special procedures have been developed to control them, as you will no doubt witness in your own laboratory.

Identification Techniques

How does one determine what sorts of microorganisms have been isolated in cultures? Certainly microscopic appearance can be valuable in differentiating the smaller, simpler prokaryotic cells from the larger, more complex eukaryotic cells. Appearance can often be used to identify eukaryotic microorganisms to the level of genus or species because of their more distinctive appearance.

Bacteria are generally not as readily identifiable by these methods because very different species may appear quite similar. For them, we must include other techniques, some of which characterize their cellular metabolism. These methods, called **biochemical tests**, can determine fundamental chemical characteristics such as nutrient requirements, products given off during growth, presence of enzymes, and mechanisms for deriving energy. **Figure 3.12a** provides an example of a multiple-test, miniaturized system for obtaining biochemical characteristics. These tests are discussed in more depth in chapter 17 and in chapters that cover identification of pathogens.

By compiling macroscopic and microscopic traits together with the results of biochemical and physiological testing a complete picture of the microbe can be developed. A traditional pathway in bacterial identification uses flowcharts, also known as keys, that apply the results of tests to a selection process (**figure 3.12b**). The top of the key provides a general category from which to begin a series of branching points, usually into two pathways at each new junction. The points of separation are based on having a positive or negative result for each test. Following the pathway that fits the characteristics leads to an end point where a name for an organism is given. This process of “keying out” the organism can simplify the identification process. In some cases identification requires testing the isolated culture against known antibodies (immunologic testing) or inoculating a suitable laboratory animal. More and more, diagnostic tools are available that analyze genetic characteristics and can detect microbes based on their DNA or RNA (see chapters 10 and 17).

Note: This method works best if the spreading tool (usually an **inoculating loop**) is resterilized (flamed) after each of steps 1–3.

16. Clarify what is involved in inoculation, growth, and contamination.
17. Name two ways that pure, mixed, and contaminated cultures are similar and two ways that they differ from each other.
18. Explain what is involved in isolating microorganisms and why it may be necessary to do this.
19. Compare and contrast three common laboratory techniques for separating bacteria in a mixed sample.
20. Describe how an isolated colony forms.
21. Explain why an isolated colony and a pure culture are not the same thing.

3.5 Media: The Foundations of Culturing

 **Expected Learning Outcomes**

20. Explain the importance of media for culturing microbes in the laboratory.
21. Name the three general categories of media, based on their inherent properties and uses.
22. Compare and contrast liquid, solid, and semisolid media, giving examples.
23. Analyze chemically defined and complex media, describing their basic differences and content.

24. Describe functional media; list several different categories, and explain what characterizes each type of functional media.
25. Identify the qualities of enriched, selective, and differential media; use examples to explain their content and purposes.
26. Explain what it means to say that microorganisms are not culturable.
27. Describe live media and the circumstances that require it.

A major stimulus to the rise of microbiology in the late 1800s was the development of techniques for growing microbes out of their natural habitats and in pure form in the laboratory. This milestone enabled the close examination of a microbe and its morphology, physiology, and genetics. It was evident from the very first that for successful cultivation, the microorganisms being cultured had to be provided with all of their required nutrients in an artificial medium.

Some microbes require only a very few simple inorganic compounds for growth; others need a complex list of specific inorganic and organic compounds. This tremendous diversity is evident in the types of media that can be prepared. At least 500 different types of media are used in culturing and identifying microorganisms. Culture media are contained in test tubes, flasks, or Petri dishes, and they are inoculated by such tools as loops, needles, pipettes, and swabs. Media are extremely varied in nutrient content and consistency, and can be specially formulated for a particular purpose.

For an experiment to be properly controlled, sterile technique is necessary. This means that the inoculation must start with a sterile medium and inoculating tools with sterile tips must be used. Measures must be taken to prevent introduction of nonsterile materials, such as room air and fingers, directly into the media.

Types of Media

Most media discussed here are designed for bacteria and fungi, though algae and some protozoa can be propagated in media. Viruses can only be cultivated in live host cells. Media fall into three general categories based on their properties: physical state, chemical composition, and functional type (table 3.5).

Physical State (Medium's Normal Consistency)	Chemical Composition (Type of Chemicals Medium Contains)	Functional Type (Purpose of Medium)*
1. Liquid	1. Synthetic (chemically defined)	1. General purpose
2. Semisolid		2. Enriched
3. Solid (can be converted to liquid)	2. Nonsynthetic (complex; not chemically defined)	3. Selective
4. Solid (cannot be liquefied)		4. Differential
		5. Anaerobic growth
		6. Specimen transport
		7. Assay
		8. Enumeration

*Some media can serve more than one function. For example, a medium such as brain-heart infusion is general purpose and enriched; mannitol salt agar is both selective and differential; and blood agar is both enriched and differential.

(a)

Figure 3.13 Sample liquid media.

(a) Liquid media tend to flow freely when the container is tilted. Urea broth is used to show a biochemical reaction in which the enzyme urease digests urea and releases ammonium. This raises the pH of the solution and causes the dye to become increasingly pink. Left: uninoculated broth, pH 7; middle: growth with no change; right: positive, pH 8.0. (b) Presence-absence broth is for detecting the presence of fecal bacteria in water samples. It contains lactose and bromocresol purple dye. As some fecal bacteria ferment lactose, they release acidic substances. This lowers the pH and changes the dye from purple to yellow (right is *Escherichia coli*). Nonfermenters such as *Pseudomonas* (left) grow but do not change the pH (purple color indicates neutral pH).

(a and b): © Kathy Park Talaro

(b)

Physical States of Media

Liquid media are defined as water-based solutions that do not solidify at temperatures above freezing and that tend to flow freely when the container is tilted (figure 3.13). These media, termed **broths**, milks, or infusions, are made by dissolving various solutes in distilled water. Growth occurs throughout the container and can then present a dispersed, cloudy, or flaky appearance. A common laboratory medium, *nutrient broth*, contains beef extract and peptone dissolved in water. Other examples of liquid media are methylene blue milk and litmus milk that contain whole milk and dyes. Fluid thioglycollate is a slightly viscous broth used for determining patterns of growth in oxygen (see figure 7.11).

At ordinary room temperature, **semisolid media** exhibit a clotlike consistency (figure 3.14) because they contain an amount of solidifying agent (agar or gelatin) that thickens them but does not produce a firm substrate. Semisolid media are used to determine the motility of bacteria and to

(a)

(b)

Figure 3.14 Sample semisolid media. (a) Semisolid media have more body than liquid media but are softer than solid media. They do not flow freely and have a soft, clotlike consistency. (b) Sulfur indole motility (SIM) medium. When this medium is stabbed with an inoculum, the appearance of growth around the stab line can be used to determine nonmotility (2) or motility (3). Tube 1 is a control that has not been inoculated, and tube 4 shows a black precipitate that occurs around the stab when H_2S gas has been produced. (a and b): © Kathy Park Talaro

localize a reaction at a specific site. Motility test medium and sulfur indole motility (SIM) medium both contain a small amount (0.3% to 0.5%) of agar. In both cases, the medium is stabbed carefully in the center with an inoculating needle and later observed for the pattern of growth around the stab line. In addition to motility, SIM can test for physiological characteristics used in identification (hydrogen sulfide production and indole reaction).

Solid media provide a firm surface on which cells can form discrete colonies (see figure 3.10.) and are advantageous for isolating and culturing bacteria and fungi. They come in two forms: liquefiable and nonliquefiable. Liquefiable solid media, sometimes called reversible solid media, contain a solidifying agent that changes its physical properties in response to temperature. By far the most widely used and effective of these agents is **agar**,³ a polysaccharide isolated from the red alga *Gelidium*. The benefits of agar

are numerous. It is solid at room temperature, and it melts (liquefies) at the boiling temperature of water (100°C or 212°F). Once liquefied, agar does not resolidify until it cools to 42°C (108°F), so it can be inoculated and poured in liquid form at temperatures (45°C to 50°C) that will not harm the microbes or the handler (body temperature is about 37°C or 98.6°F). Agar is flexible and moldable, and it provides a basic matrix to hold moisture and nutrients. Another useful property is that it is not readily digestible and thus not a nutrient for most microorganisms.

Any medium containing 1% to 5% agar usually has the word *agar* in its name. *Nutrient agar* is a common one. Like nutrient broth, it contains beef extract and peptone, as well as 1.5% agar by weight. Many of the examples covered in the section on functional categories of media contain agar.

Although gelatin is not nearly as satisfactory as agar, it will create a reasonably solid surface in concentrations of 10% to 15%. The main drawback for gelatin is that it can be digested by microbes and will melt at room and warmer temperatures, leaving a liquid. Agar and gelatin media are illustrated in **figure 3.15**.

Nonliquefiable solid media do not melt. They include materials such as rice grains (used to grow fungi), cooked meat media (good for anaerobes), and egg or serum media that are permanently coagulated or hardened by moist heat.

Chemical Content of Media

Media with a **chemically defined** composition are termed **synthetic**. Such media contain pure chemical nutrients that vary little from one source to another and have a molecular content specified by means of an exact formula. Synthetic media come in many forms. Some media, such as minimal media for fungi, contain nothing more than a few salts and amino acids dissolved in water. Others contain dozens of precisely measured ingredients (**table 3.6A**). Such standardized and reproducible media are most useful in research and cell culture. But they can only be used when the exact nutritional needs of the test organisms are known. For example, a medium developed to grow the parasitic protozoan *Leishmania* required 75 different chemicals.

If even one component of a given medium is not chemically definable, the medium is a **nonsynthetic, or complex**,⁴ **medium** (**table 3.6B**). The composition of this type of medium cannot be described by an exact chemical formula. Substances that can make it nonsynthetic are extracts from animal or plant tissues, including ground-up cells and secretions. Other examples are blood, serum, meat extracts, infusions, milk, soybean digests, and peptone. Peptone is a partially digested protein, rich in amino acids, that is often used as a carbon and nitrogen source. Nutrient broth, blood agar, and MacConkey agar, though different in function and appearance, are all complex nonsynthetic media. They present a rich mixture of nutrients for microbes with complex nutritional needs.

Tables 3.6A and 3.6B provide a practical comparison of the two categories, based on media used to grow *Staphylococcus aureus*. Every substance in medium A is known to a very precise

3. This material was first employed by Dr. Hesse (see the Significant Events in Microbiology Table found at <http://www.mhhe.com/talaro9>, 1881).

4. *Complex* means that the medium has large molecules such as proteins, polysaccharides, lipids, and other chemicals that can vary greatly in exact composition.

Figure 3.15 Solid media that are reversible to liquids.

(a) Media containing 1%–5% agar are solid and do not move when containers are tilted or inverted. Because they are reversibly solid, they can be liquefied with heat, poured into a different container, and resolidified. (b) Nutrient gelatin contains enough gelatin (12%) to take on a solid consistency. The top tube shows it as a solid. The bottom tube indicates what happens when it is warmed or when microbial enzymes digest the gelatin and liquefy it. (b): © Kathy Park Talaro

degree. The dominant substances in medium B are macromolecules that contain unknown (but potentially required) nutrients. Both A and B will satisfactorily grow the bacteria. (Which one would you rather make?)

Media to Suit Every Function

Microbiologists have many types of media at their disposal, with new ones being devised all the time. Depending upon what is

TABLE 3.6A Chemically Defined Synthetic Medium for Growth and Maintenance of Pathogenic *Staphylococcus aureus*

0.25 Grams Each of These Amino Acids	0.5 Grams Each of These Amino Acids	0.12 Grams Each of These Amino Acids
Cystine	Arginine	Aspartic acid
Histidine	Glycine	Glutamic acid
Leucine	Isoleucine	
Phenylalanine	Lysine	
Proline	Methionine	
Tryptophan	Serine	
Tyrosine	Threonine	
	Valine	
Additional ingredients		
0.005 mole nicotinamide	} Vitamins	
0.005 mole thiamine		
0.005 mole pyridoxine		
0.5 micrograms biotin		
1.25 grams magnesium sulfate	} Salts	
1.25 grams dipotassium hydrogen phosphate		
1.25 grams sodium chloride		
0.125 grams iron chloride		
Ingredients are dissolved in 1,000 milliliters of distilled water and buffered to a final pH of 7.0.		

TABLE 3.6B Brain-Heart Infusion Broth: A Complex, Nonsynthetic Medium for Growth and Maintenance of Pathogenic *Staphylococcus aureus*

27.5 grams brain-heart extract, peptone extract
2 grams glucose
5 grams sodium chloride
2.5 grams disodium hydrogen phosphate
Ingredients are dissolved in 1,000 milliliters of distilled water and buffered to a final pH of 7.0.

added, a microbiologist can fine-tune a medium for nearly any purpose. Microbiologists have always been aware of microbes that could not be cultivated artificially, and now we can detect a single bacterium in its natural habitat without cultivation (see 3.1 Secret World of Microbes). But even with this new technology, it is highly unlikely that microbiologists will abandon culturing, simply because it provides a constant source of microbes for detailed study, research, and diagnosis.

General-purpose media are designed to grow a broad spectrum of microbes that do not have special growth requirements. As a rule, these media are nonsynthetic (complex) and contain a mixture of nutrients that could support the growth of a variety of bacteria and fungi. Examples include nutrient agar and broth, brain-heart infusion, and trypticase soy agar (TSA). TSA is a complex medium that contains partially digested milk protein (casein), soybean digest, NaCl, and agar.

TABLE 3.7 Examples of Selective Media, Agents, and Functions

Medium	Selective Agent	Used For
Mannitol salt agar	7.5% NaCl	Isolation of <i>Staphylococcus aureus</i> from infectious material
<i>Enterococcus faecalis</i> broth	Sodium azide, tetrazolium	Isolation of fecal enterococci
Phenylethanol agar (PEA)	Phenylethanol chloride	Isolation of staphylococci and streptococci
Tomato juice agar	Tomato juice, acid	Isolation of lactobacilli from saliva
MacConkey agar (MAC)	Bile, crystal violet	Isolation of gram-negative enterics
Eosin-methylene blue agar (EMB)	Bile, dyes	Isolation of coliform bacteria in specimens
<i>Salmonella/Shigella</i> (SS) agar	Bile, citrate, brilliant green	Isolation of <i>Salmonella</i> and <i>Shigella</i>
Sabouraud's agar (SAB)	pH of 5.6 (acid) inhibits bacteria	Isolation of fungi

An **enriched medium** contains complex organic substances such as blood, serum, hemoglobin, or special **growth factors** that must be provided to certain species in order for them to grow. Growth factors are organic compounds such as vitamins or amino acids that microbes cannot synthesize themselves. Bacteria that require growth factors and complex nutrients are termed **fastidious**. Blood agar, which is made by adding sterile animal blood (usually from sheep) to a sterile agar base (**figure 3.16a**) is widely employed to grow fastidious streptococci and other pathogens. Pathogenic *Neisseria* and *Yersinia* species are often subcultured on chocolate agar, which is made by heating blood agar and does not contain chocolate—it just has that appearance (**figure 3.16b**).

Selective and Differential Media

Some of the cleverest and most inventive media recipes belong to the categories of selective and differential media. These media are designed for special microbial groups, and they have extensive

Figure 3.16 Examples of enriched media. (a) A blood agar plate growing the pathogenic bacterium *Streptococcus pyogenes*, which is the cause of strep throat and scarlet fever. Note that this medium can also differentiate among colonies by the types of hemolysis they display. Observe the colonies with clearly defined zones (beta hemolysis) and others with less defined zones (alpha hemolysis). (b) A culture of *Yersinia pestis* on chocolate agar, which gets its brownish color from cooked blood and does not produce hemolysis. It is used to grow fastidious pathogens like this notorious agent of bubonic plague. (a): Source: Richard R. Facklam, Ph.D./CDC; (b): © Kathy Park Talara

applications in isolation and identification. They can permit, in a single step, the preliminary identification of a genus or even a species.

A **selective medium** (**table 3.7**) contains one or more agents that inhibit the growth of a certain microbe or microbes (call them A, B, and C) but not another (D). This difference favors, or *selects*, microbe D and allows it to grow by itself. Selective media are very important in primary isolation of a specific type of microorganism from samples containing mixtures of different species—for example, feces, saliva, skin, water, and soil. They hasten isolation by suppressing the unwanted background organisms and allowing growth of the desired ones.

Bile salts, a component of feces, inhibit most gram-positive bacteria while permitting many gram-negative rods to grow. Media for isolating intestinal pathogens (EMB agar, MacConkey agar, Hektoen enteric [HE] agar) contain bile salts as a selective agent. Dyes such as methylene blue and crystal violet also inhibit certain gram-positive bacteria. The opposite effect can be achieved by using a different selective agent. Mannitol salt agar (MSA) contains a high concentration of NaCl (7.5%) that is quite inhibitory to most human pathogens, but not to the gram-positive bacteria in the genus *Staphylococcus*, which grow well and consequently can be amplified in mixed samples. Other agents that have selective properties are antimicrobial drugs and acid. Some selective media contain strongly inhibitory agents to favor the growth of a pathogen that would otherwise be overlooked because of its low numbers in a specimen. Selenite and brilliant green dye are used in media to isolate *Salmonella* from feces, and sodium azide is used to isolate enterococci from water and food.

Differential media grow several types of microorganisms but are designed to bring out visible differences among those microorganisms. Differences show up as variations in colony size or color, in media color changes, or in the formation of gas bubbles and precipitates (**table 3.8**). These variations come from the types of chemicals contained in the media and the ways that microbes react to them. For example, if microbe X metabolizes a certain substance not used by organism Y, then X will cause a visible change in the medium and Y will not. The simplest differential media show two reaction types such as a color change in some colonies but not in others. Several newer forms of differential media contain artificial substrates called chromogens that release a wide variety of colors, each tied to a specific microbe. **Figure 3.17b** shows the result from

TABLE 3.8 Examples of Differential Media		
Medium	Substances That Facilitate Differentiation	Differentiates
Blood agar (BAP)	Intact red blood cells	Types of RBC damage (hemolysis)
Mannitol salt agar (MSA)	Mannitol and phenol red	Species of <i>Staphylococcus</i>
Hektoen enteric (HE) agar*	Bromthymol blue, acid fuchsin, sucrose, salicin, thiosulfate, ferric ammonium citrate, and bile	<i>Salmonella</i> , <i>Shigella</i> , and other lactose nonfermenters from fermenters; H ₂ S reactions are also observable
MacConkey agar (MAC)	Lactose, neutral red	Bacteria that ferment lactose (lowering the pH) from those that do not
Eosin-methylene blue (EMB)	Lactose, eosin, methylene blue	Same as MacConkey agar
Urea broth	Urea, phenol red	Bacteria that hydrolyze urea to ammonia and increase the pH
Sulfur indole motility (SIM)	Thiosulfate, iron	H ₂ S gas producers; motility; indole formation
Triple-sugar iron agar (TSIA)	Triple sugars, iron, and phenol red dye	Fermentation of sugars, H ₂ S production
XLD agar	Lysine, xylose, iron, thiosulfate, phenol red	Can differentiate <i>Enterobacter</i> , <i>Escherichia</i> , <i>Proteus</i> , <i>Providencia</i> , <i>Salmonella</i> , and <i>Shigella</i>

*Contains dyes and bile to inhibit gram-positive bacteria.

(a)

(b)

(c)

Figure 3.17 Media that differentiate multiple characteristics of bacteria.

(a) Triple sugar iron agar (TSIA) inoculated on the surface and stabbed into the thicker region at the bottom (butt). This medium contains three sugars, phenol red dye to indicate pH changes (bright yellow is acid, various shades of red, basic), and iron salt to show H₂S gas production. Reactions are (1) no growth; (2) growth with no acid production (sugars not used); (3) acid production in the butt only; (4) acid production in all areas of the medium; (5) acid and H₂S production in butt (black precipitate). (b) A medium developed for culturing and identifying the most common urinary pathogens. CHROMagar Orientation™ uses color-forming reactions to distinguish at least seven species and permits rapid identification and treatment. (In the example, the bacteria were streaked so as to spell their own names. Which bacterium was probably used to write the name at the top?) (c) MacConkey agar is used to differentiate gram-negative bacteria (see text). (a–c): © K. Talaro

Figure 3.18 Carbohydrate fermentation in broths. This medium is designed to show fermentation (acid production) using phenol red broth and gas formation by means of a small, inverted Durham tube for collecting gas bubbles. The tube on the left is an uninoculated negative control; the center tube is positive for acid (yellow) and gas (open space); the tube on the right shows growth but neither acid nor gas.

© Harold J. Benson

a urine culture containing six different bacteria. Other chromogenic agar is available for identifying *Staphylococcus*, *Listeria*, and pathogenic yeasts.

Dyes are effective differential agents because many of them are pH indicators that change color in response to the production of an acid or a base. For example, MacConkey agar contains neutral red, a dye that is yellow when neutral and pink or red when acidic (**figure 3.17c**). A common intestinal bacterium such as *Escherichia coli* that produces acid when it metabolizes the lactose in the medium develops red to pink colonies, and one such as *Salmonella* that does not produce acid remains its natural color (off-white). Some fermentation broths also contain phenol red to indicate changes in pH associated with breakdown of sugars into acids (**figure 3.18**).

A single medium can be classified in more than one category depending on the ingredients it contains. MacConkey and EMB media (**figure 3.19**), for example, appear in table 3.7 (selective media) and table 3.8 (differential media). Blood agar is both enriched and differential. Media companies have developed selective-differential media for numerous common pathogens, which makes it possible to identify them with a single streak plate. We will see examples of some of these media in later chapters.

Miscellaneous Media

A **reducing medium** contains a substance (thioglycollic acid or cystine) that absorbs oxygen or slows the penetration of oxygen in a medium, thus reducing its availability. Reducing media are important for growing anaerobic bacteria or for determining oxygen requirements of isolates (described in chapter 7). Carbohydrate

fermentation media contain sugars that can be fermented (converted to acids) and a pH indicator to show this reaction (see **figure 3.18a**). Media for other biochemical reactions that provide the basis for identifying bacteria and fungi are presented in several later chapters.

Transport media are used to maintain and preserve specimens that have to be held for a period of time before clinical analysis or to sustain delicate species that die rapidly if not held under stable conditions. Stuart's and Amie's transport media contain buffers and absorbants to prevent cell destruction but will not support growth. **Assay media** are used by technologists to test the effectiveness of antimicrobial drugs (see chapter 12) and by drug manufacturers to assess the effect of disinfectants, antiseptics, cosmetics, and preservatives on the growth of microorganisms. Enumeration media are used by industrial and environmental microbiologists to count the numbers of organisms in milk, water, food, soil, and other samples.

Figure 3.19 Media with both selective and differential properties. EMB agar, commonly used to detect enteric bacteria in food and dairy products, acts both selectively and differentially at the same time. Gram-negative bacteria that do not ferment the sugar lactose will grow on the medium, producing clear or slightly colored growth (*Salmonella typhimurium*, left and *Pseudomonas aeruginosa*, top). Gram-negative bacteria that do ferment lactose will produce much darker growth, sometimes with a green metallic sheen (*Escherichia coli*, right). The growth of gram-positive bacteria (*Staphylococcus aureus*, bottom) is almost completely inhibited (i.e., selected against). © McGraw-Hill Education/Lisa Burgess, photographer

A number of significant microbial groups (viruses, rickettsias, and a few bacteria) will only grow on live cells or animals. These obligate parasites have unique requirements that must be provided by living animals such as rabbits, guinea pigs, mice, chickens, and the early life stages (embryos) of birds. Such animals can be an indispensable aid for studying, growing, and identifying microorganisms. Animal inoculation is an essential step in testing the effects of drugs and the effectiveness of vaccines before they are administered to humans. Animals are an important source of antibodies, antisera, antitoxins, and other immune products that can be used in therapy or testing.

Check Your Progress SECTION 3.5

22. Describe the main purposes of media, and compare the three categories based on physical state, chemical composition, and usage.
23. Differentiate among the ingredients and functions of enriched, selective, and differential media.
24. Explain the two principal functions of dyes in media.
25. Why are some bacteria difficult to grow in the laboratory? Relate this to what you know so far about the nutrients that are added to media.
26. What conditions are necessary to cultivate viruses in the laboratory?

* *Neisseria meningitidis* (ny-serr'ee-uh men'-in-jih'-tih-dis) From the German physician, *Neisser*, and Gr. *meninx*, a membrane.
 * *meningitis* (men'-in-jy'-tis) Gr. *meninx*, a membrane, and *itis*, an inflammation. Specifically, an inflammation of the meninges, the membranes that surround the brain.
 * *septicemia* (sep'-tih-see'-mee-uh) Gr. *septikos*, to make putrid, and *haima*, blood. The presence of infectious agents or their toxins in the blood.

CASE STUDY Part 2

A Gram stain is one of the key tests for getting quick feedback on the kind of microbes that might be present in a sample. It is routine in meningitis because it can differentiate among several types of bacteria and detect certain other infectious agents, but it will not detect viruses. Usually within moments a lab technician can tell if there are bacterial cells and can observe their Gram reaction and shape.

Lab results from the Gram stain and culture were conclusive: Kay Peterson was infected by the meningococcus, *Neisseria meningitidis*,* which is an agent of both meningitis* and septicemia.* The microscopic examination yielded the classic appearance of tiny pairs of red cocci (diplococci) and white blood cells carrying the same cocci inside. A blood culture also showed growth, indicating that the bacteria had entered her bloodstream. Plates of agar inoculated with the CSF grew typical off-white, smooth isolated colonies that tested out as *N. meningitidis*. Kay remained on the antibiotic regimen for 10 days and was released, fortunately without long-term damage.

- What kinds of media would be used to culture and identify this microbe?
- What are some other potential microbes that could have caused this infection?

For more information on the nature of this agent and its disease, see chapter 18 and log on to www.cdc.gov/meningitis/index.html.

To conclude this Case Study, go to Connect.

Chapter Summary with Key Terms

3.1 Methods of Microbial Investigation

- A. Microbiology as a science is very dependent on a number of specialized laboratory techniques.
 1. Initially, a specimen must be collected from a source, whether environmental or patient.
 2. **Inoculation** of a **medium** with the specimen is the first step in **culturing**.
 3. **Incubation** of the medium with the microbes under the right conditions creates a **culture** with visible growth.
 4. **Isolation** of the microbes in the sample into discrete, separate **colonies** is one desired goal.
 5. **Inspection** begins with macroscopic characteristics of the culture and continues with microscopic analysis.
 6. **Information gathering** involves acquiring additional data from physiological, serological, and genetic tests.
 7. **Identification** correlates the key characteristics that can pinpoint the actual species of microbe.

3.2 The Microscope: Window on an Invisible Realm

- A. Optical, or light, microscopy depends on lenses that **refract** light rays, drawing the rays to a focus to produce a magnified image.
 1. A simple microscope consists of a single magnifying lens, whereas a compound microscope relies on two lenses: the ocular lens and the objective lens.
 2. The total power of magnification is calculated as the product of the ocular and objective magnifying powers.
 3. **Resolution**, or the **resolving power**, is a measure of a microscope's capacity to make clear images of very small objects. Resolution is improved with shorter wavelengths of illumination and with a higher **numerical aperture** of the lens. Light microscopes are limited by resolution to magnifications around 2,000 \times .
 4. Modifications in the lighting or the lens system give rise to the bright-field, dark-field, phase-contrast, interference, fluorescence, and confocal microscopes.

- B. Electron microscopy depends on electromagnets that serve as lenses to focus electron beams. A **transmission electron microscope (TEM)** projects the electrons through prepared sections of the specimen, providing detailed structural images of cells, cell parts, and viruses. A **scanning electron microscope (SEM)** is more like dark-field microscopy, bouncing the electrons off the surface of the specimen to detectors.

3.3 Preparing Specimens for Optical Microscopes

- A. Specimen preparation in optical microscopy varies according to the specimen, the purpose of the inspection, and the type of microscope being used.
1. Wet mounts and hanging drop mounts permit examination of the characteristics of live cells, such as motility, shape, and arrangement.
 2. Fixed mounts are made by drying and heating a film of the specimen called a smear. This is then stained using dyes to permit visualization of cells or cell parts.
- B. Staining uses either **basic** (cationic) **dyes** with positive charges or **acidic** (anionic) **dyes** with negative charges. The surfaces of microbes are negatively charged and attract basic dyes. This is the basis of **positive staining**. In **negative staining**, the microbe repels the dye and it stains the background. Dyes may be used alone and in combination.
1. **Simple stains** use just one dye and highlight cell morphology.
 2. **Differential stains** require a primary dye and a contrasting counterstain in order to distinguish cell types or parts. Important differential stains include the **Gram stain**, **acid-fast stain**, and the endospore stain.
 3. **Structural stains** are designed to bring out distinctive characteristics. Examples include capsule stains and flagellar stains.

3.4 Additional Features of the Six “I’s”

- A. Inoculation of media followed by incubation produces visible growth in the form of **cultures**.
- B. Techniques with solid media in Petri dishes provide a means of separating individual microbes by producing **isolated colonies**.

1. With the **streak plate**, a loop is used to thin out the sample over the surface of the medium.
2. With the **loop dilution** (pour plate), a series of tubes of media is used to dilute the sample.
3. The **spread plate** method evenly distributes a tiny drop of inoculum with a special stick.
4. Isolated colonies can be **subcultured** for further testing at this point. The goal is a **pure culture**, in most cases, or a **mixed culture**. **Contaminated cultures** can ruin correct analysis and study.

3.5 Media: The Foundations of Culturing

- A. Artificial media allow the growth and isolation of microorganisms in the laboratory and can be classified by their physical state, chemical composition, and functional types. The nutritional requirements of microorganisms in the laboratory may be simple or complex.
- B. Physical types of media include those that are **liquid**, such as **broths** and milk, those that are **semisolid**, and those that are solid. Solid media may be liquefiable, containing a solidifying agent such as **agar** or gelatin.
- C. Chemical composition of a medium may be completely **chemically defined**, thus **synthetic**. **Nonsynthetic**, or **complex**, media contain ingredients that are not completely definable.
- D. Functional types of media serve different purposes, often allowing biochemical tests to be performed at the same time. Types include **general-purpose**, **enriched**, **selective**, and **differential media**.
1. Enriched media contain **growth factors** required by microbes.
 2. Selective media permit the growth of desired microbes while inhibiting unwanted ones.
 3. Differential media bring out visible variations in microbial growth.
 4. Others include anaerobic (reducing), assay, and enumeration media. Transport media are important for conveying certain clinical specimens to the laboratory.
- E. In certain instances, microorganisms have to be grown in cell cultures or host animals.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

1. Which of the following is not one of the six “I’s”?
 - a. inspection
 - b. identification
 - c. illumination
 - d. incubation
 - e. inoculation
2. The term *culture* refers to the _____ growth of microorganisms in _____.
 - a. rapid, an incubator
 - b. macroscopic, media
 - c. microscopic, the body
 - d. artificial, colonies
3. A mixed culture is
 - a. the same as a contaminated culture
 - b. one that has been adequately stirred
 - c. one that contains two or more known species
 - d. a pond sample containing algae of a single species

4. Agar is superior to gelatin as a solidifying agent because agar
 - a. does not melt at room temperature
 - b. solidifies at 75°C
 - c. is not usually decomposed by microorganisms
 - d. both a and c
5. The process that most accounts for magnification is
 - a. a condenser
 - b. refraction of light rays
 - c. illumination
 - d. resolution
6. A subculture is a
 - a. colony growing beneath the media surface
 - b. culture made from a contaminant
 - c. culture made in an embryo
 - d. culture made from an isolated colony
7. Resolution is _____ with a longer wavelength of light.
 - a. improved
 - b. worsened
 - c. not changed
 - d. not possible
8. A real image is produced by the
 - a. ocular
 - b. objective
 - c. condenser
 - d. eye
9. A microscope that has a total magnification of 1,500× when using the oil immersion objective has an ocular of what power?
 - a. 150×
 - b. 1.5×
 - c. 15×
 - d. 30×
10. The specimen for an electron microscope is always
 - a. stained with dyes
 - b. sliced into thin sections
 - c. killed
 - d. viewed directly
11. Motility is best observed with a
 - a. hanging drop preparation
 - b. negative stain
 - c. streak plate
 - d. flagellar stain
12. Bacteria tend to stain more readily with cationic (positively charged) dyes because bacteria
 - a. contain large amounts of alkaline substances
 - b. contain large amounts of acidic substances
 - c. are neutral
 - d. have thick cell walls
13. The primary difference between a TEM and SEM is in
 - a. magnification capability
 - b. colored versus black-and-white images
 - c. preparation of the specimen
 - d. type of lenses
14. A fastidious organism must be grown on what type of medium?
 - a. general-purpose medium
 - b. differential medium
 - c. synthetic medium
 - d. enriched medium
15. What type of medium is used to maintain and preserve specimens before clinical analysis?
 - a. selective medium
 - b. transport medium
 - c. enriched medium
 - d. differential medium
16. Which of the following is NOT an optical microscope?
 - a. dark-field
 - b. confocal
 - c. atomic force
 - d. fluorescent
17. **Multiple Matching.** For each type of medium, select all descriptions that fit. For media that fit more than one description, briefly explain why this is the case.

_____ mannitol salt agar	a. selective medium
_____ chocolate agar	b. differential medium
_____ MacConkey agar	c. chemically defined (synthetic) medium
_____ nutrient broth	d. enriched medium
_____ brain-heart infusion broth	e. general-purpose medium
_____ Sabouraud's agar	f. complex medium
_____ triple-sugar iron agar	g. transport medium
_____ SIM medium	

Case Study Review

1. Which of the following techniques from the six "I's" was not used in the diagnosis?
 - a. incubation
 - b. inoculation
 - c. inspection
 - d. All of them were used.
2. Which of these would not be a *sign* of meningitis?
 - a. brown blotches on the skin
 - b. stiff neck
 - c. cloudy spinal fluid
 - d. gram-negative cocci in specimens
3. Go to figure 3.12 and trace what information was used to "key out" and identify the bacterial species that caused meningitis in the Case Study.

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

1. a. When buying a microscope, what features are most important to check for?
b. What is probably true of a \$20 microscope that claims to magnify 1,000×?
2. How can one obtain 2,000× magnification with a 100× objective?
3. Differentiate between microscopic and macroscopic methods of observing microorganisms, citing a specific example of each method.
4. Describe the steps of the Gram stain, and explain how it can be an important diagnostic tool for infections.
5. Describe the steps you would take to isolate, cultivate, and identify a microbial pathogen from a urine sample.
6. Trace the pathway of light from its source to the eye, explaining what happens as it passes through the major parts of the microscope.
7. Evaluate the following preparations in terms of providing information on microbial size, shape, motility, and differentiation: spore stain, negative stain, simple stain, hanging drop slide, and Gram stain.

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps along with concept-mapping activities for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

- A certain medium has the following composition:

Glucose	15 g
Yeast extract	5 g
Peptone	5 g
KH ₂ PO ₄	2 g
Distilled water	1,000 ml

 - Tell what chemical category this medium belongs to, and explain why this is true.
 - How could you convert *Staphylococcus* medium (table 3.6A) into a nonsynthetic medium?
- Name four categories that blood agar fits.
 - Name four differential reactions that TSIA shows.
 - Observe figure 3.14. Suggest what causes the difference in growth pattern between nonmotile and motile bacteria.
 - Explain what a medium that is both selective and differential does, using figure 3.19.
- What kind of medium might you make to selectively grow a bacterium that lives in the ocean?
 - One that lives in the human stomach?
 - Why are intestinal bacteria able to grow on media containing bile?
- Go back to section 1.2 and observe the six micrographs in figure 1.3. See if you can tell what kind of microscope was used to make the photograph, based on magnification and appearance.
- Since the dyes for the Gram stain are not specific to the bacteria they stain, what mistakes in the procedure could cause an incorrect result?

Visual Challenge

- Examine figure 3.10*a, b* (shown here). If you performed the quadrant streak plate method using a broth culture that had 10× fewer cells than the broth used in the culture shown, which quadrant might you expect to yield isolated colonies? Explain your answer.
- Look at Scoping Out the Chapter at the start of section 3.1. Using this figure, along with the information in the rest of the chapter, identify precisely which of the six “I’s” were used in the Case Study at the start of this chapter? Which ones were used in the Case Study at the start of chapter 1? Were any used in the Case Study at the start of chapter 2?

Loop containing sample

(a) **Steps in a Streak Plate;** this one is a four-part or quadrant streak.

CASE STUDY Part 1 Heart Valves and Biofilms

On a summer morning in 2008, Maxwell Jones, a 65-year-old man, woke up complaining of abnormal **fatigue** and a **scratchy throat**. His wife said he felt hot and took his temperature. It was slightly elevated at 100°F. He dismissed his condition, saying he was probably tired from working in his garden and suffering one of his regular allergy attacks. Over the next few days, his list of symptoms grew. He lost his appetite, his **joints** and **muscles** were **sore**, and he woke up wringing wet from **night sweats**. He continued to have a **fever**, and his wife was worried over how pale he looked. She insisted he see a physician, who performed a physical and took a **throat culture**. Mr. Jones was sent home with instructions to take **oral penicillin** and acetaminophen (Tylenol), and to come back in a week.

At the next appointment the patient reported that he still had some of the same symptoms, including the fever, and that now he had begun to have **headaches**, **rapid breathing**, and **coughing**. The physician recorded a **rapid heart rate** and slight **heart murmur**. When the lab report indicated that the throat culture was **negative** for bacterial pathogens, he had to look for other causes.

“At least 65% of chronic infections are caused by microbial biofilms.”

He began to wonder if the patient had a prior medical history of possible **risk factors**. From interviewing Mr. Jones, he learned that an **artificial valve** had been implanted in his heart 10 years before, a fact that had been omitted from his medical chart. This finding immediately caused alarm, and Mr. Jones was admitted to the intensive care unit and placed on a mixture of **intravenous antibiotics**. Tests for **blood cultures** and a **white blood cell count** were ordered as backup. By that evening, Mr. Jones had become confused and lost consciousness. He was rushed to the operating room but died during open heart surgery.

- What appear to be the most important facts in this case?
- Explain why Mr. Jones’s throat culture was negative for infection.

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

SCOPING OUT THE CHAPTER

We don't need to take a course in ornithology to be able to recognize the structure of a bird's wing and describe how it functions. And even when they're too far away for us to see them clearly, we can instantly know that a group of animals flying in a "V" formation is a flock of birds, not butterflies or bats. And though they are about as different as two animals could be, we all understand intuitively that a hummingbird and a turkey are related and should be grouped together. In this chapter we will gain the same type of familiarity with bacterial cells, by studying their structure, function, and evolutionary history.

Cellular Structure The chapter opens with a discussion of what makes up a prokaryotic cell. Beginning with external structures like flagella, moving to the fluid-mosaic barrier of the cell membrane, and finally to internal structures like inclusion bodies. Understanding the anatomy of a cell is key to understanding its biology.

Bacterial Shapes and Arrangements The cell wall and cytoskeleton of a bacterial cell are responsible for its shape, and correctly recognizing the shape of a cell is one of the first steps in determining its identity. The grouping of individual cells into more complex arrangements reveals a great deal about the manner in which a cell multiplies.

Classification and Unusual Bacteria The chapter continues by explaining the ways in which prokaryotic cells may be organized based on their evolutionary relationships. Finally, we introduce several examples of novel bacteria that thrive in boiling water (top left), extraordinarily high concentrations of salt (top right), or are so big that they threaten to redefine what it means to be a bacterium (bottom).

Schulz/Max Planck Institute for Marine Microbiology

4.1 Basic Characteristics of Cells and Life Forms

Expected Learning Outcomes

1. Describe the fundamental characteristics of cells.
2. Identify the primary properties that define life and living things.

There is a universal biological truth that the basic unit of life is the cell, whether the organism is a bacterium whose entire body is just a single cell or an elephant made up of trillions of cells. Regardless of their origins, all cells share a few common characteristics. They tend to assume cubical, spherical, or cylindrical shapes, and have a **cell membrane** that encases an internal matrix called the **cytoplasm**. All cells have one or more chromosomes containing DNA. They all also possess ribosomes for protein synthesis, and exhibit highly complex chemical reactions. As we learned in chapter 1, all cells

discovered thus far are classified into one of two fundamentally different groups: the small, seemingly simple **prokaryotic cells** and the larger, structurally more complicated **eukaryotic cells**.

Eukaryotic cells are found in animals, plants, fungi, and protists. They contain a number of complex internal parts called **organelles** that perform useful functions for the cell. By convention, organelles are defined as cell components enclosed by membranes that carry out specific activities involving metabolism, nutrition, and synthesis. Organelles also partition the eukaryotic cell into smaller compartments. The most visible organelle is the nucleus, a roughly spherical mass surrounded by a double membrane that contains the DNA of the cell. Other organelles include the Golgi apparatus, endoplasmic reticulum, vacuoles, and mitochondria (all discussed in chapter 5).

Prokaryotic cells are found only in the bacteria and archaea. Sometimes it may seem that prokaryotes are the microbial “have-nots,” because, for the sake of comparison, they are described by what they lack. They have no nucleus or other organelles. This apparent simplicity is misleading, because the fine structure of prokaryotes can be complex. Overall, prokaryotic cells can engage in nearly every activity that eukaryotic cells can, and many can function in ways that eukaryotes cannot.

We start this chapter with a description of the characteristics that impart the essence of life to cells, followed by a look at prokaryotic cell anatomy and a survey of major groups of prokaryotes. In chapter 5 we will do a similar survey of the eukaryotic world.

After you have studied the cells as presented in this chapter and chapter 5, refer to table 5.2, which summarizes the major differences between prokaryotic and eukaryotic cells.

What Is Life?

Biologists have long debated over universal characteristics we see in organisms that are solid indicators of life or of being alive. What does a cell do that sets it apart from a nonliving entity? One of the first things that often comes to mind is the ability to move or to grow. Unfortunately, taken individually, these are not life signs. After all, inanimate objects can move and crystals can grow. There is probably no single property that we can hold up as the ultimate indicator of life. In fact, defining life requires a whole collection of behaviors and properties that even the simplest organisms will have. First and foremost on this list would be a self-contained and highly organized unit to carry out the activities of life, namely a **cell**. It is the cell that is the staging area for these life-supporting phenomena: heredity, reproduction, growth, development, metabolism, responsiveness, and transport (**figure 4.1**).

- **Heredity** is the transmission of an organism’s genome* to the next generation by chromosomes, which carry DNA, the molecular blueprint of life.
- **Reproduction** involves the generation of offspring necessary to continue a species’s line of evolution. All organisms manifest asexual reproduction, with one cell simply dividing into two new cells by fission or mitosis. Many organisms also display sexual reproduction, involving the union of sex cells from two parents.

* *genome* (gee'-nohm) The complete set of chromosomes and genes of an organism.

Figure 4.1 A summary of the major life-defining properties. The cell is central to the collective activities that are synonymous with being alive.

- **Growth** has two general meanings in microbiology. In the usual sense, it means an increase in size of a population through reproduction. In another case, it refers to the enlargement of a single organism during maturation.
- **Development** includes all changes over the life span of an organism that complete the full expression of its genome.
- **Metabolism** encompasses the thousands of chemical reactions that all cells need to function. Generally, these reactions either synthesize new cell components or release energy that drives cellular activities. Both types of metabolism are supported and regulated by unique molecules of life called **enzymes**.
- **Responsiveness** is the capacity of cells to interact with external factors through irritability, communication, or movement. Cells demonstrate irritability by receiving and reacting to stimuli such as light and chemicals from their environment. They may also communicate with other cells by sending or receiving signals. Some cells show self-propulsion or motility using specialized locomotor structures.
- **Transport** is a system for controlling the flow of materials. This includes carrying nutrients and water from the external environment into the cell's interior. Without these raw materials, metabolism would cease. Cells also secrete substances, or expel waste, in the reverse direction. Movement of this type is the work of the cell membrane, which functions as the gatekeeper for cellular activities. Together, all of these life properties provide microorganisms with the capacity to adapt and evolve.

One of the main reasons viruses are generally considered non-living is that they are not cellular. Even if one argues that they are tiny units somewhat like cells, and that they do show some traits of life such as heredity, development, and evolution, they do not display these characteristics independent of their living host cell. Outside of their host, they lack most other features of life we just described, and are inactive and inert. We will return to this discussion about viruses in chapter 6.

Check Your Progress SECTION 4.1

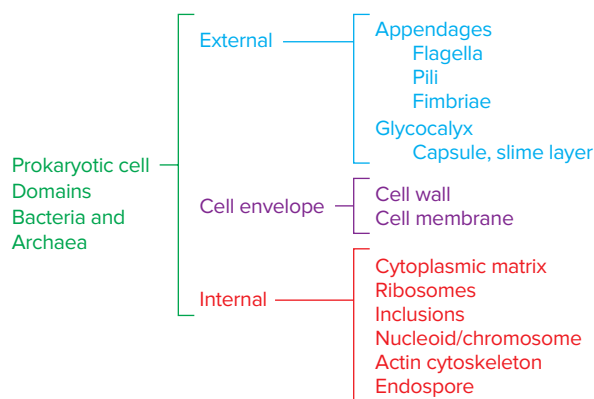

1. Outline the primary indicators of life.
2. Name several general characteristics that could be used to define the prokaryotes.

4.2 Prokaryotic Profiles: The Bacteria and Archaea

Expected Learning Outcomes

3. Describe the generalized anatomy of bacterial cells.
4. Distinguish among the types of external cell appendages.
5. Describe the structure and position of bacterial flagella and axial filaments, and their attachment patterns.
6. Explain how flagella influence motility and motile behavior.
7. Discuss the structure and functions of pili and fimbriae.
8. Define *glycocalyx*, and describe its different forms and functions.

In chapter 1 we introduced the two major types of prokaryotic cells: the bacteria and the archaea. Being the first type of cells on earth, prokaryotic cells have an evolutionary history that dates back over 3.5 billion years. At present we cannot know the precise nature of these first cells, but many microbiologists speculate that they would be similar to present-day archaea living on sulfur compounds in deep, hot oceanic vents (see figure 4.33), extreme habitats they continue to dominate 3.5 billion years later. Having evolved over the same time frame as archaea, bacteria share a similar ancient history. Biologists have estimated that these two domains together still account for at least half of the total mass of life forms on earth. The fact that these organisms have endured for so long in such a variety of habitats indicates cellular structure and function that are incredibly versatile and adaptable. The general structural plan of a prokaryotic cell can be represented with this flowchart:

Structures that are essential to the functions of all prokaryotic cells are a cell membrane, cytoplasm, ribosomes, and one, or occasionally more, chromosomes. The majority of bacteria also have a cell wall and some form of surface coating or glycocalyx. Specific structures that are found in some, but not all, bacteria are flagella, pili, fimbriae, capsules, slime layers, inclusions, an actin cytoskeleton, and endospores.

The Structure of a Generalized Bacterial Cell

Prokaryotic cells appear featureless and two-dimensional when viewed with an ordinary microscope, but this is only because of their small size. Higher magnification provides increased insight into their intricate and often complex structure (see figures 4.18 and 4.28 in later sections). The descriptions of prokaryotic structure, except where otherwise noted, refer to the **bacteria**, a category of prokaryotes with peptidoglycan in their cell walls. **Figure 4.2** shows a three-dimensional illustration of a generalized (rod-shaped) bacterial cell with most of the structures from the flowchart. As we survey the principal anatomical features of this cell, we begin with the outer cell structures and proceed to the internal contents. In sections 4.6 and 4.7 we will cover prokaryotic taxonomy, discuss the differences between bacteria and archaea, and introduce the major characteristics of archaea.

Cell Extensions and Surface Structures

Bacteria often bear accessory **appendages** sprouting from their surfaces. Appendages can be divided into two major groups: those

Figure 4.2 Structure of a typical bacterial cell. Cutaway view of a rod-shaped bacterium, showing major structural features. Note that not all components are found in all cells.

that provide motility (flagella and axial filaments) and those that provide attachment sites or channels (fimbriae and pili).

Flagella—Bacterial Propellers

The prokaryotic **flagellum*** is an appendage of phenomenal construction and is certainly unique in the biological world. Flagella provide the power of motility or self-propulsion. This allows a

cell to swim freely through an aqueous habitat. The bacterial flagellum when viewed under high magnification displays three distinct parts: the filament, the hook (sheath), and the basal body (**figure 4.3**). The **filament** is a helical structure composed of a protein called flagellin. It is approximately 20 nm in diameter and varies from 1 to 70 μm in length. It is inserted into a curved, tubular hook. The hook is anchored to the cell by the **basal body**, a stack of rings firmly anchored through the cell wall to the cell membrane. The hook and its filament are free to rotate 360°—like a tiny propeller. This is in contrast to the flagella of eukaryotic cells, which undulate back and forth.

* *flagellum* (flah-jel'-em) pl. flagella; L., a whip.

Figure 4.3 Details of the flagellar basal body and its position in the cell wall. The hook, rings, and rod function together as a tiny device that rotates the filament 360°. (a) Structure in gram-negative cells. (b) Structure in gram-positive cells.

Krieg, "Flagellar activity in an aquatic bacterium," *Can. J. Microbiol.* May 1971, 17:1133-1137, Fig. 5. Reproduced by permission of the National Research Council of Canada; (d): © PTP/Phototake

One can generalize that all spirilla, about half of the bacilli, and a small number of cocci are flagellated (these bacterial shapes are shown in figure 4.23). Flagella vary both in number and arrangement according to two general patterns: (1) In a **polar** arrangement, the flagella are attached at one or both ends of the cell. Three subtypes of this pattern are: **monotrichous**,* the only group with a single flagellum; **lophotrichous**,* possessing small bunches or tufts of flagella emerging from the same site; and **amphitrichous**,* possessing flagella at both poles of the cell. (2) In a **peritrichous*** arrangement, flagella are dispersed randomly over the surface of the cell (figure 4.4).

The presence of motility is one piece of information used in the laboratory identification of various groups of bacteria. Special stains or electron microscope preparations must be used to see the arrangement, because flagella are too minute to be seen in live preparations with a light microscope. Often it is sufficient to know simply whether a bacterial species is motile. One way to detect motility is to stab a tiny mass of cells into a soft (semisolid) medium in a test tube (see figure 3.14). Growth spreading rapidly through the entire medium is indicative of motility. Alternatively, cells can be observed

microscopically with a hanging drop slide. A truly motile cell will flit, dart, or wobble around the field, making some progress, whereas one that is nonmotile jiggles about in one place but makes no progress.

Flagellar Responses Flagella often function as more than just a locomotor device. They are sensory appendages that can detect and respond to environmental signals. When the signal is of a chemical nature, the behavior is called **chemotaxis**.* Positive chemotaxis is movement of a cell in the direction of a favorable chemical stimulus (usually a nutrient); negative chemotaxis is movement away from a repellent (potentially harmful) compound.

The flagellum can guide bacteria in a certain direction because the system for detecting chemicals is linked to the mechanisms that drive the flagellum. Located in the cell membrane are clusters of receptors¹ that bind specific molecules coming from the immediate environment. The attachment of sufficient numbers of these molecules transmits signals to the flagellum and sets it into rotary motion. If several flagella are present, they become aligned and rotate as a group (figure 4.5). As a flagellum rotates counterclockwise, the cell itself swims in a smooth linear direction toward the stimulus;

* **chemotaxis** (ke^o-moh-tak'-sis) Gr. *chemo*, chemicals, and *taxis*, an ordering or arrangement.

1. Cell surface molecules that bind specifically with other molecules.

Figure 4.5 The operation of flagella and the mode of locomotion in bacteria with polar and peritrichous flagella.

(a) **Runs.** When a polar flagellum rotates in a counterclockwise direction, the cell swims forward in runs. In peritrichous forms, all flagella sweep toward one end of the cell and rotate as a single group. (b) **Tumbles.** When the flagellum reverses direction and rotates clockwise, the cell stops and tumbles. Peritrichous flagella also reverse direction and cause the cell to lose coordination and stop.

* **monotrichous** (mah^o-noh-trik'-us) Gr. *mono*, one, and *tricho*, hair.

* **lophotrichous** (lo^o-foh-trik'-us) Gr. *lopho*, tuft or ridge.

* **amphitrichous** (am^o-fee-trik'-us) Gr. *amphi*, on both sides.

* **peritrichous** (per^o-ee-trik'-us) Gr. *peri*, around.

Figure 4.6 Chemotaxis in bacteria. (a) A cell moves via a random series of short runs and tumbles when there is no attractant or repellent. (b) The cell spends more time on runs as it gets closer to an attractant.

this action is called a *run*. Runs are interrupted at various intervals by *tumbles* caused by the flagellum reversing its direction. This makes the cell stop and change its course. It is believed that attractant molecules inhibit tumbles, increase runs, and permit progress toward the stimulus (**figure 4.6**). Repellents cause numerous tumbles, allowing the bacterium to redirect itself away from the stimulus. Some photosynthetic bacteria exhibit *phototaxis*, a type of movement in response to light rather than chemicals.

A few pathogenic bacteria use their flagella to invade the surface of mucous membranes during infections. *Helicobacter pylori*, the agent of gastric ulcers, bores through the stomach lining, and *Vibrio cholerae*, the cause of cholera, penetrates the small intestine with the help of its flagellum.

Periplasmic Flagella

Corkscrew-shaped bacteria called **spirochetes*** show a wormlike or serpentine mode of locomotion caused by two or more long, coiled threads, the periplasmic flagella or **axial filaments**. A periplasmic flagellum is a type of internal flagellum that is enclosed in the space between the outer sheath and the cell wall peptidoglycan (**figure 4.7**). The filaments curl closely around the spirochete coils yet are free to contract and impart a twisting or flexing motion to the cell. This form of locomotion must be seen in live spirochetes to be truly appreciated (see Quick Search, section 4.5).

Nonflagellar Appendages: Fimbriae and Pili

The structures termed **fimbria*** and **pili*** both refer to common bacterial surface appendages that are involved in interactions with

* *spirochete* (spy'-roh-keet) Gr. *speira*, coil, and *chaite*, hair.
 * *fimbria* (fim'-bree-ah) pl. fimbriae; L., a fringe.
 * *pilus* (py'-lus) pl. pili; L., hair.

(c) Cross section, indicating the position of the flagella with respect to other cell parts. Contraction of the filaments imparts a spinning and undulating pattern of locomotion. (a): Courtesy of Dr. Misha Kudryashev and Dr. Friedrich Frischknecht, *Mol Microbiol*, 2009 Mar; 71(6):1415-34

other cells but do not provide locomotion, except for some specialized pili. Some microbiologists use the terms interchangeably, but we will refer to the smaller common appendages as fimbriae and the ones with specialized functions as pili.

Fimbriae are small, bristlelike fibers emerging from the surface of many types of bacterial cells (**figure 4.8**). Their exact composition varies, but most of them contain protein. Fimbriae have an inherent tendency to stick to each other and to surfaces. They may be responsible for the mutual clinging of cells that leads to biofilms and other thick aggregates of cells on the surface of liquids and for the microbial colonization of inanimate solids such as rocks and glass (**4.1 Making Connections**). Some pathogens can colonize and infect host tissues because of a tight adhesion between their fimbriae and epithelial cells (**figure 4.8b**). For example, *Escherichia coli* colonizes the intestine and begins its invasion

(a)

(b)

Figure 4.8 Form and function of bacterial fimbriae.

(a) Several cells of pathogenic *Escherichia coli* covered with numerous fibers called fimbriae (30,000 \times). Note also the dark blue masses, which are chromosomes. (b) A row of *E. coli* cells tightly adheres by their fimbriae to the surface of an intestinal cell (12,000 \times). This is how the bacterium clings and gains access to the inside of cells during an infection. (G = glycocalyx). (a): © Eye of Science/Science Source; (b): From: D.R. Lloyd, S. Knutton, A. McNeish, "Identification of a New Fimbrial Structure in Enterotoxigenic *Escherichia coli* (ETEC) Serotype O148:H28 Which Adheres to Human Intestinal Mucosa: a Potentially New Human ETEC Colonization Factor," *Infection and Immunity*, January 1987, 55(1):86-92. Fig. 4A. © ASM

of tissues by this means. Mutant forms of these pathogens that lack fimbriae are unable to cause infections.

Pili come in several varieties. A versatile form called the Type IV pilus is found only in gram-negative bacteria. This structure is a flexible tube made of the protein, pilin. Bacteria with pili participate in a mating process termed **conjugation**,² which uses the pilus (also called a sex pilus) as a connector for transferring DNA from a donor cell to a recipient (**figure 4.9**). This role of pili is discussed further in chapter 9.

Type IV pili are a major contributor to the infectiousness of *Neisseria gonorrhoeae*, the agent of gonorrhea, by providing a mechanism for binding to the epithelial cells of the reproductive tract. Type IV pili found in *Pseudomonas* bacteria carry out a

Figure 4.9 Three bacteria in the process of conjugating.

Clearly evident are the sex pili forming mutual conjugation bridges between a donor (upper cell) and two recipients (two lower cells). Fimbriae can also be seen on the donor cell. © L. Caro/SPL/Science Source

remarkable sort of twitching motility. Cells can slide in jerking movements over moist surfaces by extending and then retracting pili in a repetitive motion. Microbiologists have found that this mechanism is every bit as complex and regulated as the flagellar mode of locomotion. This remarkable motility may be observed on YouTube by searching for "type IV pili twitching motility."

The Bacterial Surface Coating, or Glycocalyx

The bacterial cell surface is frequently exposed to severe environmental conditions. The **glycocalyx** develops as a coating of macromolecules to protect the cell and, in some cases, help it adhere to its environment. Glycocalyxes differ among bacteria in thickness, organization, and chemical composition. Some bacteria are covered with a loose shield called a **slime layer** that protects them from dehydration and loss of nutrients, as well as serving in adhesion (**figure 4.10a**). Other bacteria produce **capsules** composed of repeating polysaccharide units, of protein, or

Figure 4.10 Types of glycocalyxes seen through cutaway views of cells. (a) The slime layer is a loose structure that is easily washed off. (b) The capsule is a thick, structured layer that is not readily removed.

2. Although the term *mating* is sometimes used for this process, it is not a form of reproduction.

4.1 MAKING CONNECTIONS

Biofilms—The Glue of Life

Microbes rarely live in isolation. More often they cling together in complex masses called **biofilms**. The formation of these living layers is a universal phenomenon that all of us have observed. Consider the scum that builds up in toilet bowls and shower stalls in a short time if they are not cleaned; or the algae that collect on the walls of swimming pools; and, more intimately, the constant deposition of plaque on teeth.

Fossils from ancient deposits tell us that microbes have been making biofilms for billions of years. It is through this process that they have colonized most habitats on earth and created stable communities that provide access to nutrients and other essential factors. Biofilms are often cooperative associations among several microbial groups (bacteria, fungi, algae, and protozoa) as well as plants and animals.

Substrates favorable to biofilm development have a moist, thin layer of organic material such as polysaccharides or glycoproteins deposited on their exposed surface. This has a sticky texture that attracts primary colonists, usually bacteria. These early cells attach and begin to multiply on the surface. Here, they lay down a glycocalyx consisting of fimbriae, pili, slime layers, or capsules. These substances bind the cells to the substrate and begin the development of the biofilm matrix.

As the biofilm evolves, it undergoes specific adaptations to the habitat in which it forms. In many cases the earliest colonists contribute nutrients and create microhabitats for other microbes to attach and grow into the film, forming complete communities. The biofilm varies in thickness and complexity, depending upon where it occurs and how long it keeps developing. Complexity ranges from single cell layers to thick microbial mats with dozens of dynamic interactive layers.

Biofilms are a profoundly important force in the development of terrestrial and aquatic environments. They dwell permanently in bedrock and the earth's sediments, where they play essential roles in

recycling elements, leaching minerals, and forming soil. Biofilms associated with plant roots promote the mutual exchange of nutrients between the microbes and roots. As we will learn in chapter 7, the microbes in these communities have “conversations” using a special chemical vocabulary, which greatly influences the actions of the biofilm.

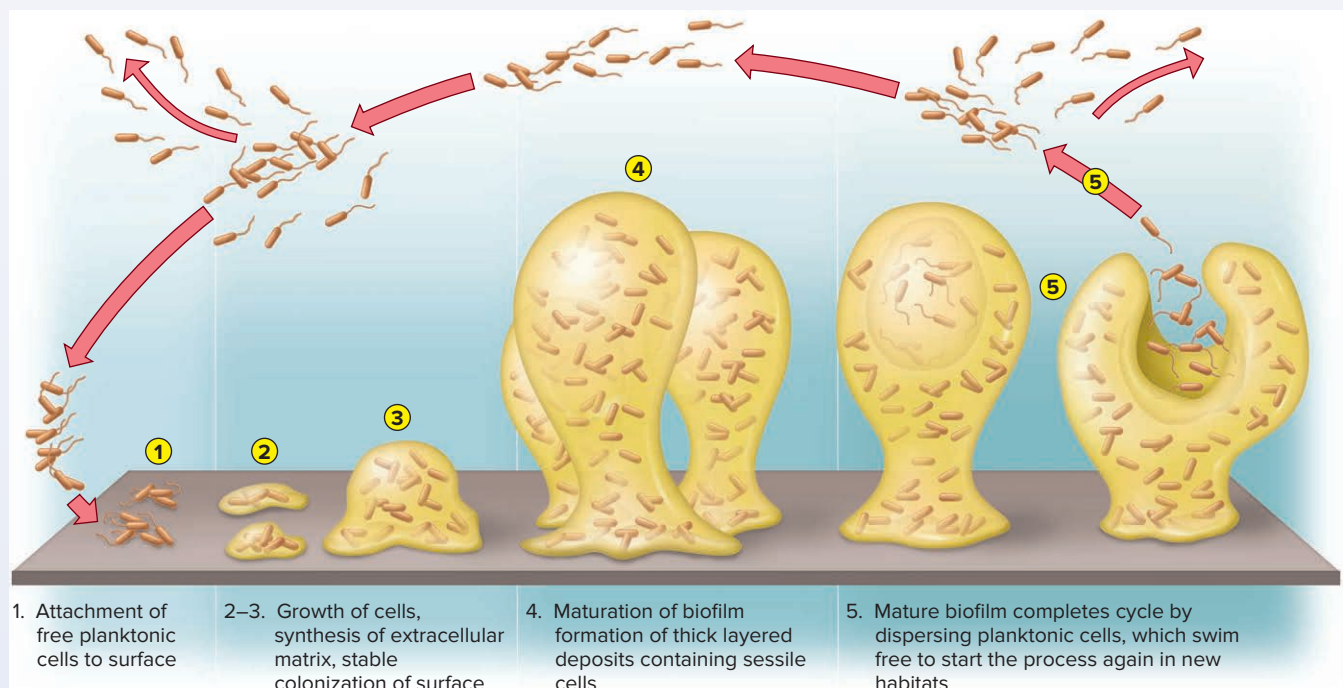

Researchers are currently analyzing the effects of biofilms created by our own microbiota—microbes that live naturally on the body. These associations are common on the skin and in the oral cavity and large intestine. In these locations, microbes signal each other as well as human cells in ways that shape the conditions there.

Biofilms accumulate on damaged tissues (such as heart valves), hard tissues (teeth), and foreign materials (catheters, intrauterine devices [IUDs], artificial hip joints). Microbial biofilms play a key role in the majority of infections and diseases—for example, cholera, urinary tract infections, sexually transmitted infections, endocarditis, middle ear infections, and pneumonia. New evidence indicates that bacteria turn on different genes when they are in a biofilm than when they are “free-floating,” or planktonic. This altered gene expression gives the bacteria a different set of characteristics, often making them impervious to antibiotics and disinfectants. For additional discussions of biofilms, see chapters 7 and 12.

of both. A capsule is bound more tightly to the cell than a slime layer is, and it has a thicker, gummy consistency that gives a prominently sticky (mucoid) character to the colonies of most encapsulated bacteria (**figure 4.11a**).

CLINICAL CONNECTIONS

The Glycocalyx and Infections

Capsules are formed by many pathogenic bacteria, such as *Streptococcus pneumoniae* (a cause of pneumonia, an infection of the lungs), *Haemophilus influenzae* (one cause of meningitis), and *Bacillus anthracis* (the cause of anthrax). Encapsulated bacterial cells generally have greater pathogenicity because capsules protect the bacteria against white blood cells called phagocytes. Phagocytes are a natural body

Figure 4.12 Magnified view of a biofilm. Scanning electron micrograph of a biofilm formed by a gram-negative bacterium, *Alcaligenes*, on a central venous catheter. Note the thick matrix of the biofilm caught in the fine fibers of the catheter.

Source: Janice Haney Carr/CDC

defense that can engulf and destroy foreign cells, which helps to prevent infection. A capsular coating blocks the phagocytes from attaching to, engulfing, and killing bacteria. By escaping phagocytosis, the bacteria are free to multiply and infect body tissues. Encapsulated bacteria that mutate to nonencapsulated forms usually lose their pathogenicity.

Other types of glycocalyxes can be important in formation of biofilm infections (see 4.1 Making Connections). The thick, white plaque that forms on teeth comes in part from the surface slimes produced by certain streptococci in the oral cavity. This slime protects them from being dislodged from the teeth and provides a niche for persistent colonization that can lead to dental disease. The glycocalyx of some bacteria is so highly adherent that it is responsible for harmful biofilms developing on nonliving materials implanted in the body, such as plastic catheters, intrauterine devices, and metal pacemakers (**figure 4.12**).

Biofilms on heart valves can give rise to infections in other areas of the body. Explain how this happens by looking at the figure in 4.1 Making Connections. Answer available on Connect.

4.3 The Cell Envelope: The Outer Boundary Layer of Bacteria

Expected Learning Outcomes

9. Explain the concept of the cell envelope, and describe its structure.
10. Outline the structure and functions of cell walls, and explain the role of peptidoglycan.
11. Contrast the major structure of gram-positive and gram-negative cell walls.
12. Summarize how gram-positive and gram-negative cells differ in their reactions.
13. Relate the characteristics of other types of cell walls and wall-free cells.
14. Describe the structure of the cell membrane, and explain several of its major roles in bacterial cells.

The majority of bacteria have a chemically complex external covering, termed the cell envelope, that encloses the cytoplasm. It is composed of two main layers: the cell wall and the cell membrane. These layers are stacked together and often tightly bound into a unit like the outer husk and casings of a coconut. Although each envelope layer performs a distinct action, together they act as a single unit required for a cell's normal function and integrity.

Basic Types of Cell Envelopes

Long before the detailed anatomy of bacteria was even remotely known, a Danish physician named **Hans Christian Gram** developed a staining technique, the **Gram stain**,³ which is commonly used to delineate two different groups of bacteria known as the gram-positive bacteria and the gram-negative bacteria. You may wish to review this stain, described in 3.2 Making Connections. Because the Gram stain does not reveal the reasons these two groups stain differently, we must turn to the electron microscope and to biochemical analysis of their structure.

The extent of the differences between gram-positive and gram-negative bacteria is evident in the physical appearance of their cell envelopes (**figure 4.13**). In **gram-positive**

3. This text follows the American Society for Microbiology style, which calls for capitalization of the terms *Gram stain* and *Gram staining* and lowercase treatment of gram-negative and gram-positive, except in headings.

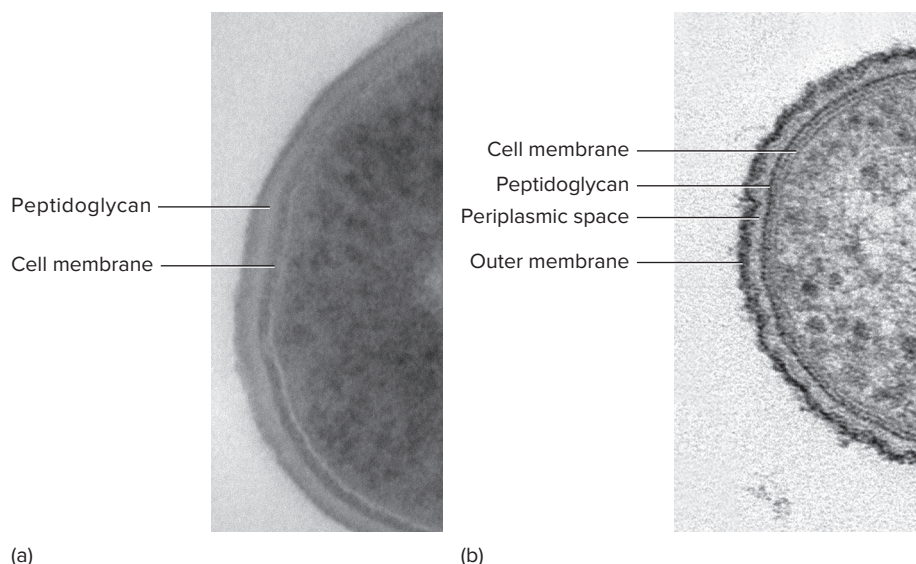

Figure 4.13 Comparative views of the envelopes of gram-positive and gram-negative cells. (a) A section through a gram-positive cell wall/membrane with an interpretation of the main layers visible (92,000 \times). (b) A section through a gram-negative cell wall/membrane with an interpretation of its three sandwich-style layers (90,000 \times). (a): Courtesy of Newcastle University Electron Microscopy Unit; (b): Source: Cynthia Goldsmith and Melissa Bell/CDC

cells, a microscopic section resembles an open-faced sandwich with two layers: the thick cell wall, composed primarily of peptidoglycan (defined in the next section), and the cell membrane. A similar section of a gram-negative cell envelope shows a complete sandwich with three layers: an outer membrane, a thin peptidoglycan layer, and the cell membrane. The reactions of the Gram stain are the result of these basic differences. The thick peptidoglycan of the gram-positive cell traps the crystal violet-mordant complex and makes it inaccessible to the decolorizer, leaving the cells purple. Gram-negative cell walls are thinner, and the crystal violet is relatively easy to remove with the decolorizer. In addition, the alcohol dissolves the outer membrane of the cell, which increases this loss of dye. These factors create a colorless cell that will stain with a red counterstain. **Table 4.1** provides a summary of the major similarities and differences between the wall types.

TABLE 4.1 Comparison of Gram-Positive and Gram-Negative Cell Walls

Characteristic	Gram-Positive	Gram-Negative
Number of major layers	One	Two
Chemical composition	Peptidoglycan Teichoic acid Lipoteichoic acid Mycolic acids and polysaccharides*	Lipopolysaccharide (LPS) Lipoprotein Peptidoglycan Porin proteins
Overall thickness	Thicker (20–80 nm)	Thinner (8–11 nm)
Outer membrane	No	Yes
Periplasmic space	Narrow	Extensive
Permeability to molecules	More penetrable	Less penetrable

*In some cells.

(a) The peptidoglycan of a cell wall is a huge, three-dimensional latticework that is actually one giant molecule to surround and support the cell.

(b) This shows the molecular pattern of peptidoglycan. It has alternating glycans (NAG and NAM) bound together in long strands. The NAG stands for N-acetyl glucosamine, and the NAM stands for N-acetyl muramic acid. Adjacent muramic acid molecules on parallel chains are bound by a cross-linkage of peptides (brown spheres).

(c) An enlarged view of the links between the NAM molecules. Tetrapeptide chains branching off the muramic acids connect by amino acid interbridges. The amino acids in the interbridge can vary or may be lacking entirely. It is this linkage that provides rigid yet flexible support to the cell.

Figure 4.14 Structure of peptidoglycan component of cell walls.

Structure of Cell Walls

The cell wall accounts for a number of important bacterial characteristics. In general, it helps determine the shape of a bacterium, and it also provides the kind of strong structural support necessary to keep a bacterium intact despite constant changes in environmental conditions. The cell walls of most bacteria gain their relative strength and stability from a unique macromolecule called **peptidoglycan (PG)**. This compound is composed of a repeating framework of long **glycan*** chains cross-linked by short peptide fragments (**figure 4.14**). The amount and exact composition of peptidoglycan vary among the major bacterial groups.

* **glycan** (gly'-kan) Gr., sugar. These are large polymers of simple sugars.

Because many bacteria live in aqueous habitats with a low solute concentration, they are constantly absorbing excess water by osmosis. Were it not for the structural support of the peptidoglycan in the cell wall, they would rupture from internal pressure. Several types of drugs used to treat infection (penicillin, cephalosporins) are effective because they target the peptide cross-links in the peptidoglycan, thereby disrupting its integrity. With their cell walls incomplete or missing, such cells have very little protection from **lysis**.* Lysozyme, an enzyme contained in tears and saliva, provides a natural defense against certain bacteria by hydrolyzing the bonds in the glycan chains and causing the wall to break down. Chapters 11 and 12 provide more information on the actions of antimicrobial chemical agents and drugs.

The Gram-Positive Cell Wall

The bulk of the gram-positive cell wall is a thick, homogeneous sheath of peptidoglycan ranging from 20 to 80 nm in thickness. It also contains tightly bound acidic polysaccharides, including teichoic acid directly attached to the peptidoglycan and lipoteichoic acid (**figure 4.15**). Cell wall **teichoic acid** is a polymer of ribitol or glycerol and phosphate embedded in the peptidoglycan sheath. Lipoteichoic acid is similar in structure but is attached to the lipids in the plasma membrane. These molecules appear to function in cell wall maintenance, enlargement during cell division, and binding of some pathogens to tissues. The cell wall of gram-positive bacteria is

loosely adherent to the cell membrane, but at their junction lies a small compartment called the **periplasmic* space**. This is analogous to the larger space in gram-negatives, but it has different functions. It is a site for temporary storage of enzymes that have been released by the cell membrane. More recent studies have found that this space serves as the major site for peptidoglycan synthesis.

The Gram-Negative Cell Wall

The gram-negative cell wall is more complex in morphology because it is composed of an **outer membrane (OM)** and a thinner

* **lysis** (ly'-sis) Gr., to loosen. A process of cell destruction, as occurs in bursting.

* **periplasmic** (per'-ih-plaz'-mik) Gr. *peri*, around, and *plastos*, the fluid substances of a cell.

Figure 4.15 A comparison of the detailed structure of gram-positive and gram-negative cell envelopes and walls.

shell of peptidoglycan (see figures 4.13 and 4.15). The outer membrane is somewhat similar in construction to the cell membrane, except that it contains specialized types of **lipopolysaccharides (LPS)** and **lipoproteins**. Lipopolysaccharides consist of lipid molecules bound to polysaccharides. The lipids form the matrix of the top layer of the OM, and the polysaccharide strands project from the lipid surface. The lipid portion may become toxic when it is released during infections. Its role as an endotoxin is described in chapter 13. The polysaccharides give rise to the somatic (O) antigen in gram-negative pathogens and can be used in identification. They may also function as receptors and interfere with host defenses.

Two types of proteins are located in the OM. The **porins** are inserted in the upper layer of the outer membrane. They have some regulatory control over molecules entering and leaving the cell. Many qualities of the selective permeability of gram-negative bacteria to bile, disinfectants, and drugs are due to the porins. Some structural proteins are also embedded in the upper layer of the OM. The bottom layer of the outer membrane is similar to the cell membrane in its overall structure and is composed of phospholipids and lipoproteins.

The bottom layer of the gram-negative wall is a single, thin (1–3 nm) sheet of peptidoglycan. Although it acts as a somewhat rigid protective structure, as previously described, its thinness gives gram-negative bacteria a relatively greater flexibility and sensitivity to lysis. There is a well-developed **periplasmic space** above and below the peptidoglycan. This space in gram-negative bacteria is a site of many metabolic reactions related to synthesis and transport of proteins, actions of enzymes, and energy release.

Nontypical Cell Walls

Several bacterial groups lack the cell wall structure of gram-positive or gram-negative bacteria, and some bacteria have no cell wall at all. Although these exceptional forms can stain positive or negative in the Gram stain, examination of their fine structure and chemistry shows that they do not fit the descriptions for typical gram-negative or gram-positive cells. For example, the cells of *Mycobacterium* and *Nocardia* contain peptidoglycan and stain gram-positive, but the bulk of their cell wall is composed of unique types of lipids. One of these is a very-long-chain fatty acid called *mycolic acid*, or cord factor, that contributes to the pathogenicity of this group. The thick, waxy nature imparted to the cell wall by these lipids is also responsible for a high degree of resistance to certain chemicals and dyes. Such resistance is the basis for the **acid-fast stain** used to diagnose tuberculosis and leprosy. In this stain, hot carbol fuchsin dye becomes tenaciously attached (is held fast) to these cells so that an acid-alcohol solution will not remove the dye.

CLINICAL CONNECTIONS

The Cell Wall and Infections

Variations in cell wall anatomy contribute to several differences between the two cell types besides staining reactions. The outer membrane contributes an extra barrier in gram-negative bacteria that makes them more impervious to some antimicrobial chemicals such as dyes and disinfectants, so they are generally more difficult to

inhibit or kill than are gram-positive bacteria. One exception is for alcohol-based compounds, which can dissolve the lipids in the outer membrane and disturb its integrity. Treating infections caused by gram-negative bacteria often involves different drugs than gram-positive infections, because of the special requirement that the drugs must cross the outer membrane.

The cell wall or its parts can interact with human tissues and contribute to disease. The lipopolysaccharides have been referred to as *endotoxins* because they stimulate fever and shock reactions in gram-negative infections such as meningitis and typhoid fever. Proteins attached to the outer portion of the cell wall of several gram-positive species, including *Corynebacterium diphtheriae* (the agent of diphtheria) and *Streptococcus pyogenes* (the cause of strep throat), also have toxic properties. The lipids in the cell walls of certain *Mycobacterium* species are harmful to human cells as well. Because most macromolecules in the cell walls are foreign to humans, they stimulate antibody production by the immune system (see chapter 15).

Explain why penicillin can be an effective drug to treat gram-positive bacterial infections but is ineffective against most gram-negative bacteria. Answer available on Connect.

Mycoplasmas and Other Cell-Wall-Deficient Bacteria

Mycoplasmas are bacteria that naturally lack a cell wall. Although other bacteria require an intact cell wall to prevent the bursting of the cell, the mycoplasma cell membrane contains sterols that make it resistant to lysis. These extremely tiny bacteria range from 0.1 to 0.5 μm in size. They range in shape from filamentous to coccus or doughnut-shaped. This property of extreme variations in shape is a type of **pleomorphism**.^{*} They can be grown on artificial media, although added sterols are required for the cell membranes of some species. Mycoplasmas are found in many habitats, including plants, soil, and animals. The most important medical species is *Mycoplasma pneumoniae* (figure 4.16), which adheres to the epi-

^{*} *pleomorphism* (plee'-oh-mor'-fizm) Gr. *pleon*, more, and *morph*, form or shape. The tendency for cells of the same species to vary to some extent in shape and size.

Figure 4.16 Scanning electron micrograph of *Mycoplasma pneumoniae* (10,000 \times). Cells exhibit extreme variation in shape due to the lack of a cell wall. Courtesy of Dr. Heinrich Lünsdorf, HZI

Figure 4.17 Cell membrane structure. A generalized version of the fluid mosaic model of a cell membrane indicates a bilayer of lipids with proteins embedded to some degree in the lipid matrix. Molecules attached to the proteins provide surface features for cell responsiveness and binding. This structure explains many characteristics of membranes, including flexibility, permeability, specificity, and transport.

thelial cells in the lung and causes an atypical form of pneumonia (sometimes referred to as walking pneumonia) in humans.

Some bacteria that ordinarily have a cell wall can lose it during part of their life cycle. These wall-deficient forms are referred to as **L forms** or L-phase variants (for the Lister Institute, where they were discovered). L forms arise naturally from a mutation in the wall-forming genes, or they can be induced artificially by treatment with a chemical such as lysozyme or penicillin that disrupts the cell wall. When a gram-positive cell loses its cell wall completely, it becomes a **protoplast**,^{*} a fragile cell bounded only by a membrane that is highly susceptible to lysis. A gram-negative cell that loses the peptidoglycan layer of its cell wall generally retains its outer membrane, leaving a less fragile but nevertheless weakened **spheroplast**.^{*} Evidence points to a role for L forms in certain chronic infections.

Cell Membrane Structure

A layer in the cell envelope appearing just beneath the cell wall is the **cell**, or **cytoplasmic membrane**, a very thin (5–10 nm), flexible sheet structured as one complete sheath around the cytoplasm. In general composition, it is a lipid bilayer with proteins embedded to varying degrees (figure 4.17). This configuration, first proposed by S. J. Singer and G. L. Nicolson, is called the **fluid mosaic model**. The model describes a membrane as a continuous bilayer formed by lipids with the polar heads oriented toward the outside and the nonpolar tails toward the center of the membrane. Embedded at numerous sites in this bilayer are proteins of various sizes. Peripheral proteins are situated only at the surface and are readily removed. Integral proteins extend fully through the entire membrane and are often fixed in place. The configurations of the inner and outer sides of the membrane can be quite different because of the variations in protein shape and position.

^{*} *protoplast* (proh'-toh-plast) Gr. *proto*, first, and *plastos*, formed.

^{*} *spheroplast* (sfer'-oh-plast) Gr. *sphaira*, sphere.

Membranes are dynamic and constantly changing because the lipid phase is in motion, which allows some proteins to migrate to specific locations where they are needed. This fluidity is essential to such activities as cell enlargement and discharge or secretion by cells. The structure of the lipid phase provides an impenetrable barrier to many substances. This property accounts for the selective permeability and capacity to regulate transport of molecules. Bacterial cell membranes contain primarily phospholipids (making up about 30%–40% of the membrane mass) and proteins (contributing 60%–70%). Major exceptions to this description are the membranes of mycoplasmas, which contain high amounts of sterols—rigid lipids that stabilize and reinforce the membrane—and the membranes of archaea, which contain unique branched hydrocarbons rather than fatty acids. Look back at figure 2.20 to observe eukaryotic membrane structure, which is very similar to bacteria, except for the presence of cholesterol in the eukaryotic variety.

Although bacteria lack complex internal membranous organelles, some members develop stacked layers of internal membranes that carry out physiological processes related to energy and synthesis. These membranes are usually an outgrowth of the cell membrane extending into the cytoplasm, which can increase the membrane surface area available for these reactions. Examples of cells with internal membranes are cyanobacteria, whose thylakoid membranes are the sites of photosynthesis (see figure 4.28c). Even eukaryotic mitochondria, considered bacterial in origin, function by means of a series of internal membranes.

Functions of the Cell Membrane

Because bacteria have none of the eukaryotic organelles, the cell membrane provides a site for energy reactions, nutrient processing, and synthesis. The most important function of the cell membrane, however, is to act as a barrier between the inside and outside of the cell, regulating *transport*—the passage of nutrients into the cell and the discharge of wastes. Although water and small uncharged molecules can diffuse across the membrane unaided, the membrane is a *selectively permeable* structure with special carrier mechanisms for passage of most molecules (see chapter 7). The glycocalyx and cell wall can bar the passage of large molecules, but they are not the primary transport apparatus. The cell membrane is also involved in *secretion*, or the release of metabolic products into the extracellular environment.

The membranes of bacteria are an important site for a number of metabolic activities. For example, most enzymes that handle the energy reactions of respiration reside in the cell membrane (see chapter 8). Enzyme structures located in the cell membrane also help synthesize structural macromolecules to be incorporated into the cell envelope and appendages. Other products (enzymes and toxins) are secreted by the membrane into the extracellular environment.

17. Characterize the bacterial ribosomes and cytoskeleton.
18. Describe inclusion bodies and granules, and explain their importance to cells.
19. Describe the life cycle of endospore-forming bacteria, including the formation and germination of endospores.
20. Discuss the resistance and significance of endospores.

Contents of the Cell Cytoplasm

The cell membrane surrounds a complex solution referred to as **cytoplasm**, or cytoplasmic matrix. This chemical “pool” is a prominent site for many of the cell’s biochemical and synthetic activities. Its major component is water (70%–80%), which serves as a solvent for a complex mixture of nutrients including sugars, amino acids, and other organic molecules and salts. The components of this pool serve as building blocks for cell synthesis or as sources of energy. The cytoplasm also holds larger, discrete bodies such as the chromosome, ribosomes, granules, and actin strands.

Bacterial Chromosomes and Plasmids: The Sources of Genetic Information

The hereditary material of most bacteria exists in the form of a single circular strand of DNA designated as the **bacterial chromosome**, although a few bacteria have multiple or linear chromosomes. By definition, bacteria do not have a true nucleus. Their DNA is not enclosed by a nuclear membrane but instead is aggregated in a central area of the cell called the **nucleoid**. The chromosome is actually an extremely long molecule of DNA that is tightly coiled to fit inside the cell compartment. Arranged along its length are genetic units (genes) that carry information required for bacterial

Figure 4.18 Bacterial cells stained to highlight their chromosomes. The individual cocci of *Deinococcus radiodurans* contain one or more prominent bodies that are the chromosomes or nucleoids (1,200 \times). Some cells are in the process of dividing. Notice how much of the cell's space the chromosomes (light blue bodies) occupy. Courtesy of Michael J. Daly

maintenance and growth. When exposed to special stains or observed with an electron microscope, chromosomes have a granular or fibrous appearance (**figure 4.18**).

Although the bacterial chromosome contains all the genetic material a cell needs to survive, many bacteria contain additional genetic elements called **plasmids**. Plasmids are generally small, circular pieces of DNA that exist independently within the cytoplasm, although at times they may become integrated into the much larger bacterial chromosome. During bacterial reproduction, they are duplicated and passed on to offspring. Although plasmids are not essential for survival, they often carry genes that confer favorable traits on the bacterial cell, such as toxin production or resistance to certain antibiotics (see chapter 9). Because they can be readily manipulated in the laboratory and transferred from one bacterial cell to another, plasmids are an important component of modern genetic engineering techniques.

Ribosomes: Sites of Protein Synthesis

Every bacterial cell contains tens of thousands of **ribosomes**, which are made of RNA and protein. When viewed even by very high magnification, ribosomes show up as fine, spherical specks dispersed throughout the cytoplasm that often occur in chains (polyosomes). Many are also attached to the cell membrane. Chemically, a ribosome is a combination of a special type of RNA called ribosomal RNA, or rRNA (about 60%), and protein (40%).

One method of characterizing ribosomes is by S, or Svedberg,⁴ units, which rate the molecular sizes of various cell parts that have been spun down and separated by molecular weight and shape in a centrifuge. Heavier, more compact structures sediment faster and are assigned a higher S rating. Combining this method of analysis

Figure 4.19 A model of a prokaryotic ribosome, showing the small (30S) and large (50S) subunits, both separate and joined.

with high-resolution electron micrography has revealed that the prokaryotic ribosome, which has an overall rating of 70S, is actually composed of two smaller subunits (**figure 4.19**). They fit together to form a miniature “factory” where protein synthesis occurs. We examine the more detailed functions of ribosomes in chapter 9.

Inclusions: Structures Within the Cell

Although prokaryotic cells lack organelles, they do possess compartmentalized structures within the cytoplasm that perform a variety of functions. For example, most bacteria are exposed to severe shifts in the availability of food. During periods of nutrient abundance, some can compensate by storing nutrients as **inclusion bodies**, or **inclusions**, of varying size, number, and content. As the environmental source of these nutrients becomes depleted, the bacterial cell can mobilize its own storehouse as required. Some inclusion bodies contain condensed, energy-rich organic substances, such as glycogen and poly β -hydroxybutyrate (PHB), within special single-layered membranes (**figure 4.20a**). Gas vesicles are a unique type of inclusion found in some aquatic bacteria that provide buoyancy and flotation. Other inclusions, also called **granules**, contain crystals of inorganic compounds and are not enclosed by membranes. Sulfur granules of photosynthetic bacteria and polyphosphate granules of *Corynebacterium* and *Mycobacterium* are of this type. The latter are an important source of building blocks for nucleic acid and ATP synthesis. They have been termed **metachromatic granules** because they stain a contrasting color (red, purple) in the presence of methylene blue dye.

A second type of inclusion does far more than simply store nutrients for later use. **Microcompartments** are polyhedral (many-sided) packets formed by proteins bound together in compact units (**figure 4.20b**). The microcompartment encloses one or more enzymes along with the reactants needed for a specific metabolic process. The best-understood microcompartment is the carboxysome, found in many cyanobacteria and other photosynthetic bacteria. It is the storage site of the enzyme responsible for CO₂ fixation, the process of converting CO₂ into organic compounds like sugar.

4. Named in honor of T. Svedberg, the Swedish chemist who developed the ultracentrifuge in 1926.

Figure 4.20 Bacterial inclusion bodies. (a) Large, dark particles of polyhydroxybutyrate are deposited in an insoluble, concentrated form that provides an ample, long-term supply of that nutrient (32,500 \times). (b) Rendering of a bacterial microcompartment. The outer protein shell (blue) encloses the enzymes (green) required for a specific metabolic process. (c) A section through *Aquaspirillum* reveals a chain of tiny iron magnets (magnetosomes = MP). These unusual bacteria use these inclusions to orient within their habitat (123,000 \times). (a): © Kwangshin Kim/Science Source; (c): © D. Balkwill and D. Maratea

Perhaps the most remarkable cell granule is involved neither in nutrition nor in metabolism but rather in navigation. Magnetotactic bacteria contain crystalline particles of iron oxide (magnetosomes) that have magnetic properties (figure 4.20c). These granules occur in a variety of bacteria living in oceans and swamps. Their primary function is to orient the cells in the earth's magnetic field, somewhat like a compass. It is thought that magnetosomes direct these bacteria into locations with favorable oxygen levels or nutrient-rich sediments.

The Bacterial Cytoskeleton

Like eukaryotes, prokaryotic cells contain a cytoskeleton.⁵ Protein polymers running throughout the cell play a crucial role in defining cell shape, along with aiding the processes of cell division, partitioning of cellular structures like DNA and microcompartments, and cell motility. Some cytoskeletal proteins are analogous to the actin, tubulin, and intermediate filament proteins found in eukaryotes, while others are unique to bacterial cells. Several of these cytoskeleton systems have been studied, but the best-understood is made of actin filaments that curl within the body of the cell and help maintain its shape during cell enlargement (figure 4.21).

Figure 4.21 Bacterial cytoskeleton of *Bacillus*. Fluorescent stain of actin fibers appears as fine helical ribbons wound inside the cell. The inset provides a three-dimensional interpretation of its structure. © Rut Carballido-Lopez/I.N.R.A. Jouy-en-Josas, Laboratoire de Génétique Microbienne

What Exactly Is a Spore?

The word *spore* can have more than one usage in microbiology. It is a generic term that refers to any of the tiny compact cells that are produced by vegetative or reproductive structures of microorganisms. Spores can be quite variable in origin, form, and function. The bacterial type discussed next is more properly called an endospore, because it is produced inside a cell. It functions in *survival*, not in reproduction. In contrast, the fungi produce many different types of spores, which serve primarily as a means of reproduction (see chapter 5).

Bacterial Endospores: An Extremely Resistant Life Form

Ample evidence indicates that the anatomy of bacteria helps them adjust rather well to adverse habitats. But of all microbial structures, nothing can compare to the bacterial **endospore** (or simply spore) for withstanding hostile conditions and facilitating survival. Endospores are dormant bodies produced by *Bacillus*, *Clostridium*, and several other bacterial genera. These bacteria have a two-phase life cycle that shifts between a **vegetative cell** (figure 4.22, step 1) and an endospore (figure 4.22, step 8). The vegetative cell is the metabolically active and growing phase. When exposed to certain environmental signals, it forms an endospore by a process termed **sporulation**. The spore exists in an inert, resting condition that is capable of extreme resistance and very long-term survival.

5. An intracellular framework of fibers and tubules that bind and support eukaryotic cells.

Process Figure 4.22 A typical sporulation cycle from the active vegetative cell to release and germination. This process takes, on average, about 10 hours. Inset is a high magnification (10,000 \times) cross section of a single spore showing the dense protective layers that surround the core with its chromosome. (photo): SJ Jones, CJ Paredes, B Tracy, N Cheng, R Sillers, RS Senger, ET Papoutsakis, "The transcriptional program underlying the physiology of clostridial sporulation," *Genome Biol.*, 2008. 9:R114

Endospore Formation and Resistance

The major stimulus for endospore formation is the depletion of nutrients, especially amino acids. Once this stimulus has been received by the vegetative cell, it converts to a committed sporulating cell called a **sporangium**. Complete transformation of a vegetative cell into a sporangium and then into an endospore requires 6 to 12 hours in most spore-forming species. Figure 4.22 illustrates some major physical and chemical events in this process.

Bacterial endospores are the hardiest of all life forms, capable of withstanding extremes in heat, drying, freezing, radiation, and chemicals that would readily kill ordinary cells. Their survival under such harsh conditions is due to several factors. The heat resistance of spores has been linked to their high content of calcium and *dipicolinic acid*, although the exact role of these chemicals is not yet clear. We know, for instance, that heat destroys cells by inactivating proteins and DNA and that this process requires a certain amount of water in the protoplasm. Because the deposition of calcium dipicolinate in the endospore removes water and leaves the endospore very dehydrated, it is less vulnerable to the effects of

heat. It is also metabolically inactive and highly resistant to damage from further drying. The thick, impervious cortex and spore coats provide additional protection against radiation and chemicals.

The longevity of bacterial spores verges on immortality! One record describes the isolation of viable endospores from a fossilized bee that was 25 million years old. More recently, microbiologists unearthed a viable endospore from a 250-million-year-old salt crystal. Initial analysis of this ancient microbe indicates it is a species of *Bacillus* that is genetically different from known species.

The Germination of Endospores

After lying in a state of inactivity, endospores can be revitalized when favorable conditions arise. The breaking of dormancy, or **germination**, happens in the presence of water and a specific germination agent. Once initiated, it proceeds to completion quite rapidly (1½ hours). Although the specific germination agent varies among species, it is generally a small organic molecule such as an amino acid or an inorganic salt. This agent stimulates the formation of hydrolytic (digestive) enzymes by the endospore membranes.

These enzymes digest the cortex and expose the core to water. As the core rehydrates and takes up nutrients, it begins to grow out of the endospore coats. In time it reverts to a fully active vegetative cell, resuming the vegetative cycle (figure 4.22).

CLINICAL CONNECTIONS

The Impact of Endospores

Although the majority of spore-forming bacteria are relatively harmless, several bacterial pathogens are sporeformers. In fact, some aspects of the diseases they cause are related to the persistence and resistance of their spores. Spores of *Bacillus anthracis*, the agent of anthrax, are classified as a high-level bioterrorism agent. The genus *Clostridium* includes even more pathogens, including *C. tetani*, the cause of tetanus (lockjaw), and *C. perfringens*, the cause of gas gangrene. When the spores of these species are embedded in a wound that contains dead tissue, they can germinate, grow, and release potent toxins. Another toxin-forming species, *C. botulinum*, is the agent of botulism, a deadly form of food poisoning. These diseases are discussed further in chapter 19.

Because they inhabit the soil and dust, endospores are a constant intruder where sterility and cleanliness are important. They resist ordinary cleaning methods that use boiling water, soaps, and disinfectants, and they frequently contaminate cultures and media. Hospitals and clinics must take precautions to guard against the potential harmful effects of endospores in wounds. Endospore destruction is a particular concern of the food-canning industry. Several endospore-forming species cause food spoilage or poisoning. Ordinary boiling (100°C) will usually not destroy such spores, so canning is carried out in pressurized steam at 120°C for 20 to 30 minutes. Such rigorous conditions will ensure that the food is sterile and free from viable bacteria.

***Clostridium difficile* is an emerging pathogen that causes thousands of intestinal infections in hospital patients every year. What qualities of this bacterium make it such a serious concern?** Answer available on Connect.

25. Explain why an endospore is not considered a reproductive body.
26. Why are spores so difficult to destroy?

4.5 Bacterial Shapes, Arrangements, and Sizes

Expected Learning Outcomes

21. Describe the shapes of bacteria and their possible variants.
22. Identify several arrangements of bacteria and how they are formed.
23. Outline the size ranges among bacteria and in comparison to other organisms.

For the most part, bacteria function as independent single-celled, or unicellular, organisms. Although it is true that an individual bacterial cell can live attached to others in colonies or other such groupings, each one is fully capable of carrying out all necessary life activities, such as reproduction, metabolism, and nutrient processing unlike the more specialized cells of a multicellular organism.

Bacteria exhibit considerable variety in shape, size, and colonial arrangement. It is convenient to describe most bacteria by one of three general shapes as dictated by the configuration of the cell wall (**figure 4.23**). If the cell is spherical or ball-shaped, the bacterium is described as a **coccus**.* Cocci can be perfect spheres, but they also can exist as oval, bean-shaped, or even pointed variants.

A cell that is cylindrical (longer than wide) is termed a rod, or **bacillus**.* There is also a genus named *Bacillus* named for its rod shape. As might be expected, rods are also quite varied in their actual form. Depending on the bacterial species, they can be blocky, spindle-shaped, round-ended, long and threadlike (filamentous), or even clubbed or drumstick-shaped. When a rod is short and plump, it is called a **coccobacillus**; if it is gently curved, it is a **vibrio**.*

A bacterium having the shape of a curviform or spiral-shaped cylinder is called a **spirillum**,* a rigid helix, twisted twice or more along its axis (like a corkscrew). Another spiral cell mentioned earlier in conjunction with periplasmic flagella is the **spirochete**, a more flexible form that resembles a spring. Refer to **table 4.2** for a comparison of other features of the two helical bacterial forms. Because bacterial cells look two-dimensional and flat with traditional staining and microscope techniques, they are best observed using a scanning electron microscope to emphasize their striking three-dimensional forms (**figure 4.23**).

TABLE 4.2 Comparison of the Two Spiral-Shaped Bacteria

	Overall Appearance Helical or Spiral Forms	Mode of Locomotion	Number of Helical Turns	Gram Reaction (Cell Wall Type)	Examples of Important Types
Spirilla	Rigid helix  Spirilla	Polar flagella; cells swim by rotating around like corkscrews; do not flex; have one to several flagella; can be in tufts	Varies from 1 to 20	Gram-negative	Most are nonpathogenic. One species, <i>Spirillum minor</i> , causes rat bite fever.
Spirochetes	Flexible helix  Spirochete	Periplasmic flagella within sheath; cells flex; can swim by rotation or by creeping on surfaces; have 2 to 100 periplasmic flagella	Varies from 3 to 70	Gram-negative	<i>Treponema pallidum</i> , cause of syphilis; <i>Borrelia</i> and <i>Leptospira</i> , important pathogens

Figure 4.24 Pleomorphism and other morphological features of *Corynebacterium*. Cells are irregular in shape and size (800 \times). This genus typically exhibits a palisades arrangement, with cells in parallel array (inset). Close examination will also reveal darkly stained metachromatic granules. Source: Dr. P.B. Smith/CDC

It is common for cells of a single species to show **pleomorphism*** (figure 4.24). This is due to individual variations in cell wall structure caused by nutritional or slight hereditary differences. For example, although the cells of *Corynebacterium diphtheriae* are generally considered rod-shaped, in culture they display club-shaped, swollen, curved, filamentous, and coccoid variations. Pleomorphism reaches an extreme in the mycoplasmas, which entirely lack cell walls and thus display extreme variations in shape (see figure 4.16).

Bacterial cells can also be categorized according to **arrangement**, or style of grouping. The main factors influencing the arrangement of a particular cell type are its pattern of division and how the cells remain attached afterward. The greatest variety in arrangement occurs in cocci (figure 4.25). They may exist as singles, in pairs (**diplococci***), in tetrads (groups of four), in irregular clusters (both **staphylococci*** and **micrococci**), or in chains of a few to hundreds of cells (**streptococci**). An even more complex grouping is a cubical packet of 8, 16, or more cells called a **sarcina***. These different coccal groupings are the result of the division of a coccus in a single plane, in two perpendicular planes, or in several intersecting planes; after division, the resultant daughter cells remain attached.

Bacilli are less varied in arrangement because they divide only in the transverse plane (perpendicular to the axis). They occur either as single cells, as a pair of cells with their ends attached

Figure 4.25 Arrangement of cocci resulting from different planes of cell division. (a) Division in one plane produces diplococci and streptococci. (b) Division in two planes at right angles produces tetrads and packets. (c) Division in several planes produces irregular clusters.

(**diplobacilli**), or as a chain of several cells (**streptobacilli**). A **palisades*** arrangement, typical of the corynebacteria, is formed when the cells of a chain remain partially attached by a small hinge region at the ends. The cells tend to fold (snap) back upon each other, forming a row of cells oriented side by side (see figure 4.24). The reaction can be compared

Quick Search

- How are spirochetes and spirilla different?

- What are vibrios and coccobacilli?
- Describe pleomorphism, and give examples of bacteria with this trait.
- What is the difference between the use of the shape bacillus and the name *Bacillus*? *Staphylococcus* and staphylococcus?
- Rank the size ranges of bacteria according to shape, and compare bacterial size with viruses and eukaryotic cells.

4.6 Classification Systems of Prokaryotic Domains: Archaea and Bacteria

Expected Learning Outcomes

- Describe the purposes of classification and taxonomy in the study of prokaryotes.
- Summarize characteristics used to classify bacteria.
- Outline a basic system of bacterial taxonomy.
- Explain the species and subspecies levels for bacteria.

Classification systems serve both practical and academic purposes. They aid in differentiating and identifying unknown species in medical and applied microbiology. They are also useful in organizing bacteria and as a means of studying their relationships and evolutionary origins. Since classification was first initiated around 200 years ago, several thousand species of bacteria and archaea have been identified, named, and catalogued.

Tracing the origins of and evolutionary relationships among bacteria has not been an easy task. As a rule, tiny, relatively soft organisms do not form fossils very readily. Several times since the 1960s, however, scientists have discovered billion-year-old fossils of prokaryotes that look very much like modern bacteria (see **figure 4.28c**).

One of the questions that has plagued taxonomists is, What characteristics are reliable indicators of closeness in ancestry? Early bacteriologists found it convenient to classify bacteria according to shape, variations in arrangement, growth characteristics, and habitat. However, as more species were discovered and as techniques for studying their biochemistry were developed, it soon became clear that similarities in cell shape, arrangement, and staining reactions do not automatically indicate relatedness. Even though gram-negative rods look alike, there are hundreds of different species with highly significant differences in biochemistry and genetics. If we attempted to classify them on the basis of Gram stain and shape alone, we could not assign them to a more specific level than Phylum! As a result, the newer classification schemes are incorporating more specific genetic and molecular data to increase accuracy.

In general, the methods a microbiologist uses to identify bacteria to the level of genus and species fall into the categories of morphology (microscopic and macroscopic), bacterial physiology or biochemistry, serological analysis, and genetic techniques (see **chapter 17** and **Appendix table C.1**). Data from a cross section of such tests can produce a unique profile of each species. Many identification systems are automated and computerized to process data

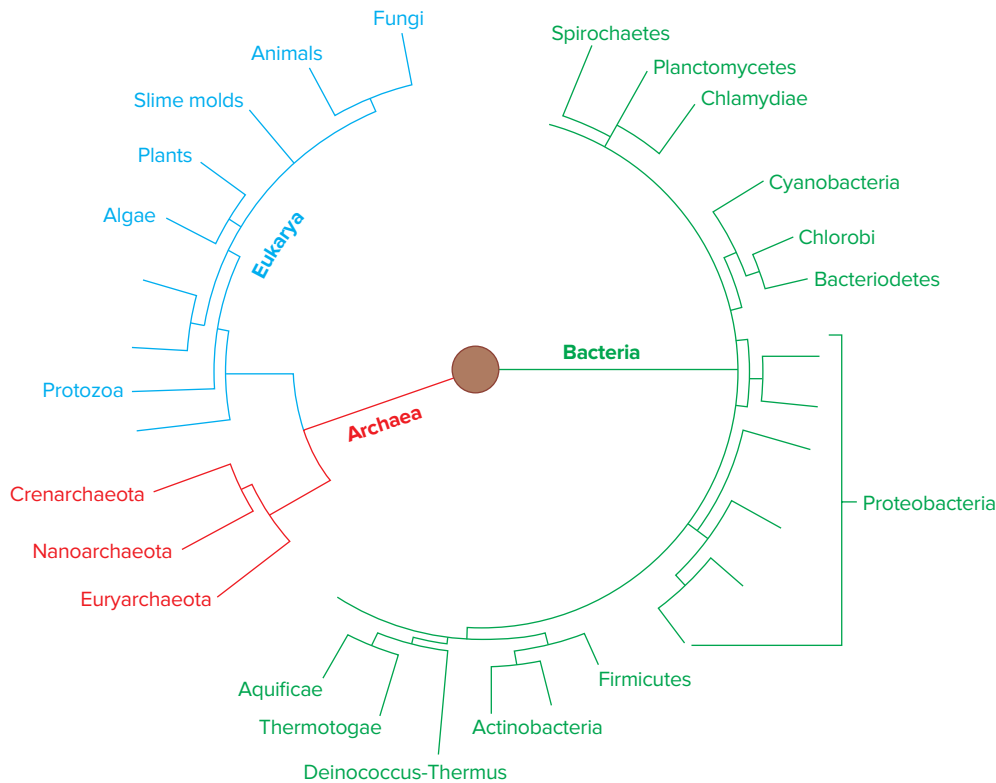

Figure 4.27 A master classification scheme based on ribosomal analysis. This pattern displays the major phyla within Domains Bacteria and Archaea. Branches indicate the origins of each group, and their relative positions estimate ancestral relationships. Major groups of Domain Eukarya are shown here for comparison.

and provide a “best fit” identification. However, not all methods are used on all bacteria. A few bacteria can be identified by a special technology that analyzes only the kind of fatty acids they contain; in contrast, some are identifiable by a Gram stain and a few physiological tests; others may require a diverse spectrum of morphological, biochemical, and genetic analyses.

Bacterial Taxonomy: A Work in Progress

There is no single official system for classifying the prokaryotes. Indeed, most plans are in a state of flux as new information and methods of analysis become available. One widely used reference is *Bergey’s Manual of Systematic Bacteriology*, a major resource that covers all known prokaryotes. In the past, the classification scheme in this guide has been based mostly on characteristics such as Gram stain and metabolic reactions. This is called a **phenetic**, or phenotypic, method of classification.

The second edition of this large collection now includes genetic information that clarifies the **phylogenetic** (evolutionary) history and relationships of the thousands of known species (**figure 4.27**). This change has redefined our presentation of their classification, so that prokaryotes are now placed in five major subgroups and 25 different phyla instead of two domains split into four divisions. The Domains Archaea and Bacteria based on genetic characteristics have been retained, but the bacteria of clinical importance are no longer as closely aligned, and the 250 or so species that cause disease in humans are found within seven or eight

of the revised phyla. The grouping by Gram reaction remains significant but primarily at the lower taxonomic levels. This being an introduction to the subject, we will follow a pragmatic organization that simplifies the presentation and avoids increasingly complex and often conflicting taxonomy.

The major categories of this revised taxonomic scheme are presented in **table 4.3**, which provides a brief survey of characteristics of the major taxonomic groups, along with examples of representative members (A–O). For a complete version of the major taxonomic groups and genera, go to **Appendix table C.2**.

A Diagnostic Scheme for Medical Use

Many medical microbiologists prefer an informal working system that outlines the major families and genera (**table 4.4**). This scheme uses the phenotypic qualities of bacteria in identification. It is restricted to bacterial disease agents and depends less on nomenclature. It also divides the bacteria into gram-positive, gram-negative, and those without cell walls and then subgroups them accord-

ing to cell shape, arrangement, and certain physiological traits such as oxygen usage: *Aerobic* bacteria use oxygen in metabolism; *anaerobic* bacteria do not use oxygen in metabolism; and facultative bacteria may or may not use oxygen. Further tests not listed on the table would be required to separate closely related genera and species. Many of these are included in later chapters on specific bacterial groups.

Species and Subspecies in Bacteria

Among most organisms, the **species** level is a distinct, readily defined, and natural taxonomic category. In animals, for instance, a species is a distinct type of organism that can produce viable offspring only when it mates with others of its own kind. This definition does not work for bacteria primarily because they do not exhibit a typical mode of sexual reproduction. They can accept DNA from unrelated forms, and they can also alter their genetic makeup by a variety of mechanisms. Thus, it is necessary to use a modified definition for a bacterial species. Theoretically, it is a collection of bacterial cells, all of which share an overall similar pattern of traits, in contrast to other groups whose pattern differs significantly. Although the boundaries that separate two closely related species in a genus can be somewhat arbitrary, this definition still serves as a method to separate the bacteria into various kinds that can be cultured and studied. As additional information on bacterial genomes is discovered, it may be possible to define species according to specific combinations of genetic codes found only in a particular

TABLE 4.3 Overview of a Classification System for Prokaryotes Based on *Bergey's Manual*, 2nd Edition (See Appendix Table C.2 for a full outline.)

Volume 1 Domain Archaea Includes prokaryotes with unusual morphology, ecology, and modes of nutrition. Many of the known members are adapted to a habitat with extremes of temperature (hyperthermophiles), salt (halophiles), acidity (acidophiles), pressure, or lack of oxygen (anaerobic), and sometimes combinations of these. The domain has great ecological importance due to its actions in biogeochemical cycling. More coverage can be found in section 4.7.

Phylum Crenarchaeota Members depend on sulfur for growth and may inhabit hot and acidic sulfur pools and vents. Some species have adapted to cold habitats. See examples in **figures A** and 4.33.

Phylum Nanoarchaeota A newly discovered group of extremely small archaea found in salt mines and caves (see 4.1 Secret World of Microbes).

Phylum Euryarchaeota The largest and best-studied group of archaea; members' adaptations include methane production (methanogens), high saline or salt (halobacteria or halophiles), high temperature (thermophiles), and reduction of sulfur compounds. An example is *Methanocaldococcus* (**figure B**).

Volume 1 Domain Bacteria I This domain contains deeply branching and photosynthetic bacteria that are considered the oldest evolutionary lines still in existence. It contains a wide diversity of prominent bacteria, including photosynthesizers (cyanobacteria), thermophiles, radiation-resistant bacteria, halophiles, and sulfur metabolizers.

Phylum Aquificae This group contains small thermophilic rods that inhabit underwater volcanoes.

Phylum Thermotogae A phylum similar to Aquificae; includes thermophilic halophiles that live in deep-sea vents. An example is *Desulfurobacterium* (**figure C**).

Phylum Chlorobi Also known as green sulfur bacteria, this phylum consists of anaerobic bacteria that live in the muddy layers of lakes and ponds, where they photosynthesize and metabolize sulfides.

Phylum Deinococcus-Thermus A small phylum of extremophiles whose members range from being highly radiation- and desiccation-resistant cocci that live in soil and fresh water to rods that live in very hot aquatic habitats, such as hot springs and pools. *Deinococcus* can be seen in figure 4.18.

Phylum Cyanobacteria Very ubiquitous photosynthetic bacteria found in aquatic habitats, soil, and often associated with plants, fungi, and other organisms; blue-green, green, yellow, red, and orange in color. An example is *Gloeotrichia* (**figure D**; see section 4.7 for more coverage).

Volume 2 Domain Bacteria II This domain, along with the phyla that are covered in volumes 3, 4, and 5, contains bacteria that have the greatest medical impact.

Phylum Proteobacteria This phylum contains five classes representing an extremely varied cross section of over 2,000 identified species of bacteria. Though all share the characteristic of a gram-negative cell wall, the group contains bacteria with a wide range of adaptations, shapes, habitats, and ecology. Medically significant members include the obligately parasitic

rickettsias; *Neisseria*; enterics such as *Escherichia coli* and *Salmonella*; *Vibrio* species; and other bacteria that live in the intestinal tracts of animals. The myxobacteria have the unique characteristic of being the only bacteria that can aggregate into multicellular structures (see figure 4.30; see also **figures E, F, and G** for examples).

TABLE 4.3 (continued)

Volume 3 Phylum Firmicutes This collection of mostly gram-positive bacteria is characterized by having a low G + C content* (less than 50%). The three classes in the phylum display significant diversity, and a number of the members are pathogenic. Endospore-forming genera include *Bacillus* and *Clostridium*. Other important pathogens are found in genera *Staphylococcus* and *Streptococcus*. Although they lack a cell wall entirely, mycoplasmas (see figure 4.17) have been placed with the Firmicutes because of their genetic relatedness. (See figures H and I.)

Volume 4 Phylum Actinobacteria This taxonomic category includes the high G + C (over 50%) gram-positive bacteria. Members of this small group differ considerably in life cycles and morphology. Prominent members include the branching filamentous Actinomycetes, the spore-bearing Streptomycetes, *Corynebacterium* (see figure 4.24), *Mycobacterium*, and *Micrococcus* (see figure 4.23a). (See figures J and K.)

Volume 5 This represents a mixed assemblage of nine phyla, all of which are gram-negative but otherwise widely varied. The following is a selected array of examples.

Phylum Chlamydiae Another group of obligate intracellular parasites that reproduce inside host cells. These are among the smallest of bacteria, with a unique mode of reproduction. Several species cause diseases of the eyes, reproductive tract, and lungs. An example is *Chlamydia* (figure L).

Phylum Spirochetes These bacteria are distinguished by their shape and mode of locomotion. They move their slender, twisted cells by means of periplasmic flagella. Members live in a variety of habitats, including the bodies of animals and protozoans, fresh and marine water, and even muddy swamps. Important genera are *Treponema* (figure M) and *Borrelia* (see figure 4.23e).

Phylum Planctomycetes This group lives in fresh and marine water habitats and reproduces by budding. Many have a stalk that they use to attach to substrates. A unique feature is having a membrane around their DNA and special compartments enclosed in membranes. This has led to the speculation that they are similar to an ancestral form that gave rise to eukaryotes. An example is *Gemmata* (figure N).

Phylum Bacteroidetes These are widely distributed gram-negative anaerobic rods inhabiting soil, sediments, and water habitats, and frequently found as normal residents of the intestinal tracts of animals. They may be grouped with related Phyla Fibrobacteres and Chlorobi. Several members play an important role in the function of the human gut and some are involved in oral and intestinal infections. An example is *Bacteroides* (figure O).

O. *Bacteroides* species—may cause intestinal infections. Source: V.R. Dowell/CDC

*G + C base composition The overall percentage of guanine and cytosine in DNA is a general indicator of relatedness because it is a trait that does not change rapidly. Bacteria with a significant difference in G + C percentage are less likely to be genetically related. This classification scheme is partly based on this percentage.

TABLE 4.4 Important Families and Genera of Pathogenic Bacteria, with Notes on Some Diseases*

I. Bacteria with gram-positive cell wall structure (Phyla Firmicutes and Actinobacteria)

A. Cocci in clusters or packets that are aerobic or facultative

Family Staphylococcaceae:

Staphylococcus (members cause boils, skin infections)

B. Cocci in pairs and chains that are facultative

Family Streptococcaceae:

Streptococcus (species cause strep throat, dental caries)

C. Anaerobic cocci in pairs, tetrads, irregular clusters

Family Peptococcaceae: *Peptococcus*,

Peptostreptococcus (involved in wound infections)

D. Spore-forming rods

Family Bacillaceae: *Bacillus*

(anthrax), *Clostridium* (tetanus, gas gangrene, botulism)

E. Non-sporeforming rods

Family Lactobacillaceae:

Lactobacillus, *Listeria* (food infection), *Erysipelothrix* (erysipeloid)

Family Propionibacteriaceae:

Propionibacterium (involved in acne)

Family Corynebacteriaceae:

Corynebacterium (diphtheria)

Family Mycobacteriaceae:

Mycobacterium (tuberculosis, leprosy)

Family Nocardiaceae:

Nocardia (lung abscesses)

Family Actinomycetaceae:

Actinomyces (dental infections)

Family Streptomycetaceae:

Streptomyces (important source of antibiotics)

II. Bacteria with gram-negative cell wall structure (Phyla Proteobacteria, Bacteroidetes, Fusobacterium, Spirochaetes, Chlamydiae)

F. Aerobic cocci

Family Neisseriaceae: *Neisseria*

(gonorrhea, meningitis)

G. Aerobic coccobacilli

Family Moraxellaceae: *Moraxella*,

Acinetobacter

H. Anaerobic cocci

Family Veillonellaceae: *Veillonella*

(dental disease)

I. Aerobic rods

Family Pseudomonadaceae:

Pseudomonas (pneumonia, burn infections)

Miscellaneous rods (different families):

Brucella (undulant fever), *Bordetella* (whooping cough), *Francisella* (tularemia), *Coxiella* (Q fever), *Legionella* (Legionnaires' disease)

J. Facultative rods and vibrios

Family Enterobacteriaceae:

Escherichia, *Edwardsiella*, *Citrobacter*, *Salmonella* (typhoid fever), *Shigella* (dysentery), *Klebsiella*, *Enterobacter*, *Serratia*, *Proteus*, *Yersinia* (one species causes plague)

Facultative rods and vibrios (continued)

Family Vibrionaceae: *Vibrio* (cholera, food infection)

Family Campylobacteraceae: *Campylobacter* (enteritis)

Family Helicobacteraceae: *Helicobacter* (ulcers)

Miscellaneous genera:

Flavobacterium, *Haemophilus* (meningitis), *Pasteurella* (bite infections), *Streptobacillus*

K. Anaerobic rods

Family Bacteroidaceae:

Bacteroides, *Fusobacterium*

(anaerobic wound and dental infections)

L. Helical and curviform bacteria

Family Spirochaetaceae: *Treponema*

(syphilis), *Borrelia* (Lyme disease),

Leptospira (kidney infection)

M. Obligate and facultative intracellular bacteria

Family Rickettsiaceae: *Rickettsia*

(Rocky Mountain spotted fever)

Family Anaplasmataceae:

Ehrlichia (human ehrlichiosis)

Family Chlamydiaceae:

Chlamydia (sexually transmitted infection)

Family Bartonellaceae:

Bartonella (trench fever, cat scratch disease)

III. Bacteria with no cell walls (Class Mollicutes)

Family Mycoplasmataceae: *Mycoplasma*

(pneumonia), *Ureaplasma* (urinary infection)

*Details of pathogens and diseases in later chapters.

isolate. The criterion currently used by most taxonomists dictates that organisms within a single species share at least 97% of the nucleotide sequence of their 16S ribosomal RNA gene. If two organisms share less than 97% of the sequence of this gene, they may be classified as two distinct species.

Because the individual members of given species can show variations, we must also define levels within species (subspecies) called **strains** and **types**. A strain or variety of bacteria is a culture derived from a single parent that differs in structure or metabolism from other cultures of that species (also called biovars or morphovars). For example, there are pigmented and nonpigmented strains of *Serratia marcescens* and flagellated and nonflagellated strains of *Pseudomonas fluorescens*. A **type** is a subspecies that can show differences in antigenic makeup (serotype or serovar), in susceptibility to bacterial viruses (phage type), and in pathogenicity (pathotype).

33. What general characteristics are used to classify bacteria?
34. What are the most useful characteristics for categorizing bacteria into phyla?
35. Explain some of the ways species level in bacteria is defined, and name at least three ways bacteria are classified below the species level.

4.7 Survey of Prokaryotic Groups with Unusual Characteristics

Expected Learning Outcomes

28. Differentiate various groups of photosynthetic bacteria.
29. Characterize the types of obligate intracellular bacteria.
30. Summarize the basic characteristics of archaea.
31. Compare Domain Archaea with Domains Bacteria and Eukarya.
32. Explain archaeal adaptations that place them in the category of extremophiles.

So far in our introduction to the bacterial world, we have covered a rich variety of members with exceptional modes of living and behaving. And yet we are still in the early phases of discovery. Investigations of unexplored areas of the earth continue to surprise and instruct us about the adaptations and importance of these remarkable organisms. Doing justice to such incredible diversity would require more space than we can set aside in an introductory textbook, but in this section we have selected some of the more prominent and unusual groups to present. In this mini-survey, we consider some medically important groups and some representatives of bacteria living free in the environment that are ecologically important. Many of the bacteria mentioned here do not have the morphology typical of bacteria discussed previously,

and in a few cases, they are vividly different (**4.1 Secret World of Microbes**).

Free-Living Nonpathogenic Bacteria

Photosynthetic Bacteria

The nutrition of many bacteria is heterotrophic; this means that the bacteria feed primarily off nutrients from other organisms. Photosynthetic bacteria, however, are independent cells that contain special light-trapping pigments and can use the energy of sunlight to synthesize all required nutrients from simple inorganic compounds. The two general types of photosynthetic bacteria are those that produce oxygen during photosynthesis and those that produce some other substance, such as sulfur granules or sulfates.

Cyanobacteria: Microbial Marvels

Cyanobacteria, gram-negative phototrophic* bacteria in the Phylum Cyanobacteria, are among the most dominant microorganisms on earth, with a long list of significant contributions to the planet. They are ancient in origin, probably having existed in some form for around 3 billion years. We can still find remnants of these early cells in fossil biofilms called stromatolites (**figure 4.28b 1,2**). Many evolutionary microbiologists theorize that, because cyanobacteria were the very first photosynthesizers, they were responsible for converting the atmosphere from anaerobic to aerobic through their production of oxygen, which made it possible for the evolution of aerobic eukaryotes. Other contributions they have made to eukaryotic evolution include the chloroplasts of algae and plants. When chloroplasts are subjected to genetic analysis, it turns out that they are close relatives of some of the oldest groups of cyanobacteria, and probably arose through endosymbiosis (see chapter 5). So the green color of a forest or a field of corn actually comes from these tiny bacteria that became a part of photosynthetic eukaryotes billions of years ago. The earth would be an entirely different place if it were not for these microorganisms.

Cyanobacteria are very diverse in distribution and morphology. They flourish in every type of aquatic environment, whether ocean, hot springs, or Antarctic ice, and they can also survive in a wide range of terrestrial habitats. Because of this widespread distribution, they are huge contributors to worldwide productivity. Two species of cyanobacteria alone—*Prochlorococcus* and *Trichodesmium*—account for 30% to 40% of biomass formation and 50% of oxygen production through photosynthesis in the oceans. They are also one of a few groups of microbes that can convert nitrogen gas (N_2) into ammonium (NH_4^+) that can be used by plants, making them essential players in the nitrogen cycle.

Their structure and arrangement are varied, from coccoid, rodlike, and spiral-shaped cells, with arrangements in filaments, clusters, and sheets, usually surrounded by a gelatinous sheath (**figure 4.28a, 2**). Although their primary photosynthetic pigments include green chlorophyll *b* and the bluish pigment phycocyanin, they may take on shades of yellow, orange, and red derived from other pigments.

* *literally* “to feed with light.”

4.1 Secret World of Microbes

Redefining Bacterial Size

Microbiologists keep being reminded how far we are from having a complete assessment of the bacterial world, mostly because the world is so large and bacteria are so small. There seem to be frequent reports of exceptional bacteria discovered in places like the deep-ocean volcanoes or Antarctic ice. Among the most remarkable are giant and dwarf bacteria.

Big Bacteria Break Records

In 1985 biologists discovered a new bacterium living in the intestine of surgeonfish that at the time was a candidate for the *Guinness Book of World Records*. The large cells, named *Epulopiscium fishelsoni* (“guest at a banquet of fish”), measure around 100 μm in length, although some specimens were as large as 300 μm . This record was broken when a marine microbiologist discovered an even larger species of bacteria living in ocean sediments near the African country of Namibia. These gigantic cocci are arranged in strands that look like pearls and contain hundreds of golden sulfur granules, inspiring their name, *Thiomargarita namibia* (“sulfur pearl of Namibia”) (see photo). The size of the individual cells ranges from 100 up to 750 μm (0.75 mm), and many are large enough to see with the naked eye. By way of comparison, if the average bacterium were the size of a mouse, *Thiomargarita* would be as large as a blue whale!

These bacteria are found in such large numbers in the sediments that it is thought that they are essential to the ecological cycling of H_2S and other substances in this region, converting them to less toxic substances.

Miniature Microbes—Are They for Real?

At the other extreme, microbiologists are being asked to reevaluate the lower limits of bacterial size. Up until now it has been generally accepted that the smallest cells on the planet are some form of mycoplasma with dimensions of 0.2 to 0.3 μm , which is right at the limit of resolution with light microscopes. A new controversy is brewing over the discovery of tiny cells that look like dwarf bacteria but are 10 times smaller than mycoplasmas and 100 times smaller than the average bacterial cell. These minute cells have been given the name **nanobacteria** or **nanobes** (Gr. *nanos*, one-billionth).

Nanobacteria-like forms were first isolated from blood and serum samples. The tiny cells appear to grow in culture, have cell walls, and contain protein and nucleic acids, but their size range is only from 0.05 to

Thiomargarita namibia—giant cocci. Approximately how many times larger is *Thiomargarita* than the nanobe shown on the right? © Heide N. Schulz/Max Planck Institute for Marine Microbiology

0.2 μm . Similar nanobes have been extracted by mineralogists studying deposits in the ocean at temperatures up to 170°C. Many geologists are convinced that these nanobes are real cells, that they are probably similar to the first microbes on earth, and that they play a strategic role in the development of the earth’s crust.

Microbiologists have been more skeptical. Experts have postulated that the minimum cell size to contain a functioning genome and reproductive and synthetic machinery is approximately 0.14 μm , which means that some of the nanobes could be artifacts or bits of larger cells that have broken free. It seems that the archaea may be the ultimate definers of smallness in prokaryotes. Microbiologists exploring acid mines in California have discovered ultrasmall archaea living in pink biofilms. These extremophiles, called ARMAN, are at the lower limits of size, between 100 and 400 nm. They are real cells, complete with a tiny genome and a reduced number of ribosomes, and are perhaps the first indisputable nanobes. Additional studies are needed to test this curious question of nanobes and possibly to answer some questions about the origins of life on earth and elsewhere in the universe.

What are some of the adaptations that a giant *Thiomargarita* would require for its survival? Answer available on Connect.

Within an individual cell are found extensive specialized membranes called **thylakoids**, the locations of pigments and the sites of photosynthesis (**figure 4.28c**). They also have gas vesicles that keep the cells suspended high in the water column to facilitate photosynthesis. Cyanobacteria periodically overgrow in aquatic environments to form blooms that are harmful to fish and other inhabitants, and some produce toxins that

could cause illness if ingested, but they are generally not medically important.

Green and Purple Sulfur Bacteria

The green and purple bacteria are also photosynthetic and contain pigments. They differ from the cyanobacteria in having a different type of chlorophyll called *bacteriochlorophyll* and by not giving off oxygen as a product of photosynthesis. They live in sulfur springs, freshwater lakes, and swamps that are deep enough for the anaerobic conditions they require yet where their pigment can still absorb wavelengths of light (**figure 4.29**). These bacteria are named for

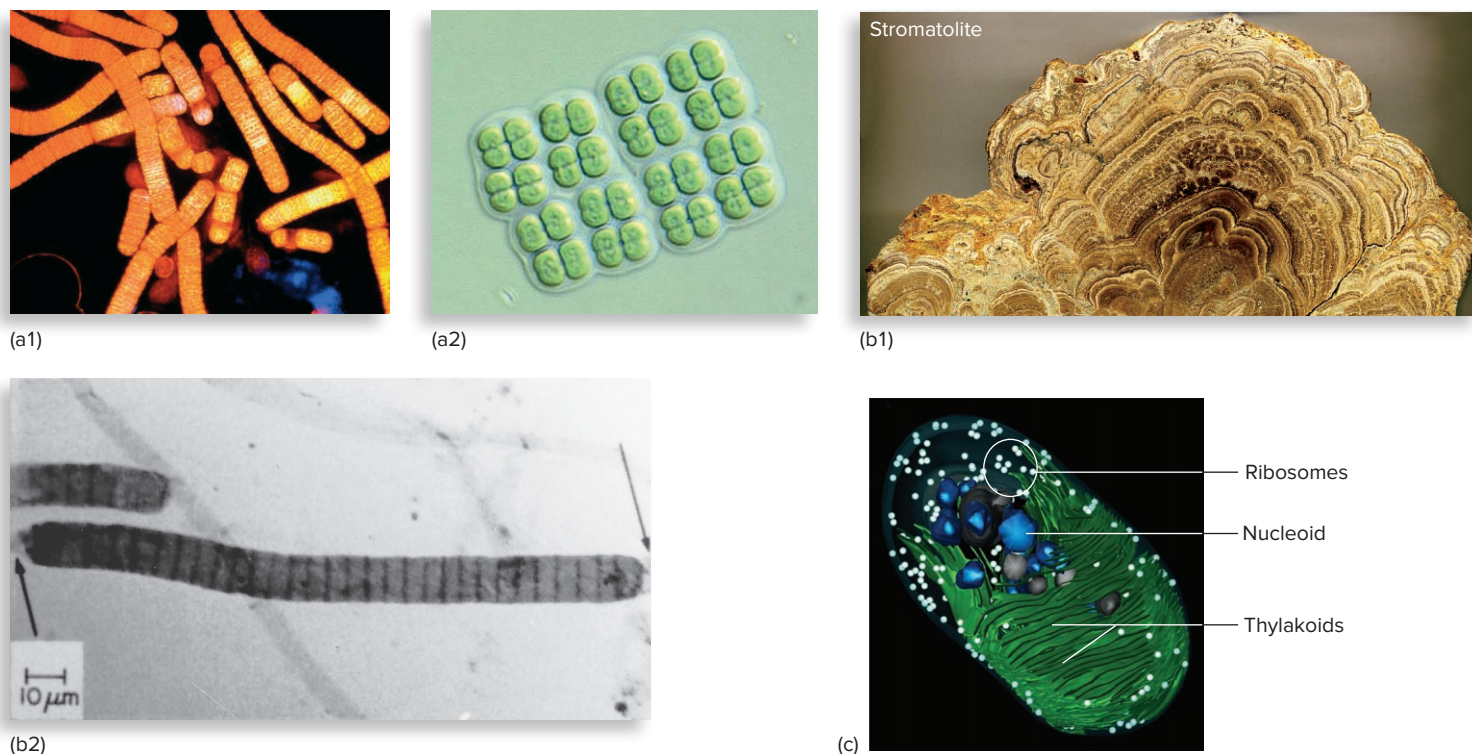

Figure 4.28 Cyanobacterial characteristics. (a) Striking colors and arrangements of cells. (1) *Trichodesmium* is one of the dominant planktonic forms on earth. Howard Berg, and Himadri B. Pakrasi, "Unique Thylakoid Membrane Architecture of a Unicellular N₂-Fixing Cyanobacterium Revealed by Electron Tomography" *Plant Physiology*, vol. 155 no. 4, p. 1656-1666, Fig 2G © American Society of Plant Biologists

their predominant colors, but they can also develop brown, pink, purple, blue, and orange coloration. Both groups utilize sulfur compounds (H_2S , S) in their metabolism.

Gliding, Fruiting Bacteria

The gliding bacteria are a mixed collection of gram-negative bacteria in Phylum Proteobacteria that live in water and soil. The name

Figure 4.29 Photosynthetic bacteria. Purple-colored masses in a fall pond contain a concentrated bloom of purple sulfur bacteria (inset 1,500 \times). The pond also harbors a mixed population of algae (green clumps). © Kathy Park Talaro; (inset): © David J. Patterson

is derived from the tendency of members to glide over moist surfaces. The gliding property evidently involves rotation of filaments or fibers just under the outer membrane of the cell wall. They do not have flagella. Several morphological forms exist, including slender rods, long filaments, cocci, and some miniature, tree-shaped fruiting bodies. Probably the most intriguing and exceptional members of this group are the slime bacteria, or myxobacteria. What sets the myxobacteria apart from other bacteria is the complexity and advancement of their life cycle. During this cycle, the vegetative cells respond to chemotactic signals by swarming together and differentiating into a many-celled, colored structure called the fruiting body, making it one of the few bacteria that can generate a multicellular body form (**figure 4.30**). The fruiting body is a survival structure that makes spores by a method very similar to that of certain fungi. These fruiting structures are often large enough to be seen with the unaided eye on tree bark and plant debris.

Unusual Forms of Medically Significant Bacteria

Most bacteria are free-living or parasitic forms that can metabolize and reproduce by independent means. Two groups of bacteria—the rickettsias and chlamydias—have adapted to living inside host cells. Because they cannot function without some essential factors from the host, they are considered **obligate intracellular parasites**.

Figure 4.30 Life cycle of *Myxococcus*. This multicellular bacterium goes through several developmental stages in response to environmental signals.

Figure 4.31 Transmission electron micrograph of *Rickettsia conorii* inside its host cell (100,000X). This species causes tick-borne Mediterranean fever. *Source:* From C. Rovey, P. Brouqui, D. Raoult, “Questions on Mediterranean Spotted Fever a Century after Its Discovery,” *Emerging Infectious Diseases*, 14(9), September 2008, Fig. 2. CDC

Rickettsias

Rickettsias⁶ are distinctive, very tiny, gram-negative bacteria (figure 4.31). Although they have somewhat typical morphology, they are atypical in their life cycle and other adaptations. Most are pathogens that alternate between a mammalian host and blood-sucking arthropods,⁷ such as fleas, lice, or ticks. Rickettsias cannot survive or multiply outside a host cell and cannot carry out metabolism completely on their own, so they are closely attached to their hosts. Several important human diseases are caused by rickettsias. Among these are Rocky Mountain spotted fever, caused by *Rickettsia rickettsii* (transmitted by ticks), and endemic typhus, caused by *Rickettsia typhi* (transmitted by lice). It is worth noting, in advance

6. Named for Howard Ricketts, a physician who first worked with these organisms and later lost his life to typhus.

7. An arthropod is an invertebrate with jointed legs, such as an insect, tick, or spider.

of chapter 5, that the mitochondrion, a eukaryotic organelle, is a close genetic relative to rickettsias, indicating an evolutionary link between them.

Chlamydias

Bacteria of the genera *Chlamydia* and *Chlamydomphila*, termed **chlamydias**, are similar to the rickettsias in that they require host cells for growth and metabolism. But they are not closely related to them and are not transmitted by arthropods. Because of their tiny size and obligately parasitic lifestyle, they were at one time considered a type of virus (see table 4.3L). Species that carry the greatest medical impact are *Chlamydia trachomatis*, the cause of both a severe eye infection (trachoma) that can lead to blindness and one of the most common sexually transmitted diseases, and *Chlamydomphila pneumoniae*, an agent in lung infections.

Diseases caused by rickettsias and chlamydias are described in more detail in the infectious disease chapters.

Archaea: The Other Prokaryotes

The discovery and characterization of novel prokaryotic cells that have unusual anatomy, physiology, and genetics changed our views of microbial taxonomy and classification (see chapter 1 and table 4.3). These single-celled, simple organisms, called **archaea**, or **archaeons**, are considered a third cell type in a separate superkingdom (the Domain Archaea). We include them in this chapter because they are prokaryotic in general structure and they do share many bacterial characteristics. But evidence is accumulating that they are more closely related to Domain Eukarya than to bacteria. For example, archaea and eukaryotes share a number of ribosomal RNA sequences that are not found in bacteria, and their protein synthesis and ribosomal subunit structures are similar. **Table 4.5** outlines selected points of comparison of the three domains.

Other ways in which the archaea differ significantly from other cell types are that certain genetic sequences are found only in their ribosomal RNA. Their cell walls are also quite different, being composed of polysaccharide or protein and lacking peptidoglycan, and some lack cell walls altogether (see figure 4.33). It is likely that the archaea are the most ancient of all life forms and have retained characteristics of the first cells that originated on the earth nearly 4 billion years ago. The early earth is thought to have contained a hot, anaerobic “soup” with sulfuric gases and salts in abundance. Many of the present-day archaea occupy the remaining habitats on the earth that have some of the same extreme conditions. For this reason they are considered **extremophiles**, or **hyperextremophiles**, meaning that they “love” the most extreme habitats on earth. Although there are also some examples of extremophilic bacteria (refer to table 4.3), they are not as widespread as archaea in ultra-extreme environments.

Metabolically the archaea exhibit nearly incredible adaptations to what would be deadly conditions for other organisms. Many of these hardy microbes are living in severe combinations of extremes as well—for instance, high acidity and high temperature, high salt and alkalinity, low temperature and high pressure. Included in this group are methane producers, hyperthermophiles, extreme halophiles, and sulfur reducers. It is worth noting that not all archaea are adapted to extremes, and many are widely distributed in more

TABLE 4.5 Comparison of Three Cellular Domains

Characteristic	Bacteria	Archaea	Eukarya
Cell type	Prokaryotic	Prokaryotic	Eukaryotic
Chromosomes	Single, or few, circular	Single, circular	Several, linear
Types of ribosomes	70S	70S but structure is similar to 80S	80S
Unique ribosomal RNA signature sequences	+	+	+
Number of RNA sequences shared with Eukarya	One	Three	
Protein synthesis similar to Eukarya	–	+	
Presence of peptidoglycan in cell wall	+	–	–
Cell membrane lipids	Fatty acids with ester linkages	Long-chain, branched hydrocarbons with ether linkages	Fatty acids with ester linkages
Sterols in membrane	– (some exceptions)	–	+

moderate environments such as soils, oceans, and even animal intestines. By some estimates, archaea are the most common cells on the earth, and they have made major contributions to the development of the earth itself.

Members of the group called **methanogens** can convert CO_2 and H_2 into methane gas (CH_4) through unusual and complex pathways. These archaea are common inhabitants of anaerobic mud and the bottom sediments of lakes and oceans. Some are even found in the oral cavity and large intestine of humans. The gas they produce in aquatic habitats collects in swamps and may become a source of fuel. Methane may also contribute to the “greenhouse effect,” which maintains the earth’s temperature and can contribute to global warming.

Other types of archaea—the **extreme halophiles**—require salt to grow and may have such a high salt tolerance that they can multiply in sodium chloride solutions (36% NaCl) that would destroy most cells. They exist in the saltiest places on the earth—inland seas, salt lakes, and salt mines. They are not particularly common in the ocean because the salt content is not high enough to support them. Many of the “halobacteria” use a red pigment to synthesize ATP in the presence of light. These pigments are responsible for “red herrings,” the color of the Red Sea, and the red color of salt ponds (**figure 4.32**).

Archaea adapted to growth at very low temperatures are described as **psychrophiles** (loving cold temperatures); those growing at very high temperatures are **hyperthermophiles** (loving very high temperatures). Hyperthermophiles flourish at temperatures between 80°C and 121°C (21°C above boiling) and cannot grow at 50°C . They live in volcanic waters and soils and submarine vents, and are often salt- and acid-tolerant as well (**figure 4.33**). Researchers sampling sulfur vents in the deep ocean discovered thermophilic archaea flourishing at temperatures up to 250°C —which is 150° above the temperature of boiling water! Not only were these archaea growing prolifically at this high temperature, but they were also living at 265 atmospheres of pressure. (On the earth’s surface, pressure is about 1 atmosphere.) For additional discussion of the unusual adaptations of archaea, see chapter 7.

Figure 4.32 Halophiles around the world. (a) An aerial view of a salt pond at San Francisco Bay, California. The archaea that thrive in this warm, highly saline habitat produce brilliant red, pink, and orange pigments. Check Your Progress SECTION 4.7

36. Discuss several ways in which bacteria are medically and ecologically important.
37. Name two main groups of obligate intracellular parasitic bacteria and explain why these groups can't live independently.
38. Explain the characteristics of archaea that indicate that they constitute a unique domain of living things that is neither bacterial nor eukaryotic.
39. What is meant by the terms *extremophile* and *hyperextremophile*?
40. Describe the three major archaeal lifestyles and adaptations to extreme habitats.

Chapter Summary with Key Terms

4.1 Basic Characteristics of Cells and Life Forms

- A. All living things are composed of cells, which are complex collections of macromolecules that carry out living processes. All cells must have the minimum structure of an outer **cell membrane**, **cytoplasm**, a **chromosome**, and **ribosomes**.
- B. Cells can be divided into two basic types: **prokaryotes** and **eukaryotes**.
 1. Prokaryotic cells are the basic structural unit of bacteria and archaea. They lack a nucleus or organelles. They are highly successful and adaptable single-cell life forms.

CASE STUDY Part 2

During an autopsy of Mr. Jones's body, the pathologist observed that the prosthetic valve was covered with small patches he called vegetations.

The later blood cultures grew a strain of *Staphylococcus aureus** known as MRSA. Microscopic examination of the valve revealed a thick biofilm coating containing that same bacterium. The pathologist concluded that the patient had infective endocarditis,* and that vegetations on the valve lesions had broken loose and entered the circulation. This event created emboli that blocked arteries in his brain and gave rise to a massive stroke. Upon closer review of Mr. Jones's case, the physician discovered that he had suffered from a skin infection the previous spring that had been treated and cured by a different physician. It turned out to be caused by the MRSA type of *Staphylococcus aureus*.

Most bacteria can form structured multicellular communities, or biofilms, on objects in a moist environment. This is even true of bacterial pathogens in the body. The CDC estimates that at least 65% of chronic infections are caused by microbial biofilms. In this case, the MRSA bacteria in the patient's skin infection must have entered the circulation and colonized the artificial valve over several weeks to months. Most cases of chronic endocarditis are caused by biofilms on valves. When the biofilm grows into larger vegetations, portions of it break loose into the circulation. These infect the blood and are spread into organs, causing fever and other signs and symptoms, including the ones that were fatal. MRSA is an emerging pathogen that started as a problem in the hospital but is now prominent in nonhospital settings as well.

- What does the acronym MRSA mean, and what is its significance?
- Why wasn't penicillin effective in treating the infection?

For more background on MRSA and endocarditis, see chapter 18.

To conclude this Case Study, go to Connect.

* *Staphylococcus aureus* (staf'-uh-loh-cok'-us ar-ee-us) Gr. *staphyle*, a bunch of grapes, *kokkus*, berry, and *aurum*, golden.

* *endocarditis* (en'-doh-car-dye'-tis) Gr. *endon*, within, *kardia*, heart, and *itis*, an inflammation. An inflammation of the lining of the heart and its valves usually caused by infection.

2. Eukaryotic cells contain a membrane-surrounded nucleus and a number of organelles that function in specific ways. A wide variety of organisms, from single-celled protozoans to humans, are composed of eukaryotic cells.
3. Viruses are not generally considered living or cells, and rely on host cells to replicate.
- C. Cells show the basic essential characteristics of life. Parts of cells and macromolecules do not show these characteristics independently.
 1. The primary life indicators are heredity, reproduction, growth, metabolism, responsiveness, and transport.

4.2 Prokaryotic Profiles: The Bacteria and Archaea

- Prokaryotes consist of two major groups, the bacteria and the archaea. Life on earth would not be possible without them.
- Prokaryotic cells lack the membrane-surrounded organelles and nuclear compartment of eukaryotic cells but are still complex in their structure and function. All prokaryotes have a cell membrane, cytoplasm, ribosomes, and a chromosome.
- Appendages:** Some bacteria have projections that extend from the cell.
 - Flagella** and internal **axial filaments** found in spirochetes are used for motility.
 - Fimbriae** function in adhering to the environment; pili can be involved in adhesion, movement, and genetic exchange.
 - The **glycocalyx** may be a slime layer or a capsule.

4.3 The Cell Envelope: The Boundary Layer of Bacteria

- Most prokaryotes are surrounded by a protective envelope that consists of the cell wall and the cell membrane.
- The wall is relatively rigid due to **peptidoglycan**.
- Structural differences give rise to **gram-positive** and **gram-negative cells**, as differentiated by the **Gram stain**.
 - Gram-positive bacteria contain a thick wall composed of peptidoglycan and teichoic acid in a single layer.
 - Gram-negative bacteria have a thinner, two-layer cell wall with an **outer membrane**, a thin layer of **peptidoglycan**, and a well-developed **periplasmic space**.
 - Wall structure gives rise to differences in staining, toxicity, and effects of drugs and disinfectants.
 - The **cell** or **cytoplasmic membrane** is a flexible sheet that surrounds the cytoplasm. It is composed of a bilayer of lipids with attached proteins. It is a multifunctional structure involved in transport, synthesis, and energy reactions.

4.4 Bacterial Internal Structure

The cell cytoplasm contains some or all of the following internal structures in bacteria: the **chromosome(s)** condensed in the **nucleoid**; **ribosomes**, which serve as the sites of protein synthesis and are 70S in size; extra genetic information in the form of **plasmids**; storage structures known as **inclusions**, **granules**, and **microcompartments**; a **cytoskeleton** of **bacterial actin**, which helps give the bacterium its shape; and in some bacteria an **endospore**, which is a highly resistant structure for survival, not reproduction.

4.5 Bacterial Shapes, Arrangements, and Sizes

- Most bacteria are unicellular and are found in a great variety of shapes, arrangements, and sizes. General shapes include **cocci**, **bacilli**, and helical forms such as **spirilla** and **spirochetes**. Some show great variation within the species in shape and size and are **pleomorphic**. Other variations include **coccobacilli**, **vibrios**, and filamentous forms.
- Prokaryotes divide by binary fission and do not utilize mitosis. Various **arrangements** result from cell division and are termed **diplococci**, **streptococci**, **staphylococci**, **tetrads**, and **sarcina** for cocci; bacilli may form pairs, chains, or **palisades**.
- Variant members of bacterial species are called strains and types.

4.6 Classification Systems of the Prokaryotic Domains: Archaea and Bacteria

- An important taxonomic system is standardized by *Bergey's Manual of Systemic Bacteriology*, which presents the prokaryotes in five major groups, as organized by volume.
 - Volume 1: Domain Archaea Domain Bacteria: Deeply Branching and Phototropic Bacteria Domain Bacteria
 - Volume 2: Phylum Proteobacteria
 - Volume 3: Phylum Firmicutes
 - Volume 4: Phylum Actinobacteria
 - Volume 5: Phyla Chlamydiae, Spirochaetes, Planctomyces, Bacteroidetes, and others

4.7 Survey of Prokaryotic Groups with Unusual Characteristics

- Several groups of bacteria have unusual adaptations and life cycles.
 - Medically important bacteria: **Rickettsias** and **chlamydias** are within the gram-negative group but are small **obligate intracellular parasites** that replicate within cells of the hosts they invade.
 - Nonpathogenic bacterial groups: The majority of bacterial species are free-living and not involved in disease. Unusual groups include photosynthetic bacteria such as **cyanobacteria**, which provide oxygen to the environment, and the green and purple bacteria.
- Archaea** share many characteristics with bacteria but vary in certain genetic aspects and structures such as the cell wall and ribosomes.
 - Many are **extremophiles**, adapted to extreme environments similar to the earliest of earth's inhabitants.
 - They are not considered medically important but are of ecological and potential economic importance.

Level I Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

- Which structure is not a component of all cells?
 - cell wall
 - cell membrane
 - genetic material
 - ribosomes
- Viruses are not considered living things because
 - they are not cells
 - they cannot reproduce by themselves
 - they lack metabolism
 - All of these are correct.

- Which of the following is not found in all bacterial cells?
 - cell membrane
 - a nucleoid
 - ribosomes
 - actin cytoskeleton
- The major locomotor structures in bacteria are
 - flagella
 - pili
 - fimbriae
 - cilia
- Pili are appendages in _____ bacteria that serve as a means of _____.
 - gram-positive, genetic exchange
 - gram-positive, attachment
 - gram-negative, genetic exchange
 - gram-negative, protection
- An example of a glycocalyx is
 - a capsule
 - pili
 - outer membrane
 - a cell wall
- Which of the following is a primary bacterial cell wall function?
 - transport
 - motility
 - support
 - adhesion
- Which of the following is present in both gram-positive and gram-negative cell walls?
 - an outer membrane
 - peptidoglycan
 - teichoic acid
 - lipopolysaccharides
- Metachromatic granules are concentrated _____ found in _____.
 - fat, *Mycobacterium*
 - dipicolinic acid, *Bacillus*
 - sulfur, *Thiobacillus*
 - PO₄, *Corynebacterium*
- Which of the following prokaryotes lacks cell walls?
 - rickettsias
 - mycoplasmas
 - Mycobacterium*
 - archaea
- The LPS layer in gram-negative cell walls releases _____ that cause _____.
 - enzymes, pain
 - endotoxins, fever
 - teichoic acid, inflammation
 - phosphates, lysis
- Bacterial endospores function in
 - reproduction
 - survival
 - protein synthesis
 - storage
- An arrangement in packets of eight cells is described as a _____.
 - micrococcus
 - diplococcus
 - tetrad
 - sarcina
- The major difference between a spirochete and a spirillum is
 - presence of flagella
 - the presence of twists
 - the nature of motility
 - size
- Which phylum contains bacteria with a gram-positive cell wall?
 - Proteobacteria
 - Chlorobi
 - Firmicutes
 - Spirochetes
- To which taxonomic group do cyanobacteria belong?
 - Domain Archaea
 - Phylum Actinobacteria
 - Domain Bacteria
 - Phylum Fusobacteria
- Which stain is used to distinguish differences between the cell walls of medically important bacteria?
 - simple stain
 - acridine orange stain
 - Gram stain
 - negative stain
- The first living cells on earth would most likely resemble which of these?
 - a cyanobacterium
 - an endospore former
 - a gram-positive cell
 - an archaeon

Case Study Review

- What is true of the condition endocarditis?
 - It occurs in the heart muscle.
 - It is caused by microbes growing in the internal organs.
 - It is an infection of the heart valves and lining.
 - It can be transmitted to others.
- Where did the MRSA pathogen likely originate?
 - from the artificial valve itself
 - from the patient's earlier skin infection
 - from the surgery
 - from the patient's wife
- What is a biofilm, and how did it form on the heart valve?

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

- Label the parts on the bacterial cell featured here and write a brief description of its function.

- Discuss the collection of properties that are used to define life and the prokaryotic cell structures that are involved in carrying out these life processes.
- Describe the basic process of biofilm formation.
- What leads microbiologists to believe the archaea are more closely related to eukaryotes than to bacteria?
- What is required to kill endospores? How do you suppose archaeologists were able to date some spores as being thousands (or millions) of years old?

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps along with concept-mapping activities for this chapter.

Level II Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

- Using clay, demonstrate how cocci can divide in several planes and show the outcome of this division. Show how the arrangements of bacilli occur, including palisades.
- Using a corkscrew and a spring to compare the flexibility and locomotion of spirilla and spirochetes, explain which cell type is represented by each object.
- Under the microscope, you see a rod-shaped cell that is swimming rapidly forward.
 - What do you automatically know about that bacterium's structure?
 - Propose another function of flagella besides locomotion.
- Name an acid-fast bacterium and explain what characteristics make this bacterium different from other gram-positive bacteria.
- Name a bacterial group that uses chlorophyll to photosynthesize.
 - Describe the two major groups of photosynthetic bacteria and how they are similar and different.
- Propose a hypothesis to explain how bacteria and archaea could have, together, given rise to eukaryotes.
- Explain or illustrate exactly what will happen to the cell wall if the synthesis of the interbridge is blocked by penicillin.
- Ask your lab instructor to help you make a biofilm and examine it under the microscope. One possible technique is to suspend a glass slide in an aquarium for a few weeks, then carefully air-dry, fix, and Gram stain it. Observe the diversity of cell types.
- Describe the shapes and arrangements of bacteria in figure 4.23a, b, e, and f.

Visual Challenge

- From chapter 3, figure 3.20b. Which bacteria have a well-developed capsule: "*Klebsiella*" or "*S. aureus*"? Defend your answer.
- What kinds of cells are shown here? Explain what causes the colors and appearance of the stages you see.

A Survey of Eukaryotic Cells and Microorganisms

Hookworm larvae burrowing into the intestine (20x)

Larval schistosome, a parasitic roundworm (200x)

Trypanosoma, a flagellated protozoan (1,500x)

Examples of microorganisms that cause neglected diseases, distributed across the earth's tropical and subtropical zones (bands of blue) (top): Source: NASA Earth Observations; (bottom: left): Source: CDC; (bottom: middle): Source: Dr. Sulzer/CDC; (bottom: right): Source: Dr. Myron G. Schultz/CDC

CASE STUDY Part 1 Neglected Tropical Diseases

Some of the worst suffering in the world originates from a group of ancient infectious diseases that exist primarily in the **tropical** and **subtropical** regions of Africa, India, Latin America, and Asia. Nearly 1.4 billion people worldwide, sometimes referred to as the “**bottom billion**,” experience disability or death as a result of 17 common diseases.

These **neglected tropical diseases**, or **NTDs**, have received less attention than highly publicized diseases such as **AIDS**, **malaria**, and **tuberculosis**, and they have been largely ignored by the medical establishment in many countries. Unfortunately, they also tend to occur in the poorest rural areas, where access to treatment is often severely limited. “Almost everyone in the bottom billion has at least one of these diseases,” said Dr. Peter Hotez, a **parasitologist** and medical doctor at George Washington University. Taken together, NTDs rank second only to HIV/AIDS in their medical, social, and economic impact.

Eleven of the 17 neglected disease pathogens are **eukaryotic parasites**, either parasitic **helminth worms** or **protozoans**. The leading parasitic worm infections are **ascariasis**,* **trichiuriasis**, **hookworm**,

and **schistosomiasis**, and the leading protozoan infections are **Chagas disease**, **African trypanosomiasis**, and **leishmaniasis**. The **chronic, progressive** actions of these infectious agents can cause debility and disfigurement. Consider Chagas disease, caused by the protozoan ***Trypanosoma cruzi***, which over time **lodges in the heart and other organs**, destroys health, and shortens life. Some forms of leishmaniasis affect the skin and give rise to growths that **deform** the face and other body parts. The growth of **hookworms** causes **blood loss**, saps strength, and impairs development. Some parasites cause **blindness** and others **disfigure the limbs**. In addition to medical effects, many victims become unable to go to school or work and are harshly ostracized by their communities.

“The impact of Avermectin and Artemisinin goes far beyond reducing the disease burden of individuals.”

Hans Forssberg of the Nobel Committee

- What subjects are studied by the science of parasitology?
- What can you conclude about the total number of NTD cases, given that everyone in the bottom billion has at least one infection?

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

* Some diseases are named by adding the suffix *-iasis* to the name of the organism that causes it.

SCOPING OUT THE CHAPTER

At the heart of all eukaryotic organisms is the eukaryotic cell. An evolutionary leap from its prokaryotic predecessor, this cell is hundreds of times larger than a typical prokaryotic cell and far more complex. The development of cellular organelles allow biochemical reactions to occur more efficiently, and organisms based on eukaryotic cells are free to evolve in ways that simply aren't available to prokaryotes. This chapter provides an introduction to these incredibly complex cells.

The cellular organelles within eukaryotic cells work in concert with one another to accomplish complex tasks like synthesizing and modifying proteins.

Although the vast majority of fungi are harmless saprobes which recycle nutrients in the environment, we tend to be more interested in the few that cause disease, or are used in the production of food and drink.

Algae typically have few health risks associated with them but many industrial uses. The cell walls of the diatoms seen here are used to filter drinking water, and their photosynthetic activity is responsible for most of the oil on Earth.

Protozoans like *Giardia intestinalis* are routinely present in natural bodies of water and ingestion can cause severe disease.

Parasitic worms like this pork tapeworm (*Taenia solium*) use a combination of hooks and suckers to attach to the intestinal wall of their host. These infestations are exceedingly difficult to treat because the worm's size and biology makes it more like its human host than an invading microbial organism.

5.1 The History of Eukaryotes

Expected Learning Outcomes

1. Describe the evolutionary history of eukaryotic cells.
2. Provide a substantial theory regarding how eukaryotic cells originated and how multicellularity came to be.
3. List the eukaryotic groups and their body plans.

Using evidence from ancient sediments, paleontologists estimate that the earliest eukaryotic cells first evolved around 2 billion years ago. Other intriguing evidence comes from fossilized cells discovered in shale deposits from China and Russia that are 600 million to nearly a billion years old. It is remarkable how much they resemble modern-day algae or protozoa (**figure 5.1**).

When biologists began to focus on the possible origins of these cells, they turned to an analysis of modern cells, and from these studies emerged convincing evidence that eukaryotic cells evolved from prokaryotic cells through a process of **endosymbiosis**. According to the endosymbiotic hypothesis, eukaryotic cells arose when a much larger prokaryotic cell engulfed smaller prokaryotic cells, which began to live and reproduce inside the larger cell rather than being destroyed. As the smaller cells took up permanent residence, they came to perform specialized functions for the larger cell, such as food synthesis and oxygen utilization, that enhanced the larger cell's versatility and survival. Over time the cells evolved into a single functioning entity, and the relationship became obligatory; some of the smaller cells had become **organelles**, the distinguishing feature of eukaryotic cells (**figure 5.2**). The structure of these early cells was so versatile that eukaryotic microorganisms soon spread out into available habitats and adopted greatly diverse styles of living.

(a)

(b)

Figure 5.1 Ancient eukaryotic protists discovered in fossilized rocks. (a) A cell preserved in Siberian shale deposits dates from 850 million to 950 million years ago. (b) A disclike cell was recovered from a Chinese rock dating 590 million to 610 million years ago. Both cells are relatively simple, with (a) showing chloroplast-like bodies that would be found in an alga. Example (b) has a cell wall with spines, very similar to the modern alga *Pediastrum*. (a and b): © Andrew H. Knoll

A larger prokaryotic cell, possibly an archaea, containing a flexible outer envelope and folded internal membranes.

A smaller prokaryotic cell, related to modern rickettsias, that can live intracellularly.

Membrane forms around the DNA, creating a primitive nucleus.

The larger cell engulfs the smaller one; smaller one survives and remains surrounded by the vacuolar membrane.

Smaller bacterium becomes a permanent resident of its host's cytoplasm; it multiplies and is passed on during cell division. It utilizes aerobic metabolism and increases energy availability for the host.

Early endoplasmic reticulum

Early mitochondria

Ancestral eukaryotic cell develops additional membrane pouches that become the endoplasmic reticulum and Golgi apparatus.

Photosynthetic bacteria (ancient cyanobacteria) are also engulfed; they develop into chloroplasts.

Ancestral cell

Many protozoa, animals

Some groups of algae, higher plants

Figure 5.2 A possible model for evolution of eukaryotic organisms according to the endosymbiotic theory. A large archaeal cell with its flexible envelope engulfs a smaller bacterial cell. Folds in the archaeal cell membrane wrap around the chromosome to form a nuclear envelope. The engulfed bacterial cell forges a metabolic relationship with the archaea, making use of archaeal molecules and contributing energy through aerobic respiration. Evolution of a stable mutualistic existence would maintain both cell types and create the eukaryotic cell and its organelles.

TABLE 5.1 Eukaryotic Organisms Studied in Microbiology

Unicellular, a Few Colonial	May Be Unicellular, Colonial, or Multicellular	Multicellular Except Reproductive Stages
Protozoa	Fungi, Algae	Helminths (parasitic worms) Arthropods (animal vectors of diseases)

Much of the evidence supporting the endosymbiotic theory concerned the similarity between the organelles of modern eukaryotic cells and the structure of bacteria. In many ways the mitochondrion of eukaryotic cells behaves as a tiny cell within a cell. It is capable of independent division, contains a circular chromosome with bacterial DNA sequences, and has ribosomes that are clearly prokaryotic. Mitochondria also have bacterial membranes and can be inhibited by drugs that affect only bacteria. In a similar vein, genetic studies indicate that chloroplasts likely originated from endosymbiotic cyanobacteria that provided their host cells with a built-in feeding mechanism. Evidence is seen in protists, such as *Paulinella chromatophora*, that harbor specialized chloroplasts with cyanobacterial origins. The endosymbiotic theory is so well accepted that bacteriologists have placed both mitochondria and chloroplasts on the family tree of bacteria (see figure 1.15). In fact, the closest relative of mitochondria are rickettsias, which are also obligate intracellular bacteria!

The first primitive eukaryotes were probably single-celled, independent microorganisms, but over time some forms began to cluster in permanent groupings called colonies. With further evolution, some of the cells within colonies became *specialized*, or adapted to perform a particular function advantageous to the whole colony, such as locomotion, feeding, or reproduction. Complex multicellular organisms evolved as individual cells in the organism lost the ability to survive apart from the intact colony. Although a multicellular organism is composed of many cells, it is more than just a disorganized assemblage of cells like a colony. Rather, it is composed of distinct groups of cells that cannot exist independently of the rest of the body. Within a multicellular organism, groupings of cells that have a specific function are termed *tissues*, and groups of tissues make up *organs*.

Looking at modern eukaryotic organisms, we find examples of many levels of cellular complexity (table 5.1). All protozoa, as well as numerous algae and fungi, are unicellular. Truly multicellular organisms are found only among plants and animals and some of the fungi (mushrooms) and algae (seaweeds). Only certain eukaryotes are traditionally studied by microbiologists—primarily the protozoa, the microscopic algae and fungi, and animal parasites, or helminths.

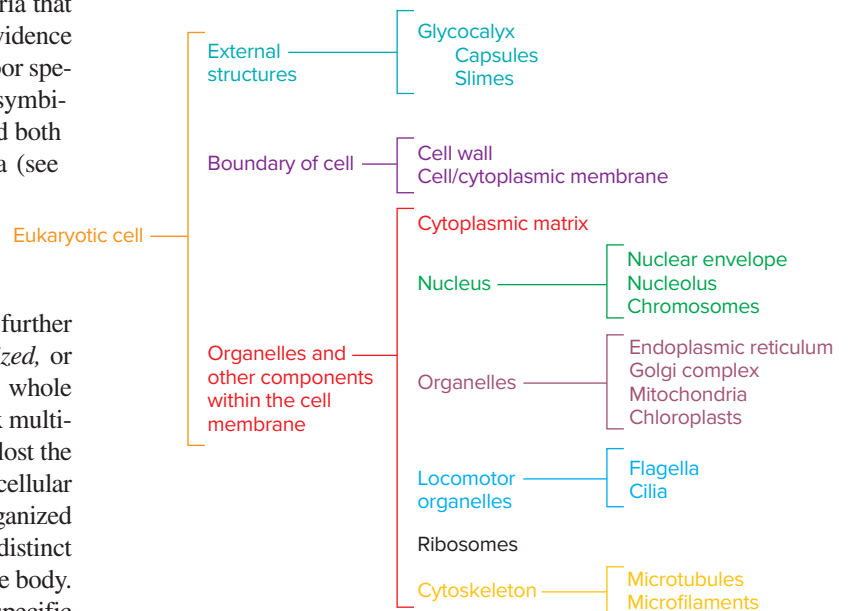

5.2 Form and Function of the Eukaryotic Cell: External Structures

Expected Learning Outcomes

- Describe the plan of a basic eukaryotic cell and organelles, and indicate the structures all cells possess and those found only in some groups.
- Describe the types of eukaryotic locomotor appendages.
- Differentiate the structure and functions of flagella and cilia, and the types of cells that possess them.
- Define the glycocalyx for eukaryotic cells and list its basic functions.
- Characterize the cell wall and membrane of eukaryotic cells.

The cells of eukaryotic organisms are so varied that no one member can serve as a typical example, so a composite structure of a eukaryotic cell is depicted in figure 5.3. No single type of microbial cell would contain all structures represented. It is evident that the organelles impart much greater complexity and compartmentalization compared to a prokaryotic cell. Differences among fungi, protozoa, algae, and animal cells are introduced in later sections.

The flowchart shown here maps the structural organization of a eukaryotic cell. Compare this outline to the one found in chapter 4.

In general, eukaryotic microbial cells have a cytoplasmic membrane, nucleus, mitochondria, endoplasmic reticulum, Golgi apparatus, vacuoles, cytoskeleton, and glycocalyx. A cell wall, locomotor appendages, and chloroplasts are found only in some groups. In the following sections, we cover the microscopic structure and functions of the eukaryotic cell. As with the prokaryotes, we begin on the outside and proceed inward through the cell.

Locomotor Appendages: Cilia and Flagella

Motility allows a microorganism to locate life-sustaining nutrients and to migrate toward positive stimuli such as sunlight; it also permits avoidance of harmful substances and stimuli. Locomotion by means of flagella is common in protozoa, algae, and a few fungal and animal cells. Cilia are found only in protozoa and animal cells.

Figure 5.3 Overview of composite eukaryotic cell. This drawing represents all structures associated with eukaryotic cells, but no microbial cell possesses all of them. See figures 5.16, 5.23, and 5.25 for examples of individual cell types.

Although they share the same name, the **flagella** of eukaryotes are much different from those of prokaryotes. The eukaryotic flagellum is thicker (by a factor of 10), has a much different construction, and is covered by an extension of the cell membrane. A flagellum is a long, sheathed cylinder containing regularly spaced hollow tubules—**microtubules**—that extend along its entire length (**figure 5.4b**). A cross section reveals nine pairs of closely attached microtubules surrounding a single central pair. This scheme, called the 9 + 2 arrangement, is a typical pattern of flagella and cilia (**figure 5.4a**). The nine pairs are linked together and anchored to the pair in the center. This architecture permits the microtubules to “walk” by sliding past each other, whipping the flagellum back and forth. Although details of this process are too complex to discuss here, it involves expenditure of energy and a coordinating mechanism in the cell membrane. Flagella can move the cell by pushing it

forward like a fishtail or by pulling it by a lashing or twirling motion (**figure 5.4c**). The placement and number of flagella can be useful in identifying flagellated protozoa and certain algae.

Cilia are very similar in overall architecture to flagella, but they are shorter and more numerous (some cells have several thousand). They are found only in certain protozoa and animal cells. In the ciliated protozoa, the cilia occur in rows over the cell surface, where they beat back and forth in regular oarlike strokes (**figure 5.5**) and provide rapid motility. The fastest ciliated protozoan can swim up to 2,500 $\mu\text{m/s}$ —a meter and a half per minute! On some cells, cilia also function as feeding and filtering structures.

Quick Search

Find videos using the search words *amoebic*, *flagellate*, and *ciliate movement* on YouTube.

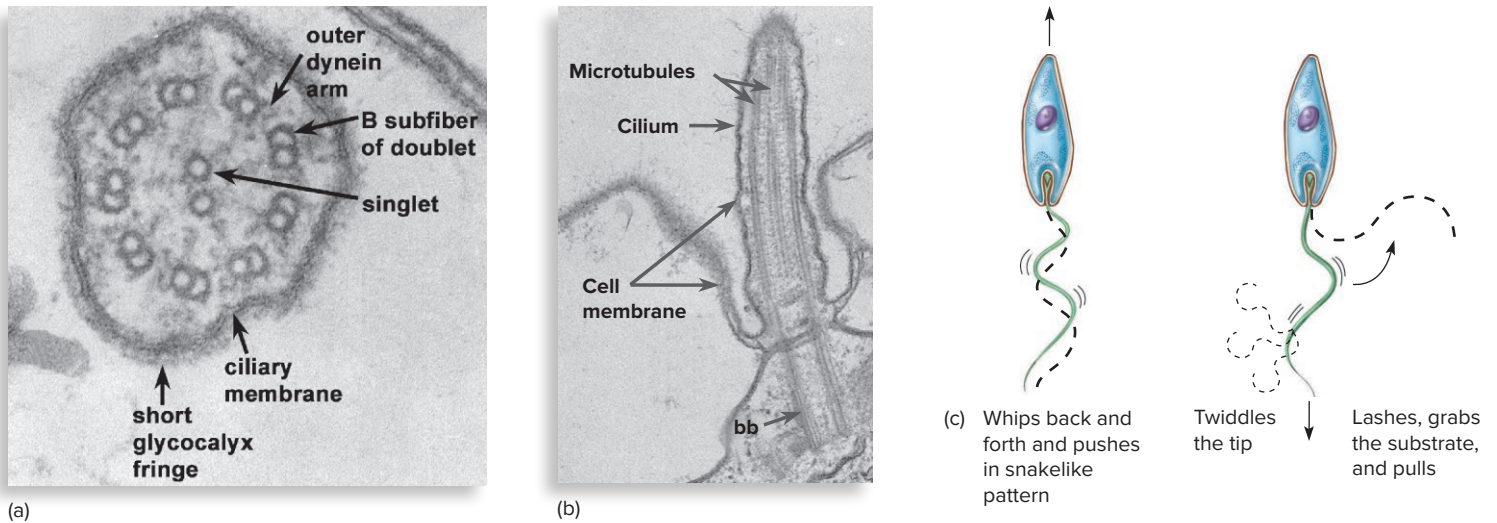

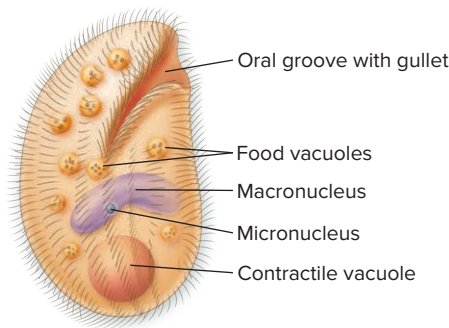

Figure 5.4 The structure of cilia and flagella. (a) A cross section through a protozoan cilium reveals the typical 9 + 2 arrangement of microtubules seen in both cilia and flagella. (b) Longitudinal section through a cilium, showing the lengthwise orientation of the microtubules and the basal body (bb) from which they arise. Note the membrane that surrounds the cilium that is an extension of the cell membrane and shows that it is indeed an organelle. (c) Locomotor patterns seen in flagellates. (a)

(b)

Figure 5.5 Locomotion in ciliates. (a) A simple ciliate, *Balantidium*, has regular rows of cilia over its surface and within its oral groove and gullet for capturing and transporting food. (b) Cilia beat in coordinated waves, driving the cell forward and backward. The pattern of ciliary movement is like a swimmer's arms, with a power forward stroke and a repositioning stroke. Ciliary moves are made possible by the microtubules they contain.

The Glycocalyx

Most eukaryotic microbes have a **glycocalyx**, an outermost boundary that comes into direct contact with the environment. This structure is usually composed of polysaccharides and appears as a network of fibers, a slime layer, or a capsule much like the glycocalyx of prokaryotes. From its position as the exposed cell layer, the

glycocalyx serves a variety of functions. Most prominently, it promotes adherence to environmental surfaces and the development of biofilms and mats. It also serves important receptor and communication functions and offers some protection against environmental changes.

The nature of the layer beneath the glycocalyx varies among the several eukaryotic groups. Fungi and most algae have a thick, rigid cell wall surrounding a cell membrane. Protozoa, a few algae, and all animal cells lack a cell wall and are encased primarily by a cell membrane.

Form and Function of the Eukaryotic Cell: Boundary Structures

The Cell Wall

The cell walls of the fungi and algae are rigid and provide structural support and shape, but they are different in chemical composition from prokaryotic cell walls. Fungal cell walls have a thick, inner layer of polysaccharide fibers composed of chitin or cellulose and a thin outer layer of mixed glycans. The cell walls of algae are quite varied in chemical composition. Substances commonly found in various algal cell walls include various forms of sugar, such as cellulose, pectin,¹ and mannans,² along with minerals such as silicon dioxide and calcium carbonate.

The Cytoplasmic Membrane

The cytoplasmic (cell) membrane of eukaryotic cells is a typical bilayer of phospholipids in which protein molecules are embedded (see figures 2.20 and 4.17). In addition to phospholipids, eukaryotic membranes also contain *sterols* of various kinds. Sterols are different

1. A polysaccharide composed of galacturonic acid subunits.

2. A polymer of the sugar known as mannose.

TABLE 5.2 Function of External and Boundary Structures of the Eukaryotic Cell

Cilia and flagella	Cell movement
Glycocalyx	Adherence to surfaces; development of biofilms and mats; protection
Cell wall	Structural support and shape
Cytoplasmic membrane	Selective permeability; cell-cell interactions; adhesion to surfaces; signal transduction

from phospholipids in both structure and behavior, as you may recall from chapter 2. Their relative rigidity confers stability on eukaryotic membranes. This strengthening feature is extremely important in cells that lack a cell wall. Cytoplasmic membranes of eukaryotes are functionally similar to those of prokaryotes, serving as selectively permeable barriers in transport. Unlike prokaryotes, eukaryotes have extensive membrane-bound structures that can account for 60% to 80% of the membrane's volume. These structures, primarily proteins and carbohydrates, are responsible for interactions between cells, adhesion to surfaces, secretion of products made within the cell, and communication between the cell and its environment (signal transduction).

Check Your Progress SECTIONS 5.1 AND 5.2

1. Briefly explain how the eukaryotic cell could have evolved from prokaryotic ones.
2. Which kingdoms of the five-kingdom system contain eukaryotic microorganisms?
3. How do unicellular, colonial, and multicellular organisms differ from each other? Give examples of each type.
4. How are flagella and cilia similar? How are they different?
5. Which eukaryotic cells have a cell wall?
6. What are the functions of the glycocalyx, cell wall, and membrane?

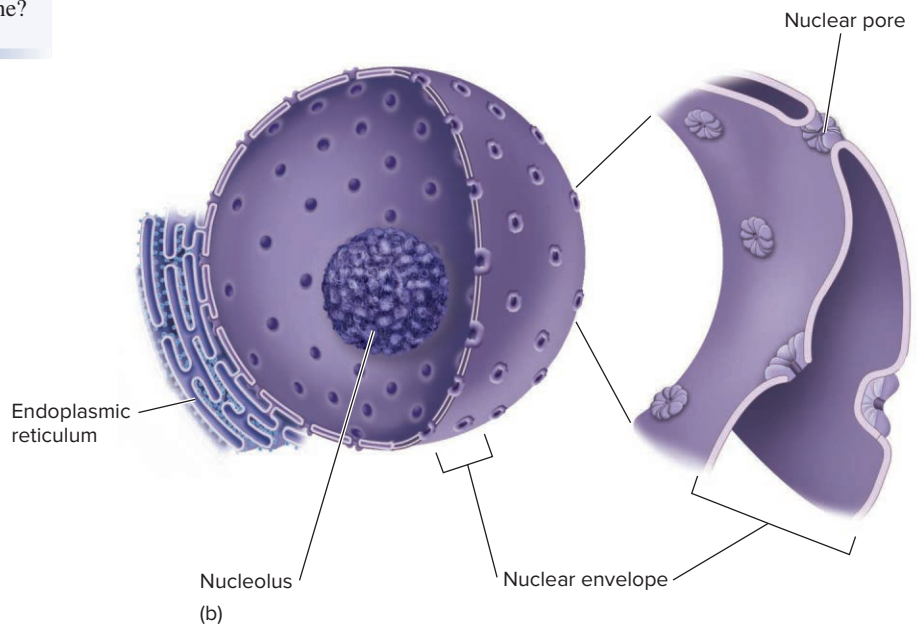

Figure 5.6 The nucleus. (a) Electron micrograph section of an interphase nucleus, showing its most prominent features. (b) Cutaway three-dimensional view of the relationships of the nuclear envelope, pores, and endoplasmic reticulum. (a): © Don W. Fawcett/Science Source

5.3 Form and Function of the Eukaryotic Cell: Internal Structures

Expected Learning Outcomes

9. Describe the structure of the nucleus and its outstanding features.
10. Outline the stages in cell division and mitosis.
11. Describe the structure of the two types of endoplasmic reticulum and their functions.
12. Identify the parts of the Golgi apparatus, and explain its basic actions and uses in the cell.
13. Summarize the stages in processing by the nucleus, endoplasmic reticulum, and Golgi apparatus involved in synthesis, packaging, and export.
14. Describe the structure of a mitochondrion, and explain its importance and functions.
15. Describe the structure of chloroplasts, and explain their importance and functions.
16. Discuss features of eukaryotic ribosomes.
17. Indicate the basic structure of the cytoskeleton, and explain its main features and functions.

The Nucleus: The Control Center

The **nucleus** is a large compact body that is the most prominent organelle of eukaryotic cells. It is separated from the cell cytoplasm by an external boundary called a **nuclear envelope** or membrane. The envelope has a unique architecture. It is composed of two parallel membranes separated by a narrow space, and it is perforated with small, regularly spaced openings, or pores, at sites where the two membranes unite (**figure 5.6**). The pores are structured to serve as selective passageways for molecules to migrate between the nucleus

Process Figure 5.7 Changes in the cell and nucleus during mitosis of a eukaryotic cell. (1) Before mitosis (at interphase), chromosomes are visible only as chromatin. (2) As mitosis proceeds (early prophase), chromosomes take on a fine, threadlike appearance as they condense, and the nuclear membrane and nucleolus are temporarily disrupted. (3)–(4) By metaphase, the chromosomes are fully visible as X-shaped structures. The shape is due to duplicated chromosomes attached at a central point, the centromere. (5)–(6) Spindle fibers attach to these and facilitate the separation of individual chromosomes during anaphase. (7)–(8) Telophase completes chromosomal separation and division of the cell proper into daughter cells. Note: This mechanism is how wall-free cells divide. Cells with walls will have a different pattern.

and cytoplasm. The main body of the nucleus consists of a matrix called the nucleoplasm and a granular mass, the **nucleolus**. The nucleolus is the site for ribosomal RNA synthesis and a collection area for ribosomal subunits. The subunits are transported through the nuclear pores into the cytoplasm for final assembly into ribosomes.

A prominent feature of the nucleoplasm in stained preparations is a network of dark fibers known as **chromatin** because of its attraction for dyes. Chromatin consists primarily of DNA, along with many small proteins called **histones**. **Chromosomes**, the large structures within the nucleus of eukaryotic cells that contain the genetic information of the cell are composed of chromatin. In non-dividing cells, the chromosomes within the nucleus are not readily visible because they are long, linear DNA molecules bound in varying degrees to histone proteins, and are far too fine to be resolved as distinct structures without extremely high magnification. During **mitosis**, however, when the duplicated chromosomes are separated equally into daughter cells, the chromosomes themselves become

readily visible as discrete bodies (**figure 5.7**). This appearance arises when the DNA becomes highly condensed by forming coils and supercoils around the histones to prevent the chromosomes from tangling as they are separated into new cells. This process is described in more detail in chapter 9.

Although we correctly view the nucleus as the primary genetic center, it does not function in isolation. As we show in the next three sections, it is closely tied to cytoplasmic organelles that perform elaborate cell functions.

Endoplasmic Reticulum: A Passageway and Production System for Eukaryotes

The **endoplasmic reticulum (ER)** is an interconnected network of membranous, hollow sacs that synthesize and transport cell substances (**figure 5.8a**). Originating from, and continuous with, the outer membrane of the nuclear envelope, the ER serves as a passageway for

Figure 5.8 The origin and structures of the rough endoplasmic reticulum (RER) and Golgi apparatus. (a) Schematic view of the origin of the endoplasmic reticulum from the outer membrane of the nuclear envelope. (b) Three-dimensional projection of the RER. (c) Detail of the orientation of a ribosome on the RER membrane. Proteins are collected within the RER cisternae and distributed through its network to other destinations. (d) The flattened layers of the Golgi apparatus receive protein-carrying transport vesicles from the RER, process their contents, and transport condensing vesicles to sites of various cellular functions.

materials between the nucleus and the cytoplasm. It also provides significant compartmentalization for numerous cell activities. The two types of endoplasmic reticulum are the **rough endoplasmic reticulum (RER)** and the **smooth endoplasmic reticulum (SER)**. These two ER networks are similar in origin and are directly connected to each other, but they differ in some aspects of structure and function.

The RER consists of parallel, flattened sacs called **cisternae**,* and it appears “rough” in electron micrographs because its outer surface is studded with ribosomes (figure 5.8b). This architecture ties in with its role in synthesis of proteins, which are collected in the lumen (figure 5.8c) of the cisternae and processed for further transport to the Golgi apparatus (figure 5.8d). The SER lacks ribosomes and is more tubular in structure (see figures 5.3 and 5.8a). Although it communicates with the RER and also transports molecules within the cell, it has specialized functions. Most important among them

are the synthesis of nonprotein molecules such as lipids, and detoxification of metabolic waste products and other toxic substances.

Golgi Apparatus: A Packaging Machine

The **Golgi³ apparatus**, also called the **Golgi complex** or body, is the site in the cell that collects proteins and packages them for transport to their final destinations. It is a discrete organelle consisting of layers of flattened, disc-shaped sacs also called cisternae, giving an appearance of a stack of pita breads. These sacs have outer limiting membranes and cavities like those of the endoplasmic reticulum, but they do not form a continuous network (figure 5.8d). This organelle is always closely associated with the endoplasmic reticulum both in its location and function. At a site where it

* *cisternae* (siss-tur'-nee) L., *cisterna*, reservoir.

3. *golgi* (gol'-jee) Named for C. Golgi, an Italian histologist who first described the apparatus in 1898.

Figure 5.9 The synthesis and transport machine. Function requires cooperation and interaction among the system of organelles. The nucleolus provides a constant supply of ribosomes that travel through the nuclear pores to the RER. Once in place, ribosomes synthesize proteins that are assembled by the RER into vesicles and moved to the nearby Golgi. Finished vesicles leave the Golgi after processing and migrate to the cell membrane. From there they may be secreted (as here) or act internally.

borders on the Golgi apparatus, the endoplasmic reticulum buds off tiny membrane-bound packets of protein called **transport vesicles** that are picked up by the forming face of the Golgi apparatus. Once in the complex itself, the proteins are further modified for transport by the addition of polysaccharides and lipids. The final action of this apparatus is to pinch off finished **condensing vesicles** that will be conveyed to organelles such as lysosomes or transported outside the cell as **secretory vesicles** (figure 5.9).

Nucleus, Endoplasmic Reticulum, and Golgi Apparatus: Nature's Assembly Line

As the keeper of the eukaryotic genetic code, the nucleus ultimately governs and regulates all cell activities. But because the nucleus remains fixed in a specific cellular site, it must direct these activities through a structural and chemical network (figure 5.9). This network includes ribosomes, which originate in the nucleus, and the rough endoplasmic reticulum, which is continuously connected with the nuclear envelope.

Initially, a segment of the genetic code of DNA containing the instructions for producing a protein is copied into RNA and passed out through the nuclear pores directly to the ribosomes on the endoplasmic reticulum. Here, specific proteins are synthesized from the RNA code and deposited in the lumen (space) of the endoplasmic reticulum. Details of this process are covered in chapter 9. After being transported to the Golgi apparatus, the protein products are

chemically modified and packaged into **vesicles*** that can be used by the cell in a variety of ways. Some of the vesicles contain enzymes to digest food inside the cell; other vesicles are secreted to digest materials outside the cell; and yet others are important in the enlargement and repair of the cell wall and membrane.

A **lysosome*** is one type of vesicle originating from the Golgi apparatus that contains a variety of enzymes. Lysosomes are involved in intracellular digestion of food particles and in protection against invading microorganisms. They also participate in digestion and removal of cell debris in damaged tissue.

Other types of vesicles include **vacuoles,*** which are membrane-bound sacs containing fluids or solid particles to be digested, excreted, or stored. They are formed in phagocytic cells (certain white blood cells and protozoa) in response to food and other substances that have been engulfed. The contents of a food vacuole are digested through the merger of the vacuole with a lysosome. This merged structure is called a phagosome (figure 5.10). Other types of vacuoles are used in storing reserve food such as fats and glycogen. Protozoa living in freshwater habitats regulate osmotic pressure by means of contractile vacuoles, which regularly expel excess water that has diffused into the cell (discussed in section 7.3).

Mitochondria: Energy Generators of the Cell

None of the cellular activities of the genetic assembly line could proceed without a constant supply of energy, the bulk of which is generated in most eukaryotes by **mitochondria.*** When viewed with light microscopy, mitochondria appear as tiny round or elongated particles scattered throughout the cytoplasm. Higher magnification reveals that a mitochondrion consists of a smooth, continuous outer membrane that forms the external contour and an inner, folded membrane nestled neatly within the outer membrane (figure 5.11). The folds on the inner membrane, called **cristae,*** vary in exact structure among eukaryotic cell types. Plant, animal, and fungal mitochondria have lamellar cristae folded into shelflike layers. Those of algae and protozoa are tubular, fingerlike projections or flattened discs.

The cristae membranes hold the enzymes and electron carriers of aerobic respiration. This is an oxygen-using process that extracts chemical energy contained in nutrient molecules and stores it in the form of high-energy molecules, or ATP. More detailed functions of mitochondria are covered in chapter 8. The spaces around the cristae are filled with a chemically complex fluid called the **matrix,*** which holds ribosomes, DNA, and a pool of enzymes and other compounds involved in the metabolic cycle. Mitochondria (along with chloroplasts) are unique among organelles in that they divide independently of the cell, contain circular strands of DNA, and have prokaryote-sized 70S ribosomes. These findings have given support to the endosymbiotic theory of their evolutionary origins discussed in section 5.1.

Chloroplasts: Photosynthesis Machines

Chloroplasts are remarkable organelles found in algae and plant cells that are capable of converting the energy of sunlight into

* **vesicle** (ves'-ik-l) L. *vesios*, bladder. A small sac containing fluid.

* **vacuole** (vak'-yoo-ohl) L. *vacuus*, empty. Any membranous space in the cytoplasm.

* **mitochondria** (my''-toh-kon'-dree-uh) sing. mitochondrion; Gr. *mitos*, thread, and *chondrion*, granule.

* **cristae** (kris'-te) sing. *crista*; L. *crista*, a comb.

* **matrix** (may'-triks) L. *mater*, mother or origin.

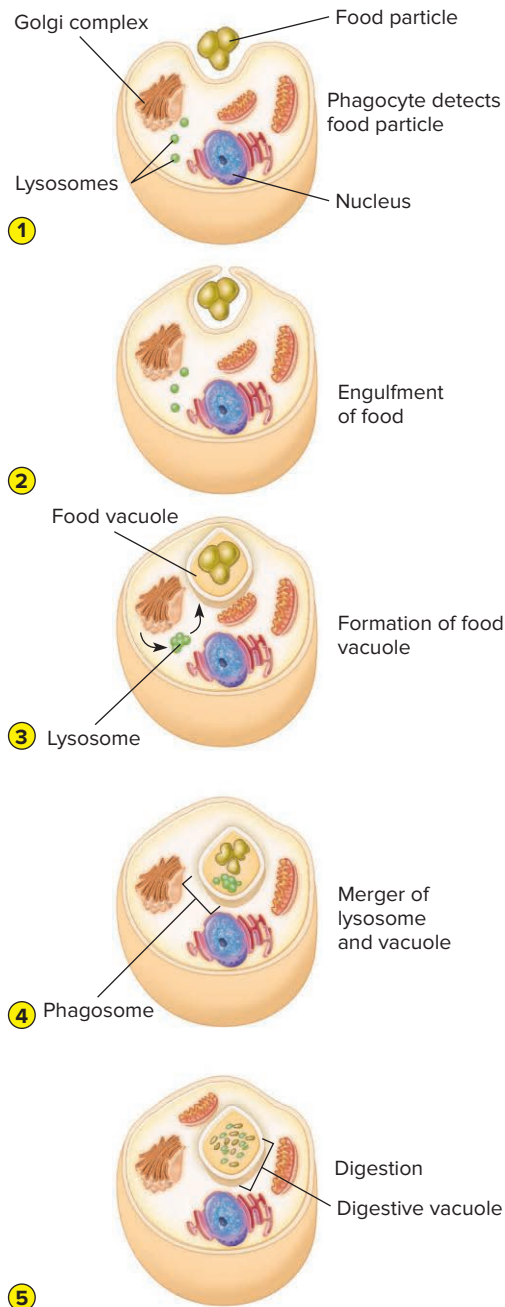

Figure 5.10 The functions of lysosomes during phagocytosis.

chemical energy through photosynthesis. The photosynthetic role of chloroplasts makes them important primary producers of organic nutrients upon which all other organisms (except certain bacteria and archaea) ultimately depend. Another important photosynthetic product of chloroplasts is oxygen gas. Although chloroplasts resemble mitochondria, chloroplasts are larger, contain special pigments, and are much more varied in shape. Be reminded that chloroplasts are thought to have originated from intracellular cyanobacteria and resemble them in many ways.

There are differences among various algal chloroplasts, but most are generally composed of two membranes, one enclosing the other. The smooth, outer membrane completely covers an inner membrane folded into small, disc-like sacs called **thylakoids** that are stacked

(a)

(b)

Figure 5.11 General structure of a mitochondrion. (a) An electron micrograph of a cross section. In most cells, mitochondria are elliptical or spherical, or occasionally filament-like. upon one another into **grana**. These structures carry the green pigment chlorophyll and sometimes additional pigments as well. Surrounding the thylakoids is a ground substance called the **stroma*** (figure 5.12). The role of the photosynthetic pigments is to absorb and transform solar energy into chemical energy, which is then used during reactions in the stroma to synthesize carbohydrates. We further explore some important aspects of photosynthesis in chapters 7 and 8.

Ribosomes: Protein Synthesizers

In an electron micrograph of a eukaryotic cell, ribosomes are numerous, tiny particles that give a “dotted” appearance to the cytoplasm. Ribosomes are distributed in two ways: Some are scattered freely in the cytoplasm and cytoskeleton; others are intimately associated with the rough endoplasmic reticulum, as previously described. Multiple ribosomes are often found arranged in short

* *stroma* (stroh'-mah) Gr. *stroma*, mattress or bed.

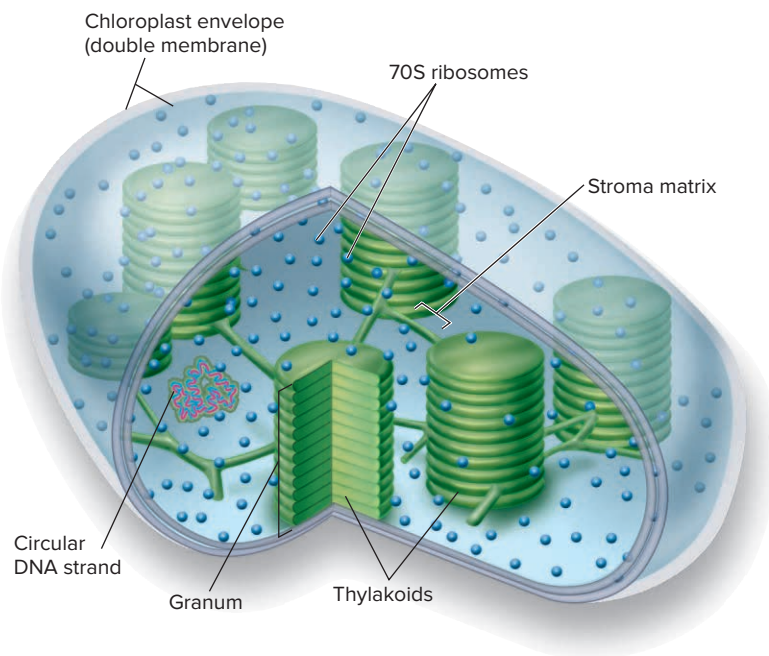

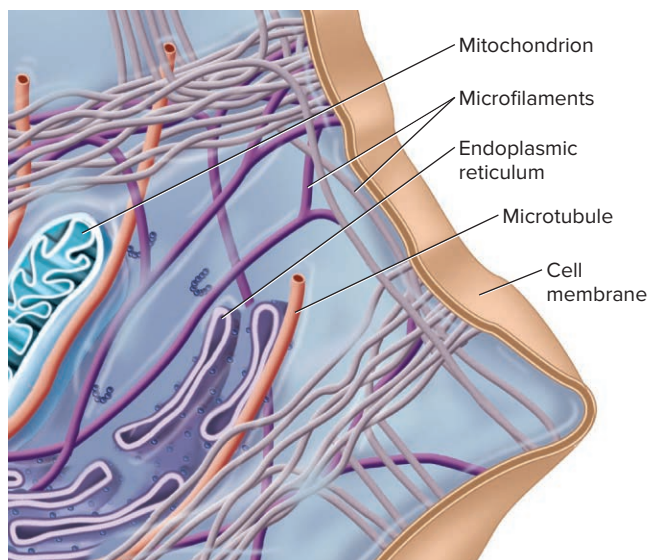

Figure 5.12 Details of an algal chloroplast. An artist's three-dimensional rendition of a chloroplast and its major features.

chains called polyribosomes (polysomes). The basic structure of eukaryotic ribosomes is similar to that of prokaryotic ribosomes, described in chapter 4. Both are composed of large and small subunits of ribonucleoprotein (see figure 5.8). By contrast, however, the ribosomes of eukaryotes (except in the mitochondria and chloroplasts) are of the larger 80S variety that is a combination of 60S and 40S subunits. As in the prokaryotes, eukaryotic ribosomes are the staging areas for protein synthesis.

The Cytoskeleton: A Support Network

All cells share a generalized region encased by the cell membrane called the cytoplasm or, in eukaryotic cells, the **cytoplasmic matrix**.

(a)

TABLE 5.3 Function of Internal Structures within the Eukaryotic Cell	
Nucleus	Genetic center of the cell; repository of DNA; synthesis of RNA
Nucleolus	Ribosomal RNA synthesis; ribosome construction
Endoplasmic reticulum	Transport of materials; lipid synthesis
Golgi apparatus	Packaging and modification of proteins prior to secretion
Lysosomes	Intracellular digestion
Vacuoles	Temporary storage and transport; digestion (food vacuoles); regulation of osmotic pressure (water vacuoles)
Mitochondria	Energy production using the Krebs cycle, electron transport, and oxidative phosphorylation
Chloroplast	Conversion of sunlight into chemical energy through photosynthesis
Ribosomes	Protein synthesis
Cytoskeleton	Composed of microfilaments and microtubules; provides cell structure and movement; anchors organelles

This complex area houses the organelles and sustains major metabolic and synthetic activities. It also contains the framework of support in cells lacking walls. The matrix is interwoven by a flexible framework of molecules called the **cytoskeleton (figure 5.13)**. This framework appears to have several functions, such as anchoring organelles, providing support, and permitting shape changes and movement in some cells. The two main types of cytoskeletal elements are *microfilaments* and *microtubules*.

Microfilaments are thin strands composed of the protein actin that attach to the cell membrane and form a network through the

(b)

(b) The cytoskeleton of a large eukaryotic cell is highlighted by fluorescent dyes. Microtubules are stained green, microfilaments are red, and the nucleus is blue. (b): Courtesy of Life Technologies, Carlsbad, CA

cytoplasm. Some microfilaments are responsible for movements of the cytoplasm, often made evident by the streaming of organelles around the cell in a cyclic pattern. Other microfilaments are active in *amoeboid motion*, a type of movement, typical of cells such as amoebas and phagocytes, that produces extensions of the cell membrane (pseudopods) into which the cytoplasm flows.

Microtubules are long, hollow tubes that maintain the shape of eukaryotic cells such as protozoa that lack cell walls. They may also serve as an alternative transport system for molecules. The spindle fibers that play an essential role in mitosis are actually microtubules that attach to chromosomes and separate them into daughter cells. As indicated earlier, microtubules are also responsible for the movement of cilia and flagella.

Check Your Progress SECTION 5.3

- In what ways does the nucleus function like the “brain” of the cell?
- Explain how ribosomes and the nucleolus are related.
- How does the nucleus communicate with the cytoplasm?
- Compare and contrast the smooth ER, the rough ER, and the Golgi apparatus in structure and function.
- Compare the structures and functions of the mitochondrion and the chloroplast.

- What makes the mitochondrion and chloroplast unique among the organelles?
- Describe some of the ways that organisms use lysosomes.
- For what reasons would a cell need a “skeleton”?

5.4 Eukaryotic-Prokaryotic Comparisons and Taxonomy of Eukaryotes

Expected Learning Outcomes

- Compare and contrast prokaryotic cells, eukaryotic cells, and viruses.
- Outline the basics of eukaryotic taxonomy.
- Explain what is meant by the term *protist*, and outline the types of organisms belonging to this designation.

Now that we have introduced the major characteristics of eukaryotic cells, in this section we will summarize these characteristics and compare and contrast them with prokaryotic cells (see chapter 4), especially from the standpoints of structure, physiology, and other traits (**table 5.4**). We have included viruses for the purposes of summarizing the biological characteristics of all microbes and to show you just

how much viruses differ from cells. We will explore this fascinating group of microbes in chapter 6.

Overview of Taxonomy

Exploring the origins of eukaryotic cells with molecular technology has significantly clarified our understanding of relationships among the organisms in Domain Eukarya. The phenetic characteristics traditionally used for placing plants, animals, and fungi into separate kingdoms are general cell type, level of organization or body plan, and nutritional type. It now appears that these criteria really do reflect accurate differences among these organisms and give rise to the same basic kingdoms, as do genetic tests using ribosomal RNA (see figure 1.15).

Because our understanding of the phylogenetic relationships is still in development, there is not yet a single official system of taxonomy for presenting all of the eukaryotes. One of the proposed alternate plans of classification is shown in **figure 5.14**. This simplified system, also based on data from ribosomal RNA analysis, retains some of the traditional kingdoms.

The one group that has created the greatest challenge in establishing reliable relationships is **Kingdom Protista**—the protists. Any simple eukaryotic cell that lacked multicellular structure or cell specialization has been placed into the Kingdom Protista generally as an alga (photosynthetic) or protozoan (nonphotosynthetic). Although exceptions arise with this classification scheme—notably multicellular algae and the photosynthetic protozoans—most eukaryotic microbes have been readily accommodated in the Kingdom Protista as traditionally presented.

Newer genetic data reveal that the organisms we call protists may be as different from each other as plants are different from animals. They are highly complex organisms that are likely to have evolved from a number of separate ancestors.

Microbiologists prefer to set up taxonomic systems that reflect true relationships based on all valid scientific data, including genotypic, molecular, morphological, physiological, and ecological. As a result, several alternative taxonomic strategies are being proposed to deal with this changing picture. The number of new kingdoms suggested for distributing the protists range from five to 25 or more.

Note that figure 5.14 compares an rRNA-based system as first outlined in chapter 1 alongside the original Kingdom Protista with its assorted phyla and divisions. One advantage of this original plan is that it continues to use most of the original taxa at the phylum, division, and lower levels, especially as they relate to medically significant microbial groups. We feel the term **protist** is still a useful shorthand reference and will continue to use it for any eukaryote that is not a fungus, animal, or plant.

In the interest of space and ease in presentation, we have adopted a system of taxonomy that emphasizes natural groupings with

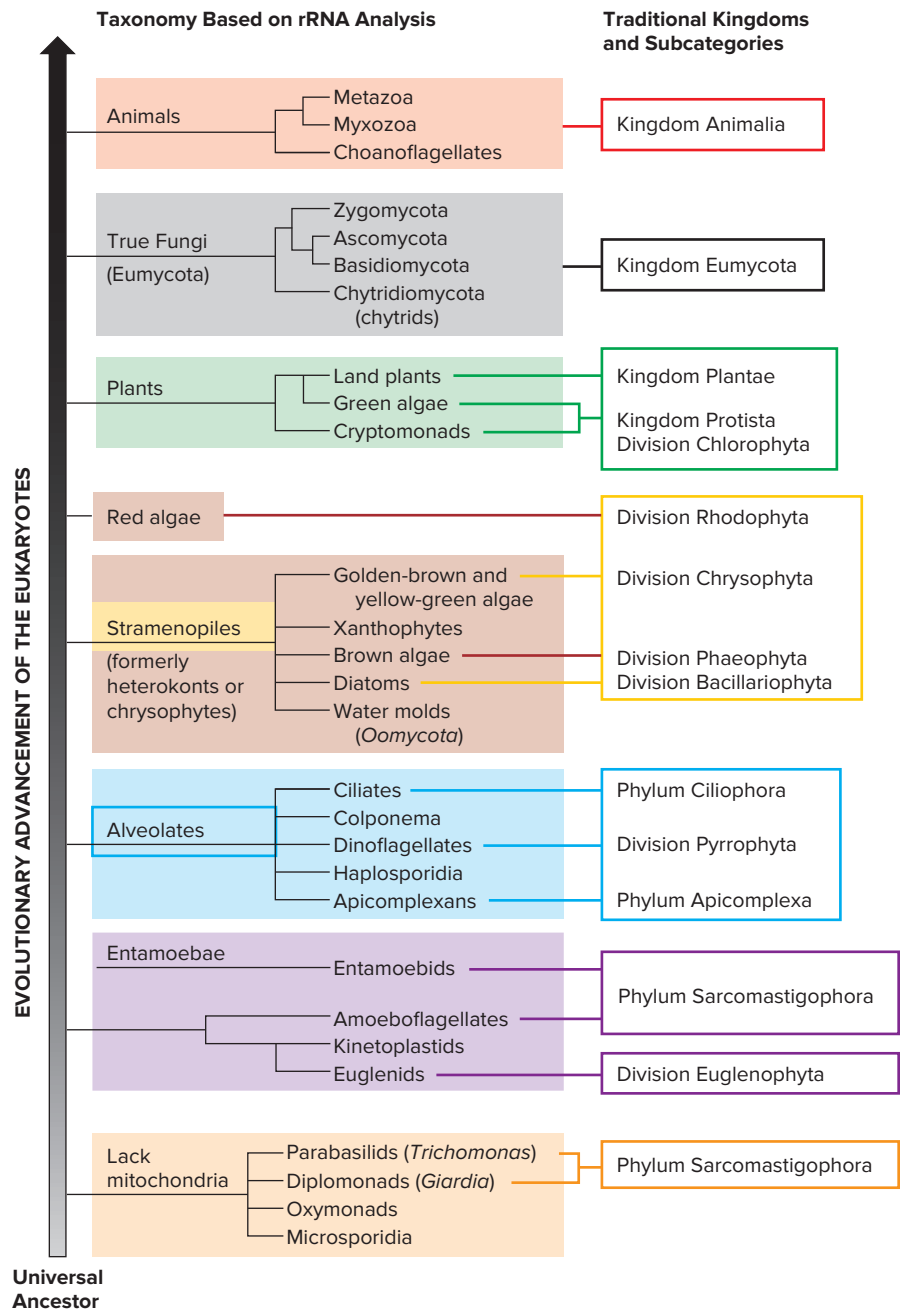

Figure 5.14 RNA-based phylogenetic tree and taxonomy of Domain Eukarya. A comparison of two possible systems for presenting the taxonomy of major eukaryotic groups. This textbook will largely follow the simpler system on the right, using Kingdoms, Divisions, and Phyla to separate the groups of eukaryotes.

the least complexity. A final note about taxonomy: No one system is perfect or permanent. Let your instructor guide you as to which one is satisfactory for your course.

With the general structure of the eukaryotic cell in mind, let us next examine the range of adaptations that this cell type has undergone. The following sections contain a general survey of the principal eukaryotic microorganisms—fungi, algae, protozoa, and parasitic worms—while also introducing elements of their structure, life history, classification, identification, and importance. A survey of diseases associated with some of these microbes is found in chapters 22 and 23.

5.5 The Kingdom of the Fungi

Expected Learning Outcomes

21. Describe the basic characteristics of the Kingdom Fungi in terms of general types of cells and organisms, structure, and nutrition.
22. Differentiate between characteristics of yeasts and of molds, and define fungal spores.
23. Classify types of fungal spores and explain their functions.
24. Discuss the main features of fungal classification and representative examples of each group.
25. Explain how fungi are identified.
26. Discuss the importance of fungi in ecology, agriculture, commerce, and medicine.

The position of the **fungi*** in the biological world has been debated for many years. They were originally classified with the green plants (along with algae and bacteria), and later they were placed in a group with algae and protozoa (the Protista). Even at that time, however, many microbiologists were struck by several unique qualities of fungi that warranted placement into a separate kingdom. Confirmation of their status by genetic testing eliminated any question that they belong in a kingdom of their own.

* *fungi* (fun'-jy) sing. fungus; Gr. *fungos*, mushroom.

The **Kingdom Fungi**, or **Eumycota**, is filled with organisms of great variety and complexity that have survived on earth for approximately 650 million years. About 100,000 species are known, although experts estimate a count much higher than this—perhaps as high as 1.5 million. For practical purposes, mycologists divide the fungi into two groups: the *macroscopic fungi* (mushrooms, puffballs, gill fungi) and the *microscopic fungi* (molds, yeasts). Although the majority of fungi are either unicellular or colonial, a few complex forms such as mushrooms and puffballs are considered multicellular.

Chemical traits of fungal cells include the possession of a polysaccharide, **chitin**, in their cell walls and a sterol, ergosterol, in their cell membranes. Cells of the microscopic fungi exist in two basic morphological types: hyphae and yeasts. **Hyphae*** are long, threadlike cells that make up the bodies of filamentous fungi, or **molds** (**figure 5.15**). A **yeast** cell is distinguished by its round to oval shape and by its mode of asexual reproduction. It grows swellings on its surface called buds, which then become separate cells (**figure 5.16a**). Some species form a **pseudohypha***, a chain of yeasts formed when buds remain attached in a row (**figure 5.16c**); because of its manner of formation, it is not a true hypha like that of molds. Although some fungal cells exist only in a yeast form and others occur primarily as hyphae, a few, called **dimorphic***, can take either form, depending upon growth conditions, such as changing temperature. This variability in growth form is particularly characteristic of some pathogenic molds.

* *hyphae* (hy'-fuh) pl. hyphae (hy'-fee); Gr. *hyphe*, a web.

* *pseudohypha* (soo'-doh-hy'-fuh) pl. pseudohyphae; Gr. *pseudo*, false, and *hyphe*.

* *dimorphic* (dy-mor'-fik) Gr. *di*, two, and *morphe*, form.

Fungal Nutrition

All fungi are **heterotrophic**.^{*} They acquire nutrients from a wide variety of organic sources or **substrates** (figure 5.17). Most fungi are **saprobies**,^{*} meaning that they obtain these substrates from the remnants of dead plants and animals in soil or aquatic habitats. Fungi can also be parasites on the bodies of living animals or plants, although very few fungi absolutely require a living host. In general, the fungus penetrates the substrate and secretes enzymes that reduce it to small molecules that can be absorbed. Fungi have enzymes for digesting an incredible

^{*} *heterotrophic* (het-ur-oh-tro'-fik) Gr. *hetero*, other, and *troph*, to feed. A type of nutrition that relies on an organic nutrient source.

5.1 Secret World of Microbes

Fungi: A Force of Nature

Life in the Fungal Jungle

Fungi are among the most prolific microbes on earth. So dominant are they that, by one estimate, the average topsoil contains nearly 9 tons of fungal mycelia per acre. In this habitat, they associate with a wide variety of other organisms, from bacteria to animals to plants.

The activities of fungi under natural conditions include nutritional and protective interactions with plants and algae, decomposition of organic matter and recycling of the minerals it contains, and contributions to biofilm networks that are needed to successfully colonize new habitats.

Some fungi have developed into normal residents of plants called endophytes. These fungi live inside the tissues of the plant itself and protect it against disease, presumably by secreting chemicals that deter infections by other, pathogenic fungi. Understanding the roles of endophytes promises to open up a new field of biological control to inoculate plants with harmless fungi rather than using more toxic fungicides.

Lichens are unusual hybrid organisms that form when a fungus combines with a photosynthetic microbe, either an alga or a cyanobacterium. The fungus acquires nutrients from its smaller partner and probably provides a protective haven that favors survival of the lichen body. Lichens occur in most habitats on earth, but they are especially important as early invaders of rock and in soil formation. Fungi also interact with animals in their habitats, most notably with small roundworms, called nematodes, and insects. Several species of molds prey upon or parasitize nematodes.

Is There a Fungus in the House?

The fact that fungi are so widespread also means that they frequently share human living quarters, especially in locations that provide ample moisture and nutrients. Often their presence is harmless and limited to a film of mildew on shower stalls or in other moist environments.

In some cases, depending on the amount of contamination and the type of mold, these indoor fungi can also give rise to various medical problems. Such common air contaminants as *Aspergillus*, *Cladosporium*, and *Stachybotrys* all have the capacity to give off airborne spores and toxins that, when inhaled, cause a whole spectrum of symptoms sometimes referred to as “sick building syndrome.” The usual source of harmful fungi is the presence of chronically water-damaged walls, ceilings, and other building materials that have come to harbor these fungi. People exposed to these houses or buildings report symptoms that range from

Mycelium and spores in the ascomycete *Stachybotrys*. This black mold (400×) is implicated in building contamination that leads to toxic diseases. © Neil Carlson, Department of Environmental Health and Safety

skin rash, flulike reactions, sore throat, and headaches to fatigue, diarrhea, allergies, and immune suppression.

Bat Populations Decimated by Fungal Infections

For several years wildlife personnel and animal experts have reported mass deaths of bats in caves throughout the Northeast and some parts of the southern United States. At first the cause was not clear, but workers observed a whitish growth on the muzzle of the dead bats and called the condition “white nose syndrome.” Closer inspection revealed that the white growth was *Pseudogymnoascus destructans*, a newly recognized fungal pathogen that inhabits the caves where bats hibernate. The animals apparently became infected in the winter, and by spring they were already dead or sick and dying. By 2015 the infection had been noted in 25 states, and bat populations in the Northeast had declined by approximately 80%. Unfortunately, little can be done at this point, because the infection is spread from bat to bat and no viable treatment is possible. Though many people might at first not be concerned by losses in the bat population, bats are the primary predator of insects, and the agricultural damage from unsuppressed insect populations has been estimated at up to \$50 billion per year in the United States.

What characteristics of fungi allow them to spread into such a wide variety of habitats? Answer available on Connect.

Organization of Microscopic Fungi

The cells of most microscopic fungi grow in loose associations or colonies. The colonies of yeasts are much like those of bacteria in that they have a soft, uniform texture and appearance. The colonies of filamentous fungi are noted for the striking cottony, hairy, or velvety textures that arise from their microscopic organization and morphology. The woven, intertwining mass of hyphae that makes up the body or colony of a mold is called a **mycelium**.*

array of substances, including feathers, hair, cellulose, petroleum products, wood, even rubber. It is likely that every naturally occurring organic material on the earth can be attacked by some type of fungus.

Fungi are often found in nutritionally poor or adverse environments. Various fungal types thrive in substrates with higher amounts of salt, sugar, or acid content, at relatively high temperatures, and even in snow and glaciers.

The medical and agricultural impact of fungi is extensive. A number of species cause **mycoses** (fungal infections) in animals, and thousands of species are important plant pathogens. Fungal toxins may cause disease in humans, and airborne fungi are a frequent cause of allergies and other medical conditions (**5.1 Secret World of Microbes**).

* *mycelium* (my'-see-lee-yum) pl. mycelia; Gr. *mykes*, root word for fungus.

Although hyphae contain the usual eukaryotic organelles, they also have some unique organizational features. In most fungi, the hyphae are divided into segments by cross walls, or **septa**, and such hyphae are referred to as septate (see figure 5.15c). The nature of the septa varies from solid partitions with no communication between the compartments to partial walls with small pores that allow the flow of organelles and nutrients between adjacent compartments. Nonseptate hyphae consist of one long, continuous cell *not* divided into individual compartments by cross walls. With this construction, the cytoplasm and organelles move freely from one region to another, and each hyphal element can have several nuclei (see figure 5.15c).

Hyphae can also be classified according to their particular function. Vegetative hyphae (mycelia) are responsible for the visible mass of growth that appears on the surface of a food source and penetrates it to digest and absorb nutrients. During the development of a fungal colony, the vegetative hyphae give rise to structures called reproductive, or fertile, hyphae that branch off vegetative mycelium. These hyphae are responsible for the production of fungal reproductive bodies called spores, discussed next. Other specializations of hyphae are illustrated in **figure 5.18**.

Reproductive Strategies and Spore Formation

Fungi have many complex and successful reproductive strategies. Most can propagate by the simple outward growth of existing

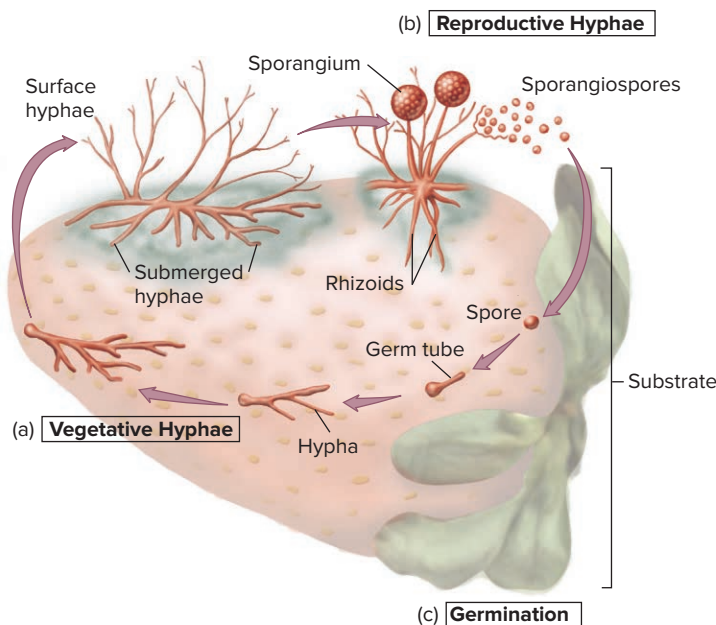

Figure 5.18 Functional types of hyphae using the mold *Rhizopus* as an example. (a) Vegetative hyphae are those surface and submerged filaments that digest, absorb, and distribute nutrients from the substrate. This species also has special anchoring structures called rhizoids. (b) Later, as the mold matures, it sprouts reproductive hyphae that produce asexual spores called sporangiospores. (c) During the asexual life cycle, the free mold spores settle on a substrate and send out germ tubes that elongate into hyphae that produce an extensive mycelium. So prolific are the fungi that a single colony of mold can easily contain 5,000 spore-bearing structures. If each of these released 2,000 single spores, and if every spore were able to germinate, we would soon find ourselves in a sea of mycelia. Most spores do not germinate, but enough are successful to keep the numbers of fungi and their spores very high in most habitats.

hyphae or by fragmentation, in which a separated piece of mycelium can generate a whole new colony. But the primary reproductive mode of fungi involves the production of various types of **spores**. Do not confuse fungal spores with the extremely resistant, nonreproductive bacterial endospores. Fungal spores function not only in multiplication but also in survival (providing genetic variation) and dissemination. Because of their compactness and relatively light weight, fungal spores are dispersed widely through the environment by air, water, and living things. Upon encountering a favorable substrate, a spore will germinate and produce a new fungal colony in a very short time (figure 5.18).

The fungi exhibit such a marked diversity in spores that they are largely classified and identified by their spores and spore-forming structures. Although there are some elaborate systems for naming and classifying spores, we present only a basic overview of the principal types. The most general subdivision is based on the way the spores arise. Asexual spores are the products of mitotic division of a single parent cell, and sexual spores are formed through a process involving the fusing of two parental nuclei followed by meiosis.

Asexual Spore Formation

On the basis of the nature of the reproductive hypha and the manner in which the spores originate, there are two subtypes of asexual spore (**figure 5.19**):

1. **Sporangiospores** (figure 5.19a) are formed by successive cleavages within a saclike head called a **sporangium**,* which is attached to a stalk, the sporangiophore. These spores are initially enclosed but are released when the sporangium ruptures. Some sporangiospores are the end result of the sexual phase of the life cycle as seen in figure 5.20.
2. **Conidia*** (conidiospores) are free spores not enclosed by a spore-bearing sac (figure 5.19b). They develop either by pinching off the tip of a special fertile hypha or by segmentation of a preexisting vegetative hypha. Conidia are the most common asexual spores, and they occur in these forms:

arthrospore (ar'-thro-spor) Gr. *arthron*, joint. A rectangular spore formed when a septate hypha fragments at the cross walls.

chlamydo-spore (klam-ih'-doh-spor) Gr. *chlamys*, cloak. A spherical conidium formed by the thickening of a hyphal cell. It is released when the surrounding hypha fractures, and it serves as a survival or resting cell.

blastospore. A spore produced by budding from a parent cell that is a yeast or another conidium; also called a bud.

phialospore (fy'-ah-lo-spor) Gr. *phialos*, a vessel. A conidium budded from the mouth of a vase-shaped spore-bearing cell called a phialide or *sterigma*, leaving a small collar.

microconidium and *macroconidium*. The smaller and larger conidia formed by the same fungus under varying conditions. Microconidia are one-celled, and macroconidia have two or more cells.

porospore. A conidium that grows out through small pores in the spore-bearing cell; some are composed of several cells.

* *sporangium* (spo-ran'-jee-um) pl. sporangia; Gr. *sporos*, seed, and *angeion*, vessel.

* *conidia* (koh-nid'-ee-uh) sing. conidium; Gr. *konidion*, a particle of dust.

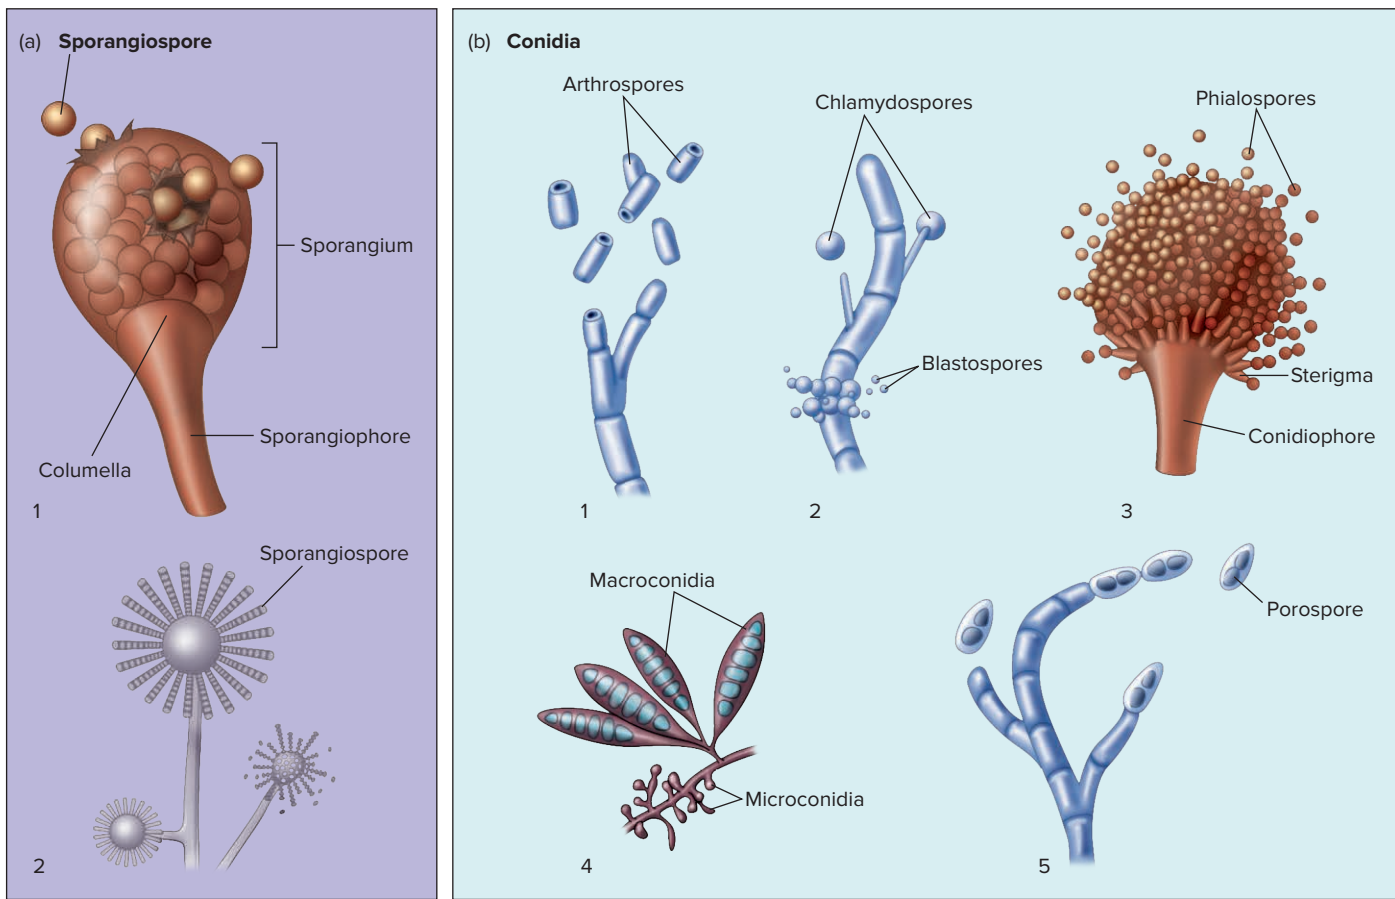

Figure 5.19 Types of asexual mold spores. (a) Sporangiospores: (1) *Absidia*, (2) *Syncephalastrum*, (table 5.5) (b) Conidia: (1) arthrospores (e.g., *Coccidioides*), (2) chlamydo- and blastospores (e.g., *Candida albicans*), (3) phialospores (e.g., *Aspergillus*, table 5.5), (4) macroconidia and microconidia (e.g., *Microsporium*, table 5.5), and (5) porospores (e.g., *Alternaria*).

Sexual Spore Formation

Because fungi can propagate successfully by producing millions of asexual spores, it is natural to wonder about the survival potential of sexual spores. The answer lies in important variations that occur when fungi of different genetic makeup combine their genetic material. As in plants and animals, a union of genes from two parents creates offspring with combinations of genes different from that of either parent. The offspring from such a union can have slight variations in form and function that are potentially advantageous to the adaptation and evolution of their species.

The majority of fungi produce sexual spores at some point. The nature of this process varies from the simple fusion of fertile hyphae of two different strains to a complex union of differentiated male and female structures and the development of special fruiting bodies. We consider the three most common sexual spores: zygospores, ascospores, and basidiospores. These spore types provide an important basis for classifying the major fungal divisions.

Zygospores* are sturdy diploid spores formed when hyphae of two opposite strains (called the plus and minus strains) fuse and create a diploid zygote that swells and becomes covered by strong, spiny walls (**figure 5.20**).

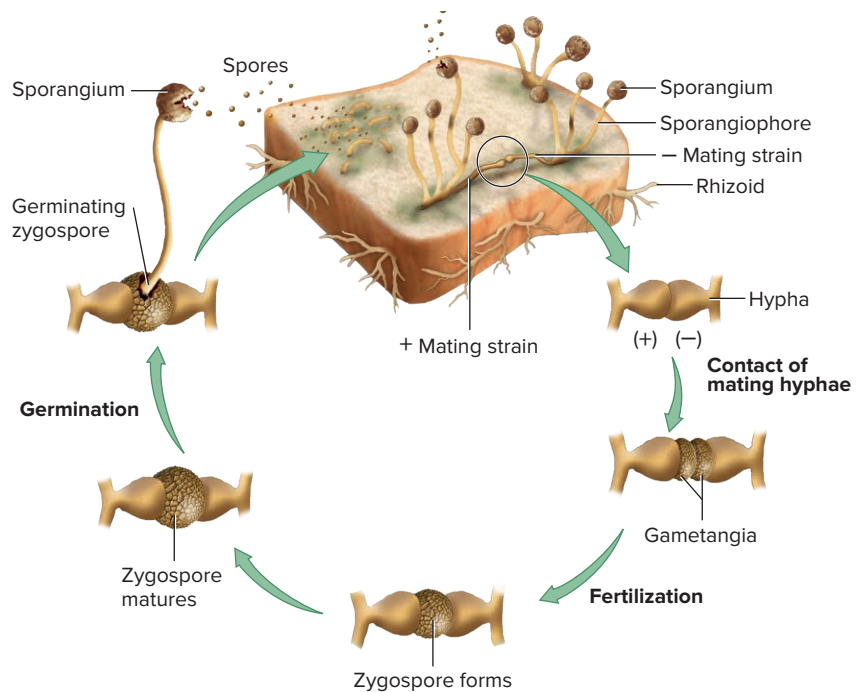

Figure 5.20 Formation of zygospores in *Rhizopus stolonifer*. Sexual reproduction occurs when two mating strains of hyphae grow together, fuse, and form a mature diploid zygospore. Germination of the zygospore involves production of a haploid sporangium that looks just like the asexual one shown in figure 5.19, but the individual spores contain genes from two different parents. So, in this case, the sporangiospores are the result of sexual recombination.

* *zygospores* (zy'-goh-sporz) Gr. *zygon*, yoke, to join.

When its wall is disrupted and moisture and nutrient conditions are suitable, the zygosporangium germinates and forms a mycelium that gives rise to a sporangium. Meiosis of diploid cells of the sporangium results in haploid nuclei that develop into sporangiospores. Both the sporangia and the sporangiospores that arise from sexual processes are outwardly identical to the asexual type, but because the spores arose from the union of two separate fungal parents, they are not genetically identical.

In general, haploid spores called **ascospores*** are created inside a special fungal sac, or **ascus** (pl. **asci**) (**figure 5.21**). Although details can vary among types of fungi, the ascus and ascospores are formed when two different strains or sexes join together to produce offspring. In many species, the male sexual organ fuses with the female sexual organ. The end result is a number of terminal cells called *dikaryons*, each containing a diploid nucleus. Through differentiation, each of these cells enlarges to form an ascus, and its diploid nucleus undergoes meiosis to form four to eight haploid nuclei that will mature into ascospores. A ripe ascus breaks open and releases the ascospores. Some species form an elaborate fruiting body to hold the asci (inset, figure 5.21).

Basidiospores* are haploid sexual spores formed on the outside of a club-shaped cell called a **basidium** (**figure 5.22**). In general, spore formation follows the same pattern of two mating types coming together, fusing, and forming terminal cells with diploid nuclei. Each of these cells becomes a basidium, and its nucleus produces, through

* *ascospores* (as'-koh-sporz) Gr. *ascos*, a sac.

* *basidiospores* (bah-sid'-ee-oh-sporz) Gr. *basidi*, a pedestal.

Figure 5.21 Production of ascospores in a cup fungus. Inset shows the cup-shaped fruiting body that houses the asci.

meiosis, four haploid nuclei. These nuclei are extruded through the top of the basidium, where they develop into basidiospores. Notice the location of the basidia along the gills in mushrooms, which are often dark from the spores they contain. It may be a surprise to discover that the fleshy part of a mushroom is actually a fruiting body designed to protect and help disseminate its sexual spores.

Fungal Classification

It is often difficult for microbiologists to assign logical and useful classification schemes to microorganisms that also reflect their evolutionary relationships. This difficulty is due to the fact that the organisms do not always perfectly fit the neat categories made for them, and even experts cannot always agree on the nature of the categories. The fungi are no exception, and there are several ways to classify them. For our purposes, we adopt a classification scheme with a medical mycology emphasis, in which the Kingdom Eumycota is subdivided into several phyla based upon the type of sexual reproduction, hyphal structure, and genetic profile. **Table 5.5** outlines the major phyla, their characteristics, and typical members.

Figure 5.22 The cycle of sexual spore formation in basidiomycota. A mushroom is one example to observe formation of the sexual spores. Following mating between parental hyphae underground, the mycelium gives rise to the fruiting body that we commonly identify as a mushroom. Under the cap are gills bearing club-shaped basidia which form and release basidiospores. Because they are genetically different, these basidiospores produce different parental hyphae that begin the cycle again.

TABLE 5.5 A Survey of Fungal Groups, Characteristics, and Representative Members

Phylum I—Zygomycota (also Zygomycetes)

- Sexual spores: zygospores
- Asexual spores: mostly sporangiospores, some conidia
- Hyphae are usually nonseptate. If septate, the septa are complete
- Most species are free-living saprobes; some are animal parasites
- Can be obnoxious contaminants in the laboratory, food spoilage agents, and destructive to crops
- Examples of common molds: *Rhizopus*, a black bread mold; *Mucor*; *Absidia*; *Circinella* (**figure A**, *Syncephalastrum*, and **figure B**, *Circinella*)

A. *Syncephalastrum*, a common inhabitant of soil and plants (400×). © Dennis Kunkel Microscopy, Inc./Phototake

B. A beautiful mold, *Circinella* is known for its curved sporangiophore (500×). © Kathy Park Talaro

Phylum II—Ascomycota (also Ascomycetes)

- Sexual spores: most produce ascospores in asci
- Asexual spores: many types of conidia, formed at the tips of conidiophores
- Hyphae with porous septa
- Examples: This is by far the largest phylum. Members vary from macroscopic mushrooms to microscopic molds and yeasts.
 - *Penicillium* is one source of antibiotics (see figure 5.17).
 - *Aspergillus* is a common airborne mold that may be involved in respiratory infections and toxicity (**figure C**).
 - *Saccharomyces* is a yeast used in making bread and beer (**figure D**).
 - Includes many human and plant pathogens, such as *Pneumocystis (carinii) jiroveci*, a pathogen of AIDS patients.
 - *Histoplasma* is the cause of Ohio Valley fever (see figure 1.3).
 - *Trichophyton* is one cause of ringworm, which is a common name for certain fungal skin infections that often grow in a ringed pattern (see figure 22.18).
 - *Coccidioides immitis* is the cause of Valley fever; *Candida albicans* is the cause of various yeast infections; and *Stachybotrys* is a toxic mold (see 5.1 Secret World of Microbes).

C. *Aspergillus fumigatus*, displaying its flowery conidial heads (600×). Source: CDC

D. X-ray photograph of *Saccharomyces* with a prominent nucleus (blue sphere) and bud (5,000×). Source: Carolyn Larabell. www.cellimagelibrary.org/images/143

Phylum III—Basidiomycota (also Basidiomycetes)

Many members are familiar macroscopic forms such as mushrooms and puffballs, but this phylum also includes a number of microscopic plant pathogens called rusts and smuts that attack and destroy major crops. This has extensive impact on agriculture and global food production.

- Sexual reproduction by means of basidia and basidiospores
- Asexual spores: conidia
- Incompletely septate hyphae
- Some plant parasites and one human pathogen
- Fleshy fruiting bodies are common.
- Examples: mushrooms (**figure E**), puffballs, bracket fungi, and plant pathogens (rusts and smuts)
- The one human pathogen, the yeast *Cryptococcus neoformans*, causes an invasive systemic infection in several organs, including the skin, brain, and lungs (**figure F**).

E. *Armillaria* (honey) mushrooms, sprouting from the base of a tree, arose from a vast underground mycelium that covers 2,200 acres and stretches 3.5 miles across. © Gregory M. Filip

F. *Cryptococcus neoformans*—a yeast that causes cryptococcosis (400×). Note the capsule around each cell. Source: Dr. Leanor Haley/CDC

Phylum IV—Chytridimycota

Members of this phylum are unusual, primitive fungi commonly called **chytrids**.^{*} Their cellular morphology ranges from single cells to clusters and colonies. They generally do not form hyphae or yeast-type cells. The one feature that most characterizes them is the presence of special flagellated spores, called zoospores and gametes. Most chytrids are saprobic and free-living in soil, water, and decaying matter. A significant number are parasites of plants, animals, and other microbes (**figure G**), but they are not known to cause human disease. They are known to be serious frog pathogens, often responsible for destroying whole populations in some habitats.

G. Parasitic chytrid fungi. The filamentous diatom *Chaetoceros* is attacked by flagellated chytrids that dissolve and destroy their host (400×). © Joyce E. Longcore, University of Maine

^{*} *chytrid* (kit'-rid) Gr. *chytridion*, little pot.

Fungi That Produce Only Asexual Spores (Imperfect)

From the beginnings of fungal classification, any fungus that lacked a sexual state was called “imperfect” and was placed in a catchall category, the Fungi Imperfecti. A species would remain classified in that category until its sexual state was described. Gradually many species were found to make sexual spores, and they were assigned to the taxonomic grouping that best fit those spores. In other cases they have been reassigned because genetic analysis indicated they belonged to an established phylum, usually to Ascomycota. This means that there is really no need for the “imperfect” taxon.

Fungal Identification and Cultivation

Fungi are identified in medical specimens by first being isolated on special types of media and then being observed macroscopically and microscopically. Examples of media for cultivating fungi are cornmeal, blood, and Sabouraud’s agar. The latter medium is useful in isolating fungi from mixed samples because of its low pH, which inhibits the growth of bacteria but not of most fungi. Because the fungi are classified into general groups by the presence and type of sexual spores, it would seem logical to identify them in the same way, but sexual spores are rarely if ever demonstrated in the laboratory setting. As a result, the asexual spore-forming structures and spores are usually used to identify organisms to the level of genus and species. Other characteristics that contribute to identification are hyphal type, colony texture and pigmentation, physiological characteristics, and genetic makeup.

Fungi in Medicine, Nature, and Industry

Nearly all fungi are free-living and do not require a host to complete their life cycles. Even among those fungi that are pathogenic, most human infection occurs through accidental contact with an environmental source such as soil, water, or dust. Humans are generally quite resistant to fungal infection, except for two main types of fungal pathogens: the primary pathogens, which can infect even healthy persons, and the opportunistic pathogens, which attack persons who are already weakened in some way.

Mycoses (fungal infections) vary in the way the agent enters the body and the degree of tissue involvement (**table 5.6**). The list of opportunistic fungal pathogens has been increasing in the past few years because of newer medical techniques that keep immunocompromised patients alive. Even so-called harmless species found in the air and dust around us may be able to cause opportunistic infections in patients who already have AIDS, cancer, or diabetes.

Fungi are involved in other medical conditions besides infections. Fungal cell walls give off chemical substances that can cause allergies. The toxins produced by poisonous mushrooms can induce neurological disturbances and even death. The mold *Aspergillus flavus* synthesizes a potentially lethal poison called aflatoxin,⁴

TABLE 5.6 Major Fungal Infections of Humans

Degree of Tissue Involvement and Area Affected	Name of Infection	Name of Causative Fungus
Superficial (not deeply invasive)		
Outer epidermis	Tinea versicolor	<i>Malassezia furfur</i>
Epidermis, hair, and dermis can be attacked	Dermatophytosis, also called tinea or ringworm of the scalp, body, feet (athlete’s foot), toenails	<i>Microsporum</i> , <i>Trichophyton</i> , and <i>Epidermophyton</i>
Mucous membranes, skin, nail	Candidiasis, or yeast infection	<i>Candida albicans</i> *
Systemic (deep; organism enters lungs; can invade other organs)		
Lung	Coccidioidomycosis (San Joaquin Valley fever)	<i>Coccidioides immitis</i>
	North American blastomycosis (Chicago disease)	<i>Blastomyces dermatitidis</i>
	Histoplasmosis (Ohio Valley fever)	<i>Histoplasma capsulatum</i>
	Cryptococcosis (torulosis)	<i>Cryptococcus neoformans</i>
Lung, skin	Paracoccidioidomycosis (South American blastomycosis)	<i>Paracoccidioides brasiliensis</i>

*This fungus can cause severe, invasive systemic infections in patients with cancer, AIDS, or other debilitating diseases.

which is the cause of a disease in domestic animals that have eaten grain contaminated with the mold and is also a cause of liver cancer in humans.

Fungi pose an ever-present economic hindrance to the agricultural industry. A number of species are pathogenic to field plants such as corn and grain, and fungi also rot fresh produce during shipping and storage. It has been estimated that as much as 40% of the yearly fruit crop is consumed not by humans but by fungi.

On the beneficial side, however, fungi play an essential role in decomposing organic matter and returning essential minerals to the soil. They form stable associations with plant roots (mycorrhizae) that increase the ability of the roots to absorb water and nutrients. Industry has tapped the biochemical potential of fungi to produce large quantities of antibiotics, alcohol, organic acids, and vitamins. Some fungi are eaten or used to impart flavorings to food. The yeast *Saccharomyces* produces the alcohol in beer and wine and the gas that causes bread to rise. Blue cheeses, soy sauce, and cured meats derive their unique flavors from the actions of fungi.

4. From *aspergillus, flavus*, toxin.

CLINICAL CONNECTIONS

An Outbreak of Fungal Meningitis

Most fungi are not invasive and do not ordinarily cause serious infections unless a patient's immune system is compromised or the fungus is accidentally introduced into sterile tissues. In 2012 we witnessed how a simple medical procedure could turn into a medical nightmare because a common, mostly harmless fungus got into the wrong place at the wrong time. It all started when a small compounding pharmacy in Massachusetts unknowingly sent out hundreds of mold-contaminated vials of medication to medical facilities for injections to control pain. These vials were sent to 23 states and used to inject the drug into the spinal columns or joints of around 14,000 patients. By the time any problems were reported, several hundred cases of infection had occurred, half of which settled in the meninges. The most drastic outcome was the deaths of 39 patients from complications of meningitis. After months of investigation, the CDC isolated a black mold, *Exserohilum rostratum*, from both the patients and the drug vials.

This mold resides in plants and soil, from which it spreads into the air and many human habitats. But it is not considered a human pathogen, and infections with it are very rare. Examination of the compounding facility uncovered negligence and poor quality controls, along with dirty preparation rooms. Mold spores were introduced during filling of the vials, and because the medication lacked preservatives, they survived and grew. The owner of the compounding pharmacy and the head pharmacist were each charged with 25 counts of second-degree murder, their trial is expected to start in late 2016.

This case drives home several important facts about fungi: (1) They can grow rapidly even in low nutrient environments; (2) just a single spore introduced into a sterile environment, whether it is a vial of medicine or the human body, can easily multiply into millions of fungal cells; and (3) even supposedly “harmless” fungi are often opportunistic, meaning that they will infect tissues “if given an opportunity.” This case also emphasizes the need for zero tolerance for microbes of any kind in a drug that is being injected—such a procedure demands sterility. When you think of it, the patients were actually being inoculated in a way that assured the development of serious mycoses.

Explain how a supposedly harmless, airborne mold could get all the way into the brain and cause meningitis. Answer available on Connect.

Check Your Progress SECTIONS 5.4 AND 5.5

- Review the major differences and similarities between prokaryotic and eukaryotic cells.
- Compare the structures of yeast and hyphal cells and differentiate between yeasts and molds.
- Tell how fungi obtain nutrients, and in what habitats one would expect to find them.

- Describe the two main types of asexual fungal spores and how they are formed. Name several types of conidia.
- Describe the three main types of sexual spores, and construct a simple diagram to show how each is formed.
- Explain general features of fungal classification, give examples of the four fungal phyla, and describe their structure and significance.
- Define the term *mycosis* and explain the levels of invasion of the body by fungi.

5.6 Survey of Protists: Algae

Expected Learning Outcomes

- Discuss the major characteristics of algae, and explain how they are classified.
- Describe several ways that algae are important microorganisms.

Even though the terms *algae* and *protozoa* do not have taxonomic status, they are still scientifically useful. These are terms, like *protist*, that provide a shorthand label for certain eukaryotes. Microbiologists use such general terms to reference organisms that possess a collection of predictable characteristics. For example, protozoa are considered unicellular eukaryotic protists that lack tissues and share similarities in cell structure, nutrition, life cycles, and biochemistry. They are all microorganisms, and most of them are motile. Algae are eukaryotic protists, usually unicellular or colonial, that photosynthesize with chlorophyll *a*. They lack vascular systems for transport and have simple reproductive structures.

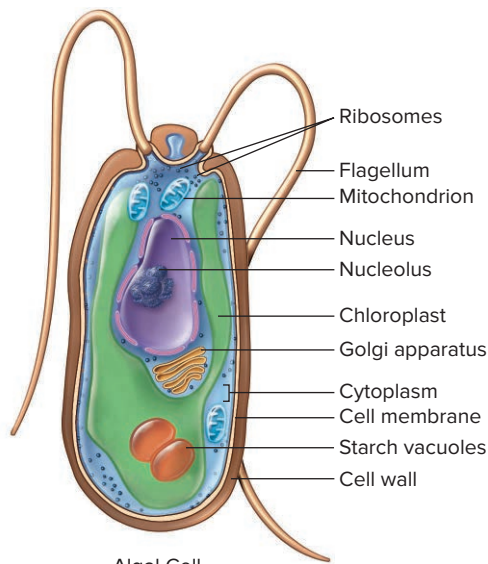

The Algae: Photosynthetic Protists

The **algae** are a group of photosynthetic organisms most readily recognized by their larger members, such as seaweeds and kelps. In addition to being beautifully colored and diverse in appearance, they vary in length from a few micrometers to 100 meters. Algae occur in unicellular, colonial, and filamentous forms, and the larger forms can possess tissues and simple organs. Examples of algal forms are shown in **figure 5.23** and **table 5.7**. An algal cell exhibits most of the organelles (figure 5.23a). The most noticeable of these are the chloroplasts, which contain, in addition to the green pigment chlorophyll, a number of other pigments that create the yellow, red, and brown coloration of some groups.

Algae are widespread inhabitants of fresh and marine waters. They are one of the main components of the large floating community of microscopic organisms called **plankton**. In this capacity,

TABLE 5.7 Summary of Algal Characteristics

Division/Common Name	Organization	Cell Wall	Pigmentation	Ecology/Importance
Euglenophyta (euglenids)	Mainly unicellular, motile by flagella	None, pellicle instead	Chlorophyll, carotenoids, xanthophyll	Some are close relatives of Mastigophora
Pyrrophyta (dinoflagellates)	Unicellular, dual flagella	Cellulose or atypical wall	Chlorophyll, carotenoids	Cause of “red tide”
Chrysophyta (diatoms or golden-brown algae)	Mainly unicellular, some filamentous forms, unusual form of motility	Silicon dioxide	Chlorophyll, fucoxanthin	Diatomaceous earth, major component of plankton
Phaeophyta (brown algae—kelps)	Multicellular, vascular system, holdfasts	Cellulose, system, holdfasts	Chlorophyll, carotenoids, fucoxanthin	Source of an emulsifier, alginate
Rhodophyta (red seaweeds)	Multicellular	Cellulose	Chlorophyll, carotenoids, xanthophyll, phycobilin	Source of agar and carrageenan, a food additive
Chlorophyta (green algae, grouped with plants)	Varies from unicellular, colonial, filamentous, to multicellular	Cellulose	Chlorophyll, carotenoids, xanthophyll	Precursor of higher plants

they play an essential role in aquatic food webs and contribute significantly to the oxygen content of the atmosphere through photosynthesis. One of the most prevalent groups on earth are single-celled chrysophyta called *diatoms* (figure 5.23*b*). These beautiful algae have silicate cell walls and golden pigment in their chloroplasts.

Other algal habitats include the surface of soil, rocks, and plants; and several species are even hardy enough to live in hot springs or snowbanks. A desert-adapted green alga blooms during spring rains and survives by forming resistant spores (figure 5.23*c, d*).

Animal tissues would be rather inhospitable to algae, so algae are rarely infectious. One exception, *Prototheca*, is an unusual non-photosynthetic alga associated with skin and subcutaneous infections in humans and animals.

The primary medical threat from algae is due to a type of food poisoning caused by the toxins of marine algae such as dinoflagellates. During particular seasons of the year, the overgrowth of these motile algae imparts a brilliant red color to the water, which is referred to as a “red tide” (see figure 26.16). When intertidal animals feed, their bodies accumulate toxins given off by the algae that can persist for several months. Paralytic shellfish poisoning is caused by eating exposed clams or other invertebrates. It is marked by severe neurological symptoms and can be fatal. Ciguatera is a serious intoxication caused by algal toxins that have accumulated in fish such as bass and mackerel. Cooking does not destroy the toxin, and there is no antidote.

Several episodes of a severe infection caused by *Pfiesteria piscicida*, a toxic algal form, have been reported over the past several years in the United States. The disease was first reported in fish and was later transmitted to humans. This newly identified species occurs in at least 20 forms, including spores, cysts, and amoebas, that can release potent toxins. Both fish and humans develop neurological symptoms and bloody skin lesions. The cause of the epidemic has been traced to nutrient-rich agricultural runoff water that promoted the sudden “bloom” of *Pfiesteria*. These microbes first attacked and killed millions of fish and later people whose occupations exposed them to fish and contaminated water.

5.7 Survey of Protists: Protozoa

Expected Learning Outcomes

29. Summarize the main characteristics of protozoan form, nutrition, and locomotion.
30. Describe the general life cycle and mode of reproduction in protozoans.
31. Explain how protozoans are identified and classified.
32. Outline a classification scheme for protozoans, and provide examples of important members of each group.
33. Explain some biological properties of parasites, and list some common protozoan pathogens.

If a poll were taken to choose the most engrossing and vivid group of microorganisms, many biologists would choose the protozoa. Although their name comes from the Greek for “first animals,”

they are far from being simple, primitive organisms and they are not animals. The protozoa constitute a diverse large group (about 65,000 known species) of single-celled creatures that display startling properties when it comes to movement, feeding, and behavior. Although most members of this group are harmless, free-living inhabitants of water and soil, a few species are parasites collectively responsible for hundreds of millions of infections of humans each year.

Protozoan Form and Function

Most protozoan cells are single cells containing the major eukaryotic organelles except chloroplasts. Their organelles can be highly specialized for feeding, reproduction, and locomotion. The cytoplasm is usually divided into a clear outer layer called the **ectoplasm** and a granular inner region called the **endoplasm**. Ectoplasm is involved in locomotion, feeding, and protection. Endoplasm houses the nucleus, mitochondria, and food and contractile vacuoles. Some ciliates and flagellates⁵ even have organelles that work somewhat like a primitive nervous system to coordinate movement. Because protozoa lack a cell wall, they have a certain amount of flexibility. Their outer boundary is a cell membrane that regulates the movement of food, wastes, and secretions. Cell shape can remain constant (as in most ciliates) or can change constantly (as in amoebas). Certain amoebas (foraminiferans) encase themselves in hard shells made of calcium carbonate. The size of most protozoan cells falls within the range of 3 to 300 μm . Some notable exceptions are giant amoebas and ciliates that are large enough (3–4 mm in length) to be seen swimming in pond water.

Nutritional and Habitat Range

Protozoa are heterotrophic and usually require their food in a complex organic form. Free-living species graze on live cells of bacteria and algae, and even scavenge dead plant or animal debris. Some species have special feeding structures such as oral grooves, which carry food particles into a passageway or gullet that packages the captured food into vacuoles for digestion. A remarkable feeding adaptation can be seen in the ciliate *Didinium* (see table 5.8, figure E), which can easily devour another microbe that is nearly its size. Some protozoa absorb food directly through the cell membrane. Parasitic species live on the fluids of their host, such as plasma and digestive juices, or they can actively feed on tissues.

Although protozoa have adapted to a wide range of habitats, their main limiting factor is the availability of moisture. Their predominant habitats are fresh and marine water, soil, plants, and animals. Even extremes in temperature and pH are not a barrier to their existence; hardy species are found in hot springs, ice, and habitats with low or high pH.

Styles of Locomotion

Except for one group (the Apicomplexa), protozoa are motile by means of **pseudopods** (“false foot”), **flagella**, or **cilia**. A few species have both pseudopods (also called pseudopodia) and

5. The terms *ciliate* and *flagellate* are common names of protozoan groups that move by means of cilia and flagella.

flagella. Some unusual protozoa move by a gliding or twisting movement that does not appear to involve any of these locomotor structures. Pseudopods are blunt, branched, or long and pointed, depending on the particular species. The flowing action of the pseudopods results in amoeboid motion, and pseudopods also serve as feeding structures in many amoebas.

The structure and behavior of flagella and cilia were discussed in section 5.1. Flagella vary in number from one to several, and in certain species they are attached along the length of the cell by an extension of the cytoplasmic membrane called the *undulating membrane* (see figure 5.27a). In most ciliates, the cilia are distributed over the surface of the cell in characteristic patterns. Because of the tremendous variety in ciliary arrangements and functions, ciliates are among the most diverse and awesome cells in the biological world. In certain protozoa, cilia line the oral groove and function in feeding; in others, they fuse together to form stiff props that serve as primitive rows of walking legs.

Life Cycles and Reproduction

Most protozoa are recognized by a motile feeding stage called the **trophozoite*** that requires ample food and moisture to remain active. A large number of species are also capable of entering into a dormant, resting stage called a **cyst** when conditions in the environment become unfavorable for growth and feeding. During *encystment*, the trophozoite cell rounds up into a sphere, and its ectoplasm secretes a tough, thick cuticle around the cell membrane (**figure 5.24**). Because cysts are more resistant than ordinary cells to heat, drying, and chemicals, they can survive adverse periods. They can be dispersed by air currents and may even be an important factor in the spread of

diseases such as amebic dysentery. If provided with moisture and nutrients, a cyst breaks open and releases the active trophozoite.

The life cycles of protozoans vary from simple to complex. Several protozoan groups exist only in the trophozoite state. Many alternate between a trophozoite and a cyst stage, depending on the conditions of the habitat. The life cycle of a parasitic protozoan dictates its mode of transmission to other hosts. For example, the flagellate *Trichomonas vaginalis* causes a common sexually transmitted infection. Because it does not form cysts, it is more delicate and must be transmitted by intimate contact between sexual partners. In contrast, intestinal pathogens such as *Entamoeba histolytica* and *Giardia lamblia* form cysts that are readily transmitted in contaminated water and foods.

All protozoa reproduce by relatively simple, asexual methods, usually mitotic cell division. Several parasitic species, including the agents of malaria and toxoplasmosis, reproduce asexually inside a host cell by multiple fission. Sexual reproduction also occurs during the life cycle of most protozoa. Ciliates participate in **conjugation**, a form of genetic exchange in which members of two different mating types fuse temporarily and exchange nuclei. This process of sexual recombination yields new and different genetic combinations that can be advantageous in evolution.

Protozoan Identification and Cultivation

Taxonomists have not escaped problems classifying protozoa, which are very diverse and frequently frustrate attempts to generalize or place them in neat groupings. We will use a simple system of four groups, based on method of motility, mode of reproduction, and stages in the life cycle.

Figure 5.24 The general life cycle exhibited by many protozoa. All protozoa have a trophozoite form, but not all produce cysts.

* *trophozoite* (trof'-oh-zoh'-yte) Gr. trophonikos, to nourish, and zoon, animal.

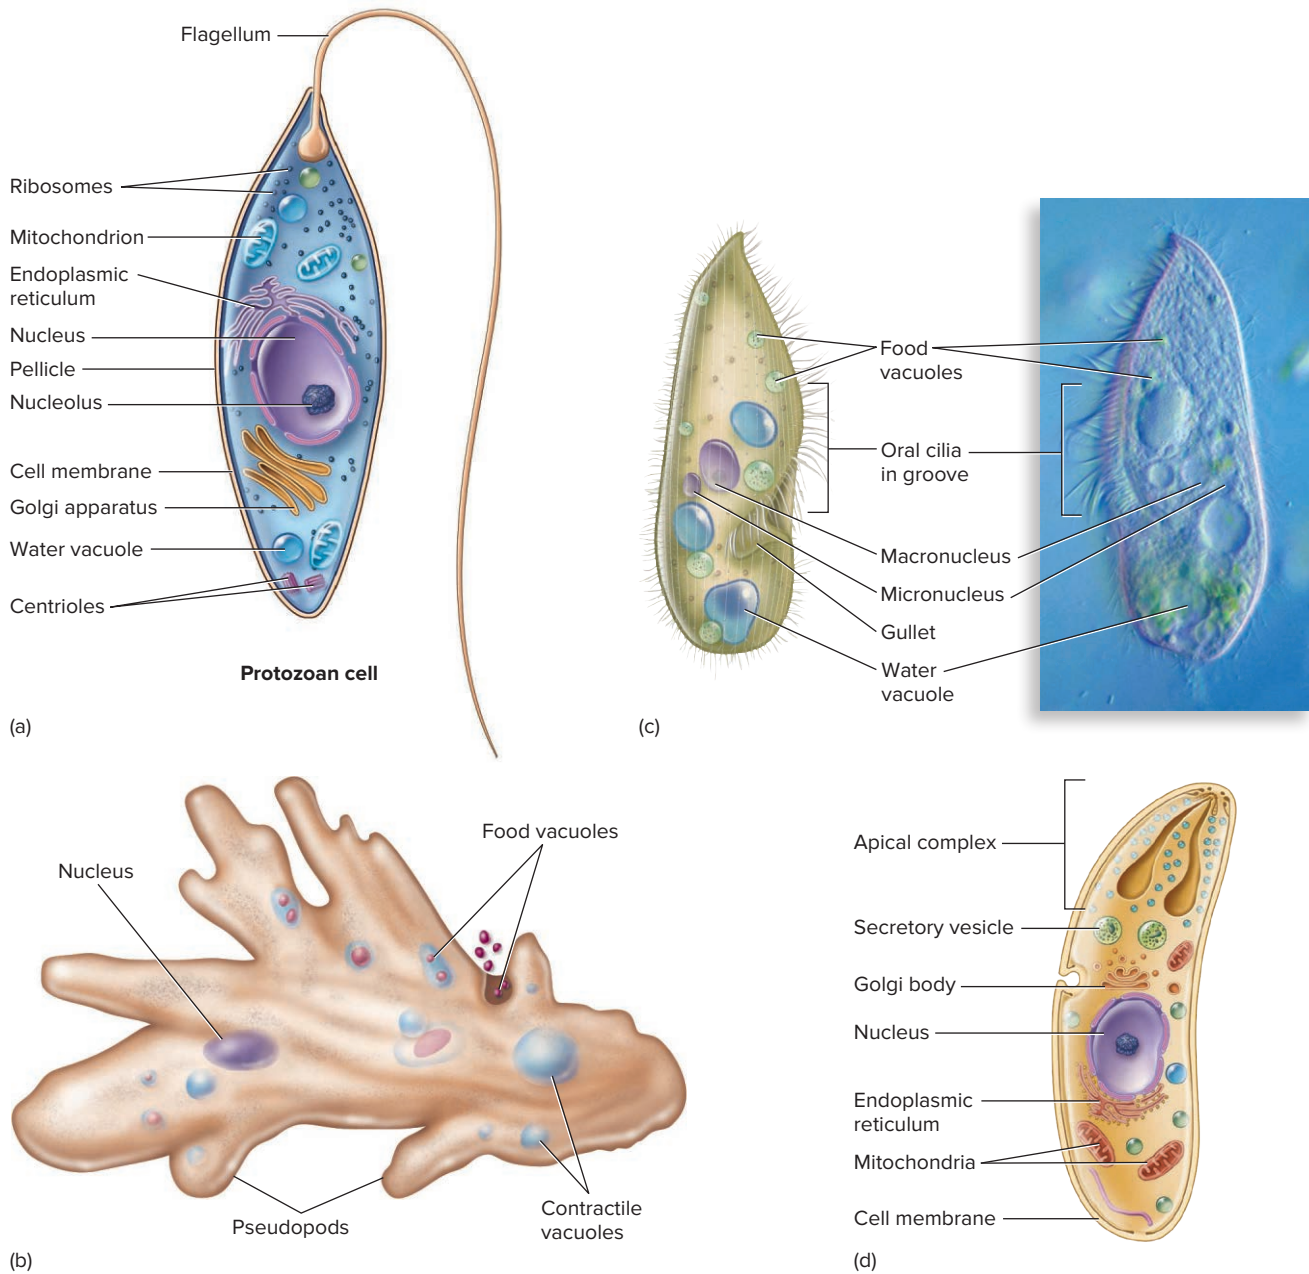

Figure 5.25 Comparisons of the trophozoite structure of four Phyla of protozoa. (a) General structure of a mastigophoran such as *Peranema*. The outer pellicle is flexible and allows for some shape changing in this group. (b) Structural appearance of a typical amoeba. Pseudopods are active in both movement and feeding. (c) Ciliate structure. Image and artist’s interpretation of the ciliate *Blepharisma*, a common inhabitant of pond water. Note the pattern of ciliary movement evident on the left side of the cell and the details of its internal structure. (d) Apicomplexan trophozoite structure. Apicomplexans have many of the usual protozoan organelles but also contain an unusual body, the apical complex, involved in feeding. Unlike other protozoa, they lack specialized motility organelles. (c): © BioMedia/Science Source

The unique appearance of most protozoa makes it possible for a knowledgeable person to identify them to the level of genus and often species by microscopic morphology alone. Characteristics to consider in identification include the shape and size of the cell; the type, number, and distribution of locomotor structures; the presence of special organelles or cysts; and the number of nuclei. Medical specimens taken from blood, sputum, cerebrospinal fluid, feces, or the vagina are smeared directly onto a slide and observed with or without special stains. Occasionally protozoa are cultivated on artificial media or in laboratory animals for further identification or study.

Classification of Selected Medically Important Protozoa

Most protozoa fit the basic morphology of one of four types of cells: the flagellated mastigophorans, the pseudopod-bearing amoebas, the ciliated ciliophorans, and the nonmotile apicomplexans. **Figure 5.25** depicts various aspects of these protozoan types. The overall taxonomy we are using here classifies the protozoa into four Phyla based on motility and other cell characteristics that are outlined with examples in **table 5.8**.

TABLE 5.8 Selected Taxonomy of Protozoa, with Group Characteristics and Examples

The Mastigophora (Also Called Zoomastigophora)

- Motility is primarily by flagella alone or by both flagellar and amoeboid motion.
- Single nucleus.
- Sexual reproduction, when present, by syngamy*; division by longitudinal fission.
- Several parasitic forms lack mitochondria and Golgi apparatus.
- Most species form cysts and are free-living; the group also includes several parasites.
- Some species are found in loose aggregates or colonies, but most are solitary.
- Members include: *Trypanosoma* and *Leishmania*, important blood pathogens spread by insect vectors (see figure 5.26); *Giardia*, an intestinal parasite spread in water contaminated with feces (see figure B); *Trichomonas*, a parasite of the reproductive tract of humans spread by sexual contact (see figure 23.6).
- A large symbiont found in termites, *Trichonympha*, sprouts masses of flagella from its oral cavity (figure A).

A. *Trichonympha*—a common symbiotic flagellate in termite intestines, displaying numerous flagella (400 \times).
© David J. Patterson

B. Trophozoite of *Giardia lamblia*—a widespread intestinal pathogen (2,000 \times).
Source: Janice Carr/CDC

The Sarcodina* (Amoebas)

- Cell form is primarily an amoeba (see figure 5.24b).
- Major locomotor organelles are pseudopods, although some species have flagellated reproductive states.
- Asexual reproduction by fission.
- Mostly uninucleate; usually encyst
- Most amoebas are free-living and not infectious (figure C).
- *Entamoeba histolytica* is a parasite of humans (figure D).

C. *Polychaos*—a giant amoeba uses several pseudopods to feed on diatoms (100 \times).
© David J. Patterson/MBL/Biological Discovery in Woods Hole

D. Trophozoite of *Entamoeba histolytica*—the cause of amebic dysentery (1,000 \times).
Source: Dr. Green/CDC

The Ciliophora (Ciliates)

- Trophozoites are motile by cilia.
- Some have cilia in tufts for feeding and attachment; most develop cysts.
- Have both macronuclei and micronuclei; division by transverse fission.
- Most have a well-developed mouth and feeding organelle.
- Show relatively advanced behavior (figure E).
- The majority of ciliates are free-living and harmless.
- One pathogen is *Balantidium* (figure F).

E. *Didinium* (predator, right)—preparing to attack and engulf *Paramecium* (prey, left) in an age-old ciliate struggle (1,200 \times). Source: Gregory Antipa, San Francisco State University. www.cellimagelibrary.org/images/22781

F. *Balantidium coli*—a parasite of swine that can also cause intestinal infections in humans. Source: Oregon Department of Health/CDC-DPDx

The Apicomplexa (Sporozoa)

- Motility is absent in most cells except male gametes.
- Life cycles are complex, with well-developed asexual and sexual stages.
- Sporozoa produce special sporelike cells called **sporozoites*** (figures G and H) following sexual reproduction, which are important in transmission of infections.
- Most form thick-walled zygotes called oocysts; entire group is parasitic.
- *Plasmodium*, the most prevalent protozoan parasite, causes 100 million to 300 million cases of malaria each year worldwide. It is an intracellular parasite with a complex cycle alternating between humans and mosquitoes (figure H).
- *Toxoplasma gondii* causes an acute infection (toxoplasmosis) in humans, which is acquired from cats and other animals (see figure 23.16).
- *Cryptosporidium* is an emerging intestinal pathogen transmitted by contaminated water (see figure G).

G. Sporozoite of *Cryptosporidium*—a common water-borne pathogen. In this colorized electron micrograph the sporozoite is attached to the surface of the intestines.

H. Sporozoite of *Plasmodium*—the agent of malaria, migrating through the gut of a mosquito. Source: Ute Frevert; false color by Margaret Shear doi:10.1371/image.pbio.v03.i06.g001

*The fusion of haploid gametes to produce a diploid zygote.

*Some biologists prefer to combine Mastigophora and Sarcodina into the phylum Sarcomastigophora. Because the algal group Euglenophyta has flagella, it may also be included in the Mastigophora.

* *sporozoite* (spor'-oh-zoh'-yte) Gr. sporos, seed, and zoon, animal.

TABLE 5.9 Major Pathogenic Protozoa, Infections, and Primary Sources

Protozoan/Disease	Reservoir/Source
Amoeboid Protozoa	
Amoebiasis: <i>Entamoeba histolytica</i>	Human/water and food
Brain infection: <i>Naegleria</i> , <i>Acanthamoeba</i>	Free-living in water
Ciliated Protozoa	
Balantidiosis: <i>Balantidium coli</i>	Zoonotic in pigs
Flagellated Protozoa	
Giardiasis: <i>Giardia lamblia</i>	Zoonotic/water and food
Trichomoniasis: <i>T. hominis</i> , <i>T. vaginalis</i>	Human
Hemoflagellates	
Trypanosomiasis: <i>Trypanosoma</i> <i>brucei</i> , <i>T. cruzi</i>	Zoonotic/vector-borne
Leishmaniasis: <i>Leishmania</i> <i>donovani</i> , <i>L. tropica</i> , <i>L. brasiliensis</i>	Zoonotic/vector-borne
Apicomplexan Protozoa	
Malaria: <i>Plasmodium vivax</i> , <i>P. falciparum</i> , <i>P. malariae</i>	Human/vector-borne
Toxoplasmosis: <i>Toxoplasma gondii</i>	Zoonotic/vector-borne
Cryptosporidiosis: <i>Cryptosporidium</i>	Free-living/water and food
Cyclosporiasis: <i>Cyclospora</i> <i>cayetanensis</i>	Water/fresh produce

CLINICAL CONNECTIONS

The Parasitic Way of Life

Protozoa are traditionally studied along with the helminths in the science of parasitology. Although a parasite is usually defined as an organism that obtains food and other requirements at the expense of a host, the term *parasite* is also used to denote protozoan and helminth pathogens. The range of host-parasite relationships can be very broad. At one extreme are the so-called “good” parasites, which occupy their host with little harm. An example is *Trichomonas tenax*, a flagellate found in the mouth that may infect and damage the gingiva in people with poor oral hygiene. At the other extreme are parasites (*Plasmodium*, *Trypanosoma*) that multiply in host tissues such as the blood or brain, causing severe damage and disease. Between these two extremes are parasites of varying pathogenicity, depending on their particular adaptations.

Most human parasites go through three general stages:

- The microbe is transmitted to the human host from a source such as soil, water, food, other humans, or animals.
- The microbe invades and multiplies in the host, producing more parasites that can infect other suitable hosts.
- The microbe leaves the host in large numbers by a specific means and must enter a new host to survive.

There are numerous variations on this theme. For instance, the microbe can invade more than one host species (alternate hosts) and undergo several changes as it cycles through these hosts, such as sexual reproduction or encystment. Some microbes are spread from human to human by means of **vectors**,* defined as animals such as insects that carry diseases. Others can be spread through bodily fluids and feces.

What correlation can be made between the geographic location of a parasite and its vector? Answer available on Connect.

* **vector** (vek'-tur) L. vectur, one who carries.

The trypanosome of Chagas disease relies on the close relationship of a warm-blooded mammal and an insect that feeds on mammalian blood. The mammalian hosts are numerous, including dogs, cats, opossums, and armadillos. The vector is the *reduviid** bug, an insect that is sometimes called the “kissing bug” because of its habit of biting its host at the corner of the mouth. Transmission occurs from bug to mammal and from mammal to bug but usually not from mammal to mammal, except across the placenta during pregnancy. The general phases of this cycle are presented in **figure 5.26**.

The trypanosome trophozoite multiplies in the intestinal tract of the reduviid bug and is harbored in the feces. The bug seeks a host and bites the mucous membranes, usually of the eye, nose, or lips, releasing the trypanosome in feces near the bite. Ironically, the victims themselves inadvertently contribute to the entry of the microbe by scratching the bite wound. Once in the body, the trypanosomes become established and multiply in muscle and white blood cells. Periodically these parasitized cells rupture, releasing large numbers of new trophozoites into the blood. Eventually the trypanosomes can spread to many

Important Protozoan Pathogens

Although protozoan infections are very common, they are actually caused by only a small number of species often restricted geographically to the tropics and subtropics (**table 5.9**). In this survey, we look at examples from two protozoan groups that illustrate some of the main features of protozoan diseases.

Quick Search

Look for “What Are Malaria Protozoa” on YouTube to learn about the most dominant parasitic protozoan.

Pathogenic Flagellates: Trypanosomes

Trypanosomes are protozoa belonging to the genus *Trypanosoma*.* The two most important representatives are *T. brucei* and *T. cruzi*, species that are closely related but geographically restricted. *Trypanosoma brucei* occurs in Africa, where it causes an estimated 50,000 new cases of sleeping sickness each year. *Trypanosoma cruzi*, the cause of Chagas disease,⁶ is endemic to South and Central America, where it infects several million people a year. Both species have long, crescent-shaped cells with a single flagellum that is sometimes attached to the cell body by an undulating membrane. Both occur in the blood during infection and are transmitted by blood-sucking vectors. We use *T. cruzi* to illustrate the phases of a trypanosomal life cycle and to demonstrate the complexity of parasitic relationships.

* *Trypanosoma* (try'-pan-oh-soh'-mah) Gr. *Trypanon*, borer, and *soma*, body.

6. Named for Carlos Chagas, the discoverer of *T. cruzi*.

* *reduviid* (ree-doo'-vee-id) A member of a large family of flying insects with sucking, beaklike mouths.

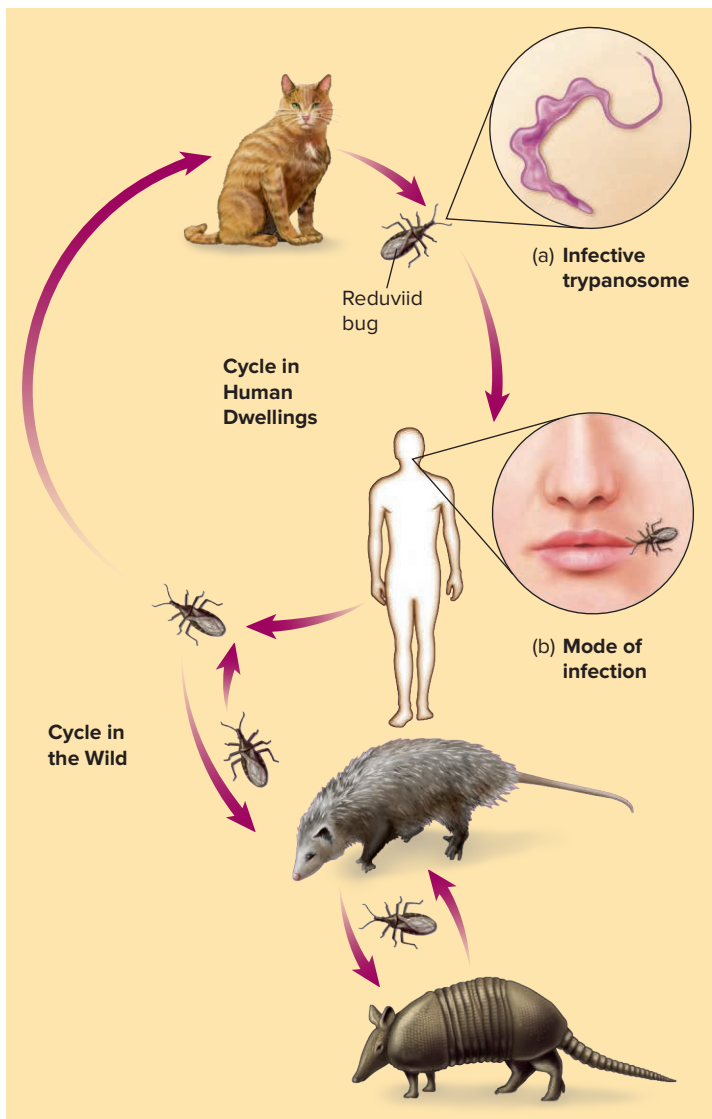

Figure 5.26 Cycle of transmission in Chagas disease. Trypanosomes (inset a) are transmitted among domestic and wild mammalian hosts and human hosts by means of a bite from the kissing bug (inset b).

systems, including the lymphoid organs, heart, liver, and brain. Manifestations of the resultant disease range from mild to very severe and include fever, inflammation, and heart and brain damage. In many cases the disease has an extended course and can cause death.

Infective Amoebas: *Entamoeba*

Several species of amoebas cause disease in humans, but probably the most common disease is amoebiasis, or amebic **dysentery**,* caused by *Entamoeba histolytica*. This microbe is widely distributed in the world, from northern zones to the tropics, and is nearly always associated with humans. Amebic dysentery is the fourth most common protozoan infection in the world. This microbe has a life cycle quite different from the trypanosomes in that it does not involve multiple hosts and a blood-sucking vector. It lives part of its cycle as a trophozoite

* *dysentery* (dis'-en-ter'-ee) Any inflammation of the intestine accompanied by bloody stools. It can be caused by a number of factors, both microbial and nonmicrobial.

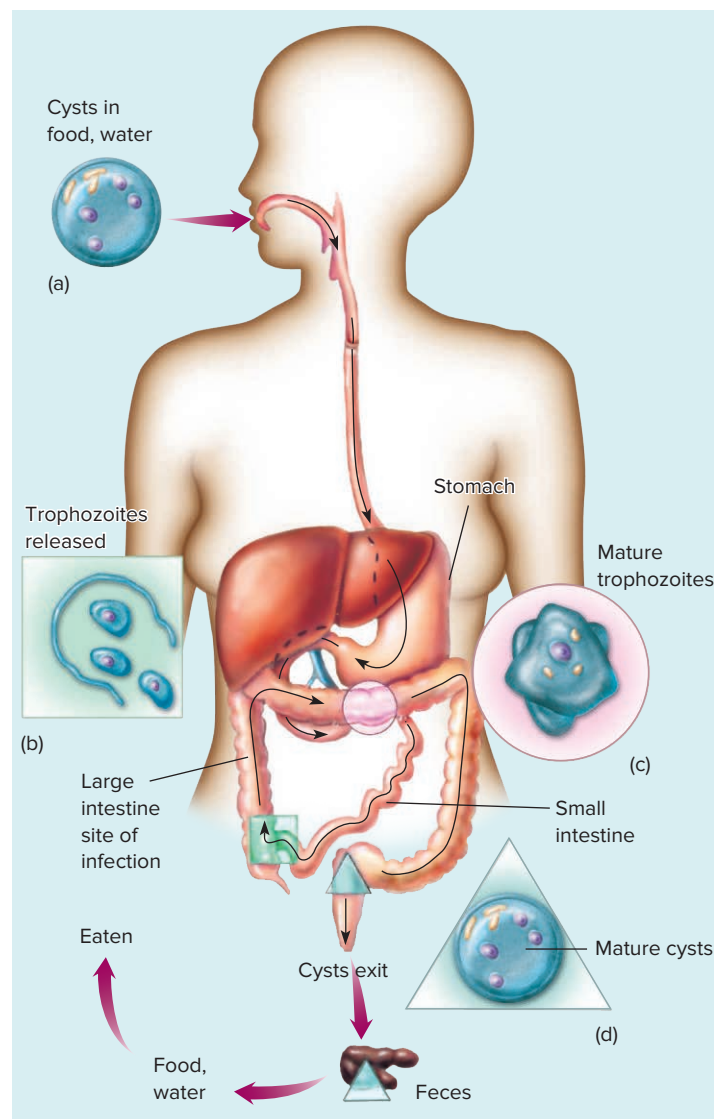

Figure 5.27 Stages in the infection and transmission of amebic dysentery. Arrows show the route of infection; insets show the appearance of *Entamoeba histolytica*. (a) Cysts are eaten. (b) Trophozoites (amoebas) emerge from cysts. (c) Trophozoites invade the large intestinal wall (see table 5.8, figure D). (d) Mature cysts are released in the feces and may be spread through contaminated food and water.

and part as a cyst. Because the cyst is the more resistant form and can survive in water and soil for several weeks, it is the more important stage for transmission. The primary way that people become infected is by ingesting food or water contaminated with human feces.

Figure 5.27 shows the major features of the amebic dysentery cycle, starting with the ingestion of cysts. The viable, heavy-walled cyst passes through the stomach unharmed. Once inside the small intestine, the cyst germinates into a large multinucleate amoeba that subsequently divides to form small amoebas (the trophozoite stage). These trophozoites migrate to the large intestine and begin to feed and grow. From this site, they can penetrate the lining of the intestine and invade the liver, lungs, and skin. Common symptoms include gastrointestinal disturbances such as nausea, vomiting, and diarrhea, leading to weight loss and dehydration. The cycle is

completed in the infected human when certain trophozoites in the feces begin to form cysts, which then pass out of the body with fecal matter. Knowledge of the amoebic cycle and role of cysts has been helpful in controlling the disease. Important preventive measures include sewage treatment, curtailing the use of human feces as fertilizer, and adequate sanitation of food and water.

5.8 The Parasitic Helminths

Expected Learning Outcomes

34. Describe the major groups of helminths and their basic morphology and classification.
35. Explain the elements of helminth biology, life cycles, and reproduction.
36. Discuss the importance of the helminth parasites.

Tapeworms, flukes, and roundworms are collectively called *helminths*, from the Greek word meaning “worm.” Adult animals are usually large enough to be seen with the naked eye, and they range from the longest tapeworms, measuring up to about 25 m in length, to roundworms less than 1 mm in length. Traditionally they have been included among microorganisms because of their infective abilities and because the microscope is needed to identify their tiny egg and larval stages.

On the basis of morphological form, the two major groups of parasitic helminths are the **flatworms** (Phylum Platyhelminthes), with a very thin, often segmented body plan (**figure 5.28**), and the **roundworms** (Phylum Aschelminthes, also called **nematodes**),* with an elongate, cylindrical, unsegmented body (**figure 5.29**). The flatworm group is subdivided into the **cestodes**,* or tapeworms, named for their long, ribbonlike arrangement, and the **trematodes**,*

* *nematode* (neem'-ah-tohd) Gr. nemato, thread, and eidos, form.

* *cestode* (sess'-tohd) L. cestus, a belt, and ode, like.

* *trematode* (treem'-a-tohd) Gr. trema, hole. Named for the appearance of having tiny holes.

also known as flukes, characterized by flat, ovoid bodies. Not all flatworms and roundworms are parasites by nature; many live freely in soil and water.

General Worm Morphology

All helminths are multicellular animals equipped to some degree with organs and organ systems. In parasitic helminths, the most developed organs are those of the reproductive tract, with some degree of reduction in the digestive, excretory, nervous, and muscular systems. In particular groups, such as the cestodes, reproduction is so dominant that the worms are reduced to little more than a series of flattened sacs filled with ovaries, testes, and eggs (**figure 5.28a**). Not all worms have such extreme adaptations as cestodes, but most have a highly developed reproductive potential, thick cuticles for protection, and mouth glands for breaking down the host's tissue.

Life Cycles and Reproduction

The complete life cycle of helminths includes the fertilized egg (embryo), larval, and adult stages. In the majority of helminths, adults derive nutrients from and reproduce sexually in a host's body. In nematodes, the sexes are separate and usually different in appearance; in trematodes, the sexes can be either separate or **hermaphroditic**, meaning that male and female sex organs are in the same worm; cestodes are generally hermaphroditic. For a parasite's continued survival as a species, it must complete the life cycle by transmitting an infective form, usually an egg or larva, to the body of another host, either of the same or a different species. By convention, the host in which larval development occurs is the **intermediate (secondary) host**, and adulthood and mating occur in the **definitive (final) host**. A transport host is an intermediate host that experiences no parasitic development but is an essential link in the completion of the cycle.

In general, sources for human infection are contaminated food, soil, water, or infected animals, and routes of infection are by oral intake or penetration of unbroken skin. Humans are the definitive hosts for many of the parasites, and in about half the diseases, they

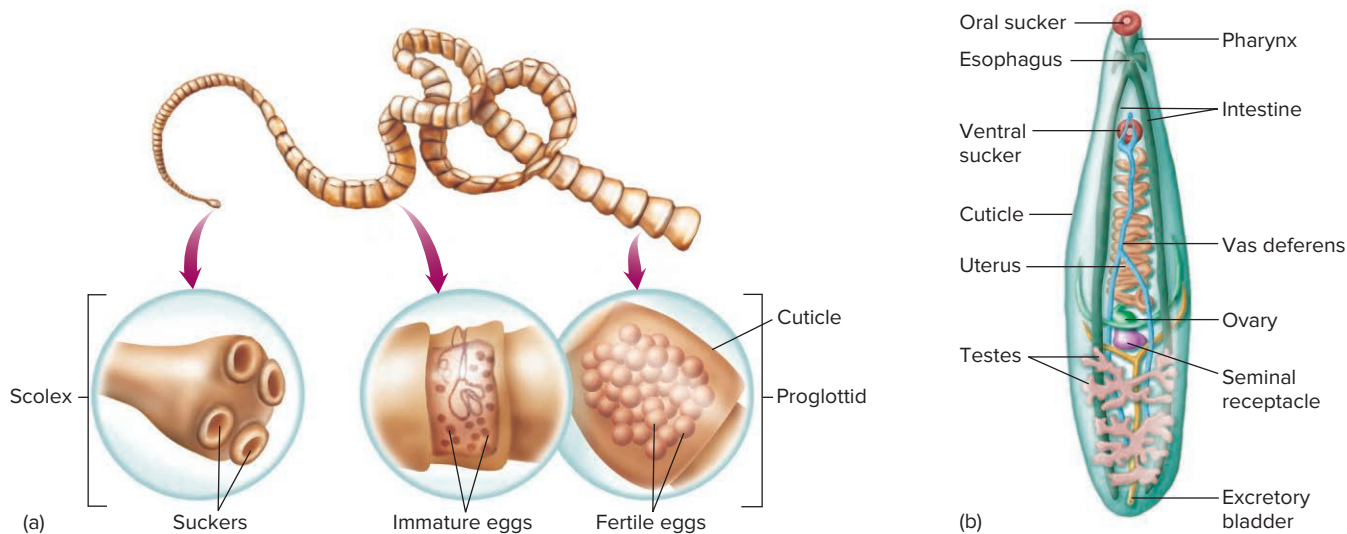

Figure 5.28 Parasitic flatworms. (a) A cestode (beef tapeworm), showing the scolex; long, tapelike body; and magnified views of immature and mature proglottids (body segments). (b) The structure of a trematode (liver fluke). Note the suckers that attach to host tissue and the dominance of reproductive and digestive organs.

are also the sole biological reservoir. In other cases, animals or insect vectors serve as reservoirs or are required to complete worm development. In the majority of helminth infections, the worms must leave their host to complete the entire life cycle.

Fertilized eggs are usually released to the environment and are provided with a protective shell and extra food to aid their development into larvae. Even so, most eggs and larvae are vulnerable to heat, cold, drying, and predators, and are destroyed or unable to reach a new host. To counteract this formidable mortality rate, certain worms have adapted a reproductive capacity that borders on the incredible: A single female *Ascaris*⁷ can lay 200,000 eggs a day, and a large female can contain over 25 million eggs at varying stages of development! If only a tiny number of these eggs makes it to another host, the parasite will have been successful in completing its life cycle.

A Helminth Cycle: The Pinworm

To illustrate a helminth cycle in humans, we use the example of a roundworm, *Enterobius vermicularis*, the pinworm or seatworm. This worm causes a very common infestation of the large intestine (figure 5.29). Worms range from 2 to 12 mm long and have a tapered, curved cylinder shape. The condition they cause, enterobiasis, is usually a simple, uncomplicated infection that does not spread beyond the intestine.

A cycle starts when a person swallows microscopic eggs picked up from another infected person by direct contact or by touching contaminated surfaces. The eggs hatch in the intestine and then release larvae that mature into adult worms within about one month. Male and female worms mate, and the female migrates out to the anus to deposit eggs, which cause intense itchiness that is relieved by scratching. Herein lies a significant means of dispersal: Scratching contaminates the fingers, which, in turn, transfers eggs to bedclothes and other inanimate objects. This person becomes a host and a source of eggs, and can spread them to others in addition to reinfesting himself, a cycle known as the oral-fecal route of transmission. Enterobiasis occurs most often among families and in other close living situations. Its distribution is worldwide among all socioeconomic groups, but it occurs more frequently in children, presumably through their less careful attention to hygiene.

Helminth Classification and Identification

The helminths are classified according to their shape; their size; the degree of development of various organs; the presence of hooks, suckers, or other special structures; the mode of reproduction; the kinds of hosts; and the appearance of eggs and larvae. They are identified in the laboratory by microscopic detection of the adult worm or its larvae and eggs, which often have distinctive shapes or external and internal structures. Occasionally, they are cultured in order to verify all of the life stages.

Distribution and Importance of Parasitic Worms

About 50 species of helminths parasitize humans. They are distributed in all areas of the world that support human life. Some worms are restricted to a given geographic region, and many have a higher incidence in tropical areas. This knowledge must be tempered with

Figure 5.29 The life cycle of the pinworm, a roundworm. Eggs are the infective stage and are transmitted by unclean hands. Children frequently reinfest themselves and also pass the parasite on to others.

the realization that jet-age travel, along with human migration, is gradually changing the patterns of worm infections, especially of those species that do not require alternate hosts or special climatic conditions for development. The yearly estimate of worldwide cases numbers in the billions, and these are not confined to developing countries. A conservative estimate places 50 million helminth infections in North America alone. The primary targets are children lacking access to adequate diet and medical care.

Check Your Progress SECTIONS 5.6–5.8

22. What is a working definition of a “protist”?
23. Describe the principal characteristics of algae that separate them from protozoa.
24. How are algae important? Give examples of algae with medical importance.
25. Explain the general characteristics of the protozoan life cycle.
26. Describe the protozoan adaptations for feeding.
27. Briefly outline the characteristics of the four protozoan groups and name important pathogens in each group.
28. What characteristics set the apicomplexa apart from the other protozoan groups?
29. Discuss the adaptations of parasitic worms to their lifestyles, and explain why these adaptations are necessary or advantageous to the worms’ survival.
30. Outline the basic steps in an infection cycle of a pathogenic protozoan and a helminth.

7. *Ascaris* is a genus of parasitic intestinal roundworms.

CASE STUDY Part 2

There is much more to the story of neglected diseases of poverty. Most victims first become infected as children and continue to harbor the parasite for years, even for a lifetime. The chronic nature of the infection adds enormously to the accumulated damage that occurs. Infected people may become involved in an ongoing cycle that continues to produce more parasites and increase their survival and transmission. Many protozoans produce resistant survival cells called cysts, and worms go through complex reproductive phases with eggs and larvae. Some parasites are spread by direct contact with an infected person, some burrow into the skin, and others are ingested in contaminated soil or water. A significant factor in transmission of several parasites is the involvement of arthropod vectors such as mosquitoes and flies.

For most of these diseases, there is effective drug therapy, but getting the drugs to the poorest of the poor has been difficult. Many of the countries are not only deeply impoverished,

but are involved in civil wars and other conflicts, creating upheaval in an already overburdened system. One billion of the world's poorest live on less than \$1 per day, and 2.7 billion live on less than \$2 per day. Most of these people are “out of sight and out of mind”—living in remote rural areas far removed from medical facilities. NTDs are not given much priority for funding because they are not high-profile diseases with noticeable, acute symptoms requiring immediate medical care. Any progress in controlling these NTDs will require a global partnership that brings together resources from many countries.

- *What is the definition of a vector, and how are vectors involved in these diseases?*
- *What are some possible solutions to the problem of neglected diseases?*

For information on NTDs and their current status, search for NTDs on the World Health Organization website.

To conclude this Case Study, go to Connect.

Chapter Summary with Key Terms

5.1 The History of Eukaryotes

5.2 Form and Function of the Eukaryotic Cell: External Structures

- A. The exterior configuration of eukaryotic cells is complex and displays numerous structures not found in prokaryotic cells. Biologists have accumulated much evidence that eukaryotic cells evolved through **endosymbiosis** between early prokaryotic cells.
- B. Major external structural features include: appendages (**cilia**, **flagella**), **glycocalyx**, cell wall, and cytoplasmic (or cell) membrane.

5.3 Form and Function of the Eukaryotic Cell: Internal Structures

- A. The internal structure of eukaryotic cells is compartmentalized into individual organelles.
- B. Major **organelles** and internal structural features include: **nucleus**, **nucleolus**, **endoplasmic reticulum**, **Golgi complex**, **mitochondria**, **chloroplasts**, **ribosomes**, **cytoskeleton** (**microfilaments**, **microtubules**).

5.4 Eukaryotic-Prokaryotic Comparisons and Taxonomy of Eukaryotes

- A. Comparisons between eukaryotic cells and prokaryotic cells show major differences in structure, size, metabolism, motility, and body form.
- B. Taxonomic groups of the Domain Eukarya are based on level of organization, body plan, cell structure, nutrition, metabolism, and certain genetic characteristics.

5.5 The Kingdom of the Fungi

Common names of the macroscopic fungi are mushrooms, bracket fungi, and puffballs. Microscopic fungi are known as **yeasts** and **molds**.

- A. **Overall Morphology:** At the cellular (microscopic) level, fungi are typical eukaryotic cells, with thick cell walls. Yeasts are single cells that form buds and **pseudohyphae**. **Hyphae** are long, tubular filaments that can be septate or nonseptate and grow in a network called a **mycelium**; hyphae are characteristic of the filamentous fungi called molds.

- B. **Nutritional Mode/Distribution:** All are **heterotrophic**. The majority are harmless **saprobies** living off organic substrates such as dead animal and plant tissues. A few are **parasites**, living on the tissues of other organisms, but none is obligate. Distribution is extremely widespread in many habitats.
- C. **Reproduction:** Primarily through **spores** formed on special reproductive hyphae. In asexual reproduction, spores are formed through budding, partitioning of a hypha, or in special sporogenous structures; examples are **conidia** and **sporangiospores**. In sexual reproduction, spores are formed following fusion of male and female strains and the formation of a sexual structure; sexual spores are one basis for classification.
- D. **Major Groups:** The four main phyla among the terrestrial fungi, given with sexual spore type, are **Zygomycota** (**zygospores**), **Ascomycota** (**ascospores**), **Basidiomycota** (**basidiospores**), and **Chytridiomycota** (motile zoospores).
- E. **Importance:** Fungi are essential decomposers of plant and animal detritus in the environment. Economically beneficial as sources of antibiotics; used in making foods and in genetic studies. Adverse impacts include decomposition of fruits and vegetables, and human infections, or **mycoses**; some produce substances that are toxic if eaten or inhaled.

5.6 Survey of Protists: Algae

General group that traditionally includes single-celled and colonial eukaryotic microbes that lack organization into tissues.

- A. **Overall Morphology:** Are unicellular, colonial, filamentous or larger forms such as seaweeds.
- B. **Nutritional Mode/Distribution:** Photosynthetic; freshwater and marine water habitats; main component of **plankton**.
- C. **Importance:** Provide the basis of the food web in most aquatic habitats and are major producers of oxygen. Certain algae produce neurotoxins that are harmful to humans and animals.

5.7 Survey of Protists: Protozoa

Include large single-celled organisms; a few are pathogens.

- A. *Overall Morphology*: Most are unicellular; lack a cell wall. The cytoplasm is divided into ectoplasm and endoplasm. Active, feeding stage is the **trophozoite**; many convert to a resistant, dormant stage called a **cyst**. All but one group has some form of organelle for **motility**.
- B. *Nutritional Mode/Distribution*: All are heterotrophic. Most are free-living in a moist habitat (water, soil); feed by engulfing other microorganisms and organic matter.
- C. *Reproduction*: Asexual by binary fission and **mitosis**, budding; sexual by fusion of free-swimming gametes, conjugation.
- D. *Major Groups*: Protozoa are subdivided into four groups based upon mode of locomotion and type of reproduction: **Mastigophora**, the flagellates, motile by flagella; **Sarcodina**, the amoebas, motile by **pseudopods**; **Ciliophora**, the ciliates, motile by cilia; **Apicomplexa**, motility not well developed; produce unique reproductive structures.

- E. *Importance*: Ecologically important in food webs and decomposing organic matter. Medical significance: hundreds of millions of people are afflicted with one of the many protozoan infections (malaria, trypanosomiasis, amoebiasis). Can be spread from host to host by insect **vectors**.

5.8 The Parasitic Helminths

Includes three categories: roundworms, tapeworms, and flukes.

- A. *Overall Morphology*: Animal cells; multicellular; individual organs specialized for reproduction, digestion, movement, protection, though some of these are reduced.
- B. *Reproductive Mode*: Includes embryo, larval, and adult stages. Majority reproduce sexually. Sexes may be **hermaphroditic**.
- C. *Epidemiology*: Developing countries in the tropics are hardest hit by helminth infections; transmitted via ingestion, vectors, and direct contact with infectious stages. They afflict billions of humans.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

- Both flagella and cilia are found primarily in
 - a. algae
 - b. protozoa
 - c. fungi
 - d. both b and c
- Features of the nuclear envelope include
 - a. ribosomes
 - b. a double membrane structure
 - c. pores that allow communication with the cytoplasm
 - d. b and c
 - e. all of these
- The cell wall is usually found in which eukaryotes?
 - a. fungi
 - b. algae
 - c. protozoa
 - d. a and b
- What is embedded in rough endoplasmic reticulum?
 - a. ribosomes
 - b. Golgi apparatus
 - c. chromatin
 - d. vesicles
- Yeasts are _____ fungi, and molds are _____ fungi.
 - a. macroscopic, microscopic
 - b. unicellular, filamentous
 - c. motile, nonmotile
 - d. water, terrestrial
- In general, fungi derive nutrients through
 - a. photosynthesis
 - b. engulfing bacteria
 - c. digesting organic substrates
 - d. parasitism
- A hypha divided into compartments by cross walls is called
 - a. nonseptate
 - b. imperfect
 - c. septate
 - d. perfect
- Algae generally contain some type of
 - a. spore
 - b. chlorophyll
 - c. locomotor organelle
 - d. toxin
- Which algal group is most closely related to plants?
 - a. diatoms
 - b. Chlorophyta
 - c. Euglenophyta
 - d. dinoflagellates
- Which characteristic(s) is/are not typical of protozoan cells?
 - a. locomotor organelle
 - b. cyst
 - c. spore
 - d. trophozoite
- The protozoan trophozoite is the
 - a. active feeding stage
 - b. inactive dormant stage
 - c. infective stage
 - d. spore-forming stage
- All mature sporozoa are
 - a. parasitic
 - b. nonmotile
 - c. carried by an arthropod vector
 - d. both a and b
- Parasitic helminths reproduce with
 - a. spores
 - b. eggs and sperm
 - c. mitosis
 - d. cysts
 - e. all of these

14. Mitochondria likely originated from
 - a. archaea
 - b. invaginations of the cell membrane
 - c. rickettsias
 - d. cyanobacteria
15. Human fungal infections involve and affect what areas of the human body?
 - a. skin
 - b. mucous membranes
 - c. lungs
 - d. all of these
16. Most helminth infections
 - a. are localized to one site in the body
 - b. spread through major systems of the body
 - c. develop within the spleen
 - d. develop within the liver

Multiple Matching. Select the description that best fits the word in the left column.

- | | |
|-------------------------------|--|
| 17. _____ diatom | a. the cause of malaria |
| 18. _____ <i>Rhizopus</i> | b. single-celled alga with silica in its cell wall |
| 19. _____ <i>Histoplasma</i> | c. fungal cause of Ohio Valley fever |
| 20. _____ <i>Cryptococcus</i> | d. the cause of amebic dysentery |
| 21. _____ euglenid | e. genus of black bread mold |
| 22. _____ dinoflagellate | f. helminth worm involved in pinworm infection |
| 23. _____ <i>Trichomonas</i> | g. motile flagellated alga with an eyespot |
| 24. _____ <i>Entamoeba</i> | h. a yeast that infects the lungs |
| 25. _____ <i>Plasmodium</i> | i. flagellated protozoan genus that causes an STD |
| 26. _____ <i>Enterobius</i> | j. alga that causes red tides |

Case Study Review

1. Which of these is/are an example(s) of neglected tropical protozoan diseases?

a. hookworm	d. a and b
b. Chagas disease	e. b and c
c. leishmaniasis	f. all of these
2. Which is a possible vector of a tropical eukaryotic parasite?

a. contaminated drinking water	c. biting fly
b. spoiled food	d. person with a cough
3. Provide some explanations for why the eukaryotic parasites are so widespread and successful.

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

1. Describe the anatomy and functions of each of the major eukaryotic organelles.
2. Trace the synthesis of cell products, their processing, and their packaging through the organelle network.
3.
 - a. What is the reproductive potential of molds in terms of spore production?
 - b. How do mold spores differ from bacterial endospores?
4.
 - a. Fill in the following summary table for defining, comparing, and contrasting eukaryotic cells.
 - b. Briefly describe the manner of nutrition and body plan (unicellular, colonial, filamentous, or multicellular) for each group.
 - c. Explain some ways that helminths differ from the protozoa and algae in structure and behavior.

Organelle/ Structure	Briefly Describe Functions in Cell	Commonly Present In (Check)		
		Fungi	Algae	Protozoa
Flagella				
Cilia				
Glycocalyx				
Cell wall				
Cell membrane				
Nucleus				
Mitochondria				
Chloroplasts				
Endoplasmic reticulum				
Ribosomes				
Cytoskeleton				
Lysosomes				
Microvilli				
Centrioles				

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps along with concept-mapping activities for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

1. Explain the ways that mitochondria resemble rickettsias and chloroplasts resemble cyanobacteria.
2. Give the common name of a eukaryotic microbe that is unicellular, walled, nonphotosynthetic, nonmotile, and bud-forming.
3. How are the eukaryotic ribosomes and cell membranes different from those of prokaryotes?
4. What general type of multicellular parasite is composed primarily of thin sacs of reproductive organs?
5. a. Name two parasites that are transmitted in the cyst form.
b. How must a non-cyst-forming pathogenic protozoan be transmitted? Why?
6. Explain what factors could cause opportunistic mycoses to be a growing medical problem.
7. a. How are bacterial endospores and cysts of protozoa alike?
b. How do they differ?
8. For what reasons would a eukaryotic cell evolve an endoplasmic reticulum and a Golgi apparatus?
9. Can you think of a simple test to determine if a child is suffering from pinworms? Hint: Clear adhesive tape is involved.

Visual Challenge

1. What term is used to describe a single species exhibiting both cell types shown below, and which types of organisms would most likely have this trait?
2. Label the major structures you can observe in the images in figure 5.17a, table 5.5A, B, and D, and table 5.8C.

CASE STUDY Part 1 A Killer Virus

On May 12, 2015, U.S. inspectors detected the presence of a highly **pathogenic influenza virus** circulating within a large population in Nebraska. To slow the spread of the virus, all 1.7 million members of the population were killed.

Of course, the population in which the virus was discovered was a commercial chicken flock and not humans, but there are nonetheless serious consequences involved. The 1.7 million reflected only the latest **outbreak** in an **epidemic** that had led to the culling of 48 million chickens and turkeys since the beginning of the year. For the ranchers involved, such an outbreak means reduced profits at best and, at worst, bankruptcy and loss of family farms going back generations. By the end of May the cost of eggs had risen 120%, forcing stores and restaurants across the country to raise prices. In some cases, chickens, ducks, and pigeons that were kept as pets in backyard flocks were also euthanized to prevent the spread of avian influenza.

The virus was identified as **H5N2** by researchers, an alphanumeric designation based on two types of proteins found on the viral surface. H refers to **hemagglutinin**, a protein that allows the virus to initiate infection by binding to cells of the respiratory tract. N is shorthand for **neuraminidase**, an enzyme that digests a component of mucus, allowing the virus to penetrate further into the respiratory tract. Together, these two molecules help define exactly what type of cells are susceptible to infection and how serious that infection

may eventually become. With regard to birds, there are 16 H **subtypes** (H1–H16) and 9 N subtypes (N1–N9) resulting in 144 possible combinations. The H5N2 subtype moves rapidly from bird to bird and causes a serious infection, leading to its designation as a **highly pathogenic avian influenza**—HPAI H5N2—but the virus seems to move very poorly from birds to humans and from one human to another.

“The H5N2 subtype was characterized as a highly pathogenic avian influenza.”

The standard response to an outbreak of avian influenza in domestic birds consists of five steps: (1) **Quarantine**—the movement of birds and equipment is restricted. (2) **Eradicate**—all birds within the affected flock are euthanized. (3) **Monitor**—Wild and domestic birds in a broad area surrounding the quarantine site are scrutinized for the presence of the virus. (4) **Disinfect**—The virus is destroyed in the affected location. (5) **Test**—Confirm that the poultry farm is free of avian influenza virus. Despite repeatedly applying this protocol to flocks throughout the country, the virus continued to reappear.

- Which viral protein is most involved in determining the “host range” of the influenza virus?
- If the standard response to viral outbreaks outlined above is correctly followed, why does the virus keep returning?

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

SCOPING OUT THE CHAPTER

Smaller and simpler than even the most modest prokaryotic cell, viruses are responsible for some of the most virulent diseases on Earth (Ebola fever) as well as some of the most mundane (the common cold). In this chapter we survey viruses—so small they cannot be seen without an electron microscope, so simple that most scientists don't consider them to be alive, and yet each of us has been infected by them many, many times.

Composed only of an inner molecule of genetic material surrounded by a protein coat, and occasionally an outer envelope, viruses are far simpler than cells.

Proteins anchored in the viral envelope guide the attachment of the virus to its host cell. The virus enters the host and redirects the metabolism of the host cell toward the production of hundreds of additional viral particles.

After replication, the newly created viruses exit the cell and commence the search for a new host.

Unlike bacterial cells, the growth of viruses in the lab requires that a living host be used as the "growth medium." Cell culture, live animals, and eggs are all commonly used to cultivate viruses.

Even simpler than viruses, prions consist exclusively of protein. They cause a number of transmissible spongiform encephalopathies, named for the spongy appearance of brain cells infected with the pathogen.

6.1 Overview of Viruses

Expected Learning Outcomes

1. Indicate how viruses were discovered and characterized.
2. Describe the unique characteristics of viruses.
3. Discuss the origin and importance of viruses.

Early Searches for the Tiniest Microbes

The discovery of the light microscope made it possible to see firsthand the agents of many bacterial, fungal, and protozoan diseases. But the techniques for observing and cultivating these relatively large microorganisms were useless for viruses. For many years the cause of viral infections such as smallpox and polio was unknown, even though it was clear that the diseases were transmitted from person to person. The French bacteriologist Louis Pasteur was

certainly on the right track when he postulated that rabies was caused by a “living thing” smaller than bacteria, and in 1884 he was able to develop the first vaccine for rabies.

The first substantial revelations about the unique characteristics of viruses occurred in the 1890s. First, Dmitri Ivanovski and Martinus Beijerinck showed that a disease in tobacco was caused by a virus (tobacco mosaic virus). In fact, it was Beijerinck who first proposed the term **virus** (L., “poison”) to denote this particular group of infectious agents. This discovery was followed by Friedrich Loeffler and Paul Frosch’s isolation of the virus that causes foot-and-mouth disease in cattle. These early researchers found that when infectious fluids from host organisms were passed through porcelain filters designed to trap bacteria, the filtrate remained infectious even though they could not see the infectious agent with a microscope.

Over the succeeding decades, a remarkable picture of the physical, chemical, and biological nature of viruses began to take form. Years of experimentation were required to show that viruses were noncellular particles with a definite size, shape, and chemical composition. Specialized techniques were developed to culture them in the laboratory. In time, virology grew into a multifaceted discipline that promised to provide much information on disease, genetics, and even life itself (**6.1 Making Connections**).

The Position of Viruses in the Biological Spectrum

Viruses are a unique group of biological entities known to infect every type of cell, including bacteria, algae, fungi, protozoa, plants, and animals. Although the emphasis in this chapter is on animal viruses, much credit for our knowledge must be given to experiments with bacterial and plant viruses. The exceptional and curious nature of viruses prompts numerous questions, including:

1. How did viruses originate?
2. Are they organisms; that is, are they alive?
3. What are their distinctive biological characteristics?
4. How can particles so small, simple, and seemingly insignificant be capable of causing disease and death?
5. What is the connection between viruses and cancer?

In this chapter we address these ideas and many others.

There is no universal agreement on how and when viruses originated. But there is little disagreement that they have been in existence for billions of years, probably ever since the early history of cells. One theory explains that viruses arose from loose strands of genetic material released by cells. These then developed a protective coating and a capacity to reenter a cell and use its machinery to reproduce. An alternate explanation for their origins suggests that they were once cells that have regressed to a highly parasitic existence inside other cells. Both of these viewpoints have some supportive evidence, and it is entirely possible that viruses have originated in more than one way.

In terms of numbers, viruses are considered the most abundant microbes on earth. To quote microbiologist Carl Zimmer, we live on “a planet of viruses.” Based on a decade of research on the viral populations in the ocean, “virus hunters” now have

evidence that there are hundreds of thousands of distinct virus types that have never been described. Many of them are parasites of bacteria, which are also abundant in most ecosystems. By one estimate, viruses outnumber bacteria by a factor of 10. Because viruses tend to interact with the genetic material of their host cells and can carry genes from one host cell to another (chapter 9), they have played an important part in the evolution of Bacteria, Archaea, and Eukarya.

Viruses are different from their host cells in size, structure, behavior, and physiology. They are a type of **obligate intracellular parasite** that cannot multiply unless it invades a specific host cell and instructs its genetic and metabolic machinery to make and release quantities of new viruses. Because of this characteristic, viruses are capable of causing serious damage and disease. Other unique properties of viruses are summarized in **table 6.1**.

The unusual structure and behavior of viruses have led to debates about their connection to the rest of the microbial world. One viewpoint holds that viruses are unable to exist independently from the host cell, so they are not living things but are more akin to large, infectious molecules. Another viewpoint proposes that even though viruses do not exhibit most of the life processes of cells (look back at section 4.1), they can direct those processes and thus are certainly more than inert and lifeless molecules. Depending upon the circumstances, both views are defensible. The importance of this debate is more philosophical than practical, because viruses are agents of disease and must be dealt with through control, therapy, and prevention, whether we regard them as living or not. In keeping with their special position in the biological spectrum, it is best to describe viruses as *infectious particles* (rather than organisms) and as either *active* or *inactive* (rather than alive or dead).

TABLE 6.1 Properties of Viruses

- Obligate intracellular parasites of bacteria, protozoa, fungi, algae, plants, and animals
- Ultramicroscopic size, ranging from 20 nm up to 450 nm (diameter)
- Not cellular in nature; structure is very compact and economical
- Do not independently fulfill the characteristics of life
- Inactive macromolecules outside the host cell and active only inside host cells
- Basic structure consists of protein shell (capsid) surrounding nucleic acid core
- Nucleic acid of the viral genome is either DNA or RNA but not both
- Nucleic acid can be double-stranded DNA, single-stranded DNA, single-stranded RNA, or double-stranded RNA
- Molecules on virus surface impart high specificity for attachment to host cell
- Multiply by taking control of host cell’s genetic material and regulating the synthesis and assembly of new viruses
- Lack enzymes for most metabolic processes
- Lack machinery for synthesizing proteins

6.1 MAKING CONNECTIONS

An Alternate View of Viruses

Looking at this beautiful tulip, one would never guess that its beauty derives partly from the flower's being infected with tulip mosaic virus, which alters the development of the plant cells and causes varying patterns of colors in the petals. Aside from this, the virus does not immediately destroy the plants. Despite the reputation of viruses as destructive pathogens, there is another side to viruses—that of being benign and, in some cases, even beneficial.

Research in extreme habitats in Antarctica uncovered a surprisingly rich diversity of viruses inhabiting a frigid lake. Analysis of the genetic material of the samples revealed more than 10,000 unique viruses gathered from just a small area. Other studies of the ocean have documented the presence of 10 million viruses per milliliter of water—10 times the number of cellular microbes. This hints at the dominant role viruses have in the world's ecosystems, not only because they infect and can control populations of eukaryotic and prokaryotic cells, but also because they appear to influence a number of biological activities, including photosynthesis and the cycling of nutrients.

Over the past several years, biomedical experts have been looking at viruses as vehicles to treat infections and disease. Vaccine experts have engineered new types of vaccines by combining a less harmful virus such as vaccinia or adenovirus with genetic material from a pathogen such as HIV and herpes simplex. This technique creates a vaccine that provides immunity but does not expose the person to the intact pathogen. Several of these types of vaccines are being tested.

© Kathy Park Talaro

The “harmless virus” approach is also being used to treat genetic diseases such as cystic fibrosis and sickle-cell anemia. With gene therapy, the normal gene is inserted into a virus vector, such as an adenovirus, and the patient is infected with this altered virus. It is hoped that the virus will introduce the needed gene into the cells and correct the defect. Dozens of experimental trials are under way to develop potential cures for diseases, with mixed success (look ahead to chapter 10).

An older therapy getting a second look involves use of bacteriophages to treat bacterial infections (phage therapy). The basis behind the therapy is that bacterial viruses can selectively attack and destroy their host bacteria without damaging human cells. Experiments with animals indicate that this method controls some infections as well as traditional drugs can. Potential applications include adding phage suspensions to skin grafts and to intravenous fluids to control infections.

The U.S. Department of Agriculture has recently approved bacteriophage treatments to prevent food infections. One type is designed to spray on livestock to reduce the incidence of pathogenic *Escherichia coli*. The other is intended for use on processed meats and poultry to control *Listeria monocytogenes*, another prominent food-borne pathogen.

Explain why bacterial viruses would be harmless to humans.
Answer available on Connect.

Check Your Progress SECTION 6.1

1. Describe 10 *unique* characteristics of viruses (can include structure, behavior, multiplication).
2. After consulting table 6.1, what additional facts can you state about viruses, especially as compared with cells?
3. Explain what it means to be an obligate intracellular parasite.
4. What are some other ways to describe the sort of parasitism exhibited by viruses?

6.2 The General Structure of Viruses

Expected Learning Outcomes

4. Describe the general structure and size range of viruses.
5. Distinguish among types of capsids and nucleocapsids.
6. Describe envelopes and spikes, and discuss their origins.
7. Explain the functions of capsids, nucleocapsids, envelopes, and spikes.
8. Summarize the different viral groups based on their basic structure.

Size Range

As a group, viruses are the smallest infectious agents (with some unusual exceptions to be discussed in section 6.8). Their size places them in the realm of the *ultramicroscopic*. This term means that most of them are so minute ($< 0.2 \mu\text{m}$) that an electron microscope is necessary to detect them or to examine their fine structure. They are dwarfed by their host cells: More than 2,000 bacterial viruses could fit into an average bacterial cell, and more than 50 million polioviruses could be accommodated by an average human cell. Animal viruses range in size from the small parvoviruses¹ (around 20 nm in diameter) to megaviruses and pandoraviruses² that are as large as small bacteria (up to 1,000 nm in width) (**figure 6.1**). Some cylindrical viruses are relatively long (800 nm in length) but so narrow in diameter (15 nm) that they still cannot be seen without the high magnification and resolution of an electron microscope. Figure 6.1 compares the sizes of several viruses with prokaryotic and eukaryotic cells and molecules.

1. DNA viruses that cause respiratory infections in humans.

2. Groups of large, complex viruses that are parasites inside cells of ocean-dwelling amoebas.

Figure 6.1 Size comparison of viruses with a yeast cell colored blue (eukaryotic) and various bacteria (prokaryotic). Viruses range from largest (1) to smallest (10). A molecule of a large protein (11) is included to indicate relative size of macromolecules.

Viral architecture is most readily observed through special stains in combination with electron microscopy. Negative staining uses an opaque salt to outline the shape of the virus against a dark background and to enhance textural features on the viral surface. Internal details are revealed by positive staining of specific parts of the virus such as protein or nucleic acid. The *shadowcasting* technique shows a virus preparation with a dense metallic vapor directed from a certain angle. These techniques are featured in several figures throughout this chapter.

Monster Viruses

In chapter 4 we featured discoveries of unusual types of bacteria. There are also some exceptional viruses. Probably the most outstanding examples are megaviruses (figure 6.2) and pandoraviruses. These are giants in the viral world, averaging about 500 to

1,000 nm in diameter, 20 to 50 times larger than an average virus and even larger than small bacteria such as rickettsias. The megaviruses were first discovered as parasites inside the cells of amoebas living in aquatic habitats. Pandoraviruses were isolated from their amoebic hosts living in sediments deep in the floor of the ocean. Both giant viruses lack cellular structure and ribosomes, metabolic enzymes, and fission-style division. They have a typical viral cycle, multiplying in the host cytoplasm in well-developed “virus factories.” Although both are unusually large for viruses, the pandoraviruses have the largest capsids and genomes ever discovered in a virus, containing 2,500 genes!

Where these unusual viruses fit on the “tree of life,” if anywhere at all, is still the subject of debate. Some microbiologists suggest that they may belong to a separate evolutionary line of microbes that is different in origin from other viral groups. Another possibility is that these viruses are related to ancient forms that evolved into the first cells.

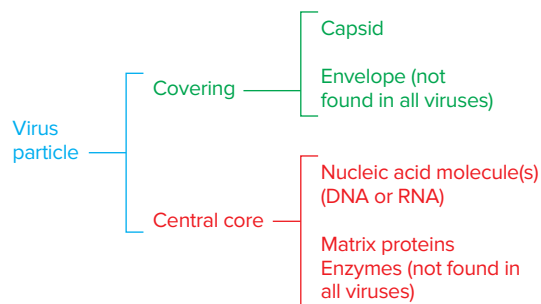

Figure 6.2 A monster virus—the megavirus. A TEM of one virus particle reveals its unique geometric shape, dark DNA core, and fine surface fibrils (4,500 \times). These viruses would be readily visible with an ordinary light microscope. Courtesy of C. Abergel/IGS-IMM, CNRS-AMU

Viral Components: Capsids, Nucleic Acids, and Envelopes

It is important to realize that viruses bear no real resemblance to cells and that they lack any of the synthetic machinery found in even the simplest cells. Their molecular structure consists of regular, repeating molecules that give rise to their crystalline appearance. Indeed, many purified viruses can form large aggregates or crystals if subjected to special treatments (**figure 6.3**). The general plan of virus organization is very simple and compact. Viruses contain only those parts needed to invade and control a host cell: an external coating and a core containing one or more nucleic acid strands of either DNA or RNA. This pattern can be represented with a flowchart:

All viruses have a protein **capsid**,* or shell, that surrounds the nucleic acid in the central core. Together, the capsid and the nucleic acid are referred to as the **nucleocapsid**. Viruses that consist of only a nucleocapsid are considered **naked viruses** (**figure 6.4a**). Of

* *capsid* (kap'-sid) L. *capsa*, box.

Figure 6.3 The crystalline nature of viruses. (a) Light microscope magnification (1,200 \times) of purified poliovirus crystals. (b) Highly magnified (200,000 \times) negative stain of hundreds of polioviruses shows the tight geometric arrangements of particles. (a): Source: F. L. Schaffer, C. E. Schwerdt, "Crystallization of purified MEF-1 poliomyelitis virus particles," *PNAS*, 41(12): 1020-1023, 1955, fig. 2b; (b): Source: CDC

the 20 families of animal viruses, 13 are **enveloped**—that is, they possess an additional covering external to the capsid called an envelope, which is a modified section of the host's cell membrane (**figure 6.4b**). As we shall see later, the enveloped viruses also

(a) Naked Nucleocapsid Virus

(b) Enveloped Virus

Figure 6.4 Generalized structure of viruses. (a) The simplest virus is a naked nucleocapsid consisting of a geometric capsid assembled around one or more nucleic acid strands. (b) An enveloped virus is composed of a nucleocapsid surrounded by a flexible membrane called an envelope. The envelope usually has special receptor spikes inserted into its membrane.

differ from the naked viruses in the possible ways that they enter and leave a host cell.

The Viral Capsid: The Protective Outer Shell

When a virus particle is magnified several hundred thousand times, the capsid appears as the most prominent geometric feature (figure 6.4). In general, the capsid of any virus is constructed from a number of identical protein subunits called **capsomers**.* The capsomers can spontaneously self-assemble into the finished capsid. The shape and arrangement of the capsomers results in the production of one of two different types of capsids: helical or icosahedral.

Quick Search

Fun with viruses! Search the Internet for “paper virus models” or a “bacteriophage balloon.”

The simpler **helical capsids** have rod-shaped capsomers that bind together to form a series of hollow discs resembling a bracelet. During the formation of the nucleocapsid, these discs link together and form a continuous helix into which the nucleic acid strand is coiled (**figure 6.5**). In electron micrographs, the appearance of a helical capsid varies with the type of virus. The nucleocapsids of naked helical viruses are very rigid and tightly wound into a cylinder-shaped package (**figure 6.6a**). Several viruses that infect plants are of this type (**figure 6.6b**). Enveloped helical nucleocapsids are more flexible and tend to be arranged as a looser helix within the envelope (**figure 6.6c, d**). This type of capsid is found in several enveloped human viruses, including those of influenza, measles, and rabies.

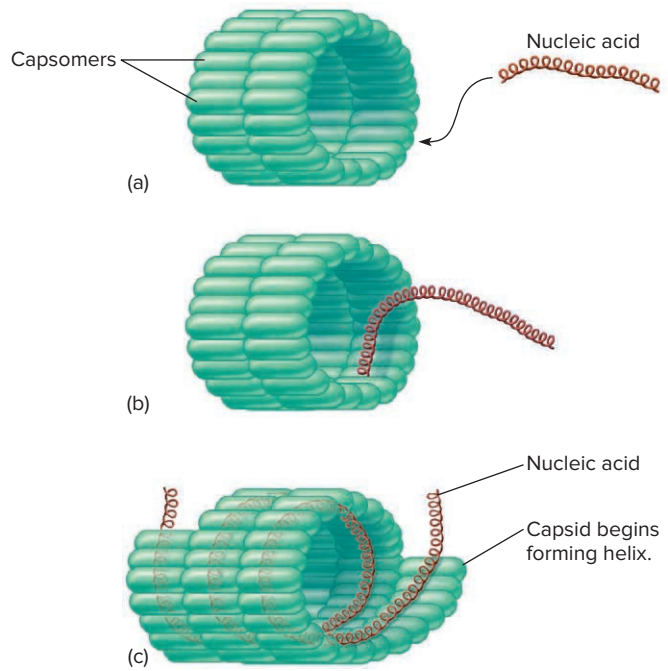

Figure 6.5 Assembly of helical nucleocapsids. (a) Capsomers assemble into hollow discs. (b) The nucleic acid is inserted into the center of the disc. (c) Elongation of the nucleocapsid progresses from both ends, as the nucleic acid is wound “within” the lengthening helix.

Several major virus families have capsids arranged in an **icosahedron***—a three-dimensional, symmetrical polygon, with 20 sides and 12 evenly spaced corners. The arrangements of the

* *capsomer* (kap'-soh-meer) L. *capsa*, box, and *mer*, part.

* *icosahedron* (eye'-koh-suh-hee'-drun) Gr. *eikosi*, twenty, and *hedra*, side. A type of polygon.

Department of Agriculture; (d): Source: Frederick Murphy/CDC

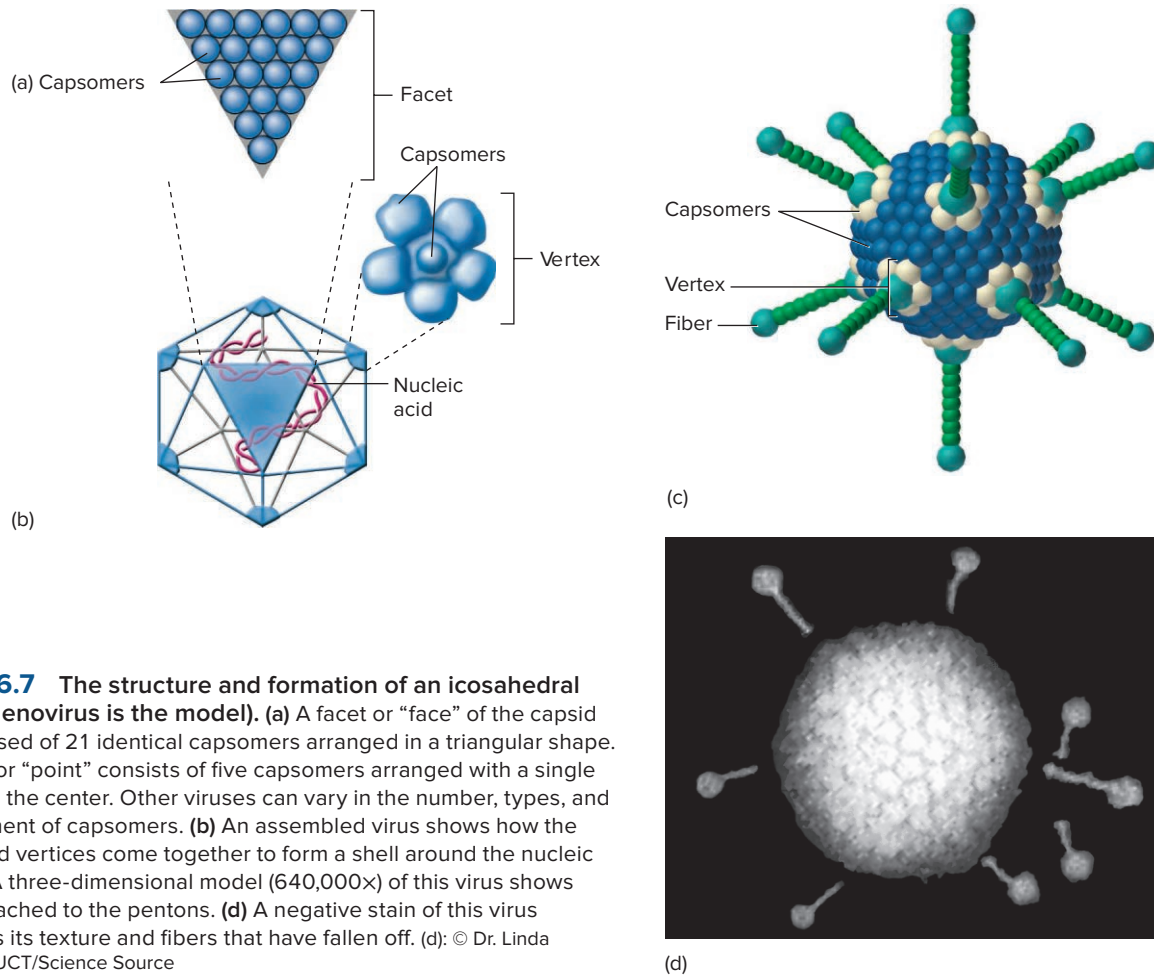

Figure 6.7 The structure and formation of an icosahedral virus (adenovirus is the model). (a) A facet or “face” of the capsid is composed of 21 identical capsomers arranged in a triangular shape. A vertex or “point” consists of five capsomers arranged with a single penton in the center. Other viruses can vary in the number, types, and arrangement of capsomers. (b) An assembled virus shows how the facets and vertices come together to form a shell around the nucleic acid. (c) A three-dimensional model (640,000x) of this virus shows fibers attached to the pentons. (d) A negative stain of this virus highlights its texture and fibers that have fallen off. (d): © Dr. Linda Stannard, UCT/Science Source

capsomers vary from one virus to another. The capsid of some viruses contains a single type of capsomer, whereas others may contain several types of capsomers (**figure 6.7**). Although the capsids of all icosahedral viruses have this sort of symmetry, they can vary in the number of capsomers; for example, a poliovirus has 32 capsomers and an adenovirus has 242. During assembly of the virus, the nucleic acid is packed into the center of this icosahedron, forming a nucleocapsid. Another factor that alters the appearance of icosahedral viruses is whether or not they have an outer envelope. Inspect **figure 6.8** to compare a rotavirus and its naked nucleocapsid with herpes simplex (cold sores) and its enveloped nucleocapsid.

The Viral Envelope

When enveloped viruses (mostly animal) are released from the host cell, they take with them a bit of the host’s membrane system in the form of an envelope. Some viruses bud off the cell membrane; others leave via the nuclear envelope or the endoplasmic reticulum. Although the envelope is derived from the host, it is different because some or all of the regular membrane proteins are replaced with special viral proteins during the virus assembly process (see **figure 6.11**). Some proteins form a binding layer between the envelope and capsid of the virus, and glycoproteins (proteins bound to a carbohydrate) remain exposed on the outside of the envelope. These

protruding molecules, called **spikes** or peplomers, are essential for the attachment of viruses to the next host cell. Because the envelope is more supple than the capsid, enveloped viruses are pleomorphic and range from spherical to filamentous in shape.

Functions of the Viral Capsid/Envelope

The outermost covering of a virus is indispensable to viral function because it protects the nucleic acid from the effects of various enzymes and chemicals when the virus is outside the host cell. We see this in the capsids of enteric (intestinal) viruses such as polio and hepatitis A, which are resistant to the acid- and protein-digesting enzymes of the gastrointestinal tract. Capsids and envelopes are also responsible for helping to introduce the viral DNA or RNA into a suitable host cell, first by binding to the cell surface and then by assisting in penetration of the viral nucleic acid (discussed in later sections). In addition, parts of viral capsids and envelopes stimulate the immune system to produce antibodies that can neutralize viruses and protect the host’s cells against future infections (see **chapter 15**).

Complex Viruses: Atypical Viruses

Two special groups of viruses, termed **complex viruses** (**figure 6.9**), are more intricate in structure than the helical, icosahedral, naked, or enveloped viruses just described. The **poxviruses** (including the agent

(a)

(b)

(a) Left view: A negative stain of rotaviruses with unusual capsomers that look like spokes on a wheel (150,000 \times); right view is a three-dimensional model of this virus. (b) Herpes simplex virus, a type of enveloped icosahedral virus (300,000 \times). (a: left): Source: Fred P. Williams, Jr./EPA; (a: right): © Dr. Linda Stannard, UCT/Science Source; (b): © Eye of Science/Science Source

of smallpox) are very large DNA viruses that lack a typical capsid and are covered by a dense layer of lipoproteins and coarse fibrils on their outer surface. Some members of another group of very complex viruses, the **bacteriophages**,* have a polyhedral capsid head as well as a helical tail and fibers for attachment to the host cell. Their mode of multiplication is covered in section 6.5. **Figure 6.10** summarizes the primary morphological types found among the viruses.

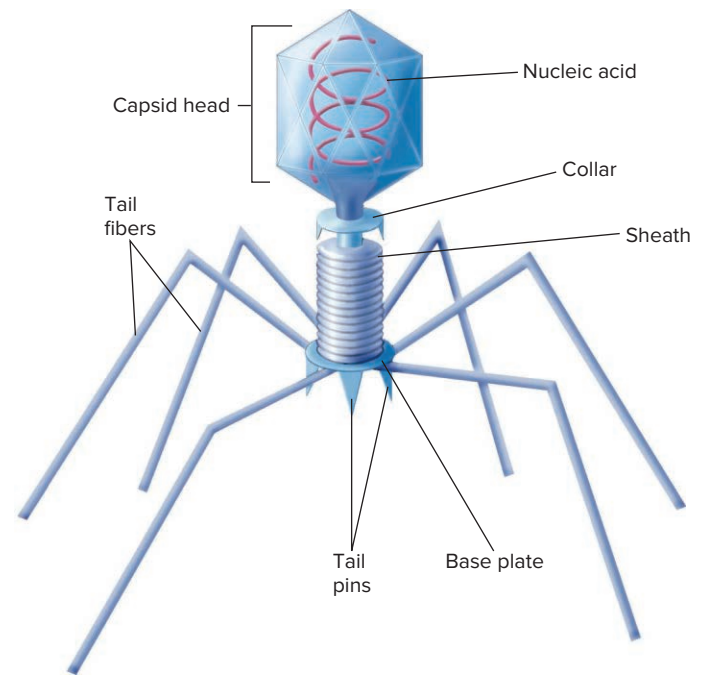

Nucleic Acids: At the Core of a Virus

The sum total of the genetic information carried by an organism is known as its **genome**. So far, one biological constant is that the genome of all organisms is carried by and expressed through nucleic acids (DNA, RNA). Even viruses are no exception to this rule, but there is a significant difference. Unlike cells, which contain both DNA and RNA, **viruses contain either DNA or RNA, but not both, as the primary genetic material**. Because viruses must pack into a tiny space all of the genes necessary to instruct the host cell to make new viruses, the number of viral genes is usually quite

* *bacteriophage* (bak-ter'ee-oh-fayj") From *bacteria*, and Gr. *phagein*, to eat. These viruses parasitize bacteria.

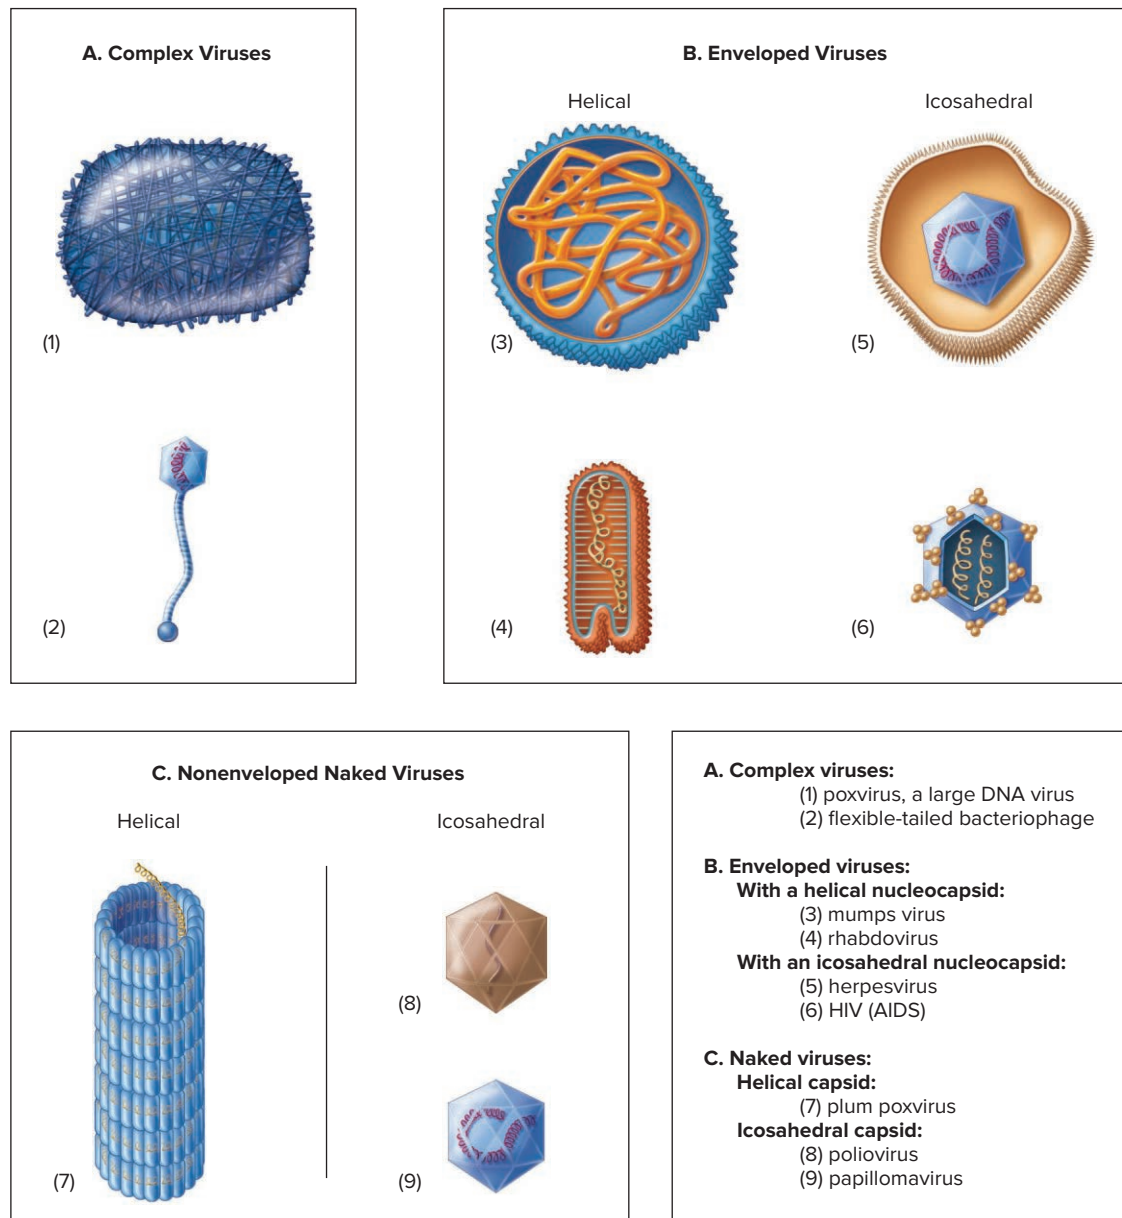

Figure 6.10 Basic types of viral morphology.

small compared with that of a cell. It varies from nine genes in human immunodeficiency virus (HIV) to as many as 2,500 genes in pandoraviruses. By comparison, the bacterium *Escherichia coli* has approximately 4,000 genes, and a human cell has around 21,000 genes. Having a larger genome allows cells to carry out the complex metabolic activity necessary for independent life. Viruses typically possess only the genes needed to invade host cells and redirect their synthetic machinery to make new viruses.

In chapter 2 you learned that DNA usually exists as a double-stranded molecule and that RNA is single-stranded. Although most viruses follow this same pattern, viruses exhibit variety in how their RNA or DNA is configured. DNA viruses can have single-stranded (ss) or double-stranded (ds) DNA; the dsDNA can be arranged linearly or in circles. RNA viruses can be double-stranded but are more often single-stranded. Notable examples are the parvoviruses,

which contain single-stranded DNA, and reoviruses (a cause of respiratory and intestinal tract infections), which contain double-stranded RNA. You will learn in chapter 9 that all proteins are made by “translating” the nucleic acid code on a single strand of RNA into an amino acid sequence. Single-stranded RNA genomes that are ready for immediate translation into proteins are called *positive-strand* RNA. RNA genomes that have to be converted into the proper form for translation are called *negative-strand* RNA.

RNA genomes may also be *segmented*, meaning that the individual genes exist in separate RNA molecules, similar to the way that the human (DNA) genome is spread across 23 separate chromosomes. The influenza virus (an orthomyxovirus) is an example of this form. Another RNA virus with some unusual features is a *retrovirus*, one of the few virus types that converts its nucleic acid from RNA to DNA inside its host cell.

Whatever the virus type, these tiny strands of genetic material carry the blueprint for viral structure and functions. In a very real sense, viruses are genetic parasites because they cannot multiply until their nucleic acid has reached their haven inside the host cell. At a minimum, they must carry genes for synthesizing the viral capsid and genetic material, for regulating the actions of the host, and for packaging the mature virus.

Other Substances in the Virus Particle

In addition to the protein of the capsid, the proteins and lipids of envelopes, and the nucleic acid of the core, viruses can contain enzymes for specific operations within their host cell. They may come with preformed enzymes that are required for viral **replication**.^{*} Examples include **polymerases**^{*} that synthesize DNA and RNA and replicase enzymes that copy RNA. The human immunodeficiency virus (HIV) comes equipped with *reverse transcriptase* for synthesizing DNA from RNA. However, viruses completely lack the genes for synthesis of metabolic enzymes. As we shall see, this deficiency has little consequence, because viruses have adapted to assume total control over the cell's metabolic resources. Some viruses can actually carry away substances from their host cell. For instance, arenaviruses pack along host ribosomes, and retroviruses “borrow” the host's tRNA molecules.

6.3 How Viruses Are Classified and Named

Expected Learning Outcomes

9. Explain the classification scheme used for viruses.
10. Indicate the characteristics used in identifying and naming viruses.

Although viruses are not classified as members of the domains discussed in chapter 1, they are diverse enough to require their own classification scheme to aid in their study and identification. In an informal and general way, we have already begun classifying viruses—as animal, plant, or bacterial viruses; enveloped or naked viruses; DNA or RNA viruses; and helical or icosahedral viruses. These introductory categories are certainly useful in organization and description, but the study of specific viruses requires a more standardized method of nomenclature. For many years, the animal viruses were classified mainly on the basis of their hosts and the kind of diseases they caused. Newer systems for naming viruses also take into account the actual nature of the virus particles themselves, with only partial emphasis on host and disease. The main criteria presently used to group viruses are structure, chemical composition, and similarities in genetic makeup, which indicate evolutionary relatedness.

The International Committee on the Taxonomy of Viruses lists seven orders, 104 families, and 505 genera of viruses. Nomenclature of viruses follows these conventions: Virus families are italicized and given the suffix *-viridae*, and virus genera are likewise italicized and end in *-virus*.

^{*} *replication* (rep-lih-kay'-shun) L. *replicare*, to reply. To make an exact duplicate.
^{*} *polymerase* (pol-im'-ur-ace) An enzyme that synthesizes a large molecule from smaller subunits.

Historically, some virologists had created an informal *species* naming system that mirrors the species names in higher organisms, using genus and species epithets such as *Measles morbillivirus*. The species category has created a lot of controversy within the virology community. Many scientists argue that nonorganisms such as viruses are too changeable and that fine distinctions used for deciding on species classifications will quickly disappear. All the same, over the past decade virologists have largely accepted the concept of viral species, defining them as distinct virus types that share a collection of properties such as host range, pathogenicity, and genetic makeup. The influenza viruses are an example of how variations in the receptors can give rise to different strains or subtypes, even though they are basically the same viruses in other characteristics (Case Study, this chapter).

Because the use of standardized species names are not as widely used, the genus or common English vernacular names (such as poliovirus and rabies virus) predominate in discussions of specific viruses in this text. **Table 6.2** illustrates a system of classification for important viruses and the diseases they cause. To-scale examples of each virus family are included.

Characteristics used for placement in a particular family include type of capsid, nucleic acid strand number, presence and type of envelope, overall viral size, and area of the host cell in which the virus multiplies. Some virus families are named for their microscopic appearance (shape and size). Examples include **rhabdoviruses**,^{*} which have a bullet-shaped envelope, and **togaviruses**,^{*} which have a cloaklike envelope. Anatomical or geographic areas have also been used in naming. For instance, **adenoviruses**^{*} were first discovered in adenoids (one type of tonsil), and **hantaviruses** were originally isolated in the Korean Province of Hantaan. Viruses can also be named for their effects on the host. **Lentiviruses**^{*} tend to cause slow, chronic infections. Acronyms made from blending several characteristics include **picornaviruses**,^{*} which are tiny RNA viruses, and **hepadnaviruses** (for hepatitis and DNA).

Check Your Progress SECTIONS 6.2 AND 6.3

5. Characterize viruses according to size range. What does it mean to say that they are ultramicroscopic?
6. Describe the general structure of viruses.
7. What is the capsid, and what is its function? How are the two types of capsids constructed?
8. What is a nucleocapsid? Give examples of viruses with the two capsid types.
9. What is an enveloped virus, and how does the envelope arise? What are spikes, how are they formed, and what is their function?
10. What are bacteriophages, and what is unique about their structure?
11. How are the poxviruses different from other animal viruses?
12. Explain the characteristics used in viral classification and the nature of viral families.
13. How are generic and common names used?

^{*} *rhabdovirus* (rab'-doh-vy'-rus) Gr. *rhabdo*, little rod.

^{*} *togavirus* (toh'-guh-vy'-rus) L. *toga*, covering or robe.

^{*} *adenovirus* (ad'-uh-noh-vy'-rus) G. *aden*, gland.

^{*} *lentivirus* (len'-tee-vy'-rus) Gr. *lente*, slow. HIV, the AIDS virus, belongs in this group.

^{*} *picornavirus* (py-kor'-nah-vy'-rus) Sp. *pico*, small, plus RNA.

TABLE 6.2 Important Human Virus Families, Genera, Common Names, and Types of Diseases

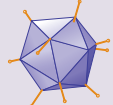

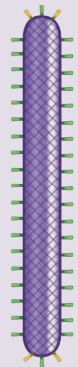

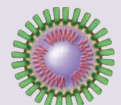

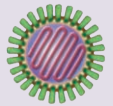

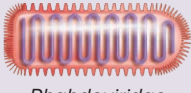

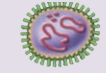

Nucleic Acid Type	Family	Genus of Virus	Common Name of Genus Members	Name of Disease		
DNA Viruses						
 Poxviridae Chordopoxvirinae	 Herpesviridae	<i>Poxviridae</i>	<i>Orthopoxvirus</i>	Variola and vaccinia	Smallpox, cowpox

		<i>Rhabdoviridae</i>	<i>Lyssavirus</i>	Rabies virus	Rabies (hydrophobia)
<i>Rhabdoviridae</i>	<i>Retroviridae</i>	<i>Retroviridae</i>	<i>Oncornavirus</i>	Human T-cell leukemia virus (HTLV)	T-cell leukemia
			<i>Lentivirus</i>	HIV (human immunodeficiency viruses 1 and 2)	Acquired immunodeficiency syndrome (AIDS)
		<i>Arenaviridae</i>	<i>Arenavirus</i>	Lassa virus	Lassa fever
<i>Arenaviridae</i>	<i>Coronaviridae</i>	<i>Coronaviridae</i>	<i>Coronavirus</i>	Infectious bronchitis virus (IBV)	Bronchitis
100 nm				Enteric corona virus	Coronavirus enteritis
				SARS virus	Severe acute respiratory syndrome

6.4 Modes of Viral Multiplication

Expected Learning Outcomes

- Describe the virus-host relationship.
- Relate the stages in the multiplication cycle of animal viruses, and summarize what is happening in each stage.
- Describe three ways in which animal viruses enter into a host cell.
- Define *replication* as it relates to viruses.
- Explain two ways in which animal viruses are released by a host cell.
- Describe cytopathic effects of viruses and the possible results of persistent viral infections.

Viruses are closely associated with their hosts. In addition to providing the viral habitat, the host cell is absolutely necessary for viral multiplication, which is synonymous with infection. The way in which viruses invade a host cell is an extraordinary biological phenomenon. Viruses have been aptly described as minute parasites that seize control of the synthetic and genetic machinery of cells. The nature of this cycle profoundly affects pathogenicity, transmission, the responses of the immune defenses, and human measures to control viral infections. From these perspectives, we cannot overemphasize the importance of a working knowledge of the relationship between viruses and their host cells.

Multiplication Cycles in Animal Viruses

The general phases in the life cycle of animal viruses are **adsorption**,* **penetration**, **synthesis**, **assembly**, and **release** from the host cell. Viruses vary in the exact mechanisms of these processes, but we will use a simple animal virus to illustrate the major events (**figure 6.11**). Other examples are given in chapter 9.

Adsorption and Host Range

Invasion begins when the virus encounters a susceptible host cell and adsorbs specifically to receptor sites on the cell membrane. The membrane receptors that viruses attach to are usually glycoproteins the cell requires for its normal function. For example, the rabies virus affixes

to receptors found on mammalian nerve cells, and the human immunodeficiency virus (HIV) attaches to the CD4 protein on certain white blood cells. The mode of attachment varies between the two general types of viruses. In enveloped forms such as influenza virus and HIV, glycoprotein spikes bind to the cell membrane receptors. Viruses with naked nucleocapsids (adenovirus, for example) use surface receptors on their capsids that adhere to cell membrane receptors (**figure 6.12**).

Because a virus can invade its host cell only through making an exact fit with a specific host molecule, the range of hosts it can infect in a natural setting is limited. This limitation, known as the **host range**, can vary from one virus to another. For example, hepatitis B infects only liver cells of humans; the poliovirus infects primarily intestinal and nerve cells of primates (humans, apes, and monkeys); and the rabies virus infects nerve cells of most mammals. Cells that lack compatible virus receptors are resistant to adsorption and invasion by that virus. This explains why, for example, human liver cells are not infected by the canine hepatitis virus and dog liver cells cannot host the human hepatitis A virus. It also explains why viruses usually have tissue specificities called **tropisms*** for certain cells in the body. The hepatitis B virus targets the liver, and the mumps virus targets salivary glands. Many viruses can be manipulated in the laboratory to infect cells that they do not infect naturally, thus making it possible to cultivate them.

Penetration/Uncoating of Animal Viruses

For an animal virus to successfully infect a cell, it must penetrate the cell membrane of the host cell and deliver the viral nucleic acid into the host cell's interior. How animal viruses do this varies with the type of virus and type of host cell, but most of them enter through one of two means, fusion or endocytosis. In the case of **fusion**, the viral envelope fuses directly with the host cell membrane, so it can occur only in enveloped viruses (**figure 6.13a**). Following attachment of the virus to host cell receptors, the lipids within the adjacent membranes become rearranged so that the nucleocapsid can be translocated into the cytoplasm for the synthesis phase.

In the **endocytosis** version of penetration, the virus can be either enveloped (**figure 6.13b**) or naked (**figure 6.13c**), and it is

* *adsorption* (ad-sorp'-shun) L. *ad*, to, and *sorbere*, to suck. The attachment of one thing onto the surface of another.

* *tropism* (troh'-pizm) Gr. *trope*, a turn. Having a special affinity for an object or substance.

Process Figure 6.11 General features in the multiplication cycle of an enveloped animal virus. Using an RNA virus (rubella virus), the major events are outlined, although other viruses will vary in exact details of the cycle.

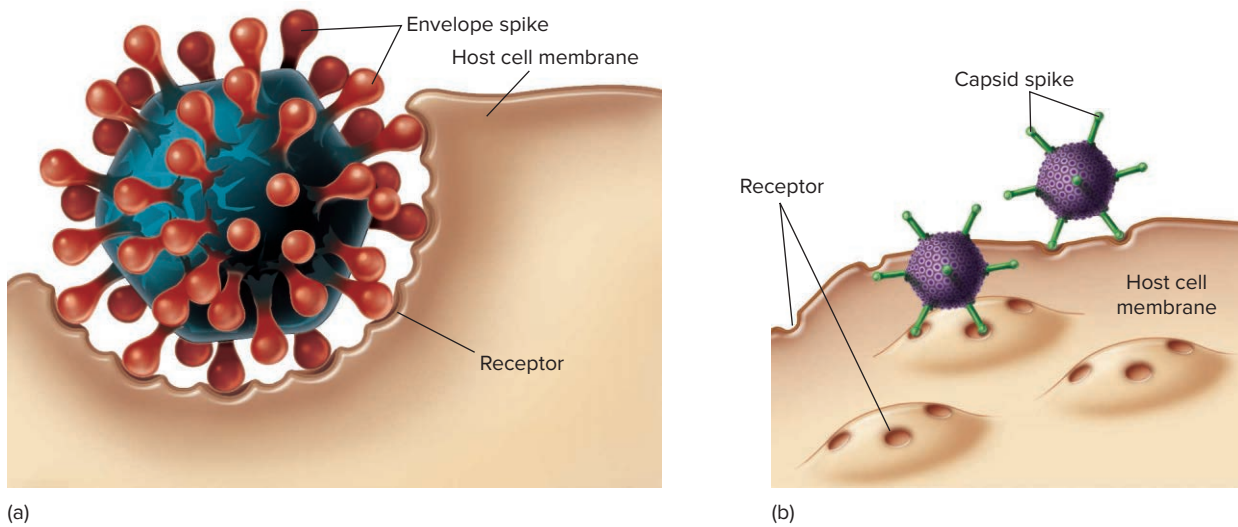

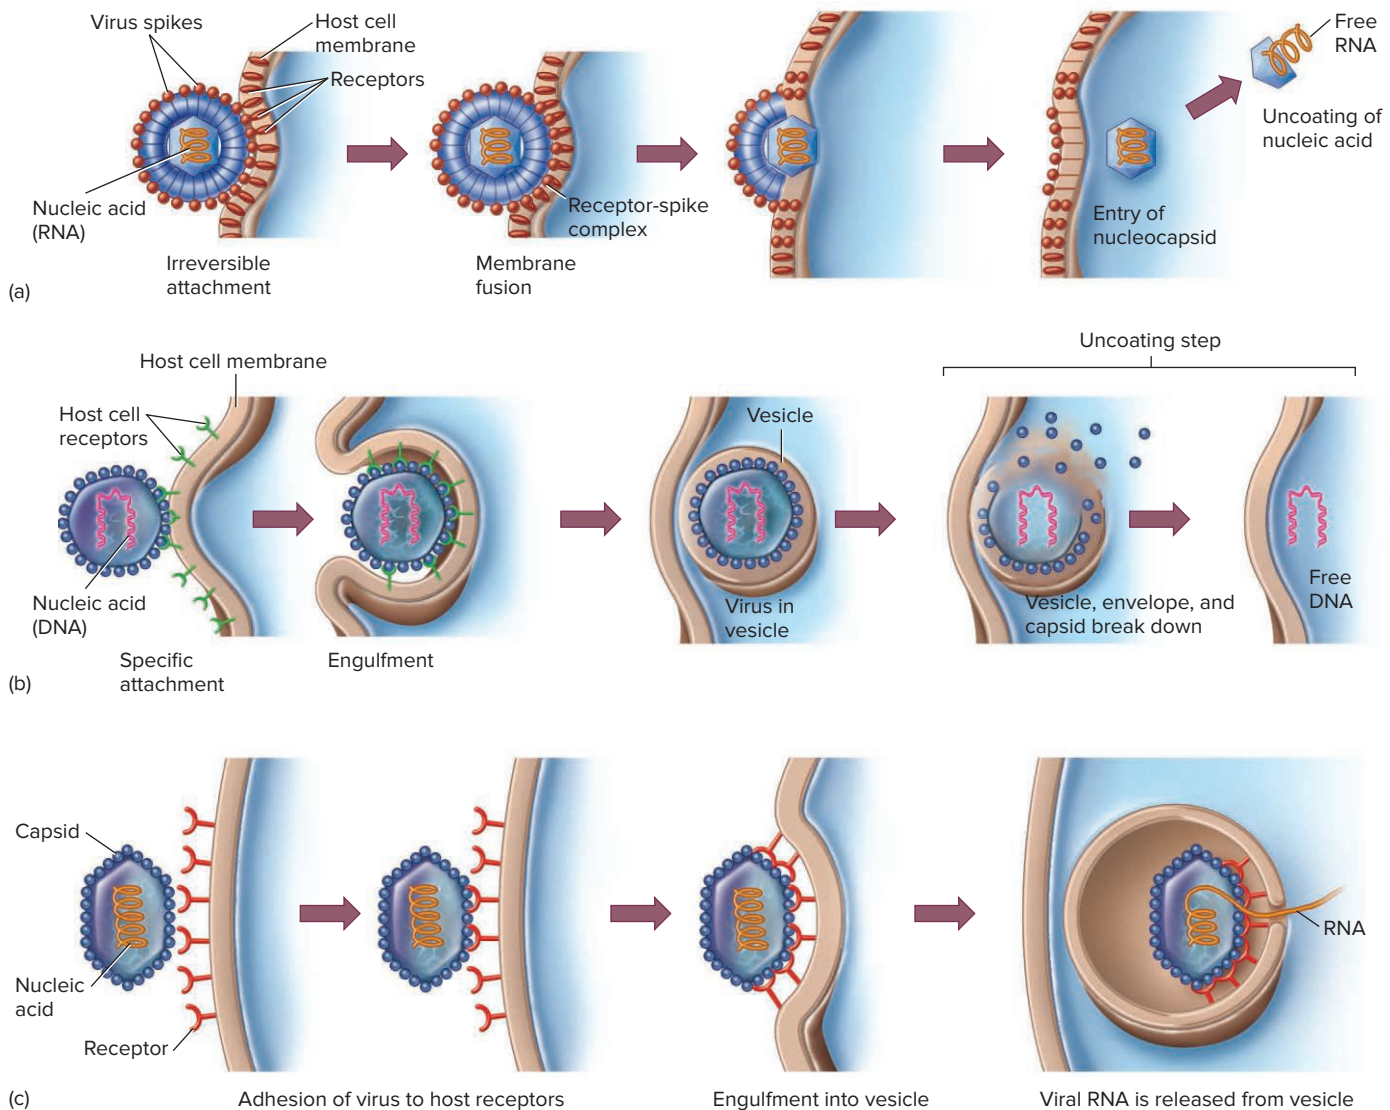

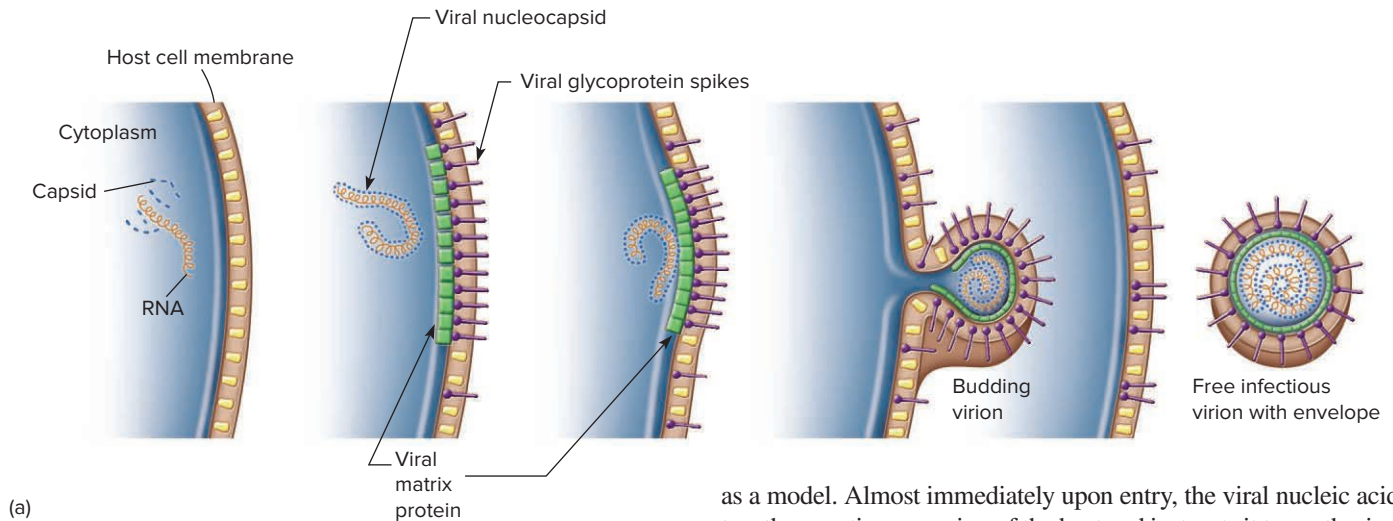

Figure 6.12 The mode by which animal viruses adsorb to the host cell membrane. **(a)** An enveloped coronavirus with prominent spikes. The configuration of the spike has a complementary fit for cell receptors. The process in which the virus lands on the cell and plugs into receptors is termed docking. **(b)** An adenovirus has a naked capsid that adheres to its host cell by nestling surface molecules on its capsid into the receptors on the host cell's membrane.

Process Figure 6.13 Modes of virus penetration. Pictured in **(a)** is the process of fusion between the envelope of the virus and the host cell membrane, with release of the nucleocapsid into the cytoplasm. This is the mechanism for mumps and HIV viruses. Both **(b)** and **(c)** are examples of entry by endocytosis or engulfment, followed by uncoating. **(b)** In an enveloped virus such as herpesvirus, the entire virus is taken into a vesicle with subsequent release of the DNA. **(c)** A naked virus such as poliovirus is first taken into a vesicle and then releases its nucleic acid through a pore or rupture in the membrane.

(a)

(b)

Figure 6.14 Maturation and release of enveloped viruses.

(a) As parainfluenza virus is budded off the membrane, it simultaneously picks up an envelope and spikes. (b) Ebola viruses leave their host cell by budding off its surface. (b): Source: National Institute of Allergy and Infectious Diseases (NIAID)/CDC

engulfed entirely into a vesicle called an endosome after its initial attachment. Once inside the cell, the virus is **uncoated**. This means that the vesicle membrane becomes altered so that the viral nucleocapsid or nucleic acid can be released into the cytoplasm. In some viruses the vesicle membrane fuses with the virus, and in other cases the vesicle membrane develops openings for the virus to leave. There are numerous variations in the details of this process.

Synthesis: Replication and Protein Production

The synthetic and replicative phases of animal viruses are highly regulated and extremely complex at the molecular level. Free viral nucleic acid exerts control over the host's metabolism and synthetic machinery. How this control proceeds will vary, depending on whether the virus is a DNA or an RNA virus. In general, the DNA viruses (except poxviruses) enter the host cell's nucleus and are replicated and assembled there. RNA viruses are replicated and assembled in the cytoplasm, with some exceptions.

The details of animal virus replication are discussed in chapter 9. Here we provide a brief overview of the process, using an RNA virus

as a model. Almost immediately upon entry, the viral nucleic acid alters the genetic expression of the host and instructs it to synthesize the building blocks for new viruses. For example, it was recently shown that HIV depends on the expression of 250 human genes to complete its multiplication cycle. First, the RNA of the virus becomes a message for synthesizing viral proteins (translation). Most viruses with positive-strand RNA molecules already contain the correct message for translation into proteins. Viruses with negative-strand RNA molecules must first be converted into a positive-strand message. Some viruses come equipped with the necessary enzymes for synthesis of viral components; others utilize those of the host. During the final phase, the host's replication and synthesis machinery produces new RNA, proteins for the capsid, spikes, and viral enzymes.

Assembly of Animal Viruses: Host Cell as Factory

Toward the end of the cycle—during the assembly stage—mature virus particles are constructed from the growing pool of parts. In most instances, the capsid is first laid down as an empty shell that will serve as a receptacle for the nucleic acid strand. Electron micrographs taken during this time show cells with masses of viruses, often enclosed in packets (see figure 6.15a). One important event leading to the release of enveloped viruses is the insertion of viral spikes into the host's cell membrane so they can be picked up as the virus buds off with its envelope, as discussed.

Release of Mature Viruses

To complete the cycle, assembled viruses leave their host in one of two ways. Nonenveloped and complex viruses that reach maturation in the cell nucleus or cytoplasm are released through cell **lysis** or rupturing. Enveloped viruses are liberated by **budding** or **exocytosis**³ from the membranes of the cytoplasm, nucleus, endoplasmic reticulum, or vesicles. During this process the nucleocapsid binds to the membrane, which curves completely around it and forms a small pouch. Pinching off the pouch releases the virus with its envelope (**figure 6.14**). Budding of enveloped viruses causes them to be shed gradually, without the sudden destruction of the cell. Regardless of how the virus leaves, most active viral infections are ultimately lethal to the cell because of accumulated damage. Lethal

3. For enveloped viruses, these terms are interchangeable. They mean the release of a virus from an animal cell by enclosing it in a portion of membrane derived from the cell.

damages include a permanent shutdown of metabolism and genetic expression, destruction of cell membrane and organelles, toxicity of virus components, and release of lysosomes.

The length of a multiplication cycle, from adsorption to lysis, varies to some extent, but it is usually measured in hours. A simple virus such as poliovirus takes about 8 hours; parvovirus takes 16 to 18 hours; and more complex viruses, such as herpesviruses, require 72 hours or more.

A fully formed, extracellular virus particle that is virulent and able to establish infection in a host is called a **virion**.* The number of virions released by infected cells is variable, controlled by factors such as the size of the virus and the health of the host cell. About 3,000 to 4,000 virions are released from a single cell infected with poxviruses, whereas a poliovirus-infected cell can release over 100,000 virions. If even a small number of these virions happens to meet other susceptible cells and infect them, the potential for viral proliferation is immense.

Visible Damage to the Host Cell

The short- and long-term effects of viral infections on animal cells are well documented. **Cytopathic*** effects (CPEs) are defined as virus-induced damage to the cell that alters its microscopic appearance. Individual cells can become disoriented, undergo gross changes in shape or size, or develop intracellular changes (**figure 6.15a**). It is common to note **inclusion bodies**, or compacted masses of viruses or damaged cell organelles, in the nucleus and cytoplasm (**figure 6.15b**). Examination of cells and tissues for cytopathic effects has been a traditional tool for diagnosing viral infections that is usually supplemented with more specific serological and molecular methods (see chapter 17). **Table 6.3** summarizes some prominent cytopathic effects associated with specific viruses. One very common CPE is the

* *virion* (vir'-ee-on) Gr. *iso*, poison.

* *cytopathic* (sy"-toh-path'-ik) Gr. *cyto*, cell, and *pathos*, disease.

CLINICAL CONNECTIONS

Persistent Viral Infections

As a general rule, a virus infection kills its host cell, but some cells escape destruction by harboring the virus in some form. These so-called **persistent infections** can last from a few weeks to years and even for the life of the host. Take, for example, the hepatitis B virus, which produces a chronic progressive infection of the liver that may lead to cirrhosis and cancer. Several viruses remain in a **latent state**, meaning that they remain inactive or nonproductive over long periods. Examples of this are herpes simplex viruses (cold sores and genital herpes) and herpes zoster virus (chickenpox and shingles). Both viruses go into latency in nerve cells and later emerge under the influence of various stimuli to cause recurrent symptoms.

Some animal viruses enter their host cell and permanently alter its genetic material, in many cases leading to cancer. These viruses are termed **oncogenic**, and their effect on the cell is called **transformation**. A startling feature of some of these viruses is that their nucleic acid becomes integrated into the host DNA. Transformed cells generally have an increased rate of growth, alterations in chromosomes, changes in the cell's surface molecules, and the capacity to divide for an indefinite period. Mammalian viruses involved in the development of tumors are called **oncoviruses**. Some of these are DNA viruses such as papillomavirus, which is associated with cervical cancer, and herpesviruses such as Epstein-Barr virus, which is a cofactor in Burkitt's lymphoma in genetically predisposed individuals. These findings have spurred a great deal of speculation on the possible involvement of viruses in cancers whose cause is still unknown. Additional information on the connection between viruses and cancer is found in chapter 24.

Why would the integration of viral genes into a human chromosome cause cancer? Answer available on Connect.

Figure 6.15 Cytopathic changes in cells and cell cultures infected by viruses. (a) Human epithelial cells (400 \times) infected by herpes simplex virus demonstrate multinucleate giant cells; inset with a cluster of viruses from an intranuclear inclusion (100,000 \times). (b) Fluorescently stained human cells infected with cytomegalovirus. Note the inclusion bodies (1,000 \times) and the loss of cohesive junctions between cells.

TABLE 6.3 Cytopathic Changes in Selected Virus-Infected Animal Cells

Virus	Response in Animal Cell
Smallpox virus	Cells round up; inclusions appear in cytoplasm
Herpes simplex	Cells fuse to form multinucleated syncytia; nuclear inclusions (see figure 6.15)
Adenovirus	Clumping of cells; nuclear inclusions
Poliovirus	Cell lysis; no inclusions
Reovirus	Cell enlargement; vacuoles and inclusions in cytoplasm
Influenza virus	Cells round up; no inclusions
Rabies virus	No change in cell shape; cytoplasmic inclusions (Negri bodies)
Measles virus	Syncytia form (multinucleate)

fusion of multiple host cells into a **syncytium**, a single large cell containing multiple nuclei. These syncytia are a result of some viruses' ability to fuse together the membranes of several host cells. One virus (respiratory syncytial virus) is even named for this effect.

Check Your Progress SECTION 6.4

- Write a narrative that describes the stages in the multiplication of an enveloped animal virus.
- Describe some ways animal viruses penetrate the host cell. What is uncoating?
- Summarize the two major ways in which animal viruses leave their host cells.
- What is meant by the term *virion*?
- Describe several cytopathic effects of viruses. What causes the changed appearance of the host cell, and how might it be used to diagnose viral infections?
- Explain what it means for a virus to become persistent or latent, and how these events are important.
- Briefly describe the effects of an oncogenic virus.

6.5 The Multiplication Cycle in Bacteriophages

Expected Learning Outcomes

- Describe the stages in the multiplication cycle of bacteriophages.
- Explain what is meant by *lysogeny*, *prophage*, *lysogenic induction*, and *lysogenic conversion*.
- Compare the major stages in multiplication of animal viruses and bacteriophages.

For the sake of comparison, we now turn to multiplication in bacterial viruses—the **bacteriophages**. When Frederick Twort and Felix d'Herelle discovered these viruses in 1915, they first thought that the bacterial host cells were being eaten by some unseen parasite, which they called a bacteriophage.

So far as is known, all bacteria are parasitized by various specific viruses. Most bacteriophages (often shortened to *phage*) contain double-stranded DNA, though single-stranded DNA and RNA types exist as well. Bacteriophages are of great interest to medical microbiologists because they can make the bacteria they infect more virulent for humans.

Probably the most widely studied bacteriophages are those of the intestinal bacterium *Escherichia coli*—especially the T-even **phages** and the lambda phages. They are complex in structure, with an icosahedral capsid head containing DNA, a central tube (surrounded by a sheath), collar, base plate, tail pins, and fibers (see figure 6.9b). Momentarily setting aside a strictly scientific and objective tone, it is tempting to think of these extraordinary viruses as minute spacecrafts docking on an alien planet, ready to unload their genetic cargo.

Bacteriophages go through stages similar to those of the animal viruses described earlier (**figure 6.16**). First, they adsorb to host bacteria using specific receptors on the bacterial surface. Although the entire phage cannot enter the host cell, the nucleic acid is injected through a rigid tube the phage inserts through the bacterial membrane and wall (**figure 6.17**). The empty capsid remains attached to the cell surface. Entry of the nucleic acid stops host cell DNA replication and protein synthesis, and it soon prepares the cell machinery for viral replication and synthesis of viral proteins. As the host cell produces new phage parts, the parts spontaneously assemble into bacteriophages.

An average-size *Escherichia coli* cell can contain up to 200 new phage units at the end of this period. Eventually, the host cell becomes so packed with viruses that it undergoes **lysis** and splits open, thereby releasing the mature virions (**figure 6.18**). This process is hastened by viral enzymes produced late in the infection cycle that weaken the cell envelope. Upon release, the virulent phages can spread to other susceptible bacterial cells and begin a new cycle of infection.

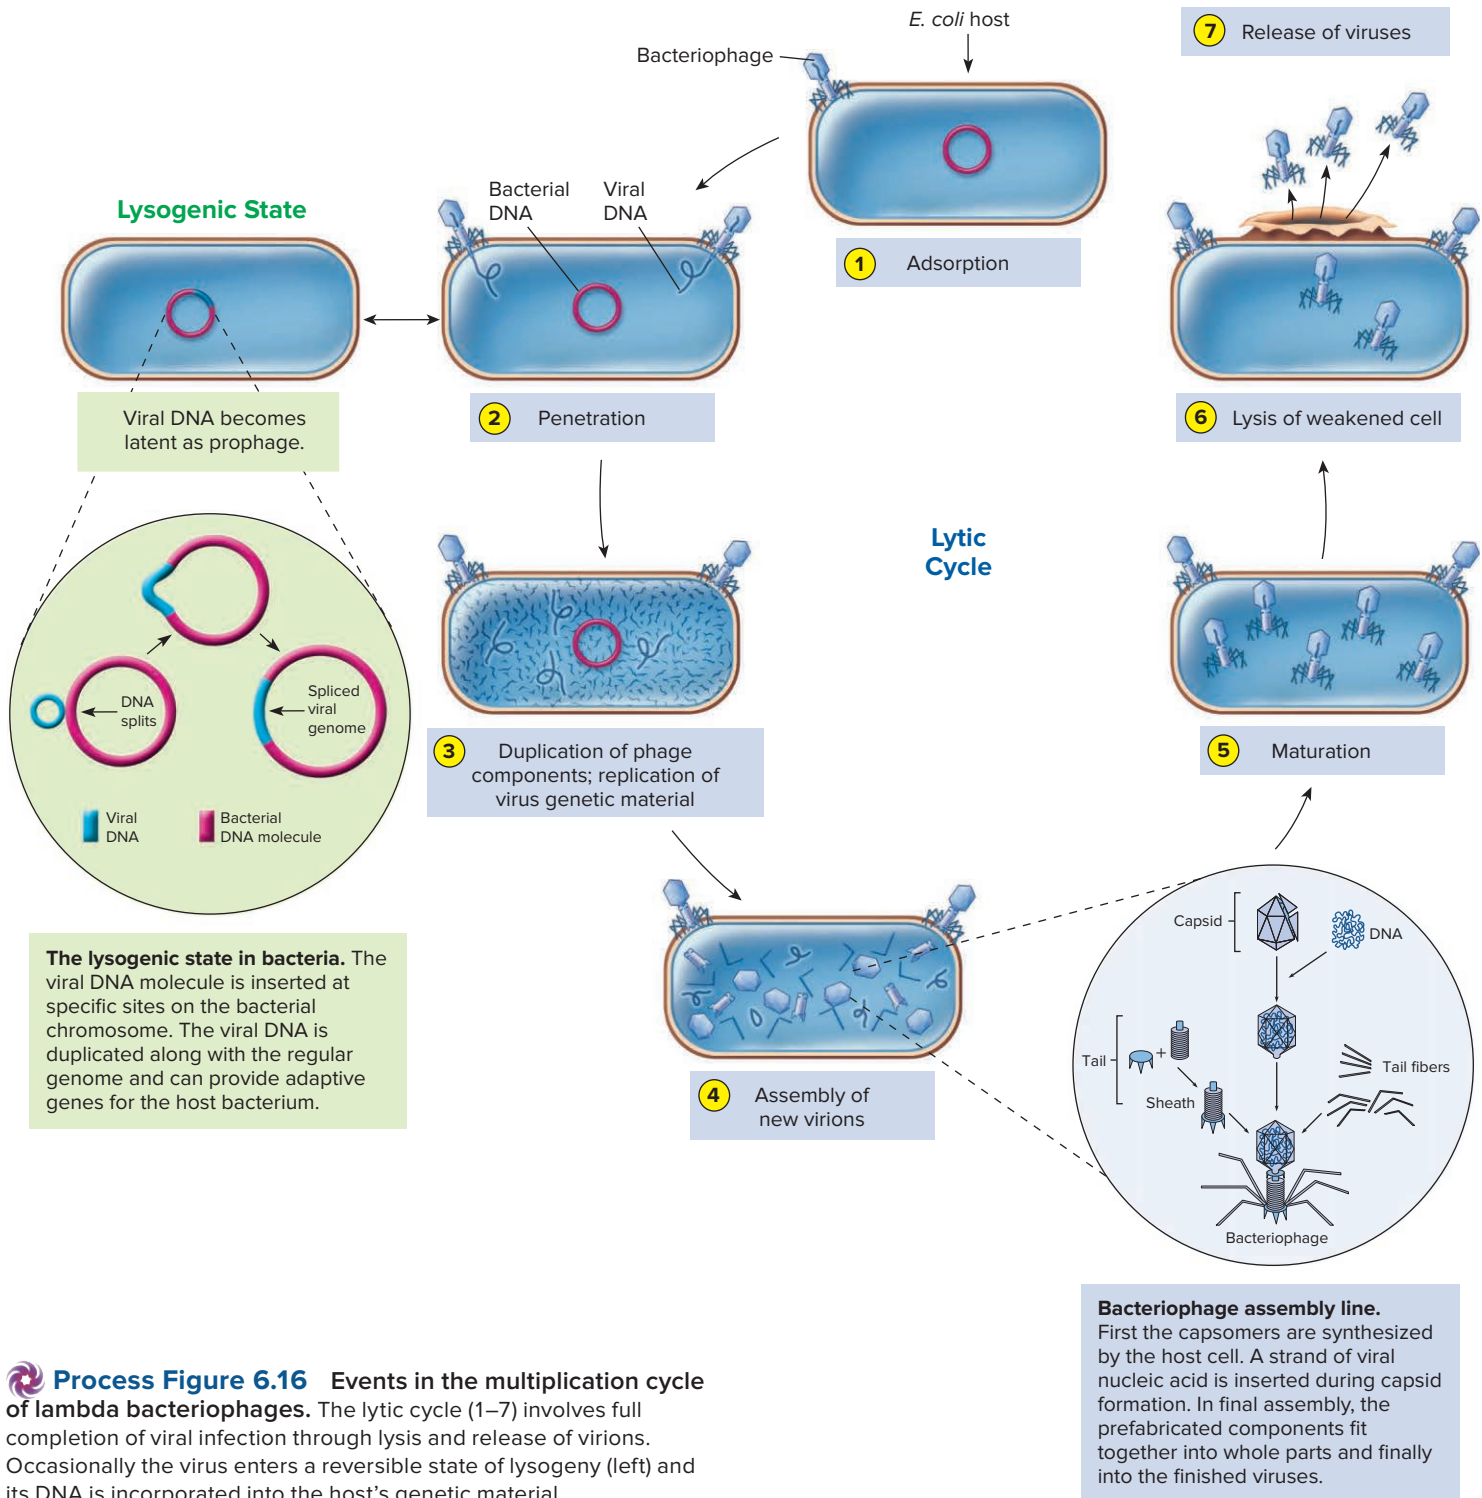

Lysogeny: The Silent Virus Infection

The lethal effects of a virulent phage on the host cell present a dramatic view of virus-host interaction. However, not all bacteriophages go immediately into a lytic cycle. Depending upon the conditions in the bacterial host, some special DNA viruses, called **temperate* phages**, undergo adsorption and penetration into the bacterial host but are not replicated or released immediately. Instead, the viral DNA enters an inactive **prophage*** state, during which it is usually inserted into the bacterial chromosome. This viral DNA will be retained by the bacterial cell and copied during its normal cell division so that the cell's progeny will also have the phage DNA. This condition, in which the host chromosome carries bacteriophage DNA, is termed **lysogeny.*** Because viral particles are not produced, the bacterial cells carrying temperate phages do not lyse and they appear entirely normal. Later, in a process called **induction**, the prophage in a lysogenic cell will be activated and progress directly into viral replication and the lytic cycle. The lysogenic phase is depicted in the green section of figure 6.16. Lysogeny is a less deadly

* *temperate* (tem'-pur-ut) A reduction in intensity.

* *prophage* (pro'-fayj) L. pro, before, plus phage.

* *lysogeny* (ly-soj'-uhn-ee) The potential ability to produce phage.

Process Figure 6.16 Events in the multiplication cycle of lambda bacteriophages. The lytic cycle (1–7) involves full completion of viral infection through lysis and release of virions. Occasionally the virus enters a reversible state of lysogeny (left) and its DNA is incorporated into the host’s genetic material.

form of infection than the full lytic cycle and is thought to be an advancement that allows the virus to spread without killing the host.

Because of the intimate association between the genetic material of the virus and host, phages occasionally serve as transporters of bacterial genes from one bacterium to another and consequently can play a profound role in bacterial genetics. This phenomenon, called transduction, is one way that genes for toxin production and drug resistance are transferred between bacteria (see chapters 9 and 12).

Phages have profound effects on the infectiousness and virulence of pathogenic bacteria. Viral genomes often encode toxins, enzymes, and other factors that can alter the course and outcome of infections. When a bacterium acquires genes from its temperate phage, it is called **lysogenic conversion** (see figure 6.16). The phenomenon was first discovered in the 1950s in *Corynebacterium diphtheriae*, the pathogen that causes diphtheria. The diphtheria toxin responsible for the severe nature of the disease is a bacteriophage product. *C. diphtheriae*

Figure 6.17 Penetration of a bacterial cell by a bacteriophage. After adsorption, the phage plate becomes embedded in the cell wall, and the sheath contracts, pushing the tube through the cell wall and membrane and releasing the nucleic acid into the interior of the cell.

Figure 6.18 A weakened bacterial cell, crowded with viruses. The cell has ruptured and released numerous virions that can then attack nearby susceptible host cells. Note the empty heads of "spent" phages lined up around the ruptured wall. © Lee D. Simon/Science Source

cells without the phage are less pathogenic. Other bacteria that are made virulent by their prophages are *Vibrio cholerae*, the agent of cholera, and *Clostridium botulinum*, the cause of botulism.

The cycles of bacterial and animal viruses illustrate different patterns of viral multiplication, which are summarized in **table 6.4**.

Check Your Progress SECTION 6.5

21. In simple terms, what does the viral nucleic acid do once it gets into the cell?
22. What processes are involved in bacteriophage assembly?
23. What is a prophage or temperate phage? What is lysogeny?
24. Compare and contrast the main phases in the lytic multiplication cycle in bacteriophages and animal viruses.
25. Why is penetration so different between the two groups?

TABLE 6.4 Comparison of Bacteriophage and Animal Viral Multiplication

	Bacteriophage	Animal Virus
Adsorption	Precise attachment of special tail fibers to cell wall	Attachment of capsid or envelope to cell surface receptors
Penetration	Injection of nucleic acid through cell wall; no uncoating of nucleic acid	Whole virus is engulfed and uncoated, or virus surface fuses with cell membrane; nucleic acid is released
Synthesis and Assembly	Occurs in cytoplasm (no nucleus present) Cessation of host synthesis Viral DNA or RNA replicated Viral components synthesized	Occurs in cytoplasm and nucleus Cessation of host synthesis Viral DNA or RNA replicated Viral components synthesized
Viral Persistence	Lysogeny	Latency, chronic infection, cancer
Release from Host Cell	Cell lyses after being weakened by viral enzymes.	Some cells lyse; enveloped viruses bud off host cell membrane.
Cell Destruction	Sudden by lysis	Sudden (lysis) or slow (budding)

6.6 Techniques in Cultivating and Identifying Animal Viruses

Expected Learning Outcomes

20. Describe the general purposes of cultivating viruses.
21. Compare the methods and uses of cell culture, bird embryos, and live animals in growing viruses.

One problem hampering early animal virologists was their inability to propagate specific viruses routinely in pure culture and in sufficient quantities for their studies. Virtually all of the pioneering attempts at cultivation had to be performed in an organism that was the usual host for the virus. But this method had its limitations. How could researchers have ever traced the stages of viral multiplication if they had been restricted to the natural host, especially in the case of human viruses? Fortunately, systems of cultivation with broader applications were developed, including **in vitro*** cell (or tissue) culture methods and **in vivo*** inoculation of laboratory-bred animals and embryonic bird tissues. Such use of substitute host

* **in vitro** (in vee'-troh) L. *vitros*, glass. Experiments performed in test tubes or other artificial environments.

* **in vivo** (in vee'-voh) L. *vivos*, life. Experiments performed in a living body.

systems permits greater control, uniformity, and wide-scale harvesting of viruses.

The primary purposes of viral cultivation are (1) to isolate and identify viruses in clinical specimens; (2) to prepare viruses for vaccines; and (3) to do detailed research on viral structure, multiplication cycles, genetics, and effects on host cells.

Using Cell (Tissue) Culture Techniques

The most important early discovery that led to easier cultivation of viruses in the laboratory was the development of a simple and effective way to grow populations of isolated animal cells in culture. These types of *in vitro* cultivation systems are termed **cell culture** or **tissue culture**. Although these terms are used interchangeably, cell culture is probably a more accurate description. This method makes it possible to propagate most viruses. Much of the virologist's work involves developing and maintaining these cultures. Animal cell cultures are grown in sterile chambers with special media that contain the correct nutrients required by animal cells to survive. The cultured cells grow in the form of a *monolayer*, a single, confluent sheet of cells that supports viral multiplication and permits close inspection of the culture for signs of infection (**figure 6.19**).

Cultures of animal cells usually exist in the primary or continuous form. *Primary cell cultures* are prepared by placing freshly isolated animal tissue in a growth medium. Embryonic, fetal, adult, and even cancerous tissues have served as sources of primary

cultures. A primary culture retains several characteristics of the original tissue from which it was derived, but this original line generally has a limited existence. Eventually it will die out or mutate into a line of cells that can grow by continuous subculture in fresh nutrient medium. One very clear advantage of cell culture is that a specific cell line can be available for viruses with a very narrow host range. Strictly human viruses can be propagated in one of several primary or continuous human cell lines, such as embryonic kidney cells, fibroblasts, bone marrow, or heart cells.

One way to detect the growth of a virus in culture is to observe degeneration and lysis of infected cells in a monolayer of a cell culture (**figure 16.19a**). The areas where virus-infected cells have been destroyed show up as clear, well-defined patches in the cell sheet called **plaques*** (**figure 6.19c**). Plaques are essentially the macroscopic manifestation of cytopathic effects (CPEs), discussed in section 6.4. This same technique is used to detect and count bacteriophages, because they also produce plaques when grown in soft agar cultures of their host cells. A plaque develops when the viruses released by an infected host cell radiate out to adjacent host cells. As new cells become infected, they die and release more viruses, and so on. As this process continues, the infection spreads gradually and symmetrically from the original point of infection, causing the macroscopic appearance of round, clear spaces that correspond to areas of lysed cells.

* *plaque* (plak) Fr. *placke*, patch or spot.

Figure 6.19 Microscopic views of normal and infected cell cultures. (a) Cell culture plate infected with herpes simplex virus. Clear, round spaces are regions of infection (plaques) where the host cells have been destroyed by viruses. (b) Closeup of a normal, uninfected region of cultured cells. (c) Closeup of plaques, which consist of open spaces where cells have been disrupted by viral infection.

Using Bird Embryos

An embryo is an early developmental stage of animals marked by rapid differentiation of cells. Birds undergo their embryonic period within the closed protective case of an egg, which makes an incubating

(a)

(b)

Figure 6.20 Cultivating animal viruses in a developing bird embryo. (a) A technician inoculates fertilized chicken eggs with viruses in the first stage of preparing vaccines. This process requires the highest levels of sterile and aseptic precautions. Some types of Influenza vaccine are prepared this way. (b) The shell is perforated using sterile techniques, and a virus preparation is injected into a site selected to grow the viruses. Targets include the allantoic cavity, a sac for embryonic waste removal; the amniotic cavity that cushions and protects the embryo; the chorioallantoic membrane, for embryonic gas exchange; the yolk sac, for the nourishment of the embryo; and the embryo itself. (a): © State Hygienic Laboratory at The University of Iowa

bird egg a nearly perfect system for viral propagation. It is an intact and self-supporting unit, complete with its own sterile environment and nourishment. Furthermore, it furnishes several embryonic tissues that readily support viral multiplication. Every year hundreds of millions of chicken embryos are inoculated to prepare influenza vaccines.

Chicken, duck, and turkey eggs are the most common choices for inoculation. The egg must be injected through the shell, necessitating rigorous sterile techniques to prevent contamination by bacteria and fungi from the air and the outer surface of the shell. The exact tissue inoculated is guided by the type of virus being cultivated and the goals of the experiment (**figure 6.20**).

Viruses multiplying in embryos may or may not cause effects visible to the naked eye. The signs of viral growth include death of the embryo, defects in embryonic development, and localized areas of damage in the membranes, resulting in discrete, opaque spots called pocks (a variant of *pox*). Embryonic fluids and tissues can be prepared for direct examination with an electron microscope. Certain viruses can also be detected by their ability to agglutinate red blood cells (form big clumps) or by their reaction with an antibody of known specificity that will affix to its corresponding virus, if it is present.

Using Live Animal Inoculation

Specially bred strains of white mice, rats, hamsters, guinea pigs, and rabbits are the usual choices for animal cultivation of viruses. Invertebrates or nonhuman primates are occasionally used as well. Because viruses can exhibit host specificity, certain animals can propagate a given virus more readily than others. Depending on the particular experiment, tests can be performed on adult, juvenile, or newborn animals. The animal is exposed to the virus by injection of a viral preparation or specimen into the brain, blood, muscle, body cavity, skin, or footpads.

A very unusual method of cultivating viruses that also became a source of controversy happened when scientists at the State University of New York were able to artificially create a virus that is virtually identical to natural poliovirus in a test tube without live cells. They used DNA nucleotides to synthesize the viral genome according to the published poliovirus sequence. They then added an enzyme that would transcribe the DNA sequence into the RNA genome characteristic of poliovirus. They ended up with viruses that mimicked the structure, infectivity, and replication cycle of the poliovirus.

6.7 Viral Infection, Detection, and Treatment

Expected Learning Outcomes

22. Discuss the medical impact and importance of viruses.
23. Explain how animal viral infections are treated and detected.

The number of viral infections worldwide is nearly impossible to measure accurately. Certainly viruses are the most common cause of acute infections that do not result in hospitalization, especially when one considers widespread diseases such as colds, measles, chickenpox, influenza, herpes, and warts. If one also takes into account

6.1 Secret World of Microbes

Seeking Your Inner Viruses

Would you be alarmed to be told that your cells carry around bits and pieces of fossil viruses? Well, we now know that they do. A fascinating aspect of the virus–host relationship is the extent to which viral genetic material becomes affixed to host chromosomes and is passed on, possibly even for millions of years. We know this from data obtained by the Human Genome Project, which sequenced all of the genetic codes on the 46 human chromosomes. While searching through the genome sequences, virologists began to find DNA they identified as viral in origin. So far they have found about 100,000 different fragments of viral DNA. In fact, over 8% of the DNA in human chromosomes comes from viruses!

These researchers are doing the work of molecular fossil hunters, locating and identifying these ancient viruses. Many of them are retroviruses that converted their RNA codes to DNA codes, inserted the DNA into a site in a host chromosome, and then became dormant and did not kill the cell. When this happened in an egg or sperm cell, the virus could be transmitted basically unchanged for hundreds of generations. One of the most tantalizing questions is what effect, if any, such retroviruses might have on modern humans. Some virologists contend that these virus genes would not have been maintained for thousands and even millions of years if they did not serve some function. Others argue that they are just genetic “garbage” that has accumulated over a long human history.

So far, we have only small glimpses of the possible roles of these viruses. One type of endogenous retrovirus has been shown to be inti-

Does this virus make us look fat?

Source: CDC

mately involved in forming the human placenta, leading microbiologists to conclude that some viruses have become an essential factor in evolution and development. Other retroviruses may be involved in diseases such as prostate cancer and chronic fatigue syndrome.

Evidence is mounting that certain viruses may contribute to human obesity. Several studies with animals revealed that chickens and mice infected with a human adenovirus (see figure) had larger fat deposits and were heavier than uninfected animals. Studies in humans show a similar association between infection with the strain of virus—called Ad-36—and an increase in adipose (fat) tissue.

Although adenoviruses have usually been involved in respiratory and eye infections, they can also infect adipose cells. One of the possible explanations for this association suggests that a chronic infection with the virus allows its DNA to regulate cellular differentiation of stem cells into adipocytes (fat cells). This increase in both the number and the size of fat cells adds adipose tissue, more fat production and storage, and more body fat. Simultaneously, the adipocytes may also store more sugar, helping to keep blood sugar levels under control and maintaining insulin sensitivity to glucose. In general, such an association does not prove causation, but it certainly warrants additional research.

Using information you have learned about viruses, explain how viruses could become a permanent component of an organism’s genetic material. *Answer available on Connect.*

prominent viral infections found only in certain regions of the world (dengue fever, Rift Valley fever, and yellow fever), the total could easily exceed several billion cases each year. Although most viral infections do not result in death, some, such as rabies, HIV, and Ebola, have very high mortality rates, and others (polio, hepatitis) can lead to long-term debility. Continuing research is focused on the connection of viruses to chronic afflictions of unknown cause, such as type 1 diabetes, multiple sclerosis, various cancers, and even conditions such as obesity (**6.1 Secret World of Microbes**).

Because some viral diseases can be life threatening, it is essential to have a correct diagnosis as soon as possible. Obtaining the overall clinical picture of the disease (specific signs) is often the first step in diagnosis. This may be followed by identification of the virus in clinical specimens by means of rapid tests that detect the virus or signs of cytopathic changes in cells or tissues (see CMV herpesvirus, figure 6.15). Immunofluorescence techniques or direct examination with an electron microscope are often used for this (see figure 6.8). Samples can also be screened for the presence of indicator molecules (antigens) from the virus itself. A standard procedure for many viruses is the polymerase chain reaction (PCR), which can detect and amplify minute amounts of viral nucleic acid in a sample.

In certain infections, definitive diagnosis requires cultivation of the virus using cell culture, embryos, or animals, but this method can be time-consuming and slow to give results. Screening tests can detect specific antibodies that indicate signs of virus infection in a patient’s blood. This is the main test for HIV infection (see figure 17.16). Additional details of viral diagnosis are provided in chapter 17.

The nature of viruses has at times been a major impediment to effective therapy. Because viruses are not bacteria, antibiotics aimed at bacterial infections do not work for viruses. Although more antiviral drugs are being developed, most of them block virus replication by targeting the function of host cells. This can cause severe side effects. Antiviral drugs are designed to target one of the steps in the viral life cycle you learned about earlier in this chapter. Azidothymidine (AZT), a drug used to treat AIDS, targets the nucleic acid synthesis stage. A different class of HIV drugs, the protease inhibitors, disrupts the final assembly phase of the viral life cycle. Another compound that shows some potential for treating and preventing viral infections is a naturally occurring human cell product called *interferon* (see chapters 12 and 14). Vaccines that stimulate immunity are an extremely valuable tool but are available for only a limited number of viral diseases (see chapter 15).

Check Your Progress SECTIONS 6.6 AND 6.7

26. Describe the three main techniques for cultivating viruses.
27. What are the advantages of using cell culture, and what are the disadvantages?
28. What are cell lines and monolayers, and how are plaques formed?
29. What are the primary problems in treating viral infections with drugs?

6.8 Prions and Other Nonviral Infectious Particles

Expected Learning Outcomes

24. Describe the properties of nonviral infectious particles.
25. Discuss the importance of prions and viroids and the diseases they cause.

Prions are a group of noncellular infectious agents that are not viruses and really belong in a category all by themselves. The term *prion* is derived from the words **proteinaceous infectious particle** to suggest its primary structure—that of a naked protein molecule. They are quite remarkable in being the only biologically active agent that lacks any sort of nucleic acid (DNA or RNA). Up until their discovery about 35 years ago, it was considered impossible that an agent lacking genetic material could ever be infectious or transmissible.

The diseases associated with prions are known as **transmissible spongiform encephalopathies (TSEs)**. This description recognizes that the diseases are spread from host to host by direct contact, contaminated food, or other means. It also refers to the effects of the agent on nervous tissue, which develops a spongelike appearance due to loss of nerve and glial cells (see figure 25.28*b*). Another pathological effect observed in these diseases is the buildup of tiny protein fibrils in the brain tissue (**figures 6.21*a* and 6.21*b***). Several forms of prion diseases are known in mammals, including scrapie in sheep, bovine spongiform encephalopathy (mad cow disease) in cattle, and wasting disease in elk, deer, and mink. These diseases have a long latent period (usually several years) before the first symptoms of brain degeneration appear. The animals lose

Process Figure 6.21 The appearance and mechanisms of prion-based diseases. (a) A magnified view of nerve cells infected with prion protein. Red areas indicate places in the cytoplasm where the prion fibers have deposited. (b) A diagram of a nerve cell to outline the stages in the conversion of normal cell proteins into prions and the formation of prion fibers. (a): Source: National Institute of Allergy and Infectious Diseases

coordination, have difficulty moving, and eventually progress to collapse and death.

Humans are host to similar chronic diseases, including *Creutzfeldt-Jakob Disease* (CJD), kuru, fatal familial insomnia, and others. In all of these conditions, the brain progressively deteriorates and the patient loses motor coordination, along with sensory and cognitive abilities. There is no treatment and most cases so far have been fatal. In the 1990s, a different variant of CJD that appeared in Europe was traced to people eating meat from cows infected with the bovine form of encephalopathy. Several hundred people developed the disease and a majority of them have since died. This was the first indicator that prions of animals could cause infections in humans. It sparked a crisis in the beef industry and strict controls on imported beef. Although only three cases of human disease have occurred in the United States, infected cattle have been reported.

The medical importance of these novel infectious agents has led to a great deal of research into how they function. Researchers have discovered that prion or prionlike proteins are very common in the cell membranes of plants, yeasts, and animals. One widely accepted theory suggests that the prion protein is an abnormal version of a normal protein. When the prion comes in contact with a normal protein, it can induce spontaneous abnormal folding in the normal protein. Ultimately the buildup of these converted proteins damages and kills the cell (figure 6.21*b*).

Another serious issue with prions is their extreme resistance. They are not destroyed by disinfectants, radiation, or the usual sterilization techniques. Even treatments with extreme high temperatures and concentrated chemicals are not always reliable methods to eliminate them. Additional information on prion diseases can be found in chapter 25.

Other fascinating viruslike agents in human disease are defective forms called satellite viruses that depend on other viruses for replication. Two remarkable examples are the adeno-associated virus (AAV), which can replicate only in cells infected with adenovirus, and the delta agent, a naked strand of RNA that is expressed only in the presence of the hepatitis B virus and can worsen the severity of liver damage.

Plants are also parasitized by viruslike agents called **viroids** that differ from ordinary viruses by being very small (about one-tenth the size of an average virus) and being composed of only naked strands of RNA, lacking a capsid or any other type of coating. The existence of these unusual agents is one bit of supportive evidence that viruses may have evolved from naked bits of nucleic acid. Viroids are significant pathogens in several economically important plants, including tomatoes, potatoes, cucumbers, citrus trees, and chrysanthemums.

Looking Ahead at the Chapters to Come

We have completed our survey of prokaryotes, eukaryotes, and viruses and have described the significant characteristics of these three groups. Now that we know more about these microbes, we will use chapters 7, 8, and 9 to explore how they maintain themselves, beginning with microbial nutrition (chapter 7) followed by metabolism (chapter 8), and ending with genetics (chapter 9).

Check Your Progress SECTION 6.8

30. What is the principal effect of the prion agent of Creutzfeldt-Jakob disease?
31. Explain how prions and viroids are different from viruses.

CASE STUDY Part 2

Avian influenza viruses are found worldwide in both wild and domestic birds, and are generally adapted to migratory waterfowl and shorebird species. The birds usually suffer no ill effects as a result of infection, but they do excrete the virus in their feces and through secretions from their nose, mouth, and eyes. As the birds travel along major migratory pathways from the northernmost reaches of Canada to South America, they carry the virus with them, creating opportunities for viral exchange as they commingle with domestic flocks. Recommendations made by the U.S. Department of Agriculture to reduce avian influenza outbreaks include eliminating pools of standing water that attract wild birds, reducing food sources, and installing wildlife deterrents like scarecrows, all actions meant to minimize contact between wild and domestic flocks. Unfortunately, even the best attempts at eliminating interactions between domestic and wild fowl are not completely effective.

Most migration corridors are restricted to continental landmasses; birds rarely cross oceans. However, the area between the eastern edge of Russia and western Alaska is uniquely an area where major migratory pathways cross continental boundaries. The East Asian–Australasian Flyway extends from Australia north through Asia and Russia, and east to Alaska, where it intersects the Mississippi Americas Flyway, which descends south through Canada, the United States, Mexico, and Central and South America. This overlap allows birds from Asia to come into direct contact with North American birds, establishing a path for viral transmission across continents.

The Asian connection in this case was especially interesting when a highly pathogenic avian influenza virus of Asian origin, HPAI H5N8, spread rapidly along wild-bird migratory pathways during 2014 and was found in a state along the Mississippi river in 2015. The H5N8 virus then mixed with North American avian influenza viruses, creating a new, mixed-origin virus, HPAI H5N2. This mixed-origin virus contains the Asian-origin H5 part of the virus, which is highly pathogenic to poultry. The N parts of the virus came from North American low-pathogenic avian influenza viruses.

- All influenza viruses contain both H and N proteins. Why is HPAI H5N2 referred to as a “mixed origin” virus?
- What are “sentinel chickens”? (A trip to the Internet may be useful.)

See chapter 25 for additional details on influenza and track the latest information on flu outbreaks at www.cdc.gov/flu/.

To conclude this Case Study, go to Connect.

Chapter Summary with Key Terms

6.1 Overview of Viruses

- A. Viruses, being much smaller than bacteria, fungi, and protozoa, had to be indirectly studied until the 20th century, when they were finally seen with an electron microscope.
- B. Scientists don't agree about whether viruses are living or not, but it is clear they do not fulfill all of the requirements of life. They are obligate intracellular and genetic parasites.

6.2 The General Structure of Viruses

- A. Viruses are infectious particles and not cells; lack organelles and locomotion of any kind; are large, complex molecules; and can be crystalline in form. A virus particle is composed of a **nucleic acid** core (DNA or RNA, not both) surrounded by a geometric protein shell, or **capsid**; the combination is called a **nucleocapsid**; a capsid is **helical** or **icosahedral** in configuration; many are covered by a membranous **envelope** containing viral protein **spikes**. Complex viruses have additional external and internal structures.
- B. *Shapes/Sizes*: Icosahedral, helical, spherical, and cylindrical shaped. Smallest infectious forms range from the largest poxvirus (0.45 mm or 450 nm) to the smallest viruses (0.02 mm or 20 nm).
- C. *Nutritional and Other Requirements*: Lack enzymes for processing food or generating energy; are tied entirely to the host cell for all needs (obligate intracellular parasites).
- D. Viruses are known to parasitize all types of cells, including bacteria, algae, fungi, protozoa, animals, and plants. Each viral type is limited in its host range to a single species or group, mostly due to specificity of adsorption of virus to specific host receptors.

6.3 How Viruses Are Classified and Named

- A. The two major types of viruses are **DNA** and **RNA viruses**. These are further subdivided into families, depending on shape and size of capsid, presence or absence of an envelope, whether double- or single-stranded nucleic acid, antigenic similarities, and host cell.
- B. Viruses are classified into orders, families, and genera. These groupings are based on virus structure, chemical composition, and genetic makeup.

6.4 Modes of Viral Multiplication

- A. *Multiplication Cycle: Animal Cells*
- B. The life cycle steps of an animal virus are **adsorption**, **penetration**, **synthesis** and **assembly**, and **release** from the host cell. A fully infective virus particle is a **virion**.

- C. Some animal viruses cause chronic and **persistent infections**.
- D. Viruses that alter host genetic material may cause *oncogenic* effects.

6.5 The Multiplication Cycle in Bacteriophages

- A. **Bacteriophages** are viruses that attack bacteria. They penetrate by injecting their nucleic acid and are released as virulent phages upon **lysis** of the cell.
- B. Some viruses go into a **latent**, or **lysogenic**, phase in which they integrate into the DNA of the host cell and later may be active and produce a lytic infection.

6.6 Techniques in Cultivating and Identifying Animal Viruses

- A. The need for an intracellular habitat makes it necessary to grow viruses in living cells, either in **cell culture** (cultures of live, isolated host cells), in bird embryos, or in the intact host animal.
- B. *Identification*: Viruses are identified by means of **cytopathic effects** (CPE) in host cells, direct examination of viruses or their components in samples, genetic analysis to detect virus nucleic acid, and growing viruses in culture.

6.7 Viral Infection, Detection, and Treatment

- A. *Medical*: Viruses attach to specific target hosts or cells. They cause a variety of infectious diseases, ranging from mild respiratory illnesses (common cold) to destructive and potentially fatal conditions (rabies, AIDS). Some viruses can cause birth defects and cancer in humans and other animals.
- B. *Research*: Viruses have become an invaluable tool for studying basic genetic principles. Current research is focused on the connection of viruses to afflictions of unknown causes, such as type I diabetes and multiple sclerosis.
- C. Viral infections are detected by direct examination of specimens, genetic tests, testing patients' blood, and characteristic symptoms. Some viral infections can be treated with drugs that block viral replication.

6.8 Prions and Other Nonviral Infectious Particles

- A. Spongiform encephalopathies are chronic persistent neurological diseases caused by **prions**.
- B. Prions are infectious agents composed of a protein that can alter the structure of nerve cells.
- C. Examples of neurological diseases include "mad cow disease" and Creutzfeldt-Jakob disease.
- D. Other noncellular infectious agents include satellite viruses and **viroids**.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

1. A virus is a tiny infectious
 - a. cell
 - b. living thing
 - c. particle
 - d. nucleic acid
2. Viruses are known to infect
 - a. plants
 - b. bacteria
 - c. fungi
 - d. all organisms

3. The capsid is composed of protein subunits called
 - a. spikes
 - b. protomers
 - c. virions
 - d. capsomers
4. The envelope of an animal virus is derived from the _____ of its host cell.
 - a. cell wall
 - b. membrane
 - c. glycocalyx
 - d. receptors
5. The nucleic acid of a virus is
 - a. DNA only
 - b. RNA only
 - c. both DNA and RNA
 - d. either DNA or RNA
6. The general steps in a viral multiplication cycle are
 - a. adsorption, penetration, synthesis, assembly, and release
 - b. endocytosis, replication, assembly, and budding
 - c. adsorption, duplication, assembly, and lysis
 - d. endocytosis, penetration, replication, maturation, and exocytosis
7. A prophage is a/an _____ stage in the cycle of _____.
 - a. latent, bacterial viruses
 - b. infective, RNA viruses
 - c. early, poxviruses
 - d. late, enveloped viruses
8. The nucleic acid of animal viruses enters the host cell through
 - a. injection
 - b. fusion
 - c. endocytosis
 - d. b and c
9. In general, RNA viruses multiply in the cell _____, and DNA viruses multiply in the cell _____.
 - a. nucleus, cytoplasm
 - b. cytoplasm, nucleus
 - c. vesicles, ribosomes
 - d. endoplasmic reticulum, nucleolus
10. Enveloped viruses carry surface receptors called
 - a. buds
 - b. spikes
 - c. fibers
 - d. sheaths
11. Viruses that persist in the cell and cause recurrent disease are considered
 - a. oncogenic
 - b. cytopathic
 - c. latent
 - d. resistant
12. Viruses cannot be cultivated in
 - a. cell culture
 - b. bird embryos
 - c. live mammals
 - d. blood agar
13. Clear patches in cell cultures that indicate sites of virus infection are called
 - a. plaques
 - b. pocks
 - c. colonies
 - d. prions
14. Which of these is *not* a general pattern of virus morphology?
 - a. enveloped, helical
 - b. naked, icosahedral
 - c. enveloped, icosahedral
 - d. complex, helical
15. Which of these is true of prions?
 - a. They are small RNA viruses.
 - b. They replicate in the nucleus.
 - c. They lack protein.
 - d. They cause death of brain cells.

Case Study Review

1. Which receptor of the influenza virus is most involved in binding to the respiratory cells?
 - a. neuraminidase spikes
 - b. hemagglutinin spikes
 - c. the viral capsid
 - d. the viral envelope
2. While H5N2 is of great concern economically, it is not considered an imminent threat to human health. This is mostly because _____.
 - a. if birds are properly cooked the virus cannot spread
 - b. the virus moves poorly from bird to bird
 - c. the virus cause only mild disease in most birds
 - d. the virus moves poorly from bird to human and from human to human
3. The standard response to an outbreak of avian influenza consists of five steps: (1) Quarantine, (2) Eradicate, (3) Monitor, (4) Disinfect, and (5) Test. Explain the importance of each step in stopping the spread of the virus.

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

1. a. What characteristics of viruses could be used to describe them as life forms?
b. What makes them more similar to lifeless molecules?
2. HIV attacks only specific types of human cells, such as certain white blood cells and nerve cells. Can you explain why a virus can enter some types of human cells but not others?
3. a. Since viruses lack metabolic enzymes, how can they synthesize necessary components?
b. Name some enzymes that viruses may have for invading and completing their cycles.
4. a. What dictates the host range of animal viruses?
b. How is the influenza virus different in its host range from most other viruses?

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps along with concept-mapping activities for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

1. Comment on the possible origin of viruses. Is it not curious that the human cell welcomes a virus in and hospitably removes its coat as if it were an old acquaintance?
2. a. If viruses that normally form envelopes were prevented from budding, would they still be infectious? Why or why not?
b. If only the RNA of an influenza virus were injected into a cell by itself, could it cause a lytic infection?
3. The end result of most viral infections is death of the host cell.
a. If this is the case, how can we account for such differences in the damage that viruses do? (Compare the effects of the cold virus with those of the rabies virus.)
b. Describe the adaptations of viruses that do not immediately kill the host cell and explain what their functions may be.
4. a. Given that DNA viruses can be carried in the DNA of the host cell's chromosomes, comment on what this phenomenon means in terms of inheritance in the offspring.
b. Discuss the connection between viruses and cancers, giving possible mechanisms for viruses that cause cancer.
5. a. If you were involved in developing an antiviral drug, what would be some important considerations? (Can a drug "kill" a virus?)
b. How could multiplication be blocked?
6. Is there such a thing as a "good virus"? Explain why or why not. Consider both bacteriophages and viruses of eukaryotic organisms.
7. Discuss some advantages and disadvantages of bacteriophage therapy in treating bacterial infections.
8. a. Consult table 6.2, right-hand column, to determine which viral diseases you have had and which ones you have been vaccinated against.
b. Which viruses would more likely be possible oncoviruses? Why?
9. Of the following, list those that are viral infections: cholera, rabies, plague, cold sores, whooping cough, tetanus, genital warts, gonorrhea, mumps, Rocky Mountain spotted fever, syphilis, rubella, rat bite fever.

Visual Challenge

1. Label the parts of viruses in figures 6.7d, 6.9c, and 6.10.
2. How would you describe the kind of capsid found on this virus from figure 6.2? In what ways is this virus different from other viruses?

CASE STUDY Part 1 A Creature of Habitat

Molly Kenner had suffered from **persistent respiratory symptoms** since she was a young child. Her family physician originally diagnosed her with **asthma**, complicated by **bronchitis** and **pneumonia**, and prescribed anti-allergy medicines, antibiotics, and steroid inhalers. This therapy worked for a few months, but eventually her symptoms of **coughing**, **chest pain**, and **congestion** would return. On many occasions she was ill enough to require hospitalization and a breathing machine. This cycle went on for several years. By the time she was in her twenties, her lungs showed signs of permanent damage and she often struggled to breathe.

As her quality of life continued to decline, her family and friends urged her to seek more expert medical **intervention** with a **lung specialist** at a university teaching hospital. Based on her history, a physician at the clinic ordered a **lung biopsy** and **chest X-rays**. Samples of her lung tissues grew a pure culture of ***Pseudomonas aeruginosa***, described as gram-negative bacillus with a single flagellum and noticeable blue-green pigment. The species is extremely **flexible** in its environmental and nutritional requirements. Although its usual **habitat** is soil, water, and plant matter, it is frequently isolated from skin and other regions of the human body. It occasionally causes infections, especially in those with **weakened host defenses**, but it is not generally pathogenic to healthy individuals.

Molly's doctor immediately understood the significance of this finding, because the lungs are ordinarily supposed to be **sterile** and do not harbor a **resident microbial population**. Yet here was direct

“Samples of her lung tissues grew a pure culture of *Pseudomonas aeruginosa*.”

evidence of a **massive infection** developing as large **nodules** and patches throughout the lungs. The combination of her history and the isolation of this particular species were powerful clues in understanding the real basis of Molly's medical condition. The specialist immediately ordered a **genetic test** that came back as positive for a disease called **cystic fibrosis (CF)**. Cystic fibrosis is a **recessive disorder** caused by a **mutation** in a gene called the **CFTR** or cystic fibrosis transmembrane receptor gene. The normal, nonmutated gene codes for a protein that controls the **active transport** of **chloride** across epithelial cells. Chloride helps to maintain the liquid content of the **mucous** coating of lung membranes needed by the **natural host defenses** to maintain lung health. Because Molly inherited a **defective CFTR gene** from each parent, her cells **cannot secrete** a sufficient amount of chloride into the lung tissues.

As a result, the mucus becomes thick and tenacious and creates a specialized habitat that supports the **long-term establishment** of *P. aeruginosa*.

- What terms from the chapter would you use to describe the natural habitat, biochemical characteristics, and ecological niche of *Pseudomonas aeruginosa*?
- What sorts of adjustments would *P. aeruginosa* have to make in adapting successfully to the human lung?

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

SCOPING OUT THE CHAPTER

The earth is home to an incredibly complex web of organisms that is constantly interacting with each other as well as with the environment. This network is ubiquitous and inseparable and has existed in some form for billions of years. It has shaped the very structure and function of the earth. In this chapter we are introduced to the endless ways that microbes make a living, including nutrition and energy sources, adaptations, interrelationships, and growth.

How Microbes Get Nourishment

Just like their larger counterparts, microorganisms must absorb a broad array of chemical substances from their immediate environments and convert them to their own particular forms of molecules.

What Drives Microbial Engines?

Microbes require a usable form of energy (sunlight is one example) to power metabolic activities such as synthesis, growth, and transport.

Transport Mechanisms

Many microbial activities are dependent on the movement of materials into and out of their cells. Membranes have very specialized passageways for carrying out this process.

Adaptations to Habitat and Niche

Microbes set up residence in almost every nook and cranny of the earth. Wherever they end up, they experience a range of conditions that favors their survival (for example, this little pink algae that thrives in glaciers).

Abundant Partnerships

Most microorganisms live closely with other organisms, often forming long term associations such as symbiosis, parasitism, and biofilms.

Expanding the Population

As is true of all organisms, microbes must produce offspring to maintain their lineage. A common way they can rapidly increase their numbers is for cells to undergo numerous, repeated cycles of division.

7.1 Microbial Nutrition

Expected Learning Outcomes

1. Describe the major environmental factors to which microbes must adapt for survival.
2. Define *nutrition* and *nutrients* and their subcategories based on need and quantity.
3. Differentiate between organic and inorganic nutrients.
4. Discuss the origins, types, and functions of bioelements and nutrients.

There are millions of habitats on earth, of both natural and human origin. In these settings, microorganisms are exposed to a tremendous variety of conditions that affect their survival. Environmental factors with the greatest impact on microorganisms are nutrient and energy sources, temperature, gas content, water, salt, pH, radiation, and other organisms (**figure 7.1**). Microbes survive in their habitats through the process of gradual adjustment of anatomy and physiology, a process called **adaptation**.^{*} It is this adaptability that allows microbes to inhabit all parts of the biosphere. The process is also a major force behind the evolution of species, in that those species with greater adaptability will survive and pass on favorable characteristics to their offspring.

Microbial **nutrition** is a complex activity through which microbes acquire chemical compounds from the environment in order to sustain life. These compounds, called **nutrients**, are absorbed, assimilated, and subsequently used for cellular metabolism, growth, energy, and many other functions. With respect to their nutrition, microbes are not really so different from humans and other macroorganisms. Although bacteria living deep in a swamp on a diet of inorganic sulfur, or protozoa digesting wood in a termite's intestine, may seem to show radical adaptations, even these organisms require a constant influx of certain specific substances from their habitat.

In general, all living things have an absolute need for the **bioelements**, traditionally listed as carbon, hydrogen, oxygen, phosphorus, potassium, nitrogen, sulfur, calcium, iron, sodium, chlorine, magnesium, and a few other elements.¹ Beyond these basic requirements, microbes show significant differences in the source, chemical form, and amount of the elements they use. Any substance, whether an element or compound, that an organism must get from a source outside its cells is called an **essential nutrient**. Once absorbed, these nutrients are processed and transformed into the chemicals of the cell.

Two categories of essential nutrients are **macronutrients** and **micronutrients**. Macronutrients are required in relatively large quantities and play principal roles in cell structure and metabolism. Examples of macronutrients are compounds such as sugars and amino acids that contain carbon, hydrogen, and oxygen. Micronutrients, or **trace elements**, such as manganese, zinc, and nickel are present in much smaller amounts and are involved in enzyme function and maintenance of protein structure. What constitutes a micronutrient can vary from one microbe to another and often must be

determined in the laboratory. This determination is made by deliberately omitting the substance in question from a growth medium to see if the microbe can grow in its absence.

Another way to categorize nutrients is according to their carbon content. Most **organic** nutrients are molecules that contain a basic framework of carbon and hydrogen. Natural organic molecules are nearly always the products of living things. They range from the simplest organic molecule, methane (CH₄), to large polymers (carbohydrates, lipids, proteins, and nucleic acids).

In contrast, an **inorganic** nutrient is composed of an element or elements lacking some combination of both carbon and hydrogen. The natural reservoirs of many inorganic compounds are mineral deposits in the soil, bodies of water, and the atmosphere. Examples include metals and their salts (magnesium sulfate, ferric nitrate, sodium phosphate), gases (oxygen, carbon dioxide), and water.

Chemical Analysis of Cell Contents

To gain insight into a cell's nutritional makeup, it can be useful to analyze its chemical composition. The following list is a brief summary of some nutritional patterns in the intestinal bacterium *Escherichia coli*. Some nutrients are absorbed in a ready-to-use form, and others must be synthesized by the cell from simple compounds:

- Water content is the highest of all components (70%).
- About 97% of the dry cell weight is composed of organic compounds.
- Proteins are the most prevalent organic compound.
- About 96% of the cell is composed of six elements (represented by CHONPS).
- Chemical elements are needed in the overall scheme of cell growth, but most of them are available to the cell as compounds and not as pure elements.
- A cell as "simple" as *E. coli* contains on the order of 5,000 different compounds, yet it needs to absorb only a few types of nutrients to synthesize this great diversity. These include (NH₄)₂SO₄, FeCl₂, NaCl, trace elements, glucose, KH₂PO₄, MgSO₄, CaHPO₄, and water.

Escherichia coli

Forms, Sources, and Functions of Essential Nutrients

The elements that comprise nutrients ultimately exist in an environmental inorganic reservoir of some type. These reservoirs not only serve as a source of these elements but can be replenished by the activities of organisms. Thus, elements cycle in a pattern from an inorganic form in an environmental reservoir to an organic form in organisms. Organisms may, in turn, serve as a continuing source of that element for other organisms. Eventually the element is recycled to the inorganic form, usually by the actions of microorganisms. All in all, a tremendous variety of microorganisms are involved in processing the elements. From a larger perspective, the overall cycle of life on this planet depends upon the combined

^{*} *adaptation* L. *adaptare*, to fit. Changes in structure and function that improve an organism's survival in a given environment.

1. See critical thinking question 1. b for a useful mnemonic device to recall the essential elements.

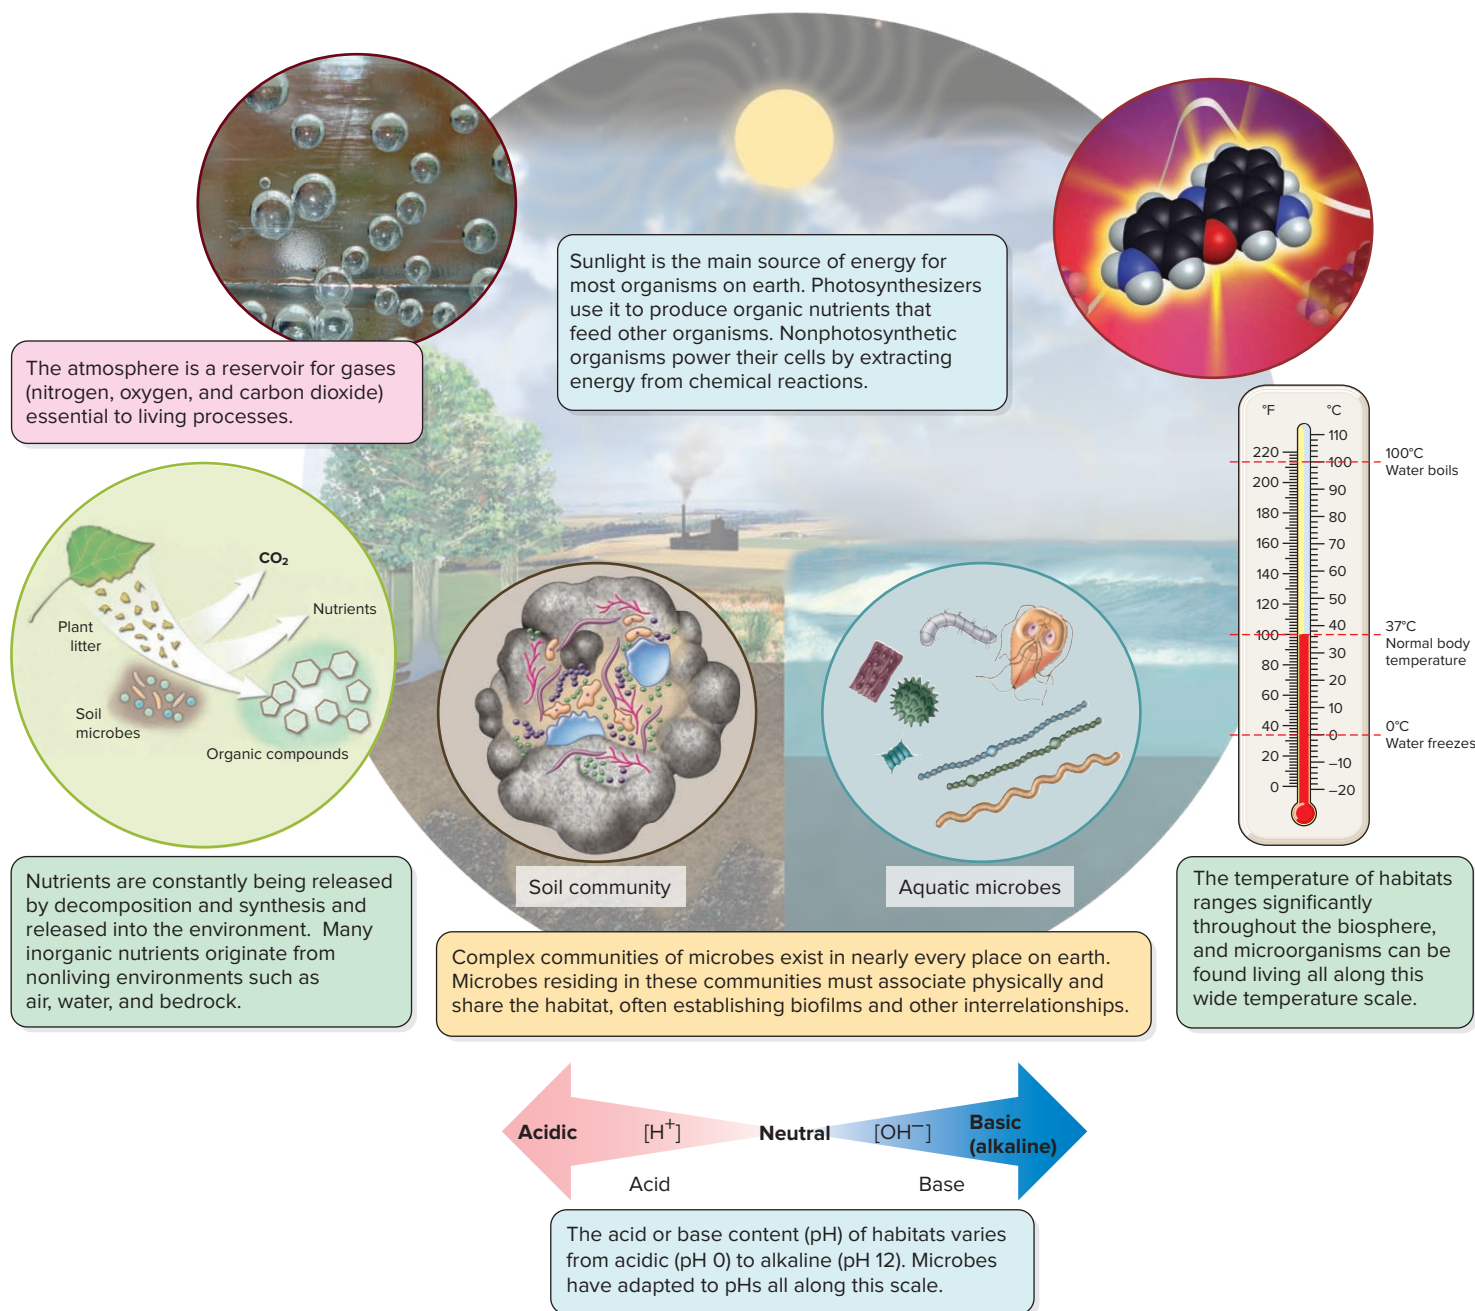

Figure 7.1 Environmental conditions that influence microbial adaptations. The earth's habitats provide a constant supply of energy, nutrients, and gases; maintain a certain pH and temperature; and establish communities of interactive organisms. (photo, top left): © K. Talaro

action of several interacting nutritional schemes, each performing a necessary step. In fact, as we shall see in a later chapter, the framework of microbial nutrition underlies the nutrient cycles of all life on earth.

The source of nutrients is extremely varied: Microbes such as photosynthetic bacteria obtain their nutrients entirely in inorganic form from the environment. Others require a combination of organic and inorganic nutrients. For example, parasites that invade and live on the human body derive all essential nutrients from host tissues, tissue fluids, secretions, and wastes.

Refer to **table 7.1** to see an overview of the major bioelements, compounds, their sources, and their importance to microorganisms.

Carbon-Based Nutritional Types

The element carbon is so key to the structure and metabolism of all life forms that the source of carbon defines two basic nutritional groups:

- A **heterotroph*** is an organism that must obtain its carbon in an organic form. Because most organic carbon originates from organisms, heterotrophs are nutritionally dependent on other life forms. Among the common organic molecules that can satisfy this requirement are proteins, carbohydrates, lipids, and nucleic acids. In most cases, these nutrients provide several

* *heterotroph* (het'-uhr-oh-trohff) Gr. *hetero*, other, and *troph*, to feed.

TABLE 7.1 Sources and Biological Functions of Essential Elements and Nutrients

Element/Nutrient Forms Found in Nature		Sources/Reservoirs of Compounds	Significance to Cells
Carbon	CO ₂ (carbon dioxide) gas CO ₃ ²⁻ (carbonate) Organic compounds	Air (0.036%*) Sediments/soils Living things	CO ₂ is produced by respiration and used in photosynthesis; CO ₃ ²⁻ is found in cell walls and skeletons; organic compounds are essential to the structure and function of all organisms and viruses.
Nitrogen	N ₂ gas NO ₃ ⁻ (nitrate) NO ₂ ⁻ (nitrite) NH ₃ (ammonium) Organic nitrogen (proteins, nucleic acids)	Air (79%*) Soil and water Soil and water Soil and water Organisms	Nitrogen gas is available only to certain microbes that fix it into other inorganic nitrogen compounds—nitrates, nitrites, and ammonium—the primary sources of nitrogen for algae, plants, and the majority of bacteria; animals and protozoa require organic nitrogen; all organisms use NH ₃ to synthesize amino acids and nucleic acids.
Oxygen	O ₂ gas Oxides H ₂ O	Air (20%*), a major product of photosynthesis Soil	Oxygen gas is necessary for the metabolism of nutrients by aerobes. Oxygen is a significant element in organic compounds and inorganic compounds (see water, sulfates, phosphates, nitrates, carbon dioxide in this table).
Hydrogen	H ₂ gas H ₂ O H ₂ S (hydrogen sulfide) CH ₄ (methane) Organic compounds	Waters, swamps, mud Volcanoes, vents Swamps organisms	Water is the most abundant compound in cells and a solvent for metabolic reactions; H ₂ , H ₂ S, and CH ₄ gases are produced and used by bacteria and archaea; H ⁺ ions are the basis for transfers of cellular energy and help maintain the pH of cells.
Phosphorus	PO ₄ ³⁻ (phosphate)	Rocks, mineral deposits Soil	Phosphate, a key component of DNA and RNA, is critical to the genetic makeup of cells and viruses; also found in ATP and NAD, where it takes part in numerous metabolic reactions; its presence in phospholipids provides stability to cell membranes.
Sulfur	S SO ₄ ²⁻ (sulfate) SH (sulfhydryl)	Mineral deposits, volcanic sediments Soil	Elemental sulfur (S) is oxidized by some bacteria as an energy source; sulfur is found in vitamin B1; sulfhydryl groups are part of certain amino acids, where they form disulfide bonds that shape and stabilize proteins.
Potassium	K ⁺	Mineral deposits, ocean water, soil	Plays a role in protein synthesis and membrane transport
Sodium	Na ⁺	Same as potassium	Major participant in membrane actions; maintains osmotic pressure in cells
Calcium	Ca ⁺	Oceanic sediments, rocks, and soil	A component of protozoan shells (as CaCO ₃); stabilizes cell walls; adds resistance to bacterial endospores
Magnesium	Mg ²⁺	Geologic sediments, rocks, and soil	A central atom in the chlorophyll molecule; required for function of membranes, ribosomes, and some enzymes
Chloride	Cl ⁻	Ocean water, salt lakes	May function in membrane transport; required by obligate halophiles to regulate osmotic pressure
Zinc	Zn ²⁺	Rocks, soil	An enzyme cofactor; regulates eukaryotic genetics
Iron	Fe ²⁺	Rocks, soil	Essential element for the structure of respiratory proteins (cytochromes)
Micronutrients: copper, cobalt, nickel, molybdenum, manganese, iodine		Geologic sediments, soil	Required in tiny amounts to serve as cofactors in specialized enzyme systems of some microbes but not all

*As a portion of the earth's atmosphere.

other elements as well. Some organic nutrients (such as **mono-saccharides** and amino acids) already exist in a form that is simple enough for absorption, but many larger molecules must be digested by the cell before absorption. Not all heterotrophs can use the same organic carbon sources. Some are restricted to a few substrates, whereas others (certain *Pseudomonas* bacteria, for example) are so versatile that they can metabolize hundreds of different substrates.

- An **autotroph*** is an organism that uses inorganic CO₂ as its carbon source. Because autotrophs have the special capacity to convert CO₂ into organic compounds, they are not nutritionally dependent on other living things. We later enlarge on the topic of nutritional types based on carbon and energy sources.

* *autotroph* (aw'-toh-trohff) Gr. *auto*, self, and *troph*, to feed.

Carbon Source Versus Carbon Function

It may be helpful to clear up any confusion about the *source* of carbon as opposed to the *intracellular function* of carbon compounds. Although a distinction is made between the form of carbon compounds that cells absorb as nutrients (inorganic or organic), the majority of carbon compounds involved in the normal structure and metabolism of all cells are organic. So, even microbes that use carbon dioxide as their primary source of carbon will convert this CO₂ into organic compounds once it gets into the cell.

Growth Factors: Essential Organic Nutrients

Many **fastidious** bacteria are not as versatile as *E.coli* and lack the genetic and metabolic mechanisms to synthesize every organic compound they need for survival. An essential nutrient such as an amino acid, nitrogenous base, or vitamin that cannot be synthesized by an organism and must be provided as a nutrient is considered a **growth factor**. For example, all cells require 20 different amino acids for proper assembly of proteins, but many cells cannot synthesize all of them. Those that must be obtained from food are called essential amino acids. A notable example of the need for growth factors occurs in *Haemophilus influenzae*, a bacterium that causes meningitis and respiratory infections in humans. It can grow only when hemin (factor X), NAD⁺ (factor V), thiamine and pantothenic acid (vitamins), uracil, and cysteine are provided by another organism or a growth medium.

Check Your Progress SECTION 7.1

1. Summarize the main environmental factors that microbes encounter and their basic characteristics.
2. Differentiate between micronutrients, macronutrients, and essential nutrients.
3. List the general functions of the essential bioelements in the cell.
4. Define growth factors and metallic ions with examples, and explain their functions in cells.

7.2 Classification of Nutritional Types

Expected Learning Outcomes

5. Describe the main categories of nutritional types among organisms.
6. Distinguish different types of autotrophs and their energy sources.
7. Distinguish different types of heterotrophs and their energy sources.

The earth's limitless habitats and microbial adaptations are matched by an elaborate menu of microbial nutritional schemes. Fortunately, most organisms show consistent trends and can be described by a few general categories (**table 7.2**) and a few selected terms (**7.1 Making Connections**).

The main determinants of a microbe's nutritional type are its sources of carbon and energy. We saw earlier that microbes can be defined according to their carbon sources as autotrophs or heterotrophs. Another system classifies them according to their energy source as

TABLE 7.2 Nutritional Categories of Microbes by Energy and Carbon Source

Category/ Carbon Source	Energy Source	Example
Autotroph/CO₂	Nonliving Environment	
Photoautotroph	Sunlight	Photosynthetic organisms, such as algae, plants, cyanobacteria
Chemoautotroph	Simple inorganic chemicals	Only certain bacteria and archaea, such as methanogens and deep-sea vent bacteria
Heterotroph/ Organic Carbon	Other Organisms or Sunlight	
Chemoheterotroph	Metabolic conversion of the nutrients from other organisms	Protozoa, fungi, many bacteria, animals
1. Saprobe	Metabolize the organic matter from dead organisms	Fungi, bacteria, some protozoa (decomposers)
2. Symbiotic microbes	Obtain organic matter from living organisms	Parasites, commensals, mutualistic microbes
Photoheterotroph	Sunlight or organic matter	Purple and green photosynthetic bacteria

phototrophs or **chemotrophs**. Microbes that photosynthesize (acquire energy from light) are phototrophs, and those that gain energy from chemical compounds are chemotrophs. The terms for carbon and energy source are often merged into a single word for convenience (as in table 7.2). The categories described here are meant to cover only the major nutritional groups and do not include unusual exceptions.

Autotrophs and Their Energy Sources

Autotrophs derive energy from one of two possible nonliving sources: sunlight and chemical reactions involving simple chemicals.

Photoautotrophs and Photosynthesis **Photoautotrophs** are photosynthetic; that is, they capture the energy of light rays and transform it into chemical energy that can be used in cell metabolism. In general, photosynthesis relies on special pigments to collect the light and uses the energy to convert CO₂ into simple organic compounds. There are two major variations in the mechanisms of photosynthesis.

Oxygenic (oxygen-producing) photosynthesis can be summed up by the equation:

in which (CH₂O)_n is shorthand for a carbohydrate. This type of photosynthesis occurs in plants, algae, and cyanobacteria and uses chlorophyll as the primary pigment. Carbohydrates formed by the reaction can be used by the cell to synthesize other cell components.

7.1 MAKING CONNECTIONS

A Guide to Terminology

Much of the vocabulary for describing microbial adaptations is based on some common root words. These are combined in various ways that assist in discussing the types of nutritional or ecological adaptations, as shown in the list below.

Modifier terms are also used to specify the nature of an organism's adaptations. **Obligate** or **strict** means being confined to a narrow niche or habitat, such as an obligate thermophile that requires high temperatures to grow. By contrast, **facultative*** means not being so restricted

but adapting to a wider range of environmental conditions. A facultative halophile can grow with or without high salt concentrations. **Tolerance** is another term that can be used to describe the capacity to survive a range of conditions.

Using this guide, define obligate halophile, facultative psychrophile, and aerotolerant anaerobe. Answer available on the Connect website.

* *facultative* (fak'-uhl-tay-tiv) Gr. *facult*, capability or skill, and *tatos*, most.

Root	Meaning	Example of Use
troph-	Food, nourishment	Trophozoite—the feeding stage of protozoa
-phile	To love	Extremophile—an organism that has adapted to (“loves”) extreme environments
-obe	To live	Microbe—to “live small”
hetero-	Other	Heterotroph—an organism that requires nutrients from other organisms
auto-	Self	Autotroph—an organism that “feeds by itself”
photo-	Light	Phototroph—an organism that uses light as an energy source
chemo-	Chemical	Chemotroph—an organism that uses chemicals rather than light for energy
sapro-	Rotten	Saprobe—an organism that lives on dead organic matter
halo-	Salt	Halophile—an organism that can grow in high-salt environments
thermo-	Heat	Thermophile—an organism that grows at high temperatures
psychro-	Cold	Psychrophile—an organism that grows at cold temperatures
aero-	Air (O ₂)	Aerobe—an organism that uses oxygen in metabolism

This topic is covered in greater depth in chapter 8. Because these organisms are the primary producers in most ecosystems, they constitute the basis of food chains by providing nutrition for heterotrophs. This type of photosynthesis is also responsible for maintaining the level of oxygen gas in the atmosphere that is so vital to many organisms.

The other form of photosynthesis is termed **anoxygenic** (no oxygen produced). It may be summarized by the equation:

Note that this type of photosynthesis is different in several respects. (1) It uses a unique pigment, bacteriochlorophyll; (2) its hydrogen source is hydrogen sulfide gas; (3) it gives off elemental sulfur as one product, and (4) the reactions all occur in the absence of oxygen. Common groups of photosynthetic bacteria are the purple and green sulfur bacteria that live in various aquatic habitats, often in mixtures with other photosynthetic microbes (see figure 4.32).

Chemoautotrophy—A Radical Existence Compared to common, familiar organisms, **chemoautotrophs** have adapted to the most stringent nutritional strategy on earth. All chemoautotrophs are bacteria or archaea that survive totally on inorganic substances such as minerals and gases. They require neither light nor organic nutrients in any form, and they derive energy in diverse and sometimes surprising ways. In very simple terms, they remove electrons from inorganic substrates such as hydrogen gas, hydrogen sulfide, sulfur, or iron and combine them with other inorganic substances such as carbon dioxide, oxygen, and hydrogen. These reactions release simple organic

molecules and a modest amount of energy to drive the synthetic processes of the cell. **Figure 7.2a** provides an example of an unusual bacterium that inhabits hot springs in New Zealand. Chemoautotrophs play an important part in recycling inorganic nutrients and elements. For an example of chemoautotrophy and its importance to deep-sea communities, see 7.1 Secret World of Microbes.

The Methanogen World **Methanogens*** are a unique type of chemoautotroph widely distributed in the earth's habitats. All known methanogens are archaea, and many of them are found in extreme habitats, ranging from hot springs and vents to the deepest, coldest parts of the ocean (**figure 7.2b**). Others are common in soil, swamps, and even the intestines of humans and other animals.

Methanogens' metabolism is adapted to producing methane gas (CH₄ or “swamp gas”) by reducing carbon dioxide, using hydrogen gas under anaerobic conditions, summarized as:

Researchers sampling deep underneath the seafloor have uncovered massive deposits of methanogens. The immensity of this community has led one group of scientists to estimate that it comprises nearly one-third of all life on the planet! Evidence points to its extreme age: It has been embedded in the earth's crust for billions of years. Placed under tremendous pressures, the methane it releases becomes

* *methanogen* (meth-an'oh-gen') From *methane*, a colorless, odorless gas, and *gennan*, to produce.

Figure 7.2 Examples of chemotrophy. (a) *Veenivibrio*, an extremophilic bacterium that lives in acidic hot springs and derives energy by combining hydrogen gas with oxygen to form water and hydrogen peroxide. (b) *Methanocaldococcus jannaschii* is an archaeon and methanogen that inhabits hot vents in the seafloor. It also metabolizes hydrogen gas but its product is methane gas (180,000 \times). (a): © Dr. Adrian Hetzer; (b): © Electron Microscope Lab, UC Berkeley

frozen into crystals. Some of it serves as a nutrient source for other extreme archaea, and some of it escapes into the ocean. From this position, it may be a significant factor in the development of the earth's climate and atmosphere. Some microbial ecologists suggest that rises in sea temperature could increase the melting of these methane deposits. Because methane is an important “greenhouse gas,” this process could contribute considerably to ongoing global climate change.

Heterotrophs and Their Energy Sources

The majority of heterotrophic microorganisms are **chemoorganotrophs** that derive both carbon and energy from organic compounds. Processing these organic molecules by respiration or fermentation releases energy in the form of ATP. We will explore these topics in greater depth in chapter 8. An example of chemoheterotrophy is *aerobic respiration*, the principal energy-yielding pathway in animals, most protozoa and fungi, and aerobic bacteria. It can be simply represented by the equation:

Note that this reaction is complementary to photosynthesis. Here, glucose and oxygen are reactants and carbon dioxide is given off. Indeed, the earth's balance of both energy and metabolic gases greatly depends on this relationship. Chemoheterotrophic microbes are all similar in requiring an organic carbon source, but they differ in how they obtain it. This category includes a wide variety of organisms that feed on other organisms: animals, protozoa, fungi, and many types of bacteria. Examples of varied nutritional patterns include grazers, scavengers, and predators, but the dominant chemoheterotrophic microorganisms fit the description of saprobes or symbionts. **Saprobes**² are free-living microbes that feed primarily on organic detritus released by dead organisms, and **symbionts*** derive their organic nutri-

ents from the bodies of living organisms. These categories are not absolute, in that some saprobes can adapt to living organisms, and some symbionts can obtain nutrients from a nonliving source. Because many of these nutritional patterns are also ecological in nature, they will be given fuller coverage in section 7.5. In this section, we introduce saprobes and parasites as they relate to nutrition.

Saprobic Microorganisms The primary niche of saprobes is as decomposers of plant litter, animal matter, and dead microbes. If not for the work of decomposers, the earth would gradually fill up with organic material and the nutrients it contains would not be recycled. Most saprobes, notably bacteria and fungi, have a rigid cell wall and cannot engulf large particles of food. To compensate, they release enzymes to the extracellular environment and digest the food particles into smaller molecules that can be transported into the cell (**figure 7.3**).

Many saprobes exist strictly on dead organic matter in environmental reservoirs such as soil and water, and are unable to adapt to the body of a live host. This group includes free-living protozoa, most fungi, and a variety of bacteria. Apparently there are fewer of these microbes than was once thought, and many supposedly nonpathogenic saprobes can adapt to and invade a susceptible host. When a saprobe does infect a host, it is considered a *facultative parasite*. Because such an infection usually occurs when the host is compromised, the microbe is said to be an **opportunistic pathogen**. A notable example is *Pseudomonas aeruginosa*—its natural habitat is soil and water, yet it is a frequent cause of infections in hospital patients and compromised individuals (as seen in this chapter's Case Study).

Parasitic Microorganisms Most human infections are caused by heterotrophic microorganisms, but those having the greatest adverse impact on human health are **parasites**. By definition, a parasite is a microbe that invades the body of a host, uses it as a habitat and source of nutrients, and, in the process, harms the host to some degree. Such parasitic microbes that grow inside sterile tissues and cause damage, and even death, are also termed **pathogens**. Parasites range from viruses to helminth worms, and they can live on the body (ectoparasites), in the organs and tissues (endoparasites), or even within cells

2. Synonyms are *saprotroph* and *saprophyte*. We prefer to use the terms *saprobe* and *saprotroph* because they are more consistent with other terminology.

* *symbiont* (sim-bee'-ont) An organism that lives in association with another organism, from the term symbiosis (sim'-bye-oh'-sis) Gr, *syn*, together, and *bios*, to live. Literally, living together.

Figure 7.3 Extracellular digestion in a saprobe with a cell wall (bacterium or fungus). (a) A walled cell is inflexible and cannot engulf large pieces of organic debris. (b) In response to a usable food substrate, the cell synthesizes enzymes that are transported across the wall into the extracellular environment. (c) The enzymes hydrolyze the bonds in the debris molecules. (d) Digestion produces molecules small enough to be transported into the cytoplasm.

(intracellular parasites, the most extreme type). The more successful parasites generally have no fatal effects and may eventually evolve to a less harmful relationship with their host (see section 7.5).

Obligate parasites (for example, the leprosy bacillus and the syphilis spirochete) are so dependent on their hosts that they are unable to grow outside of the host. Less strict parasites such as the gonococcus and pneumococcus can be cultured artificially if provided with the correct nutrients and environmental conditions in the laboratory.

Check Your Progress SECTION 7.2

- Compare autotrophs and heterotrophs with respect to the form of carbon-based nutrients they require.
- Describe the nutritional strategy of two types of chemoautotrophs described in this section.
- Contrast chemoautotrophs and chemoheterotrophs as to carbon and energy sources and other unique strategies they may have.
- What are the main differences between saprobes, symbionts, and parasites?

7.3 Transport: Movement of Substances Across the Cell Membrane

Expected Learning Outcomes

- Describe the basic factors in diffusion and passive transport systems.
- Define *osmosis* and describe varying osmotic conditions.
- Analyze adaptations microbes make in response to osmosis.
- Describe the features of active transport and differentiate among its mechanisms.

A microorganism's habitat provides necessary substances—some abundant, others scarce—that must still be taken into the cell for nutrition. The reverse is also true: cells must transport waste materials out of the cell (and into the environment). Whatever the direction, transport occurs across the **cell membrane**, the structure specialized for this role. This is true even in organisms with cell walls (bacteria, algae, and fungi), because the cell wall is usually only a partial, nonselective barrier. In this section we discuss some important physical forces in cell transport.

Diffusion and Molecular Motion

All atoms and molecules, regardless of being in a solid, liquid, or gas, are in continuous movement. As the temperature increases, the molecular movement becomes faster due to an increase in kinetic energy. In any solution, including cytoplasm, these moving molecules cannot travel very far without having collisions with other molecules, and they will bounce off each other like millions of colliding pool balls every second (**figure 7.4**). As a result of each collision, the directions of the colliding molecules are altered and the direction of any one molecule is unpredictable and considered random. An example would be a situation in which molecules of a substance are more concentrated in one area than in another. Just by random thermal movement, the molecules will become dispersed away from an area of higher concentration to an area of lower concentration. Over time this will evenly distribute the molecules in the solution. This net movement of molecules down their concentration gradient by random thermal motion is known as **diffusion**. It can be demonstrated by a variety of simple observations. A drop of perfume released into one part of a room is soon smelled in another part, or a lump of sugar in a cup of tea spreads through the whole cup without stirring (**figure 7.4**).

How Molecules Diffuse in Aqueous Solutions

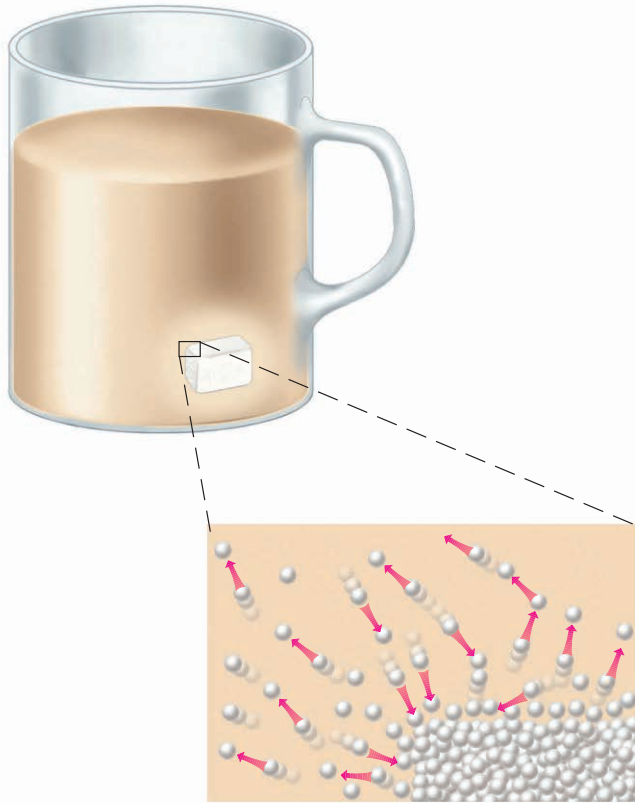

Figure 7.4 Diffusion of molecules in aqueous solutions.

A high concentration of sugar exists in the cube at the bottom of the liquid. An imaginary molecular view of this area shows that sugar molecules are in a constant state of motion. Those at the edge of the cube diffuse from the concentrated area into more dilute regions. As diffusion continues, the sugar will spread evenly throughout the aqueous phase, and eventually there will be no gradient. At that point, the system is said to be in equilibrium.

Diffusion is a driving force in cell activities, but its effects are greatly controlled by membranes. Two special cases are osmosis and facilitated diffusion. Both processes are considered a type of **passive transport**. This means that the cell does not expend extra energy for them to function. The inherent energy of the molecules moving down a gradient does the work of transport.

The Diffusion of Water: Osmosis

Diffusion of water through a selectively permeable membrane, a process called **osmosis**,* is a physical phenomenon that is easily demonstrated in the laboratory with nonliving materials. Simple experiments provide a model of how cells deal with various solute concentrations in aqueous solutions (**figure 7.5**). In an osmotic system, the membrane is *selectively*, or *differentially*, *permeable*, having passageways that allow free diffusion of water but can block certain dissolved molecules. When this type of membrane is placed between solutions of differing concentrations where the solute (protein, for example) cannot pass across, then under the laws of diffusion, water will diffuse at a faster rate from the side that has more water to the side that has less

water. As long as the concentrations of the solutions differ, one side will experience a net loss of water and the other a net gain of water until equilibrium is reached and the rate of diffusion is equalized.

Osmosis in living systems is similar to the model shown in **figure 7.5**. Living membranes generally block the entrance and exit of larger molecules and permit free diffusion of water. Because most cells contain and are surrounded by some sort of aqueous solution, osmosis can have far-reaching effects on cellular activities and survival. Depending on the water content of a cell as compared with its environment, a cell can gain or lose water, or it may remain unaffected. Terms that we use for describing these conditions are *isotonic*, *hypotonic*, and *hypertonic*³ (**figure 7.6**).

Under **isotonic*** conditions, the environment is equal in solute concentration to the cell's internal environment; and because diffusion of water proceeds at the same rate in both directions, there is no net change in cell volume. Isotonic solutions are generally the most stable environments for cells, because they are already in an osmotic steady state with the cell. Parasites living in host tissues are most likely to be living in isotonic habitats.

Under **hypotonic*** conditions, the solute concentration of the external environment is lower than that of the cell's internal environment. Pure water provides the most hypotonic environment for cells because it has no solute. Because the net direction of osmosis is from the hypotonic solution into the cell, cells without walls swell and can burst when exposed to this condition.

Slight hypotonicity is tolerated quite well by most bacteria because of their rigid cell walls. The light flow of water into the cell keeps the cell membrane fully extended and the cytoplasm full. This is the optimum condition for the many processes occurring in and on the membrane.

A cell in a **hypertonic*** environment is exposed to a solution with higher solute concentration than its cytoplasm. Because hypertonicity will force water to diffuse out of a cell, it is said to create high *osmotic pressure* or potential. In cells with a wall, water loss causes shrinkage of the protoplast away from the wall, a condition called **plasmolysis**.* Although the whole cell does not collapse, this event can still damage and even kill many kinds of cells. The effect on cells lacking a wall is to shrink down and usually to collapse (**figure 7.6**). The growth-limiting effect of hypertonic solutions on microbes is the principle behind using concentrated salt and sugar solutions as preservatives for food, such as in salted hams and fish. Such solutions effectively remove moisture from the food, which inhibits the growth of microbial contaminants.

Adaptations to Osmotic Variations in the Environment

Let us now see how specific microbes have adapted osmotically to their environments. In general, isotonic conditions place little stress on cells, so survival depends on counteracting the adverse effects of hypertonic and hypotonic environments.

3. It will help you to recall these osmotic conditions if you remember that the prefixes *iso-*, *hypo-*, and *hyper-* refer to the environment *outside* of the cell.
 * *isotonic* (eye-soh-tahn'-ik) Gr. *iso*, same, and *tonos*, tension.
 * *hypotonic* (hy-poh-tahn'-ik) Gr. *hypo*, under, and *tonos*, tension.
 * *hypertonic* (hy-pur-tahn'-ik) Gr. *hyper*, above, and *tonos*, tension.
 * *plasmolysis* (plaz'-moh-ly'-sis)

* *osmosis* (oz-moh'-sis) Gr. *osmos*, impulsion, and *osis*, a process.

- (a) Inset shows a close-up of the osmotic process. The gradient goes from the outer container (higher concentration of H_2O) to the sac (lower concentration of H_2O). Some water will diffuse the opposite direction but the net gradient favors osmosis into the sac.
- (b) As the H_2O diffuses into the sac, the volume increases and forces the excess solution into the tube, which will rise continually.
- (c) Even as the solution becomes diluted, there will still be osmosis into the sac. Equilibrium will not occur because the solutions can never become equal. (Why?)

Figure 7.5 Model system to demonstrate osmosis. Here we have a solution enclosed in a membranous sac and attached to a hollow tube. The membrane is permeable to water (solvent) but not to solute. The sac is immersed in a container of pure water and observed over time. (a) Inset shows a close-up of the osmotic process. The gradient goes from the outer container (higher concentration of H_2O) to the sac (lower concentration of H_2O). Some water will diffuse the opposite direction but the net gradient favors osmosis into the sac. (b) As the H_2O diffuses into the sac, the volume increases and forces the excess solution into the tube, which will rise continually. (c) Even as the solution becomes diluted, there will still be osmosis into the sac. Equilibrium will not occur because the solutions can never become equal. (Why?)

An alga and an amoeba living in fresh pond water are examples of cells that live in constantly hypotonic conditions. The rate of water diffusing across the cell membrane into the cytoplasm is rapid and constant, and the cells would die without a way to adapt. As with bacteria, the majority of algae have a cell wall that protects them from bursting even as the cytoplasmic membrane becomes **turgid*** from pressure. The amoeba has no cell wall to protect it, so it must expend energy to deal with the influx of water. This is accomplished with a water, or contractile, vacuole that siphons excess water out of the cell like a tiny pump.

A microbe living in a high-salt environment (hypertonic) has the opposite problem and must either restrict its loss of water to the environment or increase the salinity of its internal environment. Halobacteria living in the Great Salt Lake and the Dead Sea must absorb salt to make their cells isotonic with the environment; thus, they have a physiological need for a high-salt concentration in their habitats (see halophiles in section 7.4).

The Movement of Solutes Across Membranes

Simple diffusion works well for movement of small nonpolar molecules such as oxygen or lipid soluble molecules that readily pass

through membranes. But many substances that cells require are polar and ionic chemicals with greatly reduced permeability. Simple diffusion alone would be unable to transport these substances. One way that cells have adapted to this limitation involves a process called **facilitated diffusion (figure 7.7)**. This passive transport mechanism utilizes a carrier protein in the membrane that will bind a specific substance. This binding changes the conformation of the carrier proteins in a way that facilitates movement of the substance across the membrane. Once the substance is transported, the carrier protein resumes its original shape and is ready to transport again. These carrier proteins exhibit **specificity**, which means that they bind and transport only a single type of molecule. For example, a carrier protein that transports sodium will not bind glucose. A second characteristic exhibited by facilitated diffusion is **saturation**. The rate of transport of a substance is limited by the number of binding sites on the transport proteins. As the substance's concentration increases, so does the rate of transport until the concentration of the transported substance causes all of the transporters' binding sites to be occupied. Then the rate of transport reaches a steady state and cannot move faster despite further increases in the substance's concentration.

Other examples of passive protein carriers found in a wide variety of cells are **aquaporins**, also known as water channels. These openings in the membrane facilitate passive transport of water

* *turgid* (ter'-jid) A condition of being swollen or congested.

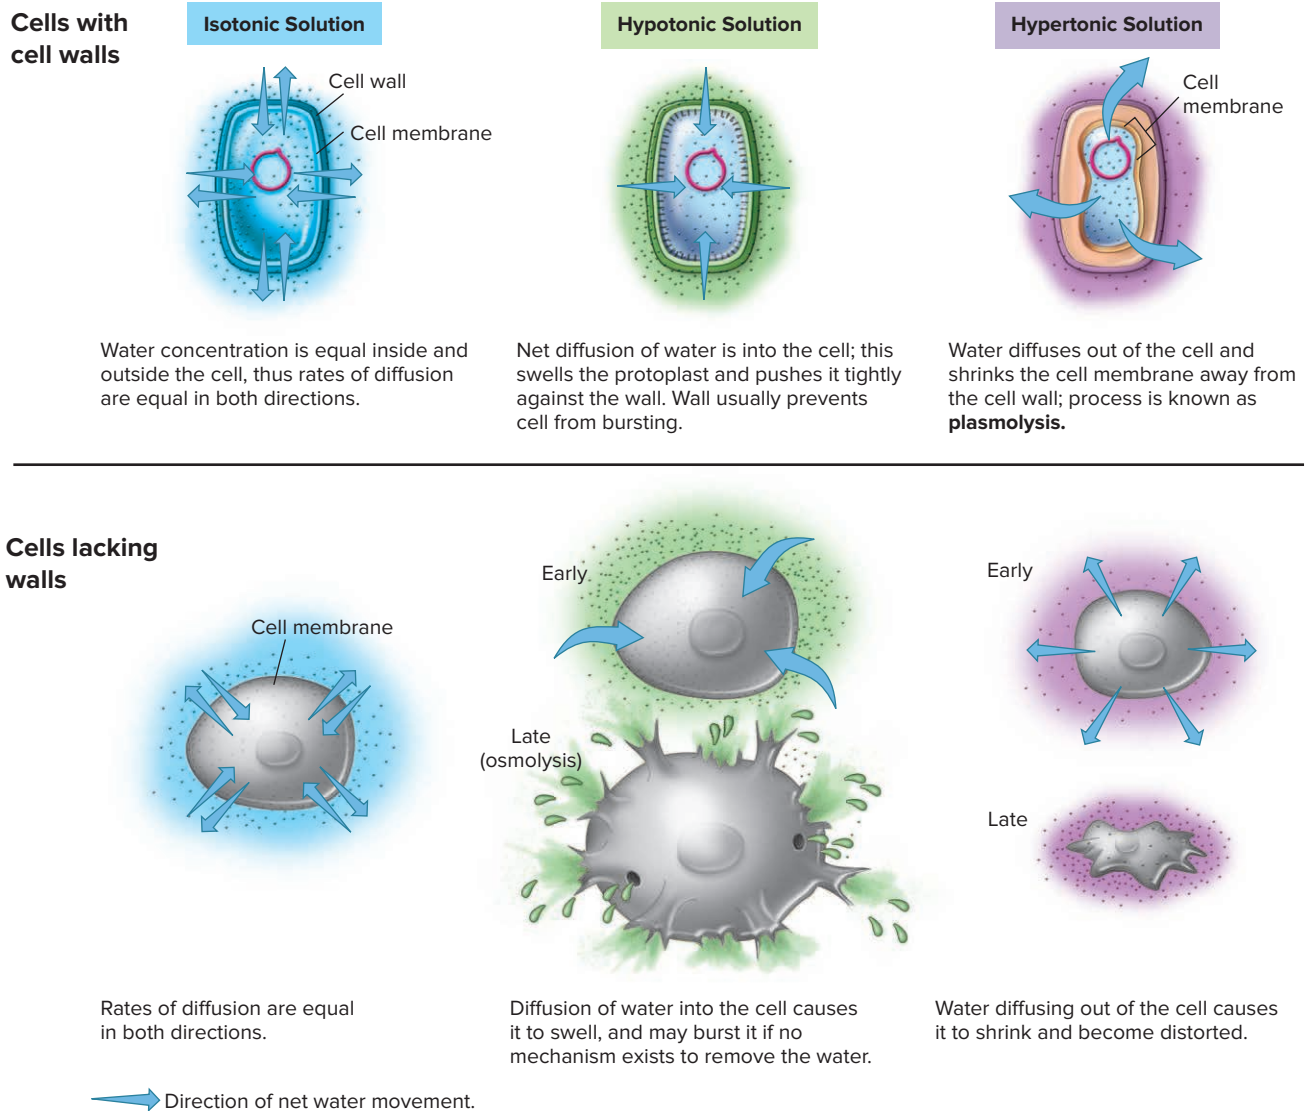

Figure 7.6 Cell responses to solutions of differing osmotic content.

molecules following an existing osmotic gradient. They appear to be involved in regulating volume and osmotic pressure.

Active Transport: Bringing in Molecules Against a Gradient

Free-living microbes exist under relatively nutrient-starved conditions and cannot rely completely on slow and rather inefficient passive transport mechanisms. To ensure a constant supply of nutrients and other required substances, microbes must capture those that are in low concentrations and actively transport them into the cell. Cells must likewise transport substances in the reverse direction to the external environment. Some microbes have such efficient active transport

Figure 7.7 **Facilitated diffusion.** Facilitated diffusion involves the attachment of a molecule to a specific protein carrier. Bonding of the molecule causes a conformational change in the protein that facilitates the molecule's passage across the membrane (left view). The membrane protein releases the molecule into the cell interior (right view). The cell does not have to expend energy for transport.

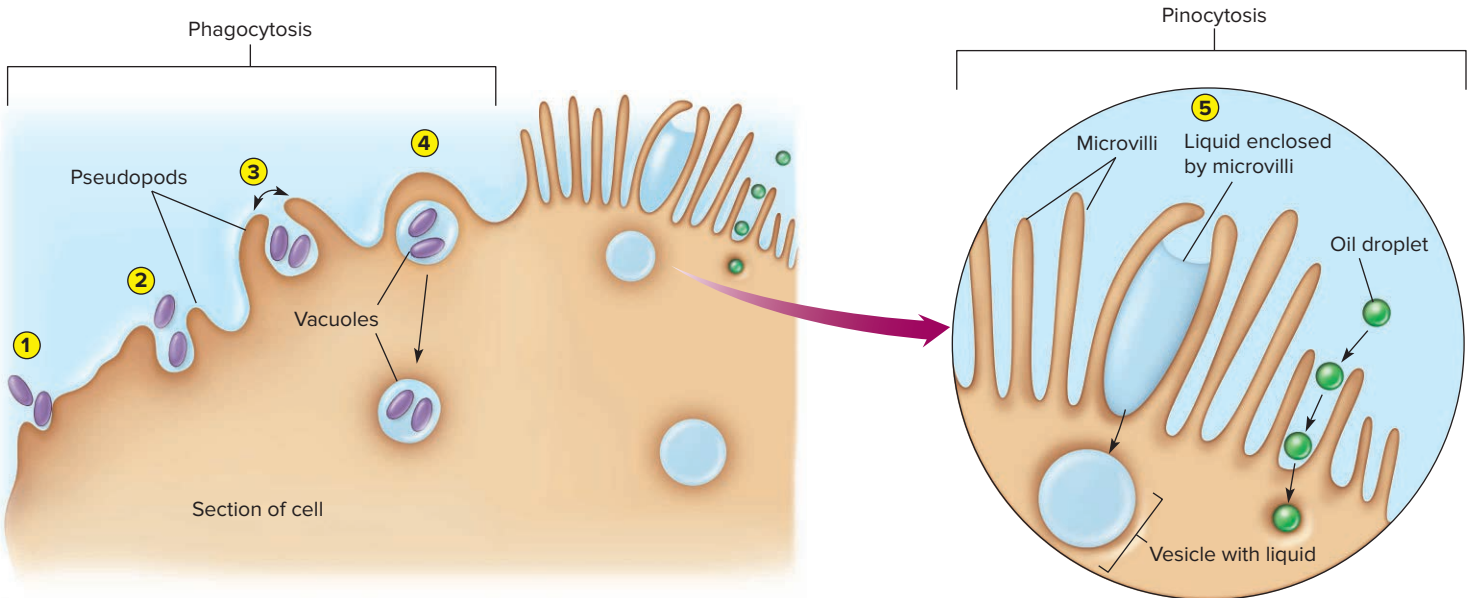

(a) **Carrier-mediated active transport.** (1) Membrane-bound transporter proteins (permeases) interact with nearby solute binding proteins that carry essential solutes (sodium, iron, sugars). (2) Once a binding protein attaches to a specific site, an ATP is activated and generates energy to pump the solute into the cell's interior through a special channel in the permease.

(b) **In group translocation,** (1) a specific molecule is actively captured, but on its passage through the membrane protein carrier (2) it is chemically altered or activated for use in the cell. By coupling transport with synthesis, the cell conserves energy.

(c) **Endocytosis.** With phagocytosis, solid particles are engulfed by flexible cell extensions or pseudopods (1-4) (1,000X). (5) With pinocytosis, fluids and/or dissolved substances are enclosed in vesicles by very fine protrusions called microvilli (3,000X). Oil droplets fuse with the membrane and are released directly into the cell.

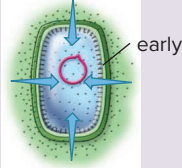

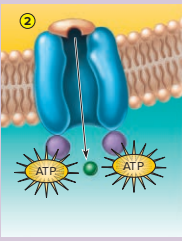

Figure 7.8 Active transport. In active transport mechanisms, energy is expended (ATP) to transport the molecule across the cell membrane.

systems that an essential nutrient can be found in intracellular concentrations that are hundreds of times greater than in the habitat.

Features inherent in **active transport** systems are:

1. the transport of nutrients against the diffusion gradient or in the same direction as the natural gradient but at a rate faster than by diffusion alone,
2. the presence of specific membrane proteins (permeases and pumps; **figure 7.8a**), and
3. the expenditure of additional cellular energy in the form of ATP-driven uptake. Examples of substances transported actively are monosaccharides, amino acids, organic acids, phosphates, and metal ions.

TABLE 7.3 Summary of Transport Processes in Cells

General Process	Nature of Transport	Examples	Description	Qualities
Passive 	Energy expenditure by the cell is not required. Substances exist in a gradient and move from areas of higher concentration toward areas of lower concentration in the gradient.	Diffusion osmosis	A fundamental property of atoms and molecules that exist in a state of random motion	Nonspecific Brownian movement Movement of small uncharged molecules across membranes
		Facilitated diffusion	Molecule binds to a carrier protein in membrane and is carried across to other side.	Molecule specific; transports both ways Transports sugars, amino acids, water
Active 	Energy expenditure is required. Molecules need not exist in a gradient. Rate of transport is increased. Transport may occur against a concentration gradient.	Carrier-mediated active transport	Atoms or molecules are pumped into or out of the cell by specialized receptors; driven by ATP or other high-energy molecules	Transports simple sugars, amino acids, inorganic ions (Na^+ , K^+)
		Group translocation	Molecule is moved across membrane and simultaneously converted to a metabolically useful substance.	Alternate system for transporting nutrients (sugars, amino acids)
		Bulk transport	Mass transport of large particles, cells, and liquids by engulfment and vesicle formation	Process is endocytosis; examples are phagocytosis and pinocytosis

Carrier-mediated active transport involves specific membrane proteins that bind both ATP and the molecules to be transported. Release of energy from ATP drives the movement of the molecule through the protein carrier. This can occur in either direction. Some bacteria transport certain sugars, amino acids, vitamins, and phosphate into the cell by this mechanism. Other bacteria can actively pump drugs out of the cell, thereby providing them resistance to the drugs. Another type of active transport pumps can rapidly carry ions such as K^+ , Na^+ , and H^+ across the membrane. It is this type of transport protein being defective in cystic fibrosis patients that is responsible for its basic pathology (see this chapter's Case Study).

Another type of active transport, **group translocation**, couples the transport of a nutrient with its conversion to a substance that is immediately useful inside the cell (**figure 7.8b**). This method is used by certain bacteria to transport sugars (glucose, fructose) while simultaneously adding phosphate molecules that activate them in preparation for a metabolic cycle.

Endocytosis: Eating and Drinking by Cells

Some cells can transport large molecules, particles, liquids, or even other cells across their cell membranes. Because the cell usually expends energy to carry out this movement, it is also a form of active transport. The substances transported do not pass physically through the membrane but are carried into the cell by **endocytosis**. First the cell encloses the substance in its membrane, simultaneously forming a vacuole and engulfing it (**figure 7.8c**). Amoebas and certain white blood cells ingest whole cells or large solid matter by a type of endocytosis called **phagocytosis**. Liquids, such as oils or molecules in solution, enter the cell through **pinocytosis**. The mechanisms for transport of molecules into cells are summarized in **table 7.3**.

Check Your Progress SECTION 7.3

- Compare and contrast passive and active forms of transport, using examples of what is being transported and the requirements for each.
- How are phagocytosis and pinocytosis similar? How are they different?
- Explain the differences between facilitated diffusion and group translocation.
- Compare the effects of isotonic, hypotonic, and hypertonic solutions on an amoeba and on a bacterial cell. If a cell lives in a hypotonic environment, what will occur if it is placed in a hypertonic one? Answer for the opposite case as well.

7.4 Environmental Factors That Influence Microbes

Expected Learning Outcomes

- Differentiate between habitat and niche.
- Describe the range of temperatures a microbe can function within.
- Explain the adaptive temperature groups, with examples of microbes that exist in them.
- List the major gases and describe microbial requirements for these gases.
- Outline the adaptations of microbial groups to variations in pH.
- Identify microbial adaptations to osmotic pressure.

7.1 Secret World of Microbes

Going to Extremes

Any extreme habitat—whether hot, cold, salty, acidic, alkaline, high-pressure, arid, oxygen-free, or toxic—is likely to harbor microorganisms with special adaptations to these conditions. Most such inhabitants are archaea and bacteria, but certain fungi, protozoans, algae, and even viruses are also capable of living in severe habitats. Microbiologists have termed such remarkable organisms **extremophiles**. Discoveries of new types of extremophiles flourishing in forbidding environments are reported rather frequently. For microbiologists these findings are often astounding but not unexpected, because they confirm our perception that the earth has been “incubating” microbes for billions of years and there are still multitudes of hidden life forms to uncover.

Extreme Temperatures

Some of the most extreme habitats are hot springs, geysers, volcanoes, and ocean vents, all of which support flourishing microbial populations. Temperatures in these regions range from 50°C (122°F) to well above the boiling point of water, with some ocean vents approaching 350°C (662°F). Many heat-adapted microbes are ancient archaea whose genetics and metabolism are extremely modified for this mode of existence. A unique ecosystem based on hydrogen sulfide–oxidizing bacteria exists in the hydrothermal vents lying along deep oceanic ridges. Other denizens of hot volcanic waters are unusual invertebrates such as the Pompeii worm, which frequents rocky hideouts around sea vents measuring 80°C (176°F) (**photo a**). Their survival is greatly dependent on symbiotic bacteria that form an insulated coat on the worm’s surface.

A large part of the earth exists at cold temperatures. Microbes settle and grow throughout the Arctic and Antarctic and in the deepest parts of the ocean in near-freezing temperatures. Several species of algae and fungi thrive on the surfaces of snow and glacier ice (see figure 7.10).

More surprising still is that some bacteria and algae flourish in the sea ice of Antarctica. Although the ice appears to be completely solid, it is honeycombed by various-size pores and tunnels filled with a solution that is –20°C (–4°F). These frigid microhabitats are home to a microcosm of planktonic bacteria, algae, and predators that feed on them.

Life in Very Salty Places

The growth of most microbial cells is inhibited by high amounts of salt; for this reason, salt is a common food preservative. But there are many salt lovers, including rich communities of bacteria and algae living in oceans, salt lakes, and inland seas, some of which are saturated with salt (30%). Microbiologists recently discovered salt pockets that supported archaea living in water 100 times more concentrated than seawater.

“Conan the Bacterium”

A tiny gram-positive coccus, *Deinococcus radiodurans* (**photo b**), has been called “Conan the bacterium” because of its capacity to survive extreme drying and very high levels of radiation. This bacterium is widespread in many habitats, but its resistance to radiation sets it apart from every other known organism. The DNA and proteins of most organisms are very sensitive to gamma rays and other high-energy radiation, which is why radiation is so damaging to cells. But we now know its secret. *Deinococcus* carries around several copies of its genome, making it easily replaceable, and it contains radiation-resistant enzymes that help it rapidly repair DNA damage. This microbe is being studied for its potential in bioremediation of radioactive waste and as a model organism for Mars studies.

Brave “Old” World

When samples of ancient Antarctic ice (several million years old) were brought into the lab, they yielded up living bacteria. Some of the oldest

Microbes are exposed to a wide variety of environmental factors that affect growth and survival. Microbial ecology focuses on ways in which microorganisms deal with or adapt to such factors as heat, cold, gases, acid, radiation, osmotic and hydrostatic pressures, and even other microbes. Adaptation involves a complex adjustment in biochemistry or genetics that enables long-term survival and growth. The term biologists use to describe the totality of adaptations organisms make to their habitats is **niche**.^{*} For most microbes, environmental factors fundamentally affect the function of metabolic enzymes. Thus, survival is largely a matter of whether the enzyme systems of microorganisms can continue to function even in a changing environment. Looking at **7.1 Secret World of Microbes**, will introduce you to the broad range of conditions that support microbial life.

Adaptations to Temperature

Microbial cells cannot control their temperature and therefore assume the ambient temperature of their natural habitats. So, to survive they must adapt to whatever temperature variations are encountered in their habitat. The range of temperatures for microbial growth can be expressed as three **cardinal temperatures**. The **minimum temperature**

is the lowest temperature that permits a microbe’s continued growth and metabolism; below this temperature, its activities are inhibited. The **maximum temperature** is the highest temperature at which growth and metabolism can proceed. If the temperature rises slightly above maximum, growth will stop. If it continues to rise beyond that point, the enzymes and nucleic acids will eventually become permanently inactivated—a condition known as **denaturation**—and the cell will die. This is why heat works so well as an agent in microbial control. The **optimum temperature** covers a small range, intermediate between the minimum and maximum, which promotes the fastest rate of growth and metabolism. Only rarely is the optimum a single point.

Depending on their natural habitats, some microbes have a narrow cardinal range, others a broad one. Some strict parasites will not grow if the temperature varies more than a few degrees below or above the host’s body temperature. For instance, rhinoviruses (one cause of the common cold) multiply successfully only in tissues that are slightly below normal body temperature (33°C to 35°C or 91°F to 95°F). Other microbes are not so limited. Strains of *Staphylococcus aureus* grow within the range of 6°C to 46°C (43°F to 114°F), and the intestinal bacterium *Enterococcus faecalis* grows within the range of 0°C to 44°C (32°F to 112°F).

Another way to express temperature adaptation is to describe whether an organism grows optimally in a cold, moderate, or hot

^{*} *niche* (nitch) Fr. *nichier*, to nest.

isolates were unusual, very slow-growing forms, but others were similar to modern bacteria.

Another bizarre, ancient ultraextremophile was discovered 3 kilometers down in an African gold mine. The bacterium *Desulforudis* is the only occupant of this totally dark, anaerobic, hot, alkaline habitat, and it derives its energy from the radioactive decay of uranium. This is the first organism on earth known to have established its own ecosystem and to sustain itself without the contributions of other organisms.

Numerous species have carved a niche for themselves in the deepest layers of mud, swamps, and oceans, where oxygen gas and sunlight cannot penetrate. The predominant living things in the deepest part of the oceans (10,000 m or below) are pressure- and cold-loving microorgan-

isms. Even parched zones in sand dunes and deserts harbor a hardy brand of microbes; and thriving bacterial populations can be found in petroleum, coal, and mineral deposits containing copper, zinc, gold, and uranium. Microbes that can adapt and survive under such lethal conditions are called toxophiles.

As a rule, a microbe that has adapted to an extreme habitat will not survive in a moderate one. And except for rare cases, none of the organisms living in these extremes is a pathogen, because the human body would be a rather hostile habitat for them.

Explain how extremophiles can survive such severe and adverse conditions. Answer available on Connect.

Cary, College of Marine Studies, University of Delaware; (b): © Dea Slade

temperature range. The terms used for these ecological groups are *psychrophile*, *mesophile*, and *thermophile* (figure 7.9).

A **psychrophile*** is a microorganism (bacterium, archaea, fungus, or alga) with an optimum temperature below 15°C (59°F) but generally can grow at 0°C (32°F). It is obligate with respect to cold and generally cannot grow above 20°C (68°F). Laboratory work with true psychrophiles can be a real challenge. Inoculations have to be done in a cold room because ordinary room temperature can be lethal to these organisms. Unlike most laboratory cultures, storage in the refrigerator incubates rather than inhibits them. As one might predict, true psychrophiles are not capable of surviving in the human body and do not cause infections. Instead, they populate some of the coldest places on earth, including snowfields (figure 7.10), polar ice, permafrost, and the deep ocean. Recently bacteria were isolated from an undersea lake in Antarctica that were living at -15°C (5°F). True psychrophiles must

Figure 7.9 Ecological groups by temperature of adaptation. Psychrophiles can grow at or near 0°C and have an optimum below 15°C. As a group, mesophiles can grow between 10°C and 50°C, but their optima usually fall between 20°C and 40°C. One type of mesophile termed a psychrotroph is capable of growth at temperatures below 20°C. Generally speaking, thermophiles require temperatures above 45°C and grow optimally between this temperature and 80°C. Extreme thermophiles (hyperthermophiles) are bacteria and archaea with optima above 80°C. Note that the extremes of the ranges can overlap to some extent.

* *psychrophile* (sy'-kroh-fyl) Gr. *psychros*, cold, and *philos*, to love.

be distinguished from *psychrotrophs* or *facultative psychrophiles* that grow slowly in cold but have an optimum temperature above 20°C (68°F). Psychrotrophs such as *Staphylococcus aureus* and *Listeria monocytogenes* are a concern because they can grow in refrigerated food and cause food-borne illness.

The majority of medically significant microorganisms are **mesophiles**,* organisms that grow at intermediate temperatures. Although an individual species can grow between the extremes of 10°C and 50°C (50°F and 122°F), the optimum growth temperatures (optima) of most mesophiles fall into the range of 20°C to 40°C (68°F to 104°F). Organisms in this group inhabit animals and plants as well as soil and water in temperate, subtropical, and tropical regions. Most human pathogens have optima somewhere between 30°C and 40°C (human body temperature is 37°C or 98°F). *Thermophilic* microbes, which can survive short exposure to high temperatures but are normally mesophiles, are common contaminants of heated or pasteurized foods (see chapter 11). Examples include heat-resistant cysts such as *Giardia* or sporeformers such as *Bacillus* and *Clostridium*.

A **thermophile*** is a microbe that grows optimally at temperatures greater than 45°C (113°F). Such heat-loving microbes live in soil and water associated with volcanic activity, in compost piles, and in habitats directly exposed to the sun. Thermophiles generally range in growth temperatures from 45°C to 80°C (113°F to 176°F). Most eukaryotic forms cannot survive above 60°C (140°F), but a few bacteria and archaea, called **hyperthermophiles**, are adapted to life in extreme temperatures. They can grow at between 80°C and 121°C (250°F), currently thought to be the highest temperature limit endured by enzymes and cell structures. Strict thermophiles are so heat tolerant that researchers can use a heat-sterilizing device to isolate them from non-thermophiles in culture.

Currently biotechnology companies are intensely interested in thermal microorganisms. One of the most profitable discoveries so far was a strict thermophile *Thermus aquaticus*, which produces an

enzyme that can make copies of DNA even at high temperatures. This enzyme—Taq polymerase—is now an essential component of the polymerase chain reaction or PCR, a process used in many areas of medicine, forensics, and biotechnology (see chapter 10).

Gas Requirements

The atmospheric gases that most influence microbial growth are oxygen (O₂) and carbon dioxide (CO₂). Oxygen comprises about 20% of the atmosphere and CO₂ about 0.04%. Oxygen gas has a great impact on microbial adaptation. It is an important respiratory gas, and it is also a powerful oxidizing agent that exists in many toxic forms. In general, microbes fall into one of three categories: those that use oxygen and can detoxify it; those that can neither use oxygen nor detoxify it; and those that do not use oxygen but can detoxify it.

How Microbes Process Oxygen

As oxygen gas enters into cellular reactions, it can be transformed into several toxic products. Singlet oxygen (¹O₂) is an extremely reactive molecule produced by both living and nonliving processes. Notably, it is one of the substances produced by phagocytes to kill invading bacteria (see chapter 14). The buildup of singlet oxygen and the oxidation of membrane lipids and other molecules can damage and destroy a cell. The highly reactive superoxide ion (O₂⁻), peroxide (H₂O₂), and hydroxyl radicals (OH) are other destructive metabolic by-products of oxygen. To survive these toxic oxygen products, many microorganisms have developed enzymes capable of scavenging and neutralizing these chemicals. The complete conversion of superoxide ion into less harmful oxygen gas involves a two-step process and at least two enzymes:

In this series of reactions essential for aerobic organisms, the superoxide ion is first converted to hydrogen peroxide and normal oxygen by the action of an enzyme called superoxide dismutase. Because hydrogen peroxide is also toxic to cells (it is used as a disinfectant and antiseptic), it must be degraded by an enzyme—either catalase or peroxidase—into water and oxygen. If a microbe is not capable of dealing with toxic oxygen by these or similar mechanisms, it will be restricted to habitats free of oxygen.

With respect to oxygen requirements, several general categories are recognized. An **aerobe*** (aerobic organism) can use gaseous oxygen in its metabolism and possesses the enzymes needed to process toxic oxygen products. An organism that cannot grow without oxygen is an **obligate aerobe**. Most fungi and protozoa, as well as many bacteria (genera *Micrococcus* and *Bacillus*), have strict requirements for oxygen in their metabolism.

A **facultative anaerobe** is an aerobe that does not require oxygen for its metabolism and is capable of growth in its absence. This type of organism metabolizes by aerobic respiration when oxygen is present, but in its absence, it adopts an anaerobic mode of metabolism such as fermentation. Facultative anaerobes usually possess catalase and superoxide dismutase. A number of bacterial pathogens

* *mesophiles* (mez'-oh-fylz) Gr. *mesos*, middle.

* *thermophile* (thur'-moh-fyl) Gr. *therme*, heat.

* *aerobe* (air'-ohb) Although the prefix means air, it is used in the sense of oxygen.

fall into this group. This includes gram-negative intestinal bacteria and staphylococci. A **microaerophile*** does not grow at normal atmospheric concentrations of oxygen but requires a small amount of it (1%–15%) in metabolism. Most organisms in this category live in a habitat such as soil, water, or the human body that provides small amounts of oxygen but is not directly exposed to the atmosphere.

A true **anaerobe** (anaerobic microorganism) lacks the metabolic enzyme systems for using oxygen gas in respiration. Because **strict**, or **obligate**, **anaerobes** also lack the enzymes for processing toxic oxygen, they cannot tolerate any free oxygen in the immediate environment and will die if exposed to it. Strict anaerobes live in highly reduced habitats, such as deep muds, lakes, oceans, and soil.

Determining the oxygen requirements of a microbe from a biochemical standpoint can be a very time-consuming process. An initial clarification comes from cultures made with reducing media that contain an oxygen-removing chemical such as thioglycollate. The location of growth in a tube of fluid thioglycollate medium is a fair indicator of an organism's adaptation to oxygen use (**figure 7.11**). Growing strictly anaerobic bacteria usually requires special media, methods of incubation, and handling chambers that exclude oxygen. **Figure 7.12** shows special systems for handling and growing anaerobes.

Even though human cells use oxygen, and oxygen is found in the blood and tissues, some body sites present anaerobic pockets or microhabitats where colonization or infection can occur. Dental caries are partly due to the complex actions of aerobic and anaerobic bacteria in plaque. Most gingival infections consist of similar mixtures of oral bacteria that have invaded damaged gum tissues. Another common site for anaerobic infections is the large intestine, a

* *microaerophile* (myk'-roh-air'-oh-fyl)

Figure 7.11 Use of thioglycollate broth to demonstrate oxygen requirements. Thioglycollate is a reducing medium that can establish a gradation in oxygen content. Oxygen concentration is highest at the top of the tube and absent in the deeper regions. When a series of tubes is inoculated with bacteria that differ in O_2 requirements, the relative position of growth provides some indication of their adaptations to oxygen use. Tube 1 (far left): aerobic (*Pseudomonas aeruginosa*); Tube 2: facultative (*Staphylococcus aureus*); Tube 3: facultative (*Escherichia coli*); Tube 4: obligate anaerobe (*Clostridium butyricum*). © Terese M. Barta, Ph.D.

relatively oxygen-free habitat that harbors a rich assortment of strictly anaerobic bacteria. Anaerobic infections can occur following abdominal surgery and traumatic injuries (gas gangrene and tetanus).

Aerotolerant anaerobes do not utilize oxygen gas but can survive and grow in its presence. These anaerobes are not harmed by oxygen, and some of them possess alternate mechanisms for breaking down peroxide and superoxide. For instance, lactobacilli, which are common residents of the intestine, inactivate these compounds with manganese ions.

Although microbes require some carbon dioxide in their metabolism, **capnophiles** grow best at higher CO_2 concentrations (3%–10%) than are normally present in the atmosphere (0.033%). This becomes important in the initial isolation of some pathogens from clinical specimens, notably *Neisseria* (gonorrhea, meningitis),

Brucella (undulant fever), and *Streptococcus pneumoniae*. Incubation is carried out in a CO₂ incubator that provides the correct range of CO₂ (figure 7.12b). Keep in mind that CO₂ is an essential nutrient for autotrophs, which use it to synthesize organic compounds.

Effects of pH

Microbial growth and survival are also influenced by the pH of the habitat. The pH was defined in chapter 2 as the degree of acidity or alkalinity of a solution. It is expressed by the pH scale, a series of numbers ranging from 0 to 14, pH 7 being neither acidic nor alkaline. As the pH value decreases toward 0, the acidity increases, and as the pH increases toward 14, the alkalinity increases. The majority of organisms live or grow in habitats between pH 6 and pH 8 because stronger acids and bases can be highly damaging to enzymes and other cellular substances.

Although most microorganisms living in soil, fresh water, or the bodies of plants and animals are **neutrophiles**, living within the range of pH 5.5 to 8, some can manage exposure to pH extremes. Highly acidic or alkaline habitats such as acidic bogs and streams or alkaline soils and ponds can provide numerous habitats for specialized microbial communities. Obligate **acidophiles** include *Euglena mutabilis*, an alga that grows in acid pools between 0 and 1.0 pH, and *Thermoplasma*, an archaea that lives in hot coal piles at a pH of 1 to 2 and will lyse if exposed to pH 7. A few species of algae, archaea, and bacteria can survive at a pH near that of concentrated hydrochloric acid near a pH of 0. Not only do they require such a low pH for growth, but a few species of bacteria actually help maintain the low pH by releasing strong acid. Because many molds and yeasts tolerate moderate acidity, they are the most common spoilage agents of acid-pickled foods.

Alkaliphiles live in hot pools and soils that contain high levels of basic minerals. Probably the upward limit of tolerance is shown by proteobacteria in California's Mono Lake that have adapted to pH 12. Bacteria that decompose urine create alkaline conditions, because ammonium (NH₄⁺) can be produced when urea (a component of urine) is digested. Metabolism of urea is one way that *Proteus* spp. can neutralize the acidity of the urine to colonize and infect the urinary system.

Osmotic Pressure

Although most microbes exist under hypotonic or isotonic conditions, a few, called **osmophiles**, live in habitats with a high solute concentration. Common types of osmophiles that survive and grow in high concentrations of salt are referred to as **halophiles**.*

Obligate halophiles such as *Halobacterium* and *Halococcus* inhabit salt lakes, ponds, and other hypersaline habitats. They grow optimally in solutions of 25% NaCl but require at least 9% NaCl (combined with other salts) for growth. These archaea have significant modifications in their cell walls and membranes, and will lyse in hypotonic habitats. Perhaps the most extreme saline habitat exists in a shallow pond in frigid Antarctica. The salt concentration of Don Juan Pond tests at 33% CaCl₂. For a time researchers thought this site would be a good model for duplicating the lifeless conditions on Mars, until they discovered an active biofilm community of cyanobacteria and diatoms residing there!

Some microbes adapt to wide concentrations in solutes. These are considered **osmotolerant** and are sometimes referred to as **facultative**

halophiles. Such organisms are remarkably resistant to salt, even though they do not normally reside in high-salt environments. For example, *Staphylococcus aureus* can grow on NaCl media ranging from 0.1% up to 20%. Although it is common to use high concentrations of salt and sugar to preserve food (jellies, syrups, and brines), many bacteria and fungi thrive under these conditions and are common spoilage agents. One particularly hardy sugar-loving or **saccharophilic** yeast withstands the high sugar concentration of honey and candy.

Miscellaneous Environmental Factors

Descent into the ocean depths subjects organisms to increasing hydrostatic pressure. Deep-sea microbes called **barophiles** exist under pressures many times that of the atmosphere. Marine biologists sampling deep-sea trenches 7 miles below the surface isolated unusual eukaryotes called foraminifera that were being exposed to pressures 1,100 times greater than what would occur at the sea's surface. These microbes are so strictly adapted to high pressures that they will rupture when exposed to normal atmospheric pressure at sea level.

Because of the high water content of cytoplasm, all cells require water from their environment to sustain growth and metabolism. Water is the solvent for cell chemicals, and it is needed for enzyme function and digestion of macromolecules. A certain amount of water on the external surface of the cell is required for the diffusion of nutrients and wastes. Even in apparently dry habitats, such as sand or dry soil, the particles retain a thin layer of water usable by microorganisms. Only dormant, dehydrated cell stages (for example, spores and cysts) tolerate extreme drying because of the inactivity of their enzymes.

7.5 Ecological Associations Among Microorganisms

Expected Learning Outcomes

18. Outline the types of associations among microorganisms and describe their basic differences.
19. Explain what occurs in symbiosis and in coevolution.
20. Differentiate among mutual, commensal, and parasitic associations, providing examples.
21. Explain syntrophy and amensalism, using examples.
22. Describe interactions between humans and their microbiota.

Two major unifying themes of this chapter are microbial adaptability and **ubiquity**. The presence of microbes in most natural settings and their interactions with other organisms in these settings have

* *halophiles* (hay'-loh-fylz)

7.2 Secret World of Microbes

A Mutual Attraction

A tremendous variety of mutualistic symbioses occur in nature. These associations gradually coevolve as participating members come to require some substance or habitat that the other members provide. In many cases they become so interdependent that they will not survive outside of this association.

Many protozoan cells receive growth factors from symbiotic bacteria and algae that are mutually nurtured by the protozoan cell. One peculiar ciliate propels itself by affixing symbiotic bacteria to its cell membrane to act as “oars.” Other ciliates and amoebas harbor specialized bacteria or algae inside their cells to provide nutrients.

Mutualism Between Microbes and Animals

Microorganisms carry on mutual symbiotic relationships with animals as diverse as sponges, worms, and mammals. Complex, multipartner mutualism is especially striking in termites, which harbor 250 or more specialized microbes inside their gut. The termite’s role is simply to gnaw off pieces of wood, but it cannot digest the wood. **Endosymbiotic** protozoans and bacteria do the final work of breaking down the wood particles, and all of the mutualists share in the nutrients provided (see photos).

Bacteria and protozoa are essential in the operation of the rumen (a complex, four-chambered stomach) of cud-chewing mammals. These mammals produce no enzymes of their own to break down the cellulose that is a major part of their diet, but the microbial population harbored in their rumens does. The complex food materials are digested through

several stages, during which time the animal regurgitates and chews the partially digested plant matter (the cud) and occasionally burps methane produced by the microbial symbionts.

Thermal Vent Communities

Another fascinating relationship has been found in the deep hydrothermal vents in the seafloor, where geologic forces spread the crustal plates and release superheated fluid (over 350°C or 662°F) and gas. These vents are a focus of tremendous biological and geologic activity. The source of energy in this community is not the sun, because the vents are too deep for light to penetrate (2,600 m). Instead, this ecosystem is based on a massive chemoautotrophic bacterial population that oxidizes the abundant hydrogen sulfide (H₂S) gas given off by the volcanic activity there. As the bottom of the food web, these bacteria serve as the primary producers of nutrients that service a broad spectrum of specialized animals. One example, the tube worm *Riftia*, has become so specialized that it has lost its gastrointestinal tract and feeds solely from its bacterial symbionts.

produced an abundance of specialized adaptations and niches of incredible diversity. If we go by the constant discoveries of new organisms and new associations, it is likely that every possible combination and example of microbial association exists somewhere on earth. Even with such a great variety, we can organize these microbial alliances into six basic patterns, ranging from organisms living a totally codependent existence to free-living microbes that interact in loose and temporary unions.

Probably the best-described and best-understood interactions are **symbioses**,⁴ defined as close associations between organisms that are advantageous to at least one of the members. Recall that the

members of symbiotic relationships are termed symbionts. Symbioses can be obligatory or nonobligatory, can involve animals, plants, and other microbes, and can include complex multipartner interactions. Some symbionts live internally (endosymbionts), whereas others are affixed to the outside surfaces of their partners (ectosymbionts). **Figure 7.13** provides an overview of the major categories of symbiosis with examples.

The most intimate and interdependent type of symbiosis is **mutualism**, a relationship in which all members share in the benefits of the relationship. Many mutualistic associations have developed over hundreds of millions, and even billions, of years of shared evolution, a process termed **coevolution**. Coevolving symbionts remain in very close contact and must evolve together to sustain themselves. Any changes in partner A exert a selective pressure on partner B to adapt to these changes, and vice versa. These adaptations occur at the genetic level, and in some cases genes are

4. Although it is sometimes misused as a synonym for mutualism, be aware that the term *symbiosis* does not refer only to mutually beneficial associations, as parasitism is also a form of symbiosis.

Mathison/CDC DPDx

Obligate Mutualism Organisms are so intimately associated that they require each other to survive. Root nodules (a1) have nitrogen-fixing endosymbiotic bacteria that supply the plant with usable nitrogen and provide a nurturing habitat for the bacteria (a2 inset). Jellyfish (b1) and corals rely on endosymbiotic algae called dinoflagellates (b2 inset) for survival.

(a1) Root nodules on a legume; (a2) *Bradyrhizobium* bacteria inside a nodule (3,000x)

(b1) A *Casseopeia* jellyfish gets its color and nutrition from (b2) dinoflagellates (400x).

Nonobligate Mutualism

Organisms interact at the cellular level for mutual benefit, but they can be separated and live apart. The protozoan in (c) engulfs the algae but absorbs the nutrients they release and shelters them. (d) The plant supplies nutrients to the fungus and the fungus protects the plants against drying and insects.

(c) The ciliophoran *Euplotes* (800x) harbors unicellular green algae.

(d) Fungal hyphae (blue filaments—500x) growing in close contact with the cells of a grass leaf.

Commensalism The members have an unequal relationship. One partner is favored by the association and the other is not harmed or helped. (e) Tiny colonies of *Haemophilus* absorb required growth factors given off by *Staphylococcus*. (f1 and 2) Human commensals associated with the epidermis make a living off flakes and excretions, generally with neutral effects.

(e) Satellite *Haemophilus* colonies clustered around *Staphylococcus* (white line of growth).

(f1) *Demodex* mite lives in or around human hair follicles. (100x) and (f2) *Micrococcus luteus* bacteria live on the skin surface (2,000x)

Parasitism A microbe invades the sterile regions of a host and occupies its tissues and cells, causing some degree of damage. (g) All viruses are parasites that invade cells and take over their function. (h) Malaria shows multilevel parasitism. Mosquitoes (h1) are blood-sucking ectoparasites of humans that carry their own parasites (h2) that can also infect humans.

(g) Sin Nombre hantavirus, a human pathogen carried in the waste of mice (5,000x).

(h1) The malaria vector, a female *Anopheles* mosquito; (h2) malaria parasites (*Plasmodium*, 1,000x) from blood

Syntrophy Microbes sharing a habitat feed off substances released by other organisms, (i) *Azotobacter* releases NH_4^+ that feeds *Cellulomonas*, and *Cellulomonas* degrades cellulose that feeds *Azotobacter*. (j) A dust mite lives in human settings and feeds off dead skin flakes.

(i) Cycle of cross-feeding in two soil bacteria

(j) *Dermatophagoides* mite (100×)

Amensalism One member of an association produces a substance that harms or kills another.

(k) Ants have complex symbiotic relationships that involve mutualism and amensalism with fungi and bacteria. (l1 and l2) In the amensal phase of their ecology, the ants cultivate actinomycetes to protect their habitat from microbial pests.

(k) Leaf cutting ants gathering food for a fungus garden that is their source of food.

(l1) Antibiosis by an actinomycete against a pathogenic fungus; (l2) micrograph of actinomycete (800×)

exchanged between the partners. Over very long periods, the mutualists can become completely interdependent. We see this in *Buchnera* endosymbionts of certain aphids. These bacteria provide the aphid with needed amino acids and the aphid provides them a protective habitat. The bacteria are now so obligate that they have lost a large part of their genome and cannot survive outside the aphid. The aphids too have come to require the bacteria for survival. Be reminded that endosymbiotic bacteria likely gave rise to the mitochondria and chloroplasts of eukaryotic cells. Other well-studied examples of obligate mutualism can be found in termites, corals, root nodules, tube worms, and ants (figure 7.13a, and 7.2 Secret World of Microbes).

The nondependent forms of mutualism are also referred to as **cooperation**. Here, organisms gain mutual benefit from their association, but they can survive independently outside of the partnership. Many of these cooperative relationships are coevolving to greater dependency. One example is the protozoan *Euplotes*, which harbors endosymbiotic algae in its cells (figure 7.13c). Although both members can survive apart from this mutualistic interaction, they appear to receive significant survival benefits from being together.

Other examples include fungi that grow within plant tissues and protect the plant from drought and insects while being harbored and fed (figure 7.13d). Hot-vent Pompeii worms harbor ectosymbiotic filamentous bacteria on their surfaces to protect against high temperatures and toxic metals (7.2 Secret World of Microbes).

Another common symbiotic relationship is **commensalism**.* Commensal organisms live in close contact, but only one partner benefits, while the other receives neither benefit nor harm from the union. The members of the association are called **commensals**. One form of commensalism observed in cultured microbes is termed the “satellite phenomenon,” in which one species releases various growth factors that are required by a nearby species to grow. The feeder microbe grows around its partner as tiny colonies, while the passive partner is not harmed or helped (figure 7.13e). Many of the microbes that occupy a niche on the human body are considered commensals. They make a living by feeding off dead skin and secretions, but do not usually cause harm (figure 7.13f, 2). The ongoing microbiome studies will no doubt find that many human residents are actually mutualists that contribute to human health.

The last type of symbiotic interrelationship is **parasitism**, first introduced in section 7.2. This is the one type of symbiosis that is primarily beneficial to the parasite and harmful to the host. Parasitism is widespread throughout nature. All organisms host parasites, and even some viruses have recently been found to harbor their own viral parasites! Many parasitic relationships also undergo coevolution, and it is rather common for the parasite to be completely dependent on the host.

* *commensalism* (kuh-men'-sul-izm) L. *com*, together, and *mensa*, table.

There are various degrees of parasitism. The most extreme form is **obligate intracellular parasitism**, which means the microbe spends all or most of its life cycle inside the host cell, from which it derives essential nutrients and other types of support. Examples include viruses (genetic and metabolic parasites) (**figure 7.13g**); *Rickettsia* and *Chlamydia* bacteria (energy parasites); and apicomplexan protozoans like *Plasmodium* (cause of malaria and hemoglobin parasites) (**figure 7.13h1, 2**). The kinds of harm that parasites do to their hosts varies from superficial damage (ringworm on the skin from a fungal infection) to significant damage (peptic ulcers) to rapid death (rabies virus). It is reasonable to think that most parasites modulate the damage they do and can even coevolve into a commensal or mutualistic existence as the host develops tolerance.

Additional interactions can be important factors in the ecology and adaptations of organisms. One of these, **syntrophy**,* or **cross-feeding**, is communal feeding between organisms sharing a habitat. In essence, products given off by one organism are usable by another (**figure 7.13i**). The organisms involved do not require this relationship for survival, but they generally benefit from it. Many syntrophic associations occur in aquatic habitats and soils within biofilms and are related to nutrient and bioelement recycling. A simple example involves a pair of free-living soil bacteria that share their metabolic products cyclically (**figure 7.13j**). *Cellulomonas* uses its enzymes to digest plant cellulose into glucose, but it cannot fix nitrogen. *Azotobacter* fixes nitrogen gas from the air and releases ammonium, but it does not digest cellulose. The glucose is a source of carbon for *Azotobacter*, and the ammonium supplies *Cellulomonas* with usable nitrogen. Even more complex interactions occur in the cycling of elements such as sulfur, phosphorus, and nitrogen.

Amensalism* describes an action of one microbe that causes an adverse effect in another microbe. It usually involves antagonism or competition and occurs in a community where microbes are sharing space and nutrient sources. Some microbes effectively compete by using up a vital nutrient to grow faster and dominate the habitat. Other microbes may release specific inhibitory chemicals into the surrounding environment. This is the description of **antibiosis**—the release of natural chemicals or **antibiotics**—that inhibit or kill microbes. Many fungi and bacteria are adapted to this survival strategy. An intriguing example can be found in the complex symbiosis of certain ants that actively cultivate specialized gardens of fungi as a source of food. To protect the fungi from other microbes, the ants also cultivate species of filamentous bacteria called actinomycetes that produce antibiotics. The ants spread the actinomycetes through their gardens to protect the fungi from invasion by parasites. **Figure 7.13k, l** features some aspects of this relationship.

Biofilms—A Microbial Conversation

Among the most common and prolific associations of microbes are **biofilms**, first described in 4.1 Making Connections. Biofilms result when organisms attach to a substrate by some form of extracellular matrix that binds them together in complex organized layers. Biofilms are so prevalent that they dominate the structure of most natural

CLINICAL CONNECTIONS

Our Microbial Passengers

Microbial interrelationships obviously affect humans in many ways, but those having the most impact are microbes that naturally live on or in the body and parasites that attack the body. The normal residents, called **microbiota**, are so abundant that, cell-for-cell, they outnumber us by 3 to 10 times.* From this standpoint, one could argue that we are more microbial than human. Obviously, a community of microbes this large is bound to have enormous effects on our physiology, immunity, and genetics.

Resident microbes come from nearly all groups and include viruses, archaea, bacteria, fungi, and protozoa that have adapted to specialized niches throughout our surfaces. Certainly some are commensals that make a living on the body without harm or benefit, but a greater number are probably mutualistic, providing some form of nutrition or protection. For example, lactobacilli growing in the vagina maintain an acidic pH that can protect the female reproductive tract from infections (see photo), and other species are involved in digestive processes and the function of the intestine. The mutualist *Bacteroides thetaiotaomicron* processes complex food molecules and even regulates the expression of the human genome. The stabilizing effects of bacteria on the intestinal environment are the basis behind probiotic supplements and foods. Results of hundreds of new studies are rapidly accumulating information on the complex interrelationships we have with our microbiota.

Most of the time our 100 trillion microbial passengers do more good than harm, but if certain types are displaced from their niche or are allowed to enter the sterile tissues, they become opportunistic pathogens and can cause infections. Microbes living in biofilms can create mixed infections, meaning that several microbes acting together invade the tissues and cause damage. This is the pattern in dental caries, periodontal disease, and gas gangrene.

Stained vaginal smear reveals a large pink epithelial cell harboring gram-positive rods of *Lactobacillus*, an important member of the normal microbiota that helps protect against infection. *Source:* Dr. Mike Miller/CDC

* On average, the human body contains 10^{13} cells (30 trillion) and 10^{14} microbes (100 trillion). These figures are estimates, which is why it is more accurate to provide a range.

environments on earth. This tendency of microbes to form biofilm communities is an ancient and effective adaptive strategy. Not only do biofilms favor microbial persistence in habitats, but they also offer greater access to life-sustaining conditions. In a sense, these living networks operate as “superorganisms” that influence such microbial activities as adaptation to a particular habitat, content of soil and water, nutrient cycling, and even the course of infections.

It is generally accepted that the individual cells in the bodies of multicellular organisms such as animals and plants have the capacity to produce, receive, and react to chemical signals such as hormones made by other cells. For many years biologists regarded most single-celled microbes as simple individuals without comparable properties, other than to cling together in colonies. But these assumptions have turned out to be incorrect. It is now evident that microbes show a well-developed capacity to communicate and cooperate in the formation and function of biofilms. This is especially true of bacteria, although fungi and other microorganisms can participate in these activities.

One idea to explain the development and behavior of biofilms is termed **quorum sensing**. This process occurs in several stages, including self-monitoring of cell density, secretion of chemical signals, and genetic activation (**figure 7.14**). Early in biofilm formation, free-floating or swimming microbes—often described as **planktonic**—are attracted to a surface and come to rest or settle down. Settling stimulates the cells to secrete a slimy or adhesive matrix, usually made of polysaccharide, that binds them to the substrate. Once attached, cells begin to release **inducer* molecules** that accumulate as the cell population grows. By this means, they can monitor the size of their own population. In time, a critical number of cells, termed a **quorum,*** accumulates and this ensures that there will be sufficient quantities of inducer molecules. These inducer molecules enter biofilm cells and stimulate specific genes on their chromosomes to begin expression.

The nature of this expression varies, but generally it allows the biofilm to react as a unit. For example, by coordinating the expression of genes that code for proteins, the biofilm can simultaneously produce large quantities of a digestive enzyme or toxin. This regulation of expression accounts for several observations made about microbial activities. For instance, it explains how saprobic microbes in soil and water rapidly break down complex substrates and how some pathogens release their toxins into the tissues simultaneously.

The effect of quorum sensing has also given greater insight into how pathogens invade their hosts and produce large quantities of substances that damage host defenses. It has been well studied in a number of pathogenic bacteria. Infections by *Pseudomonas aeruginosa* give rise to tenacious lung biofilms in cystic fibrosis patients (see the Case Study for this chapter) and some types of pneumonia. *Staphylococcus aureus* commonly forms biofilms on

* **inducer** (in-dooos'-ur) L. *inducere*, to lead. Something that brings about or causes an effect.

* **quorum** (kwor'-uhm) L. *qui*, who. Indicates the minimum number of group members necessary to conduct business.

- 1 Free-swimming cells lose their motility and settle down onto a surface or substrate.
- 2 Cells synthesize an adhesive matrix that holds them tightly to the substrate.
- 3 When biofilm grows to a certain density (quorum), the cells release inducer molecules that can coordinate a response.
- 4 Enlargement of one cell to show genetic induction. Inducer molecule stimulates expression of a particular gene and synthesis of a protein product, such as an enzyme.
- 5 Cells secrete their enzymes in unison to digest food particles.

Process Figure 7.14 Stages in biofilm formation, quorum sensing, induction and expression, shown in progression from left to right.

inanimate medical devices and in wounds. *Streptococcus* species are the initial colonists that create dental plaque on tooth surfaces.

Although the best-studied biofilms involve just a single type of microorganism, most biofilms observed in nature are polymicrobial. In fact, many symbiotic and cooperative relationships are based on complex communication patterns among coexisting organisms. As each organism in the biofilm carries out its specific niche, signaling among the members sustains the overall partnership. Biofilms are known to be a rich ground for genetic transfers among neighboring cells that involve conjugation and transformation (see chapter 9). As our knowledge of biofilm patterns grows, it will likely lead to greater understanding of their involvement in infections and their contributions to disinfectant and drug resistance (see chapter 12).

7.6 The Study of Microbial Growth

Expected Learning Outcomes

23. Define *growth* and explain the process of binary fission.
24. Describe the process of population growth and how it is measured.
25. Explain the stages in the population growth curve and its practical importance.
26. Relate the techniques and tools used to detect and count cells in culture.

When microbes are provided with nutrients and the required environmental factors, they become metabolically active and grow. Growth takes place on two levels. On one level, a cell synthesizes new cell components and increases its size; on the other level, the number of cells in the population increases. This capacity for multiplication, increasing the size of the population by cell division, has tremendous importance in microbial control, infectious disease, and biotechnology. In the following sections, we focus primarily on the characteristics of bacterial growth that are generally representative of single-celled microorganisms.

1 A parent cell at the beginning of the cell cycle

What cannot be seen is the synthesis and activity gearing up for cell division.

2 Chromosome replication and cell enlargement

The parent cell duplicates the chromosome and synthesizes new structures that enlarge the cell in preparation for the daughter cells.

3 Chromosome division and septation

The chromosomes affix to the cytoskeleton and are separated into the forming cells. The cell lays down a septum that begins to wall off the new cells. Other components (ribosomes) are equally distributed to the developing cells.

4 Completion of cell compartments

The septum is synthesized completely through the center, and the cell membrane patches itself so that there are two separate cell chambers.

5 End of cell division cycle

Daughter cells are now independent units. Some species will separate completely as shown here, while others will remain attached, forming chains or pairs, for example.

The Basis of Population Growth: Binary Fission and the Bacterial Cell Cycle

The division of a bacterial cell occurs mainly through **binary**, or **transverse**, **fission**.⁵ The term *binary* means that one cell becomes two, and *transverse* refers to the division plane forming across the width of the cell. During the bacterial cell division cycle, the parent cell enlarges, duplicates its chromosome, and forms a central transverse septum that divides the cell into two daughter cells. This process is repeated at intervals by each new daughter cell in turn; and with each successive round of division, the population increases. The stages in this continuous process are shown in greater detail in **figures 7.15** and **7.16**.

Quick Search

Search the Internet for the video “A Nice Introduction to Bacterial Growth.”

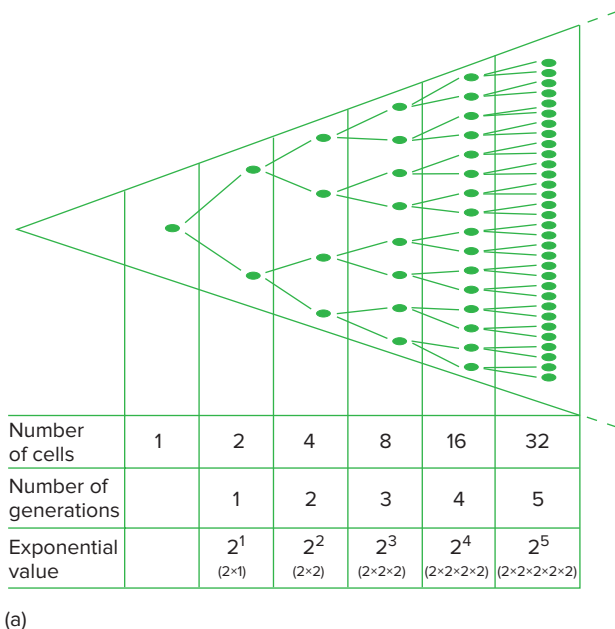

The Rate of Population Growth

The time required for a complete fission cycle—from parent cell to two new daughter cells—is called the **generation**, or **doubling**,

5. Research with bacteria that are not culturable indicates that not all cells divide this way. Some bud and others divide by multiple fission.

Process Figure 7.15 Stages in the bacterial cell cycle and binary fission of a rod-shaped bacterium.

(a)

Figure 7.16 The mathematics of population growth. (a) Starting with a single cell, if each product of reproduction goes on to divide by binary fission, the population doubles with each new cell division or generation. This process can be represented by logarithms (2 raised to an exponent) or by simple numbers. (b) Plotting the logarithm of the cells produces a straight line indicative of exponential growth, whereas plotting the cell numbers arithmetically gives a curved slope. *Note that the left scale is logarithmic and the right scale is arithmetic.

time. The term *generation* has a meaning similar to that for humans. It is the period between an individual's birth and the time of producing offspring. In bacteria, each new fission cycle or generation increases the population by a factor of 2, or doubles it. Thus, the initial parent stage consists of 1 cell, the first generation consists of 2 cells, the second 4, the third 8, then 16, 32, 64, and so on. As long as the environment remains favorable, this doubling effect can continue at a constant rate. With the passing of each generation, the population will double, over and over again.

The length of the generation time is a measure of the growth rate of an organism. Compared with the growth rates of most other living things, bacteria are notoriously rapid. The average generation time is 30 to 60 minutes under optimum conditions. The shortest generation times average 5 to 10 minutes, and longest generation times require days. For example, *Mycobacterium leprae*, the cause of Hansen's disease, has a generation time of 10 to 30 days—as long as in some animals. Most pathogens have relatively short doubling times. Cultures of *Salmonella enteritidis* and *Staphylococcus aureus*, bacteria that cause food-borne illness, double in 20 to 30 minutes, which explains why leaving food at room temperature even for a short period has caused many a person to be suddenly stricken with an attack of food-borne disease. In a few hours, a population of these bacteria can easily grow from a small number of cells to several million.

Figure 7.16 shows some quantitative characteristics of growth: (1) The cell population size can be represented by the number 2 with an exponent (2^1 , 2^2 , 2^3 , 2^4); (2) the exponent increases by one in each generation; and (3) the number of the exponent also gives the number of the generation. This growth pattern is termed **exponential**. Because these populations often contain very large numbers of cells, it is useful to express them by means of exponents or logarithms (see “Exponents,” Online Appendix 3). The data from a growing bacterial population are graphed by plotting the number of cells as a function of time. The cell number can be represented logarithmically or arithmetically.

Plotting the logarithm number over time provides a straight line indicative of exponential growth. Plotting the data arithmetically gives a constantly curved slope. In general, logarithmic graphs are preferred because an accurate cell number is easier to read, especially during early growth phases.

Predicting the number of cells that will arise during a long growth period (yielding millions of cells) is based on a relatively simple concept. One could use the method of addition $2 + 2 = 4$; $4 + 4 = 8$; $8 + 8 = 16$; $16 + 16 = 32$, and so on, or a method of multiplication (for example, $2^5 = 2 \times 2 \times 2 \times 2 \times 2$), but it is easy to see that for 20 or 30 generations, this calculation could be very tedious. An easier way to calculate the size of a population over time is to use an equation such as:

$$N_f = (N_i)2^n$$

In this equation, N_f is the total number of cells in the population at some point in the growth phase, N_i is the starting number, the exponent n denotes the generation number, and 2^n represents the number of cells in that generation. If we know any two of the values, the other values can be calculated. Let us use the example of *Staphylococcus aureus* to calculate how many cells (N_f) will be present in an egg salad sandwich after it sits in a warm car for 4 hours. We will assume that N_i is 10 (number of cells deposited in the sandwich while it was being prepared). To derive n , we need to divide 4 hours (240 minutes) by the generation time (we will use 20 minutes). This calculation comes out to 12, so 2^n is equal to 2^{12} . Using a calculator or table,⁶ we find that 2^{12} is 4,096.

$$\begin{aligned} \text{Final number } (N_f) &= 10 \times 4,096 \\ &= 40,960 \text{ bacterial cells in the sandwich} \end{aligned}$$

This same equation, with modifications, is used to determine the generation time, a more complex calculation that requires

6. See “Exponents” found at <http://www.mhhe.com/talaro9> for a table with powers of 2.

knowing the number of cells at the beginning and end of a growth period. Such data are obtained through actual testing by a method discussed in the following section.

Determinants of Population Growth

In reality, a population of bacteria does not maintain its potential growth rate and does not double endlessly, because in most systems numerous factors prevent the cells from continuously dividing at their maximum rate. Quantitative laboratory studies indicate that a population typically displays a predictable pattern, or **growth curve**, over time. The method traditionally used to observe the population growth pattern is a viable count technique, in which the live cells in a culture are sampled, grown, and counted during a growth period, as described in the next section.

The Viable Plate Count: Batch Culture Method

A growing population is established by inoculating a flask containing a known quantity of sterile liquid medium with a few cells of a pure culture. The flask is incubated at that bacterium's optimum temperature and timed. The population size at any point in the growth cycle is quantified by removing a tiny measured sample of the culture from the growth chamber and plating it out on a solid medium to develop isolated colonies. This procedure is repeated at evenly spaced intervals (i.e., every hour for 24 hours) (figure 7.17).

Evaluating the samples involves a common and important principle in microbiology: One colony on a plate represents one cell or colony-forming unit (CFU) from the original sample. Because the CFU of some bacteria is actually composed of several cells (consider the clustered arrangement of *Staphylococcus*, for instance), using a colony count can underestimate the exact population size to an extent. This is not a serious problem, because in such bacteria the CFU is the smallest unit of colony formation and dispersal. Multiplication of the number of colonies in a single sample by the container's volume gives a fair estimate of the total population size (number of cells) at any given point. The growth curve is determined by graphing the number for each sample in sequence for the whole incubation period (see figure 7.18).

Because of the scarcity of cells in the early stages of growth, some samples can give a zero reading even if there are viable cells in the culture. The sampling itself can remove enough viable cells to alter the tabulations, but because the purpose is to compare relative trends in growth, these factors do not significantly change the overall pattern.

Stages in the Normal Growth Curve

The system of batch culturing just described is *closed*, meaning that nutrients and space are finite and there is no mechanism for the removal of waste products. Data from an entire growth period of 3 to 4 days typically produce a curve with a series of phases termed the lag phase, the exponential growth (log) phase, the stationary phase, and the death phase (figure 7.18).

*The culture is probably in lag period with no new cells added.

Figure 7.17 The general steps in a viable plate count. 1. Place a few cells into a sterile liquid medium. 2. Incubate this culture over a period of several hours. 3. Sample the broth at regular intervals during incubation. 4. Plate each sample onto solid media. 5. Count the number of colonies present after incubation.

Figure 7.18 The growth curve in a bacterial culture. On this graph, the number of viable cells expressed as a logarithm (log) is plotted against time. See text for discussion of the various phases. Note that with a generation time of 30 minutes, the population has risen from 10^1 cells to 1,000,000,000 (10^9) cells in only 16 hours. Even though they are not counted, dead cells are indicated to show stages in the cycle where death affects the appearance of the curve.

The **lag phase** is an early “flat” period on the graph when the population appears not to be growing or is growing at less than the exponential rate. Growth lags primarily because

1. the newly inoculated cells require a period of adjustment, enlargement, and synthesis of DNA, enzymes, and ribosomes;
2. the binary fission cycle has not reached its maximum rate; and
3. the population of cells is so sparse or dilute that the sampling misses them.

The length of the lag period varies from one population to another, depending on the condition of the microbes and medium. It is important to note that even though the population of cells is not increasing (growing), individual cells are metabolically active as they synthesize new components and prepare to divide.

The cells reach the maximum rate of cell division during the **exponential growth (logarithmic or log) phase**, a period during which the curve increases geometrically. This phase will continue as long as cells have adequate nutrients and the environment is favorable. During this phase, the population realizes its potential generation time, and growth is balanced and genetically coordinated.

At the **stationary growth phase**, the population reaches a size limit in which some cells divide more slowly or stop dividing entirely and may even have died. The curve levels off because the rate of cell inhibition or death balances out the rate of multiplication. The number of viable cells has reached maximum and remains relatively constant during this period. The decline in the growth rate is caused by several factors. A common reason is the depletion of nutrients and oxygen. Another is that the increased cell density often causes an accumulation of organic acids and other toxic biochemicals.

As the limiting factors intensify, the population begins to show a decline, seen as a downward slope on the curve. This stage has been called the **death phase**, but what is actually happening is more complex. Some cells go into dormancy and remain viable but do not grow. Some cells enter a starvation mode that helps them resist the lack of

nutrients and other factors. Depending upon the species, some microbes could remain in these states for long periods. It is also apparent that many cells go through a programmed cell death and lyse during this phase, which accounts for the overall reduction in population size. Under these conditions, it is possible for persistent members of the culture to survive by using the nutrients released by the dead cells.

Practical Importance of the Growth Curve The tendency for populations to exhibit phases of rapid growth, slow growth, and death has important implications in microbial control, infection, food microbiology, and culture technology. Antimicrobial agents such as heat and disinfectants rapidly accelerate the death phase in all populations, but microbes in the exponential growth phase are more vulnerable to these agents than are those that have entered the stationary phase. In general, actively growing cells are more vulnerable to conditions that disrupt cell metabolism and binary fission.

Growth patterns in microorganisms can account for the stages of infection (see chapter 13). A person shedding bacteria in the early and middle stages of an infection is more likely to spread it to others than is a person in the late stages. The course of an infection is also influenced by the relatively faster rate of multiplication of the microbe, which can overwhelm the slower growth rate of the host’s own cellular defenses.

Understanding the stages of cell growth is crucial for work with cultures. Sometimes a culture that has reached the stationary phase is incubated under the mistaken impression that enough nutrients are present for the culture to continue to multiply. In most cases it is unwise to incubate a culture beyond the stationary phase, because doing so will reduce the number of active cells and the culture could die out completely. It is also preferable to do stains (an exception is the spore stain) and motility tests on young cultures, because the cells will show their natural size and correct reaction, and motile cells will have functioning flagella.

For certain research or industrial applications, closed-batch culturing with its four phases is inefficient. The alternative is an

Figure 7.19 Turbidity measurements as indicators of population density and amount of growth. (a) Holding a broth to the light is a practical method of checking for gross differences in cloudiness (turbidity). The broth on the left is transparent, indicating little or no growth; the broth on the right is cloudy and opaque, indicating heavy growth. (b) The eye is not sensitive enough to pick up fine degrees in turbidity; more sensitive measurements can be made with a spectrophotometer. A culture placed into the machine is exposed to a beam of light. A detector picks up the amount of light transmitted through the tube and registers this on a screen as absorbance. In (b1), very little light is being scattered and the absorbance reads low, indicating few cells are present. In (b2), more light is scattered, and the absorbance reads higher, indicating significant numbers of cells and growth. (a): © K. Talaro

automatic growth chamber called the **chemostat**, or continuous culture system. This device can admit a steady stream of new nutrients and siphon off used media and old bacterial cells, thereby stabilizing the growth rate and cell number. The chemostat is very similar to industrial fermentors used to produce vitamins and antibiotics. It has the advantage of maintaining the culture in a biochemically active state and preventing it from entering the death phase.

Other Methods of Analyzing Population Growth

Microbiologists have developed several alternative ways of analyzing bacterial growth qualitatively and quantitatively. One of the simplest methods for estimating the size of a population is through turbidometry. This technique relies on the simple observation that a tube of clear nutrient solution becomes cloudy, or **turbid**, as microbes grow in it. In general, a greater turbidity indicates a higher microbial count. Differences in turbidity can be measured by means of sensitive instruments such as a spectrophotometer, which measures the ability of cells to scatter light as it passes through a liquid culture, a phenomenon called absorbance. The higher the absorbance measurement, the more growth or cell mass there is in the culture, and vice versa (**figure 7.19b**).

Quantifying and Analyzing Cultures

Turbidity readings are useful for evaluating relative amounts of growth, but if a more quantitative evaluation is required, the viable colony count or some other enumeration (counting) procedure is necessary. The **direct**, or **total, cell count** involves counting the number of cells in a sample microscopically (**figure 7.20**). This technique, very similar to that used in blood cell counts, employs a special microscope slide (cytometer) calibrated to accept a tiny sample that is spread over a premeasured grid. The cell count from a cytometer can be used to estimate the total number of cells in a larger sample (for instance, of milk or water). One inherent inaccuracy in this method as well as in spectrophotometry is that no distinction can be made between dead and live cells, both of which

Figure 7.20 Direct microscopic count of bacteria. A small sample is placed on the grid under a cover glass. Individual cells, both living and dead, are counted. This number can be used to calculate the total count of a sample.

are included in the count. Additional procedures that can assay the microbial content of water are the most probable number (MPN) and membrane filtration techniques discussed later in the book.

Counting can be automated by sensitive devices such as the *Coulter counter*, which electronically scans a culture as it passes through a tiny pipette. As each cell flows by, it is detected and registered on an electronic sensor. A **flow cytometer** is a device that works on a similar principle. It is widely used for counting, sorting, sizing, and identifying cells in suspension (**figure 7.21a**). For most applications, the cells to be analyzed have to be stained with different fluorescent dyes. They are streamed one at a time through a flow chamber and illuminated by a laser that causes each one to fluoresce in a specific color. As each color signal is detected, it is compiled in graph form (**figure 7.21b**). Final separation is accomplished by magnets that pull the cells into collection chambers according to their charge. Some of the more common applications include blood cell counts and blood cell separation and identification; analysis of cancer cells; and differentiation of gram-negative and gram-positive bacteria. Even live and dead cells can be differentiated with this method.

Although flow cytometry can be used to count bacteria in natural samples without the need for culturing them, it still requires

Figure 7.21 Design and functions of a flow cytometer. (a) The main body of the device is a sheath and flow chamber, which holds fluid and cells. As the labeled cells pass through it, they are lasered and detected by the color they emit. The cells are then diverted into collection chambers. (b) A graphic readout analyzes the pattern of cells detected. The result here reveals live and dead bacterial cells stained with red and green fluorescent colors. Each dot on the graph represents one bacterial cell. To see an animation of this process go to <http://www.helmholtz-muenchen.de/imi/zs/e-prinzip.html>.

fluorescent labeling of the cells, which is not always possible. In this event, there are newer DNA-based techniques (for instance, real-time PCR) that can detect and differentiate microbes that have not been isolated, cultured, or identified.

Check Your Progress SECTION 7.6

22. What is microbial growth? Explain the stages in the bacterial cell cycle and binary fission.
23. Why is growth called exponential? What causes the pattern of the growth curve?
24. Contrast two different methods of detecting and counting microbial populations, and discuss their advantages and disadvantages.
25. Explain the relationship between colony counts and colony-forming units. Why can one use the number of colonies as an index of population size?

Micro CASE STUDY Part 2

Cystic fibrosis is the most common autosomal recessive disease reported in the United States, affecting approximately one person in 2,500. Most cases are diagnosed within the first three years of life, although a number of cases are not diagnosed until adulthood, as happened with Molly Kenner. Currently there are about 30,000 children and adults living with some manifestations of CF. Although pulmonary symptoms are a dominant feature, CF also affects any organ or system that requires open chloride channels to function normally. This would include the gastrointestinal tract, liver, pancreas, and reproductive tract.

The exact pathology of CF is still being studied, but it appears that when lung epithelial cells cannot secrete chloride into the extracellular spaces, the osmosis of water into the lung mucus is also greatly reduced. This drying effect causes thick plugs of mucus to collect within the alveoli and along the smaller bronchioles. As a consequence, the natural defenses, primarily cilia and white blood cells, are unable to trap bacteria and remove them from the lungs. Inhaled bacteria that remain in this environment can become firmly entrenched.

This situation sets the scene for *Pseudomonas aeruginosa*, the bacterial pathogen that causes the greatest morbidity and mortality in CF. Around 80% of CF patients will eventually become colonized by this species, which stimulates a constant state of inflammation that damages the airways and alveoli. A significant factor in the life cycle of *P. aeruginosa* is its formation of biofilms through quorum sensing. The most common strain found in CF patients is the “mucoid” variety, which produces thick, sticky polysaccharide slime layers that help it adhere to the lung epithelium. Once established, it undergoes physiological changes that increase its virulence. The biofilm is extremely difficult to treat and eradicate.

- Explain the possible mechanisms by which *Pseudomonas aeruginosa* invades and creates biofilms through quorum sensing.
- What are some major difficulties in treating cystic fibrosis as it relates to this infection?

To conclude this Case Study, go to Connect.

Chapter Summary with Key Terms

7.1 Microbial Nutrition

Environmental factors that have the greatest impact on microbes are nutrients, temperature, pH, amount of available water, atmospheric gases, light, pressure, and other organisms.

Nutrition consists of taking in chemical substances (nutrients) and assimilating and extracting energy from them.

- Substances required for survival are **essential nutrients**—usually containing the elements (C, H, N, O, P, S, Na, Cl, K, Ca, Fe, Mg). Essential nutrients are considered **macronutrients** (required in larger amounts) or **micronutrients** (trace elements required in smaller amounts—Zn, Mn, Cu). Nutrients are classed as either **inorganic** or **organic**.
- A **growth factor** is an organic nutrient (amino acid and vitamin) that cannot be synthesized and must be provided.

7.2 Classification of Nutritional Types

- An **autotroph** depends on carbon dioxide for its carbon needs. An autotroph that derives energy from light is a **photoautotroph**; one that extracts energy from inorganic substances is a **chemoautotroph**. **Methanogens** are chemoautotrophs that produce methane.
- A **heterotroph** or **chemoorganotroph** acquires carbon from organic molecules originating from the bodies of dead or living organisms. A **saprobe** is a decomposer that feeds primarily upon dead organic matter, and a **parasite** feeds from a live host and usually causes harm. Parasites that cause damage or death are called **pathogens**.

7.3 Transport: Movement of Substances Across the Cell Membrane

- A microbial cell must take in nutrients from its surroundings by transporting them across the cell membrane.
- Passive transport involves the natural movement of substances down a concentration gradient and requires no additional energy (**diffusion**). A form of passive transport that can move specific substances is **facilitated diffusion**.
- Osmosis** is diffusion of water through a selectively permeable membrane.
- Osmotic changes that affect cells are **hypotonic** solutions, which contain less solute than the cell, and **hypertonic** solutions, which contain more solute than the cell. **Isotonic** solutions have the same solute concentration as the inside of the cell. A **halophile** thrives in hypertonic surroundings, and an **obligate halophile** requires a salt concentration of at least 15% but grows optimally in 25%.
- In **active transport**, substances are taken into the cell by a process that consumes energy. In **group translocation**, molecules are altered during transport.
- Phagocytosis** and **pinocytosis** are forms of active transport in which bulk quantities of solid and fluid material are taken into the cell.

7.4 Environmental Factors That Influence Microbes

Every organism adapts to a particular habitat and niche.

- Temperature**: An organism exhibits **optimum**, **minimum**, and **maximum temperatures**. Organisms that cannot grow above 20°C but thrive below 15°C and continue to grow even at 0°C are known as **psychrophiles**. **Mesophiles** grow from 10°C to 50°C, having temperature optima from 20°C to 40°C. The growth range of **thermophiles** is 45°C to

80°C. Extreme thermophiles may grow to temperatures of 250°C.

- Oxygen Requirements**: The ecological need for free oxygen (O₂) is based on whether a cell can handle toxic by-products such as superoxide and peroxide.
 - Aerobes** grow in normal atmospheric oxygen and have enzymes to handle toxic oxygen by-products. An aerobic organism capable of living without oxygen if necessary is a **facultative anaerobe**. An aerobe that requires a small amount of oxygen but does not grow under anaerobic conditions is a **microaerophile**.
 - Strict (obligate) anaerobes** do not use free oxygen and cannot produce enzymes to dismantle reactive oxides. They are actually damaged or killed by oxygen. An aerotolerant anaerobe cannot use oxygen for respiration yet is not injured by it.
- Effects of pH**: Acidity and alkalinity affect the activity and integrity of enzymes and the structural components of a cell. Optimum pH for most microbes ranges from 6 to 8. **Acidophiles** prefer a pH below 7, **alkalinophiles** prefer a pH above 7, and **neutrophils** grow best around pH 7.
- Other Environmental Factors**: Radiation and barometric pressure affect microbial growth. A **barophile** is adapted to life under high pressure (bottom dwellers in the ocean, for example).

7.5 Ecological Associations Among Microorganisms

- Microbial Interactions**: Microbes coexist in varied relationships in nature.
 - Types of **symbiosis** are **mutualism**, a reciprocal, obligatory, and beneficial relationship between two organisms, and **commensalism**, an organism receiving benefits from another without harming the other organism in the relationship. **Parasitism** occurs between a host and an infectious agent; the host is harmed in the interaction.
 - Syntrophism** is a beneficial but not obligatory coexistence in which organisms cross-feed. **Amensalism** entails competition, inhibition, and injury directed against an opposing organism. A special case is antibiotic production.
 - Quorum sensing** is an interaction among members of a biofilm that results in a coordinated reaction, such as secretion of **inducer molecules** and enzymes. By behaving as a unit, the biofilm remains stable and organized. It can occupy and exploit a wide variety of habitats.

7.6 The Study of Microbial Growth

- During the bacterial cell cycle, the parent cell splits to form a pair of daughter cells by means of **binary**, or **transverse**, **fission**.
- It involves replication of the chromosome and the equal division of other cell components.
- The duration of each division is called the **generation**, or **doubling time**. A population theoretically doubles with each generation, so the growth rate is **exponential**, and each cycle increases in geometric progression.
- A **growth curve** is a graphic representation of a closed population over time, using an estimate of live cells called a viable count. The initial flat period of the curve is called the **lag phase**, followed by the **exponential growth phase**, in

which viable cells increase in logarithmic progression. Adverse environmental conditions create a plateau, or **stationary growth phase**. In the **death phase**, nutrient depletion and waste buildup cause increased cell death.

E. Cell numbers can be counted by a viable plate count, microscope counting chamber, Coulter counter, or **flow cytometer**. Cell growth can also be determined by turbidometry and a total cell count.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

- An organic nutrient essential to an organism's metabolism that cannot be synthesized itself is termed *a/an*
 - trace element
 - micronutrient
 - growth factor
 - mineral
- The source of the necessary elements of life is
 - an inorganic environmental reservoir
 - the sun
 - rocks
 - the air
- An organism that can synthesize all its required organic components from CO₂ using energy from the sun is a
 - photoautotroph
 - photoheterotroph
 - chemoautotroph
 - chemoheterotroph
- An obligate halophile requires high
 - pH
 - temperature
 - salt
 - pressure
- Chemoautotrophs can survive on _____ alone.
 - minerals
 - CO₂
 - minerals and CO₂
 - methane
- Which of the following substances are required by *all* organisms?
 - organic nutrients
 - inorganic nutrients
 - growth factors
 - oxygen gas
- A pathogen would most accurately be described as a
 - parasite
 - commensal
 - saprobe
 - symbiont
- Which of the following is true of passive transport?
 - it requires a gradient
 - it uses the cell wall
 - it includes endocytosis
 - it only moves water
- A cell exposed to a hypertonic environment will _____ by osmosis.
 - gain water
 - lose water
 - neither gain nor lose water
 - burst
- Active transport of a substance across a membrane requires
 - a gradient
 - the expenditure of ATP
 - water
 - diffusion
- Psychrophiles would be expected to grow
 - in hot springs
 - on the human body
 - at refrigeration temperatures
 - at low pH
- Which of the following is *not* involved in quorum sensing?
 - accumulation of inducer molecules
 - a certain level of biofilm density
 - self-monitoring
 - release of genetic material
- Superoxide ion is toxic to strict anaerobes because they lack
 - catalase
 - peroxidase
 - dismutase
 - oxidase
- The time required for a cell to undergo binary fission is called the
 - exponential growth rate
 - growth curve
 - generation time
 - lag period
- In a viable plate count, each _____ represents a _____ from the sample population.
 - cell, colony
 - colony, cell
 - hour, generation
 - cell, generation
- The stage in population growth with the highest rate of cell division is the
 - stationary phase
 - lag phase
 - exponential phase
 - enlargement phase

Case Study Review

- What dysfunction tied to cystic fibrosis increases the establishment of *Pseudomonas aeruginosa* in the lungs?
 - increased chloride transport
 - decreased chloride transport
 - lack of mucus
 - pneumonia
- Select a factor or factors that favor the invasion and growth of *Pseudomonas aeruginosa* in the lungs.
 - fimbriae
 - mucoid glycocalyx
 - blockage of host defenses.
 - b and c
 - a, b, and c
- Describe how active transport and osmosis play a part in the normal lung compared to that of cystic fibrosis.

Writing Challenge

For each question (except 7), compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

- Look at the following diagrams and predict in which direction osmosis will take place. Use arrows to show the net direction of osmosis. Is one of these microbes a halophile? Which one?

- Describe the basic metabolism of methanogens.
- Discuss extreme environments and types of extremophiles that live there.
- Differentiate between mutualism and syntrophy with examples.
- What biochemical events in quorum sensing ensure that a biofilm can function as a unit?
 - Explain how biofilm self-monitoring would favor infections.

- Explain what is happening to the population at points A, B, C, and D in the following diagram.

- Fill in the following table:

Source of Carbon	Usual Source of Energy	Example
Photoautotroph		
Photoheterotroph		
Chemoautotroph		
Chemoheterotroph		
Saprobe		
Parasite		

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps and a sample concept map for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

- Is there a microbe that could grow on a medium that contains only the following compounds dissolved in water: CaCO_3 , MgNO_3 , FeCl_2 , ZnSO_4 , and glucose? Defend your answer.
 - A useful mnemonic device for keeping track of major elements required by most organisms is: **C HOPKINS Ca Fe, Na Cl M**good. Read aloud, it becomes “See Hopkin’s Cafe, NaCl (salt) M good!” What does each letter stand for?
- Describe how one might determine the nutrient requirements of a microbe from Mars. If, after exhausting various nutrient schemes, it still does not grow, what other factors might one take into account?
- Patients with ketoacidosis associated with diabetes are especially susceptible to fungal infections. Propose why this might be the case.

4. a. Explain how osmotic pressure and pH are used in preserving foods.
b. What effects do they have on microbes?
5. Provide some suggestions for treating anaerobic infections by manipulating the gas content of the environment.
6. Could anaerobes and aerobes coexist in the same habitat? Why or why not?
7. a. If an egg salad sandwich sitting in a warm car for 4 hours develops 40,960 bacterial cells, how many more cells would result with just one more hour of incubation? Use the same criteria that were stated in the sample problem under the heading "Rate of Population Growth" in section 7.6.
b. How many would result after 10 additional hours of incubation?
c. What do your answers tell you about using clean techniques in food preparation and storage (other than aesthetic considerations)?
8. The noted microbial ecologist Martin W. Beijerinck has stated: "Everything is everywhere, the environment selects." Use this concept to explain what ultimately determines whether a microorganism can live in a certain habitat.
9. Describe the similarities and differences between a mutualistic endosymbiont and a parasitic endosymbiont.

Visual Challenge

1. Place appropriate points on the axes and draw and label separate graphs that fit a psychrotroph and an obligate thermophile.
2. Enter points on the axes and graph the probable results for an acidophile, a neutrophile, and an alkaliphile.

CASE STUDY Part 1 Recipe for a Toxic Brew

This Case Study provides insight into the practical importance of microbial biochemistry to everyday life. It brings together elements of **fermentation** and **alcohol formation** and introduces the concept of anaerobic respiration by a microbe that synthesizes a toxin with deadly potential. To help understand the circumstances of this Case Study, we will revisit several concepts from chapter 7, including nutrition, temperature, pH, and metabolism in the absence of oxygen gas.

In October 2011 an inmate at Utah State Prison was brought to the infirmary with **vision** and **swallowing difficulties, muscular weakness, and vomiting**. The man was hospitalized for medical evaluation. When he admitted to having recently consumed an illegal, **prison-made wine**, his doctors believed they were dealing with a case of food poisoning. A number of other inmates were interviewed about drinking this substance, and 12 of them confessed that they had also consumed it about **30 hours earlier**. When some of these prisoners started having similar symptoms, medical personnel concluded that the wine was probably the source of the attack and hospitalized the other sick inmates. Specimens from the **wine, stool, stomach, and bloodstream** were sent for analysis. Final results were delayed because specialized testing done by the Centers for Disease Control and Prevention takes several days.

Preparation of the illicit homemade wine called “pruno” is rather common in prisons. This alcohol is usually made from a

mixture of crushed fruit, juice, water, a source of sugar, and a starter culture from an older brew. The preparation is placed in **sealed, airtight** plastic containers and incubated in warm tap water for several days. These conditions foster **anaerobic growth** and alcoholic fermentation, which will bring final alcohol levels as high as 15%. The orange-colored liquid portion is strained off and consumed. The rank smell and taste of pruno often cause prisoners to gag, but they swallow it anyway. Unfortunately their desire for alcohol overcomes the beverage’s foul qualities.

Investigators continued to trace the possible events that led to this outbreak. Examination of the materials used to brew the wine yielded bits of a baked **potato**, which is a departure from the usual “recipe.” One of the inmates admitted that he had stored the potato in a **sealed container** for several days before using it. Other batches of pruno that had been made at the same time did not contain potato and did not cause illness.

- *What substances and conditions are required for fermentation, and what are its usual products?*
- *What possible signs, if any, might have indicated that the prison brew was tainted?*

“The rank smell and taste of pruno often cause prisoners to gag, but they swallow it anyway.”

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

SCOPING OUT THE CHAPTER

Metabolism: The chemical traffic of cell metabolism can be compared to a busy highway going in all directions, with on ramps and off ramps, intersections, side streets, green lights, and stop signs, all producing a constant flurry of change—but in the case of metabolism the changes are to the biochemical structure of cells.

Enzymes: Chemical Gatekeepers

Like traffic signals and signs, enzymes ensure the correct biochemical reactions by providing specific sites for these changes to take place.

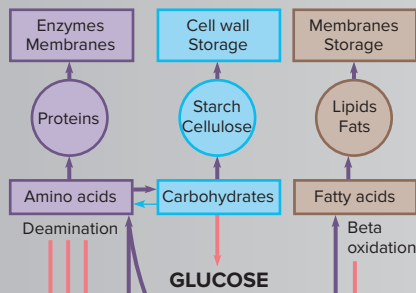

Metabolic Pathways—Guiding the Flow of Reactions Down the Right Track

These exist in two basic patterns

Sources of Energy: Keeping the Metabolic Machine Powered

Photosynthetic organisms operate by collecting light energy and converting it into cellular energy.

Anabolic pathways synthesize and build up cellular components and structures.

Catabolic pathways break down fuels and release their potential energy for cellular work.

The chemical reactions of life are fueled by changes to molecular bonds that can release energy.

8.1 An Introduction to Metabolism and Enzymes

Expected Learning Outcomes

1. Define *metabolism* and differentiate its two types.
2. Describe the basic functions of enzymes in cells.
3. Outline the prominent characteristics of enzymes.

4. Explain how enzymes lower the energy required for a reaction to occur.
5. Discuss enzyme structure, and interactions between enzymes and substrates.
6. Describe the types of enzyme functions and methods of naming them.
7. Summarize key features of enzyme regulation.

Metabolism, from the Greek term *metaballein*, meaning change, pertains to all chemical workings of cells. It is a shorthand term for encapsulating almost any activity or behavior of an organism, from the general to the specific, including growth, synthesis, transport, digestion, energy release and consumption, and movement. Although metabolism entails thousands of different reactions, most of them can be placed into one of two general categories. In the case of **catabolism**, larger molecules are degraded or broken down into smaller molecules, usually with the release of energy. In the case of **anabolism**, also called biosynthesis, larger molecules are built from smaller ones, which results in the formation of cell structures. It is usually driven by energy derived from catabolism. Even though they have somewhat opposite effects, these two forms of metabolism are tightly linked and highly complementary. As we will see, the result of them working together is that all metabolism is coordinated for the cell to carry out essential life functions (**figure 8.1**). The major metabolic functions in cells and the sections of the chapter that cover them are listed here:

1. Enzymes serve as catalysts for both catabolic and anabolic activities. Because of their importance in all areas of microbiology, the remainder of section 8.1 is devoted to characteristics of enzymes.
2. Cells acquire energy from an external source (outside the cell) such as nutrients or the sun. Discussion of this idea began in chapter 7 and continues in sections 8.2 and 8.6.
3. Cells extract the energy and transfer it to a high-energy molecule, adenosine triphosphate (ATP), a universal compound for managing energy. This is accomplished by several different types of catabolic pathways, covered in sections 8.3 and 8.4.
4. Cells use ATP to power anabolic processes. Simple building blocks are bonded into larger molecules and cell structures,

thereby creating greater complexity through the input of this energy. Anabolic pathways are covered in section 8.5.

We suggest you review relevant sections in chapter 2 covering organic molecules and biochemistry.

Enzymes: Catalyzing the Chemical Reactions of Life

A microbial cell could be viewed as a microscopic factory, complete with basic building materials, a source of energy, and a genetic “blueprint” for running its extensive network of metabolic reactions. But the chemical reactions of life would never proceed without a special class of proteins called **enzymes**. Enzymes are a remarkable example of **catalysts**, chemicals that increase the rate of a chemical reaction without becoming part of the products or being consumed in the reaction. Do not make the mistake of thinking that an enzyme creates a reaction. Because of the free energy inherent in molecules, a reaction could occur spontaneously at some point even without an enzyme but at a very slow rate. A study of the enzyme urease shows that it increases the rate of the breakdown of urea by a factor of 100 trillion as compared to an uncatalyzed reaction. Because most uncatalyzed metabolic reactions do not occur fast enough to sustain cell processes, enzymes are indispensable to life. Other major qualities of enzymes are summarized in **table 8.1**.

How Do Enzymes Work?

We have said that an enzyme speeds up the rate of a metabolic reaction, but just how does it do this? During a chemical reaction, reactants are converted to products by bond formation or breakage. A certain amount of energy is required to initiate every such reaction,

Figure 8.1 Simplified model of metabolism. Chemical reactions that occur in cells fall into two major categories. Catabolism involves the breakdown of complex organic molecules to extract energy and form simpler end products. Anabolism uses the energy to synthesize necessary macromolecules and cell structures from simple precursors, increasing chemical complexity. The two systems interact in a continuous cycle that maintains the metabolic balance inside cells.

8.1 MAKING CONNECTIONS

Enzymes as Biochemical Levers

An analogy will allow us to envision the relationship of enzymes to the energy of activation. A large boulder sitting precariously on a cliff's edge contains a great deal of potential energy, but it will not fall to the ground and release this energy unless something disturbs it. It might eventually be disturbed spontaneously as the cliff erodes below it, but that could take a very long time. Maneuvering it with a crowbar (to overcome the resistance of the boulder's weight) will cause it to tumble down freely by its own momentum. If we relate this analogy to chemicals, the reactants are the boulder on the cliff, the activation energy is the energy needed to move the boulder, the enzyme is the crowbar, and the product is the boulder at the bottom of the cliff. Like the crowbar, an enzyme permits a reaction to occur rapidly by getting it over the energy "hump." Although this analogy concretely illustrates the concept of the energy of activation, it is imperfect in that the enzyme, unlike the person with the crowbar, does not actually add any energy to the system.

This phenomenon can be represented by plotting the energy of the reaction against the direction of the reaction. The curve of reaction is shown in the accompanying graph. Reactants must overcome the energy of activation (E_{act}) for the reaction to proceed. When a catalyst is present, it lowers the E_{act} . It does this by providing the reactants with an alternate pathway, requiring less energy, by which they can progress to the final state. Note that the products reach the same final energy state with or without an enzyme.

What is the actual physical process performed by the enzyme that speeds up a reaction? *Answer available on Connect.*

TABLE 8.1 Checklist of Enzyme Characteristics

- Composed mostly of protein; may require nonprotein cofactors
- Act as organic catalysts to speed up the rate of cellular reactions
- Lower the activation energy required for a chemical reaction to proceed (see 8.1 Making Connections)
- Enable metabolic reactions to proceed at a speed compatible with life
- Have unique characteristics such as shape, specificity, and function
- Provide an active site for target molecules called substrates
- Are much larger in size than their substrates
- Associate closely with substrates but do not become integrated into the reaction products
- Are not used up or permanently changed by the reaction
- Can be recycled and function in extremely low concentrations
- Are greatly affected by temperature and pH
- Can be regulated by feedback and genetic mechanisms

which limits its rate. This resistance to a reaction, which must be overcome for a reaction to proceed, is measurable and is called the **energy of activation** or activation energy (**8.1 Making Connections**). In the laboratory, overcoming this initial resistance can be achieved by

- increasing thermal energy (heating) to increase molecular velocity,

- increasing the concentration of reactants to increase the rate of molecular collisions, or
- adding a catalyst.

In most living systems, the first two alternatives are not feasible, because elevating the temperature is potentially harmful, and higher concentrations of reactants are often not practical. This leaves only the action of catalysts, and enzymes fill this need efficiently and potently.

At the molecular level, an enzyme promotes a reaction by serving as a physical site upon which the reactant molecules, called **substrates**, can be positioned for various interactions. The enzyme is much larger in size than its substrate, and it presents a uniquely shaped pocket that fits only that particular substrate. Although an enzyme binds to the substrate and participates directly in changes to the substrate, it does not become a part of the products, is not used up by the reaction, and it can function over and over again. Enzyme speed, defined as the number of substrate molecules converted per enzyme per second, is well documented. Speeds range from several million for catalase to a thousand for lactate dehydrogenase. A key to understanding the roles of enzymes in metabolism is their structure.

8.2 MAKING CONNECTIONS

A Different Kind of Catalyst

The molecular reactions of cells are still an active and rich source of discovery, and new findings come along on a regular basis that break older “rules” and adjust our understanding. Originally proteins were considered the only biological molecules that act as catalysts. Then biologists found a novel type of RNA they termed **ribozymes**. Ribozymes appear to be rather common, with around 500 having been identified in all types of cells and some viruses. They display some of the properties of protein catalysts, such as having a specific active site and interacting with a substrate. But these molecules are remarkable because their substrates are other molecules of RNA. Ribozymes are thought to be remnants of the earliest molecules on

earth that could have served as both catalysts and genetic material. In natural systems, ribozymes are involved in self-splicing or cutting of RNA molecules during processing of the genetic code, and even ribosomes function as ribozymes during protein synthesis (see chapter 9). Further research has shown that ribozymes can be designed to handle other kinds of activities, such as inhibiting gene expression. Several companies have developed and are testing ribozyme-based therapies for treating cancer and HIV infection.

Propose some effects that ribozymes have on microorganisms that would make them suitable for therapy. Answer available on Connect.

A ribozyme (here a “hairpin loop” type) can clip RNA and remove sections of it.

Enzyme Structure

Enzymes are composed largely of protein molecules, although certain types of RNA can function as nonenzyme catalysts (8.2 Making Connections). Enzymes can be classified as simple or conjugated. Simple enzymes consist of protein alone, whereas conjugated enzymes (figure 8.2) contain protein and nonprotein molecules. A conjugated enzyme, sometimes referred to as a **holoenzyme**, is a combination of a protein, now called the **apoenzyme**, and one or more **cofactors** (table 8.2). Cofactors are either organic molecules, called **coenzymes**, or inorganic elements (metal ions) that many enzymes require to become functional. In some enzymes, the cofactor is loosely associated with the apoenzyme by noncovalent bonds; in others, it is linked by covalent bonds.

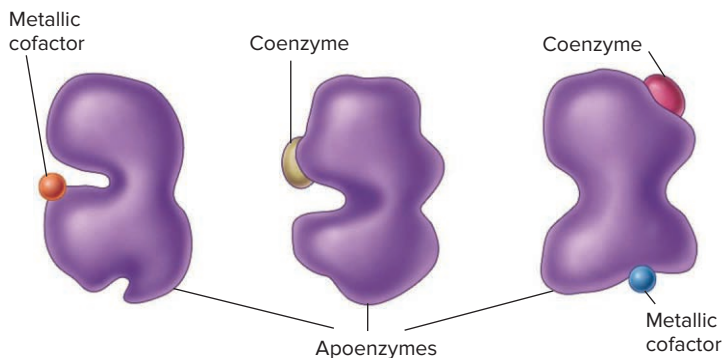

Figure 8.2 Conjugated enzyme structure. All examples have an apoenzyme (polypeptide or protein) component and one or more cofactors.

TABLE 8.2 Selected Enzymes, Catalytic Actions, and Cofactors*		
Enzyme	Action	Cofactor Required
Catalase	Breaks down hydrogen peroxide	Iron (Fe)
Oxidase	Adds electrons to oxygen	Iron, copper (Cu)
Hexokinase	Transfers phosphate to glucose	Magnesium (Mg)
Arginase	Acts on the amino acid arginine	Manganese
Nitrate reductase	Reduces nitrate to nitrite	Molybdenum (Mo)
DNA polymerase	Synthesis of DNA	Zinc (Zn) and Mg
Botulinum toxin	Hydrolyzes protein needed for vesicle transport	Zinc
Pyruvate dehydrogenase	Converts pyruvic acid to acetyl CoA and CO ₂	Thiamine and magnesium
Succinate dehydrogenase	Oxidizes succinate to fumarate in the Krebs cycle	FAD (contains riboflavin)

* The first seven are metals and the last two are coenzymes containing vitamins.

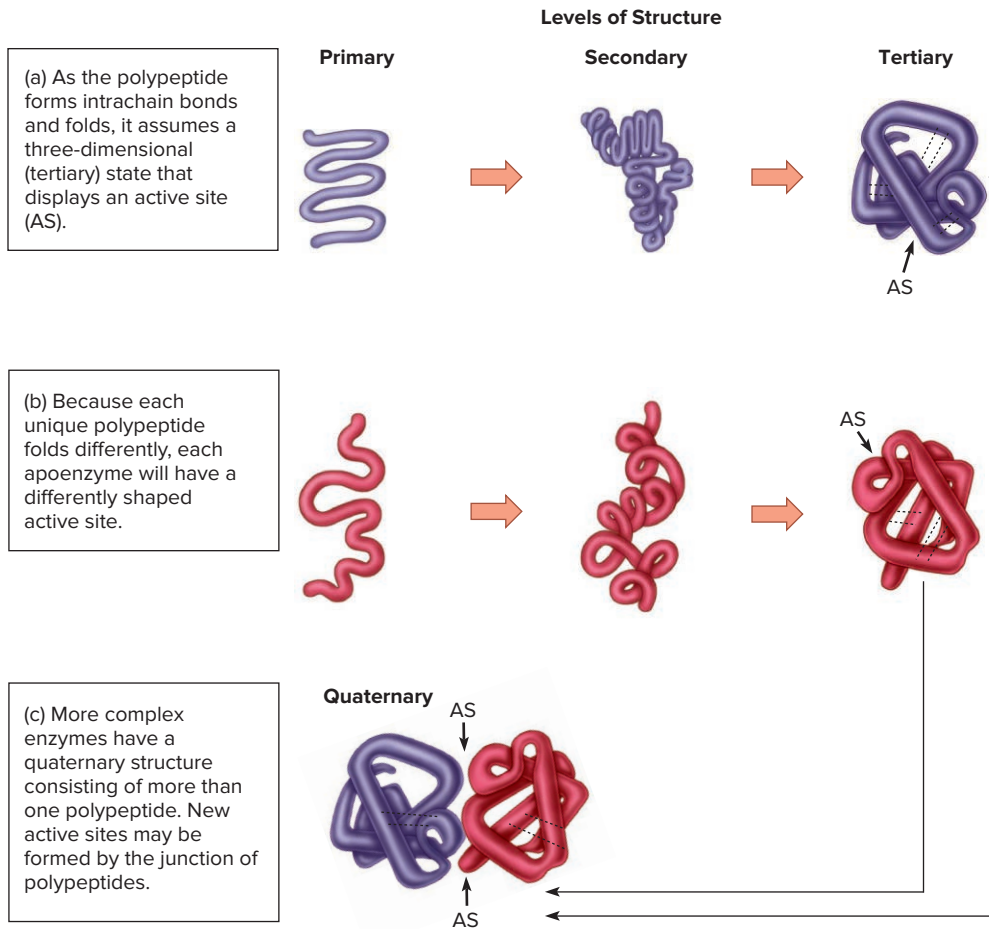

Figure 8.3 How the active site and specificity of the apoenzyme arise. Review figure 2.22 for details of this process.

Apoenzymes: Specificity and the Active Site

Apoenzymes range in size from small polypeptides with about 100 amino acids and a molecular weight of 12,000 to large polypeptide conglomerates with thousands of amino acids and a molecular weight of over 1 million. Like all proteins, an apoenzyme exhibits levels of molecular complexity called the primary, secondary, tertiary, and, in larger enzymes, quaternary organization (**figure 8.3**). As we saw in chapter 2 (see figure 2.22), the first three levels of structure arise when a single polypeptide chain undergoes an automatic folding process and achieves stability by forming disulfide and other types of bonds. Folding causes the surface of the apoenzyme to acquire three-dimensional features that create the enzyme's specificity for substrates. The actual pocket where the substrate binds is called the **active site**, or **catalytic site**, and there can be from one to several such sites (**figure 8.3**). Because each type of enzyme has a different primary structure (type and sequence of amino acids), this gives rise to variations in folding and unique active sites.

Enzyme-Substrate Interactions

For a reaction to take place, a temporary **enzyme-substrate** union must occur at the active site. There are several explanations for the way this happens (**figure 8.4**).

Figure 8.4 Enzyme-substrate reactions.

(a) When the enzyme and substrate come together, the substrate (S) will have a correct fit and position with respect to the enzyme (E). (b) When the ES complex is formed, it enters a transition state. During this temporary but tight interlocking union, the enzyme participates directly in breaking or making bonds. (c) Once the reaction is complete, the enzyme releases the products. (d) The induced-fit model proposes that the enzyme recognizes its substrate and adapts slightly to it so that the final binding is even more precise.

The specificity is often described as a “lock-and-key” fit in which the substrate is inserted into the active site’s pocket. This is a useful analogy, but an enzyme is not a rigid lock mechanism. It is likely that the enzyme actually helps the substrate move into the active site through slight changes in its shape. This is called an *induced fit* (figure 8.4d). The bonds formed between the substrate and enzyme are weak and, of necessity, easily reversible. Once the enzyme–substrate complex has formed, appropriate reactions occur on the substrate, often with the aid of a cofactor, and a product is formed and released. The enzyme can then attach to another substrate molecule and repeat this action.

Cofactors: Supporting the Work of Enzymes

In chapter 7 you learned that microorganisms require specific metal ions called trace elements and certain organic growth factors. In many cases, the need for these substances arises from their roles as **cofactors** (table 8.2). The **metallic cofactors**, including iron, copper, magnesium, manganese, zinc, cobalt, selenium, and many others, participate in precise functions between the enzyme and its substrate. In general, metals activate enzymes, help bring the active site and substrate close together, and participate directly in chemical reactions with the enzyme–substrate complex.

Coenzymes are organic cofactors that work in conjunction with the apoenzyme to perform a necessary alteration of a substrate. The general function of a coenzyme is to remove a chemical group from one substrate molecule and add it to another substrate, thereby serving as a temporary carrier of this group (**figure 8.5**). The specific activities of coenzymes are many and varied. In section 8.3 we shall see that coenzymes carry and transfer hydrogen atoms, electrons, carbon dioxide, and amino groups. Some of the most common components of coenzymes are **vitamins**, which explains why vitamins are important to nutrition and may be required as growth factors for living things. Vitamin deficiencies prevent the complete holoenzyme from forming, which compromises both the chemical reaction and the structure or function that is dependent upon that reaction.

Classification of Enzyme Functions

Enzymes are classified and named according to characteristics such as site of action, type of action, and substrate (**8.3 Making Connections**).

Location and Regularity of Enzyme Action

Enzymes perform their tasks either inside or outside of the cell in which they were produced. After initial synthesis in the cell, **exoenzymes** are transported extracellularly, where they break down large food molecules or harmful chemicals (see discussion of hydrolysis reactions under the next heading). Examples of exoenzymes are cellulase, amylase, and penicillinase. By contrast, **endoenzymes** are retained intracellularly and function there (**figure 8.6**). Most enzymes of the metabolic pathways are of this variety.

In terms of their presence in the cell, enzymes are not all produced in equal amounts or at equal rates. Some, called **constitutive**

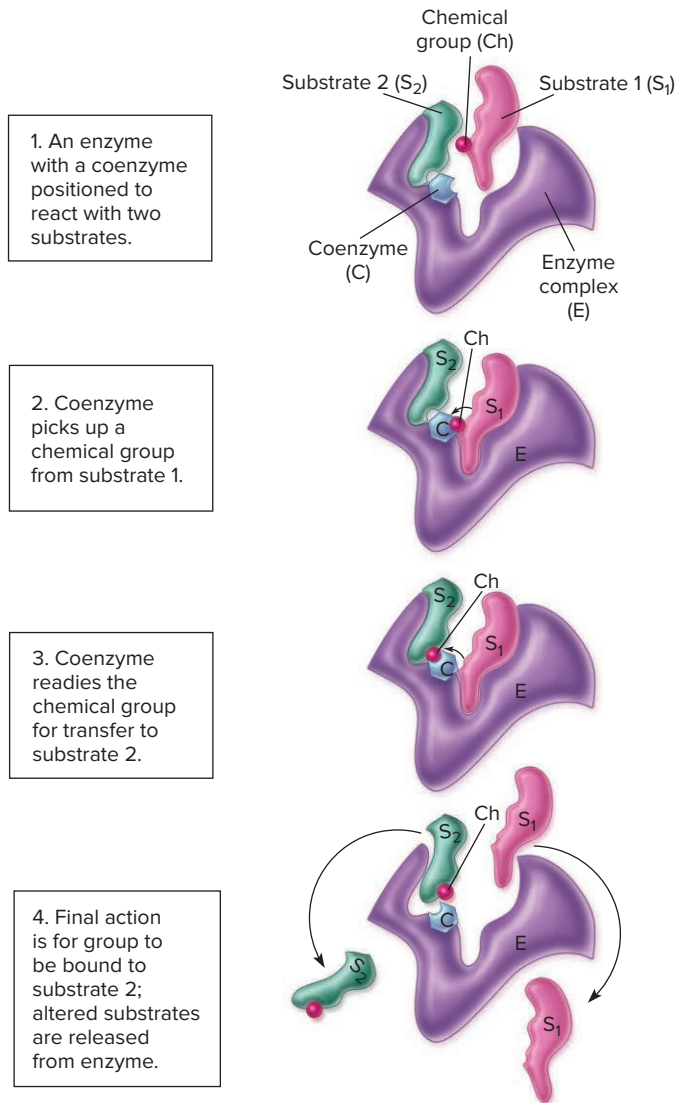

Figure 8.5 The carrier functions of coenzymes. Many enzymes use coenzymes to transfer chemical groups from one substrate to another.

Figure 8.6 Types of enzymes, as described by their location of action. (a) Exoenzymes are transported outside the cell to become active. (b) Endoenzymes remain in the cell and function there.

8.3 MAKING CONNECTIONS

The Enzyme Name Game

Most metabolic reactions require a separate and unique enzyme. Up to the present time, researchers have discovered and named over 5,000 of them. Given the complex chemistry of the cell and the extraordinary diversity of living things, many more enzymes probably remain to be discovered. A standardized system of nomenclature and classification was developed to prevent discrepancies.

In general, an enzyme name is composed of two parts: a prefix or stem word derived from a certain characteristic—usually the substrate acted upon or the type of reaction catalyzed, or both—followed by the ending *-ase*.

The system classifies the enzyme in one of these six classes, on the basis of its general biochemical action:

1. *Oxidoreductases* transfer electrons from one substrate to another, and *dehydrogenases* transfer a hydrogen from one compound to another.
2. *Transferases* transfer functional groups from one substrate to another.
3. *Hydrolases* cleave bonds on molecules with the addition of water.
4. *Lyases* add groups to or remove groups from double-bonded substrates.
5. *Isomerases* change a substrate into its isomeric form. An **isomer** is a compound that has the same molecular formula as another compound but differs in arrangement of the atoms.

6. *Synthases* are enzymes that catalyze the formation of large molecules; for example, fatty acid synthase makes one component of triglycerides.

Each enzyme is also assigned a technical name that indicates the specific reaction it catalyses. These names are useful for biochemists but are often too lengthy for routine use. More often a common name is derived from some notable feature such as the substrate or enzyme action. For example, *hydrogen peroxide oxidoreductase* is more commonly known as *catalase*. With this simpler system, an enzyme that digests a carbohydrate substrate is a *carbohydrase*; a specific carbohydrase, *amylase*, acts on starch (amylose is a major component of starch). An enzyme that hydrolyzes peptide bonds of a protein is a *proteinase*, *protease*, or *peptidase*, depending on the size of the protein substrate. Some fats and other lipids are digested by *lipases*. DNA is hydrolyzed by *deoxyribonuclease*, generally shortened to *DNase*, and a *polymerase* synthesizes DNA or RNA. Other examples of enzymes are presented in **table 8.A**. (See also table 8.2.)

Give the common names for enzymes that digest collagen, that make ATP, and that clot blood. *Answer available on Connect.*

TABLE 8.A A Sampling of Enzymes, Their Substrates, and Their Reactions

Common Name	Systematic Name	Enzyme Class	Substrate	Action
Lactase	β ,D galactosidase	Hydrolase	Lactose	Breaks lactose down into glucose and galactose
Penicillinase	Beta-lactamase	Hydrolase	Penicillin	Hydrolyzes beta-lactam ring
DNA polymerase	DNA nucleotidyl-transferase	Synthase	DNA nucleosides	Synthesizes a strand of DNA using the complementary strand as a model
Lactate dehydrogenase	Same as common name	Oxidoreductase	Pyruvic acid	Catalyzes the conversion of pyruvic acid to lactic acid
Oxidase	Cytochrome oxidase	Oxidoreductase	Molecular oxygen	Catalyzes the reduction (addition of electrons and hydrogen ions) to O ₂

enzymes (figure 8.7a), are continually present in relatively constant amounts, regardless of the amount of substrate. The enzymes involved in utilizing glucose, for example, are very important in metabolism and thus are constitutive. Other enzymes are **regulated enzymes (figure 8.7b)**, the production of which is either turned on (induced) or turned off (repressed) in response to changes in concentration of the substrate or product. The level of inducible and repressible enzymes is controlled by variations in expression of the genes for these proteins, as discussed in chapter 9.

Synthesis and Hydrolysis Reactions A growing cell is in a constant state of synthesis. All such anabolic reactions require enzymes (synthases) to form covalent bonds between smaller substrate molecules. Also known as **condensation** (dehydration) **reactions**, synthesis reactions release one water molecule for each bond made (**figure 8.8a**). Catabolic reactions are also highly active in a growing cell and require their own, different set of enzymes.

For example, large substrates must be broken down or digested by enzymes into smaller molecules so they can be used. Because the breaking of bonds usually requires the input of water, digestion is also termed a **hydrolysis* reaction (figure 8.8b)**.

The Sensitivity of Enzymes to Environmental Conditions

The activity of an enzyme is highly influenced by the cell's environment. In general, enzymes operate only under the natural temperature, pH, and osmotic pressure of an organism's habitat. When enzymes are subjected to departures from these normal conditions, they tend to be chemically unstable, or **labile**. Low temperatures inhibit catalysis, and high temperatures can denature the apoenzyme.

* *hydrolysis* (hy-drol'-uh-sis) Gr. *hydro*, water, and *lysis*, setting free.

Figure 8.7 Constitutive and regulated enzymes
 (a) Constitutive enzymes are present in constant amounts in a cell. The addition of more substrate does not increase the numbers of these enzymes. (b) The concentration of some regulated enzymes in a cell increases or decreases in response to substrate levels.

Denaturation is a process by which the bonds that collectively maintain the native shape of the apoenzyme are disrupted. This loss causes extreme distortion of the enzyme's shape and prevents the substrate from attaching to the active site (look ahead to chapter 11). Such nonfunctional enzymes block metabolic reactions and can lead to cell death. Low or high pH and certain chemicals (heavy metals, alcohol) are also denaturing agents.

Regulation of Enzymatic Activity and Metabolic Pathways

Metabolic pathways proceed in a stepwise, highly regulated manner that maximizes the use of available nutrients and energy. The cell responds to environmental conditions by adopting those metabolic

(a) **Condensation Reaction.** Forming a glycosidic bond between two glucose molecules to generate maltose requires the removal of a water molecule.

(b) **Hydrolysis Reaction.** Breaking a peptide bond between two amino acids requires a water molecule that adds OH to one amino acid and H to the other.

Figure 8.8 Examples of enzyme-catalyzed synthesis and hydrolysis reactions.

CLINICAL CONNECTIONS

The Role of Microbial Enzymes in Disease

Many pathogens secrete unique exoenzymes that help them avoid host defenses or promote their multiplication in tissues. Because these enzymes contribute to pathogenicity, they are referred to as virulence factors, or toxins in some cases (look ahead to chapter 13). *Streptococcus pyogenes* (a cause of throat and skin infections) produces a streptokinase involved in the digestion of blood clots and can assist the pathogen in invading wounds. Another exoenzyme from this bacterium is called streptolysin.¹ In mammalian hosts, streptolysin damages blood cells and tissues. It is also responsible for lysing red blood cells used in blood agar media, which can be used to identify some bacteria growing in culture (see figure 3.17).

Pseudomonas aeruginosa, a respiratory and skin pathogen, produces elastase and collagenase, which digest elastin and collagen, two proteins found in connective tissue. These increase the severity of certain lung and burn infections. Members of the genus *Clostridium* secrete toxins with significant pathological effects. Many of these toxins—for example, botulinum and tetanus toxins—have an enzymatic component that causes the symptoms of the diseases. Both of them prevent cell vesicles containing neurotransmitters from releasing their contents and thus block nerve transmission to muscles. The botulism toxin causes loss of muscle tone (flaccid paralysis); the tetanus toxin causes sustained muscle tone (rigid paralysis). *Clostridium perfringens*, an agent of gas gangrene, synthesizes lecithinase C, a lipase that profoundly damages cell membranes and accounts for the tissue death associated with this disease. Other medically important enzymes of microbes do not target tissues. Some, such as the beta-lactamases, act on portions of some penicillin and cephalosporin antibiotics and inactivate them. This makes the bacteria drug-resistant and protected from the effects of the drugs.

Even though viruses lack most features of metabolism, a few of them can express genes for enzymes. How would you describe the actions of the following viral enzymes: neuraminidase, reverse transcriptase, and integrase? *Answers available on Connect.*

1. Even though most enzyme names end in *-ase* (see 8.3 Making Connections), not all do.

reactions that most favor its growth and survival. Because enzymes are critical to these reactions, the regulation of metabolism is largely the regulation of enzymes by an elaborate system of checks and balances. Let us take a look at some general features of metabolic pathways.

Patterns of Metabolic Pathways

Metabolic reactions rarely consist of a single action or step. More often, they occur in a multistep series or pathway, with

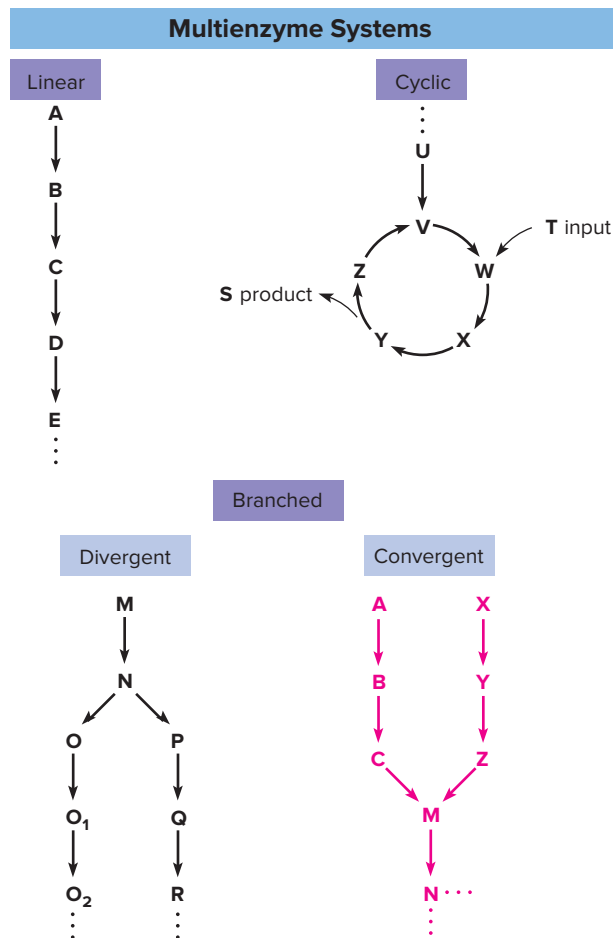

Figure 8.9 Patterns of metabolic pathways. In general, metabolic pathways consist of a linked series of individual chemical reactions that produce intermediary metabolites and lead to a final product. These pathways occur in several patterns, including linear, cyclic, and branched. Anabolic pathways involved in biosynthesis result in a more complex molecule, each step adding on a functional group, whereas catabolic pathways involve the dismantling of molecules and can generate energy. Virtually every reaction in a series involves a specific enzyme.

each step catalyzed by an enzyme. An individual reaction is shown in various ways, depending on the pathway pattern (**figure 8.9**). The product of one reaction is often the reactant (substrate) for the next, forming a linear chain of reactions. Many pathways have branches that provide alternate methods for nutrient processing. Others take a cyclic form, in which the starting molecule is regenerated to initiate another turn of the cycle. Pathways generally do not stand alone; they are interconnected and merge at many sites.

Every pathway has one or more enzyme pacemakers that set the rate of a pathway's progression. Regulation of pacemaker enzymes proceeds on two fundamental levels. Either the enzyme itself is directly inhibited or activated, or the amount of the enzyme in the system is altered (decreased or increased). When factors affect the enzyme directly, the system can be finely controlled or "tuned." When regulation is at the genetic level (enzyme synthesis), control is slower and less sensitive.

Figure 8.10 Examples of two common modes of competitive inhibition that regulate enzyme action. For a quick animation of these mechanisms, go to “Cellular Metabolism, Pathways, & Feedback” on YouTube.

Direct Controls on the Action of Enzymes

The bacterial cell has many ways of directly influencing the activity of its enzymes. It can inhibit enzyme activity by supplying a molecule that resembles the enzyme’s normal substrate. The “mimic” can then occupy the enzyme’s active site, preventing the actual substrate from binding there. Because the mimic cannot actually be acted on by the enzyme and a product is not released, the enzyme is effectively shut down. This is one example of **competitive inhibition**, because the mimic is competing with the substrate for the binding site (figure 8.10). In chapter 12 you will see that some antibiotics work on the same strategy of competing with enzymatic active sites to shut down metabolic processes.

Another form of competitive inhibition can occur with special types of enzymes that have two binding sites: the active site and another area called the **regulatory** or **allosteric*** site (figure 8.10). The action of these enzymes is controlled by the binding of molecules other than the substrate in the regulatory site. Often the regulatory molecule is the product of the enzymatic reaction itself. This provides a **negative feedback** mechanism that can slow down enzymatic activity once a certain concentration of product is produced.

* *allosteric* (al-oh-stair'-ik) Gr. *allos*, other, and *steros*, solid. Literally, “another space.”

Noncompetitive inhibition is a third mechanism that does not involve an inhibitor molecule competing with substrate for the active site or disable the active site. This type of inhibitor binds to the entire enzyme-substrate complex and prevents the enzyme from completing its action on the substrate.

Controls on Enzyme Synthesis

Controlling enzymes by controlling their synthesis is another effective mechanism. Because enzymes do not last indefinitely, they eventually degrade and must be replaced. This cycle works into the scheme of the cell, where replacement of enzymes can be regulated according to cell demand. The mechanisms of this system are genetic in nature; that is, they require regulation of DNA and protein synthesis, a topic we cover in more depth in chapter 9.

Enzyme repression is a means to stop further synthesis of an enzyme somewhere along its pathway. As the level of the end product from a given enzymatic reaction has built to excess, the genetic apparatus responsible for replacing these enzymes is automatically suppressed (figure 8.11). The response time is longer than for feedback inhibition, but its effects are more enduring.

A response that resembles the inverse of enzyme repression is **enzyme induction**. In this process, enzymes appear (are induced)

Process Figure 8.11 One type of genetic control of enzyme synthesis: enzyme repression. (1–5) Genetic controls are active and the enzyme is synthesized continuously until enough product has been made. (6)–(7) Excess product reacts with a site on DNA that regulates the enzyme's synthesis, thereby inhibiting further enzyme production.

only when suitable substrates are present; that is, the synthesis of enzyme is induced by its substrate. This response enables the organism to adapt to a variety of nutrients, and it also prevents a microbe from wasting energy by making enzymes for which substrates are lacking.

Check Your Progress SECTION 8.1

1. Differentiate between catabolism and anabolism using examples.
2. Describe 10 important biochemical properties of enzymes.
3. Describe the chemistry of enzymes, and explain how the apoenzyme forms.
4. Show diagrammatically the interaction of holoenzyme and its substrate and general products that can be formed from a reaction.
5. Differentiate among the chemical composition and functions of various cofactors. Provide examples of each type.
6. Summarize the direct and indirect controls that regulate enzymes.

8.2 The Pursuit and Utilization of Energy

Expected Learning Outcomes

8. Relate the diverse sources of energy and the cellular management of energy.
9. Describe biological oxidation-reduction and energy transfer.
10. Discuss the structure, basic formation, and roles of ATP in cells.

Energy is defined as the capacity to do work or to cause change. In order to carry out the work of an array of metabolic processes, cells require constant input and expenditure of some form of usable energy. Energy commonly exists in these forms:

- thermal (heat) energy from molecular motion,
- radiant (wave) energy from visible light or other rays,
- electrical energy from a flow of electrons,
- mechanical energy from a physical change in position,
- atomic energy from reactions in the nucleus of an atom, and
- chemical energy present in the bonds of molecules.

Cells are far too fragile to rely in any constant way on thermal or atomic energy for cell transactions. Except for certain chemoautotrophic bacteria, the ultimate source of energy is the sun, but only phototrophs can tap this source directly. This capacity of photosynthesis to convert solar energy into chemical energy provides both a nutritional and an energy basis for all heterotrophic living things. We cover this essential form of metabolism in section 8.6. For the most part, only chemical energy and reactions can fuel cellular energetics of nonphotosynthetic organisms.

In this section, we further explore the role of energy as it is related to the use of nutrients, redox carriers, and the generation of ATP.

Cell Energetics

Cells manage energy in the form of chemical reactions that change molecules. This often involves activities such as the making or breaking of bonds and the transfer of electrons. Not all cellular

reactions have the same relation to energy. Some release energy and others require it to proceed. For example, a reaction with this equation:

releases energy as it goes forward. This type of reaction is termed **exergonic**.^{*} Energy of this type is considered free: it is available for doing cellular work. Energy transactions such as the following:

are called **endergonic**^{*} because they are driven forward with the addition of energy.

Summaries of metabolism might make it seem that cells “create” energy from nutrients, but they do not. What they actually do is extract chemical energy already present in nutrient fuels and apply that energy toward useful work in the cell, much like a gasoline engine releases energy as it burns fuel. The engine does not actually produce energy, but it converts the potential energy of the fuel to the free energy that drives a machine.

The basis for cell energetics lies in the chemical bonds, electron transfers, and special pathways along with their enzymes. During exergonic reactions, electrons are pulled out of atoms, thereby releasing their inherent energy. These electrons are picked up by special carriers and transferred through a series of reactions until they reach a **final electron acceptor**. As we will see in section 8.3, the production of ATP is intimately tied to this process. As ATP is formed, it is used to support endergonic reactions such as synthesis. These reactions are balanced and cyclic, so that ATP is constantly being made, used, regenerated, and so on. The actual process of electron transfer is a type of redox reaction that was first described in chapter 2. Let us revisit this topic and see how it is involved in metabolism.

Biological Oxidation and Reduction: Electron and Energy Transfer

Many chemical substances readily donate or receive electrons and participate in oxidation (the loss of electrons) or reduction (the gain of electrons). The compound that loses the electrons is **oxidized**, and the compound that receives the electrons is **reduced**. Such oxidation-reduction or **redox reactions** are common in cells and indispensable to energy transactions (look back at figure 2.9). Redox reactions always occur in pairs, with an electron donor and an electron acceptor, which constitute a *conjugate pair*, or *redox pair*. The reaction can be represented as follows:

^{*} **exergonic** (ex-er-gon'-ik) Gr. *exo*, without, and *ergon*, work. In general, catabolic reactions are exergonic.

^{*} **endergonic** (en-der-gon'-ik) Gr. *endo*, within, and *ergon*, work. Anabolic reactions tend to be endergonic.

Redox reactions in cells involve not only electrons but also the hydrogen atoms which donate them. Recall that a hydrogen atom consists of a single proton and a single electron. When a hydrogen atom gives up its single electron to a positively charged molecule, this leaves a hydrogen ion or proton (H^+). For simplicity's sake, our discussions will emphasize the process of electron transfer. But be aware that many pathways need hydrogen ions (protons) generated by oxidation-reduction to carry out essential functions in the metabolic pathways.

One example of a typical redox reaction is seen in this overall equation associated with aerobic respiration:

Note that the electron donor is hydrogen and the electron acceptor is oxygen. The electrons are transported and energy is released through a stepwise series of reactions, covered in section 8.3.

For energy to be biologically useful, it must ultimately be captured through **phosphorylation**, a process that adds an inorganic phosphate P_i to adenosine diphosphate, converting it to ATP:

Several different types of carriers exist for handling and transporting electrons and protons until they can be transferred to a final electron acceptor. Such redox reactions are a constant supplier of electrons for the final “processing plant” operating in cells—the electron transport system (look ahead to figure 8.16).

Managing Electrons in Metabolism

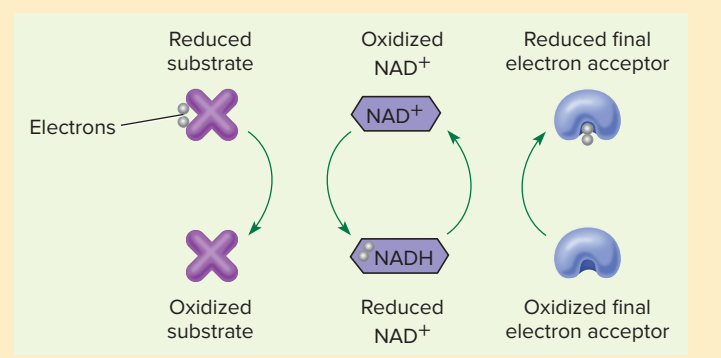

We learned in chapter 2 that electrons are highly reactive, negatively charged particles, and that they are transferred or shared between atoms during bond formation. These electrons do not bounce around randomly in cells. Generally, they are captured and transported by some form of carrier molecule.

Much of the work of electron capture and transport in metabolic pathways falls to molecules with enhanced affinity for electrons. They readily accept electrons from one substrate and donate them to another substrate. The most common of these carriers is the coenzyme **nicotinamide adenine dinucleotide (NAD⁺)** (figure 8.12). Other related carriers are FAD (flavin adenine dinucleotide), coenzyme A, and the compounds of the respiratory chain, all discussed in section 8.3.

NAD⁺ reduces 2 hydrogen atoms and carries 2 electrons away from this reaction, represented as NADH. The electrons are carried in the nicotinamide ring, where they can be accessed during other electron transfers (figure 8.12).

At the end point the electrons will be received by a final electron acceptor, which in aerobic metabolism is molecular oxygen. An important function of this carrier system is that every transfer of electrons from NADH to another carrier molecule automatically

replenishes NAD^+ for use in the numerous redox reactions in cells (see example in figure below).

Adenosine Triphosphate: Metabolic Money

ATP has been described as metabolic currency because it can be earned, spent, and exchanged. You can gain some appreciation for the enormous need for ATP if you consider that even one tiny cell of *Escherichia coli* consumes around 2.5 million ATP molecules per second for synthesis alone! As a temporary energy repository, ATP provides a connection between energy-yielding catabolism and all other cellular activities that require energy. Some clues to its energy-storing properties lie in its unique molecular structure.

The Molecular Structure of ATP ATP is a three-part molecule consisting of a nitrogen base (adenine) linked to a 5-carbon sugar

Figure 8.12 Structure of NAD^+ and its carrier function. (a) The coenzyme NAD^+ contains the vitamin nicotinamide (niacin) bound to two ribose phosphates and an adenine. (b) The site of reduction is at the nicotinamide ring portion (box), which carries 2 electrons, one at the ring nitrogen and the other on a hydrogen bound to a ring carbon.

— Bond that releases energy when broken

Figure 8.13 A model of adenosine triphosphate (ATP).

A structural view of ATP and its related components ADP and AMP. Note that the last two phosphate bonds release energy when they are cleaved.

(ribose), with a chain of three phosphate groups bonded to the ribose (**figure 8.13**). The type, arrangement, and especially the proximity of atoms in ATP combine to form a compatible but unstable high-energy molecule. The high energy of ATP originates in the orientation of the phosphate groups, which are relatively bulky and carry negative charges. The proximity of these repelling electrostatic charges imposes a strain that is most acute on the bonds between the last two phosphate groups. When the strain on the phosphate bonds is released by removal of the terminal phosphates, free energy is released.

Breaking the bonds between the second and third phosphates of ATP yields adenosine diphosphate (ADP), which can then be converted to adenosine monophosphate (AMP). It is worthwhile noting how economically a cell manages its pool of adenosine nucleotides. AMP derivatives help form the backbone of RNA and are also a major component of certain coenzymes (NAD^+ , FAD, and coenzyme A).

The Metabolic Roles of ATP ATP is at the center of a cell's energy cycle, regardless of whether it is a chemoheterotroph using respiration, a photosynthetic organism, or a chemoautotroph. Expenditure of ATP powers nearly all processes that are part of cellular work. This energy cycle can be depicted as shown here:

In many instances, the energy released from the high-energy bond in ATP activates individual subunits before they are enzymatically bonded during synthesis. ATP is also used to prepare a

Figure 8.14 The phosphorylation of glucose by ATP. The first step in catabolizing glucose is the addition of a phosphate from ATP by an enzyme called hexokinase. This use of high-energy phosphate as an activator is a recurring feature of many metabolic pathways.

molecule for catabolism such as the phosphorylation of a 6-carbon sugar during the early stages of glycolysis (**figure 8.14**).

Because ATP needs to be constantly replenished, reactions are constantly continuing in the reverse order. The ADPs generated during phosphorylation will repeat the cycle by reacting immediately with inorganic phosphate and a high-energy source that can regenerate ATP. The energy for these high-energy phosphate bonds comes from catabolic pathways where substrates or electron carriers are harvesting energy.

Most ATPs in aerobic organisms are formed during **oxidative phosphorylation**, a series of reactions involving electron transport and an enzyme (ATP synthase) that can trap energy and store it in ATP (look ahead to **figure 8.20**). Some ATP molecules are formed through **substrate-level phosphorylation**, a process that all cells carry out, regardless of their metabolic type. In this mode of phosphorylation, ATP is formed by transfer of a phosphate group from a high-energy compound (substrate) directly to ADP (**figure 8.15**; see also **figure 8.17**, step 6).

Photosynthetic organisms have a system involving **photophosphorylation**, in which the ATP is formed by means of a light-driven

Figure 8.15 ATP formation by substrate-level phosphorylation. The substrate has been bound to a phosphate, creating a bond with high potential energy. Transfer of the high-energy phosphate to ADP gives rise to ATP and returns the substrate to its original form.

electron transport mechanism that we discuss in more detail in section 8.6.

Check Your Progress SECTION 8.2

- Explain how oxidation of a substrate proceeds without oxygen.
- Refer to the blue redox equation for glucose. Which substance is reduced? Which is oxidized? Which is the oxidizing agent? Which is the reducing agent?
- In the following redox pairs, which compound is reduced and which is oxidized?
 - NAD^+ and NADH
 - FADH_2 and FAD
 - NO_3^- and NO_2^-
- Describe the roles played by ATP and NAD^+ in metabolism.
 - What particular features of their structure lend them to these functions?
- Name the major ways that substrate-level phosphorylation is different from oxidative phosphorylation.
- What is meant by the concept of the “final electron acceptor”?

8.3 Pathways of Bioenergetics

Expected Learning Outcomes

- Relate the main points of bioenergetics and energy strategies in microorganisms.
- Describe the main catabolic pathways and their locations in aerobic respiration.
- Define *glycolysis* and explain its input and output, its basic steps, and how it is linked to the Krebs cycle and oxidative phosphorylation.
- Explain the basic steps in the Krebs cycle, its input and output, and how it is linked to oxidative phosphorylation.
- Describe the components of the respiratory chain and their functions.
- Explain the chemiosmotic mechanism of ATP formation, its relationship to electron transport, and the final step in electron transfer.
- Summarize the results of aerobic respiration.
- Define and describe some reactions of anaerobic respiration.

One of the scientific community’s greatest achievements was deciphering the biochemical pathways of cells. Initial work with bacteria and yeasts, followed by studies with animal and plant cells, clearly demonstrated metabolic similarities and strongly supported the presence of metabolic patterns that are universal. **Bioenergetics** is a study of the mechanisms of cellular energy release, including catabolic and anabolic routes. Although these pathways are interconnected and interdependent, anabolic pathways are not simply reversals of catabolic ones. At first glance it may seem more economical to use identical pathways, but having different enzymes and divided pathways allows anabolism and catabolism to proceed simultaneously without interference.

In the following sections, we focus our discussion on the most common catabolic pathways that illustrate general principles of other pathways as well.

Catabolism: An Overview of Nutrient Breakdown and Energy Release

For most chemoheterotrophs, the primary catabolism of fuels (such as glucose) that release energy proceeds through a series of three coupled pathways:

1. **glycolysis**,* also called the Embden-Meyerhof-Parnas (EMP) pathway;²
2. the **Krebs cycle**, also known as the citric acid or tricarboxylic acid cycle TCA;² and

* *glycolysis* (gly-kol'-ih-sis) Gr. *glykys*, sweet, and *lysis*, to split.

2. The EMP pathway is named for the biochemists who first outlined its steps. Krebs is in honor of Sir Hans Krebs who, with F. A. Lipmann, delineated this pathway, an achievement for which they won the Nobel Prize in Physiology or Medicine in 1953. TCA refers to the involvement of several organic acids containing three carboxylic acid groups, citric acid being the first tricarboxylic acid formed.

3. the **respiratory chain** (electron transport and oxidative phosphorylation).

Each segment of the pathway is responsible for a specific set of actions on various products of glucose. The major interconnections of these pathways in aerobic respiration are represented in **figure 8.16**, and their reactions are summarized in **table 8.3**. In the following sections, we consider each of these pathways in greater detail.

Energy Strategies in Microorganisms

In chapter 7 we gained insight into the metabolic diversity of microbes. There are numerous strategies used by microbes to derive energy and synthesize cell components. Because microbial metabolism is so varied, we have chosen to cover elements of the most common types of metabolism, based on the three basic catabolic pathways. In previous discussions, microorganisms were

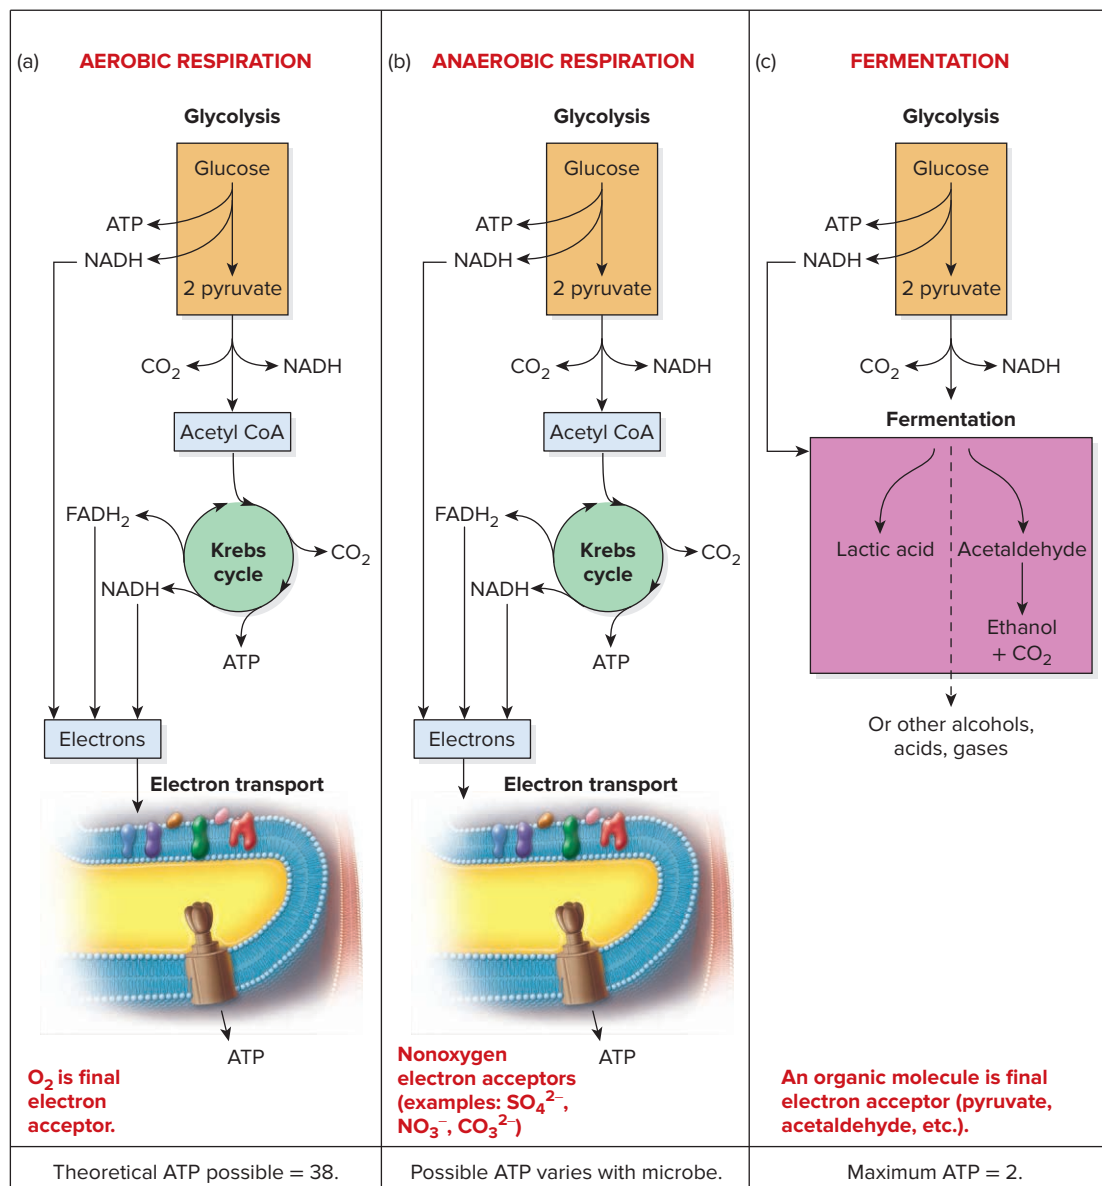

Figure 8.16 Side-by-side comparison of the stages, reactions, and major products of pathways for aerobic respiration, anaerobic respiration, and fermentation. Note that all begin with glycolysis but vary in use of other pathways, electron acceptors, and ATP yield.

TABLE 8.3 Metabolic Strategies Among Heterotrophic Microorganisms Growing on Glucose

Scheme	Pathways Involved	Final Electron Acceptor	Products	Primary Pathway Found In
Aerobic respiration	Glycolysis, Krebs cycle, electron transport	O ₂	ATP, CO ₂ , H ₂ O	Aerobes; facultative anaerobes
Anaerobic metabolism Fermentative	Glycolysis	Organic molecules	ATP, CO ₂ , ethanol, lactic acid*	Facultative, aerotolerant, strict anaerobes
Respiration	Glycolysis, Krebs cycle, electron transport	Various inorganic ions (NO ₃ ⁻ , SO ₄ ²⁻ , CO ₃ ³⁻)	Highly varied, but can include CO ₂ , ATP, organic acids, H ₂ S, CH ₄ , N ₂	Anaerobes; some facultatives and aerotolerants

* The products of microbial fermentations are extremely varied and include organic acids, alcohols, and gases.

categorized according to their requirement for oxygen gas, and this requirement is related directly to their mechanisms of energy release. As we shall see, **aerobic respiration** is a series of reactions (glycolysis, Krebs cycle, and the respiratory chain) that converts glucose to CO₂, produces H₂O, and generates energy (figure 8.16a). It relies on molecular oxygen (O₂) as the final acceptor for electrons and hydrogens, and releases a relatively large amount of ATP. Aerobic respiration is characteristic of fungi, protozoa, animals, plants, and many bacteria, and it will be the system we emphasize here.

Some facultative and aerotolerant anaerobes may use only glycolysis or similar pathways to ferment glucose. In this case, oxygen is not required, organic compounds are the final electron acceptors, and a relatively small amount of ATP is synthesized (figure 8.16c and section 8.4).

Some anaerobic microorganisms metabolize by means of **anaerobic respiration**. This system may involve the same three pathways as aerobic respiration, but it does not use molecular oxygen as the final electron acceptor (figure 8.16b). Instead, it uses other oxidized ions such as NO₃⁻, SO₄²⁻, or CO₂ for the final electron acceptor. Aspects of anaerobic respiration and fermentation are covered later in this section and the next one.

Aerobic Respiration

Aerobic respiration is a series of enzyme-catalyzed reactions in which electrons are transferred from fuel molecules such as glucose to oxygen as a final electron acceptor. This pathway is the principal energy-yielding scheme for aerobic heterotrophs, and it provides both ATP and metabolic intermediates for many other pathways in the cell, including those of protein, lipid, and carbohydrate synthesis (see figure 8.25).

Aerobic respiration in microorganisms can be summarized by this equation:

The seeming simplicity of the equation for aerobic respiration conceals the complexity of the process. Fortunately we do not have to present all of the details to address some important concepts concerning its reactants and products, as follows:

1. the steps in the oxidation of glucose,
2. the involvement of coenzyme carriers and the final electron acceptor,
3. where and how ATP originates,

4. where carbon dioxide originates, and
5. where oxygen is required.

Glucose: The Starting Compound

Carbohydrates such as **glucose** are good fuels because these compounds are readily oxidized; that is, they are superior electron donors. The electrons they donate can be used in energy transfers. The end products of the oxidation of such organic compounds are energy-rich ATP and energy-poor carbon dioxide and water. Polysaccharides (starch, glycogen) and disaccharides (maltose, sucrose) are stored sources of glucose also available for the respiratory pathways. Although we use glucose as the main starting compound, other hexoses (fructose, galactose) and fatty acid subunits can enter the pathways of aerobic respiration as well, as we will see in section 8.5.

Glycolysis: The Starting Lineup

The process called **glycolysis (EMP)** is a pathway that converts glucose through several steps into **pyruvic acid**. Depending on the organism and the conditions, it may be only the first phase of respiration, or it may serve as the primary metabolic pathway for fermentative microbes. Glycolysis provides a way to synthesize a small amount of ATP, to release another potential source of energy—NADH, and to generate pyruvic acid, an essential intermediary metabolite. None of these reactions involve the direct input of oxygen.

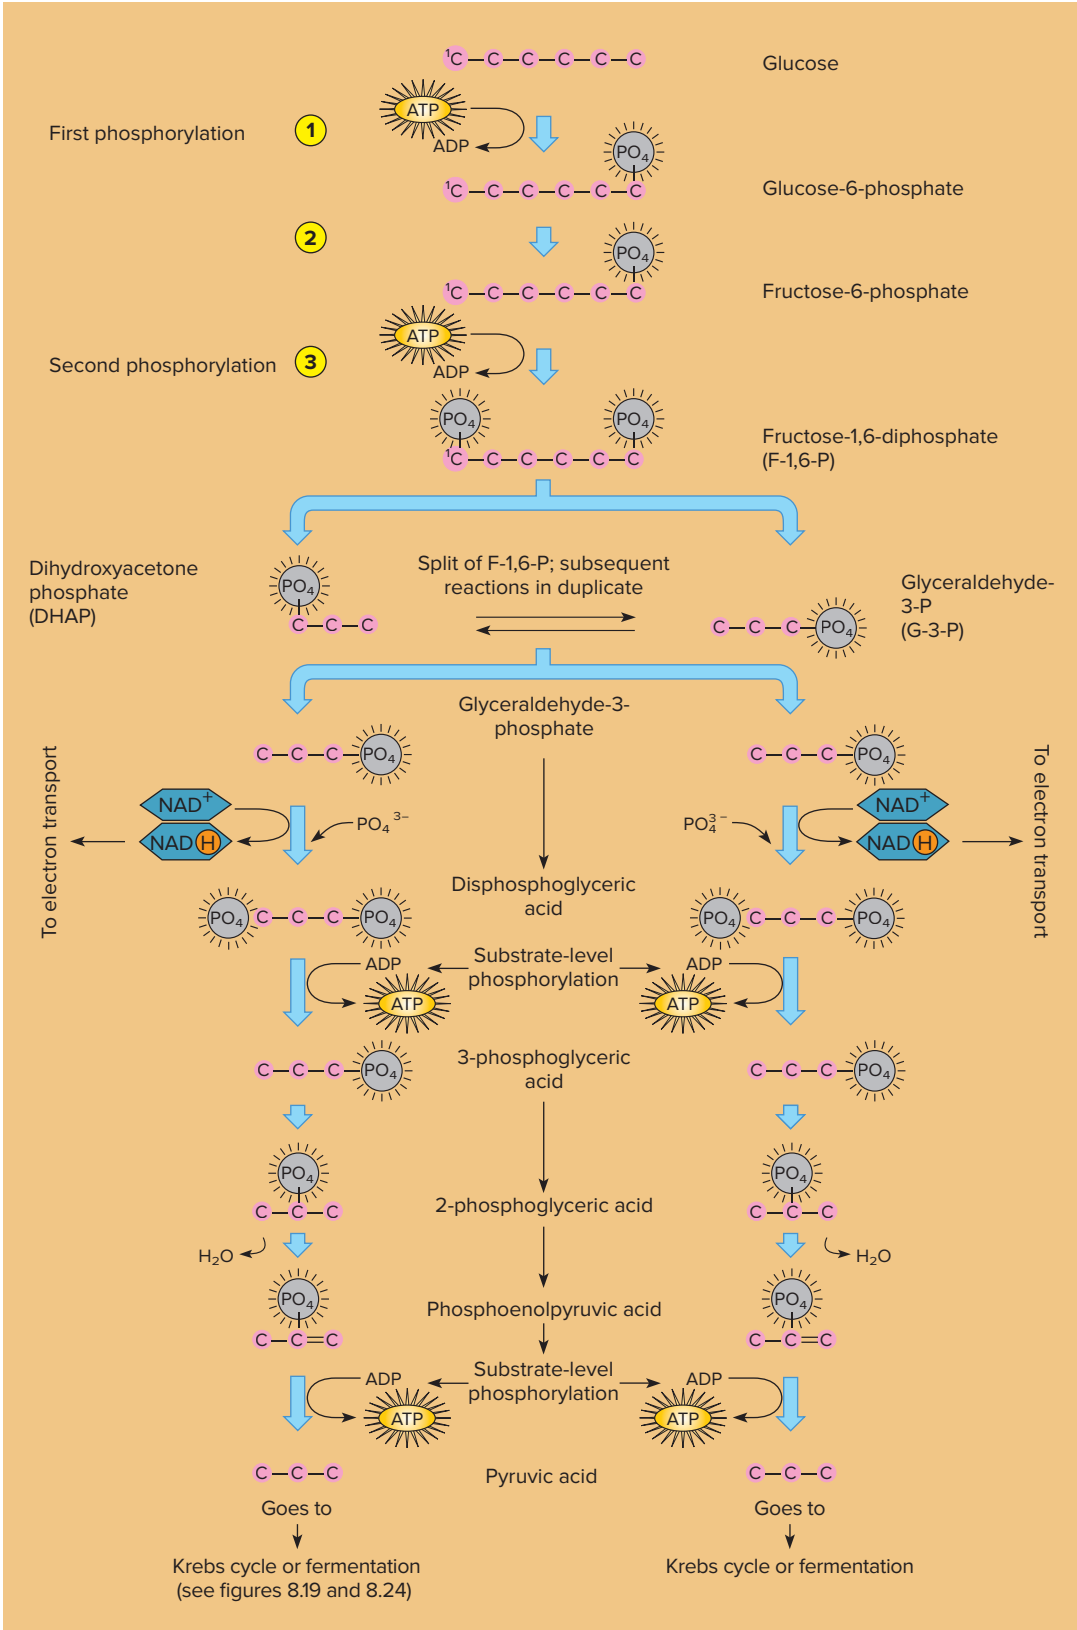

Steps in the Glycolytic Pathway Glycolysis proceeds along nine linear steps. The first portion of glycolysis involves activation of glucose, which is followed by oxidation reactions of the glucose fragments, the synthesis of ATP, and the formation of pyruvic acid. Although each step of metabolism is catalyzed by a specific enzyme, we will mention only certain key ones. The following outline lists the principal steps of glycolysis. To see an overview of glycolysis, go to **figure 8.17**. Detailed illustrations appear in Appendix A.

1. First, glucose is phosphorylated at the number six carbon by an **ATP** to produce glucose-6-phosphate (see figure 8.14). This is a way of “priming” the system and preventing the glucose from being transported out of the cell.
2. Glucose-6-phosphate is converted to its isomer, fructose-6-phosphate.
3. Another ATP is spent in phosphorylating the first carbon of fructose-6-phosphate, which yields a molecule with two phosphates called fructose-1,6-diphosphate.

These steps take place in the cytoplasm of both prokaryotic and eukaryotic cells.

- 9

Process Figure 8.17 Summary of the steps in glycolysis. The primary reaction steps are described in the accompanying text. These reactions all take place in the cytoplasm, regardless of the cell type. Inset in upper corner has a gold box to show the position of this pathway in the scheme of aerobic respiration. Only the pink carbon skeleton is shown to simplify the dynamics of the reactions. A detailed analysis of specific chemical structures and reactions can be found in Appendix A.

Up to this point, no energy has been released, no oxidation-reduction has occurred, and, in fact, 2 ATPs have been used and the molecules remain in the 6-carbon state.

- Fructose-1,6-diphosphate is split into two 3-carbon fragments: glyceraldehyde-3-phosphate (G-3-P) and dihydroxyacetone phosphate (DHAP). These molecules are isomers, and DHAP is converted to G-3-P, which is the more reactive form for the following reactions.

The effect of the splitting of fructose diphosphate is to double every subsequent reaction, because where there was once a single molecule, there are now two to be fed into the remainder of glycolysis and other pathways.

- Each molecule of glyceraldehyde-3-phosphate becomes involved in the single oxidation-reduction reaction of glycolysis. This sets the scene for ATP synthesis. The NAD^+ coenzyme complex picks up hydrogens from G-3-P, forming **NADH**. This step is accompanied by the addition of an inorganic phosphate (PO_4^{3-}) to form an unstable bond on the third carbon of the G-3-P substrate. The product of these reactions is diphosphoglyceric acid (DPGA).
- One of the high-energy phosphates of diphosphoglyceric acid is donated to ADP via **substrate-level phosphorylation** resulting in a molecule of ATP. The other product of this reaction is 3-phosphoglyceric acid (3-PGA).
- 7, 8. During this phase, the 3-phosphoglyceric acid is converted to 2-phosphoglyceric acid (2-PGA) through the shift of a phosphate from the third to the second carbon. Then, the removal of a water molecule from 2-phosphoglyceric acid converts it to phosphoenolpyruvic acid (PEPA). The result gives rise to a high-energy phosphate bond.
- In the final reaction of glycolysis, phosphoenolpyruvic acid gives up its high-energy phosphate to form a second ATP, again via **substrate-level phosphorylation**. This reaction also produces **pyruvic acid** (pyruvate), a compound with many roles in metabolism.

The reactions of glycolysis thus give rise to two pyruvic acids per glucose. The two substrate-level phosphorylations produce a total of 4 ATPs. However, 2 ATPs were expended for steps 1 and 3, so the net number of ATPs available to the cell from these reactions is 2.

In aerobic organisms, the two NADHs formed during step 5 are shuttled to the electron transport system, where the final electron acceptor will be oxygen, and additional ATPs will be generated per NADH. In organisms that ferment glucose, the NADH will be oxidized back to NAD^+ , and the electron acceptor will be an organic compound (see figure 8.23).

Pyruvic Acid—A Central Metabolite

Pyruvic acid occupies an important position in several pathways, and different organisms handle it in different ways (**figure 8.18**). In strictly aerobic

organisms and some anaerobes, pyruvic acid is channeled into the Krebs cycle for processing and energy release. Facultative anaerobes can adopt a fermentative metabolism, in which pyruvic acid is further reduced into acids or other products.

The Preparation of Pyruvic Acid for the Krebs Cycle

The oxidation of glucose by glycolysis yields a comparatively small amount of energy. Pyruvic acid is still energy-rich, containing a number of extractable electrons to power ATP synthesis, and this will be achieved through the work of the second and third phases of respiration, during which pyruvic acid is converted to CO_2 and H_2O . In the following section, we examine the second phase—the Krebs cycle—which takes place in the mitochondrial matrix in eukaryotes and in the cytoplasm of bacteria.

To connect the glycolysis pathway to the Krebs cycle, the pyruvic acid is first converted to a starting compound for that cycle (**figure 8.19**, tan oval at top). This step brings in an enzyme complex and coenzyme A to participate in the oxidation of pyruvic acid, the reduction of NAD^+ to NADH, and the decarboxylation of pyruvic acid to a 2-carbon acetyl group accompanied by release of carbon dioxide. The acetyl group remains

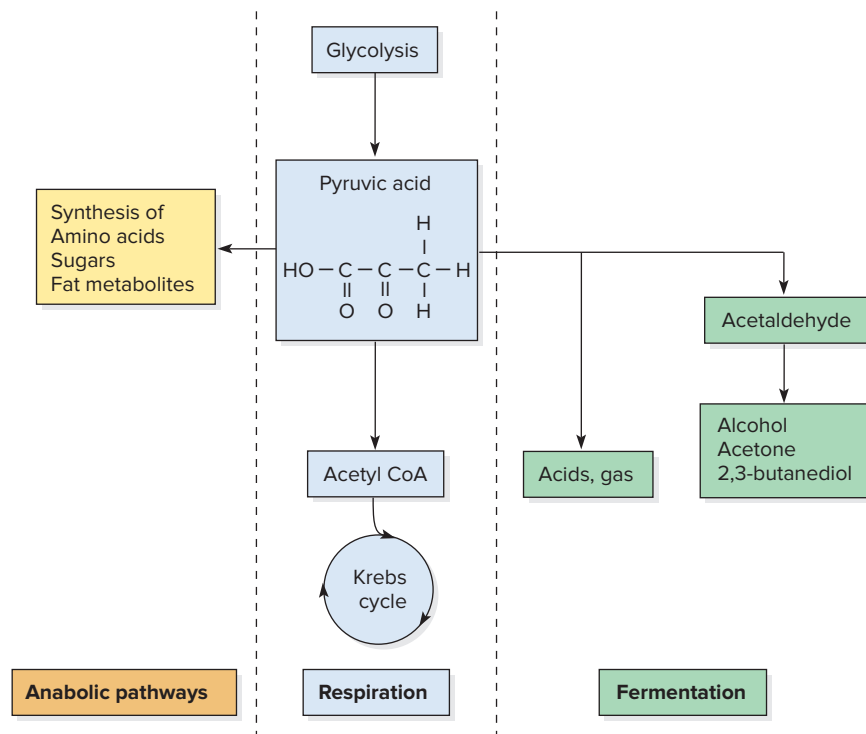

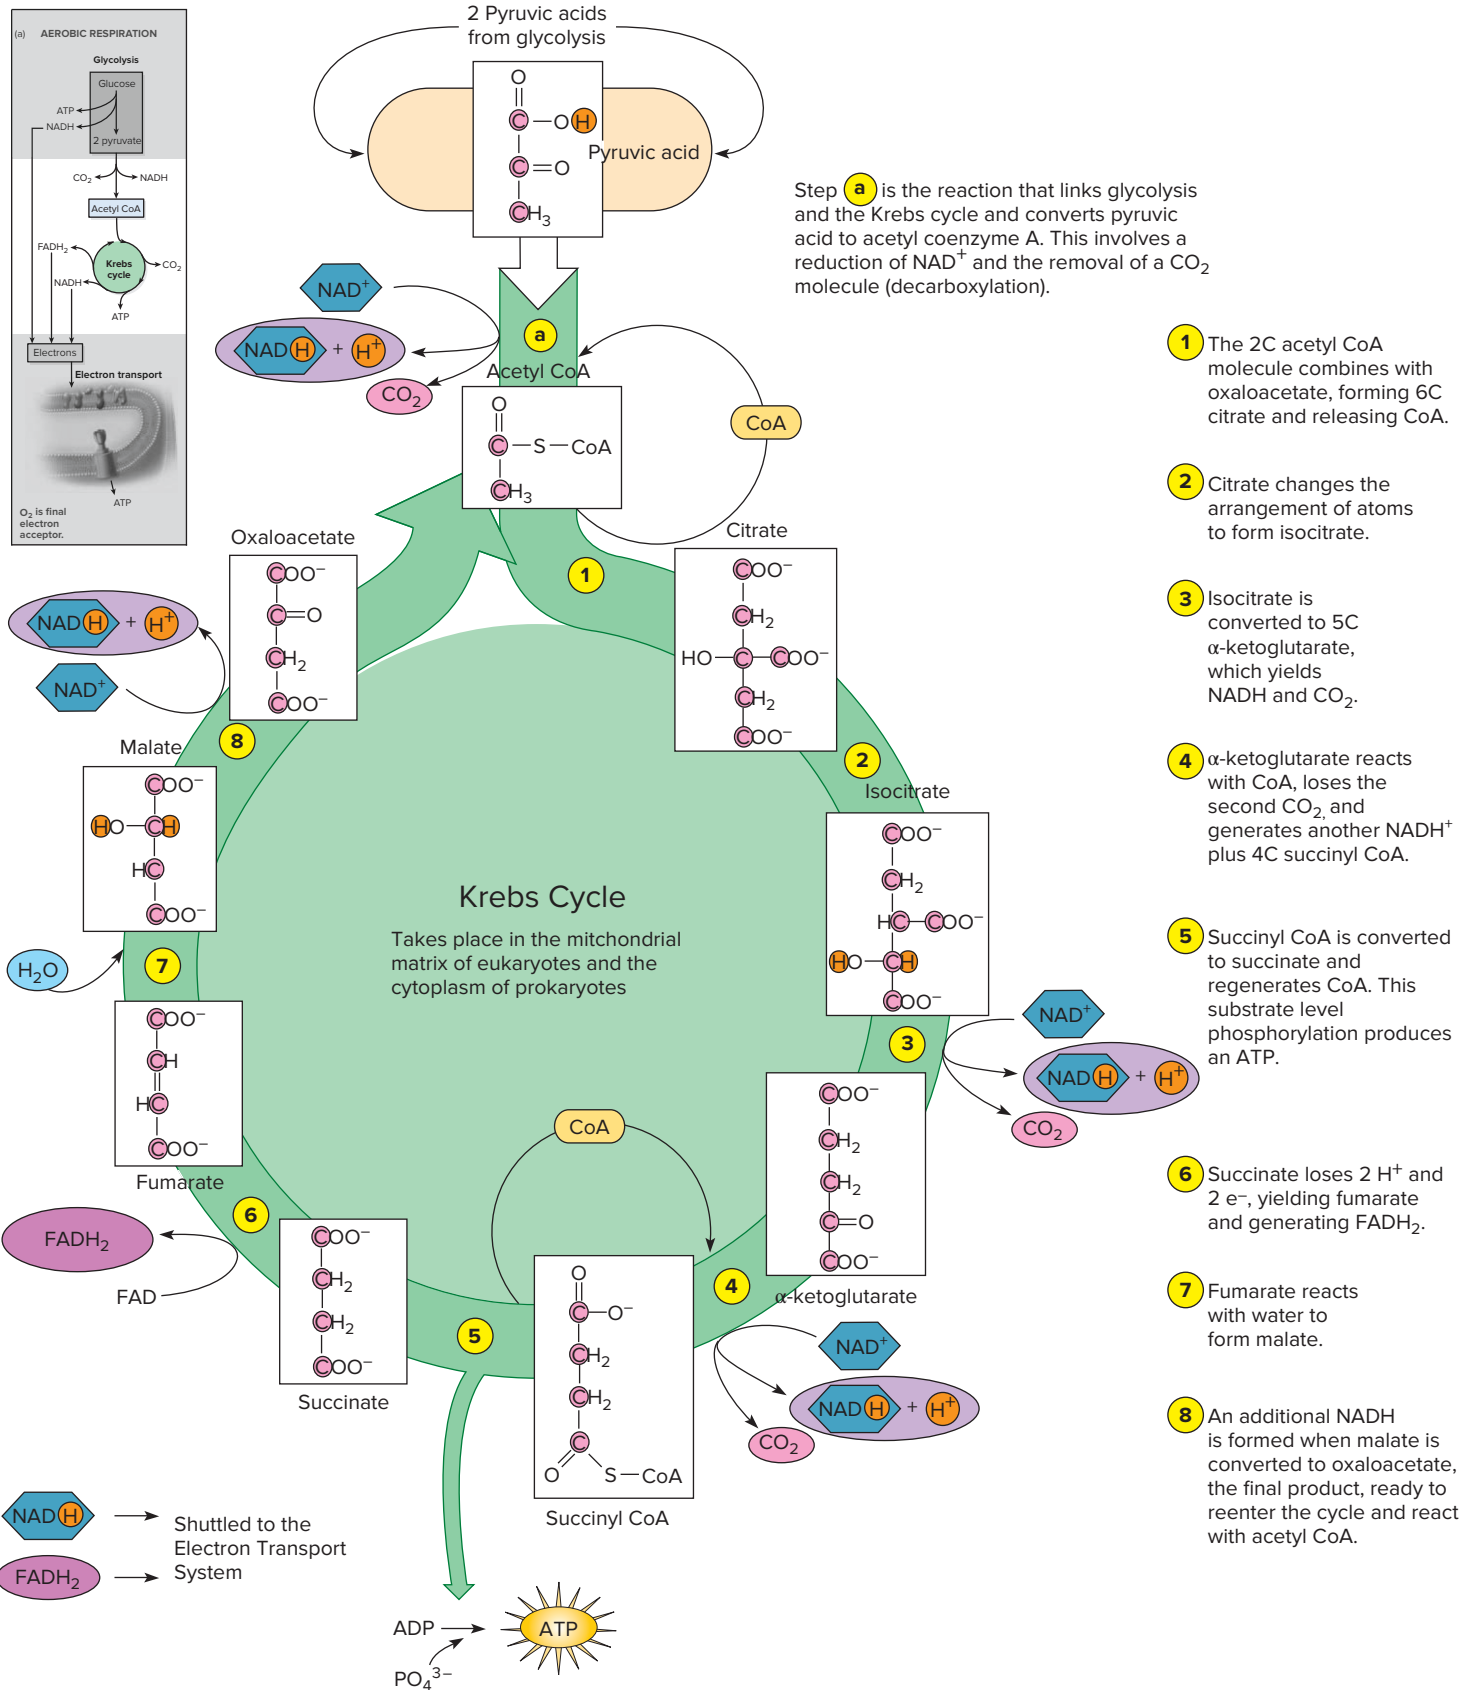

Figure 8.18 The fates of pyruvic acid (pyruvate). This metabolite is an important hub in the processing of nutrients by microbes. It may be fermented anaerobically to several end products or oxidized completely to CO_2 and H_2O through the Krebs cycle and the electron transport system. It can also serve as a source of raw material for synthesizing amino acids and carbohydrates (see figure 18.25).

Process Figure 8.19 The reactions of a single turn of the Krebs cycle. Each glucose will produce two turns of this pathway. The top portion (a) depicts the conversion of pyruvic acid to acetyl Co enzyme A, a necessary reaction that sets up the first step of Krebs. Note that this is an enlarged, more detailed view of the central portion of figure 8.16a.

attached to coenzyme A, forming **acetyl coenzyme A** (acetyl CoA) that feeds into the Krebs cycle. Pyruvate dehydrogenase, the enzyme complex that makes this reaction possible, is huge. In *E. coli*, it contains four vitamins and has a molecular weight of 6 million—larger than a ribosome!

The NADH produced in the formation of acetyl CoA will be shuttled into electron transport and used to generate ATP via oxidative phosphorylation in the third phase of aerobic respiration.

Keep in mind that all reactions during these subsequent phases happen twice for each glucose because of the two pyruvates that are released during glycolysis.

The Krebs Cycle—A Carbon and Energy Wheel

As you learned earlier, a cyclic pathway is one in which the starting compound is regenerated at the end of the cycle so it will be ready to go around again. The Krebs cycle has eight steps, beginning with citrate formation and ending with oxaloacetate (figure 8.19). The 2-carbon acetyl groups from coenzyme A combine with a 4-carbon oxaloacetate molecule to form citrate, a 6-carbon molecule. Although this seems a cumbersome way to dismantle such a small molecule, it is necessary in biological systems for extracting the remaining energy from the acetyl fragment.

As we take a single spin around the Krebs cycle, it will be helpful to keep track of

1. the numbers of carbons (#C) of each substrate and product,
2. reactions where CO₂ is generated,
3. reductions of the electron carriers NAD⁺ and FAD, and
4. the site of ATP synthesis.

Be aware that the terms and structures used for organic acids can be shown as either the acid form (oxaloacetic acid) or its salt (oxaloacetate). We present the salt form in this text for the most part.

The eight reactions in the Krebs cycle are:

1. Oxaloacetate (4C) reacts with the acetyl group (2C) on acetyl CoA, thereby forming citrate (6C) and releasing coenzyme, making it immediately available for another acetyl group.
2. Citrate is converted to its isomer, isocitrate (6C), to prepare this substrate for the decarboxylation and redox reaction of the next step.
3. Isocitrate is acted upon by an enzyme complex including NAD⁺ or NADP (depending on the organism) in a reaction that generates NADH or NADPH, splits off a carbon dioxide, and leaves α -ketoglutarate (5C).
4. Alpha-ketoglutarate serves as a substrate for the final decarboxylation reaction and yet another redox reaction, involving coenzyme A and yielding NADH. The product is the high-energy compound succinyl CoA (4C).

At this point, the cycle has completed the formation of 3 CO₂ molecules that balance out each original 3-carbon pyruvic acid released by glycolysis. The remaining steps serve not only to regenerate the oxaloacetate to start the cycle again but also to extract more energy from the intermediate compounds leading to oxaloacetate.

5. Succinyl CoA is the source of the one substrate level phosphorylation in the Krebs cycle. In most bacteria, it proceeds with the formation of ATP, although eukaryotes produce guanosine triphosphate (GTP), an equivalent source of energy. The other product at this step is succinate (4C).
6. Succinate undergoes a redox reaction, but in this case, the electron and H⁺ acceptor is flavin adenine dinucleotide (FAD). The enzyme that catalyzes this reaction, succinyl dehydrogenase, is found in the bacterial cell membrane and mitochondrial crista of eukaryotic cells. The FADH₂ generated directly enters the electron transport system but at a different carrier site than NADH. Fumarate (4C) is the product of this reaction.
7. The addition of H₂O to fumarate results in malate (4C). This is one of the few reactions in respiration that directly incorporates a water molecule.
8. Malate is dehydrogenated (with formation of a final NADH), and oxaloacetate is formed. This step brings the cycle back to its original starting position, where the oxaloacetate molecule is available to react with acetyl coenzyme A.

An important feature of this pathway is that acetyl groups from the breakdown of certain fats can enter the pathway at step one and be used as an energy source (discussed in section 8.5).

The full Krebs cycle is not present in all cells, and it may not function under all metabolic conditions. But even in cells with alternate metabolic schemes, it is essential for generating small organic molecules that microbes require for synthesis (look ahead to figure 8.25).

The Respiratory Chain: Electron Transport and Oxidative Phosphorylation

We now come to the energy chain, which is the final “processing mill” for electrons and protons. Overall, the electron transport system (ETS) consists of a chain of special carriers that receive electrons from reduced carriers (NADH, FADH₂) generated by glycolysis and the Krebs cycle. The ETS shuttles the electrons through a series of redox transfers (**figure 8.20**). The flow of electrons down this chain is highly energetic and ultimately drives the synthesis of ATP. The step that finalizes the transport process is the acceptance of electrons and hydrogen ions by oxygen, with the production of water.

Some variability exists from one organism to another, but the principal compounds that carry out these complex reactions are NADH dehydrogenase, iron-sulfide complexes (FeS), coenzyme Q (**ubiquinone**),* and several **cytochromes**.* The cytochromes contain a tightly bound metal atom at their center that is actively involved in accepting electrons and donating them to the next

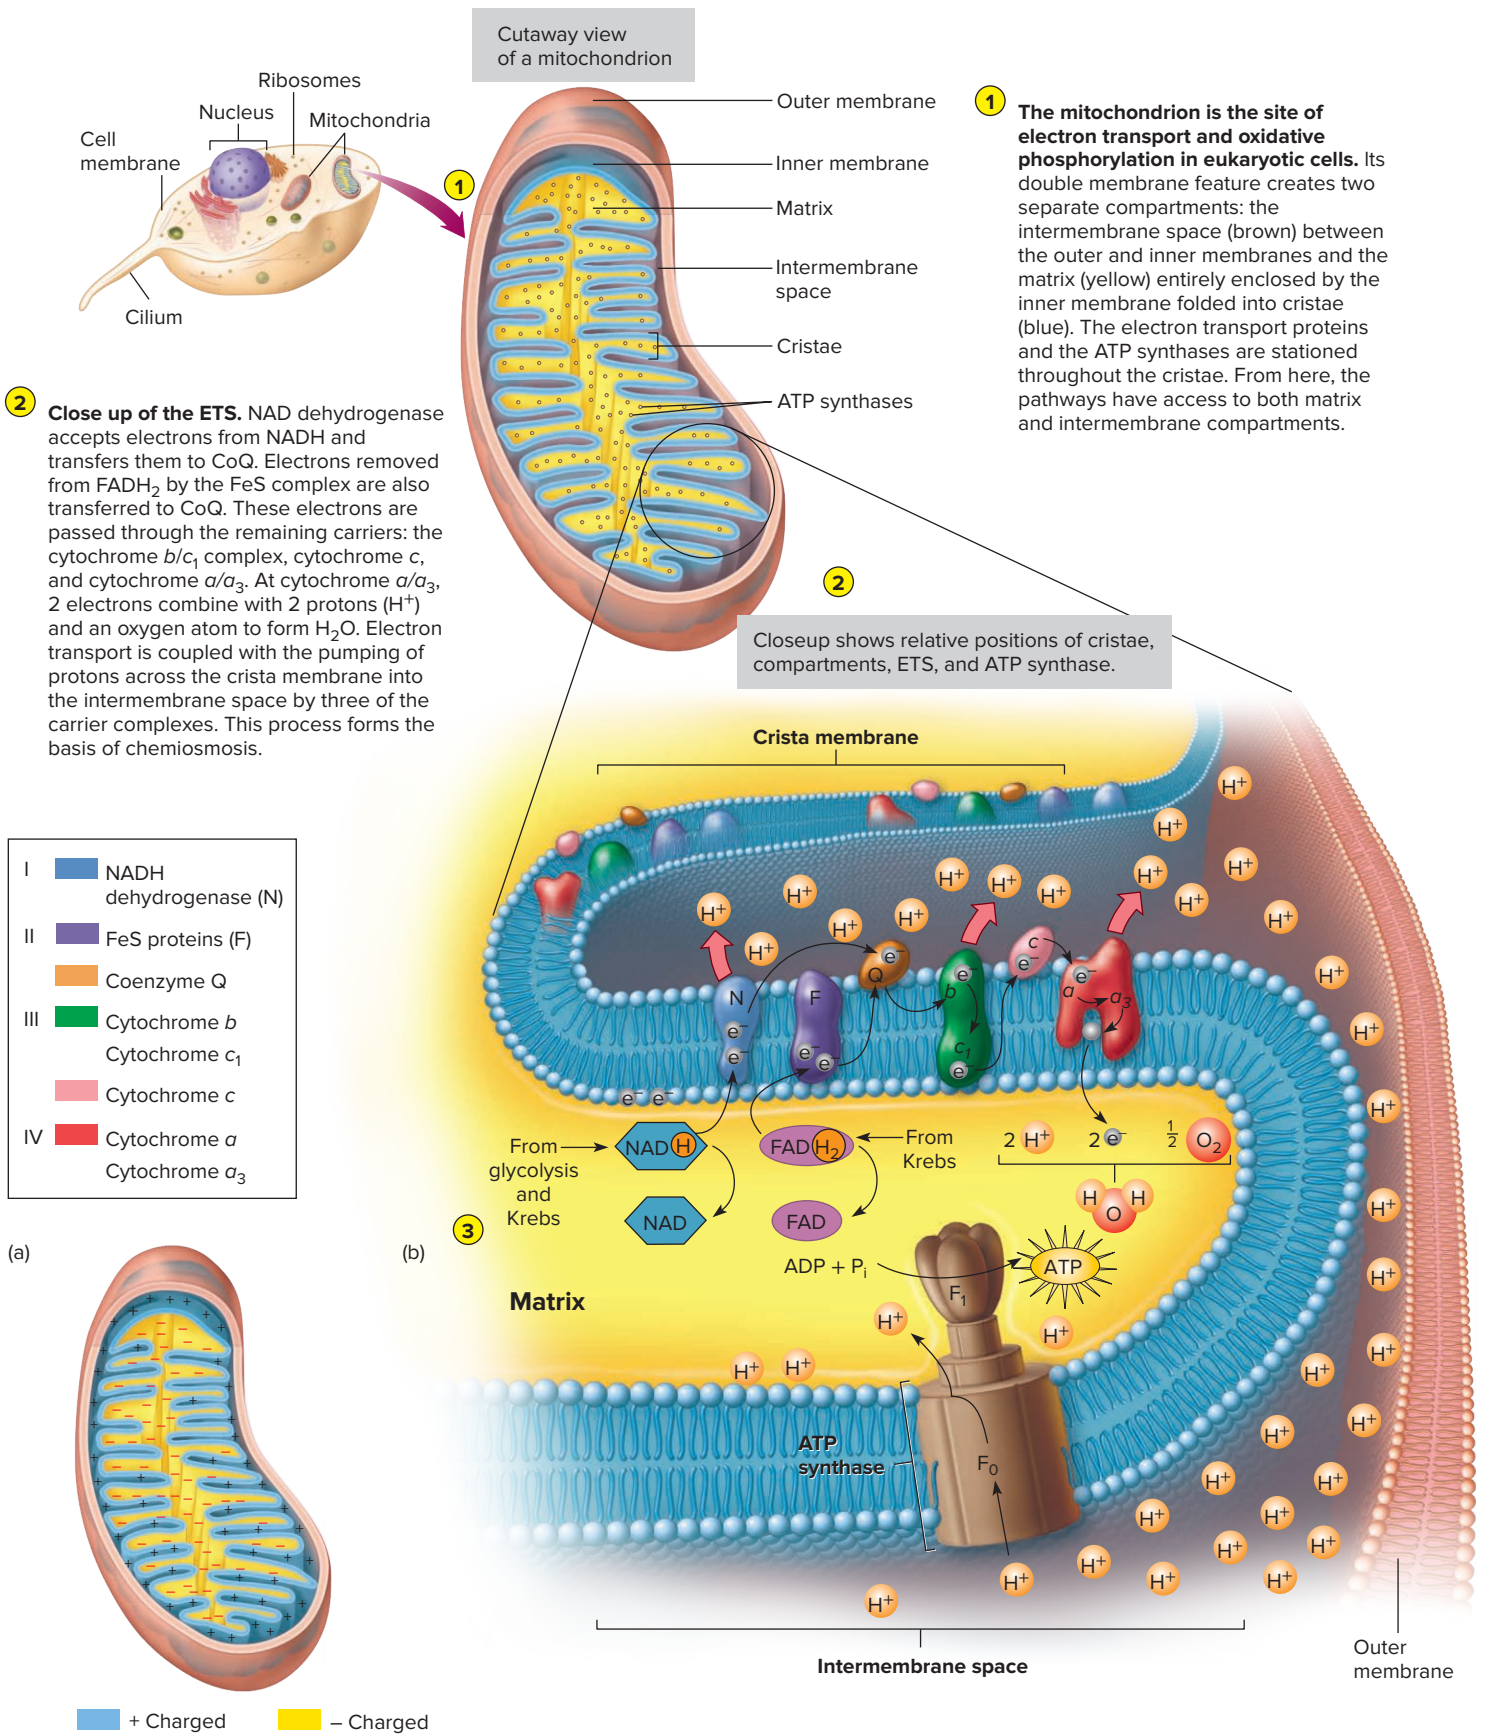

Figure 8.20 Electron transport, oxidative phosphorylation, the proton motive force, chemiosmosis, and ATP synthesis in the mitochondrion.

carrier in the series. The highly compartmentalized structure of the respiratory chain is an important factor in its function. Note in figure 8.20 that the electron transport carriers and enzymes are associated in complexes in the inner mitochondrial membranes in eukaryotes. The cell membrane is the equivalent structure for housing them in bacteria (figure 8.21).

The Carriers of Electron Transport: The Energy Cascade in the Mitochondria

The principal questions about the electron transport system are these: How are the electrons passed from one carrier to another in the series? How is this progression coupled to ATP synthesis? Where and how is oxygen utilized? Although the biochemical details of this process are somewhat complicated, the basic reactions consist of a number of redox reactions now familiar to us. In general, the carrier compounds and their associated enzymes are arranged in linear sequence and are reduced and oxidized while shuttling the electrons along to their final acceptor (figure 8.20, part 2).

The electron carrier complexes and associated molecules present in aerobic organisms are as follows:

1. **Complex I** consists of a huge multienzyme cluster termed NADH dehydrogenase (reductase), which receives the NADH from glycolysis and the Krebs cycle.
2. **Complex II** is made up of a series of iron-sulfur (FeS) proteins that receive electrons from FADH₂ produced in the sixth step of the Krebs cycle.
3. **Coenzyme Q**, or **ubiquinone**, is a mobile carrier not embedded in the membrane that can pick up electrons from both complexes I and II and donate them to complex III.
4. **Complex III** is comprised of cytochromes *b* and *c*₁, which deliver electrons to cytochrome *c*.
5. **Cytochrome *c*** is another mobile carrier that shuttles electrons between complexes III and IV.
6. **Complex IV** catalyzes the reaction between electrons, H⁺, and oxygen, yielding H₂O and completing the electron transport process.

In addition to the roles outlined here, complexes I, III, and IV have the additional function of pumping protons from the matrix into the intermembrane space to establish a charge gradient (discussed under the next heading). With each redox exchange, the energy level of the reactants is lessened. This free energy is captured and processed by **ATP synthase** complexes stationed in the cristae in close association with the ETS carriers. Each NADH that enters electron transport can potentially give rise to a maximum of 3 ATPs. Because FADH₂ from the Krebs cycle enters the cycle after complex I, its reactions result in a maximum yield of about 2 ATPs. This coupling of ATP synthesis to electron transport is termed **oxidative phosphorylation**.

The Formation of ATP and Chemiosmosis What biochemical processes are involved in coupling electron transport to the

production of ATP? According to a widely accepted concept called **chemiosmosis**, during electron transport, some of the carriers actively transport protons across the cristae membrane and into the intermembrane compartment of the mitochondrion. This process sets up a concentration gradient of hydrogen ions called the **proton motive force (PMF)**. The PMF consists of a difference in charge between the intermembrane compartment (+) and the matrix compartment (−) (figure 8.20, part 3).

Separating the charge has an effect similar to a battery, which can temporarily store potential energy. This charge will be maintained by the impermeability of the cristae membranes to protons (H⁺). The only sites where protons can diffuse into the matrix compartment is at the ATP synthase complexes, which sets the stage for ATP synthesis.

ATP synthase is one of the most remarkable enzymes in the molecular world. Its structure includes two motors, an ion pump, and an enzyme that can capture energy and store it as ATP. These synthases are located throughout the membranes of the cristae in high numbers (one estimate is around 10,000 per mitochondrion). Each ATP synthase complex consists of two large units, F₀ and F₁ (figure 8.20, part 3). The F₀ portion is embedded in the membrane and can rotate like a motor to pull in protons. As protons flow through the F₀ portion by diffusion, the F₁ compartments pull in ADP and P_i. Rotation induces a change in the three-dimensional structure of ATP synthase. This adjustment creates a high-energy bond between ADP and P_i. The ATP that forms is released into the matrix, where it will serve as a constant supply for cellular reactions (figure 8.20, part 3). The enzyme is then rotated back to the start position for the next round of ATP synthesis.

An important issue is just how the ATP is delivered out of the mitochondrion and into the cytoplasm for use in cell synthesis and other activities. The mitochondrial membranes are impregnated with a number of specialized active transporters called ATP-ADP translocases that constantly transport ATP out of, and ADP into, the mitochondrion.

Bacterial ATP synthesis occurs by means of this same overall process. However, bacteria have the ETS stationed in the cell membrane, and the direction of the proton movement is from the cytoplasm to the periplasmic space between the membrane and cell wall. Bacteria may also show variations in the number and types of electron carriers (figure 8.21). As we will see, these differences will affect the amount of ATP produced. In both cell types, the chemiosmotic theory has been supported by tests showing that oxidative phosphorylation is blocked if the mitochondrial or bacterial cell membranes are disrupted.

The Terminal Step of Electron Transport

The terminal step, during which oxygen accepts the electrons, is catalyzed by cytochrome *a/a*₃, also called cytochrome oxidase. This large enzyme complex is specifically adapted to receive electrons from cytochrome *c*, pick up hydrogen ions from solution, and react with oxygen to form a molecule of water (figure 8.20, part 3). This reaction, though in actuality more complex, is summarized as follows:

Most eukaryotic aerobes have a fully functioning cytochrome system, but bacteria exhibit wide-ranging variations in this part of the

Figure 8.21 Chemiosmosis in bacteria. Enlarged view of bacterial cell envelope to show the relationship of electron transport and ATP synthesis. Bacteria have the ETS carriers and ATP synthase stationed in the cell membrane. As the ETS shuttles electrons delivered by NADH and FADH_2 , some of the ETS carriers also transport protons into the periplasmic space between the membrane and the cell wall, which sets up a gradient similar to mitochondria. Bacteria will vary in the exact nature of the carriers in the ETS.

system. Some species lack one or more of the redox steps; others have several alternative electron transport schemes. Because many bacteria lack cytochrome oxidase, this variation can be used to differentiate among certain genera of bacteria. An oxidase detection test can be used to help identify members of the genera *Neisseria* and *Pseudomonas* and some species of *Bacillus*. Another variation in the cytochrome system is evident in certain bacteria (*Klebsiella*, *Enterobacter*) that can grow even in the presence of cyanide because they lack cytochrome oxidase. Cyanide will cause rapid death in humans and other eukaryotes because it blocks cytochrome oxidase, thereby completely terminating aerobic respiration, but it is harmless to these bacteria.

A potential side reaction of the respiratory chain in aerobic organisms is the incomplete reduction of oxygen to superoxide ion (O_2^-) and hydrogen peroxide (H_2O_2). As mentioned in chapter 7, these toxic oxygen products can be very damaging to cells. Aerobes have neutralizing enzymes to deal with these products, including *superoxide dismutase* and *catalase*. One exception is the genus *Streptococcus*, which can grow well in oxygen yet lacks both cytochromes and catalase. The tolerance of these organisms to oxygen can be explained by the neutralizing effects of a special peroxidase. The lack of cytochromes, catalase, and peroxidases in strict anaerobes as a rule limits their ability to process free oxygen and contributes to its toxic effects on them.

Summary of Aerobic Respiration

Reviewing the summary equation for respiration, we are now in a position to estimate the theoretical total of ATP molecules arising from a single glucose molecule through a combination of substrate-level phosphorylation and oxidation of NADH and FADH_2 .

- There are 3 substrate-level reactions that give rise directly to ATP—2 in glycolysis and 1 in the Krebs cycle. Because these are happening **twice** for each event, they provide **6 ATPs** overall.
- There are **5 NADHs**—1 from glycolysis, 1 from pyruvic acid oxidation, and 3 from the Krebs cycle. Each NADH could

potentially power the synthesis of 3 ATPs, yielding $5 \times 3 = 15$ ATPs. Again, this happens **twice for each glucose** and could potentially generate **30 ATPs**.

- There is a single reaction in the Krebs cycle that yields FADH_2 , which can power synthesis of 2 ATPs, and multiplied by 2 provides **4 ATPs**.
- The theoretical total for ATP synthesis could be **6 + 30 + 4 = 40**; however, because the first and second reactions of glycolysis use up 2 ATPs, the **final net number** is **38 ATPs**.

We emphasize that these totals are theoretical because the yields for NADH and FADH_2 are lower when the actual conditions in cells are taken into account. It is likely that oxidation of each NADH^+ provides closer to 2.5 ATPs and oxidation of FADH_2 , about 1.75 ATPs. This will decrease the practical total to around **32 ATPs**. Another reason this total will be reduced for eukaryotic cells is that they must use active transport (and ATP) to carry the NADH from glycolysis into the mitochondrial cristae, bringing the total down to **30 ATPs** per glucose. Most prokaryotic cells probably produce even less ATP because they lack one or more of the carriers in the electron transport system or do not generate as much NADH. **Figure 8.22** charts the course of these calculations as they occur in the three phases of aerobic respiration.

No summary would be complete without considering three other key participants:

- Six carbon dioxide molecules are generated by reactions just prior to and during the Krebs cycle. These represent all of the carbons and oxygens from the original glucose molecule.
- Six oxygen molecules are consumed during the final transfer of electrons and hydrogens to cytochrome oxidase a_3 .
- Six water molecules are produced in electron transport and 2 in glycolysis, but because 2 are used in the Krebs cycle, this leaves a net number of 6.

Anaerobic Respiration

Some bacteria have evolved an anaerobic respiratory system that functions like the aerobic cytochrome system, except that it utilizes

*These compounds are processed by the electron transport system.

**This net figure accounts for total ATPs minus the 2 used in glycolysis and the doubling of the products after the split into 2 3C compounds in glycolysis.

Figure 8.22 Summary of aerobic metabolism products and ATP yields. Compare this figure with the original equation: $\text{Glucose (C}_6\text{H}_{12}\text{O}_6) + 6\text{O}_2 + 38\text{ADP} + 38\text{P}_i \rightarrow 6\text{CO}_2 + 6\text{H}_2\text{O} + 38\text{ATP}$.

oxygen-containing ions rather than free oxygen as the final electron acceptor. Of these, the nitrate (NO_3^-) and nitrite (NO_2^-) reduction systems are best known. The reaction in species such as *E. coli* is represented as follows:

The enzyme nitrate reductase catalyzes the removal of oxygen from nitrate, leaving nitrite and water as products. This reaction is the basis for a physiological test used in identifying certain bacteria.

Some species of *Pseudomonas* and *Bacillus* possess enzymes that can further reduce nitrite to nitric oxide (NO), nitrous oxide (N_2O), and even nitrogen gas (N_2). This process, called **denitrification**, is a very important step in recycling nitrogen in the biosphere. Other oxygen-containing nutrients reduced anaerobically by various bacteria are carbonates and sulfates.

Most obligate anaerobes use the NADH they generate during glycolysis and the Krebs cycle to reduce some compound other than

O_2 but still follow the oxidative phosphorylation pathway. Methanogens (described in chapter 7) reduce CO_2 or CO_3^- (carbonate) to CH_4 (methane gas), and certain sulfate bacteria reduce SO_4^{2-} to S (sulfide) or hydrogen sulfide gas (H_2S). Some use metals or organic compounds as the final electron acceptor. These microbes live in subterranean habitats such as swamps and deep oceanic vents that are devoid of O_2 gas.

Check Your Progress SECTION 8.3

- Describe the basic energy strategies of microbes and the catabolic pathways they use.
- Compare and contrast the location of glycolysis, Krebs cycle, and electron transport in prokaryotic and eukaryotic cells.
- Outline the basic steps in glycolysis, indicating where ATP is used and where it is given off.
- Where does NADH originate, and what is its fate in an aerobe?
- What is the fate of NADH in a fermentative organism?
- Summarize the chemiosmotic theory of ATP formation.
- How many ATPs could *theoretically* be formed from a glucose molecule carried through aerobic respiration, and how many are *probably* formed?
- Why does the total of ATPs generated differ between bacteria and many eukaryotes?
- Name the sources of oxygen in bacteria that use anaerobic respiration.
- What are the final electron acceptors in aerobic, anaerobic, and fermentative metabolism?
- Describe the reaction between electrons, H^+ , and oxygen at the final step of electron transport.

8.4 The Importance of Fermentation

Expected Learning Outcomes

- Explain what is meant by the term *fermentation* and how fermentation is used by natural biological systems and biotechnology.
- Describe some of the processes of fermentation and the products that result.

Of all the results of pyruvate metabolism, probably the most varied is fermentation. Technically speaking, **fermentation*** is a process that involves (1) the incomplete oxidation of glucose or other carbohydrates in the absence of oxygen, (2) the oxidation of NADH to NAD^+ , which is essential to the continuation of the glycolytic pathway, (3) the use of organic compounds as the terminal electron acceptors, and (4) the release of a small amount of ATP.

Over time, the term *fermentation* has acquired several looser meanings. Originally Pasteur called the microbial action of yeast

* *fermentation* (fur-men-tay'-shun) L. *fervere*, to boil, or *fermentum*, leaven or yeast.

during wine production *ferments*, and to this day, biochemists use the term in reference to the production of ethyl alcohol by yeasts acting on glucose and other carbohydrates. Fermentation is traditionally what bacteriologists call the formation of acid, gas, and other products by the action of various bacteria on pyruvic acid. Industrial processes that produce chemicals on a massive scale through the actions of microbes are also called fermentations. Each of these usages is acceptable for one application or another.

It may seem that fermentation yielding only meager amounts of energy (2 ATPs maximum per glucose) would slow down growth. And yet the process is a common metabolic strategy among bacteria. What actually happens is that many bacteria can grow as fast as they would in the presence of oxygen. This rapid growth is made possible by an increase in the rate of glycolysis. From another standpoint, fermentation permits survival and growth in the absence of molecular oxygen and allows colonization of anaerobic environments. It also enables microorganisms with a versatile metabolism to adapt to variations in the availability of oxygen. For such facultative microbes, fermentation provides a means to function even when oxygen levels are too low for aerobic respiration or the usual electron acceptor is unavailable. An additional advantage of fermentation is that it generates a number of intermediates that can be used in **anabolic** pathways and shared within a population of microbes.

Bacteria that digest cellulose in the rumens of cattle and other ruminants are largely fermentative. After initially hydrolyzing cellulose to glucose, they ferment the glucose to organic acids, which are then absorbed as the bovine's principal energy source. Even human muscle cells can undergo a form of fermentation that permits short periods of activity after the oxygen supply in the muscle has been exhausted. Muscle cells convert pyruvic acid into lactic acid, which allows anaerobic production of ATP to proceed for a time. But this cannot go on indefinitely, and after a few minutes, the accumulated lactic acid causes muscle fatigue.

Products of Fermentation in Microorganisms

Alcoholic beverages (wine, beer, whiskey) are perhaps the most prominent among fermentation products; others are solvents (acetone, butanol), organic acids (lactic, acetic), dairy products, and many other foods. Derivatives of proteins, nucleic acids, and other organic compounds are fermented to produce vitamins, antibiotics, and even hormones such as hydrocortisone.

Fermentation products can be grouped into two general categories: alcoholic fermentation products and acidic fermentation products (**figure 8.23**). **Alcoholic fermentation** occurs in yeast or bacterial species that have metabolic pathways for converting pyruvic acid to ethanol. This process involves a decarboxylation of pyruvic acid to acetaldehyde, followed by a reduction of the acetaldehyde to ethanol. In oxidizing the NADH formed during glycolysis, NAD^+ is regenerated, thereby feeding back to and maintaining the glycolytic pathway. These processes are crucial in the production of beer and wine, though the actual techniques for arriving at the desired amount of ethanol and the prevention of unwanted side reactions are important tricks of the brewer's trade (**8.4 Making Connections**). Note that the

Figure 8.23 The fermentation systems that produce acid and alcohol. In both cases, the final electron acceptor is an organic compound. In yeasts, pyruvic acid is decarboxylated to acetaldehyde and CO_2 , and the NADH given off in the glycolytic pathway reduces acetaldehyde to ethyl alcohol. In homolactic fermentative bacteria, pyruvic acid is reduced by NADH to lactic acid. Both systems regenerate NAD^+ to feed back into glycolysis or other cycles (pink dotted lines).

products of alcoholic fermentation include both ethanol and CO_2 , a gas that accounts for the bubbles in champagne and beer and the rising of bread dough.

Alcohols other than ethanol can be produced during bacterial fermentation pathways. Certain clostridia produce butanol and isopropanol through a complex series of reactions. Although this process was once an important source of alcohols for industrial use, it has been largely replaced by a nonmicrobial petroleum process.

The pathways of **acidic fermentation** are extremely varied. Lactic acid bacteria ferment pyruvate in the same way that humans do—by reducing it to lactic acid. If the product of this fermentation is mainly lactic acid, as in certain species of *Streptococcus* and *Lactobacillus*, it is termed *homolactic*. The souring of milk is due largely to the production of this acid by bacteria. When glucose is fermented to a mixture of lactic acid, acetic acid, and carbon dioxide, as is the case with *Leuconostoc* and other species of *Lactobacillus*, the process is termed *heterolactic fermentation*.

Many members of the family Enterobacteriaceae (*Escherichia*, *Shigella*, and *Salmonella*) possess enzyme systems for converting pyruvic acid to several acids simultaneously (**figure 8.24**). **Mixed**

8.4 MAKING CONNECTIONS

Pasteur and the Wine-to-Vinegar Mystery

The microbiology of alcoholic fermentation was greatly clarified by Louis Pasteur after French winemakers hired him to uncover the causes of periodic spoilage in wines. Especially troublesome was the conversion of wine to vinegar and the resultant sour flavor. Up to that time, wine formation had been considered strictly a chemical process. After extensively studying beer making and wine grapes, Pasteur concluded that wine, both fine and not so fine, was the result of microbial action on the juices of the grape and that wine “disease” was caused by contaminating organisms that produced undesirable products such as acid. Although he did not know it at the time, the bacterial contaminants responsible for the acidity of the spoiled wines were likely to be *Acetobacter* or *Gluconobacter* introduced by the grapes, air, or wine-making apparatus. These common gram-negative genera further oxidized ethanol to acetic acid and are presently used in production of some types of vinegar. The following formula shows how this is accomplished:

Pasteur’s far-reaching solution to the problem is still with us today—mild heating, or *pasteurization*, of the grape juice to destroy the contaminants, followed by inoculation of the juice with a pure yeast culture. The topic of pasteurization is explored further in chapter 11.

© Kathy Park Talaro

An analysis of wine shows that it contains, in addition to water and ethyl alcohol, thousands of other chemical compounds (see “Wine Chemistry” on Wikipedia). What does this tell you about the metabolism of yeasts during alcoholic fermentation? Answer available on Connect.

acid fermentation produces a combination of acetic, lactic, succinic, and formic acids, and it lowers the pH of a medium to about 4.0. *Propionibacterium* produces primarily propionic acid, which gives the characteristic flavor to Swiss cheese; gas (CO_2) from the same fermentation reaction produces the holes. Some members also further decompose formic acid completely to carbon dioxide and hydrogen gases. Because enteric bacteria commonly occupy

the intestine, this fermentative activity accounts for the accumulation of some types of gas—primarily CO_2 and H_2 —in the intestine. Some bacteria reduce the organic acids and produce the neutral end product 2,3-butanediol. Several of these end products are the basis of biochemical tests described in chapter 17.

We have provided only a brief survey of fermentation products, but it is worth noting that microbes can be harnessed to synthesize

Figure 8.24 Miscellaneous products of pyruvate fermentation and some of the bacteria involved in their production.

a variety of other substances by varying the raw materials provided them. In fact, so broad is the meaning of the word *fermentation* that the large-scale industrial syntheses by microorganisms are not technically fermentations and often utilize entirely different mechanisms from those described here. They even occur aerobically, particularly in antibiotic, hormone, vitamin, and amino acid production, but they still produce a valuable commercial product.

Check Your Progress SECTION 8.4

24. What adaptive advantages does a fermentative metabolism confer on a microbe?
25. Describe three patterns of fermentation typical of microbes.

8.5 Biosynthesis and the Crossing Pathways of Metabolism

Expected Learning Outcomes

21. Explain how cells perform anabolic functions and what is involved in amphibolism.
22. Identify major pathways where molecules can be redirected or converted into useful cell products.
23. Briefly describe several mechanisms in biosynthesis of macromolecules.

Our discussion now turns from catabolism and energy extraction to anabolic functions and biosynthesis. In this section, we will explore this area, also called intermediary metabolism, that includes amphibolic pathways, the synthesis of simple molecules, and the synthesis of macromolecules.

The Frugality of the Cell—Waste Not, Want Not

It must be obvious by now that cells have mechanisms for careful management of carbon compounds. Rather than being dead ends, most catabolic pathways contain strategic molecular intermediates (metabolites) that can be diverted into anabolic pathways. In this way, a given molecule can serve multiple purposes, and the maximum benefit can be derived from all nutrients and metabolites of the cell pool. The property of a system to integrate catabolic and anabolic pathways to improve cell efficiency is termed **amphibolism**.*

* *amphibolism* (am-fee-bol'-izm) Gr. *amphi*, two-sided, and *bole*, a throw.

At this point in the chapter, you can appreciate a more complex view of metabolism than that presented at the beginning in figure 8.1. **Figure 8.25** demonstrates the amphibolic nature of intermediary metabolism. The pathways of glucose catabolism are an especially rich “metabolic marketplace.” The principal sites of amphibolic interaction occur during glycolysis (glyceraldehyde-3-phosphate and pyruvic acid) and the Krebs cycle (acetyl coenzyme A and various organic acids).

Amphibolic Sources of Cellular Building Blocks

Glyceraldehyde-3-phosphate can be diverted away from glycolysis and converted into precursors for amino acid, carbohydrate, and triglyceride (fat) synthesis. (A precursor molecule is one that gives rise to a different compound.) Earlier, we noted the numerous directions that pyruvic acid catabolism can take. In terms of synthesis, pyruvate also plays a pivotal role in providing intermediates for amino acids. In the event of an inadequate glucose supply, pyruvate serves as the starting point in glucose synthesis from various metabolic intermediates, a process called **gluconeogenesis**.*

* *gluconeogenesis* (gloo'-koh-nee'-oh-gen'-uh-sis) Literally, the formation of “new” glucose.

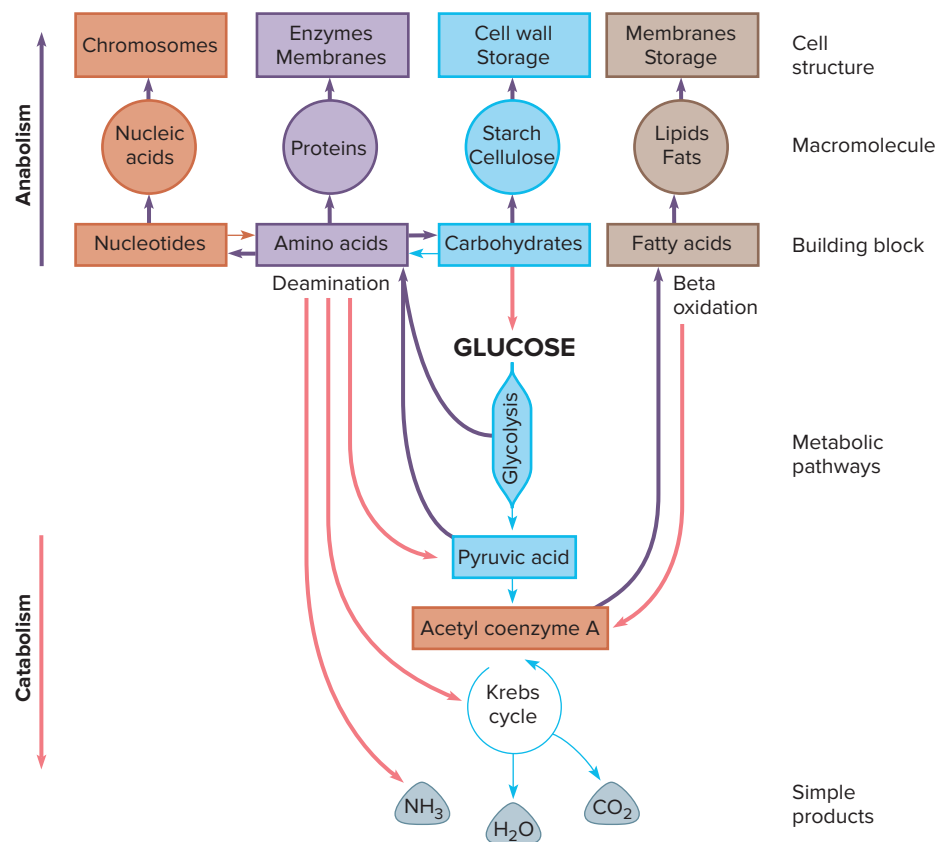

Figure 8.25 An amphibolic view of metabolism. Intermediate compounds such as pyruvic acid and acetyl coenzyme A serve multiple functions. With comparatively small modifications, these compounds can be converted into other compounds and enter a different pathway. Note that catabolism of glucose (center) furnishes numerous intermediates for anabolic pathways that synthesize amino acids, fats, nucleic acids, and carbohydrates. These building blocks can serve in further synthesis of larger molecules to construct a wide array of cell components.

Figure 8.26 Reactions that produce and convert amino acids. All of the reactions require energy as ATP or NADH and specialized enzymes. (a) Through amination (the addition of an ammonium molecule [amino group]), a carbohydrate can be converted to an amino acid. (b) Through transamination (transfer of an amino group from an amino acid to a carbohydrate), metabolic intermediates can be converted to amino acids that are in low supply. (c) Through deamination (removal of an amino group), an amino acid can be converted to a useful intermediate of carbohydrate catabolism. This is how proteins are used to derive energy. Ammonium is one waste product of deamination. Note that carbohydrate structures are in brown and amino acids are in blue.

The acetyl group that starts the Krebs cycle is another extremely versatile metabolite that can be fed into a number of synthetic pathways. This 2-carbon fragment can be converted as a single unit into one of several amino acids, or a number of these fragments can be condensed into hydrocarbon chains that are important building blocks for fatty acid and lipid synthesis. Note that the reverse is also true: Fats can be degraded to acetyl and thereby enter the Krebs cycle via acetyl coenzyme A. This aerobic process, called **beta oxidation**, releases significant energy. Oxidation of a 6-carbon fatty acid with glycerol potentially yields 50 ATPs, compared with 38 for a 6-carbon sugar.

Two carbohydrate metabolites from the Krebs cycle are oxaloacetic acid and α -ketoglutaric acid—essential intermediates in the synthesis of certain amino acids. This occurs through **amination**, the addition of an amino group to a carbon skeleton (**figure 8.26a**). A certain core group of amino acids can then be used to synthesize others. Amino acids and carbohydrates can be interchanged through **transamination** as well (**figure 8.26b**).

Pathways that synthesize the nitrogen bases (purines, pyrimidines), which are components of DNA and RNA, originate in amino acids and so can be dependent on intermediates from the Krebs cycle as well. Because the coenzymes NAD^+ , NADP , FAD , and others contain purines and pyrimidines similar to the nucleic acids, their synthetic pathways are also dependent on amino acids. During times of carbohydrate deprivation, organisms can likewise convert amino acids to intermediates of the Krebs cycle by **deamination**

(removal of an amino group) and thereby derive energy from proteins. Deamination results in the formation of nitrogen waste products such as ammonium ions or urea (**figure 8.26c**).

Formation of Macromolecules

Monosaccharides, amino acids, fatty acids, nitrogen bases, and vitamins—the building blocks that make up the various macromolecules and organelles of the cell—come from two possible sources. They can enter the cell from the outside as nutrients, or they can be synthesized through various cellular pathways. The degree to which an organism can synthesize its own building blocks (simple molecules) is determined by its genetic makeup, a factor that varies tremendously from group to group. In chapter 7 you learned that autotrophs require only CO_2 as a carbon source, a few minerals to synthesize all cell substances, and no organic nutrients. Even some heterotrophic organisms (*E. coli*, yeasts) are so metabolically complete that they can synthesize all cellular substances from minerals and one organic carbon source such as glucose. Compare this with a strict parasite lacking or having lost significant synthetic capabilities and having to obtain most essential nutrient molecules from its host.

Whatever their source, once these building blocks are added to the metabolic pool, they are available for synthesis of polymers by the cell. The details of synthesis vary among the types of macromolecules, but all of them involve the formation of bonds by specialized enzymes and the expenditure of ATP.

Carbohydrate Biosynthesis

The role of glucose in bioenergetics is so crucial that its biosynthesis is ensured by several alternative pathways. Certain structures in the cell depend on an adequate supply of glucose as well. It is the major component of the cellulose cell walls of some eukaryotes and of certain storage granules (starch, glycogen). One of the intermediaries in glycolysis, glucose-6-P, is used to form glycogen. Monosaccharides other than glucose are important in the synthesis of bacterial cell walls. Peptidoglycan contains a linked polymer of muramic acid and glucosamine. Fructose-6-P from glycolysis is used to form these two sugars. Carbohydrates (deoxyribose, ribose) are also essential building blocks in nucleic acids. Polysaccharides are the predominant components of cell surface structures such as capsules and the glycocalyx, and they are commonly found in slime layers (dextran is an example). Remember that most polymerization reactions occur via loss of a water molecule (see figure 2.16) and the input of energy.

Assembly of the Cell

The component parts of a bacterial cell are being synthesized on a continuous basis, and catabolism is also taking place, as long as nutrients are present and the cell is in a nondormant state. When anabolism produces sufficient macromolecules, and when DNA replication produces duplicate copies of the cell's genetic material, the cell undergoes binary fission. The two new cells will need twice as many ribosomes, twice as many enzymes, and so on. The cell has created these during the initial anabolic phases we have described. Before cell division, the membrane(s) and the cell wall will have increased in size to create a cell that is almost twice as big as a “new-born” cell. Once synthesized, the phospholipid bilayer components of the membranes assemble themselves spontaneously, but proteins and other components must be added to the membranes. Growth of the cell wall, accomplished by the addition and coupling of sugars and peptides, requires energy input. The catabolic processes provide constant energy for these complex building reactions.

8.6 Photosynthesis: The Earth's Lifeline

Expected Learning Outcomes

24. Outline the general reactions of photosynthesis and the importance it holds for the energetics of life.
25. Describe the pigment systems and how they function.
26. Describe the main events in the light-dependent reactions and the products that result.
27. Describe the main events in the light-independent reactions and the products that result.

As mentioned earlier, the ultimate source of most of the chemical energy in cells is the sun. Because this source is *directly* available only to the cells of photosynthesizers, most organisms on earth are either directly or indirectly dependent on photosynthesis, except for a few chemoautotrophs that derive their energy and nutrients solely from inorganic substrates. The other major products of photosynthesis are organic carbon compounds, which are produced from carbon dioxide through a process called **carbon fixation**. On land, green plants are the primary photosynthesizers; and in aquatic ecosystems, where 80% to 90% of all photosynthesis occurs, this role is filled by algae, cyanobacteria, and green sulfur, purple sulfur, and purple nonsulfur bacteria.

The summary equation for the main reactants and products of photosynthesis in aerobic organisms is

The anatomy of photosynthetic cells is adapted to trapping sunlight, and their physiology effectively uses this solar energy to produce high-energy glucose from low-energy CO₂ and water. Photosynthetic organisms achieve this remarkable feat through a series of reactions involving light, pigment, CO₂, and water, which is used as a source for electrons.

Photosynthesis proceeds in two phases: the **light-dependent reactions**, which proceed only in the presence of light waves, and the **light-independent reactions**, which can operate without direct exposure to light, but are still reliant on the energy molecules made in the light-dependent reactions (**figure 8.27**).

Solar energy is delivered in discrete energy packets called **photons** (also called quanta) that travel as waves. The wavelengths of light operating in photosynthesis occur in the visible spectrum between 400 nanometers (violet) and 700 nanometers (red) and above. As this light strikes photosynthetic pigments, some wavelengths are absorbed, some pass through, and some are reflected. The activity that has the greatest impact on photosynthesis is the absorbance of light by photosynthetic pigments. These include the **chlorophylls**, which are green; **carotenoids**, which are yellow, orange, or red; and **phycobilins**, which are red or blue-green.³ By far the most important of these pigments are the chlorophylls, which contain a *photocenter* that consists of a magnesium atom held in the center of a complex ringed molecule called a *porphyrin* (**figure 8.28, part 3**). As we will see, the chlorophyll molecule harvests the energy of photons and converts it to electron (chemical) energy. Accessory photosynthetic pigments such as carotenes trap light energy and shuttle it to chlorophyll, thereby functioning like antennae. These light-dependent reactions are responsible for **photophosphorylation**,

3. The color of the pigment corresponds to the wavelength of light it reflects.

Figure 8.27 Overview of photosynthesis. The general reactions of photosynthesis, divided into two phases called light-dependent reactions and light-independent reactions. The light-dependent reactions involve two major events: (1) the trapping of light with a photosensitive pigment, such as chlorophyll, and converting the light energy into chemical energy in the form of ATP and NADPH; and (2) the splitting of water molecules with the release of oxygen gas. The light-independent reactions utilize ATP and NADPH produced during the light-dependent reactions to fix CO₂ into organic compounds such as glucose.

the channeling of energy extracted from light to make high-energy bonds of ATP. This sets the scene for the light-independent reactions, which use both ATP and NADPH for synthesis. During this phase, carbon atoms from CO₂ are fixed to the carbon backbones of organic molecules.

The detailed biochemistry of photosynthesis is beyond the scope of this text, but we will provide an overview of the general process as it occurs in green plants, algae and cyanobacteria. It is worth noting that many of the basic activities are biochemically similar to certain pathways of aerobic metabolism.

Light-Dependent Reactions

The systems that carry the photosynthetic pigments are also the sites for the light-dependent reactions. They occur in the **thylakoid** membranes of compartments called **grana** (singular, granum) in chloroplasts (**figure 8.28, part 1**) and in thylakoid layers of the cell

membranes of cyanobacteria (see figure 4.28c). These systems exist as two separate complexes called **photosystem I (PS700)** and **photosystem II (PS680)**⁴ (**figure 8.28, part 4**).

Both systems contain chlorophyll, but their chlorophylls are sensitive to different wavelengths: PS I absorbs longer wavelengths (above 680 nm) and PS II absorbs shorter wavelengths (680 nm and below), which efficiently covers the range of light to which phototrophs are exposed. Both photosystems are stationed in **antennae**—clusters of about 300 molecules of chlorophyll located in the thylakoid membranes. Antennae absorb light and convey it to **reaction centers**, where the light-dependent reactions take place (figure 8.28, part 4).

The chloroplast is composed of separate compartments similar to mitochondria. One compartment—the **stroma**—is the region surrounding the grana and thylakoids, and the other one is the space inside the thylakoids called the **lumen** (figure 8.28, part 4).

Overview of the Light-Dependent Reactions and Photophosphorylation

The thylakoids are specially situated to bring together all components of the light-dependent reactions. Most of these components are embedded in the thylakoid membranes and are accessible from both the lumen and the stroma. They include chlorophyll molecules and their photosystems (PS II and PS I)⁵; an oxygen-evolving complex; electron transport systems—consisting of a mobile electron carrier plastoquinone (PQ); cytochrome *b_f* complex; plastocyanin (PC), a second mobile electron carrier; ferredoxin (Fd) with nicotinamide adenine dinucleotide phosphate (NADP⁺) reductase (FNR); and ATP synthase. Several of the systems and their actions are very similar to those we previously examined in mitochondria.

The light-dependent pathway proceeds as follows:

PS II Reactions

1. When light strikes the magnesium in PS II, an electron becomes excited (is raised to a higher energy level) and is released by PS II to the first electron transport system.
2. An oxygen-evolving complex associated with PS II splits two water molecules into 4 electrons, 4 protons (H⁺), and oxygen. Because it occurs in the presence of light, this step is termed **photolysis**, and it results in **the first major product** of the light-dependent reactions—the **O₂ gas** required by all aerobic organisms, including even most photosynthesizers. In addition, the electrons released by photolysis return the PS II complex to a ground state so it is again ready to respond to light. Another important effect of photolysis is the release of protons into the lumen, which contributes to the chemiosmotic proton gradient so essential to ATP synthesis.

4. The numbers refer to the wavelength of light to which each system is most sensitive.

5. These numbers signify the order in which they were discovered, not the order of reactivity.

Process Figure 8.28 The location and participants in the light-dependent reactions of a chloroplast. (1) A cell of the algae, *Chlamydomonas*, with a cutaway view of a single chloroplast to show the internal structure of stroma and grana. (2) A granum consists of a stack of hollow membrane-bound discs called thylakoids, which house (3) the chlorophyll molecules, arranged in arrays (antennae) for capturing light. (4) The chlorophylls exist in separate systems called PS II and PS I, embedded in the thylakoid membrane. Other players in the process are an electron transport chain, an oxygen-evolving complex, a final electron acceptor (NADP $^+$), and ATP synthase. The text covers the main mechanisms of this process.

Electron Transport

1. An electron given off by PS II is picked up by the first compound of the electron transport chain—PQ—which moves it to the cytochrome b_f complex. From here, it is transported to plastocyanin and to the PS I complex.
2. An event coupled to electron transport is the delivery of protons (H^+) from the stroma side to the lumen side by the actions of the cytochrome b_f complex, which helps maintain the electrochemical gradient between the stroma and lumen.

PS I Reactions

1. When PS I is excited by light, it also releases an electron that will be transported through a different series of carriers. In addition, it picks up the electrons from PS II delivered by plastocyanin.
2. These electrons are shuttled to the final electron acceptors—ferredoxin and the FNR complex. The function of the FNR is to transfer 2 electrons (and 2 protons) to NADP^+ , converting it to **NADPH**. This is the **second major product** of the light-dependent reactions, one which provides reducing power for the light-independent reactions.

ATP Synthase and Photophosphorylation ATP synthase complexes are distributed throughout the thylakoid membranes. They have the same structure as those of mitochondria and they, too, capture the free energy inherent in the proton motive force to synthesize ATP. As protons flow through the F_0 portion of the synthase from the lumen to the stroma, the F_1 component pulls in ADP and P_i , releasing ATP, the **third major product** of the light reactions. You may notice that the energy-associated molecules (NADPH and ATP) are released in the stroma, which situates them for immediate use in the light-independent reactions covered in the next section.

Light-Independent Reactions

The anabolic reactions of photosynthesis occur in the stroma of a chloroplast or the cytoplasm of cyanobacteria. These reactions use energy produced by the light phase to synthesize glucose by means of the Calvin cycle (**figure 8.29**).

The cycle begins at the point where CO_2 is combined with a 5-carbon acceptor molecule with two terminal phosphates called ribulose-1,5-bisphosphate (**RuBP**). This first critical step in **carbon fixation** generates a 6-carbon intermediate compound that immediately splits into two 3-carbon molecules of 3-phosphoglyceric acid (PGA). The subsequent steps use ATP and NADPH generated by the photosystems to form high-energy intermediates. First, 2 ATPs are expended to add a second phosphate to 3-PGA, producing two molecules of 1,3-bisphosphoglyceric acid (BPG). This is followed by NADPH contributing its electrons to BPG with the removal of one high-energy phosphate. These events give rise to two glyceraldehyde-3-phosphate (G3P). This molecule and its isomer dihydroxyacetone phosphate (DHAP) are key compounds in hexose synthesis leading to fructose and glucose. Some of the G3P is conveyed to the remainder of the cycle, where it participates in the regeneration of RuBP. This involves numerous steps not

Figure 8.29 The Calvin cycle. This includes the main events of photosynthesis during which carbon is fixed into organic form using the energy (ATP and NADPH) released by the light reactions. The end product, glucose, can be stored as complex carbohydrates, or it can be used in various amphibolic pathways to produce other carbohydrate intermediates or amino acids. Some PGAL is used in the regeneration of RuBP, which uses additional ATP made during the light-dependent reactions.

depicted in figure 8.29. You may notice that this pathway is very similar to glycolysis, except that it runs in reverse (see figure 8.17).

Other Mechanisms of Photosynthesis

The **oxygenic**, or oxygen-releasing, photosynthesis described in the previous section occurs in plants, algae, and cyanobacteria and is the dominant type on the earth. Other photosynthesizers such as green and purple sulfur bacteria possess bacteriochlorophyll, which is more versatile in capturing light. They have only a cyclic photosystem I, which routes the electrons from the photo-center to the electron carriers and back to the photosystem again. This pathway generates a relatively small amount of ATP, and it may not produce NADPH. As photolithotrophs, these bacteria use H_2 , H_2S , or elemental sulfur rather than H_2O as a source of electrons and reducing

power. As a consequence, they are **anoxygenic** (non-oxygen-producing), and many are strict anaerobes.

CASE STUDY Part 2

Results of the tests were positive for the bacterium *Clostridium botulinum** type A, as well as its toxin, botulinum.* This finding, along with the symptoms, clearly confirmed the cases as botulism. Although the pathogen is quite sensitive to acid, the addition of water and other pH-neutral substances to the fruit-potato mixture probably maintained a low enough acid content to allow germination of *Clostridium* endospores and growth of its vegetative cells.

Botulinum neurotoxin is a complex protein molecule described as an AB toxin that consists of two functional parts (look ahead to chapter 13). It is transported in the bloodstream and carried to motor neurons in the muscles. One part of the toxin molecule (A) attaches to the membrane of the nerve cell and is transferred into the interior of the cell along with an enzyme component (B). B is a protease that hydrolyzes key secretory proteins, thereby blocking the release of a neurotransmitter (acetylcholine) from secretory vesicles. This

Molecule of botulinum toxin
Courtesy of Lacy, D.B., Tepp, W., Cohen, A.C., DasGupta, B.R., Stevens, R.C.

blockade prevents the muscle from receiving a chemical stimulus necessary for contraction. The result is the paralysis of many large muscles, including those of the jaw, skeleton, eyes, neck, and diaphragm.

Altogether, eight prisoners developed botulism, several with severe morbidity and breathing problems. The only effective treatment for botulism is antitoxin, a serum containing antibodies that attach to the toxin and inactivate it. To be most effective, it must be given early on. Four inmates required prolonged hospitalization and continued to have residual neurological and muscular symptoms for several months, but there were no fatalities. In the past, botulism was often a death sentence because it caused respiratory failure, but modern medical care and use of mechanical ventilation have greatly improved survival. Despite its extreme toxicity, this toxin formulated as “Botox” is applied to treat a wide variety of muscular disorders, migraines, and, of course, for temporary elimination of wrinkles.

- Why must the antitoxin be administered in the earliest phases of botulism?
- How could the inmates have prevented making such a toxic brew?

To conclude this Case Study, go to Connect.

* *Clostridium botulinum* (klawss-trih'-dee-um bawt'-yoo-ly'-num) Gr. *kloster*, spindle, and *idion*, of a shape; L. *botulus*, sausage, and *ismus*, the result of.

* *botulinum* This toxin is one of the most potent chemical compounds on earth.

Chapter Summary with Key Terms

8.1 An Introduction to Metabolism and Enzymes

A. Metabolism

- Metabolism** is the sum of biochemical activities in cells; it involves chemical changes to reactants and the release of products using well-established pathways.
- Metabolism is a complementary process consisting of **anabolism**, synthetic reactions that convert small

molecules into large molecules, and **catabolism**, in which large molecules are degraded. Together, they generate thousands of intermediate molecular states, called metabolites, which are regulated at many levels.

B. Enzymes: Metabolic Catalysts

- Metabolism is made possible by organic **catalysts**, or **enzymes**, that speed up reactions by lowering the

energy of activation. Enzymes are not consumed and can be reused. Each enzyme acts specifically upon its matching molecule or **substrate**.

2. *Enzyme Structure:* A conjugated enzyme consists of a protein component called the **apoenzyme** and one or more activators called **cofactors**.
3. *Enzyme Specificity:* Substrate attachment occurs in the special pocket called the **active**, or **catalytic, site**. In order to fit, a substrate must conform to the active site of the enzyme. This three-dimensional state is determined by the shape of the apoenzyme, making enzymes **substrate-specific**.
4. *Cofactors:* Metallic cofactors impart greater reactivity to the enzyme-substrate complex. **Coenzymes** such as **NAD⁺** (nicotinamide adenine dinucleotide) are transfer agents that pass functional groups from one substrate to another. Coenzymes usually contain **vitamins**.
5. *Enzyme Classification:* Enzyme names often consist of a prefix derived from the type of reaction or the substrate and the ending *-ase*.
6. *Microbial Enzymes and Disease:* Many pathogens secrete enzymes or toxins, which are referred to as virulence factors, that enable them to avoid host defenses.
7. *Types of Enzyme Function:* The release of water that comes with formation of new covalent bonds is a **condensation** reaction. **Hydrolysis** reactions involve addition of water to break bonds. Functional groups may be added, removed, or traded in many reactions. Coupled **redox reactions** transfer electrons and protons (H^+) from one substrate to another.
8. *Enzyme Sensitivity:* Enzymes are **labile** (unstable) and function only within narrow operating ranges of temperature, osmotic pressure, and pH; extreme conditions can cause **denaturation**. Enzymes are frequently the targets for physical and chemical agents used in control.

C. Regulation of Enzymatic Activity

Regulatory controls can act on enzymes directly or on the process that gives rise to the enzymes.

1. A substance that resembles the normal substrate and can occupy the same active site is said to exert **competitive inhibition**.
2. **Allosteric inhibition** occurs when a substance binds to a regulatory site and prevents substrate binding.
3. **Noncompetitive inhibition** occurs when the regulator molecule binds the enzyme-substrate complex and keeps a product from being formed.
4. The mechanisms of **enzyme repression** and **enzyme induction** exert control at the genetic level by controlling the synthesis of key enzymes.

8.2 The Pursuit and Utilization of Energy

A. Cell Energetics

Energy is the capacity of a system to perform work. It is consumed in **endergonic reactions** and is released in **exergonic reactions**.

B. A Closer Look at Biological Oxidation and Reduction

1. Extracting energy requires a series of electron carriers arrayed in a downhill redox chain between electron donors and electron acceptors.
2. **NAD⁺** is the primary carrier of electrons from one pathway to another.

3. In **substrate-level** and **oxidative phosphorylation**, energy is transferred to high-energy compounds such as ATP.

8.3 Pathways of Bioenergetics

A. Pathways in Aerobic Respiration

These use oxygen as a final electron acceptor and glucose as the electron and energy source. The three pathways involved are glycolysis, the Krebs cycle, and electron transport.

1. **Glycolysis** is a pathway that degrades glucose to **pyruvic acid** without requiring oxygen.

2. Pyruvic acid is an important key molecule in several catabolic and anabolic pathways.

B. Fate of Pyruvic Acid in Krebs Cycle and Electron Transport

1. Pyruvic acid is completely metabolized via the **Krebs cycle** and its associated electron transport chain.
2. **Acetyl coenzyme A** is the initial product of pyruvic acid processing that undergoes further oxidation and decarboxylation in the Krebs cycle and generates ATP, CO_2 , and H_2O .
3. The respiratory chain carries electrons that support final energy extraction.
4. The **chemiosmotic** theory and **proton motive force** are conceptual models that explain the origin and maintenance of electropotential gradients across a membrane that leads to ATP synthesis by **ATP synthase**.
5. The final electron acceptor in aerobic respiration is oxygen. In **anaerobic respiration**, compounds such as sulfate, nitrate, or nitrite serve this function. Bacteria serve as important agents in the nitrogen cycle (**denitrification**).

8.4 The Importance of Fermentation

- A. **Fermentation** is based on the glycolysis pathway in which both the electron donor and final electron acceptors are organic compounds. It is an essential source of **NAD⁺** required for electron transport.
- B. Fermentation enables anaerobic and facultative microbes to survive in environments devoid of oxygen. Production of alcohol, vinegar, and certain industrial solvents relies upon fermentation.

8.5 Biosynthesis and the Crossing Pathways of Metabolism

A. Amphibolism

The ability of a cell or system to integrate catabolic and anabolic pathways to improve efficiency is called **amphibolism**.

B. Anabolism: Formation of Macromolecules

Macromolecules, such as proteins, carbohydrates, and nucleic acids, are made of building blocks from two possible sources: from outside the cell (preformed) or via synthesis in one of the anabolic pathways.

C. Versatility of Glycolysis and Krebs Cycle

Glycolysis and the Krebs cycle are central pathways that link catabolic and anabolic pathways, allowing cells to break down different classes of molecules in order to synthesize compounds required by the cell.

1. Metabolites of these pathways double as building blocks and sources of energy. Intermediates such as pyruvic acid are convertible into amino acids through **amination**. Amino acids can be **deaminated** and used as a source of glucose and other carbohydrates (**gluconeogenesis**).
2. Two-carbon acetyl molecules from pyruvate **decarboxylation** can be used in fatty acid synthesis.

8.6 Photosynthesis: The Earth's Lifeline

Photosynthesis takes place in two stages—**light-dependent** and **light-independent reactions**.

- A. During the light-dependent reactions, **photons** of solar energy are absorbed by **chlorophyll** and other pigments in **thylakoid** membranes of **chloroplast grana** in eukaryotes and the cell membrane in cyanobacteria. Light energy is captured by two photosystems (**PS II** and **PS I**), and water is split by **photolysis**. This releases oxygen gas. The light energy harvested by photosystems becomes the chemical energy of electrons; electron transport energy is stored in NADPH and ATP; ATP is formed through

photophosphorylation and chemiosmosis. Light energy is used to synthesize ATP and NADPH.

- B. The **Calvin cycle** (light-independent) occurs in the **stroma** of chloroplasts and uses ATP to **fix** carbon dioxide to a carrier molecule, ribulose-1,5-bisphosphate, and convert it to glucose in a multistep process.
- C. The type of photosynthesis commonly found in plants, algae, and cyanobacteria is called **oxygenic** because it liberates molecular oxygen as a by-product of the light-dependent reactions. **Anoxygenic** photosynthesis occurs in photolithotrophs, which do not produce oxygen.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

- _____ is another term for biosynthesis.
 - Catabolism
 - Anabolism
 - Metabolism
 - Catalyst
- Catabolism is a form of metabolism in which _____ molecules are transformed into _____ molecules.
 - larger, smaller
 - smaller, larger
 - amino acid, protein
 - glucose, starch
- An enzyme _____ the activation energy required for a chemical reaction.
 - increases
 - converts
 - lowers
 - catalyzes
- An enzyme
 - becomes part of the final products
 - is nonspecific for substrate
 - is consumed by the reaction
 - is heat and pH labile
- An apoenzyme is where the _____ is located.
 - cofactor
 - coenzyme
 - redox reaction
 - active site
- Many coenzymes contain
 - metals
 - vitamins
 - proteins
 - substrates
- To digest cellulose in its environment, a fungus produces a/an
 - endoenzyme
 - exoenzyme
 - catalase
 - polymerase
- Energy in biological systems is primarily
 - electrical
 - chemical
 - radiant
 - mechanical
- Energy is carried from catabolic to anabolic reactions in the form of _____.
 - ADP
 - high-energy ATP bonds
 - coenzymes
 - inorganic phosphate
- Exergonic reactions
 - release potential energy
 - consume energy
 - form bonds
 - occur only outside the cell
- A reduced compound is
 - NAD⁺
 - FAD
 - NADH
 - ADP
- Most oxidation reactions in microbial bioenergetics involve the
 - removal of electrons
 - addition of electrons
 - addition of oxygen
 - removal of oxygen
- A product or products of glycolysis is/are
 - ATP
 - pyruvic acid
 - CO₂
 - both a and b
- Fermentation of a glucose molecule has the potential to produce a net number of _____ ATPs.
 - 4
 - 2
 - 38
 - 32
- Complete oxidation of glucose in aerobic respiration by a eukaryote could potentially yield a net maximum output of _____ ATPs.
 - 40
 - 30
 - 38
 - 2
- The compound that enters the Krebs cycle is
 - citric acid
 - oxaloacetic acid
 - pyruvic acid
 - acetyl coenzyme A
- The FADH₂ formed during the Krebs cycle enters the electron transport system at which site?
 - NADH dehydrogenase
 - complex II
 - complex IV
 - ATP synthase
- The proton motive force is the result of
 - ATP synthase transporting protons during ATP synthesis
 - an electron gradient between the matrix and the intermembrane space of a mitochondrion
 - a proton gradient between the matrix and intermembrane space of a mitochondrion
 - a buildup of negatively charged ions

19. Photosynthetic organisms convert the energy of _____ into chemical energy.
- electrons
 - protons
 - photons
 - hydrogen atoms
20. The Calvin cycle operates during which part of photosynthesis?
- only the light-dependent phase
 - only in the dark
 - the light-independent phase
 - only during photosystem I
21. The oxygen produced by photosynthesis comes from:
- CO₂
 - NO₃
 - H₂O
 - glucose
22. **Multiple Matching.** Match the process a, b, or c with the metabolic events in the list.
- glycolysis
 - Krebs cycle
 - electron transport/oxidative phosphorylation
- _____ H⁺ and e⁻ are delivered to O₂ as the final acceptor.
 _____ Pyruvic acid is formed.
 _____ ATP is formed.
 _____ H₂O is produced.
 _____ CO₂ is formed.
 _____ Fructose diphosphate is split into two 3-carbon fragments.
 _____ NADH is oxidized.
 _____ ATP synthase is active.

Case Study Review

- What is the most likely source of the botulism bacteria that grew in the prison wine?
 - fruit
 - air
 - potato
 - sugar
- Could other inmates develop botulism from being in contact with the ill prisoners?
 - Yes, it can be spread in body fluids.
 - No, a person must ingest the toxin.
 - Yes, it can be carried by inanimate objects.
 - No, *C. botulinum* bacteria cannot grow in human tissue.
- Describe the conditions of nutrition, pH, temperature, oxygen, and life cycle that made it possible for both the yeast and *Clostridium* to grow and synthesize their products in the pruno mixture.

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

- Discuss the relationship of
 - anabolism to catabolism
 - ATP to ADP
 - glycolysis to fermentation
 - electron transport to oxidative phosphorylation
- Give the general name of the enzyme that
 - converts citrate to isocitrate
 - reduces pyruvic acid to lactic acid
 - reduces nitrate to nitrite
- Explain what is unique about the actions of ATP synthase.
- Compare the general equation for aerobic metabolism (section 8.3) with the summary of aerobic metabolism (figure 8.22), verify the final totals of reactants and products, and indicate where they occur in the pathways.
- Describe four requirements required for fermentation to take place.
- Is fermentation catabolic or anabolic? Explain your choice.
- Name three electron carriers and the vitamins that are essential to their function. Explain what actions the electron carriers and their associated vitamins have in metabolic reactions.
- Explain the similarities and differences between anaerobic respiration and fermentation.

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps and a sample concept map for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

- Use the following graph to diagram the energetics of a chemical reaction, with and without an enzyme. Be sure to position reactants and products at appropriate points and to indicate the stages in the reaction and the energy levels.

- Explain what is meant by the “biochemical circle of life” that exists between phototrophs and heterotrophs.

- Explain how it is possible for certain microbes to survive and grow in the presence of cyanide, which would kill many other organisms.
- Suggest the advantages of having metabolic pathways staged in specific membrane or organelle locations rather than being free in the cytoplasm.
- Two steps in glycolysis are catalyzed by allosteric enzymes. These are: (1) step 2, catalyzed by phosphoglucosomerase, and (2) step 9, catalyzed by pyruvate kinase. Suggest what metabolic products might regulate these enzymes. How might one place these regulators in figure 8.17?
- Beer production requires an early period of rapid aerobic metabolism of glucose by yeast. Given that anaerobic conditions are necessary to produce alcohol, can you explain why this step is necessary?
- What would be the expected pHs of the matrix and intermembrane space of the mitochondrion? What about the stroma and thylakoid lumen of the chloroplast? Explain your answers.
- At which site in the mitochondrion and chloroplast do the ATP molecules collect after being made by ATP synthases, and what is the advantage of this?
- Explain the relationship between enzyme sensitivity and the adaptations microbes make to their environments
- Why wouldn't antibiotics work as therapy for botulism?

Visual Challenge

- From **chapter 7, figure 7.11** (reproduced below). Describe the likely metabolic strategies of the microbes growing in tubes 1 through 4. Specify the pathways, final electron acceptor, and end products.

© Terese M. Barta, Ph.D.

- Look at the two figure parts (a) and (b) from figure 8.8 (reproduced below), and explain what processes are depicted and what the results of the reactions will be.

CASE STUDY Part 1 At War with an Emerging Pathogen

A 55-year-old woman recovering from **lung transplant** surgery developed a case of pneumonia from a ventilator she needed for breathing. The bacteria isolated from her lungs were identified as *Acinetobacter baumannii*, a widespread resident of soil and water that has found its way into hospitals and long-term care facilities. Tests showed that all of the drugs available to treat the infection were ineffective against the pathogen—except for **colistin**. Early on, the drug appeared to be curing the infection, but after a few days it returned and the patient died of respiratory failure. Cultures taken late in the case detected a **new strain** of the infectious agent that had developed **resistance** to all known drugs, including colistin.

During the same period, several other patients in the ICU developed drug-resistant *A. baumannii* infections. This sudden outbreak of **health-care-associated infections** spurred an investigation by an infection control nurse, who took samples from multiple locations and cultured them. The **bacteria** were **isolated** from **nearly every possible source**, including medical devices, patient skin samples, bedding, hospital workers, the air, and room surfaces.

But this sort of problem with *A. baumannii* was not restricted to North America. A continent away in Iraq and Afghanistan, this same

microbe became one of the most **fearsome pathogens** to infect soldiers with **battle injuries**. In the case of a 55-year-old man who sustained a grenade injury while transporting soldiers, shrapnel penetrated his thigh and fractured the femur. When X rays revealed the presence of an infection in his broken bone, he was transported to a trauma hospital. Cultures of the **wound** isolated a **gram-negative coccobacillus** that was a different strain of *A. baumannii*. Testing indicated that it was **resistant** to all drugs except for a new type of drug called **tigecycline**. After a several weeks' course of tigecycline, the infection was resolved and the patient was released. Over time, so many soldiers suffered

battlefield-related infections by this ubiquitous pathogen that it was given the nickname “Iraqnobacter.”

- What are the probable origins of the pathogen, and what conditions increase its transmission in a hospital setting?
- What is the meaning of drug resistance from a genetic standpoint?

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

SCOPING OUT THE CHAPTER

You probably have at least some insight into the role of DNA in the heredity of all life forms on earth. DNA has sometimes been likened to a molecular blueprint or to a chemical language, and in a sense both of these comparisons are valid. The coded nature of DNA lays out a master plan detailing how a cell will construct new parts of itself. One could also say that the DNA code spells out a complete library of information for expression of cell structure and function. In this chapter our aim is to show you what it means to say “It’s in your DNA.”

Chromosomes and Genes:

Packages of DNA

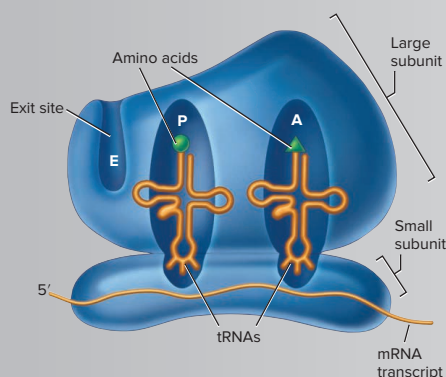

All cells tightly wind their elongate strands of DNA into compact chromosomes. Genes bearing specific codes are located at sites along the length of the chromosomes.

DNA Replication:

Copying the DNA Blueprint

The codes carried by DNA are conserved for offspring and future generations. This ensures that organisms will inherit the complete and accurate collection of genes required to survive and reproduce.

Transcription/translation: Interpreting the Blueprint

DNA acts as a model for assembling RNA copies of its codes. RNAs are transported to ribosomes to read the coded message and express it into useful cell proteins. A shorthand formula for this is: DNA→RNA→Protein.

Mutations: Changes in the DNA Code

Like any blueprint or language, mistakes can change the meaning of the DNA message, so that transcription and translation are unable to produce the intended protein, with a variety of outcomes, usually harmful.

Recombination: Transmission of DNA from One Cell to Another.

Some bacteria readily share their DNA codes with other bacteria and even with viruses, as seen in this small vignette. This results in bacteria with “new” genes and traits that help them adapt to changes in their environments.

9.1 Introduction to Genetics and Genes: Unlocking Secrets of Heredity

Expected Learning Outcomes

1. Define *heredity*, *genetics*, *genome*, *gene*, *phenotype*, and *genotype*.
2. Compare the basic nature of genetic material in eukaryotes, prokaryotes, and viruses.
3. Explain how DNA is organized and packaged.
4. Describe the chemical structure of DNA and its significance.
5. List the nitrogen bases and explain their bonding patterns.
6. Describe the process of DNA replication as it occurs in prokaryotic cells.

Genetics is the science that studies the inheritance of biological characteristics by life forms. This subject, also known as heredity, is a wide-ranging science that examines:

- the transmission of biological properties (traits) from parent to offspring,
- the expression and variation of those traits,
- the structure and function of the genetic material, and
- how this material changes or evolves.

The study of genetics takes place on several levels (**figure 9.1**). Organismal genetics looks at the transmission and expression of genetic factors in the whole organism or cell; chromosomal genetics examines the characteristics and actions of chromosomes; and molecular genetics deals with the biochemistry of gene function. All of these levels provide insight into microbial structure, physiology, evolution, and pathogenicity. It should also be noted that the study of microbial genetics will emphasize universal themes in the genetics of all organisms, and it will increase appreciation for the astounding advances in genetic engineering covered in chapter 10.

The Nature of the Genetic Material

Deoxyribonucleic acid or **DNA** serves as the foundation for most genetic studies. In order to appreciate and understand a broad range of genetic principles, it will be essential to develop a working knowledge of DNA's characteristics. With this in mind, we will use the first section of this chapter to lay some groundwork on DNA organization, structure, and duplication. This will be followed by coverage of related concepts such as RNA and protein synthesis, genetic control, mutations, and genetic recombination in the remaining five sections.

The Levels of Structure and Function of the Genome

The **genome** is the sum total of genetic material (DNA) carried within a cell. Although most of the genome exists in the form of chromosomes, genetic material can appear in nonchromosomal sites as well (**figure 9.2**). For example, bacteria and some fungi contain tiny extra pieces of DNA (**plasmids**), and the mitochondria and chloroplasts of eukaryotes are equipped with their own functional chromosomes. Genomes of cells are composed exclusively of DNA, but viruses contain either DNA or RNA as the principal genetic material. Although the specific genome of an individual organism is unique, the general pattern of nucleic acid structure and function is similar among all organisms and viruses.

In general, a **chromosome** is a discrete cellular structure composed of a neatly packaged DNA molecule. The chromosomes of eukaryotes and bacterial cells differ in several respects. The structure of eukaryotic chromosomes consists of a DNA molecule tightly wound around histone proteins, whereas a bacterial chromosome is condensed and secured into a packet by means of a different type of protein. Eukaryotic chromosomes are located in the nucleus; they vary in number from a few to hundreds; they can occur in pairs (diploid) or singles (haploid); and they are linear in format. In contrast, most bacteria have a single, circular chromosome, although some have multiple chromosomes and a few have linear chromosomes.

All chromosomes contain a series of basic informational “packets” called genes. A **gene** can be defined from more than one

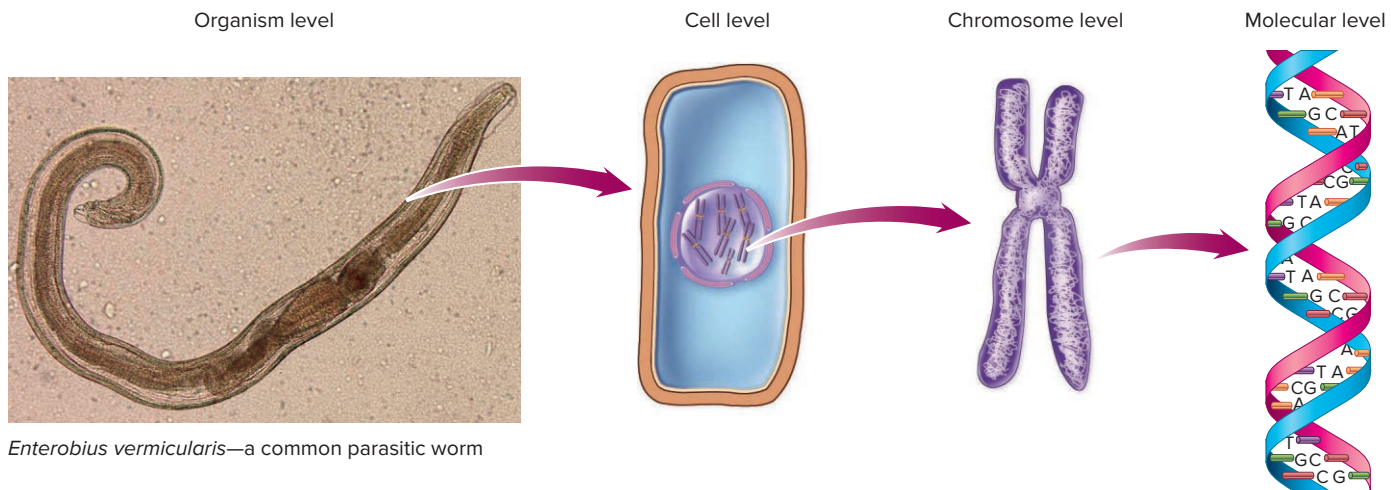

Figure 9.1 Levels of genetic study. Genetic processes can be observed at the levels of organism, cell, chromosome, and DNA sequence (molecular level). Although levels shown here are for a eukaryotic organism they would follow a similar pattern in prokaryotes.

Source: Image contributed by the Centre for Tropical Medicine and Imported Infectious Diseases, Bergen, Norway./CDC-DPDx

perspective. In classical genetics, the term refers to the fundamental unit of heredity responsible for a given trait in an organism. In the molecular and biochemical sense, it is a portion of the chromosome that provides information for a given cell function. More specifically still, it is a specific segment of DNA that contains the necessary codes to make a molecule of **protein** or **RNA**. This last definition of a gene is emphasized in this chapter.

Cells

Viruses

Figure 9.2 The general location and forms of the genome in two cell types and selected viruses (not to scale).

Genes fall into three basic categories: *structural genes* that code for proteins, genes that code for RNA, and *regulatory genes* that control gene expression. The collection of all of these types of genes constitutes an organism's distinctive genetic makeup, or **genotype**.* The expression of the genotype creates traits (certain structures or functions) referred to as the **phenotype**.* For example a person inherits a combination of genes (genotype) that gives a certain eye color or height (phenotype), a bacterium inherits genes that direct the formation of a flagellum or the ability to metabolize a certain substrate, and a virus has genes that dictate its capsid structure. All organisms contain more genes in their genotypes than are being seen as a phenotype at any given time. In other words, the phenotype can change depending on which genes are “turned on” or expressed.

The Size and Packaging of Genomes

Genomes vary greatly in size. Viruses have anywhere from a few to over a thousand genes; the bacterium *Escherichia coli* has a single chromosome containing 4,288 genes, and a human cell packs about five times that many into 46 chromosomes. The chromosome of *E. coli* would measure about 1 mm if unwound and stretched out linearly, and yet this fits within a cell that measures just over 1 μm across, making the stretched-out DNA 1,000 times longer than the cell (**figure 9.3**). Still, the bacterial chromosome takes up only about one-third to one-half of the cell's volume. Likewise, if the sum of all DNA contained in the 46 human chromosomes were unraveled and laid end to end, it would measure about 6 feet. How can such elongated genomes fit into the minuscule volume of a cell and, in the case of eukaryotes, into an even smaller compartment, the nucleus? The answer lies in the complex coiling of the DNA chain.

* *genotype* (jee'-noh-ty) Gr. *gennan*, to produce, and *typos*, type.

* *phenotype* (fee'-noh-ty) Gr. *phainein*, to show. The physical manifestation of gene expression.

Figure 9.3 A disrupted *Escherichia coli* cell. The cell has ejected its unraveled chromosome, which now appears as thin strings radiating around the outer surface (10,000 \times). These strings are the uncoiled DNA strand. © Dr. Jack Griffith

The Packaging of DNA

Packing the mass of DNA into the cell involves compacting the DNA molecule by means of supercoils or superhelices. In the simpler system of prokaryotes, the circular chromosome is packaged by the action of a special enzyme called a **topoisomerase** (specifically, DNA **gyrase**). This enzyme coils the chromosome into a tight bundle by introducing a reversible series of twists into the DNA molecule.

The system in eukaryotes is more complex, with three or more levels of coiling. First, the DNA molecule of a chromosome, which is linear, is wound twice around the histone proteins, creating a chain of **nucleosomes**. The nucleosomes fold in a spiral formation upon one another. An even greater supercoiling occurs when this spiral arrangement further twists on its radius into a giant spiral with loops radiating from the outside. This extreme degree of compactness is what makes the eukaryotic chromosome visible during mitosis (figures 9.4 and 5.6).

The condensation of DNA and protein into chromatin was once thought to function mainly as a way to fit such a long molecule into a cell. However, it is now evident that the coiling of DNA also serves to make certain segments of the genetic program either more or less available. This action provides a major control on the expression of many traits, especially in eukaryotes. Having an additional regulatory function creates an alternate mechanism to guide when and how genes are accessed. The realization that the phenotype of a cell is due to more than just the order of nucleotides in the DNA (genotype) has led to a rethinking of some of the most basic concepts of genetics (see 9.2 Making Connections).

Figure 9.4 Eukaryotic DNA interacts with a variety of proteins and small molecules. This relationship modulates the expression of many genes while at the same time allowing for the ordered condensation of DNA into a compact supermolecule.

The Structure of DNA: A Double Helix with Its Own Language

To analyze the structure of DNA at the molecular level, imagine being able to magnify a small piece of a gene about 5 million times. What you would see is one of the great marvels of life. The pieces of this molecular puzzle were finally worked out by James Watson and Francis Crick in 1953 (9.1 Making Connections). They determined that DNA is a giant molecule with two strands bound together into a double helix. Extensive evidence shows that the general structure of DNA is universal, except in some viruses that contain single-stranded DNA.

The basic unit of DNA structure is a **nucleotide**, composed of **phosphate**, **deoxyribose sugar**, and a **nitrogen base**, as shown in this simplified model (figure 9.5):

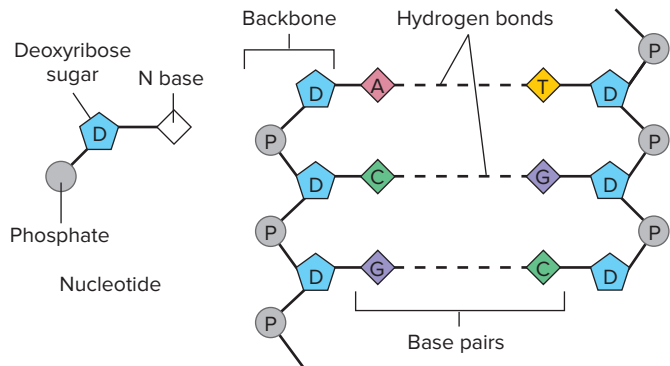

Figure 9.5 Simplified structure of DNA. Nucleotides stack together to form two opposing strands held together by hydrogen bonds between the base pairs.

Figure 9.6 lays out the structure of DNA going from general (a,b,c) to specific (d). To make the vertical sugar-phosphate backbones of the molecule, each deoxyribose sugar bonds covalently in a repeating pattern with two phosphates. One of the bonds is to the number 5' (read "five prime") carbon on deoxyribose, and the other is to the 3' (three prime) carbon. This pattern will format the direction of the strands, which run opposite to each other, as shown in figure 9.6d and discussed next.

The nitrogen bases—**purines** and **pyrimidines**—attach by covalent bonds at the 1' position of the sugar (figure 9.6c,d). When these nitrogen bases span the center of the molecule and bind with their complementary bases from the opposite strand, they form a double-stranded helix. The **paired bases** are held together by hydrogen bonds, which can be readily disrupted, allowing the molecule to be "unzipped" into two strands. This feature is of great importance in gaining access to the information encoded in the nitrogen base sequence. Pairing of purines and pyrimidines is not random; it is dictated by the structure of the bases and how they align to form hydrogen bonds. Thus, in DNA, the purine **adenine** (A) pairs with the pyrimidine **thymine** (T), and the purine **guanine** (G) pairs with the pyrimidine **cytosine** (C). Note that adenine forms two hydrogen bonds with thymine, and cytosine forms three hydrogen bonds with guanine. This difference will influence a number of DNA functions. Evidence also indicates that the bases are attracted to each other in this pattern because each base has a three-dimensional shape that conforms exactly to its mate. Although

9.1 MAKING CONNECTIONS

Deciphering the Structure of DNA

The search for the primary molecules of heredity was a serious focus throughout the first half of the twentieth century. At first many biologists thought that protein was the genetic material. An important milestone occurred in 1944 when Oswald Avery, Colin MacLeod, and Maclyn McCarty purified DNA and demonstrated at last that it was indeed the blueprint for life. This was followed by an avalanche of research, which continues today.

“We Have Discovered the Secret of Life!”*

One area of extreme interest concerned the molecular structure of DNA. In 1951, American biologist James Watson and English physicist Francis Crick collaborated on solving the DNA puzzle. Although they did little of the original research, they were intrigued by several findings from other scientists. It had been determined by Erwin Chargaff that any model of DNA structure would have to contain deoxyribose, phosphate, purines, and pyrimidines arranged in a way that would provide variation and a simple way of copying itself. Watson and Crick spent long hours constructing models with cardboard cutouts and kept alert for any and every bit of information that might give them an edge.

Two English biophysicists, Maurice Wilkins and Rosalind Franklin,* had been painstakingly collecting data on X-ray crystallographs of

* comment by Watson and Crick after publication of their monumental discovery.

* Unfortunately Dr. Franklin died before she could be properly recognized by receiving a Nobel Prize. Without her contributions, Watson and Crick could not have deciphered the puzzle as quickly as they did.

Dr. James Watson (left) and Dr. Francis Crick (right) stand next to their model that finally explained the structure of DNA in 1953.

© A. Barrington Brown/Science Source

DNA for several years. With this technique, molecules of DNA bombarded by X rays produce a photographic image that can predict the three-dimensional structure of the molecule. After Dr. Wilkins allowed them to view their data, Watson and Crick noticed an unmistakable pattern: The molecule appeared to be a double helix. In a short time the pieces of the puzzle fell into place and a final model was assembled—a model that explained all of the qualities of DNA, including how it is copied. Although Watson and Crick were hailed for the clarity of their solution, it must be emphasized that their success was built on the considerable efforts of a number of English and American scientists. This historic discovery spawned ingenious research in all areas of molecular genetics that is still ongoing.

Quick Search

Find out more of the story by googling “The Secret of Life: Discovery of DNA Structure.”

Since the discovery of the double helix in 1953, an extensive body of biochemical, microscopic, and crystallographic analysis has left little doubt that the model first proposed by Watson and Crick is correct. Scanning tunneling microscopes produce three-dimensional images of DNA that verify the helical shape and twists of DNA represented by models.

How did Watson and Crick’s model of DNA accurately fit the requirements needed to predict its structure? *Answer available on Connect.*

the base-pairing partners generally do not vary, the sequence of base pairs along the DNA molecule can assume any order, resulting in an infinite number of possible nucleotide sequences. One significant finding that has emerged from sequencing chromosomal DNA is how extremely long it can be for a single molecule. An average bacterial chromosome consists of 5 million to 6 million nucleotides; the 46 chromosomes (diploid) of humans total about 6.4 billion nucleotides.

Other important considerations of DNA structure concern the nature of the double helix itself. As indicated previously, one side of the helix runs in the opposite direction of the other, in what is called an *antiparallel arrangement*. Using the order of the bond between the carbon on deoxyribose and the phosphates, we see that one helix runs from the 5' to 3' direction and the other runs from the 3' to 5' direction (figure 9.6d). This characteristic is a significant factor in DNA synthesis, transcription, and translation. Although the DNA is constructed somewhat like a twisted ladder, it is not symmetrical. The curvature of the helix and the stepwise stack-

ing of the nitrogen bases produce two different-size surface features, the major and minor grooves (figure 9.7).

DNA Replication: Preserving the Code and Passing It On

For its long-term survival, a species must reproduce. In bacteria, this involves division of the cell by means of binary fission or budding, but it also involves the accurate duplication and separation of the genetic material into each daughter cell to ensure that each offspring receives a functional genome.

The sequence of bases along the length of DNA constitutes its “language.” For this language to be preserved for hundreds of generations, the codes it contains will need to be duplicated with high fidelity. This process of duplication is called **DNA replication**. In the following example, we will show replication in bacteria, but with some exceptions it generally applies to the process as it occurs in eukaryotes and some viruses. Recall from chapter 7 that early in

binary fission, the metabolic machinery of a bacterium is programmed to initiate the duplication of the chromosome. Despite its complexity, DNA replication can be very rapid: This must be completed in a single generation time (around 20 minutes in *E. coli*).

The Significance of DNA Structure

The pairing and arrangement of nitrogen bases in DNA has two profound and essential results:

1. Maintenance of the genetic message during reproduction.

The constancy of base-pairing guarantees that the correct order of the DNA bases will be retained during cell division. When the two strands are separated, each one provides a **template** (pattern or model) for the replication (exact copying) of a new molecule (figure 9.7). Because the sequence of one strand provides the correct pattern for its complementary strand, the codes can be duplicated with accuracy.

2. Providing variety. The order of bases along the length of the DNA strand provides information needed to produce RNA and protein molecules, which in turn are responsible for the **phenotype** of the cell. As we will see, changing the identity of the bases or their order in the DNA molecule can have a dramatic effect on the phenotype of the organism.

Figure 9.6 Levels of DNA structure. (a) A space-filling model of DNA shows its basic configuration as a double helix of sugar-phosphate backbones holding the nitrogen bases between them. (b) The twisted ladder model depicts how the complementary nitrogen bases (bars) pair with each other across the center of the molecule. (c) A schematic lays out the basic chemical makeup and bonding pattern of the molecule. (d) A more detailed view of the base pairs, hydrogen bonds, and the antiparallel arrangement of the two helices. Note that in one strand, the deoxyribose-phosphate runs in the 5' to 3' direction and the other side is oriented from 3' to 5'.

It is remarkable how such a seemingly simple set of codes can account for the extreme differences among forms as diverse as a virus, a bacterium, and a human. We know that the English language, based on 26 letters, can create an infinite variety of words, but how can an apparently complex genetic language such as DNA be based on just four nitrogen base “letters”? The answer lies in the fact that the four bases of DNA are arranged into much longer sequences. An average bacterial gene may contain 1,000 nucleotides: so while DNA is made up of fewer “letters,” they are arranged into much longer “words.” Mathematically speaking, 1,000 nucleotides can be arranged in $4^{1,000}$ different sequences, a number so large (1.5×10^{602}) that it provides nearly endless degrees of variation.

The Overall Replication Process

What features allow the DNA molecule to be exactly duplicated, and how is its integrity retained? DNA replication requires a careful orchestration of the actions of 30 different enzymes (partial list in **table 9.1**), which separate the strands of the existing DNA molecule, copy its template, and produce two complete daughter molecules.

A simplified version of replication is shown in **figure 9.7** and includes the following:

1. uncoiling the parent DNA molecule, beginning at a predetermined point of origin;
2. unzipping the hydrogen bonds between the base pairs, thus separating the two strands and exposing the nucleotide sequence of each strand (which is normally hidden in the center of the helix) to serve as templates; and
3. synthesizing two new strands by using each single-stranded template as a pattern for adding the correct complementary nucleotides to the newly forming strand.

A critical requirement of DNA replication is that each completed daughter molecule be identical to the parent in composition, but neither one is completely new. The strand that serves as a template is an original parental DNA strand and is retained in the daughter molecule. The preservation of the parent molecule in this way, termed **semiconservative replication**, helps explain the reliability and accuracy of replication.

TABLE 9.1 Some Enzymes Involved in DNA Replication and Their Functions

Enzyme	Function
Helicase	Unzipping the DNA helix
Primase	Synthesizing an RNA primer
DNA polymerase III	Adding bases to the new DNA chain; proofreading the chain for mistakes
DNA polymerase I	Removing RNA primers, replacing gaps between Okazaki fragments with correct nucleotides, repairing mismatched bases
Ligase	Final binding of nicks in DNA during synthesis and repair
Gyrase	Supercoiling

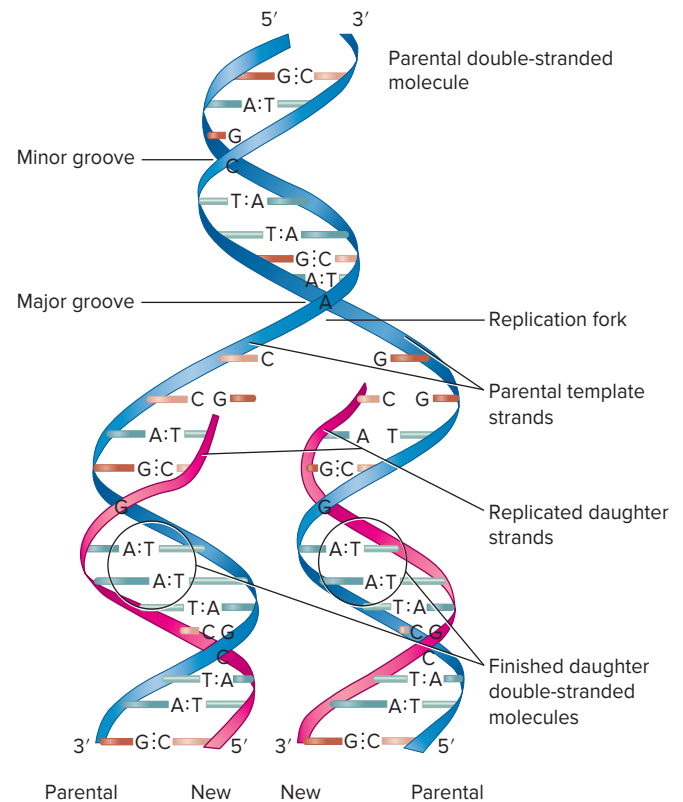

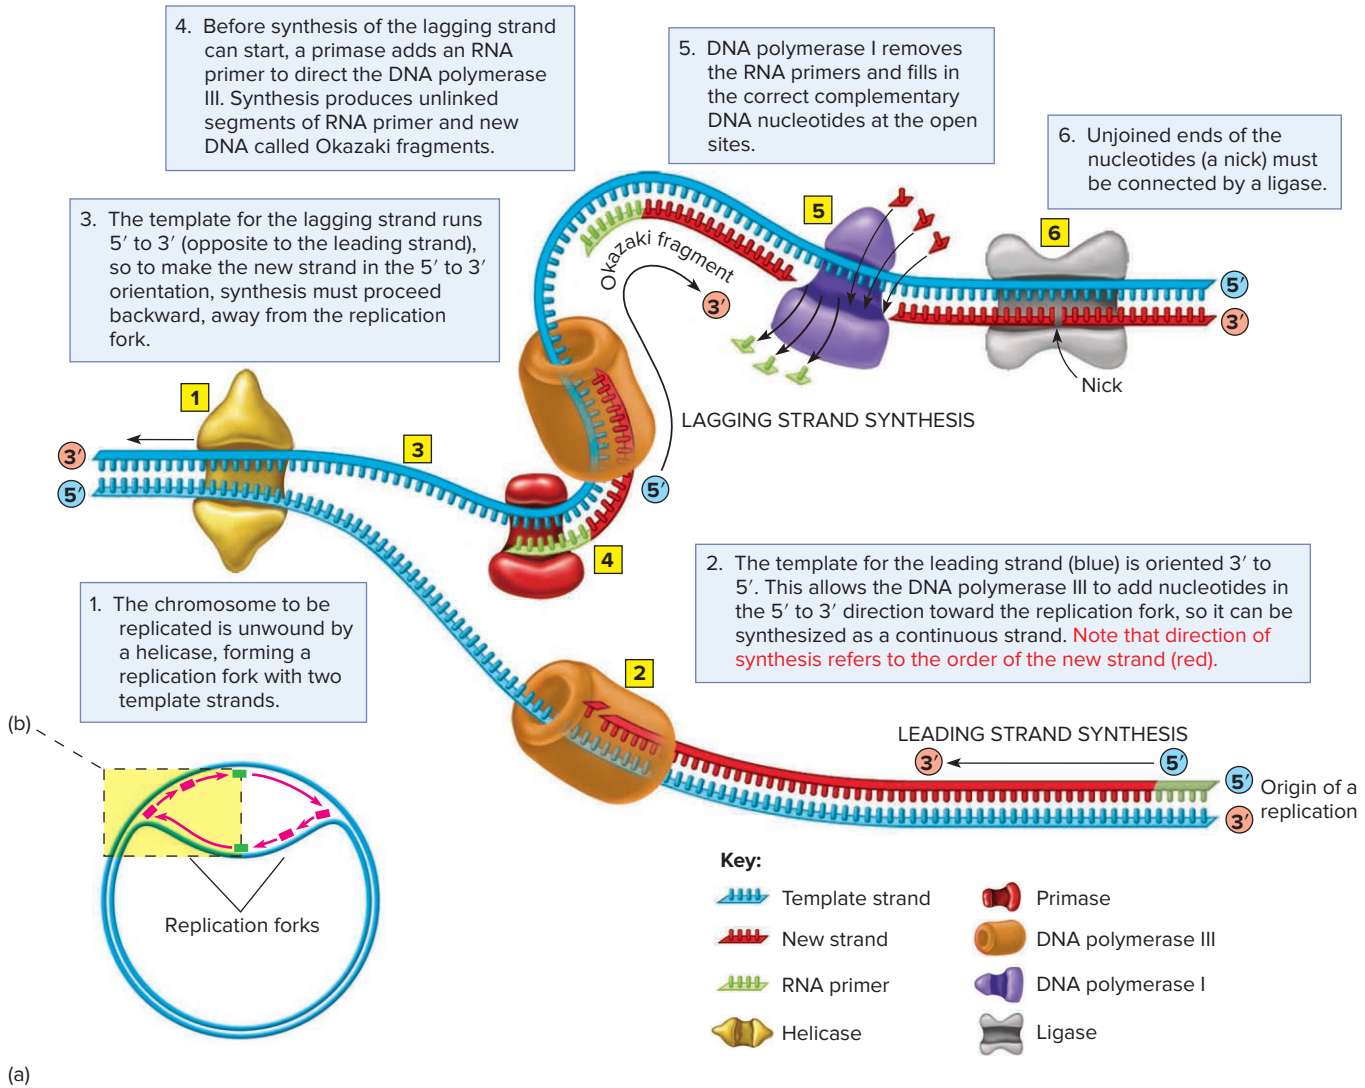

Figure 9.7 Simplified steps to show the semiconservative replication of DNA. The two strands of the parental double helix are unwound and separated. Each single strand will serve as a template (blue) to synthesize a new strand of DNA (red), starting at the replication fork. As synthesis proceeds, the correct nucleotides are added according to the pattern of the template. An A on the template will pair with a T on the new molecule, and a C will pair with a G. The finished daughter DNA molecules contain one strand of the newly synthesized DNA and the original template (parental) strand. This keeps the code intact because the same linear arrangement of the bases is maintained during this process. This process is covered in greater detail in figure 9.8.

Events in Replication

All chromosomes have a specific **origin of replication** site that serves as the place where replication will be initiated. It is recognized by a short sequence rich in adenine and thymine that, you will recall, are held together by only two hydrogen bonds rather than three. Because the origin of replication is AT-rich, less energy is required to separate the two strands than would be required if the origin were rich in guanine and cytosine.

The process of synthesizing a new daughter strand of DNA using the parental strand as a template is carried out by a giant enzyme complex that brings in the primary replication enzyme—**DNA polymerase III**—along with numerous accessory enzymes. The DNA polymerase III is responsible for deciphering and duplicating DNA codes, but it has some major conditions that will affect the overall process (**figure 9.8**):

- DNA polymerase cannot add nucleotides to a DNA template strand without a guide that can serve as the starting point for nucleotides to be bonded during synthesis.

Process Figure 9.8 The assembly line of DNA replication in a circular bacterial chromosome. (a) A bacterial chromosome showing the overall pattern of replication. There are two replication forks where new DNA is being synthesized. (b) An enlarged view of the left replication fork to show the details of replication.

- Before replication can begin, a piece of RNA called a primer is inserted at the origin of replication to provide the first nucleotide with a free 3'—OH group for binding.
- DNA polymerase can **read** the template only in the 3' to 5' direction and can add nucleotides to the newly synthesized strand only in the 5' to 3' direction. Because the two template strands are oriented in opposite directions, this will necessitate an alternative type of synthesis for the template strand oriented in the 5' to 3' direction (see lagging strand in **figure 9.8b, part 3**).

Prior to the start of replication, enzymes called helicases (unzipping enzymes) bind to the DNA at the origin. These enzymes untwist the helix and break the hydrogen bonds holding the two strands together, resulting in two separate strands, each of which will be used as a template for the synthesis of a new strand (**figure 9.8b, step 1**).

Replication begins when RNA **primers** are synthesized by a primase at the origin of replication (**figure 9.8a**). DNA polymerase III

will use this short strand of RNA as a starting point for adding nucleotides. In the circular DNA molecule of bacteria, there are two **replication forks**, each containing its own set of replication enzymes. Each fork requires two active DNA polymerases along with several other proteins and enzymes whose main functions are to stabilize the polymerase and provide a means of removing and replacing nucleotides. The enzyme complex encircles the DNA near the replication fork and synthesizes new DNA as guided by the parental strand. As synthesis proceeds, the forks are continually opened up to expose the template for replication.

Because DNA polymerase III can only synthesize new DNA in the 5' to 3' direction, just one strand, called the **leading strand**, will be synthesized continuously (**figure 9.8b, step 2**). After addition of an RNA primer, a DNA polymerase complex enters and moves along the template strand in the 3' to 5' order toward the replication fork, adding nucleotides in the 5' to 3' order on the new strand.

The other template strand runs the opposite direction, which prevents the DNA polymerase from synthesizing a continuous,

unbroken strand of new DNA. This other strand, termed the **lagging strand** will be synthesized in a series of shorter fragments that will later be connected into a continuous strand (figure 9.8b, steps 3 and 4). It still requires primers, and each new fragment will require its own separate primer. The DNA polymerase adds nucleotides to the new strand in the 5' to 3' order, but it does this by going in a backward direction away from the fork. This manner of synthesis produces short fragments of DNA (100 to 1,000 bases long) called **Okazaki fragments** on the lagging strand. The lagging strand will be completed when the enzyme, **DNA polymerase I**, removes the RNA primers from the Okazaki fragments, and fills in the missing segments with the correct complementary DNA nucleotides (figure 9.8b, step 5). The replacement strand is not completely bonded to the finished part of the new strand, so an enzyme, **ligase**, makes these final phosphate-sugar connections (figure 9.8b, step 6).

The addition of nucleotides proceeds at an astonishing pace, estimated in some bacteria to be 750 bases per second at each fork! As replication proceeds, one newly synthesized strand loops down (figure 9.9a). When the forks have gone full circle, a termination site shuts replication down. The two circular daughter molecules remain connected briefly but are nicked and separated by a helicase (figure 9.9b).

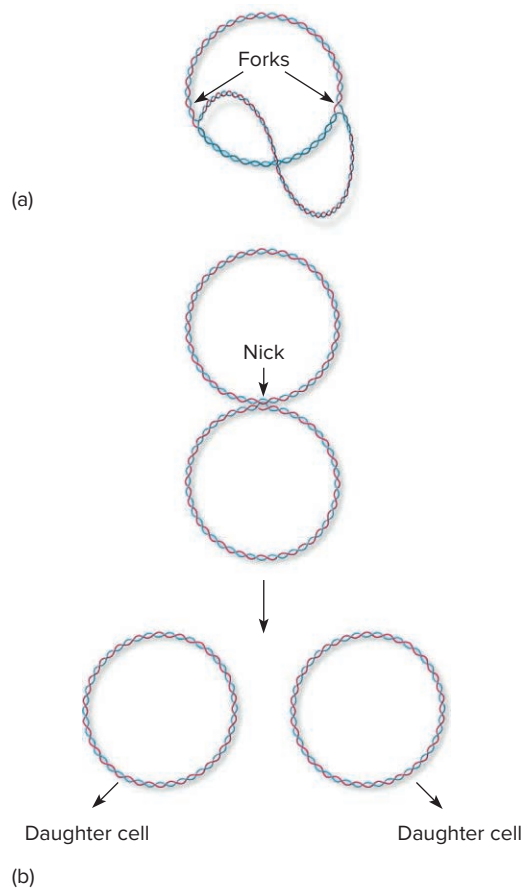

Figure 9.9 Completion of chromosome replication in bacteria. (a) As replication proceeds, one strand loops down. (b) Final separation is achieved when an enzyme cuts and releases the two completed molecules. Each daughter cell receives one completed chromosome during binary fission.

Like any language, DNA is occasionally “misspelled” when an incorrect base is added to the growing chain. Studies have shown that such mistakes are made once in approximately 10^8 to 10^9 bases, but most of these are corrected. If not corrected, they are considered mutations that can lead to major cell dysfunction. Because continued cellular integrity is very dependent on accurate replication, cells have evolved their own proofreading function for DNA. DNA polymerase III, the enzyme that elongates the molecule, can also detect incorrect, unmatching bases; excise them; and replace them with the correct base. DNA polymerase I is also involved in proofreading the molecule and repairing damaged DNA.

Expected Learning Outcomes

7. Present an overview of the main aspects of the flow of genetic information in cells.
8. Explain the relationship between the structure of DNA and the structure of proteins.
9. Describe the different types of RNA and their basic functions in genetic expression.
10. Relate the major events of transcription.
11. Describe the genetic code, codons, and anticodons, and how they relate to one another.
12. Recount the participants and steps in translation (protein synthesis).
13. Distinguish major points of difference between prokaryotic and eukaryotic transcription and translation.

We have explored how the genetic language of the DNA molecule is conserved through replication. Next we consider exactly how this language is expressed. Given that the sequence of bases in DNA is a genetic code, just what is the nature of this code and how is it

utilized? Although the genome is full of critical information, the DNA molecule itself cannot perform cell processes directly. Instead, its information is conveyed to RNA molecules, which carry out the instructions it contains. The concept that genetic information flows from DNA to RNA to protein has long been a central theme of molecular biology (**figure 9.10a**). It states that the master code of DNA is first used to synthesize RNA via a process called **transcription**, and the information contained in the RNA is then used to produce proteins in a process known as **translation**. The principal exceptions to this pattern are found in RNA viruses, which convert RNA to other RNA, and in retroviruses, which can convert RNA to DNA.

As with many established concepts in biology, the science of molecular genetics continues to add significant discoveries to our

understanding. In addition to the RNA used to produce proteins, a wide variety of specialized RNAs act by regulating gene function (**figure 9.10b**). We will introduce some of the expanded functions for RNA in 9.3 Making Connections, but we will start with its direct participation in protein synthesis.

The Gene-Protein Connection

The Triplet Code and Its Relationship to Proteins

Several questions invariably arise concerning the relationship between genes and cell function. For instance, how does gene structure lead to the expression of traits in the individual, and what features of gene expression cause one organism to be so distinctly different from another? For answers, we must turn to the correlation between gene and protein structure. We know that each structural gene is an ordered sequence of nucleotides that codes for a protein. Because each protein is different, each gene must also differ somehow in its composition. In fact, the language of DNA exists in the order of groups of three consecutive bases designated as **triplets** or **codons**, on one DNA strand (**figure 9.11**). In short, one gene differs from another in the order and number of its triplets. An equally important part of this concept is that each triplet represents a code for a particular amino acid. When the triplet code is transcribed and translated, it dictates the type and order of amino acids in a polypeptide (protein) chain.

To summarize the key points that connect DNA and protein function:

1. DNA is a blueprint that indicates which kinds of proteins to make and how to make them. This blueprint exists in the order of triplets along the DNA strands.
2. The order of triplets directs a protein's primary structure—the order and type of amino acids in the chain—which determines its characteristic shape and function.

Figure 9.10 Summary of the flow of genetic information in cells. DNA is the ultimate storehouse and distributor of genetic information. (a) DNA must be deciphered into a usable cell language. It does this by transcribing its code into RNA helper molecules that translate that code into protein. (b) Other sections of DNA are copied to make additional types of RNA molecules that regulate genes and their products.

Figure 9.11 Simplified view of the DNA-protein relationship. The DNA molecule is a continuous chain of base pairs, but the sequence must be interpreted in groups of three base pairs (a triplet or codon). Each triplet transcribed into mRNA codons will translate into one amino acid; consequently, the ratio of base pairs to amino acids is 3:1.

- Proteins contribute significantly to the phenotype by functioning as enzymes and structural molecules.

The Major Participants in Transcription and Translation

Transcription, the formation of RNA using DNA as a template, and translation, the synthesis of proteins using RNA as a template, are highly complex. A number of components participate: most prominently, messenger RNA, transfer RNA, ribosomes, several types of enzymes, and a storehouse of raw materials. After first examining each of these components, we shall see how they come together in the assembly line of the cell.

RNAs: Tools in the Cell's Assembly Line

Ribonucleic acid (RNA) is an encoded molecule like DNA, but its general structure is different in several ways:

- It is a **single-stranded** molecule that can assume secondary and tertiary levels of complexity due to bonds within the molecule, leading to specialized forms of RNA (mRNA, tRNA, and rRNA—**figure 9.12**).
- RNA contains **uracil**, instead of thymine, as the complementary base-pairing mate for adenine. This does not change the inherent DNA code in any way because the uracil still follows the pairing rules.
- Although RNA, like DNA, is structured with a backbone of alternating sugar and phosphate molecules, the sugar in RNA is **ribose** rather than deoxyribose (see figure 2.24).

The many functional types of RNA range from small regulatory pieces to large structural ones. All types of RNA are formed through

transcription of a DNA gene, but only mRNA is further translated into protein. See **table 9.2** for a comparison of major types of RNA and their functions. Additional forms of RNA are introduced in section 9.3.

Messenger RNA: Carrying DNA's Message

Messenger RNA (mRNA) is a transcribed version of a structural gene or genes in DNA. It is synthesized by a process similar to synthesis of the leading strand during DNA replication, and the complementary base-pairing rules ensure that the code will be faithfully copied in the mRNA transcript. The message of this transcribed strand is later read as a series of triplets called **codons** (**figure 9.12a**), and the length of the mRNA molecule varies from about 100 nucleotides to several thousand. The details of transcription and the function of mRNA in translation are covered later in this section.

Transfer RNA: The Key to Translation

Transfer RNAs (tRNAs) are also complementary copies of specific regions of DNA; however, they differ from mRNA. Transfer RNAs typically range from 75 to 95 nucleotides in length, and they contain sequences of bases that form hydrogen bonds with complementary sections in the same tRNA strand. At these points, the molecule bends back upon itself into several *hairpin loops*, giving the molecule a secondary *cloverleaf* structure that folds even further into a complex, three-dimensional helix (**figure 9.12b**). This compact molecule acts as a translator that converts RNA language into protein language. The bottom loop of the cloverleaf exposes a triplet, the **anticodon**, that both designates the specificity of the tRNA and complements mRNA's codons. At the opposite end of the molecule is a binding site for the amino acid that is specific for that tRNA's anticodon. For each of the 20 amino acids, there is at least one specialized type of tRNA to carry

Figure 9.12 Characteristics of messenger and transfer RNA.

TABLE 9.2 Major Types of Ribonucleic Acid Involved in Protein Synthesis

RNA Type	Contains Codes For	Function In Cell	Translated
Messenger (mRNA)	Sequence of amino acids in protein	Carries the DNA master code to the ribosome	Yes
Transfer (tRNA)	Specifying a given amino acid	Carries amino acids to ribosome during translation	No
Ribosomal (rRNA)	Several large structural rRNA molecules	Forms the major part of a ribosome and participates in protein synthesis	No
Primer	An RNA that can begin DNA replication	Primes DNA	No

it. Binding of an amino acid to its specific tRNA requires a specific enzyme that can correctly match each tRNA with its amino acid.

The Ribosome: A Mobile Molecular Factory for Translation

The prokaryotic (70S) ribosome is a particle composed of tightly packaged **ribosomal RNA (rRNA)** and protein. The rRNA component of the ribosome is an extensive polynucleotide molecule. It forms complex three-dimensional figures that contribute to the structure and function of ribosomes. The interactions of proteins and rRNA create the two subunits of the ribosome that engage in final translation of the genetic code (see figure 9.14). A metabolically active bacterial cell can accommodate up to 20,000 of these tiny factories—all actively engaged in reading the genetic program, taking in raw materials, and producing proteins at an impressive rate.

Transcription: The First Stage of Gene Expression

Like so many other genetic events, transcription is a marvel of efficiency. It is highly organized and guided by special codes on DNA itself. To describe it in more detail, we use the formation of mRNA in bacteria as a model. It is important to keep in mind that all types of RNA are synthesized by a similar process. The other RNAs have important functions; they just do not provide the code for the amino acids in a protein as mRNA does.

During transcription, an RNA molecule is synthesized using the codes on DNA as a guide or template. A large enzyme complex, **RNA polymerase**, is responsible for this process. This polymerase is more multipurpose than DNA polymerase, because the RNA enzyme works alone and does not require a helicase. It can bind to DNA and unwind it, as well as synthesize RNA (**figure 9.13**).

Transcription proceeds in three stages: *initiation*, *elongation*, and *termination*. Initiation requires the RNA polymerase to recognize a region on a gene called the **promoter region (figure 9.13, step 1)**. This region consists of two sets of DNA sequences located just before the *initiation site*. The first sequence is about 35 nucleotides from the initiation site, and the second is about 10 nucleotides from it. The primary function of the promoter is to provide a position for initial binding of the RNA polymerase. A special protein molecule, the *sigma factor*, guides the RNA polymerase to the correct position on the promoter. These promoter sequences are not highly varied, and they tend to be rich in adenine and thymine

base pairs, which have one less hydrogen bond than guanine-cytosine pairs, which facilitates the separation of the DNA strands.

Prior to the first synthesis step of transcription, the RNA polymerase begins to separate the two strands of the DNA helix and forms an open “bubble” for transcription (**figure 9.13, steps 2 and 3**). This bubble serves as the space where the nucleotides of mRNA will actually be assembled. Only one strand of DNA—the **template strand**—is transcribed. This strand will have a reading frame oriented in the 3' to 5' direction recognized by the RNA polymerase, similar to replication. The mRNA made by transcription of the template strand is a message for the correct sequence of amino acids that will be linked together during translation (protein synthesis). The other strand—the **nontemplate strand**—is sometimes called the coding strand because its sequence is the same order as the mRNA (although it will have thymine instead of uracil). In some cases, this strand may serve a genetic function, but it is not transcribed. Which strand acts as the template varies from one gene to another. One important triplet appearing early in a DNA template is **TAC**. This will be transcribed into **AUG** on the mRNA, which we can see in figures 9.15 and 9.17 is the start codon, as it signals the location on the mRNA where translation starts. Note that the promoter sequences are not transcribed as part of the final mRNA molecule.

As elongation proceeds, the polymerase moves the transcription bubble forward, exposing subsequent sections of DNA. It simultaneously brings in nucleotides that are complementary to the DNA template and continues to assemble the mRNA strand. As with replication, this growing mRNA strand runs in the 5' to 3' direction. DNA that has already been transcribed rewinds back into its double helix structure (**figure 9.17, step 4**). The part of the mRNA strand that is already assembled remains attached to the enzyme complex but is kept out of the way of the processing machinery.

At termination, the polymerase recognizes a site on DNA near the end of the gene that signals the separation and release of the completed mRNA, which will next enter the ribosome for translation. As we will see in section 9.3, this mRNA delivers its message in codons that are the master code for protein synthesis. The length of the final mRNA molecule depends upon the polypeptide or protein that it encodes. In bacteria, the smallest mRNA might consist of 100 nucleotides, an average one, 600 nucleotides, and the largest, 1500.*

Quick Search

Get an animated view of this dynamic process by searching online for “Stages of Transcription—McGraw-Hill.”

*What would be the corresponding numbers of amino acids in the final proteins for these three mRNAs?

1 Each gene contains a specific promoter region and a leader sequence for guiding the beginning of transcription. Next is the region of the gene that codes for a polypeptide and ends with a series of terminal sequences that stop translation.

2 DNA is unwound at the promoter by RNA polymerase. Only one strand of DNA, called the template strand, supplies the codes to be transcribed by RNA polymerase. This strand runs in the 3' to 5' direction.

3 The RNA polymerase moves along the DNA strand, adding complementary nucleotides as dictated by the DNA template. The mRNA strand reads in the 5' to 3' direction.

4 The polymerase continues transcribing until it reaches a termination site, and the mRNA transcript is released to be translated. Note that the section of the transcribed DNA is rewound into its original configuration.

Process Figure 9.13 The major events in transcription, using mRNA as a model.

Translation: The Second Stage of Gene Expression

In translation, all of the elements needed to synthesize a protein, from the mRNA to the tRNAs with amino acids, are brought together on the ribosomes (**figure 9.14**). The process occurs in five stages: initiation, elongation, termination, and protein folding and processing.

Initiation of Translation

In prokaryotic cells, the mRNA molecule leaves the DNA transcription site and is transported directly to ribosomes. Ribosomal subunits are specifically assembled in a way that forms sites to hold the mRNA and tRNAs. The ribosome thus recognizes these molecules and stabilizes reactions between them. The small subunit binds to the 5' end of the mRNA and provides molecules to initiate translation. The large subunit holds the tRNAs and is actively involved in peptide bond formation by means of a specialized ribozyme, which is an RNA-based catalyst (see 8.2 Making Connections). The small subunit of the ribosome binds at a specific

Figure 9.14 The “players” in translation. A ribosome serves as the stage for protein synthesis. Assembly of the small and large subunits results in specific sites for placement of the mRNA (small subunit) and two tRNAs with their amino acids (P and A sites).

* This codon initiates translation.
 **For these codons, which give the orders to stop translation, there are no corresponding tRNAs with amino acids.

Figure 9.15 The genetic code: Codons of mRNA that specify a given amino acid. The master code for translation is provided by mRNA codons.

site on the mRNA and places the **start codon** AUG (rarely GUG) in correct alignment with the P site.

With the mRNA message in place on the assembled ribosome, the next step in translation involves entrance of tRNAs with their amino acids. The pool of cytoplasm around the region contains a complete array of tRNAs, previously charged by having the correct amino acid attached. The step in which the complementary tRNA meets with the mRNA code is guided by the two sites on the large subunit of the ribosome called the P site (left) and the A site (right).¹ Think of these sites as recessed spaces tucked within the two subunits of the ribosome, with each site accommodating a tRNA. The ribosome also has an exit or E site where used tRNAs are released.

The Master Genetic Code: The Message in Messenger RNA

By convention, the master genetic code is represented by the mRNA codons and the amino acids they specify (figure 9.15). Except in a very few cases (the genes of mitochondria and chloroplasts, for example), this code is universal, whether for prokaryotes, eukaryotes, or viruses. It is worth noting that once the mRNA codon is known, the original DNA sequence, the complementary tRNA code, and the types of amino acids in the protein are automatically known (figure 9.16). However, one cannot predict (backward) from protein structure what the exact mRNA codons are because of a factor

¹ P stands for peptide site; A stands for aminoacyl (amino acid) site; E stands for exit site.

Figure 9.16 Interpreting the DNA code. If the DNA sequence is known, the mRNA codon can be surmised. If a codon is known, the anticodon and, finally, the amino acid sequence can be determined. The reverse is not possible (determining the exact codon or anticodon from amino acid sequence) due to the redundancy of the code.

called **redundancy** or **degeneracy**, meaning that a particular amino acid can be coded for by more than one codon.

In figure 9.15 the mRNA codons and their corresponding amino acid specificities are given. Because there are 64 different triplet codes² and only 20 different amino acids, it is expected that some amino acids are represented by several codons. For example, leucine and serine can each be represented by any of six different triplets, but only tryptophan and methionine are represented by a single codon. In such codons as leucine, only the first two nucleotides are required to encode the correct amino acid, and the third nucleotide does not change its sense. This property, called *wobble*, is thought to permit some level of variation or mutation without changing the message.

The Beginning of Protein Synthesis

With mRNA serving as the guide, the stage is finally set for actual protein assembly. The correct tRNA (labeled **1** on **figure 9.17**) enters the P site and binds to the **start codon (AUG)** presented by the mRNA. Rules of pairing dictate that the **anticodon** of this tRNA will complement the mRNA codon AUG; thus, the tRNA with anticodon UAC will first occupy site P. It happens that the amino acid carried by the initiator tRNA in bacteria is *formyl methionine* (f Met; see figure 9.15), though in many cases, it may not remain a permanent part of the finished protein.

Continuation and Completion of Protein Synthesis: Elongation and Termination

The mRNA comes with a specific order of codons called the *reading frame* that must be translated in that exact order. In general, the ribosome is mobile and moves along the mRNA from one codon to the next. As it moves the ribosome, it brings each succeeding mRNA codon into place and facilitates entry of the tRNA with its matching anticodon. The actual joining of the amino acids is carried out by a *ribozyme* (a catalytic RNA molecule) that is part of the large subunit of the ribosome. It forms a peptide bond between the amino acids on the adjacent tRNAs, and the polypeptide grows in length. Several steps of this process are outlined here:

- Elongation begins with the filling of the A site by a second tRNA (**figure 9.17, step 1**). The identity of this tRNA and its amino acid is dictated by the second mRNA codon.
- The entry of tRNA 2 into the A site brings the two adjacent tRNAs in favorable proximity for a peptide bond to form between the amino acids they carry. The f Met is transferred from the first tRNA to amino acid 2, resulting in two coupled amino acids called a dipeptide (**figure 9.17, step 2**).
- For the next step to proceed, some room must be made on the ribosome, and the next codon in sequence must be brought into position for reading. This process is accomplished by *translocation*, the enzyme-directed shifting of the ribosome to the next position on the mRNA strand, which causes the blank tRNA (1) to be discharged from the ribosome (**figure 9.17, step 3**) at the E site.
- This simultaneously shifts the tRNA holding the dipeptide into P position. Site A is temporarily left empty. The tRNA that has

been released is now free to drift away and become recharged with an amino acid for later additions to this or another protein.

- The stage is now set for the insertion of tRNA 3 at site A as directed by the third mRNA codon (**figure 9.17, step 4**). This insertion is followed once again by peptide bond formation between the dipeptide and amino acid 3 (making a tripeptide), splitting of the peptide from tRNA 2, and translocation (**figure 9.17, step 5**).
- This action releases tRNA 2, shifts mRNA to the next position, moves tRNA 3 to position P, and opens position A for tRNA 4 (**step 6**). From this point on, peptide elongation proceeds repetitively by this same series of actions out to the end of the mRNA (**steps 7 and 8**).

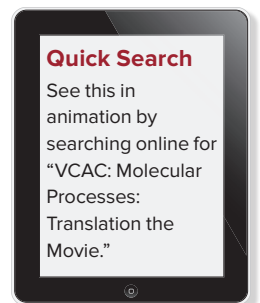

The termination of protein synthesis is not simply a matter of reaching the last codon on mRNA. It is brought about by the presence of at least one special codon occurring just after the codon for the last amino acid. Termination codons—UAA, UAG, and UGA—are codons for which there is no corresponding tRNA. Also termed **non-sense** or **stop codons**, they carry a necessary message: *Stop here*. When this codon is reached, a special enzyme breaks the bond between the final tRNA and the finished polypeptide chain, releasing it from the ribosome.

Before newly made proteins can carry out their structural or enzymatic roles, they often require finishing touches. Even before the peptide chain is released from the ribosome, it begins folding upon itself to achieve its biologically active tertiary conformation. Other alterations, called *posttranslational modifications*, may be necessary. Some proteins must have the starting amino acid (formyl methionine) clipped off; proteins destined to become complex enzymes have **cofactors** added; and some join with other completed proteins to form **quaternary** levels of structure.

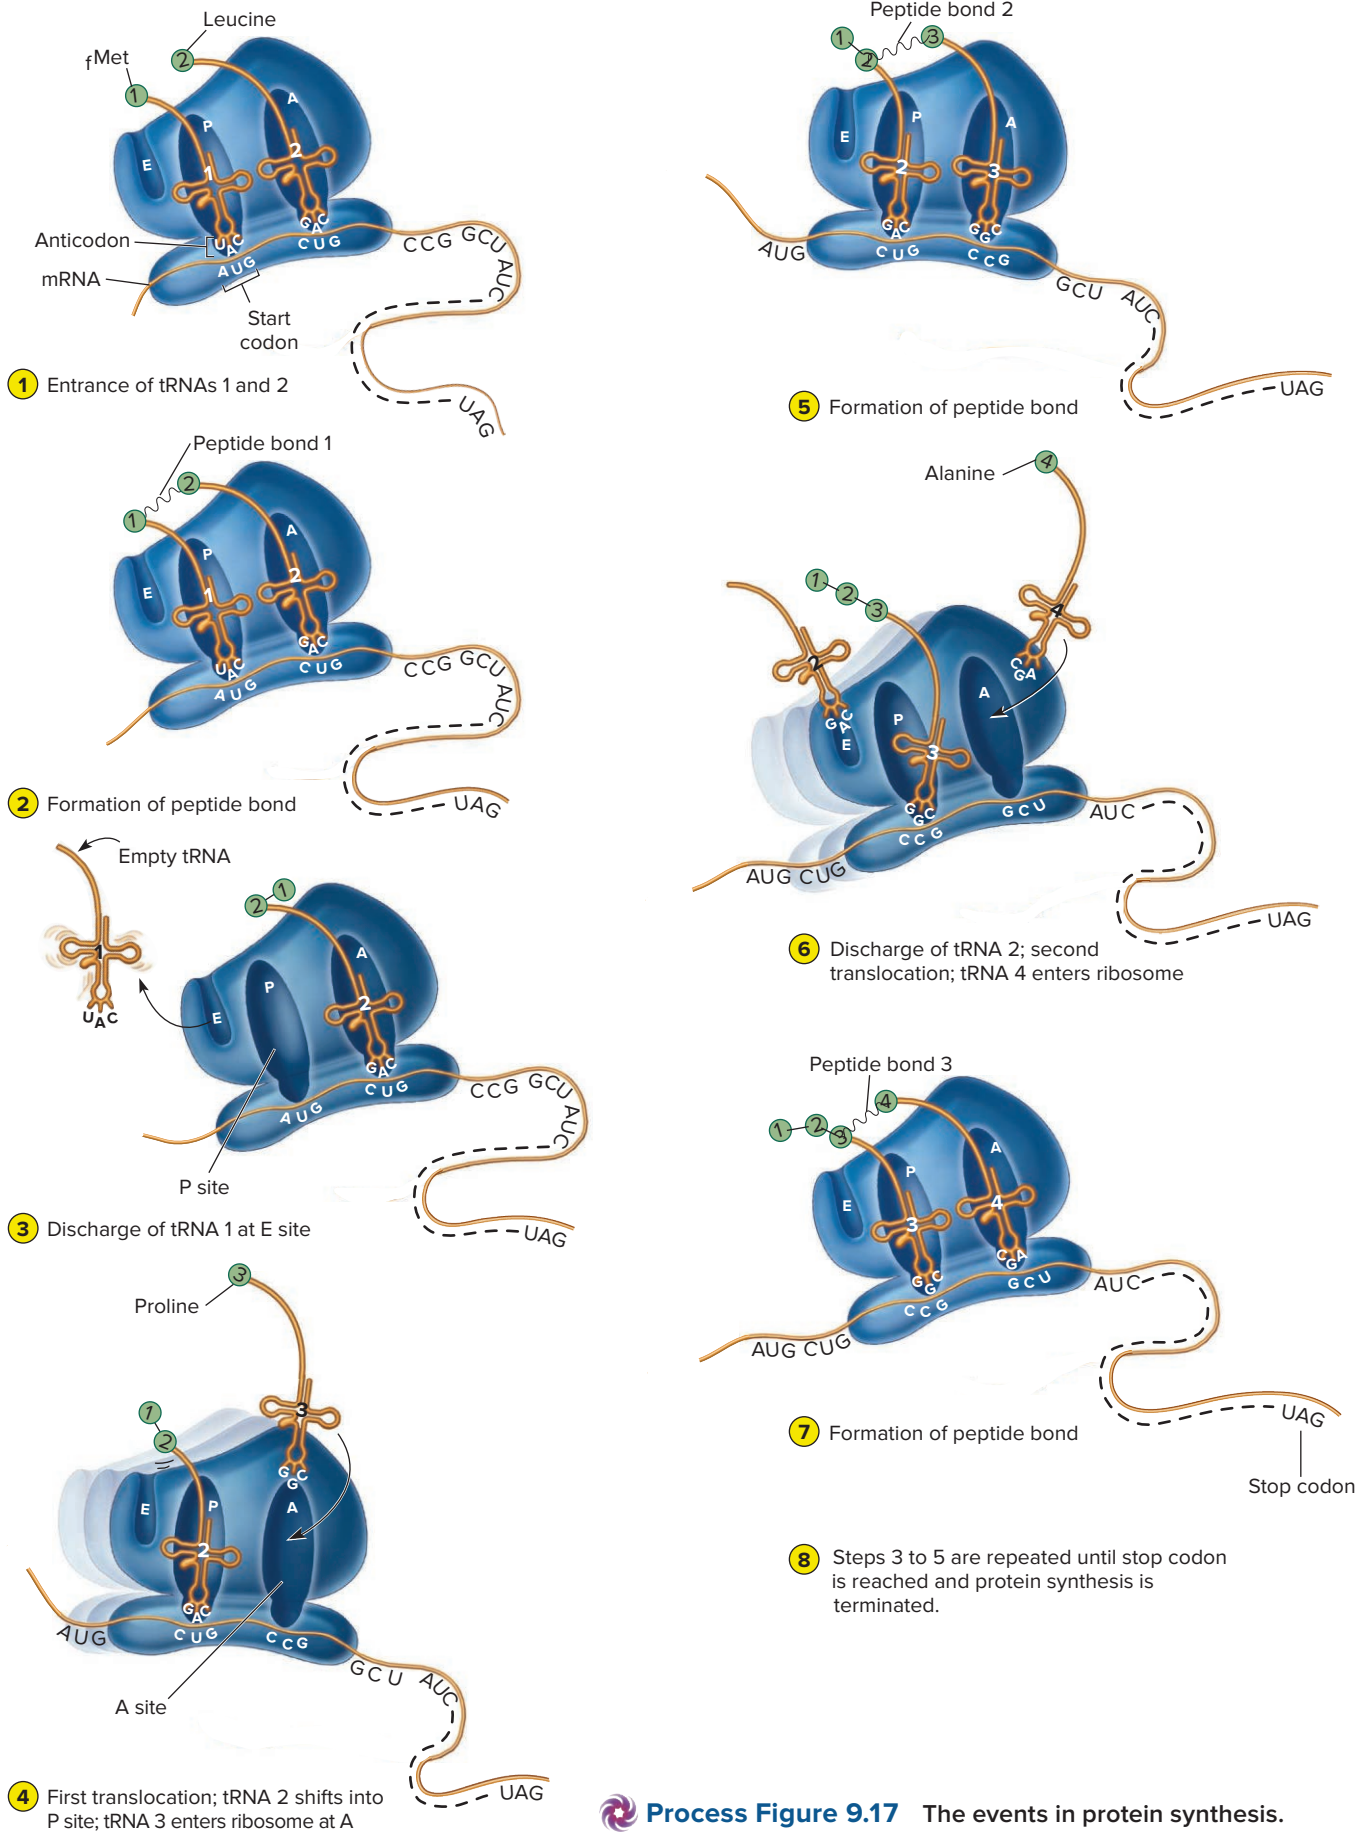

The operation of transcription and translation is machinelike in its precision. Protein synthesis in bacteria is both efficient and rapid. At 37°C, 12 to 17 amino acids per second are added to a growing peptide chain. An average protein consisting of about 400 amino acids requires less than half a minute for complete synthesis. Further efficiency is gained when the translation of mRNA starts while transcription is still occurring (**figure 9.18**). A single mRNA is long enough to be fed through more than one ribosome simultaneously. This permits the synthesis of hundreds of protein molecules from the same mRNA transcript arrayed along a chain of ribosomes. This **polyribosomal complex** is indeed an assembly line for mass production of proteins. Protein synthesis consumes an enormous amount of energy. Approximately 1,200 ATPs or ATP equivalents are consumed just for synthesis of an average-size protein.

Eukaryotic Transcription and Translation: Similar yet Different

Eukaryotes share many aspects of protein synthesis with prokaryotes. They show similarities in the operation of the ribosomes, the functions of start and stop codons, and the mass production of proteins by means of polyribosomes. But they do differ in significant ways. The start codon in eukaryotes is also AUG, but it codes for an alternate

² This number 64 comes from 4³ (the 4 different nucleotides in all possible combinations of 3).

Process Figure 9.17 The events in protein synthesis.

(c)

Figure 9.18 Speeding up the protein assembly line in bacteria.

(a) The mRNA transcript encounters ribosomal parts immediately as it leaves the DNA. (b) The ribosomal factories assemble along the mRNA in a chain, each ribosome reading the message and translating it into protein. Many products will thus be well along the synthetic pathway before transcription has even terminated. (c) Photomicrograph of a polyribosomal complex in action. form of methionine. Another difference is that eukaryotic mRNAs code for just one protein, unlike bacterial mRNAs, which often contain information from several genes in series. See 9.2 Making Connections to discover other exceptional aspects of eukaryotic genetics.

Prokaryotic and eukaryotic cells also differ in location and structure of genes. The presence of DNA in the nucleus of eukaryotic cells means that eukaryotic transcription and translation cannot be simultaneous as it is in prokaryotes. The mRNA transcript must pass through pores in the nuclear membrane and be carried to the ribosomes in the cytoplasm or on the endoplasmic reticulum for translation.

So far we have introduced a simplified definition of a gene that fits well for the majority of prokaryotes. The pattern of their genes is colinear, meaning that their message can be directly read into proteins without any additional processing.³ Eukaryotic genes differ significantly in this characteristic because they are not colinear. Located within their genes are one to several intragenic regions, called **introns**, that do not code for protein.⁴ These introns are interspersed between coding regions, called **exons**, that will be translated into protein (figure 9.19). To

Figure 9.19 The split gene of eukaryotes. Eukaryotic genes have an additional complication in their transcription/translation. Their coding sequences, or exons (E), are interrupted at intervals by segments called introns (I) that are not part of that protein’s code. Introns are transcribed but not translated, which necessitates their removal by RNA splicing enzymes before translation.

3 With colinearity, an mRNA transcript can be translated directly into the correct sequence of amino acids.

4 Introns have also been found in some prokaryotes (cyanobacteria), archaea) and even viruses.

illustrate this we can use words as examples. A short section of colinear prokaryotic gene might read: SAM SAW HIS NEW CAR GET HIT; a eukaryotic gene that codes for the same portion would read SAM SAW SVXF FPL HIS NEW CAR QZWVP GET HIT. The recognizable words are the exons, and the nonsense letters represent the introns.

This discontinuous genetic structure, also called a split gene, requires further processing before translation. Transcription of the entire gene with both exons and introns occurs first, producing a pre-mRNA. Next, an RNA-protein complex called a *spliceosome* recognizes the exon-intron junctions and enzymatically cuts through them in a process called RNA splicing. The action of this splicer enzyme loops the introns into lariat-shaped pieces, excises them, and joins the exons end to end. By this means, a strand of mRNA with no intron material is produced. This completed mRNA strand can then proceed to the cytoplasm to be translated.

Several different types of introns have been discovered, some of which do code for cell substances. For example, certain introns have been found to code for an enzyme called reverse transcriptase, which can convert RNA into DNA. Other introns are translated into endonucleases, enzymes that can snip DNA and allow insertions and deletions into the DNA sequence. Some introns have an innate catalytic function and can splice themselves out of an RNA transcript. A great deal of non-protein-coding DNA is proving to be vital for cell function. Human DNA has an average of 8 introns per gene, which represents a significant percentage of the DNA found in chromosomes. One role alternative splicing plays is in providing greater flexibility in creating alternative versions of genes. It is likely that future research will discover additional roles of introns in regulating gene expression (**9.2 Making Connections**).

9.3 Genetic Regulation of Protein Synthesis and Metabolism

Expected Learning Outcomes

14. Explain the functions of operons in bacterial genetic control.
15. Describe the main features of the lactose operon and inducible operons.
16. Describe the main features of repressible operons.
17. Summarize some aspects of genetic control by RNA.

In chapter 8 we surveyed the metabolic reactions in cells and the enzymes involved in those reactions. There we learned that some enzymes are regulated and that one form of regulation occurs at the genetic level. This control mechanism ensures that genes are active only when their products are required. In this way, enzymes will be produced as they are needed and the waste of energy and materials in dead-end synthesis is prevented. A major form of gene regulation in prokaryotes is through systems called **operons**. An operon is a section of DNA that contains one or more structural genes along with a corresponding operator gene that controls transcription. Having this kind of setup will permit genes for a particular metabolic pathway to be induced or repressed in unison by the same regulatory element.

Operons are described as either inducible or repressible. The category of an operon is determined by how it is affected by the environment within the cell. Many catabolic operons are **inducible**, meaning that the operon is turned on (induced) by the substrate of the enzyme for which the structural genes code. In this way, the enzymes needed to metabolize a nutrient (lactose, for example) are produced only when that nutrient is present. **Repressible operons** often contain genes coding for anabolic enzymes, such as those used to synthesize amino acids. In the case of these operons, several genes in series are turned off (repressed) by the product synthesized by the enzyme.

The Lactose Operon: A Model for Inducible Gene Regulation in Bacteria

The best understood cell system for explaining control through genetic induction is the **lactose (*lac*) operon**. The system, first described in 1961 by François Jacob and Jacques Monod, accounts for the regulation of lactose metabolism in *Escherichia coli*. Many other operons with similar modes of action have since been identified, and together they furnish convincing evidence that a cell's metabolic actions can have great impact on gene expression.

The lactose operon has three important features (**figure 9.20**):

1. the **regulator**, composed of the gene that codes for a protein capable of repressing the operon (a **repressor**);
2. the **control locus**, composed of two areas, the promoter recognized by RNA polymerase (see figure 9.13) and the **operator**, a sequence that acts as an on/off switch for transcription; and

9.2 MAKING CONNECTIONS

Revising Some Rules of Genetics

What was true for E. coli would be true for the elephant.

Jacques Monod, Nobel laureate and discoverer of the *lac* operon

Bacteria—with their small genomes and short generation times—have been ideal models for research into molecular genetics. From this research came elegant and universal rules governing the workings of DNA. This led to the “Central Dogma of Biology,” which says that DNA is the repository of genetic information, RNA is a molecule that ferries information between DNA and the ribosome, and proteins produced from the RNA codes are responsible for carrying out the structural and metabolic needs of the cell. And all of this is still accurate.

It is just that there is more to the story. Significant discoveries in eukaryotic organisms have revealed that certain aspects of their genetics have turned out to be somewhat more complex and varied. This does not change our introduction to microbial genetics for two reasons. First, the laws of genetics covered in this chapter do hold true for the vast majority of prokaryotic organisms. Second, this is an *introduction* to genetics and it is certainly fair to leave the exceptions, the unusual, and the overly complex for future courses. We would like to use this feature to introduce some of these revolutionary new findings.

The Genetic Code Is Universal with Some Exceptions

Based on early studies, it was assumed that the master genetic code was the same in all cells and viruses, as no exceptions had ever been seen. Even more convincing, eukaryotic mRNAs were appropriately translated by bacterial cells, arguing for a single genetic dictionary. But later work with mitochondria isolated from yeast and humans found a slightly different code; for example, the stop codon UGA specifies the amino acid tryptophan in mitochondria. This discovery was followed by the detection of other exceptions to the genetic code in a few prokaryotic and eukaryotic organisms. This difference in the genetic code of mitochondria is one of the more compelling pieces of evidence supporting the endosymbiotic theory (see chapter 5).

Genetic Expression Can Be Modified by Epigenetic Mechanisms

For years, geneticists have debated the effects of nature (genes) versus nurture (environment) on the development of organisms. Though both have profound influence, we now have greater understanding about the direct effects of nongenetic factors.

The term *epigenetics* is used to designate factors that effect genetic expression other than the specific sequence of nucleotides in genes. One major epigenetic affect is in the manner that DNA coils around proteins during chromatin formation. This layer of information is only now being fully appreciated and is still far from being completely understood. Epigenetic effects seem to work by increasing or decreasing the expression of certain genes by making them more or less accessible for transcription. For example, having methyl groups ($-\text{CH}_3$) attached to

numerous cytosine nucleotides reduces the level of transcription of a section of DNA that is methylated (**figure a**).

To illustrate this effect, a study in mice determined that the mother's diet during gestation could greatly alter gene expression in her offspring. Genetically identical mothers (clones) were placed into two groups—one that was fed a diet high in the soy chemical genistein and the other a normal diet. The soy group had young mice with significant differences in color coat and weight. They were larger and yellower than the mice from the normal group. This was a permanent effect, because the soy group remained unchanged even when placed on a normal diet. The effect appears to be due to methylation of the embryonic genes by genistein during fetal development (**figure b**).

90,000 Proteins . . . 21,000 Genes?

Humans have about 90,000 different proteins, and, going by our earlier understanding, we would have expected at least 90,000 different genes. Imagine the surprise most biologists felt when the Human Genome Project revealed that we have fewer than 21,000 protein-coding sequences, about 20,000 fewer than a simple corn plant.

For some time it has been known that eukaryotic genes consist of expressed sequences (exons) interspersed with intervening sequences (introns) and that the final mRNA need not contain every exon. Until our low gene count was revealed, however, no one realized how often a single gene could be used to make several different proteins. Utilizing *alternative splicing*, a cell can select which exons will be retained and spliced into a final mRNA. Like a Scrabble player deciding which lettered tiles to use to make a word, a cell can place any combination of the exons in a gene to produce many alternate mRNAs (and resulting proteins). It is currently estimated that three of every four human genes are edited in this way and that the prevalence of alternative splicing appears to increase with the complexity of an organism.

Suggest some reasons for having large parts of the genome silenced or unused. *Answer available on Connect.*

- the *structural locus*, made up of three genes, each coding for a different enzyme needed to catabolize lactose. One of the enzymes, β -galactosidase, hydrolyzes the lactose into its monosaccharides; another, permease, brings lactose across the cell membrane.

The promoter, operator, and structural components lie adjacent to one another, but the regulator can be at a distant site.

In inducible systems such as the *lac* operon, the operon is normally in an *off mode* and does not initiate enzyme synthesis when the appropriate substrate is absent (**figure 9.20, step 1**). How is the operon maintained in this mode? The key is in the repressor protein that is encoded by the regulatory gene. This relatively large molecule is **allosteric**, meaning that its activity can be altered, depending on which active site and substrate are in play. A substrate binding to one active site can distort a different active site and pre-

vent it from accepting its substrate (see figure 8.10*b*). In the absence of lactose, the repressor protein interacts with the operator and causes the operator to distort into a temporary loop configuration. This loop blocks access of the RNA polymerase to the DNA of the operator and prevents transcription. Think of the repressor as a lock on the operator, and if the operator is locked, the structural genes cannot be transcribed. Importantly, the regulator gene is located in a separate site from the operator region and is not affected by this block on the operon.

If lactose is added to the cell's environment, it triggers several events that turn the operon *on*. First, the binding of lactose to the repressor protein creates a shape change in the repressor that dislodges it from the operator segment (**figure 9.20, step 2**). This opens up the operator to allow RNA polymerase to bind to it and begin transcription. The structural genes are transcribed

1 Operon Off: No Lactose
 In the absence of lactose, a repressor protein (the product of a regulatory gene located elsewhere) attaches to the operator of the operon. This effectively blocks transcription of structural genes downstream (to its right). Suppression of transcription (and translation) prevents the unnecessary synthesis of enzymes for processing lactose.

2 Operon On: Lactose Present
 Upon entering the cell, the substrate (lactose) becomes a genetic inducer by attaching to the repressor, which is rendered inactive and falls away. The operator is no longer closed off and its DNA becomes accessible to the RNA polymerase. The RNA polymerase transcribes the structural genes, and the mRNA is translated into enzymes that can act on the lactose substrate.

Process Figure 9.20 The lactose operon in bacteria: How inducible genes are controlled by substrate.

in a single unbroken transcript coding for all three enzymes. During translation, however, each protein is synthesized separately. Because lactose is ultimately responsible for stimulating the chain of events leading to protein synthesis, it is considered an **inducer**.

As lactose is depleted, further enzyme synthesis is not necessary, so the order of events reverses. At this point, there is no longer sufficient lactose to inhibit the repressor; hence, the repressor regains its active shape for attachment to the operator. The operator is locked, and transcription of the structural genes and enzyme synthesis related to lactose are arrested.

A fine but important point about the *lac* operon is that it functions only in the absence of glucose or if the cell's energy needs are not being met by the available glucose. Glucose is the preferred carbon source because it can be used immediately in growth and does not require induction of an operon. When a supply of glucose is present, a second regulatory system ensures that the *lac* operon is inactive, regardless of lactose levels in the environment.

A Repressible Operon

Bacterial systems for synthesis of amino acids, purines and pyrimidines, and other processes work on a principle that is the reverse of the *lac* operon—that of repression. Similar factors such as repressor proteins, operators, and a series of structural genes are part of a repressible operon, but with some important differences. Unlike the *lac* operon, this operon is normally in the *on* mode and will be turned *off* only when the product of the pathway is no longer required. Excess product plays a role as a **corepressor** that slows the transcription of the operon.

A metabolically active cell that is consuming large amounts of the amino acid arginine (*arg*) will serve to illustrate the operation of a repressible operon. Under these conditions, the *arg* operon is set to *on*, and arginine is being actively synthesized through the action of the operon's enzymatic products (**figure 9.21, step 1**). In such an active cell, the arginine will be used immediately, and the repressor will remain inactive (unable to bind the operator) because there is too little free arginine to activate it. As the cell's metabolism begins to slow

1 Operon On: Arginine being used by cell
A repressible operon remains on when its nutrient products (here, arginine) are in great demand by the cell. The repressor has the wrong shape to bind to the DNA operator without a corepressor, so that RNA polymerase is free to actively transcribe the genes and translation actively proceeds.

2 Operon Off: Arginine building up
The operon is repressed when (1) arginine builds up and, serving as a corepressor, activates the repressor. (2) The activated repressor complex affixes to the operator and blocks the RNA polymerase and further transcription of genes for arginine synthesis.

Process Figure 9.21 Repressible operon: Genetic control through excess product.

9.3 MAKING CONNECTIONS

Is it Really an RNA World?

Evidence about the roles of RNAs in gene expression is accumulating rapidly. We have learned how the introns of eukaryotic mRNAs are removed by the catalytic RNA of the spliceosome complex, and the peptide bonds of proteins are catalyzed by ribosomal RNA. Based on our current understanding, it is clear that various forms of RNA dominate genetic control of transcription and translation. This type of RNA, called noncoding RNA (ncRNA) because it does not code for protein, regulates how the coded molecules are expressed.

Recently described ncRNAs in bacteria are **riboswitches**—short leader segments of mRNA that are transcribed but not expressed in a finished protein. Acting as a switch means that they can be turned on or off, depending on their folding pattern, which means they can both start or stop a step in gene expression. Some riboswitches work at the level of transcription and others alter translation, but the outcome of both is to affect protein synthesis. Riboswitches have a unique ability to sense and bind a specific molecule (ligand) such as an amino acid, vitamin, or cofactor that changes their folding pattern and action.

Riboswitches in gram-negative bacteria regulate translation at the ribosome. When the riboswitch is on, the leader sequence of mRNA forms a loop with itself that opens up the binding sequence and makes it available for the ribosome and protein synthesis. The riboswitch is turned off when a ligand binds to it and repositions the binding sequence. This makes the mRNA binding position on the ribosome inaccessible, thereby blocking translation (see figure). Like the *lac* operon, this mechanism will be reversed in the absence of the ligand, and translation can proceed. This riboswitch regulates synthesis of some vitamins.

Eukaryotes have their own versions of controls on transcription and translation. We are just beginning to understand the functions of small RNAs containing around 20 to 25 nucleotides that are found in animal and plant cells. Small RNAs have been termed “gene silencers” because they shut down final products of gene expression. Examples are microRNAs and si (short interfering) RNAs, both of which control the fate of mRNA following transcription. Both types of small RNAs attach to mRNA and keep it from being translated. In some cases, they suppress mRNA functions, and in others, they actually control the synthesis of enzymes that can destroy the mRNA. siRNA is also known to signal the destruction of foreign RNA from viruses.

Another form of eukaryotic regulation acts at the level of the chromosomes, by means of reorganization and modification of the chromatin—a

type of epigenetic effect. By fine-tuning the tightness and looseness of the chromatin structure, certain small RNAs can control which genes are accessible for function (see figure 9.4). Other small RNAs are involved in methylation of DNA, which also modulates gene availability.

Knowledge of these novel types of RNA molecules has answered some questions that came out of genome sequencing studies. Most of the DNA in organisms was found *not* to code for functional proteins. This DNA was once considered “junk,” but its percentage in humans was 85%! Obviously, in bacteria as well as in humans, it is far from junk. In fact, this DNA has been preserved in the same form for many millions of years of evolution, suggesting it has a very important function. We now know that much of it codes for these important RNA regulatory molecules.

In what ways could knowledge of these regulatory RNAs inspire new types of drug therapies? *Answer available on Connect.*

down, however, the synthesized arginine is no longer used up and accumulates. The free arginine is then available to act as a corepressor by attaching to the repressor. This reaction changes the shape of the repressor, making it capable of binding to the operator and stopping transcription. Arginine will cease to be synthesized until the cell once again requires it in metabolism (**figure 9.21, step 2/2**).

Non-Operon Control Mechanisms

Analogous gene control mechanisms in eukaryotic cells are not as well understood, but it is known that gene function can be altered

by intrinsic regulatory segments similar to operons. Some molecules, called transcription factors, insert on the grooves of the DNA molecule and enhance transcription of specific genes. These transcription factors can regulate gene expression in response to environmental stimuli such as nutrients, toxin levels, or even temperature. Eukaryotic genes are also regulated during growth and development, leading to the hundreds of different tissue types found in higher multicellular organisms. Considerable interest has been generated in the functions of regulatory RNAs that exert control on several levels in both prokaryotic and eukaryotic cells (**9.3 Making Connections**).

9.4 Mutations: Changes in the Genetic Code

Expected Learning Outcomes

18. Define a mutation and explain how mutant forms are identified.
19. Summarize the causes and types of mutations and their effects.
20. Describe some mutation repair mechanisms.
21. Compare beneficial and detrimental effects of mutations.

As precise and predictable as the rules of genetic expression seem, permanent changes do occur in the genetic code. Indeed, genetic change is the driving force of evolution through its addition of variation to populations of organisms. Changes may become evident in altered gene expression, such as in the appearance or disappearance of anatomical or physiological traits. For example, a pigmented bacterium can lose its ability to form pigment, or a strain of the malarial parasite can develop resistance to a drug. A phenotypic change that is due to an alteration in the genotype is called a **mutation**. On a strictly molecular level, a mutation is an alteration in the nitrogen base sequence of DNA. It can involve the loss of base pairs, the addition of base pairs, or a rearrangement in the order of base pairs. Do not confuse this with genetic recombination, in which microbes transfer whole segments of genetic information between themselves.

A microorganism that exhibits a natural, nonmutated characteristic is known as a **wild type**, or wild strain. If a microorganism develops a mutation, it is called a **mutant strain**. Mutant strains can show variance in morphology, nutritional characteristics, genetic mechanisms, resistance to chemicals, temperature preference, and nearly any type of enzymatic function. Mutant strains are very useful for tracking genetic events, unraveling genetic organization, and pinpointing genetic markers.

The simplest way to detect mutant bacteria is to inoculate solid media containing differential or selective agents such as metabolic substrates or antibiotics. Growing a pure culture on a plate of media

and observing the appearance of colonies can reveal strains of a species that express genetic variations. For instance, in cultures of wild-type *E. coli* grown on differential MacConkey agar, most of the isolated colonies will indicate a positive result for lactose fermentation, but invariably there will be a small number of colonies that are negative and have lost the genes for using lactose. This colony can be readily pulled out for further study. Antibiotics are frequently added to media as selective agents for separating out strains of bacteria that are drug resistant. Figure 10.12 shows how this method works for detecting recombinant cells used in genetic engineering.

Another method for detecting and isolating mutant strains of microbes that grow in colonies is the *replica plating* technique (figure 9.22). This method is based on a variation between wild strains that can synthesize a nutrient, such as an amino acid, and mutant strains that cannot synthesize it. First a culture of test microbes is exposed to a chemical agent known to cause mutations and then

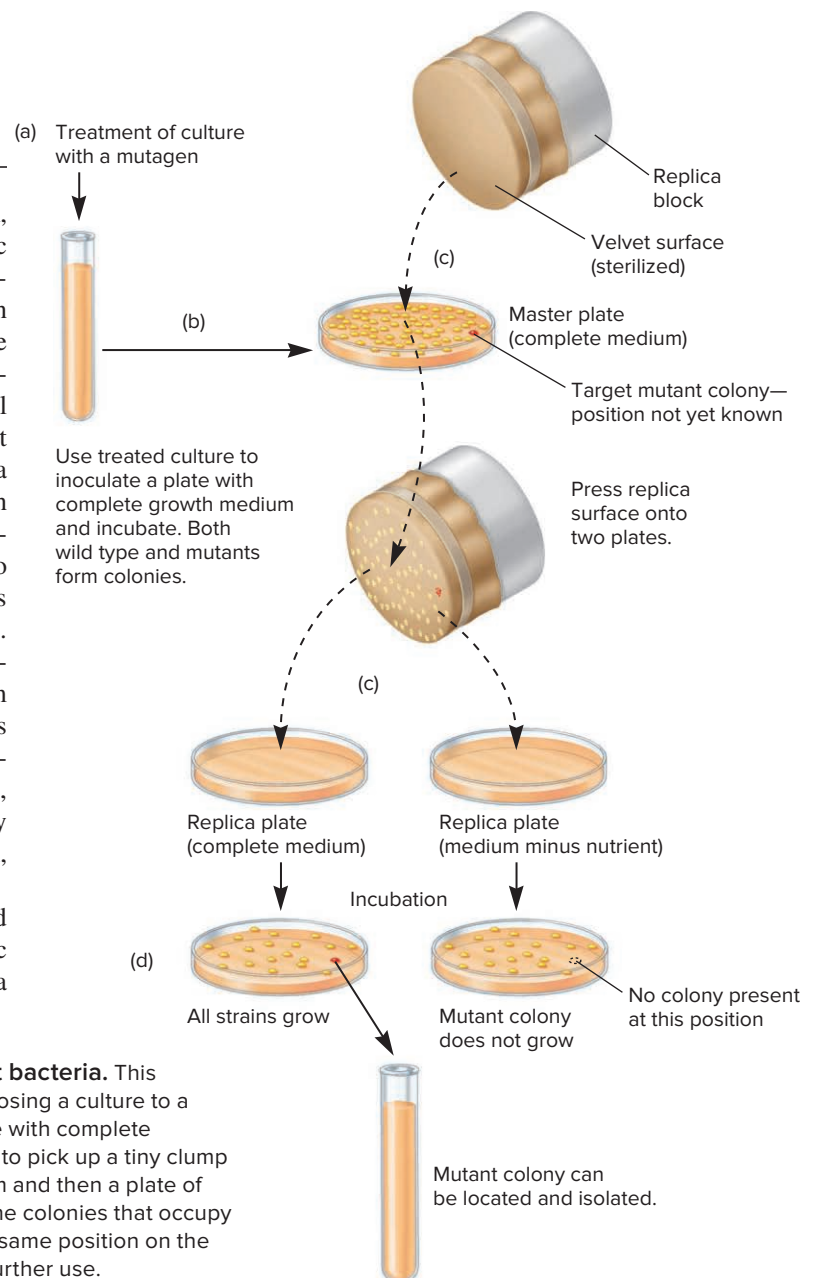

Figure 9.22 The replica plating method for isolating mutant bacteria. This technique was developed by Joshua Lederberg. It is based on (a) exposing a culture to a mutagen, (b) plating the culture for isolated colonies on a master plate with complete nutrients, (c) pressing a sterile carrier onto the surface of the colonies to pick up a tiny clump of cells and pressing it again to inoculate a plate of complete medium and then a plate of incomplete medium. (d) After growth, the two plates are compared. The colonies that occupy a specific position on the complete medium but are missing from that same position on the incomplete medium are mutant colonies that can be subcultured for further use.

plated on a complete medium that contains the particular nutrient. It is important for this to be done in a way that enables individual colonies to form. Colony position on the plate is retained by pressing a pickup or replica carrier onto the colonies and then using the carrier to inoculate two plates in the same orientation. These two plates contain (1) a complete medium containing the nutrient being tested for and (2) an incomplete medium that lacks it. Colonies that grow on the complete medium could be of either the wild or mutant type, but only the wild strains will grow on the incomplete medium. By comparing the two plates side by side, it is possible to locate the position of the colony on the complete medium that does not grow on the incomplete one. This mutant colony is now detectable and can be isolated.

Replica plating has been an effective technique to screen for phenotypic variants of bacteria and other microbes. It has the potential to provide information on a wide variety of metabolic characteristics. For example, it is used to detect mutants that vary in biochemical characteristics such as amino acid synthesis, substrate utilization, and sensitivity to antibiotics. A technique related to this can provide information on the rates of mutation caused by various mutagenic agents (see the Ames test, figure 9.23).

Causes of Mutations

A mutation is described as spontaneous or induced, depending upon its origin. A **spontaneous mutation** is a random change in the DNA arising from errors in replication that occur without a known cause. The frequency of spontaneous mutations has been measured for a number of organisms, and can vary considerably. Bacteria show rates ranging from high (10^{-4} or 1 mutation per base per replication out of 4,000 events) to low (10^{-11} or 1 mutation per base per replication out of 10,000,000,000). The rapid rate of bacterial reproduction allows these mutations to be observed more readily in bacteria than in most eukaryotes.

Induced mutations result from exposure to known **mutagens**, which are primarily physical or chemical agents that damage DNA and interfere with its functioning (table 9.3). The carefully controlled use of mutagens has proved a useful way to induce mutant strains of microorganisms for study.

Agent	Effect
Chemical	
Nitrous acid, bisulfite	Remove an amino group from some nitrogen bases
Ethidium bromide	Inserts between the paired bases
Acridine dyes	Cause frameshifts due to insertion between base pairs
Nitrogen base analogs	Compete with natural bases for sites on replicating DNA
Radiation	
Ionizing (gamma rays, X rays)	Form free radicals that cause single or double breaks in DNA
Ultraviolet	Causes cross-links between adjacent pyrimidines

Chemical mutagenic agents act in a variety of ways to change the DNA. Agents such as acridine dyes insert completely across the DNA helices between adjacent bases. This results in distortion of the helix and can cause frameshift mutations. Analogs⁵ of the nitrogen bases (5-bromodeoxyuridine and 2-aminopurine, for example) are chemical mimics of natural bases that are incorporated into DNA during replication. Addition of these abnormal bases leads to mistakes in base-pairing. Many chemical mutagens are also carcinogens, or cancer-causing agents (see the discussion of the Ames test later in this section).

Physical agents that alter DNA are primarily types of radiation. High-energy gamma rays and X rays introduce major physical changes into DNA, which can accumulate breaks that may not be repairable. Ultraviolet (UV) radiation induces abnormal bonds between adjacent pyrimidines so that normal replication of that region is blocked. Exposure to large doses of radiation can be fatal, which is why radiation is so effective in microbial control; it can also be carcinogenic in animals. The use of radiation to control microorganisms is described further in chapter 11.

Categories of Mutations

Mutations range from large mutations, in which longer genetic sequences are gained or lost, to small ones that affect only a single base on a gene. These latter mutations, which involve addition, deletion, or substitution of single bases, are called **point mutations**.

To understand how a change in DNA influences the cell, remember that the DNA code appears in a particular order of triplets (three bases) that is transcribed into mRNA codons, each of which specifies an amino acid. A permanent alteration in the DNA that is copied faithfully into mRNA and translated can change the structure of the protein. A change in a protein can likewise change the morphology and physiology of a cell. Most mutations have a harmful effect on the cell, leading to cell dysfunction or death; these are called lethal mutations. Neutral mutations produce neither adverse nor helpful changes. A small number of mutations are beneficial in that they provide the cell with a useful change in structure or physiology.

Any change in the code that leads to placement of a different amino acid is called a **missense mutation**. A missense mutation can do one of the following:

- create a faulty, nonfunctional (or less functional) protein,
- produce a protein that functions in a different manner, or
- cause no significant alteration in protein function.

A **nonsense mutation**, on the other hand, changes a normal codon into a stop codon that does not code for an amino acid and stops the production of the protein wherever it occurs. A nonsense mutation almost always results in a nonfunctional protein. A **silent mutation** alters a base but does not change the amino acid and thus has no effect. For example, because of the redundancy of the code, ACU, ACC, ACG, and ACA all code for threonine, so a mutation that changes only the last base will not alter the sense of the message in any way. A **back-mutation** occurs when a gene that has undergone

⁵ An analog is a chemical structured very similarly to another chemical except for minor differences in functional groups.

mutation reverses (mutates back) to its original base composition. An **inversion** occurs when two nucleotides have switched their order, which will nearly always change the amino acid, as we see by inverting GUC (valine) to GCU (threonine).

Mutations also occur when one or more bases are inserted into or deleted from a newly synthesized DNA strand (see **table 9.4, IIB**). This type of mutation, known as a **frameshift**, is so named because the reading frame of mRNA will shift to the left or right, depending on the type of change. Frameshift mutations nearly always result in a nonfunctional protein because the codon structure will become reset from that point on, will code for a different sequence of amino acids from the original DNA, and is likely to introduce stop codons. Also note that insertion or deletion of bases in multiples of three (3, 6, 9, etc.) does not disturb the reading frame downstream from the mutation site. It can still disrupt the structure of the protein, depending on the change in the amino acid sequence. The effects of these types of mutations is modelled in **table 9.4**.

TABLE 9.4 Classification of Major Types of Mutations

	Example
I. Wild-type (nonmutated) sequence	THE BIG BAD CAT ATE THE FAT RED BUG
The wild-type sequence of a gene is the DNA sequence found in most organisms and is generally considered the “normal” sequence.	
II. Categories of mutations based on type of DNA alteration	
A. Substitution mutations	
1. Missense	THE BIG MAD CAT ATE THE FAT RED BUG
A missense mutation causes a different amino acid to be incorporated into a protein. Effects range from unnoticeable to severe, based on how the new amino acid alters protein function.	
2. Nonsense	THE BIG BAD XXX (stop)
A nonsense mutation converts a codon to a stop codon, resulting in premature termination of protein synthesis. Effects of this type of mutation are almost always severe.	
B. Inversion mutations	THE BIG ABD CAT ATE THE FAT RED BUG THE BIB GAD CAT ATE THE FAT RED BUG
Inversions arise when adjacent letters exchange places, which alters 1 or 2 bases, depending on the location of the inversion. This does not change the reading frame, but can result in significant changes in amino acids and protein function.	
C. Frameshift Mutations	
1. Insertion	THE BIG BAB DCA TAT ETH EFA TRE DBU G →
2. Deletion	THE BIG *ADC ATA TET HEF ATR EDB UG ←
Insertion (addition of letter) and deletion (removal of letter) mutations cause a change in the reading frame ↔ of the mRNA, resulting in a protein in which every amino acid after the mutation can be affected. Because of this, frameshift mutations almost always result in a nonfunctional protein.	

Repair of Mutations

Earlier, we indicated that DNA has a proofreading mechanism to repair mistakes in replication that might otherwise become permanent. Because mutations are potentially life-threatening, the cell has additional systems for finding and repairing DNA that has been damaged by various mutagenic agents and processes. Most ordinary DNA damage is resolved by enzymatic systems specialized for finding and fixing such defects.

DNA that has been damaged by ultraviolet radiation can be restored by photoactivation or light repair. This repair mechanism requires visible light and a light-sensitive enzyme, DNA photolyase, which can attach to sites of abnormal pyrimidine bonding and restore the original DNA structure. Ultraviolet repair mechanisms are successful only for a relatively small number of UV mutations. Mutations can be excised by a series of enzymes that remove the incorrect bases and add the correct ones. This process is known as *excision repair*. First, enzymes break the bonds between the bases and the sugar-phosphate strand at the site of the error. A different enzyme subsequently removes the defective bases one at a time, leaving a gap that will be filled in by DNA polymerase I and ligase. A repair system can also locate mismatched bases that were missed during proofreading: for example, C mistakenly paired with A, or G with T. The base must be replaced soon after the mismatch is made, or it will not be recognized by the repair enzymes.

The Ames Test

New agricultural, industrial, and medicinal chemicals are constantly being added to the environment, and exposure to them is widespread. The discovery that many such compounds are mutagenic and that up to 83% of these mutagens are linked to cancer is significant. Although animal testing has been a standard method of detecting chemicals with carcinogenic potential, a more rapid screening system called the **Ames test**⁶ is also commonly used. In this inventive test, the experimental subjects are bacteria whose gene expression and mutation rate can be readily observed and monitored. The premise is that any chemical capable of mutating bacterial DNA can similarly mutate mammalian (and thus human) DNA and is therefore potentially hazardous. Many potential carcinogens (benzanthracene and aflatoxin, for example) are mutagenic agents only after being acted on by mammalian liver enzymes, so an extract of these enzymes is added to the test medium.

One indicator organism in the Ames test is a mutant strain of *Salmonella enterica*⁷ that has lost the ability to synthesize the amino acid histidine, a defect highly susceptible to back-mutation because the strain also lacks DNA repair mechanisms. Mutations

⁶ Named for its creator, Bruce Ames.

⁷ *S. enterica* inhabits the intestine of poultry and causes food poisoning in humans. It is used extensively in genetic studies of bacteria.

that cause reversion to the wild strain, which is capable of synthesizing histidine, occur spontaneously at a low rate. A test agent is considered a mutagen if it enhances the rate of back-mutation beyond levels that would occur spontaneously. **Figure 9.23** compares a standard version of the test with a multiwell method that streamlines result taking. The Ames test has proved invaluable

for screening an assortment of environmental and dietary chemicals for mutagenicity and carcinogenicity without resorting to animal studies.

Positive and Negative Effects of Mutations

Many mutations are not repaired. How the cell copes with them depends on the nature of the mutation and the strategies available to that organism. Mutations are passed on to the offspring of organisms during reproduction and to new viruses during replication. They become a long-term part of the gene pool. Most mutations are harmful to organisms, but some can provide adaptive advantages.

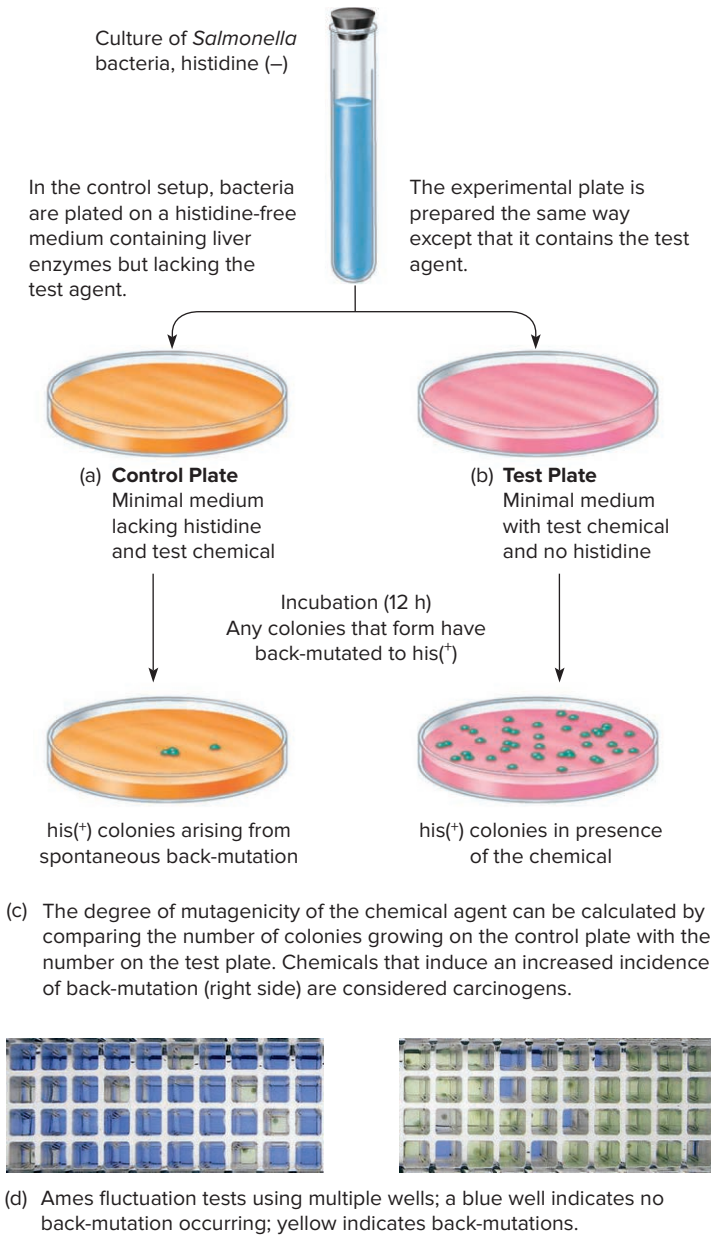

If a mutation leading to a nonfunctional protein occurs in a gene for which there is only a single copy, as in haploid or simple organisms, the cell will probably die. This happens when certain mutant strains of *E. coli* acquire mutations in the genes needed to repair damage by UV radiation. Mutations of the human genome affecting the action of a single protein (mostly enzymes) are responsible for more than 3,500 diseases.

Although most spontaneous mutations are not beneficial, a small number contribute to the success of the individual and the population by creating variant strains with alternate ways of expressing a trait. Microbes are not “aware” of this advantage and do not direct these changes; they simply respond to the environment they encounter. In the long-range view, mutations and the variations they produce are the raw materials for change in the population and, thus, for evolution.

Mutations that create variants occur frequently enough that any population contains mutant strains for a number of characteristics, but as long as the environment is stable, these mutants will never comprise more than a tiny percentage of the population. When the environment changes, however, it can become hostile for the survival of certain individuals, and only those microbes bearing protective mutations will be equipped to survive in the new environment.

Such observations can be explained by the important biological principles of natural selection and survival of the fittest. This theory states that environmental pressure selects for organisms that have greater adaptability due to beneficial mutations. They are more likely to survive, reproduce, and pass the changed genes on to succeeding generations. In time, these survivors become the dominant members of the population as long as the mutation continues to favor their survival. One of the clearest models for natural selection in action is acquired drug resistance in bacteria (discussed in chapter 12).

As we will see in section 9.5, bacteria have additional mechanisms for changing their genetic makeup by sharing genes with other bacteria through recombination.

Counting the number of (+) yellow wells provides the number of back-mutations; the result on the right indicates a strong mutagen.

Figure 9.23 The Ames test. (a, b, c) In this traditional plate method, a strain of *Salmonella enterica* that cannot synthesize histidine [his (-)] is the test species. If the chemical causes an increase in mutation rate to histidine-producing cells as compared to a control, the chemical is considered mutagenic. (d) The newer well fluctuation test is based on the same basic scheme, however, it has greater sensitivity and is easier to evaluate. (d) Courtesy of Xenometrix AG

24. Describe the primary causes, types, and outcomes of mutations. Give an example of a mutation that is beneficial and one that is lethal or harmful.
25. Explain the purposes behind replica plating and the Ames test.

9.5 DNA Recombination Events

Expected Learning Outcomes

22. Explain recombination in bacteria and what it involves.
23. Describe the main features of conjugation and its outcomes.
24. Discuss what is required for bacterial transformation and its outcomes.
25. Identify the basic processes involved in transduction and the end results.
26. Discuss transposons and their importance to microorganisms.

Genetic recombination through sexual reproduction is an important means of genetic variation in eukaryotes. Although bacteria have no exact equivalent to sexual reproduction, they exhibit a primitive means for sharing or recombining parts of their genomes. An event in which one bacterium donates DNA to another bacterium is a type of genetic transfer termed **recombination**, the end result of which is a new strain different from both the donor and the original recipient strain. In general, any organism that has acquired genes that originated in another organism is called a **recombinant**.

Recombination in bacteria depends largely on their extreme versatility in acquiring and expressing the genetic material of other bacteria and even other organisms. This capacity for genetic sharing has tremendous effects on the diversity and evolution of bacteria. Unlike spontaneous mutations, recombinations are generally beneficial. They can provide additional genes for resistance to drugs and metabolic poisons, new nutritional and metabolic schemes, increased virulence, and adaptations to changing environmental conditions.

Transmission of Genetic Material in Bacteria

DNA transfer between bacterial cells typically involves small pieces of DNA in the form of **plasmids** or chromosomal fragments. Plasmids are small, circular pieces of DNA that contain their own origin of replication and therefore can replicate independently of the bacterial chromosome. Plasmids are found in many bacteria (as well as some fungi) and typically contain a few dozen genes. Although plasmids are not necessary for bacterial survival, they often carry adaptive genes, such as those for drug resistance.

The Case Study that opens this chapter details a pathogen that has received dozens of resistance genes from other species. Chromosomal fragments that have escaped from a lysed bacterial cell are also commonly involved in the transfer of genetic information between cells. An important difference between plasmids and fragments is that, while a plasmid can be stably replicated and inherited, chromosomal fragments must integrate themselves into the bacterial chromosome in order to be replicated and eventually passed to progeny cells. The rate of natural genetic recombination varies a great deal among bacteria, but its frequency can be increased in the laboratory, where the ability to transfer genes between organisms has become an important tool of research and technology.

Depending upon the mode of transmission, the means of genetic recombination in bacteria is called conjugation, transformation, or transduction. **Conjugation** requires the attachment of two cells and the formation of a bridge that can transport DNA. **Transformation** entails the transfer of free DNA and requires no special vehicle. **Transduction** is DNA transfer mediated through the action of bacterial viruses (table 9.5).

Conjugation: Genetic Transmission Through Direct Contact

Conjugation is a mode of genetic recombination in which a plasmid or fragment of DNA is transferred from a donor cell to a recipient cell via a direct connection. Both gram-negative and gram-positive bacteria can conjugate, but only gram-negative cells operate with a specialized plasmid called a **fertility**, or **F factor**. This plasmid directs the synthesis of a unique **pilus**, also called a sex pilus,⁸ that functions in most conjugation transfers. The recipient cell is usually a related bacterium with a recognition site on its surface for interacting with the pilus (figure 9.24, step 1).

A cell's role in conjugation is denoted by F^+ for the cell that has the F plasmid and by F^- for the cell that lacks it. Contact is made when a pilus grows out from the F^+ cell, attaches to the surface of the F^- cell, contracts, and draws the two cells together (figure 9.24, step 1). At the site where the pilus attaches the two cells, a mating or conjugative bridge is formed that serves as a transfer

⁸ This term refers to its function in the mating of bacteria, but it has nothing to do with sexual reproduction, which is absent in bacteria.

TABLE 9.5 Types of Genetic Recombination in Bacteria

Mode	Factors Involved	Direct or Indirect*	Examples of Genes Transferred
Conjugation	Donor cell with pilus Fertility plasmid in donor Both donor and recipient alive Bridge forms between cells to transfer DNA.	Direct	Drug resistance; resistance to metals; toxin production; enzymes; adherence molecules; degradation of toxic substances; uptake of iron
Transformation	Free donor DNA (fragment or plasmid) Live, competent recipient cell, donor usually dead	Indirect	Polysaccharide capsule; metabolic enzymes; drug resistance; unlimited with cloning techniques
Transduction	Donor is lysed bacterial cell. Defective bacteriophage is carrier of donor DNA. Live recipient cell of same species as donor	Indirect	Exotoxins; enzymes for sugar fermentation; drug resistance

*Direct means the donor and recipient are in contact during exchange; indirect means they are not.

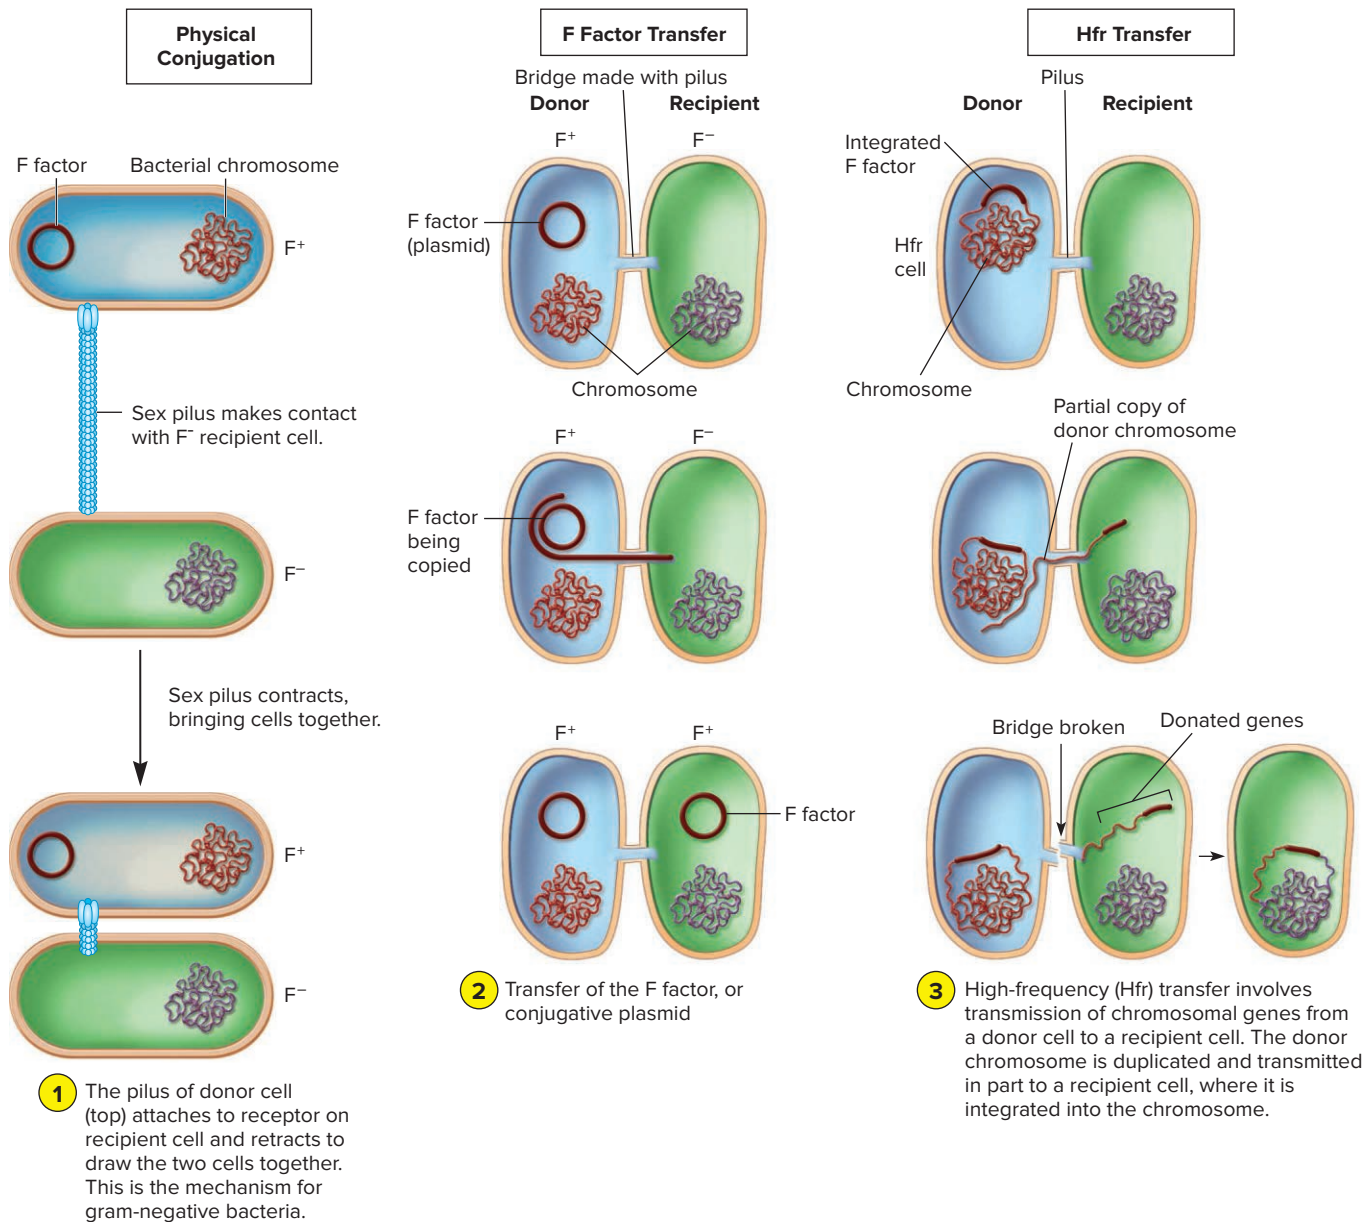

system for the plasmid. The latest reliable information indicates that the pilus becomes part of a complex secretory system that opens a gateway between the cell walls and membranes of the two cells and serves as a passageway for the plasmid.

There are hundreds of conjugative plasmids with some variations in their properties. One of the best understood plasmids is the F factor in *E. coli*, which exhibits these patterns of transfer:

1. Because bacteria tend to conserve plasmids, the donor cell first makes a copy of the F factor, which is simultaneously transferred across the bridge (figure 9.24, step 2). This way, it retains the original plasmid, remains F⁺, and can continue to conjugate with other bacteria. The F⁻ cell has been changed into an F⁺ cell capable of producing a pilus and conjugating with other cells. No additional donor genes are transferred during this transfer.
2. In high-frequency recombination (Hfr) donors, the fertility factor has been integrated into the F⁺ donor chromosome.

The term *high-frequency recombination* denotes that a cell with an integrated F factor transmits its chromosomal genes at a higher frequency than other cells. This is because the F factor can direct a more comprehensive transfer of part of the donor chromosome to a recipient cell. This transfer occurs through replication of the donor chromosome along with the F factor. One strand of DNA is retained by the donor, and the other strand is transported across to the recipient cell (figure 9.24, step 3). The F factor may not be transferred during this process. The transfer of an entire chromosome takes about 100 minutes, but the pilus bridge between cells is ordinarily broken before this time, and rarely is the entire genome of the donor cell transferred.

Conjugation has great biomedical importance. Special **resistance (R) plasmids**, or **factors**, that bear genes for resisting antibiotics and other drugs are commonly shared among bacteria through conjugation. Transfer of R factors can confer multiple resistance to antibiotics such as tetracycline, chloramphenicol, sulfonamides,

Process Figure 9.24 Conjugation: Genetic transmission through direct contact between two cells.

and penicillin. This phenomenon is discussed further in chapter 12. Other types of R factors carry genetic codes for resistance to heavy metals (nickel and mercury) or for synthesizing virulence factors (toxins, enzymes, and adhesion molecules) that increase the pathogenicity of the bacterial strain. Conjugation studies have also provided a means to map the bacterial chromosome.

A few gram-positive bacteria (*Bacillus* and *Streptococcus*, for example) are known to recombine through conjugation. Because they lack pili, they must transport the plasmids via specialized proteins activated during adhesion of the two cells. The mechanisms involved are yet to be fully worked out.

Transformation: Capturing Free DNA from Solution

One of the cornerstone discoveries in microbial genetics was made in the late 1920s by the English biochemist Frederick Griffith working with *Streptococcus pneumoniae* and laboratory mice. The pneumococcus exists in two major strains based on the presence of the capsule, colonial morphology, and pathogenicity. Encapsulated strains bear a smooth (S) colonial appearance and are virulent; strains lacking a capsule have a rough (R) appearance and are nonvirulent. (Recall from chapter 4 that the capsule protects a bacterium from the phagocytic host defenses.) Griffith first showed that when mice were injected with a live, virulent (S) strain, they soon died (**figure 9.25a**). Mice injected with a live, nonvirulent (R) strain remained alive and healthy (**figure 9.25b**). Next he tried a variation on this theme. He heat-killed an S strain and injected it into mice, which remained healthy (**figure 9.25c**). Then came the ultimate test: Griffith injected both dead S cells and live R cells into mice, with the result that the mice died from pneumococcal blood infection (**figure 9.25d**). If killed bacterial cells do not come back to life and the nonvirulent live strain was harmless, why did the mice die? Although he did not know it at the time, Griffith had demonstrated that dead S cells, while passing through the body of the mouse, broke open and released some of their DNA (by chance, a segment containing the genes for making a capsule). A few of the live R cells subsequently picked up this loose DNA and were transformed by it into virulent, capsule-forming strains.

Later studies supported the concept that a chromosome released by a lysed cell breaks into fragments small enough to be accepted by a recipient cell and that DNA, even from a dead cell, retains its genetic code. This nonspecific acceptance by a bacterial cell of small fragments of soluble DNA from the surrounding environment is termed **transformation** (**figure 9.26**). Transformation is facilitated by special DNA-binding proteins on the cell wall that capture DNA from the surrounding medium. Cells that are capable of accepting genetic material through this means are termed **competent**. The new DNA is passed through a DNA uptake system in the cell wall and membrane. Within the cytoplasm, the donated strand is inserted into the chromosome of the recipient cell, now said to be *transformed*. Natural transformation is found in several groups of gram-positive and gram-negative bacterial species. In addition to genes coding for the capsule, bacteria also exchange genes for antibiotic resistance and bacteriocin synthesis in this way.

Because transformation requires no special appendages, and the donor and recipient cells do not have to be in direct contact, the process

Figure 9.25 Griffith's classic experiment in transformation. In essence, this experiment proved that DNA released from a killed cell can be acquired by a live cell. The cell receiving this new DNA is genetically transformed—in this case, from a nonvirulent strain to a virulent one.

Figure 9.26 Steps in bacterial transformation as seen in *S. pneumoniae*. This shows how genes coding for capsule formation are brought into the cell and inserted into the chromosome. Cap^+ indicates genes for forming a capsule.

is useful for applications in recombinant DNA technology. With this technique, foreign genes from a completely unrelated organism are inserted into a plasmid, which is then introduced into a competent bacterial cell through transformation. These recombinations can be carried out in a test tube, and human genes can be experimented upon and even expressed outside the human body by placing them in a microbial cell. Transformation is often used in the production of genetically engineered organisms such as yeasts, plants, and animals, and has been proposed as a future technique for curing genetic diseases in humans. These topics are covered in more detail in chapter 10.

Transduction: Viruses as Vectors

Bacteriophages (bacterial viruses) have been previously described as destructive bacterial parasites. Viruses can also serve as genetic vectors (an entity that can bring foreign DNA into a cell). The process by which a bacteriophage serves as the carrier of DNA from a donor cell to a recipient cell is **transduction**. Although it occurs naturally in a broad spectrum of bacteria, the participating bacteria

Process Figure 9.27 Generalized transduction: Genetic transfer by means of a virus carrier. (1) A phage infects cell A (the donor cell) by normal means. (2) During replication and assembly, a phage particle incorporates a segment of bacterial DNA by mistake. (3) Cell A then lyses and releases the mature phages, including the genetically altered one. (4) The altered phage adsorbs to and penetrates another host cell (cell B), injecting the DNA from cell A rather than viral nucleic acid. (5) Cell B receives this donated DNA, which recombines with its own DNA. Because the virus is defective (biologically inactive as a virus), it is unable to complete a lytic cycle. The transduced cell survives and can use this new genetic material.

in a single transduction event must be the same species because of the specificity of viruses for host cells.

There are two versions of transduction. In *generalized transduction* (figure 9.27), random fragments of disintegrating host DNA are taken up by the phage during assembly. Virtually any

gene from the bacterium can be transmitted through this means. In *specialized transduction* (**figure 9.28**), a highly specific part of the host genome is regularly incorporated into the virus. This specificity is explained by the prior existence of a temperate prophage inserted in a fixed site on the bacterial chromosome. When activated, the prophage DNA separates from the bacterial chromosome, carrying a small segment of host genes with it. During a lytic cycle, these specific viral-host gene combinations are incorporated into

Process Figure 9.28 Specialized transduction: Transfer of specific genetic material by means of a virus carrier. (1) Specialized transduction begins with a cell that contains a prophage (red). (2) When the virus enters a lytic cycle, it excises itself from its host cell, carrying along some host DNA. (3) Replication and assembly results in production of a **chimeric** virus containing viral and bacterial DNA. (4) Release of the recombinant virus and infection of a new host result in transfer of bacterial DNA between cells. (5) Recombination can occur between the new host chromosome and the virus DNA, resulting in either bacterial DNA or a combination of viral and bacterial DNA being incorporated into the bacterial chromosome.

the viral particles and carried to another bacterial cell. Instances of transduction include the transfer of drug resistance seen in *Staphylococcus* spp. and the transmission of gene regulators in gram-negative rods such as *Escherichia* and *Salmonella*.

Transposons: “The Case of the Jumping Genes” One type of genetic transferral of great interest involves transposable elements, or **transposons**. Transposons have the distinction of shifting from one part of the genome to another and so are termed “jumping genes.” When the idea of their existence in corn plants was first postulated by the geneticist Barbara McClintock, it was greeted with wide skepticism, because it had long been believed that the location of a given gene was set and that genes did not or could not move around. Now it is evident that jumping genes are widespread among prokaryotic and eukaryotic cells and viruses. Results from analysis of human DNA indicates that they make up nearly 45% of the human genome.

All transposons share the general characteristic of traveling from one location to another on the genome—from one chromosomal site to another, from a chromosome to a plasmid, or from a plasmid to a chromosome (**figure 9.29**). Because transposons can occur in plasmids, they can also be transmitted from one cell to another in bacteria and a few eukaryotes. Some transposons replicate themselves before jumping to the next location, and others simply move without replicating first.

Transposons contain DNA that codes for the enzymes needed to remove and reintegrate the transposon at another site in the genome. Flanking the coding region of the DNA are sequences called inverted repeats, which mark the point at which the transposon is

Figure 9.29 Transposons: Shifting segments of the genome. (1) A transposon exists as a small piece of DNA integrated into the host cell chromosome (red). (2) The transposon may excise itself and move from one location to another in the genome, maintaining itself as a single copy per cell. (3) It may also replicate prior to moving, leading to an increase in the copy number and a greater effect on the genome of the host. (4) Finally, the transposon may jump to a plasmid, which can then be transferred to another bacterial cell.

removed or reinserted into the genome. The smallest transposons consist of only these two genetic sequences and are often referred to as *insertion elements*. A type of transposon called *retrotransposon* can transcribe DNA into RNA and then back into DNA for insertion in a new location. Another example is the *integron*, which can carry large blocks of genetic material that are especially prominent in transmitting drug resistance.

The overall effect of transposons—to scramble the genetic language—can be beneficial or adverse, depending upon such variables as where insertion occurs in a chromosome, what kinds of genes are relocated, and the type of cell involved. In bacteria, transposons are known to be involved in

- changes in traits such as colony morphology, pigmentation, and antigenic characteristics;
- replacement of damaged DNA; and
- the transfer of drug resistance in bacteria.

9.6 The Genetics of Animal Viruses

Expected Learning Outcomes

27. Explain the major elements of viral genetics.
28. Compare aspects of the genetics of DNA and RNA viruses, using examples.

Viruses essentially consist of one or more pieces of DNA or RNA enclosed in a protective coating. They are genetic parasites that require access to their host cell's genetic and metabolic machinery to be replicated, transcribed, and translated, and they also have the potential for genetically changing the cells. Because they contain mainly those genes needed for the production of new viruses, the genomes of viruses tend to be very small and compact.

Viruses show extensive variety in genetic patterns. In many viruses, the nucleic acid is linear in form; in others, it is circular. The genome of most viruses exists in a single molecule, though in a few, it is segmented into several smaller molecules. Most viruses contain normal double-stranded (ds) DNA or single-stranded (ss) RNA, but other patterns exist. There are ssDNA viruses, dsRNA viruses, and retroviruses, which work backward by making dsDNA from ssRNA. In some instances, viral genes overlap one another, and in a few DNA viruses, both strands contain a translatable message.

With few exceptions, replication of the DNA molecule of DNA animal viruses occurs in the nucleus, where the cell's DNA replication

machinery lies. The genome of most RNA viruses is replicated in the cytoplasm. In all viruses, viral mRNA is translated into viral proteins on host cell ribosomes using host tRNA.

Replication Strategies in Animal Viruses

Replication, Transcription, and Translation of dsDNA Viruses

Replication of dsDNA viruses is divided into phases (**figure 9.30**). During the early phase, viral DNA enters the nucleus, where several genes are transcribed into a messenger RNA. Next, the mRNA transcript then moves into the cytoplasm to be translated into viral proteins (enzymes) needed to replicate the viral DNA. This replication usually occurs in the nucleus with the host cell's own DNA polymerase, though some viruses (herpes, for example) have their own. During the late phase, other viral genes are transcribed and

Figure 9.30 General stages in the multiplication of double-stranded DNA viruses. The virus penetrates the host cell and releases DNA, which, (1) enters the nucleus and (2) is transcribed by host cell enzymes into mRNA. (3) Viral mRNA leaves the nucleus and is translated into structural proteins; these proteins are transported into the nucleus. (4) Viral DNA is replicated repeatedly in the nucleus. (5) Viral DNA and proteins are assembled into a mature virus in the nucleus. (6) Because it is double-stranded, some viral DNA can insert itself into host DNA (latency). Some exceptions to this pattern occur in the poxviruses.

translated into proteins required to form the capsid and other structures. The new viral genomes and capsids are assembled, and the mature viruses are released by budding or cell disintegration.

Double-stranded DNA viruses can interact directly with the DNA of their host cell. In some viruses, the viral DNA becomes silently *integrated* into the host's genome by insertion at a particular site on the host genome. Persistence of viral DNA may also lead to the transformation of the host cell into a cancer cell. Several DNA viruses, including hepatitis B (HBV), the herpesviruses, and papillomaviruses (warts), are known to be initiators of cancers and are thus termed **oncogenic**. The mechanisms of oncogenic transformation involve viral genes that regulate cellular genomes and control the cell division cycle.

Replication, Transcription, and Translation of RNA Viruses

RNA viruses exhibit several differences from DNA viruses. Their genomes are smaller, they enter the host cell already in an RNA form, and the virus cycle occurs entirely in the cytoplasm for most viruses. RNA viruses can have one of the following genetic messages:

1. a positive-strand (+) genome that comes ready to be translated into proteins,
2. a negative-strand (–) genome that must be converted to a positive-strand before translation, and
3. a positive-strand (+) genome that can be converted to DNA or a dsRNA genome.

Positive-Strand Single-Stranded RNA Viruses

The ssRNA of positive-strand viruses such as polio come ready to be translated, so it is immediately translated into a large protein and cleaved into individual functional units. One of these is an RNA polymerase that initiates the replication of the viral strand. Replication of a positive-message strand happens in two steps (**figure 9.31**). First, a negative strand is synthesized using the positive strand as a template by the usual base-pairing mechanism. The resultant negative strand becomes a master template that formats the formation of new positive daughter strands. Further translation of the viral genome produces large numbers of structural proteins for final assembly and maturation of the virus.

RNA Viruses with Reverse Transcriptase: Retroviruses

A most unusual class of viruses can reverse the order of the flow of genetic information. Thus far in our discussion, all genetic entities have shown the patterns DNA → DNA, DNA → RNA, or RNA → RNA. Retroviruses, including HIV, the cause of AIDS, and HTLV I, a cause of one type of human leukemia, synthesize DNA using their RNA genome as a template. They accomplish this by means of a **reverse transcriptase** that comes packaged with each virus particle. This enzyme synthesizes a single-stranded DNA against the viral RNA template and then directs the formation of a complementary strand of this ssDNA, resulting in a double strand of viral DNA. The dsDNA strand enters the nucleus, where it can be

Figure 9.31 Replication of positive-strand, single-stranded RNA viruses. In general, these viruses do not enter the nucleus. (1) Penetration of viral RNA. (2) Because it is positive in message and single-stranded, the RNA can be directly translated on host cell ribosomes into various necessary viral proteins. (3) A negative genome is synthesized against the positive template to produce large numbers of positive genomes for final assembly. (4) The negative template is then used to synthesize a series of positive replicates. (5) RNA strands and proteins assemble into mature virus released when the cell lyses.

transcribed by the usual mechanisms into new viral ssRNA and used to assemble new viral particles. When the DNA of some retroviruses becomes inserted into the host's DNA as a provirus, cells may be transformed and produce tumors. Insertion allows HIV to remain latent in an infected cell for several years.

CASE STUDY Part 2

Cases of *A. baumannii* infections were first reported in the 1970s. At that time it was not considered a serious pathogen, and it was sensitive to most available drugs. How did it go from being an uncommon infectious agent to one that accounts for 20% of infections acquired in intensive care units? How did the number of MDR strains increase from 3% to 40%? It had not developed greater virulence.* It is actually relatively harmless for most healthy people with intact immune systems. It is an opportunist that attacks mainly immunocompromised patients with various underlying medical problems. This pathogen infects a variety of organs and systems, including respiratory, skin, urinary, and the bloodstream. Medical specialists suspect that its rapid evolution can be explained by the combination of four factors: the widespread distribution of the bacteria in the environment, the drug-rich environment of hospitals and clinics, the increase in severely compromised patients, and the pathogen's extreme genetic adaptability to challenges from new drugs.

For many years the rise of “superbugs” has become a major concern of the medical community. The working definition of this term includes any bacterial species that have developed significant resistance to several drugs that would ordinarily have been given in therapy. Two of the *A. baumannii* strains described here are defined as multiple drug resistant (MDR), in that they resist a fairly broad range of drugs. One strain fits the category of extreme drug resistance (XDR), meaning that it is resistant to all possible drugs. Both versions of this pathogen have been added to the list of emerging diseases.

- *In what ways is Acinetobacter an opportunist?*
- *Which genetic events have allowed Acinetobacter to become so resistant?*

To conclude this Case Study, go to Connect.

These topics are discussed further in chapter 12.

* *virulence* (veer'-yoo-lents) Ability of a microbe to invade and damage a host.

Chapter Summary with Key Terms

9.1 Introduction to Genetics and Genes: Unlocking the Secrets of Heredity

- A. Genetics is the study of heredity and can be studied at the level of the organism, genome, chromosome, gene, and DNA. Genes provide the information needed to construct proteins, which have structural or catalytic functions in the cell.
- B. DNA is a long molecule in the form of a double helix. Each strand of the helix consists of a string of nucleotides.
 1. A **nucleotide** consists of a phosphate, **deoxyribose sugar**, and **nitrogen base**. The bases form **hydrogen bonds** with their counterparts on the other strand.
 2. **Adenine** base-pairs with **thymine** while **guanine** base-pairs with **cytosine**.
 3. The order of the nucleotides specifies which amino acids will be used to construct proteins during the process of translation.
- C. **Replication** of DNA—making copies of the genetic program.
 1. Requires unwinding the double helix and exposing the nucleotides to serve as templates for synthesis of 2 identical molecules by **DNA polymerase**.
 2. Is **semiconservative** and proceeds in the 5' to 3' direction of the newly synthesized DNA.

9.2 Applications of the DNA Code: Transcription and Translation

- A. DNA is used to produce RNA (**transcription**) and RNA is then used to produce protein (**translation**).
- B. **RNA**: Unlike DNA, RNA is single stranded, contains **uracil** instead of thymine and **ribose** instead of deoxyribose.
 1. Major forms of RNA found in the cell include **mRNA**, **tRNA**, and **rRNA**.
 2. The genetic information contained in DNA is copied to produce an RNA molecule. **Codons** in the mRNA pair

with **anticodons** on the tRNA to specify which amino acids to assemble on the **ribosome** during translation.

C. *Transcription and Translation*:

1. Transcription occurs when **RNA polymerase** copies the template strand of a segment of DNA. RNA is always made in the 5' to 3' direction.
 2. Translation occurs when the mRNA is used to direct the synthesis of proteins on the ribosome.
 3. Codons in the mRNA pair with anticodons on the tRNA to assemble a string of amino acids. This occurs until a stop codon is reached.
- D. *Eukaryotic Gene Expression*: Eukaryotic genes are composed of **exons** (expressed sequences) and **introns** (intragenic regions). The introns must be removed and the exons spliced together to create the final mRNA.

9.3 Genetic Regulation of Protein Synthesis and Metabolism

Protein synthesis is regulated through gene induction or repression, as controlled by an **operon**. Operons consist of several structural genes controlled by a common regulatory element.

- A. **Inducible operons** such as the lactose operon are normally off but can be turned on by a lactose inducer.
- B. **Repressible operons** are usually on but can be turned off when their end product is no longer needed.
- C. Newly described types of RNA can serve in gene regulation.
 1. Micro and small interfering RNAs can block the action of other RNAs and shut down gene expression in eukaryotes.
 2. **Riboswitches** can also control RNA functions related to transcription and translation in bacteria.

9.4 Mutations: Changes in the Genetic Code

- Changes in the genetic code occur primarily through mutation and recombination.
- Inheritable changes in the genome of a microorganism are known as mutations. They usually entail an alteration in the nucleotide composition of the genetic material. Mutations may be **spontaneous** or **induced**.
- Mutations are detected by the use of selective media and the replica plating technique.
- Point mutations entail a change in one or a few bases and are categorized as **missense**, **nonsense**, **silent** mutations, and **back-mutations**, based on the effect of the change in nucleotide(s).
- Frame-shift mutations** that reset the reading frame and alter downstream coding structure are caused by **deletions** and **insertions** of nucleotides.
- The **Ames test** measures the mutagenicity of chemicals by their ability to induce mutations in bacteria.

9.5 DNA Recombination Events

- Recombination** involves the acquisition of new genetic material from an outside source.

- Intermicrobial transfer and genetic recombination permit gene sharing between bacteria. Major types of recombination include **conjugation**, **transformation**, and **transduction**.
- Transposons** are DNA sequences that regularly move to different places within the genome of a cell, generating mutations and variations in chromosome structure.

9.6 The Genetics of Animal Viruses

- Viruses contain various forms of DNA and RNA that are transcribed and translated by the genetic machinery of their host cells to form functioning viral particles.
 - Genomes of viruses are found in double-stranded (ds) DNA and single-stranded (ss) RNA forms. A few contain unusual ssDNA and dsRNA not found in cells.
 - DNA viruses tend to replicate in the nucleus while RNA viruses replicate in the cytoplasm. **Retroviruses** synthesize dsDNA using ssRNA as a template.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

- What is the smallest unit of heredity (genotype)?
 - chromosome
 - gene
 - codon
 - nucleotide
- A nucleotide contains which of the following?
 - 5-carbon sugar
 - nitrogen base
 - phosphate
 - b and c only
 - all of these
- The nitrogen bases in DNA are bonded to the
 - phosphate
 - deoxyribose
 - ribose
 - hydrogen
- DNA replication is considered semiconservative because the _____ strand will remain as half of the _____ molecule.
 - antisense, DNA
 - template, final DNA
 - sense, mRNA
 - codon, anticodon
- In DNA, adenine is the complementary base for _____, and cytosine is the complement for _____.
 - guanine, thymine
 - uracil, guanine
 - thymine, guanine
 - thymine, uracil
- The base pairs are held together primarily by
 - covalent bonds
 - ionic bonds
 - hydrogen bonds
 - gyrases
- Why must the lagging strand of DNA be replicated in short pieces?
 - because of limited space
 - otherwise, the helix will become distorted
 - the DNA polymerase can synthesize in only one direction
 - to make proofreading of code easier
- Messenger RNA is formed by _____ of a gene on the DNA template strand.
 - transcription
 - replication
 - translation
 - transformation
- Transfer RNA is the molecule that
 - contributes to the structure of ribosomes
 - adapts the genetic code to protein structure
 - transfers the DNA code to mRNA
 - provides the master code for amino acids
- As a general rule, the first codon on a the DNA template strand that signals the start for a protein is
 - TAC
 - AUG
 - ATG
 - UAC
- What components are involved in transcription?
 - sigma factor
 - RNA polymerase
 - promotor
 - only b and c
 - all of these
- The *lac* operon is usually in the _____ position and is activated by a/an _____ molecule.
 - on, repressor
 - off, inducer
 - on, inducer
 - off, repressor
- For mutations to have an effect on populations of microbes, they must be
 - inheritable
 - permanent
 - beneficial
 - a and b
 - all of these

14. Which of the following characteristics is *not* true of a plasmid?
- It is a circular piece of DNA.
 - It is required for normal cell function.
 - It is found in bacteria.
 - It can be transferred from cell to cell.
15. Which genetic material could be transmitted naturally by all three methods of intermicrobial transfer?
- an *E. coli* chromosome
 - F factor
 - drug resistance genes
 - a and c
 - all of these
16. Which of these features is found in eukaryotes but not bacteria?
- polygene mRNAs
 - introns
 - stop codon
 - AUG codon
17. Which of the following is present in prokaryotes but not eukaryotes?
- exons
 - polyribosomes
 - spliceosomes
 - simultaneous transcription and translation
18. **Multiple Matching.** Fill in the blanks with all the letters of the words below that apply.
- _____ site of protein synthesis
 - _____ carries the codon
 - _____ carries the anticodon
 - _____ a process synonymous with mRNA synthesis
 - _____ bacteriophages participate in this transfer
 - _____ duplication of the DNA molecule
 - _____ process in which transcribed DNA code is deciphered into a polypeptide
 - _____ involves plasmids
- replication
 - tRNA
 - conjugation
 - ribosome
 - transduction
 - mRNA
 - transcription
 - transformation
 - translation
 - none of these

Case Study Review

- Which of the following is not a factor in the rise of drug-resistant *Acinetobacter baumannii*?
 - It is very widespread in many habitats.
 - It has acquired greater toxicity.
 - It readily acquires genetic material from other species.
 - The hospital environment brings together vulnerable patients and drugs.
- Drug-resistance plasmids could be transferred in *A. baumannii* by which of the following mechanisms:
 - conjugation pilus
 - bacteriophages
 - capture by cell wall
 - a and b
 - a, b, and c
- Explain how it would be possible for *A. baumannii* to develop drug resistance to a drug in the body of a patient while he or she is receiving therapy.

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

- Explain what is meant by the following diagram.

- On paper, replicate the following segment of DNA:

5' ATCGGCTACGTTTCACT 3'
3' TAGCCGATGCAAGTGT 5'

- Show the direction of replication of the new strands and explain what causes lagging and leading strands to show different patterns of replication.
 - Explain how this is semiconservative replication. Are the new strands identical to the original segment of DNA?
- The following sequence represents triplets on DNA:
TAC CAG ATA CAC TCC CCT GCG ACT
 - Give the mRNA codons and tRNA anticodons that correspond with this sequence, and then give the sequence of amino acids in the polypeptide.
 - Provide a different mRNA strand that can be used to synthesize this same protein.
 - Describe the actions of all of the enzymes involved in replication of a DNA molecule.
 - Compare and contrast the actions of DNA polymerase and RNA polymerase.
 - Examine the following series of words and identify what kind of a mutation occurred in each, starting with the first word in non-mutated form: BEAST FEAST BREAST BEST BEATS

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps and a sample of a concept map for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

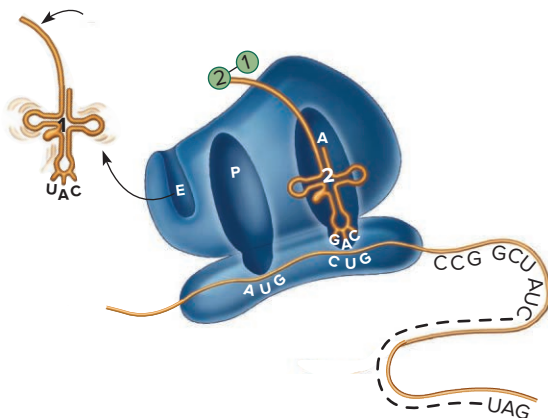

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

- Knowing that retroviruses operate on the principle of reversing the direction of transcription from RNA to DNA, propose a drug that might possibly interfere with their replication.
- Using the piece of DNA in writing-challenge question 3, show a deletion, an insertion, a substitution, and nonsense mutations. Which ones are frameshift mutations? Are any of your mutations nonsense? Are any missense? (Use the universal code to determine this.)
- Why will a mistake in the RNA code alone not become a mutation?
- The enzymes required to carry out transcription and translation are themselves produced through these same processes. Speculate which may have come first in evolution—proteins or nucleic acids—and explain your choice.
- Why can one not reliably predict the sequence of nucleotides on mRNA or DNA by observing the amino acid sequence of proteins?
- Activation, transcription, and translation of the *lac* operon will release which exact nutrients?
- Explain the mechanisms by which RNA can control transcription, translation, and gene expression.
- Explain how epigenetics is related to the expression: phenotype = genotype + environment.
- Use the concepts of chapters, letters, a whole library, words, and books to make an analogy that fits the levels of genetic structure and function.

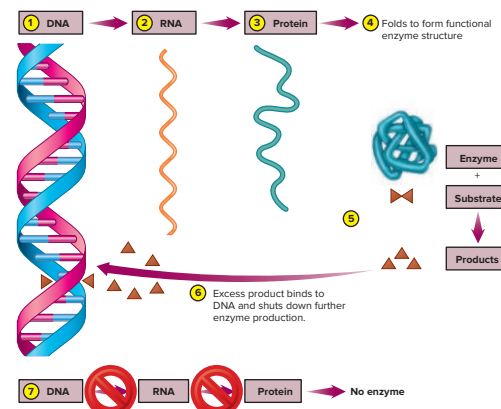

Visual Challenge

- From **figure 9.17, step 3**. Label each part of the illustration.

- Examine **figure 8.11**, and explain which type of operon is functioning here. How would another operon differ from this?

CHAPTER 10 Genetic Engineering: A Revolution in Molecular Biology

DNA sequence readings for the normal and mutated forms of the *XIAP* gene on the X chromosome. Top is a normal reference with guanine (black G) at the site; middle is Nicholas's reading with a single mutation that substitutes an adenine (green A), and bottom is Nicholas's mother, who has a normal gene on one X chromosome and a mutated gene on the other X chromosome. (right): Source: Jane Ades, NHGRI

CASE STUDY Part 1 Nicholas's Story: A New Frontier in Genomic Medicine

In 2007 a desperately ill 2-year-old boy was brought to the Medical College of Wisconsin for consultation about his condition, which appeared to be a type of **inflammatory bowel disease** (IBD). The child, Nicholas Volker, had symptoms of **abscesses** and penetrating **fistulas*** in his lower gastrointestinal tract that led to severely **stunted development** and **chronic infections**.

The doctors tried everything in their arsenal to control his disease. Over time, Nicholas had hundreds of surgeries in an attempt to repair the fistulas, and he was placed on a whole range of antimicrobial and **immunosuppressive drugs**. The doctors redirected his colon with a **colostomy** and placed him on **intravenous nutrition**. After bouts of sepsis and continued deterioration of his lower intestine and abdominal cavity, they finally removed his entire colon. After each intervention, he would be relatively free of symptoms for a few months, but then he would experience a sudden setback, which was often **life-threatening**. For most of his young life he had been unable to eat solid food and so far had spent 600 days in the hospital.

Nicholas's situation became so urgent that his physicians realized they must dig deeper to find the root cause of this complex medical mystery. They agreed that he was suffering from some form of **inborn genetic disease** that caused chronic inflammation, inter-

fered with the normal **immune protection** in his colon, and prevented healing. They started with a detailed battery of tests for immune function and compared his profile with known causes of inflammatory bowel disease. After months of analysis, they were unable to link the condition to any known defects, which meant that it was likely due to some type of rare, **unknown mutation**. Finding that mutation hidden among **6.4 billion nucleotides** of the human genome seemed like an impossible task—a one-in-a-billion gamble—that that was Nicholas's only hope.

The medical team immediately made preparations to **sequence** his genome and locate the exact genetic defect, something that had been attempted only once before on a much smaller scale. One advantage lay in the availability of the entire sequence of the **human genome** completed several years before. Its huge **database** could be used to compare genomic information, and the newer sequencing machines were becoming cheaper and faster than ever before. This search would put the emerging technology of **genomics** and **informatics** to the test and become one of the earliest uses of **genomic diagnosis**.

- What is meant by an inborn genetic disease?
- What is involved in DNA sequencing?

“Finding that mutation hidden among 6.4 billion nucleotides of the human genome seemed like an impossible task.”

**fistula* (fiss'-chew-lah) An abnormal passageway between a hollow organ and the skin.

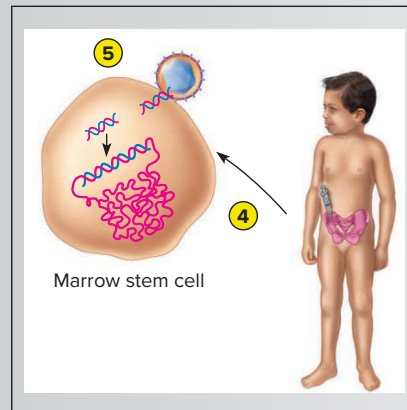

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

SCOPING OUT THE CHAPTER

The advances in DNA science, whether medical, industrial, agricultural, or forensic, are a dominant force in many areas of our lives. None of these applications would exist if it were not for studies completed on microorganisms over the past 50 years. Simple basic research on bacteria and viruses first opened up the possibilities of modifying and manipulating DNA. Out of this came valuable tools for analyzing, cloning, cutting, splicing, hybridizing, probing, sequencing, synthesizing, and identifying DNA. Often, this knowledge has made what seemed impossible, possible. Look below for a few of the highlights.

Manipulating DNA. DNA can be removed intact from cells and altered by unzipping, cutting, splicing, and adding tracer molecules to locate and identify genes.

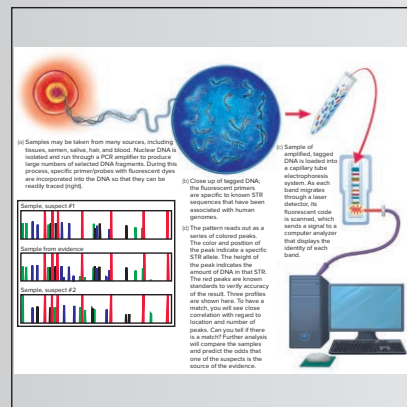

Medicine for Genetic Disorders. New technologies have the potential for correcting genetic disorders. With gene therapy, for example, recombinant microbes containing the healthy gene are inserted into cells of afflicted patients.

Techniques for Amplifying and Sequencing DNA. By imitating the processes in cells, DNA can be copied in a test tube. Then, specialized machines can read out the precise nucleotide codes of this isolated DNA.

Recombinant DNA and Cloned Genes. Selected DNA from two different organisms can be combined and introduced into a host cell, creating an entirely new genetic combination or recombinant organism.

DNA Profiling and Identification. Many areas of discovery benefit from an abbreviated “picture” of DNA that displays the unique signature of a person, microbe, or unknown DNA sample. Often termed a DNA profile or fingerprint, this technique is an essential part of forensics, medicine, and research.

Genetically-modified Organisms (GMO). Animals and plants can have new genes inserted into their genomes, creating novel and highly unique forms for agricultural, medical, and research purposes.

10.1 Basic Elements and Applications of Genetic Engineering

Expected Learning Outcomes

1. Define *genetic engineering*, and describe some of its subcategories and aims.
2. Explain the properties of DNA that lend to its manipulation in the laboratory.
3. Summarize the major methods of analyzing DNA and their results.
4. Describe the technology behind identifying, synthesizing, sequencing, and amplifying DNA.

The knowledge of DNA that has emerged since its structure was decoded 60 years ago has spawned a revolution in a wide variety of human endeavors. In many ways it has changed our view of the world, and in fact it has profoundly changed the world. It now dominates research and development in hundreds of specialties in biotechnology, medicine, forensics, diagnosis of disease, drug development and treatment, agriculture, industrial production, and ecology. Today it is possible to accomplish feats that were once only imagined. The new wave of DNA explorers have gone back in history to identify the remains of the last czar of Russia and King Richard III of England. They have extended their searches even to prehistoric eras by analyzing the genomes of the Neanderthals and a woolly mammoth. They

have changed the face of agriculture by developing plants that resist disease and animals that can synthesize human hormones, and they have created entirely new strains of viruses and bacteria. Applications of this technology have diagnosed and cured genetic diseases, identified the mass victims of disasters, and become a key part of law enforcement. Because of our expanding knowledge, we are on the brink of fully understanding the complexities of life forms and their capacity to adapt and evolve.

The primary goals of this science are to isolate, identify, and manipulate DNA in various ways. A major part of its work falls into the category of **genetic engineering** or **bioengineering**, defined as the direct, deliberate modification of an organism's genome. It also belongs to the larger scheme of **synthetic biology** and **biotechnology**, whose major aims are the design of biological systems that can synthesize new forms of molecules, cells, organs, and even organisms.

Information on genetic engineering and its biotechnological applications is growing at such an expanding rate that some new discovery or product is disclosed almost daily. To keep this subject somewhat manageable, we present essential concepts and applications, organized under the following six topics:

- Basic techniques in manipulating and analyzing DNA
- Recombinant DNA technology

- Biochemical products of recombinant DNA technology
- Genetically modified organisms
- Genetic treatments
- Genome analysis

Tools and Techniques of DNA Technology

In chapter 9 we examined the ways in which microorganisms duplicate, change, and express their genomes. All of the intrinsic properties of DNA that we touched on hold true whether the DNA is in a bacterium or a test tube. For example, the enzyme helicase is able to unwind the two strands of the double helix just as easily inside or outside a bacterial cell. But in the laboratory we can take advantage of our knowledge of DNA chemistry to make helicase unnecessary. It turns out that when DNA is heated to just below boiling (90°C to 95°C), the two strands separate, revealing the information contained in their bases. With the nucleotides exposed, DNA can be easily identified, replicated, or transcribed. If heat-denatured DNA is then slowly cooled, complementary nucleotides will hydrogen-bond with one another, and the strands will renature or regain their familiar double-stranded form (**figure 10.1a**). As we shall see, this process is a necessary feature of the polymerase chain reaction and nucleic acid probes described later in this section.

- (a) **DNA heating and cooling.** DNA responds to heat by denaturing—losing its hydrogen bonding and thereby separating into its two strands. When cooled, the two strands rejoin at complementary regions. The two strands need not be from the same organisms as long as they have matching sites.

Endonuclease	<i>EcoRI</i>	<i>HindIII</i>	<i>HaeIII</i>
Cutting pattern	<pre> G↓A A T T C C T T A A↑G </pre>	<pre> A↓A G C T T T T C G A↑A </pre>	<pre> G G↓C C C C↑G G </pre>

- (b) **Examples of endonucleases, palindromes and cutting patterns.** The first two are staggered cuts, and the third is a blunt cut.

Figure 10.1 Some properties of DNA that are an integral part of DNA manipulation. The method in (a) can be used to separate the DNA strands lengthwise and make them single-stranded. The method in (b) uses enzymes called endonucleases to make cuts across both DNA strands at specific sites called palindromes.

Enzymes for Dicing, Splicing, and Reversing Nucleic Acids

The polynucleotide strands of DNA can also be clipped crosswise at selected positions by means of **restriction endonucleases**¹ that are a natural product of bacterial cells. They recognize foreign DNA and are capable of breaking the phosphodiester bonds between adjacent nucleotides on both strands of DNA, leading to a break in the DNA strand. In the bacterial cell, these enzymes protect against the incompatible DNA from bacteriophages or plasmids. In the biotechnologist's lab, the enzymes can be used to cleave DNA at desired sites and are a must for the techniques of recombinant DNA technology.

So far about 3,000 restriction endonucleases have been discovered in bacteria. Each type has a known sequence of 4 to 10 base pairs as its target, so sites of cutting can be finely controlled. These enzymes have the unique property of recognizing and clipping at sites called **palindromes**² (figure 10.1b). Palindromes are sequences of DNA bases that are identical when read from the 5' to 3' direction on one strand and the opposite direction on the complementary strand.

Endonucleases are named by combining the first letter of the bacterial genus, the first two letters of the species, and the endonuclease number. Thus, *EcoRI* is the first endonuclease found in *Escherichia coli*'s R strain, and *HindIII* is the third endonuclease discovered in *Haemophilus influenzae* Type d (figure 10.1b).

Endonucleases are used in the laboratory to cut DNA into smaller pieces for further study as well as to remove and insert it during recombinant DNA techniques, described in section 10.2. Usually the enzymes make staggered symmetrical cuts that leave short, single-stranded tails called "sticky ends." Such adhesive tails will base-pair with complementary tails on other DNA fragments or plasmids. This effect makes it possible to splice genes into specific sites (figure 10.2). A few endonucleases such as *HaeIII* make straight, blunt cuts on DNA and do not form sticky ends.

The separated segments of DNA produced by restriction endonucleases are termed **restriction fragments**. Because DNA sequences vary, even among members of the same species, differences in the cutting pattern of specific restriction endonucleases give rise to restriction fragment length polymorphisms (RFLPs). RFLPs allow the direct comparison of the DNA cutting patterns of two different organisms with the same endonuclease, which is one step in preparing genes from different organisms to be spliced together (see figure 10.11).

3-D view of restriction endonuclease cutting DNA (yellow strands).
Courtesy Konrad F. Koehler, PhD

Action of restriction endonucleases. (1) A restriction endonuclease recognizes and cleaves DNA at the site of a specific palindromic sequence. Cleavage usually produces staggered tails called sticky ends that accept complementary tails for gene splicing. This palindrome is cut by *Acl* I. (2) The sticky ends can be used to join DNA from different organisms by cutting it with the same restriction enzyme, ensuring that both fragments have two complementary ends. This palindrome is cut by *Taq* I.

Figure 10.2 Examples of cutting patterns by restriction endonucleases and how they are used in gene splicing.

Another enzyme, called a **ligase**, is necessary to seal the sticky ends together by rejoining the phosphate-sugar bonds cut by endonucleases. Its main application is in final splicing of genes into plasmids and chromosomes.

An enzyme called **reverse transcriptase** is best known for its role in the replication of HIV and other retroviruses. It also provides geneticists with a valuable tool for converting RNA into DNA. Copies called **complementary DNA**, or **cDNA**, can be made from messenger, transfer, ribosomal, and other forms of RNA. The technique provides a valuable means of synthesizing eukaryotic genes from processed mRNA transcripts (figure 10.3). The bacteria often used to transcribe and translate eukaryotic genes in genetic engineering lack the cellular machinery to splice out introns (intrinsic sequences) found in unprocessed eukaryotic mRNA. So the advantage with synthesized cDNA genes is that they already have the introns removed and consist only of exons and can be readily transcribed and translated by bacteria. cDNA also provides a powerful tool for converting RNA for sequencing, analyzing ribosomes and identifying RNA viruses.

Analysis of DNA

One way to produce a readable pattern of DNA fragments is through **electrophoresis** (figure 10.4). In this technique, samples are placed in compartments (wells) in a soft agar gel or similar soft medium and

1. The meaning of restriction is that the enzymes do not act upon the bacterium's own DNA; an endonuclease nicks DNA internally, not at the ends.
2. This term originated from words or phrases with letters that read the same backward or forward, as in *radar*, "Madam, I'm Adam," and "Can I attain a C?"

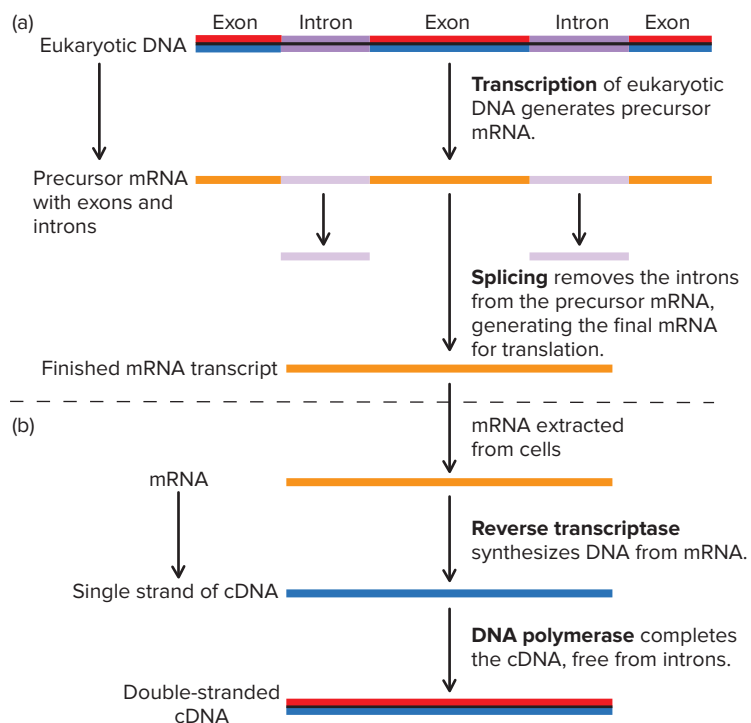

Figure 10.3 Synthesizing cDNA from eukaryotic mRNA. Bacterial cloning hosts cannot process intact eukaryotic genes. To provide a gene that will be transcribable and translatable by a bacterium, (a) first modified mRNA, lacking introns, is isolated from the source eukaryotic cell. (b) This strand is converted in a test tube to a single-stranded DNA by reverse transcriptase and double-stranded DNA by a polymerase. This copy of DNA (cDNA) can be transcribed and translated by bacteria.

Figure 10.4 Electrophoresis setup. Electrophoresis uses an electrical current to separate charged molecules of different sizes. The samples are loaded into small wells in a gel bathed in a buffer solution. The gel contains tiny pores that allow the passage of molecules according to their size. Current and movement go from the negative pole to the positive pole. The bands produced by the fragments are arrayed along a range from larger fragments higher up and smaller ones nearer the bottom.

subjected to an electrical current. The phosphate groups in DNA give the entire molecule an overall negative charge, which causes the DNA to move toward the positive pole in the gel. The rate of movement is based primarily on the size of the fragments. The larger fragments are pulled into the gel more slowly and remain nearer the wells, whereas the smaller fragments migrate faster and are positioned farther from the wells. The positions of DNA fragments are visualized by one of several methods (**figure 10.5**). Electrophoresis patterns can be quite distinctive and are very useful in displaying DNA fragments and comparing the degree of genetic similarities among samples in a Southern blot or DNA profile (see Visual Challenge #1).

Nucleic Acid Hybridization and Probes

Two different nucleic acids can **hybridize** by uniting at their complementary sites. All different combinations are possible: Single-stranded DNA can unite with other single-stranded DNA or RNA, and RNA can hybridize with other RNA. This knowledge has led to the development of short, single strands of 6 to 25 nucleotides called *oligonucleotides* to be used as **gene probes**. These probes consist of a segment of DNA or RNA of known sequence that can base-pair with a stretch of DNA that has a complementary sequence, if one exists in a test sample. Hybridization probes have practical value because they can detect specific nucleotide sequences in unknown samples. So that areas of hybridization can be visualized, the probes carry reporter molecules, such as fluorescent dyes, which can be visualized with ultraviolet radiation (see figure 10.6), or radioactive labels, which are revealed by placing photographic film in contact with the test reaction (figure 10.5b).

When probes hybridize with an unknown sample of DNA or RNA, they tag the precise area and degree of hybridization, and help determine the nature of nucleic acid present in a sample. In a method called the **Southern blot**,³ DNA fragments are first separated by electrophoresis and then denatured and transferred to a special filter. A DNA probe is then incubated with the sample, and wherever this probe encounters the segment for which it is complementary, it will attach and form a hybrid. Development of the hybridization pattern will show up as one or more bands. This method is a sensitive and specific way to isolate fragments from a complex mixture and to find specific gene sequences on DNA. Much of the information obtained through Southern blotting can be achieved in more detail from another hybridization procedure called a microarray, discussed in section 10.4.

Probes have numerous applications in diagnosing the cause of an infection from a patient's specimen or identifying a culture of an unknown bacterium or virus (see chapter 17). One example is a simple and rapid method called a *hybridization test*. DNA from a test sample is isolated, denatured, placed on an absorbent filter, and combined with a microbe-specific probe. The blot is then developed and observed for areas of hybridization. Commercially available diagnostic kits are now on the market for identifying intestinal pathogens such as *E. coli*, *Salmonella*, *Campylobacter*, *Shigella*, *Clostridium difficile*, rotaviruses, and adenoviruses. Other bacterial probes exist for *Mycobacterium*, *Neisseria*, *Staphylococcus*, *Mycoplasma*, *Bordetella*,

3. Named for its developer, E. M. Southern. The "northern" blot is a similar method used to analyze RNA, whereas the "western" blot detects proteins. There is a reason scientists became scientists and not comedians.

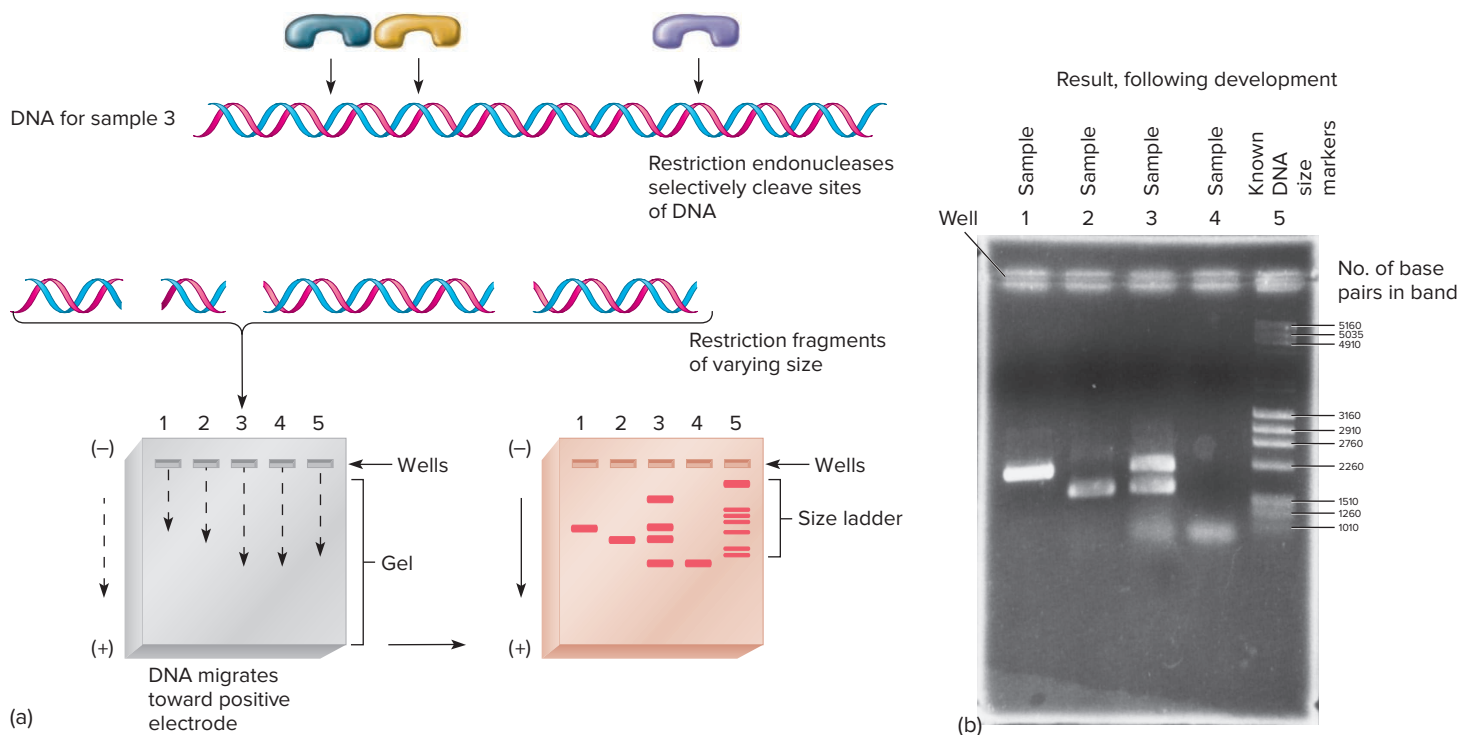

Figure 10.5 Separating DNA restriction fragments with electrophoresis. (a) A restriction endonuclease is applied to a sample (using sample 3 as an example). The sample with DNA fragments is loaded into a well at the top of a gel and electrophoresed. The final position of the fragments will be visualized by staining or the method shown in (b). (b) A developed gel reveals the separated bands of DNA fragments. The size of a given DNA band can be determined by comparing the distance traveled to the distance traveled by a set of DNA fragments of known size called a size ladder (lane 5), measured in number of base pairs. This gel contained DNA with radioactive bases that can expose a photographic negative. (b) © Kathy Park Talaro

and *Chlamydia*; probes are available for herpes simplex and zoster, papilloma, hepatitis A and B, and HIV viruses. DNA probes have also been developed for human genetic markers and some types of cancer.

With another method, called *fluorescent in situ hybridization* (FISH), probes are applied to intact cells *in situ*, meaning that the

DNA is left intact in the cell and probed in place rather than being extracted. The preparation is then observed microscopically for signs of genetic marker sequences on genes that have hybridized with the probe. FISH is a very effective way to locate genes on chromosomes (figure 10.6). *In situ* techniques can also be used to identify unknown

Figure 10.6 Fluorescent in situ hybridization (FISH) technique. This is a microscopic technique using fluorescently labeled probes to react with intact cells and chromosomes. The probe is mixed with test cells or chromosomes to hybridize any matching DNA sequences and observed with a UV microscope for fluorescence indicative of a particular location and type of gene. The inset displays chromosomes that have DNA from a papillomavirus integrated into chromosomes (yellow dots). Jaana Tammur, Hiljar Sibul, Ene Ustav, Mart Ustav, Andres Metspalu, "A bovine papillomavirus-1 based vector restores the function of the low-density lipoprotein receptor in the receptor-deficient CHO-IdIA7 cell line," *BMC Molecular Biology* 2002, 3:5

bacteria living in natural habitats without having to culture them, and they can be used to detect RNA in cells and tissues.

DNA Sizing, Sequencing, and Synthesizing

The relative sizes of nucleic acids are usually denoted by the number of base pairs (bp) or nucleotides they contain. For example, the palindromic sequences recognized by endonucleases are usually 4 to 10 bp in length; an average gene in *E. coli* is approximately 1,300 bp, or 1.3 kilobases (kb); and its entire genome is approximately 4,700,000 bp, 4,700 kb, or 4.7 megabases (mb). The DNA of the human mitochondrion contains 16 kb, and the Epstein-Barr virus (a cause of infectious mononucleosis) has 172 kb. Humans have approximately 6.4 billion base pairs (bbp) arrayed along 46 chromosomes. The Human Genome Project, finished in 2001, produced a map containing every base in the entire human genome (10.1 Making Connections).

DNA Sequencing: Determining the Exact Genetic Code One of the most powerful kinds of genetic knowledge attainable for organisms is to decipher the order and types of base pairs in their genes and genome. This process, called **DNA sequencing**, can be used on all types of DNA, including genomic, cDNA, chromosomal, plasmid, and mitochondrial DNA. Many sequencing techniques are based on Frederick Sanger’s original idea, using the synthesis and analysis of a complementary strand of DNA (figure 10.7). Even though mostly automated techniques are used today, we will illustrate the basic principles behind this process using the Sanger type of sequencing as a model.

Because most DNA being sequenced is usually very long, it is made more manageable by cutting it into a number of shorter fragments, which are then separated. The test strands, typically several hundred nucleotides long, are denatured to expose single strands that will serve as templates to synthesize complementary strands.

(1) Original DNA to be sequenced.

(2) DNA is denatured to produce single template strand.

(3) Strand is labeled with specific primer molecule.

(4) A reaction tube contains DNA polymerase, primed single strands, all four regular nucleotides, and a small amount of the four fluorescently labeled dideoxy (dd) nucleotides that provide a visible tracer of the locations of terminal bases added by the polymerase.

(5) During replication each new strand is terminated (↓) at the point of addition of a dd nucleotide.

(6) Left: A schematic view illustrating how finished fragments will end with a labeled dideoxynucleotide. Electrophoresis separates the labeled fragments and displays them in order by size. The color of the label gives the type of base in its exact sequence. Note that this sequence is not the final product – it is the complement of the template strand of interest.

(7) Automated display of a short segment of human DNA. The computer substitutes black for G for ease in reading.

Figure 10.7 Some basic techniques in DNA sequencing (1-6) The sequencing of a 9 base strand using the Sanger method. The sequence in #6 is read from the bottom to the top and must be converted to its complement to get the true nucleotide order of TCGGCTAGG. (7) An example of an automated read-out. (8) Enlarged illustration of a nanopore sequencer depicting one strand of DNA threaded through a pore to be analyzed.

10.1 MAKING CONNECTIONS

OK, the Genome's Sequenced—What's Next?

In early 2001 a news conference was held to announce that the human genome had been sequenced. The 3.2 billion base pairs (which translates to 6.4 billion nucleotides) that make up the DNA found in (nearly) every human cell had been put in the proper order. Champagne corks popped, balloons fell, bands played, reporters reported on the significance of the occasion, and . . . nothing else seemed to change for a while. Here are some important FAQs about the Human Genome Project (HGP) and what has happened since that monumental event.

Q: How big was this project?

A: The Human Genome Project was first discussed in the mid-1980s and got under way in 1990. Although the project was to have taken at least 15 years, advances in technology led to its being completed in just over 10 years at a cost of about 3 billion dollars. It was finally determined that the 6.4 billion nucleotides of DNA code for only about 21,000 genes, not the 100,000 or so that the genome was thought to contain only a few years ago. Still, this is the equivalent of a million-page book—a long read.

Q: Will we ever see any benefits from this project?

A: We already are. Sequencing the genome was only the first step. Knowing what proteins are produced in the body, what they do, and how they interact with one another is essential to understanding the workings of human physiology. By knowing the genetic signatures of different diseases, we will be able to design extraordinarily specific diagnostic tests that detect thousands of genetic diseases and their many forms. For example, the cancer drugs Iressa and Erbitux are so specific in their actions that they are only prescribed after a genetic test of the cancer has found it to be a suitable target.

Q: What have we learned so far?

A: The first HGP maps sequenced the DNA of five humans of different sexes and ethnicities. As expensive as these first whole genome maps were, improvements in the technology have made the current cost more reasonable at about \$5,000 per person. Keep in mind that such an undertaking will not yet provide complete information on health, future medical problems, and other genetic information. But as more data are made available, genomic sequencing will become a viable method of diagnosis (see this chapter's Case Study).

An important research finding that emerged from worldwide analyses of DNA samples was that the genome

sequence is shared among 99.9% of humans and varies by only 0.1%. But even this 0.1% amounts to at least 1 million different haplotypes (a block of DNA inherited as a unit). Studying “hap maps” has provided new data to trace the incidence of and risk for genetic diseases, the genetic makeup of modern-day populations, and the possible origins of ancestral humans.

Another significant discovery coming from comparative genome analysis was that humans have about 2.4 million polymorphisms called single nucleotide polymorphisms or SNPs, which involve variations in just a single nucleotide at the same location in a gene, meaning they are alleles. SNPs are known to affect the onset of some genetic diseases (diabetes, cancer) and to cause variations in the response to drugs, vaccines, and infectious agents. For more information, go to <http://www.ornl.gov/hgmis/> or log on to the National Human Genome Research Institute.

Once the sequence of bases in an organism's genome is known, what are the next logical steps in deciphering the information it contains?

Answer available on Connect.

SNP variations at a locus of a gene. There are over 3 billion of these polymorphisms in the human genome, enough to create significant differences in human development.

Usually these fragments must be increased in number by PCR (see figure 10.8). The concepts behind the sequencing procedure involve the same enzymes and raw materials as would be present for regular DNA synthesis as performed in a cell. The fragments are bound to an RNA primer, which positions the attachment of nucleotides at its 3' end, then a DNA polymerase adds the complementary nucleotides using the pattern of the template strand as a guide.

The reaction tube also contains all of the regular nucleotides (A, T, C, G) and a small amount of dideoxynucleotides (ddNP) that have two special features: (1) They are color-labeled with four different fluorescent dyes that can report their position in a sequence,

and (2) they are missing the hydroxyl group (OH^-) bound to the 3' carbon of deoxyribose that is required for the chemical bonding of a nucleotide to the growing DNA strand. The addition of a ddNP at any location terminates the further elongation of the strand. As the synthesis proceeds, most strands will elongate normally, except for a small percentage of fragments that will randomly have a ddNP nucleotide incorporated and be terminated there. Late in the process, all possible positions in the sequence will have a terminal ddNP nucleotide. The reaction tube will thus have a series of strands reflecting the correct sequence that can be traced by its color from the first nucleotide to the last.

During analysis, the reaction products are subjected to electrophoresis in fine capillaries that separate strands differing by only a single nucleotide in length. This arrays the fragments in order of size, and only the fragments carrying the labeled nucleotides will be readable (figure 10.7). Automatic sequencing machines scan the electrophoresis pattern and record the DNA sequence by detecting the color of each band with a sensing device. In this way, the DNA sequence of the synthesized strand is analyzed and that of the template strand can easily be inferred. Most sequencers have computers that read the sequence and display it as a graphic figure. This method of sequencing is remarkably accurate, with only about one mistake in every 1,000 bases. All of these steps have been automated to obtain the speed necessary to sequence the entire genomes of humans and other organisms. A next generation sequencer called nanopore technology is based on DNA strands being fed through tiny pores and sequenced directly without the need to synthesize complementary copies (figure 10.7, step 8). It has the potential for highly rapid sequencing of very long molecules and will probably replace many of the older sequencers.

Whole genome sequencing projects have increased as the efficiency and speed of new sequencing technologies has improved. The case study provides a striking example of how it is being used in genomic medicine to diagnose diseases. As of 2016, whole genome sequence maps of thousands of viruses, prokaryotes, and eukaryotes have been published. The eukaryotic genomes include chimpanzee, rat, mouse, a nematode worm, yeast, honeybee, cats, dogs, horses, cows, rice, and corn. One of the remarkable discoveries in this huge enterprise has been how similar the genomes of relatively unrelated organisms can be. Humans share around 99% of their genome with chimpanzees, 80% with mice, about 50% with corn, and even 30% with the roundworm *Caenorhabditis elegans*.

Although sequencing provides the ultimate genetic map, it does not automatically identify the exact genes or alleles, nor will it immediately inform us about gene function. For that we need additional information about gene expression. Analysis and storage of this massive amount of new data require specialized computers. Because the data consist of information of both a biological and mathematical content, whole new disciplines have grown up around managing these data: **genomics** (see “A Guide to the New ‘-Omic’ Sciences”) and **bioinformatics**. The job of these specialties is to analyze, compare, and classify DNA, determine protein sequences, and ultimately understand the functions of specific genes and proteins. This fact is likely to bring another golden era in biology and microbiology, that of unraveling the complexity of relationships of genes and gene regulation. Eventually it will provide a more complete understanding of such phenomena as normal cell function, disease, development, aging, and many other issues. The case study for this chapter is a powerful example of what can be possible using these new tools.

A Guide to the New “-Omic” Sciences

The ability to obtain the entire DNA sequences of organisms has spawned new terms that refer to the “total picture” of some aspect of a cell, organism, or community:

genomics The systematic study of an organism’s genes and their functions.

transcriptomics Analysis of all RNA molecules in a cell. This includes mRNA, tRNA, rRNA, and the regulatory RNAs. It is an intermediate link between the activity of genes and the protein products of translation.

proteomics The study of an organism’s complement of proteins (its “proteome”) and functions mediated by the proteins.

metagenomics (also called “community genomics”) The study of all the genomes in a particular ecological niche, as opposed to individual genomes from single species.

metabolomics The study of the complete complement of small chemicals present in a cell at any given time. Provides a snapshot of the physiological state of the cell and the end products of its metabolism.

One of the fastest growing areas of the new “-omics” is designed to survey the scope of organisms that live in various habitats. This science is called environmental genomics, or **metagenomics**. In the past it was difficult to study complex communities where millions of organisms coexist, and it has not been possible to isolate and culture most of them. Metagenomics provides microbiologists a window through which to view the diversity of such habitats and makes it possible to pull out the microbial genomes, study them, and begin to understand their interactions. This technique has been used for several years in the large-scale genetic sampling of the oceans. Other research efforts on dozens of habitats, including the human body, are yielding massive amounts of new genetic data.

Polymerase Chain Reaction: A Molecular Copy Machine for DNA Some of the techniques used to analyze DNA and RNA are limited by the small amounts of test nucleic acid available. This problem was largely solved by the invention of a simple, versatile way to amplify DNA called the **polymerase chain reaction (PCR)**. This technique rapidly increases the amount of DNA in a sample without the need for making cultures or carrying out complex purification techniques. It is so sensitive that it holds the potential to detect cancer from a single cell or to diagnose an infection from a single gene copy. It is comparable to being able to pluck a single DNA “needle” out of a “haystack” of other molecules and make unlimited copies of the DNA. The rapid rate of PCR makes it possible to replicate a target DNA from a few copies to billions of copies in a few hours. It can amplify DNA fragments that consist of a few base pairs to whole genomes containing several million base pairs.

To understand the idea behind PCR, it will be instructive to review figures 9.5 and 9.6, which model DNA synthesis as it occurs naturally in cells. The PCR method uses essentially the same events, with the opening of the double strand, using the exposed strands as templates, the addition of primers, and the actions of a DNA polymerase.

Initiating the reaction requires a few specialized ingredients (**figure 10.8**). The **primers** are synthetic oligonucleotides (short DNA strands) of a known sequence of 15 to 30 bases that serve as landmarks to indicate where DNA amplification will begin. These take the place of RNA primers that would normally be provided by the cell. Depending upon the purposes and what is known about the DNA being replicated, the primers can be random, attaching to any sequence they may fit, or they may be highly specific and chosen to

(a) In cycle 1, the DNA to be amplified is denatured, primed, and replicated by a polymerase that can function at high temperatures. The two resulting strands then serve as templates for a second cycle of denaturation, priming, and synthesis.

(b) A view of the process after 6 cycles, with 64 copies of amplified DNA. Continuing this process for 20 to 40 cycles can produce millions of identical DNA molecules.

Process Figure 10.8 Diagram of the polymerase chain reaction. (a) Details of the process over two cycles. (b) Yield after the cycle continues past the second cycle.

amplify a known gene. To keep the DNA strands separated, processing must be carried out at a relatively high temperature. This necessitates the use of heat-resistant DNA polymerases isolated from thermophilic bacteria. Examples of these unique enzymes are Taq polymerase obtained from *Thermus aquaticus* and Vent polymerase from *Thermococcus litoralis*. Enzymes isolated from these thermophilic organisms remain active at the elevated temperatures used in PCR. Another useful component of PCR is a machine called a thermal cycler that automatically initiates the cyclic temperature changes.

The PCR technique operates by repetitive cycling of three basic steps: denaturation, priming, and extension:

- 1. Denaturation.** The first step involves heating target DNA to 94°C to separate it into two strands. Each strand will become a template DNA, or *amplicon*.
- 2. Priming.** As the reaction is cooled to between 50°C and 65°C (depending on the exact sequence of the primers), the oligonucleotide primers base-pair with specific sites on the amplicons.
- 3. Extension.** In the third phase, which proceeds at 72°C, the DNA polymerase is activated and begins to synthesize DNA from a pool of available nucleotides. Beginning at the free end of the primers on both strands, the polymerases move along the strands, which serve as templates for the synthesis of two complete double strands of DNA.

It is through cyclic repetition of these steps that DNA becomes amplified. When the DNAs formed in the first cycle are denatured, they become amplicons to be primed and extended in the second cycle. Each subsequent cycle converts the new DNAs to amplicons and doubles the number of copies. The number of cycles required to produce a million molecules is 20, but the process is usually carried out to 30 or 40 cycles. One significant advantage of this technique has been its natural adaptability to automation. A thermal cycler can perform 20 cycles on nearly 100 samples in 2 or 3 hours.

DNA amplified by PCR can be analyzed by any of the techniques discussed earlier. PCR can also be adapted to analyze RNA by initially converting an RNA sample to DNA with reverse transcriptase. This cDNA can then be amplified by PCR in the usual manner. It is by such means that ribosomal RNA and messenger RNA are readied for sequencing and RNA viruses are sequenced and identified. The PCR technique has found prominence as a powerful workhorse of molecular biology, medicine, and biotechnology. It often plays an essential role in gene mapping, the study of genetic defects and cancer, forensics, taxonomy, and evolutionary studies.

For all of its advantages, PCR techniques can encounter problems. One concern is the introduction and amplification of nontarget DNA from the surrounding environment, such as a skin cell from the technician carrying out the PCR rather than material from the sample DNA that was supposed to be amplified. Such contamination can be minimized by using equipment and rooms dedicated for DNA analysis and maintained with the utmost degree of clean-

liness. Problems with contaminants can also be reduced by using gene-specific primers and treating samples with enzymes that can degrade the contaminating DNA before it is amplified.

10.2 Recombinant DNA Technology: A New Take on Nature

Expected Learning Outcomes

5. Explain what is involved in recombinant DNA technology.
6. Characterize the events in cloning, using an example.
7. List and discuss some protein products of recombinant DNA and their applications.

The primary intent of **recombinant DNA (rDNA) technology** is to deliberately remove genetic material from one organism and combine it with that of a different organism. Its origins can be traced to 1970, when microbiologists first began to duplicate the clever tricks bacteria do naturally with bits of extra DNA such as plasmids, transposons, and proviruses. The discovery that bacteria can readily accept, replicate, and express foreign DNA made them powerful agents for studying the genes of other organisms in isolation. The practical applications of this work were soon realized by biotechnologists. Bacteria could be genetically engineered to mass-produce substances such as hormones, enzymes, and vaccines that have been difficult to synthesize by the usual industrial methods.

Figure 10.9 provides an overview of the recombinant DNA procedure. An important objective of this technique is to form genetic **clones**. This type of cloning involves the removal of a selected

gene from an animal, plant, or microorganism (the genetic donor) followed by its propagation in a different host organism. Cloning requires that the desired donor gene first be selected, excised by restriction endonucleases, and isolated. The gene is next inserted into a **vector** (usually a plasmid or a virus) that will insert the DNA into a **cloning host**. The cloning host is usually a bacterium or a

yeast that can replicate the gene and transcribe and translate it into the protein product for which it codes. Next we examine the elements of gene isolation, vectors, and cloning hosts and show how they participate in a complete recombinant DNA procedure.

Technical Aspects of Recombinant DNA and Gene Cloning

The first hurdles in cloning a target gene are to locate its exact site on the genetic donor's chromosome and to isolate it. Some of the first isolated genes came from viruses, which have extremely small and manageable genomes, and later genes were isolated from bacteria and yeasts. At first the complexity of the human genome made locating specific genes very difficult. However, this process has been greatly improved by tools for mapping, identifying, and excising genes. There are many common strategies for obtaining genes in an isolated state, including these:

1. A gene can be synthesized from isolated mRNA transcripts using reverse transcriptase (cDNA).
2. A gene can be amplified from a chromosome or larger segment of isolated DNA using PCR.
3. Gene-sized segments of DNA can be synthesized with an apparatus that polymerizes nucleotides in a chosen order. This makes it possible to create genes with almost any sequence.

Although the initial phases of gene isolation and cloning can be labor-intensive, a fortunate outcome is that, once isolated, genes can be maintained in a cloning host and vector just like a microbial pure culture. Genomic libraries, which contain fragments of DNA representing all the genes in a particular species, have been created for thousands of organisms and viruses.

Characteristics of Cloning Vectors

A good recombinant vector has two indispensable qualities: It must be capable of carrying a significant piece of the donor DNA, and it must be readily accepted by the cloning host. Plasmids are excellent vectors because they are small, well characterized, and easy to manipulate, and they can be transferred into appropriate host cells through transformation. Bacteriophages also serve well because they have the natural ability to inject DNA into bacterial hosts through transduction. A modified phage vector, the *Charon*⁴ phage, has had sections of its genome deleted so it can carry a fairly large segment of foreign DNA.

Today thousands of unique cloning vectors are available commercially. Although every vector has characteristics that make it ideal for a specific project, all vectors can be thought of as having three important attributes (**figure 10.10**):

1. An origin of replication (ORI) is needed somewhere on the vector so that it will be replicated by the DNA polymerase of the cloning host.
2. The vector must accept DNA of the desired size. Early plasmids were limited to an insert size of less than 10 kb of DNA, far too small for most eukaryotic genes, with their sizable introns. Newer vectors called cosmids can hold 45 kb, whereas

4. Named for the mythical boatman in Hades who carried souls across the River Styx.

Other important components are genes for ampicillin and tetracycline resistance and the origin of replication.

complex *bacterial artificial chromosomes* (BACs) and *yeast artificial chromosomes* (YACs) can hold as much as 300 kb and 1,000 kb, respectively.

3. Vectors typically contain a gene that confers drug resistance to their cloning host. In this way, cells can be inoculated into drug-containing media, and only those cells that harbor a plasmid will be selected for growth.

Characteristics of Cloning Hosts

The best cloning hosts possess several key characteristics (**table 10.1**). The traditional cloning host—and the one still used in basic

TABLE 10.1 Desirable Features in a Microbial Cloning Host

Will secrete a high yield of proteins from expressed foreign genes

experiments—is *Escherichia coli*. Because this bacterium was the original recombinant host, the protocols using it are well established, relatively easy, and reliable. Hundreds of specialized cloning vectors have been developed for it. The main disadvantages with this species are that the splicing of mRNA and the modification of proteins that would normally occur in the eukaryotic endoplasmic reticulum and Golgi apparatus are unavailable in this prokaryotic cloning host. One alternative host for certain industrial processes and research is the eukaryotic yeast *Saccharomyces cerevisiae*, which would be able to process and modify eukaryotic genes and products.

Certain techniques may also employ animal cell culture, and even live animals and plants to serve as cloning hosts. Although a number of recombinant proteins are produced by transformed bacterial hosts, many of the enzymes, hormones, and antibodies used in drug therapy are currently being manufactured with mammalian cell cultures as the cloning and expression hosts. One of the primary advantages to this alternative procedure is that these cell cultures can modify the proteins (adding carbohydrates, for example) so that they are biologically more active. Some forms of reproductive hormones, human growth hormone, and interferon are products of cell culture. In our coverage, we present the recombinant process as it is performed in bacteria and yeasts.

Construction of a Recombinant, Insertion into a Cloning Host, and Genetic Expression

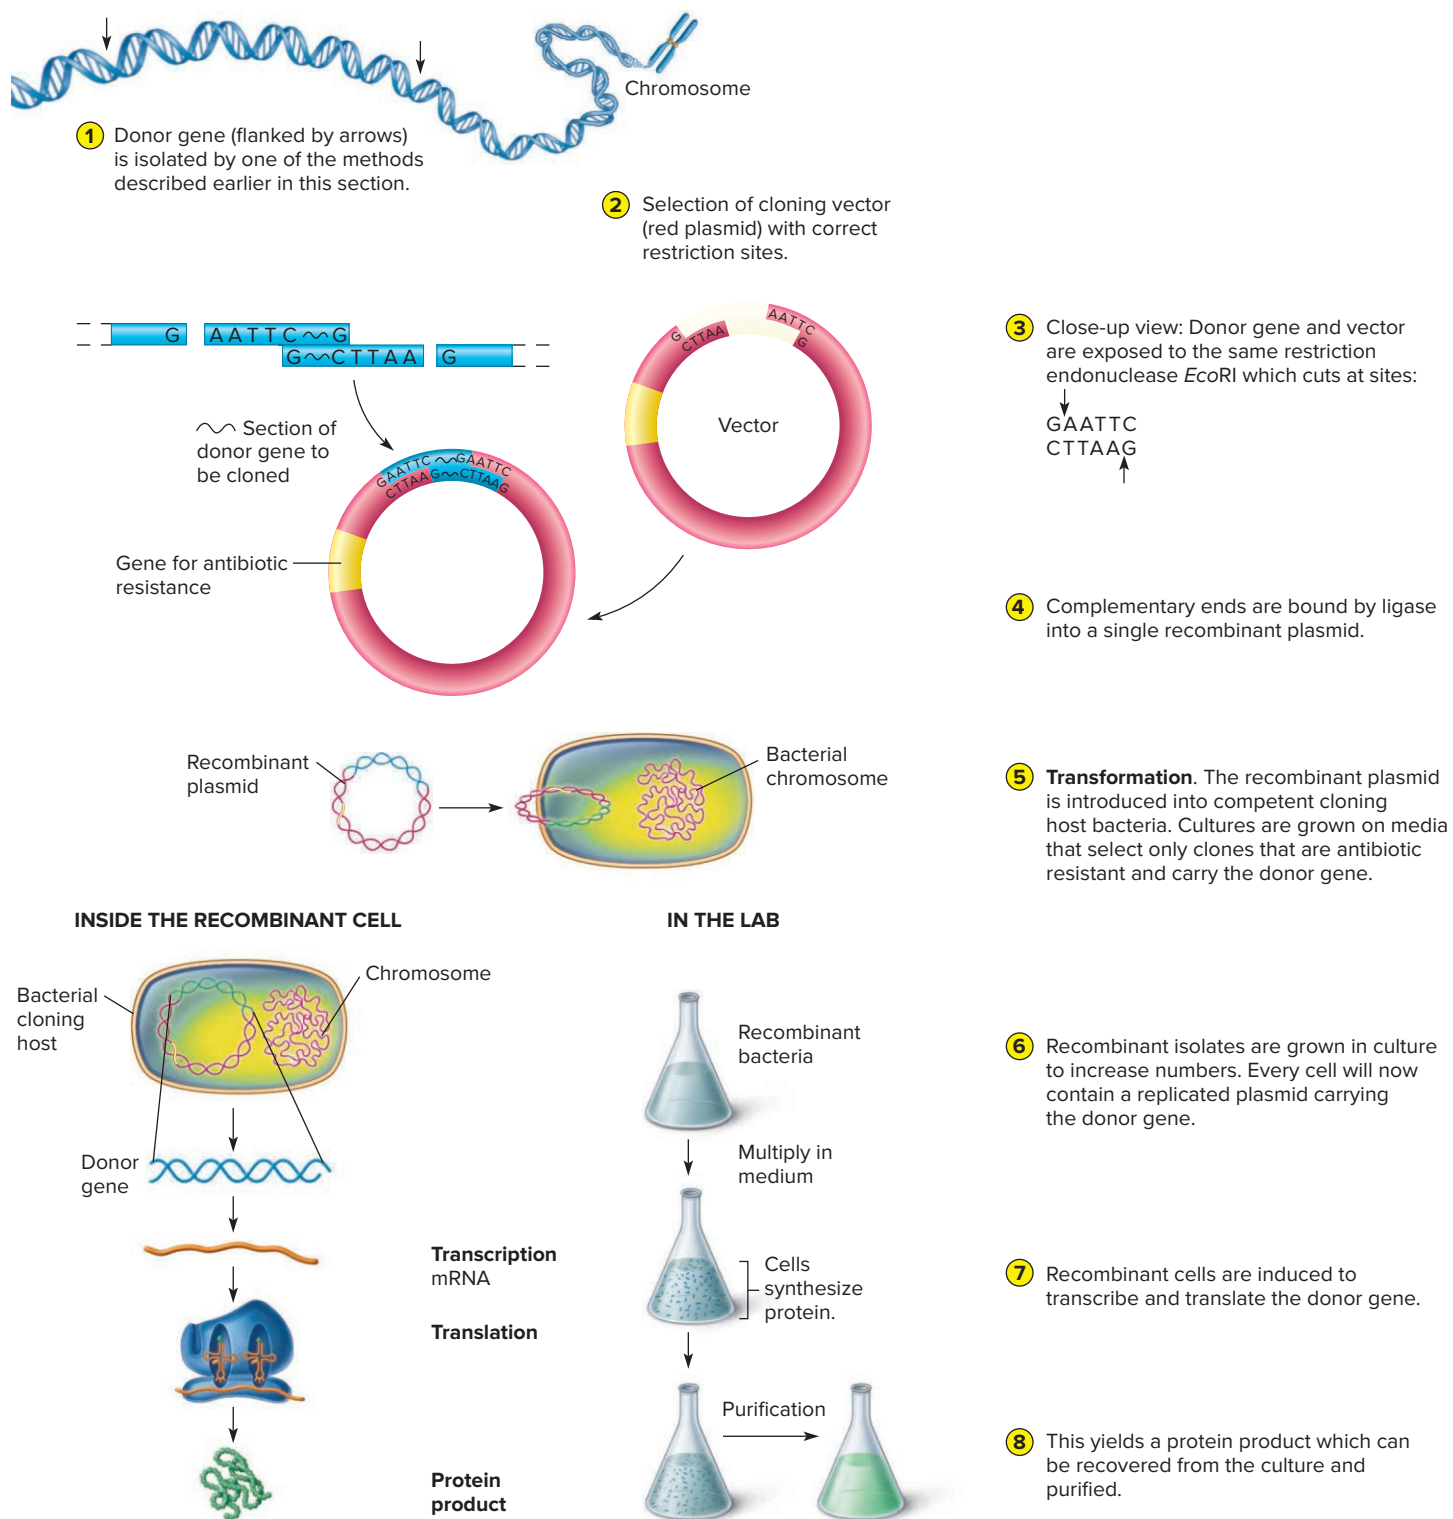

This section emphasizes the main steps in recombinant DNA technology needed to produce a protein. A drug called alpha-2a interferon (Roferon-A) will serve as an example, but it should be remembered that the steps are essentially the same regardless of the protein being produced. This form of interferon is used to treat cancers such as hairy-cell leukemia and Kaposi sarcoma in AIDS patients (see chapter 14). The human alpha interferon gene is a DNA molecule of approximately 500 bp that codes for a polypeptide of 166 amino acids. It was originally isolated and identified from human blood cells and prepared from processed mRNA transcripts that are free of introns.

The first step in cloning the interferon gene or any desired gene is to prepare it for splicing into an *E. coli* plasmid (**figure 10.11**). This can be accomplished by digesting both the gene and the plasmid with the same restriction enzyme, resulting in complementary sticky ends on both the vector and insert DNA. In the presence of the endonuclease, the plasmid's circular molecule is nicked open, and its sticky ends are exposed. When the gene and plasmid are placed together, their free ends base-pair, and a ligase makes the final covalent seals. The resultant gene and plasmid combination is called a **recombinant**.

Following this procedure, the recombinant is introduced by transformation into the cloning host, a special laboratory strain of *E. coli* that lacks any extra plasmids that could complicate the

Quick Search

Process Figure 10.11 An overview of recombinant DNA and gene cloning.

expression of the gene. Because the recombinant plasmid enters only some of the cloning host cells, it is necessary to locate these recombinant clones. Cultures are plated out on medium containing an antibiotic such as ampicillin or tetracycline, and only those clones that carry the plasmid with resistance to this antibiotic can form colonies (**figure 10.12**). These recombinant colonies are

selected from the plates and cultured. As the cells multiply, the plasmid is replicated along with the cell's chromosome. In a few hours of growth, there can be billions of cells, each containing the target donor gene. Once the gene has been successfully cloned and tested, this step does not have to be repeated; the recombinant strain can be maintained in culture indefinitely.

Figure 10.12 One method for screening clones of bacteria that have been transformed with the donor gene. (a) Plating the culture on nonselective medium will not separate the transformed cells from normal cells, which lack the plasmid. (b) Plating on selective medium containing ampicillin will permit only cells containing the plasmid to multiply. Colonies growing on this medium that carry the cloned gene can be used to make a culture for gene libraries, industrial production, and other processes. (Plasmids are shown disproportionate to size of cell.)

The bacteria's ability to express the eukaryotic gene is ensured because the plasmid has been modified with the necessary transcription and translation recognition sequences. As the *E. coli* culture grows, it transcribes and translates the donor gene, synthesizes the peptide, and secretes it into the growth medium. Final processing to excise a terminal amino acid from the peptide yields the protein product in a relatively pure form. The scale of this procedure can range from test tube size to gigantic industrial tanks that can manufacture thousands of gallons of product. The basic process we have presented here can be harnessed to mass-produce a variety of immune treatments such as interferon, hormones, enzymes, vaccines, and agricultural products (see table 10.2).

Protein Products of Recombinant DNA Technology

Recombinant DNA technology is used by pharmaceutical companies to manufacture medications that are difficult to procure by other means. Diseases such as diabetes and dwarfism, caused by the lack of an essential hormone, are treated by replacing the missing hormone. Insulin of animal origin was once the only form available to treat diabetes, even though such animal products can cause allergic reactions in sensitive individuals. In contrast, dwarfism cannot be treated with animal growth hormones, so originally the only source of human growth hormone (HGH) was the pituitaries of cadavers. At one time,

not enough HGH was available to treat the thousands of children in need.

Another serious problem with using natural human products is the potential for infection. For example, infectious agents such as the prion responsible for Creutzfeldt-Jakob disease, described in chapter 6, can be transmitted in this manner. Similarly, clotting factor VIII, a protein needed for blood to clot properly, is missing in persons suffering from hemophilia A. In the early 1980s a large percentage of the patients receiving plasma-derived factor VIII contracted HIV infections as a result of being exposed to the virus through the donated plasma.

Recombinant technology changed the outcome of these and many other conditions by enabling large-scale manufacture of hormones and enzymes derived from human genes. Recombinant human insulin was the first rDNA hormone to be marketed for diabetics, followed by recombinant HGH for children with dwarfism and Turner syndrome. HGH is also used to prevent the wasting syndrome that occurs in AIDS and cancer patients. In all of these applications, recombinant DNA technology has led to both a safer product and one that can be manufactured in mass quantities. Other protein-based hormones, enzymes, and vaccines produced through recombinant DNA are summarized in table 10.2.

Nucleic acid products also have a number of medical applications. A new development in vaccine formulation involves using microbial DNA as a stimulus for the immune system. So far, animal tests using DNA vaccines for HIV and influenza indicate that this may be a breakthrough in vaccine design. Recombinant DNA could also be used to produce DNA-based drugs for some types of gene therapy, discussed in section 10.3.

13. Summarize the characteristics of bacteria and yeasts that make them good cloning hosts.
14. Outline the main steps in cloning a gene, including how this gene is used.
15. What is one way to determine whether a bacterial culture has received a recombinant plasmid?
16. Characterize several products that have resulted from recombinant DNA technology.

TABLE 10.2 Examples of Protein Products Made by Recombinant DNA Technology

Immune Treatments
Interferons—peptides used to treat some types of cancer, multiple sclerosis, and viral infections such as hepatitis and genital warts
Interleukins—types of cytokines that regulate the immune function of white blood cells; used in cancer treatment
Orthoclone—an immune suppressant in transplant patients
Macrophage-colony-stimulating factor—used to stimulate bone marrow activity after bone marrow grafts
Tumor necrosis factor (TNF)—used to treat cancer
Granulocyte-colony-stimulating factor (Neupogen)—developed for treating cancer patients suffering from low neutrophil counts
Hormones
Insulin—a small protein that is used to treat some forms of diabetes
Erythropoietin (EPO)—a peptide that stimulates bone marrow used to treat some forms of anemia
Tissue plasminogen activator (tPA)—can dissolve potentially dangerous blood clots
Hemoglobin A—form of artificial blood to be used in place of real blood for transfusions
Factor VIII—needed as replacement blood-clotting factor in type A hemophilia
Human growth hormone (HGH)—stimulates growth in children with dwarfism; prevents wasting syndrome
Enzymes
rH DNase (pulmozyme)—a treatment that can break down the thick lung secretions of cystic fibrosis
Antitrypsin—replacement therapy to benefit emphysema patients
PEG-SOD—a form of superoxide dismutase that minimizes damage to brain tissue after severe trauma
Lipases—added to laundry detergents
Vaccines
Vaccines for hepatitis A and B, <i>Haemophilus influenzae</i> , meningitis, influenza, rotavirus, and human papillomavirus
Experimental malaria and HIV vaccines based on recombinant surface antigens
Miscellaneous
Bovine growth hormone or bovine somatotropin (BST)—given to cows to increase milk production
Apolipoprotein—used to deter the development of fatty deposits in the arteries and to prevent strokes and heart attacks
Spider silk—a light, tough fabric for parachutes and bulletproof vest

10.3 Genetically Modified Organisms and Other Applications

Expected Learning Outcomes

- Define what is meant by the term *transgenic* or *genetically modified organisms*.
- Describe the uses of genetically modified bacteria and viruses.
- Discuss genetic modifications in plants and animals, explaining how they are carried out and giving examples of applications.
- Explain how DNA technology can be used to treat genetic diseases.

Recombinant organisms produced through the introduction of foreign genes are called **genetically modified organisms (GMOs)**, or **transgenic organisms**. Although foreign genes have been inserted into a variety of life forms including microbes, plants, and animals, the techniques used to create them owe their existence to the early work that took place in bacterial systems.

Recombinant Microbes: Modified Bacteria and Viruses

One of the first practical applications of recombinant DNA was the creation of a genetically altered strain of the bacterium *Pseudomonas syringae*. The wild strain ordinarily contains an ice formation gene that promotes ice or frost formation on moist plant surfaces. Genetic alteration of the frost gene using recombinant plasmids created a different strain that could prevent ice crystals from forming. A commercial product called Frostban was developed but never marketed due to the controversy arising from its release into the environment. In another trial, a strain of *Pseudomonas fluorescens* was engineered with the gene from a bacterium (*Bacillus thuringiensis*) that codes for an insecticide (*Bt toxin*). These recombinant bacteria are released to colonize plant roots and help destroy invading insects. All releases of recombinant microbes must be approved by the U.S. Environmental Protection Agency and are closely monitored.

Although primarily known for its ability to cause colds, the adenovirus has been bioengineered to attack and destroy cancer cells. These *oncolytic adenoviruses* have been altered so that their host range consists exclusively of cells that produce cancer-specific proteins. By simply infecting a cancerous cell and replicating, the engineered virus will eventually lyse and kill the cell. Although this

10.2 MAKING CONNECTIONS

A Moment to Think

“When we seed millions of acres of land with these plants, what happens to foraging birds, to insects, to microbes, to other animals, when they come in contact with and digest plants that are producing materials ranging from plastics to vaccines to pharmaceutical products?”

Jeremy Rifkin, Foundation on Economic Trends

“If you put a label on genetically modified food, you might as well put a skull and crossbones on it.”

Norman Brasick, of Monsanto, the largest biotechnology firm selling engineered seeds

“There is a profound difference between the types of expected effects from traditional breeding and genetic engineering.”

Dr. Louis Pribyl, FDA microbiologist

There is no denying that many aspects of synthetic biology are highly controversial and emotionally charged, but few would deny that this technology is here to stay. As evidenced by the graph, as of 2015, 85% to 95% of major crops are now composed of genetically modified plants. Most of these plants have been altered to either make their own insecticide or resist herbicides that kill weeds. The edible crops are already winding up in the foods we eat. With regard to animals, so far only one GMO has received approval for human consumption—the AquAdvantage salmon—a farmed Atlantic salmon that has been engineered with genes from other fish. Time will tell what kind of acceptance these fish will have in the consumer market.

What effects, if any, will these GMOs have? In many cases we do not yet know the answer, but so far we have relied on the scientists who developed this technology to test its effects and report their findings. Those who will determine the limits of genetic technology include not only scientists and politicians but voters and consumers as well. History is rife with both knee-jerk rejections to new technologies that have later proven to be invaluable (vaccinations) and complacency while harmful products were released with inadequate scrutiny (for example, Fen-Phen, Vioxx).

Ethical choices can be properly made only from a standpoint of intellectual awareness; and in this era of advertising, polling, and focus groups, people with a stake in genetic technology know that the most effective way to drum up support (both for or against) is *not* by carefully educating the public as to the uses and limits of our newfound powers but, rather, by publicizing exaggerated claims or frightening scenarios. Enlightenment is often a casualty of these advertising campaigns, and you as a student, voter, and potential consumer of bioengineered products need to realize that the truth lies somewhere between nightmare scenarios and the blissful utopia often portrayed by some proponents of biotechnology.

Throughout this chapter, a common theme has been that biotechnology, genetically modified organisms, and gene-based therapies are simply new ways of achieving long-held goals. This is, of course, a vast understatement. Society has never before had the ability to do even a fraction of the things we can do today, and at some point we must decide where we as individuals and as a society draw the line. The answer will differ for each person, based on his or her unique experiences and personal philosophy, but should certainly include a factual knowledge of the probable benefits and possible risks. We live in serious times, and these are choices requiring serious thought.

Can you think of any adverse effects might arise from eating GMO corn or fish? After all, every type of non-GMO food we eat already contains large amounts of foreign DNA from the food organism. Answer available on Connect.

procedure is not yet approved for use in humans, this novel use of viral vectors speaks to the potential of genetically engineered viruses. This technology is currently used to engineer viruses to deliver genes into animals and humans (see figure 10.15).

In 2010 a milestone was reached when Craig Venter’s laboratory team created an entirely new bacterial species by inserting a completely synthesized genome of artificial origin into *Mycoplasma genitalium*. The new species, named *Mycoplasma laboratorium*,

contains the smallest functional genome of any bacterium, with 382 genes of around 1.1 million base pairs. So far the scale of this experiment is small—a single-celled organism—but its implications are large. The growing power of genetic engineering and synthetic biology has fostered a deeper examination of the **bioethics**⁵ involved in wielding the genetics of organisms (10.2 Making Connections).

5. A field that relates biological issues to human conduct and moral judgment.

Recombination in Multicellular Organisms

Although the terms *genetically modified*, *genetically engineered*, and *transgenic organism* apply to any life form whose genome has been deliberately altered, it is often used in reference to plants and animals that possess genes that were not acquired through traditional breeding. The basic techniques covered in this chapter have given scientists a limited ability to custom-build an organism that expresses a certain trait, in a sense accelerating the pace of evolution. Because of the universal nature of the genetic code, however, scientists can go nature one step farther and combine genes from more than a single species, creating plants or animals that would never have existed otherwise. Examples of genetically modified organisms include plants with added nutritional value, animals that excrete clot-dissolving proteins in their milk, and humans who have gained the ability to produce an enzyme crucial to the immune response.

Transgenic Plants

Engineering plants to produce new traits often revolves around *Agrobacterium tumefaciens*, a plant pathogen particularly adept at transferring small amounts of DNA to plant cells. These bacteria live in soil and can invade injured plant tissues. Inside the wounded tissue, the bacteria adhere to plant cells and introduce a large plasmid termed **Ti** (tumor-inducing). This plasmid inserts into the genome of the infected plant cell and transforms it (**figure 10.13**). Over time this causes development of a tumor called *crown gall disease*, a mass of undifferentiated tissue on the stem.

The primary factor that induces this transformation is a discrete region of the Ti plasmid called T-DNA. This series of genes is integrated into a plant cell's chromosome, where it directs the synthesis of nutrients to feed the bacteria and hormones to stimulate plant growth. Even after the bacteria in a tumor are dead, the plasmid genes remain in the cell nucleus and the tumor continues to grow.

This plasmid is an effective vector for inserting foreign genes into plant genomes. The procedure involves removing the Ti plasmid, inserting a specially selected gene such as herbicide resistance into it, and returning the plasmid to *Agrobacterium*. Infection of the plant by the recombinant bacteria automatically transfers the plasmid with the foreign gene into the plant cells. Transformed cells can be grown into mature plants that express the donor gene and transmit it to their offspring. The insertion of genes with a Ti plasmid works primarily to engineer important plants such as potatoes, tomatoes, cotton, and grapes.

For plants that cannot be transformed with *Agrobacterium*, seed embryos have been successfully implanted with additional genes using gene guns—small “shotguns” that shoot the genes into plant embryos with tiny gold bullets.

Figure 10.13 Bioengineering of plants. Most techniques employ a natural tumor-producing bacterium called *Agrobacterium tumefaciens* (a). The example here shows the insertion of a gene to create a herbicide-resistant plant (b-e).

Agricultural officials had approved more than 1,200 genetically modified plants for field testing through the year 2014. Around 240 million acres of these plants were grown in the United States alone in 2012, with herbicide- and insecticide-resistant soybeans, corn, cotton, and canola making up the vast majority. The principal concern about such plants is the potential for genetic recombination with nearby wild plants, leading to the creation of “superweeds” that are resistant to herbicides and disease. This has already happened in parts of Canada, where canola plants have transferred their genes to wild mustard. Because this could alter the ecology of natural environments, the U.S. Department of Agriculture is increasing the regulation of all releases of transgenic plants. See **table 10.3** for examples of plants that have been engineered.

TABLE 10.3 Examples of Genetically Modified Plants

Plant	Trait(s)	Results
Cherry tomatoes	High levels of anthocyanin, an antioxidant	Tomatoes were engineered with pigment gene from snapdragons, producing five times the purple pigment anthocyanin and greatly increasing the nutrition value (figure a).
Wheat	Resistance to head blight	Genes added to break down the cell wall of the fungus <i>Fusarium</i> protect wheat plants from being attacked (figure b).
Wheat	Improved nutrition	Engineered with genes to increase zinc and iron levels in the plant.
Golden rice	Improved nutrition	Genes added to produce beta-carotene, a precursor to vitamin A; aim is to prevent deficiencies in developing countries that lead to blindness.
Soybeans, corn, cotton	Herbicide resistance	Plants were engineered to withstand chemical herbicides.
Peanuts	Insect resistance	Genes for a biopesticide called Bt were added to kill insects that feed on the plants (figure c).
Banana	Vaccine production	Vaccines for hepatitis B in development
Plum	Viral resistance	Genes for resistance to plum poxvirus prevent infection and destruction of plant

(a) This purple tomato contains high levels of a pigment that has numerous health benefits.

(b) Researcher holds a genetically engineered wheat plant being tested for its resistance to a fungal infection.

(c) Peanut plant (left) genetically modified to produce its own insecticide is unharmed by larvae; unmodified plant (right) shows damage from insect larvae.

Transgenic Animals: Engineering Embryos

Animals such as mice, pigs, sheep, cattle, fish, and poultry are prominent candidates for genetic engineering. Thousands of animal strains now exist for the purposes of agriculture, industry, and research into genetic diseases.

The most effective way to insert genes into animals is to use a virus to transfect the fertilized egg or early embryo (germ-line engineering). Foreign genes can also be delivered into a fertilized egg by pulsing the egg with high voltage or by injection (**figure 10.14**). The success rate does not have to be high, because once created, a transgenic animal will pass the genes on to its offspring. An inventive newer technology known as **CRISPR** (see “CRISPR—A Power Tool for Gene Editing”) is rapidly becoming the chosen method for manipulating embryonic DNA, especially to create mouse models of human disease.

The dominant animals in the genetic engineer’s laboratory are transgenic forms of mice. In one pioneering experiment, fertilized mouse embryos were injected with a gene from a jellyfish that produces a green fluorescent protein. The cells of these mice fluoresce in ultraviolet radiation. One serious use has been to study the developmental stages in mice. This strategy has led to the design of animal

Several embryos recovered from female

Embryos transferred to a depression slide containing culture medium

Figure 10.14 Steps in the creation of a transgenic animal. Hundreds of mice and other mammals with genetic modifications have been produced this way.

models to study human genetic diseases and to use these natural systems to test new genetic therapies before they are used in humans. Animals such as sheep or goats can also be engineered to become “factories” capable of manufacturing proteins and excreting them in their milk or semen, a process often referred to (when done to produce medically useful proteins) as “pharming.”

One benefit of transgenic animals is that they will automatically transcribe and translate eukaryotic genes and accurately carry out posttranslational modification of the protein. By ensuring that the protein product is produced in the milk or semen of animals, recovery and purification are made that much simpler. For

Embryonic mouse displaying green fluorescent protein

example, alpha-1 antitrypsin (AAT), produced in sheep, is used to treat an inherited form of emphysema. A single animal produces AAT at concentrations of 35 grams per liter of milk. A few hundred sheep could easily meet the needs of the 20,000 people a year who suffer from this debilitating disease. See **table 10.4** to examine some other examples and applications of transgenic animals.

Medical Applications of DNA Technology

One offshoot of studies with transgenic animals has been the advancement of medical treatments for human diseases that involve manipulating genetics, rather than administering drugs. The applications that show the most promise are gene therapy, which aims to replace a nonfunctional gene with its normal counterpart, and regulatory RNAs, which manage DNA expression of abnormal genes.

Gene Therapy

We have known for decades that for certain diseases, the disease phenotype is due to a missing or non-functioning protein. Often referred to as “loss of function” diseases, examples include cystic

TABLE 10.4 Selected Applications for Transgenic Animals

Animal/Product	Application
Production of Pharmaceuticals	
Pig/Factors VIII and IX	Treatment of human blood-clotting disorders.
Sheep/Alpha antitrypsin	Replacement protein to prevent emphysema.
Rabbit/Human interleukin-2	Stimulates the production of T cells to fight cancer.
Cow/Lactoferrin	Iron-binding protein inhibits bacterial and viral infections.
Cow/Human albumin	Used in surgery to maintain blood volume.
Goat/Tissue plasminogen activating factor	Dissolves blood clots and reduces heart damage.
Goat/Antithrombin	<i>Atryn</i> was the first drug from a genetically engineered animal approved by the FDA; used to prevent blood clots.
Research/Industry/Environment	
<i>Anopheles</i> mosquito malaria resistance	Mosquito embryos have new genes inserted to make them resistant to infection by <i>Plasmodium</i> , the malaria parasite. Modified mosquitoes would no longer carry and spread the parasite.
Goat/Silk fibers	Female animals secrete silk protein in their milk. Silk has many uses for constructing strong, lightweight material.
Pig/Pork meat	<i>Enviropig</i> has enzymes in its saliva to process excess phosphate in its feed, reducing pollution.
Mice, cats, pigs, monkeys/research animals, Tropical fish	Engineered with the green fluorescent protein from jellyfish that causes their cells to glow green in UV light. Animals are used to trace development in embryos and the stages of certain diseases.
Cats and dogs/Hypoallergenic	Genes that code for allergens from animal’s saliva and sebaceous glands have been silenced.
Salmon/Farmed fish	Atlantic salmon engineered with the growth hormone gene from a different species of salmon to increase growth rate.
Cow/Human breast milk	Produces milk with the same composition as human breast milk.
Genetically engineered Atlantic salmon grow two times faster than regular salmon.

fibrosis, hemophilia, sickle-cell anemia, some forms of dwarfism, and muscular dystrophy. A few of these diseases can be treated by administering the correct protein—recall the use of recombinant growth hormone to treat dwarfism. But in the majority of cases, a replacement drug is not yet available. About 30 years ago, medical geneticists began to explore the possibility of restoring function by means of **gene therapy**, by inserting the normal functioning gene into the cells of afflicted patients.

The inherent potential of gene therapy would be to permanently cure the physiological dysfunction by repairing the genetic defect. There are two strategies for this therapy. In *ex vivo* therapy, the normal gene is cloned in vectors such as adenoviruses or retroviruses that have been modified to carry a corrective gene into cells of the patient. Tissues removed from the patient are incubated with these genetically modified viruses to transfect them with the normal gene. The transfected cells are then reintroduced into the patient's body by transfusion (**figure 10.15**). In contrast, the *in vivo* type of therapy skips the intermediate step of incubating excised patient tissue. Instead, the naked DNA or a virus vector is directly introduced into the patient's tissues.

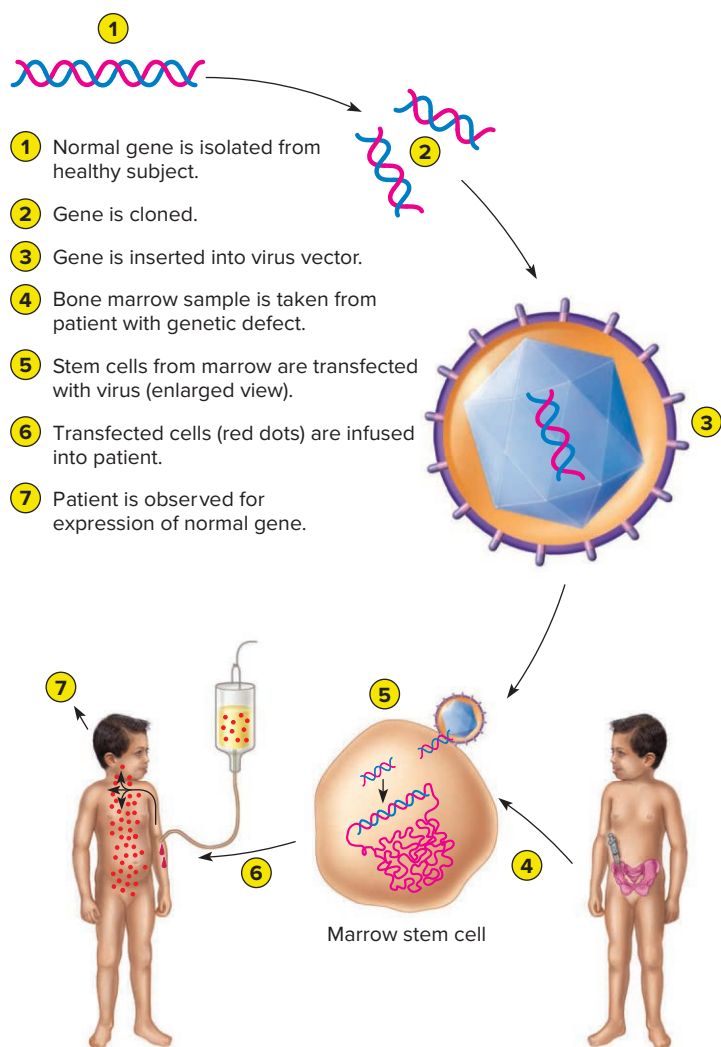

Figure 10.15 Protocol for the *ex vivo* type of gene therapy in humans.

Clinical testing using various types of gene therapy is performed on human volunteers with a diagnosed genetic disorder. Over 2,000 of these trials have been or are being implemented in the United States and other countries. Most trials target cancer, single-gene defects, and infections. The most dramatic example of this type of treatment was seen in the very first gene therapy trial conducted in 1990. In this case, two girls suffering from adenosine deaminase (ADA) deficiency, a fatal immunologic disorder caused by a missing enzyme, received infusions of their own hematopoietic stem cells that had been transformed with a healthy copy of the adenosine deaminase gene.

As with most medical experimentation, some of the earlier gene therapy trials experienced setbacks. A serious problem arose with the use of the viral vectors. Even though they were supposed to be “harmless,” five children infused with a recombinant mouse retrovirus developed leukemia when the vector DNA integrated at a cancer-inducing site on a chromosome. After this event, researchers worked to develop modified adeno-associated viral vectors to greatly reduce the chances of this happening.

Over the past 5 years, medical geneticists reported major successes in curing 20 children born with the devastating genetic disease termed X-1-linked SCID (severe combined deficiency disease). These children lacked a functioning immune system from birth, which researchers restored by inserting copies of the functioning gene into their stem cells using a safer recombinant virus. In another case, a team of physicians improved the vision of several children with a genetic form of progressive blindness by transferring the gene directly into the retina. Other genetic specialists have engineered T cells to treat melanoma and leukemia and have cured a form of the hemoglobin disorder called thalassemia. Other trials under way to target hemophilia and Parkinson disease appear to restore some function to patients with these conditions. A newer therapy for the treatment of lipoprotein lipase deficiency (LLD) is called alipogene tiparvovec (**Glybera**). It is based on an engineered adeno-associated virus that carries the normal gene for processing certain types of fats. When injected into the muscles of the legs, it is assimilated locally and can restore normal function to fat metabolism. So far, it is the only gene therapy approved for routine use in the United States.

Therapy with Regulatory RNAs

Tens of thousands of genetic disorders have been described. Most are due to nonfunctional or missing genetic material, but a proportion of them result from the expression of abnormal, mutated genes. These conditions, termed “gain of function” diseases, include a number of cancers, some forms of Alzheimer disease, Huntington disease, and fragile X syndrome. Since every cell in the body carries these faulty but active genes, merely replacing them is not yet an option.

For these types of diseases, genetic researchers are taking a lesson from the natural strategies used by bacteria and eukaryotic organisms for regulating gene expression (chapter 9). Recall that these

organisms use regulatory RNA or RNAi, including small interfering RNAs and microRNAs, to silence gene expression. This knowledge has driven the development of genetic-based drugs that interfere with mRNA processing and protein synthesis. Some of the most promising therapies involve the targeting of RNA virus genomes by small RNAs. They have been used to degrade HIV and respiratory syncytial viruses. They have also been tested as a treatment for macular degeneration and as a therapy to silence cancer genes.

Early clinical trials of RNAi therapeutics have been promising, with most of them dramatically lowering the rate of synthesis of the targeted protein. Because the RNAi agent can be targeted to a specific sequence of DNA, side effects are rare. The biggest obstacles involve how to deliver the RNAi drugs into deep tissues where their targets lie and the fact that these drugs would have to be taken for life.

CRISPR—A Power Tool for Gene Editing

Novel “tricks” of microbial genetics continue to be a valuable source of innovations in biotechnology. One of the newest and most powerful methods of DNA manipulation, based on a natural system found in many bacterial and archaeal cells, is termed “clustered regularly-interspersed short palindromic repeats,” thankfully shortened to its acronym—**CRISPR** (pronounced “krisper”). These short segments of DNA are associated with enzymes—**CRISPR-associated proteins** or **Cas**—whose actions are somewhat similar to those of restriction endonucleases. For example, CRISPR/Cas combinations recognize and cut DNA at precise palindrome-like markers, which provides a survival defense against the foreign DNA of invading viruses and plasmids. A surprising feature is that CRISPR functions like an acquired immune system; it not only destroys foreign DNA sequences but also maintains a “memory” copy of each foreign DNA, which can be reactivated if this same DNA invades again.

The CRISPR/Cas system has revolutionized the process of **gene editing**. The technology is simpler, faster, and more versatile than anything else yet discovered. Researchers and biotechnologists working in almost any field can apply it as a means to remove unwanted DNA from, or add new DNA to, any genome, whether microbial, plant, animal, or human. So far most of the research has involved bacteria, yeasts, and simple animals.

Here is a brief outline of how the system works in bacteria: Bacteria are constantly accumulating foreign DNA from invading viruses and plasmids that could harm or even kill them. The genes contained in CRISPR code for the Cas nuclease enzymes that are the primary destroyers of this foreign DNA. Part of the CRISPR gene complex is a section that stores the copies of foreign DNA (called spacers). These constitute the immune memory for future encounters. Once any foreign DNA (injected by a virus, for example) has first entered the cell, it is copied onto a spacer and also transcribed into a CRISPR RNA (crRNA) molecule (the guide), which the Cas enzyme picks up and transports around the cell. When the enzyme-crRNA complex encounters any foreign DNA that matches the guide RNA, the Cas enzyme cuts the DNA at exact targeted sites, which will permanently disable the virus or disrupt the plasmid. To view a dynamic animation of this process, go to https://www.youtube.com/watch?v=2pp17E4E-O8&list=PLEbm7wJ3WiYxd19t4TiuM_HXRymY22PT1.

CRISPR/Cas has been widely used to “knock out” genes in bacteria and animals to study the effects on organism function when a particular gene has been lost. It is gaining favor as a means of creating transgenic plants and animals. A recent application of CRISPR was to insert genes into embryonic mosquitoes to make the adult mosquitoes resistant to malaria. Because of its high potential to alter genomes, the technology has met with some controversy. It has been known to cause insertional and deletional mutations and other unforeseen problems. After Chinese researchers used it on nonviable human embryos to test the possibilities of gene therapy to knock out dysfunctional genes, scientists around the world called for a moratorium to halt this sort of germ line experimentation until its safety could be ensured. Many biologists think that once these ethical issues have been worked out, CRISPR will become a source of viable treatments for genetic diseases, cancers, and even infections.

Check Your Progress SECTION 10.3

- Describe several uses of genetically modified bacteria and viruses in medicine or industry.
- Explain the techniques for genetically modifying plants.
- Why must animals usually be modified in the embryo stage to arrive at successful outcomes?
- Describe the possible ethical or biological problems associated with eating peanuts from an engineered plant or pork from a transgenic pig.
- What are some ethical and biological considerations when using transgenic animals to manufacture various human products?
- Outline the uses of gene therapy and gene editing to control genetic diseases and the possible harm they may cause.

10.4 Genome Analysis: DNA Profiling and Genetic Testing

Expected Learning Outcomes

- Discuss the concept of the use of DNA in genome identification.
- Describe two methods in performing a DNA analysis, its possible applications, and how it can be so precise.
- Describe several applications of DNA profiling and microarray analysis.

A geneticist’s joke begins: “How would you describe a cat?” The answer, “ACATACATACAT . . .,” is becoming more and more a reality. As we mentioned earlier, DNA technology has allowed us to accomplish many age-old goals by new and improved means. By remembering that phenotypes, whether human, bacterial, or even viral, are the result of specific sequences of DNA, we are now at a point where knowledge of DNA can be even more effective than observing phenotypes to differentiate among organisms and people. Additionally, DNA can be used to “see” the phenotype of an organism or person no longer present, as when a criminal is

identified by DNA extracted from a strand of hair left behind at the crime scene. Finally, possession of a particular sequence of DNA may indicate an increased risk of a genetic disease. Detection of a specific and unique region of DNA, or **marker**, can identify a person as being at increased risk for cancer or Alzheimer disease long before symptoms arise. The ability to detect diseases before symptoms arise is especially important for conditions such as cancer, where early treatment can make the difference between life and death. With examples like this in mind, let's look at several ways in which new DNA technology offers extraordinary glimpses into the present, past, and future.

DNA Profiling: A Unique Picture of a Genome

Although all DNA is based on a structure of nucleotides, the exact way these nucleotides are combined is unique for each organism. Such genetic variations, or polymorphisms, will vary to some extent even among close relatives (except identical twins, whose DNA comes from the same fertilized egg). A major goal of DNA technology is to discover these unique qualities, emphasize their differences, and provide a pattern for comparison and identification. **DNA profiling** (sometimes called DNA fingerprinting or typing) was developed as a **forensic*** technique in the mid-1980s by English geneticist Alex Jeffreys. The first methods of analysis used restriction enzymes to cut DNA located at specific recognition sites and to target genetic polymorphisms called RFLPs, introduced earlier in the chapter. The results were rendered into a series of bands or “barcodes” that could be used to compare several samples alongside each other. It turns out that hidden within genomes are large numbers of other types of DNA variations that can be used in identifying individuals that are even more specific and widespread than RFLP fingerprints.

Several of the methodologies discussed previously in this chapter are essential to creating a DNA profile. This includes PCR amplification for increasing the number of copies of a certain gene, electrophoresis to separate DNA fragments, and hybridization probes or primers that link to specific nucleotide sequences. The primary idea is to distinguish one isolated piece of DNA from another by comparing the genetic variations at a specific location, or **locus***. Note that DNA profiling is not the same as whole genome sequencing but instead focuses on a few selected genetic loci to produce a “snapshot” of a particular polymorphism pattern. Millions of such differences are known to exist throughout the genome. Many of these polymorphisms are located in regions of the DNA that do not code for protein and are considered normal rather than harmful variations.

The most reliable methods of DNA profiling presently available are (1) **short tandem repeats (STRs)**, relatively short fragments of nuclear DNA that are covered below in some detail; (2) **mtDNA** or mitotyping to identify the DNA found in mitochondria; and (3) **single nucleotide polymorphisms (SNPs)** that locate variants of a single nucleotide in the population. Important features of STR analysis and mitochondrial profiling will be discussed under the next headings.

STR Profiling

The most routine methods in forensic identification are based on short tandem repeats (STRs). These are segments of DNA that consist of a short chain 2 to 8 nucleotides long. These STRs are repeated in series multiple times. Both the number of nucleotides in a sequence and the number of repeats of it vary throughout the genome. An example of this type of sequence in which 4 bases (GATA) repeat 5 times would read:

AGCT**GATA**GATA**GATA**GATA**GATA**GATA**GGCC**

Studies have identified thousands of these repeated sequences, which provide the background data for producing a profile. Almost all of them occur in noncoding regions of the genome, but they are inherited the same way that genes are—as a pair of alleles, one from each parent. The genotype of a given allele can be the same or can be different, just as for eye color or blood type. At the heart of STR analysis is the pattern of nucleotides and number of repeats detected. This form of DNA profiling is mostly conducted by specialized machinery that is computer-driven and computer-analyzed, as outlined in **figure 10.16** and discussed below.

A sample of DNA is isolated from a person or object and tagged with a number of known STR-specific primers to ready them for PCR amplification. These primers not only complement a known sequence of DNA, they also carry fluorescent dyes for later detection. After these sequences are amplified, they are electrophoresed and scanned by a laser that detects the fluorescent pattern of the primers and thus the specific STR alleles. The resultant readout, called an electropherogram, is a series of colored peaks that coincide with the STRs from that sample (figure 10.16d). This pattern undergoes further analysis to indicate possible matches and a mathematical probability of the pattern being anyone other than the individual from the sample. The database contains a cross reference of the frequencies of the combinations of STRs from real populations for accuracy in comparisons.

Let us examine how this analysis would work: Imagine that a sample of blood found at a crime scene is thought to have come from a suspect and has tested positive for STR markers (alleles) A, B, C, and D. If marker A is normally present in 1 person out of 80, marker B in 1 person out of 60, marker C in 1 person out of 45, and marker D in 1 person out of 70, the probability that a single person would have all four markers is $(1/80 \times 1/60 \times 1/45 \times 1/70)$ or 1 out of 15,120,000. When the suspect's result matches the evidence blood, it is a powerful indicator that the suspect was involved in the crime, especially when supported by traditional evidence, such as the suspect's having been seen near the crime scene. Adding even more STR loci can increase the probability to as high as 1 out of several billion or trillion, solidifying the match to an undeniable degree.

DNA profiling has been widely used to convict or exonerate many thousands of accused defendants in criminal cases. Besides actual fingerprints, criminals often leave other evidence at the site of a crime—hair, skin, semen, blood, saliva, and even “touch DNA” from fingertips. In fact, the technology is so reliable that many older cases for which samples are available are being reopened and solved. The FBI has established a national database (the **Combined DNA Index System** or **CODIS**) to support this

* **forensic** (for'-en-sik) The application of science to law, especially as it relates to the investigation of crime.

* **locus** (loh'-kuss) The specific site on a DNA molecule where a particular gene or sequence of nucleotides is located.

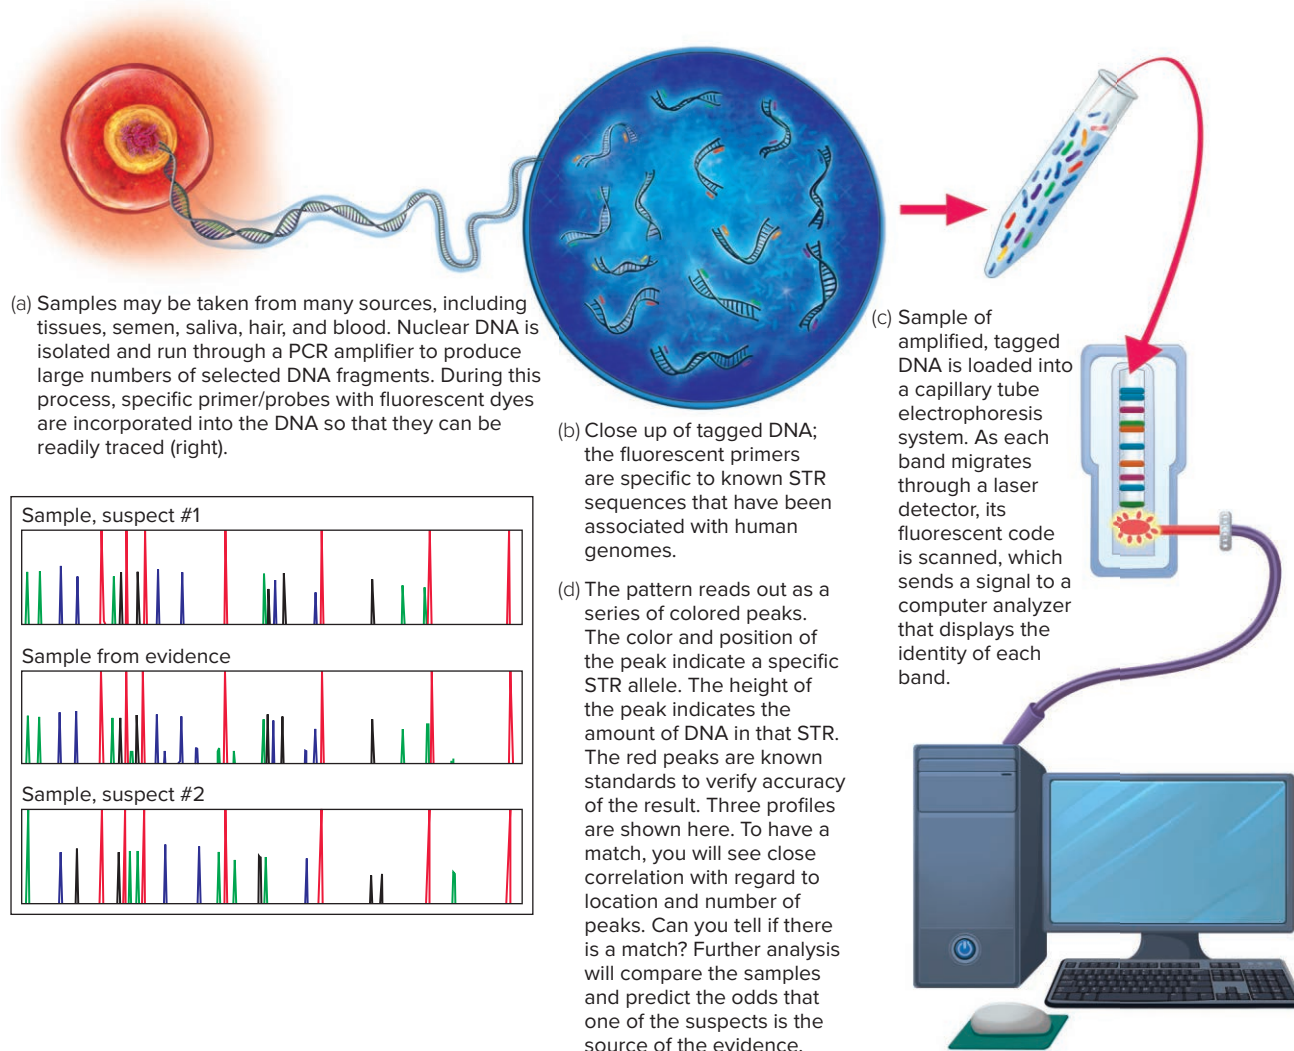

Figure 10.16 (a-d) An Outline of Short Tandem Repeat (STR) Profiling. This technique is widely used in forensics, genealogy, population studies, identification of types of cancer, and genetic diseases. For excellent coverage of these techniques, go to <http://nij.gov/training/pages/dna-multimedia.aspx>.

effort. The CODIS technology analyzes 13 common STRs, with a 14th that determines sex. This provides a uniform source for comparisons across law enforcement and forensics. Present laws require that prisoners, felons, and other violent offenders have their CODIS profiles entered into this system to keep tabs on known criminals.

The most frequent uses of DNA profiling are in forensics, identifying missing persons, detecting genetic diseases, determining parentage, analyzing the family trees of humans and animals, tracing the lineage of organisms, and identifying microorganisms. In a stunning application of DNA profiling, forensic scientists were able to positively identify the Unibomber, Ted Kaczynski, by DNA recovered from the back of postage stamps he had licked. This same technology has also been effective in identifying the remains of astronauts from the shuttle *Columbia*, some victims of Hurricane Katrina, nearly 2,000 individuals from the World Trade Center attack, and even to verify that the person killed in the raid on a Pakistani compound in 2011 was indeed Osama Bin Laden. This sort of identification of unknown DNA always requires a sample of the known DNA

of the suspected person or close relatives who would share some of the STR alleles.

Mitotyping

Recall that only eukaryotic organisms have mitochondria and that each mitochondrion is self-sustaining and carries its own chromosome. Mitochondrial DNA (mtDNA) consists of about 16,500 base pairs that code for 37 genes. One advantage of mtDNA is that it is highly conserved in evolution and does not change greatly over long periods of time. Even with this small genome, it has a number of unique variations that are sufficiently varied to identify humans, plants, and animals to the level of species and even individuals. Another advantage of mtDNA is that it does not break down as readily as chromosomal DNA and remains intact even after being exposed to harsh conditions for thousands of years. Also, it is inherited only from the mother's egg, because sperm do not contain mitochondria. This means that children from the same mother will have the same mtDNA profile. MtDNA was integral to the identification of the Romanovs—the family of the last czar of Russia, who

were assassinated and buried in a mass grave in 1919. It has also become a tool of genealogy as a way to trace the maternal lineage of families and to clarify cases of maternity

Because even fossilized or ancient DNA can remain partially intact, ancient DNA is being studied for comparative and evolutionary purposes. Anthropologists have traced the migrations of ancient people by analyzing the mitochondrial DNA found in bone fragments. Evolutionary biologists have been able to recover Neanderthal mtDNA and use it to show that these ancient primates were in a line of evolution separate from the modern human line. Biologists studying canine origins have also been able to show that the wolf is the ancestral species for modern canines

Several large databanks are currently collecting genomic profiles on mtDNA markers for thousands of species of plants, animals, and fungi. Two of these—Genbank and Barcodes of Life—offer these sites as a way to keep track of biodiversity (the varieties of life on earth) and to provide information for researchers and commercial operations needing to identify specimens of fish, invertebrates, plants, and other organisms that cannot be identified by the usual methods.

Miscellaneous DNA analysis Single nucleotide polymorphisms, or “SNIPs,” are the most specific polymorphisms because they are the most variable, occurring around 10 million times among a person’s 3.2 billion base pairs. They appear as single base differences at random sites throughout the chromosomes, both in genes and noncoding DNA. SNPs are a valuable tool in disease diagnosis, population genetics, personalized medicine, and biomedical research. More and more, infectious disease laboratories are employing DNA test procedures based on SNPs to identify bacteria. Other forms of DNA typing are rapidly becoming the method of choice to identify pathogens, including *Neisseria gonorrhoeae*, *Chlamydia*, the syphilis spirochete, *Staphylococcus MRSA*, *M. tuberculosis*, and a number of viruses. It is also an essential tool for determining genetic similarities between microbes involved in disease outbreaks. For more information on SNPs, refer to 10.1 Making Connections. To see a virtual version of bacterial identification, go to <http://www.hhmi.org/biointeractive/bacterial-identification-virtual-lab>.

Determining Gene Activity with Microarrays

Having a DNA profile or a sequence of a genome is really only half the battle. With very few exceptions, all cells in a multicellular organism contain the same DNA, so knowing the sequence of that DNA, while certainly helpful, is of very little use when comparing two cells or tissues from the same organism. Recall that genes are expressed in response to both internal needs and external stimuli, and that although the DNA content of a cell remains constant, the mRNA (and hence protein) content at any given time provides scientists with a profile of genes currently being expressed in the cell. What truly distinguishes a liver cell from a kidney cell or a healthy cell from a diseased cell is their manner of gene expression.

Twin advances in biology and electronics have allowed biologists to view the expression of genes in any given cell using a technique called DNA *microarray analysis*. Prior to the advent of this technology, scientists were able to track the expression of at most only a few genes at a time. Given the complex interrelationship that exists between genes in a typical cell, tracking two or three genes would be of very little practical use. Microarrays are able to track the

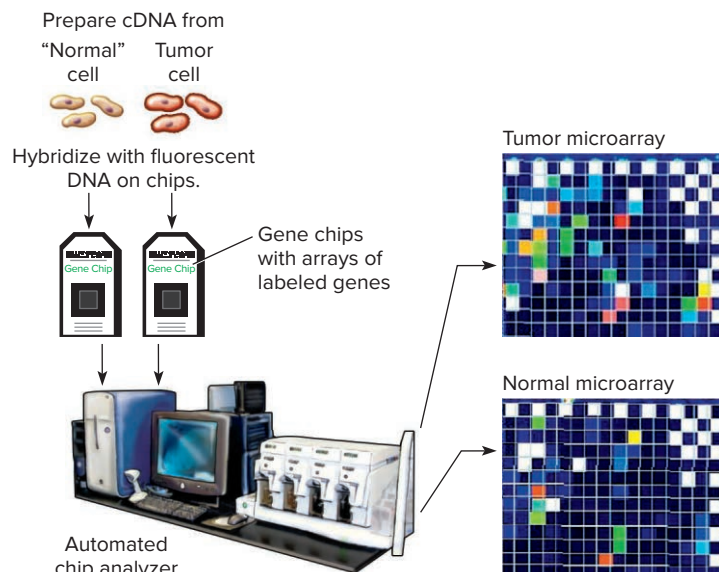

Figure 10.17 Gene expression analysis using microarrays.

Microarrays display large numbers of genes being expressed at the same time in the same cell. Small slides or chips are coated with fluorescently labeled genes and exposed to unknown cDNAs. A laser excites the bound cDNAs, while a detector records those spots that fluoresce. The color of each spot reveals whether the DNA on the microarray is present in the normal cell, the cancer cell, both cells, or neither. Source: Darryl Leja, NHGRI

expression of thousands of genes at once and are able to do so in a single efficient experiment. Microarrays consist of a “chip” (made of glass, silicon, or nylon) that carries bound sequences from tens of thousands of different known genes. A solution containing fluorescently labeled cDNA, representing all of the mRNA molecules active in a cell at a given time, is applied to the chip. The labeled cDNA is allowed to hybridize with any complementary DNA bound to the chip. Bound cDNA is then detected by exciting the fluorescent tag on the cDNA with a laser and recording the fluorescence with a detector linked to a computer. The computer is programmed to interpret this data by highlighting what mRNAs are present in the cell under a variety of conditions. Look at **figure 10.17** for an example of results comparing a normal cell with a cancer cell.

Microarrays permit the development of extraordinarily sensitive diagnostic tests that search for a specific pattern of gene expression. As an example, being able to identify a patient’s cancer as one of many subtypes (rather than just, for instance, breast cancer) will allow selection of a cancer drug that appears to be most effective. Again, we see how genetic technology can greatly assist in medical decisions.

Check Your Progress SECTION 10.4

- Describe what a DNA profile is and how STRs and other polymorphic fragments can be used to display the unique qualities of DNA.
- Discuss briefly how DNA profiling is being used routinely by medicine, the law, the military, and studies of human biology and history.
- Explain the origins of mtDNA and its importance in identification.
- Explain the difference between a DNA profile and a microarray.

CASE STUDY Part 2

In 2009, with the clock ticking down on a gravely ill child, specialists in sequencing arranged for Nicholas's genome to be analyzed. Blood samples were used to extract a significant quantity of his genomic DNA. Although a complete sequencing of his genome was considered, it would have added layers of complexity and expense, so the team decided it would be more effective to sequence only the exons—a process called *exome sequencing*—to ensure that they would be looking only at segments of DNA that code for proteins. Even this shortcut was far from easy or simple. It would require examination of 180,000 known exons. They arranged for a software specialist to design a program that could filter out “normal” exons and identify potential bits of his genome that encoded mutations that could produce abnormal proteins. The search located 16,124 possible exons of this type.

After additional passes of the DNA through the sequencer to eliminate mutations that were common and harmless, the program eventually narrowed the potentially harmful exon mutations down to about 2,000. Now the search became focused on which of these genes would be most likely involved in immune dysfunction and inflammatory bowel disease. After several weeks the specialists found a gene

termed *XIAP* known to be involved in immune regulation. It was located on the X chromosome, which means that a male child will express the mutated form of it because there is no protection from an alternate allele on the Y chromosome. This gene and its protein, also termed *XIAP*, is an immune regulator with the normal function of preventing programmed cell death. If it has become mutated and unable to perform its usual function, cells will spontaneously die, leading to destruction of tissues and organs.

With further scrutiny, the nature of Nicholas's mutation became clear. He had inherited a single base substitution on the *XIAP* gene from his mother. The substitution was a guanine (G) being replaced with an adenine (A), changing the codon from TGT to TAT (see the figure in the Case Study for this chapter). This would also switch the amino acid at that position on the *XIAP* protein from cysteine to tyrosine, which would interfere with the normal three-dimensional folding of the protein. The result was such a rare alteration that it has not been found in any other known genome.

- Describe what exons are and why they would be the best choice for diagnosing a genetic disease.
- Explain how bioinformatics were applied in this case.

To conclude this Case Study, go to Connect.

Chapter Summary with Key Terms

10.1 Basic Elements and Applications of Genetic Engineering

Genetic engineering refers to the manipulation of an organism's genome and is often used in conjunction with biotechnology, the use of an organism's biochemical and metabolic pathways for industrial production of proteins.

A. Practical Properties of DNA

1. **Restriction endonucleases** are used to cut DNA at specific recognition sites, resulting in small segments of DNA that can be more easily managed in the laboratory.
2. The enzyme **ligase** is used to covalently join DNA molecules, whereas **reverse transcriptase** is used to obtain a DNA copy of a particular mRNA.
3. Short strands of DNA called oligonucleotides are used either as probes for specific DNA sequences or as primers for DNA polymerase.

B. Nucleic Acid Hybridization and Probes

1. The two strands of DNA can be separated (denatured) by heating. These single-stranded nucleic acids will bind, or **hybridize**, to their complementary sequence, allowing them to be used as **gene, hybridization, or probes**.
 - a. In the Southern blot method, DNA isolated from an organism is probed to identify specific DNA sequences.
 - b. **FISH** is a method of hybridizing and identifying intact DNA inside cells.

C. Methods Used to Size, Synthesize, and Sequence DNA

1. A technique called **DNA sequencing**, originally developed by Frederick Sanger, allows for the determination of the exact sequence of DNA.

- a. The ultimate map is a whole genome sequence map, which provides the exact order of all of the nucleotides that make up an entire genome of an organism. This can provide detailed information on the function of genes and can be useful in identification of genetic diseases. Sequencing is also a common method of choice to identify microbes.
2. The **polymerase chain reaction** is a technique used to amplify a specific segment of DNA several million times in just a few hours.
3. The Human Genome Project has completed a sequence map for humans, identifying the sequence of the approximately 21,000 genes found in our DNA.

10.2 Recombinant DNA Technology: How to Imitate Nature

A. Technical Aspects of Recombinant DNA Technology

1. **Recombinant DNA (rDNA)** methods have as their goal the transfer of DNA from one organism to another. This commonly involves inserting the DNA into a **vector** (usually a plasmid or virus) and transferring the recombinant vector to a **cloning host** (usually a bacterium or yeast) for expression.
 - a. Examples of cloning vectors include plasmids, bacteriophages, and cosmids, as well as the larger bacterial and yeast artificial chromosomes (BACs and YACs).
 - b. Cloning hosts are fast-growing, nonpathogenic organisms that are genetically well understood. Examples include *E. coli* and *Saccharomyces cerevisiae*.

2. **Recombinant organisms** are created by cutting both the donor DNA and the plasmid DNA with restriction endonucleases and then joining them together with ligase. The vector is then inserted into a cloning host by transformation, and those cells containing the vector are cultured and selected by their resistance to antibiotics.
3. When the appropriate recombinant cell has been identified, it is grown on an industrial scale. The cloning host expresses the gene it contains, and the resulting protein is excreted from the cell where it can be recovered from the media and purified.

B. Protein Products of Recombinant DNA Technology

1. In many instances, the final product of recombinant DNA technology is a protein.
2. Medical conditions such as diabetes, dwarfism, and blood-clotting disorders can be treated with recombinant insulin, human growth factor, and clotting factors produced by rDNA.

10.3 Genetically Modified Organisms and Other Applications

- A. Recombinant organisms, also known as **transgenics** and **genetically-modified organisms** (GMO) include microbes, plants, and animals that have been engineered to express genes inserted from another organism.
 1. Transformed bacteria produce a wide variety of drugs, vaccines, and other useful materials.
 2. Modified viruses function as genetic vectors and vaccines.
 3. Plants are **transfected** by a bacterium *Agrobacterium*, that can shuttle donor genes into cells.
 4. Animals are genetically engineered by having selected genes inserted into an embryo.

B. Medical Applications of DNA Technology

1. **Gene therapy** describes a collection of techniques in which defective genes are replaced or have their expression increased or decreased. Therapy is said to be *in vivo* if cells are altered within the body and *ex vivo* if the alteration is done on cells taken from the body.
2. Several proposed treatments involve gene silencing with regulatory RNA.

10.4 Genome Analysis: DNA Profiling and Genetic Testing

A. DNA Profiling

1. Because the DNA sequence of an organism is unique, it can be analyzed by identifying specific genetic markers or combinations of DNA sequences unique to each individual. These are known as **polymorphisms** (“many forms”) because they vary widely within a population.
2. Common polymorphisms include **short tandem repeats (STRs)**, which are repeats of the same nucleotide sequence, and **single nucleotide polymorphisms (SNPs)**, which are variations of a single nucleotide at a given locus on a chromosome.
3. Technologies exist for targeting these markers for use in forensic identification, disease diagnosis, anthropology, and identifying microorganisms.
4. **Mitochondrial DNA (MtDNA)** also has sequences unique to a given eukaryotic species. It is useful in tracing family history and ancient origins, and in identifying species of animals, plants, and fungi.

- B. **Microarray analysis** is a method of determining which genes are actively transcribed in a cell under a variety of conditions, such as health versus disease or growth versus differentiation.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

1. Which gene is incorporated into plasmids to detect recombinant cells?
 - a. restriction endonuclease
 - b. virus receptors
 - c. a gene for antibiotic resistance
 - d. reverse transcriptase
2. Which of the following is *not* essential to carry out the polymerase chain reaction?
 - a. primers
 - b. DNA polymerase
 - c. gel electrophoresis
 - d. high temperature
3. Which of the following is *not* a part of the Sanger method to sequence DNA?
 - a. dideoxynucleotides
 - b. DNA polymerase
 - c. electrophoresis
 - d. reverse transcriptase
4. The function of ligase is to
 - a. rejoin segments of DNA
 - b. make longitudinal cuts in DNA
 - c. synthesize cDNA
 - d. break down ligaments
5. The pathogen of plant roots that is used as a cloning host is
 - a. *Pseudomonas*
 - b. *Agrobacterium*
 - c. *Escherichia coli*
 - d. *Saccharomyces cerevisiae*
6. Which of the following sequences, when combined with its complement, would be clipped by a restriction endonuclease?
 - a. ATCGATCGTAGCTA
 - b. AAGCTTCGAA
 - c. GAATTC
 - d. ACCATTGGA
7. Which DNA fragment will be closest to the top (negative pole) of an electrophoretic gel?
 - a. 450 bp
 - b. 3,560 bp
 - c. 5 kb
 - d. 1,500 bp
8. Which of the following is or are required for cloning a gene?
 - a. restriction endonuclease
 - b. vector
 - c. cloning host
 - d. a and b
 - e. all of these

9. For which of the following would not require a nucleic acid probe?
- locating a gene on a chromosome
 - developing a Southern blot
 - identifying a microorganism with FISH
 - constructing a recombinant plasmid
10. **Multiple Matching.** Match the term with its description.
- | | |
|-----------------------------|---|
| _____ nucleic acid probe | _____ RNAi |
| _____ nontemplate strand | _____ primer |
| _____ template strand | _____ restriction endonuclease |
| _____ reverse transcriptase | a. enzyme that transcribes RNA into DNA |
| _____ Taq polymerase | b. complementary strand that blocks mRNA expression |
| | c. the nontranslated strand of DNA or RNA |
| | d. enzyme that snips DNA at palindromes |
| | e. oligonucleotide that initiates the PCR |
| | f. strand of nucleic acid that is transcribed or translated |
| | g. thermostable enzyme for synthesizing DNA |
| | h. oligonucleotide used in hybridization |

Case Study Review

- What type of mutation caused Nicholas's disease?
 - frameshift
 - missense
 - nonsense
 - insertion
- Which type of cells were used to extract the DNA that was sequenced?
 - red blood cells
 - intestinal epithelium
 - white blood cells
 - cheek swab
- Lay out the genetics of Nicholas's case, including where the mutation occurred, what exact nucleotide defect was present, why this was a serious type of defect, and why he was so affected by the mutation but his mother was not.

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

- Why do bacteria make restriction endonucleases?
- What is it about the endonucleases that prevents bacteria from destroying their own DNA? Using nucleotide letters, show the kind of cut that could be made on a DNA molecule to circularize it into a plasmid.
- Why would it be an advantage to synthesize eukaryotic genes by using reverse transcriptases to make cDNA?
- Explain what hybridization is and how it is used in the Southern blot.
 - Explain how gene probes and FISH techniques work.
- Look at figure 10.7, and determine the correct DNA sequence for the fragment's template strand. (Be careful of orientation.)
- Explain why the PCR is unlikely to amplify contaminating bacterial DNA in a sample of human DNA.
 - Explain how PCR could be used to pick a gene out of a complex genome and amplify it.
- The way PCR amplifies DNA is similar to the doubling in a population of growing bacteria—a single DNA strand is used to synthesize 2 DNA strands, which become 4, then 8, then 16, etc. If a complete cycle takes 3 minutes, how many strands of DNA would theoretically be present after 10 minutes? After 1 hour?
- Explain the kinds of study involved in genomics, proteomics, and bioinformatics.
- For what reasons would gene therapy be more effective performed on embryos rather than fully developed animals?
- Explain the basics of DNA STR profiling for identification of unknown DNA.

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps and a sample of a concept map for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

- Give an example of a benefit of genetic engineering to society and a possible adverse outcome. Discuss.
 - Give an example of an ecological benefit and a possible adverse side effect. Discuss.
- When gene probes, DNA profiling, and sequencing make it possible to detect genetic diseases in you or one of your children, would you want you or them to be tested?
 - How would you react to it being used as a screening method for employment or insurance?
 - Most of us would agree to growth hormone therapy for a child with dwarfism, but what would you think about parents who want to give growth hormones to their 8-year-old son so that he will be “better at sports”?
- Which suspect is the likely perpetrator according to the profile in figure 10.16? Explain your reasoning.
- Trace the genetic steps in the development of a peanut plant that is resistant to insect larvae (table 10.3). (Hint: You need to use *Agrobacterium*.)
- You are on a jury to decide whether a person committed a homicide, and you have to weigh evidence from DNA profiling. Two different sets of profiles were done: one that tested 5 markers, and one that tested 10. Both sets match the defendant’s profile. Which one is more reliable and why?
- Can you think of some reasons it would *not* be possible to re-create dinosaurs using the technology we have described in this chapter?
- What would be some major impediments to genetically modifying human embryos with CRISPR?
- Could actual fingerprints taken from human fingers be used to perform a DNA profile? Explain.
- Describe the main differences between genome sequencing and DNA profiling as a means of identifying a person or microbe.
- Itemize all of the ways that microbes have contributed to the development of genetic engineering and biotechnology.

Visual Challenge

- Below are two unrelated DNA paternity tests: one indicates the man is the father and the other shows he is not. Can you tell which is which? C/AF = Child/Alleged father in one lane combined.

Courtesy of Genelex Corporation

- Figure 9.25d**, shown here, shows the original transformation experiment as done by Griffith. Explain how this outcome would be accomplished with modern technology, using figure 10.11 as your guide.

Physical and Chemical Agents for Microbial Control

CASE STUDY Part 1 The Billion Dollar Medical Error

Late in 2007 a middle-aged man was hospitalized in Las Vegas with acute symptoms of **abdominal pain, nausea, and vomiting**. The attending physician also noticed that his eyes and skin were **jaundiced** (yellowed) and his urine was a dark color. Laboratory tests revealed an increased level of **liver enzymes** and **antibodies to hepatitis C virus (HCV)**, and a **nucleic acid test** confirmed that **RNA** from HCV was present in his blood. Upon questioning, the patient denied having any of the **risk factors** for this infection, such as **IV drug abuse** or **exposure to blood or blood products**. Further probing disclosed that he had recently undergone a dental procedure and two **endoscopic examinations** of his gastrointestinal tract. This case was immediately reported to the Nevada Office of Epidemiology.

Within a month, two other cases of **acute HCV** infection were diagnosed. These patients also claimed to lack the risk factors that caused this infection and they, too, had recently had endoscope procedures performed at the same clinic as the first patient. The seriousness of these findings made it necessary to request assistance from the **Centers for Disease Control and Prevention (CDC)**. The connection of the three patients to the same endoscopy center made this facility the prime focus of the investigation.

“An RN-anesthetist was observed drawing a second dose of the drug from a large, multidose vial using the same syringe that had been used to take the first dose, although he did replace the needle.”

The clinic had a large, thriving practice doing **colonoscopies** and other procedures on several thousand people each year. Because this raised the potential for other patients to have become infected with the virus, the CDC required that 63,000 persons who had a procedure in this clinic be immediately notified of their possible **exposure to the virus**.

It was essential to verify whether the three patients were infected by the same **genetic strain** of HCV. When it turned out that the viruses were genetically identical, authorities were certain that the infections originated from the same **source**. Knowing that the three patients had never had any kind of contact, **epidemiologists** concluded that the clinic had to be the origin of the infection. This finding alone did not provide any clues as to what went wrong, but it had tremendous repercussions on the clinic, its patients, and the medical and insurance companies involved.

- How are acute and chronic infections different, and why was it so important to differentiate them in this case?
- What sorts of procedures in a clinic might expose a person to bloodborne diseases?

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

SCOPING OUT THE CHAPTER

Though we may not be aware of it, most of us go through a daily routine of activities that prevent infection and reduce contamination of the substances and objects around us. Whether it is brushing teeth, washing hands, refrigerating food, or scrubbing out the sink, we count on these simple habits to make our lives more healthful. In the medical and industrial arena, it is even more critical to use proven techniques that will get rid of unwanted microbes in body tissues, products, food, and the environment. In this chapter we will examine the numerous ways we go about managing the microbes that are all around us and on us.

Basic Goals of Antimicrobial Control

Antimicrobial means “against microbes” and includes any method for keeping undesirable, harmful microbes out of the “wrong places”. Control agents are applied for sterilization, disinfection, or antisepsis.

Physical Methods: Heat that is

Wet or Dry Applying increased temperature or heat is the most common method of achieving microbial death. Heat can be applied in combination with water (moist heat), or water-free (dry heat).

Agents of Microbial Death: How

Do They Work? Both physical (energy-based) and chemical (molecule-based) agents are directed against microbial structures and functions and designed to block their reproduction and survival.

Physical Methods: Zapping with Radiation

High energy wavelengths such as gamma rays, X-rays, and even ultraviolet rays can sterilize and disinfect materials without using heat.

Chemical Methods: Molecules That Destroy Microbes.

A wide range of chemicals can kill or inhibit microbes on inanimate objects or the human body. Examples are disinfectants, antiseptics, sanitizers, or degermers.

Common Chemical Categories:

Antimicrobial chemicals come in the form of liquids, gases, or solids. Classes of chemical agents include chlorine, iodine, alcohol, phenolics, peroxides, aldehydes, gases, detergents, and soaps.

11.1 Controlling Microorganisms

Expected Learning Outcomes

1. Summarize the major categories of microbial control and its purposes.
2. Evaluate the relative resistance of different groups of infectious agents.
3. Define and differentiate among the major terms for microbial control, citing examples of each.
4. Characterize the parameters of microbial death, and describe several factors that influence the rate of death.
5. Summarize what factors influence the effectiveness of an antimicrobial agent.
6. Identify the targets of antimicrobial control agents, and explain what effects these agents have.

Much of the time in our daily existence, we take for granted tap water that is drinkable, food that is not spoiled, shelves full of products to eradicate “germs,” and drugs to treat infections. Controlling our degree of exposure to potentially harmful microbes is of monumental concern to our lives, and it has been a concern even before we were aware of the germ-disease connection.

Historians have discovered that during the great plague pandemic of the Middle Ages it was commonplace to bury corpses in mass graves, burn the clothing of plague victims, and ignite aromatic woods in the houses of the sick in the belief that fumes would combat the disease. In a desperate search for some sort of protection, survivors wore peculiar garments and anointed their bodies with herbs, strong perfume, and vinegar (**figure 11.1**). These attempts may sound foolish and antiquated, but it now appears that

Figure 11.1 Illustration of protective clothing used by doctors in the 1700s to avoid exposure to plague victims. The beaklike portion of the hood contained volatile perfumes to protect against foul odors and possibly inhaling “bad air.”

© Universal History Archive/UIG/Getty Images

they may have had some benefits. Burning wood releases formaldehyde, which could have acted as a disinfectant; herbs, perfume, and vinegar contain mild antimicrobial substances. Each of these early methods, although somewhat crude, laid the foundations for microbial control methods that are still in use today.

General Considerations in Microbial Control

The methods of microbial control belong to the general category of *decontamination* procedures, in that they destroy or remove contaminants. In microbiology, contaminants are microbes present at a given place and time that are undesirable or unwanted. Most decontamination methods employ either physical agents, such as heat or radiation, or chemical agents, such as disinfectants and antiseptics. This separation is convenient, even though the categories overlap in some cases; for instance, radiation can cause damaging chemicals to form, and chemicals can generate heat. A flowchart (**figure 11.2**) summarizes the major applications and aims in microbial control.

Relative Resistance of Microbial Forms

Processes for controlling microbes generally target microorganisms that are constantly present in the external environment and on the human body and that could cause infection or spoilage. This targeted population is rarely simple or uniform; in fact, it often contains mixtures of microbes with extreme differences in resistance and harmfulness. Contaminants that can have detrimental effects if not adequately controlled include bacterial vegetative cells and endospores, fungal hyphae and spores, yeasts, protozoan trophozoites and cysts, worms, viruses, and prions. This scheme compares the general resistance of these forms to physical and chemical methods of control:

Highest resistance

Prions: proteinaceous infectious particles (see “The Problem with Prions”); bacterial endospores, primarily from bacteria in the genera *Bacillus* and *Clostridium*.

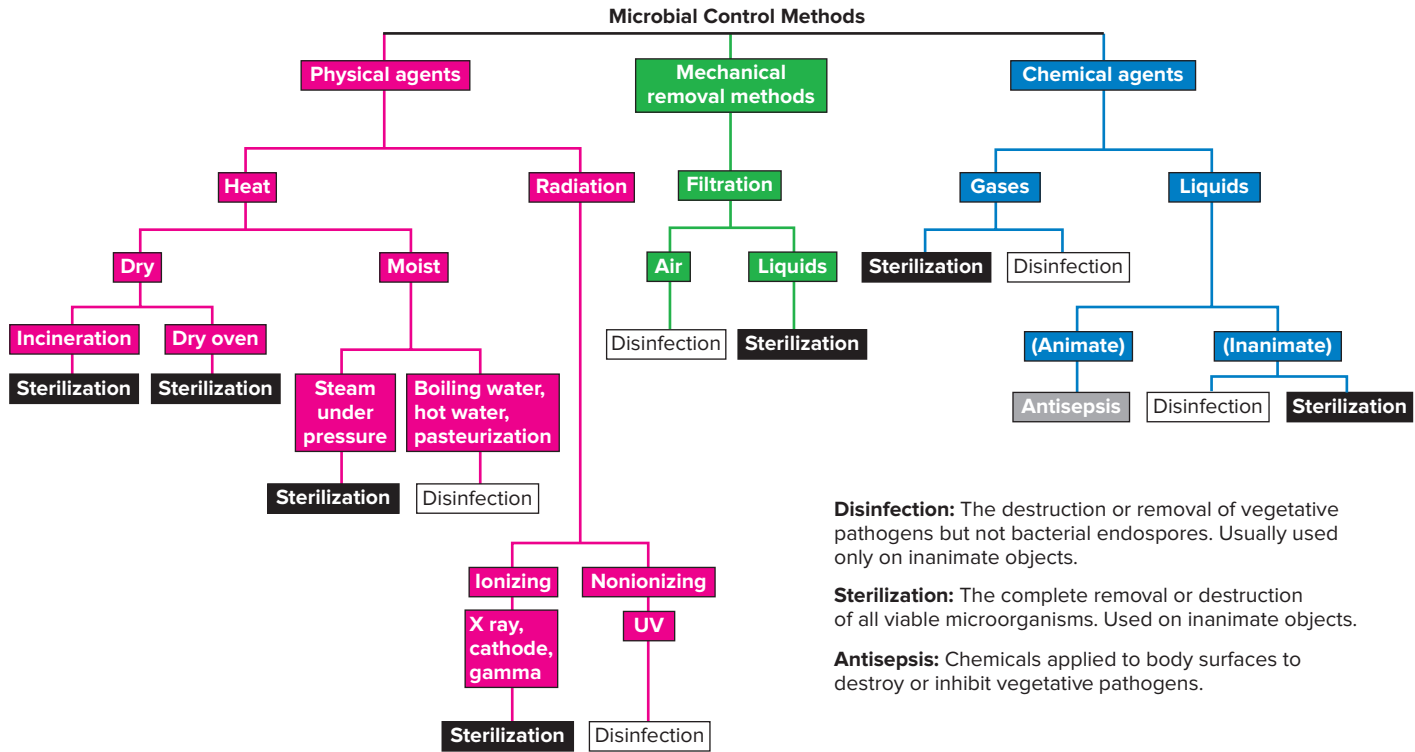

Moderate resistance

Protozoan cysts; some fungal sexual spores (zygospores); some viruses. In general, naked viruses are more resistant than enveloped forms.

Several groups of bacteria lack endospores but have vegetative cells with increased resistance to microbial control agents. These include *Mycobacterium*, whose cell walls have thick, waxy layers that can block the entrance of many disinfectants. The cell walls of *Pseudomonas*, *Acinetobacter*, and other gram-negative pathogens have an outer membrane that also prevents penetration of some chemical agents. *Staphylococcus* species are among the most heat- and chemical-resistant of all bacteria due to their thick, protective peptidoglycan cell walls.

Least resistance

Most bacterial vegetative cells; fungal spores (other than zygospores) and hyphae; enveloped viruses; yeasts; and protozoan trophozoites

Disinfection: The destruction or removal of vegetative pathogens but not bacterial endospores. Usually used only on inanimate objects.

Sterilization: The complete removal or destruction of all viable microorganisms. Used on inanimate objects.

Antisepsis: Chemicals applied to body surfaces to destroy or inhibit vegetative pathogens.

Figure 11.2 An overview of microbial control methods.

Actual comparative figures on the requirements for destroying various groups of microorganisms are shown in **table 11.1**. Bacterial endospores have traditionally been considered the most resistant microbial entities, being as much as 18 times harder to destroy than vegetative cells. Because endospores show such high resistance to microbial control and have widespread distribution, destroying them is the goal of **sterilization**. Any process that kills endospores will invariably kill all less-resistant microbial forms. Other methods of control (disinfection, antisepsis) target primarily microbes that are less hardy than endospores.

Endospore of *Bacillus* sp
 S.J. Jones, C.J. Paredes, B. Tracy, N. Cheng, R. Sillers, R.S. Senger, E.T. Papoutsakis, "The transcriptional program underlying the physiology of clostridial sporulation," *Genome Biol.*, 2008. 9:R114

The Problem with Prions

The role of prions as infectious protein particles in certain progressive brain diseases (such as Creutzfeldt-Jakob disease) was first introduced in chapter 6. Not only are prions highly unusual in their actions, but they are also in a class of their own when it comes to "sterilization" procedures. This chapter defines *sterile* as the absence of all viable microbial life. But prions are not microbes or living, and most of the procedures described here are not sufficient to destroy them. Prion proteins are extraordinarily resistant to heat, chemicals, and radiation. Instruments or other objects contaminated with these unique agents must be incinerated, at very

high temperatures, or decontaminated with a combination of chemicals. The substances that have proved most effective are sodium hydroxide and hypochlorite (bleach) solutions that render them noninfectious after a significant period of exposure. When tissues, fluids, or instruments are suspected of containing prions, consultation with the CDC is recommended to ensure effective sterilization conditions. In terms of routine sterilization procedures, this chapter will treat bacterial endospores as the most resistant form of microbial life targeted by antimicrobial agents. Prions are not environmentally widespread in the way that bacterial endospores and other microbes are.

TABLE 11.1 Relative Resistance of Bacterial Endospores and Vegetative Cells to Control Agents			
Method	Endospores*	Vegetative Forms*	Relative Resistance**
Heat (moist)	120°C	80°C	1.5×
Radiation (X-ray) dosage	4,000 grays	1,000 grays	4×
Sterilizing gas (ethylene oxide)	1,200 mg/1	700 mg/1	1.7×
Sporicidal liquid (2% glutaraldehyde)	3 hours	10 min	18×

*Values are based on methods (concentration, exposure time, intensity) that are required to destroy the most resistant pathogens in each group.
 **This number is a comparison of the conditions required to kill endospores versus vegetative cells and is an average of the most resistant pathogens in each group.

Terminology and Methods of Microbial Control

Through the years, a growing terminology has emerged for describing and defining measures that control microbes. To complicate matters, the everyday use of some of these terms can at times be vague or inexact. For example, occasionally one may be directed to “sterilize” or “disinfect” a patient’s skin, even though this usage does not fit the technical definition of either term. To lay the groundwork for the coverage to follow, we present here a series of concepts, definitions, and usages in antimicrobial control.

Sterilization

Sterilization is a process that destroys or removes all viable microorganisms, including viruses. Any material that has been subjected to this process is said to be **sterile**. These terms should be used only in the strictest sense for methods that have been proved to sterilize. An object cannot be slightly sterile or almost sterile—it is either sterile or not sterile. Control methods that sterilize are generally reserved for inanimate objects, because sterilizing tissues within a living body would call for such harsh treatment that it would be highly dangerous and impractical. As we shall see in chapter 13, many parts of the body—the brain and most internal organs, for example—are naturally free of microbes.

Sterilized products—surgical instruments, syringes, and commercially packaged foods, just to name a few—are essential to human well-being. Although most sterilization is performed with a physical agent such as heat, a few chemicals called *sterilants* can be classified as sterilizing agents because of their ability to destroy spores.

At times, sterilization is neither practicable nor necessary, and only certain groups of microbes are of concern. Some antimicrobial agents eliminate only the susceptible vegetative states of microorganisms but do not destroy the more resistant endospore and cyst stages. Keep in mind that the destruction of spores is not always a necessity, because most of the infectious diseases of humans and animals are caused by non-spore-forming microbes.

Microbicidal Agents

The root *-cide*, meaning to kill, can be combined with other terms to define an antimicrobial agent aimed at destroying a certain group of microorganisms. For example, a **bactericide** is a chemical that destroys bacteria except for those in the endospore stage. It may or may not be effective on other microbial groups. A **fungicide** is a chemical that can kill fungal spores, hyphae, and yeasts. A **virucide** is any chemical known to inactivate viruses, especially on living tissue. A **sporocidal** agent can destroy bacterial endospores, which makes it also a sterilizing agent.

Agents That Cause Microbistasis

The words *stasis* and *static* mean to stand still. They can be used in combination with various prefixes to denote a condition termed

microbistasis in which microbes are temporarily prevented from multiplying but are not killed outright. Although killing or permanently inactivating microorganisms is the usual goal of microbial control, microbistasis can have meaningful applications. **Bacteriostatic** agents prevent the growth of bacteria on tissues or on objects in the environment, and *fungistatic* chemicals inhibit fungal growth. Materials used to control microorganisms in the body (antiseptics and drugs) often have microbistatic effects because many microbicidal compounds are highly toxic to human cells.

Germicides, Disinfection, Antisepsis

A **germicide**,* also called a *microbicide*, is any chemical agent that kills pathogenic microorganisms. A germicide can be used on inanimate (nonliving) materials or on living tissue, but it ordinarily cannot kill resistant microbial cells. Any physical or chemical agent that kills “germs” is said to have germicidal properties.

The related term **disinfection*** refers to the use of a physical process or a chemical agent—a **disinfectant**—to destroy vegetative pathogens but not bacterial endospores. It is important to note that disinfectants are normally used only on inanimate objects because, at the concentrations required to be effective, they can be toxic to living tissue. Disinfection processes can also remove the harmful products of microorganisms (toxins) from materials. Examples of disinfection include applying a diluted solution of bleach to an examination table, exposing drinking water to UV radiation, and pasteurizing milk with heat.

In modern usage, **sepsis** is defined as the growth of microorganisms in the blood and other tissues. The term **asepsis*** refers to any practice that blocks the entry of infectious agents into sterile tissues and thus prevents infection. Aseptic techniques commonly practiced in health care range from sterile methods that exclude all microbes to **antisepsis**.* With antisepsis, chemical agents called **antiseptics** are applied directly to exposed body surfaces (skin and mucous membranes), wounds, and surgical incisions to destroy or inhibit vegetative pathogens. Examples of antisepsis include preparing the skin before surgical incisions with iodine compounds, swabbing a wound with hydrogen peroxide, and ordinary hand washing with a germicidal soap.

Methods That Reduce the Numbers of Microorganisms

Although medical applications quite often require sterility, especially with regard to invasive instruments such as scalpels, clamps, dental hand tools, and the like, in other situations this high level of microbial control is often unwarranted and perhaps even unwanted. In many cases it is more important to focus on reducing the size of a microbial population, or its *microbial load*. **Sanitization*** refers to any cleansing technique that removes debris, soil, microorganisms, and toxins, and in this way reduces the potential for infection and spoilage. Soaps and detergents are the most commonly

* **germicide** (jer'-mih-syd) L. *germen*, germ, and *caedere*, to kill. *Germ* is a common term for a pathogenic microbe.

* **disinfection** (dis'-in-fek'-shun) L. *dis*, apart, and *inficere*, to corrupt.

* **asepsis** (ay-sep'-sis) Gr. *a*, no or none, and *sepsis*, decay.

* **antiseptics** *anti*, against.

* **sanitization** (san''ih-tih-zay'-shun) L. *sanitas*, health.

TABLE 11.2 Microbial Control Terminology

Term	Definition	Example
Decontamination	The destruction, removal, or reduction in number of undesirable microbes	Asepsis, disinfection, sanitization, degermation, sterilization
Sepsis	The growth of microorganisms in the tissues	The presence of infected wounds, blood infection
Asepsis	Techniques that prevent the entry of microorganisms into sterile tissues	Cleansing the skin with iodine prior to surgery, using sterile needles
Antiseptic	Chemicals applied to body surfaces to destroy or inhibit vegetative pathogens	Iodophors, antibacterial soap, chlorhexidine
Disinfection	Destruction of vegetative pathogens on inanimate objects	5% bleach, boiling water
Sanitization	Cleansing technique that removes microorganisms and debris from inanimate surfaces	Dishwashing, laundering clothes
Degermation	Cleansing technique that removes microorganisms and debris from living tissue	Surgical handscrub, alcohol wipes
Sterilization	The removal or destruction of all viable microbes	Autoclaving, ionizing radiation (correctly applied)

employed sanitizers. From a practical standpoint, sanitization can have an advantage over sterilization. For example, in a restaurant you could be given a sterile fork with someone else's old food on it and a sterile glass with lipstick on the rim. Given that sanitization is in general far less expensive than sterilization, its cleansing effect has obvious advantages.

With living tissues the reduction in microbial load through mechanical means is referred to as **degermation**. This process usually involves scrubbing the skin or immersing it in chemicals, or both. Microorganisms are removed both mechanically and indirectly by emulsifying the oils that coat the skin and provide a habitat for their growth. Examples of degerming procedures include the surgical handscrub, the application of alcohol wipes, and the cleansing of a wound with germicidal soap and water. **Table 11.2** summarizes several of the important terms involved in microbial control.

What Is Microbial Death?

Death is a phenomenon that involves the permanent termination of an organism's vital processes. Signs of life in complex organisms such as animals are self-evident, and death is made clear by loss of nervous function, respiration, or heartbeat. In contrast, death in microscopic organisms that are composed of just one or a few cells is hard to detect, because such organisms often reveal no conspicuous vital signs to begin with. Lethal agents (such as radiation and chemicals) do not necessarily alter the overt appearance of microbial cells. Even the loss of movement in a motile microbe cannot be used to indicate death. This situation has made it necessary to develop special qualifications that define and delineate microbial death and answer the questions: How do antimicrobial agents cause death? and Why do they vary in their effects?

The destructive effects of chemical or physical agents occur at the cellular and molecular level. As a cell is exposed to an agent such as intense heat or toxic chemicals, various cell structures break down, and the entire cell can sustain irreversible damage. At present, the most practical way to detect this damage is to determine if a microbial cell can still reproduce when exposed to a suitable environment. If the microbe has sustained metabolic or structural

damage to such an extent that it can no longer reproduce, even in an ideal environment, then it is considered nonviable. **In most circumstances of testing, the permanent loss of reproductive capacity, even under optimal growth conditions, has become the working definition of microbial death.**¹

Factors That Affect Death Rate

The ability to define microbial death has tremendous theoretical and practical importance. It allows medicine and industry to test the conditions required to destroy microorganisms, to pinpoint the ways antimicrobial agents kill cells, and to establish standards of sterilization and disinfection in these fields. Hundreds of testing procedures have been developed for evaluating physical and chemical agents. Some examples can be found in Appendix B.

The cells of a culture show marked variation in susceptibility to a given microbicidal agent. Death of the whole population is not instantaneous but begins when a certain threshold of the microbicidal agent (some combination of time and concentration) is met. Death continues in a logarithmic manner as the time of exposure is increased (**figure 11.3**). Because many microbicidal agents target the cell's metabolic processes, active cells (younger, rapidly dividing) tend to die more quickly than those that are less metabolically active (older, dormant). Eventually a point is reached at which survival of any cells is highly unlikely; this point is equivalent to sterilization.

The effectiveness of a particular agent is governed by several factors besides time. These additional factors influence the action of antimicrobial agents:

1. The number of microorganisms (**figure 11.3b**). A higher load of contaminants requires more time to destroy.
2. The nature of the microorganisms in the population (**figure 11.3c**). In most actual circumstances of disinfection and sterilization, the target population is not a single species of

1. One drawback to using this definition of microbial death is that some microbes may have entered a viable but nonculturable state, making it difficult to know if the antimicrobial agent is microbicidal or microbistatic.

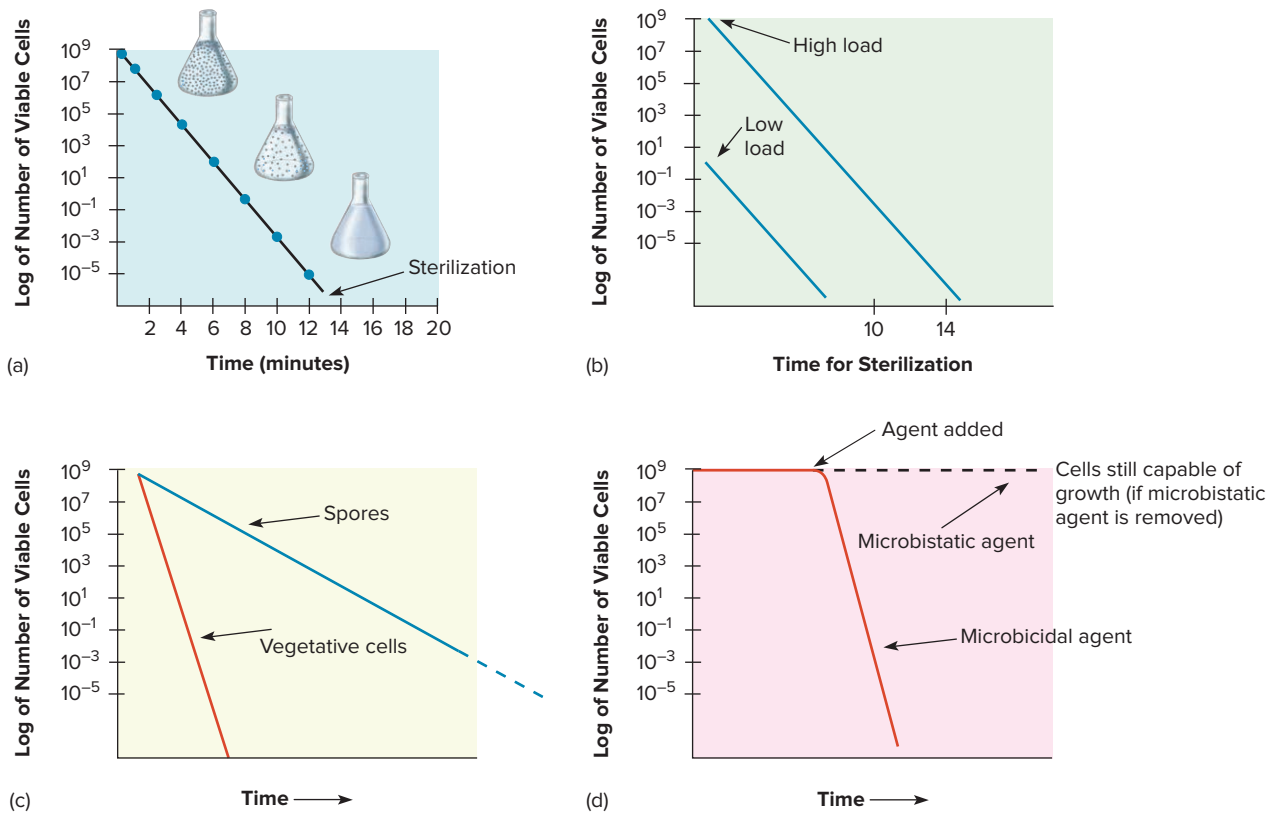

Figure 11.3 Factors that influence the rate at which microbes are killed by antimicrobial agents. (a) Length of exposure to the agent. During exposure to a chemical or physical agent, all cells of a microbial population, even a pure culture, do not die simultaneously. Over time, the number of viable organisms remaining in the population decreases logarithmically, giving a straight-line relationship on a graph. The point at which the number of survivors is infinitesimally small is considered sterilization. (b) Effect of the microbial load. (c) Relative resistance of spores versus vegetative forms. (d) Action of the agent, whether microbicidal or microbistatic.

microbe but a mixture of bacteria, fungi, spores, and viruses, presenting a broad spectrum of microbial resistance.

3. The temperature and pH of the environment.
4. The concentration (dosage, intensity) of the agent. For example, UV radiation is most effective at 260 nm and most disinfectants are more active at higher concentrations.
5. The mode of action of the agent (**figure 11.3d**). How does it kill or inhibit microorganisms?
6. The presence of solvents, interfering organic matter, and inhibitors. Saliva, blood, and feces can inhibit the actions of disinfectants and even of heat.

Some Practical Concerns in Selecting Antimicrobial Agents

A remarkable variety of substances and objects require sterilization, disinfection, and other forms of decontamination. They range from durable materials made of glass and rubber to highly sensitive liquids such as blood plasma and even human tissues such as bone. Sometimes entire rooms with their contents and large pieces of equipment such as space vehicles and satellites may need to be sterilized. In accordance with an international agreement, all spacecraft landing on extraterrestrial bodies must have a highly reduced microbe load. This policy is to prevent the introduction of earth microbes that could potentially alter those environments or interfere with experiments being conducted by NASA. Parts of the probes are sterilized with heat, radiation, and certain chemicals (peroxide), and

then maintained in very controlled clean rooms that require extreme precautions against contamination by workers (**figure 11.4**).

There are literally hundreds of situations in health care settings alone where prevention of infection must be taken into consideration

Figure 11.4 NASA employees work in an ultraclean room at the Jet Propulsion Lab (JPL) in Pasadena, California. Though not sterile, the levels of microbes in the air and on surfaces are kept to a minimum. Take a tour through a JPL cleanroom at <https://www.google.com/search?q=%E2%80%9CTour+the+JPL+Clean+Room%E2%80%9D+on+Ustream&ie=utf-8&oe=utf-8>. Source: NASA/JPL-Caltech

at all times. The CDC provides guidelines for recommended sterilization and disinfection procedures. The case study for this chapter provides a good example of some of the difficulties in ensuring that proper techniques are followed in every situation.

When choosing a procedure, one of the first questions to arise is, What will render materials free of potential pathogens? Consider, for instance, reusable dental instruments that are highly contaminated with saliva, blood, and other fluids and tissues. These are all potential sources of infection, so it is critical that they be sterilized between patients with a method that will kill endospores.

The next concern is selecting the best method of sterilization. Because they are mostly made of metal, dental instruments can be sterilized with heat, although some forms of radiation and chemical treatments could also work. Clinics generally opt for a method such as steam sterilization that is simplest, fastest, and least expensive. This would not work on other types of delicate instruments such as endoscopes, which must be sterilized between patients using heat-free techniques.

On the other hand, certain single-use medical supplies used in hospitals and clinics, such as plastic syringes and catheters, come already sterilized and packaged at the factory. Because they are usually made of heat-sensitive plastics, this is done with penetrating radiation or chemicals. These items are not meant to be reused, but they still must be decontaminated before being discarded to prevent the transmission of disease. Disposal of such medical wastes is regulated by various governmental agencies.

How Antimicrobial Agents Work: Their Modes of Action

An antimicrobial agent's adverse effect on cells is known as its **mode** (or **mechanism**) of **action**. Agents affect one or more cellular targets, inflicting damage progressively until the cell is no longer viable. Antimicrobials have a range of cellular targets, with the agents that are least selective in their targeting tending to be effective against the widest range of microbes (examples include heat and radiation). More selective agents (drugs, for example) tend to target only a single cellular component and are much more restricted in their effect on microbes.

The cellular targets of physical and chemical agents fall into four general categories: (1) cell walls, (2) cell membranes, (3) protein and nucleic acid synthesis, and (4) protein structure and function.

The Effects of Agents on the Cell Wall

The cell wall maintains the structural integrity of bacterial and fungal cells. Several types of chemical agents damage the cell wall by blocking its synthesis, digesting it, or breaking down its surface. A cell deprived of a functioning cell wall becomes fragile and is lysed very easily. Examples of this mode of action include some antimicrobial drugs (penicillins) that interfere with the synthesis of the cell wall in bacteria (described in chapter 12). Detergents and alcohol can also disrupt cell walls, especially in gram-negative bacteria.

How Agents Affect the Cell Membrane

All microorganisms have a cell membrane composed of lipids and proteins, and even some viruses have an outer membranous

Figure 11.5 Mode of action of surfactants on the cell membrane. Surfactants inserting in the lipid bilayer disrupt it and create abnormal channels that alter permeability and cause leakage both into and out of the cell.

envelope. As we learned in previous chapters, a cell's membrane provides a two-way system of transport. If this membrane is disrupted, a cell loses its selective permeability and can neither prevent the loss of vital molecules nor bar the entry of damaging chemicals. Loss of those functions usually leads to cell death. Chemicals called **surfactants*** work as microbicidal agents because they lower the surface tension of cell membranes. Surfactants are polar molecules such as detergents with hydrophilic and hydrophobic regions that can physically bind to the lipid layer and penetrate the internal hydrophobic regions of membranes. In effect, this process "opens up" the once tight interface, leaving leaky spots that allow harmful chemicals to seep into the cell and important ions to seep out (**figure 11.5**). Alcohols exert a related effect by dissolving membrane lipids and stripping membranes away from cells.

Agents That Affect Protein and Nucleic Acid Synthesis

Microbial life depends upon an orderly and continuous supply of proteins to function as enzymes and structural molecules. As we saw in chapter 9, these proteins are synthesized on the ribosomes during translation. Any chemical that blocks this process can affect function and survival. For example, certain drugs bind to the ribosomes of bacteria in a way that stops peptide bonds from forming. In the presence of such a chemical, many bacterial cells are inhibited from forming proteins required in growth and metabolism and are thus inhibited from multiplying. Many of the drugs used to treat infections are chemicals that block protein synthesis in microbes without adversely affecting human cells. This subject is discussed in greater detail in chapter 12.

The nucleic acids are likewise necessary for the continued functioning of microbes. DNA must be regularly replicated and transcribed in growing cells, and any agent that either impedes

* *surfactant* (sir-fak'-tunt) A word derived from **surface-acting agent**.

these processes or changes the genetic code is potentially antimicrobial. Some agents bind irreversibly to DNA, preventing both transcription and translation, whereas others are mutagenic agents. Gamma, ultraviolet, or X radiation causes mutations that result in permanent inactivation of DNA. Chemicals such as formaldehyde and ethylene oxide also interfere with DNA and RNA function.

Agents That Alter Protein Function

A microbial cell contains large quantities of proteins that function properly only if they remain in a normal three-dimensional configuration called the *native state*. The antimicrobial properties of some agents arise from their capacity to disrupt the structure of, or **denature**, proteins. In general, **denaturation** occurs when the bonds that maintain the secondary and tertiary structure of the protein are broken. Breaking these bonds will cause the protein to unfold or create random, irregular loops and coils (**figure 11.6**). One way to denature proteins is through coagulation by moist heat (think of the irreversible solidification of egg white when cooked). Chemicals such as strong organic solvents (alcohols, acids) also coagulate proteins. A few antimicrobial agents, such as metallic ions, attach to the active site of the protein and prevent it from interacting with its correct substrate. Regardless of the exact mechanism, such losses in normal protein function can promptly arrest metabolism and exert broad effects on all types of microbes.

Figure 11.6 Modes of action affecting protein function.

(a) The native (functional) state is maintained by bonds that create active sites to fit the substrate. Some agents denature the protein by breaking all or some secondary and tertiary bonds. Results are (b) complete unfolding or (c) random bonding and incorrect folding. (d) Some agents react with functional groups on the active site and interfere with bonding.

Check Your Progress SECTION 11.1

1. Explain the purposes of microbial control and differentiate between physical, mechanical, and chemical methods.
2. Compare sterilization with disinfection and sanitization. Describe the relationship of the concepts of sepsis, asepsis, and antisepsis.
3. Contrast various microbes and rate their variations in resistance to control agents.
4. Explain how the types and numbers of microorganisms can influence the effectiveness of control agents.
5. How is microbial death defined?
6. Explain why a population of microbes does not die instantaneously when exposed to an antimicrobial agent.
7. Distinguish between microbicidal and microbistatic effects on microbes, and tell why it is important to understand the difference.
8. Describe four modes of action of antimicrobial agents, and provide examples of how they work.

11.2 Physical Methods of Control: Heat

Expected Learning Outcomes

7. List the major types of physical agents used in controlling microbes.
8. Describe the basic effects of temperature on microbes.
9. Define *moist* and *dry* heat, and explain their modes of action and relative effectiveness.
10. Differentiate between thermal death point and thermal death time, and provide examples of their uses.
11. Describe several moist heat methods and their chief applications for sterilization and disinfection.
12. Describe some methods using dry heat and its chief applications.
13. Explain how cold temperatures and desiccation are used in microbial control.

Microorganisms have adapted to a tremendous diversity of habitats on earth, some having severe conditions of temperature, moisture, pressure, and light. For microbes that normally withstand such extreme physical conditions, our usual attempts at control would probably have little effect. Fortunately for us, we are most interested in controlling microbes that flourish in the same environment in which humans live. The vast majority of these microbes are readily controlled by abrupt changes in their environment. Most prominent among antimicrobial physical agents is heat. Other less widely used agents include radiation and filtration. The following sections examine these and other methods, and explore their practical applications in medicine, commerce, and the home.

Effects of Temperature on Microbial Activities

A sudden departure from a microbe's temperature of adaptation is likely to have a detrimental effect on it. As a rule, temperatures that exceed the maximum growth temperature are microbicidal, whereas

temperatures below the minimum growth temperature are microbistatic. This essentially means that, for most microbes, the effects of temperatures below minimum can be reversible, whereas the effects of temperatures above maximum are not reversible and most microbes will be destroyed by them.

The two physical states of heat used in microbial control are moist and dry. **Moist heat** occurs in the form of hot water, boiling water, or steam (vaporized water). In practice, the temperature of moist heat usually ranges from 60°C to 135°C. As we shall see, the temperature of steam can be regulated by adjusting its pressure in a closed container. The expression **dry heat** denotes air with a low moisture content that has been heated by a flame or electric heating coil. In practice, the temperature of dry heat ranges from 160°C to several thousand degrees Celsius.

Mode of Action and Relative Effectiveness of Heat

Moist heat and dry heat differ in their modes of action as well as in their efficiency. Moist heat operates at lower temperatures and shorter exposure times to achieve the same effectiveness as dry heat (**table 11.3**). Although many cellular structures are damaged by moist heat, its most microbicidal effects are the coagulation and denaturation of proteins, which quickly and permanently halt cellular metabolism.

Dry heat with a moderate temperature dehydrates the cell, removing the water necessary for metabolic reactions, and it alters protein structure. However, the lack of water actually increases the stability of some protein conformations, necessitating the use of higher temperatures when dry heat is employed as a method of microbial control. At very high temperatures, dry heat oxidizes cells, burning them to ashes. This method is the one used in the laboratory when a loop is flamed or in industry when medical waste is incinerated.

Heat Resistance and Thermal Death of Spores and Vegetative Cells

Bacterial endospores exhibit the greatest resistance, and vegetative states of bacteria and fungi are the least resistant to both moist and dry heat. Destruction of spores usually requires temperatures above

boiling, although resistance varies widely. The following table compares some times and temperatures required to kill sporeformers using moist versus dry heat:

Moist Heat	Temp/Time	Dry Heat	Temp/Time
<i>Bacillus subtilis</i>	121°C/1 min	<i>Bacillus subtilis</i>	121°C/120 min
<i>B. stearothermophilis</i>	121°C/12 min	<i>B. stearothermophilis</i>	140°C/5 min
<i>Clostridium botulinum</i>	120°C/10 min	<i>Clostridium botulinum</i>	120°C/120 min
<i>C. tetani</i>	105°C/10 min	<i>C. tetani</i>	100°C/60 min

In general, reliable killing of the most heat-resistant species of sporeformers requires 121°C for 20 minutes in moist heat.

Vegetative cells also vary in their sensitivity to heat, though not to the same extent as spores. Among bacteria, the death conditions for moist heat range from 50°C for 3 minutes (*Neisseria gonorrhoeae*) to 60°C for 60 minutes (*Staphylococcus aureus*). It is worth noting that vegetative cells of sporeformers are just as susceptible as vegetative cells of non-sporeformers and that pathogens are neither more nor less susceptible than nonpathogens. Other microbes, including fungi, protozoa, and worms, are rather similar in their sensitivity to heat. Viruses can be surprisingly resistant to heat, with a tolerance range extending from 55°C for 2 to 5 minutes (adenoviruses) to 60°C for 600 minutes (hepatitis A virus). For practical purposes, all non-heat-resistant forms of bacteria, yeasts, molds, protozoa, worms, and viruses are destroyed by exposure to 80°C for 20 minutes.

Practical Concerns in the Use of Heat: Thermal Death Measurements

Adequate sterilization requires that both temperature and length of exposure be considered. As a general rule, higher temperatures allow shorter exposure times, and lower temperatures require longer exposure times. A combination of these two variables constitutes the **thermal death time**, or **TDT**, defined as the shortest length of time required to kill all test microbes at a specified temperature. The TDT has been experimentally determined for the microbial species that are common or important contaminants in various heat-treated materials. Another way to compare the susceptibility of microbes to heat is the **thermal death point (TDP)**, defined as the lowest temperature required to kill all microbes in a sample in 10 minutes.

Many perishable substances are processed with moist heat. Some of these products are intended to remain on the shelf at room temperature for several months or even years. The chosen heat treatment must render the product free of agents of spoilage or disease. At the same time, the quality of the product and the speed and cost of processing must be considered. For example, in the commercial preparation of canned green beans, one of the cannery's greatest concerns is to prevent growth of the agent of botulism. From several possible TDTs (that is, combinations of time and temperature) for *Clostridium botulinum* spores, the cannery must choose one that kills all spores but does not turn the beans to mush. These many considerations produce an optimal TDT for a given processing method. Commercial canneries heat low-acid foods like green beans at 121°C for 30 minutes, a treatment that renders the

TABLE 11.3 Comparison of Times and Temperatures to Achieve Sterilization with Moist and Dry Heat

	Temperature	Time to Sterilize
Moist Heat	121°C	15 min
	125°C	10 min
	134°C	3 min
Dry Heat	121°C	600 min
	140°C	180 min
	160°C	120 min
	170°C	60 min

foods sterile. Because of such strict controls in canneries, cases of botulism from commercially canned foods are rare.

Common Methods of Moist Heat Control

The four ways moist heat is employed to control microbes are (1) steam under pressure, (2) nonpressurized steam, (3) boiling water, and (4) pasteurization.

Sterilization with Steam Under Pressure At sea level, normal atmospheric pressure is 15 pounds per square inch (psi), or 1 atmosphere. At this pressure, water will boil (change from a liquid to a gas) at 100°C, and the resultant steam will not go above 100°C, regardless of the method of heating. But boiling temperature is not hot enough to reliably kill all targeted microbes. The only way to raise the temperature of steam is to expose it to increased pressure. At higher pressures the temperature at which water boils and the temperature of steam both rise. For example, at a pressure of 20 psi (5 psi above normal), the temperature of steam is 109°C. As the temperature is increased to 10 psi above normal, the steam's temperature rises to 115°C, and at 15 psi above normal (a total of 2 atmospheres), it will be 121°C. It is not the pressure by itself that is killing microbes but the increased temperature it produces.

Such pressure-temperature combinations can be achieved only with a special device that can subject pure steam to pressures greater than 1 atmosphere. Health and commercial industries use an **autoclave** for this purpose, and a comparable home appliance is the pressure cooker. Autoclaves have a fundamentally similar plan: an enclosed metal chamber with an airtight door on one end and racks to hold materials (**figure 11.7**). Its construction includes a network of valves, pressure and temperature gauges, and ducts for regulating and measuring pressure and conducting the steam into the chamber. Sterilization is achieved when the steam condenses against the objects in the chamber and gradually raises their temperature.

Experience has shown that the most efficient pressure-temperature combination for achieving sterilization is 15 psi, which yields 121°C. It is possible to use higher pressure to reach higher temperatures (for instance, increasing the pressure to 30 psi raises the temperature to 132°C), but doing so will not significantly reduce the exposure time and can harm the items being sterilized.

The duration of the process is adjusted according to the bulkiness of the items in the load (thick bundles of material or large flasks of liquid) and how full the chamber is. The range of holding times varies from 10 minutes for light loads to 40 minutes for heavy or bulky ones; the average time is 20 minutes.

Nonpressurized Steam Selected substances that cannot withstand the high temperature of the autoclave can be subjected to **intermittent sterilization**, also called **tyndallization**.² This technique requires a chamber to hold the materials and a reservoir for boiling water. Items in the chamber are exposed to free-flowing steam for

30 to 60 minutes. This temperature is not sufficient to reliably kill spores, so a single exposure will not suffice. On the assumption that surviving spores will germinate into less resistant vegetative cells, the items are incubated at appropriate temperatures for 23 to

(a)

(b)

2. Named for the British physicist John Tyndall, who did early experiments with sterilizing procedures.

24 hours, and then again subjected to steam treatment. This cycle is repeated for 3 days in a row. Because the temperature never gets above 100°C, highly resistant spores that do not germinate could survive even after 3 days of this treatment.

Boiling Water: Disinfection A simple boiling water bath or chamber can quickly decontaminate items in the clinic and home. Because a single processing at 100°C will not kill all resistant cells, this method can be relied on only for disinfection and not for sterilization. Exposing materials to boiling water for 30 minutes will kill most non-spore-forming pathogens, including resistant species such as the tubercle bacillus and staphylococci. Probably the greatest disadvantage with this method is that the items can be easily recontaminated when removed from the water.

Pasteurization: Disinfection of Beverages Fresh beverages such as milk, fruit juices, beer, and wine are easily contaminated during collection and processing. Because microbes have the potential to spoil these foods or cause illness, heat is frequently used to reduce the microbial load and destroy pathogens. **Pasteurization** is a technique of applying heat to consumable liquids to kill potential agents of infection and spoilage, while at the same time retaining the liquid's flavor and food value.

A widely used pasteurization technique is the **flash method**, that exposes the liquid to heat exchangers at 71.6°C for 15 seconds. This first method does not appreciably change flavor and nutrient content, and it is effective against certain resistant pathogens such as *Coxiella* and *Mycobacterium*. Although these treatments inactivate most viruses and destroy the vegetative stages of 97% to 99% of bacteria and fungi, they do not kill endospores or **thermoduric** microbes (mostly nonpathogenic lactobacilli, micrococci, and yeasts). Flash-pasteurized milk is not sterile after regular pasteurization. In fact, it can contain 20,000 microbes per milliliter or more, which explains why even an unopened carton of milk will eventually spoil. Many commercial dairies now produce *sterile milk* with an increased storage life of several months. This ultrapasteurized milk is processed using ultrahigh temperature (UHT) —134°C for 2 to 5 seconds.

One important aim in pasteurization is to prevent the transmission of milk-borne diseases from infected cows or milk handlers. The primary targets of pasteurization are non-spore-forming pathogens: *Salmonella* species (a common cause of food infection), *Campylobacter jejuni* (acute intestinal infection), *Listeria monocytogenes* (listeriosis), *Brucella* species (undulant fever), *Coxiella burnetii* (Q fever), *Mycobacterium bovis*, *M. tuberculosis*, and several enteric viruses.

Dry Heat: Hot Air and Incineration

Dry heat is not as versatile or as widely used as moist heat, but it has several important sterilization applications. The temperatures and times employed in dry heat vary according to the particular method, but in general they are greater than with moist heat. **Incineration** in a flame or electric heating coil is perhaps the most rigorous of all heat treatments. The flame of a Bunsen burner reaches 1,870°C at its hottest point, and furnaces/incinerators operate at temperatures of 800°C to 6,500°C. Direct exposure to

such intense heat ignites and reduces microbes and other substances to ashes and gas.

Incineration of microbial samples on inoculating loops and needles using a Bunsen burner is a very common practice in the microbiology laboratory. This method is fast and effective, but it is also limited to metals and heat-resistant glass materials. Tabletop infrared incinerators (see table 11.4), an alternative to Bunsen burners, are safer and prevent splatter of the inoculum.

The hot-air oven provides another means of dry-heat sterilization. The so-called *dry oven* is usually electric (occasionally gas) and has coils that radiate heat within an enclosed compartment. Heated, circulated air transfers its heat to the materials in the oven. Depending on the type of oven and the material being decontaminated, a cycle takes 12 minutes to 4 hours to complete and involves temperatures of 150°C to 180°C.

Table 11.4 presents an illustrated summary of heating methods for microbial control.

The Effects of Cold and Desiccation

The principal benefit of cold treatment is to slow the growth of cultures and microbes in food and other perishable materials during processing and storage. *It must be emphasized that cold merely retards the activities of most microbes.* Although it is true that some sensitive microbes are killed by cold temperatures, most are not adversely affected by gradual cooling, long-term refrigeration, or deep-freezing. In fact, freezing temperatures, ranging from -70°C to -135°C, provide an environment that can preserve cultures of bacteria, viruses, and fungi for long periods. Recall from chapter 7 that some psychrotrophs grow very slowly even at freezing temperatures and can continue to secrete toxic products. Pathogens able to survive several months in the refrigerator are *Staphylococcus aureus*; *Clostridium* species (sporeformers); *Listeria*; and several types of yeasts, molds, and viruses. Outbreaks of *Salmonella* food infection traced back to refrigerated foods such as ice cream and eggs are testimony to the inability of cold temperatures to reliably kill pathogens.

Most vegetative cells directly exposed to normal room air gradually become dehydrated, or **desiccated**.^{*} Delicate pathogens such as *Streptococcus pneumoniae*, the spirochete of syphilis, and *Neisseria gonorrhoeae* can die after a few hours of air-drying, but many others are not killed and some are even preserved. Staphylococci and streptococci in dried secretions and the tubercle bacillus surrounded by sputum can remain viable in air and dust for lengthy periods. Many viruses (especially nonenveloped) and fungal spores can also withstand long periods of desiccation. Endospores of *Bacillus* and *Clostridium* are viable for millions of years under extremely arid conditions. Desiccation can be a valuable way to preserve foods because it greatly reduces the amount of water available to support microbial growth.

It is interesting to note that a combination of freezing and drying—**lyophilization**^{*}—is a common method of preserving microorganisms and other cells in a viable state for many years. Pure

^{*} *desiccate* (des'-ih-kayt) To dry at normal environmental temperatures.

^{*} *lyophilization* (ly-off''-il-ih-za'-shun) Gr. *lyein*, to dissolve, and *philein*, to love.

TABLE 11.4 Applications Using Heat for Sterilization and Disinfection

Form of Heat	Equipment Temperature/Time	Medical and Commercial Uses and Limitations
Moist heat: Employs steam, boiling, or hot water; mode of action coagulates proteins		
Steam under pressure	Autoclave, pressure cooker; 121°C, pressure of 15 psi for 10 to 40 minutes, depending on load size; kills endospores.	Sterilization of heat-resistant materials made of glass, cloth, rubber, metal; media; a few plastics; canned food, spices. Decontamination of cultures. Not appropriate for moisture-repellent oil or powder.
Unpressurized steam (tyndallization)	Arnold's Sterilizer—100°C for 30 minutes on 3 days; items are incubated between treatments to allow endospores to germinate.	Limited uses in sterilizing some media and foods that cannot be autoclaved; can be used to disinfect but not sterilize some medical supplies
Pasteurization	Pasteurizer; flash method works at 71.6°C for 15 seconds; ultrahigh temperature (UHT) uses 134°C for a few seconds.	Disinfection of milk and dairy products to destroy milk-borne pathogens; UHT can sterilize for longer shelf life. Fruit juices, beer, and wine may be pasteurized to destroy contaminants and preserve the products.
Boiling water	Water bath or pan heated to 100°C; items are placed in water for 30 minutes to kill vegetative pathogens.	Limited to disinfection and sanitization of heat-resistant household objects such as eating utensils, clothing, sick room supplies, baby supplies, bedding, and water in emergencies; problem with recontamination
Dry heat: Employs dried hot air, flame, or heat coil; works by dehydration or combustion		
Dry oven	Electric or gas chamber heated to 150°C to 180°C for 2 to 4 hours	Materials that can withstand hot temperatures and dehydration; glassware, metals, powders, oils. Poor choice for liquids, rubber, plastics; time-consuming.
Incineration	Bunsen burner flame up to 1,800°C; small infrared incinerators to 800°C	Furnaces, incinerators up to 6,500°C For sterilizing tips of inoculation instruments; limited to high-temperature metals. Permanent disposal of waste material from laboratories; burning reduces bulky packages and garbage to ashes. For permanent disposal only.

cultures are frozen instantaneously and exposed to a vacuum that rapidly removes the water. This method avoids the formation of ice crystals that would damage the cells. Although not all cells survive this process, enough of them do to permit future reconstitution of that culture.

As a general rule, chilling, freezing, and desiccation should not be construed as methods of disinfection or sterilization, because their antimicrobial effects are erratic and uncertain and one cannot be sure that pathogens subjected to them have been killed.

Check Your Progress SECTION 11.2

- What happens to microbes that encounter temperatures below their minimum and above their maximum growth temperatures?
- Summarize the nature, mode of action, and effectiveness of moist and dry heat on spores and vegetative cells.
- Explain the concepts of TDT and TDP, using examples.
- What are the minimum TDTs for vegetative cells and endospores?
- How can the temperature of steam be raised above 100°C? Which instrument is based on this technique and how is it used?
- What are the primary purposes of pasteurization, and what is ultrapasteurization?
- What are several microbial targets of pasteurization?
- Explain why desiccation and cold are not reliable methods of disinfection but how they can still be effective in microbial control.

11.3 Physical Methods of Control: Radiation and Filtration

Expected Learning Outcomes

- Define *radiation* and assess the use of irradiation as a method of microbial control.
- Differentiate between ionizing and nonionizing radiation in their modes of action.
- Summarize the primary uses of ionizing and nonionizing radiation in sterilization and disinfection.
- Describe the concept behind sterilization by filtration, including examples of applications.

Radiation as a Microbial Control Agent

Another form of energy that can serve as an antimicrobial agent is radiation. **Radiation** is defined as energy emitted from atomic activities and dispersed at high velocity through matter or space. It is characterized by a range of wavelengths known as the electromagnetic spectrum (**figure 11.8**). Although radiation exists in many energy states, we will consider only those types suitable for microbial control: gamma rays, X rays, and ultraviolet radiation.

Modes of Action of Ionizing Versus Nonionizing Radiation

The actual physical effects of radiation on microbes can be understood by visualizing the process of **irradiation**, or bombardment with radiation, at the cellular level (**figure 11.9**). When a cell is bombarded by certain waves or particles, its molecules absorb some of the available energy, leading to one of two consequences: (1) If the radiation ejects orbital electrons from an atom, it causes ions to form; this type of radiation is termed **ionizing radiation**. One of the most sensitive targets for ionizing radiation is DNA, which will undergo mutations on a broad scale. Secondary lethal effects appear to be chemical changes in organelles and the production of

Figure 11.8 The electromagnetic spectrum. Waves range from the shortest gamma rays to the longest radio waves. Inset shows the spectrum of visible light between ultraviolet (UV) and infrared. Only ionizing radiation, UV, and infrared have applications in microbial control.

toxic substances. Gamma rays, X rays, and high-speed electrons are all ionizing in their effects. (2) **Nonionizing radiation**, best exemplified by UV, excites atoms by raising them to a higher energy state, but it does not ionize them. This atomic excitation, in turn, leads to the formation of abnormal bonds within molecules such as DNA and is thus a source of mutations (see figure 11.11).

Ionizing Radiation: Gamma Rays, X Rays, and Cathode Rays

Over the past several years, ionizing radiation has become safer and more economical to use, and its applications have expanded. It is a highly effective alternative for sterilizing materials that are sensitive to heat or chemicals. Because it sterilizes in the absence of heat, irradiation is a type of **cold** (or low-temperature) **sterilization**.³ Devices that emit ionizing rays include gamma-ray machines containing radioactive cobalt, X-ray machines similar to those used in medical diagnosis, and cathode-ray machines that operate like the vacuum tube in a television set. Items are placed in these machines and irradiated for a short time with a carefully chosen dosage. The dosage of radiation is measured in grays (which has replaced the older term, *rads*). Depending on the application, exposure ranges from 5 to 50 kilograys (kGy; a kilogray is equal to 1,000 grays). Although all ionizing radiations can penetrate liquids and most solid materials, gamma rays are most penetrating, X rays are intermediate, and cathode rays least penetrating.

3. To clarify the use of the word *cold*, in this context, it only means the absence of heat. Beer manufacturers have sometimes used this terminology as well. When they say that their product is “cold-filtered,” they mean that it has been freed of contaminants via filtration, without heating.

Figure 11.9 Cellular effects of irradiation. (a) Ionizing radiation can penetrate a solid barrier, bombard a cell, enter it, and dislodge electrons from molecules. Breakage of DNA creates massive mutations. (b) Nonionizing radiation enters a cell, strikes molecules, and excites them. The effect on DNA is mutation by formation of abnormal bonds. (c) A solid barrier cannot be readily penetrated by nonionizing radiation.

Irradiation as a Method of Microbial Control

Foods have been subject to irradiation in limited circumstances for more than 50 years. From flour to pork and ground beef, to fruits and vegetables, radiation is used to kill bacterial pathogens, insects, and worms, and even to inhibit the sprouting of white potatoes. As soon as radiation is involved, however, consumers become concerned that ionizing radiation could make food less nutritious, unpalatable, or even unsafe. But irradiated food has been extensively studied, and each of these concerns has been addressed.

Figure 11.10 Sterilization with ionizing radiation. Many foods can be effectively sterilized by utilizing the penetrating power of ionizing radiation. The “radura” symbol (meaning treated with radiation); see the green image on the package on the left) applied to fresh foods signifies that the food has been irradiated and is required to be displayed on all food so treated. (photos: © Kathy Park Talaro)

Figure 11.10 demonstrates how irradiation of fruit can greatly reduce spoilage and improve shelf life.

Irradiation may lead to a small decrease in the amount of thiamine (vitamin B₁) in food, but this change is small enough to be inconsequential. The irradiation process does produce short-lived free-radical oxidants, which disappear almost immediately (this same type of chemical intermediate is produced through cooking as well). Certain foods do not irradiate well and are not good candidates for this type of treatment. The white of eggs becomes milky and alfalfa seeds do not germinate properly. It should be emphasized that food is not made radioactive by the irradiation process, and many studies, in both animals and humans, have concluded that there are no ill effects from eating irradiated food. In fact, NASA relies on irradiated meat for its astronauts.

One of the potential benefits of irradiated foods has to do with infection control. It has been estimated that irradiation of 50% of the meat and poultry in the United States would result in 900,000 fewer cases of infection, 8,500 fewer hospitalizations, and 350 fewer deaths each year. Radiation is currently approved in the United States for the reduction of bacterial pathogens such as *E. coli* and *Salmonella* in beef and chicken, reduction of *Trichinella* worms in pork, and the reduction of pathogens and pests on fruits and vegetables. An additional benefit of irradiation is that microbes responsible for food spoilage are killed along with pathogens, leading to an increased shelf life. In any event, no irradiated food can be sold to consumers without clear labeling that this method has been used (figure 11.10).

Sterilizing medical products with ionizing radiation is a rapidly expanding field. Drugs, vaccines, medical instruments (especially plastics), and other delicate materials can be irradiated without harming them. Its main advantages include speed, high

Quick Search
Access YouTube to view the video “Irradiation in Food Processing.”

penetrating power (it can sterilize materials through outer packages and wrappings), and the absence of heat. Its main disadvantages are potential dangers from factory exposure to radiation and possible damage to some materials. See table 11.5 for a summary of the applications of ionizing radiation.

Nonionizing Radiation: Ultraviolet Rays

Ultraviolet (UV) radiation ranges in wavelength from approximately 100 nm to 400 nm. It is most lethal from 240 nm to 280 nm (with a peak at 260 nm). In everyday practice, the source of UV rays is the germicidal lamp, which generates radiation at 254 nm. Owing to its lower energy state, UV radiation is not as penetrating as ionizing radiation. Because UV radiation passes readily through air, slightly through liquids, and only poorly through solids, the object to be disinfected must be directly exposed to it for full effect.

As UV radiation passes through a cell, it is initially absorbed by DNA. Specific molecular damage occurs on the pyrimidine bases (thymine and cytosine), which form abnormal linkages with each other called **pyrimidine dimers (figure 11.11)**. These bonds occur between adjacent bases on the same DNA strand and interfere with normal DNA replication and transcription. The results are inhibition of growth and cellular death. In addition to altering DNA directly, UV radiation also disrupts cells by generating toxic photochemical products called free radicals. These highly reactive molecules interfere with essential cell processes by binding to DNA, RNA, and proteins. Ultraviolet rays are a powerful tool for destroying fungal cells and spores, bacterial vegetative cells, protozoa, and viruses. Bacterial spores are about 10 times more resistant to radiation than are vegetative cells, but they can be killed by increasing the time of exposure.

Figure 11.11 Formation of pyrimidine dimers by the action of ultraviolet (UV) radiation. This shows what occurs when two adjacent thymine bases on one strand of DNA are induced by UV rays to bond laterally with each other. The result is a thymine dimer shown in greater detail. Dimers can also occur between adjacent cytosines and thymine and cytosine bases. If they are not repaired, dimers can prevent that segment of DNA from being correctly replicated or transcribed. High levels of dimerization are lethal to cells.

Figure 11.12 An ultraviolet (UV) treatment system for disinfection of water. Water is directed through channels at a water treatment plant, past racks of UV lamps (green glow). This system has a capacity of several million gallons per day and can be used as an alternative to chlorination. Home systems that fit under the sink are also available. Photo Courtesy of Xylem Inc.

Ultraviolet radiation is usually aimed more at disinfection than at sterilization. Germicidal lamps can cut down on the concentration of airborne microbes by as much as 99%. Ultraviolet disinfection of air has proved effective in reducing postoperative infections, preventing the transmission of infections by respiratory droplets, and curtailing the growth of microbes in food-processing plants and slaughterhouses.

Ultraviolet irradiation of liquids requires special equipment to spread the liquid into a thin, flowing film that is exposed directly to a lamp. This method can be used to treat water (figure 11.12) and to purify other liquids (milk and fruit juices) as an alternative to heat. The surfaces of solid, nonporous materials such as walls and floors, as well as meat, nuts, tissues for grafting, and drugs, can be successfully disinfected with UV. Several types of small UV disinfection appliances have been marketed for personal items.

One major disadvantage of UV is its poor powers of penetration through solid materials such as glass, metal, cloth, plastic, and even paper. Another drawback to UV is the damaging effect of overexposure on human tissues, including sunburn, retinal damage, cancer, and skin wrinkling. These harmful results occur only if a person is directly exposed to the UV rays, but it necessitates placement of barriers to cut down on this possibility. **Table 11.5** summarizes UV applications.

Filtration—A Physical Removal Process

Filtration is an effective method to remove microbes from air and liquids. In practice, a fluid is strained through a filter with openings large enough for the fluid to pass through but too small for microorganisms to pass through (figure 11.13a).

Most modern microbiological filters are thin membranes of cellulose acetate, polycarbonate, and a variety of plastic materials (Teflon, nylon) whose pore size can be carefully controlled and standardized. Ordinary substances such as charcoal, diatomaceous earth, or unglazed porcelain are also used in some applications. Viewed microscopically, most filters are perforated by very precise, uniform pores (figure 11.13b). The pore diameters vary from coarse (8 μm) to ultrafine (0.02 μm), permitting selection of the minimum particle size to be trapped. Those with even smaller pore diameters permit true sterilization by removing viruses, and some will even remove large proteins. A sterile liquid filtrate is typically

TABLE 11.5 Applications Using Radiation for Sterilization and Disinfection

Form of Radiation	Equipment/Mode of Action	Medical and Commercial Uses and Limitations
Ionizing radiation Sporicidal and penetrating	Cobalt radiation gives off gamma rays; others are X rays, cathode rays. Rays fragment DNA and create ionized bases; highly mutagenic.	Cold sterilization of packaged products such as medical supplies and instruments that cannot be heat sterilized Sterilization of foods, including fruits, lettuce and spinach, grains, spices, meats, and packaged meals Sterilization of drugs and vaccines Rapid and penetrating, prevents infection and spoilage
Nonionizing ultraviolet (UV) radiation Sporicidal and nonpenetrating	Germicidal lamps or generators set to deliver UV rays from 240 to 280 nm in wavelength; action creates abnormal bonds between adjacent thymines and cytosines and produces deletion mutations on DNA.	Mostly disinfection of air, some liquids, a few solids; reduces airborne pathogens in medical and dental offices, hospital rooms, and operating rooms Commercial use for clean rooms, food processing areas Works on liquids such as water, milk, drugs, vaccines if exposed to UV in thin layers Solid materials such as room surfaces, foods, tissue grafts, drugs, and instruments Lack of penetration through solids limits applications; direct exposure can be dangerous to eyes and skin.

Figure 11.13 Membrane filtration. (a) Vacuum assembly for achieving filtration of liquids through suction. Inset shows filter as seen in cross section, with tiny passageways (pores) too small for the microbial cells to enter but large enough for liquid to pass through. (b) Scanning electron micrograph of *Enterococcus* trapped on the surface of a membrane filter (10,400 \times). Average cells measure about 0.5 μm to 1 μm in diameter, and average pore size is about 0.3 μm . (b) *Source:* Janice Haney Carr/CDC

produced by suctioning the liquid through a sterile filter into a presterilized container. These filters are also used to separate mixtures of microorganisms and to enumerate bacteria in water analysis.

Applications of Filtration Sterilization

Sterilization by means of filtration is used to prepare liquids that cannot withstand heat, including serum and other blood products, vaccines, drugs, IV fluids, enzymes, and media. Filtration has been employed as an alternative method for sterilizing milk and beer without altering their flavor. It is also an important step in water purification. Its use extends to filtering out particulate impurities (crystals, fibers) that can cause severe reactions in the body. It has the disadvantage of not removing soluble molecules (toxins) that can cause disease.

Filtration is a very effective means of removing airborne contaminants that are a common source of infection and spoilage. High-efficiency particulate air (HEPA) filters are widely used to provide a flow of sterile air to hospital rooms and sterile rooms.

17. Define *radiation* and *irradiation*.
18. Differentiate between the modes of action of ionizing radiation and ultraviolet radiation.
19. What are some advantages and disadvantages of ionizing radiation as a method of control?
20. Describe some applications of ionizing and ultraviolet radiation.
21. What are the advantages and disadvantages of using filtration as a method of control?

11.4 Chemical Agents in Microbial Control

Expected Learning Outcomes

18. Define the terms that are used to describe chemical control of microbes.
19. Explain the desirable features of antimicrobial chemicals and what factors influence their effectiveness.
20. Describe the types of halogens, their modes of action, and their clinical and commercial applications.
21. Identify the characteristics of phenolic compounds and alcohols, explain how they act, and evaluate their primary uses.
22. Describe the characteristics of oxidizing agents and aldehydes, and summarize their main applications.
23. Differentiate among the sterilizing gases and aerosols, and describe how they are used.
24. Explain how detergents, soaps, and heavy metals can be employed in clinical, commercial, and household microbial control.

Chemical control of microbes probably emerged as a serious science in the early 1800s, when physicians used chloride of lime and iodine solutions to treat wounds and to wash their hands before surgery. At the present time, approximately 10,000 different antimicrobial chemical agents are manufactured; probably 1,000 of them are used routinely in the health care and home environments. A genuine need exists to avoid infection and spoilage, but the abundance of products available to “kill germs,” “disinfect,” “antisepti- cize,” “clean and sanitize,” “deodorize,” “fight plaque,” and “purify the air” indicates a preoccupation with eliminating microbes from the environment that, at times, seems excessive (**11.1 Making Connections**).

Antimicrobial chemicals occur in the liquid, gaseous, or even solid state. They serve as **disinfectants**, **antiseptics**, **sterilants** (chemicals that sterilize), degermers, or preservatives (chemicals that inhibit the deterioration of substances). In most cases, solid or gaseous antimicrobial chemicals are dissolved in water, alcohol, or a mixture of the two to produce a liquid solution. Solutions containing pure water as the solvent are termed **aqueous**, whereas those dissolved in pure alcohol or water-alcohol mixtures are termed **tinctures**.

Choosing a Microbicidal Chemical

The choice and appropriate use of antimicrobial chemical agents are of constant concern in medicine and dentistry. Although actual clinical practices of chemical decontamination vary widely, some desirable qualities in a germicide have been identified, including:

- rapid action in low concentrations,
- solubility in water or alcohol and long-term stability,
- broad-spectrum microbicidal action without being toxic to human and animal tissues,
- penetration of inanimate surfaces to sustain a cumulative or persistent action,
- resistance to becoming inactivated by organic matter,
- noncorrosive or nonstaining properties,
- sanitizing and deodorizing properties,
- affordability and ready availability

As of yet, no chemical can completely fulfill all of those requirements, but chlorhexidine and hydrogen peroxide approach this ideal. At the same time, we should question the rather overinflated claims made about certain commercial agents such as mouthwashes and disinfectant air sprays.

Germicides are evaluated in terms of their effectiveness in destroying microbes in medical and dental settings. The three levels of chemical decontamination procedures are *high*, *intermediate*, and *low* (**table 11.6**).

- High-level germicides kill endospores and, if properly used, are **sterilants**. Materials that necessitate high-level control are medical devices—for example, catheters, endoscopes, and implants—that are not heat-sterilizable and are intended to enter body tissues during medical procedures.
- Intermediate-level germicides kill fungal (but not bacterial) spores, resistant pathogens such as the tubercle bacillus, and viruses. They are used to disinfect items (respiratory equipment, thermometers) that come into intimate contact with the mucous membranes but are noninvasive.
- Low levels of disinfection eliminate only vegetative bacteria, vegetative fungal cells, and some viruses. They are used to clean materials such as electrodes, straps, and fixtures that touch the skin surfaces but not the mucous membranes.

Factors That Affect the Germicidal Activities of Chemical Agents

Several concepts of microbial control introduced in section 11.1 apply to germicides and other chemical agents. Many of these substances target the same cellular structures and functions previously discussed: cell walls and membranes, proteins, and nucleic acids. The effectiveness of the agents depends on several factors, including (1) the numbers and kinds of microbes that are present, (2) the kinds of materials that are being treated, (3) the time of exposure required, and (4) the strength and mode of action of the agent. Here, we focus on the latter two because of their importance to chemical agents.

Length of Exposure Most compounds require adequate contact time for the chemical to penetrate and to act on the microbes present. The composition of the material being treated can greatly affect this process. Smooth, solid objects are more rapidly disinfected

TABLE 11.6 Qualities of Chemical Agents Used in Health Care

Agent	Target Microbes	Level of Germicidal Activity	Toxicity	Comments
Chlorine	Sporicidal (slowly)	Intermediate	Gas is highly toxic; solution irritates skin	Inactivated by organics; unstable in sunlight
Iodine	Sporicidal (slowly)	Intermediate	Can irritate tissue; toxic if ingested	Iodophors* are milder forms
Phenolics	Some bacteria, viruses, fungi	Low to intermediate	Can be absorbed by skin; can cause CNS damage	Poor solubility; expensive
Chlorhexidine*	Most bacteria, some viruses, fungi	Low to intermediate	Low toxicity	Fast-acting, mild, has residual effects
Alcohols	Most bacteria, viruses, fungi	Intermediate	Toxic if ingested; a mild irritant; dries skin	Flammable, fast-acting
Hydrogen peroxide,* stabilized	Sporicidal	High (sterilant)	Toxic to eyes; toxic if ingested	Improved stability; works well in organic matter
Quaternary ammonium compounds	Some bactericidal, virucidal, fungicidal activity	Low to intermediate	Irritating to mucous membranes; poisonous if taken internally	Weak solutions can support microbial growth; easily inactivated
Soaps	Certain very sensitive species	Very low	Nontoxic; few if any toxic effects	Used for removing soil, oils, debris
Mercurials	Weakly microbistatic	Low	Highly toxic if ingested, inhaled, absorbed	Easily inactivated
Silver nitrate	Bactericidal	Low	Toxic, irritating	Discolors skin
Glutaraldehyde*	Sporicidal	High (sterilant)	Can irritate skin; toxic if absorbed	Not inactivated by organic matter; unstable
Ortho-phthaldehyde*	Sporicidal, with time	Intermediate to high	Mild, no odor	less toxic than glutaraldehyde, highly stable, stains skin
Ethylene oxide gas*	Sporicidal	High (sterilant)	Very dangerous to eyes, lungs; carcinogenic	Explosive in pure state; good penetration; materials must be aerated
Dyes	Weakly bactericidal, fungicidal	Low	Low toxicity	Stains materials, skin

*These chemicals approach the ideal by having many of the following characteristics: broad spectrum, low toxicity, fast action, penetrating abilities, residual effects, stability, potency in organic matter, and solubility.

than are those with pores or pockets that can trap soil. An item contaminated with common biological matter such as serum, blood, saliva, pus, fecal material, or urine presents an additional barrier to effective disinfection. Large amounts of this organic material can hinder penetration and, in some cases, can form bonds that reduce a chemical's activity. Adequate cleaning of instruments and other reusable materials will ensure that the germicide or sterilant will better accomplish the job for which it was chosen.

Concentration of the Chemical Agent A chemical's strength or concentration is expressed in various ways, depending upon convention and the method of preparation. The content of many chemical agents can be formulated in more than one way. For dilutions, a small volume of the liquid chemical (solute) is diluted in a larger volume of solvent to achieve a certain ratio. For example, a common laboratory phenolic disinfectant such as Lysol is usually diluted 1:200; that is, one part of chemical (solute) has been added to 200 parts of water (solvent) by volume. Solutions such as chlorine that

are effective in very diluted concentrations are expressed in parts per million (ppm). In percentage solutions, the solute is added to solvent by weight or volume to achieve a certain percentage in the solution. Alcohol, for instance, is used in percentages ranging from 50% to 95%. In general, solutions of low dilution or high percentage have more of the active chemical (are more concentrated) and tend to be more germicidal, but expense and potential toxicity can necessitate using the minimum strength that is effective.

Standardized procedures for testing the effectiveness of germicides are summarized in Appendix B.

Categories of Chemical Agents

Several general groups of chemical compounds are widely used for antimicrobial purposes in medicine and commerce (table 11.6). Prominent agents include halogens, phenolic compounds, alcohols, oxidizers, aldehydes, gases, detergents, and heavy metals. These groups are surveyed in the following section from the standpoint of

11.1 MAKING CONNECTIONS

Pathogen Paranoia: “The Only Good Microbe Is a Dead Microbe”

The sensational publicity over influenza outbreaks, MRSA infections, *E. coli* and *Salmonella* foodborne illnesses, noroviruses, and many others has dramatically increased public awareness of microorganisms. This glut of coverage has also had certain benefits, such as greater emphasis on hand washing, food handling, and personal hygiene. But sometimes a little knowledge can be dangerous. The trend also seems to have escalated into an obsessive fear of “germs” lurking around every corner and a fixation on eliminating as many microbes as possible from the environment and the human body.

As might be expected, commercial industries have found a way to capitalize on these fears. A widespread array of commonplace household materials now contain chemicals that provide antibacterial or germicidal “protection.” First it was hand soaps and dishwashing detergents, and eventually the list grew to include shampoos, laundry aids, hand lotions, deodorants, sponges, kitty litter, cutting boards, garbage bags, toys, toothpaste, and even building products.

Chemical agents that are frequently added to these products are phenolics called triclosan and triclocarban. These substances do indeed kill most pathogenic bacteria, but they do not reliably destroy viruses or fungi, and they have been culprits in skin rashes due to hypersensitivity. Some published reports have also linked them to some forms of hormone and muscle disorders. Others point to a possible accumulative effect they may have that could interfere with development in young children. Because of concerns for these possible toxic side effects, in 2016 the FDA directed industries to phase out all non-medical uses by 2017.

Medical experts are concerned that the widespread overuse of antibacterial chemicals could favor the survival and growth of resistant

strains of bacteria. One study reported that pathogens such as *Mycobacterium tuberculosis* and *Clostridium* are naturally resistant to triclosan and that *E. coli* and *Staphylococcus aureus* have developed decreased sensitivity to it. One fear has been that overuse could select for “superbugs” that can survive all attempts at disinfection.

Another outcome of excess contact with environmental germicides is to reduce our natural contact with microbes that is required to maintain the normal microbial residents of the body and stimulate immunities. Constant use of these agents could also shift the balance in our normal resident microbiota by killing off beneficial microbes that we now know are essential to our health.

An unfortunate side effect of negative views of microbes is how they foster the feeling that all microbes are harmful. We must not forget that most human beings manage to remain healthy despite the fact that they live in continual intimate contact with microorganisms. We really do not have to be preoccupied with microbes every minute or feel overly concerned that the things we touch, drink, or eat are sterile, as long as they are somewhat clean and free of pathogens. For most of us, resistance to infection is well maintained by our numerous host defenses. Infectious disease specialists urge a happy medium approach. Instead of filling the home with questionable germicidal products, they encourage cleaning with traditional soaps and detergents, reserving more potent products to reduce the spread of infection in clinical settings.

Can you name other undesirable consequences of mass usage of antimicrobial chemicals in addition to those mentioned here? *Answer available on Connect.*

each agent’s specific forms and modes of action. Applications and methods of delivery are described in tables.

The Halogen Antimicrobial Chemicals

The **halogens*** are fluorine, bromine, chlorine, and iodine, a group of nonmetallic elements with similar chemical properties. Although they can exist in either the ionic (halide) or nonionic state, most halogens exert their antimicrobial effect primarily in the nonionic state, not the halide state (chloride, iodide, for example). Because fluorine and bromine are difficult and dangerous to handle and no more effective than chlorine and iodine, only the latter two are used routinely in germicidal preparations. These elements are highly effective components of disinfectants and antiseptics because they are microbicidal and not just microbistatic, and they are sporicidal with longer exposure. For these reasons, halogens are the active ingredients in nearly one-third of all antimicrobial chemicals currently marketed.

Chlorine and Its Compounds Chlorine has been used for disinfection and antiseptics for approximately 200 years. The major forms used in microbial control are liquid and gaseous chlorine (Cl_2), hypochlorites (O^-Cl), and chloramines (NH_2Cl). In solution, these compounds combine with water and release hypochlorous acid (HClO):

Hypochlorous acid oxidizes the sulfhydryl (S—H) groups on the amino acid cysteine and breaks disulfide (S—S) bridges on numerous enzymes. The resulting denaturation of the enzymes is permanent and suspends metabolic reactions. It also damages the structure of DNA, RNA, and fatty acids. Death of almost all microorganisms usually occurs within 30 minutes, although endospores may require several hours. Chlorine compounds are less effective and relatively unstable if exposed to light, alkaline pH, and excess organic matter.

Iodine and Its Compounds Iodine (I_2) is a pungent blue-black element that forms a brown-colored solution when dissolved in

* *halogens* (hay'-loh-jenz) Gr. *halos*, salt, and *gennan*, to produce.

TABLE 11.7 Applications of Halogen Compounds

Form of Chlorine	Primary Applications	How Delivered/Concerns
Chlorine Gas (Cl ₂)	Large-scale disinfection of drinking water, sewage, and wastewater.	Chlorination to a concentration of 0.6 to 1.0 parts of chlorine per million parts of water destroys most vegetative pathogens.*
Hypochlorites (HClO) Bleach	Used extensively in sanitization and disinfection of food equipment, treatment of swimming pools, spas, drinking water, and fresh foods; for wound antisepsis and routine medical and household disinfection, deodorizing, and stain removal.	Common household bleach is a 5% solution of sodium hypochlorite; dilutions of 1:10-1:1,000 are highly effective germicides.
Chloramines (Dichloramine, Halazone)	An alternative to pure chlorine in treating water supplies; also as sanitizers and disinfectants; for treating wounds and skin surfaces.	Because standard gas chlorination of water is now believed to produce unsafe levels of trihalomethanes, some water districts are required to use chloramine treatment of water supplies.
Form of Iodine	Primary Applications	How Delivered/Concerns
Iodophors	Most common iodine for skin and mucous membranes; antiseptic prep for surgery and injections; for surgical handscrubs; to disinfect equipment and surfaces; possibly for burns; and may be an alternative preventive for eye infections in newborns.	A complex of iodine and a neutral protein polymer provides slow release and reduced toxicity or irritation of tissues; less prone to staining. Common products are povidone-iodine (PVI; Betadine), which contain 2% to 10% available iodine.
Elemental iodine: Aqueous or Tinctures	Topical antiseptic prior to surgery; sometimes for burned or injured skin. Medium-level disinfection for plastic instruments, thermometers; tablet form available for disinfection of contaminated water.	Weak solutions of 1% to 3% in water or in alcohol tinctures. Aqueous solutions or tinctures of 5% to 10%; somewhat limited by their toxicity and tendency to stain.

Cantaloupes are disinfected with chlorine treated water to kill *Salmonella* carried on their surfaces.

Patient has been treated with a povidone-iodine solution in preparation for surgery.

*Some cyst-forming protozoans such as *Giardia* and *Cryptosporidium* can survive this level of chlorination. (left): Source: Paul Pierlott, USDA-ERRC/VGT; (right): Used with permission from 3M

water. It rapidly penetrates the cells of microorganisms, where it disturbs a variety of metabolic functions by interfering with the disulfide bonds of proteins. This mode of action is similar to that seen in chlorine, although iodine is less susceptible to inactivation by organic material. All classes of microorganisms can be killed if proper exposure times and iodine concentrations are used.

See **table 11.7** for information on the main uses and forms of halogens.

Phenol and Its Derivatives

Phenol (carbolic acid) is an acrid, poisonous compound derived from the distillation of coal tar. First adopted by Joseph Lister in 1867 as a surgical germicide, phenol was the dominant antimicrobial chemical until other phenolics with fewer toxic and irritating effects were

developed. Solutions of phenol are now used only in certain limited cases, but it remains one standard against which other phenolic disinfectants are rated. The *phenol coefficient* quantitatively compares a chemical's antimicrobial properties to those of phenol. Substances chemically related to phenol are often referred to as phenolics.

Phenolics consist of one or more aromatic carbon rings with added functional groups (**figure 11.14**). Among the more common phenolics are alkylated phenols (cresols), chlorinated phenols (see triclosan, discussed in 11.1 Making Connections), and bisphenols. In high concentrations, phenolics are cellular poisons, rapidly disrupting cell walls and membranes and precipitating proteins; in lower concentrations they inactivate certain critical enzyme systems. The phenolics will destroy vegetative bacteria (including the tuberculosis bacillus), fungi, and many viruses (not hepatitis B), but they are not reliably sporicidal. Their sustained activity in the

Figure 11.14 Examples of phenolic structures. All contain a basic aromatic ring, but they differ in the types of additional side groups, such as Cl and CH₃.

presence of organic matter and their detergent actions contribute to their usefulness. Unfortunately, the toxicity of many of the phenolics makes them a questionable choice as antiseptics.

Chlorhexidine

The compound chlorhexidine (Hibiclens, Hibitane) is a complex organic base containing chlorine and two phenolic rings. Its mode of

action targets cell membranes by lowering surface tension and causing denaturation of proteins. At moderate to high concentrations it is bactericidal for both gram-positive and gram-negative bacteria but inactive against spores. Its effects on viruses and fungi vary. It possesses distinct advantages over many other antiseptics because of its mildness, low toxicity, and rapid action, and it is not absorbed into deeper tissues to any extent. It is the antiseptic cleanser of choice to control *Staphylococcus* MRSA and *Acinetobacter* outbreaks in hospitals.

Applications for phenolic compounds and chlorhexidine are given in **table 11.8**.

Alcohols as Antimicrobial Agents

Alcohols are colorless hydrocarbons with one or more —OH functional groups. Of several alcohols available, only ethyl and isopropyl are suitable for microbial control. Methyl alcohol is not particularly microbicidal, and more complex alcohols are either poorly soluble in water or too toxic for routine use. Alcohols are employed alone in aqueous solutions or as solvents for tinctures (with iodine, for example).

Alcohol's mechanism of action depends in part upon its concentration. Concentrations of 50% and higher dissolve membrane lipids, disrupt cell surface tension, and compromise membrane integrity. Alcohol that has entered the protoplasm denatures proteins through coagulation but only in alcohol-water solutions of 50% to 95%. Alcohol is the exception to the rule that higher concentrations of an antimicrobial chemical have greater microbicidal activity. Because water is needed for proteins to coagulate, alcohol shows a greater microbicidal activity at 70% concentration (that is, 30% water) than at 100% (0% water). Absolute alcohol (100%) dissolves cell membranes and inhibits cell growth but is generally not a protein coagulant.

TABLE 11.8 Applications of Phenolics and Chlorhexidine

Form of Phenolic	Primary Applications	How Delivered/Concerns
Creolin	Common household version of phenol; for low or intermediate levels of disinfection in rooms, floors, and veterinary clinics.	1% to 3% emulsions that are combined with soap; can be too toxic for antiseptics; tend to be absorbed by membranes into the blood.
Bisphenols	Widely employed commercially, clinically, and in the home.	Orthophenyl phenol is a major ingredient in fungicides. This same phenolic is also found in some disinfectants used in the hospital and laboratory.
Hexachlorophene	Formerly a widespread additive of cleansing soaps (pHisoHex) for hospital and home use; may be used to control outbreaks of skin infections.	When hexachlorophene was found to be absorbed through the skin and a cause of neurological damage, it was no longer available without a prescription.
Triclosan (Dichlorophenoxyphenol)	Widely used antibacterial compound added to soaps, cosmetics, and many other household products.	It acts as both disinfectant and antiseptic and is broad-spectrum in its effects. New uses include surgical preps, handwashing, and bathing patients.
Form of Chlorhexidine	Primary Applications	How Delivered/Concerns
Chlorhexidine (Hibiclens, Hibitane)	Alcoholic or aqueous solutions are now commonly used for hand scrubbing, preparing skin sites for surgical incisions and injections, and patient cleansing. Solutions also serve as an obstetric and neonatal wash, a wound degermer, a mucous membrane irrigant, and a preservative for eye solutions.	Complex base containing chlorine and two phenolic rings; mode of action targets cell membranes and protein structure. At moderate to high concentrations, destroys both gram-positive and gram-negative bacteria but not spores. It may be fungicidal and virucidal. It is milder and less toxic than phenolics and is not absorbed into the skin.

Although useful in intermediate- to low-level germicidal applications, alcohol does not destroy bacterial spores at room temperature. Alcohol can, however, destroy resistant vegetative forms, including tuberculosis bacteria and fungal spores, provided the time of exposure is adequate. Alcohol tends to inactivate enveloped viruses more readily than nonenveloped viruses because of the surfactant effect on the envelope.

Hydrogen Peroxide and Related Germicides

Hydrogen peroxide (H_2O_2) is a colorless, caustic liquid that decomposes in the presence of light, metals, or catalase into water and oxygen gas. Early formulations were unstable and inhibited by organic matter, but manufacturing methods now permit synthesis of H_2O_2 so stable that even dilute solutions retain activity through several years of storage.

The germicidal effects of hydrogen peroxide are due to the direct and indirect actions of oxygen. Oxygen forms hydroxyl free radicals ($-OH$), which, like the superoxide radical (see chapter 7), are highly toxic and reactive to cells. Although most microbial cells produce catalase to inactivate the metabolic hydrogen peroxide, catalase cannot neutralize the amount of hydrogen peroxide penetrating these cells during disinfection and antiseptics. Hydrogen peroxide is bactericidal, virucidal, fungicidal, and, in higher concentrations, sporicidal. The need for heat-free rapid sterilization of small medical devices has led to the development of chambers that circulate combinations of peroxide and peracetic acid. A vaporized form of hydrogen peroxide is effective as an environmental sterilant used in decontaminating large spaces and objects (see figure 11.4).

Coverage on the applications of alcohols and peroxides is provided in **table 11.9**.

Form of Alcohol*	Primary Applications	How Delivered/Concerns
Ethyl Alcohol (Ethanol, Grain Alcohol)	Skin degerming agent and antiseptic; surfactant action removes skin oil, soil, and some microbes sheltered in deeper skin layers; occasionally used to disinfect electrodes and face masks.	Solutions of 70% to 95% are germicidal, inexpensive, nonirritating; limited by its rate of evaporation. Items need to be first cleaned and then soaked in alcohol for 15 to 20 minutes.
Isopropyl Alcohol (Rubbing Alcohol)	Some disinfection of objects, surfaces; limited skin cleansing.	More microbicidal and less expensive than ethanol, but these benefits must be weighed against its toxicity; inhaling its vapors can adversely affect the nervous system.
Form of Oxidizing Agent	Primary Applications	How Delivered/Concerns
Hydrogen Peroxide (H_2O_2)	Versatile use as an antiseptic, including skin and wound cleansing, bed sore care, and mouthwashing; disinfectant for soft contact lenses, surgical implants, plastics, bedding, and room interiors.	3% hydrogen peroxide—most common form—is useful in treating infections by anaerobic bacteria because of the lethal effects of the oxygen released.
Sterilizing H_2O_2	Vaporized H_2O_2 is a major sterilant; hydrogen peroxide plasma sterilizers used for industrial parts or medical items; for isolators, clean rooms, and space vehicles.	Hydrogen peroxide (35%) penetrates into delicate medical instruments, kills the most resistant microbes, and does not corrode small parts; vapors are sporicidal.
Peracetic Acid	Used to sterilize rooms, space shuttle; a chemical sterilant for medical devices.	Oxidizing agent—actions similar to those of hydrogen peroxide.
Ozone (O_3)	A gas used to disinfect air, water, industrial air conditioners, and cooling towers.	Difficult to handle in gaseous form

A nurse takes advantage of an alcohol gel hand cleansing station. These are very common in hospitals and clinics to encourage hand antiseptics.

Disinfection of contact lenses with peroxide-based cleaner. Note the bubbles produced, indicating the release of oxygen gas.

CLINICAL CONNECTIONS

When “Clean” is Not Enough

A number of clinical procedures rely on reusable instruments such as endoscopes and dental handpieces. Because these devices can become heavily contaminated by tissues and fluids, they need to undergo decontamination between patients to prevent transmission of infections such as hepatitis, tuberculosis, and HIV. These expensive diagnostic tools (depending on the tool, they can cost \$10,000 to \$80,000 each) have created a medical dilemma. Their intricate parts may trap infectious agents where they cannot be easily removed, and the tools are delicate and difficult to decontaminate. Traditional methods are either too damaging to the instruments (heat) or unable to sterilize them in a timely fashion between patients (radiation).

From 2013 to 2015 eight clusters of patients were infected and 20 died due to complications from contaminated endoscopes called duodenoscopes that are threaded through the mouth into the intestine. Hospitals were immediately forced to reevaluate how these devices were being cleaned or “reprocessed” between patients. In many cases the methods were found to be inadequate because they failed to eliminate a category of pathogens called CRE (carbapenem-resistant enterobacteriaceae). These are normal residents of the gastrointestinal tract of many people, but they can cause deadly infections in compromised patients, and newer strains of them carry multiple-drug-resistant genes (see 12.3 Making Connections).

Ordinarily the entire scope was scrubbed, soaked in detergent, and rinsed in alcohol, which is considered a high level of disinfection. It was now apparent that this treatment was not rigorous enough, because the CRE bacteria had formed biofilms that were not being removed completely, and small amounts of them remained in the microscopic crevices of the tiny tools located on the tip of an endoscope (figure 11.15). About 700,000 endoscopic procedures are

Figure 11.15 Types of endoscope attachments. A close-up view of different endoscope tips shows a camera (top), biopsy tool (middle), and suction device (bottom). Others are equipped with lights and air or water outlets to flush or blow away debris. It is evident how readily microbes could become hidden or entrenched in these devices. Source: Linda Bartlett/National Cancer Institute

performed every year in the United States, making their safety a very high priority. Two governmental agencies (the CDC and FDA) intervened by requiring that this type of endoscope be sterilized through multistep techniques to remove debris, followed by extensive exposure to sterilants. Their effectiveness would have to be checked after every procedure by sampling and culturing. Chemicals that are currently recommended for this level of reprocessing are glutaraldehyde, peracetic acid/peroxide combination, and ethylene oxide gas.

Using lab techniques you learned in chapter 3, tell how would you conduct tests to determine whether sterilization of the endoscopes had been achieved. Answer available on Connect.

Aldehyde Sterilants and Disinfectants

Organic substances bearing a —CHO functional group (a strong reducing group) on the terminal carbon are called aldehydes. The two aldehydes used most often in microbial control are *glutaraldehyde* and *ortho-phthalaldehyde*.

Glutaraldehyde is a yellow liquid with a mild odor. The molecule’s two aldehyde groups favor the formation of polymers. The mechanism of activity involves cross-linking protein molecules on the cell surface. In this process, amino acids are alkylated, meaning that a hydrogen atom on an amino acid is replaced by the glutaraldehyde molecule itself. This irreversibly disrupts the activity of enzymes and other proteins within cells. Glutaraldehyde is rapid and broad-spectrum, and is officially labeled as a sterilant and high-level disinfectant. It is one of the few chemicals that can be used to sterilize delicate reusable medical and dental instruments (see **Clinical Connections, “When ‘Clean’ Is Not Enough”**, and figure 11.15). It kills spores in 3 hours and fungi and vegetative bacteria (even *Mycobacterium* and *Pseudomonas*) in a few minutes. Viruses, including the most resistant forms, appear to be inactivated after relatively short exposure. A special device known as a

chemiclave (similar to an autoclave) vaporizes the solution under pressure to sterilize delicate instruments without heat. Glutaraldehyde retains its potency even in the presence of organic matter, is noncorrosive, does not damage plastics, and is less toxic or irritating than formaldehyde. Its principal disadvantage is that it is somewhat unstable, especially with increased pH and temperature.

Another aldehyde, *ortho-phthalaldehyde* (OPA), has been approved by the EPA as a high-level disinfectant. OPA is a pale blue liquid with a barely detectable odor. It has a mechanism of action similar to glutaraldehyde, is stable and nonirritating, and for most uses is much faster acting than glutaraldehyde. It is effective against vegetative bacteria, including *Mycobacterium* and *Pseudomonas*, fungi, and viruses. Chief among its disadvantages are an inability to reliably destroy spores and a tendency to stain proteins, including those in human skin.

Formaldehyde is a sharp, irritating gas that readily dissolves in water to form an aqueous solution called **formalin**. Pure formalin is a 37% solution of formaldehyde gas dissolved in water. The chemical is microbicidal through its attachment to nucleic acids and functional groups of amino acids. Formalin is an intermediate- to

high-level disinfectant, but its extreme toxicity (it is classified as a carcinogen) and irritating effects on the skin and mucous membranes greatly limit its clinical usefulness.

Gaseous Sterilants and Disinfectants

Processing inanimate substances with chemical vapors, gases, and aerosols provides a versatile alternative to heat or liquid chemicals. Currently the vapors and aerosols having the broadest applications are ethylene oxide (ETO), propylene oxide, and chlorine dioxide.

Ethylene oxide (ETO) and its relative propylene oxide (PO) are colorless gases at room temperature. The structure of ETO is shown below:

ETO is very explosive in air, a feature that can be eliminated by combining it with a high percentage of carbon dioxide or fluorocarbon. Like the aldehydes, ETO is a very strong alkylating agent, and it reacts vigorously with functional groups of DNA and proteins. Through these actions, it blocks both DNA replication and enzymatic actions. Ethylene oxide is one of a very few gases generally accepted for chemical sterilization because, when employed according to strict procedures, it is a sporicide. A specially designed ETO sterilizer is equipped with a chamber, gas ports, and controls for temperature, pressure, and humidity (**figure 11.16**). Ethylene oxide is rather penetrating but relatively slow-acting, requiring from 90 minutes to 3 hours. Some items absorb ETO residues and must be aerated with sterile air for several hours after exposure to remove as much residual gas as possible. For all of its effectiveness, ETO has some unfortunate features. Its explosiveness makes it dangerous to handle; it

Figure 11.16 Sterilization using an ethylene oxide sterilizer. The machine is equipped with gas canisters containing ethylene oxide (ETO) and carbon dioxide, a chamber to hold items, and mechanisms that evacuate gas and introduce air.

can damage the lungs, eyes, and mucous membranes if contacted directly; and it is rated as a carcinogen by the government. Both ETO and propylene oxide are used mainly as disinfectant-sterilants for some foods and plastic items.

Chlorine dioxide is another gas used for sterilization. Despite the name, chlorine dioxide works in a completely different way from the chlorine compounds discussed earlier in the chapter. It is a strong alkylating agent, which disrupts proteins and is effective against vegetative bacteria, fungi, viruses, and endospores. Chlorine dioxide has mainly been used for the treatment of drinking water, wastewater, food-processing equipment, and medical waste, but it also has numerous applications in decontamination of rooms, buildings, and large spaces or objects.

Betapropiolactone (BPL) is a substance somewhat similar to ETO in applications. It is rapidly microbicidal when used as an aerosol or liquid to disinfect whole rooms and instruments, to sterilize bone and arterial grafts, and to inactivate viruses in vaccines.

A summary of applications for aldehydes and sterilizing gases is presented in **table 11.10**.

Chemicals with Surface Action: Detergents and Soaps

Detergents are polar molecules that act as surfactants. Most anionic detergents have limited microbicidal power. This includes most soaps. Much more effective are positively charged (cationic) detergents, particularly the **quaternary ammonium compounds** (usually shortened to *quats*). The activity of cationic detergents arises from the attachment of four organic radicals (the origin of the term quaternary) to a central, positively charged nitrogen atom. At least one of these radicals is a long-chain hydrocarbon surfactant that disrupts the cell membranes of sensitive microbes (see **table 11.11**). After a few minutes of contact, the cells burst and die.

The effects of detergents are varied. When used at high enough concentrations, quaternary ammonium compounds are effective against some gram-positive bacteria, viruses, fungi, and algae. In low concentrations, they exhibit only microbistatic effects. Drawbacks to the quats include their ineffectiveness against the tuberculosis bacterium, hepatitis virus, *Pseudomonas*, and spores at any concentration. Furthermore, their activity is greatly reduced in the presence of organic matter, and they require alkaline conditions to function. As a result of these limitations, quats are rated only for low to moderate-level disinfection in the clinical setting.

Soaps are alkaline compounds made by combining the fatty acids in oils with sodium or potassium salts. In usual practice, soaps alone are weak microbicides, and they destroy only highly sensitive forms such as the agents of gonorrhea, meningitis, and syphilis. The common hospital pathogen *Pseudomonas* is so resistant to soap that various species grow abundantly in soap dishes. Soaps function primarily as cleansing agents and sanitizers in industry, the home, and the medical setting. Combining germicides such as chlorhexidine or iodophor with soaps produces highly active antiseptics, degermers, and disinfectants. Vigorously brushing the hands with germicidal soap over a 15-second period can remove dirt, oil, and surface contaminants as well as some superficial

TABLE 11.10 Applications of Aldehydes and Sterilant Gases

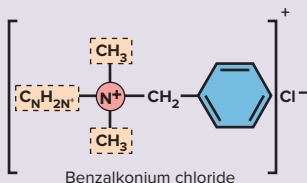

Form of Aldehyde	Primary Applications	How Delivered/Concerns
Glutaraldehyde	A sterilant for materials usually damaged by heat. Examples include respiratory therapy equipment, hemostats, fiberoptic endoscopes, kidney dialysis equipment, and dental instruments; an alternate vaccine preservative, and sanitizer for poultry carcasses.	Solutions diluted to 2% are relatively mild but require 2 to 4 hours' soaking. Usual commercial products are Cidex, Sporocidin. Instrument sterilization involves precleaning along with autoclaving to inactivate hepatitis B and other blood-borne viruses.
Ortho-phthalaldehyde (OPA)	High-level disinfectant similar in uses and effects to glutaraldehyde.	Faster acting and more stable than glutaraldehyde but less sporicidal.
Form of Gas	Primary Applications	How Delivered/Concerns
Ethylene Oxide (ETO)	An official sterilant for heat-sensitive plastics and delicate instruments in hospitals and industries—prepackaged medical supplies and disposable Petri dishes; used extensively to disinfect foods, spices, dried fruits, and drugs.	Carboxide and cryoxide are commercial products; gas is explosive and must be used with a stabilizer; ETO is rather toxic to humans; penetrating but slow, requiring 1 to 3 hours of exposure inside a special chamber.
Propylene Oxide	Sterilization of foods such as nuts, powders, starches, and spices.	Physical properties and mode of action similar to ETO but safer because it breaks down into a relatively harmless substance.
Chlorine Dioxide	Air and surface sterilant; for treatment of water, food-processing equipment, and medical waste; decontamination of whole rooms and space probes.	Similar in action to ETO but does not require a chamber; thus, effective for large spaces or objects.

Technician treats surgical instruments with glutaraldehyde prior to heat sterilization. (left): Courtesy of AirClean Systems

Examples of prepackaged medical supplies sterilized in an ethylene oxide sterilizer (right): Courtesy of Printpack, Inc.

TABLE 11.11 Applications of Detergents and Soaps

Form of Detergents or Soaps	Primary Applications	How Delivered/Concerns
Quaternary Ammonium Compounds (Quats)  Benzalkonium chloride	Mixed with cleaning agents to disinfect and sanitize floors, equipment surfaces, and restrooms; for sanitizing restaurant utensils, food-processing equipment, and clothing; common preservatives in ophthalmic solutions and cosmetics.	Names include benzalkonium chloride (Zephiran), the active ingredient in Lysol spray, and cetylpyridinium chloride (Ceepryn); in dilutions ranging from 1:100 to 1:1,000; the level of disinfection is too low for disinfecting medical instruments. Quats are active ingredients in many household disinfectant sprays.
Soaps 	Cleansing agents and sanitizers in industry and the home; preparing instruments for heat sterilization; degerming patients' skin, routine hand washing by medical and dental personnel, surgical and preoperative hand scrubbing. Proper hand washing with soap is one of the most important control methods for health care and personal hygiene. © OJO Images/SuperStock RF	Alkaline salts of fatty acids; weak germicides with superior sudsing and wetting properties; can remove large amounts of surface soil, grease, and other debris; antimicrobial chemicals added to make germicidal soaps with greater disinfection power.

CLINICAL CONNECTIONS

The Quest for Sterile Skin

About 140 years ago, before sterile gloves were a routine part of medical procedures, the hands remained bare during surgery. Even then, medical practitioners understood the risk for infections and attempted to “sterilize” the hands of surgeons and their assistants. Several stringent (and probably very painful) techniques involving strong chemical germicides and vigorous scrubbing were practiced. Here are a few examples.

In Schatz’s method, the hands and forearms were first cleansed by brisk scrubbing with liquid soap for 3 to 5 minutes, then soaked in a saturated solution of permanganate at a temperature of 110°F until they turned a deep mahogany brown. Next, the limbs were immersed in saturated oxalic acid until the skin became decolorized. Then, as if this were not enough, the hands and arms were rinsed with sterile limewater and washed in warm bichloride of mercury for 1 minute.

Park’s method was even more like torture. First the surfaces of the hands and arms were rubbed completely with a mixture of corn-meal and green soap to remove loose dirt and superficial skin. Next a paste of water and mustard flour was applied to the skin until it began to sting. This potion was rinsed off in sterile water, and the hands and arms were then soaked in hot bichloride of mercury for a few minutes, during which time the solution was rubbed into the skin.

Another method once earnestly suggested for getting rid of microorganisms was to expose the hands to a hot-air cabinet to “sweat the germs” out of skin glands. Pasteur himself advocated a quick flaming of the hands to maintain asepsis.

The old dream of sterilizing the skin was finally reduced to some basic realities: The microbes entrenched in the epidermis and skin glands cannot be completely eradicated even with the most intense efforts, and the skin cannot be sterilized without also seriously damaging it. Because this is true for both medical personnel and their patients, the chance always exists that infectious agents can be introduced

Heavy growth of microbial colonies on a plate of blood agar prepared by having a classroom of 30 students touch its surface. The result was a mixed population of bacteria and fungi, many of which could be pathogens (clear zones of hemolysis). © Kathy Park Talaro

during invasive medical procedures. Safer surgery had to wait until 1890, when rubber gloves first became available to place a sterile barrier around the hands. Of course, this did not mean that skin cleansing and antiseptic procedures were abandoned or downplayed. A thorough scrubbing of the skin with antiseptic soap is still needed to remove the most dangerous source of infections—the superficial contaminants constantly picked up from whatever we touch.

What would be some of the more serious problems associated with sterilizing or trying to sterilize the skin? *Answer available on Connect.*

resident microbes, but it is unable to remove those deeply entrenched in the skin (see **Clinical Connections**, “**The Quest for Sterile Skin**,” and **figure 11.17**).

See table 11.11 for coverage on the main uses of detergents and soaps.

Heavy Metal Compounds

Various forms of the metallic elements mercury, silver, gold, copper, arsenic, and zinc have been applied in microbial control over several centuries. These are often referred to as heavy metals because of their relatively high atomic weights. However, from this list, only preparations containing mercury and silver still have any significance as germicides. Although some metals (zinc, iron) are needed

Figure 11.17 Graph showing some effects of hand scrubbing.

Comparison of scrubbing over several days with a nongermicidal soap versus a germicidal soap. Germicidal soap has persistent effects on skin over time, reducing and keeping the microbial count low. Soap alone does not cause a sustained reduction in the microbial count, it even raises it. This effect is presumably due to the uncovering of skin layers with higher levels of normal residents.

Figure 11.18 Demonstration of the oligodynamic action of heavy metals. A pour plate inoculated with saliva has small fragments of heavy metals pressed lightly into it. During incubation, clear zones indicating growth inhibition developed around both fragments. The slightly larger zone surrounding the amalgam (used in tooth fillings) probably reflects the combined effect of the silver and mercury it contains. © Kathy Park Talaro

in small concentrations as cofactors on enzymes, the higher molecular weight metals (mercury, silver, gold) can be very toxic, even in minute quantities (parts per million). This property of having antimicrobial effects in exceedingly small amounts is called an **oligodynamic* action (figure 11.18)**. Heavy metal germicides contain either an inorganic or an organic metallic salt, and they come in the form of aqueous solutions, tinctures, ointments, or soaps.

Mercury, silver, and most other metals exert microbicidal effects by binding onto functional groups of proteins and inactivating them, rapidly bringing metabolism to a standstill (see figure 11.6c). This mode of action can destroy many types of microbes, including vegetative bacteria, fungal cells and spores, algae, protozoa, and viruses (but not endospores). A newer use of metals is their incorporation into medical supplies and hospital facilities. Silver is now added to catheters, IV lines, and prostheses to prevent biofilm formations and infections. Studies have demonstrated that copper has superior killing powers over chrome and aluminum when added to

* *oligodynamic* (ol^ə-ih-goh-dy-nam'-ik) Gr. *oligos*, little, and *dynamis*, power.

metal parts of lavatory fixtures, doors, and doorknobs. It destroys the most problematic drug-resistant pathogens such as MRSA, as well as *Clostridium difficile* vegetative cells, influenza virus, and gram-negative opportunists.

The main drawbacks to heavy metals are (1) metals (especially mercury) are very toxic to humans if ingested, inhaled, or absorbed through the skin, even in small quantities, for the same reasons that they are toxic to microbial cells; (2) they commonly cause allergic reactions; (3) large quantities of biological fluids and wastes neutralize their actions; and (4) microbes can develop resistance to metals.

Table 11.12 provides an overview of applications for heavy metals.

Dyes as Antimicrobial Agents

Dyes are important in staining techniques and as selective and differential agents in media; they are also a primary source of certain drugs used in chemotherapy. Their antimicrobial effects are apparently due to the way they insert into nucleic acids and cause mutations. There is also some evidence they can interfere with cell wall synthesis. Because aniline dyes such as crystal violet and malachite green are most active against gram-positive species of bacteria and some fungi, they are incorporated into solutions and ointments to treat skin infections (ringworm, for example). The yellow acridine dyes, acriflavine and proflavine, are sometimes utilized for antiseptics and wound treatment in medical and veterinary clinics. For the most part, applications for dyes will continue to be limited because dyes stain and have a narrow spectrum of activity.

Acids and Alkalis

Conditions of very low or high pH can destroy or inhibit microbial cells, but they are limited in applications due to their corrosive, caustic, and hazardous nature. Alkaline solutions are good for cleaning and some types of disinfection because they inactivate proteins. Ammonium hydroxide is a major component of detergents and cleansers, and a strong sodium hydroxide solution is one of the few substances that reliably destroys prions. Organic acids are widely used in food preservation because they prevent spore germination and bacterial and fungal growth and because they are generally regarded as safe to eat. Acetic acid (in the form of vinegar) is a pickling agent that inhibits bacterial growth; propionic acid is commonly

TABLE 11.12 Applications of Heavy Metals

Form of Metal	Primary Applications	How Delivered/Concerns
Organic Mercury	Thimerosal (Merthiolate) and nitromersol (Metaphen) are weak antiseptics and infection preventives; can be preservatives in cosmetics and ophthalmic solutions.	Tinctures (0.001% to 0.2%) are fairly effective but a poor choice for broken skin because they are toxic and can delay healing. Mercurochrome is now considered one of the poorest of antiseptics.
Silver Sulfadiazine Ointment	Added to dressings, it effectively prevents infection in second- and third-degree burn patients.	A yellow ointment containing silver salts and a sulfa drug.
Silver Nitrate (AgNO ₃)	Primarily as a topical germicide for mouth ulcers and occasionally root canals.	1% to 2% solutions have been used as antiseptics, but they discolor skin and other tissues.
Metallic Silver	Incorporated into catheters to prevent urinary tract infections in the hospital; added to paint, plastics, and steel as a way to control microbial survival on items such as toilet seats, stethoscopes, and even walls and floors in homes.	
Colloidal Silver	Mild germicidal ointments or rinses for the mouth, nose, eyes, and vagina.	

TABLE 11.13 Active Ingredients of Various Commercial Antimicrobial Products

Product	Specific Chemical Agent	Antimicrobial Category
Lysol and Clorox Sanitizing Wipes	Dimethyl benzyl ammonium chloride	Detergent (quat)
Tilex and Lysol Mildew Remover	Sodium hypochlorites	Halogen
Ajax and Dial Antibacterial Hand Soap	Triclosan	Phenolic
Lysol Disinfecting Spray	Alkyl dimethyl benzyl ammonium/ethanol	Detergent (quat)/alcohol
ReNu Contact Lens Solution	Polyaminopropyl biguanide	Chlorhexidine
Wet Ones Antibacterial Moist Towelettes	Benzethonium chloride	Detergent (quat)
Noxzema Triple Clean	Triclosan	Phenolic
Scope Mouthwash	Ethanol	Alcohol
Purell Instant Hand Sanitizer	Ethanol	Alcohol
Pine-Sol	Pine oil and surfactant	Aldehydes, alcohols
Allergan Eye Drops	Sodium chlorite	Halogen

incorporated into breads and cakes to retard molds; lactic acid is added to sauerkraut and olives to prevent growth of anaerobic bacteria (especially the clostridia); and benzoic and sorbic acids are added to beverages, syrups, and margarine to inhibit yeasts.

For a look at the antimicrobial chemicals found in some common household products, see **table 11.13**.

- What does it mean to say that a chemical has an oligodynamic action, and which compounds have this effect?

CASE STUDY Part 2

The preliminary investigations linked nine diagnosed cases and 115 possible cases of HCV to the facility. It was the largest outbreak of health-care-associated hepatitis ever reported. Not only were 63,000 clinic patients tested for HCV, all of them were directed to have additional tests for hepatitis B virus (HBV) and human immunodeficiency virus (HIV).

In the meantime, the big question was: What went wrong at the endoscopy center? Teams of epidemiologists reviewed the records on the days the patients had procedures. Essentially, their investigation identified four potential problem areas and possible modes of transmission: staff to patient; contaminated endoscopes, which have to be reused and sterilized be-

tween patients; techniques for inserting the IV ports; and the method of preparing syringes for sedation drugs.

First they tested all of the health care workers at the clinic for HCV, none of whom registered a positive result. The endoscopes were found to have been scrubbed with an enzymatic cleaner, soaked in glutaraldehyde for 30 minutes, and flushed with alcohol. Other equipment was either new and sterile or disinfected in the clinic. The IV lines were inserted in a standard fashion with sterile needles and syringes. Protocols for preparing drugs for sedation were not standardized, however, and varied among the RN-anesthetists who did the procedures.

A report was made about an RN-anesthetist who was observed taking out a second dose of a drug from a large, multi-dose vial using the same syringe that had been used to take the first dose, although he did replace the needle. It was common practice to store these partly used vials and reuse them on other patients.

In 2010 a judge awarded the claimants in a lawsuit the huge sum of \$500 million to be paid by the drug manufacturers and distributor for negligence in packaging of the drug. Several patients were awarded an additional \$500 million in a civil lawsuit against the health maintenance organization that hired the endoscopy clinic. In 2013 the owner and two assistants were tried and convicted on a number of charges, including criminal neglect and failure to report unsafe medical procedures. The owner was found guilty of second-degree murder, because two of the patients died from the effects of HCV infection, and was sentenced to 18 years in prison. He has since been found guilty of medical fraud, overbilling, and other federal charges.

- Why was it necessary to also test the patients for HBV and HIV?
- Why is it a mistake to use the same syringe, even with a new, sterile needle?

To conclude this Case Study, go to Connect.

Additional coverage of these topics can be found in chapter 13.

A summary of this case can be found at <http://www.cdc.gov/mmwr/preview/mmwrhtml/mm5719a2.htm>.

Chapter Summary with Key Terms

11.1 Controlling Microorganisms

- A. **Decontamination** procedures involve the destruction or removal of contaminants. Contaminants are defined as microbes present at a given place and time that are undesirable or unwanted.
- B. **Sterilization** is a process that destroys or removes all microbes, including viruses.
 1. A **bactericide** is a chemical that destroys vegetative stages of bacteria. A **sporicide** can destroy bacterial endospores.
 2. **Bacteriostatic** agents inhibit or prevent the growth of bacteria on tissues or on other objects in the environment.
 3. A **germicide** or **microbicide** is a chemical that will kill any pathogenic microorganisms.
- C. **Disinfection** refers to a physical or chemical process that destroys vegetative pathogens but not bacterial endospores on objects. An **antiseptic** is a chemical applied to living tissues to render them free of pathogens.
- D. **Sanitization** is forceful cleaning that removes contaminants and makes objects hygienic and safe to use. **Degermation** is the same process applied to the body to remove potential pathogens.
- E. Several factors influence the rate at which antimicrobial agents work. These factors are:
 1. Exposure time to the agent
 2. Numbers of microbes present
 3. Relative resistance of microbes (for example, endospores versus vegetative forms)
 4. Activity of the agent (microbicidal versus microbistatic)
- F. How antimicrobial agents work: their **modes of action**. Agents affect cell wall synthesis, membrane permeability, and protein and nucleic acid synthesis and function.

11.2 Physical Methods of Control: Heat

- A. **Moist heat** denatures proteins and DNA while destroying membranes.
 1. **Sterilization: Autoclaves** utilize steam under pressure (121°C) to sterilize heat-resistant materials, whereas intermittent sterilization uses steam at 100°C to sterilize more delicate items.
 2. **Disinfection: Pasteurization** subjects liquids to temperatures below 100°C and is used to lower the microbial load in liquids. Boiling water can be used to destroy vegetative pathogens in the home.
- B. **Dry heat**, using higher temperatures than moist heat, can also be used to sterilize.
 1. **Incineration** can be carried out using a Bunsen burner or incinerator. Temperatures range between 800°C and 6,500°C.
 2. **Dry ovens** operate at temperatures of 150°C to 180°C.
- C. Cold temperatures (refrigeration and freezing) are microbistatic and are commonly used to preserve food, media, and cultures.
- D. Drying and **desiccation** lead to (often temporary) metabolic inhibition by reducing water in the cell.

11.3 Physical Methods of Control: Radiation and Filtration

- A. **Radiation**: Energy in the form of **radiation** can be used for **cold sterilization**, which works by killing microbes without heat.
 1. **Ionizing radiation**, such as gamma rays and X rays, has deep penetrating power and works by causing breaks in the DNA of target organisms.

2. **Nonionizing radiation** uses **ultraviolet** waves with very little penetrating power and works by creating dimers between adjacent pyrimidines, which interferes with replication.

- B. **Using Filtration to Remove Microbes**: Filtration involves the physical removal of microbes by passing a gas or liquid through a fine filter, and can be used to sterilize air as well as heat-sensitive liquids.

11.4 Chemical Agents in Microbial Control

- A. Chemicals are divided into **disinfectants, antiseptics, sterilants, sanitizers, and degermers** based on their level of effectiveness and the surfaces to which they are applied.
- B. Antimicrobial chemicals are found as solids, gases, and liquids. Liquids can be either **aqueous** (water based) or **tinctures** (alcohol based).
- C. **Halogens** are chemicals based on elements from group VII of the periodic table.
 1. Chlorine gas, hypochlorites, and chloramines all work by disrupting disulfide bonds and, given adequate time, are sporicidal.
 2. Iodine compounds include free iodine (I₂) and **iodophors**. Iodine has a mode of action similar to chlorine and can also be sporicidal.
- D. **Phenolics** work by disrupting cell membranes and precipitating proteins. They are bactericidal, fungicidal, and virucidal but not sporicidal. Bisphenols are mild forms for disinfection and antiseptics.
- E. **Chlorhexidine** (Hibiclens, Hibitane) is a surfactant and protein denaturant with broad microbicidal properties, although it is not sporicidal. Solutions of chlorhexidine are used as skin degerming agents for preoperative scrubs, skin cleaning, and burns.
- F. Ethyl and isopropyl **alcohol**, in concentrations of 50% to 90%, are useful for microbial control. Alcohols act as **surfactants**, dissolving membrane lipids and coagulating proteins of vegetative bacterial cells and fungi. They are not sporicidal.
- G. **Hydrogen peroxide** produces highly reactive hydroxyl free radicals that damage protein and DNA while also decomposing to O₂ gas, which is toxic to anaerobes. Strong solutions of H₂O₂ are sporicidal.
- H. Aldehydes such as **glutaraldehyde** kill microbes by alkylating protein and DNA molecules and can be used as sterilants.
 - I. Gases and aerosols such as **ethylene oxide (ETO)**, propylene oxide, and chlorine dioxide are strong alkylating agents, all of which are sporicidal.
- J. **Detergents and soaps**
 1. Cationic detergents known as **quaternary ammonium compounds (quats)** act as surfactants that alter the membrane permeability of some bacteria and fungi. They are not sporicidal.
 2. Soaps function by removing grease and soil that contain microbes.
- K. **Heavy metals**: Compounds containing silver or mercury kill vegetative cells (but not spores) despite being highly diluted (**oligodynamic action**) by inactivating proteins.
- L. **Dyes, acids, and alkalis** can also inhibit or destroy microbes but are limited in use.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

- A microbicidal agent has what effect?
 - sterilizes
 - inhibits microorganisms
 - is toxic to human cells
 - destroys microorganisms
- Microbial control methods that kill _____ are able to sterilize.
 - viruses
 - the tubercle bacillus
 - endospores
 - cysts
- Any process that destroys the non-spore-forming contaminants on inanimate objects is
 - antisepsis
 - disinfection
 - sterilization
 - degermation
- Sanitization is a process by which
 - the microbial load on objects is reduced
 - objects are made sterile with chemicals
 - utensils are scrubbed
 - skin is debrided
- An example of an agent that lowers the surface tension of cells is
 - phenol
 - chlorine
 - alcohol
 - formalin
- High temperatures _____ and low temperatures _____.
 - sterilize, disinfect
 - kill cells, inhibit cell growth
 - denature proteins, burst cells
 - speed up metabolism, slow down metabolism
- The primary action of _____ heat is to _____.
 - dry, destroy cell walls
 - moist, kill vegetative cells
 - dry, dissolve lipids
 - moist, denature proteins
- The standard temperature-pressure combination for an autoclave is
 - 100°C and 4 psi
 - 121°C and 15 psi
 - 131°C and 9 psi
 - 115°C and 3 psi
- Microbe(s) that is/are the target(s) of pasteurization include(s)
 - Clostridium botulinum*
 - Mycobacterium* species
 - Salmonella* species
 - both b and c
- Ionizing radiation like _____ removes _____ from atoms.
 - UV, protons
 - X-rays, the charge
 - gamma rays, electrons
 - cathode rays, ions
- The primary mode of action of nonionizing radiation is to
 - produce superoxide ions
 - make pyrimidine dimers
 - denature proteins
 - break disulfide bonds
- The most versatile method of sterilizing heat-sensitive liquids is
 - UV radiation
 - exposure to ozone
 - beta propiolactone
 - filtration
- _____ is the iodine antiseptic of choice for wound treatment.
 - 8% tincture
 - 5% aqueous
 - 5% Iodophor
 - 7.5% potassium iodide solution
- A chemical with sporicidal properties is
 - phenol
 - alcohol
 - quaternary ammonium compound
 - glutaraldehyde
- Silver sulfadiazine is used
 - in antisepsis of burns
 - as a mouthwash
 - to treat genital gonorrhea
 - to disinfect water
- Detergents are
 - high-level germicides
 - surfactants
 - excellent antiseptics
 - used in disinfecting surgical instruments
- Which of the following is an approved sterilant?
 - chlorhexidine
 - betadyne
 - ethylene oxide
 - ethyl alcohol

Case Study Review

- How would one best describe the state of being a *carrier* of HCV?
 - It is on the skin and transmitted through direct contact.
 - The person shows symptoms and is jaundiced.
 - The person has a chronic infection of the liver and harbors the virus.
 - The person has had contact with blood in a medical setting.
- The main issue in the case of clinic-acquired HCV infections was:
 - use of unclean equipment
 - a high number of carriers
 - contamination of drugs
 - health workers who were IV drug abusers
- Outline the chain of events involved in the transmission of HCV from an infected patient to several other patients through the actions of a medical worker.

 **Writing Challenge**

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

1. What is wrong with this statement: “Prior to vaccination, the patient’s skin was sterilized with alcohol”? What would be the more correct wording?
2. Would it be proper to say that a patient has been disinfected? Why or why not?
3. Why are antimicrobials inhibited in the presence of organic matter?
4. Think of three situations in which the same microbe would be considered a serious contaminant in one case and completely harmless in another.
5. Explain what features of endospores make them so resistant to microbial control, and what sterilizing techniques could destroy them.
6. Explain some of the problems involved in sterilizing delicate and heat-sensitive instruments such as endoscopes, syringes, needles, catheters, and other instruments.
7. The shelf life and keeping qualities of fruit and other perishable foods are greatly enhanced through irradiation, saving industry and consumers billions of dollars. How would you personally feel about eating irradiated fruit? How about spices that had been sterilized with ETO?

 **Concept Mapping**

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps and a sample of a concept map for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

 **Critical Thinking**

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

1. For each item on the following list, propose a reasonable method of sterilization. You cannot use the same method more than three times for the whole list. The method must sterilize, not just disinfect; and the method must not destroy the item or render it useless unless there is no other choice. After considering a workable method, think of a method that would not work. Note: Where an object containing something is given, you must sterilize everything (for example, both the jar and the petroleum jelly [Vaseline] in it). Some examples of sterilizing methods are autoclave, ethylene oxide gas, dry oven, and ionizing radiation.

room air	disposable syringes
serum	carcasses of cows with “mad cow” disease
a pot of soil	inside of a refrigerator
plastic Petri dishes	wine
heat-sensitive drugs	a jar of Vaseline
cloth dressings	fruit in plastic bags
leather shoes from a thrift shop	milk
a cheese sandwich	orchid seeds
a flask of nutrient agar	metal instruments
an entire room (walls, floor, etc.)	mail contaminated with anthrax spores
rubber gloves	
2. Using pasteurization techniques as a model, compare the TDTs and explain the relationships between temperature and length of exposure.
3. It may seem contradictory that lyophilization can be used to preserve foods yet also be used to keep cultures of microbes viable. Explain how these applications can be reconciled.
4. A supermarket/drugstore assignment: Look at the labels of 10 different products used to control microbes, and make a list of their active ingredients, their suggested uses, and information on toxicity and precautions.
5. Devise an experiment that will differentiate between bactericidal and bacteriostatic effects.
6. There is quite a bit of concern that chlorine used as a water purification chemical presents serious dangers. What alternative methods covered by this chapter could be used to purify water supplies and keep them safe from contamination?
7. Was the source patient in the case study most likely acutely or chronically infected? Explain.
8. Explain why surfactant chemicals are more effective against gram-negative bacteria than against gram-positive bacteria.

 Visual Challenge

1. From **chapter 2, figure 2.20**. Study this illustration of a cell membrane. In what ways could alcohol damage this membrane? How would that harm the cell?

2. Explain what is happening with this graph that charts the reactions of a mesophilic bacterium to temperature. Blue shows the survival curve and brown the growth curve under various temperatures.

CASE STUDY Part 1 An Ounce of Prevention and a Pound of Cure

Joan Mitchell, a 48-year-old registered nurse, had safely removed needles from intravenous **catheters** hundreds of times, yet all of those years of care and experience seemed to evaporate in an instant. The needle accidentally jabbed with some force into her arm. She immediately reported it and began the **standard precautions** for a **needlestick**. She washed the site of the laceration with water and **Betadine**, as indicated by hospital protocol.

Needlesticks are a regular occurrence in hospitals and clinics, and usually the greatest concern is the possibility of **infectious agents** being carried by the offending needle. Unfortunately for Nurse Mitchell, the patient had been suffering from **acquired immune deficiency syndrome (AIDS)** caused by **human immunodeficiency virus (HIV)**. Within 2 hours it was necessary for her to begin a regimen of **anti-HIV drugs** that are routinely given for **postexposure prophylaxis**. The drug chosen was a combination of lamivudine and zidovudine (Combivir), a pill containing two different **reverse transcriptase inhibitors**. She was tested right away for HIV to establish a baseline for the possibility of a prior infection, and the result was negative.

Despite treatment, the AIDS patient died unexpectedly a few days later of respiratory failure apparently from **Pneumocystis pneumonia**. Unfortunately his medical history did not indicate other

infections he may have had, and this lack of information turned the next several weeks into a nightmare for the nurse. She was supposed to take the Combivir for 6 weeks, but it caused **severe side effects**, including nausea, headache, muscle pain, weakness, abdominal pain, and rash. She discontinued taking it after 2 weeks with the hope that it had succeeded in preventing the HIV from infecting her.

During the next month, the site of Nurse Mitchell's injury became **abscessed** and painful, and she suffered from a **fever** up to 102°F. Because the wound was obviously infected, her doctor **biopsied** it and had routine **bacterial** and **fungal cultures** made, but they came back negative. The course of **dicloxacillin** she was taking did not seem to be working. A sign that the infection was spreading came in the form of an **enlarged lymph node** in her armpit.

“The needle accidentally jabbed with some force into her arm.”

- What is meant by prophylactic drug treatment, and what are its purposes?
- Why is it necessary for two drugs to be given in the Combivir treatment?

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

SCOPING OUT THE CHAPTER

Modern antimicrobial drugs have revolutionized medical treatment. Literally billions of lives have been saved since they were first introduced 80 years ago. Having an effective drug to treat most infectious diseases is now expected, whether bacterial, viral, fungal, protozoan, or helminth. Though we may take this availability for granted, there are numerous factors that complicate their use. In this chapter we will explore “the good, the bad, and the ugly” elements of antimicrobial drug therapy.

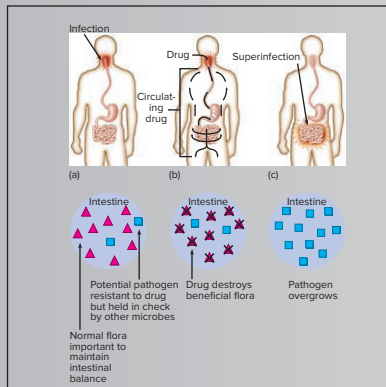

Drug Discovery Antimicrobial drugs come from many sources. Most of them, called antibiotics, are produced by certain bacteria or fungi, others are synthesized through chemical reactions alone, and some are made by combining the two methods.

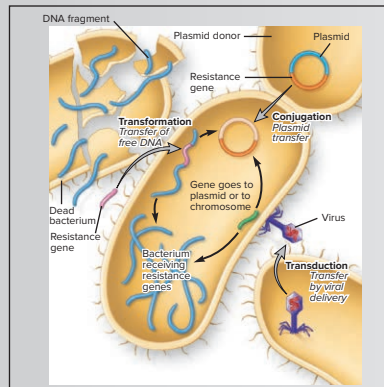

Do No Harm: Selective Toxicity Antibiotic literally means “against life”, but the actual intention of these drugs is to target only microbial life. This is a very important guiding principle—that drugs do not harm humans while they are getting rid of the infectious agent.

How Antimicrobial Drugs Stop Infections Drugs are chemicals that can interfere with some specific microbial structure or function such as the cell wall, cell membrane, proteins, DNA, RNA, ribosomes, or metabolic pathways. While in contact with the drug, the microbes are either destroyed or severely inhibited and can no longer grow.

Toxicity and Other Side Effects The promise of antimicrobial therapy is spoiled by the numerous possibilities of adverse side effects. Drugs can harm body tissues and organs, disrupt the normal microbiota that help keep a balance in the body's organs, and induce allergies and hypersensitivities.

The Global Race Against Drug Resistance Microbes are very adept at rapidly altering their physiology and genetics to adapt to drugs, making them less effective. They may develop enzyme systems that dismantle the drugs, block the drug's entrance, expel the drugs, or use an alternate pathway that bypasses the drug's effects.

Choosing an Appropriate Drug Selection of an effective drug is guided by several factors. Among the most important considerations are the nature of the infectious agent, knowing which drugs it is sensitive to, the possible side effects of the drug, and the medical condition of the patient.

12.1 Principles of Antimicrobial Therapy

Expected Learning Outcomes

1. State the goals of antimicrobial therapy.
2. Discuss the origins of antimicrobial drugs.
3. Differentiate between antibiotics, synthetic drugs, and semisynthetic drugs.
4. Describe some of the special strategies of antimicrobial therapy.
5. Explain what is meant by a drug's spectrum and how narrow- and broad-spectrum drugs differ.
6. Summarize the five modes of action of antimicrobial drugs, with specific examples of their effects.

More than a century ago in the United States, one out of three children was expected to die of an infectious disease before the age of 5. Early death or severe lifelong debilitation from scarlet fever, diphtheria, tuberculosis, meningitis, and many other bacterial diseases was a fear-some yet undeniable fact of life to most of the world's population.

The introduction of modern drugs to control infections in the 1930s was a medical revolution that has added significantly to the life span and health of humans. It is no wonder that for many years, antibiotics in particular were regarded as miracle drugs. In later discussions, we evaluate this misconception in light of the shortcomings of drug therapy. Although antimicrobial drugs have greatly reduced the incidence of certain infections, they have definitely not eradicated infectious disease and probably never will. In fact, in some parts of the world, mortality rates from infectious diseases are as high as before the arrival of antimicrobial drugs. Nevertheless, humans have been taking medicines to try to control diseases for thousands of years (**12.1 Making Connections**).

The goal of **antimicrobial chemotherapy**¹ is deceptively simple: administer to an infected person a drug that destroys the infectious agent without harming the host's cells. In actuality this goal is rather difficult to achieve, because many often-contradictory factors must be taken into account. The ideal drug should be easily administered and able to reach the infectious agent anywhere in the body. It should be able to kill the infectious agent rather than merely inhibit its growth, and remain active in the body as long as needed, yet be safely and easily broken down and excreted. In short, the perfect drug does not exist, but by balancing drug characteristics against one another, a satisfactory compromise can usually be achieved (**table 12.1**).

The Origins of Antimicrobial Drugs

Modern antimicrobial drugs are highly varied in their origins. The type of drugs traditionally termed **antibiotics** are substances produced by the natural metabolic processes of certain microorganisms that can inhibit or destroy other microorganisms (**figure 12.1a**).

1. The word *chemotherapy*, meaning the use of chemicals in therapy, is often associated with the treatment of cancer, but its official meaning also includes antimicrobial treatment.

TABLE 12.1 Characteristics of the Ideal Antimicrobial Drug

- Selectively toxic to the microbe but nontoxic to host cells
- Microbicidal rather than microbistatic
- Remains potent long enough to act and is not broken down or excreted prematurely
- Is not subject to the development of antimicrobial resistance
- Complements or assists the activities of the host's defenses
- Remains active even when diluted in body fluids and tissues
- Readily delivered to the site of infection
- Reasonably priced
- Does not disrupt the host's health by causing allergies or predisposing the host to other infections

(a)

Figure 12.1 (a) Mining for antibiotic-producing microbes. One strategy is to seed a plate with a sample (here, soil) and then spray its surface with a fine mist of a bacteria and incubate it. Zones of inhibition (clear areas with no growth) surrounding several colonies indicate colonies that produce antibiotics. (b) Two colonies with antibiotic secretions on their surfaces. Left is *Penicillium chrysogenum*, with yellow droplets of penicillin; right is *Streptomyces coelicolor*, with blue droplets of actinorhodin, an experimental antibiotic. This release of the antibiotics is an important factor in the isolation and production of the drugs. (a, b left) © Kathy Park Talaro; (b right) Photo courtesy of Dr. Ramón Santamaría/IMB. CSIC/USAL. Salamanca, Spain

12.1 MAKING CONNECTIONS

From Witchcraft to Wonder Drugs

Early human cultures relied on various types of primitive medications concocted from plant, animal, and mineral products that had been found, usually through trial and error or accident, to have some curative effect upon ailments. In one ancient Chinese folk remedy, a fermented soybean curd was applied to skin infections. The Greeks used wine and plant resins (myrrh and frankincense), rotting wood, and various mineral salts to treat diseases. Some folk medicines were effective, but others either had no effect or were harmful. It is interesting that the Greek word *pharmakeutikos* originally meant the practice of witchcraft. These ancient remedies were handed down from generation to generation, but it was not until the Middle Ages that a specific disease was first treated with a specific chemical. Dosing syphilitic patients with inorganic arsenic and mercury compounds may have proved the ancient axiom: *Graviora quaedam sunt remedia periculus* (“Some remedies are worse than the disease”).

In the late 1800s Paul Ehrlich was the first scientist to formulate basic theoretical concepts in chemotherapy. Ehrlich had observed that certain dyes affixed themselves to specific microorganisms and not to animal tissues. This observation led to the profound idea that if a drug was properly selective in its actions, it would zero in on and destroy a microbial target and leave human cells unaffected. His first discovery was an arsenic-based drug that was very toxic to the spirochete of syphilis but, unfortunately, was toxic to humans as well. After 606 attempts he arrived at a compound he called *salvarsan*. This drug had some therapeutic merit and was used for a few years, but it eventually had to be discontinued because it was still not selective enough in its toxicity. Ehrlich’s work had laid important foundations for many of the developments to come.

Another pathfinder in early drug research was Gerhard Domagk, whose discoveries in the 1930s launched a breakthrough in therapy that marked the true beginning of broad-scale usage of antimicrobial drugs. Domagk showed that the red dye prontosil was chemically changed by the body into a compound with specific activity against bacteria. This substance was sulfonamide—the first *sulfa* drug. Once the structure of this drug was determined, it became possible to synthesize it on a wide scale and to develop scores of other sulfonamide drugs. Although these drugs had immediate applications in therapy (and still do), still another fortunate discovery ushered in the “age of antibiotics.”

The discovery of antibiotics dramatically demonstrates how developments in science and medicine often occur through a combination of accident, persistence, collaboration, and vision. In 1928 in the London laboratory of Sir Alexander Fleming, a plate of *Staphylococcus aureus* became contaminated with the mold *Penicillium (notatum) chrysogenum* (see figure 12.1). Observing these plates, Fleming noted that the colonies of *Staphylococcus* were evidently being destroyed by some

A pioneer in the discovery of antibiotics. A Scottish physician, Sir Alexander Fleming, accidentally discovered penicillin in a culture plate contaminated with mold. From this mold he extracted the antibiotic, setting the scene for the development of the drug 10 years later. © Davies/Getty Images

activity of the nearby mold colonies. Struck by this curious phenomenon, he extracted from the fungus a compound he called penicillin and showed that it was responsible for the inhibitory effects.

A decade after his discovery, English chemists Howard Florey and Ernst Chain worked out methods for industrial production of penicillin to help in the war effort. Clinical trials conducted in 1941 ultimately proved penicillin’s effectiveness, and by 1945 the drug had been used to save hundreds of thousands of lives. This event paved the way for an era of drug research and development that soon made penicillin only one of a large assortment of antimicrobial drugs. But in time, because of extreme overuse and misunderstanding of its capabilities, penicillin also became the model for one of the most serious drug problems—namely, drug resistance.

Once the first significant antibiotic was developed, the world immediately witnessed a scientific scramble to find more. Hundreds of investigators began searching for antibiotic-producing bacteria and fungi by screening of samples from soil, dust, muddy lake sediments, rivers, oceans, plant surfaces, compost heaps, sewage, skin, and even the hair and skin of animals. Finding a new antimicrobial substance is only a first step. The complete pathway of drug development from discovery to therapy can take more than a dozen years and cost several billion dollars.

Name some potential “therapies” you could employ to prevent and treat infections if you were a castaway on a desert island. *Answer available on Connect.*

Nature is a prolific producer of antimicrobial drugs. Many thousands of antibiotics have been discovered (although, surprisingly, only a relatively small number have actually been used clinically). Antibiotics are made primarily by aerobic spore-forming bacteria and fungi. The antibiotics appear to have some survival value for these microbes, because the genes for antibiotic production are preserved in evolution. Some experts theorize that microorganisms synthesize antibiotics to inhibit or destroy nearby competitors or

predators (antagonism); others propose that antibiotics are connected to the formation of spores.

The greatest numbers of antibiotics are derived from bacteria in the genera *Streptomyces* and *Bacillus* and molds in the genera *Penicillium* and *Cephalosporium* (figure 12.1b and table 12.2). Of these, species of *Streptomyces* are the most fertile producers. Nearly 9,000 different bioactive compounds have been isolated from them, and they are currently the source of one-third of all prescribed antibiotics.

TABLE 12.2 Selected Microbial Sources of Antibiotics

Producer Genus	Type of Microbe	Drugs Formed
<i>Penicillium</i>	Mold	Penicillins Griseofulvin
<i>Cephalosporium</i>	Mold	Cephalosporins
<i>Micromonospora</i>	Bacteria	Gentamicin
<i>Bacillus</i>	Bacteria	Bacitracin Polymyxin B
<i>Chromobacterium</i>	Bacteria	Aztreonam
<i>Streptomyces</i>	Filamentous bacteria	Streptomycin Erythromycin Tetracycline Vancomycin Chloramphenicol Amphotericin B

The pharmaceutical industry has harnessed the power of these microbes by growing them in vast quantities and harvesting their products to be sold as drugs. Researchers have facilitated the work of nature by selecting mutant species that yield more abundant or effective products, by varying the growth medium, or by altering the procedures for large-scale industrial production.

A few classes of antimicrobial drugs, termed **synthetic**, are not considered antibiotics because they are synthesized entirely through chemical processes and not secreted by microorganisms. Synthetic drugs include sulfa drugs, quinolones (ciprofloxacin), quinines, azoles and most antiviral drugs.

Probably the most common approach to drug production is the **semisynthetic** method, combining both natural and synthetic methods. Think of it as improving on nature by using chemical reactions to combine the basic antibiotic made by microorganisms with various preselected functional groups that tailor the action of the drug. Drugs produced in this way are designed to have new and improved functions over the original antibiotic. We can see examples of this technology in the design of the semisynthetic penicillins (see figure 12.7), cephalosporins and tetracyclines. The potential for using bio-engineering techniques to design drugs seems almost limitless, and, indeed, several drugs have already been produced by manipulating the genes of antibiotic producers.

Antimicrobial drugs can be organized by their origin, range of effectiveness, and whether they are naturally produced or chemically synthesized. A few of the more important terms you will encounter are found in **table 12.3**.

Common Drug Strategies

You will encounter the terms **prophylaxis**, **combined therapy**, and drug **synergy** in several areas of this chapter. Each idea has its own special niche in drug therapy. With prophylaxis, drugs are administered to *prevent* an infection from happening. This is brought into play in cases of known or possible exposure. For example, certain dental patients are often pretreated with antibiotics prior to instrument procedures that could leak saliva into the bloodstream.

TABLE 12.3 Terminology of Chemotherapy

Chemotherapeutic drug	Any chemical used in the treatment, relief, or prophylaxis of a disease.
Prophylaxis*	Use of a drug to prevent potential for infection in a person at risk.
Antimicrobial chemotherapy*	The use of chemotherapeutic drugs to control infection
Antimicrobials	All-inclusive term for any antimicrobial drug, regardless of its origin
Antibiotics*	Substances produced by the natural metabolic processes of some microorganisms that can inhibit or destroy other microorganisms
Semisynthetic drugs	Drugs that are chemically modified in the laboratory after being isolated from natural sources
Synthetic drugs	Antimicrobial compounds synthesized entirely in the laboratory through chemical reactions
Narrow spectrum (limited spectrum)	Antimicrobials effective against a limited array of microbial types; for example, a drug effective mainly on gram-positive bacteria
Broad spectrum (extended spectrum)	Antimicrobials effective against a wide variety of microbial types; for example, a drug effective against both gram-positive and gram-negative bacteria

* **prophylaxis** (proh"-fih-lak'-sis) Gr. *prophylassein*, to keep guard before. A process that prevents infection or disease in a person at risk.

* **chemotherapy** (kee"-moh-ther'-uh-pee) Gr. *chemieia*, chemistry, and *therapeia*, service to the sick. Use of drugs to treat disease.

* **antibiotic** (an-tee'-by-aw"-tik) Gr. *anti*, against, and *bios*, life.

Combined therapy, also known as combination therapy, is a protocol for taking at least two drugs at a time to treat an infection. This is the usual method of treatment for tuberculosis, HIV/AIDS, and gonorrhea. Its main rationale is to prevent the survival of drug-resistant microbes, but it is also used for treating mixed infections by microbes that differ in the correct drug of choice.

Another advantage comes from the synergistic effect that two drugs working together can often provide. Synergy can produce an improved result over either drug used alone, and this enhanced effectiveness means that smaller quantities of the drugs can be used. Figure 12.18b shows a test result for this effect.

Interactions Between Drugs and Microbes

The goal of antimicrobial drugs is either to disrupt the cell processes or structures of bacteria, fungi, and protozoa or to inhibit the virus multiplication cycle. Most of the drugs used in chemotherapy interfere with the function of enzymes required to synthesize or assemble macromolecules, but a few destroy structures already formed in the cell. Above all, drugs should be **selectively toxic**, which means they can kill or inhibit the growth of microbes without simultaneously damaging host tissues. This concept of selective toxicity is central to chemotherapy. The best drugs are those that act

TABLE 12.4 General Actions of Drugs on Microbial Groups

Microbe Type	Drug Groups/ Examples	Effects of Drugs	Microbe Type	Drug Groups/ Examples	Effects of Drugs
Bacteria	Penicillins	Cell wall damage and lysis	Fungi	Amphotericin B	Loss of membrane permeability
	Cephalosporins	Cell wall damage and lysis		Azoles	Loss of membrane permeability
	Bacitracin	Cell wall damage and lysis		Flucytosine	Inhibits DNA and RNA synthesis
	Aminoglycosides	Inhibit ribosomal protein synthesis	Protozoa	Quinines	Buildup of toxic wastes in the parasite's cells
	Macrolides	Inhibits ribosomal protein synthesis		Metronidazole	Buildup of toxic free radicals
	Erythromycin		Helminths	Benzazoles	Inhibit glucose metabolism
	Vancomycin	Cell wall damage and lysis		Diethylcarbamide	Kills larval forms
	Tetracyclines	Inhibit protein synthesis on ribosomes		Piperazine	Paralyzes muscular system
	Chloramphenicol	Inhibits protein synthesis on ribosomes		Niclosamide	Loosens worm hold
	Fluoroquinolones	Block replication of DNA		Ivermectin	Inhibits neuromuscular system
	Rifampin	Stops mRNA synthesis	Viruses	Oseltamivir	Prevents viral budding

Trimethoprim	Inhibits folic acid metabolism	Azidothymidine		Blocks formation of DNA from RNA strand	

specifically on microbial structures or functions not found in vertebrate cells. Examples of drugs with excellent selective toxicity are those that block the synthesis of the cell wall in bacteria (penicillins). They have low toxicity and few direct effects on human cells, because human cells lack a cell wall and are thus unaffected by this action of the antibiotic. Among the most toxic to human cells are drugs that act upon a structure common to both the infectious agent and the host cell, such as the cell membrane (for example, amphotericin B used to treat fungal infections). As the characteristics of the pathogen become more similar to those of the host cell, selective toxicity becomes more difficult to achieve and undesirable side effects are more likely to occur. We will cover the subject of toxicity in section 12.5.

Mechanisms of Drug Action

The primary basis of chemotherapy is to target an infectious agent with a chemical that irreversibly damages or inhibits it. This knowledge guides drug development as well. Most classes of antimicrobial drugs are active against some unique feature of microbial structure or metabolism. Observe **table 12.4** and take note of the diversity of cell types and possible effects of drug action. Overall, there are five major components that are useful drug targets in an actively dividing cell. These are the cell wall, the cell membrane, the genetic material, protein synthesis, and metabolic pathways. We cover the effects of drugs on these cell components based on **figure 12.2** and this outline:

1. inhibition of cell wall synthesis,
2. breakdown of the cell membrane structure or function,
3. interference with functions of DNA and RNA,
4. inhibition of protein synthesis, and
5. blockage of key metabolic pathways.

These targets are not completely discrete, and some have overlapping effects. For example, if DNA transcription is inhibited, protein

synthesis will be as well. Viruses are a special case and have very specialized targets for drugs (see **table 12.6**).

The Spectrum of an Antimicrobial Drug One result of drugs acting upon a particular microbial structure or function is that each drug has a given range of activity. This has been termed the drug's **spectrum**. Traditionally, **narrow-spectrum** drugs are effective over a limited range of cell types. This is usually because they target a specific component that is found only in certain bacteria. For instance, bacitracin blocks the elongation of the peptidoglycan in gram-positive bacteria but has no effect on most gram-negative bacteria because of the outer membrane on their cell wall that serves as a barrier to the drug. Polymyxin breaks down the outer membrane on gram-negative cells but does not target gram-positive cells because they lack this structure.

Drugs that are effective against a wider range of microbes are termed medium or broad spectrum, depending on the particular drug. For example, the **medium-spectrum** drug ampicillin is effective on both gram-positive and gram-negative bacteria, but not a wide range of them. **Broad-spectrum** drugs, such as tetracycline, have the greatest range of activity. They work on most gram-negative and gram-positive bacteria, rickettsias, mycoplasmas, and spirochetes. The broad-spectrum drugs usually exert their effects on common cell components such as ribosomes, which are found in all cells and mitochondria. Consult **table 12.5** to see an array of antibacterial drugs and their spectra.

1. Antimicrobial Drugs That Affect the Bacterial Cell Wall

The cell walls of most bacteria contain a rigid girdle of peptidoglycan, which protects the cell against rupture from hypotonic environments. Active cells must constantly synthesize new peptidoglycan and transport it to its proper place in the cell envelope. Drugs such as penicillins and cephalosporins react with one or more of the

Figure 12.2 Major targets of drugs acting on bacterial cells. Each mode of action correlates with the numbered section where it is discussed in the text.

Spectrum of Action	Gram-Positive Bacteria	Gram-Negative Bacteria	Rickettsias	Chlamydias	Mycoplasmas	Examples of Drugs with This Spectrum
Broad	+	+	+	+	+	Tetracyclines Quinolones Chloramphenicol Doripenem
Intermediate	+	+	-	V*	V*	Ampicillin Cephalexin (Keflex) Sulfa/trimethoprim Macrolides (erythromycin)
Narrow Group 1	+	-*	-	-	-	Penicillin G, V Vancomycin Bacitracin Rifampin Isoniazid (for TB)
Narrow Group 2	-	+	-	-	-	Polymyxin Streptomycin Cefaclor Aztreonam

*Some drugs in the list are effective on these microbes.

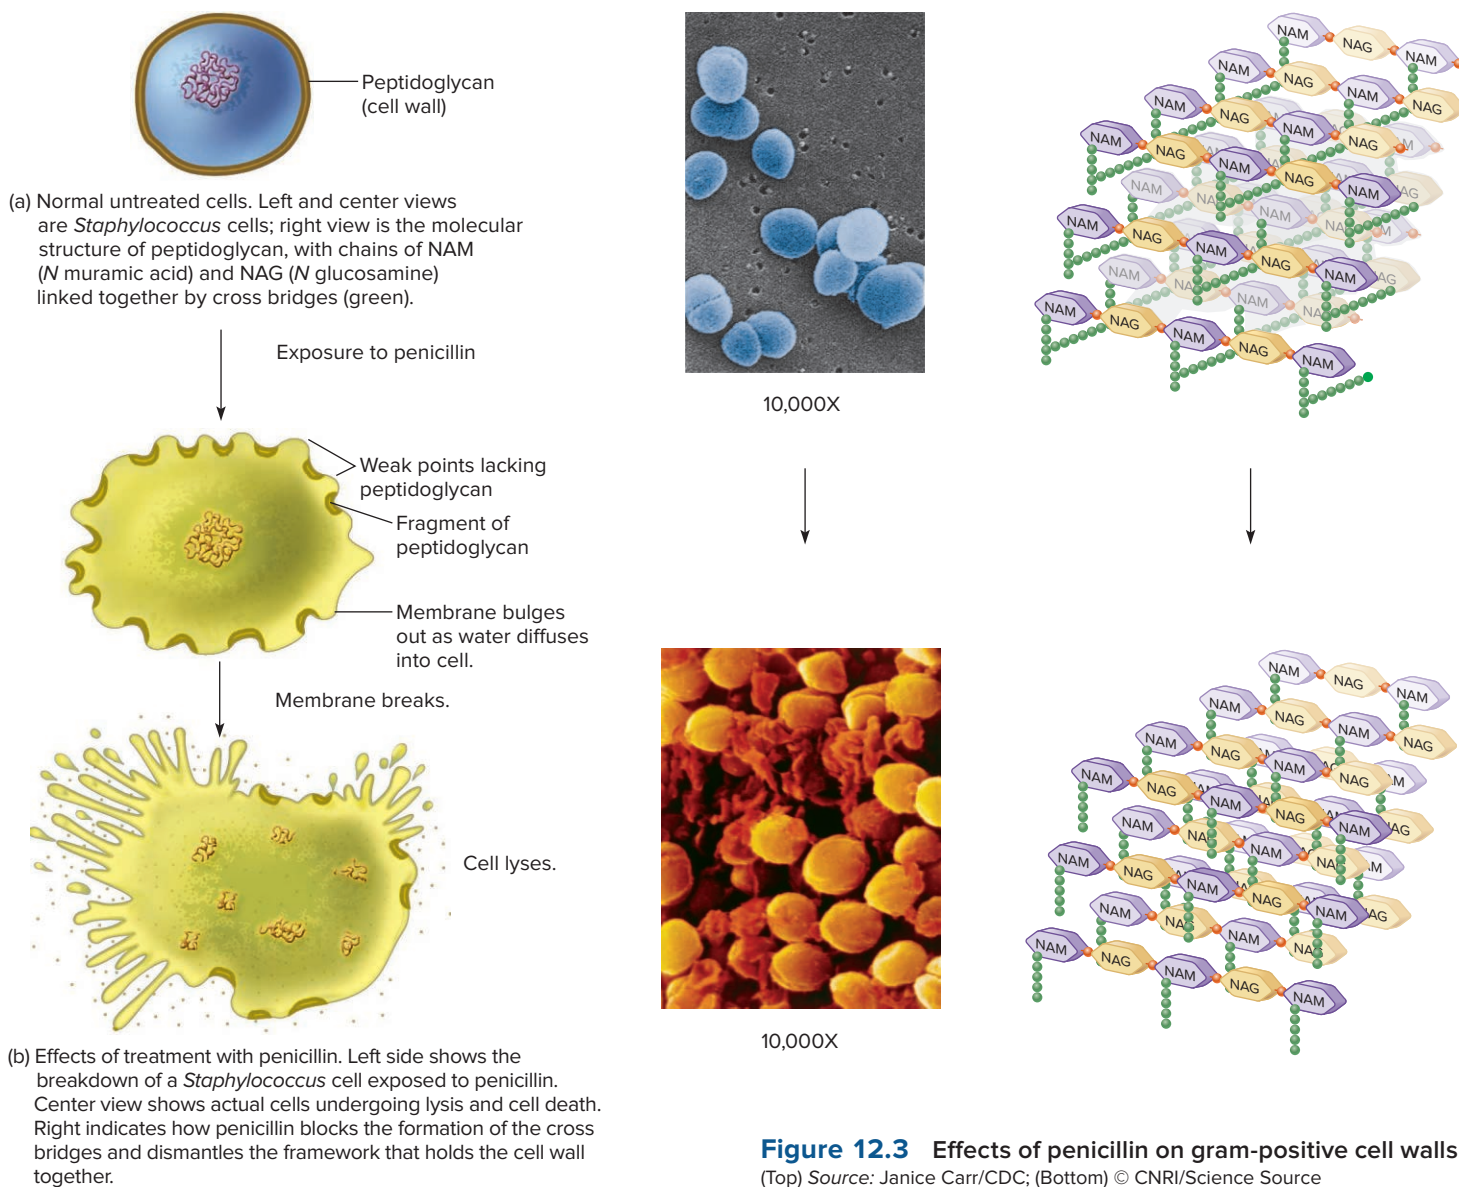

Figure 12.3 Effects of penicillin on gram-positive cell walls.

(Top) Source: Janice Carr/CDC; (Bottom) © CNRI/Science Source

enzymes required to complete this process, causing the cell to develop weak points at growth sites and to become osmotically fragile (**figure 12.3**). Antibiotics that produce this effect are considered bactericidal, because the weakened cell usually undergoes **lysis**. However, cells that are old, inactive, or dormant and are not synthesizing peptidoglycan may resist these effects. (One exception is a class of antibiotics abbreviated as “-penems.”)

Penicillins and cephalosporins bind and block peptidases that cross-link the glycan molecules, thereby interrupting the completion of the cell wall (**figure 12.3b**). Penicillins that do not penetrate the outer membrane are less effective against gram-negative bacteria. Many broad-spectrum penicillins (ampicillin) and cephalosporins (ceftriaxone) can pass into the cell walls of gram-negative species. Cycloserine inhibits the formation of the basic peptidoglycan subunits, and vancomycin hinders the elongation of the peptidoglycan.

2. Antimicrobial Drugs That Disrupt Cell Membrane Function

A cell with a damaged membrane invariably dies from disruptions in metabolism or complete breakdown and lysis. It does not even

have to be actively dividing to be destroyed. The antibiotic classes that damage cell membranes usually have specificity for particular microbial groups, based on differences in the types of lipids in their cell membranes.

Polymyxins interact with membrane phospholipids and cause leakage of proteins and nitrogen bases, particularly in gram-negative bacteria (**figure 12.4**). The polyene antifungal antibiotics (amphotericin B and nystatin) form complexes with the sterols on fungal membranes, which causes abnormal openings and seepage of small ions. Unfortunately this selectivity is not exact, and the similarities in membranes of microbial and animal cells means that most of these antibiotics have greater toxicity to humans cells.

3. Antimicrobial Drugs That Affect Nucleic Acid Synthesis

As you learned in chapter 9, the pathway that generates DNA and RNA involves an extensive series of enzyme-catalyzed reactions. Like any complicated process, it is subject to breakdown at many different points along the way, and inhibition at any point in the sequence can block subsequent events. Antimicrobial drugs

Figure 12.4 Effects of drugs on membranes. Polymyxin binds to the outer and cell membranes of gram-negative bacteria and creates abnormal openings that cause leakage and lysis.

interfere with nucleic acid synthesis by blocking synthesis of nucleotides, inhibiting replication, or stopping transcription. Because functioning DNA and RNA are required for proper translation as well, the effects on protein metabolism can be far-reaching.

Several antimicrobials inhibit DNA synthesis. The broad-spectrum quinolones inhibit DNA-unwinding enzymes or helicases, thereby stopping DNA replication and repair. Certain antiviral drugs are **analogs*** of purines and pyrimidines that will insert in the viral nucleic acid in place of a normal base. When this abnormal base stops synthesis, viral replication will be blocked (see table 12.6). The antifungal drug flucytosine is an analog of uracil that creates dysfunctional RNA. By inhibiting an enzyme that acts in purine synthesis, it also stops DNA replication. This double assault shuts down metabolism and causes cell death.

4. Antimicrobial Drugs That Block Protein Synthesis Most drugs that inhibit protein synthesis react with the ribosome-mRNA complex. Although human cells also have ribosomes, the ribosomes of eukaryotes are different in size and structure from those of prokaryotes, so these antimicrobials usually have a selective action against bacteria. One potential therapeutic consequence of drugs that bind to the prokaryotic ribosome is the damage they can do to eukaryotic mitochondria, which contain a prokaryotic type of ribosome.

Two possible targets of ribosomal inhibition are the 30S subunit and the 50S subunit (**figure 12.5**). Aminoglycosides (streptomycin, gentamicin, for example) insert on sites on the 30S subunit and cause the misreading of the mRNA, leading to abnormal proteins. Tetracyclines block the attachment of tRNA on the A acceptor site

Quick Search

Search for the video "Antibiotic and Protein Interactions" on YouTube to see an animation of the effects of antibiotics on ribosomes.

and effectively stop further synthesis of that protein. Other antibiotics attach to sites on the 50S subunit in a way that prevents the formation of peptide bonds and blocks protein synthesis (chloramphenicol). A few inhibit translocation of the subunit during translation (erythromycin). The oxazolidinones are a newer drug class that affects the assembly of the completed ribosome by blocking the attachment site for the 50S and 30S subunits.

Figure 12.5 Sites of inhibition on the prokaryotic ribosome and major antibiotics that act on these sites. All have the general effect of blocking protein synthesis. Blockage actions are indicated by X.

* *analog* (an'-uh-log) A compound whose configuration closely resembles another compound required for cellular reactions.

5. Antimicrobial Drugs That Affect Metabolic Pathways Some drugs act by mimicking the normal substrate of an enzyme through a process called **competitive inhibition**. These drugs, termed **metabolic analogs**, are structurally similar to the natural substrate and compete with it for the active site on the enzyme. When the drug is supplied to a target cell in high concentrations, it will occupy the active site and displace the normal substrate. But the metabolic analog drug is a "dead end" and cannot function as required. As the enzyme is no longer able to produce a needed product, cellular metabolism slows or stops. Antibacterial drugs called sulfonamides and trimethoprim provide an example of this mode of action. Some antiviral drugs (example: retrovir) discussed in section 12.3 also function as competitive inhibitors.

Sulfonamides and trimethoprim interfere with folate metabolism by blocking enzymes required for the synthesis of tetrahydrofolate, which is needed by bacterial cells for the synthesis of folic acid and the eventual production of DNA and RNA and amino acids. Trimethoprim and sulfonamides are often given simultaneously to achieve a synergistic effect so that a lower dosage of each drug can be used. **Figure 12.6** illustrates sulfonamides' competition with PABA for the active site of the enzyme that synthesizes the folic acid precursor. The selective toxicity of these compounds is explained by the fact that mammals derive folic acid from their diet

and so do not possess this enzyme system. This makes it possible to inhibit bacterial and protozoan parasites, which must synthesize folic acid, while leaving the human host unaffected.

Check Your Progress SECTION 12.1

1. Differentiate between antibiotics and synthetic drugs.
2. Differentiate between narrow-spectrum and broad-spectrum antibiotics.
3. Can you determine why some drugs have narrower spectra than others? (Hint: Look at their mode of action.)
4. What is the major source of antibiotics and what appears to be the natural function of antibiotics in microbes that produce them?
5. What drug characteristics are most important to consider in therapy?
6. Why is it better for a drug to be microbicidal than microbistatic?
7. Explain the major modes of action of antimicrobial drugs, and give an example of each.
8. Explain the concept of competitive inhibition, and describe how a metabolic analog molecule inhibits metabolism.
9. What would be the extended effects of drugs that block transcription?

(b) Left: Formula of a sulfanilamide molecule compared alongside one of PABA. Note that, despite a similarity in overall shape, sulfa drugs cannot be used to make folic acid. Right: The sulfa drug molecules can insert into the active site in the enzyme that would ordinarily fit the PABA. This will work only when the sulfa molecules are more prevalent and can outcompete with the PABA and keep the enzyme sites filled. Since little or no PABA can bind, the synthesis of folic acid will be inhibited.

Figure 12.6 Competitive inhibition as a mode of action. This example shows how sulfa drugs block a metabolic pathway used by bacteria to synthesize folic acid.

12.2 Survey of Major Antibacterial Drug Groups

Expected Learning Outcomes

- Describe the classes of antibacterial drugs that act on the cell wall and membrane, and list some of their applications.
- Describe the classes of antibacterial drugs that act on DNA or RNA, and characterize their uses.
- Indicate which types of antibacterial drugs block protein synthesis, and explain how they are used.
- Describe some new classes of antibacterial drugs and their applications.

Scores of antimicrobial drugs are marketed in the United States. Although the medical and pharmaceutical literature contains a wide array of names for antimicrobials, most of them are variants of a small number of drug families. About 280 different antimicrobial drugs are currently classified in about 24 drug families. Drug reference books may give the impression that there are 10 times that many, because various drug companies assign different trade names to the very same generic drug. Ampicillin, for instance, is listed under 50 different names. Most antibiotics are useful in controlling bacterial infections, although we shall also consider a number of antifungal, antiviral, and antiprotozoan drugs in the section to follow.

Antibacterial Drugs That Act on the Cell Wall

The beta-lactam* group of antibiotics all contain a 3-carbon, 1-nitrogen ring that is highly reactive. Its primary mode of action is to interfere with proteins involved in synthesis of the cell wall, leading to lysis and cell death. More than half of all antimicrobial drugs are beta-lactams, with the penicillins and cephalosporins being the most prominent representatives.

Structure of penicillin G

Penicillin and Its Relatives

The **penicillin** family of antibiotics, named for the parent compound, is a large, diverse group of compounds, most of which end in the suffix *-cillin*. Although penicillins could be completely synthesized in the laboratory from simple raw materials, it is more practical and economical to obtain natural penicillin through microbial fermentation. The major source of the drug is a unique strain of *Penicillium chrysogenum* that has been manipulated experimentally to synthesize 1,000 times more penicillin than the original strain. The natural product can then be used either in unmodified form or to make semisynthetic derivatives. All penicillins consist of three parts: a beta-lactam ring, a thiazolidine ring, and a variable side chain that dictates its microbicidal activity (**figure 12.7**).

Penicillin G was the first antibiotic and is the parent compound for all “-cillin” drugs. It is narrow spectrum and cannot be given by mouth. It is often considered the drug of choice for infections by sensitive gram-positive bacteria (streptococci) and some gram-negative bacteria (meningococci). A close relative, *penicillin V*, has similar uses but has been modified to be stable in the stomach acid and so can be taken orally. The narrow-spectrum penicillins *dicloxacillin* and *nafcillin* are often given in place of penicillin G or V. So many pathogens have become resistant to *methicillin* that it has largely been replaced by newer varieties.

Other semisynthetic penicillins such as *ampicillin* and *amoxicillin* have been chemically altered with side chains that help them move across the outer membrane of gram-negative cell walls. This increases their spectrum and makes them useful in treating many types of gram-negative infections. *Ticarcillin* and *piperacillin* have such an extended spectrum that they can be substituted for combinations of antibiotics.

Many bacteria produce enzymes that are capable of severing the beta-lactam ring of some penicillins, thereby destroying the mode of action. The enzymes are referred to as **penicillinases** or **beta-lactamases**, and they confer resistance on the bacteria that possess them. One way to bypass this problem was to develop penicillinase-resistant penicillins such as nafcillin and cloxacillin for treating infections caused by penicillinase-producing bacteria. Another strategy for reducing drug resistance has been to pair a beta-lactamase inhibitor with the penicillin to increase the longevity of the antibiotic in the presence of resistant bacteria. For example, clavulanic acid is often added to broad-spectrum penicillins to augment their effectiveness. *Clavamox* is a combination of amoxicillin and clavulanate marketed under the trade name Augmentin. *Zosyn*, a similar combination of the beta-lactamase inhibitor tazobactam and piperacillin, is used for a wide variety of systemic infections. These combined medications show an extended spectrum because of the synergy of the two drugs working together (see **figure 12.18b**).

All of the “-cillin” drugs are relatively mild and well tolerated because of their specific mode of action on cell walls (which humans lack). The primary problems in therapy include resistant strains of pathogens and allergy (which is altogether different from toxicity). Showing an allergy to any of the penicillin drugs will require avoidance of all of them, regardless of the type.

The Cephalosporin Group of Drugs

The **cephalosporin** antibiotics currently account for one-third of all antibiotics administered. Cephalosporins are similar to penicillins; they have a beta-lactam structure that can be synthetically altered (**figure 12.8**) and have a similar mode of action. The generic names of these compounds are often recognized by the presence of the root *cef*, *ceph*, or *kef* in their names.

The cephalosporins are versatile. They are relatively broad spectrum, resistant to most penicillinases, and cause fewer allergic reactions than penicillins. Although some cephalosporins are given orally, many are poorly absorbed from the intestine and must be administered **parenterally**,* by injection into a muscle or a vein.

Four generations of cephalosporins exist, with each group being more effective against gram-negative organisms than the generation

* **beta-lactam** (bey'-tuh-lak'-tam) The chemical name of a molecular group found in a number of drug families.

* **parenterally** (par-ehn'-tur-ah-lee) Gr. *para*, beyond, and *enteron*, intestine. A route of drug administration other than the gastrointestinal tract.

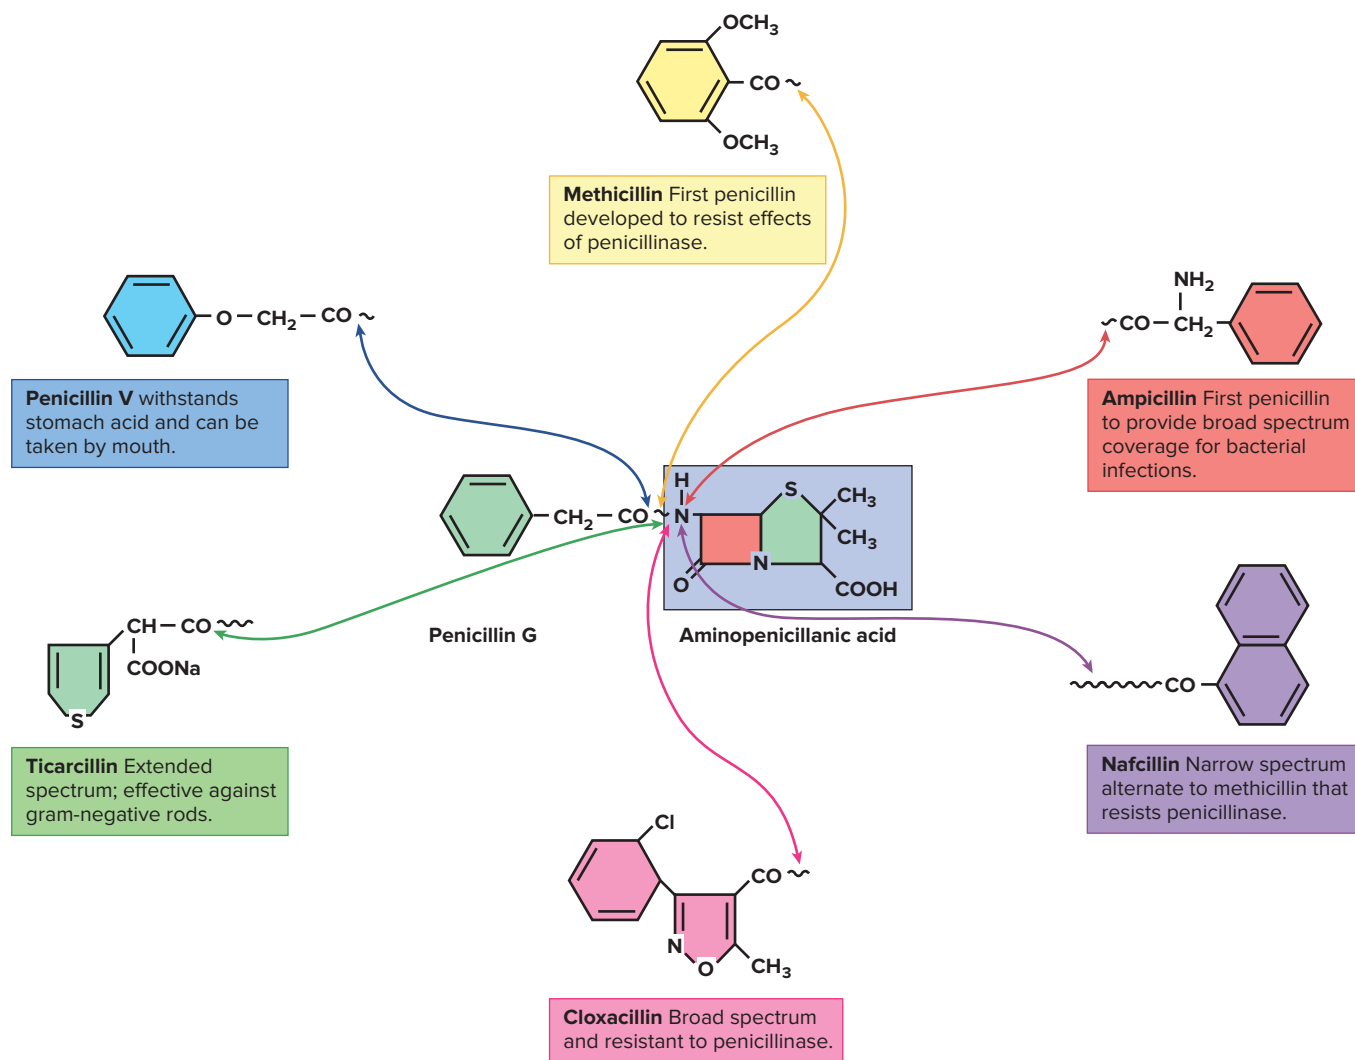

Figure 12.7 Chemical structure and functions of semisynthetic penicillins. All penicillins start with a central molecule called a nucleus that forms the basic framework (blue box). The nucleus is an inactive penicillin derivative—aminopenicillanic acid—which has a bonding site on the nitrogen on the beta lactam ring for addition of a side chain or R group. This “fine-tunes” the end product to create finished molecules with a specialized desired action. Here we see penicillins that have resistance to penicillinase (methicillin, nafcillin), a broader-activity spectrum (ticarcillin, ampicillin), and acid resistance (penicillin V).

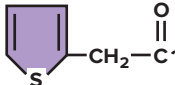

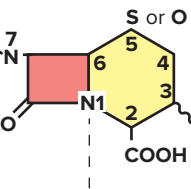

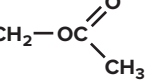

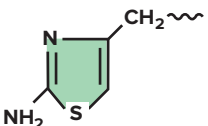

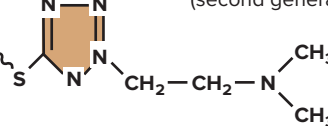

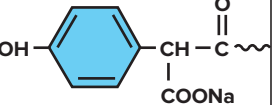

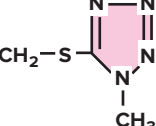

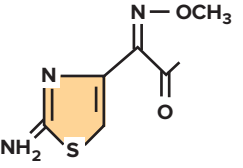

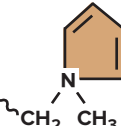

before it. In addition, succeeding generations typically have improved dosing schedules and fewer side effects. First-generation cephalosporins (cephalothin and cefazolin) are most effective against gram-positive cocci and a few gram-negative bacteria. Second-generation forms (*cefaclor* and *cefonicid*) are more effective than the first-generation forms in treating infections by gram-negative bacteria such as *Enterobacter*, *Proteus*, and *Haemophilus*. Third-generation cephalosporins, such as *cephalexin* (Keflex) and *ceftriaxone* (Rocephin), are broad spectrum with especially well-developed activity against enteric bacteria that produce beta-lactamases. Fourth-generation drugs, such as *cefepime*, have the widest range of antimicrobial properties. They are effective with both gram-negative and gram-positive bacterial infections and are rapidly microbicidal.

Some recent additions to this drug family are two combination drugs that pair a broad spectrum cephalosporin with a beta-lactamase inhibitor. *Zerbaxa* is a combination of *ceftolozene* with *tazobactam* for treating resistant urinary tract and abdominal infections. *Avycaz*,

which combines *ceftizadime* and *avibactam*, is being limited to the most life-threatening cases of kidney and abdominal infections.

Carbapenems and Monobactams Other beta-lactam drugs are the carbapenems or “penems” and aztreonam. *Imipenem* and *ertapenem* are broad-spectrum antibiotics with a mode of action similar to penicillin but with greater resistance to beta-lactamases. They are active in very low concentrations and can be taken by mouth with few side effects except for allergies. Starting in 2001 some carbapenem-resistant strains of gram-negative enteric bacteria began to emerge in hospital outbreaks. These pathogens, termed CRE, have continued to increase in numbers and are currently causing concern in some clinical settings (see 12.3 Making Connections).

Aztreonam, a monobactam, is a narrow-spectrum antibiotic for treating pneumonia, septicemia, and urinary tract infections by gram-negative aerobic bacilli. Aztreonam is especially useful when treating persons who are allergic to penicillin, because it is

R Group 1	Basic Nucleus	R Group 2
		 Cephalothin (first generation*)
	2nd	 Cefotiam (second generation)
	3rd	 Moxalactam (third generation)
	4th	 Cefepime (fourth generation)

*New improved versions of drugs are referred to as new “generations.”

Figure 12.8 The structure of cephalosporins. Like penicillin, their main nucleus consists of a beta-lactam ring (red) and a second ring (yellow). However, unlike penicillins, they have two sites for placement of R groups (at positions 3 and 7). This makes possible several generations of molecules with greater versatility in function and complexity in structure.

chemically different and does not cross-react with antibodies made to penicillin.

Miscellaneous Cell Wall Inhibitors (Non-Beta-Lactam) *Vancomycin* is a narrow-spectrum antibiotic most effective in treating staphylococcal infections in cases of penicillin and methicillin resistance or in patients with an allergy to penicillins. It has also been chosen to treat *Clostridium* infections in children and endocarditis (infection of the lining of the heart) caused by *Enterococcus faecalis*. Because it is very toxic and hard to administer, vancomycin is usually restricted to the most serious, life-threatening conditions. Two relatives of vancomycin—Dalavancin and Orbactive—were recently introduced as alternative choices for skin and structure infections, especially those caused by MRSA.

Bacitracin is a narrow-spectrum peptide antibiotic produced by a strain of *Bacillus subtilis*. Its primary effect is to block the elongation of the peptidoglycan in gram-positive bacteria. Since it was first isolated, its greatest claim to fame has been as a major ingredient in a common drugstore antibiotic ointment (Neosporin) for combating superficial skin infections by streptococci and staphylococci. For this purpose, bacitracin is usually combined with neomycin (an aminoglycoside) and polymyxin.

Isoniazid (INH) works by interfering with the synthesis of mycolic acid, a necessary component of the cell wall of acid-fast organisms. It is used to treat infections with *Mycobacterium tuberculosis* but is effective only against growing cells. It is often prescribed along with rifampin (see the section “Drugs That Act on DNA or RNA” below) and other drugs to treat tuberculosis. Oral doses are indicated for both active tuberculosis and prophylaxis in cases of a positive TB test. Ethambutol, a closely related compound, is another antituberculosis drug added to treatment regimens.

Antibiotics That Damage Bacterial Cell Membranes

Bacillus polymyxa is the source of the **polymyxins**, narrow-spectrum peptide antibiotics with a unique fatty acid component that contributes to their detergent activity (see figure 12.4). Only two polymyxins—B and E (also known as colistin)—have any routine applications, and even these are limited by their toxicity to the kidney. Either drug is indicated to treat drug-resistant infections caused by gram-negative rods such as *Pseudomonas aeruginosa* and *Acinetobacter baumannii*. It is also one of the topical agents in ointments to prevent skin infections, such as Neosporin.

Drugs That Act on DNA or RNA

Much excitement was generated by a class of synthetic drugs chemically related to quinine called **fluoroquinolones**. These drugs work by binding to DNA gyrase and a related enzyme, topoisomerase IV—both of which are essential for replication of the bacterial DNA. While DNA gyrase tends to be the primary target in gram-negative organisms, topoisomerase is targeted in gram-positive cells. It is not known how these drugs target different enzymes in different cell types, but this mode of action ensures that fluoroquinolones provide broad-spectrum effectiveness. In addition to being broad spectrum and highly potent, the drugs are readily absorbed from the intestine.

Since their introduction, quinolones have gone through four generations of development. There are currently about two dozen different types. Two of the more commonly used quinolones, *norfloxacin* and *ciprofloxacin* (Cipro), are prescribed in many cases of urinary tract infections, sexually transmitted diseases, gastrointestinal infections, osteomyelitis, respiratory infections, and soft tissue infections. Newer drugs in this category are *sparfloxacin* and *levofloxacin*. These agents are especially recommended for pneumonia, bronchitis, and sinusitis. Now that concerns have arisen regarding the overuse of quinolone drugs, the CDC is recommending careful

monitoring of their use to prevent the emergence of ciprofloxacin-resistant bacteria (see 12.3 Making Connections). Side effects that can limit the use of quinolones include damage to tendons and brain disturbances.

Another drug that disrupts nucleic acids is *rifampin*. The primary action of this drug is to block the action of RNA polymerase, thereby preventing transcription. It is somewhat limited in spectrum because the molecule cannot pass through the cell envelope of many gram-negative bacilli. It is mainly used to treat infections by selected gram-positive rods and cocci and a few gram-negative bacteria. Rifampin figures most prominently in treating mycobacterial infections, especially tuberculosis and leprosy, but it is usually given in combination with other drugs to prevent development of resistance. Rifampin is also recommended for prophylaxis in *Neisseria meningitidis* carriers and their contacts, and it is occasionally used to treat *Legionella*, *Brucella*, and *Staphylococcus* infections.

Drugs That Interfere with Protein Synthesis

The Aminoglycoside Drugs

Antibiotics composed of one or more amino sugars and an aminocyclitol (6-carbon) ring are referred to as **aminoglycosides** (figure 12.9). These complex compounds are exclusively the products of various species of soil **actinomycetes** in the genera *Streptomyces* and *Micromonospora*.

Subgroups and Uses of Aminoglycosides The aminoglycosides have a relatively broad antimicrobial spectrum because they inhibit protein synthesis by binding to one of the ribosomal subunits. They are especially useful in treating infections caused by aerobic gram-negative rods and certain gram-positive bacteria. *Streptomycin* is one of the oldest drugs but has gradually been replaced by

Figure 12.9 The structure of an aminoglycoside: *Streptomycin*. Colored portions of the molecule are found in all numbers of this drug class.

(a) Tetracyclines

(b) Chloramphenicol

(c) Erythromycin

Figure 12.10 Structures of three antibiotics that act on prokaryotic ribosomes. (a) Tetracyclines. These are named for their regular group of four rings. The several types vary in structure and activity by substitution at the four R groups. (b) Chloramphenicol. (c) Erythromycin, an example of a macrolide drug. Its central feature is a large lactone ring to which two hexose sugars are attached.

newer forms with less mammalian toxicity. It is still the antibiotic of choice for treating bubonic plague and tularemia, and is considered an effective antituberculosis agent. *Gentamicin* is less toxic and is widely administered for infections caused by gram-negative rods (*Escherichia*, *Pseudomonas*, *Salmonella*, and *Shigella*). Two relatively new aminoglycosides, tobramycin and amikacin, are also used for gram-negative infections; tobramycin is especially useful for treating *Pseudomonas* infections in cystic fibrosis patients.

Tetracycline Antibiotics

The first antibiotic in this class was *aureomycin*. It was used to synthesize terramycin, tetracycline, and several semisynthetic derivatives, commonly known as the **tetracyclines** (figure 12.10a). Their action of binding to ribosomes and blocking protein synthesis accounts for the broad-spectrum effects in the group.

Subgroups and Uses of Tetracyclines The scope of microorganisms inhibited by tetracyclines is very broad. It includes gram-positive and gram-negative rods and cocci, aerobic and anaerobic bacteria,

mycoplasmas, rickettsias, and spirochetes. Tetracycline compounds such as *doxycycline* and *minocycline* are administered orally to treat several sexually transmitted diseases, Rocky Mountain spotted fever, Lyme disease, typhus, *Mycoplasma pneumonia*, cholera, leptospirosis, acne, and even some protozoan infections. A newer derivative of minocycline—*tigecycline*—was developed to treat serious hospital skin and soft tissue infections in cases of drug resistance (*Acinetobacter* and MRSA). Although generic tetracycline is low in cost and easy to administer, its use can be limited by its side effects. In addition to gastrointestinal disruption due to changes in the normal microbiota and staining of the teeth, ingestion during pregnancy can interfere with fetal bone development (see table 12.9).

Chloramphenicol

Chloramphenicol is a potent broad-spectrum antibiotic with a unique nitrobenzene structure (figure 12.10b). Its primary effect on cells is to block peptide bond formation and protein synthesis. It is one type of antibiotic that is no longer derived from the natural source but is entirely synthesized through chemical processes. Although this drug is as broad spectrum as the tetracyclines, it is so toxic to human cells that its uses are restricted. A small number of people undergoing long-term therapy with this drug incur irreversible damage to the bone marrow that usually results in a fatal form of aplastic anemia.² Its administration is now limited to typhoid fever, brain abscesses, and rickettsial and chlamydial infections for which an alternative therapy is not available. Chloramphenicol should never be given in large doses repeatedly over a long time period, and the patient's blood must be monitored during therapy.

Macrolides and Related Antibiotics

Erythromycin is a representative of antibiotics termed macrolides.³ Its structure consists of a large lactone ring with sugars attached (figure 12.10c). This drug has a moderate spectrum and fairly low toxicity. Its mode of action is to block protein synthesis by attaching to the 50S subunit of the ribosome. It is administered orally for *Mycoplasma pneumonia*, legionellosis, *Chlamydia* infections, pertussis, and diphtheria, and as a prophylactic drug prior to intestinal surgery. It also offers a useful substitute for dealing with penicillin-resistant streptococci and gonococci and for treating syphilis and acne. Newer semisynthetic macrolides include *clarithromycin* and *azithromycin* (Zithromax). Both drugs are useful for middle ear, respiratory, and skin infections and have been approved for *Mycobacterium* (MAC) infections in AIDS patients. Clarithromycin has additional applications in controlling infections and gastric ulcers caused by *Helicobacter pylori*. Azithromycin is one of the most prescribed antibiotics in the world. It is used to treat respiratory, gastrointestinal, and sexually transmitted infections. One serious side effect it causes in some people is heart arrhythmias, which limits its use in sensitive people.

Clindamycin is a broad-spectrum antibiotic derived from lincosamycin. The tendency of clindamycin to cause adverse reactions in the gastrointestinal tract limits its applications to (1) serious infections in the large intestine and abdomen due to anaerobic bacteria

(*Bacteroides* and *Clostridium*), (2) infections with penicillin-resistant staphylococci, and (3) acne medications applied to the skin.

Drugs That Block Metabolic Pathways

Several of the drugs that interfere with metabolism are synthetic. These antimicrobials as a group do not originate from bacterial or fungal fermentations. Some were synthesized from aniline dyes, and others were originally isolated from plants. Although they have been largely replaced by antibiotics, a few of them remain essential to chemotherapy.

The most important drugs in this class are the **sulfonamides**, or **sulfa drugs**. Their name is derived from sulfanilamide, an early form of the drug (figure 12.11). These drugs function as metabolic analogs to block the synthesis of folic acid by bacteria (see figure 12.6). Dozens of these drugs have been developed, most of them narrow spectrum. Because of its solubility, sulfisoxazole is an effective choice for treating shigellosis, urinary tract infections, and certain protozoan infections. Silver sulfadiazine ointment and solution are prescribed for treatment of burns and eye infections. Another drug, *trimethoprim*, inhibits a second enzymatic step in the synthesis of folic acid. Because of this, trimethoprim is often given in combination with sulfamethoxazole to take advantage of the synergistic effect of the two drugs (Septra, Bactrim). This combination is one of the primary treatments for *Pneumocystis jiroveci* pneumonia (PCP), urinary tract infections, and otitis media.

Sulfones are compounds chemically related to the sulfonamides but lacking their broad-spectrum effects. They still remain important as key drugs in treating Hansen's disease (leprosy). The most active form is dapson, usually given in combination with rifampin and clofazimine (an antibacterial dye) over long periods.

Newly Developed Classes of Antibiotics

Although most new antibiotics are formulated from the drug classes that already exist, a few classes of drugs with novel actions against bacteria have been added to drug regimens. Medical experts are urging physicians to prescribe these medications only when no other drugs are available to slow the development of drug resistance.

2. A failure of the blood-producing tissue that results in very low levels of blood cells.
3. Macrolide antibiotics get their name from the type of chemical ring structure (macrolide ring) they all possess.

Fosfomycin trimethamine is a phosphoric acid agent effective as alternate treatment for urinary tract infections caused by enteric bacteria. It works by inhibiting an enzyme necessary for cell wall synthesis.

Synercid is an antibiotic from the streptogramin group of drugs that contains two active chemicals (quinupristin and dalfopristin) that together exert a synergistic action on certain bacteria. It has bactericidal effects against *Staphylococcus* and *Enterococcus* species that cause endocarditis and surgical infections, and against resistant strains of *Streptococcus*. It is one of the main choices when other drugs are ineffective due to resistance. Synercid works by binding to sites on the 50S ribosome, inhibiting peptide transfer and elongation.

Daptomycin (Cubicin) is a lipopeptide directed mainly against gram-positive bacteria, acting to disrupt multiple aspects of membrane function.

Another new class of drugs, the ketolides, is similar to macrolides like erythromycin but has a different ring structure. The main representative, *telithromycin* (Ketek), is used for respiratory tract infections caused by macrolide-resistant bacteria.

The *oxazolidinone* class of drugs operates using a unique mechanism, namely to inhibit the *initiation* of protein synthesis. It does this by interfering with the interaction between the mRNA and the two ribosomal subunits necessary for the initiation of translation. The two drugs in this class are *linezolid* (sold under the trade name Zyvox) and *tedizolid* (Sivextro). They are important alternate choices to treat infections caused by two prominent clinical pathogens, methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant *Enterococcus* (VRE). Because they are synthetic and not found in nature, it is hoped that drug resistance will be slow to develop.

Drugmakers have developed a new antituberculosis drug for the first time in 40 years. Called bedaquiline (Sirturo), this drug will be restricted to use only for multidrug-resistant and extremely drug-resistant TB cases that are currently on the rise.

Check Your Progress SECTION 12.2

- Why do the penicillin and cephalosporin groups of drugs have milder toxicity than other antibiotics? What are their primary side effects?

12.3 Drugs to Treat Fungal, Parasitic, and Viral Infections

Expected Learning Outcomes

- Categorize antimicrobial drugs that are effective against fungi, and describe how they are used.
- Discuss the categories of drugs used to treat parasite infections, and describe their applications.
- Discuss some of the difficulties in giving antiviral drug treatments.
- Identify several categories of antiviral drugs, and explain how they are used.

Antifungal Drugs

Because the cells of fungi are eukaryotic, they present special problems in chemotherapy. The great majority of chemotherapeutic drugs are designed to act on bacteria and are generally ineffective in combating fungal infections. And because fungal and human cells are so similar, drugs toxic to fungal cells are also capable of harming human tissues. A few agents with special antifungal properties have been developed for treating systemic and superficial fungal infections. Five main drug groups currently in use are the macrolide polyene antibiotics, griseofulvin, synthetic azoles, flucytosine, and echinocandins (**figure 12.12**).

Polyenes bind to fungal membranes and cause loss of selective permeability. They are specific for fungal membranes because fungal membranes contain a particular sterol component called *ergosterol*, which human membranes do not contain. The toxicity of polyenes is not completely selective, however, because mammalian cell membranes contain compounds similar to ergosterol that bind polyenes to a small extent.

Macrolide polyenes, represented by *amphotericin B* (Fungizone) (named for its acidic and basic—amphoteric—properties) and *nystatin* (for New York State, where it was discovered), have a structure that mimics the lipids in some cell membranes. Amphotericin B is by far the most versatile and effective of all antifungals. Not only does it work on most fungal infections, including skin and mucous membrane lesions caused by *Candida albicans*, but it is one of the few drugs that can be injected to treat systemic fungal infections such as histoplasmosis and cryptococcus meningitis. A significant drawback to the widespread use of amphotericin centers on its serious side effects, which can include fatigue and irregular heartbeat. Nystatin (Mycostatin) is used only topically or orally to treat mycoses of the skin and mucous membranes, but it is not useful for subcutaneous or systemic fungal infections or for ringworm.

(a)

(b)

(c)

Figure 12.12 Some antifungal drug structures. (a) Polyenes. The example shown is amphotericin B, a complex steroidal antibiotic that inserts into fungal cell membranes. (b) Azoles, complex cyclic (ringed) compounds, such as ketoconazole which inhibits synthesis of ergosterol, a component of the fungal cell membrane. (c) Flucytosine, a structural analog of cytosine that inhibits DNA and protein synthesis.

Griseofulvin is an antifungal product especially active in treating certain dermatophyte infections such as athlete's foot. The drug is deposited in the epidermis, nails, and hair, where it inhibits fungal growth. Because complete eradication requires several months and griseofulvin is relatively nephrotoxic, this therapy is given only for the most stubborn cases. A newer drug for treatment of ringworm and athlete's foot, *terbinafine* (Lamisil), is an inhibitor of ergosterol synthesis that is readily deposited in skin and nails. Unfortunately, it must also be taken for an extended period and has a number of side effects, including hepatotoxicity.

The **azoles** are broad-spectrum antifungal agents with a complex ringed structure that also inhibits ergosterol and cell membrane synthesis. They have fewer adverse side effects when compared with other antifungal drugs. The most effective drugs are *ketoconazole* (Nizoral), *fluconazole* (Diflucan), *clotrimazole* (Gyne-Lotrimin), *miconazole* (Monistat), *voriconazole* (VFEND), and *itraconazole* (Sporanox). Ketoconazole is used orally and topically for cutaneous mycoses, vaginal and oral candidiasis, and some systemic and invasive mycoses. Fluconazole can be used in selected patients for AIDS-related mycoses such as aspergillosis and cryptococcus meningitis. Clotrimazole and miconazole are used mainly as topical ointments for infections in the skin, mouth, and vagina. Itraconazole is generally used orally for fungal infections of the nails and systemic candidiasis. Because voriconazole crosses the blood-brain barrier, it is the treatment of choice for fungal meningitis. A new member of the azole family, Cresemba, is designated for severe systemic mycoses such as aspergillosis and mucormycosis.

Flucytosine is an analog of the nucleotide cytosine that has antifungal properties. It is rapidly absorbed after oral therapy, and it is readily dissolved in the blood and cerebrospinal fluid. Alone, it can be used to treat certain cutaneous mycoses. Many fungi are resistant to flucytosine, so it is usually combined with amphotericin B to effectively treat systemic mycoses.

After many years of testing, a new antifungal drug category has been introduced. Echinocandins, such as *Caspofungin*, damage the cell walls of several types of fungi, thereby making them sensitive to lysis. A significant advantage of this mode of action is that it cannot target human cells.

Antiparasitic Chemotherapy

The enormous diversity among protozoan and helminth parasites and their corresponding therapies reaches far beyond the scope of this textbook; however, a few of the more common drugs are surveyed here. Presently a small number of approved and experimental drugs are used to treat malaria, leishmaniasis, trypanosomiasis, amebic dysentery, and helminth infections, but the need for new and better drugs has spurred considerable research in this area.

Antimalarial Drugs: Quinine and Its Relatives

Quinine, a toxic chemical extracted from the bark of the cinchona tree, was the principal treatment for malaria for hundreds of years, but it has largely been replaced by the synthesized quinolines, mainly *chloroquine* and *primaquine*, which have less toxicity to humans. Because of the several species of *Plasmodium* (the malaria parasite) and many stages in its life cycle, no single drug is

universally effective for every species and stage, and each drug is restricted in application. For instance, primaquine eliminates the liver phase of infection, and chloroquine suppresses acute attacks associated with infection of red blood cells. It is also given as a prophylactic treatment in endemic regions. Chloroquine is usually taken in combination with another drug to reduce the chances of parasite resistance.

Mefloquine is a semisynthetic analog of quinine used to treat infections caused by chloroquine-resistant strains of *Plasmodium*, an increasing problem in Southeast Asia. The latest drug approved for treating uncomplicated malaria is a combination of artemisinin and lumefantrine called *Coartem*. It was designed to prevent drug resistance and has become the drug of choice in many parts of the world.

Chemotherapy for Other Protozoan Infections

A widely used amoebicide, metronidazole (Flagyl), is effective in treating mild and severe intestinal infections and hepatic disease caused by *Entamoeba histolytica*. It appears to inactivate essential metabolic enzymes of the pathogens. Given orally, it also has applications for infections by *Giardia lamblia* and *Trichomonas vaginalis*. Other drugs with antiprotozoan activities are quinacrine (a quinine-based drug), sulfonamides, and tetracyclines.

Antihelminthic Drug Therapy

Treating helminthic infections has been one of the most challenging of all chemotherapeutic tasks. Flukes, tapeworms, and roundworms are much larger parasites than other microorganisms and, being animals, have greater similarities to human physiology. Also, the usual strategy of using drugs to block their reproduction is usually not successful in eradicating the adult worms. The most effective drugs immobilize, disintegrate, or inhibit the metabolism of all stages of the life cycle.

Mebendazole and *thiabendazole* are broad-spectrum antiparasitic drugs used to treat several types of roundworm infections. These drugs work locally in the intestine to inhibit the function of the microtubules of worms, eggs, and larvae, which blocks a key step in glucose metabolism and disables them. The compounds *pyrantel* and *piperazine* paralyze the muscles of intestinal roundworms. Niclosamide destroys the scolex and the adjoining proglottids of tapeworms, thereby loosening the worm's holdfast. In these forms of therapy, the worms are unable to maintain their grip on the intestinal wall and are expelled along with the feces by the normal peristaltic action of the bowel. A drawback can be the severe abdominal cramps that often accompany treatment. Two newer antihelminthic drugs are *praziquantel*, a treatment for various tapeworm and fluke infections, and *ivermectin*, a veterinary drug now used for strongyloidiasis and oncocercosis in humans.

Antiviral Chemotherapeutic Agents

The chemotherapeutic treatment of viral infections presents unique challenges. Throughout our discussion of infections caused by bacteria, fungi, protozoa, and helminths, we've emphasized differences in structure and metabolism that guide drug choice. With viruses, we are dealing with an infectious agent that relies upon the host cell for the vast majority of its metabolic functions. Disrupting viral function may require that we disrupt the metabolism of the host cell to a much greater extent than is desirable. Put another way, selective toxicity with regard to viral infection can be difficult to achieve because a single metabolic system is responsible for the well-being of both virus and host. A few viral diseases, such as measles, mumps, and hepatitis, are routinely prevented by effective vaccinations. Unfortunately, vaccines are unavailable for many serious viral diseases, creating a real need for antiviral medications.

Over the past few years several antiviral drugs have been developed that target specific points in the infectious cycle of certain types of viruses. But due to marked differences among viruses, antiviral compounds tend to be limited in their spectrum.

Most antiviral drugs are designed to block a step in completion of the virus cycle. Major modes of action include

1. barring penetration of the virus into the host cell;
2. blocking replication, transcription, and/or translation of viral genetic material; and
3. preventing the normal maturation of viral particles.

Although antiviral drugs protect uninfected cells by keeping viruses from being synthesized and released, most are unable to eliminate extracellular viruses or those in a latent or persistent state within the host's DNA. A summary covering the actions of several antiviral drugs appears in **table 12.6**.

Drugs for Treating Influenza

Zanamivir (*Relenza*) and oseltamivir (*Tamiflu*) are broader-spectrum antiinfluenza medications that block neuraminidase actions in both influenza A and influenza B viruses. Without the functions of neuraminidase, the virus cannot be budded off and released from the host cell, so cells cannot produce active viruses. Both types of drugs may be used prophylactically and must be given early in an infection to be most effective (table 12.6).

Amantadine and its relative, rimantadine, have been essentially discontinued as flu treatments because the current viral strains have developed almost complete resistance to them. They function by blocking envelope receptors that are essential for the uncoating and release of RNA from the influenza A virus.

Antiherpes Drugs

Many antiviral agents mimic the structure of nucleotides (i.e., act as *analogs*) and compete for sites on replicating DNA. Once one of these nucleotide analogs is incorporated into the growing chain of DNA, replication of that strand stops, interrupting the viral life cycle. **Acyclovir** (Zovirax) and the related compounds *valacyclovir*

(Valtrex), *famciclovir* (Famvir), and *penciclovir* (Denavir) all work in this manner and (with small exceptions from drug to drug) can be used either orally or topically to treat common herpesvirus infections such as oral and genital herpes, chickenpox, and shingles. A related drug, *ganciclovir* (Cytovene), is used parenterally to treat cytomegalovirus infection in patients with compromised immune systems.

An interesting aspect of some of these antiviral agents (specifically valacyclovir and famciclovir) is that they are activated by an enzyme encoded by the virus itself, making the drug active only in virally infected cells. The enzyme thymidine kinase is used by the virus to process nucleosides before incorporating them into viral RNA or DNA. When the inactive drug enters a virally infected cell, the virus's own thymidine kinase converts it to a working antiviral agent. In cells without viruses, the drug is never activated and normal DNA replication is allowed to continue.

Antihepatitis C Drugs

The chapter 11 Case Study gave a dramatic example of the danger of hepatitis C (HCV) infection. This infection has been difficult to manage because the usual drugs are either nonspecific (ribavirin) or have severe side effects (interferon). Pharmaceutical companies have now developed highly effective new drugs called *Sofosbuvir* and *Harvoni* that improve the cure rate and have fewer side effects and a shorter course of treatment. They both work to inhibit the RNA polymerase that HCV uses to replicate its genome. Sofosbuvir is a nucleotide analog that acts much like the cyclovir drugs to block further synthesis of an RNA strand. The primary drawback is its cost, which can amount to nearly \$100,000 per treatment series, but many medical experts feel that the 94–97% cure rate is worth the cost.

Drugs for Treating HIV Infection and AIDS

The global epidemic of HIV-related disease has been a powerful stimulus for drug discovery. Most of the newer drugs being introduced are designed to treat HIV infection and AIDS. There is now a considerable array of drugs and drug combinations to manage HIV, which can complicate treatment. All of the antiretroviral drugs target a specific part of the multiplication cycle of HIV. There are currently drugs that can inhibit or block every strategic step in the virus cycle (table 12.6).

One of the most important targets is the **reverse transcriptase (RT)** enzyme that HIV brings into the host cell. Recall from chapter 9 that HIV is a retrovirus with an RNA genome. Upon entering a host, the RNA is used as a template by reverse transcriptase to produce a DNA copy of this RNA. This activity offers two types of targets for anti-HIV drugs. The first type of anti-RT drugs are *nucleoside or nucleotide reverse transcriptase analogs* (NRTIs) that directly stop DNA synthesis through competitive inhibition. *Zidovudine* was the first NRTI and the first drug developed to treat HIV and AIDS. It is an analog of thymine that becomes incorporated into the DNA strand of HIV but terminates synthesis because it does not offer the correct sites for binding additional nucleotides. Other examples are stavudine and lamivudine.

Table 12.6 Actions of Selected Antiviral Drugs*

*Details of viral cycles are omitted for ease in observing drug effects.

TABLE 12.7 Overview of Anti-HIV Drugs, Effects, and Examples

Category of Anti-HIV Drug	Effects of Drug on Virus	Examples of Drugs
Nucleotide and nucleoside reverse transcriptase inhibitors (NRTIs)	Drugs are chemical analogs that insert into the HIV DNA and prevent further addition of new bases. This terminates DNA synthesis and stops viral replication. This is a type of competitive inhibition.	Retrovir (azidothymidine [AZT], zidovudine), lamivudine (Epivir), abacavir, didanosine, stavudine, tenofovir, emtricitabine (Emtriva) Truvada, a combination of tenofovir and emtricitabine used for pre-exposure prophylaxis in high-risk persons.
Nonnucleoside reverse transcriptase inhibitors (NNRTIs)	Drugs interact with reverse transcriptase and block its active site; this is a type of noncompetitive inhibition that causes a shape change in the enzyme.	Nevirapine, efavirenz, delavirdine, rilpivirine
Protease inhibitors	HIV protease that completes viral assembly is blocked, leading to incomplete and dysfunctional viruses.	Amprenavir, atazanavir, darunavir, indinavir, saquinavir
Entry or fusion blockers	Maraviroc covers an entry receptor on the human cell (CCR5) and keeps the virus from binding; enfuvirtide (Fuzeon) stops the viral envelope from fusing with the cell membrane.	Maraviroc, enfuvirtide
Integrase inhibitors	Drugs interact with HIV integrase, which is required for the viral DNA to be inserted (integrated) into the human chromosome; this stops the action of the viral DNA.	Raltegravir, elvitegravir

The second type of anti-RT drugs are *nonnucleoside reverse transcriptase inhibitors* (NNRTIs) that attach to a site on the reverse transcriptase enzyme itself and alter its shape—a type of noncompetitive inhibition (see table 12.7). NNRTIs accomplish a similar goal in preventing reverse transcription of the HIV RNA, but they bind to the enzyme itself and prevent its reactive site from synthesizing DNA. They are usually given together or in combination with NRTIs.

Another enzyme essential to the virus's release is HIV protease, which is involved in cutting the proteins that are an essential part of the virus structure (capsids, enzymes). The class of drugs called *protease inhibitors* has the effect of blocking this enzyme and causing the assembly of faulty viruses that are not infective.

Newer classes of anti-HIV drugs are two that block entry or fusion of the virus at the beginning of its invasion and one that prevents viral integration into the host genome. The drug *maraviroc* keeps HIV out of cells by preventing the viruses from adhering to host cells, and without this step, they cannot invade. Enfuvirtide (*Fuzeon*) prevents infection when it stops the envelope of the virus from fusing with the host cell after it has attached. Another important enzyme targeted for HIV therapy is *HIV integrase*. This enzyme is essential for the final step in HIV DNA processing. Integrase inhibitors prevent this viral DNA from being incorporated or integrated into a host cell's chromosome. Because this step must occur for full viral function, the cycle is terminated by this action.

The strategy for HIV and AIDS treatment currently involves antiretroviral therapy (ART) that uses combinations of drugs to reduce the development of drug resistance. Combinations are avail-

able with two, three, or four drugs together in one pill. Most have at least one NRTI and one NNRTI, and some have protease inhibitors and an integrase inhibitor. They are used to treat ongoing HIV infection and AIDS, and for preexposure* and postexposure prophylaxis. In 2015 a new combination drug, Truvada, was approved as a prophylactic medication to prevent infection in people whose lifestyle increases their possible exposure to HIV. **Table 12.7** summarizes HIV drug types, their modes of action, and examples.

Interferons A sensible alternative to artificial antiviral drugs has been the human-based substance **interferon (IFN)**. Interferon is a glycoprotein produced primarily by fibroblasts and leukocytes in response to various immune stimuli. It has numerous biological activities, including antiviral and anticancer properties. Studies have shown that it is a versatile part of animal host defenses, having a major role in natural immunities. Its mechanism is discussed in chapter 14.

The first investigations of interferon's antiviral activity were limited by the extremely minute quantities that could be extracted from human blood. Several types of interferon (Betaseron, Roferon) are currently produced by the recombinant DNA technology techniques outlined in chapter 10. Extensive clinical trials have tested interferon's effectiveness in viral infections and cancer. Some of the known therapeutic benefits of interferon include

1. reducing the time of healing and some of the complications in certain infections (mainly of herpesviruses);

*Pre-exposure prophylaxis (PrEP)—treatment given to uninfected persons to prevent infection, such as a daily dose of anti-HIV medication given to a person who is HIV negative—is now considered a viable way to prevent infection in people whose lifestyles may increase the risk of infection.

12.2 MAKING CONNECTIONS

Alternative Antimicrobial Therapies

“The enemy of my enemy is my friend.”

This old saying might well describe a novel way to kill bacteria using viruses. This technique, called phage therapy, was first attempted over a hundred years ago after the discovery of bacteriophages. The concept behind it is rather simple: When you expose bacterial cells to their specific viruses, the viruses will invade and destroy them. If you apply the viruses in large quantity to treat a human or animal infection, they could lyse the bacteria and cure the infection. Phage therapy went out of favor for many years except in Russia, but it is currently making a comeback worldwide. An important push for renewed interest is the search for solutions to the high levels of drug resistance among bacteria. Bacteria do not become resistant to viruses as they do to drugs. Other significant advantages are that viruses are very narrow spectrum—they can target just one species of bacteria—and they would not be as toxic to humans as many drugs are.

For now, phage therapy in the United States is restricted to removing contaminants from meats, reducing the incidence of *Salmonella* and *Escherichia coli* in young farm animals, treating skin infections, and sanitizing food. In some clinics it is in experimental trials for treatment of skin ulcers, wounds, and urinary tract infections. It will require extensive testing before it becomes a first-line therapy.

Other novel approaches to controlling infections include the use of **probiotics*** and **prebiotics**. Probiotics are preparations of live microorganisms that are fed to animals and humans to modify the resident intestinal bacteria. These microorganisms can replace microbes lost during antimicrobial therapy or simply augment the normal microbiota that is already there. Culture-enriched dairy products are the latest commercial source of probiotics. Several new types of yogurt now claim specific health benefits can be gained from eating high numbers of special strains of bacteria. According to some published research findings, the ingestion of *Bifidobacterium lactis regularis* can help to maintain regular bowel function, and *Lactobacillus casei immunitas* may boost the immune function of the gut. Purposely eating such high numbers of bacterial cells—estimated at from 1 billion to 10 billion per

* *probiotic* (proh'-by-ah-tik') Gr. *pro*, for, and *bios*, life.

- preventing or reducing some symptoms of cold and papillomaviruses (warts);
- slowing the progress of certain cancers, including bone cancer and cervical cancer, and certain leukemias and lymphomas; and
- treating a rare cancer called hairy-cell leukemia, hepatitis C (a viral liver infection), genital warts, and Kaposi's sarcoma in AIDS patients.

Medical science is giving close scrutiny to alternate methods of preventing or treating infections beyond the usual antibiotics and synthesized drugs (12.2 Making Connections).

© Kathy Park Talaro

serving—is quite a departure from the usual view of microbes as disease agents. Bon appetit!

A probiotic approach is frequently used in female patients with recurring urinary tract infections. There is evidence that vaginal inserts or perineal swabs of *Lactobacillus* can restore a healthy acidic environment to the region and displace disease-causing microorganisms. Probiotics also seem to inhibit the development of food allergies.

Prebiotics are nutrients that encourage the growth of beneficial microbes in the intestine. For instance, fruit sugars such as fructans are thought to encourage the growth of *Bifidobacterium* in the large intestine and to discourage the growth of potential pathogens. Clearly, the use of these agents is a different type of antimicrobial strategy than we are used to, but they can provide an alternative to traditional antibiotics that have become less effective.

New attention is being paid to the curative properties of honey. Several studies have found that honey appears to limit infection, but even more, it can speed the healing of wounds and burns through its beneficial effects on the immune system. When applied to wounds, honey helps remove wound debris and promotes the growth of new tissue. A type of wound dressing marketed as Medihoney (antimicrobial active Manuka honey) has been approved by the FDA. Other home remedies that show pharmacologic potential are pomegranate, cranberry, and grape juices and bitter orange leaves.

12.4 Interactions Between Microbes and Drugs: The Acquisition of Drug Resistance

Expected Learning Outcomes

- Describe the development of microbial drug resistance, and explain how it is acquired.
- Explain the major mechanisms by which microbes become resistant to drugs.
- Review some of the ways to reduce levels of drug resistance.
- Discuss how drug resistance spreads through a population of microbes and the long-term effects of this.

One unfortunate outcome of the use of antimicrobials is the development of microbial **drug resistance**, an adaptive response in which microorganisms begin to tolerate an amount of drug that would previously have been inhibitory. The development of mechanisms for resisting antimicrobial drugs is a result of the genetic versatility and adaptability of microbial populations. The property of drug resistance can be an intrinsic characteristic as well as acquired. Intrinsic drug resistance would be found in bacteria that must be resistant to any antibiotic that they produce or bacteria that have natural barriers that block the drug (the outer membrane of gram-negative bacteria, for example). This type of resistance is not the main problem with regard to antimicrobial chemotherapy. Of much greater importance is the acquisition of resistance by a microbe that was previously sensitive to the drug. In our context, the term *drug resistance* will refer to this type of acquired resistance.

How Does Drug Resistance Develop?

Contrary to popular belief, antibiotic resistance is not a recent phenomenon. Resistance to penicillin developed in some bacteria as early as 1940, 3 years before the drug was even approved for public use. The scope of the problem became apparent in the 1980s and 1990s when scientists and physicians observed treatment failures on a large scale.

Microbes become newly resistant to a drug after one of the following events occurs: (1) spontaneous mutations in critical chromosomal genes, or (2) acquisition of entirely new genes or sets of genes via transfer from another species. Chromosomal drug resistance usually results from spontaneous random mutations in bacterial populations. The chance that such a mutation will be advantageous is minimal, and the chance that it will confer resistance to a specific drug is lower still. Nevertheless, given the huge numbers of microorganisms in any population and the constant rate of mutation, such mutations do occur. The end result varies from slight changes in microbial sensitivity, which can be overcome by larger doses of the drug, to complete loss of sensitivity.

Resistance through intermicrobial transfer originates from chromosomal genes and plasmids called **resistance (R) factors** being transferred through the processes we considered in chapter 9: conjugation, transformation, or transduction (**figure 12.13**). Studies have shown that plasmids encoded with drug resistance are naturally present in microorganisms before they have been exposed

Figure 12.13 Transfer of drug resistance. Bacteria transmit R factors, often containing numerous genes for drug resistance by means of conjugation, transduction, and transformation. The widespread occurrence of such exchanges accounts for the rapid spread of drug resistance.

to the drug. Such traits are “lying in wait” for an opportunity to be expressed and to confer adaptability on the species. Many bacteria also maintain transposable drug-resistance sequences (transposons) that are duplicated and inserted from one plasmid to another or from a plasmid to the chromosome. Chromosomal genes and plasmids containing codes for drug resistance are faithfully replicated and inherited by all subsequent progeny. This sharing of resistance genes accounts for the rapid proliferation of drug-resistant species. A growing body of evidence points to the ease and frequency of gene transfers in biofilms between totally unrelated bacteria living in the body’s microbiota and the environment.

Specific Mechanisms of Drug Resistance

Inside a bacterial cell, the net effect of these genetic transfers is one of the following, which actually causes the bacterium to be resistant (note that the numbers that follow correspond to the numbers seen in **figure 12.14**):

- The development of alternate enzymes that inactivate the drug (occurs only when new genes are acquired).
- Permeability or uptake of drug into bacterium is decreased or eliminated.

Quick Search

Explore this topic by going to “Animation of Antibiotic Resistance” on YouTube.

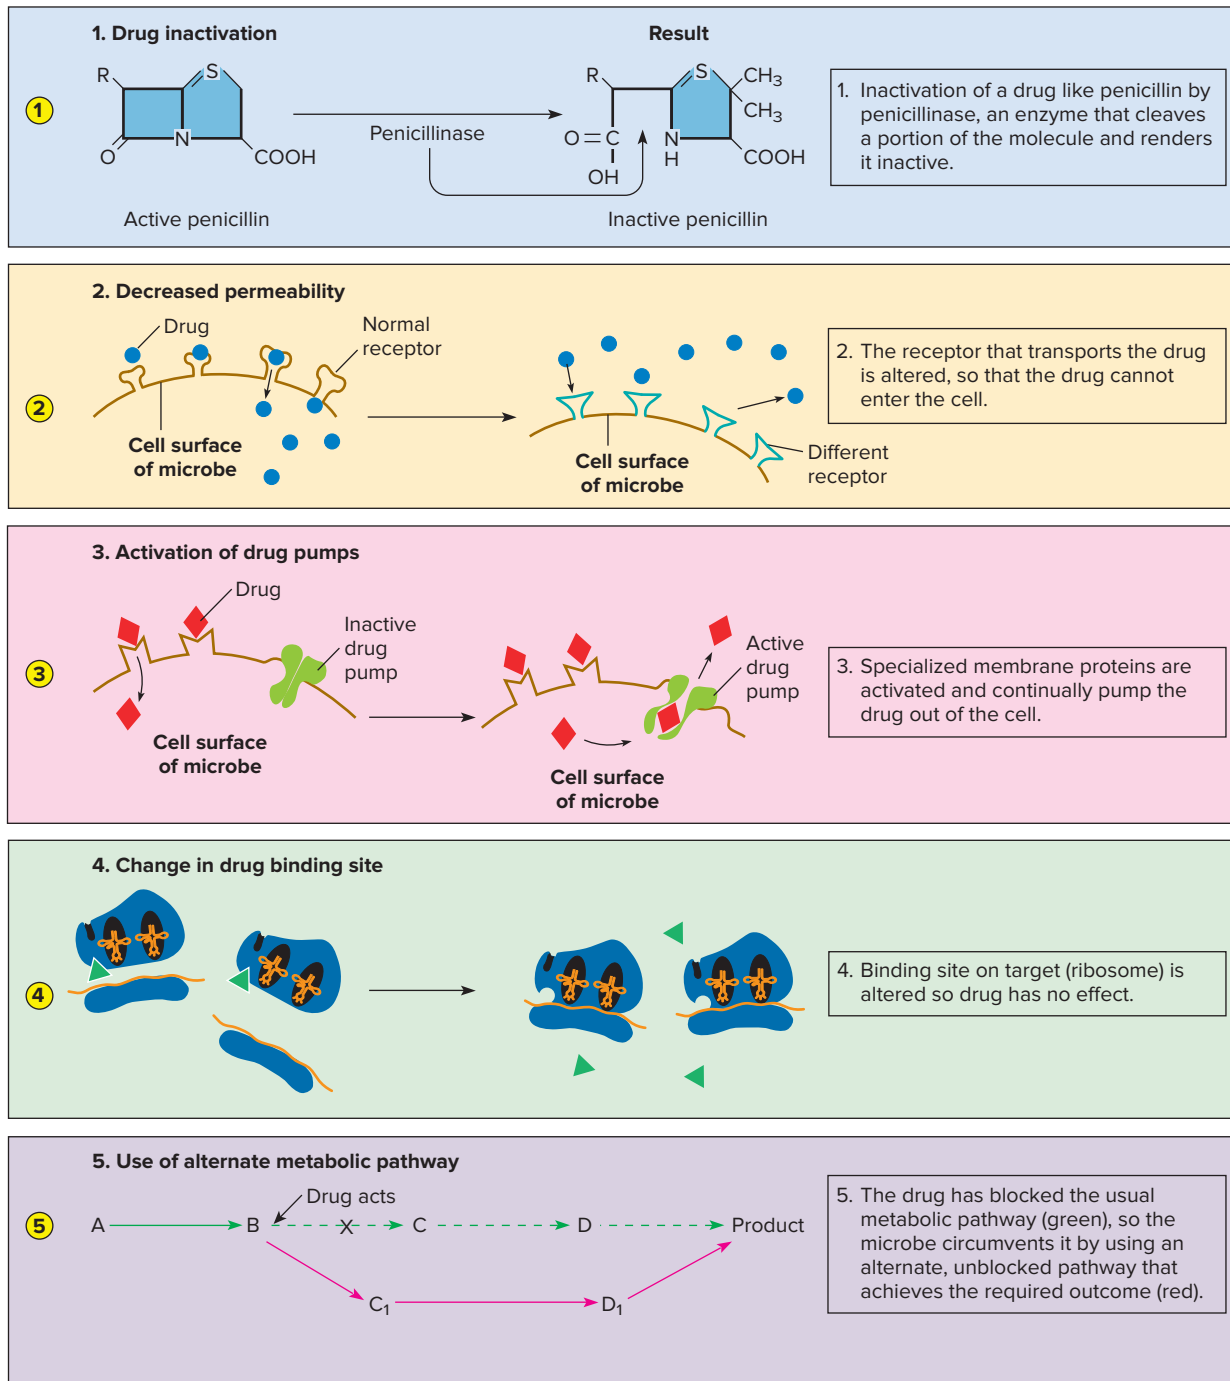

Figure 12.14 Examples of mechanisms of acquired drug resistance.

- The microbe engages special drug transport pumps that remove the drug.
- Binding sites for drug are decreased in number or affinity (can occur via mutation or acquisition of new genes).
- An affected metabolic pathway is shut down or an alternate pathway is used (occurs due to mutation of original enzyme[s]).

Some bacteria can become resistant indirectly by lapsing into dormancy or, in the case of penicillin, by converting to a

cell-wall-deficient form (L form) that penicillin cannot affect. A number of infections, including endocarditis, urinary infections, otitis media, osteomyelitis, and pneumonias, are more resistant to drugs because they develop as biofilms (see Clinical Connections).

Drug Inactivation Mechanisms

Microbes inactivate drugs by producing enzymes that permanently alter drug structure. One example, bacterial exoenzymes called

CLINICAL CONNECTIONS

Biofilms and Drug Resistance

In chapters 4 and 7 we described the development of microbial biofilms in various habitats. Recall that in these complex communities, certain “pioneer” microbes anchor themselves to a substrate by secreting a sticky matrix. This initial colonization stimulates a network of other microbes to migrate into the film.

It is estimated that around 60% of infections involve biofilms containing single or multiple species of microbes. Often the infections occur on natural tissues—for example, bacterial infections of the heart valves, middle ear, and teeth. The increased use of indwelling medical devices has created yet another habitat in which biofilms may become tenaciously attached. Catheters, artificial valves, and prosthetic devices can harbor persistent biofilm colonizations that are very difficult to treat and remove.

Microbes in infectious biofilms may be hundreds of times more drug resistant than the same free, unattached microbes. For one thing, microbes are protected by the impenetrable nature of the extracellular matrix—drugs may be blocked from entry. We also know that microbes communicate and regulate resistance mechanisms such as drug pumps, and the contact within the biofilm facilitates the transfer of drug-resistant plasmids and genes. Numerous studies have discovered the presence of persisters—microbes that remain embedded in the infection long after the drug has been discontinued, only to erupt at a later time in a new infection. These factors alone or in combination allow the persistence of the biofilm and a long-term source of infection for the patient.

With knowledge of biofilms, drug companies are researching newer drug strategies that can prevent or disrupt their formation. One concept already in use is to incorporate antimicrobial chemicals into implants, catheters, and other metal or plastic devices to inhibit microbial growth.

Would broad-spectrum or narrow-spectrum drugs be more effective in treating infections involving biofilms? Explain your reasoning. *Answer available on Connect.*

beta-lactamases, hydrolyze the beta-lactam ring structure of some penicillins and cephalosporins, rendering the drugs inactive. Two beta-lactamases—penicillinase and cephalosporinase—disrupt the structure of certain penicillin or cephalosporin molecules so their activity is lost (**figure 12.14, part 1**). So many strains of *Staphylococcus aureus* produce penicillinase that regular penicillin is rarely a possible therapeutic choice. Now that some strains of *Neisseria gonorrhoeae*, called PPNG,⁴ have also acquired penicillinase genes, alternative drugs are required to treat gonorrhea. A large number of other gram-negative species are inherently resistant to some of the penicillins and cephalosporins because of naturally occurring beta-lactamases.

4. Penicillinase-producing *Neisseria gonorrhoeae*.

Decreased Drug Permeability or Increased Drug Elimination

The resistance of some bacteria can be due to a mechanism that prevents the drug from entering the cell and acting on its target. For example, the outer membrane of the cell wall of certain gram-negative bacteria is a natural blockade for some of the penicillin drugs. Aminoglycoside resistance is known to develop through changes in drug permeability caused by point mutations in proteins of the transport system or outer membrane (**figure 12.14, parts 2 and 3**).

Many bacteria possess multidrug-resistant (MDR) pumps that actively transport drugs and other chemicals out of cells. These pumps are proteins encoded by plasmids or chromosomes. They are stationed in the cell membrane and expel molecules by a proton-motive force similar to ATP synthesis (**figure 12.14, part 3**). They confer drug resistance on many gram-positive pathogens (*Staphylococcus*, *Streptococcus*) and gram-negative pathogens (*Pseudomonas*, *E. coli*). Because MDRs lack selectivity, one type of pump can expel a broad array of antimicrobial drugs, detergents, and other toxic substances.

Change of Drug Receptors

As most drugs act on a specific target such as protein, RNA, DNA, or membrane structure, microbes can circumvent drugs by altering the nature of this target. Bacteria can become resistant to aminoglycosides when point mutations in ribosomal proteins arise (**figure 12.14, part 4**). Erythromycin and clindamycin resistance is associated with an alteration on the 50S ribosomal binding site. Penicillin resistance in *Streptococcus pneumoniae* and methicillin resistance in *Staphylococcus aureus* are related to an alteration in the binding proteins in the cell wall. Several species of enterococci have acquired resistance to vancomycin through a similar alteration of cell wall proteins. Fungi can become resistant by decreasing their synthesis of ergosterol, the principal receptor for certain antifungal drugs.

Changes in Metabolic Patterns

The action of antimetabolites can be circumvented if a microbe develops an alternative metabolic pathway or enzyme (**figure 12.14, part 5**). Sulfonamide and trimethoprim resistance develops when microbes deviate from the usual patterns of folic acid synthesis. Fungi can acquire resistance to flucytosine by completely shutting off certain metabolic activities.

Natural Selection and Drug Resistance

So far we have been considering drug resistance at the cellular and molecular levels, but its full impact is felt only if this resistance occurs throughout the cell population. Let us examine how this might happen and its long-term therapeutic consequences.

Any large population of microbes is likely to contain a few individual cells that are already drug resistant because of prior mutations or transfer of plasmids (**figure 12.15a**). As long as the

12.3 MAKING CONNECTIONS

Are We Losing the Drug Resistance Race?

“The rise of antibiotic resistance is a global health crisis. Antimicrobial resistance is on the rise in every region of the world. We are losing first line antibiotics. This makes a broad range of common infections much more difficult to treat, and replacement treatments are most costly, more toxic, and need much longer durations of treatment”

Margaret Chan, MD, WHO Director General.

It is a fact of nature that, when a large number of microbes are exposed to a variety of drugs, there will always be some genetically favored strains or types that survive in the presence of those drugs. One could even say that microbes are merely practicing what they do best—adapt and survive. Our very use of drugs is a catalyst that speeds their evolution toward drug resistance.

Approximately 2 million hospital-acquired infections causing 90,000 fatalities occur every year. About 70% of these infections are caused by bacteria resistant to at least one drug. For many years, concerned observers reported the gradual development of drug resistance in a number of pathogens, but during the past decade the scope of the problem has escalated. It is now a common event to discover microbes that have become resistant to relatively new drugs in a very short time. The clinical setting is a prolific source of drug-resistant strains of bacteria. This environment continually exposes large numbers of pathogens to a wide variety of drugs. The hospital also maintains patients with weakened defenses, making them highly susceptible to infections.

We can readily see the pattern by examining the case of *Staphylococcus aureus* and penicillin. In the 1950s, hospital strains began to show resistance to this drug, and because of indiscriminate use of penicillin, these strains became nearly 100% resistant to penicillin within 25 years. In response, drugmakers created methicillin as an alternative to penicillin, but within a few years MRSA (methicillin-resistant *S. aureus*) strains began to appear that ultimately came to tolerate nearly all antibiotics. To complicate this problem, strains of MRSA found their way from the clinic into the community. Fortunately MRSA was universally treatable with the drug vancomycin—at least for a while. Then there arose reports of

VISA strains that were less sensitive, followed by reports of VRSA strains with complete resistance to this drug, all within a few years. It is this creeping pattern of drug resistance to newer replacement drugs that has health officials most concerned.

One of the more urgent alerts has arisen over carbapenem-resistant Enterobacteriaceae (CRE). This description refers to resistance among members of this family of gram-negative rods to the carbapenem drugs (imipenem, ertapenem), which had traditionally been used in cases of drug resistance to other beta-lactam drugs. Many new resistant strains of *Klebsiella pneumoniae*, *Enterobacter cloacae*, and *Escherichia coli* have emerged as significant hospital-acquired pathogens (see figure). In the hospital setting, enteric bacteria cause infections of the bloodstream and urinary tract. The fatality rate for compromised or debilitated patients can be as high as 40%. Similar to *Acinetobacter*, which was featured in the chapter 9 Case Study, the genes for carbapenem resistance are readily and rapidly transmitted by means of several mechanisms. Since 2001 the number of cases has risen by three to five times.

Drugs in Animal Feeds

Another practice that has contributed significantly to growing drug resistance is the addition of antimicrobials to livestock feed, with the idea of decreasing infections and thereby improving animal health and size. Eighty percent of all antibiotics used in the United States are added to animal food. Enteric bacteria such as *Salmonella*, *E. coli*, and enterococci that live as normal intestinal residents of these animals readily share resistance plasmids and are constantly selected and amplified by exposure to drugs. These pathogens subsequently “jump” to humans and cause drug-resistant infections, oftentimes at epidemic proportions. In a deadly outbreak of *Salmonella* infection in Denmark, the pathogen was found to be resistant to seven different antimicrobial drugs. The opportunistic pathogen called VRE (vancomycin-resistant enterococcus) has been traced to the use of a vancomycin-like drug in cattle feed. It is now one of the most tenacious of hospital-acquired infections, for which there are few drug choices.

Figure 12.15 A model of natural selection for drug resistance. (a) Generally, any population of microbes will harbor a few cells carrying a prior mutation that confers drug resistance. (b) Environmental pressure (here, exposure to the drug) selects for survival of these cells. (c) In time, the resistant cells become the dominant cells.

Worldwide Drug Resistance

The drug dilemma has become a widespread problem, affecting all countries and socioeconomic groups. In general, the majority of infectious diseases, whether bacterial, fungal, protozoan, or viral, are showing increases in drug resistance. In parts of India, the main drugs used to treat cholera (furazolidone, ampicillin) have gone from being highly effective to essentially useless in 10 years. In Southeast Asia, 98% of gonococcus infections are multidrug resistant. Many strains of the malaria parasite have become resistant to the mainstay drug chloroquine, which means that it must be combined with an alternate drug or not given at all. The influenza drugs amantadine and rimantadine had to be discontinued because the virus had become almost completely resistant to these medications. In some parts of Africa, strains of the TB bacillus have developed such extreme resistance that there are no effective treatments available. To add to the problem, global travel and globalization of food products mean that drug-resistant pathogens can be spread around the world in a short time.

In the United States alone, the extra cost for treating drug-resistant infections is around \$10 billion per year. In many developing countries, drugs are mishandled by overuse and underuse, either of which can contribute to drug resistance. Many countries that do not regulate the sale of prescription drugs make them readily available to purchase over the counter. For example, the antituberculosis drug INH (isoniazid) is sometimes used as a “lung vitamin” to improve health, and antibiotics are often taken in the wrong dose for undiagnosed conditions. These countries serve as breeding grounds for drug resistance that can eventually be carried to other countries.

“Bad Bugs—No Drugs”

The development of new antimicrobial drugs is considered an urgent goal. Medical experts are seeing an increase in the incidence of the “bad bugs—no drugs” dilemma. A case in point is the alarming trend of pathogens known collectively as ESKAPE. This acronym comes from the first letters of their generic names, but it also tells us that these six pathogens are very successful at escaping the effects of drugs and are getting better at it all the time. The bacteria—*Enterococcus*, *Staphylococcus aureus*, *Klebsiella*,

Acinetobacter, *Pseudomonas*, and *Enterobacter*—make up the majority of hospital-acquired infections, and are also the most drug-resistant. It is not unusual to isolate extremely drug-resistant strains or “superbugs” for which there are only two, one, and sometimes no drugs available. To avert a public health crisis, a number of governments are actively working with pharmaceutical companies on drug discovery and development, sometimes called the “new bugs—new drugs” approach. There may be renewed hope in gaining an advantage in this race with the microbes. Between 2013 and 2015, six new antibiotics and other drugs were approved by the FDA through an accelerated program that fast-tracks new drugs.

To see an excellent documentary addressing this crisis, go to the PBS Frontline website and search for “Hunting the Nightmare Bacteria.”

What are some of the reasons microbes develop drug resistance so rapidly? Answer available on Connect.

Plates comparing sensitivity test results for two bacterial cultures exposed to 12 different antibiotic discs. The plate on the left shows large, uniform zones of inhibition, indicating complete sensitivity of the culture to all 12 drugs. On the right is a sample of a CRE pathogen (here, *Enterobacter*) that has slight sensitivity to two of the drugs but is resistant to all of the rest. Source: James Gathany/CDC

drug is not present in the habitat, the numbers of these resistant forms will remain low because they have no particular growth advantage. But if the population is subsequently exposed to this drug (**figure 12.15b**), sensitive individuals are inhibited or destroyed, and resistant forms survive and proliferate. As the population continues to grow, offspring of these resistant microbes will inherit this drug resistance. In time, the replacement population will have more of the drug-resistant forms and can eventually become completely resistant (**figure 12.15c**). In ecological and evolutionary terms, the environmental factor (in this case, the drug) has put selection pressure on the population, allowing the better adapted microbe (the drug-resistant one) to survive and grow. The end result is a population that has evolved to a condition of drug resistance.

Natural selection for drug-resistant forms is apparently a common phenomenon. It takes place most frequently in various natural habitats, medical environments, and it also can occur within the

bodies of humans and animals during drug therapy. See **12.3 Making Connections** to find out some of the current implications of drug resistance. **Table 12.8** summarizes a number of actions that are being considered to slow its development.

Check Your Progress SECTION 12.4

16. Explain the phenomenon of drug resistance from the standpoint of microbial genetics (include a description of R factors).
17. Describe the five basic mechanisms of drug resistance.
18. Outline several situations or events that increase the development of drug resistant microbes.
19. Name several ways drug resistance can be prevented by medical personnel and patients (see table 12.8).

TABLE 12.8 Strategies to Limit Drug Resistance of Microorganisms**Drug Usage**

- Physicians have the responsibility for making an accurate diagnosis and prescribing the correct drug therapy.
- Compliance with physicians' guidelines: The patient should take the correct dosage, by the best route, for the appropriate period. This diminishes the selection for mutants that can resist low drug levels and ensures elimination of the pathogen.
- Combined therapy with two or more drugs together increases the chances that at least one of the drugs will be effective and that a strain resistant to one drug will be eliminated by the other.

Drug Research

- Research focuses on developing shorter-term, higher-dose antimicrobials that are more effective, less expensive, and have fewer side effects.
- Pharmaceutical companies continue to seek new antimicrobial drugs with structures that are not readily inactivated by microbial enzymes or drugs with modes of action that are not readily circumvented.

Long-Term Strategies

- Proposals to reduce the abuse of antibiotics range from educational programs for medical workers to requiring justification for prescribing certain types of antibiotics.
- Especially valuable antimicrobials may be restricted in their use to only one or two types of infections.
- The addition of antimicrobials to animal feeds must be curtailed worldwide.
- Government programs that make effective therapy available to low-income populations should be increased.
- Vaccines should be used whenever possible to provide alternative protection.

12.5 Interactions Between Drugs and Hosts

Expected Learning Outcomes

19. Summarize the adverse effects of drugs on the human body.
20. Describe some of the toxic effects of drugs on organs and tissues.
21. Discuss how drugs can cause damaging immune responses.
22. Explain the ways in which drugs alter the normal microbiota and the results.

Until now this chapter has focused on the interactions between antimicrobial drugs and the microorganisms they target. During an infection, the microbe is living in or on a host, which means that the drug is administered to the host, even though its target is the microbe. Because of this, the effect of the drug on the host must always be considered.

Although selective antimicrobial toxicity is the ideal constantly being sought, chemotherapy by its very nature involves contact with foreign chemicals that can harm human tissues. In fact, estimates indicate that at least 5% of all persons taking an antimicrobial drug experience some type of serious adverse reaction to it. Antibiotics cause one out of five emergency visits due to adverse drug reactions. The major **side effects** of drugs fall into one of three categories: direct damage to tissues through toxicity, allergic reactions, and disruption in the balance of normal microbial flora. The damage incurred by antimicrobial drugs can be short term and reversible or permanent, and it ranges in severity from cosmetic to lethal effects.

Toxicity to Organs

Drugs can adversely affect the following organs: the liver (hepatotoxic), kidneys (nephrotoxic), gastrointestinal tract, cardiovascular

system and blood-forming tissue (hemotoxic), nervous system (neurotoxic), respiratory tract, skin, bones, and teeth.

Because the liver is responsible for metabolizing and detoxifying foreign chemicals in the blood, it can be damaged by a drug or its metabolic products. Injury to liver cells can result in enzymatic abnormalities, fatty liver deposits, hepatitis, and liver failure. The kidney is involved in excreting drugs and their metabolites. Some drugs irritate the nephron tubules, creating changes that interfere with their filtration abilities. Drugs such as sulfonamides can crystallize in the kidney and form stones that obstruct the flow of urine.

The most common complaint associated with oral antimicrobial therapy is diarrhea, which can progress to severe intestinal irritation or colitis. Although some drugs directly irritate the intestinal lining, the usual gastrointestinal complaints are caused by disruption of the intestinal microbiota (shown in figure 12.17).

Many drugs given for parasitic infections are toxic to the heart, causing irregular heartbeats and even cardiac arrest in extreme cases. Chloramphenicol can severely depress blood-forming cells in the bone marrow, resulting in either a reversible or a permanent (fatal) anemia. Some drugs hemolyze the red blood cells, others reduce white blood cell counts, and still others damage platelets or interfere with their formation, thereby inhibiting blood clotting.

Certain antimicrobials act directly on the brain and cause seizures. Others, such as aminoglycosides, damage nerves (very commonly, the eighth cranial nerve), leading to dizziness, deafness, or motor and sensory disturbances. When drugs block the transmission of impulses to the diaphragm, respiratory failure can result.

The skin is a frequent target of drug-induced side effects. The skin response can be a symptom of drug allergy or a direct toxic effect. Some drugs interact with sunlight to cause photodermatitis,

a skin inflammation. Tetracyclines are contraindicated (not advisable) for children from birth to 8 years of age because they bind to the enamel of the teeth, creating a permanent gray to brown discoloration (**figure 12.16**). Pregnant women should avoid tetracyclines because they cross the placenta and can be deposited in the developing fetal bones and teeth.

Allergic Responses to Drugs

One of the most frequent drug reactions is heightened sensitivity, or **allergy**. This reaction occurs because the drug acts as an antigen (a foreign material capable of stimulating the immune system) and stimulates an allergic response. This response can be provoked by the intact drug molecule or by substances that develop from the body's metabolic alteration of the drug. In the case of penicillin, for instance, it is not the penicillin molecule itself that causes the allergic response but a product, *benzylpenicilloyl*. Allergic reactions have been reported for every major type of antimicrobial drug, but the penicillins account for the greatest number of antimicrobial allergies, followed by the sulfonamides.

People who are allergic to a drug become sensitized to it during the first contact, usually without symptoms. Once the immune system is sensitized, a second exposure to the drug can lead to a reaction such as a skin rash (hives); respiratory inflammation; and, rarely, anaphylaxis—an acute, overwhelming allergic response that develops rapidly and can be fatal. This topic is discussed in greater detail in chapter 16.

Suppression and Alteration of the Microbiota by Antimicrobials

Most normal, healthy body surfaces, such as the skin, large intestine, outer openings of the urogenital tract, and oral cavity, provide numerous habitats for a virtual “garden” of microorganisms. These normal colonists or residents, called the microbiota, consist mostly of harmless or beneficial bacteria, but a small number of them can potentially be pathogens. We defer a more detailed discussion of this topic to chapter 13 and later chapters. Here we focus on the general effects of drugs on this population.

If a broad-spectrum antimicrobial drug is administered to treat infection, it will destroy microbes regardless of their roles in maintaining a balance, affecting not only the targeted infectious agent but also many others in sites far removed from the original infection (**figure 12.17**). When this therapy destroys beneficial resident species, resistant microbes that were once in small numbers begin

Figure 12.17 The role of antimicrobials in disrupting microbiota and causing superinfections. (a) A primary infection in the throat is treated with an oral antibiotic. (b) The drug is carried to the intestine and is absorbed into the circulation. (c) The primary infection is cured, but drug-resistant pathogens have survived and create an intestinal superinfection.

to overgrow and cause disease. This complication is called a **superinfection**.

Some common examples demonstrate how a disturbance in the microbiota leads to replacement pathogens and superinfection. A broad-spectrum cephalosporin used to treat a urinary tract infection by *E. coli* will cure the infection, but it will also destroy the lactobacilli in the vagina that normally maintain a protective acidic environment there. The drug has no effect, however, on *Candida albicans*, a yeast that also resides in normal vaginas. Released from the inhibitory environment provided by lactobacilli, the yeasts proliferate and cause symptoms. *Candida* can cause similar superinfections of the oropharynx (thrush) and the large intestine.

Oral therapy with tetracyclines, clindamycin, and broad-spectrum penicillins and cephalosporins is associated with a serious and potentially fatal condition known as *antibiotic-associated colitis* (pseudomembranous colitis). This condition is due to the overgrowth in the bowel of *Clostridium difficile*, an endospore-forming bacterium that is resistant to the antibiotic. It invades the intestinal lining and releases toxins that induce diarrhea, fever, and abdominal pain.

Refer to **table 12.9** for a general summary of major drug groups and their side effects.

TABLE 12.9 Major Adverse Toxic Reactions to Common Drug Groups

Antimicrobial Drug	Primary Damage or Abnormality Produced
Antibacterials	
Penicillin G	Skin allergy
Ampicillin	Diarrhea and enterocolitis
Cephalosporins	Inhibition of prothrombin synthesis Decreased circulation Nephritis
Tetracyclines	Diarrhea and enterocolitis Discoloration of tooth enamel Reactions to sunlight (photosensitization)
Chloramphenicol	Injury to red and white blood cell precursors
Aminoglycosides (streptomycin, gentamicin)	Diarrhea and enterocolitis; loss of hearing, dizziness, kidney damage
Azithromycin	Heart arrhythmias
Isoniazid	Hepatitis Seizures Dermatitis
Sulfonamides	Formation of kidney crystals; blockage of urine flow Hemolysis Reduction in number of platelets
Polymyxin	Damage to membranes of kidney tubules Weakened muscular responses
Quinolones (floxacin)	Headache, dizziness, GI distress, tendinitis
Rifampin	Damage to hepatic cells Dermatitis
Antifungals	
Amphotericin B	Disruption of kidney filtration
Flucytosine	Decreased number of white blood cells
Antiprotozoan Drugs	
Metronidazole	Nausea, vomiting
Chloroquine	Vomiting Headache Itching
Anthelmintics	
Niclosamide	Nausea, abdominal pain
Pyrantel	Irritation Headache, dizziness
Antivirals	
Acyclovir	Seizures, confusion Skin rash
Amantadine	Nervousness, light-headedness Nausea
AZT	Immunosuppression, anemia
Protease inhibitors	Hepatic damage Abnormal deposition of fats Diabetes

Check Your Progress SECTION 12.5

- Why do drugs that act on bacterial and fungal membranes generally have high toxicity?
- Describe the series of events that gives rise to a superinfection, using an example.
- What characteristic of antibiotics and other drugs causes hypersensitivity and allergic reactions?
- Explain why it is better to use a narrow-spectrum drug instead of a broad-spectrum one, if possible.

12.6 The Process of Selecting an Antimicrobial Drug

Expected Learning Outcomes

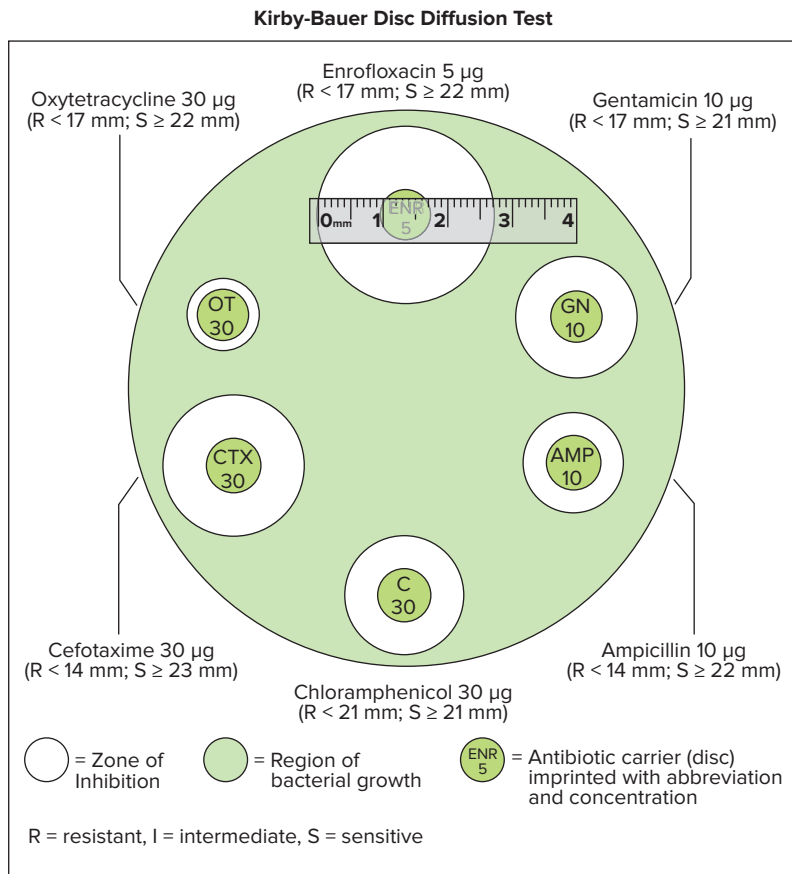

- Outline some important factors to consider in drug therapy.
- Describe the principles behind sensitivity testing for infectious agents.
- Explain the uses of the minimum inhibitory concentration and the therapeutic index in drug selection.
- Discuss medical considerations in final drug selection.
- Summarize the problems in managing antimicrobial drugs.

Before actual antimicrobial therapy can begin, consideration must be given to at least three factors:

- the nature of the microorganism causing the infection,
- the degree of the microorganism's susceptibility (also called sensitivity) to various drugs, and
- the overall medical condition of the patient.

Identifying the Agent

Identification of infectious agents from body specimens should be attempted as soon as possible. It is especially important that such specimens be taken before any antimicrobial drug is given, to prevent loss of the infectious agent. Direct examination of body fluids, sputum, or stool can provide a rapid detection method for bacteria or fungi. Newer methods of molecular diagnosis have greatly improved the speed of identification in many cases. A doctor often begins the therapy on the basis of such immediate findings. The choice of drug will be based on experience with drugs that are known to be effective against the microbe. For instance, if a sore throat appears to be caused by *Streptococcus pyogenes*, the physician may prescribe penicillin, because this species seems to be almost universally sensitive to it so far. If the infectious agent is not or cannot be isolated, epidemiological statistics may be required to predict the most likely agent in a given infection. For example, *Streptococcus pneumoniae* accounts for the majority of cases of meningitis in children, followed by *Neisseria meningitidis* and *Haemophilus influenzae*.

(a) Example and evaluation of an agar diffusion sensitivity test. If the test bacterium is sensitive to a drug, a zone of inhibition develops around its disc. The larger the size of this zone, the greater is the bacterium's sensitivity to the drug. The diameter of each zone is measured in millimeters and evaluated for susceptibility or resistance by means of a comparative standard (R, I, or S).

(b) Result for gram-negative *Klebsiella pneumoniae*, with zones of inhibition indicating sensitivity to cefotaxime (CTX) and ampicillin and clavulanic acid (AMC). Observe the expanded zone between these two drugs that indicates their enhanced action, or synergy, when combined.

(c) Result for gram-positive *Staphylococcus aureus* using gentamicin (GM, left) and aztreonam (ATM, right). Although the bacteria are sensitive to both drugs, the GM has a few colonies growing in the zone of inhibition, indicating some cells that have developed resistance to that concentration of the drug.

Figure 12.18 Techniques for preparation and interpretation of disc diffusion tests. To see photographs of completed Kirby-Bauer tests, refer to the figure in 12.3 Making Connections. (b) © Prof. Patrice Courvalin, MD, FRCP, Unité des Agents Antibactériens, Institut Pasteur, Paris, France; (c) © Kathy Park Talaro

Testing for the Drug Susceptibility of Microorganisms

Testing is essential in those groups of bacteria commonly showing resistance, primarily *Staphylococcus* species, *Neisseria gonorrhoeae*, *Streptococcus pneumoniae*, *Enterococcus faecalis*, and the aerobic gram-negative enteric bacilli. However, not all infectious agents require antimicrobial sensitivity testing. When certain groups, such as group A streptococci and most anaerobic bacteria, are known to be uniformly susceptible to penicillins, testing may not be necessary unless the patient is allergic to penicillin. Testing methods are available for fungi (see figure 12.21), protozoa, and viruses, although testing might not be done as often for these groups.

Selection of a proper antimicrobial agent begins by demonstrating the *in vitro* activity of several drugs against the infectious agent by means of standardized methods. In general, these tests involve exposing a pure culture of the bacterium to several different drugs and observing the effects of the drugs on growth.

The *Kirby-Bauer* technique is an agar diffusion test that provides useful data on antimicrobial susceptibility. In this test, the

surface of a plate of special medium is spread with the test bacterium, and small discs containing a premeasured amount of antimicrobial are dispensed onto the bacterial lawn. After incubation, the zone of inhibition surrounding the discs is measured and compared with a standard for each drug (figure 12.18). The profile of antimicrobial sensitivity, or *antibiogram*, provides data for drug selection. The Kirby-Bauer procedure is less effective for bacteria that are anaerobic, highly fastidious, or slow-growing (*Mycobacterium*).

An alternative system that provides a quantitative rating of drug effectiveness is the *E-test*[®] (figure 12.19). In addition to providing a precise numerical rating (discussed in the next paragraph), this method allows testing for a wide variety of drugs and microbial types, including anaerobes, mycobacteria, and fungi.

More sensitive and quantitative results can also be obtained with tube dilution tests. First the antimicrobial is diluted serially in tubes of broth, and then each tube is inoculated with a small uniform sample of pure culture, incubated, and examined for growth (turbidity). The smallest concentration of drug in the series that visibly inhibits growth is called the **minimum inhibitory concentration**, or **MIC**. The MIC is useful in determining the smallest effective dosage of a drug and in providing a comparative index

Figure 12.19 Etest®: A quantitative method for determining sensitivity. This test uses a plastic strip that contains a premeasured gradient of a drug and is labeled with a scale that indicates varying concentrations of the drug in µg. The concentration ranges from higher at the top of the strip to lower toward the bottom. When the strips are placed on a plate swabbed with the test microbe and incubated, an oval area called the ellipse of inhibition develops adjacent to the strip. The lowest point on the scale where the ellipse begins to form corresponds with the minimum inhibitory concentration (IP= imepenem and TZ= ceftazidime). against other antimicrobials (figures 12.20 and 12.21, and table 12.10). In many clinical laboratories, these antimicrobial testing procedures are performed in automated machines that can test dozens of drugs and microbes simultaneously.

The MIC and the Therapeutic Index

The results of antimicrobial sensitivity tests guide the physician’s choice of a suitable drug. If therapy has already commenced, it is imperative to determine if the tests bear out the use of that particular drug. Once therapy has begun, it is important to observe the

Figure 12.20 Tube dilution test for determining the minimum inhibitory concentration (MIC). The antibiotic is diluted through tubes of liquid nutrient so that the concentration in successive tubes ranges from 6.4 µg/ml (far right) to 0.1 µg/ml. All tubes are inoculated with an identical amount of a test bacterium and then incubated. The first tube on the left is a control that lacks the drug and shows cloudiness indicative of normal growth. Reading from left to right, the MIC is the dilution of the first tube in the series that has no growth (is not cloudy). © Kathy Park Talaro

Figure 12.21 Microbroth dilution in a multiwell plate adapted for a pathogenic yeast. Drugs being tested are amphotericin B (AmB), flucytosine (5FC), fluconazole (Fluc),azole drugs (itraconazole [itra], ketoconazole [Keto], Voriconazole [vori], and caspofungin [caspo]). Pink indicates growth, blue indicates no growth. Reading across numbers 2–12 are increasing concentrations of the drugs in µg/ml. Row 1 has no drug. The first dilution with no growth is crossed out, indicating the MIC for that drug. Results are given in the box on the left. Image courtesy of David Ellis

NA = not available

patient's clinical response, because the *in vitro* activity of the drug is not always correlated with its *in vivo* effect. When antimicrobial treatment fails, the failure is usually due to

1. the inability of the drug to diffuse into that body compartment (the brain, joints, skin);
2. a few resistant cells in the culture that did not appear in the sensitivity test; or
3. an infection caused by more than one pathogen (mixed), some of which are resistant to the drug.

If therapy does fail, a different drug, combined therapy, or a different method of administration must be considered.

Many factors influence the choice of an antimicrobial drug besides microbial sensitivity to it. The nature and spectrum of the drug, its potential adverse effects, and the condition of the patient can be critically important. When several antimicrobial drugs are available for treating an infection, final drug selection advances to a new series of considerations. In general, it is better to choose the narrowest-spectrum drug of those that are effective if the causative agent is known. This decreases the potential for superinfections and other adverse reactions.

Because drug toxicity is of concern, it is best to choose the drug with high selective toxicity for the infectious agent and low human toxicity. The **therapeutic index (TI)** is defined as the ratio of the dose of the drug that is toxic to humans as compared to its minimum effective (therapeutic) dose. The closer these two figures are (the smaller the ratio), the greater is the potential for toxic drug reactions. For example, a drug that has a therapeutic index of

$$\frac{10 \mu\text{g/ml: toxic dose}}{9 \mu\text{g/ml (MIC)}} \quad \boxed{\text{TI} = 1.1}$$

is a riskier choice than one with a therapeutic index of

$$\frac{10 \mu\text{g/ml}}{1 \mu\text{g/ml}} \quad \boxed{\text{TI} = 10}$$

Drug companies recommend dosages that will inhibit the microbes but not adversely affect patient cells. When a series of drugs being considered for therapy have similar MICs, the drug with the highest therapeutic index usually has the widest margin of safety.

Patient Factors in Choosing an Antimicrobial Drug

The physician must also take a careful history of the patient to discover any preexisting medical conditions that will influence the activity of the drug or the response of the patient. A history of allergy to a certain class of drugs should preclude the administration of that drug and any drugs related to it. Underlying liver or kidney disease will ordinarily necessitate the modification of drug therapy, because these organs play such an important part in metabolizing or excreting the drug. Infants, the elderly, and pregnant women require special precautions. For example, age can diminish gastrointestinal absorption and organ function, and most antimicrobial drugs cross the placenta and could affect fetal development.

The intake of other drugs must be carefully scrutinized, because incompatibilities can result in increased toxicity or failure of one or more of the drugs. For example, the combination of aminoglycosides

and cephalosporins increases nephrotoxic effects; antacids reduce the absorption of isoniazid; and the interaction of tetracycline or rifampin with oral contraceptives can abolish the contraceptive's effect. Some drugs (penicillin with certain aminoglycosides, or amphotericin B with flucytosine) act synergistically, so that reduced doses of each can be used. Other concerns in choosing drugs include any genetic or metabolic abnormalities in the patient, the site of infection, the route of administration, and the cost of the drug.

CLINICAL CONNECTIONS

An Antimicrobial Drug Dilemma

We began this chapter with a view of the exciting strides made in antimicrobial therapy, but we must be realistic about its downside. There is now a worldwide problem in the management of antimicrobial drugs, which rank second only to nervous system drugs in overall usage. The remarkable progress in treating many infectious diseases has spawned a view of antimicrobials as a "cure-all" for infections as diverse as the common cold and acne. And although it is true that nothing is as dramatic as curing an infectious disease with the correct antimicrobial drug, in many instances drugs have no effect and can even be harmful. The depth of this problem can perhaps be appreciated better with a few facts:

1. Roughly 200 million prescriptions for antimicrobials are written in the United States every year. One study found that 75% of antimicrobial prescriptions are for pharyngeal, sinus, lung, and upper respiratory infections. A fairly high percentage of these are viral in origin, and antibacterial drugs will have little or no effect.
2. Drugs are often prescribed without benefit of culture or susceptibility testing, even when such testing is clearly warranted.
3. Therapy is often applied in a "shotgun" approach for minor infections, which involves administering a broad-spectrum drug that destroys our protective resident microbes instead of a more specific narrow-spectrum one. This practice can lead to superinfections and other adverse reactions.
4. More expensive newer drugs are chosen when a less costly older one would be just as effective.
5. Tons of excess antimicrobial drugs produced in this country are exported to other countries, where controls are not as strict. Nearly 200 different antibiotics are sold over the counter in Latin American and Asian countries. Self-medication without understanding the correct medical indication is largely ineffectual, and unhealthy, but, worse yet, it is partly responsible for emergence of drug-resistant bacteria that subsequently cause epidemics.

The medical community recognizes the motivation for immediate therapy to protect a sick patient and for defensive medicine to provide the very best care possible. But in the final analysis, every allied health professional should be critically aware of not only the admirable and utilitarian nature of antimicrobials but also their limitations.

What efforts can people make in their everyday lives to help to solve these problems? *Answer available on Connect.*

Even when all the information is in, the final choice of a drug is not always straightforward. Consider the case of an elderly alcoholic patient with pneumonia caused by *Klebsiella* and complicated by diminished liver and kidney function. All drugs must be given parenterally because of prior damage to the gastrointestinal lining and poor absorption. Drug tests show that the infectious agent is sensitive to fourth-generation cephalosporins, gentamicin, imipenem, and ticarcillin. The patient's history shows previous allergy to the penicillins, so these would be ruled out. Cephalosporins are associated with serious bleeding in elderly patients, so this may not be a good choice. Aminoglycosides such as gentamicin are nephrotoxic and poorly cleared by damaged kidneys. Imipenem is probably the best choice because of its broad spectrum and low toxicity.

Check Your Progress SECTION 12.6

24. How are dilution susceptibility tests and disc diffusion tests used to determine microbial drug sensitivity?
25. Briefly describe the Kirby-Bauer test and its purpose.
26. If a technician examined a Kirby-Bauer assay and found individual colonies of the plated microbe growing within the zone of inhibition for a drug, what should her conclusion be?
27. Explain the relationship between the minimum inhibitory concentration and the therapeutic index. What is optimum for each?
28. Discuss the general factors to consider in selecting an appropriate antimicrobial drug.

CASE STUDY Part 2

After a few weeks, Nurse Mitchell was given a routine skin test for tuberculosis, and rather surprisingly, developed a raised red patch that indicated TB positive. A new specimen taken from the wound verified *Mycobacterium tuberculosis*. Unknown to the medical staff was the fact that the AIDS patient's lungs were infected with both *Pneumocystis* and tuberculosis. This now explained his sudden death, because tuberculosis is a deadly risk factor for AIDS patients, and he had not received any therapy for TB. The blood in the needle must have contained a high level of tubercle bacilli that were inoculated into the nurse's arm when the needle penetrated the skin.

Diagnosis of the tuberculosis skin infection called for an entirely different drug regimen. The dicloxacillin given early on was ineffective because this relative of penicillin does not have a mode of action that works on *M. tuberculosis*. Major problems with drug treatment for tuberculosis are that (1) the pathogen can already have or can develop drug resistance,

and (2) the TB pathogen takes longer to eliminate than most other pathogenic bacteria, even with effective drugs.

This meant that it was necessary to test for drug sensitivity, to choose drugs that would prevent resistance from happening, and to administer the drugs for several months. When tests indicated that the culture was sensitive to isoniazid, rifampin, and pyrazinamide, the nurse was started on this three-drug combined pill for 2 months, followed by 4 additional months on isoniazid and rifampin alone. By the end of this treatment, the infection was cured and Nurse Mitchell was relieved of her worst fears when a final HIV test came out negative.

- Suggest some reasons the cause of Nurse Mitchell's infection was not immediately evident.
- What are the purposes of doing drug sensitivity tests for TB?

To conclude this Case Study, go to Connect.

Chapter Summary with Key Terms

12.1 Principles of Antimicrobial Therapy

- A. **Chemotherapeutic drugs** are used to control microorganisms in the body. Depending on their source, these drugs are described as **antibiotics**, either **semisynthetic** or **synthetic**.
- B. Based on their mode and spectrum of action, they are described as **broad spectrum** or **narrow spectrum** and **microbistatic** or **microbicidal**.
- C. Strategic approaches to the use of chemotherapeutics include
 1. **Prophylaxis**, where drugs are administered to *prevent* infection in susceptible people.
 2. **Combined therapy**, where two or more drugs are given simultaneously, either to prevent the emergence of resistant species or achieve **synergism**.

D. Interactions Between Drugs and Microbes

1. The ideal antimicrobial is **selectively toxic**, highly potent, stable, and soluble in the body's tissues and fluids.
2. It does not disrupt the immune system or microflora of the host and is exempt from drug resistance.

12.2 Survey of Major Antimicrobial Drug Groups

A. Drugs That Act on the Cell Envelope

1. **Penicillins** are beta-lactam-based drugs originally isolated from the mold *Penicillium chrysogenum*. The natural form is penicillin G, although various semisynthetic forms, such as ampicillin and methicillin, vary in their spectrum and applications.
 - a. Penicillin is bactericidal, blocking completion of the cell wall, which causes eventual rupture of the cell.

- b. Major problems encountered in penicillin therapy include allergic reactions and bacterial resistance to the drug through **beta-lactamase**.
 2. **Cephalosporins** include both natural and semisynthetic drugs initially isolated from the mold *Cephalosporium*. Cephalosporins inhibit peptidoglycan synthesis (like penicillin) but have a much broader spectrum.
 3. Bacitracin and **polymyxin** are narrow-spectrum antibiotics.
 - a. Bacitracin prevents cell wall synthesis in gram-positive organisms and is used in antibacterial skin ointments.
 - b. Polymyxin interferes with the cell membrane. It is added to skin ointments and can be used to treat *Pseudomonas* infections.
 4. Vancomycin interferes with the early stages of cell wall synthesis and is used for life-threatening, methicillin-resistant staphylococcal infection.
 5. Isoniazid (INH) blocks the synthesis of cell wall components in *Mycobacteria*. It is used in the treatment of tuberculosis.
- B. *Drugs That Affect Nucleic Acid Synthesis*
 1. Fluoroquinolones (ciprofloxacin) represent a newer class of broad-spectrum synthetic drugs that have proven useful in a variety of infections.
 2. Rifampin interferes with RNA polymerase (thereby affecting transcription) and is primarily used for tuberculosis and leprosy infections.
- C. *Drugs That Inhibit Protein Synthesis*
 1. **Aminoglycosides** include several narrow-spectrum drugs isolated from unique bacteria found in the genera *Streptomyces*. Examples include streptomycin, gentamicin, tobramycin, and amikacin.
 2. **Tetracyclines** and chloramphenicol are very broad-spectrum drugs isolated from *Streptomyces*. Both interfere with translation but their use is limited by adverse effects.
 3. Erythromycin and clindamycin both affect protein synthesis. Erythromycin is a broad-spectrum alternative for use with penicillin-resistant bacteria, while clindamycin is used primarily for intestinal infection by anaerobes.
- D. *Antimetabolite Drugs*
 1. **Sulfonamides** are synthetic drugs that act as **metabolic analogs, competitively inhibiting** enzymes needed for nucleic acid synthesis.
 2. Trimethoprim is often used in combination with sulfa drugs.
 3. Dapsone is a narrow-spectrum drug used (often in combination with rifampin) to treat leprosy.
- E. *Newly Developed Antibiotics* are useful when bacteria have developed resistance to more traditional drugs.
 1. Fosfomicin inhibits cell wall synthesis and is effective against gram-negative organisms.
 2. Synercid inhibits translation and is most effective against gram-positive cocci.
 3. Ketek is a new ketolide antibiotic with broad-spectrum effects.
 4. Oxazolidinones are another new class of synthetic drug that work by inhibiting the start of protein synthesis. They are useful for treatment of staphylococci that are resistant to other drugs (MRSA and VRE).

12.3 Drugs to Treat Fungal, Parasitic, and Viral Infections

- A. *Antifungal Drugs*
 1. Amphotericin B and nystatin disrupt fungal membranes by detergent action.
 2. **Azoles** are synthetic drugs that interfere with membrane synthesis. They include ketoconazole, fluconazole, and miconazole.
 3. Flucytosine inhibits DNA synthesis. Due to fungal resistance, flucytosine must usually be used in conjunction with amphotericin.
- B. *Drugs for Protozoan Infections*
 1. Quinine or the related compounds chloroquine, primaquine, or mefloquine are used to treat infections by the malarial parasite *Plasmodium*.
 2. Other antiprotozoan drugs include metronidazole, suramin, melarsoprol, and nitrofurimox.
- C. *Drugs for Helminth Infections* include mebendazole, thiabendazole, praziquantel, pyrantel, piperazine, and niclosamide.
- D. *Drugs for Viral Infections* inhibit viral penetration, multiplication, or assembly. Because viral and host metabolism are so closely related, toxicity is a potential adverse reaction.
 1. **Acyclovir**, valacyclovir, famciclovir, and ribavirin act as nucleoside analogs, inhibiting viral DNA replication, especially in herpesviruses.
 2. Tamiflu acts to stop uncoating of the influenza A virus.
 3. Two varieties of reverse transcriptase inhibitors, protease inhibitors, integrase inhibitors, and entry/fusion inhibitors are the main categories of anti-HIV drugs, usually given in combinations of two or three.
 4. **Interferon** is a naturally occurring protein with both antiviral and anticancer properties.

12.4 Interactions Between Microbes and Drugs: The Acquisition of Drug Resistance

- A. Microbes can lose their sensitivity to a drug through the acquisition of **resistance (R) factors**. Drug resistance takes the form of drug inactivation, decreased permeability to drug or increased elimination of drug from the cell, change in drug receptors, or change of metabolic patterns.
- B. New approaches to antimicrobial therapy include the use of **probiotics** and prebiotics.

12.5 Interactions Between Drugs and Hosts

Side effects of chemotherapy include organ toxicity, allergic responses, and alteration of microflora.

12.6 The Process of Selecting an Antimicrobial Drug

- A. Rapid identification of the infectious agent is important.
- B. The pathogenic microbe should be tested for its susceptibility to different antimicrobial agents. This involves using standardized methods such as the *Kirby-Bauer* and **minimum inhibitory concentration (MIC)** techniques. The **therapeutic index** factors in the toxicity of a drug as compared with its MIC so as to guide proper drug selection.
- C. Medical conditions of the patient such as age, allergy, disease, and pregnancy are also important guides.
- D. The inappropriate use of drugs on a worldwide basis has led to numerous medical and economic problems.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

- A compound synthesized by bacteria or fungi that destroys or inhibits the growth of other microbes is a(n)
 - synthetic drug
 - antibiotic
 - antimicrobial drug
 - competitive inhibitor
- Which statement is *not* an aim in the use of drugs for antimicrobial chemotherapy? The drug should
 - have selective toxicity
 - be active even in high dilutions
 - be broken down and excreted rapidly
 - be microbicidal
- Microbial resistance to drugs is acquired through
 - conjugation
 - transformation
 - transduction
 - all of these
- R factors are _____ that contain a code for _____.
 - genes, replication
 - plasmids, drug resistance
 - transposons, interferon
 - plasmids, conjugation
- When a patient's immune system becomes reactive to a drug, this is an example of
 - superinfection
 - drug resistance
 - allergy
 - toxicity
- An antibiotic that disrupts the normal flora can cause
 - the teeth to turn brown
 - aplastic anemia
 - a superinfection
 - hepatotoxicity
- Most antihelminthic drugs function by
 - weakening the worms so they can be flushed out by the intestine
 - inhibiting worm metabolism
 - blocking the absorption of nutrients
 - inhibiting egg production
 - all of these
- Select a drug or drugs that can prevent a viral nucleic acid from being replicated.
 - retrovir
 - acyclovir
 - saquinavir
 - both a and b
- Which of the following effects do antiviral drugs *not* have?
 - destroying extracellular viruses
 - stopping virus synthesis
 - inhibiting virus maturation
 - blocking virus receptors
- Which of the following modes of action would be most selectively toxic?
 - interrupting ribosomal function
 - dissolving the cell membrane
 - preventing cell wall synthesis
 - inhibiting DNA replication
- The MIC is the _____ of a drug that is required to inhibit growth of a microbe.
 - largest concentration
 - standard dose
 - smallest concentration
 - lowest dilution
- An antimicrobial drug with a _____ therapeutic index is a better choice than one with a _____ therapeutic index.
 - low, high
 - high, low
- Matching.** Select the mode of action for each drug in the left column; all but one choice is used.

_____ sulfonamides	a. reverse transcriptase inhibitor
_____ zidovudine	b. blocks the attachment of tRNA on the ribosome
_____ penicillin	c. interferes with viral budding and release
_____ tetracycline	d. interferes with synthesis of folic acid
_____ erythromycin	e. breaks down cell membrane integrity
_____ quinolone	f. prevents the ribosome from translocating
_____ relenza	g. blocks synthesis of peptidoglycan
_____ polymyxin	h. inhibits DNA gyrase

Case Study Review

- What was the purpose of giving postexposure prophylaxis to the nurse?
 - to treat AIDS
 - to prevent pneumocystis pneumonia
 - to prevent HIV replication in cells
 - to stimulate an immune response
- What is a probable reason that tuberculosis therapy must continue for several months?
 - to prevent drug resistance
 - to keep the infection from spreading
 - the TB bacillus grows very slowly
 - the drugs are slow acting
- Summarize the major problems with drug therapy as demonstrated in this case.

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

- Using the diagram as a guide, briefly explain how the three factors in drug therapy interact.

- Observe table 12.4 with regard to type of microbe and structures or functions that are affected by drugs. Write a paragraph or two that explains the different ways in which drugs can affect microbes and how this affects selectivity of drugs and their spectrum.

- Drugs are often given to patients before going into surgery, to dental patients with heart disease, or to healthy family members exposed to contagious infections.
 - What word would you use to describe this use of drugs?
 - What is the purpose of this form of treatment?
 - Explain some potential undesired effects of this form of therapy.
 - Define probiotics and list some ways they are used.
- Write an essay covering some of the main concerns in antimicrobial drug therapy, including resistance, allergies, superinfections, and other adverse effects.
 - Explain the basis for combined therapy.
 - What are some reasons it could be helpful to use combined therapy in treating HIV infection?
- Explain the kinds of tests that would differentiate between a broad or narrow spectrum antibiotic.
- Summarize the primary reasons that we find ourselves in a “drug dilemma” with regard to antimicrobial drugs.

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps and a sample of a concept map for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

- In 2015 the WHO surveyed 10,000 people on the subject of drug resistance. Seventy-five percent of them said that antibiotic resistance is due to the body becoming resistant to the drug. Explain how you would respond to someone having this misconception.
- Explain a simple test one could do to determine if drug resistance is developing in a culture.
- Your pregnant neighbor has been prescribed a daily dose of oral tetracycline for acne. Do you think this therapy is advisable for her? Why or why not?
 - A woman has been prescribed a broad-spectrum oral cephalosporin for a strep throat. What are some possible consequences in addition to cure of the infected throat?
 - A man has a severe case of sinusitis that is negative for bacterial pathogens. A physician prescribes an oral antibacterial drug for treatment. What is right or wrong with this therapy?
- You have been directed to take a sample from a growth-free portion of the zone of inhibition in the Kirby-Bauer test and inoculate it onto a plate of nonselective medium.
 - What does it mean if growth occurs on the new plate?
 - What if there is no growth?
- From the results shown in figure 12.21, determine which drugs could be used to treat the yeast infection. Taking into account their adverse side effects, which drug would probably be the best choice?

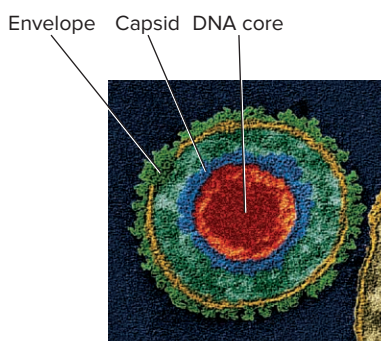

6. Explain why drugs that interfere with the prokaryotic ribosome can have harmful side effects on a human patient.
7. In cases in which it is not possible to culture or drug-test an infectious agent (such as middle ear infection), how would the appropriate drug be chosen?
8. Reviewing drug characteristics, choose an antimicrobial for each of the following situations (explain your choice):
 - a. for an adult patient suffering from *Mycoplasma pneumoniae*
 - b. for a child with bacterial meningitis (drug must enter into cerebrospinal fluid)
 - c. for a patient who has chlamydiosis and an allergy to azithromycin
 - d. for PPNG drug-resistant gonorrhea
9.
 - a. Using table 12.10 as a reference, find and explain the differences between the results for *Staphylococcus* and *Pseudomonas*. Are any of these drugs broad spectrum?
 - b. Explain the difference in the MIC of *E. coli* for penicillin versus ampicillin.
 - c. Refer to figure 12.18a, take measurements, and interpret the results.

Visual Challenge

For the following figures a–e, research the chapter and book to find an appropriate drug to treat an infection with the microbe shown, and explain what the drug's effects on the microbe will be.

(a) Figure 18.1

(b) Figure 6.8b

Medical personnel in Africa preparing to assist in containing the epidemic that devastated parts of West Africa in 2014. Note that the hazmat suits cover the workers completely so that no body surfaces are exposed to infected patients or their fluids. *Source:* Lindsey Horton/CDC

CASE STUDY Part 1 Fatal Filaments from Faraway Africa

In late December 2013 an 18-month-old child in a remote village in Guinea, West Africa, came down with an **acute** illness marked by high **fever**, severe **diarrhea**, and **vomiting**. He died two days later without being diagnosed. Within 2 weeks several family members and other villagers developed a similar illness that also led to fatalities. New **cases** began to appear in health care workers who had treated some of the sick patients. Local medical officers began to suspect a cholera **outbreak** based on the condition of the patients. This mystery **disease** escaped more serious notice until a member of the dead child's family traveled to a larger city, became ill, and died in the hospital. Local authorities were concerned but made no attempt to formally report it. When they suspected the unidentified disease might be **Lassa fever**, an outreach center for the **World Health Organization (WHO)** tested a blood sample and identified a **filovirus**. It took until March 2014 for them to finally clarify the diagnosis as **Ebola virus disease**; by then there had been 49 cases and 29 deaths.

Unfortunately the **virulence** of this virus, its small **infectious dose**, and the unpredictability of the **incubation period** were working against the patients and their caretakers. Very little attempt had been made to **isolate** the patients, and many people in both the clinics and the communities had been exposed. What had started as a local outbreak was becoming primed to explode into an Ebola **epidemic**. And that is precisely what happened. Within a month, cases appeared in the small African nations of Liberia and Sierra Leone, and by early summer of 2014 the disease had spread to several other countries and even beyond the continent of Africa. With thousands of cases and hundreds of deaths, a public health emergency

“What had started as a local outbreak was becoming primed to explode into an Ebola epidemic.”

was finally declared by officials in August 2014. Even with great attention being focused on stopping the spread of Ebola, there were not enough safeguards to prevent it from finding other exit routes.

In late September 2014 a Liberian citizen, Thomas Duncan, traveled to Texas to visit family. Although he arrived in a healthy state, within a few days he began to have nonspecific **symptoms** of fever, abdominal pain, and nasal drainage and sought treatment at a hospital. He was given antibiotics and sent home, but he was not tested for infection or questioned about his recent **travel history**. Soon after, he returned to the hospital with more severe symptoms of vomit-

ing, diarrhea, muscle pain, and weakness. Once medical personnel learned he had flown in from Africa, he was placed in **strict isolation** and tested for Ebola virus. When the result came back as positive, the hospital immediately initiated protocols as required by the **Centers for Disease Control and Prevention (CDC)** to use personal protective gear (masks, gowns, gloves, biosafety suits) and **universal precautions**, but workers were not fully trained

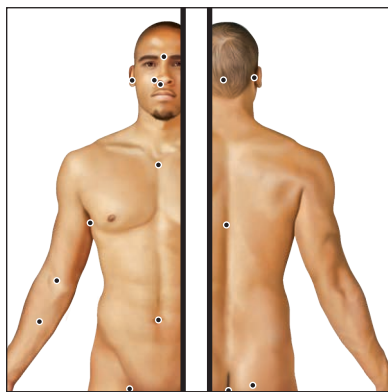

in techniques specific to Ebola. After a week of constant care, Mr. Duncan died. At some time during his stay, caretakers were exposed directly to his **infectious fluids**.

- Explain why it took so long for the African outbreak to be recognized and acted upon.
- Give some reasons the protective gear did not prevent infection in the American nurses.

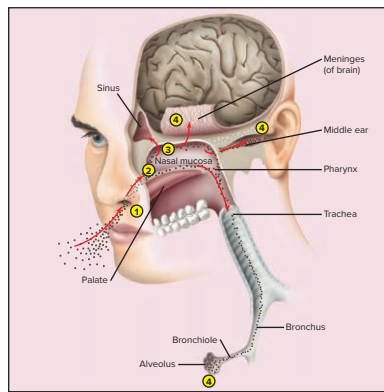

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

SCOPING OUT THE CHAPTER

The lives of microbes and humans intersect in numerous ways, but none is more profound than the intimate contact with the 100 trillion microbes that occupy our bodies. These residents influence many aspects of our development and body functions. And to balance out this partnership, we nourish them and provide them with abundant habitats. Yet with all of its benefits, there is a downside to this close association, because sometimes we encounter pathogens that invade us and cause damage and disease. The goals of this chapter are to further explore the entire range of the microbe/human relationship that can provide both powerful benefits and do serious harm.

The Microbial Menagerie Our bodies are home to a complex community of tiny creatures that live and feed and reproduce there. All major groups are represented in the microbiota, from bacteria and viruses to fungi, protozoa, and archaea. This evolving coexistence has become an essential contributor to our nutrition, immunities, and general health.

Infection Portals and Pathways Through the chain of infection, pathogens ultimately gain access to sterile tissues and grow there. Many exposed areas of the body provide an entrance that leads the way to vulnerable targets within the body. This figure depicts how the pneumococcus first enters the nasal passages and spreads from there to the lungs, ear, or brain.

Tricks Invaders Play on Their Hosts Microbes come armed with a variety of special appendages such as capsules, hooks, or fibers for clinging to host cells and holding them in place. Once pathogens are successfully established in a tissue, they can begin the process of invasion.

Toxins and Enzymes and Damage, Oh My! Once they reach a target site and begin to multiply, pathogens release factors that aid in their invasion or avoidance of host defenses. Many of these substances cause the damage that leads to signs and symptoms of disease.

How Microbes Travel Between Hosts In a later phase of the chain of infection, infectious agents are released from the body through exit portals such as body fluids or excretions. This provides pathogens with a route to a new host and increases the chances for the microbe's survival and spread.

Keeping Tabs on Pathogens and Disease Infectious diseases can be monitored from many different perspectives. Epidemiologists aim to know their origins, how they are transmitted, who is infected, the cause of epidemics, the rate of infection, the location of outbreaks, and how they are recorded and reported.

13.1 We Are Not Alone

Expected Learning Outcomes

1. Describe some of the major interactions between humans and the microbes that share our habitats.
2. Identify and define the terms associated with infectious diseases.
3. Discuss the characteristics of the normal microbiota and the types of functions they serve.
4. Briefly relate the sources and conditions that influence the development of microbiota in the major body systems.
5. Identify which bodily sites remain free of living organisms, and explain why this is necessary.
6. Explain the germ-free condition and how it is important to microbiologists.

The human body exists in a state of dynamic equilibrium with microorganisms. The healthy individual is able to maintain a balanced coexistence with them. But on occasion the balance is disrupted, allowing microorganisms to cause an infection or disease. In this chapter we explore each component of the human–microbe relationship, beginning with the nature and function of normal microbial residents, moving to the stages of infection and disease, and closing with a study of epidemiology and the patterns of disease in populations. These topics will set the scene for chapters 14 and 15, which deal with host defenses and the protections we use to fight off the agents of infectious disease.

Many of the interactions between the human body and microorganisms involve the development of biofilms (see 4.1 Making Connections). These associations result from the binding of microbial cells to our cells and to those of other microorganisms to form complex partnerships. As we discuss topics in this chapter, keep in mind that colonization of the body involves a constant “give and take” between us and them. The most significant of these interactions can be summarized as follows:

- Microbes provide a protective and stabilization effect on body surfaces by establishing themselves as normal residents.
- Microbes are involved in maturation of host defenses and development of the immune system.
- Microbes can invade and grow in sterile tissues, where they cause disease by damaging tissues and organs.

Contact, Colonization, Infection, Disease

In chapter 7 we first considered several of the basic interrelationships between humans and microorganisms. Most of the microbial inhabitants benefit from the nutrients and protective habitat the body provides. Our microbial partnerships run the gamut from mutualism to commensalism to parasitism and can have beneficial, neutral, or harmful effects.

Microbes that engage in mutual or commensal associations with humans belong to the **normal resident microbiota**. Other terms commonly used to refer to these residents are **indigenous***

microflora, normal flora, and commensals. Even though these microbes have colonized the body, they are more or less restricted to the outer surfaces without penetrating into sterile tissues or fluids. When a microbe has penetrated the host defenses, invaded sterile tissues, and multiplied, the result is an **infection**, and the microbe is considered an infectious agent or **pathogen**. If the infection causes damage or disruption to tissues and organs, it is now considered an **infectious disease**. Note that the term *disease* is defined as any deviation from health. There are hundreds of diseases caused by such factors as infections, diet, genetics, and aging. In this chapter, however, we discuss only diseases arising from the disruption of a tissue or organ caused by microbes or their products.

Figure 13.1 provides a diagrammatic view of the potential phases in infection and disease. Because of numerous factors relating to host resistance and degree of pathogenicity, not all contacts lead to infection and not all infections lead to disease. In fact, contact without infection and infection without disease are the rule. Before we consider further details of infection and disease, let us examine what happens when microbes colonize the body, thereby establishing a long-term, usually beneficial, relationship.

Resident Microbiota: The Human as a Habitat

The human body offers a seemingly endless variety of microenvironments and niches, with variations in temperature, pH, nutrients, moisture, and oxygen tension from one area to another. With such a wide range of habitats, it should not be surprising that the body supports an abundance of microbes. In fact, it is so favorable that our bodies hold 3 to 10 times more microbes than our own cells. The importance of this relationship has recently become the focus of a comprehensive initiative (**13.1 Secret World of Microbes**).

As shown in **table 13.1**, most areas of the body in contact with the outside environment harbor resident microorganisms. Mucosal surfaces provide a particularly attractive surface for attachment. Most other body sites, including internal organs, tissues, and the fluids they contain, are generally microbe-free (**table 13.2**). In fact, the presence of microbes in these areas is usually indicative of infection.

The vast majority of microbes that come in contact with the body are removed or destroyed by the host’s defenses long before they are able to colonize a particular area. Those organisms that occupy the body for only short periods are known as **transients**. The remaining microbes that do become established more permanently are considered **residents**. One of their most important adaptations is to avoid the attention of the body’s defenses. The resident organisms have coevolved along with their human hosts toward a complex relationship in which the effects of normal microflora are generally not harmful to the host, and vice versa.

Although generally stable, the microbiota fluctuates with general health, age, variations in diet, hygiene, hormones, and drug therapy. In many cases the microbiota actually benefits the human host by preventing the overgrowth of harmful microorganisms.

Quick Search

Seek out the video “The Human Microbiome and What We Do to It” on YouTube.

**indigenous* (in-dih’-juh-nus) Belonging or native to.

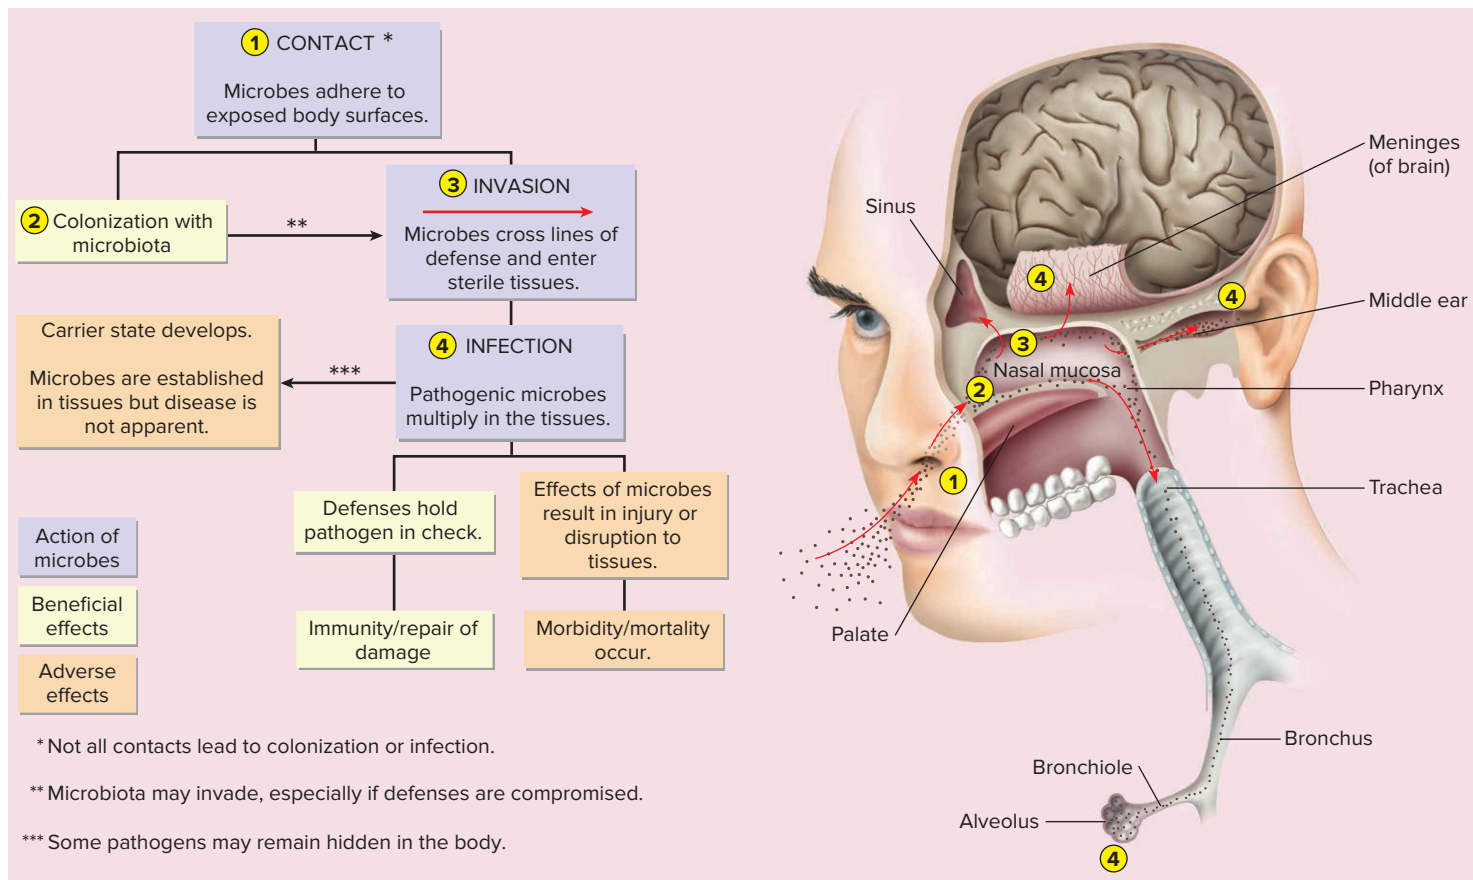

Figure 13.1 Associations between microbes and humans. Effects of contact with microbes can progress in a variety of directions, ranging from no effect to colonization, and from infection to disease and immunity. The example shown here follows the possible events in the case of contact with a pathogen such as *Streptococcus pneumoniae* (the pneumococcus). This bacterium can be harbored harmlessly in the upper respiratory tract, but it may also invade and infect the ear, cranium, and lower respiratory tract.

TABLE 13.1 Sites That Harbor Normal Resident Microbes

- Skin and its contiguous mucous membranes
- Upper respiratory tract (oral cavity, pharynx, nasal mucosa)
- Gastrointestinal tract (mouth, colon, rectum, anus)
- Outer opening of urethra
- External genitalia
- Vagina
- External ear and canal
- External eye (lids, lash follicles)

A common example is the fermentation of glycogen by lactobacilli, which keep the pH in the vagina acidic enough to prevent the overgrowth of the yeast *Candida albicans* and other pathogens. A second example is seen in the large intestine, where a protein produced by *Escherichia coli* can prevent the growth of pathogenic bacteria such as *Salmonella* and *Shigella*.

The generally antagonistic effect that “good” microbes have against intruder microorganisms is called **microbial antagonism**. Microbiota that exists in an established biofilm is unlikely to be displaced by incoming microbes. This antagonistic protection may simply be a result of a limited number of attachment sites in

TABLE 13.2 Sterile (Microbe-Free) Anatomical Sites and Fluids

All Internal Tissues and Organs

Liver	Ovaries/testes
Kidneys and bladder	Glands (pancreas, salivary)
Lungs	Sinuses
Brain and spinal cord	Middle and inner ear
Muscles	Internal eye

Fluids Within an Organ or Tissue

Blood
Urine in kidneys, ureters, bladder
Cerebrospinal fluid
Saliva prior to entering the oral cavity
Semen prior to entering the urethra

the host site, all of which are stably occupied by normal flora. Antagonism may also result from the chemical or physiological environment created by the resident microbiota, which is hostile to other microbes.

In experiments performed with mice, scientists discovered that a species of the intestinal bacterium *Bacteroides* controlled the host's production of a defense compound that suppressed other microbes in the area. This is an extreme case of microbial antagonism, but the general phenomenon is of great importance to human health.

Generally the normal residents will have beneficial or benign effects only if the host is in good health with a fully functioning immune system, and if the microbiota remain in their natural microhabitats within the body. Hosts with compromised immune systems could very easily be infected by these residents (see table 13.4). We see this outcome when AIDS patients develop recurring bouts of pneumonia from *Streptococcus pneumoniae*, often carried as normal residents in the nasopharynx. Other microbiota-associated infections can occur when residents are introduced to a site that was previously sterile, as when *E. coli* from the large intestine gets into the bladder, resulting in a urinary tract infection.

Initial Colonization of the Fetus and Newborn

It has long been the consensus that the uterus and its contents are normally sterile during embryonic and fetal development and remain essentially germ-free until just before birth. A recent study now suggests that this is not the case. Samples taken from healthy placentas and amniotic sacs yielded a small collection of bacteria similar to those found in the oral cavity. So it now appears that our microbiomes begin to be established even before birth. As intriguing as these findings are, we do not yet understand the functions of the placental microbiota and what effects it may have on the fetus, whether negative or positive. Answering these questions will no doubt give rise to numerous research studies on the subject.

The early resident microbiota of fetuses is soon joined by a massive influx of additional microbes during birth and its aftermath. From the point of the amniotic sac breaking, microbes from the mother's vagina enter the womb. Even more extensive exposure occurs during the birth process itself, when the baby unavoidably comes into intimate contact with the birth canal (**figure 13.2**). Within 8 to 12 hours after delivery, the newborn typically has been colonized by bacteria such as streptococci, staphylococci, and lactobacilli, acquired primarily from its mother. The skin, gastrointestinal tract, and portions of the respiratory and genitourinary tracts all continue to be colonized as contact continues with family members, health care personnel, the environment, and food.

The nature of the microbiota initially colonizing the large intestine is greatly influenced by whether the baby receives breast milk or formula. Milk and breast tissues contain their own microbiomes that seed the baby's digestive tract with beneficial bacteria. A surprising part of neonatal research has revealed that mother's milk contains short carbohydrate chains (oligosaccharides) that cannot be digested by the infant. Only certain species of *Bifidobacterium (infantis)* produce enzymes to break them down. This ensures that the milk selects for the growth of these beneficial bacteria, and the baby's GI tract will become populated almost exclusively by them. It is likely that these bacteria provide

Figure 13.2 The origins of microbiota in newborns. Once a newborn baby emerges, it goes through a second phase of colonization from many sources. This includes exposure to the birth canal, breast milk or other foods, family members, medical personnel, and the environment. Within a short time the infant has developed its initial microbiota in major areas of the skin, oral cavity, and intestine.

protection against colonization by potentially harmful species and invasion by pathogens. In contrast, bottle-fed infants (receiving milk or a milk-based formula) tend to acquire a mixed population of coliforms, lactobacilli, enteric streptococci, and staphylococci. This combination is similar to an adult's microbiota and does not offer the same protective effect.

Milestones that contribute to further development of the microbiota are weaning, eruption of teeth, and introduction of the first solid food. Although exposure to microbes is unavoidable and even necessary for the maturation of the infant's microbiome, contact with pathogens is dangerous. The immune defenses of neonates have not yet fully developed, which makes them extremely susceptible to infection (see figure 13.9 and the discussion of STORCH in that section).

Indigenous Microbiota of Specific Regions

Although we tend to speak of the microbiota as a single unit, it contains a complex mixture of thousands of species, differing somewhat in quality and quantity from one individual to another. Studies have shown that most people harbor certain specially adapted bacteria, fungi, and protozoa and, occasionally, viruses and

13.1 Secret World of Microbes

The Human Microbiome—A Superorganism

Microbiologists have recognized for many years that the microbes residing on the human body exert profound effects on our health and disease. This is to be expected, because they outnumber our cells many times over and occupy about 2% to 5% of our body's mass. Knowledge of this intimate coexistence inspired the concept of a superorganism—the merger of humans and their microbiota into a single, functioning, interactive unit that shares nutrients, metabolism, and genetic information and stays in constant communication. Up until recently we had an incomplete understanding of the scientific details of our interactions with our microbiota and many of their functions. A complete picture has been hampered by having to rely on knowledge of cultured microbes, and many species that cannot be cultured have not been explored to any extent.

This all began to change when the National Institutes of Health launched a massive program to study the superorganism from a different perspective. The project, called the **Human Microbiome Project (HMP)**, uses advanced technology in metagenomics to analyze the genomes of as many of the microbial residents as possible. Researchers took samples from 300 healthy volunteers, primarily from such locations as the oral cavity, skin, nose, digestive tract, and vagina. By extracting and sequencing the DNA, it was possible to identify a number of microbes that we already knew were part of the microbiota and to tabulate many others that were entirely new and unknown. After 5 years of analysis, the researchers estimated that the human body is home to at least 10,000 different species of microbes. Even more astonishing was the isolation of 8 million distinct microbial genes, which is 360 times more than our own genome holds. This means that, genetically, we are more microbe than we are human! The collective total of genetic material from all microbiota has been termed the human **microbiome**.

Preliminary results of the study provide some interesting insights. Representatives of all microbial groups were isolated, including bacteria (the largest group), archaea (the smallest group), fungi, protozoa, and viruses. Most of the microbes have a mutualistic relationship and do not cause disease, although a few pathogens, such as *Staphylococcus aureus* and *Helicobacter pylori*, were among the isolates. Although many bacteria were common to all volunteers, the precise content of microbiota is apparently unique to each individual, begins developing even before birth, and varies with age and sex. Because of these studies, we now know that many unculturable bacteria will not grow on artificial media because they have lost genes required for certain metabolic processes that are now derived from their hosts.

Approximately 500 species of bacteria and yeasts were associated with the skin, with notable differences depending on the location sampled.

For example, the skin of the hands and body creases had much greater microbial diversity than areas such as the ear and navel. Most bacterial isolates are members of four phyla: Actinobacteria, Firmicutes, Proteobacteria, and Bacteroidetes (discussed in chapter 4). See the figure for the sites sampled and the proportion of bacterial groups found in each site. One finding suggests that the skin harbors a large number and diversity of viruses. Most of the viruses appear to be bacteriophages, probably those that accompany bacteria also residing on the skin, but a number of human and other eukaryotic viruses were also discovered. Obviously this aspect of the microbiota has far greater complexity than was previously thought.

The intestinal microbiota is the largest and most varied, containing 500 to 1,000 different species of bacteria, fungi, archaea, and protozoa. The dominant phyla in this habitat are the Firmicutes and Bacteroidetes. Most of them occupy the colon, where they influence a number of physiological activities. The most common member is a species of *Bacteroides* that helps digest complex carbohydrates and contributes to the development of the protective mucous layer. There is evidence that these bacteria also signal intestinal cells to regulate development of the intestine in newborns. Other types of bacteria apparently communicate with cells of the immune system and assist in its development. Some newer research findings appear to suggest that microbes affect even brain development, biochemistry, and behavior.

The HMP has reemphasized the idea that a balanced microbiota is protective, and that a disturbed microbiota increases the susceptibility to a number of diseases. A well-established example can be seen with the colitis caused by *Clostridium difficile*, which arises when the normal intestinal residents have been eliminated by antibiotic therapy. Several studies are investigating the impact of an altered microbiota on other intestinal diseases such as irritable bowel syndrome, Crohn's disease, and colorectal cancer. Some findings indicate that composition of the microbiome can influence fat cell metabolism and can be a factor in obesity in certain individuals. There are also new data to show that the skin microbiota in diseases such as psoriasis, eczema, and acne differs significantly from that found in normal subjects. As hundreds of researchers continue to unravel the secrets of the microbiome, they are already on a quest for new strategies and therapies that may prevent these and many other diseases linked to our microbial passengers.

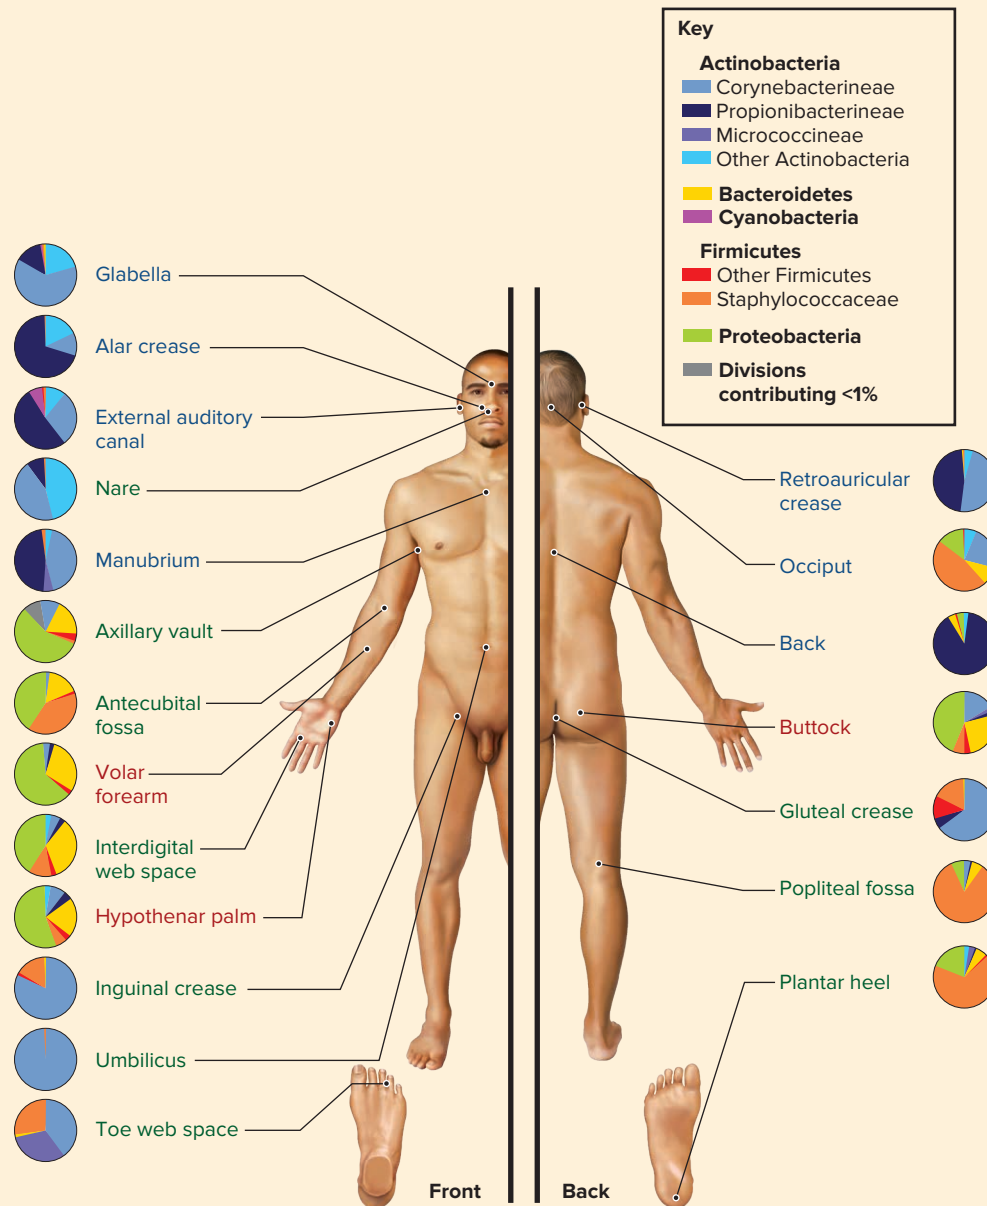

What effects on the development of our microbiome might be expected from excessive cleanliness in our habits and habitats?
Answer available on Connect.

arthropods. **Table 13.3** provides an overview of the primary locations and types of normal residents.

Viruses as Normal Microbiota

The role of viruses as normal residents is complicated by their usual reputation as infectious agents. In addition, they are harbored inside cells, which makes them very different from most resident microbes.

But we now know that they can be harmless and even beneficial inhabitants of the body. Discoveries from the human genome sequencing project have shown that about 8% to 10% of the genetic material consists of endogenous retroviruses (ERVs). It has been postulated that these ERVs started out as ancient infections, but through coevolution the virus established a mutualistic existence with the human genetic material. Over time the viruses may have become an important factor in development and gene expression of their hosts.

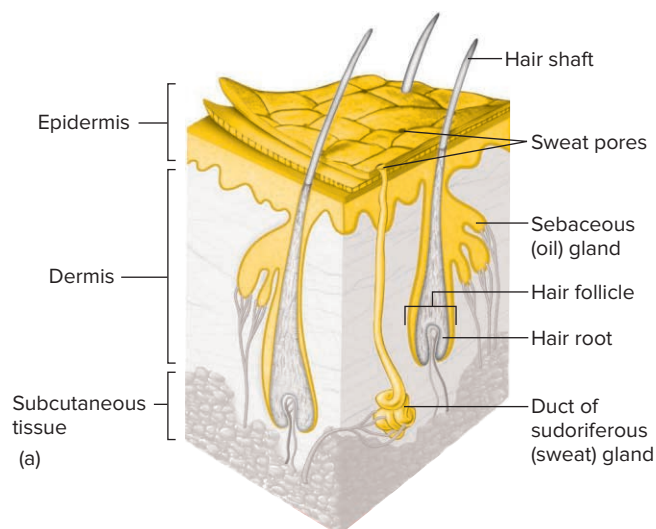

Colonizers of the Human Skin

The skin is the largest and most accessible of all organs. Its major layers are the epidermis, an outer layer of dead cells continually being sloughed off and replaced, and the dermis, which lies atop the subcutaneous layer of tissue (**figure 13.3a**). Depending on its location, skin also contains hair follicles and several types of glands; and the outermost surface is covered with a protective, waxy cuticle that can help

microbes adhere. The normal microbiota reside only in or on the dead cell layers, and except for areas around follicles and glands, it does not extend into the dermis or subcutaneous levels. The nature of the population varies according to site. Oily, moist skin supports a more prolific flora than dry skin. Humidity, occupational exposure, and clothing also influence its character. Transition zones where the skin joins with the mucous membranes of the nose, mouth, and external genitalia harbor a particularly rich set of microbial colonists.

TABLE 13.3 Life on Humans: Sites Containing Well-Established Microbiota and Representative Examples

Anatomic Sites	Common Genera	Remarks
Skin	Bacteria: <i>Pseudomonas</i> , <i>Micrococcus</i> , <i>Corynebacterium</i> , <i>Propionibacterium</i> , <i>Staphylococcus</i> , <i>Streptococcus</i> Fungi: <i>Candida</i> , <i>Malassezia</i> , <i>Rhodotorula</i> Arthropods: <i>Demodex</i> mite	Microbes live only in upper dead layers of epidermis, glands, and follicles; dermis and layers below are sterile. Dependent on skin lipids for growth Present in sebaceous glands and hair follicles
GI Tract		
Oral cavity	Bacteria: <i>Streptococcus</i> , <i>Neisseria</i> , <i>Veillonella</i> , <i>Fusobacterium</i> , <i>Lactobacillus</i> , <i>Bacteroides</i> , <i>Actinomyces</i> , <i>Eikenella</i> , <i>Treponema</i> , <i>Haemophilus</i> Fungi: <i>Candida</i> spp. Protozoa: <i>Entamoeba gingivalis</i>	Colonize the epidermal layer of cheeks, gingiva, pharynx; surface of teeth; found in saliva in huge numbers; some members involved in dental caries and periodontal diseases. <i>C. albicans</i> can cause thrush. Inhabit the gingiva of persons with poor oral hygiene.
Large intestine and rectum	Bacteria: <i>Bacteroides</i> , <i>Fusobacterium</i> , <i>Bifidobacterium</i> , <i>Clostridium</i> , fecal streptococci and staphylococci, <i>Lactobacillus</i> , coliforms (<i>Escherichia</i> , <i>Enterobacter</i>), <i>Proteus</i> spp. Fungi: <i>Candida</i> Protozoa: <i>Entamoeba coli</i> , <i>Trichomonas hominis</i>	Areas of lower gastrointestinal tract other than large intestine and rectum have sparse or nonexistent residents. Microbiota consist predominantly of strict anaerobes; other microbes are aerotolerant or facultative. Yeast can survive this habitat, but not molds. Feed on waste materials in the large intestine.
Upper Respiratory Tract	Microbial population exists in the nasal passages, throat, and pharynx; owing to proximity, microbes are similar to those of oral cavity.	Trachea may harbor a sparse population; bronchi, bronchioles, and alveoli are essentially sterile due to local host defenses.
Genital Tract	Bacteria: <i>Lactobacillus</i> , <i>Streptococcus</i> , <i>diphtheroids</i> (<i>Corynebacterium</i> and relatives) <i>Escherichia</i> , <i>Gardnerella</i> Fungi: <i>Candida</i>	In females, microbes occupy the external genitalia and vaginal and cervical surfaces; internal reproductive structures normally remain sterile. Vaginal colonists respond to hormonal changes during life. Cause of yeast infections.
Urinary Tract	Bacteria: <i>Staphylococcus</i> , <i>Streptococcus</i> , <i>Corynebacterium</i> , <i>Lactobacillus</i>	In females, microbiota exist only in the first portion of the urethral mucosa; the remainder of the tract is sterile. In males, the entire reproductive and urinary tract is sterile except for a short portion of the anterior urethra.
Eye	Bacteria: coagulase-negative Staphylococci, <i>Streptococcus</i> , <i>Neisseria</i>	The lids and follicles harbor similar microbes as skin; the conjunctiva has a transient population; deep tissues are sterile.
Ear	Bacteria: Staphylococci, diphtheroids Fungi: <i>Aspergillus</i> , <i>Penicillium</i> , <i>Candida</i> , yeasts	The external ear is similar to the skin in content; areas internal to the tympanum are generally sterile.

(b)

Figure 13.3 The landscape of the skin. (a) The epidermis, along with associated glands and follicles (colored), provides rich and diverse habitats. Noncolored regions (dermis and subcutaneous layers) are free of microbes. (b) A highly magnified view (7,500x) of skin layers reveals rod- and coccus-shaped bacteria adhering to skin cells (blue). (b): Janice Carr/CDC

Ordinarily there are two cutaneous populations. The **transients** cling to the skin surface but do not ordinarily grow there. They are acquired by routine contact and vary markedly from person to person and over time. The transients include any microbe a person has picked up, often species that do not ordinarily live on the body, and are greatly influenced by the hygiene of the individual.

The **resident populations** live and multiply in deeper layers of the epidermis and in glands and follicles (**figure 13.3b**). The composition of the resident microbiota is more stable, predictable, and less influenced by hygiene than are the transients. The normal skin residents consist primarily of bacteria (notably *Staphylococcus*, *Corynebacterium*, and *Propionibacterium*) and yeasts. Moist skin folds, especially between the toes, tend to harbor fungi, whereas lipophilic mycobacteria and staphylococci are prominent in sebaceous¹ secretions of the axilla, external genitalia, and external ear canal. One species, *Mycobacterium smegmatis*, lives in the waxy secretion, or *smegma*, on the external genitalia of men and women.

Microbial Residents of the Gastrointestinal Tract

The gastrointestinal (GI) tract receives, moves, digests, and absorbs food and removes waste. It encompasses the oral cavity, esophagus, stomach, small intestine, large intestine, rectum, and anus. Stating that the GI tract harbors residents may seem to contradict our earlier statement that internal organs are generally sterile, but it is not an exception to the rule. How can this be true? In reality, the GI tract is a long, hollow tube (with numerous pockets and curves), bounded by the mucous membranes of the oral cavity on one extreme and those of the anus on the other. Because the innermost surface of this tube is exposed to the environment, it is topographically outside the body, so to speak.

The shifting conditions of pH and oxygen tension and differences in the microscopic anatomy of the GI tract are reflected by the variations in or distribution of the microbiota (**figure 13.4**). Some microbes remain attached to the mucous epithelium or its associated structures, and others dwell in the lumen.* Although the abundance of nutrients invites microbial growth, the only areas that harbor appreciable permanent microbes are the oral cavity, large intestine, and rectum. The esophagus contains an extremely light load of microbiota, primarily bacteria swallowed with saliva. The stomach acid inhibits most microbes, although small numbers of lactobacilli and *Helicobacter pylori* (associated with stomach ulcers) can become established there. The small intestine has a sparse population of lactobacilli and streptococci except for its terminal segment, which has flora more similar to that of the adjacent large intestine.

Microbiota of the Mouth

The oral cavity has unique residents that are some of the most diverse and abundant of the body. Microhabitats, including the cheek epithelium, gingiva, tongue, floor of the mouth, and tooth enamel, provide numerous adaptive niches. By one estimate, there are more than 600 species residing there. The most common residents are aerobic *Streptococcus* species—*S. sanguis*, *S. salivarius*, *S. mitis*—

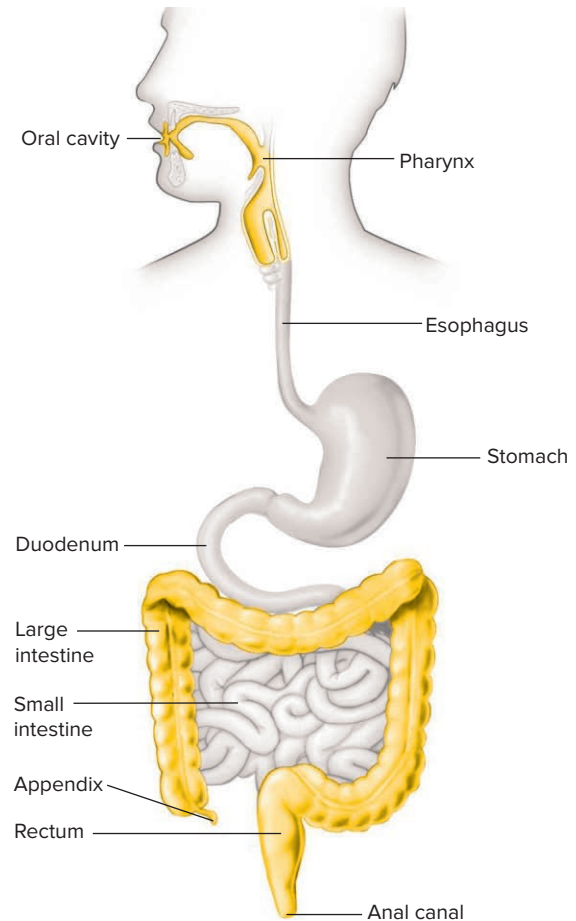

Figure 13.4 Distribution of microbes in the GI tract. Areas of the gastrointestinal tract that shelter major communities of resident microbes are highlighted in color. Noncolored areas do not harbor residents in significant numbers.

that colonize the smooth superficial epithelial surfaces. Two species, *S. mutans* and *S. sanguis*, make a major contribution to dental caries by forming sticky dextran slime layers in the presence of simple sugars. The adherence of dextrans to the tooth surface establishes the basis for a biofilm that attracts other bacteria.

Eruption of the teeth establishes an anaerobic habitat in the gingival crevice that favors the colonization by anaerobic bacteria that can be involved in dental caries and periodontal² infections. The instant that saliva is secreted from ducts into the oral cavity, it becomes laden with resident and transient bacteria. Saliva normally has a high bacterial count (up to 5×10^9 cells per milliliter), a fact that tends to make mouthwashes rather ineffective and a human bite quite dangerous.

Microbiota of the Large Intestine

Microbes inhabiting the intestinal tract have complex and profound interactions with the host. The large intestine (cecum and colon) and the rectum harbor a huge population of microbes (10^8 – 10^{11} per gram of feces). So abundant and prolific are these microbes that they constitute 30% or more of the fecal volume. Even an individual on a long-term fast passes feces consisting primarily of bacteria.

1. From *sebum*, a lipid material secreted by glands in the hair follicles.

* *lumen* (loo'-men) The space within a tubular structure.

2. Situated or occurring around the tooth.

CLINICAL CONNECTIONS

The Appendix: A Safe Haven for Microbiota?

The appendix, a 4-inch-long wormlike pouch that sprouts from the junction between the small and large intestine, had been written off for years as a lingering remnant of tissue without any real functions. Evidence offered for its uselessness is that it can be removed without real medical consequences. In recent times the medical establishment has been reconsidering the accuracy of this claim. For one thing, immunologists have known for some time that the appendix contains a significant population of white blood cells, and they consider it a modest form of lymphatic organ that protects the intestines from pathogens in the same way that tonsils protect the respiratory tract.

Studies at Duke University have produced strong evidence that the appendix has an additional role to play—that of harboring and supporting the normal resident microbiota. Researchers uncovered an extensive biofilm of beneficial microbes on the internal surfaces of the organ that periodically reinoculates the large intestine and maintains the correct composition necessary for normal colon function—enabling rapid replacement of the colon’s own biofilms after a case of diarrhea or other intestinal disruption. These experts reason that humans can function normally without an appendix because we don’t need it as much today, in light of our improved medical care and sanitation, which greatly reduce the incidence of intestinal infections.

An unusual but effective therapy for a serious form of diarrhea caused by *Clostridium difficile* involves the transplantation of fecal microbiota. The idea behind this has been around for hundreds of years, but it involves implanting a fecal sample from a healthy donor directly into the infected colon or swallowing a pill containing normal microbiota. This technique is often more successful than taking antibiotics alone for this disease. It likely restores the normal microbial residents of the colon and the appendix, which inhibits the growth of the pathogen.

There are thousands of microbial species in a “normal” intestine. What could be some unintended but harmful consequences of implanting one person’s intestinal microbiota into another person’s colon? Answer available on Connect.

The appendix has been considered an organ without much use, but recent research is verifying its importance in replenishment of the normal microbiota (**Clinical Connections**). The state of the intestinal environment favors strictly anaerobic bacteria (*Bacteroides*, *Bifidobacterium*, *Fusobacterium*, and *Clostridium*). **Coliforms*** such as *E. coli*, *Enterobacter*, and *Citrobacter* are present in smaller numbers. Many species ferment waste materials in the feces, generating vitamins (B₁₂, K, pyridoxine, riboflavin, and thiamine) and acids (acetic, butyric, and propionic) of potential value to the host. Occasionally significant are bacterial digestive enzymes that convert disaccharides to monosaccharides or promote steroid metabolism.

Intestinal bacteria contribute to intestinal odor by producing **skatole**,* amines, and gases (CO₂, H₂, CH₄, and H₂S). Intestinal gas

is known in polite circles as *flatus*, and the expulsion of it as *flatulence*. Some of the gas arises through the action of bacteria on dietary carbohydrate residues from vegetables such as cabbage, corn, and beans. The bacteria produce an average of 8.5 liters of gas daily, but only a small amount is ejected in flatus. Combustible gases occasionally form an explosive mixture in the presence of oxygen that has reportedly ignited during intestinal surgery and ruptured the colon!

Late in childhood many people lose the ability to secrete the enzyme lactase, a condition known as lactase deficiency or intolerance. Difficulties arise when an individual with this condition ingests milk or other lactose-containing dairy products. Lactose is a disaccharide that cannot be absorbed, and when lactose lies undigested, it increases the osmotic pressure in the gut, resulting in cramps, diarrhea, and intestinal distress. To complicate matters, the lactose can be digested by intestinal bacteria, which release gas and intestinal irritants. The recommended treatment for this deficiency is avoiding these foods or eating lactose-free substitutes.

Inhabitants of the Respiratory Tract

The first microorganisms to colonize the upper respiratory tract (nasal passages and pharynx) are predominantly oral streptococci. *Staphylococcus aureus* preferentially resides in the nasal entrance, nasal vestibule, and anterior nasopharynx, and *Neisseria* species take up residence in the mucous membranes of the nasopharynx behind the soft palate (**figure 13.5**). Lower in the tract are assorted streptococci and species of *Haemophilus* that colonize the tonsils and lower pharynx. Conditions even lower in the respiratory tree (bronchi and lungs) are unfavorable habitats for permanent residents.

Microbiota of the Genitourinary Tract

The regions of the genitourinary tract that harbor resident microbes are the vagina and outer opening of the urethra in females and the

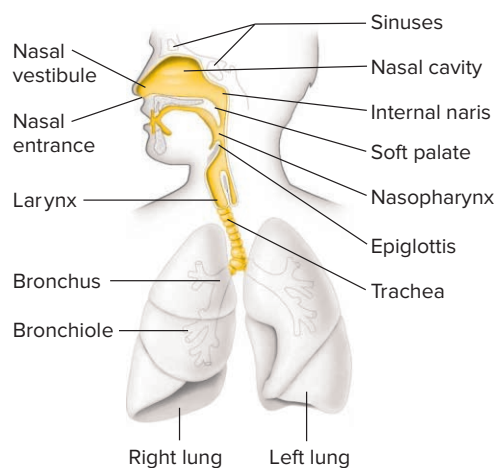

Figure 13.5 Colonized regions of the respiratory tract. The moist mucous blanket of the nasopharynx has well-entrenched resident microbes (indicated by color). Some colonization occurs in the upper trachea, but lower regions (bronchi, bronchioles, and lungs) lack resident microbes.

* *skatole* (skat'-ohl) Gr. *skatos*, dung. One chemical that gives feces their characteristic stench.

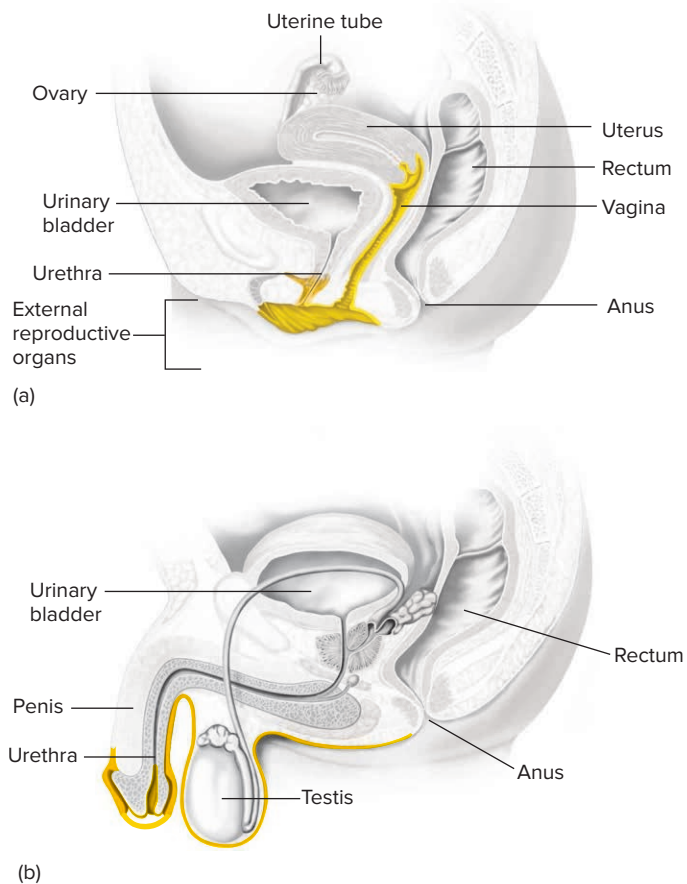

Figure 13.6 Microbiota of the reproductive tract. (a) Female and (b) male genitourinary residents (location indicated by color).

anterior urethra in males (**figure 13.6**). The internal reproductive organs are kept sterile through physical barriers such as the cervical plug and other host defenses. The kidney, ureter, bladder, and upper urethra are presumably kept sterile by urine flow and regular bladder emptying. The shortness of the urethra in women (about 3.5 cm long), frequently leads to urinary tract infections. The principal residents of the urethra are nonhemolytic streptococci, staphylococci, corynebacteria, and occasionally, coliforms.

The vagina presents a notable example of how changes in physiology can greatly influence the composition of the normal microbiota. An important factor influencing these changes in women is the hormone estrogen. Estrogen normally stimulates the vaginal mucosa to secrete glycogen, which certain bacteria (primarily *Lactobacillus* species) ferment, thus lowering the pH to about 4.5. Before puberty a girl produces little estrogen and little glycogen and has a vaginal pH of about 7. These conditions favor the establishment of diphtheroids,³ staphylococci, streptococci, and some coliforms. As hormone levels rise at puberty, the vagina begins to deposit glycogen, and the microbiota shift to the acid-producing lactobacilli. It is thought that the acidic pH of the vagina during this time prevents the establishment and invasion of microbes with potential to harm a developing fetus. The estrogen-glycogen effect continues, with minor disruption, throughout the childbearing years until menopause, when the microbiota return to

a mixed population similar to that of prepuberty. These transitions are not abrupt but occur over several months to years.

Maintenance of the Normal Microbiota

There is no question that the normal residents are essential to the health of humans and other animals. When living in balance with their host, the flora create an environment that may prevent infections and can enhance certain host defenses. In general, the microbes replace themselves naturally on a regular basis to maintain the types and numbers in their zones. However, because the exact content of the microbiota is not fixed, a number of changes can disrupt this balance. Use of broad-spectrum antibiotics, changes in diet, and underlying disease all have the potential to alter the makeup of the microbiota and tilt the system toward disease. A growing trend in therapy is the use of live cultures of known microbes in the form of **probiotics** (discussed in chapter 12). This essentially involves introducing pure cultures of known microbes into the body through ingestion or inoculation. The microbes chosen for this process are known to be beneficial and are considered nonpathogenic.

For a look into laboratory studies that address the effects of microbiota, see **13.1 Making Connections**.

3. Any nonpathogenic species of *Corynebacterium*.

13.1 MAKING CONNECTIONS

A Germ-Free Existence

For years questions lingered about how essential the microbiota are to normal life and what functions they might serve. The need for animal models to further investigate these questions led eventually to development of laboratory strains of *germ-free*, or **axenic**,* mammals and birds. After the young mammals are taken from the mother aseptically by cesarean section, they are immediately transferred to a sterile isolator or incubator. The newborns must be fed by hand through gloved ports in the isolator until they can eat on their own, and all materials entering their chamber must be sterile. Mice, rats, rabbits, guinea pigs, monkeys, and dogs are some of the mammals raised in the germ-free state.

Experiments with germ-free animals are of two basic varieties: (1) general studies on how the lack of normal microbial residents influences the nutrition, metabolism, and anatomy of the animal; and (2) **gnotobiotic*** studies, in which the germ-free subject is inoculated either with a single type of microbe to determine its individual effect or with several known microbes to determine interrelationships. Results are validated by comparing the germ-free group with a conventional, normal control group. **Table 13.A** summarizes some major conclusions arising from studies with germ-free animals.

A dramatic characteristic of germ-free animals is that they live longer and have fewer diseases than normal controls, as long as they remain in a sterile environment. From this standpoint, it seems that the microbiota are not absolutely necessary for survival and may even be the source of infectious agents. But it is also clear that axenic life is highly impractical for humans and will probably never be an option. We will have to rely on germ-free animals for valuable insights into the powerful influence microbiota exert on development, biochemistry, and behavior.

Additional studies have revealed that microbiota contribute significantly to the development of the immune system. When germ-free animals are placed in contact with normal control animals, they gradually develop resident microbes similar to those of the controls. However,

* *axenic* (aye-zeen'-ik) Gr. *a*, not and *xeno*, strange or foreign

* *gnotobiotic* (noh"-toh-by-aw'-tik) Gr. *gnotos*, known and *biosis*, life

Laboratory technician handles germ-free mouse being reared in a sterile isolator. Most gnotobiotic studies are based on specially created strains of mice. © LookatSciences/Phototake

germ-free subjects are less tolerant of these microorganisms and can die when infected by relatively harmless species. This susceptibility is due to the immature character of the immune systems of germ-free animals. These animals have a reduced number of certain types of white blood cells and slower immune responses.

One puzzling observation revolved around the fact that germ-free mice had as much as 42% less body fat than their normal counterparts. Later experiments revealed that indigenous bacteria acted to increase the body fat of mice in two ways. First, certain bacteria in the gut helped to digest complex carbohydrates, making extra calories available to the mice. Second, these same bacteria secreted a substance that, by acting on mouse hormones, caused the animal to store more fat than it otherwise would.

Gnotobiotic experiments have clarified the dynamics of several infectious diseases. For years the precise involvement of microbes in dental caries had been ambiguous. Studies with germ-free rats, hamsters, and beagles confirmed that caries development is influenced by heredity, a diet high in sugars, and poor oral hygiene. Even when all these predisposing factors are present, however, germ-free animals still remain free of caries unless they have been inoculated with specific bacteria.

TABLE 13.A A Sampling of Effects of the Germ-Free State

Germ-Free Animals Display	Significance
Enlargement of the cecum; other degenerative diseases of the intestinal tract of rats, rabbits, chickens	Microbes are needed for normal intestinal development.
Vitamin deficiency in some animals	Microbes can be a significant nutritional source of vitamins.
Underdevelopment of immune system in most animals	Microbes are needed to stimulate development of certain host defenses.
Absence of dental caries and periodontal disease in dogs, rats, hamsters	Microbes are key players in caries formation and gum disease.
Heightened susceptibility to enteric pathogens (<i>Shigella</i> , <i>Salmonella</i> , <i>Vibrio cholerae</i>) and to fungal infections	Normal bacterial residents are antagonistic against pathogens.
Lessened susceptibility to amebic dysentery	Normal resident microbes facilitate the completion of the life cycle of the amoeba in the gut.
Less body fat	Normal microbiota help to break down indigestible carbohydrates and increase fat storage in the body.
Increased anxiety and nervousness	Mice are much more sensitive to stressful conditions and produce increased levels of stress hormones.

Why is a cesarean section necessary for developing axenic mammals?

Answer available on Connect.

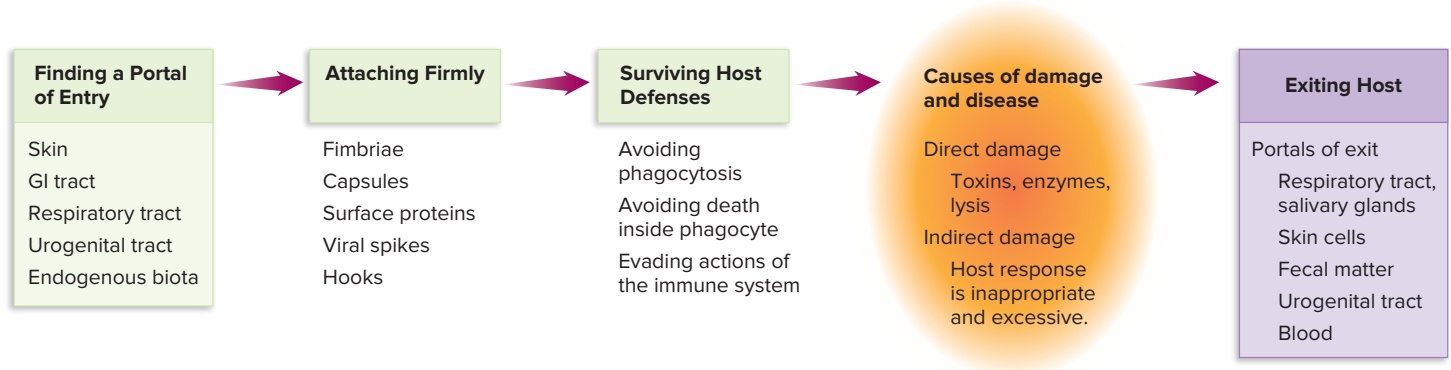

Figure 13.7 A flow diagram that relates the events in entry, establishment, and exit of infectious agents.

In this section we trace the course or “chain” of infection, a sequence of events that is summarized in **figure 13.7**. Pathogens are parasitic microbes whose relationship with a host results in infection and disease. The type and severity of infection depend on both the **pathogenicity** of the organism and the condition of the host. Pathogenicity, you will recall, is a broad concept that describes an organism’s potential to cause infection or disease and is used to divide pathogenic microbes into one of two general groups.

True pathogens (primary pathogens) are capable of causing disease in healthy persons with normal immune defenses. They are generally associated with a specific, recognizable disease, which may vary in severity from mild (colds) to severe (malaria) to fatal (rabies). Other examples of true pathogens are the influenza virus, plague bacillus, and meningococcus.

Opportunistic pathogens cause disease when the host’s defenses are compromised⁴ or when they become established in a part of the body that is not natural to them. Opportunists are not considered pathogenic to a normal healthy person and, unlike primary pathogens, do not generally possess well-developed virulence properties. Examples of opportunistic pathogens include *Pseudomonas* species and *Candida albicans*. Factors that greatly predispose a person to infections, both primary and opportunistic, are shown in **table 13.4**.

As with many concepts, the idea of a pathogen being true or opportunistic is a convenience to simplify discussion. In reality, pathogenicity extends along a range from low to high. To recognize this, the CDC has adopted a system of biosafety categories for

pathogens based on their degree of pathogenicity and the relative danger in handling them. This system assigns microbes to one of four levels or classes. Microbes not known to cause disease in humans are assigned to class 1, and highly contagious viruses that pose an extreme risk to humans are classified as class 4. Microbes of intermediate virulence are assigned to class 2 or 3. Details of this system are presented in more detail in Appendix B.

The relative severity of the disease caused by a particular microorganism depends on its **virulence**.^{*} Although the terms *pathogenicity* and *virulence* are often used interchangeably, virulence is the accurate term for describing the degree of pathogenicity. The virulence of a microbe is determined by its ability to establish itself in the host and cause damage. There is much involved in both of these steps. To invade, microbes must enter the host, attach firmly to host tissues, and survive the host defenses. To cause damage, microbes must grow in tissues, produce toxins, or induce a host response that is more injurious than protective. Any characteristic or structure of the microbe that contributes to the infection or disease state is called a **virulence factor**. Virulence can be due to a single factor or to multiple factors. In some microbes, the causes of virulence are clearly established, but in others, they are not as well understood. In the following section we examine the effects of virulence factors and their roles in the progress of an infection.

Becoming Established: Phase 1—Portals of Entry

To initiate an infection, a microbe enters the tissues of the body by a characteristic route, the **portal of entry** (**figure 13.8**), usually some sort of cutaneous or membranous boundary. The source of the infectious agent can be **exogenous**, originating from a source outside the body such as the environment or another person or animal, or **endogenous**, already existing on or in the body from microbiota or a latent infection.

For the most part, the portals of entry are the same anatomical regions that also support resident microbes: the skin, gastrointestinal tract, respiratory tract, and urogenital tract. The majority of pathogens have adapted to a specific portal of entry, one that provides a habitat for further growth and spread. This adaptation can be so restrictive that if certain pathogens enter the “wrong” portal,

TABLE 13.4 Factors That Weaken Host Defenses and Increase Susceptibility to Infection*

- Old age and extreme youth (infancy, prematurity)
- Genetic defects in immunity and acquired defects in immunity
- Surgery and organ transplants
- Organic disease: cancer, liver malfunction, diabetes
- Chemotherapy/immunosuppressive drugs
- Physical and mental stress
- Other infections

*These conditions compromise defense barriers or immune responses.

4. People with weakened immunity are often termed *immunocompromised*.

* *virulence* (veer-yoo-lents) *L. virulentia*, virus, poison.

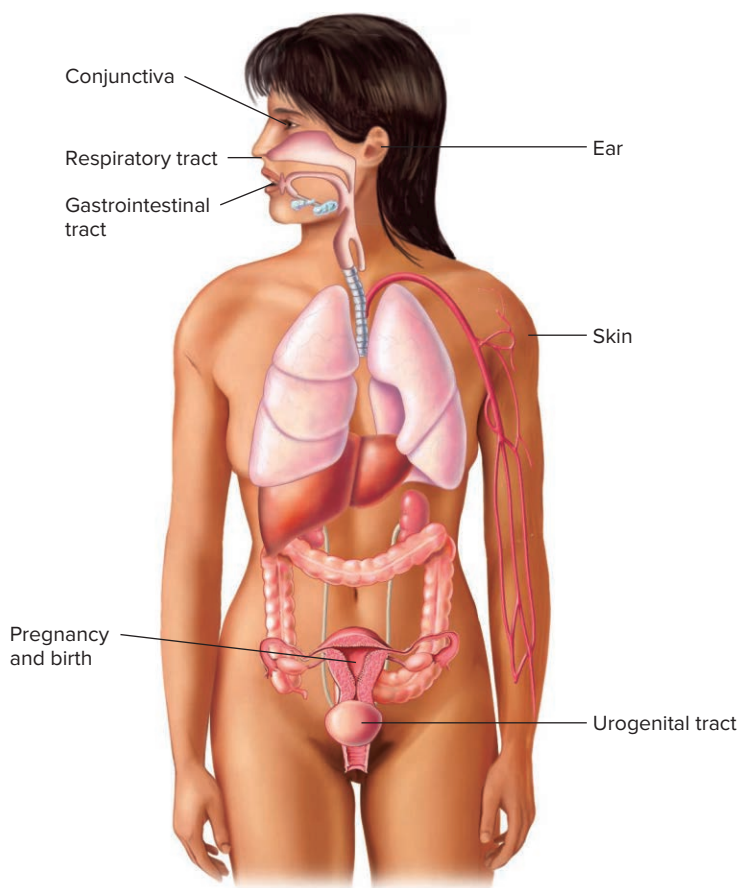

Figure 13.8 Portals of entry. Infectious microbes first enter the body through characteristic routes. Most microbes have adapted to a specific means of entry. Only one of these (the uterus) is an internal portal of entry as it may allow microbes to access a developing fetus.

they will not be infectious. For instance, inoculation of the nasal mucosa with the influenza virus invariably gives rise to the flu, but if this virus contacts only the skin, no infection will result. Likewise, contact with athlete's foot fungi in small cracks in the toe webs can induce an infection, but inhaling the spores from this same fungus will not infect a healthy individual.

Occasionally an infectious agent can enter by more than one portal. For instance, *Mycobacterium tuberculosis* enters through both the respiratory and gastrointestinal tracts, and pathogens in the genera *Streptococcus* and *Staphylococcus* have adapted to invasion through several portals of entry such as the skin, urogenital tract, and respiratory tract. Understand that the same pathogen entering different portals of entry will likely lead to different infections or diseases. Infection of a skin follicle by *Staphylococcus aureus* will produce an abscess, but its invasion of the respiratory tract causes a serious form of pneumonia.

Infectious Agents That Enter the Skin and Associated Mucous Membranes

The skin is a very common portal of entry. The actual sites of entry are usually nicks, abrasions, and punctures (many of which are tiny and inapparent) rather than smooth, unbroken skin. *Staphylococcus aureus* (the cause of boils), *Streptococcus pyogenes* (an agent of

impetigo), the fungal dermatophytes, and agents of gangrene and tetanus gain access through damaged skin. The cold sore virus (herpes simplex) enters through the mucous membranes near the lips.

Some infectious agents create their own passageways into the skin using digestive enzymes. For example, certain helminth worms burrow through the skin directly to gain access to the tissues. Other infectious agents enter through bites. The bites of insects, ticks, and other animals offer an avenue to a variety of viruses, rickettsias, and protozoa. An artificial means for breaching the skin barrier is contaminated hypodermic needles by intravenous drug abusers. Users who inject drugs are predisposed to a disturbing list of well-known diseases: hepatitis, HIV/AIDS, tetanus, tuberculosis, osteomyelitis, and malaria. A resurgence of some of these infections is directly traceable to drug use. Contaminated needles often contain bacteria from the skin or environment that induce heart disease (endocarditis), lung abscesses, and chronic infections at the injection site.

Although the conjunctiva, the outer protective covering of the eye, is a relatively good barrier to infection, bacteria such as *Chlamydia trachomatis* (trachoma), and *Neisseria gonorrhoeae* readily attach to this membrane. Many childhood viruses (measles, mumps, rubella) can gain access through the eye. As was described in this chapter's Case Study, the ebolavirus readily invades the eye surface and other membranes through direct contact with infectious fluids.

The Gastrointestinal Tract Portal of Entry

The gastrointestinal tract is the portal of entry for pathogens contained in food, drink, and other ingested substances. These pathogens are adapted to survive digestive enzymes and abrupt pH changes. Most enteric pathogens possess specialized mechanisms for entering and localizing in the mucosa of the small or large intestine. The best-known enteric agents of disease are gram-negative rods in the genera *Salmonella*, *Shigella*, and *Vibrio* and in certain strains of *Escherichia coli*. Viruses that enter through the gut are poliovirus, hepatitis A virus, echovirus, and rotavirus. Important enteric protozoans are *Entamoeba histolytica* (amebiasis) and *Giardia lamblia* (giardiasis). Although the anus is not a typical portal of entry, it becomes one in people who practice anal sex.

The Respiratory Portal of Entry

The oral and nasal cavities are also the gateways to the respiratory tract, the portal of entry for the greatest number of pathogens. Because there is a continuous mucous membrane surface covering the upper respiratory tract, the sinuses, and the auditory tubes, microbes are often transferred from one site to another. The extent to which an agent is carried into the respiratory tree is based primarily on its size. In general, small cells and particles are inhaled more deeply than larger ones.

Infectious agents with this portal of entry include the bacteria of streptococcal sore throat, meningitis, diphtheria, and whooping cough and the viruses of influenza, measles, mumps, rubella, chickenpox, and the common cold. Pathogens that are inhaled into the lower regions of the respiratory tract (bronchioles and lungs) can cause pneumonia, an inflammatory condition of the lung. Bacteria (*Streptococcus pneumoniae*, *Klebsiella*, *Mycoplasma*) and fungi (*Cryptococcus* and *Pneumocystis*) are a few of the agents involved in pneumonias. Other agents causing unique recognizable lung diseases are *Mycobacterium tuberculosis* and fungal pathogens such as *Histoplasma*.

Urogenital Portals of Entry

The urogenital tract is the portal of entry for pathogens that are contracted by sexual means (intercourse or intimate direct contact). These conditions are termed **sexually transmitted infections (STIs)** or **sexually transmitted diseases (STDs)**. The term *sexually transmitted infections* may be preferred in some cases because it recognizes the fact that many of the sexually related conditions are asymptomatic and do not lead to symptoms of disease, even though they are still transmissible. STIs and STDs account for an estimated 4% of infections worldwide, with approximately 20 million new cases each year, caused by just eight bacteria and viruses. **Table 13.5** provides the most recent available statistics (2014) and estimates of the most common sexually related infections and diseases.

The microbes of STI/STDs enter the skin or mucosa of the penis, external genitalia, vagina, cervix, and urethra. Some can penetrate an unbroken surface; others require a cut or abrasion. Once-predominant STDs such as syphilis and gonorrhea have been surpassed by a growing list led by genital warts (HPV), chlamydia, and trichomoniasis. Evolving sexual practices have increased the incidence of STI/STDs that were once uncommon, and diseases that were not originally considered sexually acquired are now so classified.⁵ Other common sexually transmitted agents include HIV, herpes simplex virus, *Candida albicans* (a yeast), and hepatitis B virus.

Not all urogenital infections are transmitted sexually. Some of these infections are caused by displaced organisms, as when normal flora from the gastrointestinal tract cause urinary tract infections, or by opportunistic overgrowth of normal microbiota (“yeast infections”).

TABLE 13.5 Estimated Case Numbers of Most Common Sexually Transmitted Infections/Diseases in the United States*

STI/STD	Estimated Number of New Cases per Year (Incidence)	Estimated Number of Cumulative Cases over Extended Time Frame (Prevalence)
Human papillomavirus	14,000,000	79,200,000
Trichomoniasis	2,230,000	3,710,000
Chlamydiosis**	1,360,000	1,570,000
Herpes simplex	510,000	24,100,000
Gonorrhea**	355,000	800,000
Hepatitis B	40,000	420,000
New HIV infections	35,000	900,000
Syphilis**	21,000	117,000

*Data from CDC, 2015, based on reported statistics and clinical data; Prevalence data predicts the cases that are undiagnosed or not treated or cured.

** These are the only STDs that are officially reported by health authorities to the CDC.

Pathogens That Infect During Pregnancy and Birth

The placenta is an exchange organ formed by maternal and fetal tissues that separate the blood of the developing fetus from that of the mother yet permit diffusion of dissolved nutrients and gases to the fetus. The placenta is ordinarily an effective barrier against pathogens that have entered the maternal circulation. However, a few microbes, such as the syphilis spirochete, can cross the placenta, enter the umbilical vein, and spread by the fetal circulation into the fetal tissues (**figure 13.9**).

5. Amebic dysentery, scabies, salmonellosis, and *Strongyloides* worms are examples.

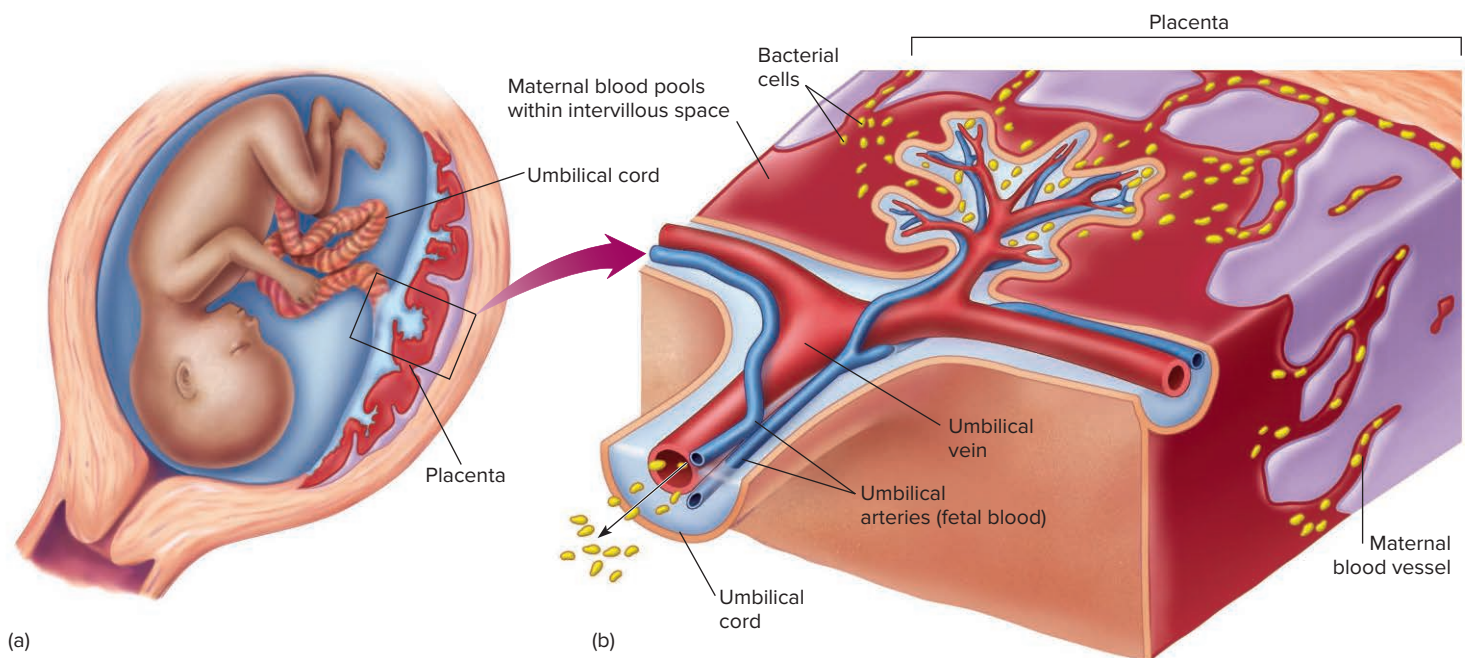

Figure 13.9 Transplacental infection of the fetus. (a) Fetus in the womb. (b) In a closer view, microbes are shown penetrating the maternal blood vessels and entering the blood pool of the placenta. They subsequently travel into the fetal circulation by way of the umbilical vein.

TABLE 13.6 Estimated Infectious Doses of Selected Pathogens*

Agent of	Infectious Dose Estimate	Primary Route of Infection
Measles	1 virus	Respiratory
Shigellosis	1–10 cells	Ingestion
Norovirus gastroenteritis	18 viruses or less	Ingestion
Tuberculosis	10–50 cells	Various
Smallpox	10–100 viruses	Respiratory
Bruceellosis	10–100 cells	Various
Viral encephalitis	10–100 viruses	Mosquito bite
Plague	100–500 cells	Flea bite
Gonorrhea	1,000 cells	Sexual contact
Anthrax	8,000–50,000 spores	Respiratory, cutaneous
Salmonellosis	10,000 cells	Ingestion
Cholera	100,000,000 cells	Ingestion

* Several of these agents are considered potential bioterror pathogens.

Not all neonatal infections occur through the placenta. Some, such as herpes simplex and chlamydia, develop perinatally when the infant is contaminated by the birth canal. The most prominent infections of fetus and neonate are grouped together in a unified cluster known by the acronym **STORCH** that medical personnel are on the alert to detect. **STORCH** stands for syphilis, toxoplasmosis, other diseases (hepatitis B, AIDS, and chlamydia), rubella, cytomegalovirus, and herpes simplex virus. The most serious complications of **STORCH** infections are spontaneous abortion, congenital abnormalities, brain damage, prematurity, and stillbirths.

The Requirement for an Infectious Dose

Another factor crucial to the course of an infection is the quantity of microbial cells or particles that enters the portal of entry. For most agents, infection will proceed only if a minimum number, called the **infectious dose (ID)**, is present. This number has been determined experimentally for many microbes. It is theorized that microbes with lower IDs tend to act locally and immediately, whereas those with higher IDs produce substances that must travel through the body to have their effect. **Table 13.6** presents examples of dose sizes for a number of pathogens, ranging from small to large infectious doses. Certain microbes (cholera, salmonellosis) have a significantly higher ID because they are inhibited or destroyed by acid as they pass through the stomach on their way into the lower GI tract. If the number of microbes entering a portal is below an infectious dose, infection and disease will generally not result. But if the quantity is far in excess of the ID, the onset of disease can be extremely rapid. Even weakly pathogenic species can be rendered more virulent with a large inoculum. Much of our knowledge of modes of infection and infectious dose has come from human and animal experimentation (**13.2 Making Connections**).

Attaching to the Host: Phase 2

Once a pathogen has penetrated the portal of entry in adequate numbers, its next must establish a stable association with the host's cells through **adhesion**. Such a firm attachment is almost always a prerequisite for invasion, because the body has so many mechanisms for flushing microbes and foreign materials from its tissues. Adhesion is dependent on binding between specific molecules on both the host and the pathogen, so a particular pathogen is limited to only those cells (and organisms) to which it can bind. Once attached, the pathogen is poised advantageously to invade the body compartments. Bacterial, fungal, and protozoal pathogens attach most often by appendages and surface structures such as fimbriae, pili, or flagella, and adhesive slimes or capsules; viruses attach by means of specialized receptors (**figure 13.10**). Larger pathogens like parasitic worms are mechanically fastened to the portal of entry by suckers, hooks, and barbs. Adhesion methods of various microbes and the diseases they cause are shown in **table 13.7**.

Invading the Host and Becoming Established: Phase 3

Microbes have numerous properties that improve their invasiveness, that is, their capacity to evade host defenses and enter into deeper tissues where they will grow and become established. These properties all contribute to virulence and thus are considered some type of **virulence factor**. These same factors determine the degree of tissue damage that occurs and hence the severity of the disease. The effects

Figure 13.10 Mechanisms of adhesion by pathogens. (a) Fimbriae, minute bristlelike appendages. (b) Adherent extracellular capsules made of slime or other sticky substances. (c) Viral envelope spikes. See table 13.7 for specific examples.

TABLE 13.7 Adhesion Properties of Microbes

Microbe	Disease	Adhesion Mechanism
<i>Neisseria gonorrhoeae</i>	Gonorrhea	Type IV pili attach to genital epithelium.
<i>Escherichia coli</i>	Diarrhea	Well-developed fimbriae adhere to intestinal cells.
<i>Shigella</i> and <i>Salmonella</i>	Gastroenteritis	Fimbriae attach to intestinal epithelium.
<i>Vibrio cholerae</i>	Cholera	Glycocalyx anchors to intestinal epithelium.
<i>Treponema</i>	Syphilis	Tapered hook embeds in host cell.
<i>Mycoplasma</i>	Pneumonia	Specialized tip fuses to lung epithelium.
<i>Pseudomonas aeruginosa</i>	Lung infections	Fimbriae and slime layer stick to host cells.
<i>Streptococcus mutans</i>	Dental caries	Dextran slime layer glues cocci to tooth surface.
Influenza virus	Influenza	Viral spikes dock to respiratory receptors.
Poliovirus	Polio	Capsid attaches to receptors on target cells.
HIV	AIDS	Viral spikes adhere to white blood cell receptors.
<i>Giardia lamblia</i>	Giardiasis	Suction disc on underside attaches to intestinal surface.
<i>Trypanosoma</i>	Trypanosomiasis	Flagellum assists in penetration of host cell.

of a pathogen's virulence factors on tissues vary greatly. Cold viruses, for example, invade and multiply but cause relatively little damage to their host. At the other end of the spectrum, pathogens such as the tetanus bacillus or rabies virus can severely damage or even kill their host.

Most of the common virulence factors fall into one or more of three categories: antiphagocytic effects, exoenzymes, and toxins. **Figure 13.11** illustrates the workings of some of these factors.

Antiphagocytic Factors

Microbes are likely to encounter resistance from host defenses when first entering the portal of entry. The

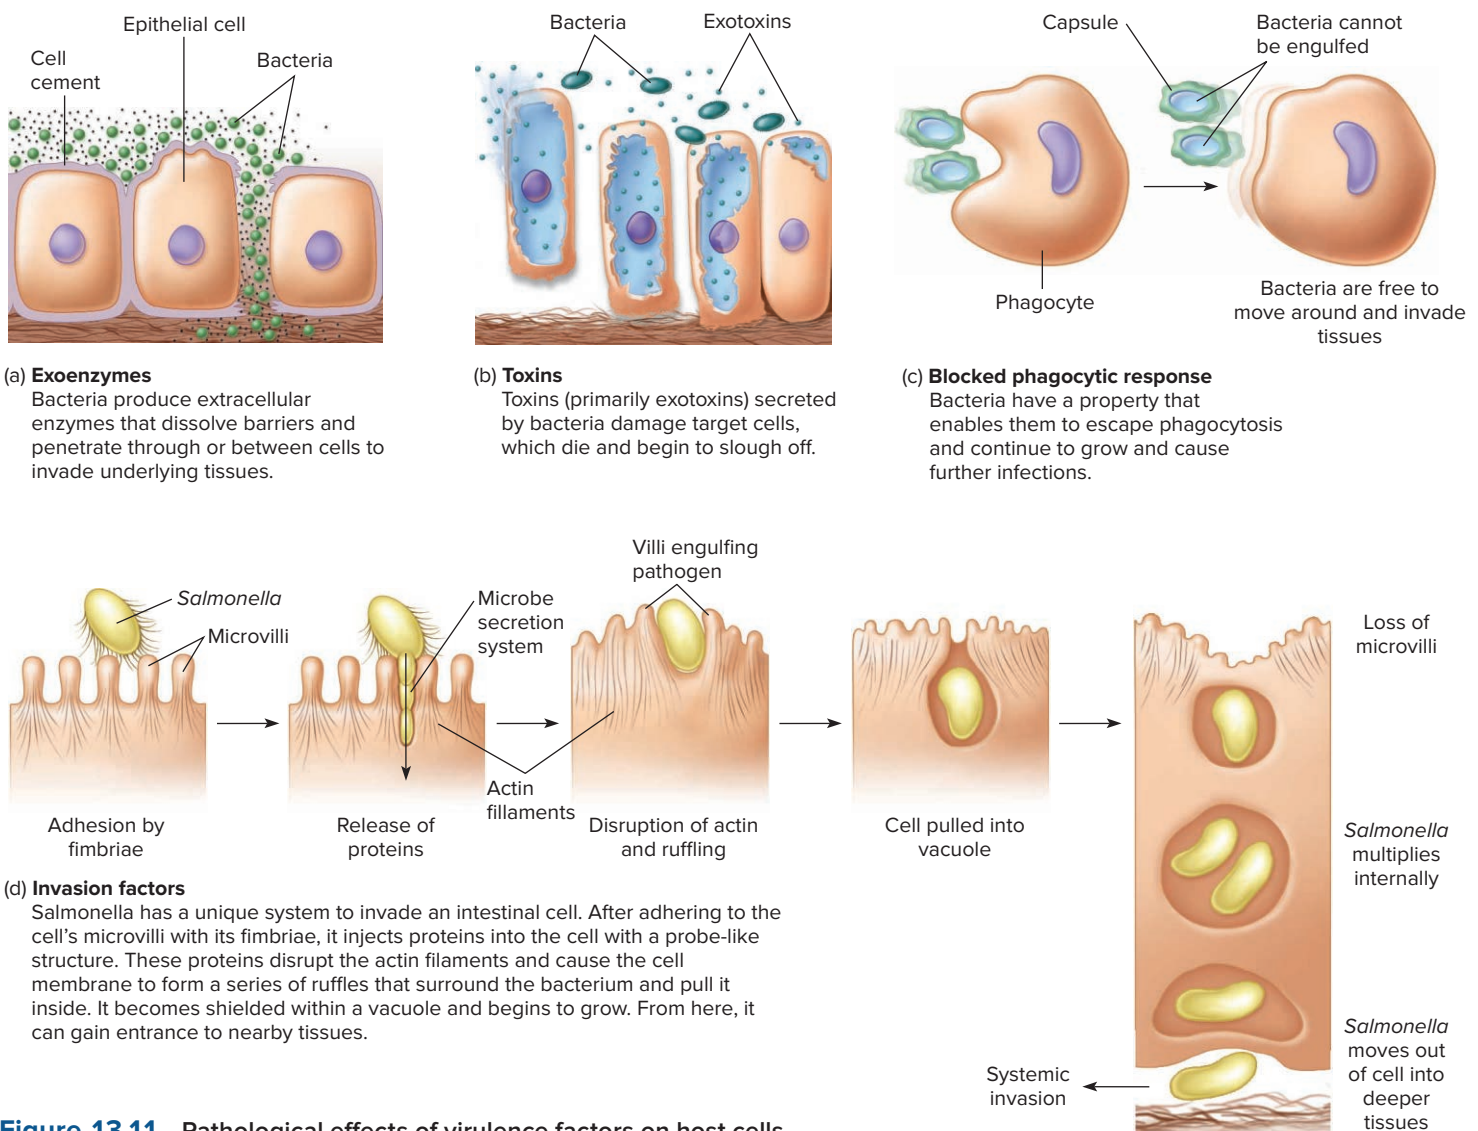

Figure 13.11 Pathological effects of virulence factors on host cells.

13.2 MAKING CONNECTIONS

Human Guinea Pigs

These days, human beings are not used as subjects for determining the effects of infectious disease, but in earlier times they were. The tradition of human experimentation dates well back into the eighteenth century, and the subject frequently was the experimenter himself. In some studies, mycologists inoculated their own skin and even that of family members with scrapings from fungal lesions to demonstrate that the disease was transmissible. In the early days of parasitology, it was not uncommon for a brave researcher to swallow worm eggs in order to study the course of his infection and the life cycle of the worm.

In a sort of reverse test, one of Robert Koch's German colleagues, named Max von Petenkofer, believed so strongly that cholera was *not* caused by a bacterium that he and his assistant swallowed cultures of *Vibrio cholerae*. Fortunately for them, they acquired only a mild form of the disease. Many self-experimenters have not been so fortunate.

One of the most famous cases is that of Jesse Lazear, a Cuban physician who worked with Walter Reed on the etiology of yellow fever in 1900. Dr. Lazear was convinced that mosquitoes were directly involved in the spread of yellow fever; and by way of proof, he allowed himself and two volunteers to be bitten by mosquitoes infected with the blood of yellow fever patients. All three became ill as a result of this exposure; Dr. Lazear's sacrifice was the ultimate one: he died of yellow fever.

A remarkable, more recent use of human guinea pigs occurred from 1954 to 1973, when the U.S. government staged 153 separate tests using biological warfare agents. The scientists in charge of so-called "Operation Whitecoat" wanted to determine the infectivity of certain agents and how readily they could be acquired through airborne or other means. A group of about 2,000 courageous volunteers agreed to be exposed to some highly virulent pathogens, including the agents of Q fever, tularemia, and leishmaniasis. None of the deadliest pathogens (anthrax, plague, smallpox) was tested on humans. The test subjects all shared some important characteristics: they were young male draftees, and they belonged to the Seventh-Day Adventist religion.

What made them uniquely suited to this highly secret study was their status as conscientious objectors—opposed to service as combat

A specially constructed chamber with vents for exposing test subjects to pathogens Source: US Army

soldiers on religious grounds. Many of them were assigned to other military positions of a medical or clerical type. One of the expectations was that they would consent to be subjects for experiments. The tests, run by the biological warfare program at Fort Detrick, Maryland, involved direct exposure to airborne pathogens released inside special chambers, or in some cases breathing aerosols of pure cultures released into the air. Frequently monkeys and actual guinea pigs were exposed simultaneously as a way to track the same infectious agent in animals for comparison.

A number of important discoveries were made. The infectious doses of several pathogens were determined by these studies, as were the effects of particle size. Other tests helped determine the effectiveness of vaccines. It is quite extraordinary that none of the men experienced long-term diseases as a result of these studies, given the high risks involved. It is very unlikely that this sort of testing would be sanctioned in the present era, but there is no doubt that the sacrifices of these men greatly advanced our understanding of the risks of biological warfare.

What are some reasons epidemiologists might have needed to use human subjects to test for the effects of pathogens? Answer available on Connect.

initial response comes from white blood cells called **phagocytes**. These cells can ordinarily engulf pathogens and destroy them by means of enzymes and antimicrobial chemicals (see chapter 14).

Antiphagocytic factors are a type of virulence factor used by some pathogens to avoid phagocytes or to circumvent some part of the phagocytic process (**figure 13.11c**). The most aggressive strategy involves bacteria that kill phagocytes outright. Species of both *Streptococcus* and *Staphylococcus* produce **leukocidins**, substances that are toxic to white blood cells. Some microorganisms secrete an extracellular surface layer (slime or capsule) that makes it physically difficult for the phagocyte to engulf them. *Streptococcus pneumoniae*, *Salmonella typhi*, *Neisseria meningitidis*, and *Cryptococcus neoformans* are notable examples. Some bacteria are well adapted to survival inside phagocytes after ingestion. For instance, pathogenic species of *Legionella* and *Mycobacterium* are readily engulfed but

are capable of avoiding further destruction. This survival inside phagocytes has special significance because it provides a place for the microbes to hide, grow, and be spread throughout the body.

Getting Inside Host Cells Intracellular pathogens in particular must gain entrance to a host cell to complete their life cycles. Rickettsias, chlamydias, and viruses have evolved specific virulence mechanisms for entering a cell through some variation of engulfment or fusion. Some bacterial pathogens invade their target cells by using a secretion system that inserts specialized virulence proteins directly into them (**figure 13.11d**). In the case of *Salmonella* and

Quick Search

Search on "Salmonella video HHMI Biointeractive" to view a short animation of this process.

E. coli, the virulence proteins disrupt the actin cytoskeleton of an intestinal cell and force the cell surface to form ruffles that pull the pathogens into the cell interior. Once inside, they multiply within vacuoles and use the cell as a passageway to break out into the underlying layers of tissues. Other pathogens (*Listeria* and *Shigella*) collect actin filaments and use them as motility organelles to move about in the cells.

Extracellular Enzymes

Many pathogenic bacteria, fungi, protozoa, and worms secrete **exoenzymes** that disrupt the structure of tissues. Other enzymes dissolve the host's defense barriers and promote the spread of microbes to deeper regions of the body. A few examples include:

1. mucinase, which digests the protective coating on mucous membranes and is a factor in amoebic dysentery;
2. keratinase, which digests the principal component of skin and hair and is secreted by fungi that cause ringworm;
3. collagenase, which digests the protein fibers of connective tissue and is an invasive factor for *Clostridium* species and some parasitic worms; and
4. hyaluronidase, which digests hyaluronic acid, the ground substance that cements animal cells together. This enzyme is an important virulence factor in staphylococci, clostridia, streptococci, and pneumococci (figure 13.11a).

Some enzymes react with components of the blood. Coagulase, an enzyme produced by pathogenic staphylococci, causes clotting of blood or plasma. By contrast, the bacterial kinases (streptokinase, staphylokinase) activates a pathway that breaks down fibrin clots, which expedites the invasion of damaged tissues by the pathogen. In fact, a drug containing streptokinase (Streptase) is administered to patients with life-threatening thrombi and emboli.⁶

Bacterial Toxins: Poisonous Products

A **toxin** is a specific chemical product of microbes, plants, and some animals that has poisonous effects on other organisms. **Toxigenicity**, the power to produce toxins, is a genetically controlled characteristic of many bacterial species and is responsible for the adverse effects of a variety of diseases generally called **toxinoses**. Toxinoses in which the toxin is spread by the blood from the site of infection are called **toxemias** (tetanus and diphtheria, for example), whereas those caused by ingestion of toxins are **intoxications** (botulism). A toxin is named according to its specific target of action: neurotoxins act on the nervous system; enterotoxins act on the intestine; hemotoxins damage red blood cells; and nephrotoxins target the kidneys.

A more traditional scheme classifies bacterial toxins according to their origins (figure 13.12). A toxin molecule secreted by a living bacterial cell into the infected tissues is an **exotoxin**. A toxin that is not secreted but is released only after the cell is damaged or lysed is an **endotoxin**. Other important differences between the two groups are summarized in table 13.8.

Figure 13.12 The origins and effects of circulating exotoxins and endotoxin. (a) Exotoxins, given off by live cells, have highly specific targets and physiological effects. (b) Endotoxin, given off when the cell wall of gram-negative bacteria disintegrates, has more generalized physiological effects.

TABLE 13.8 Differential Characteristics of Bacterial Exotoxins and Endotoxin

Characteristic	Exotoxins	Endotoxin
Toxicity	Toxic in small amounts	Toxic in higher quantities
Effects on the Body	Specific to a cell type (blood, liver, nerve)	Systemic and less specific: fever, inflammation, weakness, shock
Chemical Composition	Small proteins	Lipopolysaccharide of cell wall
Heat Denaturation at 60°C	Unstable	Stable
Toxoid Formation	Can be converted to toxoid*	Cannot be converted to toxoid
Immune Response	Stimulate antitoxins**	Does not stimulate antitoxins
Fever Stimulation	Usually not	Yes
Manner of Release	Secreted from live cell	Released from cell wall during lysis
Typical Sources	A few gram-positive and gram-negative bacteria	All gram-negative bacteria
Examples of Diseases	Tetanus, diphtheria, cholera, anthrax	Meningitis, endotoxic shock, salmonellosis

*A toxoid is an inactivated toxin used in vaccines.

**An antitoxin is an antibody that reacts specifically with a toxin.

6. These conditions are intravascular blood clots that can cause circulatory obstructions.

Exotoxins are proteins with a strong specificity for a target cell and extremely powerful, sometimes deadly, effects. They generally affect cells by damaging the cell membrane and initiating lysis or by disrupting intracellular function (**figure 13.11b**). **Hemolysins*** are a class of bacterial exotoxins that disrupt the cell membrane of red blood cells (and some other cells, too). This damage causes the red blood cells to hemolyze—to burst and release hemoglobin pigment. Hemolysins that increase pathogenicity include the streptolysins of *Streptococcus pyogenes* and the alpha (α) and beta (β) toxins of *Staphylococcus aureus*. When colonies of bacteria growing on blood agar produce hemolysin, distinct zones appear around the colony. The pattern of hemolysis is one characteristic used to identify bacteria and determine their degree of pathogenicity.

The exotoxins of diphtheria, tetanus, and botulism, among others, attach to a particular target cell, become internalized, and interrupt an essential cell pathway. This type of exotoxin is specified as an **A-B toxin (figure 13.13)**, so named because it consists of two parts, an A (active) component and a B (binding) component. The B component binds to a specific receptor molecule on the surface of the host cell, then the A component is moved across the host cell membrane. The A components of most A-B toxins interfere with the production of a normal cell protein. Loss of that protein's function then damages and disrupts a specific target cell or tissue. The consequences of cell disruption depend upon the target.

Examples include a toxin of *Clostridium tetani* that blocks the action of certain spinal neurons; the toxin of *Clostridium botulinum* that interferes with transmission of nerve-muscle stimuli; pertussis toxin that inactivates the respiratory cilia; and cholera toxin that provokes profuse salt and water loss from intestinal cells. Review the Case Study in chapter 8, which deals with some characteristics of botulinum toxin.

Unlike exotoxins, of which there are many specific examples, there is just a single type of endotoxin. It is chemically a substance called lipopolysaccharide (LPS), which is part of the outer membrane of gram-negative cell envelopes. When gram-negative bacteria cause infections, some of the bacteria eventually lyse and release these LPS molecules into the infection site or into the circulation. Endotoxin differs from exotoxins in having a variety of systemic effects on tissues and organs. Depending upon the amounts present, endotoxin can cause fever, inflammation, hemorrhage, and diarrhea. Blood infection by gram-negative bacteria such as *Salmonella*, *Shigella*, *Neisseria meningitidis*, and *Escherichia coli* is particularly dangerous. It can lead to fatal endotoxic shock caused by large amounts of endotoxins being released into the blood stream.

Effects of Infection on Organs and Body Systems

In addition to the adverse effects of enzymes, toxins, and other factors, multiplication by a pathogen frequently weakens host tissues. Pathogens can obstruct tubular structures such as blood vessels, lymphatic channels, fallopian tubes, and bile ducts. Accumulated damage can lead to cell and tissue death, a condition called **necrosis**.

Figure 13.13 The actions of A-B toxin of *Corynebacterium diphtheriae*. The B part attaches to a specific receptor on the cell membrane, and the toxin is engulfed into a vacuole. The A and B parts separate, and the A portion is released into the cytoplasm, where it blocks the synthesis of a protein required for normal cell function. The diphtherotoxin is highly destructive of cells, especially those of the heart and nervous system.

Although viruses do not produce toxins or destructive enzymes, they destroy cells by multiplying in and lysing them. Many of the cytopathic effects of viral infection arise from the impaired metabolism and death of cells (see chapter 6).

The direct effects of virulence factors such as enzymes and toxins can cause significant harm to cells, tissues, and organs. It is important to note that many microbial diseases are actually the result of indirect damage, or the host's excessive or inappropriate response to a microorganism. This means that pathogenicity is not a trait inherent in microorganisms alone but is really a consequence of the interplay between microbe and host. The capsule of *Streptococcus pneumoniae* is a good example. It prevents the bacterium from being cleared from the lungs by phagocytic cells, leading to a powerful inflammatory response by white blood cells and a continuous influx of fluids into the lung spaces—a condition we know as pneumonia.

*hemolysins (hee-mahl'-uh-sinz) Gt. *hemo*, blood, and *lysin*, to split.

Of course, it is easier to study and characterize the microbes that cause direct damage through toxins or enzymes. For this reason, these true pathogens were the first to be fully understood as the science of microbiology progressed. But in the last 15 to 20 years, microbiologists have come to appreciate exactly how important the relationship between microbe and host is, and this has greatly expanded our understanding of infectious diseases.

Check Your Progress SECTION 13.2

8. Explain several ways in which true pathogens differ from opportunistic pathogens.
9. Distinguish between pathogenicity and virulence.
10. Explain the concept of portal of entry, and list the major portals of entry with examples of associated infections.
11. Differentiate between exogenous and endogenous infections.
12. What factors possibly affect the size of the infectious dose?
13. Describe several components of pathogens that are involved in microbial adhesion.
14. Define virulence factors and give examples of them in gram-positive and gram-negative bacteria, viruses, and parasites.
15. Discuss the effects of several virulence factors that help microbes invade hosts and evade host defenses.
16. Define *toxigenicity* and summarize the main features of exotoxins and endotoxins.
17. Which body cells or tissues are affected by hemolysins, leukocidins, hyaluronidase, kinases, tetanus toxin, pertussis toxin, and enterotoxin?

13.3 The Outcomes of Infection and Disease

Expected Learning Outcomes

14. Describe the clinical stages of infection.
15. Use key terms to describe different patterns of infection.
16. Use correct terminology to explain the manifestations of infections and inflammation.
17. Discuss the major portals of exit and how they influence the end stages of infection and disease.

The Stages of Clinical Infections

As the body of the host responds to the invasive and toxigenic activities of a pathogen, it passes through four distinct phases of infection and disease: the incubation period, the prodromal stage, the period of invasion, and the convalescent period (**figure 13.14**).

The **incubation period** is the time from initial contact with the infectious agent (at the portal of entry) to the appearance of the first symptoms. During the incubation period, the agent is multiplying at the portal of entry but has not yet caused enough damage to elicit symptoms. Although this period is relatively well defined and predictable for each microorganism, it does vary according to host

Figure 13.14 Stages in the course of infection and disease. Dashed lines represent periods with a variable length.

resistance, degree of virulence, and distance between the target organ and the portal of entry (the farther apart, the longer the incubation period). Overall, an incubation period can range from several hours in pneumonic plague to several years in leprosy. The majority of infections, however, have incubation periods ranging between 2 and 30 days.

The earliest notable symptoms of infection appear as a vague feeling of discomfort, such as head and muscle aches, fatigue, upset stomach, and general malaise. This short period (1–2 days) is known as the **prodromal stage**. The infectious agent next enters a **period of invasion**, during which it multiplies at high levels, exhibits its greatest toxicity, and becomes well established in its target tissues and organs. This period is often marked by fever and other prominent and more specific signs and symptoms, which can include cough, skin lesions, diarrhea, loss of muscle control, swelling, jaundice, discharge of exudates, or severe pain, depending on the pathogen. The length of this period is extremely variable.

As the patient begins to respond to the infection, the symptoms decline—sometimes dramatically, other times slowly. During the recovery that follows, called the **convalescent period**, the patient's strength and health gradually return as the immune response begins to clear the infectious agent and restore normal function to damaged tissues. In the event that the patient does not recover and dies, the infection is considered *terminal*.

The transmissibility of the microbe during these four stages must be considered on an individual basis. A few agents are released mostly during incubation (measles, for example); many are released during the invasive period (*Shigella*); and others can be transmitted during all of these periods (hepatitis B virus, norovirus).

Patterns of Infection

Patterns of infection are many and varied. In the simplest situation, a **localized infection**, the microbe enters the body and remains confined to a specific tissue (**figure 13.15a**). Examples of localized infections are boils, fungal skin infections, and warts.

Many infectious agents do not remain localized but spread from the initial site of entry to other tissues. In fact, spreading is necessary for pathogens such as rabies and hepatitis A virus, whose target tissue may be some distance from the site of entry. The rabies

Figure 13.15 The occurrence of infections with regard to location and sequence. (a) A localized infection, in which the pathogen is restricted to one specific site. (b) Systemic infection, in which the pathogen spreads through circulation to many sites. (c) A focal infection occurs initially as a local infection, but circumstances cause the microbe to be carried to other sites systemically. (d) A mixed infection, in which the same site is infected with several microbes at the same time. (e) In a primary-secondary infection, an initial infection is complicated by a second one in the same or a different location and caused by a different microbe.

virus travels from a bite wound along nerve tracts to its target in the brain, and the hepatitis A virus moves from the intestine to the liver via the circulatory system. When an infection spreads to several sites and tissue fluids, usually in the bloodstream, it is called a **systemic infection** (figure 13.15b). Examples of systemic infections are viral diseases (measles, rubella, chickenpox, and AIDS); bacterial diseases (brucellosis, anthrax, typhoid fever, and syphilis); and fungal diseases (histoplasmosis and cryptococcosis). Infectious agents can also travel to their targets by means of nerves (as in rabies) or cerebrospinal fluid (as in meningitis).

A **focal infection** is said to exist when the infectious agent breaks loose from a local infection and is seeded or *disseminated* into other tissues (figure 13.15c). This pattern is exhibited by tuberculosis or by streptococcal pharyngitis, which gives rise to scarlet fever. In the condition called **toxemia**,⁷ the infection itself remains localized at the portal of entry, but the toxins produced by the pathogens are carried by the blood to the actual target tissue. In this way, the cells initially infected by the bacterial cells can be different from the targets of their toxin. Examples include diphtheria and some staphylococcal diseases.

An infection is not always caused by a single microbe. In a **mixed infection**, several agents establish themselves simultaneously at the infection site (figure 13.15d). In some mixed infections, the microbes cooperate in breaking down a tissue. In other cases, one microbe creates an environment that enables another

microbe to invade. Gas gangrene, wound infections, dental caries, and human bite infections tend to be mixed. These are sometimes called **polymicrobial** diseases and may be the result of biofilm formation at the site of infection.

Some diseases are described according to the sequence of occurrence. When an initial, or **primary**, infection is complicated by another infection caused by a different microbe, this subsequent infection is termed a **secondary infection** (figure 13.15e). This pattern is seen in a child whose chickenpox (primary infection) becomes infected with *Staphylococcus aureus* (secondary infection). Another significant combination is seen in patients who develop secondary pneumonia as a complication of influenza. The secondary infection need not be in the same site as the primary infection, and it usually indicates weakened host defenses.

Infections that come on rapidly, with severe but short-lived effects, are called **acute infections**. Infections that progress and persist over a long period of time are **chronic infections**. A Guide to the Terminology of Infection and Disease illustrates other common words used to describe infectious diseases.

A Guide to the Terminology of Infection and Disease

Words in medicine have great power and economy. A single technical term can often replace a whole phrase or sentence, thereby saving time and space in charting. The beginning student may feel overwhelmed by what seems like a mountain of new words. However, having a grasp of a few root words and a fair amount of

7. Not to be confused with toxemia of pregnancy, which is a metabolic disturbance and not an infection.

anatomy can help you learn many of these words and even deduce the meaning of unfamiliar ones. Some examples of medical shorthand follow.

The suffix *-itis* means an inflammation and, when affixed to the end of an anatomical term, indicates an inflammatory condition in that location. Thus, meningitis is an inflammation of the meninges surrounding the brain; encephalitis is an inflammation of the brain itself; hepatitis involves the liver; gastroenteritis, the intestine; and otitis media, the middle ear. Although not all inflammatory conditions are caused by infections, many infectious diseases inflame their target organs.

The suffix *-emia* is derived from the Greek word *haeima*, meaning blood. When added to a word, it means “associated with the blood.” Thus, septicemia means sepsis (infection) of the blood; bacteremia, bacteria in the blood; viremia, viruses in the blood; and fungemia, fungi in the blood. It is also applicable to specific conditions such as toxemia, gonococcemia, and spirochetemia.

The suffix *-osis* means “a disease or morbid process.” It is frequently added to the names of pathogens to indicate the disease they cause: for example, listeriosis, histoplasmosis, toxoplasmosis, shigellosis, salmonellosis, and borreliosis. A variation of this suffix is *-iasis*, as in trichomoniasis and candidiasis.

The suffix *-oma* comes from the Greek word *onkomas* (swelling) and means tumor. Although the root is often used to describe cancers (lymphoma, melanoma), it is also applied in some infectious diseases that cause masses or swellings (tuberculoma, leproma).

Signs and Symptoms: Warning Signals of Disease

When an infection causes pathologic changes leading to disease, it is often accompanied by a variety of signs and symptoms. A **sign** is any objective evidence of disease as noted by an observer; a **symptom** is the subjective evidence of disease as sensed by the patient. Signs tend to be more precise than symptoms and are often measured. Both can be the result of the same underlying cause. For example, an infection of the brain may present with the sign of bacteria in the spinal fluid and the symptom of headache. Or a streptococcal infection may produce a sore throat (symptom) and inflamed pharynx (sign). Disease indicators that can be sensed and observed can qualify as either a sign or a symptom depending upon how they are reported. When a disease can be identified or described by a defined collection of signs and symptoms, it is termed a **syndrome**. Signs and symptoms with considerable importance in diagnosing infectious diseases are shown in **table 13.9**.

Signs and Symptoms of Inflammation

The earliest manifestations of disease generally result from the activation of the defense process called **inflammation**.^{*} The inflammatory response includes cells and chemicals that are activated when there has been damage to tissues by a microbe or its products. This subject is discussed in greater detail in chapter 14, but as noted earlier, many symptoms and signs of infection are caused by the

^{*}*inflammation* (in-flam-aye'-shun) L. *inflammation*, to set on fire.

TABLE 13.9 Common Signs and Symptoms of Infectious Diseases

Signs*	Symptoms
Fever	Chills
Septicemia	Pain, irritation
Microbes in tissue fluids that should be sterile	Nausea
Abnormal chest sounds	Malaise, fatigue
Skin eruptions	Chest tightness
Leukocytosis	Itching
Leukopenia	Headache
Swollen lymph nodes	Weakness
Abscesses	Abdominal cramps
Tachycardia (increased heart rate)	Anorexia (lack of appetite)
Antibodies in serum	Sore throat

*The technical terms for signs are defined in the body of the text

mobilization of this system. Inflammation is always a likely cause of symptoms such as redness, pain, soreness, and swelling. A general term for a noticeable sign of infection or disease is **lesion**.^{*} Some lesions typical of inflammation include **edema**,^{*} the accumulation of fluid in an afflicted tissue; **granulomas** and **abscesses**, walled-off collections of inflammatory cells and microbes in the tissues; and **lymphadenitis**, swollen lymph nodes.

Rashes and other skin eruptions are some of the most common lesions in many diseases, and because they tend to mimic each other, it can be difficult to differentiate among diseases on this basis alone. Skin lesions can be restricted to the epidermis and its glands and follicles, or they can extend into the dermis and subcutaneous regions. The lesions of some infections (boils, chickenpox, athlete's foot, warts) undergo characteristic changes in appearance and location during the course of disease and thus fit more than one category.

Signs of Infection in the Blood

Changes in the number of circulating white blood cells, as determined by blood cell counts, are considered to be a significant sign of possible infection. **Leukocytosis**^{*} is an increase in the level of white blood cells, whereas **leukopenia**^{*} is a decrease. Other signs of infection revolve around the occurrence of a microbe or its products in the blood. The clinical term for blood infection, **septicemia**, refers to a general state in which microorganisms are multiplying in the blood and are present in large numbers. When small numbers of bacteria or viruses are found in the blood, the correct terminology is **bacteremia** or **viremia**, which means that these microbes are present in the blood but are not necessarily multiplying.

During infection, a normal host will invariably show signs of an immune response in the form of antibodies in the serum or some type of sensitivity to the microbe. This fact is the basis for

^{*}*lesion* lee'-zhun L. *laesio*, to hurt.

^{*}*edema* (uh-dee'-muh) Gr. *oidema*, swelling.

^{*}*leukocytosis* (loo'-koh'-sy-toh'-sis) From *leukocyte*, a white blood cell, and the suffix *-osis*.

^{*}*leukopenia* (loo'-koh'-pee'-nee-uh) From *leukocyte* and *penia*, a loss or lack of.

several serological tests used in diagnosing infectious diseases such as HIV infection or syphilis. Such specific immune reactions indicate the body's attempt to develop specific immunities against pathogens. We concentrate on this role of the host defenses in chapters 14 and 15.

Infections That Go Unnoticed

It is rather common for an infection to produce no noticeable or typical symptoms, even though the microbe is active in the host tissue. In these cases the person does not show overt indications of infection. Infections of this nature are known as **asymptomatic**, **subclinical**, or *inapparent* because the patient experiences no symptoms usually associated with disease and does not seek medical attention. However, it is important to note that most infections are attended by some sort of detectable *sign*. In section 13.4 we further address the significance of subclinical infections in the transmission of infectious agents.

The Portal of Exit: Vacating the Host

Earlier we introduced the idea that a parasite is considered *unsuccessful* if it does not have a provision for leaving its host and moving to other susceptible hosts. With few exceptions, pathogens depart by a specific avenue called the **portal of exit** (figure 13.16).

Figure 13.16 Major portals of exit of infectious diseases. Pathogens are released from the body through secretion, excretion, discharge, or shedding.

In most cases the pathogen is shed or released from the body through secretion, excretion, discharge, or sloughed tissue. The high number of pathogens in these materials increases both virulence and the likelihood that the pathogen will reach other hosts. One of the most dramatic examples of this is ebolavirus (Case Study), which is at its most transmissible late in the disease and is released in massive numbers in every bodily fluid. In many cases the portal of exit is the same as the portal of entry, but a few pathogens use a different route. As we will see in section 13.4, the portal of exit concerns epidemiologists because it greatly influences the dissemination of infection in a population.

Respiratory and Salivary Portals

Mucus, sputum, nasal drainage, and other moist secretions are the fluids of escape for the pathogens that infect the lower or upper respiratory tract. The most forceful means of releasing these secretions are coughing and sneezing (see figure 13.19), although they can also be released during talking and laughing. Tiny particles of liquid released into the air form aerosols or droplets that can spread the infectious agent to other people. The agents of tuberculosis, influenza, measles, and chickenpox most often leave the host through airborne droplets. Droplets of saliva are also the exit route for several viruses, including those of mumps, rabies, and infectious mononucleosis.

Epithelial Cells

The outer layers of the skin and scalp are constantly being shed into the environment. A large proportion of household dust is actually composed of skin cells. A single person can shed several billion skin cells a day, and some persons, called shedders, disseminate massive numbers of bacteria into their immediate surroundings. Skin lesions and their exudates can serve as portals of exit in warts, fungal infections, boils, herpes simplex, smallpox, and syphilis.

Fecal Exit

Feces are a very common portal of exit. Some intestinal pathogens grow in the intestinal mucosa and create an inflammation that increases the motility of the bowel. This increased motility speeds up peristalsis, resulting in diarrhea. The more-fluid stool provides a rapid exit for the pathogen, as we see with dysentery, cholera, salmonellosis, and noroviruses. A number of helminth worms release cysts and eggs through the feces. Feces containing pathogens are a public health problem when allowed to contaminate drinking water or when used to fertilize crops.

Urogenital Tract

A number of agents involved in sexually transmitted infections leave the host in vaginal discharge or semen. This is also the source of neonatal infections such as herpes simplex, *Chlamydia*, and *Candida albicans*, which infect the infant as it passes through the birth canal. Less commonly, certain pathogens that infect the kidney are discharged in the urine; examples are the agents of leptospirosis, typhoid fever, tuberculosis, and schistosomiasis.

Removal of Blood or Bleeding

Although the blood does not have a direct route to the outside, it can serve as a portal of exit when it is removed or released through a vascular puncture made by natural or artificial means. Blood-feeding animals such as ticks, fleas, and mosquitoes are common transmitters of pathogens. Human immunodeficiency and hepatitis viruses are transmitted by shared needles or through small abrasions in a mucous membrane during sexual intercourse.

Because many microbes can be transferred through blood donation, the monitoring of both donors and donated blood has to be scrupulous. In the mid-1980s, several thousand people suffering from hemophilia were infected with HIV as a result of receiving blood-clotting factors contaminated with the virus. The current risk for transfusion-transmitted infections is about one case in 10 million transfusions. One factor that increases risk is the presence of emerging disease agents in the blood supply that have not yet been detected. This has already happened with West Nile virus and Chagas disease.

The Persistence of Microbes and Pathologic Conditions

The apparent recovery of the host does not always mean that the microbe has been completely removed or destroyed by the host defenses. After the initial symptoms in certain chronic infectious diseases, the infectious agent retreats into a state called **chronic persistence** or **latency**. In some cases of latency, the microbe can periodically become active and produce recurrent disease. The viral agents of herpes simplex, herpes zoster, hepatitis B, AIDS, and Epstein-Barr can persist in the host for long periods. The agents of syphilis, typhoid fever, tuberculosis, and malaria also enter into latent stages. The person harboring a persistent infectious agent may or may not shed it during the latent stage. If it is shed, such persons are chronic carriers who serve as sources of infection for the rest of the population.

Some diseases leave **sequelae*** in the form of long-term or permanent damage to tissues or organs. For example, meningitis can result in deafness, a strep throat can lead to rheumatic heart disease, Lyme disease can cause arthritis, and hepatitis B can initiate cirrhosis and liver cancer.

13.4 Epidemiology: The Study of Disease in Populations

Expected Learning Outcomes

18. Define *epidemiology*, and summarize the major goals of its studies.
19. Relate the significant factors involved in the transmission of infectious diseases.
20. Explain the concept of carriers and describe several types.
21. Use examples to distinguish between the types of vectors, and discuss the importance of zoonoses.
22. Differentiate between communicable and noncommunicable infectious diseases.
23. Characterize the patterns of transmission for communicable diseases.

So far our discussion has revolved primarily around the impact of an infectious disease in individuals. We now turn our attention to the effects of diseases on the community—the realm of **epidemiology**.* By definition, this term involves the study of the frequency and distribution of disease and other health-related factors in defined human populations. It involves many disciplines—not only microbiology but also anatomy, physiology, immunology, medicine, psychology, sociology, ecology, and statistics—and it considers many diseases other than infectious ones, including heart disease, cancer, drug addiction, and mental illness.

The epidemiologist is a medical sleuth who collects clues on the causative agent, pathology, and sources and modes of transmission and tracks the numbers and distribution of cases of disease in the community. In fulfilling these demands, the epidemiologist looks for the “chain of infection” involving the who, when, where, how, why, and what that surrounds the spread of diseases. The outcome of these studies helps public health departments develop prevention and treatment programs and establish a basis for predictions.

Origins and Transmission Patterns of Infectious Microbes

Reservoirs: Where Pathogens Persist

One of the important concerns of epidemiology is discovering where pathogens originate and how they are transmitted. As we saw in the Case Study, these aspects are intensely scrutinized from the very first signs of an outbreak.

For an infectious agent to continue to exist and be spread, it must have a permanent place to reside. The **reservoir** is the primary habitat in the natural world from which a pathogen originates. Often it is a human or animal carrier, although soil, water, and plants are also reservoirs. The reservoir can be distinguished from the infection **source**, which is the individual or object from which an infection is actually acquired. An infectious agent that does not survive well outside of its host and is usually transmitted directly tends to have the same reservoir and source, whereas one that can remain viable outside of the host can have a different

* *epidemiology* (ep'-ih-dee-mee-ah'-uh-gee) Gr. *epidemos*, prevalent.

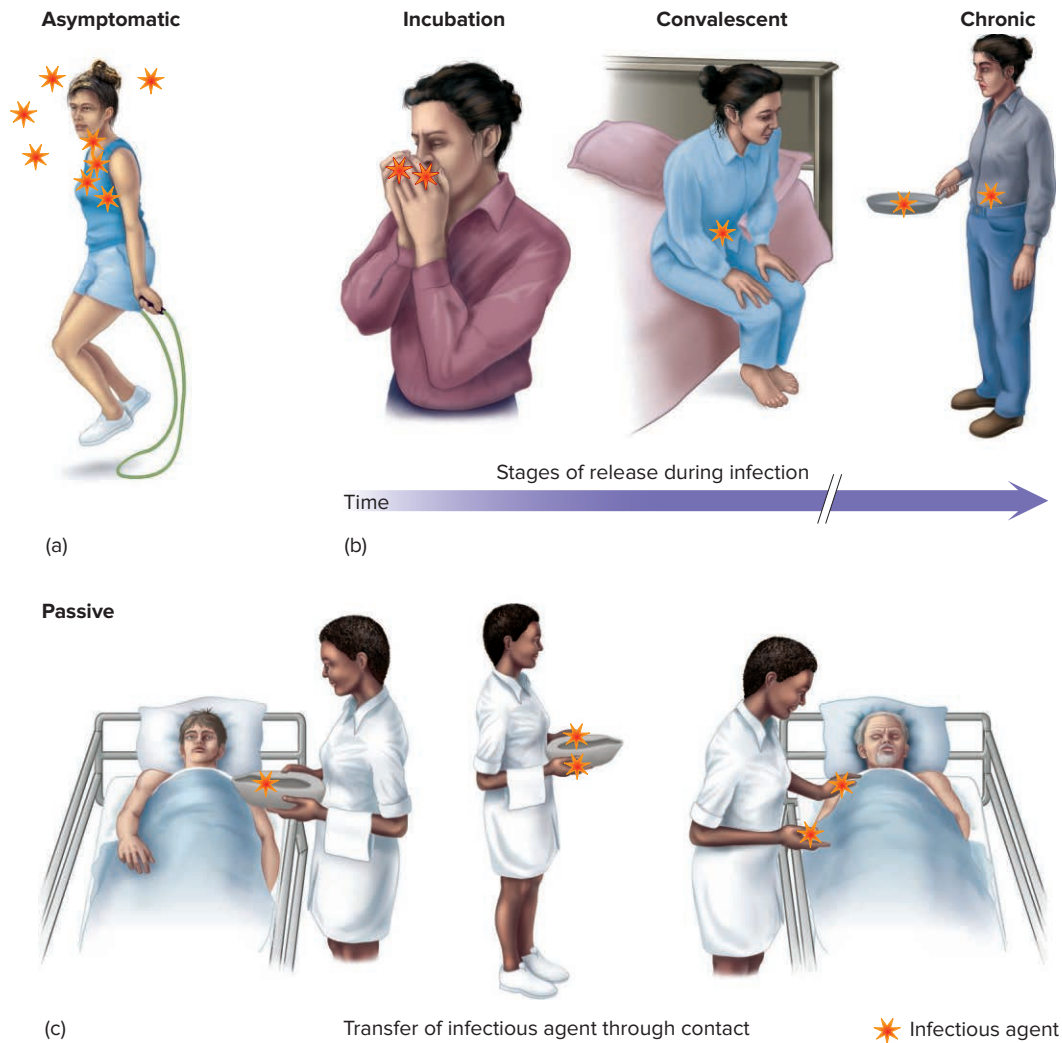

Figure 13.17 Involvement of carriers in transmission of infectious agents. (a) An asymptomatic carrier is infected without symptoms. (b) Incubation, convalescent, and chronic carriers can transmit the infection either before or after the period of symptoms. (c) A passive carrier is contaminated but not infected and spreads the pathogen through physical contact.

reservoir and source. For example, gonorrhea has the same reservoir and source (the human body), whereas hepatitis A usually has a different reservoir (a human carrier) and source (contaminated food).

Living Reservoirs

Many pathogens continue to exist and spread because they are harbored by members of a host population. A person or animal with an obvious or *overt* symptomatic infection is clearly a source of infection, as opposed to a **carrier** who is, by definition, an individual who *inconspicuously* shelters a pathogen and spreads it to others unknowingly. Although human carriers are occasionally detected through routine screening (blood tests, cultures) and other epidemiological devices, they are unfortunately very difficult to discover and control. As long as a pathogenic reservoir is maintained, the disease will continue to exist in that population or location, and the potential for epidemics will be a constant threat. The duration of the carrier state can be short or long term, and the carrier may or may not have experienced disease due to the microbe.

Several situations can produce the carrier state. **Asymptomatic** (apparently healthy) carriers are infected, but as previously indicated, they show no outward symptoms (**figure 13.17a**). A few asymptomatic infections (such as gonorrhea and genital warts) can carry out their entire course without overt manifestations. **Figure 13.17b** demonstrates three types of carriers who show no indications of infection at the time they transmit the pathogen. *Incubation carriers* spread the infectious agent during the incubation period before symptoms have appeared. For example, patients with HIV infection can harbor and spread the virus for months and years before their infection is evident. Recuperating patients without symptoms are considered *convalescent carriers* when they continue to shed viable microbes and convey the infection to others after symptoms have subsided. Norovirus, the most common cause of gastroenteritis, can be transmitted for weeks after an infection is resolved.

An individual who continues to shelter the infectious agent for a long period after recovery is a *chronic carrier*. Patients who have recovered from tuberculosis, hepatitis, and herpes infections frequently carry the agent chronically. About one in 20 victims of typhoid fever harbors *Salmonella typhi* in the gallbladder for several

years and sometimes for life. The most infamous of these was “Typhoid Mary,” a cook who spread the infection to hundreds of victims in the early 1900s.

The **passive carrier** state is of great concern during patient care (see the discussion of health-care-associated infections in section 13.5). Medical and dental personnel who must constantly handle materials that are heavily contaminated with body fluids and blood are at risk of picking up pathogens mechanically and accidentally transferring them to other patients (**figure 13.17c**). Proper hand washing, handling of contaminated materials, and aseptic techniques greatly reduce this likelihood.

Animals as Reservoirs and Sources Up to now we have lumped animals with humans in discussing living reservoirs or carriers, but animals deserve special consideration as vectors of infections. The word **vector** is used by epidemiologists to indicate a live animal that transmits an infectious agent from one host to another. (The term is sometimes misused to include any object that spreads disease.) The majority of vectors are arthropods such as fleas, mosquitoes, flies, and ticks, although larger animals can also spread infection; for example, mammals (rabies), birds (ornithosis), or lower vertebrates (salmonellosis).

By tradition, vectors are placed into one of two categories, depending upon the animal’s relationship with the microbe. A **biological vector** actively participates in a pathogen’s life cycle, serving as a site in which it can multiply or complete its development. A biological vector communicates the infectious agent to the human host by biting, aerosol formation, or touch. In the case of biting vectors, the animal can inject infected saliva into the blood (mosquito), defecate around the bite wound (flea), or regurgitate blood into the wound (tsetse fly).

Mechanical vectors are not necessary to the life cycle of an infectious agent and merely transport it without being infected. The external body parts of these animals become contaminated when they come into physical contact with a source of pathogens. The agent is subsequently transferred to humans indirectly by an intermediate such as food or occasionally by direct contact (as in certain eye infections). Houseflies are notorious mechanical vectors. They feed on decaying garbage and feces, and while they are feeding, their feet and mouthparts easily become contaminated. They also regurgitate juices onto food to soften and digest it. Flies spread more than 20 bacterial, viral, protozoan, and worm infections. Other nonbiting flies transmit tropical ulcers, yaws, and trachoma. Cockroaches, which have unsavory habits similar to those of flies, play a role in the mechanical transmission of fecal pathogens, as well as contributing to allergic attacks in asthmatic children.

Many vectors and animal reservoirs spread their own infections to humans. An infection indigenous to animals but naturally transmissible to humans is a **zoonosis**.* In these types of infections, the human is essentially a dead-end host and does not contribute to the natural persistence of the microbe. Some zoonotic infections

Mosquito

Housefly

TABLE 13.10 Common Zoonotic Infections

Disease/Agent	Primary Animal Reservoirs	Mode of Infection
Viruses		
Rabies	All mammals	Bite; aerosol
Yellow fever	Wild birds, mammals, mosquitoes	Mosquito bite
Viral fevers	Wild mammals	Various mosquitoes
Hantavirus	Rodents	Airborne wastes
Influenza	Chickens, swine	Airborne secretions
West Nile virus	Wild birds, mosquitoes	Mosquito bite
Bacteria		
Rocky Mountain spotted fever	Dogs, ticks	Tick bite
Psittacosis	Birds	Airborne secretions
Leptospirosis	Domestic animals	Animal wastes (urine)
Anthrax	Domestic animals	Airborne spores, cutaneous contact
Brucellosis	Cattle, sheep, pigs	Air- and food-borne
Plague	Rodents, fleas	Flea bite; aerosol
Salmonellosis	Variety of mammals, birds, and rodents	Food-borne
Tularemia	Rodents, birds, arthropods	Tick bite, airborne
Miscellaneous		
Ringworm	Domestic mammals	Cutaneous contact
Toxoplasmosis	Cats, rodents, birds	Food-borne, contact
Trypanosomiasis	Domestic and wild mammals	Tsetse fly; reduviid bug
Trichinosis	Swine, bears	Ingestion of cysts
Tapeworm	Cattle, swine, fish	Ingestion of eggs
Scabies	Domestic animals	Cutaneous contact

(rabies, for instance) can have multihost involvement, and others (such as plague) can have very complex cycles in the wild. Zoonotic spread of disease is promoted by close associations of humans with animals, and people in animal-oriented or outdoor professions are at greatest risk. At least 150 zoonoses exist worldwide; the most common ones are listed in **table 13.10**. Zoonoses make up a full 70% of all new emerging diseases worldwide. It is worth noting that zoonotic infections are impossible to completely eradicate without also eradicating the animal reservoirs. Attempts have been made to eradicate mosquitoes and certain rodents. During influenza epidemics, millions of chickens and thousands of pigs are slaughtered in the attempt to control its spread.

One technique that can provide an early warning signal for the occurrence of certain mosquito-borne zoonoses has been the use of *sentinel animals*. These are usually domestic animals (most often chickens or horses) that can serve as hosts for diseases such as West Nile fever, various viral encephalitides, and malaria. Sentinel animals are placed at various sites throughout the community, and their blood is monitored periodically for antibodies to the infectious

* **zoonosis** (zoh'-uh-noh'-sis) Gr. *zoion*, animal, and *nosos*, disease.

agents that would indicate a recent infection by means of a mosquito bite. The presence of infected animals provides useful data on the potential for human exposure, and it also helps establish the epidemiological pattern of the zoonosis, including where it may have spread.

Nonliving Reservoirs

Clearly, microorganisms have adapted to nearly every habitat in the biosphere. They thrive in soil and water and often find their way into the air. Although most of these microbes are saprobic and cause little harm and considerable benefit to humans, some are opportunists and a few are regular pathogens. Because human hosts are in regular contact with these environmental sources, acquisition of pathogens from natural habitats is of diagnostic and epidemiological importance.

Soil harbors the vegetative forms of bacteria, protozoa, helminths, and fungi, as well as their resistant or developmental stages such as spores, cysts, ova, and larvae. Bacterial pathogens that live in soil include the anthrax bacillus and species of *Clostridium* that are responsible for gas gangrene, botulism, and tetanus. Pathogenic fungi in the genera *Coccidioides* and *Blastomyces* are spread by spores in the soil and dust. The invasive stages of the hookworm *Necator* occur in the soil. Natural bodies of water carry fewer nutrients than soil does but still support pathogenic species such as *Legionella*, *Cryptosporidium*, and *Giardia*.

The Acquisition and Transmission of Infectious Agents

Infectious diseases can be categorized on the basis of how they are acquired. A disease is **communicable** when an infected host can transmit the infectious agent to another host and establish infection in that new host. Although this terminology is standard, one must realize that it is not the disease that is communicated but the microbe. Also be aware that the word *infectious* is sometimes used interchangeably with the word *communicable*, but this is not precise usage. The transmission of the agent can be direct or indirect, and the ease with which the disease is transmitted varies considerably from one agent to another. If the agent is highly communicable, especially through direct contact, the correct term to use is **contagious**. Influenza and measles move readily from host to host and thus are contagious, whereas leprosy is only weakly communicable. Because they can be spread through the population, communicable diseases are our main focus in the following sections.

In contrast, a **noncommunicable** infectious disease does *not* arise through transmission of the infectious agent from host to host. The infection and disease are acquired through some other, special circumstance. Noncommunicable infections occur primarily when a compromised person is invaded by his or her own microflora (as with certain pneumonias, for example) or when an individual has accidental contact with a facultative parasite that exists in a nonliving reservoir such as soil. Some examples are certain mycoses, acquired through inhalation of fungal spores, and tetanus, in which *Clostridium tetani* spores from a soiled object enter a cut or wound. Persons thus infected do not become a source of infection.

Patterns of Transmission in Communicable Diseases

The routes or patterns of disease transmission are many and varied. The spread of diseases is by direct or indirect contact with animate or inanimate objects and can be horizontal or vertical. The term *horizontal* means the disease is spread through a population from one infected individual to another; *vertical* signifies transmission from parent to offspring via the ovum, sperm, placenta, or milk. Although exact transmission patterns can vary, a general system of organization divides microorganisms into two major groups, as shown in **figure 13.18**: those transmitted by direct routes or those transmitted by indirect routes, which involve some sort of vehicle to transport them.

Modes of Direct Transmission For microbes to be directly transferred, some type of contact must occur between the skin or mucous membranes of the infected person and those of the infectee. It may help to think of this route as the portal of exit meeting the portal of entry without the involvement of an intermediate object or substance. Included in this category are fine droplets sprayed directly upon a person during sneezing or coughing (as distinguished from droplet nuclei that are transmitted some distance by air). Most sexually transmitted diseases are spread directly. In addition, infections that result from kissing or bites by biological vectors are direct. Most obligate parasites are far too sensitive to survive for long outside the host and can be transmitted only through direct contact. Diseases transmitted vertically from mother to baby fit in this contact category as well.

Routes of Indirect Transmission For microbes to be indirectly transmitted, the infectious agent must pass from an infected host to an intermediate conveyor and from there to another host. This form of communication is especially pronounced when the infected individuals contaminate inanimate objects, food, or air through their activities. The transmitter of the infectious agent can be either openly infected or a carrier.

Indirect Spread by Vehicles: Contaminated Materials The term **vehicle** specifies any inanimate material commonly used by humans that can transmit infectious agents. A **common vehicle** or **source** is a single material that serves as the source of infection for many individuals. Some specific types of vehicles are food, water, various biological products (such as blood, serum, and tissue), and fomites.

A **fomite** is an inanimate object that harbors and transmits pathogens. The list of possible fomites is as long as your imagination allows. Probably highest on the list would be objects commonly in contact with the public, such as doorknobs, telephones, push buttons, and faucet handles that are readily contaminated by touching. Shared bed linens, handkerchiefs, toilet seats, toys, eating utensils, clothing, personal articles, and syringes are other examples. Although paper money is impregnated with a disinfectant to inhibit microbes, pathogens are still isolated from bills as well as coins.

Outbreaks of food poisoning often result from the role of food as a common vehicle. The source of the agent can be soil, the handler, or a mechanical vector. Because milk provides a rich

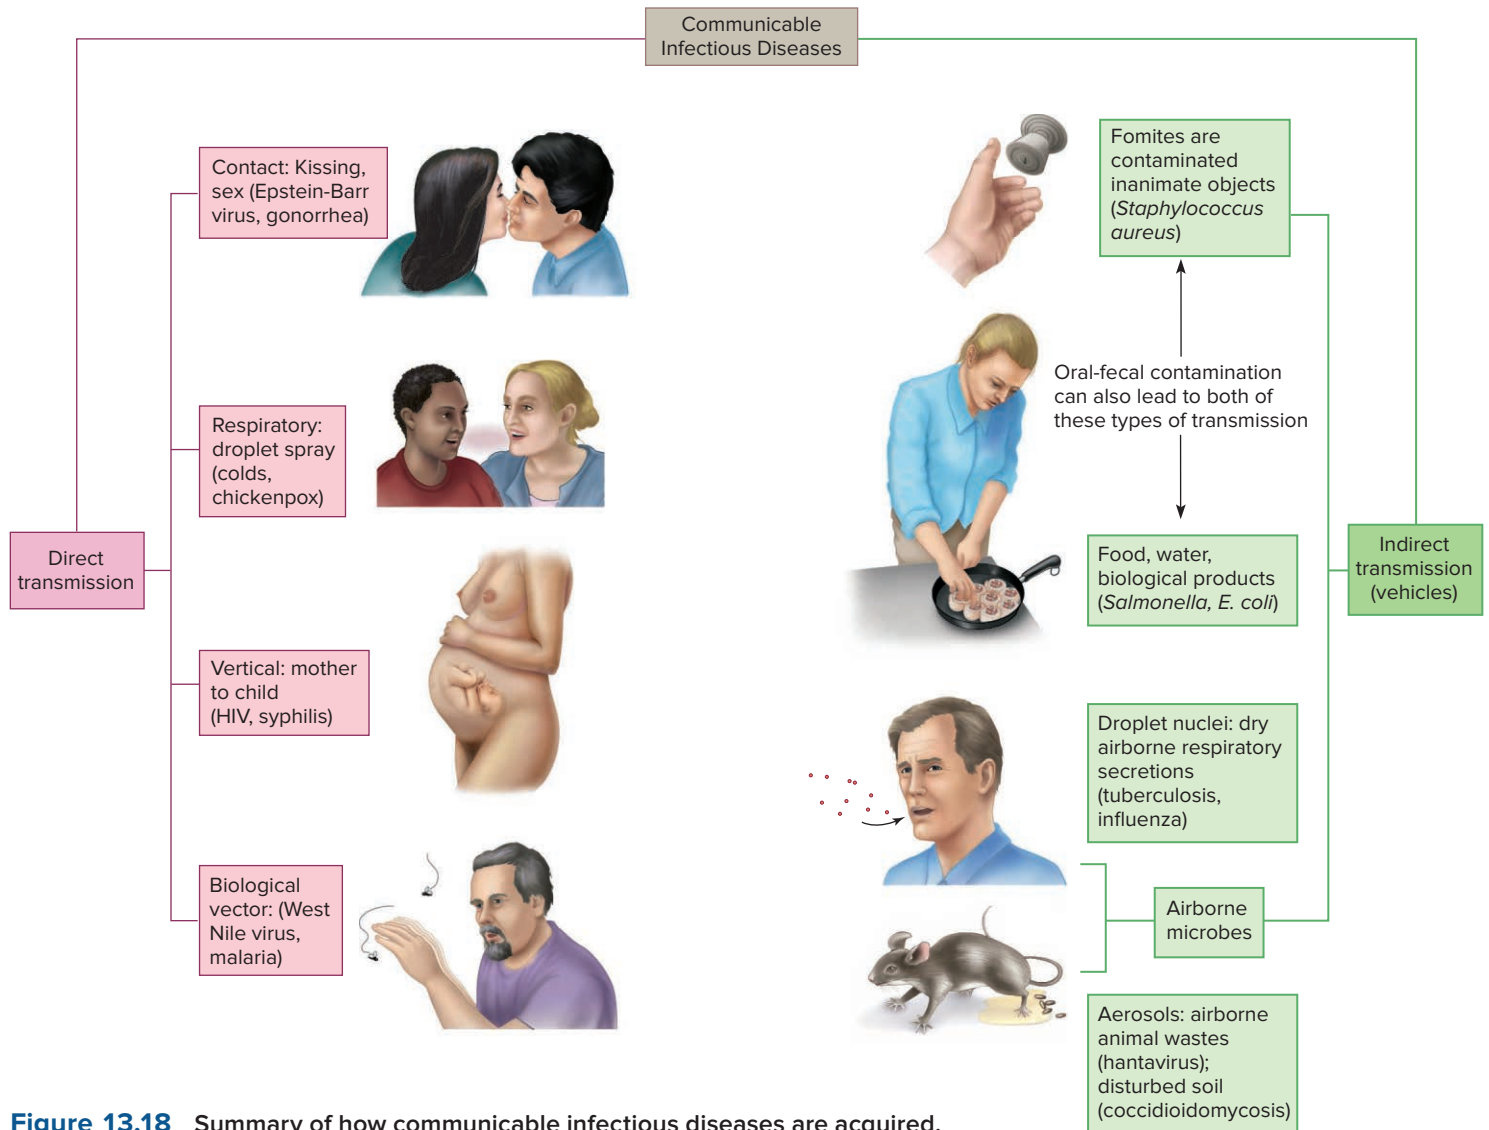

Figure 13.18 Summary of how communicable infectious diseases are acquired.

growth medium for microbes, it is a significant means of transmitting pathogens from diseased animals, infected milk handlers, and environmental sources of contamination. The agents of brucellosis, Q fever, salmonellosis, and listeriosis are transmitted by contaminated milk. Water that has been contaminated by excretions can carry *Salmonella*, *Vibrio* (cholera), viruses (hepatitis A, polio), *Leptospira*, and pathogenic protozoans (*Giardia*, *Cryptosporidium*).

The **oral-fecal route** is a special category of indirect transmission, which specifies that a vehicle first becomes contaminated through contact with fecal material and is then transported to someone's mouth. A common scenario would involve a fecal carrier contaminating food during handling and an unsuspecting person ingesting it. Hepatitis A, amebic dysentery, shigellosis, and typhoid fever are often transmitted this way. Oral-fecal transmission can

also involve contaminated materials such as toys, diapers, and other inanimate objects. An example would be the norovirus, which is readily picked up through contact with public facilities touched by an infected person. Handwashing anyone?

Indirect Spread by Vehicles: Air as a Vehicle Unlike soil and water, outdoor air cannot provide nutritional support for most microbial growth and is less likely to transmit airborne pathogens. On the other hand, indoor air (especially in a closed space) can serve as an important medium for the suspension and dispersal of certain respiratory pathogens via droplet nuclei and aerosols.

Droplet nuclei are dried microscopic residues created when microscopic pellets of mucus and saliva are ejected from the mouth and nose. They are generated forcefully in an unstifled sneeze or cough (**figure 13.19**) or mildly during other vocalizations. Although the larger beads of moisture settle rapidly, smaller particles evaporate and remain suspended for longer periods and can be drawn deeply into the lungs. Droplet nuclei are implicated in the

Figure 13.19 The explosiveness of a sneeze. Special photography dramatically captures droplet formation in an unstifled sneeze. Even the merest attempt to cover a sneeze with one's hand will reduce this effect considerably. When such droplets dry and remain suspended in air, they become droplet nuclei.

Source: James Gathany/CDC

spread of hardier pathogens such as the tubercle bacillus and the influenza virus.

Aerosols are suspensions of fine dust or moisture particles in the air that contain live pathogens. Q fever is spread by dust from animal quarters, and psittacosis by aerosols from infected birds. Outbreaks of coccidioidomycosis (a lung infection) often occur in areas where soil is disturbed by wind or digging, releasing clouds of dust bearing the spores of *Coccidioides*.

Check Your Progress SECTION 13.4

22. Explain the differences between communicable and noncommunicable infectious diseases, and between (direct) contact and indirect modes of transmission.
23. Distinguish between reservoirs and sources, using examples.
24. State the primary differences between mechanical and biological vectors.
25. Define *zoonosis* and describe the difficulties in controlling zoonotic infections.
26. Explain what it means to be a carrier of infectious disease, and describe four ways in which humans can be carriers.
27. What is epidemiologically and medically important about carriers in the population?

13.5 The Work of Epidemiologists: Investigation and Surveillance

Expected Learning Outcomes

24. Explain the primary methods of tracking infections and diseases in a population.
25. Differentiate among the patterns of disease outbreaks according to frequency, number, and location.

26. Summarize the steps in Koch's postulates, and explain their importance to microbiologists.
27. Discuss important aspects of health-care-associated infections and their impact on patients in clinical settings.
28. Explain what is meant by universal precautions, and discuss how they are implemented.

Epidemiologists are concerned with all of the factors covered earlier in this chapter: virulence, portals of entry and exit, and the course of disease. But they are also interested in **surveillance**; that is, collecting, analyzing, and reporting data on the rates of occurrence, mortality, morbidity, and transmission of infections. A well-developed network of individuals and agencies at the local, district, state, national, and international levels keeps constant track of infectious diseases. Surveillance involves monitoring data for a large number of diseases observed in the medical setting and reported to public health authorities. By law, certain **reportable diseases**, also called notifiable diseases, must be reported to authorities; others are reported on a voluntary basis. Physicians and hospitals must contact the appropriate agency for all reportable diseases that are brought to their attention. Case reporting can focus on a single individual or collectively on group data.

Local public health agencies first receive the case data and determine how the data will be handled. In most cases, health officers investigate the history and movements of patients to trace their prior contacts and to control the further spread of the infection as soon as possible through drug therapy, immunization, and education. In sexually transmitted diseases, patients are asked to name their partners so that these persons can be notified, examined, and treated. It is very important to maintain the confidentiality of the persons in these reports. The principal government agency responsible for keeping track of infectious diseases nationwide is the Centers for Disease Control and Prevention (CDC) in Atlanta, Georgia, which is home to the National Notifiable Infectious Conditions Group (NNICG). The CDC publishes a weekly notice of diseases (the *Morbidity and Mortality Weekly Report*) that provides weekly and cumulative summaries of the case rates and deaths for about 50 notifiable and 65 reportable diseases, highlights important and unusual diseases, and presents data concerning disease occurrence in the major regions of the United States. This notice is available to anyone at <http://www.cdc.gov/mmwr/>. Ultimately the CDC shares its statistics on diseases with the World Health Organization (WHO) for worldwide tabulation and control.

Epidemiological Statistics: Frequency of Cases

The **prevalence** of a disease is the accumulated total of existing cases with respect to the entire population. It is usually reported as the percentage of the population having a particular disease and provides an indicator of how commonly a disease occurs in a population. Disease **incidence** measures the number of new cases over a certain time period, as compared with the general healthy population. This statistic,

also called the case rate or morbidity rate, indicates both the rate and the risk of infection at the time of reporting. The equations used to figure these rates follow:

$$\text{Prevalence} = \frac{\text{Total number of cases in population}}{\text{Total number of persons in population}} \times 100 = \%$$

$$\text{Incidence} = \frac{\text{Number of new cases}}{\text{Total number of susceptible persons}} \quad (\text{Usually reported per 100,000 persons})$$

As an example, let us use a classroom of 50 students exposed to a new strain of influenza. Before exposure, the prevalence and incidence in this population are both zero (0/50). If in one week, 5 out of the 50 people contract the disease, the prevalence is 5/50 = 10%, and the incidence is 1 in 10 (10 is used instead of 100,000 due to smaller population). If within a month 25 more people acquire the flu, the prevalence becomes 30/50 or 60%, and the incidence (the number of new infections) is 25/50, or 5 in 10. Using reported cases of AIDS as a real-life example, the most recent statistics show a cumulative total of cases (prevalence) between 1981 and 2014 of 1,350,000 cases, or 0.42% of the population. The incidence of 44,608 cases for just the year 2014 averages out to 16.6 cases per 100,000 people.

The changes in incidence and prevalence are usually followed over a seasonal, yearly, and long-term basis and are helpful in predicting trends (figure 13.20). Statistics of concern to the epidemiologist are the rates of disease with regard to sex, race, or geographic region. Also of importance is the **mortality rate**, which measures the total number of deaths in a population due to a certain disease. Over the past century, the overall death rate from infectious diseases has dropped, although the **morbidity*** rate, or the number of persons afflicted with infectious diseases, has remained relatively high.

Monitoring statistics also makes it possible to define how often a disease appears in a given population. An infectious disease that exhibits a relatively steady and predictable frequency over a long time period and is tied to a particular geographic locale is **endemic** (figure 13.21a). Often the reason for endemicity is the presence of a reservoir restricted to that location. For example, Lyme disease is endemic to certain areas of the United States where the tick vector is found. New cases are expected to appear in these areas every year. For a disease to be considered **sporadic**, occasional cases are reported at irregular intervals in widely dispersed locations (figure 13.21b). Tetanus and typhoid fever are reported sporadically in the United States (fewer than 500 cases a year in a random distribution).

When statistics indicate that the number of new cases of an endemic or sporadic disease is increasing beyond what is expected for that population, this trend is known as an **epidemic** (figure 13.21c). The time period is not defined. It can range from hours in food poisoning to years in STDs, such as gonorrhea or chlamydisis.

Note: Data include persons with a diagnosis of HIV infection regardless of stage of disease at diagnosis. All displayed data have been statistically adjusted to account for reporting delays, but not for incomplete reporting.

Figure 13.20 Samples of epidemiological data as analyzed by the CDC. (a) A graph that shows the reported incidence of pertussis according to age group over a 24-year period. (b) A histogram that tracks the Ebola epidemic in Africa over 8 weeks in 2014, comparing diagnosed versus unknown cases and mortality numbers. (c) A map that tracks new cases of HIV infection in the U.S. and territories for a single year. All data are from the CDC.

* **morbidity** (mor-bih'-dih-tee) *L. morbidis*, sick. A condition of being diseased.

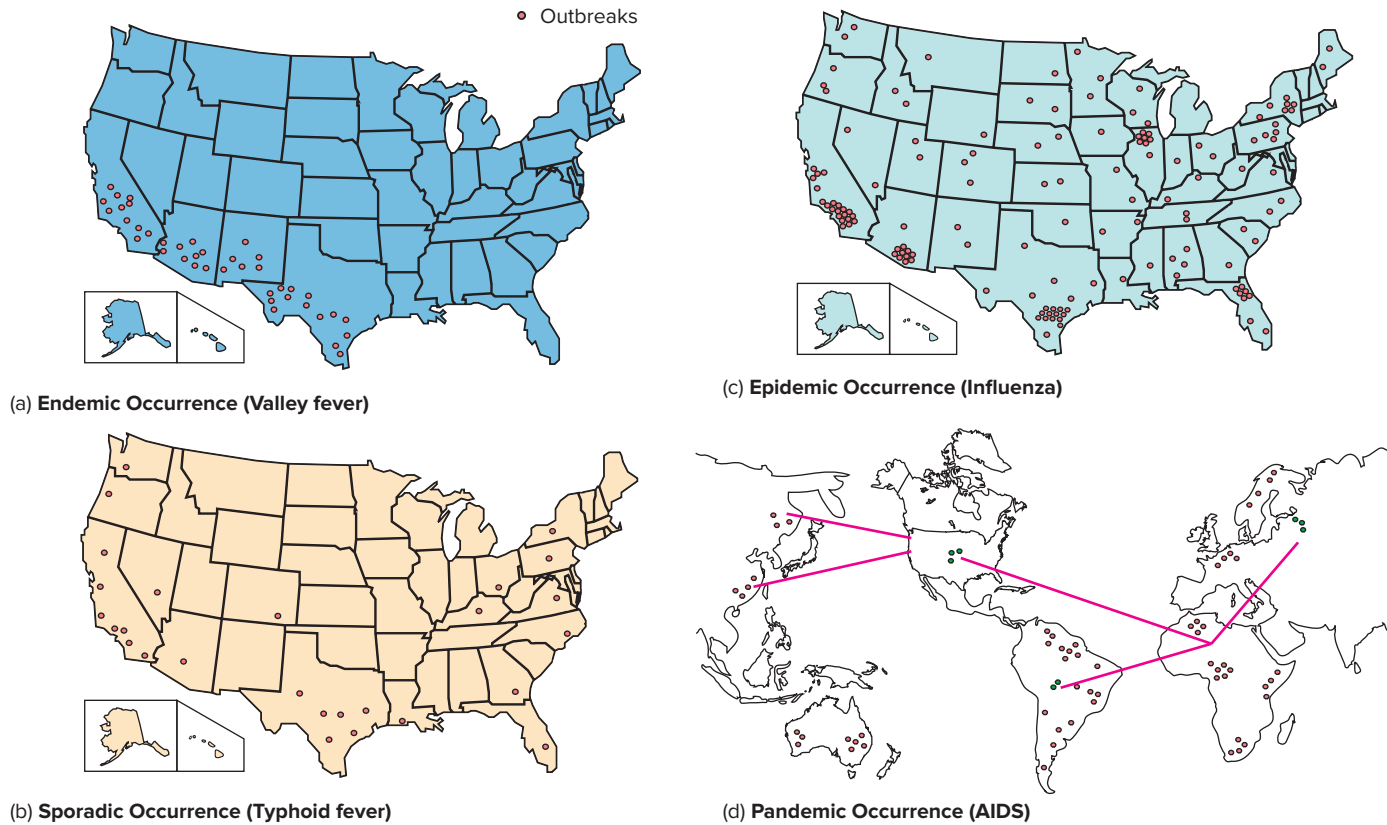

Figure 13.21 Patterns of infectious disease occurrence. (a) In endemic occurrence, cases are concentrated in one region at a relatively stable rate. (b) In sporadic occurrence, a few cases occur randomly over a wide area. (c) An epidemic is an increased number of cases that often appear in geographic clusters. The clusters may be local, as in the case of a restaurant-related food-borne epidemic, or nationwide, as is the case with influenza. (d) A pandemic results when an epidemic ranges across continents and borders.

The term **outbreak** is often used interchangeably with *epidemic*, but an outbreak is usually on a smaller scale in a more limited area. In this chapter's Case Study, the Ebola cases in Africa started as outbreaks, but as time went on, the numbers of cases and regions affected rose to the level of an epidemic. There is no exact percentage of increase required before an outbreak can qualify as an epidemic. Several diseases are at epidemic levels in the United States, the most recent examples being hepatitis C and pertussis.

One useful way to analyze data from outbreaks is to graph the number of cases over time in an epicurve format (**figure 13.22**). The pattern of epidemics will ordinarily follow one of three patterns: (1) a **point-source epidemic**, which indicates that the infectious agent came from a single source more or less simultaneously; (2) a **common-source epidemic**, in which all cases came from exposure to the same source, which continued to infect others over a period of time; and (3) a **propagated epidemic**, which shows a sustained increase over time, indicating that it is being communicated from person to person.

The spread of an epidemic across continents or international borders is a **pandemic**, as exemplified by AIDS and influenza (**figure 13.21d**). Review the Case Study in chapter 6 for an example of pandemic spread. One important epidemiological truism might be called the “iceberg effect,” which refers to the fact that only a small portion of an iceberg is visible above the surface of the ocean,

with a much more massive part lying unseen below the surface. Regardless of case reporting and public health screening, a large number of cases of infection in the community go undiagnosed and unreported. In the instance of salmonellosis, approximately 40,000 cases are reported each year. Epidemiologists estimate that the actual number of infections is more likely somewhere between 1 million and 2 million. The iceberg effect can be even more lopsided for sexually transmitted diseases or for infections that are not reported to agencies. For a list of reportable diseases in the United States, refer to the Appendix on Connect.

Investigative Strategies of the Epidemiologist

Initial evidence of a new disease or an epidemic in the community is fragmentary. A few sporadic cases are seen by health care providers and are eventually reported to authorities. It can take several reports before any alarm is registered. Epidemiologists and public health departments play the part of medical detectives who must piece together odds and ends of data from similar cases and attempt to find any connections they may have. This often involves

Figure 13.22 Epicurve graphs of the three main patterns typically shown by epidemics.

working backward to reconstruct factors that could play some part in the outbreak or epidemic. A completely new disease requires even greater preliminary investigation, because the infectious agent must be isolated and linked directly to the disease (**13.3 Making Connections**). An early piece of information that drives an investigation is the **index case**, defined as the first case to bring the infection or disease to the attention of medical authorities. It may not even be the first case, but it is the first one reported. Usually other cases will follow, and the ensuing statistics

will help fine-tune the investigation. An example of an index case was the first case of hepatitis C discovered in the Las Vegas outbreak (see the Case Study in chapter 11).

All factors possibly impinging on the disease are scrutinized. Investigators search for *clusters* of cases indicating transmission between persons or a public (common) source or vehicle. They also look at possible contact with animals, contaminated food, water, and public facilities and at human interrelationships or changes in community structure. Out of this maze of case information, the investigators hope to recognize a pattern that indicates the source of infection so that they can quickly move to control it.

Hospital Epidemiology and Health-Care-Associated Infections

Infectious diseases that are acquired or develop during a stay in a medical facility are known as **health-care-associated infections (HAIs)** or **nosocomial* infections**. This concept seems incongruous at first thought, because a hospital or clinic is regarded as a place to get treatment for a medical problem, not a place to acquire one. Yet it is not uncommon for a surgical incision to become infected or a patient with a catheter to develop a urinary tract infection after being treated in a hospital or clinic. The rate of hospital-acquired infections can be as low as 0.1% or as high as 20% of all admitted patients, depending on the clinical setting or hospital. The average rate is about 4% (1 out of 25 patients). In light of the number of admissions, this adds up to 1 million to 2 million cases a year, which result in around 72,000 deaths. Nosocomial infections cost time and money as well as suffering. By one estimate, they amount to 8 million additional days of hospitalization a year and an increased cost of \$5 billion to \$10 billion.

So many factors unique to the hospital environment create conditions that favor HAIs that a certain number of them are virtually unavoidable. After all, the hospital both attracts and creates compromised patients, and it serves as a collection point for opportunistic pathogens. Some patients become infected when surgical procedures or lowered defenses permit resident microbes to invade their bodies. Other patients acquire infections directly or indirectly from contaminated catheters or ventilators and other medical equipment, other patients, medical personnel, visitors, air, and water.

The health care process itself increases the likelihood that infectious agents will be transferred from one patient to another. Treatments using reusable instruments such as respirators and endoscopes constitute a possible source of infectious agents. Indwelling devices such as catheters, prosthetic heart valves, grafts, and tracheostomy tubes form a ready portal of entry and habitat for infectious agents. Because such high numbers of the hospital population receive antimicrobial drugs during their stay, drug-resistant microbes are selected for at a much greater rate compared to outside the hospital.

* *nosocomial* (nohz'-oh-koh'-mee-al) Gr. *nosos*, disease, and *komeion*, to take care of. Also known as health care-acquired infections.

13.3 MAKING CONNECTIONS

Koch's Postulates: Solving the Puzzle of New Diseases

An essential aim in the study of infection and disease is determining the precise **etiologic**, or causative, **agent**. In our modern technological age, we take it for granted that a certain infection is caused by a certain microbe, but such has not always been the case. More than 130 years ago, Robert Koch realized that in order to support the germ theory of disease, he would have to develop a standard for determining causation that would stand the test of scientific scrutiny. Out of his experimental observations on the transmission of anthrax in cows came a series of proofs, called **Koch's postulates**, that established the principal criteria for etiologic studies. A summary of these postulates is as follows:

1. find evidence of a particular microbe in every case of a disease,
2. isolate that microbe from an infected subject and cultivate it artificially in the laboratory,
3. inoculate a susceptible healthy animal with the laboratory isolate and observe the same resultant disease in that animal, and
4. re-isolate the agent from the diseased animal.

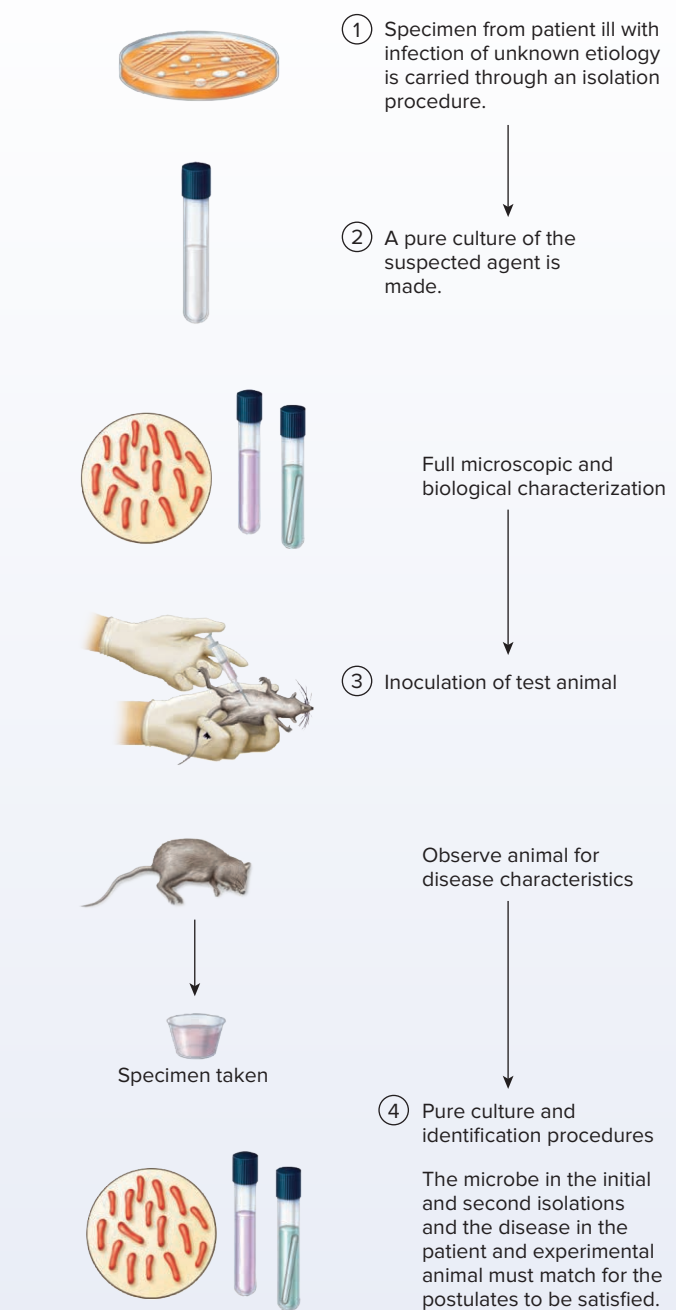

Valid application of Koch's postulates involves several critical details. Each culture must be pure, observed microscopically, and identified by means of characteristic tests; the first and second isolate must be identical; and the pathologic effects, signs, and symptoms of the disease in the first and second subject must be the same. Once established, these postulates were rapidly put to the test. Within a short time they had helped determine the causative agents of tuberculosis, diphtheria, and plague. Today most infectious diseases have been directly linked to a known agent.

Many infectious agents such as viruses and obligately parasitic bacteria can be difficult to culture or cannot be cultured. For these pathogens, the postulates have been modified to take this into account. It is now considered significant to repeatedly observe the infectious agent in tissue samples taken from people with the same disease. A good case in point is Whipple disease, a chronic intestinal infection that for many years could not be tied to a known causative agent. Finally medical researchers had sufficient evidence of a bacterium being consistently present in infected tissues to give an identity to the mystery pathogen, which they named *Tropheryma whippeli*. Modern sequencing techniques to analyze unculturable microbes and their genes have added a new type of evidence for fulfilling the postulates.

Koch's original postulates—or a modified version—continue to play an essential role in modern epidemiology. Nearly every year, new diseases arise or old ones spread out of their usual range. Notable examples include dengue fever, influenza, SARS, and West Nile fever. Viral diseases require some modifications to the postulates. These include that the virus must be cultivated in cell culture, it must be filterable through bacteriological filters, and it must cause a detectable specific immune response.

Explain how we can be so certain that HIV causes AIDS even though there is no effective animal model for it. *Answer available on Connect.*

The most common HAIs involve surgical incisions and the respiratory tract, GI tract, skin, urinary tract, and blood (sepsis) (**figure 13.23**). Gram-negative intestinal flora (*Escherichia coli*, *Klebsiella*, *Pseudomonas*) are cultured in more than half of patients with HAIs. Gram-positive bacteria (staphylococci and streptococci)

and yeasts (*Candida*) make up most of the remainder. True pathogens such as the tubercle bacillus, *Salmonella*, hepatitis B, and influenza virus can be transmitted in the clinical setting as well.

The potential seriousness and impact of health-care-associated infections have required hospitals to develop committees that

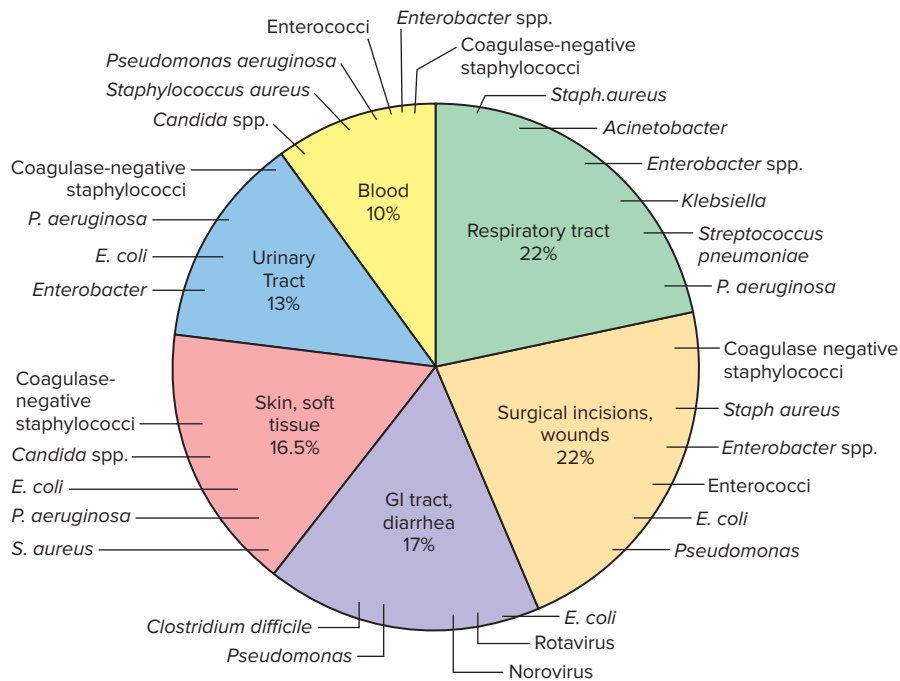

Figure 13.23 Prevalence of health-care-associated infections (HAIs).

Relative frequency by body site. These are the most common isolates out of the nearly 500 pathogens that are known to cause HAIs. Source: Data from 2011 are compiled by the National Health Safety Network, a unit of the CDC.

monitor infectious outbreaks and develop guidelines for infection control and aseptic procedures. *Medical asepsis* includes practices that lower the microbial load in patients, caregivers, and the hospital environment. These practices include proper

hand washing, disinfection, and sanitization, as well as patient isolation. **Table 13.11** summarizes guidelines for the major types of isolation. The goal of these procedures is to limit the spread of infectious agents from person to person. The most rigorous level of precautions is associated with *surgical asepsis*, which involves all of the strategies listed previously plus ensuring that all surgical procedures are conducted under sterile conditions. This includes sterilization of surgical instruments, dressings, sponges and the like, as well as clothing personnel in sterile garments and scrupulously disinfecting the room surfaces and air.

Hospitals generally employ an *infection control officer* who not only implements proper practices and procedures throughout the hospital but also is charged with tracking potential outbreaks, identifying breaches in asepsis, and training other health care workers in aseptic technique. Among those most in need of this training are nurses and other caregivers whose work, by its very nature, exposes them to needles, infectious secretions, blood, and physical contact with the patient. The same practices that interrupt the routes of infection in the patient can also protect the health care worker. It is for this reason that most hospitals have adopted universal precautions that recognize that all secretions from all persons in the clinical setting are potentially infectious and that transmission can occur in either direction.

TABLE 13.11 Levels of Isolation Used in Clinical Settings

Type of Isolation*	Protective Measures**	To Prevent Spread of
Enteric Precautions	Gowns and gloves must be worn by all persons having direct contact with patient; masks are not required; special precautions are taken for disposing of feces and urine.	Diarrheal diseases; <i>Shigella</i> , <i>Salmonella</i> , <i>E. coli</i> , and <i>Clostridium difficile</i> ; cholera; hepatitis A; rotavirus; and giardiasis
Respiratory Precautions	Private room with closed door is necessary; gowns and gloves are not required; masks are usually indicated; items contaminated with secretions must be disinfected.	Tuberculosis, measles, mumps, meningitis, pertussis, rubella, chickenpox
Drainage and Secretion Precautions	Gowns and gloves are required; masks are not needed; contaminated instruments and dressings require special precautions.	Staphylococcal and streptococcal infections; gas gangrene; herpes zoster; burn infections
Strict Isolation	Private room with closed door is required; gowns, masks, and gloves must be worn; contaminated items must be wrapped and decontaminated.	Mostly highly virulent or contagious microbes; includes tuberculosis, some types of pneumonia, extensive skin and burn infections, herpes simplex and zoster
Reverse Isolation (Also Called Protective Isolation)	Same guidelines as for strict isolation are required; room may be ventilated by laminar airflow filtered through a high-efficiency particulate (HEPA) filter that removes airborne pathogens; infected persons must be barred.	Used to protect patients extremely immunocompromised by cancer therapy, surgery, genetic defects, burns, prematurity, or AIDS and therefore vulnerable to opportunistic pathogens

*Precautions are based upon the primary portal of entry and communicability of the pathogen.

**In all cases, visitors to the patient's room must report to the nurses' station before entering the room; all visitors and personnel must wash their hands upon entering and leaving the room.

Universal Blood and Body Fluid Precautions

Medical and dental settings require stringent measures to prevent the spread of infectious agents from patient to patient, from patient to worker, and from worker to patient. But even with precautions, the rate of such infections can be rather high. An established body of evidence indicates that more than one-third of health-care-acquired infections could be prevented by consistent and rigorous infection control methods.

Previously control guidelines were disease-specific, and clearly identified infections were managed with particular restrictions and techniques. With this arrangement, personnel tended to handle materials labeled *infectious* with much greater care than those that were not so labeled. The AIDS epidemic spurred a reexamination of that policy. Because of the potential for patients with undiagnosed infections, the CDC laid down more-stringent guidelines for handling patients and body substances. These guidelines have been termed **universal precautions (UPs)**, because they are based on the assumption that all patient specimens could harbor infectious agents and so must be treated with the same degree of care. They also include body substance isolation (BSI) techniques to be used in known cases of infection.

CASE STUDY Part 2

Despite the attempts to prevent transmission of the virus, two people acquired Ebola infections from contact with Mr. Duncan. Both were nurses who had provided round-the-clock care during the time he was hospitalized. First, Nina Pham began to register a low-grade fever 4 days after his death. She was immediately tested for Ebola virus and moved into an isolation unit. Two days later Amber Vinson reported a fever and was also isolated. Both women tested positive for the virus. They were continuously monitored and provided intensive medical support at other hospitals, but they received no antiviral medicines because specific drugs were not yet available. Within 2 weeks both nurses recovered, were found to be free of the virus, and were released from isolation.

Even though these cases were the only ones that originated in the United States, they still fostered a wave of fear in the populace that this epidemic could evolve into a pandemic. In addition to the anguish of the two nurses and their families, repercussions were felt in the lives of many other people. In this situation, a carrier in the prodromal phase can actively transmit the virus, so it was necessary for public health officers to implement tracing, monitoring, and quarantining of all contacts. This included all hospital workers and their families, crews and passengers on Mr. Duncan's airline flight, and Mr. Duncan's family and contacts, which eventually totaled over 200 people. Several other American health care workers came down with Ebola, but all of them were infected while caring for patients in West Africa, and all but one of them survived.

The story of Ebola virus outbreaks is not a new one. The first cases, originally termed Ebola hemorrhagic fever, occurred near the Ebola River of Zaire (now the Central African

Republic) in 1976. Since then, there have been 24 additional outbreaks, but the one in 2014–2015 was by far the most severe. It affected 28,638 people and killed 11,315 in Africa, with the mortality rate varying from 25% to 90% (average is 50%). The epidemic was declared over in January 2016, following a period with no new case reports.

Check Your Progress SECTION 13.5

- Outline the science of epidemiology and the work of an epidemiologist.
- What types of information do epidemiologists require to differentiate between incidence and prevalence of infectious diseases?
- Distinguish between point-source, common-source, and propagated epidemics, and explain what is meant by an index case.
- List the main features of Koch's postulates and explain why it is so difficult to prove them for some diseases.
- Health-care-associated infections can arise from what general sources?
- Outline the major factors involved in health-care-associated infections and describe the levels of precaution that are followed to prevent HAIs.

Republic) in 1976. Since then, there have been 24 additional outbreaks, but the one in 2014–2015 was by far the most severe. It affected 28,638 people and killed 11,315 in Africa, with the mortality rate varying from 25% to 90% (average is 50%). The epidemic was declared over in January 2016, following a period with no new case reports.

Virologists who have been studying the origins of the Ebola virus for 4 decades have long considered it a zoonosis transmitted by biological vectors. It has been isolated from primates such as great apes and monkeys, but it causes a deadly infection in these animals, which means they are probably not reservoir hosts. The current consensus is that species of fruit bats and insectivorous bats are the most likely reservoirs. We know that the source of most human infections is other humans and animals, especially forest animals that are butchered for meat. In humans it is transmitted only by direct contact with patient fluids such as blood, feces, vomit, saliva, urine, breast milk, and semen. It is likely that infections occur when these body fluids contaminate portals of entry such as exposed skin, cuts, and mucous membranes of the mouth, nose, and eyes. There is little evidence that infection occurs through airborne droplet nuclei, coughing, sneezing, food (except wild meat), fomites, or mosquitoes.

- Explain why this epidemic of Ebola virus disease was not considered a pandemic.
- Provide some explanations why Ebola virus would be transmitted by fresh droplets but not droplet nuclei.

 Chapter Summary with Key Terms

13.1 We Are Not Alone

- A. The human body is in contact with microbes that are constantly present in the environment. Microbes are classified as either part of the normal residents of the body or as **pathogens**, depending on whether or not their colonization of the body results in infection.
- B. *Resident Microbiota: The Human as Habitat*
 1. **Normal resident microbiota** consist of a huge and varied population of microbes that reside permanently on all surfaces of the body exposed to the environment.
 2. Colonization begins prior to birth and continues throughout life. Variations in normal residents occur in response to changes in an individual's age, diet, hygiene, and health.
 3. Normal residents often provide some benefit to the host but are also capable of causing disease, especially when the immune system of the host is compromised or when they invade a normally sterile area of the body.
 4. An important benefit provided by microbiota is **microbial antagonism**.
- C. *Indigenous Microbiota of Specific Regions* Resident microbes include bacteria, fungi, and protozoa. They occupy the skin, mouth, gastrointestinal tract, large intestine, respiratory tract, and genitourinary tract.

13.2 Major Factors in the Development of an Infection

- A. **Pathogenicity** is the ability of microorganisms to cause infection and disease; **virulence** refers to the degree to which a microbe can invade and damage host tissues.
 1. **True pathogens** are able to cause disease in a normal healthy host with intact immune defenses.
 2. **Opportunistic pathogens** can cause disease only in persons whose host defenses are compromised by *predisposing conditions*.
- B. *Becoming Established: Phase 1—Portals of Entry*
 1. Microbes typically enter the body through a specific **portal of entry**. Portals of entry are generally the same as those areas of the body that harbor microflora.
 2. The minimum number of microbes needed to produce an infection is termed the **infectious dose**, and these pathogens may be classified as **exogenous** or **endogenous**, based on their source.
- C. *Attaching to the Host: Phase Two* Microbes attach to the host cell, a process known as **adhesion**, by means of fimbriae, capsules, or receptors.
- D. *Invading the Host and Becoming Established: Phase Three* Microbes that persist in the human host have developed mechanisms of disabling early defensive strategies.
- E. *How Virulence Factors Contribute to Tissue Damage and Disease* **Virulence factors** are structures or properties of a microbe that lead to pathologic effects on the host. Some virulence factors are those that enable entry or adhesion, but many virulence factors lead directly to damage. These fall in three categories: enzymes, toxins, and the inhibition or destruction of phagocytes.
 1. **Exoenzymes** digest epithelial tissues and permit **invasion** of pathogens.
 2. **Toxigenicity** refers to a microbe's capacity to produce **toxins** at the site of multiplication. Toxins are divided

into **endotoxins** and **exotoxins**, and diseases caused by toxins are classified as **intoxications**, **toxemias**, or **toxinoses**.

13.3 The Outcomes of Infection and Disease

- A. **Infectious diseases** follow a typical pattern consisting of an **incubation period**, **prodromal stage**, **period of invasion**, and **convalescent period**. Each stage is marked by symptoms of a specific intensity.
- B. Infections are classified by
 1. whether they remain localized at the site of inoculation (**localized infection**, **systemic infection**, **focal infection**);
 2. the number of microbes involved in an infection, and the order in which they infect the body (**mixed infection**, **primary infection**, **secondary infection**); and
 3. the persistence of the infection (**acute infection**, **chronic infection**, subacute infection).
- C. **Signs** of infection refer to *objective* evidence of infection, and **symptoms** refer to *subjective* evidence. A **syndrome** is a disease that manifests as a predictable complex of symptoms.
- D. After the initial infection, pathogens may remain in the body in a **latent** state and may later cause recurrent infections. Long-term damages to host cells are referred to as **sequelae**.
- E. Microbes are released from the body through a specific **portal of exit** that allows them access to another host.

13.4 Epidemiology: The Study of Disease in Populations *Origins and Transmission Patterns of Infectious Microbes*

- A. The **reservoir** of a microbe refers to its natural habitat; a pathogen's **source** refers to the immediate origin of an infectious agent.
- B. **Carriers** are individuals who inconspicuously shelter a pathogen and spread it to others. Carriers are divided into **asymptomatic carriers**, incubation carriers, convalescent carriers, chronic carriers, and **passive carriers**.
- C. **Vectors** refer to animals that transmit pathogens.
 1. **Biological vectors** are animals that are involved in the life cycle of the pathogen they transmit; **mechanical vectors** transmit pathogens without being involved in the life cycle.
 2. **Zoonoses** are diseases that can be transmitted to humans but are normally found in animal populations.
- D. Agents of disease are either **communicable** or **noncommunicable**, with highly communicable diseases referred to as **contagious**.
 1. Direct transmission of a disease occurs when a portal of exit meets a portal of entrance.
 2. Indirect transmission occurs when an intermediary such as a **vehicle**, **fomite**, or **droplet nuclei** connects portals of entrance and exit.

13.5 The Work of Epidemiologists: Investigation and Surveillance

- A. Epidemiologists are involved in the surveillance of **reportable** and notifiable diseases in populations.
- B. Infectious diseases are tabulated with regard to their **prevalence** and **incidence**.
- C. Populations are analyzed with regard to **morbidity**, **mortality**, age, sex, and geographic region.

- D. Disease patterns are described as being **endemic, sporadic, epidemic, or pandemic** based on the frequency of their occurrence in a population.
- E. Epidemiologists look for **index cases** and changes in the occurrence of diseases such as clusters of new cases. They compile evidence and **trace back** to the original source or reservoir.
- F. **Health-care-acquired infections (HAIs)** are diseases acquired in a hospital or other clinical setting. Special vigilance is required to reduce their occurrence. Most HAIs involve the respiratory tract, surgical incisions, the GI tract, urinary tract, skin, and blood. Infectious agents may originate from the microbiota, medical devices, patients, health care workers, and the environment.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

- The best descriptive term for the resident microbes is
 - commensals
 - parasites
 - pathogens
 - contaminants
- Resident microbiota is commonly found in the
 - liver
 - kidney
 - salivary glands
 - urethra
- Normal resident microbes are absent from the
 - pharynx
 - lungs
 - intestine
 - hair follicles
- Virulence factors include
 - toxins
 - exoenzymes
 - capsules
 - all of these
- The specific action of hemolysins is to
 - damage white blood cells
 - cause fever
 - damage red blood cells
 - cause leukocytosis
- The _____ is the time that lapses between encounter with a pathogen and the first symptoms.
 - prodrome
 - period of invasion
 - period of convalescence
 - period of incubation
- A short period early in a disease that manifests with general malaise and achiness is the
 - period of incubation
 - prodrome
 - sequela
 - period of invasion
- The presence of a few bacteria in the blood is termed
 - septicemia
 - toxemia
 - bacteremia
 - a secondary infection
- A(n) _____ infection is acquired through exposure in a hospital setting.
 - subclinical
 - focal
 - HAI (nosocomial)
 - secondary
- A/an _____ is a passive animal transporter of pathogens.
 - zoonosis
 - biological vector
 - mechanical vector
 - asymptomatic carrier
- An example of a noncommunicable infection is
 - measles
 - leprosy
 - tuberculosis
 - tetanus
- A general term that refers to an increased white blood cell count is
 - leukopenia
 - inflammation
 - leukocytosis
 - leukemia
- The occurrence of Lyme disease mainly in areas where certain species of ticks live would define it as a(n) _____ disease.
 - epidemic
 - pandemic
 - endemic
 - sporadic
- A positive antibody test for HIV would be a _____ of infection.
 - sign
 - symptom
 - syndrome
 - sequela
- Which of the following would *not* be a portal of entry?
 - the meninges
 - the placenta
 - skin
 - small intestine
- Which of the following is *not* a condition of Koch's postulates?
 - isolate the causative agent of a disease
 - cultivate the microbe in a lab
 - inoculate a test animal to observe the disease
 - test the effects of a pathogen on humans

Case Study Review

- Which of these would be the index case for the Ebola epidemic?
 - Nina Pham
 - the baby in Guinea
 - Thomas Duncan
 - a dead monkey
- Ebola virus is a(n) _____ virus classified in the _____ family.
 - enveloped RNA, rhabdovirus
 - naked DNA, adenovirus
 - enveloped DNA, herpesvirus.
 - enveloped RNA, filovirus.
- Explain what features of the virulence, infectious dose, and incubation period of Ebola virus increase its transmission from person to person.

 Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

1. What are the important clinical implications of blood or cerebrospinal fluid that tests positive for microbes?
2. What is the expected result if a compromised person is exposed to a true pathogen?
3. Explain how endotoxin gets into the bloodstream of a patient with endotoxic shock.
4. Give a brief description of how the A-B type of toxin works.
5. For each portal of entry, give a vehicle that carries the pathogen and the course it must travel to invade the tissues.
6. What are some important considerations about the portal of exit?
7. What does it mean for salmonellosis to have an iceberg effect?
8. a. Outline the five types of clinical isolation.
b. Describe the work of an infection control officer.
9. Complete the following table.

	Exotoxins	Endotoxins
Chemical makeup		
General source		
Degree of toxicity		
Effects on cells		
Symptoms in disease		
Examples		

 Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps and a sample of a concept map for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

 Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

1. Discuss the relationship between the vaginal residents and the colonization of the newborn.
2. Can you think of some medical consequences of this relationship?
3. How could the microbiome cause some infections to be more severe and other infections to be less severe?
4. Each of the nine patient specimens listed below has produced a positive culture when inoculated and grown on appropriate media. Indicate whether this result is indicative of infection and explain why or why not.

Urine from urethra	Liver biopsy	Blood
Lung biopsy	Throat	Urine from bladder
Saliva	Cerebrospinal fluid	Semen
5. Use the following formula to explain the relationships among the several factors and what happens when they change:

$$\text{Infection (infectious disease)} = \frac{\text{No. of organisms} \times \text{Virulence}}{\text{Host resistance}}$$
6. Assume that you have been given the job of developing a colony of germ-free chickens.
 - a. What will be the main steps in this process?
 - b. What possible experiments can you do with these animals?
7. Describe each of the following infections using correct technical terminology. (Descriptions may fit more than one category.) Use terms such as *primary*, *secondary*, *nosocomial*, *STD*, *mixed*, *latent*, *toxemia*, *chronic*, *zoonotic*, *asymptomatic*, *local*, *systemic*, *-itis*, *-emia*.
 - Caused by needlestick in dental office
 - Pneumocystis pneumonia* in AIDS patient
 - Bubonic plague from rat flea bite
 - Diphtheria
 - Undiagnosed chlamydiosis
 - Acute necrotizing gingivitis
 - Syphilis of long duration
 - Large numbers of gram-negative rods in the blood
 - A boil on the back of the neck
 - An inflammation of the meninges

8. a. Suggest several reasons why respiratory, surgical, and gastrointestinal infections are the most common health-care-associated infections.
- b. Name several measures that health care providers must exercise at all times to prevent or reduce these types of infections.

9. Summarize the epidemiological findings in the three graphs in figure 13.20.
10. Looking at figure 13.20b. Which pattern of epicurve does it show?

Visual Challenge

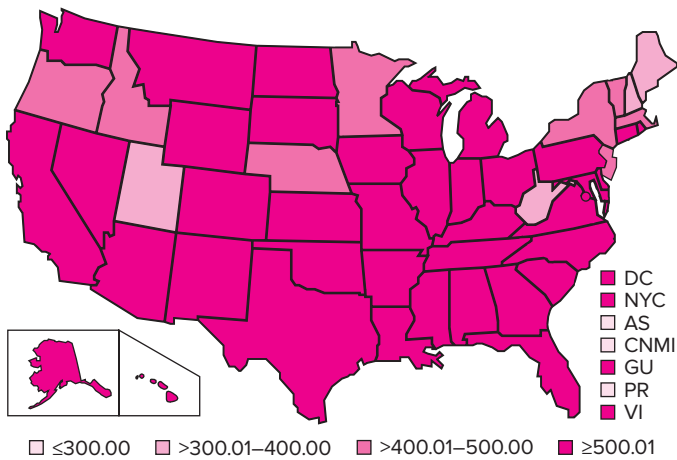

1. Using figure 13.11 (reproduced below) as a guide, explain the processes occurring between *Salmonella* (pink) and the surface of a host cell (yellow) on both the left and the right side of the photo.

Source: National Institute of Allergy and Infectious Diseases (NIAID)/CDC

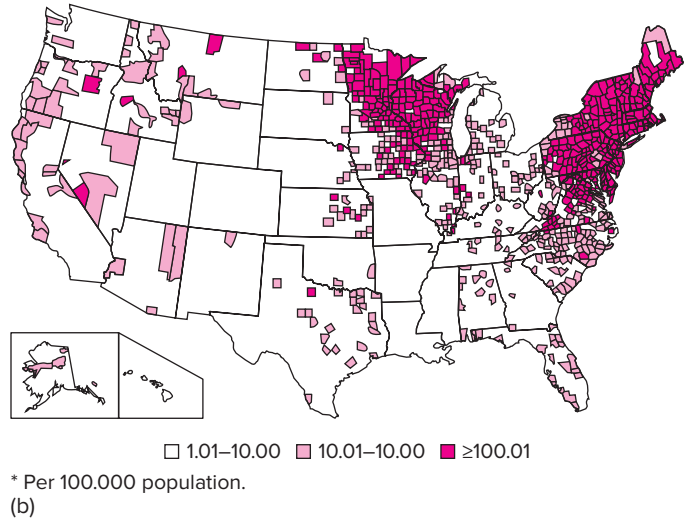

2. Observe the following maps (a)–(c) of three diseases. Determine which show endemic, sporadic, or epidemic pattern, and explain what features have helped you to make this decision.

CASE STUDY Part 1 When Phagocytes Fail

The 5-year-old boy's medical history included several episodes of **bacterial pneumonia**, starting at 7 months of age, that cleared up with antibiotic therapy. At some point his parents began to notice a troubling new set of symptoms and signs. He complained of **constant pain** in his **wrist** and **jawbone**, and the **tissues** overlying these bones were **swollen** and **inflamed**. They took him to the hospital, where he was admitted for lab tests. The results revealed no abnormalities, and the standard tests for infectious agents came out negative. When an X ray detected small spots in the bones of his wrist and jaw, a biopsy was performed that uncovered **granuloma-like lesions and signs of osteomyelitis**. Because of his history of recurrent infections, he was checked for **immune function**, but his B- and T-cell activities were normal. Based on the assumption that he had an infection of **unknown etiology**, he was placed on a **broad range of therapy** consisting of antibacterial, antifungal, and antiviral medications and went home as soon as his condition improved.

After 8 months, his parents took him back to the hospital. He was in a state of severe distress and was readmitted. This time, he had coughing spells, had difficulty breathing, and complained of chest and abdominal pain. He was immediately given antibiotics and **scanned** by computerized tomography (CT), which revealed a **mass in the liver** that extended into the ribcage. Physicians drew a sample

of fluid from the liver and sent it for testing. From the liver sample, technicians isolated a pure culture with greenish-gray, woolly colonies typical of the mold *Aspergillus fumigatus*. Microscopic preparations yielded branched, septate hyphae with **brushlike conidial heads** typical of this fungus.

It now became clear that the child had a serious **systemic fungal infection** that was likely responsible for his earlier episodes as well.

This finding required a different regimen using a powerful **intravenous antifungal drug**, amphotericin B, backed up with interferon and rifampin. He responded well to the medications and was able to return home.

After considering the nature of these new infections, his doctors began to search for an unknown **loss of host defenses** that could account for the child's recurring **opportunistic** infections. They were

aware, for instance, that systemic **aspergillosis** is one of the most common infections in children and adults with **defective phagocytes**.

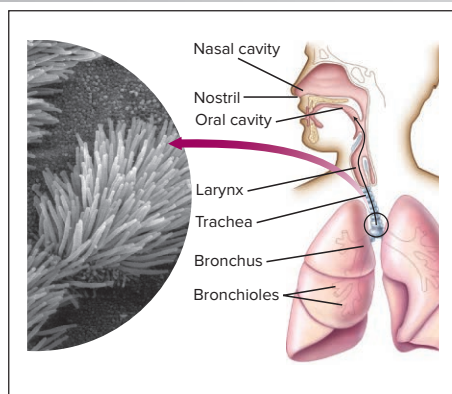

“Systemic aspergillosis is one of the most common infections in children and adults with defective phagocytes.”

- What physiological activities account for the inflammation and swelling?
- What is osteomyelitis, and what are some of its causes?

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

SCOPING OUT THE CHAPTER

The human body is equipped with a deluxe set of defenses that are constantly brought into play with each challenge from foreign materials or pathogens. These defenses do their work behind the scenes, from the largest organs down to the smallest cluster of cells.

An Obstacle Course for Microbes Much of the body is protected by barriers that stop or deflect microbes near the body surfaces before they get too far. One example of these defenses is cilia in the trachea that brush foreign matter out of the respiratory system.

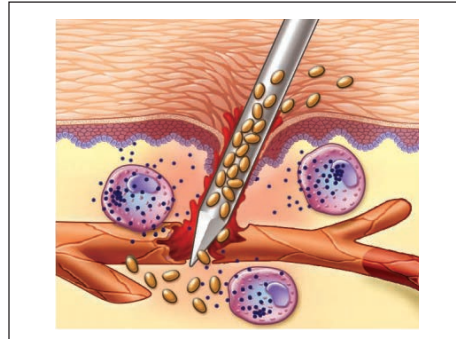

Some defenses are non-specific and present at birth and others are specific and must be acquired over time, but all are essential for complete immune protection. This chapter will survey the anatomy and physiology of the inborn and non-specific defenses that set up immediate zones of protection.

The Origins of Immunity: Blood cells Tissues in the bone marrow produce several different types of white blood cells that become the basis of our defense system. Some of them are phagocytes, some function during inflammation, and some react against specific infectious agents.

Wandering Search Parties Most blood cells are highly active and motile, with an ability to seek out and recognize abnormal or harmful cells and substances. They are also guides that recruit other cells to fight off infections.

A Flood of Protection: When Inflammation Strikes An injury to tissues and cells triggers a spontaneous series of reactions at the site of the damage. This event will alter the size and permeability of nearby blood vessels, stimulate migration of white blood cells, and cause an outpouring of chemical substances, all designed to contain pathogens and stimulate immunities.

Phagocytes: Powerful Predators A special breed of white blood cells is stationed throughout the body to actively pursue foreign intruders, swallow them up, and kill and dismantle them.

14.1 Overview of Host Defense Mechanisms

Expected Learning Outcomes

1. Summarize the characteristics of basic host defenses.
2. Differentiate between the three lines of defense, describing examples of each.
3. Explain the nature of the different types of innate, nonspecific defenses.

The survival of the host depends upon an elaborate network of defenses that keep harmful microbes and other foreign materials from entering the body and causing damage. Should they penetrate, additional host defenses are immediately summoned to prevent them from becoming established in tissues. Defenses involve barriers, cells, and chemicals, and they range from nonspecific to specific and from inborn or innate to acquired. This chapter introduces the main lines of defense intrinsic to all humans. Topics included in this survey are the anatomical and physiological systems that detect, recognize, and destroy foreign substances and the major activities that account for an individual's nonspecific resistance to infection and disease.

In chapter 13 we explored the human-microbe relationship, with emphasis on the role of microorganisms in disease. In this chapter, we examine the other side of the relationship—that of the host defending itself against microorganisms. As previously stated, in light of the unrelenting microbial contact with and colonization of humans, it is something of a miracle that we are not constantly infected and diseased. Our ability to overcome this continual assault on our bodies is the result of a fascinating, highly complex system.

To protect the body against pathogens, the immune system relies on an overlapping network of **host defenses** that operate on several levels. These include **innate, natural defenses** present at birth that provide nonspecific resistance to infection and **adaptive immunities** that are specific and must be acquired. These levels of protection are sometimes divided into categories called the *first, second, and third lines of defense* (table 14.1).

The *first line of defense* includes any barrier that blocks invasion at the portal of entry. This mostly nonspecific line of defense limits access to the internal tissues of the body. However, it is not considered a true immune response because it does not involve recognition of a specific foreign substance and is very general in its actions.

The *second line of defense* is a more internalized system of protective cells and fluids, which includes inflammation and phagocytosis. It acts rapidly at both the local and systemic levels once the first line of defense has been circumvented, and in most reactions it is also nonspecific.

The highly specific *third line of defense* is adaptive and acquired on an individual basis as each foreign substance is encountered by white blood cells called lymphocytes. Responses directed toward each different microbe produce unique protective substances and memory cells that can come into play if that microbe is encountered again. Details of how this third line of defense provides long-term immunity are discussed in chapter 15, whereas this chapter focuses on the first and second lines of defense.

The various levels of defense do not operate in a completely separate fashion; most defenses overlap and are even redundant in some of their effects. This cooperative reaction targets invading microbes on several different fronts simultaneously, making their survival unlikely. To present the interactive nature of host defenses, we start with basic concepts that will build a foundation for understanding the more complex reactions of the immune system to come later.

Barriers at the Portal of Entry: An Inborn First Line of Defense

A number of defenses are a normal part of the body's anatomy and physiology. These inborn, nonspecific defenses can be divided into physical, chemical, and genetic barriers that impede the entry of not only microbes but any foreign agent, whether living or not (figure 14.1).

Physical or Anatomical Barriers at the Body's Surface

The skin and mucous membranes of the respiratory and digestive tracts have several built-in defenses. The outermost layer (stratum corneum) of the skin is composed of epithelial cells that have become compacted, cemented together, and impregnated with an insoluble protein, keratin. The result is a thick, tough layer that is highly impervious and waterproof. Few pathogens can penetrate this unbroken barrier, especially in regions such as the soles of the feet or the palms of the hands, where the stratum corneum is much thicker than on other parts of the body. Other cutaneous barriers include hair follicles and skin glands. The hair shaft is periodically extruded, and the follicle cells are **desquamated**,* or shed. The flushing effect of sweat glands also helps remove microbes.

The mucocutaneous membranes of the digestive, urinary, and respiratory tracts and of the eye are moist and permeable. Despite the normal wear and tear upon these epithelia, damaged cells are rapidly replaced. The mucous coat on the free surface of some membranes impedes the entry and attachment of bacteria. Blinking and tear production (lacrimation) flush the eye's surface with tears and rid it of irritants. The constant flow of saliva helps carry microbes into the harsh conditions of the stomach. Vomiting and defecation also evacuate noxious substances or microorganisms from the body.

The respiratory tract is constantly guarded from infection by elaborate and highly effective adaptations. Nasal hair traps larger particles. Rhinitis, the inflammation of the nasal mucosa often seen with allergy and colds, creates a copious flow of mucus and fluids that helps to flush out the nasal passageways. In the respiratory tree (primarily the trachea and bronchi), a ciliated epithelium (called the

TABLE 14.1 General Features of Host Defenses

Line of Defense	Innate/ Acquired	Specific or Nonspecific	Development of Immunologic Memory	Examples
First	Innate	Nonspecific	No	Physical barriers: skin, tears, coughing, sneezing Chemical barriers: low pH, lysozyme, digestive enzymes Genetic barriers: resistance inherent in genetic makeup of host (pathogen cannot invade)
Second	Innate	Mostly nonspecific	No	Phagocytosis, inflammation, fever, interferon, complement
Third	Acquired	Specific	Yes	T lymphocytes, B lymphocytes, antibodies

Figure 14.1 Defenses. Some nonspecific defense barriers that help prevent entry of microorganisms into the host's tissues.

ciliary escalator) conveys foreign particles entrapped in mucus toward the pharynx to be removed (**figure 14.2**). Irritation of the nasal passage reflexively initiates a sneeze, which expels a large volume of air at high velocity. Similarly, the acute sensitivity of the bronchi, trachea, and larynx to foreign matter triggers coughing, which ejects irritants.

The genitourinary tract derives partial protection from the continuous trickle of urine through the ureters and from periodic bladder emptying that flushes the urethra.

The composition of microbiota and its protective effect were discussed in chapter 13. Even though the normal microbial residents do not constitute a physical or anatomical barrier, their presence can block the access of pathogens to epithelial surfaces and can create an unfavorable environment for pathogens by competing for limited nutrients or by altering the chemical make up of various

body regions. Some bacterial residents of the large intestine secrete bacteriocins or antibiotics, which can inhibit or kill other bacteria.

Nonspecific Chemical Defenses

The skin and mucous membranes offer a variety of chemical defenses. Sebaceous secretions exert an antimicrobial effect, and specialized glands such as the meibomian glands of the eyelids lubricate the conjunctiva with an antimicrobial secretion. Other defenses in tears and saliva include **lysozyme** and **defensins**. Lysozyme is an enzyme that hydrolyzes the peptidoglycan in the cell wall of bacteria. Defensins are peptides produced by various cells and tissues that damage cell membranes and lyse bacteria and fungi. Skin cells produce a defensin called dermicidin that helps eliminate bacteria, and paneth cells in the intestine secrete defensins that can destroy or inhibit several types of infectious agents. The high concentrations of lactic acid and electrolytes in sweat and the skin's acidic pH and fatty acid content are also inhibitory to many microbes.

Internally, the hydrochloric acid content of the stomach renders protection against many pathogens that are swallowed. The intestine's digestive juices and bile are also potentially destructive to microbes. Even semen contains an antimicrobial chemical that inhibits bacteria, and the vagina has a protective acidic pH maintained by lactobacilli that are part of the microbiota.

Genetic Resistance to Infection

In certain cases, the genetic makeup of an individual is different enough to ensure protection from some pathogens. One explanation for this phenomenon is that some pathogens have such great specificity for one host species that they are incapable of infecting other species. Another way of putting it is, "Humans can't acquire distemper from cats, and cats can't get mumps from humans." This specificity is particularly true of viruses, which can invade only by attaching to a specific host receptor. But this defense does not hold true for zoonotic infectious agents that attack a broad spectrum of animals. Genetic differences in susceptibility can also exist within members of one

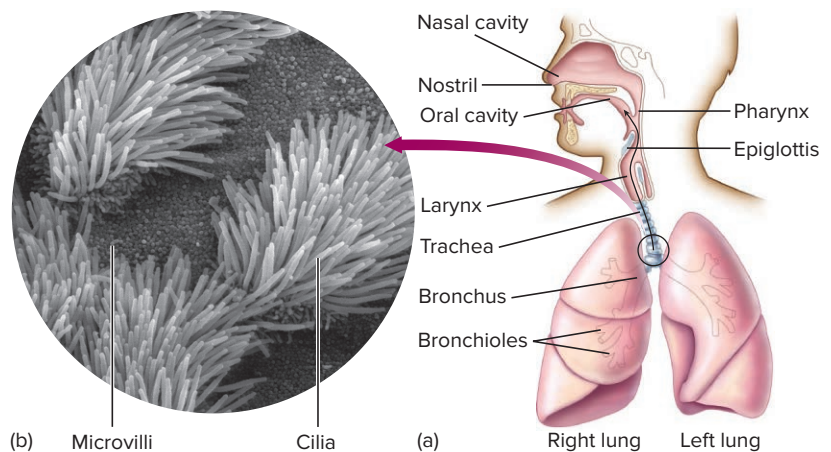

Figure 14.2 The ciliary defense of the respiratory tree. (a) The trachea and bronchi are structured to entrap and propel particles upward toward the pharynx. (b) Detail of trachea (5,000X) features tufts of cilia on the surface of epithelial cells that sweep away particles and microbes. (b): Source: Courtesy Charles P. Daghljan. <http://www.dartmouth.edu/~emlab/gallery>

species. Humans carrying a gene or genes for sickle-cell anemia are resistant to malaria. Genetic differences also exist in susceptibility to tuberculosis, leprosy, and certain systemic fungal infections.

The vital contribution of barriers is clearly demonstrated in people who have lost them or never had them. Patients with severe skin damage due to burns are extremely susceptible to infections; those with blockages in the salivary glands, tear ducts, intestine, and urinary tract are also at greater risk for infection. But as important as it is, the first line of defense alone cannot provide adequate protection. Because many pathogens find a way to circumvent the barriers by using their virulence factors (discussed in chapter 13), a whole new set of defenses—inflammation, phagocytosis, specific immune responses—is ready to react to them.

Check Your Progress SECTION 14.1

1. Explain the functions of the three lines of defense and indicate which are the most essential to survival.
2. What is the difference between nonspecific host defenses and immune responses?
3. Differentiate innate defenses and acquired immunity. What are the general characteristics of each? Discuss the advantages of having multiple defenses (innate and acquired) against the same microbe.
4. List four innate defensive responses present in the body, and explain how each type functions to combat infection.

14.2 Structure and Function of the Organs of Defense and Immunity

Expected Learning Outcomes

4. Describe the primary functions and organs of the immune system.
5. Describe several features of the recognition system of host defenses.
6. Characterize pattern recognition receptors and pathogen-associated molecular patterns.
7. Describe the microscopic anatomy of body compartments and how they interconnect.
8. Outline the anatomy and functions of the reticuloendothelial system.
9. Outline the origin and composition of the blood, and characterize the types of blood cells and their functions.
10. Explain the behavior of white blood cells with regard to the blood circulation and tissues.
11. Describe the characteristics and functions of the lymphatic system.

Immunology encompasses the study of all features of the body's second and third lines of defense. Although this chapter is concerned primarily with infectious microbes, be aware that immunology is central to the study of fields as diverse as cancer and allergy. In chapters 15, 16, and 17 you will see that many of the most powerful applications of immunology have been developed for use in health care, laboratory, or commercial settings.

The primary functions of a healthy immune system can be summarized as

1. surveillance of organs, tissues, and other compartments;
2. recognition and differentiation of normal components of the body and foreign material such as pathogens; and
3. attack against and destruction of foreign invaders.

Because infectious agents could potentially enter through any number of portals, the cells of the immune system constantly move about the body, surveying the tissues for potential pathogens (see figure 14.3). This process is carried out primarily by **white blood cells (WBCs)** or **leukocytes**, which have an innate capacity to recognize and differentiate any foreign material in the body, such as invading bacterial cells. Such foreign matter is often referred to as **nonsel**. Normal cells of the body, called **self**, are monitored and recognized and are usually not attacked by the immune system. The ability to differentiate nonself and thus spare self from attack is central to the effectiveness of the immune system. In chapter 16 we will see how autoimmune diseases can arise when this system goes awry. Foreign cells must be recognized as a potential threat and dealt with appropriately, but normal, healthy cells should not come under attack by the immune defenses. Exceptions to this would be abnormal or damaged self such as cancer cells.

How Do White Blood Cells Carry Out Recognition and Surveillance?

White blood cells are motile, migratory cells that move about the tissues and body compartments in search of any foreign matter that may have gotten through the first line of defense. Even though each type of blood cell has a particular role to play in defense, most of them have some capacity to locate and interact with foreign matter (**figure 14.3**). They display special molecules on their membranes known as **pattern recognition receptors (PRRs)**, which are like “feelers” for sensing pathogens. There are several different types of PRRs involved in this recognition, including kinases, lectins, and mannose-type molecules. The best-understood PRRs are the **toll-like receptors (TLRs)**, which reside within the membranes of early responders such as phagocytes.

Although PRRs and TLRs are not specific to a particular microbe, they can immediately recognize and interact with molecules on the surface of many pathogens called **pathogen-associated molecular patterns**, or **PAMPs**. PAMPs are molecules shared by many microorganisms that act like “red flags” that signal white blood cells involved in innate immunity. The detection of PAMPs on pathogens by PRRs and TLRs provides an early alert of invasion, and triggers reactions that help to control pathogens before they can invade further. Examples of PAMPs include peptidoglycan, lipoteichoic acid, and lipopolysaccharide from bacterial cell walls, double-stranded RNA found in some viruses, zymosan from fungal cell walls, and bacterial flagellin. We will return to this topic again in section 14.4 on phagocytes.

Because these components are shared among many pathogens and not specific to a single cell type, only a small number of TLRs are needed to recognize a very wide variety of microbes. It is important to emphasize that this type of recognition is not specific or

Figure 14.3 To search, to recognize, and to eliminate are the functions of the immune system. White blood cells (WBCs) as seen in this view are equipped with a highly developed sense of “touch.” (a, b) As they sort through the tissues, they “feel” the surrounding environment by means of their pattern recognition receptors (PRRs), which detect what is foreign or nonself. (c) When nonself molecules called PAMPs are detected, WBCs mount a reaction to eliminate the microbes that carry them. PAMPs are pathogen-associated molecular patterns that many pathogens display. Self molecules do not trigger these reactions

selective for a single type of microbe, making it a type of nonspecific, innate immunity that should not be confused with the specific acquired immunity from the third line of defense.

Compartments and Connections of the Immune System

It will soon become clear, in this and subsequent chapters, that unlike many body systems, the immune “system” does not exist in a single, well-defined organ. Instead, it encompasses a large, complex, and diffuse network of cells and fluids that penetrate into every organ and tissue. It is this very arrangement that promotes the surveillance and recognition processes that help screen the body for microbes and harmful substances.

The body is partitioned into several fluid-filled spaces called the intracellular, extracellular, lymphatic, cerebrospinal, and circulatory compartments. Although these compartments are physically separated, they have numerous connections. Their structure and position permit extensive interchange and communication

(figure 14.4). The most extensive body compartments that participate in immune function are

1. the **reticuloendothelial system (RES)**,*
2. the spaces surrounding tissue cells that contain **extracellular fluid (ECF)**,
3. the **bloodstream**, and
4. the **lymphatic system**.

For effective immune responsiveness, the activities in one fluid compartment must be conveyed to other compartments. Let us see how this occurs by viewing tissue at the microscopic level (figure 14.4a). At this level, clusters of tissue cells are in direct contact with the reticuloendothelial system (RES) and the extracellular fluid (ECF), which bathes all cells and is an important site of exchange for nutrients and gases. Other compartments (vessels) that penetrate at this level are blood and lymphatic capillaries. This close association allows cells and chemicals that originate in the RES and ECF to seep or migrate into the blood and lymphatics; any products of a lymphatic reaction can be transmitted directly into the

Figure 14.4 Connections between the body compartments. **(a)** The meeting of the major fluid compartments at the microscopic level. The close proximity of these compartments at the cellular level allows for continuous exchange of cells, fluids, and molecules (arrows). **(b)** Schematic view of how main fluid compartments form a continuous cyclic system of exchange. Positioning of the compartments favors rapid circulation from one site to another, either through direct (→) or indirect (⇌) connections.

blood through the connection between these two systems; and certain cells and chemicals originating in the blood can move through the vessel walls into the extracellular spaces and migrate into the lymphatic system (figure 14.4b).

The flow of events among these systems depends on where an infectious agent or foreign substance first intrudes. A typical progression might begin in the extracellular spaces and RES, move to the lymphatic circulation, and ultimately end up in the bloodstream. Regardless of which compartment is first exposed, an immune reaction in any one of them will eventually be communicated to the others at the microscopic level. An obvious benefit of such an integrated system is that no cell of the body, even the most isolated, is far removed from competent protection. Let us take a closer look at each of these compartments separately.

Immune Functions of the Reticuloendothelial System

The tissues of the body are permeated by a network of connective tissue fibers, or a reticulum, that originates in the cellular basal lamina, interconnects nearby cells, and meshes with the massive connective tissue network surrounding all organs. This network, or reticuloendothelial system (**figure 14.5**), is intrinsic to immune function because it provides a passageway within and between tissues and organs. It also is heavily endowed with white blood cells of the **mononuclear phagocyte system**. This system is waiting to attack passing foreign intruders as they arrive in the skin, lungs, liver, lymph nodes, spleen, and bone marrow. The RES serves an additional role in carrying extracellular fluid through-out its network.

Figure 14.5 The reticuloendothelial system occurs as a continuous connective tissue framework throughout the body. **(a)** This system begins at the microscopic level with a fibrous support network (reticular fibers) enmeshing each cell. This web connects one cell to another within a tissue or organ and provides a niche for phagocytic white blood cells, which can crawl within and between tissues. **(b)** The degrees of shading in the body indicate variations in phagocyte concentration (darker = greater).

Origin, Composition, and Functions of the Blood

The circulatory system proper includes the heart, arteries, veins, and capillaries that circulate blood, and the lymphatic system, which includes lymphatic vessels and lymphatic organs (lymph nodes) that circulate lymph. As you will see, these two circulations parallel, interconnect with, and complement one another.

The substance that courses through the arteries, veins, and capillaries is **whole blood**, a liquid connective tissue consisting of **blood cells** (formed elements) suspended in **plasma**. One can see these two components with the naked eye when a tube of unclotted blood is allowed to sit or is spun in a centrifuge. The cells' density causes them to settle into an opaque layer at the bottom of the tube, leaving the plasma, a clear, yellowish fluid, on top (**figure 14.6**). **Serum** is essentially the same as plasma, except it is the clear fluid from clotted blood so it lacks the clotting proteins that plasma contains. Serum is often used in immune testing and therapy (chapter 15).

Fundamental Characteristics of Plasma Plasma contains hundreds of different chemicals produced by the liver, white blood cells, endocrine glands, and nervous system and absorbed from the digestive tract. The main component of this fluid is water (92%), and the remainder consists of proteins such as albumin and globulins (including antibodies); other immunochemicals; fibrinogen and other clotting factors; hormones; nutrients; ions and electrolytes; dissolved gases (O₂ and CO₂); and waste products (urea). These substances support the normal physiological functions of nutrition, development, protection, homeostasis, and immunity.

A Survey of Blood Cells The production of blood cells, known as **hemopoiesis**, or **hematopoiesis**,* begins early in embryonic development in the yolk sac (an embryonic membrane). Later it is

* *hematopoiesis* (hem"-mat-o-poy-ee'-sis) Gr. *haima*, blood, and *poiesis*, a making.

Figure 14.6 The macroscopic composition of whole blood.

(a) When uncoagulated blood sits in a tube, it stratifies into a clear layer of plasma, a thin layer of off-white material called the buffy coat (which contains the white blood cells), and a layer of red blood cells in the bottom. (b) Serum is the clear fluid that separates from clotted blood. Clotting causes the red and white cells to clump in the bottom of the tube in a single mass. *Source:* National Cancer Institute; Created by: Bruce Wetzel and Harry Schaefer (Photographers)

taken over by the liver and lymphatic organs, and it is finally assumed entirely and permanently by the red bone marrow. Although much of a newborn's red marrow is devoted to hematopoietic function, the active marrow sites gradually recede, and by the age of 4 years, only the ribs, sternum, pelvic girdle, flat bones of the skull and spinal column, and proximal portions of the humerus and femur are devoted to blood cell production.

The relatively short life of blood cells demands a rapid turnover that is continuous throughout a human life span. The primary precursor of new blood cells is a pool of undifferentiated cells called pluripotential **stem cells**¹ maintained in the marrow. During development, these stem cells proliferate and *differentiate*—meaning that immature or unspecialized cells develop the specialized form and function of mature cells. The primary lines of cells that arise from this process produce red blood cells (RBCs), white blood cells (WBCs, or leukocytes), and platelets (thrombocytes). The white blood cell lines are programmed to develop into several secondary lines of cells during the final process of differentiation (**figure 14.7**). These committed lines of WBCs are largely responsible for immune function.

The leukocytes* traditionally are evaluated by their reactions with a hematologic stain that contains a mixture of dyes and can differentiate cells by color and morphology. When this stain is used on blood smears and evaluated using the light microscope, the leukocytes appear either with or without noticeable colored granules in the cytoplasm; on that basis they are divided into two groups: **granulocytes** and **agranulocytes**. Greater magnification reveals that even the agranulocytes have tiny granules in their cytoplasm, so some hematologists also use the appearance of the nucleus to distinguish them. Granulocytes have a lobed nucleus, and agranulocytes have an unlobed, rounded nucleus. You can see both of these characteristics in circulating leukocytes shown in figure 14.7.

Granulocytes The types of granular leukocytes present in the bloodstream are neutrophils, eosinophils, and basophils. All three are known for prominent cytoplasmic granules that stain with some combination of acidic dye (eosin) or basic dye (methylene blue). Although these granules are useful diagnostically, they also function in numerous physiological events. Refer to figure 14.7 to view the cell types described.

Neutrophils* are distinguished from other leukocytes by their conspicuous lobed nuclei and their fine, pale lavender granules. In cells newly released from the bone marrow,

1. Pluripotential stem cells can develop into several different types of blood cells; unipotential cells have already committed to a specific line of development.

* *leukocyte* (loo'-koh-syte) Gr. *leukos*, white, and *kytos*, cell. The whiteness of unstained WBCs is best seen in the white layer, or buffy coat, of sedimented blood.

* *neutrophil* (noo'-troh-fil) L. *neuter*, neither, and Gr. *philos*, to love. The granules are neutral and do not react markedly with either acidic or basic dyes. In clinical reports, they are often called “polys” or PMNs for short.

Figure 14.7 Simplified diagram of blood cell and platelet development. The details of several intermediate steps have been omitted. Undifferentiated stem cells in the red marrow give rise to several different cell lines that become increasingly specialized until mature cells are released into circulation. The yellow area indicates mature leukocytes (white blood cells). Photomicrographs of major circulating leukocytes are featured with the descriptions below.

the nuclei are horseshoe-shaped, but as they age, they form multiple lobes (up to five). These cells, also called polymorphonuclear neutrophils (PMNs), make up 55% to 90% of the circulating leukocytes—about 25 billion cells in the circulation at any given moment. The main work of the neutrophils is in phagocytosis. Their high numbers in both the blood and the tissues suggest that there is a constant

challenge from resident microbiota and environmental sources. Most of the cytoplasmic granules carry digestive enzymes and other chemicals that degrade the phagocytosed materials (see the discussion of phagocytosis in section 14.4). The average neutrophil lives only about 2 days, spending much of this time in the tissues and only about 4 to 10 hours in circulation.

Eosinophils* are readily distinguished in a stain preparation by their larger, orange to red (eosinophilic) granules and bilobed nucleus. They are much more numerous in the bone marrow and the spleen than in the circulation, contributing only 1% to 3% of the total WBC count. Their granules contain peroxidase, lysozyme, and other digestive enzymes, as well as toxic proteins and inflammatory chemicals.

Eosinophil
© Harold J. Benson

The main protective action of eosinophils is their ability to attack and destroy large eukaryotic pathogens. They are also involved in inflammation and allergic reactions. Among their most important targets are the larval forms of worm parasites that cause ascariasis, filariasis, and schistosomiasis. The binding of eosinophils to the larval surface and the release of toxic compounds into their cells causes disintegration of the larvae. Eosinophils are among the earliest cells to accumulate near sites of inflammation and allergic reactions, where they attract other leukocytes and release chemical mediators.

Basophils* are characterized by pale-stained, 2-lobed nuclei and very prominent dark blue to black granules. They are the scarcest type of leukocyte, making up less than 0.5% of the total circulating WBCs in a normal individual. Basophils share some morphological and functional similarities with widely distributed tissue cells called **mast* cells**. Although these two cell types were once regarded as identical, mast cells are nonmotile elements bound to connective tissue around blood vessels, nerves, and epithelia, and basophils are motile elements that migrate within and between compartments. Both cell types originate from the same bone marrow stem cell line.

Basophil
© Harold J. Benson

Basophils parallel eosinophils in many of their actions, because they also contain granules with potent chemical mediators. These mediators act on other cells and tissues of the body. For example, they may attract white blood cells toward the site of an infection or cause blood vessels to dilate in response to an injury. Mast cells are first-line defenders against the local invasion of pathogens; they recruit other inflammatory cells; and they are directly responsible for the release of histamine and other allergic stimulants during immediate allergies (see chapter 16).

Agranulocytes

Agranular leukocytes have globular, nonlobed nuclei and lack prominent cytoplasmic granules when viewed with the light microscope. The two general types are monocytes and lymphocytes. Refer to figure 14.7 to review their origins.

Although lymphocytes are the cornerstone of the third line of defense, which is the subject of chapter 15, their origin and morphology are described here so their relationship to the other blood components is clear. **Lymphocytes** are the second most common

WBC in the blood, comprising 20% to 35% of the total circulating leukocytes. The fact that their overall number throughout the body is among the highest of all cells indicates how important they are to immunity. One estimate suggests that about one-tenth of all adult body cells are lymphocytes, exceeded only by erythrocytes and fibroblasts.

Lymphocytes
© Harold J. Benson

In a stained blood smear, most lymphocytes are small, spherical cells with a uniformly dark, rounded nucleus surrounded by a thin fringe of clear cytoplasm, although in tissues they can become much larger and can even mimic monocytes in appearance. Lymphocytes exist as two functional types—the **B lymphocytes (B cells, for short)**, and the thymus-derived or **T lymphocytes (T cells, for short)**. In humans, B cells mature in special bone marrow sites. T cells mature in the thymus gland. Both populations of cells are transported by the bloodstream and lymph and move about freely between lymphoid organs and connective tissue.

Lymphocytes are the key cells of the third line of defense and the specific immune response. When stimulated by foreign substances (antigens), lymphocytes are transformed into activated cells that neutralize and destroy those foreign substances. B cells contribute to **humoral immunity**, defined as protective molecules carried in the fluids of the body. Activated B cells form specialized **plasma cells**, which produce **antibodies***. Antibodies are protein molecules that interlock with foreign cells or molecules and participate in their destruction. Activated T cells engage in a spectrum of immune functions, called **cell-mediated immunity**, that modulate immune functions and directly kill foreign cells. The action of both classes of lymphocytes account for the specificity and memory typical of immunity. Lymphocytes are so important to the defense of the body that most of chapter 15 is devoted to their reactions.

Monocytes* are generally the largest of all white blood cells and the third most common in the circulation (3% to 7%). As a monocyte matures, its nucleus becomes oval- or kidney-shaped—indented on one side, off center, and often contorted with fine wrinkles. The cytoplasm holds many fine vacuoles containing digestive enzymes. Monocytes are discharged by the bone marrow into the bloodstream, where they live as phagocytes for a few days. Later they leave the circulation to undergo final differentiation into **macrophages***. Macrophages are key players in immunity, in general, responsible for

Monocyte
© Harold J. Benson

1. many types of specific and nonspecific phagocytic and killing functions (they assume the job of cellular housekeepers, “mopping up the messes” created by infection and inflammation);

2. processing foreign molecules and presenting them to lymphocytes; and
3. secreting biologically active compounds that assist, mediate, attract, and inhibit immune cells and reactions.

* *eosinophil* (ee'-oh-sin'-oh-fil) Gr. eos, dawn, rosy, and *philos*, to love. Eosin is a red, acidic dye attracted to the granules.

* *basophil* (bay'-soh-fil) Gr. *basis*, foundation. The granules attract to basic dyes.

* *mast* From Ger. *mast*, food. Early cytologists thought these cells were filled with food vacuoles.

* *antibody* (an'-tih-bahd'-ee) Gr. *anti*, against, and O. E., *bodig*, body.

* *monocyte* (mon'-oh-syte) From *mono*, one, and *cytos*, cell.

* *macrophage* (mak'-roh-fayj) Gr. *macro*, large, and *phagein*, to eat. They are the “large eaters” of the tissues.

TABLE 14.2 Characteristics of Leukocytes

Cell Type	Prevalence in Circulation	Primary Function	Features	Appearance*
Neutrophils	55%–90% of white blood cells	General phagocytosis	Life span of 2 days, with only 4–10 hours spent in the circulation	Multilobed nuclei; small purple granules containing digestive enzymes
Eosinophils	1%–3% of white blood cells	Destruction of parasitic worms; mediators of allergy	Found in much higher numbers in the spleen and bone marrow	Bilobed nucleus with large orange granules containing toxic proteins, inflammatory mediators, and digestive enzymes
Basophils	0.5% of white blood cells	Active in allergy, inflammation, parasitic infections	Cytoplasmic granules contain histamines, prostaglandins, and other chemical mediators of the allergic response.	Pale-staining, constricted nuclei with dark blue to black granules
Monocytes	3%–7% of white blood cells	Phagocytosis, followed by final differentiation into macrophages and dendritic cells	Monocytes also secrete several chemicals that moderate the functions of the immune system.	Largest WBC; nuclei large, ovoid, and often indented—no cytoplasmic granules visible using a light microscope
Lymphocytes	20%–35% of white blood cells	Specific (acquired) immunity	Two types of lymphocytes exist. T cells are responsible for cell-mediated immunity, whereas B cells are responsible for humoral immunity.	Small spherical cells with uniformly staining dark, round nuclei

*See examples in figure 14.7.

We touch upon these functions in several ensuing sections.

Another product of the monocyte cell line is **dendritic cells**, named for their long, thin cell processes. Immature dendritic cells move from the blood to the reticuloendothelial system and lymphatic tissues, where they trap pathogens. Ingestion of bacteria and viruses stimulates dendritic cells to migrate to lymph nodes and the spleen to participate in reactions with lymphocytes.

Some of the major characteristics of leukocytes are summarized in **table 14.2**.

Erythrocyte and Platelet Lines These elements stay in the circulatory system proper and are not generally considered part of the immune system. Their development is also shown in figure 14.7.

Erythrocytes are produced by stem cells that go through several stages of differentiation and lose their nucleus just prior to entering the circulation. The resultant red blood cells are simple, biconcave sacs of hemoglobin that transport oxygen and carbon dioxide to and from the tissues. These are the most numerous of circulating blood cells, appearing in stains as small pink circles. Red blood cells do not ordinarily have immune functions, though they can be the target of immune reactions.

Platelets are formed elements in circulating blood that are *not* whole cells. They are formed by the disintegration of a large, multinucleate cell, the megakaryocyte. In stains, platelets are blue-gray with fine red granules and are readily distinguished from cells by their small size. Platelets function primarily in hemostasis (plugging broken blood vessels to stop bleeding) and in releasing chemicals that act in blood clotting and inflammation.

Components and Functions of the Lymphatic System

The lymphatic part of the circulatory system is a compartmentalized network of vessels, cells, and specialized accessory organs (**figure 14.8**). It begins in the farthest reaches of the tissues as tiny capillaries that transport a special fluid (lymph) through an increasingly larger system of vessels and filters (lymph nodes). It eventually connects to major vessels that drain back into the regular circulatory system. Some major functions of the **lymphatic** or **lymphoid system** relating to immune defenses are:

1. to provide an auxiliary route for the return of extracellular fluid to the circulatory system proper;
2. to act as a “drain-off” system for the inflammatory response; and
3. to render surveillance, recognition, and protection against foreign materials through a system of lymphocytes, phagocytes, and antibodies.

Lymphatic Fluid **Lymph** is a plasmalike liquid carried by the lymphatic circulation. It is formed when certain blood components move out of the blood vessels into the extracellular spaces and diffuse or migrate into the lymphatic capillaries. Because of this, the composition of lymph parallels that of plasma in many ways. It is made up of water, dissolved salts, and 2% to 5% protein (especially antibodies and albumin). Like blood, it also transports numerous white blood cells (especially lymphocytes) and miscellaneous materials such as fats, cellular debris, and infectious agents that have gained access to the tissue spaces. Unlike blood, red blood cells are not normally found in lymph.

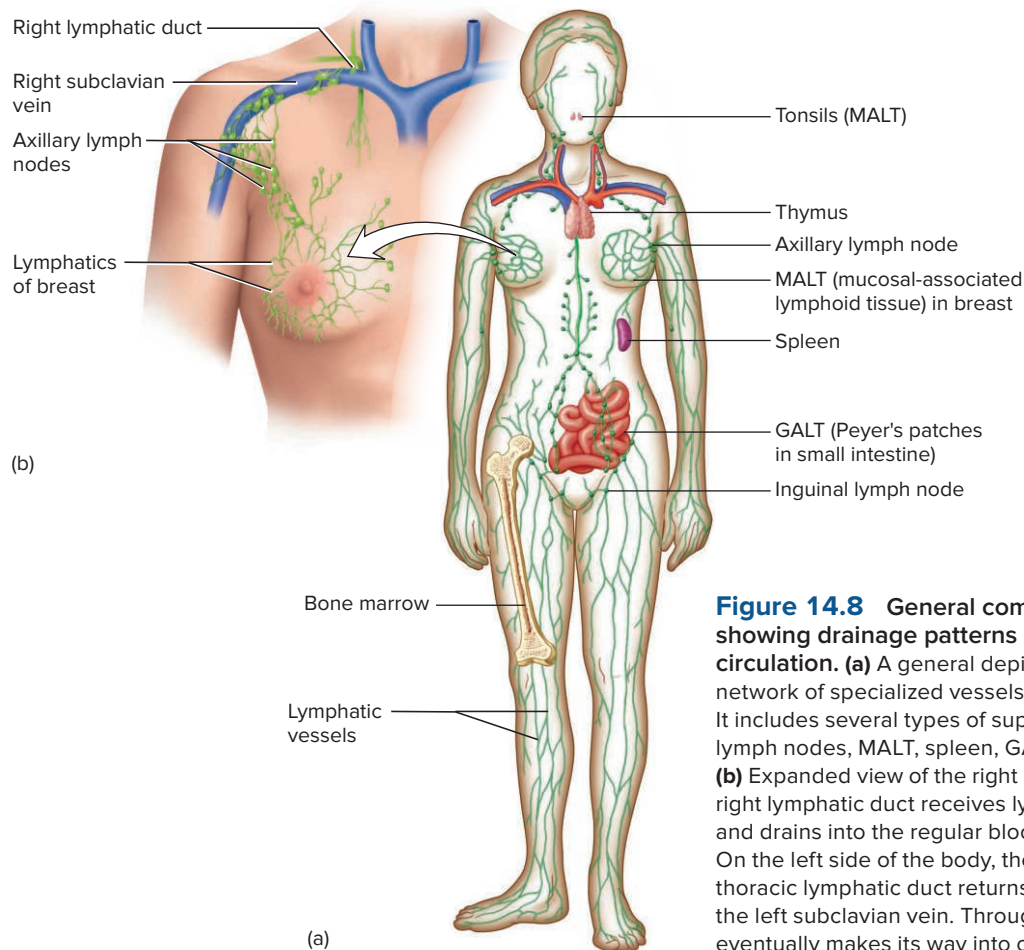

Figure 14.8 General components of the lymphatic system, showing drainage patterns and connections with the regular circulation. **(a)** A general depiction of the lymphatic system, a branching network of specialized vessels that extend into most regions of the body. It includes several types of supportive tissues and organs, including the lymph nodes, MALT, spleen, GALT, thymus gland, tonsils, and bone marrow. **(b)** Expanded view of the right breast and axillary lymphatic circulation. The right lymphatic duct receives lymph from the right axillary and head region and drains into the regular blood circulation at the right subclavian vein. On the left side of the body, there is a similar arrangement in which the thoracic lymphatic duct returns lymph from the remainder of the body at the left subclavian vein. Through these direct connections, all lymph eventually makes its way into circulating blood.

Lymphatic Vessels The system of vessels that transport lymph is constructed along the lines of blood vessels (**figure 14.9**). The tiniest vessels, **lymphatic capillaries**, accompany the blood capillaries. The lymphatic capillaries permeate all parts of the body except the central nervous system and certain organs such as bone, placenta, and thymus. Their thin walls have a single layer of epithelial cells similar to blood capillaries, with loose junctions that allow free entry of extracellular fluid that collects from the circulatory system (see **figure 14.4**). Lymphatic vessels are found in particularly high numbers in the hands and feet and around the areolae of the breast.

Two important differences between the bloodstream and the lymphatic system should be mentioned (**figure 14.10**). First, given that one of the main functions of the lymphatic system is returning lymph to the circulation, lymph flows only in one direction, moving from the extremities toward the heart. Eventually it will be returned to the bloodstream through the thoracic duct and the right lymphatic duct near the base of the neck (see **figure 14.8**). The second difference concerns how lymph travels through the vessels of the lymphatic system. Whereas blood is transported through the body by means of a dedicated pump (the heart), lymph is moved only through the contraction of skeletal muscles that surround the lymphatic ducts. This dependence on muscle movement helps to explain the swelling of the hands and feet that sometimes occurs during the night (when muscles are inactive) yet goes away soon after waking.

The parasitic infection filariasis presents a dramatic example of what happens when the lymphatic drainage is blocked by infectious agents. Filarial worms from the infection become caught in the lymph nodes and channels of the extremities and plug them up. This prevents lymph from flowing into the accessory ducts and back to the circulation. The buildup of lymph massively distorts limbs and other body parts such as the scrotum and breasts.

Lymphoid Organs Lymphatic organs and tissues with immune functions can be classified as primary and secondary, as summarized here:

Primary organs

- Thymus gland
- Bone marrow

Secondary organs and tissues

- Lymph nodes
- Spleen
- MALT—mucosal-associated lymphoid tissue
- SALT—skin-associated lymphoid tissue
- GALT—gut-associated lymphoid tissue (Peyer’s patches)

(a) The finest level of lymphatic circulation begins with blind capillaries (green) that pick up foreign matter from the surrounding tissues and transport it in lymph away from the extremities via a system of small ducts.

(b) The ducts carry lymph into a circuit of larger ducts that ultimately flow into clusters of filtering organs, the lymph nodes.

(c) A section through a lymph node reveals the afferent ducts draining lymph into sinuses that house several types of white blood cells. Here, foreign material is filtered out and processed by lymphocytes, macrophages, and dendritic cells.

(d) and (e) Lymph continues to trickle from the lymph nodes via efferent ducts into a system of larger drainage vessels, which ultimately connect with large veins near the heart. In this way, cells and products of immunity continually enter the regular circulation.

Figure 14.9 Scheme of circulation in the lymphatic vessels and lymph nodes.

The **primary lymphoid organs** include the thymus and bone marrow, because they are a source of immune cells and a “nursery” for developing white blood cells. They are the sites of origin and maturation of lymphocytes—white blood cells with specific immune function. They subsequently release these cells to populate the secondary lymphatic sites.

Secondary lymphoid organs, such as the spleen and lymph nodes, are circulatory-based locations where encounters with microbes and immune responses often take place. Associated lymphoid tissues are collections of cells widely dispersed throughout body tissues such as the skin and mucous membranes, ready to react with any locally entering infectious agents.

Figure 14.10 Comparison of the circulation patterns of the regular circulatory and lymphatic systems. The movement of lymphatic flow is in one direction (green) from lymphatic capillaries to collecting vessels and ducts to large lymphatic trunks to subclavian veins to the heart. The flow of blood, on the other hand, is cyclic, with blood continuously flowing through arteries to capillaries to veins to the heart and back around. With this combined system the lymphatics can collect excess tissue fluid and return it to the bloodstream. The two systems can also participate together in surveillance of the tissues for foreign invaders. Note: The lymphatic flow (green) is shown on only one side to keep the comparison uncluttered.

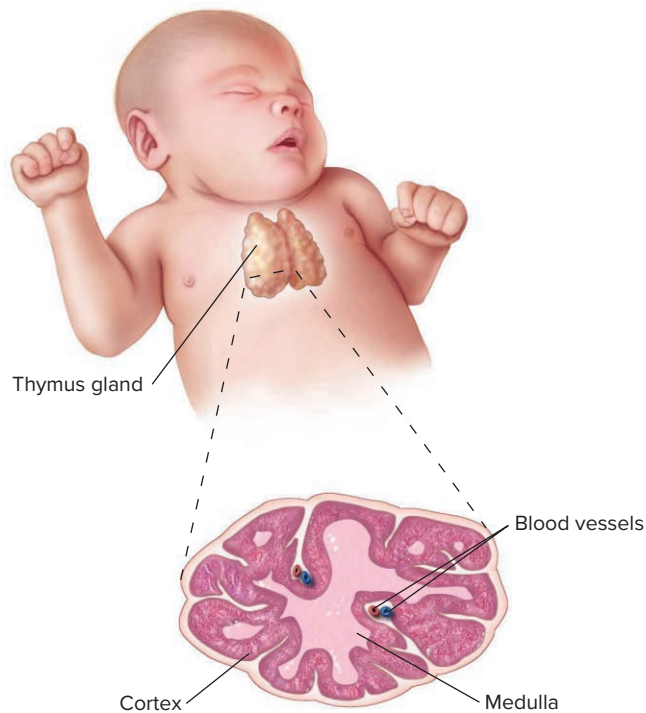

Figure 14.11 The thymus gland. Immediately after birth, the thymus is a large organ that nearly fills the region over the midline of the upper thoracic region. In the adult, however, it is proportionately smaller (to compare, see figure 14.8a). Section shows the main anatomical regions of the thymus. Immature T cells enter through the cortex and migrate into the medulla as they mature.

The Thymus Gland The **thymus** originates in the embryo as two lobes in the pharyngeal region that fuse into a triangular structure. It is located in the thoracic cavity near the tip of the sternum. The size of the thymus is greatest proportionately at birth (**figure 14.11**), and it continues to exhibit high rates of activity and growth until puberty, after which it begins to shrink gradually through adulthood.

Children born without a complete thymus (DiGeorge syndrome, see chapter 16) or who have had their thymus surgically removed are severely immunodeficient and fail to thrive. Adults have developed enough mature T cells that removal of the thymus or reduction in its function has milder effects. Do not confuse the thymus with the thyroid gland, which is located in the cervical region near the larynx and has an entirely different function.

Lymph Nodes Lymph nodes are small, encapsulated, bean-shaped organs stationed, usually in clusters, along lymphatic channels and large blood vessels of the thoracic and abdominal cavities (see figure 14.8). Major aggregations of nodes occur in the loose connective tissue of the armpit (axillary nodes), groin (inguinal nodes), and neck (cervical nodes). Both the location and the architecture of these nodes clearly specialize them for filtering out materials that have entered the lymph and providing appropriate cells and niches for immune reactions.

Spleen The spleen is a lymphoid organ in the upper portion of the abdominal cavity nestled below the diaphragm and left of the

stomach. It is somewhat similar to a lymph node except that it serves as a filter for blood instead of lymph. While the spleen's primary function is to remove worn-out red blood cells from circulation, its most important immunologic function centers on the filtering of pathogens from the blood and their subsequent phagocytosis by resident macrophages. Adults whose spleens have been surgically removed can live a relatively normal life, but children who have failed to develop or lost their spleen are severely immunocompromised.

Associated Lymphoid Tissue Embedded throughout systems lined with mucous membranes are discrete bundles of lymphocytes and other white blood cells termed the **mucosal-associated lymphoid tissue** or **MALT**. The positioning of this widespread system provides a local, rapid mechanism for responding to the constant influx of microbes entering via the gastrointestinal, respiratory, urinary, and other portals of entry. The pharynx houses a prominent source of MALT in the form of tonsils. The breasts of pregnant and lactating women also become temporary sites of lymphoid tissues that add protective antibodies to breast milk (see colostrum, described in Clinical Connections, “The Immunological Benefits of Breast-Feeding,” in chapter 15).

The intestinal tract houses the best-developed collection of lymphoid tissue, called **gut-associated lymphoid tissue**, or **GALT**. Examples of GALT include the appendix, and **Peyer's patches**, compact aggregations of lymphocytes in the ileum of the small intestine. GALT provides immune functions against intestinal pathogens and is a significant source of some types of antibodies. Other, less well organized collections of secondary lymphoid tissue include *skin-associated lymphoid tissue* and *bronchial-associated lymphoid tissue*.

- Outline the functions of the lymphatic system and describe the actions of associated lymphatic tissues such as MALT and GALT.

14.3 Second-Line Defenses: Inflammation

Expected Learning Outcomes

- Describe the main events in the inflammatory reaction, and explain what is occurring in each.
- Summarize the functions of cytokines, chemokines, and other inflammatory mediators.
- Describe the mechanism behind fever, and explain its beneficial and harmful effects.

Now that we have introduced the principal anatomical and physiological framework of the immune system, we address some mechanisms that play important roles in host defenses: (1) inflammation, (2) phagocytosis, (3) interferon, and (4) complement. Because of the generalized nature of these defenses, they are primarily nonspecific in their effects, but they also support and interact with the specific immune responses described in chapter 15.

The Inflammatory Response: A Complex Concert of Reactions to Injury

At its most general level, **inflammation** is a reaction to any traumatic event in the tissues that attempts to restore homeostasis: It is a normal and necessary process that helps to clear away invading microbes and cellular debris left by immune reactions. Most people manifest inflammation in some way every day. It appears in the flare of a cut, the blistering of a burn, the painful lesion of an infection, and the symptoms of allergy, and at times it can even go unnoticed.

Inflammation is readily identifiable by a classic series of signs and symptoms characterized succinctly by four Latin terms: *rubor*, *calor*, *tumor*, and *dolor*. *Rubor* (redness) is caused by increased circulation and vasodilation in the injured tissues; *calor* (warmth) is the heat given off by the increased flow of blood; *tumor* (swelling) is caused by increased extracellular fluid accumulating in the tissues; and *dolor* (pain) is caused by the stimulation of nerve endings from the pressure of swelling or by chemical mediators (**figure 14.12**). A fifth symptom, *loss of function*, is sometimes added for a complete picture of effects that can accompany inflammation. Although these manifestations are often unpleasant, they serve an important warning that injury has taken place and will set in motion responses that can save the body from further injury.

Factors that can elicit an inflammatory response include trauma from infection (the primary emphasis here), tissue injury or death, and specific immune reactions. Although the details of

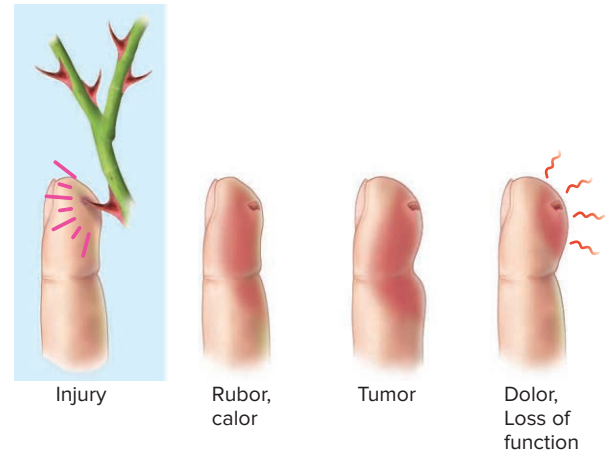

Figure 14.12 The response to injury. This classic series summarizes the reactions of the tissues to an assault. Each of the events is an indicator of one of the mechanisms of inflammation described in this section.

inflammation are very complex, its chief functions can be summarized as follows:

- to mobilize and attract immune cells and chemicals to the site of the injury,
- to set in motion mechanisms to repair tissue damage and localize and clear away harmful substances, and
- to destroy and block microbes from further invasion (see figure 14.13).

The inflammatory response is a powerful defensive reaction, a means for the body to maintain stability and restore itself after an injury. But when it is chronic, it has the potential to actually *cause* tissue injury, destruction, and disease (see Clinical Connections, “The Downside of Inflammation”).

The Stages of Inflammation

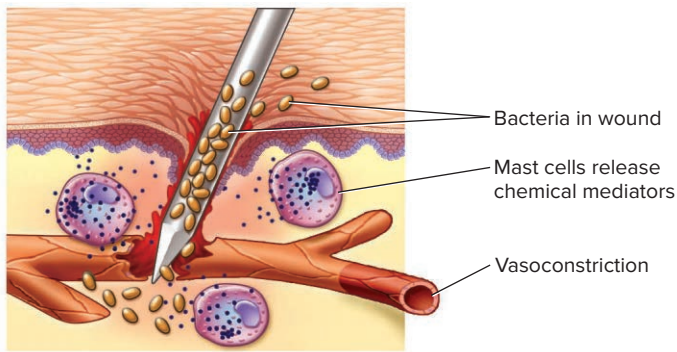

The inflammatory response is a dynamic sequence of events that can be acute (lasting from a few minutes or hours) to chronic (lasting for days, weeks, or years). Once the initial injury has occurred, a chain reaction takes place at the site of damaged tissue, summoning beneficial cells and fluids into the injured area. To envision this process in action, we start with an injury and observe the flow of major events at the microscopic level (**figure 14.13**).

Vascular Changes: Early Inflammatory Events

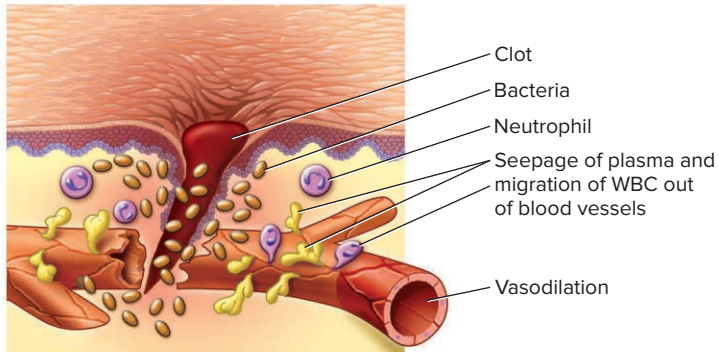

Following an injury, some of the earliest changes occur in the vasculature (arterioles, capillaries, venules) in the vicinity of the damaged tissue. These changes are controlled by nervous stimulation, **chemical mediators**, and **cytokines*** released by blood cells, tissue cells, and platelets in the injured area. Some mediators are *vasoactive*; that is, they affect the endothelial cells and smooth muscle cells of blood

* *cytokine* (sy'-toh-kyne) Gr. *cytos*, cell, and *kemein*, to move. A protein or polypeptide produced by WBCs that regulates host defenses.

(a) **Injury/Immediate Reactions:** Blood vessels narrow (vasoconstriction); blood clots; and mast cells release chemokines and cytokines into injured area.

(b) **Vascular Reactions:** Nearby blood vessels dilate; increased blood flow; increased vascular permeability; increased leakage of fluid forms exudate.

(c) **Edema and Pus Formation:** Collection of fluid; edema/swelling; infiltration by neutrophils and formation of pus.

(d) **Resolution/Scar Formation:** Macrophages, lymphocytes, and fibroblasts migrate in; initiate immune response and repair of injury; scar and loss of normal tissue.

Rubor/calor of inflammation
 Edema (tumor) and dolor
 Repaired or damaged tissue

Process Figure 14.13 The major events in inflammation.

vessels. Others are **chemotactic factors**, also called **chemokines**, that affect white blood cells. Inflammatory mediators cause fever, stimulate lymphocytes, prevent infection spread, and cause allergic symptoms (**figure 14.14** and **14.1 Making Connections**). Although the constriction of arterioles is stimulated first, it lasts for only a few seconds or minutes. Once a clot has formed to prevent blood loss, it is followed in quick succession by the opposite reaction, **vasodilation**. The overall effect of vasodilation is to increase the flow of blood into the area, which facilitates the influx of immune components and also causes redness and warmth (rubor and calor).

An Early Chemical Indicator of Inflammation

C-reactive protein* (CRP) is a pattern recognition receptor that is an early indicator of inflammation. It is a large protein synthesized by the liver that circulates in the blood. CRP is released in response to cytokines produced by macrophages during infections and other pathologic conditions. It attaches to PAMPs and other receptors on dead or injured body cells and infectious agents, an action that increases phagocytosis and promotes the complement system (see next section). In this way it serves as another source of localized, immediate, innate protection. Because it can be detected within the first few hours of the onset of inflammation, it is an effective marker for inflammation and can be measured with blood tests. Elevated levels of CRP can also be found in cardiovascular disease, cancer, tissue injury, and necrosis, and are often used to diagnose risks for these conditions.

Postcapillary venules, small veins that drain blood from the capillary beds, are important in several aspects of inflammation. When they constrict, this causes a slowing of circulation and a pooling of extracellular fluid at the site. Some vasoactive substances cause the endothelial cells in the walls of these venules to separate and form gaps through which blood-borne components exude into the extracellular spaces. Capillaries also become leaky under the influence of cytokines. The plasma that escapes from small vessels into the tissues is called the *exudate*. Accumulation of this fluid gives rise to local swelling and hardness known as **edema**. The edematous exudate contains varying amounts of plasma proteins, such as globulins, albumin, the clotting protein fibrinogen, blood cells, and cellular debris. Depending upon its content, the exudate may be clear (called *serous*), or it may contain red blood cells or **pus**. Pus is composed mainly of white blood cells, microbes, and the debris generated by phagocytosis. In some types of edema, the fibrinogen is converted to fibrin threads that enmesh the injury site (see figure 14.13c). Within an hour multitudes of neutrophils, responding chemotactically to special signaling molecules, converge on the injured site.

Unique Dynamic Characteristics of White Blood Cells In order for WBCs to leave the blood vessels and enter the tissues, they adhere to the inner walls of the smaller blood vessels such as capillaries and venules. From this position, they are poised to migrate out of the blood into the tissue spaces by a process called **diapedesis**.*

Diapedesis, also known as transmigration, is aided by several related characteristics of WBCs. For example, they are actively motile and readily change shape. Their migration is assisted by the nature of the endothelial cells lining venules. Venues contain

* Not to be confused with the complement system.

* *diapedesis* (dye"-ah-puh-dee'-sis) Gr. *dia*, through, and *pedan*, to leap.

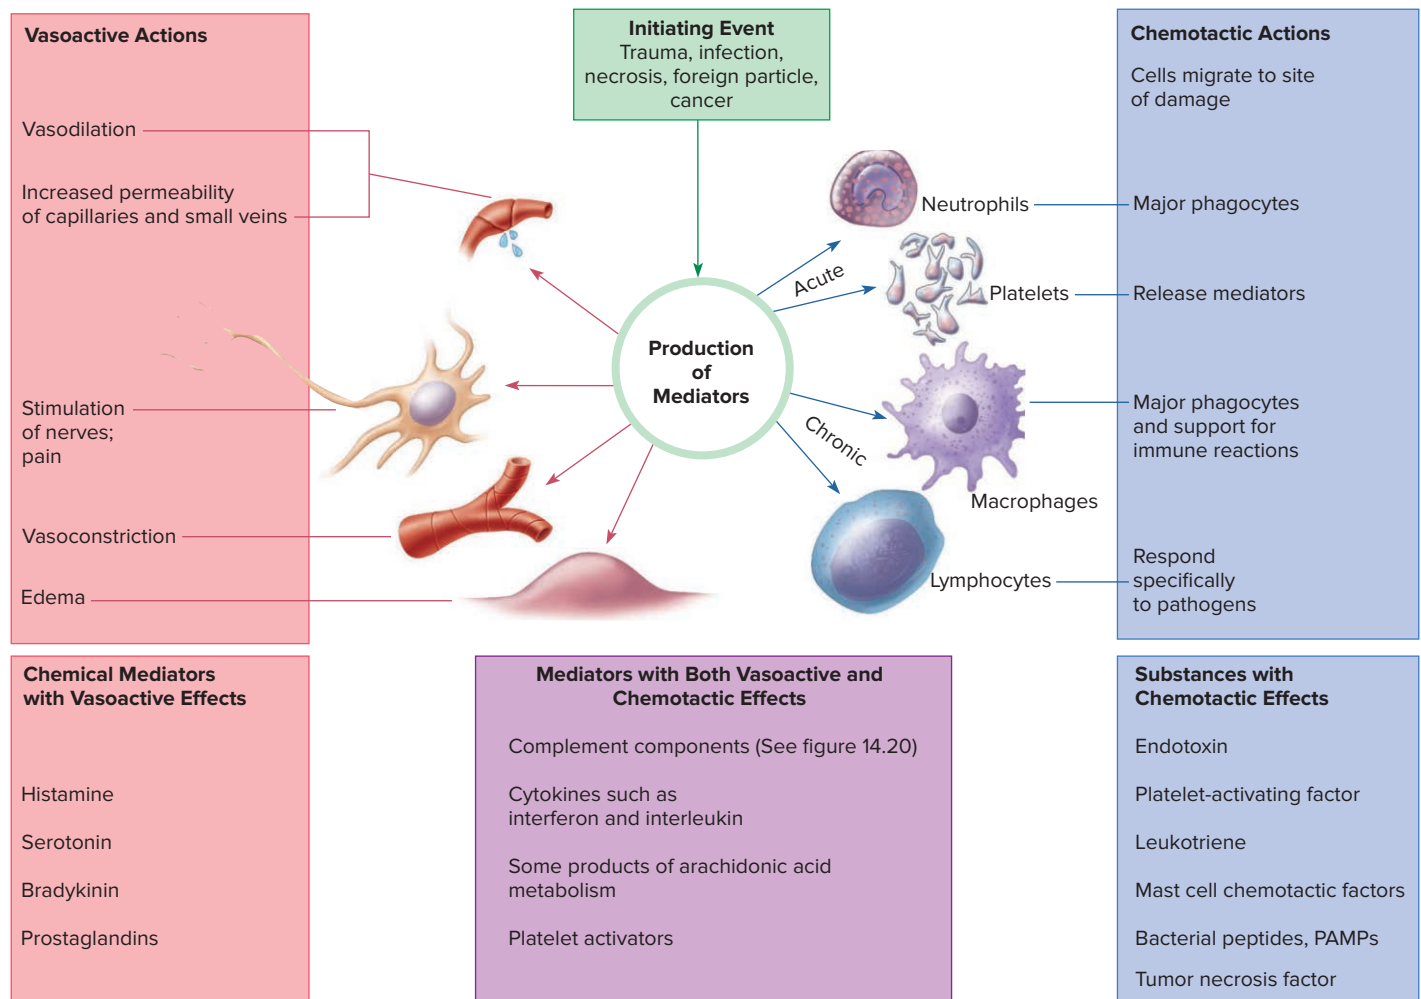

Figure 14.14 Major chemical mediators of the inflammatory response and their effects. See 14.1 Making Connections for more information on the effects of mediators.

complex adhesive receptors that develop increased “stickiness” under the influence of inflammatory mediators. This causes WBCs to adhere or marginate at the endothelial cells. From this location, they can readily crawl into the extracellular spaces (**figure 14.15**).

Another factor in the migratory habits of these WBCs is **chemotaxis**,* defined as the tendency of cells to migrate in response to a specific chemical stimulus released at a site of injury or infection. Through this means, cells swarm from many compartments to the site of infection and remain there to perform general functions such as phagocytosis, repair, and specific immune reactions. These basic properties are absolutely essential for the sort of intercommunication and deployment of cells required for most immune reactions.

The Benefits of Edema and Chemotaxis Both the formation of edematous exudate and the infiltration of neutrophils are physiologically beneficial activities. The influx of fluid dilutes toxic substances, and the fibrin clot can effectively trap microbes and prevent their further spread. The neutrophils that aggregate in the inflamed site are immediately involved in phagocytosing and destroying microbes, dead tissues, and particulate matter (by mecha-

nisms discussed in section 14.4 on phagocytosis). In some types of inflammation, accumulated phagocytes contribute to pus. Certain bacteria (streptococci, staphylococci, gonococci, and meningococci) are especially powerful attractants for neutrophils and are thus termed **pyogenic**, or pus-forming, bacteria.

Late Reactions of Inflammation Sometimes a mild inflammation can be resolved by edema and phagocytosis. Inflammatory reactions that last more than a few days attract a collection of monocytes, lymphocytes, and macrophages to the reaction site. Clearance of pus, cellular debris, dead neutrophils, and damaged tissue is performed by macrophages, the only cells that can engulf and dispose of such large masses. At the same time, specific immune reactions of acquired immunity are brought into play. B lymphocytes react with foreign molecules and cells by producing specific antimicrobial proteins (antibodies), and T lymphocytes kill intruders directly. Late in the process, the tissue undergoes various levels of repair and may be replaced by connective tissue in the form of a scar (see **figure 14.13d**). If the inflammation cannot be relieved or resolved in this way, it can become chronic and create long-term pathologic conditions discussed in **Clinical Connections**, “The Downside of Inflammation.”

* *chemotaxis* (kee-moh-tak'-sis) NL. *chemo*, chemical, and *taxis*, arrangement.

14.1 MAKING CONNECTIONS

The Dynamics of Inflammatory Mediators

Just as the nervous system is coordinated by a complex communications network, so too is the immune system. Hundreds of small, active molecules are constantly being secreted to regulate, stimulate, suppress, and otherwise control the many aspects of cell development, inflammation, and immunity. These substances are the products of several types of cells, including monocytes, macrophages, lymphocytes, fibroblasts, mast cells, platelets, and endothelial cells of blood vessels. Their effects may be local or systemic, short term or long lasting, nonspecific or specific, protective or pathologic.

The field of cytokines has become so increasingly complex that we can include here only an overview of the major groups of important cytokines and other mediators. The major functional types can be categorized into

1. cytokines that mediate nonspecific immune reactions such as inflammation and phagocytosis,
2. cytokines that regulate the growth and activation of lymphocytes,
3. cytokines that activate immune reactions during inflammation,
4. hematopoiesis factors for white blood cells,
5. vasoactive mediators, and
6. miscellaneous inflammatory mediators.

Nonspecific Mediators of Inflammation and Immunity

- *Tumor necrosis factor (TNF)*, a substance from macrophages, lymphocytes, and other cells. It increases chemotaxis and phagocytosis and stimulates other cells to secrete inflammatory cytokines. It also triggers fever (is an endogenous pyrogen) and stimulates blood coagulation. Unfortunately it has the potential to cause damage to tissues when produced in excess.
- *Interferon alpha and interferon beta*, produced by leukocytes and fibroblasts, inhibit virus replication and cell division and increase the action of certain lymphocytes that kill other cells.
- *Interleukin* is a term that refers to a group of small peptides originally isolated from leukocytes. There are currently more than 50 known interleukins. We now know that other cells besides leukocytes can synthesize them and that they have a variety of biological activities.
 - *Interleukin-1 (IL-1)*, a product of macrophages and epithelial cells. It has many of the same biological activities as TNF, such as inducing fever and activating certain white blood cells.
 - *Interleukin-6*, secreted by macrophages, lymphocytes, and fibroblasts. Its primary effects are to stimulate the growth of B cells and to increase the synthesis of liver proteins such as C-reactive protein.
