- *Various chemokines*. By definition, chemokines are cytokines that stimulate the movement and migration of white blood cells (chemotactic factors). Included among these are complement C5_a, interleukin-8, and platelet-activating factor.

Cytokines That Regulate Lymphocyte Growth and Activation

- *Interleukin-2*, the primary growth factor from T cells. Interestingly, it acts on the same cells that secrete it. It stimulates cell division and secretion of other cytokines. In B cells, it is a growth factor and stimulus for antibody synthesis.
- *Interleukin-4*, a stimulus for the development of B cells and production of antibodies that mediate allergies. It inhibits macrophage actions.
- *Granulocyte colony-stimulating factor (G-CSF)*, produced by T cells, macrophages, and neutrophils. It stimulates the activation and differentiation of neutrophils.
- *Macrophage colony-stimulating factor (M-CSF)*, produced by a variety of cells. M-CSF promotes the growth and development of stem cells that differentiate into macrophages.
- *Interferon gamma*, a T-cell-derived mediator whose primary function is to activate macrophages. It also promotes the differentiation of T and B cells, activates neutrophils, and stimulates diapedesis.

Vasoactive Mediators

- *Histamine*, a vasoactive mediator produced by mast cells and basophils. It causes vasodilation, increased vascular permeability, and mucus production. It functions primarily in inflammation and allergy.
- *Serotonin*, a mediator produced by platelets and intestinal cells. It causes smooth muscle contraction, inhibits gastric secretion, and acts as a neurotransmitter.
- *Bradykinin*, a vasoactive amine from the blood or tissues. It stimulates smooth muscle contraction and increases vascular permeability, mucus production, and pain. It is particularly active in allergic reactions.

Miscellaneous Inflammatory Mediators

- *Prostaglandins*, produced by most body cells, are complex chemical mediators that can have opposing effects (for example, dilation or constriction of blood vessels) and are powerful stimulants of inflammation and pain.
- *Leukotrienes* stimulate the contraction of smooth muscle and enhance vascular permeability. They are implicated in the more severe manifestations of immediate allergies (constriction of airways).
- *Platelet-activating factor*, a substance released from basophils, causes the aggregation of platelets and the release of other chemical mediators during immediate allergic reactions.

Which inflammatory mediators would be involved in rubor? in tumor? in dolor? in calor? *Answers available on Connect.*

Fever: An Adjunct to Inflammation

An important systemic component of inflammation is fever, defined as an abnormally elevated body temperature. Although fever is a nearly universal symptom of infection, it is also associated with certain allergies, cancers, and other organic illnesses. Fevers whose causes are undiagnosed are called fevers of unknown origin, or FUOs.

The body temperature is normally maintained by a control center in the hypothalamus region of the brain. This thermostat regulates the body's heat production and heat loss and sets the core temperature at around 37°C (98.6°F), with slight fluctuations (1°F) during a daily cycle. Fever is initiated when a circulating substance

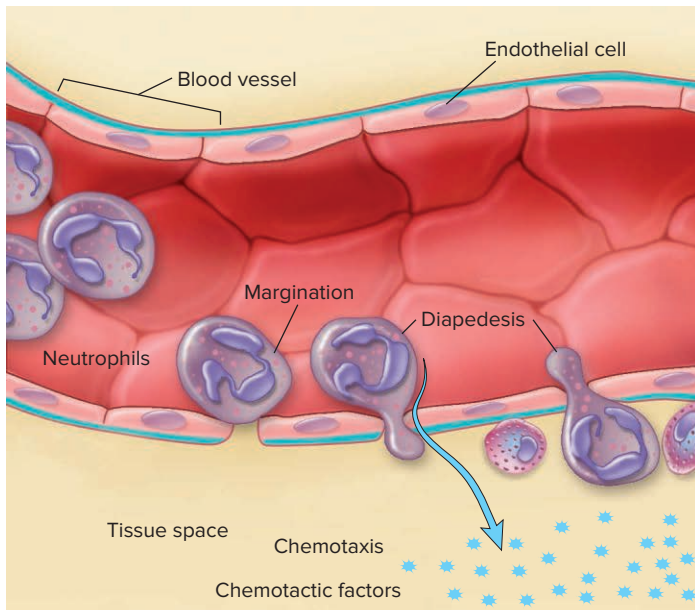

Figure 14.15 Diapedesis and chemotaxis of leukocytes.

Cross section of a venule depicts white blood cells squeezing themselves between spaces in the vessel wall through diapedesis. This process also indicates how the pool of leukocytes adheres to receptors in the endothelial wall. From this site, they are poised to migrate out of the vessel into the tissue space and respond to chemotactic factors released as part of the generalized inflammatory process.

called **pyrogen*** resets the hypothalamic thermostat to a higher setting. This change signals the musculature to increase heat production and peripheral arterioles to decrease heat loss through vasoconstriction. Fevers range in severity from low-grade (37.7°C to 38.3°C, or 100°F to 101°F) to moderate (38.8°C to 39.4°C, or 102°F to 103°F) to high (40.0°C to 41.1°C, or 104°F to 106°F).

Pyrogens are described as *exogenous* (coming from outside the body) or *endogenous* (originating internally). Exogenous pyrogens are products of infectious agents such as viruses, bacteria, protozoans, and fungi. One well-characterized exogenous pyrogen is endotoxin, the lipopolysaccharide found in the cell walls of gram-negative bacteria. Blood, blood products, vaccines, or injectable solutions can also contain exogenous pyrogens. Endogenous pyrogens are liberated by monocytes, neutrophils, and macrophages during the process of phagocytosis and appear to be a natural part of the immune response. Two potent pyrogens released by macrophages are interleukin-1 (IL-1) and tumor necrosis factor (TNF).

Fever is usually accompanied by chills. What would cause a febrile (feverish) person to periodically feel cold and tremble uncontrollably? The explanation lies in how the brain reacts to pyrogen and the natural physiological interaction between the hypothalamus and the temperature of the blood. For example, if the thermostat has been reset (by pyrogen) at 102°F but the blood temperature is 99°F, the muscles are stimulated by the brain to contract involuntarily (shivering) as a means of producing more heat. In addition, the vessels in the skin constrict, creating a sensation of cold, and the piloerector muscles in the skin cause goose bumps to form.

* **pyrogen** (py'-roh-jen) Gr. *pyr*, fire, and *gennan*, produce. Same origin as *funeral pyre* and *pyromaniac*.

CLINICAL CONNECTIONS

The Downside of Inflammation

Not every aspect of inflammation is protective or results in the proficient resolution of tissue damage. As one looks over a list of diseases, it is rather striking how many of them are due in part or even completely to an overreactive or dysfunctional inflammatory response.

Some *-itis* reactions mentioned in chapter 13 are a case in point. Inflammatory exudates that build up in the brain in African trypanosomiasis, cryptococcosis, and other brain infections can be so injurious to the nervous system that impairment is permanent. Inflammatory reactions frequently lead to abscess, a swollen mass of neutrophils and dead, liquefied tissue that can harbor live pathogens in the center. Abscesses are a prominent feature of staphylococcal, amebic, and enteric infections.

Other pathologic manifestations of chronic diseases—for example, the tubercles of tuberculosis, the lesions of late syphilis, the disfiguring nodules of leprosy, and the cutaneous ulcers of leishmaniasis—are due to an aberrant tissue response called *granuloma formation* (see Case Study figure). Granulomas develop in response not only to microbes but also to inanimate foreign bodies that are difficult to break down. This condition is initiated when neutrophils and macrophages ineffectively and incompletely phagocytose the pathogens or materials involved in an inflammatory reaction. This failure to manage the debris of inflammation is sometimes referred to as “frustrated phagocytosis.” Macrophages respond by storing ingested materials in vacuoles and becoming inactive. Over a given time period, macrophages fuse into giant, inactive multinucleate cells called foreign body giant cells. These sites are further infiltrated with lymphocytes. The resultant collections make the tissue appear granular—hence the name. A granuloma can exist in the tissue for months, years, or even a lifetime. This chapter’s Case Study provides a striking example of massive proliferation of failed phagocytes.

One common cytokine, tumor necrosis factor (TNF), is a potent inflammatory mediator. It regulates a wide variety of early immune activities such as phagocytosis, and it is a powerful **pyrogen**. Unfortunately the overproduction of TNF is also involved in a number of diseases, such as septic shock, psoriasis, asthma, and autoimmunity. Several drugs (adalimumab [Humira] and etanercept [Enbrel], for example) have been developed as therapy to counteract the damaging effects of TNF.

Medical science is rapidly searching for additional applications based on new information about inflammatory mediators. One highly promising area appears to be the use of chemokine inhibitors that could reduce chemotaxis and the massive, destructive influx of leukocytes. Such therapy could ultimately be used to treat certain cancers, hardening of arteries, and Alzheimer disease.

Explain how inflammatory mediators stimulate tissue injury and disease. Answer available on Connect.

Benefits and Treatment of Fever Medical experts have abundant evidence that fever serves an important biological function. Work with tissue cultures showed that increased temperatures stimulate the activities of T cells and increase the effectiveness of interferon. Artificially infected rabbits and pigs allowed to remain febrile survive at a higher rate than those given suppressant drugs. Fever appears to enhance phagocytosis of staphylococci by neutrophils in many mammalian species. The appearance of fever during infections strongly suggests that it is normal and beneficial reaction to invading microbes. Some other effects of fever include:

- It inhibits multiplication of temperature-sensitive microorganisms, such as the poliovirus, cold viruses, herpes zoster virus, systemic and subcutaneous fungal pathogens, *Mycobacterium* species, and the syphilis spirochete.
- It impedes the nutrition of bacteria by reducing the availability of iron. Research has demonstrated that during fever, the macrophages stop releasing their iron stores, which could retard several enzymatic reactions needed for pathogen growth.
- It increases metabolism and stimulates immune reactions and naturally protective physiological processes. It speeds up hematopoiesis, phagocytosis, and specific immune reactions.

Understanding that fever is possibly more beneficial than harmful, deciding whether to suppress it is an important medical question. Some advocates feel that a slight to moderate fever (99–101°F) in an otherwise healthy person should be allowed to run its course in light of its potential as an immune stimulant and its minimal side effects. All medical experts do agree that high and prolonged fevers or fevers in children or patients with cardiovascular disease, seizures, and respiratory ailments are risky and must be treated immediately with fever-suppressant drugs. The classic therapy for fever is an antipyretic drug such as aspirin or acetaminophen (Tylenol) that lowers the setting of the hypothalamic center and restores normal temperature. Any physical technique that increases heat loss (tepid baths, for example) can also help reduce the core temperature.

19. What causes pus, and what does it indicate?
20. In what ways can edema be beneficial and in what ways is it harmful?
21. Describe the physiological events leading to fever and review the ways in which fever is naturally beneficial.
22. Explain the processes of diapedesis and chemotaxis, and show how they interrelate.
23. Briefly account for the origins and actions of the major types of inflammatory mediators and cytokines.

14.4 Second-Line Defenses: Phagocytosis, Interferon, and Complement

Expected Learning Outcomes

15. Define *phagocytosis* and identify which cells serve this function.
16. Indicate the major stages of phagocytosis, and describe what is happening at each stage.
17. Explain how phagocytes kill pathogens.
18. Describe the origin of interferon, and explain its role in controlling viruses and other immune functions.
19. Characterize the complement system, its origins, and its basic functions.

Phagocytosis: Ingestion and Destruction by White Blood Cells

By any standard, a phagocyte represents an impressive piece of living machinery, meandering through the tissues to seek, capture, and destroy a target. The following is a summary of the major activities of phagocytes:

1. to survey the tissue compartments and target microbes, particulate matter (dust, carbon particles, antigen-antibody complexes), and injured or dead cells;
2. to ingest and eliminate these materials; and
3. to extract immunogenic information (antigens) from foreign matter.

Major Categories of Phagocytes

It is generally accepted that all cells have some capacity to engulf materials, but professional phagocytes do it for a living. The main types of phagocytes are neutrophils, monocytes, macrophages, and dendritic cells.

Neutrophils and Eosinophils As previously stated, neutrophils are general-purpose phagocytes that react early in the inflammatory response to bacteria and other foreign materials and to damaged tissue. A common sign of bacterial infection is a high neutrophil count in the blood (neutrophilia), and neutrophils are also a primary component of pus. Eosinophils are attracted to sites of parasitic infections and antigen-antibody reactions, though they play only a minor phagocytic role.

Extended Functions of Neutrophils Neutrophils are truly one of the “workhorses” of innate immunity. In addition to their phagocytic functions, they also have a distinct system for capturing pathogens called *neutrophil extracellular traps*, or NETS. Neutrophils are programmed to die after they have gone through their regular engulfment and killing of bacteria and other pathogens. But their death does not end their protective actions. Dying neutrophils throw out a fibrous matrix composed of DNA, enzymes, histones, and other cell contents that continue to stop invading microbes even after the neutrophils are completely lysed. The NET works at

several levels to trap and immobilize bacteria and fungi, degrade their virulence factors, kill them with microbicidal chemicals, and ultimately, prevent them from spreading.

Macrophages: Dynamic Scavengers After emigrating out of the bloodstream into the tissues, monocytes are transformed by various inflammatory mediators into macrophages. This process is marked by an increase in size and by enhanced development of lysosomes and other organelles (**figure 14.16**). At one time macrophages were classified as either fixed (adherent to tissue) or wandering, but this terminology can be misleading. All macrophages retain the capacity to move about. Whether they reside in a specific organ or wander depends upon their stage of development and the immune stimuli they receive. Specialized macrophages called *histiocytes* migrate to a certain tissue and remain there during their life span. Examples are alveolar (lung) macrophages; Kupffer cells in the liver; Langerhans cells in the skin; and macrophages in the spleen, lymph nodes, bone marrow, kidney, bone, and brain. Other macrophages do not reside permanently in a particular tissue but instead drift nomadically throughout the reticuloendothelial system. Dendritic cells—another product of the monocyte line—are concentrated in skin and the linings of mucous membranes, where they process foreign substances and prepare them for reactions with selected lymphocytes (see chapter 15).

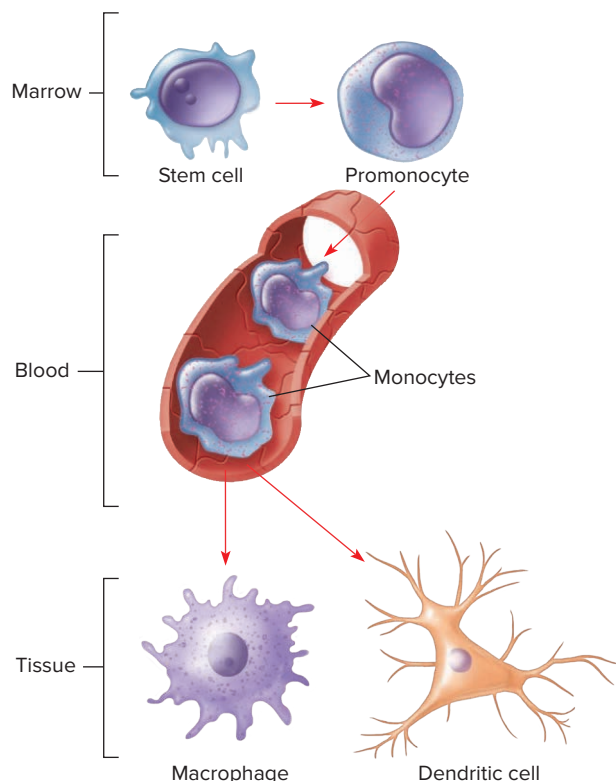

Figure 14.16 The developmental stages of monocytes and macrophages. The cells progress through maturational stages in the bone marrow and peripheral blood. Once in the tissues, macrophage and dendritic cells can remain nomadic or take up residence in a specific organ.

Mechanisms of Phagocytic Recognition, Engulfment, and Killing

The term **phagocytosis** literally means “eating cell process.” But phagocytosis is more than just the physical act of engulfment, because phagocytes also actively attack and dismantle foreign cells using a wide array of antimicrobial substances. Phagocytosis can occur as an isolated event performed by a lone phagocytic cell responding to a minor irritant in its area or as part of the orchestrated events of inflammation described in section 14.3. The events in phagocytosis include chemotaxis, ingestion, phagolysosome formation, destruction, and elimination (**figure 14.17**).

Chemotaxis, Binding, and Ingestion Phagocytes migrate into a region of inflammation with a deliberate sense of direction, attracted by a gradient of stimulant products from the pathogen and host tissue at the site of injury.

Once a phagocyte encounters the pathogen, it uses its toll-like receptors (TLRs, discussed in section 14.2) to make contact with the pathogen (**figure 14.17**). Recall that TLRs are receptors that recognize and bind the pathogen-associated molecular pattern (PAMP) receptors of various microbes. There are about 10 different TLRs in the membranes of phagocytes. The exposed end of a receptor hooks on to a PAMP and immediately dimerizes or joins with a second TLR to encase the molecule (**figure 14.18**). This relays a signal into the nucleus that stimulates the intracellular phagocytic processes and the release of chemical mediators.

Phagolysosome Formation On the scene of an inflammatory reaction, phagocytes often trap cells or debris against the fibrous network of connective tissue or the wall of blood and lymphatic vessels. Once the phagocyte has “caught” its prey, it extends pseudopods that enclose the cells or particles in a pocket and internalize them in a vacuole called a **phagosome**.

In a short time, **lysosomes** migrate to the scene of the phagosome and fuse with it to form a **phagolysosome**. Other granules containing antimicrobial chemicals are released into the phagolysosome, forming a potent brew designed to poison and then dismantle the ingested material (see **figure 14.17**). The destructiveness of phagocytosis is evident by the death of bacteria within 30 minutes after contacting this battery of antimicrobial substances.

Destruction and Elimination Systems Destructive chemicals await the microbes in the phagolysosome. The oxygen-dependent system known as the **respiratory burst**, or oxidative burst, elaborates products of oxygen metabolism called **reactive oxygen intermediates (ROIs)**. Myeloperoxidase, an enzyme found in granulocytes, forms halogen ions (OCl^-) that are strong oxidizing agents. Other products of oxygen metabolism such as hydrogen peroxide, the superoxide anion (O_2^-), activated or singlet oxygen ($^1\text{O}^-$), and the hydroxyl free radical (HO) separately and together have formidable killing power. This series of reactive oxygen products delivers a “knockout” punch necessary to kill aerobic pathogens such as fungi and many bacteria (see this chapter’s

Process Figure 14.17 The sequential events in phagocytosis.

Case Study). Other chemicals that come into play are lactic acid, lysozyme, and *nitric oxide* (NO), a powerful mediator that kills bacteria and inhibits viral replication. Cationic proteins that injure bacterial cell membranes and a number of **hydrolytic** enzymes complete the job. The bits of undigestible debris are released from the macrophage by exocytosis. As we shall see in chapter 15, macrophages and dendritic cells combine phagocytosis with further processing of microbial antigens required for specific immune responses with lymphocytes.

Interferon: Antiviral Cytokines and Immune Stimulants

Interferon (IFN) was described in chapter 12 as a small protein produced naturally by certain white blood and tissue cells. It is used in therapy against certain viral infections and cancer and can be used as an immune enhancer, as we saw in this chapter's Case Study. Although the interferon system was originally thought to be directed exclusively against viruses, it is now known to be involved also in defenses against other microbes and in immune regulation and intercommunication. Three major types are *interferon alpha*, a product of

lymphocytes and macrophages; *interferon beta*, a product of fibroblasts and epithelial cells; and *interferon gamma*, a product of T cells. See 14.1 Making Connections for a summary of interferon actions.

All three classes of interferon are produced in response to viruses, RNA, immune products, and a variety of foreign molecules. Their biological activities are extensive. In all cases, they bind to cell surfaces and induce changes in genetic expression, but the exact results vary. In addition to antiviral effects, discussed next, all three IFNs can inhibit the expression of cancer genes and have tumor suppressor effects. Interferon alpha and IFN beta stimulate phagocytes, and IFN gamma is an immune regulator of macrophages and T and B cells.

Characteristics of Antiviral Interferon

When a virus binds to the receptors on a host cell, a signal is sent to the nucleus that directs the cell to synthesize interferon. After transcription and translation of the interferon gene, newly synthesized interferon molecules are rapidly secreted by the cell into the extracellular space, where they bind to other host cells. The binding of interferon to a second cell induces the production of another class of

Figure 14.18 Phagocyte detection and signaling with toll-like receptors. Toll-like receptors (TLRs) span the membrane of phagocytes and other cells of the immune system. When a molecule such as a PAMP on a particular pathogen is recognized by this receptor, the TLRs merge and bind the foreign molecule. This induces production of chemicals and triggers engulfment.

proteins that inhibit viral multiplication by preventing the translation of viral proteins (**figure 14.19**). Interferon is not virus-specific, so its synthesis in response to one type of virus will also protect against other types. Because this protein is an inhibitor of viruses, it has been a valuable treatment for a number of viral infections.

Other Roles of Interferon

Interferons are also important immune regulatory cytokines that activate or instruct the development of white blood cells. For example, interferon alpha produced by T lymphocytes activates a

Figure 14.19 The antiviral activity of interferon. When a cell is infected by a virus, its nucleus is triggered to transcribe and translate the interferon (IFN) gene. Interferon diffuses out of the cell and binds to IFN receptors on nearby uninfected cells, where it induces production of proteins that eliminate viral genes and block viral replication. Note that the initial cell is not protected by its own IFN and that IFN does not prevent recipient cells from being invaded by viruses, but the viruses are inactivated before they can start replicating.

subset of cells called natural killer (NK) cells. In addition, one type of interferon beta plays a role in the maturation of B and T lymphocytes and in inflammation. Interferon gamma inhibits cancer cells, stimulates B lymphocytes, activates macrophages, and enhances the effectiveness of phagocytosis.

Complement: A Versatile Backup System

Among its many overlapping functions, the immune system has another complex and multiple-duty system called **complement** that is brought into play at several levels. The complement system, named for its property of “complementing” immune reactions, consists of at least 30 blood proteins released by liver cells, lymphocytes, and monocytes. Complement factors are a form of pattern recognition receptor (PRR) that works in concert with inflammation and phagocytosis to destroy a wide variety of bacteria, viruses, and parasites. This system is generally nonspecific and innate, but it can also play a role in acquired immune responses. The three primary defensive features of the complement system are (1) the **membrane attack complex (MAC)**, which kills pathogens directly, (2) the coating of pathogens with molecules that make them more attractive to phagocytes (**opsonization**), and (3) the recruitment of inflammatory cells and triggering of cytokine release. Having introduced the second and third topics previously, we will focus here on the main mechanisms of the membrane attack complex.

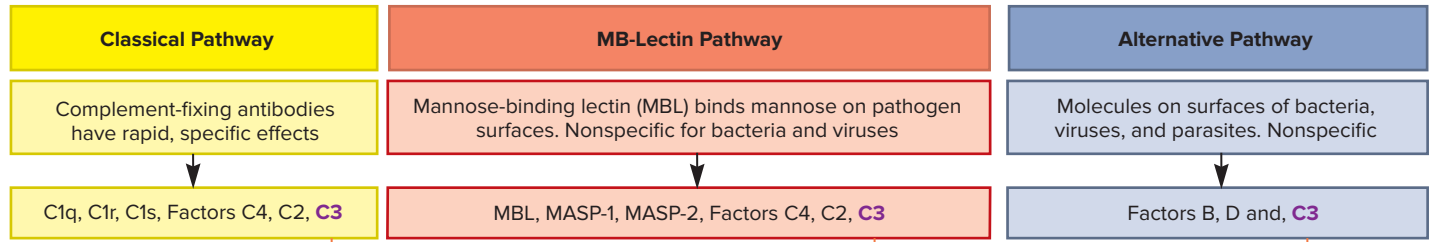

The membrane attack function of complement is a series of reactions like that of blood clotting, in which the first substance in a chemical series activates the next substance, which activates the next, and so on, until a desired end product is reached. Three different versions of the complement pathways exist (**figure 14.20**). Their main distinguishing features are how they are activated, major

participating factors, and specificity. The end stages of all three converge at the same point and yield a similar end result, that is, destruction of a microbe or infected cell. Because the focus of damage is on the cell membrane, this portion of the complement defense is not as effective on microbes whose outer walls block access to the membrane, but is effective on cells and viruses with exposed membranes.

The *classical pathway* is the most specific, activated mainly by the presence of antibody bound to microorganisms. It is this pathway that links complement to reactions of acquired immunity. The other two pathways are nonspecific and triggered by common foreign molecules on the surfaces of microbes. In the *lectin pathway*, a host serum protein or lectin binds a sugar called mannan present in the walls of bacteria and other microbes. The *alternative pathway* is initiated by complement proteins that bind to certain surface molecules of microbes (PAMPs),

(a) Initiation

Process Figure 14.20 Overview of the complement pathways leading to membrane attack. (a) All three pathways have different triggers and starting points, but they all converge at the same place, C3 convertase. This enzyme begins the series of reactions (b,c,d) that give rise to the membrane attack complex characteristic of the complement “machinery.” The final result is the formation of tiny openings in the cell membrane and the destruction of the target pathogen.

although it may also be triggered spontaneously. Note that, because the complement numbers (C1 to C9) are based on the order of their discovery, some factors are not activated in numerical order.

Stages in the Complement Cascade

In general, the complement pathways go through four stages: initiation, amplification and cascade, polymerization, and membrane attack. The starting reaction requires some type of initiator molecule such as antibodies, lectins, or microbial surface receptors (**figure 14.20a**), depending on the pathway. The presence of this initiator on the pathogen's membrane propels the chain of actions involving complement chemicals C1 through C4, with each step serving a dual purpose. We are omitting the fine details of the amplification part of the complement system, but the end result is a molecule, **C3**, that is a key factor in subsequent polymerization of the remaining complement factors in the membrane of the target cell. C3 is acted on by a convertase enzyme that splits it into factors C3_a and C3_b. C3_b forms the recognition site and anchor for the final series of reactions to come (**figure 14.20b**). C3_b by itself is also an important factor in opsonization and thus facilitates phagocytosis. More information on opsonization can be found in chapter 15.

C3_b moves the cascade reaction forward by splitting factor C5 into C5_a and C5_b. One of these molecules—C5_b—is key to finishing up polymerization of the remaining complement factors

described next. You will notice that the two cleavage products that do not continue in the cascade reaction—C3_a and C5_a—still have a number of immune functions (**figure 14.20**—right side of *b*). Both of them are chemotactic factors that recruit white blood cells and trigger the release of inflammatory mediators such as histamine.

The final events in the complement series involve factors C5_b, C6, C7, and C8, which join together and give rise to an anchoring complex within the membrane (**figure 14.20c**). This is followed by the insertion of several **C9** molecules in the pattern of a ring-shaped formation that is the membrane attack complex (MAC) (**figure 14.20d**). The MAC is the primary destructive force of the complement system. It effectively perforates and lyses the membranes of gram-negative bacteria, some parasitic protozoans, enveloped viruses, and virally infected host cells. Except for the classical pathway, these reactions are nonspecific and can be active against a wide spectrum of microbes.

An Outline of Major Host Defenses

At this point, it should be apparent that the body's defenses often work in both parallel and redundant ways to fight pathogens. The result is a constant onslaught of defenses functioning at many levels. This can be illustrated by **figure 14.21**, organized by the three lines of defense that started out our discussion and that lead us naturally into chapter 15.

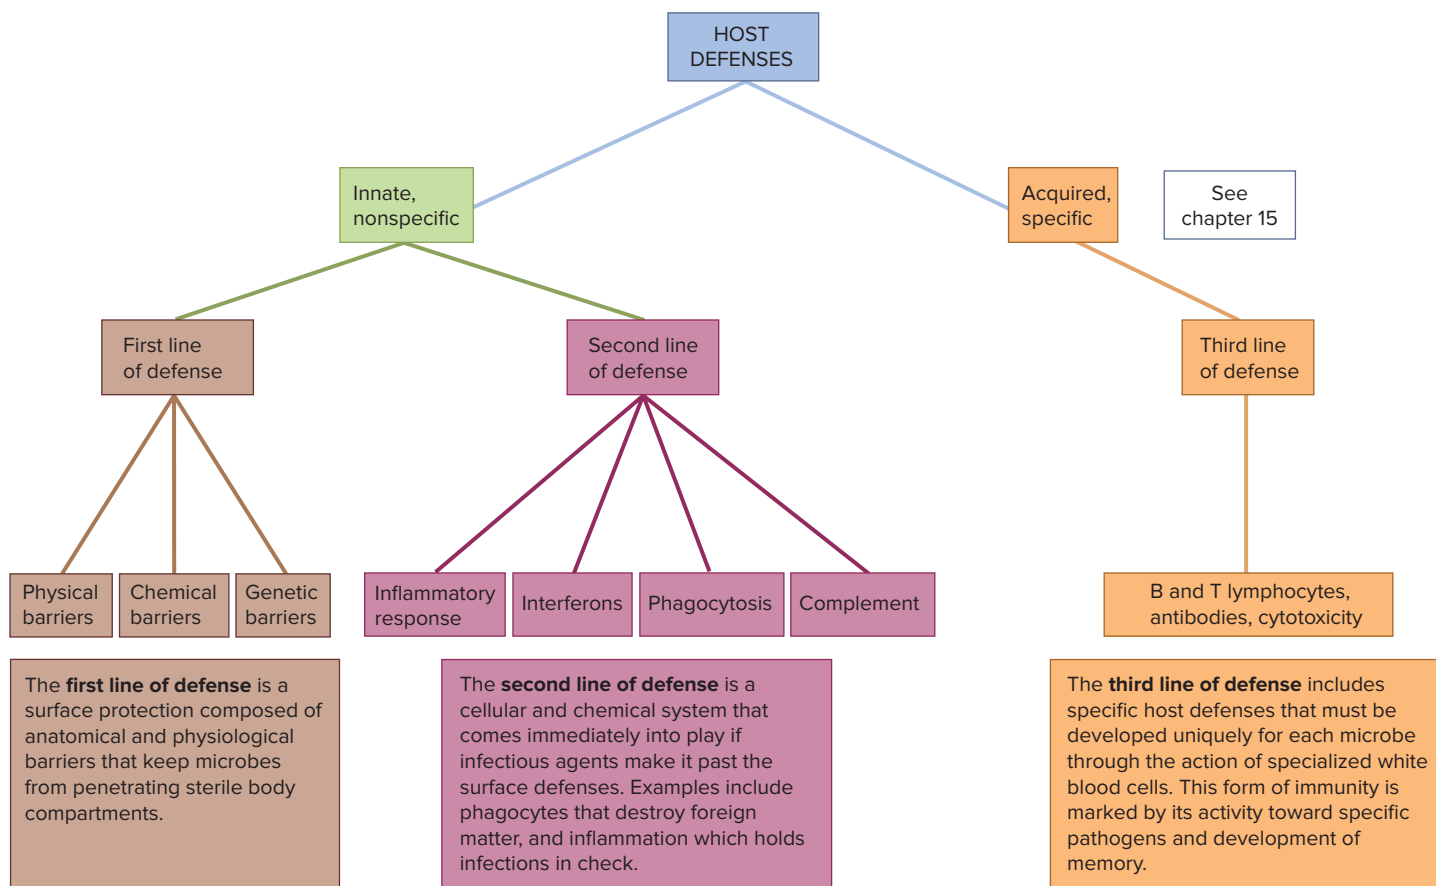

Figure 14.21 Flowchart summarizing the major components of the host defenses. Defenses are classified into one of two general categories: (1) innate and nonspecific or (2) acquired and specific. These can be further subdivided into the first, second, and third lines of defense, each being characterized by a different level and type of protection. The third line of defense, the most varied, is responsible for specific immunity. It is covered in greater detail in chapter 15.

CASE STUDY Part 2

The boy's physicians examined his white blood cells using the nitroblue tetrazolium test, which monitors the effectiveness of phagocyte activity, and the neutrophil cytochrome assay, which can measure activities associated with the metabolism of oxygen. Both tests indicated a low rate of phagocyte responsiveness, which is highly diagnostic of a genetic disease known as chronic granulomatous disease (CGD).

About one in 200,000 children in the United States are diagnosed yearly with chronic granulomatous disease (CGD); of these, around 90% are males. CGD is somewhat complex in its inheritance, but there are essentially two forms. The X-linked type occurs as a defective gene on the X chromosome and is more severe. Over half of all cases are X-linked. The autosomal defect is located on a different chromosome and tends to be milder. In both types, the genetic codes carry errors that prevent phagocytes from producing certain key metabolic enzymes.

The neutrophils and macrophages of CGD patients can carry out the usual phagocytic activities such as amoeboid motion, chemotaxis, engulfment, and digestion of microbes in phagocytic vesicles, but they are unable to actively kill certain types of aerobic pathogens. They lack the enzymes to synthesize

the battery of reactive oxygen intermediates (ROIs)—superoxide ion, hydrogen peroxide, and hydroxyl radical—that are essential to kill these microbes. As a result, the ineffective phagocytes harbor live microbes that can break away and continue their infectious path. In time these phagocytes shut down, die, and build up in the infected tissue in masses (granulomas).

This case is a striking example of how important every element of immunity can be. Although the components do overlap in some of their effects, each one carries out some essential function that cannot be totally duplicated. CGD individuals have a mostly intact immune response, but they lack a complete phagocyte defense that comes into play early in the infection process. Phagocytes (neutrophils, monocytes, and macrophages) are most active against bacteria and eukaryotic pathogens, but they also are important participants in many other immune reactions.

- *What elements of host defenses and immunity would remain intact in a child with CGD?*
- *What is a granuloma, and what factors in CGD cause it?*

To conclude this Case Study, go to Connect.

For additional information on this disease, go to <http://emedicine.medscape.com/article/1116022-print>. Other immune disorders are covered in chapter 16.

Chapter Summary with Key Terms

14.1 Overview of Host Defense Mechanisms

The *first line of defense* is an inborn, nonspecific system composed of anatomical, chemical, and genetic barriers that block microbes at the portal of entry. The *second line of defense* is also inborn and nonspecific and includes protective cells and fluids in tissues, and the *third line of defense* is acquired and specific and is dependent on the function of T and B cells.

14.2 Structure and Function of the Organs of Defense and Immunity

- A. **Immunology** is the study of **immunity**, which refers to the development of resistance to infectious agents by white blood cells (WBCs). WBCs conduct surveillance of the body, recognizing and differentiating **nonsel** (foreign) cells by means of molecules or **pattern recognition receptors (PRRs)** in their membranes. PRRs recognize a number of indicators carried on foreign cells called **pathogen-associated**

molecular patterns (PAMPs). Under normal conditions, **self** cells are left alone but **nonsel** cells are destroyed by the concerted efforts of several types of immune reactions.

- B. For purposes of immunologic study, the body is divided into three compartments: the blood, lymphatics, and the **reticuloendothelial system**. A fourth component, the extracellular fluid, surrounds the first three and allows constant communication between all areas of the body.
- C. **Circulatory System: Blood and Lymphatics**
 1. **Whole blood** consists of **blood cells** (formed by **hematopoiesis** in the bone marrow) dispersed in **plasma**. **Stem cells** in the bone marrow differentiate to produce white blood cells (**leukocytes**), red blood cells (**erythrocytes**), and megakaryocytes, which give rise to **platelets**.

2. Leukocytes are the primary mediators of immune function and can be divided into **granulocytes** (**neutrophils**, **eosinophils**, and **basophils**) and **agranulocytes** (**monocytes** and **lymphocytes**) based on their appearance. Monocytes later differentiate to become **macrophages**. Lymphocytes are divided into **B cells**, which produce **antibodies** as part of **humoral immunity**, and **T cells**, which participate in **cell-mediated immunity**. Leukocytes display both **chemotaxis** and **diapedesis** in response to chemical mediators of the immune system.
- D. *Lymphatic System*
1. The **lymphatic system** parallels the circulatory system and transports lymph while also playing host to cells of the immune system. Lymphoid organs and tissues include **lymph nodes**, the spleen, and the **thymus**, as well as areas of less well-organized immune tissues such as **GALT** and **MALT**.

14.3 Second-Line Defenses: Inflammation

- A. The inflammatory response is a complex reaction to tissue injury marked by *redness*, *heat*, *swelling*, and *pain*.
 1. Blood vessels narrow and then dilate in response to **chemical mediators**, **cytokines**, and **chemokines**.
 2. **Edema** swells tissues, helping prevent the spread of infection.

14.4 Second-Line Defenses: Phagocytosis, Interferon, and Complement

- A. Phagocytosis: Partner to Inflammation
 1. Macrophages and neutrophils engage in **phagocytosis**, engulfing microbes in a phagosome. Uniting the phagosome with a **lysosome** results in destruction of the phagosome contents.
 2. Phagocytes use a type of PRRs called **toll-like receptors (TLRs)** to recognize and adhere to foreign markers on microbes such as PAMPs.
- B. **Interferon (IFN)** is a family of proteins produced by leukocytes and fibroblasts that inhibit the reproduction of viruses by degrading viral RNA or blocking the synthesis of viral proteins.
- C. **Complement** is an innate defense system that plays a role in the destruction of bacteria, viruses, and parasites. It causes reactions on the surfaces of cells which result in the formation of a **membrane attack complex (MAC)** that kills microbial cells by creating holes in their membranes. It also plays roles in inflammation and phagocytosis.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

1. An example/examples of a nonspecific chemical barrier to infection is/are

a. unbroken skin	c. cilia in respiratory tract
b. lysozyme in saliva	d. all of these
2. Which nonspecific host defense is associated with the trachea?

a. lacrimation	c. desquamation
b. ciliary lining	d. lactic acid
3. Which of the following blood cells function primarily as phagocytes?

a. eosinophils	c. lymphocytes
b. basophils	d. neutrophils
4. Which of the following is *not* a lymphoid tissue?

a. spleen	c. lymph node
b. thyroid gland	d. GALT
5. What is included in GALT?

a. thymus	c. tonsils
b. Peyer's patches	d. breast lymph nodes
6. A signaling molecule from microbes recognized by phagocytes is

a. pyrogen	c. complement
b. PAMP	d. lectin
7. Monocytes are _____ leukocytes that develop into _____.

a. granular, phagocytes	c. agranular, macrophages
b. agranular, mast cells	d. granular, T cells
8. Which of the following inflammatory signs specifies pain?

a. tumor	c. dolor
b. calor	d. rubor
9. Toll-like receptors are proteins on _____.

a. phagocytes that recognize foreign molecules
b. viruses that stimulate immune reactions
c. skin cells that provide barriers to infection
d. lymphocytes that damage parasitic worms
10. An example of an inflammatory mediator that stimulates vasodilation is

a. histamine	c. complement C5 _a
b. collagen	d. interferon
11. _____ is an example of an inflammatory mediator that stimulates chemotaxis.

a. Endotoxin	c. A fibrin clot
b. Serotonin	d. Interleukin-2

12. An example of an exogenous pyrogen is
 - a. interleukin-1
 - b. complement
 - c. interferon
 - d. endotoxin
13. _____ interferon, produced by T lymphocytes, activates cells called _____ and is involved in destroying viruses.
 - a. Gamma, fibroblasts
 - b. Beta, lymphocytes
 - c. Alpha, natural killer cells
 - d. Beta, fibroblasts
14. In what process is tumor necrosis factor (TNF) *not* involved?
 - a. chemotaxis of phagocytes
 - b. fever
 - c. the inflammatory response
 - d. the classic complement pathway
15. Which of the following substances is *not* produced by phagocytes to destroy engulfed microorganisms?
 - a. hydroxyl radical
 - b. superoxide anion
 - c. hydrogen peroxide
 - d. bradykinin
16. Which of the following is the end product of the complement system?
 - a. properdin
 - b. cascade reaction
 - c. membrane attack complex
 - d. complement factor C9

Case Study Review

1. What are signs of chronic granulomatous disease?
 - a. unresolved inflammation
 - b. opportunistic fungal infections
 - c. low levels of white blood cells
 - d. recurrent infections
 - e. a, b, and c
 - f. a, b, and d
2. What feature of CGD phagocytes is defective?
 - a. the ability to engulf pathogens
 - b. production of toxic forms of oxygen
 - c. mechanisms to eliminate viruses
 - d. chemotaxis
3. Explain why children with CGD would be more prone to infections from fungi and bacteria than from viruses.

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

1. Use the lines on the figure to the right to locate and describe the eight components of the first line of defense.
2. What effects do these defenses have on microbes? Describe the initial steps taken by the primary responders to foreign matter.
3. Explain what PRRs and TLRs are and the nature of their interaction with PAMPs.
4. Make a simple drawing of the functions of toll-like receptors.
5. Describe the mechanisms by which leukocytes migrate from the bloodstream into an area of infection. What chemical factors are they reacting to?

6. Prepare a simplified outline of the cell lines of hematopoiesis.
7. Differentiate between the functions of primary and secondary lymphoid organs.
8. In what ways is a phagocyte a tiny container of disinfectants?
9. Macrophages perform the final job of removing tissue debris and other products of infection. Indicate some of the possible effects when these scavengers cannot successfully complete the work of phagocytosis.
10. Briefly outline what leads to the result shown in the figure on the right. Give the name and actions of this structure.

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps and a sample of a concept map for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

- Suggest some reasons that there is so much redundancy of action and there are so many interacting aspects of immune responses.
- What are some possible elements missing in children born without a functioning lymphocyte system?
 - What is the most important component extracted in bone marrow transplants?
- A patient's chart shows an increase in eosinophil levels.
 - What does this cause you to suspect?
 - What does it mean if the basophil levels are very high?
 - What if the neutrophil levels are very high?
- How can adults continue to function relatively normally after surgery to remove the thymus, tonsils, spleen, or lymph nodes?
- An obsolete treatment for syphilis involved inducing fever by deliberately infecting patients with the agent of relapsing fever. An experimental AIDS treatment involved infecting patients with malaria to induce high fevers. Can you provide some possible explanations behind these peculiar forms of treatment?
- Patients with a history of tuberculosis often show scars and other lesions in the lungs and experience recurrent infection. Account for these effects on the basis of the inflammatory response.
- Shigella*, *Mycobacterium*, and numerous other pathogens have developed mechanisms that prevent them from being killed by phagocytes.
 - Suggest two or three factors that help them avoid destruction by the powerful antiseptics in macrophages.
 - Suggest the potential implications that these infected macrophages can have on the development of disease.
- Account for the several inflammatory symptoms that occur in the injection site when one has been vaccinated against influenza and tetanus.
- What is the specific target of fever-suppressing drugs? Knowing that fever is potentially both harmful and beneficial, what are some possible guidelines for deciding whether to suppress it or not?
- Discuss the multiple, overlapping functions of the immune system. Which tissues and organs are involved in the immune response, and how does each function?

Visual Challenge

- Each numbered figure 1–4 represents a cell that provides an immune defense. Each lettered figure A–D shows a pathogenic microbe. Name the type of defense and match it with its primary target microbe and effects.

CASE STUDY Part 1 A Tale of Two Bat Bites

Case #1. In the fall of 2000, a 9-year-old Canadian boy awoke with a **fever and shooting pain** affecting his left arm. Over the next several days, he became **restless**, had difficulty sleeping, and developed tremors in his arm and hand. While being hospitalized for observation, he developed **increased salivation, hydrophobia, uncontrollable lower body contractions**, and visual **hallucinations**. His respirations became so labored that he required a breathing tube. Medical personnel were forced to consider the dreadful diagnosis of **rabies**. The only definitive diagnostic result showed **antibodies** against the rabies virus in his blood. A week after he first developed symptoms, his medical team decided to intervene with **postexposure prophylaxis (PEP)** therapy. This involved administering both **human rabies immune globulin (HRIG)** and five spaced-out doses of **rabies vaccine** in an effort to stop the infection from spreading.

Digging deeper to discover how the child may have become infected, the physicians learned that about a month before he showed symptoms, the father had captured and released a live bat trapped in the boy's bedroom. A day or so later, the child complained to his mother about a small **laceration** on his upper arm. It was cleaned and bandaged, but no further action was taken at the time.

Case #2. In October 2008, a 15-year-old Brazilian youth was **attacked by a bat**, which bit him in several places. The bat escaped

and was not available for testing. Clinical workers washed his wounds and applied peroxide and iodine **antiseptics** to them. Even though he seemed fine, he was taken to a hospital for further evaluation. Four days after the injuries, concerned physicians began

treating him with a version of PEP that included five doses of rabies vaccine but not rabies immune globulin.

Over the next 2 weeks the young man displayed early symptoms of rabies, including weakness, headache, fever, and a **prickling sensation around the bites**. Tests done on his blood and spinal fluid about this same time indicated antibodies specific to the rabies virus but no

virus antigen. The medical staff had heard about a case of a young woman in Wisconsin who had survived rabies by being placed in a **medically induced coma** and given **antiviral drugs** for several weeks, and they decided to try this therapy on him. About 3 weeks from the time of the bite, it appeared that his condition had stabilized, and they removed him from sedation.

- *What are the basic immunological principles behind PEP with rabies immune globulin and rabies vaccine?*

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

SCOPING OUT THE CHAPTER

We recognize the first symptoms of an infection coming on—the scratchy throat, swollen lymph nodes, runny nose, earache. But what is not so evident is the entire army of immune cells working behind the scenes to contain it before it gets too far along. Among the most important soldiers in fighting infections are lymphocytes in partnership with macrophages. Like a special strike force, they can track down infectious agents, dismantle them, and call into service a set of weapons for immobilizing and killing them. And after that, they leave a long term back up force of trained cells ready to attack at the first sign of another infection. This is the most critical of all of our defenses, and counts as the major contributor to our immunities, whether to cold viruses or strep bacteria or the tetanus vaccine.

Antigens: Red Flags of Foreign Invaders

Infectious agents carry around molecules that are unique to them and can provoke the immune cells to go into attack mode. These antigens can be complex whole microbes or parts of microbes such as toxins.

T cells: The Helpers and Killers Once they have been properly stimulated, T cells go down one of two different pathways, leading either to helpers that assist other cells get ready to fight infections or to killers that are involved in cell-to-cell combat. These cells bring smart bombs that can take out foreign cells with great precision.

Lymphocytes: Skilled Troops of Immunity

During development, millions of lymphocytes in the bone marrow each become programmed to go after a specific infectious agent and are primed for future battles with these microbes. Eventually they are deployed into lymphatic tissues throughout the body to be ready for attack.

Preparing for Battle Captured microbes are taken in by macrophages, where they are imprisoned and reduced to their most antigenic parts. The macrophages then display the antigens and make them available to lymphocytes. This brings about an activating process which prepares the T and B lymphocytes for their extended roles.

B cells and Antibodies: A Protein Defense

Stimulated B cells go into active growth mode, making many clones of themselves that will produce their key defense molecules—antibodies. These weapons are released into circulation to surround and hold microbes hostage so that they can be dealt with and destroyed.

Vaccines and Other Therapies to Mimic Nature

One significant advantage of having an organized and well-equipped strike team is that it can be trained for future conflicts. If an antigen is carefully selected and processed, it can be used to induce immunities before an infection has even occurred.

15.1 Specific Immunities: The Adaptive Line of Defense

Expected Learning Outcomes

1. Summarize the general features of adaptive, acquired immunity.
2. Define *immunocompetence*, *antigens*, *specificity*, and *memory* as they relate to the immune system.
3. Outline the overall phases in a specific immune response.
4. Explain the functions and types of immune receptors, including where and how they develop.
5. Describe the major events in the origin of diversity of the immune system and features of the clonal selection theory.
6. Describe the development of antigen receptors on lymphocytes
7. Discuss the events in B-cell and T-cell maturation and how they differ.

In chapter 14 we described the capacity of the immune system to survey, recognize, and react to foreign cells and molecules. Our main focus in that chapter was to overview innate host defenses such as anatomical and physiological barriers, phagocytosis, and inflammation. We also provided essential background for the main systems involved, such as blood cells and lymphatic tissues. Refer to figure 14.21 and use the flowchart to refresh yourself on the relationships among various host defenses. An essential system of defense that is not innate but must be acquired will be the main subject of this chapter.

Normal humans have an extremely specific and powerful system for resisting infectious agents. This system is called **adaptive** or **acquired immunity**, sometimes known as the third line of defense. It is responsible for the long-term protection we develop through infections (measles or mumps) or vaccinations. The absolute need for adaptive immunity is impressively documented in children with genetic defects in this system or in AIDS patients who have lost it. Even with heroic measures to isolate the patient, combat infections, or restore lymphoid tissue, immunodeficient people are constantly vulnerable to life-threatening infections.

Acquired adaptive immunity is the product of a dual system of specialized leukocytes—the B and T lymphocytes. During fetal development, these lymphocytes undergo a selective process that prepares them to react only to one specific antigen. During this time, **immunocompetence**, the ability of the body to interact with a wide spectrum of foreign substances, begins to develop. Through this process, an infant is born with the theoretical *potential* to produce an immune response to hundreds of millions of different foreign molecules or antigens. But the completion of this immunocompetence takes many years, extending into late puberty.

Antigens figure very prominently in specific immunity. They are defined as any molecules that can stimulate a response by T and B cells. They consist of protein, polysaccharide, and other compounds from cells and viruses. Environmental chemicals can also be antigens, as we shall see in section 16.2 dealing with allergy. In fact, any exposed or released substance is potentially an antigen, even those from our own cells. For reasons we discuss later, our own antigens do not usually evoke a response from our own immune systems, but they may do so in other persons.

In chapter 14 we discussed pathogen-associated molecular patterns (PAMPs) that stimulate responses by phagocytic cells during an innate defense response. PAMPs are molecules shared by many types of microbes that stimulate a nonspecific response. In contrast, antigens are molecules unique to a microbe that stimulate specific immune responses. The two kinds of molecules do share two characteristics: (1) they are “parts” of foreign cells (microbes), and (2) they provoke a reaction by the white blood cells of the host.

Two features that make adaptive immunity very different from innate immunity are **specificity** and **memory**. Unlike mechanisms such as anatomical barriers or phagocytosis, acquired immunity is selective. For example, the antibodies produced against the chickenpox virus during an infection will protect against that virus but not against the measles virus. Demonstrating memory means that lymphocytes have been programmed to “recall” their first engagement with an invader and respond rapidly to that same invader during subsequent exposures, which is a critical feature of immunity. These topics will be covered in greater depth in several later sections.

An Overview of Specific Immune Responses

Immune responses are highly complex and regulated, and they represent one of the most elegant and coordinated networks of cells and chemicals in the body. To present this system in an organized and clear manner, we have found it helpful to divide it into separate but related sections, each detailing some event in development of the immune response. The sections of coverage are as follows:

- I. Development and differentiation of the immune system (section 15.1)
- II. Lymphocyte maturation, and the nature of antigens (section 15.2)
- III. Immune reactions to antigens and the activities of T cells (section 15.3)
- IV. Immune activities of B Cells and the production and actions of antibodies (section 15.3)

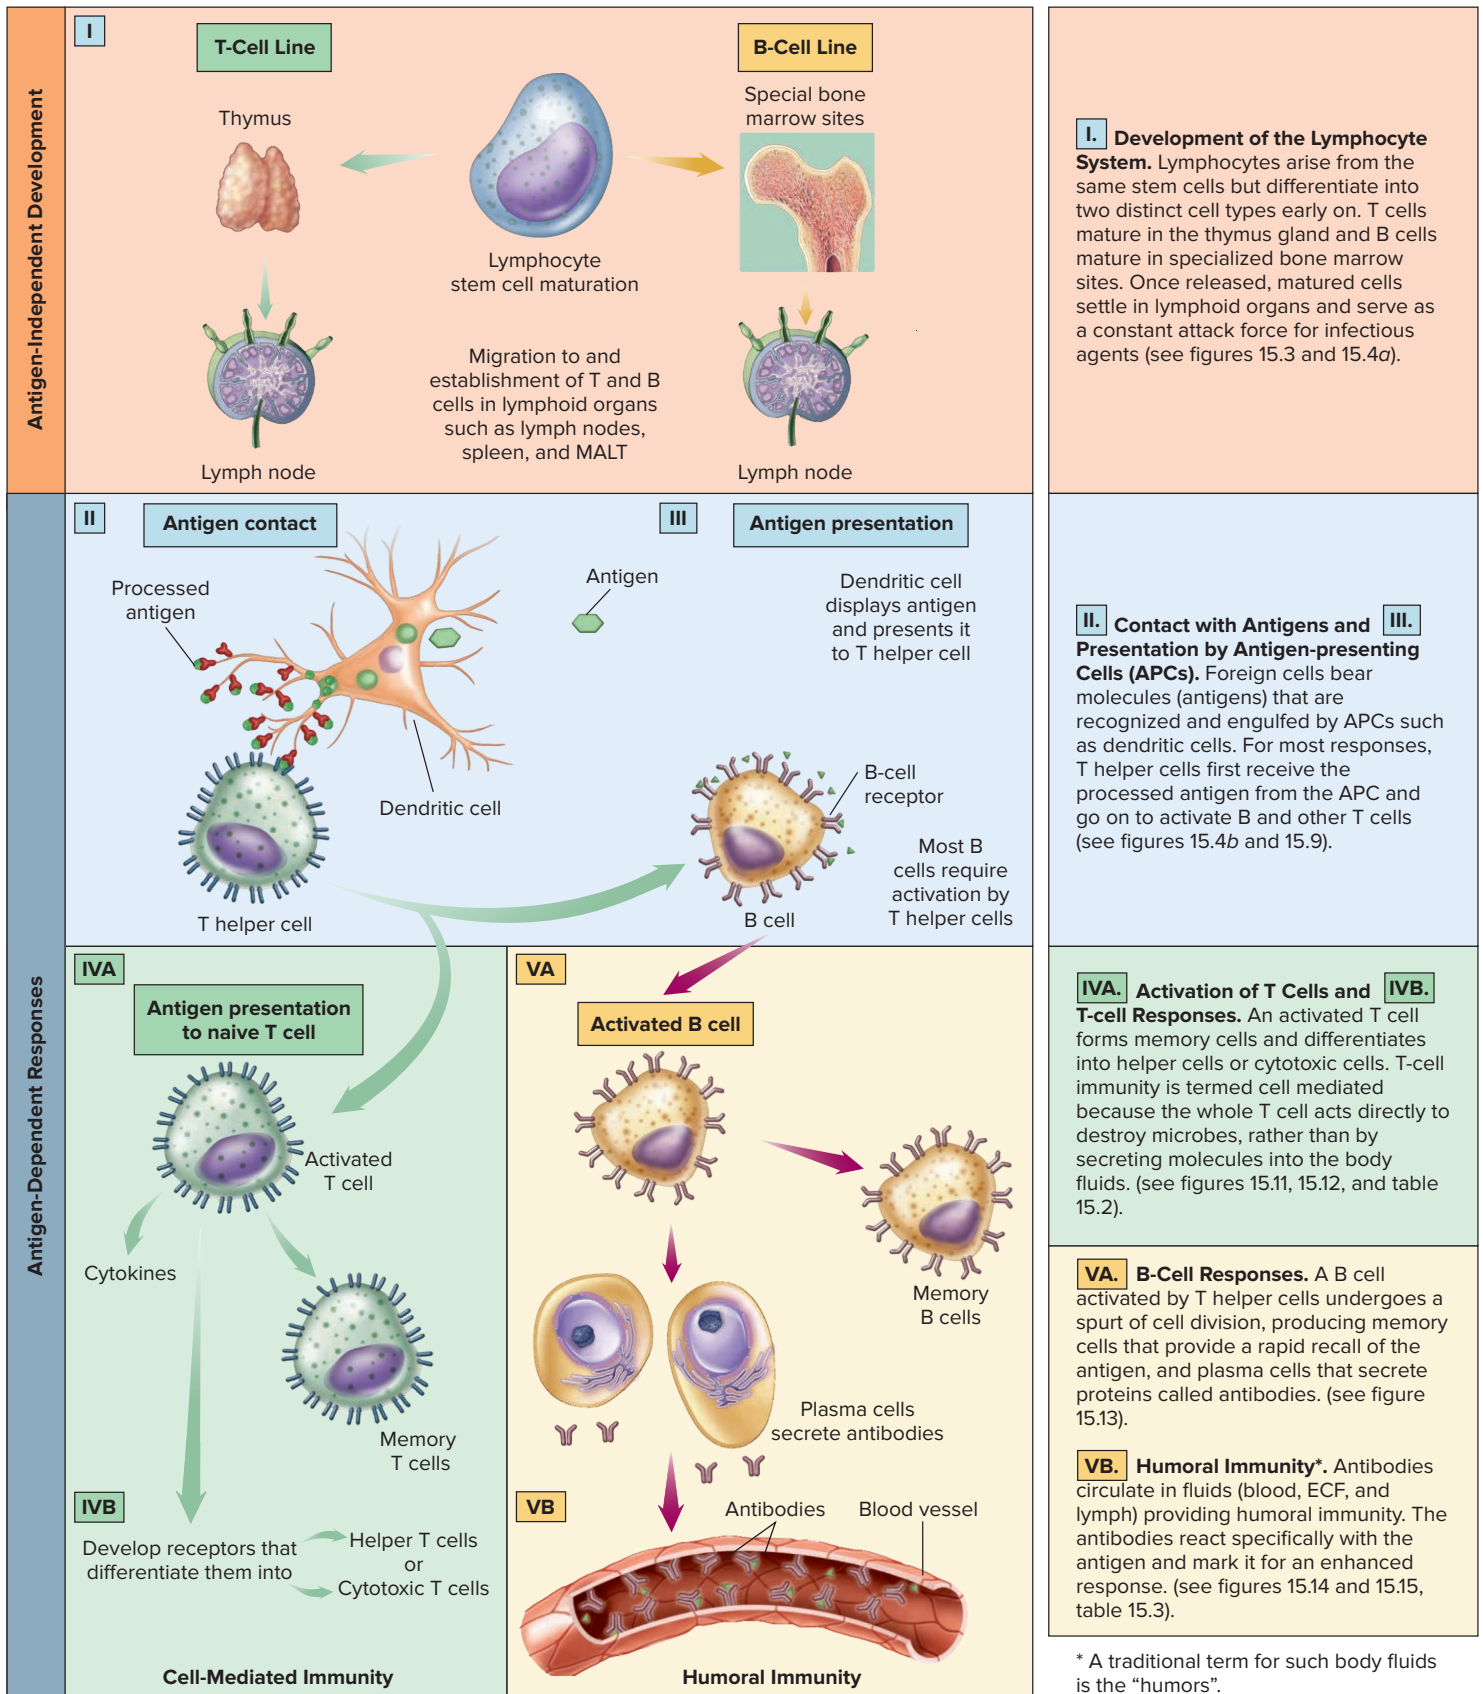

As we explore the information contained in these sections, we will be following a “map” of sorts. **Figure 15.1** lays out the flow of the main stages and will serve to coordinate the presentation. It also includes figure numbers that enlarge on the topics in that section.

Development of the Immune Response System

Before we examine lymphocyte development and function in greater detail, we must initially review concepts such as the unique structure of molecules (especially proteins), the characteristics of cell surfaces (membranes and envelopes), the ways that genes are expressed, immune recognition, and identification of self and non-self. Ultimately the shape and function of protein receptors and markers protruding from the surfaces of certain white blood cells are the result of genetic expression, and these molecules are responsible for specific immune recognition and, thus, immune reactions.

Markers on Cell Surfaces Involved in Recognition of Self and Nonself

Chapter 14 touched on the fundamental idea that cell surface receptors confer specificity and identity. A given cell can express several

Process Figure 15.1 Overview of the origins and events of adaptive immune responses. This summary lays out the plan of sections 15.2, 15.3, and 15.4.

different receptors, each type playing a distinct and significant role in detection, recognition, and cell communication. Major functions of immune receptors are as follows:

- to perceive and attach to nonself or foreign antigens,
- to promote the recognition of self antigens,
- to receive and transmit chemical messages among other cells of the system, and
- to aid in cellular development.

Because of their importance in the immune response, we concentrate here on the major receptors of lymphocytes and macrophages.

Major Histocompatibility Complex One set of genes that codes for human cell receptors is the **major histocompatibility complex (MHC)**. This gene complex gives rise to a series of glycoproteins (called MHC molecules) found on all cells except red blood cells. The MHC is also known as the **human leukocyte antigen (HLA)** system. This receptor complex plays a vital role in recognition of self by the immune system and in rejection of transplanted tissues.

The functions of the MHC groups have been identified. **Class I MHC** genes code for markers that display unique characteristics of self and allow for the recognition of self molecules and the regulation of immune reactions. Coverage in section 15.4 will outline how some T cells require interaction with class I MHC before they can react with foreign cells.

The system is rather complicated in its details, but in general, each person inherits a particular combination of class I MHC (HLA) genes in a relatively predictable fashion. Although millions of different combinations and variations of these genes are possible among humans, the closer two people are related, the greater the probability their MHC profiles will be similar. Individual differences in the exact inheritance of MHC genes, however, make it highly unlikely that even closely related persons will express an identical MHC profile. This fact introduces an important recurring theme: Although humans are genetically the same species, the cells of each individual express molecules that are foreign (antigenic) to other humans. This is where the term *histo-* (tissue) *compatibility* (acceptance) originated. This fact necessitates testing for MHC and other antigens when blood is transfused and organs are transplanted (see blood types and graft rejection, chapter 16).

Class II MHC genes code for immune regulatory receptors. The cells that express class MHC II are grouped together by the term **antigen-presenting cells (APCs)**. This includes macrophages, dendritic cells, and B cells. These are the only “professional” antigen presenters, in that they possess both class I and II receptors necessary for interactions with T cells. See **figure 15.2** for depictions of the two MHC classes.

Lymphocyte Receptors and Specificity to Antigen The part lymphocytes play in immune surveillance and recognition is very much a function of their receptors. B-cell receptors bind free antigens; T-cell receptors bind processed antigens together with the MHC molecules on the cells that present antigens to them. Because antigens are molecules, their chemical structures can vary over a very wide range, potentially exhibiting billions of uniquely different structures and shapes. The many sources of antigens include microorganisms as well as an awesome array of chemical

Figure 15.2 Molecules of the human major histocompatibility complex.

compounds in the environment. One of the most fascinating questions in immunology is: How can the lymphocyte receptors be varied to react with such a large number of different antigens? After all, it is generally accepted that there will have to be a different lymphocyte receptor for each unique antigen. Some additional questions naturally follow: How can a cell accommodate enough genetic information to respond to possibly billions of different antigens? When, where, and how does the capacity to distinguish self from foreign tissue arise? To answer these questions, we must first introduce a central theory of immunity.

The Origin of Diversity and Specificity in the Immune Response

The Clonal Selection Theory and Lymphocyte Development

Research findings have shown that lymphocytes use slightly more than 500 genes to produce the tremendous repertoire of specific receptors they must display for antigens. The most widely accepted explanation for how this diversity is generated is called the **clonal selection theory**. According to this theory, early undifferentiated lymphocytes in the embryo and fetus undergo a continuous series of divisions and genetic changes that generate hundreds of millions of different cell types, each carrying a particular receptor specificity.

The mechanism, generally true for both B and T cells, can be summarized as follows: Certain stem cell lines in the bone marrow will develop into specialized white blood cells such as granulocytes, monocytes, or lymphocytes. The lymphocytic line of stem cells differentiates into either T cells or B cells. Cells destined to become B cells stay in the bone marrow; T cells “home” to the thymus. Mature B and T cells then migrate to secondary lymphoid tissues (**figure 15.3**). These secondary lymphoid tissues will constantly be resupplied with B and T cells through this series of activities in the primary lymphoid tissues.

By the time T and B cells reach the lymphoid tissues, each one is already equipped to respond to a single unique antigen. This

Figure 15.3 Major stages in the development of B and T cells.

amazing diversity is generated by extensive rearrangements of the gene segments that code for the antigen receptors on the T and B cells (**figure 15.4a**). These extensive genetic recombinations give rise to a huge assortment of lymphocytes.¹ Each genetically unique line of lymphocytes arising from this process is termed a **clone**. Keep in mind that the genetic code is expressed as a protein receptor of unique configuration on the surface of the lymphocyte, something like a “signpost” announcing its specificity and reactivity for an antigen.

This *proliferative* stage of lymphocyte development does not require the actual presence of foreign antigens. But it does require another important action—namely, the removal or “silencing” of clones of lymphocytes that can react against *self* MHC antigens. The presence of such “forbidden clones” could cause severe damage if the immune system mistakenly identifies self molecules as foreign and mounts a response against the host’s own tissues. Thus, part of the clonal selection theory says that some clones are eliminated during development through clonal *deletion*. The removal of such potentially harmful clones is one basis of **immune tolerance**

or tolerance to self. Some diseases (such as autoimmunity) are thought to be caused by a loss of immune tolerance that can lead to immune reactions directed at self (covered in chapter 16).

The second stage of development—**clonal selection and expansion**—does require stimulation by antigens such as those that come from microbes. When an antigen enters the immune surveillance system, it encounters specific lymphocytes ready to recognize it. Such contact stimulates that clone to undergo mitotic divisions and expands it into a larger population of lymphocytes, all bearing the same specificity. This increases the capacity of the immune response for that antigen.

Two important generalities one can derive from the clonal selection theory are (1) that lymphocyte specificity is preprogrammed, existing in the genetic makeup before an antigen has ever entered the tissues; and (2) that each genetically distinct lymphocyte expresses only a single specificity and can react to only one type of antigen. Other important features of the lymphocyte response system are detailed in later sections.

The Specific B-Cell Receptor: An Immunoglobulin Molecule

In the case of B lymphocytes, the receptor genes that undergo the recombination process are those governing **immunoglobulin* (Ig)** synthesis. Immunoglobulins are large glycoprotein molecules that serve as the specific receptors of B cells and as antibodies. The basic immunoglobulin molecule is a composite of four polypeptide chains: a pair of identical heavy (H) chains and a pair of identical light (L) chains (**figure 15.5a**). Each light chain binds to a heavy chain, and the two heavy chains bind to each other with disulfide bonds, creating a symmetrical, Y-shaped arrangement.

The ends of the forks formed by the light and heavy chains contain pockets called the **antigen binding sites**. These sites can be highly variable in shape to fit a wide range of antigens. This extreme versatility is due to **variable (V) regions**, where amino acid composition is highly varied from one clone of B lymphocytes to another (**figure 15.5b**). The remainder of the light chains and heavy chains consist of **constant (C) regions** whose amino acid content does not vary greatly from one antibody to another. Figure 15.14 provides further details of antibody structure.

Development of B-Lymphocyte Receptors During Maturation

The genes that code for immunoglobulins lie on three different chromosomes. An undifferentiated lymphocyte has about 150 different genes that code for the variable region of light chains and about 250 genes for the **variable (V)** and **diversity (D) regions** of the heavy chains. The **constant (C)** regions and the **joining (J) regions** that link segments of the final molecule are represented by only a small number of genes. A result of the extensive genetic recombination that occurs during development is that only the selected V and D gene segments are active in the mature cell, and all the other V and D genes have been deleted (**figure 15.5b**). This is how the specificity of lymphocytes is maintained.

One can envision this process by comparing it to a molecular “cut and paste.” The gene segments lie in an established sequence along a chromosome. A complex enzyme system randomly selects

1. Estimates of the theoretical number of possible variations that may be created vary from 10^{14} to 10^{18} different specificities—clearly enough to react with all potential antigens that might be encountered.

* *immunoglobulin* (im'-yoo-noh-glahb'-yoo-lin)

Figure 15.4 Overview of the clonal selection theory of lymphocyte development and diversity. Receptors are stylized to show diversity in shape that clonal selection generates. See figure 15.5 for the details of receptor development in B cells.

and cuts out particular blocks of DNA and splices them together. All remaining unused gene segments are permanently removed from the genome of this cell, leaving only the selected segments, which will code for a specific polypeptide receptor. A summary of the steps in the process is as follows:

- For a heavy chain, a variable region gene segment and diversity region gene segment are selected from among the hundreds available and spliced to one joining region gene and one constant region gene.
- For a light chain, one variable, one joining, and one constant gene segment are spliced together.
- After transcription and translation of each gene complex into a polypeptide, a heavy chain combines with a light chain to form half an immunoglobulin; two of these combine to form a completed protein (figure 15.5b).

Once synthesized, the immunoglobulin product is transported to the cell membrane and inserted there to act as a receptor that expresses the specificity of that cell and to react with an antigen, as

(a) **Antigen-Independent Period**

1 During development of early lymphocytes from stem cells, a given stem cell undergoes rapid cell division to form numerous progeny.

During early cell differentiation, there are random rearrangements of the genes that code for cell surface protein receptors. The result is a large array of genetically distinct cells, called clones, each clone bearing a different receptor to react with only a single type of foreign molecule or antigen.

2 At this time, any lymphocyte clones that carry a specificity for self molecules and could be harmful are eliminated from the pool of diversity. This is a way to achieve immune tolerance.

3 The specificity for a single antigen molecule is programmed into the lymphocyte and is set for the life of a given clone. The end result is an enormous pool of mature but naive lymphocytes that are ready to further differentiate under the influence of their “home” organs and immune stimuli.

(b) **Antigen-Dependent Period**

4 Lymphocytes migrate home to the lymphatic organs where they are situated to encounter antigens. Entry of a specific antigen selects only the lymphocyte clone or clones that carry matching surface receptors. This will trigger an immune response, which varies according to the type of lymphocyte involved.

shown in figure 5.5. It is notable that for each lymphocyte, the genes that were selected for the variable region, and thus for its specificity, will be locked in for the rest of the life of that lymphocyte and its progeny. But the constant region may be altered to provide different functional properties (see table 15.3). We discuss the different classes of Ig molecules further in section 15.4.

T-Cell Receptors for Antigen The T-cell receptor for antigen belongs to the same protein family as the B-cell receptor. It is similar to B cells in being formed by genetic modification, having variable and constant regions, being inserted into the membrane, and having an antigen binding site formed from two parallel polypeptide chains (figure 15.6). Unlike the immunoglobulins, the T-cell receptor is relatively small. It is equivalent to one fork of the B-cell receptor and is not secreted. Additional receptors of T cells are described in section 15.3.

With a working knowledge of some factors in the development of immune specificity, we can now continue our coverage of the immune response as outlined in figure 15.1.

Figure 15.5 The basic structure and genetics of immunoglobulins. (a) Simple model of an immunoglobulin molecule. The main components are four polypeptide chains—two identical light chains and two identical heavy chains—bound by disulfide bonds as shown. Each chain consists of a variable region (V) and a constant region (C). The variable regions of light and heavy chains form a binding site for antigen. (b) The final gene that codes for a heavy or light chain is assembled by splicing blocks of genetic material from several regions (1, 2, 3). These genes are transcribed and translated into the polypeptides that join to form the final molecule (4).

Figure 15.6 Structure of the T-cell receptor (TCR) for antigen and CD receptors. The structure of the TCR is similar to that of an immunoglobulin. It consists of two polypeptides that mimic the structure of one “arm” of an immunoglobulin. The TCR has variable (V) regions that can show high levels of diversity for antigens, and constant (C) regions that do not greatly vary. Another class of T-cell receptors called CD receptors, function in cell signaling. The CD4 and CD8 receptors will be discussed in section 15.3.

Specific Events in T-Cell Maturation

The further development and maturation of T cells are directed by the thymus gland and its hormones. The complexity of T-cell function, discussed in section 15.3, is partly due to different classes of T-cell surface molecules termed **clusters of differentiation** or **CD receptors** added during maturation. CD molecules serve multiple roles as cell receptors and may be involved in cell adhesion and communication in a variety of cells. They are denoted with a

number—CD1, CD2, and so on. Our focus will be primarily on two CD groups found on T cells: CD4 receptors on T helper cells and CD8 receptors on T cytotoxic cells. These CD receptors interact with a particular MHC marker on other white blood cells during immune reactions. As was shown in figure 15.3, mature T cells migrate to specific sites in lymphoid organs and constantly circulate from there. It is estimated that 25×10^9 T cells pass between the lymphatic and general circulation per day.

TABLE 15.1 Contrasting Properties of T Cells and B Cells

	Site of Maturation	Immune Surface Markers	Circulation in Blood	Receptors for Antigen	Distribution in Lymphatic Organs	Require Antigen Presented with MHC	Product of Antigenic Stimulation	General Functions
T Cells	Thymus gland	T-cell receptor, CD molecules, MHC I receptors	High numbers	T-cell receptor (TCR)	Paracortical sites (interior to the follicles)	Yes	Helper and cytotoxic T cells and memory cells	Regulate immune functions, kill foreign and infected cells, synthesize cytokines
B Cells	Bone marrow	Immunoglobulin MHC I and MHC II receptors	Low numbers	Immunoglobulins D and M	Cortex (in follicles)	No	Plasma cells and memory cells	Produce antibodies to target, inactivate, and neutralize, antigens

Specific Events in B-Cell Maturation

The sites of B-cell maturation exist in certain bone marrow regions that harbor *stromal cells*. These huge cells nurture the lymphocyte stem cells and provide chemical signals that initiate B-cell development. The result of gene modification and selection is the development of hundreds of millions of distinct B cells (see figure 15.4a). Just as T cells do, these naive B lymphocytes travel to specific sites in the lymph nodes, spleen, and mucosal-associated lymphoid tissue (MALT), where they adhere to specific binding molecules. Here they will come into contact with antigens throughout life. B cells display immunoglobulins as surface receptors for antigens (see table 15.3).

Table 15.1 summarizes the main differences in the structure, functions, and actions of B cells and T cells.

Check Your Progress SECTION 15.1

1. Discuss what is meant by immunocompetence, immune specificity and memory, and adaptive immunity.
2. What function do receptors play in specific immune responses and how can they be made to vary so widely?
3. Describe the major histocompatibility complex, and explain how it participates in immune reactions.
4. Explain the clonal selection theory of receptor specificity and diversity in lymphocytes.
5. Why must the body develop tolerance to self?
6. Trace the origin and development of T lymphocytes and of B lymphocytes.
7. What is happening during lymphocyte maturation?
8. Describe three ways in which B cells and T cells are similar and at least five major ways in which they are different.

15.2 The Nature of Antigens and Antigenicity

Expected Learning Outcomes

8. Explain the characteristics of antigens, the property of antigenicity, and epitopes.
9. Discuss the main categories of antigens, based on function.

Characteristics of Antigens and Immunogens

Earlier we encountered the concept of an **antigen**,² which can now be more fully defined as any molecule or fragment of a molecule that has the *potential* to trigger a specific immune response by lymphocytes. This property is known as **antigenicity**. For a substance to be antigenic, it must meet several criteria related to foreignness, size, shape, and accessibility that are discussed next. A related set of more specific terms are **immunogen** and *immunogenicity*. An immunogen is a type of antigen that actually *does* induce a specific immune response when introduced into the body.

The difference between these terms is subtle and addresses the fact that some antigens may not fit all of the actual conditions to stimulate an immune reaction, whereas immunogens do. One example involves the small **polysaccharides** from the capsule of the bacterium *Haemophilus influenzae*, one cause of meningitis. These molecules are foreign and antigenic, but they are too small to trigger a lymphocyte response: They are antigenic but not immunogenic. To produce a vaccine from this type of antigen, it must be altered so that the immune system can more readily recognize and react to it (see the discussion of haptens later in this section). In most of the succeeding discussions on immune responsiveness, we will use the more general term *antigen* because it encompasses all possibilities of eliciting immune reactions.

One important characteristic of an antigen is that the immune cells react to it as nonself or as foreign, meaning that it is not a “normal” constituent of the body. Whole microbes or their parts, cells, or substances that arise from other humans, animals, plants, and various molecules all possess this quality of foreignness and thus are potentially antigenic to the immune system of an individual (**figure 15.7**). Molecules of complex composition such as proteins and protein-containing compounds prove to be more immunogenic than repetitious polymers composed of a single type of unit. Most materials that serve as antigens fall into these chemical categories (with examples):

- proteins and large polypeptides (enzymes, cell surface receptors, hormones, exotoxins);
- molecules that contain two or more different macromolecules bound together. Examples of these include:
 - lipoproteins (combinations of lipids and proteins) and lipopolysaccharides (combinations of lipids and carbohydrates). These substances originate from the cell membranes or cell walls of microbes.

2. *Antigen* (an'-tih-jen) means, literally, an **antibody generator**.

Figure 15.7 Characteristics of antigens. (a) Whole cells of bacteria, fungi, and viruses make good immunogens. So do plant parts and animal cells. (b) Complex molecules with several epitopes make good immunogens. (c) Poor immunogens include small, simple molecules not attached to a carrier molecule (1, 2) and larger molecules with repetitive chains of monomers that have reduced complexity (3, 4).

- nucleoproteins (DNA complexed to proteins); unbound DNA is too regular and repetitive in structure to be antigenic;
- polysaccharides (certain bacterial capsules) and glycolipids (mycolic acid of *M. tuberculosis*).

Effects of Molecular Shape and Size on Antigenicity

To initiate an immune response, a substance must also be large enough to “catch the attention” of the surveillance cells. Molecules with a molecular weight (MW) of less than 1,000 are seldom complete antigens, and those between 1,000 MW and 10,000 MW are weakly so. Complex macromolecules of at least 100,000 MW are the most immunogenic, a category also dominated by large proteins. Note that large size alone is not sufficient for antigenicity. Glycogen, a polymer of glucose with a highly repetitious structure,

has an MW over 100,000 and is not normally antigenic, whereas insulin, a protein with an MW of 6,000, can be antigenic.

A lymphocyte’s capacity to discriminate differences in molecular shape is so fine that it recognizes and responds to only a portion of the antigen molecule. This molecular fragment, called the **epitope** or antigenic determinant, provides the primary signal that the molecule is foreign (figure 15.7b). The shape of this determinant fits like a key to the receptor “lock” of the lymphocyte, which then recognizes and responds to it.

Certain amino acids accessible at the surface of proteins or carbohydrate side chains protruding from a protein receptor are typical examples. Many foreign cells and molecules are very complex antigenically, with numerous determinants, each of which will elicit a separate and different lymphocyte response. Examples of these multiple, or *mosaic*, antigens include bacterial cell wall, membrane, flagellar, capsular, and toxin antigens; and viruses, which express various surface and core antigens.

Small foreign molecules that consist only of a determinant group and are too small by themselves to elicit an immune response are termed **haptens**. However, if such an incomplete antigen is linked to a larger carrier molecule, the combination develops immunogenicity (figure 15.8). The carrier group contributes to the size of the complex and enhances the orientation of the antigen, while the hapten serves as the epitope. Haptens include such molecules as vaccine antigens; drugs; metals; and household, industrial, and environmental chemicals. Many haptens develop immunogenicity in the body by combining with large carrier molecules such as serum proteins (see section 16.2).

Functional Categories of Antigens

Because each human being is genetically and biochemically unique (except for identical twins), the proteins and other molecules of one person can be antigenic to another. **Alloantigens** are cell surface markers and molecules that occur in some members of the same species but not in others. Alloantigens are the basis for an individual’s blood group and major histocompatibility profile, and they are responsible for incompatibilities that can occur in blood transfusion or organ grafting.

Some bacterial proteins, called **superantigens**, are potent stimuli for T cells. Notable examples of these types of antigens are toxic shock toxin and enterotoxin of *Staphylococcus*. Reactions with superantigens may cause the massive release of cytokines, leading to cell death. The role of these compounds is covered in section 15.3.

Antigens that evoke allergic reactions, called **allergens**, will be characterized in detail in chapter 16.

On occasion, even a normal part of self can take on the character of an antigen. During lymphocyte differentiation, immune tolerance to self tissue occurs, but a few anatomical sites can contain sequestered (hidden) molecules that escape

Figure 15.8 The hapten-carrier phenomenon. **(a)** Haptens are antigens that are too small to be discovered by an animal's immune system and do not elicit a response. **(b)** When a hapten binds to a large molecule, the hapten serves as an epitope and stimulates a response and an antibody that is specific for it.

this assessment. Such molecules, called **autoantigens**, can occur in tissues (of the eye and thyroid gland, for example) that are walled off early in embryonic development before the surveillance system is in complete working order. Because tolerance to these substances has not yet been established, they can subsequently be mistaken as foreign; this mechanism appears to account for some types of auto-immune diseases such as rheumatoid arthritis (chapter 16).

With a working knowledge of some factors in the development of immune specificity, we can now continue our coverage of the immune response as outlined in figure 15.1.

Check Your Progress SECTION 15.2

9. What are antigens, immunogens, and epitopes, and what role do they play in immune reactions?
10. How do foreignness, size, and complexity contribute to antigenicity?
11. Compare five unique types of antigens, and explain their functions or actions.

15.3 Immune Reactions to Antigens and the Activities of T Cells

Expected Learning Outcomes

10. Describe the cooperative interactions between antigen-presenting cells, T cells, and B cells.
11. Discuss the actions of interleukins in the early reactions of recognition and activation.
12. Outline the main activities of cell-mediated immunities.
13. Analyze the relationships between the types of T cells and their receptors, and how they are activated.
14. Describe the primary functions of helper T cells and cytotoxic T cells.
15. Explain the concepts of natural killer cells and superantigens.

The basis for most immune responses is the encounter between antigens and white blood cells. Microbes and other foreign substances enter most often through the respiratory or gastrointestinal mucosa and less frequently through other mucous membranes or the skin. Antigens introduced intravenously become localized in

the liver, spleen, bone marrow, kidney, and lung. If introduced by some other route, antigens are carried in lymphatic fluid and concentrated by the lymph nodes. The lymph nodes and spleen are important in concentrating antigens in areas where they will come in contact with antigen-presenting cells (APCs) and lymphocytes. APCs and lymphocytes can subsequently circulate into fluid compartments to seek out the antigens for which they are specific.

The Role of Antigen Processing and Presentation

In most immune reactions, the antigen is in a “raw” state and must be further acted upon by **antigen-presenting cells (APCs)** before it is ready for contact with T cells. Three different cells can serve as APCs: **macrophages**, **dendritic* cells**, and B cells, although dendritic cells are the most common APC in the first contact with an antigen. Antigen-presenting cells modify the antigen so that it will be more immunogenic and recognizable. After processing is complete, the antigen is

moved to the surface of the APC and bound to an MHC class II receptor to make it readily accessible to T cells during presentation (**figure 15.9**). Before a T cell can respond to APC-bound antigens, certain conditions must be met. *T-cell-dependent antigens*, usually protein-based, require recognition steps between the APC, antigen, and lymphocytes. The first cells on the scene to assist in activating B cells and other T cells are a special class of **T helper cells (T_H)**. The T-cell receptor (TCR) of this class of T cell will bind simultaneously with the class II MHC receptor on the APC and with the antigen (figure 15.9). A second interaction involves the binding of the T-cell CD4 receptor to the MHC of the APC. Once this identification step has occurred, a cytokine, **interleukin-1 (IL-1)**, produced by the APC, activates this T helper cell. The T_H cell, in turn, produces a different cytokine, **interleukin-2 (IL-2)**, which stimulates a general increase in activity of committed B and T cells. The manner in which B and T cells subsequently become activated by the APC–T helper cell complex and their individual responses to antigen are addressed below and in section 15.4.

* *dendritic* (den'-drih-tik) Gr. *dendron*, branching like a tree.

Process Figure 15.9 Interactions between antigen-presenting cells (APCs) and T helper (CD4) cells required for T-cell activation. For T cells to recognize foreign antigens, the antigen must be processed and presented to them by a professional APC such as a dendritic cell. See figure 15.10 and figure 15.13 for next phases.

A few antigens can trigger a response from B lymphocytes without the cooperation of APCs or T helper cells. These *T-cell-independent antigens* are usually simple molecules such as carbohydrates with many repeating and invariable determinant groups. Examples include lipopolysaccharide from the cell wall of *Escherichia coli*, polysaccharide from the capsule of *Streptococcus pneumoniae*, and molecules from rabies and Epstein-Barr virus. Because so few antigens are of this type, most B-cell reactions require assistance from T helper cells.

T-Cell Responses and Cell-Mediated Immunity (CMI)

The responses of T cells, referred to as **cell-mediated immunities (CMIs)**, are among the most complex and diverse in the immune system. They involve several subsets of T cells that differ in their types of CD receptors and the precise ways they react against

foreign antigens and cells (**table 15.2**). T cells are restricted, meaning that before they can be activated, they must have the antigen offered by an MHC complex on an APC (figure 15.9), to ensure recognition of self. All produce cytokines that, working together, carry out a spectrum of biological effects and immune functions. T cells differ notably from B cells in function. We will see that B cells combat foreign antigens by secreting molecules into the circulation, but in the case of T cells, the whole cell reacts directly in contact with target cells. T cells also stimulate other T cells, B cells, and phagocytes.

A T cell is initially sensitized by the binding of antigen/MHC to its receptors. This event activates the T cell, which transforms it in preparation for mitotic divisions, and targeted by interleukin signals. It divides to form one of the subsets of effector cells and memory cells that can interact with the antigen upon subsequent contact. Memory T cells are some of the longest-lived blood cells known (decades, rather than weeks or months for other lymphocytes).

TABLE 15.2 Characteristics of Subsets of T Cells

Types	Primary Receptors on T Cell	Functions/Important Features
T helper cell 1 (T _{H1})	CD4	Activates other CD4 and CD8 cells; secretes IL-2, tumor necrosis factor, and interferon gamma; responsible for delayed hypersensitivity; interacts with MHC-II receptors
T helper cell 2 (T _{H2})	CD4	Drives B-cell proliferation; secretes IL-4, IL-5, IL-6, IL-10; can dampen T _{H1} activity
T regulatory cell (T _{reg})	CD4, CD25	Involved in development of immune tolerance; suppression of pathological immune responses, inflammation, autoimmunity
T cytotoxic cell (T _C)	CD8	Destroys a target foreign cell by lysis; important in destruction of cancer cells, virus-infected cells; graft rejection; requires MHC I for function May have some regulatory functions.

The Activation of T Cells and Their Differentiation into Subsets

Mature T cells in lymphoid organs are primed to react with antigens that have been processed and presented to them by dendritic cells and macrophages. They recognize an antigen only when it is presented in association with a particular MHC carrier, but they differ in which carrier comes into play (**figure 15.10**). T cells with CD4 receptors recognize endocytosed peptides presented on MHC II, and T cells with CD8 receptors recognize peptides presented on MHC I.

T Helper (T_H) Cells: Activators of Specific Immune Responses T helper (CD4) cells play a central role in regulating immune reactions to antigens, including those of B cells and other T cells. They are also involved in activating macrophages and increasing phagocytosis. They do this directly by receptor contact and indirectly by releasing cytokines such as interleukin-2, which stimulates the primary growth and activation of B and T cells, and interleukin-4, -5, and -6, which stimulate development of B cells. T helper cells are the most prevalent type of T cell in the blood and lymphoid organs, making up about 65% of this population. The severe depression of the CD4 class of T cells by HIV is a major factor in the immunopathology of AIDS.

When T helper cells are activated by antigen/MHC II, they differentiate into either **T helper 1** (T_{H1}) cells, or **T helper 2** (T_{H2}) cells, depending on what type of cytokines the antigen-presenting cells secrete. It is thought that if the dendritic cell (APC) secretes IL-1 or IL-12, the T cell will become a T_{H1} cell that can activate

more T cells. It is also involved in delayed hypersensitivity (**figure 15.10a**). Delayed hypersensitivity is a type of response to allergens, distinct from immediate allergies such as hay fever and anaphylaxis. Both of these reactions are discussed in chapter 16.

If the APC secretes another set of cytokines (IL-4, IL-5, IL-6), the T cell will differentiate into a T_{H2} cell. These cells have the function of secreting substances that influence B-cell differentiation and consequently affect the antibody response.

Cytotoxic T (T_C) Cells: Cells That Kill Other Cells

When CD8 cells are activated by antigen/MHC I, they differentiate into **T cytotoxic cells (T_C or killer T cells)**. **Cytotoxicity** is the capacity of certain T cells to kill a specific target cell. It is a fascinating and powerful property that accounts for much of our immunity to foreign cells and cancer; and yet, under some circumstances, it can lead to disease. For a cytotoxic T cell to become activated, it must recognize a foreign peptide carried by an MHC-I receptor and mount a direct attack upon the target cell. The T_C cell severely injures the target cell by secreting **perforins**³ and **granzymes** (**figure 15.10b**). Perforins are proteins that can punch holes in the membranes of target cells, and granzymes are enzymes that digest proteins. First the perforins cause ions to leak out of target cells and create a passageway for granzymes to enter. Granzymes induce the loss of selective permeability followed by target cell death through a process called *apoptosis*.^{*} The apoptosis is genetically programmed and results in destruction of the nucleus and complete cell lysis and death.

Target cells that can be destroyed by T_C cells include the following:

- Virally infected cells (**figure 15.10b**). Cytotoxic cells recognize and react against other cells that carry virus peptide MHC combinations expressed on their surface. Cytotoxic defenses are an essential protection against viral infections.
- Cancer cells. T cells constantly survey the tissues and immediately attack any abnormal cells they encounter (**figure 15.11**). The importance of this function is clearly demonstrated in the susceptibility of T-cell-deficient people to cancer (chapter 16).
- Cells from other animals and humans. Cytotoxic CMI is the most important factor in graft rejection. In this instance, the T_C cells attack the foreign tissues that have been implanted into a recipient's body.

Other Types of Killer Cells **Natural killer (NK)** cells are a type of lymphocyte related to T cells that are part of cytotoxic CMI. They circulate through the spleen, blood, and lungs, and are probably the first killer cells to attack cancer cells and virus-infected cells. They destroy these cells by similar mechanisms as cytotoxic T cells (**figure 15.12**). They are considered part of cell-mediated immunity because their activities are moderated by cytokines such as interleukin-12 and interferon.

3. *Perforin* is taken from the term perforate, to make holes in.

* *apoptosis* (ah-poh-toh'-sis) Gr., *apo*, away from, and *ptosis*, a falling or dropping.

Process Figure 15.10 Overall scheme of T-cell activation and differentiation into different types of T cells. Antigen-presenting cells (APCs) present antigenic peptides to T cells bearing either CD4 (a) or CD8 (b) markers. (a) CD4 cells bind antigen/MHC-II complexes on APCs and, depending on the type of cytokine released by the APC, become either T_H1 or T_H2 cells. T_H1 cells synthesize IL-2 that activates CD8 cells and causes macrophages to destroy ingested microbes or to become more active. T_H2 cells secrete cytokines that enhance B-cell activation. (b) Upon binding antigen/MHC-I complex, CD8 cells become cytotoxic T (T_C) cells, which bind infected host cells displaying antigen/MHC-I complexes and release perforins and granzymes. This leads to the apoptosis (programmed cell death) of the infected cell.

Figure 15.12 The action of natural killer (NK) cell.

Immune Regulation by T Cells

Most physiological processes operate under a system of checks and balances as a way to maintain normal stability of functions. This is also true of the immune system. Abnormal or out-of-control actions that could disrupt the beneficial effects of immunity are partly controlled by a subset of T_H cells called **regulatory T cells** or T_{regs} that express CD4 and CD25 receptors (see table 15.2). These cells were once called “suppressor T cells” for their modulating effects on immune responses of other T and B cells. Although the exact mechanisms are yet to be totally clarified, evidence is growing that they are responsible for maintaining immune tolerance and preventing the immune system from overreacting in a harmful or pathological way. They play important roles in moderating inflammation, allergy, autoimmunity, antibody production, cancer, and transplant rejection.

One well-defined mechanism of immune regulation involves the action of *programmed cell death protein-1* (PD-1), a receptor expressed by CD8 T cells. Its function is to “down regulate” or negatively regulate the immune system by acting as a checkpoint that can either 1) allow CD8 cells to become activated and attack their targets or 2) shut down the activation of CD8 cells to block an immune reaction. Most of the time this checkpoint “brake” on T cells maintains balanced immune function. It appears to be an important factor in developing tolerance for self antigens and preventing adverse events in pregnancy, transplant rejection, and autoimmune reactions. Once the PD-1 receptor has been engaged, it blocks further actions by the CD8 cell and causes it to undergo apoptosis and death, which is where the term PD-1 originated.

Malfunctions in the PD-1 system are a factor in the development of some types of cancer. Many cancer cells evade destruction by producing substances that inactivate the PD-1 receptor and put the brakes on the cytotoxic T-cell response that would ordinarily destroy those cancer cells. It is by this means that cancers become metastatic and spread. Two new successful anticancer drugs (Opdivo and Keytruda) are based on monoclonal antibodies that prevent cancer cells from accessing the PD-1 receptor, thus allowing activation of CD8 cells and destruction of the cancer cells. To see a short video explaining this go to <https://www.youtube.com/watch?v=v9NBUeU3PG0>.

T Cells and Superantigens

Most of the T-cell responses we have covered so far are primarily beneficial and protective. But there is one type of reaction that often has drastic consequences and may lead to serious diseases. Such is the case in exposure of T cells to **superantigens**. These antigens, found primarily in bacteria and viruses, are actually a form of virulence factor. Examples include enterotoxin given off by pathogenic staphylococci, certain toxins of group A streptococci, and proteins of Epstein-Barr virus. They can provoke overwhelming immune responses by large

numbers of T cells regardless of specificity. Superantigen molecules are structured so that they can span both MHC-II receptors and some antigen receptors (TCR) on T cells. This event can “trick” large numbers of T cells into releasing massive amounts of cytokines such as tumor necrosis factor and interleukins-1 and -6. The overwhelming influx of such potent mediators leads to blood vessel damage, toxic shock, and multiorgan failure. This is thought to be the underlying mechanism of toxic shock syndrome and other serious infections.

Check Your Progress SECTION 15.3

12. Describe the actions of an antigen-presenting cell.
13. Explain the difference between a T-cell-dependent and a T-cell-independent response.
14. Trace the immune response system, beginning with the entry of a T-cell-dependent antigen, antigen processing, presentation, the cooperative response among the macrophage and lymphocytes, and the reactions of activated B cells.
15. What are the actions of interleukins-1, -2, -4, and -12?
16. Why are the immunities involving T cells called cell-mediated?
17. Explain how the different types of T cells are activated and their responses.
18. What are the targets of cytotoxic cells and how do they destroy them?
19. Discuss how superantigens are different from other antigens and how they contribute to pathology.

15.4 Immune Activities of B Cells

Expected Learning Outcomes

16. List and analyze the stages in activation of B lymphocytes, clonal expansion, and antibody formation.
17. Describe the structure and basic functions of the five major types of immunoglobulins.
18. Explain the actions of antibodies in protective immune reactions.
19. Analyze the primary and secondary responses to antigens and immunogens, including the importance of the anamnestic response and boosters.

Events in B-Cell Responses

Activation of B Lymphocytes: Clonal Selection, Expansion, and Antibody Production

The immunologic activation of most B cells requires a series of events as outlined in the numbered steps that follow and illustrated in **figure 15.13**.

1. Clonal selection and binding of antigen. In this case, a pre-committed B cell of a particular clonal specificity picks up the antigen on its Ig receptors and processes it into small peptide

determinants. The antigen is then bound to the MHC-II receptors on the B cell. The MHC/Ag complex on the B cell is bound by T-cell receptors.

2. Induction by chemical mediators. The B cell receives developmental signals from macrophages and T cells (interleukin-2 and interleukin-6) and other growth factors, especially IL-4 and IL-5.

Quick Search

Watch "B Cells & Antibody" on YouTube to see this process animated.

1 Clonal Selection and Antigen Binding

B cells can independently recognize microbes (example here is a virus) and their foreign antigens, and can bind them with their Ig receptors. This is how the initial selection of the antigen-specific B-cell clone occurs.

2 Antigen Processing and Presentation

Once the microbe is attached, the B-cell endocytoses it, processes it into smaller protein units, and displays these on the MHC-II complex (similar to other APCs). This event readies the antigen for presentation to a specific T_H cell.

3 B-Cell/T_H-Cell Cooperation and Recognition

For most B cells to become functional, they must interact with a T helper cell that bears receptors for antigen from the same microbe. This T cell may have been activated by an APC (see figure 15.9, part A). The two cells engage in linked recognition, in which the MHC-II receptor bearing antigen on the B cell binds to both the T-cell antigen receptor and the CD4 molecule on the T cell (inset).

4 B-Cell Activation

The T cell gives off additional signals in the form of interleukins and B-cell growth factors. The linked receptors and the chemical stimuli serve to activate the B cell. Such activation signals an increase in cell metabolism, leading to cell enlargement, proliferation, and differentiation.

5-6 Clonal Expansion/Memory Cells

The activated B cell undergoes numerous mitotic divisions, which expand the clone of cells bearing this specificity and produce memory cells and plasma cells. The memory cells are persistent, long-term cells that can react with the same antigen on future exposures.

7 Plasma Cells/Antibody Synthesis

The plasma cells are short-lived, active secretory cells that synthesize and release antibodies. These antibodies (here IgM) have the same specificity as the Ig receptor and circulate in the fluid compartments of the body, where they react with the same antigens and microbes shown in step 1.

Process Figure 15.13 Events in B-cell activation and antibody synthesis. These steps are tied to the numbered text. Only key receptors for these reactions are shown in the inset.

3. The combination of these stimuli on the membrane receptors causes a signal to be transmitted internally to the B-cell nucleus.
4. These events trigger B-cell activation. An activated B cell—referred to as a *lymphoblast*—enlarges and increases its synthesis of DNA and protein in preparation for entering the cell cycle and mitosis.
- 5–6. **Clonal expansion.** The stimulated B cell multiplies through successive mitotic divisions and produces a large population of genetically identical daughter cells. Some cells that stop short of becoming fully differentiated are **memory cells**, which remain for long periods to react with that same antigen at a later time. This reaction also expands the clone size, so that subsequent exposure to that antigen provides more cells with that specificity. This expansion of the clone size is one factor in the increased memory response. The more numerous progeny are large, specialized, terminally differentiated B cells called **plasma cells**.
7. **Antibody production and secretion.** The primary action of plasma cells is to secrete copious amounts of antibodies with the same specificity as the original receptor into the surrounding tissues (**figure 15.13, #7**). Although an individual plasma cell can produce around 2,000 antibodies per second, production does not continue indefinitely. The plasma cells do not survive for long, and they deteriorate after they have synthesized antibodies.

Products of B Lymphocytes: Antibody Structure and Functions

Earlier we saw that a basic **immunoglobulin (Ig)**⁴ molecule

4. *Ig* is a shorthand term. Immunoglobulins are proteins found in the globulin fraction of the serum and have immune function as antibodies.

contains four polypeptide chains connected by disulfide bonds. Because antibodies are a type of immunoglobulin, they all feature this same basic structure. Let us review it using an IgG molecule as a model. Two functionally distinct segments called *fragments* can be differentiated. The two “arms” that bind antigen are termed **antigen binding fragments (Fabs)**, and the rest of the molecule is the **crystallizable fragment (Fc)**, so called because it can be crystallized in pure form. The amino-terminal end of each antigen binding fragment (consisting of the variable regions of the heavy and light chains) folds into a groove that will accommodate one epitope of the antigen. The presence of a special hinge region at the site of attachment between the Fabs and the Fc allows swiveling of the Fabs. In this way, they can change their angle to accommodate nearby antigen sites that vary slightly in distance and position. The Fc portion is involved in binding to various cells and molecules of the immune system itself. **Figure 15.14** shows two views of antibody structure.

Antibody-Antigen Interactions and the Function of the Fab The site on the antibody where the antigenic determinant binds is composed of *hypervariable regions* with an extremely variable amino acid content. The groove of this antigen binding site has a specific three-dimensional fit for the antigen (**figure 15.15**). The specificity of antigen binding sites for antigens is very similar to enzymes and substrates, and some antibodies have been used as enzymes. So specific are some immunoglobulins for antigen that they can distinguish between a single functional group of a few atoms. Because the specificity of the two Fab sites is identical for each antigen, an Ig molecule can bind antigenic determinants on the same cell or on two separate cells and thereby link them.

The principal activity of secreted antibodies is to unite with, immobilize, call attention to, or neutralize the antigen that initiated

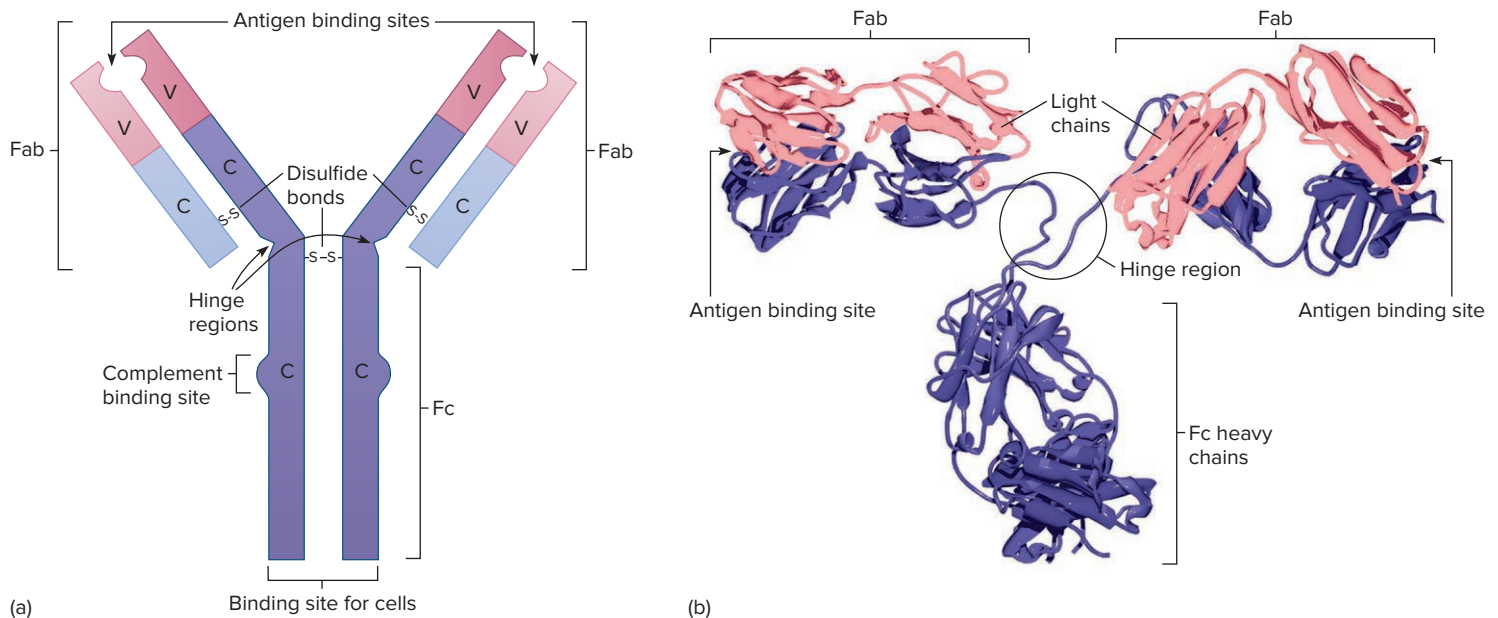

Figure 15.14 Working models of antibody structure. (a) Diagrammatic view of IgG depicts the principal regions (Fabs and Fc) of the molecule. Note that the Fabs can swivel at the hinge region and provide flexibility in position. (b) Three-dimensional model of immunoglobulin shows the tertiary and quaternary structure achieved by intrachain and interchain bonds and the positioning of the light- and heavy-chain components. (b): Source: Dr. Timothy Vickers

Figure 15.15 Antigen-antibody binding. The union of antibody (Ab) and antigen (Ag) is characterized by a certain degree of fit and is supported by a multitude of weak linkages, especially hydrogen bonds and electrostatic attraction. A better fit (i.e., antigen in **(a)** vs antigen in **(c)**) provides greater lymphocyte stimulation during the activation stage.

the antibody's formation (**figure 15.16**). Antibodies called opsonins stimulate **opsonization**,* a process in which microorganisms or other particles are coated with specific antibodies so that they will be more readily recognized by phagocytes, which dispose of them. Opsonization has been likened to putting handles on a slippery object to provide a better grip.

Antibodies can aggregate or **agglutinate** cells by cross-linking them into large clumps. Agglutination renders microbes immobile and enhances their phagocytosis. **Precipitation** is a similar reaction

that occurs with small free antigen molecules. Both processes provide a basis for certain immune tests discussed in chapter 17. The interaction of an antibody with complement can result in the specific rupturing of cells and some viruses. This is seen in complement fixation, which refers to the classical pathway of complement activation (see figures 14.20 and 17.13).

In **neutralization** reactions, antibodies fill the surface receptors on a virus or the active site on a bacterial protein, which prevents them from attaching to their target cells. **Antitoxins** are special types of antibodies that neutralize bacterial exotoxins. It should be noted that not all antibodies are protective; some neither benefit nor harm, and a few, such as autoantibodies and those originating from allergic reactions, can actually cause diseases.

* *opsonization* (awp'-son-uh-zay'-shun) L., *opsonium*, food or provisions, and *izare*, to become.

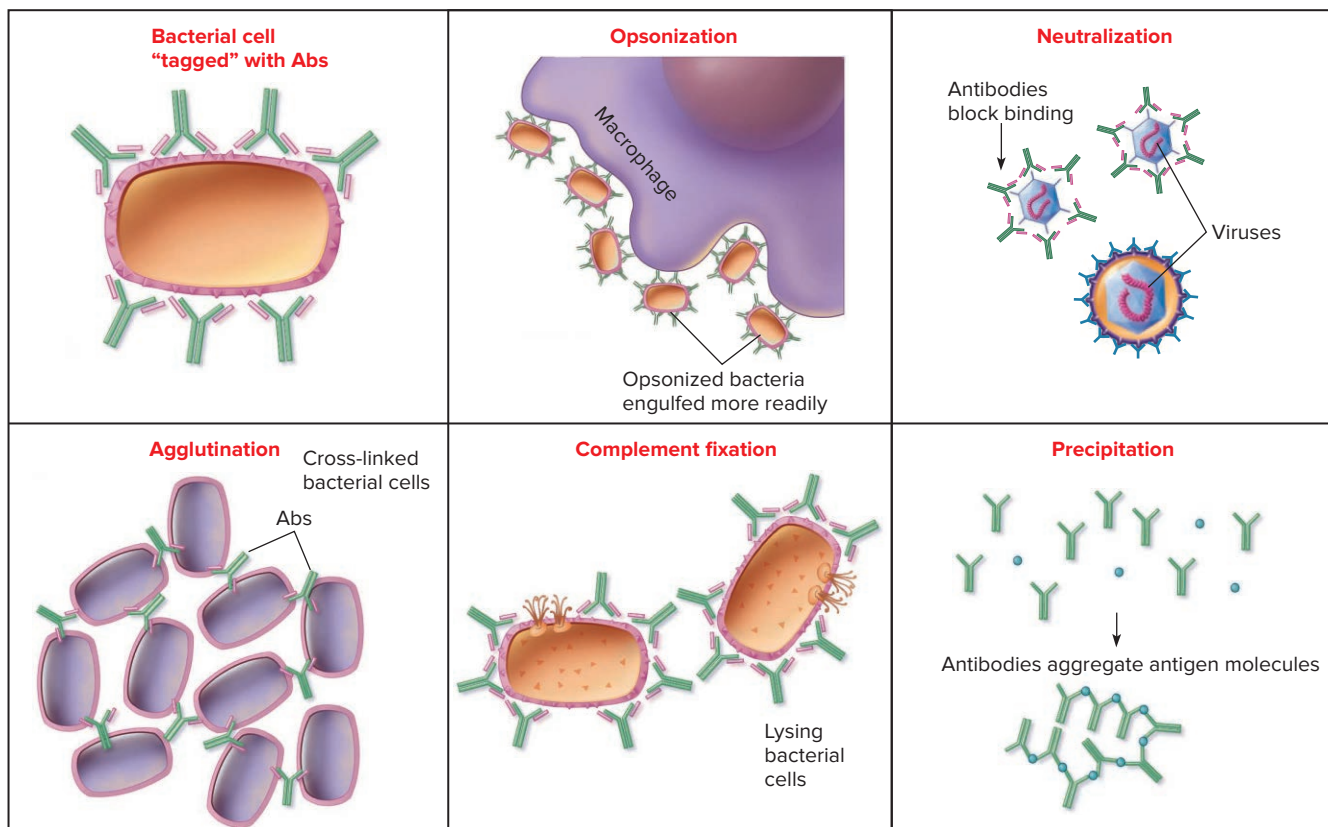

Figure 15.16 Summary of antibody functions. Complement fixation, agglutination, and precipitation are covered further in chapter 17.

Functions of the Crystallizable Fragment Although the Fabs bind antigen, the Fc has a different binding function. In most classes of immunoglobulin, the end of the Fc contains an effector that can bind to the membrane of cells, such as macrophages, neutrophils, eosinophils, mast cells, basophils, and lymphocytes. The effect of an antibody's Fc binding to a cell depends upon that cell's role. In the case of opsonization, the attachment of antibody to foreign cells and viruses exposes the Fcs to phagocytes.

Certain antibodies have regions on the Fc portion for fixing complement, and in some immune reactions, the binding of the Fc causes the release of cytokines. For example, the Fc end of the antibody of allergy (IgE) binds to basophils and mast cells, which causes the release of allergic mediators such as histamine. The size and amino acid composition of the Fc also determine an antibody's permeability, its distribution in the body, and its class.

Accessory Molecules on Immunoglobulins All antibodies contain molecules other than the basic polypeptides. Varying amounts of carbohydrates are affixed to the constant regions in most instances (see figure 15.14*b* and **table 15.3**). Two additional accessory molecules are the *J chain*, which helps keep the monomers of

IgA and IgM together, and the *secretory component*, which helps move IgA across mucous membranes. These proteins occur only in certain immunoglobulin classes.

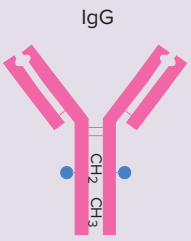

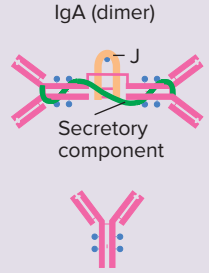

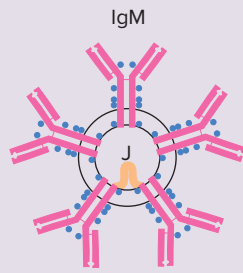

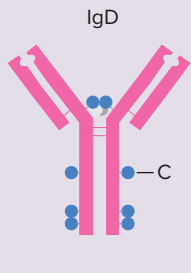

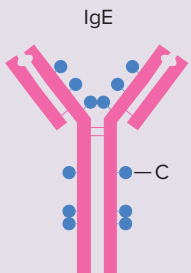

The Classes of Immunoglobulins Immunoglobulins exist as structural and functional classes called *isotypes* (compared and contrasted in table 15.3). The differences in these classes are due primarily to variations in the Fc. The classes are differentiated with shorthand names—Ig, followed by a letter: IgG, IgA, IgM, IgD, IgE.⁵

The structure of **IgG** has already been presented. It is a monomer⁶ produced by a plasma cell late in a primary response and by memory cells responding the second time to a given antigenic stimulus. It is by far the most prevalent antibody circulating throughout the blood, lymph, and extracellular fluids. It has numerous functions: It neutralizes toxins, opsonizes, and fixes complement, and it is the only antibody that crosses the placenta and provides protection to the fetus.

5. The letters correspond to the Greek letters gamma, alpha, mu, delta, and epsilon, which also refer to the distinct structures of their constant regions.

6. *Monomer* means "one unit" or "one part." Accordingly, *dimer* means "two units," *pentamer* means "five units," and *polymer* means "many units."

TABLE 15.3 Characteristics of the Immunoglobulin (Ig) Classes

					
	Monomer	Dimer, Monomer	Pentamer	Monomer	Monomer
Number of Antigen Binding Sites	2	2 or 4	10	2	2
Molecular Weight	150,000	170,000–385,000	900,000	180,000	200,000
Percentage of Total Antibody in Serum	80%	13%	6%	0.001%	0.002%
Average Life in Serum (Days)	23	6	5	3	2.5
Crosses Placenta?	Yes	No	No	No	No
Fixes Complement?	Yes	No	Yes	No	No
Binds To	Phagocytes	Epithelial cells	NA	NA	Mast cells and basophils
Biological Function	Long-term immunity; memory antibodies; neutralizes toxins, viruses	Secretory antibody; on mucous membranes	Produced at first response to antigen; can serve as B-cell receptor	Receptor on B cells for antigen recognition	Antibody of allergy; worm infections

C = carbohydrate. J = J chain.

The two forms of **IgA** are (1) a **monomer** that circulates in small amounts in the blood, and (2) a **dimer** that is a significant component of the mucous and serous secretions of the salivary glands, intestine, nasal membrane, breast, lung, and genitourinary tract. The dimer, called secretory IgA, is formed in a plasma cell by two monomers held together by a J chain. To facilitate the transport of IgA across membranes, a secretory piece is later added by the epithelial cells of the mucosa. IgA coats the surface of these membranes and appears free in saliva, tears, colostrum, and mucus. It confers essential local immunity against enteric, respiratory, and genitourinary pathogens by excluding foreign intruders on mucosal membranes. Its contribution in protecting newborns who derive it passively from nursing is the focus of Clinical Connections.

IgM is a huge molecule composed of five monomers (making it a pentamer) attached by the Fc portions to a central J chain. With its 10 binding sites, this molecule has tremendous capacity for binding antigen. IgM is the first class synthesized following the host's first encounter with antigen. Its ability to agglutinate and fix *complement* make it an important antibody in many immune reactions. It circulates mainly in the blood and is far too large to cross the placental barrier.

IgD is a monomer found in minuscule amounts in the serum, and it does not fix complement, opsonize, or cross the placenta. Its main function is to serve as a receptor for antigen on B cells, usually along with IgM, and it is the triggering molecule for B-cell activation.

IgE is also a less common blood component unless one is allergic or has a parasitic worm infection. Its Fc region interacts with receptors on mast cells and basophils. Its biological significance is to stimulate an inflammatory response through the release of potent physiological

substances by the basophils and mast cells. Because inflammation would enlist blood cells such as eosinophils and lymphocytes to the site of infection, it would certainly be one defense against parasites. Unfortunately, IgE has another, more insidious effect—that of mediating anaphylaxis, asthma, and certain other allergies (see chapter 16).

Evidence of Antibodies in Serum

Regardless of the site where antibodies are first secreted, a large quantity eventually ends up in the blood by way of the body's communicating networks. If one subjects a sample of **antiserum** (serum containing specific antibodies) to electrophoresis, the major groups of proteins migrate in a pattern consistent with their mobility and size. The albumins show up in one band, and the globulins in four bands called alpha-1 (α_1), alpha-2 (α_2), beta (β), and gamma (γ) globulins. Most of the globulins represent antibodies, which explains how the term *immunoglobulin* was derived. **Gamma globulin** is composed primarily of IgG, whereas β and α_2 globulins are a mixture of IgG, IgA, and IgM.

Monitoring Antibody Production over Time: Primary and Secondary Responses to Antigens

We can learn a great deal about how the immune system reacts to an antigen by studying the levels of antibodies in serum over time (**figure 15.17**). This level is expressed quantitatively as the **titer**,⁷ or

7. **Titer** (ty'-tur) Fr. *titre*, standard. One method for determining titer is shown in figure 17.9.

Figure 15.17 A graphic view of the primary and secondary immune responses to antigenic stimuli. Monitoring the antibody titer or concentration throughout the initial (primary) response and the second (secondary) response produces a distinct pattern. Note that the anamnestic response yields an amount of antibody that is nearly 1,000 times that of the primary response (the scale is logarithmic). This in effect “boosts” this defense to even more effective levels.

concentration, of antibodies. Upon the first exposure to an antigen or immunogen, the system undergoes a **primary response**. The earliest part of this response, the *latent period*, is marked by a lack of antibodies for that antigen, but much activity is occurring. During this time, the antigen is being concentrated in lymphoid tissue and is being processed by the correct clones of B lymphocytes. As plasma cells synthesize antibodies, the serum titer increases to a certain plateau and then tapers off to a low level over a few weeks or months.

When the class of antibodies produced during this response is tested, an important characteristic of the response is uncovered. It turns out that, early in the primary response, most of the antibodies are the IgM type, which is the first class to be secreted by plasma cells. Later, the class of the antibodies (but not their specificity) is switched to IgG or some other class (IgA or IgE).

When the immune system is exposed again to the same antigen or immunogen within weeks, months, or even years, a **secondary response** occurs. The rate of antibody synthesis, the peak titer, and the length of antibody persistence are greatly increased over the primary response. The rapidity and amplification seen in this response are attributable to the memory B cells that were formed during the primary response. Because of its association with recall, the secondary response is also called the **anamnestic* response**. The recall effect shortens the latent or lag period and yields a faster, stronger, and longer-lasting antibody response. The main factors in creating the anamnestic effect are that the memory B cells do not have to go through the early steps in activation, and they do not require as many signals to form plasma cells.

The advantage of this response is evident: It provides a quick and potent strike against subsequent exposures to infectious agents. This memory effect is the fundamental basis for **vaccine boosters**, which we discuss in section 15.6.

Monoclonal Antibodies: Useful Products from Cancer Cells

The value of antibodies as tools for locating or identifying antigens is well established. For many years, antiserum extracted from human or animal blood was the main source of antibodies for tests and therapy, but most antiserum has a basic problem. It contains **polyclonal antibodies**, meaning that it is a mixture of different antibodies because it reflects dozens of immune reactions from a wide variety of B-cell clones. This characteristic is to be expected, because several immune reactions may be occurring simultaneously; and even a single species of microbe can induce several different types of antibodies. Certain applications in immunology require a pure preparation of **monoclonal antibodies (MABs)** that originate from a single clone and have a single specificity for antigen. The development of human MABs and other novel approaches using genetic engineering are being widely pursued by pharmaceutical companies (**15.1 Making Connections**).

15.5 A Classification Scheme for Specific, Acquired Immunities

Expected Learning Outcomes

- Outline the major categories of adaptive immunity.
- Differentiate between natural and artificial immunities and between active and passive immunities.
- Expand on the four combinations of the defining categories, using examples.

Humans develop their adaptive immunity by several general routes, as summarized in **figure 15.18**. These categories are based on the source of the immunity and whether the protection is produced by one's own immune system or whether it is received from another person. This classification system is a useful medical guide that can rapidly identify and explain the sources of immunity.

Defining Categories by Mode of Acquisition

Active immunity occurs when an individual receives an immune stimulus (microbe) that activates specific lymphocytes, causing an immune response such as production of antibodies. Active immunity is marked by several characteristics: (1) it is an essential attribute of an immunocompetent individual; (2) it creates a memory that renders the person ready for quick action upon reexposure to that same microbe; (3) it requires several days to develop; and (4) it can last for a relatively long time, sometimes for life. Active immunity can be stimulated by natural or artificial means.

Passive immunity occurs when an individual receives immune substances (primarily antibodies) that were produced actively by the immune system of another human or animal donor. Recipients are protected for a time even though they have not had actual exposure to the microbe. It is characterized by (1) lack of memory for the original antigen, (2) no production of new antibodies against that disease, (3) immediate onset of protection, and

* *anamnestic* (an-am-ness'-tik) Gr. *anamnesis*, a recalling.

15.1 MAKING CONNECTIONS

Of Mice and MABs?

The technology for producing monoclonal antibodies began with the discovery that tumors isolated from multiple myelomas in mice consist of identical plasma cells. These monoclonal plasma cells secrete a strikingly pure form of antibodies with a single specificity and continue to divide indefinitely. Immunologists recognized the potential in these plasma cells and devised a **hybridoma** approach to creating **monoclonal antibodies (MABs)**. The basic idea behind this approach is to hybridize or fuse a **myeloma*** cell with a normal plasma cell from a mouse spleen to create an immortal cell that secretes a supply of functional antibodies with a single specificity. Most new technologies for making the hybridomas involve transgenic mice that have been engineered with a complete human immune system. This ensures that the antibodies made from the hybridoma contain no mouse immunoglobulin and will be less likely to cause adverse reactions to the mouse proteins.

This technology is being used for a wide variety of biomedical applications. Monoclonal antibodies have provided immunologists with excellent standardized tools for studying the immune system and for expanding disease diagnosis and treatment. Many of the successful applications thus far use MABs for diagnostic testing and research.

Monoclonals can be complexed with plant or bacterial toxins to form immunotoxins that attach to a target cell and poison it. The most exciting prospect of this therapy is that it can target a specified cancer cell and not normal cells. This type of monoclonal is currently employed in treatment of breast and colon cancers. Drugs such as Rituxan and Herceptin bind to cancer cells and trigger their death.

Pharmaceutical companies have created over 300 MABs as potential therapeutic agents. As of this date, about 70 are in use in some form of treatment, mainly for cancer and diseases caused by immune disorders such as allergies and autoimmunity. See **table 15.A** for examples of these drugs.

* **myeloma** (my-uh-loh'-muh) Gr. *myelos*, marrow, and *oma*, tumor. A malignancy of the bone marrow.

TABLE 15.A Selected Monoclonal Antibody–Based Drugs

Drug Names (Chemical and Trade)	Used in Therapy for	
Cancer Drugs		
Trastuzumab	Herceptin	Breast cancer
Rituximab	Rituxan	B-cell disorders (lymphomas, leukemias)
Alemtuzumab	Campath	Chronic T-cell leukemia and lymphoma
Pembrolizumab	Keytruda	Metastatic melanoma and lung cancer
Other Applications		
Omalizumab	Xolair	Asthma
Vedolizumab	Entyvio	Ulcerative colitis
Infliximab	Remicade	Crohn's disease
Palivizumab	Synagis	Respiratory syncytial virus (RSV)
Adalimumab	Humira	Rheumatoid arthritis, psoriasis

Note that the chemical names are coded to end in *mab*—short for monoclonal antibody.

What would be the major drawback to using monoclonal antibodies that are made using a mouse that is not genetically engineered to have a human immune system? Answer available on Connect.

Summary of the technique for producing monoclonal antibodies by hybridizing myeloma tumor cells with normal plasma cells. Newer MABs take advantage of mice that have been genetically engineered to develop a human immune system.

(a) A mouse is inoculated with an antigen having the desired specificity, and activated plasma cells are isolated from its spleen. Myeloma cells are cultured from a different mouse that has this cancer.

(b) The two cell populations are mixed with polyethylene glycol, which causes some cells in the mixture to fuse and form hybridomas.

(c) Surviving cells are cultured and separated into individual wells. Tests are performed on each hybridoma to determine the specificity of the antibody (Ab) it secretes.

(d) The hybridoma is maintained in a susceptible mouse for future use. A hybridoma with the desired specificity is grown in cell culture. Antibody product is isolated and purified.

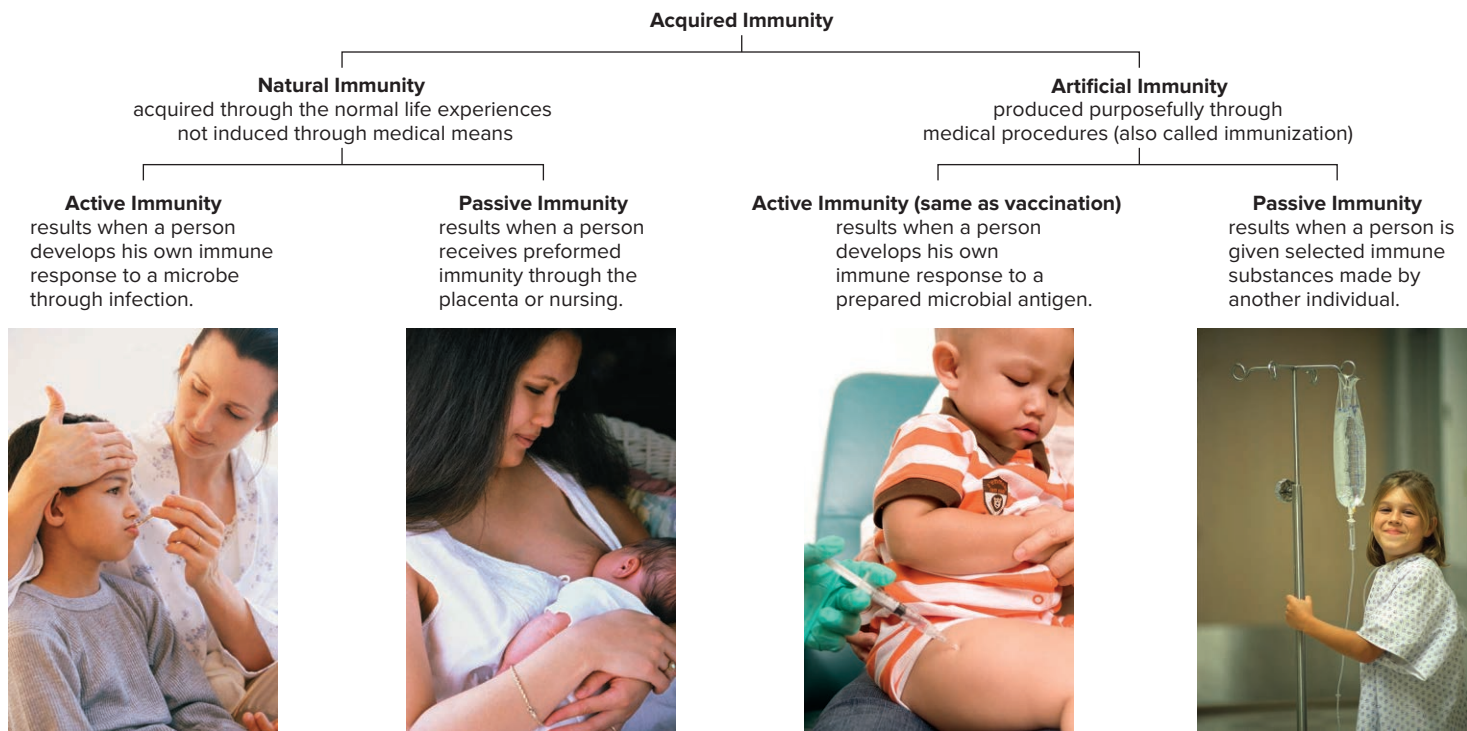

Figure 15.18 Categories of acquired immunities. Natural immunities, which occur during the normal course of life, are either active (acquired from an infection and then recovering) or passive (antibodies donated by the mother to her child). Artificial immunities are acquired through medical practices and can be active (vaccinations with antigen, to stimulate an immune response) or passive (immune therapy with a serum containing antibodies). (4) short-term effectiveness because antibodies have a limited period of function. Ultimately, the recipient's body disposes of them. Passive immunity can also be natural or artificial in origin.

Natural immunity encompasses immunity that is acquired during any normal biological experiences of an individual but not through medical intervention.

Artificial immunity is protection from infection obtained through medical procedures. This type of immunity is induced by immunization with vaccines and immune serum.

Putting together all combinations of these categories, we arrive at four possible examples of origins of immunity.

1. Natural Active Immunity: Getting an Infection

After recovering from infectious disease, a person may be actively resistant to reinfection for a period that varies according to the disease. In the case of childhood viral infections such as measles, mumps, and rubella, this natural active stimulus provides nearly lifelong immunity. Other diseases result in a less extended immunity of a few months to years (such as pneumococcal pneumonia and shigellosis), and reinfection is possible. Even a subclinical infection can stimulate natural active immunity. This probably accounts for the fact that some people are immune to an infectious agent without ever having been noticeably infected with or vaccinated for it.

2. Natural Passive Immunity: Mother to Child

Natural, passively acquired immunity occurs as a result of the prenatal and postnatal, mother-child relationship. During fetal life, IgG

antibodies circulating in the maternal bloodstream are small enough to pass or be actively transported across the placenta. Antibodies against tetanus, diphtheria, pertussis, and several viruses regularly cross the placenta. This natural mechanism provides an infant with a mixture of many maternal antibodies that can protect it for the first few critical months outside the womb, while its own immune system is gradually developing active immunity. Depending upon the microbe, passive protection lasts anywhere from a few months to a year, but it eventually wanes. Most childhood vaccinations are timed so that there is no lapse in protection against common childhood infections.

Another source of natural passive immunity comes to the baby by way of mother's milk (**Clinical Connections**). Although the human infant acquires most natural passive immunity in utero and some through nursing, the milk-borne antibodies provide IgA antibodies that react against microbes entering the intestine. This unique protection is not available from transplacental antibodies.

Artificial Immunity: Immunization

Immunization is any clinical process that produces immunity in a subject. Because it is often used to give advance protection against infection, it is also called *immunoprophylaxis*. The details of this form of immunity are presented in section 15.6.

3. Artificial Active Immunization: Vaccination

The term *vaccination* originated from the Latin word *vacca* (cow), because the cowpox virus was used in the first preparation for active immunization against smallpox (see 15.2 Making Connections). Vaccination exposes a person to a specially prepared

CLINICAL CONNECTIONS

The Immunological Benefits of Breast-Feeding

An advertising slogan from the past claims that cow's milk is "nature's most nearly perfect food." One could go a step further and assert that human milk is nature's *perfect* food for young humans. Clearly, it is loaded with essential nutrients, not to mention being available on demand from a readily portable, hygienic container that does not require refrigeration or warming. But there is another and perhaps even greater benefit. During lactation, the breast becomes a site for the proliferation of lymphocytes that produce IgA antibodies that protect the mucosal surfaces from local invasion by microbes.

The very earliest secretion of the breast, a thin, yellow milk called **colostrum**, is very high in these antibodies. They form a protective coating in the gastrointestinal tract of a nursing infant that guards against infection by a number of enteric pathogens (*Escherichia coli*, *Salmonella*, poliovirus, rotavirus). Protection at this level is especially critical because an infant's own antibodies and natural intestinal barriers are not yet developed. As with immunity in utero, the necessary antibodies will be donated only if the mother herself has active immunity to the microbe through a prior infection or vaccination.

A critical benefit of breast-feeding that has not been given adequate credit is the connection between nursing, the breast microbiome, and

International symbol for breast feeding

Courtesy <http://www.mothing.com/articles/the-international-breastfeeding-symbol/> Artist Matt Daigle

the neonatal microbiome. For many years milk was thought to be sterile unless the mother's breasts were infected. Now we know from studies on the human microbiome that breast milk and tissues harbor a diverse bacterial community that is distinct from that of the skin or the mouth. This discovery acknowledges that, in addition to its nutritional and immunological support, breast milk is an important early source of microbes that populate the newborn intestine and other body sites. A related function of the breast microbiome could be to supply bacterial stimuli for the continuing development of the baby's immune system.

For a number of years, the ready availability of artificial formulas and the changing lifestyles of women have reduced the incidence of breast-feeding. According to UNICEF, only about 38% of mothers worldwide breast-feed their babies for 6 months or more. Where adequate hygiene and medical care prevail, bottle-fed infants get through the critical period with few problems because the foods given them are relatively free of pathogens and they have received protection against some childhood infections in utero. Mothers in developing countries with untreated water supplies or poor medical services are strongly discouraged from using prepared formulas, because they can actually inoculate the baby's intestine with pathogens from the formula. Millions of neonates suffer from severe and life-threatening diarrhea that could have been prevented by sustained breast-feeding. The use of formula has been so damaging to infant health that the World Health Organization issued an *International Code on the Marketing of Breast Milk Substitutes*, discouraging the use of formula in the developing world.

Explain the reasons donated antibodies (either placental or in breast milk) are only a temporary protection. Answer available on Connect.

microbial (antigenic) stimulus, which then triggers the immune system to produce antibodies and memory cells to protect the person upon future exposure to that microbe. As with natural active immunity, the degree and length of protection vary. Commercial vaccines are currently available for many diseases (see table 15.5).

4. Artificial Passive Immunization: Immunotherapy

In immunotherapy, a patient at risk for acquiring a particular infection is administered a preparation that contains specific antibodies against that infectious agent. Pooled human serum from donor blood (gamma globulin) and immune serum globulins containing high quantities of antibodies are the usual sources. Immune serum globulins are used to protect people who have been exposed to certain diseases such as hepatitis A, rabies, and tetanus.

Check Your Progress SECTION 15.5

28. Contrast active and passive immunity in terms of how each is acquired, how long it lasts, whether memory is triggered, how soon it becomes effective, and what immune cells and substances are involved.
29. Name at least two major ways in which natural and artificial immunities are different.
30. Explain why the passive transfer of T-cell immunities would be highly unlikely.

15.6 Immunization: Providing Immune Protection Through Therapy

Expected Learning Outcomes

23. Explain the purposes of immunotherapy and immunization.
24. Describe the sources and uses of artificial passive immunization and artificial active immunization or vaccination.
25. Discuss which factors are involved in vaccine development and new strategies for developing vaccines.
26. Identify the major categories of vaccine antigens, citing examples.
27. Describe the medical guidelines for vaccination, its side effects, and how it relates to herd immunity.

Methods that actively or passively immunize people are widely used in disease prevention and treatment. The use of these terms is sometimes imprecise; thus, it should be stressed that active immunization, in which a person is administered some form of antigen, is synonymous with vaccination. Passive immunization, in which a person is given antibodies, is a type of **immunotherapy**.

Artificial Passive Immunization

The first attempts at passive immunization involved the transfusion of horse serum containing antitoxins to prevent tetanus and to treat patients exposed to diphtheria. Since then, antisera from animals have been largely replaced with products of human origin that function with various degrees of specificity. **Immune serum globulin (ISG)**, sometimes called *gamma globulin*, contains immunoglobulin extracted from the pooled blood of at least 1,000 human donors. The method of processing ISG concentrates the antibodies to increase potency and eliminates potential pathogens (such as the hepatitis B and HIV viruses). It is a treatment of choice in preventing measles and hepatitis A and in replacing antibodies in immunodeficient patients. Most forms of ISG are injected intramuscularly to minimize adverse reactions, and the protection they provide lasts 2 to 3 months.

A serum product called **specific immune globulin (SIG)** is derived from a more defined group of donors. SIG preparations are made with serum from patients who are in a hyperimmune state after being vaccinated or infected by pertussis, tetanus, chickenpox, and hepatitis B. This chapter's Case Study examines how a specific antirabies immune globulin (HRIG) can be used in cases of rabies exposure. These globulins are preferable to ISG because they contain higher titers of specific antibodies obtained from a smaller pool of patients. Although useful for prophylaxis in persons who may be exposed to infectious agents, these sera can be limited in availability.

When a human immune globulin is not available, antisera and antitoxins of animal origin can be effective. Sera produced in horses are available for diphtheria, botulism, rabies, and spider and snake bites. Unfortunately, horse antigens often stimulate allergies such as serum sickness or anaphylaxis (chapter 16). With the development of monoclonal therapies, many of these older sources will be replaced by pure antibody drugs that have been tailored to just one specific pathogen. Although all of these passive immunities only last a relatively short time, they act immediately and can protect patients for whom no other useful medication or vaccine exists, such as immunocompromised patients who cannot be vaccinated.

Artificial Active Immunity: Vaccination

Active immunity can be conferred artificially by **vaccination**—exposing a person to material that is immunogenic but not pathogenic. The discovery of vaccination was one of the farthest-reaching and most important developments in medical science (**15.2 Making Connections**). The basic principle behind vaccination is to stimulate a primary response that primes the immune system for future exposure to a pathogen. If this pathogen enters the body, the secondary immune response will be immediate, powerful, and sustained. Second or additional doses of vaccines can also stimulate the anamnestic response.

Vaccines have profoundly reduced the prevalence and impact of many infectious diseases that were once common and often deadly. In this section, we survey the principles of vaccine preparation and important considerations surrounding vaccine indication and safety. Vaccines are also given specific consideration in later chapters on infectious diseases and organ systems.

Principles of Vaccine Preparation

A vaccine must be considered from the standpoints of immunogen selection, effectiveness, ease in administration, safety, and cost. In natural immunity, an infectious agent stimulates a relatively long-term protective response. In artificial active immunity, the objective is to obtain this same response with a modified version of the microbe or its components. Most vaccine preparations are based on one of the following antigen preparations (**figure 15.19**):

1. killed whole cells or inactivated viruses;
2. live, attenuated bacterial cells or viruses;
3. antigenic molecules derived from bacterial cells or viruses; or
4. genetically engineered microbes or microbial antigens.

The main qualities of an effective vaccine are listed in **table 15.4**.

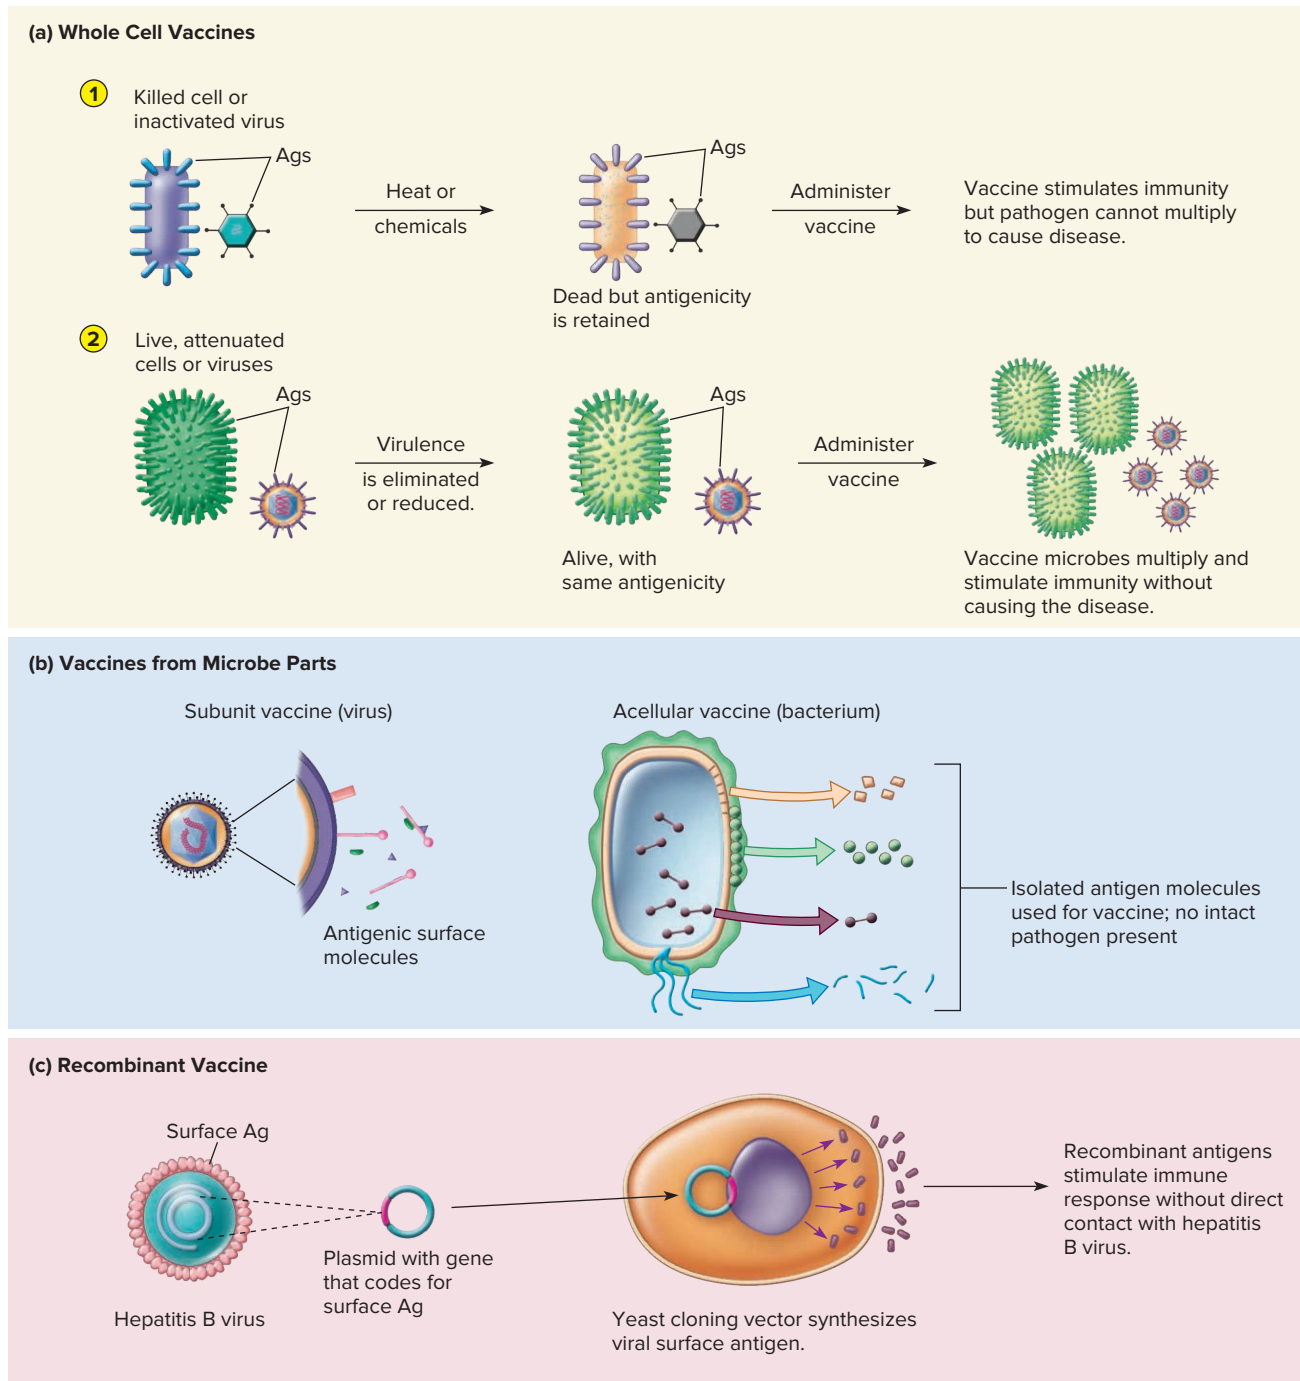

Large, complex antigens such as whole cells or viruses are very effective immunogens. Depending on the vaccine, these are either killed or attenuated. **Killed or inactivated vaccines** are prepared by cultivating the desired strain or strains of a bacterium or virus and treating them with formalin, radiation, heat, or some other agent that kills the microbe but does not change its antigenic structure. One type of vaccine for the bacterial disease cholera is of this type. The IPV polio vaccine and some forms of influenza vaccine contain inactivated viruses. Because the microbe does not multiply, killed vaccines often require a larger dose and more boosters to be effective.

A number of vaccines are prepared from **attenuated** microbes. Attenuation is any process that substantially lessens or negates the virulence of viruses or bacteria. It is usually achieved by modifying the growth conditions or manipulating microbial genes in a way that eliminates virulence factors. Attenuation methods include long-term cultivation, selection of mutant strains that grow at colder temperatures (cold mutants), passage of the microbe through unnatural hosts or tissue culture, and removal of virulence genes. The vaccine for tuberculosis (BCG) was obtained after 13 years of subculturing the agent of bovine tuberculosis. Vaccines for measles, mumps, polio (oral vaccine), and rubella contain active, non-virulent viruses. The primary advantages of these preparations are that (1) viable microorganisms can multiply and produce infection (but not disease) like the natural organism, (2) they confer long-lasting protection, and (3) they usually require fewer doses and boosters than other types of vaccines.

Disadvantages of using live microbes in vaccines are that they require special storage facilities, can be transmitted to other people, and can conceivably mutate back to a virulent strain.

If the exact antigenic determinants that stimulate immunity are known, these substances can be isolated from microorganisms and serve as the basis for a vaccine (**figure 15.19b**). Vaccines made from bacterial cell parts are called **acellular** or **subcellular vaccines**. If isolated from viruses, they are called **subunit vaccines**. The antigen used in these vaccines may be extracted from cultures of the microbes, produced by genetic engineering, or synthesized chemically.

Examples of extracted antigens currently in use are the capsules of the pneumococcus and meningococcus, the protein surface antigen of anthrax, and the surface proteins of hepatitis B virus. A

Process Figure 15.19 Strategies in vaccine design. (a) Whole cells or viruses, killed or attenuated. (b) Acellular or subunit vaccines are made by disrupting the virus or cell to release antigenic molecules or components that can be isolated and purified. (c) Recombinant vaccines are made by isolating a gene for the antigen from the pathogen (here a hepatitis virus) and splicing it into a plasmid. Insertion of the recombinant plasmid into a cloning host (yeast) results in the production of large amounts of viral surface antigen to use in vaccine preparation.

special type of vaccine is the **toxoid**, which consists of a purified fragment of bacterial exotoxin that has been inactivated. By eliciting the production of antitoxins that can neutralize the natural toxin, toxoid vaccines provide protection against toxinoses such as diphtheria and tetanus.

A survey of major licensed vaccines and their indications is presented in **table 15.5**.

Development of New Vaccines

Despite considerable successes, dozens of bacterial, viral, protozoan, and fungal diseases still remain without a functional vaccine. At the present time, no reliable vaccines are available for malaria, HIV/AIDS, various diarrheal diseases (*E. coli*, *Shigella*), a number of respiratory diseases, and worm infections, which affect over

15.2 MAKING CONNECTIONS

The Lively History of Active Immunization

The basic notion of immunization has existed for thousands of years. It probably stemmed from the observation that persons who had recovered from certain communicable diseases rarely, if ever, got a second case of it. The earliest crude vaccination attempts involved bringing a susceptible person into contact with a diseased person or animal. The first recorded attempt occurred in sixth-century China. It consisted of drying and grinding up smallpox scabs and blowing them with a straw into the nostrils of vulnerable family members.

By the tenth century, this practice had changed to the deliberate inoculation of dried pus from the smallpox pustules of one patient into the arm of a healthy person, a technique later called **variolation** (variola is the smallpox virus). This method was used in parts of Asia for centuries before it was first brought to England in 1721. Although the principles of the technique had some merit, unfortunately many recipients and their contacts died of smallpox. This outcome vividly demonstrates a cardinal rule for a workable vaccine: It must contain an antigen that will provide protection but not cause the disease. Variolation was so controversial that any English practitioner caught doing it was charged with a felony.

Eventually this human experimentation paved the way for the first really effective vaccine, developed by the English physician Edward Jenner in 1796. Jenner conducted the first scientific test of a vaccine, one that had a tremendous impact on the advance of medicine. His work gave rise to the words *vaccine* and *vaccination* (from L., *vacca*, cow), which now apply to any immunity obtained by inoculation with selected antigens. Jenner was inspired by the case of a milkmaid who had been infected by a pustular infection called cowpox. This related virus afflicts cattle but causes a milder condition in humans. She explained that she and other milkmaids had remained free of smallpox. To test the effectiveness of this cross protection, Jenner prepared material from human cowpox lesions and inoculated a young boy. When challenged 2 months later with an injection of crusts from a smallpox patient, the boy was immune to it.

Jenner's discovery—that a less pathogenic agent could confer protection against a more pathogenic one—is especially remarkable in view of the fact that microscopy was still in its infancy and the nature of viruses was unknown. When Jenner's method proved successful and word of its significance spread, it was eventually adopted in many other countries. Eventually the original virus mutated into a unique strain

A modern setup for smallpox vaccination; note the two-pronged needle used to scratch the vaccine into the skin. Source: James Gathany/CDC

(*vaccinia* virus) that became the basis of the current vaccine. In 1979 the World Health Organization declared that smallpox had been eradicated. As a result, smallpox vaccination had been discontinued until recently, due to the threat of bioterrorism.

Other historical developments in vaccination included using heat-killed bacteria in vaccines for typhoid fever, cholera, and plague, and techniques for using neutralized toxins for diphtheria and tetanus. Throughout the history of vaccination, there have been vocal opponents and minimizers, but one fact seems clear: Whenever a vaccine has been introduced, the prevalence of that disease has declined dramatically (look back at figure 1.10). The number of cases of childhood diseases such as diphtheria, measles, mumps, rubella, and polio have declined 98% to 100% when compared to the numbers reported for these diseases prior to the development of vaccines.

Using principles of immunology, explain how a vaccine based on one type of microbe (*vaccinia*) could produce an effective immunity to a different microbe (*variola*). Answer available on Connect.

TABLE 15.4 Checklist of Requirements for an Effective Vaccine

- It should have a low level of adverse side effects or toxicity and not cause serious harm.
- It should protect against exposure to natural, wild forms of pathogen.
- It should stimulate both antibody (B-cell) response and cell-mediated (T-cell) response.
- It should have long-term, lasting effects (produce memory cells).
- It should work with minimal doses or boosters.
- It should be inexpensive, have a relatively long shelf life, and be easy to administer.

200 million people per year worldwide. Of all of the challenges facing vaccine specialists, probably the most difficult has been choosing a vaccine antigen that is safe and that properly stimulates immunity. Currently much attention is being focused on newer strategies for vaccine preparation that employ antigen synthesis, recombinant DNA, and gene cloning technology.

When the exact composition of an antigenic determinant is known, it is sometimes possible to artificially synthesize it. This ability permits preservation of antigenicity while greatly increasing antigen purity and concentration. A malaria vaccine currently being tested in areas of South America and Africa is composed of three synthetic peptides from the parasite. One candidate has been carried through 4 trial phases and is currently awaiting approval.

TABLE 15.5 Vaccines Currently Licensed in the United States

Disease/Vaccine Preparation	Trade Names	Recommended Usage/Comments
Contain live, attenuated bacteria		
Tuberculosis	BCG	For high-risk occupations only; protection variable
Typhoid	Vivotif	Mainly for travelers to endemic areas
Acellular vaccines (capsular polysaccharides or proteins)		
Anthrax	BioThrax	For protection in military recruits, occupationally exposed
Meningitis (meningococcal)**	Menactra, Menomune, Trumenba*	For protection in high-risk infants, military recruits, college students; For ages 10-25 years
Meningitis (<i>Haemophilus influenzae</i>)**	PedvaxHIB, ActHIB	For infants and children; may be administered with DTaP
Pneumococcal pneumonia	Prennar, Pneumovax	Important for people at high risk: the young, elderly, and immunocompromised; moderate protection
Toxoids (formaldehyde-inactivated bacterial exotoxins)		
Diphtheria**	Dt	Used for boosters in teens and adults (uppercase letter indicates a higher dose of this antigen)
Tetanus**	Td	Used for boosters in teens and adults
Contain inactivated whole viruses		
Hepatitis A	Havrix, Vaqta	Protection for travelers, institutionalized people
Influenza	FluLaval, Flucelvax	For high-risk populations; requires constant updating for new strains; immunity not durable
Japanese encephalitis	JE-Vax	For those residing in endemic areas, lab workers
Poliomyelitis**	IPOL (inactivated polio)	Routine childhood vaccine; preferred over live vaccine
Rabies	Imovax, RabAvert	For victims of animal bites or otherwise exposed; effective
Contain live, attenuated viruses		
Adenovirus	Nasal	For immunizing military recruits
Chickenpox (varicella)**	Varivax	Routine childhood vaccine; immunity can diminish over time
Influenza	FluMist	No longer widely used
Measles (rubeola)**	Attenuvax	Routine childhood vaccine; very effective
Mumps (parotitis)**	Mumpsvax	Routine childhood vaccine; very effective
Rotavirus (RotaTeq)	RotaTeq, Rotarix	Live oral vaccine for infants at risk for rotavirus infection
Rubella**	Meruvax	Routine childhood vaccine; very effective
Smallpox and monkeypox	Dryvax	Since 2003 offered on voluntary basis for health care workers, some military personnel
Yellow fever	YF-Vax	Travelers, military personnel in endemic areas
Subunit viral vaccines		
Hepatitis B*, **	Engerix, Recombivax	Recommended for all children, starting at birth; also for health care workers and others at risk
Human papillomavirus*	Gardasil, Cervarix	To prevent infection in girls and boys and various cancers associated with HPV that may arise in adulthood.
Combined vaccines contain antigens for two or more diseases to cut down on the number of injections		
Diphtheria, tetanus, pertussis, <i>H. influenzae</i> , type b	DTaP, Tripedia, Infanrix	Routine infant and child vaccination
Diphtheria, tetanus, pertussis,	TriHIBit	Same as above
Diphtheria, tetanus, pertussis, hepatitis B, polio	Pediarix	Routine childhood vaccination
Hepatitis B and A	Twinrix	Combination of Havrix and Recombivax given at birth, one at 6 months of age
Measles, mumps, rubella	MMR II	Recommended childhood vaccination—all attenuated viruses
Measles, mumps, rubella, chickenpox	ProQuad	Recommended childhood vaccination—all attenuated viruses

*These vaccines are made by recombinant methods.

**Usually given in combination with other vaccines.

Source of Data: Centers for Disease Control and Prevention

Several biotechnology companies are using plants to mass produce vaccine antigens. Tests are underway to grow tomatoes, potatoes, and bananas that synthesize proteins from cholera, hepatitis, papillomavirus, and *E. coli* pathogens. This strategy aims to economically harvest vaccine antigens and make vaccines for populations that otherwise would not have access to them.

Genetically Engineered Vaccines

Some of the genetic engineering concepts introduced in chapter 10 offer novel approaches to vaccine development. These methods are particularly effective in designing vaccines for obligate parasites that are difficult or expensive to culture, such as the syphilis spirochete or the malaria parasite. Recombinant DNA technology provides a means of isolating the genes that encode various microbial antigens, inserting them into plasmid vectors, and cloning them in appropriate hosts. The outcome of recombination can be as varied as desired. For instance, the cloning host can be stimulated to synthesize and secrete a protein product (antigen), which is then harvested and purified (**figure 15.19c**). Vaccines for hepatitis and human papillomavirus are currently being prepared in this way. Antigens from the agents of syphilis, *Schistosoma*, and influenza have been similarly isolated and cloned and are currently being considered as potential vaccine material.

Another technique using genetic recombination has been nicknamed the *Trojan horse* vaccine. The term derives from an ancient legend in which the Greeks sneaked soldiers into the fortress of their Trojan enemies by hiding them inside a large, mobile wooden horse. In the microbial equivalent, genetic material from a selected infectious agent is inserted into a live carrier microbe that is non-pathogenic. In theory, the recombinant microbe will multiply and express the foreign genes, and the vaccine recipient will be immunized against the microbial antigens. Vaccinia, the virus originally used to vaccinate for smallpox, and adenoviruses have proved practical agents for this technique. Vaccinia has been used as the carrier in experimental vaccines for AIDS, herpes simplex 2, leprosy, and tuberculosis.

DNA vaccines are another promising approach to immunization. The technique in these formulations is very similar to gene

therapy as described in chapter 10, except in this case, microbial (not human) DNA is inserted into a plasmid vector and inoculated into a recipient (**figure 15.20**). The expectation is that the human cells will take up some of the plasmids and express the microbial DNA in the form of proteins. Because these proteins are foreign, they will be recognized during immune surveillance and cause B and T cells to be sensitized and form memory cells. Note: Even though the DNA is from a microbe, it will not cause an immune response because the structure of the DNA molecule by itself is not highly immunogenic.

Experiments with animals have shown that these vaccines are very safe and that only a small amount of the foreign antigen need be expressed to produce effective immunity. Another advantage to this method is that any number of potential microbial proteins can be expressed, making the antigenic stimulus more complex and improving the likelihood that it will stimulate both antibody and cell-mediated immunity. At the present time, vaccines for Lyme disease, hepatitis C, herpes simplex, influenza, tuberculosis, papillomavirus, malaria, and SARS are undergoing trials.

Routes of Administration and Side Effects of Vaccines

Most vaccines are injected by subcutaneous, intramuscular, or intradermal routes. Oral vaccines are available for only a few diseases (table 15.5), but they have some distinct advantages. An oral dose of a vaccine can stimulate protection (IgA) on the mucous membrane of the portal of entry. Oral vaccines are also easier to give, more readily accepted, and well tolerated. Other methods that show promise are an intranasal vaccine delivered into the nose by aerosol or drops (FluMist for influenza, for example) and skin patches.

Some vaccines are made more effective by adding an **adjuvant**.* An adjuvant is any compound that enhances immunogenicity and prolongs antigen retention at the injection site. The adjuvant precipitates the antigen and holds it in the tissues so that it will be

* *adjuvant* (ad'-joo-vunt) L., *adjuvans*, a thing that helps or aids.

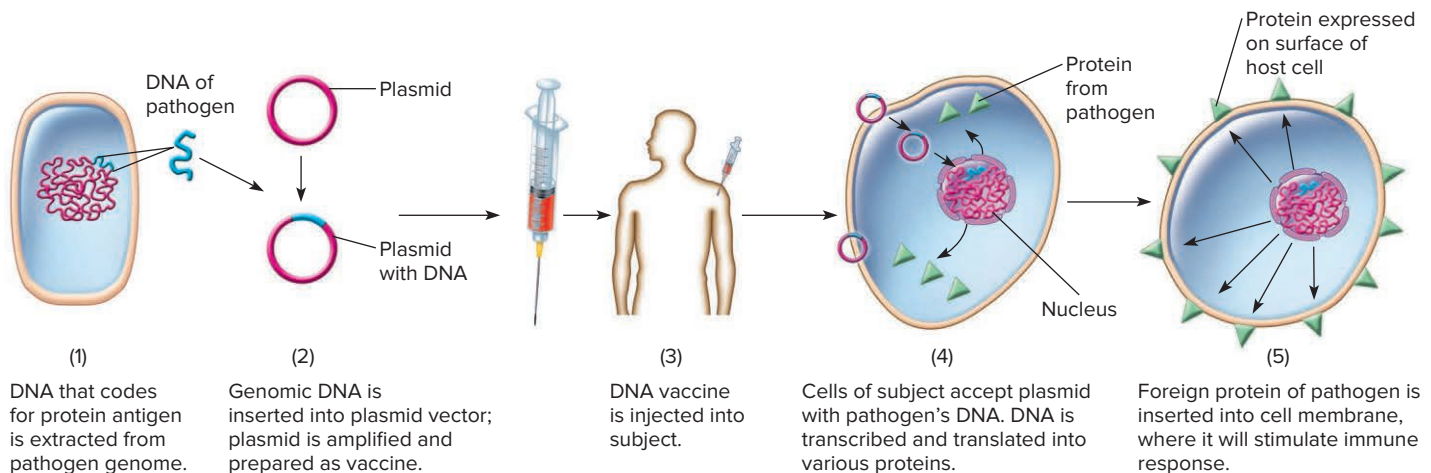

Figure 15.20 DNA vaccine preparation. DNA vaccines contain all or part of the pathogen's DNA, which is used to "infect" a recipient's cells. Processing of the DNA leads to production of an antigen protein that can stimulate a specific response against that pathogen.

released gradually. Its gradual release presumably facilitates contact with antigen-presenting cells and lymphocytes. Common adjuvants are alum (aluminum hydroxide salts), Freund's complete adjuvant (emulsion of mineral oil, water, and extracts of mycobacteria), and beeswax.

Vaccines must go through many years of trials in experimental animals and human volunteers before they are licensed for general use. Even after they have been approved, like all therapeutic products, they are not without complications. The most common of these are local reactions at the injection site, fever, allergies, and other adverse reactions. Relatively rare reactions (about one case out of 300,000 vaccinations) are panencephalitis (from measles vaccine), back-mutation to a virulent strain (from polio vaccine), disease due to contamination with dangerous viruses or chemicals, and neurological effects of unknown cause (from pertussis and swine flu vaccines). Some patients experience allergic reactions to the medium (eggs or tissue culture) rather than to vaccine antigens.

When known or suspected adverse effects have been detected, vaccines are altered or withdrawn. For example, the whole-cell pertussis vaccine was replaced by the acellular capsule (aP) form when it was associated with adverse neurological effects. The Lyme disease vaccine was withdrawn when recipients developed arthritis and other side effects. Polio vaccine was switched from live, oral to inactivated when too many cases of paralytic disease occurred from back-mutated vaccine stocks. Vaccine companies have also phased out certain preservatives, such as thimerosal, that could cause allergies and other medical problems in some patients.

Professionals involved in giving vaccinations must understand their inherent risks but also realize that the risks from the infectious disease almost always outweigh the chance of an adverse vaccine reaction. The greatest caution must be exercised in giving live vaccines to immunocompromised or pregnant patients, the latter because of possible risk to the fetus.

To Vaccinate: Why, Whom, and When?

Vaccination confers long-lasting, sometimes lifetime, protection in the individual, but an equally important effect is to protect public health. Vaccination is a proven method of establishing **herd immunity** in the population. According to this concept, individuals immune to a communicable infectious disease will not harbor it, thus reducing the occurrence of that pathogen. With a larger number of immune individuals in a population (herd),

it will be less likely that an unimmunized member of the population will encounter the agent and become infected. In effect, collective immunity through mass immunization confers indirect protection on the nonimmune members (such as children). The most effective herd immunity outcome occurs when the healthiest members are vaccinated. Because most vaccine programs target the youngest and oldest (and thus weaker) people instead, herd immunity in many populations is not complete. Herd immunity maintained through immunization is considered a valuable factor in preventing epidemics.

CLINICAL CONNECTIONS

Has Vaccination Become a Victim of Its Own Success?

Vaccination has always been considered one of humanity's triumphs, one that has made an enormous contribution to health and well-being. Most people are no longer at risk for such life-threatening diseases as tetanus, diphtheria, polio, and others. But lately, vaccination's good reputation is being tarnished. It began with a poorly designed 1998 British study that hinted at a link between autism and the MMR (mumps, measles, and rubella) vaccine. The publicity from this report spurred a controversy that led some parents to stop vaccinating their children against the usual childhood diseases. The study's results have since been thoroughly refuted, but the vaccine phobia persists. More than a dozen separate epidemiologic studies have discounted any connection between the MMR vaccine and autism, and additional studies show that the preservative thimerosal is also not correlated with autism (MMR is a live attenuated vaccine and would not contain this substance anyway). Recently the CDC reported findings of the latest in-depth study that found no correlation between vaccine type or vaccine number and the development of autism. In fact, the study identified a significant number of unvaccinated children who were diagnosed with some form of autism.

Many decisions not to vaccinate are based on misconceptions and emotion rather than science, yet consequences are being felt in some populations. Recent outbreaks of measles, mumps, meningitis, and pertussis have been tied to inadequate vaccinations. The reality is that these diseases are still around, and they pose a greater risk for young children than the possibility of a vaccine reaction. In fact, 1% of babies develop a severe brain condition from measles virus, and mumps, meningitis, and pertussis all have their own serious complications. Any reduction in vaccinations will lead to less herd immunity and create unknown pockets where children lack protection. Now more than ever before, health care workers have a responsibility to educate and counsel patients about the importance of routine immunizations for both individuals and the community.

Explain how vaccination has been responsible for the worldwide eradication of smallpox and the near elimination of polio and many other infectious diseases. *Answer available on Connect.*

Table 15.6 contains the recommended childhood and adolescent immunization schedule, categorized by age group and by medical condition. An additional table found on the CDC website at <http://www.cdc.gov/mmwr/preview/mmwrhtml/su6201a3.htm> lists the current recommended schedule for adult immunizations. Some vaccines are combination vaccines—mixtures of antigens from several pathogens as a way to decrease the number of injections given at one time (see the last listing on table 15.5). It is still common for several vaccines to be given simultaneously, as occurs in military recruits who receive as many as 15 injections within a few minutes

TABLE 15.6 Recommended Immunization Schedule for Persons Aged 0 through 18 Years—2016*

Figure 1. Recommended immunization schedule for persons aged 0 through 18 years – United States, 2016. (FOR THOSE WHO FALL BEHIND OR START LATE, SEE THE CATCH-UP SCHEDULE [FIGURE 2]).

These recommendations must be read with the footnotes that follow. For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the green bars in Figure 1. To determine minimum intervals between doses, see the catch-up schedule (Figure 2). School entry and adolescent vaccine age groups are shaded.

Vaccine	Birth	1 mo	2 mos	4 mos	6 mos	9 mos	12 mos	15 mos	18 mos	19–23 mos	2–3 yrs	4–6 yrs	7–10 yrs	11–12 yrs	13–15 yrs	16–18 yrs
Hepatitis B ¹ (HepB)	1 st dose	2 nd dose	3 rd dose		4 th dose											
Rotavirus ² (RV) RV1 (2-dose series); RV5 (3-dose series)		1 st dose	2 nd dose	See footnote 2												
Diphtheria, tetanus, & acellular pertussis ³ (DTaP; <7 yrs)		1 st dose	2 nd dose	3 rd dose	4 th dose		5 th dose									
<i>Haemophilus influenzae</i> type b ⁴ (Hib)		1 st dose	2 nd dose	3 rd dose		4 th dose		5 th dose								
Pneumococcal conjugate ⁵ (PCV13)		1 st dose	2 nd dose	3 rd dose	4 th dose		5 th dose									
Inactivated poliovirus ⁶ (IPV; <18 yrs)		1 st dose	2 nd dose	3 rd dose		4 th dose		5 th dose								
Influenza ⁷ (IIV; LAIV)				Annual vaccination (IIV only) 1 or 2 doses				Annual vaccination (LAIV or IIV) 1 or 2 doses		Annual vaccination (LAIV or IIV) 1 dose only						
Measles, mumps, rubella ⁸ (MMR)				1 st dose		2 nd dose		3 rd dose								
Varicella ⁹ (VAR)				1 st dose		2 nd dose		3 rd dose								
Hepatitis A ¹⁰ (HepA)				1 st dose		2 nd dose		3 rd dose								
Meningococcal ¹¹ (Hib-MenCY ≥6 weeks; MenACWY-D ≥9 mos; MenACWY-CRM ≥2 mos)		See footnote 11										1 st dose	Booster			
Tetanus, diphtheria, & acellular pertussis ¹² (Tdap; ≥7 yrs)													(Tdap)			
Human papillomavirus ¹³ (2vHPV: females only; 4vHPV, 9vHPV: males and females)													(3-dose series)			
Meningococcal B ¹⁴													See footnote 11			
Pneumococcal polysaccharide ⁵ (PPSV23)												See footnote 5				

This schedule includes recommendations in effect as of January 1, 2016. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Vaccination providers should consult the relevant Advisory Committee on Immunization Practices (ACIP) statement for detailed recommendations, available online at <http://www.cdc.gov/vaccines/hcp/acip-recs/index.html>. Clinically significant adverse events that follow vaccination should be reported to the Vaccine Adverse Event Reporting System (VAERS) online (<http://www.vaers.hhs.gov>) or by telephone (800-822-7967). Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for vaccination, is available from CDC online (<http://www.cdc.gov/vaccines/recs/vac-admin/contraindications.htm>) or by telephone (800-CDC-INFO [800-232-4636]). This schedule is approved by the Advisory Committee on Immunization Practices (<http://www.cdc.gov/vaccines/acip>), the American Academy of Pediatrics (<http://www.aap.org>), the American Academy of Family Physicians (<http://www.aafp.org>), and the American College of Obstetricians and Gynecologists (<http://www.acog.org>).

NOTE: The above recommendations must be read along with the footnotes of this schedule.

Source of Data: Centers for Disease Control and Prevention

and children who receive boosters for DTaP and polio at the same time they receive the MMR vaccine. Experts doubt that immune interference (inhibition of one immune response by another) is a significant problem in these instances, and the mixed vaccines are carefully balanced to prevent this eventuality. The main problem with simultaneous administration is that side effects can be amplified.

Check Your Progress SECTION 15.6

- Describe the preparation of killed vaccines; live, attenuated vaccines; subunit vaccines; recombinant vaccines; and DNA vaccines. Explain the advantages and disadvantages of
- Explain the purposes of boosters, adjuvants, Trojan horse vaccines, and toxoids.
- Describe the concept of herd immunity, and explain how vaccination contributes to its development in a community.
- List some possible adverse side effects of vaccination.

CASE STUDY Part 2

Case #1. Despite intensive medical intervention on behalf of the Canadian boy, his condition deteriorated and he died about 6 weeks after the initial bat bite. By this time the laboratory had isolated rabies virus from the skin on the back of his neck and from his saliva and tears. Genetic testing of the virus revealed that it was a variant carried by silver-haired bats. Due to the boy's contact with his family and medical personnel, it was important that they also be given a course of PEP to prevent them from contracting the disease. This meant that around 60 people were injected with HRIG and rabies vaccine. Fortunately, none of his contacts became infected.

Case #2. The Brazilian youth was one of those rare cases in which medical intervention was successful. When he first came out of the coma, he could open his eyes and

respond, and he continued to improve from that point on. By November he was well enough to return home. He was the first recorded case in Brazil to survive rabies. Tests done from skin samples detected rabies virus RNA, which was found to be a variant of the virus carried by vampire bats. One finding that may have made a difference in his case was the early presence of neutralizing antibodies that continued to increase during his hospital stay.

Rabies is a type of encephalitis in which the virus migrates by nerve cell processes from the portal of entry, enters the brain, multiplies, and causes severe inflammation and damage to brain cells. It has the distinction of being the most deadly of all infectious diseases, being considered 100% fatal once symptoms appear. Worldwide, only 10 people have ever been known to survive the disease, and most of these survivors received some treatment, as in the cases presented

here. The disease is rather rare in humans but not in certain wild mammals. About two to three human cases are reported per year in the United States, but 3,000 to 4,000 animal cases are reported. The most prevalent animal carriers are raccoons, skunks, coyotes, foxes, and bats, but the virus can infect all mammals. Infection is most likely to occur following an animal bite or scratch, although exposure to saliva and other infectious fluids has been implicated.

- Provide some likely reasons the first boy died and the second did not.
- Explain the strategy behind giving several injections of rabies vaccine.

To conclude this Case Study, go to Connect.

To read more about rabies immunization, go to <http://www.cdc.gov/rabies/exposure/index.html>.

Chapter Summary with Key Terms

15.1 Specific Immunities: The Adaptive Line of Defense

Development of Lymphocyte Specificity/Receptors Acquired immunity involves the reactions of B and T lymphocytes to foreign molecules, or **antigens**. Before they can react, each lymphocyte must undergo differentiation into its final functional type by developing protein receptors for antigen, the specificity of which is randomly generated and unique for each lymphocyte.

- A. Development of the Immune Response System
 1. Genetic recombination and mutation during embryonic and fetal development produce billions of different lymphocytes, each bearing a different receptor. The process by which diversity is generated is **clonal selection**.
 2. **Immune tolerance** or tolerance to self occurs during this time.
 3. The receptors on B cells are **immunoglobulin (Ig)** molecules, and receptors on T cells are smaller unrelated glycoprotein molecules called **CD** markers.
 4. T-cell receptors bind antigenic determinants on **MHC** molecules, which in humans are called **human leukocyte antigens (HLA)**.

15.2 The Nature of Antigens and Antigenicity

An antigen (Ag) is any substance that stimulates an immune response.

- A. Requirements for **antigenicity** include foreignness (recognition as nonself), large size, and complexity of cell or molecule.
- B. Foreign molecules less than 1,000 MW (**haptens**) are not antigenic unless attached to a larger carrier molecule.
- C. The epitope is the small molecular group of the foreign substance that is recognized by lymphocytes. Cells, viruses, and large molecules can have numerous antigenic determinants.
- D. Other antigens are mosaic alloantigens, superantigens, allergens, and autoantigens.

15.3 Immune Reactions to Antigens and the Activities of T Cells

- A. T-cell-dependent antigens must be processed by large phagocytes such as dendritic cells or macrophages called **antigen-presenting cells (APCs)**.

- B. The presentation of a single antigen involves a direct collaboration between an APC, a T helper (T_H), and an antigen-specific B or T cell.
- C. Cytokines involved are **interleukin-1** from the APC, which activates the T_H cells, and **interleukin-2** produced by the T_H cell, which activates B and other T cells.
- D. **T helper cells (T_H or CD4)** are the dominant T cells.
 1. They regulate immune reactions to antigens and require interaction with MHC-II receptors on host cells.
 2. They activate macrophages, B cells, and other T cells by means of secreted interleukins.
 - a. **T_H1** cells function as T-cell activators and stimulate delayed hypersensitivity.
 - b. **T_H2** cells modulate B-cell functions and may suppress certain undesirable T cells' actions.
- E. **Cytotoxic T cells (T_C or CD8)** are responsive to MHC-I receptors on host cells and are sometimes called killer cells.
 1. They recognize and react to foreign cells, cancer cells, and graft tissues and secrete chemicals that directly damage and kill these cells.
- F. **Natural killer cells (NK)** are T-cell relatives responsible for early killing of infected cells and cancer cells in response to various cytokines.

15.4 Immune Activities of B Cells

1. Once B cells process the antigen, interact with T_H cells, and are stimulated by B-cell growth and differentiation factors, they enter the cell cycle in preparation for mitosis and clonal expansion.
2. Divisions give rise to **plasma cells** that secrete antibodies and **memory cells** that can react to that same antigen later.
 - a. *Nature of antibodies* (immunoglobulins): A single immunoglobulin molecule (monomer) is a large Y-shaped protein molecule consisting of four polypeptide chains. It contains two identical regions with ends that form the **antigen binding fragments (Fabs)** that bind with a unique specificity to an antigen. The **crystallizable fragment (Fc)** determines the location and the function of the antibody molecule.

- b. *Antigen-antibody (Ag-Ab) reactions* include **opsonization, neutralization, agglutination**, and complement fixation.
 - c. The five **antibody or immunoglobulin classes**, which differ in size and function, are **IgG, IgA** (secretory Ab), **IgM, IgD**, and **IgE**.
3. *Antibodies in serum (antiserum)*
- a. The first introduction of an Ag to the immune system produces a **primary response**, with a gradual increase in Ab titer.
 - b. The second contact with the same Ag produces a **secondary, or anamnestic, response** due to memory cells produced during initial response.
 - c. **Monoclonal antibodies (MABs)** are pure forms of immunoglobulins produced in hybridoma cells. They may be tailored to high specificities and have numerous applications in medicine and research.

15.5 A Classification Scheme for Specific, Acquired Immunities

Immunities acquired through B and T lymphocytes can be classified by a simple system.

- A. **Active immunity** results when a person is challenged with antigen that stimulates production of antibodies. It creates memory, takes time, and is lasting.
- B. In **passive immunity**, preformed antibodies are donated to an individual. It does not create memory, acts immediately, and is short term.

- C. **Natural immunity** is acquired as part of normal life experiences.
- D. **Artificial immunity** is acquired through medical procedures such as immunization.

15.6 Immunization: Providing Immune Protection Through Therapy

- A. Passive **immunotherapy** includes administering immune serum globulin and specific immune globulins pooled from donated serum to prevent infection and disease in those at risk; antisera and antitoxins from animals are occasionally used.
- B. Active immunization is synonymous with **vaccination** and provides an antigenic stimulus that does not cause disease but can produce long-lasting, protective immunity. **Vaccines** are made with:
 1. **Killed** whole cells or **inactivated viruses** that do not reproduce but are antigenic
 2. Live, **attenuated** cells or viruses that are able to reproduce but have lost virulence
 3. **Acellular or subunit** components of microbes such as surface antigens or neutralized toxins (**toxoids**)
 4. Genetic engineering techniques, including cloning of antigens, recombinant attenuated microbes, and DNA-based vaccines
 5. Boosters (additional doses) are often required.
- C. Vaccination increases **herd immunity**, protection provided by mass immunity in a population.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

1. Which of these characteristics is not a major factor in adaptive or acquired immunity?

a. specificity	c. recognition
b. chemotaxis	d. memory
2. The primary B-cell receptor is

a. IgD	b. IgA	c. IgE	d. IgG
--------	--------	--------	--------
3. In humans, B cells mature in the _____ and T cells mature in the _____.

a. GALT, liver	c. bone marrow, thymus
b. bursa, thymus	d. lymph nodes, spleen
4. Small, simple molecules are _____ antigens.

a. poor	b. never	c. effective	d. mosaic
---------	----------	--------------	-----------
5. Which type of cell actually secretes antibodies?

a. T cell	b. macrophage	c. plasma cell	d. monocyte
-----------	---------------	----------------	-------------
6. CD4 cells are _____ cells and CD8 cells are _____ cells.

a. killer, suppressor	c. cytotoxic, helper
b. helper, cytotoxic	d. B, T
7. Helper T cells receive antigen from _____, and cytotoxic T cells receive antigen from _____.

a. macrophages, B cells	c. viruses, bacteria
b. class II MHC, class I MHC	d. class I MHC, class II MHC
8. The cross-linkage of antigenic cells by antibodies is known as

a. opsonization	c. agglutination
b. a cross-reaction	d. complement fixation
9. The greatest concentration of antibodies is found in the _____ fraction of the serum.

a. gamma globulin	c. beta globulin
b. albumin	d. alpha globulin
10. T _____ cells assist in the functions of certain B cells and other T cells.

a. sensitized	c. helper
b. cytotoxic	d. natural killer
11. Cytotoxic T cells are important in controlling

a. virus infections	c. autoimmunity
b. allergy	d. all of these
12. Vaccination is synonymous with _____ immunity.

a. natural active	c. artificial active
b. artificial passive	d. natural passive
13. Which of the following can serve as antigen-presenting cells (APCs)?

a. T cells	d. dendritic cells
b. B cells	e. b, c, and d
c. macrophages	

14. A living microbe with reduced virulence that is used for vaccination is considered
- a toxoid
 - attenuated
 - denatured
 - an adjuvant
15. A vaccine that contains parts of viruses is called
- acellular
 - recombinant
 - subunit
 - attenuated
16. Widespread immunity that protects the population from the spread of disease is called
- seropositivity
 - cross-reactivity
 - epidemic prophylaxis
 - herd immunity
17. DNA vaccines contain _____ DNA that stimulates cells to make _____ antigens.
- human, RNA
 - microbial, protein
 - human, protein
 - microbial, polysaccharide
18. What is the purpose of an adjuvant?
- to kill the microbe
 - to stop allergic reactions
 - to improve the contact between the antigen and lymphocytes
 - to make the antigen more soluble in the tissues
19. **Multiple Matching.** Place all possible matches in the spaces at the left of each Ig.
- | | |
|-----------|--|
| _____ IgG | |
| _____ IgA | |
| _____ IgD | |
| _____ IgE | |
| _____ IgM | |
20. **Multiple Matching.** An outline summarizing the general host defenses covered in chapters 14 and 15 was presented in figure 14.21. You may want to use this resource to review major aspects of immunity and to guide you in answering this question. In the blanks on the left, place the letters of all of the host defenses and immune responses in the right column that can fit the description.
- | | |
|--|---------------------------|
| _____ vaccination for tetanus | a. active |
| _____ lysozyme in tears | b. passive |
| _____ immunization with horse serum | c. natural |
| _____ in utero transfer of antibodies | d. artificial |
| _____ booster injection for diphtheria | e. acquired |
| _____ colostrum | f. innate, inborn |
| _____ interferon | g. chemical barrier |
| _____ action of neutrophils | h. mechanical barrier |
| _____ injection of gamma globulin | i. genetic barrier |
| _____ recovery from a case of mumps | j. specific |
| _____ edema | k. nonspecific |
| _____ humans having protection from canine distemper virus | l. inflammatory response |
| _____ stomach acid | m. second line of defense |
| _____ cilia in trachea | |

Case Study Review

- What does the rabies vaccine contain that rabies immunoglobulin does *not*?
 - antibodies
 - inactive virus
 - live virus
 - animal serum
- What types of cells could be involved in specific immune reactions against the rabies virus?
 - T cells
 - B cells
 - macrophages
 - dendritic cells
 - a, b, and d
 - all of these
- Describe the specific components of acquired immunity that would be necessary to control rabies virus.

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

- Using words and arrows, complete a flow outline of an immune response, beginning with entrance of antigen; include processing, cell interaction, involvement of cytokines, and the end results for B and T cells.
- Explain why most immune reactions result in a polyclonal collection of antibodies.
 - How do monoclonal antibodies differ from this?
 - Describe several applications of monoclonals in medicine.
- Give an immunological explanation as to why people can get influenza every year even though they have been vaccinated.
- How can the anamnestic response be explained in immunologic terms?
- Differentiate between humoral and cell-mediated immunity.
- Combine information on the functions of different classes of Ig to explain the exact mechanisms of natural passive immunity (both transplacental and colostrum-induced).

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps and a sample of a concept map for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

- Cells contain built-in suicide genes to self-destruct by apoptosis under certain conditions. Can you explain why development of the immune system might depend in part on this sort of adaptation?
- Describe what could be summarized as the three Rs of immunity: recognize, react, remember.
 - Why would it be necessary for the T cells to bind both antigen and self (MHC) receptors?
- Double-stranded DNA is a large, complex molecule, but it is not generally immunogenic unless it is associated with proteins or carbohydrates. Can you think why this might be so? (Hint: How universal is DNA?)
- Explain how it is possible for people to give a false-positive reaction in blood tests for syphilis, AIDS, and infectious mononucleosis.
- Describe the relationship between an antitoxin, a toxin, and a toxoid.
- It is said that a vaccine does not prevent infection; rather, it primes the immune system to undergo an immediate response to prevent an infection from spreading. Explain what is meant by this statement, and outline what is happening at the cellular/molecular level from the time of vaccination until subsequent contact with the infectious agent actually occurs.
- A study by the CDC reported that less than 80% of children in some areas of the United States are being adequately vaccinated. Several million children are at high risk for infections.
 - Name some factors that account for this trend.
 - Explain how the reduction in vaccination impacts herd immunity.
- From tables 15.6 and <http://www.cdc.gov/mmwr/preview/mmwrhtml/su6201a3.htm>, determine the vaccines you have been given and those for which you will require periodic boosters.
 - Suggest vaccines you may need in the future.
- When traders and missionaries first went to the Hawaiian Islands, the natives there experienced severe disease and high mortality rates from smallpox, measles, and certain STDs. Explain what immunologic factors are involved in the devastating effects of new diseases in previously unexposed populations.

Visual Challenge

- Using figure 15.13, label the lines and arrows, and explain what is happening at numbers 1, 2, and 3.

- Examine figure 6.6c and determine which components would act as epitopes or antigens.

Antibodies (IgM) agglutinate RBCs due to incorrect blood transfusion.

Packs of washed red blood cells ready for transfusions.

Source: U.S. Department of Health & Human Services/National Institutes of Health

CASE STUDY Part 1 A Deadly Transfusion Reaction

In late 2007 a 67-year-old male patient at a medical center in Florida underwent a minor procedure that required a **blood transfusion**. In anticipation of this surgery, the patient's blood had been **typed** by a lab technician a few days earlier. The man was transfused with one pint of **type A⁺** blood during the surgery. Within a few hours he had a sudden onset of fever, chills, and difficulty in breathing. When a vital sign check noted **tachycardia**,* **hypotension**,** and **urine** with a **pinkish tinge**, an emergency team was called in to evaluate his condition and administer treatment. A blood sample taken at this time showed unusual levels of **hemoglobin** in the plasma and **clumping of red blood cells** (RBCs). Despite being surrounded by state-of-the-art medical technology, nothing could be done to save his life. The patient died just a few hours after his operation from heart failure, shock, and **disseminated intravascular coagulation** (DIC).*** Attending physicians concluded that he had experienced an **acute hemolytic transfusion reaction** (AHTR).

The usual cause of a transfusion reaction is the presence of RBCs of the wrong blood type in the patient's body. A pathological reaction occurs when these **donated RBCs** carry **antigens** on their surface that react with IgM and IgG antibodies that already exist in the plasma of the recipient. When the antibodies combine with the antigens on the RBCs, the complement system in the blood is activated, which leads to the formation of **membrane attack**

“Despite being surrounded by state-of-the-art medical technology, nothing could be done to save his life.”

complexes and **hemolysis** of the donated red blood cells. Because such a reaction can occur even if only 5 to 20 ml of blood is transfused, the 500-ml transfusion was more than enough to be fatal.

What seemed most puzzling to investigators in this case was that the records showed that the **donated blood** (type A⁺) had been matched to the patient's by **cross-matching** just minutes before the transfusion. This procedure involves mixing a drop of the patient's blood with a drop of the blood to be transfused and observing the mixture macroscopically and microscopically for evidence of **agglutination**. Technicians had reported that the cross-match was successful and showed no evidence of a reaction.

- What is responsible for the ABO and Rh blood types, and why does transfusion of an incompatible blood type lead to such severe complications?
- What causes the abnormal signs indicative of a transfusion reaction?

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

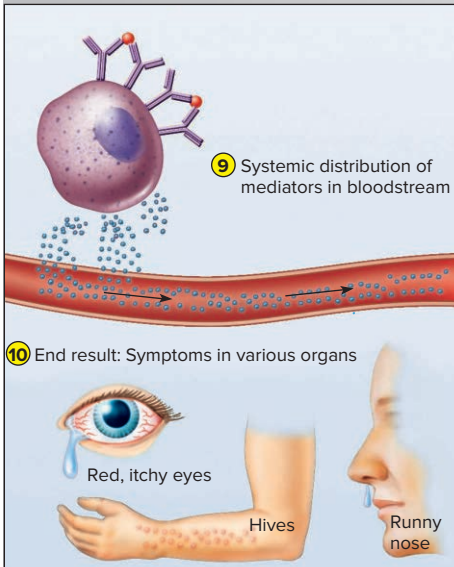

* Tachycardia is an increased heart rate.

** Hypotension is decreased blood pressure.

*** DIC is a clumping of RBCs in blood vessels throughout the body.

SCOPING OUT THE CHAPTER

Up to now, we have focused primarily on the ways our powerful and intricate immune systems defend us against infection, but by their very nature, these systems also carry tremendous potential to cause injury and disease. In most instances an immune dysfunction presents itself in commonplace but miserable symptoms of hay fever or skin rashes. But abnormal immune function is also the basis of debilitating or life-threatening diseases such as asthma, anaphylactic shock, rheumatoid arthritis, and cancer. In this chapter we get to examine the flip side of this double-edged “sword” of immunity.

B cells and antibodies are involved in immediate allergies such as hay fever and asthma.

Allergies: The Immune System Running Rampant

Allergies arise when the immune system has been primed to overreact to commonplace substances such as pollen grains, foods, cat hair, and poisonous plants. These reactions use the same systems in place for protective immunity—the B and T lymphocytes. But the end results damage the respiratory system, skin, intestinal tract, and other organs. Some of these reactions are rapid and others take time, but in both cases, they cause medical problems, often for life.

Blood Types and Complications Humans inherit markers on their red blood cells that determine their blood types. Because one person's blood markers can be foreign to another person, it is necessary to check for incompatibilities during transfusions and between pregnant women and their fetuses.

T cells are responsible for delayed allergies such as poison ivy sensitivity.

Immune Interference in Transplants

Immune-based diseases may also arise from medical interventions such as transplants and grafts of organs or tissues that are often incompatible with the recipient. T cells inhabiting the person or the graft can become sensitized and cause life-threatening rejection of the tissue or organ.

Autoimmunity: A Case of Mistaken Identity

A devastating and unexpected immune dysfunction happens when a person's tissues and organs are targeted by his own immune system. Diseases such as rheumatoid arthritis, lupus, and multiple sclerosis are the consequences of “self attacking self.”

Weakened Immune Function

The immune system is the silent partner in human health, but when it is missing or compromised, the body is subjected to out-of-control infections. Immune deficiencies are either inborn and genetic, caused by lack of development in critical blood cells types, or acquired after birth through infections and cancers.

16.1 The Immune Response: A Two-Sided Coin

Expected Learning Outcomes

1. Summarize the main categories of immunopathology and their medical consequences.
2. Discuss the factors involved in allergies and hypersensitivities.

Our previous discussions of the immune response centered primarily around its numerous beneficial effects. The precisely coordinated system that recognizes and destroys invading microbes is clearly protective, but it also presents another side—a side that promotes rather than prevents disease. In this chapter, we survey **immunopathology**, the study of disease states associated with overreactivity or underreactivity of the immune response (**figure 16.1**). In the cases of **allergy** and **autoimmunity**, the tissues are innocent bystanders to immune attacks that do not distinguish between one's own cells and foreign antigens. In **grafts** and **transfusions**, a recipient reacts to the foreign tissues and cells of another individual. In **immunodeficiency** diseases, immune function is incompletely developed, suppressed, or destroyed. **Cancer** falls into a special category, because it is both a cause and an effect of immune dysfunction. As we shall see, one fascinating by-product of studies of immune disorders has been our increased understanding of the basic workings of the immune system.

Overreactions to Antigens: Allergy/Hypersensitivity

The term **allergy** means a condition of altered reactivity or exaggerated immune responsiveness that is manifested by inflammatory symptoms. Although it is sometimes used interchangeably with **hypersensitivity**, some experts use the term *allergy* in reference to immediate reactions (hay fever, asthma) and use *hypersensitivity* in reference to other forms of overreactions to antigens (contact dermatitis). Allergic and hypersensitive individuals are acutely sensitive to repeated contact with antigens called **allergens** that do not noticeably affect other “normal” individuals. Although the general effects of these immune pathologies are usually detrimental, we must emphasize that they involve the very same types of immune reactions as protective immunities. These include humoral and cell-mediated actions, the inflammatory response, phagocytosis, and complement. Such an association means that all humans have the potential to develop allergy or hypersensitivity under particular circumstances.

Originally allergies and hypersensitivities were defined as either immediate or delayed, depending upon the time lapse between contact with the allergen and onset of symptoms. Subsequently they were esedifferentiated as humoral versus cell-mediated. But as information accumulated on these types of dysfunctional immune responses, it became evident that, although useful, these schemes oversimplified what is really a very complex spectrum of reactions.

Figure 16.1 Overview of diseases of the immune system (immunopathologies). Just as the system of T cells and B cells provides necessary protection against infection and disease, the same system can cause serious and debilitating conditions by overreacting or underreacting to immune stimuli.

TABLE 16.1 Classification of Immunopathologies Caused by Overreactions to Antigens

Type		Systems and Mechanisms Involved	Examples
I	Immediate allergies	IgE-mediated; involves mast cells, basophils, and allergic mediators	Anaphylaxis, allergies such as hay fever, asthma
II	Antibody-mediated incompatibilities	IgG, IgM antibodies act upon cells with complement and cause cell lysis; includes some autoimmune diseases	Blood group incompatibility, pernicious anemia; myasthenia gravis
III	Immune complex diseases	Antibody-mediated inflammation; circulating IgG complexes deposited in basement membranes of target organs; includes some autoimmune diseases	Systemic lupus erythematosus; rheumatoid arthritis; serum sickness; rheumatic fever
IV	T-cell-mediated hypersensitivities	Delayed hypersensitivity and cytotoxic reactions in tissues	Infection reactions; contact dermatitis; graft rejection; some types of autoimmunity

The most widely accepted classification, first introduced by immunologists P. Gell and R. Coombs, includes four major categories of immune system pathologies involving overreactions to antigens: type I (“common” allergy and anaphylaxis), type II (IgG- and IgM-mediated cell damage), type III (immune complex diseases), and type IV (delayed hypersensitivity) (**table 16.1**). In general, types I, II, and III involve a B-cell–immunoglobulin response, and type IV involves a T-cell response (figure 16.1). The antigens that elicit these reactions can be exogenous, originating from outside the body (microbes, pollen grains, and foreign cells and proteins), or endogenous, arising from self tissue (autoimmunities).

One of the reasons allergies and hypersensitivities are easily mistaken for infections is that both involve damage to the tissues and thus trigger the inflammatory response, as described in chapter 14. Many symptoms and signs of inflammation (redness, heat, skin eruptions, edema, and granuloma) are prominent features of allergies and are caused by some of the same chemical mediators.

Check Your Progress SECTION 16.1

1. Explain what is meant by immunopathology and give some examples of this condition.
2. Define *allergy/hypersensitivity* and explain what accounts for the reactions that occur in these conditions.
3. What is involved in the four categories of B-cell and T-cell-mediated immunopathologies outlined by Gell and Coombs?
4. What does it mean for a reaction to be immediate or delayed?

16.2 Allergic Reactions: Atopy and Anaphylaxis

Expected Learning Outcomes

3. Describe general characteristics of allergic reactions.
4. Outline the major allergen categories, giving examples.
5. Explain the mechanism of immediate allergies, including the concepts of IgE, mast cells, sensitization, and provocation.

6. Summarize the physiological effects of allergies that cause major symptoms.
7. Define the types of atopic allergies and describe their major features.
8. Explain the process of anaphylaxis and its outcome.
9. Relate the primary methods of diagnosing, treating, and preventing allergies.

Type 1 allergies share a similar physiological mechanism, are immediate in onset, and are associated with exposure to specific antigens. However, it is convenient to recognize two levels of severity: **Atopy*** is any chronic allergy, such as hay fever or eczema, whose effects are localized to a region and usually not life-threatening; and **anaphylaxis*** is a systemic, sometimes fatal reaction that involves airway obstruction and circulatory collapse. In the following sections we consider the allergens, routes of inoculation, mechanisms of disease, and specific syndromes involved in type I allergies.

Modes of Contact with Allergens

Allergies exert profound medical and economic impact. Allergists (physicians who specialize in treating allergies) estimate that about 10% to 30% of the population is prone to atopic allergy. It is generally acknowledged that self-treatment with over-the-counter medicines accounts for significant underreporting of cases. The 40 million people afflicted with hay fever (15% to 20% of the population) together spend about half a billion dollars annually for medical treatment. The monetary loss due to employee debilitation and absenteeism is immeasurable. The majority of allergies are relatively mild, but certain forms, such as asthma and anaphylaxis, may require hospitalization and can cause death.

The predisposition for atopic allergies has a strong familial association. Be aware that what is hereditary here is a generalized *susceptibility*, not an allergy to a specific substance. For example, a parent who is allergic to ragweed pollen can have a child who is allergic to cat hair. The prospect of a child’s developing an atopic allergy is at least 25% if one parent is atopic, increasing up to 50% if grandparents

* *atopy* (at’-oh-pee) *Gr.* *atop*, out of place.

* *anaphylaxis* (an’-uh-fih-lax’-us) *Gr.* *ana*, excessive, and *phylaxis*, protection.

CLINICAL CONNECTIONS

Are Some Allergies a Consequence of Clean Living?

Allergists have been observing an increased incidence of allergies such as asthma, allergic rhinitis, and other atopic allergies that is not tied to genetic factors or better diagnosis. Most of these increases have occurred in more affluent regions of the United States and Europe. Although this phenomenon cannot easily be explained, many medical experts think it is connected to something called the **hygiene or biodiversity hypothesis**. This explanation basically says that ultraclean lifestyles and living environments prevent the kind of contact with microbes that is required for the normal development of the immune system. The effects of modern housekeeping, lifestyles, and antimicrobial drugs, mean that children are not exposed as much to noninfectious environmental microbes and viral and parasitic infections. Some support for this exists in the fact that levels of allergies are lower in developing countries and rural areas, where children have greater exposure to soil, infectious agents, and household pets.

Although the factors involved appear to be complex, it is thought that contact with certain types of microbes initiates protective responses and shapes the future direction of immune system development. The immune systems of children who lack sufficient microbial contact become programmed to react to allergens such as household chemicals, animal and plant molecules, and even food, which sets the scene for long-term allergies. Because people are unlikely to return to less clean lifestyles, researchers are on the trail of finding out what kinds of stimuli can inoculate people against allergies. It may turn out that “a little dirt can’t hurt” and may even be beneficial.

Explain how the hygiene hypothesis relates to the overuse of household disinfectants and antibiotics as discussed in chapters 11 and 12. *Answer available on Connect.*

or siblings are also afflicted. The actual basis for atopy appears to be the inheritance of genes that favor allergic antibody (IgE) production, increased reactivity of mast cells, and increased susceptibility of target tissue to allergic mediators. Allergic persons often exhibit a combination of syndromes, such as hay fever, eczema, and asthma.

Other factors that affect the onset of allergy are age, infection, and geographic locale. New allergies tend to crop up throughout an allergic person’s life, especially as new exposures occur after moving or changing lifestyle. In some persons, atopic allergies last for a lifetime; others “outgrow” them, and still others suddenly develop them later in life. Some features of allergic pathology are not yet completely explained.

The Nature of Allergens and Their Portals of Entry

As with other antigens, allergens have certain immunogenic characteristics. Not unexpectedly, proteins are more allergenic than carbohydrates, fats, or nucleic acids. Some allergens are haptens, nonproteinaceous substances with a molecular weight of less than 1,000 that can form complexes with carrier molecules in the body (shown in figure 15.9). Organic and inorganic chemicals found in

TABLE 16.2 Common Allergens, Classified by Portal of Entry

Inhalants	Ingestants	Injectants	Contactants
Pollen	Food (milk, peanuts, wheat, shellfish, soybeans, nuts, eggs, fruits)	Hymenopteran venom (bee, wasp)	Topical drugs
Dust		Insect bites	Cosmetics
Mold spores		Drugs	Heavy metals
Dander	Food additives	Vaccines	Detergents
Animal hair	Oral drugs (aspirin, penicillin)	Serum	Formalin
Insect parts		Enzymes	Rubber
Formalin		Hormones	Solvents
Aerosols			Dyes

industrial and household products, cosmetics, food, and drugs are commonly of this type. **Table 16.2** lists a number of common allergenic substances and their portal of entry.

Allergens typically enter through the epithelia of the respiratory tract, gastrointestinal tract, and skin. The mucosal surfaces of the gut and respiratory system present a thin, moist surface that is normally quite penetrable. The dry, tough keratin coating of skin is less permeable, but access still occurs through tiny breaks, glands, and hair follicles. It is worth noting that the organ of allergic expression may or may not be the same as the portal of entry.

Airborne environmental allergens such as pollen, house dust, dander (shed skin scales), or fungal spores are termed *inhalants*. Each geographic region harbors a particular combination of airborne substances; this combination varies with the season and humidity (**figure 16.2a**). Pollen, the most common offender, is given off seasonally by the reproductive structures of pines and flowering plants (weeds, trees, and grasses). Unlike pollen, mold spores are released throughout the year and are especially profuse in moist areas of the home and garden. Airborne animal hair and dander (skin flakes), feathers, and the saliva of dogs and cats are common sources of allergens.

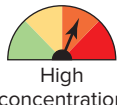

House dust is a complex mixture of organic debris, soil, human skin cells, and a wide array of bacteria and fungi. The component of house dust that appears to account for most dust allergies is not the debris or microbes but the decomposed skeletons of tiny mites that commonly live in this dust (**figure 16.2b**). Some people are allergic to their work, in the sense that they are exposed to allergens on the job. Examples include florists, woodworkers, farmers, drug processors, and plastics manufacturers whose work can aggravate inhalant and contact allergies.

Allergens that enter by mouth, called *ingestants*, often cause food allergies. *Injectant* allergies are an important adverse side effect of injected drugs or other substances used in diagnosing, treating, or preventing disease. A natural source of injectants is venom from stings by hymenopterans, a family of insects that includes honey-bees and wasps. *Contactants* are allergens that enter through the skin. Many contact allergies are of the type IV, delayed variety discussed in section 16.5.

Mechanisms of Allergy: Sensitization and Provocation

What causes some people to sneeze and wheeze every time they step out into the spring air, while others suffer no ill effects? We can answer this question by examining what occurs in the tissues of the allergic individual that does not occur in the normal person. What

is not as easy to answer is the question of why allergy is so common, affecting over 40% of the world's population. What useful function, if any, can it possibly serve? See 16.1 Making Connections for some possible explanations.

In general, allergies develop in stages (figure 16.3). The initial encounter with an allergen provides a **sensitizing dose** that primes the immune system for a subsequent encounter with that allergen but generally elicits no signs or symptoms. The memory cells and immunoglobulin produced during this encounter are then ready to react with a subsequent **provocative dose** of the same allergen. It is this dose that precipitates the first signs and symptoms that an allergy exists. Despite numerous anecdotal reports of people showing an allergy upon first contact with an allergen, it is generally believed that these individuals unknowingly had contact at some previous time. Fetal exposure to allergens from the mother's bloodstream is one possibility, and foods can be a prime source of "hidden" allergens such as penicillin.

The Physiology of IgE-Mediated Allergies

During primary contact and sensitization, the allergen penetrates the portal of entry (figure 16.3, steps 1–6). When large particles such as pollen grains, hair, and spores encounter a moist membrane, they are first captured by dendritic cells, which process the allergen and present it to T helper cells in the lymph nodes. Here, the T cells interact with clones of B cells, which they activate to respond to the specific allergen. This causes proliferation of plasma cells, following a sequence similar to the typical immune response to an antigen. These plasma cells produce **immunoglobulin E (IgE)**, the antibody of allergy. IgE is different from other immunoglobulins in having an Fc region with great affinity for mast cells and basophils. The binding of IgE to these

cells in the tissues sets the scene for the reactions that occur upon repeated exposure to the same allergen (figure 16.3, steps 7–10).

The Role of Mast Cells and Basophils

The most important characteristics of mast cells and basophils relating to their roles in allergy are these:

1. Their ubiquitous location in tissues. Mast cells are located in the connective tissue of virtually all organs, but particularly high concentrations exist in the lungs, skin, gastrointestinal tract, and genitourinary tract. Basophils circulate in the blood but migrate readily into tissues.
2. Their capacity to bind IgE during sensitization (figure 16.3). Each cell carries 30,000 to 100,000 cell receptors that bind 10,000 to 40,000 IgE antibodies.
3. Their cytoplasmic granules (secretory vesicles), which contain physiologically active cytokines (histamine, serotonin—introduced in chapter 14).
4. Their tendency to **degranulate** (figures 16.3 and 16.4) or release the contents of the granules into the tissues when triggered by a specific allergen through the IgE bound to them.

SEM of mast cell with ruffled membrane and receptors for IgE
Source: Oliver, Janet M., and Wilson, Bridget. *The Cell: An Image Library*, CIL:222. Available at <http://www.cellimagelibrary.org>

Let us now see what occurs when sensitized cells are challenged with allergen a second time.

(a) Sensitization/IgE Production**(b) Subsequent Exposure to Allergen and Provocation**

Process Figure 16.3 A schematic view of cellular reactions during the allergic response. **(a)** Sensitization (initial contact with sensitizing dose), includes stages 1–6. **(b)** Provocation (later contacts with provocative dose), stages 7–10.

The Provocative Contact with Allergen

After sensitization, the IgE-primed mast cells can remain in the tissues for years. Even after long periods without contact, a person can retain the capacity to react immediately upon reexposure. The next time allergen molecules contact these sensitized cells, they bind across adjacent receptors and stimulate degranulation. As chemical mediators are released, they diffuse into the tissues and bloodstream. Cytokines give rise to numerous local and systemic reactions, many of which appear quite rapidly (**figure 16.3, step 10**). Thus, the symptoms of allergy are caused, not by the direct action of allergen on tissues, but by the physiological effects of mast cell mediators on target organs.

Cytokines, Target Organs, and Allergic Symptoms

Numerous substances involved in mediating allergy (and inflammation) have been identified. The principal chemical mediators produced by mast cells and basophils are histamine, serotonin, leukotriene, platelet-activating factor, prostaglandins, and bradykinin

(**figure 16.4**). These chemicals, acting alone or in combination, account for the tremendous scope of allergic symptoms. Targets of these mediators include the skin, upper respiratory tract, gastrointestinal tract, and conjunctiva. The general responses of these organs include rashes, itching, redness, rhinitis, sneezing, diarrhea, and shedding of tears. Systemic targets include smooth muscle, mucous glands, and nervous tissue. Because smooth muscle is responsible for regulating the size of blood vessels and respiratory passageways, changes in its activity can profoundly alter blood flow, blood pressure, and respiration. Pain, anxiety, agitation, and lethargy are also attributable to the effects of mediators on the nervous system.

Histamine* is the most profuse and fastest-acting allergic mediator. It is a potent stimulator of smooth muscle, glands, and eosinophils. Histamine's actions on smooth muscle vary with location. It *constricts* the smooth muscle layers of the bronchioles and intestine, thereby causing labored breathing and increased intestinal motility. In contrast, histamine *relaxes* vascular smooth muscle and

* *histamine* (his'-tah-meen) Gr. *histio*, tissue, and amine.

Figure 16.4 The spectrum of reactions to inflammatory cytokines released by mast cells and the common symptoms they elicit in target tissues and organs. Note the extensive overlapping effects.

dilates arterioles and venules. It is responsible for the **wheel* and flare reaction** in the skin (see figure 16.6), pruritis (itching), and headache. More severe reactions such as anaphylaxis can be accompanied by edema and vascular dilation, which lead to hypotension, tachycardia, circulatory failure, and, frequently, shock. Salivary, lacrimal, mucous, and gastric glands are also histamine targets.

Although the role of **serotonin*** in human allergy is uncertain, its effects appear to complement those of histamine. In experimental animals, serotonin increases vascular permeability, capillary dilation, smooth muscle contraction, intestinal peristalsis, and respiratory rate, but it diminishes central nervous system activity.

A type of **leukotriene***, known as the “slow-reacting substance of anaphylaxis,” induces gradual contraction of smooth muscle.

This leukotriene is responsible for the prolonged bronchospasm, vascular permeability, and mucous secretion of the asthmatic individual. Other leukotrienes stimulate the activities of polymorphonuclear leukocytes.

Platelet-activating factor is a lipid released by basophils, neutrophils, monocytes, and macrophages. The physiological response to this factor is similar to that of histamine, including increased vascular permeability, pulmonary smooth muscle contraction, pulmonary edema, hypotension, and a wheal and flare response in the skin.

Prostaglandins* are a group of powerful inflammatory agents. Normally these substances regulate smooth muscle contraction. For example, they stimulate uterine contractions during delivery. In allergic reactions, they are responsible for vasodilation, increased vascular permeability, increased sensitivity to pain, and bronchoconstriction. Certain anti-inflammatory drugs work by preventing the actions of prostaglandins.

* **wheel** (weel) A smooth, slightly elevated, temporary welt (wheal) that is surrounded by a flushed patch of skin (flare).

* **serotonin** (ser'-oh-toh'-nin) L. *serum*, fluid, and *tonin*, stretching.

* **leukotriene** (loo'-koh-try'-een) Gr. *leukos*, white blood cell, and *triene*, a chemical suffix.

* **prostaglandin** (pross'-tah-glan'-din) From prostate gland. The substance was originally isolated from semen.

16.1 MAKING CONNECTIONS

The Origins of Allergy

Why would humans and other mammals evolve an allergic response that is capable of doing so much harm and even causing death? It is unlikely that this limb of immunity exists merely to make people miserable; it must have a role in protection and survival. What are the underlying biological functions of IgE, mast cells, and the array of potent cytokines? Analysis has revealed that, although allergic persons have high levels of IgE, trace quantities are present even in the sera of nonallergic individuals, just as mast cells and inflammatory chemicals are also part of normal human physiology. In chapter 14 you learned that inflammatory mediators serve valuable functions, such as increasing blood flow and vascular permeability to summon essential immune components to an injured site. They are also responsible for increased mucus secretion, gastric motility, sneezing, and coughing, which help expel noxious agents. The difference is that, in allergic persons, the quantity and quality of these reactions are excessive and uncontrolled.

SEM of cockroach chitin exoskeleton and its complex allergenic surface.

Source: Janice Carr/CDC

Some surprising insights have emerged from studies at the University of California. It seems that a significant source of many allergies is the polysaccharide *chitin*. This ubiquitous compound is found in insect exoskeletons, fungal cell walls, and parasitic worms. The digestion of chitin by enzymes present in the human body causes the release of smaller antigen molecules. These set off powerful immune and inflammatory reactions. There is even a specific pathway in lymphocytes and other white blood cells for responding to chitin and its antigens. It is theorized that this system originally functioned in the attack against worms, fungi, and other pathogens containing chitin, but modern hygiene and therapy have greatly reduced these infections. The remnant of this formerly protective mechanism now actually causes “out of control” reactions such as asthma and other respiratory allergies. This appears to be one basis of allergies to cockroaches and dust mites and the increase in childhood asthma.

What are some potential benefits of allergy? *Answer available on Connect.*

Bradykinin* is related to a group of plasma and tissue peptides known as kinins that participate in blood clotting and chemotaxis. In allergy, it causes prolonged contraction of the bronchioles, dilation of peripheral arterioles, increased capillary permeability, and increased mucus secretion.

Specific Diseases Associated with IgE- and Mast-Cell-Mediated Allergy

The mechanisms just described are basic to hay fever, allergic asthma, food allergy, drug allergy, eczema, and anaphylaxis. In this section we cover the main characteristics of these conditions, followed by methods of detection and treatment.

Atopic Diseases

Hay fever is a generic term for **allergic rhinitis**,* a seasonal reaction to inhaled plant pollen or molds or a chronic, year-round reaction to a wide spectrum of airborne allergens or inhalants (see table 16.2). The targets are typically respiratory membranes, and the symptoms include nasal congestion; sneezing; coughing; profuse mucus secretion; itchy, red, and teary eyes; and mild bronchoconstriction.

Allergic asthma* is a respiratory disease characterized by episodes of impaired breathing due to severe bronchoconstriction. The airways of asthmatic people are exquisitely responsive to minute amounts of inhalant allergens, food, or other stimuli, such as

infectious agents. The symptoms of asthma range from occasional, annoying bouts of difficult breathing to fatal suffocation. Labored breathing, shortness of breath, wheezing, cough, and ventilatory **rales*** are present to one degree or another. The respiratory tract of an asthmatic person is chronically inflamed and severely over-reactive to allergy chemicals, especially leukotrienes and serotonin from pulmonary mast cells. Other pathologic components are thick mucous plugs in the air sacs and lung damage that can result in long-term respiratory compromise. An imbalance in the nervous control of the respiratory smooth muscles is apparently involved in asthma, and the episodes are influenced by the psychological state of the person, which strongly supports a neurological connection.

The number of asthma sufferers in the United States is estimated at more than 20 million, with nearly one-third of them children. For reasons that are not completely understood, asthma and deaths from it have been increasing over the last 30 years, even though effective agents to control it are more available now than they have ever been before. Surprisingly, asthma is more common in developed regions of the world (the United States and parts of Europe) than in less developed countries in Asia and Africa. It has been suggested that modern insulated buildings have created indoor conditions that harbor higher concentrations of airborne allergens and ozone. This suggests a pronounced influence of environmental factors on the development of allergies and asthma (**16.1 Making Connections**).

Quick Search

For an overview, watch the video “Allergies—Hypersensitivity Type I” on YouTube.

* **bradykinin** (brad’-ee-kye’-nin) Gr. *bradys*, slow, and *kinein*, to move.

* **rhinitis** (rye-nye’-tis) Gr. *rhis*, nose, and *itis*, inflammation.

* **asthma** (az’-muh) The Greek word for gasping.

* **rales** (rails) Abnormal breathing sounds.

Atopic dermatitis is an intensely itchy inflammatory condition of the skin, also known as **eczema**.^{*} Sensitization occurs through ingestion, inhalation, and, occasionally, skin contact with allergens. It usually begins in infancy with reddened, vesicular, weeping, encrusted skin lesions (**figure 16.5a**). It then progresses in childhood and adulthood to a dry, scaly, thickened skin condition. Lesions can occur on the face, scalp, neck, and inner surfaces of the limbs and trunk. The itchy, painful lesions cause considerable discomfort, and they are often predisposed to secondary bacterial infections. An anonymous writer once aptly described eczema as “the itch that rashes” or “one scratch is too many but one thousand is not enough.”

Food Allergy

The ordinary diet contains a vast variety of compounds that are potentially allergenic. Although food allergies have an intestinal mode of entry, they can affect the skin and respiratory tract as well. Gastrointestinal symptoms include vomiting, diarrhea, and abdominal pain. In severe cases, nutrients are poorly absorbed, leading to growth retardation and failure to thrive in young children. Other manifestations of food allergies include rashes, hives (**figure 16.5b**), rhinitis, asthma, and occasionally anaphylaxis. Classic food hypersensitivity involves IgE and degranulation of mast cells, but not all reactions involve this mechanism. The most common food allergens come from peanuts, fish, cow’s milk, eggs, shellfish, and soybeans.¹ A recent investigation of babies who were considered at risk for peanut allergy concluded that eating a small amount of peanuts early in life greatly reduced their developing sensitivity to peanuts. Allergists are now thinking that in some cases, certain foods should be introduced earlier to prevent sensitization of children to that food.

^{*} **eczema** (eks'-uh-mah; also ek-zeem'-uh) Gr. *ekzeo*, to boil over.

1. Do not confuse food allergy with food intolerance. Many people are lactose intolerant, for example, due to a deficiency in the enzyme that degrades the sugar in milk.

Figure 16.5 Skin manifestations in atopic allergies. **(a)** Atopic dermatitis, or eczema. Vesicular, encrusted lesions are typical in afflicted infants. This condition is prevalent enough to account for 1% of pediatric care. **(b)** Skin rash caused by an allergy to strawberries. The slightly raised red lesions, termed urticaria or hives, can sometimes merge to form a solid red rash.

Drug Allergy

Modern chemotherapy has been responsible for many medical advances. Unfortunately it has also been hampered by the fact that drugs are foreign compounds capable of stimulating allergic reactions. In fact, allergy to drugs is one of the most common side effects of treatment (present in 5% to 10% of hospitalized patients). Depending upon the allergen, route of entry, and individual sensitivities, virtually any tissue of the body can be affected, and reactions range from mild atopy to fatal anaphylaxis. Compounds implicated most often are antibiotics (penicillin is number one in prevalence), synthetic antimicrobials (sulfa drugs), aspirin, opiates, and contrast dye used in X rays. The actual allergen is not the intact drug itself but a hapten given off when the liver processes the drug. Some forms of penicillin sensitivity are due to the presence of small amounts of the drug in meat, milk, and other foods and to exposure to *Penicillium* mold in the environment.

Anaphylaxis: A Powerful Systemic Reaction to Allergens

The term **anaphylaxis** was first used to denote a reaction of animals injected with a foreign protein. Although the animals showed no response during the first contact, upon reinoculation with the same protein at a later time, they exhibited acute symptoms—itching, sneezing, difficult breathing, prostration, and convulsions—and many died in a few minutes. Two clinical types of anaphylaxis are seen in humans. **Cutaneous anaphylaxis** is the wheal and flare inflammatory reaction to the local injection of allergen. **Systemic anaphylaxis**, also called **anaphylactic shock**, is characterized by sudden respiratory and circulatory disruption that can be fatal in a few minutes. In humans, the allergen and route of entry are

Source: Rob Flynn/USDA

(b)

variable, though bee stings and injections of antibiotics or serum are implicated most often. Honeybee and other hymenopteran stings are one of the most frequent causes of anaphylactic shock. Bee venom often creates a sensitivity that can last for decades after exposure.

The underlying physiological events in systemic anaphylaxis parallel those of atopy, but the concentration of chemical mediators and the strength of the response are greatly amplified. The immune system of a sensitized person exposed to a provocative dose of allergen responds with a sudden, massive release of chemicals into the tissues and blood, which act rapidly on the target organs. The throat swells, respiration is compromised, blood pressure falls, and the heart may stop. Anaphylactic persons have been known to die within 15 minutes from complete airway blockage. Peanut allergies, the leading cause of death related to food allergy, are notorious for their rapid onset and tiny allergen dose. Fatal cases have occurred from merely kissing a person who had eaten peanuts or sharing a drinking glass that had been in contact with peanuts.

Diagnosis of Allergy

Because allergy mimics infection and other conditions, it is important to determine if a person is actually allergic. If possible or necessary, it is also helpful to identify the specific allergen or allergens. Allergy diagnosis involves several levels of tests, including nonspecific, specific, in vitro, and in vivo methods.

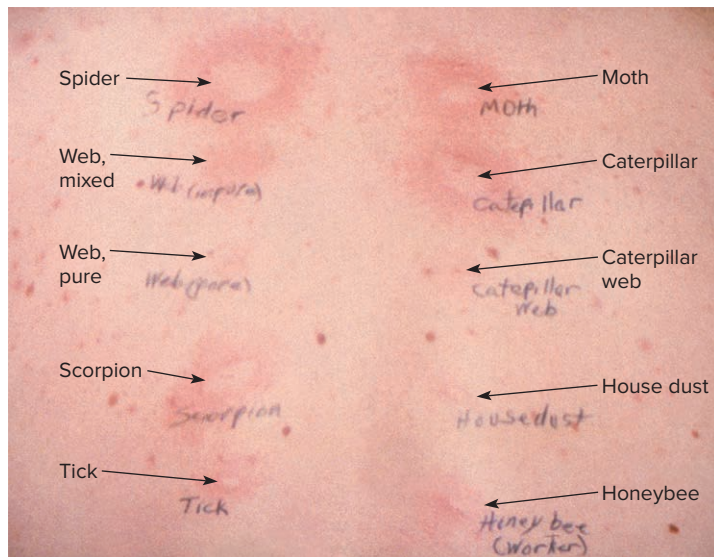

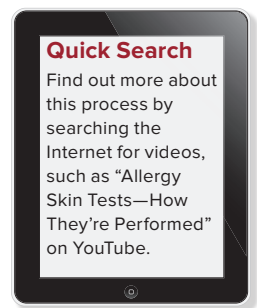

A test that can distinguish whether a patient has experienced an allergic attack measures elevated blood levels of tryptase, an enzyme released by mast cells. The enzyme level increases during an allergic response. Several types of specific in vitro tests can determine significant signs of allergy from a patient's blood sample. A

differential blood cell count can indicate the levels of basophils and eosinophils—a higher level of these indicates allergy. The leukocyte histamine-release test measures the amount of histamine released from the patient's basophils when exposed to a specific allergen. Serological tests that use radioimmune assays to reveal the quantity and type of IgE are also clinically helpful (see chapter 17).

Skin Testing

Skin testing can precisely detect atopic or anaphylactic sensitivities. With this technique, a patient's skin is injected, scratched, or pricked with a small amount of a pure allergen extract. Drug companies can supply a large battery of standard allergen extracts containing common airborne allergens (plant and mold pollen) and more unusual allergens (mule dander, theater dust, bird feathers). Unfortunately, skin tests for food allergies using food extracts are unreliable in most cases.

In patients with numerous allergies, the allergist maps the skin on the inner aspect of the forearms or back and injects the allergens intradermally according to this predetermined pattern (figure 16.6a). Approximately 20 minutes after antigenic challenge, each site is appraised for a wheal response indicative of histamine release. The diameter of the wheal is measured and rated on a scale of 0 (no reaction) to 4+ (greater than 15 mm). Figure 16.6b shows skin test results for a person with extreme inhalant allergies. A newer rapid test provides an alternate system for testing that has greater accuracy than skin testing and does not require injection of allergen.

Figure 16.7 Strategies for circumventing allergic attacks. These range from avoidance of the allergen, inhibiting immune reactions, inhibiting IgE release, stopping degranulation, to preventing the effects of cytokines.

Treatment and Prevention of Allergy

In general, the methods of treating and preventing allergy involve (1) avoiding the allergen, although this may be very difficult in many instances; (2) taking drugs that block the action of lymphocytes, mast cells, or chemical mediators; and (3) undergoing allergen desensitization therapy.

It is not possible to completely prevent initial sensitization, because there is no way to tell in advance if a person will develop an allergy to a particular substance. There has been a trend to prevent food allergies in babies by not feeding them solid foods for the first several months. Unfortunately babies could still be exposed through breast milk that contains allergens ingested by the mother. Rigorous cleaning and air conditioning can reduce contact with airborne allergens, but it is not feasible to isolate a person from all allergens, which is the reason drugs are so important in control.

Therapy to Counteract Allergies

The aim of antiallergy medication is to block the progress of the allergic response somewhere along the route between IgE production and the appearance of symptoms (**figure 16.7**). Oral anti-inflammatory drugs such as corticosteroids inhibit the activity of lymphocytes and thereby reduce the production of IgE, but they also have dangerous side effects and should not be taken for prolonged periods. Some drugs block the degranulation of mast cells and reduce the levels of inflammatory cytokines. The most effective of these are diethylcarbamazine and cromolyn. Asthma and rhinitis sufferers can find relief with a drug that blocks synthesis of leukotriene (montelukast [Singulair]) and a monoclonal antibody that inactivates IgE (omalizumab [Xolair]).

Widely used medications for preventing symptoms of atopic allergy are **antihistamines**, the active ingredients in most over-the-counter allergy-control drugs. Antihistamines interfere with histamine activity by binding to histamine receptors on target organs. Although many of them have major side effects such as

drowsiness, many of the newer antihistamines lack this side effect because they do not cross the blood-brain barrier. Other drugs that relieve inflammatory symptoms are aspirin and acetaminophen, which reduce pain by interfering with prostaglandin, and theophylline, a bronchodilator that reverses spasms in the respiratory smooth muscles. Persons who suffer from anaphylactic attacks are urged to carry at all times injectable epinephrine (adrenaline) and an identification tag indicating their sensitivity. An aerosol inhaler containing epinephrine can also provide rapid relief. Epinephrine reverses constriction of the airways and slows the release of allergic mediators.

Approximately 70% of allergic patients benefit from controlled injections of specific allergens as determined by skin tests. This technique is a form of allergen immunotherapy called **desensitization**, or **hyposensitization**, that prevents reactions between allergen, IgE, and mast cells. The allergen preparations contain pure, preserved suspensions of plant antigens, venoms, dust mites, dander, and molds. A newer experimental method of hyposensitization involves sublingual therapy, in which a tiny dose of premeasured allergen is placed under the tongue to be absorbed. It is being tested for peanut and other food allergies and even rhinitis and dermatitis with some success.

The immunologic basis of this treatment is open to differences in interpretation. One theory suggests that injected allergens stimulate the formation of high levels of allergen-specific IgG (**figure 16.8**)

Figure 16.8 The blocking antibody theory for allergic desensitization. An injection of allergen causes IgG antibodies to be formed instead of IgE; these blocking antibodies cross-link and effectively remove the allergen before it can react with the IgE in the mast cell.

instead of IgE. It has been proposed that these IgG **blocking antibodies** remove allergen from the system before it can bind to IgE, thus preventing the degranulation of mast cells. It is also possible that allergen delivered in this fashion combines with the IgE itself and takes it from circulation before it can react with the mast cells.

Check Your Progress SECTION 16.2

5. Give some examples of allergens and explain their routes of access to the body.
6. Describe several factors that influence types and severity of allergic responses.
7. Describe the events in sensitization and provocation.
8. How are atopic allergies similar to anaphylaxis, and how are they different?
9. Trace the course of a pollen grain through sensitization and provocation in allergies. Include in the discussion the role of mast cells, basophils, IgE, and allergic mediators.
10. Relate the roles of major mediators to the signs and symptoms of allergy.
11. Outline the target organs and symptoms of the principal atopic diseases and their diagnosis and treatment.
12. Explain how hyposensitization is achieved and suggest a credible mechanism by which it might work.

16.3 Type II Hypersensitivities: Reactions That Lyse Foreign Cells

Expected Learning Outcomes

10. Explain the requirements for developing a type II hypersensitivity.
11. Define what is meant by blood groups, explain how they are inherited and expressed, and relate the primary medical concerns of blood transfusions.
12. Discuss how blood is typed and notated.
13. Explain the special concerns about the Rh factor, the causes of hemolytic disease of the newborn, and how to prevent it.

The diseases termed type II hypersensitivities are a complex group of syndromes that involve complement-assisted destruction (lysis) of

cells by antibodies (IgG and IgM) directed against those cells' surface antigens. This category includes transfusion reactions and some types of autoimmunities (discussed in section 16.6). The cells targeted for destruction are often red blood cells, but other cells can be involved.

Chapters 14 and 15 described the functions of unique surface markers on cell membranes. Ordinarily these molecules play essential roles in transport, recognition, and development, but they become medically important when the tissues of one person come in intimate contact with the body of another person. Blood transfusions and organ donations introduce **alloantigens** (molecules that differ in the same species) on donor cells that are recognized by lymphocytes of the recipient. These reactions are not really immune dysfunctions in the way that allergy and autoimmunity are. The immune system is in fact working normally, but it is not equipped to distinguish between the beneficial foreign cells of a transplanted tissue and the harmful cells of a microbe.

The Basis of Human ABO Antigens and Blood Types

The existence of human blood types was first demonstrated by an Austrian pathologist, Karl Landsteiner, in 1904. While studying incompatibilities in blood transfusions, he found that the serum of one person could clump the red blood cells of another. Landsteiner identified four distinct types, subsequently called the **ABO blood groups**.

Like the **MHC/HLA** antigens on white blood cells described in chapter 15, the ABO antigen markers on red blood cells are genetically determined and composed of glycoproteins. These ABO antigens are inherited as two (one from each parent) of three alternative **alleles**:* A, B, or O. A and B alleles are dominant over O and codominant with one another. As **table 16.3** indicates, this mode of inheritance gives rise to four blood types (phenotypes), depending on the particular combination of genes (genotypes). Thus, a person with an *AA* or *AO* genotype has type A blood; genotype *BB* or *BO* gives type B; genotype *AB* produces type AB; and genotype *OO* produces type O. Some important points about the blood types are:

1. they are named for the dominant antigen(s);
2. the RBCs of type O persons lack the A and B antigens, but they do have other types of antigens; and
3. tissues other than RBCs carry A and B antigens which can complicate organ transplantation.

* *allele* (ah-lee'l') Gr. *allelon*, of one another. An alternate form of a gene for a given trait.

TABLE 16.3 Characteristics of ABO Blood Groups

Genotype	Blood Type	Antigen Present on Erythrocyte Membranes	Antibody in Plasma	Incidence of Type in United States		
				Among Whites (%)	Among Asians (%)	Among Those of African and Caribbean Descent (%)
<i>AA, AO</i>	A	A	Anti-b	41	28	27
<i>BB, BO</i>	B	B	Anti-a	10	27	20
<i>AB</i>	AB	A and B	Neither anti-a nor anti-b	4	5	7
<i>OO</i>	O	Neither A nor B	Anti-a and anti-b	45	40	46

Figure 16.9 The genetic/molecular basis for the A and B antigens (receptors) on red blood cells. In general, persons with blood types A, B, and AB inherit a gene or genes for enzymes that add a terminal sugar to the basic RBC receptor. Type O persons do not have these enzymes and lack a terminal sugar.

A diagram of the AB antigens and blood types is shown in **figure 16.9**. The A and B genes each code for an enzyme that adds a terminal carbohydrate to RBC surface molecules during maturation. RBCs of type A contain an enzyme that adds *N*-acetylgalactosamine to the molecule; RBCs of type B have an enzyme that adds D-galactose; RBCs of type AB contain both enzymes that add both carbohydrates; and RBCs of type O lack the genes and enzymes to add a terminal molecule and are not antigenic.

Antibodies Against A and B Antigens

Although an individual does not normally produce antibodies in response to his or her own RBC antigens, the serum can contain antibodies that react with blood of another antigenic type, even though contact with this other blood type has *never* occurred. These preformed antibodies account for the immediate and intense quality of transfusion reactions. As a rule, type A blood contains antibodies (anti-b) that react against the B antigens on type B and AB red blood cells. Type B blood contains antibodies (anti-a) that react with A antigen on type A and AB red blood cells. Type O blood contains antibodies against both A and B antigens. Type AB blood does not contain antibodies against either A or B antigens² (see table 16.3). Where do these anti-a and anti-b antibodies originate? Immunologists have evidence that they develop in early infancy through exposure to certain antigens that are widely distributed in nature. These antigens are surface molecules on bacteria and plant cells that mimic the structure of A and B antigens and stimulate the production of the antibodies that cause transfusion reactions. Once the immune system has been primed to form these antibodies, they will continue to circulate in the blood throughout life.

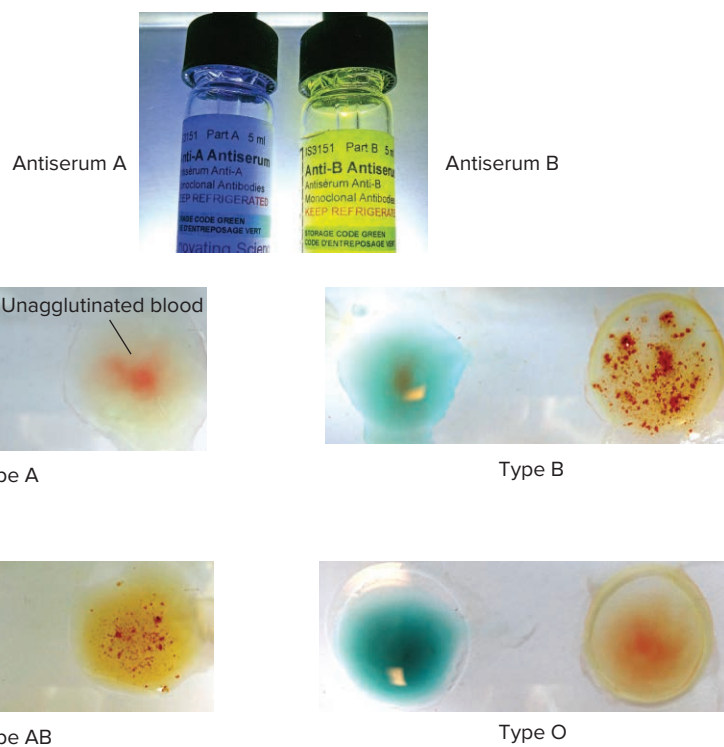

Figure 16.10 Interpretation of blood typing. In this test, a drop of blood is mixed with antiserum A, containing antibodies to type A antigen (blue), and antiserum B, containing antibodies to type B antigen (yellow). If that particular antigen is not present, the red blood cells in that droplet do not agglutinate, and form a uniform suspension. If that antigen is present, agglutination occurs and the RBCs form visible clumps (small red particles). The patterns and interpretations for the four blood types are shown. © Kathy Park Talaro

Clinical Concerns in Transfusions

The presence of ABO antigens and a, b antibodies underlies several clinical concerns in giving blood transfusions. First, the individual blood types of donor and recipient must be determined. By use of a standard technique, drops of blood are mixed with **antisera** that contain antibodies against the A and B antigens and are then observed for the evidence of agglutination (**figure 16.10**).

Knowing the blood types involved makes it possible to determine which transfusions are safe to do. The general rule of compatibility is that the RBC antigens of the donor must not be agglutinated by antibodies in the recipient's blood (**figure 16.11**). The ideal

2. Why would this be true? The answer lies in the first sentence of the paragraph.

Figure 16.11 Microscopic view of a transfusion reaction. **(a)** Incompatible blood types. The red blood cells of the type A donor contain antigen A, whereas the serum of the type B recipient contains anti-a antibodies that can agglutinate donor cells. **(b)** Agglutination complexes can block the circulation in vital organs. **(c)** Activation of the complement by antibody on the RBCs causes hemolysis and anemia. This sort of incorrect transfusion is very rare because of the great care taken by blood banks to ensure a correct match.

practice is to transfuse blood that is a perfect match (A to A, B to B). But even in this event, blood samples must be cross-matched before the transfusion because other blood group incompatibilities can exist. This test involves mixing the blood of the donor with the serum of the recipient to check for agglutination.

Under certain circumstances (medical emergencies, the battlefield) the concept of universal transfusions can be used. To appreciate how this works, we must apply the rule stated in the previous paragraph. Type O blood lacks A and B antigens and will not be agglutinated by other blood types, so it could theoretically be used in any transfusion. We call a person with this blood type a **universal donor**. Because type AB blood lacks agglutinating antibodies, an individual with this blood could conceivably receive any type of blood. Type AB persons are consequently called **universal recipients**. Although both types of transfusions involve antibody incompatibilities, these are of less concern because of the dilution of the donor's blood in the circulatory system of the recipient. Additional RBC markers that can be significant in transfusions are the Rh, MN, and Kell antigens, but they do not create the same transfusion risks as ABO types.

Transfusion of the wrong blood type causes differing degrees of adverse reactions. The severest reaction is massive hemolysis when the donated red blood cells react with recipient antibody and trigger the complement cascade (figure 16.11). The resultant

destruction of red cells leads to systemic shock and kidney failure brought on by the blockage of glomeruli (blood-filtering apparatus) by cell debris. Death is a common outcome. Other reactions caused by RBC destruction are fever, anemia, and jaundice. A transfusion reaction is managed by immediately halting the transfusion, administering drugs to remove hemoglobin from the blood, and beginning another transfusion with red blood cells of the correct type. See this chapter's Case Study for a description of a transfusion reaction.

The Rh Factor and Its Clinical Importance

Another RBC antigen of major clinical concern is the **Rh factor** (or D antigen). This factor was first discovered in experiments exploring the genetic relationships among animals. Rabbits inoculated with the RBCs of rhesus monkeys produced an antibody that also reacted with human RBCs. Further tests showed that this monkey antigen (termed Rh for rhesus) was present in about 85% of humans and absent in the other 15%. The details of Rh inheritance are more complicated than those of ABO; but in simplest terms, a person's Rh type results from a combination of two possible alleles—a dominant one that codes for the factor and a recessive one that does not. A person inheriting at least one Rh gene will be Rh⁺; only those persons inheriting no Rh genes are Rh⁻. The “+” or “-” appearing after a blood type refers to the Rh status of the person, as in O⁺ or AB⁻. However, unlike the ABO antigens, exposure to environmental antigens does not sensitize Rh⁻ persons to the Rh factor. The only ways one can develop antibodies against this factor are through placental sensitization or incorrect transfusion.

Hemolytic Disease of the Newborn and Rh Incompatibility

The potential for placental sensitization occurs when a mother is Rh⁻ and her unborn child is Rh⁺. The obvious intimacy between mother and fetus makes it possible for fetal RBCs to leak into the mother's circulation during childbirth, especially when the detachment of the placenta creates avenues for fetal blood to enter the maternal circulation. The mother's immune system detects the foreign Rh factors on the fetal RBCs and is sensitized to them by producing antibodies and memory B cells. The first Rh⁺ child is usually not affected because the process begins so late in pregnancy that the child is born before maternal sensitization is completed. However, the mother's immune system has been strongly primed for a second contact with this factor in a subsequent pregnancy (**figure 16.12a**).

If a mother has been sensitized and becomes pregnant again with an Rh⁺ fetus, fetal blood cells escape into the maternal circulation late in pregnancy and elicit a memory response. The fetus is at risk when the maternal anti-Rh antibodies cross the placenta into the fetal circulation, where they affix to fetal RBCs and cause complement-mediated lysis. The outcome is a potentially fatal **hemolytic disease of the newborn (HDN)** called *erythroblastosis fetalis*.^{*} This term is derived from the presence of immature nucleated RBCs called erythroblasts in the blood. They are released into the infant's circulation to compensate for the massive destruction of

^{*} *erythroblastosis fetalis* (eh-rith'-roh-blas-toh'-sis fee-tal'-is).

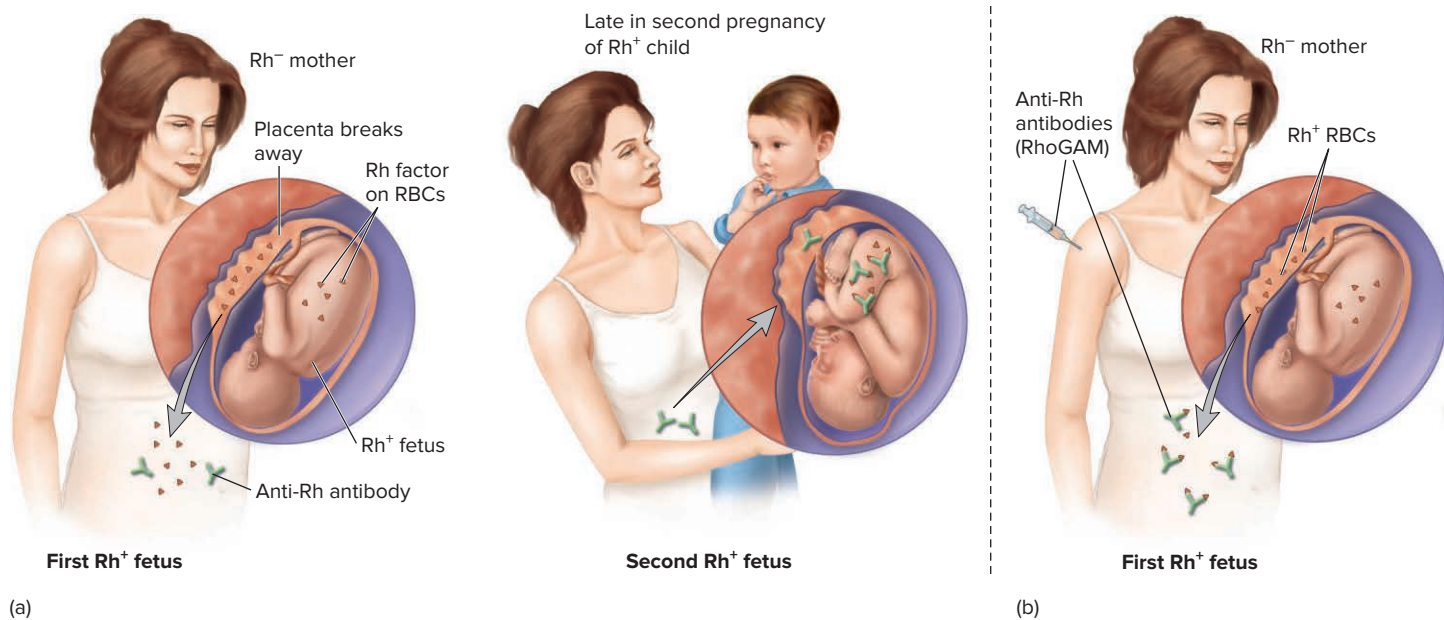

Figure 16.12 Rh factor incompatibility can result in RBC lysis and hemolytic disease of the newborn. **(a)** A naturally occurring blood cell incompatibility results when a Rh⁺ fetus develops within a Rh⁻ mother. Initial sensitization of the maternal immune system occurs when fetal blood crosses through the placenta near the time of birth. In most cases, the fetus develops normally and is born without illness. A subsequent pregnancy with an Rh⁺ fetus results in a severe hemolysis of fetal RBCs. **(b)** Control of incompatibility: Anti-Rh antibody (RhoGAM) can be administered to Rh⁻ mothers during pregnancy to help bind, inactivate, and remove any Rh factor that may be transferred from the fetus. In some cases, RhoGAM is administered before sensitization occurs.

RBCs stimulated by maternal antibodies. Additional symptoms are severe anemia, jaundice, and enlarged spleen and liver.

Maternal-fetal incompatibilities are also possible in the ABO blood group, but adverse reactions occur less frequently than with Rh sensitization because the antibodies to these blood group antigens are IgM rather than IgG and are unable to cross the placenta in large numbers. The maternal-fetal relationship itself is a fascinating instance of foreign tissue not being rejected, despite the extensive potential for contact. It is thought that the placenta forms a barrier to keep the fetus isolated in its own antigen-free environment. The placenta is surrounded by a dense, many-layered envelope that prevents the passage of maternal cells; and it actively absorbs, removes, and inactivates circulating antigens.

Preventing Hemolytic Disease of the Newborn

Once sensitization of the mother to Rh factor has occurred, all other Rh⁺ fetuses will be at risk for hemolytic disease of the newborn. Prevention requires a careful family history of an Rh⁻ pregnant woman. It can predict the likelihood that she is already sensitized or is carrying an Rh⁺ fetus. It must take into account other children she has had, their Rh types, and the Rh status of the father. If the father is also Rh⁻, the child will be Rh⁻ and free of risk, but if the father is Rh⁺, the probability that the child will be Rh⁺ is 50% or 100%, depending on the exact genetic makeup of the father. If there is any possibility that the fetus is Rh⁺, the mother must be passively immunized with antiserum containing antibodies against the Rh factor (*Rh₀ [D] immune globulin*, or RhoGAM³). This antiserum, injected

at 28 to 32 weeks and again immediately after delivery, keeps the maternal immune system from recognizing fetal RBCs that have escaped into the mother's circulation. This prevents the sensitization of her immune system to Rh factor (**figure 16.12b**). Anti-Rh antibody must be given with each pregnancy that involves an Rh⁺ fetus. It is ineffective if the mother has already been sensitized by a prior Rh⁺ fetus or an incorrect blood transfusion, which can be determined by a serological test.

As in ABO blood types, the Rh factor should be matched for a transfusion, although it is acceptable to transfuse Rh⁻ blood if the recipient's Rh type is not known.

13. What is the mechanism of type II hypersensitivity?
14. Explain why the tissues of some people are antigenic to others, and why this would not be a problem except for transfusions and transplants.
15. What is the molecular basis of the ABO and Rh blood groups?
16. Where do we derive our natural hypersensitivities to the A or B antigens that we do not possess?
17. How does a person become sensitized to Rh factor?
18. Describe the sequence of events in an Rh incompatibility between mother and fetus.
19. Explain the rules of transfusion. Illustrate what will happen if type A blood is accidentally transfused into a type B person.

3. RhoGAM: Immunoglobulin fraction of human anti-Rh serum, prepared from pooled human sera.

16.4 Type III Hypersensitivities: Immune Complex Reactions

Expected Learning Outcomes

- Describe the background features of immune complex reactions.
- Differentiate between the major types of immune complex diseases, and discuss their physiological effects.

Type III hypersensitivity involves the reaction of soluble antigen with antibody and the deposition of the resulting complexes in basement membranes of epithelial tissue. It is similar to type II because it involves the production of IgG and IgM antibodies after repeated exposure to antigens and the activation of complement. Type III differs from type II because its antigens are not attached to the surfaces of cells. The interaction of these antigens with antibodies produces free-floating complexes that can be deposited in the tissues, causing an **immune complex reaction** or disease. This category includes therapy-related disorders (serum sickness and the Arthus reaction) and a number of autoimmune diseases (such as glomerulonephritis and lupus erythematosus).

Mechanisms of Immune Complex Diseases

After initial exposure to a profuse amount of antigen, the immune system produces large quantities of antibodies that circulate in the fluid compartments. When this same antigen enters the system a second time, it reacts with the antibodies to form antigen-antibody complexes (**figure 16.13**). These complexes summon the usual inflammatory components such as complement and neutrophils, which would ordinarily eliminate antibody-antigen (Ab-Ag) complexes as part of the normal immune response. In an immune complex disease, however, these complexes are so abundant that they deposit in the **basement membranes**⁴ of epithelial tissues and become inaccessible. In response to these events, neutrophils release lysosomal granules that digest tissues and cause destructive inflammatory reactions at these sites. The symptoms of type III hypersensitivities are due in great measure to this pathology.

Types of Immune Complex Disease

During the early tests of immunotherapy using animals, hypersensitivity reactions to serum and vaccines were common. In addition to anaphylaxis, two syndromes, the **Arthus reaction**⁵ and **serum sickness**, were identified. These syndromes are associated with certain types of passive immunization (especially with animal serum).

- Basement membranes** are basal partitions of epithelia that normally filter out circulating antigen-antibody complexes.
- Named after Maurice Arthus, the physiologist who first identified this localized inflammatory response.

Serum sickness and the Arthus reaction are like anaphylaxis in requiring sensitization and preformed antibodies. Characteristics that set them apart from anaphylaxis are (1) they depend upon IgG, IgM, or IgA (precipitating antibodies) rather than IgE; (2) they require large doses of antigen (not the small dose required for anaphylaxis); and (3) their symptoms are delayed by a few hours to days. The Arthus reaction and serum sickness differ from each other in some important ways. The Arthus reaction is a *localized* dermal injury due to inflamed blood vessels in the vicinity of any injected antigen. Serum sickness is a *systemic* injury initiated by antigen-antibody complexes that circulate in the blood and settle into membranes at various sites.

The Arthus Reaction

The Arthus reaction is usually an acute response to a second injection of vaccines (boosters) or drugs at the same site as the first injection. In a few hours, the area becomes red, hot to the touch, swollen, and very painful. These symptoms are mainly due to the destruction of tissues in and around the blood vessels and the release of histamine from mast cells and basophils. Although the reaction is usually self-limiting and rapidly cleared, intravascular blood clotting can occasionally cause necrosis and loss of tissue.

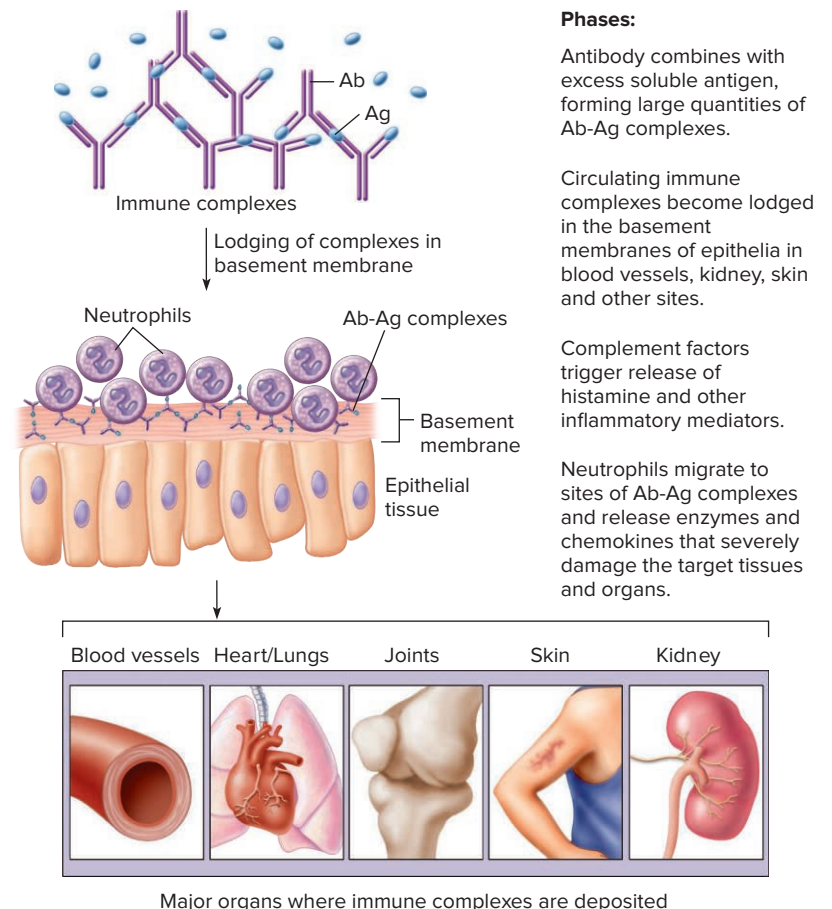

Figure 16.13 Pathology of immune complex disease. Deposition of circulating Ab-Ag complexes in tissues results in major organ damage.

Serum Sickness

Serum sickness was named for a condition that appeared in soldiers after repeated injections of horse serum to treat tetanus. It can also be caused by injections of animal hormones and drugs. The immune complexes enter the circulation; are carried throughout the body; and are eventually deposited in blood vessels of the kidney, heart, skin, and joints (figure 16.13). The condition can become chronic, causing symptoms such as enlarged lymph nodes, rashes, painful joints, swelling, fever, and renal dysfunction.

21. Explain what occurs in immune complex diseases and give examples.

16.5 Immunopathologies Involving T Cells

Expected Learning Outcomes

16. Define what is meant by *type IV hypersensitivities*.
17. Describe the origins of allergies to infectious agents and contact dermatitis.
18. Outline the primary mechanisms in contact dermatitis.
19. Discuss the involvement of T cells in organ transplantation and the different ways that grafted tissues may be rejected.
20. Describe the categories of grafts and how rejection is prevented.

Type IV Delayed-Type Hypersensitivity

The adverse immune responses we have covered so far are explained primarily by B-cell involvement and antibodies. A notable difference exists in type IV hypersensitivity, which involves primarily the T-cell branch of the immune system. Type IV immune dysfunction has traditionally been known as delayed hypersensitivity because the symptoms arise one to several days following the second contact with an antigen. In general, type IV diseases result when T cells respond to antigens displayed on self tissues or transplanted foreign cells. Examples of type IV hypersensitivity include delayed allergic reactions to infectious agents, contact dermatitis, and graft rejection.

Hypersensitivity Caused by Infections

A classic example of a delayed-type hypersensitivity occurs when a person sensitized by tuberculosis infection is injected with an extract (tuberculin) of the bacterium *Mycobacterium tuberculosis*. The so-called tuberculin reaction is an acute skin inflammation at the injection site appearing within 24 to 48 hours. So useful and diagnostic is this technique for detecting present or prior tuberculosis

that it is the chosen screening device. Other infections that use similar skin testing are leprosy, syphilis, histoplasmosis, toxoplasmosis, and candidiasis. This form of hypersensitivity arises from a specific class of T cells (T_H1) that receive the processed allergens from dendritic cells. Activated T_H cells release cytokines that recruit inflammatory cells such as macrophages, neutrophils, and eosinophils. The buildup of fluid and cells at the site gives rise to a red papule characteristic of a positive tuberculin test (see https://commons.wikimedia.org/wiki/File:Mantoux_test.jpg). Other type IV reactions that occur in chronic infection (tertiary syphilis, for example), cause granuloma formation that can lead to severe organ damage.

Contact Dermatitis

The most common delayed allergic reaction, **contact dermatitis**, is caused by exposure to resins in poison ivy or poison oak (**16.2 Making Connections**), to simple haptens in household and personal articles (jewelry, cosmetics, elasticized undergarments), and to certain drugs. Like immediate atopic dermatitis, the reaction to these allergens usually requires a sensitizing and a provocative dose. The allergen first penetrates the outer skin layers, is processed by Langerhans cells (skin dendritic cells), and is presented to T cells. When subsequent exposures attract CD8 lymphocytes and macrophages to this area, these cells give off enzymes and inflammatory cytokines that severely damage the epidermis in the immediate vicinity (**figure 16.14a**). This response accounts for the intensely itchy papules and blisters that are the early symptoms (**figure 16.14b**). As healing progresses, the epidermis is replaced by a thick, horny layer. Depending upon the dose and the sensitivity of the individual, the time from initial contact to healing can take up to 2 weeks. Many allergists conduct a variation on skin testing called a patch test to detect delayed-type hypersensitivities to contact allergens (**figure 16.15**).

T Cells in Relation to Organ Transplantation

Transplantation or grafting of organs and tissues is a common medical procedure. Although it is life-giving, this technique is plagued by the natural tendency of lymphocytes to seek out foreign antigens and mount a campaign to destroy them through **graft rejection**. The bulk of the damage that occurs in graft rejections can be attributed to expression of cytotoxic T cells and other killer cells described in chapter 15. This section covers the mechanisms involved in graft rejection, tests for transplant compatibility, reactions against grafts, prevention of graft rejection, and types of grafts.

The Genetic and Biochemical Basis for Graft Rejection: T-Cell-Mediated Recognition of Foreign MHC Receptors

In chapter 15 we discussed the role of **major histocompatibility** (MHC or HLA) genes and surface markers in immune function. In general, the genes and markers in MHC classes I and II are extremely important in recognizing self and in regulating the immune response. These molecules also set the events of graft rejection in motion. The MHC genes of humans are inherited from among a

(a)

- 1 Lipid-soluble catechols are absorbed by the skin.
- 2 Dendritic cells close to the epithelium pick up the allergen, process it, and display it on MHC receptors.
- 3 Previously sensitized T_H1 ($CD4^+$) cells recognize the presented allergen.
- 4 Sensitized T_H1 cells are activated and secrete cytokines (IFN, TNF).
- 5 These cytokines attract macrophages and cytotoxic T cells to the site.
- 6 Macrophages release mediators that stimulate a strong, local inflammatory reaction. Cytotoxic T cells directly kill cells and damage the skin. Fluid-filled blisters result.

(b)

Process Figure 16.14 Contact dermatitis. (a) Stages in the development of contact dermatitis. (b) A case of contact dermatitis on the leg caused by poison ivy. Figure 16.15 Patch testing for contact dermatitis. Most tests are done with household chemicals, cosmetics, plant materials, and metals. Small allergen-impregnated patches are applied to the skin and held in place for 48 hours. Most reactions shown here are negative, but three have varying degrees of positive reactions. The strongest reaction is for colophonium (below #9), a plant resin used in many products; nickel (below #7) produces a moderate positive; and cobalt (below #5) produces a weak reaction. © DermNet New Zealand Trust

large pool of genes, so the cells of each person can exhibit variability in the pattern of cell surface molecules. The pattern is identical in different cells of the same person and can be similar in related siblings and parents, but the more distant the relationship, the less likely that the MHC genes and markers will be similar. When donor tissue (a graft) displays surface molecules of a different MHC type than the recipient, the T cells of the recipient (also called the host) will recognize its foreignness and mount an immune attack against the donated tissue (**figure 16.16a**).

Host Rejection of Graft When certain T cells of a host recognize foreign class I MHC markers on the surface of cells in grafted tissues or organs such as the heart, kidney, or liver, they release interleukin-2 as part of a general immune mobilization. The effect is to expand the helper and cytotoxic T cells specific to the antigens displayed by the donated cells. The cytotoxic cells bind to the grafted tissue and secrete lymphokines that begin the rejection process within 2 weeks of transplantation. Late in this process, antibodies formed against the graft contribute to immune damage. A final blow is the destruction of the vascular supply, promoting death of the grafted tissue or organ.

Graft Rejection of Host Some types of immunodeficiencies prevent the host from rejecting a graft. But this failure may not protect the host from serious damage, because graft incompatibility is a two-way phenomenon. Some grafted tissues (especially bone

16.2. MAKING CONNECTIONS

Pretty, Pesky, Poisonous Plants

As a cause of allergic contact dermatitis (affecting about 10 million people a year), nothing can compare with a single family of plants belonging to the genus *Toxicodendron*. At least one of these plants—poison ivy, poison oak, or poison sumac—flourishes in the forests, woodlands, or along the trails of most regions of America. The allergen in these plants, an oil called urushiol, has such extreme potency that a pinhead-sized amount could spur symptoms in 500 people, and it is so long-lasting that botanists must be careful when handling 100-year-old plant specimens. Although degrees of sensitivity vary among individuals, it is estimated that 85% of all Americans are potentially hypersensitive to this compound. Some people are so acutely sensitive that even the most minuscule contact, such as handling pets or clothes that have touched the plant or breathing vaporized urushiol, can trigger an attack.

Humans first become sensitized by contact during childhood. Individuals at great risk (firefighters, hikers) are advised to determine their

degree of sensitivity using a skin test, so that they can be adequately cautious and prepared. Some odd remedies include skin potions containing bleach, buttermilk, ammonia, hair spray, and meat tenderizer. Commercial products are available for blocking or washing away the urushiol. Allergy researchers have found that oral vaccines containing a form of urushiol could desensitize experimental animals. An effective method using poison ivy desensitization injection is currently available to people with extreme sensitivity.

Learning to identify these common plants can prevent exposure and sensitivity. One old saying that might help warns, “Leaves of three, let it be; berries white, run with fright.” Search YouTube for videos that help you differentiate between these three poisonous plants.

marrow) contain an indigenous population called passenger lymphocytes. This makes it quite possible for the graft to reject the host, causing **graft versus host disease (GVHD)** (**figure 16.16b**). Because any host tissue bearing MHC markers foreign to the graft can be attacked, the effects of GVHD are widely systemic and toxic. A papular, peeling skin rash is the most common symptom. Other organs affected are the liver, intestine, muscles, and mucous membranes. Previously, GVHD occurred in approximately 30% of bone marrow transplants within 100 to 300 days of the graft. This percentage is declining with the development of better screening and selection of tissues.

Classes of Grafts Grafts are generally classified according to the genetic relationship between the donor and the recipient. Tissue transplanted from one site to another on an individual’s body is known as an **autograft**. Typical examples are skin replacement in burn repair and the use of a vein to fashion a coronary artery bypass. In an **isograft**, tissue from an identical twin is used. Because

isografts do not contain foreign antigens, they are not rejected, but this type of grafting has obvious limitations. **Allografts** also called **allogeneic grafts**, the most common type of grafts, are exchanges between genetically different individuals belonging to the same species (two humans). A close genetic correlation is sought for most allograft transplants (see next section). A **xenograft** is a tissue exchange between individuals of different species. Until rejection can be better controlled, most xenografts are experimental or for temporary therapy only.

Avoiding and Controlling Graft Incompatibility

Graft rejection can be averted or lessened by directly comparing the tissue of the recipient with that of potential donors. Several tissue matching procedures are used. In the *mixed lymphocyte reaction (MLR)*, lymphocytes of the two individuals are mixed and incubated. If an incompatibility exists, some of the cells will become activated and proliferate. *Tissue typing* is similar to blood typing,

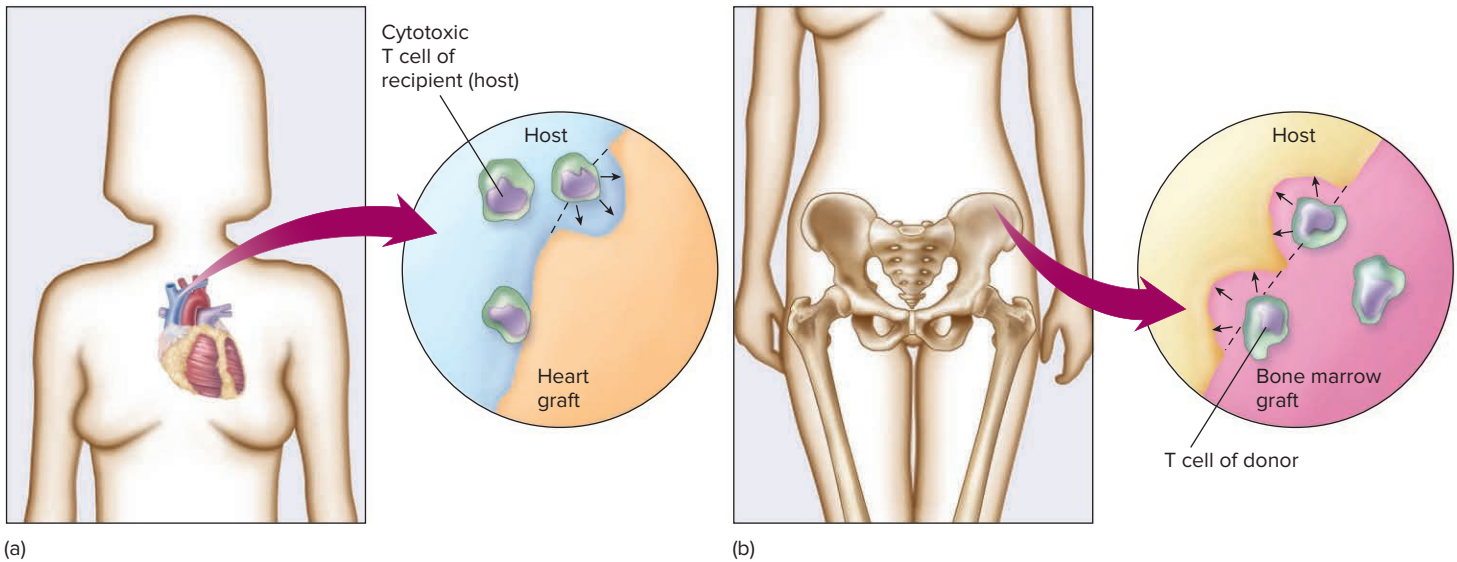

Figure 16.16 Potential reactions in transplantation. (a) The host's immune system (primarily cytotoxic T cells) encounters the cells of the donated organ (heart) and mediates the rejection of the organ. (b) Grafted tissue (bone marrow) contains endogenous T cells that recognize the host's tissues as foreign and mount an attack on many tissues and organs. The recipient will develop symptoms of graft versus host disease.

except that specific antisera are used to disclose the HLA antigens on the surface of lymphocytes. In most grafts (one exception is bone marrow transplants), the ABO blood type must also be matched. Although a small amount of incompatibility is tolerable in certain grafts (liver, heart, kidney), a closer match is more likely to be successful, so the closest match possible is sought.

Practical Examples of Transplantation

Today transplantation is a recognized medical procedure whose benefit is reflected in the fact that more than 100,000 transplants take place each year in the United States. It has been performed on every major organ, including parts of the brain. The most frequent transplant operations involve skin, liver, heart, kidney, coronary artery, cornea, and blood stem cells. The sources of organs and tissues are live donors (kidney, skin, bone marrow, liver), cadavers (heart, kidney, cornea), and fetal tissues. In the past decade, we have witnessed some unusual types of grafts. For instance, the fetal pancreas has been implanted as a potential treatment for diabetes and fetal brain tissues for Parkinson's disease.

Allogeneic hematopoietic stem cell transplantation is one of the most common medical procedures for patients suffering from immune deficiencies, aplastic anemia, leukemia and other cancers, and radiation damage. The three primary sources of stem cells used for this procedure are bone marrow, peripheral blood, and umbilical cord blood. These transplants are attempted in only the most severe cases because of a relatively high mortality rate associated with them. They are also costly, ranging from \$100,000 to \$250,000 for the entire process. For bone marrow transplants, a compatible donor with a closely matched MHC profile is sought. This person is sedated, and a bone marrow sample is aspirated by inserting a special needle into an accessible marrow cavity. The most favorable sites are the crest and spine of the ilium (major bone of the pelvis). During this procedure, between 500 and 800 ml of bone marrow are extracted with a special syringe. In a few weeks, the donor's marrow

will naturally replace itself. Implanting the harvested bone marrow is rather convenient, because it is not necessary to place it directly into the marrow cavities of the recipient. Instead, it is dripped intravenously into the circulation, and the new marrow cells automatically settle in the appropriate bone marrow regions.

To prepare recipients for the infusion procedure, they must be treated with chemotherapy and whole-body irradiation, a procedure designed to destroy their own blood stem cells and thus prevent rejection of the new stem cells. Within 2 weeks to a month after infusion, the grafted cells become established in the host. Because donor lymphoid cells can still cause GVHD, antirejection drugs may be necessary. A surprising consequence of bone marrow transplantation is that a recipient's blood type may change to the blood type of the donor.

Advances in stem cell technology have made it possible to harvest stem cells directly from the blood of donors by using *leukapheresis** to separate them and flow cytometry to identify and collect them (see discussion in chapter 7). Another potential source is the umbilical cord blood from a newborn infant. A decided advantage to cord blood is that its stem cells have yet to develop the donor's receptors and are less likely to cause transplant rejections.

* The process of selectively removing and collecting WBCs from the circulating blood, then returning the rest of the blood components back to the circulation.

23. Compare the four types of grafts.
24. What does it mean to say that tissues from two different individuals show a close match?
25. Describe the procedures involved in a bone marrow transplant and stem cell isolation.

16.6 Autoimmune Diseases: An Attack on Self

Expected Learning Outcomes

21. Outline the pathology of autoimmune diseases.
22. Explain the origins of autoimmunity and describe which persons are most often targeted by it.
23. Review the major types of autoimmune diseases and the adverse medical effects they have.

The immune diseases we have covered so far are all caused by foreign antigens. In the case of autoimmunity, individuals actually develop hypersensitivity to their own cells. This pathologic process accounts for **autoimmune diseases**, in which **autoantibodies**, T cells, and in some cases, both, mount an abnormal attack against antigens that originate from one's own cells. The scope of autoimmune diseases is extremely varied. In general, they are either *systemic*, involving several major organs, or *organ-specific*, involving only one organ or tissue. They usually fall into categories II or III hypersensitivity, depending upon how the autoantibodies bring about injury. Some major autoimmune diseases, their targets, and basic pathology are presented in **table 16.4**. (For a reminder of the four Gell and Combs categories, refer to table 16.1.)

Genetic and Gender Correlation in Autoimmune Disease

In most cases the precipitating cause of autoimmune disease remains obscure, but we do know that susceptibility is determined by genetics

and influenced by gender and environmental factors. Cases cluster in families, and even unaffected members tend to develop autoantibodies for that disease. More direct evidence comes from studies of the major histocompatibility gene complexes. Particular genes in the class I and class II major histocompatibility complexes coincide with certain autoimmune diseases. For example, autoimmune joint diseases such as rheumatoid arthritis and ankylosing spondylitis are more common in persons with the B-27 human leukocyte antigen (HLA) type; systemic lupus erythematosus, Graves' disease, and myasthenia gravis are associated with the B-8 HLA. Why autoimmune diseases (except ankylosing spondylitis) afflict more females than males also remains a mystery. Females are more susceptible during childbearing years than before puberty or after menopause, suggesting possible disruption of the immune system by hormones and pregnancy.

The Origins of Autoimmune Disease

Because otherwise healthy individuals show low levels of autoantibodies, it is suspected that there is a normal function for them. A moderate, regulated amount of autoimmunity is probably required to dispose of old cells and cellular debris. Disease apparently arises when this regulatory or recognition apparatus goes awry. Although there is not yet a complete explanation for autoimmune diseases, several theories have been proposed.

The **sequestered antigen theory** explains that during embryonic growth, some tissues are immunologically privileged; that is, they are sequestered behind anatomical barriers and cannot be surveyed by the immune system. Examples of these sites are regions of the central nervous system, which are shielded by the meninges and blood-brain barrier; the lens of the eye, which is enclosed by a thick sheath; and antigens in the thyroid and testes, which are sequestered behind an epithelial barrier. In time, the antigen becomes exposed

TABLE 16.4 Selected Autoimmune Diseases

Disease	Target	Type of Hypersensitivity	Characteristics
Systemic lupus erythematosus (SLE)	Systemic	II and III	Inflammation of many organs; antibodies against red and white blood cells, platelets, clotting factors, nucleus DNA
Rheumatoid arthritis and ankylosing spondylitis	Systemic	III and IV	Vasculitis; frequent target is joint lining; antibodies against other antibodies (rheumatoid factor)
Scleroderma	Systemic	II	Excess collagen deposition in organs; antibodies formed against many intracellular organelles
Hashimoto's thyroiditis	Thyroid	II	Destruction of the thyroid follicles
Graves' disease	Thyroid	II	Antibodies against thyroid-stimulating hormone receptors
Pernicious anemia	Stomach lining	II	Antibodies against receptors prevent transport of vitamin B ₁₂
Myasthenia gravis	Muscle	II	Antibodies against the acetylcholine receptors on the nerve-muscle junction alter function
Type I diabetes	Pancreas	II	Antibodies stimulate destruction of insulin-secreting cells
Multiple sclerosis	Myelin	II and IV	T cells and antibodies sensitized to myelin sheath destroy neurons
Goodpasture syndrome (glomerulonephritis)	Kidney	II	Antibodies to basement membrane of the glomerulus damage kidneys
Rheumatic fever	Heart	II	Antibodies to group A streptococci cross-react with heart valve tissue

by means of infection, trauma, or deterioration and is perceived by the immune system as a foreign substance.

According to the clonal selection theory, the immune system of a fetus develops tolerance to self by eradicating or silencing all self-reacting lymphocyte clones, called **forbidden clones**, while retaining only those clones that react to foreign antigens. Some of these forbidden clones may survive; and because they have not been subjected to this tolerance process, they can attack tissues carrying self molecules, which they mistake as antigens.

The **theory of immune deficiency** proposes (1) that mutations in the receptor genes of some lymphocytes render them reactive to self and (2) that T-cell regulatory cells that normally maintain tolerance to self have become dysfunctional. These would both set the scene for autoimmunity. Abnormal expression of MHC II markers on cells that don't normally express them has been found to cause other immune reactions against self. In a related phenomenon, T-cell activation has been known to mistakenly "turn on" B cells that can react with self antigens. This phenomenon is called the bystander effect.

Some autoimmune diseases appear to be caused by **molecular mimicry**, in which microbial antigens bear molecular determinants similar to normal human cells. An infection with this type of microbe could stimulate antibodies that can cross-react with tissues. This is one purported explanation for the pathology of rheumatic fever. Another probable example of mimicry leading to autoimmune disease is the skin condition psoriasis. Although the etiology of this condition is complex and involves the inheritance of certain types of MHC alleles, infection with group A streptococci also plays a role. Scientists report that T cells primed to react with streptococcal surface proteins also react with keratin cells in the skin, causing them to proliferate. For this reason, psoriasis patients often report flare-ups after a streptococcal throat infection.

Other autoimmune disorders such as type I diabetes and multiple sclerosis are likely triggered by *viral infection*. Viruses can noticeably alter cell receptors, thereby causing immune cells to attack the tissues bearing viral receptors.

Some researchers believe that many, if not most, autoimmune diseases will someday be found to have an underlying microbial cause or influence. The basis for this could be molecular mimicry, viral alteration of host antigens, or the presence of as yet undetectable microbes in the sites affected by the autoimmunity.

Examples of Autoimmune Disease

Systemic Autoimmunities

One of the most severe chronic autoimmune diseases is **systemic lupus erythematosus*** (SLE), or *lupus*. This name originated from the characteristic butterfly-shaped rash positioned across the nose and cheeks (**figure 16.17a**). Apparently ancient physicians thought the rash resembled a wolf bite (*lupus* is Latin for "wolf"). Although the manifestations of the disease vary considerably, all patients produce autoantibodies against a great variety of organs and tissues. Antibodies to intracellular materials such as the nucleoprotein of the nucleus and mitochondria are an additional diagnostic feature. In addition to a facial rash, lesions also occur on the skin of the

Figure 16.17 Common autoimmune diseases. (a) Systemic lupus erythematosus. One symptom is a prominent rash extending across the nose, cheeks and forehead. Papules and blotches can also occur on the chest and limbs. (b) Rheumatoid arthritis commonly targets the synovial membranes of joints. Chronic inflammation thickens this membrane, erodes the articular cartilage, and fuses the joint. These effects severely limit motion and can swell and distort the joints as evidenced by the second and third panel. (a): © DermNet New Zealand Trust; (b): © Mediscan/Alamy Stock Photo

limbs and body. Other affected organs are the kidneys, bone marrow, nervous system, joints, muscles, heart, and GI tract.

In SLE, autoantibody-autoantigen complexes appear to be deposited in the basement membranes of various organs. Kidney failure, blood abnormalities, lung inflammation, myocarditis, and skin lesions are the predominant symptoms. The disease often cycles between periods of flare-ups and remission. One form of chronic lupus (called discoid) is influenced by exposure to UV radiation and primarily afflicts the skin. The etiology of lupus is still not completely understood. It is not known how such a generalized loss of self-tolerance arises, though viral infection or loss of T-cell suppressor function is suspected. The fact that women of childbearing years account for 90% of cases indicates that immune suppression during pregnancy may be involved. The diagnosis of SLE can usually be made with a combination of symptoms and blood tests. Antibodies against nuclear DNA and RNA and various tissues (detected by indirect fluorescent antibody or radioimmune assay techniques) are common, and a positive test for the lupus factor (an antinuclear factor) is indicative of the disease. Treatment aims at controlling flare-ups with steroids, methotrexate, and the monoclonal antibody belimumab (Benlysta).

Rheumatoid arthritis (RA),* another systemic autoimmune disease, incurs progressive, debilitating damage to the joints. In some patients, the lung, eye, skin, and nervous systems are also involved. In the joint form of the disease, autoantibodies form immune complexes that bind to the synovial membrane of the joints and activate phagocytes and stimulate release of cytokines. Chronic inflammation leads to scar tissue and joint destruction. The joints in the hands and feet are affected first, followed by the knee and hip joints (**figure 16.17b**). The precipitating cause in rheumatoid arthritis is not known, though infectious agents such as Epstein-Barr virus have been suspected. The most common feature of the disease is the presence of an IgM antibody, called rheumatoid factor (RF), directed

L. *lupus*, wolf, and *erythema*, redness.

* *rheumatoid arthritis* (roo'-muh-toyd ar-thry'-tis) Gr. *rheuma*, a moist discharge, and *arthron*, joint.

against other antibodies. This does not cause the disease but is used mainly in diagnosis. More drugs have been developed to treat rheumatoid arthritis than other autoimmune diseases. They include methotrexate, TNF inhibitors (etanercept [Enbrel], adalimumab [Humira], infliximab [Remicade]), rituximab (Retuxan), abatacept (Orencia), and tocilizumab (Actrema). All of these inhibit some key immune cell or substance responsible for the pathology of RA.

Autoimmunities of the Endocrine Glands

On occasion, the thyroid gland is the target of autoimmunity. The underlying cause of **Graves' disease** is the attachment of autoantibodies to receptors on the follicle cells that secrete the hormone thyroxin. The abnormal stimulation of these cells causes the overproduction of this hormone and the symptoms of hyperthyroidism. In **Hashimoto's thyroiditis**, both autoantibodies and T cells are reactive to the thyroid gland, but in this instance, they reduce the levels of thyroxin by destroying follicle cells and by inactivating the hormone. As a result of these reactions, the patient suffers from hypothyroidism.

The pancreas and its hormone, insulin, are other autoimmune targets. Type I **diabetes mellitus** is caused by a dysfunction in insulin production by beta cells in the pancreas or its utilization by cells. This form is associated with autoantibodies and sensitized T cells that damage the beta cells. A complex inflammatory reaction leading to lysis of these cells greatly reduces the amount of insulin secreted. For several years it has been proposed that type I diabetes is linked to infection by the coxsackievirus, a common cause of colds and enteric infections, possibly due to molecular mimicry.

Neuromuscular Autoimmunities

Myasthenia gravis* is named for the pronounced muscle weakness that is its principal symptom. Although the disease afflicts all skeletal muscle, the first effects are usually felt in the muscles of the eyes and throat. In some cases it can progress to complete loss of muscle function and death. Its cause is unknown, but it appears most often in females less than 40 years old and in males more than 60 years old, and it is often associated with having other autoimmune diseases. The classic syndrome is caused by autoantibodies binding to the receptors for acetylcholine, a chemical required to transmit a nerve impulse across the synaptic junction to a muscle. The immune attack so severely damages the muscle cell membrane that transmission is blocked and paralysis ensues. Treatment usually includes immunosuppressive drugs and therapy to remove the autoantibodies from the circulation. Experimental therapy using immunotoxins to destroy lymphocytes that produce autoantibodies shows some promise.

Multiple sclerosis (MS) is a paralyzing neuromuscular disease associated with lesions in the insulating myelin sheath that surrounds neurons in the white matter of the central nervous system. The underlying pathology involves damage to the sheath by both T cells and autoantibodies; this damage severely compromises the capacity of neurons to send impulses. The principal motor and sensory symptoms are muscular weakness and tremors, difficulties in speech and vision, and some degree of paralysis. Most MS patients first experience symptoms as young adults, and they tend to have remissions (periods of relief) alternating with recurrences of disease throughout their lives.

**Myasthenia gravis* (my-uss'-theen'-ee-uh grah'vis.) L *myo*, muscle and *aesthene*, weakness.

Despite years of research, no definitive cause for MS has been pinpointed. It appears to arise from a combination of genetics, environmental exposure, and possibly viral infections. It is immune-mediated, but the antigen that triggers the attack on the myelin sheath has not yet been identified. A number of studies have examined the involvement of viral infections of the brain such as measles, herpes, and rubella. The only one that has a verifiable connection to MS is Epstein-Barr virus, but isolating the virus alone is not enough to show causation.

The disease can be treated with oral medications that suppress immune functions of lymphocytes, including cortisone, beta interferon, and monoclonal antibody drugs (natalizumab or Tysabri). An unfortunate side effect of many of these therapies is that they compromise normal immune function and increase the risks for infections and cancer. There has been some interest in techniques to restore the normal immune system through autologous (self) stem cell transplants taken from the marrow of the MS patient, which would bypass some of these complications.

Check Your Progress SECTION 16.6

26. Explain the pathologic process in autoimmunity.
27. Draw diagrams that explain five possible mechanisms for the development of autoimmunity.
28. Describe four major types of autoimmunity, comparing target organs and symptoms.

16.7 Immunodeficiency Diseases and Cancer: Compromised Immune Responses

Expected Learning Outcomes

24. Outline the categories of immunodeficiency diseases.
25. Describe the origins and effects of primary immune diseases caused by B-cell, T-cell, or combined defects.
26. Relate examples of secondary immunodeficiencies.
27. Describe the characteristics of cancer, and explain the mechanism of oncogenesis.
28. Explain how immune function relates to the development of cancer.

It is a marvel that development and function of the immune system proceed as normally as they do. On occasion, however, an error occurs and a person is born with or develops weakened immune responses. In many cases, these “experiments of nature” have provided penetrating insights into the exact functions of certain cells, tissues, and organs because of the specific signs and symptoms shown by the immunodeficient individuals. The pronounced consequences of **immunodeficiencies** are recurrent, overwhelming infections, often with opportunistic microbes, and adverse effects on overall health. Dysfunctional immunities can be grouped into two general categories: **primary diseases**, present at birth (congenital) and usually stemming from genetic errors, and **secondary diseases**, acquired after birth and caused by natural or artificial agents (**table 16.5**).

TABLE 16.5 General Categories of Immunodeficiency Diseases with Selected Examples

Primary Immune Deficiencies (Genetic)
B-Cell Defects (Low Levels of B Cells and Antibodies)
Agammaglobulinemia (X-linked, non-sex-linked)
Hypogammaglobulinemia
Selective immunoglobulin deficiencies
T-Cell Defects (Lack of All Classes of T Cells)
Thymic aplasia (DiGeorge syndrome)
Chronic mucocutaneous candidiasis
Combined B-Cell and T-Cell Defects (Severe combined immunodeficiency disease (SCID))
Adenosine deaminase (ADA) deficiency
X-SCID due to an interleukin defect
Wiskott-Aldrich syndrome
Ataxia-telangiectasia
Phagocyte Defects
Chédiak-Higashi syndrome
Chronic granulomatous disease of children (discussed in the chapter 16 Case Study)
Lack of surface adhesion molecules
Complement Defects
Lacking one of C components
Hereditary angioedema
Associated with rheumatoid diseases
Secondary Immune Deficiencies (Acquired)
From Natural Causes
Infection: AIDS, leprosy, tuberculosis, measles
Other disease: cancer, diabetes
Nutrition deficiencies
Stress
Pregnancy
Aging
From Immunosuppressive Agents
Irradiation
Severe burns
Steroids (cortisones)
Drugs to treat graft rejection and cancer
Removal of spleen

Primary Immunodeficiency Diseases

Deficiencies affect both specific immunities such as antibody production and less-specific ones such as phagocytosis, as featured in the chapter case study. Check out **figure 16.18** to survey the places in the normal sequential development of lymphocytes where defects can occur and the possible consequences. In many cases the deficiency is due to an inherited abnormality, though the exact nature of the abnormality is not known for a number of diseases. Because the development of B cells and T cells departs at some point, an individual can lack one or both cell lines. It must be emphasized, however, that some deficiencies affect other cell functions. For example, a T-cell deficiency can affect B-cell function because of the role of

CD4 T helper cells. In some deficiencies, the lymphocytes in question are completely absent or is present at very low levels, whereas in others, lymphocytes are present but do not function normally.

Clinical Deficiencies in B-Cell Development or Expression

Genetic deficiencies in B cells usually appear as an abnormality in immunoglobulin expression. In some instances, only certain immunoglobulin classes are absent; in others, the levels of all types of immunoglobulins (Ig) are reduced. A significant number of B-cell deficiencies are X-linked (also called sex-linked) recessive traits, meaning that the gene occurs on the X chromosome and the disease appears primarily in male children.

The term **agammaglobulinemia** literally means the absence of gamma globulin, the fraction of serum that contains immunoglobulins (Ig). Because it is very rare for Ig to be completely absent, some physicians prefer the term **hypogammaglobulinemia**.* T-cell function in these patients is usually normal. The symptoms of recurrent, serious bacterial infections usually appear about 6 months after birth. The bacteria most often implicated are pyogenic cocci, *Pseudomonas*, and *Haemophilus influenzae*; and the most common infection sites are the lungs, sinuses, meninges, and blood. Many Ig-deficient patients can have recurrent infections with viruses and protozoa, as well. Patients often manifest a wasting syndrome and may have a reduced life span, but modern therapy has improved their prognosis. About the only treatments available for this condition are passive immunotherapy with immune serum globulin and continuous antibiotic therapy.

The lack of a particular class of immunoglobulin is a relatively common condition. Although genetically controlled, its underlying mechanisms are not yet clear. IgA deficiency is the most prevalent, occurring in about 1 person in 600. Such persons have normal quantities of B cells and other immunoglobulins, but they are unable to produce IgA. Consequently, they lack protection against local microbial invasion of the mucous membranes and suffer recurrent respiratory and gastrointestinal infections. The usual treatment using Ig replacement does not work, because conventional preparations are high in IgG, not IgA.

Clinical Deficiencies in T-Cell Development or Expression

Due to T cells' critical role in immune defenses, a genetic defect in T cells results in a broad spectrum of disease, including severe opportunistic infections, wasting, and cancer. In fact, a dysfunctional T-cell line is usually more devastating than a defective B-cell line because T helper cells are required to assist in most specific immune reactions. The deficiency can occur anywhere along the developmental spectrum, from thymus to mature, circulating T cells.

Abnormal Development of the Thymus The most severe of the T-cell deficiencies involve a thymus gland that is underdeveloped (hypoplastic) or congenitally absent (aplastic). The disease associated with thymic dysfunction, **DiGeorge syndrome**, is caused by failure in the embryonic development of the third and

* *hypogammaglobulinemia* (hy'-poh-gem-ah-glob-yoo-lin-ee'-mee-ah) Gr. *hypo*, denoting a lowered level of Ig.

Figure 16.18 The stages of development and the functions of B cells and T cells, whose failure causes severe immunodeficiencies. Dotted lines represent the phases in development where breakdown can occur.

fourth pharyngeal pouches, and in most cases is associated with a deletion mutation in chromosome 22. The adverse effects on thymic function range from reduced immune activity to complete lack of cell-mediated immunity, especially of the CD4 or helper class of T cells. This makes children highly susceptible to persistent infections by fungi, protozoa, and viruses. Common, usually benign childhood infections such as chickenpox, measles, or mumps can be fatal if not diagnosed and treated right away. Even vaccinations using attenuated microbes pose a danger. Part of the severity of DiGeorge syndrome is the lack of antibodies resulting from deficiencies in helper T cells that are needed to activate B cells. Other symptoms of this syndrome are heart defects, reduced growth, wasting of the body, unusual facial characteristics (**figure 16.19**), and an increased incidence of lymphatic cancer. The only therapy that could restore their immune system is a thymus transplant. Other conditions are alleviated by surgery and drugs to treat the recurrent infections.

Severe Combined Immunodeficiencies: Dysfunction in B and T Cells

Severe combined immunodeficiencies (SCIDs) are the most dire and potentially lethal of the immunodeficiency diseases because they involve a loss of both T and B lymphocyte functions. Some SCIDs are due to the complete absence of the lymphocyte stem cell in the marrow; others are attributable to the dysfunction of B cells and T cells later in development. Infants with SCIDs usually manifest the T-cell deficiencies within days after birth by developing

Figure 16.19 A composite showing facial appearance of a child with DiGeorge syndrome, sometimes referred to as **velocardiofacial syndrome**. Altered development of the facial regions of the embryo leads to some degree of anatomical abnormalities. Examples of the most common features include low-set, deformed earlobes; prominent ears; wide-set eyes; folds in the eyelids; wide nose bridge and small nostrils; small jaw and chin; a small, bow-shaped mouth; and the absence of a philtrum (the vertical furrow between the nose and upper lip). Not every child manifests all of these together.

candidiasis, sepsis, pneumonia, or systemic viral infections. This debilitating condition appears to have several forms. In the two most common forms, Swiss-type agammaglobulinemia and thymic aplasia, the numbers of all types of lymphocytes are extremely low, the blood antibody content is greatly diminished, and the thymus and cell-mediated immunity are poorly developed. Both diseases are due to a genetic defect in the development of the lymphoid cell line.

A rare form of SCID is **adenosine deaminase (ADA) deficiency**, which is caused by an autosomal recessive defect in the metabolism of adenosine. In this case, lymphocytes develop, but a metabolic product builds up to abnormal levels and selectively destroys the cells. Infants with ADA deficiency are subject to recurrent infections and severe wasting typical of severe deficiencies. Some SCID cases are due to a developmental defect in receptors for B and T cells. One of these, termed **X-SCID**, is a deficiency in interleukin receptors that occurs in about 1 in 50,000 to 100,000 births. Because it is X-linked, it occurs most often in male infants and was responsible for the disease of David, the child in the “plastic bubble” (**figure 16.20**). As heart-wrenching as David’s life was, he also provided a means to study and understand the disease in a way that had never been possible. Later studies found that he had inherited a defective gene for essential molecules in several interleukin receptors. This prevented both T and B cells from receiving signals that control growth, development, and responsiveness. Both cytotoxic and humoral immunities were shut down, leaving the body vulnerable to infections and cancers.

Because of their profound lack of specific adaptive immunities, children with SCID require the most rigorous kinds of aseptic techniques to protect them from opportunistic infections. Nowadays a better option for long-term survival is an immediate bone marrow or stem cell transplant right after the disease is diagnosed, rather than placing them into sterile bubbles. Because they lack functioning lymphocytes, the requirement for a bone marrow match is not as important with SCID children. Although transplanting bone marrow has been about 50% successful in curing the disease, it is complicated by graft versus host disease. This outcome can be corrected by selectively removing the reactive T cells from the donated marrow. Some infants have benefited from fetal liver or stem cell grafts, and some ADA-deficient patients can remain healthy through periodic transfusions of blood containing large amounts of the normal enzyme. A more lasting treatment for all types of SCID has emerged from gene therapy. So far medical geneticists have cured two dozen children with SCID by inserting normal genes to replace the defective genes (see figure 10.15).

Secondary Immunodeficiency Diseases

Secondary acquired deficiencies in B cells and T cells are caused by one of four general agents: (1) infection, (2) organic disease, (3) chemotherapy, or (4) radiation.

The most recognized infection-induced immunodeficiency is **acquired immunodeficiency syndrome** or **AIDS**. This syndrome is caused when several types of immune cells, including T helper cells, monocytes, macrophages, and antigen-presenting cells, are infected by the human immunodeficiency virus (HIV). It is generally thought that

Figure 16.20 An answer to the mystery of David. David Vetter, the best-known SCID child, lived all but the last 2 weeks of his life in a sterile environment to isolate him from the microorganisms that could have quickly ended his life. When David was 12, his doctors attempted a bone marrow transplant using his sister’s bone marrow, but the marrow harbored Epstein-Barr virus. Because he lacked any form of protective immunities against this oncogenic virus, a cancer spread rapidly through his body. © Baylor College of Medicine, Public Affairs

the depletion of T helper cells and functional impairment of immune responses ultimately account for the cancers and opportunistic protozoan, fungal, and viral infections associated with this disease. (See chapter 25 for an extensive discussion of HIV and AIDS.) Other infections that can deplete immunities are tuberculosis, leprosy, and malaria.

Cancers that target the bone marrow or lymphoid organs can be responsible for extreme malfunction of both humoral and cellular immunity. In leukemia, the massive numbers of cancer cells compete for space and literally displace the normal cells of the bone marrow and blood. Plasma cell tumors produce large amounts of nonfunctional antibodies, and thymus gland tumors cause severe T-cell deficiencies.

The Role of the Immune System in Cancer

The term **cancer** comes from the Latin word for crab and presumably refers to the appendage-like projections that a spreading tumor develops. A cancer is defined as the new growth and spread of abnormal cells. The disease is also known by the synonym **neoplasm**,* or by more specific terms that usually end in the suffix **-oma**. **Oncology*** is the field of medicine that specializes in cancer.

An abnormal growth or tumor is generally characterized as benign or malignant. A **benign tumor** is a self-contained mass within an organ that does not spread into adjacent tissues. The mass is usually slow-growing, rounded, and not greatly different from its tissue of origin. Benign tumors do not ordinarily cause death unless they grow into critical spaces such as the heart valves or brain ventricles. The feature that most distinguishes a **malignant tumor** (cancer) is uncontrolled growth of abnormal cells within normal tissue. As a general rule, cancer originates in cells such as skin and bone marrow cells that have retained

* **neoplasm** (nee'-oh-plazm) Gr. *neo*-, new, and *plasm*, formation.

* **oncology** (awn-kaw'-luh-gee") Gr. *onkos*, cancer.

the capacity to divide, whereas mature cells that have lost this power (some neurons, for instance) do not commonly become cancerous.

Research findings link cancers to genetic damage or inherited genetic predispositions that alter the function of certain genes called oncogenes found normally in all cells. These genetic alterations disrupt the normal cell division cycle and *transform* a normal cell into a cancer cell. Cancer development involves many complex interactions between genes, their products, and external signals received by the cell. There is no single mechanism. Consider the fact that at least eight different genetic defects lead to colon cancer and nearly that many are implicated in breast cancers.

It is increasingly evident that susceptibility to certain cancers is inherited. At least 30 neoplastic syndromes that run in families have been described. A particularly stunning discovery is that some cancers in animals are actually due to endogenous viral genomes passed from parent to offspring in the gametes. Many cancers reflect an interplay of both hereditary and environmental factors. An example is lung cancer, which is associated mainly with tobacco smoking. But not all smokers develop lung cancer, and not all lung cancer victims smoke tobacco.

What is the role of the immune system in controlling cancer? To understand the connection, we need to review the actions of certain lymphocytes discussed in chapter 15. A concept that readily explains the detection and elimination of cancer cells is **immune surveillance**. Many experts postulate that cells with cancer-causing potential arise constantly in the body but that the immune system ordinarily discovers and destroys these cells, thus keeping cancer in check. Experiments with mammals have amply demonstrated that components of cell-mediated immunity interact with tumors and their antigens. The primary types of cells that operate in surveillance and destruction of tumor cells are cytotoxic T cells, natural killer (NK) cells, and macrophages. It appears that these cells recognize abnormal or foreign surface markers on the tumor cells and destroy them by mechanisms shown in figure 15.16. Antibodies help destroy tumors by interacting with macrophages and natural killer cells. This involvement of the immune system in destroying cancerous cells has inspired a number of specific immunotherapies.

How do we account for the commonness of cancer in light of this powerful range of defenses against tumors? To an extent, the answer is simply that, as with infection, the immune system can and does fail. In some cases, the cancer may not be immunogenic enough; it may display self markers and not be targeted by the surveillance system. In other cases, the tumor antigens may have mutated to escape detection. As we saw earlier, patients with immunodeficiencies such as AIDS and SCID are more susceptible to various cancers because they lack essential T-cell or cytotoxic functions. It may turn out that most cancers are associated with some sort of immunodeficiency, even a slight or transient one. See the discussion of immune regulation by T cells in section 15.3.

An ironic outcome of lifesaving medical procedures is the possible suppression of a patient's immune system, which could leave them susceptible to cancer. Although radiation and anticancer drugs are the first line of therapy for many types of cancer, both agents are extremely damaging to the bone marrow and other body cells. Some immunosuppressive drugs that prevent graft rejection by T cells can likewise suppress responses against neoplastic cells.

Check Your Progress SECTION 16.7

- In general, how do primary immunodeficiencies and acquired immunodeficiencies differ in their basic causes?
- What kinds of symptoms accompany B-cell defects, T-cell defects, and combined defects, and why is this the case?
- Give examples of specific diseases that involve each type of defect.
- Define *cancer*, and differentiate between a benign tumor and a malignant tumor, using examples.
- Describe the relationship between cancer and the immune system.

CASE STUDY Part 2

Hospital investigators reviewing the events in the case were faced with explaining the fatal blood transfusion to the patient's family. What could have gone wrong? Going by the first typing of the patient's blood and the cross-match with the transfused blood, nothing unusual would have been expected. But there was no question that he suffered an extreme transfusion reaction. When the patient's blood was retyped after death, it turned out that he was actually O⁺, the most common blood type among humans. One possible explanation for the adverse outcome is that he reacted to a blood group other than ABO. But his blood had the same Rh factor as the transfused blood and was compatible for Rh factor. And in cases of the minor RBC antigens such as MN and Kell, the reactions are usually quite mild and never result in mass hemolysis and death. As the investigation continued, it became evident that the cause of this tragedy was not a mistake in the technology of the blood typing or some unusual characteristic of the blood, but rather it was placed squarely on human error in record keeping.

The patient in this case was caught in a worst-case scenario. First, he had the misfortune of being mistaken for his hospital roommate, and second, he was given type A blood, one of the most serious incompatibilities for type O. The blood vial was labeled with his correct name but was used to take blood from the man in the adjacent bed. This same blood was also used in the cross-match, so it did not react with the transfusion blood. A safer system used by many hospitals to prevent this sort of error is to have a microchip embedded in the patient's armband that reads out his blood type. It is compared to the blood being transfused and sounds an alarm if the bloods are incompatible.

- Why do people carry antibodies against other blood types even when they have never been sensitized by prior contact with that blood?
- If the transfusion reaction had not progressed so rapidly, what blood could have been safely given to the patient and why?

To conclude this Case Study, go to Connect.

To read more about the subject of transfusion reactions, go to <http://emedicine.medscape.com/article/780074-overview>.

 Chapter Summary with Key Terms

16.1 The Immune Response: A Two-Sided Coin

The study of disease states involving malfunctions of the immune system is called immunopathology.

- Allergy** and hypersensitivity are terms for an exaggerated, misdirected expression of certain immune responses. “Allergy” is used mainly for immediate type reactions and “hypersensitivity” for other forms of overreactions to allergens.
- Autoimmunity involves abnormal responses to self antigens. A deficiency or loss in immune function is called **immunodeficiency**.
- Immediate-onset allergies involve contact with **allergens**, antigens that affect certain people; susceptibility is inherited.
- Allergens enter through four portals: Inhalants are breathed in (pollen, dust); ingestants are swallowed (food, drugs); injectants are inoculated (drugs, bee stings); contactants react on skin surface (cosmetics, glue).

16.2 Allergic Reactions: Atopy and Anaphylaxis

- On first contact with allergen, specific B cells react with allergen and form a special antibody class called IgE, which affixes by its Fc receptor to mast cells and basophils.
 - This **sensitizing dose** primes the allergic response system.
 - Upon subsequent exposure with a **provocative dose**, the same allergen binds to the IgE–mast cell complex.
 - This causes **degranulation**, release of intracellular granules containing mediators (**histamine, serotonin, leukotriene, prostaglandin**), with physiological effects such as vasodilation and bronchoconstriction.
 - Conditions that are common types of atopy are **eczema**, food allergies, and **asthma**; severe systemic reaction is **anaphylaxis**.
 - Other symptoms are rash, itching, redness, increased mucous discharge, pain, swelling, and difficulty in breathing.
- Diagnosis of allergy can be made by a histamine release test on basophils; serological assays for IgE; and skin testing, which injects allergen into the skin and mirrors the degree of reaction.
- Control of allergy involves drugs to interfere with the action of histamine, inflammation, and release of cytokines from mast cells. **Desensitization** or hyposensitization therapy involves the administration of purified allergens.

16.3 Type II Hypersensitivities: Reactions That Lyse Foreign Cells

- Type II reactions involve the interaction of antibodies, foreign cells, and complement, leading to lysis of the foreign cells. In transfusion reactions, humans may become sensitized to special antigens on the surface of the red blood cells of other humans.
- The **ABO blood groups** are genetically controlled: Type A blood has A antigens on the RBCs; type B has B antigens; type AB has both A and B antigens; and type O has neither antigen. People produce antibodies against A or B antigens if they lack these antigens. Antibodies can react with antigens if the wrong blood type is transfused.
- Rh factor** is another RBC antigen that becomes a problem if an Rh⁻ mother is sensitized by an Rh⁺ fetus. A second fetus can receive antibodies she has made against the factor and develop hemolytic disease of the newborn. Prevention involves therapy with Rh immune globulin.

16.4 Type III Hypersensitivities: Immune Complex Reactions

Exposure to a large quantity of soluble foreign antigens (serum, drugs) stimulates antibodies that produce small, soluble Ab-Ag complexes. These **immune complexes** are trapped in various organs and tissues, which incites a damaging inflammatory response.

16.5 Immunopathologies Involving T Cells

- Type IV Delayed Hypersensitivity**
 - A delayed response to antigen involving the activation of and damage by T cells.
 - Skin response to allergens, including infectious agents. Example is tuberculin reaction.
 - Contact dermatitis is caused by exposure to plants (ivy, oak) and simple environmental molecules (metals, cosmetics).
 - Cytotoxic T cells acting on allergen elicit a skin reaction.
- Graft Rejection:** Reaction of cytotoxic T cells directed against foreign cells of a grafted tissue; involves recognition of foreign human leukocyte antigens (HLA) by T cells and rejection of tissue.
 - Host may reject graft; graft may reject host.
 - Types of grafts include: **autograft**, from one part of body to another; **isograft**, between identical twins; **allograft**, between two members of same species; **xenograft**, between two different species.
 - All major organs may be successfully transplanted.
 - Allografts require tissue match (HLAs must correspond); rejection is controlled with drugs.

16.6 Autoimmune Diseases—An Attack on Self

- In certain type II and type III hypersensitivities, the immune system has lost tolerance to self molecules (**autoantigens**) and forms **autoantibodies** and sensitized T cells against them. Disruption of function can be systemic or organ-specific.
- Autoimmune diseases** are genetically determined and more common in females.
- Examples include **systemic lupus erythematosus, rheumatoid arthritis, diabetes mellitus, and multiple sclerosis**.

16.7 Immunodeficiency Diseases and Cancer: Compromised Immune Responses

I. Immunodeficiency Diseases

Components of the immune response system are absent. Deficiencies involve B and T cells, phagocytes, and complement.

- Primary immunodeficiency is genetically based, congenital; defect in inheritance leads to lack of B-cell activity, T-cell activity, or both.
- B-cell defect is called **agammaglobulinemia**; patient lacks antibodies; serious recurrent bacterial infections result. In Ig deficiency, one of the classes of antibodies is missing or deficient.
- In T-cell defects, the thymus is missing or abnormal. In **DiGeorge syndrome**, the thymus fails to develop; afflicted children experience recurrent infections with eukaryotic pathogens and viruses; immune response is generally underdeveloped.
- In **severe combined immunodeficiency (SCID)**, both limbs of the lymphocyte system are missing or defective; no adaptive immune response exists; fatal without replacement of bone marrow or other therapies.

- E. Secondary (acquired) immunodeficiency is due to damage after birth (infections, drugs, radiation). **HIV/AIDS** is the most common of these; T helper cells are main target; deficiency manifests in numerous opportunistic infections and cancers.

II. Cancer: The Role of the Immune System

- A. **Cancer** is characterized by overgrowth of abnormal tissue, also known as a **neoplasm**. It can arise when normal **immune surveillance** by lymphocytes malfunctions and fails to detect and destroy tumors and cancers, allowing them to grow and spread.
- Tumors** can be **benign** (a nonspreading local mass of tissue) or **malignant** (a cancer) that spreads (metastasizes) from the tissue of origin to other sites.
 - Cancers occur in nearly every cell type (except mature, nondividing cells).
- B. Cancer cells appear to share a common basic mechanism involving a genetic alteration that **transforms** a normally dividing cell into one that grows out of control.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

- Pollen is which type of allergen?
 - contactant
 - ingestant
 - injectant
 - inhalant
- B cells are responsible for which conditions?
 - asthma
 - anaphylaxis
 - tuberculin reactions
 - both a and b
- Which hypersensitivities are T-cell mediated?
 - type I
 - type II
 - type III
 - type IV
- The contact with allergen that results in symptoms is called the
 - sensitizing dose
 - degranulation dose
 - provocative dose
 - desensitizing dose
- Production of IgE and degranulation of mast cells are involved in
 - contact dermatitis
 - anaphylaxis
 - Arthus reaction
 - both a and b
- The direct, immediate cause of allergic symptoms is the action of
 - the allergen directly on smooth muscle
 - the allergen on B lymphocytes
 - allergic mediators released from mast cells and basophils
 - IgE on smooth muscle
- Theoretically, type _____ blood can be donated to all persons because it lacks _____.
 - AB, antibodies
 - O, antigens
 - AB, antigens
 - O, antibodies
- An example of a type III immune complex disease is
 - serum sickness
 - contact dermatitis
 - graft rejection
 - atopy
- Type II hypersensitivities are due to
 - IgE reacting with mast cells
 - activation of cytotoxic T cells
 - IgG-allergen complexes that clog epithelial tissues
 - complement-induced lysis of cells in the presence of antibodies
- Production of autoantibodies may be due to
 - emergence of forbidden clones of B cells
 - production of antibodies against sequestered tissues
 - infection-induced change in receptors
 - All of these are possible.
- Rheumatoid arthritis is an _____ that affects the _____.
 - immunodeficiency disease, muscles
 - autoimmune disease, nerves
 - allergy, cartilage
 - autoimmune disease, joints
- A positive tuberculin skin test is an example of
 - a delayed-type allergy
 - autoimmunity
 - acute contact dermatitis
 - eczema
- Contact dermatitis can be caused by
 - pollen grains
 - chemicals absorbed by the skin
 - microbes
 - proteins found in foods
- Which disease would be most similar to AIDS in its pathology?
 - X-linked agammaglobulinemia
 - SCID
 - ADA deficiency
 - DiGeorge syndrome
- Which of these immunopathologies could be treated with a stem cell transplant?
 - arthus reaction
 - SCID
 - anaphylaxis
 - a and b only
 - b and c only
- How is the immune system involved in development of cancer?
 - failure in immune surveillance
 - mutation in cytotoxic T cells
 - autoantibody formation
 - overreaction to environmental chemicals

 Case Study Review

- Which blood type antibodies would the patient normally have carried in his plasma? (Explain your answer.)
 - anti-a alone
 - anti-b alone
 - anti-Rh alone
 - anti-a and -b
 - anti-a, -b, and -Rh
 - neither anti-a nor anti-b
- If the patient had a blood type different from O⁺, which one would *not* have resulted in his death? (Explain your answer.)
 - type A⁻
 - type B⁺
 - type AB⁻
 - type O⁻
- Given that it is the donated RBCs and not the patient's normal RBCs that are hemolyzed, how can a hemolytic transfusion reaction still be fatal?

 Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

- Compare and contrast atopic allergy and type IV (delayed) hypersensitivity as to mechanism, symptoms, eliciting factors, and allergens.
- Go through the sequence of events that gives rise to an anaphylactic response to peanuts.
- How does a baby inherit Rh⁺ blood from an Rh⁻ mother?
- Why is a hemolytic transfusion reaction considered a type of hypersensitivity?
- Describe three circumstances that might cause antibodies to develop against self tissues.
- Explain how people with autoimmunity could develop antibodies against intracellular components (nucleus, mitochondria, and DNA).

 Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps and a sample of a concept map for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

 Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

- Suggest some possible physiological benefits of allergy.
- A 3-week-old neonate develops severe eczema after being given penicillin therapy for the first time. Explain what probably has happened.
- Why would a person be allergic to strawberries when he eats them but show a negative skin test to them?
 - Where in the course of type I allergies do antihistamine drugs, cortisone, and desensitization work? Exactly what do they do?
 - Compare the sites of action of montelukast (Singulair) and omalizumab (Xolair).

5. Explain how cleaner living and medical advances could contribute to allergies.
6. Why would it be necessary for an Rh⁻ woman who has had an abortion, miscarriage, or an ectopic pregnancy to be immunized against the Rh factor?
7. How can a person prevent becoming allergic to poison oak? What is the basis for infectious allergy?
8. Why are primary immunodeficiencies considered “experiments of nature”?
9.
 - a. Explain why babies with agammaglobulinemia do not develop opportunistic infections until about 6 months after birth.
 - b. Explain why people with B-cell deficiencies can benefit from artificial passive immunotherapy. Explain whether vaccination would work for them.
 - c. Explain why T-cell deficiencies usually cause more severe effects than B-cell deficiencies.
10. In what ways can cancer be both a cause and a symptom of immunodeficiency?

Visual Challenge

1. Looking at **figure 15.8**, reproduced here, explain how this phenomenon pertains to allergies.

2. Observe the blood typing results shown here and label the blood types, including Rh. Which types are the most and least common?

Like tiny green sausages, these vibrios (13,000x) cause the majority of food infections that originate from shellfish. *Source:* Janice Haney Carr/CDC

Seafood: A hidden source of pathogens.

CASE STUDY Part 1 A Hospital Outbreak of Seafood Sickness

Personnel working in a Taiwanese hospital during a spring heat wave were alerted to a possible outbreak of **health-care-associated infections**.

The first evidence came in a report from the nursing staff about nine patients in two adjacent wards with severe **diarrhea, fever, nausea, and vomiting** several hours after eating a seafood meal. An **infection control** team was immediately brought in to monitor and record all hospital-wide cases of **gastroenteritis**. Stool and food samples were sent to their clinical laboratory and the local public health department for testing. Over the next 48 hours the staff logged 16 additional cases spread among five wards in two separate buildings.

Specimens were screened for **common enteric pathogens**, including *Salmonella* species, *Shigella* species, *Staphylococcus aureus*, *Vibrio* species., *Campylobacter jejuni*, *Bacillus cereus*, and *Clostridium* species. Plating for initial isolation was performed on **blood agar**, **MacConkey agar**, and other selective and differential media. **Gram stains** of the stool samples were performed early on, but

they were inconclusive, yielding mostly gram-negative rods mixed with some gram-positive rods and cocci. After 2 days, colonies grew in the presence of air on blood agar and on **selective media** containing **bile**. A second Gram stain of pure cultures indicated that the isolates were **gram-negative rods**, and a **hanging drop slide** viewed with **dark-field microscopy** revealed **curved and comma-shaped rods with darting motility**. **Case Study table 1** summarizes the profiles of the potential pathogens in this case. They can be compared with results from actual patient and food specimens as a means of narrowing the initial identification.

“A hanging drop slide viewed with dark-field microscopy revealed curved and comma-shaped rods with darting motility.”

- Explain the reason for using bile as a selective agent and the rationales for the preliminary biochemical tests listed in table 1.
- Given the data so far, identify the possible infectious agents that best fit the pathogen profile.

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

CASE STUDY TABLE 1

TEST	<i>Salmonella</i>	<i>Shigella</i>	<i>Vibrio</i>	<i>Campylobacter</i>	Patient and Food Isolate Results
Motility	+	–	+	+	+
Shape	Straight rods	Straight rods	Curved rods	Curved, spiral rods	Curved rods
Oxidase	–	–	+	+	+
Growth on 6% salt medium	–	–	+	+	+
Oxygen requirements	Facultative	Facultative	Aerobic	Microaerophilic	Aerobic
Fermentation of glucose	+	+	+	–	+

SCOPING OUT THE CHAPTER

Any time an infection rears its ugly head, the occasion always begins with a mystery. What exactly is the cause of this illness? Is that red patch on my foot a fungus or a wart? Is this rash measles or chickenpox? Is my sore throat caused by strep or a cold? Fortunately, modern medicine has reached a point in diagnosis that most infections don't remain a mystery for very long. Specimens are taken, cultures are made and inspected, symptoms assessed, and high powered diagnostic tests ordered—all usually within a few hours after seeking medical attention. This chapter focuses on what goes on behind the scenes of a clinical microbiology laboratory as it processes samples, identifies pathogens, and helps support medical treatment.

Directly Examining Microbes: Gathering

Background Data The earliest instrument of the microbiology laboratory was the microscope, and even now, a magnified specimen or culture is a powerful tool for revealing unique characteristics of the cells or viruses discovered there. Observing microbes grown on a variety of specialized media can be an indispensable way to develop morphological and biochemical profiles of a suspected infectious agent.

Checking out DNA and RNA Another essential method for detecting and identifying pathogens is to extract their nucleic acids, develop a genetic profile of their DNA or RNA, and compare it with profiles of known organisms or viruses. The uniqueness of a genetic profile makes this one of the most specific methods available, although it does require additional technology and expertise.

Tests Based on Antibodies and Antigens

Labs On the Go: Rapid Testing Some of the newest diagnostic and identification techniques are based on compact, quick tests that can be done in a medical office, at home, or in the field. These tests are generally designed to detect the possible presence of pathogens from specimens and provide immediate feedback on the possibility of an infection that can read out as a simple color change.

Identifying Microbes With Antibodies

Another form of immune testing is the use of specially-made antibodies to interact with unknown pathogens to form a visible reaction. This technique supports the identification of viral and bacterial pathogens isolated from a variety of samples, including the body, food, and water.

Looking for Signs of Infection in the Blood

Most infections leave behind a tell-tale sign—antibodies that have been formed in response to the pathogen. When detected in a blood or serum sample, they can provide the immune history of an individual and a possible diagnosis. Tests of this type rely on the specificity that antibodies have for their targets, so that a positive reaction can verify that a person has had some contact with a pathogen such as HIV.

17.1 An Overview of Clinical Microbiology

Expected Learning Outcomes

1. Describe what is involved in the main categories of laboratory identification of infectious agents.
2. Explain several techniques in specimen collection and the concerns in acquiring good cultures.
3. Summarize the main procedures in isolation, cultivation, and identification of pathogens.

In earlier chapters (3, 4, 5, 6, and 10) we introduced a variety of laboratory procedures used in cultivating and isolating microorganisms from samples. These techniques are an important part of studying and characterizing microbes, whether it be for research purposes or diagnosing infectious diseases. For many professionals and even beginning microbiology students, the most pressing concern is *how to identify unknown microbes* in specimens or **cultures**. The methods microbiologists use to identify bacteria to the level of genus and species fall into three main categories: **phenotypic**, which includes a consideration of morphology (microscopic and macroscopic) as well as physiology or biochemistry; **immunologic**, which entails analysis of the blood (serology) and other fluids; and **genotypic** (or genetic) techniques.

Data from a cross section of such tests can produce a unique profile of each isolate. Increasingly, genetic means of identification are being used as a sole resource for identifying bacteria. As universally used databases of genetic profiles of microbes become more complete, these types of analyses provide a more accurate and speedy way of identifying microbes than was possible even a decade ago. There are still many organisms, however, that must be identified through traditional means. Biochemical tests and rapid testing systems continue to be a mainstay of the clinical laboratory. Serology is a highly reliable procedure for some diseases, and is still favored as a way to screen large numbers of people rapidly and economically. In the next sections we emphasize cultural, serological, and genetic methods of analysis. Additional information on the methods for identifying bacteria can be found in Appendix C. The specialized techniques required for identification and diagnosis of viruses and viral diseases are covered in section 17.6.

Phenotypic Methods

Microscopic Morphology

Traits that can factor in identification of bacteria are combinations of cell shape and size, Gram stain reaction, acid-fast reaction, and special structures, including endospores, granules, and capsules. Electron microscope studies can pinpoint additional structural features (such as the cell wall, flagella, pili, and fimbriae). Microscopic analysis is also used to evaluate specimen contents prior to culturing. This can often narrow the causative agent as bacterial, fungal, or protozoan.

Macroscopic Morphology

Cultural traits that can be assessed with the naked eye are also useful in diagnosis. These include the appearance of growth, including texture, size, shape, pigment of colonies, speed of growth, and reactions to special types of selective and differential media.

Physiological/Biochemical Characteristics

Physiological and biochemical characteristics have been the traditional mainstay of bacterial identification. Enzymes and other biochemical properties of bacteria are fairly reliable and stable expressions of the chemical identity of each species. Dozens of diagnostic tests exist for determining the presence of specific enzymes and for assessing nutritional and metabolic activities. Examples include tests for fermentation of sugars; capacity to digest or metabolize complex polymers such as proteins and polysaccharides; production of gas; presence of enzymes such as catalase, oxidase, and decarboxylases; and sensitivity to antimicrobial drugs. Special rapid identification test systems that record the major biochemical reactions of a culture have streamlined data collection and analysis.

Genotypic Methods

Examining the genetic material itself has revolutionized the identification and classification of bacteria. There are many advantages of genotypic methods over phenotypic methods, when they are available. The primary advantage is that actually culturing the microorganisms is not always necessary. In recent decades, scientists have come to realize that there are many more microorganisms that we can't grow in the lab compared with those that we can (3.1 Secret World of Microbes). Another advantage is that genotypic methods are increasingly automated, and results are obtained very quickly, often with more precision than with phenotypic methods.

Immunologic Methods

Bacteria and other microbes have surface and other molecules called antigens that are recognized by the immune system. One immune response to antigens is the production of antibodies that are designed to bind tightly to the antigens. The nature of the antibody response can be determined from a blood (or other tissue) sample. The presence of specific antibodies to a suspected pathogen is highly suggestive of infection. This is often easier than testing for the microbe itself, especially in the case of viral infections. Most HIV testing entails examination of a person's blood for presence of antibody to the virus. Laboratory kits based on this technique are available for immediate identification of a number of pathogens. These methods are covered in greater detail in section 17.4.

On the Track of the Infectious Agent: Specimen Collection

Regardless of the method of diagnosis, specimen collection is the common point that guides the health care decisions of every member of a clinical team. Indeed, the success of identification and

treatment depends on how specimens are collected, handled, and stored. Specimens can be taken by a clinical laboratory scientist or medical technologist, nurse, physician, or even by the patient himself. However, it is imperative that general aseptic procedures be used, including sterile sample containers and other tools to prevent contamination from the environment or the patient. **Figure 17.1a** delineates the most common sampling sites and procedures.

In sites that normally contain resident microbiota, care should be taken to sample only the infected site and not surrounding areas. One common type of collection system is the sterile swab transport tube (**figure 17.1b**). This allows for sampling, transporting, and maintaining the specimen in its original condition. When using a swab to take a sample from throat and nasopharyngeal regions, the swab should not touch the tongue, cheeks, or saliva. Saliva is an especially undesirable contaminant because it contains millions of bacteria per milliliter, most of which are normal microbiota. Sputum, the mucus secretion that coats the lower respiratory surfaces, especially the lungs, is discharged by coughing or taken by catheterization to avoid contamination with saliva. Depending on the nature of the lesion, skin can be swabbed or scraped with a scalpel to expose deeper layers. The mucous lining of the vagina, cervix, or urethra can be sampled with a swab or applicator stick.

If sterile urine is required, it is usually removed aseptically from the bladder with a thin tube called a catheter. Another method,

called a “clean catch,” is taken by washing the external urethra and collecting urine midstream during urination. The latter method inevitably incorporates a few normal microbiota into the sample, but these can usually be differentiated from pathogens in an actual infection. Sometimes diagnostic techniques require first-voided “dirty catch” urine.

Sterile materials such as blood, cerebrospinal fluid, and tissue fluids must be taken by sterile needle aspiration. Antisepsis of the puncture site is extremely important in these cases. Additional sources of specimens are the vagina, eye, ear canal, nasal cavity (all by swab), and diseased tissue that has been surgically removed (biopsied).

After proper collection, the specimen is promptly transported to a lab and stored appropriately (usually refrigerated) if it must be held for a time. Nonsterile samples in particular, such as urine, feces, and sputum, are especially prone to deterioration at room temperature. The overgrowth of normal microbiota in these samples could interfere with isolation of the pathogens. It could also alter the numbers and proportions of cells, making analysis more difficult. Many transport devices contain nonnutritive maintenance media (so the microbes do not grow), a buffering system, and an aerobic or sometimes anaerobic environment as necessary for maintaining microbes that require oxygen or are damaged by it.

A summary of specimen collection guidelines can be found in **table 17.1**.

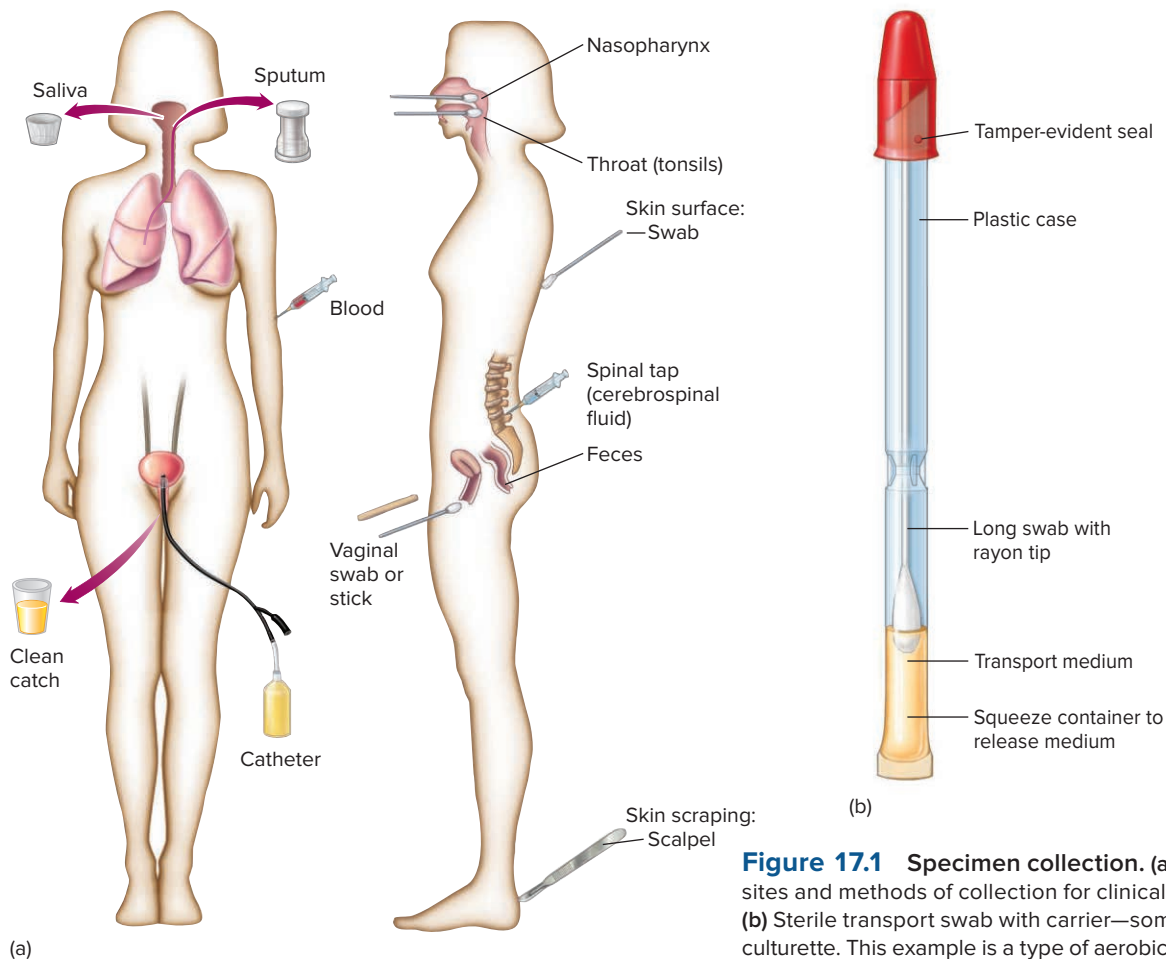

Figure 17.1 Specimen collection. (a) Sampling sites and methods of collection for clinical laboratories. (b) Sterile transport swab with carrier—sometimes called a culturette. This example is a type of aerobic transport swab.

TABLE 17.1 General Guidelines for Specimen Collection*

Type of Specimen	Collection Method	Comments
Abscess of skin or membrane or decubitus ulcer	Debride surface with sterile wipe; suction fluid with sterile needle and syringe.	Aspiration of tissue samples preferred to swab; transfer to anaerobic transport system.
Anaerobic cultures	Collect from deeper tissue below the surface, using sterile syringe.	Sample must not be exposed to air; transport immediately in anaerobic system to lab.
Blood	Prep area of skin with iodine; use Vacutainer or Bactec blood collection tubes.	Inoculate blood culture bottle immediately.
Bone marrow	Prepare site for surgical incision; extract sample with special needle.	Most samples taken from sternum or ilium; placed in blood bottle for culture.
Cerebrospinal fluid (CSF)	Remove CSF aseptically by lumbar puncture.	Place CSF into sterile tubes; do not refrigerate; transport immediately to lab for processing.
Feces	Take a small specimen into sterile container, cover and transport.	Refrigerate samples held over 1 hour; culture is mainly to rule out enteric pathogens; special kits available to detect cysts and trophozoites of protozoans and ova and larvae of intestinal worms.
Genital/urinary tract	Sterile swab of cervical mucus; swab urethral membrane or insert into lumen and twist.	Plate directly onto selective culture media with high CO ₂ atmosphere or collect with anaerobic transport swab system; process immediately.
Respiratory tract, lower	Have patient cough to loosen phlegm and expectorate sputum into sterile cup for transport.	Patient should brush teeth and rinse mouth with water prior to any sampling. If coughing does not work, induce sputum by having patient inhale sterile saline from a nebulizer.
Respiratory tract, upper	Cleanse and debride oral cavity membranes; vigorously swab area of lesion; throat cultures are taken by swabbing the posterior pharynx, tonsils, and inflamed sites.	Tissue aspirates of infected tissue preferred; throat samples are processed for strep throat; culturing for other throat pathogens (except viruses) is done when specifically requested; care must be taken to avoid normal tissue and saliva.
Urine (two methods)	Sample by clean midstream catch into a sterile container.	Clean external genitalia, separate labia (female) or pull back foreskin (male) and urinate for a short time, followed by collection of 100- to 200-cc sample (midstream); samples not immediately processed must be refrigerated.
	Sample by sterile catheter inserted into bladder; urine is drained into sterile container.	Clean and rinse the urethral opening; only a specimen catheter should be used to sample for bladder infection; patients with indwelling catheters will always have microbes in their bladders.

*For a detailed account of collecting and managing specimens, log on to http://www.dshs.state.tx.us/LAB/bac_guidelines.shtm#guidelines.

Special Considerations in Specimen Analysis

The routes taken in specimen analysis come under the heading of (1) direct tests of microscopic, immunologic, or genetic characteristics that provide immediate clues as to the identity of the microbes in the sample; and (2) cultivation, isolation, and identification of pathogens using general and specific tests that may require several days for results (**figure 17.2**).

Most test results fall into two categories: presumptive data, which place the isolated microbe (isolate) in a preliminary category such as a genus; and more specific, confirmatory data, which provide more definitive evidence for a species. Some tests are more important for some groups of bacteria than for others. The time required for analysis may take a few minutes in a streptococcal sore throat to several days in tuberculosis.

Some diseases are diagnosed without the need to identify microbes from specimens. Serological tests on a patient's serum

can detect signs of an antibody response. One method that clarifies whether a positive test indicates current or prior infection is to take two samples several days apart to see if the antibody titer is rising. Skin testing can pinpoint a delayed allergic reaction to a microorganism and can be used to screen the general population for exposure to infectious agents such as rubella or tuberculosis.

Microbiology is experiencing an era of tremendous change in availability of testing choices. The methods used by clinical microbiology labs are governed by cost, availability of specialized materials and equipment, and established practices. **Clinical Connections** introduces some of the newer technologies that are no doubt going to be the wave of the future.

CLINICAL CONNECTIONS

The Changing Scene of Clinical Microbiology

Although it is true that most testing to identify pathogens must be carried out in a laboratory setting, medical researchers are continuing to look for ways to support the diagnosis of infections right at a patient's bedside or even at home. Such tests, called **point of care tests (POCTs)**, have the benefits of speeding up treatment and giving patients greater charge of their own medical choices. These tests are usually performed in the presence of the patient and provide immediate feedback, similar to taking blood pressure or monitoring blood sugar, except that POC tests aim to detect infections or infectious agents.

POC tests range from nonspecific, over-the-counter kits that can help determine whether an infection is present (vaginal pH tests and ear checks that detect fluid in the middle ear, for example) to **rapid**

diagnostic tests (RDTs) that identify specific microbes or diseases in a few minutes. Rapid *Staphylococcus* and *Streptococcus* kits used in clinics for several years to detect possible skin and throat infections were among the earliest examples. But these have been joined by dozens of other RDTs. There is now some type of RDT available for most major infectious agents, including Ebola virus and parasitic protozoa. Recent examples include an oral test for HIV; small inoculation modules for hepatitis C and B; and a panel for malaria (**figures a, b, c**). Depending on the particular microbe and site of infection, these tests can be performed directly from saliva, vaginal fluids, blood, urine, and food, and do not require isolation of the infectious agent or a great deal of technical skill to read. The accuracy of RDTs is not yet as

high as that of traditional cultural testing, but they are good early screening tools for possible infections.

An even more technologically advanced form of microbial identification (but not an RDT) is MALDI, which stands for matrix-assisted laser desorption/ionization. MALDI uses a mass spectrometer to ionize the organic molecules in cells with a UV laser and analyze their content. In practice, a sample of microbe (like an isolated colony) is mixed on a small metal plate (**figure d**) with a matrix chemical and dried. The plate is placed in a spectrometer and bombarded by a UV laser until the sample has been completely ionized. Irradiation emits a specific spectrum of ions that is unique to each microbe, which can be graphically analyzed and displayed. When the pattern is compared with a computer data bank that compiles spectra of known microbes, an immediate identification is possible. It is limited only by the numbers of species that have been programmed into the data bank. This process can be completely automated and, except for the initial equipment costs, will greatly reduce the time and cost of testing. Although it has a relatively high level of accuracy, it is still not as accurate as traditional laboratory tests, but this is likely to change with increased usage.

Looking back at genome analysis in chapter 10, you will no doubt recall that the DNA or RNA profile of an organism is a powerful tool of identification and the most specific of all tests available. In this chapter, we cover the use of hybridization probes (FISH) and PCR. As more and more tests are developed, genome testing is gradually becoming the method of choice for many diseases. Companies are developing miniature “labs on a chip” or microarray biochips that can identify several pathogens at once. They consist of small platforms (like slides) that have been loaded with probes made to hybridize with specific genes of pathogens. When a sample of unknown nucleic acid is inserted onto the biochip and allowed to hybridize, any probes that have reacted with the nucleic acid will report by fluorescing. Fluorescence detectors create an image of the pattern that can identify the probable pathogen(s). So far, these have had the most extensive use in detecting some forms of enteric pathogens in food and water.

Do you expect that sometime in the future, the traditional microbiology labs, with media, Petri dishes, biochemical tests, microscopes, and the like, will no longer be needed? Base your answer on your own experiences and observations. Answer available on Connect.

Check Your Progress SECTION 17.1

1. Summarize the major techniques in identifying and diagnosing pathogens and infections.
2. Describe the general principles in specimen collection.
3. Explain why it is important to prevent microbes from growing in specimens, and why speed is so important in the clinical laboratory.
4. Summarize the kinds of tests that are used to identify microbes and detect signs of infection.

17.2 Phenotypic Methods

Expected Learning Outcomes

4. Describe some direct methods of testing a specimen.
5. Summarize the aims in selection of culture techniques and media.
6. Explain the basis of biochemical and other methods of testing.
7. Describe how flowcharts and comparison tables are used in identification of bacterial pathogens.

Immediate Direct Examination of Specimen

Direct microscopic observation of a fresh or stained specimen is one of the most rapid methods of determining presumptive and sometimes confirmatory characteristics. Stains most often employed for bacteria are the Gram stain (see 3.2 Making Connections) and the acid-fast stain (see figure 3.8). For many species, these ordinary stains can be useful, but they do not work with certain organisms.

For these types of microbes, direct immunofluorescent antibody (DIFA) tests can highlight the presence of the microbe by means of antibodies labelled with fluorescent dyes (**figure 17.3**). DIFA tests are particularly useful for bacteria, such as the syphilis and Lyme disease spirochetes that are not readily cultivated in the laboratory.

Another way that specimens can be analyzed is through *direct antigen testing*. This technique is similar to direct fluorescent antibody testing in that known antibodies are used to identify antigens on the surface of bacterial isolates. But in direct antigen testing, the reactions can be seen with the naked eye (see figure 17.8b). Quick test kits that greatly speed clinical diagnosis are available for *Staphylococcus aureus*, *Streptococcus* species, *Neisseria gonorrhoeae*, *Haemophilus influenzae*, *Neisseria meningitidis*, and *Salmonella*. However, when the microbe is very sparse in the specimen, direct testing is less effective, and identification will require more sensitive methods.

(b) Photomicrograph results for *Borrelia burgdorferi*, the spirochete of Lyme disease. Fluid from a lesion observed with a UV microscope reveals numerous fluorescing spirochetes. The two colors indicate different surface antigens reacting with antibodies specific to *B. burgdorferi*. (b): Source: National Institute of Allergy and Infectious Diseases (NIAID)/CDC

Cultivation of Specimen

Isolation Media

Such a wide variety of media exist for microbial isolation that a certain amount of preselection must occur, depending on the nature of the specimen. When the sample contains such small numbers of the pathogen that it could be easily lost or overgrown by competing microbes, the specimen is often cultured in enrichment media that can amplify the pathogen. In this chapter's Case Study, for instance, 1% to 2% salt is added to favor the growth of any *Vibrio* that may be present. In specimens such as feces, mucus, or urine that may have high bacterial counts and a diversity of species, selective media are chosen to make the target microbes more prominent by inhibiting microbes that are part of the normal microbiota. These media can be moderately inhibitory, such as those that grow only gram-positive or gram-negative bacteria, or highly inhibitory, being specific to a single group or species. One example is a medium used to screen clinical specimens that will grow only *Listeria monocytogenes*, a serious foodborne pathogen. This agar medium contains six selective agents, three of which are antibiotics. This type of media has the benefit of selecting the pathogen from the sample in a single step.

In most cases, specimens are also inoculated into differential media that define such characteristics as reactions in blood (blood agar) and fermentation patterns (mannitol salt and MacConkey agar). A patient's blood is usually cultured in a special bottle of broth that can be periodically sampled for growth. Numerous other examples of isolation, differential, and biochemical media were presented in chapter 3. So that subsequent steps in identification will be as accurate as possible, all work must be done from isolated colonies or pure cultures, because working with a mixed or contaminated culture gives misleading and inaccurate results. From such isolates, clinical microbiologists obtain information about a pathogen's microscopic morphology and staining reactions, cultural appearance, motility, oxygen requirements, and biochemical characteristics.

Biochemical Testing

The physiological reactions of bacteria to nutrients and other substrates provide useful indirect evidence of the types of enzyme systems present in a particular species. Many of these tests are based on the following scheme:

The microbe is cultured in a medium with a special substrate and then tested for a particular end product. The presence of the end product indicates that the enzyme is expressed in that species; its absence means it lacks the enzyme for utilizing the substrate in that particular way. These types of reactions are particularly meaningful in bacteria, which are haploid and generally express their genes for utilizing a given nutrient.

Figure 17.4 Rapid miniature tests for lab identification.

The API 20E manual biochemical system for bacterial identification. Each cupule is inoculated with the same bacterial culture and the strip is incubated for a few hours. This cross section of biochemical tests can be sufficient to differentiate many common species of bacteria. Positive results are shown for a 20-test strip. Courtesy of bioMérieux, Inc.

Among the prominent biochemical tests are carbohydrate fermentation (acid and/or gas); hydrolysis of gelatin, starch, and other polymers; enzyme actions such as catalase, oxidase, and coagulase; and various by-products of metabolism. Many are presently performed with rapid, miniaturized systems that can simultaneously determine up to 23 characteristics in small individual cups or spaces (**figure 17.4**). An important plus, given the complexity of biochemical profiles, is that such systems are readily adapted to computerized analysis.

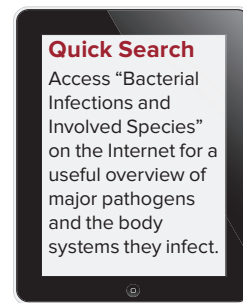

Common schemes for identifying bacteria are somewhat artificial but convenient. They are based on easily recognizable characteristics such as motility, oxygen requirements, Gram stain reactions, shape, spore formation, and various biochemical reactions. Schemes can be set up as flowcharts (**figure 17.5**) or keys that trace a route of identification by offering pairs of opposing characteristics (positive versus negative, for example) from which to select. Eventually, an endpoint is reached, and the name of a genus or species that fits that particular combination of characteristics appears. Diagnostic tables structured like this chapter's Case Study that provide more complete information are preferred by many laboratories because variations from the general characteristics used on the flowchart can be misleading. Both systems are used in this text.

Miscellaneous Tests

In many situations, morphological and biochemical tests are not definitive or relevant and need to be supplemented by other methods.

Bacteria host viruses called bacteriophages that are very species- and strain-specific. Such selection by a virus for its host is useful in typing some bacteria, primarily *Staphylococcus* and *Salmonella*. The technique of *phage typing* involves inoculating a lawn of cells onto a Petri dish, mapping it off into blocks, and applying a different phage to each block. Cleared areas corresponding to lysed cells indicate sensitivity to that phage. Phage typing is chiefly used for tracing strains of bacteria in epidemics.

Animals may be needed to cultivate bacteria such as *Mycobacterium leprae* and *Treponema pallidum*, whereas avian embryos and cell cultures are used to grow rickettsias, chlamydias, and viruses. Animal inoculation is also occasionally used to test bacterial or fungal virulence.

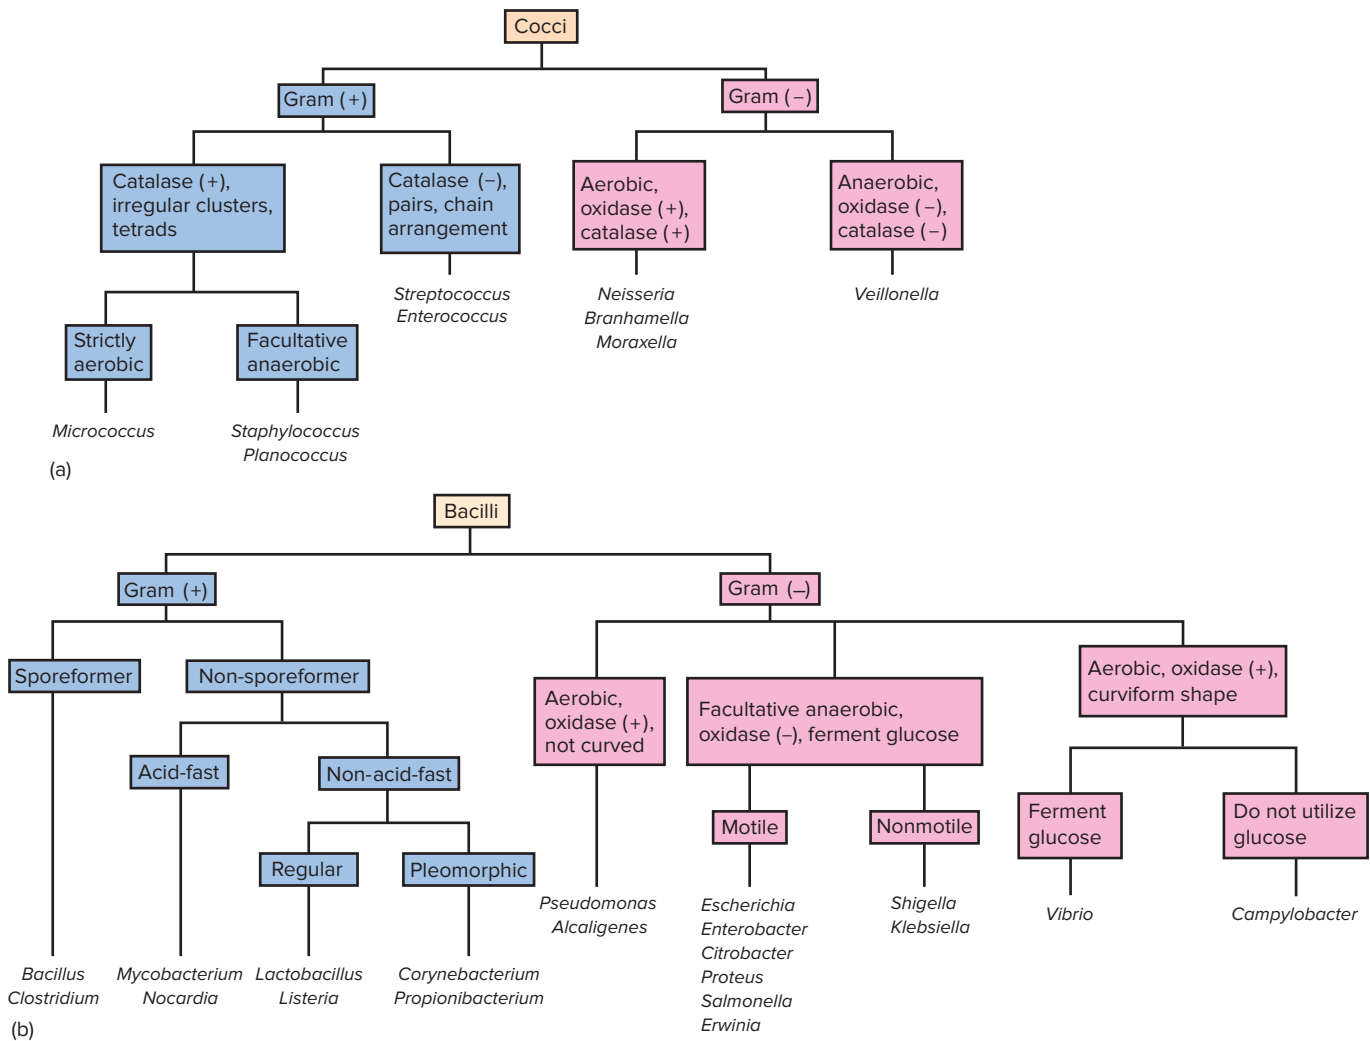

Figure 17.5 Flowchart key that separates genera of gram-positive and gram-negative bacteria often isolated from specimens. (a) Cocci and (b) bacilli of clinical interest.

Antimicrobial sensitivity tests are not only important in determining the drugs to be used in treatment (see figure 12.18), but the patterns of sensitivity can also be used in presumptive identification of some species of *Streptococcus*, *Pseudomonas*, and *Clostridium*. Antimicrobials are also used as selective agents in many media.

Determining Clinical Significance of Cultures

Questions that can be difficult but necessary to answer in this era of debilitated patients and opportunists are: Is an isolate clinically important, and how can one know whether it is a contaminant or just part of the normal microbiota? The number of microbes in a sample is one useful criterion. For example, a few colonies of *Escherichia coli* in a urine sample can simply indicate normal microbiota, whereas several hundred can mean active infection. In contrast, the presence of a single colony of a true pathogen such as *Mycobacterium tuberculosis* in sputum or an opportunist in sterile sites such as cerebrospinal fluid or blood is highly suggestive of its role in disease. Furthermore, the repeated isolation of a relatively pure culture of any microorganism can mean it is an agent of disease, though care must be taken in this diagnosis. Another challenge

facing the clinical laboratory is that of differentiating a pathogen from species in the normal microbiota that are similar in morphology from their more virulent relatives. Medical microbiologists are able to apply their expertise, supported by the tools of laboratory science, to solve even the most difficult identifications.

17.3 Genotypic Methods

Expected Learning Outcome

8. Explain the different variations on genetic testing and how they can be used in identification and diagnosis.

DNA Analysis Using Genetic Probes

The exact order and arrangement of the DNA code is unique to each organism. With a technique called *hybridization*, it is possible to identify a bacterial species by analyzing segments of its DNA. This requires small fragments of single-stranded DNA (or RNA) called

probes that are known to be complementary to the specific sequences of DNA from a particular microbe. The test is conducted by extracting unknown test DNA from cells in specimens or cultures and binding it to special blotter paper. After several different probes have been added to the blotter, it is observed for visible signals that the probes have become fixed (hybridized) to the test DNA. The binding of probes onto several areas of the test DNA indicates close correspondence and makes positive identification possible. This forms the basis for certain DNA analysis techniques discussed in chapter 10.

A form of DNA hybridization with numerous applications for rapid identification of unknown bacteria is **fluorescent in situ hybridization**, or **FISH** (see figure 10.6). An uncultured specimen such as blood, a skin lesion, or a throat swab can be smeared on a slide and reacted with a nucleic acid probe that carries a peptide and a fluorescent dye marker. The probe can detect a specific segment of ribosomal RNA. If the unknown cells are a match to the probe, they will retain the dye and fluoresce under a UV microscope (**figure 17.6**). This has decreased the time for identification of septic blood cultures to 90 minutes instead of 24 hours.

Another genetic-based technique often brought in to analyze outbreaks or epidemics is **pulse-field gel electrophoresis** (PFGE). This rapid method of DNA typing makes a restriction fragment fingerprint of the suspected pathogens on a single gel that identifies and compares the isolates alongside each other. It is especially useful to trace a causative agent to the same source or reservoir. An example of its application can be found at <http://wwwnc.cdc.gov/eid/article/8/5/01-0373-f1>.

Roles of the Polymerase Chain Reaction and Ribosomal RNA in Identification

The polymerase chain reaction (PCR) is one of the most valuable high technology tools for DNA and RNA analysis. A review of chapter 10 (see figure 10.8) will remind you how it can rapidly

synthesize hundreds of thousands and even millions of copies of a particular segment of DNA. It is both highly sensitive and specific, amplifying minute quantities from unknown samples that would otherwise be lost. It is a widely-used technique of forensics and molecular biology, but it can also be applied to the identification of microbes. With this method, laboratories can often completely dispense with traditional culturing techniques and go directly to diagnosis in a few hours.

PCR-based tests are used routinely for detecting HIV, Lyme disease, the human papillomavirus, tuberculosis, hepatitis, and a number of other bacterial and viral infections (**Figure 17.7**). In many laboratories, the PCR or a similar rapid test is the method of choice for identifying gonorrhea and chlamydiosis. A version of this technique called real-time PCR can simultaneously pull DNA from a sample, register the amount that is amplified, and identify it.

One particularly versatile aspect to PCR is that it can be combined with other technologies for additional applications. For example, if the sample being analyzed contains mainly RNA (from an RNA virus or ribosome), the initial introduction of reverse transcriptase (RT) will convert the RNA in the sample to DNA, and this DNA can then be amplified by PCR. This technique—RT-PCR—is valuable for verifying RNA-based viruses such as rabies virus (see figure 17.17f). DNA of PCR origin can be analyzed with the other tools of technology: it can be probed, hybridized, profiled, and sequenced.

One of the most viable indicators of evolutionary relatedness and affiliation is comparison of the nucleotide sequence of ribosomal RNA, a major component of ribosomes. Ribosomes have the same function (protein synthesis) in all cells, and their nucleic acid content tends to remain more or less stable over long periods. Thus, any major differences in the sequence, or “signature,” of the rRNA is likely to indicate some distance in ancestry. This technique is powerful at two levels: It is effective for differentiating general group differences (it was used to separate the three superkingdoms of life discussed in chapter 1), and it can be fine-tuned to identify species.

Figure 17.6 Peptide-nucleic acid (PNA) FISH test for *Staphylococcus aureus* performed on a blood culture. Once staphylococci are established by microscopic examination, a fluorescent peptide-nucleic acid combination is hybridized to a sample on a slide. UV illumination reveals a positive reaction of fluorescing cocci in clusters. (right) Image provided by AdvanDx, Inc.

Figure 17.7 PCR testing for identification of pathogens. PCR gels (B, C) identify isolates of *Vibrio vulnificus* from patients with unusual symptoms. Band patterns appearing in lanes 1-4 are specific for the cytotoxin genes of *V. vulnificus*. M = molecular size standard. See figure 10.5 to refresh your memory on how these DNA profiles are made. 5. Describe what is involved in direct specimen testing, presumptive and confirmatory tests, cultivating and isolating the pathogen, biochemical testing, and gene probes.
6. Summarize the important aspects for determining if a clinical isolate is involved in infection.
7. Describe the applications of PCR in identification techniques.

17.4 Immunologic Methods

Expected Learning Outcomes

9. Describe the background aims of immunologic testing.
10. Identify how antigen-antibody reactions are detected and quantified.
11. Differentiate between agglutination and precipitation, and describe how they are used in diagnosis.
12. Explain the basic methods behind the Western blot and complement fixation tests.
13. Interpret the outcome of direct and indirect immunofluorescent antibody testing.

The antibodies formed during an immune reaction are important in combating infection, but they hold additional practical value. Characteristics of antibodies such as their quantity or specificity can reveal the history of a patient's contact with microorganisms or other antigens. This is the underlying basis of serological testing. **Serology** is the branch of immunology that traditionally deals with in vitro

diagnostic testing of serum. Serological testing is based on the familiar concept that antibodies have extreme specificity for antigens, so when a particular **antigen** is exposed to its specific **antibody**, it will bind tightly to it. Being able to visualize this interaction provides a powerful tool for detecting, identifying, and quantifying antibodies—or for that matter, antigens. The scheme works both ways, depending on the situation. One can detect or identify an unknown antibody using a known antigen, or one can use an antibody of known specificity to help detect or identify an unknown antigen (**figure 17.8**). Modern serological testing has grown into a field that tests more than just serum. Urine, cerebrospinal fluid, whole tissues, and saliva can also be used to determine the immunologic status of patients. These and other immune tests are helpful in confirming a suspected diagnosis or in screening a certain population for disease.

General Features of Immune Testing

The strategies of immunologic tests are diverse, and they underline some of the brilliant and imaginative ways that antibodies and antigens can be used as tools. We summarize them under the headings of agglutination, precipitation, complement fixation, fluorescent antibody tests, and immunoassay tests. First, we overview the general characteristics of immune testing and then look at each type specifically.

The most effective serological tests have a high degree of specificity and sensitivity (**figure 17.9**). **Specificity** is the property of a test to focus upon only a certain antibody or antigen and not to react with unrelated or distantly related ones. **Sensitivity** means that the test can detect even very small amounts of antibodies or antigens that are the targets of the test. A test with high sensitivity will diagnose even patients who are weakly positive. Modern systems using monoclonal antibodies have greatly improved specificity, and those using radioactivity, enzymes, and electronics have improved sensitivity.

Visualizing Antigen-Antibody Interactions

The primary basis of most tests is the binding of an antibody (Ab) to a specific molecular site on an antigen (Ag). Because this reaction cannot be readily seen without an electron microscope, tests involve some type of endpoint reaction visible to the naked eye or with regular magnification that tells whether the result is positive or negative. In the case of large antigens such as cells, Ab binds to Ag and creates large clumps or aggregates that are visible macroscopically or microscopically (**figure 17.10a**). Smaller Ab-Ag complexes that do not result in readily observable changes will require special indicators in order to be visualized. Endpoints are often revealed by dyes or fluorescent reagents that can tag molecules of interest. Similarly, radioactive isotopes incorporated into antigens or antibodies constitute sensitive tracers that are detectable with photographic film.

An antigen-antibody reaction can be used to read a **titer**, or the quantity of antibodies in serum. Titer is determined by serially diluting a sample in tubes or in a multiple-welled microtiter plate and mixing it with antigen (**figure 17.10b**). It is determined by observing the highest dilution of serum that produces a visible reaction with an antigen. The titer is the denominator of this dilution. The more a sample can be diluted and yet still react with antigen, the greater is the concentration of antibodies in that sample and the higher is its titer. Possible interpretations of test results are discussed in **Clinical Connections, “When Positive Is Negative.”**

(a1) In serological diagnosis of disease, a blood sample is tested for the presence of antibody using an antigen of known specificity. A positive reaction is usually evident as some visible sign, such as color change or clumping, that indicates a specific interaction between antibody and antigen. (The reaction at the molecular level is rarely observed.)

(b1) An unknown microbe is mixed with serum containing antibodies of known specificity, a procedure known as serotyping. Macroscopic or microscopic clumping indicates a correct match between antibody and antigen and permits identification of the microbe.

(a2) Test of unknown serum on card with five different known antigens and a positive control. Clumps indicate precipitated antigens and a possible infection in the patient.

(b2) Unknown test colonies from streak plate mixed with antiserum against *Neisseria meningitidis*; agglutination on left is positive for that pathogen.

Figure 17.8 Basic principles of serological testing using antibodies and antigens. (a) Serological diagnosis (b) Direct antigen testing (a2) Reproduced by kind permission of Thermo Fisher Scientific Inc.;

(b2) Source: Ortika BD, Habib H, Dunne EM, Porter BD, Satzke C: Production of latex agglutination reagents for pneumococcal serotyping. BMC Res Notes 2013, 6:49.

Figure 17.9 Specificity and sensitivity in immune testing. (a) This test shows specificity in which an antibody (Ab) attaches with great exactness with only one type of antigen (Ag). (b) Sensitivity is demonstrated by the fact that Ab can detect antigens even when the antigen is greatly diluted.

- (a) Agglutination involves clumping of whole cells; precipitation is the formation of antigen-antibody complexes in cell-free solution. Both reactions can be observed by noticeable clumps or precipitates in test tubes (see (b) and figure 17.11).

- (b) The tube agglutination test. A sample of patient's serum is serially diluted with saline. The dilution is made in a way that halves the number of antibodies in each subsequent tube. An equal amount of the antigen (here, blue bacterial cells) is added to each tube. The control tube has antigen, but no serum. After incubation and centrifugation, each tube is examined for agglutination clumps as compared with the control, which will contain unagglutinated cells and no clumps. The titer is equivalent to the denominator of the dilution of the last tube in the series that shows agglutination.

*Although IgG is shown as the Ab, IgM is also involved in these reactions.

Figure 17.10 Antigen-Antibody Testing. (a) Cellular/molecular view of agglutination and precipitation reactions that produce visible antigen-antibody complexes. (b) An agglutination test for determining the antibody titer of serum.

Agglutination and Precipitation Reactions

The essential differences between agglutination and precipitation are in size, solubility, and location of the antigen. In agglutination, the antigens are whole cells such as red blood cells or bacteria with determinant groups on the surface. In precipitation, the antigen is a soluble molecule. In both instances, when Ag and Ab are optimally combined so that neither is in excess, one antigen is interlinked by several antibodies to form an insoluble, three-dimensional aggregate so large that it cannot remain suspended and it settles out.

Agglutination Tests

Agglutination is discernible because the antibodies cross-link the antigens to form visible clumps. **Agglutination** tests are performed routinely by blood banks to determine ABO and Rh (Rhesus) blood types in preparation for transfusions. In this type of test, antisera containing antibodies against the blood group antigens on red blood cells are mixed with a small sample of blood and read for the presence or absence of clumping (see figure 16.10). The **Widal test** is an example of a tube agglutination test for diagnosing salmonellosis and undulant fever. In addition to detecting specific antibody, it also gives the serum titer.

Numerous variations of agglutination testing exist. The rapid plasma reagin (RPR) test is one of several tests commonly used to test for antibodies to syphilis. The cold agglutinin test, named for antibodies that react only at lower temperatures (4°C to 20°C), was developed to diagnose *Mycoplasma pneumoniae*. The *Weil-Felix reaction* is an agglutination test sometimes used in diagnosing rickettsial infections.

In some tests, agglutinating antigens are affixed to the surface of an inert particle. In **latex agglutination** tests, the inert particles are tiny latex beads. Kits based on agglutination are available for assaying pregnancy hormone in the urine; for identifying *Candida* yeasts, staphylococci, streptococci, and meningococci (see figure 17.8b2); and for diagnosing rheumatoid arthritis.

Precipitation Tests

In **precipitation** reactions, the soluble antigen is precipitated (made insoluble) by an antibody. This reaction is observable in a test tube in which an antigen sample has been carefully laid over an antiserum solution. At the point of contact, a cloudy or opaque zone forms. One example of this technique is the **VDRL** (Venereal Disease Research Laboratory) test that also detects antibodies to syphilis. Although it is a good screening test, it contains a heterophilic antigen (cardiolipin) that may give rise to false positive results.

Although precipitation is a useful detection tool, the precipitates are so easily disrupted in liquid media that most precipitation reactions are carried out in agar gels. These substrates are sufficiently soft to allow the reactants (Ab and Ag) to freely diffuse, yet firm enough to hold the Ab-Ag precipitate in place. One technique with applications in microbial identification and diagnosis of disease is the double diffusion (Ouchterlony) method (**figure 17.11**). It is called double diffusion because it involves diffusion of both antigens and antibodies. The test is performed by punching a pattern of small wells into an agar medium and filling them with test antigens and antibodies. A band forming between two wells

CLINICAL CONNECTIONS

When Positive Is Negative: How to Interpret Serological Test Results

What does it mean if a patient's serum gives a positive reaction—in a serological test? In most situations it indicates that antibodies specific for a particular microbe have been detected in the serum sample. But one must be cautious in proceeding to the next level of interpretation. The mere presence of antibodies does not necessarily indicate that the patient has a disease but only that he or she has possibly had contact with a microbe or its antigens through infection or vaccination. In screening tests for determining a patient's history (rubella, for instance), finding a measurable titer of antibodies can be significant, because it shows that the person has some protection against that infectious agent.

When the test is being used to diagnose ongoing infection or disease, however, it is necessary to show a rising titer of antibodies over time. The figure indicates how such a test can be used to diagnose patients who have nonspecific symptoms that could fit several diseases. Lyme disease, for instance, can be mistaken for arthritis or viral infections. In the first group, note that the antibody titer against *Borrelia burgdorferi*, the causative agent, increased steadily over a 6-week period. A control group that shared similar symptoms did not exhibit a rise in titer for antibodies to this microbe. Clinicians call samples collected early and late in an infection *acute* and *convalescent* sera.

Another important consideration in testing is the occasional appearance of **biological false positives**. These results show a positive reaction even though, in reality, the patients are not or have not been infected by the microbe. False positives, such as those in syphilis and HIV testing, arise when antibodies or other substances present in the serum cross-react with the test reagents, producing a positive result. Such false results may require retesting by a method that greatly minimizes cross-reactions.

I. In one method of setting up a double diffusion test, wells are punctured in soft agar, and antibodies (Ab) and antigens (Ag) are added in a pattern. As the contents of the wells diffuse toward each other, a number of reactions can result, depending on whether antibodies meet and precipitate antigens.

II. Example of test pattern and results. Antigen (Ag) is placed in the center well and antibody (Ab) samples are placed in outer wells. The control contains known Abs to the test Ag. Note bands that form where Ab/Ag meet. The other wells (1, 2) contain unknown test sera. One is positive and the other is negative. Double bands indicate more than one antigen and antibody that can react.

III. Actual test results for detecting infection with the fungal pathogen *Histoplasma*. Numbers 1 and 4 are controls and 2, 3, 5, and 6 are patient test sera. Can you determine which patients have the infection and which do not?

Figure 17.11 Precipitation reactions. The example shown here is a double diffusion (Ouchterlony) test in a semisolid matrix. (III): © National Institute Slide Bank/The Wellcome Centre for Medical Sciences

indicates that antibodies from one well have met and reacted with antigens from the other well. Variations on this technique provide a means of identifying unknown antibodies or antigens.

The Western Blot for Detecting Proteins

The **Western blot test** involves the **electrophoretic** separation of proteins, followed by an immunoassay to detect these proteins. This test is a counterpart of the Southern blot test for identifying DNA, described in chapter 10. It is a highly specific and sensitive method to identify or verify a particular protein (antibody or antigen) in a sample (**figure 17.12**). First, the test material is electrophoresed in a gel to separate out particular bands. The gel is then transferred to a special blotter that binds the reactants in place. The blot is developed by incubating it with a solution of antigen or antibody that has been labeled with radioactive, fluorescent, or luminescent labels. Sites of specific binding will appear as a pattern of bands that can be compared with known positive and negative samples. This is usually the second test used to verify the status of people who are antibody-positive for HIV in the ELISA test (described in section 17.5), because it tests more types of antibodies and is less subject to

Define a false negative reaction. What might cause such a reaction? Answer available on Connect.

misinterpretation and false positives than are other antibody tests. The technique has significant applications for detecting microbes and their antigens in specimens.

Successive tests on an HIV+ patient over 30 days reveals an increase in band intensity over time. This is due to continued formation of anti-HIV antibodies.

Figure 17.12 The Western blot procedure. Examples shown here test for antibodies to several HIV antigens. The test strips are prepared by electrophoresing the major HIV surface and core antigens and then blotting them onto special filters. The test strips are incubated with a serum sample and developed with radioactive or colorimetric labels. Sites where HIV antigens have bound antibodies show up as bands. A positive control strip (SRC) containing antibodies for all HIV antigens serves as a comparison.

Interpretation of bands to report a positive test

- Labels correspond with glycoproteins (gp) or proteins (p) that are part of HIV-1 antigen structure.
- The test is considered positive if bands occur at at least two locations: gp160 or gp120 and p31 or p24.
- The test is considered negative if no bands are present for any HIV antigen.
- The test is considered indeterminate if bands are present but not at the primary locations. This result may require retesting at a later date.

Complement Fixation

In chapter 14 we introduced the functions of complement as a defense system for destroying foreign cells (see figure 14.20). An antibody that requires the actions of complement to complete the lysis of its antigenic target cell is termed a **lysin** or cytolysin. When lysins act in conjunction with the intrinsic complement system on red blood cells,

the cells hemolyze (lyse and release their hemoglobin). This lysis-mediated hemolysis is the basis of a type of test called **complement fixation**, or CF (figure 17.13). Complement fixation tests are used to diagnose some viral, rickettsial and fungal infections, but are often replaced by more sensitive and accurate ELISA and genetic tests.

Complement fixation testing uses four components—antibody, antigen, complement, and sensitized sheep red blood cells—and it is conducted in two stages.

In the first stage, the test antigen is allowed to react with the test antibody (at least one must be of known identity) in the absence of complement. If the antibody and antigen are specific for each other, they form complexes. To this mixture, purified complement proteins from guinea pig blood are added. If the antibody and antigen have complexed during the previous step, they attach, or fix, the complement to them, thus preventing it from participating in further reactions.

The extent of any complement fixation is determined in the second stage by means of sheep red blood cells (RBCs) with surface lysin molecules. The sheep RBCs serve as an indicator complex that can also fix complement. Contents of the stage 1 tube are mixed with the stage 2 tube and observed with the naked eye for hemolysis.

- If hemolysis *does not* occur, it means that the complement was used up by the first stage Ab-Ag complex and that the unknown antigen or antibody was indeed present. This result is considered positive.
- If hemolysis *does* occur, it means that unfixed complement from tube 1 reacted with the RBC complex instead, thereby causing lysis of the sheep RBCs. This result is negative for the antigen or antibody that was the target of the test.

A relative of the CF test, the antistreptolysin O (ASO) titer test, measures the levels of antibody against the streptolysin toxin, an important hemolysin of group A streptococci. A serum sample is exposed to known suspensions of streptolysin and then allowed to incubate with RBCs. Lack of hemolysis indicates antistreptolysin antibodies in the patient's serum that have neutralized the streptolysin and prevented hemolysis. This can be a useful procedure to verify scarlet fever, rheumatic fever, and other related streptococcal syndromes.

Miscellaneous Serological Tests

A test that relies on changes in cellular activity as seen microscopically is the ***Treponema pallidum* immobilization (TPI)** test for syphilis. The impairment or loss of motility of the *Treponema* spirochete in the presence of test serum and complement indicates that the serum contains anti-*Treponema pallidum* antibodies. In **toxin neutralization** tests, a test serum is incubated with the microbe that produces the toxin. If the serum inhibits the growth of the microbe, one can conclude that antitoxins to inactivate the toxin are present.

Serotyping is an antigen-antibody technique for identifying, classifying, and subgrouping certain bacteria into categories called serotypes, using antisera for cell antigens such as the capsule, flagellum, and cell wall. It is widely used in typing *Salmonella* species and strains and is the basis for identifying the numerous serotypes of streptococci (see figure 17.8, part b1). The Quellung test, which identifies serotypes of the pneumococcus, involves a precipitation reaction in which antibodies react with the capsular polysaccharide. Although the reaction makes the capsule seem to swell, it is actually creating a zone of Ab-Ag complexes on the cell's surface.

Figure 17.13 Complement fixation test. In this example, two serum samples are being tested for antibodies to a certain infectious agent. In reading this test, one observes the cloudiness of the tube. If it is cloudy, the RBCs are not hemolyzed and the test is positive. If it is clear and pink, the RBCs are hemolyzed and the test is negative.

In Vivo Testing

Probably the first immunologic tests were performed not in a test tube but on the body itself. A classic example of one such technique is the **tuberculin test**, which uses a small amount of purified protein derivative (PPD) from *Mycobacterium tuberculosis* injected into the skin. The appearance of a red, raised, thickened lesion in 48 to 72 hours can indicate previous exposure to tuberculosis. In practice, in vivo tests employ principles similar to serological tests, except in this case, an antigen or an antibody is introduced into a patient to elicit some sort of visible reaction. Like the tuberculin test, some of these diagnostic skin tests are useful for evaluating infections due to fungi (coccidioidin and histoplasmin tests, for example) or allergens. Testing for allergic reactions was covered in chapter 16.

Fluorescent Antibody and Immunofluorescent Testing

The property of certain dyes to emit visible light in response to ultraviolet radiation was discussed in chapter 3. This property of fluorescence has found numerous applications in diagnostic immunology. The fundamental tool in immunofluorescent testing is a **fluorescent antibody**—a monoclonal antibody labeled by a fluorescent dye (fluorochrome).

The two ways that fluorescent antibodies (FABs) can be used are shown in **figure 17.14**. In **direct testing**, an unknown test specimen or antigen is fixed to a slide and exposed to a fluorescent antibody solution of known composition. If the antibodies are complementary to antigens in the material, they will bind to it. After the slide is rinsed to remove unattached antibodies, it is observed with the fluorescent microscope. Fluorescing cells or specks indicate the presence of Ab-Ag complexes and a positive result. These tests are valuable for identifying and locating antigens on the surfaces of cells or in tissues and in identifying the disease agents of syphilis, gonorrhea, chlamydiosis, whooping cough, Legionnaires' disease, plague, trichomoniasis, meningitis, and listeriosis.

In **indirect testing** methods, the fluorescent antibodies are antibodies made to react with the Fc region of another antibody (remember that antibodies can be antigenic). In this scheme, an antigen of known identity (a bacterial culture, for example) is combined with a test serum of unknown antibody content. The fluorescent antibody solution that can react with the unknown antibody is applied and rinsed off to visualize whether the serum contains antibodies that have affixed to the antigen. A positive test shows fluorescing aggregates or cells, indicating that the fluorescent antibodies have combined with the unlabeled antibodies. In a negative test, no fluorescing complexes will appear. This technique is frequently used to diagnose syphilis and various viral infections.

Figure 17.14 Immunofluorescent testing. **Direct Testing:** Unidentified antigen (Ag) is directly tagged with fluorescent Ab. See figure 17.3 to view an example of actual test results.

(b)

15. What is meant by complement fixation? What are cytolytins?
16. Describe the principles behind direct and indirect fluorescent antibody tests.

17.5 Immunoassays: Tests with High Sensitivity

Expected Learning Outcome

14. Describe the concepts behind the main types of immunoassays, and discuss their uses in diagnosis.
15. Explain how in vivo testing differs from in vitro testing.

The elegant tools of the microbiologist and immunologist are being used increasingly in athletics, criminology, government, and business to test for trace amounts of substances such as hormones, metabolites, and drugs. But traditional techniques in serology are not refined enough to detect a few molecules of these chemicals. Extremely sensitive alternative methods that permit rapid and accurate measurement of trace antigens or antibodies are called **immunoassays**. Examples of the technology for detecting an antigen or antibody in minute quantities include radioactive isotope labels, enzyme labels, and sensitive electronic sensors. Many of these tests are based on specifically formulated monoclonal antibodies.

Radioimmunoassay (RIA)

Antibodies or antigens labeled with a radioactive isotope can be used to pinpoint minute amounts of a corresponding antigen or antibody. Very complex in practice, these assays compare the amount of radioactivity present in a sample before and after incubation with a known, labeled antigen or antibody. The labeled substance competes with its natural, nonlabeled partner for a reaction site. Large amounts of a bound radioactive component indicate that the unknown test substance was not present. The amount of radioactivity is measured with an isotope counter or a photographic emulsion (autoradiograph). Radioimmunoassay has been employed to measure the levels of insulin and other hormones and to diagnose allergies, chiefly by the radioimmunosorbent test (RIST) for measurement of IgE in allergic patients and the radioallergosorbent test (RAST) to standardize allergenic extracts.

Enzyme-Linked Immunosorbent Assay (ELISA)

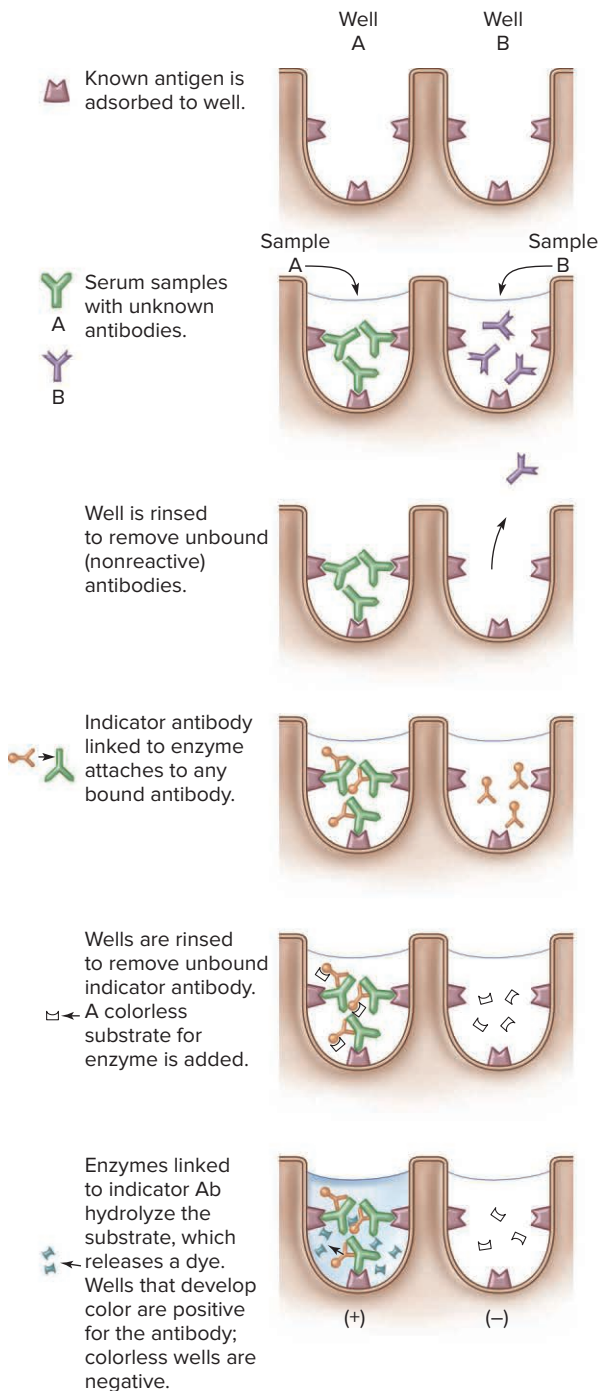

The **ELISA**, also known as enzyme immunoassay (EIA), contains an enzyme-antibody complex that can be used as a color tracer for antigen-antibody reactions. The enzymes used most often are horse-radish peroxidase and alkaline phosphatase, both of which release a dye (chromogen) when exposed to their substrate. This technique also relies on a solid support such as a plastic microtiter plate that can *adsorb* (attract on its surface) the reactants (**figure 17.16**).

Quick Search

To learn more about this topic, search the Internet for “Enzyme-Linked Immunosorbent Assay (ELISA).”

The **indirect ELISA** can capture antibodies in a serum sample. As with other indirect tests, the final positive reaction is achieved by means of an antibody-antibody reaction. The indicator antibody is complexed to an enzyme that produces a color change with positive serum samples (**figure 17.16a, b**). The starting reactant is a known antigen that is adsorbed to the surface of a

(a) **Indirect ELISA**, comparing a positive vs. negative reaction. This is the basis for HIV screening tests.

(b) **Microtiter ELISA Plate with 96 Tests for HIV Antibodies.** Colored wells indicate a positive reaction.

(c) **Capture or Antibody Sandwich ELISA Method.** Note that an antigen is trapped between two antibodies. This test is used to detect the measles virus.

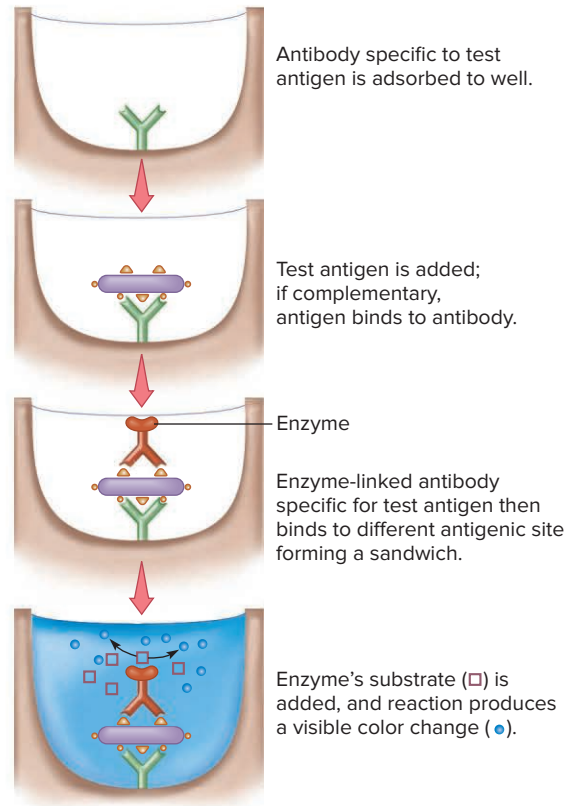

Figure 17.16 Methods of ELISA testing. © Hank Morgan/Science Source

well. To this, the unknown test serum is added. After rinsing, an enzyme-Ab reagent that can react with the unknown test antibody is placed in the well. The substrate for the enzyme is then added, and the wells are scanned for color changes. Color development indicates that all the components reacted and that the antibody was present in the patient's serum. This is the common screening test for the antibodies to HIV, various rickettsial species, hepatitis A and C, the cholera vibrio, and *Helicobacter*, a cause of gastric ulcers. Because false positives can occur, a verification test may be necessary (such as Western blot for HIV).

In **capture ELISA** (or sandwich) tests, a known antibody is adsorbed to the bottom of a well and incubated with a solution containing unknown antigen (**figure 17.16c**). After excess unbound components have been rinsed off, an enzyme-antibody indicator that can react with the antigen is added. If antigen is present, it will attract the indicator-antibody and hold it in place. Next, the substrate for the enzyme is placed in the wells and incubated. Enzymes affixed to the antigen will hydrolyze the substrate and release a colored dye. Thus, any color developing in the wells is a positive result. Lack of color means that the antigen was not present and that the subsequent rinsing removed the enzyme-antibody complex. The capture technique is used to detect antibodies to hantavirus, rubella virus, and *Toxoplasma*.

17.6 Viruses as a Special Diagnostic Case

Expected Learning Outcome

16. Summarize the protocols in identifying the causative agent in a viral infection.

All of the methods discussed so far—phenotypic, genotypic, and immunologic—are applicable to many different types of microorganisms. Viruses can present special difficulties because they are not cells and they are more labor intensive to culture in the laboratory. **Figure 17.17** presents an overview of various techniques available to diagnose viral infections. These range from observing symptoms, to direct microscopic examination, to cultivation, and to serological and genetic analysis.

Check Your Progress SECTIONS 17.5 AND 17.6

17. Explain the differences between direct and indirect procedures in immunoassay tests, giving examples.
18. How does a positive reaction in an ELISA test appear? How many wells are positive in figure 17.16b?
19. Provide some reasons in vivo tests would not be as reliable as immunoassay tests.
20. Explain how a clinical technologist would have determined that the causative agent in this chapter's Case Study was a virus instead of *Vibrio* bacteria.
21. Observing figure 17.17, indicate whether each method (a) through (f) is phenotypic, genotypic, or immunologic.

CASE STUDY Part 2

This case provides some insight into the protocol behind a clinical identification process. Preliminary laboratory investigations are designed to narrow the scope of possible infectious agents using as few tests as possible. The selective media and the second Gram stains informed the technologists relatively early on that the gram-positive *Bacillus cereus*, *Staphylococcus aureus*, and *Clostridium* were not involved in the outbreak, even though two of them are common hospital pathogens. Being able to eliminate them saved the lab from doing unnecessary specialized testing.

The microbiologists at the medical center were able to identify the pathogen as belonging to the genus *Vibrio* based on the fact that *Campylobacter*, the only other genus that would have fit, is known to exhibit spiral-shaped cells and is micro-aerophilic and nonfermentative in its physiology. The next step was to perform additional tests that could differentiate among the three major species in genus *Vibrio*, all of which are associated with intestinal infections. The panel of standard tests performed on the patient and food isolates is provided in **Case Study table 2**, with expected results from the three pathogens for comparison.

- Which species is responsible for the outbreak of gastroenteritis, and what additional confirmatory tests can verify this identification?
- Why is it so important to identify the infectious agent to the level of species?

To conclude this Case Study, go to Connect.

For more information on *Vibrio* detection, go to <http://www.fda.gov/Food/FoodScienceResearch/LaboratoryMethods/ucm070830.htm>.

 Chapter Summary with Key Terms

17.1 An Overview of Clinical Microbiology

- A. **Phenotypic** methods are those that assess microscopic morphology, macroscopic morphology, physiological and biochemical characteristics, and chemical composition.
- B. **Genotypic** methods examine the genetic composition of a microorganism.
- C. **Immunologic** methods exploit the host's antibody reaction to microbial antigens for purposes of diagnosis.
- D. Diagnosis begins with accurate **specimen collection**, which means the sampling of body sites or fluids that are suspected to contain the infectious agent. Strategies vary depending on the source.
- E. Laboratory methods yield either presumptive data or confirmatory data. Sometimes pathogens are diagnosed based solely on signs and symptoms in the patient. The route of diagnosis depends on the particular microbe and the technologies available to the lab.

17.2 Phenotypic Methods

- A. The most obvious phenotypic characteristics of a microbe are gleaned from its **microscopic** and **macroscopic** appearance. Many infections can be diagnosed by microscopic examination of fresh or stained microorganisms from specimens. Direct antigen or antibody testing can also be performed on uncultured specimens.
- B. Cultivation of specimens allows the examination of **cultural** characteristics such as colony morphology, growth characteristics, or both, which can be useful in identifying microbes.
- C. **Biochemical** tests determine whether microbes possess particular enzymes or metabolic pathways that can serve to identify them.
- D. Of utmost importance is the determination of whether an identified microbe is actually causing an infection or is simply a bystander, or member of the normal **microbiota**.

17.3 Genotypic Methods

- A. Genetic methods of identification are being used increasingly in diagnostic microbiology.
- B. **Probes** can detect specific genetic patterns, and advanced technology can characterize unique DNA sequences.
- C. An increasingly common procedure is the **polymerase chain reaction (PCR)** to amplify DNA present in a sample and apply labeled hybridization probes specific to known genetic signatures of microbes.
- D. RNA in ribosomes and other cultures or specimens (RNA viruses) can be converted to DNA and treated with methods of DNA analysis.

17.4 Immunologic Methods

- A. **Serology** is a science that tests a patient's serum to detect signs of infection, for example, finding specific antibodies for a particular microbe.
- B. The basis of serological tests is that **antibodies** (Abs) bind to their specific **antigens** (Ags) in vitro. Known Ags can be used to react with Abs in an unknown serum sample. The reverse is also true; known Abs can be used to detect and type unidentified Ags.

- C. These Ab-Ag reactions are visible in the form of obvious clumps and precipitates, color changes, or the release of radioactivity. Test results are read as positive or negative.
- D. Desirable properties of tests are high **specificity** and **sensitivity**.
- E. Types of Tests
 1. In **agglutination** tests, antibody cross-links whole-cell antigens, forming complexes that settle out and form visible clumps in the test chamber.
 - a. Examples are tests for blood type, some bacterial diseases, and viral diseases.
 - b. These tests can determine the amount of antibody in serum, or **titer**.
 2. Double diffusion **precipitation** tests involve the diffusion of Ags and Abs in a soft agar gel, forming zones of Ab/Ab complexes where they meet and react.
 3. In **immuno-electrophoresis**, migration of serum proteins in gel is combined with precipitation by antibodies.
 4. The **Western blot** test separates antigen into bands. After the gel is affixed to a blotter, it is reacted with a test specimen and developed by radioactivity or with dyes.
 5. A **complement fixation** test detects **lysins**—antibodies that fix complement and can lyse target cells. It involves first mixing test Ag and Ab with complement and then with sensitized sheep RBCs. If the complement is fixed by the Ab-Ag, the RBCs remain intact, and the test is positive. If RBCs are hemolyzed, specific antibodies are lacking.
 6. In direct assays, known marked Ab is used to detect unknown Ag (microbe).
 - a. In indirect testing, known Ag reacts with unknown Ab, and the reaction is made visible by a second Ab that can affix to and identify the unknown Ab.
 - b. **Immunofluorescent** testing uses **fluorescent antibodies** (FABs tagged with fluorescent dye) either directly or indirectly to visualize cells or cell aggregates that have reacted with the FABs.

17.5 Immunoassays: Tests of Great Sensitivity

Immunoassays are highly sensitive tests for Ag and Ab.

- A. In **radioimmunoassay**, Ags or Abs are labeled with radioactive isotopes and traced.
- B. The **enzyme-linked immunosorbent assay (ELISA)** can detect unknown Ag or Ab by direct or indirect means. A positive result is visualized when a colored product is released by an enzyme-substrate reaction.
- C. With in vivo testing, Ags are introduced into the body directly to determine a patient's immunologic condition.

17.6 Viruses as a Special Diagnostic Case

- A. Viral diseases are diagnosed through patient observation supported by microscopic, cultural, serological, and genetic tests.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

- Multiple Matching.** Match each of the following culture results to the most likely interpretation, and explain your choice.

a. probable infection	_____ 1. Isolation of two colonies of <i>E. coli</i> on a plate streaked from the urine sample
b. normal microbiota	_____ 2. Fifty colonies of <i>Streptococcus pneumoniae</i> on culture of sputum
c. environmental contaminant	_____ 3. A mixture of 80 colonies of various streptococci on a culture from a throat swab
	_____ 4. Colonies of black bread mold on selective media used to isolate bacteria from stool
	_____ 5. Blood culture bottle with heavy growth
- Which of the following methods is most sensitive for identifying different strains of a microbe?

a. microscopic examination	c. DNA analysis
b. hemolysis on blood agar	d. agglutination test
- In agglutination reactions, the antigen is a _____; in precipitation reactions, it is a _____.

a. soluble molecule, whole cell	c. bacterium, virus
b. whole cell, soluble molecule	d. protein, carbohydrate
- Which reaction requires complement?

a. hemagglutination	c. hemolysis
b. precipitation	d. toxin neutralization
- A patient with a _____ titer of antibodies to an infectious agent generally has greater protection than a patient with a _____ titer.

a. high, low	c. negative, positive
b. low, high	d. old, new
- Direct immunofluorescent tests use a labeled antibody to identify

a. an unknown microbe	c. fixed complement
b. an unknown antibody	d. agglutinated antigens
- The Western blot test can be used to identify

a. unknown antibodies	c. specific DNA
b. unknown antigens	d. both a and b
- An example of an in vivo serological test is

a. indirect immunofluorescence
b. radioimmunoassay
c. tuberculin test
d. complement fixation
- Which of the following specimens must be removed by sterile techniques?

a. feces	c. upper respiratory tract
b. urine	d. blood

Case Study Review

- On what basis were both *Shigella* and *Salmonella* eliminated as possible causes of the outbreak pathogen?

a. Gram reaction	c. oxidase results
b. fermentation of glucose	d. motility
- Which *Vibrio* test results does *V. parahaemolyticus* most resemble?

a. <i>V. cholerae</i> , salt tolerance	c. <i>V. cholerae</i> , sucrose fermentation
b. <i>V. vulnificus</i> , salt tolerance	d. <i>V. vulnificus</i> , ONPG
- What other forms of testing from this chapter could differentiate the *Vibrio* pathogens?

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

- Why do we interpret positive hemolysis in the complement fixation test to mean negative for the test substance?
- What information can the antibody titer tell us about the immune status of a person?
- Briefly describe the principles and give an example of the use of a specific test using immunoelectrophoresis, Western blot, complement fixation, fluorescent testing (direct and indirect), and immunoassays (direct and indirect ELISA).
- Differentiate between the serological tests used to identify isolated cultures of pathogens and those used to diagnose disease from patients' serum as shown in figure 17.8.
- How would the staining and cultural tests have differed if *Staphylococcus* or *Clostridium* had been the cause of the outbreak of gastroenteritis described in this chapter's Case Study?
- Explain what must be done to identify RNA viruses using genetic techniques.

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps and a sample of a concept map for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

- How would you explain to a biology class that in the next decade, some diseases currently thought to be noninfectious will probably be found to be caused by microbes?
- In what way could the extreme sensitivity of the PCR method be a problem when working with clinical specimens?
- Why do some tests for antibody in serum (such as for HIV and syphilis) require backup verification with additional tests at a later date?
- Look at figure 17.10*b*. What is the titer as shown?
 - If the titer had been 40, would a different interpretation be made as to the immune status of the patient?
- Which patients are positive in figure 17.11, part III?
 - What would it mean if a test 2 weeks later revealed a titer of 280?
 - What would it mean if no agglutination had occurred in any tube?
- Observe figure 17.15 and make note of the several steps in the indirect ELISA test. What four essential events are necessary to develop a positive reaction (besides having antibody A)? Hint: What would happen without rinses?
- Distinguish between point of care tests that can be used to diagnose infection and those that can be used to identify pathogens, using examples.

Visual Challenge

- From **chapter 3, fig 3.17a** (reproduced on the right) shows triple sugar iron agar. What biochemical characteristics does this figure illustrate? How could this medium be used to begin the identification of the isolated bacteria in this chapter's Case Study?
- Starting with figure 17.5 and using data from Case Study tables 1 and 2, devise a flowchart that outlines the steps in identifying all of the *Vibrio* species.

CASE STUDY Part 1 A Rapidly Advancing Pathogen Deserves an Equally Rapid Response

Some **signs** and **symptoms** are more likely than others to get the attention of medical professionals. Patients suffering chest pain or sudden paralysis receive immediate attention because heart attacks and strokes are medical emergencies that require prompt treatment if there is to be any hope of a successful outcome. Similarly, **headache** and **fever**, accompanied by a **stiff neck**—the hallmarks of **meningitis**—will never fail to rouse medical personnel into immediate action.

On the morning of March 10, 2010, the Oklahoma State Department of Health (OSDH) was notified of a 7-year-old boy admitted to the hospital with meningitis, an **inflammation** of the tissue covering the **brain** and **spinal cord**. A swift, definitive diagnosis was necessary for a number of reasons: Meningitis may result from infection with bacteria, viruses, fungi, or parasites, each of which requires different treatment, and if, as suspected, the meningitis was bacterial in nature, proper medical intervention must begin immediately, because even when treated, the disease has a **mortality rate** approaching

“It’s only been eight hours, and already two students have died.”

15%. Furthermore, bacterial meningitis is **contagious**, and the appearance of a single case could be a harbinger of more cases to come. A **spinal tap** was ordered, and laboratory culture and analysis

of **cerebrospinal fluid** from the patient revealed the presence of *Neisseria meningitidis*, a **gram-negative diplococcus** that is the second most common cause of the disease. The patient was admitted to the intensive care unit and successfully treated, while four household members of the patient were **prophylactically** treated with the antibiotics **rifampin** or **ceftriaxone**. Unfortunately, this was not the end of the case.

- What are the signs and symptoms of meningococcal meningitis?
- How is *N. meningitidis* commonly spread?

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

Pathogen Profiles and Systems Profiles

Scoping Out the Chapter does not appear in chapters 18–25 but will return in chapter 26. Beginning with this chapter we are introducing two features called *Pathogen Profiles* and *Systems Profiles*. Pathogen Profiles are short boxes describing the characteristics of major pathogens in the chapter. Each profile also

includes a figure indicating the organs and systems most commonly infected by the pathogen. Systems Profiles categorize the major pathogens found in each chapter by the organ system(s) each pathogen generally affects, the name of the infection or disease it causes, and certain signs and symptoms associated with it.

Systems Profile 18.1 Pathogenic Gram-Positive and Gram-Negative Cocci						
Organism	Skin/Skeletal	Nervous/ Muscle	Cardiovascular/ Lymphatic/ Systemic	Gastrointestinal	Respiratory	Urogenital
<i>Staphylococcus aureus</i>	1. Boils, carbuncles 2. Impetigo 3. Scalded skin syndrome 4. Osteomyelitis		1. Endocarditis 2. Toxic shock syndrome	Food intoxication	Pneumonia	
Coagulase-negative staphylococci	Surgical infections		Endocarditis			Urinary tract infections
<i>Streptococcus pyogenes</i> (group A)	1. Pyoderma (Impetigo) 2. Erysipelas 3. Necrotizing fasciitis		1. Scarlet fever 2. Rheumatic fever		1. Pharyngitis (strep throat) 2. Sinusitis	Glomerulonephritis
<i>Streptococcus agalactiae</i> (group B)	Wound infections	Neonatal meningitis	1. Neonatal sepsis 2. Endocarditis		Neonatal pneumonia	
Enterococci	Wound and surgical infections					Healthcare-associated urinary tract infections
Viridans streptococci			Subacute endocarditis	Dental caries		
<i>Streptococcus pneumoniae</i>		Pneumococcal meningitis (adult)			1. Pneumonia 2. Otitis media 3. Sinusitis	
<i>Neisseria gonorrhoeae</i>	Gonococcal ophthalmia					Gonorrhea
<i>Neisseria meningitidis</i>		Meningococcal meningitis				

Gram-positive and gram-negative cocci are among the most significant infectious agents of humans as well as prevalent members of the normal microbiota of the skin, oral cavity, and intestine. Because infections with these bacteria tend to stimulate pus formation, they are often referred to collectively as the **pyogenic cocci**. The most common infectious species in this group belong to four genera: *Staphylococcus*, *Streptococcus*, *Enterococcus*, and *Neisseria*. See **Systems Profile 18.1** for an outline of organs and systems targeted by these pathogens.

18.1 General Characteristics of the Staphylococci

Expected Learning Outcomes

1. Name the five most important human pathogens in the genus *Staphylococcus*.
2. Describe the ability of *S. aureus* to withstand extremes of salt, pH, temperature, and desiccation, and how these abilities contribute to pathogenicity.
3. Name the enzymes and toxins found in *S. aureus*, and explain their role in increasing the virulence of the species.
4. Summarize the cutaneous, systemic, and toxigenic diseases caused by *S. aureus*, along with how the body defends against infection.
5. Differentiate between staphylococcal species in the laboratory through the examination of physiological and biochemical traits.
6. Explain strategies used to prevent and treat staphylococcal infections, and how infection with drug-resistant strains of *Staphylococcus* affects these strategies.

The genus *Staphylococcus* is a common inhabitant of the skin and mucous membranes, and it accounts for a considerable proportion of human infections (often called “staph” infections). Its spherical cells are arranged primarily in irregular clusters and occasionally in short chains and pairs (**figure 18.1**). Although typically gram-positive, older cultures and clinical specimens sometimes do not stain true. As a group, the staphylococci lack spores and flagella and may be encapsulated.

Currently 47 species have been placed in the genus *Staphylococcus*, but the most important human pathogens are:

1. *Staphylococcus aureus*;¹
2. *Staphylococcus epidermidis*, *Staphylococcus capitis*, *Staphylococcus hominis*; and
3. *Staphylococcus saprophyticus*.

1. From *L. aurum*, gold. Named for the tendency of some strains to produce a golden-yellow pigment.

Figure 18.1 Views of *Staphylococcus aureus* shape and arrangement. This genus owes its name to the grapelike clusters it commonly displays. (Left) A Gram stain shows gram-positive cocci in irregular clusters (1,000 \times). (Right) A colorized scanning electron micrograph of methicillin resistant *Staphylococcus aureus* cells being engulfed by a neutrophil (7,500 \times). (left): © Eye of Science/Science Source; (right): Source: National Institute of Allergy and Infectious Diseases (NIAID)/CDC

Of these, *S. aureus* is considered the most serious pathogen, although the other species have become increasingly associated with opportunistic infections and can no longer be regarded as harmless commensals. As a group, the staphylococci are implicated, annually in the United States, in nearly 80,000 deaths and a not insignificant percentage of healthcare-associated infections. The following sections focus on the significant characteristics of each species separately.

Growth and Physiological Characteristics of *Staphylococcus aureus*

Staphylococcus aureus produces round, opaque colonies (figure 18.2) and grows at an optimum temperature of 37°C, though it can grow at any temperature between 10°C and 46°C. The species is a facultative anaerobe whose growth is enhanced in the presence of O₂ and CO₂. Its nutrient requirements can be satisfied by routine laboratory media, and most strains are metabolically versatile; that is, they can digest proteins and lipids, and ferment a variety of sugars. This species is considered one of the most resistant of all non-spore-forming pathogens, with well-developed capacities to withstand high salt (7.5%–10%), extremes in pH, and high temperatures (up to 60°C for 60 minutes). It also remains viable after months of air drying and resists the effects of many disinfectants and antibiotics. These properties contribute to the reputation of *S. aureus* as a troublesome hospital pathogen.

Virulence Factors of *Staphylococcus aureus*

Staphylococcus aureus exhibits a great variety of virulence factors, with no single toxin or enzyme completely responsible for the virulence seen in the species (table 18.1).

Pathogenic *S. aureus* typically produces **coagulase**, an enzyme that clots plasma (see figure 18.6b). The precise importance of coagulase to the disease process remains uncertain. It may be that coagulase causes fibrin to be deposited around staphylococcal cells. Fibrin can stop the action of host defenses such as phagocytosis, or

Figure 18.2 Blood agar plate growing *Staphylococcus aureus*. Some strains show two zones of hemolysis. The relatively clearer inner zone is caused by α -toxin, whereas the outer zone is fuzzy and appears only if the plate has been refrigerated. This outer zone is the β , or “hot-cold,” hemolysin that shows up when the plate is refrigerated. © Kathy Park Talaro

it may promote staphylococcal adherence to tissues. Because 97% of all human isolates of *S. aureus* produce this enzyme, its presence is considered the most diagnostic species characteristic.

An enzyme that appears to promote invasion is hyaluronidase, or the “spreading factor,” which digests the intercellular “glue” (hyaluronic acid) that binds connective tissue in host tissues. Other enzymes associated with *S. aureus* include staphylokinase, which

TABLE 18.1 Major Virulence Factors of *Staphylococcus aureus*

Name	Enzyme/Toxin	Effect
Coagulase	Enzyme	Coagulates blood plasma
Hyaluronidase	Enzyme	Digests connective tissue of the host
Staphylokinase	Enzyme	Digests blood clots
Lipase	Enzyme	Digests oils, allowing bacteria to more easily colonize the skin
Penicillinase	Enzyme	Inactivates penicillin, rendering the bacterium resistant
Hemolysins (α , β , γ , δ)	Toxin	Lyse red blood cells
Leukocidin	Toxin	Lyses neutrophils and macrophages
Enterotoxins	Toxin	Induce nausea, vomiting, and diarrhea
Exfoliative toxins (A, B)	Toxin	Cause desquamation of the skin
Toxic shock syndrome toxin	Toxin	Induces fever, vomiting rash, organ damage

digests blood clots; a nuclease that digests DNA (DNase); and lipases that help bacteria colonize oily skin surfaces. Enzymes that inactivate penicillin (penicillinase) or other drugs are produced by a majority of strains, and many isolates show multiple resistance.

The toxic products of this species include blood cell toxins (hemolysins and leukocidins), intestinal toxins, and epithelial toxins. **Hemolysins** lyse red blood cells, an effect that can be seen in the laboratory (figure 18.2). The most important, in terms of biological effect, is alpha-toxin (α -toxin), which lyses red blood cells while also causing damage to leukocytes, renal tissue, and both skeletal and heart muscle. Other hemolysins are designated by the Greek letters β , δ , and γ . (Note that the Greek letters used to describe the hemolysins do not correspond to the Greek letters describing patterns of hemolysis in chapter 13. For example, alpha-toxin produces beta-hemolysis.)

Other staphylococcal exotoxins include **leukocidin**, which damages cell membranes of neutrophils and macrophages, causing them to lyse. This toxin probably helps incapacitate the phagocytic line of defense. Some strains produce exotoxins called **enterotoxins** that act upon the gastrointestinal tract of humans. A few strains produce an **exfoliative* toxin** that separates the epidermal layer from the dermis and causes the skin to peel away. This toxin is responsible for staphylococcal scalded skin syndrome, in which the skin looks burned (see figure 18.5b). The most recent toxin brought to light is **toxic shock syndrome toxin (TSST)**. The presence of this toxin in victims of toxic shock syndrome indicates its probable role in the development of this dangerous condition. The contributions of these toxins and enzymes to disease are discussed in the section on pathology.

Epidemiology and Pathogenesis of *S. aureus*

It is surprising that a bacterium with such great potential for virulence as *Staphylococcus aureus* is a common, intimate human

* *exfoliative* (eks-foh'-lee-ay"-tiv) *L. exfoliatio*, falling off in layers.

(a) Sectional view of a boil or furuncle, a single pustule that develops in a hair follicle or gland and is the classic lesion of the species. The inflamed infection site becomes abscessed when masses of phagocytes, bacteria, and fluid are walled off by fibrin.

(b) Appearance of folliculitis caused by *S. aureus*. Note the clusters of inflamed papules and pustules.

(c) An abscess on the knee caused by methicillin-resistant *Staphylococcus aureus* (MRSA).

associate. The microbe is present in most environments frequented by humans and is readily isolated from fomites. Colonization of some infants begins within hours after birth and continues throughout life. Anywhere from 20% to 60% of healthy adults may carry *S. aureus*, and in these instances the pathogen tends to be harbored intermittently rather than chronically. Carriage occurs mostly in the anterior nares (nostrils) and to a lesser extent in the skin, nasopharynx, and intestine. Usually this colonization is not associated with symptoms, nor does it ordinarily lead to disease in carriers or their contacts. Circumstances that predispose an individual to infection include poor hygiene and nutrition, tissue injury, preexisting primary infections, diabetes mellitus, and immunodeficiency states. *Staphylococcus aureus* is the third most common cause of infections in the newborn nursery and surgical wards. The “hospital strains” can readily spread in an epidemic pattern within and outside the hospital.

A serious concern has arisen from the increase in community infections by strains of *S. aureus* called MRSA (**m**ethicillin-**r**esistant *S. aureus*). Several outbreaks have been reported in prison inmates, athletes, and schoolchildren. The infections are spread by contact with skin lesions and have proved to be very difficult to treat and control.

The Scope of Staphylococcal Disease

Depending on the degree of invasion or toxin production by *S. aureus*, disease ranges from localized to systemic. A local staphylococcal infection often presents as an inflamed, fibrous lesion enclosing a core of pus called an **abscess (figure 18.3a)**. Toxigenic disease—disease that is due to the presence of toxins rather than the bacterium itself—can present as a toxemia if the toxins are produced in the body, or as food intoxication if *S. aureus* toxins present in food are ingested.

Localized Cutaneous Infections

Staphylococcus aureus usually invades the skin through wounds, follicles, or skin glands. The most common infection is a mild, superficial inflammation of hair follicles termed **folliculitis (figure 18.3b)** or glands (hidradenitis). Although these lesions are usually resolved with no complications, they can lead to infections of subcutaneous tissues. A **furuncle*** (boil) results when the inflammation of a single hair follicle or sebaceous gland progresses into a

* *furuncle* (fur'-unkl) *L. furunculus*, little thief.

Figure 18.3 Cutaneous lesions of *Staphylococcus aureus*. Fundamentally, all are skin abscesses that vary in size, depth, and degree of tissue involvement. (b) © DermNet New Zealand Trust; (c) © Gregory Moran

large, red, and extremely tender abscess or pustule (**figure 18.3c**). Furuncles often occur in clusters (furunculosis) on parts of the body such as the buttocks, armpit, and back of the neck, where skin rubs against other skin or clothing. A **carbuncle*** is a deeper lesion created by aggregation of a cluster of furuncles into one large mass (sometimes as big as a baseball). It is usually found in areas of thick, tough skin such as the back of the neck. Carbuncles are extremely painful and can even be fatal in elderly patients when they give rise to systemic disease. One staphylococcal skin infection not confined to follicles and skin glands is the *bullous* type of **impetigo**.* It is characterized by bubblelike epidermal swellings that can break and peel away like a localized form of scalded skin syndrome (see figure 18.5a). This form of impetigo is most common in newborns.

Miscellaneous Systemic Infections

Most systemic staphylococcal infections have a focal pattern spreading from a local cutaneous infection to other sites via the bloodstream. In **osteomyelitis** (**figure 18.4**) the pathogen is established in the highly vascular metaphyses of a variety of bones (often the femur, tibia, ankle, or wrist). Abscess formation in the affected area results in an elevated, tender lump leading to necrosis or breakage of the bony tissue. Symptoms of osteomyelitis include fever, chills, pain, and muscle spasm. This form of osteomyelitis is seen most frequently in growing children, adolescents, and intravenous drug abusers. Another type, secondary osteomyelitis, develops after traumatic injury (compound fracture) or surgery in cancer and diabetes patients.

Systemic staphylococcal infections affect a variety of organs. Because these bacteria inhabit the nasopharynx, they can be aspirated into the lungs and cause a form of pneumonia involving multiple lung abscesses and symptoms of fever, chest pain, and bloody sputum. Although staphylococci account for only a small proportion of such pneumonia cases, the fatality rate is 50%. Most cases occur in infants and children suffering from cystic fibrosis and measles; this form of pneumonia is also one of the most serious complications of influenza in elderly patients.

Staphylococcal bacteremia causes a high mortality rate among hospitalized patients with chronic disease. Its primary origin is bacteria that have escaped from an infection site or from colonized medical devices (catheters, shunts). Circulating bacteria transported to the kidneys, liver, and spleen often form abscesses and give off toxins into the circulation. One consequence of staphylococcal bacteremia is a fatal form of endocarditis associated with the colonization of the heart's lining, cardiac abnormalities, and rapid destruction of the valves. Infection of the joints can produce a deforming arthritis (pyoarthrititis). A severe form of meningitis (accounting for less than 10% of cases) occurs when *S. aureus* invades the brain.

Toxigenic Staphylococcal Disease

Diseases associated with toxin production by *S. aureus* are food intoxication, scalded skin syndrome, and toxic shock syndrome

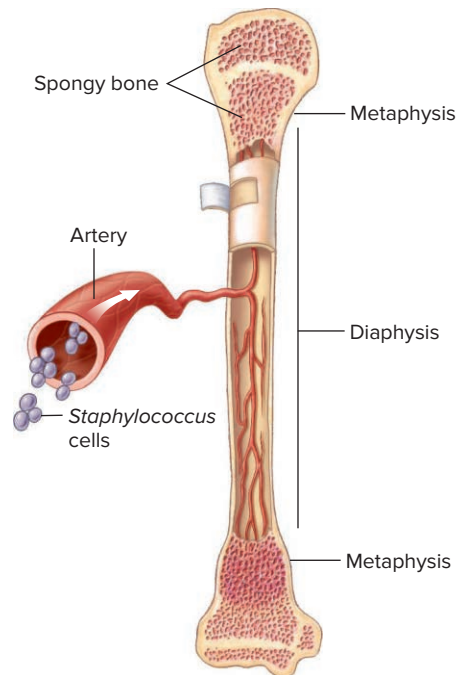

Figure 18.4 Staphylococcal osteomyelitis in a long bone. In the most common form, the bacteria spread in the circulation from some other infection site, enter the artery, and lodge in the small vessels in bony pockets of the marrow. Growth of the cells causes inflammation and damage that manifest as swelling and necrosis.

(18.1 Making Connections). Enterotoxins produced by certain strains are responsible for a common type of food poisoning in the United States. This illness is associated with foods such as custards, sauces, cream pastries, processed meats, potato salad, or dressings that have been contaminated during preparation and then left unrefrigerated for a few hours. Because of the high salt tolerance of *S. aureus*, even foods containing salt as a preservative are not exempt. The toxins produced by the multiplying bacteria do not noticeably alter the food's taste or smell. Enterotoxins are heat-stable (inactivation requires 100°C for at least 30 minutes), so heating the food after toxin production may not prevent disease. The ingested toxin acts upon the gastrointestinal epithelium and stimulates nerves, with acute symptoms of cramping, nausea, vomiting, and diarrhea that appear in 2 to 6 hours. Recovery is rapid, usually within 24 hours.

Children with *S. aureus* infection of the umbilical stump or eyes are susceptible to a toxemia called **staphylococcal scalded skin syndrome (SSSS)**. Upon reaching the skin, the toxin induces a painful, bright red flush over the entire body that first blisters and then causes desquamation of the epidermis (**figure 18.5**). The vast majority of SSSS cases have been described in infants and children under the age of 4. This same exfoliative toxin causes the local reaction in bullous impetigo, which can afflict people of all ages.

Host Defenses Against *S. aureus*

Humans have a well-developed resistance to staphylococcal infections. Studies performed on human volunteers established that an injection of several hundred thousand staphylococcal cells into

* *carbuncle* (car'-bunkl) L. *carbunculus*, little coal.

* *anaphylaxis* (an'-uh-fih-lax'-us) Gr. *ana*, excessive, and *phylaxis*, protection.

18.1 MAKING CONNECTIONS

Tampons and TSS

Toxic shock syndrome (TSS) was first identified as a discrete clinical entity in 1978 in young women using vaginal tampons, even though the disease probably existed before that time. Two discoveries helped to clarify the link between TSS and tampon use. The first was that ultra absorbent brands of tampons bind magnesium ions that are normally present in the blood; the second was that in the absence of these ions, *Staphylococcus aureus* produces much greater levels of exotoxins, including the toxin responsible for toxic shock syndrome. These findings also helped to explain why TSS was most likely to occur when menstrual flow was low. During periods of high flow, even the most absorbent tampons cannot absorb all the magnesium present; during low-flow days, magnesium may be completely depleted, leading to an increase in toxin production.

Toxic shock syndrome toxin is a type of superantigen that initiates a massive immune response by T cells when it enters the bloodstream. What results is an outpouring of cytokines that can wreak havoc on

several systems. Symptoms are fever, rash, low blood pressure, shock, vomiting, and diarrhea. Potentially fatal complications occur in the renal, hepatic, and nervous systems.

A small percentage of TSS cases are seen in women using diaphragms or sponge-type contraceptives, as well as in children, men, non-menstruating women, and patients recovering from nasal surgery. The evidence implicating ultra absorbent tampons as a major factor in the disease was so compelling that those tampons were taken off the market, and tampon packages now contain a warning that the least-absorbent tampon that is effective should be used. From the highest yearly count of 880 TSS cases in 1981, the number has gradually decreased to a current average of about 100.

Provide an explanation for how cases of TSS have developed in men, children, and surgical patients. Answer available on Connect.

Figure 18.5 Effects of staphylococcal toxins on skin.

(a) Bullous impetigo, a localized staphylococcal infection with filled and collapsed bullae. (b) Staphylococcal scalded skin syndrome results when exfoliative toxin produced in local infections causes blistering and peeling away of the outer layer of skin. (c) Photomicrograph of a segment of skin affected with SSSS. The point of epidermal shedding, or desquamation, is between the epidermis and the dermis. The lesion will heal because the level of separation is so superficial. (a): © Kathy Park Talaro; (b): © National Institute Slide Bank/The Wellcome Centre for Medical Sciences; (c): © Rejendra Singh

unbroken skin was not sufficient to cause abscess formation. Yet when sutures containing only a few hundred cells were sewn into the skin, a classic lesion rapidly formed, indicating that the presence of a foreign body to provide a surface for biofilm production dramatically lowered the infectious dose. Specific antibodies are produced against most of the staphylococcal antigens, though none of these antibodies appears to be effective (except for the antitoxin to SSSS toxin). The most powerful defense lies in the phagocytic response by neutrophils and macrophages. When aided by the opsonic action of complement, phagocytosis effectively disposes of staphylococci that have gained access to tissues. Inflammation and cell-mediated immunity, which stimulate abscess formation, also help contain staphylococci and prevent their further spread.

Other Important Staphylococci

Because they lack the coagulase present in most *S. aureus*, other *Staphylococcus* species are called the **coagulase-negative staphylococci**. Several species are included in this group, some of human origin and others of nonhuman, mammalian origin. Although this group was once considered clinically nonsignificant, its importance has greatly increased over the past 20 years. Coagulase-negative staphylococci currently account for a large proportion of healthcare-associated and opportunistic infections in immunocompromised patients.

The normal habitats of *Staphylococcus epidermidis* are the skin and mucous membranes. *Staphylococcus hominis* lives in skin areas rich in apocrine glands; and *S. capitis* populates the scalp, face, and external ear. From these sites, the bacteria are positioned to enter breaks in the protective skin barrier. Infections usually occur after surgical procedures, such as insertion of shunts, catheters, and various prosthetic devices that require incisions through the skin. It appears that any foreign object can support biofilm formation by these bacteria, which develop thick adherent capsules. It is particularly alarming that these infections are increasing because of

CLINICAL CONNECTIONS

Biofilms in Infections

Many species of gram-positive cocci produce slimes or capsules that contribute to biofilm formation in the body. These thick tenacious films increase adherence in infections and can lead to a variety of complications. For example, staphylococci lay down a slimy matrix that binds them to surfaces and allows them to colonize catheters, artificial valves, and other indwelling medical devices (see the chapter 4 Case Study). Certain species of oral streptococci are active initiators of plaque on teeth and are ultimately responsible for many types of oral diseases. The streptococci that cause endocarditis produce thick vegetations on damaged areas of the heart valves and heart lining. Such biofilms can have several adverse effects. Acting as an impenetrable shield, they hide the infectious agent and make it inaccessible to the host defenses. They can also block the effects of antimicrobial drugs by slowing passage into the embedded microbes. In some infections the biofilm holds the infectious agent in the body, where it becomes a continued source of pathogens. The subsequent release of bacteria into the circulation may give rise to sepsis and focal infections.

How could drugs that affect biofilm formation be used in the treatment of infection with biofilm-forming bacteria? Answer available on Connect.

technological advances in maintaining patients. Although *S. epidermidis* is not as invasive or toxic as *S. aureus*, it can also cause endocarditis, bacteremia, and urinary tract infections.

Less is known about the distribution and epidemiology of *S. saprophyticus*. It is an infrequent resident of the skin, lower intestinal tract, and vagina, but its primary importance is in urinary tract infections. For unknown reasons, urinary *S. saprophyticus* infection is found almost exclusively in sexually active young women and is the second most common cause of urinary infections in this group.

Identification of *Staphylococcus* Isolates in Clinical Samples

Staphylococci are frequently isolated from pus, tissue exudates, sputum, urine, and blood. Primary isolation is achieved by inoculation on sheep or rabbit blood agar; or in heavily contaminated specimens, selective media such as mannitol salt agar are used. In addition to culturing, the specimen can be Gram stained and observed for irregular clusters of gram-positive cocci.

Because differentiating among gram-positive cocci is not possible using colonial and morphological characteristics alone, other presumptive tests are required (see figure 17.5). Traditionally, *Staphylococcus* has been differentiated from *Streptococcus* by the production of catalase, which is produced in the former but not the latter (figure 18.6a), and from *Micrococcus* through biochemical and cultural differences (figure 18.7). *S. aureus* may be distinguished from other species of *Staphylococcus* as it is the only

Figure 18.6 Tests for differentiating the genus *Staphylococcus* from *Streptococcus* and for identifying *Staphylococcus aureus*. (a) Staphylococci produce catalase to break down the hydrogen peroxide generated during oxidative metabolism. Catalase is lacking in streptococci. In the *plate catalase test*, adding a 3% solution of hydrogen peroxide to a bacterium growing on a plate will cause the sample to bubble vigorously if catalase is present and to remain undisturbed if catalase is lacking. (b) Staphylococcal coagulase is an enzyme that reacts with factors in plasma to initiate clot formation. In the coagulase test, a tube of plasma is inoculated with the bacterium. If it remains liquid, the test is negative. If the plasma develops a lump or becomes completely clotted, the test is positive. © Barry Chess

species within the genus to produce coagulase (figure 18.6b). Newer identification methods rely on antibody-coated latex beads or the polymerase chain reaction (PCR) to provide a far more rapid identification, reducing the time required from 2 or 3 days to just a few hours. The PCR method has the added advantage of identifying in a single step those *S. aureus* isolates that are methicillin resistant (MRSA).

Differentiating the common coagulase-negative staphylococci from one another relies primarily upon the novobiocin resistance of *S. saprophyticus*, mannose fermentation in *S. epidermidis*, the lack of urease production in *S. capitis*, and lack of anaerobic growth in *S. hominis*. Commercial systems that allow rapid identification of staphylococcal species based on their biochemical and physiological characteristics (figure 18.7) have largely replaced the need to perform a great number of individual tests (table 18.2).

Quick Search

To see how quickly antibody-coated latex beads can be used to identify *S. aureus*, search the Internet for “Staphaurex test for Staph aureus.”

Figure 18.7 Miniaturized test system used in further identification of *Staphylococcus* isolates. Microbiologists can separate 23 species of gram-positive cocci with this system, including 20 clinically important species of *Staphylococcus*. Each cupule contains a sugar or other biochemical substrate important to the differentiation of gram-positive cocci, along with a chemical indicator. The combination of positive and negative results obtained allows for the identification of an unknown species. Courtesy of bioMérieux, Inc.

Clinical Concerns in Staphylococcal Infections

The staphylococci are notorious for their acquisition of resistance to new drugs, and they continue to defy attempts at medical control. Because resistance to common drugs is likely, antimicrobial susceptibility tests are essential in selecting a correct therapeutic agent.

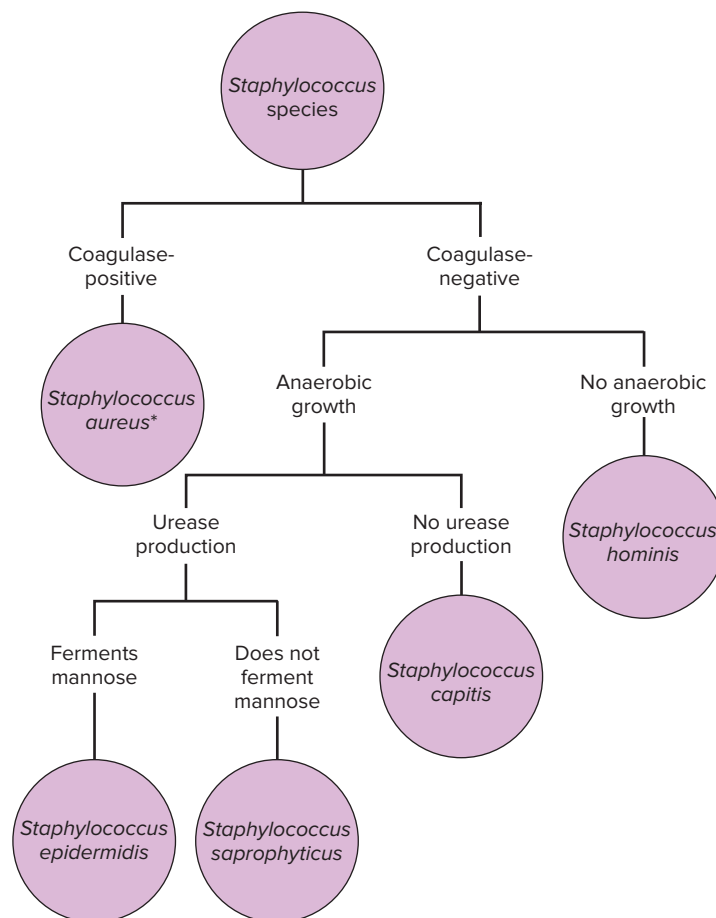

Ninety-five percent of strains of *S. aureus* have acquired genes for penicillinase, which makes them resistant to the traditional drugs penicillin and ampicillin. Equally problematic are strains of MRSA that carry multiple resistance to a wide range of antimicrobics, including methicillin, gentamicin, cephalosporins, tetracycline, erythromycin, and even quinolones. The CDC estimates about 82,000 new cases per year, with 11,500 deaths caused by this “superbug.” A few strains have acquired resistance to all major drug groups except vancomycin. Most of these isolates are found in hospitals (HA-MRSA), where they account for 80% of staphylococcal infections. Now that there have been reports of vancomycin resistance in *S. aureus*, infectious disease specialists are keeping close track of this trend.

The latest cause for concern is a form of resistant *S. aureus* acquired outside of the hospital during community contact (CA-MRSA). This strain causes the usual staph-type skin infections, but it has also been implicated in fatal systemic diseases. It is contracted most often from locations where people congregate and may share fomites, such as in gyms, schools, and prisons. Although its numbers are increasing, its overall incidence is still far below that of hospital MRSA. CA-MRSA is also sensitive to a wider array of antibiotics, so more treatment options are available. The CDC is currently being urged to include this strain on the notifiable diseases list to monitor its epidemiology.

Treatment of Staphylococcal Infections

Selecting the correct drug to treat staphylococcal infections is highly dependent on culture and sensitivity testing of the staphylococcal isolates. The less resistant forms of *S. aureus* can generally be treated with cephalexin, sulfa drugs, tetracyclines, or clindamycin. If the strain is MRSA, there are still a few drugs that will generally work, including vancomycin, ceftaroline, linezolid, and daptomycin. It may be necessary to administer two of these in combination to lessen the development of further drug resistance. For cases of VISA and VRSA, quinupristin/dalfopristin is the last drug of choice.

TABLE 18.2 Separation of Clinically Important Species of *Staphylococcus*

*A few strains of *S. aureus* are coagulase-negative.

Clinical experience has shown that abscesses will not respond to therapy unless they are surgically perforated and cleared of pus and foreign bodies. Severe systemic conditions such as endocarditis, septicemia, osteomyelitis, pneumonia, and toxemia respond slowly and require intensive, lengthy therapy by oral or injected drugs or some combination of the two.

Prevention of Staphylococcal Infections

Because humans are the principal reservoir of the pathogenic staphylococci, there will probably always be carriers and infections. It is difficult to block the colonization of the human body, but one can minimize the opportunity for healthcare-associated infections by careful hygiene and adequate cleansing of surgical incisions and burns. Controlling the increasing incidence of healthcare associated outbreaks, especially among people at greatest risk (surgical patients and neonates), is a real challenge for hospital staff. Patients or hospital personnel who are asymptomatic carriers or have frank infections are the most common source. The burden of effective deterrence again falls to meticulous hand washing, proper disposal of infectious dressings and discharges, isolation of people with open lesions, and attention to indwelling catheters and needles.

CLINICAL CONNECTIONS

Acronyms and Antibiotic Resistance

So many strains of gram-positive cocci have developed resistance to drugs that specialists have resorted to using acronyms to keep easier track of them. The five most significant strains in healthcare-associated infections are methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), methicillin-resistant *Staphylococcus epidermidis* (MRSE), drug-resistant *Streptococcus pneumoniae* (DRSP), vancomycin-resistant *Staphylococcus aureus* (VRSA), and vancomycin intermediate *Staphylococcus aureus* (VISA). The current rates of resistance (based on how often a strain is isolated from patients) are 63% for MRSA, 30% for VRE, 90% for MRSE, and 22% for DRSP. So far the rates of VRSA have been very low—only 14 cases have been diagnosed. VISA, which shows slightly increased resistance to vancomycin, is considered a harbinger of a potential increase in the rate of VRSA infections. The number of VISA infections is on the increase, numbering well over 50 per year. Although these strains are named for their primary drug resistance, they are often also resistant to other drugs (cephalosporins, macrolides, and fluoroquinolones). In many cases it appears that the resistance

has been acquired through transfer of resistance plasmids. As a result, the prevalence of these strains is increasing and will continue to be a serious challenge for health care workers.

In response to this trend, drug companies have developed several new antimicrobial agents as alternate treatments to target these resistant strains. Quinupristin/dalfopristin (Synercid) is one such alternative, a combination antibiotic recommended for treatment of some types of VRE and staphylococcal infections. Moving beyond combinations of naturally occurring compounds, a number of semi-synthetic drugs have been developed to combat bacterial resistance. Daptomycin (Cubicin) is often the first choice for treating skin infections and bacteremia caused by any of several species of *Staphylococcus*, *Streptococcus*, and *Enterococcus*, whereas telavancin (Vibativ) targets skin infections caused by the same three genera of bacteria. Two other semisynthetics, linezolid (Zyvox) and ceftaroline (Teflaro), are used to treat skin and lung infections caused by MRSA or DRSP.

Explain why VISA is of concern to clinicians and why VRSA could be a more serious problem than MRSA. Answer available on Connect.

Pathogen Profile #1 *Staphylococcus aureus*

Source: Janice Carr/CDC

Microscopic Morphology Gram-positive cocci in irregular clusters; nonmotile; non-spore-forming. May form biofilm infections on catheters and other indwelling devices.

Identified by Growth on high-salt (7.5% NaCl or more) media, Gram reaction, and arrangement. Fermentation of sugars distinguishes *Staphylococcus* from *Micrococcus*; catalase production distinguishes *Staphylococcus* from *Streptococcus*. Coagulase production distinguishes *S. aureus* from other species of *Staphylococcus*. Commercially available rapid identification tests rely on antibody-coated latex beads that bind specifically with *S. aureus*.

Habitat Carried by 20% to 60% of healthy persons in the nostrils, skin, nasopharynx, and intestine. Very resistant to harsh environmental conditions and routinely present on fomites.

Virulence Factors *S. aureus* possesses enzymes that destroy host tissue (hyaluronidase), digest blood clots (staphylokinase), colonize oily skin (lipase), and resist the effects of penicillin (penicillinase). Toxins (leukocidins) destroy neutrophils and macrophages, lyse red blood cells (hemolysins), and cause damage throughout the body (enterotoxins, exfoliative toxins, toxic shock syndrome toxin).

Primary Infections/Disease Local cutaneous infections include folliculitis, furuncles, and carbuncles, as well as bullous impetigo. Systemic infections include osteomyelitis, pneumonia, and endocarditis. Diseases due to *S. aureus* toxins include food intoxication, scalded skin syndrome, and toxic shock syndrome.

Control and Treatment Control of healthcare-associated infection relies on careful hygiene, adequate cleansing of surgical incisions and burns; isolation of persons with open lesions; and barring of *S. aureus* carriers from sensitive areas such as operating rooms and nurseries. Special concern is paid to the strains known as MRSA, which have high levels of drug resistance. Community-acquired infections are controlled through disinfection of shared environments and equipment. Treatment involves intensive chemotherapy, often with multiple antimicrobics. The problem of MRSA strains requires antimicrobial susceptibility testing to select a correct chemotherapeutic agent. Many cutaneous lesions require perforation and drainage prior to antimicrobial therapy.

When possible, other preventive measures must be instituted. For example, hospital workers who carry *S. aureus* nasally may be barred from nurseries, operating rooms, and delivery rooms. Carriers can be treated for several months with

a combination of antimicrobial drugs such as bactroban and dicloxacillin to reduce the source of this pathogen in clinical settings. A vaccine aimed at providing protection against *S. aureus* is currently in clinical trials.

Check Your Progress SECTION 18.1

1. List the most clinically significant pathogens in the genus *Staphylococcus*, and identify the species that is defined by production of coagulase.
2. Discuss why food intoxication in salty foods, such as ham, is often due to the growth of *S. aureus*.
3. Explain how unbroken skin, the phagocytic action of neutrophils and macrophages, inflammation, and cell-mediated immunity all help to protect against staphylococcal infection.
4. List the strategies commonly used to prevent and treat staphylococcal infections.
5. Explain the meanings of the acronyms *MRSA*, *VRE*, *MRSE*, *DRSP*, *VRSA*, and *VISA*.

18.2 General Characteristics of the Streptococci and Related Genera

Expected Learning Outcomes

7. Name the most important human pathogens in the genus *Streptococcus*.
8. Summarize the virulence factors of *S. pyogenes*, as well as the diseases and long-term complications associated with *S. pyogenes* infection.
9. Recall the epidemiology and pathogenesis of the streptococcal species most often associated with human disease and how these groups are separated in the laboratory.
10. Explain strategies used to prevent and treat streptococcal infections.
11. Relate the pathogenesis and epidemiology of *S. pneumoniae*.

The genus *Streptococcus** includes a large and varied group of bacteria. Some are commensals or pathogens in humans and animals; others are free-living in the environment. Members of this group are known for the arrangement of cocci in long, beadlike chains, especially when grown in a liquid culture. The length of these chains varies, and it is common to find them in pairs (**figure 18.8**). The general shape of the cells is spherical, but they can also appear ovoid or rodlike, especially in actively dividing young cultures.

Streptococci are non-spore-forming and nonmotile (except for an occasional flagellated strain), and they can form capsules and slime layers. They are facultative anaerobes that ferment a variety of sugars, usually with the production of lactic acid (homofermentative). Streptococci do not form catalase, but they do have a peroxidase system for inactivating hydrogen peroxide, which allows their survival in the presence of oxygen. Most pathogenic forms are fastidious in nutrition and require enriched media for cultivation. Colonies are usually small, nonpigmented, and glistening. Most members of the genus are quite sensitive to drying, heat, disinfectants, and drugs. A few members, such as the pneumococci and enterococci, have developed significant drug resistance.

Species of *Streptococcus* were first classified using a system devised by Rebecca Lancefield in the 1930s. This system divided

* *Streptococcus* (strĕp'tā-kōk'əs) Gr. *streptos*, winding, twisted. The chain arrangement is the result of division in only one plane.

Figure 18.8 One of the truly great sights in microbiology: A freshly isolated *Streptococcus* with its long, intertwining chains. These occur only in liquid media and are especially well developed if nutrients are in limited supply (1,000X). © Kathy Park Talaro

streptococcal isolates into 17 alphabetically named Lancefield groups (group A, group B, etc.) based on cell wall carbohydrates displayed by each species. The system is somewhat incomplete—for example, some streptococcal species possess no cell wall carbohydrates and need additional methods of identification. One technique commonly employed in the clinical laboratory uses the reaction in blood agar of a given culture to begin the identification of streptococcal isolates (**figure 18.9a–c**). **Table 18.3** summarizes the streptococcal groups based on their habitat, hemolysis, and pathogenicity.

Many species of *Streptococcus* exist as microbiota of the oral cavity, whereas others live as commensals of domestic animals, including pets, and may colonize or infect humans. Human disease is most often associated with *S. pyogenes*, *S. agalactiae*, *viridans streptococci*, *S. pneumoniae*, and *Enterococcus faecalis* (formally known as *Streptococcus faecalis*).

Beta-Hemolytic Streptococci: *Streptococcus pyogenes*

By far the most serious streptococcal pathogen of humans is *Streptococcus pyogenes*, a beta-hemolytic species that is the main representative of group A. It is a relatively strict pathogen, inhabiting the throat, nasopharynx, and occasionally the skin of humans. The involvement of this species in severe disease is partly due to the substantial array of surface antigens, toxins, and enzymes it can generate.

Cell Surface Antigens and Virulence Factors

Streptococci display numerous surface antigens (**figure 18.10**).

- C-carbohydrates, specialized polysaccharides found on the surface of the cell wall, are the basis for Lancefield groups. Their apparent contribution to pathogenesis is to protect the bacterium from being dissolved by the lysozyme defense of the host.
- Lipoteichoic acid bound to fimbriae contributes to the adherence of *S. pyogenes* to epithelial cells in the skin or pharynx.
- Another type-specific molecule is the M-protein, of which about 80 different subtypes exist. This substance makes up

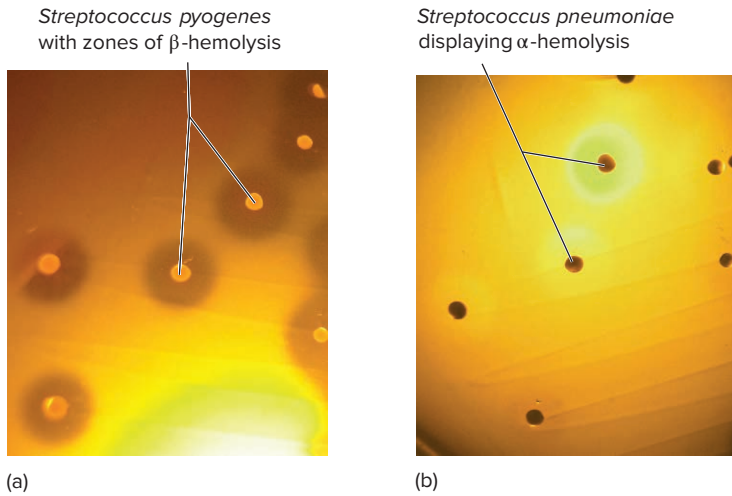

Figure 18.9 Hemolysis patterns on blood agar may be used to separate streptococci into major subgroups. (a) Throat cultures with colonies of *Streptococcus pyogenes* showing β -hemolysis. Note clear zones with completely lysed red blood cells. (b) Colonies of *S. pneumoniae* demonstrate the greenish zones, with partial lysis of RBCs, typical of α -hemolysis. TABLE 18.3 Major Species of *Streptococcus* and Related Genera

Species	Lancefield Group	Hemolysis Type	Habitat	Pathogenicity to Humans
<i>S. pyogenes</i>	A	Beta (β)	Human throat	Skin, throat infections, scarlet fever
<i>S. agalactiae</i>	B	β	Human vagina, cow udder	Neonatal, wound infections
<i>S. equi</i>	C	β	Various mammals	Rare, in abscesses
<i>S. dysgalactiae</i>	C	β	Cattle	Rare
<i>Enterococcus faecalis</i>	D	α , β , N	Human, animal intestine	Endocarditis, UTI*
<i>E. faecium</i> , <i>E. durans</i>	D	Alpha (α)	Human, animal intestine	Similar to <i>E. faecalis</i>
<i>S. bovis</i>	D	N	Cattle	Subacute endocarditis, bacteremia
<i>S. anginosus</i>	F, G, L	β	Humans, dogs	Endocarditis, URT** infections
<i>S. sanguinis</i>	H	α	Human oral cavity	Endocarditis
<i>S. salivarius</i>	K	N	Human saliva	Endocarditis
<i>Lactococcus lactis</i>	N	V	Dairy products	Very rare
<i>S. mutans</i>	NI***	N	Human oral cavity	Dental caries
<i>S. uberis</i> , <i>S. acidominimus</i>	NI	V	Domestic mammals	Rare
<i>S. pneumoniae</i>	NI	α	Human respiratory tract	Bacterial pneumonia

Note: Species in bold type are the most significant sources of human infection and disease. N = none; V = varies.
 *Urinary tract infection. **Upper respiratory tract. ***No group C-carbohydrate identified.

spiky surface projections that contribute to virulence by resisting phagocytosis and improving adherence.

- A capsule made of hyaluronic acid (HA) is formed by most *S. pyogenes* strains. The HA is chemically indistinguishable from HA found in human tissues, so it does not provoke an immune response from the host.
- C5a protease catalyzes the cleavage of the C5a protein of the complement system. Experiments suggest that this not only hinders the complement-associated aspects of the immune system but also interferes with the chemotactic response of neutrophils.

Major Extracellular Toxins Group A streptococci owe some of their virulence to the effects of hemolysins called **streptolysins**. The two types are streptolysin O (SLO) and streptolysin S (SLS).² (Both types cause beta-hemolysis of sheep blood agar.) Both hemolysins rapidly injure many cells and tissues, including leukocytes, liver, and heart muscle.

2. In SLO, O stands for oxygen because the substance is inactivated by oxygen. SLO is produced by most strains of *S. pyogenes*. In SLS, S stands for serum because the substance has an affinity for serum proteins. SLS is oxygen-stable.

Figure 18.10 Cutaway view of group A *Streptococcus*. (a) The outermost fringe consists of fimbriae composed in part of M-protein antigens. Other layers making up the cell envelope are the capsule, protein antigens, and C-carbohydrate antigens. (b) Detail of M-protein and its position in the cell envelope.

A key toxin in the development of scarlet fever (discussed in a later section of this chapter) is **erythrogenic*** (also known as the pyrogenic) toxin. This toxin is responsible for the bright red rash typical of this disease, and it also induces fever by acting upon the temperature regulatory center. Only lysogenic strains of *S. pyogenes* that contain genes from a temperate bacteriophage can synthesize this toxin.

Some of the streptococcal toxins (erythrogenic and streptolysin O) contribute to increased tissue injury by acting as **superantigens** (see chapter 15). These toxins increase the stimulation of certain T lymphocytes. Overactive T cells proliferate and produce a cascade of immune responses that release *tumor necrosis factor* and other cytokines, which lead to vascular injury. This is the likely mechanism behind the severe pathology of streptococcal toxic shock syndrome and necrotizing fasciitis.

Major Extracellular Enzymes Several enzymes for digesting macromolecules are virulence factors of the group A streptococci. Streptokinase, similar to staphylokinase, activates a pathway leading to the digestion of fibrin clots and may play a role in invasion. Hyaluronidase breaks down the binding substance in connective tissue and promotes spreading of the pathogen into the tissues, while streptodornase (DNase) liquefies purulent discharges by hydrolyzing DNA.

Epidemiology and Pathogenesis of *Streptococcus pyogenes*

Streptococcus pyogenes has traditionally been linked with a diverse spectrum of disease. Before the era of antibiotics, it accounted for a major portion of serious human infections and deaths from such diseases as rheumatic fever and puerperal sepsis. Although its importance has diminished over the past several years, recent epidemics have reminded us of its potential for sudden and serious illness (**18.2 Making Connections**).

* **erythrogenic** (eh-rith'-roh-jen'-ik) Gr. *erythros*, red, and *gennan*, to produce. The term *pyrogenic* refers to its fever-causing effects.

Humans are the only significant reservoir for *S. pyogenes*. About 5% to 15% of the population are subclinical carriers of virulent strains. Infection is generally transmitted through direct contact, droplets, and occasionally fomites. The bacteria gain a foothold at periods of lowered host resistance, primarily on the skin or in the pharynx. The incidence and types of infections are altered by climate, season, and living conditions. Skin infections occur more frequently during the warm temperatures of summer and fall, and pharyngeal infections increase in the winter months. Children 5 to 15 years of age are the predominant group affected by both types of infections. In addition to local cutaneous and throat infections, *S. pyogenes* can give rise to a variety of systemic infections and progressive sequelae if not properly treated.

Skin Infections When virulent streptococci invade a nick in the skin or the mucous membranes of the throat, an inflammatory primary lesion is produced. Pyogenic infections appearing after local invasion of the skin are pyoderma or erysipelas; those developing in the throat are pharyngitis or tonsillitis.

Streptococcal **impetigo**, or **pyoderma**, is marked by burning, itching papules that break and form a highly contagious yellow crust (**figure 18.11a**). Impetigo often occurs in epidemics among schoolchildren, and it is also associated with insect bites, poor hygiene, and crowded living conditions. A slightly more invasive form of skin infection is **erysipelas**.* The pathogen usually enters through a small wound or incision on the face or extremities and eventually spreads to the dermis and subcutaneous tissues. Early symptoms are edema and redness of the skin near the portal of entry, fever, and chills. The lesion begins to spread outward, producing a slightly elevated edge

that is noticeably red, hot, and often vesicular (**figure 18.11b**). Depending on the depth of the lesion and how the infection progresses, cutaneous lesions can remain superficial or produce long-term systemic complications. Some severe cases involving large areas of skin have been fatal.

Most people associate streptococci with the condition called *strep throat* or, more technically, **streptococcal pharyngitis**. Most humans will acquire this particular infection at some time during

(a)

(b)

Figure 18.11 Streptococcal skin infections. (a) Impetigo lesions on the face. (b) Erysipelas of the face. Tender, red, puffy lesions have a sharp border that can burst and release fluid. Also note the release of purulent discharge from the eye.

* **erysipelas** (er'-ih-sip'-eh-las) Gr. *erythros*, red, and *pella*, skin.

18.2 MAKING CONNECTIONS

Invasive Group A Streptococci and “Flesh-Eating” Syndrome

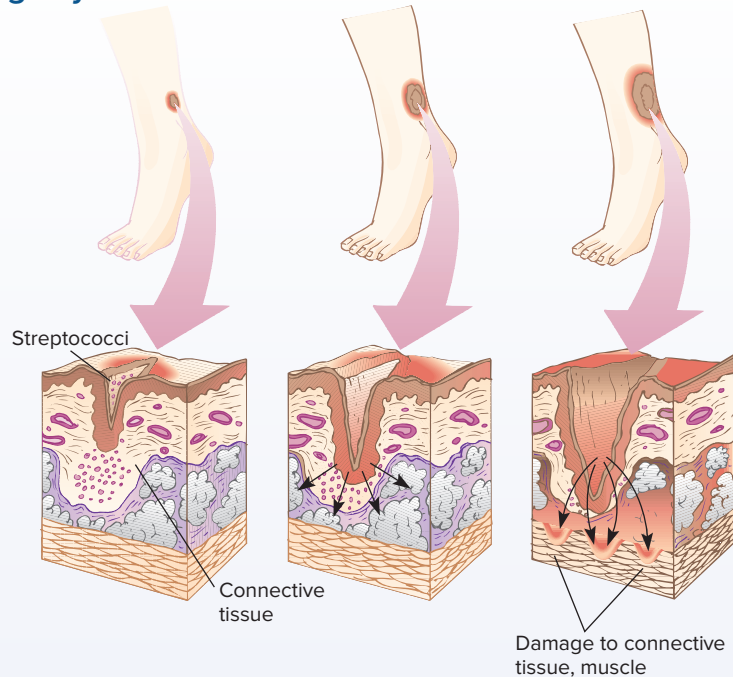

Streptococcal infections are “occupational diseases of childhood” that usually follow a routine and uncomplicated course. The greatest cause for concern are those few occasions when such infections erupt into far more serious ailments. One dramatic example is **necrotizing fasciitis**,* a complication of *S. pyogenes* infection that has received heavy publicity as the “flesh-eating disease.” It should be emphasized that cases of this disease are rather rare, but its potential for harm is high. It can begin with an innocuous cut in the skin and spread rapidly into nearby tissue, causing severe disfigurement and even death.

There is really no mystery to the pathogenesis of necrotizing fasciitis. It begins very much like impetigo and other skin infections: Streptococci on the skin are readily introduced into small abrasions or cuts, where they begin to grow rapidly. These strains of group A streptococci release special enzymes and toxins that greatly increase their invasiveness and virulence. Some of the toxins acting as superantigens can trigger harmful immune responses.

The enzymes digest the connective tissue in skin, and their toxins poison the epidermal and dermal tissues. As the flesh dies, it separates and sloughs off, forming a pathway for the bacteria to spread into deeper tissues such as muscle. More dangerous infections involve a mixed infection with anaerobic bacteria, systemic spread of toxins to other organs, or both. It is true that some patients have lost parts of their limbs and faces and others have required amputation, but early diagnosis and treatment can prevent these complications. Fortunately, even virulent strains of *Streptococcus pyogenes* are not usually drug resistant.

Explain what is meant by the terms necrotizing and fasciitis. Does the disease really eat flesh? Answer available on Connect.

* *necrotizing fasciitis* (nee'-kroh-ty'-zing fass"-ee-eye'-tis) Gr. *nekrosis*, deadness, and L. *fascia*, the connective tissue sheath around muscles and other organs.

The phases of *Streptococcus pyogenes* induced necrotizing fasciitis.

their lifetime. The organism multiplies in the tonsils or pharyngeal mucous membranes, causing redness, edema, enlargement, and extreme tenderness, which make swallowing difficult and painful (**figure 18.12**). These symptoms can be accompanied by fever, headache, nausea, and abdominal pain. Other signs include a **purulent*** exudate over the tonsils; swollen lymph nodes; and occasionally, white, pus-filled abscesses on the tonsils.

Systemic Infections Streptococcal throat infection can lead to **scarlet fever** (scarlatina) when it involves a strain of *S. pyogenes*

carrying a prophage that codes for erythrogenic toxin. Systemic spread of this toxin results in high fever and a bright red, diffuse rash over the face, trunk, inner arms and legs, and even the tongue. Within 10 days the rash and fever usually disappear, often accompanied by sloughing of the epidermis. Many cases of pharyngitis and even scarlet fever are mild and uncomplicated, but on occasion they lead to severe sequelae. The dissemination of streptococci into the lymphatics and the blood can give rise to septicemia, an infrequent complication limited to people who are already weakened by underlying disease. Another relatively rare infection is *S. pyogenes* pneumonia, which accounts for less than 5% of bacterial pneumonias and is usually secondary to influenza or some other lung

* *purulent* (puh'-roo-lent) L. *purulentus*, inflammation. In reference to pus.

Figure 18.12 The appearance of the throat in pharyngitis and tonsillitis. The pharynx and tonsils become bright red and suppurative. The white areas are pus-containing nodules. In severe cases, where the tonsils meet, they are said to be “kissing.” © Scott Camazine/PhotoTake

infection. One of the most severe and invasive infections is *streptococcal toxic shock syndrome*. It is the result of a profound bacteremia and deep tissue infection and rapidly progresses to multiple organ failure. Even with treatment, around 30% of patients die.

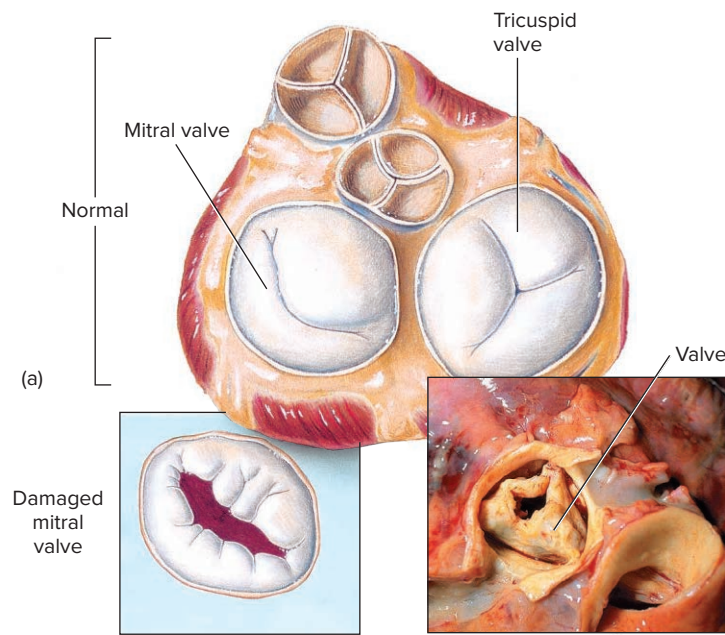

Long-Term Complications of Group A Infections

Even when an initial group A streptococcal infection appears to be resolved, occasional long-term sequelae can appear within a few weeks. The two most important ones are (1) **rheumatic* fever (RF)**, a delayed inflammatory condition of the joints, heart, and subcutaneous tissues; and (2) **acute glomerulonephritis (AGN)**, a disease of the kidney glomerulus and tubular epithelia. In both cases the body’s own immune system is responsible for the pathology of the condition. In RF, damage to cardiac tissue occurs as part of a type II hypersensitivity reaction. This reaction comes about when antibodies formed against the streptococcal cell wall and membranes cross-react with molecules in the host that resemble the bacterial antigens. In AGN, damage can be traced to a type III hypersensitivity, occurring when immune complexes deposited in the epithelia inflame and damage the filtering apparatus (see chapter 16).

Rheumatic Fever Rheumatic fever usually follows an overt or subclinical case of streptococcal pharyngitis in children. Its major clinical features are carditis, an abnormal electrocardiogram, painful arthritis, chorea, nodules under the skin, and fever.³ The course of the syndrome extends from 3 to 6 months, usually without lasting

* *rheumatic* (roo-mat’-ik) Gr. *rheuma*, flux. Involving inflammation of joints, muscles, and connective tissues.

3. Carditis is inflammation of heart tissues; chorea is a nervous disorder characterized by involuntary, jerky movements.

(b)

Figure 18.13 The cardiac complications of rheumatic fever. Pathologic processes of group A streptococcal infection can extend to the heart. In this example, it is believed that cross-reactions between host-produced antibodies to streptococci and heart proteins have a gradual destructive effect on the valves (especially the mitral valve). Scarring and deformation change the capacity of the valves to close and shunt the blood properly. (a) Normal valves, viewed from above. (b) Left inset depicts scar tissue on a damaged mitral valve; right inset is a photograph of the valve revealing the narrowing typical of rheumatic scarring. (b): Source: Dr. Edwin P. Ewing, Jr./CDC

damage. In patients with severe carditis, however, extensive damage to the heart valves and muscle can occur (**figure 18.13**). Although the degree of permanent damage does not usually reveal itself until middle age, it is often extensive enough to require the replacement of damaged valves. Heart disease due to RF is on the wane because of medical advances in diagnosing and treating streptococcal infections, but it is still responsible for thousands of deaths each year in the United States and many times that number in the rest of the world.

Acute Glomerulonephritis In AGN the kidney cells are so damaged that they cannot adequately filter blood. The first symptoms are nephritis (appearing as swelling in the hands and feet and low urine output); increased blood pressure; and, occasionally, heart failure. Urine samples are abnormal, with high levels of red and white blood cells and protein. Many cases of AGN clear up spontaneously, but some become chronic and lead to kidney failure.

Two antibodies can give long-term protection against group A infections. One is the type-specific antibody produced in response to the M-protein, though it will not prevent infections with a different strain (which explains why a person can have recurring cases of streptococcal pharyngitis). The other is a neutralizing antitoxin against the erythrogenic toxin that prevents the fever and rash of scarlet fever. Serological tests for antistreptococcal antibodies are used primarily to detect continuing or recent streptococcal infection and to judge a patient’s susceptibility to rheumatic fever and glomerulonephritis.

Pathogen Profile #2 *Streptococcus pyogenes*

Modified image reprinted with permission from Medscape Reference (<http://emedicine.medscape.com/>), 2013, available at: <http://emedicine.medscape.com/article/228936-overview>.

Microscopic Morphology Gram-positive cocci arranged in chains and pairs; very rarely motile; non-spore-forming.

Identified by Results of a catalase test are used to distinguish *Streptococcus* (negative) from *Staphylococcus* (positive). Beta-hemolysis and sensitivity to bacitracin are hallmarks of *S. pyogenes*. Rapid methods of identification use monoclonal antibodies to detect the C-carbohydrate found on the cell surface of *S. pyogenes*. Such tests provide accurate identification in as little as 10 minutes.

Habitat A fairly strict parasite, *S. pyogenes* is found in the throat, nasopharynx, and occasionally the skin of humans. From 5% to 15% of persons are asymptomatic carriers.

Virulence Factors *S. pyogenes* possesses several cell surface antigens that serve as virulence factors. C-carbohydrate helps prevent the bacterium from being dissolved by the lysozyme of the host; fimbriae on the outer surface of the cell enhance adherence of the bacterium; M-protein helps the cell resist phagocytosis while also improving adherence; and C5a protease catalyzes the cleavage of the C5a protein of the complement system, inhibiting the actions of complement. Most strains of *S. pyogenes* are covered with a capsule composed of hyaluronic acid

(HA) identical to the HA found in host cells, preventing an immune response by the host. Two different hemolysins, streptolysin O (SLO) and streptolysin S (SLS), cause damage to leukocytes, and liver and heart muscle, whereas erythrogenic toxin produces fever and the bright red rash characteristic of *S. pyogenes* disease. Invasion of the body is aided by several enzymes that digest fibrin clots (streptokinase), connective tissue (hyaluronidase), or DNA (streptodornase).

Primary Infections/Disease Local cutaneous infections include pyoderma (impetigo) or the more invasive erysipelas. Infection of the tonsils or pharyngeal mucous membranes can lead to streptococcal pharyngitis (strep throat), which, if left untreated, may lead to scarlet fever. Rarer infections include streptococcal toxic shock syndrome, *S. pyogenes* pneumonia, and necrotizing fasciitis. Long-term complications of *S. pyogenes* infections include rheumatic fever and acute glomerulonephritis.

Control and Treatment Control of *S. pyogenes* infection involves limiting contact between carriers of the bacterium and immunocompromised potential hosts. Patients should be isolated, and care must be taken when handling infectious secretions. As the bacterium shows little drug resistance, treatment is generally a simple course of penicillin.

The possibility of one of these serious or long-term complications is the reason that severe sore throats should be taken seriously. A simple throat swab can distinguish between group A streptococci and other causes so that antibiotics, if called for, can be administered immediately.

Group B: *Streptococcus agalactiae*

Several other species of beta-hemolytic *Streptococcus* in groups B, C, and D live among the normal microbiota of humans and other mammals and can be isolated in clinical specimens from diseased human tissue. The group B streptococci (GBS), represented by the species *S. agalactiae*, demonstrate clearly how the distribution of a pathogen can change in a relatively short time. The species has been associated with cattle, in which it is a frequent cause of bovine mastitis.⁴ It has also become a resident in the human vagina, pharynx, and large intestine. Since its colonization of humans, there has been a dramatic increase in serious infections in newborns and compromised people. The CDC estimates there are approximately 20,000 cases per year.

Streptococcus agalactiae is primarily implicated in neonatal meningitis, wound and skin infections, and endocarditis. Elderly people suffering from diabetes and vascular disease are particularly susceptible to wound infections. Because of its location in the vagina, GBS can be transferred to the infant during delivery, sometimes with dire consequences. An early-onset infection develops a few days after birth and is accompanied by sepsis, pneumonia, and high mortality.

This bacterial pathogen is the most prevalent cause of neonatal pneumonia, sepsis, and meningitis in the United States and Europe. Approximately 2,200 babies a year acquire infection in the United States alone. A later complication arises in 2 to 6 weeks, with symptoms of meningitis—fever, vomiting, and seizures. About 20% of children have long-term neurological damage. Because most cases occur in the hospital, personnel must be aware of the risk of passively transmitting this pathogen, especially in the neonatal and surgical units. Pregnant women should be screened for colonization in the third trimester and immunized with globulin and treated with a course of antibiotics if infection is found.

Group D Enterococci and Groups C and G Streptococci

Enterococcus faecalis, *E. faecium*, and *E. durans* are collectively referred to as “enterococci” because they are normal colonists of the human large intestine. Two other members of group D, *Streptococcus bovis* and *S. equinus*, are nonenterococci that colonize other animals and occasionally humans. Infections caused by *E. faecalis* arise most often in elderly patients undergoing surgery and affect the urinary tract, wounds, blood, the endocardium, the appendix, and other intestinal structures. Enterococci are emerging as serious opportunists in the health care setting, primarily because of the rising incidence of multidrug-resistant strains, especially vancomycin-resistant enterococci (VRE).

Groups C and G are common microbiota of domestic animals but are frequently isolated from the human upper respiratory tract.

4. Inflammation of the mammary glands.

Figure 18.14 A rapid, direct test kit for diagnosis of group A infections. With this method, a patient's throat swab is mixed with a drop of latex beads and monoclonal antibodies. (left, right): © Diagnostic Products Corporation/Siemens Healthcare

Occasionally they imitate group A strep in causing pharyngitis and glomerulonephritis. More often they cause bacteremia and disseminated deep-seated infections in severely compromised patients.

Laboratory Identification Techniques

As mentioned previously, the failure to recognize group A streptococcal infections (even very mild ones) can have devastating effects. Rapid cultivation and diagnostic techniques that will ensure proper treatment and prevention measures are essential. Several companies have developed rapid diagnostic test kits to be used in clinics or offices to detect group A streptococci from pharyngeal swab samples. These tests, based on monoclonal antibodies that react with the C-carbohydrates of group A, are highly specific and sensitive (**figure 18.14**).

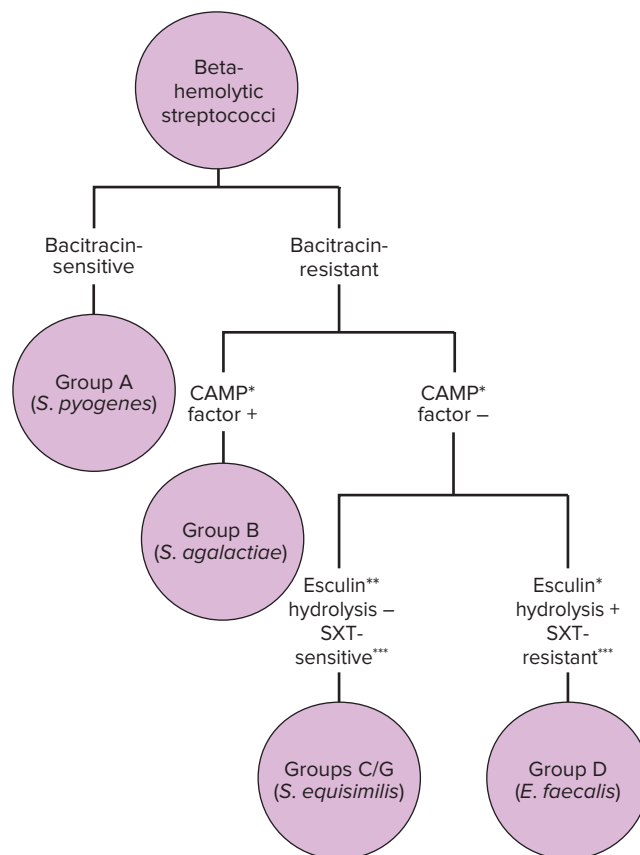

Today's large clinical labs rarely use traditional microbiological techniques to identify streptococcal species. Instead, monoclonal antibodies supplied in commercially available test kits can be enriched and then used to rapidly identify most samples. The speed and accuracy of these tests can rarely be matched by methods that depend on culturing samples. In some cases, however—including small or isolated labs, and equivocal results when using serological tests—cultural techniques are still relied upon, and in fact they remain the gold standard for identification of any isolate. **Table 18.4** summarizes the characteristics that are used to separate the various beta-hemolytic streptococci, and **figure 18.15** illustrates some of these tests (see also figure 18.14).

Treatment and Prevention of Group A, B, and D Streptococcal Infections

Antimicrobial therapy is aimed at curing infection and preventing complications. Most strains of *S. pyogenes* continue to be very sensitive to penicillin or one of its derivatives, although more penicillin resistant strains are being encountered. In cases of pharyngitis, small children usually receive an intramuscular injection of 600,000 units of benzathine penicillin to achieve the necessary circulating levels for a period of 10 days; older children receive 900,000 units, and adults receive 1.2 million units. An alternative therapy often used for impetigo is oral cephalexin or dicloxacillin.

The only certain way to arrest rheumatic fever or acute glomerulonephritis is to treat the preceding infection, because once these two pathologic states have developed, there are no specific treatments.

TABLE 18.4 Scheme for Differentiating Beta-Hemolytic Streptococci

*Name is derived from the first letters of the names of its discoverers. CAMP is a diffusible substance of group B, which lyses sheep red blood cells in the presence of staphylococcal hemolysin.

**A sugar that can be split into glucose and esculentin. Group D streptococci can accomplish this in the presence of 40% bile.

***Sulfamethoxazole and trimethoprim. The test is performed (like bacitracin) with discs containing this combination drug.

Some physicians recommend that people with a history of rheumatic fever or recurring streptococcal pharyngitis receive continuous, long-term penicillin prophylaxis. Mass prophylaxis has also been indicated for young people exposed to epidemics in boarding schools, military camps, and other institutions and for known carriers. Tonsillectomy (removal of the tonsils) has been used extensively in the past but with questionable effectiveness, because these bacteria can infect other parts of the throat. In hospitals, carriers of *S. pyogenes* should not be allowed to work with surgical, obstetric, or immunocompromised patients. Patients with group A infections must be isolated, and high-level precautions must be practiced in handling infectious secretions.

The antibiotic treatment of choice for group B streptococcal infection is penicillin G; alternatives are vancomycin and gentamicin. Some physicians advocate routine penicillin prophylaxis in colonized mothers and infants, but others fear that this practice can increase the rate of allergies and infections by resistant strains. Artificial passive immunization with human immunoglobulins is currently being considered for treatment and prevention in mothers and infants at high

Figure 18.15 Test for characterizing other β -hemolytic streptococci. In the CAMP test, a special strain of β -hemolytic *Staphylococcus aureus* that reacts synergistically with group B streptococcus (GBS) is streaked between two smears of the sample. If the isolate is GBS, increased areas of hemolysis (resembling an arrowhead) appear where the smears meet. (Note that group B streptococci are also negative for bacitracin and SXT tests.) Courtesy of Dr. David Schlaes

risk. A Group B streptococcal vaccine to protect women from colonization has shown promising results in clinical trials.

Treating enterococcal infection usually requires combined therapy with penicillin and an aminoglycoside (gentamicin) to take advantage of the synergism of these drugs and to overcome antimicrobial resistance.

Alpha-Hemolytic Streptococci: The Viridans Group

The **viridans*** category includes streptococci of human origin not entirely groupable by Lancefield serology. They are the most numerous and widespread residents of the oral cavity (gingiva, cheeks, tongue, saliva) and are also found in the nasopharynx, genital tract, and skin. These species can cause serious systemic infections, although most of them are opportunists and lack a full set of toxins and enzymes common in more virulent streptococci. The one characteristic shared by major species (*Streptococcus mitis*, *S. mutans*, *S. anginosus*, *S. salivarius*, *S. sanguinis*) is alpha-hemolysis. Other characteristics used to distinguish them are beyond the scope of this textbook.

Because viridans streptococci are not highly invasive, their entrance into tissues usually occurs through dental or surgical instrumentation and manipulation. These organisms are constant inhabitants of the gums and teeth, and even chewing hard candy or brushing the teeth can provide a portal of entry for them. Dental procedures can lead to bacteremia, meningitis, abdominal infection, and tooth abscesses. But the most important complication of all viridans streptococcal infections is **subacute endocarditis**. In this condition, blood-borne bacteria settle on areas of the heart lining or valves that have previously been injured by rheumatic fever, valve surgery, or the like. Colonization of these surfaces leads to a

Figure 18.16 Effects of streptococcal colonization. Bacterial vegetations can be seen along the upper edge of a surgically opened mitral valve. The vegetations (whitish patches) constantly release bacteria into the circulation. Image reprinted with permission from Allen Patrick Burke, MD, University of Maryland School of Medicine, published by Medscape Reference (<http://emedicine.medscape.com/>), 2013, available at: <http://emedicine.medscape.com/article/1954887-overview>.

thick biofilm called a *vegetation* (**figure 18.16**). As the disease progresses, vegetations increase in size, occasionally releasing masses of bacteria into the circulation. These masses, or emboli, can travel to the lungs and brain, blocking circulation and damaging those organs. Because of its gradual and somewhat concealed course, endocarditis is considered subacute rather than acute or chronic. Symptoms and signs range from fever and heart murmur to weight loss and anemia.

Endocarditis is diagnosed almost exclusively by blood culture, and repeated blood samples positive for bacteremia are highly suggestive of it. The goal in treatment is to completely destroy the microbes in the vegetations, which usually can be accomplished by long-term therapy with penicillin G. Because persons with preexisting heart conditions are at high risk for this disease, they sometimes receive prophylactic antibiotics prior to dental and surgical procedures.

Another very common dental disease involving viridans streptococci is dental caries. In the presence of sugar, *S. oralis* and *S. gordonii* (the *S. mutans* group) produce slime layers made of glucose polymers that adhere tightly to tooth surfaces. These sticky polysaccharides are the basis for plaque, the adhesive white material on teeth that becomes coinfecting with other bacteria and fosters dental disease.

Streptococcus pneumoniae: The Pneumococcus

High on the list of significant human pathogens is *Streptococcus pneumoniae*, a unique species that was formerly called *Diplococcus* until its genetic similarity to the streptococci was demonstrated. *S. pneumoniae* is also referred to as the **pneumococcus**. This bacterium is involved in the majority of **bacterial pneumonias**, which primarily affect immunocompromised patients. It also is a major cause of **meningitis** and **otitis media** in young children. Gram stains of sputum specimens from pneumonia patients reveal small, lancet-shaped cells arranged in pairs and short chains (see Pathogen Profile #3). Because it is fastidious, *S. pneumoniae* must be cultured on blood agar, on which it produces smooth or mucoid colonies and alpha-hemolysis (see figure 18.9b). Growth is improved by the presence of 5% to 10% CO₂, and cultures die in the presence of oxygen because they lack catalase and peroxidases.

All pathogenic strains form rather large capsules, this being their major virulence factor. These colonies appear smooth on solid media. Rough strains lack a capsule and are nonvirulent. Capsules

* *viridans* (vih'-rih-denz) L. *viridis*, green. This term comes from the green color that develops around colonies that produce alpha-hemolysis.

help the streptococci escape phagocytosis, which is the major host defense in pyogenic infections. They contain a polysaccharide antigen called the specific soluble substance (SSS) that varies chemically among the pneumococcal types and stimulates antibodies of varying specificity. So far, 90 different capsular types (specified by numerals 1, 2, 3, . . .) have been identified.

Epidemiology and Pathology of the Pneumococcus

From 5% to 50% of all people carry *S. pneumoniae* as part of the normal microbiota in the nasopharynx. Although infection is often acquired endogenously from one's own microbiota, it occasionally occurs after direct contact with respiratory secretions or droplets from carriers. *Streptococcus pneumoniae* is very delicate and does not survive long out of its habitat. Factors that predispose patients to pneumonia are old age, the season (rate of infection is highest in the winter), other lung diseases or viral infections that weaken defenses, and living in close proximity to infected people.

The Pathology of *Streptococcus pneumoniae* Healthy people commonly inhale microorganisms into the respiratory tract without serious consequences because of the host defenses present there. Pneumonia is likely to occur when mucus containing a load of bacterial cells is aspirated from the pharynx into the lungs of susceptible individuals who have lowered defenses. Passing into the bronchioles and alveoli, the pneumococci multiply and induce an overwhelming inflammatory response. This is marked by exudation of fluids into the lungs. In a form of pneumococcal pneumonia termed **lobar pneumonia**, this fluid accumulates in the alveoli along with red and white blood cells. As the infection and inflammation spread rapidly through the lung, the patient can actually “drown” in his own secretions. If this mixture of exudate, cells, and bacteria solidifies in the air spaces, a

Figure 18.17 The course of bacterial pneumonia. As the pneumococcus traces a pathway down the respiratory tree, it provokes intense inflammation and exudate formation. The blocking of the bronchioles and alveoli by consolidation of inflammatory cells and products is shown.

Figure 18.18 Cutaway view of ear anatomy indicating the route of infection and its primary targets. The direct connection between the pharynx and middle ear via the eustachian tube makes this possible.

condition known as **consolidation*** occurs (**figure 18.17**). In infants and the elderly, the areas of infection are usually spottier and centered more in the bronchi than in the alveoli (bronchial pneumonia).

Symptoms of pneumococcal pneumonia are chills, shaking, rapid breathing, and fever. The patient can experience severe pain in the chest wall, cyanosis (due to compromised oxygen intake), a cough that produces rusty-colored (bloody) sputum, and abnormal breathing sounds. Systemic complications of pneumonia are pleuritis and endocarditis, but pneumococcal bacteremia and meningitis are the greatest danger to the patient.

It is common for this agent to gain access to the chamber of the middle ear by way of the eustachian tube and cause a middle ear infection called **otitis media** (**figure 18.18**). This occurs readily in children under 2 years of age because of their relatively short eustachian tubes. Otitis media is the third most common childhood disease in the United States, and the pneumococcus accounts for the majority of cases. The severe inflammation in the small space of the middle ear induces acutely painful earaches and sometimes even temporary deafness (**figure 18.19**).

Pathogen Profile #3 *Streptococcus pneumoniae* (pneumococcus)

Source: Dr. Mike Miller/
CDC

Microscopic Morphology Gram-positive, lancet (arrowhead) shaped cells arranged in pairs and short chains.

Identified by Gram stain is often enough to provide presumptive identification. Alpha-hemolysis distinguishes pneumococcus from beta-hemolytic streptococci, and its sensitivity to optochin distinguishes it from group D and viridans streptococci. Identification can be confirmed by testing for bile solubility and fermentation of inulin (pneumococcus

produces a positive reaction in both cases). A serological test called the Quellung reaction uses antibodies to detect the bacterial capsule and provides a rapid, definitive test for the organism.

Habitat Between 5% and 10% of adults and 20% to 40% of children carry *S. pneumoniae* as part of their nasopharyngeal microbiota. Because the organism is quite delicate, it rarely survives outside the host.

Virulence Factors The major virulence factor is a thick capsule which helps streptococcus escape phagocytosis. Nonencapsulated strains are avirulent. Over 90 different capsular serotypes exist.

Primary Infections/Disease *Streptococcus pneumoniae* is the most common cause of community-acquired pneumonia, particularly

among the elderly and those suffering from weakened host defenses (asthma, viral lung diseases, or smoking). Pneumococcus is a major causative agent of meningitis in all age groups and is the leading cause of adult meningitis. The bacterium can also travel to the middle ear—primarily in young children with short eustachian tubes—leading to otitis media, where swelling of the middle ear leads to painful earaches.

Control and Treatment *S. pneumoniae* can be prevented in most cases through vaccination. Pneumovax contains capsular antigens from 23 of the most commonly encountered serotypes and is recommended for adults over 65 and those from 19 to 65 with underlying health issues. Prevnar 13 provides protection against 13 different serotypes and a four-dose series of the vaccine is recommended for children between 2 and 59 months of age and adults older than 65 years. Treatment of pneumococcal infection relies on penicillin in the 85% of cases where the organism is susceptible. In cases where penicillin is ineffective, or contraindicated, cephalosporins, sulfonamides, quinolones, or telithromycin are commonly used.

In young children, *S. pneumoniae* is a common agent of upper respiratory tract infections that can spread to the meninges and cause meningitis. The pneumococcus accounts for 10% to 50% of reported cases of meningitis depending on the age group. It is currently the most common cause of this disease in adults.

Healthy people have high natural resistance to the pneumococcus. The effects of mucus and ciliary responses of the respiratory tract help capture and flush out transient organisms. Respiratory phagocytes are also essential in the eradication process, but this system works only if the capsule is coated by opsonins in the presence of complement. After recovery, the individual will be immune to future infections by that particular pneumococcal type. This immunity is the basis for a successful vaccine (see subsequent section on prevention).

Laboratory Cultivation and Diagnosis A specimen is usually necessary before diagnosing pneumococcal infections because a number of other microbes can cause pneumonia, sepsis, and meningitis. Blood cultures, sputum, pleural fluid, and spinal fluid are common specimens. A Gram stained specimen is very instructive (see Pathogen Profile #3), and presumptive identification can often be made by this method alone. Also highly definitive is the Quellung reaction, a serological test in which sputum is mixed with anticapsular antisera and observed microscopically. Precipitation of antibodies on the surface of the capsule gives the appearance of swelling. Alpha-hemolysis helps differentiate the pneumococcus from the beta-hemolytic streptococci. Diagnosis can then be confirmed by testing for the agent's sensitivity to optochin, a positive bile solubility, and positive inulin fermentation tests.

Treatment and Prevention of Pneumococcal Infections The treatment of choice for pneumococcal infections has traditionally been a large daily dose of penicillin G or penicillin V. In recent times, however, clinics have reported increased cases of drug-resistant strains. In fact, an average of 15% of isolates, termed DRSP, have shown multidrug resistance. Drug sensitivity testing is therefore essential. Alternative drugs are cephalosporins, sulfonamides, quinolones, and telithromycin. The Centers for Disease Control and Prevention recommends daily drug prophylaxis to protect children with sickle-cell anemia against recurrent pneumococcal infections. Untreated cases in these children have a mortality rate up to 30%.

Along with more widespread antibiotic resistance, the need to prevent recurrences has shifted the focus of treatment toward the development of active immunity. Fortunately, *S. pneumoniae* is one of the few streptococcal species for which an effective vaccination exists. There are two vaccines. An older vaccine (Pneumovax) consists of capsular antigens from 23 of the most frequently encountered serotypes. It is indicated for older adults and patients at particularly high risk, including those with sickle-cell anemia, lack of a spleen, congestive heart failure, lung disease, diabetes, and kidney disease. This vaccine is effective for about 5 years in 60% to 70% of those vaccinated. Immunization with a pneumococcal **conjugate*** vaccine (Prevnar 13) is recommended for all children younger than five years and adults older than 65 years as an effective preventative therapy for otitis media and meningitis.

* *conjugate* vaccines consist of the capsule polysaccharide complexed to a protein carrier to make it more immunogenic in young children.

Check Your Progress SECTION 18.2

- List the clinically significant pathogens in the genus *Streptococcus*, and summarize the virulence factors seen in the group.
- Describe the immediate effects and long-term complications of *S. pyogenes* infection.
- List the drugs commonly used to treat streptococcal infection, and explain why combined drug therapy is sometimes required.
- Differentiate between pneumococcal disease typically seen in the very young and that seen in the elderly.

18.3 The Family Neisseriaceae: Gram-Negative Cocci

Expected Learning Outcomes

- Name the most important human pathogens in the genus *Neisseria*, along with the body systems affected by each.
- Compare the differences in pathologies of *N. gonorrhoeae* infection in men, women, and children.
- Summarize the pathogenesis and epidemiology of *N. meningitidis*.
- Recall the medically important genera, besides *Neisseria*, that contain gram-negative cocci and coccobacilli.

Members of the Family Neisseriaceae are residents of the mucous membranes of warm-blooded animals. Most species are relatively innocuous commensals, but two are primary human pathogens with far-reaching medical impact. The genera contained in this group are *Neisseria*, *Branhamella*, and *Moraxella*. Of these, *Neisseria* has the greatest clinical significance.

One distinguishing feature of the *Neisseriae** is their cellular morphology. Rather than being perfectly spherical, the cells are bean-shaped and paired, with their flat sides touching (**figure 18.20**). None develops flagella or spores, but capsules can be found on the pathogens. The cells are gram-negative, possessing an outer membrane with lipopolysaccharides in the cell wall and, in many cases, fimbriae.

* *Neisseriae* (ny-serr'-ee-uh) After the German physician Albert Neisser who first observed the agent of gonorrhea in 1879.

Figure 18.20
Transmission electron micrograph of *Neisseria* (52,000 \times). This cross section shows how the cocci are flattened on their adjacent sides. Note the fine fimbriae that arise from their surfaces. © Charles C. Brinton, Jr., John A. Tainer, Michael E. Piques and Lisa Craig

Most *Neisseria* are strict parasites that do not survive long outside the host, particularly where hostile conditions of drying, cold, acidity, or light prevail. *Neisseria* species are aerobic or microaerophilic and have an oxidative form of metabolism. They produce catalase, enzymes for fermenting various carbohydrates, and the enzyme cytochrome oxidase that can be used in identification. The pathogenic species, *N. gonorrhoeae* and *N. meningitidis*, require complex enriched media and grow best in an atmosphere containing additional CO₂. We shall concentrate on other features of the pathogenic *Neisseria* in the following sections.

Neisseria gonorrhoeae: The Gonococcus

Gonorrhea* has been known as a sexually transmitted disease since ancient times. Its name originated with the Greek physician Claudius Galen, who thought that it was caused by an excess flow of semen. For a fairly long period in history, gonorrhea was confused with syphilis. Later, microbiologists went on to cultivate *N. gonorrhoeae*, also known as the **gonococcus**, and to prove conclusively that it alone was the etiologic agent of gonorrhea.

Factors Contributing to Gonococcal Pathogenicity

The virulence of the gonococcus is due chiefly to the presence of fimbriae and other surface molecules that promote mutual attachment of cocci to each other and invasion and infection of epithelial tissue. In addition to their role in adherence, the fimbriae also seem to slow phagocytosis by macrophages and neutrophils. Another contributing factor in pathogenicity is a protease that cleaves the secretory antibody (IgA) on mucosal surfaces and stops its protective effects.

Epidemiology and Pathology of Gonorrhea

Gonorrhea is a strictly human infection that occurs worldwide and ranks among the top five sexually transmitted diseases (STDs). Although 300,000 cases are reported in the United States each year, it is estimated that the actual incidence is much higher—in the millions if one counts asymptomatic infections. Most cases occur in young adults (18–24 years old) with multiple sex partners. Figures on the prevalence of sexually transmitted diseases, including gonorrhea, syphilis, and chlamydia often show a fluctuating pattern corresponding to periods of societal turmoil or changing sexual attitudes. The two large increases in the prevalence of gonorrhea since 1940 (**figure 18.21**) provide an interesting historical perspective. The first occurs during World War II, when casual sexual encounters involving servicemen spiked. The second took place during the sexual revolution of the 1960s, when reliance on oral contraceptives rather than condoms to prevent pregnancy led to an epidemic in gonorrhea cases. The relationship of gonorrhea with infertility, especially in women, is discussed in **18.3 Making Connections**.

Experiments done with male volunteers revealed that an infectious dose can range from 100 to 1,000 colony-forming units. *Neisseria gonorrhoeae* does not survive more than 1 or 2 hours on fomites and is most infectious when transferred through direct contact. Except for neonatal infections, the gonococcus is acquired when the pathogen is introduced into a genital or extragenital

* *gonorrhea* (gä-n-'re-) Gr. *gonos*, seed, and *rhein*, to flow.

Figure 18.21 The rate of sexually transmitted disease is related to societal changes. (a) The rate of gonorrhea infection shows sharp increases during World War II and during the sexual revolution of the 1960s. (b) A government poster from the 1940s meant to warn soldiers of the risk of contracting a sexually transmitted disease. (b): Source: U.S. National Library of Medicine

(rectum, eye, or throat) portal of entry. After attaching to the epithelial surface by fimbriae, the bacteria invade the underlying connective tissue. In 2 to 6 days, this process results in an inflammatory reaction that may or may not produce noticeable symptoms. The infection is asymptomatic in approximately 10% of males and 50% of females. It is this phenomenon that is most important in the

persistence and spread of the pathogen. The following sections survey the several manifestations of gonorrhea.

Genital Gonorrhea in the Male Infection of the urethra causes urethritis, with painful urination and a purulent discharge in most cases (**figure 18.22b**). Infection tends to be limited to the distal urogenital tract, but it can occasionally spread from the urethra to the prostate gland and epididymis (**figure 18.22a**). Scar tissue formed in the spermatic ducts during healing of an invasive infection can render the individual infertile. This outcome is becoming increasingly rare with improved diagnosis and treatment regimens.

Figure 18.22 Gonorrheal damage to the male reproductive tract. (a) Frontal view of the male reproductive tract. (Left side) The normal, uninfected state. The sperm-carrying ducts are continuous from the testis to the urethral opening. (Right side) The route of ascending gonorrhea complications. Infection begins at the tip of the urethra, ascends the urethra through the penis, and passes into the vas deferens. Occasionally, it can even enter the epididymides and testes. (Inset) Damage to the ducts carrying sperm can create scar tissue and blockage, which reduce sperm passage and can lead to sterility. (b) A milky or yellow discharge from the urethra is a common sign of gonorrheal infection. (b): Source: Renelle Woodfall/CDC

18.3 MAKING CONNECTIONS

Pelvic Inflammatory Disease and Infertility

The National Center for Health Statistics estimates that more than 6 million women in the United States have impaired fertility. There are many different reasons for infertility, but the leading cause is pelvic inflammatory disease, or PID. PID is caused by infection of the upper reproductive structures in women, namely the uterus, fallopian tubes, and ovaries. These organs lack normal microbiota. When bacteria from the vagina are spread higher in the tract, they initiate an infection that may or may not be noticeable to the patient. Inflammation caused by the infection can be acute, resulting in pain, abnormal vaginal discharge, fever, and nausea, or it can be chronic, with less noticeable symptoms. In acute cases, women usually seek care; in some ways these can be considered the lucky ones. If the inflammation is curbed at an early stage by using antibiotics to kill the bacteria, chances are better that the long-term sequelae of PID can be avoided.

The most notable long-term consequence is tubal infertility. Inflammatory repair processes, especially in the fallopian tubes, can lead to the deposition of scar tissue that narrows the lumen in the tubes, in some cases closing them off completely. If the lumen is only narrowed, fertilization could still occur, but a fertilized egg would be unable to travel through the tube and implant in the uterine wall. In some cases fertilized eggs implant in the tube walls or even leave the fallopian tubes and

implant elsewhere in the abdominal cavity. Both of these situations are known as ectopic pregnancies. Women with a history of PID have a 7 to 10 times greater chance of experiencing an ectopic pregnancy than other women. Ectopic pregnancy is a life-threatening situation. An embryo growing in the tube usually causes the tube to rupture in about 12 weeks, and an embryo in the abdominal cavity can cause the same complication as a tumor. Surgical intervention is usually required in either case to save the woman's life.

Chlamydia infection is the leading cause of PID, followed closely by *N. gonorrhoeae* infection. But other bacteria, perhaps also including normal microbiota of the reproductive tract, can also cause PID if they are traumatically introduced into the uterus. Intercourse, tampon usage, the use of an intrauterine contraceptive device, and even douching can encourage the transmission of bacteria into the upper genital tract. Women who suspect for any reason that they may have a reproductive tract infection should always seek diagnosis and treatment as early as possible.

Describe the possible events leading to invasion of infectious agents into the sterile tissues of the reproductive tract. Answer available on Connect

Genitourinary Gonorrhoea in the Female The proximity of the genital and urinary tract openings increases the likelihood that both systems can be infected during sexual intercourse. A mucopurulent or bloody vaginal discharge occurs in about half the cases, along

with painful urination if the urethra is affected. Major complications occur when the infection ascends from the vagina and cervix to higher reproductive structures such as the uterus and fallopian tubes (**figure 18.23**). One disease resulting from this progression is

Figure 18.23 Ascending gonorrhoea in women. (Left) Normal state. (Right) In ascending gonorrhoea, the gonococcus is carried from the cervical opening up through the uterus and into the fallopian tubes. On rare occasions, it can escape into the peritoneum and invade the ovaries, or cause peritonitis. Pelvic inflammatory disease (PID) is a serious complication that can lead to scarring in the fallopian tubes, ectopic pregnancies, and mixed anaerobic infections.

salpingitis,* also known as **pelvic inflammatory disease (PID)**, a condition characterized by fever, abdominal pain, and tenderness. It is not unusual for the microbe to become involved in mixed infections with anaerobic bacteria. The buildup of scar tissue from these infections can block the fallopian tubes, causing sterility and ectopic pregnancies. (Note: PID can also be caused by *Chlamydia* bacteria and, less frequently, by nonsexually transmitted bacteria; see 18.3 Making Connections.)

Extragenital Gonococcal Infections in Adults Extragenital transmission and carriage of the gonococcus can occur under some circumstances. Anal intercourse can lead to proctitis, and oral sex can result in pharyngitis and gingivitis. Careless personal hygiene can account for self-inoculation of the eyes and a serious form of conjunctivitis. In a small number of cases, the gonococcus enters the bloodstream and is disseminated to the joints and skin. Involvement of the wrist and ankle can lead to chronic arthritis and a painful, sporadic, papular rash on the limbs. Rare complications of gonococcal bacteremia are meningitis and endocarditis.

Gonococcal Infections in Children Infants born to gonococcus carriers are in danger of being infected as they pass through the birth canal. Because of the potential harm to the fetus, physicians usually screen pregnant mothers for its presence. Gonococcal eye infections are very serious and often manifest sequelae such as keratitis, ophthalmia neonatorum, and even blindness (figure 18.24). A universal precaution to prevent those complications is the instillation of antibiotics, silver nitrate, or other antiseptics into the conjunctival sac of newborn babies. The pathogen may also infect the pharynx and respiratory tract of neonates. Finding gonorrhea in children other than babies is strong evidence of sexual abuse by infected adults, and it mandates child welfare consultation along with thorough bacteriologic analysis.

Clinical Diagnosis and Control of Gonococcal Infections

Diagnosing gonorrhea is relatively straightforward. The presence of gram-negative diplococci in neutrophils from urethral, vaginal, cervical,

* *salpingitis* (sal'-pin-jy'-tis) Gr. *salpinx*, tube, and *itis*, inflammation. An inflammation of the fallopian tubes.

Figure 18.24 Gonococcal ophthalmia neonatorum in an infant infected during birth. The infection is marked by intense inflammation and edema; if allowed to progress, it causes damage that can lead to blindness. Fortunately, this infection is completely preventable and treatable. Source: CDC

Figure 18.25 Gram stain of urethral pus from a patient with gonorrhea (1,000x). Note the intracellular (phagocytosed) gram-negative diplococci in polymorphonuclear leukocytes (neutrophils). Source: Bill Schwartz/CDC

or eye exudates is especially diagnostic because gonococci tend to be engulfed and remain viable within phagocytes (figure 18.25). Thus, a simple Gram stain can provide at least presumptive evidence of gonorrhea. Other tests used to identify *Neisseria gonorrhoeae* and differentiate it from related species are discussed in a later section.

Approximately 350,000 new cases of gonorrhea are reported each year in the United States and *N. gonorrhoeae* has progressively developed resistance to each of the antimicrobials used for treatment of gonorrhea. Currently the only treatment recommended by the CDC is combination therapy with ceftriaxone and azithromycin. Beyond treating just the gonococcal infection, combination therapy also typically resolves concurrent STDs such as chlamydiosis, a common complication in many gonorrhea infections.

Although gonococcal infections stimulate local production of antibodies and activate the complement system, these responses do not produce lasting immunity, and some people experience recurrent infections.

Gonorrhea is a reportable infectious disease, which means that any physician diagnosing it must forward the information to a public health department. The follow-up to this finding involves tracing sexual partners to offer prophylactic antibiotic therapy. There is a pressing need to seek out and treat asymptomatic carriers and their sexual contacts, but complete control of this group is nearly impossible. Other control measures include education programs that emphasize the effects of all STDs and promote safer sexual practices such as the use of condoms.

Neisseria meningitidis: The Meningococcus

Another serious human pathogen is *Neisseria meningitidis*, a bacterium known commonly as the **meningococcus** and usually associated with epidemic **cerebrospinal meningitis**. Important factors in meningococcal invasiveness are a polysaccharide capsule, adhesive fimbriae, and IgA protease. Although 12 different strains of capsular antigens exist, serotypes A, B, and C are responsible for most cases of infection. Another virulence factor with potent pathologic effects is the lipopolysaccharide (**endotoxin**) released from the cell wall when the microbe lyses.

Pathogen Profile

#4 *Neisseria gonorrhoeae* (gonococcus)

Source: U.S. Centers for Disease Control and Prevention - Medical Illustrator/CDC

Microscopic Morphology Gram-negative, flattened cocci, arranged as diplococci; very rarely motile; non-spore-forming.

Identified by Visualization of gram-negative diplococci in neutrophils. Because gonococcus tends to remain alive after being engulfed by neutrophils, their appearance in urethral, vaginal, cervical, or eye exudates is presumptive evidence of infection. Biochemical and DNA testing can both be used to confirm identification.

Habitat A strictly human infection, *N. gonorrhoeae* is an obligate parasite and may be found in the mucosal cells of the genitourinary tract, eye, rectum, and throat.

Virulence Factors Fimbriae and other cell surface molecules serve as the primary virulence factor by promoting attachment of the cocci both to themselves and to the surface of mucosal cells. Gonococcus also produces a protease that cleaves IgA, preventing it from functioning.

Primary Infections/Disease Genital gonorrhea can lead to urethritis and painful urination in males while in females, infection can cause pelvic inflammatory disease and ectopic pregnancy. The buildup of scar tissue within the spermatic ducts of men or the fallopian tubes of women can cause sterility. Infants born to gonococcus carriers can be infected as they pass through the birth canal, often infecting the eyes and potentially causing blindness.

Control and Treatment Because of widespread resistance to a growing list of antimicrobials, the only recommended treatment for *N. gonorrhoeae* infection is dual therapy with ceftriaxone and azithromycin. A large proportion of gonorrhea infections are complicated by infection with another sexually transmitted disease (most commonly chlamydia), and multi-drug treatment has the added benefit of generally resolving these infections as well. Control of future infections depends on the emphasis of safe sexual practices such as the use of condoms.

Epidemiology and Pathogenesis of Meningococcal Disease

The diseases of *N. meningitidis* generally have a sporadic or epidemic incidence in late winter or early spring. The continuing reservoir of infection is humans who harbor the pathogen in the nasopharynx. Because this bacterium does not survive long in the environment, meningococci are usually acquired through close contact with secretions or droplets. The carriage state, which can last from a few days to several months, exists in 3% to 30% of the adult population and can exceed 50% in institutional settings. The scene is set for transmission when carriers live in close quarters with nonimmune individuals, as might be expected in college dormitories, day care facilities, and military barracks. The highest-risk groups are young children (6–36 months old) and older children and young adults (10–20 years old). *N. meningitidis* is the second most common cause of meningitis in adults, after *Streptococcus pneumoniae*.

Upon reaching its portal of entry in the nasopharynx, the meningococcus attaches there with fimbriae. In many people, this can result in simple asymptomatic colonization. In more vulnerable individuals, however, the meningococci are engulfed by epithelial cells of the mucosa and penetrate into the nearby blood vessels, along the way damaging the epithelium and causing pharyngitis. If the bacteria remain confined to the bloodstream, the result is **meningococcemia**, marked initially by cough, headache, and sore throat, and later by malaise, nausea, vomiting, and stiffness in the joints. The pathogen sheds endotoxin into the systemic circulation, stimulating certain classes of white blood cells to release cytokines. Damage to the blood vessels caused by a rush of cytokines triggers hemorrhage and coagulation, leading to vascular damage, and a lack of oxygen perfusion of the tissues, especially in the limbs.

Crops of lesions called **petechiae*** (figure 18.26) develop on the trunk and appendages in about half of the cases. In a small number of cases, meningococcemia progresses to shock, necrosis of tissues in extremities, and loss of limbs. Generalized intravascular clotting, cardiac failure, and death can occur within a few hours.

In other cases, instead of remaining within the blood vessels, the bacteria rapidly cross the blood-brain barrier, permeate the meninges, and multiply within the cerebrospinal fluid, resulting in **meningitis**. Symptoms of meningitis include fever, sore throat, headache, stiff neck, convulsions, vomiting, and photophobia (figure 18.27). These symptoms may be missing in infants and the elderly. The permanent effects of central nervous system infection are cognitive impairment, learning disabilities, and deafness in about 10% to 20% of patients.

* **petechiae** (pee-tee'-kee-ee) Small, nonraised, purple blotches caused by hemorrhage into the skin. Larger spots are called **echymoses** (ek'-ih-moh'-seez).

Figure 18.26 One clinical sign of meningococcemia. The release of endotoxins during meningococcemia may cause hemorrhage, coagulation, and vascular damage, leading to necrosis of tissue, especially in the extremities. This infant displays necrosis of both legs due to meningococcemia. Source: Mr. Gust/CDC

Pathogen Profile #5 *Neisseria meningitidis* (meningococcus)

© CNRI/Science Source

Microscopic Morphology Gram-negative, flattened cocci, found growing as diplococci. Very rarely motile, non-spore-forming.

Identified by Presence of gram-negative diplococci in blood, cerebrospinal fluid, or within the cytoplasm of neutrophils. A positive oxidase test, the ability to ferment maltose, and an

inability to ferment sucrose or lactose helps to distinguish *N. meningitidis* from normal microbiota of the oropharynx. Rapid identification methods rely on the detection of *N. meningitidis* DNA or antigens specific to the pathogen within the blood or cerebrospinal fluid.

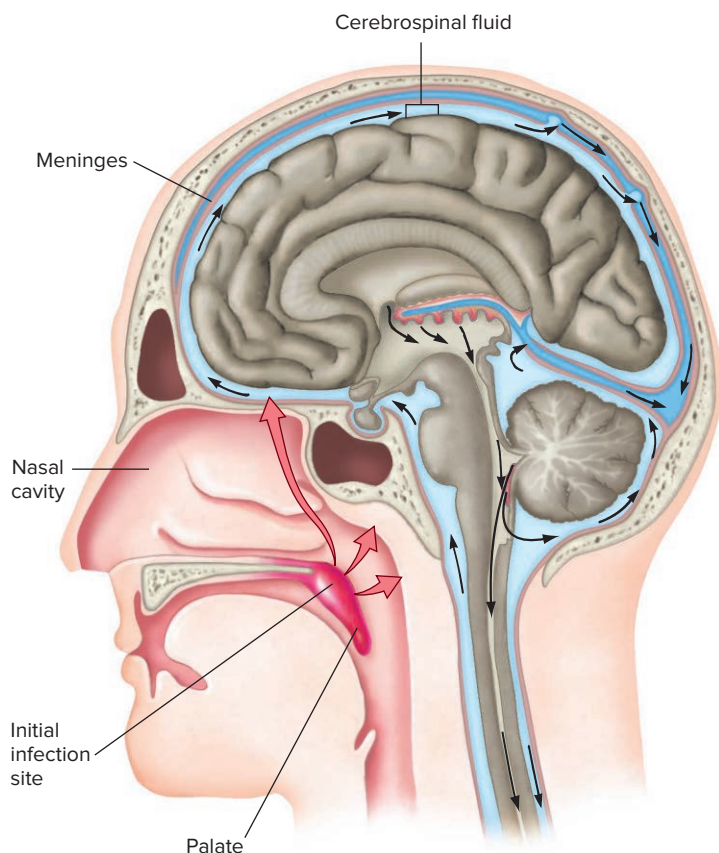

Habitat Humans are the sole reservoir for *Neisseria meningitidis*, with 3% to 30% of the adult population harboring the pathogen in their nasopharynx at any given time. When carriers live with nonimmune individuals in close quarters—college dormitories, military barracks, day care centers—transmission is common. The pathogen does not survive for long outside the body.

Virulence Factors Virulence factors of *N. meningitidis* include an antiphagocytic polysaccharide capsule and fimbriae that facilitate attachment of the bacterium to cells of the nasopharynx. The pathogen also releases large quantities of a potent endotoxin into the systemic circulation.

Primary Infections/Disease There are two overlapping conditions that together constitute meningococcal disease. Meningococemia is

marked by the appearance of petechiae or ecchymoses on the skin or mucous membrane. These lesions are the result of endotoxin-induced subcutaneous hemorrhage. Meningococemia may progress to include generalized intravascular clotting, tissue necrosis in the extremities, cardiac failure, and death. Meningitis refers to inflammation of the meninges—the membranes surrounding the brain and spinal cord—and most commonly affects young children between 6 and 36 months, older children, and young adults between 10 and 20 years old. Even when treated, meningitis has a mortality rate of up to 15%. The permanent effects of cerebrospinal meningitis include cognitive impairment and deafness in 10% to 20% of patients.

Control and Treatment Vaccination provides protection against *N. meningitidis* infection and is recommended for all persons between 11 and 18 years of age as well as those in high-risk populations, including students, military recruits, and people exposed during outbreaks. Available vaccines include: MCV4 (Menactra) for persons between 2 and 55 years of age, MPSV4 (Menomune) for those older than 55, and Tremenba specifically for ages 10–25.

Clinical Diagnosis of Meningococcal Disease

Suspicion of meningococcal infection constitutes a medical emergency, and differential diagnosis must be done with great haste and accuracy because complications can arise rapidly and with lethal consequences. Cerebrospinal fluid and blood samples are stained and observed directly for the typical gram-negative diplococci. Cultivation may be necessary to differentiate the bacterium from other species (see subsequent section on laboratory diagnosis). Specific rapid tests are also available for detecting the capsular polysaccharide or the cells directly from specimens without culturing.

Immunity, Treatment, and Prevention of Meningococcal Infection

The infection rate in most populations is rather low, indicating that most people have a natural immunity to the meningococcus. This probably develops during the early years of life as one is exposed to the meningococcus and its close relatives. Resistance is due to the production of antibodies against the capsular polysaccharides in groups A and C and against membrane antigens in group B.

Figure 18.27 Dissemination of the meningococcus from a nasopharyngeal infection. Bacteria spread to the roof of the nasal cavity, which borders a highly vascular area at the base of the brain. From this location, they can enter the blood and escape into the cerebrospinal fluid. Infection of the meninges leads to meningitis and an inflammatory purulent exudate over the brain surface.

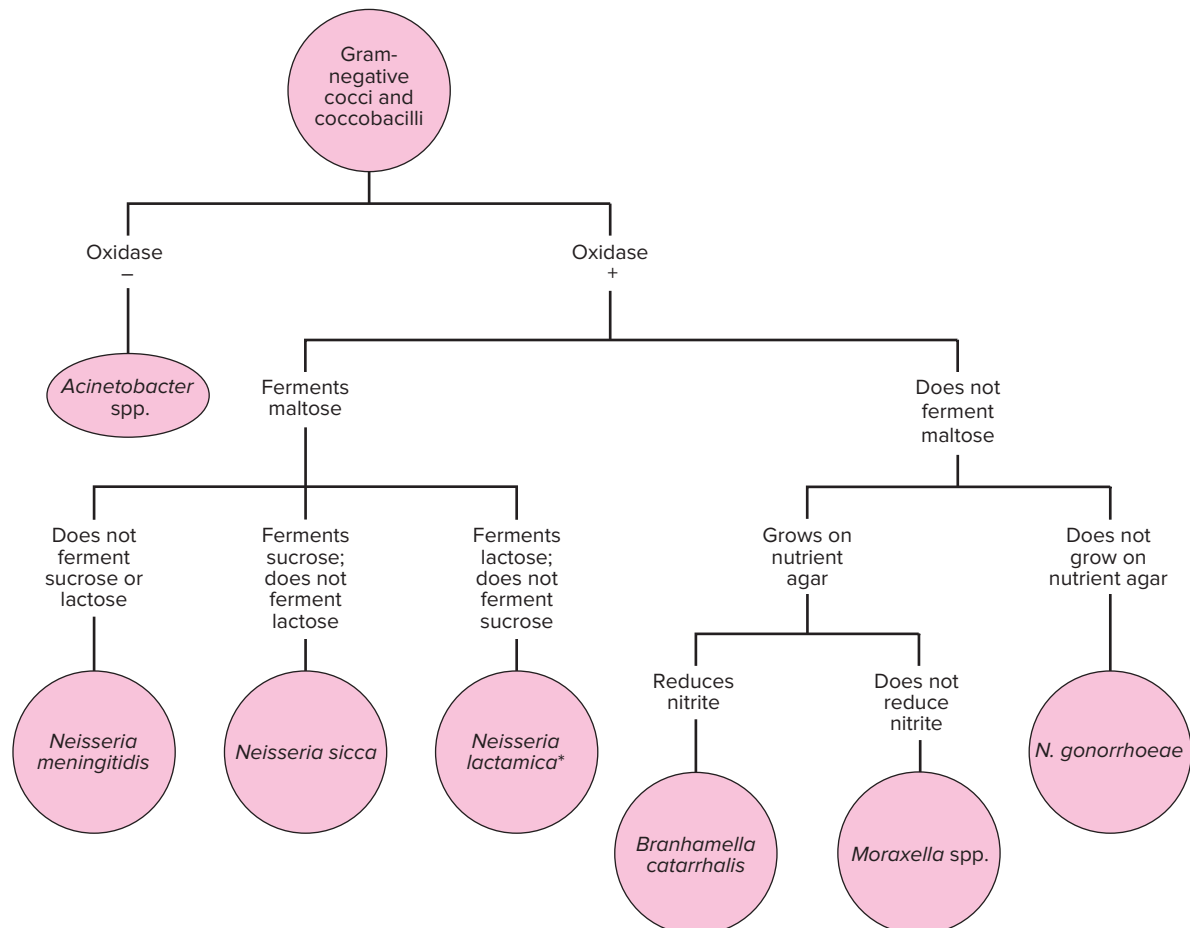

Because even treated meningococcal disease has a mortality rate of up to 15%, it is vital that therapy begin as soon as possible with one or more drugs. It can even be given while tests for the causative agent are under way. The treatment of choice for meningococcal meningitis is a third-generation cephalosporin such as ceftriaxone that is broad spectrum and crosses the blood-brain barrier. Patients may also require treatment for shock and intravascular clotting.

When family members, medical personnel, or children in day care have come in close contact with infected people, preventive therapy with rifampin or ceftriaxone may be warranted. Vaccination is recommended for all persons between 11 and 18 years as well as those in high-risk populations, including students, military recruits, and people exposed during outbreaks. Vaccines that are currently available include: MCV4 (Menactra), a meningococcal conjugate vaccine recommended for persons between 2 and 55 years of age; MPSV4 (Menomune), recommended for those older than 5; and two recombinant DNA vaccines (Trumenba and Bexsero), specific for serotype B and recommended for children and young adults between the ages of 10 and 25.

Differentiating Pathogenic from Nonpathogenic *Neisseria*

It is usually necessary to differentiate true pathogens from normal *Neisseria* species that also live in the human body and can be present in infectious fluids. Immediately after collection, specimens are streaked on modified Thayer-Martin (MTM) medium or chocolate agar and incubated in a high CO₂ atmosphere. Presumptive identification of the genus is obtained by a Gram stain and oxidase testing on isolated colonies. Further testing may be necessary to differentiate the two pathogenic *Neisseria* from one another, from other oxidase-positive bacteria, and from normal microbiota of the oropharynx and genitourinary tract that can be confused with the pathogens. Sugar oxidation, growth patterns, nitrate reduction, and pigment production are useful differentiation tests at this point (**table 18.5**). Several rapid method identification kits have been developed for this purpose. Many laboratories now rely on a rapid PCR test that can detect gonococcal DNA directly from a urine sample.

TABLE 18.5 Scheme for Differentiating Gram-Negative Cocci and Coccobacilli

*A weak pathogen, found in the nasopharynx of children and sometimes mistaken for *N. meningitidis*.

Other Genera of Gram-Negative Cocci and Coccobacilli

The genera *Moraxella* and *Acinetobacter* are included in the same family as *Neisseria* because of morphological and biochemical similarities. Most species are either relatively harmless commensals of humans and other mammals or are saprobes living in soil and water. In the past few years, however, two species in particular have emerged as significant opportunists in hosts with deficient immune functions. The first species, *Moraxella (Branhamella) catarrhalis*,* is found in the normal human nasopharynx and can cause purulent disease. It is associated with several clinical syndromes such as meningitis, endocarditis, otitis media, bronchopulmonary infections, and neonatal conjunctivitis. Adult patients with leukemia, alcoholism, malignancy, diabetes, or rheumatoid disease are the most susceptible to it.

Moraxella species often appear as short, plump rods as well as cocci, and some exhibit a twitching motility. These bacteria are widely distributed on the mucous membranes of domestic mammals and humans and are generally regarded as weakly pathogenic or nonpathogenic. Some species are rarely implicated in ear infections and conjunctivitis in humans.

Because *Moraxella* is morphologically similar to the gonococcus and the meningococcus, biochemical methods are needed to discriminate it. Key characteristics are the complete lack of carbohydrate fermentation and positive nitrate reduction in *M. B. catarrhalis*. Treatment of infection by this organism is with erythromycin or cephalosporins, because many strains of this species produce penicillinase.

The second genus in this group, *Acinetobacter* is widely distributed in soil and water and extremely resistant to the environment. It can survive for months on inanimate objects such as faucets, toilets, bedclothes, doorknobs, sinks, respiratory equipment, and catheters. Most recently, the species *A. baumannii* has become a high-profile pathogen in nosocomial and community-acquired infections. Primary targets of the bacterium are wounds, the lungs, the urinary tract, burns, and blood. It has been extensively involved in infections among military personnel with traumatic injuries during wartime. Combat conditions make control and treatment more difficult and increase the risk for bloodstream infections. Another complication is the emergence of multidrug-resistant strains that are able to withstand the usual broad-spectrum drugs. Treatment involves some combination of carbapenems, colistin, and ampicillin. Control also includes isolation procedures, hand hygiene, and environmental disinfection.

* *Branhamella catarrhalis* (bran"-hah-mel'-ah cah-tahr-al'-is) After Sarah Branham, a bacteriologist working on the genus *Neisseria*, and L. *catarrhus*, to flow. We will use this genus name in her honor, although some taxonomists include this bacterium in genus *Moraxella*.

Check Your Progress SECTION 18.3

- Describe the epidemiology and pathology of *N. gonorrhoeae*, and compare them to those of *N. meningitidis*.
- List the short-term and long-term consequences of *N. gonorrhoeae* infection and compare them to those of *N. meningitidis*.
- Recall the epidemiology and pathology of the medically important organisms in the genera *Moraxella* and *Acinetobacter*.

CASE STUDY Part 2

The following morning, over the course of 2 hours, OSDH received reports of three more cases of suspected meningococcal disease, including one fatality. All four patients attended the same lower elementary school (prekindergarten through second grade), which was housed in a single building on a large campus. The campus included three other buildings providing classroom space for a total of 1,850 pre-K through twelfth-grade students. The occurrence of the additional cases within such a short time frame prompted state and local authorities to initiate measures to control the outbreak.

At noon a clinic was opened at the school to provide prophylactic antibiotics, initially targeting the 443 students and 50 faculty members of the lower elementary school. The school's automated parent-calling system was used to keep students and parents apprised of the situation and to notify those students who were being advised to receive chemoprophylaxis.

That same afternoon, at 4:00 p.m., the OSDH was notified that one of the students whose illness had been reported that morning had died, and two new students had been admitted to the hospital with fever and rash (these two students were later found not to be infected with *N. meningitidis*, but this information took several days to ascertain). The second death and additional (suspected) cases prompted the expansion of the chemoprophylaxis clinic, this time targeting older students who had participated in a program in which they read to younger students, or who had ridden on buses with any of the patients. These wider eligibility criteria resulted in an additional 400 contacts. In all, the prophylaxis clinic operated for 16 hours and administered 846 chemoprophylaxis doses.

- What age group is most at risk for meningococcal infection?
- What long-term protection exists to prevent meningococcal disease?

See: CDC. 2012. Outbreak of meningococcal disease associated with an elementary school—Oklahoma, March 2010. *MMWR* 61:217–21. To conclude this Case Study, go to Connect.

 Chapter Summary with Key Terms

Gram-positive and gram-negative cocci are frequently called **pyogenic**, due to their stimulation of pus formation.

18.1 General Characteristics of the Staphylococci

Nonmotile, gram-positive cocci arranged in irregular clusters; facultative anaerobes; fermentative; salt-tolerant, catalase-positive.

- A. *Staphylococcus aureus* produces a number of virulence factors. Enzymes include **coagulase** (a confirmatory characteristic), hyaluronidase, staphylokinase, nuclease, and penicillinase. Toxins are **beta-hemolysins**, **leukocidin**, **enterotoxin**, **exfoliative toxin**, and toxic shock syndrome toxin. Microbe carried in nasopharynx and skin.
 1. *Skin Infections*: Local **abscess** occurs at site of invasion of hair follicle, gland; manifestations are **folliculitis**, **furuncle**, **carbuncle**, and bullous **impetigo**.
 2. *Toxic Disease*: Food intoxication due to enterotoxin; **staphylococcal scalded skin syndrome (SSSS)**, a skin condition that causes desquamation; **toxic shock syndrome**, toxemia in women due to infection of vagina, associated with using tampons.
 3. *Other*: **Osteomyelitis**, bacteremia leading to endocarditis, and pneumonia.
- B. *Principal Coagulase-Negative Staphylococci*: *S. epidermidis*, a normal resident of skin and follicles; an opportunist and one of the most common causes of nosocomial infections, chiefly in surgical patients with indwelling medical devices or implants. *S. saprophyticus* is a urinary pathogen.
- C. *Treatment*: *S. aureus* has multiple resistance to antibiotics, especially penicillin, ampicillin, and methicillin (**MRSA**). Abscesses require debridement and removal of pus. Staphylococci have extreme resistance to harsh environmental conditions.
- D. Staphylococcal infections are frequently complicated by their tendency to form biofilms on medical devices.

18.2 General Characteristics of the Streptococci and Related Genera

A large, varied group of gram-positive bacteria, containing the genera *Streptococcus* and *Enterococcus*. Cocci are in chains of various lengths; nonmotile, non-spore-forming; often encapsulated; catalase-negative. Classified into Lancefield groups (A–R) according to the type of serological reactions of the cell wall carbohydrate; also characterized by type of hemolysis. The most important sources of human disease are beta-hemolytic *S. pyogenes* (group A), *S. agalactiae* (group B), *Enterococcus faecalis* (group D), and alpha-hemolytic *S. pneumoniae* and the **viridans streptococci**.

- A. *Beta-Hemolytic Streptococci*: *S. pyogenes* is the most serious pathogen of family; produces several virulence factors, including C-carbohydrates, M-protein (fimbriae), streptokinase, hyaluronidase, DNase, **streptolysins** (SLO, SLS), **erythrogenic toxin**.
 1. Skin infections include pyoderma (strep **impetigo**) and **erysipelas** (deeper, spreading skin infection).
 2. Systemic conditions include *strep throat* or **pharyngitis**; may lead to toxemia, called **scarlet fever**—also causes pneumonia.
 3. Sequelae caused by immune response to streptococcal toxins include **rheumatic fever** and **glomerulonephritis**.

- B. Other *Beta-Hemolytic*: *Streptococcus agalactiae* (group B), a pathogen increasingly found in the human vagina; causes neonatal, wound, and skin infections, particularly in debilitated persons. *Enterococcus faecalis* (sometimes beta-hemolytic) and other enteric group D species are normal flora of intestine; cause opportunistic urinary, wound, and surgical infections.
- C. *Treatment*: Group A and group B are treated primarily with some type of penicillin (G is very effective); sensitivity testing may be necessary for enterococci; no vaccines available.
- D. *Alpha-Hemolytic Streptococci*: The **viridans streptococci** *S. mitis*, *S. salivarius*, *S. mutans*, and *S. sanguinis* constitute oral flora in saliva and can form biofilms on tissues. Several species are implicated in dental caries. Principal non-oral infections are **subacute endocarditis**, mass colonization of heart valves following dental procedures.
- E. *S. pneumoniae*, the **pneumococcus**, is a heavily encapsulated, lancet-shaped diplococcus; capsule is an important virulence factor—90+ types; reservoir is nasopharynx of normal healthy carriers.
 1. The pneumococcus is the most common cause of bacterial pneumonia; attacks patients with weakened respiratory defenses; symptoms include fever/chills, cyanosis, cough.
 2. **Otitis media**, inflammation of middle ear, is common in children.
 3. It is the most common cause of meningitis in adults.
 4. Vaccination available.

18.3 The Family Neisseriaceae: Gram-Negative Cocci

Primary pathogens in the genus *Neisseria* are common residents of mucous membranes. *Neisseria* species are bean-shaped diplococci that have capsules and fimbriae; they are oxidase-positive, non-spore-forming, nonmotile; pathogens are fastidious and do not survive long in the environment.

- A. *Neisseria gonorrhoeae*: The **gonococcus**, cause of **gonorrhea**, tends to be located intracellularly in pus cells; among the most common STDs; may be transmitted from mother to newborn; asymptomatic carriage is common in both sexes.
 1. Symptoms of gonorrhea in males are urethritis and discharge; infection of deeper reproductive structures may cause scarring and infertility. Symptoms of gonorrhea in females include vaginitis and urethritis. Ascending infection may lead to **salpingitis (PID)**, mixed anaerobic infection of abdomen; common cause of sterility and ectopic tubal pregnancies due to scarred fallopian tubes. Extragenital infections may be anal, pharyngeal, conjunctivitis, septicemia, arthritis.
 2. Infections in newborns cause eye inflammation, occasionally infection of deeper tissues and blindness; can be prevented by prophylaxis immediately after birth.
 3. Preferred treatment is a combination of ceftriaxone and azithromycin due to increasing drug-resistant strains; no vaccine exists.

- B. *Neisseria meningitidis*: The **meningococcus** is a prevalent cause of **meningitis**. Infection begins when bacteria enter bloodstream, pass into the cranial circulation, multiply in meninges and brain; very rapid onset; initial disease symptoms are neurological; **endotoxin** released by pathogen causes hemorrhage and shock; can be fatal; treated with third-generation cephalosporins; vaccines exist for groups A and C.
- C. *Other Genera of Gram-Negative Cocci and Coccobacilli*
- Other Gram-Negative Cocci and Coccobacilli*: Genus **Moraxella** are short rods that colonize mammalian mucous membranes. **Moraxella (Branhamella) catarrhalis**, common member of throat flora; is an opportunist in cancer, diabetes, alcoholism.
 - Acinetobacter baumannii**, nosocomial and community-acquired infection of wounds, lungs, urinary tract, and blood. Many drug-resistant strains.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

- Which of the following is/are a pyogenic coccus/cocci?
 - Streptococcus*
 - Staphylococcus*
 - Neisseria*
 - all of these
- The coagulase test is used primarily to differentiate *Staphylococcus aureus* from
 - other staphylococci
 - streptococci
 - micrococci
 - enterococci
- The symptoms in scarlet fever are due to
 - streptolysin
 - coagulase
 - erythrogenic toxin
 - alpha-toxin
- The most severe streptococcal diseases are caused by
 - group B streptococci
 - group A streptococci
 - pneumococci
 - enterococci
- Rheumatic fever damages the _____, and glomerulonephritis damages the _____.
 - skin, heart
 - joints, bone marrow
 - heart valves, kidney
 - brain, kidney
- _____ hemolysis is the partial lysis of red blood cells due to bacterial hemolysins.
 - Gamma-
 - Alpha-
 - Beta-
 - Delta-
- Viridans streptococci commonly cause
 - pneumonia
 - meningitis
 - subacute endocarditis
 - otitis media
- Which of the following strains of pathogens has the lowest incidence?
 - VRE
 - VRSA
 - MRSA
 - MRSE
- Otitis media is a/an _____ infection often caused by _____.
 - bone, *Staphylococcus aureus*
 - eye, *N. gonorrhoeae*
 - middle ear, *Streptococcus pneumoniae*
 - brain, *N. meningitidis*
- Which genus of bacteria has pathogens that can cause blindness?
 - Streptococcus*
 - Staphylococcus*
 - Neisseria*
 - Moraxella*
- An important test for identifying *Neisseria* is
 - production of oxidase
 - production of catalase
 - sugar fermentation
 - beta-hemolysis
- A complication of genital gonorrhea in both men and women is
 - infertility
 - pelvic inflammatory disease
 - arthritis
 - blindness
- What virulence factor is associated with the development of skin hemorrhages in meningitis?
 - skin invasion by *N. meningitidis*
 - blood clots
 - erysipelas
 - endotoxins in the blood
- Which infectious agent of those covered in the chapter would most likely be acquired from a contaminated doorknob?
 - Staphylococcus aureus*
 - Streptococcus pyogenes*
 - Neisseria meningitidis*
 - Streptococcus pneumoniae*
- Which of the following effects is/are caused by formation of an infectious biofilm?
 - disseminated infection
 - failure of drug therapy
 - colonization of tissues
 - a and b
 - b and c
 - all of these
- Single Matching.** Match each description in the right-hand column with the one word in the left-hand column that fits it. (See index and glossary.)

_____ furuncle	a. complete red blood cell lysis
_____ osteomyelitis	b. substance involved in heart valve damage
_____ coagulase	c. enzyme that dissolves clots
_____ erythrogenic toxin	d. enzyme of pathogenic <i>S. aureus</i>
_____ rheumatic fever	e. cutaneous infection of group A streps
_____ beta-hemolysis	f. solidification of lung alveoli
_____ consolidation	g. unique pathologic feature of <i>N. gonorrhoeae</i>
_____ viridans streptococci	h. a boil
_____ erysipelas	i. cause of tooth abscesses
_____ endocarditis	j. focal infection of long bones
_____ streptolysin	k. heart colonization by oral streps
_____ streptokinase	l. cause of scarlet fever symptoms
	m. long-term sequelae of strep throat

 Case Study Review

- The first step in the clinical diagnosis of bacterial meningitis is a Gram stain of blood or cerebrospinal fluid. What other bacterial species could be mistaken for *N. meningitidis* at this stage of the identification process?
 - Moraxella catarrhalis*
 - Staphylococcus epidermidis*
 - Streptococcus agalactiae*
 - Enterococcus faecalis*
- Vaccination can provide protection against *N. meningitidis*, as eventually happened in this case. A vaccination also exists for what other common cause of meningococcal disease?
 - Staphylococcus aureus*
 - Streptococcus pyogenes*
 - Streptococcus pneumoniae*
 - Acinetobacter baumannii*
- In this case, the first step taken to treat students potentially exposed to meningitis was to administer antibiotics, while a meningococcal vaccination clinic was organized for the area a week after the outbreak. What were the benefits of fighting the outbreak with both antibiotics and vaccination?

 Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

- Explain the actions of each of the following that make them virulence factors:
 - hemolysins
 - leukocidin
 - kinases
 - hyaluronidase
 - coagulase
- What conditions favor staph food poisoning?
- Describe what is meant by HA-MRSA and CA-MRSA and why they are important.
 - Describe the major group A streptococcal infections.
 - Why is a “strep throat” a cause for concern?
- Discuss the apparent pathology at work in rheumatic fever and acute glomerulonephritis.
- What are the recommendations for pneumococcal vaccination?
 - Compare and contrast the characteristics of male and female genital gonorrhea.
 - Describe at least two extragenital complications of gonorrhea.

 Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps along with concept mapping activities for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

 Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

- You have been handed the problem of diagnosing gonorrhea from a single test. Which one will you choose and why?
- You have been called upon to prevent outbreaks of SSSS in the nursery of a hospital where this strain of *S. aureus* has been isolated.
 - What will be the main concerns?
 - What procedures will address these concerns?
- You have been given the assignment of obtaining some type of culture that could help identify the cause of otitis media in a small child.
 - What area might you sample?
 - Why is this disease so common in children?

4. a. Name the three species of pyogenic cocci most commonly implicated in neonatal disease.
- b. Explain how infants might acquire such diseases.
5. Explain why it is so important to take a detailed cardiovascular and infection history of dental patients.
6. Case Study. An elderly man with influenza acquires a case of pneumonia. Gram-positive cocci isolated from his sputum give

beta-hemolysis on blood agar; the infection is very difficult to treat. Later, it is shown that the man shared a room with a patient with a bone infection. Isolates from both infections were the same.

- a. What is the probable species?
- b. Justify your answer.
- c. What treatment will be necessary?
- d. What special precautions should be taken by persons attending to the patient? Why?

Visual Challenge

1. From **chapter 14, figure 14.2a**. How does this aspect of the body's defenses help protect against *Streptococcus pneumoniae* infection?

2. From **chapter 17, figure 17.8b1**. Explain how this technique can be used to diagnose infections with group A streptococci.

The Gram-Positive Bacilli of Medical Importance

Electron micrograph of a single *Listeria monocytogenes* cell. (left): Source: Dr. Balasubr Swaminathan & Peggy Hayes, photo by Elizabeth White/CDC; (right): © BananaStock/PunchStock RF

CASE STUDY Part 1 Three Patients

Dr. Mike Hauser was doing everything he could to fight back against **myeloma**, a cancer that attacks plasma cells, the blood cells responsible for **antibody production**. The 68-year-old podiatrist was dealing as best he could with the anemia and lowered immune response that are part of both the disease and its treatment, and he seemed to be regaining his strength. After breakfast with his family, he went back to planning an upcoming bow-hunting trip, a welcome respite from talk of cancer and chemotherapy. Several hundred miles from Dr. Hauser's Colorado home, Paul Schwarz was also eating breakfast, the 92-year-old crediting his long life and good health, at least in part, to a diet rich in fruit. At roughly the same time, Michelle Wakley, 6 months pregnant, was enjoying a breakfast of fresh **cantaloupe** with her family in Indianapolis. Michelle and her husband were looking forward to their second child. Within days, Mike Hauser and Paul Schwarz would be dead, and Michelle Wakley would be admitted to the hospital in premature labor.

All three patients eventually sought medical attention for what at first seemed to be the flu, a not uncommon diagnosis in September. Doctors, however, knew that severe headache and flulike symptoms in pregnant women, the elderly, and those who are **immune compromised**

“Every day when I woke up my head hurt. My legs were killing me. ... Kind of like when you get the flu, your body aches. It was painful!... and I had the chills. I should've gone to the hospital but knowing ... you get flulike symptoms when you're pregnant, I didn't go.”

Michelle Wakley

were ominous signs, suggesting infection with ***Listeria monocytogenes***, a diagnosis confirmed by the presence of the bacteria in the blood and cerebrospinal fluid of each patient. In most people **listeriosis** is a mild illness, which is rarely treated, but in susceptible hosts the disease follows a well-established pattern, as bacteria spread through the body, causing **septicemia**, **meningitis**, and **stillbirth** or premature delivery in the case of late-term pregnancy. Although treatable with antibiotics, in these cases the disease had progressed too far; Mike Hauser and Paul Schwarz died, and Michelle Wakley's daughter Kendall was born 3 months premature.

And they were only the beginning. Because listeria is a **reportable disease**, the cases were forwarded to the CDC for potential epidemiological investigation. On September 7, after receiving reports of at least 55 cases of listeriosis, the CDC began coordinating a multistate investigation into the source of the outbreak.

- What is the difference between food infection and food intoxication? Into which category does listeriosis fall?
- What foods are commonly implicated in cases of listeriosis?

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

19.1 Medically Important Gram-Positive Bacilli

Expected Learning Outcome

1. Describe how cellular characteristics are used to categorize gram-positive bacilli into major groups.

The gram-positive bacilli can be subdivided into three general groups based on the presence or absence of endospores and the characteristic of acid-fastness. Further levels of separation correspond to oxygen requirements and cell morphology. Organization of the most important gram-positive pathogens can be seen in **table 19.1** and **Systems Profile 19.1**.

Check Your Progress SECTION 19.1

1. Explain why *Bacillus*, *Clostridium*, and *Mycobacterium* are found in separate groups despite all being gram-positive bacilli.

6. Clarify why *Clostridium difficile*-associated disease is associated with the use of antibiotics.
7. Compare the course of botulism infection and disease with that of tetanus.
8. Contrast common botulism with infant botulism, and relate prevention and treatment strategies for both.
9. Compare food intoxication caused by *Bacillus cereus* with that caused by *Clostridium perfringens*.

Most endospore-forming bacteria are gram-positive, motile, rod-shaped forms in the genera *Bacillus* and *Clostridium*. An endospore is a dense survival unit that develops in a vegetative cell in response to nutrient deprivation (**figure 19.1**; see figure 4.22). The extreme resistance to heat, drying, radiation, and chemicals accounts for the survival, longevity, and ecological niche of sporeformers, and it is also a significant factor in their pathogenicity.

General Characteristics of the Genus *Bacillus*

The genus *Bacillus* includes a large assembly of mostly saprobic bacteria widely distributed in the earth's habitats. *Bacillus* species are aerobic and catalase-positive, and, though they have varied nutritional requirements, none is fastidious. The group is noted for its versatility in degrading complex macromolecules, and it is also a common source of antibiotics. Because the primary habitat of many species is the soil, spores are continuously dispersed by means of dust into water and onto the bodies of plants and animals. Despite their ubiquity, the two species with primary medical importance are *B. anthracis*, the cause of anthrax, and *B. cereus*, the cause of one type of food poisoning.

Bacillus anthracis and Anthrax

Bacillus anthracis is among the largest of all bacterial pathogens, composed of block-shaped, angular nonmotile rods 3 to 5 μm long

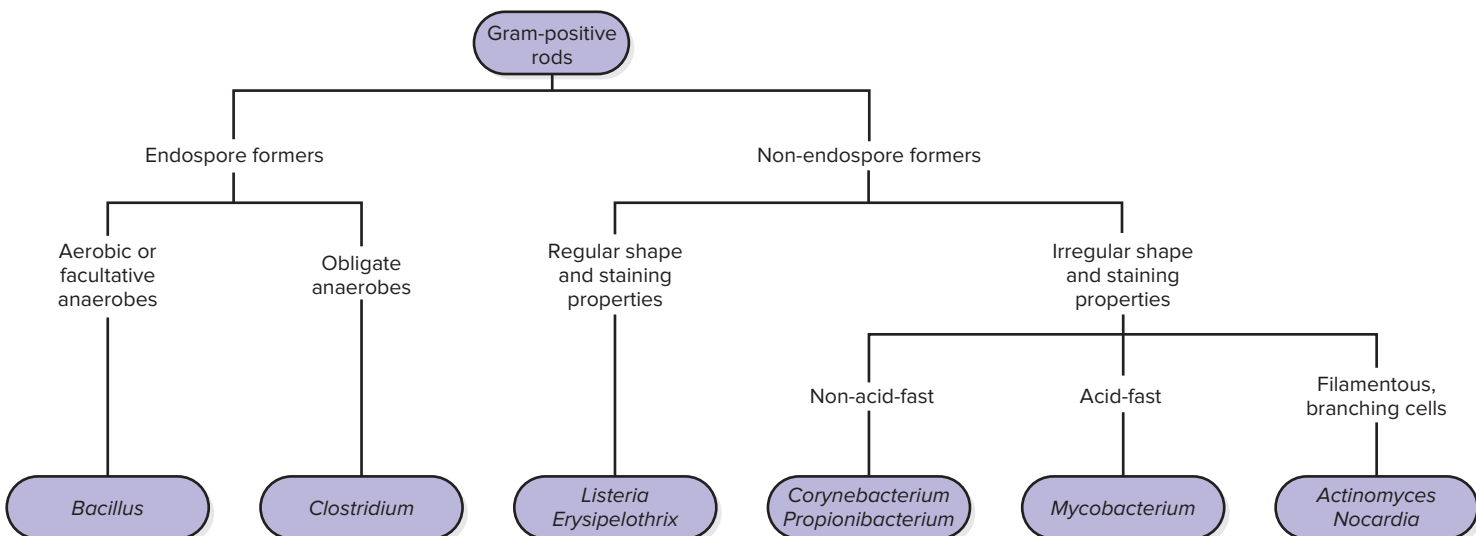

19.2 Gram-Positive Spore-Forming Bacilli

Expected Learning Outcomes

2. Recall the general characteristics of the genus *Bacillus*.
3. Distinguish between cutaneous and pulmonary anthrax, and describe how anthrax is controlled.
4. State the general characteristics of the genus *Clostridium*, and distinguish between *Bacillus* and *Clostridium*.
5. Recall the organisms responsible for myonecrosis and what is required for infection and disease to progress.

TABLE 19.1 Scheme for Differentiating Gram-Positive Bacilli

Systems Profile 19.1		Pathogenic Gram-Positive Bacilli			
Organism	Skin/Skeletal	Nervous/Muscle	Cardiovascular/ Lymphatic/Systemic	Gastrointestinal	Respiratory
<i>Bacillus anthracis</i>	Cutaneous anthrax				Pulmonary anthrax
<i>Bacillus cereus</i>					Food poisoning
<i>Clostridium perfringens</i>	Gas gangrene (myonecrosis)	Gas gangrene (myonecrosis)	Food poisoning (mild)		
<i>Clostridium tetani</i>	Tetanus				
<i>Clostridium difficile</i>					<i>C. difficile</i> -associated disease
<i>Clostridium botulinum</i>	Wound botulism	Botulism (wound, infant, and food-borne)			
<i>Listeria monocytogenes</i>	Meningitis (in immunocompromised hosts)		Septicemia	Diarrhea	Sore throat
<i>Erysipelothrix rhusiopathiae</i>	Erysipelas				
<i>Corynebacterium diphtheriae</i>	Cutaneous diphtheria				Diphtheria
<i>Propionibacterium acne</i>	Acne				
<i>Mycobacterium tuberculosis</i>	Recurrent tuberculosis		Extrapulmonary tuberculosis	Primary tuberculosis	
<i>Mycobacterium leprae</i>	Leprosy	Leprosy (tuberculoid)	Leprosy (lepromatous)		

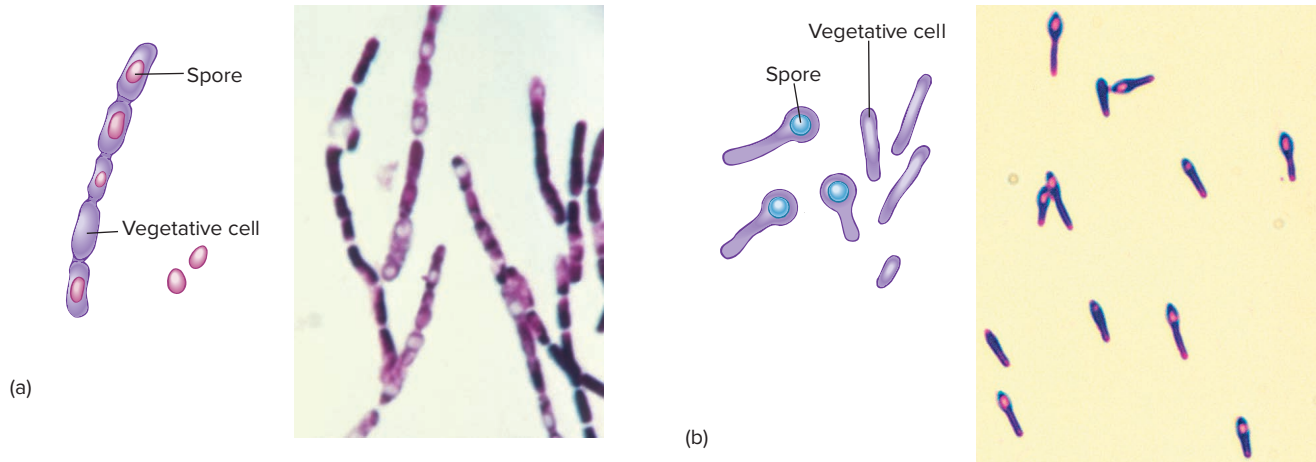

Figure 19.1 Examples of endospore-forming pathogens. (a) The morphological appearance of *Bacillus anthracis*, showing centrally placed endospores and a streptobacillus arrangement (600 \times). and 1 to 1.2 μm wide and central spores that develop under all growth conditions except in the living body of the host (**figure 19.1a**). Its virulence factors include a polypeptide capsule and exotoxins that in varying combinations produce edema and cell death. For centuries, **anthrax*** has been known as a zoonotic disease of herbivorous livestock (sheep, cattle, goats). It has an important place in the history of medical microbiology because it was Robert Koch's

model for developing his postulates in 1877; and later Louis Pasteur used the disease to prove the usefulness of vaccination.

The anthrax bacillus is a facultative anaerobe that undergoes its cycle of vegetative growth and sporulation in the soil. Animals become infected while grazing on grass contaminated with spores. When the pathogen is returned to the soil in animal excrement or carcasses, it can sporulate and become a long-term reservoir of infection for the animal population. The majority of anthrax cases are reported in livestock from Africa, Asia, and the Middle East. Most recent human cases in the United States have occurred in textile

* *anthrax* (an's-thraks) Gr. *anthrax*, carbuncle.

Pathogen Profile #1 *Bacillus anthracis*

Source: CDC

Microscopic Morphology Large gram-positive bacilli, often present in long chains. Cells are block shaped with endospores developing in the center of the cell.

Identified by Gram reaction and endospore formation. *Bacillus* is aerobic, whereas *Clostridium* is a strict anaerobe. Physiological and biochemical tests are used to differentiate *B. anthracis* from other members of the genus.

Habitat Both vegetative growth and endospore formation occur in soil, with spores easily spreading to water, plants, and the bodies of animals. The majority of human infection occurs in workers handling animal hair, hides, or products made from them.

Virulence Factors Cells are covered in a thick capsule that inhibits phagocytosis and produce exotoxins that cause the death of macrophages. Lysosomes within the dying macrophages release their contents, leading to capillary thrombosis, cardiovascular shock, and rapid death.

Primary Infections/Disease Cutaneous anthrax is the most common and least dangerous form of infection and occurs when *B. anthracis* spores enter broken skin. Growth of the bacterium is noted as a papule that becomes necrotic and gives rise to a painless black eschar. Without antibiotic treatment, mortality can be as high as 20%. Pulmonary anthrax (wool sorter's disease) may occur when a relatively small number (8,000–50,000) of spores are inhaled and germinate in the lungs. Antibiotic treatment must commence before a critical concentration of toxin accumulates; otherwise, mortality may exceed 99%.

Control and Treatment Anthrax is rare in the United States, typically less than 1 case per year, primarily due to vaccination of animals such as cattle and regulations surrounding the importation of animal hides. A vaccine also exists for military personnel and those in high-risk occupations.

workers handling imported animal hair or hide or products made from them. In 2008 a drum maker in London died of inhalational anthrax, contracted while scraping goat hides to be used as drumheads. The hides had been imported from Africa, where anthrax is endemic. Remarkably similar incidents occurred in New York in 2006 and Scotland in 2005. Because of effective control procedures, the number of cases in the United States is extremely low (fewer than 10 a year).

The circumstances of human infection depend upon the portal of entry. The most common and least dangerous of all forms is **cutaneous anthrax**, caused by spores entering the skin through small cuts and abrasions. Germination and growth of the pathogen in the skin are marked by the production of a papule that becomes increasingly necrotic and later ruptures to form a painless, black **eschar*** (figure 19.2).

A far more destructive infection is **pulmonary anthrax** (wool sorter's disease) associated with the inhalation of airborne spores, either from animal products or from contaminated soil. The infectious dose is relatively small—8,000 to 50,000 spores. Upon reaching the lungs, the spores are phagocytosed and transported to lymph nodes, where they germinate and secrete exotoxins that enter the circulatory system. The toxins attach to membranes of macrophages and gain entry into these cells through engulfment. The toxins are highly lethal, causing massive macrophage death and release of chemical mediators. The pathologic effects of these events are wide-ranging: capillary thrombosis, cardiovascular shock, and rapid death in over 99% of untreated cases. The gastrointestinal form of infection is a rare (1 U.S. case in the last 70 years) but deadly condition that follows a course similar to pulmonary anthrax but is acquired through the ingestion of contaminated meat.

The terrorist attacks of 2001 focused a great deal of attention on the threat of bioterrorism, but it was hardly the first time the

Figure 19.2 Cutaneous anthrax. In early stages, the tissue around the site of invasion is inflamed and edematous, later developing into a thick, necrotic lesion called the eschar. It usually separates and heals spontaneously. Source: CDC

virulent nature of anthrax had been considered as a weapon of war (19.1 Making Connections).

Methods of Anthrax Control Active cases of anthrax are treated with clindamycin, doxycycline, or ciprofloxacin. Because drug therapy targeting the bacteria itself does nothing to lessen the effects of toxemia, people can still die from it. Antibiotics are generally given along with a second drug, Raxibacumab, which uses monoclonal antibodies to bind to one of the toxins secreted by *B. anthracis*, preventing it from entering cells and dramatically

* *eschar* (ess's-kar) Gr. *eschara*, scab.

19.1 MAKING CONNECTIONS

A Bacillus That Could Kill Us

Mechanisms of biological warfare are frequently based on the pathogenic potential of microorganisms. Because spore-forming bacteria such as *Bacillus* are so hardy, they have held a particular attraction to scientists as research subjects and, in one case, as the basis of a deadly bomb.

During World War II, the mounting outrage over German bombings of London forced the British and American governments to collaborate on a powerful means of striking back. Given the knowledge that pneumonic anthrax was rapidly fatal in most cases, a highly secret council designed a bomb containing the spores of *Bacillus anthracis*. In the original plan, the detonation of these deadly projectiles over six German cities would have caused a shower of spores to be inhaled by humans and animals. Some estimates predicted that this could have wiped out the population over hundreds of square miles. In 1943 the British government conducted a bomb test on Gruinard, a small island near Scotland, using sheep as test subjects. Late in the war, a plant in Indiana actually began to manufacture the bombs, but by this time the war had started to wind down. An unfortunate long-term result was the creation of a dangerous source of the infectious agent on “anthrax island.” This island remained uninhabitable until its decontamination in 1986.

During the cold war, the U.S. Army’s Special Operations Division conducted a chilling experiment using *Bacillus subtilis*. The plan was to simulate a possible method of germ warfare by releasing spore aerosols into the air of a crowded Washington, DC, airport and bus terminal. Agents carried suitcases to spray the air, while hundreds of unsuspecting people inhaled “large and acceptably uniform” doses, presumably with no ill effects.

This study and several others like it were based on the disturbing assumption that *B. subtilis* is a harmless air contaminant. It should be clear even to beginning students that many species of bacteria are opportunists and are capable of causing disease, especially if present in large numbers. In fact, *B. subtilis* can cause lung and blood infections in people with weakened immunity. The tests were able to determine that if smallpox virus had been used instead of *B. subtilis*, 300 people in 93 cities would have become infected. Similar exposures at terminals in several other large cities would have spread the disease rapidly to thousands of others. It was also shown that this contamination procedure could be accomplished without detection.

The potential threat from biological warfare is not only a concern of the past. Recent reports indicate that rogue states and terrorist organizations may have access to germ agents, including anthrax spores and botulinum toxin (another product of a gram-positive sporeformer). The fear that these agents could be incorporated into bombs or missiles to be

Anthrax island—once a forbidden zone
© Stan Pritchard/Alamy Stock Photo

spread over long distances has spurred international monitoring for potential sources of deadly agents. All U.S. military personnel are vaccinated to protect them against the use of biowarfare agents. The anthrax attacks of late 2001 and the continuing tensions abroad underscore our need to be educated on the potential dangers.

In late 2001, only one week after the terrorist attack on the World Trade Center, anthrax-tainted letters were mailed to several media outlets and two senators, resulting in a total of 22 cases of anthrax and five deaths. The media raised loud alarms about these anthrax attacks, but in perspective more than 10 times this many people are killed annually by lightning strikes. So in reality, this attack, while certainly tragic, was not nearly the national threat that was feared. Epidemiologists were quick to trace the route of the envelopes implicated in the attack and to prescribe prophylactic antibiotics (ciprofloxacin or doxycycline) to more than 32,000 people who may have come in contact with the letters. If the attack had consisted of multiple pathogens, been initiated in more sites, involved multiple modes of transmission, or employed antibiotic-resistant agents, the effects could have been considerably worse. Such a drastic bioterrorism attack would have tested the capacity of our health care system, our ability to manufacture large quantities of drugs, even our food distribution networks. All of our safety nets would have been stretched, perhaps to the point of breaking.

How many years elapsed before anthrax bacteria were eliminated from the contaminated island? Explain why it could persist there for so long. *Answer available on Connect.*

decreasing the severity of the disease. A vaccine containing live spores and a toxoid prepared from a special strain of *B. anthracis* are used to protect livestock in areas of the world where anthrax is endemic. A vaccine, Biothrax, based on a purified toxoid, is recommended for people in high-risk occupations and military personnel. Effective vaccination requires five inoculations given over 18 months, with yearly boosters. The potential side effects reported for this vaccine have spurred research and development of alternative vaccines. Animals that have died from anthrax must be burned or chemically decontaminated before burial to prevent establishing the microbe in the soil; and imported items containing animal hides, hair, and bone should be gas-sterilized.

Other Bacillus Species Involved in Human Disease

Bacillus cereus is a common airborne and dust-borne contaminant that multiplies very readily in cooked foods such as rice, potato, and meat dishes. The spores survive short periods of cooking and reheating; when the food is stored at room temperature, the spores germinate and release enterotoxins. Ingestion of toxin-containing food causes nausea, vomiting, abdominal cramps, and diarrhea. There is no specific treatment, and the symptoms usually disappear within 24 hours.

For many years, most common airborne *Bacillus* species were dismissed as harmless contaminants with weak to nonexistent pathogenicity. However, infections by these species are increasingly

TABLE 19.2 Differentiation of Important Spore-Forming Species

Species	Oxygen Requirements	Motility	Disease in Humans	Treatment
<i>Bacillus anthracis</i>	Aerobe	–	Cutaneous anthrax Pulmonary anthrax Gastrointestinal anthrax	Antibiotics Vaccines for high risk Antibiotics
<i>Bacillus cereus</i>	Facultative anaerobe	+	Food poisoning	None; disease self-limiting
<i>Clostridium perfringens</i>	Strict anaerobe	–	Gas gangrene Food poisoning (mild)	Debridement; antibiotics; oxygen therapy None; disease self-limiting
<i>Clostridium difficile</i>	Strict anaerobe	+/-	Antibiotic-associated colitis	Withdrawal of antibiotics; administration of probiotics; fecal microbiota transplant
<i>Clostridium tetani</i>	Strict anaerobe	+	Tetanus	Vaccination; passive immunization
<i>Clostridium botulinum</i>	Strict anaerobe	+/-	Botulism	Antitoxin

reported in immunosuppressed and intubated patients and in drug addicts who do not use sterile needles and syringes. Two important contributing factors are the abundance of spores in the environment and how ineffective the usual methods of disinfection and antiseptics are when it comes to spores.

The Genus *Clostridium*

Another genus of gram-positive, spore-forming rods that is widely distributed in nature is *Clostridium*.* It is differentiated from *Bacillus* on the basis of being anaerobic and catalase-negative (**table 19.2**). The large genus (over 120 species) resides in a variety of habitats. Saprobic members are frequently found in soil, sewage, vegetation, and organic debris; and commensals inhabit the bodies of humans and other animals. Infections caused by pathogenic species are not normally communicable but occur when spores are introduced into injured skin.

Clostridia produce oval or spherical spores that often swell the vegetative cell (see figure 19.1*b*). Spores are produced only under anaerobic conditions. Their nutrient requirements are complex, and they can decompose a variety of substrates. They can also synthesize organic acids, alcohols, and other solvents through fermentation. This capacity makes some clostridial species essential tools of the biotechnology industry (see chapter 27). Other extracellular products, primarily **exotoxins**, play an important role in various clostridial diseases such as botulism and tetanus.

The Role of Clostridia in Infection and Disease

Clostridial disease can be divided into (1) wound and tissue infections, including myonecrosis, antibiotic-associated colitis, and tetanus; and (2) food intoxication of the perfringens and botulism varieties. Most of these diseases are caused by the release of potent exotoxins that act on specific cellular targets. In fact, the exotoxins responsible for these diseases are among the most poisonous substances on earth, being millions of times more toxic than strychnine or arsenic.

Gas Gangrene/Myonecrosis

The majority of clostridial soft tissue and wound infections are caused by *Clostridium perfringens*, *C. novyi*, and *C. septicum*. The spores of these species can be found in soil, on human skin, and in the human intestine and vagina. The disease they cause has the common name **gas gangrene*** in reference to the gas produced by the bacteria growing in the tissue. It is technically termed anaerobic cellulitis or **myonecrosis**.* The conditions that predispose a person to gangrene are surgical incisions, compound fractures, diabetic ulcers, septic abortions, puncture and gunshot wounds, and crushing injuries contaminated by spores from the body or the environment.

Because clostridia are not highly invasive, infection requires damaged or dead tissue that supplies growth factors and an anaerobic environment. The low oxygen tension results from an interrupted blood supply and the growth of aerobic contaminants that deplete oxygen. Due to this interaction, gas gangrene is considered a type of mixed infection. These conditions stimulate spore germination, rapid vegetative growth in the dead tissue, and release of exotoxins. *Clostridium perfringens* produces several physiologically active toxins; the most potent one, *alpha-toxin* (lecithinase), causes red blood cell rupture, edema, and tissue destruction (**figure 19.3**). Additional virulence factors that enhance tissue destruction are collagenase, hyaluronidase, and DNase. The gas formed in tissues, due to fermentation of muscle carbohydrates, can also destroy muscle structure.

Extent and Symptoms of Infection Two forms of gas gangrene have been identified. In anaerobic cellulitis, the bacteria spread within damaged necrotic muscle tissue, producing toxins and gas, but the infection remains localized and does not spread into healthy tissue. The pathology of true myonecrosis is more destructive and mimics some aspects of necrotizing fasciitis. Toxins produced in large muscles, such as the thigh, shoulder, and buttocks, diffuse into nearby healthy tissue and cause local necrosis there. This damaged tissue then supports continued clostridial growth, toxin formation, and gas production. The disease can progress through an entire

* *Clostridium* (klawz-trid's-ee-um) Gr. *closter*, spindle.

* *gangrene* (gang's-green) Gr. *gangraina*, an eating sore. A necrotic condition associated with the release of gases.

* *myonecrosis* (my'-oh-neh-kro'ssis) Gr. *myo*, muscle, and *necros*, dead.

Figure 19.4 The clinical appearance of myonecrosis. This patient developed myonecrosis after injecting cocaine. Note the severe degree of involvement, with blackening, general tissue destruction and bubbles on the skin caused by gas formation in underlying tissue. *Clostridium septicum* was isolated from the wound. Image reprinted with permission from Medscape Reference (<http://emedicine.medscape.com/>), 2013, available at: <http://emedicine.medscape.com/article/217943-overview>.

limb or body area, destroying tissues as it goes (**figure 19.4**). Initial symptoms of pain, edema, and a bloody exudate in the lesion are followed by fever, tachycardia, and blackened necrotic tissue filled with bubbles of gas. Gangrenous infections of the uterus due to septic abortions and clostridial septicemia are particularly serious complications. If treatment is not initiated early, the disease is invariably fatal.

Treatment and Prevention of Gangrene One of the most effective ways to prevent clostridial wound infections is immediate and rigorous cleansing and surgical repair of deep wounds, pressure sores (bedsores), compound fractures, and infected incisions. **Debridement*** of diseased tissue eliminates the conditions that promote the spread of gangrenous infection. This is most difficult in the intestine or body cavity, where only limited amounts of tissue can be removed. Surgery is accompanied by antibiotic therapy to

* *debridement* (dih-breed'-ment) Surgical removal of dead or damaged tissue.

Figure 19.5 Hyperbaric treatment for wound infections and diabetic ulcers. This therapy involves holding patients in a chamber that exposes them to higher levels of oxygen to inhibit anaerobic infection and to promote healing. © Charlie Neuman/San Diego Union-Tribune/Zuma Press/Corbis

control the infection. The preferred treatment is clindamycin, supplemented with penicillin for the 5% of clostridial species that are clindamycin-resistant. Hyperbaric oxygen therapy, in which the affected part is exposed to an increased oxygen tension in a pressurized chamber, can also lessen the severity of infection (**figure 19.5**). The increased oxygen content of the tissues blocks further bacterial multiplication and toxin production, while simultaneously promoting healing. Extensive myonecrosis of a limb may call for surgical removal, or amputation. Because there are so many different antigen subtypes in this group, active immunization is not possible.

Tetanus, or Lockjaw

Tetanus* is a neuromuscular disease whose alternate name, lockjaw, refers to an early effect of the disease on the jaw muscle. The etiologic agent, *Clostridium tetani*, is a common resident of cultivated soil and the gastrointestinal tracts of animals. Spores usually enter the body through accidental puncture wounds, burns, the umbilicus, frostbite, and crushed body parts.

The incidence of tetanus is low in North America. Most cases occur among geriatric patients and intravenous drug abusers. The incidence of neonatal tetanus—predominantly the result of an infected umbilicus or circumcision—is higher in cultures that apply dung or mud to these sites to arrest bleeding or as a customary ritual. The disease accounts for several hundred thousand infant deaths a year in developing countries.

The Course of Infection and Disease The risk for tetanus occurs when spores of *Clostridium tetani* are forced into injured tissue. But the mere presence of spores in a wound is not sufficient to initiate infection because the bacterium is unable to invade damaged tissues readily. It is also a strict anaerobe, and the spores cannot become established unless tissues at the site of the wound are necrotic and poorly supplied with blood, conditions that favor germination.

As the vegetative cells multiply, various metabolic products are released into the infection site. Of these, the most serious is **tetanospasmin**, a potent neurotoxin that accounts for the major symptoms

* *tetanus* (tet's-ah-nus) Gr. *tetanos*, to stretch.

Figure 19.6 The events in tetanus. (a) After traumatic injury, bacilli infecting the local tissues secrete tetanospasmin, which is absorbed by the peripheral axons and is carried to the target neurons in the spinal column (not to scale). (b) In the spinal cord, the toxin attaches to the junctions of regulatory neurons that inhibit inappropriate contraction. Released from inhibition, the muscles, even opposing members of a muscle group, receive constant stimuli and contract uncontrollably. (c) Muscles contract spasmodically, without regard to regulatory mechanisms or conscious control. Note the clenched jaw typical of *risus sardonicus*.

of tetanus. The toxin spreads to nearby motor nerve endings in the injured tissue, binds to them, and travels by axons to the ventral horns of the spinal cord (figure 19.6). In the spinal column, the toxin binds to specific target sites on the spinal neurons that are responsible for inhibiting skeletal muscle contraction. The toxin inhibits the release of neurotransmitter, and only a small amount is required to initiate the symptoms. The incubation period varies from 4 to 10 days, and shorter incubation periods signify a more serious condition.

Tetanospasmin alters the usual regulatory mechanisms for muscle contraction. As a result, the muscles are released from normal inhibition and begin to contract uncontrollably. Powerful muscle groups are most affected, and the first symptoms are clenching of the jaw, followed in succession by extreme arching of the back, flexion of the arms, and extension of the legs (figure 19.7). Lockjaw confers the bizarre appearance of *risus sardonicus* (sarcasmic grin) that looks eerily as though the person is smiling (see figure 19.6c). These contractions are intermittent and extremely painful and may be forceful enough to break bones, especially the vertebrae. Death is most often due to paralysis of the respiratory muscles and respiratory failure. The fatality rate, ranging from 10% to 70%, is highest in cases involving delayed medical attention, a short incubation time, or head wounds. Full recovery requires a few weeks, and other than transient stiffness, no permanent damage to the muscles usually remains.

Treatment and Prevention of Tetanus Tetanus treatment is aimed at reducing the level of toxemia and providing supportive care for the patient. A patient with a clinical appearance suggestive of

Figure 19.7 Neonatal tetanus. Baby with neonatal tetanus, showing spastic paralysis of the paravertebral muscles, which locks the back into a rigid, arched position. Also note the abnormal flexion of the arms and legs. Courtesy of Dr. T.F. Sellers

tetanus should immediately receive antitoxin therapy with human tetanus immune globulin (TIG). Although the antitoxin inactivates circulating toxin, it will not counteract the effects of toxin already bound to neurons. Other methods include thoroughly cleansing and removing the afflicted tissue, controlling infection with metronidazole or penicillin, and administering muscle relaxants. The patient may require a respirator, and a tracheostomy¹ is sometimes performed to prevent complications such as aspiration pneumonia or lung collapse.

1. The surgical formation of an air passage by perforation of the trachea.

Pathogen Profile #2 *Clostridium perfringens*, *Clostridium tetani*

Source: CDC

Microscopic Morphology Gram-positive bacilli, present singly or in pairs. Endospores distend the cell, altering its shape. In *C. tetani*, spores are located terminally, whereas in *C. perfringens*, spores are central to terminal in location.

Identified by Gram reaction and endospore formation. *Clostridium* is differentiated from *Bacillus* as the former is typically a strict anaerobe and the latter is not. A variety of physiological, biochemical, and cultural tests are used to distinguish individual species. Many laboratories employ ELISA, PCR, or toxicity testing as a means of differentiation.

Habitat Endospores of both species of bacteria may be found in soil. In addition, *C. perfringens* may be found in the human intestine and vagina, whereas *C. tetani* is found in the gastrointestinal tract of animals.

Virulence Factors Clostridial species produce some of the most potent exotoxins ever encountered, and these are responsible for most of each species' pathological effects. *C. perfringens* produces several enzymes that cause tissue destruction, including collagenase, hyaluronidase, and DNase. The species' most potent toxin, alpha-toxin

(lecithinase), causes red blood cell rupture, edema, and tissue damage. The primary virulence factor in *C. tetani* is tetanospasmin, a neurotoxin that accounts for the major symptoms of tetanus.

Primary Infections/Disease *C. tetani* is responsible for tetanus. The primary disease associated with *C. perfringens* is variously known as myonecrosis, gas gangrene, or anaerobic cellulitis. The bacterium is also responsible for clostridial gastroenteritis, a mild and widespread form of food poisoning.

Control and Treatment Gas gangrene is prevented through thorough cleansing of deep wounds and surgical debridement of diseased tissue to eliminate anaerobic environments. Vaccination with tetanus toxoid is the primary means of preventing tetanus. Human tetanus immune globulin (TIG) can alleviate symptoms of the disease by binding to toxin that is already in the body but has yet to bind to neurons, while the infection itself is treated with metronidazole or penicillin. Supportive care may include the use of assisted ventilation and muscle relaxants.

Tetanus is one of the world's most preventable diseases, chiefly because of effective vaccines (DTaP, Td) containing tetanus toxoid. During World War II, only 12 cases of tetanus occurred among 2,750,000 wounded soldiers who had been previously vaccinated. The recommended vaccination series for babies consists of three injections given 2 months apart, followed by booster doses about 1 and 4 years later. Childhood immunization provides protection for 10 years. Additional protection against neonatal tetanus may be achieved by vaccinating women prior to pregnancy so they will have antibodies to pass on to a fetus. Toxoid should also be given to injured persons who have never been immunized, have not completed the series, or whose last booster was received more than 10 years previously. The vaccine can be given simultaneously with passive TIG immunization to provide immediate and long-term protection.

Clostridium difficile Infection

A clostridial disease most commonly called **C-diff infection**, or **CDI**, is the second most common intestinal disease after salmonellosis in industrialized countries. It is caused by *Clostridium difficile*, a normal resident of the intestine that is usually present in low numbers. Most instances of this infection are traced to therapy with broad-spectrum drugs such as clindamycin, ceftriaxone, or ciprofloxacin (which is the origin for the older name of the disease, *antibiotic-associated colitis*). It is a major cause of diarrhea in hospitals.

Over the last several years, *Clostridium difficile* infections have become both more common and more severe. In 2013 the CDC estimated 250,000 infections and 14,000 deaths from *C. difficile*, statistics that surpass even those of MRSA infections. Many cases today involve a strain that produces about 20 times the usual amount of exotoxins. This strain is far more likely to be found

outside the hospital and is not always associated with antimicrobial therapy. The use of gastric acid inhibitors such as famotidine (Pepcid) and omeprazole (Prilosec) increase prevalence of the disease, as less gastric acidity may improve survival of the pathogen in the stomach and intestine.

Although *C. difficile* is relatively noninvasive, it can superinfect the colon when the normal microbiota have been disrupted. It produces enterotoxins that trigger necrosis in the wall of the intestine. The predominant symptom is diarrhea commencing late in therapy or even after therapy has stopped. More severe cases exhibit abdominal cramps, fever, and leukocytosis. The colon is inflamed and gradually sloughs off loose, membrane-like patches called *pseudomembranes* consisting of fibrin and cells (**figure 19.8**). If the condition is not arrested, cecal perforation and death can result.

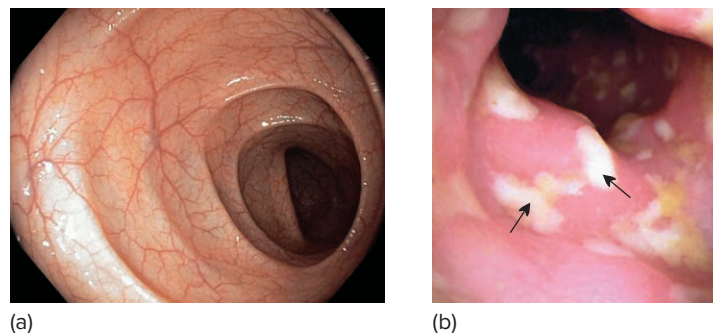

Figure 19.8 Antibiotic-associated colitis as imaged by a sigmoidoscope during colonoscopy. (a) View of a normal colon. Beck, University of Calgary

Pathogen Profile #3 *Clostridium difficile*

Source: CDC

Microscopic Morphology Gram-positive bacilli, present singly or in short chains. Endospores are subterminal and distend the cell, altering its shape.

Identified by Gram reaction and endospore formation. *Clostridium* is differentiated from *Bacillus* as the former is typically a strict anaerobe and the latter is not. ELISA is often used to detect toxins of *C. difficile* in fecal samples.

Habitat Found in small numbers as part of the normal microbiota of the intestine.

Virulence Factors Enterotoxins that cause epithelial necrosis of the colon.

Primary Infections/Disease *Clostridium difficile* infection (CDI) refers to disease caused by the overgrowth of *C. difficile*. Symptoms may range from diarrhea to inflammation of the colon, cecal perforation, and, rarely, death. Although *C. difficile* is ordinarily present in low numbers, treatment with broad-spectrum antibiotics may disrupt the normal microbiota of the colon, leading to a *C. difficile* superinfection.

Control and Treatment Mild cases generally respond to withdrawal of the antibiotic. Severe cases are treated with oral vancomycin or metronidazole, along with probiotics or fecal microbiota transplants to restore the normal microbiota.

Mild, uncomplicated cases respond to withdrawal of antibiotics and replacement therapy for lost fluids and electrolytes. More severe infections are treated with oral vancomycin or metronidazole and replacement cultures to restore normal microbiota. Fecal microbiota transplantation, a procedure in which feces from a healthy donor are transferred via enema, swallowed capsules, or colonoscopy directly to the colon of patients suffering *C. difficile* infection, has gained prominence—though not FDA approval—in recent years. Anecdotal evidence suggests that the technique produces a rapid cure in 80% to 90% of patients, as the transplanted microbiota quickly establishes itself throughout the colon. Because of the potential risks and ethical questions involved in purposefully inoculating a patient with another person's microbiota, federal agencies have been hesitant to oversee the process. In 2016 the FDA began to increase oversight of fecal microbiota transplants, tightening the regulations governing the procedure.

In the clinical setting, stringent precautions are necessary to prevent the spread of the agent from infected persons, who shed large numbers of spores in their feces, to other patients who may be on antimicrobial therapy. Immediate diagnosis is obtained by a rapid ELISA that detects toxins in fecal samples. Work is progressing on a vaccine containing *C. difficile* toxoid for use in high-risk populations.

Clostridial Food Poisoning

Two *Clostridium* species are involved in food poisoning. *Clostridium botulinum* produces a severe intoxication, usually from home-canned food. *Clostridium perfringens*, type A, accounts for a mild intestinal illness that is one of the most common forms of food poisoning worldwide.

Epidemiology of Botulinum Food Poisoning *Clostridium botulinum* is a spore-forming anaerobe that commonly inhabits soil and water and, occasionally, the intestinal tract of animals. It is distributed worldwide but occurs most often in the Northern Hemisphere. The species has eight distinctly different types (designated A, B, C_α and C_β, D, E, F, and G), which vary in distribution among animals, regions of the world, and type of exotoxin produced. Human disease is usually associated with types A, B, E, and F, and animal disease with types A, B, C, D, and E.

Botulism* is an intoxication usually associated with eating improperly canned or poorly preserved foods, though it can occur as a result of infection. Until recent times it was relatively prevalent and commonly fatal, but modern techniques of food preservation and medical treatment have reduced both its incidence and its fatality rate. However, botulism is a common cause of death in livestock that have grazed on contaminated food and in aquatic birds that have eaten decayed vegetation.

There is a high correlation between cultural dietary preferences and food-borne botulism. In the United States, the disease is often associated with low-acid vegetables (green beans, corn) and, occasionally, meats, fish, and dairy products. Most botulism outbreaks occur in home-processed foods, including canned vegetables, smoked meats, and cheese spreads. The demand for prepackaged convenience foods such as vacuum-packed cooked vegetables and meats has created a new risk, but commercially canned foods are only rarely a source of botulism.

One of the most recent outbreaks of botulism traced to a commercial source occurred in 2007 among people who had consumed canned chili sauce. The cans were traced to a food plant that apparently had defects in its sterilization procedures. Due to the potential for additional cases, 90 other food products processed by that plant were recalled and millions of cans removed from stores. Most foods contained peppers, potatoes, or meats. This outbreak was one of the first incidents of commercial botulism in more than a decade, and it emphasized the reality that preventing botulism must always remain a priority for canneries. The constant presence of *C. botulinum* spores in the soil and on produce means that there is zero tolerance for errors in quality control.

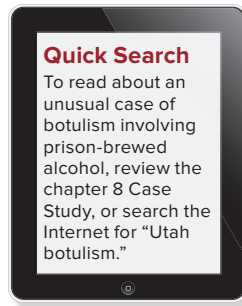

Pathogenesis of Botulism The factors in food processing that lead to botulism depend upon several circumstances. Spores are present on the vegetables or meat at the time of gathering and are difficult to remove by washing alone. When contaminated food is bottled and steamed in a pressure cooker that does not reach reliable pressure and temperature, some spores survive (botulinum spores are highly heat-resistant). At the same time, the pressure is sufficient

* *botulism* (boch's-oo-lizm) *L. botulis*, sausage. The disease was originally linked to spoiled sausage.

to evacuate the air and create anaerobic conditions ideal for spore germination and vegetative growth. One of the products of metabolism is **botulinum toxin**, the most potent microbial toxin known.

Bacterial growth may not be evident in the appearance of the bottle or can or in the food's taste or texture, and only minute amounts of toxin may be present. Swallowed toxin enters the small intestine and is absorbed into the lymphatics and circulation. From there, it travels to its principal site of action, the neuromuscular junctions of skeletal muscles (**figure 19.9**).

Botulinum toxin prevents the release of the neurotransmitter acetylcholine, that initiates the signal for muscle contraction. The usual time before onset of symptoms is 12 to 72 hours, depending on the size of the dose. Neuromuscular symptoms first affect the muscles of the head and include double vision, difficulty in swallowing,

and dizziness, but there is no sensory or mental lapse. Although nausea and vomiting can occur at an early stage, they are not common. Later symptoms are descending muscular paralysis and respiratory failure. In the past, death resulted from stoppage of respiration, but mechanical respirators have reduced the fatality rate to about 10%. A fascinating medical use for targeting unwanted muscle contractions with the toxin is discussed in **19.2 Making Connections**.

Infant and Wound Botulism Food botulism is a result of ingesting botulinum toxin already present in food. By contrast, in infant and wound botulism, *C. botulinum* causes infections when endospores germinate in the body and produce the toxin in vivo.

Infant botulism was first described in the late 1970s in children between the ages of 2 weeks and 6 months who had ingested spores. It is currently the most common type of botulism in the United States, with approximately 80 to 100 cases reported annually. The exact food source is not always known, although raw honey and homemade baby food have been implicated in some cases, while others have been attributed to ingesting small amounts of dust or dirt. Apparently the immature state of the neonatal intestine and resident microbiota allows the spores to gain a foothold, germinate, and produce neurotoxin. As in adults, babies exhibit flaccid paralysis, usually with a weak sucking response, generalized loss of tone ("floppy baby syndrome"), and respiratory complications. Although adults can also ingest botulinum spores in contaminated vegetables and other foods, the adult intestinal tract normally inhibits this sort of infection.

In wound botulism, the spores enter a wound or puncture much as in tetanus, but the symptoms are similar to those of food-borne botulism. Increased cases of this form of botulism are being reported in injecting drug users. The rate of infection is highest in people who inject black tar heroin into the skin.

Treatment and Prevention of Botulism Differentiating botulism from other neuromuscular conditions usually involves testing food samples, intestinal contents, and feces for evidence of toxin or *C. botulinum*. Treatment involves administration of botulinum antitoxin, supplied by the CDC, and which must be administered early for greatest effectiveness. The antitoxin does not reverse the paralysis but does stop its progression and can dramatically shorten the course of the disease. Patients are also managed with intensive respiratory and cardiac support care. Infectious botulism is treated with penicillin to control the microbe's growth and toxin production.

Botulism will always be a potential threat for people who consume home-preserved foods. Preventing it depends on educating the public about the proper methods of preserving and handling canned foods. Pressure cookers should be tested for accuracy in sterilizing, and home canners should be aware of the types of food and conditions likely to cause botulism (see food microbiology in chapter 27). Other effective preventives include addition of preservatives such as sodium nitrite, salt, or vinegar (which lowers pH). Bulging cans or bottles that look or smell spoiled should be discarded, and all home-bottled foods should be boiled for 10 minutes before eating, because the toxin is heat-sensitive and is rapidly inactivated at 100°C.

Clostridial Gastroenteritis *Clostridium perfringens* spores contaminate many kinds of food, but those most frequently involved in disease are animal flesh (meat, fish) and vegetables (beans) that

Figure 19.9 The pathophysiological effects of botulinum toxin. (a) The relationship between the motor neuron and the muscle at the neuromuscular junction. (b) In the normal state, acetylcholine released at the synapse crosses to the muscle and creates an impulse that stimulates muscle contraction. (c) In botulism, the toxin enters the motor end plate and attaches to the presynaptic membrane, where it blocks release of the neurotransmitter, prevents impulse transmission, and keeps the muscle from contracting. This causes flaccid paralysis.

19.2 MAKING CONNECTIONS

Botox: No Wrinkles. No Headaches. No Worries?

In 2015, people paid more than \$2 billion to have one of the most potent toxins on earth injected into their face. The toxin, of course, is botulinum toxin type A, or **Botox**, a medical form of botulism toxin. The story of how these injections came to be the most common cosmetic procedure in the United States is a welcome respite from talk of flesh-eating bacteria and germ warfare.

It has long been known that death from *Clostridium botulinum* intoxication is due to paralysis of the respiratory muscles. In fact, it was even known that botulinum toxin causes death by interfering with the release of acetylcholine, a neurotransmitter that causes the contraction of skeletal muscles. The trick was finding a safe application for this remarkable action.

In 1989 Botox was first approved to treat cross-eyes and uncontrollable blinking, two conditions resulting from the inappropriate contracting of muscles around the eye. Success soon led to Botox treatment for a variety of disorders that cause painful contraction of neck and shoulder muscles. A much wider use of Botox was “off-label”—doctors found that injecting facial muscles with the toxin relaxed these muscles and reduced wrinkling of the overlying skin. The “lunch hour facelift” became so common that it won official FDA approval in 2002. In a surprise twist, patients undergoing Botox treatment for wrinkles reported fewer headaches, especially migraines. After clinical trials found this result to be widespread and reproducible, Botox injections were approved for treating chronic migraines and are now a routine part of therapy.

Is Botox a miracle drug? Not so fast. In the rush to embrace the admittedly dramatic results of Botox injections, most patients have paid scant

Before

After

Effects of Botox. By preventing the transmission of nerve impulses to muscles, botulinum toxin reduces the appearance of wrinkles, as seen here in the lower photograph. Excessive amounts of the toxin or poor positioning of the injections can lead to an inability to raise the eyebrows or eyelids. (both): Courtesy of M. Kayser, MD, F.A.C.S.

attention to potential problems that can arise from the use of a potent paralytic agent. The dominant side effect of Botox treatment is excessive paralysis of facial muscles resulting from poorly targeted injections. Other results include drooping eyelids, facial paralysis, slurred speech, and drooling. Even if the treatment works perfectly, patients are generally unable to move their eyebrows; some become unable to frown or squint. Although most experts agree that Botox is relatively safe, some rare cases of severe reactions and deaths have been reported. Reacting to a spate of adverse events, the FDA in 2009 required all packages of Botox to display a “black box warning”—one of the strongest safety actions the agency can take—informing doctors and consumers of dangers associated with the toxin. This action came as a result of more than 200 incidents in which the toxin spread from the initial injection site and led to symptoms of botulism poisoning. In most of these cases the toxin was being used for unapproved therapies, such as controlling spastic limbs in children suffering from cerebral palsy.

Botox effects are not permanent. As the toxin wears off, the wrinkles (or headaches, as the case may be) return, and every 4 to 6 months the treatment must be repeated. This last fact has been welcomed by plastic surgeons because a permanent solution to wrinkles would rule out any repeat clientele. Malpractice lawsuits are also reduced, because by the time a patient has consulted a lawyer, any consequences of a botched treatment have usually worn off.

Explain why the effects of Botox are short term. *Answer available on Connect.*

have not been cooked thoroughly enough to destroy the spores. When these foods are cooled, spores germinate and the germinated cells multiply, especially if the food is left unrefrigerated. When the food is eaten without adequate reheating, live *C. perfringens* cells enter the small intestine and release enterotoxin. The toxin, acting upon epithelial cells, initiates acute abdominal pain, diarrhea, and nausea in 8 to 16 hours. Recovery is rapid, and deaths are extremely rare. *Clostridium perfringens* also causes enterocolitis similar to that caused by *C. difficile*. This infectious type of diarrhea is acquired from contaminated food, or it may be transmissible by inanimate objects.

Differential Diagnosis of Clostridial Species

Although clostridia are common isolates, their clinical significance is not always immediately evident. Diagnosis frequently depends on the microbial load, the persistence of the isolate on resampling, and the condition of the patient. Laboratory differentiation relies on testing morphological and cultural characteristics, exoenzymes,

carbohydrate fermentation, reaction in milk, and toxin production and pathogenicity. Some laboratories use a sophisticated method of gas chromatography that analyzes the chemical differences among species. Other valuable procedures are direct ELISA testing of isolates, toxicity testing in mice or guinea pigs, serotyping with anti-toxin neutralization tests, and PCR analysis of samples.

- Why are *Bacillus* infections commonly associated with exposure to soil and dust?
- Compare the three common forms of anthrax, and identify people at increased risk for contracting the disease.
- What are the common elements of puncture wounds, crush injuries, and compound fractures that encourage the growth of *Clostridium perfringens*? Explain the rationale for debridement and oxygen therapy for such injuries.

5. What is the relationship between the normal microbiota of the large intestine, antibiotic treatment, and the development of *Clostridium difficile*-associated disease?
6. Botulism is commonly associated with ingestion of specific types of food prepared in a particular manner. What is it about both the food and preparation that encourages infection?
7. Compare the effect of tetanospasmin (tetanus toxin) with the effect of botulinum on muscles.
8. In what way is the ingested agent responsible for adult botulism different from that responsible for infant botulism? Why?

19.3 Gram-Positive Regular Non-Spore-Forming Bacilli

Expected Learning Outcomes

10. Relate the severity of listeriosis with the immunocompetency of its host.
11. Explain why people in certain occupations are at increased risk of becoming infected with *Erysipelothrix rhusiopathiae*.

The non-spore-forming gram-positive bacilli are a mixed group of genera subdivided on the basis of morphology and staining characteristics. One loose aggregate of seven genera is characterized as **regular** because they stain uniformly and do not assume pleomorphic shapes. Regular genera include *Lactobacillus*, *Listeria*, *Erysipelothrix*, *Kurthia*, *Caryophanon*, *Brochothrix*, and *Renibacterium*.

The predominant pathogens in this group are *Listeria monocytogenes* and *Erysipelothrix rhusiopathiae*. *Lactobacillus* is widely distributed in the environment and is a common resident of the intestinal tract and vagina of humans. Some species are also important in processing dairy products. Only rarely are they pathogens.

An Emerging Food-Borne Pathogen: *Listeria monocytogenes*

*Listeria monocytogenes** ranges in morphology from coccobacilli to long filaments in palisades formation. Cells show tumbling motility, with one to four flagella, and do not produce capsules or spores. *Listeria* is not fastidious and is resistant to cold, heat, salt, pH extremes, and bile. The bacterium is an intracellular pathogen during part of its life cycle. It displays a unique multiplication cycle in which it replicates within the cytoplasm of a host cell after inducing its own phagocytosis. By moving directly from cell to cell, *Listeria* is able to avoid the humoral immune system, enhancing its own virulence (**figure 19.10**).

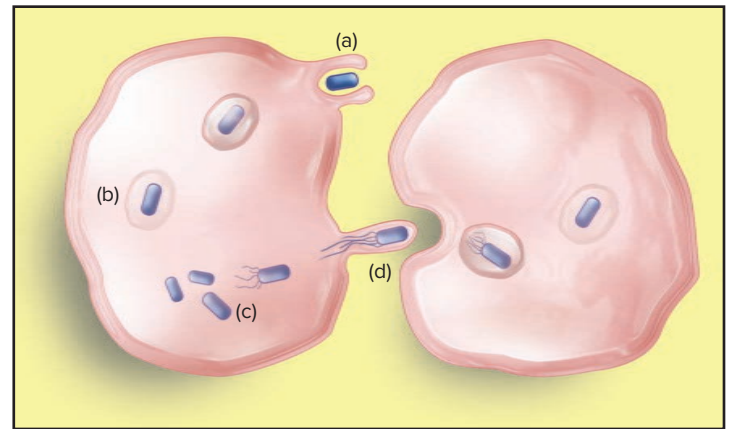

Figure 19.10 Multiplication cycle of *Listeria monocytogenes*. (a) Beginning in the intestinal mucosa, *Listeria monocytogenes* invades cells by inducing its own phagocytosis. (b) Once in the host cell, the bacterium lyses the phagosome in which it is enclosed and multiplies rapidly within the cytoplasm. (c) Mature bacteria develop long proteinaceous tails derived from the actin of the host cell. These propel them from one host cell to the next and (d) facilitate the spread of the pathogen to other cells.

Epidemiology and Pathology of Listeriosis

The distribution of *L. monocytogenes* is so broad that its reservoir has been difficult to determine. It has been isolated all over the world from water, soil, plant materials, and the intestines of healthy mammals (including humans), birds, fish, and invertebrates. Apparently, the primary reservoir is soil and water, whereas animals, plants, and food are secondary sources of infection. Although most cases of **listeriosis** are associated with ingesting contaminated dairy products, poultry, and meat, a highly unusual outbreak in 2011—responsible for 33 deaths and one miscarriage—was linked to contaminated cantaloupes (see this chapter's Case Study). Recent epidemics have spurred an in-depth investigation into the prevalence of *L. monocytogenes* from these sources. The pathogen has been isolated in 12% of ground beef and in 15% of chicken carcasses. It was also present in 6% of luncheon meats, hot dogs, and cheeses. Aged cheeses made from raw milk are of special concern because *Listeria* readily survives through long storage and can grow during refrigeration. Listeriosis is the third most prevalent cause of food-borne fatalities, after salmonellosis and toxoplasmosis.

A predisposing factor in listeriosis seems to be the weakened condition of host defenses in the intestinal mucosa, because studies have shown that immunocompetent individuals are rather resistant to infection. Listeriosis in normal adults is often a mild or subclinical infection with nonspecific symptoms of fever, diarrhea, and sore throat. However, listeriosis in immunocompromised patients, fetuses, and neonates usually affects the brain and meninges and results in septicemia. The death rate is around 20% due to the pathogen's virulence. Pregnant women are especially susceptible to infection, which is transmitted to the infant prenatally when the microbe crosses the placenta or perinatally through the birth canal. Intrauterine infections are systemic and usually result in miscarriage and fetal death. Neonatal infections that localize in the meninges cause extensive damage to the nervous system if not treated at an early stage.

Pathogen Profile #4 *Listeria monocytogenes*

Source: CDC

Microscopic Morphology Gram-positive bacilli, typically found singly or in short chains.

Identified by Gram reaction, type of motility, hemolysis, and CAMP reaction. Cold enrichment helps improve isolation but is time-consuming. Assays dependent on DNA analysis or ELISA are available for rapid identification.

Habitat Very widespread; the primary reservoir is soil and water, and secondary sources of infection include animals, plants, and food. Most cases are associated with contaminated dairy products, poultry, and meat.

Virulence Factors *L. monocytogenes* replicates within the cytoplasm of a host cell after inducing its own phagocytosis. By moving directly

from cell to cell, the bacterium avoids the humoral immune system, enhancing its own virulence.

Primary Infections/Disease Listeriosis is often mild or subclinical in immunocompetent adults but may affect the brain and meninges of immunodeficient patients. Pregnant women are highly susceptible to infection and may pass the bacterium to the fetus across the placenta or during birth, commonly resulting in fetal death or severe damage to the nervous system.

Control and Treatment Control of *L. monocytogenes* centers on pasteurization and adequate cooking of foods that may be contaminated with animal feces. Recommended drugs include ampicillin/gentamicin and trimethoprim/sulfamethoxazole.

**Diagnosis and Control of Listeriosis**

Diagnosing listeriosis can be delayed by difficulties in isolating the pathogen. Isolation can be improved by using a procedure called cold enrichment, in which the specimen is held at 4°C and periodically plated onto media, but this procedure can take 4 weeks. *Listeria monocytogenes* can be differentiated from the nonpathogenic *Listeria* and from other bacteria to which it bears a superficial resemblance by comparing traits such as cell shape, arrangement, motility, production of catalase, and positive CAMP reaction. Rapid diagnostic kits using ELISA, immunofluorescence, and DNA analysis are now available for direct testing of foods.

Antibiotic therapy should be started as soon as listeriosis is suspected. Ampicillin and gentamicin are the first choices, followed by trimethoprim/sulfamethoxazole. Prevention can be improved by adequate pasteurization temperatures and by cooking foods that could be contaminated with animal feces. The U.S. Department of Agriculture implemented regulations designed to prevent the incorporation of *Listeria* into processed meat and poultry products. Under these rules, companies that use less stringent methods of microbial control will be subject to more frequent government testing, while those employing more effective strategies will be subject to fewer inspections.

Erysipelothrix rhusiopathiae: A Zoonotic Pathogen**Epidemiology, Pathogenesis, and Control**

*Erysipelothrix rhusiopathiae** is a gram-positive rod widely distributed in animals and the environment. Its primary reservoir appears to be the tonsils of healthy pigs. It is also a normal microbiota of other vertebrates and is commonly isolated from sheep, chickens, and fish. It can persist for long periods in sewage, seawater, soils, and foods. The pathogen causes epidemics of swine erysipelas and sporadic infections in other domestic and wild animals.

**Figure 19.11** Erysipeloid on the hand of an animal handler.

© DermNet New Zealand Trust

Humans at greatest risk for infection are those who handle animals, carcasses, and meats, such as slaughterhouse workers, butchers, veterinarians, farmers, and fishermen.

The common portal of entry in human infections is a scratch or abrasion on the hand or arm. The microbe multiplies at the invasion site to produce a disease known as **erysipeloid**, characterized by inflamed, dark red lesions that burn and itch (**figure 19.11**). Although the lesions usually heal without complications, rare cases of septicemia and endocarditis do arise. Inflamed red sores on the hands of people in high-risk occupations suggest erysipeloid, but the lesions must be cultured for confirmatory diagnosis. The condition is treated with penicillin or erythromycin. Swine erysipelas can be prevented by vaccinating pigs, but the vaccine does not protect humans. Animal handlers can lower their risk by wearing protective gloves.

19.4 Gram-Positive Irregular Non-Spore-Forming Bacilli

Expected Learning Outcomes

12. Relate the stages of diphtherial disease to infection and metabolism of its infectious agent.
13. Outline methods for the detection, prevention, and treatment of diphtheria.

The **irregular** non-spore-forming bacilli tend to be pleomorphic and to stain unevenly. Of the 20 genera in this category, *Corynebacterium*, *Mycobacterium*, and *Nocardia* have the greatest clinical significance. These three genera are grouped together because of similar morphological, genetic, and biochemical traits. They produce catalase and possess mycolic acids and a unique type of peptidoglycan in the cell wall. The following sections discuss the primary diseases associated with *Corynebacterium*, a similar genus called *Propionibacterium*, *Mycobacterium*, *Actinomyces*, and *Nocardia*.

Corynebacterium diphtheriae

Although several species of *Corynebacterium** are found on the human body, most human disease is associated with *C. diphtheriae*. In general morphology, this bacterium is a straight or somewhat curved rod that tapers at the ends, but it has many pleomorphic variants, including club, filamentous, and swollen shapes. Older cells are filled with metachromatic (polyphosphate) granules and can occur in side-by-side palisades arrangement (figure 19.12).

Epidemiology of Diphtheria

For hundreds of years, **diphtheria*** was a significant cause of morbidity and mortality, but for more than five decades, both the number of

* *Corynebacterium* (kor-eye'-nee-bakter's-ee-um) Gr. *koryne*, club, and *bakterion*, little rod.

* *diphtheriae* (dif-thee'-ree-ah) Gr. *diphthera*, membrane.

Figure 19.12 *Corynebacterium diphtheriae*. A photomicrograph of *Corynebacterium diphtheriae*, showing pleomorphism and palisades arrangement (1200X). Source: CDC

cases and the fatality rate have steadily declined throughout the world. The current rate for the entire United States is 0.01 cases per million population with the last confirmed case seen in 2003. Recent outbreaks of the cutaneous form of the disease have occurred among Native American populations and the homeless. Because many populations harbor a reservoir of healthy carriers, the potential for diphtheria is constantly present. Most cases occur in nonimmunized children from 1 to 10 years of age living in crowded, unsanitary situations.

Pathology of Diphtheria

Exposure to the diphtheria bacillus usually results from close contact with the droplets from human carriers or active infections and occasionally with fomites or contaminated milk. The clinical disease proceeds in two stages: (1) local infection by *Corynebacterium diphtheriae* and (2) toxin production and toxemia. The most common location of primary infection is in the upper respiratory tract (tonsils, pharynx, larynx, and trachea). *Cutaneous diphtheria* usually starts as a secondary infection manifesting as deep, erosive ulcers that are slow to heal (figure 19.13a). The bacterium becomes established by means

(a)

(b)

Figure 19.13 Clinical aspects of diphtheria. (a) Cutaneous diphtheria appears as a deep erosive ulcer that is slow to heal. (b) Respiratory diphtheria includes gross inflammation of the pharynx and tonsils marked by grayish patches (a pseudomembrane) and swelling over the entire area. (a): Source: CDC; (b): © Mediscan/Alamy Stock Photo

of virulence factors that assist in its attachment and growth. The cells are not ordinarily invasive and usually remain localized at the portal of entry. This form of the disease is on the rise in the United States.

Diphtherotoxin and Toxemia Although infection is necessary for disease, the cardinal determinant of pathogenicity is the production of **diphtherotoxin**. The ability of some *C. diphtheriae* strains to produce toxin is the result of infection with a lysogenic bacteriophage that carries the genes for the toxin. This cytotoxin consists of two polypeptide fragments. Fragment B binds to and is endocytosed by mammalian target cells in the heart and nervous system. Fragment A interacts metabolically with factors in the cytoplasm and arrests protein synthesis (see figure 13.13).

The toxin affects the body on two levels. The local infection produces an inflammatory reaction, sore throat, nausea, vomiting, enlarged cervical lymph nodes, severe swelling in the neck, and fever. One life-threatening complication is the **pseudomembrane**, a greenish-gray film that develops in the pharynx from the solidification of fluid expressed during inflammation (**figure 19.13b**). The pseudomembrane is so leathery and tenacious that attempts to pull it away result in bleeding; and if it forms in the airways, it can cause asphyxiation.

The most dangerous systemic complication is **toxemia**, which occurs when the toxin is absorbed from the throat and carried by the blood to certain target organs, primarily the heart and nerves. The action of the toxin on the heart causes myocarditis and abnormal EKG patterns. Cranial and peripheral nerve involvement can cause muscle weakness and paralysis. Although toxic effects are usually reversible, patients with inadequate treatment often die from asphyxiation, respiratory complications, or heart damage.

Diagnostic Methods for *Corynebacterium*

Diphtheria has such great potential for harm that often the physician must make a presumptive diagnosis and begin treatment before the bacteriologic analysis is complete. A gray membrane and swelling in the throat are somewhat indicative of diphtheria, although several diseases present a similar appearance. Epidemiological factors such as living conditions, travel history, and immunologic history (a positive Schick test) can also aid in initial diagnosis.

A simple stain of *C. diphtheriae* isolates with alkaline methylene blue reveals pleomorphic granulated cells. Other methods include the Elek test, an assay that relies on antibodies to detect toxins, as well as amplification of specific DNA sequences specific to *C. diphtheriae*. It is important to differentiate *C. diphtheriae* from “diphtheroids”—similar species often present in clinical materials that are not primary pathogens. *Corynebacterium xerosis** normally lives in the eye, skin, and mucous membranes and is an occasional opportunist in eye and postoperative infections. *Corynebacterium pseudodiphtheriticum*,* a normal inhabitant of the human nasopharynx, can colonize natural and artificial heart valves.

Treatment and Prevention of Diphtheria

The adverse effects of toxemia are treated with diphtheria antitoxin (DAT) derived from horses. Prior to injection, the patient must be

tested for allergy to horse serum and be desensitized, if necessary. The infection is treated with antibiotics from the penicillin or erythromycin family. Bed rest, heart medication, and tracheostomy or bronchoscopy to remove the pseudomembrane may be indicated. Diphtheria can be easily prevented by a series of vaccinations with toxoid, usually given as part of a mixed vaccine against tetanus and pertussis (DTaP). Five vaccines are recommended for children under 7 years of age beginning at age 2 months, with boosters at 4 months, 6 months, 15 to 18 months, and 4 to 6 years. Children from ages 7 to 18 and adults who are not immune to the toxin can be immunized with two doses of tetanus, diphtheria, and pertussis (Tdap) vaccine.

The Genus *Propionibacterium*

*Propionibacterium** resembles *Corynebacterium* in morphology and arrangement, but it differs by being aerotolerant or anaerobic and nontoxigenic. The most prominent species is *P. acnes*,* a common resident of the **pilosebaceous*** glands of human skin and occasionally the upper respiratory tract. The primary importance of this bacterium is its relationship with the familiar acne vulgaris lesions of adolescence. Acne is a complex disease influenced by genetic and hormonal factors as well as by the structure of the epidermis, but it is also an infection. *Propionibacterium* is occasionally involved in infections of the eye and artificial joints.

19.5 Mycobacteria: Acid-Fast Bacilli

Expected Learning Outcomes

14. Compare the clinical manifestations of tuberculosis at different stages of the disease.
15. Understand how tuberculosis is detected and treated.
16. Contrast the two forms of leprosy.
17. Relate the effect of *M. leprae* to the physical manifestation of the disease.
18. Explain the significance of nontuberculous mycobacterial diseases.

The genus *Mycobacterium** is distinguished by its complex layered structure containing high-molecular-weight mycolic acids and waxes. The high lipid content of the cell wall imparts the characteristic of **acid-fastness** and is responsible for the resistance of the group to

* *Propionibacterium* (pro'-pee-on'-ee-bak-tee's-ree-um) Gr. *pro*, before, *prion*, fat, and *bacterion*, little rod. Named for its ability to produce propionic acid.

* *acnes* (ak's-nee-z) Gr. *akme*, a point. (The original translators incorrectly changed an *m* to an *n*.)

* *pilosebaceous* (py'-loh-see-bay's-shus) L. *pilus*, hair, and *sebaceous*, tallow.

* *Mycobacterium* (my'-koh-bak-tee's-ree-um) Gr. *myces*, fungus, and *bakterion*, little rod.

* *xerosis* (zee-roh's-sis) Gr. *xerosis*, parched skin.

* *pseudodiphtheriticum* (soo'-doh-dif-ther-it's-ih-kum) Gr. *pseudes*, false, and *diphtheriticus*, of diphtheria.

drying, acids, and various germicides. The cells of mycobacteria are long, slender, straight, or curved rods with a slight tendency to be filamentous or branching (**figure 19.14**). Although they usually contain granules and vacuoles, they do not form capsules, flagella, or spores.

Most mycobacteria are strict aerobes that grow well on simple nutrients and media. Compared with other bacteria, the growth rate is generally slow, with generation times ranging from 2 hours to several days. Some members of the genus exhibit colonies containing yellow, orange, or pink carotenoid pigments that require light for development; others are nonpigmented. Many of the 50 mycobacterial species are saprobes living free in soil and water, and several are highly significant human pathogens. Worldwide, hundreds of millions of people are afflicted with tuberculosis and leprosy. Certain opportunistic species loosely grouped into a category called NTM (nontuberculous mycobacteria) have become an increasing problem in immunosuppressed patients.

Mycobacterium tuberculosis: The Tubercle Bacillus

The **tubercle*** bacillus is a long, thin rod that grows in sinuous masses or strands called cords. Unlike many pathogens, it produces no exotoxins or enzymes that contribute to infectiousness. Most strains contain complex waxes and a cord factor (**figure 19.15**) that contribute to virulence by preventing the mycobacteria from being destroyed by the lysosomes of macrophages. Their survival contributes to further invasion and persistence as intracellular parasites.

Epidemiology and Transmission of Tuberculosis

Mummies from the Stone Age, ancient Egypt, and Peru provide unmistakable evidence that tuberculosis (TB) is an ancient human disease. In fact, it was such a prevalent cause of death that it was called “Captain of the Men of Death” and “White Plague.”

Tuberculosis is an extraordinarily complex disease exerting profound effects on the health and economy of much of the world’s population. People in developing countries are often infected as

(a)

(b)

Figure 19.15 Diagnosing tuberculosis. (a) The cultural appearance of *Mycobacterium tuberculosis*. Colonies with a typical granular, waxy pattern of growth. (b) Cord formation in infected tissue. Strands are elongate, massed filaments of TB bacilli. Note that they have stained red, denoting acid-fastness. infants and harbor the microbe for many years until the disease is reactivated in young adulthood. Estimates indicate that possibly one-third of the world’s population and 15 million people in the United States carry the TB bacillus.

Cases in the United States show a strong correlation with the age, sex, and recent immigration history of the patient. The highest case rates occur in people over 65 years of age, as well as in new immigrant populations from certain areas of Southeast Asia, Latin America, and Africa and in AIDS patients. For recent trends in the epidemiology of tuberculosis, see **19.3 Making Connections**.

The agent of tuberculosis is transmitted almost exclusively by fine droplets of respiratory mucus suspended in the air. The tubercle bacillus is very resistant and can survive for 8 months in fine aerosol particles. Although larger particles become trapped in the mucus and expelled, tinier ones can be inhaled into the bronchioles and alveoli. This effect is especially pronounced among people sharing closed, small rooms with limited access to sunlight and fresh air. Factors that significantly affect a person’s susceptibility to

* *tubercle* (too’s-ber-kul) *L. tuberculum*, a swelling or knob.

19.3 MAKING CONNECTIONS

The Threat from Tuberculosis

After 80 years of decline, a tiny wax-coated bacillus that hides in human lungs has re-emerged as a serious threat to the world's health. The hope for eradicating tuberculosis is becoming an unlikely prospect in parts of Africa, Southeast Asia, and Latin America. A new infection occurs somewhere in the world every second, and at least 2 billion people have been exposed to it. With 1.4 million deaths per year, TB is second only to AIDS as a cause of death.

The United States has fared somewhat better. After a sharp increase in reported tuberculosis cases due in no small measure to the spread of HIV, reported cases declined steadily. There were 9,421 reported cases of TB in the United States in 2014—the last year for which complete statistics are available—a 1.5% reduction compared to 2013. In spite of these encouraging numbers, complacency must be avoided like the proverbial plague, as many of the underlying conditions that led to the reemergence of tuberculosis still exist.

One especially troubling trend both worldwide and in the United States has been the increasing proportion of *Mycobacterium tuberculosis* infections resistant to the first-line drugs isoniazid and rifampin. These multidrug-resistant tuberculosis (MDR-TB) cases required treatment with second-line drugs that were less effective, more toxic, and costlier. Continuing this trend, we are now seeing a rise of extensively drug-resistant TB (XDR-TB) infections, which are defined as MDR TB plus resistance to any fluoroquinolone and to any of the three second-line injectable drugs (i.e., amikacin, kanamycin, capreomycin). Data from the World Health Organization indicate that 9.7% of patients with MDR-TB have XDR-TB.

Major factors contributing to new TB cases in the United States come from immigration, drug addiction, the HIV epidemic, reduced government support of TB programs, and homelessness. In 2014, 66% of reported cases

Source: CDC

occurred in foreign-born residents. These populations are less likely to have access to good medical care and to comply with the necessarily long course of therapy. Fully one-fifth of cases occur in AIDS patients. The mortality rate in this group is very high: Up to 80% die within 16 weeks of diagnosis.

The lack of well-funded TB control programs has contributed to the epidemic by discontinuing low-cost treatments, limiting surveillance, and not following up on treatment regimens. Experts at the CDC believe that patients with active TB who do not follow their treatment regimen are a breeding ground for many of the resistant strains of TB seen today. Implementation of a program of directly observed therapy (DOT), wherein health care workers visit each patient to observe the actual ingestion of each day's medication, has greatly contributed to the decrease in case rates, because it ensures that drugs are taken according to the correct schedule. At-home treatment also saves money, because hospitalization for TB patients can cost thousands of dollars even for a few days of care.

Suggest reasons TB is more prevalent among the homeless, drug addicts, and AIDS patients. Answer available on Connect.

tuberculosis are inadequate nutrition, debilitation of the immune system, poor access to medical care, lung damage, and genetics.

The Course of Infection and Disease

A clear-cut distinction can be made between infection with the tubercle bacillus and the disease it causes. In general, humans are rather easily infected with the bacillus but are resistant to the disease. Estimates project that only about 5% to 10% of infected people actually develop a clinical case of tuberculosis. Untreated tuberculosis progresses slowly and is capable of lasting a lifetime, with periods of health alternating with episodes of morbidity. The majority (85%) of TB cases are contained in the lungs, even though disseminated tubercle bacilli can give rise to tuberculosis in any organ of the body. The major clinical manifestations are primary tuberculosis, latent (reactivation) tuberculosis, and disseminated (extrapulmonary) tuberculosis, covered in the following sections and **figure 19.16a**.

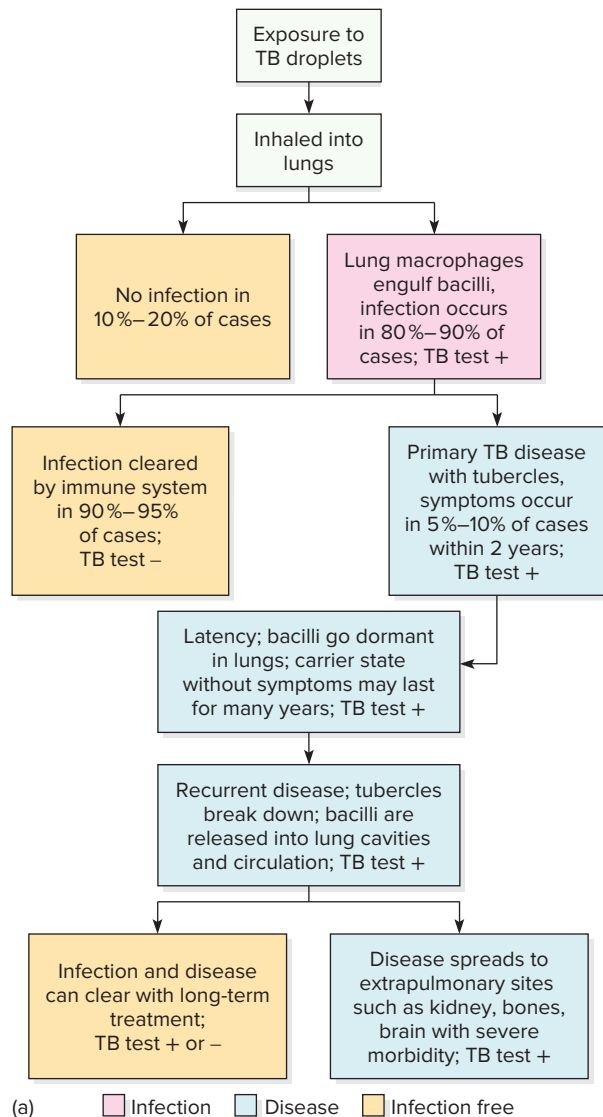

Initial Infection and Primary Tuberculosis The minimum infectious dose for lung infection is around 10 cells. As part of the body's

immune response the bacilli are phagocytosed by alveolar macrophages where they multiply intracellularly. This period of hidden infection is asymptomatic or accompanied by mild fever, but some cells escape from the lungs into the blood and lymphatics. After 3 to 4 weeks, the immune system mounts a complex, cell-mediated assault against the bacilli. The large influx of mononuclear cells into the lungs plays a part in the formation of specific infection sites called **tubercles**. Tubercles are granulomas with a central core containing TB bacilli and enlarged macrophages, and an outer wall made of fibroblasts, lymphocytes, and neutrophils (**figure 19.16b**). Although this response further checks spread of infection and helps prevent the disease, it also carries a potential for lung damage. Frequently, the centers of tubercles break down into necrotic, **caseous***

(b)

lesions that gradually heal by calcification when lung tissue is replaced by calcium deposits. The response of T cells to *M. tuberculosis* proteins also causes a cell-mediated immune response evident in the **tuberculin reaction** used in diagnosis and epidemiology (**figure 19.17**).

Latent and Recurrent Tuberculosis Although the majority of TB patients recover more or less completely from the primary infection or disease, live bacilli can remain latent and become reactivated weeks, months, or years later, especially in people with weakened immunity. In reactivated tuberculosis, tubercles filled with masses of bacilli expand and drain into the bronchial tubes and upper respiratory tract. Gradually, the patient experiences more severe symptoms, including violent coughing, greenish or bloody sputum, low-grade fever, anorexia, weight loss, extreme fatigue, night sweats, and chest pain. It is the gradual wasting of the body that accounts for an older name for tuberculosis—*consumption*. Untreated reactivated disease has nearly a 60% mortality rate.

Extrapulmonary Tuberculosis During the course of reactivated TB, the bacilli disseminate rapidly to sites other than the lungs. Organs most commonly involved in **extrapulmonary TB** are the regional lymph nodes, kidneys, long bones, genital tract, brain, and meninges. Because of the debilitation of the patient and the high load of tubercle bacilli, these complications are usually grave.

Renal tuberculosis results in necrosis and scarring of the renal medulla and the pelvis, ureters, and bladder. Genital TB often damages the reproductive organs in both sexes. Tuberculosis of the bone and joints is a common complication. The spine is a frequent site of infection, though the hip, knee, wrist, and elbow can also be involved. Degenerative changes can collapse the vertebrae, resulting in abnormal curvature of the thoracic or lumbar regions. Neurological damage stemming from compression on nerves can cause extensive paralysis and sensory loss.

Tubercular meningitis is the result of an active brain lesion seeding bacilli into the meninges. Over a period of several weeks, the infection of the cranial compartment can create mental deterioration, permanent retardation, blindness, and deafness. Untreated tubercular meningitis is invariably fatal, and even treated cases can have a 30% to 50% mortality rate.

Clinical Methods of Detecting Tuberculosis

Clinical diagnosis of tuberculosis traditionally includes some combination of these techniques:

1. tuberculin or immunologic testing,
2. radiography (X rays) of the chest,
3. direct identification of acid-fast bacilli (AFB) in sputum or some other specimen, and
4. cultural isolation and identification.

Figure 19.16 Features of tuberculosis. (a) The staging of tuberculosis from initial contact to infection, latency, and disease. Disease is the result of chronic infection and does not occur with every infected person. With proper treatment, all stages may be controlled and cured. Infection and disease may induce a permanent positive reaction to the tuberculin test. (b) Section of a tubercle shows how the granuloma infiltrate has set up a dense collar of fibroblasts, lymphocytes, and epithelioid cells. The core of this tubercle is a caseous (cheesy) material containing the bacilli.

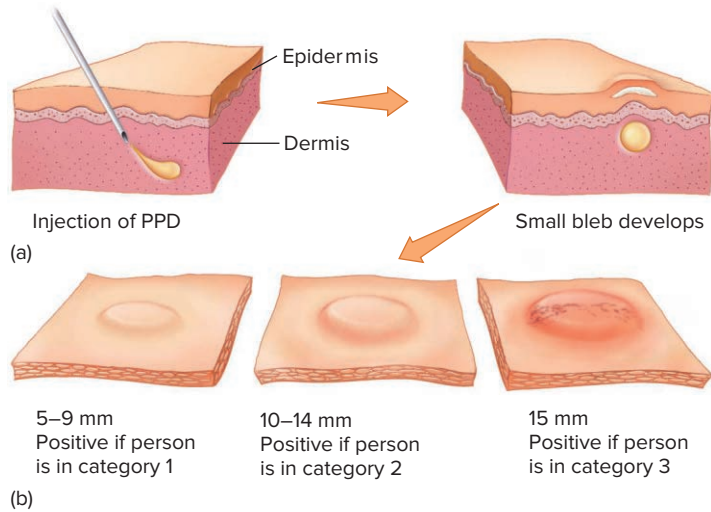

Figure 19.17 Skin testing for tuberculosis. (a) The Mantoux test. Tuberculin is injected into the dermis. A small bleb from the injected fluid develops but will be absorbed in a short time. (b) After 48 to 72 hours, the skin reaction (induration) is rated by its degree (or size). A reaction of less than 5 mm is negative in all cases. (c) Category 3 positive Mantoux test. Measurement is made only across the raised area and does not include the reddened margin.

Final diagnosis of overt or latent TB cannot be made on a single test alone but requires an overall medical evaluation.

Tuberculin Sensitivity and Testing Because infection with the TB bacillus can lead to delayed hypersensitivity to tuberculo-proteins, testing for hypersensitivity has been an important way to screen populations for tuberculosis infection. The tuberculin test, called the **Mantoux test**, involves local injection of tuberculin, a purified protein derivative (PPD), taken from culture fluids of *M. tuberculosis*. The injection is done intradermally into the forearm to produce an immediate small bleb. After 48 and 72 hours, the site is observed for a red wheal called an **induration**, which is measured and classified according to size (figure 19.17).

The current practices for interpreting tuberculin tests are focused on selected groups known to have higher risk for tuberculosis. It is no longer a routine screening method among populations of children or adults who are not within the target groups. The reasoning behind this change is to allow more focused screening and to reduce expensive and unnecessary follow-up tests and treatments. Guidelines for test groups and methods of interpreting tests are listed in the following summary.

Category 1. Induration (skin reaction) that is equal to or greater than 5 mm is classified as positive in persons who

- Have had contact with actively infected TB patients
- Are HIV positive
- Have past history of tuberculosis as determined through chest X rays
- Are organ transplant recipients
- Are immunosuppressed for other reasons

Category 2. Induration that is equal to or greater than 10 mm is classified as positive in persons who are not in category 1 but who fit the following high-risk groups:

- HIV-negative intravenous drug users
- Persons with medical conditions that put them at risk for progressing from latent TB infection to active TB
- Persons who live or work in high-risk residences
- New immigrants from countries with high rates of TB
- Children who have contact with members of high-risk adult populations
- Mycobacteriology laboratory personnel

Category 3. Induration that is equal to or greater than 15 mm is classified as positive in persons who do not meet criteria in categories 1 or 2.

A positive reaction in a person from one of the categories is fairly reliable evidence of recent infection or a latent infection, but a diagnosis of TB should not be made based on this result alone. Vaccination with the tuberculosis vaccine (BCG) can also cause a TB positive result, so clinicians must weigh a patient's history, especially among individuals who have immigrated from countries where the vaccine is routinely given. Another cause of a false positive reaction is the presence of an infection with a closely related species of *Mycobacterium*.

A negative skin test usually indicates that ongoing TB infection is not present. In some cases, it may be a false negative, meaning that the person is infected but is not yet reactive. One cause of a false negative test may be that it is administered too early in the infection, requiring retesting at a later time. Subgroups with severely compromised immune systems, such as those with AIDS, advanced age, and chronic disease, may be unable to mount a reaction even though they are infected. Skin testing may not be a reliable diagnostic indicator in these populations.

The In Vitro TB Test

The CDC has accepted two new tests for aiding in TB diagnosis and ruling out most false positives. Both the QuantiFERON-TB Gold test and the T-SPOT TB test are indirect methods of detecting infection based on a blood test. A fresh sample of blood is incubated with synthetic *M. tuberculosis* proteins for about a day. If the blood contains lymphocytes with a prior sensitivity to the tuberculo-proteins, the cells will release interferon gamma. The amount of this substance can be measured by machine. The advantage to this test is that it is rapid, it is easy to read, it does not sensitize the patient to TB (which tuberculin can do), and it is not affected by prior BCG vaccination. This will make it particularly useful in ruling out TB in immigrants who have been vaccinated.

Radiography and Tuberculosis Chest X rays may be suggestive of—but are never diagnostic of—TB. They may, however, be used to rule out the possibility of pulmonary TB in a person who has a positive reaction to the tuberculin skin test and no symptoms of disease. X-ray films reveal abnormal radiopaque patches whose appearance and location can be very indicative. Primary tubercular infection presents the appearance of fine areas of infiltration and enlarged lymph nodes in the lower and central areas of the lungs. Secondary tuberculosis films show more extensive infiltration in the upper lungs and bronchi and marked tubercles (figure 19.18). Scars from older infections often show up on X rays and can furnish a basis for comparison with which to identify newly active disease.

Acid-Fast Staining Acid-fast staining of sputum or other specimens may be used to detect *Mycobacterium*, with several variations of the technique currently in use. The Ziehl-Neelsen stain produces bright red acid-fast bacilli (AFB) against a blue background. Fluorescence staining shows luminescent yellow-green bacilli against a dark background (figure 19.19). The fluorescent acid-fast stain is becoming the method of choice because it is easier to read and provides a more striking contrast.

Laboratory Cultivation and Identification *Mycobacterium tuberculosis* infection is most accurately diagnosed by isolating and

Figure 19.18 X ray of a secondary tubercular infection shows dozens of tubercles and cavities throughout the lung.

Figure 19.19 A fluorescent acid-fast stain of *Mycobacterium tuberculosis* from sputum. Using this technique, a cluster of mycobacterial cells fluoresces bright yellow under ultraviolet light. Smears are evaluated in terms of the number of AFB seen per field. This quantity is then applied to a scale ranging from 0 to 4+, 0 being no AFB observed and 4+ being more than 9 AFB per field.

Source: CDC

identifying the causative agent in pure culture. Because of the specialized expertise and technology required, this is not done by most clinical laboratories as a general rule. In the United States, the handling of specimens and cultures suspected of containing the pathogen is strictly regulated by federal laws.

Diagnosis that differentiates between *M. tuberculosis* and other mycobacteria must be accomplished as rapidly as possible so that appropriate treatment and isolation precautions can be instituted. Cultures are incubated under varying temperature and lighting conditions to clarify thermal and pigmentation characteristics and are then observed for signs of growth. Several newer cultivation schemes have shortened the time to several days instead of the 6 to 8 weeks once necessary. Other identification techniques use DNA probes to detect specific genetic markers and can confirm positive specimens early in the infection. Rapid diagnosis is particularly important for public health and treatment considerations.

Management and Prevention of Tuberculosis

Treatment of TB involves administering drugs for a sufficient period of time to kill the bacilli in the lungs, organs, and macrophages, usually 6 to 9 months in uncomplicated cases (but as long as 24 months in more complex infections). Because many strains of *M. tuberculosis* are resistant to at least one of the drugs commonly used for treatment, the most commonly followed anti-TB chemotherapeutic regimen begins with an initial phase of four drugs—isoniazid (INH), rifampin (RIF), ethambutol (EMB), and pyrazinamide (PZA)—taken daily for eight weeks. After this, a continuation phase involves daily doses of INH and RIF for 18 weeks. At this point treatment is generally deemed completed, although modifications are made in some circumstances (HIV infection, drug resistance, pregnancy, or the treatment of children for example). A one-pill regimen called *Rifater* combines isoniazid, rifampin, and pyrazinamide, and may be supplemented with ethambutol if needed. The simplicity of the one pill regimen increases the rate of patient compliance, a common problem with anti-TB therapy. In 2012 the first new drug in 40 years—bedaquiline (Sirturo)—was introduced primarily for cases of multi- and extensively-drug-resistant

Pathogen Profile #5 *Mycobacterium tuberculosis*

Source: Janice Carr/CDC

Microscopic Morphology Acid-fast rods, often present as long, enmeshed filaments of cells.

Identified by Acid-fast reaction, morphology, biochemical testing, and DNA tests. Infection with *M. tuberculosis* is usually inferred through some combination of tuberculin and serological testing, X rays, and laboratory tests.

Habitat Humans are the primary habitat, with over 15 million people in the United States and 2 billion worldwide carrying the pathogen.

Virulence Factors The acid-fast cell wall of *M. tuberculosis* provides it with protection against lysozyme and many antibacterial agents. Resistance to drying and a very low infectious dose (10 cells) facilitate infection, while resistance to multiple drugs makes antibiotic therapy challenging. Cord factor is responsible for the long strands of cells often seen upon examination and is correlated with increased virulence.

Primary Infections/Disease Primary tuberculosis manifests as tubercles within the lungs and may be marked only by mild fever. In recurrent tuberculosis, bacilli within the tubercles drain into the bronchi and upper respiratory tract. Symptoms gradually become worse, with the patient experiencing violent coughing, green or bloody sputum, low-grade fever, anorexia, weight loss, fatigue, night sweats, and chest pain. Untreated reactivated disease has a 60% mortality rate. Extrapulmonary tuberculosis occurs when the bacterium disseminates to sites other than the lungs, most commonly lymph nodes, kidneys, long bones, genital tract, brain, and meninges. Prognosis is exceedingly poor at this point.

Control and Treatment Control of *M. tuberculosis* relies on early detection of those infected or at risk of becoming infected. Treatment consists of multidrug therapy lasting from 6 to 24 months. Although the BCG vaccine is available, because of the low incidence of TB in the United States and the vaccine's relative ineffectiveness, it is only recommended for certain health professionals and military personnel.

tuberculosis. Clinicians expect it to significantly reduce the spread of these dangerous strains of TB, but severe side effects limit its use to those instances where no other drug combination is effective. When evaluating the effectiveness of chemotherapy, the presence of a negative culture or a gradual decrease in the number of AFB on a smear indicates success. However, a cure will not occur if the patient does not comply with drug protocols, which accounts for many relapses.

Although it is essential to identify and treat people with active TB, it is equally important to seek out and treat those in the early stages of infection or at high risk of becoming infected. Treatment groups are divided into tuberculin-positive “converters,” who appear to have a latent infection, and tuberculin-negative people in high-risk groups such as the contacts of tubercular patients. The standard treatment is a daily dose of INH for 9 months or RIF for 4 months. An equally effective, and far simpler, treatment for patients who fit a specific criteria is a single dose of INH and rifapentine (RPT) once weekly for 12 weeks. This treatment is recommended for patients older than 12 years who are not receiving antiretroviral treatment for HIV, not infected with a resistant strain of *M. tuberculosis*, and not pregnant or planning to become pregnant during the course of treatment. In the hospital, the use of UV lamps in air-conditioning systems and negative pressure rooms to isolate TB patients can help control the spread of infection.

A vaccine based on the attenuated “bacille Calmette-Guérin” (BCG) strain of *M. bovis* is often given to children in countries that have high rates of tuberculosis. Studies have shown that the success rate of vaccinations is around 80% in children and less than that (20% to 50%) in adults. The length of protection varies from 5 to 15 years. Because the United States does not have as high an incidence as other countries, BCG vaccination is not generally recommended except among certain health professionals and military personnel who may be exposed to TB carriers. Vaccine trials using an attenuated strain of *M. tuberculosis* are currently under way.

Mycobacterium leprae: The Leprosy Bacillus

Mycobacterium leprae, the cause of leprosy, was first detected by a Norwegian physician named Gerhard Hansen, and it is sometimes called the Hansen bacillus in his honor. The general morphology and staining characteristics of the leprosy bacillus are similar to those of other mycobacteria, but it is exceptional in two ways: (1) It is a strict parasite that has not been grown in artificial media or human tissue cultures, and (2) it is the slowest growing of all the species. *Mycobacterium leprae* multiplies within host cells in large packets called globi at an optimum temperature of 30°C. *Mycobacterium lepromatosis*, a species first described in 2008, is thought to be responsible for a few cases of a unique form of leprosy endemic to Mexico.

Leprosy* is a chronic, progressive disease of the skin and nerves known for its extensive medical and cultural ramifications. From ancient times, leprosy victims were stigmatized because of their severe disfigurement and the belief that leprosy was a divine curse. As if the torture of the disease were not enough, leprosy patients once suffered terrible brutalities, including imprisonment under the most gruesome conditions. The modern view of leprosy is more enlightened. We know that it is not readily communicated and that it should not be accompanied by social banishment. Because of the unfortunate connotations associated with the term *leper* (a person who is shunned or ostracized), more acceptable terms such as *leprosy patient*, *Hansen's disease patient*, or *leprotic* are preferred.

Epidemiology and Transmission of Leprosy

The incidence of leprosy has been declining due to a worldwide control effort. World Health Organization (WHO) estimates about

* *leprosy* (lep'-roh-see) Gr. *lepros*, scaly or rough. Translated from a Hebrew word that refers to uncleanness.

175,000 cases, mostly in endemic areas of Asia, Africa, Central and South America, and the Pacific islands. Leprosy is not restricted to warm climates, however, because it has been reported in Siberia, Korea, and northern China. The disease is also reported in a few limited locales in the United States, including parts of Hawaii, Texas, Louisiana, Florida, and California. The total number of new cases reported nationwide is from 50 to 100 per year, many of which are associated with recent immigrants.

The mechanism of transmission among humans is yet to be fully verified. Theories propose that the bacillus is directly inoculated into the skin through contact with a leprosy patient, that mechanical vectors are involved, or that inhalation of droplet nuclei is a factor.

Although the human body was long considered the sole host and reservoir of the leprosy bacillus, it is now clear that armadillos also harbor *M. leprae* and may develop a granulomatous disease similar to leprosy. Although the risk of contracting leprosy from armadillos is exceedingly low, zoonotic infection is thought to be responsible for the 30 to 40 new cases of leprosy seen each year in U.S.-born citizens who have never traveled to regions where the disease is prevalent.

Because the leprosy bacillus is not highly virulent, most people who come into contact with it do not develop clinical disease. As with tuberculosis, it appears that health and living conditions influence susceptibility and the course of the disease. An apparent predisposing factor is some defect in the regulation of T cells. Mounting evidence also indicates that some forms of leprosy are associated with a specific genetic marker. Long-term household contact with leprotics, poor nutrition, and crowded conditions increase the risks of infection. Many people become infected as children and harbor the microbe through adulthood.

The Course of Infection and Disease

Once *M. leprae* has entered a portal of entry, macrophages successfully destroy the bacilli, and there are no initial manifestations of infection. But in a small percentage of cases, a weakened or slow macrophage and T-cell response leads to intracellular survival of the pathogen. The usual incubation period varies from 2 to 5 years, with extremes of 3 months to 40 years. The earliest signs of leprosy appear on the skin of the trunk and extremities as small, spotty lesions colored differently from the surrounding skin (**figure 19.20**). In untreated cases, the bacilli grow slowly in the skin macrophages and Schwann cells of peripheral nerves, and the disease progresses to one of several outcomes.

A useful rating system for leprosy was developed by D. S. Ridley and W. H. Jopling. At the two extremes are tuberculoid leprosy (TL) and lepromatous leprosy (LL) (**table 19.3**); and in between are borderline tuberculoid (BT), borderline (BB), and borderline lepromatous (BL) leprosy. Patients can have more than one form of leprosy simultaneously, and one type can progress to another. Currently, epidemiologists at the CDC and World Health Organization are transitioning to a system in which leprosy is classified as **paucibacillary** (few bacteria found in skin scrapings, otherwise classified as tuberculoid or borderline tuberculoid leprosy) or **multibacillary** (many bacteria found in skin scrapings, corresponding to borderline, borderline lepromatous, or lepromatous leprosy).

Tuberculoid (Paucibacillary) leprosy, the most superficial form, is characterized by asymmetrical, shallow skin lesions

Figure 19.20 Leprosy. (a) Tuberculoid (paucibacillary) infection often appears as hypopigmented patches, especially in dark-skinned persons. (b) Borderline (multibacillary) leprosy is the most common form of the disease. Tuberculoid-like lesions are present in greater numbers, and peripheral nerves in the area are affected, causing weakness and a loss of sensation. (a, b): Source: CDC

TABLE 19.3 The Two Major Clinical Forms of Leprosy

Tuberculoid (Paucibacillary) Leprosy	Lepromatous (Multibacillary) Leprosy
Few bacilli in lesions	Many bacilli in lesions
Shallow skin lesions in many areas	Numerous deeper lesions concentrated in cooler areas of body
Loss of pain sensation in lesions	Sensory loss more generalized; occurs late in disease
No skin nodules	Gross skin nodules
Occasional mutilation of extremities	Mutilation of extremities common
Reactive to lepromin*	Not reactive to lepromin
Lymph nodes not infiltrated by bacilli	Lymph nodes massively infiltrated by bacilli
Well-developed cell-mediated (T-cell) response	Poorly developed T-cell response

*Lepromin is an extract of the leprosy bacillus injected intradermally, like tuberculin, to detect delayed allergy to leprosy.

Figure 19.21 A clinical picture of lepromatous (multibacillary) leprosy. Infection of the nose, lips, chin, and brows produces moderate facial deformation, typical of lepromas. *Source:* CDC

containing very few bacilli (figure 19.20). Microscopically, the lesions appear as thin granulomas and enlarged dermal nerves. Damage to these nerves usually results in local loss of pain reception and feeling. This form has fewer complications and is more easily treated than other types of leprosy.

Lepromatous (Multibacillary) leprosy is responsible for the disfigurements commonly associated with the disease. It is marked by chronicity and severe complications due to widespread dissemination of the bacteria. Leprosy bacilli grow primarily in macrophages in cooler regions of the body, including the nose, ears, eyebrows, chin, and testes. As growth proceeds, the face of the afflicted person develops folds and granulomatous thickenings, called lepromas, which are caused by massive intracellular overgrowth of *M. leprae* (figure 19.21). Advanced LL causes a loss of sensitivity that predisposes the patient to trauma and mutilation, secondary infections, blindness, and kidney or respiratory failure. Diffuse lepromatous leprosy, a unique form of the disease endemic to Mexico, is thought to be caused by *M. lepromatosis*, a species first described in 2008.

The condition of borderline (multibacillary) leprosy patients can progress in either direction along the scale, depending upon their treatment and immunologic competence. The most severe effect of intermediate forms of leprosy is early damage to nerves that control the muscles of the hands and feet. The subsequent wasting of the muscles and loss of control produce drop foot and claw hands (figure 19.22). Sensory nerve damage can lead to trauma and loss of fingers and toes.

Diagnosing Leprosy

Leprosy is diagnosed by a combination of symptomatology, microscopic examination of lesions, and patient history. A simple yet effective field test in endemic populations is the feather test. A skin area that has lost sensation and does not itch may be an early symptom. Numbness in the hands and feet, loss of heat and cold sensitivity, muscle weakness, thickened earlobes, and chronic

Figure 19.22 Deformation of the hands caused by borderline leprosy. The clawing and wasting are chiefly due to nerve damage that interferes with musculoskeletal activity. Individuals in a later phase of the disease can lose their fingers. © Medicshots/Alamy Stock Photo

stuffy nose are additional evidence. Laboratory diagnosis relies upon the detection of acid-fast bacilli in smears of skin lesions, nasal discharges, and tissue samples. Knowledge of a patient's prior contacts with leprotics also supports diagnosis. Laboratory isolation of the leprosy bacillus is difficult and not ordinarily attempted.

Treatment and Prevention of Leprosy

Leprosy can be controlled by drugs, but therapy is most effective when started before permanent damage to nerves and other tissues has occurred. Because of an increase in resistant strains, multidrug therapy is necessary. Tuberculoid (paucibacillary) leprosy can be managed with rifampin and dapsone for 12 months. Lepromatous (multibacillary) leprosy requires a combination of rifampin, dapsone, and clofazimine until the number of AFB in skin lesions has been substantially reduced (requiring up to 2 years).

Preventing leprosy requires constant surveillance of high-risk populations to discover early cases, chemoprophylaxis of healthy persons in close contact with leprotics, and isolation of leprosy patients. No vaccine for leprosy is currently available, but it is thought that the bacille Calmette-Guérin (BCG) vaccine that is used in many countries to prevent tuberculosis also provides some protection against infection with the leprosy bacillus.

Infections by Nontuberculous Mycobacteria (NTM)

For many years, most mycobacteria were thought to have low pathogenicity for humans. Saprobic and commensal species are isolated so frequently in soil, drinking water, swimming pools, dust, air, raw milk, and even the human body that both contact and asymptomatic infection appear to be widespread. However, the recent rise in opportunistic and healthcare-associated mycobacterial infections has demonstrated that many species are far from harmless.

Pathogen Profile #6 *Mycobacterium leprae*

Source: CDC

Microscopic Morphology Acid-fast rods.

Identified by Laboratory isolation of *M. leprae* is difficult and so is rarely attempted. Instead, leprosy (Hansen's disease) is diagnosed through a combination of microscopic examination of lesions, patient history, and symptomatology, especially the loss of sensation on the skin.

Habitat Humans and armadillos are the sole reservoir for *M. leprae*.

Virulence Factors *M. leprae* is not highly virulent. Predisposing factors for infection include defects in T-cell regulation, poor overall health, inadequate nutrition, and long-term household contact with leprotics.

Primary Infections/Disease Most people exposed to *M. leprae* do not go on to develop the disease. For those who do, an incubation period of several years is followed by the earliest signs of leprosy, small spotty lesions appearing on the trunk or extremities.

Untreated disease may progress to tuberculoid (paucibacillary) leprosy—the milder form, marked by loss of sensation—or lepromatous (multibacillary) leprosy, the more severe form of the disease. Lepromatous leprosy is commonly associated with disfigurement. Some forms of leprosy may initially present as borderline (multibacillary) and may progress toward the more or less severe subtypes, depending on treatment and immunologic competence.

Control and Treatment Control of *M. leprae* relies on early detection of those infected, chemoprophylaxis of healthy persons in close contact with leprotics, and isolation of leprosy patients. Because of an increase in resistant strains, treatment involves multidrug therapy and is most effective when started before permanent damage to nerves and other tissues has occurred.

Disseminated Mycobacterial Infection in AIDS Bacilli of the *Mycobacterium avium* complex (MAC) frequently cause secondary infections in AIDS patients with low T-cell counts. These common soil bacteria usually enter through the respiratory tract, multiply, and rapidly disseminate. In the absence of an effective immune counterattack, the bacilli flood the body systems, especially the blood, bone marrow, bronchi, intestine, kidney, and liver. Recommended treatment is combined drug therapy using clarithromycin and ethambutol, occasionally supplemented with rifabutin. This therapy usually has to be given for several months or even years.

Nontuberculous Lung Disease Pulmonary infections caused by commensal mycobacteria have symptoms like a milder form of tuberculosis, but they are not communicable. *Mycobacterium kansasii* infection is endemic to urban areas in the midwestern and southwestern United States and parts of England. It occurs most often in adult White males who already have emphysema or bronchitis. *Mycobacterium fortuitum* complex causes postsurgical skin and soft-tissue infection and pulmonary complications in immunosuppressed patients.

A form of TB caused by *M. bovis* was once quite common but is now extremely rare due to efforts to control the disease in cattle. Occasional clusters of cases have appeared, all probably from imported cheese made with unpasteurized milk.

Miscellaneous Mycobacterial Infections An infection by *M. marinum* has been labeled fish tank granuloma because of the strong relationship between the disease and work around aquariums. Interestingly, the same disease was referred to as swimming

Figure 19.23 Chronic fish tank granulomas on the arm of a fish store employee. Image reprinted with permission from Medscape Drugs & Diseases (<http://emedicine.medscape.com/>), 2016, available at: <http://emedicine.medscape.com/article/223363-overview>.

pool granuloma for many years but consistent chlorination of pools has led to its eradication in pools. The disease begins when *M. marinum*, found in both fresh and salt water, enters a cut or scrape. A nodule begins to form, which then enlarges, ulcerates, and drains (**figure 19.23**). The granuloma can clear up spontaneously, but it can also persist and require long-term treatment.

Mycobacterium scrofulaceum causes an infection of the cervical lymph nodes in children living in the Great Lakes region, Canada, and Japan. Infection is apparently associated with ingestion of food or milk and generally affects the oral cavity and cervical lymph nodes. In most cases the infection is without complications,

but certain children develop *scrofula*, in which the affected lymph nodes ulcerate and drain.

Research on a chronic intestinal syndrome called Crohn's disease has uncovered a strong association between the disease and a form of *Mycobacterium paratuberculosis*. When technicians used a PCR technique to analyze the DNA of colon specimens, it was found that 65% of Crohn's disease patients tested positive for *M. paratuberculosis*. Further studies have shown that this bacterium is found in cow's milk, which may well be the source of infection.

Check Your Progress SECTION 19.5

- Outline the differences in sites of infection and pathology among primary, reactivated, and extrapulmonary tuberculosis.
- Compile a list of the advantages, disadvantages, and information gained through TB skin tests, immunological blood tests, chest X rays, acid-fast staining, and cultural isolation and identification.
- Explain how and why antibacterial treatment for tuberculosis differs from that for other bacterial pathogens.
- List several differences between lepromatous and tuberculoid leprosy.
- Explain the association between *M. leprae* infection and deformation of the fingers and toes.
- List the diseases and at-risk populations associated with infection by *Mycobacterium avium*, *Mycobacterium kansasii*, and *Mycobacterium marinum*.

19.6 Actinomycetes: Filamentous Bacilli

Expected Learning Outcomes

- Identify and describe the pathogenic actinomycetes.
- Describe the types of infections attributable to bacteria in the genus *Nocardia*.

A group of bacilli closely related to *Mycobacterium* are the pathogenic **actinomycetes**.^{*} These are nonmotile filamentous rods that may be acid-fast. Certain members produce a mycelium-like growth and spores reminiscent of fungi. They also produce chronic granulomatous diseases. The main genera of actinomycetes involved in human disease are *Actinomyces* and *Nocardia*.

Actinomycosis

Actinomycosis is an endogenous infection of the cervicofacial, thoracic, or abdominal regions by species of *Actinomyces* living normally in the human oral cavity, tonsils, and intestine. The cervicofacial form of disease can be a common complication of tooth extraction, poor oral hygiene, and rampant dental caries. The lungs, abdomen, and uterus are also sites of infection.

Figure 19.24 Clinical signs of actinomycosis. Early periodontal lesions work their way to the surface in cervicofacial disease. The lesions eventually break out and drain. Note the dimpling around the lesion, indicating loss of underlying bone to the infection. Source: CDC

Cervicofacial disease is caused by *A. israelii*, which enters a damaged area of the oral mucous membrane and begins to multiply there. Diagnostic signs are swollen, tender nodules in the neck or jaw that give off a discharge containing macroscopic (1–2 mm) sulfur granules (**figure 19.24**). In most cases, infection remains localized, but bone invasion and systemic spread can occur in people with poor health. Thoracic actinomycosis is a necrotizing lung disorder that can project through the chest wall and ribs. Abdominal actinomycosis is a complication of burst appendixes, gunshot wounds, ulcers, or intestinal damage. Uterine actinomycosis has been increasingly reported in women using intrauterine contraceptive devices. Infections are treated with surgical drainage and drug therapy with penicillin, amoxicillin, erythromycin, or doxycycline.

Compelling evidence indicates that oral actinomycetes play a strategic role in the development of plaque and dental caries. Studies of the oral environment show that *A. viscosus* and certain oral streptococci are the first microbial colonists of the tooth surface. Both groups have specific tooth-binding powers and can adhere to each other and to other species of bacteria (see chapter 21).

Nocardiosis

Nocardia^{*} is a genus of bacilli widely distributed in the soil. Most species are not infectious, but *N. brasiliensis* is a primary pulmonary pathogen, and *N. asteroides* and *N. caviae* are opportunists. Nocardioses fall into the categories of pulmonary, cutaneous, or subcutaneous infection. Most cases in the United States are reported

^{*} *actinomycetes* (ak'-tih-noh-my'-seets) Gr. *actinos*, a ray, and *myces*, fungi. Members of the Order Actinomycetales.

^{*} *Nocardia* (noh-kar'-dee-ah) After Edmund Nocard, the French veterinarian who first described the genus.

in patients with deficient immunity, but a few occur in normal individuals.

Pulmonary nocardiosis is a form of bacterial pneumonia with pathology and symptoms similar to tuberculosis. The lung develops abscesses and nodules and can consolidate. Often, the lesions extend to the pleura and chest wall and disseminate to the brain, kidneys, and skin (**figure 19.25**). *Nocardia brasiliensis* is also one of the chief etiologic agents in mycetoma, discussed in chapter 22.

Check Your Progress SECTION 19.6

19. Compare the types of infections caused by the primary members of the actinomycetes.

CASE STUDY Part 2

The investigation initiated in response to the illnesses was one of thousands, big and small, done every year to track down the source of an outbreak. The first step in such an inquiry is decidedly low-tech, with investigators quizzing ill persons as to their actions over the weeks leading up to the outbreak, searching for behaviors that could have put them at risk for infection; with *Listeria*, the questioning centered on food and drink. Investigators found that 93% of ill persons reported consuming fresh cantaloupe in the month before falling ill. This was unusual, as *Listeria* is generally associated with unpasteurized milk, soft cheeses, and processed meats, although outbreaks in 2009 and 2010 had been linked to sprouts and celery. Investigators from the Colorado Department of Public Health and Environment collected all available cantaloupes from local markets and from patients' homes. Several patients specifically reported eating “Rocky Ford” cantaloupes, which are grown only in the Rocky Ford region of Colorado. These were traced back to Jensen Farms and had been shipped from July 24 through September 10.

A second front in the investigation centered on molecular typing of the *Listeria* bacterium, generating a DNA profile—or fingerprint—of the strain responsible for infection. This phase of the effort was carried out by PulseNet, a national network of laboratories that use a DNA profiling technique called pulsed-field gel electrophoresis (PFGE) to distinguish strains at the molecular level. PulseNet analysis found five strains of *Listeria monocytogenes* associated with the outbreak. A team headed by FDA inspectors began an investigation of Jensen Farms, a fixture in southeastern Colorado, where four generations had grown cantaloupe, hay, and alfalfa. The current owners, Ryan and Eric Jensen, had made a number of changes to a packing shed just prior to the 2011 harvest. Investigators discovered several problems that may have contributed to the outbreak. Among them were the following:

- A refrigeration drain line allowed water to pool directly under packing facility equipment, and testing of the water revealed the presence of one of the outbreak strains of *Listeria monocytogenes*.

Figure 19.25 Nocardiosis. This case of pulmonary disease has extended from the shoulders and trunk to the skin of the upper arm. Source: CDC

- The floor of the packing facility was not easily cleanable, creating a refuge for bacteria.
- Jensen Farms had recently installed packing equipment that had previously been used in the harvesting of potatoes. This created a potential problem because potatoes, unlike cantaloupe, are generally cooked prior to being consumed. The equipment had visible dirt and corrosion, and was also designed in a manner that prevented adequate cleaning.
- Removal of an initial antimicrobial wash meant that a single contaminated melon could spread bacteria to other packing equipment and potentially cross-contaminate every melon that passed through the facility.

Jensen Farms immediately halted sales of cantaloupes and a nationwide recall was instituted, but this was of no help to those already affected. Nationwide, 147 persons reported illness, 143 of these were hospitalized, and 33 deaths were attributed to the outbreak, making it the third deadliest food-related outbreak in U.S. history. Mike Hauser and Paul Schwarz, along with Michelle and Kendall Wakely, fairly represent those hit hardest by the outbreak. The median age of those infected was 78, and those who died had a median age of 81. Seven cases were diagnosed in newborns or pregnant women, and one miscarriage was reported. An onslaught of medical claims and civil suits related to the outbreak led Jensen Farms to file for bankruptcy in May 2012; Eric and Ryan Jensen pleaded guilty to misdemeanor charges in October 2013. Each received five years probation and six months home detention. Each also was ordered to pay \$150,000 in restitution and perform 100 hours of community service.

- Explain the importance of PFGE subtyping of *Listeria* in this case.
- Milk and meat are kept cool during processing in order to slow the growth of *E. coli*. Would cooling be an effective method of controlling *Listeria*?

To learn more about this case, go to <http://www.cdc.gov> and search “jensen farms cantaloupe.”

To conclude this Case Study, go to Connect.

 Chapter Summary with Key Terms
19.1 Medically Important Gram-Positive Bacilli

The gram-positive bacilli include about a dozen genera of medically significant bacteria. They are differentiated on the basis of endospores, acid-fastness, and cell morphology.

19.2 Gram-Positive Spore-Forming Bacilli

Endospore-forming rods include species in the genera *Bacillus* and *Clostridium*.

- A. *Bacillus* is an aerobic genus, the most prominent member of which, *Bacillus anthracis*, is the causative agent of **anthrax**, a zoonosis that exists in **cutaneous**, **pulmonary**, and **gastrointestinal** forms.
- B. *Clostridium* is an anaerobic genus whose members exert their effects primarily through the release of powerful **exotoxins**, each of which attack specific tissues.
 1. *Clostridium perfringens* causes **gas gangrene**, a soft tissue and muscle infection. Ingestion of cells may cause clostridial food poisoning.
 2. *C. difficile* causes antibiotic-associated colitis, a gastrointestinal infection acquired during drug therapy.
 3. *C. tetani* causes **tetanus** (lockjaw) when the toxin **tetanospasmin** affects cells in the central nervous system.
 4. *C. botulinum* is the causative agent of **botulism**, a food intoxication associated with home-canned foods.
 5. Infant and wound botulism are unusual types of infectious botulism contracted like tetanus.

19.3 Gram-Positive Regular Non-Spore-Forming Bacilli

Non-spore-forming rods are divided among those that have **regular** and irregular shapes and staining properties. Straight, nonpleomorphic rods stain evenly and include the genera *Listeria* and *Erysipelothrix*.

- A. *Listeria monocytogenes* causes **listeriosis**, a food infection associated with contaminated meat and dairy products.
- B. *Erysipelothrix rhusiopathiae* is a zoonosis normally carried by swine. It is the cause of **erysipeloid** among people who handle animals or animal products.

19.4 Gram-Positive Irregular Non-Spore-Forming Bacilli

Irregular non-spore-forming rods include *Corynebacterium* and *Propionibacterium*.

- A. *Corynebacterium diphtheriae* is a pleomorphic aerobic rod with metachromatic granules and a palisades arrangement. It is the causative agent of both respiratory and cutaneous **diphtheria**.
- B. *Propionibacterium acnes* is an anaerobic rod associated with acne vulgaris lesions.

19.5 Mycobacteria: Acid-Fast Bacilli

Acid-fast bacilli contain large amounts of mycolic acid and waxes; they are strict aerobes that are widely distributed in the environment.

- A. *Mycobacterium tuberculosis* causes tuberculosis (TB). The disease is divided into primary pulmonary infection, involving the formation of **tubercles** in the lungs; reactivated TB, which occurs in people with latent or reactivated disease; and disseminated **extrapulmonary TB**, due to the TB bacilli being carried throughout the body.
- B. *Mycobacterium leprae* causes **leprosy**, a chronic disease that begins in the skin but quickly moves to the nerves. **Tuberculoid (paucibacillary) leprosy** is a superficial infection, whereas **lepromatous (multibacillary) leprosy** causes more severe disfigurement.
- C. Nontuberculous mycobacteria (NTM) are common environmental species that may be involved in disease. Examples include *M. avium* complex and *M. marinum*.

19.6 Actinomycetes: Filamentous Bacilli

The genera *Actinomyces* and *Nocardia* are filamentous bacteria related to mycobacteria that may cause chronic infection of the skin and soft tissues.

- A. *Actinomyces* species such as *A. israelii* are responsible for diseases of the oral cavity and intestines.
- B. *Nocardia brasiliensis* causes pulmonary disease similar to TB as well as cutaneous nodules.

**Level I. Knowledge and Comprehension**

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

 Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

1. What is/are the usual habitat(s) of endospore-forming bacteria that are agents of disease?

a. intestines of animals	c. water
b. soil	d. foods
2. Most *Bacillus* species are

a. true pathogens	c. nonpathogens
b. opportunistic pathogens	d. commensals
3. Many clostridial diseases require a/an _____ environment for their development.

a. living tissue	c. aerobic
b. anaerobic	d. low pH
4. *Clostridium perfringens* causes

a. myonecrosis	c. antibiotic-induced colitis
b. food poisoning	d. both a and b

5. The action of tetanus exotoxin is on the
 a. neuromuscular junction
 b. sensory neurons
 c. spinal interneurons
 d. cerebral cortex
6. The action of botulinum toxin is on the
 a. spinal nerves
 b. cerebellum
 c. neuromuscular junction
 d. smooth muscle
7. An infection peculiar to swine causes _____ when transmitted to humans.
 a. anthrax
 b. diphtheria
 c. tuberculosis
 d. erysipeloid
8. TB is spread by
 a. contaminated fomites
 b. food
 c. respiratory droplets
 d. vectors
9. The form of leprosy associated with severe disfigurement of the face is
 a. paucibacillary
 b. multibacillary
 c. facio-cranial
 d. papular
10. Soil mycobacteria can be the cause of
 a. tuberculosis
 b. leprosy
 c. fish tank granuloma
 d. erysipeloid
11. Caseous lesions containing inflammatory white blood cells are
 a. lepromas
 b. pseudomembranes
 c. eschars
 d. tubercles
12. Which infectious agent is an obligate parasite?
 a. *Mycobacterium tuberculosis*
 b. *Corynebacterium diphtheriae*
 c. *Mycobacterium leprae*
 d. *Clostridium difficile*
13. Which infection(s) would be categorized as a zoonosis?
 a. anthrax
 b. diphtheria
 c. gas gangrene
 d. both a and b
14. Actinomycetes are _____ that cause _____.
 a. filamentous rods, chronic granuloma infections
 b. pleomorphic bacteria, erysipeloid
 c. sporeformers, tooth decay
 d. hyphae, pseudomembranes
15. **Multiple Matching.** Choose all descriptions that fit.
 _____ *Bacillus* 1. is acid-fast
 _____ *Clostridium* 2. cells irregular, pleomorphic
 _____ *Mycobacterium* 3. can form metachromatic granules
 _____ *Corynebacterium* 4. regular-shaped rods
 _____ *Listeria* 5. forms endospores
 6. is psychrophilic
 7. is primarily anaerobic
 8. is aerobic
 9. is associated with dairy products
 10. cells can be elongate filaments
 11. shows palisades arrangement
16. **Matching.** Match the disease with the principal portal of entry.
 _____ 1. anthrax a. skin
 _____ 2. botulism b. gastrointestinal tract
 _____ 3. gas gangrene c. traumatized tissue
 _____ 4. antibiotic colitis d. respiratory tract
 _____ 5. tetanus e. urogenital tract
 _____ 6. diphtheria f. placenta
 _____ 7. listeriosis g. none of these
 _____ 8. tuberculosis
 _____ 9. leprosy

Case Study Review

1. Which of the conditions below would make someone more susceptible to infection with *Listeria monocytogenes*?
 a. being pregnant
 b. being elderly
 c. undergoing chemotherapy
 d. all of these would make a person more susceptible
2. During this outbreak, some people sickened with listeriosis tested positive for *Listeria monocytogenes* in their bloodstream, but a DNA profile of the bacterium showed that it was not the outbreak strain. What likely conclusion can be drawn from this information?
 a. It is a false positive.
 b. The person is not part of the outbreak.
 c. *Listeria monocytogenes* mutates frequently, making DNA profiling unreliable.
 d. The person has already begun to recover from the disease.
3. No *Listeria monocytogenes* was discovered in the field where the cantaloupes were grown, and the original source of the bacterium in this case was never found. The FDA report on the farm made mention of a truck that was used to carry rotted or broken cantaloupe to a nearby ranch where they were fed to cattle. What could be the importance of this fact, and what steps would you take to investigate it further?

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

1. a. What is the role of spores in infections?
 b. Describe the general distribution of spore-forming bacteria.
2. a. What characteristics of *Clostridium* contribute to its pathogenicity?
 b. Compare the toxigenicity of tetanospasmin and botulinum toxin.
 c. What predisposes a patient to clostridial infection?
3. a. Outline the epidemiology of the major wound infections and food intoxications of *Clostridium*.
 b. What is the origin of the gas in gas gangrene?
4. a. What causes the jaw to “lock” in lockjaw?
 b. How would it be possible for patients with no noticeable infection to present with symptoms of tetanus?

5. How are botulism and tetanus alike and different?
6. a. Why is listeriosis a serious problem even with refrigerated foods?
b. Which groups are most at risk for serious complications?
7. Why is erysipeloid an occupation-associated infection?
8. a. What are the distinctive morphological traits of *Corynebacterium*?
b. How can the pseudomembrane be life threatening?
c. What is the ultimate origin of diphtherotoxin?
9. a. Outline the unique characteristics of *Mycobacterium*.
b. What is the epidemiology of TB?
c. Differentiate between TB infection and TB disease.
- d. What are tubercles?
- e. Describe the applications of BCG vaccine.
10. a. What characteristics make *M. leprae* different from other mycobacteria?
b. Differentiate between tuberculoid and lepromatous leprosy.
11. a. What is the importance of NTM?
b. Describe the effects of *Mycobacterium avium* complex in AIDS patients.
12. a. Describe the bacteria in the actinomycete group, and explain what characteristics make them similar to fungi.
b. Briefly describe two of the common diseases caused by this group.

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps along with concept mapping activities for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

1. a. What is the main clinical strategy in preventing gas gangrene?
b. Why does it work?
2. a. Why is it unlikely that diseases such as tetanus and botulism will ever be completely eradicated?
b. Name some bacterial diseases in this chapter that could be completely eradicated and explain how.
3. Why is the cause of death similar in tetanus and botulism?
4. a. Why does botulinum toxin not affect the senses?
b. Why does botulism not commonly cause intestinal symptoms?
5. Account for the fact that boiling does not destroy botulism spores but does inactivate botulinum toxin.
6. Adequate cooking is the usual way to prevent food poisoning. Why doesn't it work for *Clostridium perfringens* and *Bacillus* food poisoning?
7. a. Why do patients who survive tetanus and botulism often have no sequelae?
b. How has modern medicine improved the survival rate for these two diseases?
8. What would be the likely consequence of diphtheria infection alone without toxemia?
9. How can one tell that acne involves an infection?
10. Do you think the spittoons of the last century were effective in controlling tuberculosis? Why or why not?
11. a. Provide an explanation for the statement that TB and leprosy are "family diseases."
b. What, if anything, can be done about multidrug-resistant tuberculosis?
c. Explain an important rationale for *not* administering BCG vaccine in the United States to the general public.
12. Carefully compare figures 19.11 and 19.23.
a. Describe the main differences observable in the lesions of these two conditions.
b. Explain how you would go about diagnosing them differentially.
13. Which diseases discussed in this chapter have no real portal of exit?
14. Eighty-six people at a St. Patrick's Day celebration developed diarrhea, cramps, and vomiting after eating a traditional dinner of corned beef, cabbage, potatoes, and ice cream. Symptoms appeared within 10 hours of eating, on average. Of those afflicted, 85 had eaten corned beef and one had not. The corned beef had been cooked in an oven the day before the event, stored in the refrigerator, and sliced and placed under heat lamps 1½ hours before serving.
a. Use this information to diagnose the food poisoning agent.
b. What sorts of lab tests could one do to verify it as this bacterium?
c. What would you have done to prevent this incident?
15. An outbreak of gastrointestinal illness was reported in a day care center. Of 67 people, 14 came down with symptoms of nausea, cramps, and diarrhea within 2 to 3 hours of eating. Food items included fried rice, peas, and apple rings. Symptoms occurred in 14 of the 48 who had eaten the fried rice and in none of those who had

not eaten it. The rice had been cooked the night before and refrigerated. The next morning, it had been fried with leftover chicken and held without refrigeration until lunchtime.

a. On the basis of symptoms and food types, what do you expect the etiological agent to be?

b. What would you expect to culture from the food?

c. To what other disease is this one similar?

d. How can it be differentiated from the agent and disease in question 14?

Visual Challenge

1. From **chapter 7, figure 7.11**. Which of the thioglycollate tubes in the figure would be indicative of *Bacillus* and which would be characteristic of *Clostridium*? Explain why this is true.

© Terese M. Barta, Ph.D.

2. From **chapter 3, figure 3.8**. What type of bacterial infection could be diagnosed using the stain shown in the figure? What does this result indicate?

© Steven R. Spilatro, Department of Biology, Marietta College, Marietta, OH

CHAPTER 20

The Gram-Negative Bacilli of Medical Importance

Bordetella pertussis, the gram-negative bacterium responsible for whooping cough, as viewed through a scanning electron microscope at 5,000x.
© Dennis Kunkel Microscopy, Inc./Phototake

CASE STUDY Part 1 The More Things Change, the More They Stay the Same

On April 3, 2012, in response to an increase in the number of reported cases of pertussis, the Washington State Secretary of Health declared an epidemic. Within 11 weeks the number of **reported** cases in the state had soared to 2,520 for the year, an increase of 1,300% compared to the same period in 2011 and the highest number of cases since 1942. Pertussis, commonly known as *whooping cough*, looks at first like nothing more sinister than a common cold—runny nose, coughing, and congestion—but soon worsens to include uncontrollable coughing followed by a deep inhalation of air whistling through the congested larynx, causing the “whooping” sound for which the disease is known.

Whooping cough results from infection with *Bordetella pertussis*, a gram-negative bacillus that spreads rapidly from person to person. Historically, infants and young children are hardest hit by the disease, with infants having the highest incidence rate and accounting for the

majority of deaths. Due primarily to an aggressive vaccination campaign in the United States, pertussis cases dropped from an average of 175,000 a year in the 1940s to 1,010 cases by 1976. While the group most affected by the 2012 Washington State outbreak were children under 1 year of age, high rates of disease were seen in 10-, 13-, and 14-year-olds, despite the fact that most had completed the entire five-dose vaccination series recommended by the ACIP (Advisory Committee for Immunization Practices).

“It’s the largest epidemic I’ve ever seen. They don’t have time to call and say who’s positive and who’s negative.”

Becky Neff, RN

- How is *Bordetella pertussis* spread?
- What conclusion can be drawn from the fact that many adolescents who had completed the immunization series were still hard hit by pertussis?

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

The gram-negative bacilli comprise a large group of non-spore-forming bacteria adapted to a wide range of habitats and niches. Members of this group are classified in Phylum Proteobacteria, a large assembly of 500 different genera that are highly diverse in metabolism and pathogenicity. Because the group is so large and complex and many of its members are not medically important, we have included mainly those that are human pathogens.

A large number of representative genera are inhabitants of the large intestine (enteric); some are zoonotic; some are adapted to the human respiratory tract; and still others live in soil and water. It is useful to distinguish between true pathogens (*Salmonella*, *Yersinia pestis*, *Bordetella*, and *Brucella*, for example), which are infectious to the general population, and the opportunists (*Pseudomonas* and coliforms), which may be resident microbiota or saprobes that cause infection in people with weakened host defenses (**Systems Profile 20.1**).

20.1 Aerobic Gram-Negative Nonenteric Bacilli

Expected Learning Outcomes

1. Explain the effect of the virulence factor common to all gram-negative bacteria.
2. Identify those people most at risk of developing a *Pseudomonas* infection.

The aerobic gram-negative bacteria of medical importance are a loose assortment of genera including the soil bacteria *Pseudomonas* and *Burkholderia*; the zoonotic pathogens *Brucella* and

Francisella; and *Bordetella* and *Legionella*, which are mainly human pathogens. The gram-negative rods can be organized in several ways. To simplify coverage here, they are grouped into three major categories based on oxygen requirements and fermentation of lactose (**table 20.1**).

One notable component of all gram-negative rods is a lipopolysaccharide in the outer membrane of the cell wall that acts as an **endotoxin** (see chapter 13). The release of endotoxin in the blood from gram-negative septicemia can have severe and far-reaching pathophysiological effects (**20.1 Making Connections**).

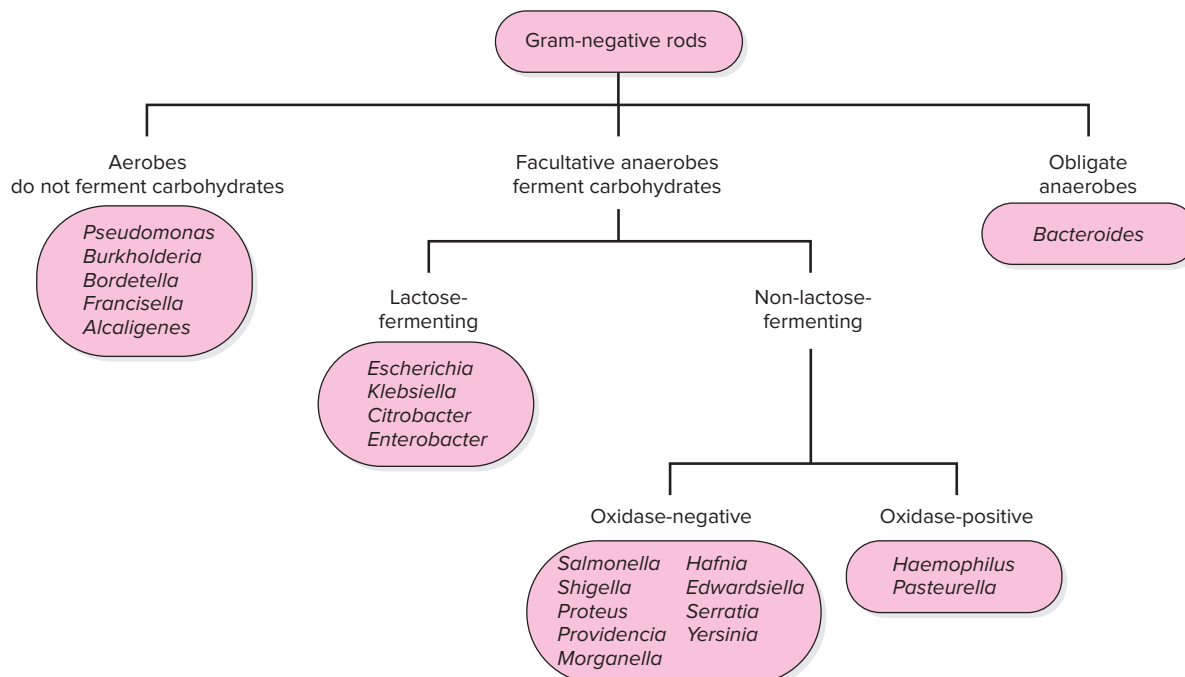

Pseudomonas: The Pseudomonads

The pseudomonads are members of the Family Pseudomonadaceae, a large group of free-living bacteria that live primarily in soil, seawater, and fresh water. They also colonize plants and animals and are frequent contaminants in homes and clinical settings. These small, gram-negative rods have a single polar flagellum (**figure 20.1**), produce oxidase and catalase, and do not ferment carbohydrates. Although they ordinarily obtain energy aerobically through oxidative metabolism, some species can grow anaerobically if provided with a salt such as nitrate. Many species produce green, brown, red, or yellow pigments that diffuse into the medium and change its color.

*Pseudomonas** species are highly versatile. They can adapt to a wide range of habitats and manage to extract needed energy from minuscule amounts of dissolved nutrients. Most members can grow in a medium containing minerals and a simple organic compound. This adaptability accounts for their constant presence in the environment and their capacity to thrive on hosts. They degrade

* *Pseudomonas* (soo"-doh-moh'-nas) Gr. *pseudes*, false, and *monas*, a unit.

numerous extracellular substances by means of protease, amylase, pectinase, cellulase, and numerous other enzymes.

Pseudomonads have extensive impact on ecology, agriculture, and commerce. They are important decomposers and bioremediators,

capable of degrading hundreds of natural substrates. These characteristics make them useful in cleaning up oil spills and clearing pesticides (see chapter 27). Various species have roles as food spoilage agents and plant pathogens. Some species produce antibiotics termed pseudomycins that are being tested for their effectiveness in treating fungal infections.

*Pseudomonas aeruginosa** is a common inhabitant of soil and water and an intestinal resident in about 10% of healthy people. On occasion it can be isolated from saliva or even the skin. Because the species is resistant to soaps, dyes, certain disinfectants, drugs, and drying, it is a frequent contaminant of ventilators, intravenous solutions, and anesthesia equipment. Even disinfected instruments, utensils, bathroom fixtures, and mops have been incriminated in hospital outbreaks.

In a pattern similar to that of the enteric bacteria discussed in section 20.3, *P. aeruginosa* is a typical opportunist. It is unlikely to cross healthy, intact anatomical barriers; thus, its infectiousness results from invasive medical procedures or weakened host defenses. Once in the tissues, *P. aeruginosa* expresses virulence factors including exotoxins, a phagocytosis-resistant slime layer, and various enzymes that degrade host tissues. It also causes endotoxic shock.

The most common health-care associated *Pseudomonas* infections occur in compromised hosts with severe burns, neoplastic

* *aeruginosa* (uh-roo'-jih-noh'-suh) L. *aeruginosa*, full of blue-green copper rust.

20.1 MAKING CONNECTIONS

Gram-Negative Sepsis and Endotoxic Shock

Blood infection is one of the most serious consequences with gram-negative bacteria, even if the species involved is not a virulent pathogen. Nationwide, over 100,000 patients a year die from a condition called **septic shock**. Shock is a pathologic state of low blood pressure accompanied by a reduced amount of blood circulating to vital organs, particularly the brain, heart, lungs, and kidneys. Its major symptoms and signs are nausea, tachycardia, cold and clammy skin, and weak pulse. Damage to the organs can elicit respiratory failure, coma, heart failure, and death in a few hours. Although the endotoxins of all gram-negative bacteria can cause shock, the most common clinical cases are due to gram-negative rods.

Section of gram-negative cell wall showing the location and structure of lipopolysaccharide.

The adverse factor in gram-negative sepsis is the presence of an endotoxin called **lipopolysaccharide (LPS)** in the outer membrane of the gram-negative cell wall. The component that accounts for most of the adverse effects is *lipid A* embedded in the external layer of the membrane. This lipid is active only after it is liberated by bacteria that are growing or lysed by host defenses and other factors. In general, lipid A is a potent immune stimulator that triggers the secretion of interleukins, tumor necrosis factor, and other cytokines by macrophages. In a local infection with only small amounts of endotoxin, the effects of the cytokines are protective. But massive sepsis attracts large numbers of macrophages that cause the dying

bacteria to release profuse amounts of LPS into the bloodstream. Some of the cytokines are pyrogenic and induce fever, some activate the complement cascade, and others promote intravascular blood coagulation. The end results are circulation failure, tissue damage, hypotension, and shock.

Ironically, traditional treatments with antibiotics can compound the problem of septic effects because these drugs can increase the lysis of bacteria and the release of endotoxins. Drug companies are actively developing new drugs that will block the effects of endotoxin. One clinical

Micrograph of gram-negative rod in the process of lysis. Small blue spheres are molecules of lipopolysaccharide being shed. © Dr. Kari Lounatmaa/Science Source

trial is testing an endotoxin antagonist that would work on all forms of lipid A. Other possible treatments contain monoclonal antibodies specific for endotoxin. Although these drugs are not yet available, they show some promise in controlling the more severe effects of endotoxemia.

Describe a scenario that could lead to shock, beginning with a hospitalized diabetic patient, and that ends with endotoxemia. *Answer available on Connect.*

disease, and premature birth. Cystic fibrosis patients in particular suffer from a lung condition in which mucus collects and creates a protective biofilm tenaciously colonized by *Pseudomonas aeruginosa*. *Pseudomonas*-related septicemia can disseminate into such conditions as endocarditis, meningitis, and bronchopneumonia. Even healthy people can be subject to outbreaks of skin rashes, urinary tract infections, and external ear infections picked up in community hot tubs and swimming pools. Sponges and washcloths are common sources of these bacteria and can lead to local infections when they are used to clean skin. (**figure 20.2**). Wearers of contact lenses are also vulnerable to corneal ulcers from contaminated storage and disinfection solutions.

Unusual characteristics of *P. aeruginosa* infections are a grape-like odor and the noticeable color that appears in tissue

Figure 20.2 *Pseudomonas* skin infection. The subcutaneous blue color is due to the production of a blue-green pigment that diffuses out from the infection. © DermNet New Zealand Trust

Pathogen Profile #1 *Pseudomonas aeruginosa*

Source: Janice Carr/CDC

Microscopic Morphology Small, gram-negative rods with a single polar flagellum.

Identified by Gram reaction and cellular morphology. *P. aeruginosa* is aerobic and does not ferment lactose, traits that distinguish it from members of the Enterobacteriaceae. Cultures typically produce a greenish pigment that fluoresces under ultraviolet light, as well as a distinctive odor.

Habitat *P. aeruginosa* is commonly found in soil and water and is an intestinal resident of about 10% of healthy people. The species is a frequent colonist of plants and animals and a routine contaminant of the home and clinical setting.

Virulence Factors Virulence factors include pili that aid in attachment of the bacterium to host cells, a phagocytosis-resistant slime layer that contributes to the formation of biofilms, enzymes that degrade host

tissues, and exotoxins that damage or destroy neutrophils and lymphocytes. The LPS layer of the outer membranes also causes endotoxic shock.

Primary Infections/Disease *P. aeruginosa* is a prime example of an opportunistic pathogen, with the most serious infections seen in patients with severe burns, neoplastic disease, or cystic fibrosis, in many cases leading to endocarditis, bronchopneumonia, or meningitis. Otherwise-healthy persons may acquire skin rashes, urinary tract infections, or outer ear infections, often connected to the use of community hot tubs and swimming pools.

Control and Treatment The metabolic versatility of *Pseudomonas* makes controlling the bacterium difficult; soap, mops, and sponges are all commonly implicated in outbreaks. Effective treatment makes susceptibility testing an absolute necessity. Effective drugs include third- and fourth-generation cephalosporins, aminoglycosides, and polymyxins.

Figure 20.3 Characteristics of *Pseudomonas aeruginosa*. *Pseudomonas* produces a blue to green pigment that diffuses into the medium. *Pseudomonas* also commonly displays drug resistance, as demonstrated by the weak or incomplete zones of inhibition surrounding several of the antibiotic discs. © Kathy Park Talaro

imperative. Drugs which have had some success in controlling *Pseudomonas* infection include third- and fourth-generation cephalosporins, aminoglycosides such as amikacin, and polymyxins like colistin.

Check Your Progress SECTION 20.1

1. Briefly describe the human infections caused by *Pseudomonas*.
2. How can antibiotic treatment of a gram-negative infection lead to septic shock?

20.2 Related Gram-Negative Aerobic Rods

Expected Learning Outcomes

3. Name the genera of bacteria that are physiologically similar to *Pseudomonas* and also account for a variety of opportunistic infections.
4. Outline the pathology and epidemiology of *Brucella*.
5. Explain the epidemiology of *Francisella tularensis* and the pathology of infection with the bacterium.
6. Recall the epidemiology of pertussis.
7. Describe the stages of whooping cough, and identify those persons most likely to experience the disease.
8. Identify the bacterium responsible for legionellosis and the environmental conditions that promote its growth.

One group of proteobacteria is represented by the genera *Burkholderia* and *Stenotrophomonas*. These genera share similarities with *Pseudomonas* in many of their physiological and pathogenic characteristics. Both are obligate aerobes that can utilize a variety of organic substrates but do not ferment sugars. They can be readily

exudates (“blue pus”). The color is due to the bacterium’s production of a blue-green or greenish-yellow pigment (pyocyanin) that can fluoresce (figure 20.3). Lab identification relies on a battery of tests similar to those given for the Enterobacteriaceae (see figure 20.9). The notorious multidrug resistance of *P. aeruginosa* makes testing for the drug sensitivity of most isolates

Figure 20.4 Lung Infection due to *Burkholderia pseudomallei*. (a) X ray indicates cavities in the middle lung zone where infection is concentrated. (b) Gram stain of sputum reveals typical gram-negative rods with bipolar staining (1,500 \times). (a) Source: Dr. Thomas Hooten/CDC; (b) Source: Andrew J. Brent, “Misdiagnosing Melioidosis,” *Emerging Infectious Diseases*, 13(2), February 2007, Fig. A. Centers for Disease Control and Prevention

cultured on blood agar, MacConkey agar, and other common lab media. They occupy a wide variety of habitats in soil, water, and related environmental locations, where they have established niches in nutrient recycling, but are also known as opportunists that readily invade a compromised human host.

Burkholderia cepacia is a common isolate from moist environments; it appears to play an important ecological role in controlling fungal disease on plants. It is also active in biodegradation of a wide variety of toxic substances, which would ordinarily make it a useful addition to bioremediation programs. Unfortunately it also has a potential for opportunistic infections in the respiratory tract, the urinary tract, and occasionally the skin. Pneumonia caused by *B. cepacia* holds heightened risks for cystic fibrosis patients, whose lung abnormalities favor the entrenchment of pathogens. Because of its tendency to mutate rapidly and resist antimicrobial drugs, finding a successful treatment can be a challenge. Coinfection with *Pseudomonas* may lead to severe respiratory compromise and death in 80% of patients.

Burkholderia pseudomallei is a relative of *B. cepacia* that resides in the soil and water of tropical climates. The disease it causes, melioidosis, is prevalent in many areas of Southeast Asia and parts of Africa, India, and the Middle East. It is generally acquired through a penetrating injury by a soiled object or inhalation from an environmental reservoir rather than from an infected person. Manifestations of wound infection are localized skin nodules along with symptoms of fever and muscle aches. Lung infection gives rise to bronchitis and pneumonia (figure 20.4), which are attended by cough and chest pain. Chronic infection may progress to septicemia, endotoxic shock, and abscesses in organs such as the liver and brain. In persons with compromised immune systems, the infection can cause severe disseminated disease that is occasionally fatal.

Stenotrophomonas maltophilia. The natural habitat of this bacterium appears to be fresh water and soil associated with plant roots. It is also a member of the fecal microbiota in humans and may be isolated from domestic animals. It appears in the clinical setting primarily as a contaminant of disinfectants, dialysis equipment, respiratory equipment, water dispensers, and catheters. One factor that favors colonization of the environment appears to be its formation of biofilms, which protect it against drugs and disinfectants.

It is a prominent clinical isolate most often found in respiratory, blood, spinal fluid, and ophthalmic specimens. Higher rates of

infection occur in cancer patients and people with indwelling invasive devices. Although this species is one of the most drug-resistant of bacteria, therapy with a combination of trimethoprim and sulfamethoxazole is usually effective.

Brucella and Brucellosis

Undulant fever, Malta fever, and Bang disease¹ are synonyms for **brucellosis**, a zoonosis transmitted to humans from infected animals or contaminated animal products harboring *Brucella*.^{*} Two species of these tiny, gram-negative coccobacilli are *B. abortus* (from cattle) and *B. suis* (from pigs). Animal brucellosis results from an infection of the placenta and fetus that can cause abortion, as typified by Bang disease in cattle. Humans infected with either of these two agents experience a severe febrile illness but not abortion.

Brucellosis occurs worldwide, with concentrations in Europe, Africa, India, and Latin America. It is associated predominantly with occupational contact in slaughterhouses, livestock handling, and the veterinary trade. Infection takes place through contact with blood, urine, placentas, and consumption of raw milk and cheese. Human-to-human transmission is rare. Brucellosis is also a common disease of wild herds of bison and elk. Cattle sharing grazing land with these wild herds often suffer severe outbreaks of Bang disease.

In humans, *Brucella* enters through damaged skin or mucous membranes of the digestive tract, conjunctiva, and respiratory tract.

One of *Brucella*'s most effective virulence factors lies in its capacity to survive and grow inside of macrophages. These infected macrophages transport the pathogen into the bloodstream, creating focal lesions in the liver, spleen, bone marrow, and kidney. The cardinal manifestation of human brucellosis is a fluctuating pattern of fever, which is the origin of the common name, undulant fever. It is also accompanied by chills, profuse sweating, headache, muscle pain and weakness, and weight loss. Fatalities are not common, though the syndrome can last for a few weeks to a year, even with treatment. Such chronic infections can be linked to the hidden bacteria carried by macrophages.

The patient's history can be very helpful in diagnosis, as are serological tests of the patient's blood (figure 20.5) and blood culture of the pathogen. Newer genetic tests are being developed but are not yet widely used. A combination of doxycycline and streptomycin taken for 6 weeks is usually effective in controlling infection. Prevention is effectively achieved by testing and elimination of infected animals, quarantine of imported animals, and pasteurization of milk. Though several types of animal vaccines are available, those developed for humans are ineffective or unsafe. The status of this pathogen as a potential germ warfare agent makes the need for a reliable vaccine even more urgent.

Francisella tularensis and Tularemia

*Francisella tularensis** is the causative agent of **tularemia**, a zoonotic disease of assorted mammals endemic to the Northern Hemisphere. Its characteristics are similar enough to *Yersinia pestis*, the cause of plague (discussed in section 20.5) that the two species were once included in the same genus, *Pasteurella*. Because tularemia has been associated with outbreaks of disease in wild rabbits, it is sometimes called *rabbit fever*.

Tularemia is distributed throughout numerous animal reservoirs and vectors in northern Europe, Asia, and North America but not in the tropics. This disease is noteworthy for its complex epidemiology and spectrum of symptoms. Although rabbits and rodents (muskrats and ground squirrels) are the chief reservoirs, other wild animals (skunks, beavers, foxes, opossums) and some domestic animals are implicated as well. Of the more than 50 bloodsucking arthropod vectors known to carry *F. tularensis*, about half also bite humans. Ticks are most often involved, followed by biting flies, mites, and mosquitoes.

Tularemia is strikingly varied in its portals of entry and disease manifestations. In a majority of cases, infection results when the skin or eye is inoculated through contact with infected animals, animal products, contaminated water, and dust. Vector bites are also a frequent source of infection, but the disease is not communicated from human to human. With an estimated infective dose of between 10 and 50 organisms, *F. tularensis* is often considered one of the most infectious of all bacteria. Along with plague and several other virulent pathogens, it is currently listed as a pathogen of concern on the lists of bioterrorism agents.

* *Francisella tularensis* (fran-sih-sel'-uh too-luh-ren'-sis) After Edward Francis, one of its discoverers, and Tulare County, California, where the agent was first identified.

Francisella is similar to *Brucella* in being an intracellular pathogen that survives and spreads in macrophages to multiple sites. After an incubation period ranging from a few days to 3 weeks, acute symptoms of headache, backache, fever, chills, and malaise appear. Clinical manifestations include ulcerative skin lesions, swollen lymph glands, conjunctival inflammation, sore throat, intestinal disruption, and pulmonary involvement. The death rate in systemic and pulmonic forms is 10%, but proper treatment with gentamicin or streptomycin reduces it to almost zero. Because the intracellular persistence of *F. tularensis* can lead to relapses, antimicrobial therapy must not be discontinued prematurely. Protection is afforded by protective gloves, masks, and eyewear for laboratory workers and other occupationally exposed personnel. No vaccine is currently available.

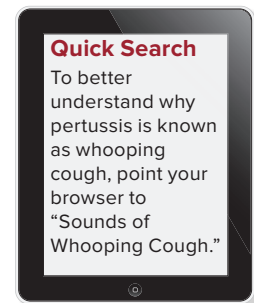

Bordetella pertussis and Relatives

*Bordetella pertussis** is a minute, encapsulated coccobacillus responsible for **pertussis**, or **whooping cough**, a communicable childhood affliction that causes an acute respiratory syndrome. Contrary to the common impression that the disease is mild and self-limiting, it often causes severe, life-threatening complications in babies. *Bordetella parapertussis* is a closely related species that causes a milder form of the infection.

The primary route of infection is direct contact with inhaled droplets or aerosols given off during the coughing stage of infection. About half of pertussis cases occur in children between birth and 4 years of age.

The primary virulence factors of *B. pertussis* are (1) adhesion molecules that specifically recognize and bind to ciliated respiratory epithelial cells and (2) toxins that destroy and dislodge ciliated cells (a primary host defense). The loss of the ciliary mechanism leads to buildup of mucus and blockage of the airways. The initial phase of pertussis is the *catarrhal stage*, marked by nasal drainage and congestion, sneezing, and occasional coughing. As symptoms deteriorate into the *paroxysmal stage*, the child experiences recurrent, persistent coughing. Fits of several abrupt, hacking coughs are followed by a deep inhalation that pulls air through the congested larynx and produces a “whoop” (figure 20.6). Many of the complications of pertussis are due to compromised respiration. Standard therapy and prophylaxis requires a weeklong course of azithromycin or clarithromycin.

An acellular vaccine (aP) is available for all routine immunizations, starting at 6 weeks of age. This vaccine contains toxoid and other antigens and is well tolerated when given with DT vaccine (DTaP). The vaccine is administered in a five-dose series between

* *Bordetella pertussis* (bor-duh-tel'-uh pur-tus'-is) After Jules Bordet, a discoverer of the agent, and *L. per.* severe, and *tussis*, cough.

Pathogen Profile #2 *Bordetella pertussis*

Source: Janice Carr/CDC

Microscopic Morphology Small gram-negative coccobacillus typically found singly or in pairs. It is encapsulated and nonmotile.

Identified by Gram reaction, cellular morphology, and motility. The bacterium is aerobic and is distinguished from similar species using biochemical

tests. *B. pertussis* is oxidase positive but urease, nitrate reductase, and citrate negative. The polymerase chain reaction is used in many laboratories to detect *B. pertussis* DNA.

Habitat Humans, and perhaps some higher primates, are the only known reservoirs.

Virulence Factors The primary virulence factors are fimbriae-like adhesion molecules that allow *B. pertussis* to recognize and bind to ciliated respiratory epithelial cells and exotoxins that destroy these host cells after the bacterium has bound.

Primary Infections/Disease *B. pertussis* is the etiological agent of whooping cough, which occurs in two stages. The catarrhal stage

occurs as mucus builds up in the airways and is marked by nasal drainage, congestion, sneezing, and occasional coughing. The second, or paroxysmal, stage manifests as episodes of persistent coughing followed by deep inhalations that produce a characteristic “whoop” as air is pulled through the congested larynx. Complications of pertussis are generally due to compromised respiration. The disease is responsible for only a few deaths a year in the United States but as many as 300,000 worldwide.

Control and Treatment Even with a robust vaccination program, pertussis has reached epidemic levels in many parts of the United States, primarily due to the fact that the childhood vaccine series does not provide long-term protection. Teenagers and adults often contract a mild form of the disease that can nevertheless be passed on to infants who are not yet vaccinated and have a much greater risk of contracting serious disease. The vaccine consists of a five-dose series with an additional booster given to adolescents and adults. Standard therapy for pertussis is a 1-week course of azithromycin or clarithromycin.

Figure 20.6 Young child suffering the coughing stages of pertussis (whooping cough). The majority of young children with this condition will require hospitalization for monitoring. Source: CDC

ages 2 months and 6 years. Due to changes in disease epidemiology (figure 20.7), it is clear that more booster doses are necessary. In response, the Centers for Disease Control and Prevention (CDC) now recommends an additional booster containing diphtheria and tetanus antigens, along with an acellular pertussis component, at 11 or 12 years of age. Further isolation and barrier precautions are implemented in child and health care settings to prevent infected workers from coming in contact with children or infants, who represent the highest-risk group for serious disease.

In 2013 a strain of pertussis was identified that was missing the protein pertactin, a protein that helps the bacteria attach to the

lining of the airways. Pertactin is one of several components of all pertussis vaccines. The CDC is currently conducting studies in the United States to determine whether an increase in pertactin deficient *B. pertussis* strains is one of the factors contributing to the increase in the number of reported pertussis cases. Current evidence suggests however that pertussis vaccines continue to prevent disease caused by both pertactin-positive and pertactin-negative pertussis strains since other components of the vaccines provide protection.

Figure 20.7 Incidence of pertussis (whooping cough) in the United States. Despite the availability of a vaccine, the number of pertussis cases continue to rise. Children under one year of age have not received the full vaccination series and are at greatest risk of infection. The CDC now recommends an additional booster at age 11 or 12.

Pathogen Profile #3 *Legionella pneumophila*

Source: Janice Carr/CDC

Microscopic Morphology Small gram-negative rods. *L. pneumophila* is motile and does not produce a capsule.

Identified by *Legionella* is fastidious and difficult to isolate, with disease often diagnosed by symptomatology and patient history. Laboratory identification of the pathogen usually relies on some combination of DNA probes, fluorescent antibody staining

of urinary and respiratory specimens, or cultivation on charcoal yeast extract agar, a medium selective for *Legionella*.

Habitat *Legionella* is widely distributed in freshwater habitats, where amoebas in the water serve as the primary reservoir. Human infections are commonly traced to tap water, spas, ponds, air conditioners, and misting systems.

Virulence Factors Most strains contain pili that allow the bacterium to bind to respiratory epithelial cells and have the ability to actively grow within macrophages.

Primary Infections/Disease Two distinct clinical forms of legionellosis exist. Shared symptoms include fever, cough, diarrhea, and abdominal pain. While the less severe form, Pontiac fever, is self-limiting, Legionnaires' disease—the more severe manifestation—progresses to pneumonia and has a mortality rate of 3% to 30%.

Control and Treatment Control is difficult due to the widespread nature of the pathogen, but cleaning and chlorination of artificial aquatic habitats provides some benefits. Levofloxacin is the primary treatment for Legionnaires' disease. Pontiac fever does not require antimicrobial treatment.

The genus *Alcaligenes** is another group of nonfermentative, oxidase-positive, motile bacteria in the same family as *Bordetella*. Members of *Alcaligenes* live primarily in soil and water habitats, and they may also become established as normal microbiota. The most common clinical species, *A. faecalis*, is isolated from feces, sputum, and urine. It is occasionally associated with opportunistic infections such as pneumonia, septicemia, and meningitis.

Minding Your T's and D's

The vaccines used to provide protection against pertussis, diphtheria, and tetanus provide an alphabet soup of acronyms—DPT, DTwP, DTaP, Tdap, DT and Td—that can confuse even trained medical personnel, potentially placing patients in danger. In order to lessen this confusion, we offer this brief primer.

Diphtheria and tetanus vaccines elicit the production of protective antibodies through the use of **toxoids**, inactivated exotoxins that are harmless but still provoke an immune response. Uppercase abbreviations (such as *D* in DPT or *T* in Tdap) refer to full-strength doses of toxoid, whereas lowercase letters (*d* in Tdap) denote reduced-strength formulations. Historically, pertussis vaccines contained whole-cell (*w*) pertussis antigens, whereas newer formulations of the vaccine contain acellular (*a*) antigens, meaning that only a portion of the cell is included in the vaccine. During the 1990s the whole-cell diphtheria/tetanus/pertussis vaccine (DPT or DTwP) series was replaced by one that relied on an acellular pertussis component (DTaP), whereas DT vaccines, containing only high levels of diphtheria and tetanus antitoxins, were given to children who could not tolerate the pertussis antigen. Current recommendations require administration of a Tdap booster—Boostrix or Adacel—during early adolescence. Tetanus and diphtheria boosters (Td) are recommended every 10 years, or after potential exposure to tetanus.

Legionella and Legionellosis

*Legionella** is a bacillus unrelated to other strictly aerobic gram-negative bacteria. Although the bacterium was originally described in the late 1940s, it was not clearly associated with human disease until 1976. The incident that brought it to the attention of medical microbiologists was a sudden outbreak of pneumonia that afflicted 200 American Legion members attending a convention and killed 29 of them. After 6 months of painstaking analysis, epidemiologists isolated the pathogen and traced its source to contaminated air-conditioning vents in the Legionnaires' hotel. The news media latched onto the name **Legionnaires' disease**, and the experts named their new isolate *Legionella*.

Legionellas are weakly gram-negative motile rods that range in morphology from cocci to filaments. They have fastidious nutrient requirements and can be cultivated only in special media (**figure 20.8a**) and cell cultures. Several species or subtypes have been characterized, but *L. pneumophila* (lung-loving) is the one most frequently isolated in infections.

Legionella appears to be widely distributed in aqueous habitats as diverse as tap water, cooling towers, spas, ponds, and other fresh waters. Its survival and persistence in these habitats is now known to be related to *Legionella*'s close associations with free-living amoebas (**figure 20.8b**). The bacteria can be released during aerosol formation and are often carried for long distances. Cases have been traced to supermarket vegetable sprayers and the fallout from the Mount Saint Helens volcano.

Studies since 1976 have determined that Legionnaires' disease is not a new disease and that earlier outbreaks occurred sporadically in conjunction with accidental exposure to contaminated environments. The disease is now known to be worldwide and prevalent in males over 50 years of age. Healthcare-associated infections occur most often in elderly patients hospitalized with diabetes, malignant

* *Alcaligenes* (alk'-uh-lij'-uh-nee-z) ME. *alkaly*, salt, and *L. generatus* to produce.

* *Legionella* (lee"-jun-ell'-uh).

Figure 20.8 Appearance of *Legionella pneumophila*. (a) A mixed culture of *Legionella* and other isolated bacteria on charcoal yeast extract medium. Arrows point to *Legionella* colonies, which are differentiated by their blue periphery and pale center. (b) *Legionella* living intracellularly in the amoeba *Vermamoeba vermiformis* (4,000 \times). Amoebas inhabiting natural waters are the reservoir for this pathogen and a means for it to survive in rather hostile environments. The pathogenesis of *Legionella* in humans is likewise dependent on its uptake by and survival in phagocytes. (both): Source: CDC

disease, transplants, alcoholism, and lung disease. Patients with the disease cannot communicate it to other persons.

Two major clinical forms of the disease are *Legionnaires' disease* and *Pontiac fever*. The symptoms of both are a rising fever (up to 41°C), cough, diarrhea, and abdominal pain. Legionnaires' disease is the more severe of the two, progressing to lung consolidation and impaired respiration and organ function. It has a fatality rate of 3% to 30%. In contrast, Pontiac fever does not lead to pneumonia and rarely causes death.

Legionellosis is diagnosed by symptomatology and the patient's history. Laboratory analyses include fluorescent antibody staining of specimens, cultivation on charcoal yeast extract (CYE) agar, and DNA probes. The disease is treated with levofloxacin or azithromycin. *Legionella*'s wide dispersal in aquatic habitats makes control difficult, though chlorination and regular cleaning of artificial habitats are of some benefit.

Check Your Progress SECTION 20.2

- List the four genera of bacteria that cause opportunistic infections and are physiologically similar to *Pseudomonas*.
- Compare the genera *Brucella* and *Francisella*. Include the pathology for each disease, reservoirs, portal of entry, and treatment.
- What is the pathologic effect of whooping cough?
- Who is most likely to contract whooping cough, and how would the disease be recognized?
- What is unusual about the reservoir of *Legionella*? What is the epidemiological pattern of the disease?

20.3 Identification and Differential Characteristics of Family Enterobacteriaceae

Expected Learning Outcomes

- Recall the medically important members of the Enterobacteriaceae and the characteristics they have in common.
- Name the biochemical tests commonly used to differentiate common opportunistic enterics.
- Explain the importance of the three major surface antigens seen in gram-negative enteric rods.

One large family of gram-negative bacteria that exhibits a considerable degree of relatedness is the Enterobacteriaceae. Although many members of this group inhabit soil, water, and decaying matter, they are also common occupants of the large bowel of humans and animals. All members are small (the average is 1 μm by 2–3 μm) non-spore-forming rods. The bacteria in this group grow best in the presence of air, but they are facultative and can ferment carbohydrates by an anaerobic pathway. This group is probably the most common one isolated in clinical specimens—both as normal microbiota and as agents of disease.

Enteric pathogens are the most frequent cause of diarrheal illnesses (**20.2 Making Connections**), which account for an annual mortality rate of 3 million people and an estimated 4 billion infections worldwide. Counting the total number of cases that receive medical attention, along with estimates of unreported, subclinical cases, enteric illness is probably responsible for more morbidity than any other disease. Prominent enteric pathogens include *Salmonella*, *Shigella*, and strains of *Escherichia*, many of which are harbored by human carriers.

Gram-negative enterics (along with *Pseudomonas* and *Acinetobacter*) account for more than 30% of all isolates in health-care associated infections (see figure 13.22). Their widespread involvement in hospital-acquired infections can be attributed to their constant presence in the hospital environment and their capacity to resist drying, disinfectants, and drugs. Enterics are commonly isolated from soap dishes, sinks, and invasive devices such as tracheal cannulas and indwelling catheters. The most important enteric opportunists are *E. coli*, *Klebsiella*, *Enterobacter*, *Serratia*, *Proteus*, and *Citrobacter*. Although these pathogens live in the intestine, the diseases they cause usually involve other body systems such as the lungs and the urinary tract.

The genera in this family share several key characteristics:

- glucose fermentation;
- nitrate reduction;
- oxidase-negative;
- in most, presence of flagella (except in *Shigella* and *Klebsiella*); and
- regular, straight rods.

A battery of biochemical tests is commonly used to identify the principal genera and species. Although the details of this process

20.2 MAKING CONNECTIONS

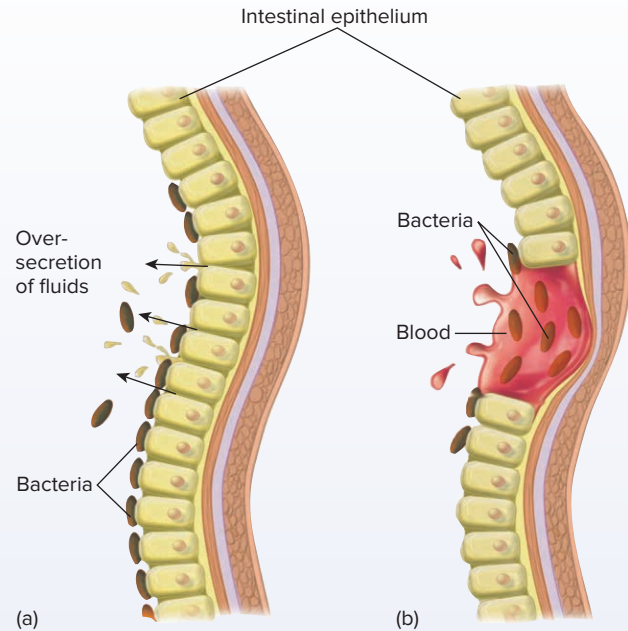

Diarrheal Disease

Diarrhea is an acute syndrome of the intestinal tract in which the volume, fluid content, and frequency of bowel movements increase. It is usually a symptom of **gastroenteritis** (inflammation of the lining of the stomach and intestine) and can be accompanied by severe abdominal pain. Diarrhea is generated by several pathologic states—most commonly infection, intestinal disorders, and food poisoning. Although the human large intestine ordinarily harbors a huge microbial population, most agents of diarrhea are not members of this normal gut microbiota but are acquired through contaminated food or water.

Infectious diarrhea occurs by one of two basic mechanisms: (1) The secretion of enterotoxins, or (2) Invasion of the intestinal epithelium by the microbe. In the toxigenic type of disease, bacteria release **enterotoxins** that bind surface receptors of the small intestine. These toxins disrupt the physiology of epithelial cells and cause increased secretion of electrolytes and water loss, a condition called secretory diarrhea. The organism itself does not invade the tissues. Secretory diarrhea is characterized by its large volume, and there is little blood in the stool. This is the mechanism of cholera (see chapter 21) and some types of *Escherichia coli* and *Shigella* infectious damage.

In a more invasive diarrheal disease, the microbe invades the tissues of the small or large intestine and damages cells that line the mucosa and underlying tissue layers. Signs and symptoms include pain in the rectum, blood in the stool, and ulceration of the inner lining. *Salmonella*, different strains of *Shigella* and *E. coli*, *Campylobacter*, and *Entamoeba histolytica* are responsible for this type of intestinal disease. Regardless of the cause, the loss of fluid that accompanies diarrhea results in severe dehydration and sometimes death. It is the second leading cause of death in children under five years old, and is responsible for killing approximately 760,000 children every year. Infants are especially vulnerable to diarrheal illness because of their smaller fluid reserves and undeveloped immunity.

See 21.2 Making Connections to review a successful support treatment that offsets some of the complications of diarrhea.

Mechanisms of infectious diarrhea. (a) In a toxigenic infection, the microbe remains on the surface of epithelial cells and secretes toxin into the cells. This results in disruption of cell metabolism and loss of electrolytes and water. (b) In an invasive infection, the microbe destroys epithelial cells and forms ulcerations, resulting in loss of the intestinal lining and bleeding.

Explain how toxigenic disease with no intestinal damage can be as severe as invasive disease. Answer available on Connect.

are beyond the scope of this text, a summary reviews the major steps (figure 20.9).

Because fecal specimens contain such a high number of normal residents, they can be inoculated first into enrichment media (selenite or GN—gram-negative—broth) that inhibit the normal microbiota and favor the growth of pathogens. Enrichment and nonfecal specimens are streaked onto selective, differential media such as MacConkey, EMB, or Hektoen enteric agar and incubated for 24 to 48 hours. Colonies developing on these media will provide the initial separation into lactose-fermenters and non-lactose-fermenters (figure 20.10; see figure 3.17c).

Isolated colonies are subcultured on triple-sugar iron (TSI) agar slants for further analysis. As is evident in figure 20.9, additional tests can differentiate isolates to the level of genus (table 20.2). One series of reactions, the IMViC (indole, methyl red, Voges-Proskauer, *i* for pronunciation, and citrate), is a traditional panel that can be used to differentiate among several genera (table 20.3). In general, whether an isolate is clinically significant depends upon the specimen's origin. For example, normal microbiota isolated from stool specimens do not usually signify

infection in that site, but the same organisms isolated from extraintestinal sites in sputum, blood, urine, and spinal fluid are considered likely agents of opportunistic infections.

The Family Enterobacteriaceae is traditionally divided into two subcategories. The **coliforms** include *Escherichia coli* and other gram-negative normal enteric microbiota that ferment lactose rapidly (within 48 hours). **Noncoliforms** are generally non-lactose-fermenting or slow lactose-fermenting bacteria that are either normal microbiota or regular pathogens. Although minor exceptions occur, this distinction has considerable practical merit in laboratory, clinical, and epidemiological terms. The following outline provides a framework for organizing the discussion of the Enterobacteriaceae.

Coliforms in Normal Microbiota: Rapid lactose-fermenting enteric bacteria that are normal residents and opportunistic (some serotypes of *E. coli* are true pathogens). Examples include:

<i>Escherichia coli</i>	<i>Klebsiella</i>
<i>Enterobacter</i>	<i>Hafnia</i>
<i>Serratia</i>	<i>Citrobacter</i>

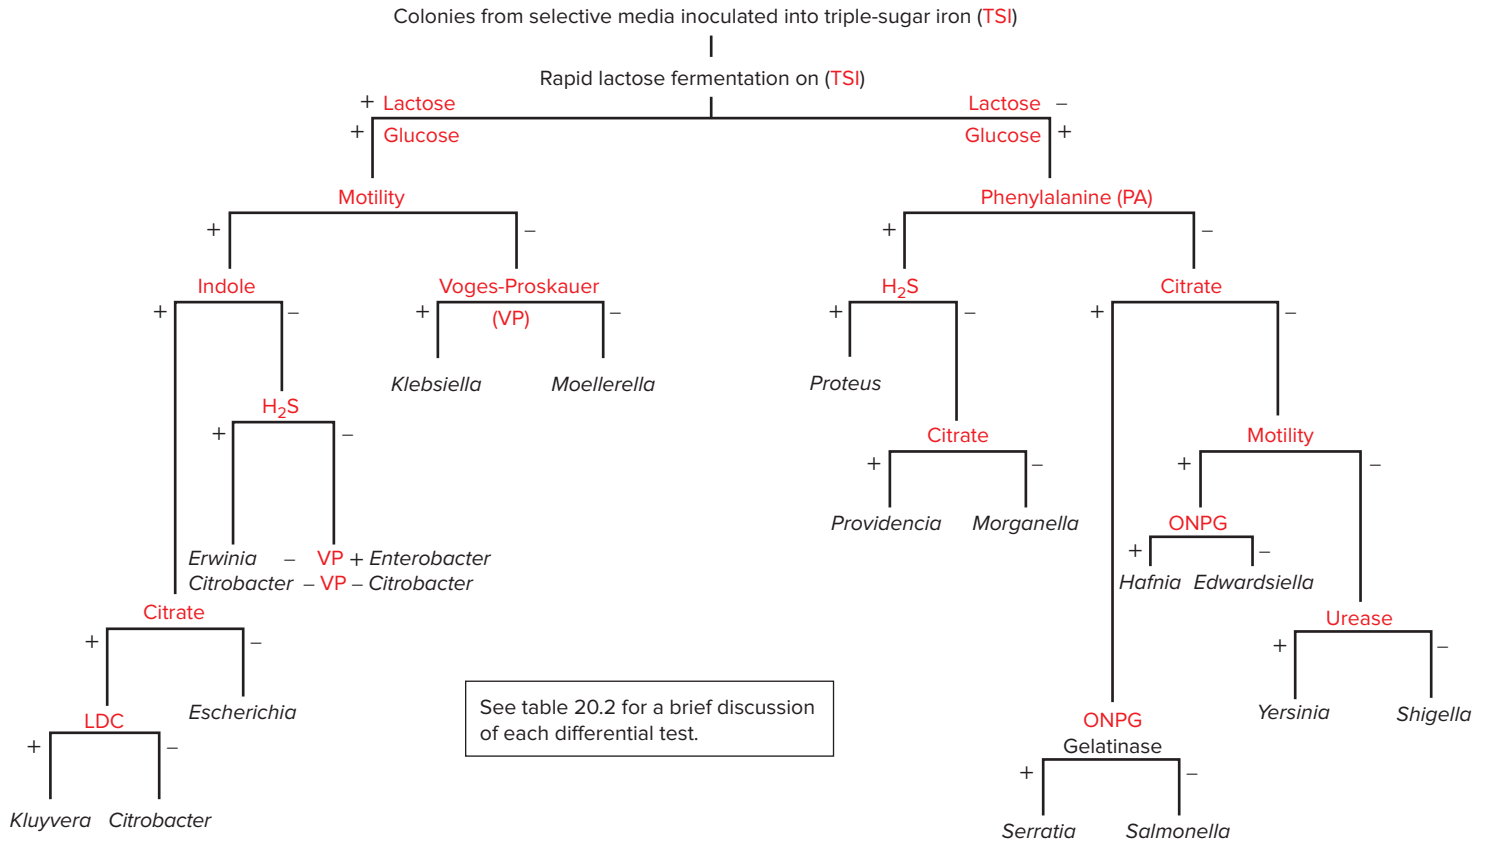

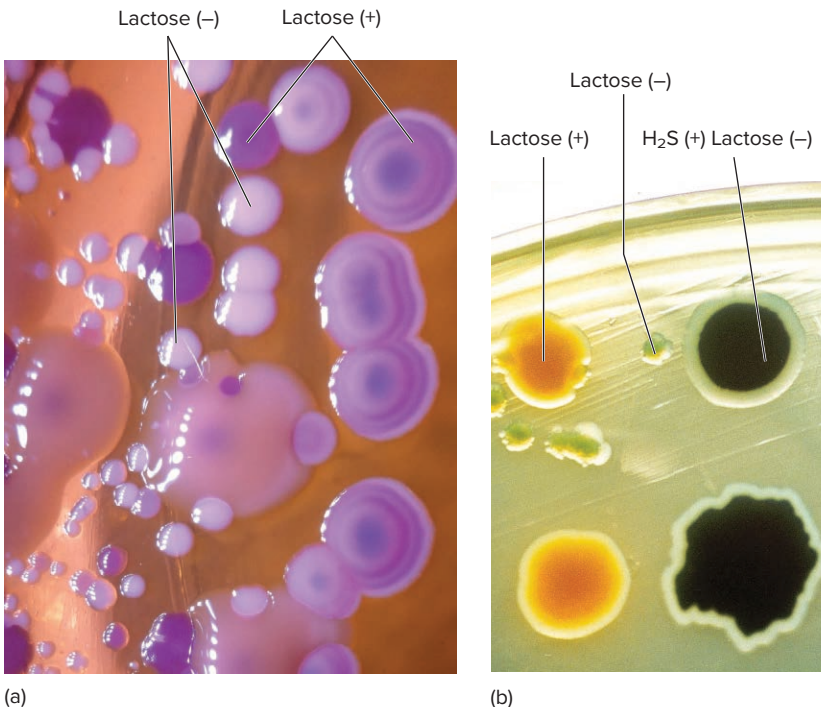

Figure 20.9 Outline of biochemical traits for separating selected enteric genera. Flowchart is based on the usual or dominant characteristics of examples used here.

Antigenic Structures and Virulence Factors

The gram-negative enterics have complex surface antigens that are important in pathogenicity and are also the basis of immune responses (figure 20.11). By convention, they are designated **H**, the **flagellar antigen**; **K**, the **capsule** and/or **fimbrial antigen**; and **O**, the **somatic or cell wall antigen**.² Not all species carry the H and K antigens, but all have O, the lipopolysaccharide implicated in endotoxic shock. Most species of gram-negative enterics exhibit a variety of

2. H comes from the German word *hauch* (breath) in reference to the spreading pattern of motile bacteria grown on moist solid media. K is derived from the German term *kapsel*. O is for *ohne-hauch*, or nonmotile.

TABLE 20.2 Protocol in Isolating and Identifying Selected Enteric Genera*

- **MacConkey agar** contains bile salts and crystal violet to inhibit gram-positive bacteria. It contains lactose and neutral red dye to indicate pH changes and differentiate the rapid lactose-fermenting bacteria from non-lactose-fermenters or slow fermenters. Lactose (+) colonies are red to pink from the accumulation of acid acting on the neutral red indicator (see figure 3.17c).
- **Levine's EMB agar** also contains bile salts, plus eosin and methylene blue dyes that cause lactose-fermenters to develop a dark nucleus and sometimes a metallic sheen over the surface. Non-lactose-fermenters are pale lavender and nonnucleated (**figure 20.10a**).
- **Hektoen enteric agar** also contains bile salts and is especially good for isolating pathogens. The bromthymol blue and acid fuchsin indicators differentiate the lactose-fermenters (salmon pink to orange) from the non-lactose-fermenters (green, blue-green) and also detect the production of H₂S gas, which turns the center of a colony black (**figure 20.10b**).
- **Utilization of lactose**, a disaccharide, requires two enzymes: a permease to bring lactose into the cell and β-galactosidase to split it into the monosaccharides glucose and galactose. Rapid fermenters have both enzymes. Slow fermenters have only galactosidase. **ONPG** is chemical shorthand for a test that detects these slow lactose-fermenters.
- **TSI** is a nonselective medium that indicates some combination of fermentation reactions (primarily lactose and glucose and possibly sucrose) by means of a phenol red indicator dye. It also reveals gas and **hydrogen sulfide (H₂S) production** (see figure 3.17a). Hydrogen sulfide gas is a product of the reduction of sulfur and is indicated by reacting with iron salts to form a black precipitate of ferric sulfide.
- The **indole test** indicates the capacity of an isolate to cleave a compound called indole off the amino acid tryptophan. If cleaving occurs, Kovac's reagent reacts with indole to form a bright red ring at the surface of the tube.
- The **methyl red (MR)** test indicates a form of glucose fermentation in which large amounts of mixed acids accumulate in the medium. The pH is lowered to around 4.2, so that methyl red dye remains red when added to the tube.
- The **Voges-Proskauer (VP)** test determines whether the product of glucose fermentation is a neutral metabolite called acetyl-methylcarbinol (acetoin). This substance reacts with Barritt's reagent to form a rosy-red tinge in the medium.
- **Citrate media** contain citrate as the only usable carbon source and a pH indicator, bromthymol blue. If an isolate can utilize this carbon source, it produces alkaline by-products, resulting in a conversion of the medium's color from green (neutral) to blue (alkaline).
- **Lysine and ornithine decarboxylase (LDC, ODC)** detect the presence of enzymes that remove carbon dioxide from amino acids. The end products are alkaline amines that raise the pH.
- **Urea media** contain 2% urea, a nitrogenous waste product of mammals, and phenol red pH indicator. The enzyme urease hydrolyses urea into ammonium, which raises the pH of the medium and turns the indicator bright pink.
- **Phenylalanine (PA)** deaminase, an enzyme produced primarily by the *Proteus* group, removes an amino group from the amino acid phenylalanine to produce phenylpyruvic acid. This reaction is visualized with ferric chloride, which turns olive green when it reacts with the phenylpyruvic acid.
- **Motility** is tested by a hanging drop slide or motility test medium (see figure 3.15b).

*The metabolic basis for some tests is discussed in chapter 8.

subspecies or serotypes caused by slight variations in the chemical structure of the HKO antigens. These are usually identified by serotyping, a technique in which specific antibodies are mixed with a culture to measure the degree of agglutination or precipitation (see chapter 17). Not only is serotyping helpful in classifying some species, but it also helps pinpoint the source of outbreaks by a particular serotype, making it an invaluable epidemiological tool.

Figure 20.11 Antigenic structures in gram-negative enteric rods. Variations in the composition of these antigens provide the basis for the serological types found in most genera.

The pathogenesis of enterics is tied to their production of endotoxins, exotoxins, capsules, fimbriae, and molecules that favor attachment to host cells. These factors function in invasion and destruction of tissues. Although most enterics are commensals, a significant number have a potential to rapidly alter their pathogenicity. As we saw in chapters 9 and 12, gram-negative bacteria freely transfer chromosomal or plasmid-borne genes that can mediate drug resistance, toxigenicity, and other adaptive traits. When this transference occurs in mixed populations of fecal residents (for example, in the intestines of carriers), it is possible for nonpathogenic or less pathogenic residents to acquire greater virulence (see the discussion of *E. coli* in section 20.4). The most common virulence genes transferred contain the codes for toxins, capsules, hemolysins, and fimbriae that promote invasion of the intestinal or urinary epithelia.

11. Which bacteria in the Family Enterobacteriaceae are true enteric pathogens and which ones are opportunists?
12. Briefly describe the methods used to isolate and identify enterics.
13. What is the basis of serological tests, and what is their main use for enterics?

20.4 Coliform Organisms and Diseases

Expected Learning Outcomes

12. Differentiate among the major enteric pathologies seen among various strains of *E. coli*.
13. Explain the role of *E. coli* in infantile and traveler's diarrhea.
14. State the significance of *E. coli* O157:H7.
15. Explain the importance of carbapenem-resistant Enterobacteriaceae infections and identify the organisms responsible for the majority of these infections.

Escherichia coli: The Most Prevalent Enteric Bacillus

*Escherichia** *coli* is the best-known coliform, largely because of its use as a subject for laboratory studies. Although it is called the colon bacillus and sometimes regarded as the predominant species in the intestine of humans, *E. coli* is actually outnumbered 9 to 1 by strictly anaerobic bacteria of the gut (*Bacteroides* and *Bifidobacterium*) that are not readily cultured. Its prevalence in clinical specimens and infections is due to its being the most common aerobic and nonfastidious bacterium in the gut. Even though *E. coli* is usually a commensal, it is far from harmless. Many of the 150 strains are not highly infectious, but some have developed greater virulence

through plasmid transfer, and others are opportunists. Pathogenic *E. coli* strains are grouped into **pathotypes**—strains of a single bacterial species that possess a common set of virulence factors. Six *E. coli* pathotypes are associated with diarrhea.

- **Enterohemorrhagic *E. coli* (EHEC)** causes hemorrhagic colitis and may lead to hemolytic uremic syndrome (HUS), which can cause severe damage to the kidney. Because much of its virulence is derived from the shiga toxin acquired from *Shigella*, it is also known **Shiga toxin producing *E. coli***, or **STEC**.
- **Enterotoxigenic *E. coli* (ETEC)** causes a severe diarrheal illness brought on by two exotoxins, termed heat-labile toxin (LT) and heat-stable toxin (ST), that stimulate heightened secretion and fluid loss. In this way, it mimics the pathogenesis of cholera (see figure 21.11). This serotype of *E. coli* also has fimbriae that provide adhesion to the small intestine.
- **Enteroinvasive *E. coli* (EIEC)** causes an inflammatory disease similar to **dysentery*** from *Shigella* that involves invasion and ulceration of the mucosa of the large intestine.
- **Enteropathogenic strains of *E. coli* (EPEC)** are linked to a wasting form of infantile diarrhea whose pathogenesis is not well understood.
- **Enteroaggregative *E. coli* (EAEC)** cells aggregate and colonize the intestinal mucosa; enterotoxins they release damage the host cells and induce inflammation, leading to diarrhea. Pediatric diarrhea is commonly caused by EAEC.
- **Diffusely adherent *E. coli* (DAEC)** is thought to be a minor cause of pediatric diarrhea.

Clinical Diseases of *E. coli*

Most clinical diseases of *E. coli* are transmitted exclusively among humans. Pathogenic strains of *E. coli* are frequent agents of infantile diarrhea, the greatest single cause of mortality among babies. Worldwide, 15% of childhood deaths are due to diarrhea. The rate of infection is higher in crowded tropical regions where sanitary facilities are poor, water supplies are contaminated, and adults carry pathogenic strains to which they have developed immunity.

The immature, nonimmune neonatal intestine has no protection against these pathogens entering in unsanitary food or water. The practice of preparing formula from dried powder mixed with contaminated water can be tantamount to inoculating the infant with a pathogen. Often the babies are already malnourished, and further loss of body fluids and electrolytes is rapidly fatal. Mothers in developing countries especially are being urged to nurse their infants so that the children get better and safer nutrition as well as gastrointestinal immunity (see Clinical Connections, “The Immunological Benefits of Breast-Feeding,” in section 15.5).

Despite the popular belief that “Montezuma’s revenge,” “Delhi belly,” and other travel-associated gastrointestinal diseases are caused by more exotic pathogens, up to 70% of traveler’s diarrhea cases are due to an enterotoxigenic strain of *E. coli*. Travelers pick up more virulent strains while eating or drinking contaminated foods. Within 5 to 7 days, victims are stricken with profuse, watery diarrhea, low-grade fever, nausea, and vomiting. Some travelers develop more chronic enteroinvasive dysentery that resembles *Shigella* or *Salmonella* infection.

* *Escherichia* (ess-shur-eeek'-ee-uh) After the German physician Theodor Escherich.

* *dysentery* (dis'-en-ter''-ee) Gr. *dys*, bad, and *enteria*, bowels.

Oral antimicrobics may be effective in the early phases of infection. Over-the-counter preparations that slow gut motility (kaolin or *loraperamide* [Imodium]) afford symptomatic relief, but they can also serve to retain the pathogen longer. They are probably not as effective as bismuth salicylate mixture (Pepto-Bismol), which counteracts the enterotoxin and also provides an antimicrobial effect.

The Role of *Escherichia coli* in Food Infections

The most highly publicized strain of *Escherichia coli* is an enterohemorrhagic strain famous for its involvement in infections traced to fast-food hamburgers that first appeared in 1982. Since that time, it has been commonly referred to by its antigen profile: **O157:H7**, which stands for somatic (O) type 157 and flagellar (H) type 7. This bacterial strain owes much of its virulence to a cell wall receptor that can fuse with the host cell membrane, creating a direct port into which the bacteria secrete toxins and other proteins into the host cell. This strain is also referred to as STEC—for shiga toxin producing *E. coli*—because it has acquired the gene for shiga toxin from *Shigella*. The toxin enters the host cell, binds ribosomes, and disrupts protein synthesis, leading to death and shedding of intestinal cells (see 20.2 Making Connections).

The pathogen has a reservoir in the intestine of cattle, who are unaffected by the bacterium. From there, it can enter the food chain in contaminated beef, water, and fresh vegetables. Commercially supplied hamburger is practically a “recipe” for transmission, because of the policy in meat processing plants to mix meats from hundreds of sources. A single animal carrier can potentially contaminate thousands of pounds of beef. The infectious dose is a mere 100 cells—even a small bit of uncooked meat could contain this amount. It has also become a contaminant in vegetables, fruit drinks, and groundwater into which animal waste has seeped. Approximately 2,000 to 4,000 cases per year are currently reported to the CDC; the actual number of cases is likely to be many times higher.

This strain of *E. coli* causes a range of symptoms and signs, from gastroenteritis and dysentery to fever and acute abdominal pain, similar to shigellosis. In about 10% of cases, a much more severe form of disease called hemolytic uremic syndrome (HUS) appears. This condition is caused by the effects of the shiga toxin on the blood and kidney, leading to hemolysis and kidney damage and failure. Children, the elderly, and immunocompromised people have the highest risk for this complication. Antibiotic treatments often are not effective.

The emergence of this pathogen has prompted the food and safety inspection section of the U.S. Department of Agriculture (USDA) to increase its monitoring of fresh meats and sausages. The primary way to rapidly identify it is with selective media in the lab or using serological tests that detect the somatic (O) and flagellar (H) antigens (figure 20.12). Currently, testing for O157:H7 is performed randomly, and it is not required by slaughterhouses and meat suppliers, but it has been successful in identifying pathogens in meats and has resulted in the recall of millions of pounds of hamburger. Largely because of this pathogen, the USDA now requires that all fresh meat and poultry products bear small warning labels to remind the consumer of safer handling instructions (see 20.3 Making Connections).

Miscellaneous Infections

Escherichia coli often invades sites other than the intestine. For instance, it causes 50% to 80% of urinary tract infections (UTI) in

Figure 20.12 Rapid identification of *E. coli* (EHEC). Rapid serotyping of *E. coli* is accomplished using latex beads coated with antibodies that recognize and bind to specific somatic or cellular antigens. Here the red clumps in the left sample indicate that the O111 bacteria have bound with the O111 antibody-coated latex beads. The sample on the right tested negative. *E. coli* O111 is, like *E. coli* O157:H7, a shiga toxin-producing strain of *E. coli*. © Peggy Greb/USDA/Science Source

healthy people. Urinary tract infections usually result when the urethra is invaded by its own endogenous bacterial colonists. The infection is more common in women because their relatively short urethras promote ascending infection to the bladder (cystitis) and occasionally the kidneys. Patients with bladder catheters are also at risk for *E. coli* urethritis. Other extraintestinal infections in which *E. coli* is involved are neonatal meningitis, pneumonia, septicemia, and wound infections. These often complicate surgery, endoscopy, tracheostomy, catheterization, renal dialysis, and immunosuppressant therapy.

E. coli and the Coliform Count

Because of its prominence as a normal intestinal bacterium in most humans, *E. coli* is currently one of the indicator bacteria to monitor fecal contamination in water, food, and dairy products. According to this rationale, if *E. coli* is present in a water sample, fecal pathogens such as *Salmonella*, viruses, or even pathogenic protozoa may also be present. Coliforms such as *E. coli* are used because they are present in larger numbers, can survive in the environment, and are easier and faster to detect than true pathogens. If a certain number of coliforms are detected in a sample, the water is judged unsafe to drink. This topic is covered in more detail in chapter 26.

Other Coliforms

Other coliforms of clinical importance mostly as opportunists are *Klebsiella*, *Enterobacter*, *Serratia*, and *Citrobacter* (see figure 20.9). These bacteria cause infection primarily when the natural host defenses fail, often in conjunction with medical procedures. Various members of this group can infect nearly any organ, but the most serious complications involve septicemia and endotoxemia. Because of their widespread occurrence, their drug resistance, and the poor medical state of the patients they infect, complete control will probably never be possible.

In addition to inhabiting the intestines of humans and animals, *Klebsiella** species are also found in the respiratory tracts of normal individuals. This colonization leads to the chronic lung infections with which the species is associated. Infection by this organism is promoted by the large capsule, which prevents phagocytosis (figure 20.13). Some strains also produce toxins. The most important species in this group is *Klebsiella pneumoniae*, a frequent

* *Klebsiella* (kleb-see-el'-uh) After Theodor Klebs, a German bacteriologist.

Pathogen Profile #4 *Escherichia coli*

Source: CDC

Microscopic Morphology Small, motile, gram-negative rods.

Identified by Gram reaction, morphology, and physiological and biochemical tests. *E. coli* is a facultative anaerobe that ferments lactose. It produces positive results for both the methyl red and indole tests and negative reactions for the Voges-Proskauer and citrate tests, results that distinguish it from other common enteric genera.

Habitat *E. coli* is a common inhabitant of the digestive tract of most warm-blooded animals.

Virulence Factors All strains of *E. coli* possess a capsule and LPS endotoxin. Individual serotypes express a variety of other virulence factors, including fimbriae, which allow attachment to host cells; heat-labile (LT) and heat-stable (ST) toxins that stimulate increased secretion and water loss (causing diarrhea); and shiga toxin, which can lead to hemorrhagic colitis.

Primary Infections/Disease *E. coli* is responsible for up to 70% of traveler's diarrhea, with some strains causing more severe enteroinvasive disease with ulceration of the mucosa of the large intestine.

Enteropathogenic strains of the bacterium are a leading cause of infantile diarrhea in developing countries. *E. coli* O157:H7 causes hemorrhagic colitis and, in about 10% of cases, progresses to hemolytic uremic syndrome (HUS), which can cause kidney failure. Up to 80% of urinary tract infections can be traced to *E. coli* originating from the body's own residents.

Control and Treatment Control of *E. coli* rests on preventing the entry of the bacterium into the food chain and water supply. Proper disinfection of water, isolation of potable water and sewage, care in harvesting fruits and vegetables, pasteurization of milk and fruit juices, along with a aseptic slaughtering of meat animals all contribute to this goal.

Treatment of *E. coli* infections in otherwise healthy people may be contraindicated because it often increases the speed with which endotoxin is released into the system. Preparations that slow gut motility (diphenoxylate/atropine [Lomotil]) relieve symptoms but allow the pathogen to remain in the gut for a longer period, increasing the risk of HUS. Bismuth salicylate (Pepto-Bismol), which both counteracts toxins and provides an antimicrobial effect, is the best treatment in most cases.

Figure 20.13 The mucoid colonies of *Klebsiella pneumoniae* are evidence of the bacterium's heavy capsule. Source: CDC

secondary invader and cause of nosocomial pneumonia, meningitis, bacteremia, wound infections, and UTIs.

Enterobacter and a closely related genus, *Hafnia*, commonly inhabit soil, sewage, and dairy products. Urinary tract infections account for the majority of clinical diseases associated with *Enterobacter*. The bacterium is also isolated from surgical wounds, spinal fluid, sputum, and blood. Although sometimes regarded as a minor pathogen, this organism is lethal when introduced into the bloodstream. In one outbreak of *Enterobacter* septicemia associated with contaminated intravenous fluids, 150 people were infected and 9 died.

Citrobacter, a regular inhabitant of soil, water, and the human colon, is an occasional opportunist in urinary tract infections and bacteremia in debilitated persons.

Figure 20.14 The two faces of *Serratia marcescens*. (Left) A culture incubated at 20–30°C produces colonies with a distinctive red pigment (prodigiosin). (Right) A culture incubated at 38°C (body temperature) grows but stops producing this pigment and has off-white colonies (10X). Cultures from infections will not usually show the distinctive red pigment because the incubation temperature is too high. (both): © Kathy Park Talaro

Serratia occurs naturally in soil and water as well as in the intestine. A common species, *Serratia marcescens*,* produces an intense red pigment when grown at temperatures between 20°C and 30°C, and produces little or no pigment above 37°C (figure 20.14). This production of pigment has been used in the past in a misguided attempt to track movements of air currents in hospitals and over

* *Serratia* (sur-at'-ee-uh) In memory of the great physicist S. Serrati and *marcescens* (mar-sess'-uns) for "fading away."

cities and even to demonstrate transient bacteremia after dental extraction. Unfortunately this species is far from benign and is fully capable of invading a compromised host. *Serratia pneumonia*, particularly prevalent in alcoholics, is transmitted by contaminated respiratory-care equipment and infusions. The organism is often implicated in burn and wound infections, as well as in fatal septicemia and meningitis in immunosuppressed patients.

Carbapenem-Resistant Enterobacteriaceae

Of urgent concern is a group of bacteria referred to as **carbapenem-resistant Enterobacteriaceae**, or **CRE**. These bacteria, mostly species of *Klebsiella*, *Enterobacter*, and certain strains of *E. coli*—always troublesome opportunists in the hospital setting—have taken on added importance as they have become resistant to many classes of antibiotics, particularly carbapenems, which are frequently the antibiotic of last resort for these infections. The resistant bacteria have acquired genes for one of three different enzymes, known as KPC (*Klebsiella pneumoniae* carbapenemase), NDM (New Delhi Metallo-beta-lactamase) or VIM (Verona Integron-Mediated Metallo-β-lactamase), any one of which provides resistance to carbapenem antibiotics. KPC is the most common of the three enzymes, especially in the United States, and was first identified in 2001.

An estimated 140,000 healthcare-associated Enterobacteriaceae infections occur in the United States each year; with about 9,300 of these caused by CRE. Each year, approximately 600 deaths result from infections caused by carbapenem-resistant *Klebsiella spp.* and carbapenem-resistant *E. coli*. Patients whose care requires indwelling devices like ventilators, urinary or intravenous catheters, or endoscopes are at particular risk. Duodenoscopes—a specialized type of endoscope inserted through the mouth and down to the intestine to study the bile ducts, pancreatic duct and gallbladder—have been implicated in the transfer of CRE from patient to patient. Read more about the difficulty in sterilizing reusable medical devices in chapter 11.

Quick Search

To learn more about the CRE outbreak at the UCLA medical center, search the Internet for “A Killer on the Loose at UCLA.”

20.5 Noncoliform Enterics

Expected Learning Outcomes

16. Differentiate between true noncoliform enteric pathogens and opportunistic genera.
17. Distinguish the pathologies of typhoidal and nontyphoidal salmonellosis.
18. Identify the possible sources of *Shigella* infection.
19. Recall the etiologic agent of plague, and create a simple diagram of the infection cycle.
20. Recall the diseases attributable to infection with species in the genus *Haemophilus*, and identify which is most severe.

Opportunists: *Proteus* and Its Relatives

The three closely related genera *Proteus*,* *Morganella*,* and *Providencia** are saprobes in soil, manure, sewage, and polluted water and commensals of humans and other animals. Despite widespread distribution, they are ordinarily harmless to a healthy individual. *Proteus* species swarm on the surface of moist agar in an unmistakable concentric pattern (figure 20.15). They are commonly involved in urinary tract infections, wound infections, pneumonia, septicemia, and occasionally infant diarrhea. *Proteus* urinary infections appear to stimulate renal stones and damage due to the urease they produce and the rise in urine pH this causes. *Morganella morganii* and *Providencia* species are involved in similar infections. One opportunist, *P. stuartii*, is a frequent invader of burns. Because of widespread antibiotic resistance, therapy is guided by susceptibility testing.

True Enteric Pathogens: *Salmonella* and *Shigella*

The salmonellae and shigellae are distinguished from the coliforms and the *Proteus* group by having well-developed virulence factors,

* *Proteus* (pro'-tee-us) After Proteus, a Greek sea god who could assume many forms.

* *Morganella* (mor-gan-ell'-uh) after T. H. Morgan.

* *Providencia* (prah-vih-den'-see-uh) after Providence, RI.

Check Your Progress SECTION 20.4

14. Explain the difference between enterohemorrhagic, enterotoxigenic, enteroinvasive, enteropathogenic, enteroaggregative, and diffusely adherent strains of *E. coli*.
15. Describe the kinds of infections for which *E. coli* is primarily responsible.
16. Justify treating *E. coli* O157:H7 differently from other strains of the species.
17. Relate the pathology of hemolytic uremic syndrome.
18. Explain the concern that CRE infection causes in the healthcare community.

Figure 20.15 The wavelike swarming pattern of *Proteus vulgaris* is typical of this genus. Growth on agar creates concentric rings rather than discrete colonies. This makes isolation of colonies in mixtures containing *Proteus* difficult. © K. Talaro

being primary pathogens, and not being normal residents of humans. The illnesses they cause—called **salmonellosis** and **shigellosis**, respectively—show some gastrointestinal involvement and diarrhea but often affect other systems as well.

Typhoid Fever and Other Salmonellosis

The naming of bacteria in the genus *Salmonella** is more complicated than that seen with other organisms. The genus contains two species, *Salmonella enterica*, and *Salmonella bongori* (a species found almost exclusively in cold-blooded animals like lizards). *Salmonella enterica* is divided into six subspecies; *enterica*, *salamae*, *arizonae*, *diarizonae*, *houtenae*, and *indica*. Additionally, each isolate is identified as belonging to one of over 2,500 serotypes, based on its expression of O and H antigens. The serotype typically reflects the source of the isolate, such as Typhimurium (found in rodents) or Newport (the city of isolation). Therefore, the formal designation of a *Salmonella* serotype is its genus–species–subspecies name, followed by “serotype” and the serotype name. To make matters even more confusing, the formal name is often abbreviated to include only the genus and serotype. Examples include:

- *Salmonella enterica* subspecies *enterica* serotype Typhimurium
- *Salmonella* serotype Newport
- *Salmonella* ser. Enteritidis

* *Salmonella* (sal-moh-nel'-uh) After Daniel Salmon, an American pathologist.

Figure 20.16 Prevalence of salmonellosis from 1971 to 2013. The vast majority of cases are nontyphoidal gastroenteritis and food poisoning. Cases of typhoid fever are depicted with an inset. This disease is sporadic and is often brought back to the United States by travelers.

Commonly the word “serotype” is also eliminated from the full name (*Salmonella* Typhimurium), but this naming convention is discouraged. Occasionally the serotype is written as a species (*Salmonella typhimurium*), a practice that is simply incorrect because serotypes have no taxonomic standing.

Salmonellae are flagellated, grow readily on most laboratory media, and survive outside the host in environments such as fresh water and freezing temperatures. These pathogens are resistant to chemicals such as bile and dyes (the basis for isolation on selective media) and do not lose virulence after long-term artificial cultivation. The complexity of identifying *Salmonella* serotypes usually requires specialists at the CDC.

Typhoid fever is so named because it bears a superficial resemblance to typhus, a rickettsial disease, even though the two diseases are otherwise very different. Typhoid fever is caused by *Salmonella* serotype Typhi. *Salmonella* serotype Paratyphi causes paratyphoid, a very similar disease; both bacteria are considered typhoidal *Salmonella*. In the United States, the incidence of typhoid fever has remained at a steady rate since the early 1970s, appearing sporadically (**figure 20.16**). Of the 200 to 400 hundred cases reported annually, roughly half are imported from endemic regions. In other parts of the world, typhoid fever is still a serious health problem responsible for 200,000 deaths each year and millions of cases.

The typhoid bacillus usually enters the alimentary canal along with water or food contaminated by feces, although it is occasionally spread by close personal contact. Because humans are the exclusive hosts for *Salmonella* serotype Typhi, asymptomatic carriers are important in perpetuating and spreading typhoid. Even 6 weeks after convalescence, about half of recovered patients still shed the bacillus. A small number of people chronically carry the bacilli for longer periods in the gallbladder; from this site the bacilli are constantly released into the intestine and feces.

The number of bacilli that must be swallowed to initiate infection is between 1,000 and 10,000. Within the small intestine, the bacilli adhere to the mucosa and then initiate an invasive infection that leads eventually to septicemia. Symptoms are fever and abdominal pain, along with alternating diarrhea and constipation. The typhoid bacillus infiltrates the mesenteric lymph nodes and the phagocytes of the liver and spleen. In some people the small intestine develops areas of ulceration that are vulnerable to hemorrhage, perforation, and peritonitis (**figure 20.17**). Its presence in the general circulation may lead to nodules or abscesses in the liver or urinary tract. Prompt treatment greatly reduces the possibility of death.

A preliminary diagnosis of typhoid fever can be based upon the patient’s history and presenting symptoms, supported by a rising antibody titer (see chapter 17). However, definitive diagnosis requires isolation of the typhoid bacillus. Either ciprofloxacin or ceftriaxone is the drug of choice, though some strains are resistant to these. Antimicrobial drugs are usually effective in treating the chronic carrier, but surgical removal of the gallbladder may be necessary in individuals with chronic gallbladder inflammation. Two vaccines are available: One is a live attenuated oral vaccine, and the other is based on the capsular polysaccharide. Both provide temporary protection for travelers and military personnel.

Figure 20.17 The phases of typhoid fever. (a) Ingested cells invade the small intestinal lining. (b) From this site, they enter the bloodstream, causing septicemia and endotoxemia. (c) Infection of the lymphatic tissue of the small intestine can produce varying degrees of ulceration and perforation of the intestinal wall. (d) Image of an infected jejunum; note large areas of ulceration and a deep perforation. (d): Source: CDC

Animal Salmonellosis

Salmonellosis other than typhoid fever are designated as food poisoning or gastroenteritis and are usually less severe than typhoid fever. The nontyphoidal members all belong to the same species (*Salmonella enterica*) and one of the six subspecies (*enterica*, *salamae*, *arizonae*, *diarizonae*, *houtenae*, and *indica*), but have different serotypes. Of the 2,500 different serotypes, half of all infections are caused by the serotypes Enteritidis, Typhimurium, Newport, and Javiana.

Nontyphoidal salmonellosis are more prevalent than typhoid fever and are currently holding steady at 40,000 to 50,000 cases a year.

The CDC estimates that the true incidence is actually much higher, around 1.5 million cases per year (see figure 20.16). Unlike typhoid, all strains are zoonotic in origin, but humans may become carriers under certain circumstances. *Salmonella* are normal intestinal microbiota in cattle, poultry, rodents, and reptiles. Animal products such as meat and milk can be readily contaminated during slaughter, collection, and processing. There are inherent risks in eating poorly cooked beef or unpasteurized fresh or dried milk, ice cream, and cheese. A particular concern is the contamination of foods by rodent feces. Several outbreaks of infection have been traced to unclean food storage or to food-processing plants infested with rats and mice.

It is estimated that one out of every three chickens is contaminated with *Salmonella*, and other poultry such as ducks and turkeys are also affected. Eggs are a particular problem because the bacteria may actually enter the egg while the shell is being formed in the chicken. The poultry industry has begun using a probiotic containing a mixture of normal microbiota sprayed on newly hatched chicks to colonize them. This inoculation appears to curb the acquisition of *Salmonella* in a high percentage of treated animals. In general, one should always assume that poultry and poultry products harbor *Salmonella* and handle them accordingly, with clean techniques and adequate cooking (**20.3 Making Connections**). Drug resistance in the salmonellas is on the rise, some of which can be traced to the practice of adding antibiotics to animal feeds.

Most cases are traceable to a common food source such as milk or eggs. Outbreaks have occurred in association with milk, homemade ice cream made with raw eggs, and Caesar salad. Some cases may be due to poor sanitation. In one outbreak, about 60 people became infected after visiting the Komodo dragon (a large lizard) exhibit at the Denver zoo. They apparently neglected to wash their hands after handling the rails and fence of the dragon's cage.

The symptoms, virulence, and prevalence of *Salmonella* infections can be described by means of a pyramid, with typhoid fever at the peak, gastroenteritis at intermediate levels, and asymptomatic infection at the base. In typhoid fever, elevated body temperature and septicemia are much more prominent than gastrointestinal disturbances. Gastroenteritis is manifested by symptoms of vomiting, diarrhea, fluid loss, and mucosal lesions. In contrast to typhoid fever, the symptoms of nontyphoidal salmonellosis, in otherwise healthy adults, subside after 2 to 5 days without medical intervention. In the United States, *Salmonella* causes the highest death rate among enteric pathogens, usually in elderly persons.

Serotyping is not necessary before administering treatment; it is attempted primarily when the source of infection must be traced, as in the case of outbreaks and epidemics. Culturing of *Salmonella* from blood, urine, or stool remains the diagnostic method of choice. Treatment for complicated cases of gastroenteritis is similar to that for typhoid fever; uncomplicated cases are handled by fluid and electrolyte replacement.

Shigella and Bacillary Dysentery

*Shigella** causes a common but often incapacitating dysentery called shigellosis, which is marked by fever, nausea, painful abdominal cramps, and frequent defecation of watery stool filled

* *Shigella* (shih-gel'-uh) After K. Shiga, a Japanese physician.

20.3 MAKING CONNECTIONS

Avoiding Gastrointestinal Infections

Most food infections or other enteric illnesses caused by *Salmonella*, *Shigella*, *Vibrio*, *Escherichia coli*, and other enteric pathogens are transmitted by a combination of the Five *F*'s—feces, food, fingers, flies, and fomites—as well as by water. Individuals can protect themselves from infection by taking precautions when preparing food and traveling; communities can protect their members by following certain public health measures.

In the Kitchen

A little knowledge and good common sense go a long way. Food-related illnesses can be prevented by

1. Use of good sanitation methods while preparing food. This includes liberal hand washing, disinfecting surfaces, sanitizing utensils, and preventing contamination by mechanical vectors such as flies and cockroaches.
2. Use of temperature. Sufficient cooking of meats, eggs, and seafood is essential. Bringing meat up to 155°F (68°C) for 10 minutes would kill most food-borne pathogens. Refrigeration and freezing prevent multiplication of bacteria in fresh food that is not to be cooked (but remember, it does not kill them).
3. Sell-by dates are guidelines for supermarkets to remove unsold fresh meat off their shelves. They also give consumers information about how fresh the products are. Storage recommendations issued by the USDA are that chicken and fish be cooked or frozen no later than 2 days after its sell-by date. You should cook or freeze beef, pork, and lamb no more than 5 days after their sell-by dates.*
4. Do not taste uncooked batter made with raw eggs or ground meats before cooking. Do not consume rare or pink hamburger.

*For more information, consult the food and safety inspection service of the USDA on the Internet.

with mucus and blood. The etiologic agents (*Shigella dysenteriae*, *S. sonnei*, *S. flexneri*, and *S. boydii*) are primarily human pathogens, though they can infect apes. All produce a similar disease that can vary in intensity. They are nonmotile, nonencapsulated, and not fastidious. The shigellae resemble some types of pathogenic *E. coli* so closely that they are placed in the same subgroup.

Although *S. dysenteriae* causes the severest form of dysentery, it is uncommon in the United States and occurs primarily in the Eastern Hemisphere. In the past decade, the prevalent agents in the United States have been *S. sonnei* and *S. flexneri*, which cause approximately 20,000 reported cases each year, half of them in children between 1 and 10 years of age. Shigellosis is acquired primarily by eating fecally contaminated foods. A quick guide to remembering the sources is “feces transferred to food, fingers, flies, and sometimes fomites (Five *F*'s).” It is also acquired through direct person-to-person contact, largely because of the small infectious dose required (100–200 cells). The disease is mostly associated

SAFE HANDLING INSTRUCTIONS

THIS PRODUCT WAS PREPARED FROM INSPECTED AND PASSED MEAT AND/OR POULTRY. SOME FOOD PRODUCTS MAY CONTAIN BACTERIA THAT COULD CAUSE ILLNESS IF THE PRODUCT IS MISHANDLED OR COOKED IMPROPERLY. FOR YOUR PROTECTION, FOLLOW THESE SAFE HANDLING INSTRUCTIONS.

 <p>KEEP REFRIGERATED OR FROZEN. THAW IN REFRIGERATOR OR MICROWAVE.</p>	 <p>KEEP RAW MEAT AND POULTRY SEPARATE FROM OTHER FOODS. WASH WORKING SURFACES (INCLUDING CUTTING BOARDS), UTENSILS, AND HANDS AFTER TOUCHING RAW MEAT OR POULTRY.</p>	 <p>COOK THOROUGHLY.</p>  <p>KEEP HOT FOODS¹ HOT. REFRIGERATE LEFTOVERS IMMEDIATELY OR DISCARD.</p>
--	---	--

Supermarket label emphasizes precautions in handling, storing, and cooking meat and poultry products, as a way to avoid food-borne disease. Source: United States Department of Agriculture. www.fsis.usda.gov

While Traveling

1. Combat the Five *F*'s with the Five *B*'s—bread, bananas, beer, bottled beverages, and boiled water. In other words, food and drink that are packaged or heated.
2. Do not brush your teeth or wash fruit or vegetables in tap water.
3. Pack anti-diarrheal medicines and water disinfection tablets.

Community Measures

1. Water purification: most enteric pathogens are destroyed by ordinary chlorination
2. Pasteurization of milk
3. Detection and treatment of carriers
4. Restriction of carriers from food handling
5. Constant vigilance during floods and other disasters that result in sewage spillage and contamination of food and drink
6. Implementation of PulseNet database for following outbreaks of enteric pathogens

What are some preventive measures for safely consuming fruits and vegetables that won't be heated or cooked? Answer available on Connect.

with lax sanitation, malnutrition, and crowding, and is spread epidemically in day care centers, prisons, mental institutions, nursing homes, and military camps. As in other enteric infections, *Shigella* can establish a chronic carrier condition in some people that lasts several months.

Shigellosis is different from salmonellosis in that *Shigella* invades the villus cells of the large intestine, rather than the small intestine. In addition, it is not as invasive as *Salmonella* and does not perforate the intestine or invade the blood. It enters the intestinal mucosa by means of lymphoid cells in Peyer's patches. Once in the mucosa, *Shigella* instigates an inflammatory response that causes extensive tissue destruction. The most important virulence factors of *Shigella* are toxins. The release of endotoxin causes fever, and enterotoxin damages the mucosa and villi. Local areas of erosion give rise to bleeding and heavy mucus secretion (**figure 20.18**). *Shigella dysenteriae* produces a heat-labile exotoxin (shiga toxin) that has a number of effects, including injury to nerve

Pathogen Profile #5 *Salmonella typhi*, *Salmonella enterica*

Source: Janice Haney Carr/CDC

Microscopic Morphology Small, motile, gram-negative rods.

Identified by Gram reaction, morphology, and biochemical and serological tests. Because of the complexity of the genus, with thousands of different serotypes, specialized antibody-based tests are generally required to achieve full identification, and this process is not often attempted by most laboratories.

Habitat Humans are the exclusive hosts for *Salmonella enterica* serotypes Typhi and Paratyphi, whereas other serotypes of *Salmonella* are normal intestinal residents of cattle, poultry, rodents, and reptiles.

Virulence Factors In addition to LPS endotoxin, *Salmonella* species produce a capsule (referred to as the V_i antigen) that increases the infectivity of the bacterium. The entire genus is robust and survives well outside the host environment. Antibiotic resistance is common in many strains.

Primary Infections/Disease *Salmonella enterica* serotype Typhi is the causative agent of typhoid fever, a rare (400 U.S. cases per year) yet serious illness that progresses from fever and diarrhea to septicemia and peritonitis. Untreated, the disease has a mortality

rate of about 20%. Two of the three strains of *Salmonella enterica* serotype Paratyphi cause paratyphoid, a disease very similar to typhoid fever. The remainder of the approximately 2,500 serotypes of *Salmonella enterica* may cause *Salmonella* food poisoning and gastroenteritis (nontyphoidal salmonellosis), with over 40,000 reported cases per year in the United States (the number of unreported U.S. cases may be as high as 1.5 million annually). The disease is marked by fever, vomiting, diarrhea, fluid loss, and mucosal lesions.

Control and Treatment Because humans are the sole host of the Typhi and Paratyphi serotypes, asymptomatic carriage must be controlled, either through antibiotic treatment—ciprofloxacin or ceftriaxone—or removal of the gallbladder, where the bacterium often resides. Because other species of *Salmonella* exist as part of the microbiota of a wide variety of animals, elimination of the bacterium is effectively impossible, and control focuses on preventing ingestion of live bacteria. Adequate sanitation during food preparation, proper hand washing, and refraining from consuming unwashed fruits or vegetables, inadequately cooked meat and eggs, and unpasteurized milk all contribute to this goal. In otherwise healthy people, nontyphoidal salmonellosis is self-limiting, and symptoms subside after 2 to 5 days.

cells and damage to the intestine. Shiga toxin also causes damage to the kidneys by the same mechanism seen in *E. coli* O157:H7-related hemolytic uremic syndrome.

Diagnosis is complicated by the coexistence of several alternative candidates for bloody diarrhea such as *E. coli* and the protozoans *Entamoeba histolytica* and *Giardia lamblia*. Isolation and identification follow the usual protocols for enterics. Infection is

treated by fluid replacement and oral drugs such as ciprofloxacin and sulfatrimethoprim (SxT) unless drug resistance is detected, in which case azithromycin or cephalosporins are prescribed. Prevention follows the same steps as for salmonellosis (see 20.3 Making Connections). There is no vaccine yet available.

(b) A section through the large intestine reveals points of hemorrhage that release bloody discharges. Source: CDC

Fresh Foods and Infection

Fresh produce is responsible for half of all food-borne infections. The most common sources in order of occurrence are lettuce, sprouts, juice, melon, tomatoes, and spinach. One major reason for this association is that produce is consumed raw and thus not subject to heating that would reduce the microbial load. The predominant agents of infection are *E. coli*, *Salmonella*, *Listeria*, and *Shigella*. If produce is grown in contaminated soil and water and not properly cleaned or stored, it may harbor and even grow pathogens. The consumption of such products has increased tremendously in the past 10 years, and this has been accompanied by thousands of outbreaks all over the world. In a well-studied case, several outbreaks of diarrheal disease were reported in restaurant patrons who had consumed parsley. Tracing back the source of infection, investigators found a strain of *Shigella* in salads and appetizers. The parsley, grown in Baja, Mexico, had been stored and shipped in ice made from contaminated, unchlorinated water. This pathogen is notorious for having a low infectious dose, and this one source ultimately led to dozens of infections nationwide.

Other outbreaks of food infection that received significant publicity are shown in the following table.

Pathogen	Number of Cases	Food Involved	Probable Source of Pathogen
<i>E. coli</i> O157:H7	907	Cucumbers	Soil contaminated by livestock
<i>Listeria</i>	146	Cantaloupe	Contaminated packing equipment
<i>Salmonella</i>	561	Alfalfa sprouts	Field contamination?
<i>Shigella</i>	406	Bean dip	Produce contaminated by human carrier

Due to the globalization of food, these products can originate from anywhere in the world, from local farms to countries thousands of miles away. A national information-sharing system—PulseNet—has been set up to investigate and tabulate these outbreaks, using a powerful, specific tool called pulsed-field gel electrophoresis. Additional information on this subject can be accessed at “CDC Foodborne Outbreaks.”

The Enteric *Yersinia* Pathogens

The genus *Yersinia** contains three species, all of which cause zoonotic infections called *yersinoses*. *Yersinia enterocolitica* and *Y. pseudotuberculosis* are intestinal inhabitants of wild and domestic animals that cause enteric infections in humans, and *Y. pestis* is the nonenteric agent of bubonic plague.

Yersinia enterocolitica has been isolated from healthy and sick farm animals, pets, wild animals, and fish, as well as fruits, vegetables, and drinking water. During the incubation period of about 4 to 10 days, the bacteria invade the small intestinal mucosa, and some cells enter the lymphatics and are harbored intracellularly in phagocytes. Inflammation of the ileum and mesenteric lymph nodes gives rise to severe abdominal pain that mimics appendicitis. Although it shares many characteristics with *Y. enterocolitica*, *Yersinia pseudotuberculosis* infections tend to be less serious and center upon lymph node inflammation rather than mucosal involvement.

Yersinia pestis and Plague

The word **plague**⁴ conjures up visions of death and morbidity unlike any other infectious disease. Although pandemics of plague have probably occurred since antiquity, the first one that was reliably chronicled killed an estimated 100 million people in the sixth century. The last great pandemic occurred in the late 1800s and was transmitted around the world, primarily by rats transported in ships. The disease was brought to the United States through the port of San Francisco around 1906. Eventually infected rats mingled with native populations of rodents and gradually spread the populations throughout the West and Midwest. The cause of this dread disease is a tiny, harmless-looking gram-negative rod called *Yersinia pestis*, with unusual bipolar staining and capsules (figure 20.19).

Figure 20.19 A Gram stained preparation of *Yersinia pestis* in the blood of an infected mouse. The cells exhibit a distinctive bipolar morphology in which the ends of the cell stain darker—making it look like a “safety pin” (1,000X). Source: CDC

Virulence Factors

Strains of the plague bacillus are just as virulent today as in the Middle Ages. Some of the virulence factors that coincide with its high morbidity and mortality are capsular and envelope proteins, which protect against phagocytosis and foster intracellular growth. The bacillus also produces coagulase, which clots blood and is involved in clogging the esophagus in fleas and obstructing blood vessels in humans. Other factors that contribute to pathogenicity are endotoxin and a highly potent murine toxin.

The Complex Epidemiology and Life Cycle of Plague

The plague bacillus exists naturally in many animal hosts throughout the world, even though the incidence of disease has been reduced in most areas. Plague still exists endemically in large areas of Africa, South America, the Mideast, Asia, and the former Soviet Union, where it sometimes erupts into epidemics. In the United States, sporadic cases (usually fewer than 10) occur as a result of contact with wild and domestic animals. No cases of human-to-human transmission have been recorded since 1924. Persons most at risk for developing plague are veterinarians and people living and working near woodlands and forests. Cases are restricted to locations west of the Mississippi River in the United States.

The epidemiology of plague is among the most complex of all diseases. It involves several different types of vertebrate hosts and flea vectors, and its exact cycle varies from one region to another. A general scheme of the cycle is presented in figure 20.20. Humans can develop plague through contact with wild animals (**sylvatic plague**), domestic or semidomestic animals (**urban plague**), or infected humans.

The Animal Reservoirs The plague bacillus occurs in 200 different species of mammals. The primary long-term *endemic reservoirs* are various rodents such as mice and voles that harbor the

4. From the Latin *plaga*, meaning to strike, infest, or afflict with disease, calamity, or some other evil.

Pathogen Profile #6 *Shigella sonnei*, *S. dysenteriae*, *S. flexneri*, *S. boydii*

Source: CDC

Microscopic Morphology Small, nonmotile, gram-negative rods.

Identified by Gram reaction, morphology, and physiological and biochemical tests. Motility can be used to distinguish *Shigella* (nonmotile) from *E. coli* (motile).

Habitat *Shigella* is primarily a pathogen of humans, whose sources include the Five F's (feces, food, fingers, flies, and fomites).

Virulence Factors The primary virulence factor of the genus is heat-labile shiga toxin, which causes injury to nerve cells, the intestine, and kidneys.

Primary Infections/Disease Shigellosis results when *Shigella* (usually *S. sonnei*) invades the mucosa of the large intestine, with the initial damage being caused by an inflammatory response. As

the disease progresses, endotoxins promote fever, while enterotoxins damage the intestinal mucosa and villi, leading to bleeding and heavy mucus secretion.

Control and Treatment As in control of *Salmonella*, control of *Shigella* aims to prevent entry of the pathogen into the food chain. Adequate sanitation during food preparation, proper hand washing, and refraining from consuming unwashed fruits or vegetables, inadequately cooked meat and eggs, and unpasteurized milk all contribute to this goal. Treatment involves the administration of oral antimicrobics such as ciprofloxacin or sulfatri-methoprim (SxT), whereas resistant strains may be treated with azithromycin or cephalosporins.

organism but do not develop the disease. These **hosts** spread the disease to other mammals called *amplifying hosts* that become infected with the bacillus and experience massive die-offs during epidemics. These hosts, including rats, ground squirrels, chipmunks, and rabbits, are the usual sources of human plague. The particular mammal that is most important in this process depends on the area of the world. Other mammals (camels, sheep, coyotes, deer, dogs, and cats) can also be involved in the transmission cycle.

Flea Vectors The principal agents in the transmission of the plague bacillus from reservoir hosts to amplifying hosts to humans are fleas. These tiny, bloodsucking insects (see figure 23.26) have a special relationship with the pathogen. After a flea ingests a blood meal from an infected animal, the bacilli multiply in its gut. In fleas that effectively

transmit the bacillus, the esophagus becomes blocked by coagulated blood. Being unable to feed properly, the ravenous flea jumps from animal to animal in a futile attempt to get nourishment. During this process, regurgitated infectious material is inoculated into the bite wound.

Normally the flea transmits the pathogen within that population, but many fleas are not host-specific and will attempt to feed on other species, even humans. Fleas of rodents such as rats and squirrels are most often vectors in human plague, though occasionally the human flea is involved. Humans can also be infected by handling infected animals, animal skins, or meat and by inhaling droplets.

Pathology of Plague

The number of bacilli required to initiate a plague infection is small—perhaps 3 to 50 cells. The manifestations of infection lead

Figure 20.20 The infection cycle of *Yersinia pestis*, simplified for clarity.

Pathogen Profile #7 *Yersinia pestis*

Source: CDC

with symptoms, knowledge of patient's travel to endemic regions often can aid diagnosis.

Habitat *Y. pestis* is found in over 200 small rodents, which do not develop disease but serve as the primary endemic reservoir of the bacterium. Fleas are the primary arthropod vectors, spreading the bacterium from the primary hosts to amplifying hosts such as rats, squirrels, and rabbits.

Virulence Factors Capsular and envelope proteins that allow *Y. pestis* to survive and multiply within phagocytic cells. The bacterium also produces coagulase, which coagulates blood and causes the obstruction of blood vessels. *Y. pestis* has a small infective dose (3–50 cells), and produces both exotoxins and endotoxin.

Primary Infections/Disease Humans contract plague through the bite of an infected flea, handling infected animals, skins,

Microscopic Morphology

Small, gram-negative, encapsulated rod. The cells often stain darker at the end, giving them a “safety pin” appearance.

Identified by Gram reaction, morphology, and biochemical and serological tests. Along

meat, or inhaling droplets. Symptoms of bubonic plague include fever, chills, headache, exhaustion, and the development of enlarged lymph nodes called bubos. Septicemic plague occurs as massive growth of bacteria in the blood, and release of virulence factors leads to disseminated intravascular coagulation, subcutaneous hemorrhage, and necrosis. The name “black death” is a reference to the darkening of the skin at this point. In pneumonic plague, infection is localized to the lungs and is contagious through sputum and aerosols.

Control and Treatment Plague is held at bay through quarantines during periods of epidemic disease and by reducing the population of endemic hosts and fleas through the use of traps, poisons, and insecticides. Treatment of plague must commence quickly, as death can occur in as little as 2 days after the appearance of symptoms. Streptomycin, gentamicin, doxycycline, and ciprofloxacin are all effective, and treated disease has a 90% to 95% survival rate.

to bubonic, septicemic, or pneumonic plague. In **bubonic plague**, the plague bacillus multiplies in the flea bite, enters the lymph, and is filtered by the local lymph nodes. Infection causes necrosis and swelling of the node, called a **bubo**,* typically in the groin (inguinal) and less often in the armpit (axilla) or neck (cervical). The incubation period lasts 2 to 8 days, ending abruptly with the onset of fever, chills, headache, nausea, weakness, and tenderness of the bubo.

Cases of bubonic plague often progress to massive bacterial growth in the blood termed **septicemic plague**. The release of virulence factors causes disseminated intravascular coagulation, subcutaneous hemorrhage, and purpura that may degenerate into necrosis and gangrene. Because of the visible darkening of the skin, the plague has often been called the “black death.” In **pneumonic plague**, infection is localized to the lungs and is highly contagious through sputum and aerosols. Without proper treatment, it is invariably fatal.

Diagnosis, Treatment, and Prevention Because death can ensue as quickly as 2 to 4 days after the appearance of symptoms, prompt diagnosis and treatment of plague are imperative. The patient's history, including recent travel to endemic regions, symptoms, and laboratory findings from bubo aspirates, helps establish a diagnosis. Streptomycin is the antibiotic of choice. Treated plague has a 90% to 95% survival rate.

The menace of plague is proclaimed by its status as one of the internationally quarantinable diseases (the others are cholera and yellow fever). In addition to quarantine during epidemics, plague is

controlled by trapping and poisoning rodents near urban and suburban communities and by dusting rodent burrows with insecticide to kill fleas. These methods, however, cannot begin to control the reservoir hosts, so the potential for plague will always be present in endemic areas, especially as humans encroach into rodent habitats.

Oxidase-Positive Nonenteric Pathogens in Family Pasteurellaceae

Pasteurella multocida

Pasteurella is a zoonotic genus that occurs as normal microbiota in animals and is mainly of concern to the veterinarian. Of the six recognized species, *Pasteurella multocida** is responsible for the broadest spectrum of opportunistic infections. For example, poultry and wild fowl are susceptible to cholera-like outbreaks, and cattle are especially prone to epidemic outbreaks of hemorrhagic septicemia or pneumonia known as “shipping fever.” The species has also adapted to the nasopharynx of the household cat and is normal microbiota in the tonsils of dogs. Because many hosts are domesticated animals with relatively close human contact, zoonotic infections are an inevitable and serious complication.

Animal bites or scratches, usually from cats and dogs, cause a local abscess that can spread to the joints, bones, and lymph nodes. Patients with weakened immune function due to liver cirrhosis or rheumatoid arthritis are at great risk for septicemic complications

* *bubo* (byoo'-boh) G. *boubon*, the groin.

* *Pasteurella* (pas'-teh-rel'-uh mul-toh-see'-duh) From Louis Pasteur, plus L. *multi*, many, and *cidere*, to kill.

involving the central nervous system and heart. Patients with chronic bronchitis, emphysema, pneumonia, or other respiratory diseases are vulnerable to pulmonary failure. Contrary to the antibiotic resistance of many gram-negative rods, *P. multocida* and other related species are susceptible to amoxicillin, and doxycycline is an effective alternative.

Haemophilus: The Blood-Loving Bacilli

*Haemophilus*⁵ cells are small ($1 \times 2 \mu\text{m}$) gram-negative encapsulated rods (figure 20.21). The members of this group tend to be fastidious and sensitive to drying, temperature extremes, and disinfectants. Even though their name means blood-loving, none of these organisms can grow on blood agar alone without special techniques. *Haemophilus* members require certain factors released by lysed red blood cells for energy metabolism. These factors are made available to them in media such as chocolate agar (a form of cooked blood agar; see chapter 3) and Fildes medium. Some *Haemophilus* species are normal colonists of the upper respiratory tract or vagina, and others (primarily *H. parainfluenzae* and *H. ducreyi*) are virulent species responsible for childhood meningitis and chancroid.

Haemophilus influenzae was originally named after it was isolated from patients with “flu” about 100 years ago. For over 40 years it was erroneously considered the causative agent until the real agent, the influenza virus, was discovered. The potential of this species to act as a pathogen remained in question until it was clearly shown to be an agent of acute bacterial meningitis in humans, caused primarily by the b serotype. The case rates in children have declined over the past years, likely because of an increased emphasis on vaccination (figure 20.22). Other prominent causes of meningitis are *N. meningitidis* and *S. pneumoniae*. Together these three agents comprise 85% of all cases of bacterial meningitis. The effect of vaccines and better diagnosis and treatments have reduced the numbers of these infections in recent times.

In contrast to *Neisseria meningitidis*, *Haemophilus meningitis* is not associated with epidemics in the general population but tends to

Figure 20.22 Meningitis in the United States. Graph of case rates for *Haemophilus influenzae*. Note the decrease in childhood meningitis seen by 1991, the point at which most children under 5 years of age were being immunized against *Haemophilus influenzae*.

occur sporadically in day care and family settings. It is transmitted by close contact with nose and throat discharges. Healthy adult carriers are the usual reservoirs of the bacillus.

Haemophilus meningitis is very similar to meningococcal meningitis (see chapter 18), with symptoms of fever, vomiting, stiff neck, and neurological impairment. Untreated cases have a fatality rate of nearly 90%; but even with prompt diagnosis and aggressive treatment, 20% of children sustain residual disability. Other important diseases caused by *H. influenzae* are an intense form of epiglottitis common in older children and young adults that may require immediate intubation or tracheostomy to relieve airway obstruction. This species is also an agent of otitis media, sinusitis, pneumonia, and bronchitis.

Haemophilus meningitis is usually treated with ceftriaxone as well as dexamethasone. Outbreaks of disease in families and day care centers may necessitate rifampin prophylaxis for all contacts. Routine vaccination with a subunit vaccine (Hib) based on type b polysaccharide is recommended for all children, beginning at age 2 months, with three follow-up boosters. It is frequently given in combination with DTaP.

Haemophilus influenzae subtype *aegyptius* is the primary agent of acute communicable conjunctivitis, sometimes called pinkeye. The subconjunctival hemorrhage that accompanies infection imparts a bright pink tinge to the sclera (figure 20.23). The disease occurs primarily in children, is distributed worldwide, and is spread through contaminated fingers and shared personal items

⁵ Also spelled *Hemophilus*.

Figure 20.21 *Haemophilus influenzae* as seen with fluorescent microscopy. During the influenza epidemic of 1918, *H. influenzae* was found in the sputum of many influenza patients and was mistakenly thought to be the cause of the disease. Source: CDC

Figure 20.23 Acute conjunctivitis, or pinkeye, caused by *H. influenzae* subtype *aegyptius*. © Biophoto Associates/Science Source

as well as mechanically by gnats and flies. It is treated with antibiotic eyedrops.

Haemophilus ducreyi is the agent of **chancroid** (soft chancre), a sexually transmitted disease prevalent in the tropics and subtropics that afflicts mostly males. It is transmitted by direct contact with infected lesions and is favored by sexual promiscuity and unclean personal habits. After an incubation period lasting 2 to 14 days, lesions develop in the genital or perianal area. First to appear is an inflammatory macule that evolves into a painful, necrotic ulcer similar to those found in lymphogranuloma venereum and syphilis (see chapter 21). Often the regional lymph nodes develop into bubolike swellings that burst open. Treatment with azithromycin or ceftriaxone is usually effective.

Haemophilus parainfluenzae and *H. aphrophilus*, members of normal oral and nasopharyngeal microbiota, are involved in infective endocarditis in adults who have underlying congenital or rheumatic heart disease. Such infections typically stem from routine dental procedures, periodontal disease, or some other oral injury.

Check Your Progress SECTION 20.5

- Name three genera of noncoliform enteric bacteria that are opportunistic pathogens.
- Compare typhoidal and nontyphoidal salmonellosis with regard to the number of cases normally seen, common sources of infection, and pathology of each disease.
- Make a comparison chart for *Shigella* and *Salmonella* based on differences in morphology, epidemiology, and pathogenesis.
- What are the Five *F*'s and how do they relate to enteric pathogens?
- Who is most at risk for contracting plague and why?
- Which body systems are commonly infected by *Haemophilus* species?
- Describe the epidemiology and pathology of *Haemophilus influenzae* meningitis.

CASE STUDY Part 2

The credit for lowering pertussis rates so dramatically from 1940 to 1976 went to the DTwP vaccine, which consisted of antigens against diphtheria, tetanus (the *D* and *T*), and a whole-cell pertussis component. The whole-cell designation meant that the vaccine contained whole (though very much dead) pertussis cells, which, when injected into the body, instigated the production of a powerful and long-lasting immune response. Unfortunately, the whole-cell pertussis vaccine was also linked to a large number of

local reactions (swelling, pain, and redness at the injection site) along with a smaller number of more serious neurological complications. In response to this, in 1992 the fourth and fifth doses of the pertussis vaccine were changed to contain an acellular pertussis component (DTaP). The acellular version of the vaccine contained toxoid along with a number of other antigens from *B. pertussis*, but no whole cells. In 1997 the vaccine recommendation was again changed, so that all five doses contained the acellular pertussis component. The end result of this shift in vaccine strategy was that in 2012, children 14 years old and younger most likely received acellular vaccines for the complete series, whereas those 16 to 19 years of age received whole-cell vaccines for the first three doses and acellular vaccines for the last two. Adolescents who were 15 years old in 2012 may have fallen into either category, depending on when they received their vaccinations.

Incidence of Pertussis Among Persons Aged ≤ 19 Years, by Patient Age and Vaccines Received – National Notifiable Diseases Surveillance System, United States, January 1, 2011–June 14, 2012

According to a 2010 study, the DTaP vaccine works well for 2 years, after which protection begins to wane. Five years after vaccination with the acellular vaccine, less than 30% of the vaccine effectiveness remains. This information moved the Advisory Committee on Immunization Practices to recommend an additional booster for persons age 11 through 18 who have completed the full childhood pertussis series.

- What type of pertussis vaccines were received by persons who were older than 20 in 2012?
- What correlation exists between the type of vaccine received and the likelihood of illness?

See: CDC. 2012. Pertussis epidemic—Washington, 2012. *MMWR* 61:517–22.

To conclude this Case Study, go to Connect.

Chapter Summary with Key Terms

The gram-negative rods are a loosely affiliated group of bacterial genera, often separated into groups based on oxygen usage. A virulence factor common to most species is **lipopolysaccharide (LPS)**, which acts as an **endotoxin**, producing systemic effects.

20.1 Aerobic Gram-Negative Nonenteric Bacilli

- A. *Pseudomonas* species are widely distributed throughout the environment. *P. aeruginosa* is a medically important opportunist, causing infections in compromised hosts such as burn patients and those suffering from cystic fibrosis. Drug resistance is common.

20.2 Related Gram-Negative Aerobic Rods

- A. Members of the genera *Burkholderia* and *Stenotrophomonas* are residents of soil and water that may cause opportunistic lung, wound, and blood infections.
- B. *Brucella* is a zoonotic genus responsible for **brucellosis** and **undulant fever** in humans, who usually contract the disease through contact with infected animals or animal products.
- C. *Francisella tularensis* is the causative agent of **tularemia**, a zoonosis of small mammals.
- D. *Bordetella pertussis* causes the strictly human disease **pertussis (whooping cough)**. The disease is contagious and prevalent in children under 6 months but can be prevented by vaccination. Two new vaccines for older children and adolescents with lapsed immunity have been introduced.
- E. *Legionella pneumophila* causes the lung diseases **legionellosis** and the milder Pontiac fever. The bacterium is often found in artificial aquatic environments such as cooling towers and air conditioners.

20.3 Identification and Differential Characteristics of Family Enterobacteriaceae

The Family Enterobacteriaceae is the largest group of gram-negative bacteria. Many species are found in animal intestines and cause diarrheal disease through the use of **enterotoxins**. Division of the family is often made between **coliforms** (lactose-fermenters) and **noncoliforms** (non-lactose-fermenters).

20.4 Coliform Organisms and Diseases

- A. *Escherichia coli* is a prominent member of the group, strains of which are responsible for infantile diarrhea, traveler's diarrhea, urinary tract infections, nosocomial pneumonia, and **septicemia**. *E. coli* O157:H7 is a highly virulent strain that may lead to **hemolytic uremic syndrome**.
- B. The coliforms *Klebsiella*, *Enterobacter*, *Serratia*, and *Citrobacter* are common healthcare-associated pathogens in

cases of pneumonia, septicemia, and other opportunistic infections.

20.5 Noncoliform Enterics

- A. Noncoliform opportunists include *Proteus*, *Morganella*, and *Providencia*.
- B. *Salmonella* is a true pathogen that causes **salmonellosis**. The species *Salmonella enterica* is divided into six subspecies and 2500 serotypes
1. The most serious salmonellosis is **typhoid fever**, caused by *Salmonella enterica* serotypes Typhi and Paratyphi, which are spread only by humans through contaminated food and water
 2. Other salmonellosis are zoonoses caused by other serotypes of the species *S. enterica*. These diseases are usually food infections spread by contaminated meat, milk, eggs, and produce.
- C. *Shigella* is a true pathogen that causes shigellosis, a bacillary **dysentery** characterized by painful diarrhea with bloody, mucus-filled stools. Primary species include *Shigella dysenteriae*, *S. sonnei*, and *S. flexneri*, all of which are spread by feces, fingers, food, flies, and fomites.
- D. *Yersinia* causes several zoonoses that are spread from mammals to humans. *Yersinia pestis* is the causative agent of **plague**, which in humans can take the form of **bubonic plague**, **septicemic plague**, or **pneumonic plague**. Control often is focused on reducing the number of *mice*, *rats*, *squirrels*, and *fleas* that make up the normal **hosts** and **vectors** for this bacillus.
- E. *Pasteurella multocida* is a zoonosis that is responsible for a small number of opportunistic infections in humans.
- F. *Haemophilus influenzae* is a significant pathogen in acute **bacterial meningitis**. It causes significant morbidity in infants and children. It is spread by droplets during close contact. Hib vaccination has dramatically reduced the prevalence of *H. influenzae* infection in children.
- G. A special strain of *H. influenzae* (*aegyptius*) is the causative agent of a form of **conjunctivitis** (pinkeye).
- H. *H. ducreyi* causes the STD known as a **chancroid**.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

1. A unique characteristic of many isolates of *Pseudomonas* useful in identification is
 - a. fecal odor
 - b. fluorescent green pigment
 - c. drug resistance
 - d. motility
2. Human brucellosis is also known as
 - a. Bang disease
 - b. undulant fever
 - c. rabbit fever
 - d. Malta fever

3. *Francisella tularensis* has which portal(s) of entry?
 - a. tick bite
 - b. intestinal
 - c. respiratory
 - d. all of these
4. A classic symptom of pertussis is
 - a. labored breathing
 - b. paroxysmal coughing
 - c. convulsions
 - d. headache
5. The severe symptoms of pertussis are due to what effect(s)?
 - a. irritation of the glottis by the microbe
 - b. pneumonia
 - c. the destruction of the respiratory epithelium
 - d. blocked airways
 - e. both c and d are involved
6. *Escherichia coli* displays which antigens?
 - a. capsular
 - b. somatic
 - c. flagellar
 - d. all of these
7. Which of the following is *not* an opportunistic enteric bacterium?
 - a. *Serratia*
 - b. *Klebsiella*
 - c. *Proteus*
 - d. *Shigella*
8. Which of the following is a major difference between *Salmonella* and *Shigella* infections?
 - a. mode of transmission
 - b. likelihood of septicemia
 - c. the portal of entry
 - d. presence/absence of fever and diarrhea
9. A complication/complications of typhoid fever is/are
 - a. neurological damage
 - b. intestinal perforation
 - c. liver abscesses
 - d. b and c
10. *Shigella* is transmitted by
 - a. food
 - b. flies
 - c. feces
 - d. all of these
11. The bubo of bubonic plague is a/an
 - a. ulcer where the flea bite occurred
 - b. granuloma in the skin
 - c. enlarged lymph node
 - d. infected sebaceous gland
12. *Haemophilus influenzae* is _____ and requires special _____ for growth.
 - a. motile, temperatures
 - b. encapsulated, minerals
 - c. intracellular, sample swabs
 - d. fastidious, blood factors
13. Which of the following is *not* associated with *H. influenzae* infections?
 - a. fever
 - b. flu
 - c. stiff neck
 - d. headache
14. Which of the following are primarily zoonoses?
 - a. tularemia
 - b. salmonellosis
 - c. shigellosis
 - d. brucellosis
 - e. pasteurellosis
 - f. bubonic plague
15. **Single Matching.** Match the infectious agent with the disease it is most associated with.

_____ <i>Francisella tularensis</i>	a. dysentery
_____ <i>Yersinia pestis</i>	b. local abscess
_____ <i>Escherichia coli</i> O157:H7	c. chancroid
_____ <i>Shigella species</i>	d. enteric fever
_____ <i>Salmonella enterica</i>	e. whooping cough
_____ <i>Salmonella typhi</i>	f. meningitis
_____ <i>Pseudomonas aeruginosa</i>	g. typhoid fever
_____ <i>Bordetella pertussis</i>	h. hemolytic uremic syndrome
_____ <i>Legionella pneumophila</i>	i. bubonic plague
_____ <i>H. influenzae aegyptius</i>	j. Pontiac fever
_____ <i>Haemophilus influenzae</i>	k. folliculitis
_____ <i>Haemophilus ducreyi</i>	l. rabbit fever
_____ <i>Pasteurella multocida</i>	m. pinkeye

Case Study Review

1. One vaccine administered to protect against whooping cough also contains antigens meant to provide protection against
 - a. toxoplasmosis
 - b. tetanus
 - c. dysentery
 - d. *Pseudomonas*
 - e. *Proteus*
2. Which vaccine utilizes intact *Bordetella pertussis* cells to initiate an immune response?
 - a. DTaP
 - b. DT
 - c. DTwP
 - d. Td
 - e. Tdap
3. When treating teenagers and adults afflicted with pertussis (who often show only mild disease symptoms), health care professionals will generally ask what type of work the patient does and who else lives in the household. What exactly is the health care worker trying to determine, and why is this important?

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

1. Write a short essay that summarizes the circumstances in which gram-negative bacteria are involved in opportunistic infections.
2. What are unique features in the epidemiology of *E. coli* O157:H7 (STEC)?
3. Explain several practices an individual can use to avoid enteric infection and disease at home and when traveling.
 4. a. List the bacteria from this chapter for which general, routine vaccines are given.
 - b. For which special groups of bacteria are there vaccines?
 - c. For which bacteria is there no vaccines?
5. Briefly outline the zoonotic infections in this chapter, and describe how they are spread to humans.

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps along with concept mapping activities for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

1. What is the logic behind testing for *E. coli* to detect fecal contamination of water?
2. Identify the genera with the following characteristics from figure 20.9:
 - a. Lactose (–), phenylalanine and urease (–), citrate (+), ONPG (–)
 - b. Lactose (+), motility (–), VP (–), indole (+)
 - c. Lactose (+), motility (+), indole (–), H₂S (+)
 - d. Lactose (–), phenylalanine and urease (+), H₂S (–), citrate (+)
3. Given that so many infections are caused by gram-negative opportunists, what would you predict will happen as the number of compromised patients increases, and on what do you base these predictions?
4. An infectious dose of several million cells in enteric infections seems like a lot.
 - a. In terms of the size and abundance of microbes, could you see a cluster containing that many cells with the naked eye?
 - b. Refer to chapter 7 on microbial growth cycles. About how long would it take an average bacterial species to reach the infectious dose of a million cells, starting from a single cell?
 - c. Why do enteric diseases require a relatively higher infectious dose than nonenteric diseases?
 - d. Explain why antimicrobial therapy used on gram-negative bacterial infections could actually lead to illness rather than cure it.
5. Students in our classes sometimes ask how it is possible for a single enteric carrier to infect 1,000 people at a buffet or for a box turtle to expose someone to food infection. We always suggest that they use their imagination. Provide a detailed course of events that would lead to these types of outbreaks.
6. Explain the reasons for an increase in numbers of pertussis cases. (Think vaccine.)
7. Compare and contrast the pathology, diagnosis, and treatment of meningococcal meningitis and *Haemophilus influenzae* meningitis.
8. Several persons working in an exercise gym acquired an acute disease characterized by fever, cough, pneumonia, and headache. Treatment with erythromycin cleared it up. The source was never found, but an environmental focus was suspected.
 - a. What do you think might have caused the disease?
 - b. People in a different gym got skin lesions after sitting in a redwood hot tub. Which pathogen could have caused that?
9. A 3-year-old severely ill child was admitted to a hospital with symptoms of diarrhea, fever, and malaise. Laboratory testing showed abnormal renal and liver values and anemia. She had no history of previous illness, and her food history was a recent meal of teriyaki beef consumed at a local restaurant.
 - a. What was the probable pathogen?
 - b. What was the likely source?
 - c. What is the pathologic effect of the pathogen?
10.
 - a. Name six bacteria discussed in this chapter or in chapter 19 that could be used in biological warfare.
 - b. What are some possible ways these bacteria could be used in warfare?
 - c. What is your personal opinion of using microorganisms as weapons?
11. “There is no circumstance [in which] you can cook out 230 million bacteria. I’m not willing to take the risk that one pathogen isn’t going to survive”—Ron Schnitzer (microbiologist). Comment on this quote. What do you think this microbiologist is referring to?

 Visual Challenge

1. Use **figure 20.5 a,b** as a reference guideline for interpretation. Lanes numbered 1 through 6 are different patient sera and A through H are increasing dilutions of these sera. Identify the samples that show *Brucella* infection and give their titers. Which positive sample has the fewest antibodies? What conclusion can be made if a second test done on this same patient a week later indicates no change? What is the conclusion if all lane wells are positive for this patient?

Source: Dr. Edwin P. Ewing, Jr./CDC

CASE STUDY Part 1 A different kind of tourism

Often a good patient history is as important as any laboratory test. During the fall of 2014 five patients with similar complaints were seen by doctors in the New York area. All five presented with fever, fatigue, chills, and headache, a combination of **signs** and **symptoms** so general that they provide little diagnostic information. Three of the five reported preexisting medical conditions: one patient with atrial fibrillation and kidney stones, one with Parkinson disease and osteoarthritis, and one with multiple sclerosis. Questioning revealed that all five patients had recently traveled to Germany to receive injections of processed cells from sheep fetuses, a treatment known as **live cell therapy**, with at least two of the patients traveling to Germany twice a year in each of the previous five years to receive the treatments. Despite a complete lack of clinical evidence since the procedure was first introduced in the 1930s, the procedure is commonly advertised as having anti-aging effects and as a treatment for a variety of ailments, including those

“Live Cell Therapy injections have long been a celebrity secret in preserving a youthful appearance and prolonging vital health.”

—From an Internet advertisement promoting live cell therapy

displayed by the three patients reporting preexisting conditions.

Live cell therapy is considered a form of **xenotransplantation**, as living cells are transplanted across species boundaries, and is associated with serious risks, including **anaphylaxis** and exposure of the recipient to a number of **zoonotic** infections. The procedure has been linked in the past to **vasculitis**, **encephalitis**, **clostridial** infections, **paresis** (weakening of the limbs), and death.

- Why did the patients in this case travel to Germany to obtain treatment?
- What groups are normally at greatest risk for contracting zoonotic infections?

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

Systems Profile 21.1		Miscellaneous Bacterial Pathogens				
Organism	Skin/Skeletal	Nervous/Muscle	Cardiovascular/ Lymphatic/ Systemic	Gastrointestinal	Respiratory	Urogenital
<i>Treponema pallidum pallidum</i>	Skin rash (secondary syphilis)	Tertiary syphilis	Secondary syphilis Tertiary syphilis			Chancre (primary syphilis)
<i>Leptospira interrogans</i>		Leptospirosis	Leptospirosis			Leptospirosis
<i>Borrelia burgdorferi</i>	Lyme disease	Lyme disease	Lyme disease			
<i>Vibrio cholerae</i>				Secretory diarrhea		
<i>Vibrio parahaemolyticus</i>				Gastroenteritis		
<i>Campylobacter jejuni</i>				Gastroenteritis		
<i>Helicobacter pylori</i>				Gastritis, peptic and duodenal ulcers		
<i>Rickettsia prowazekii</i>	Epidemic typhus	Epidemic typhus				
<i>Rickettsia rickettsii</i>	Rocky Mountain spotted fever	Rocky Mountain spotted fever	Rocky Mountain spotted fever			
<i>Ehrlichia</i> spp.			Ehrlichiosis			
<i>Coxiella burnetii</i>			Q fever			
<i>Bartonella henselae</i>	Local papules		Cat scratch disease			
<i>Chlamydia trachomatis</i>	1. Neonatal conjunctivitis 2. Trachoma					Chlamydiosis, lymphogranuloma venereum
<i>Mycoplasma pneumoniae</i>					Atypical pneumonia	

A number of bacterial pathogens do not fit the usual categories of gram-positive or gram-negative rods or cocci. This group includes spirochetes and curviform bacteria, obligate intracellular parasites such as rickettsias and chlamydias, and mycoplasmas. This chapter covers not only those agents but also the mixed bacterial infections that are responsible for the diseases of the oral cavity (**Systems Profile 21.1**).

21.1 The Spirochetes

Expected Learning Outcomes

1. Differentiate among the different stages of syphilis.
2. Explain the different ways in which syphilis infections may be diagnosed.
3. List the nonsyphilitic treponematoses.
4. Justify the strategies used to prevent leptospirosis.
5. Identify the vectors and behaviors associated with *Borrelia* infection.

Spirochetes typically display a helical form and flagellar mode of locomotion that appear especially striking in live, unstained preparations using the dark-field or phase-contrast microscope.

Other traits include a typical gram-negative cell wall and a well-developed periplasmic space that encloses the flagella (called endoflagella or periplasmic flagella) (**figure 21.1a**). Although internal flagella are constrained somewhat like limbs in a sleeping bag, their flexing propels the cell by rotation and even crawling motions. The spirochetes are classified in the Phylum Spirochaetes, which contains three families and 13 genera. The majority of spirochetes are free-living saprobes or commensals of animals and are not primary pathogens. Major pathogens are found in three genera: *Treponema*, *Leptospira*, and *Borrelia* (**figures 21.1b** and 21.6).

Treponemes: Members of the Genus *Treponema*

Treponemes are thin, somewhat regular, coiled bacteria that live in the oral cavity, intestinal tract, and perigenital regions of humans and animals. The pathogens are strict parasites with complex growth requirements that necessitate cultivating them in live cells. Diseases caused by *Treponema* are called treponematoses. The

Figure 21.1 Typical spirochete. (a) Representation of general spirochete morphology with endoflagella inserted in the opposite poles, lying beneath the outer membrane and within the periplasmic space. (b) Members vary in the number of coils. For example, *Borrelia* have 3 to 10 loose, irregular coils (1,500X). (b): Source: Janice Haney Carr/CDC

subspecies *Treponema pallidum pallidum** is responsible for venereal and congenital syphilis (**Pathogen Profile #1**); the subspecies *T. p. endemicum* causes nonvenereal endemic syphilis, or bejel; and *T. p. pertenue* causes yaws. *Treponema carateum* is the cause of pinta. Infection begins in the skin, progresses to other tissues in gradual stages, and is often marked by periods of healing interspersed with relapses. The major portion of this discussion centers on syphilis, and any mention of *T. pallidum* refers to the subspecies *T. p. pallidum*. Other treponemes of importance are involved in infections of the gingiva.

Treponema pallidum: The Spirochete of Syphilis

The origin of *syphilis** is an obscure yet intriguing topic of speculation. The disease was first recognized at the close of the fifteenth century in Europe, a period coinciding with the return of Columbus from the West Indies, which led some medical scholars to conclude that syphilis was introduced to Europe by early explorers. DNA analyses indicate that treponemal disease is ancient and widespread. Even wild primates carry strains of *Treponema* that are related to the human forms. Whatever its origins, once it became sexually transmitted, the pathogen was ultimately carried worldwide.

Epidemiology and Virulence Factors of Syphilis

Although infection can be induced in laboratory animals, the human is evidently the sole natural host and source of *T. pallidum*. It is an extremely fastidious and sensitive bacterium that cannot survive for long outside the host, being rapidly destroyed by heat, drying, disinfectants, and other adverse conditions. It survives a few minutes to hours when protected by body secretions and about 36 hours in stored blood. Research with human subjects has demonstrated that the risk of infection from an infected sexual partner is 12% to 30%. The bacterium may also be passed from an infected mother to the fetus in utero. Syphilitic infection through blood transfusion or exposure to fomites is rare.

Syphilis, like other sexually transmitted diseases (STDs), has experienced periodic increases during times of social disruption. After experiencing a decline during the 1990s, case reports are once again increasing (see figure 18.22). In fact, the case rate has more than tripled since 2000. Major contributors to this trend are gay and bisexual men, who now account for 83% of new infections. Other increases are associated with prostitution and intravenous drug abuse. Because many cases go unreported, the actual incidence is likely to be several times higher than these reports show. Syphilis continues to be a serious problem worldwide, especially in Africa and Asia. Persons with syphilis often suffer concurrent infection with other STDs such as chlamydia, herpes simplex, gonorrhea, and AIDS.

A Dark Event in Human Experimentation

One of the most disturbing events in the study of syphilis occurred in the United States. Beginning in 1932, the U.S. government conducted a study called the “Tuskegee Study of Untreated Syphilis in the Negro Male,” which eventually involved 399 indigent African-American men living in the South. Infected men were recruited into the study, which sought to document the natural progression of the disease. These men were never told that they had syphilis and were never treated for it, even after penicillin was shown to be an effective cure. The study ended in 1972 after it became public. In 1997 the federal government issued a public apology for having permitted the study to proceed for so long and began paying millions of dollars in compensation to the victims and their heirs.

Pathogenesis and Host Response

Brought into direct contact with mucous membranes or abraded skin, *T. pallidum* binds avidly by its hooked tip to the epithelium. The number of cells required for infection using human volunteers was established at 57 organisms. At the binding site, the spirochete multiplies and penetrates the capillaries within a short time. Once in the general circulation, the pathogen grows in virtually any tissue.

Specific factors that account for the virulence of the syphilis spirochete appear to be its outer membrane proteins. It produces no toxins and does not appear to kill cells directly, but rather causes damage by invoking an inflammatory response in the host. Studies have shown that phagocytes are active against it and several types of antitreponemal antibodies are formed, but cell-mediated immune

* *Treponema pallidum* (trep’-oh-nee’-mah pal’-ih-dum) Gr. *trepo*, turn, and *nema*, thread; *L. pallidum*, pale. The spirochete does not stain with the usual bacteriologic methods.

* The term *syphilis* first appeared in a poem entitled “Syphilis sive Morbus Gallicus” by Fracastorius (1530) about a mythical shepherd whose name eventually became synonymous with the disease from which he suffered.

Pathogen Profile #1 *Treponema pallidum* (*T. pallidum pallidum*)

Source: CDC

Microscopic Morphology Thin, gram-negative spirochetes.

Identified by The slender nature of *T. pallidum* often makes it invisible in a Gram stain. Wet mounts of fluid taken from suspected syphilitic lesions may be examined with dark-field microscopy for motile spirochetes.

Immunofluorescent staining and DNA probes may also be used to detect the pathogen. Infection may be determined using serological testing to detect antibodies to *T. pallidum*.

Habitat Humans are the only host of *T. pallidum*.

Virulence Factors The hooked tip of the spirochete is responsible for initial binding of the pathogen to epithelial cells. Proteins within the outer membrane of *T. pallidum* induce an inflammatory response in the host, eventually leading to tissue damage.

Primary Infections/Disease Infection with *T. pallidum* causes syphilis, a sexually transmitted disease. The disease has three distinct stages, separated by periods of latency. Primary syphilis occurs within 3 months of infection and is marked by the formation of a chancre at the site of infection. Secondary syphilis appears a few weeks to

several months later and is marked by fever, headache, sore throat, lymphadenopathy, and a red or brown rash that occurs on all skin surfaces. Like chancres, the lesions spontaneously heal after a few weeks. Complications of secondary syphilis may occur in the bones, hair follicles, joints, eyes, liver, and brain and may remain for years. Tertiary syphilis occurs in about 30% of untreated syphilis cases—often many years later—and is marked by the formation of swollen tumors called gummas, along with neural and cardiovascular complications. Congenital syphilis occurs when *T. pallidum* passes from the circulation of a pregnant woman to the placenta, infecting the fetus and causing a wide variety of symptoms.

Control and Treatment Penicillin G is the treatment of choice for syphilis. Control of the disease relies on detection and treatment of sexual contacts of syphilitic patients. The use of latex condoms reduces but does not eliminate the chance of infection because *T. pallidum* may infect sites that are not normally protected by a condom.

responses are unable to contain it. The primary lesion occurs when the spirochetes invade the spaces around arteries and stimulate an inflammatory response. Organs are damaged when granulomas form at these sites and block circulation.

Clinical Manifestations Untreated syphilis is marked by distinct clinical stages designated as primary, secondary, and tertiary syphilis. These phases exhibit multiple signs and symptoms, which cause it to “imitate” many other diseases (table 21.1). It also has latent periods of varying duration during which the disease is quiescent. The spirochete appears in the lesions and blood during the primary and secondary stages and, thus, is communicable at these times. Syphilis is largely noncommunicable during the tertiary stage, though it can be transmitted during early latency.

Primary Syphilis The earliest indication of syphilis infection is the appearance of a hard **chancre*** at the site of inoculation, after an incubation period that varies from 9 days to 3 months (figure 21.2). The chancre begins as a small, red, hard bump that enlarges and breaks down, leaving a shallow crater with firm margins. The base of the chancre beneath the encrusted surface swarms with spirochetes. Most chancres appear on the internal and external genitalia, but about 20% occur on the lips, nipples, or fingers or around the anus. Because genital lesions tend to be painless, they may escape notice in some cases. Lymph nodes draining the affected region become enlarged and firm, but systemic symptoms are usually

Figure 21.2 Primary syphilis lesion: chancre. The chancre is a dense, off-colored patch that ulcerates. Common locations for chancres include the genitals and mouth. Source: Dr. Gavin Hart, Dr. N. J. Fiumara/CDC

absent. The chancre heals spontaneously without scarring in 3 to 6 weeks, but this healing is deceptive, because the spirochete is entering a period of tremendous systemic activity.

Secondary Syphilis About 3 weeks to 6 months (average is 6 weeks) after the chancre heals, the secondary stage appears. By then many systems of the body have been invaded, and the signs and symptoms are more profuse and intense. Initially fever, headache, and sore throat occur, followed by lymphadenopathy and a peculiar red or brown rash that breaks out on all skin surfaces, including the palms and the soles (figure 21.3). Like the chancre, the

* *chancre* (shang'-ker) Fr. for canker; from L. *cancer*, crab. An injurious sore.

TABLE 21.1 Syphilis: Stages, Symptoms, Diagnosis, and Control

Stage	Average Duration	Clinical Setting	Diagnosis	Treatment
Incubation	3 weeks	No lesion; treponemes adhere and penetrate the epithelium; after multiplying, they disseminate.	Asymptomatic phase	Not applicable
Primary	2–6 weeks	Initial appearance of chancre at inoculation site; intense treponemal activity in body; chancre later disappears.	Dark-field microscopy; VDRL, FTA-ABS, MHA-TP testing	Benzathine penicillin G, 2×10^6 units; doxycycline
Primary latency	2–8 weeks	Healed chancre; little scarring; treponemes in blood; few, if any, symptoms.	Serological tests (+)	As above
Secondary	2–6 weeks after chancre leaves	Skin, mucous membrane lesions; hair loss; patient highly infectious; fever, lymphadenopathy; symptoms can persist for months.	Dark-field testing of lesions; serological tests (+)	As above
Latency	6 months to 8 or more years	Treponemes quiescent unless relapse occurs; lesions can reappear.	Seropositive blood test	As above
Tertiary	Variable, up to 20 years	Neural, cardiovascular symptoms; gummas develop in organs; seropositivity.	Treponeme may be demonstrated by DNA analysis of tissue.	As above

lesions contain viable spirochetes and disappear spontaneously in a few weeks. The major complications, occurring in the bones, hair follicles, joints, liver, eyes, and brain, can linger for months and years.

Latency and Tertiary Syphilis After resolution of secondary syphilis, about 30% of infections enter a highly varied latent period that can last for 20 years or longer. Latency is divisible into early and late phases, and though antitreponemal antibodies are readily detected, the spirochete itself is not. The final stage of disease—late, or tertiary, syphilis—is quite rare today because of widespread use of antibiotics to treat other infections. By the time a patient reaches this phase, numerous pathologic complications occur in

Figure 21.3 Symptom of secondary syphilis. The skin rash in secondary syphilis can form on most areas of the body. The rash does not hurt or itch and can persist for months. Source: CDC

susceptible tissues and organs. Cardiovascular syphilis is a late complication of the disease. Infection of the small blood vessels that supply blood to the heart and aorta causes constriction and blockage. In time, compromised circulation to these organs can give rise to heart failure and aortic aneurysms.

In one form of tertiary syphilis, painful swollen syphilitic tumors called **gummas*** develop in tissues such as the liver, skin, bone, and cartilage (**figure 21.4**). Gummas are usually benign and only occasionally lead to death, but they can impair function. Neurosyphilis can involve any part of the nervous system, but it shows particular affinity for the blood vessels in the brain, cranial nerves, and dorsal roots of the spinal cord. Destruction of parts of the spinal cord can lead to muscle wasting and loss of activity and coordination. Other manifestations include severe headaches, convulsions, mental derangement, atrophy of the optic nerve, blindness, and the Argyll-Robertson pupil reaction. The latter condition being small pupils that do not react to light (**figure 21.4**). This is perhaps the most common sign still seen today and is caused by adhesions along the inner edge of the iris that fix the pupil's position into an irregular-shaped circle.

Congenital Syphilis *Treponema pallidum* can pass from a pregnant woman's circulation into the placenta and can be carried throughout the fetal tissues. An infection leading to congenital syphilis can occur in any of the three trimesters, though it is most common in the second and third. The pathogen inhibits fetal growth and disrupts critical periods of development with varied consequences, ranging from mild to the extremes of spontaneous miscarriage or stillbirth. Early congenital syphilis encompasses the period

from birth to 2 years of age and is usually first detected 3 to 8 weeks after birth. Infected infants often demonstrate such signs as nasal discharge, skin eruptions and loss, bone deformation, and nervous system abnormalities. The late form gives rise to an unusual assortment of stigmata in the bones, eyes, inner ear, and joints, and causes the formation of Hutchinson's teeth (**figure 21.5**). The number of congenital syphilis cases is closely tied to the incidence in adults; because it is sometimes not diagnosed, some children sustain life-long disfiguring disease.

Clinical and Laboratory Diagnosis The pattern of syphilis imposes many complications on diagnosis. Not only do the stages mimic other diseases, but their appearance can be so separated in time as to seem unrelated. The chancre and secondary lesions must be differentiated from various bacterial, fungal, and parasitic infections, tumors, and even allergic reactions. Overlapping symptoms of concurrent, sexually transmitted infections such as gonorrhea or chlamydiosis can further complicate diagnosis. The clinician must weigh presenting symptoms, patient history, and microscopic and serological tests in rendering a definitive diagnosis.

Although spirochetes like *Treponema* do not stain well with traditional dyes, certain special techniques using silver can make them more visible with a bright-field microscope (**figure 21.6**). A faster and less involved technique for diagnosing primary, early congenital, and, to a lesser extent, secondary syphilis is dark-field microscopy of a suspected lesion (see Pathogen Profile #1). The lesions are gently squeezed or scraped to extract clear serous fluid. A wet mount prepared from the exudate is then observed for the characteristic size, shape, and motility of *T. pallidum*. A single negative test is insufficient to exclude syphilis, so follow-up tests are recommended. Another microscopic test for discerning the spirochete directly in samples is direct immunofluorescent staining with monoclonal antibodies (see figure 17.3). Patient samples can also be tested with a DNA probe specific to various spirochete gene sequences.

Testing Blood for Syphilis Serological tests are based upon detection of antibody formed in response to *T. pallidum* infection (see table 21.1). Several of the tests (rapid plasma reagin [RPR], VDRL, Kolmer) are variations on the original test developed by Wasserman using cardiolipin, a natural constituent of many cells, as the antigen. Although anticardiolipin antibodies are not specific for syphilis, the test is an effective way to screen the population for people who may be infected. This includes high-risk groups such as homosexual men, male and female prostitutes, people with other STDs, and pregnant women.

With positive results, it is important to detect an elevated antibody titer indicative of active infection and to rule out residual antibodies from a prior cured infection. Because the most common screening tests (RPR and VDRL) are based on reactions to a substance found normally in human tissue, biological false positives can occur, especially in patients with other infections or

immunopathologies. A more specific test is needed for those who are suspected of having a false-positive result.

Typical of these specific tests is the *T. pallidum* microhemagglutination assay (MHA-TP), which employs red blood cells that have been coated with treponemal antigen. Agglutination of the cells by serum indicates antitreponemal antibodies and infection. Another standard test is an indirect immunofluorescent method called the FTA-ABS (fluorescent treponemal antibody absorbance) test. The test serum is first absorbed with treponemal cells and reacted with antihuman globulin antibody labeled with fluorescent dyes. If antibodies to the treponeme are present, the fluorescence on the outside of these cells is highly visible with a fluorescent microscope. Another variant, the *T. pallidum* immobilization (TPI) test, mixes live syphilis spirochetes with test serum to assay the spirochete's loss of motility. These tests are highly sensitive and specific and can rule out false-positive results. Children with suspected cases of congenital syphilis may be verified by a Western blot test.

Treatment and Prevention Penicillin G retains its status as a wonder drug in the treatment of all stages and forms of syphilis. It is given parenterally in large doses with benzathine or procaine to maintain a blood level lethal to the treponeme for at least 7 days (see table 21.1). Alternative drugs (tetracycline and doxycycline) are less effective and indicated only if penicillin allergy has been documented. It is important that all patients be monitored for compliance or possible treatment failure.

The core of an effective prevention program depends upon detection and treatment of the sexual contacts of syphilitic patients. Public health departments and physicians are charged with the task of questioning patients and tracing their contacts. All individuals identified as being at risk, even if they show no signs of infection, are given immediate prophylactic penicillin in a single, long-acting dose. Protective immunity does arise in humans and in experimentally infected rabbits, which raises the prospect of an effective immunization program in the future. The cloning of treponemal surface antigens using recombinant DNA technology will support development of vaccines and new diagnostic testing methods.

Nonsyphilitic Treponematoses

The other treponematoses are ancient diseases that closely resemble syphilis in their effects, though they are rarely transmitted sexually or congenitally. These infections, known as bejel, yaws, and pinta, are endemic to certain tropical and subtropical regions of the world. The treponemes that cause these infections are nearly indistinguishable from those of syphilis in morphology and behavior. The diseases are slow developing and progressive and involve primary, secondary, and tertiary stages. They begin with local invasion by the treponeme into the skin or mucous membranes and its subsequent spread to subcutaneous tissues, bones, and joints. Drug therapy with penicillin, erythromycin, or tetracycline remains the treatment of choice for these treponematoses.

Bejel Bejel is also known as endemic syphilis and nonvenereal childhood syphilis. The pathogen, the subspecies *T. pallidum endemicum*, is harbored by a small reservoir of nomadic and seminomadic people in arid areas of the Middle East and North Africa. It is a chronic, inflammatory childhood disease transmitted by direct contact or shared

Figure 21.7 Endemic treponematoses. (a) Skin and membrane nodules in a young boy with endemic syphilis (bejel). (b) The clinical appearance of yaws. The bowing of the lower leg is seen in some children with congenital syphilis, and in patients with yaws. (a, b): Source: CDC

household utensils and other fomites and is facilitated by minor abrasions or cracks in the skin or a mucous membrane. Often the infection begins as small, moist patches in the oral cavity (figure 21.7a) and spreads to the skin folds of the body and to the palms.

Yaws Yaws is a West Indian name for a chronic disease known by the regional names boubas, frambesia tropica, and patek. It is endemic to warm, humid, tropical regions of Africa, Asia, and South America. The microbe, subspecies *T. pallidum pertenuis*, is readily spread by direct contact with skin lesions or fomites. Crowded living conditions and poor community or personal hygiene are contributing factors. The earliest sign is a large, abscessed papule called the “mother yaw,” usually on the legs or lower trunk. After the initial lesion has healed, a secondary crop of moist nodular masses develop in the skin, periosteum, and bones but do not penetrate to the viscera (figure 21.7b). Yaws can be prevented by improved hygiene, shielding minor skin injuries from contamination, and surveillance for new cases.

Pinta The names *mal del pinto* and *carate* are regional synonyms for pinta, a chronic skin infection caused by *T. p. carateum*.^{*} Transmission evidently requires several years of close personal contact accompanied by poor hygiene and inadequate health facilities. Even though pinta is not currently widespread, the disease is still found in isolated populations inhabiting the tropical forest and valley regions of Latin America. Infection begins in the skin with a dry, scaly papule reminiscent of psoriasis or leprosy. In time, pigmented secondary macules and blanched tertiary lesions appear. Pinta is not life-threatening, but it often creates scars on the afflicted area.

Leptospira and Leptospirosis

Leptospire are typical spirochetes marked by 12 to 18 tight, regular, individual coils with a bend or hook at one or both ends. There are only two species in the genus: *Leptospira interrogans*,^{*} which causes

^{*} *carateum* (kar-uh'-tee-um) From *carate*, the South American name for pinta.

^{*} *Leptospira interrogans* (lep'-toh-spy'-rah in-terr'-oh-ganz) Gr. *leptos*, slender or delicate, and *speira*, a coil; *interrogans* because it has a single hook that makes it look like a question mark.

leptospirosis in humans and animals, and *L. biflexa*, a harmless, free-living saprobe. The two species are serologically, genetically, and physiologically distinct. *Leptospira interrogans* demonstrates nearly 200 serotypes distributed among various animal groups, which accounts for the extreme variations in leptospirosis among humans.

Epidemiology and Transmission of Leptospirosis

Leptospirosis is a zoonosis associated with wild animals such as rodents, skunks, raccoons, foxes, and some domesticated animals, particularly horses, dogs, cattle, and pigs. Although these reservoirs are distributed throughout the world, the disease is concentrated mainly in the tropics. Leptospire shed in the urine of an infected animal can survive for several months in neutral or alkaline soil or water. Infection occurs almost entirely through contact of skin abrasions or mucous membranes with animal urine or some environmental source containing urine. It is not associated with animal bites, inhalation, or human contact. In the United States, about 100 cases of leptospirosis are reported annually, with about half of the cases occurring in Hawaii. Persons most commonly affected include older children and young adults exposed to water polluted with animal urine and soldiers involved in jungle training.

Pathology of Leptospirosis and Host Response

Leptospirosis proceeds in two phases, and its principal targets are the kidneys, liver, brain, and eyes. During the early, or leptospiremic, phase, the pathogen appears in the blood and cerebrospinal fluid. Symptoms are sudden high fever, chills, headache, muscle aches, conjunctivitis, and vomiting. During the second, or immune, phase, the blood infection is cleared by natural defenses. This period is marked by milder fever, headache due to leptospiral meningitis, and *Weil's syndrome*, a cluster of symptoms characterized by kidney invasion, hepatic disease, jaundice, anemia, and neurological disturbances. Long-term disability and even death can result from injury to the kidneys and liver, but they occur primarily with virulent strains and in elderly patients.

Diagnosis, Treatment, and Prevention

A history of environmental exposure, along with presenting symptoms, can support initial diagnosis of leptospirosis, but definitive diagnosis relies on dark-field microscopy of specimens, *Leptospira* culture, and serological tests. Because leptospiral infection stimulates a strong humoral response, it is possible to test the patient's serum for its antibody titer. A fast, specific, and effective test called the macroscopic slide agglutination test is most often employed for routine screening. Live or formalinized *L. interrogans* is mixed with the patient's serum and observed for agglutination or lysis with a dark-field microscope.

Early treatment, prior to the fifth day of illness, with penicillin or doxycycline rapidly reduces symptoms and shortens the course of disease, but delayed therapy is less effective. A vaccine made from killed cells is available for pets, but not for humans. Protection is less than 100% because the vaccine confers protection only to a few specific strains. The best controls are to wear protective footwear and clothing and to avoid swimming or wading in natural waters used by animals.

Borrelia: Arthropod-Borne Spirochetes

Members of the genus *Borrelia** are larger than other pathogenic spirochetes, ranging from 0.2 to 0.5 μm in width and from 10 to 20 μm in length, and they contain 3 to 10 irregularly spaced and loose coils (see figure 21.1b) with many (30–40) periplasmic flagella. The nutritional requirements of *Borrelia* are so complex that the bacterium can be grown artificially only on specially formulated media.

Human infections with *Borrelia*, termed borrelioses, are all transmitted by some type of arthropod vector, usually ticks or lice. The two most important human diseases are relapsing fever and Lyme disease.

Epidemiology of Relapsing Fever

Borrelia hermsii, the cause of tick-borne relapsing fever, is carried by soft ticks of the genus *Ornithodoros*. The mammalian reservoirs of this zoonosis are squirrels, chipmunks, and other wild rodents, and the human is generally an accidental host. The spirochetes mature and persist in the salivary glands and intestines of the tick. As a result, both the bite itself and attempts to scratch it can initiate infection. Tick-borne relapsing fever occurs sporadically in the United States, usually in campers, backpackers, and forestry personnel who frequent the higher elevations of western states. The incidence of infection is higher in endemic areas of the tropics, especially where rodents have easy access to dwellings.

Epidemics of louse-borne relapsing fever occur whenever famine, war, or natural disasters are coupled with poor hygiene, crowding, and inadequate medical attention. Such conditions favor the survival and spread of the louse vector *Pediculus humanus*, which harbors the spirochete *B. recurrentis* in its body cavity. A host is infected when lice are smashed and scratched into a wound or the skin. Louse-borne fever is most common in parts of sub-Saharan Africa, China, and Afghanistan.

Pathogenesis and the Nature of Relapses The pathologic manifestations are similar in tick- and louse-borne relapsing fever. After a 2- to 15-day incubation period, patients experience the abrupt onset of high fever, shaking chills, headache, and fatigue. Later features of the disease include nausea, vomiting, muscle aches, and abdominal pain. Extensive damage to the liver, spleen, heart, kidneys, and cranial nerves occurs in many cases. Half of the patients hemorrhage profusely into organs, and some develop a rash on the shoulders, trunk, and legs. Untreated cases are often lengthy and debilitating and may have a 40% mortality rate.

As the name *relapsing fever* indicates, the fever follows a fluctuating course that is explained by changes in the spirochete and the attempts of the immune system to control it (figure 21.8). *Borrelia* have adopted a remarkable strategy for evading the immune system and avoiding destruction. They change surface antigens during growth, so that, in time, the antibodies formed against the earlier antigens lose effectiveness. Cells in the new antigen phase survive, multiply, and cause a second wave of symptoms. Over time the immune system forms new antibodies, but it is soon challenged with yet another antigenic phase. A single strain has been known to generate 24 distinct serological types. Eventually cumulative immunity against the variety of antigens develops, and complete recovery can occur.

* *Borrelia* (boh-ree'-lee-ah) Named after Amédé Borrel, a French bacteriologist

21.1 MAKING CONNECTIONS

The Disease Named for a Town

In the 1970s an enigmatic cluster of arthritis cases appeared in the town and surrounding suburbs of Old Lyme, Connecticut. This phenomenon caught the attention of nonprofessionals and professionals alike, whose persistence and detective work ultimately disclosed the unusual nature and epidemiology of Lyme disease. The process of discovery began in the home of Polly Murray, who, along with her family, was beset for years by recurrent bouts of stiff neck, swollen joints, malaise, and fatigue that seemed vaguely to follow a rash from tick bites. When Mrs. Murray's son was diagnosed as having juvenile rheumatoid arthritis, she became skeptical. Conducting her own literature research, she began to discover inconsistencies. Rheumatoid arthritis was described as a rare, noninfectious disease, yet over an 8-year period she found that 30 of her neighbors had experienced similar illnesses. Eventually this cluster of cases and several others were reported to state health authorities.

The reports caught the attention of Dr. Allen Steere, a rheumatologist with a Centers for Disease Control and Prevention (CDC) background. He was able to forge the vital link between the case histories, the disease symptoms, and the presence of unique spirochetes in ticks preserved by some of the patients. These same spirochetes had been previously characterized in 1981 by Dr. Willy Burgdorfer, though he did not realize their importance at the time.

In the years since Lyme disease was formally characterized, retrospective studies showed that this is not really a new disease and was first reported in Europe at the turn of the twentieth century. Recent PCR analysis of tick museum specimens from 50 years ago documents the presence of *Borrelia burgdorferi*. It is now thought that Lyme disease has been present in North America for centuries.

Explain how an infection such as Lyme disease mimics other non-infectious diseases. Answer available on Connect.

Figure 21.8 The pattern in relapsing fever, based on symptoms (fever) over time. The antigen phase changes can continue for several more days.

Diagnosis, Treatment, and Prevention A patient's history of exposure, clinical symptoms, and the presence of *Borrelia* in stained blood smears are very definitive evidence of borreliosis. Except for pregnant women and young children, doxycycline or tetracycline is the treatment of choice, with erythromycin serving as an alternative. Because vaccines are not available, prevention of relapsing fever is dependent upon controlling rodents and avoiding tick bites. Louse-borne relapsing fever can be controlled with improved hygiene.

Borrelia burgdorferi and Lyme Disease

Lyme disease, the most prominent borreliosis in the United States (see 21.1 Making Connections), is caused by *Borrelia*

*burgdorferi** and is transmitted primarily by hard ticks of the genus *Ixodes*. In the northeastern part of the United States, *Ixodes scapularis* (the black-legged deer tick) passes through a complex 2-year cycle that involves two principal hosts (**figure 21.9**). The larva or nymph stage feeds on the white-footed mouse, where it picks up the infectious agent. The nymph is relatively nonspecific and will try to feed on nearly any type of vertebrate; thus, it is the form most likely to bite humans. The adult tick reproductive phase of the cycle is completed on deer. In California, the transmission cycle involves *Ixodes pacificus* and the dusky-footed

* *burgdorferi* (berg-dor'-fer-eye) Named for its discoverer, Dr. Willy Burgdorfer.

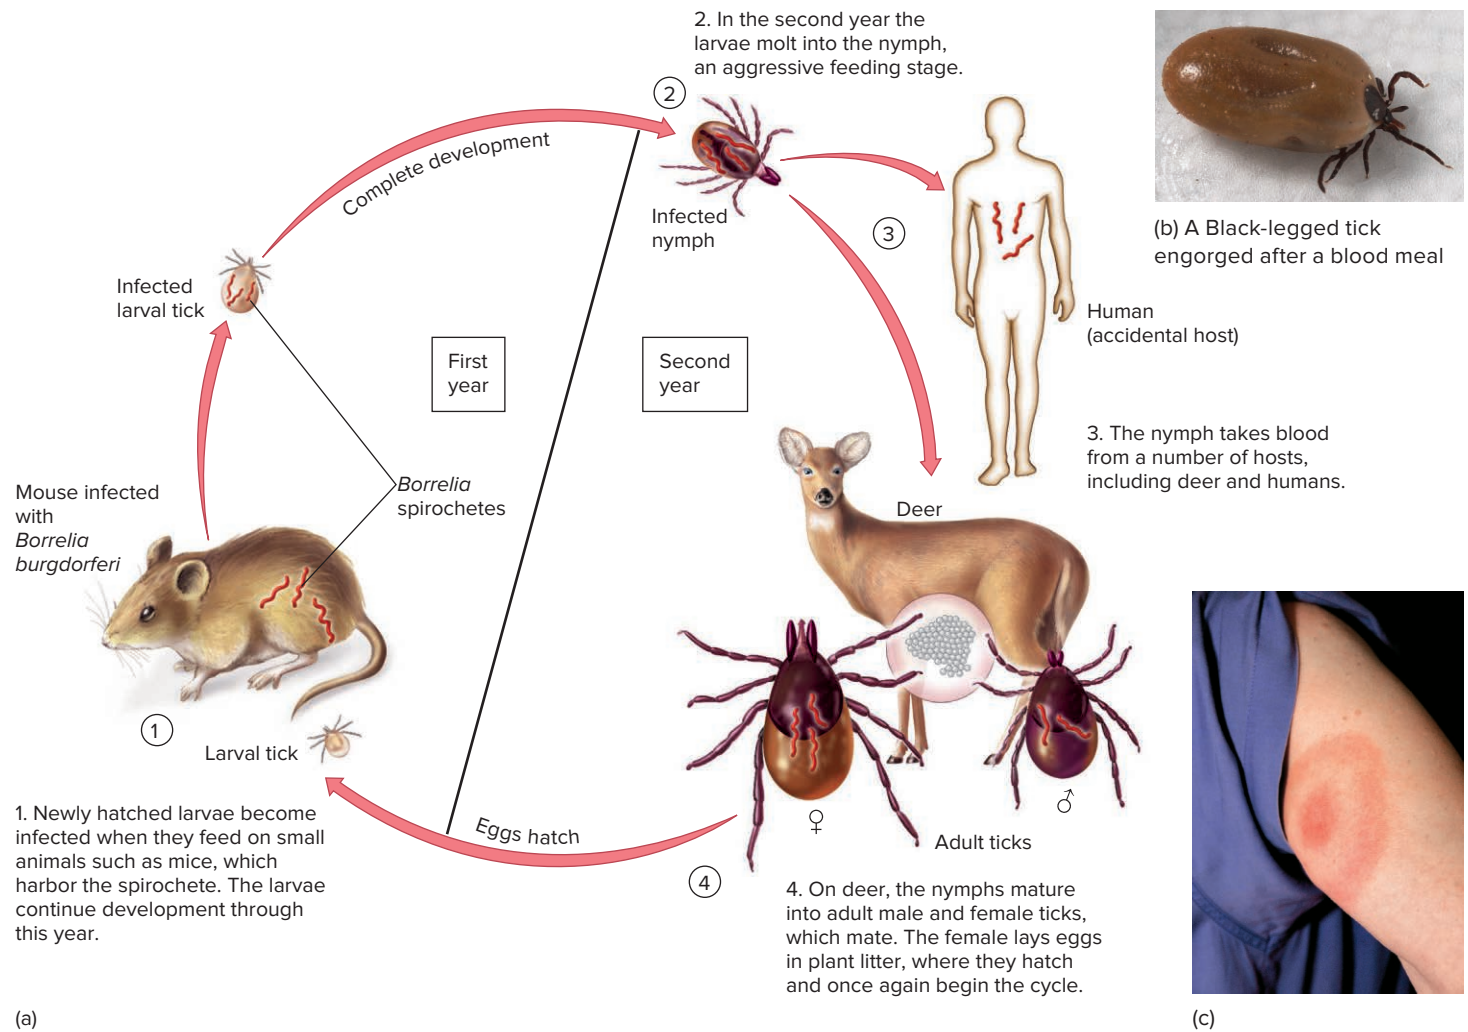

Figure 21.9 The cycle of Lyme disease in the northeastern United States. (a) The disease is tied intimately into the life cycle of a tick vector, which generally is completed over a 2-year period. The exact hosts and species of tick vary from region to region but still display this basic pattern. (b) Black-legged ticks, *Ixodes scapularis*, transmit Lyme disease to humans and animals during feeding. (c) About 70% to 80% of Lyme disease cases present with erythema migrans, a red, often bull's-eye-shaped rash surrounding the initial infection site. (b): Source: Dr. Gary Alpert - Urban Pests - Integrated Pest Management (IPM)/CDC; (c): Source: CDC

woodrat reservoir. In 2016 a new species of bacteria, provisionally named *Borrelia mayonii*, was discovered in the blood of six people with suspected Lyme disease, all living in the upper midwestern United States. The illness caused by *B. mayonii* seems similar to that caused by *B. burgdorferi*, but it may be less likely to cause the bull's-eye rash characteristic of the disease.

The incidence of Lyme disease is showing a gradual upward trend from about 10,000 cases per year in 1991 to around 24,000 in 2014. This increase may be partly due to improved diagnosis, but it also reflects changes in the numbers of hosts and vectors. The greatest concentrations of Lyme disease are in areas having large populations of mice and deer. Most of the cases have occurred in New York, Pennsylvania, Connecticut, New Jersey, Rhode Island, and Maryland, though the number in the Midwest and West is growing. Highest-risk groups include hikers, backpackers, and people living in newly developed communities near woodlands and forests. Peak seasons for infection are the summer and early fall.

Lyme disease is nonfatal but often evolves into a slowly progressive syndrome that mimics neuromuscular and rheumatoid conditions. An early symptom in 70% to 80% of cases is a rash at the site of

a larval tick bite. The lesion, called *erythema migrans*, can appear something like a bull's-eye, with a raised erythematous ring that gradually spreads outward and a pale central region (see figure 21.9c). In other cases it may be a series of red papules or a spotty rash. Other early symptoms are fever, headache, stiff neck, and dizziness.

If not treated or if treated too late, the disease can advance to the second stage, during which cardiac and neurological symptoms (facial palsy) develop. After several weeks or months, a crippling polyarthritis can attack joints, especially in the European strain of the agent. Some people acquire chronic neurological complications that are severely disabling.

Diagnosis of Lyme disease can be difficult because of the range of symptoms it presents. Most suggestive are the ring-shaped lesions, isolation of spirochetes from the patient, and early serological testing with an ELISA method that tracks a rising antibody titer (see chapter 17). Tests for spirochetal DNA in specimens is especially helpful for late-stage diagnosis. Early treatment with doxycycline or amoxicillin is effective, and other antibiotics such as ceftriaxone and azithromycin are used in late Lyme disease therapy.

Because dogs can also acquire the disease, a vaccine has been marketed to protect them. A human vaccine for high-risk populations has been discontinued due to lack of sales over fear of side effects. The best means of preventing Lyme disease is to avoid the vector. Anyone involved in outdoor activities should wear protective clothing, boots, leggings, and insect repellent containing **DEET**.^{*} Individuals exposed to heavy infestation should routinely inspect their bodies for ticks and remove ticks gently without crushing, preferably with forceps or fingers protected with gloves, because it is possible to become infected by tick feces or body fluids.

Check Your Progress SECTION 21.1

1. Construct a table comparing the symptoms of primary, secondary, and tertiary syphilis.
2. How is syphilis diagnosed?
3. Besides syphilis, what other diseases are caused by bacteria in the genus *Treponema*?
4. List several behaviors that would put one at risk for infection with *Leptospira* or *Borrelia* and explain why.

21.2 Curviform Gram-Negative Bacteria and Enteric Diseases

Expected Learning Outcomes

6. Relate the physical characteristics seen in the three groups of curviform bacteria.
7. Understand the pathogenesis of cholera.
8. Name the usual source of infection for each genus of commonly acquired curviform bacteria.
9. Explain the adaptations present in *Helicobacter* that help the pathogen survive in the stomach.

Three groups of curviform bacteria are represented by the following families, genera, and characteristics:

Vibrionaceae	Campylobacteraceae	Helicobacteraceae
<i>Vibrio</i> [*]	<i>Campylobacter</i> [*]	<i>Helicobacter</i> [*]
Comma-shaped rods with one flagellum	Short spirals or curved rods with one flagellum	Tight spirals and curved rods with several polar flagella

Many of the pathogens in these groups share adaptations to survival in the often inhospitable environment of the intestine. They readily move within the mucous coating and avoid being swept away by intestinal motility. Species of *Helicobacter* are uniquely adapted to survival in the stomach with its high acid content.

Figure 21.10 The agent of cholera. *Vibrio cholerae*, showing its characteristic curved shape. Visible on some cells is a single polar flagellum. Members of the genus *Vibrio* (here *Vibrio vulnificus*) possess a characteristic curved shape and are sometimes referred to as “comma bacteria” (10,000 \times). Source: Louisa Howard/Dartmouth Electron Microscope Facility

The Biology of *Vibrio cholerae*

The most prominent species of pathogenic vibrios is *Vibrio cholerae*,^{*} the cause of cholera. A freshly isolated specimen reveals quick, darting cells occasionally resembling a comma (**figure 21.10**). *Vibrio* shares many cultural and physiological characteristics with members of the Enterobacteriaceae, a closely related family. They are fermentative and grow on ordinary or selective media containing bile at 37°C. They possess unique O (somatic) antigens, H (flagella) antigens, and membrane receptor antigens that provide some basis for classifying members of the family.

Epidemiology of Cholera

Epidemic cholera, or Asiatic cholera, has been a devastating disease for centuries. Although the human intestinal tract was once thought to be the primary reservoir, it is now known that the pathogen is free-living in certain endemic regions.

The pattern of cholera transmission and the onset of epidemics are greatly influenced by the season of the year and the climate. Cold, acidic, dry environments inhibit the migration and survival of *Vibrio*, whereas warm, monsoon, alkaline, and saline conditions favor them. The disease has persisted in a pandemic pattern since 1961, when the *El Tor* biotype began to prevail worldwide. This strain survives longer in the environment, infects a higher number of people, and is more likely to be chronically carried than any other strain. One of the worst epidemics in recent history started shortly after the 2010 earthquake in Haiti and continues to the present time. In the five years since the earthquake, the WHO has reported 750,000 cases and 9,000 deaths, most of which were probably preventable. The overwhelming disruption to vital services and sanitation greatly complicated control measures. It ranks among the top seven causes of morbidity and mortality, affecting several million people in endemic regions of Asia and Africa.

In nonendemic areas such as the United States, the microbe is spread by water and food contaminated by asymptomatic carriers, but it is relatively uncommon. Sporadic outbreaks occasionally

^{*} *Campylobacter* (kam'-pih-loh-bak'-ter) Gr. *campylo*, curved, and *bacter*, rod.

^{*} *Helicobacter* (hee'-lih-koh-bak'-ter) Gr. *helicos*, a coil.

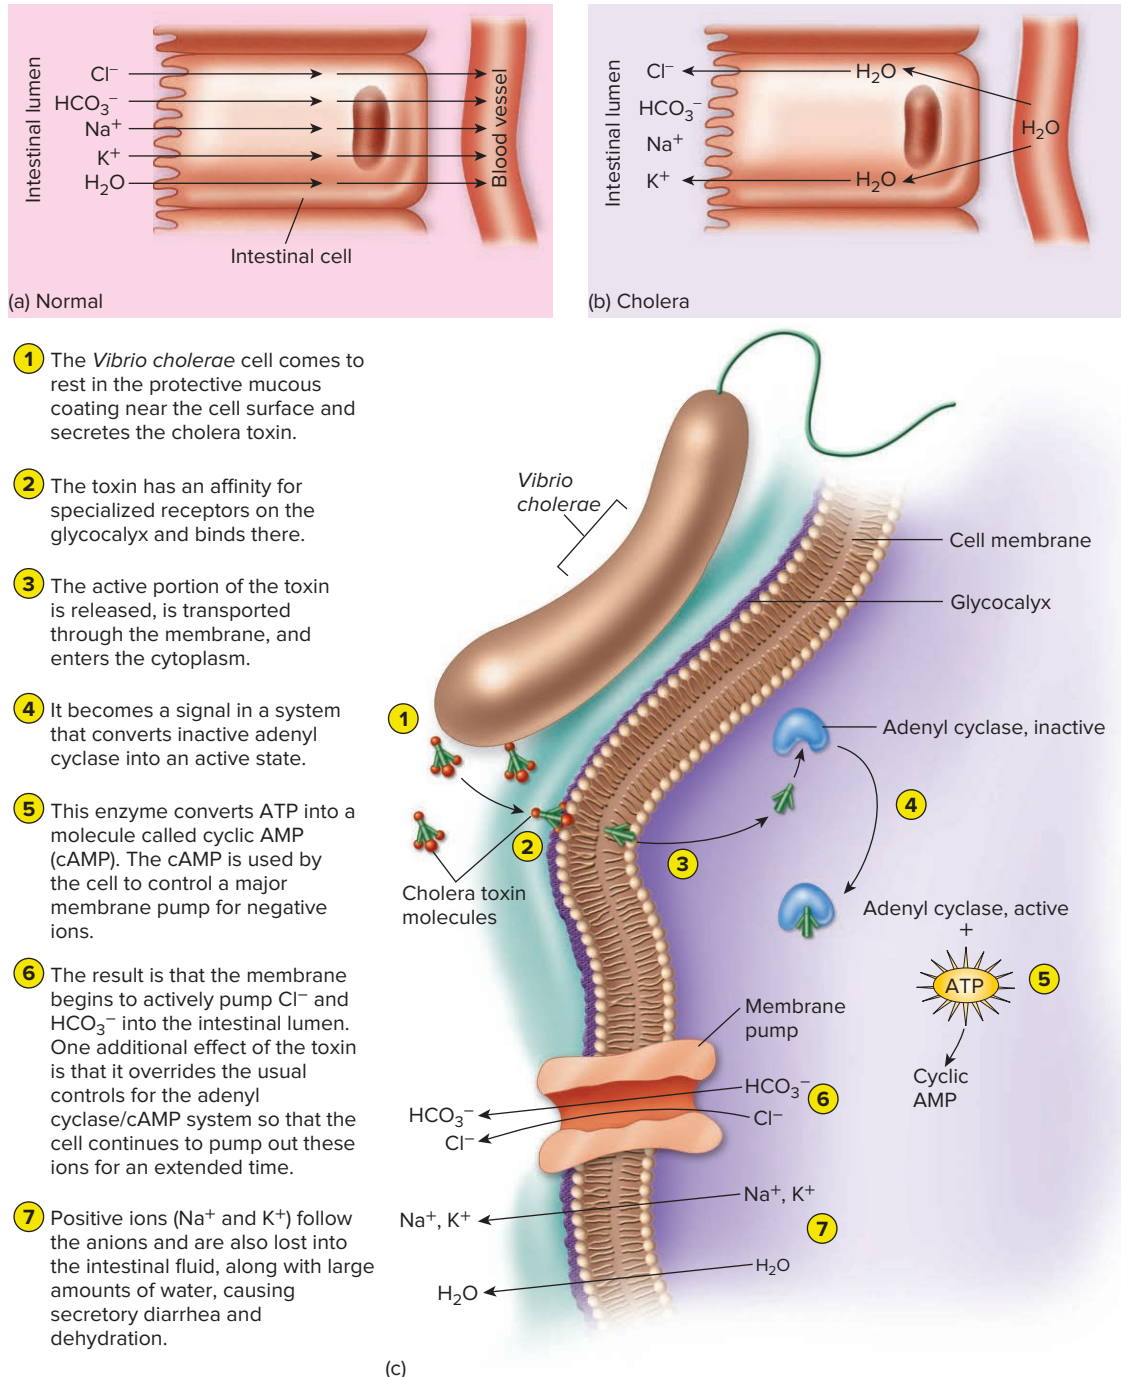

^{*} *cholerae* (kol'-ur-ee) Gr. *chole*, bile. The bacterium was once named *V. comma* for its comma-shaped morphology.

occur along the Gulf of Mexico, and the cholera vibrio is sometimes isolated from shellfish in this region.

Pathogenesis of Cholera: Toxigenic Diarrhea

After being ingested with food or water, *V. cholerae* must pass through the acid environment of the stomach. To compensate, the size of the infectious dose is quite high (10^8 cells). The dose may be reduced by certain types of food that can more readily shelter the pathogen. At the mucosa of the duodenum and jejunum, the vibrios penetrate the mucous barrier and come to rest near the surface of

the epithelial cells. The cholera vibrio is strictly an epipathogen that does not enter cells or deeper tissues. The virulence is due entirely to an enterotoxin called *cholera toxin* (CT) that disrupts the normal physiology of intestinal cells. When this toxin binds to specific intestinal receptors, a secondary signaling system is activated. Under the influence of this system, the cells shed large amounts of electrolytes into the intestine, an event that is accompanied by profuse water loss (**figure 21.11**). Most cases of cholera are mild or self-limited, but in children and weakened individuals, the disease can strike rapidly and violently.

Process Figure 21.11 Alterations in intestinal function caused by cholera toxin. (a) Normal actions of intestinal absorption. (b) General actions of cholera toxin on electrolytes and water. (c) Magnified view of intestinal cell reacting to cholera toxin.

21.2 MAKING CONNECTIONS

Oral Rehydration Therapy

Drinking a simple sugar-salt mixture is often a miracle cure for cholera. This solution, developed by the World Health Organization and termed oral rehydration therapy (ORT), consists of a mixture of sodium chloride, sodium bicarbonate, potassium chloride, and glucose or sucrose dissolved in water (**table 21.A**). When administered early in amounts ranging from 100 to 400 ml/hour, the solution can restore patients in 4 hours, literally bringing them back from the brink of death. It works even if the individual has diarrhea, because the particular combination of ingredients is well tolerated and rapidly absorbed. Infants and small children who once would have died now survive so often that the mortality rate for treated cases of cholera is near zero. This therapy has several advantages, especially for countries with few resources. It does not require medical facilities, high-technology equipment, or complex medication protocols. It is also inexpensive, noninvasive, fast-acting, and useful for a number of diarrheal diseases besides cholera.

How could one put this solution together from everyday kitchen supplies? *Answer available on Connect.*

TABLE 21.A Recommendations for Oral Rehydration Therapy (ORT)

Standard Composition of Oral Rehydration Solution (ORS)	Grams per Liter (g/l)	Concentration in Millimoles
NaCl	3.5 g/l	90 (Na) 80 (Cl)
NaHCO ₃	2.5 g/l	30 (HCO ₃)
KCl	1.5 g/l	20 (K)
Glucose*	20.0 g/l	111

Guidelines for Preparation and Treatment

- Components are dissolved in 1 liter of water that has been boiled to disinfect it. It is thoroughly mixed and tasted for saltiness. It should be only slightly salty. This product is similar to a commercial product called Pedialyte or Oralyte.
- Moderately dehydrated children and adults should receive frequent small amounts of ORS at the rate of 4 to 8 ounces per hour over 6 hours. Plain water can be administered in between ORS administrations.
- To check the patient for the return of normal hydration, test the skin turgor (pinch it to see if a fold remains), and observe whether the eyes are still sunken.

*Sucrose or rice powder may be substituted if glucose is not available.

After an incubation period of a few hours to a few days, symptoms begin abruptly with vomiting, followed by copious watery feces called **secretory diarrhea**. This voided fluid contains flecks of tissue debris, hence the description “rice-water stool.” Fluid losses of nearly 1 liter per hour have been reported in severe cases, and an untreated patient can lose up to 50% of body weight during the course of the disease. The diarrhea causes reduced blood volume, acidosis from bicarbonate loss, and potassium depletion. These conditions predispose the patient to muscle cramps, severe thirst, flaccid skin, and sunken eyes and, in young children, coma and convulsions. Secondary circulatory consequences can include hypotension, tachycardia, cyanosis, and collapse from shock within 18 to 24 hours. If cholera is left untreated, death can occur in less than 48 hours, and the mortality rate approaches 55%.

Diagnosis and Remedial Measures

During epidemics, clinical evidence is usually sufficient to diagnose cholera. But confirmation of the disease is often required for epidemiological studies and detection of sporadic cases. *Vibrio cholerae* can be readily isolated and identified in the laboratory from stool samples. Direct dark-field microscopic observation reveals characteristic curved cells with brisk, darting motility as confirmatory evidence. Rapid tests utilizing *Vibrio cholerae* specific monoclonal-antibodies may be used when laboratory facilities are unavailable—such as in remote locations or after natural disasters—but the tests lack the sensitivity and specificity needed to confirm the presence of the pathogen. Difficult or elusive cases can be traced by detecting a rising antitoxin titer in the serum.

The key to cholera therapy is prompt replacement of water and electrolytes. This can be accomplished by various rehydration techniques that replace the lost fluid and electrolytes (oral rehydration therapy [ORT]; **21.2 Making Connections**).

Cases in which the patient is unconscious or has complications from severe dehydration require intravenous replenishment as well. Oral antibiotics such as doxycycline and azithromycin can terminate the diarrhea in 48 hours, and they also promote recovery and diminish the period of vibrio excretion.

Effective prevention is contingent upon proper sewage disposal and water purification. Detecting and treating carriers with mild or asymptomatic cholera are serious goals but ones that are frequently difficult to attain because of inadequate medical provisions in those countries where cholera is endemic. Vaccines are available for travelers and people living in endemic regions. Both are whole-cell killed vaccines that provide limited protection for about 2 years. The World Health Organization (WHO) recommends immunization in endemic areas, while long-term improvements to water quality and sanitation are undertaken.

Vibrio parahaemolyticus and *Vibrio vulnificus*: Pathogens Carried by Seafood

Two pathogenic relatives of *V. cholerae* share its morphology, physiology, and ecological adaptation. *Vibrio parahaemolyticus* and *V. vulnificus* are both salt-tolerant inhabitants of coastal waters and associate with marine invertebrates. In temperate zones, vibrios survive over the winter by settling into the ocean sediment; when resuspended by upwelling during the warmer seasons, they

become incorporated into the food web, eventually growing on fish, shellfish, and other edible seafood.

Features of *V. parahaemolyticus* Gastroenteritis

Vibrio parahaemolyticus infection, an acute form of **gastroenteritis**, was first described in Japan more than 30 years ago. The great majority of cases appear in individuals who have eaten raw, partially cooked, or poorly stored seafood. The vehicles most often implicated are squid, mackerel, sardines, crabs, tuna, shrimp, oysters, and clams. Outbreaks tend to be concentrated along coastal regions during the summer and early fall. The incubation period of nearly 24 hours is followed by explosive, watery diarrhea accompanied by nausea, vomiting, abdominal cramps, and sometimes fever. *Vibrio* toxins cause symptoms that last about 72 hours but can persist for 10 days.

Food infection caused by *V. vulnificus* is similar in symptoms to that caused by *V. parahaemolyticus*. It is most often associated with ingesting raw oysters and can have a much more severe outcome in critically ill patients with diabetes or liver disease. It is the leading cause of death from food-borne illness in some areas.

Treatment of severe gastroenteritis can require fluid and electrolyte replacement and occasionally antibiotics. Control measures aim to keep the bacterial count in all seafood below the infective dose by continuous refrigeration during transport and storage, sufficient cooking temperatures, and prompt serving. Consumers of raw oysters (or other shellfish) should understand their possible risk. In some regions, the U.S. Department of Agriculture mandates that health warnings be posted about this danger in markets and restaurants.

Review the chapter 17 Case Study for information on the identification of *Vibrio* species.

Diseases of the *Campylobacter* Vibrios

Campylobacters are curved or spiral bacilli, often appearing in S-shaped or gull-winged pairs (**figure 21.12**). Their polar flagellum imparts active spinning motility. Their physiological profile includes being

Figure 21.12 Scanning micrograph of *Campylobacter jejuni*. The S form is seen here, but the pathogen also appears as a shorter, comma-shaped bacillus and in a longer, spiral form. Source: Emerging Infectious Diseases <http://wwwnc.cdc.gov/eid/>

microaerophilic, oxidase-positive, and nonfermenting. These bacteria are common residents of the intestinal tract, genitourinary tract, and oral cavity of birds and mammals. Species of *Campylobacter* most significant in medical and veterinary practice are *C. jejuni* and *C. fetus*.

Campylobacter jejuni Enteritis

*Campylobacter jejuni** has emerged as a pathogen of such imposing proportions that it is considered one of the most important causes of bacterial gastroenteritis worldwide (**Pathogen Profile #2**). In the United States, approximately 1.3 million cases occur every year. Epidemiological and pathologic studies have shown that this species is a primary pathogen transmitted through contaminated beverages and food, especially water, milk, meat, and chicken.

Ingested *C. jejuni* cells travel to the mucosa at the last segment of the small intestine (ileum) near its junction with the colon. They adhere, burrow through the mucus, and are taken in by intestinal cells. The pathogen disrupts the cytoskeleton, damages the epithelium, and penetrates the intestinal wall. After an incubation period of 1 to 7 days, acute symptoms of headache, fever, abdominal pain, and bloody or watery diarrhea develop. The mechanisms of pathology involve a heat-labile enterotoxin called CJT that stimulates secretory diarrhea like cholera. An occasional sequela of this infection is the development of a neurological disease called Guillain-Barré syndrome.

Diagnosis of *C. jejuni* enteritis is usually made with fecal samples and occasionally blood samples. This species is microaerophilic and thermophilic, and isolation requires special culturing media. It can be grown on CCD medium, under conditions of reduced oxygen, and at 42°C, typical avian body temperature. More rapid presumptive diagnosis can be obtained from examination of feces with a dark-field microscope, which accentuates the characteristic curved rods and darting motility.

Resolution of infection occurs in most instances with rehydration and electrolyte balance therapy. In more severely affected patients, it may be necessary to administer erythromycin or azithromycin. Because vaccines are yet to be developed, prevention depends upon rigid sanitary control of water and milk supplies and care in food preparation.

Traditionally of interest to the veterinarian, *C. fetus* (subspecies *venerealis*) causes a sexually transmitted disease of sheep, cattle, and goats. Its role as an agent of abortion in these animals has considerable economic impact on the livestock industry. About 40 years ago, the significance of *C. fetus* as a human pathogen was first uncovered, though its exact mode of transmission in humans is yet to be clarified. This bacterium appears to be an opportunistic pathogen that attacks debilitated persons or women late in pregnancy. Diseases to which *C. fetus* has been linked are meningitis, pneumonia, arthritis, septicemic infection in the newborn, and occasionally, sexually transmitted proctitis in adults.

Helicobacter pylori: Gastric Pathogen

Although the human stomach is too harsh for most bacteria, it serves as a primary habitat for an unusual spiral bacterium, *Helicobacter pylori*. Like *Campylobacter*, it is microaerophilic and oxidative, but it differs in having multiple sheathed polar flagella. Not only does it thrive in the

* *jejuni* (jee-joo'-nye) *L. jejunum*. The small section of intestine between the duodenum and the ileum.

Pathogen Profile #2 *Campylobacter jejuni*

Source: CDC

Microscopic Morphology Small, curved, gram-negative rods.

Identified by Dark-field examination of stool samples, revealing curved cells with a darting motility provides presumptive identification. Positive identification requires culturing the pathogen on specialized media under conditions of low oxygen concentration.

Habitat *C. jejuni* is a common resident of the intestinal tract, genitourinary tract, and oral cavity of birds and mammals.

Virulence Factors The primary virulence factor in *C. jejuni* is CJT, a heat-labile enterotoxin that stimulates secretory diarrhea.

Primary Infections/Disease *C. jejuni* is one of the most important causes of gastroenteritis, with over 1.3 million cases of the disease

occurring every year in the United States. Common symptoms include fever, diarrhea, and abdominal pain within 2 to 5 days after exposure to the organism. Illness typically lasts about 1 week and is self-limiting, although it is estimated that *C. jejuni* is responsible for about 75 deaths annually in the United States, mostly among people with compromised immune systems.

Control and Treatment Prevention depends on proper sanitary control of water and milk supplies, along with care in food harvesting and preparation. Rehydration therapy is usually adequate to resolve infection, whereas antibiotics—erythromycin or azithromycin—may be necessary in more severe cases.

acidic environment, but evidence has clearly linked it to a variety of gastrointestinal ailments. It is known to cause an inflammation of the stomach lining called gastritis and is implicated in 90% of stomach and duodenal ulcers. It is also an apparent cofactor in the development of a common type of stomach cancer called adenocarcinoma.

This novel pathogen was first detected by J. Robin Warren in 1979 in stomach biopsies from ulcer patients. He and an assistant, Barry J. Marshall, isolated the microbe in culture and even tested its effects by swallowing a good-sized inoculum. Both developed a short-term case of gastritis. For their extraordinary discovery of this microbe and its connection to gastric diseases, the two scientists were awarded the Nobel Prize in Physiology or Medicine in 2005.

Continued research has revealed that the bacterium is present in a large proportion of people. It occurs in the stomachs of 25% of healthy middle-aged adults and in more than 50% of adults over 60 years of age. *Helicobacter pylori* is probably transmitted from person to person by the oral-oral or oral-fecal route. It can also be spread by houseflies acting as mechanical vectors. It seems to be acquired early in life and carried asymptotically until its activities begin to damage the digestive mucosa. Because other animals are also susceptible to *H. pylori* and even develop chronic gastritis, it has been proposed that the disease is a zoonosis transmitted from an animal reservoir. Several other species of this genus have been isolated from cats, dogs, and other mammals.

Other studies have helped to explain how infection with the pathogen progresses, eventually leading to the formation of a peptic ulcer. First, it bores through the outermost mucus that lines the epithelial tissue. Then it attaches to specific binding sites on the cells and entrenches itself (figure 21.13). It turns out that one receptor specific for *Helicobacter* is the same receptor as type O blood, which accounts for the finding that people with this blood type have a 1.5 to 2 times higher rate of ulcers than people in other blood groups. Another protective adaptation is the formation of urease, an enzyme that converts urea into ammonium and bicarbonate, both alkaline compounds that can neutralize stomach acid. As the immune system recognizes and attacks the pathogen, certain white blood cells

damage the epithelium to some degree, leading to chronic active gastritis. In some people these lesions lead to deeper erosions and ulcers and eventually can lay the groundwork for cancer to develop.

Helicobacter pylori is isolated primarily from biopsy specimens. Serological detection of *H. pylori* antigens in the stool has become a favored diagnostic test as it is noninvasive and has a high degree of sensitivity.

Understanding the underlying pathology has useful applications in treatment. Gastritis and ulcers have traditionally been treated with drugs (cimetidine [Tagamet], or ranitidine [Zantac]) that suppress symptoms by slowing the secretion of acid in the stomach. They must be taken continuously for indefinite periods, and relapses are common. Current recommended therapy is 2 to 4 weeks of clarithromycin to eliminate the bacterial infection, along with stomach acid inhibitors. This regimen can cure the infection and eliminate symptoms.

- Briefly describe the nature of food infection in species of *Vibrio* and the diseases of *Campylobacter*.
- What diseases involve *Helicobacter pylori* infection?

21.3 Medically Important Bacteria of Unique Morphology and Biology

Expected Learning Outcomes

- Recall the characteristics seen in the *Rickettsia* that make them unique.
- Understand the epidemiology and pathology of Rocky Mountain spotted fever.
- Name the human pathogens within the genera *Ehrlichia* and *Anaplasma* and the diseases they cause.
- Recognize behaviors or activities that would increase the risk of contracting Q fever.
- Recall the body systems commonly affected by species in the genus *Chlamydia*.
- Recall the names and characteristics of diseases attributable to infection with *Chlamydomphila* species.

Pathogenic bacteria that exhibit atypical morphology, physiology, and behavior include: (1) rickettsias and (2) chlamydias, which are obligately parasitic gram-negative coccobacilli, and (3) mycoplasmas, which are highly pleomorphic bacteria that lack cell walls (see figure 21.24). The three groups are not closely related but are included together because of similar morphology and pathogenicity.

Order Rickettsiales

The Order Rickettsiales contains about two dozen species of pathogens, mostly in the genus *Rickettsia*.^{*} Other members include *Ehrlichia*,^{*} *Anaplasma*, and *Orientia*. These organisms are known commonly as **rickettsias**, or rickettsiae, and the diseases they cause are called rickettsioses.

The rickettsias are all obligate to their host cells and require live cells for cultivation; they also spend part of their life cycle in the bodies of arthropods, which serve as vectors. Rickettsioses are among the most important emerging diseases. Six of the 14 recognized diseases have been identified in the last 20 years.

^{*} *Rickettsia* (rik'-ett'-see-ah) After Howard Ricketts, an American bacteriologist who worked extensively with this group.

^{*} *Ehrlichia* (ur-lik'-ee-ah) After Paul Ehrlich, a German immunologist.

Figure 21.14 The order *Rickettsiales*. (b) Transmission electron micrograph of an *Orientia tsutsugamushi* cell budding from the surface of a mouse cell that had been experimentally infected. (a, b): Source: CDC

Morphological and Physiological Distinctions of Rickettsias

Rickettsias possess a gram-negative cell wall, binary fission, metabolic pathways for synthesis and growth, and both DNA and RNA. They are among the smallest cells, ranging from 0.3 to 0.6 μm wide and from 0.8 to 2.0 μm long. They are nonmotile pleomorphic rods or coccobacilli (**figure 21.14**).

The precise nutritional requirements of the rickettsias have been difficult to demonstrate because of a close association with host cell metabolism. Their obligate parasitism originates from an inability to metabolize AMP, an important precursor to ADP and ATP, which they must obtain from the host. Rickettsias are generally sensitive to environmental exposure, although *R. typhi* can survive several years in dried flea droppings.

Distribution and Ecology of Rickettsial Diseases

The Role of Arthropod Vectors The rickettsial life cycle depends upon a complex exchange between blood-sucking arthropod¹ hosts and vertebrate hosts (see section 23.8). Eight tick genera, two fleas, and one louse are involved in the spread of rickettsias to humans. Humans accidentally enter the zoonotic life cycles through occupational contact with the animals except in the cases of louse-borne typhus and trench fever. Most vectors apparently harbor rickettsias with no ill effect, but others, like the human body louse, die from typhus infection and do not continuously harbor the pathogen. In certain vectors (Rocky Mountain spotted fever ticks), rickettsias are transferred to offspring by the eggs of an infected female. Such continuous inheritance of the microbe through multiple generations of ticks creates a long-standing reservoir.

These arthropods feed on the blood or tissue fluids of their mammalian hosts, but not all of them transmit the rickettsial pathogen through direct inoculation with saliva. Ticks directly inoculate the skin lesion from their mouths, but fleas and lice harbor the infectious agents in their intestinal tracts. During their stay on the host's body, these latter insects defecate or are smashed, thereby releasing the rickettsias onto the skin or into a wound. Ironically, scratching the bite helps the pathogen invade deeper tissues.

1. Ticks are in the Class Arachnida, and lice and fleas are in the Class Insecta, both in the Phylum Arthropoda.

General Factors in Rickettsial Pathology and Isolation

A common target in rickettsial infections is the endothelial lining of the small blood vessels. The bacteria recognize, enter, and multiply within endothelial cells, causing necrosis of the vascular lining. Among the immediate pathologic consequences are vasculitis, perivascular infiltration by inflammatory cells, vascular leakage, and thrombosis. These pathologic effects are manifested by skin rash, edema, hypotension, and gangrene. Intravascular clotting in the brain accounts for the stuporous mental changes and other neurological symptoms that sometimes occur.

Isolation of most rickettsias from clinical specimens requires a suitable live medium and specialized laboratory facilities, including controlled access and safety cabinets. The usual choices for routine growth and maintenance are the yolk sacs of embryonated chicken eggs, chick embryo cell cultures, and, to a lesser extent, mice and guinea pigs.

Specific Rickettsioses

Rickettsioses can be differentiated on the basis of their clinical features and epidemiology as (table 21.2):

1. the typhus group,
2. the spotted fever group,
3. scrub typhus, and
4. ehrlichiosis and anaplasmosis.

Rickettsia prowazekii and Epidemic Typhus

Epidemic, or louse-borne, **typhus*** has been a constant accompaniment to war, poverty, and famine. The extensive investigations of

* *typhus* (ty'-fus) Gr. *typhos*, smoky or hazy, underlining the mental deterioration seen in this disease. The term *typhus* is commonly confused with typhoid fever, an unrelated enteric illness caused by *Salmonella typhi*.

Dr. Howard Ricketts and Stanislas von Prowazek in the early 1900s led to the discovery of the vector and the rickettsial agent but not without mortal peril; both men died of the very disease they investigated. *Rickettsia prowazekii* was named in honor of their pioneering efforts.

Epidemiology of Epidemic Typhus Humans are the sole hosts of human body lice and the only reservoirs of *R. prowazekii*. The louse spreads infection by defecating into its bite wound or other breaks in the skin. Infection of the eye or respiratory tract can take place by direct contact or inhalation of dust containing dried louse feces, but this is a rarer mode of transmission.

The transfer of lice is increased by crowding, infrequently changing clothing, and sharing clothing. The overall incidence of epidemic typhus in the United States is very low, with no epidemics since 1922. Although no longer common in regions of the world with improved standards of living, epidemic typhus presently persists in regions of Africa, Central America, and South America.

Disease Manifestations and Immune Response in Typhus

After entering the circulation, rickettsias pass through an intracellular incubation period of 10 to 14 days. The first clinical manifestations are sustained high fever, chills, frontal headache, and muscular pain. Within 7 days, a generalized rash appears, initially on the trunk, and then spreads to the extremities. Personality changes, oliguria (low urine output), hypotension, and gangrene complicate the more severe cases. Mortality is lowest in children and as high as 40% to 60% in patients over 50 years of age.

Recovery usually confers resistance to typhus, but in some cases, the rickettsias are not completely eradicated by the immune response and enter into latency. After several years, a milder recurring form of the disease, known as *Brill-Zinsser disease*, can appear. This disease is seen most often in people who have immigrated from endemic areas and is of concern mainly because these immigrants provide a continuous reservoir of the pathogen.

TABLE 21.2 Characteristics of Major Rickettsias Involved in Human Disease

Disease Group	Species	Disease	Vector	Primary Reservoir	Mode of Transmission to Humans	Where Found
Typhus	<i>Rickettsia prowazekii</i>	Epidemic typhus	Body louse	Humans	Louse feces rubbed into bite; inhalation	Worldwide
	<i>R. typhi</i> (<i>mooseri</i>)	Murine typhus	Flea	Rodents	Flea feces rubbed into skin; inhalation	Worldwide
Spotted Fever	<i>R. rickettsii</i>	Rocky Mountain spotted fever	Tick	Small mammals	Tick bite; aerosols	North and South America
	<i>R. akari</i>	Rickettsialpox	Mite	Mice	Mite bite	Worldwide
Scrub Typhus	<i>Orientia tsutsugamushi</i>	—	Immature mite	Rodents	Bite	Asia, Australia, Pacific Islands
Human Ehrlichiosis	<i>Ehrlichia chaffeensis</i>	Human monocytic ehrlichiosis	Tick	—	Tick bite	Similar to Rocky Mountain spotted fever
Human Anaplasmosis	<i>Anaplasma phagocytophilum</i>	Human granulocytic anaplasmosis	Tick	Deer, rodents	Tick bite	Unknown

Treatment and Prevention of Typhus Standard chemotherapy for typhus is doxycycline or chloramphenicol. Despite antibiotic therapy, however, the prognosis can be poor in patients with advanced circulatory or renal complications. Eradication of epidemic typhus is theoretically possible by exterminating the vector. Widespread dusting of human living quarters with insecticides has provided some environmental control, and individual treatment with an antilouse shampoo or ointment is also effective.

Epidemiology and Clinical Features of Endemic Typhus

The agent for endemic typhus is *Rickettsia typhi*, which shares many characteristics with *R. prowazekii* except that *R. typhi* has pronounced virulence. Synonyms for this rickettsiosis are endemic typhus, murine (mouse) typhus, and flea-borne typhus. The disease is endemic to certain parts of Central and South America and the Southeast, Gulf Coast, and Southwest regions of the United States. The native rodents and opossums in these areas are a reservoir for *R. typhi* and transmit it to fleas feeding on blood. Humans become infected through flea bites and occasionally inhalation of dried feces from infected rats. In the United States, most reported cases arise sporadically among workers in rat-infested industrial sites.

The clinical manifestations of endemic typhus include fever, headache, muscle aches, and malaise. After 5 days, a skin rash, transient in milder cases, begins on the trunk and radiates toward the extremities. Symptoms dissipate in about 2 weeks. Doxycycline and chloramphenicol are effective therapeutic agents, and various pesticides are available for vector and rodent control.

Rocky Mountain Spotted Fever: Epidemiology and Pathology

The rickettsial disease with greatest impact on people living in North America is Rocky Mountain spotted fever (RMSF), named for the place it was first seen—the Rocky Mountains of Montana and Idaho (**Pathogen Profile #3**). Ricketts identified the etiologic agent *Rickettsia rickettsii* in smears from infected animals and patients and later discovered that it was transmitted by ticks. Despite its geographic name, this disease occurs infrequently in the western United States. The majority of cases are concentrated in the Southeast and eastern seaboard regions (**figure 21.15**). It also occurs in Canada and Central and South America. Infections occur most frequently in the spring and summer, when the tick vector is most active. The yearly rate of RMSF averages six to seven cases per million population, with fluctuations coinciding with weather and tick infestations. The incidence has been generally increasing since 2000.

The principal reservoirs and vectors of *R. rickettsii* are hard ticks such as the wood tick (*Dermacentor andersoni*), the American dog tick (*D. variabilis*, among others), and the Lone Star tick

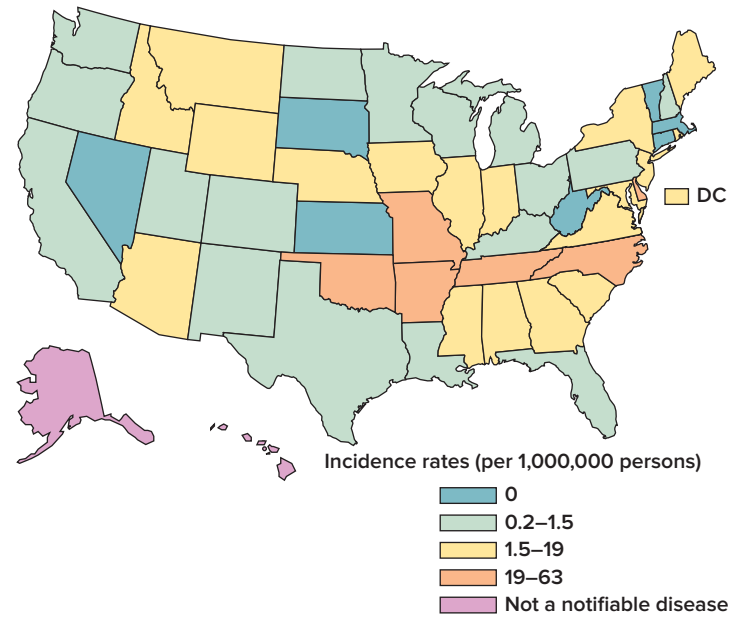

Figure 21.15 Trends in infection for Rocky Mountain spotted fever. A summary map showing the distribution of Rocky Mountain spotted fever cases. The disease is not reportable in Alaska or Hawaii. Source of data: CDC

Figure 21.16 The transmission cycle in Rocky Mountain spotted fever. Dog ticks and wood ticks (*Dermacentor*) are the principal vectors. (a) Ticks are infected from a mammalian reservoir during a blood meal. (b) Transovarial passage of *Rickettsia rickettsii* to tick eggs serves as a continual source of infection within the tick population. Infected eggs produce infected adults. (c) A tick attaches to a human, embeds its head in the skin, feeds, and sheds rickettsias into the bite. (d) Systemic involvement includes severe headache, fever, rash, coma, and vascular damage such as blood clots and hemorrhage.

(*Amblyomma americanum*). The dog tick is probably most responsible for transmission to humans because it is the major vector in the southeastern United States (**figure 21.16**).

Pathogenesis and Clinical Manifestations of Spotted Fever After 2 to 4 days incubation, the first symptoms are sustained fever,

Pathogen Profile #3 *Rickettsia rickettsii*

Source: CDC

Microscopic Morphology Very small, gram-negative pleomorphic rods or coccobacilli.

Identified by Cultivation of *R. rickettsii* is difficult, and detection of bacterial cells from tissue samples is often accomplished using fluorescent antibodies. Definitive identification may be achieved using PCR and a presumptive diagnosis can be achieved through an ELISA test that detects a rising antibody titer.

Habitat Within the United States, *R. rickettsii* is found in the Southeast and eastern seaboard regions, where it is transmitted by several species of hard tick, including the wood tick, American dog tick, and Lone Star tick. With the tick serving as a biological vector, the bacterium is spread between mammalian reservoirs and humans.

Virulence Factors Proteins residing on the outer membrane of *R. rickettsii* are responsible for binding to the endothelial cells of

the host. The bacterium is able to induce its own phagocytosis by cells of the body and multiply within the cytoplasm, eventually leading to disease.

Primary Infections/Disease Symptoms of Rocky Mountain spotted fever (RMSF) are first noticed 2 to 4 days after infection and include fever, chills, headache, and muscle pain. Shortly thereafter, a red spotted rash appears and worsens, occasionally becoming necrotic in some areas. Progression of the disease includes cardiovascular disruption and involvement of the central nervous system. Fatality results in 10% of untreated cases but less than 1% of treated cases.

Control and Treatment Early doxycycline therapy is the treatment of choice for RMSF. Prevention of the disease is synonymous with prevention of tick bites when involved in outdoor activities, and the use of protective clothing, boots, and insect repellent containing DEET is recommended.

chills, headache, and muscular pain. The distinctive spotted rash appears within 1 to 3 days after the prodromium (**figure 21.17**). Early lesions are slightly mottled like measles, but later ones are macular, maculopapular, and even petechial. In the severest untreated cases, the enlarged lesions merge and can become necrotic, predisposing to gangrene of the toes or fingertips.

Grave manifestations of disease are cardiovascular disruption, including hypotension, thrombosis, and hemorrhage. Conditions of restlessness, delirium, convulsions, tremor, and coma are alarming indications of central nervous system involvement. Fatalities occur in an average of 10% of untreated cases but less than 1% of treated cases.

Diagnosis, Treatment, and Prevention of Spotted Fever Any case of Rocky Mountain spotted fever is a cause for great concern and requires immediate treatment, even before laboratory confirmation. Indications sufficiently suggestive to start antimicrobial therapy are the following:

1. a cluster of symptoms, including sudden fever, headache, and rash;
2. recent contact with ticks or dogs; and
3. possible occupational or recreational exposure in the spring or summer.

Early diagnosis can be made by staining rickettsias directly in a tissue biopsy using fluorescent antibodies. Isolating rickettsias from the patient's blood or tissues is desirable, but it is expensive and requires specially qualified personnel and laboratory facilities. Specimens taken from the rash lesions are suitable for PCR assay, which is very specific and sensitive and can circumvent the need for culture. Because antibodies appear relatively soon after infection, a change in serum titer detected through an ELISA test can confirm a presumptive diagnosis.

The drug of choice for suspected and known cases is doxycycline administered for 1 week. Chloramphenicol is an alternate choice used for pregnant patients or if an allergic reaction to tetracycline-class

Figure 21.17 The spotted appearance of the rash in RMSF. This case occurred in a child several days after the onset of fever. It may occur on most areas of the body. Source: CDC

antibiotics is noted. Preventive measures follow the pattern for Lyme disease and other tick-borne disease: wearing protective clothing, using insect sprays, and fastidiously removing ticks.

Emerging Rickettsioses

Other genera that share similarities with *Rickettsia* are *Ehrlichia* and *Anaplasma*, two closely related obligate parasites spread by ticks. Although these rickettsial pathogens have been known as pathogens of dogs, horses, and other mammals for some time, infections caused by them have emerged more recently in humans. *Ehrlichia chaffeensis* is the cause of human monocytic ehrlichiosis (HME), and *Anaplasma phagocytophilum* is the cause of human granulocytic anaplasmosis (HGA). The diseases are reported in many regions of the United States and Europe and appear to be on the increase at the present time. Both human pathogens cause an acute flulike disease that ranges from mild to severe and can even

be fatal. In both pathogens, white blood cells are the primary targets of infections.

Human monocytic ehrlichiosis is associated with contact with the Lone Star tick. The rickettsia enters the tick bite and is phagocytosed by monocytes and macrophages, which can lead to cell death and leukopenia. It is carried to many organs, leaving widespread inflammation in its path. The main symptoms are fever, muscle pains, headache, and a rash. Approximately 850 cases per year are reported to the CDC.

Anaplasma phagocytophilum is the cause of human granulocytic anaplasmosis (HGA). The primary reservoirs and vectors for the pathogen are very similar to those of *Borrelia burgdorferi*. It is carried by white-footed mice and deer, and its vectors are ticks in the genus *Ixodes*. The primary targets of infection are neutrophils and other granulocytes. The pathogen disrupts neutrophil function and causes diminished immunities. The symptoms are similar to ehrlichiosis but can also involve the respiratory and gastrointestinal tracts, kidney, and liver. Approximately 1,000 cases are reported each year in the United States, but epidemiologists suspect the true number of cases is much higher.

Most patients recover rapidly with no lasting effects, but around 5% of older chronically ill patients die from disseminated infection. Rapid diagnosis is enabled by PCR tests and indirect fluorescent antibody tests. It can be critical to differentiate or detect coinfection with the Lyme disease *Borrelia*, which is carried by the same tick. Doxycycline will clear up most infections within 7 to 10 days.

Coxiella and *Bartonella*: Other Vector-Borne Pathogens

Q fever² was first described in Queensland, Australia. Its origin was mysterious for a time, until Harold Cox working in Montana and Frank Burnet in Australia discovered the agent later named *Coxiella burnetii*.^{*} This bacterium is similar to rickettsias in being an intracellular parasite, but it is much more resistant because it produces an unusual type of spore (**figure 21.18**). It is apparently harbored by a wide assortment of vertebrates and arthropods, especially ticks, which play an essential role in transmission between wild and domestic animals. Humans acquire infection largely by means of environmental contamination and airborne spread. Sources of infectious material include urine, feces, milk, and airborne particles from infected animals. The primary portals of entry are the lungs, skin, conjunctiva, and gastrointestinal tract.

Coxiella burnetii has been isolated from most regions of the world. In the United States, it occurs sporadically, primarily in the western states, and it is believed that most cases probably go undetected. People at highest risk are farm workers, meat cutters, veterinarians, laboratory technicians, and consumers of raw milk. The clinical manifestations typical of *Coxiella* infection are abrupt onset of fever, chills, head and muscle ache, and, occasionally, a rash. Disease is sometimes complicated by pneumonitis, hepatitis, and endocarditis. Mild or subclinical cases resolve spontaneously, and more severe cases respond to doxycycline therapy. A vaccine is available in many parts of the world and is used on military personnel in the United States. People working with livestock should

Figure 21.18 The agent of Q fever. The vegetative cells of *Coxiella burnetii* produce unique endospores (visible in most of the cells above) that are released when the cell disintegrates. Free spores survive outside the host and are important in transmission (100,000 \times). Source: National Institute of Allergy and Infectious Diseases (NIAID); Rocky Mountain Laboratories, NIH/CDC

avoid contact with excrement and secretions and should observe decontamination precautions.

The Family Bartonellaceae contains the genus *Bartonella*,^{*} which now includes species formerly known as *Rochalimaea*. These small, gram-negative rods are fastidious but not obligate intracellular parasites, readily cultured on blood agar. *Bartonella* species are currently considered a group of emerging pathogens. One disease with a long history is **trench fever**, once a common condition of soldiers in battle. The causative agent, *Bartonella quintana*, is carried by lice. Most cases occur in endemic regions of Europe, Africa, and Asia. Highly variable symptoms can include a 5- to 6-day fever (hence, 5-day, or quintana, fever); leg pains, especially in the tibial region (shinbone fever); headache; chills; and muscle aches. A macular rash can also occur. The microbe can persist in the blood long after convalescence and is responsible for later relapses.

Bartonella henselae is the most common agent of **cat-scratch disease (CSD)**, an infection connected with being clawed or bitten by a cat. The pathogen can be isolated in over 40% of cats, especially kittens. There are approximately 25,000 cases per year in the United States, 80% of them in children 2 to 14 years old. Symptoms start after 1 to 2 weeks, with a cluster of small papules at the site of inoculation. In a few weeks, the lymph nodes along the lymphatic drainage swell and can become pus-filled (**figure 21.19**). Most infections remain localized and resolve in a few weeks, but drugs such as doxycycline and erythromycin can be effective therapies. The disease can be prevented by thorough degerming of a cat bite or scratch.

Bartonella is recognized as an important emerging pathogen in AIDS patients. It is the cause of bacillary angiomatosis, a severe cutaneous and systemic infection. The cutaneous lesions arise as reddish nodules or crusts that can be mistaken for Kaposi's sarcoma. Systems most affected are the liver and spleen, and symptoms are fever, weight loss, and night sweats. Treatment is similar to that for CSD.

2. For "query," meaning to question, or of unknown origin.

Other Obligate Parasitic Bacteria: The Chlamydiaceae

Even though they are not close relatives of rickettsias, members of Family Chlamydiaceae are also obligate intracellular parasites that depend on certain metabolic constituents of host cells for growth and maintenance. They show further resemblance to the rickettsias with their small size and pleomorphic morphology, but they are markedly different in several aspects of their life cycle. The species of greatest medical significance is *Chlamydia trachomatis*,* a very common pathogen involved in sexually transmitted, neonatal, and ocular disease (trachoma). A related genus, *Chlamydophila*, includes *C. pneumoniae*, the cause of one type of atypical pneumonia; and *C. psittaci*,* a zoonosis of birds and mammals that causes ornithosis in humans.

The Biology of Chlamydia and Related Forms

Chlamydias alternate between two distinct stages: (1) a metabolically inactive, infectious form called the **elementary body** that is released by the infected host cell; and (2) a noninfectious, actively dividing form called the **reticulate body** that grows within host cell vacuoles. The reticulate body completes the cycle by forming new elementary bodies (**figure 21.20**). Elementary bodies are shielded by a rigid, impervious envelope that ensures survival outside the eukaryotic host cell. Reticulate bodies are energy parasites, lacking enzyme systems for catabolizing glucose and synthesizing ATP. They do possess ribosomes and pathways for synthesizing proteins, DNA, and RNA.

Diseases of *Chlamydia trachomatis*

The reservoir of pathogenic strains of *Chlamydia trachomatis* is the human body. The microbe shows astoundingly broad distribution within the population, often being carried with no symptoms. Elementary bodies are transmitted through contact with secretions. Although infection occurs in all age groups, disease is most severe in infants and children. The two human strains are the *trachoma* strain, which attacks the squamous or columnar cells of mucous membranes in the eyes, genitourinary tract, and lungs; and the *lymphogranuloma venereum* (LGV) strain, which invades the lymphatic tissues of the genitalia.

Chlamydial Diseases of the Eye The two forms of chlamydial eye disease, **ocular trachoma** and **inclusion conjunctivitis**, differ in their patterns of transmission and ecology. Ocular trachoma, an infection of the epithelial cells of the eye, is an ancient disease and a major cause of blindness in certain parts of the world. Although a few cases occur yearly in the United States, several million cases occur endemically in parts of Africa and Asia. Transmission is favored by contaminated fingers, fomites, flies, and a hot, dry climate.

The first signs of infection are a mild conjunctival exudate and slight inflammation of the conjunctiva. These are followed by marked infiltration of lymphocytes and macrophages into the

Process Figure 21.20 The life cycle of *Chlamydia*. (1) The infectious stage, or elementary body (EB), is taken into phagocytic vesicles by the host cell. (2) In the phagosome, each elementary body develops into a reticulate body (RB). (3) Reticulate bodies multiply by regular binary fission. (4–5) Mature RBs become reorganized into EBs. (6) Completed EBs are released from the host cell.

Pathogen Profile #4 *Chlamydia trachomatis*

Reticulocyte bodies in the vacuole of an infected cervical cell.

Source: Dr. Lance Liotta Laboratory/ National Cancer Institute

Microscopic Morphology Very small, gram-negative pleomorphic rods.

Identified by Definitive identification involves cultivation in chicken, mice, or tissue cell lines but is rarely done due to time and cost constraints. Immunofluorescent staining of specimens and PCR are commonly employed.

C. trachomatis resides within the human body, where it is often carried without symptoms. It invades primarily epithelial and lymphatic cells.

Virulence Factors The cell wall of *Chlamydia* is able to inhibit phagolysosome fusion, allowing reticulate bodies to survive and multiply within phagosomes. Elementary bodies are encased in an impervious envelope that ensures survival outside of the host cell.

Primary Infections/Disease *Chlamydia trachomatis* is the causative agent of chlamydiosis, nongonococcal urethritis, pelvic inflammatory disease, and lymphogranuloma venereum. It also causes the eye infections ocular trachoma and inclusion conjunctivitis.

Control and Treatment Condoms provide limited protection as the pathogen can invade multiple cell types. Newborns are treated prophylactically with erythromycin or doxycycline; the treatment of urogenital infections relies on doxycycline or azithromycin.

infected area. As these cells build up, they impart a pebbled (rough) appearance to the inner aspect of the upper eyelid (**figure 21.21a**). In time, a vascular pseudomembrane of exudate and inflammatory leukocytes forms over the cornea, a condition called *pannus* that lasts a few weeks. Chronic and secondary infections can lead to corneal damage and impaired vision. Early treatment of this disease with azithromycin is highly effective and prevents all of the complications. It is a tragedy that in this day of preventive medicine, millions of children worldwide will develop blindness for lack of a few dollars' worth of antibiotics.

Inclusion conjunctivitis is usually acquired through contact with secretions of an infected genitourinary tract. Infantile conjunctivitis develops 5 to 12 days after a baby has passed through the birth canal of its infected mother and is the most prevalent form of conjunctivitis in the United States (100,000 cases per year). The initial signs are conjunctival irritation, a profuse adherent exudate,

redness, and swelling (**figure 21.21b**). Although the disease usually heals spontaneously, trachoma-like scarring occurs often enough to warrant routine eye prophylaxis of all newborns (as for gonococcal infection) with antibiotics such as erythromycin and doxycycline.

Sexually Transmitted Chlamydial Diseases It has been estimated that *C. trachomatis* is carried in the reproductive tract of up to 10% of the population, with even higher rates among promiscuous individuals. About 70% of infected women harbor it asymptotically on the cervix, while 10% of infected males show no signs or symptoms. The potential for this disease to cause long-term reproductive damage has initiated its listing as a reportable disease since 1995. Statistics now show that chlamydiosis is the most prevalent bacterial STD. The reported incidence for 2015 was over 1.4 million cases, but its true incidence probably exceeds that level by 10 times. The occurrence of this infection in young, sexually

(a): © Western Ophthalmic Hospital/Science Source; (b): Source: J. Pledger/CDC

active teenagers is increasing by 8% to 10% per year. Medically and socioeconomically, its clinical significance now eclipses gonorrhea, herpes simplex 2, and syphilis.

A syndrome among males with chlamydial infections is an inflammation of the urethra called nongonococcal urethritis (NGU). This diagnosis is derived from the symptoms that mimic gonorrhea yet do not involve gonococci. Women with symptomatic chlamydial infection have cervicitis accompanied by a white drainage, endometritis, and salpingitis (pelvic inflammatory disease—PID). As is often the rule with sexually transmitted diseases, chlamydia frequently appears in mixed infections with the gonococcus and other genitourinary pathogens, thereby greatly complicating treatment.

When a particularly virulent strain of *Chlamydia* chronically infects the genitourinary tract, the result is a severe, often disfiguring disease called **lymphogranuloma venereum**.³ The disease is endemic to regions of South America, Africa, and Asia but occasionally occurs in other parts of the world. Its incidence in the United States is about 500 cases per year. Chlamydias enter through tiny nicks or breaks in the perigenital skin or mucous membranes and form a small, painless vesicular lesion that often escapes notice. Other acute symptoms are headache, fever, and muscle aches. As the lymph nodes near the lesion begin to fill with granuloma cells, they enlarge and become firm and tender (**figure 21.22**). These nodes, or buboes, can cause long-term lymphatic obstruction that leads to chronic, deforming edema of the genitalia and anus.

Identification, Treatment, and Prevention of Chlamydiosis

Because chlamydias reside intracellularly, specimen sampling requires enough force to dislodge some of the cells from the mucosal surface. Genital samples are taken with a swab inserted a few centimeters into the urethra or cervix, rotated, and removed. Although the most reliable diagnosis comes from culture in chicken embryos, mice, or cell lines, this procedure is too costly and time-consuming to be used routinely in STD clinics; however, it is an essential part of diagnosing neonatal infections. The most sensitive and specific tests currently available are a direct assay of specimens using immunofluorescence and a PCR-based probe. Methods useful in diagnosing inclusion conjunctivitis are Giemsa or iodine stains (**figure 21.23**), but they are not recommended for

Figure 21.23 Cells in tissue culture infected with *Chlamydia trachomatis*. The dark-staining inclusion bodies (arrows) indicate a phagosome containing *Chlamydia* in various stages of development. These can be diagnostic of chlamydiosis. Source: CDC

urogenital specimens because of low sensitivity and the possibility of obtaining false-negative results in asymptomatic patients.

Urogenital chlamydial infections are most effectively treated with drugs that act intracellularly, such as doxycycline and azithromycin. Because of the high carrier rate and the difficulty in detection, prevention of chlamydial infections is a public health priority. As a general rule, sexual partners of infected people should be treated with drug therapy to prevent infection, and sexually active people can achieve some protection with a condom.

Chlamydophila Species

Chlamydophila is a genus of obligate pathogens; it contains members that used to be included with *Chlamydia*. One of these is *Chlamydophila pneumoniae*, a strict human pathogen with characteristics that distinguish it from other species in the genus. It has been linked to a type of respiratory illness that includes pharyngitis, bronchitis, and pneumonitis. It is usually a mild illness in young adults, though it can cause a severe reaction in asthmatic patients that is responsible for increased rates of death in this group. Some evidence exists to implicate it in heart disease.

Chlamydophila psittaci

The term *psittacosis* was adopted to describe a pneumonia-like illness contracted by people working with imported parrots and other psittacine birds in the last century. As outbreaks of this disease appeared in areas of the world having no parrots, it became evident that other birds could carry and transmit the microbe to humans and other animals. The term **ornithosis*** is sometimes used to refer to the same infection.

Psittacosis is a worldwide zoonosis that is carried in a latent state in wild and domesticated birds but becomes active under stressful conditions such as overcrowding. In the United States, poultry have been subject to extensive epidemics that killed as many as 30% of flocks. Infection is communicated to other birds, mammals, and humans by contaminated feces and other discharges that become airborne and are inhaled. Sporadic cases in the United States occur mainly among poultry and pigeon handlers.

The symptoms of human psittacosis mimic those of influenza and pneumococcal pneumonia. Early manifestations are fever, chills,

* *ornithosis* (or'-nih-thoh'-sis) Gr. *ornis*, bird. More than 90 species of birds harbor *C. psittaci*.

3. Also called tropical bubo or lymphogranuloma inguinale.

Figure 21.22 The clinical appearance of advanced lymphogranuloma venereum in a man. A chronic local inflammation blocks the lymph channels, causing swelling and distortion of the tissues near the scrotum. Source: CDC

frontal headache, and muscle aches, and later ones are coughing and lung consolidation. Unchecked, infection can lead to systemic complications involving the meninges, brain, heart, or liver. Although most patients respond well to doxycycline or erythromycin therapy, recovery is often slow and fraught with relapses. Control of the disease is usually attempted by quarantining imported birds and by taking precautions in handling birds, feathers, and droppings.

21.4 Mollicutes and Other Cell-Wall-Deficient Bacteria

Expected Learning Outcomes

16. Describe the characteristics and diseases of mycoplasmas.
17. Describe how L forms may arise.

Bacteria in the Class Mollicutes, also called the **mycoplasmas**, are among the smallest self-replicating microorganisms. All of them naturally lack a cell wall (**figure 21.24a**), and except for one genus, all species are parasites of animals and plants. The two most clinically important genera are *Mycoplasma* and *Ureaplasma*. Disease of the respiratory tract has been primarily associated with *Mycoplasma pneumoniae*; *M. hominis* and *Ureaplasma urealyticum* are implicated in urogenital tract infections.

Biological Characteristics of the Mycoplasmas

Without a rigid cell wall to delimit their shape, mycoplasmas are exceedingly pleomorphic. The small (0.3–0.8 μm), flexible cells assume a spectrum of shapes, ranging from cocci and filaments to doughnuts, clubs, and helices (see figure 4.16). Mycoplasmas are not strict parasites, and they can grow in cell-free media, generate metabolic energy, and synthesize proteins with their own enzymes. However, most are fastidious and require complex media containing sterols, fatty acids, and preformed purines and pyrimidines. Mycoplasmas are sometimes referred to as membrane parasites because they acquire certain necessary lipids from host cell membranes (**figure 21.24b**). Infections are chronic and difficult to eliminate, because mycoplasmas bind tenaciously to receptor sites

(a)

(b)

Figure 21.24 The morphology of mycoplasmas. (a) A color-enhanced scanning electron micrograph of *Mycoplasma pneumoniae* (10,000 \times). Note pleomorphic shapes and elongate attachment tips. This fusion makes destruction and removal of the pathogen very difficult. (a): VEM/ Science Source

on cells of the respiratory and urogenital tracts and they are not easily removed by usual defense mechanisms.

Mycoplasma pneumoniae and Atypical Pneumonia

Mycoplasma pneumoniae is a human parasite that is the most common agent of primary atypical pneumonia (PAP).⁴ This syndrome is atypical in that its symptoms do not resemble those of pneumococcal pneumonia. Mycoplasmal pneumonia is transmitted by aerosol droplets among people confined in close living quarters, especially families, students, and the military. Community resistance to this pneumonia is high; only 3% to 10% of those exposed become infected, and fatalities are rare.

Mycoplasma pneumoniae binds to specific receptors of the epithelial cells of the respiratory tract. Gradual spread of the bacteria over the next 2 to 3 weeks disrupts the cilia and damages the respiratory epithelium. The first symptoms—fever, malaise, sore

4. Primary atypical pneumonia can also be caused by rickettsias, chlamydias, respiratory syncytial viruses, and adenoviruses.

throat, and headache—are not suggestive of pneumonia. A cough is not a prominent early symptom, and when it does appear, it is mostly unproductive. As the disease progresses, nasal symptoms, chest pain, and earache can develop. The lack of acute illness in most patients has given rise to the nickname “walking pneumonia.”

Diagnosis Because a culture can take 2 or 3 weeks, early diagnosis of mycoplasma pneumonia is difficult and relies chiefly on close clinical observation to rule out other bacterial or viral agents. Stains of sputum appear devoid of bacterial cells, leukocyte counts are within normal limits, and X-ray findings are nonspecific. Serological tests based on complement fixation, immunofluorescence, and indirect hemagglutination are useful later in the disease.

Doxycycline and azithromycin inhibit mycoplasmal growth and help to rapidly diminish symptoms, but they do not stop the shedding of viable mycoplasmas. Patients frequently experience relapses if treatment is not continued for 14 to 21 days. Preventive measures include controlling contamination of fomites, avoiding contact with droplet nuclei, and reducing aerosol dispersion.

Other Mycoplasmas

Mycoplasma genitalium and *Ureaplasma urealyticum* are regarded as weak reproductive pathogens. They are frequently encountered in samples from the urethra, vagina, and cervix of newborns and adults. These species initially colonize an infant at birth and subsequently diminish through early and late childhood. A second period of colonization and persistence is initiated by the onset of sexual intercourse.

Evidence linking genital mycoplasmas to human disease is substantial and growing every year. *Ureaplasma urealyticum* is implicated in some types of nonspecific or nongonococcal urethritis and prostatitis. There is increasing evidence that this mycoplasma plays a role in opportunistic infections of the fetus and fetal membranes. It appears to cause some cases of miscarriage, stillbirth, premature birth, and respiratory infections of newborns.

Mycoplasma genitalium is an agent of STDs. It is very common in the genital tract of both women and men, and it often accompanies other STDs. In women, it is one cause of PID, cervicitis, urethritis, and vaginitis. Studies have also shown it can be carried into the uterus by spermatozoa. In males, *M. genitalium* can cause a form of NGU, prostatitis, and epididymitis.

Bacteria That Have Lost Their Cell Walls

Exposure of typical walled bacteria to certain drugs (penicillin) or enzymes (lysozyme) can result in wall-deficient bacteria called L forms or L-phase variants. L forms are induced or occur spontaneously in numerous species and can even become stable and reproduce themselves, but they are not naturally related to mycoplasmas.

L Forms and Disease

The role of certain L forms in human and animal disease is a distinct possibility, but proving etiology has been complicated because infection is difficult to verify. One theory proposes that antimicrobial therapy with cell-wall-active agents induces certain infectious agents to become L forms. In this wall-free state, they resist further treatment with these drugs and remain latent until the therapy ends,

at which time they reacquire walls and resume their pathogenic behavior. Infections involving L-phase variants of group A streptococci, *Proteus*, and *Corynebacterium* have occasionally been reported. In a number of chronic pyelonephritis and endocarditis cases, cell-wall-deficient bacteria have been the only isolates. Research on people with a chronic intestinal syndrome called Crohn's disease has uncovered a strong association with a wall-deficient form of *Mycobacterium avium paratuberculosis* (MAP), a relative of the TB bacillus. When technicians used a PCR technique to analyze the DNA of colon specimens, it was found that 65% of Crohn's patients tested positive for *M. a. paratuberculosis*. It is likely to be at least a cofactor for developing this disease.

21.5 Bacteria in Dental Disease

Expected Learning Outcomes

18. Discuss the formation of plaque on tooth surfaces.
19. Relate the formation of plaque to periodontitis.

The relationship between humans and their oral microbiota is a complex, dynamic microecosystem. The mouth contains a diversity of surfaces for colonization, including the tongue, teeth, gingiva, palate, and cheeks; and it provides numerous aerobic, anaerobic, and microaerophilic microhabitats for the estimated 600 different oral species with which humans coexist. The habitat of the oral cavity is warm, moist, and greatly enriched by the periodic infusion of food. In most humans this association remains in balance with little adverse effect, but in people with poor oral hygiene, it teeters constantly on the brink of disease.

The Structure of Teeth and Associated Tissues

Dental diseases can affect nearly any part of the oral cavity, but most of them involve the dentition (teeth) and the surrounding supportive structures, collectively known as the **periodontium*** (gingiva, ligaments, membrane, bone) (**figure 21.25**). A tooth is composed of a flared crown that protrudes above the gum and a root that is inserted into a bony socket. The outer surface of the crown is protected by a dense coating of enamel, an extremely hard, noncellular material composed of tightly packed rods of hydroxyapatite crystals $[(Ca_{10}(OH)_2(PO_4)_6)]$. The root is surrounded by a layer of cementum, which is anchored by ligaments to the periodontal membrane that

* **periodontium** (per'-ee-oh-don'-shee-um) Gr. *peri*, around, and *odous*, tooth. Gums, bones, and cementum.

Figure 21.25 The anatomy of a tooth.

lines the socket. The major portion of the tooth inside the crown and root is composed of a highly regular calcified material called dentin, and the core contains a pulp cavity that supplies the living tissues with blood vessels and nerves. The root canal is the portion of the pulp that extends into the roots. The space surrounding the teeth is protected by the gingiva (gum), a soft tissue composed of connective tissue covered by a mucous membrane. The primary sites for dental infections are grooves in the enamel, especially the cusps, and the crevice, or sulcus, formed where the gingiva meets the tooth.

Dental pathology generally affects both hard and soft tissues (**figure 21.26**). Although both categories of disease are initiated when microbes adhere to the tooth surface and produce dental plaque, their outcomes vary. In the case of dental caries, the gradual breakdown of the enamel leads to invasive disease of the tooth itself. In soft-tissue disease, calcified plaque damages the delicate gingival tissues and predisposes them to bacterial invasion of the periodontium. These conditions are responsible for the loss of teeth, though dental caries are usually implicated in children and periodontal infections in adults.

Hard-Tissue Disease: Dental Caries

Dental caries* is the most common human disease. It is a complex **biofilm infection** of the dentition that gradually destroys the enamel

* *caries* (kar'-eez) L. rotteness.

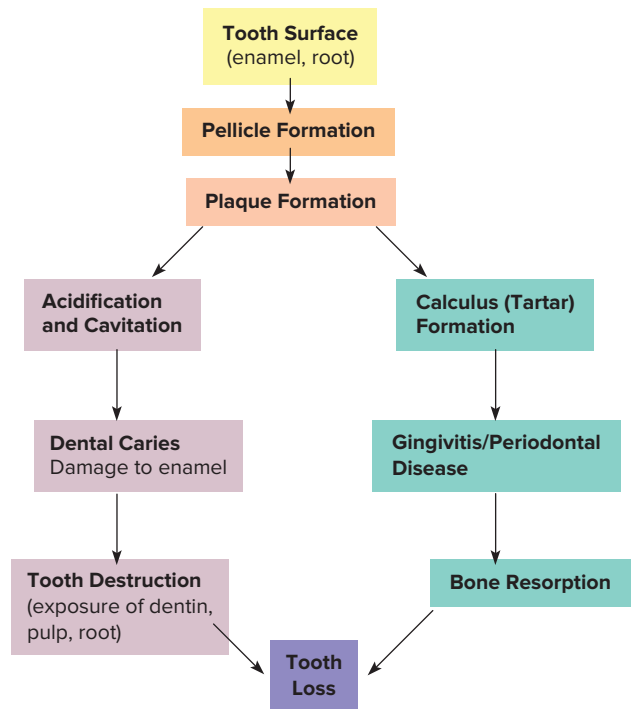

Figure 21.26 Summary of the events leading to dental caries, periodontal disease, and bone and tooth loss.

and often lays the groundwork for the destruction of deeper tissues. It occurs most often on tooth surfaces that are less accessible and harder to clean and on those that provide pockets or crevices where bacteria can cling. Caries commonly develop on enamel pits and fissures, especially those of the occlusal (grinding) surfaces, though they can also occur on the smoother crown surfaces and subgingivally on the roots.

Several views have been suggested to explain how dental caries originate. For some time experts knew that sugar, microbes, and acid were involved in tooth decay. It was studies with germ-free animals that finally showed that no single factor can account for caries—all three are necessary. Caries development occurs in many phases and requires multiple interactions involving the anatomy, physiology, diet, and microbiota of the host.

Plaque and Dental Caries Formation

A freshly cleaned tooth is a perfect landscape for colonization by microbes (**figure 21.27**). Within a few moments it develops a thin, mucous coating called the acquired pellicle, which is made up of adhesive salivary proteins. This structure presents a potential substrate upon which certain bacteria first gain a foothold. The process of colonization of the tooth follows a classic pattern of biofilm formation. The most prominent pioneering colonists belong to the genus *Streptococcus*. These gram-positive cocci have adhesive receptors such as lectins and slime layers that allow them to cling to the tooth surfaces and to each other, forming a foundation for the mature biofilm aggregate known as **plaque**.* Fed by a diet high in

* *plaque* (plak) Fr. a patch.

- 1 A freshly cleaned tooth surface immediately develops a thin layer of salivary glycoproteins (the acquired pellicle).
- 2 Fibers of proteins, antibodies, salivary enzymes, bacterial debris, and other salivary molecules adhere to the pellicle (M).
- 3 The earliest tooth colonizers are the *Streptococcus mutans* group(s) (*S. oralis* and *S. gordonii*). These bacteria have specific receptors that adhere to the outer pellicle molecules. The streptococci likewise bind to each other, forming the initial base of plaque.
- 4 The next phase involves cell-cell signaling and coaggregation with additional colonists. The most common bacteria to add to the biofilm during this phase are filamentous rods in the genus *Actinomyces* (A). Other species of *Streptococcus* (the *mutans* group) use dietary carbohydrates to secrete glucans that add bulk to the matrix and serve as a source of sugars.
- 5 Once this initial framework has been laid down, it enters a second phase of aggregation which creates the final dense mat of plaque. Bacteria that colonize at this point are frequently anaerobes such as *Fusobacterium* (F), *Porphyromonas* (PO), *Prevotella* (PR), *Veillonella* (V), and *Treponema* (T).
- 6 See upper left. Initial damage to the enamel occurs when streptococci near the enamel surface ferment the sugars in plaque to lactic, acetic, and other acids. When these acids are trapped against the tooth surface and etch through it, a dental caries has developed.

Process Figure 21.27 Stages in the formation of plaque biofilm and dental caries. The process involves specific binding to enamel by a multilayered biofilm of oral microbes that interact, recognize, and aggregate.

sucrose, glucose, and certain complex carbohydrates, the *Streptococcus mutans* group secretes sticky polymers of glucose called fructans and glucans that form the majority of the plaque biofilm. As these primary invaders continue to build up on the tooth surface, they aggregate with thin, branching *Actinomyces* cells. As the plaque biofilm thickens, it creates an oxygen-free microenvironment that favors colonization by anaerobic bacteria. Among these secondary invaders are

species of *Fusobacterium*, *Porphyromonas*, and *Treponema*. A microscopic view of plaque reveals a rich and varied network of bacteria and their products along with epithelial cells and fluids (**figure 21.28**).

If mature plaque is not removed from sites that readily trap food, it can develop into a dental caries (see figure 21.27). The role of plaque in caries development is related directly to the fermentation of dietary carbohydrates by streptococci. In the denser regions

of plaque, the acid can accumulate in direct contact with the enamel surface and lower the pH to below 5, which is acidic enough to begin to dissolve (decalcify) the calcium phosphate of the enamel in that spot. This initial lesion can remain localized in the enamel (first-degree caries) and can be repaired with various inert materials (fillings). Once the deterioration has reached the level of the dentin (second-degree caries), tooth destruction speeds up, and the tooth can be rapidly destroyed. Exposure of the pulp (third-degree caries) is attended by severe tenderness and toothache, and the chance of saving the tooth is diminished.

Soft-Tissue and Periodontal Disease

Gingival and periodontal disease are so common that 97% to 100% of the population has some manifestation of it by age 45. The most common predisposing condition occurs when the plaque becomes mineralized (calcified) with calcium and phosphate crystals. This process produces a hard, porous substance called **calculus** above and below the gingiva that can induce varying degrees of periodontal damage (see **figure 21.28b**). Other factors that contribute to gingival and periodontal disease are diabetes, smoking, immune deficiency, and stress.

Calculus accumulating in the gingival sulcus causes abrasions to the delicate gingival membrane, and the chronic trauma causes a pronounced inflammatory reaction. The damaged tissues become a portal of entry for a variety of bacterial residents. These include genera such as *Actinobacillus*, *Porphyromonas*, *Bacteroides*, *Fusobacterium*, *Prevotella*, and *Treponema* spirochetes. The anaerobic bacteria in these infections outnumber aerobes by 100 to 1. In response to the mixed infection, the damaged area becomes infiltrated by white blood cells, which cause further inflammation and tissue damage (**figure 21.29a**). The initial signs of **gingivitis** are swelling, loss of normal contour, patches of redness, and increased bleeding of the gingiva. Spaces or pockets of varying depth also develop between the tooth and the gingiva.

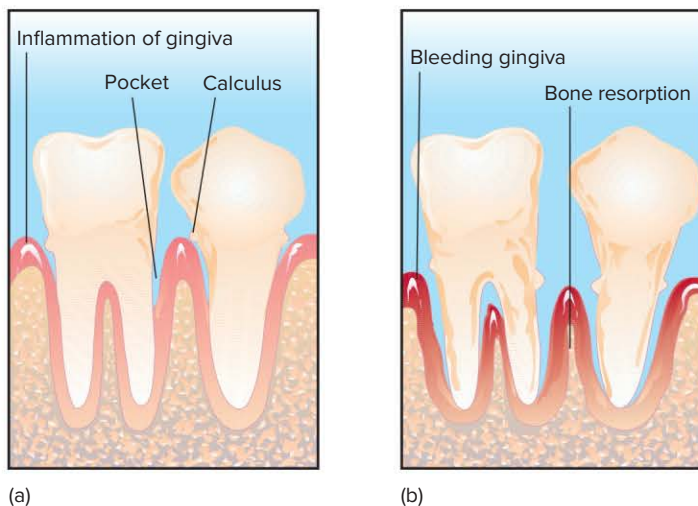

Figure 21.29 Stages in soft-tissue infection, gingivitis, and periodontitis. (a) Calculus buildup and gingivitis. (b) Late-stage periodontitis, with tissue destruction, deep pocket formation, loosening of teeth, and bone loss.

If this condition persists, a more serious disease called **periodontitis** results. This is the natural extension of the disease into the periodontal membrane and cementum. The deeper involvement results in chronic inflammation, loss of the ligament, and deeper pockets in the sulcus. It can cause bone resorption severe enough to loosen the tooth in its socket. If the condition is allowed to progress, the tooth can be lost (**figure 21.29b**).

Chronic periodontal infections may lead to necrotizing ulcerative gingivitis (NUG), formerly called trench mouth or Vincent disease. This disease is a synergistic infection involving *Treponema vincentii*, *Bacteroides forsythus*, and fusobacteria (**figure 21.30**). These pathogens together produce several invasive factors that cause rapid advancement into the periodontal tissues. The condition is associated with severe pain, bleeding, pseudomembrane formation, and necrosis. NUG usually results from poor oral hygiene, altered host defenses, or prior gum disease, and is not considered communicable. It does respond well to broad-spectrum antibiotics.

Factors in Dental Disease

Nutrition and eating patterns are closely tied to oral diseases. People whose diet is high in refined sugar (sucrose, glucose, and fructose) tend to have more caries, especially if these foods are eaten constantly throughout the day without brushing the teeth. The practice of putting a baby down to nap with a bottle of fruit juice or formula can lead to rampant dental caries (“nursing bottle caries”). In addition to diet, numerous anatomical, physiological, and hereditary factors influence oral diseases. The structure of the tooth enamel can be influenced by genetics and by environmental factors such as fluoride, which strengthens the enamel bonds. Inhibitory factors in saliva such as antibodies and lysozyme can also help prevent dental disease by inhibiting bacterial attachment and growth.

The best control of dental diseases comes from preventive dentistry, including regular brushing and flossing to remove plaque, because stopping plaque buildup automatically reduces caries and calculus production. Mouthwashes are relatively ineffective in

Figure 21.30 SEM of a sample of exudate from a gingival pocket (7,040 \times). Note the wide variations in sizes and shapes of bacteria which create a mixed infection that invades periodontal tissues. © Scimat/Science Source

controlling plaque formation because of the high bacterial content of saliva and the relatively short acting time of mouthwashes.

Once calculus has formed on teeth, it cannot be removed by brushing but can be dislodged only by special mechanical procedures (scaling) in the dental office. One of the most exciting prospects is the possibility of a vaccine to protect against the primary colonization of the teeth. Some success in inhibiting plaque formation has been achieved in experimental animals with vaccines raised against the whole cells of cariogenic *Streptococcus* and the fimbriae of species of *Actinomyces*.

CASE STUDY Part 2

In June 2014 a resident of Canada sought medical care for fever, pain, and erythema at the site of a recent injection. A few weeks earlier she too had traveled to Germany, where she had undergone injections of fetal sheep cells two days before the New York patients were treated. In July she was diagnosed with Q fever and the Public Health Agency of Canada notified German authorities in September 2014. At the time of notification, public health authorities in Germany were investigating an outbreak of human Q fever associated with inhalation exposure to a sheep flock. The flock was used for the production of fetal sheep cell injections by the German physician who treated the Canadian woman and the five New York patients.

In September, patients who had received live cell therapy at the German clinic between January and July 2014 were informed of their potential exposure to *Coxiella burnetii*, the organism responsible for Q fever. Immunofluorescence testing revealed *C. burnetii*-specific antibodies in all six patients, with especially high IgM titers, suggesting acute infection. The

Check Your Progress SECTION 21.5

22. What is the relationship between dietary carbohydrates, plaque, and dental caries?
23. Explain the stepwise progression of plaque deposition to periodontal disease.
24. Describe areas of the teeth and gums that support growth of microbes and infections.
25. Explain the colonization of teeth and the development of a biofilm.

patients were successfully treated with doxycycline, although three patients reported lingering symptoms of the disease (fatigue, chills, sweats, and difficulty sleeping) up to 10 months after exposure. Public health officials in New York notified the CDC and posted a report on the CDC's Epidemic Information Exchange to solicit additional cases, but none were found.

Xenotransplantation practices like live cell therapy are prohibited in both the United States and Canada, but patients are of course free to travel to other countries where the procedure is less tightly regulated. In Germany, for instance, live cell therapy is permitted if the cells are prepared by a doctor for use only in his or her own patients. According to an assessment by the World Health Organization, between 1994 and 2009 xenotransplantation procedures were identified in 12 countries, of which nine had no clear national regulations on the process.

- *What other diseases in this chapter are considered zoonotic in origin?*

Chapter Summary with Key Terms

21.1 The Spirochetes

- A. Spirochetes are helical, flexible bacteria that move by periplasmic flagella. Several *Treponema* species are obligate parasitic spirochetes with 8 to 12 regular spirals; best observed under dark-field microscope; cause treponematoses.
 1. Direct observation of treponeme in tissues and blood tests is important in diagnosis.
 2. Cannot be cultivated in artificial media; treatment by large doses of penicillin or doxycycline.
- B. **Treponemes: Members of the Genus *Treponema***
 1. *Syphilis: Treponema pallidum* causes complex progressive disease in adults and children.
 - a. Sexually transmitted syphilis is acquired through close contact with a lesion; untreated sexual disease occurs in stages over long periods.
 - (1) At site of entrance, multiplying treponemes produce a primary lesion, a hard ulcer or **chancre**, which disappears as the microbe becomes systemic.
 - (2) Secondary syphilis is marked by skin rash, fever, damage to mucous membranes. Both primary and secondary syphilis are communicable. Latent period establishes pathogen in tissues.
 - (3) Final, noncommunicable **tertiary stage** is marked by tumors called **gummas** and life-threatening cardiovascular and neurological effects.
 - b. **Congenital syphilis** is acquired transplacentally; disrupts embryonic and fetal development; survivors may have respiratory, skin, bone, teeth, eye, and joint abnormalities if not treated.
 2. *Nonsyphilitic treponematoses*: Slow progressive cutaneous and bone diseases endemic to specific regions of tropics and subtropics; usually transmitted under unhygienic conditions.
 - a. Bejel is a deforming childhood infection of the mouth, nasal cavity, body, and hands.
 - b. Yaws occurs from invasion of skin cut, causing a primary ulcer that seeds a second crop of lesions.
 - c. Pinta is superficial skin lesion that depigments and scars the skin.
- C. *Leptospira interrogans* causes leptospirosis, a worldwide zoonosis acquired through contact with urine of wild and domestic animal reservoirs. Spirochete enters cut, multiplies in blood and spinal fluid. Long-term infections may affect the kidneys and liver.

- D. *Borrelia* species are loose, irregular spirochetes that cause borreliosis; infections are vector-borne (mostly by ticks). Borrelias cause recurrent fever and other symptoms because the spirochetes repeatedly change antigenically and force the immune system to keep adapting.
- Both *B. hermsii* and *B. recurrentis* cause relapsing fever.
 - Borrelia burgdorferi*.
 - Causes **Lyme disease**, a syndrome that occurs endemically in several regions of the United States.
 - A zoonosis carried by mice and spread by a hard tick (*Ixodes*) that lives on deer and mice.
 - Tick bite leads to fever and a prominent ring-shaped rash; if left untreated, may cause cardiac, neurological, and arthritic symptoms.
 - Can be controlled by antibiotics and by avoiding tick contact.

21.2 Curviform Gram-Negative Bacteria and Enteric Diseases

- A. Vibrios are short spirals or sausage-shaped cells with polar flagella.
- Vibrio cholerae* causes **epidemic cholera**, a human disease that is distributed worldwide in natural waters.
 - Organism is ingested in contaminated food and water and infects the surface of the small intestine, is not invasive.
 - Severity of cholera due to potent cholera toxin that causes electrolyte and water loss through secretory diarrhea.
 - Resulting dehydration leads to muscle, circulatory, and neurological symptoms.
 - Treatment is with oral rehydration (electrolyte and fluid replacement); vaccine available.
 - Vibrio parahaemolyticus* causes food infection associated with seawater and seafood; symptoms similar to mild cholera.
- B. *Campylobacter* species: *C. jejuni* is a common cause of severe **gastroenteritis** worldwide; acquired through water contaminated by animal feces and meats, eggs, and other food products; enteritis is due to enterotoxin; *C. fetus* causes diseases in pregnant women and fatal septicemia in neonates.
- C. *Helicobacter pylori* is a helical cell adapted to the stomach lining that may invade it and cause gastric diseases such as ulcers and gastritis. Treatment includes antibiotics and antacid drugs.

21.3 Medically Important Bacteria of Unique Morphology and Biology

- A. **Rickettsias** are tiny, gram-negative rods or cocci that are metabolic and intracellular parasites; diseases treatable with doxycycline and chloramphenicol. *Rickettsia* causes rickettsioses; most are zoonoses spread by arthropod vectors.
- Epidemic typhus**: Caused by *Rickettsia prowazekii*; carried by lice; disease starts with high fever, chills, headache; rash occurs; Brill-Zinsser disease is a chronic, recurrent form.
 - Endemic (murine) typhus**: Zoonosis caused by *R. typhi*, harbored by mice and rats; occurs sporadically in areas of high flea infestation; symptoms like epidemic form but milder.
 - Rocky Mountain spotted fever**: Etiologic agent is *R. rickettsii*; zoonosis carried by dog and wood ticks (*Dermacentor*); most cases on eastern seaboard; infection causes distinct spotted, migratory rash; effects may include heart damage, CNS damage; disease controlled by drug therapy and avoidance of ticks.
 - Ehrlichia and Anaplasma** are two species of rickettsias that infect humans. These tick-borne bacteria cause

human monocytic ehrlichiosis and human granulocytic anaplasmosis. Both cause acute febrile infections.

- B. **Coxiella and Bartonella: Other Vector-Borne Pathogens**
- Q fever**: Caused by *Coxiella burnetii*; agent has a resistant spore form that can survive out of host; a zoonosis of domestic animals; transmitted by air, dust, unpasteurized milk, ticks; usually inhaled, causing pneumonitis, fever, hepatitis.
 - Bartonella**: A related genus is the cause of trench fever, spread by lice; and cat-scratch disease, a lymphatic infection associated with a clawing or biting injury by cats.
- C. **Chlamydia** is another genus of tiny, gram-negative coccobacilli that are obligate intracellular parasites of animals.
- Organisms in the genus *Chlamydia* pass through a transmission phase involving a hardy elementary body and an intracellular reticulate body that has pathologic effects.
 - Chlamydia trachomatis*: A strict human pathogen that causes eye diseases and STDs. Ocular trachoma is a severe infection that deforms the eyelid and cornea and may cause blindness. **Conjunctivitis** occurs in babies following contact with birth canal; prevented by ocular prophylaxis after birth.
 - C. trachomatis* causes very common bacterial STDs: nongonococcal urethritis in males, and cervicitis, salpingitis (PID), infertility, and scarring in females; also lymphogranuloma venereum, a disfiguring disease of the external genitalia and pelvic lymphatics.
 - Obligate pathogens in the related genus *Chlamydophila* are involved in pneumonia and **psittacosis**, a zoonosis associated with birds.

21.4 Mollicutes and Other Cell-Wall-Deficient Bacteria

- A. **Mycoplasmas** naturally lack cell walls and are thus highly pleomorphic; not obligate parasites but require special lipids from host membranes; diseases treated with doxycycline and azithromycin.
- Mycoplasma pneumoniae*: Causes primary atypical pneumonia; pathogen slowly spreads over interior respiratory surfaces, causing fever, chest pain, and sore throat.
 - L. forms*: Bacteria that normally have cell walls but have transiently lost them through drug therapy. They may be involved in certain chronic diseases.

21.5 Bacteria in Dental Disease

- A. The oral cavity contains hundreds of microbial species that participate in interactions between themselves, the human host, and the nutritional role of the teeth and mouth.
- Hard-Tissue (Tooth) Disease** **Dental caries** is a slow, progressive breakdown of irregular areas of tooth enamel; it begins with colonization of teeth by slime-forming species of *Streptococcus*, *Actinomyces*, and numerous other oral bacteria. This process forms a layer of thick, adherent material called **plaque**. Acid formed by agents in plaque dissolves the inorganic salts in enamel and may lead to caries and tooth damage.
- B. **Disease of Tooth Support Structures** Infection occurs in the **periodontium** (gingiva and surrounding tissues); it starts when plaque forms on root of tooth and is mineralized to a hard concretion called **calculus**; this irritates tender gingiva; inflammatory reaction and swelling create **gingivitis** and pockets between tooth and gingiva invaded by bacteria (spirochetes and anaerobic bacilli); tooth socket may be involved (**periodontitis**), and the tooth may be lost.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

- Treponema pallidum* is cultured in/on
 - blood agar
 - animal tissues
 - serum broth
 - eggs
- A gumma is
 - the primary lesion of syphilis
 - a syphilitic tumor
 - the result of congenital syphilis
 - a damaged aorta
- The treatment of choice for syphilis is
 - chloramphenicol
 - antiserum
 - penicillin
 - sulfa drugs
- Which of the treponematoses is/are *not* (an) STD(s)?
 - yaws
 - pinta
 - syphilis
 - both a and b
- Lyme disease is caused by _____ and spread by _____.
 - Borrelia recurrentis*, lice
 - Borrelia hermsii*, ticks
 - Borrelia burgdorferi*, fleas
 - Borrelia burgdorferi*, ticks
- Which of the following conditions may occur in untreated Lyme disease?
 - arthritis
 - rash
 - heart disorder
 - a and b
 - all of these
- Relapsing fever is spread by
 - lice
 - ticks
 - animal urine
 - a and b
- The primary habitat of *Vibrio cholerae* is
 - intestine of humans
 - intestine of animals
 - natural waters
 - exoskeletons of crustaceans
- The most effective therapy for cholera is
 - oral doxycycline
 - oral rehydration therapy
 - antiserum injection
 - oral vaccine
- Rickettsias and chlamydias are similar in being
 - free of a cell wall
 - the cause of eye infections
 - carried by arthropod vectors
 - obligate intracellular bacteria
- Which of the following is *not* an arthropod vector of rickettsioses?
 - mosquito
 - louse
 - tick
 - flea
- Chlamydiosis caused by *C. trachomatis* attacks which structure(s)?
 - eye
 - urethra
 - fallopian tubes
 - all of these
- What stage(s) of *Chlamydia* is/are infectious?
 - reticulate body
 - elementary body
 - vegetative cell
 - both a and b
- Psitticosis is a _____ infection associated with _____.
 - rickettsial, parrots
 - chlamydial, mice
 - chlamydial, birds
 - rickettsial, flies
- Mycoplasmas attack the _____ of host cells.
 - nucleus
 - cell walls
 - ribosomes
 - cell membranes
- The earliest process at the basis of most dental disease is
 - acquired pellicle
 - acid release
 - enamel destruction
 - plaque accumulation
- Dental caries are directly due to
 - microbial acid etching away tooth structures
 - buildup of calculus
 - death of tooth by root infection
 - the acquired pellicle
- Necrotizing ulcerative gingivitis is a _____ infection.
 - contagious
 - mixed
 - spirochete
 - systemic
- Single Matching.** Match each disease in the left column with its vector or vectors in the right column.

_____ leptospirosis	a. wild animals
_____ Lyme disease	b. flea
_____ murine typhus	c. tick
_____ psitticosis	d. birds
_____ relapsing fever	e. louse
_____ lymphogranuloma venereum	f. domestic animals
_____ cat-scratch disease	g. none of these
_____ epidemic typhus	
_____ Rocky Mountain spotted fever	
_____ Q fever	
_____ cholera	
_____ anaplasmosis	
- Single Matching.** Match each disease in the left column with its portal of entry in the right column.

_____ Q fever	a. skin
_____ psitticosis	b. mucous membrane
_____ dental caries	c. respiratory tract
_____ NUG	d. urogenital tract
_____ mycoplasma	e. eye
_____ syphilis	f. oral cavity
_____ leptospirosis	g. gastrointestinal tract
_____ lymphogranuloma venereum	
_____ cholera	
_____ Lyme disease	
_____ trachoma	
_____ <i>Campylobacter</i> infection	
_____ gastric ulcers	

 Case Study Review

- The patients in this case were probably treated with
 - fluoroquinolones
 - specific immunoglobulin
 - vaccination
 - doxycycline
- What other risk factors could have alerted physicians to the possibility of Q fever in this case?
 - Recent hospitalization
 - consumption of raw milk
 - Working in a veterinarians office
 - advanced age
 - b and c
- What characteristics of *Coxiella* are important factors in its transmission to humans?

 Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

- Describe the conditions leading to congenital syphilis and the long-term effects of the disease.
- Trace the route of the infectious agent from a tick bite to infection in relapsing fever.
 - Explain the events in infection that give rise to relapses.
- In what ways are dental diseases mixed infections?
 - Discuss the major factors in the development of dental caries and periodontal infections.
- Which diseases in this chapter are zoonoses?
 - Name them and the major vector involved.

 Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps along with concept mapping activities for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

 Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

- Why does syphilis have such profound effects on the human body?
 - Why is long-term immunity to syphilis so difficult to achieve?
- In view of the fact that cholera causes the secretion of electrolytes into the intestine, explain what causes the loss of water.
 - Explain why ORT is so effective in restoring victims of cholera.
- What would be the best type of vaccine for cholera?
- Explain the general relationships of the vector, the reservoir, and the agent of infection.
 - Can you think of an explanation for Lyme disease having such a low incidence in the southern United States? (Hint: In this region, the larval stages of the tick feed on lizards, not on mice.)
- Humans are accidental hosts in many vector-borne diseases. What does this indicate about the relationship between the vector and the microbial agent?
- Name four bacterial diseases for which the dark-field microscope is an effective diagnostic tool.

7. Describe the conditions that lead to disease by L forms.
8. Which two infectious agents covered in this chapter would be the most resistant to the environment and why are they so resistant?
9.
 - a. In what way is the oral cavity an ecological system?
 - b. What can cause an imbalance in the oral ecology?
 - c. Explain how it is possible for the gingiva and tooth surface to provide an anaerobic habitat.
 - d. What are some logical ways to prevent dental disease besides removing plaque?
10. Have Koch's postulates been carried out for Lyme disease? Explain.
11. A journalist returning from a trip experienced severe fever, vomiting, chills, and muscle aches, followed by symptoms of meningitis and kidney failure. Early tests were negative for septicemia; throat cultures were negative; and penicillin was an effective treatment. Doctors believed the patient's work in the jungles of South America was a possible clue to his disease. What do you think might have been the cause?
12. A man went for a hike in the mountains of New York State and later developed fever and a rash. What two totally different diseases might he have contracted, and what could have been the circumstances of infection?

Visual Challenge

1. Identification of a unique skin rash can often be the first step in diagnosing a disease. What infectious agents are indicated by the rashes below?

CASE STUDY Part 1 Sun, Fun, and Fungi

Histoplasmosis Outbreak Among Day-Camp Attendees—Nebraska, June 2012

Mention microbial infections and most people think of hospitals, not summer camp. But being outdoors in the sunshine and fresh air is not without risk. In June 2012 a camp counselor in Omaha, Nebraska, was diagnosed with **histoplasmosis**, a fungal infection with symptoms similar to pneumonia: fever, headache, and respiratory distress. Although most people suffering from histoplasmosis will recover without medical treatment, the very young, the very old, and people with chronic lung conditions are at greater risk for developing severe disease, which can on rare occasions prove fatal. In areas of the eastern and central United States, where *Histoplasma capsulatum* is **endemic**, dirt contaminated with bird and bat **guano** often contains **spores** of the fungus. Disturbing such contaminated dirt is a known risk factor for developing the disease.

“The counselors spent the week raking leaves, cleaning picnic tables, digging fire pits, and moving firewood.”

Because the sick camp counselor was one of 32 that worked at the camp, and the camp served 797 children, the Douglas County Department of Health (DCDH) and the Nebraska Department of Health and Human Services (NDHHS) began an investigation to determine the extent and source of the outbreak, so as to prevent further infections. Initial testing revealed 17 counselors (53%) whose blood serum or urine contained **antigens** from *Histoplasma capsulatum*; these were deemed confirmed cases of the disease. Of 153 responses to a questionnaire sent to camp attendees, 17 campers (11%) had confirmed or suspected histoplasmosis (suspected cases were those in which illness was present but laboratory results were inconclusive or unavailable).

- What activities would be associated with an increased risk of *Histoplasma capsulatum* infection?
- What other fungal pathogens are found in the United States?

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

22.1 Fungi as Infectious Agents

Expected Learning Outcomes

1. Distinguish between the characteristics indicative of true versus opportunistic fungal pathogens.
2. Relate opportunistic fungal infections to conditions that predispose patients to infection.
3. Explain the geographical limits associated with fungal pathogens.
4. List the most important antifungal defenses found in humans.
5. Understand why direct examination of patient samples is often part of the diagnostic process.

Molds and yeasts are so widely distributed in air, dust, and fomites, and even in our normal microbiota, that humans are incessantly exposed to them. The fact that the planet's surface is totally dusted with spores led noted California mycologist W. B. Cooke to christen it "our moldy earth." Fortunately, because of the relative resistance of humans and the comparatively nonpathogenic nature of fungi, most exposures do not lead to overt infection. Of the estimated 100,000 fungal species, only about 300 have been linked to disease in animals, though among plants, fungi are the most common and destructive of

all pathogens. Human mycotic disease, or **mycosis**,* is associated with true fungal pathogens that exhibit some degree of virulence or with opportunistic pathogens that take advantage of defective host resistance (**Systems Profile 22.1**, **tables 22.1** and **22.2**).

Primary/True Fungal Pathogens

A **true** or **primary** fungal **pathogen** is a species that can invade and grow in a healthy, non-compromised animal host. This behavior is contrary to the metabolism and adaptation of fungi, most of which are inhibited by the relatively high temperature and low oxygen tensions of a warm-blooded animal's body. But a small number of fungi have the morphological and physiological adaptations required to survive and grow in this habitat. By far their most striking adaptation is a switch from hyphal cells typical of the mycelial or mold phase to yeast cells typical of the parasitic phase (figure 22.1). This biphasic characteristic of the life cycle is termed **thermal dimorphism*** because it is initiated by changing temperature. In general, these organisms grow as molds at 30°C and as yeasts at 37°C.

* *mycosis* (my-koh'-sis) pl. mycoses; Gr. *mykos*, fungi, and *osis*, a disease process.

* *dimorphism* (dy-mor'-fizm) Gr. *dimorphos*, having two forms; the property of existing in two distinct cell types.

TABLE 22.1 Representative Fungal Pathogens, Degree of Pathogenicity, and Habitat

Microbe	Disease/Infection*	Primary Habitat and Distribution
I. Primary True Pathogens		
<i>Histoplasma capsulatum</i>	Histoplasmosis	Soils high in bird guano; Ohio and Mississippi valleys of United States; Mexico; Central and South America; Africa
<i>Blastomyces dermatitidis</i>	Blastomycosis	Presumably soils, but isolation has been difficult; southern Canada; Midwest, Southeast, Appalachia in United States; along drainage of major rivers
<i>Coccidioides immitis</i>	Coccidioidomycosis	Highly restricted to alkaline desert soils in southwestern United States (California, Arizona, Texas, and New Mexico)
<i>Paracoccidioides brasiliensis</i>	Paracoccidioidomycosis	Soils of rain forests in South America (Brazil, Colombia, Venezuela)
II. Pathogens with Intermediate Virulence		
<i>Sporothrix schenckii</i>	Sporotrichosis	In soil and decaying plant matter; widely distributed
Genera of dermatophytes (<i>Microsporum</i> , <i>Trichophyton</i> , <i>Epidermophyton</i>)	Dermatophytosis (various ringworms or tineas)	Human skin, animal hair, soil throughout the world
III. Secondary Opportunistic Pathogens		
<i>Candida albicans</i>	Candidiasis	Normal flora of human mouth, throat, intestine, vagina; also normal in other mammals, birds; ubiquitous
<i>Aspergillus</i> spp.	Aspergillosis	Soil, decaying vegetation, grains; common airborne contaminants; extremely pervasive in environment
<i>Cryptococcus neoformans</i>	Cryptococcosis	Pigeon roosts and other nesting sites (buildings, barns, trees); worldwide distribution
<i>Pneumocystis jirovecii</i>	<i>Pneumocystis</i> pneumonia (PCP)	Upper respiratory tract of humans, animals
Genera in Mucorales (<i>Rhizopus</i> , <i>Absidia</i> , <i>Mucor</i>)	Mucormycosis	Soil, dust; very widespread in human habitation

*Specific mycotic infections are usually named by adding *-mycosis*, *-iasis*, or *-osis* to the generic name of the pathogen.

Systems Profile 22.1		Fungal Pathogens				
Organism	Skin/Skeletal	Nervous/ Muscle	Cardiovascular/ Lymphatic/ Systemic	Gastrointestinal	Respiratory	Urogenital
<i>Histoplasma capsulatum</i>					Histoplasmosis (Ohio Valley fever)	
<i>Coccidioides immitis</i>	Coccidioidomycosis	Meningitis	Fungemia		Coccidioidomycosis (valley fever)	
<i>Blastomyces dermatitidis</i>	Cutaneous blastomycosis				Pulmonary blastomycosis (North American blastomycosis)	
<i>Paracoccidioides brasiliensis</i>	Paracoccidioidomycosis				Paracoccidioidomycosis (South American blastomycosis)	
<i>Sporothrix schenckii</i>	Cutaneous sporotrichosis				Pulmonary sporotrichosis	
<i>Madurella</i> spp.	Mycetoma					
Dermatophytes (<i>Trichophyton</i> spp., <i>Microsporum</i> spp., <i>Epidermophyton</i> spp.)	Ringworm					
<i>Candida albicans</i>	Thrush			Esophageal and anal infections		Vulvovaginal candidiasis
<i>Cryptococcus neoformans</i>		Meningitis			Pulmonary cryptococcosis	
<i>Pneumocystis jirovecii</i>					<i>Pneumocystis</i> pneumonia	
<i>Aspergillus</i> spp.	Ocular infections				Aspergillosis	

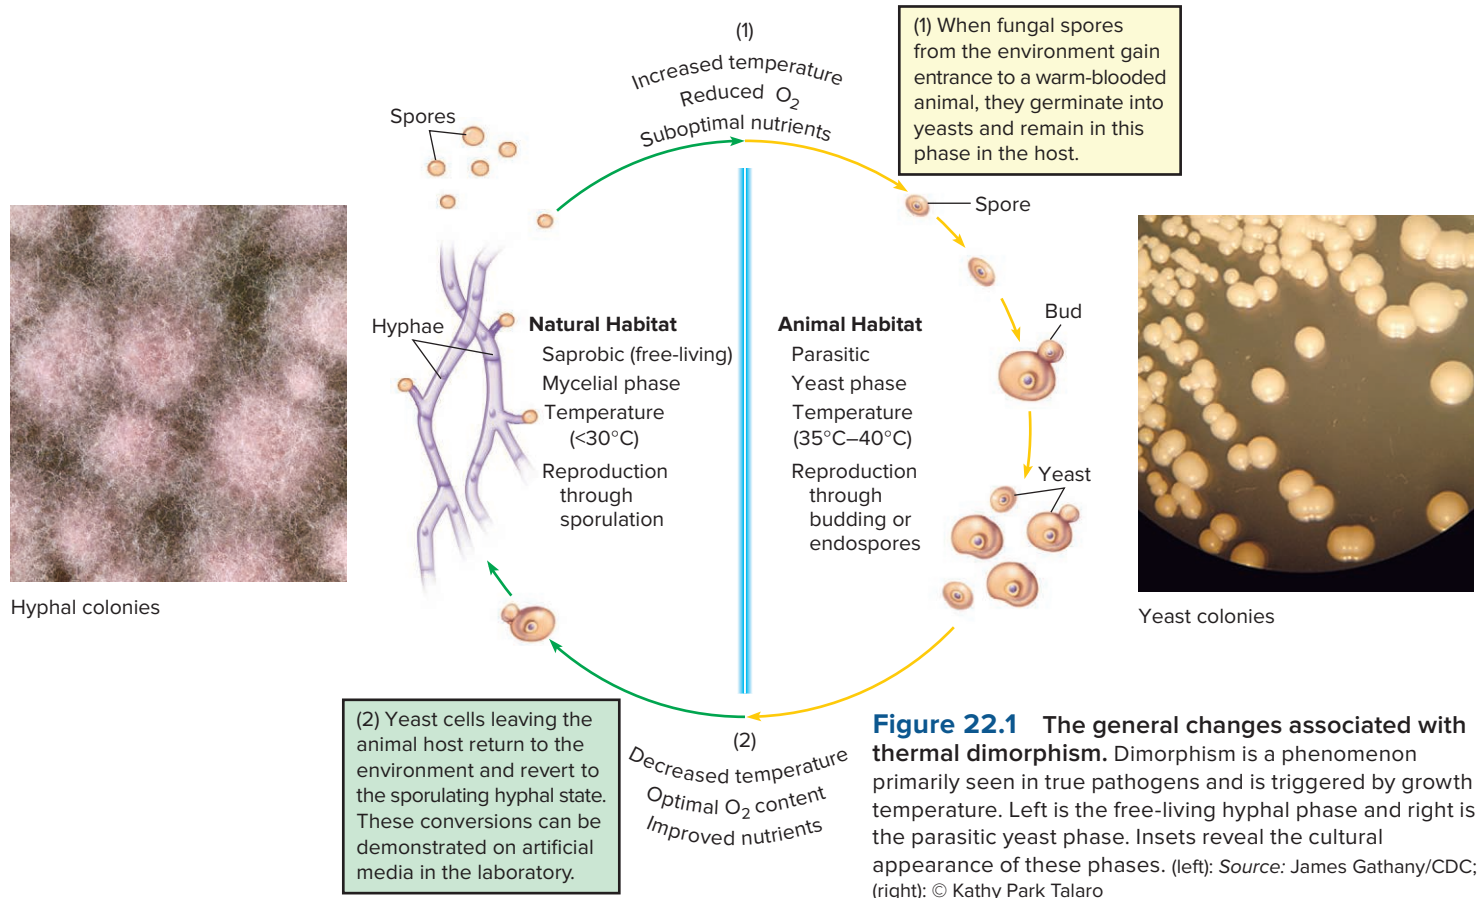

TABLE 22.2 Comparison of True and Opportunistic Fungal Infections

Characteristic of Fungus/Disease	True Pathogenic Infections	Opportunistic Infections
Degree of Virulence	Well-developed	Limited
Condition of Host	Resistance high or low	Resistance low
Primary Portal of Entry	Respiratory	Respiratory mucocutaneous
Nature of Infection	Usually primary pulmonary and systemic; often asymptomatic	Varies from superficial skin to pulmonary and systemic; usually symptomatic
Nature of Immunity	Well-developed, specific	Weak, short-lived
Infecting Form	Primarily conidial	Conidial or mycelial
Thermal Dimorphism	Highly characteristic	Absent
Habitat of Fungus	Soil	Varies from soil to flora of humans and animals
Geographic Location	Restricted to endemic regions	Distributed worldwide

Emerging Fungal Pathogens

An opportunistic fungal pathogen is different from a true pathogen in several ways (table 22.2). An opportunist has weak to nonexistent invasiveness or virulence, and the host's defenses must be impaired to some degree for the microbe to gain a foothold. Although some species have both mycelial and yeast stages in their life cycles, they usually do not show thermal dimorphism. Opportunistic mycoses vary in their manifestations from superficial and benign colonizations to spreading systemic disease that is rapidly fatal.

Opportunistic mycotic infections are an emerging medical concern. By one estimate they account for around 10% of all health-care associated infections. This presents a dilemma for hospitals—having to maintain patients with conditions that inhibit their ability to fight off infections, yet also keeping them from getting infections. In the past these types of patients would have died from their cancer or diabetes, but more often now they are being kept alive by medical technology. Like any other environment, hospitals and clinics are a common habitat for fungi, even when stringent disinfection procedures are followed. Environmental sampling for molds and yeasts shows that they are abundant in tap and bottled water, sinks, showers, and the air, as well as on the walls and floors of patients' rooms. Some opportunists also come from the normal microbiota. Such being the case, exposure is constant and hard to

 **Includes AIDS and genetic conditions that compromise host defenses.

control. **Table 22.3** presents a list of the most common fungal opportunists and medical conditions that may predispose patients to these infections.

Some fungal pathogens exist in a category between true pathogens and opportunists. These species are not inherently invasive but can grow when inoculated into the skin wounds or abrasions of healthy people. Examples are *Sporothrix*, the agent of a subcutaneous infection, and the **dermatophytes**,* which cause ringworm and

athlete’s foot. Adhering to host cells and growing readily at body temperature are factors that appear to enhance their pathogenicity.

Epidemiology of the Mycoses

Most fungal pathogens do not require a host to complete their life cycles, and the infections they cause are not communicable. Notable exceptions are some dermatophyte and *Candida* species that naturally inhabit the human body and are transmissible. For the remainder of the pathogens, exposure and infection occur when a human happens upon fungal spores in the environment (usually air, dust, or soil). True fungal pathogens, unlike opportunists, are distributed in a predictable pattern that coincides with the pathogen’s adaptation to the specific climate, soil, or other factors of a relatively restricted geographic region (**figure 22.2**).

The prevalence of fungal infections has traditionally been difficult to measure because few of the reportable infections monitored by the CDC are caused by fungi. Dermatophytoses are probably the most prevalent. It is thought that at least 90% of all humans will acquire ringworm or athlete’s foot at least once during their lifetimes. Estimates provided by routine skin testing indicate that millions of people have experienced true mycoses, though most cases probably go undiagnosed or misdiagnosed.

Epidemics of mycotic infections can occur after mass exposure to a common source (see Case Study). Coccidioidomycosis is a

* *dermatophyte* (der-mah'-toh-fyte") Gr. *dermos*, skin, and *phyte*, plant. Fungi were once included in the plant kingdom.

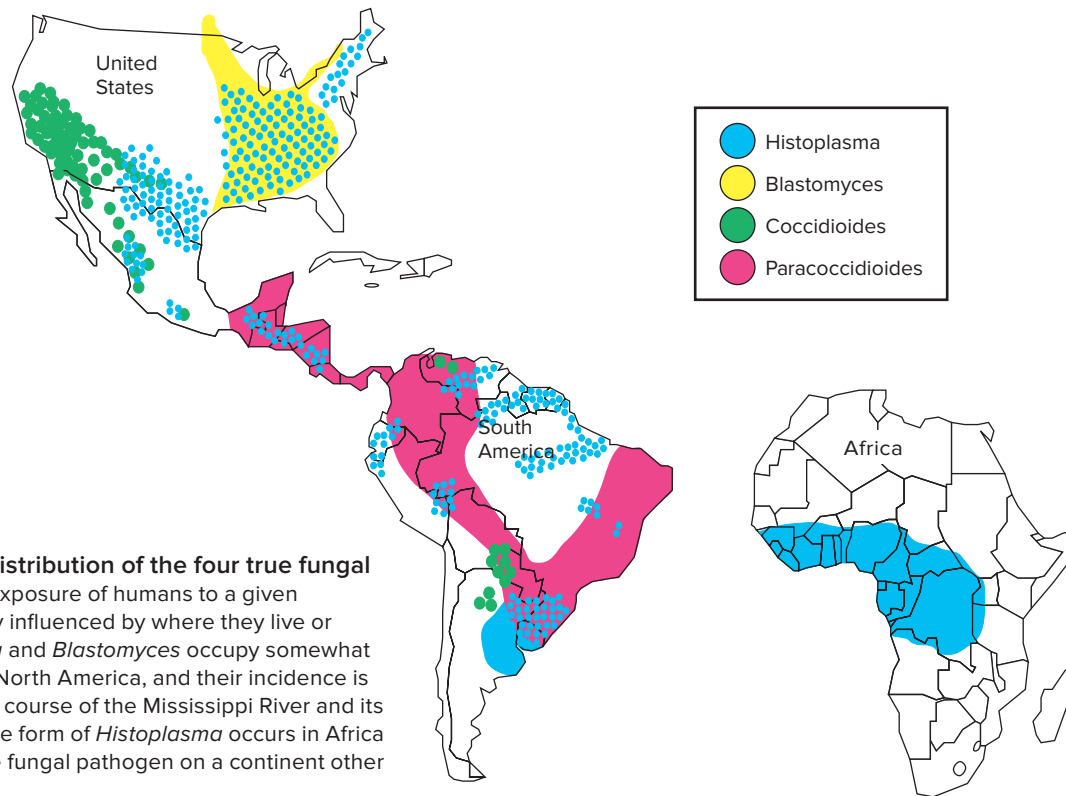

Figure 22.2 Distribution of the four true fungal pathogens. The exposure of humans to a given pathogen is greatly influenced by where they live or travel. *Histoplasma* and *Blastomyces* occupy somewhat the same areas of North America, and their incidence is correlated with the course of the Mississippi River and its tributaries. A unique form of *Histoplasma* occurs in Africa and is the only true fungal pathogen on a continent other than the Americas.

particular hazard of construction workers and people living in the paths of windstorms. Transmissible fungal infections such as dermatophytoses are readily passed by means of shared personal articles, public facilities, swimming pools, gymnasiums, and contact with infected animals. Candidiasis can be communicated during sexual contact and from mother to child at birth.

Pathogenesis of the Fungi

Mycoses involve complex interactions among the portal of entry, the nature of the infectious dose, the virulence of the fungus, and host resistance. Fungi enter the body mainly via respiratory, mucous, and cutaneous routes. In general, the agents of primary mycoses have a respiratory portal (spores inhaled from the air); subcutaneous agents enter through inoculated skin (trauma); and cutaneous and superficial agents enter through contamination of the skin surface. Spores, hyphal elements, and yeasts can all be infectious, but spores are most often involved because of their durability and abundance.

Thermal dimorphism greatly increases virulence by enabling fungi to tolerate the relatively high temperatures and low oxygen tensions of the body. Fungi in the yeast form can be more invasive than hyphal forms because they grow more rapidly and spread through tissues and blood, whereas those producing hyphae tend to localize along the course of blood vessels and lymphatics.

Specific factors contributing to fungal virulence are the subject of much research. A number of studies have isolated cell wall antigens in pathogens such as *Blastomyces* that impart virulence by enhancing adhesion to host cells and suppressing phagocytosis and inflammation. Fungi may also produce capsules, hydrolytic enzymes, toxins, inflammatory stimulants, and allergens, all of which generate strong host responses.

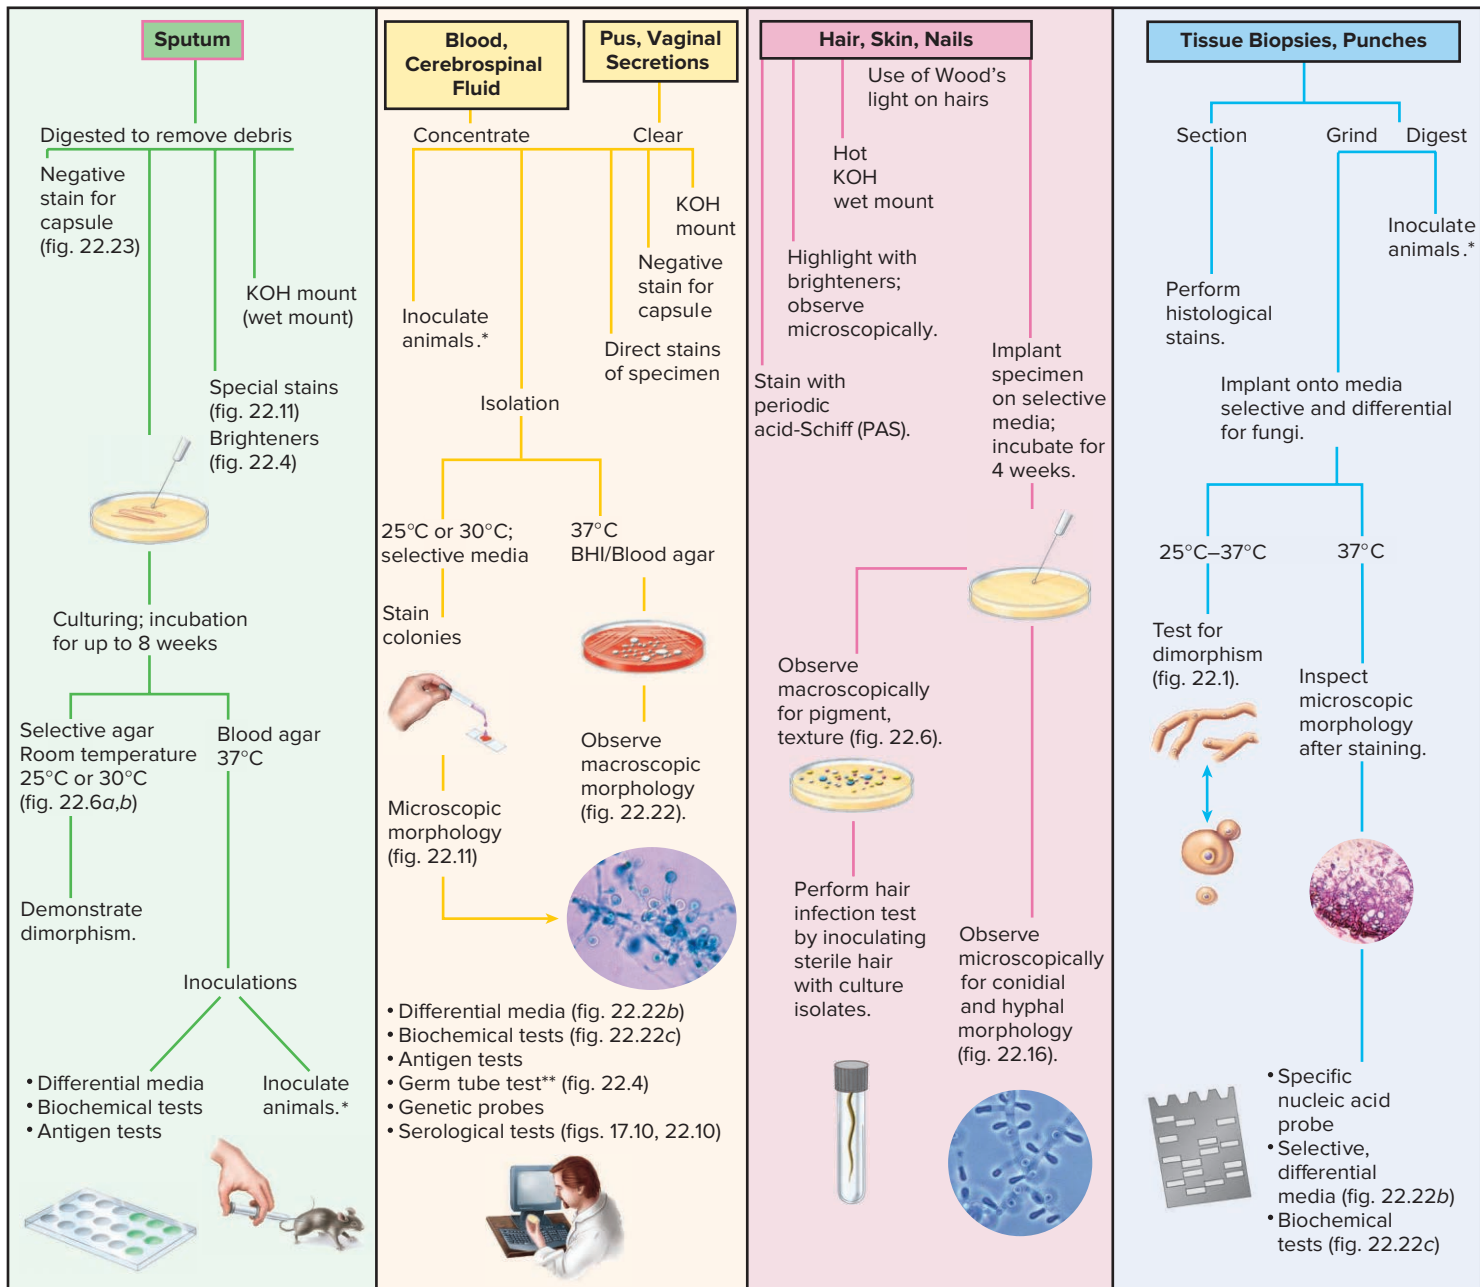

The human body is extremely resistant to establishment of fungi. Among its numerous antifungal defenses are the normal integrity of the skin, mucous membranes, and respiratory cilia, but the most important defenses are cell-mediated immunity, phagocytosis, and the inflammatory reaction. Long-term protective immunity can develop for some of the true pathogens, but for the rest, reinfection is a distinct possibility.

Diagnosis of Mycotic Infections

Satisfactory diagnosis of fungal infections depends mainly upon isolating and identifying the pathogen in the laboratory. Accurate and speedy diagnosis is especially critical to the immunocompromised patient, who must have prompt antifungal chemotherapy. For example, a patient with systemic *Candida* infection can die if the infection is not detected and treated within 5 to 7 days. Because therapy can vary among the pathogenic fungi, identification to the species level is often necessary.

A suitable specimen can be obtained from sputum, skin scrapings, skin biopsies, cerebrospinal fluid, blood, tissue exudates, urine, or vaginal samples, as determined by the patient's symptoms. Routine laboratory procedures include isolation, microscopic and macroscopic examination, histological stains, serology, animal inoculation, and genetic testing (**figure 22.3**).

Because culture of the sample can require several days, the immediate direct examination of fresh samples is recommended. Wet mounts can be prepared by mixing a small portion of the sample on a slide with saline, water, or potassium hydroxide to clear the specimen of background debris. The relatively large size and unique appearance of many fungi help them stand out. Large, spherical

*Animal inoculation is performed only to help diagnose systemic mycoses when other methods are unavailable or indeterminate.

**Some yeasts, when incubated in serum for 2–4 hours, sprout tiny hyphal tubes called germ tubes.

Figure 22.3 Methods of processing specimens and identifying fungal isolates. References indicate figures showing these techniques. (left, middle): Source: CDC; (right): Source: Dr. Libero Ajello/CDC

budding cells are evidence of yeasts, whereas elongate, branching strands suggest hyphae. A variety of stains or brighteners provide striking images of fungi from specimens and cultures (**figure 22.4**).

The fungal pathogen can be isolated with various solid media such as Sabouraud's dextrose agar, Mycosel agar, inhibitory mold medium, and brain-heart infusion agar. These media can be enriched with blood or made selective with chloramphenicol and gentamicin to inhibit bacteria or cyclohexamide to slow the growth of undesirable fungal contaminants. Cultures are incubated at room temperature, 30°C, and 37°C to observe dimorphic conversion. This may require several days to weeks. Gross colonial morphology, such as

the color and texture of the colony's surface and underside, can be very distinctive. Initial identification of the pathogen can be followed by additional confirmatory tests.

Antigen tests that capture fungus-specific surface molecules can be useful in many cases. Several PCR-based detection systems have been developed for fungal pathogens that will continue to speed diagnosis. Other examples of tests are given during discussions of specific diseases later in the chapter.

In vitro tests to detect antifungal antibodies in serum (see figure 22.10) can be a useful diagnostic tool in some infections. In vivo skin testing for delayed hypersensitivity to fungal antigens is

(a)

(b)

Figure 22.4 Special tissue stains called brighteners can amplify the presence of fungal elements in specimens. They bind tightly to the carbohydrates of the fungal surface. mostly used to trace epidemiological patterns. Its limitations are that it may not verify ongoing infection and considerable cross-reactivity exists among *Histoplasma*, *Blastomyces*, and *Coccidioides*. A negative test in a healthy person, however, can rule out infection by these fungi.

With increasing travel and globalization, it is not unusual for visitors to endemic regions to acquire infections that emerge after returning home. Here, knowledge of patients' history and versatility of the medical personnel become vital for treatment and survival.

Control of Mycotic Infections

Treatment for fungal infections is based primarily on antifungal drugs, covered in chapter 12 and on a disease-by-disease basis in this chapter. A summary is provided in **table 22.4**. Immunization is not usually effective against fungal infections, but work is proceeding on vaccines for coccidioidomycosis and histoplasmosis. Prevention measures are limited to masks and protective clothing to reduce contact with spores and, in some cases, surgical removal of damaged tissues.

TABLE 22.4 Characteristics of Antifungal Drugs

Drug Target/Drug	Comments
Plasma Membrane	
Polyenes	Disrupt the plasma membrane and cause leakage of the cytoplasm
Amphotericin B	Amphotericin B is highly toxic but most effective for treating life-threatening infections.
Nystatin	Nystatin is too toxic for systemic use, but it can be used topically.
Azoles	
Imidazoles	Interfere with ergosterol synthesis, leading to defective cell membranes; used to treat a variety of systemic and localized fungal infections
Examples are ketoconazole (Nizoral), miconazole, and clotrimazole.	
Triazoles	Examples are fluconazole and itraconazole (Sporanox).
Allylamines	
	Inhibit an enzyme in ergosterol synthesis; administered topically to treat dermatophyte infections
Naftifine, terbinafine (Lamisil)	Terbinafine can be taken orally.
Cell Wall	
Echinocandins	Block the synthesis of a polysaccharide component of the cell wall in many pathogenic fungi
Caspofungin, anidulafungin, micafungin	
Cell Division	
Griseofulvin	Used to treat skin and nail infections; concentrates in the dead keratinized layers of the skin; active only against fungi that invade keratinized cells
Nucleic Acid Synthesis	
Flucytosine	Used for systemic yeast infections; inhibits an enzyme required for nucleic acid synthesis; not effective against most molds

Check Your Progress SECTION 22.1

1. Outline the differences between true and opportunistic fungal pathogens with regard to the habitat of the fungus, its geographic location, nature of infection, and immunity developed.
2. What medical conditions commonly predispose patients to mycotic infection?
3. Name the three genera containing opportunistic fungal pathogens.
4. Name the locations where each of the four true pathogenic fungal genera would be found in the United States.
5. Why are humans typically resistant to fungal infection?
6. Why is direct examination of patient samples particularly useful when diagnosing a mycotic infection?
7. Give an overview of the major steps in fungal identification.

22.2 Organization of Fungal Diseases

Expected Learning Outcomes

- Summarize the aspects of systemic mycotic infection common to all fungal pathogens.
- Recall the habitat, geographic distribution, and diseases associated with *Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*, and *Paracoccidioides brasiliensis*.
- Summarize the pathology of each of the four fungal pathogens.
- Understand the means by which infections with *Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*, and *Paracoccidioides brasiliensis* are diagnosed in the laboratory.

Fungal infections can be presented in several schemes, depending on the purpose. Traditional methods are based on taxonomic group, location of infection, and type of pathogen. Chapter 5 presents a taxonomic breakdown of the fungi. Most pathogens belong to the Phylum Ascomycota; a few important species are scattered through Phyla Basidiomycota (*Cryptococcus*) and Zygomycota (*Mucor*). This chapter presents the mycoses according to the type and level of infection they cause and their degree of pathogenicity. The order and location of coverage are:

- true pathogens: **systemic, subcutaneous, cutaneous, and superficial mycoses (figure 22.5)**; and
- opportunistic mycoses** (starting in section 22.6).

Systemic Infections by True Pathogens

The infections of primary fungal pathogens can all be described by the same general model:

- They are restricted to certain endemic regions of the world.
- Infection occurs when soil or other matter containing the fungal conidia is disturbed and the spores are inhaled into the lower respiratory tract.
- The spores germinate in the lungs into yeasts or yeastlike cells and produce an asymptomatic or mild **primary pulmonary infection (PPI)** that parallels tuberculosis.
- In a small number of hosts, this infection becomes systemic and creates severe, chronic lesions.
- In a few cases spores are inoculated into the skin, where they form localized granulomatous lesions.
- All diseases result in immunity that can be long term and that manifests clinically as an allergic reaction to fungal antigens.

Histoplasmosis: Ohio Valley Fever

The most common true pathogen is *Histoplasma capsulatum*,* the cause of histoplasmosis. This disease has probably afflicted humans since antiquity, though it was not described until 1905 by Dr. Samuel Darling. Through the years, it has been known by various synonyms: Darling's disease, Ohio Valley fever, and reticuloendotheliosis.

* *Histoplasma capsulatum* (his'-toh-plaz'-mah kap'-soo-lay'-tum) Gr. *hist*, tissue, and *plasm*, shape; L. *capsula*, small box.

The skin and its attendant structures provide many potential sites for invasion, including the scalp, smooth skin, hair, and mucous membranes. Differing depths of involvement are: superficial, consisting of extremely shallow epidermal colonizations; cutaneous, involving the stratum corneum and occasionally the upper dermis; and subcutaneous, occurring after a puncture wound has introduced the fungus deeper into the subcutaneous tissues. In systemic (deep) mycoses, the fungus disseminates from the lungs or other sites into the circulation. Fungemia leads to infection of the brain, kidneys, and other organs.

Figure 22.5 Levels of invasion by fungal pathogens. Some species can invade more than one level.

Certain aspects of its current distribution and epidemiology suggest that it has been an important disease as long as humans have practiced agriculture.

Biology and Epidemiology of *Histoplasma capsulatum*

Histoplasma capsulatum is typically dimorphic. Growth on media below 35°C is characterized by a white or brown, hairlike mycelium; and growth at 37°C produces a creamy white, textured colony (figure 22.6).

Figure 22.6 Macroscopic appearance of *Histoplasma capsulatum*. (a) Grown at 25°C, *H. capsulatum* produces a white mycelium. (b) When incubated at 37°C, the fungus grows as a creamy yeast colony. (a, b): Source: CDC

Source: Dr. J.T. McClellan, Lexington, KY/CDC

with *H. capsulatum* is relatively common, especially in endemic areas, simple detection of antibodies is not indicative of disease. Complement fixation and immunodiffusion can detect a rising antibody titer, consistent with ongoing infection.

Habitat *H. capsulatum* is endemically distributed on all continents except Australia, with its highest rate of incidence occurring in the eastern and central regions of the United States (the Ohio Valley). It is found in moist soils high in nitrogen content and is associated with areas rich in bird or bat guano.

Microscopic Morphology Typically dimorphic, *H. capsulatum* produces a white or brown hairlike mycelium when grown below 35°C, whereas growth above 37°C results in creamy, white textured yeast colonies.

Identified by Tiny intracellular yeasts in macrophages or free yeasts in samples of sputum or cerebrospinal fluid. Because infection

Virulence Factors The principal virulence factor of all primary pathogenic fungi is the ability to grow dimorphically, being able to flourish both as a saprobic mycelium and as a pathogenic yeast.

Primary Infections/Disease Histoplasmosis (Ohio Valley fever) presents in many ways. Initial infection is usually asymptomatic and may lead to mild symptoms including aches and coughing, while more severe cases may progress to encompass fever, night sweats, and weight loss. Patients with defective cell-mediated immunity (AIDS patients, among others) can develop severe multiorgan disease, which may progress to lethality.

Control and Treatment Because *H. capsulatum* is so widespread in endemic areas, absolute avoidance is impractical. In these cases, respiratory protection will reduce the number of inhaled fungal spores when performing high-risk activities (exploring caves, cleaning bat and bird roosts, and so on). Treatment is not necessary in most cases, but amphotericin B and itraconazole are the antifungals of choice.

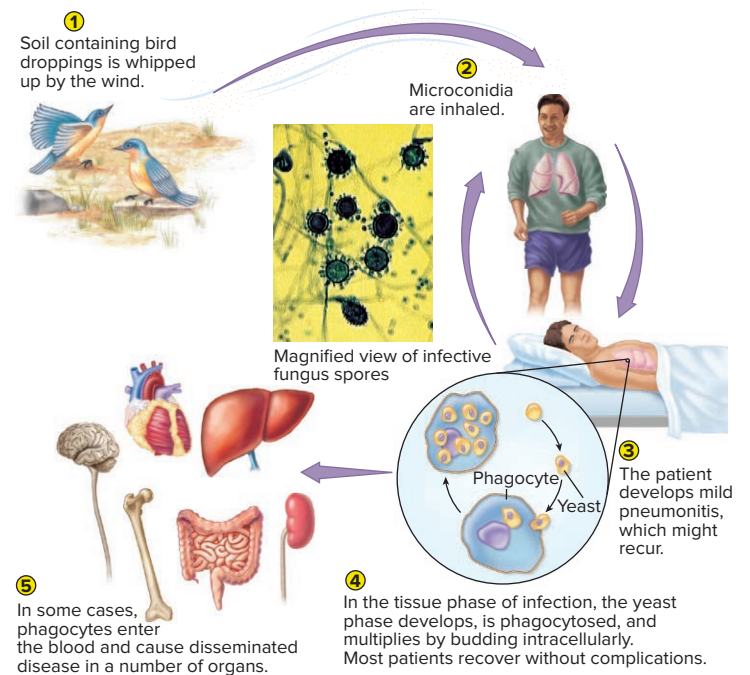

Histoplasma capsulatum is endemically distributed on all continents except Australia. Its highest rates of incidence occur in the eastern and central regions of the United States (the Ohio Valley). This fungus appears to grow most abundantly in moist soils high in nitrogen content, especially those supplemented by bird and bat guano.*

A useful tool for determining the distribution of *H. capsulatum* is to inject a fungal extract called *histoplasmin* into the skin and monitor for allergic reactions. Application of this test has verified the extremely widespread distribution of the fungus. In high-prevalence areas such as southern Ohio, Illinois, Missouri, Kentucky, Tennessee, Michigan, Georgia, and Arkansas, 80% to 90% of the population show signs of prior infection by the age of 20. Histoplasmosis incidence in the United States is estimated at about 500,000 cases per year, with several thousand of them requiring hospitalization and a small number resulting in death.

The spores of the fungus are probably dispersed by the wind and, to a lesser extent, animals. The most striking outbreaks of histoplasmosis occur when concentrations of spores have been dislodged by humans working in parks, bird roosting areas, and old buildings. People of both sexes and all ages incur infection, but adult males experience the majority of cases, probably due to higher levels of occupational exposure.

Infection and Pathogenesis of *Histoplasma* Histoplasmosis presents a formidable array of manifestations. It can be benign or severe, acute or chronic, and it can show pulmonary, systemic, or cutaneous lesions. Inhaling a small dose of microconidia (only 5 spores are required) into the deep recesses of the lung establishes a primary pulmonary infection that is usually asymptomatic. Its primary location of growth is in the cytoplasm of phagocytes such as

macrophages. Within these cells, it flourishes and is carried to other sites (figure 22.7). Some people experience mild symptoms such as aches, pains, and coughing, but a few develop more severe symptoms, including fever, night sweats, and weight loss. Primary cutaneous histoplasmosis, in which the agent enters via the skin, is very rare.

Process Figure 22.7 Events in *Histoplasma* infection and histoplasmosis. Infection begins with inhaled spores (microconidia) that give rise to the more invasive yeast phase. Source: CDC

* *guano* (gwan'-oh) Sp. *huanu*, dung. An accumulation of animal manure.

The most serious systemic forms of histoplasmosis occur in patients with defective cell-mediated immunity such as AIDS patients. In children, this can lead to liver and spleen enlargement, anemia, circulatory collapse, and death. Adults with systemic disease can acquire lesions in the brain, intestine, adrenal gland, heart, liver, spleen, lymph nodes, bone marrow, and skin. Persistent colonization of patients with emphysema and bronchitis causes *chronic pulmonary histoplasmosis*, a complication that has signs and symptoms similar to those of tuberculosis.

Diagnosis and Control of Histoplasmosis Discovering *Histoplasma* in clinical specimens is a substantial diagnostic indicator. Usually it appears as spherical, “fish-eye” yeasts intracellularly in macrophages and occasionally as free yeasts in samples of sputum and cerebrospinal fluid. Isolating the agent and demonstrating dimorphism help to confirm infection, but this step can require up to 12 weeks. Complement fixation and immunodiffusion serological tests can support a diagnosis by showing a rising antibody titer. Because a positive histoplasmin test does not indicate a new infection, it is not useful in diagnosis.

Undetected or mild cases of histoplasmosis resolve without medical management, but chronic or disseminated disease calls for systemic chemotherapy. The principal drug, amphotericin B, which disrupts the fungus membranes, is administered in daily intravenous

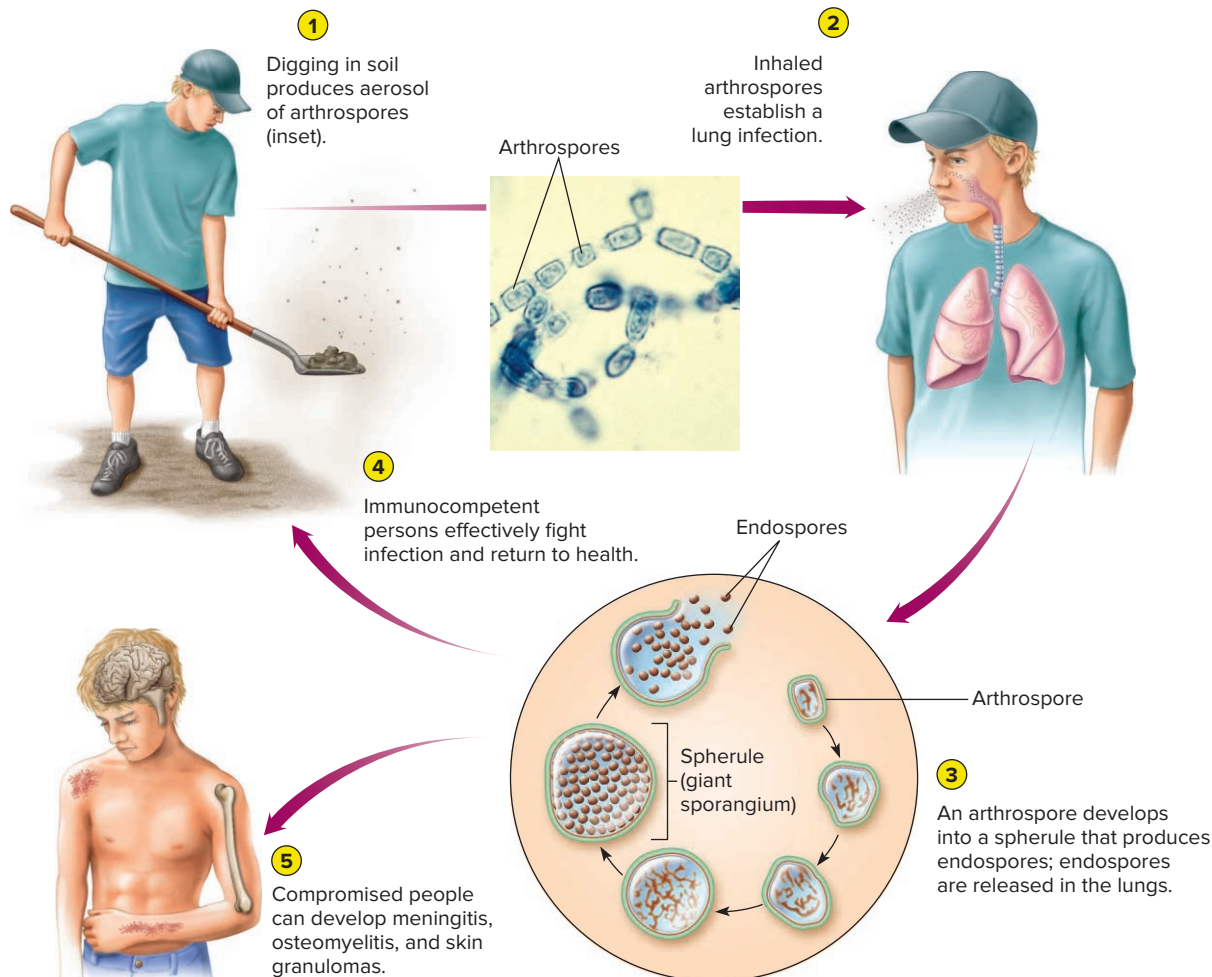

doses for a few days to a few weeks. Under some circumstances, itraconazole is the drug of choice. Surgery to remove affected masses in the lungs or other organs can also be effective.

Coccidioidomycosis: Valley Fever

*Coccidioides immitis** is the etiologic agent of coccidioidomycosis. Although the fungus has probably lived in soil for millions of years, human encounters with it are relatively recent and coincide with the encroachment of humans into its habitat. This unique and fascinating fungus demonstrates the greatest virulence of all mycotic pathogens.

Biology and Epidemiology of Coccidioides The morphology of *C. immitis* is very distinctive. At 25°C, it forms a moist, white to brown colony with abundant, branching, septate hyphae. These hyphae fragment into thick-walled, blocklike **arthroconidia** (arthrospores) at maturity (inset photo, **figure 22.8**). On special media incubated at 37°C to 40°C, an arthrospore germinates into the parasitic phase, a spherical cell called a **spherule**. This structure swells into a giant sporangium that cleaves internally to form numerous endospores that look like bacterial endospores but lack their resistance traits (**figure 22.8, step 3**).

* *Coccidioides immitis* (kok-sid'-ee-oy'-deez ih'-mih-tis) From *coccidia*, a sporozoan, and *L. immitis*, fierce. The original discoverers thought the microbe looked like a protozoan.

Pathogen Profile #2 *Coccidioides immitis*

Spherule stage of *C. immitis* from the lung
© Science Source

Microscopic Morphology At 25°C, forms moist, white to brown colonies with branching septate hyphae that fragment into thick-walled arthroconidia. At 37°C to 40°C, the arthrospores germinate into large spherical cells called spherules.

Identified by Appearance of spherules in the sputum, spinal fluid, and biopsies. Identification is enhanced by the cultivation of mycelia growth and induction of spherules. Immunodiffusion and latex agglutination tests on serum samples aid in early diagnosis.

Habitat *C. immitis* is endemic to many areas and occasionally found in many more where it may have been carried by wind or animals. A warm, dry environment with an abundance of salt and carbon favors settlement of the fungus. Highest incidence of infection with *C. immitis* occurs in the southwestern United States—particularly the San Joaquin Valley in California—as well as parts of Arizona, Mexico, and Central and South America.

Virulence Factors Like other pathogenic fungi, *C. immitis* has the ability to grow dimorphically, as both a saprobic mycelium and a pathogenic spherule.

Primary Infections/Disease Coccidioidomycosis is inapparent in about 60% of those infected with the pathogen, while in the remaining 40%, infection manifests with coldlike symptoms and malaise. In most cases, complete recovery and lifelong immunity result. Some people seem genetically predisposed to develop more serious disease, with the development of nodular growths (fungomas) and cavity formation in the lungs that compromises respiration. In about 7% of cases, endospores disseminate into the major organs of the body, leading to more severe disease. Being of Asian, Hispanic, or African descent, immunocompromised, or pregnant correlates with an increased risk of developing severe disease.

Control and Treatment Minimizing contact with *C. immitis* spores—through oiling dirt roads, planting vegetation to reduce dust, and wearing respiratory protection when digging—is the best defense. Treatment is not necessary in most cases, but amphotericin B and itraconazole are the antifungals of choice.

Coccidioides immitis occurs endemically in various natural reservoirs and casually in areas where it has been carried by wind and animals. Conditions favoring its settlement in a given habitat include high carbon and salt content and a semiarid, relatively hot climate. The fungus has been isolated from soils, plants, and numerous vertebrates. The natural history of *C. immitis* follows a cyclic pattern—a period of dormancy in winter and spring, followed by growth in summer and fall. Growth and spread are greatly increased by cycles of drought and heavy rains, followed by windstorms.

Skin testing has disclosed that the highest incidence of coccidioidomycosis (8,000–10,000 reported cases per year) is in the southwestern United States. Especially concentrated reservoirs exist in Southern Arizona and the San Joaquin Valley of California, from which it derives its common name. Outbreaks are usually associated with farming activity, archeological digs, landslides, and dust storms. Valley fever also extends into areas of Mexico and South and Central America. Several outbreaks have been reported in travelers and workers in these areas.

Infection and Pathogenesis of Coccidioidomycosis The arthrospores of *C. immitis* are lightweight and readily inhaled. Testing has found that only a single spore is required to initiate an infection. In the lung they convert to spherules, which swell, sporulate, burst, and release spores that continue the cycle. In 60% of patients this primary pulmonary infection is inapparent; in the other 40% it is accompanied by coldlike symptoms such as fever, chest pain, cough, headaches, and malaise. In uncomplicated cases, complete recovery and lifelong immunity are the rule.

All persons inhaling arthrospores probably develop some degree of infection, but certain groups have a genetic susceptibility

that gives rise to more serious disease. In about 5 out of 1,000 cases, the primary infection does not resolve and progresses with varied consequences, including infection of the skin, bones, and central nervous system. Chronic progressive pulmonary disease is manifested by nodular growths called **fungomas*** and cavity formation in the lungs, which compromise respiration. Dissemination of the endospores into major organs takes place in about 7% of cases. Increased risk for more severe, extrapulmonary disease occurs among certain ethnic groups, people with impaired immunity, pregnant women, and AIDS patients (**figure 22.9**).

Diagnosis and Control of Coccidioidomycosis Diagnosis of coccidioidomycosis is straightforward when the highly distinctive spherules are found in sputum, spinal fluid, and biopsies. This

* *fungomas* (fun-joh'-mah) A fungus tumor or growth.

Pathogen Profile #3 *Blastomyces dermatitidis*

Yeast phase
Source: CDC

Microscopic Morphology Typically dimorphic, *B. dermatitidis* grows as a white to tan, septate mycelium when grown at lower temperature, whereas high temperature growth results in creamy, white, wrinkled yeast colonies.

Identified by Smears displaying large, ovoid, thick-walled yeast cells with oversize buds provide presumptive identification. Serological tests are not usually useful.

Habitat *B. dermatitidis* is found almost exclusively in the eastern United States, where it inhabits rich organic matter found in forest soil, decaying wood, and animal manure.

Virulence Factors Like other pathogenic fungi, *B. dermatitidis* has the ability to grow dimorphically, as both a saprobic mycelium and a pathogenic yeast. Additionally, a very small infectious dose (10 to 100 spores) is sufficient to initiate infection.

Primary Infections/Disease Infection with *B. dermatitidis*, known variously as Gilchrist disease, Chicago disease, and North American blastomycosis, usually results in some pulmonary symptoms, including cough, chest pain, hoarseness, and fever. Chronic disease may produce lung abscesses and tumorlike nodules that can be mistaken for cancer. Cutaneous disease is seen more commonly with *B. dermatitidis* than with other fungal pathogens and usually begins as a nodule on the face or hands. About 20% of infections progress to include the skin, bones, prostate, or (rarely) central nervous system. Death may occur in up to 5% of cases.

Control and Treatment Control, as with other fungal disease, relies on not inhaling fungal spores. Treatment is not necessary in most cases, but amphotericin B or azole drugs such as itraconazole or voriconazole are the antifungals of choice.

finding is further supported by isolation of typical mycelia and spores on Sabouraud's agar and induction of spherules.

All cultures must be grown in closed tubes or bottles and opened in a biological containment hood to prevent laboratory infections. Newer specific antigen tests have been effective tools to identify and differentiate *Coccidioides* from other fungi. Immunodiffusion (**figure 22.10**) and latex agglutination tests on serum samples are excellent screens for detecting early infection. Skin tests using an extract of the fungus (coccidioidin or spherulin) are of primary importance in epidemiological studies.

Figure 22.10 Immunodiffusion test for coccidioidomycosis. Small wells are punched into agar, and patients' sera are placed in wells number 2, 3, 5, 6. Wells 1 and 4 contain known positive antibodies. The center well contains a known fungal antigen such as coccidioidin. Lines of precipitation forming between the outer well and the inner well indicate a reaction between antibodies in the serum and antigen diffusing from the center well. Only one patient is positive for this test. © Sean Bauman, Ph.D./Immuno-Mycolitics, Inc.

The majority of patients do not require treatment. However, in people with disseminated disease, amphotericin B is administered intravenously. One of the azole drugs can have some benefit, but it may require a longer term of therapy (up to 12 months). Minimizing contact with the fungus in its natural habitat has been of some value. For example, oiling roads and planting vegetation help reduce spore aerosols, and using dust masks while excavating soil prevents workers from inhaling spores.

Biology of *Blastomyces dermatitidis*: North American Blastomycosis

Blastomyces dermatitidis,* the cause of blastomycosis, is another fungal pathogen endemic to the United States. Alternative names for this disease are Gilchrist disease, Chicago disease, and North American blastomycosis. The dimorphic morphology of *Blastomyces* follows the pattern of other pathogens. Colonies of the hyphal phase are uniformly white to tan, with a thin, septate mycelium and simple ovoid conidia (**figure 22.11a**). Temperature-induced conversion results in a wrinkled, creamy-white colony composed of large, heavy-walled yeasts with buds nearly as large as the mother cell.

Studies indicate that *B. dermatitidis* inhabits rich organic matter found in forest soil, decaying wood, and animal manure. Its life cycle features dormancy during the warmer, dryer times of the year with growth and sporulation during the colder, wetter seasons. In general, blastomycosis occurs from southern Canada to southern Louisiana and from Minnesota to Georgia. Cases have also been

* *Blastomyces dermatitidis* (blas'-toh-my'-seez der'-mah-tit'-ih-dis) Gr. *blastos*, germ, *myces*, fungus, *dermato*, skin, and *itis*, inflammation.

Figure 22.11 The dimorphic nature of *Blastomyces dermatitidis*. (a) Hyphal filaments give rise to conidia that resemble tiny lollipops. (b) Fluorescent antibody staining of lung tissue reveals the thick walls present in the yeast stage of *Blastomyces dermatitidis*. Arrow indicates a budding yeast cell. (a, b): Source: CDC

reported in Central America, South America, Africa, and the Middle East. Humans, dogs, cats, and horses are the chief targets of infection, which is usually acquired by inhaling conidia-laden dust.

Infection and Pathology in Blastomycosis The primary portal of entry of *B. dermatitidis* is the respiratory tract, though it also may enter through accidental inoculation. Inhaling only 10 to 100 conidia is enough to initiate infection. As conidia convert to yeasts and multiply, they encounter macrophages in the lung. A large proportion of primary pulmonary infections are probably symptomatic to some degree.

Mild disease is accompanied by cough, chest pain, hoarseness, and fever. More severe, chronic blastomycosis can progress from the lungs to the skin and numerous other organs. Lung abscesses and tumorlike nodules are often mistaken for cancer or tuberculosis. Compared with other fungal diseases, the chronic cutaneous form of blastomycosis is rather common. It frequently begins on the face or limbs as a subcutaneous nodule that erupts to the skin surface (**figure 22.12**). Yeasts disseminating into the bone induce symptoms of arthritis and osteomyelitis. Involvement of the central nervous system can bring on headache, convulsions, coma, and mental confusion. Chronic systemic blastomycosis of the spleen, liver, and urogenital tract can last for weeks to years and eventually impair the host defenses.

Laboratory Diagnosis and Therapy Microscopic smears of specimens showing large, ovoid yeasts with broad-based buds can provide the most reliable diagnostic evidence of blastomycosis (see **figure 22.11b**). Dimorphic cultures are highly desirable, although they can require several weeks to develop. Serological tests are generally not useful. Although disseminated infections were once nearly 100% fatal, modern drugs have greatly improved the prognosis. The drug of choice for disseminated and cutaneous disease is amphotericin B, and milder cases typically respond to one of the azole drugs.

Paracoccidioidomycosis

The remaining dimorphic fungal pathogen would be a front-runner in a competition for the most tongue-twisting scientific name. *Paracoccidioides brasiliensis** causes paracoccidioidomycosis, also known as

* *Paracoccidioides brasiliensis* (pair'-ah-kok-sid'-ee-oy'-deez brah-sil'-ee-en'-sis)
Named for its superficial resemblance to *Coccidioides* and its prevalence in Brazil.

paracoccidioid granuloma and South American blastomycosis. Because of its relatively restricted distribution, this disease is the rarest of the primary mycoses. *Paracoccidioides* forms a small, nondescript colony with scanty, undistinctive spores at room temperature, but it develops an unusual yeast form at 37°C. The large mother cells sprout small, narrow-necked buds that radiate around the periphery.

Paracoccidioides has been isolated from the cool, humid soils of tropical and semitropical regions of South and Central America, particularly Brazil, Colombia, Venezuela, Argentina, and Paraguay. People most often afflicted with paracoccidioidomycosis are rural agricultural workers and plant harvesters. Factors that can influence the progress of infection are poor nutrition and impaired host resistance. Most infections occur in the lungs or the skin, and most of the time they are benign, self-limited events that go completely unnoticed. In a small minority of patients, the pathogen invades the lungs, skin and mucous membranes (especially of the head), and lymphatic organs.

Paracoccidioidomycosis is diagnosed by standard procedures previously described for the other mycoses in this chapter. Serological testing can be instrumental in diagnosing and monitoring the course of infection. Principal treatment drugs for disseminated disease, in order of choice, are ketoconazole, amphotericin B, and sulfa drugs.

Check Your Progress SECTION 22.2

- Differentiate between systemic, subcutaneous, cutaneous, and superficial infections.
- Briefly outline the life cycles of *Histoplasma capsulatum*, *Coccidioides immitis*, and *Blastomyces dermatitidis*.
- Name the diseases caused by each of the four primary fungal pathogens.
- Identify the common habitats of *Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*, and *Paracoccidioides brasiliensis*.
- Outline the course of a typical infection and disease with each of the four primary fungal pathogens.
- Compare the laboratory results diagnostic of infection with each of the four primary fungal pathogens.

22.3 Subcutaneous Mycoses

Expected Learning Outcomes

10. Describe the progression of a typical subcutaneous mycosis.
11. Summarize the major characteristics of *Sporothrix schenckii*.
12. Recall the characteristics of chromoblastomycosis and phaeohyphomycosis.
13. Describe the progression of events leading to mycetoma and chromoblastomycosis, as well as the prognosis of each disease.

When certain fungi are transferred from soil or plants directly into traumatized skin, they can invade the damaged site. Such infections are termed subcutaneous because they involve tissues within and just below the skin. Most species in this group are greatly inhibited by the higher temperatures of the blood and viscera, and only rarely do they disseminate. Nevertheless, these diseases are progressive and can destroy the skin and associated structures. Mycoses in this category are sporotrichosis, chromoblastomycosis, phaeohyphomycosis, and mycetoma.

The Natural History of Sporotrichosis: Rose-Gardener's Disease

The cause of **sporotrichosis**, *Sporothrix schenckii*,* is a very common saprobic fungus that exhibits both mycelial and yeast phases (**figure 22.13**). *Sporothrix* resides in warm, temperate, and moist areas of the tropics and semitropics, where it decomposes plant matter in soil and humus. The incidence of sporotrichosis is highest in Africa, Australia, Mexico, and Latin America. A prick by a rose thorn is the classic origin of the cutaneous form of infection, which has given rise to its common name, rose-gardener's disease. Most episodes of human infection follow penetration by thorns, wood, sphagnum moss, bare roots, and other vegetation, although bites and scratches from cats have been found responsible for an increasing

* *Sporothrix schenckii* (sroh'-roh-thriks shenk'-ee-ee) Gr. *sporos*, seed, and *thrix* hair. Named for B.R. Schenck, who first isolated it.

Figure 22.13 The microscopic morphology of *Sporothrix schenckii*. (b) Tiny ovate budding yeasts typical of the tissue phase (800 \times). (a): Source: Dr. Libero Ajello/CDC; (b): Source: Dr. Lucille K. Georg/CDC

Figure 22.14 The clinical appearance of lymphocutaneous sporotrichosis. A primary sore is accompanied by a series of nodules and ulcers running along the lymphatic channels of the arm. Source: CDC

number of recent cases. Horticulturists, gardeners, farmers, and basket weavers incur the majority of cases. Overt disease is uncommon unless a person has inadequate immune defenses or is exposed to a large inoculum or a virulent strain. Other mammals—notably horses, dogs, cats, and mules—are also susceptible to sporotrichosis.

Pathology, Diagnosis, and Control of Sporotrichosis

In lymphocutaneous sporotrichosis, the fungus grows at the site of penetration and develops a small, hard, nontender nodule within a few days to months. This subsequently enlarges, becomes necrotic, breaks through to the skin surface, and drains (**figure 22.14**). Infection often progresses along the regional lymphatic channels, leaving a chain of lesions at various stages of development. This condition can persist for several years, though it does not spread in the circulation. When *Sporothrix* conidia are drawn into the lungs, primary pulmonary sporotrichosis can result.

Discovery of the agent in tissue exudates, pus, and sputum is difficult because there are usually so few cells in the infection. Special stains can be used to highlight the tiny, cigar-shaped yeasts. Typical colony morphology and serological tests can confirm the diagnosis. The sporotrichin skin test can be used to determine prior infection. Itraconazole is the preferred treatment.

An older but effective drug for sporotrichosis is potassium iodide, given orally in milk or applied topically to open lesions. The fungus cannot withstand heat; thus, local applications of heat packs to lesions have helped resolve some infections. People with occupational exposure should cover their bare limbs as a preventive measure.

Chromoblastomycosis and Phaeohyphomycosis: Diseases of Pigmented Fungi

Chromoblastomycosis* is a progressive subcutaneous mycosis characterized by highly visible **verrucous*** lesions. The principal etiologic agents are a collection of widespread soil saprobes with

* *Chromoblastomycosis* (kroh'-moh-blas'-toh-my-koh'-sis) Gr. *chroma*, color, and *blasto*, germ. The fungal body is highly colored in vitro.

* *verrucous* (ver-oo'-kus) Tough, warty.

dark-pigmented mycelia and spores. *Fonsecaea pedrosoi*, *Phialophora verrucosa*, and *Cladophialophora carrionii* are among the most common causative species. **Phaeohiphomycosis**,* a closely related infection, differs primarily in the causative species and the appearance of the infectious agent in tissue. Chromoblastomycotic agents produce very large, thick, yeastlike bodies called sclerotic cells, whereas the agents of phaeohiphomycosis remain typically hyphal.

The fungi associated with these infections are of low inherent virulence, and none exhibits thermal dimorphism. Infection occurs when body surfaces, especially the legs and feet, are penetrated by soiled vegetation or inanimate objects. Chromoblastomycosis occurs throughout the world, with peak incidence in the American subtropics and tropics. Men with rural occupations who go barefoot are most vulnerable. After a very long (2- to 3-year) incubation period, a small, colored, warty plaque, ulcer, or papule appears. Because this lesion is generally not painful, many patients do not seek treatment and can go for years watching it progress to a more advanced state. Unfortunately, scratching the lesions can aggravate the spread of infection on the body and provoke secondary bacterial infections.

Chromoblastomycosis is frequently confused with cancer, syphilis, yaws, and blastomycosis. Diagnosis is based on the clinical appearance of the lesions, microscopic examination of biopsied lesions, and the results of culture. Therapy for the condition includes heat, drugs, surgical removal of early nodules, and amputation in advanced cases. Some success has been seen with amphotericin B, terbinafine, or combined therapy with itraconazole and flucytosine.

The phaeohiphomycoses are among the strangest oddities of medical science. The etiologic agents are soil fungi or plant pathogens with brown-pigmented mycelia. Victims of the disease are usually highly compromised patients who have become inoculated with these fungi, which are so widespread in household and medical environments that contact is inevitable. Genera of fungi commonly involved in these mycoses are *Alternaria*, *Aureobasidium*, *Curvularia*, *Dreschlera*, *Exophiala*, *Phialophora*, and *Wangiella*. Starting at the site of inoculation, the fungus grows into the skin, often creating crusty skin lesions and abscesses. As it invades deeper into the subcutaneous tissues, it often forms disfiguring cysts that have to be surgically removed. In patients with underlying conditions such as endocarditis, diabetes, and leukemia, the fungi can spread into the bones, brain, and lungs.

Mycetoma: A Complex Disfiguring Syndrome

Another disease elicited when soil microbes are accidentally implanted into the skin is **mycetoma**, a mycosis usually of the foot or hand that looks superficially like a tumor. It is also called *madura foot* for the Indian region where it was first described. About half of all mycetomas are caused by fungi in the genera *Pseudallescheria* or *Madurella*, though filamentous bacteria called actinomycetes (*Nocardia*, discussed in chapter 19) are often implicated. Mycetomas are endemic to equatorial Africa, Mexico, Latin America, and the Mediterranean, and cases occur sporadically in the United States.

Infection begins when bare skin is pierced by a thorn, sliver, leaf, or other type of sharp plant debris. The infectious spores and hyphae grow in the damaged epidermis, creating dark granules containing mycelium (**figure 22.15b**). First to appear is a localized

Figure 22.15 Mycetoma (a) Macroscopic view of madura foot features ulceration, swelling, and scarring. (b) Microscopic view of biopsy with masses of dark, thick-walled hyphae that has replaced much of the normal tissue. (a): © Medichshots/Alamy Stock Photo; (b): Source: Dr. Libero Ajello/CDC

abscess in the subcutaneous tissues, which gradually swells and drains (**figure 22.15a**). Untreated cases that spread to the muscles and bones can cause pain and loss of function in the affected body part. Mycetoma has an insidious, lengthy course and is exceedingly difficult to treat.

Check Your Progress SECTION 22.3

14. What weakness of host defenses typically contributes to subcutaneous mycoses?
15. Describe the disease, habitat, pathology, and diagnostic indicators of *Sporothrix schenckii*.
16. What are the risk factors associated with contracting chromoblastomycosis and phaeohiphomycosis?
17. List the similarities and differences encountered when comparing mycetoma and chromoblastomycosis.

22.4 Cutaneous Mycoses

Expected Learning Outcomes

14. Name the three dermatophytic genera and the diseases they cause.
15. Understand the pathology, epidemiology, and treatment of ringworm.

Fungal infections strictly confined to the nonliving epidermal tissues (stratum corneum) and its derivatives (hair and nails) are termed **dermatophytoses**. Common terms used in reference to these diseases are **ringworm**, because they tend to develop in circular, scaly patches (see figure 22.17), and **tinea**.* About 39 species in the genera *Trichophyton*, *Microsporum*, and *Epidermophyton* are involved in various dermatophytoses. The causative agent of a given type of ringworm differs from person to person and from place to place and is not restricted to a particular genus or species (**table 22.5**).

* *Phaeohiphomycosis* (fy''-oh-hy''-foh-my-coh'-sis) Gr. *phaeo*, brown, and *hypho*, thread.

* *tinea* (tin'-ee-ah) L. a larva or worm. Early observers thought they were caused by worms.

TABLE 22.5 The Dermatophyte Genera and Diseases

Genus	Name of Disease	Principal Targets	How Transmitted
<i>Trichophyton</i>	Ringworm of the scalp, body, beard, and nails Athlete's foot	Hair, skin, nails	Human to human, animal to human
<i>Microsporum</i>	Ringworm of scalp Ringworm of skin	Scalp hair Skin; not nails	Animal to human, soil to human, human to human
<i>Epidermophyton</i>	Ringworm of the groin and nails	Skin, nails; not hair	Strictly human to human

Characteristics of Dermatophytes

The dermatophytes are so closely related and morphologically similar that they can be difficult to differentiate. Various species exhibit unique macroconidia, microconidia, and unusual types of hyphae. In general, *Trichophyton* produces thin-walled, smooth macroconidia and numerous microconidia; *Microsporum* produces thick-walled, rough macroconidia and sparser microconidia; and *Epidermophyton* has ovoid, smooth, clustered macroconidia and no microconidia (**figure 22.16**).

Epidemiology and Pathology of Dermatophytoses

The natural reservoirs of dermatophytes are other humans, animals, and the soil (**22.1 Making Connections**). Important factors that promote infection are the hardness of the dermatophyte spores (they can last for years on fomites); presence of abraded skin; and intimate contact. Most infections exhibit a long incubation period (months), followed by localized inflammation and allergic reactions to the fungal proteins. As a general rule, infections acquired from animals and soil cause more severe reactions than do infections acquired from other humans, and infections eliciting stronger immune reactions are resolved faster.

Figure 22.16 Examples of dermatophyte spores. (a) Regular, numerous microconidia of *Trichophyton* (750 \times). (b) Macroconidia of *Microsporum gypseum*, a cause of ringworm in cats, dogs, and humans (1,000 \times). (c) Smooth-surfaced macroconidia in clusters characteristic of *Epidermophyton* (1,000 \times). (a, b, & c): Source: CDC

Dermatophytic fungi exist throughout the world. Although some species are endemic, they tend to spread rapidly to nonendemic regions through travel. Dermatophytoses endure today as a serious health concern, not because they are life-threatening but because of the extreme discomfort, stress, pain, and unsightliness they cause.

An Atlas of Dermatophytoses

In this section, the dermatophytoses are organized according to the area of the body they affect, their mode of acquisition, and their pathologic appearance. Both the common English name and body site and its equivalent Latin name (tinea) are given.

Quick Search

To appreciate the true variety of dermatophytoses, point your browser to “Tinea” and search images.

Ringworm of the Scalp (*Tinea Capitis*)

This mycosis results from the fungal invasion of the scalp and the hair of the head, eyebrows, and eyelashes (**figure 22.17a**). Very common in children, tinea capitis is acquired from other children and adults or from domestic animals. Manifestations range from small, scaly patches (gray patch) to a severe inflammatory reaction (kerion) to destruction of the hair follicle and permanent hair loss.

Ringworm of the Beard (*Tinea Barbae*) This tinea, also called “barber’s itch,” afflicts the chin and beard of adult males. Although

22.1 MAKING CONNECTIONS

The Keratin Lovers

The dermatophytic fungi are especially well adapted to breaking down keratin, the primary protein of the epidermal tissues of vertebrates (skin, nails, hair, feathers, and horns). Their affinity for this compound gives them the name *keratophiles*. Examination of infected hairs indicates that these fungi attach to the hair surface and penetrate into its cortex. In time, they grow along the hair's length to the follicle, where they initiate a skin infection. A study of dermatophyte ecology reveals a gradual evolutionary trend from saprobic soil forms that digest keratin but do not parasitize animals to soil forms that occasionally parasitize animals to species that are dependent on live animals. Some species can infect a broad spectrum of animals, and others are specific to one particular animal species or region of the body.

One adaptive challenge faced by relatively new fungal parasites is that they are likely to cause severe reactions in the host's skin and to be attacked by the host defenses and eliminated. Thus, the more successful fungi equilibrate with the host by reducing their activity (growth rate, sporulation) and lessen the inflammatory response. Eventually, these dermatophytes become such "good parasites" that they colonize the host for life. A striking example is *Trichophyton rubrum*, a fungus that causes a form of athlete's foot. It has such a tenacious hold and is so hard to cure that its carriers have been called the "*T. rubrum* people."

This microscopic view of a human hair shows dermatophyte hyphae growing along the hair and penetrating into its center.

What makes it easier for dermatophytes to gain a foothold in the body as compared with other pathogens? *Answer available on Connect.*

once a common aftereffect of unhygienic barbering, it is now contracted mainly from animals. Infection of the non-bearded areas of the face is less common, and referred to as *Tinea faciei* (**figure 22.17b**).

Ringworm of the Body (*Tinea Corporis*) This extremely prevalent infection of humans can appear nearly anywhere on the body's glabrous (smooth and bare) skin. The principal sources are other humans, animals, and soil, and it is transmitted primarily by direct contact and fomites (clothing, bedding). The infection usually appears as one or more scaly reddish rings on the trunk, hip, arm, neck, or face. The ringed pattern is formed when the infection radiates from the original site of invasion into the surrounding skin. Depending on the causal species and the health and hygiene of the patient, lesions vary from mild and diffuse to florid and pustular.

Ringworm of the Groin (*Tinea Cruris*) Sometimes known as "jock itch," crural ringworm occurs mainly in males on the groin, perianal skin, scrotum, and, occasionally, the penis. The fungus thrives under conditions of moisture and humidity created by profuse sweating or tropical climates. It is transmitted primarily from human to human and is pervasive among athletes and persons living in close situations (ships, military quarters).

Ringworm of the Foot (*Tinea Pedis*) *Tinea pedis* is known by a variety of synonyms, including athlete's foot and jungle rot. The disease is clearly connected to wearing shoes, because it is uncommon in cultures where the people customarily go barefoot. (But as you have seen, bare feet have other fungal risks!) Conditions that encase the feet in a closed, warm, moist environment increase the possibility of infection. *Tinea pedis* is a known hazard in shared

facilities such as shower stalls, public floors, and locker rooms. Infections begin with small blisters between the toes that burst, crust over, and can spread to the rest of the foot and nails (**figure 22.18**).

Ringworm of the Hand (*Tinea Manuum*) Infection of the hand by dermatophytes is nearly always associated with concurrent infection of the foot. Lesions usually occur on the fingers and palms of one hand, and they vary from white and patchy to deep and fissured.

Ringworm of the Nail (*Tinea Unguium*) Fingernails and toenails, being masses of keratin, are often sites for persistent fungus colonization. The first symptoms are usually superficial white patches in the nail bed. A more invasive form causes thickening,

Figure 22.18 Ringworm of the extremities. *Trichophyton* infection spreading over the foot in a "moccasin" pattern. The chronicity of *tinea pedis* is attributed to the lack of fatty-acid-forming glands in the feet. *Source:* CDC

distortion, and darkening of the nail. Nail problems caused by dermatophytes are on the rise as more women wear artificial fingernails, which can provide a portal of entry into the nail bed.

Diagnosis of Ringworm

Dermatologists are most often called upon to diagnose dermatophytoses. Occasionally, the presenting symptoms are so dramatic and suggestive that no further testing is necessary, but in most cases, direct microscopic examination and culturing are needed. Diagnosis of tinea of the scalp (tinea capitis) caused by some species of *Microsporum* is aided by use of a long-wave ultraviolet lamp that causes infected hairs to fluoresce. Samples of hair, skin scrapings, and nail debris treated with heated KOH show a thin, branching fungal mycelium if infection is present. Culturing specimens on selective media and growth on sterile hair can be important diagnostic aids.

Treatment of the Dermatophytoses

Ringworm therapy is based on the knowledge that the dermatophyte is feeding on dead epidermal tissues. These regions undergo constant replacement from living cells deep in the epidermis, so if multiplication of the fungus can be blocked, the fungus will eventually be sloughed off along with the skin or nail. Unfortunately, this takes time. By far the most satisfactory choice for therapy is a topical antifungal agent. Ointments containing terbinafine, miconazole, or tolnaftate are applied regularly for several weeks. Some drugs work by speeding up loss of the outer skin layer. Gentle debridement of skin and ultraviolet light treatments can have some benefit.

Check Your Progress SECTION 22.4

- Distinguish among the diseases caused by members of the genera *Trichophyton*, *Microsporum*, and *Epidermophyton*.
- List the factors involved in contracting ringworm, and outline the progression of a typical infection.
- How does simply inhibiting the growth of a fungus eventually lead to curing a dermatophytic infection?

22.5 Superficial Mycoses

Expected Learning Outcome

- Explain the significance of superficial mycoses.

Agents of superficial mycoses involve the outer epidermal surface and are ordinarily innocuous infections with cosmetic rather than inflammatory effects. **Tinea versicolor**¹ is caused by the yeast *Malassezia furfur*, a normal inhabitant of human skin that feeds on the high oil content of the skin glands. Even though this yeast is very common (carried by nearly 100% of humans tested), in some people its growth elicits mild, chronic scaling and interferes with production of pigment by melanocytes. The trunk, face, and limbs take on a mottled appearance (figure 22.19). The disease is most pronounced in young people

1. *Versicolor* refers to the color variations this mycosis produces in the skin. Also called pityriasis.

Figure 22.19 Tinea versicolor. Mottled, discolored skin pigmentation is characteristic of superficial skin infection by *Malassezia furfur*. © Medical-on-Line/Alamy Stock Photo

Figure 22.20 Example of superficial mycosis. A hair shaft exhibiting black piedra due to infection with *Piedraia hortae*. Infection is usually limited to the scalp but may be found on hairs of the beard, moustache, and pubic region. Source: CDC

who are frequently exposed to the sun. Recommended therapy zinc pyrithione shampoo scrubbed onto affected area and rinsed off after a few minutes, daily for 3 to 4 weeks. Other skin conditions in which *M. furfur* is implicated are folliculitis, psoriasis, and seborrheic dermatitis. It is also occasionally associated with systemic infections and catheter-associated sepsis in compromised patients.

Piedras* are marked by a tenacious, colored concretion forming on the outside surface of hair shafts (figure 22.20). In **white piedra**, caused by *Trichosporon beigeli*, a white to yellow adherent mass develops on the shaft of scalp, pubic, or axillary hair. At times, the mass is invaded secondarily by brightly colored bacterial contaminants, with startling results. **Black piedra**, caused by *Piedraia hortae*, is characterized by dark-brown to black gritty nodules, mainly on scalp hairs. Neither piedra is common in the United States.

* *Piedra* (pee-ay'-drah) Sp. stone. Hard nodules of fungus formed on the hair.

Check Your Progress SECTION 22.5

- Briefly describe three superficial mycoses.

22.6 Opportunistic Mycoses

Expected Learning Outcomes

17. Name the most common opportunistic fungal pathogens.
18. Explain the epidemiology of candidiasis.
19. Relate the options available for treatment of common fungal opportunists.

In section 22.1 we introduced the concept of opportunistic fungal infections and their predisposing factors (see table 22.3). The yeast *Candida* is the dominant opportunistic pathogen, and it accounts for the majority of invasive infections. The mold *Aspergillus* is the second in incidence, accounting for the most lung infections. Other fungi that are appearing more often in clinical isolates are *Cryptococcus*, *Alternaria*, *Paecilomyces*, *Fusarium*, *Rhizopus*, and *Torulopsis*—all genera that were once considered “harmless” air contaminants.

Infections by *Candida*: Candidiasis

Candida albicans,* an extremely widespread yeast, is the major cause of candidiasis (also called candidosis or moniliasis). Manifestations of infection run the gamut from short-lived, superficial skin irritations to overwhelming, fatal systemic diseases. Microscopically, *C. albicans* has budding cells of varying size that may form both elongate pseudohyphae and true hyphae (see figure 22.22a); macroscopically, it forms an off-white, pasty colony with a yeasty odor.

Epidemiology of Candidiasis

Candida albicans occurs as normal microbiota in the pharynx, genitalia, large intestine, or skin of 20% of humans. A healthy person with an unimpaired immune system can hold it in check, but the risk of invasion increases with infancy, old age, pregnancy, drug therapy, immunodeficiency, and trauma. Any situation that maintains the yeast in contact with moist skin provides an avenue for infection. Although candidiasis is usually endogenous and not contagious, it can be spread in nurseries or through surgery, childbirth, and sexual contact. *Candida albicans* and its close relatives account for around 70% of health-care-associated fungal infections.

Diseases of *Candida albicans*

Candida albicans causes local infections of the mouth, pharynx, vagina, skin, alimentary canal, and lungs, and it can also disseminate to internal organs. The mucous membranes most frequently involved are the oral cavity and vagina. **Thrush** is a white, adherent, patchy infection affecting the membranes of the oral cavity or throat, usually in newborn infants and elderly, debilitated patients (figure 22.21). **Vulvovaginal candidiasis (VC)**, known more commonly as *yeast infection*, has widespread

Figure 22.21 *Candida albicans* infection of the mouth (oral thrush). Courtesy of University of Adelaide, Australia

occurrence in adult women, especially those who are taking oral antibiotics or those who are diabetic or pregnant, all conditions that can disrupt the normal vaginal microbiota. Candidal vaginitis also poses a risk for neonates, which can be infected during childbirth, and it can be transmitted to male partners during sexual intercourse. The chief symptoms of VC are a yellow to white discharge, inflammation, painful ulcerations, and itching. The most severe cases spread from the vagina and vulva to the perineum and thighs.

Candidal attack of keratinized structures such as skin and nails, called **onychomycosis**,* is often brought on by predisposing occupational and anatomical factors. People whose occupations require their hands or feet to be constantly immersed in water are at risk for finger and nail invasion. **Intertriginous*** infection occurs in moist areas of the body where skin rubs against skin, as beneath the breasts, in the armpit, and between folds of the groin. **Cutaneous candidiasis** can also complicate burns and produce a scaldlike rash on the skin of neonates (a form of diaper rash).

Of all the areas of the gastrointestinal tract, *Candida* most often infects the esophagus and the anus. Esophageal candidiasis, which afflicts 70% of AIDS patients, causes painful, bleeding ulcerations, nausea, and vomiting.

Candidal blood infection usually becomes systemic in patients chronically weakened by surgery, bone marrow transplants, advanced cancer, or intravenous drug addiction. In fact, blood infection with *C. albicans* results in more deaths than any other fungal pathogen. Principal targets of systemic infections are the urinary tract, endocardium, and brain. Patients with valvular disease of the heart are vulnerable to candidal endocarditis, usually caused by other species (*C. tropicalis* and *C. parapsilosis*). *Candida krusei* has reportedly caused terminal infections in bone marrow transplant patients and in recipients of anticancer therapy. Another problem is the production of biofilms on artificial joints, catheters, and heart valves. In most of these cases, the colonization is very drug resistant and may require removal of the device until it can be controlled.

* *Intertriginous* (in"-ter-trij'-ih-nus) L. *inter*, between, and *trigo*, to rub.

Pathogen Profile #4 *Candida albicans*

Source: CDC

Microscopic Morphology Macroscopically, *C. albicans* produces off-white colonies, whereas microscopic examination reveals budding yeast cells, pseudohyphae, and true hyphae.

Identified by Visualization of budding yeast cells and pseudohyphae in primary specimens provides presumptive evidence of infection, whereas growth on differential media containing trypan blue can differentiate *Candida* from *Cryptococcus* species. Definitive identification may be achieved using biochemical testing or amplification of *Candida*-specific DNA sequences.

Habitat 20% of humans carry *C. albicans* in their pharynx, genitalia, large intestine, or skin as part of their normal microbiota.

Virulence Factors *C. albicans* is a prototypical opportunist, displaying little virulence in those with an unimpaired immune system but quickly causing disease when host defenses are compromised by young age, pregnancy, drug therapy, immunodeficiency disease, or trauma.

Primary Infections/Disease Infection with *C. albicans* causes a number of local infections. Thrush is a white adherent infection affecting the membranes of the oral cavity or throat, most prevalent

in newborns and elderly patients. Vulvovaginal candidiasis—yeast infection—occurs among adult women, especially those who are diabetic, pregnant, or taking oral antibiotics, all conditions that alter the normal vaginal microbiota. Onychomycosis occurs when *C. albicans* infects keratinized structures such as skin and nails. Intertriginous infection is seen where skin rubs against skin—commonly under the breasts, in armpits, and in folds of the groin. Cutaneous candidiasis may be a complication of burns or diaper rash. Systemic *Candida* infection is generally only seen in patients weakened by cancer, surgery, bone marrow transplants, or intravenous drug abuse and is a serious complication. *Candida* biofilm formation on artificial joints, catheters, and heart valves often requires removal of the device until the infection can be controlled.

Control and Treatment Because *C. albicans* is such a successful opportunist, candidiasis generally returns unless the underlying conditions predisposing the patient to infection are successfully treated. Treatment of cutaneous infection relies on topical antifungals (azoles and polyenes), whereas terbinafine is used to treat onychomycosis, and amphotericin B or fluconazole is effective against systemic infections. Vaginal candidiasis is sexually transmissible, requiring treatment of both partners to avoid reinfection.

Laboratory Techniques in the Diagnosis of Candidiasis

A presumptive diagnosis of *Candida* infection is made if budding yeast cells and pseudohyphae are found in specimens from localized infections (**figure 22.22a**). Specimens are cultured on standard fungal media incubated at 30°C. Identification is complicated by the numerous species of *Candida* and other look-alike yeasts. Growth on a selective, differential medium containing trypan blue can easily differentiate *Candida* species from the yeast *Cryptococcus* (**figure 22.22b**). Confirmatory evidence of *C. albicans* can also be obtained by the germ tube test, the presence of chlamydospores, and multiple-panel systems that test for biochemical characteristics (**figure 22.22c**). A sensitive PCR technique has been developed for identifying this species directly from clinical specimens.

Treatment of Candidiasis

Because candidiasis is almost always opportunistic, it will return in many cases if the underlying disease is not also treated. Therapy for superficial mucocutaneous infection consists of topical antifungal agents (azoles and polyenes). Terbinafine has been approved for treating onychomycosis. Amphotericin B and fluconazole are usually effective in systemic infections. Recurrent bouts of vulvovaginitis are managed by topical azole ointments, available as

over-the-counter drugs. Vaginal candidiasis is sexually transmissible; thus, it is very important to treat both sex partners to avoid reinfection.

Cryptococcus neoformans and Cryptococcosis*

Another widespread resident of human habitats is the fungus *Cryptococcus neoformans*.* This yeast has a spherical to ovoid shape, with small, constricted buds and a large capsule that is important in its pathogenesis (**figure 22.23**). Its role as an opportunist is supported by evidence that healthy humans have strong resistance to it and that frank infection occurs primarily in debilitated patients. *Cryptococcus gattii* is a newly identified species that has been seen primarily in the Northwestern United States (Oregon and Washington), Western Canada and Australia. It is very similar to *C. neoformans* in all respects except that it is more likely to cause infections in healthy hosts, and has a worse prognosis. Most **cryptococcoses** center around the respiratory, central nervous, and mucocutaneous systems.

* *cryptococcosis* (krip'-toh-kok-oh'-sis) Infections by *Cryptococcus*. Older names are torulosis and European blastomycosis.

* *Cryptococcus neoformans* (krip'-toh-kok'-us nee'-oh-for'-manz) Gr. *kryptos*, hidden, *kokkos*, berry, *neo*, new, and *forma*, shape.

Bulmer; (c): Photo courtesy of REMEL, Inc.

Epidemiology of *C. neoformans*

The primary ecological niche of *C. neoformans* is associated with birds. It is prevalent in urban areas where pigeons congregate, and it proliferates in the high nitrogen content of droppings that accumulate on pigeon roosts. Particles containing dried yeast cells are readily scattered into the air and dust. The species is sporadically

Figure 22.23 *Cryptococcus neoformans* from infected spinal fluid stained negatively with India ink. Halos around the large spherical yeast cells are thick capsules. Also note the buds forming on one cell. Encapsulation is a useful diagnostic sign for cryptococcosis, although the capsule is fragile and may not show up in some preparations (150X). Photo courtesy of Gordon Love, M.D. VA, North CA Healthcare System, Martinez, CA. G. Love, et al., "Large *Cryptococcus neoformans* Isolated from Brain Abscess," *JCM*, 22 (6): p. 1069, Reprinted by permission of American Society for Microbiology

isolated from dairy products, fruits, and the healthy human body (tonsils and skin), where it is considered a transient. The highest rates of cryptococcosis occur among patients with AIDS. It causes a severe form of meningitis that is frequently fatal. Other conditions that predispose to infection are steroid treatment, diabetes, and cancer. The disease exists throughout the world, with highest prevalence in the United States. Outbreaks have been reported in construction workers exposed to pigeon roosts, but it is not considered communicable among humans.

Pathogenesis of *Cryptococcus*

The primary portal of entry for *C. neoformans* is respiratory, and most lung infections are subclinical and rapidly resolved. A few patients with pulmonary cryptococcosis develop fever, cough, and nodules in their lungs. The escape of *C. neoformans* into the blood is more common in those with weakened host defenses and causes severe complications, including infection of the brain and meninges. The tumorlike masses formed in these locations can cause headache, mental changes, coma, paralysis, eye disturbances, and seizures. In some cases, the infection disseminates into the skin, bones, and viscera (figure 22.24).

Diagnosis and Treatment of *Cryptococcus*

The first step in diagnosis of cryptococcosis is negative staining of specimens to detect encapsulated budding yeast cells that do not occur as pseudohyphae. Isolated colonies can be used to perform screening tests that presumptively differentiate *C. neoformans* from the seven other cryptococcal species. Cryptococcal antigen can be

Figure 22.24 Cryptococcosis. An early case of cutaneous cryptococcosis. In the most serious cases, seen in patients with impaired immune function, the infection may progress to include the brain and meninges. © BSIP/UIG/Getty Images

detected in a specimen by means of serological tests, and DNA probes can make a positive genetic identification. Systemic cryptococcosis requires immediate combined therapy with amphotericin B and flucytosine for two weeks, followed by fluconazole over a period of weeks or months.

Pneumocystis jirovecii and *Pneumocystis* Pneumonia

Although *Pneumocystis jirovecii* was discovered in 1909, it remained relatively obscure until it was suddenly propelled into clinical prominence as the agent of *Pneumocystis jirovecii*² pneumonia (PCP). PCP is the most frequent opportunistic infection in AIDS patients, most of whom will develop one or more episodes during their lifetimes.

Because this unicellular microbe superficially has characteristics of both fungi and protozoa, its taxonomic status has been debated. The sequence of its ribosomal RNA indicates that it is very similar genetically to the yeast *Saccharomyces*. It differs from most other fungi because it lacks ergosterol, has a weak cell wall, and is an obligate parasite.

Unlike most of the human fungal pathogens, less is known about the life cycle or epidemiology of *Pneumocystis*. Evidently the parasite is a common, relatively harmless resident of the upper respiratory tract. Contact with the agent is so widespread that in some populations, a majority of people show serological evidence of infection. Until the AIDS epidemic, symptomatic infections by this organism were very rare, occurring only among elderly patients or premature infants who were severely debilitated or malnourished.

Pneumocystis is probably spread in droplet form between humans. In people with intact immune defenses, it is usually held in check by lung phagocytes and lymphocytes, but in those with deficient immune systems, it multiplies intracellularly and extracellularly. The massive numbers of parasites adhere tenaciously to the lung pneumocytes and cause an inflammatory condition. The lung epithelial cells slough off, and a foamy exudate builds up. Symptoms are nonspecific and include cough, fever, shallow respiration,

Figure 22.25 *Pneumocystis jirovecii* cells in the lung tissue (500x; stained with methamine silver) of an AIDS patient.

Source: CDC

and cyanosis. Improved therapy for AIDS patients (see chapter 25) has reduced the incidence of PCP and its mortality rate.

Because human strains of the species have not yet been successfully cultured, PCP must be diagnosed by symptoms and direct examination of lung secretions and tissue (**figure 22.25**). A DNA amplification probe can provide rapid confirmation of infection, but is prone to false positives. Traditional serological tests for antigens and antibodies are not useful diagnostic tools for *Pneumocystis*.

Traditional antifungal drugs that inhibit the synthesis of ergosterol are ineffective against *Pneumocystis* pneumonia because it lacks this sterol. The primary treatment is sulfamethoxazole and trimethoprim given over a 21-day period. This therapy should be applied even if disease appears mild or is only suspected. Pentamidine in an aerosol form is also given as a prophylactic measure in patients with a low T-cell count. The airways of patients in the active stage of infection often must be cleared by suctioning.

Aspergillosis: Diseases of the Genus *Aspergillus*

Molds of the genus *Aspergillus** are possibly the most pervasive of all fungi. The estimated 600 species are widely dispersed in dust and air and can be isolated from vegetation, food, and compost matter. Of the eight species involved in human diseases, the thermophilic fungus *A. fumigatus* accounts for the most cases. Aspergillosis is almost always an opportunistic infection, lately posing a serious threat to AIDS, leukemia, and immunodeficient patients. It is also involved in allergies and toxicoses.

Aspergillus infections usually occur in the lungs. People breathing clouds of conidia from the air of granaries, barns, and silos are at greatest risk. In healthy people with extensive exposure, the spores simply germinate in the lungs and form *fungus balls*. Similar benign, noninvasive infections occur in colonization of the sinuses, ear canals, eyelids, and conjunctiva (**figure 22.26a**), whereas in the more invasive form of aspergillosis, the fungus produces a necrotic pneumonia and disseminates to the brain, heart, skin, and a wide range of other organs. Systemic aspergillosis in severely ill hospitalized patients has a poor prognosis.

2. Formerly known as *Pneumocystis carinii* or *Pneumocystis (carinii) jirovecii*.

* *Aspergillus* (as'-per-jil'-us) L. *aspergere*, to scatter.

(a)

(b)

Figure 22.26 Appearance of aspergillosis (a) This chest radiograph shows probable aspergillosis with an aspergilloma, or fungus ball in the upper lobe of the right lung (arrow). (b) Scanning electron micrograph of the conidial head of *Aspergillus*, (400 \times). These molds are not dimorphic and exist only in the hyphal stage. (a): Source: CDC; (b): Source: Janice Haney Carr/CDC

An obvious branching, septate mycelium with characteristic conidial heads in a specimen is presumptive evidence of aspergillosis (**figure 22.26b**). A culture of the specimen that produces abundant colonies and growth at 37°C will rule out its being only an air contaminant. Molecular methods include a PCR test that can identify *Aspergillus*-specific DNA and a serological test that detects fungal antigen. Noninvasive disease can be treated by surgical removal of the fungus tumor or by local drug therapy of the lung using voriconazole, Cresemba (a newly approved azole drug), or amphotericin. Combined therapy with two of these drugs is the most effective treatment for systemic disease.

Mucormycosis

Members of the Division Zygomycota are extremely abundant saprobic fungi found in soil, water, organic debris, and food. Their large, prolific sporangia release multitudes of lightweight spores that literally powder the living quarters of humans and usually do little harm besides spoiling foods and rotting fruits and vegetables. But an increasing number of critically ill patients are contracting a disease called **mucormycosis**, also known as **zygomycosis**. Common airborne molds in the genera *Rhizopus*, *Mucor*, and *Absidia* (**figure 22.27a**) are most often involved in these mycoses.

Underlying debilities that seem to increase the risk for mucormycosis are leukemia, malnutrition, and skin damage (**figure 22.27b**). Uncontrolled diabetes is a special risk because it reduces the pH in the blood and tissue fluids, which enhances invasion of the fungus. The fungus enters by way of the nose, lungs, skin, or oral cavity. In rhinocerebral mucormycosis, infection begins in the nasal passages or pharynx and then grows in the blood vessels and up through the palate into the eyes and brain. Invasion of the lungs occurs most often in leukemia patients, and gastrointestinal mucormycosis is a complication in children suffering from protein malnutrition. Unfortunately, the outlook for most of these patients is poor.

Diagnosis of mucormycosis rests on clinical grounds and biopsies or smears. Very large, thick-walled, nonseptate hyphae scattered through the tissues of a gravely ill diabetic or leukemic patient are very suggestive of zygomycosis. Attempts to isolate the molds from specimens are frequently met with failure, and confusion of

22.2 MAKING CONNECTIONS

Contaminated Steroids Lead to Fungal Meningitis

In late 2012 a rare outbreak of fungal meningitis struck across the United States, killing 64 people and sickening over 753. A compounding pharmacy in Massachusetts was quickly identified as the source of the fungus, which was allowed to contaminate several thousand doses of methylprednisolone acetate, a steroid used to treat pain and swelling of the joints. Inspection of the New England Compounding Center revealed a poorly controlled—many would say filthy—laboratory environment, where spores borne on the wind could easily enter the manufacturing process.

Regrettably, dirty manufacturing facilities and large-scale outbreaks of disease are more common than we'd care to admit. What turned out to be noteworthy—especially to microbiologists—was the identity of the contaminant itself, an obscure fungus called *Exserohilum rostratum*. A plant pathogen that favors warm, moist climates, *E. rostratum* typically infects corn, sorghum, grass, and other monocot plants and fights them to a draw; being too weak to cause the death of the plant, while too resilient to be completely eliminated. The tenacious fungus is rewarded in the end, however, being first in line to devour the remains of its botanical host once the plant dies. The fungi's rapid growth rate, faster than any other related species, serves it well in the cornfield, while also making it a prime candidate for colonization of a

Conidia of *Exserohilum rostratum*
Source: CDC

dirty laboratory—an unfortunate confluence of events that could easily have been avoided.

Given the practices of the New England Compounding Center, the events leading to the deaths of so many people were entirely predictable. Top executives of the company had, for several years, blatantly broken the law in search of ever-greater profits. Documents related to cleanliness in the lab were routinely falsified and employees were ordered to prioritize speed over aseptic production techniques. Autoclave times were even shortened to allow the processing of a greater quantity of medication, according to court documents. In the fall of 2014 the federal government, along with many states, filed 131 charges against 14 people associated with the company. Two executives, including the owner of the

NECC, were charged with 25 counts of racketeering and second-degree murder; if convicted, they could face life in prison. During bankruptcy proceedings, a \$200 million fund was established to help compensate those who became sick from tainted steroids and the families of those who died.

The New England Compounding Center was faulted for, among other things, turning off the air conditioning to their manufacturing plant every evening. Why is this detail important? Answer available on Connect.

the isolates with air contaminants is also a problem. Treatment, which is effective only if commenced early in the infection, consists of surgical removal of infected areas accompanied by high doses of amphotericin B, posaconazole, or Cresemba.

Miscellaneous Opportunists

It is increasingly clear that nearly any fungus can be implicated in infections when the host's immune defenses are severely compromised. Although it is still relatively unusual to become infected by common airborne fungi, these infections are currently on the rise.

Geotrichosis is a rare mycosis caused by *Geotrichum candidum* (figure 22.28a), a mold commonly found in soil, in dairy products, and on the human body. The mold is not highly aggressive and is primarily involved in secondary infection in the lungs of tubercular or highly immunosuppressed patients.

Species of *Fusarium* (figure 22.28b), a common soil inhabitant and plant pathogen, occasionally infect the eyes, toenails, and burned skin. Mechanical introduction of the fungus into the eye (for example, by contaminated contact lenses) can induce a severe mycotic ulcer. In 2006 an outbreak of keratitis was traced to *Fusarium* in contact lens cleaning solution. It can also infect the nail bed and cause a condition like tinea unguium. *Fusarium* colonization of patients with widespread burns has occasionally led to mortalities.

Unusual opportunistic infections have been reported for other commonplace fungi such as *Alternaria*, *Malassezia*, and *Exserohilum*

Figure 22.28 Common fungi that can cause uncommon infections. (a) *Geotrichum* produces blocky arthrospores (400 \times). (b) *Fusarium* displays crescent-shaped conidia (800 \times). (a): Source: Dr. Lucille K. Georg/CDC; (b): Source: CDC

(22.2 Making Connections). The widespread genus *Penicillium* is not usually infectious, although one species, *P. marneffeii*, is a true pathogen restricted to certain parts of the world (Southeast Asia) and is occasionally isolated from cancer and AIDS patients.

Check Your Progress SECTION 22.6

22. What two genera account for the majority of opportunistic fungal infections?
23. What are the treatments for localized and systemic candidiasis?
24. List the conditions that can increase the risk of developing candidiasis.
25. Outline the diseases caused by *Candida albicans* and the area of the body where each commonly manifests.
26. Summarize the antifungal regimens recommended for treating *Cryptococcus*, *Pneumocystis*, *Aspergillus*, and Zygomycota infections.
27. Briefly outline the epidemiology and pathology of *Pneumocystis jirovecii*.

22.7 Fungal Allergies and Intoxications

Expected Learning Outcome

20. Distinguish between fungal infections, fungal allergies, and fungal intoxications.

It should be amply evident by now that fungi are constantly present in the air we breathe. In most people, inhaled fungal spores are totally without effect; in a few, they instigate infection; and in still others, they stimulate hypersensitivity. So significant is the impact of **fungal allergies** that airborne spore counts are performed by public health departments as a measure of potential risk (see figure 16.2). The most important fungal allergies are seasonal asthma and other chronic respiratory conditions that occur after occupational exposure to airborne mold spores. These allergies are typically named for the type of worker most likely afflicted: farmer's lung, teapicker's lung, barkstripper's disease.

CASE STUDY Part 2

Prior to the beginning of camp, the counselors participated in a camp cleanup, where the 12 campsites were prepared for the summer. Preparations included raking leaves, cleaning picnic tables, digging fire pits, and moving firewood. Counselors reported that they found bird and bat guano on picnic tables and the dirt floor of camp shelters at two of the campsites. Campers arrived a week later and took part in nature walks, outdoor games, wilderness training, and arts and crafts, but did not engage in high-risk activities like those performed by the counselors earlier in the summer. Analysis of data collected by the DCDH and NDHHS determined that campers assigned to campsites where guano was seen were more than twice as likely to become ill than those campers assigned to campsites more than

Another effect of contact with fungi or their products is **mycotoxicosis**, a disease caused by ingesting or inhaling fungal toxins. One of the most potent of these toxins is **aflatoxin**,* a product of *Aspergillus flavus* growing on grains, corn, and peanuts. Although the mold itself is relatively innocuous, the toxin is carcinogenic and hepatotoxic. It is especially lethal to turkeys, ducklings, pigs, and calves that have eaten contaminated feed. In humans, it appears to be a cofactor in liver cancer. The potential hazard aflatoxin poses for domesticated animals and humans necessitates constant monitoring of peanuts, grains, nuts, vegetable oils, animal feed, and even milk. A quick exposure of seeds to ultraviolet radiation is a useful screening test because they glow when contaminated by the toxin.

Toxic fungi can also be a source of illness sometimes termed “sick building syndrome.” These toxinoses are due to inhalation of toxins (and spores) from buildings heavily contaminated by certain “black molds.” The most notable of these is *Stachybotrys chartarum* (see 5.1 Secret World of Microbes), whose toxins have been known to cause severe hematologic and neurological damage, especially in animals. Recent publicity for toxic molds has caused widespread fungus phobias and spawned a large industry for environmental mold control. Although human illness with toxic fungi has been reported with increased frequency, it is not always possible to link an outbreak to a specific fungus or toxin. For example, sick building syndrome has causations other than molds, and not all molds growing in homes or buildings are highly toxic.

Check Your Progress SECTION 22.7

28. Discuss the importance of fungal infections, fungal allergies, and mycotoxicoses.

* **aflatoxin** (af'-lah-toks'-in) Acronym for *Aspergillus flavus* toxin.

20 yards away. In fact, the data showed that the farther away a camper was from a site where guano was found, the less likely they were to become ill. Based on this report, the camp was relocated to a different park, and the city's parks and recreation division was given recommendations to prevent bat roosting, recognize potentially contaminated areas, and properly deal with such sites.

- Explain why simply having antibodies specific for *H. capsulatum* in the bloodstream is not evidence of current infection.
- In what people would infection with *H. capsulatum* be especially serious?

See: CDC. 2012. Histoplasmosis outbreak among day-camp attendees—Nebraska, June 2012. *MMWR* 61(37):747–48.

To conclude this Case Study, go to Connect.

 Chapter Summary with Key Terms

22.1 Fungi as Infectious Agents

- A. Microscopic fungi (molds and yeasts) are widespread in nature. A few members cause fungal diseases or **mycoses**.
- B. Infectious fungi occur in groups based upon the virulence of the pathogen and the level of involvement, whether **systemic, subcutaneous, cutaneous, or superficial**.
- C. **True** or **primary pathogens** have virulence factors that allow them to invade and grow in a healthy host.
 1. They are also **thermally dimorphic**, occurring as hyphae in their natural habitat and converting to yeasts while growing as parasites at body temperature (37°C).
 2. Inhaled spores initiate **primary pulmonary infection (PPI)**, which can spread to the skin and other systems.
 3. Diseases are not transmissible and cause a long-term allergic reaction to fungal proteins.
 4. True pathogens are endemic to certain geographic areas.
- D. **Opportunistic fungal pathogens** are normal flora or common inhabitants of the environment that invade mainly patients whose host defenses are compromised.
 1. They are only weakly virulent and lack thermal dimorphism.
 2. Infections may be local, cutaneous, or systemic and are currently on the rise, due to more weakened patients.
- E. Immunity to fungal infections consists primarily of nonspecific barriers, inflammation, and cell-mediated defenses. Antibodies and antigens may be used to detect disease in some cases.
- F. Diagnosis and identification require
 1. microscopic examination of stained specimens,
 2. culturing of pathogen in selective and enriched media, and
 3. specific biochemical and in vitro serological tests.
 4. Skin testing for true and opportunistic pathogens can determine prior disease but is not useful in diagnosis.
- G. Control of fungal infections involves drugs such as intravenous amphotericin B, flucytosine, azoles (fluconazole), and nystatin.

22.2 Organization of Fungal Diseases

- A. Histoplasmosis (Ohio Valley fever): The agent is *Histoplasma capsulatum*, distributed worldwide but most prevalent in the soil of eastern and central regions of the United States.
 1. Inhaled conidia produce primary pulmonary infection that may progress to systemic involvement of a variety of organs and chronic lung disease.
- B. Coccidioidomycosis (valley fever): *Coccidioides immitis* has blocklike **arthroconidia** in the free-living stage and **spherules** containing endospores in the lungs.
 1. The agent lives in alkaline soils in semiarid, hot climates and is endemic to the southwestern United States.
 2. Arthrospores inhaled from dust create spherules and nodules in the lungs.
- C. **Blastomycosis** (Chicago disease): The agent is *Blastomyces dermatitidis*, a free-living species distributed in soil of a large section of the midwestern and southeastern United States.
 1. Inhaled conidia convert to yeasts and multiply in lungs.
 2. Symptoms include cough and fever; chronic cutaneous, bone, and nervous system complications may develop.

- D. Paracoccidioidomycosis (South American blastomycosis): *Paracoccidioides brasiliensis* is distributed in various regions of Central and South America. Lung infection occurs through inhalation or inoculation of spores, and systemic disease is not common.

22.3 Subcutaneous Mycoses

- A. **Sporotrichosis** (rose-gardener's disease) is caused by *Sporothrix schenckii*, a free-living fungus that accidentally infects the appendages and lungs. The lymphocutaneous variety occurs when contaminated plant matter penetrates the skin and the pathogen forms a local nodule, then spreads to nearby lymph nodes.
- B. **Chromoblastomycosis** is a deforming, deep infection of the tissues of the legs and feet by soil fungi that enter a traumatic injury.
- C. **Mycetoma** is a progressive, tumorlike disease of the hand or foot due to chronic fungal infection; may lead to loss of the body part.

22.4 Cutaneous Mycoses

- A. **Dermatophytoses** are known as **tinea, ringworm**, and athlete's foot. They are caused by fungi called **dermatophytes** in the genera *Trichophyton*, *Microsporum*, and *Epidermophyton*. These species are adapted to growing in keratinized epidermis (skin, hair, nails).
- B. Infections are communicable among humans, animals, and soil.
 1. Infection is facilitated by moist, chafed skin.
 - a. Ringworm of scalp (**tinea capitis**) affects scalp and hair-bearing regions of head; hair may be lost.
 - b. Ringworm of body (**tinea corporis**) occurs as inflamed, red ring lesions anywhere on smooth skin.
 - c. Ringworm of groin (**tinea cruris**) affects groin and scrotal regions.
 - d. Ringworm of foot and hand (**tinea pedis** and **tinea manuum**) is spread by exposure to public surfaces; occurs between digits and on soles.
 - e. Ringworm of nails (**tinea unguium**) is a persistent colonization of the nails of the hands and feet that distorts the nail bed.

22.5 Superficial Mycoses

Superficial mycoses affect the outermost epidermal structures. **Tinea versicolor** causes mild scaling, mottling of skin; **white piedra** is whitish or colored masses on the long hairs of the body; and **black piedra** causes dark, hard concretions on scalp hairs.

22.6 Opportunistic Mycoses

- A. Candidiasis is caused by *Candida albicans* and other *Candida* species, common yeasts that normally reside in the mouth, vagina, intestine, and skin. Infection predominates in cases of lowered resistance and arises from normal microbiota or is transmissible through intimate contact.
 1. **Thrush** occurs as a thick, white, adherent growth on the mucous membranes of mouth and throat.
 2. **Vulvovaginal candidiasis (VC)** (*yeast infection*) is a painful inflammatory condition of the female genital region that causes ulceration and whitish discharge.
 3. **Cutaneous candidiasis** occurs in chronically moist areas of skin and in burn patients, and onychomycosis is candidal infection of the nails.

- B. **Cryptococcosis** is caused by *Cryptococcus neoformans* and *Cryptococcus gattii*, widespread encapsulated yeasts that inhabit soils around pigeon roosts; common infection of AIDS, cancer, or diabetes patients.
1. Infection of lungs leads to cough, fever, and lung nodules.
 2. Dissemination to meninges and brain can cause severe neurological disturbance and death.
- C. **Pneumocystis jirovecii** is a small, unicellular fungus that causes PCP, the most prominent opportunistic infection in AIDS patients. This pneumonia forms secretions in the lungs that block breathing and can be rapidly fatal if not controlled with medication.
- D. Aspergillosis is caused by *Aspergillus*, a very common airborne soil fungus. Inhalation of spores causes fungus balls in lungs; it also causes invasive disease in the eyes, heart, and brain.
- E. **Mucormycosis** is caused by molds in genus *Rhizopus*, *Mucor*, and *Absidia*. These usually harmless air contaminants invade the membranes of the nose, eyes, and brain of people with acidosis (diabetes, malnutrition), with severe consequences.
- F. Other significant opportunists are *Geotrichum* (lungs) and *Fusarium* (eyes and nails).

22.7 Fungal Allergies and Intoxications

- A. Airborne fungal spores are common sources of atopic allergies.
- B. Contact with fungal toxins leads to **mycotoxicoeses**. Most cases are caused by eating poisonous or hallucinogenic mushrooms or food.
- C. **Aflatoxins** are dangerous toxins produced by *Aspergillus flavus*. When ingested in contaminated food, they may cause cancer and liver damage.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

1. The ability of a fungus to alternate between hyphal and yeast phases in response to temperature is a type of
 - a. sporulation
 - b. conversion
 - c. dimorphism
 - d. binary fission
2. Which phase of a fungal life cycle is best adapted to growing in a host's body?
 - a. yeast
 - b. hyphal
 - c. conidial
 - d. filamentous
3. Primary pathogenic fungi differ from opportunistic fungi in being
 - a. more virulent
 - b. less virulent
 - c. more prevalent
 - d. more transmissible
4. True pathogenic fungi
 - a. are transmissible from person to person
 - b. cause primary pulmonary infections
 - c. are endemic to specific geographic areas
 - d. both b and c
5. Example(s) of fungal infection(s) that is/are communicable is/are
 - a. dermatomycosis
 - b. candidiasis
 - c. sporotrichosis
 - d. both a and b
6. Histoplasmosis has the greatest endemic occurrence in which region?
 - a. midwestern United States
 - b. southwestern United States
 - c. Central and South America
 - d. North Africa
7. Coccidioidomycosis is endemic to which geographic region in the United States?
 - a. Southwest
 - b. Northeast
 - c. Pacific Northwest
 - d. Southeast
8. Skin testing with antigen is a useful epidemiological procedure for
 - a. histoplasmosis
 - b. candidiasis
 - c. coccidioidomycosis
 - d. a and c
9. A mycetoma is a
 - a. fungal tumor of the lung
 - b. collection of pus in the brain caused by *Cryptococcus*
 - c. deeply invasive fungal infection of the foot or hand
 - d. type of ringworm of the scalp
10. Dermatophytic fungi attack the _____ in the _____.
 - a. epithelial cells, lungs
 - b. melanin, stratum corneum
 - c. keratin; skin, nails, hair
 - d. bone, foot
11. Example(s) of dermatophyte genus/genera is/are
 - a. *Epidermophyton*
 - b. *Sporothrix*
 - c. *Trichophyton*
 - d. a and c
 - e. all of these

12. *Candida albicans* is the cause of _____, an infection of the _____.
- onychomycosis, root canal
 - moniliasis, lungs
 - thrush, mouth
 - salpingitis, uterus
13. Cryptococcosis is associated with
- blowing winds
 - plant debris
 - pigeon droppings
 - excavation of ancient dwellings
14. Which fungus does *not* commonly cause systemic infection?
- Blastomyces*
 - Histoplasma*
 - Cryptococcus*
 - Malassezia*
15. Which of the following is the cause of mycotoxicosis?
- Mucor*
 - Aspergillus*
 - Pneumocystis*
 - Cryptococcus*
16. **Single Matching.** Match the disease with its common name.
- | | |
|------------------------------|---------------------------------|
| _____ coccidioidomycosis | a. tinea |
| _____ histoplasmosis | b. San Joaquin Valley fever |
| _____ blastomycosis | c. South American blastomycosis |
| _____ sporotrichosis | d. Chicago disease |
| _____ paracoccidioidomycosis | e. rose-gardener's disease |
| _____ dermatophytosis | f. yeast infection |
| _____ candidiasis | g. Ohio Valley fever |

Case Study Review

- The patients in this case were probably treated with
 - penicillin
 - amphotericin B
 - specific immune globulin
 - vaccination
- The geographic location of infection was important in this case. If the students in the case had all visited Brazil, what fungal pathogens would have been suspect? (Choose all that apply.)
 - Histoplasma*
 - Blastomyces*
 - Coccidioides*
 - Paracoccidioides*
- If you were tasked with preventing an outbreak similar to the one seen in the Case Study, what recommendations would you make to workers preparing to open a similar camp the following year?

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

- Describe the concept behind an immunodiffusion test. Explain how the histoplasmin test is done.
- What are the dermatophytoses?
 - What is meant by the term *keratophile*?
 - What do the fungi actually feed upon?
 - To what do the terms *ringworm* and *tinea* refer?
- What is the difficulty in ridding the epidermal tissues of certain dermatophytes?
 - What is necessary in treatment?
- Describe three forms of fungal toxinoses and the agents involved in them.

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps along with concept mapping activities for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

1. Give reasons most humans are not constantly battling fungal infections, considering how prevalent fungi are in the environment.
2. a. Name several medical conditions that compromise the immunities of patients (see table 22.3).
b. Is there any such thing as a harmless contaminant with these patients?
c. Describe the consequences if a virulent fungal pathogen infects a severely compromised patient.
3. Using the general guidelines presented in chapter 17 and figure 22.3, explain how you can tell for sure if a fungal isolate is the actual causative agent or merely a contaminant.
4. a. Explain why some dermatophytes are considered good parasites.
b. Why would infections from soil and animal species be more virulent than ones from fungi adapted to humans?
c. Suggest a reason adult males have more cases of histoplasmosis.
5. What features of the lungs make them a favorable site for fungal infections?
6. a. Describe the difficulties in diagnosing endemic fungal infections that are acquired by travelers or nonnatives to endemic areas.
b. Which forms of diagnostic testing will improve the likelihood of rapid detection of such infections?
7. A male researcher wanting to determine the pathogenesis of a certain fungus that often attacks women did the following experiment on himself. He taped a piece of gauze heavily inoculated with the fungus to the inside of his thigh and left it there for several days, periodically moistening it with sterile saline. After a time he experienced a severe skin reaction that resembled a burn and the skin peeled off.
 - a. Suggest a species of fungus that can cause this effect.
 - b. What does this experiment tell you about the factors in pathogenesis related to portal of entry and gender?
8. A worker involved in demolishing an older downtown building is the victim of a severe lung infection.
 - a. Without any lab data, what two fungal infections do you suspect?
 - b. What is your reasoning?
 - c. How would you differentiate them?

Visual Challenge

1. Using figure 22.3 as a guide, proceed to go through the procedures to diagnose this infection.
2. What would you expect to see microscopically from a scraping of the white patch? Describe other diagnostic procedures for this infection.

CASE STUDY Part 1 Keep Your Head Above Water

Like the winter flu season, the warm temperatures and sunny days of springtime bring with them an increase in a number of diseases: food poisoning from undercooked hamburgers, **Lyme disease** from tick bites, **hookworm** from walking barefoot in new grass. But when a 28-year-old man was declared **brain-dead** only 3 days after his symptoms first appeared, there was more than the usual cause for concern.

When first admitted to the hospital, the man was mentally altered and highly combative. His symptoms had begun the previous day with a sudden **headache**, **stiff neck**, and **backache**. He was **vomiting** intermittently and on the day of his admission developed a **fever**. Suspecting **meningitis**, doctors performed a **spinal tap**, revealing **cerebrospinal fluid** that was cloudy, indicative of infection. Despite antibiotic treatment, the man was declared brain-dead 2 days after admission. Four months later, a 51-year-old woman from northern Louisiana was admitted to the hospital under similar circumstances, her stay mirroring that of the younger man. She died after 5 days in the hospital.

The Centers for Disease Control and Prevention examined both patients and determined that they died of **primary amebic**

“Despite antibiotic treatment, the man was declared brain-dead 2 days after his admission to the hospital.”

meningoencephalitis (PAM), an exceedingly rare disease caused by infection of the brain with the protozoan ***Naegleria fowleri***.

Sometimes referred to as the “**brain-eating amoeba**,” for the widespread destruction of brain tissue it causes, *N. fowleri* is commonly found in warm lakes and rivers in the southern United States, especially during the summer months. Infection begins when the amoeba enters the nose while swimming, diving, or even simply ducking underwater. From there, it migrates along the **olfactory nerve** to the brain, initiating disease in which death is a virtual certainty.

Why such a commonly encountered pathogen results in so few infections—32 cases since 2002—is not known.

- Why doesn't *Naegleria fowleri* cause infection when it is swallowed?
- What precautions do you think have been recommended to prevent infection with *N. fowleri*?

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

23.1 The Parasites of Humans

Expected Learning Outcome

1. Describe the changing epidemiology of parasitic disease.

Parasitology is traditionally the study of eukaryotic parasites. It encompasses protozoa (unicellular animal-like organisms) and helminths (worms), which are sometimes collectively called the macroparasites, as opposed to the microparasites (bacteria and viruses). This inherently fascinating and practical subject will be presented as a compact survey of the major clinically important protozoa, helminths, and some of the arthropod vectors. This chapter covers elements of their morphology, life cycles, epidemiology, pathogenic mechanisms, and methods of control. Arthropods, which are often included in the field of parasitology, are discussed as vectors for parasitic, bacterial, and viral infections.

One cannot underestimate the impact of parasites on the everyday lives of humans. The World Health Organization (WHO) estimates that parasites cause nearly 20% of all infectious diseases. We were first introduced to the parasitic diseases in chapter 5 and its Case Study. Many of these are considered a type of neglected tropical disease; such diseases afflict at least 20% of the people on earth. Although these diseases are less prevalent in industrialized countries, most humans will, at some point in their lives, have some form of parasite infection, in hidden or overt form. The distribution of parasitic diseases is influenced by many factors, including travel, immigration, and the increased number of immunocompromised patients. Because parasites can literally travel around the world, it is not uncommon to discover exotic parasitic diseases even in the United States.

The current increase in patients with severe immune suppression is changing the epidemiological pattern of parasitic diseases. AIDS patients in particular play host to a variety of opportunists that dominate their clinical picture. More and more, parasites are emerging as the agents of life-threatening diseases.

Check Your Progress SECTION 23.1

1. How do travel, immigration, and AIDS all affect the epidemiology of parasitic infection?

23.2 Major Protozoan Pathogens

Expected Learning Outcomes

2. Recall the identifying attributes of the four commonly recognized groups of protozoa.
3. Identify the amoebas generally seen as human pathogens and the portals of entry for each.
4. Depict the life cycle seen in *Entamoeba histolytica* infection.
5. Contrast the pathogenesis, treatments, and common outcomes of *Entamoeba*, *Naegleria*, and *Acanthamoeba* infections.
6. Classify and describe the important characteristics of *Balantidium coli*.

The introduction to **protozoa** in chapter 5 described them as single-celled, animal-like microbes, most of which have some form of motility. The four commonly recognized informal groups

Systems Profile 23.1		Parasitic Protozoan Pathogens			
Organism	Skin/Skeletal	Nervous/Muscle	Cardiovascular/ Lymphatic/Systemic	Gastrointestinal	Urogenital
<i>Entamoeba histolytica</i>				Chronic diarrhea dysentery	
<i>Naegleria fowleri</i>		Meningoencephalitis

<i>Toxoplasma gondii</i>		Subacute encephalitis			
<i>Sarcocystis</i> spp.				Acute diarrhea	
<i>Cryptosporidium</i>				Gastroenteritis	
<i>Cyclospora</i> spp.				Acute diarrhea	

are sarcodinians (amoebas that move with pseudopods), ciliates that move with cilia, flagellates that use flagella, and apicomplexans that lack typical organelles for movement.

Of the estimated 100,000 species of protozoans, about 25 are important pathogens of humans (table 23.1). They collectively cause billions of infections worldwide.

Although the life cycles of pathogenic protozoa can vary a great deal, most of them propagate by simple asexual cell division of the active feeding cell, called a **trophozoite**. Many species undergo formation of a **cyst** that can survive for periods outside the host and can also function as an infective body (see figure 5.24). Others have a more complex life cycle that includes asexual and sexual phases (see discussion of apicomplexans in section 23.4) and a variety of host animals.

Drugs used to treat protozoan infections were introduced in chapter 12. There are currently about a dozen different drug types available. Table 23.2 outlines a selection of drugs that target major protozoan parasites along with their general modes of action. Because these drugs target eukaryotic cells and they usually work by disrupting common cell processes, many of them have severe side effects and some of them are quite toxic to human cells.

Infective Amoebas

Entamoeba histolytica and Amebiasis

Amoebas are widely distributed in aqueous habitats and are frequent parasites of animals, but only a few of them have the necessary virulence to invade tissues and cause serious pathology.

The most significant pathogenic amoeba is *Entamoeba histolytica*.* The relatively simple life cycle of this parasite alternates between a large trophozoite that is motile by means of pseudopods and a smaller, compact, nonmotile cyst (see figure 5.24). The trophozoite lacks most of the organelles of other eukaryotes, and it has a large single nucleus that contains a prominent nucleolus called a *karyosome*. Amoebas from fresh specimens are often packed with food vacuoles containing host cells and bacteria. The mature cyst is encased in a thin yet tough wall and contains four nuclei as well as distinctive bodies called *chromatoidals*, which are actually dense clusters of ribosomes.

Epidemiology of Amebiasis Humans are the primary hosts of *E. histolytica*. Infection is usually acquired by ingesting food or drink contaminated with cysts released by an asymptomatic carrier. The cyst form of the amoeba is thought to be carried in the intestine of one-tenth of the world's population, and it kills around 100,000 people a year. Its geographic distribution is partly due to local sewage disposal and fertilization practices. Occurrence is highest in tropical regions (Africa, Asia, and Latin America), where night soil¹ or untreated sewage is sometimes used to fertilize crops, and sanitation of water and food is not always adequate. Although the prevalence of the disease is substantially lower in the United States, as many as 10 million people could harbor the agent asymptotically.

* *Entamoeba histolytica* (en'-tah-mee'-bah his'-toh-lit'-ih-kuh) Gr. *ento*, within, *histos*, tissue, and *lysis*, a dissolution.

1. Human excrement used as fertilizer.

TABLE 23.1 Major Pathogenic Protozoa, Infections, and Primary Sources

Protozoan/Disease*	Organ/System Primarily Affected**	Reservoir/Source
Amoeboid Protozoa		
Amebiasis: <i>Entamoeba histolytica</i>	Gastrointestinal tract	Human/water and food
Brain infection: <i>Naegleria</i> , <i>Acanthamoeba</i>	Nervous system	Free-living in water
Ciliated Protozoa		
Balantidiosis: <i>Balantidium coli</i>	Gastrointestinal tract	Zoonotic in pigs
Flagellated Protozoa		
Giardiasis: <i>Giardia intestinalis</i>	Gastrointestinal tract	Zoonotic/water and food
Trichomoniasis: <i>Trichomonas vaginalis</i>	Urogenital tract	Human
Hemoflagellates		
Trypanosomiasis: <i>Trypanosoma brucei</i> , <i>T. cruzi</i>	Nervous system	Zoonotic/vector-borne
Leishmaniasis: <i>Leishmania donovani</i> , <i>L. tropica</i> , <i>L. brasiliensis</i>	Skin	Zoonotic/vector-borne
Apicomplexan Protozoa		
Malaria: <i>Plasmodium vivax</i> , <i>P. falciparum</i> , <i>P. malariae</i> , <i>P. ovale</i> , <i>P. knowlesi</i>	Cardiovascular system	Human/vector-borne
Toxoplasmosis: <i>Toxoplasma gondii</i>	Nervous system	Zoonotic/vector-borne
Cryptosporidiosis: <i>Cryptosporidium</i>	Gastrointestinal tract	Free-living/water, food
Isosporosis: <i>Cystoisospora belli</i>	Gastrointestinal tract	Dogs, other mammals
Cyclosporiasis: <i>Cyclospora cayetanensis</i>	Gastrointestinal tract	Water/fresh produce

*Many flagellates are named in honor of one of their discoverers: for example, *T. cruzi*, O. Cruz; *Leishmania*, W. Leishman; *donovani*, C. Donovan; *Giardia*, A. Giard; and *brucei*, D. Bruce. Geographic location (*gambiense*, *rhodesiense*, *tropica*, *brasiliensis*, *mexicana*) is another basis for naming. Names are also derived from a certain characteristic of the organism: for example, *vaginalis*, vaginal habitat.

**Although signs and symptoms of infection may often be observed throughout the body, initial infection is often restricted to a single organ or system.

Pathogen Profile #1 *Entamoeba histolytica*

Source: CDC-DPDx

Microscopic Morphology The large trophozoite has a single nucleus with a prominent nucleolus called a karyosome and is often packed with food vacuoles. Mature cysts contain four nuclei, along with dense clusters of ribosomes called chromatoidals.

Identified by Visualization of trophozoites or cysts during microscopic examination of fecal smears; ELISA testing, specific to cells.

Habitat Humans are the primary host for *E. histolytica*. Occurrence is highest in tropical regions—Africa, Asia, and Latin America—where untreated sewage is used to fertilize crops. Prevalence is much lower in the United States but may still encompass 10 million asymptomatic carriers. Cysts are continuously shed in the feces of chronic carriers.

Virulence Factors Hardy cysts; lytic enzymes that promote invasiveness and induce tissue damage.

Primary Infections/Disease Amebiasis begins when ingested cysts undergo excystment in the small intestine. *E. histolytica* secretes enzymes that digest tissue, causing ulcerations of the intestinal mucosa, abdominal pain, fever, diarrhea, and weight loss. More severe infection may cause hemorrhage, appendicitis, and tumorlike growths called amoebomas. Extraintestinal infection may encompass the liver, pulmonary system, and, rarely, the spleen, adrenals, kidney, skin, and brain. Severe forms of the disease have about a 10% mortality rate.

Control and Treatment Control centers on adequate disinfection of water. Because cysts are resistant to levels of chlorine commonly used in water treatment, boiling or iodine treatment of water is required. Amebiasis may be treated with iodoquinol, metronidazole, or paromomycin.

TABLE 23.2 Guidelines for Antiprotozoan Drugs

Infectious Agent	Typical Infection	Drugs of Choice	Mechanism of Drug Action
<i>Entamoeba histolytica</i>	Amebiasis	Metronidazole* Iodoquinol Paromomycin	Specific for anaerobes; inhibits DNA repair Acts locally in intestine; unknown mode of action Inhibits protein syntheses
<i>Giardia intestinalis</i>	Giardiasis	Tinidazole Nitazoxanide	Selectively blocks parasite metabolism Selectively blocks parasite metabolism
<i>Plasmodium</i>	Malaria	Chloroquine Atovaquone-proguanil Mefloquine Artemether	Interferes with metabolism and use of hemoglobin Interferes with parasitic electron transport chain Interferes with metabolism and use of hemoglobin Redox reagent; produces reactive oxygen radicals
<i>Toxoplasma gondii</i>	Toxoplasmosis	Pyrimethamine Sulfadiazine	Together with sulfadiazine, inhibits enzymes in the pathway
<i>Trichomonas vaginalis</i>	Trichomoniasis	Metronidazole	Together with sulfadiazine, inhibits enzymes in the pathway for folate synthesis
<i>Trypanosoma brucei</i>	Sleeping sickness	Suramin Pentamidine Eflornithine Melarsoprol	Inhibits NADH oxidation; blocks aerobic respiration Blocks nucleic acid synthesis Inhibits deamination of amino acids Arsenic-based, very toxic, inhibits many enzymes
<i>Trypanosoma cruzi</i>	Chagas disease	Benznidazole Nifurtimox	Interferes with protein synthesis and microtubule formation Breaks up DNA and creates superoxide radicals

*Metronidazole is also called Flagyl. It is selectively toxic to anaerobic protozoa like *Entamoeba*, *Giardia*, and *Trichomonas*, which lack mitochondria.

Epidemics of amebiasis are infrequent but have been documented in prisons, hospitals, juvenile care institutions, and communities where water supplies were polluted. Amoebic infections can also be transmitted by some forms of sexual contact.

Life Cycle, Pathogenesis, and Control of *E. histolytica* Amebiasis begins when viable cysts are swallowed and arrive in the small

intestine (**figure 23.1**; more detail is shown in figure 5.27), where the alkaline pH and digestive juices of this environment stimulate excystment. The cyst releases four trophozoites (**figure 23.1c**), which are swept into the **cecum*** and large intestine. There the

Process Figure 23.1 Cellular forms of *Entamoeba histolytica*. (a) Simplified view of route of infection, development, and release. (b) A trophozoite containing a single nucleus, a karyosome, and red blood cells. (c) A mature cyst with four nuclei and two blocky chromatoidals. (d) Stages in excystment. Divisions in the cyst create four separate cells, or metacysts, that differentiate into trophozoites and are released.

trophozoites attach by fine pseudopods and multiply, actively moving about and feeding. In about 90% of patients, infection is asymptomatic or very mild, and the trophozoites do not invade beyond the most superficial layer. The severity of the infection can vary with the strain of the parasite, inoculation size, diet, and host resistance.

As hinted by its species name, tissue damage is one of the formidable characteristics of untreated *E. histolytica* infection. Clinical amebiasis exists in intestinal and extraintestinal forms. The initial targets of intestinal amebiasis are the cecum, appendix, colon, and rectum. The amoeba secretes enzymes that dissolve tissues, and it actively penetrates deeper layers of the mucosa, leaving erosive ulcerations (**figure 23.2**). This phase is marked by dysentery (bloody, mucus-filled stools), abdominal pain, fever, diarrhea,

Figure 23.2 Appearance of amebiasis and dysentery lesions of the large intestine. Red erosions are sites of amebic damage to the intestinal mucosa (pointers). Source: CDC

and weight loss. The most life-threatening manifestations of intestinal infection are hemorrhage, perforation, appendicitis, and tumorlike growths called amoebomas.

Extraintestinal infection occurs when amoebas invade the viscera of the peritoneal cavity. The most common site of invasion is the liver. Here, abscesses that contain necrotic tissue and trophozoites cause amebic hepatitis. Another regular complication is pulmonary amebiasis. Less frequent targets of infection are the spleen, adrenals, kidney, skin, and brain. Severe forms of the disease result in about a 10% fatality rate.

Entamoeba is harbored by chronic carriers whose intestines favor the encystment stage of the life cycle. Cyst formation cannot occur in active dysentery because the feces are so rapidly flushed from the body, but after recuperation, cysts are continuously shed in feces.

Initial diagnosis involves microscopic examination of a fecal smear for the presences of trophozoites or cysts typical of *E. histolytica* (**figure 23.3**). More definitive identification can be obtained with a stained smear or with a rapid ELISA test using specific monoclonal antibodies. It may be necessary to supplement laboratory findings with clinical data, including symptoms, X rays, and the patient's history, which might indicate a source of exposure.

Effective treatment for amebic dysentery usually involves the use of drugs such as metronidazole (Flagyl), tinidazole, or paromomycin, or nitazoxanide. Other drugs are given to relieve diarrhea and cramps, while lost fluid and electrolytes are replaced by oral or intravenous therapy. Infection with *E. histolytica* provokes antibody formation against several antigens, but long-term immunity is unlikely and reinfection can occur. Prevention depends upon concerted efforts similar to those for other enteric diseases (see 20.3 Making Connections).

Figure 23.3 Microscopic appearance of *Entamoeba histolytica* in fresh specimen. (a) A trophozoite (20 μm) is filled with its primary nutrient—red blood cells (black spheres). (b) A cyst (12 μm) with three nuclei (black arrows) and a single chromatoidal (red arrow). (a, b): Source: CDC-DPDx

Because regular chlorination of water supplies does not kill cysts, more rigorous methods such as boiling or iodine are required.

Amebic Infections of the Brain

Two common free-living protozoans that cause a rare and usually fatal infection of the brain are *Naegleria fowleri** and *Acanthamoeba* spp.* Both genera are accidental parasites that invade the body only under unusual circumstances. The trophozoite of *Naegleria* is a small, flask-shaped amoeba that moves by means of a single, broad pseudopod (figure 23.4). It forms a rounded, thick-walled, uninucleate cyst that is resistant to temperature extremes and mild chlorination. *Acanthamoeba* has a large, amoeboid trophozoite with spiny pseudopods and a double-walled cyst.

Both *N. fowleri* and *Acanthamoeba* ordinarily inhabit standing fresh or brackish water, lakes, puddles, ponds, hot springs, moist soil, and even swimming pools and hot tubs. They are especially abundant in warm water with a high bacterial count.

Most cases of *Naegleria* infection reported worldwide occur in people who have been swimming in warm, natural bodies of fresh

* *Naegleria fowleri* (nay-gee'-ree-uh fow'-ler-eye) After F. Nagler and N. Fowler.

* *Acanthamoeba* (ah-kan'-thah-mee'-bah) Gr. *acanthos*, thorn.

Figure 23.4 Free-living infective amoebas (a) *Naegleria fowleri* has thick, blunt pseudopods and is filled with food vacuoles. (b) *Acanthamoeba* has spinelike processes extending from its pseudopodia. (a, b): Source: CDC-DPDx

water. Infection can begin when amoebas are forced into human nasal passages as a result of swimming, diving, or other aquatic activities. Once the amoeba is inoculated into the favorable habitat of the nasal mucosa, it burrows in, multiplies, and subsequently migrates into the brain and surrounding structures. The result is primary acute meningoencephalitis, a rapid, massive destruction of brain and spinal tissue that causes hemorrhage and coma and invariably ends in death within a week or so.

Unfortunately, *Naegleria* meningoencephalitis advances so rapidly that treatment usually proves futile. Studies have indicated that early therapy with amphotericin B, sulfadiazine, or tetracycline in some combination can be of some benefit. Because of the wide distribution of the amoeba and its hardiness, no general means of control exists. Public swimming pools and baths must be adequately chlorinated and checked periodically for the amoeba.

Acanthamoeba differs from *Naegleria* in its portal of entry, invading broken skin, the conjunctiva, and occasionally the lungs and urogenital epithelia. Although it causes a meningoencephalitis somewhat similar to that of *Naegleria*, the course of infection is lengthier. At special risk for infection are people with traumatic eye injuries, contact lens wearers, and swimmers in contaminated water. Ocular infections can be avoided by attention to injured eyes and using sterile solutions to store and clean contact lenses.

An Intestinal Ciliate: *Balantidium coli*

Most ciliates are free-living in various aquatic habitats, where they assume a role in the food web as scavengers or as predators upon other microbes. Several species are pathogenic to animals, but only one, *Balantidium** *coli*, occasionally establishes infection in humans. This large ciliate (about the size of a period on this page) exists in both trophozoite and cyst states (figure 23.5). Its surface is covered by orderly, oblique rows of cilia; and a shallow depression, the cytostome (cell mouth), is at one end. These parasites will grow only under anaerobic conditions in the presence of the host's bacterial microbiota.

* *Balantidium* (bal'-an-tid'-ee-um) Gr., a small sac.

Figure 23.5 Microscopic views of *Balantidium coli*. The morphology of a trophozoite and a mature cyst.

Quick Search

To view the deliberate movements of amoebas like *Naegleria fowleri*, search the Internet for "*Naegleria fowleri*."

The large intestine of pigs and, to a lesser extent, sheep, cattle, horses, and primates constitutes the natural habitat of *B. coli*, which are shed as cysts in the feces of these animals. Although pigs are the most common source of *balantidiosis*, it can also be spread by contaminated water and from person to person in institutional settings. Healthy humans and animals are resistant to infection, but compromised hosts are vulnerable to attack.

Like cysts of *E. histolytica*, those of *B. coli* resist digestion in the stomach and small intestine and liberate trophozoites that immediately burrow into the epithelium with their cilia. The resultant erosion of the intestinal mucosa produces varying degrees of irritation and injury, leading to nausea, vomiting, diarrhea, dysentery, and abdominal colic. The protozoan rarely penetrates the intestine or enters the blood. The treatment of choice is oral tetracycline, but if this therapy fails, iodoquinol, nitrimidazine, or metronidazole can be given. Preventive measures are similar to those for controlling amebiasis, with additional precautions to prevent food and drinking water from being contaminated with pig manure.

Check Your Progress SECTION 23.2

- List the four groups into which protozoa are commonly placed, along with the characteristics used to do so.
- Describe the basic pathology of amebiasis. How and where does it invade?
- Provide several behaviors that would increase the chance of contracting *Entamoeba*, *Naegleri*, and *Acanthamoeba* infections.
- Outline the course of typical *Entamoeba*, *Naegleri*, and *Acanthamoeba* infections.
- Relate the life cycle, pathogenesis, and control of *Entamoeba histolytica* to that of *Balantidium coli*.

23.3 The Flagellates (Mastigophorans)

Expected Learning Outcomes

- Describe the important characteristics of *Trichomonas vaginalis* and the pathology of infection.
- Understand the importance of cysts to the transmission of *Giardia*.
- Describe the four developmental stages of hemoflagellates, and identify those stages that are infectious.
- Compare the vectors involved in sleeping sickness, Chagas disease, and leishmaniasis.
- Compare the pathologies of sleeping sickness, Chagas disease, and leishmaniasis.

Pathogenic flagellates play an extensive role in human diseases, ranging from milder or self-limited infections (trichomoniasis and giardiasis) to debilitating and life-threatening, vector-borne diseases (trypanosomiasis and leishmaniasis).

Trichomonads: *Trichomonas* Species

Trichomonads are small, pear-shaped protozoa with four anterior flagella and an undulating membrane, which together produce a

characteristic twitching motility in live preparations. They exist only in the trophozoite form and do not produce cysts. Three trichomonads intimately adapted to the human body are *Trichomonas vaginalis*, *T. tenax*, and *T. hominis* (figure 23.6).

The most important pathogen, *Trichomonas** *vaginalis*, causes a sexually transmitted disease called **trichomoniasis**. The reservoir for this protozoan is the human urogenital tract, and about 70% of infected people are asymptomatic carriers. Because *T. vaginalis* has no protective cysts, it is a relatively strict parasite that does not survive for long out of the host. Transmission is primarily through contact between genital membranes, although it can occasionally be transmitted through communal bathing and public facilities. The incidence of infection is highest among sexually active young women already infected with other sexually transmitted diseases such as gonorrhea or chlamydia. Approximately 7 million new cases of trichomoniasis occur every year in the United States, placing it near the top of the most common STDs.

Symptoms and signs of trichomoniasis in the female include a foul-smelling, green-to-yellow vaginal discharge; vulvitis; cervicitis; and urinary frequency and pain. Severe inflammation of the infection site causes edema, chafing, and itching. Males with overt clinical infections experience persistent or recurring urethritis, with a thin, milky discharge and occasionally prostate infection.

Infection may be preemptively diagnosed by demonstrating the active swimming trichomonads in a wet film of exudate, but

* *Trichomonas* (trik'-oh-moh'-nus) Gr. *thrix*, hair, and *monas*, unit.

Figure 23.6 The trichomonads of humans. (a) *Trichomonas vaginalis*, a urogenital pathogen. (b) Micrograph at 500 \times . (c) *T. tenax*, a gingival form (infection is rare). (d) *T. hominis*, an intestinal species (infection is rare). (b): © David M. Phillips/Science Source

culture of the parasite is the gold standard. A number of commercial serological and DNA amplification techniques exist for detection of the parasite. The infection has been successfully treated with oral and vaginal metronidazole, and it is essential to treat both sex partners to prevent “ping-pong” reinfection.

Giardia intestinalis and Giardiasis

*Giardia intestinalis** is a pathogenic, flagellated protozoan first observed by Antonie van Leeuwenhoek in his own feces. For 200 years, it was considered a harmless or weak intestinal pathogen, and only since the 1950s has its prominence as a cause of diarrhea been recognized. In fact, it is the most common flagellate isolated in clinical specimens. Observed straight on, the trophozoite has a unique, symmetrical heart shape with organelles positioned in such a way that it resembles a face (figure 23.7a,b). Four pairs of flagella emerge from the ventral surface, which is concave and acts

* *Giardia intestinalis* (jee'-ard-ee-uh in-tes'-Ti-n'a'lis) Also called *G. lamblia*.

(b) Stained example of trophozoite from a specimen (1,000 \times). The nuclei are evident but flagella are less observable. (c) A DNA probe test uses FISH (fluorescent in situ hybridization) technology to differentiate *Giardia* species using colored dyes. *G. intestinalis* glows blue, whereas *G. muris* glows green. In both forms, the cyst wall antigens are shown in red. (b): © Donald Lehman, Dept. of Medical Laboratory Sciences, University of Delaware; (c): Courtesy Stanley Erlandsen

like a suction cup for attachment to a substrate. *Giardia* cysts are small, compact, and multinucleate (figure 23.7a).

Giardiasis (gee'-ar-dy'-uh-sis) has a complex epidemiological pattern. The protozoan has been isolated from the intestines of beavers, cattle, coyotes, cats, and human carriers, all of which may serve as reservoirs. Although both trophozoites and cysts escape in the stool, the cysts play a greater role in transmission. Unlike other pathogenic flagellates, *Giardia* cysts can survive for 2 months in the environment. Cysts are usually ingested with water and food or swallowed after close contact with infected people or contaminated objects. Infection can occur with a dose of only 10 to 100 cysts.

Reported cases of giardiasis for 2015 were 11,665, a slight decrease compared to the previous few years, and only a fraction of the actual number of cases. The best estimate for the incidence of giardiasis is 1.2 million cases per year. There are several possible modes of transmission. *Giardia* epidemics have been traced to water from fresh mountain streams as well as chlorinated municipal water supplies in several states. Infections can occur in hikers and campers who used what they thought was clean water from sources in remote mountain areas. Because wild mammals such as muskrats and beavers are intestinal carriers, they could account for cases associated with drinking water from these sources. Obviously, checking water for purity with the naked eye is unreliable, because the cysts are too small to be detected.

Cases of food-borne illness have been traced to carriers who contaminate food through unclean personal habits. Day care centers have reported outbreaks associated with diaper changing and contact with other types of fomites. *Giardia* is also a well-known cause of traveler's diarrhea, which sometimes does not appear until the person has returned home.

Ingested *Giardia* cysts enter the duodenum, germinate, and travel to the jejunum to feed and multiply. Feeding trophozoites damage the epithelial cells causing edema and infiltration by white blood cells, but these effects are reversible. Typical symptoms include diarrhea, abdominal pain, and flatulence, lasting a few weeks.

Diagnosis of giardiasis can be difficult because the organism is not shed constantly in the feces. New developments include a promising DNA assay for detection of the cysts in samples (figure 23.7c) and a rapid screening test that differentiates *Giardia* from another parasite, *Cryptosporidium*, in stool samples. The infection can be eradicated with tinidazole or metronidazole therapy.

Giardia has forced many water agencies have had to rethink their policies on water maintenance and testing. The agent is killed by boiling, ozone, and iodine, but, unfortunately, the amount of chlorine used in municipal water supplies does not destroy the cysts. People who must use water from remote sources should assume that it is contaminated and take measures to disinfect it.

Hemoflagellates: Vector-Borne Blood Parasites

Other parasitic flagellates are called *hemoflagellates* because of their propensity to live in the blood and tissues of the human host. Members of this group, which include species of *Trypanosoma** and *Leishmania*, have several distinctive characteristics in common. They are obligate parasites that cause life-threatening and

* *Trypanosoma* (try-pan'-oh-soh-mah) Gr. *trypanon*, borer, and *some*, body.

TABLE 23.3 Cellular and Infective Stages of the Hemoflagellates

Genus/Species	Amastigote	Promastigote	Epimastigote	Trypomastigote
				
<i>Leishmania</i>	Intracellular in human macrophages	Found in sand fly gut; infective to humans	Does not occur	Does not occur
<i>Trypanosoma brucei</i>	Does not occur	Does not occur	Present in salivary gland of tsetse fly	In biting mouthparts of tsetse fly; infective to humans
<i>Trypanosoma cruzi</i>	Intracellular in human macrophages, liver, heart, spleen	Occurs	Present in gut of reduviid (kissing) bug	In feces of reduviid bug; transferred to humans

debilitating zoonoses; they are spread by blood-sucking insects that serve as intermediate hosts; and they are acquired in specific tropical regions. Hemoflagellates have complicated life cycles and undergo morphological changes as they pass between vector and human host. To keep track of these developmental stages, parasitologists have adopted the following set of terms:

amastigote (ay-mas'-tih-goht) Gr. *a-*, without, and *mastix*, whip.

The form lacking a free flagellum.

promastigote (proh-mas'-tih-goht) Gr. *pro-*, before. The stage bearing a single, free, anterior flagellum.

epimastigote (ep'-ih-mas'-tih-goht) Gr. *epi-*, upon. The flagellate stage, which has a free anterior flagellum and an undulating membrane.

trypomastigote (trih'-poh-mas'-tih-goht) Gr. *trypanon*, auger. The large, fully formed stage characteristic of *Trypanosoma*.

These stages suggest an evolutionary transition from the simple, nonmotile amastigote form to the highly complex trypomastigote form. All four stages are present in *T. cruzi*, but *T. brucei* lacks the amastigote and promastigote forms, and *Leishmania* has only the amastigote and promastigote stages (**table 23.3**). In general, the vector host serves as the site of differentiation for one or more of the stages, and the parasite is infectious to humans only in its fully developed stage.

Trypanosoma Species and Trypanosomiasis

Trypanosoma species are distinguished by their infective stage, the trypomastigote, an elongate, spindle-shaped cell with tapered ends that is capable of eel-like motility. Two types of trypanosomiasis are distinguishable on a geographic basis. *Trypanosoma brucei* is the agent of African sleeping sickness, and *T. cruzi* is the cause of Chagas disease, which is endemic to the Americas. Both exhibit a biphasic lifestyle alternating between a vertebrate and an insect host.

Trypanosoma brucei and Sleeping Sickness

Trypanosomiasis has greatly affected the living conditions of Africans since ancient times. Today, at least 50 million people are at risk, and 7,000 to 10,000 cases are reported yearly. It imposes an additional

hardship when it attacks domestic and wild mammals. Two subspecies of *Trypanosoma brucei* exist, each of which is responsible for a distinct form of the disease. The Gambian (West African) form is caused by the subspecies *T. b. gambiense*, and the Rhodesian (East African) form is caused by *T. b. rhodesiense* (**figure 23.8a**). These geographically isolated forms of the disease are associated with different ecological niches of the principal tsetse fly vectors (genus *Glossina*). In the West African form, the fly inhabits the dense vegetation along rivers and forests typical of that region, whereas the East African form is adapted to savanna woodlands and lakefront thickets.

The cycle begins when a tsetse fly becomes infected after feeding on an infected reservoir host, such as a wild animal (antelope, lion, hyena), domestic animal (cow, goat), or human (**figure 23.8c**). In the fly's gut, the trypanosome multiplies, migrates to the salivary glands, and develops into the infectious stage. When the fly bites its host, it releases trypomastigotes into the wound. At this site, the trypanosome multiplies and produces a sore called the primary chancre. From there, the pathogen moves into the lymphatics and the blood (**figure 23.8b**).

Although an immune response occurs, it is counteracted by an unusual adaptation. The trypanosome has a genetic program that regulates constant change in its surface antigens over the course of the infection. This may give rise to at least 100 different antigens, which prevents a lasting immunity. The result is a long-term, uncontrolled infection. The Rhodesian form is acute and advances to brain involvement in 3 to 4 weeks and to death in a few months. The Gambian form, on the other hand, has a longer incubation period, is usually chronic, and may not affect the brain for several years.

Trypanosomiasis involves the lymphatics and areas surrounding blood vessels. Early symptoms include intermittent fever, enlarged spleen, swollen lymph nodes, and joint pain. In time the central nervous system is affected, the initial signs being personality and behavioral changes that progress to lassitude and sleep disturbances. The disease is commonly called sleeping sickness, but in fact, uncontrollable sleepiness occurs primarily in the day and is followed by sleeplessness at night. Signs of advancing neurological deterioration are muscular tremors, shuffling gait, slurred speech, seizures, and local paralysis. Death results from coma, secondary infections, or heart damage.

(a) The distribution of African trypanosomiasis

Figure 23.8 The generalized cycle between humans and the tsetse fly vector. Image by Piotr Rotkiewicz

Sleeping sickness may be suspected if the patient has been bitten by a distinctive fly while living or traveling in an endemic area. Trypanosomes are readily demonstrated in the blood, spinal fluid, or lymph nodes. An immunologic test—the card agglutination test for *Trypanosoma* (CATT)—is a rapid field assay that detects antibodies to the pathogen.

Chemotherapy is most successful if administered prior to nervous system involvement. Brain infection must be treated with the highly toxic drugs melarsoprol or suramin. A less toxic alternative is eflornithine. Several drug companies operating with the WHO have made these drugs available to all patients diagnosed with this disease.

Control of trypanosomiasis in western Africa, where humans are the main reservoir hosts, involves eliminating tsetse flies by applying insecticides, trapping flies, or destroying shelter and breeding sites. In eastern regions, control is less practical because large mammals are the hosts, and flies are less concentrated in specific sites.

Trypanosoma cruzi and Chagas Disease

Chagas disease accounts for 12 million to 19 million cases, thousands of deaths, and untold economic loss and human suffering in Latin America. The life cycle of its etiologic agent, *Trypanosoma cruzi* (see figure 5.26), parallels that of *T. brucei*, except that the insect hosts are “kissing,”² or **reduviid, bugs** (genus *Triatoma*) that harbor the trypanosome in the hindgut and discharge it in feces. These bugs live in numerous areas of Central and South America and may extend to the southern parts of the United States (**figure 23.9**). They often share the living quarters of human and mammalian hosts. Infection occurs when the bug bites a person, often near the corners of the eyes or mouth, and immediately defecates. The human inoculates this wound by accidentally rubbing the bug feces into it. Infection is also possible when bug feces fall onto the mucous membranes or conjunctiva, through contact with blood, and across the placenta. The course of the illness is somewhat

2. This nickname arises from the bug’s tendency to bite the corner of the mouth.

Figure 23.9 American trypanosomiasis (Chagas disease).

(a) Simplified view of disease transmission cycle. A reduviid bug infected with *Trypanosoma cruzi* carries the trypomastigote stage of the parasite in its feces. This is passed to humans, or other mammals, when the bug takes a blood meal. Trypomastigotes transform into amastigotes and multiply within infected tissues, causing symptoms of Chagas disease. When a reduviid bug bites an infected human, amastigotes pass from the human to the bug, completing the cycle.

similar to African trypanosomiasis, marked by a local lesion (Romaña's sign), fever, and swelling of the lymph nodes, spleen, and liver (**figure 23.10a**). Particular targets are the heart muscle and large intestine, both of which harbor masses of amastigotes. The infection of these organs causes enlargement and severe disruption in function (**figure 23.10b**). Chronically infected people account for 30% to 40% of heart disease in endemic regions.

Diagnosis of Chagas disease is made through microscopic examination of blood and serological testing. Although treatment is sometimes attempted with two drugs, nifurtimox and benznidazole, they are not effective if the disease has progressed too far, and they have damaging side effects. It has been shown that the prevalence of Chagas disease can be reduced both by controlling the reduviid bugs that carry the trypanosome as well as by controlling the rodent population that often serves as hosts for the insect vector. Insecticides are of some benefit, but the bugs are very tough and capable of resisting doses that readily kill flies or mosquitoes. Mass collections of reduviid bugs and housing improvements to keep them out of human dwellings have also been effective. Of concern to the Centers for Disease Control and Prevention (CDC) are recent cases of Chagas disease in Texas, indicating a possible change in vector range (**23.1 Making Connections**). There is also greater possibility of the pathogen in donated blood, necessitating increased screening for it.

Leishmania Species and Leishmaniasis

Leishmaniasis is a zoonosis transmitted among various mammalian hosts by female **phlebotomine*** flies (sand flies) that require a blood meal to produce mature eggs. *Leishmania* species have

* *phlebotomine* (flee-bot'-oh-meen) Gr. *phlebo*, vein, and *tomos*, cutting. So called because they feed on blood.

adapted to the insect host by timing their own development with periods of blood-taking (**figure 23.11**). The protozoa enter the fly's gut and then multiply and differentiate into promastigotes that migrate to the proboscis of the fly.

Leishmaniasis is endemic to equatorial regions that provide conditions for sand flies to complete their life cycle. Approximately 2 million new cases occur every year. The disease can be transmitted by over 50 species of sand flies; other reservoirs are wild and domesticated animals, especially dogs. Although humans are usually accidental hosts in the epidemiological cycle, the flies freely feed on humans. At particular risk are travelers or immigrants who have never had contact with the parasite and lack specific immunities.

Leishmania infection begins when an infected fly injects promastigotes while feeding. Inside macrophages, the parasite converts to an amastigote and multiplies. The manifestations of the disease vary with the fate of the macrophage. If they remain fixed, the infection stays localized in the skin or mucous membranes, but if the infected macrophages migrate, systemic disease occurs.

Cutaneous leishmaniasis (oriental sore, Baghdad boil) is a localized infection of the capillaries of the skin caused by *L. tropica* in certain Mediterranean, African, and Indian regions and by *L. mexicana* in Latin America. A single small, red papule occurs at the site of the bite and spreads laterally into a large ulcer (**figure 23.11c**). A form of leishmaniasis called espundia (caused by *L. brasiliensis*) is endemic to parts of Central and South America. It affects both the skin and mucous membranes of the head. After the skin ulcer heals, the protozoa can settle into a chronic infection of the nose, lips, palate, gingiva, and pharynx that is very disfiguring.

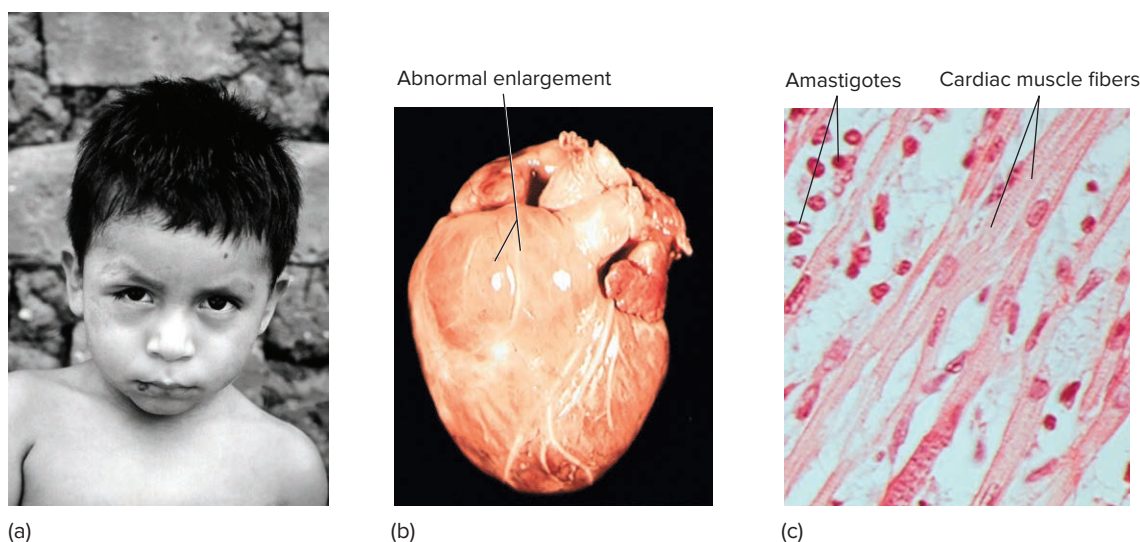

Figure 23.10 Conditions associated with Chagas disease. (a) A sign of acute infection is Romaña's sign—swelling of the eye or mouth at the entry point for the pathogen. (b) Heart pathology in chronic disease: Ventricles show abnormal swelling and enlargement. (c) Section of heart muscle with amastigotes filling the spaces between muscle fibers. Figure 23.11 The life cycle and pathology of *Leishmania* species. (a) Humans and other mammals harbor the amastigote stage in the vascular organs. This stage is infectious to sand flies, which acquire it while feeding on infected blood. After development in the sand fly gut, promastigote forms are injected into another mammalian host, and a second round of development is initiated. (b) Image of feeding sand fly. (c) View of a sore or ulcer developing on the skin of the hand. (b) © www.raywilsonbirdphotography.co.uk; (c): Source: CDC

Systemic (visceral) leishmaniasis that occurs in parts of Africa, Latin America, and China appears gradually after 2 to 18 weeks. It presents with a high, intermittent fever; weight loss; and enlargement of internal organs, especially the spleen, liver, and lymph nodes. The most deadly form, *kala azar*, is 75% to 95% fatal in untreated cases. Death is due to the destruction of blood-forming tissues, anemia, secondary infections, and hemorrhage.

Diagnosis is complicated by the similarity of leishmaniasis to several granulomatous bacterial and fungal infections. The organism can usually be detected in the cutaneous lesion or in the bone marrow during visceral disease. Additional tests include cultivating the parasite, serological tests, and leishmanin skin testing. Chemotherapy with injected pentostam or glucantime is usually effective, though it has toxic side effects. Some disease prevention has been achieved by applying insecticides and eliminating sand fly habitats. Vaccines for both humans and dogs are currently under development.

23.1 MAKING CONNECTIONS

Who's on Your Money?

Check your wallet. George Washington is on the one, Alexander Hamilton on the ten, if you're lucky enough to have a hundred, Benjamin Franklin. Good choices all. Statesmen, presidents, inventors. The question you should be asking yourself at this point in your study of microbiology is, of course, "Why are there no microbiologists on my money?" Well, for that you'd have to take a look at the Brazilian 10,000 Cruzado note, which sports a likeness of none other than Carlos Chagas on the front.

Chagas was physician and microbiologist in the early 1900s in Brazil, where he spent most of his time combating outbreaks of malaria. On one of these assignments in the riverside city of Lassance he studied the behavior of the large bloodsucking reduviid bug—commonly called a kissing bug in deference to its habit of biting the faces of its victims each night in search of a blood meal. Chagas discovered that the bug carried in its intestines a flagellated protozoan that he named *Trypanosoma cruzi*, after his mentor Oswaldo Cruz. He went on to show that the parasite could be spread through the bite of a bug, and that those bitten displayed a specific collection of signs and symptoms, especially swelling of the heart muscle. His work was recognized as one of the great achievements in parasitology, and he was twice nominated for the Nobel Prize in Physiology or Medicine.

Even more interesting than Chagas' face on the right side of the bill, though, is the life cycle of *Trypanosoma cruzi* on the left side. The reduviid bug is shown defecating into an open wound (caused by its own bite), releasing the parasite into the blood supply where it can encyst within the muscle of the heart. A second break in the skin shows the parasite reentering a reduviid bug, infecting a new vector and completing the life cycle. More information than you'd expect to find on your money. But there's more. Look at the back of your bills. The White House, the U.S. Treasury, the U.S. Capitol. Important places where important work took place. What's on the backside of the 10,000 Cruzado? Carlos Chagas' laboratory, of course.

100 years after the discovery of *Trypanosoma cruzi*, 8 million people in Mexico, Central America, and South America are infected with the parasite and 12,000 people a year will die of the disease.

23.4 Apicomplexan Parasites

Expected Learning Outcomes

12. Recall the most important apicomplexan parasites.
13. Explain the endemic occurrence of malaria.
14. Diagram the life cycle of *Plasmodium*.
15. Describe the pathogenesis of malaria.
16. Explain the strategies used to combat malaria.
17. Describe the life cycle of *Toxoplasma gondii*.
18. Explain the occasional presence of *Cryptosporidium* in domestic water sources.
19. Relate *Sarcocystis*, *Cystoisospora*, *Cyclospora*, and *Babesia* to their specific route of infection.

Among the most unusual protozoa are the apicomplexans. These tiny parasites live in a variety of animal hosts. They are distinct from

other protozoans in lacking well-developed locomotor organelles in the trophozoite state, though some forms do have a flexing, gliding form of locomotion, and others have flagellated sex cells. They are also notable for living as intracellular pathogens in host cells. Characteristics of the apicomplexan life cycle that add greatly to their complexity are alternations between sexual and asexual phases and between different animal hosts. Most members of the group also form specialized infective bodies that are transmitted by vectors, food, water, or other means, depending on the parasite. The most important human pathogens belong to *Plasmodium* (malaria), *Toxoplasma* (toxoplasmosis), and *Cryptosporidium* (cryptosporidiosis).

Plasmodium: The Agent of Malaria

Throughout human history, including prehistoric times, malaria has been one of the greatest afflictions, in the same ranks as bubonic plague, influenza, and tuberculosis. Even now, as the dominant protozoan disease, it threatens 40% of the world's population every year. The origin of the name is from the Italian words *mal*, bad, and

aria, air. The superstitions of the Middle Ages explained that evil spirits or mists and vapors arising from swamps caused malaria, because many victims came down with the disease after this sort of exposure. Of course, we now know that a swamp was mainly involved as a habitat for the mosquito vector.

The agent of malaria is an obligate intracellular sporozoan in the genus *Plasmodium*, which contains five species: *P. malariae*, *P. vivax*, *P. falciparum*, *P. ovale*, and *P. knowlesi*. The human and some primates are the primary vertebrate hosts for these species, which are geographically separate and show variations in the pattern and severity of disease. All forms are spread primarily by the female *Anopheles* mosquito and occasionally by shared needles, blood transfusions, and from mother to fetus. The detailed study of malaria is a large and engrossing field that is far too complicated for this text. We cover only the general aspects of its epidemiology, life cycle, and pathology.

Epidemiology and Events in Plasmodium Infection

Although malaria was once distributed throughout most of the world, the control of mosquitoes in temperate areas has successfully restricted it mostly to a belt extending around the equator (figure 23.12). Despite this achievement, approximately 200 million new cases are still reported each year, about 90% of them in Africa. The most frequent victims are children and young adults, of whom at least 650,000 die annually. The reported cases in the United States, generally 1,000 to 2,000 new cases a year, are mainly in new immigrants.

Life Cycle Development of the malarial parasite is divided into two distinct phases: the asexual phase, carried out in the human, and the sexual phase, carried out in the mosquito (figure 23.13). The asexual phase and infection begin when an infected female *Anopheles* mosquito injects saliva containing anticoagulant into the capillary in preparation for taking a blood meal. In the process, she inoculates the blood with spindle-shaped, asexual cells called **sporozoites**.* The sporozoites circulate through the body and gravitate to the liver in a short time. Within liver cells, the sporozoites undergo asexual division called **schizogony**,* which generates

* *sporozoites* (spor-oh-zoh-eyetz') Gr. *sporo*, seed, and *zoon*, animal.

* *schizogony* (shizz'-aw-gon-ee). Gr. *schizo*, to divide, and *gone*, seed. Multiple division of the nucleus, followed by division of the cytoplasm.

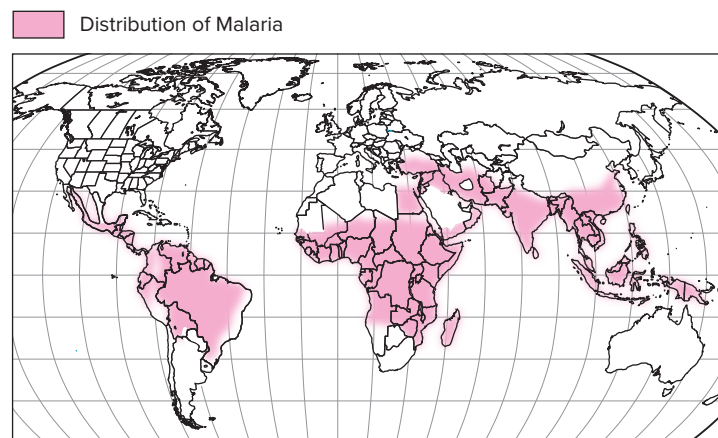

Figure 23.12 The malaria belt. Pink zones outline the major regions that harbor malaria. The malaria belt corresponds to a band around the equator.

numerous daughter parasites, or **merozoites**. This phase of *exoerythrocytic development* lasts from 5 to 16 days, depending upon the species of parasite. Its end is marked by eruption of the liver cell, which releases from 2,000 to 40,000 mature merozoites into the circulation.

During the *erythrocytic phase*, merozoites invade red blood cells (RBCs) and convert in a short time to circular (ring) trophozoites. This stage feeds upon hemoglobin, grows, and undergoes multiple divisions to produce a cell called a *schizont*, which is filled with more merozoites. Bursting red cells liberate merozoites to infect more red cells. Eventually, certain merozoites differentiate into two types of specialized gametes called *macrogametocytes* (female) and *microgametocytes* (male). Because the human does not provide a suitable environment for the next phase of development, this is the end of the cycle in humans.

The sexual phase (sporogony) results when a mosquito draws infected RBCs into her stomach, where fertilization occurs. The resultant diploid cell (oocyst) implants into the stomach wall of the mosquito and forms sporozoites that lodge in the salivary glands. This event completes the sexual cycle and makes the sporozoites available for infecting the next human host.

Pathogenesis After a 10- to 16-day incubation period, symptoms of malaise, fatigue, vague aches, and nausea are followed by bouts of chills, fever, and sweating. These symptoms occur at 48- or 72-hour intervals, as a result of the synchronous rupturing of RBCs. Their interval, length, and regularity reflect the type of malaria. Patients with falciparum malaria, the most malignant type, often manifest persistent fever, cough, and weakness for weeks without relief. Complications of malaria are hemolytic anemia from lysed blood cells and organ enlargement and rupture due to cellular debris that accumulates in the spleen, liver, and kidneys. Falciparum malaria has the highest death rate in the acute phase, especially in children. Certain kinds of malaria are subject to relapses because some infected liver cells harbor dormant infective cells for up to 5 years.

Some populations are naturally resistant to *Plasmodium* infection. One dramatic example occurs in Africans who carry one copy of the gene that codes for sickle-cell hemoglobin. Although such genetic carriers are relatively healthy, they produce some abnormal RBCs that prevent the parasite from deriving sufficient nutrition to multiply. The continued existence of sickle-cell anemia in these geographic areas can be directly attributed to the increased survival of these carriers.

Diagnosis and Control of Malaria

Malaria can be diagnosed definitively by the discovery of a typical stage of *Plasmodium* in stained blood smears (see figure 23.13). Several rapid malaria tests have been developed to detect the parasite in early stages of the infection. Other indicators are the patient's residence or travel in endemic areas and symptoms such as recurring chills, fever, and sweating.

The world's health communities once hoped to decrease the impact of malaria and possibly even eradicate it. This goal has had many setbacks. In fact, malaria is on the rise in some regions. The reasons for this failure involve the sheer adaptive and survival capacity of both the parasite and the vector. Standard chemotherapy regimens have selected for drug-resistant strains of the malarial parasite, and mosquitoes have developed resistance to some common insecticides used to control them.

Process Figure 23.13 The life and transmission cycle of *Plasmodium*, the cause of malaria. Courtesy of Stephen B. Aley, PhD, Univ. of Texas at El Paso

Most current treatments for malaria are based on some form of quinine drug. All of the drugs in this class are toxic to the parasite by preventing it from processing hemoglobin in its food vacuoles. This results in an accumulation of waste products and cell death. Chloroquine is the drug of choice in areas of the world where resistance is not a problem. In areas of the world where resistant forms predominate, a course of malarone is used. Artemisinin-based combination therapy (ACT) is the latest salvo in the malaria wars. It combines two drugs with different metabolic targets in a single pill to allow for shorter—and therefore more likely to be completed—treatment cycles, while also slowing the development of drug resistant strains of *Plasmodium*. Coartem, an ACT drug combining lumefantrine and artemether (a derivative of artemisinin), was

approved by the Food and Drug Administration for the treatment of uncomplicated malaria in 2009. The importance of the discovery and development of artemisinin was emphasized when the 2015 Nobel Prize in Physiology or Medicine was awarded to Youyou Tu for her work in the field.

Malaria prevention is attempted through long-term mosquito abatement and human prophylaxis. This includes elimination of water that could serve as a breeding site and broadcasting of insecticides to reduce populations of adult mosquitoes, especially near human dwellings.

Microscopic Morphology Each stage of the *Plasmodium* life cycle has a unique morphology, with the circular ring trophozoite stage, seen within the erythrocytes of infected persons, being the most recognizable.

Identified by The presence of any stage of the *Plasmodium* life cycle within stained blood smears offers definitive diagnosis, as does serological testing. Preliminary diagnosis is often based on residence in or travel to endemic areas, along with such symptoms as recurring chills, fever, or sweating.

Habitat Humans are the primary vertebrate hosts of the five species of *Plasmodium* that cause malaria, whereas the female *Anopheles* mosquito serves as a biological vector in the spread of the disease.

World regions that harbor malaria cluster near the equator, with 90% of new cases occurring in Africa.

Virulence Factors Multiple stages to the life cycle and multiple antigenic types enhance virulence of all species.

Primary Infections/Disease Symptoms of malaria appear after a 10- to 16-day incubation period and begin with malaise, fatigue, aches, and nausea, and then proceed to bouts of chills, fever, and sweating. These symptoms occur at 48- to 72-hour intervals and correspond to the synchronous rupture of red blood cells. *P. falciparum* produces the most severe symptoms, and patients suffering from this type of malaria may manifest uninterrupted fever, cough, and weakness for many weeks. Complications of malaria include hemolytic anemia from lysed red blood cells and organ enlargement and rupture due to cellular debris, which accumulates in the spleen, liver, and kidneys.

Control and Treatment Vector control is key to the prevention of malaria, with elimination of mosquito breeding sites and use of insecticide-laced bed nets both playing important roles. Prophylactic drugs include atovaquone/proguanil, chloroquine, mefloquine, and artemether/lumefantrine, among others, and these same drugs can be used to treat active disease.

Researchers are in the early stages of producing genetically altered mosquitoes that are immune to the malarial parasite. The immune insects can then be released in large numbers where they will mate with wild mosquitoes, spreading the resistance gene. The hope is to one day make mosquitoes resistant to the parasite without eradicating the insect (which would leave a void in the ecosystem that perhaps would be filled by something even worse). In the meantime, humans can reduce their risk of infection considerably by the following:

- using bed nets treated with insecticides, screens, and repellents (**figure 23.14**);
- remaining indoors at night; and
- taking weekly doses of prophylactic drugs such as atovaquone/proguanil (Malarone), doxycycline, or chloroquine.

People with a recent history of malaria must be excluded from blood donation. Even with massive efforts undertaken by the Roll Back Malaria initiative, the prevalence of malaria in endemic areas remains high.

Malaria and Its Elusive Vaccine

Several animal and human models have proved that effective vaccination for malaria is possible, but a practical vaccine has proved more difficult to develop. The problems arise from the four different species each having different sporozoite, merozoite, and gametocyte stages. In addition, each species can also have different antigenic types of sporozoites and merozoites. A sporozoite vaccine would prevent liver infection, whereas a merozoite vaccine would prevent infection of red blood cells. The best vaccines would

provide long-term protection against all the phases and variants so that if one immunity were to fail, another could come into play.

The most advanced vaccine currently in development is RTS,S, targeted exclusively against *Plasmodium falciparum*. In late 2015 the vaccine received a favorable recommendation from the World Health Organization, based on its phase III clinical trials, which indicated a 30% to 40% reduction in malaria among those receiving the vaccine. Targeted at the exoerythrocytic phase of the *P. falciparum*, the vaccine is designed to prevent the parasite from infecting the liver where it can

Figure 23.14 Insecticide treated bed nets (ITNs). *Anopheles* mosquitoes that spread malaria feed between dusk and dawn. Sleeping under a net treated with insecticide prevents mosquito bites during the night. If enough households are protected with netting, the number of mosquitoes, as well as their life span, is reduced, protecting even those members of the community not shielded by nets. © Andy Crump, TDR, World Health Organization/Science Source

mature, multiply, and re-enter the bloodstream. A larger pilot study—400,000 to 800,000 people in 3 to 5 locations— is currently being planned, so that any long-term effects of the drug can be studied.

Coccidian Parasites

The Order Coccidiorida of the Apicomplexa contains a number of members that are zoonotic in domestic mammals and birds and can cause severe disease in humans. These unusual protozoans exist in several stages, including dormant oocysts and pseudocysts.

Toxoplasma gondii and Toxoplasmosis

*Toxoplasma gondii** is an intracellular apicomplexan parasite with an extensive global distribution, leading some experts to speculate that it infects the majority of the world's population at some time in their lives. In most cases toxoplasmosis is asymptomatic or mild, however disease can be severe and even terminal in fetuses and in immunodeficient patients, especially those with AIDS. *Toxoplasma gondii* is a highly successful parasite with so little host specificity that it can attack at least 200 species of birds and mammals. Studies have traced its primary reservoir and hosts to members of the feline family, both domestic and wild, and their rodent prey.

To follow the transmission of toxoplasmosis, we must look at the general stages of *Toxoplasma*'s life cycle in the cat (figure 23.15a). The parasite undergoes a sexual phase in the intestine and is then released in feces, where it becomes an infective oocyst that survives in moist soil for several months. Ingested oocysts release an invasive asexual tissue phase called a tachyzoite that infects many different tissues and often causes disease in the cat. Eventually these forms enter a cyst state in tissues, called a pseudocyst. The parasite does not cycle in cats alone and is spread by oocysts to intermediate hosts, usually rodents and birds. The cycle returns to cats when they eat these infected prey animals.

Other vertebrates become a part of this transmission cycle (figure 23.15b). Herbivorous animals such as cattle and sheep ingest oocysts that persist in the soil of grazing areas and then develop pseudocysts in their muscles and other organs. Carnivores such as canines are infected by eating pseudocysts in the tissues of carrier animals.

Humans appear to be constantly exposed to the pathogen. The rate of prior infection, as detected through serological tests, can be as high as 90% in some populations. Many cases are caused by ingesting pseudocysts in raw or undercooked meat, which is customary fare in certain ethnic foods, such as raw spiced beef, raw pork, and ground lamb. The grooming habits of cats spread fecal oocysts on their body surfaces, and unhygienic handling of them presents an opportunity to ingest oocysts. Infection can also occur when tachyzoites cross the placenta to the fetus.

Most cases of toxoplasmosis are asymptomatic or marked by mild symptoms such as sore throat, lymph node enlargement, and low-grade fever. In patients whose immunity is suppressed by infection, cancer, or drugs, the outlook is grim. Chronic, persistent *Toxoplasma* infection can produce extensive brain lesions and can create fatal disruptions of the heart and lungs. A pregnant woman with toxoplasmosis has a 33% chance of transmitting the infection to her fetus. Congenital infection occurring in the first or second

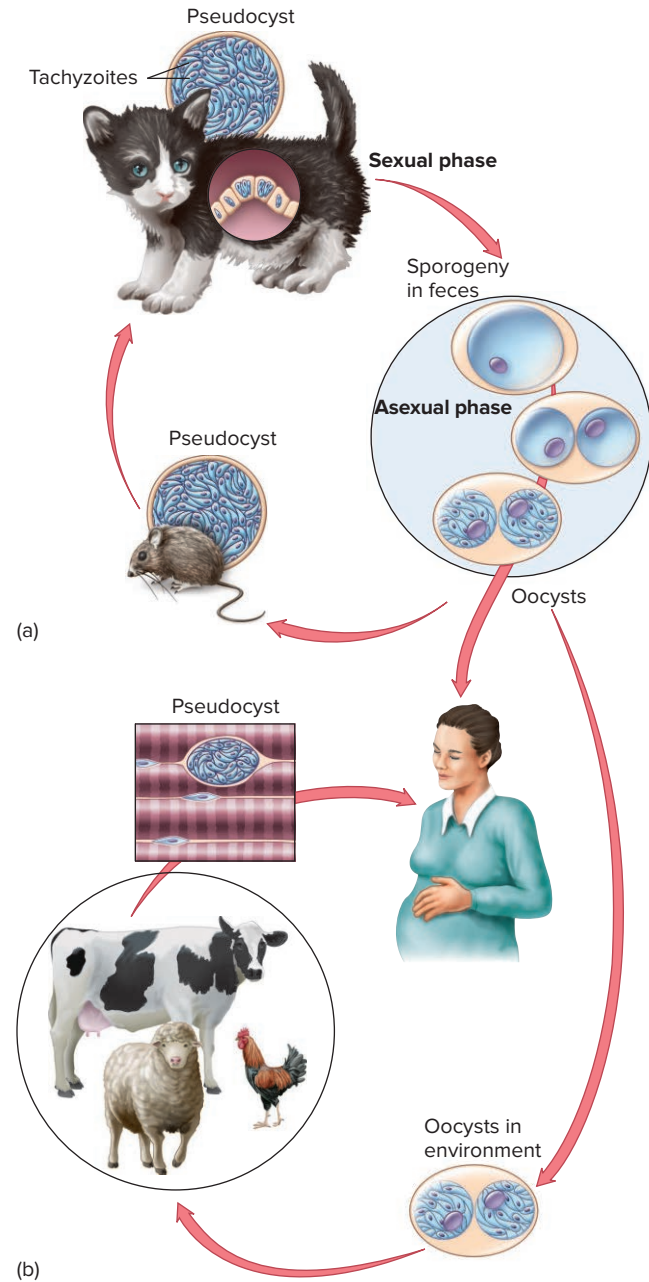

Figure 23.15 The life cycle and morphological forms of *Toxoplasma gondii*. (a) The cycle in cats and their prey. (b) The cycle in other animal hosts. The zoonosis has a large animal reservoir (domestic and wild) that becomes infected through contact with oocysts in the soil. Humans can be infected through contact with cats or ingestion of pseudocysts in animal flesh. Infection in pregnant women is a serious complication because of the potential damage to the fetus.

trimester is associated with stillbirth and severe abnormalities such as liver and spleen enlargement, liver failure, hydrocephalus, convulsions, and damage to the retina that can result in blindness.

Toxoplasmosis in AIDS and other immunocompromised patients can result from a primary acute or reactivated latent infection. The acute form is a disseminated, rapidly fatal disease with massive brain involvement that is sometimes seen in AIDS patients. Trophozoites and cysts clustered in intracerebral lesions cause seizures, altered mental state, and coma.

* *Toxoplasma gondii* (toks'-oh-plaz'-mah gawn'-dee-eye) L. *toxicum*, poison, and Gr. *plasma*, molded and *gundi*, a small rodent.

Toxoplasmosis can be differentiated by means of serological tests that detect antitoxoplasma antibodies, especially those for IgM, which appears early in infection. Disease can also be diagnosed by culture and histological analysis.

The most effective drugs are pyrimethamine and sulfadiazine alone or in combination. Because they do not destroy the cyst stage, they must be given for long periods to prevent recurrent infection.

In view of the fact that the oocysts are so widespread and resistant, hygiene is of paramount importance in controlling toxoplasmosis. Adequate cooking or freezing of meat below -20°C destroys both oocysts and tissue cysts. Oocysts can also be avoided by washing the hands after handling cats or soil that is possibly contaminated with cat feces. Pregnant women should be especially attentive to these rules and should avoid contact with cat excrement.

Sarcocystis and Sarcocystosis

Although *Sarcocystis* species are parasites of cattle, swine, and sheep, some have an interesting transmission cycle that involves passage through humans as the final host. Domestic animals are intermediate hosts that pick up infective cysts while grazing on grass contaminated by human excrement. Humans are subsequently infected when they eat beef, pork, or lamb containing tissue cysts, but human-to-human transmission does not occur. Sarcocystosis is an uncommon infection mostly caused by ingesting uncooked meats. Initial symptoms of intestinal sarcocystosis are diarrhea, nausea, and abdominal pain, which peak in a few hours after ingestion but can persist for about 2 weeks. There is no specific treatment at the present time.

Cryptosporidium: An Intestinal Pathogen

*Cryptosporidium** is a genus of apicomplexan parasites that infect a variety of mammals, birds, and reptiles, causing a disease called cryptosporidiosis. For many years, cryptosporidiosis was considered an intestinal ailment exclusive to calves, pigs, chickens, and other poultry, but it is clearly a zoonosis as well. The organism exhibits a life cycle similar to that of *Toxoplasma*, with a hardy intestinal oocyst and a tissue phase. In transmission pattern, it is very similar to *Giardia*.

Cryptosporidiosis exists worldwide, but its highest prevalence is in areas with unreliable water and food sanitation. The carrier state occurs in 3% to 30% of the population in some developing countries. The susceptibility of the general public to this pathogen has been amply demonstrated by frequent outbreaks. In the 1990s, 370,000 people developed *Cryptosporidium* gastroenteritis from tap water in Wisconsin. More recently, a similar outbreak sickened 2,800 people in Oregon. In both cases, contamination of water reservoirs by livestock wastes was thought to be responsible for the spread of the pathogen. Studies indicate that at least one-third of all fresh surface waters harbor this parasite. Recently the use of ozone or ultraviolet light to disinfect recreational water sources has become more widespread as both methods are effective against *Cryptosporidium*.

Infection is initiated when ingested oocysts release sporozoites that penetrate the intestinal cells and live intracellularly in them. The prominent symptoms in patients with clinical disease mimic other

23.16 Other apicomplexan parasites. (a) Light micrograph of gallbladder epithelium with numerous *Cryptosporidium* organisms (arrows) along the luminal surfaces of the epithelial cells. (b) Graphic of *Cystoisospora belli* oocysts to show internal sporocysts. (a): Source: CDC

types of gastroenteritis, with headache, sweating, vomiting, severe abdominal cramps, and diarrhea. AIDS patients may experience chronic persistent cryptosporidial diarrhea, which is one criterion used to diagnose AIDS. The agent can be detected in fecal samples with indirect immunofluorescence and by acid-fast staining of biopsy tissues (figure 23.16a). Immunocompetent patients may be successfully treated with nitazoxanide, but immunodeficient patients tend to suffer relapses regardless of the treatment regimen.

Cystoisospora belli and Coccidiosis

Cystoisospora (formerly known as *Isospora*) is an intracellular intestinal parasite with a distinctive stage featuring oocysts containing infective sporocysts (figure 23.16b). Of several species that colonize mammals, apparently only *Cystoisospora belli** infects humans. The parasite is transmitted in fecally contaminated food or drink and through laboratory contact. Not much is known about the incidence of infection because it is usually asymptomatic or self-limited. The more prominent symptoms are malaise, nausea and vomiting, diarrhea, fatty stools, abdominal colic, and weight loss. In cases requiring treatment, trimethoprim-sulfamethoxazole is the drug of choice.

Cyclospora cayetanensis and Cyclosporiasis

Cyclospora cayetanensis is an emerging protozoan pathogen related to *Cystoisospora*. Since its first occurrence in 1979, hundreds of outbreaks have been reported in North America. Its mode of transmission is oral-fecal, and most cases have been associated with consumption of fresh produce and water, presumably contaminated with feces. Cyclosporiasis occurs worldwide; although primarily of human origin, it is not spread directly from person to person. Outbreaks have been traced to imported raspberries, fresh greens, and drinking water. The parasite has also been identified as a significant cause of diarrhea in travelers.

The disease is acquired when oocysts enter the small intestine and invade the mucosa. After an incubation period of about 1 week, symptoms of watery diarrhea, stomach cramps, bloating, fever, and

* *Cryptosporidium* (krip'-toh-spo-rid'-ee-um). Gr. *cryptos*, hidden, and *sporos*, seed.

* *Cystoisospora belli* (sis'-toh'-eye-saus'-poh-rah bel'-eye) Gr. *iso*, equal, and *sporos*, seed; L. *bellum*, war.

muscle aches appear. Patients with prolonged diarrheal illness experience anorexia and weight loss.

Diagnosis can be complicated by the lack of recognizable oocysts in the feces. Techniques that improve identification of the parasite are examination of fresh preparations under a fluorescent microscope and an acid-fast stain of a processed stool specimen. A PCR-based DNA test can also be used to identify *Cyclospora* and differentiate it from other coccidian parasites. Most cases of infection have been effectively controlled with a combination of trimethoprim and sulfamethoxazole for a week. Traditional antiprotozoan drugs are not effective. Some cases of disease may be prevented by cooking or freezing food to kill the oocysts.

Babesia Species and Babesiosis

Babesiosis, or piroplasmiasis, is historically important for two firsts in microbiology. *Babesia** was the first protozoan found to be responsible for a disease—specifically, redwater fever.³ This is an acute febrile hemolytic disease of cattle characterized by the destruction of erythrocytes and the presence of hemoglobin in the urine, hence its name. The disease was also the first one associated with an arthropod vector—a tick. Although the morphology and life cycle of *Babesia* are not completely understood, they probably mirror those of the plasmodia.

Human babesiosis is a zoonosis caused by a species of *Babesia* from wild rodents that has been accidentally introduced by an *Ixodes* tick bite. This infection occurs throughout the world, and was once thought to be very rare or even eliminated from the United States. Finding increased case reports spurred the CDC to place it on the notifiable disease list in 2011. Of special concern has been its transmission through blood transfusions. It appears to be endemic to several areas of the Northeast and Midwest, with about 1,700 cases per year. It parallels malaria in its symptoms and effects, destroying red blood cells and inducing fever.

Check Your Progress SECTION 23.4

- List the major characteristics of the apicomplexan parasites.
- Explain why malaria is a greater concern in some geographic areas than in others.
- What is the name of the infective stage of the malaria parasite in humans and mosquitoes?
- What stage of development of the malaria parasite is the ring form?
- Outline some of the problems which make malaria difficult to control.
- Identify the phases of the *Plasmodium* life cycle that take place in mosquitoes, blood cells, and liver cells.
- Explain the means by which cats, rodents, birds, domestic animals, and people are infected with *Toxoplasma gondii*.
- Why don't common methods of water treatment reliably exclude *Cryptosporidium* from domestic water supplies?
- Compare the infectious routes and targets of *Cryptosporidium*, *Cystoisospora*, *Cystoospora*, *Cyclospora*, and *Babesia*.

* *Babesia* (bab-ee'-see'-uh) Named for its discoverer, Victor Babes.

3. Also known as bovine babesiosis, Texas fever, or tick fever.

23.5 A Survey of Helminth Parasites

Expected Learning Outcomes

- Recall the three categories of parasitic helminths.
- Distinguish between intermediate hosts and definitive hosts.
- Describe the four basic helminth transmission cycles.
- Describe the strategies used to diagnose and control helminth infection.

So far, our survey has been limited to single-celled infectious agents; however, **helminths**,* particularly the adults, are comparatively large, multicellular animals with specialized tissues and organs similar to those of the hosts they parasitize. They are amazingly diverse, ranging from barely visible roundworms (0.3 mm) to huge tapeworms 25 meters long and varying from oblong- and crescent-shaped to whiplike or elongate flat ribbons. Their behavior and their adaptations to humans are at once fascinating and grotesque. Imagine having long, squirming white worms suddenly expelled from your nose, feeling and seeing a worm creeping beneath your skin, or having a worm slither across the front of your eye, and you have some idea of the conspicuous nature of these parasites.

In the following section, we present major facets of helminth epidemiology, life cycles, pathology, and control, followed by an accounting of the major worm diseases. A short review of taxonomy from chapter 5 may be helpful. Helminths are invertebrate worms classified into two phyla. Members of Phylum Aschelminthes are commonly known as nematodes or roundworms. They have elongate, somewhat curved, cylindrical bodies. Members of Phylum Platyhelminthes, or flatworms, have thin, flattened bodies. Parasitic flatworms come in two varieties: (1) trematodes called flukes that have ovoid, compact bodies, and (2) cestodes called tapeworms with long, ribbonlike, segmented bodies. **Table 23.4** presents a selected list of medically significant helminths in the categories of nematodes, trematodes, and cestodes.

General Life and Transmission Cycles

The complete life cycle of helminths includes the fertilized egg (embryo), larval, and adult stages. In the majority of helminths, adults derive nutrients and reproduce sexually in a host's body. In nematodes, the sexes are separate and usually different in appearance; in trematodes, the sexes can be either separate or **hermaphroditic**, meaning that male and female sex organs are in the same worm; cestodes are generally hermaphroditic. For a parasite's continued survival as a species, it must complete the life cycle by transmitting an infective form, usually an egg or larva, to the body of another host, either of the same or a different species. By convention, the host in which larval development occurs is the **intermediate (secondary) host**, and adulthood and mating occur in the **definitive (final) host**. A transport host is an intermediate host that experiences no parasitic development but is an essential link in the completion of the cycle.

* Gr. *helmins*, worm.

TABLE 23.4 Major Helminths of Humans and Their Modes of Transmission

Classification	Common Name of Disease or Worm	Life Cycle Requirement	Spread to Humans by
Nematodes (Roundworms)			
Intestinal Nematodes			Oral-fecal means
Infective in egg (embryo) stage			
<i>Trichuris trichiura</i>	Whipworm	Humans	Fecal pollution of soil with eggs
<i>Ascaris lumbricoides</i>	Ascariasis	Humans	Fecal pollution of soil with eggs
<i>Enterobius vermicularis</i>	Pinworm	Humans	Close contact and fomites
Infective in larval stage			
<i>Necator americanus</i>	New World hookworm	Humans	Fecal pollution of soil with eggs
<i>Ancylostoma duodenale</i>	Old World hookworm	Humans	Fecal pollution of soil with eggs
<i>Strongyloides stercoralis</i>	Threadworm	Humans; may live free	Fecal pollution of soil with eggs
<i>Trichinella spiralis</i>	Trichina worm	Pigs, wild mammals	Consumption of meat containing larvae
Tissue Nematodes			Burrowing of larva into tissue
<i>Wuchereria bancrofti</i>	Filariasis	Humans, mosquitoes	Mosquito bite
<i>Onchocerca volvulus</i>	River blindness	Humans, black flies	Fly bite
<i>Loa loa</i>	Eye worm	Humans, mangrove flies, or deer flies	Fly bite
Trematodes (Flukes)			
<i>Schistosoma japonicum</i>	Blood fluke	Humans and snails	Ingestion of fresh water containing larval stage
<i>S. mansoni</i>	Blood fluke	Humans and snails	Ingestion of fresh water containing larval stage
<i>S. haematobium</i>	Blood fluke	Humans and snails	Ingestion of fresh water containing larval stage
<i>Opisthorchis sinensis</i>	Chinese liver fluke	Humans, snails, fish	Consumption of fish
<i>Fasciola hepatica</i>	Sheep liver fluke	Herbivores (sheep, cattle)	Consumption of water and water plants
<i>Paragonimus westermani</i>	Oriental lung fluke	Humans, mammals, snails, freshwater crabs	Consumption of crabs
Cestodes (Tapeworms)			
<i>Taenia saginata</i>	Beef tapeworm	Humans, cattle	Consumption of undercooked or raw beef
<i>T. solium</i>	Pork tapeworm	Humans, swine	Consumption of undercooked or raw pork
<i>Diphyllobothrium latum</i>	Fish tapeworm	Humans, fish	Consumption of undercooked or raw fish
<i>Hymenolepis nana</i>	Dwarf tapeworm	Humans	Oral-fecal means; close contact

Although individual variations occur in life and transmission cycles, most can be described by one of four basic patterns (**figure 23.17**). In general, sources for human infection are contaminated food, soil, water, or infected animals; and routes of infection are by oral intake or penetration of unbroken skin. Humans are the definitive hosts for many of the parasites listed in table 23.4, and in about half, they are also the sole biological reservoir. In other cases, animals or insect vectors serve as reservoirs or are required to complete worm development. In the majority of helminth infections, the worms must leave their host to complete the entire life cycle.

General Epidemiology of Helminth Diseases

The helminths have a far-reaching impact on human health, economics, and culture. Worldwide health organizations estimate around 2.5 billion helminth infections at any one time worldwide. The statistics of the most common forms are as follows:

- ascariasis—1 billion,
- trichuriasis—700 million,
- hookworm—600 million,
- schistosomiasis—200 million, and
- filariasis—120 million.

Systems Profile 23.2		Parasitic Helminths				
Organism	Skin/Skeletal	Nervous/ Muscle	Cardiovascular/ Lymphatic/Systemic	Gastrointestinal	Respiratory	Urogenital
<i>Ascaris lumbricoides</i>				Intestinal distress		
<i>Trichuris trichiura</i>		Muscle pain		Diarrhea		
<i>Enterobius vermicularis</i>	Anal itching			Diarrhea		
<i>Necator americanus</i>	Dermatitis			Intestinal distress	Pneumonitis	
<i>Ancylostoma duodenale</i>				Intestinal distress		
<i>Strongyloides stercoralis</i>	Dermatitis			Intestinal distress	Pneumonitis	
<i>Trichinella</i> spp.	Myositis	Encephalitis		Intestinal distress		
<i>Wuchereria bancrofti</i>	Dermatitis		Elephantiasis			
<i>Onchocerca volvulus</i> (w/ <i>Wolbachia</i>)	River blindness	Loss of optic nerve				
<i>Schistosoma</i> spp.			Blood infection	Intestinal Schistosomiasis	Cough	Urinary schistosomiasis
<i>Opisthorchis sinensis</i>				Liver and intestinal disease	Pleural pain, abscess	
<i>Fasciola hepatica</i>				Liver and intestinal disease		
<i>Taenia saginata</i>				Abdominal pain		
<i>Tania solium</i>		Cysticercosis	Cystercercosis	Intestinal distress		

Although individuals from all societies and regions play host to worms at some time in their lives, the highest case rates occur among children in rural areas of the tropics and subtropics. In most developed countries with temperate climates, the major parasitic infections are pinworm and trichinosis, though tropical parasitic worms are often encountered in immigrants and travelers.

The continuing cycle between parasites and humans is often the result of practices such as using human excrement for fertilizer, defecating in open soil, exposing bare feet to soil or standing water, and eating undercooked or raw meat and fish. The burden of helminths is borne largely by the developing world. There is a clear association between poverty and malnutrition and higher levels of disease and death. Heavy worm loads can retard the physical and mental development of children. It is ironic indeed that some cultures have accepted parasites as their burden for thousands of years. Review chapter 5's Case Study, which covers many of these neglected tropical diseases.

Pathology of Helminth Infestation

Worms exhibit numerous adaptations to the parasitic habit. They have specialized mouthparts for attaching to tissues and for feeding, enzymes with which they liquefy and penetrate tissues, and a cuticle or other covering to protect them from the host defenses. In addition, their organ systems are usually reduced to the essentials: getting food and processing it, moving, and reproducing. Helminths entering by mouth undergo a period of development in the intestine that is often followed by spread to other organs. Helminths that burrow directly into the skin or are inserted by an insect bite quickly penetrate the circulation and are carried throughout the body. In both cases, most

worms do not remain in a single location, and they migrate by various mechanisms through major systems, inflicting injury as they go.

Adult helminths eventually take up final residence in the intestinal mucosa, blood vessels, lymphatics, subcutaneous tissue, skin, liver, lungs, muscles, brain, or even the eyes. Traumatic damage occurring in the course of migration and organ invasion is primarily due to tissue feeding, toxic secretions, and blockages within organs due to high worm load. Pathologic effects can include enlargement and swelling of organs, hemorrhage, weight loss, and anemia caused by the parasites' feeding on blood. Despite the popular misconception that intestinal worms cause weight loss by competing for food, such weight loss is more likely caused by malnutrition, malabsorption of food and vitamins due to intestinal damage, lack of appetite, vomiting, and diarrhea.

One common antihelminthic defense is an increase in granular leukocytes called *eosinophils* that have a specialized capacity to destroy worms (see chapter 14). Although antibodies and sensitized T cells are also formed against worms, their effects are rarely long term, and reinfection is always a distinct possibility. The inability of the immune system to completely eliminate worm infections appears to be due to the worms' relatively large size, migratory habits, and inaccessibility. The incompleteness of immunity has hampered the development of vaccines for parasitic diseases and has emphasized the use of chemotherapeutic agents instead.

Elements of Diagnosis and Control

Diagnosis of helminthic infestation may require several steps. A differential blood count showing eosinophilia and serological tests

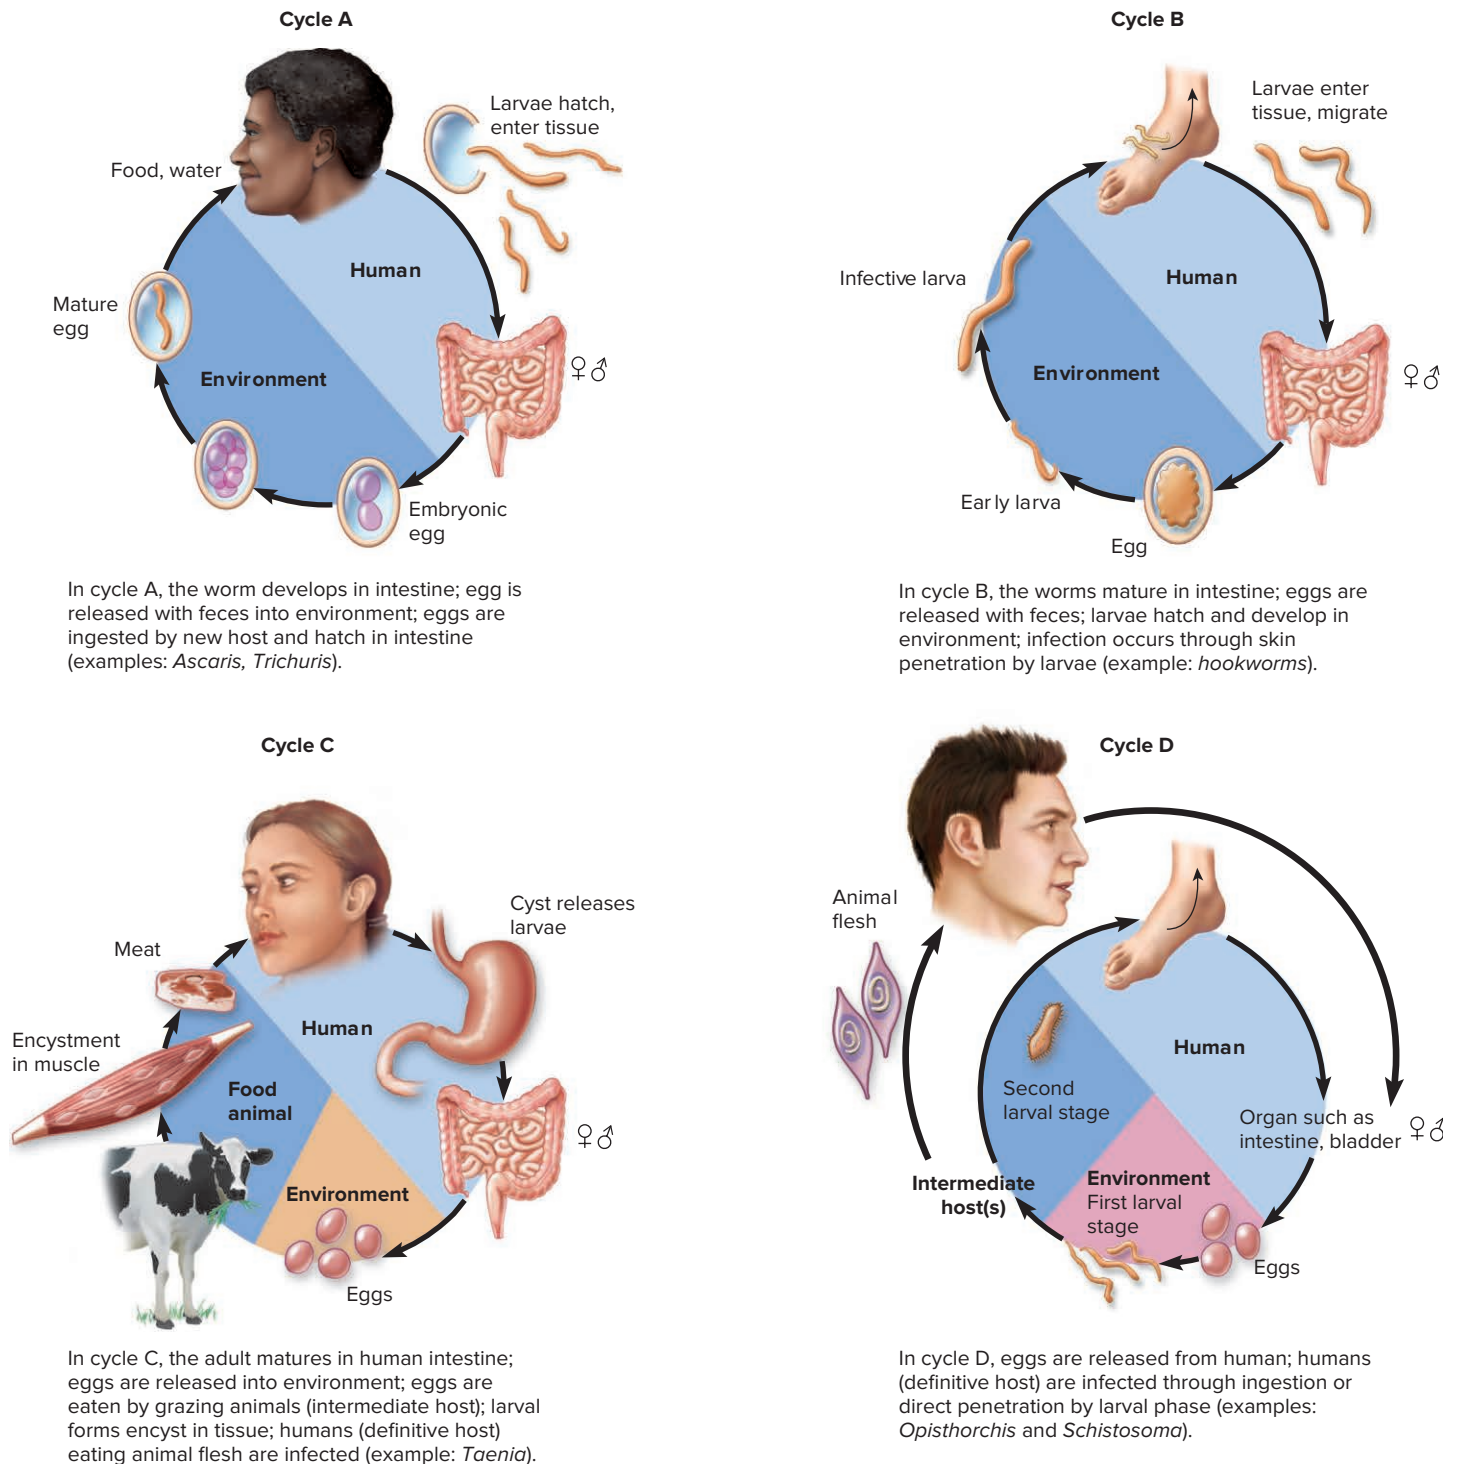

Figure 23.17 Four basic helminth life and transmission cycles.

indicating sensitivity to helminths both provide indirect evidence of worm infestation. A history of travel to the tropics or immigration from those regions is also helpful, even if it occurred years ago, because some flukes and nematodes persist for decades. The most definitive evidence, however, is the discovery of eggs, larvae, or adult worms in stools, sputum, urine, blood, or tissue biopsies. The worms are sufficiently distinct in morphology that positive identification can be based on any stage, including eggs.

Although several useful antihelminthic medications exist, the cellular physiology of the eukaryotic parasites resembles that of humans, and drugs toxic to them can also be toxic to humans. Some antihelminthic drugs act to suppress a metabolic process that is more important to the worm than to the host. Others inhibit the worm's movement or prevent it from holding a position in an organ such as the intestine. Therapy is also based on a drug's greater toxicity to the helminths or acting locally in the

TABLE 23.5 Antihelminthic Therapeutic Agents and Indications for Their Use

Drug	Effect	Used for
Albendazole	Blocks key step in worm metabolism	Filariasis, ascariasis, strongyloidiasis, and some adult worms
Diethylcarbamazine	Unknown but kills microfilariae	Filariasis, loiasis
Ivermectin	Blocks nerve transmission	Onchocerciasis, ascariasis, strongyloidiasis
Mebendazole*	Blocks key step in worm metabolism	Trichuriasis (whipworm), ascariasis, hookworm, trichinosis
Piperazine*	Paralyzes worm so it can be expelled in feces	Ascariasis, pinworm, hookworm
Praziquantel	Interferes with worm metabolism	Schistosomiasis, other flukes, tapeworm
Pyrantel	Paralyzes worm so it can be expelled in feces	Pinworm, hookworm, trichinosis

*No longer used in the United States.

intestine. Antihelminthic drugs of choice and their effects are given in **table 23.5**.

Preventive measures are aimed at minimizing human contact with the parasite or interrupting its life cycle. In areas where the worm is transmitted by fecally contaminated soil and water, disease rates are significantly reduced through proper sewage disposal, using sanitary latrines, avoiding human feces as fertilizer, and disinfection of the water supply. If the larvae are aquatic and invade through the skin, people should avoid direct contact with infested water. Food-borne disease can be avoided by thoroughly cooking vegetables and meats. Also, because adult worms, larvae, and eggs are sensitive to cold, freezing foods is a highly satisfactory preventive measure.

Check Your Progress SECTION 23.5

- Name the taxonomic groups into which parasitic helminths are classified and tell how they differ from one another.
- Differentiate between helminthic activities taking place in the intermediate host and those occurring in the definitive host.
- Contrast the important points of the four basic helminth transmission cycles with examples.
- Explain the significance of eosinophilia, a history of travel, and examination of patient specimens when diagnosing a helminth infection.
- Summarize the activities undertaken to prevent and treat helminth infections.

23.6 Nematode (Roundworm) Infestations

Expected Learning Outcomes

- Identify the transmission cycle of each of the most common intestinal nematodes.
- Summarize the mode of infestation and pathology of *Necator*, *Strongyloides*, and *Trichinella*.
- Identify risk factors for contracting trichinellosis, and list several preventative measures.
- Differentiate between tissue nematodes and intestinal nematodes.
- List the vectors associated with each of the common filarial worms.
- Describe the signs and symptoms associated with the most common tissue nematodes.

Nematodes* are elongate, cylindrical worms that biologists consider one of the most abundant animal groups (a cup of soil or mud can easily contain millions of them). The vast majority are free-living soil and freshwater worms, but around 200 are parasitic, including 50 species that affect humans. Nematodes bear a smooth, protective outer covering, or cuticle, that is periodically shed as the worms grow. They are essentially headless, tapering to a fine point anteriorly. The sexes are distinct, and the male is often smaller than the female, having a hooked posterior containing spicules for coupling with the female.

The human parasites are divided into intestinal nematodes (**figure 23.18**), which develop to some degree in the intestine (for example, *Ascaris*, *Strongyloides*, and hookworms), and tissue nematodes, which spend their larval and adult phases in various soft tissues other than the intestine (for example, various filarial worms).

Intestinal Nematodes (Cycle A)

Ascaris lumbricoides and Ascariasis

*Ascaris lumbricoides** is a giant (up to 300 mm long) intestinal roundworm that probably accounts for the greatest number of worm infections. Most reported cases of ascariasis in the United States occur in the Southeast. *Ascaris* spends its larval and adult stages in humans and releases embryonic eggs in feces, which are then spread to other humans through food, drink, or soiled objects placed in the mouth (**figure 23.18b**). The eggs thrive in warm, moist soils but are sensitive to sunlight, high temperatures, and drying. After ingested eggs hatch in the human intestine, the larvae embark upon an odyssey in the tissues. First they penetrate the intestinal wall and enter its lymphatic and circulatory drainage. From there, they are swept into the heart and eventually arrive at the capillaries of the lungs. From this point, the larvae migrate up the respiratory tree to the glottis. Worms entering the throat are swallowed and returned to the small intestine, where they reach adulthood and reproduce, producing up to 200,000 fertilized eggs a day.

Even as adults, male and female worms are not attached to the intestine and retain some of their exploratory ways. They are known to invade the biliary channels of the liver and gallbladder, and on occasion the worms emerge from the mouth and nares. Severe

* *Nematodes* (nem'-ah-tohd) Gr. *nema*, thread.

* *Ascaris lumbricoides* (as'-kah-ris lum"-brih-koy'-dees) Gr. *askaris*, an intestinal worm; L. *lumbricus*, earthworm, and Gr. *eidōs*, resemblance.

(a)

(b)

inflammatory reactions mark the migratory route, and allergic reactions such as bronchospasm, asthma, or skin rash can occur.

Trichuris trichiura and Whipworm Infection

The common name for *Trichuris** *trichiura*—whipworm—refers to its likeness to a miniature buggy whip. Although the worm is morphologically different from *Ascaris*, it has a similar transmission cycle, with humans as the sole host. Trichuriasis has its highest incidence in areas of the tropics and subtropics with widespread fecal contamination of the soil. Embryonic eggs deposited in the soil are not immediately infective and continue development for 3 to 6 weeks in this habitat. Ingested eggs hatch in the small intestine, where the larvae attach, penetrate the outer wall, and develop into adults. Mature adults move to the large intestine and gain a hold with their long, thin heads, while the thicker tail dangles free in the lumen. Following sexual maturation and fertilization, the females eventually lay 3,000 to 5,000 eggs daily into the bowel. The entire

* *Trichuris* (trik-ur'-is) Gr. *thrix*, hair, and *oura*, tail.

cycle requires about 90 days, and untreated infestation can last up to 2 years.

Worms burrowing into the intestinal mucosa can pierce capillaries, cause localized hemorrhage, and provide a portal of entry for secondary bacterial infection. Heavier infestations can cause dysentery, loss of muscle tone, and rectal prolapse, which can prove fatal in children.

Enterobius vermicularis and Pinworm Infection

The pinworm or seatworm, *Enterobius vermicularis**, was first discussed in chapter 5 (see figure 5.29). Enterobiasis is the most common worm disease of children in temperate zones. Around 30% of children tested are found to be infected. The transmission of the pinworm follows a course similar to that of the other enteric parasites. Freshly deposited eggs have a sticky coating that causes them to lodge beneath the fingernails and to adhere to fomites. Upon drying, the eggs become airborne and settle in house dust. Worms are ingested from contaminated food and drink, and self-inoculation from one's own fingers is common.

Eggs hatching in the small intestine release larvae, which migrate to the large intestine, mature, and then mate. Itching is brought on when the mature female emerges from the anus and lays eggs. Although infestation is not fatal and most cases are asymptomatic, the afflicted child can suffer from disrupted sleep and sometimes nausea, abdominal discomfort, and diarrhea. A simple, rapid test can be done by pressing a piece of transparent adhesive tape against the anal skin and then applying it to a slide for microscopic evaluation.

Intestinal Nematodes (Cycle B)

The Hookworms

Two major agents of human hookworm infestation are *Necator americanus**, endemic to the New World, and *Ancylostoma duodenale**, endemic to the Old World, though the two species overlap in parts of Latin America. Otherwise, with respect to transmission, life cycle, and pathology, they are usually lumped together. Humans are sometimes invaded by cat or dog hookworm larvae, sustaining a dermatitis called creeping eruption. The *hook* refers to the adult's oral cutting plates by which it anchors to the intestinal villi and its curved anterior end (figure 23.19). Unlike other intestinal worms, hookworm larvae hatch outside the body and infect by penetrating the skin.

Hookworm infestation remains endemic to the tropics and subtropics and is absent in arid, cold regions. In recent times, its worldwide incidence has decreased. In the past, hookworm plagued parts of the southern United States, unfortunately sapping its victims' strength and stigmatizing them. The decline of the disease can be attributed to such simple changes as improved sanitation (indoor plumbing) and better standards of living (being able to afford shoes).

* *Enterobius vermicularis* (en'-ter-oh'-bee-us ver-mik'-yoo-lah'-ris) Gr. *enteron*, intestine, and *bios*, life; L. *vermiculus*, a small worm.

* *Necator americanus* (nee-kay'-tor ah-mer'-ih-cah'-nus) L. *necator*, a murderer, and *americanus*, of New World origin.

* *Ancylostoma duodenale* (an'-kih-los'-toh-mah doo-oh-den-ah'-lee) Gr. *ankylos*, curved or hooked, *stoma*, mouth, and *duodenale*, the intestine.

23.2 MAKING CONNECTIONS

Neglected Parasitic Infections in the United States

Mention the word *parasites* and most people think of developing countries, but parasitic infections are not unknown in the United States, with 300,000 people infected with the parasite that causes Chagas disease, and 60,000,000 suffer from toxoplasmosis. Our collective mindset makes the situation even worse, as many people go undiagnosed and untreated because they don't understand that they are at risk and lack access to appropriate care. In some areas of the United States, neurocysticercosis is the single most common infectious cause of seizures, with some 2,000 people diagnosed every year. *Toxocara canis*, a roundworm that infects dogs, causes an estimated 70 cases of blindness in children annually. The actual figure is probably quite higher, but adequate surveillance of the disease is lacking. Compounding the problem are health care providers who are unfamiliar with parasitic infections and fail to diagnose or treat them properly.

The CDC has targeted five parasitic infections as public health priorities—Chagas disease, neurocysticercosis, toxocariasis, toxoplasmosis, and trichomoniasis—based on the number of people infected, the severity of the illness, and the ability to prevent and treat them. It is clear that a multifaceted approach is needed to combat a problem that manages to be both massive and invisible at the same time, and this is just what the CDC has undertaken. By increasing awareness among physicians and the public, improving diagnostic testing, and making available needed drugs, it is hoped that the toll of these diseases on individuals and the strain they place on our health care system can both be reduced.

How could U.S. Immigration and Customs officials be of use in the fight against parasitic infections? Answer available on Connect.

After being deposited into soil by defecation, hookworm eggs hatch into fine **filariform*** larvae that instinctively climb onto grass or other vegetation to improve the probability of contact with a host. Ordinarily the parasite enters sites on bare feet such as hair follicles, abrasions, or the soft skin between the toes, but cases have occurred in which mud splattered on the ankles of people wearing shoes. Infection has even been reported in people handling soiled laundry.

On contact, the hookworm larvae actively burrow into the skin. After several hours they reach the lymphatic or blood circulation

and are immediately carried into the heart and lungs. The larvae proceed up the bronchi and trachea to the throat, where they are swallowed with sputum and arrive in the small intestine. There they anchor, feed on tissues, and mature.

Initial penetration with larvae often evokes a localized dermatitis called “ground itch,” and movement of the larvae to the lungs can cause symptoms of pneumonia. The potential for injury is greatest with chronic infections, when heavy worm burdens cause vomiting and bloody diarrhea. Because of significant blood loss, iron-deficient anemia can develop, and infants are especially susceptible to hemorrhagic shock. Chronic fatigue, listlessness, apathy, and anemia worsen with chronic and repeated infections.

An experimental hookworm vaccine, now in phase II trials in Brazil, has generated a great deal of interest. Underwritten by a grant from the Gates Foundation, this could be the first vaccine available for a helminth disease.

Strongyloides stercoralis and Strongyloidiasis

The agent of strongyloidiasis, or threadworm infection, is *Strongyloides stercoralis*.* This nematode is exceptional because of its minute size and its capacity to complete its life cycle either within the human body or outside in moist soil. Its distribution and life cycle, similar to hookworms, afflicts an estimated 75 million to 100 million people worldwide. Infection occurs when soil larvae penetrate the skin. The worm then enters the circulation, is carried to the respiratory tract and swallowed, and then enters the small intestine to complete development. Although adult *S. stercoralis* lay eggs in the gut just as hookworms do, the eggs can hatch into

* *filariform* (fih-lar'-ih-form) *L. filum*, a thread.

Pathogen Profile #3 *Trichinella spiralis*

Trichinella worms encysted in muscle

Source: National Human Genome Research Institute

Microscopic Morphology Round larval worms are 1 to 2 mm in length and coiled cysts are about 1 mm in diameter.

Identified by Antibody detection. Clinical signs and symptoms vary, depending on the stage of infection, but include gastrointestinal distress, muscle pain, weakness, and eosinophilia. Visualization of encysted worms following muscle biopsy and microscopic examination offer confirmation of infection.

Habitat The entire *Trichinella* life cycle is spent within the body of a mammalian host, with pigs, bears, cats, dogs, and rats all commonly serving as reservoirs.

Primary Infections/Disease Trichinellosis is acquired by eating the meat of an infected animal, with most cases being traced to consumption of undercooked swine or bear meat. Initial symptoms include diarrhea, nausea, abdominal pain, fever, and sweating as the worm invades the intestinal mucosa, followed by muscle and joint pain, weakness, and shortness of breath as larvae encyst in the muscles. In most cases symptoms eventually subside, although involvement of the heart or brain, a rare occurrence, can lead to life-threatening complications.

Control and Treatment Adequate cooking, freezing, or smoking of pork and wild meats will kill larvae. Treatment with albendazole and steroids is useful during the initial stages of infection, but there is no cure once larvae have encysted in the muscles.

larvae in the colon and remain entirely in the host's body to complete the cycle. Eggs can likewise exit with feces and go through an environmental cycle. These numerous alternative life cycles greatly increase the chance of transmission and the likelihood for chronic infection.

The first hint of threadworm infection is usually a red, intensely itchy skin rash at the site of entry. Mild migratory activity in an otherwise normal person can escape notice, but heavy worm loads can cause symptoms of pneumonitis and eosinophilia. The nematode activities in the intestine produce bloody diarrhea, liver enlargement, bowel obstruction, and malabsorption. In immunocompromised patients, there is a risk of severe, disseminated infestation involving numerous organs. Hardest hit are AIDS patients, transplant patients on immunosuppressant drugs, and cancer patients receiving irradiation therapy, who can die if not treated promptly with ivermectin.

Trichinella spiralis and Trichinellosis

The life cycle of *Trichinella spiralis** is spent entirely within the body of a mammalian host, usually a carnivore or omnivore such as a pig, bear, cat, dog, or rat. In nature, the parasite is maintained in an encapsulated (encysted) larval form in the muscles of these animal reservoirs and is transmitted when other animals prey upon them. Humans acquire **trichinellosis** (also called trichinosis) by eating the meat of an infected animal (usually wild or domestic swine or bears), but humans are essentially dead-end hosts (**figure 23.20**).

Yearly estimates of trichinellosis average about 10,000 cases worldwide, with fewer cases occurring in regions of the world where religious or cultural traditions disapprove of the eating of pork. In the United States, pork is generally frozen or fully cooked—

both of which kill the *Trichinella* worm—prior to eating, and people have become more aware of the dangers of raw or undercooked dishes containing pork. As a result, only 10 to 20 cases are seen each year, and most of these are traced to the eating of wild game, particularly bear meat.

The cyst envelope is digested in the stomach and small intestine, which liberates the larvae. After burrowing into the intestinal mucosa, the larvae reach adulthood and mate. An unusual aspect of this worm's life cycle is that males die and are expelled in the feces, while females incubate eggs and shed live larvae. These penetrate the intestine and enter the lymphatic channels and blood. Final development occurs when the coiled larvae are encysted in the skeletal muscle (**figure 23.20**). At maturity, the cyst is about 1 mm long and can be observed by careful inspection of meat. Although larvae can deteriorate over time, they have also been known to survive for years.

The first symptoms of trichinellosis mimic influenza or viral fevers, with diarrhea, nausea, abdominal pains, fever, and sweating. The second phase, brought on by the mass migration of larvae and their entrance into muscle, produces intense muscle and joint pain, shortness of breath, and pronounced eosinophilia. The most serious life-threatening manifestations are heart and brain involvement. Although the symptoms eventually subside, a cure is not available once the larvae have encysted in muscles. The most effective preventive measures are adequately cooking, freezing, or smoking pork and wild meats.

Tissue Nematodes

As opposed to the intestinal worms previously described, tissue nematodes complete their life cycle in human blood, lymphatics, or skin. The most important members are **filarial worms**. Their most notable characteristics are having thin, filamentous bodies; being spread by biting arthropods; and causing chronic, deforming diseases.

* *Trichinella spiralis* (trik'-ih-nel'-ah spy-ral'-is) A little, spiral-shaped hair worm.

Process Figure 23.20 The cycle of trichinellosis. © Pr. Bouree/Science Source

Filarial Nematodes and Filariasis

The filarial parasites are characterized by the production of tiny microfilarial larvae that circulate in the blood and lymphatics. Their anatomy is relatively simple, but they have a complex biphasic life cycle that alternates between humans and blood-sucking mosquito or fly vectors. The species responsible for most **filariases** are *Wuchereria bancrofti* and *Onchocerca volvulus*.

***Wuchereria bancrofti* and Bancroftian Filariasis** *Wuchereria bancrofti** causes **bancroftian filariasis**, a common affliction in tropical regions where its vectors live (female *Culex*, *Anopheles*, and *Aedes* mosquitoes). The WHO estimates there are 120 million cases worldwide distributed in a pattern similar to malaria. The microfilariae are highly attuned to their vectors, such that they swarm to the skin capillary circulation to coincide with the times the mosquito feeds. The microfilariae complete development in the flight muscles of the mosquito, and the resultant larvae gather in its mouthparts. Infection begins when a mosquito bite deposits the infective larvae into the skin. These larvae penetrate the lymphatic vessels, where they develop into long-lived, reproducing adults. Mature female worms expel huge numbers of microfilariae directly into the circulation throughout their life cycle (**figure 23.21**).

The first symptoms of larval infestation in humans are inflammation and dermatitis in the skin near the mosquito bite, lymphadenitis, and testicular pain. The most conspicuous and bizarre sign of

chronic bancroftian filariasis is profound swelling of the scrotum or legs called **elephantiasis**.* This edema is caused by inflammation and blockage of the main lymphatic channels, which prevent return of lymph to the circulation and cause large amounts of fluid to

* *elephantiasis* (el'-eh-fan-ty'-ah-sis) Gr. *elephas*, elephant.

Figure 23.21 Bancroftian filariasis. Elephantiasis occurs when filarial worms block the main lymphatic channels, causing lymph to accumulate in the extremities. Inset: *Wuchereria bancrofti* microfilaria in a blood smear. Source: CDC; (inset): Source: CDC-DPDx/Oregon State Public Health Laboratory

* *Wuchereria bancrofti* (voo'-kur-ee'-ree-ah bang-krof'-tee) After Otto Wucherer and J. Bancroft.

accumulate in the extremities (figure 23.21). The condition can predispose to ulceration and infection. In extreme cases, the patient can become physically incapacitated and suffer from the stigma of having to carry massively swollen body parts. This condition occurs only in individuals in endemic regions after 1 to 5 decades of chronic infection. The microfilariae can be killed by oral medications (albendazole, ivermectin), but the lymphatic form of the disease is incurable.

Onchocerca volvulus and River Blindness *Onchocerca volvulus** is a filarial worm transmitted by small biting vectors called black flies. These voracious flies can attack in such large numbers that it is not uncommon to be bitten several hundred times a day. Onchocerciasis is found in rural settlements along rivers bordered by overhanging vegetation, which are typical breeding sites of the black fly. Most cases of this disease occur in 30 endemic countries in Africa. Estimates from the WHO project approximately 25 million infections and nearly 1 million blind from its effect on the eyes.

The life and transmission cycles are similar to those of *Wuchereria*, although the larvae are deposited into the bite wound and develop into adults in the immediate subcutaneous tissues within 1 to 2 years after initial contact. Microfilariae produced by the adult female migrate via the blood to many locations but especially the eyes. It is the blood phase that infects other feeding black flies.

As the larvae and adult worms degenerate in the skin and the subcutaneous tissues, they provoke inflammatory reactions, rashes, and nodules in these regions that can persist for years. Invasion into the eye and its surrounding tissues gives rise to its most debilitating complication—river blindness. Recent experiments provide convincing evidence that the eye damage is actually due to a coinfection with a bacterium called *Wolbachia*. The bacterium is an endosymbiont that the larval *Onchocerca* require for their normal development. Over time, the bacterial antigens given off by the infection elicit strong inflammatory reactions that permanently damage the cornea, retina, and the optic nerve. This discovery means that it may now be possible to break the cycle of the disease by using antibiotics such as tetracyclines to destroy the bacteria in worms and the antiprotozoan drug *ivermectin* to kill the microfilarial larvae themselves. These treatments, along with an insecticide program to control the black flies, are the major strategies for containing the disease—one of the current aims of the WHO.

Loa loa: The African Eye Worm Another nematode that makes disturbing migratory visits across the eye and under the skin is *Loa loa*.* This worm is larger and more apparent than *O. volvulus*. The agent occurs in parts of western and Central Africa and is spread by the bites of dipteran flies. Its life cycle is similar to *Onchocerca* in that the larvae and adults remain more or less confined to the subcutaneous tissues. The first signs of disease are itchy, marble-sized lesions called *calabar swellings* at the site of penetration. These nodules are transient, and the worm lives for only a year or so, but the infestation is often recurrent. Because the nematode is temperature-sensitive, it is drawn to the body surface in response to warmer

temperature and is frequently felt slithering beneath the skin or observed beneath the conjunctiva. One method of treatment is to carefully pull the worm from a small hole in the conjunctiva following application of local anesthesia. Some infections can be suppressed with high doses of diethylcarbamazine.

Dracunculus medinensis* and Dracontiasis Dracontiasis, caused by the guinea worm, once caused untold misery in residents of India, the Middle East, and Central Africa. The parasite is carried by *Cyclops*, a microscopic arthropod commonly found in still water. When people ingest water from a contaminated community pond or open well, the larvae are freed from their *Cyclops* host and penetrate into subcutaneous tissues of the intestine, where they form highly irritating lesions.

An intense effort by the World Health Organization in conjunction with the Carter Foundation began eradicating the disease by converting ponds to wells, filtering water through a fine nylon sieve, and treating the water with an insecticide. So successful was this strategy that dracontiasis cases have dropped from 3.5 million cases in 1986 to 24 in 2015 and will soon be eliminated from the earth.

23.7 Flatworms: The Trematodes and Cestodes

Expected Learning Outcomes

30. Identify the intermediate and definitive hosts in trematode infestation.
31. Recall the stages of the *Schistosoma* life cycle.
32. Discuss the anatomical adaptation of tapeworms to their intestinal habitat.
33. Describe the major characteristics of *Taenia saginata* and *Taenia solium*.

* *Onchocerca volvulus* (ong'-koh-ser'-kah volv'-yoo-lus) Gr. *onkos*, hook, and *kerkos*, tail; L. *volvare*, to twist.

* *Loa loa* (loh'-ah loh'-ah).

* *Dracunculus medinensis* (drah-kung'-kyoo-lus meh-dih-nen'-sis) The little dragon of Medina. Also called guinea worm.

The fluke is named for the characteristic ovoid or flattened body found in most adult worms, especially liver flukes such as *Fasciola hepatica*. Blood flukes, also called schistosomes, have a more cylindrical body plan. They are also called **trematodes** (Gr. *trema*, a hole) because of the muscular sucker containing a mouth (hole) at the fluke's anterior end (see figure 5.28b). Flukes have digestive, excretory, neuromuscular, and reproductive systems but lack circulatory and respiratory systems. Except in the blood flukes, both male and female reproductive systems occur in the same individual and occupy a major portion of the body. The trematode life cycles are closely adapted to agricultural practices such as flood irrigating and using raw sewage as fertilizer. In human fluke cycles, animals such as snails or fish are usually the intermediate hosts, and humans are the definitive hosts.

Blood Flukes: Schistosomes (Cycle D)

Schistosomiasis has afflicted humans for thousands of years. The disease is caused by *Schistosoma** *mansoni*, *S. japonicum*, or *S. haematobium*.⁴ All three species are morphologically and geographically distinct but share similar life cycles, transmission methods, and general disease manifestations. The disease is endemic to 52 countries located in Africa, South America, the Middle East, and the Far East. Schistosomiasis is one of the most prominent helminth diseases, probably affecting over 200 million people at any one time. Recent increases in its occurrence in Africa have been attributed to new dams on the Nile River, which have provided additional habitat for snail hosts.

The schistosome parasite demonstrates intimate adaptations to both humans and certain species of freshwater snails required to complete its life cycle. The cycle begins when infected humans release eggs into irrigated fields or ponds either by deliberate fertilization with excreta or by defecating or urinating directly into the water. The egg hatches in the water and gives off an actively swimming ciliated larva called a **miracidium*** (figure 23.22a), which instinctively swims to a snail and burrows into a vulnerable site, shedding its ciliated covering in the process. In the body of the snail, the miracidium multiplies and transforms into a larger, fork-tailed swimming larva called a **cercaria*** (figure 23.22b). Cercariae are given off by the thousands into the water by infected snails.

Upon contact with a human, cercariae attach themselves to the skin by ventral suckers and penetrate hair follicles. They pass into small blood and lymphatic vessels and are carried to the liver. Here the schistosomes achieve sexual maturity, and the male and female worms remain permanently entwined to facilitate mating (figure 23.22c). In time, the pair lodges in small blood vessels. *Schistosoma mansoni* and *S. japonicum* end up in the mesenteric venules of the small intestine, and *S. haematobium* enters the venous plexus of the bladder. While attached to these intravascular sites, the worms feed upon blood, and the female lays eggs that are eventually voided in feces (*Schistosoma mansoni* and *S. japonicum*) or urine (*S. haematobium*).

(a) The miracidium phase, which infects the snail (300x).

(b) The cercaria phase, which is released by snails and burrows into the human host (5,000x).

(c) *Schistosoma mansoni* trematodes, with a long slender female worm cradled within a groove (right) on the ventral canal of the larger, thicker male to facilitate mating.

Figure 23.22 Stages in the life cycle of *Schistosoma*.

(a): © Sinclair Stammers/Science Source; (b): Courtesy of Harvey Blankespoor; (c): left, right): Source: CDC-DPDx

The first symptoms of infestation are itchiness in the vicinity of cercarial entry, followed by fever, chills, diarrhea, and cough. The most severe consequences, associated with chronic infections, are hepatomegaly and liver disease, splenomegaly, bladder obstruction, and blood in the urine. Occasionally eggs carried into the central nervous system and heart cause chronic granulomatous lesions.

In parts of Africa where this disease is endemic, epidemiologists are attempting a unique form of biological control. They have introduced into local lakes a species of small fish that feeds on snails, which greatly reduces the hosts for cercariae and the possibility for infection.

Liver and Lung Flukes (Cycle D)

Several trematode species that infest humans may be of zoonotic origin. The Chinese liver fluke, *Opisthorchis (Clonorchis) sinensis*,*

* *Opisthorchis sinensis* (oh'-piss-thor'-kis sy-nen'-sis) Gr. *opisthein*, behind, *orchis*, testis, and *sinos*, oriental.

* *Schistosoma* (skis'-toh-soh'-mah) Gr. *schisto*, split, and *soma*, body.

4. The species are named after P. Manson; Japan; and Gr. *haem*, blood, and *obe*, to like.

* *miracidium* (my'-rah-sid'-ee-um) Gr. *meirakidion*, little boy.

* *cercaria* (sir-kair'-ee-uh) Gr. *kerkos*, tail.

completes its sexual development in mammals such as cats, dogs, and swine. Its intermediate development occurs in snail and fish hosts. Humans ingest cercariae in inadequately cooked or raw freshwater fish and crustaceans. Larvae hatch and crawl into the bile duct, where they mature and shed eggs into the intestinal tract. Feces containing eggs are passed into standing water that harbors the intermediate snail host. The cycle is complete when infected snails release cercariae that invade fish or invertebrates living in the same water.

The liver fluke *Fasciola hepatica** is a common parasite in sheep, cattle, goats, and other mammals and is occasionally transmitted to humans (figure 23.23). Periodic outbreaks in temperate regions of Europe and South America are associated with eating wild watercress. The life cycle is very complex, involving a mammal as the definitive host, fecal release of eggs into water, hatching of eggs into miracidia, invasion of freshwater snails (the intermediate host), development and release of cercariae, encystment of cercariae on a water plant, and ingestion of the cysts by a mammalian host eating the plant. Humans develop symptoms of vomiting, diarrhea, hepatomegaly, and bile obstruction only if they are chronically infected by a large number of flukes.

The adult lung fluke *Paragonimus westermani**, endemic to Asia, India, and South America, occupies the pulmonary tissues of various reservoir mammals, usually carnivores such as cats, dogs, foxes, wolves, and weasels, and has two intermediate hosts—snails and crustaceans. Humans accidentally contract infection by eating

* *Fasciola hepatica* (fah-see'-oh-lah heh-pat'-ih-kah) Gr. *fasciola*, a band, and *hepatos*, liver.

* *Paragonimus westermani* (par'-ah-gon'-ih-mus wes-tur-man'-eye) Gr. *para*, to bear, and *gonimus*, productive; after Westerman, a researcher in flukes.

Figure 23.23 *Fasciola hepatica*, the sheep liver fluke (2×). Flukes like this are a good example of hermaphroditism, having both sex organs in the same worm. © Sinclair Stammers/Science Source

undercooked crustaceans. After being released in the intestine, the worms migrate to the lungs, where they can cause cough, pleural pain, and abscess.

Cestode (Tapeworm) Infections (Cycle C)

The **cestodes***, or tapeworms, exhibit extreme adaptations, consisting of little more than a tiny holdfast connected to a chain of flattened sacs that contain the reproductive organs. Several anatomical features of the adult emphasize their adaptations to an intestinal existence (figure 23.24a,b and figure 5.28a). The small **scolex***, or head of the worm, has suckers or hooklets for clinging to the intestinal wall, but it has no mouth because nutrients are absorbed directly through the body of the worm. The importance of the scolex in anchoring the worm makes it a potential target for antihelminthic drugs. The head is attached by a neck to the **strobila***, a long ribbon composed of individual body segments called **proglottids***, which are generated by the neck. The contents of the proglottids are dominated by male and female reproductive organs. Each segment also contains a primitive neuromuscular system that permits feeble movements. The proglottids taper from the smaller, newly formed, and least mature segments nearest the neck to the larger, older ones containing ripe eggs at the distal end of the worm. The proglottids are either shed intact in feces after detaching from the strobila or break open in the intestine and expel free eggs into the feces.

All tapeworms for which humans are the definitive hosts require an intermediate animal host. The principal causes of human **taeniasis** are *Taenia saginata*, the beef tapeworm, and *Taenia solium*, the swine tapeworm. *Diphyllobothrium latum* is acquired through raw fish (23.3 Making Connections). The beef tapeworm follows a cycle C pattern, in which the larval worm is ingested in raw beef; and the pork tapeworm follows both a cycle C and a modified cycle A, in which the eggs are ingested and hatch in the body.

*Taenia saginata** is one of the largest tapeworms, composed of up to 2,000 proglottids and anchored by a scolex with suckers. Taeniasis caused by the beef tapeworm is distributed worldwide but is reported most often where cattle ingest proglottids or eggs from contaminated fields and water, and where raw or undercooked beef is eaten. The eggs hatch in the small intestine, and the released larvae migrate throughout the organs of the cow (figure 23.24c). Ultimately, they encyst in the muscles, becoming **cysticerci**, young tapeworms that are the infective stage for humans. When humans ingest a live cysticercus in beef, it is uncoated and firmly attaches to the intestine by the scolex, where it develops into an adult tapeworm. Humans are not known to acquire infection by ingesting the eggs. For such a large organism, it is remarkable how few symptoms a tapeworm causes. Patients may complain of vague abdominal pain and nausea and discover proglottids in their stool.

* *cestodes* (sess'-tohd) L. *cestus*, belt, and *ode*, like.

* *scolex* (skoh'-leks) Gr. *scolos*, worm.

* *strobila* (stroh-bih'-lah) Gr. *strobilos*, twisted.

* *proglottids* (proh-glot'-id) Gr. *pro*, before, and *glotta*, the tongue.

* *Taenia saginata* (tee'-nee-ah saj-ih-nah'-tah) L. *taenia*, a flat band, *sagi*, a pouch, and *natare*, to swim.

23.3 MAKING CONNECTIONS

Waiter, There's a Worm in My Fish

Various forms of raw fish or shellfish are part of the cuisine of many cultures. Popular examples are Japanese sashimi and sushi. Although these delicacies are generally safe, fish flesh often harbors various types of helminths. Humans are not usually natural hosts for these parasites, so the worms do not fully invade, but some of their effects can be quite distressing.

One of the common fish parasites transmitted this way is *Anisakis*, a nematode parasite of marine vertebrates, fish, and mammals. The symptoms of anisakiasis, usually appearing within a few hours after a person ingests the half-inch larvae, are due to the attempts of the larvae to burrow into the tissues. The first symptom is often a tingling sensation in the throat, followed by acute gastrointestinal pain, cramping, and vomiting, which mimic appendicitis. At times the worms are regurgitated or discovered during surgery, but in many cases they are probably expelled without symptoms. Another worm that can hide in raw or undercooked

freshwater fish is the tapeworm *Diphyllobothrium latum*, common in the Great Lakes, Alaska, and Canada. Because humans serve as its definitive host, this worm can develop in the intestine and cause long-term symptoms.

Students always ask about the safety of sushi and seem uncertain about how to eat it and still avoid parasites. One good safeguard is to patronize a reputable sushi bar, because a competent sushi chef carefully examines the fish for the readily visible larvae. Another is to avoid raw salmon and halibut, which are more often involved than tuna and octopus. Fish can also be freed of live parasites by freezing for 5 days at -20°C .

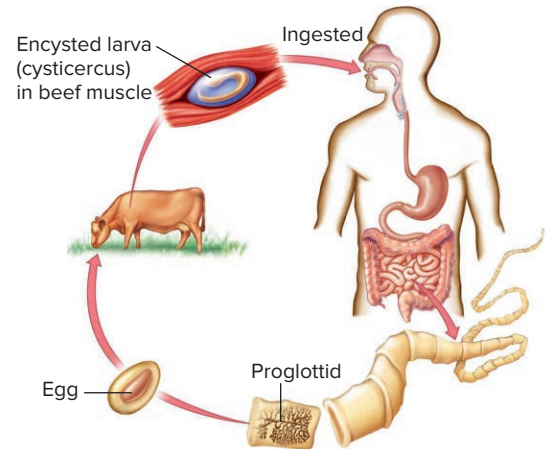

One common perception is that fish from saltwater are safer to eat raw than those from fresh water. Based on the examples here, what do you think is true? Answer available on Connect.

(a) *Taenia solium* tapeworm scolex displaying four suckers and two rows of hooklets.

(b) Adult *Taenia saginata*. The arrow points to the scolex; the remainder of the tape, called the strobila, has a total length of 5 meters.

(c) A generalized diagram of the life cycle of the beef tapeworm *T. saginata*.

Figure 23.24 Features of *Taenia* tapeworms. (a): Source: CDC; (b): © Eric Gravel/ Science Source

Taenia solium differs from *T. saginata* by being somewhat smaller, having a scolex with hooklets and suckers to attach to the intestine, and being infective to humans in both the cysticercus and egg stages. The disease is endemic to regions where pigs eat fecally contaminated food and humans consume raw or partially cooked pork (Southeast Asia, South America, Mexico, and eastern Europe). The cycle involving ingestion of cysticerci is nearly identical to that of the beef tapeworm (figure 23.24c).

A different form of the disease, called **cysticercosis**, occurs when humans ingest pork tapeworm eggs from food or water. Although humans are not the usual intermediate hosts, the eggs can still hatch in the intestine, releasing tapeworm larvae that migrate to all tissues. They finally settle down to form peculiar cysticerci, or bladder worms, each of which has a small capsule resembling a little bladder. They do the most harm when they lodge in the heart muscle, eye, or brain, especially if a large number of bladder worms occupy tissue space (figure 23.25). It is not uncommon for patients to exhibit seizures, psychiatric disturbances, and other signs of neurological impairment.

23.8 The Arthropod Vectors of Infectious Disease

Expected Learning Outcomes

34. Differentiate among the arthropod vectors of disease.
35. Describe the relationship between arthropod vectors and the parasites they carry.

The **arthropods** are a phylum of invertebrates that all share a body plan with an exoskeleton and jointed legs. Members include insects, arachnids, and crustaceans. Of the millions of species of arthropods known, a few thousand must feed on the blood or tissue fluids of a host sometime during their life cycle. In this adaptation, they are considered a type of **ectoparasite** because they remain on the outside of the host's body.

The types of ectoparasites discussed here not only feed on blood, they also transmit infectious microbes to the host. Animals with this behavior are considered *biological vectors* (see chapter 13). This means that they foster the survival of a pathogen (as do fleas with the plague bacillus) and may even provide an environment for the pathogen to complete its own life cycle (sand flies with *Leishmania*: see figure 23.11). In this way, they are alternate host organisms. Depending on the specificity of the vector and microbe, the diseases range from zoonoses that affect many different animals (trypanosomiasis) to those that attack a specific group (malaria). The types of arthropods that most often serve as vectors are insects: mosquitoes, fleas, lice, flies; and arachnids: ticks and mites. Although all vector groups are found worldwide, certain species may be found only in a particular geographic region such as the tropics. Other vectors may be endemic to a specific continent or country (Africa or South America, for example). *As a general rule, the location of the vector will dictate the origin and distribution of the disease.* **Table 23.6** provides a survey of vectors and the diseases they transmit.

Mosquitoes (Spanish for “little fly”) are cosmopolitan insects in the Class Diptera. Approximately 3,500 species inhabit regions from the tropics to the Arctic. The adult can fly up to 300 miles and live for 2 months. All but a few species require blood and an aquatic habitat to complete their life cycle. The eggs are laid in standing water and go through embryonic, larval, and adult development there. An interesting note is that only the female mosquito actually sucks blood from the host—she needs blood protein to complete the development of her eggs. The male feeds primarily on plant juices. The female penetrates the skin with her proboscis to the level of a capillary, where she injects a small amount of anticoagulant so that the blood will flow freely into her digestive tract (**figure 23.26a**). This is the route by which infections take place. Mosquitoes are

Location of descriptions of diseases: ♦ Ch 23 ☆ Ch 21 ♣ Ch 25 ♠ Ch 20			

probably the dominant vector on earth with regard to numbers of infections. The CDC estimates that mosquito-borne diseases such as malaria, filariasis, Dengue fever, and other forms of arbovirus encephalitis affect 700 million people and that 3 million people, most of them children, die every year from these diseases.

Fleas are laterally flattened, wingless insects with well-developed jumping legs and prominent probosci for piercing the skin of warm-blooded animals (**figure 23.26b**). They are known for their extreme longevity and resistance, and many are notorious in their nonspecificity, passing with ease from wild or domesticated mammals to humans. In response to mechanical stimulation and warmth, fleas jump onto their targets and crawl about, feeding as they go. Infection takes place when a carrier flea regurgitates blood into the

wound. The most common flea-borne diseases are bubonic plague (see figure 20.20) and murine typhus.

Lice are small, soft insects equipped with biting or sucking mouthparts (**figure 23.26c**). The lice of humans usually occupy head and body hair (*Pediculus humanus*) or pubic, chest, and axillary hair (*Phthirus pubis*). They feed by gently piercing the skin and sucking blood and tissue fluid. Infection develops when the louse or its feces are inadvertently crushed and rubbed into wounds, skin, eyes, or mucous membranes. Lice are involved in transmitting epidemic typhus and relapsing fever.

Quick Search

To observe an *Ixodes* tick in the empty and full state, search for “engorged tick” on Google images.

Distributed the world over are 810 species of **ticks**, all of them ectoparasites and about 100 of them carriers of infectious diseases (**figure 23.26d,e**). Ticks can be broadly characterized as hard bodied (ixodid), or soft bodied (argasid). Ticks exhibit the broadest host range of all vectors, able to feed on every vertebrate group except fish.

Hard (ixodid) ticks have tiny compact bodies suitable for hitchhiking along as their hosts wander through forest, savanna, or desert regions. Depending upon the species, ticks feed during larval, nymph, and adult metamorphic stages. The longevity of ticks is formidable; metamorphosis can extend for 2 years, and adults can survive for 4 years away from a host without feeding. The tiny, unengorged ticks cling to vegetation and attach to clothing of people. They crawl to skin surfaces and embed their mouthparts. As blood enters their gut, they expand significantly. Ixodid ticks are implicated in a number of bacterial, rickettsial, and viral diseases.

CASE STUDY Part 2

Of concern to the CDC was the fact that neither patient could be linked to the warm-water springs, lakes, or rivers that are breeding grounds for the amoeba. As an investigation of both cases began, health officials worried that they could be dealing with a strain of *Naegleria fowleri* that had become more virulent or that had evolved a new means of entering the body.

One commonality investigators did discover was that both patients used neti pots filled with warm tap water to rinse their sinuses. A neti pot resembles a small teapot with a long spout, and is used by some people to rinse the nasal passages with a saline solution as a treatment for colds, allergies, or congestion. Investigators collected water samples from both homes and testing revealed the presence of *N. fowleri* in each case. These two incidents were the first time

Soft (argasid) ticks with their flexible bodies seek sheltered habitats in caves, barns, burrows, or even birdcages. They parasitize wildlife during nesting seasons and domesticated animals throughout the year. Endemic relapsing fever is transmitted by this type of tick.

Check Your Progress SECTION 23.8

- Identify the types of arthropods that commonly serve as biological vectors of disease and summarize their characteristics.
- Explain the differences between insects and arachnids and their role as vectors.
- Explain several ways that vectors spread parasites to other hosts.

PAM was associated with the presence of *N. fowleri* in household plumbing served by treated municipal water supplies, as well as the first time that infection with the amoeba was linked to use of a neti pot or similar nasal irrigation device.

- N. fowleri* grows at temperatures up to 46°C, but can survive for many hours at even higher temperatures. What biological structure could *N. fowleri* use to survive the hottest temperatures seen in household water systems?
- What additional precautions as to the avoidance of infection may have been issued based on the information seen in this part of the Case Study?

Yoder, J. et. al. 2012. Primary amebic meningoencephalitis deaths associated with sinus irrigation using contaminated tap water. *Clin Infect Dis* 55:e79–e85.

To conclude this Case Study, go to Connect.

Chapter Summary with Key Terms

23.1 The Parasites of Humans

- Parasitology covers **protozoa** and **helminths** (worms), which live on the body of a host. Parasites are spread to humans by other humans, animal hosts, and vectors.
- Parasitic diseases have existed since ancient times but are still a major public health problem today. International travel of people and materials has facilitated the spread of parasites and their vectors worldwide. The increase in immunosuppressed people, particularly those with AIDS, has caused an increase in formerly obscure protozoan infections.
 - Some protozoans propagate only as **trophozoites** (active feeding stage found in host), whereas others alternate between a trophozoite and a **cyst** (dormant, resistant body).
 - Some have complex life cycles with sexual and asexual phases carried out in more than one host.

23.2 Major Protozoan Pathogens

A. Infective Amoebas

Entamoeba histolytica is the cause of amebiasis, or amebic dysentery, a worldwide human infection that affects approximately 500 million people in the tropics.

- The protozoan alternates between a trophozoite and a cyst. Cysts are spread through unsanitary water and food.
- Ingested cysts release trophozoites that invade the large intestine and cause ulceration and dysentery.
- Severe cases may occur when the pathogen penetrates into deeper layers.
- Amebic brain infections are caused by *Naegleria fowleri* and *Acanthamoeba* species, free-living inhabitants of natural waters. Primary acute meningoencephalitis is acquired through nasal contact with water or traumatic eye damage. Infiltration of the brain is usually fatal.

B. Infectious Ciliates

The only important ciliate pathogen is *Balantidium coli*, an occupant of the intestines of domestic animals such as pigs and cattle. It is acquired by humans when cyst-containing food or water is ingested. The trophozoite erodes the intestine and elicits intestinal symptoms.

23.3 The Flagellates (Mastigophorans)

- A. *Trichomonas* is an animal parasite or commensal. The principal human pathogen is *T. vaginalis*, the cause of a very common STD known as **trichomoniasis** that infects the vagina, cervix, and urethra.
- B. *Giardia intestinalis* is an intestinal flagellate that causes **giardiasis**. Its natural reservoir is animal intestines, and the source of infection is cyst-contaminated fresh water and food and causes severe diarrhea that may be chronic in immunodeficient patients.
- C. **Hemoflagellates** are members of *Trypanosoma* that occur in blood during infection. The pathogens have complex life cycles, with various mastigote phases that develop in the insect and human hosts. Diseases are known as **trypanosomiasis**.
 1. *T. brucei* causes **African sleeping sickness**, spread by **tsetse flies** and harbored by reservoir mammalian hosts. The biting fly inoculates skin with the trypanosome, which multiplies in the blood, and damages the spleen, lymph nodes, and brain. Chronic disease symptoms are sleep disturbances, tremors, paralysis, and coma.
 2. *T. cruzi* causes **Chagas disease**, a disease endemic to Latin America. Its cycle involves the **reduviid** (kissing) bug vector. Infection occurs when bug feces are inoculated into a cutaneous portal. Chronic inflammation occurs in the organs (especially heart and brain).
 3. *Leishmania* contains geographically separate species that cause **leishmaniasis**, a zoonosis of wild animals that is transmitted by the bite of **phlebotomine** (sand) flies. Infected macrophages carry the pathogen into the skin and bloodstream, giving rise to fever, enlarged organs, and anemia. Kala azar is the most severe and fatal form.

23.4 Apicomplexan Parasites

Apicomplexans are tiny obligate intracellular parasites that have complex life cycles and lack motility organelles in their mature stage. Infectious forms include sporozoites, fecal cysts called oocysts, and tissue cysts. Most diseases are zoonotic and vector-borne.

- A. *Plasmodium* is the cause of malaria; the human is the primary host for the asexual phase of parasite; the female *Anopheles mosquito* is the vector/host for the sexual phase.
 1. **Malaria** is the most common parasitic disease, distributed primarily in a belt around the equator.
 2. Infective forms for humans (**sporozoites**) enter blood with mosquito saliva, penetrate liver cells, multiply, and form hundreds of **merozoites**. These multiply in and lyse red blood cells.
 3. Symptoms include episodes of chills, fever, and sweating; anemia; and organ enlargement.
 4. *Toxoplasma gondii* lives naturally in cats that harbor oocysts in the GI tract.
 - a. **Toxoplasmosis** is acquired by ingesting raw or rare meats containing tissue cysts or by accidentally ingesting oocysts from substances contaminated by cat feces.

- b. In humans, infection is usually mild and fluke-like.

Immunodepressed (AIDS) patients or fetuses (fetal toxoplasmosis) suffer brain and heart damage.

5. *Cryptosporidium* is a vertebrate pathogen that exists in both tissue and oocyst phases. Most cases of cryptosporidiosis are caused by handling animals with infections or by drinking contaminated water. Infection causes enteric symptoms.
- ### B. Coccidian Parasites
1. *Cystoisospora* is an uncommon human intestinal parasite transmitted through fecal contamination that causes coccidiosis.
 2. *Cyclospora* causes a diarrheal illness when its oocysts are ingested in fecally contaminated produce and water.

23.5 A Survey of Helminth Parasites

- A. The parasitic **helminths**, or worms, are multicellular animals with specialized mouthparts and adaptations such as reduction of organs, protective cuticles, and complex life cycles.
- B. Adult worms mate and produce fertile eggs that hatch into larvae that mature in several stages to adults. In some worms, the sexes are separate; others are **hermaphroditic**.
 1. Adults live in a **definitive host**, whereas larval development occurs in the **intermediate host**.
 2. Eggs and larvae may develop in the same host, the external environment, or an intermediate host.
 3. Transmission can involve eggs, larvae, and insect vectors.
 4. Helminth pathology arises from worms feeding on and migrating through tissues and accumulation of worms and worm products.
 5. Useful antihelminthic drugs control worms by paralyzing their muscles and causing them to be shed or interfering with metabolism and killing them.
 6. Other control measures are improved sanitation of food and water, protective clothing, cooking meat adequately, and controlling vectors.

23.6 Nematode (Roundworm) Infestations

Roundworms are filamentous with protective cuticles, circular muscles, a complete digestive tract, and separate sexes with well-developed reproductive organs.

- A. *Ascaris lumbricoides* is indigenous to humans. Eggs ingested with foods hatch into larvae and burrow through the intestine into the circulation. From there, they travel to the lungs and pharynx and are swallowed. The adult worms complete the reproductive cycle in the intestine.
- B. *Trichuris trichiura*, the whipworm, is a small parasite transmitted like *Ascaris* but restricted to the intestine throughout development.
- C. *Enterobius vermicularis*, the pinworm, is a common childhood infection confined to the intestine. Eggs are picked up from surroundings and swallowed. After hatching, they develop into adults, and the females release eggs at the anus; self-inoculation is common.
- D. Hookworms have characteristic curved ends and hooked mouths. The two major species, *Necator americanus* and *Ancylostoma duodenale*, share a similar life cycle, transmission, and pathogenesis. Humans shed eggs in feces, which hatch in soil and burrow into the skin of lower legs. Larvae travel from blood to lungs and are swallowed. Adult worms reproduce in the intestine and complete the cycle.

- E. *Strongyloides stercoralis*, the threadworm, is a tiny nematode that completes its life cycle in humans or in moist soil. Larvae emerging from soil-borne eggs penetrate the skin and migrate to the lungs, are swallowed, and complete development in the intestine.
- F. *Trichinella spiralis* causes **trichinellosis**, a zoonosis in which humans are a dead-end host. Disease is acquired from eating undercooked or raw pork or bear meat containing encysted larvae. Larvae migrate from the intestine to blood vessels, muscle, heart, and brain, where they enter dormancy.
- G. **Filarial worms** are long, threadlike worms with tiny larvae (microfilariae) that circulate in blood and reside in various organs; are spread by various biting insects.
1. *Wuchereria bancrofti* causes **bancroftian filariasis**, a tropical infestation spread by mosquitoes. The vector deposits the larvae, which move into lymphatics and develop. Chronic infection causes blockage of lymphatic circulation and **elephantiasis**, which swells the extremities.
 2. *Onchocerca volvulus* causes river blindness, an African disease spread by small, river-associated insects that feed on blood. Inoculated larvae migrate to skin to mature and form nodules in the eye that can destroy the cornea.
 3. *Loa loa*, the African eye worm, is spread by the bite of small flies. The worm migrates around under the skin and may enter the eye.

23.7 Flatworms: The Trematodes and Cestodes

Trematodes, or *flukes*, are flatworms with leaflike bodies bearing suckers; most are hermaphroditic.

- A. Blood flukes and *Schistosoma* species. **Schistosomiasis** is a prevalent tropical disease. Adult flukes live in humans and release eggs into water. The early larva, or **miracidium**, develops in the freshwater snail into a second larva, or **cercaria**. This larva penetrates human skin and moves into the liver to mature; adults migrate to intestine or bladder and shed eggs, giving rise to chronic organ enlargement.
- B. Zoonotic flukes include the Chinese liver fluke *Opisthorchis sinensis*, which cycles between mammals and snails and fish. Humans are infected when eating fish containing larvae, which invade the liver. *Fasciola hepatica* cycles between herbivores, snails, and aquatic plants. Humans are infected by eating raw aquatic plants; the fluke lodges in the liver.
- C. **Cestodes or tapeworms**: These flatworms have long, very thin, ribbonlike bodies (**strobila**) composed of sacs

(**proglottids**) and a **scolex** that grips the host intestine. Each proglottid is an independent unit adapted to absorbing food and making and releasing eggs.

1. *Taenia saginata* is the beef tapeworm for which humans are the definitive host. Animals are infected by grazing on land contaminated with human feces. Humans ingest raw beef in which the larval form (**cysticercus**) has encysted. The larva attaches to the small intestine and becomes an adult tapeworm.
2. *T. solium* is the pork tapeworm that infects humans through cysticerci or by ingesting eggs in food or drink (**cysticercosis**). The larvae hatch and encyst in many organs and can damage them.

23.8 The Arthropod Vectors of Infectious Disease

Some invertebrates are ectoparasites that feed on blood and/or tissue fluids as part of their life cycles. Many of them serve as biological vectors by transmitting infectious agents during this process.

- A. **Mosquitoes** are insects that require an aquatic habitat for development. Only females take blood from humans to complete egg production. They are transmitters of major diseases, with malaria the most prominent of these; others include filariasis (roundworms) and zoonoses such as arbovirus encephalitis.
- B. **Fleas** are tiny, highly motile insects with flattened bodies that feed on warm-blooded animals. They are not specific to their hosts, so they mainly carry zoonotic diseases such as plague (bacteria) and murine typhus (rickettsias).
- C. **Lice** are small soft insects that attach to head and body hair, feeding on blood and tissue fluids while releasing feces that contaminate the wound. Epidemic typhus (rickettsias) and relapsing fever (borrelias) are the most serious diseases they spread.
- D. Other insect vectors include flies: for instance, the tsetse fly spreads African trypanosomiasis; the sand fly transmits leishmaniasis; the reduviid bug spreads Chagas disease.
- E. **Ticks** are arachnids that cling to vegetation and hitch a ride on passing host bodies. Larvae, nymph, and adults feed by piercing the skin of the host, sucking blood, and swelling many times their size.
 1. *Hard* or *ixodid* ticks (*Dermacentor*, *Ixodes*) have small, compact, somewhat rigid bodies; they transmit several rickettsial, borrelian, and viral diseases.
 2. *Soft* or *argasid* ticks (*Ornithodoros*) have more flexible outer bodies; they transmit relapsing fever.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

1. All protozoan pathogens have a _____ phase.

a. cyst	c. trophozoite
b. sexual	d. blood
2. *Entamoeba histolytica* primarily invades the

a. liver	c. small intestine
b. large intestine	d. lungs

3. *Giardia* is a/an _____ that invades the _____.
- flagellate, large intestine
 - amoeba, small intestine
 - ciliate, large intestine
 - flagellate, small intestine
4. Hemoflagellates are transmitted by
- mosquito bites
 - insect vectors
 - bug feces
 - contaminated food
5. *Plasmodium* reproduces sexually in the _____ and asexually in the _____.
- liver, red blood cells
 - mosquito, human
 - human, mosquito
 - red blood cell, liver
6. In the exoerythrocytic phase of infection, *Plasmodium* invades the
- blood cells
 - heart muscle
 - salivary glands
 - liver
7. The oocyst of *Toxoplasma* is found in _____, and a pseudocyst is found in _____.
- humans, cats
 - cats, humans
 - feces, tissue
 - tissue, feces
8. A person can acquire toxoplasmosis from
- pseudocysts in raw meat
 - oocysts in air
 - cleaning out the cat litter box
 - all of these
9. All adult helminths produce
- cysts and trophozoites
 - scolex and proglottids
 - fertilized eggs and larvae
 - hooks and cuticles
10. The _____ host is where the larva develops, and the _____ host is where the adults produce fertile eggs.
- intermediate, definitive
 - definitive, intermediate
 - secondary, transport
 - primary, secondary
11. Antihelminthic medications work by
- paralyzing the worm
 - disrupting the worm's metabolism
 - causing vomiting
 - both a and b
12. Host defenses that are most active in worm infestations:
- phagocytes
 - antibodies
 - killer T cells
 - eosinophils
13. Currently the most common nematode infestation worldwide is
- hookworm
 - ascariasis
 - tapeworm
 - trichinosis
14. Hookworm diseases are spread by
- the feces of humans
 - mosquito bites
 - contaminated food
 - microscopic invertebrates in drinking water
15. Trichinosis can only be spread from human to human by
- cannibalism
 - flies
 - raw pork
 - contaminated water
16. The swelling of limbs typical of elephantiasis is due to
- allergic reaction to the filarial worm
 - granuloma development due to inflammation by parasites
 - lymphatic circulation being blocked by filarial worm
 - heart and liver failure due to infection
17. Which of the following is *not* considered an insect vector?
- flea
 - mosquito
 - tick
 - tsetse fly
18. The _____ mosquito feeds on blood, which is required for development of _____.
- male, larvae
 - male, parasites
 - female, GI tract
 - female, eggs
19. **Single Matching.** Match the disease or condition with the causative agent, and indicate for each whether the agent is a protozoan (P) or a helminth (H).
- | | |
|-------------------------------------|-----------------------------------|
| 1. _____ amebic dysentery | a. <i>Plasmodium vivax</i> |
| 2. _____ Chagas disease | b. <i>Enterobius vermicularis</i> |
| 3. _____ tapeworm | c. <i>Onchocerca volvulus</i> |
| 4. _____ hookworm | d. <i>Toxoplasma gondii</i> |
| 5. _____ African sleeping sickness | e. <i>Trichuris trichiura</i> |
| 6. _____ pinworm | f. <i>Entamoeba histolytica</i> |
| 7. _____ filariasis | g. <i>Necator americanus</i> |
| 8. _____ amebic meningoencephalitis | h. <i>Trypanosoma brucei</i> |
| 9. _____ malaria | i. <i>Wuchereria bancrofti</i> |
| 10. _____ toxoplasmosis | j. <i>Trypanosoma cruzi</i> |
| 11. _____ trichinellosis | k. <i>Taenia saginata</i> |
| 12. _____ whipworm | l. <i>Naegleria fowleri</i> |
| 13. _____ river blindness | m. <i>Trichinella spiralis</i> |
20. **Single Matching.** Match the disease with its primary mode of transmission or acquisition in humans.
- | | |
|---------------------------|--|
| 1. _____ amebic dysentery | a. eating poorly cooked beef or pork |
| 2. _____ Chagas disease | b. ingestion of cysts in water contaminated by wild animal feces |
| 3. _____ cyclosporiasis | c. ingestion of food contaminated by human feces |
| 4. _____ toxoplasmosis | d. bite from a reduviid bug |
| 5. _____ giardiasis | e. bite from a black fly |
| 6. _____ tapeworm | f. water or food contaminated with human feces containing eggs |
| 7. _____ filariasis | g. contact with cats or ingesting rare or raw meat |
| 8. _____ schistosomiasis | h. bite from an <i>Anopheles</i> mosquito |
| 9. _____ ascariasis | i. ingesting fecally contaminated water or produce |
| 10. _____ river blindness | j. freshwater snail vector releases infectious stage |

Case Study Review

- What cellular structures would *Naegleria fowleri* use for motility?
 - cilia
 - pseudopods
 - flagella
 - None; *N. fowleri* is nonmotile.
- Infection with which organism could produce symptoms similar to those seen in primary amebic meningoencephalitis?
 - Balantidium coli*
 - Plasmodium falciparum*
 - Taenia solium*
 - Trichomonas vaginalis*
- Provide at least two reasons that primary amebic meningoencephalitis is more common in the summer months.

 Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

1. As a review, compare the four major groups of pathogenic protozoa according to overall cell structure, locomotion, infective state, and mode of transmission.
2. a. What are the primary functions of the trophozoite and the cyst in the life cycle?
b. In which diseases is a cyst stage an important part of the infection cycle?
3. a. Describe the life cycle and host range of *Toxoplasma gondii*.
b. How are humans infected?
c. What are the most serious outcomes of infection?
4. a. In what ways are helminths different from other parasites, and why are there so many parasitic worm infections worldwide?
b. What is the nature of human defenses against them?
5. In what ways is trichinellosis different from other worm infections?
6. a. Which parasites are zoonotic?
b. Which are strictly human parasites?
c. Which are borne by vectors?
d. Which cause intestinal symptoms?
e. Which are hermaphroditic?
f. Which are associated with rare or raw meat?

 Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps along with concept mapping activities for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

 Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

1. Explain why a person with overt symptoms of intestinal *Entamoeba histolytica* infection is unlikely to transmit infection to others.
2. a. Explain why *Trichomonas vaginalis* is less likely to be transmitted by casual contact.
b. What is meant by “ping-pong” infection, and why must both sex partners be treated for trichomoniasis?
3. Explain why only female mosquitoes are involved in malaria and elephantiasis.
4. Which parasitic diseases could conceivably be spread by contaminated blood and needles?
5. For which diseases can one *not* rely upon chlorination of water as a method of control? Explain why this is true.
6. a. If a person returns from traveling afflicted with trypanosomiasis or leishmaniasis, is he or she generally infective to others? Explain.
b. Explain why there is no malaria above 6,000 feet in altitude.
c. Account for all of the protective effects offered by insecticide-treated bednets.
7. Give some of the reasons that there are no really effective human vaccines so far for parasitic infections.
8. a. After comparing the maps shown in figures 23.8, 23.9, and 23.12, provide reasons to account for the patterns of distribution shown.
b. Describe some factors that would affect the changes in the patterns.
9. a. What one simple act could in time eradicate ascariasis?
b. Hookworm?
c. Beef tapeworm?
10. To achieve a cure for tapeworm, why must the antihelminthic drug either kill the scolex or slacken its grip?
11. Students sometimes react with horror and distress when they discover that cats and dogs carry parasites to humans. Give an example of a disease for each of these animals that can be spread to humans, and explain how to avoid these diseases and still enjoy your pet.
12. a. Why is it necessary for most parasites to leave their host to complete the life cycle?
b. What are some ways to prevent completion of the life cycle?
c. What is the benefit to parasites of having numerous hosts?
d. What are the disadvantages in having more than one host?
13. East Indian natives habitually chew on betel nuts as an alkaloidal stimulant and narcotic. A side effect is phlegm collection, which is eliminated by frequent spitting. The incidence of *Strongyloides*

infections is relatively low in this population. Can you account for this? (No, the betel nuts are not effective antihelminthics.)

14. In New York City, four Orthodox Jewish patients brought into an emergency clinic with seizures and other neurological symptoms tested positive for antibodies to the pork tapeworm, *Taenia solium*. This was embarrassing to them because they do not eat pork for

religious reasons. It also became something of a medical mystery, because there were no immediate explanations for how they could have become infected. Later it was shown that the patients had recently employed housekeepers and cooks who were free of symptoms yet also seropositive for the worm infection. Use this case history to give a plausible explanation for the transmission of the infection.

Visual Challenge

1. From **chapter 5, figure 5.29**. Correlate the pinworm cycle with the correct type of cycle in **figure 23.17**.

2. Observe figures **a, b, c,** and **d** and identify the parasite shown.

Varicella-zoster virus is responsible for both chickenpox (right) and shingles (center). (left and right): Source: CDC; (center): © SPL/Science Source

CASE STUDY Part 1 Childhood Diseases

A skin rash can indicate anything from an annoyance (an allergic reaction to a new laundry detergent) to a global health emergency (smallpox), and the nature of the **rash** often provides the initial clues as to its cause. In this case, a 94-year-old woman presented to her physician with a widespread rash. She appeared healthy on initial examination and had no fever but had developed a **vesicular rash** over her face, limbs, and trunk over the last 48 hours. Reddened vesicular rashes—essentially small blisters or **lesions** filled with clear fluid—concentrated in the center of the body are a hallmark of **chickenpox**. The woman mentioned that she had never had chickenpox and hadn't had recent contact with anyone (grandchildren presumably) who may have had the disease. She did volunteer that her husband had been diagnosed with **ophthalmic zoster (shingles)** several weeks previously. Based on the initial examination, the physician suspected chickenpox and prescribed **famicyclovir**, an antiviral medication.

The next day during a follow-up exam, many of the lesions had crusted over, typical of chickenpox. Blood tests revealed the presence of **varicella-zoster virus (VZV)** specific **IgM antibodies**, but no IgG; a second blood test 2 days showed the same result, but with an increased IgM titer. Two weeks later, a third blood test revealed the presence of **IgG antibodies** specific for VCV.

“Over the course of several days, the lesions began to crust over.”

Varicella-zoster virus, a member of the **herpesvirus** family, is responsible for varicella, more commonly known as chickenpox. The virus spreads easily to people who have never had the disease or received the chickenpox vaccine. Coughing and sneezing release the virus into the air, and the virus can also be contracted by inhaling viral particles released from chickenpox lesions. The illness typically lasts 5 to 10 days, after which the person is immune to a second bout of the disease. In general, having the disease when you are older results in more severe symptoms and a longer course of illness, with complicating symptoms ranging from **dehydration** to **encephalitis**.

Over the course of the next 2 weeks the patient seemed to recover without incident; all lesions were crusted over and the earliest lesions had begun to heal. Seventeen days after initially presenting to her doctor the patient developed paralysis on one side of her body. Imaging revealed an acute infarct, confirming that the patient had indeed had a stroke. She died one month later.

- *Why is the husband's ophthalmic zoster infection important in this case?*
- *What is the significance of the three serum antibody tests done on the woman?*

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

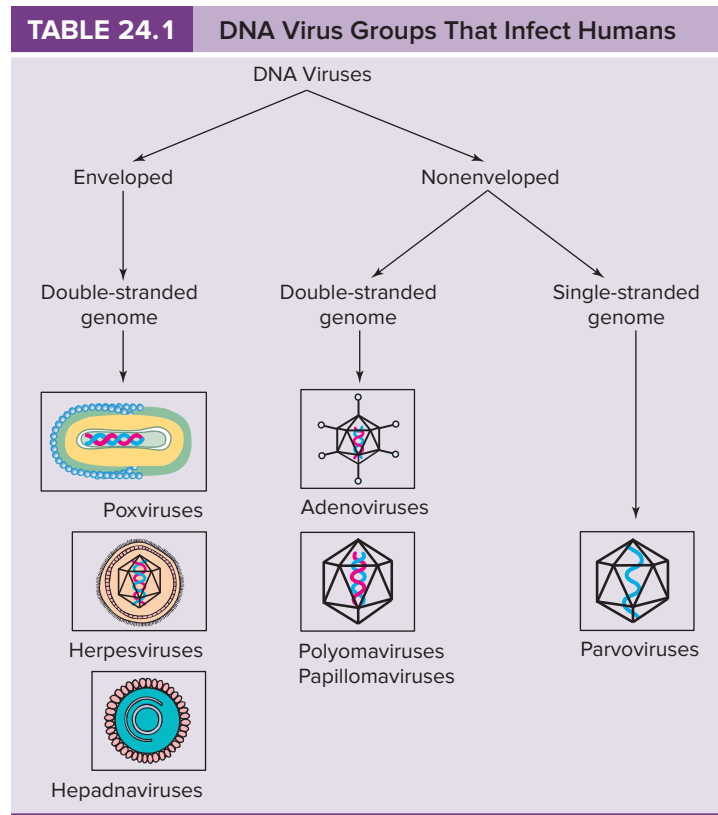

24.1 Viruses in Human Infections and Diseases

Expected Learning Outcomes

1. Recall the general characteristics of viruses.
2. Understand the progression and scope of viral infection.
3. Explain how viral structure is related to viral classification.

Viruses are the smallest parasites with the simplest biological structure. Essentially they are particles composed of DNA or RNA molecules surrounded by a protein coat. They are completely dependent on a host cell for their continued existence. Viruses have special adaptations for entering a cell and instructing the cell's genetic and molecular machinery to produce and release new viruses.

Animal viruses are divided into families based on the nature of the nucleic acid (DNA or RNA), the type of capsid, and whether or not an envelope is present. All DNA viruses that infect humans are double-stranded except for the parvoviruses, which contain single-stranded DNA. All RNA viruses that infect humans are single-stranded except for the double-stranded reoviruses. The genome of RNA viruses can be further described as segmented (consisting of more than one molecule) or nonsegmented (consisting of a single molecule). The envelope is derived from host cell membranes as the virus buds off the nuclear envelope, cell membrane, or Golgi membrane, and it contains spikes that interact with the host cell. See **tables 24.1** and 25.1 for a simple classification of DNA and RNA viruses.

Systems Profile 24.1 Pathogenic DNA Viruses						
Virus	Skin/Skeletal	Nervous/ Muscle	Cardiovascular/ Lymphatic/ Systemic	Gastrointestinal	Respiratory	Urogenital
Variola Virus	Smallpox		Viremia			
Molluscum Contagiosum Virus	Molluscum contagiosum					Genital molluscum
Herpes Simplex Virus 1 and 2	1. Oral herpes 2. Whitlows 3. Keratitis	Encephalitis				Genital herpes
Varicella-Zoster Virus	Chickenpox	Shingles				
Cytomegalovirus (CMV)	Salivary glands		CMV infection			
Epstein-Barr Virus	Oral cavity, glands		Infectious mononucleosis			
Human Herpesvirus 6 and 7	Roseola					
Hepatitis B Virus	Jaundice			Hepatitis		
Adenovirus	Conjunctivitis				Colds	
Human Papillomavirus	Warts					Genital warts
JC Virus		Progressive multifocal leukoencephalopathy				
Parvovirus B19	Erythema infectiosum (fifth disease)		Red blood cell damage			

Important Medical Considerations in Viral Diseases

Target Cells

Because viruses have specific receptors for interacting with host cells, their infectiousness is limited to a particular host or cell type in most cases. Viruses infect most types of tissues, including the nervous system (polio and rabies), liver (hepatitis), respiratory tract (influenza, colds), intestine (polio), skin and mucous membranes (herpes), and immune system (AIDS). Many DNA viruses are assembled and budded off the nucleus, whereas most RNA viruses multiply in and are released from the cytoplasm. The presence of assembling and completed viruses in the cell gives rise to various telltale disruptions called cytopathic effects. The lytic infection of cells often destroys them, which accounts for the sometimes severe pathology and loss of function associated with viral infections.

Scope of Infections

Viral diseases range from very mild or asymptomatic infections such as colds to destructive and life-threatening diseases such as rabies and AIDS. Many viral infections occur primarily in the young and are readily transmitted through droplets. Although we tend to consider these infections as self-limited and inevitable, even measles, mumps, chickenpox, and rubella can manifest severe complications. Many viruses are strictly human in origin, but an increasing number (hantavirus, West Nile fever virus, and viral encephalitis) are zoonoses transmitted by vectors.

The course of viral diseases starts with invasion at the portal of entry by a few virions and a primary infection. In some cases the viruses replicate locally and disrupt the tissue, and in others the virus enters the blood or travels along neuron pathways to tissues far from the initial entry point. Common manifestations of virus infections include rashes, fever, muscle aches, respiratory involvement, and swollen glands. Some diseases of unknown etiology are thought to have a viral basis. Examples include type I diabetes and multiple sclerosis.

Protection from viral infections arises from the combined actions of interferon, neutralizing antibodies, and cytotoxic T cells. Because of the effective immune response to viruses, infections frequently result in lifelong immunities, and many viruses have been adaptable for vaccination.

Viral Persistence, Latency, and Oncogenicity

Many human viral infections such as colds and influenza have a rapid course and result in a lytic cycle of infection (**figure 24.1**). Such infections generally end with the virus being eliminated by the body within a relatively short time. But a few important viruses establish themselves in longer-term **persistent infections** that last for many years and sometimes for life. Two types of persistence are chronic viral infections and latent viral infections, or latency (**figure 24.1, steps 3 and 4**). In a **chronic infection** the virus is detectable in tissue samples and is still multiplying at a slow rate, but symptoms of infection are usually mild or absent. Examples of viruses with chronic effects are HIV and hepatitis B virus (HBV). **Latent infections** result when the virus enters a dormant phase inside host cells and becomes inactive after a lytic infection. It is not

Process Figure 24.1 Overview of possible effects of viral infections on host cells. (1) Infection is initiated by the entry of virus genetic material into a host cell. (2) In lytic infections, the virus is assembled and released with destruction of the host cell. In persistent infections, the virus does not destroy the cell. (3) In one instance—latency—the viral nucleic acid remains inactive and new viruses are not released, but the disease may recur. (4) In the case of chronic infections the virus continues to be active. (5) The genetic material of some viruses is oncogenic and can transform the host cells into cancer cells that grow in an uncontrolled manner.

multiplying, generally not detectable, and does not cause symptoms during latency. Because the virus is still present (usually as a nucleic acid), it can become reactivated and give rise to recurrent lytic infections. The herpesviruses are prominent examples of latent viruses.

The mechanisms by which viruses become persistent are probably multiple and vary with the type of virus. Some viruses integrate their genetic material into that of the host (HIV), while others remain as separate stable genetic elements called *episomes* that stay in the nucleus but do not integrate into a host chromosome (herpesviruses).

Some persistent viruses are **oncogenic** by virtue of their tendency to induce cancer. The most well-established human

oncogenic viruses and the cancers they are associated with are as follows:

DNA Viruses

Epstein-Barr virus	Burkitt lymphoma
Human herpesvirus 8	Kaposi sarcoma
Hepatitis B	Hepatic carcinoma
Certain papillomaviruses	Cervical and penile cancer

RNA Viruses

Retrovirus HTLV 1	Leukemia
Hepatitis C	Liver cancer

Tracing the involvement of viruses in human cancers has been stymied by the obvious inability to carry out human experiments. Even if a virus is discovered in a tumor, this does not immediately prove causation. When a correlation is found to be repeatable and specific, and is supported by a suitable animal model, the case for virus oncogenicity is more readily verified.

Viruses cause cancer through a variety of genetic effects, some of which were covered in chapter 16. Some may carry a viral oncogene into the human DNA. Others may insert into a site on the genome and activate a human oncogene. Some viruses do not insert into the genome but appear to regulate or promote the cell cycle in a way to stimulate uncontrolled cell growth. In all cases of virally induced cancers, a normal cell is transformed into a cancer cell and a tumor results.

Congenital and Perinatal Transmission

Several viruses can cross the placenta from an infected mother to the embryo or fetus. For example, about one in three children born to untreated HIV-positive mothers is infected. Infection of the fetus can cause developmental disturbances and permanent defects in the child that are present at birth (congenital). Viruses with known **teratogenic*** effects include rubella and cytomegalovirus. Another risk for infants involves infection around the time of birth, as occurs with hepatitis B and herpes simplex viruses.

Viral Diagnosis

Viral diseases are diagnosed by a variety of clinical and laboratory methods, including symptoms, isolation in cell or animal culture, and serological testing for antibodies. The use of antigen detection assays is on the increase, especially those based on monoclonal antibodies. Rapid nucleic acid probes directed against DNA or RNA are another option for several viruses. These have the advantage of being so sensitive that they could conceivably detect the viral nucleic acid in a single infected cell. Review figure 17.17 for a summary of identification techniques.

Overview of DNA Viruses

Classification of viruses is based on the structure of their capsid, the presence of an envelope, and the type of nucleic acid they contain.

* **teratogenic** (tur'-ah-toh-jen'-ik) Gr. *teratos*, monster. Any process that causes physical defects in the embryo or fetus.

Based on this scheme, animal viruses are divided into seven families of DNA-containing viruses and fourteen families of RNA-containing viruses. Family names are recognizable by the suffix *-viridae* (for example, Hepadnaviridae). Within a single family, many genera exist, each ending with the suffix *-virus* (for example, herpesvirus). A single genus may contain many viral “types” or strains, which may not differ significantly from one another.

Because we are concerned less with an exhaustive taxonomic classification of all viruses and more with those viruses of importance to humans, we employ a more relaxed scheme of classification in which viral *groups* occupy the same hierarchical level as a family but contain only agents of human concern and are identified by the suffix *-virus*. Using this system of classification, DNA viruses that cause human disease are placed into six groups (see table 24.1).

Check Your Progress SECTION 24.1

1. Discuss the structures found in a typical virus.
2. Differentiate among lytic infection, latent infection, chronic infection, and transformation.
3. Relate the importance of structure to viral classification.
4. What accounts for the affinity of viruses for certain hosts or tissues?
5. What accounts for the symptoms of viral diseases?
6. In what ways can people carry viruses?

24.2 Enveloped DNA Viruses: Poxviruses

Expected Learning Outcomes

4. Recall the structures seen in poxviruses that make them unique.
5. Understand why vaccination against smallpox has been curtailed.
6. Recall the poxviruses that can infect humans and the diseases they cause.

Classification and Structure of Poxviruses

Poxviruses produce eruptive skin pustules called pocks or **pox**, which leave small, depressed scars (pockmarks) upon healing. The poxviruses are distinctive because they are the largest and most complex of the animal viruses (**figure 24.2**), and they multiply in the cytoplasm in well-defined sites called factory areas, which appear as inclusion bodies in infected cells.

Among the best-known poxviruses are variola, the cause of **smallpox**, and vaccinia, a closely related virus used in vaccinations. Other members are carried by domestic or wild animals and may occasionally be transmitted to humans. A common feature of all poxvirus infections is a specificity for the cytoplasm of epidermal cells and subcutaneous connective tissues. In these sites, they produce the typical pox lesions, and some may later stimulate cell growth and tumor formation.

Smallpox: A Perspective

Largely through the World Health Organization’s comprehensive global efforts, smallpox is now a disease of the past. It is one of the

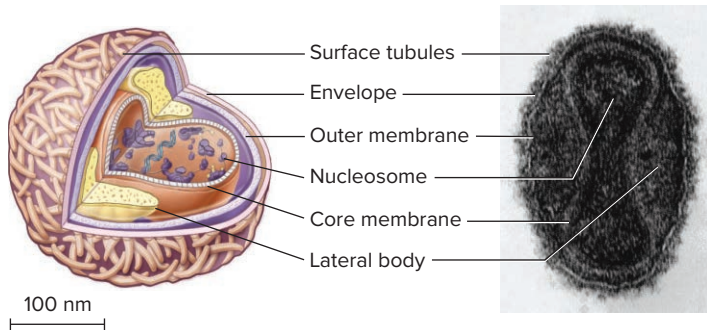

Figure 24.2 The structure of poxviruses. Poxviruses are larger and more complex than other viruses. They have an envelope and an outer membrane with a rough texture of tubules. They have a central nucleus-like core that contains the DNA strand. They lack the usual nucleocapsid found in other viruses. (Right) Photomicrograph of smallpox virus (300,000 \times). Source: CDC

few infectious agents that now exists only in government laboratories. At one time, smallpox was ranked as one of the deadliest infectious diseases, leaving no civilization untouched. When introduced by explorers into naive populations (those never before exposed to the disease) such as Native Americans and Hawaiians, smallpox caused terrible losses and was instrumental in destroying those civilizations.

The twentieth century saw one of mankind's greatest achievements when, as a result of a worldwide health campaign that focused on immunization and isolation, the last case of smallpox was seen in 1977. In 1999 the World Health Organization recommended the destruction of all remaining smallpox stocks, which at this point existed only in laboratory freezers in the United States and the former Soviet Union. Despairing at the loss of such a novel subject that could be used for research, scientists in both countries balked at this request. Since that time, reports have come out that certain Russian labs have experimented with selecting strains of the virus to withstand delivery by bombs or missiles. There remains concern that the virus has been removed from Russia and sold to terrorist groups.¹

Disease Manifestations Exposure to smallpox usually occurred through inhalation of droplets or skin crusts. Infection was associated with fever, malaise, and prostration and, later, a rash that began in the pharynx, spread to the face, and progressed to the extremities. Initially, the rash was macular, evolving in turn to papular, vesicular, and pustular before eventually crusting over, leaving nonpigmented sites pitted with scar tissue (**figure 24.3**). The two principal forms of smallpox were variola minor and variola major. Variola major was a highly virulent form that caused toxemia, shock, and intravascular coagulation. People who survived any form of smallpox nearly always developed lifelong immunity.

Smallpox Vaccination The smallpox vaccine uses a single drop of vaccinia virus punctured into the skin with a double-pronged needle. In a successful take, a large, scablike pustule with a reddened

Figure 24.3 Appearance of pocks in smallpox infections. Newer pox on face are elevated pustules filled with liquid, while older pox, on torso, have begun to crust over. Source: Dr. Michael Schwartz/CDC

periphery develops at the infection site, where it leaves a permanent scar (**figure 24.4**). The vaccine provides significant long-term protection against variola as well as other poxvirus infections. In 2009 a U.S. military service member was stricken with progressive vaccinia (PV), a rare but often fatal complication of the smallpox

Figure 24.4 Smallpox vaccination. A forked needle is dipped into the smallpox vaccine (which actually contains vaccinia virus) and used to puncture the skin repeatedly in a small area. The inset shows that in a successful take, a large, scablike crust will develop over 3 to 4 weeks, eventually falling off and leaving a permanent scar. (top) Source: James Gathany/CDC; (bottom) Source: CDC

1. If you would like to know more about this subject, read *Demon in the Freezer* by Richard Preston, published in 2002 by Random House.

vaccination. This was the first instance of PV seen since 1987 and came on the heels of a new policy under which service members and medical personnel were vaccinated against smallpox as a defense against a potential bioterrorist attack. Risks like this, along with the fact that smallpox no longer poses an immediate threat, are the reason that smallpox vaccination has been discontinued for most populations.

Other Poxvirus Diseases

A much more common poxvirus is the molluscipoxvirus. It causes a skin disease called **molluscum contagiosum**.^{*} This disease is distributed throughout the world, with highest incidence occurring in certain Pacific islands. In endemic regions, it is primarily an infection of children and is transmitted by direct contact and fomites.

Skin lesions take the form of smooth, waxy nodules on the face, trunk, and limbs. The infection can also be spread by sexual intercourse and is most common in sexually active young people in the United States. The lesions of the STD form are small, smooth macules that occur on the genital area and thighs. They may be spread to other body sites through scratching and self-inoculation. AIDS patients suffer from an atypical version of the disease, which attacks the skin of the face and forms tumorlike growths.

Treatment requires destruction of the virus by freezing (cryotherapy), electric cauterization, and chemical agents applied directly to the lesions.

Many mammalian groups host some sort of poxvirus infection. Cowpox, rabbitpox, monkeypox, mousepox, camelpox, and elephantpox are among the types that occur (chickenpox though is actually a herpesvirus infection, not a poxvirus, and it does not occur in chickens!) However, only monkeypox and cowpox appear to be capable of infecting humans symptomatically.

Historically, monkeypox has been seen primarily in Africa, occurring sporadically in humans having contact with monkeys, squirrels, or rats—traditional vectors of the disease. Since the discontinuation of smallpox vaccination, which also protected against monkeypox, more person-to-person transmission of monkeypox has been seen, an unintended consequence of the smallpox eradication effort.

Although cowpox is an eruptive cutaneous disease that can develop on cows' udders and teats, cows are not the actual reservoirs of this virus. Other mammals such as rodents, cats, and even zoo animals can carry it. Human infection is rare and usually confined to the hands, although the face and other cutaneous sites can be involved.

24.3 Enveloped DNA Viruses: The Herpesviruses

Expected Learning Outcomes

7. Characterize the herpesviruses that commonly infect humans.
8. Describe the range of pathologies associated with herpes simplex virus infection.
9. Summarize the means by which herpes simplex infection is diagnosed, treated, and controlled.
10. Understand the relationship between varicella and herpes zoster.
11. Understand the etiological agent, epidemiology, diagnosis, and control of varicella-zoster virus, cytomegalovirus, and Epstein-Barr virus.
12. Recall the complications associated with EBV infection.
13. Relate human herpesviruses 6, 7, and 8 to the diseases they cause.

The **herpesviruses**^{*} were named for the tendency of some herpes infections to produce a rash that spreads (creeps). The term is used to designate a large family whose members include the following:

- herpes simplex 1 and 2 (HSV), the cause of fever blisters and genital infections;
- varicella-zoster virus (VZV), the cause of chickenpox and shingles;
- cytomegalovirus (CMV), which infects the salivary glands and other viscera;
- Epstein-Barr virus (EBV), associated with infection of the lymphoid tissue;
- human herpesviruses 6 and 7 (HHVs), which cause roseola; and
- herpesvirus 8 (KSHV), which is implicated in Kaposi sarcoma.

An alternate system for naming herpesviruses assigns them a number. Thus, 1 and 2 are HSV, 3 is VZV, 4 is EBV, 5 is CMV, 6 and 7 are HHVs, and 8 is KSHV. A prominent feature of the family is that all members show latency and cause recurrent infections. This behavior involves entry of viral DNA into the nucleus, where it becomes an extrachromosomal particle called an episome. Two of the viruses in this group also have a well-documented association with cancers.

Virtually everyone becomes infected with at least some of the herpesviruses, usually without adverse effect. The clinical complications of latency and recurrent infections become more severe with advancing age, cancer chemotherapy, or other conditions that compromise the immune defenses. The herpesviruses are among the most common and serious opportunists among AIDS patients. Nearly 95% of this group will experience recurrent bouts of skin, mucous membrane, intestinal, and eye disease from these viruses.

The herpesviruses are among the larger viruses, with a diameter ranging from about 150 nm to 200 nm (**figure 24.5**). They are enclosed within a loosely fitting envelope that contains glycoprotein spikes. Like other enveloped viruses, herpesviruses are prone to deactivation by organic solvents or detergents and are unstable outside the host's body. The icosahedral capsid houses a core of double-stranded DNA. Replication occurs primarily within the nucleus, and viral release is usually accompanied by cell lysis.

^{*} *herpesviruses* (her'-pee-z) Gr. *herpein*, to creep.

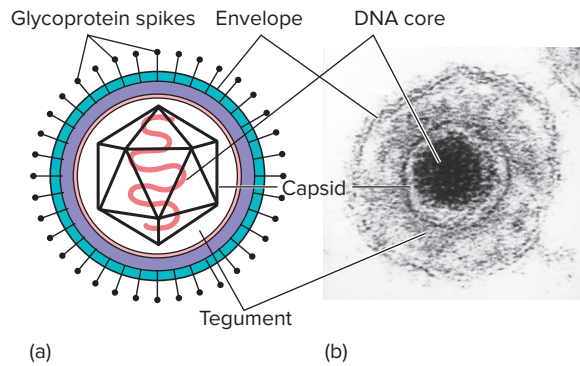

Figure 24.5 Herpesviruses. (a) A schematic of the general structure of a herpesvirus alongside (b) a herpes simplex virus particle (30,000 \times). (b): Source: Laboratory of Tumor Cell Biology, Bernard Kramarsky photographer, National Cancer Institute

General Properties of Herpes Simplex Viruses

Humans are susceptible to two varieties of **herpes simplex** viruses: **HSV-1**, usually characterized by lesions on the oropharynx, and **HSV-2**, usually producing lesions on the genitalia. The viruses are very similar in the types of cells they infect, so they are not specific to these sites. **Table 24.2** provides a summary of major characteristics and differences. Even though other mammals can be experimentally infected, humans appear to be the only natural reservoir for herpes simplex virus.

Epidemiology of Herpes Simplex

Herpes simplex infection occurs globally in all seasons and among all age groups. Because these viruses are relatively sensitive to the

TABLE 24.2 Comparative Epidemiology and Pathology of Herpes Simplex, Types 1 and 2		
	HSV-1	HSV-2
Usual Etiologic Agent of*	Herpes labialis Ocular herpes Gingivostomatitis Pharyngitis	Herpes genitalis
Transmission	Close contact, usually of face	Sexual or intimate contact
Latency	Occurs in trigeminal ganglion	Occurs primarily in sacral ganglia
Skin Lesions	On face, mouth	On internal, external genitalia, thighs, buttocks
Complications		
Whitlows	Among personnel working on oral cavity	Among obstetric, gynecological personnel
Neonatal encephalitis	Causes up to 30% of cases**	Causes most cases through contact with birth canal

*The other herpes simplex type can be involved in this infection, though not as commonly.

**Due to mothers infected genitally by HSV-1 or contamination of the neonate by oral lesions.

environment, transmission usually involves direct exposure to secretions containing the virus. People with active lesions are the most significant source of infection, though studies indicate that genital herpes can be transmitted even when no lesions are present. Occasionally cases have been traced to contact with moist secretions on inanimate objects.

Primary infections tend to be age-specific: HSV-1 frequently occurs in infancy and early childhood, and by adulthood, most people exhibit some serological evidence of infection. On the other hand, primary infection with HSV-2 occurs most frequently between the ages of 14 and 29, a pattern that reflects the sexual route of transmission. In fact, genital herpes is one of the most common STDs in the United States with an estimated 780,000 new cases each year. Cases of HSV-1 genital infection and HSV-2 oral infections are probably due to autoinoculation with contaminated hands or oral sexual contact.

The Nature of Latency and Recurrent Attacks

In approximately 20% to 50% of primary infections, herpes simplex viruses multiply in the distal regions of sensory neurons and are carried to the ganglia. Type 1 HSV enters the trigeminal, or fifth cranial nerve, which has extensive innervations in the oral region (**figure 24.6**). Type 2 HSV usually becomes latent in the ganglion of the lumbosacral spinal nerve trunk. The exact details of this unusual mode of latency are not yet fully understood, but the virus remains inside the nucleus of the neuron in a nonproliferative stage for a variable time. Recurrent infection is triggered by various stimuli such as fever, UV radiation, stress, or mechanical injury, all of which reactivate the virus genes. Newly formed viruses migrate to the body surface and produce a local skin or membrane lesion, often in the same site as a previous infection. The number of such attacks can range from one to dozens each year.

The Spectrum of Herpes Infection and Disease

Herpes simplex infections, often called simply herpes, usually target the mucous membranes. The virus enters cracks or cuts in the

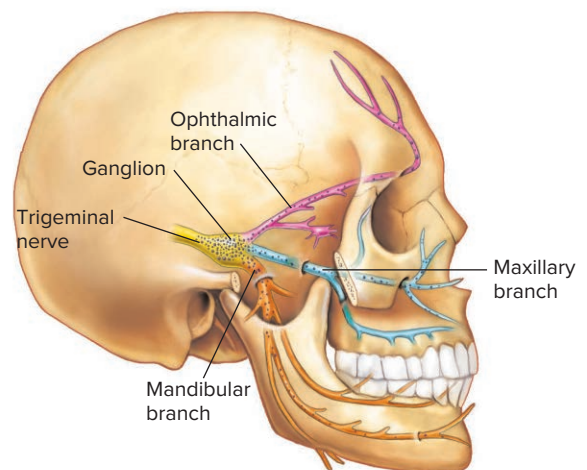

Figure 24.6 The site of latency and routes of recurrence in herpes simplex, type 1. Following primary infection, the virus invades the trigeminal, or fifth cranial, nerve and is harbored in its ganglion. Various provocative stimuli cause it to migrate back to the skin surface by the mandibular, maxillary, or ophthalmic branch.

membrane surface and then multiplies in basal and epithelial cells in the immediate vicinity. This results in inflammation, edema, cell lysis, and a characteristic thin-walled vesicle. The main diseases of herpes simplex viruses are facial herpes (oral, optic, and pharyngeal), genital herpes, neonatal herpes, and disseminated disease.

Type 1 Herpes Simplex in Children and Adults

Herpes labialis, otherwise known as fever blisters or cold sores, is the most common recurrent HSV-1 infection. Vesicles usually crop up on the mucocutaneous junction of the lips or on adjacent skin (**figure 24.7**). A few hours of tingling or itching precede the formation of one or more vesicles at the site. Pain is most acute in the earlier stage as vesicles ulcerate; lesions crust over in 2 or 3 days and heal completely in a week.

Although most herpetic infections remain localized, a condition known as herpetic **gingivostomatitis** can occur as the primary manifestation, especially in young children. Inflammation of the oral mucosa can involve the gums, tongue, soft palate, and lips, sometimes with ulceration and bleeding. A common complication in adolescents is pharyngitis, a syndrome marked by sore throat, fever, chills, swollen lymph nodes, and difficulty in swallowing.

Herpetic keratitis (also called ocular herpes) is an infective inflammation of the eye in which a latent virus travels into the ophthalmic rather than the mandibular branch of the trigeminal nerve. In some cases, it is introduced into the eye by contaminated fingers or contact lenses. Preliminary symptoms are a gritty feeling in the eye, conjunctivitis, sharp pain, and sensitivity to light. Some patients develop characteristic branched or opaque corneal lesions as well. In 25% to 50% of cases, keratitis is recurrent and chronic and can interfere with vision.

Type 2 Herpes Infections

Type 2 herpes infection usually coincides with sexual maturation and an increase in sexual encounters. **Genital herpes** (herpes genitalis) starts out with malaise, anorexia, fever, and bilateral swelling and tenderness in the groin. Then, intensely sensitive vesicles break

Figure 24.7 Type I herpes simplex. Recurrent lesions of herpes labialis (cold sore, fever blister). Tender, itchy papules erupt on the perioral regions and progress to vesicles that burst, drain, and scab over. These sores and fluid are highly infectious and should not be touched. *Source:* CDC

Figure 24.8 Genital herpes. Vesicles start out separate, but become confluent and ulcerate into red erosions so tender that any contact can be highly painful. *Source:* CDC

out in clusters on the genitalia, perineum, and buttocks (**figure 24.8**). The chief symptoms are urethritis, painful urination, cervicitis, and itching. After a period of days to weeks, the vesicles ulcerate and develop a light-gray exudate before healing. Bouts of recurrent genital herpes are usually less severe than the original infection and are triggered by menstruation, stress, and concurrent bacterial infection.

Herpes of the Newborn

Although HSV infections in healthy adults are annoying, unpleasant, and painful, only rarely are they life-threatening. However, in the neonate and fetus (**figure 24.9**), HSV infections are very destructive and can be fatal. Most cases occur when infants are contaminated by the mother's reproductive tract immediately before or during birth, but they have also been traced to hand transmission from the mother's lesions to the baby. Infections are evenly split between type 1 and type 2, and both types act similarly to one another. In infants whose disease is confined to the mouth, skin, or eyes, the mortality rate is 30%, but disease affecting the central nervous system has a 50% to 80% mortality rate.

Because of the danger of herpes to fetuses and newborns and also the increase in the number of cases of genital herpes, it is now

Figure 24.9 Neonatal herpes simplex. Babies can be born with the lesions or develop them 1 to 2 weeks after birth. © Dr. M.A. Ansary/Science Source

standard procedure to screen pregnant women for the herpesvirus early in their prenatal care. Women with a history of recurrent infections must be monitored for any signs of viral shedding during the last period of pregnancy. Acyclovir may be prescribed to lessen viral shedding during the third trimester. In the absence of lesions or symptoms, vaginal birth is safe. Any evidence of an outbreak at the time of delivery will require a cesarean section.

Miscellaneous Herpes Infections

When either form of herpesvirus enters a break in the skin, a local infection can develop. This route of infection is most often associated with occupational exposure or severely damaged skin. A hazard for health care workers who handle patients or their secretions without hand protection is a disease called herpetic **whitlow**.^{*} Workers in the fields of obstetrics, gynecology, dentistry, and respiratory therapy are probably at greatest risk for contracting it. Whitlows are deep-set, usually occur on one finger, and are extremely painful and itchy (**figure 24.10**). Afflicted personnel should not work with patients until the whitlow has healed, usually in 2 to 3 weeks.

Life-Threatening Complications

Although herpes simplex encephalitis is a rare complication of type 1 infection, it is probably the most common sporadic form of viral encephalitis in the United States. The infection disseminates along nerve pathways to the brain or spinal cord. The effects on the CNS begin with headache and stiff neck and can progress to mental disturbances and coma. The fatality rate in untreated cases is 70%. Patients with underlying immunodeficiency are more prone to severe, disseminated herpes infection than are immunocompetent patients. Of greatest concern are patients receiving organ grafts, cancer patients on immunosuppressive therapy, those with congenital immunodeficiencies, and AIDS patients.

Diagnosis, Treatment, and Control of Herpes Simplex

Small, painful vesicles on the mucous membranes of the mouth or genitalia, lymphadenopathy, and exudate are typical diagnostic

^{*} *whitlow* (hwit'-loh) ME *white*, flaw. An abscess on the distal portion of a finger.

Figure 24.10 Herpetic whitlows. These painful, deep-set vesicles can become inflamed and necrotic and are difficult to treat. They occur most frequently in dental and medical personnel or people who carelessly touch lesions on themselves or others. © Kathy Park Talaro

symptoms of herpes simplex. Further diagnostic support is available by examining scrapings from the base of such lesions stained with Giemsa, Wright, or Papanicolaou (Pap) methods (**figure 24.11**). The presence of multinucleate cells, giant cells, and inclusion bodies inside the nucleus can help establish herpes infection. This method, however, will not distinguish among HSV-1, HSV-2, or other herpesviruses, which require more specific subtyping. Direct tests on specimens or cell cultures using fluorescent antibodies or DNA probes can differentiate among HSV-1, HSV-2, and closely related herpesviruses.

Laboratory culture and specific tests are essential for diagnosing severe, disseminated herpes infection. A specimen of tissue or fluid is introduced into a primary cell line such as monkey kidney or human embryonic kidney tissue cultures and is then observed for cytopathic effects within 24 to 48 hours.

Several agents are available for treatment. Acyclovir (Zovirax) is the most effective therapy developed to date that is nontoxic and highly specific to HSV. Famciclovir and valacyclovir are alternate drugs. Topical medications applied to genital and oral lesions cut the length of infection and reduce viral shedding. Systemic therapy is available for more serious complications such as herpes keratitis and disseminated herpes. Daily doses of oral valacyclovir (Valtrex) have been shown to be an effective suppressive therapy for genital herpes, preventing recurrent outbreaks for at least 6 months in more than half of those adhering to the regimen.

Although the barrier protection afforded by condoms can diminish the prospects of spreading genital herpes sexually, people with active infection should avoid any sexual contact. Mothers with cold sores should observe extreme care in handling their newborns; infants should never be kissed on the mouth. Medical and dental workers who deal directly with patients can reduce their risk of exposure by wearing gloves.

Figure 24.11 Diagnosis of herpesvirus infection from stained specimen. A direct Papanicolaou (Pap) smear of a cervical scraping shows enlarged (multinucleate giant) cells and intranuclear inclusions typical of herpes simplex, type 2. This technique is not specific for HSV, but most other herpesviruses do not infect the reproductive mucosa. © Dr. Walker/Science Source

Pathogen Profile #1 *Herpes simplex virus 1 and 2 (HSV-1, HSV-2)*

Source: CDC

Microscopic Morphology Enveloped virus with an icosahedral capsid; 150 to 200 nm in diameter.

Identified by Clinical presentation, examination of stained scrapings from the base of lesions, growth in tissue culture, antibody tests, PCR.

Habitat Humans are the only natural reservoir for herpes simplex virus.

Virulence Factors Latency with entry of the HSV episome into the nucleus of neurons.

Primary Infections/Disease HSV-1 is usually characterized by lesions on the oropharynx, whereas HSV-2 causes lesions primarily on the genitalia. Both types of HSV can cause neonatal herpes simplex, a disease of the mouth, skin, eyes, or nervous system, with a mortality rate approaching 80%. Herpetic whitlows are

deep, painful vesicles on the skin caused when either type of HSV enters a cut. Whitlows are associated with health care workers who don't use gloves when touching infected patients or their secretions. Herpes simplex encephalitis is a rare but serious complication of HSV-1 infection, with mortality rates of up to 70%.

Control and Treatment The use of barrier protection—gloves for health care procedures, condoms for sexual activity—is the best strategy to prevent herpes infection. Treatment with acyclovir reduces both the length of infection and the intensity of viral shedding. Oral valacyclovir (Valtrex) is often used as a suppressive therapy, preventing recurrent outbreaks for as long as 6 months at a time.

**The Biology of Varicella-Zoster Virus**

Another herpesvirus causes both **varicella*** (commonly known as **chickenpox**) and a recurrent infection called **herpes zoster,*** or **shingles.*** Because the same virus causes two forms of disease, it is known by a composite name, **varicella-zoster virus (VZV)**. At one time, the differences in clinical appearance and time separation between varicella and herpes zoster were sufficient to foster the notion that they were caused by different infectious agents. In time, it was noted that young children acquired chickenpox from family members afflicted with shingles, giving the first hint that the two diseases were related (see this chapter's Case Study). More recently doctors used Koch's postulates to follow the two diseases in a single patient. They demonstrated that the same virus caused both diseases and that zoster is a reactivation of a latent varicella virus (**figure 24.12**).

Epidemiological Patterns of VZV Infection

Humans are the only natural hosts for varicella-zoster virus. The virus is harbored in the respiratory tract, but it is communicable from both respiratory droplets and the fluid of active skin lesions. Infected persons are most infectious a day or two prior to the development of the rash. The dried scabs are not infectious because the virus is unstable and loses infectivity when exposed to the environment. Patients with shingles are a source of infection for nonimmune children, but the attack rate is significantly lower than with exposure to chickenpox. Only in rare instances will a child acquire chickenpox more than once, and even a subclinical case can result in long-term immunity. Immunity protects against reinfection with chickenpox but not against an attack of shingles.

Varicella (Chickenpox)

The respiratory epithelium serves as the chief portal of entry and the initial site of viral replication for varicella-zoster virus, which initially produces no symptoms. After an incubation period of 10 to 20 days, the first symptoms to appear are fever and an abundant rash that begins on the scalp, face, and trunk and radiates in sparse crops to the extremities. Skin lesions progress from small red macules to itchy blisters that encrust and drop off, usually healing completely but sometimes leaving a tiny scar (**figure 24.12a**). Lesions number from a few to hundreds and are more abundant in adolescents and adults than in young children.

Herpes Zoster (Shingles)

Most cases of varicella result in the entry of the varicella-zoster virus into ganglia of neurons that supply innervation to skin dermatomes, especially thoracic and trigeminal nerves (**figure 24.12b**). VZV becomes latent in these ganglia and may later reemerge with its characteristic asymmetrical distribution on the skin of the trunk or head or occasionally on the neck or limbs (**figure 24.12c**).

Shingles develops abruptly after reactivation by such stimuli as X-ray treatments, immunosuppressive and other drug therapy, surgery, or developing malignancy. It may be associated with declining immune function and is more common in older patients. About 1 million cases occur per year in the United States. The virus is believed to migrate down the ganglion to the skin, where multiplication resumes and produces crops of tender, persistent vesicles. Inflammation of the ganglia and the pathways of nerves causes pain and tenderness (radiculitis) that can last for several months. Involvement of cranial nerves can lead to eye inflammation and ocular and facial paralysis. A vaccine (Zostavax) has recently been approved as a prevention for shingles in patients over 60. It is indicated only for people who have already had a case of chickenpox.

* **varicella** (var''-ih-sel'-ah) The Latin diminutive for smallpox or variola.

* **zoster** (zahs'-tur) Gr. *zoster*, girdle.

* **shingles** (shing'-gulz) L. *cingulus*, cinch. (Both *zoster* and *shingles* refer to the beltlike encircling nature of the rash.)

Pathogen Profile #2 *Varicella-zoster virus (VZV)*

Source: CDC

Microscopic Morphology Enveloped virus with an icosahedral capsid; 150 to 200 nm in diameter.

Identified by Nearly always by clinical presentation alone.

Habitat Humans are the only natural reservoir for varicella-zoster virus.

Virulence Factors Latency, especially in ganglia.

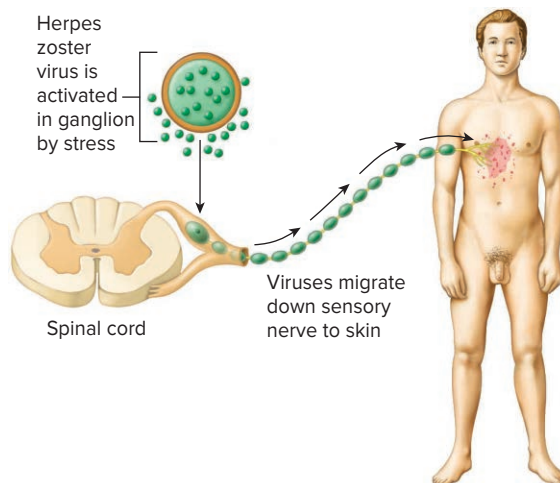

Primary Infections/Disease Initial infection with VZV results in varicella (chickenpox), which is marked by numerous small, red lesions that eventually encrust and drop off. Reemergence of VZV after a long latency period—often many decades—results in zoster

(shingles), a highly localized, painful rash that may last several months.

Control and Treatment The addition of a live, attenuated chickenpox vaccine to the recommended childhood vaccination schedule has dramatically lessened the occurrence of the disease. Although a small number of vaccinated children still acquire chickenpox, the course of the disease is far milder. A shingles vaccine (Zostavax) is recommended for persons over the age of 60. Treatment for both conditions generally focuses on the alleviation of discomfort and the prevention of secondary bacterial infections. In some cases, acyclovir or famciclovir may be administered to combat the virus directly.

(a)

(b)

(c)

Figure 24.12 The relationship between varicella (chickenpox) and zoster (shingles) and the clinical appearance of each. (a) First contact with the virus (usually in childhood) results in a macular, papular, vesicular rash distributed primarily on the face and trunk. (b) The virus becomes latent in the dorsal ganglia of nerves that supply dermatomes of mid-thoracic nerves and the cranial nerves that supply facial regions. (c) The clinical appearance of shingles. Early symptoms are acute pain in the nerve root and redness of the dermatome, followed by a vesicular-papular rash on the chest and back that is usually asymmetrical and does not cross the midline of the body. (a): Source: CDC; (c): © DermNet New Zealand Trust

Diagnosis, Treatment, and Control of VZV Infection

The cutaneous manifestations of varicella and shingles are sufficiently characteristic for ready clinical recognition. Supportive evidence for a diagnosis of varicella usually comes from recent close contact with a source or with an active case of VZV infection. A diagnosis of shingles is supported by the distribution pattern of skin lesions and confirmed from multinucleate giant cells in stained smears prepared from vesicle scrapings. However, unequivocal identification is best done with fluorescent antibody detection of viral antigen in skin lesions, DNA typing, or culture.

Uncomplicated varicella is self-limited and requires no therapy aside from alleviation of discomfort. Secondary bacterial infections that can cause dangerous complications (especially streptococcal and staphylococcal) are prevented by application of antimicrobial

ointments. Drugs that can be beneficial for systemic disease are intravenous acyclovir or famciclovir. Varicella-zoster immune globulin (Varizig) is a passive immunotherapy containing antibodies against the varicella-zoster virus. It may be administered up to 96 hours after exposure to reduce symptoms of viral infection.

A live, attenuated vaccine (Varivax) is currently recommended for routine childhood vaccination against chickenpox. Vaccination is indicated for children between 2 months and 12 years of age. Immunity will be longer lasting if two doses are given. Some children can still acquire chickenpox, but it is a milder case. Older children and adults with risk factors may also be vaccine candidates. Because some parents regard the disease as mild and inevitable, they purposely expose their children to infected individuals as a means of “immunizing” them. This practice is not recommended because of the potential complications of VZV infection.

The Cytomegalovirus Group

Another group of herpesviruses, the **cytomegaloviruses*** (CMVs), are named for their tendency to produce giant cells with nuclear and cytoplasmic inclusions (**figure 24.13**). These viruses, also termed salivary gland virus and cytomegalic inclusion virus, are among the most ubiquitous pathogens of humans.

Epidemiology of CMV Disease

The testing of human populations has indicated that antibodies to CMV developed during a prior infection are very common. For instance, 50% of women of childbearing age had CMV antibodies, and nearly 10% of newborns reveal some evidence of infection as well, making CMV the most prevalent fetal infection. Cytomegalovirus is transmitted in saliva, respiratory mucus, milk, urine, semen, and cervical secretions. Transmission usually involves intimate exposure such as sexual contact, vaginal birth, transplacental infection, blood transfusion, and organ transplantation. As with other herpesviruses, CMV is commonly carried in a latent state in white blood cells such as monocytes.

Infection and Disease

Most healthy adults and children with primary CMV infection are asymptomatic. However, three groups that develop a more virulent form of disease are fetuses, newborns, and immunodeficient adults. The incidence of congenital CMV infection occurs in about 20% of pregnancies in which the mother has concurrent infection. Newborns with clinical disease exhibit enlarged liver and spleen, jaundice, capillary bleeding, microcephaly, and ocular inflammation. In some cases, damage can be so severe and extensive that death follows within a few days or weeks. Many babies who survive develop long-term neurological sequelae, including hearing and visual disturbances and even mental retardation. In the United States, about 5,000 babies a year are affected. Perinatal CMV infection, which occurs after exposure to the mother's vagina, is chiefly asymptomatic, although pneumonitis and a mononucleosis-like syndrome can develop during the first 3 months after birth.

* *cytomegaloviruses* (sy'-toh-may'-gah-loh-vy'-rus) Gr. *cyto*, cell, and *megale*, big, great.

Figure 24.13 Identifying cytomegaloviruses. Infection of lung cells with cytomegalovirus shows the cellular enlargement and distortion of the nucleus by a large inclusion, called an “owl’s eye” effect (1,500X). Source: Dr. Edwin P. Ewing, Jr./CDC

Cytomegalovirus mononucleosis* is a syndrome characterized by fever and lymphocytosis, somewhat similar to the disease caused by Epstein-Barr virus. Although it can occur in children, it is chiefly an illness of adults. Disseminated cytomegalovirus is a severe opportunistic infection of AIDS patients. It produces overwhelming systemic disease, with fever, severe diarrhea, hepatitis, pneumonia, and high mortality. Invasion of the retina can lead to blindness. Most patients undergoing kidney transplantation and half of those receiving bone marrow develop CMV pneumonitis, hepatitis, myocarditis, meningoencephalitis, hemolytic anemia, and thrombocytopenia.

Diagnosis, Treatment, and Prevention of CMV Infection

In neonates, CMV infection must be differentiated from toxoplasmosis, rubella, and herpes simplex. In adults, it must be distinguished from Epstein-Barr infection and hepatitis. The cytomegalovirus can be isolated from specimens taken from virtually all organs as well as from epithelial tissue. Cell enlargement and prominent inclusions in the cytoplasm and nucleus are suggestive of CMV. The virus can be cultured and tested with monoclonal antibody against the early nuclear antigen. Polymerase chain reaction assays, which detect viral DNA, have become the most commonly used clinical detection method.

Drug therapy is reserved for immunosuppressed patients. The main drugs are ganciclovir and valganciclovir. The development of a vaccine is hampered by the lack of an animal that can be infected with human cytomegalovirus.

Epstein-Barr Virus

Although the lymphatic disease known as **infectious mononucleosis** was described more than a century ago, its cause was finally discovered through a series of accidental events starting in 1958. First, Michael Burkitt working with African children detected an unusual malignant tumor (Burkitt lymphoma) that appeared to be infectious. Later, Michael Epstein and Yvonne Barr cultured a virus from tumors that showed typical herpesvirus morphology. Proof that the two diseases had a common cause was completed when a laboratory technician accidentally acquired mononucleosis while working with the Burkitt lymphoma virus. The **Epstein-Barr virus (EBV)** shares morphological and antigenic features with other herpesviruses. In addition, it contains genes that, when expressed, transform certain lymphocytes into malignant cells.

Epidemiology of Epstein-Barr Virus

This virus has a firmly established niche in human lymphoid tissue and salivary glands. Salivary excretion occurs in about 20% of otherwise normal individuals. Direct oral contact and contamination with saliva are the principal modes of transmission, although transfer through blood transfusions and organ transplants is also possible.

* *mononucleosis* (mah'-noh-noo'-klee-oh'-sis) Gr. *mono*, one, *nucleo*, nucleus, and *sis*, state.

The nature of infection depends on the patient's age at first exposure, socioeconomic level, geographic region, and genetic predisposition. In less-developed regions of the world, infection usually occurs in early childhood. Such early and chronic infection means that children living in Africa have higher rates of Burkitt lymphoma. Likewise, residents of certain areas of Asia show high levels of nasopharyngeal carcinoma, another tumor linked to EBV.

In industrialized countries, exposure to EBV is usually postponed until adolescence and young adulthood. This delay is generally ascribed to improved sanitation and less frequent and intimate contact with other children. Because nearly 70% of college-age Americans have never had EBV infection, this population is vulnerable to infectious mononucleosis, often dubbed the "kissing disease" or "mono." However, by midlife, 90% to 95% of all people, regardless of geographic region, show serological evidence of infection. EBV is one of the herpesviruses that researchers suspect as a trigger for multiple sclerosis. A National Institutes of Health study found an association between EBV infection and the presence of T cells that attack the myelin sheath, triggering an autoimmune disease.

Diseases of EBV

The epithelium of the oropharynx is the portal of entry for EBV during the primary infection. From this site, the virus moves to the parotid gland, which is the major area of viral replication and latency. After extended dormancy in B cells, the virus is reactivated by some ill-defined mechanism. In some people, the entire course of infection and latency is asymptomatic.

The symptoms of infectious mononucleosis are sore throat, high fever, and cervical lymphadenopathy, which develop after a long incubation period (30–50 days). Many patients also have a gray-white exudate in the pharynx (**figure 24.14**), a skin rash, and enlarged spleen and liver. A notable sign of mononucleosis is sudden leukocytosis, consisting initially of infected B cells and later T cells. The strong, cell-mediated immune response is decisive in controlling the infection and preventing complications. Some people can become chronically infected with EBV, but a link to debilitating illnesses like chronic fatigue syndrome is now thought to be unlikely.

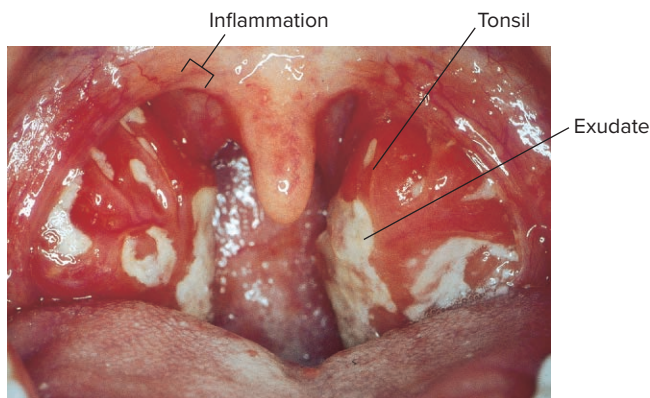

Figure 24.14 Infectious mononucleosis. This view of the pharynx shows the swollen tonsils and throat tissues, a gray-white exudate, and an inflammation of the palate that can be of some use in diagnosis. Kane, Kay et al., *Color Atlas and Synopsis of Pediatric Dermatology, 2/e* © 2010 McGraw-Hill Education. Reproduced with permission of McGraw-Hill Education

Tumors and Other Complications Associated with EBV

Burkitt lymphoma is a B-cell malignancy that usually develops in the jaw and grossly swells the cheek (**figure 24.15**). Most cases are reported in central African children 4 to 8 years old, and a small number are seen in North America. The prevalence in Africa may be associated with chronic coinfections with other diseases, such as malaria, that weaken the immune system and predispose the body to tumors. One theory to explain the neoplastic effect is that persistent EBV infection in young children transforms B lymphocytes into immortalized cells. During this time, chronic infections overwhelm the T-cell cytotoxic response needed to control the overgrowth of these B-cell clones, which develop into malignant tumors.

Unlike Burkitt lymphoma, **nasopharyngeal carcinoma** is a malignancy of epithelial cells that occurs in older Chinese and African men. Although much about this disease is still to be explained, high antibody titer to EBV is a consistent finding. It is not known how the virus invades epithelial cells (not its usual target), why the incidence of malignancy is so high in particular areas, or to what extent dietary carcinogens are involved.

In general, any person with an immune deficiency (especially of T cells) is highly susceptible to Epstein-Barr virus. Organ transplant patients carry a high risk because their immune systems are weakened by measures to control rejection. The oncogenic potential of the virus is another factor. It has been associated with some types of lymphatic tumors in kidney transplant patients and is commonly isolated from AIDS-related lymphomas. AIDS patients also develop oral *hairy leukoplakia*, white adherent plaques on the tongue due to invasion of the epithelium by EBV. Lesions can be reduced by oral acyclovir therapy.

Benson; (b): © Joaquin Carrillo-Farga/Science Source

Diagnosis, Treatment, and Prevention of EBV Infection

Because clinical symptoms in EBV infection are common to many other illnesses, laboratory diagnosis is necessary. A differential blood count that shows lymphocytosis, neutropenia, and large, atypical lymphocytes with lobulated nuclei and vacuolated cytoplasm is suggestive of EBV infection (**figure 24.16**). Serological assays to detect antibody against the capsid and DNA are helpful, as are direct viral antigen tests using probes and labeled antibodies.

The usual treatments for infectious mononucleosis are directed at symptomatic relief of fever and sore throat. In more severe cases antiviral agents like acyclovir can be given to block virus replication directly while corticosteroids can reduce airway obstruction. Burkitt lymphoma requires systemic chemotherapy with an anti-cancer drug such as cyclophosphamide or vincristine. These measures, along with surgical removal of the tumor, have considerably reduced the mortality rate.

Diseases of Herpesviruses 6, 7, and 8

Human herpesvirus 6 (HHV-6), also known as human B-lymphotropic virus, was originally isolated from infected lymphocytes (see **figure 17.17b**). It has characteristics similar to CMV, but it is genetically distinct from the other herpesviruses. The virus can enter and replicate in T lymphocytes, macrophages, and salivary gland tissues. It is probably transmitted by close contact with saliva and other secretions. It is among the most common herpesviruses, with up to 95% prevalence in tested human populations. It is the cause of **roseola** (also known as **roseola infantum**), an acute febrile disease in babies between 2 and 12 months of age (**figure 24.17**). It begins with fever that can spike as high as 105°F (40°C) and is followed a few days later by a faint maculopapular rash over the neck, trunk, and buttocks. The disease is usually self-limited, and the children recover spontaneously with support care.

Figure 24.17 Roseola infantum in 12-month-old baby. Disease is marked by confluent rash over face, neck, and trunk. This viral infection is the most common febrile disease in young babies. Courtesy of Stephen Dewhurst

Infected adults present with mononucleosis-like symptoms and may develop lymphadenopathy and hepatitis. Patients with renal or bone marrow transplants often acquire HHV-6 infections that suppress the function of the grafted tissues and are possibly a factor in rejection. Because HHV-6 is known for causing encephalitis and neurological disease, it is another herpesvirus that could play a role in multiple sclerosis (MS). Over 70% of MS patients have positive serological signs of HHV-6 infection, and the brain lesions of many of them have active virus infection. Although this is not conclusive proof of etiology, it is the first crucial step in connecting this disease to a virus. Much additional study will be necessary before specialists can verify any link between MS and herpesviruses. Experts consider HHV-6 infection an important emerging disease.

The fact that herpesviruses are persistent, can develop latency in the cell nucleus, and have demonstrated oncogenesis has spurred an active search for the roles of these viruses in cancers of unknown cause. A number of clinical studies have disclosed a relationship between HHV-6 and Hodgkin's lymphoma, oral carcinoma, and certain T-cell leukemias. Keep in mind that isolating a virus or its antigens from a tumor is not sufficient proof of causation and requires further evidence, but it is highly suggestive of some role in cancer. Another human herpesvirus, HHV-7, is very closely related to HHV-6, and it causes similar diseases in children and adults.

The latest herpesvirus was isolated from Kaposi sarcoma, a tumor of AIDS patients. This virus, termed *human herpesvirus 8 (HHV-8)* or *Kaposi sarcoma-associated herpesvirus (KSHV)*, is not found in other normal tissues or in patients without sarcoma. Its primary target cells are endothelial cells and B cells. The genetic mechanisms and pathology behind this cancer are an ongoing focus of study.

Pathogen Profile #3 Epstein-Barr virus (EBV)

Source: CDC

Microscopic Morphology Enveloped virus with an icosahedral capsid; 150 to 200 nm in diameter.

Identified by Differential blood count, which reveals increased lymphocytes and decreased neutrophils, along with large, atypical lymphocytes, is suggestive of infection. Serological assays can confirm the diagnosis.

Habitat Epstein-Barr virus is carried in the lymphoid tissue and salivary glands of more than 90% of the world's population.

Virulence Factors Latency, along with the ability to easily incorporate its DNA into that of its host.

Primary Infections/Disease Symptomatic infection with EBV leads to mononucleosis, a disease marked by sore throat, high fever, and cervical lymphadenopathy occurring after a long (30–50 day) incubation period. Some patients also display a gray-white exudate in the throat, skin rash, and an enlarged spleen and liver. Cancer is a potential complication of EBV infection, with Burkitt lymphoma, a B-cell cancer, and nasopharyngeal carcinoma both being linked to previous EBV infection.

Control and Treatment Treatment is directed at the alleviation of symptoms such as fever and sore throat. Acyclovir may be administered in some cases and corticosteroids may be used in the case of severe pharyngitis that obstructs the airway. Burkitt lymphoma is treated with anticancer drugs and surgery.

24.4 The Viral Agents of Hepatitis

Expected Learning Outcomes

14. Contrast the major characteristics of the three most common agents of viral hepatitis.
15. Understand the epidemiology, diagnosis, pathology, and management of hepatitis B.

When certain viruses infect the liver, they cause **hepatitis**, an inflammatory disease marked by necrosis of hepatocytes and a mononuclear response that swells and disrupts the liver architecture. This pathologic change interferes with the liver's excretion of bile pigments such as bilirubin into the intestine. When bilirubin, a

greenish-yellow pigment, accumulates in the blood and tissues, it causes **jaundice**,* a yellow tinge in the skin and eyes. Characteristics of the three principal viruses responsible for human hepatitis are summarized in **table 24.3**.

The major group of DNA viruses involved in hepatitis are the **hepadnaviruses**.* These enveloped viruses have never been grown in tissue culture and have an unusual genome containing both double- and single-stranded DNA. Hepadnaviruses show a decided tropism for the liver, where they persist and usually trigger liver cell carcinoma. One member of the group, **hepatitis B virus (HBV)**, causes a common form of hepatitis in humans, and related viruses cause hepatitis in other vertebrates.

Other hepatitis viruses are RNA based and are covered in chapter 25. We include them here primarily to contrast basic characteristics of viral hepatitis agents. Incidence of the major forms is presented in table 24.3.

Hepatitis A virus (HAV) is a nonenveloped RNA enterovirus transmitted through contaminated food. In general, HAV disease is far milder, shorter term, and less virulent than the other forms. Another significant RNA virus is **hepatitis C virus (HCV)**, a flavivirus that causes many cases of transfusion hepatitis. HCV is involved in a chronic liver infection that can go undiagnosed, later leading to severe liver damage and cancer. It is spread primarily by exposure to blood and blood products (see the chapter 11 Case Study). It is considered one of the most common unreported agents of hepatitis (an estimated 3 million cases nationally). Another agent is hepatitis E (HEV), a newly identified RNA virus that causes a disease similar to HAV. It is associated with poor hygiene and sanitation and is spread through fecally contaminated foods.

An unusual virus, hepatitis D, or delta agent, is a defective RNA virus that cannot produce infection unless a cell is also infected with

* **jaundice** (jon'-dis) Fr. *jaunisse*, yellow. Also called icterus.

* **hepadnaviruses** (hep'-ah-dee'-en-ay-vy'-rus) Gr. *hepatos*, liver, plus DNA and virus.

TABLE 24.3 Principal Morphological and Pathologic Features of the Major Hepatitis Viruses

Property/Diseases	HAV*	HBV	HCV*
Biology

Diagnostic Tests to Differentiate	+	+	+

*Details of these viruses are covered in chapter 25.

HBV. Hepatitis D virus has a circular RNA genome more closely related to viroids than other viruses. HDV infection can only occur simultaneously or subsequent to HBV infection because the delta agent lacks the genes for structural proteins and is reliant on hepatitis B virus for completing its multiplication cycle. When HBV infection is accompanied by the delta agent, the disease becomes more severe and is more likely to progress to permanent liver damage.

Hepatitis B Virus and Disease

Because a cell culture system for propagating hepatitis B virus is not yet available, by far the most significant source of information about its morphology and genetics has been obtained from viral fragments, intact virions, and antibodies, which are often abundant in patients' blood. One of these blood-borne pieces, the *Dane particle*, often seen in electron micrographs of infected blood, is considered the intact virion. Blood-borne viral components are shown in **figure 24.18**.

Epidemiology of Hepatitis B

An important factor in the transmission pattern of hepatitis B virus is that it is a chronic infection of the liver, which continuously seeds the blood with viruses. Electron microscopic studies have revealed up to 10^7 virions per milliliter of infected blood. Even a minute amount of blood or serum (10^{-6} to 10^{-7} ml) can transmit infection. The abundance of circulating virions is so high and the minimal dose so low that such simple practices as sharing a toothbrush or a razor can transmit infection. HBV has also been detected in semen and vaginal secretions, and it is currently believed to be transmitted

Figure 24.18 Hepatitis B. Blood from hepatitis B virus–infected patients presents an array of particles, including Dane particles (the intact virus), the envelope (or surface shell), and filaments that are polymers of the envelope antigen. Source: CDC

by these fluids in certain populations. Spread of the virus by means of close contact in families or institutions is also clearly involved.

The incidence and risk for hepatitis B are highest among people having unprotected sexual intercourse with multiple partners, drug addicts, and certain occupations, including people who conduct medical procedures involving blood or blood products such as serum. The incidence of HBV infection and carriage among drug addicts who routinely share needles is very high. Homosexual males constitute another high-risk group because such practices as

anal intercourse can traumatize membranes and permit transfer of virus into injured tissues. Heterosexual intercourse can also spread infection but is less likely to do so. Infection of a newborn during birth occurs readily and predisposes to development of the carrier state and increased risk of liver cancer in the child. The role of mosquitoes, which can harbor the virus for several days after biting infected persons, has been well documented in the tropics and in some parts of the United States.

The tropism of HBV for the liver becomes a significant epidemiological complication in some people. Persistent or chronic carriers harbor the virus and continue to shed it for many years. Worldwide, 300 million people are estimated to carry the virus, but it is most prevalent in Africa, Asia, and the western Pacific and is least prevalent in North America and Europe.

Pathogenesis of Hepatitis B Virus

The hepatitis B virus enters the body through a break in the skin or mucous membrane or by injection into the bloodstream. Eventually, it reaches the liver cells (hepatocytes), where it multiplies and releases viruses into the blood during an incubation period of 4 to 24 weeks (7 weeks average). Surprisingly, the majority of those infected exhibit few overt symptoms and eventually develop an immunity to HBV. But some people experience malaise, fever, chills, anorexia, abdominal discomfort, and diarrhea. In people with more severe disease, the symptoms and the aftermath of hepatic damage vary widely. Fever, jaundice, rashes, and arthritis are common reactions (**figure 24.19**), and a smaller number of patients develop glomerulonephritis and arterial inflammation. Most patients experience complete liver regeneration and restored function. However, a small percentage of patients develops chronic liver disease

in the form of necrosis or cirrhosis (permanent liver scarring and loss of tissue).

The association of HBV with **hepatocellular carcinoma**² is based on these observations:

1. certain hepatitis B antigens are found in malignant cells and are often detected as integrated components of the host genome;
2. persistent carriers of the virus are more likely to develop this cancer; and
3. people from areas of the world with a high incidence of hepatitis B (Africa and the Far East) are more frequently affected. This connection is probably a result of infection early in life and the long-term carrier state.

In general, people with chronic hepatitis are 200 times more likely to develop liver cancer, though the exact role of the virus is still the object of molecular analysis. One explanation is that HBV infection increases the rate of cell division in liver cells. As these cells accumulate mutations, oncogenes become activated and cause malignancy.

Diagnosis and Management of Hepatitis B Infection

Hepatitis symptoms are so similar that differential diagnosis on this basis alone is unlikely. A careful examination of possible risk factors could distinguish between hepatitis B and A. For example, HBV infection is associated with occupational exposure, drug abuse, and relatively long incubation period. Serological tests can detect either virus antigen or antibodies. Serological testing permits detection of the surface antigen very early in the infection. These same tests are essential for screening blood destined for transfusions, semen in sperm banks, and organs intended for transplant.

It is possible for mothers who are carriers of HBV to transmit the infection to the fetus transplacentally and highly likely that infection occurs during delivery. Unfortunately, infection with this virus early in life is a known risk factor for chronic liver disease. In light of the increasing incidence of HBV-positive pregnant women, routine testing of all pregnant women is now an important prenatal screen. It has been added to the standard procedures to detect infections that are especially harmful to fetuses and neonates, known collectively as STORCH (see chapter 13).

Mild cases of hepatitis B are managed by symptomatic treatment and supportive care. Chronic infection can be controlled with recombinant interferon, which stops virus multiplication and prevents liver damage in up to 60% of patients. Active disease may also be treated with nucleoside analogs such as entecavir, tenofovir, and lamivudine, which inhibit the DNA polymerase of the virus. Passive immunization with hepatitis B immune globulin (HBIG) gives significant protection to people who have been exposed to the virus through needle puncture, broken blood containers, or skin and mucosal contact with blood. Other groups for whom prophylaxis is highly recommended are the sexual contacts of actively infected people or carriers and neonates born to infected mothers.

The primary prevention for HBV infection is vaccination. The most widely used vaccines (Recombivax, Energix) contain the pure surface antigen cloned in yeasts. They are given in three doses over

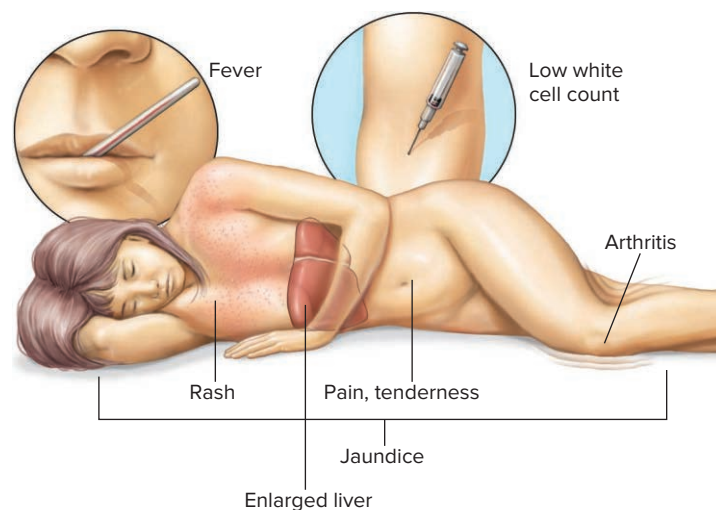

Figure 24.19 The clinical features of hepatitis B. Among the most prominent symptoms are fever, jaundice, and intestinal discomfort. The liver is also enlarged and tender.

2. HOC. Also called hepatoma, a primary malignant growth of hepatocytes.

Pathogen Profile #4 *Hepatitis B virus (HBV)*

Source: CDC

Microscopic Morphology Small, enveloped virus about 42 nm in diameter.

Identified by Serological tests (radioimmunoassay or ELISA) can detect either the virus itself or antibodies manufactured in response to infection.

Habitat Hepatitis B virus is chronically carried, and this population serves as the reservoir for infection. The virus remains infective for days in dried blood, months in serum at room temperature, and decades if frozen. Transfusions or injections of blood products, such as plasma and clotting factors, served as prime means of infection prior to routine testing of donated blood. Currently, kidney dialysis equipment, reusable needles (such as those used for acupuncture), tattooing and piercing equipment, and needleless vaccine guns have all been linked to infection.

Virulence Factors Persistence in liver cells and integration into the genome, leading to oncogenesis.

Primary Infections/Disease Most people infected with HBV show no symptoms and eventually develop immunity to the virus. Initial

symptomatic infection is marked by malaise, fever, and discomfort, with rashes, arthritis, and jaundice occurring in some cases. Most patients experience complete recovery, whereas a small number may develop chronic liver disease as a result of necrosis or cirrhosis. Long-term complications include a greatly increased risk of hepatocellular carcinoma (liver cancer).

Control and Treatment Mild HBV infections are treated by managing symptoms, whereas chronic infection may be treated with interferon, which stops virus multiplication. Passive immunization with hepatitis B immune globulin (HBIG) is administered to those who may have been exposed to the virus through needle punctures or other contact with blood. Extreme care when handling needles, broken blood vials, and splashed blood or serum is essential to reduce the risk of occupational exposure to the virus. Vaccination is available and is recommended for persons under 18 years of age and for adults with potential medical or occupational exposure to blood and blood products.

18 months, with occasional boosters. Immunization to protect against hepatitis B is part of the routine schedule of childhood vaccinations recommended by the Advisory Committee on Immunization Practices.

Check Your Progress SECTION 24.4

19. Summarize the symptoms, complications, route of transmission, and type of nucleic acid found in hepatitis A, B, and C viruses. What is the effect of the delta agent?
20. How is hepatitis B virus commonly spread, diagnosed, and treated?
21. What groups are most at risk for developing hepatitis B?
22. What is the nature of the vaccines for hepatitis B, and who should receive them?

24.5 Nonenveloped DNA Viruses

Expected Learning Outcomes

16. Recall the structure, epidemiology, and diseases caused by adenovirus.
17. Describe the epidemiology and pathology of papillomaviruses.
18. Explain how HPV infection can be prevented.
19. Understand the epidemiology and pathology of the human polyomaviruses.
20. Recall the characteristics of parvovirus that make it unique.
21. Identify the most important human parvovirus and the disease it causes.

The Adenoviruses

During a study seeking the cause of the common cold, a new virus was isolated from the **adenoids*** of young children. It turned out that this virus, termed **adenovirus**, was not the sole agent of colds but one of numerous others (described in chapter 25). It was also the first of about 80 strains of nonenveloped, double-stranded DNA viruses classified as adenoviruses, including 30 types associated with human infection (**figure 24.20**). Besides infecting lymphoid tissue, adenoviruses have a preference for the respiratory and intestinal epithelia and the conjunctiva. Adenoviruses produce aggregations of incomplete and assembled viruses that usually lyse the cell. In cells that do not lyse, the viral DNA may persist in the nucleus. Experiments show that some adenoviruses are oncogenic in animals but none of them causes cancer in humans.

Epidemiology of Adenoviruses

Adenoviruses are spread from person to person by means of respiratory and ocular secretions. Most cases of conjunctival infection involve preexisting eye damage and contact with contaminated sources such as swimming pools, dusty working places (shipyards and factories), and unsterilized optical instruments. Infection by adenoviruses usually occurs by age 15 in most people, and certain individuals become chronic respiratory carriers. Although the reason is obscure, military recruits are at greater risk for infection than

* *adenoids* (ad'-eh-noyd) Gr. *adeno*, gland, and *eidōs*, form. A lymphoid tissue (tonsil) in the nasopharynx that sometimes becomes enlarged.

Figure 24.20 Distinctive adenovirus structures at high magnification. Colorized electron micrograph of adenovirus particles (220,000 \times). Source: Dr. G. William Gary, Jr/CDC

the general population, and respiratory epidemics are common in armed services installations. Civilians, even of the same age group and living in close quarters, seldom experience such outbreaks.

Respiratory, Ocular, and Miscellaneous Diseases of Adenoviruses

The patient infected with an adenovirus is typically feverish, with acute rhinitis, cough, and inflammation of the pharynx and enlarged cervical lymph nodes. Certain adenoviral strains produce an acute follicular lesion of the conjunctiva. Usually one eye is affected by a watery exudate, redness, and partial closure. A deeper and more serious complication is **keratoconjunctivitis**, an inflammation of the conjunctiva and cornea.

Acute hemorrhagic cystitis in children has been traced to an adenovirus. This self-limiting illness of 4 to 5 days duration is marked by hematuria (blood in the urine), frequent and painful urination with occasional episodes of fever, bedwetting, and suprapubic pain. Because the virus apparently infects the intestinal

epithelium and can be isolated from some diarrheic stools, adenovirus is also considered an agent of infantile gastroenteritis.

Severe cases of adenovirus infection, especially in immunocompromised hosts, can be treated with the antiviral drug cidofovir, but nephrotoxicity is a concern. An attenuated oral vaccine effective against two strains of the virus is routinely administered to military recruits, but no vaccine is available to the public.

Papilloma- and Polyomaviruses

Two families of small, nonenveloped double-stranded DNA viruses are **papillomaviruses*** and **polyomaviruses.*** They are similar in having circular DNA and causing persistent infections and tumors. They differ in their size and the makeup of their genomes.

Epidemiology and Pathology of the Human Papillomaviruses

A papilloma is a squamous epithelial growth commonly referred to as a **wart**, or **verruca**, caused by over 100 different strains of **human papillomavirus (HPV)**. Some warts are specific for the mucous membranes; others invade the skin. The appearance and seriousness of the infection vary somewhat from one anatomical region to another. Painless, elevated, rough growths on the fingers and occasionally on other body parts are called **common, or seed, warts (figure 24.21a)**. These commonly occur in children and young adults. **Plantar warts** are deeper, painful papillomas on the soles of the feet; flat warts are smooth, skin-colored lesions that develop on the face, trunk, elbows, and knees. A special form of verruca known as **genital warts** is a prevalent STD and is linked to some types of cancer. Warts are transmissible through direct contact with a wart or contaminated fomites, and they can also spread on the same person by autoinoculation. The incubation period varies from 2 weeks to more than a year. Papillomas are extremely common in all human populations.

Genital Warts: An Insidious Papilloma Genital warts are the latest concern among young, sexually active people. Although this

* *papillomaviruses* (pap^o-il-oh'-mah) L. *papilla*, pimple, and Gr. *oma*, tumor. A nodular epithelial tumor.

* *polyomaviruses* (paw^o-lee-oh'-mah) L. *poly*, many. A glandular tumor caused by a virus.

Figure 24.21 Human papillomas.

(a) Common warts. Virus infection induces a neoplastic change in the skin and growths on the fingers, face, or trunk. One must avoid picking, scratching, or otherwise piercing the lesions to avoid spread and secondary infections. (b) Chronic genital warts (condylomata acuminata) that have extended into the labial, perineal, and perianal regions. (a): © DermNet New Zealand Trust; (b): Source: CDC

(a)

Condylomata acuminata

(b)

disease is not new, case reports have increased to such an extent that it is now regarded as the most common STD in the United States, with millions of new cases per year. There are probably in excess of 30 million carriers of 35 types of HPV associated with genital warts (most commonly types 6, 11, 16, 18, and 31). The virus invades the external and internal genital membranes, especially of the vagina and the head of the penis. Wart morphology ranges from tiny, flat, inconspicuous bumps to extensive, branching, cauliflower-like masses called **condylomata acuminata*** (figure 24.21b). Infection is also common in the cervix, urethra, and anal skin. Most cases (90%) present with no or minimal symptoms, which can interfere with detection and diagnosis.

The most disturbing aspect of the sudden increase in HPV infection is its strong association with cancer of the reproductive tract, especially the cervix and penis. Ten HPV types increase the risk for developing reproductive cancer, but numbers 16 and 18 account for 70% of metastatic tumors. These viruses are latent in the genome of epithelial cells and contain two oncogenes that transform genital wart lesions into malignant tumors. In the United States, oncogenic HPVs cause over 17,000 cancers in women (mostly cervical) and 9,000 cancers (mostly oropharyngeal) in men each year. Infectious disease specialists are also reporting an increasing number of HPV-related oropharyngeal cancers, which is now the leading cause of mouth and throat cancers in both men and women.

Susceptibility to this infection and its potential for cancer can be greatly reduced by early detection and treatment of both the patient and the sexual partner. Such early diagnosis depends on thorough inspection of the genitals and, in women, a Papanicolaou (Pap) smear to screen for abnormal cervical cells (figure 24.22).

Diagnosis, Treatment, and Prevention of HPV Infection

The warts caused by papillomaviruses are usually distinctive enough to permit reliable clinical diagnosis without much difficulty. However,

* *condylomata acuminata* (kahn'-dee-loh'-mah-tah ah-kyoo'-min-ah'-tah) Gr. *kondyloma*, knob, and *L. acuminatus*, sharp, pointed. Not to be confused with *condyloma lata*, a broad, flat lesion of syphilis.

Figure 24.22 Pap smear of cervix in patient with HPV infection. The major sign is the koilocyte, an abnormal cell with a marked clear space around the enlarged abnormal nucleus. Normal cells are labeled for comparison. Detection of such abnormal cells is indicative of a precancerous condition. © Roger Dachez/Science Source

a biopsy and histological examination can help clarify ambiguous cases. A sensitive DNA probe can detect HPV by means of a hybridization procedure. This technique has the advantage of also determining the type of HPV in the infection. The Pap smear procedure is a highly effective microscopic method for detecting cells that are infected or converting to cancer. Both provide valuable assessments of the patient's risk for developing cervical cancer.

Although most common warts regress over time, they cause sufficient discomfort and cosmetic concern to require treatment. Treatment strategies for all types of warts include physical removal of the affected skin or membrane by cauterization, freezing, or laser surgery. Additionally, chemicals may be directly applied to warts to speed their removal, with podophyllin typically applied to genital warts and salicylic acid to all others. Because treatments may not destroy the virus in all cells, warts can recur.

Three effective HPV vaccines—Cervarix, Gardasil, and Gardasil 9—have been approved by the FDA. All three are based on viral protein surface receptors made by recombinant DNA technology. Protection is aimed at the most prevalent strains that cause infection and cancer. Bivalent Cervarix contains antigens only from the two HPV types associated with cervical cancer (16 and 18). Quadrivalent Gardasil contains antigens from four types of HPV (6, 11, 16, 18) that are responsible for 70% of cervical cancers and 90% of genital warts. The newest vaccine, Gardasil 9 contains antigens from 5 additional types of HPV (31, 33, 45, 52, and 58) that, altogether, are responsible for 90% of cervical cancers and 90% of genital warts. Immunization is now recommended for both males and females at the age of 11 or 12, prior to becoming sexually active.

The Polyomaviruses

In the mid-1950s the search for a leukemia agent in mice led instead to the discovery of a new virus capable of inducing an assortment of tumors—hence its name, polyomavirus. Among the most important human polyomaviruses are the JC virus and BK virus.³ Although many polyomaviruses are fully capable of transforming host cells and inducing tumors in experimental animals, none causes cancer in its natural host.

Epidemiology and Pathology On the basis of serological surveys, it appears that infections by JC virus and BK virus are commonplace throughout the world. Because the majority of infections are asymptomatic or mild, not a great deal is known about their mode of transmission, portal of entry, or target cells, but urine and respiratory secretions are suspected as possible sources of the viruses. The main complications of infection occur in patients who have cancers or are immunosuppressed. **Progressive multifocal leukoencephalopathy*** (PML) is an uncommon but generally fatal infection by JC virus that attacks accessory brain cells and gradually demyelinizes certain parts of the cerebrum. Infection with BK viruses, usually associated with renal transplants, causes complications in urinary function. By the time PML is diagnosed, the patient is usually immunocompromised with extensive brain damage. A prevention for BK infection is to treat all renal transplant patients with human leukocyte interferon.

3. The initials signify the cancer patients from whom the viruses were first isolated.
* *leukoencephalopathy* (loo'-koh-en-sef'-uh-lop'-uh-thee) Gr. *leuko*, white, *cephalos*, brain, and *pathos*, disease.

Pathogen Profile #5 *Human papillomavirus (HPV)*

Source: Laboratory of Tumor Virus Biology/National Cancer Institute

Microscopic Morphology Nonenveloped virus about 55 nm in diameter.

Identified by Clinical appearance. Biopsy and histological examination, DNA probes, and PCR can be used to confirm clinical diagnosis.

Habitat HPV is common in human carriers throughout the world.

Virulence Factors Ability to persist in epithelial cells of the genitalia; can insert in genome and cause oncogenesis.

Primary Infections/Disease Human papillomavirus is the causative agent

of verruca, or warts. The various manifestations of HPV infection—common warts, plantar warts, and genital warts—are the result of different strains of the virus. Infection with some types of HPV both causes genital warts and increases the risk of developing cancer of the reproductive tract, especially of the cervix and penis;

types 16 and 18 account for 70% of metastatic tumors. Infections of the mouth and throat can give rise to oropharyngeal cancers.

Control and Treatment HPV is transmissible through direct contact with a wart or contaminated fomites; therefore, control rests with barrier protection such as gloves or condoms, as appropriate. Treatment involves removal of the wart using chemicals such as podophyllin or physical methods such as surgery, freezing, or cauterization. While these treatments remove the wart, virally infected cells almost always remain and may reappear. Three vaccines—Cervarix, Gardasil and Gardasil 9—effective against those strains of HPV most closely linked to cancer of the reproductive tract have been approved, and their administration is part of the recommended vaccination schedule for children eleven to eighteen.

Nonenveloped Single-Stranded DNA Viruses: The Parvoviruses

The **parvoviruses*** (PVs) are unique among the human viruses in having single-stranded DNA molecules. They are also notable for their extremely small diameter (18–26 nm) and genome size. Parvoviruses are indigenous to and can cause disease in several mammalian groups: for example, distemper in cats, an enteric disease in adult dogs, and a potentially fatal cardiac infection in puppies.

The most important human parvovirus is B19, the cause of **erythema infectiosum (figure 24.23)**. It is also known as fifth disease because it is the fifth rash of childhood (the four others being rubella, rubeola, scarlet fever, and scarletina). It is a common childhood infection spread primarily by droplets. Once it enters the circulation, it selectively attacks and lyses erythrocytes. Often the infection goes unnoticed, though the child may have a low-grade fever and a bright red rash on the cheeks. This same virus can be more dangerous in children with immunodeficiency or sickle-cell anemia because of its destruction of red blood stem cells. Adults can acquire the infection, and they often experience a rash along with joint swelling and pain. If a pregnant woman contracts infection and transmits it to the fetus, a severe and often fatal anemia can result.

One type of parvovirus, the adeno-associated virus (AAV), is another example of a defective virus that cannot replicate in the host cell without the function of a helper virus (in this case, an adenovirus). The possible impact of this coinfection on humans is still obscure.

Figure 24.23 Typical “slapped face” rash of human parvovirus (B19). Confluent red rash on the cheek gives this child a “slapped face” appearance. This is one symptom of erythema infectiosum, a common childhood ailment caused by human parvovirus (B19). © DermNet New Zealand Trust

Check Your Progress SECTION 24.5

- Describe the general structure of an adenovirus.
- List the diseases caused by adenoviruses and explain how they are spread.
- Compare the locations and other characteristics of the three types of warts; what types are most serious and why?
- What is the importance of the HPV vaccines?
- Describe the unique structure of parvoviruses.
- Explain the importance of B19.

* *parvoviruses* (par'-voh-vy'-rus) *L. parvus*, small.

CASE STUDY Part 2

A common characteristic of herpesviruses is their ability to cause latent infections and then reemerge in the future, and VZV is no different in this regard. When a varicella infection has resolved, the virus typically retreats to dorsal root ganglia and remains there. Years later—most likely responding to a combination of decreased cellular immunity and unknown environmental cues—the virus may reactivate, resulting in a painful maculopapular rash called herpes zoster, and more commonly known as shingles. Those with active zoster lesions can spread varicella zoster virus to people who have never had chickenpox or been vaccinated. If this happens, the newly infected person may develop varicella (chickenpox), but not zoster (shingles). In this case the woman's infection was almost certainly attributable to her husband's zoster.

A rare complication of both varicella and zoster is delayed paralysis on one side of the body (hemiplegia). One can speculate that there was a connection between the illness and delayed paralysis in this case, but a much more likely explanation is that a 94-year-old woman succumbed to a stroke, without the involvement of a virus. In any case, no postmortem

was ordered, so blood and tissue samples that might have supported such a connection were never collected.

Chickenpox is the epitome of a childhood disease. Prior to the introduction of a chickenpox vaccination in 1995, 4 million people would get chickenpox each year in the United States. Although most cases were mild and self-limiting, 10,600 people were hospitalized and 100 to 150 died each year. Despite its occasional severity, the disease was treated as a rite of childhood, with parents routinely holding “pox parties” where infected and uninfected children could mingle, ensuring that children got the disease when they were young (and in the case of families with several children, that all children had the disease simultaneously).

- *Many of the complications of chickenpox involve bacterial infections that are able to enter the body more easily because of breaks in the skin caused by the lesions. How would you describe this type of infection?*
- *Aside from complications of chickenpox, why else might a “pox party” be a bad idea?*

For a synopsis of this Case Study, search the Internet for “Chickenpox at Ninety four.”

To conclude this Case Study, go to Connect.

Chapter Summary with Key Terms

24.1 Viruses in Human Infections and Diseases

- A. Viruses are minute intracellular parasites containing a genome of RNA or DNA. They appropriate the metabolic machinery of their host to ensure their reproduction.
- B. Viruses infect a variety of hosts, although the host range of a specific virus is usually quite limited. The effects of viral infection range from mild to fatal, again depending on the particular virus. Some viruses persist in the host in a **chronic** or **latent** state; others are potentially **oncogenic** or **teratogenic**.
- C. Identification and diagnosis of viral infection depends on culture, microscopy, genetic probes, and serology. Limited treatments are available for viral infection.
- D. DNA viruses are classified based on the presence of an envelope and whether they contain double- or single-stranded DNA.

24.2 Enveloped DNA Viruses: Poxviruses

- A. **Poxviruses** are large, complex viruses that produce skin lesions called **pox** (pocks).
 1. **Variola** is the agent of **smallpox**, the first disease to be eliminated from the world by vaccination.
 2. **Molluscum contagiosum** is caused by a molluscipoxvirus. It causes an STD with waxy skin nodules.
 3. Cowpox and monkeypox represent other human diseases caused by poxviruses.

24.3 Enveloped DNA Viruses: The Herpesviruses

- A. **Herpesviruses** are persistent latent viruses that cause recurrent infections and are implicated in neoplastic transformations.
 1. **Herpes simplex virus (HSV)**: Both **HSV-1** and **HSV-2** create lesions of the mucous membranes, with type 1 affecting the lips, eyes, and oropharynx and type 2 usually affecting the genitals. Infections are treated with valacyclovir or related compounds.

2. **Varicella-zoster virus (VZV)**: Responsible for both **varicella (chickenpox)** and **zoster (shingles)**. Chickenpox is the familiar childhood infection; zoster occurs when virus in the spinal/cranial nerves is reactivated. Vaccines now offer protection against both aspects of the virus.
3. **Cytomegalovirus** is perhaps the most common herpesvirus. Healthy adults may be asymptomatic; more serious disease is seen in neonates, newborns, and immunocompromised patients. Drug therapy is reserved for immunocompromised patients.
4. **Epstein-Barr virus (EBV)** is a herpesvirus of the lymphoid and glandular tissue. Leads to **mononucleosis** and potentially **Burkitt lymphoma** or **nasopharyngeal carcinoma**. Disseminated EBV infection is a complication of AIDS and organ transplant patients.
5. **Herpesviruses 6 and 7** are the cause of **roseola infantum** in children; **herpesvirus 8** is the viral agent of Kaposi sarcoma, a tumor of AIDS patients.

24.4 The Viral Agents of Hepatitis

- A. **Hepadnaviruses**: One cause of viral hepatitis, an inflammatory disease of liver cells that may result from several different viruses.
 1. **Hepatitis B virus (HBV)** causes **hepatitis B**. Infection is via body fluids and is marked by fever and **jaundice**. Chronic carriage may lead to liver disease and liver cancer. Management is by vaccine, immune serum globulin, interferon, and antiviral chemotherapy.
- B. Other agents of viral hepatitis (HAV, HCV) are RNA viruses covered in the next chapter (25).

24.5 Nonenveloped DNA Viruses

- A. **Adenoviruses**: Common infectious agent of the lymphoid organs, respiratory tract, eyes. Diseases include the common

cold, **keratoconjunctivitis** (eye infections), and cystitis (urinary tract infections).

B. Papilloma- and polyomaviruses.

1. **Human papillomaviruses (HPVs)** are the causative agent of **papillomas, verrucas, common warts, plantar warts, and genital warts**, the last of which may progress to **condylomata acuminata**. Chronic latent infection with HPV is associated with cervical and penile cancer. Treatment includes surgery and interferon. Vaccination is available for prevention.

2. **Polyomaviruses** include JC virus, which causes **progressive multifocal leukoencephalopathy**, and BK virus, which causes complications in renal transplants.

- C. Nonenveloped Single-Stranded DNA Viruses: The Parvoviruses** Parvoviruses: Human parvovirus (B19) causes **erythema infectiosum**, a relatively mild infection common in children.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

1. Which of the following is *not* caused by a poxvirus?
 - a. molluscum contagiosum
 - b. smallpox
 - c. cowpox
 - d. chickenpox
2. In general, zoonotic viral diseases are _____ in humans.
 - a. mild and asymptomatic
 - b. self-limited
 - c. severe and systemic
 - d. not contagious
3. Which virus is used in smallpox vaccination?
 - a. variola
 - b. vaccinia
 - c. cowpox
 - d. varicella
4. Herpes simplex 1 usually causes _____, and herpes simplex 2 usually causes _____.
 - a. cold sores, genital herpes
 - b. fever blisters, cold sores
 - c. canker sores, fever blisters
 - d. shingles, stomatitis
5. Herpetic whitlows are _____ infections of the _____.
 - a. pox, oral cavity
 - b. CMV, lymph nodes
 - c. EBV, skin
 - d. herpes, fingers
6. Neonatal herpes simplex is usually acquired through
 - a. contaminated mother's hands
 - b. other babies in the newborn nursery
 - c. crossing the placenta
 - d. an infected birth canal
7. _____ is an effective treatment for herpes simplex lesions.
 - a. Amantadine
 - b. Interferon
 - c. Acyclovir
 - d. Cortisone
8. Which herpesvirus is most commonly associated with a dangerous fetal infection?
 - a. herpes simplex
 - b. herpes zoster
 - c. EBV
 - d. CMV
9. Varicella and zoster are caused by
 - a. the same virus
 - b. two different strains of VZV
 - c. herpes simplex and herpes zoster
 - d. CMV and VZV
10. A common sign of hepatitis is
 - a. liver cancer
 - b. jaundice
 - c. anemia
 - d. bloodshot eyes
11. A virus associated with chronic liver infection and cancer is
 - a. hepatitis C
 - b. hepatitis B
 - c. hepatitis A
 - d. both a and b
12. Benign epithelial growths on the skin of fingers are called
 - a. polyomas
 - b. verrucas
 - c. whitlows
 - d. pox
13. Parvoviruses are unique because they contain
 - a. a double-stranded RNA genome
 - b. reverse transcriptase
 - c. a single-stranded DNA genome
 - d. an envelope without spikes
14. Adenoviruses are the agents of
 - a. hemorrhagic cystitis
 - b. keratoconjunctivitis
 - c. common cold
 - d. all of these
15. Which of the following viruses causes chronic persistent infections?
 - a. hepatitis B
 - b. smallpox
 - c. parvovirus
 - d. varicella-zoster virus
16. Which of the following viruses can be oncogenic in humans?
 - a. papillomavirus
 - b. Epstein-Barr virus
 - c. adenovirus
 - d. both a and b
17. **Multiple Matching.** Match the virus with the disease or condition. (Some viruses may match more than one condition.)

_____ herpes simplex 1	a. gingivostomatitis
_____ variola	b. condylomata acuminata
_____ polyoma	c. chickenpox
_____ varicella zoster	d. erythema infectiosum
_____ herpes simplex 2	e. fever blisters
_____ adenovirus	f. mononucleosis
_____ papilloma	g. smallpox
_____ Epstein-Barr	h. genital herpes
_____ cytomegalovirus	i. leukoencephalopathy
_____ parvovirus	j. roseola
_____ herpesvirus 6	k. cancer
	l. keratoconjunctivitis

Case Study Review

- The varicella-zoster virus that causes chickenpox is classified as a _____.
 - herpes virus
 - pox virus
 - papillomavirus
 - parvovirus
- For which viral infections are vaccines available to the general public?
 - varicella-zoster
 - human papillomavirus
 - hepatitis C virus
 - adenovirus
 - both a and b
- The woman in this case contracted chickenpox from her husband, yet the husband was suffering from shingles. Why did the woman not contract shingles?

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

- Outline 10 characteristics of viruses that add significantly to their medical impact and complications.
- Explain the involvement of viruses in cancer and congenital infections.
- Briefly clarify the difference between chronic and latent viral infections.
- Develop a table for the herpesviruses that summarizes virus name, tissues infected, names of diseases, and special characteristics.
- Compare the two types of human herpes simplex virus according to the types of diseases they cause, body areas affected, and complications.
 - Why is neonatal infection accompanied by such severe effects?
 - How are herpes simplex infections diagnosed and treated?
- Why does mononucleosis occur most commonly among college-age Americans?
- Name the DNA viruses that are oncogenic, sexually transmitted, spread by blood and blood products, and spread by respiratory droplets, kissing, and other nonsexual intimate contact.

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps along with concept mapping activities for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

- Discuss the pros and cons of salvaging or destroying the smallpox virus stocks.
- Describe several measures health care workers can take to avoid whitlows.
- Explain why a baby whose mother has genital herpes is not entirely safe even with a cesarean birth.
- What specific host defenses do immunodeficient, cancer, and AIDS patients lack that make them so susceptible to the viral diseases in this chapter?
 - Given the ubiquity of most of these viruses, what can health care workers do to prevent transmission of infection to other patients and themselves?

5. a. Name two different defective viruses that require another virus for function.
b. Explain how they might interrelate with the host virus.
6. Explain this statement: One acquires chickenpox from others, but one acquires shingles from oneself.
7. A man wants to divorce his wife because he believes her genital herpes could only have been acquired sexually. Her doctor says she is infected with type 1. Suggest a more likely source.
8. Weigh the following observation: High titers of antibodies for EBV are found in a leukemia patient; a chronically tired, ill businessman; a

healthy military recruit; and an AIDS patient. Comment on the probable significance of antibodies to EBV in human serum.

9. Give some pros and cons of exposing children to chickenpox to infect them and provide subsequent immunity, as opposed to vaccination.
10. What type of virus is most likely to be transmitted by vaccination guns and acupuncture tools?
11. What two different DNA viral infections can be identified with a Pap smear? Explain what abnormalities one would see.

Visual Challenge

1. Using **figure 24.1** and **table 24.1** as references, match each virus (a–d) with its usual infection pattern (1–5). Explain the outcomes of the disease process for each virus.

Source: Jim Goodson, M.P.H./CDC

CASE STUDY Part 1 This Can't Be From That

In 2011, an 11 year-old boy first presented to his family physician with a rapidly progressing collection of disturbing **neurological** symptoms. Four months earlier the boy had been a straight-A student in the fifth grade, with a healthy interest in basketball and soccer, when he began to have trouble completing assignments in school. His coordination and attention suffered; at home he would drop utensils and fall asleep during meals. Over the next month his **symptoms intensified**; he was inattentive and **confused** and would sometimes fall asleep while walking. His **coordination deteriorated** and he began to experience involuntary hand and arm movements that became increasingly severe. He lost weight as his appetite decreased.

The boy was referred to a pediatric neurologist, who ordered a **lumbar puncture, magnetic resonance imaging (MRI)** of the brain, and an **electroencephalogram (EEG)**. The lumbar puncture and MRI were normal. The EEG showed a number of abnormalities that unfortunately did little to explain the boy's rapidly worsening neurological condition. His cognitive and motor skills continued to decline and included frequent falling, the asking of meaningless questions, and **increased aggression**. By the third month after the onset of symp-

“He no longer appeared to recognize his family members’ faces or voices.”

toms, the boy had deteriorated dramatically. His speech became difficult to understand, he experienced worsening **spasticity** and rapid decline in mental status; he became **incontinent** and was unable to eat or drink. He did not fix on or follow objects, and he no longer appeared to recognize his family members’ faces or voices.

In 2012 the boy was admitted to the hospital. He was unresponsive to questions, could not follow commands, and continued to exhibit **spastic movements** of the arms and legs. An EEG displayed results indicative of **subacute sclerosing panencephalitis (SSPE)**, a neurodegenerative disease with no treatment and no cure. After 14 days the boy was discharged from the hospital and entered home hospice care, where he died 43 months later, in 2015.

- *Subacute sclerosing panencephalitis is a complication of what viral infection?*
- *How long does it take for SSPE to appear after the initial infection?*

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

The RNA viruses that cause disease in humans are a remarkably diverse group of microbes. Viruses are assigned to one of 12 families on the basis of their envelope, their capsid, and the nature of their RNA genome (**table 25.1**). RNA viruses are etiologic agents in a number of serious and prevalent human diseases, including influenza, AIDS, hepatitis, and viral encephalitis. Many experts believe that these viruses and several others have the potential of becoming the most important disease threats of the future (**25.1 Making Connections**).

25.1 Enveloped Segmented Single-Stranded RNA Viruses

Expected Learning Outcomes

1. Describe the structure of influenza virus and its spikes.
2. Understand what is meant by antigenic shift and antigenic drift.
3. Recall the epidemiology and complications associated with influenza.
4. Describe the production of influenza vaccine.
5. Recall the most important bunyaviruses found in the United States, and explain how infection commonly occurs.

The Biology of Orthomyxoviruses: Influenza

Orthomyxoviruses are spherical particles with an average diameter of 80 nm to 120 nm. There are three distinct influenza virus types (A, B, C), but type A causes the most cases of infection and is the one we discuss in the greatest detail. The virus attaches to and multiplies in cells of the respiratory tract (**figure 25.1**). It is engulfed and uncoated, and the segments of its RNA genome enter the nucleus to be transcribed and replicated. Gene expression gives rise

to glycoprotein spikes and capsid proteins. Finished viruses are assembled and budded off the cell with an envelope. Key to the many aspects of virus behavior and pathology are the glycoprotein spikes—termed **hemagglutinin (H)** and **neuraminidase (N)**. Virologists have characterized 17 different H subtypes and 9 N subtypes and have used these numbers to distinguish them. Influenza viruses of human origin are primarily of the H1, H2, and H3 and N1 and N2 subtypes. **Table 25.2** is a listing of significant influenza epidemics and the strains involved.

The name *hemagglutinin* is derived from its property of agglutinating (clumping) red blood cells, a property useful in identifying the virus. Hemagglutinin is the most important virulence factor because it is needed to bind to the respiratory mucosal receptors and induce viral entry. Neuraminidase is an enzyme that breaks down the respiratory mucus, keeps viruses from sticking together, and assists in budding from the host cell. Both types of spikes undergo frequent alterations due to genetic changes (**figure 25.2**).

The ssRNA genome of the influenza virus is known for its extreme variability. Research has shown that genetic changes are very frequent in the areas of the glycoprotein spikes recognized by the host immune response but very rare in the areas used for attachment to the host cell. In this way the virus can continue to attach to host cells while managing to decrease the effectiveness of the host response to its presence. This constant genetic change of the glycoproteins through mutation is called **antigenic drift**—the antigens gradually change their amino acid composition, resulting in decreased ability of host memory cells to recognize them.

A change with even more dramatic effects is known as **antigenic shift**. The genome of the virus consists of just 10 genes encoded on eight separate RNA strands. Antigenic shift is the substitution of one of those genes or strands with a gene or strand from an influenza virus originating from a different animal host. This is made possible when a strain of influenza A virus infects both humans and swine and a different strain of influenza A virus

*Infection during pregnancy causes various birth defects in the developing fetus.

infects birds and swine. The genes of all of these viruses code for the same important influenza proteins (including H and N)—but the actual sequence of the genes is different in the different types of viruses. When a bird virus and a human virus infect a single swine host, it is not uncommon for both virus types to infect the same host cell. Then the viral packaging step (figure 25.1, step 6) can randomly produce a human influenza virus that contains seven human influenza virus RNA strands plus a single bird influenza virus RNA strand (figure 25.3). When that virus infects a human, the protein receptors from the bird virus will not be recognized by memory cells, so there will not be a rapid response. Antibodies from any prior influenza virus will not be protective. As a result, there are deficiencies in both individual and herd immunities and epidemics become a real possibility. Experts have traced the flu pandemics of 1918, 1957, 1968, 1977, and 2009 to virus strains that were hybrid recombinants from bird and pig viruses that were also infective to humans.

To characterize each virus strain, virologists have developed a special nomenclature that chronicles the influenza virus type, the presumed animal of origin, the location, and the year of origin. For example, A/duck/Ukraine/63 identifies the strain isolated from domestic or migratory fowl; likewise, A/seal/Mass/1/80 is the causative agent of seal influenza. From this convention come such expressions as “swine flu” and “Hong Kong flu” (see table 25.2).

Emerging Avian Influenza Viruses

Starting in 2003, strains of influenza A viruses that usually infect birds underwent an antigenic shift and began to infect humans. The first of these emerging bird flu viruses, *H5N1*, originated from poultry in Southeast Asia and caused a highly virulent disease with about a 60% fatality rate in humans. All of these cases apparently arose through bird-to-human transmission, and there was no

evidence of person-to-person transmission. In 2013 another bird flu virus, *H7N9*, appeared in Chinese patients. By the middle of 2016 at least 807 cases and 151 deaths had been attributed to the flu, almost all of them in China. The vast majority of the cases involved direct contact with birds, often at live poultry markets, indicating that while the strain moved quickly from bird to human, person to person transmission was far less efficient.

Type	H/N Subtype	Strain/History
A	H1N1	Spanish flu pandemic of 1918
		A/New Jersey/76* (swine flu outbreak)

C	None	C/JHB/2/66

*The last number is the year the virus appeared.

Epidemiology and Pathology of Influenza A

Influenza is an acute, highly contagious respiratory illness afflicting people of all ages and marked by seasonal regularity and pandemics at irregular intervals. One of its first names was an Italian derivative of *un influenza di freddo*, an “influence of mystery.” This name has remained and is now contracted to the vernacular “flu.” Periodic

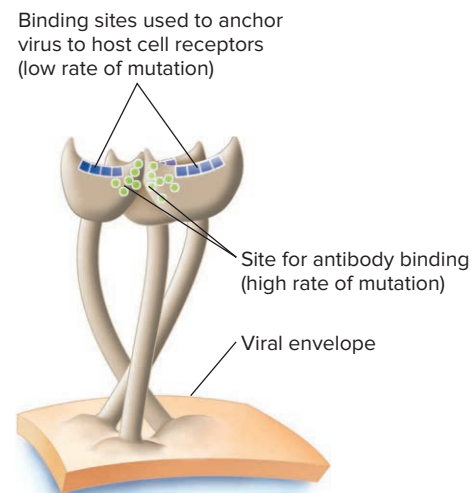

Figure 25.2 Schematic drawing of hemagglutinin (H) of influenza virus. Blue boxes depict site used to attach virus to host cells; green circles depict sites for anti-influenza antibody binding.

Figure 25.3 Antigenic shift event. Where swine, birds (ducks here), and humans live close together, the swine can serve as a melting pot for creating “hybrid” influenza viruses that are not rapidly neutralized by the human immune system.

outbreaks of respiratory illness that were probably influenza have been noted throughout recorded history. Note that the term *flu* is often used as a shorthand for any short-term acute illness such as “stomach flu.” Influenza does not affect the gastrointestinal tract in humans.

Influenza pandemics are accelerated by the contagiousness of the virus and widespread migrations or travel. They also occur in cycles, with episodes spaced about a decade apart. By compiling extensive serological profiles of populations and the influenza strains to which they are immune, the Centers for Disease Control and Prevention (CDC) have a scientific basis for predicting expected epidemic years and the probable strains involved. One advantage

of forecasting the expected viral subtypes is that the most vulnerable people can be vaccinated ahead of time with the appropriate virus strain(s).

Mode of Influenza Transmission

Inhalation of virus-laden aerosols and droplets constitutes the major route of influenza infection, although fomites can play a secondary role. The virus survives for 24 hours on nonliving surfaces. Transmission is greatly facilitated by crowding and poor ventilation in living quarters during the late fall and winter. In the tropics, infection occurs throughout the year, without a seasonal distribution. Occupational contact with chickens, other poultry, and swine constitutes a special high-risk category for disease. Rates of infection are highest among school-age children (30%) and lowest in adults (6%). The overall mortality rate for influenza A is about 0.1% of cases. Influenza or influenzal pneumonia rank among the top 10 causes of death in the United States, usually among elderly persons and small children.

Infection and Disease

The influenza virus binds primarily to ciliated cells of the respiratory mucosa. Infection causes the rapid destruction of these cells, releasing a load of viruses. Stripping the respiratory epithelium to the basal layer eliminates protective ciliary clearance and leads to severe inflammation and irritation. The illness is further aggravated by fever, headache, myalgia, pharyngeal pain, shortness of breath, and repetitive bouts of coughing. As the normal ciliated columnar epithelium is restored in a week or two, the symptoms usually abate.

Patients with emphysema or cardiopulmonary disease, along with very young, elderly, or pregnant patients, are more susceptible to serious complications. Most often, the weakened host defenses predispose patients to secondary bacterial infections, especially pneumonia caused by *Streptococcus pneumoniae* and *Staphylococcus aureus*. Although less common than bacterial pneumonia, primary influenza virus pneumonia is a dangerous complication that can cause rapid death—even of people in their prime. Other complications are bronchitis, meningitis, and neuritis.

Diagnosis, Treatment, and Prevention of Influenza

Except during epidemics, influenza must be differentiated from other acute respiratory diseases. Rapid serological tests can detect influenza antigens in a pharyngeal specimen in less than 30 minutes but have poor sensitivity, often producing false negative results. Assays which detect and amplify the RNA of the virus are the gold standard, and can be completed less than two hours.

The primary treatments for influenza include three prescription drugs: Zanamivir (Relenza), oseltamivir (Tamiflu), and peramivir (Rapivab). These drugs both target the function of neuraminidase as a way to block viral budding and release (see table 12.6). These drugs have replaced amantadine and rimantadine in routine therapy due to the viruses’ high levels of resistance to these older drugs. They must be taken as early as possible after infection to be beneficial. If clinical signs point to influenza, it is recommended that treatment be started immediately, without waiting for laboratory confirmation. Primary effects of the drugs

25.1 MAKING CONNECTIONS

A Global Viral Threat

Over the last several decades, some of humankind's most deadly viral diseases have been vanquished. Two cases in point are polio, now restricted to a few small areas of the globe, and smallpox, which has been eliminated entirely. Yet these successes are being overshadowed by a rise in the incidence of new and emerging viruses. Since 1967 at least 20 new viruses have been identified during an outbreak or epidemic of human disease (table 25.A). All but one of these viruses is an RNA virus, and most of them are zoonotic in origin, so in that sense they are new only to humans.

What accounts for the appearance of these viral diseases? One explanation is that RNA viruses mutate and evolve very rapidly. This creates opportunities for them to adapt in a short time to host species other than their natural ones. To quote Dr. Eddie Holmes at the Centers for Infectious Disease Dynamics:

“What a virus wants to do is simply to self-replicate. And if it means jumping species boundaries to find that cell, that will happen. What viruses are interested in . . . is to reproduce quickly with as much progeny as possible.”

Another major factor in the changing face of viruses on the world scene has to do with alterations in human ecology. We have much greater exposure to animals and animal habitats that were formerly isolated in remote areas of the world. When you combine this situation with movements to cities, increased population size, and rapid modes of travel, there is a “perfect storm” for transmission of any virus that has made the jump to humans. A particularly illustrative example of this was the West African Ebola outbreak of 2014–2016, which accounted for more than 28,000 cases and over 11,300 deaths (see the chapter 13 Case Study). The next largest outbreak on record took place in 2000–2001 in Uganda and was responsible for 224 deaths. Urbanization is clearly a driver of increasingly severe viral outbreaks.

Not only do we have to be vigilant about unidentified viruses, we also have to stay aware of the threat of emerging and reemerging viruses—those that have been around for a time but are increasing in numbers or range. High on the list of emerging viruses are the mosquito-borne arboviruses. West Nile fever virus, which had been endemic to Africa for years, has since become well-entrenched in North America while Dengue virus and Zika virus have been steadily extending their northward range in parts of Asia and the Americas. Virus watchers are also concerned about the continuing spread of Chikungunya arbovirus. In 2014, transmission of Chikungunya virus was identified in Florida, Puerto Rico, and the U.S. Virgin Islands. It causes debilitating arthritis and encephalitis that can be highly damaging to children.

Fortunately the methods we use to track the emergence of new viruses have improved as well, allowing scientists to characterize novel agents in a fraction of the time it took even a few years ago. When severe acute respiratory syndrome (SARS) emerged in China in 2002, it took scientists 3 months to identify the pathogen as a new type of coronavirus and notify the World Health Organization. In the meantime the ensuing epidemic infected over 8,000

people and killed nearly 1,000. In late 2012 and early 2013, 17 people were hospitalized with respiratory distress brought on by infection with a virus thought to be similar to the SARS virus. A new technology known as *deep sequencing* allowed scientists to swiftly identify areas of the genome where the new virus differed from previously identified coronaviruses. The virus—now known as Middle East Respiratory Syndrome Coronavirus, or MERS-CoV—was found to be unique, and WHO was warned of the potential dangers just 3 weeks after the second patient began to show symptoms. Ultimately this new means of viral classification allows for a more rapid identification of the source of the virus, better treatment, and smaller outbreaks.

Why do viruses that have jumped hosts (such as from bats to humans) cause a much more severe infection? Answer available on *Connect*.

TABLE 25.A Novel Virus Discoveries Since 1967

Microbe	Source	Infection	Year of Emergence
Marburg virus	Bats	Hemorrhagic fever	1967
Lassa fever virus	Rodents	Lassa fever	1969
Monkeypox virus	Monkeys, rodents	Monkeypox	1970

Pathogen Profile #1 *Influenza virus*

Source: CDC

Microscopic Morphology Enveloped, spherical virus, 80 to 120 nm in diameter, possessing a segmented genome of seven or eight strands of single-stranded RNA.

Identified by Serological tests to detect influenza antigens in pharyngeal samples, virus isolation in cell culture. Genetic analysis is the gold standard for detection and can be used to determine the origin, or specific strain, of a virus.

Habitat Influenza virus infects humans, swine, and birds.

Virulence Factors Hemagglutinin (H) and neuraminidase (N) spikes. Ability to undergo antigenic shift.

Primary Infections/Disease Influenza is a respiratory illness marked by seasonal regularity along with irregular pandemics. Infection of cells in the respiratory tract leads to the death of ciliated

epithelial cells and causes inflammation and irritation of the respiratory epithelium. Other symptoms include fever, headache, myalgia, pharyngeal pain, coughing, and shortness of breath. As the epithelium is replaced by healthy cells, usually over a week or two, symptoms abate.

Control and Treatment Vaccine, which must be repeated for each year's dominant influenza strains, remains the best preventative measure. Three prescription drugs are currently recommended for the treatment of influenza—zanamivir (Relenza), oseltamivir (Tamiflu), and peramivir (Rapivab)—each of which interferes with viral entry into the cell. These drugs typically decrease both the duration of the disease and the severity of symptoms. Two older drugs, amantadine and rimantadine are not currently recommended because of high levels of resistance.

include reduction of symptoms, shortened disease duration, and slowed virus transmission.

Nonspecific treatments, mainly to control symptoms, include fluids, bed rest, and nonaspirin pain relievers and anti-inflammatory drugs. Aspirin is not indicated because it significantly increases the risk for **Reye's syndrome**, a rare disease that strikes the brain, liver, and kidney and is characterized by the fatty degeneration of those organs.

Influenza Vaccination Because of the changing nature of the antigens on the viral surface, a result of antigenic drift and shift, annual vaccination is considered the best way to avoid infection. Anyone over the age of 6 months can take the vaccine, and it is especially recommended for high-risk groups or those who have extensive contact with the public. New guidelines add young children as a target group for vaccination.

Preventing influenza infections and epidemics is one of the top priorities for public health officials. In that the standard inactivated whole-virus vaccine requires nearly a year to prepare, much advance planning takes place. Here is the general time line with the events involved:

1. In January, three or four virus variants are selected according to evidence that predicts the most prominent strains to circulate that year. For example, the 2016–2017 vaccines contained A/California/7/2009 (H1N1)pdm09-like virus; A/Hong Kong/4801/2014 (H3N2)-like virus; B/Brisbane/60/2008-like virus (B/Victoria lineage). Four component vaccines add an additional virus, B/Phuket/3073/2013-like virus (B/Yamagata lineage).
2. CDC delivers the correct virus seed stock to manufacturers.
3. From February to May, viruses are grown in millions of fertilized eggs from a special breed of chickens.

4. The viruses are harvested, processed, and inactivated by chemical treatment to create the vaccine.
5. In June/July, the vaccine is tested for purity, safety, and sterility.
6. In August/September, the vaccine is dispensed, prepared for injection, and shipped to medical centers and pharmacies.
7. In October/November, the vaccination programs begin.

Currently the majority of influenza vaccines are produced by this method, but two vaccines (Flublok, Flucelvax) not grown in eggs are available. Not using eggs to make the vaccine has clear benefits, including shorter lead times in production, faster alterations to accommodate new strains midseason, and less likelihood of allergies.

Several types of influenza vaccines exist. Traditional vaccination, approved for the majority of individuals 6 months or older, is an inactivated trivalent vaccine (containing antigens from 3 viral strains) injected intramuscularly. A newer alternative is an intradermal vaccine that injects the same three inactivated strains into the skin, using a needle one-tenth the size of the traditional vaccine. Currently approved only for adults between 18 and 64 years of age, intradermal vaccination is helpful for those who have a fear of needles. An additional benefit is that the vaccination requires 40% less antigen than a traditional vaccine, helping to guard against vaccine shortages by allowing more doses to be manufactured from a given amount of antigen.

A serious complication of influenza vaccines has been **Guillain-Barré syndrome**. It is a neurological condition that can arise in approximately 1 in 100,000 vaccine recipients. This syndrome appears to be an autoimmunity induced by viral proteins and marked by varying degrees of demyelination of the peripheral nervous system, leading to weakness and sensory loss. Most patients recover function, but the disease can also be debilitating and fatal.

Other Viruses with a Segmented Genome: Bunyaviruses and Arenaviruses

Between them the **bunyavirus*** and **arenavirus*** groups contain hundreds of viruses whose normal hosts are arthropods or rodents. Although none of the viruses is a natural parasite of humans, they can be transmitted zoonotically and periodically cause epidemics in human populations. Examples of important bunyavirus diseases are California encephalitis, spread by mosquitoes; Rift Valley fever, an African disease transmitted by sand flies; and Korean hemorrhagic fever, caused by a hantavirus and transmitted by rodents. Other bunyaviruses are discussed in section 25.4 along with other arboviruses because most of them are transmitted by insects and ticks.

The most important American bunyavirus is **Sin Nombre** (no name) **hantavirus**. The first cases came to light in 1993 in the Four Corners area of New Mexico, when a cluster of unusual cases was reported to the CDC. The victims were struck with high fever, lung edema, and pulmonary failure. Most of them died within a few days. Similar cases were reported sporadically in Arizona, Colorado, and other western states.

The disease was termed **hantavirus pulmonary syndrome (HPS)**. Comprehensive studies of rodent populations have revealed that the virus is carried by deer and harvest mice. It is probably spread by dried animal wastes that have become airborne when rodent nests are disturbed. The disease occurs sporadically at a rate of 25 to 50 cases per year but with a high (33%) mortality rate.

During the summer of 2012, 10 confirmed cases of hantavirus infection—and three deaths—occurred among visitors to Yosemite National Park, with 9 of the 10 cases occurring in people staying in tent cabins in the same campground. Inspection revealed mice to be nesting within the walls of several cabins. Outbreaks like this, which exemplify the ease with which humans can intermingle with a large rodent reservoir, are a primary reason that hantavirus pulmonary syndrome is considered an emerging disease.

Four major arenavirus diseases are Lassa fever, found in parts of Africa; Argentine hemorrhagic fever, typified by severe weakening of the vascular bed, hemorrhage, and shock; Bolivian hemorrhagic fever; and lymphocytic choriomeningitis, a widely distributed infection of the brain and meninges. The viruses are closely associated with a rodent host and are continuously shed by the rodent throughout its lifetime. Transmission of the virus to humans is through aerosols and direct contact with the animal or its excreta. These diseases vary in symptomatology and severity from mild fever and malaise to complications such as hemorrhage, renal failure, cardiac damage, and shock syndrome. The lymphocytic choriomeningitis virus can cross the placenta and infect the fetus. Pathologic effects include hydrocephaly, blindness, deafness, and mental retardation. So dangerous are these viruses to laboratory workers that the highest level of containment procedures and sterile techniques must be used in handling them.

* **bunyavirus** (bun'-yah-vy'-rus) From Bunyamwera, an area of Africa where this type of virus was first isolated.

* **arenavirus** (ah-ree'-nah-vy'-rus) L. *arena*, sand. In reference to the appearance of virus particles in electron micrographs.

Check Your Progress SECTION 25.1

1. Describe the structure and functions of the hemagglutinin and neuraminidase spikes in influenza virus.
2. What is unusual about the genome of influenza virus?
3. Explain how antigenic shift and drift differ and how they affect the immune status of populations.
4. Explain the course of infection and disease and the complications of influenza.
5. Explain generally how flu vaccines are prepared. For which groups is vaccination indicated?
6. Give examples of bunyaviruses and arenaviruses, and briefly describe the nature of the diseases they cause.
7. Describe the manner in which hantavirus is typically contracted.

25.2 Enveloped Nonsegmented Single-Stranded RNA Viruses

Expected Learning Outcomes

6. Recall the enveloped viruses possessing a nonsegmented RNA genome.
7. Describe the epidemiology, pathology, diagnosis, treatment, and prevention of mumps and measles.
8. Identify those most at risk of contracting respiratory syncytial virus.
9. Name the common reservoirs of rabies.

Paramyxoviruses

The important human paramyxoviruses are **Paramyxovirus** (parainfluenza and mumps viruses), **Morbillivirus** (measles virus), and **Pneumovirus** (respiratory syncytial virus), all of which are readily transmitted through respiratory droplets. The envelope of a paramyxovirus possesses specialized glycoprotein spikes that initiate attachment to host cells. They also bear fusion (F) spikes that initiate the cell-to-cell fusions typical of these viruses (**figure 25.4**). A series of multiple cell fusions produces a **syncytium***, or **multinucleate giant cell** with cytoplasmic inclusion bodies, a cytopathic effect that is useful in diagnosis.

Epidemiology and Pathology of Parainfluenza

One type of infection by **Paramyxovirus**, called **parainfluenza**, is as widespread as influenza but usually more benign. It is spread by droplets and respiratory secretions that are inhaled or inoculated into the mucous membranes by contaminated hands. Parainfluenzal respiratory disease is seen most frequently in children, most of whom have been infected by the age of 6. Newborns lacking passive antibodies are particularly susceptible, and they develop more severe symptoms. The usual effects of parainfluenza are minor upper respiratory symptoms (a cold), bronchitis, bronchopneumonia, and laryngotracheobronchitis (croup). **Croup*** manifests as labored

* **syncytium** (sin-sish'-yum) Gr. *syn*, together, and *kytos*, cell.

* **croup** (kroop) Scot. *kropan*, to cry aloud.

Figure 25.4 The effects of paramyxoviruses. When they infect a host cell, paramyxoviruses induce the cell membranes of adjacent cells to fuse into large multinucleate giant cells, or syncytia. This fusion allows direct passage of viruses from an infected cell to uninfected cells. Through this means, the virus evades antibodies.

and noisy breathing accompanied by a hoarse cough that is most common in infants and young children.

Diagnosis, Treatment, and Prevention of Parainfluenza

Presenting symptoms typical of a cold are often sufficient to presume respiratory infection of viral origin. Determining the actual viral agent, however, is difficult and usually unnecessary in older children and adults whose infection is usually self-limited and benign. Primary infection in infants can be severe enough to be life-threatening. So far no specific chemotherapy is available, but supportive treatment with immune serum globulin or ribavirin (Virazole), a nucleoside analog, can be of benefit.

Mumps: Epidemic Parotitis

Another infection caused by *Paramyxovirus* is **mumps** (Old English for lump or bump). So distinctive are the pathologic features of this disease that Hippocrates clearly characterized it several thousand years ago as a self-limited, mildly epidemic illness associated with painful swelling at the angle of the jaw (**figure 25.5**). Also called **epidemic parotitis**, this infection typically targets the parotid salivary glands, but it is not limited to this region. The mumps virus bears morphological and antigenic characteristics similar to the parainfluenza virus and has only a single serological type.

Epidemiology and Pathology of Mumps Humans are the exclusive natural hosts for the mumps virus. It is communicated

Figure 25.5 The external appearance of swollen parotid glands in mumps (parotitis). Usually both sides are affected, though parotitis affecting one side occasionally develops. Source: Patricia Smith; Barbara Rice/CDC

primarily through salivary and respiratory secretions. Infection occurs worldwide, with epidemic increases in the late winter and early spring in temperate climates. High rates of infection arise among crowded populations or communities with low levels of immunity. Most cases occur in children under the age of 15, and as many as 40% are subclinical. Because lasting immunity follows any form of mumps infection, no long-term carrier reservoir exists in the population. The incidence of mumps has been reduced in the United States to several hundred cases per year, although a 2009 outbreak was responsible for nearly 1,500 cases, and a similar outbreak in 2006 sickened over 6,500 people. These outbreaks as well as those of measles are associated with a lapse in vaccination of babies and young children.

After an average incubation period of 2 to 3 weeks, symptoms of fever, nasal discharge, muscle pain, and malaise develop. These may be followed by inflammation of the salivary glands (especially the parotids), producing the classic gopherlike swelling of the cheeks on one or both sides that can induce considerable discomfort (see figure 25.5). The virus can multiply in other organs, especially the testes, ovaries, thyroid gland, pancreas, meninges, heart, and kidney. Despite the invasion of multiple organs, the prognosis for most infections is complete, uncomplicated recovery, with permanent immunity.

Complications in Mumps In 20% to 30% of young adult males, mumps infection localizes in the epididymis and testis, usually on one side only. The resultant syndrome of orchitis and epididymitis may be rather painful, but no permanent damage usually occurs. The popular belief that mumps readily causes sterilization of adult males is still held, despite medical evidence to the contrary. Perhaps this notion has been reinforced by the tenderness that continues long after infection and by the partial atrophy of one testis that occurs in about half the cases. Permanent sterility due to mumps is very rare.

Diagnosis, Treatment, and Prevention of Mumps

Mumps can be tentatively diagnosed in a child with swollen parotid glands and a known exposure 2 or 3 weeks previously. Because swelling is not always present and the incubation period can range from 7 to 23 days, a practical diagnostic alternative is to test the serum by a direct fluorescent antibody or ELISA method.

The general pathology of mumps is mild enough that symptomatic treatment to relieve fever, dehydration, and pain is usually adequate. A live, attenuated mumps vaccine (part of the MMR vaccine) is given routinely at 12 to 15 months of age, followed by at least one booster. A separate single vaccine is available for adults who require protection. Although the antibody titer is lower than that produced by wild mumps virus, protection usually lasts at least a decade.

Measles: *Morbillivirus* Infection

Measles, an acute disease caused by *Morbillivirus*, is also known as **red measles*** and **rubeola**.* A somewhat similar disease—rubella or German measles—is caused by an unrelated togavirus (section 25.3). Some differentiating criteria for these two forms are summarized in **table 25.3**. Despite a tendency to think of red measles as a mild childhood illness, several recent outbreaks have reminded us that measles can kill babies and young children and that it is a frequent cause of death worldwide.

Epidemiology of Measles

Measles is one of the most contagious infectious diseases, transmitted principally by respiratory aerosols. There is no reservoir other than humans, and a person is infectious during the periods of incubation, prodromium, and the skin rash but not usually during convalescence. Epidemic spread is favored by crowding, low levels of herd immunity, malnutrition, and inadequate medical care. Several outbreaks of measles have been linked to the lack of immunization in children or the failure of a single dose of vaccine in many children. The importance of vaccinating children cannot be overemphasized, and the latest trends toward fear of vaccines are unfounded. Parents need to be reminded of the dangers of measles and its complications. In the United States, the incidence of measles is sporadic, usually less than 100 cases per year.

Infection, Disease, and Complications of Measles

The measles virus invades the mucosal lining of the respiratory tract during an incubation period of nearly 2 weeks. The initial

(a)

(b)

Figure 25.6 Signs and symptoms of measles. (a) Koplik's spots, named for the physician who described them in the 1800s, are tiny white lesions with a red border that form on the inside of the mouth adjacent to the molars. (b) Appearance of measles rash. Individual lesions are flat or slightly raised bumps (maculopapular) distributed over most of the body. (a and b): Source: CDC

symptoms are sore throat, dry cough, headache, conjunctivitis, lymphadenitis, and fever. In a short time, unusual oral lesions called **Koplik's spots** appear as a prelude to the characteristic red maculopapular **exanthem*** that erupts on the head and then progresses to the trunk and extremities, until most of the body is covered (**figure 25.6**). The rash gradually coalesces into red patches that fade to brown.

A small number of children develop laryngitis, bronchopneumonia, encephalitis, and bacterial secondary infections such as otitis media and sinusitis. Children afflicted with leukemia or thymic deficiency are especially predisposed to pneumonia because of their lack of the natural T-cell defense. Undernourished children may have severe diarrhea and abdominal discomfort, which add to their debilitation.

Pathogen Profile #2 *Morbillivirus (measles virus)*

Source: CDC

Microscopic Morphology Enveloped virus, 100 to 200 nm in diameter, containing a nonsegmented, single-stranded RNA genome.

Identified by Clinical presentation, especially the appearance of a maculopapular rash and Koplik's spots, which are indicative of measles. Serological testing that reveals measles-specific IgM antibodies early in the course of the disease or a rising IgG

titer when comparing acute and convalescent samples confirms a diagnosis of measles.

Habitat Humans are the only natural reservoir for *morbillivirus*.

Virulence Factors Syncytium formation.

Primary Infections/Disease Early symptoms of measles (rubeola) include sore throat, dry cough, headache, conjunctivitis,

lymphadenitis, and fever, followed by oral lesions called Koplik's spots and a maculopapular rash over most of the body. The most serious complication is subacute sclerosing panencephalitis (SSPE), a progressive neurological disease resulting in coma and death. Less serious complications include secondary bacterial infections such as pneumonia and otitis media.

Control and Treatment The MMR (measles, mumps, rubella) vaccine has greatly reduced the incidence of measles, with deaths in the United States being extremely rare. Worldwide, the disease still claims about 150,000 lives each year. Treatment of measles centers on reducing fever, suppressing cough, and replacing lost fluids. In some cases, secondary bacterial infections may be treated with antibiotics, and children may receive vitamin A supplements.

**CLINICAL CONNECTIONS****The Happiest Place on Earth?**

Measles was declared eliminated from the United States in 2000, which begs the question, “How did 111 people contract measles at Disneyland?” Like most things, the answer is more complex than it first appears.

On January 7, 2015, health officials warned the public of an outbreak of measles associated with Disneyland theme park. Of the nine people initially affected—seven from California and two from Utah—eight had not been vaccinated against the disease. Based on the incubation period for measles, the first infected person was determined to have visited the park between December 15 and December 20, 2014. The highly contagious measles virus spreads quickly among unvaccinated populations, and by January 17 the outbreak had been expanded to 42 people in three states. The following week, a student at nearby Huntington Beach High School was diagnosed and 23 students who had not been vaccinated were ordered to stay home for 21 days in an attempt to interrupt transmission of the virus. At about the same time, a bank employee in Ventura County (100 miles from Disneyland) was diagnosed with measles, eliciting concern that the employee may have infected others who visited the bank. And on it went, with epidemiologist knowing that each new case only made it more likely that another susceptible person would be infected. Finally, on April 17, with two incubation periods having passed with no new infections, the outbreak was declared over. A total of 111 cases had

been attributed to the outbreak and 80% of those affected were unvaccinated or did not know their vaccination status. Fortunately none of the people in this outbreak experienced complications of measles, which can range from hearing loss to death.

Although high population immunity led the United States to declare that measles had been “eliminated,” this only meant that year-round, endemic transmission of the disease no longer occurred. The few cases seen each year were “import associated” measles, brought to the United States by one of the 20 million people a year infected by the virus elsewhere in the world. In point of fact, the high rate of vaccination that led to the elimination of endemic measles in the United States may have been a victim of its own success. In recent years, with few cases of measles, no missed school, no sick children, and no reports of measles deaths, the impetus for vaccination weakened. Worse still, some people were swayed by erroneous reports of vaccine complications like autism, and not knowing whom to trust, chose to do nothing at all. After all, autism rates continued to rise while cases of measles were virtually unheard of, what could be the harm in not vaccinating? Dr. William Schaffner, a specialist in infectious diseases at Vanderbilt University's School of Medicine may have put it best: “They don't fear or respect the measles, so they don't value the vaccine.”

What aspects of Disneyland make it an ideal environment for an epidemic of a disease such as measles to begin?

Answer available on Connect.

The most serious complication is **subacute sclerosing panencephalitis (SSPE)**,* a progressive neurological degeneration of the cerebral cortex, white matter, and brain stem. Its incidence is approximately one case in a million measles infections, and it afflicts primarily male children and adolescents. The pathogenesis of SSPE appears to involve a defective virus, one that has lost its ability to form a capsid and be released from an infected cell. Instead, it spreads unchecked through the brain by cell fusion, gradually destroys neurons and accessory cells, and breaks down myelin. The disease is known for profound intellectual and neurological impairment. The course of the disease invariably leads to coma and death in a matter of months or years (see this chapter's Case Study).

Diagnosis, Treatment, and Prevention of Measles

The patient's age, a history of recent exposure to measles, and the season of the year are all useful epidemiological clues for diagnosis. Clinical characteristics such as dry cough, sore throat, conjunctivitis, lymphadenopathy, fever, and especially the appearance of Koplik's spots and a rash are presumptive of measles.

Treatment relies on reducing fever, suppressing cough, and replacing lost fluid. Complications require additional remedies to relieve neurological and respiratory symptoms and to sustain nutrient, electrolyte, and fluid levels. Therapy includes antibiotics for bacterial complications and doses of vitamin A for children.

Vaccination with attenuated viral vaccine administered by subcutaneous injection achieves immunity that persists for about 20 years. It must be stressed that because the virus is live, it can cause an atypical infection sometimes accompanied by a rash and fever. Measles immunization is recommended for all healthy children at the age of 12 to 15 months (MMR vaccine, with mumps and rubella), and a booster is given before a child enters school. A single antigen vaccine (Meruvax) is also available for older patients who require protection against measles alone. As a general rule, anyone who has had the measles is protected against reinfection.

Respiratory Syncytial Virus: RSV Infections

As its name indicates, **respiratory syncytial virus (RSV)**, also called *Pneumovirus*, infects the respiratory tract and produces giant multinucleate cells. Outbreaks of droplet-spread RSV disease occur regularly throughout the world, with peak incidence in the winter and early spring. Children 6 months of age or younger are especially susceptible to serious disease of the respiratory tract. Approximately 5 in 1,000 newborns are affected, making RSV the most prevalent cause of respiratory infection in this age group. An estimated 100,000 children are hospitalized with RSV infection each year in the United States. The mortality rate is highest for children who have complications such as prematurity, congenital disease, and immunodeficiency.

The epithelia of the nose and eye are the principal portals of entry, and the nasopharynx is the main site of RSV replication. The first symptoms of primary infection are fever that lasts for 3 days, rhinitis, pharyngitis, and otitis. Infections of the bronchial tree and lung parenchyma give rise to symptoms of croup that include acute bouts of coughing, wheezing, **dyspnea**,* and abnormal breathing sounds (rales). Adults and older children with RSV infection can experience cough and nasal congestion but are frequently asymptomatic.

Diagnosis, Treatment, and Prevention of RSV Diagnosis of RSV infection is more critical in babies than in older children or adults. The afflicted child is conspicuously ill, with signs typical of pneumonia and bronchitis. The preferred diagnostic technique is reverse transcriptase-polymerase chain reaction (RT-PCR), which detects viral RNA.

Some newer treatments include Synagis, a monoclonal antibody that blocks viral attachment to cells, and RSV immunoglobulin obtained from people with high RSV antibody titers. Both can greatly reduce complications and the need for hospitalization. An antiviral drug, ribavirin, can also be administered as an inhaled aerosol. Supportive measures include drugs to reduce fever, providing ventilation, and treatment for secondary bacterial infection if present. An effective vaccine has not yet been developed.

Rhabdoviruses

The most conspicuous **rhabdovirus*** is the **rabies*** virus, genus *Lyssavirus*.* The particles of this virus have a distinctive bullet-like appearance, round on one end and flat on the other. Additional features are a helical nucleocapsid and spikes that protrude through the envelope (**figure 25.7**). The family contains approximately

60 different viruses, but only the rabies lyssavirus, and emerging Bas-Congo virus, infect humans.

Epidemiology of Rabies

Rabies is a slow, progressive zoonotic disease characterized by a fatal meningoencephalitis. It is distributed nearly worldwide, except for 34 countries that have remained rabies-free by practicing rigorous animal control. The primary reservoirs of the virus are wild mammals such as canines, skunks, raccoons, cats, and bats. These can spread the infection to domestic cats and dogs. Cats are so important in spreading the virus that most states require vaccination of pet cats as well as dogs. Both wild and domestic mammals can spread the disease to humans through bites, scratches, and inhalation of droplets. The annual worldwide total for human rabies is estimated at about 55,000 cases, but only a tiny number of these cases occur in the United States. Most U.S. cases of rabies occur in wild animals (about 6,000 cases per year), while dog rabies has declined.

The epidemiology of animal rabies in the United States varies with geographic region and vector. The most common wild animal reservoir hosts have changed from foxes to skunks to raccoons. Regional differences in the dominant reservoir also occur. Bats and skunks are the predominant carriers of rabies in much of the country while raccoons dominate in the East. Foxes are a reservoir of the virus in parts of Alaska, Arizona, and Texas (figure 25.8). Review the Case Study in chapter 15 to refresh yourself on other aspects of rabies.

Infection and Disease

Infection with rabies virus typically begins when an infected animal's saliva enters a puncture site. Occasionally, the virus is inhaled or inoculated orally. The virus remains up to a week at the trauma site, where it multiplies. It then gradually enters nerve endings and advances toward the ganglia, spinal cord, and brain. Viral multiplication throughout the brain is eventually followed by

migration to such diverse sites as the eye, heart, skin, and oral cavity. The infection cycle is completed when the virus replicates in the salivary glands and is shed into the saliva. Clinical rabies proceeds through several distinct stages and ends in death except in rare cases.

Clinical Phases of Rabies

The average incubation period of rabies is 1 to 2 months or more, depending upon the wound site, its severity, and the inoculation dose. The incubation period is shorter in facial, scalp, or neck wounds because of greater proximity to the brain. The prodromal phase begins with fever, nausea, vomiting, headache, fatigue, and other nonspecific symptoms. Some patients continue to experience pain, burning, prickling, or tingling sensations at the wound site.

In the *furious* phase of rabies, the first acute signs of neurological involvement are agitation, disorientation, seizures, and twitching. Spasms in the neck and pharyngeal muscles lead to severe pain upon swallowing. As a result, attempts to swallow or even the sight of liquids brings on *hydrophobia* (fear of water). Throughout this phase, the patient is fully coherent and alert. When rabies enters the *dumb* phase, a patient is not hyperactive but paralyzed, disoriented, and stuporous. Ultimately, both forms, when untreated, progress to the coma phase, resulting in death from cardiac or respiratory arrest. In the past, humans were never known to survive a full-blown case of rabies, but recently 3 patients recovered after receiving intensive, long-term treatment.

Diagnosis and Management of Rabies

When symptoms appear after a rabid animal attack, the disease is readily diagnosed. But the diagnosis can be obscured when contact with an infected animal is not clearly defined or when symptoms are absent or delayed. Anxiety, agitation, and depression can pose as a psychoneurosis; muscle spasms resemble tetanus; and encephalitis with convulsions and paralysis mimics a number of other viral infections. Often the disease is diagnosed at autopsy. Criteria indicative of rabies are intracellular inclusions (Negri bodies) in nervous tissue, isolation of rabies virus from saliva or brain tissue, and demonstration of rabies virus antigens in specimens of the brain, serum, cerebrospinal fluid, or cornea using immunofluorescent methods.

Rabies Prevention and Control A bite from a wild or stray animal demands assessment of the animal, meticulous care of the wound, and a specific treatment regimen. A wild mammal, especially a skunk, raccoon, coyote, or bat that bites without provocation, is presumed to be rabid, and therapy is immediately commenced. If the animal is captured, brain samples and other tissue are examined for verification of rabies. Healthy domestic animals are observed closely for signs of disease and sometimes quarantined. Preventive therapy is initiated if any signs of rabies appear.

After an animal bite, the wound should be scrupulously washed with soap or detergent and water, followed by debridement and application of a povidine-iodine antiseptic, such as Betadine, which can decrease the risk of infection by 90%. Rabies is one of the few infectious diseases for which a combination of passive and active postexposure immunization is indicated and successful. Initially, the wound is infused with human rabies immune globulin (HRIG) to impede the spread of the virus, and globulin is also injected intramuscularly to

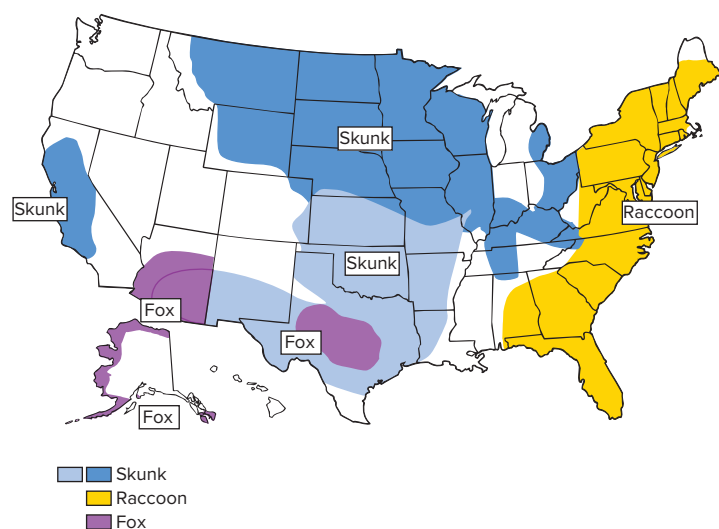

Figure 25.8 Distribution of rabies in the United States.

Rabies is found in 10 distinct geographic areas. In each area, a particular animal is the reservoir as illustrated by different shades of color. Not shown is the occurrence of insectivorous bats that cause sporadic cases of rabies in wild animals throughout the country.

provide immediate systemic protection. A full course of vaccination is started simultaneously. The current vaccine of choice is the **human diploid cell vaccine (HDCV)**. This potent inactivated vaccine is cultured in human embryonic fibroblasts. The routine in postexposure vaccination entails intramuscular or intradermal injection on the first, third, seventh, and fourteenth days. High-risk groups such as veterinarians, animal handlers, and laboratory personnel should receive three doses to protect against possible exposure.

Control measures such as vaccination of domestic animals, elimination of strays, and strict quarantine practices have helped reduce the virus reservoir. In recent years, the United States and other countries have utilized a live oral vaccine made with a vaccinia virus that carries the gene for the rabies virus surface antigen. The vaccine has been incorporated into bait (sometimes peanut butter sandwiches!) placed in the habitats of wild reservoir species such as skunks and raccoons.

25.3 Other Enveloped RNA Viruses: Coronaviruses, Togaviruses, and Flaviviruses

Expected Learning Outcomes

- Recall the diseases caused by coronaviruses.
- Understand the epidemiology, diagnosis, and prevention of rubella.
- Describe the pathology of rubella.
- Summarize the transmission and pathology of the hepatitis C virus.

Coronaviruses

Coronaviruses¹ are relatively large RNA viruses with distinctive, widely spaced spikes on their envelopes. These viruses are common

in domesticated animals and are responsible for epidemic respiratory, enteric, and neurological diseases in pigs, dogs, cats, and poultry. Thus far, five types of human coronaviruses have been characterized. One of these is an etiologic agent of the common cold. The same virus is also thought to cause some forms of viral pneumonia and myocarditis. Another human coronavirus is very closely associated with the intestine and may have a role in some human enteric infections.

Severe Acute Respiratory Syndrome–Associated Coronavirus

Historically, most coronaviruses were considered mildly pathogenic, and the infections tended to be relatively innocuous in healthy persons. In 2002, reports of an acute respiratory illness started to filter in from Asia. The disease was given the name **SARS** for **severe acute respiratory syndrome**. By early 2003 the World Health Organization (WHO) issued a global health alert about the new illness. In a short time, scientists had sequenced the entire genome of the causative agent, revealing it to be a new type of coronavirus.

The epidemic was contained by mid-year, but in less than a year, it had sickened more than 8,000 people. About 9% of those died. Most cases were concentrated in China and Southeast Asia. Several dozen countries, from Australia and Canada to the United States, reported cases, many of which originated in people who had traveled to Asia or had contact with travelers. Close contact (direct or droplet) is involved in its transmission. Eventually, no further cases were reported and the virus had evidently disappeared. The most recent research has linked its origin from fruit bats in Southeast Asia.

Symptoms begin with a fever of above 38°C (100.4°F) and progress to body aches and an overall feeling of malaise. Early in the infection, there seems to be little virus in the patient and a low probability of transmission. Within a week, viral numbers surge and transmissibility is very high. After 3 weeks, viral levels decrease significantly and symptoms subside. Patients may or may not experience classical respiratory symptoms, but severe cases of the illness can result in respiratory distress and death.

Diagnosis of the disease relies first on exclusion of other likely agents, using a Gram stain (for bacterial pneumonia) and identification of influenza and RSV viruses. Acute and convalescent sera should be collected to document a rise in antibodies against the coronavirus. Specimens can be sent to reference labs where PCR will be performed to confirm the diagnosis. There is no specific treatment other than supportive care.

In late 2012 a novel coronavirus caused 130 infections and 58 deaths in patients in the United Kingdom and Arabian peninsula. Christened Middle East respiratory syndrome coronavirus (MERS-CoV), it was, like the virus that causes SARS, similar to coronaviruses found in bats in certain parts of the world. Since 2012, 27 countries have reported a total of 1,806 infections, and the virus has been responsible for 643 deaths. The largest outbreak of the virus outside of the Arabian Peninsula was in the Republic of Korea in 2015, where 185 confirmed cases and 36 deaths were reported. Only two cases of the disease have been seen in the United States, both occurring in healthcare providers who lived and worked in Saudi Arabia. The World Health Organization currently recommends testing for MERS-CoV in patients with unexplained respiratory

1. Named for the resemblance of the viral spikes to a crown.

illness, especially for persons residing in or traveling from parts of the world known to be affected.

Rubivirus: The Agent of Rubella

Togaviruses are nonsegmented, single-stranded RNA viruses with a loose envelope.² There are several important members, including *Rubivirus*, the agent of rubella, and certain arboviruses.³ **Rubella**, or German measles, was first recognized as a distinct clinical entity in the mid-eighteenth century and was considered a benign childhood disease until its teratogenic effects were discovered. It was first observed that cataracts often developed in neonates born to mothers who had contracted rubella in the first trimester. Epidemiological investigations over the next generation confirmed the link between rubella and many other congenital defects as well.

Epidemiology of Rubella

Rubella is an endemic disease with worldwide distribution. Infection is initiated primarily through contact with respiratory secretions. The virus is shed during the prodromal phase and up to a week after the rash appears. Because the virus is only moderately communicable, close living conditions are required for its spread. Although epidemics and pandemics of rubella once regularly occurred in 6- to 9-year cycles, the introduction of vaccination has essentially stopped this pattern in the United States. Most cases are reported among adolescents and young adults in military training camps, colleges, and summer camps. The greatest concern is that nonimmune women of childbearing age might be caught up in this cycle, raising the prospect of congenital rubella.

Infection and Disease

Two forms of rubella can be distinguished: Postnatal infection develops in children or adults, and congenital (prenatal) infection of the fetus is expressed in the newborn as various types of birth defects.

Postnatal Rubella During an incubation period of 2 to 3 weeks, the virus multiplies in the respiratory epithelium, infiltrates local lymphoid tissue, and enters the bloodstream. Early symptoms include malaise, mild fever, sore throat, and lymphadenopathy. The rash of pink macules and papules first appears on the face and progresses down the trunk and toward the extremities, advancing and resolving in about 3 days (**figure 25.9**). Adult rubella is often accompanied by joint inflammation and pain rather than a rash. Except for an occasional complication, postnatal rubella is generally mild and produces lasting immunity.

Congenital Rubella Because the rubella virus is teratogenic, its transmission to a fetus can result in a serious complication called **congenital rubella**. The mother is able to transmit the virus even if she is asymptomatic. Fetal injury varies according to the time of infection. It is generally accepted that infection in the first trimester is most likely to induce miscarriage or multiple permanent defects

Figure 25.9 One sign of postnatal rubella is a maculopapular rash similar to measles, but less intensely red. *Source:* CDC

in the newborn such as cardiac abnormalities, ocular lesions, deafness, and mental and physical retardation. Less drastic sequelae that usually resolve in time are anemia, hepatitis, pneumonia, carditis, and bone infection.

Diagnosis and Prevention of Rubella

Rubella mimics other diseases and is often asymptomatic, so it should not be diagnosed on clinical grounds alone. The confirmatory methods of choice are serological testing and virus isolation systems. IgM tests can determine recent infection, and a rising titer is a clear indicator of continuing rubella infection. The latex-agglutination card, a simple, miniaturized test, provides a rapid method for IgM assay.

Postnatal rubella is generally benign and requires only symptomatic treatment. Because no specific therapy for rubella is available, most control efforts are directed at maintaining herd immunity with attenuated rubella virus vaccine. This vaccine is usually given to children in the combined form (the MMR vaccination) at 12 to 15 months and a booster at 4 or 6 years of age. One complication regarding this method of protection is that the rubella vaccine does not always provide lasting immunity. Because congenital rubella is such a serious concern, testing of adult women is often recommended to confirm prior infection and protective antibodies. The current recommendation for nonpregnant, antibody-negative women is immediate immunization. Because the vaccine contains live virus and a teratogenic effect is possible, sexually active women must utilize contraception for 4 weeks after the vaccine is administered. Antibody-negative pregnant women should not be vaccinated and must be monitored for rubella infection.

Hepatitis C Virus

Hepatitis C is a type of hepatitis caused by an RNA virus called a **flavivirus**. Hepatitis C is sometimes referred to as the “silent epidemic” because more than 3 million Americans are infected with the virus, but it takes many years to cause noticeable symptoms. In the United States, epidemiologists estimate that at least 30,000 new infections occur every year. Liver failure from hepatitis C is one of the most common reasons for liver transplants in the U.S. See table 24.3 for a complete comparison of the viral hepatitises.

2. Reminiscent of a toga.

3. A group of viruses transmitted by arthropods. See section 25.4.

Transmission and Epidemiology

This virus is acquired in ways similar to hepatitis B (HBV). It is most commonly transmitted through blood contact such as in blood transfusions or needle sharing by injecting drug users. It may occasionally be acquired through transfer of other body fluids or across the placenta. Unlike HBV, sexual contact is not a major mode of transmission for HCV. See the Case Study in chapter 11 to revisit a dramatic HCV outbreak.

Pathogenesis and Virulence Factors

Hepatitis C virus is so adept at establishing chronic infections that researchers are studying the ways that it evades immunologic detection and destruction. The virus's core protein seems to play a role in the suppression of cell-mediated immunity as well as in the production of various cytokines.

Before a test was available to test blood products for this virus, it seems to have been frequently transmitted through blood transfusions. Hemophiliacs who were treated with clotting factor prior to 1985 were infected at a high rate with HCV. Once blood began to be tested for HIV and screened for so-called “non-A non-B” hepatitis, the risk of contracting HCV from blood was greatly reduced. The current risk for transfusion-associated HCV is thought to be 1 in 2 million units transfused.

Because HCV was not recognized sooner, a relatively large percentage of the population is infected. Eighty percent of the 3.5 million carriers in the United States are suspected to be chronic carriers. It also has a very high prevalence in parts of South America and Central Africa and in China.

Signs and Symptoms

People have widely varying experiences with this infection. It shares characteristics of hepatitis B disease, but it is much more likely to become chronic. Without treatment, 75% to 85% will remain infected for life. (In contrast, only about 6% of persons who acquire hepatitis B after the age of 5 will be chronically infected.) While it is possible to have severe symptoms without permanent liver damage, it is more common to have chronic liver disease without overt symptoms. As the infection progresses, HCV disease may give rise to liver cancer. Infection is usually diagnosed with a blood test for antibodies to the virus.

Prevention, Treatment, and Cure

There is currently no vaccine for hepatitis C due to the extreme antigenic variation it shows. In 2014 the FDA approved a new combination of drugs that for the first time offers a cure for hepatitis C. Ledipasvir and sofosbuvir inhibit two proteins crucial to the replication of the hepatitis C RNA genome. Marketed as a single pill under the trade name Harvoni, a 12 week course of the drug results in a 93-99% cure rate, meaning that no hepatitis C virus is detectable in the blood three months after treatment is completed. For those patients for whom the drug doesn't work, or who cannot

afford the \$90,000 a 12-week course of therapy typically costs, other treatments are still available. A combination of pegylated interferon and ribavirin can reduce the viral load dramatically. Although not curative, damage to the liver can be prevented or reduced.

25.4 Arboviruses: Viruses Spread by Arthropod Vectors

Expected Learning Outcomes

14. Understand the relationship between arthropod vectors and the spread of arboviruses.
15. Describe the pathology of arboviral disease.
16. Recall the arboviruses and vectors responsible for encephalitides and hemorrhagic fevers.

Vertebrates are hosts to more than 400 viruses transmitted primarily by arthropods. To simplify presentation, these viruses are often lumped together in a loose grouping called the **arboviruses (arthropod-borne viruses)**. The major arboviruses pathogenic to humans belong to the togaviruses (*Alphavirus*), flaviviruses (*Flavivirus*), some bunyaviruses (*Bunyavirus* and *Phlebovirus*), and reoviruses (*Orbivirus*). The chief vectors are blood-sucking arthropods such as mosquitoes, ticks, flies, and gnats. Most types of illness caused by these viruses are mild, undifferentiated fevers, though some cause severe encephalitides (plural of *encephalitis*) and life-threatening hemorrhagic fevers. Although these viruses have been assigned taxonomic names, they are more often known by their common names, which are based on geographic location and primary clinical profile.

Epidemiology of Arbovirus Disease

Because arthropod vectors are found worldwide, so too are the arboviruses they carry. The vectors and viruses tend to be clustered in the tropics and subtropics, but many temperate zones report periodic epidemics (**figure 25.10**). A given arbovirus type may have very restricted distribution, even to a single isolated region; some range over several continents; and others can spread along with their vectors.

The Influence of the Vector

All aspects of the arbovirus life cycle are closely tied to the ecology of the vectors. Factors that weigh most heavily are the arthropod's

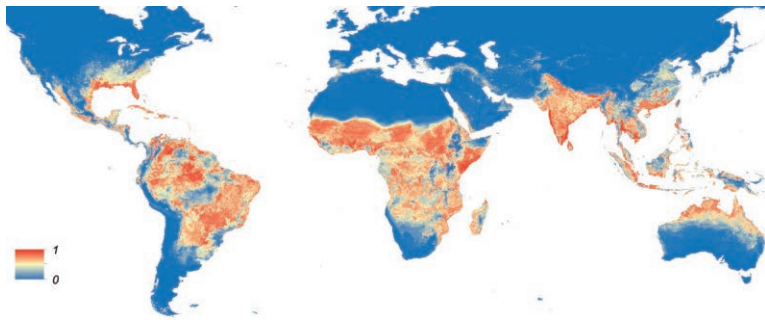

Figure 25.10 Worldwide distribution of *Aedes aegypti*. The geographic distribution of arthropod borne viruses mirrors that of the insect vectors that carry them. Distribution of the *Aedes aegypti* mosquito, which serves as a vector for chikungunya virus, dengue virus and Zika virus is indicated on the map. Blue areas correspond to regions free of the mosquito while red areas equate to a 100% chance of encountering the vector. In general the colder northern and southern regions are free of the vector. Source: National Center for Biotechnology Information.

life span, the availability of food and breeding sites, and climatic influences such as temperature and humidity. Most arthropod vectors become infected by feeding on the blood of hosts. Infections show a peak incidence from late spring through early fall, when the arthropod is actively feeding and reproducing. Warm-blooded vertebrates also maintain the virus during the cold and dry seasons. Humans can serve as dead-end, accidental hosts, as in equine encephalitis and Colorado tick fever, or they can be a maintenance reservoir, as in dengue fever and yellow fever. Risk of arboviral infection is greatest in wilderness areas where encounters with arthropod vectors are frequent. Clearing remote forest habitats for human colonization greatly increases this form of contact.

Arboviral diseases have a great impact on humans. Although exact statistics are unavailable, there is a consensus that millions of people acquire infections each year and thousands of them die. The uncertain nature of vector and viral cycles frequently results in sudden, unexpected epidemics, sometimes with previously unreported viruses. Travelers and military personnel entering endemic areas are at special risk because, unlike the natives of that region, they have no immunity to the viruses.

General Characteristics of Arbovirus Infections

Our coverage of the arboviruses will be focused on these main areas:

1. the manifestations of disease in humans;
2. aspects of the most important North American viruses; and
3. methods of diagnosis, treatment, and control.

Febrile Illness and Encephalitis

One type of disease elicited by arboviruses is an acute, undifferentiated fever, often accompanied by rash. These infections, typified by dengue fever and Colorado tick fever, are usually mild and leave no long-term effects. Prominent symptoms are fever, prostration, headache, myalgia, orbital pain, muscle aches, and joint stiffness. About midway through the illness, a maculopapular or petechial rash can erupt over the trunk and limbs.

When the brain, meninges, and spinal cord are invaded, symptoms of viral encephalitis occur. The viruses cycle between wild animals (primarily birds) and mosquitoes or ticks, but humans are not usually reservoir hosts. The disease begins with a bite, which releases the virus into the tissues and nearby lymphatics. Prolonged viremia establishes the virus in the nervous system, where inflammation can cause swelling and damage to the brain, nerves, and meninges. Symptoms are extremely variable and can include coma, convulsions, paralysis, tremor, loss of coordination, memory deficits, changes in speech and personality, and heart disorders. In a small number of cases, there will be some degree of permanent brain damage. Young children and the elderly are most sensitive to injury by arboviruses.

West Nile virus is the most prevalent cause of arboviral disease in the United States. Mosquitoes generally become infected when they feed on birds infected with the virus. Infected mosquitoes can then bite and transmit the virus to humans. Because 80% of people infected show no symptoms, the 2,060 cases reported to the CDC in 2015 most likely represented only a small fraction of the actual number of cases. For the 1 in 5 people who do suffer symptoms, fever, headache, body aches, joint pains, vomiting, diarrhea, or rash can be expected. Recovery from this less severe type of West Nile virus disease is typically complete, but fatigue and weakness can last for weeks or months. Fewer than 1% of people who are infected will develop neurological illness such as encephalitis or meningitis, and people over 60 or with certain underlying medical conditions (cancer, diabetes, hypertension, kidney disease or organ transplant recipients) are at greatest risk for serious illness. Approximately 10% of the people who develop neurologic infection with West Nile virus will die.

Colorado tick fever (*CTF*) is the most common tick-borne viral fever in the United States. Restricted in its distribution to the Rocky Mountain states, it occurs sporadically during the spring and summer, corresponding to the time of greatest tick activity and human contacts. Two hundred to three hundred endemic cases are reported each year, and deaths are rare.

Eastern equine encephalitis (*EEE*) is endemic to an area along the eastern coast of North America and Canada. The usual pattern is sporadic cases, but occasional epidemics can occur in humans and horses. High periods of rainfall in the late summer increase the chance of an outbreak, and disease usually appears first in horses and caged birds. The case fatality rate is among the highest (35%) for all encephalitides.

LaCrosse encephalitis virus (*LACV*) is responsible for roughly 100 cases of viral encephalitis a year, primarily in the Midwest and across the Appalachian mountains. Severe disease—which is rare, most people show no symptoms of infection—occurs most often in children under 16 years of age.

St. Louis encephalitis (*SLE*) appears sporadically, primarily in the Eastern and Central states. Silent infection is very common, and the total number of cases is probably thousands of times greater than the 5 to 10 reported each year. The seasons of peak activity are spring and summer, depending on the region and species of mosquito.

Chikungunya virus has garnered more attention in the United States since infections were seen on Caribbean islands in 2013, the first time it had been detected in the Americas. In contrast to many arboviral diseases, the majority of people infected with chikungunya

CLINICAL CONNECTIONS

Three Viruses, One Vector

Recently, increasing attention has been paid to three formerly obscure viral diseases that have become more prevalent, especially in the Americas. Dengue fever virus is actually a collection of four similar viruses that cause over 100 million cases of disease each year. The milder form of the disease is marked by high fever, severe headache, muscle, bone and joint pain, and mild bleeding from the nose or gums. Severe cases, termed dengue hemorrhagic fever, includes most of the above symptoms plus a period of excessive capillary permeability, in which the fluid component of the blood leaks from the blood vessels, potentially leading to failure of the circulatory system, shock and death. The symptomatology of chikungunya is similar to mild dengue, with headache, muscle and joint pain, lasting a week or so, although the joint pain may persist for months.

Zika virus, which had been seen previously in Africa, Southeast Asia, and some Pacific Islands, achieved notoriety when an outbreak in Brazil was thought to be linked to cases of Guillain-Barré syndrome and an increase in birth defects, especially microcephaly. After a months-long examination of affected infants, the CDC confirmed that the virus can cause abnormal brain development. They issued an alert advising pregnant women to postpone travel to any region where Zika virus was currently being transmitted. A more general alert advised everyone traveling to these regions to take extra precautions—to wear long-sleeved shirts and long pants, use mosquito repellent, and stay indoors as much as possible—to prevent mosquito bites. The virus was also found to be present in the semen of infected men and several cases were identified in which women were infected with the virus after having unprotected sex with an infected man. In response, the CDC issued guidelines meant to reduce sexual transmission of the virus, especially when the woman is pregnant. Although some cases result in the serious complications mentioned above, usually an infection with Zika virus causes only a mild illness similar to dengue fever or chikungunya.

virus become symptomatic, suffering fever, headache, muscle and joint pain, nausea and vomiting, and occasionally rash, clinical features very similar to dengue fever. Most symptoms abate in 7 to 10 days and mortality is rare.

Infection with **Zika virus** produces symptoms very similar to infection with chikungunya or dengue viruses, and the three viruses are carried by the same biological vector (see Clinical Connections). Zika concerns were amplified when a 2015 outbreak in Brazil led to reports of viral infection being linked to the autoimmune disease Guillain-Barré syndrome, as well as birth defects (most notably microcephaly) in the children of women who were infected while pregnant. In 2016 the CDC recommended that pregnant women not travel to areas where Zika virus transmission was ongoing, a geographic distinction that included some parts of Florida. The Zika virus was also found to be transmissible through sexual intercourse, and abstinence or the use of a condom is recommended if the partner of a pregnant woman has recently

Aedes mosquitoes serve as biological vectors for chikungunya, dengue, and Zika viruses. In this photo of an *Aedes aegypti* mosquito, both the fascicle that the mosquito uses to feed, and the insect's abdomen are filled with blood from a recent meal and appear red.

Source: James Gathany/CDC

The common denominator of all three viruses is the *Aedes* mosquito, an aggressive, daytime feeder that is found throughout the Americas and is particularly adept at surviving in a hostile environment. Its eggs can remain viable for several months without water, meaning that even if all active mosquitoes in an area were killed, the population could completely recover in as little as 2 weeks after the addition of water to dried eggs (rainfall, for example). According to the World Health Organization, it may only be a matter of time before these viruses, like West Nile virus a decade before, become endemic to the United States.

Unlike the *Anopheles* mosquito that spreads malaria, the *Aedes* mosquito is most active during the day. What protective strategy used against the *Anopheles* mosquito is ineffective against *Aedes* mosquitoes? Answer available on Connect.

traveled to at-risk areas. Clinical trials of a Zika vaccine are currently underway.

Hemorrhagic Fevers

Certain arboviruses, principally the yellow fever and dengue fever viruses, cause capillary fragility and disrupt the blood clotting system. These effects lead to localized bleeding, fever, and shock, which explains the common name for the disease. Hemorrhagic fevers are caused by a variety of viruses, are carried by a variety of vectors, and are distributed globally. Reservoir animals are usually small mammals, although yellow fever and dengue fever can be harbored in the human population.

Until Zika virus took center stage in 2015, the best-known arboviral disease has historically been **yellow fever**. Although this disease was at one time widespread in its distribution, mosquito control measures have eliminated it in many countries, including

the United States. Two patterns of transmission occur in nature. One is an urban cycle between humans and the mosquito *Aedes aegypti*, which reproduces in standing water in cities. The other is a sylvan cycle, maintained between forest monkeys and mosquitoes. Most cases in the Western Hemisphere occur in the jungles of Brazil, Peru, and Colombia during the rainy season. Infection begins acutely with fever, headache, and muscle pain. In some patients the disease progresses to oral hemorrhage, nosebleed, vomiting, jaundice, and liver and kidney damage, with significant mortality rates.

Dengue* fever is caused by a flavivirus and is also carried by the *Aedes* mosquitoes. Although mild infection is the usual pattern, a form called dengue hemorrhagic shock syndrome can be lethal. This disease is also called “breakbone fever” because of the severe pain it induces in the muscles and joints. The illness is endemic to Southeast Asia and India, and several epidemics have occurred in South and Central America, the Caribbean, and Mexico. It is a serious risk factor for about 40% of the world’s population. The WHO has estimated that more than 100 million cases occur every year, with about 500,000 hemorrhagic fever cases. It is thought that climate change, including heavy rains and warmer weather that favor the mosquito life cycle, is a contributing factor in several major epidemics across Asia.

Concern over the possible spread of the disease in the United States led the CDC to add dengue fever to the notifiable diseases list and to survey mosquito populations in states along the southern border. Several states, primarily in the southeastern United States, harbor the *Aedes* mosquitoes that serve as vectors for dengue virus. Contact with infected human carriers could establish the virus in these mosquito populations. About 200 locally acquired cases per year are diagnosed in the United States, mostly in Puerto Rico, Texas, Hawaii, and Florida.

Diagnosis, Treatment, and Control of Arbovirus Infections

Except during epidemics, detecting arboviral infections can be difficult. The patient’s history of travel or contact with vectors, along with serum analysis, is highly supportive of a diagnosis. In most cases specific diagnosis of arbovirus infection is based on detection of arboviral RNA in the blood or serological detection of antibodies against specific viral proteins. Treatment of the various arbovirus diseases relies completely on support measures to control fever, convulsions, dehydration, shock, and edema.

The most reliable arbovirus vaccine is a live, attenuated yellow fever vaccine that provides relatively long-lasting immunity. Vaccination is a requirement for travelers in the tropics and can be administered to entire populations during epidemics. A dengue fever vaccine was approved for use in Mexico, the Philippines and Brazil in late 2015. The live virus vaccine reduced the chance of developing dengue by 60% but is only approved for use in people between 9 and 45 years of age who live in dengue endemic areas.

* *dengue* (den'-gha) A corruption of Sp. “dandy” fever. Other synonyms are dengue shock syndrome and stiffneck fever.

Check Your Progress SECTION 25.4

- Name several activities that increase the risk of acquiring an arbovirus infection.
- Summarize the signs and symptoms of encephalitis and hemorrhagic fever.
- Specify the arboviruses responsible for encephalitides and hemorrhagic fevers and their proper vectors.
- How is the cycle of the viruses maintained in the wild?
- Describe the symptoms of the encephalitis type of infection (EEE, SLE) and the hemorrhagic fevers (yellow fever).
- Discuss the factors in the worldwide spread of arboviral diseases.

25.5 Retroviruses and Human Diseases

Expected Learning Outcomes

- Describe the main characteristics of retroviruses that make them unique.
- Identify the causative agent of acquired immunodeficiency syndrome.
- Describe the structural features of the human immunodeficiency virus and the host cell membrane that are required for infection to occur.
- Discuss the routes of HIV transmission.
- Understand the progression of HIV infection.
- Describe how testing for HIV infection is accomplished.
- Recall how AIDS is defined.
- Understand why an HIV vaccine has not been developed.
- Describe the mode of action of each class of retroviral agent used to treat infection with HIV.
- Understand the purpose of using combination therapy to treat HIV infection.
- Describe the diseases associated with HTLV-I.

HIV Infection and AIDS

The sudden emergence of AIDS in the early 1980s focused an enormous amount of public attention, research studies, and financial resources on the virus and its disease.

The first cases of AIDS were seen by physicians in Los Angeles, San Francisco, and New York City. They observed clusters of young male patients with one or more of a complex of symptoms: severe pneumonia caused by *Pneumocystis jirovecii* (ordinarily a harmless fungus), a rare vascular cancer called Kaposi sarcoma, sudden weight loss, swollen lymph nodes; and general loss of immune function. Eventually, virologists at the Pasteur Institute in France isolated a novel retrovirus, later named the **human immunodeficiency virus (HIV)**. The cluster of symptoms resulting from the degradation of the immune system by HIV was termed **acquired immunodeficiency syndrome**, or **AIDS**, by the medical community.

Characteristics of Human Retroviruses

HIV is a **retrovirus**, in the genus *Lentivirus*. Most retroviruses have the potential to cause cancer, produce dire, often fatal diseases, and

alter the host's DNA in profound ways. They are named “retroviruses” because they reverse the usual order of transcription. They contain an enzyme called **reverse transcriptase (RT)** that catalyzes the replication of double-stranded DNA from single-stranded RNA. The association of retroviruses with their hosts can be so intimate that viral genes are permanently integrated into the host genome. Not only can this retroviral DNA be incorporated into the host genome as a provirus that can be passed on to progeny cells, but some retroviruses also transform cells and regulate certain host genes.

The most prominent human retroviruses are HIV and the T-cell lymphotropic viruses I and II (HTLV-I and HTLV-II). The two types of HIV are HIV-1, which is the dominant form in most of the world, and HIV-2, found mainly in parts of Africa. HTLV type I is associated with leukemia and lymphoma (discussed in a later section).

HIV and other retroviruses display structural features typical of enveloped RNA viruses (**figure 25.11**). The outermost component is a lipid envelope with transmembrane glycoprotein spikes and knobs that mediate viral adsorption and fusion to the host cell. HIV can only infect host cells that present the required receptors, which is a combination receptor consisting of the CD4 marker plus a co-receptor. The virus uses these receptors to gain entrance to several types of leukocytes and tissue cells (**figure 25.11b**).

Epidemiology of HIV Infection

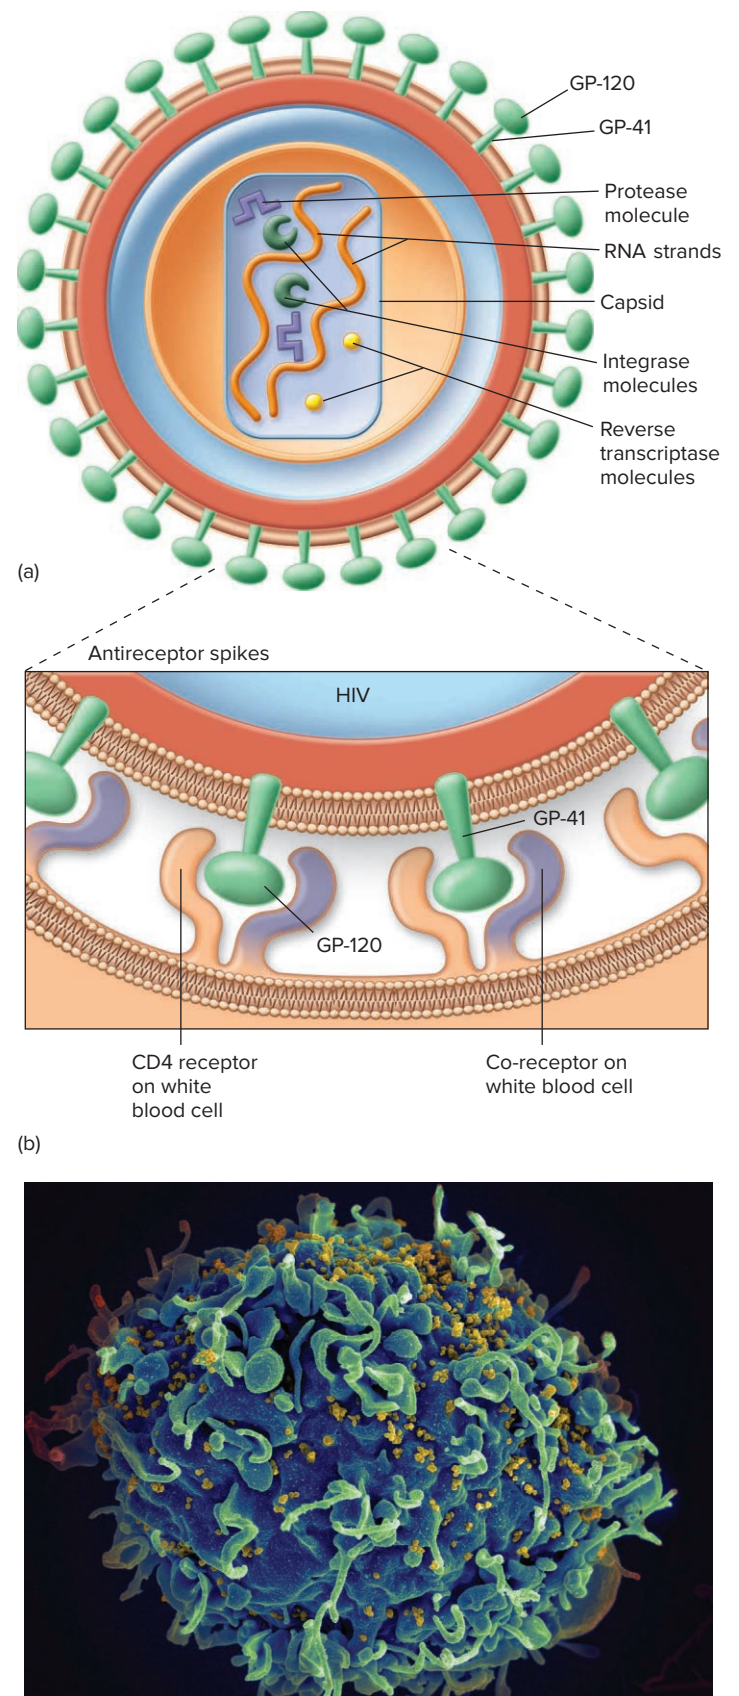

One important question about HIV—*Where did it come from?*—seems to have been answered. Researchers have been comparing the genetics of HIV with various African monkey viruses called simian immunodeficiency viruses, or SIVs. The genetic sequences in these viruses led researchers to conclude that HIV is a hybrid virus that has evolved from two separate monkey SIVs. One of the SIVs has as its natural host the greater spot-nosed monkey, and the other infects red-capped mangabeys. Apparently, when these two monkey viruses infected chimpanzees, a third type of virus emerged that contained genetic sequences from both SIVs. This new type of SIV was probably transmitted to humans, possibly when they used the chimps for food. The crossover into humans probably occurred in the early part of the 1900s; the earliest record we have of human infection is a blood sample preserved from an African man who died in 1959.

HIV probably remained in small isolated villages, causing sporadic cases and mutating into more virulent strains that were readily transmitted from human to human. When this pattern was combined with changing social and sexual practices and increased immigration and travel, a pathway was opened up for rapid spread of the virus pandemically.

Modes of Transmission

HIV transmission occurs mainly through two forms of contact: sexual intercourse and transfer of blood or blood products. Babies

Figure 25.11 The general structure of HIV. (a) The envelope contains two types of glycoprotein (GP) spikes; the capsid contains two identical RNA strands and several molecules of reverse transcriptase, protease, and integrase. (b) The snug attachment of HIV glycoprotein molecules (GP-41 and GP-120) to their specific receptors on a human cell membrane. These receptors are CD4 and a co-receptor, which control docking with the host cell and fusion with its cell membrane. (c) Electron micrograph of HIV (yellow) infecting a T cell (blue). Figure 25.12 Primary sources and suggested routes of infection by HIV.

can also be infected before or during birth, as well as through breast feeding. The mode of transmission is similar to that of hepatitis B virus, except that the HIV does not survive for as long outside the host and is far more sensitive to heat and disinfectants. And HIV is not transmitted through saliva, as hepatitis B can be.

In general, HIV is spread only by direct and rather specific routes (figure 25.12). Because the blood of HIV-infected people harbors high levels of free virus in early and late stages of infection and high levels of infected leukocytes throughout infection, any form of intimate contact involving transfer of blood (trauma, needle sharing) can be a potential source of infection. Semen and vaginal secretions also harbor free virus and infected white blood cells, which accounts for another source in sexual transmission. The virus can be isolated from urine, tears, sweat, and saliva but in such small numbers (less than 1 virion per cubic millimeter) that these fluids are not considered sources of infection.

AIDS Morbidity

AIDS first became a notifiable disease at the national level in 1984, and it has continued in an epidemic pattern, although the number of people developing the disease in the United States has decreased since 1994. This situation is due to the advent of effective therapies that prevent the progression of HIV infection to full-blown AIDS. But in developing countries, which are hardest hit by the HIV epidemic, access to these lifesaving drugs has been limited. And even in the United States, despite treatment advances, HIV infection and AIDS are the eighth most common cause of death among people ages 25 to 34, although they have fallen out of the top 10 list for overall causes of death. Unfortunately, new HIV infections are remaining at a steady rate of 35,000 to 50,000 per year.

Figure 25.13 contrasts the number of new infections in the United States, broken down by state of residence, sex, and behavior.

(a) **Diagnosis of HIV Infection Among Adults and Adolescents, by Transmission Category, 2014**

(b) **Rates of HIV Infection Among Adults and Adolescents, 2014**

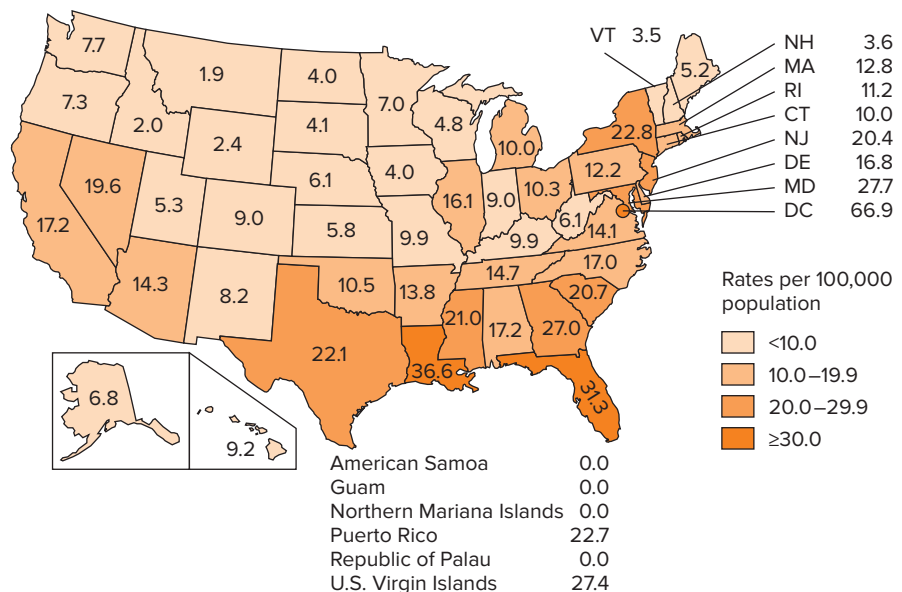

Figure 25.13 Patterns of HIV infections. (a) Percentage of new infections by mode of transmission. (b) Incidence of new infections by state. Source of Data: Centers For Disease Control

Men account for 81% of new infections. Sixty-seven percent of all new infections are acquired through male homosexual activity. Men having sex with other men (a group labeled MSM) have increased susceptibility because of the practice of anal sex, which is known to lacerate the rectal mucosa and can provide an entrance for viruses from semen into the blood. The receptive partner (whether male or female) is the more likely of the two to become infected. In addition, bisexual men are a significant factor in spreading the virus to women.

Especially in large metropolitan areas, many intravenous drug users (IDUs) are also HIV carriers. Infection from contaminated needles continues to grow rapidly, and it is another significant factor in the spread of HIV to the heterosexual population.

HIV infection and AIDS have been reported in every country. Parts of Africa and Asia have the highest case rates. In 2014 the WHO estimated that 37 million people were living with HIV or AIDS worldwide. Even with improved treatments, the disease continues to have devastating repercussions. Reports from the CDC estimate approximately 1.2 million people in the United States living with HIV/AIDS. A number of these people may be in the latent phase of the disease and not yet aware of their infection.

In most parts of the world heterosexual intercourse is the primary mode of transmission. In the industrialized world, the overall rate of heterosexual infection has increased dramatically in the past several years, especially in adolescent and young adult women. In the United States, about 25% of HIV infections arise from unprotected sexual intercourse with an infected partner of the opposite sex.

Now that donated blood is routinely tested for antibodies to HIV, transfusions are no longer considered a serious risk. Because there can be a lag period of a few weeks to several months before antibodies appear in an infected person, it is remotely possible to be infected through donated blood. Rarely, organ transplants can carry HIV, so they too are tested. Other blood products (serum, coagulation factors) were once implicated in HIV infection. Thousands of hemophiliacs died from AIDS in the 1980s and 1990s. It is now standard practice to heat-treat any therapeutic blood products to destroy all viruses.

A small percentage of HIV infections (around 1%) occur in people without apparent risk factors. This does not mean that some other unknown route of spread exists. Factors such as patient denial, unavailability of history, death, or uncooperativeness make it impossible to explain every case. We should note that not everyone is susceptible to HIV infection, and not everyone who becomes infected or is antibody-positive develops AIDS. In the case of natural resistance, HIV researchers have discovered people with a mutated coreceptor (primarily CCR5) that is used by the virus to fuse with its host cell. About 1% of the population has inherited a pair of these mutated genes, which when expressed, give rise to abnormal receptors that keep HIV from entering cells. This confers a greatly reduced susceptibility to HIV infection. Researchers are focusing on this knowledge as a basis for developing new types of anti-HIV drugs. About 5% of people who are antibody-positive remain free of disease, indicating that some people can develop immunity or are less susceptible to infection.

Treatment of HIV-infected mothers with combination antiretroviral therapy (cART) has dramatically decreased the rate of maternal to infant transmission during pregnancy. Current estimates indicate that fewer than 200 HIV-infected infants are born each year in the United States. The cost of perinatal prevention strategies

(\$1,000 per pregnancy) and the scarcity of medical counseling in underserved areas have led to an increase in maternal transmission of HIV in developing countries, at the same time that the developed world has seen a marked decrease.

Medical and dental personnel are not considered a high-risk group. A relatively small number of medical and dental workers have acquired HIV or become antibody-positive as a result of clinical accidents. A health care worker involved in an accident in which gross inoculation with contaminated blood occurs (as in the case of a needlestick) has a less than 1 in 1,000 chance of becoming infected. Experts emphasize that transmission of HIV will not occur through casual contact or routine patient care procedures and that universal precautions for infection control (see chapter 13) provide protection for both worker and patient.

Some Harsh Statistics

A powerful way to drive home the staggering effect of HIV and AIDS is to examine some of its statistics in everyday terms (data generated by WHO and CDC up to 2016):

- Globally, 37 million people are infected with HIV or have AIDS; 2.6 million are children.
- In 2015, 1.1 million people died of AIDS.
- Each day, almost 5,800 people are newly infected.

Parts of Africa are harder hit than other regions. Consider the following:

- 70% of cases worldwide occur in sub-Saharan Africa.
- One in 20 adults is infected with HIV.
- Fourteen million African children are orphaned by AIDS.

The United States has its own disturbing set of statistics:

- Over 1.2 million people are currently infected with HIV.
- Nearly 45,000 new HIV infections are reported each year.
- African Americans represent 12% of the U.S. population but account for 44% of new HIV infections.
- Almost 7,000 people diagnosed with AIDS die each year.
- HIV infection is the eighth leading cause of death in people 25 to 34 years old, and the fifth leading cause of death for African American men ages 35 to 54.

Pathogenesis and Virulence Factors of HIV

As summarized in figure 25.12, HIV enters a mucous membrane or the skin and is phagocytosed by a dendritic cell. In the dendritic cell, the virus grows and is shed from the cell without killing it. New viruses are taken up and amplified by macrophages in the skin, lymph organs, bone marrow, and blood. One of the great ironies of HIV is that it infects and destroys many of the very cells needed to combat it, especially the helper (CD4 or T4) class of lymphocytes. It also infects monocytes, dendritic cells, and macrophages.

Once the virus is inside a target cell, its reverse transcriptase converts its RNA into DNA. Although initially many viruses produce a lytic infection, in some cells the DNA becomes inactive in the nucleus of the host cell and its DNA becomes integrated into host DNA (**figure 25.14**). This event accounts for the lengthy course of the disease. Because different host cells are in different stages of infection, some host cells are releasing new viruses and being lysed, and new T cells are constantly being infected.

(a) The virus is adsorbed and fuses with the cell. The twin RNAs are uncoated. Reverse transcriptase catalyzes the synthesis of a single complementary strand of DNA (ssDNA). This single strand serves as a template for synthesis of a double strand (ds) of DNA. In latency, dsDNA is inserted into the host chromosome as a provirus.

(b) After a latent period, various immune activators stimulate the infected cell, causing reactivation of the provirus genes and production of viral mRNA.

(c) HIV mRNA is translated by the cell's synthetic machinery into virus components (capsid, reverse transcriptase, spikes), and the viruses are assembled. Budding of mature viruses lyses the infected cell.

Figure 25.14 The general multiplication cycle of HIV.

The primary effects due directly to HIV infection are extreme leukopenia, with lowered levels of lymphocytes in particular. Both T cells and monocytes undergo extensive die-offs through programmed cell suicide (apoptosis). The CD4 memory clones and stem cells are among the prime targets. HIV also causes formation of giant syncytial T cells, which allow the spread of viruses directly from cell to cell, followed by mass destruction of the syncytia. The central nervous system is affected when infected macrophages cross the blood-brain barrier and spread HIV into brain cells. It appears that some of the viral envelope proteins have a direct toxic effect on the brain's glial cells and other cells. Research has shown that some peripheral nerves become demyelinated and the brain becomes inflamed.

The secondary effects of HIV infection are the opportunistic infections and malignancies associated with destruction of essential CD4 functions needed to control pathogens. These are summarized in **25.2 Making Connections**.

Stages, Signs, and Symptoms of HIV Infection and AIDS

The clinical spectrum of HIV infection ranges from acute early symptoms to the end stage symptoms of AIDS. To understand the progression, closely follow **figures 25.15** and **25.16**. Pathology in HIV infection is directly tied to two factors: (1) the level of viruses, and (2) the level of T cells in the blood. Figure 25.16 presents relative amounts of viruses and T cells over the course of the infection and disease. Note that the figure is showing the pattern of HIV infection in the absence of medical intervention or chemotherapy.

The initial infection is acute and often attended by vague, mononucleosis-like symptoms that soon disappear. This phase is marked by high levels of free virus in the blood (figure 25.16, phase I), followed by a rapid drop (figure 25.16, phase II). Observe that the antibody levels rise (figure 25.16, phases II and III) at the same

Figure 25.15 Time line in HIV infection, asymptomatic HIV disease, and AIDS.

time that the virus load is dropping. The antibodies are responsible for neutralizing the free viruses in circulation during this stage. One feature of the ongoing HIV infection is a period of mostly asymptomatic disease (sometimes called latency) that varies in length from 2 to 15 years, with the average being about 10 years (figure 25.15, phase III). Another important occurrence during the mid-to-late asymptomatic periods is how the number of T cells in the blood steadily decreases (figure 25.16, phase III). This is critical to the progression of the disease as T helper cells are responsible for regulating B-cell antibody production and macrophage stimulation. As the number of T helper cells declines, so too does the efficiency of the macrophage response and the ability to produce antibodies. Once the CD4 cell levels fall below 200 cells/mm³ (μl) of blood, symptoms of AIDS appear (figure 25.16, phase IV).

Initial symptoms of AIDS may be fatigue, diarrhea, weight loss, and neurological changes, but most patients first notice this phase of infection because of one or more opportunistic infections or neoplasms. These **AIDS-defining illnesses** are detailed in 25.2 Making Connections. Other disease-related symptoms appear to accompany severe immune deregulation, hormone imbalances, and metabolic disturbances. Pronounced wasting of body mass is a consequence of

Figure 25.16 Changes in the quantity of virus antigen, antibody, and T cells in circulation over time.

weight loss, diarrhea, and poor nutrient absorption. Protracted fever, fatigue, sore throat, and night sweats are significant and debilitating. Both a rash and generalized lymphadenopathy in multiple lymph nodes are presenting symptoms in many AIDS patients.

Some of the most virulent complications are neurological. Lesions occur in the brain, meninges, spinal column, and peripheral nerves. Patients with nervous system involvement show some degree of withdrawal, persistent memory loss, spasticity, sensory loss, and progressive AIDS dementia.

Diagnosis of HIV Infection

A person is diagnosed as having HIV infection if he or she has tested positive on a series of tests for the human immunodeficiency virus. This diagnosis is not the same as having AIDS.

Most viral testing is based on detection of antibodies specific to the virus in serum or other fluids, which allows for the rapid, inexpensive screening of large numbers of samples. Testing usually proceeds at two levels. The initial screening tests include the older ELISA and newer latex agglutination and rapid antibody tests. The advantage of these tests is that results are available within minutes instead of the days to weeks previously required for the return of results from ELISA testing. Several kits have been approved by the Food and Drug Administration for home use. Most kits require the user to submit a small sample of blood or saliva, which is then sent to

25.2 MAKING CONNECTIONS

AIDS-Defining Illnesses (ADIs)

In HIV patients who do not receive or do not comply with antiretroviral therapy (and even in some who do), the slow destruction of the immune system results in a wide variety of infectious and noninfectious conditions, called AIDS-associated illnesses or AIDS-defining illnesses (ADIs). It is almost always one or more of these conditions that causes death in AIDS patients.

Because the virus eventually destroys an essential immune function, it is not surprising that the body is beset by normally harmless microorganisms, many of which have been living in or on the host for decades without causing disease. The spectrum of AIDS-associated illnesses also provides insight into how vital the immune system is in controlling or mitigating cancerous changes in our cells. AIDS patients are at increased risk for Burkitt lymphoma, Kaposi sarcoma (KS), and invasive cervical carcinomas, all of which are associated with viral infections.

Kaposi sarcoma lesions on the back. The flat red tumors occur in almost any tissue and frequently develop in clusters.

Source: National Cancer Institute

Since the beginning of the AIDS epidemic in the early 1980s, the CDC has maintained a list of conditions that are part of the case definition. The list has been modified periodically over almost 30 years of its existence. One of the ways that people currently meet the case definition for AIDS is if they are positive for the virus *and* experience one or more of these ADIs. The ADIs are listed in **table 25.B**. The diseases are listed according to the organ system where the presenting symptoms might be found. (Some of the conditions may be listed in more than one column.) You can see that many of them—or at least the way they occur in AIDS patients—are very rare in the otherwise healthy population.

What accounts for the enormous variety in AIDS-defining illnesses? *Answer available on Connect.*

TABLE 25.B AIDS-Defining Illnesses

Skin and/or Mucous Membranes (Includes Eyes)	Nervous System	Cardiovascular and Lymphatic System or Multiple Organ Systems	Respiratory Tract	Gastrointestinal Tract	Genitourinary and/or Reproductive Tract
Cytomegalovirus retinitis (with loss of vision)	Cryptococcosis, extrapulmonary	Coccidioidomycosis	Candidiasis	Candidiasis of esophagus, GI tract	Invasive cervical carcinoma
Herpes simplex chronic ulcers (>1 month duration)	HIV encephalopathy	Cytomegalovirus (other than liver, spleen, nodes)	Herpes simplex bronchitis	Herpes simplex chronic ulcers (>1 month duration) or esophagitis	Herpes simplex chronic ulcers (>1 month duration)
Kaposi sarcoma	Lymphoma, primarily in brain	Histoplasmosis, disseminated or extrapulmonary	<i>Mycobacterium avium</i> complex (MAC)	Isosporiasis, (diarrhea caused by <i>Cystoisospora</i>)	
	Progressive multifocal leukoencephalopathy	Burkitt lymphoma	Tuberculosis (<i>M. tuberculosis</i>)	chronic intestinal (>1 month duration)	
	Toxoplasmosis of the brain	Immunoblastic lymphoma	<i>Pneumocystis jirovecii</i> pneumonia	Cryptosporidiosis, chronic intestinal (>1 month duration)	
		<i>Mycobacterium kansasii</i> , disseminated	Pneumonia, recurrent in 12-month period		
		<i>Mycobacterium tuberculosis</i> , disseminated			
		<i>Salmonella</i> septicemia, recurrent wasting syndrome			

a testing laboratory to be analyzed. The client can call an automated phone service, enter his or her anonymous testing code, and receive results over the phone. Over-the-counter tests that detect HIV antibodies in oral fluids and saliva can be performed and read in the privacy of home, similar to a pregnancy test (see Clinical Connections, “The Changing Scene of Clinical Microbiology,” in section 17.1) Improvements in technology have increased their reliability, but positive results must still be confirmed with a more specific test.

Although the approved tests just described are largely accurate, around 1% of results are false positives, and they always require

follow-up with a more specific test called *Western blot* analysis (see figure 17.12). This test detects several different anti-HIV antibodies and can usually rule out false positive results.

Another inaccuracy can be false negative results that occur when testing is performed before the onset of detectable antibodies, a period called a window. To rule out this possibility, persons who test negative but are at some risk for exposure should be tested a second time 3 to 6 months later.

Blood and blood products are sometimes tested for HIV antigens (rather than for HIV antibodies) to determine whether a test is

possibly a false negative. For many AIDS patients, it is necessary to check viral loads in order to monitor the effectiveness of drugs.

In the United States, people are diagnosed with AIDS if they meet the following criteria: (1) they are positive for the virus, *and* (2) they fulfill one of these additional criteria:

- They have a CD4 (helper T-cell) count of fewer than 200 cells per microliter of blood.
- Their CD4 cells account for fewer than 14% of all lymphocytes.
- They experience one or more of a CDC-provided list of AIDS-defining illnesses (ADIs), as surveyed in 25.2 Making Connections.

Preventing HIV Infection

Avoidance of sexual contact with infected persons is a cornerstone of HIV prevention. Abstaining from sex is an obvious prevention method, although those who are sexually active can also take steps to decrease their risk. Epidemiologists cannot overemphasize the need to screen prospective sex partners and to follow a monogamous sexual lifestyle. The only sure way to avoid infection is for all sexually active people to consider every partner to be infected unless proven otherwise. Barrier protection (condoms) should be used when having sex with anyone whose HIV status is not known with certainty to be negative. Although avoiding intravenous drugs is an obvious deterrent, many drug addicts do not or will not choose this option. In such cases, risk can be decreased by not sharing syringes or needles or by cleaning needles with bleach and then rinsing before another use.

In 2012 the FDA for the first time approved a drug specifically for pre-exposure prophylaxis (PrEP). Marketed under the trade name Truvada and consisting of tenofovir and emtricitabine, the single daily pill has been shown to reduce the risk of HIV infection in people who are at high risk by up to 92%, provided it is taken every day.

From the very first years of the AIDS epidemic, the potential for creating a vaccine has been regarded as slim, because the virus presents many seemingly insurmountable barriers. Among them, HIV becomes latent in cells, and its cell surface antigens mutate rapidly. Although it does elicit immune responses, it is apparently not completely controlled by them. In view of the great need for a vaccine, however, none of those facts has stopped the medical community from moving ahead.

Currently, dozens of potential HIV vaccines are in clinical trials overseen by an international agency—the HIV Vaccine Trials Network. None of the trials has yet produced an effective vaccine, and even those that showed some promise have been fraught with problems. Even with the large-scale efforts, HIV specialists do not expect a viable vaccine to be approved and available for several more years.

Treating HIV Infection and AIDS

It must be forcefully stated: There is no established cure for HIV infection or AIDS. None of the therapies does more than slow the progress of the disease or diminish symptoms.

Clear-cut guidelines exist for treating people who test HIV-positive. These guidelines are updated regularly, and they differ depending on whether a person is completely asymptomatic or experiencing some of the manifestations of HIV infection, and also whether they have previously been treated with antiretroviral

agents. A person diagnosed with AIDS receives treatment for HIV infection as well as drugs to prevent or treat a variety of opportunistic infections and other ADIs such as wasting disease. These treatment regimens vary according to each patient's profile and needs.

Treatment strategies against HIV aim to disrupt some part of its multiplication cycle (see tables 12.6 and 12.7). The first effective anti-HIV drugs were described as nucleoside reverse transcriptase inhibitors (NRTIs) and consisted of synthetic nucleoside analogs that inhibit the reverse transcriptions process, including azidothymidine (AZT), didanosine (ddI), lamivudine (EpiVir, 3TC), and stavudine (d4T). They interrupt the HIV multiplication cycle by mimicking the structure of actual nucleosides being added to viral DNA by reverse transcriptase. Because these drugs lack all of the correct binding sites for further DNA synthesis, viral replication and the viral cycle are terminated (**figure 25.17a**). Non-nucleoside reverse transcriptase inhibitors (NNRTIs) include etravirine and

- (a) **Reverse transcriptase blockers.** A prominent group of drugs (AZT, ddI, 3TC) act as nucleoside analogs to inhibit reverse transcriptase. They are inserted in place of the natural nucleotide by reverse transcriptase but block further action of the enzyme and synthesis of viral DNA.

- (b) **Protease inhibitors that cause abnormal viruses to be released.** Protease inhibitors plug into the active sites on HIV protease. This enzyme is necessary to cut long HIV protein strands and produce smaller protein units. During budding viruses incorporate this uncut nonfunctioning protein. The resultant viruses are unable to mount an infection.

Microscopic Morphology Enveloped virus with an RNA genome. The envelope contains 72 glycoprotein spikes that mediate adsorption to the host cell.

Identified by Two-stage serological testing. The initial screening is completed using a sensitive ELISA or similar rapid antibody test that detects the presence of anti-HIV antibodies, while also producing some false positive results. All positive results are then rescreened using a very specific Western blot test, which relies on several different anti-HIV antibodies and rules out any false positives.

Habitat Human immunodeficiency virus resides within the blood, breast milk, semen, and vaginal secretions of HIV-infected persons.

Virulence Factors Spikes that mediate attachment to host cells, reverse transcriptase, rapid mutation, formation of syncytia.

Primary Infections/Disease HIV is the causative agent of acquired

immunodeficiency syndrome (AIDS). Initial infection with HIV is marked by vague, mononucleosis-like symptoms that quickly dissipate. This is followed by an asymptomatic phase that may last from 2 to 15 years and coincides with a gradual depletion of CD4 T cells in the blood. When these cells fall below 200 cells per mm³ of blood, the opportunistic diseases characteristic of AIDS begin to appear. These AIDS-defining illnesses (ADIs) not only signify the progression of HIV to full-blown AIDS but are also the cause of death for most AIDS patients.

Control and Treatment Control relies on preventing exposure to the HIV virus, which, for most people, involves safe sexual practices, from abstinence, to monogamy, to barrier protection. Utilizing pre-exposure prophylactic therapy can greatly reduce the risk of infection. Those who choose to inject illegal drugs must use clean needles as contaminated needles are commonly implicated in infection. No vaccine exists for HIV. Treatment of HIV relies on highly active antiretroviral therapy (HAART), in which a combination of reverse transcriptase inhibitors, protease inhibitors, fusion inhibitors, and integrase inhibitors are used to interrupt the virus in different stages of its replication cycle. It is important to note that HIV infection is incurable, and treatment serves only to slow or prevent the progression of HIV infection to AIDS.

rilpivarin, bind to the reverse transcriptase enzyme and restructure it so that it cannot properly function. Another important class of drugs, the protease inhibitors (**figure 25.17b**), block the action of the HIV enzyme (protease) involved in the final assembly and maturation of the virus. Examples of these drugs include ritonavir and darunavir.

Integrase nuclear strand transfer inhibitors (INSTIs) inhibit the viral enzyme integrase, which is responsible for the integration of the viral DNA into the DNA of the infected host cell. First line drugs in this class include elvitegravir and dolutegravir. Finally, fusion inhibitors (enfuvirtide) and entry inhibitors (maraviroc) block the entry of HIV into potential host cells, typically by interacting with receptors like CCR5 on the host cell. Because fusion and entry inhibitors have severe side effects, including hepatotoxicity, they are generally used only when other drug regimens have failed to keep a patient's viral load at low levels.

The most effective strategy in the battle against HIV has been the development of **highly active antiretroviral therapy (HAART)**. In this treatment regimen, multiple drugs are used simultaneously to interrupt the HIV multiplication cycle at several different points, so that even if a virus managed to evade one drug

due to a fortuitous mutation, viral progression would be halted by a second or third drug. Several forms of HAART exist, and generally rely on at least three drugs from two different categories. For example, an integrase plus two NRTIs or a protease inhibitor plus two NRTIs. This therapy has been shown to reduce viral load to undetectable levels and facilitate the improvement of immune function. It has also reduced the incidence of viral drug resistance, because the virus would have to undergo at least two separate mutations simultaneously to develop resistance. Patients who are HIV-positive but asymptomatic can avoid AIDS with this therapy as well. The primary drawbacks to anti-HIV drugs are high cost, toxic side effects, drug failure due to patient noncompliance, and an inability to completely eradicate the virus (see **Clinical Connections, “Curing’ HIV”**). An example of this type of therapy is Genvoya, which contains elvitegravir (an integrase inhibitor) along with emtricitabine and tenofovir alafenamide (both NRTIs). Cobicistat, which has no anti-HIV activity of its own, is used to enhance the effects of elvitegravir while reducing adverse side effects. Adhering to Genvoya's one-pill-once-daily treatment regimen is far easier than some older forms of HAART, which required patients to take up to 30 pills a day.

CLINICAL CONNECTIONS

“Curing” HIV

There is no cure for HIV infection. True, but one case calls for a short explanation.

The so-called “Berlin Patient” was infected with HIV and also suffered from acute myelogenous leukemia (AML), a cancer of bone marrow cells responsible for the production of certain white blood cells. Treatment of AML often involves treating the patient with a large dose of radiation that kills all of the bone marrow cells, both healthy and diseased, followed by a bone marrow transplant. In this case doctors in Berlin used bone marrow from a donor who possessed a rare mutation that made his cells highly resistant to HIV infection. More than 3 years after the transplant, and without benefit of antiretroviral drug treatment, the patient has HIV levels below the limit of detection. Unfortunately the utility of bone marrow transplants to cure HIV infection is limited, as the risk of the transplant is greater than the risk of a lifetime reliance on antiretroviral drugs.

Treatment for serious illnesses often includes a risk of severe side effects. What side effects could (possibly) be expected if the treatment discussed here were attempted on another patient?

Answer available on Connect.

Human T-Cell Lymphotropic Viruses

Leukemia is the general name for at least four different malignant diseases of the white blood cell forming elements originating in the bone marrow. Leukemias are all acquired, rather than being inherited; some forms are acute and others are chronic. Leukemias have many causes, some of which are thought to be viral. The **human T-cell lymphotropic virus I (HTLV-I)** is associated with a form of leukemia called *adult T-cell leukemia*.

All leukemias first manifest with conditions such as easy bruising or bleeding, paleness, fatigue, and recurring minor infections. Underlying pathologies that account for these effects are anemia, platelet deficiency, and immune dysfunction brought about by the disturbed lymphocyte ratio and function. Some cases of adult T-cell leukemia first present with cutaneous T-cell lymphoma accompanied by dermatitis, with thickened, scaly, ulcerative, or tumorous skin lesions. Other complications are lymphadenopathy and dissemination of the tumors to the lung, spleen, and liver.

The possible mechanisms by which this retrovirus induces cancer are not entirely clear. One hypothesis is that the virus carries an oncogene that, when spliced into a host’s chromosome and triggered by various carcinogens, can immortalize the cell and deregulate the cell division cycle. One of HTLV-I’s genetic targets seems to be the gene and receptor for interleukin-2, a potent stimulator of T cells.

Adult T-cell leukemia was first described by physicians working with a cluster of patients in southern Japan. Later, a similar clinical disease was described in Caribbean immigrants. In time, it was shown that these two diseases were the same. Although more common in Japan, Europe, and the Caribbean, a small number of cases occurs in the United States. The disease is not highly transmissible;

studies among families show that repeated close or intimate contact is required. Because the virus is thought to be transferred in infected blood cells, blood transfusions and blood products are potential agents of transmission. Intravenous drug users could spread it through needle sharing. The retrovirus HTLV-II is a close relative of HTLV-I but is not as clearly associated with a distinct disease.

Check Your Progress SECTION 25.5

30. What are retroviruses, and how are they different from other viruses?
31. Give examples of some human retroviruses and the diseases they cause.
32. Explain the function of reverse transcriptase.
33. Explain the importance of GP-41, GP-120, and CD4 to HIV infection.
34. Briefly explain the behaviors most likely to spread HIV.
35. Differentiate between HIV infection, HIV disease, and AIDS.
36. What are the primary target cells and pathologic effects of HIV over time?
37. Give a comprehensive definition of AIDS.
38. Describe the changes over time in virus antigen levels, antibody levels, and CD4 T cells in the blood of an HIV-infected individual.
39. List the major opportunistic bacterial, fungal, protozoan, viral, and other secondary diseases that are AIDS-defining conditions.
40. Explain how HIV affects the immune system and creates vulnerability to certain pathogens and other conditions.
41. Explain why two separate tests are generally used to diagnose HIV infection.
42. Compare the actions of NRTIs, NNRTIs, protease inhibitors, fusion inhibitors, and integrase inhibitors.
43. What is the rationale behind the use of HAART treatment?
44. Explain strategies for vaccine development; include in your answer the primary drawbacks to development of an effective vaccine.
45. Identify the virus responsible for adult T-cell leukemia.

25.6 Nonenveloped Single-Stranded and Double-Stranded RNA Viruses

Expected Learning Outcomes

28. Identify the characteristics of poliovirus that enhance its transmission.
29. Describe the range of pathologies seen in poliovirus infection.
30. Recall how polio is diagnosed, treated, and prevented.
31. Understand the epidemiology, diagnosis, and prevention of infectious hepatitis.
32. Understand why rhinovirus infections are typically limited to the upper respiratory tract.
33. Describe the epidemiology and pathology of rhinovirus and calicivirus infections.
34. Describe the unique characteristic of reoviruses and recall the diseases they cause.

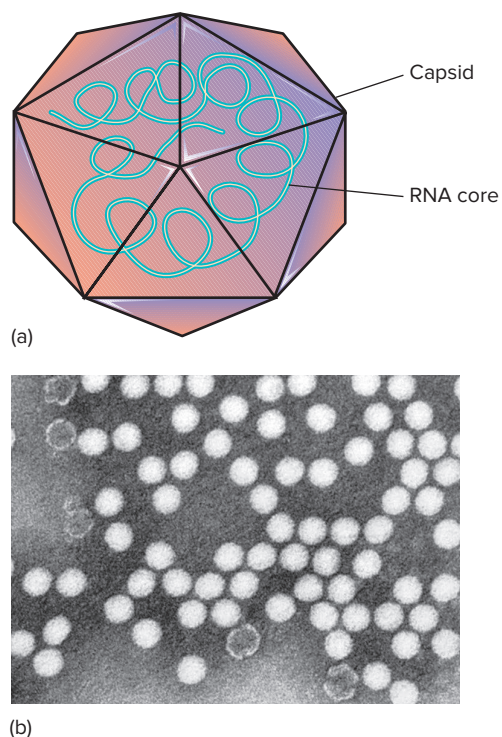

Figure 25.18 Typical structure of a picornavirus. (a) A poliovirus, a type of picornavirus that is one of the simplest and smallest viruses (30 nm). It consists of an icosahedral capsid shell around a tightly packed molecule of RNA. (b) A crystalline mass of stacked poliovirus particles in an infected host cell (300,000 \times). Picornaviruses and Caliciviruses

As suggested by the prefix, picornaviruses are named for their small (pico) size and their RNA core (**figure 25.18**). Important representatives include *Enterovirus* and *Rhinovirus*, which are responsible for a broad spectrum of human neurological, enteric, and other illnesses (**table 25.4**); and *Cardiovirus*, which infects the brain and heart in humans and other mammals. The following discussion on human picornaviruses centers upon the poliovirus and other related enteroviruses, the hepatitis A virus, and the human rhinoviruses (HRVs).

TABLE 25.4 Selected Representatives of the Human Picornaviruses		
Genus	Representative	Primary Diseases
<i>Enterovirus</i>	Poliovirus	Poliomyelitis
	Coxsackievirus A	Focal necrosis, myositis
	Coxsackievirus B	Myocarditis of newborn
	Echovirus	Aseptic meningitis, enteritis, others
	Enterovirus 72	Hepatitis A
<i>Rhinovirus</i>	Rhinovirus	Common cold
<i>Cardiovirus</i>	Cardiovirus	Encephalomyocarditis
<i>Aphthovirus</i>	Aphthovirus	Foot-and-mouth disease (in cloven-foot animals)

Poliovirus and Poliomyelitis

Poliomyelitis* (polio) is an acute enteroviral infection of the spinal cord that can cause neuromuscular paralysis. Because it often affects small children, it is also called infantile paralysis. No civilization or culture has escaped the devastation of polio.

The poliovirus has a naked capsid (**figure 25.18a**) that confers chemical stability and resistance to acid, bile, and detergents. By this means, the virus survives the gastric environment and other harsh conditions, which contributes to its ease in transmission.

Epidemiology of Polio

Sporadic cases of polio can break out at any time of the year, but its incidence is more pronounced during the summer and fall. The virus is passed within the population through food, water, hands, objects contaminated with feces, and mechanical vectors. Due to worldwide vaccination programs, the number of cases was reduced from 350,000 in 1988 to 74 by 2015. There have been no cases of wild polio in the Americas since 1991.

After being ingested, polioviruses adsorb to receptors of mucosal cells in the oropharynx and intestine (**figure 25.19**). Here, they multiply in the mucosal epithelia and lymphoid tissue. Multiplication results in large numbers of viruses being shed into the throat and feces, and some of them leak into the blood.

* *poliomyelitis* (poh'-lee-oh-my'-eh-ly'-tis) Gr. *polios*, gray, *myelos*, medulla, and *itis*, inflammation.

Figure 25.19 The stages of infection and pathogenesis of poliomyelitis. (a) First, the virus is ingested and carried to the throat and intestinal mucosa. (b) The virus then multiplies in the tonsils. Small numbers of viruses escape to the regional lymph nodes and blood. (c) The viruses are further amplified and cross into certain nerve cells of the spinal column and central nervous system. (d) Last, the intestine actively sheds viruses.

Pathogen Profile #4 Poliovirus

Source: Dr. Joseph J. Esposito; F. A. Murphy/CDC

Microscopic Morphology Small (30 nm), nonenveloped virus with a nonsegmented RNA genome.

Identified by Growing of virus in tissue culture, serological detection of antipoliovirus antibodies.

Habitat Humans are the reservoir; infection is transmitted through food, water, and close contact with infected people and their excretions. Afghanistan and Pakistan are the only countries in the world where polio remains endemic.

Virulence Factors Naked capsid that provides resistance to acid, bile, and detergents, increasing ease of transmission.

Primary Infections/Disease Most people infected with polio show no symptoms, whereas about 5% will have minor symptoms

including fever, fatigue, nausea, headache, stiffness in the neck and back, and pain in the limbs, which often resolves completely. Less than 1% of polio cases result in permanent paralysis of the limbs (usually the legs). Of those paralyzed, 5% to 10% die when the paralysis affects the respiratory muscles. Poliovirus multiplies in the gastrointestinal tract (which sheds viruses), and exerts its pathology within cells of the central nervous system, while signs and symptoms appear in the muscles.

Control and Treatment Two different polio vaccines exist, with the live, attenuated “Sabin” vaccine recommended in most of the world and the inactivated “Salk” vaccine recommended in the United States and parts of Europe. Treatment of the disease is limited to relieving pain and providing artificial ventilation if respiratory failure occurs.

Most infections are expressed in a short-term, mild viremia. Some persons develop mild nonspecific symptoms of fever, headache, nausea, sore throat, and myalgia. If the viremia persists, viruses can be carried to the central nervous system through its blood supply. The virus then spreads along specific pathways in the spinal cord and brain. Being **neurotropic**,* the virus infiltrates the motor neurons of the anterior horn of the spinal cord, though it can also attack spinal ganglia, cranial nerves, and motor nuclei. Nonparalytic disease involves the invasion but not the destruction of nervous tissue. It gives rise to muscle pain and spasm, meningeal inflammation, and vague hypersensitivity. The progression of infection and disease is shown in **figure 25.20**.

Paralytic Disease

Invasion of motor neurons causes various degrees of flaccid paralysis over a period of a few hours to several days. Depending on the

level of damage to motor neurons, paralysis of the muscles of the legs, abdomen, back, intercostals, diaphragm, pectoral girdle, and bladder can result. In rare cases of **bulbar poliomyelitis**, the brain stem, medulla, or even cranial nerves are affected. This situation leads to loss of control of cardiorespiratory centers, requiring mechanical respirators (**figure 25.21a**). In time, the unused muscles begin to atrophy, growth is slowed, and severe deformities of the trunk and limbs develop. Common sites of deformities are the spine, shoulder, hips, knees, and feet (**figure 25.21b**). Because motor function, but not sensation, is compromised, the crippled limbs are often very painful.

In recent times, a condition called post-polio syndrome (PPS) has been diagnosed in long-term survivors of childhood infection. PPS manifests as a progressive muscle deterioration that develops in about 25% to 40% of patients several decades after their original polio attack.

Diagnosis, Treatment, and Prevention of Polio

Polio is mainly suspected when epidemics of neuromuscular disease occur in the summer in temperate climates. Poliovirus can usually be isolated by inoculating cell cultures with stool or throat washings in the early part of the disease. The stage of the patient's infection can also be demonstrated by testing serum samples for the type and amount of antibody.

Treatment of polio rests largely on alleviating pain and suffering. During the acute phase, muscle spasm, headache, and associated discomfort can be alleviated by pain-relieving drugs. Respiratory failure may require artificial ventilation maintenance. Prompt physical therapy to diminish crippling deformities and to retrain muscles is recommended after the acute febrile phase subsides.

* *neurotropic* (nu^u-roh-troh'-pik) Having an affinity for the nervous system.

Figure 25.20 Diagrammatic representation of possible outcomes of poliovirus infection.

(a)

(b)

Figure 25.21 Images of polio. (a) An external respirator, or iron lung, was used to provide adequate ventilation for polio patients suffering from paralysis of the respiratory muscles. With the exception of the head, the entire body was enclosed in the vessel and modulation of the air pressure within the iron lung forced air in and out of the patient's lungs. Most patients spent a week to 10 days in the respirator, but in cases of permanent paralysis, a lifetime of confinement was required. (b) Deformed limbs are a common outcome of paralytic polio. (a and b): Source: CDC

The mainstay of prevention is vaccination as early in life as possible, usually in four doses starting at about 2 months of age. Adult candidates for immunization are travelers and members of the armed forces. The two forms of vaccine currently in use are

inactivated poliovirus vaccine (IPV), known as the Salk⁴ vaccine, and oral poliovirus vaccine (OPV), known as the Sabin⁵ vaccine. Both are prepared from animal cell cultures and are trivalent (combinations of the three serotypes of the poliovirus). Both vaccines are effective, but one may be favored over the other under certain circumstances.

For many years, the Sabin vaccine was used in the United States because it is easily administered by mouth, but it is not free of medical complications. It contains an attenuated virus that can multiply in vaccinated people and be spread to others. In very rare instances—1 out of 2.4 million doses—the attenuated virus reverts to a neurovirulent strain that causes disease rather than protects against it. Numerous instances of paralytic polio have occurred among children with hypogammaglobulinemia who have been mistakenly vaccinated. There is a tiny risk (about 1 case in 4 million) that an unvaccinated family member will acquire infection and disease from a vaccinated child. For these reasons, public health officials have revised their recommendations and now favor IPV for all immunizations in the United States.

The efforts of a WHO campaign, called National Vaccination Days, have significantly reduced the global incidence of polio. The last cases of polio infection are confined to a few pockets in Pakistan and Afghanistan. Unfortunately, the success of this campaign has been plagued by outbreaks in countries that barred the use of the oral polio vaccine because of political upheavals and concerns about its safety.

Nonpolio Enteroviruses

A few viruses related to poliovirus commonly cause short-term, usually mild infections. The most common of these are **coxsackieviruses*** A and B, **echoviruses**,* and nonpolio enteroviruses. They are similar to the poliovirus in many of their epidemiological and infectious characteristics. The incidence of infection is highest from late spring to early summer in temperate climates and is most frequent in infants and persons living under unhygienic circumstances.

Specific Types of Enterovirus Infection

Enteroviral infections are either subclinical or fall into the category of “undifferentiated febrile illness,” characterized by fever, myalgia, and malaise. Symptoms are usually mild and last only a few days. The initial phase of infection is intestinal, after which viruses enter the lymph and blood and disseminate to other organs. The outcome of this infection largely depends on the organ affected. An overview of the more severe complications follows.

4. Named for Dr. Jonas Salk, who developed the vaccine in 1954.

5. Named for Dr. Albert Sabin, who had the idea to develop an oral attenuated vaccine in the 1960s.

* **coxsackieviruses** (kok-sak'-ee-vy'-rus) Named for Coxsackie, New York, where the viruses were first isolated.

* **echoviruses** (ek'-oh-vy'-rus) An acronym for enteric cytopathic human orphan virus.

Quick Search

To read about a collision between polio and politics, search the Internet for “CIA Polio Ruse to Capture Osama Bin Laden.”

Figure 25.22 Acute viral hemorrhagic conjunctivitis. In the early phase of disease, the eye is severely inflamed, with the sclera and inner eyelids becoming bright red from subconjunctival hemorrhages. Later, edema of the lids can cause complete closure of the eye. © Kathy Park Talaro

Important Complications

Children are more prone than adults to lower respiratory tract illness, namely bronchitis, bronchiolitis, croup, and pneumonia. All ages, however, are susceptible to the “common cold syndrome” of enteroviruses. **Pleurodynia*** is an acute disease characterized by recurrent sharp, sudden intercostal or abdominal pain accompanied by fever and sore throat. Although nonpolio enteroviruses are less virulent than the polioviruses, rare cases of coxsackievirus and echovirus paralysis, aseptic meningitis, and encephalitis occur. Even in severe childhood cases involving seizures, ataxia, coma, and other central nervous system symptoms, recovery is usually complete.

Eruptive skin rashes (exanthems) that resemble the rubella rash are other manifestations of enterovirus infection. Coxsackievirus can cause a peculiar pattern of lesions on the hands, feet, and oral mucosa (hand-foot-mouth disease), along with fever, headache, and muscle pain. Acute hemorrhagic conjunctivitis is an abrupt inflammation associated with subconjunctival bleeding, serous discharge, painful swelling, and sensitivity to light (**figure 25.22**). Spread of the virus to the heart in infants can cause extensive damage to the myocardium, leading to heart failure and death in nearly half of the cases. Heart involvement in older children and adults is generally less serious, with symptoms of chest pain, altered heart rhythms, and pericardial inflammation.

Hepatitis A Virus and Infectious Hepatitis

One enterovirus that tends to affect the digestive tract alone is the **hepatitis A virus (HAV; enterovirus 72)**, the cause of infectious, or short-term, hepatitis. Although this virus is not related to the hepatitis B or C viruses, it shares their tropism for liver cells. Otherwise, the two viruses are different in almost every respect (see table 24.3). The hepatitis A virus is a cubical picornavirus relatively

resistant to heat and acid but sensitive to formalin, chlorine, and ultraviolet radiation. There appears to be only one major serotype of this virus.

Epidemiology of Hepatitis A

Hepatitis A virus is spread through the oral-fecal route, but the details of transmission vary from one area to another. In general, the disease is associated with deficient personal hygiene and lack of public health measures. In countries with inadequate sewage control, most outbreaks are associated with fecally contaminated water and food. The United States has a yearly reported incidence of 2,000 to 5,000 cases. Most of these result from close institutional contact, unhygienic food handling, eating shellfish, sexual transmission, or travel to other countries. Occasionally, hepatitis A can be spread by blood or blood products. In developing countries, children account for most cases due to exposure early in life, whereas in North America and Europe, more cases appear in adults. Because the virus is not carried chronically, the principal reservoirs are asymptomatic, short-term carriers or people with clinical disease.

The Course of HAV Infection

Swallowed hepatitis A virus multiplies in the small intestine during an incubation period of 2 to 6 weeks. The virus is then shed in the feces, and in a few days, it enters the blood and is carried to the liver. Most infections are either subclinical or accompanied by vague, flu-like symptoms. In more overt cases, the presenting symptoms are loss of appetite, nausea, diarrhea, fever, pain and discomfort in the region of the liver, and darkened urine. Jaundice is present in only about 1 in 10 cases. Occasionally hepatitis A occurs as a fulminating disease and causes liver damage, but this manifestation is quite rare. Because the virus is not oncogenic and does not predispose to liver cancer, complete uncomplicated recovery results.

Diagnosis and Control of Hepatitis A

A patient’s history, liver and blood tests, serological tests, and viral identification all play a role in diagnosing hepatitis A and differentiating it from the other forms of hepatitis. Certain liver enzymes are elevated, and leukopenia is common. Diagnosis is aided by detection of anti-HAV IgM antibodies produced early in the infection and tests to identify hepatitis A antigen or virus directly in stool samples.

There is no specific treatment for hepatitis A once the symptoms begin. Patients who receive immune serum globulin early in the disease usually experience milder symptoms than patients who do not receive it. Prevention of hepatitis A is based primarily on immunization. Two inactivated viral vaccines are approved for protection against hepatitis A, HAVRIX and VAQTA. Both vaccines are administered in two doses, between 6 and 18 months of age. TWINRIX is an inactivated vaccine that provides protection against both hepatitis A and B, but is currently approved only for adults. Pooled immune serum globulin is also recommended for travelers and armed forces personnel planning to enter endemic areas, contacts of known cases, and occupants of various institutions during epidemics. Control of this disease can be improved by sewage treatment, hygienic food handling and preparation, and adequate cooking of shellfish.

* *Pleurodynia* (plur’-oh-din’-ee-ah) Gr. *pleura*, rib, side, and *odyne*, pain.

Human Rhinovirus (HRV)

The **rhinoviruses*** are a large group of picornaviruses (more than 110 serotypes) associated with the common cold. Although the majority of characteristics are shared with other picornaviruses, two distinctions set rhinoviruses apart. First, they are sensitive to acidic environments such as that of the stomach, and second, their optimum temperature of multiplication is not normal body temperature but 33°C, the average temperature in the human nose.

Virologists have subjected rhinovirus (type 14) to a detailed structural analysis. The results of this study provided a striking three-dimensional view of its molecular surface and also explained why immunity to the rhinovirus has been so elusive. The capsid subunits are of two types: protuberances (knobs), which are antigenically diverse among the rhinoviruses, and indentations (pockets), which exist only in two forms (**figure 25.23**). Because the antigens on the surface are the only ones accessible to the immune system, a successful vaccine would have to contain hundreds of different antigens, so it is not practical. Unfortunately the recessed antigens are too inaccessible for immune actions. These factors make the development of a vaccine unlikely, but it could provide a basis for developing drugs to block the pocket receptors.

Epidemiology and Infection of Rhinoviruses

Rhinovirus infections occur in all areas and all age groups at all times of the year. Epidemics caused by a single type arise on occasion, but usually many strains circulate in the population at one time. As mutations increase and herd immunity to a given type is established, newer types predominate. People acquire infection from contaminated hands and fomites, and to a lesser extent from droplet nuclei. Children are highly susceptible to colds and often transmit the virus to the rest of a family. Although other animals have rhinoviruses, interspecies infections have never been reported. After an incubation period of 1 to 3 days, the patient can experience some combination of headache, chills, fatigue, sore throat, cough, a mild nasal drainage, and atypical pneumonia. Natural host defenses and nasal antibodies have a beneficial local effect on the infection, but immunity is short-lived.

Control of Rhinoviruses

The usual therapy is to force fluids and relieve symptoms with various cold remedies and cough syrups that contain nasal decongestants, antihistamines, and analgesics. The actual effectiveness of most of these remedies (of which there are hundreds) is rather questionable. Owing to the extreme diversity of rhinoviruses, prevention of colds through vaccination will probably never be a medical reality. Some protection is afforded by such simple measures as hand washing and care in handling nasal secretions.

Caliciviruses

Caliciviruses* are an ill-defined group of enteric viruses found in humans and mammals. The best-known human pathogen is the

(a)

(b)

Figure 25.23 Antigen structure of a rhinovirus. (a) The surface of a rhinovirus is composed of knobs and pockets. The antigens on the knobs are extremely variable in shape among the scores of viral strains, and those in the pockets do not vary among the strains. (b) The knobs are readily accessible to the immune system, and antibodies formed against them will neutralize the virus (circle). Unfortunately, being fully protected against rhinoviruses would require making antibodies that react with 100 different knob antigens. It is true that reactions against pocket antigens would be universal, but these molecules are too inaccessible for immune reactions.

norovirus also known as the **Norwalk agent**, named for an outbreak of gastroenteritis that occurred in Norwalk, Ohio, from which a new type of virus was isolated. The Norwalk virus is now believed to cause nearly 90% of all cases of viral gastroenteritis. It is transmitted oro-fecally in schools, restaurants, cruise ships, and nursing homes, and through contaminated water and shellfish. Infection occurs throughout the year among people of all ages. Onset is acute, accompanied by nausea, vomiting, cramps, diarrhea, and chills; recovery is rapid and complete.

Reoviruses: Segmented Double-Stranded RNA Viruses

Reoviruses have an unusual double-stranded RNA genome and both an inner and an outer capsid (see table 25.1). Two of the best-studied viruses of the group are *Rotavirus* and *Reovirus*. Named for

* *rhinoviruses* (ry'-noh-vy"-rus) Gr. *rhinos*, nose.

* *caliciviruses* (kal'-ih-sih-vy"-rus) L. *calix*, the cup of a flower. These viruses have cup-shaped surface depressions.

Figure 25.24 Diagnosing gastroenteritis. (a) A sample of feces from a child with gastroenteritis as viewed by electron microscopy. Note the unique “spoked-wheel” morphology that can be used to identify *Rotavirus* (150,000 \times). (b) An infant suffering from chronic rotavirus gastroenteritis shows evidence of malnutrition, failure to thrive, and stunted growth. (a): Source: Bryon Skinner/CDC; (b): From Farrar and Lambert, *Pocket Guide for Nurses: Infectious Diseases*, 1984. Williams and Wilkins, Baltimore, MD. Reprinted by permission of Dr. William Edmund Farrar, Jr.

its wheel-shaped capsid, *Rotavirus** (figure 25.24a) is a significant cause of diarrhea in newborn humans, calves, and piglets. Because the viruses are transmitted via fecally contaminated food, water, and fomites, disease is prevalent in areas of the world where access to adequate sanitation is lacking. Globally, *Rotavirus* is the primary viral cause of mortality and morbidity resulting from diarrhea. It accounts for nearly 50% of all the cases, resulting in the deaths of over 500,000 children. The effects of infection vary with the nutritional state, general health, and living conditions of the infant. Babies from 6 to 24 months of age lacking maternal antibodies have the greatest risk for fatal disease. These children present with symptoms of watery diarrhea, fever, vomiting, dehydration, and shock. The intestinal mucosa can be damaged in a way that chronically compromises nutrition, and long-term or repeated infections can retard growth (figure 25.24b).

In the United States, rotavirus infection is relatively common, but its course is generally mild. Children are treated with oral replacement fluid and electrolytes. Two vaccines (RotaTeq, Rotarix) based on various versions of live, attenuated viruses are currently available. Initial results indicate that the vaccines reduced serious illness by 85% to 98% in the groups of infants tested. They are both easily administered oral vaccines but rather costly.

*Reovirus** is not considered a significant human pathogen. Adults who were voluntarily inoculated with the virus developed coldlike symptoms. The virus has been isolated from the feces of children with enteritis and from people suffering from an upper respiratory infection and rash, but most infections are asymptomatic. Although a link to biliary, meningeal, hepatic, and renal syndromes has been suggested, a causal relationship has never been proved.

* *Rotavirus* (roh'-tah-vy'-rus) L. *rota*, wheel.

* *Reovirus* (ree'oh-vy'-rus) An acronym for respiratory enteric orphan virus.

Check Your Progress SECTION 25.6

46. Describe the epidemiology and progress of polio infection and disease.
47. Why is poliovirus spread so effectively?
48. Compare paralytic and nonparalytic polio.
49. Explain why the Salk vaccine is currently recommended over the Sabin vaccine in the United States.
50. What characteristics of enteric viruses cause them to be readily transmissible?
51. Describe some common ways that hepatitis A is spread.
52. What are its primary effects on the body?
53. List several activities that reduce the incidence of infectious hepatitis.
54. What is the common cold, and which groups of viruses can be involved in its transmission?
55. Why is it so difficult to control?
56. Describe the most important calicivirus and the disease it causes.
57. Summarize the epidemiology of noroviruses.
58. What viruses possess a double-stranded RNA genome and what diseases do they cause?

25.7 Prions and Spongiform Encephalopathies

Expected Learning Outcomes

35. Recall the structure of prions and the diseases they cause.
36. Explain the pathogenesis, transmission, and epidemiology of prion disease.
37. Understand how prion infection is diagnosed, treated, and prevented.

Devastating diseases such as subacute sclerosing panencephalitis and progressive multifocal leukoencephalopathy arising from persistent viral infections of the CNS have previously been described. They are characterized by a long incubation period, and they can progress over months or years to a state of severe neurological impairment. These types of chronic infections are caused by known viruses with conventional morphology. But there are other types of CNS infectious diseases for which no traditional microorganism has been isolated. The most serious of these are the diseases associated with **prions**.⁶

You may recall from chapter 6 that prions are proteinaceous infectious particles that appear to lack genetic material. Prions are incredibly hardy “pathogens.” They are highly resistant to chemicals, radiation, and heat. They can withstand prolonged autoclaving (table 25.5). They are known to cause diseases called **transmissible spongiform encephalopathies*** (TSEs), neurodegenerative

6. A contraction of **proteinaceous infectious particle**.

* *spongiform encephalopathies* (spunj'-ih-form en-sef'-uh-lop'-uh-theez).

TABLE 25.5 Properties of the Agents of Spongiform Encephalopathies

<p>Consist entirely of protein with no nucleic acid</p> <p>Very resistant to chemicals, radiation, and heat (can withstand autoclaving)</p> <p>Do not present virus morphology in electron microscopy of infected brain tissue</p> <p>Not integrated into nucleic acid of infected host cells</p> <p>Do not elicit inflammatory reaction or cytopathic effects in host</p> <p>Do not elicit antibody formation in host</p> <p>Responsible for vacuoles and abnormal fibers forming in brain of host</p> <p>Transmitted only by close, direct contact with infected tissues and secretions</p>

diseases with long incubation periods but rapid progressions once they begin. The human TSEs are **Creutzfeldt-Jakob disease (CJD)**, kuru, Gerstmann-Strussler-Scheinker disease, and fatal familial insomnia. TSEs are also found in animals and include a disease called **scrapie** in sheep and goats, transmissible mink encephalopathy, and bovine spongiform encephalopathy (BSE). This last disease, commonly known as mad cow disease, has been a big concern in recent years due to its apparent link to a variant form of CJD human disease in Great Britain.

Pathogenesis and Effects of CJD

The pathogenesis of the prions involves an alteration in the structure of a normal host protein (called PrP^C) found in mammalian brains. Abnormal PrP^{Sc} has acquired a significant change in its shape through mutation or some other means. The effect of this alteration is that the abnormal PrP^{Sc} itself becomes catalytic and able to spontaneously convert other normal human PrP^C proteins into the abnormal form (see figure 6.21). This becomes a self-propagating chain reaction that creates a massive accumulation of altered PrP^{Sc} that results in nerve cell death, spongiform damage (that is, holes in the brain), and severe loss of brain function. Autopsies of the brain of CJD patients reveal spongiform lesions (**figure 25.25**) as well as tangled protein fibers (neurofibrillary tangles) and enlarged astroglial cells. These changes occur primarily in the gray matter of the CNS. The PrP^{Sc} are not apparently antigenic and do not stimulate an immune response.

Symptoms of CJD include altered behavior, dementia, memory loss, impaired senses, delirium, and premature senility. Uncontrollable muscle contractions continue until death, which usually occurs within 1 year of diagnosis.

Transmission and Epidemiology

The transmissible form of CJD is not a highly communicable disease in that ordinary contact with infected people is not known to transmit the prions. Direct or indirect contact with infected brain tissue or cerebrospinal fluid is one factor in its acquisition. The classic form of CJD is considered endemic and occurs at the rate of one case per million persons in the United States per year, mainly in the elderly. Using the term *transmissible agent* may be a bit

Figure 25.25 The microscopic effects of spongiform encephalopathy. (a) Normal cerebral cortex section, showing neurons and glial cells. (b) Section of cortex in CJD patient shows numerous holes. The open spaces correspond to sites once occupied by brain cells that have been destroyed. This gives the tissue a spongy appearance. It is such massive loss of neurons and glial cells that gives rise to the deadly outcome in the disease (750 \times). (a): © M. Abbey/Science Source; (b): Source: Sherif Zaki; MD; PhD; Wun-Ju Shieh; MD; PhD; MPH/CDC

misleading, because some cases of CJD arise through genetic mutation of the PrP^C gene rather than through contact with infectious material. In fact, up to 15% of CJD cases appear to develop after inheritance of a mutated gene.

In the late 1990s it became apparent that humans were contracting a variant form of CJD (vCJD) after ingesting meat from cattle that had been afflicted by bovine spongiform encephalopathy. Presumably, meat products had been contaminated with fluid or tissues infected with the prion, although the exact food responsible for the transmission has not been pinpointed. When experimenters purposely infect cattle with prions, they subsequently detect the agent in the retina, dorsal root ganglia, parts of the digestive tract, and the bone marrow of the animals. Even so, the risk of contracting vCJD from the ingestion of meat is extremely small, even in countries such as Great Britain, where a significant number of livestock have been found to have BSE. There the risk of infection is estimated to be 1 case per 10 billion meat servings. As of 2011 a total of 224 cases of vCJD had occurred worldwide. The median age at death of patients with vCJD is 28 years. In contrast, the median age at death of patients with classic CJD is 68 years.

Health care professionals should be aware of the possibility of CJD in patients, especially when surgical procedures are performed, as cases have been reported of transmission of CJD via contaminated surgical instruments. Due to the heat and chemical resistance of prions, normal disinfection and sterilization procedures are usually not sufficient to eliminate them from instruments and surfaces. The latest CDC guidelines for handling of CJD patients in a health care environment should be consulted. CJD has also been transmitted through corneal grafts and administration of contaminated human growth hormone. Currently, no cases have been documented of transmission through blood products, although scientists have shown that it is possible in laboratory experiments. Experiments suggest that vCJD seems to be more transmissible through blood than is classic CJD. For that reason, blood donation programs screen for possible exposure to BSE by asking about travel and residence history.

Culture and Diagnosis

It can be very difficult to diagnose CJD. Definitive diagnosis requires examination of biopsied brain or nervous tissue, and this procedure is usually considered too risky because of both the trauma induced in the patient and the undesirability of contaminating surgical instruments and operating rooms. Electroencephalograms and magnetic resonance imaging can provide important clues. A new test has been developed that can detect prion proteins in cerebrospinal fluid, but it is not yet widely used because it has a relatively high error rate.

Prevention and/or Treatment

Prevention of either type of CJD relies on avoiding any contact with infected tissues. No known treatment exists for CJD, and patients inevitably die. Medical intervention focuses on easing symptoms and making the patient as comfortable as possible.

CASE STUDY Part 2

While in the hospital, samples of the boy's blood and cerebrospinal fluid were examined. His serum measles IgG level was markedly elevated, as was his cerebrospinal fluid measles IgG level; serum measles IgM was negative.

The boy had received a single dose of measles vaccine in the Philippines at 8 months of age, yet contracted the disease when he was a year old. Vaccination during early infancy has been associated with a less efficient production of antibodies when compared to children vaccinated later, likely as a result of interference by circulating maternal antibodies. Lack of adequate protection could also be due to the fact that

Check Your Progress SECTION 25.7

59. Describe the characteristics of the agents responsible for spongiform encephalopathies.
60. Explain how bovine spongiform encephalopathy can be transmitted to humans.
61. Make a flowchart to explain the mechanism of how prions can cause a progressive effect, even though they cannot divide by themselves.
62. Other than infection, how else may Creutzfeldt-Jakob disease be acquired?
63. What measures would be necessary to control infections with these agents?

the boy received only a single dose of vaccine. The Centers for Disease Control recommends that all children get two doses of measles, mumps, rubella (MMR) vaccine to ensure adequate protection. The first dose is given at 12 to 15 months of age, with a second dose between 4 and 6 years of age.

- What is the significance of the boy's IgG and IgM levels?
- What type of side effects are occasionally seen with the measles vaccine? Why?

See; Liko J, Guzman-Cottrill JA, Cieslak PR. *Notes from the Field: Subacute Sclerosing Panencephalitis Death — Oregon, 2015.* MMWR Morb Mortal Wkly Rep 2016;65:10–11.

To conclude this Case Study, go to Connect.

Chapter Summary with Key Terms

25.1 Enveloped Segmented Single-Stranded RNA Viruses

- A. **Orthomyxoviruses:** Influenza viruses have a segmented genome that encourages **antigenic shift**, **antigenic drift**, and glycoprotein spikes (**hemagglutinin** and **neuraminidase**), which are needed to bind to host cells.
- B. **Bunyaviruses:** Zoonotic viruses. *Hantavirus* is responsible for Korean hemorrhagic fever and *hantavirus pulmonary syndrome*.
- C. **Arenaviruses:** Lassa virus causes hemorrhagic fever and is spread by rodent secretions.

25.2 Enveloped Nonsegmented Single-Stranded RNA Viruses

- A. **Paramyxoviruses:** Nonsegmented genome. *Paramyxovirus* causes **parainfluenza** and **mumps**. *Morbillivirus* is responsible for **measles** (roseola). *Paramyxovirus* and *Morbillivirus* are prevented through vaccination (MMR). *Pneumovirus* (**respiratory syncytial virus, RSV**) is the causative agent of **croup** and is treated with aerosol ribavirin.

- B. **Rhabdoviruses:** *Lyssavirus* is the cause of **rabies**, a lethal zoonosis. Treatment requires both active and passive immunization.

25.3 Other Enveloped RNA Viruses: Coronaviruses, Togaviruses, and Flaviviruses

- A. **Coronaviruses** are one cause of the common cold. Other coronaviruses are responsible for **severe acute respiratory syndrome (SARS)** and **middle east respiratory syndrome (MERS)**.
- B. **Togaviruses:** **Rubella** (German measles) is of minor concern to healthy adults but can be **teratogenic** (cause birth defects) in pregnant women. Control is through immunization (MMR).
- C. Flaviviruses: **Hepatitis C virus** is a major cause of hepatitis transmitted through blood contact. Chronic infection may cause liver damage and cancer.

25.4 Arboviruses: Viruses Spread by Arthropod Vectors

- Arboviruses:** Large group (400+) of viruses spread by arthropod vectors and harbored by birds and other animals.
- Examples of viruses include *togaviruses*, *bunyaviruses*, and *reoviruses*; diseases include West Nile encephalitis, Chikungunya, and eastern equine encephalitis, **yellow fever**, **dengue fever**, and **Zika**.

25.5 Retroviruses and Human Diseases

- HIV Infection and AIDS: Retroviruses** are enveloped, single-stranded RNA viruses that encode the enzyme **reverse transcriptase**, which allows the viruses to convert their single-stranded RNA genome to a double-stranded DNA genome.
- The most prominent retrovirus is **human immunodeficiency virus** (HIV types 1 and 2), the causative agent of **acquired immunodeficiency syndrome (AIDS)**. AIDS is marked by the presence of antibodies to HIV along with some combination of opportunistic infections and a CD4 T-cell count of $<200/\mu\text{l}$ of blood. In addition, other common symptoms include fever, weight loss, and night sweats.
 - HIV is found in blood, semen, and vaginal secretions and can be transmitted by any activity that causes these fluids to be exchanged (sex, sharing needles, childbirth, etc.).
 - HIV attacks the cells of the immune system, beginning with T lymphocytes and macrophages.
 - The first signs of AIDS are the **AIDS-defining illnesses (ADIs)**, opportunistic infections such as *Pneumocystis jirovecii* pneumonia (**PCP**) and cancers such as **Kaposi sarcoma**.
 - Treatment of HIV relies on highly active antiretroviral therapy (HAART), in which a combination of reverse

transcriptase inhibitors (AZT, ddI, 3TC), protease inhibitors (ritonavir, saquinavir), fusion inhibitors, and integrase inhibitors are used to interrupt the virus in different stages of its replication cycle. Drugs are also given to prevent/treat opportunistic infections.

- Human T-cell Lymphotropic Viruses** Other retroviruses include **HTLV-I** and **HTLV-II**. The former causes adult T-cell leukemia, whereas the latter may be involved in some forms of brain disease.

25.6 Nonenveloped Single-Stranded and Double-Stranded RNA Viruses

- Picornaviruses** are the smallest human viruses and include
 - Poliovirus**, the causative agent of polio.
 - Coxsackievirus**, which is responsible for respiratory infections, hand-foot-mouth disease, and conjunctivitis.
 - Hepatitis A virus**, which is responsible for the mildest form of hepatitis.
 - Rhinovirus**, the most prominent agent of the common cold.
- Caliciviruses**, the most common of which is **norovirus** or **Norwalk agent**, a common cause of viral gastroenteritis.
- Reoviruses: Segmented Double-Stranded RNA Viruses** **Reoviruses**, the most important of which is **Rotavirus**, a leading cause of severe infantile diarrhea worldwide.

25.7 Prions and Spongiform Encephalopathies

Prions are infectious agents consisting exclusively of protein. They are responsible for **transmissible spongiform encephalopathies** such as mad cow disease, **scrapie** in animals, and **Creutzfeldt-Jakob disease** in humans.

**Level I. Knowledge and Comprehension**

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

- Which receptors of the influenza virus are responsible for binding to the host cell?
 - hemagglutinin
 - neuraminidase
 - type A
 - capsid proteins
- The primary site of attack in influenza is the
 - small intestine
 - respiratory epithelium
 - skin
 - meninges
- Which of these happen(s) in the case of antigenic shift in influenza A?
 - single mutations in hemagglutinin
 - recombination of RNA segments between bird and human strains
 - change from influenza A to influenza B
 - both a and b
- Infections with _____ virus cause the development of multinucleate giant cells.
 - rabies
 - influenza
 - pneumo
 - corona
- For which disease is an exanthem (skin rash) *not* a symptom?
 - measles
 - rubella
 - coxsackievirus infection
 - parainfluenza
- A common, highly diagnostic sign of measles is
 - viremia
 - red rash
 - sore throat
 - Koplik's spots
- Viruses that cause serious diseases in infants are _____ and _____.
 - mumps, calicivirus
 - respiratory syncytial virus, rotavirus
 - coxsackievirus, HTLV-II
 - bunyavirus, cardiovirus
- For which disease are active and passive immunization given simultaneously?
 - influenza
 - yellow fever
 - measles
 - rabies

9. What property of the retroviruses enables them to integrate into the host genome?
- the RNA they carry
 - presence of glycoprotein receptors
 - presence of reverse transcriptase
 - a positive-sense genome
10. Which of the following conditions is *not* associated with HIV infection?
- Pneumocystis jirovecii* pneumonia
 - Kaposi sarcoma
 - dementia
 - adult T-cell leukemia
11. Polio and hepatitis A viruses are _____ viruses.
- arbo
 - enteric
 - cold
 - syncytial
12. Rhinoviruses are the most common cause of
- conjunctivitis
 - gastroenteritis
 - hand-foot-mouth disease
 - the common cold
13. Which of the following is *not* a characteristic of the agents of spongiform encephalopathies?
- highly resistant
 - associated with tangled protein fibers in the brain
 - are naked fragments of RNA
 - cause chronic transmissible disease
14. **Multiple Matching.** Select all descriptions that fit each type of virus.
- | | |
|----------------------|-------------------------|
| _____ orthomyxovirus | a. enveloped |
| _____ rhabdovirus | b. double-stranded RNA |
| _____ paramyxovirus | c. single-stranded RNA |
| _____ reovirus | d. genome in segments |
| _____ morbillivirus | e. icosahedral capsid |
| _____ poliovirus | f. helical nucleocapsid |
| _____ retrovirus | g. nonenveloped |
| _____ hantavirus | |
15. **Multiple Matching.** Match the virus with its primary target organ or site of attack. Some viruses may attack more than one organ.
- | | |
|--------------------------|----------------------|
| _____ influenza | a. brain |
| _____ HIV | b. parotid gland |
| _____ mumps virus | c. respiratory tract |
| _____ measles virus | d. T lymphocytes |
| _____ hepatitis A virus | e. kidney |
| _____ hantavirus | f. spinal cord |
| _____ dengue virus | g. liver |
| _____ encephalitis virus | h. intestinal tract |
| _____ poliovirus | i. heart |
| _____ rabies virus | j. eye |
| _____ rubella virus | |
| _____ rotavirus | |
16. **Matching.** Match the virus with its primary mode of transmission. Some viruses may have more than one mode.
- | | |
|-------------------------|---------------------------|
| _____ influenza | a. respiratory droplets |
| _____ HIV | b. sexual transmission |
| _____ mumps virus | c. ingestion (oral-fecal) |
| _____ measles virus | d. arthropod bite |
| _____ hepatitis A virus | e. contact with mammals |
| _____ hantavirus | f. fomites |
| _____ chikungunya virus | |
| _____ poliovirus | |
| _____ rabies virus | |
| _____ rubella virus | |
| _____ rotavirus | |

Case Study Review

- During which periods of a measles infection is a person not usually contagious?
 - incubation
 - prodromium
 - skin rash
 - convalescence
- Match each of the statements below to measles or German measles.
 - Transmitted by a togavirus.
 - Koplik spots are a sign.
 - subacute sclerosing panencephalitis is a complication.
 - Also known as rubella.
 - May cause congenital defects.
- Why would it be especially important for someone who worked in an infant nursery to be vaccinated against the measles?

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

- Discuss the similarities in the symptoms of influenza, parainfluenza, mumps, measles, rubella, RSV, and rhinoviruses.
- What is a teratogenic virus?
 - Which RNA virus has this potential?
- Explain why patients with AIDS have deficiencies in antibody formation.
- Discuss some ways that HIV has *not* been documented to spread.
 - How is the brain affected by HIV infection?
 - What is the most sensible interpretation for a seropositive or seronegative result in HIV testing?
- What is meant by the “window” regarding antibody presence in the blood?
 - Are there any actual cures for AIDS? Explain your answer.
- For which of the RNA viruses are vaccines available?
 - For which of the RNA viruses are there specific drug treatments?
- Explain why infections such as mumps, measles, polio, rubella, and RSV regularly infect children and not adults.

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps along with concept mapping activities for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

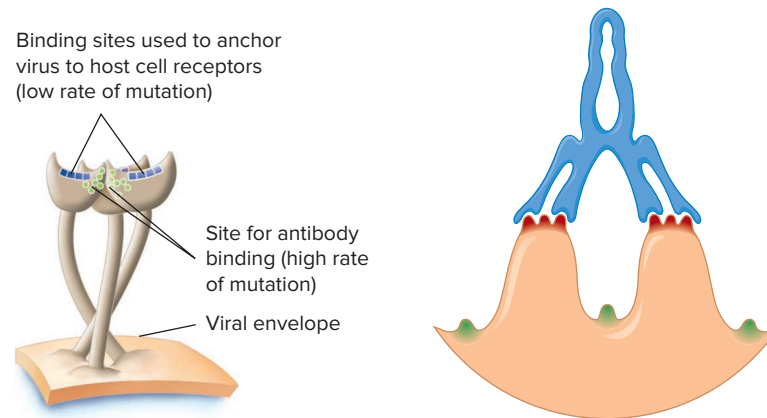

1. a. Explain the relationship between herd immunity and the development of influenzal pandemics.
b. Why will herd immunity be lacking if antigenic shift or drift occurs?
2. a. Explain how the antibody content of a patient's sera could be used to predict which strain of influenza predominated during a previous epidemic.
b. Explain the precise way that cross-species influenza infections give rise to new and different strains of virus.
c. Relate this answer to the avian influenza virus and how it could cause a human pandemic.
3. When a newborn infant is positive for HIV antibodies in both ELISA and Western blot tests, what conclusions can you make about the baby's condition? What other information do you need to be sure that this is the right conclusion?
4. a. Explain what characteristics of virus and host make zoonotic diseases possible and difficult to control.
b. Make a diagram that details the progression of arboviruses from deep in the Amazon rain forest to Florida or from Central Africa to Seattle, Washington (as happened with West Nile fever virus).
c. Observe the graph showing case reports for arboviral encephalitis from 2008–2013. Describe the general pattern that is evident and analyze the factors that would cause it.
5. a. Can you think of a plausible series of events that could explain how HIV came to be so widespread?
b. Explain why there can be such a discrepancy between the total number of reported cases of AIDS and the projected number of cases estimated by health authorities.
c. Using figure 25.15 and table 12.6 as references, outline the strategies of anti-HIV drugs and their effects as correlated with the virus cycle.
6. Explain the characteristics of HIV and its infection that make it a challenging target for the immune system and for drugs.
7. a. What precautions can a person take to prevent himself or herself from contracting HIV infection?
b. How can a health care worker prevent possible infection?
8. If wild-type polio disappeared from the Western Hemisphere by 1991, how do you explain the 11 cases of polio reported in the United States in 2000?
9. Various over-the-counter cold remedies control or inhibit inflammation and depress the symptoms of colds. Is this beneficial or not? Support your answer.
10. Late in the spring, a young man from rural Idaho developed fever, loss of memory, difficulty in speech, convulsions, and tremor and lapsed into a coma. He tested negative for bacterial meningitis and had no known contact with wild animals. He survived but had long-term neurological disabilities. What are the possible diseases he might have had, and how would he have contracted them?
11. Biopsies from the liver and intestine of an otherwise asymptomatic 35-year-old male show masses of acid-fast bacilli throughout the tissue. Explain the pathology going on here and provide a preliminary diagnosis.

Encephalitis/Meningitis, Arboviral, California Serogroup. Number of reported cases, by month of onset—United States, 2008–2013

 Visual Challenge

1. Refer to **figures 25.2** and **25.23**, and compare and contrast how both viruses use surface receptors to evade an immune reaction and neutralizing antibodies.

CASE STUDY Part 1 May I Get a Glass of Water?

On August 2, 2014, a **DO NOT DRINK** order was issued for 500,000 people in and around Toledo, Ohio. The order stated that tap water should not be used for drinking, brushing teeth, or preparing infant formula, food, or ice. The cause of the order was an increased level of **microcystins**, a toxin produced by several species of the cyanobacterial genus *Microcystis*. Environmental conditions had allowed the cyanobacterium to grow at a prodigious rate producing a **harmful algae bloom** (HAB). The immediate effects of ingesting microcystins include nausea, vomiting, and dizziness, but liver **toxicity** is the most concerning issue, with both short-term liver failure and longer-term liver cancer reported. The danger is real. One hundred patients developed liver failure (and 50 died) when water contaminated with microcystins was used at a dialysis clinic in Brazil. The **Environmental Protection Agency** has deemed that water with greater than 1.6 **parts per billion** (ppb) microcystin is unsafe to drink, and because the toxin is **heat stable**, boiling—the usual advice for water contaminated by microbes—is not helpful. In fact, because boiling reduces the volume of the water, it simply concentrates the toxin.

Shortly after the water advisory was issued, the effects could be seen throughout the area. Stores quickly sold out of bottled water and shipments destined for other parts of the state were rerouted to Toledo. The Ohio National Guard trucked in water from distant areas

and delivered **premixed infant formula** and military meals. Restaurants were urged to shut down, and the Ohio Department of Rehabilitation and Corrections converted its milk bottling plant to package safe water for the area. Toledo knew what to do when the city's water was deemed unsafe to drink, because it had been in the same situation before.

“The Ohio National Guard was used to deliver pre-made infant formula.”

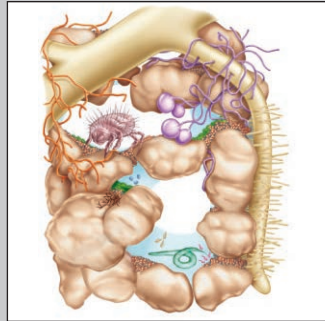

In the 1920s the city of Toledo established a water intake (called a **crib**) at Maumee Bay on the western end of Lake Erie. The lake's large size and the location of the **crib** near the water inlet for the lake were thought to offer an ideal source of clean water, distant from the industrial wastes and **raw sewage** that were routinely dumped into the rivers of Toledo. Unfortunately, over the next several decades many factors conspired to favor the growth of toxin-producing microcystin in Lake Erie.

- *What environmental factors favor the growth of microorganisms like algae and cyanobacteria?*
- *Boiling is commonly recommended when water is contaminated with *E.coli*. What does boiling do to make the water safe to drink?*

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

SCOPING OUT THE CHAPTER

Remove the microbes, and life on Earth stops. Plants don't grow, animals starve, lakes and oceans die. Even the nonliving aspects of the planet—the amount and type of nitrogen and phosphorous available to plants and animals, for instance—depends on the actions of microorganisms. Microbes are not always the heroes, though. Overgrowth of algae or bacteria can poison water supplies and cut off oxygen to other members of aquatic communities. In this chapter we discuss the impact of microorganisms on the world at large.

A single spoonful of soil contains a vibrant collection of microorganisms working together. Bacteria, fungi, protozoans, even animals like mites and nematode worms, exist in complex associations that decompose organic matter, supply nitrogen to plant roots, and enrich the surrounding soil, making it so much more than just a pile of dirt.

Boiling, acidic, sulfur filled pits—areas that would seem to be anathema to life—harbor complex microbial communities. The biogeochemical interactions found here are essential to the cycling of iron, sulfur, manganese, phosphorous, and other inorganic molecules through the environment.

Mutualistic associations between green plants and cyanobacteria like *Nostoc* are responsible for nitrogen fixation, ensuring that atmospheric nitrogen gas is converted to a form usable by plants and animals.

In the developed world we take for granted the safety of our drinking water, but safe water takes hard work. Testing for the presence of coliforms like *E. coli* is just one step in the management of drinking water.

26.1 Ecology: The Interconnecting Web of Life

Expected Learning Outcomes

1. Define *microbial ecology* and describe what it entails.
2. Characterize the organization of the biosphere, from the highest to the lowest levels.
3. Differentiate between habitat and niche, using examples.

“When we try to pick out anything by itself, we find it hitched to everything else in the universe.”

California naturalist John Muir

The study of microbes in their natural habitats is known as **microbial ecology**; the study of the practical uses of microbes in food processing, industrial production, and biotechnology is known as industrial or **applied microbiology** (chapter 27). The two areas actually overlap to a considerable degree—largely because most natural habitats have been altered by human activities. Human intervention in natural settings has changed the earth’s warming and cooling cycles, increased wastes in soil, polluted water, and altered some of the basic relationships between microbial, plant, and animal life. Now that humans are also beginning to release new, genetically recombined microbes into the environment and to alter the genes of plants, animals, and even themselves, what does the future hold? Although this question has no clear answer, we know one thing for certain: Microbes—the most vast and powerful resource of all—will be silently working in nature.

In chapter 7 we first touched upon the widespread distribution of microorganisms and their adaptations to most habitats of the world, from extreme to temperate. Regardless of their exact location or type of adaptation, microorganisms necessarily interact with their environment in complex and extraordinary ways. Microbial ecology is focused on interactions between microbes and their environment and the effects of those interactions on the earth. Unlike studies that deal with the activities of a single organism or its individual characteristics in the laboratory, ecological studies are aimed at the interactions taking place between organisms and their environment at many levels at any given moment. Therefore, ecology is a broad-based science that merges many subspecies of biology as well as geology, physics, and chemistry.

Ecological studies deal with both the biotic and the abiotic components of an organism’s environment. **Biotic*** factors are defined as any living or dead organisms¹ that occupy an organism’s habitat. **Abiotic*** factors include nonliving components such as atmospheric gases, minerals, water, temperature, and light. A term used to denote the collective interactions occurring between the biotic and abiotic factors in a given location is **ecosystem**. An ecosystem can vary in size from a single root of a plant to a whole forest, and it serves as the basic unit of ecological function.

1. Biologists make a distinction between nonliving and dead. A nonliving object has never been alive, whereas a dead organism was once alive but no longer is.

* *biotic* (by-ah'-tik) Gr. *bios*, living.

* *abiotic* (ay"-by-ah'-tik) Gr. *a*, not, and *bios*, living.

The Organization of the Biosphere

The earth initially may seem like a random, chaotic place, but it is actually an incredibly organized, fine-tuned machine. Ecological relationships exist at several levels, ranging from the entire earth all the way down to a single organism (**figure 26.1**). The most all-encompassing of these levels, the **biosphere**, contains all physical locations on

Figure 26.1 Levels of organization in an ecosystem, ranging from the biosphere to the individual organism.

earth that support life, including the thin envelope of life that surrounds the earth's surface and extends some distance into the crust. This global system comprises the **hydrosphere** (water), the **lithosphere** (3 to 6 miles into the earth's crust), and the **atmosphere** (a few miles into the air). The biosphere maintains or creates the conditions of temperature, light, gases, moisture, and minerals required for life processes. The biosphere can be naturally subdivided into terrestrial and aquatic realms. The terrestrial realm is usually distributed into particular climatic regions called **biomes**,* defined as large assemblages of organisms that have adapted to a distinct geography and climate and are characterized by dominant life forms, usually plants. Particular biomes include grassland, desert, mountain, and tropical rain forest. The aquatic biosphere is generally divisible into freshwater and marine realms. We now know that the earth's crust also supports a vast and diverse number of life forms, estimated to be equal to or even greater than life as we know it in aquatic and terrestrial realms.

Biomes and aquatic ecosystems are generally composed of mixed assemblages of organisms that live together at the same place and time and that usually exhibit well-defined nutritional or behavioral interrelationships. These clustered associations are called **communities**. Although most communities are identified by their easily visualized dominant plants and animals, they also contain a complex assortment of bacteria, fungi, algae, protozoa, and even viruses. The basic unit of community structure is the **population**, defined as a group of organisms of the same kind. For organisms with sexual reproduction, this level is the species. Populations of organisms can also be classified to a subspecies level if needed, often as strains or colonies. The organizational unit of a population is the individual organism, and each multicellular organism, in turn, has its own levels of organization (organs, tissues, cells).

Ecosystems are generally balanced, with each organism existing in its particular habitat and niche. The **habitat** is the physical location in the environment to which an organism has adapted. In the case of microorganisms, the habitat is frequently a *microenvironment*, where particular qualities of oxygen, temperature, light, and nutrient content are somewhat stable. The **niche** is the overall role that a species (or population) serves in a community. This includes such activities as nutritional intake (what it eats), position in the community structure (what is eating it), and rate of population growth. A niche can be broad (such as scavengers that feed on nearly any organic food source) or narrow (microbes that decompose cellulose in forest litter or that fix nitrogen).

Note that microbes exist as communities in and on plants and animals as well, including humans. Pure cultures are seldom found anywhere in nature.

Check Your Progress SECTION 26.1

1. Present in outline form the levels of organization in the biosphere. Define the terms *ecosystem*, *biome*, *community*, and *population*.
2. Compare the concepts of habitat and niche using *Chlamydomonas* (figure 26.1) as an example.

* *biomes* (by' ohmz) Gr. *bios*, life and *ome*, group. An extensive community of organisms whose makeup is determined by climatic region.

26.2 Energy and Nutritional Flow in Ecosystems

Expected Learning Outcomes

4. Describe the flow of energy through an ecosystem.
5. Analyze trophic structures and nutritional relationships of a community.
6. Outline several types of ecological associations with examples.

All living things must obtain nutrients and a usable form of energy from their abiotic and biotic environments. The energy and nutritional relationships in ecosystems can be described in a number of convenient ways. An **energy pyramid** or **food chain** provides a simple summary of the general trophic (feeding) levels, designated as producers, consumers, and decomposers, and traces the flow and quantity of available energy from one level to another (**figure 26.2**). It is worth noting that microorganisms are the only life forms that exist at all three major trophic levels. The nutritional roles of microorganisms in ecosystems are summarized in **table 26.1**.

Life would not be possible without **producers**, because they provide the fundamental energy source that drives the trophic pyramid. Producers are the only organisms in an ecosystem that can

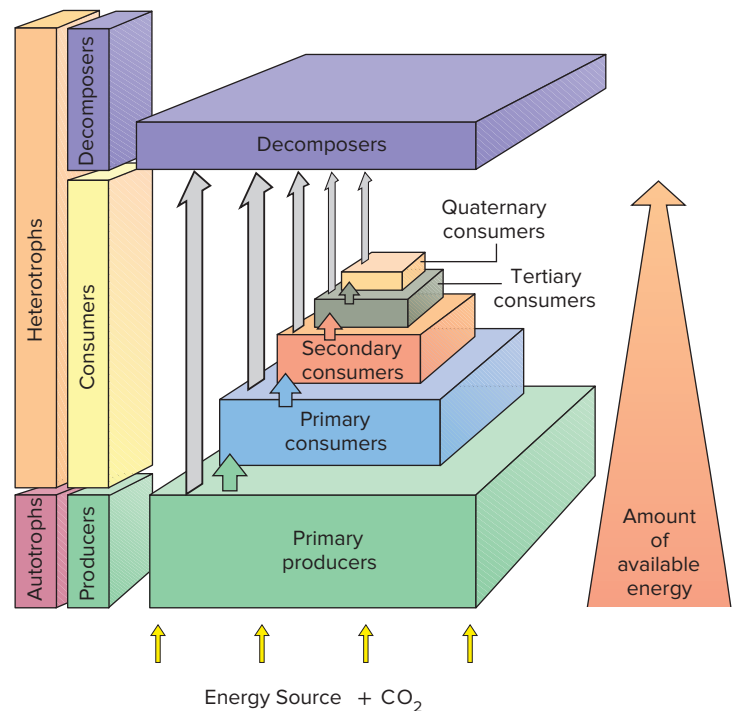

Figure 26.2 A trophic and energy pyramid. The relative size of the blocks indicates the number of individuals that exist at a given trophic level. The arrow on the right indicates the amount of usable energy from producers to top consumers. Both the number of organisms and the amount of usable energy decrease with each trophic level. Decomposers are an exception because they can feed from all trophic levels (gray arrows). Blocks at the left indicate the general nutritional types and levels that correspond with the pyramid.

TABLE 26.1 The Major Roles of Microorganisms in Ecosystems

Role	Description of Activity	Examples of Microorganisms Involved
Primary producers	Photosynthesis Chemosynthesis	Algae, bacteria, sulfur bacteria Chemolithotrophic bacteria in thermal vents
Consumers	Predation	Free-living protozoa that feed on algae and bacteria; some fungi that prey upon nematodes
Decomposers	Degrading dead organisms and wastes	Soil saprobes (primarily bacteria and fungi) that degrade cellulose, lignin, and other complex macromolecules
	Mineralization of organic compounds	Soil bacteria that reduce organic compounds to inorganic compounds such as CO ₂ and minerals
Cycling agents for biogeochemical cycles	Recycling compounds containing carbon, nitrogen, phosphorus, sulfur	Specialized bacteria that transform elements and keep them cycling from the biotic to the abiotic and back to the biotic phases of the biosphere
Parasites	Living and feeding on hosts	Viruses, bacteria, protozoa, fungi, and worms that play a role in population control

synthesize organic carbon compounds such as glucose by assimilating (fixing) inorganic carbon (CO₂) from the atmosphere. Being able to use CO₂ as a sole carbon source means that producers are **autotrophs**. Most of them are **photoautotrophs**, such as plants and cyanobacteria, that convert the sun's energy into chemical bond energy (covered in chapter 8). A smaller but not less important amount of CO₂ assimilation is brought about by bacteria called **chemoautotrophs**. These organisms derive energy from simple inorganic compounds such as ammonia, sulfides, and hydrogen by using redox reactions. In certain ecosystems (for thermal vents, see 7.2 Secret World of Microbes), chemoautotrophs are the only primary producers that support the energy pyramid.

Consumers feed on other living organisms and obtain energy from bonds present in the organic substrates they contain. The category includes animals, protozoa, fungi, and some bacteria. A pyramid usually has several levels of consumers, ranging from *primary consumers* (grazers or herbivores), which consume producers; to *secondary consumers* (carnivores), which feed on primary consumers; to *tertiary consumers*, which feed on secondary consumers; and up to *quaternary consumers* (usually the last level), which feed on tertiary consumers. **Figures 26.3** and **26.4** show specific organisms at these levels.

Decomposers, primarily microbes inhabiting soil and water, break down and absorb the organic matter of dead organisms, including plants, animals, and other microorganisms. Because of their biological function, decomposers are active at all levels of the food pyramid. Without this important nutritional class of saprobes, the biosphere would stagnate and die. The work of decomposers is to break organic matter down into inorganic minerals and gases that can be cycled back into the ecosystem, especially for the use of primary producers. This process, also termed **mineralization**, is so efficient that almost all biological compounds can be reduced by some type of decomposer. Numerous microorganisms decompose cellulose and lignin, polysaccharides from plant cell walls that account for the vast bulk of detritus in soil and water. Complex macromolecules from animal and plant bodies are also broken down by an assortment of bacteria and fungi. Surprisingly, decomposers can also break down most human-made

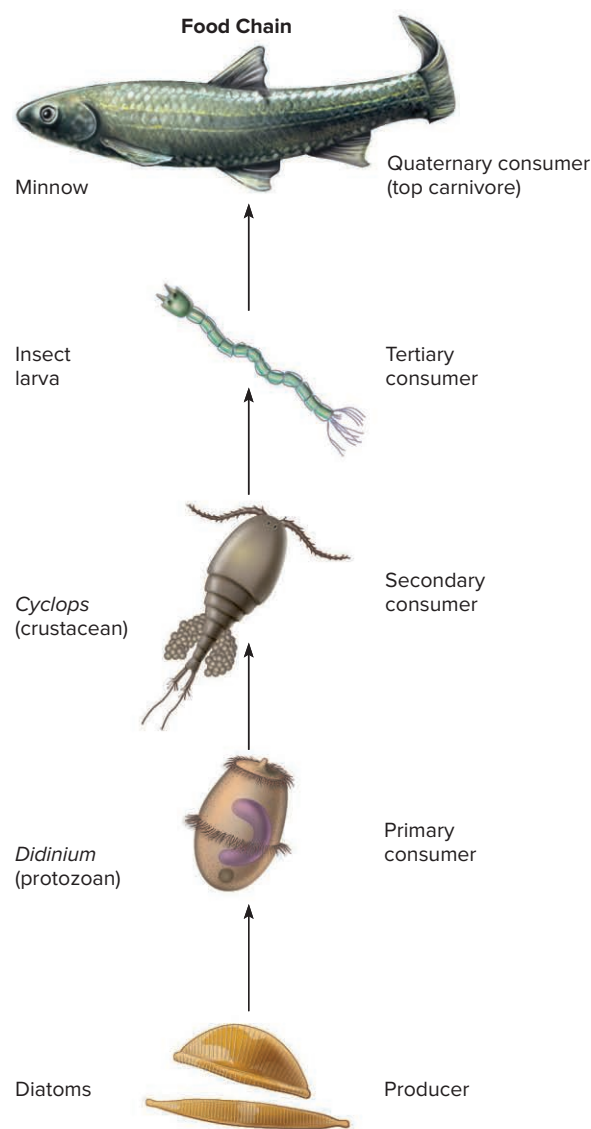

Figure 26.3 Food chain. A food chain is the simplest way to present specific feeding relationships among organisms, but it may not reflect the total nutritional interactions in a community (figure not to scale).

Figure 26.4 Food web. More complex trophic patterns are accurately depicted by a food web, which traces the multiple feeding options that exist for most organisms. Note: Arrows point toward the consumers. Compare this pattern of feeding with the chain in figure 26.3 (organisms not to scale).

compounds that are not naturally found on earth. This process, referred to as **bioremediation**, is discussed in 26.2 Making Connections. Often, bioremediation involves several types of microbes known as a *consortium* that collectively decompose and mineralize substances.

The pyramid in figure 26.2 illustrates several limitations of ecosystems with regard to energy. Unlike nutrients, which can be passed among trophic levels, recycled, and reused, energy does not cycle. Maintenance of complex interdependent trophic relationships such as those shown in figures 26.3 and 26.4 requires a constant input of energy at the producer level. As

energy is transferred to the next level, a large proportion (as high as 90%) of the energy will be lost in a form (primarily heat) that cannot be fed back into the system. Thus, the amount of energy available decreases at each successive trophic level. This energy loss also decreases the actual number of individuals that can be supported at each successive level.

The most basic image of a feeding pathway can be provided by a **food chain**. Although it is a somewhat simplistic way to describe feeding relationships, a food chain helps identify the types of organisms that are present at a given trophic level in a natural setting (see figure 26.3). Feeding relationships in communities are more accurately represented by a multichannel food chain, or a **food web** (see figure 26.4). A food web reflects the actual nutritional structure of a community. It can help to identify feeding patterns typical of herbivores (plant eaters), carnivores (flesh eaters), and omnivores (feed on both plants and flesh).

Ecological Interactions Between Organisms in a Community

Whenever complex mixtures of organisms associate, they develop various dynamic interrelationships based on nutrition and shared habitat. These relationships, some of which were described in earlier chapters, include mutualism, commensalism, parasitism, competition, synergism (cross-feeding), predation, and scavenging.

Mutually beneficial associations (**mutualism**), such as that of protozoans living in the termite intestine, are so well evolved that the two members require each other for survival. In contrast, **commensalism** is one-sided and independent (these terms describing relationships between organisms echo the terms we described in chapter 7). Although

the action of one microbe favorably affects another, the first microbe receives no benefit. Many commensal unions involve *co-metabolism*, meaning that the waste products of the first microbe are useful nutrients for the second one, a process called **syntrophy**. **Parasitism** is an intimate relationship whereby a parasite derives its nutrients and habitat from a host that is usually harmed in the process. In **competition**, one microbe gives off antagonistic substances that inhibit or kill susceptible species sharing its habitat. A **predator** is a form of consumer that actively seeks out and ingests live prey (protozoa that prey on algae and bacteria). **Scavengers** are nutritional jacks-of-all-trades; they feed on a variety of food sources, ranging from live cells to dead cells and wastes.

3. Compare autotrophs and heterotrophs; producers and consumers.
4. Where in the energy and trophic schemes do decomposers enter?
5. Using figures 26.3 and 26.4, point out specific examples of producers; primary, secondary, and tertiary consumers, herbivores; primary, secondary, and tertiary carnivores; and omnivores.
6. What is mineralization, and which organisms are responsible for it?

26.3 The Natural Recycling of Bioelements

Expected Learning Outcomes

7. Summarize the main concepts pertaining to biogeochemical cycles.
8. Discuss the primary participants in and activities of the carbon cycle.
9. Describe the forms in which nitrogen is found and the contributions of microbes to the nitrogen cycle.
10. Indicate the main components of the sulfur and phosphorus cycles.

Environmental ecosystems are exposed to the sun, which constantly infuses them with a renewable source of energy. In contrast, the bioelements and nutrients that are essential components of cells and multicellular organisms are supplied exclusively by sources somewhere in the biosphere and are not being continually replenished from outside the earth. In fact, the lack of a required nutrient in the immediate habitat is one of the chief factors limiting organismic and population growth. It is for these reasons that there must be continuous and sustained **recycling** of elements and nutrients in the biosphere. Essential elements such as carbon, nitrogen, sulfur, phosphorus, oxygen, and iron are recharged through biological, geologic, and chemical mechanisms called **biogeochemical cycles**. Although these cycles vary in certain specific characteristics, they share several general qualities, as summarized in the following list:

- All elements ultimately originate from a nonliving, long-term reservoir in the atmosphere, the lithosphere, or the hydrosphere. They cycle in pure form (N_2) or as compounds (PO_4).
- Elements make the rounds between the abiotic environment and the biotic environment.
- Recycling maintains a necessary balance of nutrients in the biosphere so that they do not build up or become unavailable.
- Cycles are complex systems that rely upon the interplay of producers, consumers, and decomposers. Often the waste products of one organism become a source of energy or building material for another.
- All organisms participate directly in recycling, but only certain categories of microorganisms have the metabolic pathways for converting inorganic compounds from one nutritional form to another.

The English biologist James Lovelock has postulated a concept called the **Gaia* theory**, after the mythical Greek goddess of earth. Its primary idea proposes that the biosphere contains a diversity of

habitats and niches favorable to life because living things have made it that way. Not only does the earth shape the character of living things, but living things shape the character of the earth. After all, we know that the compositions of the aquatic environment, the atmosphere, and even the soil would not exist as they do without the actions of living things. For billions of years, microbes have played prominent roles in the formation and maintenance of the earth's crust, the development of rocks and minerals, and the formation of fossil fuels. This revolution in understanding the biological involvement in geologic processes has given rise to the field of *geomicrobiology*.

In the next several sections we examine how, jointly and over a period of time, the varied microbial activities affect and are themselves affected by the abiotic environment.

Biogeochemical Cycles, Biofilms, and the Living Earth

We started this textbook marveling at the wondrous involvement of microbes in the dynamics of planet earth and are finally at a point at which we can explore these roles in depth. Because the earth is an ancient place and microbes are the most ancient life forms, it is not surprising that they have essentially coevolved over several billion years. This is especially true of the lithosphere and hydrosphere, where microbes penetrate miles below the earth's surface and oceans. In fact, microbes dominate in most habitats, where they form stable and usually long-lasting communities. In most cases, these communities are composed of microbial biofilms that colonize and shape the composition of their microenvironments. So when we discuss the geochemical cycles, realize that most participants have adapted to a particular niche in a shared habitat, where they cooperate in processing elements through their various phases as a survival mechanism. Geomicrobiologists are actively studying these communities and so far have documented hundreds of bacterial species that participate in transforming bioelements of organic molecules as well as minerals such as iron, manganese, and other metals (**figure 26.5**).

Figure 26.5 A hot spring in Yellowstone National Park.

Extremes of temperature and pH, along with liberal quantities of phosphorus and sulfur, create a complex habitat that many microbes have evolved to exploit. Areas of intense geochemical activity are often home to complex microbial communities. © Robert Glusic/Corbis RF

Atmospheric Cycles

The Carbon Cycle

Carbon is the fundamental atom in all biomolecules and accounts for at least one-half of the dry weight of biomass, defined as the total matter produced by biological systems in a given ecosystem. The **carbon cycle** is more intimately associated with the energy transfers and trophic patterns in the biosphere than are other elements. Carbon exists predominantly in the mineral state and as an organic reservoir in the bodies of organisms. A smaller amount of carbon also exists in the gaseous state as carbon dioxide (CO_2), carbon monoxide (CO), and methane (CH_4). In general, carbon is recycled through ecosystems via carbon fixation, respiration, or fermentation of organic molecules, limestone decomposition, and methane production. A convenient starting point from which to trace the movement of carbon is with carbon dioxide gas, which occupies a central position in the cycle and represents a large common pool that diffuses into all parts of the ecosystem (**figure 26.6**). As a general rule, the cycles of oxygen and hydrogen are closely allied to the carbon cycle.

The principal users of the atmospheric carbon dioxide pool are photosynthetic autotrophs (photoautotrophs) such as plants, algae, and bacteria. An estimated 165 billion tons of organic material per year are produced by terrestrial and aquatic photosynthesis. Although we don't yet know exactly how many autotrophs exist in the earth's crust, a small amount of CO_2 is used by these bacteria

Figure 26.6 The carbon cycle. This cycle traces carbon from the CO_2 pool in the atmosphere to the primary producers (green), where it is fixed into protoplasm. Organic carbon compounds are taken in by consumers (blue) and decomposers (yellow) that produce CO_2 through respiration and return it to the atmosphere (pink). Combustion of fossil fuels and volcanic eruptions also add to the CO_2 pool (gray). Some of the CO_2 is carried into inorganic sediments by organisms that synthesize carbonate (CO_3) skeletons. In time, natural processes acting on exposed carbonate skeletons can liberate CO_2 .

(chemoautotrophs) that derive their energy from bonds in inorganic chemicals. A review of figure 8.28 reveals that phototrophs use energy from the sun to fix CO_2 into organic compounds such as glucose that can be used in synthesis. Photosynthesis is also the primary means by which the atmospheric supply of O_2 is regenerated (see the case study for this chapter).

Just as photosynthesis removes CO_2 from the atmosphere, other modes of generating energy, such as respiration and fermentation, can be used to remove and return it. As you may recall from the discussion of aerobic respiration in chapter 8, in the presence of O_2 , organic compounds such as glucose are degraded completely to CO_2 , with the release of energy and the formation of H_2O . Carbon dioxide is also released by anaerobic respiration and by certain types of fermentation reactions.

A small but important phase of the carbon cycle involves certain limestone deposits composed primarily of calcium carbonate (CaCO_3). Limestone is produced when marine organisms such as mollusks, corals, protozoans, and algae form hardened shells by combining carbon dioxide and calcium ions from the surrounding water. When these organisms die, the durable skeletal components accumulate in marine deposits rich in limestone. As these immense deposits are gradually exposed by geologic upheavals or receding ocean levels, various decomposing agents liberate CO_2 and return it to the CO_2 pool of the water and atmosphere.

The complementary actions of photosynthesis and respiration, along with other natural CO_2 -releasing processes such as limestone erosion and volcanic activity, have maintained a relatively stable atmospheric pool of carbon dioxide. Recent figures show that this balance is being disturbed as humans burn *fossil fuels* and other organic carbon sources. Fossil fuels, including coal, oil, and natural gas, were formed through millions of years of natural biological and geologic activities. Humans are so dependent upon this energy source that, over the past 55 years, the concentration of CO_2 in the atmosphere has steadily increased from 316 ppm to 400 ppm. Although this increase may seem slight and insignificant, most climatologists now feel it has begun to disrupt the delicate temperature balance of the biosphere (**26.1 Making Connections**).

Compared with carbon dioxide, methane gas (CH_4) plays a secondary part in the carbon cycle, though it can be a significant product in anaerobic ecosystems dominated by **methanogens** (methane producers), first discussed in chapter 7. In general, when methanogens reduce CO_2 by means of various oxidizable substrates, they give off CH_4 . The practical applications of methanogens are covered in chapter 27 in a section on sewage treatment, and their contribution to the greenhouse effect is also discussed in 26.1 Making Connections.

The Nitrogen Cycle

Nitrogen (N_2) gas is the most abundant component of the atmosphere, accounting for nearly 79% of air volume. As we will see, this extensive reservoir in the air is largely unavailable to most organisms. Only about 0.03% of the earth's nitrogen is combined (or fixed) in some other form such as nitrates (NO_3), nitrites (NO_2), ammonium ion (NH_4^+), and organic nitrogen compounds (proteins, nucleic acids).

The **nitrogen cycle** is relatively more intricate than other cycles because it involves such a diversity of specialized microbes to maintain the flow of the cycle. In many ways, it is actually more of

26.1 MAKING CONNECTIONS

Greenhouse Gases, Fossil Fuels, Cows, Swamps, and Global Warming

The sun's radiant energy helps maintain the stability of the earth's temperature and climatic conditions. As radiation impinges on the earth's surface, much of it is absorbed, but a large amount of the infrared (heat) radiation bounces back into the upper levels of the atmosphere. For billions of years, the atmosphere has been insulated by a layer of gases (primarily CO₂; CH₄; water vapor; and nitrous oxide, N₂O) formed by natural processes such as respiration, mineralization, and methanogenesis, which are linked to biogeochemical cycles. This layer traps a certain amount of the reflected heat yet also allows some of it to escape into space. As long as the amounts of heat entering and leaving are balanced, the mean temperature of the earth will not rise or fall in an erratic or life-threatening way. Although this phenomenon, called the **greenhouse effect**, is popularly viewed in a negative light, it must be emphasized that its function for eons has been primarily to foster life.

The greenhouse effect has lately been a matter of concern because *greenhouse gases* appear to be increasing at a rate that could disrupt the temperature balance. In effect, a denser insulation layer will trap more heat energy and gradually heat the earth. The amount of CO₂ released collectively by respiration, anaerobic microbial activity, fuel combustion, and volcanic activity has increased more than 30% since the beginning of the industrial era. By far the greatest increase in CO₂ production results from human activities such as combustion of fossil fuels, burning forests to clear agricultural land, and manufacturing. Deforestation has the added

Methane production from swamps may have an even greater effect on global warming than CO₂.

Source: U.S. Fish & Wildlife Service

impact of removing large areas of photosynthesizing plants that would otherwise consume some of the CO₂.

Originally, experts on the greenhouse effect were concerned primarily about higher CO₂ levels, but it now appears that the other greenhouse gases combined may have a great contribution as CO₂, and they, too, are increasing. One of these gases, methane (CH₄), is released by swamps and other natural sources, and it also comes from the gastrointestinal tracts of ruminant animals. Its levels have doubled over the past century. Methane traps 21 times more heat than does carbon dioxide. Other greenhouse gases such as nitrous oxide and sulfur dioxide (SO₂) are also increasing through automobile and industrial pollution.

There is little doubt in the scientific community that global warming is a reality. It has been documented that the mean temperature of the earth has increased by approximately 1.0°C since 1860. If the rate of increase continues, by 2050 a rise in the average temperature of 4°C to 5°C will escalate the melting of the polar ice caps and raise the levels of the ocean. Some experts predict extreme weather and climate change, including massive flooding of coastal regions, changes in rainfall patterns, expansion of deserts, and long-term climatic disruptions. Some of these effects have already been set in motion.

Throughout this text, we have emphasized the adaptability of microbes. Why is global warming considered such a serious problem even for them? Answer available on Connect.

a nitrogen “web” because of the array of adaptations that occur. Higher plants can utilize two inorganic forms of nitrogen, NO₃⁻ and NH₄⁺; animals must receive nitrogen in organic form from plants or other animals; however, microorganisms can use all forms of nitrogen: NO₂⁻, NO₃⁻, NH₄⁺, N₂, and organic nitrogen. The cycle includes four basic types of reactions: nitrogen fixation, ammonification, nitrification, and denitrification (**figure 26.7**).

Nitrogen Fixation The biosphere is most dependent upon the only process that can remove N₂ from the air and convert it to a form usable by living beings. This process, called **nitrogen fixation**, is the beginning step in the synthesis of virtually all nitrogenous compounds. Nitrogen fixation is brought about primarily by nitrogen-fixing bacteria in soil and water, though a small amount is formed through nonliving processes involving lightning. Nitrogen-fixing microbes have developed a unique enzyme system capable of breaking the triple bonds of the N₂ molecule and reducing the N atoms, an anaerobic process that requires the expenditure of considerable ATP. The primary product of nitrogen fixation is the

ammonium ion, NH₄⁺. Nitrogen-fixing bacteria live free or in a symbiotic relationship with plants. Among the common free-living nitrogen fixers are the aerobic *Azotobacter* and *Azospirillum*, certain members of the anaerobic genus *Clostridium*, and the cyanobacteria *Anabaena* and *Nostoc*.

Root Nodules: Natural Fertilizer Factories A significant symbiotic association occurs between **rhizobia*** (bacteria in the genera such as *Rhizobium*, *Bradyrhizobium*, and *Azorhizobium*) and **legumes*** (plants such as soybeans, peas, alfalfa, and clover that characteristically produce seeds in pods). The infection of legume roots by these gram-negative, motile, rod-shaped bacteria causes the formation of special nitrogen-fixing organs called **root nodules** (**figure 26.8**). This interaction can be highly specific, requiring a unique rhizobial species or strain for each type of legume. Nodulation begins when rhizobia colonize specific sites on root hairs. From

* *rhizobia* (ry-zoh'-bee-uh) Gr. *rhiza*, root, and *bios*, to live.

* *legumes* (leg'-yoom) L. *legere*, to gather.

Process Figure 26.7 Simplified events in the nitrogen cycle.

(1) **Nitrogen fixation:** Gaseous nitrogen (N_2) is acted on by nitrogen-fixing bacteria, which give off ammonia (NH_4^+). (2) **Nitrification:** Ammonia is converted to nitrite (NO_2^-) and nitrate (NO_3^-) by nitrifying bacteria. (3) **Organic Synthesis:** Plants, algae, and bacteria use nitrates to synthesize nitrogenous organic compounds (proteins, amino acids, nucleic acids). (4) **Assimilation:** Organic nitrogen compounds are used by animals and other consumers. (5) **Ammonification:** nitrogenous macromolecules from wastes and dead organisms are converted to NH_4^+ by ammonifying bacteria. NH_4^+ can be directly recycled into nitrates. (6) **Denitrification:** specialized bacteria reduce nitrates to nitrogen gas, which is returned to the atmosphere.

there, the bacteria invade deeper root cells and induce the cells to form tumorlike masses. The bacterium's enzyme system supplies a constant source of reduced nitrogen to the plant, and the plant furnishes nutrients and energy for the activities of the bacterium. The legume uses the NH_4^+ to aminate (add an amino group to) various carbohydrate intermediates and thereby synthesize amino acids and other nitrogenous compounds that are used in plant and animal synthesis.

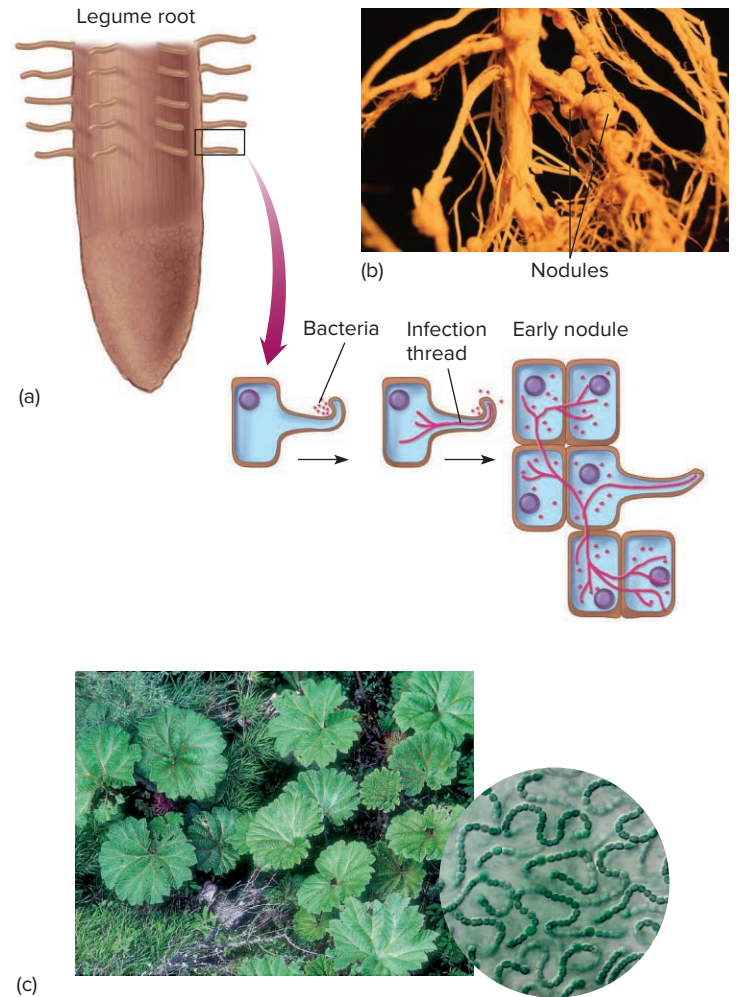

Figure 26.8 Nitrogen fixation through symbiosis. (a) Events leading to formation of root nodules. Cells of the bacterium *Rhizobium* attach to a legume root hair and cause it to curl. Invasion of the legume root proper by *Rhizobium* initiates the formation of an infection thread that spreads into numerous adjacent cells. The presence of bacteria in cells causes nodule formation. (b) Mature nodules within the roots of a legume. (c) *Gunnera* plants are involved in a mutualistic interaction with the cyanobacterial genus *Nostoc* (inset). *Nostoc* enters the base of the plant stem and initiates a symbiotic relationship, providing the plant with fixed nitrogen and receiving organic carbon in return. Lynch; (c) inset: © McGraw-Hill Education/Don Rubbelke, photographer

Plant-bacteria associations have great practical importance in agriculture, because an available source of nitrogen is often a limiting factor in the growth of crops. The self-fertilizing nature of legumes makes them valuable food plants in areas with poor soils and in countries with limited resources. It has been shown that crop health and yields can be improved by inoculating legume seeds with pure cultures of rhizobia, because the soil is often deficient in the proper strain of bacteria for forming nodules.

Ammonification, Nitrification, and Denitrification In another part of the nitrogen cycle, nitrogen-containing organic matter is decomposed by various bacteria (*Clostridium*, *Proteus*, for example)

that live in the soil and water. Organic detritus consists of large amounts of protein and nucleic acids from dead organisms and nitrogenous animal wastes such as urea and uric acid. The decomposition of these substances splits off amino groups and produces NH_4^+ . This process is thus known as **ammonification**. The ammonium released can be reused by certain plants or converted to other nitrogen compounds, as discussed next.

The oxidation of NH_4^+ to NO_2^- and NO_3^- is called **nitrification**. It is an essential conversion process for generating the most oxidized form of nitrogen (NO_3^-). This reaction occurs in two phases and involves two different kinds of chemoautotrophic bacteria in soil and water. In the first phase, certain gram-negative genera such as *Nitrosomonas*, *Nitrospira*, and *Nitrosococcus* oxidize NH_3 to NO_2^- as a means of generating energy. Nitrite is rapidly acted upon by a second group of nitrifiers, including *Nitrobacter*, *Nitrospira*, and *Nitrococcus*, which perform the *final* oxidation of NO_2^- to NO_3^- . Nitrates can be **assimilated** (incorporated into cell metabolism) through several routes by a variety of organisms (plants, fungi, and bacteria).

The nitrogen cycle is completed through **denitrification**, a series of reduction reactions that convert nitrate to atmospheric nitrogen. These reactions play a significant role in some forms of anaerobic respiration that use nitrate and other nitrogen-oxygen compounds as terminal electron acceptors. The first step, which involves the reduction of nitrate to nitrite, is so common that hundreds of different bacterial species can do it. Several species of *Bacillus*, *Pseudomonas*, *Spirillum*, *Rhodobacter*, and *Thiobacillus* can carry out denitrification to completion as follows:

The final product of this series returns nitrogen gas to its primary reservoir. Along the way, other gases—notably, nitrous oxide (N_2O)—are given off during incomplete denitrification. This is the main source of N_2O in the atmosphere and an important contributor to the greenhouse effect.

Sedimentary Cycles

The Sulfur Cycle

The **sulfur cycle** and the phosphorus cycle are similar in that both elements exist mostly in solid form and originate from natural sedimentary deposits in rocks, oceans, and lakes and not from the atmosphere. Sulfur exists in the elemental form (S) and as hydrogen sulfide gas (H_2S), sulfate (SO_4), and thiosulfate (S_2O_3). Most of the oxidations and reductions that convert one form of inorganic sulfur to another are accomplished by bacteria. Plants and many microorganisms can assimilate only SO_4 , and animals must have an organic source. Sulfur is found in the amino acids cysteine and methionine, both of which are essential to protein function.

One of the most remarkable contributors to the cycling of sulfur in the biosphere are the thiobacilli. These gram-negative, motile rods flourish in mud, sewage, bogs, mining drainage, and brackish springs that can be inhospitable to organisms that require complex organic nutrients. But the metabolism of these specialized lithotrophic bacteria is adapted to extracting energy by oxidizing elemental sulfur, sulfides, and thiosulfate. One species, *Thiobacillus thiooxidans*, is so efficient at this process that it

secretes large amounts of sulfuric acid into its environment, as shown by the following equation:

The marvel of this bacterium is its ability to create and survive in the most acidic habitats on the earth. It also plays an essential part in the phosphorus cycle, and its relative, *T. ferrooxidans*, participates in the cycling of iron. Other bacteria that can oxidize sulfur to sulfates are the photosynthetic sulfur bacteria mentioned in chapter 8.

The sulfates formed from oxidation of sulfurous compounds are assimilated into biomass by a wide variety of organisms. The sulfur cycle reaches completion when inorganic and organic sulfur compounds are reduced. Bacteria in the genera *Desulfovibrio* and *Desulfuromonas* anaerobically reduce sulfates to hydrogen sulfide (H_2S) or metal sulfide as the final step in electron transport. Sites in ocean sediments and mud where these bacteria live usually emanate a strong, rotten-egg stench from H_2S and may be blackened by the iron they contain.

The Phosphorus Cycle

Phosphorus is an integral component of DNA, RNA, and ATP, and all life depends upon a constant supply of it. It cycles between the abiotic and biotic environments almost exclusively as inorganic **phosphate** (PO_4) rather than its elemental form (**figure 26.9**). The chief inorganic reservoir is phosphate rock, which contains the insoluble compound fluorapatite, $\text{Ca}_5(\text{PO}_4)_3\text{F}$. Before it can enter biological systems, this mineral must be *phosphatized*—converted into more soluble PO_4^{3-} by the action of acid. Phosphate is released naturally when the sulfuric acid produced by *Thiobacillus* dissolves phosphate rock. Soluble phosphate in the soil and water is the principal source for autotrophs, which fix it onto organic molecules and pass it on to heterotrophs in this form. Organic phosphate is returned to the pool of soluble phosphate by decomposers, and it is finally cycled back to the mineral reservoir by slow geologic processes such as sedimentation. Because the low phosphate content of many soils can limit productivity, phosphate is added to soil to increase agricultural yields. The excess runoff of fertilizer into the hydrosphere is often responsible for overgrowth of aquatic pests (see eutrophication in section 26.5 and this chapter's Case Study).

Other Forms of Cycling

The involvement of microbes in cycling elements and compounds can be escalated by the introduction of toxic substances into the environment. Such toxic elements as arsenic, chromium, lead, and mercury, as well as hundreds of thousands of synthetic chemicals introduced into the environment over the past hundred years, are readily caught up in cycles by microbial actions. Some of these chemicals will be converted into less harmful substances, but others, such as PCB and heavy metals, persist and flow along with nutrients into all levels of the biosphere. If such a pollutant accumulates in living tissue and is not excreted, it can be accumulated by living things through the natural trophic flow of the ecosystem. These processes form the basis of **bioaccumulation** and **biomagnification**. Microscopic producers such as bacteria and algae begin the accumulation process. Consumers biomagnify the toxic substances by feeding on contaminated organisms, thereby increasing the amounts at each trophic level.

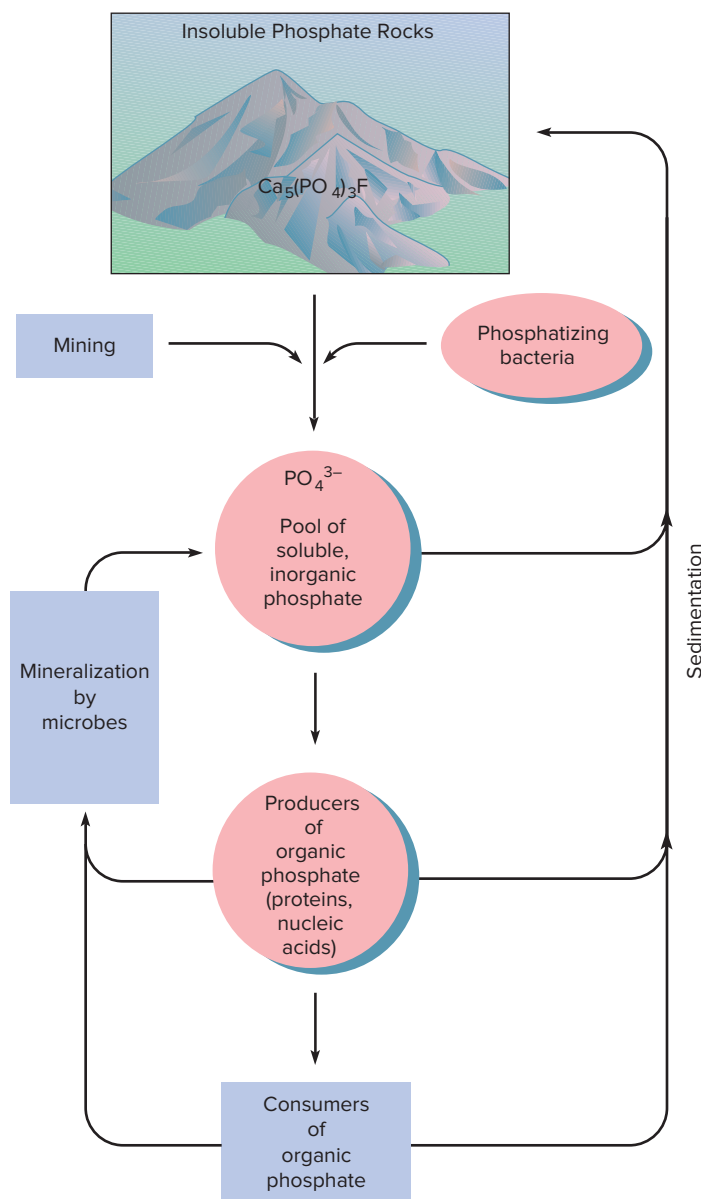

Figure 26.9 The phosphorus cycle. The pool of phosphate existing in sedimentary rocks is released into the ecosystem either naturally by erosion and microbial action or artificially by mining and the use of phosphate fertilizers. Soluble phosphate (PO_4^{3-}) is cycled through producers, consumers, and decomposers back into the soluble pool of phosphate, or it is returned to sediment in the aquatic biosphere.

One example of this is mercury compounds used in household antiseptics and disinfectants, agriculture, and industry. Mercury precipitates proteins by attaching to functional groups and is most toxic in the ethyl or methyl mercury form. Bacteria methylate mercury in sediments and contribute to its biomagnification through the food web. Recent studies have disclosed increased mercury content in fish taken from oceans and freshwater lakes in North America and even in canned tuna, adding to the risk in consumption of these products. This is another global problem that is being addressed by bioremediation (26.2 Making Connections).

Check Your Progress SECTION 26.3

- Outline the general characteristics of a biogeochemical cycle.
- What are the major sources of carbon, nitrogen, phosphorus, and sulfur?
- In what natural forms is carbon found? Name three ways carbon is returned to the atmosphere and a way it is fixed into organic compounds.
- What carbon compound is the least available for the majority of life forms and why is this the case?
- Describe nitrogen fixation, ammonification, nitrification, and denitrification and how microbes are involved.
- What form of nitrogen is required by plants? By animals?
- Summarize the main stages in the cycling of sulfur and phosphorus.
- Explain the processes of bioaccumulation and biomagnification of toxic elements and the problems they cause.

26.4 Terrestrial Microbiology: The Composition of the Lithosphere

Expected Learning Outcomes

- Describe the structure of soil and how it varies in content.
- Discuss the activities of microbes in the rhizosphere.
- Explain how bioremediation relates to soil and water.

Descriptions such as “soiled” or “dirty” may suggest to some that soil is an undesirable, possibly harmful substance; or its appearance might suggest a somewhat homogeneous, inert substance. At the microscopic level, however, soil is a dynamic ecosystem that supports complex interactions between numerous geologic, chemical, and biological factors. This rich region, part of the lithosphere, teems with microbes, serves a dynamic role in biogeochemical cycles, and is an important repository for organic detritus and dead terrestrial organisms.

The abiotic portion of soil is a composite of mineral particles, water, and atmospheric gas. The development of soil begins when geologic sediments are mechanically disturbed and exposed to weather and microbial action.

Rock decomposition releases various-size particles ranging from rocks, pebbles, and sand grains to microscopic morsels that lie in a loose aggregate (figure 26.10). The porous structure of soil creates various-size pockets or spaces that provide numerous microhabitats. Some spaces trap moisture and form a liquid phase in which mineral ions and other nutrients are dissolved. Other spaces trap air that will provide gases to soil microbes, plants, and animals. Because both water and air compete for these pockets, the water content of soil is directly related to its oxygen content. Water-saturated soils contain less oxygen, and dry soils have more. Gas tensions in soil can also vary vertically. In general, the concentration of O_2 decreases and that of CO_2 increases with the depth of soil. Aerobic and facultative organisms tend to occupy looser, drier soils, whereas anaerobes would adapt to waterlogged, poorly aerated soils.

26.2 MAKING CONNECTIONS

Bioremediation: The Pollution Solution?

The soil and water of the earth have long been considered convenient repositories for solid and liquid wastes. Humans have been burying solid wastes for thousands of years, but the process has escalated in the past 50 years. Every year in the United States, about 250 million tons of pollutants, industrial wastes, and garbage are deposited into the natural environment. Often, this dumping is done with the mistaken idea that naturally occurring microbes will eventually biodegrade (break down) waste material.

Landfills currently serve as a final resting place for hundreds of castoffs from an affluent society, including yard wastes, paper, glass, plastics, wood, textiles, rubber, metal, paints, and solvents. This conglomeration is dumped into holes and is covered with soil. Although it is true that many substances are readily biodegradable, materials such as plastics and glass are not. Successful biodegradation also requires a compost containing specific types of microorganisms, adequate moisture, and oxygen. The environment surrounding buried trash provides none of these conditions. Large, dry, anaerobic masses of plant materials, paper, and other organic materials will not be successfully attacked by the aerobic microorganisms that dominate in biodegradation. As we continue to fill up hillsides with waste, the future of these landfills is a prime concern. One of the most serious of these concerns is that they will be a source of toxic compounds that seep into the ground and water.

Pollution of groundwater, the primary source of drinking water for 100 million people in the United States, is an increasing problem. Because of the extensive cycling of water through the hydrosphere and lithosphere, groundwater is often the final collection point for hazardous chemicals released into lakes, streams, oceans, and even garbage dumps. Many of these chemicals are pesticide residues from agriculture (dioxin, selenium, 2,4-D), industrial hydrocarbon wastes (PCBs), and hydrocarbon solvents (benzene, toluene).

They are often hard to detect, and, if detected, are hard to remove. Recently, the technique of hydraulic fracturing (fracking), in which chemicals are injected into the Earth under high pressure to liberate trapped oil, has come under scrutiny as a potential source of groundwater pollution.

For many years, polluted soil and water were simply sealed off or dredged and dumped in a different site, with no attempt to get rid of the pollutant. But now, with greater awareness of toxic wastes, many Americans are adopting an attitude known as NIMBY (Not in my backyard!), and environmentalists are troubled by the long-term effects of contaminating the earth.

In a search for solutions, waste management has turned to **bioremediation**—using microbes to break down or remove toxic wastes from water and soil. Some of these waste-eating microbes are soil and water residents with a natural capacity to decompose even artificial substances. Because the normal, unaided process occurs too slowly, most cleanups are accomplished by commercial bioremediation services that treat the contaminated soil with oxygen, nutrients, and water to increase the rate of microbial action. Through these actions, levels of pesticides such as 2,4-D can be reduced to 96% of their original levels, and solvents can be reduced from 1 million parts per billion (ppb) to 10 ppb or less.

Among the most important bioremediation microbes are species of *Pseudomonas* and *Bacillus* and various toxin-eating fungi. Although much

recent work has focused on creating “superbugs” through genetic engineering, public resistance to releasing genetically modified organisms (or GMOs) in the environment is high. Thankfully, naturally occurring biodegraders are plentiful, and efforts to optimize their performance have had some success. A bacterium showing the most versatile capacity for bioremediation is *Geobacter*. This extremophile thrives on heavy metals and other toxicants. It has been used successfully to clean up petroleum spills and uranium waste.

So far about 35 recombinant microbes have been created for bioaugmentation (the release of selected GMOs to improve bioremediation). Species of *Rhodococcus* and *Burkholderia* have been engineered to decompose PCBs, and certain forms of *Pseudomonas* now contain genes for detoxifying heavy metals, carbon tetrachloride, and naphthalene. With over 3,000 toxic waste sites in the United States alone, the need for effective bioremediation is a top priority.

The passage of time has given us renewed insights into the problems of remediating huge contamination events such as oil spills. Twenty-eight years ago, the oil tanker *Exxon Valdez* ran aground on Prince William Sound in Alaska. Almost 41 million liters of crude oil were spilled into the beautiful, pristine wilderness of the sound. Initially, steam was applied under high pressure, a technique that seemed to work. The primary benefit of steam cleaning the shores was quick removal of large quantities of oil. But an adverse effect of the cleaning was to wipe out many of the bacteria that could have facilitated a more complete removal of the oil.

Another part of the cleanup strategy relied on the presence of natural communities of microorganisms that could help degrade the oil. Many microorganisms—even those inhabiting the rocks on the shores of the sound—can use oil as a source of carbon and energy. However, without added nutrients, bacterial metabolism and bioremediation often do not proceed very quickly. Understanding this, environmental microbiologists attempted to accelerate bioremediation of the oil spill by applying fertilizers containing nitrogen and phosphorus.

Today, the shores superficially appear as they were before the oil spill. Closer examination, unfortunately, reveals that oil still remains. The high-pressure cleaning forced it deeper into the rocky shores, inaccessible to microbial action. The tragedy of the *Exxon Valdez* serves as a forceful reminder of the impact of humans on nature and the limitations inherent in microbial cleanup of toxic substances.

What are some other solutions to cleaning up or getting rid of wastes and pollutants, besides microbial action? *Answer available on Connect.*

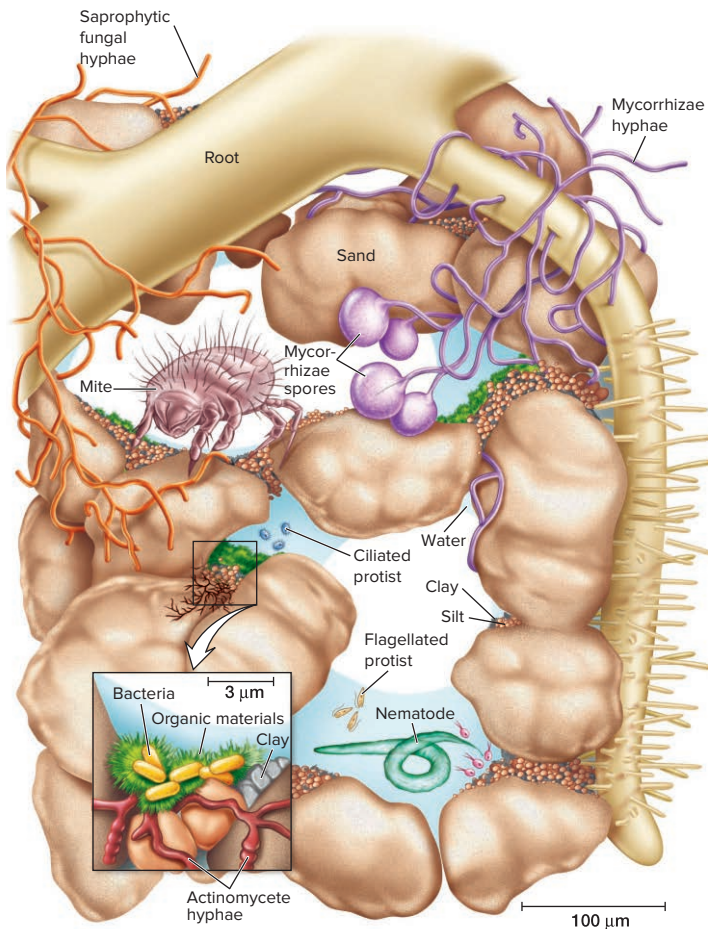

Figure 26.10 The soil habitat. A typical soil habitat contains a mixture of clay, silt, and sand along with soil organic matter. Roots and animals (e.g., nematodes and mites), as well as protozoa and bacteria, consume oxygen, which rapidly diffuses into the soil pores where the microbes live. Note that two types of fungi are present: mycorrhizal fungi, which derive their organic carbon from plant roots; and saprophytic fungi, which help degrade organic material.

Within the superstructure of the soil are varying amounts of **humus**,* the slowly decaying organic litter from plant and animal tissues. This soft, crumbly mixture holds water like a sponge. It is also an important habitat for microbes that decompose the complex litter and recycle nutrients.

The humus content varies with climate, temperature, moisture and mineral content, and microbial action. Warm, tropical soils have a high rate of humus production and microbial decomposition. Because nutrients in these soils are swiftly released and used up, they do not accumulate. Fertilized agricultural soils in temperate climates build up humus at a high rate and are rich in nutrients. The very low content of humus and moisture in desert soils greatly reduces its microbial biota, rate of decomposition, and nutrient content. Bogs are likewise nutrient-poor due to a slow rate of decomposition of the humus caused by high acid content and lack of oxygen. Humans can artificially increase the amount of humus by mixing plant refuse and animal wastes with soil and allowing natural decomposition to occur, a process called *composting*. Composting is a very active

metabolic process that generates a great deal of heat. The temperature inside a well-maintained compost can reach 80°C to 100°C.

Living Activities in Soil

The rich culture medium of the soil supports a fantastic array of microorganisms (bacteria, fungi, algae, protozoa, and viruses). A gram of moist loam soil with high humus content can have a microbe count as high as 10 billion, each competing for its own niche and microhabitat. Some of the most distinctive biological interactions occur in the **rhizosphere**, the zone of soil surrounding the roots of plants, which contains associated bacteria, fungi, and protozoa (see figure 26.10). Plants interact with soil microbes in a truly synergistic fashion. Studies have shown that a rich microbial community grows in a biofilm around the root hairs and other exposed surfaces. Their presence stimulates the plant to exude growth factors such as carbon dioxide, sugars, amino acids, and vitamins. These nutrients are released into fluid spaces, where they can be readily captured by microbes. Bacteria and fungi likewise contribute to plant survival by releasing hormonelike growth factors and protective substances. They also convert minerals into forms usable by plants. We saw numerous examples in the nitrogen, sulfur, and phosphorus cycles.

We previously observed that plants can form close symbiotic associations with microbes to fix nitrogen. Other mutualistic partnerships between plant roots and microbial fungi are **mycorrhizae**.* These associations occur when various species of basidiomycetes, ascomycetes, or zygomycetes attach themselves to the roots of vascular plants (**figure 26.11**). The plant feeds the fungus through photosynthesis, and the fungus sustains the relationship in several ways. By extending its mycelium into the rhizosphere, it helps anchor the plant and increases the surface area for capturing water from dry soils and minerals from poor soils. Plants with mycorrhizae can inhabit severe habitats more successfully than plants without them.

The topsoil, which extends a few inches to a few feet from the surface, supports a host of burrowing animals such as nematodes, termites, and earthworms. Many of these animals are decomposer-reducer organisms that break down organic nutrients through digestion and also mechanically reduce or fragment the size of particles so that they are more readily mineralized by microbes. Aerobic bacteria initiate the digestion of organic matter into carbon dioxide and water and generate minerals such as sulfate, phosphate, and nitrate, which can be further degraded by anaerobic bacteria. Fungal

26.1 Secret World of Microbes

Just How Old Is That Body?

When a body is found, crime scene investigators and medical examiners are often called upon to estimate the time of death, whether in real life or, more famously, on television. For short periods of time, body temperature, rigor mortis, and lividity (the manner in which blood settles after death) provide a good estimate. After a few days, however, bodies begin to decompose, helped along by saprophytic microorganisms. Until recently, little was known about the precise speed with which this occurred, and the rate at which decomposition was affected by the environment. Enter the Forensic Anthropology Center at the University of Tennessee, more commonly known as the “Body Farm.” On a 2.5-acre wooded area surrounded by barbed wire, as many as 40 human bodies can be found in various states of decay. Whether shaded by a tree, exposed to the sun, clothed or not, even partially buried, each corpse is attended to by researchers and graduate students, who carefully record the rate and manner at which decomposition occurs. Beginning with the first corpse—labeled 1-81, for the month and year of his death—the actions of bacteria, fungi, and insects have been meticulously cataloged, and the decomposition process divided into four stages: fresh, bloat, decay, and dry. Research on the Body Farm has allowed forensic scientists to estimate the postmortem interval with greater accuracy than ever before. Beyond the obvious support of criminal cases, scientists have also begun to study the hundreds of different chemicals produced during decomposition, using some of the chemicals to train dogs to track human corpses, an activity carried out not only with regard to the search for murder victims but also after natural disasters. Since patient 1-81, the success of the Body Farm has spawned five additional outdoor

laboratories across the United States. It seems that death may in fact be a growth industry.

How would you expect environmental factors like temperature and sunlight to affect a body’s rate of decomposition? *Answer available on Connect.*

enzymes increase the efficiency of soil decomposition by hydrolyzing complex natural substances such as cellulose, keratin, lignin, chitin, and paraffin (**26.1 Secret World of Microbes**).

The soil is also a repository for agricultural, industrial, and domestic wastes such as insecticides, herbicides, fungicides, manufacturing wastes, and household chemicals. Applied microbiologists, using expertise from engineering, biotechnology, and ecology, work to explore the feasibility of harnessing indigenous soil microbes to break down undesirable hydrocarbons and pesticides (see 26.2 Making Connections).

26.5 The Microbiology of the Hydrosphere

Expected Learning Outcomes

14. Recall the main aspects of the hydrologic cycle.
15. Describe the structure of aquatic ecosystems.
16. Explain how aquatic environments vary in nutrient content.
17. Relate the principles involved in water monitoring.
18. Summarize the primary methods of assessing the microbiological quality of water.

The Hydrologic Cycle

Water occupies nearly three-fourths of the earth’s surface. In the same manner as minerals, the earth’s supply of water is continuously cycled between the hydrosphere, atmosphere, and lithosphere (**figure 26.12**). The **hydrologic cycle** begins when surface water (lakes, oceans, rivers) exposed to the sun and wind evaporates and enters the vapor phase of the atmosphere. Living beings contribute to this reservoir by various activities. Plants lose moisture through transpiration (evaporation through leaves), and all aerobic organisms give off water during respiration. Airborne moisture accumulates in the atmosphere, most conspicuously as clouds.

Water is returned to the earth through condensation or precipitation (rain, snow). The largest proportion of precipitation falls back into surface waters, where it circulates rapidly between running water and standing water. Only about 2% of water seeps into the earth or is bound in ice, but these are very important reservoirs. **Table 26.2** shows how water is distributed in the various surface compartments. Surface water collects in extensive subterranean pockets produced by the underlying layers of rock, gravel, and sand. This process forms a deep groundwater source called an **aquifer**. The water in aquifers circulates very slowly and is an important replenishing source for surface water. It can resurface through

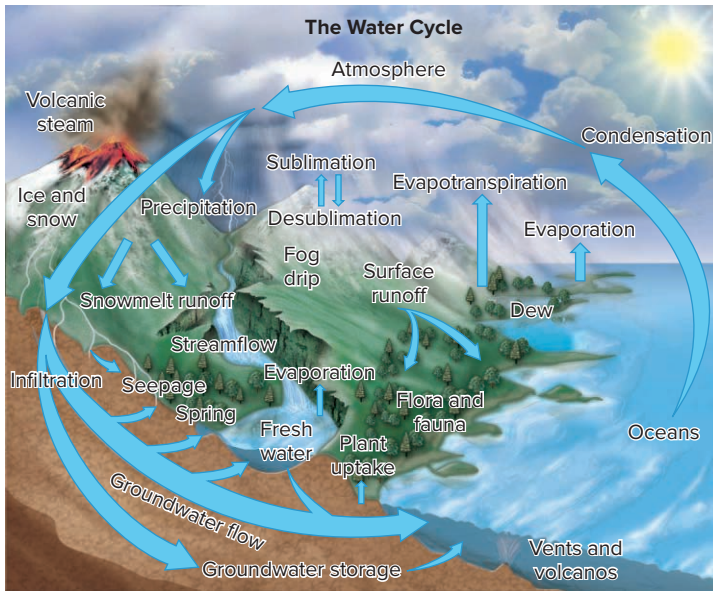

Figure 26.12 The hydrologic cycle. The largest proportion of water cycles through evaporation, transpiration (together referred to as evapotranspiration), and precipitation between the hydrosphere and the atmosphere. Other reservoirs of water exist in the groundwater or deep storage aquifers in sedimentary rocks. Plants add to this cycle by releasing water through transpiration, and heterotrophs release it through respiration.

TABLE 26.2 Distribution of Water on Earth's Surface

Water Source	Water Volume, in Cubic Miles	Percentage of Total Water
Oceans	317,000,000	97.24
Ice caps, glaciers	7,000,000	2.14
Groundwater	2,000,000	0.61
Freshwater lakes	30,000	0.009
Inland seas	25,000	0.008
Soil moisture	16,000	0.005
Atmosphere	3,100	0.001
Rivers	300	0.0001
Total		100

springs, geysers, and hot vents, and it is also tapped as the primary supply for one-fourth of all water used by humans.

Although the total amount of water in the hydrologic cycle has not changed over millions of years, its distribution and quality have been greatly altered by human activities. Two serious problems have arisen with aquifers. First, as a result of increased well drilling, land development, and persistent local droughts, the aquifers in many areas have not been replenished as rapidly as they have been depleted. As these reserves are used up, humans will have to rely on other delivery systems such as pipelines, dams, and reservoirs, which can further disrupt the cycling of water. Second, because water picks up materials when falling through air or percolating through the ground, aquifers are also important collec-

tion points for pollutants. As we will see, the proper management of water resources is one of the greatest challenges of this century.

The Structure of Aquatic Ecosystems

Surface waters such as ponds, lakes, oceans, and rivers differ to a considerable extent in size, geographic location, and physical and chemical character. Although an aquatic ecosystem is composed primarily of liquid, it is predictably structured, and it contains significant gradients or local differences in composition. Factors that contribute to the development of zones in aquatic systems are sunlight, temperature, aeration, and dissolved nutrient content. These variations create numerous macro- and microenvironments for communities of organisms. An example of zonation can be seen in the schematic section of a freshwater lake in **figure 26.13**.

A lake is stratified vertically into three zones, or strata. The uppermost region, called the **photic zone**, extends from the surface

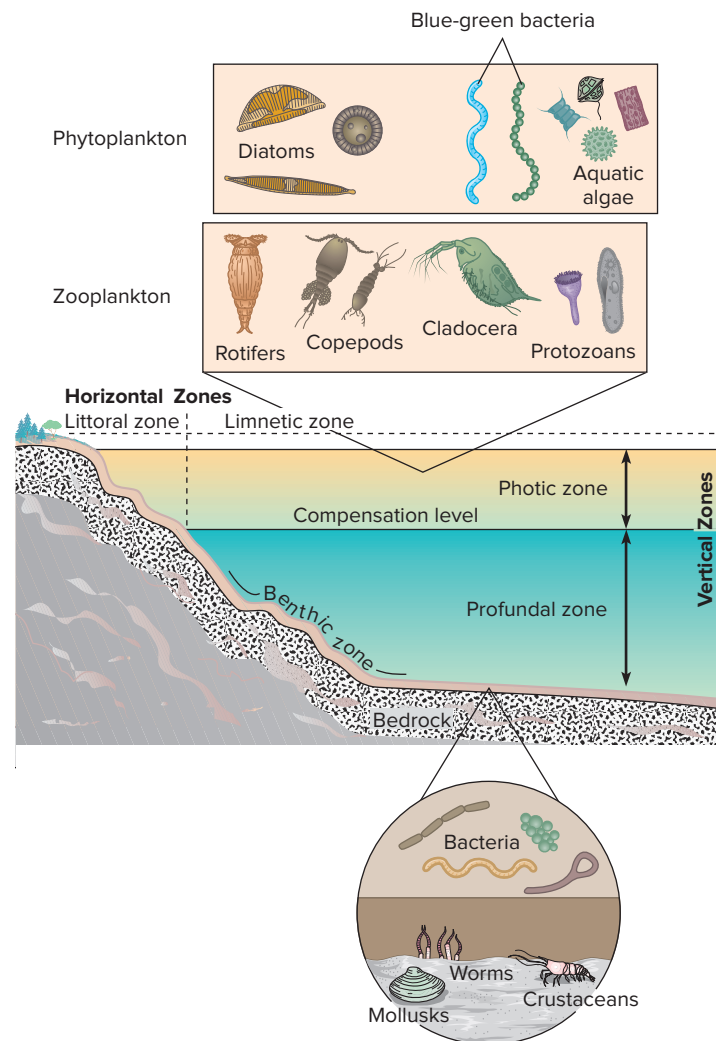

Figure 26.13 Zones of life in a freshwater lake. Depth changes in this ecosystem create significant zones that differ in light penetration, temperature, and community structure. Plankton suspended in upper zones float with the currents, whereas benthic organisms remain in or near the sediments.

to the lowest limit of sunlight penetration. Its lower boundary (the compensation depth) is the greatest depth at which photosynthesis can occur. Directly beneath the photic zone lies the **profundal* zone**, which extends from the edge of the photic zone to the lake sediment. The sediment itself, or **benthic* zone**, is composed of organic debris and mud, and it lies directly on the bedrock that forms the lake basin. The horizontal zonation includes the shoreline, or **littoral* zone**, an area of relatively shallow water. The open, deeper water beyond the littoral zone is the **limnetic* zone**.

Marine Environments

The ocean exhibits extreme variations in salinity, depth, temperature, hydrostatic pressure, and mixing. Even so, it supports a great abundance of bacteria and viruses, the extent of which has only been appreciated in very recent years. It contains a unique zone where the river meets the sea called an *estuary*. This region fluctuates in salinity, is very high in nutrients, and supports a specialized microbial community. It is often dominated by salt-tolerant species of *Pseudomonas* and *Vibrio*. Another important factor is the tidal and wave action that subjects the coastal habitat to alternate periods of submersion and exposure. The deep ocean, or **abyssal zone**, is poor in nutrients and lacks sunlight for photosynthesis, and its tremendous depth (up to 10,000 meters) makes it oxygen-poor and cold (average temperature 4°C). This zone supports communities with extreme adaptations, including halophilic, psychrophilic, barophilic, and anaerobic lifestyles.

Aquatic Communities

The freshwater environment is a site of tremendous microbiological activity. Microbial distribution is associated with sunlight, temperature, oxygen levels, and nutrient availability. The uppermost portion is the most productive self-sustaining region because it contains large numbers of **plankton***, a floating microbial community that drifts with wave action and currents. A major member of this assemblage is the phytoplankton, containing a variety of photosynthetic algae and cyanobacteria. The phytoplankton provide nutrition for **zooplankton**, microscopic consumers such as protozoa and invertebrates that filter, feed, prey, or scavenge. The plankton support numerous other trophic levels such as larger invertebrates and fish. With its high nutrient content, the deeper region also supports an extensive variety and concentration of organisms, including aquatic plants, aerobic bacteria, and anaerobic bacteria actively involved in recycling organic detritus.

The Microbial Loop

Microbes are the only collection of organisms that participate at all levels of an aquatic ecosystem. One of their most important roles is to drive a central processing scheme ecologists call the **microbial loop**. This term denotes the dynamic interplay that keeps nutrients cycling around in a continuous loop, so that they can be made available to

the entire trophic structure. Microbes contribute to this system in numerous ways, most notably as producers, primary consumers, decomposers, and mineralizers. Their actions maintain a pool of nutrients called the *dissolved organic matter* (DOM) (**figure 26.14**).

Figure 26.14 The microbial loop. This describes the complex nutrient cycle in aquatic habitats driven primarily by microorganisms. All organisms contribute to a pool of dissolved organic matter, but the protists, bacteria, and viruses keep it in dynamic flux through a constant process of removal and replenishment. The pattern of loop flow is shown in gray.

Larger bodies of standing water develop gradients in temperature or thermal stratification, especially during the summer (**figure 26.15**). The upper region, called the *epilimnion*, is warmest, and the deeper *hypolimnion* is cooler. Between these is a buffer zone, the **thermocline**, which ordinarily prevents the mixing of the two. Twice a year, during the warming cycle of spring and the cooling cycle of fall, temperature changes in the water column break down the thermocline and cause the water from the two strata to mix. Mixing disrupts the stratification and creates currents that bring nutrients up from the sediments, a process called *upwelling* (**figure 26.15b**).

Because oxygen is not very soluble in water and is rapidly used up by the plankton, its concentration exists in a gradient from highest in the epilimnion to lowest at the lower levels. In general, the amount of oxygen that can be dissolved is dependent on temperature, and warmer water holds less oxygen than cooler water. Of all the characteristics of water, the greatest range occurs in nutrient levels. Nutrient-deficient aquatic ecosystems are called **oligotrophic***. Species that can make a living on such starvation rations are *Hyphomicrobium* and *Caulobacter*. These bacteria have special

stalks that capture even minuscule amounts of hydrocarbons present in oligotrophic habitats. Viruses are also well represented in aquatic habitats, with oceans and lakes containing as many as 10 million viral particles per milliliter. Most of these viruses pose no danger to humans, but as parasites of bacteria, they appear to be a natural control mechanism for these populations.

At the other extreme are waters overburdened with organic matter and dissolved nutrients. Some nutrients are added naturally through seasonal upwelling and disasters (floods or typhoons). One outcome of upwelling in the ocean is the phenomenon known as *red tides* (**figure 26.16**). These periodic events are caused by dinoflagellates that grow rapidly in the enriched water and produce a potent muscle toxin. Shellfish that filter feed can concentrate these microbes and their toxins in their tissues. When people eat contaminated clams, mussels, and oysters, they are at risk for paralytic shellfish poisoning. People in coastal areas are cautioned not to eat shellfish during those months associated with red tides, which varies from region to region.

Another significant alteration of natural waters comes from effluents from sewage, agriculture, and industry that contain heavy loads of organic debris or nitrate and phosphate fertilizers. The addition of excess quantities of nutrients to aquatic ecosystems, termed **eutrophication**,* often wreaks havoc on the communities

* *eutrophication* (yoo'-troh-fih-kay'-shun) Gr. *eu*, good.

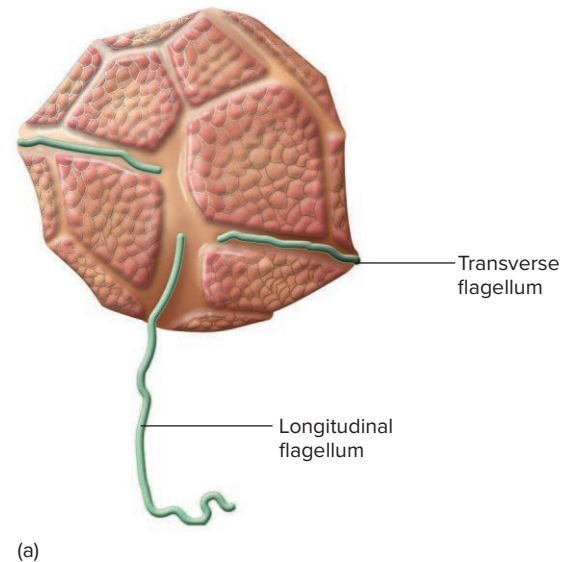

Figure 26.16 Red tides. (a) Single-celled red algae called dinoflagellates (*Karenia* shown here) bloom in high-nutrient, warm seawater and impart a noticeable red color to it, as shown in (b). involved. The sudden influx of abundant nutrients, along with warm temperatures, encourages a heavy surface growth of cyanobacteria and algae called a bloom (**figure 26.17**). This heavy mat of biomass effectively shuts off the oxygen supply to the lake below. The oxygen content below the surface is further depleted by aerobic heterotrophs that actively decompose the organic matter. The lack of oxygen greatly disturbs the ecological balance of the community. It causes massive die-offs of strict aerobes (fish, invertebrates), and only anaerobic or facultative microbes will survive.

Water Monitoring to Prevent Disease

Microbiology of Drinking Water Supplies We do not have to look far for overwhelming reminders of the importance of safe water. Worldwide epidemics of cholera have killed thousands of people, and an outbreak of *Cryptosporidium* in Wisconsin affecting over 400,000 people was traced to a contaminated municipal water supply. In a large segment of the world's population, the lack of sanitary water is responsible for billions of cases of diarrheal illness

Figure 26.17 Heavy surface growth of algae and cyanobacteria in a eutrophic pond. © McGraw-Hill Education/Pat Watson, photographer

that kills nearly a million children each year. In the United States, more than 10 million people develop water-borne illness every year.

Good health is dependent upon a clean, **potable** (drinkable) water supply. This means the water must be free of pathogens; dissolved toxins; and disagreeable turbidity, odor, color, and taste. As we shall see, water of high quality does not come easily, and we must look to microbes as part of the problem and part of the solution.

Through ordinary exposure to air, soil, and effluents, surface waters usually acquire harmless, saprobic microorganisms. But along its course, water can also pick up pathogenic contaminants. Among the most prominent water-borne pathogens of recent times are the protozoans *Giardia* and *Cryptosporidium*; the bacteria *Campylobacter*, *Salmonella*, *Shigella*, *Vibrio*, and *Mycobacterium*; and hepatitis A and noroviruses. Some of these agents (especially encysted protozoans) can survive in natural waters for long periods without a human host, whereas others are present only transiently and are rapidly lost. The microbial content of drinking water must be continuously monitored to ensure that the water is free of infectious agents.

Attempting to survey water for specific pathogens can be very difficult and time-consuming, so most assays of water purity are more focused on detecting fecal contamination. High fecal levels can mean the water contains pathogens and is consequently unsafe to drink. Thus, wells, reservoirs, and other water sources can be analyzed for the presence of various **indicator bacteria**. These species are intestinal residents of birds and mammals, and they are readily identified using routine lab procedures.

Enteric bacteria most useful in the routine monitoring of microbial pollution are gram-negative rods called *coliforms* and enteric *streptococci*, which survive in natural waters but do not multiply there. Finding them in high numbers thus implicates recent or high levels of fecal contamination. Environmental Protection Agency standards for water sanitation are based primarily on the levels of coliforms, which are described as gram-negative, lactose-fermenting, gas-producing bacteria such as *Escherichia coli*, *Enterobacter*, and *Citrobacter*. Fecal contamination of marine waters that poses a risk for gastrointestinal disease is more readily correlated with gram-positive cocci, primarily in the genus

Enterococcus. Occasionally, coliform bacteriophages and enteric viruses are good indicators of fecal pollution, but their detection is more difficult and more technically demanding.

Water Quality Analysis A rapid method for testing the total bacterial levels in water is the *standard plate count*. In this technique, a small sample of water is spread over the surface of a solid medium. The numbers of colonies that develop provide an estimate of the total viable population without differentiating coliforms from other species. This information is particularly helpful in evaluating the effectiveness of various water purification stages. Another general indicator of water quality is the level of dissolved oxygen it contains called the *biological oxygen demand (BOD)*. It is established that water containing high levels of organic matter and bacteria will have a lower oxygen content because of consumption by aerobic respiration.

Coliform Assays Water quality departments employ some standard assays for routine detection and quantification of coliforms. The techniques available are

- simple tests, such as Presence-Absence broth, that detect coliform activity but do not quantify it;
- rapid tests that isolate coliform colonies and provide quantities of coliforms present; and
- rapid tests that identify specific types of coliforms and determine their numbers.

In many circumstances (drinking water, for example), it is important to *differentiate* between facultative **coliforms** (*Enterobacter*) that are often found in other habitats (soil, water) and true **fecal coliforms** that live mainly in human and animal intestines. At one time, it was too difficult to differentiate *E. coli* from the closely related species of *Citrobacter*, *Klebsiella*, and *Enterobacter*, so laboratories instead simply reported whether a sample contained any of these isolates. All of these bacteria ferment lactose and are phenotypically similar. The terminology adopted was “coliform-,” meaning *E. coli*-like. In other words, such bacteria present in the sample were not necessarily *E. coli*.

Recently, microbiologists have noted serious problems with the use of coliform counts to indicate fecal contamination. The main issue is that the three other bacterial genera already mentioned, among others, are commonly found growing in nonfecal environments such as fresh water and plants that eventually become food. In other words, if the tests are not specifically for *E. coli*, you can't be sure that feces are present.

New Environmental Protection Agency Regulations change the way water quality testing is approached. These new rules require routine monitoring of public water systems, with the monitoring frequency correlated to the number of persons supplied by the system. For example, a public water system serving 2,500 people would be required to monitor the water supply twice a month, whereas one serving 2,500,000 would be required to monitor at least 420 times monthly. These samples would be tested for the presence of total coliforms, and a positive result would require several follow-up tests from the same area of the system. Only if a follow-up test is positive would specific testing for *E. coli* be required. Although the new rules alter the manner in which testing

will be accomplished, the tests themselves, as outlined in the following paragraphs, will remain essentially the same.

Standard Coliform Testing **Presence-Absence broth**, as its name implies, tests simply for the presence of coliforms in a water sample, whereas other selective and differential media can be used to identify *E. coli* specifically (figure 26.18a,b). The **membrane filter** method is a widely used rapid method suitable for the field or lab to process and test larger quantities of water. This method is more suitable for dilute fluids, such as drinking water, that are relatively free of particulate matter, and it is less suitable for water containing heavy microbial growth or debris. This technique is related to the method described in chapter 11 for sterilizing fluids by filtering out microbial contaminants, except that in this system, the filter containing the trapped microbes is the desired end product. The steps in membrane filtration are diagrammed in figure 26.18c,d. After filtration, the membrane filter is placed in a Petri dish containing selective and differential media. After incubation, both total and fecal coliform colonies can be counted and often presumptively identified by their distinctive characteristics on these media (figure 26.18e).

Another more time-consuming but useful technique is the **most probable number (MPN)** procedure, which detects coliforms by a series of **presumptive, confirmatory, and completed** tests. The MPN procedure requires several dozen tubes of media to be inoculated, incubated, and evaluated over the course of 3 days. The results are then subjected to a mathematical analysis, which determines the statistically most likely number of coliforms (see Appendix B and table B.2). Its main drawback, beyond time and expense, is that it does not differentiate between total and fecal coliforms.

(a) Phenol red broth supplemented with lactose is often used as a preliminary indicator of the presence of coliforms. The medium contains lactose and a pH indicator, along with nutrients needed to support bacterial growth. The presence of coliforms leads to fermentation of the lactose, lowering the pH and causing the medium to turn from red (negative) to yellow (positive). A small inverted tube (called a Durham tube) is placed within the larger culture tube to trap any gas that is produced by the bacteria.

(b) EC medium with MUG is used to detect *Escherichia coli*. Selective agents inhibit gram-positive bacteria, while MUG (4-methylumbelliferyl- β -D-glucuronide) acts as a substrate that only *E. coli* can hydrolyze to produce a fluorescent product as seen in the tube on the left (a negative reaction is seen in the tube on the right). Typically, in a positive reaction, gas from fermentation is also observed (note the bubbles at the surface of the media in the tube on the left).

When water tests negative for coliforms, it is generally considered fit for human consumption. While the new regulations—more correctly known as the *Revised Total Coliform Rule*—do allow for a small number of total coliform-positive samples, there is no acceptable level for fecal coliforms, enterococci, viruses, or pathogenic protozoans in drinking water. Water that will not be consumed, but is used for fishing or swimming, is permitted to have counts up to about 126 coliforms per 100 ml.

(c) Membrane filter technique. The water sample is filtered through a sterile membrane filter assembly and collected in a flask.

(d) The filter is removed and placed in a small Petri dish containing a differential selective medium such as M-FD endo agar and incubated.

(e) On M-FD endo medium, colonies of *Escherichia coli* often yield a noticeable metallic sheen. The medium permits easy differentiation of various genera of coliforms, and the grid pattern can be used as a guide for rapidly counting the colonies.

Check Your Progress SECTIONS 26.4 AND 26.5

15. Describe the composition of the soil, the rhizosphere, and humus.
16. Outline the modes of cycling water through the lithosphere, hydrosphere, and atmosphere.
17. What are the roles of precipitation, condensation, respiration, transpiration, surface water, and aquifers?
18. What causes the formation of the epilimnion, hypolimnion, and thermocline?
19. What is upwelling and how is it important?
20. Why must water be subjected to microbiological analysis?
21. What are the characteristics of good indicator organisms, and why are they monitored rather than pathogens?
22. Give specific examples of indicator organisms and water-borne pathogens.
23. Describe two methods of water analysis.

CASE STUDY Part 2

If you were designing an ecosystem to favor the growth of algae and cyanobacteria, you couldn't do much better than the area encompassing Lake Erie. The lake is surrounded by more cropland and pasture than any of the other Great Lakes and has far less undisturbed forests and wetlands. Consequently the Lake Erie watershed contains higher amounts of phosphorous (from fertilizer) and nitrogen (from animal waste) than any of the other Great Lakes. Lake Erie is also the shallowest of the

Great Lakes, with a depth of just 210 feet, meaning it gets far more sunlight and is warmer than the other lakes. By comparison, Lake Superior is over 1,300 feet deep. Together these factors ensure that photosynthesis occurs exceptionally well, making Lake Erie the most productive of the Great Lakes. Throughout the latter half of the twentieth century, harmful algae blooms in Lake Erie had become increasingly common, and in 2011 the microcystin levels in Maumee Bay briefly reached 1,200 PPB, more than 750 times the level considered safe. Toledo has long been aware of its water problems and has been working on a number of solutions. Over 80% of the phosphorous that enters the lake does so during severe rainstorms, so rules have been established that prohibit fertilization when rain is in the forecast. Broadcast application of fertilizer has also been discouraged, as this leaves the fertilizer on top of the soil and encourages runoff. Climate change has increased the number of storm runoff events, and an increase in the severity of storms has in many cases driven cyanobacteria far below the surface of the lake and closer to subsurface water intakes. The city of Toledo has installed a number of buoys that transmit information about water temperature, wind, and cyanobacteria concentration in the area of the water intake, allowing additional purification measures to be implemented if needed.

- *Those who study the Great Lakes describe Lake Erie as having "2% of the water but 50% of the fish." How might continued harmful algal blooms affect this description?*

Chapter Summary with Key Terms
26.1 Ecology: The Interconnecting Web of Life

This chapter emphasizes microbial activities that help maintain, sustain, and control the life support systems on the earth. This includes the natural roles of microorganisms in the environment and their contributions to the ecological balance, including soil, water, and mineral cycles.

- A. Microbial ecology deals with the interaction between the environment and microorganisms. The environment is composed of **biotic** (living or once-living) and **abiotic** (nonliving) components. The combination of organisms and the environment make up an **ecosystem**.
- B. **Ecosystem Organization**
 1. Living things inhabit only that area of the earth called the **biosphere**, which is made up of the **hydrosphere** (water), the **lithosphere** (soil), and the **atmosphere** (air).
 2. The biosphere consists of **biomes**, large-scale terrestrial systems adapted to distinct climatic and geographic environments, and aquatic ecosystems.
 3. Biomes contain **communities**, assemblages of coexisting organisms.
 4. Communities consist of **populations**, groups of like organisms of the same species.
 5. The space within which an organism lives is its **habitat**; its role in community dynamics is its **niche**.

26.2 Energy and Nutritional Flow in Ecosystems

- A. Organisms derive nutrients and energy from their habitat.
- B. Their collective trophic status relative to one another is summarized in a **food or energy pyramid**.
- C. At the beginning of the chain or pyramid are **producers**—organisms that synthesize large, complex organic compounds from small inorganic molecules.
- D. The levels above producer are occupied by **consumers**, organisms that feed upon other organisms.
- E. **Decomposers** are consumers that obtain nutrition from dead organisms and recycle and **mineralize** nutrients.
- F. **Bioremediation** is the process by which microbes, or communities of microbes, decompose chemicals that are harmful to the environment and its inhabitants.
- G. **Bioaccumulation** results when nondegradable substances are passed through trophic levels.

26.3 The Natural Recycling of Bioelements

- A. **Atmospheric Cycles**
Key compounds in the **carbon cycle** include carbon dioxide, methane, and carbonates.
 1. Carbon is fixed when autotrophs (photosynthesizers) add carbon dioxide to organic carbon compounds.

2. The **nitrogen cycle** requires four processes and several types of microbes.
 - a. In **nitrogen fixation**, atmospheric N_2 gas (the primary reservoir) is converted to NO_2^- , NO_3^- , or NH_4^+ salts.
 - b. **Ammonification** is a stage in the degradation of nitrogenous organic compounds (proteins, nucleic acids) by bacteria to ammonium.
 - c. Some bacteria **nitrify** NH_4^+ by converting it to NO_2^- and to NO_3^- .
 - d. **Denitrification** is a multistep microbial conversion of NO_3^- to atmospheric nitrogen.
- B. Sedimentary Cycles**
1. In the sulfur cycle, environmental sulfurous compounds are converted into useful substrates and returned to the inorganic reservoir through the action of microbes.
 2. The chief compound in the phosphorus cycle is phosphate (PO_4) found in certain mineral rocks. Microbial action on this reservoir makes it available to be incorporated into organic phosphate forms.
 3. Microorganisms often cycle and help accumulate heavy metals and other toxic pollutants that have been added to habitats by human activities.

26.4 Terrestrial Microbiology: The Composition of the Lithosphere

- A. Soil is a dynamic, complex ecosystem that accommodates a vast array of microbes, animals, and plants coexisting among rich organic debris, water and air spaces, and minerals.

- B. Numerous biological activities occur in soil, including decomposition of organic matter in **humus**, mineralization, and biogeochemical cycling.

26.5 The Microbiology of the Hydrosphere

- A. The surface water, atmospheric moisture, and groundwater are linked through a **hydrologic cycle** that involves evaporation and precipitation. Living things contribute to the cycle through respiration and transpiration.
- B. Aquatic ecosystems are supported by the **microbial loop**, a close community of microbes that maintain nutrient flow and cycling.
- C. The diversity and distribution of water communities are related to sunlight, temperature, aeration, and dissolved nutrients. Phytoplankton and zooplankton drifting in the uppermost zone constitute a microbial community that supports the aquatic ecosystem.
- D. Water Monitoring
 1. Providing **potable water** is central to prevention of water-borne disease.
 2. Water is constantly surveyed for **indicator bacteria** such as *E. coli*, **coliforms**, and enterococci, that may signal fecal contamination.
 3. Assays for possible water contamination include the standard plate count and membrane filter tests to identify and enumerate total and fecal coliforms.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

1. Which of the following is *not* a major subdivision of the biosphere?
 - a. hydrosphere
 - b. lithosphere
 - c. stratosphere
 - d. atmosphere
2. A/an _____ is defined as a collection of populations sharing a given habitat.
 - a. biosphere
 - b. community
 - c. biome
 - d. ecosystem
3. The quantity of available nutrients _____ from the lower levels of the energy pyramid to the higher ones.
 - a. increases
 - b. decreases
 - c. remains stable
 - d. cycles
4. Which of the following is/are considered a greenhouse gas?
 - a. CO_2
 - b. CH_4
 - c. N_2O
 - d. all of these
5. Root nodules contain _____, which can _____.
 - a. *Azotobacter*, fix N_2
 - b. *Nitrosomonas*, nitrify NH_3^-
 - c. rhizobia, fix N_2
 - d. *Bacillus*, denitrify NO_3^-
6. Which element(s) has/have an inorganic reservoir that exists primarily in sedimentary deposits?
 - a. nitrogen
 - b. phosphorus
 - c. sulfur
 - d. both b and c
7. Which of the following bacteria would be the most accurate indicator of fecal contamination?
 - a. *Enterobacter aerogenes*
 - b. *Thiobacillus acidophilus*
 - c. *Escherichia coli*
 - d. *Staphylococcus aureus*
8. The floating assemblage of microbes and animals that drifts on or near the surface of large bodies of water is the _____ community.
 - a. abyssal
 - b. benthic
 - c. littoral
 - d. plankton
9. An oligotrophic ecosystem would be most likely to exist in a/an
 - a. ocean
 - b. high mountain lake
 - c. tropical pond
 - d. polluted river
10. Which of the following does not vary predictably with the depth of the aquatic environment?
 - a. dissolved oxygen
 - b. temperature
 - c. penetration by sunlight
 - d. salinity

 Case Study Review

- The cyanobacteria in Lake Erie would best be described as _____.
 - decomposers
 - tertiary consumers
 - primary producers
 - heterotrophs
 - secondary consumers
- Increased average water temperature in Lake Erie as a result of climate change would most likely have what effect?
 - decreased harmful algal blooms, as the higher temperatures would quickly kill most algae
 - decreased fish populations as a result of eutrophication
 - longer algal blooms due to longer periods of warm water
 - b and c
 - a, b, and c
- During the summer of 2015 a harmful algal bloom took place off the coast of Central California. In the weeks and months that followed, officials banned the sale of clams, oysters, and crabs, and several sea lions in the area were found sick or dead. How do these events relate to one another?

 Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

- What factors cause energy to decrease with each trophic level?
 - How is it possible for energy to be lost and the ecosystem to still run efficiently?
 - Are the nutrients on the earth a renewable resource? Why or why not?
- Compare and contrast root nodules with mycorrhizae.
- Because elemental poisons, such as heavy metals, cannot be further degraded even by microbes, what is a possible fate of these metals?
- Draw a diagram that follows the effects of CO₂ on climate and the interactions between CO₂ levels and phytoplankton.
- Explain the significant ways in which the ocean is involved in the carbon cycle.
- Explain what is meant by the “microbial loop.”

 Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps along with concept mapping activities for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

 Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

- Biologists can set up an ecosystem in a small, sealed aquarium that continues to function without maintenance for years. Describe the minimum biotic and abiotic components it must contain to remain balanced and stable.
- Observe the carbon and nitrogen cycles and explain those places in the cycles where interactions in biofilms would be important factors.
- Is the greenhouse effect harmful under ordinary circumstances?
 - List the primary greenhouse gases and explain their effects on the earth's temperature.
 - What occurrence has made them dangerous to the global ecosystem?
 - What could each person do on a daily basis to cut down on the potential for disrupting the delicate balance of the earth's ecosystems?

4. Why are organisms in the abyssal zone of the ocean necessarily halophilic, psychrophilic, barophilic, and anaerobic?
5. a. What eventually happens to the nutrients that run off into the ocean with sewage and other effluents?
b. Why can high mountain communities usually dispense with water treatment?
6. If we are to rely on microorganisms to biodegrade wastes in landfills, aquatic habitats, and soil, list some ways that this process could be made more efficient.

Visual Challenge

1. From **chapter 3, figure 3.17c**. If this medium streaked with 1 loopful of well water showed the result below, would you report that coliforms were present in the well, and is the water potable? Explain your answer.
2. From **chapter 8, figure 8.27**. What process does this represent? How does it link to the biogeochemical cycles from this chapter?

CASE STUDY Part 1 Something You Can Really Sink Your Teeth Into

Near the end of October 2015, hospitals in Washington and Oregon treated over three dozen people suffering from **vomiting** and **bloody diarrhea**, leading to 14 hospitalizations. Stool samples revealed the presence of **shiga toxin-producing *E. coli* (STEC)**, and further testing identified all of the ill people as being infected with a strain of the bacterium known as STEC O26. On November 4 the Washington State Department of Health and the Oregon Health Authority announced as part of their **investigation** into the **outbreak** that all of the ill persons had eaten at one of several locations of Chipotle Mexican Grill in the week prior to becoming ill. Chipotle voluntarily closed 43 locations in Washington and Oregon while the U.S. Food and Drug Administration began testing various **food** items for the presence of the **suspect bacteria**. Over the next month the outbreak grew to 53 people in nine states, and the CDC noted that more cases may appear in the near future because of the long lag time (**2 to 3 weeks**) between a person becoming ill and when the illness is reported.

On April 21, 2015, a hospital in Fairfield County, Ohio, reported a case of suspected **botulism** to the Ohio Department of Health. Botulism is a severe, potentially fatal, paralytic illness marked in its early stages by **blurred vision**, slurred speech, dizziness, and difficulty swallowing. Later, as the **botulinum neurotoxin** spreads throughout the

“Everyone knows what potlucks are like. They know food poisoning can happen anywhere.”

body, facial paralysis, an impaired gag reflex, and **musculoskeletal weakness** become evident. Eventually **paralysis of the respiratory muscles** leads to death. Within two hours of the first case being reported, four others arrived at the emergency room; the **first death** occurred that afternoon. In all, 25 patients were confirmed as having botulism, the worst outbreak in 40 years. All of them had eaten at the same church potluck meal **2 days** previously.

On July 30, 2012, the emergency department at a military hospital examined 13 persons complaining of nausea, vomiting, **abdominal pain**, or diarrhea. Nine others were later identified who had similar symptoms but did not seek medical attention. All were determined to be suffering from staphylococcal food poisoning, and staphylococcal **enterotoxin** was isolated from a single dish at a lunch party that all the patients attended. The average time between eating at the party and the onset of severe illness was **3 hours**.

- *What is the difference between food infection and food intoxication?*
- *Which of these cases involved food infection and which were intoxication?*

To continue the Case Study, go to Case Study Part 2 at the end of the chapter.

SCOPING OUT THE CHAPTER

We've reached the end. We've spent quite a while discussing what a microbe is; how it survives; how we can help it to grow, or kill it; and how it causes harm, or not. Not terribly different from humans thousands of years ago discovering new plants and animals for the first time. Which were dangerous? poisonous? delicious? Which could pull a plow, or supply us with milk or eggs? In this chapter we discuss the myriad ways in which we use microbes to our own ends. In many ways, microbes are the twenty-first century's version of a domesticated animal.

A modern water reclamation plant does exactly what would happen in nature, only faster. We allow bacteria, algae, and protozoans to do what comes naturally to them—degrade organic waste, turning toxic sewage into little more than nutrient rich water.

The biochemical pathways of microbial metabolism can be harnessed to create many of our foods—turning grapes into wine, milk into yogurt, causing bread to rise, and even adding the holes to your Swiss cheese.

One person's delicacy is another person's garbage, such is the line between microbial enhancement and microbial spoilage. And while we may differ on whether kimchi or limburger is delectable or disgusting, food-borne illness is always bad, and its prevention is a top priority in any kitchen.

Using microbes to make wine or digest sewage is nice, but nothing they don't do already. With the advent of genetic engineering we now have the ability to use microbes to make proteins from other species. From vaccines to pharmaceuticals to commercial enzymes, we are now doing things in microbial cells that we used to do in brick-and-mortar factories.

27.1 Applied Microbiology and Biotechnology

Expected Learning Outcomes

1. Describe the primary interests of applied and industrial microbiology.
2. Outline the steps in treatment of municipal water supplies.
3. Summarize the stages in sewage and wastewater treatment.

In this chapter we address the diverse ways microbes are harnessed for specific metabolic tasks that can provide practical benefits to humans. One area of interest, called **applied microbiology**, takes advantage of the microbes living in natural habitats to treat wastewater and bioremediate damaged environments. Because of this, it correlates directly with several concepts introduced in chapter 26 on environmental microbiology. Another area—**industrial microbiology**—explores the use of microbes in making a wide variety of food, medical, manufacturing, and agricultural products. Although this may be an “artificial” use of microbes, it applies many of the principles we learned about the metabolic and adaptive potentials of microorganisms covered in chapters 7, 8, and 9.

In chapter 26 we witnessed the profound involvement of microbes in the natural world. Although our daily encounters with them usually go unnoticed, human and microbial life are clearly intertwined on many levels. It is no wonder that long ago humans began to discover their potential for practical applications. These efforts eventually gave rise to the large and diverse area known as **biotechnology**. Biotechnology has an ancient history, dating back nearly 6,000 years to those first observant humans who discovered that grape juice left sitting produced wine or that bread dough properly infused with a starter would rise. Today, biotechnology has become a fertile ground for hundreds of applications in industry, medicine, agriculture, food sciences, and environmental protection, and it has even come to include the genetic alterations of microbes and other organisms.

Most biotechnological systems involve the actions of bacteria, yeasts, and molds that are able to synthesize a certain food, drug, organic acid, alcohol, or vitamin. Many such end products are obtained through industrial **fermentation**, a general term used here to refer to the mass, controlled culture of microbes to produce desired organic compounds. It also includes the use of microbes in sewage control, metal mining, and bioremediation. This term in biotechnology is not used in the same sense as metabolic fermentation, even though some processes (beer, wine production) do involve biochemical fermentation as described in chapter 8.

These subjects could easily be the inspiration for a whole book, let alone a single chapter. Our coverage of necessity only touches on some basic concepts important for rounding out your background in microbiology. The rest of section 27.1 is devoted to management of water and sewage; sections 27.2, 27.3, and 27.4 cover food microbiology; and section 27.5 concerns industrial biotechnology.

Microorganisms in Water and Wastewater Treatment

Management of Drinking Water

Most drinking water comes from rivers, aquifers, and springs. Only in remote, undeveloped, or high mountain areas is this water used in its natural form. In most cities, it must be treated before it is supplied to consumers. Water supplies such as deep wells that are relatively clean and free of contaminants require less treatment than those from surface sources laden with wastes. The stepwise process in water purification as carried out by most cities is shown in **figure 27.1**.

Treatment begins with the impoundment of water in a large reservoir such as a dam or catch basin that serves the dual purpose of storage and sedimentation. The access to reservoirs is controlled to avoid contamination by animals, wastes, and runoff water. In addition, overgrowth of cyanobacteria and algae that add undesirable qualities to the water is prevented by pretreatment with copper sulfate (0.3 ppm). Sedimentation to remove large particulate matter is also encouraged during this storage period.

Next the water is pumped to holding ponds or tanks, where it undergoes further settling, aeration, and filtration. Larger contaminants are filtered out, while smaller particles are aggregated together and allowed to settle. After several rounds of filtration/settling, the water may be softened to remove minerals and adjust

Process Figure 27.1 The major steps in water purification as carried out by a modern municipal treatment plant. (1) Water destined for the tap is pumped from lakes and rivers and screened (2) to remove large objects such as tree branches. (3) Chemicals are added to cause aggregation of small particles, which settle (4) in large tanks. (5) Calcium and magnesium—responsible for water hardness—are removed, the water is allowed to settle again (6), and the pH is lowered to about 7.8 through the addition of carbon dioxide (7). After filtering the water through gravel, sand, and anthracite (8), it is disinfected with chlorine or chloramines. Chemicals, including fluoride and corrosion inhibitors, may be added at this point (9), and the now potable water is pumped to large storage tanks (10). (11) Potable water is delivered to individual households through municipal pipes.

its pH—water that is too acidic or basic is hard on plumbing and may even leach elements like lead from the pipes, as happened in Flint, Michigan, in 2015. In some communities fluoride or corrosion inhibitors are added at this point. Finally, the water is disinfected through the addition of chlorine or, more commonly, chloramines (see chapter 11). A few water plants in the United States utilize peroxide or ozone for final disinfection, but these methods are expensive and have no residual antimicrobial effects, an important point as water moves through the delivery system. The final quality varies, but most tap water has a slight odor or taste from disinfection.

Management of Wastewater and Sewage

In many parts of the world, the same water that serves as a source of drinking water is also used as a dump for solid and liquid wastes (figure 27.2). Continued pressure on the finite water resources may require reclaiming and recycling of contaminated water such as sewage. **Sewage** is the used wastewater draining out of homes and industries that contains a wide variety of chemicals, debris, and microorganisms. The dangers of typhoid, cholera, and dysentery linked to the unsanitary mixing of household water and sewage have been a threat for centuries. In current practice, some sewage is treated to reduce its microbial load before release, but a large quantity is still being emptied raw (untreated) into the aquatic environment primarily because heavily contaminated waters require far more stringent and costly methods of treatment than are currently available to most cities.

Sewage contains large amounts of solid wastes, dissolved organic matter, and toxic chemicals that pose a health risk. To remove all potential health hazards, treatment typically requires three phases: The primary stage separates out large matter; the secondary stage reduces remaining matter and can remove some toxic substances; and the tertiary stage completes the purification of the water (figure 27.3). Microbial activity is an integral part of the overall process. The systems for sewage treatment are massive engineering marvels.

Figure 27.2 The many uses of water. © Dr. Parvinder Sethi

In the **primary stage** of treatment, floating bulkier materials such as paper, plastic waste, and bottles are skimmed off. The remaining smaller, suspended particulates are allowed to settle. Sedimentation in settling tanks usually takes 2 to 10 hours and leaves a mixture rich in organic matter. This aqueous residue is carried into a **secondary stage** of active microbial decomposition, or biodegradation. In this stage, a diverse community of natural bioremediators (bacteria, algae, and protozoa) aerobically decomposes the remaining particles of wood, paper, fabrics, petroleum, and organic molecules inside a large digester tank (figure 27.4). This forms a suspension of material called *sludge* that tends to settle out and slow the process. Most processing plants improve the microbial decomposition of the sludge through a system of aeration, stirring, and recirculation, which forms **activated sludge**. This action mineralizes a large amount of organic matter into sulfates, nitrates, phosphates, carbon dioxide, and water. Certain volatile gases such as hydrogen sulfide, ammonia, nitrogen, and methane may also be released. Water from this process is siphoned off and carried to the **tertiary stage**, which involves further filtering and chlorinating prior to discharge. Such reclaimed sewage water is usually used to water golf courses and parks rather than for drinking, or it is gradually released into large bodies of water.

In some cases, the solid waste that remains after aerobic decomposition is harvested and reused. Its rich content of nitrogen, potassium, and phosphorus makes it a useful fertilizer. But if the waste contains large amounts of nondegradable or toxic substances, it must be disposed of properly. In many parts of the world, the sludge, which still contains significant amounts of simple but useful organic matter, is used as a secondary source of energy. Further digestion is carried out by microbes in sealed chambers called bioreactors, or **anaerobic digesters**. The digesters convert components of the sludge to swamp gas, primarily methane with small amounts of

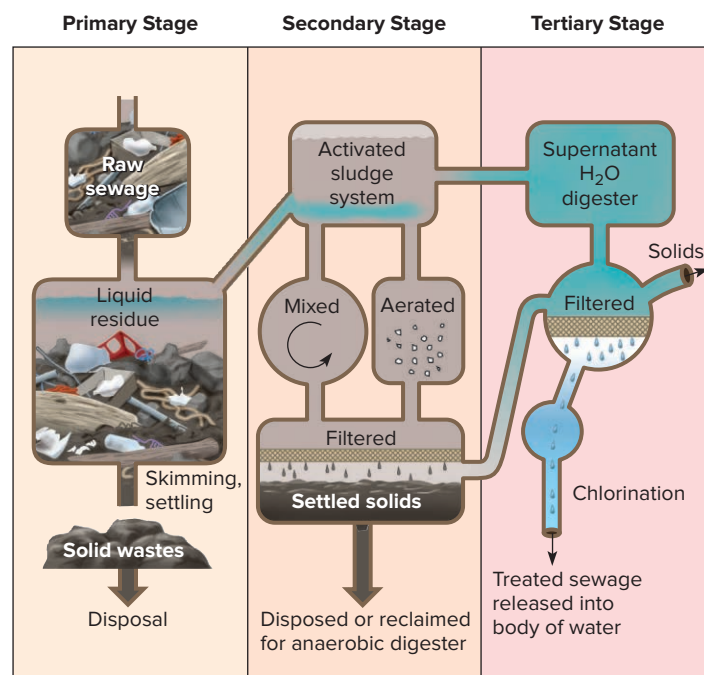

Figure 27.3 The primary, secondary, and tertiary stages in sewage treatment.

hydrogen, carbon dioxide, and other volatile compounds. Swamp gas can be burned to provide energy to run the sewage processing facility itself or to power small industrial plants.

Recently, scientists found a way to harness the bacteria found in sewage to construct a microbial fuel cell to produce usable energy. In these experiments, wastewater bacteria form biofilms on special rods inserted in the sewage that is being treated. These biofilms generate electrons that are transferred via copper wires to cathodes, producing electricity. Considering the mounting waste disposal and energy shortage problems, these technologies should gain momentum.

27.2 The Microbiology of Food

Expected Learning Outcome

4. Describe the major ways that microbes are involved with food.

All human food—from vegetables to caviar to cheese—comes from some other organism, and rarely is it obtained in a sterile, uncontaminated state. Food is but a brief stopover in the overall scheme of biogeochemical cycling. This means that microbes and humans are in direct competition for the nutrients in food, and we must be constantly aware that microbes' fast growth rates give them the winning edge. Somewhere along the route of procurement, processing, or preparation, food becomes contaminated with microbes from the soil, the bodies of plants and animals, water, air, food handlers, or utensils. The final effects depend upon the types and numbers of microbes and whether the food is cooked or preserved. In some cases, specific microbes can even be added to food to obtain a desired effect. The effects of microorganisms on food can be classified as beneficial, detrimental, or neutral to humans, as summarized by the following outline:

Beneficial effects

Food is fermented or otherwise chemically changed by the addition of microbes or microbial products to alter or improve flavor, taste, or texture.

Microbes can serve as food.

Detrimental effects

Food poisoning or food-borne illness

Food spoilage

Growth of microbes makes food unfit for consumption; adds undesirable flavors, appearance, and smell; destroys food value

Neutral effects

The presence or growth of microbes that do not cause disease or change the nature of the food

As long as food contains no harmful substances or organisms, its suitability for consumption is largely a matter of taste. But what tastes like rich flavor to some may seem like decay to others. The test of whether certain foods are edible is guided by culture, experience, and preference. The flavors, colors, textures, and aromas of many cultural delicacies are supplied by bacteria and fungi. Chocolate, pickled cabbage, fermented fish, and Limburger cheese are notable examples. If you examine the foods of most cultures, you will find some foods that derive their delicious flavor from microbes.

27.3 Microbial Fermentations in Food Products

Expected Learning Outcomes

5. Characterize the basic science behind the use of microbes in food fermentations.
6. Describe the microbiological processes involved in bread making, alcoholic beverage production, and fermented plant products.
7. Outline the fermentation processes related to the preparation of dairy products.
8. Explain several ways that microbes may be used as foods.

In contrast to methods that destroy or keep out unwanted microbes, many culinary procedures deliberately add microorganisms and encourage them to grow. Common substances such as bread, cheese, beer, wine, yogurt, and pickles are the result of **food fermentations**. These reactions actively encourage biochemical activities that impart a particular taste, smell, or appearance to food. The microbe or microbes can occur naturally on the food substrate, as in sauerkraut, or they can be added as pure or mixed samples of known bacteria, molds, or yeasts called **starter cultures**. Many food fermentations are synergistic, with a series of microbes acting in concert to convert a starting substrate to the desired end product. Because large-scale production of fermented milk, cheese, bread, alcoholic brews, and vinegar depends upon inoculation with starter cultures, considerable effort is spent selecting, maintaining, and preparing these cultures and excluding contaminants that can spoil the fermentation. Most starting raw materials are of plant origin (grains, vegetables, beans) and, to a lesser extent, of animal origin (milk, meat).

Bread Making

Microorganisms accomplish three functions in bread making:

1. leavening the flour-based dough,
2. imparting flavor and odor, and
3. conditioning the dough to make it workable.

Leavening is achieved primarily through the release of gas to produce a porous and spongy product. Without leavening, bread dough remains dense, flat, and hard. Although various microbes and leavening agents can be used, the most common ones are various strains of the baker's yeast *Saccharomyces cerevisiae*. Other gas-forming microbes such as coliform bacteria, certain *Clostridium* species, heterofermentative lactic acid bacteria, and wild yeasts can be employed, depending on the type of bread desired.

Yeast metabolism requires a source of fermentable sugar such as maltose or glucose. Because the yeast respire aerobically in bread dough, the chief products of maltose fermentation are carbon dioxide and water rather than alcohol (the main product in beer and wine). Other contributions to bread texture come from kneading, which incorporates air into the dough, and from microbial enzymes, which break down flour proteins (gluten) and give the dough elasticity.

Besides carbon dioxide production, bread fermentation generates other volatile organic acids and alcohols that impart delicate flavors

and aromas. These are especially well developed in home-baked bread, which is leavened more slowly than commercial bread. Yeasts and bacteria can also impart unique flavors, depending upon the culture mixture and baking techniques used. The pungent flavor of rye bread, for example, comes in part from starter cultures of lactic acid bacteria such as *Lactobacillus plantarum*, *L. brevis*, *L. bulgaricus*, *Leuconostoc mesenteroides*, and *Streptococcus thermophilus*. Sour-dough bread gets its unique tang from *Lactobacillus sanfrancisco*.

Production of Beer and Other Alcoholic Beverages

The production of alcoholic beverages takes advantage of another useful property of yeasts. By fermenting carbohydrates in fruits or grains anaerobically, they produce ethyl alcohol, as shown by this equation:

Depending upon the starting materials and the processing method, alcoholic beverages vary in alcohol content and flavor. The principal types of fermented beverages are beers, wines, and spirit liquors.

Brewing

The earliest evidence of beer brewing appears in ancient tablets by the Sumerians and Babylonians around 6000 BC. The starting ingredients for both ancient and present-day versions of beer, ale, stout, porter, and other variations are water, malt (barley grain), hops, and special strains of yeasts. The steps in brewing include malting, mashing, adding hops, fermenting, aging, and finishing.

For brewer's yeast to convert the carbohydrates in grain into ethyl alcohol, the barley must first be sprouted and softened to make its complex nutrients available to yeasts. This process, called **malting**,* releases amylases that convert starch to dextrins and maltose, and proteases that digest proteins. Other sugar and starch supplements added in some forms of beer are corn, rice, wheat, soybeans, potatoes, and sorghum. After the sprouts have been separated, the remaining malt grain is dried and stored in preparation for mashing.

The malt grain is soaked in warm water and ground up to prepare a **mash**. Sugar and starch supplements are then introduced to the mash mixture, which is heated to a temperature of about 65°C to 70°C. During this step, the starch is hydrolyzed by amylase and simple sugars are released. Heating this mixture to 75°C stops the activity of the enzymes. Solid particles are next removed by settling and filtering. **Wort**,* the clear fluid that comes off, is rich in dissolved carbohydrates. It is boiled for about 2.5 hours with **hops**, the dried scales of the female flower of *Humulus lupulus* (**figure 27.5**), to extract the bitter acids and resins that give aroma and flavor to the finished product.¹ Boiling also caramelizes the sugar and imparts a golden or brown color, destroys any bacterial contaminants that can destroy flavor, and concentrates the mixture. The filtered and cooled supernatant is then ready for the addition of yeasts and fermentation.

Primary fermentation begins when wort is inoculated with a species of *Saccharomyces* that has been specially developed for beer

* **malting** (mawlt'-ing) Gr. malz, to soften.

* **wort** (wurt) O.E. wurt, a spice

1. This substance, called humulus, provides some rather interesting side effects besides flavor. It is a moderate sedative, a diuretic, and a mild antiseptic.

making. Top yeasts such as *Saccharomyces cerevisiae* function at the surface and are used to produce the higher alcohol content of ales. Bottom yeasts such as *S. uvarum* (*carlsbergensis*) function deep in the fermentation vat and are used to make other beers. In both cases, the initial inoculum of yeast starter is aerated briefly to promote rapid growth and increase the load of yeast cells. Shortly thereafter, an insulating blanket of foam and carbon dioxide develops on the surface of the vat and promotes anaerobic conditions. During 8 to 14 days of fermentation, the wort sugar is converted chiefly to ethanol and carbon dioxide. The diversity of flavors in the finished product is partly due to the release of small amounts of glycerol, acetic acid, and esters. Fermentation is self-limited, and it essentially ceases when a concentration of 3% to 6% ethyl alcohol is reached.

Freshly fermented, or “green,” beer is **lagered**,* meaning it is held for several weeks to months in vats near 0°C. During this maturation period, yeast, proteins, resin, and other materials settle, leaving behind a clear, mellow fluid. Lager beer is subjected to a final filtration step to remove any residual yeasts that could spoil it. Finally, it is carbonated with carbon dioxide collected during fermentation, and packaged in kegs, bottles, or cans.

Preparation of Wine and Liquors

Wine is traditionally considered any alcoholic beverage arising from the fermentation of grape juice, but practically any fruit can be rendered into wine. The essential starting point is the preparation of **must**, the juice given off by crushed fruit that is used as a substrate for fermentation. In general, grape wines are either white or red. The color comes from the skins of the grapes, so white wine is prepared either from white-skinned grapes or from red-skinned grapes that have had the skin removed. Red wine comes from the red- or purple-skinned varieties. Major steps in making wine include must preparation (crushing), fermentation, pasteurization, storage, and aging (**figure 27.6**).

The right amount of sugar is essential for proper fermentation. The must should contain 12% to 25% glucose or fructose, so the art

27.1 Secret World of Microbes

The Noble Rot

Harvesting grapes for wine making requires the balancing of several factors: sugar, acid, and tannin levels within the grapes, time left in the growing season, even the expected onset of inclement weather such as heat or hail, which can damage the crop. In eighteenth-century Germany, grape producers traditionally began their harvest only when the estate owner gave his approval. During the 1775 growing season, in the Rheingau region, the messenger delivering the order to harvest the grapes was delayed for several weeks, time enough for a fungus to infest much of the vineyard. Cutting their losses, the grapes were culled and given to local farmers who used them to create an unexpectedly enjoyable sweet wine. The fungus, *Botrytis cinerea*, came to be valued throughout Europe for the taste it imparted to the wine, while the dry decay and partial dehydration of the grapes it produced was called the “Noble Rot.” Look back at figure 1.5b, to view this interesting fungus. Today, botrytized wines can be found all over the world; if *Botrytis* is not naturally present in the environment it may be imported and the spores sprayed over the grapes. The growing fungus slowly dehydrates the grapes and concentrates the solids responsible for the final flavor of the wine. Some of the finest botrytized wines owe their flavor to the fact the grapes were picked one at a time, when each grape had exactly the correct amount of Noble Rot.

In what way are botrytized wines and sourdough bread similar?
Answer available on Connect.

of wine making begins in the vineyard. Grapes are harvested when their sugar content reaches 15% to 25%, depending on the type of wine to be made. Grapes from the field carry a mixed biofilm on their surface called the *bloom* that can serve as a source of wild yeasts (**27.1 Secret World of Microbes**). Some winemakers allow these natural yeasts to dominate, but many wineries inoculate the must with a special strain of *Saccharomyces cerevisiae*, variety *ellipsoideus*. To discourage yeast and bacterial spoilage agents, winemakers usually treat grapes with sulfur dioxide or potassium metabisulfite. The inoculated must is thoroughly aerated and mixed to promote rapid aerobic growth of yeasts, but when the desired level of yeast growth is achieved, anaerobic alcoholic fermentation is begun.

The temperature of the vat during fermentation must be carefully controlled to facilitate alcohol production. The length of fermentation varies from 3 to 5 days in red wines and from 7 to 14 days in white wines. The initial fermentation yields ethanol concentrations reaching 7% to 15% by volume, depending upon the type of yeast, the source of the juice, and ambient conditions. The fermented juice (raw wine) is decanted and transferred to large vats to settle and clarify. Before the final aging process, it is flash-pasteurized to kill microorganisms and filtered to remove any remaining yeasts and sediments. Wine is aged in wooden casks for varying time periods (months to years), after which it is bottled and stored for further aging. During aging, nonmicrobial changes produce aromas and flavors (the bouquet) characteristic of a particular wine.

The fermentation processes discussed thus far can only achieve a maximum alcoholic content of 17%, because concentrations above

this level inhibit the metabolism of the yeast. The fermentation product must be distilled to obtain higher concentrations such as those found in liquors. During distillation, heating the liquor separates the more volatile alcohol from the less volatile aqueous phase. The alcohol is then condensed and collected. The alcohol content of distilled liquors is rated by *proof*, a measurement that is usually two times the alcohol content. Thus, 80 proof vodka contains 40% ethyl alcohol.

Distilled liquors originate through a process similar to wine making, although the starting substrates can be extremely diverse. In addition to distillation, liquors can be subjected to special treatments such as aging to provide unique flavor or color. Vodka, a colorless liquor, is usually prepared from fermented potatoes, and rum is distilled from fermented sugarcane. Assorted whiskeys are derived from fermented grain mashes; rye whiskey is produced from rye mash, and bourbon from corn mash. Brandy is distilled from grape, peach, or apricot wine.

Other Fermented Plant Products

Fermentation provides an effective way of preserving vegetables, as well as enhancing flavor with lactic acid and salt. During pickling fermentations, vegetables are immersed in an anaerobic salty solution (brine) to extract sugar and nutrient-laden juices. The salt also disperses bacterial clumps, and its high osmotic pressure inhibits proteolytic bacteria and sporeformers that can spoil the product.

Sauerkraut is the fermentation product of cabbage. Cabbage is washed, wilted, shredded, salted, and packed tightly into a fermentation vat. Weights cover the cabbage mass and squeeze out its

juices. The fermentation is achieved by natural cabbage microbiota or by an added culture. The initial agent of fermentation is *Leuconostoc mesenteroides*, which grows rapidly in the brine and produces lactic acid. It is followed by *Lactobacillus plantarum*, which continues to raise the acid content to as high as 2% (pH 3.5) by the end of fermentation. The high acid content restricts the growth of spoilage microbes.

Fermented cucumber pickles come chiefly in salt and dill varieties. Salt pickles are prepared by washing immature cucumbers, placing them in barrels of brine, and allowing them to ferment for 6 to 9 weeks. The brine can be inoculated with *Pediococcus cerevisiae* and *Lactobacillus plantarum* to avoid unfavorable qualities caused by natural microbiota and to achieve a more consistent product. Fermented dill pickles are prepared in a somewhat more elaborate fashion, with the addition of dill herb, spices, garlic, onion, and vinegar.

Natural vinegar is produced when the ethyl alcohol in fermented plant juice is oxidized to acetic acid, which is responsible for the pungent odor and sour taste. Although a reasonable facsimile of vinegar could be made by mixing about 4% acetic acid and a dash of sugar in water, this preparation would lack the traces of various esters, alcohol, glycerin, and volatile oils that give natural vinegar its pleasant character. Vinegar is actually produced in two stages. The first stage is similar to wine or beer making, in which a plant juice is fermented to alcohol by *Saccharomyces*. The second stage involves aerobic metabolism carried out by acetic acid bacteria in the genera *Acetobacter* and *Gluconobacter*. These bacteria oxidize the ethanol in a two-step process, as shown here:

The abundance of oxygen necessary in commercial vinegar making is furnished by exposing inoculated raw material to air by arranging it in thin layers in open trays, allowing it to trickle over loosely packed beechwood twigs and shavings, or aerating it in a large vat. Different types of vinegar are derived from substrates such as apple cider (cider vinegar), malted grains (malt vinegar), and grape juice (wine vinegar).

Microbes in Milk and Dairy Products

Milk has a highly nutritious composition. It contains an abundance of water and is rich in minerals, protein (chiefly casein), butterfat, sugar (especially lactose), and vitamins. It starts its journey in the udder of a mammal as a sterile substance, but as it passes out of the teat, it is inoculated by the animal's normal biota. Other microbes can be introduced by milking utensils. Because milk is a nearly perfect culture medium, it is highly susceptible to

microbial growth. When raw milk is left at room temperature, a series of bacteria ferment the lactose, produce acid, and alter the milk's content and texture (**figure 27.7a**). This progression can occur naturally, or it can be induced, as in the production of cheese and yogurt.

In the initial stages of milk fermentation, lactose is rapidly attacked by *Streptococcus lactis* and *Lactobacillus* species (**figure 27.7b**). The resultant lactic acid accumulation and lowered pH cause the milk proteins to coagulate into a solid mass called the **curd**. Curdling also causes the separation of a watery liquid called **whey** on the surface. Curd can be produced by microbial action or by an enzyme, **rennin** (casein coagulase), which is isolated from the stomach of unweaned calves.

Cheese Production

Since 5000 BC, various forms of cheese have been produced by spontaneous fermentation of cow, goat, or sheep milk. Present-day, large-scale cheese production is carefully controlled and uses only freeze-dried samples of pure cultures. These are first inoculated into a small quantity of pasteurized milk to form an active starter

(a)

(b)

Figure 27.7 Microbes at work in milk products. (a) Litmus milk is used to indicate pH and consistency changes in milk resulting from microbial action. The first tube is an uninoculated control. The second tube has a white, decolorized zone indicative of litmus reduction. The third tube shows acid production (pink), and its proteins have formed a loose curd. In the fourth tube, digestion of milk proteins has caused complete clarification or peptonization of the milk. The fifth tube has a solid curd overlaid by a clear fluid, the whey. (b) Chart depicting changes in the numbers and types of microorganisms and the pH of raw milk as it incubates. Early acid production by streptococci and lactobacilli favors desirable effects such as curds and whey needed for flavor and texture. Late growth spoilage agents turn milk alkaline and cause undesirable changes such as protein digestion. (a): © Kathy Park Talaro

culture. This amplified culture is subsequently inoculated into a large vat of milk, where rapid curd development takes place. Such rapid growth is desired because it promotes the overgrowth of the desired inoculum and prevents the activities of undesirable contaminants. Rennin is usually added to increase the rate of curd formation.

After its separation from whey, the curd is rendered to produce one of the 20 major types of soft, semisoft, or hard cheese (**figure 27.8**). The composition of cheese is varied by adjusting water, fat, acid, and salt content. Cottage and cream cheese are examples of the soft, more perishable variety. After light salting and the optional addition of cream, they are ready for consumption without further processing. Other cheeses acquire their character from “ripening,” a complex curing process involving bacterial, mold, and enzyme reactions that develop the final flavor, aroma, and other features characteristic of particular cheeses.

The distinctive traits of soft cheeses such as Limburger, Camembert, and Liederkranz are acquired by ripening with a reddish-brown mucoid coating of yeasts, micrococci, and molds. The microbial enzymes permeate the curd and ferment lipids, proteins, carbohydrates, and other substrates. This process leaves assorted acids and other by-products that give the finished cheese powerful aromas and delicate flavors. Semisoft varieties of cheese such as Roquefort, bleu, or Gorgonzola are infused and aged with a strain of *Penicillium roqueforti* mold. Hard cheeses such as Swiss, cheddar, and Parmesan develop a sharper flavor by aging with selected bacteria. The pockets in Swiss cheese come from entrapped carbon dioxide formed by *Propionibacterium*, which is also responsible for its bittersweet taste.

Other Fermented Milk Products

Yogurt is formed by the fermentation of milk by *Lactobacillus bulgaricus* and *Streptococcus thermophilus*. These organisms produce organic acids and other flavor components and can grow in such numbers that a gram of yogurt regularly contains 100 million bacteria. Live cultures of *Lactobacillus acidophilus* are an important additive to acidophilus milk, which is said to benefit digestion and to help maintain the normal biota of the intestine. Fermented milks

Figure 27.8 Cheese making. The curd-cutting stage in the making of cheddar cheese. © Joe Munroe/Science Source

such as kefir, koumiss, and buttermilk are a basic food source in many cultures.

Microorganisms as Food

At first, the thought of eating bacteria, molds, algae, and yeasts may seem odd or even unappetizing. We do eat their macroscopic relatives such as mushrooms, truffles, and seaweed, but we are used to thinking of the microscopic forms as agents of decay and disease or, at most, as food flavorings. The consumption of microorganisms is not a new concept. In Germany during World War II, it became necessary to supplement the diets of undernourished citizens by adding yeasts and molds to foods.

At present, most countries are able to produce enough food for their inhabitants, but in the future, countries with exploding human populations and dwindling arable land may need to consider microbes as a significant source of protein, fat, and vitamins. Several countries already commercially mass-produce food yeasts; bacteria; and, in a few cases, algae. Although eating microbes has yet to win total public acceptance, their use as feed supplements for livestock is increasing. A technology that shows some promise in increasing world food productivity is single-cell protein (SCP). This material is produced from waste materials such as molasses from sugar refining, petroleum by-products, and agricultural wastes. Quorn, a mycoprotein product made from the fungus *Fusarium venenatum*, is sold worldwide as a high protein alternative to meat.

Health food stores carry bottles of dark green pellets or powder that are a culture of a spiral-shaped cyanobacterium called *Spirulina*. This microbe is harvested from the surface of lakes and ponds, where it grows in great mats. In some parts of Africa and Mexico, *Spirulina* has become a viable alternative to green plants as a primary nutrient source. It can be eaten in its natural form or added to other foods and beverages.

27.4 Microbial Involvement in Food-Borne Diseases

Expected Learning Outcomes

9. Explain the importance of microbes as agents of food-borne illnesses.
10. Classify the types of food poisoning, providing examples of each.
11. Identify the major methods of food preservation.
12. Describe methods for preventing food-borne diseases.

Diseases caused by ingesting food are usually referred to as **food poisoning**, and although this term is often used synonymously with microbial food-borne illness, not all food poisoning is caused by microbes or their products. Several illnesses are caused by poisonous plant and animal tissues or by ingesting food contaminated by pesticides or other poisonous substances. **Table 27.1** summarizes the major types of bacterial food-borne disease.

TABLE 27.1 Major Forms of Bacterial Food Poisoning

Disease	Microbe	Foods Involved	Comments/with Chapter References
Food Intoxications: Caused by Ingestion of Foods Containing Preformed Toxins			
Staphylococcal enteritis	<i>Staphylococcus aureus</i>	Custards, cream-filled pastries, ham, dressings	Very common; symptoms come on rapidly; usually nonfatal; chapter 18
Botulism	<i>Clostridium botulinum</i>	Home-canned or poorly preserved low-acid foods	Rarely seen in commercially prepared foods; can be fatal; chapter 19
<i>Bacillus cereus</i> enteritis	<i>Bacillus cereus</i>	Reheated rice, potatoes, puddings, custards	Mimics staphylococcal enteritis; usually self-limited; chapter 19
Food Infections: Caused by Ingestion of Live Bacterial Pathogens That Invade the Intestine			
Campylobacteriosis	<i>Campylobacter jejuni</i>	Raw milk, raw chicken, shellfish and meats	Very common; animals are carriers of other species; chapter 21
Salmonellosis	<i>Salmonella typhimurium</i> and <i>S. enteritidis</i>	Poultry, eggs, dairy products, meats	Very common; can be severe and life-threatening; chapter 20
Perfringens enterotoxemia	<i>Clostridium perfringens</i>	Inadequately cooked meats	Vegetative cells produce toxin within the intestine; chapter 19
Shigellosis	Various <i>Shigella</i> species	Unsanitary cooked food; fish, shrimp, potatoes, salads	Carriers and flies contaminate food; the cause of bacillary dysentery; chapter 20
<i>Vibrio</i> enteritis	<i>Vibrio parahaemolyticus</i> <i>Vibrio vulnificus</i>	Raw or poorly cooked seafoods	Microbe lives naturally on marine animals; chapter 21
Listeriosis	<i>Listeria monocytogenes</i>	Poorly pasteurized milk, cheeses	Most severe in fetuses, newborns, and the immunodeficient; chapter 19
<i>Escherichia</i> enteritis	<i>Escherichia coli</i>	Contaminated raw vegetables, cheese	Various strains can produce infantile and traveler's diarrhea; chapter 20
	<i>E. coli</i> O157:H7	Raw or rare beef, vegetables, water	The cause of hemolytic uremic syndrome; chapter 20

Food poisoning of microbial origin can be divided into two general categories (**figure 27.9**). **Food intoxication** results from the ingestion of exotoxin secreted by bacterial cells growing in food. The absorbed toxin disrupts a particular target such as the intestine (if an enterotoxin) or the nervous system (if a neurotoxin). The symptoms of intoxication vary from bouts of vomiting and diarrhea (staphylococcal intoxication) to severely disrupted muscle function (botulism). In contrast, **food infection** is associated with the ingestion of live, intact microbial cells that target the intestine. In some cases, they infect the surface of the intestine, and in others, they invade the intestine and other body structures. Most food infections manifest some degree of diarrhea and abdominal distress (see 20.2 Making Connections). It is important to realize that disease symptoms in food infections such as *Clostridium perfringens* enterotoxemia can be initiated by toxins released by microbes growing in the infected tissue rather than in the food.

Reports of food poisoning are escalating in the United States and worldwide. Outbreaks attributed to common pathogens (*Salmonella*, *Escherichia coli*, *Vibrio*, hepatitis A, and various protozoa) have doubled in the past 25 years. The Centers for Disease Control and Prevention (CDC) estimate that nearly one-sixth of the population suffers each year from some form of food poisoning. A major factor in this changing pattern

is the mass production and distribution of processed food such as raw vegetables, fruits, and meats. Improper handling can lead to gross contamination of these products with soil or animal wastes.

Estimated Incidence of Food-Borne Illness in the United States*

Illnesses	48,000,000 cases
Hospitalizations	128,000 cases
Deaths	3,000 cases

*One-third of all reported cases result from eating restaurant food.

Many reported food poisoning outbreaks occur where contaminated food has been served to large groups of people, but most cases probably occur in the home and are not reported. On occasion, even commercially prepared foods can be a source of infections.

Data collected by food microbiologists indicate that the most common bacterial food-borne pathogens are *Campylobacter*, *Salmonella*, *Shigella*, and *Staphylococcus aureus*. The dominant protozoa causing food infections are *Giardia*, *Cryptosporidium*, and *Toxoplasma*. The top viruses are noroviruses and hepatitis A viruses. These microbes and their diseases were previously discussed in chapters 18, 19, 20, and 21 (see table 27.1 along with chapters 23 and 25).

Figure 27.9 Food-borne illnesses of microbial origin.

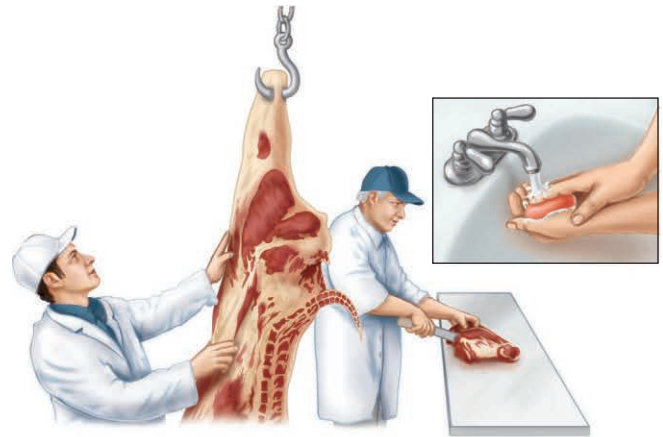

(a) Food intoxication. The toxin is released by microbes growing in the food. After the toxin is ingested, it acts upon its target tissue and causes symptoms. (b) Food infection. The infectious agent comes from food or is introduced into it through poor food processing and storage. After the cells are ingested, they invade the intestine and cause symptoms of gastroenteritis.

Prevention Measures for Food Poisoning and Spoilage

The current approach used to regulate the food industry is called Hazard Analysis & Critical Control Points, or HACCP, and it is adapted from procedures crafted for the space program in the 1970s. It involves principles that are more systematic and scientific than previous random-sampling quality procedures. The program focuses on the identification, evaluation, control, and prevention of hazards at all stages of the food production process. Recent data show that some food-borne illnesses have begun to decline, due in part to implementation of HACCP procedures.

It will never be possible to avoid all types of food-borne illness because of the ubiquity of microbes in air, water, food, and the human body. But most types of food poisoning require the growth of microbes in the food. In the case of food infections, an infectious

dose (sufficient cells to initiate infection) must be present, and in food intoxication, enough cells to produce the toxin must be present. Thus, food poisoning or spoilage can be prevented by proper food handling, preparation, and storage. The methods shown in **figure 27.10** are aimed at preventing the incorporation of microbes

into food, removing or destroying microbes in food, and keeping microbes from multiplying.

Preventing the Incorporation of Microbes into Food

Most agricultural products such as fruits, vegetables, grains, meats, eggs, and milk are naturally exposed to microbes. Vigorous washing reduces the levels of contaminants in fruits and vegetables, whereas meat, eggs, and milk must be taken from their animal source as aseptically as possible. Aseptic techniques are also essential in the kitchen. Contamination of foods by fingers can be easily remedied by hand washing and proper hygiene, and contamination by flies or other insects can be stopped by covering foods or eliminating pests from the kitchen. Care and common sense also apply in managing utensils. It is important to avoid cross-contaminating food by not using the same cutting board for meat and vegetables without disinfecting it between uses.

Preventing the Survival or Multiplication of Microbes in Food

Because it is not possible to eliminate all microbes from certain types of food by clean techniques alone, a more efficient approach is to preserve the food by physical or chemical methods. Hygienically preserving foods is especially important for large commercial companies that process and sell bulk foods and must ensure that products are free from harmful contaminants. Regulations and standards for food processing are administered by two federal agencies: the Food and Drug Administration (FDA) and the U.S. Department of Agriculture (USDA).

Temperature and Food Preservation

Heat is a common way to destroy microbial contaminants or to reduce the load of microorganisms. Commercial canneries preserve food in hermetically sealed containers that have been exposed to high temperatures over a specified time period. The temperature used depends upon the type of food, and it can range from 60°C to 121°C, with exposure times ranging from 20 minutes to 115 minutes. The food is usually processed at a thermal death time (TDT; see chapter 11) that will destroy the main spoilage organisms and pathogens but will not alter the nutrient value or flavor of the food. For example, tomato juice must be heated to between 121°C and 132°C for 20 minutes to ensure destruction of the spoilage agent *Bacillus coagulans*. Most canning methods are rigorous enough to sterilize the food completely, but some only render the food “commercially sterile,” which means it contains live bacteria that are unable to grow under normal conditions of storage.

Another use of heat is **pasteurization**, usually defined as the application of heat below 100°C to destroy nonresistant bacteria and yeasts in liquids such as milk, wine, and fruit juices. The heat is applied in the form of steam, hot water, or even electrical current. The most prevalent technology is the *high-temperature short-time (HTST)*, or flash method, using a pasteurizer with extensive networks of tubes that expose the liquid to 72°C for

15 seconds. An alternative method, ultrahigh-temperature (UHT) pasteurization, steams the product until it reaches a temperature of 134°C for at least 2 seconds. Although milk processed this way is not actually sterile, it is often marketed as sterile, with a shelf life of up to 3 months. Older methods involve large bulk tanks that hold the fluid at a lower temperature for a longer time, usually 62.3°C for 30 minutes.

Cooking temperatures used to boil, roast, or fry foods can render them free or relatively free of living microbes if carried out for sufficient time to destroy any potential pathogens. A quick warming of chicken or an egg is inadequate to kill microbes such as *Salmonella*. In fact, any meat is a potential source of infectious agents and should be adequately cooked. Because most meat-associated food poisoning is caused by nonsporulating bacteria, heating the center of meat to at least 80°C and holding it there for 30 minutes is usually sufficient to kill pathogens. Roasting or frying food at temperatures of at least 200°C or boiling it will achieve a satisfactory degree of disinfection.

Any perishable raw or cooked food that could serve as a growth medium must be stored to prevent the multiplication of bacteria that have survived during processing or handling. Because most food-borne bacteria and molds that are agents of spoilage or infection can multiply at room temperature, manipulation of the holding temperature is a useful preservation method (**figure 27.11**). A good general directive is to store foods at temperatures below 4°C or above 60°C.

Regular refrigeration reduces the growth rate of most mesophilic bacteria by 10 times, although some psychrotrophic microbes can continue to grow at a rate that causes spoilage. This factor limits the shelf life of milk, because even at 7°C, a population could go from a few cells to a billion in 10 days. Pathogens such as *Listeria monocytogenes* and *Salmonella* can also continue to grow in refrigerated foods. Freezing is a longer-term method for cold preservation. Foods can be either slow-frozen for 3 to 72 hours at –15°C to –23°C or rapidly frozen for 30 minutes at –17°C to –34°C. Because freezing cannot be counted upon to kill microbes, rancid, spoiled, or infectious foods will still be unfit to eat after freezing and defrosting. *Salmonella* is known to survive several months in frozen chicken and ice cream, and *Vibrio parahaemolyticus* can survive in frozen shellfish. For this reason, frozen foods should be defrosted rapidly and immediately cooked or reheated. However, even this practice will not prevent staphylococcal intoxication if the toxin is already present in the food before it is heated.

Foods such as soups, stews, gravies, meats, and vegetables that are generally eaten hot should not be maintained at warm or room temperatures, especially in settings such as cafeterias, banquets, and picnics. The use of a hot plate, chafing dish, or hot water bath will maintain foods above 60°C, well above the incubation temperature of food-poisoning agents.

As a final note about methods to prevent food poisoning, remember the simple axiom: “When in doubt, throw it out.”

Irradiation

Ultraviolet (nonionizing) lamps are commonly used to destroy microbes on the surfaces of foods or utensils, but they do not

Figure 27.11 Temperatures favoring and inhibiting the growth of microbes in food. Most microbial agents of disease or spoilage grow in the temperature range of 15°C to 40°C. To ensure safety, foods should not be allowed to remain at temperatures between 4°C and 60°C for more than two hours. The red area represents temperatures at which bacteria grow most rapidly while yellow areas allow for microbial growth at a reduced rate; green areas correspond to greatly decreased rates of microbial growth. Preventing unwanted growth in foods in long-term storage is best achieved by refrigeration (4°C) or freezing (0°C or lower). Preventing microbial growth in foods intended to be consumed warm in a few minutes or hours requires maintaining the foods above 60°C.

penetrate far enough to sterilize bulky foods or food in packages. Food preparation areas are often equipped with UV radiation devices that are used to destroy spores on the surfaces of cheese, breads, and cakes and to disinfect packaging machines and storage areas.

Food itself is usually sterilized by gamma rays, electron beams, or X rays, because these ionizing rays can penetrate denser materials. It must also be emphasized that this method does not cause the targets of irradiation to become radioactive.

Although public opinion polls routinely find resistance to eating irradiated food, there is little scientific evidence to support the belief that food irradiation is harmful. Small changes in flavor, odor, texture, and the level of some vitamins have been noted, but these changes are generally so minor that it is difficult to distinguish between irradiated and nonirradiated foods. More than three decades of research have shown that irradiation is a safe and effective means of greatly reducing the risk of food-borne illness, lengthening shelf life, and even delaying ripening of some fruits and vegetables (slowing the sprouting of potatoes, for example). The safety of irradiated food is endorsed by the Food and Drug Administration (FDA), the Centers for Disease Control and Prevention

(CDC), the U.S. Department of Agriculture (USDA), and the World Health Organization (WHO). Although irradiation is approved for treatment of beef, pork, poultry, fish, eggs, spices, grain, and some fruits and vegetables, less than 10% of these products are sterilized this way.

Other Forms of Preservation

The addition of chemical preservatives to many foods can prevent the growth of microorganisms that could cause spoilage or disease. Preservatives include natural chemicals such as salt (NaCl) or table sugar and artificial substances such as ethylene oxide. The main classes of preservatives are organic acids, nitrogen salts, sulfur compounds, oxides, salt, and sugar.

Organic acids, including lactic, benzoic, and propionic acids, are among the most widely used preservatives. They are added to baked goods, cheeses, pickles, carbonated beverages, jams, jellies, and dried fruits to reduce spoilage from molds and some bacteria. Nitrites and nitrates are used primarily to maintain the red color of cured meats (hams, bacon, and sausage). By inhibiting the germination of *Clostridium botulinum* spores, they also prevent botulism intoxication, but their effects against other microorganisms are limited. Sulfite prevents the growth of undesirable molds in dried fruits, juices, and wines and retards discoloration in various foodstuffs. Ethylene and propylene oxide gases disinfect various dried foodstuffs. Their use is restricted to fruit, cereals, spices, nuts, and cocoa.

The high osmotic pressure contributed by hypertonic levels of salt plasmolyzes bacteria and fungi and removes moisture from food, thereby inhibiting microbial growth. Salt is commonly added to brines, pickled foods, meats, and fish.

However, it does not retard the growth of pathogenic halophiles such as *Staphylococcus aureus*, which grows readily even in 7.5% salt solutions. The high sugar concentrations of candies, jellies, and canned fruits also exert an osmotic preservative effect. Other chemical additives that function in preservation are alcohols and antibiotics. Alcohol is added to flavoring extracts, and antibiotics are approved for treating the carcasses of chickens, fish, and shrimp.

Food can also be preserved by **desiccation**, a process that removes moisture needed by microbes for growth by exposing the food to dry, warm air. Solar drying was traditionally used for fruits and vegetables, but modern commercial dehydration is carried out in rapid-evaporation mechanical devices. Drying is not a reliable microbicidal method, however. Numerous resistant microbes such as micrococci, coliforms, staphylococci, salmonellae, and fungi survive in dried milk and eggs, which can subsequently serve as agents of spoilage and infections.

In 2006 the FDA approved the spraying of bacteriophages onto ready-to-eat meat products. The bacteriophages are specific for *Listeria* and will kill this pathogen in cold cuts and poultry that are usually not cooked before consumption. Efforts are currently underway to use *Salmonella*-specific bacteriophage—in the same manner, but it has not yet been approved for use.

27.5 General Concepts in Industrial Microbiology

Expected Learning Outcomes

- Recall the major concepts in industrial microbiology.
- Describe industrial fermentations and the role of the fermentor.

- Outline the steps in industrial mass production of organic substances.
- Describe several types of products made with fermentation technology and how they are used.

“Never underestimate the power of the microbe.”

—Jackson W. Foster,
pioneering microbiologist in the
development of antibiotics

Virtually any large-scale commercial enterprise that enlists microorganisms to manufacture consumable materials is part of the realm of industrial microbiology. Here, the term pertains primarily to bulk production of organic compounds such as antibiotics, hormones, vitamins, acids, solvents (**table 27.2**), and enzymes (**table 27.3**). Many of the processing steps involve fermentations similar to those described in food technology, but industrial processes usually occur on a much larger scale, produce a specific compound, and involve numerous complex stages. The aim of industrial microbiology is to produce chemicals that can be purified and packaged for sale or for use in other commercial processes. Thousands of tons of organic chemicals worth several billion dollars are produced by this industry every year. To create just one of these products, an industry must determine which microbes, starting compounds, and growth conditions work best. The research and development involved require an investment of 10 to 15 years and billions of dollars.

The microbes used by fermentation industries are mutant strains of fungi or bacteria that selectively synthesize large amounts

TABLE 27.2 Industrial Products of Microorganisms

Chemical	Microbial Source	Substrate	Applications
Pharmaceuticals			
Cephalosporins	<i>Cephalosporium</i>	Glucose	Antibacterial antibiotics, broad spectrum
Penicillins	<i>Penicillium chrysogenum</i>	Lactose	Antibacterial antibiotics, broad and narrow spectrum
Vitamin B ₁₂	<i>Pseudomonas</i>	Molasses	Dietary supplement
Steroids (hydrocortisone)	<i>Rhizopus</i> , <i>Cunninghamella</i>	Deoxycholic acid, stigmasterol	Treatment of inflammation, allergy; hormone replacement therapy
Food Additives and Amino Acids			
Citric acid	<i>Aspergillus</i> , <i>Candida</i>	Molasses	Acidifier in soft drinks; used to set jam; candy additive; fish preservative; retards discoloration of crabmeat; delays browning of sliced peaches
Xanthan	<i>Xanthomonas</i>	Glucose medium	Food stabilizer; not digested by humans
Acetic acid	<i>Acetobacter</i>	Any ethylene source, ethanol	Food acidifier; used in industrial processes
Miscellaneous			
Ethanol	<i>Saccharomyces</i>	Beet, cane, grains, wood, wastes	Additive to gasoline (gasohol)
Acetone	<i>Clostridium</i>	Molasses, starch	Solvent for lacquers, resins, rubber, fat, oil
Glycerol	Yeast	By-product of alcohol	Explosive (nitroglycerine)
Dextran	<i>Klebsiella</i> , <i>Acetobacter</i> , <i>Leuconostoc</i>	Glucose, molasses, sucrose	Polymer of glucose used as adsorbents, blood expanders, and in burn treatment; a plasma extender; used to stabilize ice cream and in sugary syrup and candies

TABLE 27.3 Industrial Enzymes and Their Uses

Enzyme	Source	Application
Amylase	<i>Aspergillus, Bacillus, Rhizopus</i>	Flour supplement, desizing textiles, mash preparation, syrup manufacture, digestive aid, precooked foods, spot remover in dry cleaning
Cellulase	<i>Aspergillus, Trichoderma</i>	Denim finishing (“stone-washing”), digestive aid, increase digestibility of animal feed, degradation of wood or wood by-products
Hyaluronidase	Various bacteria	Medical use in wound cleansing, preventing surgical adhesions
Keratinase	<i>Streptomyces</i>	Hair removal from hides in leather preparation
Pectinase	<i>Aspergillus, Sclerotinia</i>	Clarifies wine, vinegar, syrups, and fruit juices by degrading pectin, a gelatinous substance; used in concentrating coffee
Proteases	<i>Aspergillus, Bacillus, Streptomyces</i>	To clear and flavor rice wines, process animal feed, remove gelatin from photographic film, recover silver, tenderize meat, unravel silkworm cocoon, remove spots
Rennet	<i>Mucor</i>	To curdle milk in cheese making
Streptokinase	<i>Streptococcus</i>	Medical use in clot digestion, as a blood thinner

of various metabolic intermediates, or **metabolites**. Two basic kinds of metabolic products are harvested by industrial processes: (1) *Primary metabolites* are produced during the major metabolic pathways and are essential to the microbe’s function. (2) *Secondary metabolites* are by-products of metabolism that may not be critical to the microbe’s function (**figure 27.12**). In general, primary products are compounds such as amino acids and organic acids synthesized during the logarithmic phase of microbial growth; and secondary products are compounds such as vitamins, antibiotics, and steroids synthesized during the stationary phase (see chapter 7).

Figure 27.12 The origins of primary and secondary microbial metabolites harvested by industrial processes.

Most strains of industrial microorganisms have been chosen for their high production of a particular primary or secondary metabolite. Certain mutated strains of yeasts and bacteria can produce 20,000 times more metabolite than a wild strain of that same microbe.

Industrial microbiologists have several tricks to increase the amount of the chosen end product. First, they can manipulate the growth environment to increase the synthesis of a metabolite. For instance, adding lactose instead of glucose as the fermentation substrate increases the production of penicillin by *Penicillium*. Another strategy is to select microbial strains that genetically lack a feedback system to regulate the formation of end products, thus encouraging mass accumulation of this product. Many syntheses occur in sequential fashion, wherein the waste products of one organism become the building blocks of the next. During these *biotransformations*, the substrate undergoes a series of slight modifications, each of which gives off a different by-product (**figure 27.13**). The production of an antibiotic such as tetracycline requires several microorganisms and 72 separate metabolic steps.

From Microbial Factories to Industrial Factories

Industrial fermentations begin with microbial cells acting as living factories. When exposed to optimum conditions, they multiply in massive numbers and synthesize large volumes of a desired product. Producing appropriate levels of growth and fermentation requires cultivation of the microbes in a carefully controlled environment. This process is basically similar to culturing bacteria in a test tube of nutrient broth. It requires a sterile medium containing appropriate nutrients, protection from contamination, provisions for introduction of sterile air or total exclusion of air, and a suitable temperature and pH.

Many commercial fermentation processes have been worked out on a small scale in a lab and then *scaled up* to a large commercial venture. An essential component for scaling up is a **fermentor**

Figure 27.13 An example of biotransformation by microorganisms in the industrial production of steroid hormones.

Desired hormones such as cortisone and progesterone can require several steps and microbes, and rarely can a single microbe carry out all the required synthetic steps. (a) Beginning with starting compound Δ^4 -pregnene-3,20-dione (blue), (b) 11-dehydrocortisone (orange) is synthesized in three stages by two species of mold. (c) Cortisone (yellow) is synthesized in two stages by a pair of molds. (d) 15 α -hydroxyprogesterone (green) is synthesized in a single step by a pair of molds.

or **bioreactor** (figure 27.14), a device in which mass cultures are grown, reactions take place, and product develops. Some fermentors are large tubes, flasks, or vats, but most industrial types are metal cylinders with built-in mechanisms for stirring, cooling, monitoring, and harvesting product (figure 27.15). Fermentors are made of materials that can withstand pressure and are rustproof, nontoxic, and leakproof. They range in holding capacity from small, 5-gallon systems used in research labs to larger, 5,000- to 100,000-gallon vessels and, in some industries, to tanks of 250 million to 500 million gallons.

For optimum yield, a fermentor must duplicate the actions occurring in a tiny volume (a test tube) on a massive scale. Most microbes performing fermentations have an aerobic metabolism, and the large volumes make it difficult to provide adequate oxygen. Fermentors have a built-in device called a *sparger* that aerates the medium to promote aerobic growth. Paddles (*impellers*) located in the central part of the fermentor increase the contact between the

Figure 27.15 A schematic diagram of an industrial fermentor for mass culture of microorganisms. Such instruments are equipped to add nutrients and cultures; to remove product under sterile or aseptic conditions; and to aerate, stir, and cool the mixture automatically.

microbe and the nutrients by vigorously stirring the fermentation mixture. Their action also maintains its uniformity.

Substance Production

The general steps in mass production of organic substances in a fermenter are illustrated in **figure 27.16**. These can be summarized as follows:

1. introduction of microbes and sterile media into the reaction chamber;
2. fermentation;
3. **downstream processing** (recovery, purification, and packaging of product); and
4. removal of waste.

All phases of production must be carried out aseptically and monitored (usually by computer) for rate of flow and quality of product. The starting raw substrates include crude plant residues, molasses, sugars, fish and meat meals, and whey. Additional chemicals can be added to control pH or to increase the yield. In *batch fermentation*,

Figure 27.16 The general layout of a fermentation plant for industrial production of drugs, enzymes, fuels, vitamins, and amino acids.

the substrate is added to the system all at once and taken through a limited run until product is harvested. In *continuous feed systems*, nutrients are continuously fed into the reactor and the product is siphoned off throughout the run.

Ports in the fermentor allow the raw product and waste materials to be recovered from the reactor chamber when fermentation is complete. The raw product is recovered by settling, precipitation, centrifugation, filtration, or cell lysis. Some products come from this process ready to package, whereas others require further purification, extraction, concentration, or drying. The end product is usually in a powder, cake, granular, or liquid form that is placed in sterilized containers. The waste products can be siphoned off to be used in other processes or discarded, and the residual microbes and nutrients from the fermentation chamber can be recycled back into the system or removed for the next run.

Fermentation technology for large-scale cultivation of microbes and production of microbial products is versatile. Table 27.2 itemizes some of the major pharmaceutical substances, food additives, and solvents produced by microorganisms. Some newer technologies employ extremophiles and their enzymes to run the processes at high or low temperatures or in high-salt conditions. Hyperthermophiles have been adapted for high-temperature detergent and enzyme production. Psychrophiles are used for cold processing of reagents for molecular biology and medical tests. Halophiles are effective for processing of salted foods and dietary supplements.

Pharmaceutical Products

Health care products derived from microbial biosynthesis are antibiotics, hormones, vitamins, and vaccines. The first mass-produced antimicrobial was penicillin, which came from *Penicillium chrysogenum*, a mold first isolated from a cantaloupe in Wisconsin. The current strain of this species has gone through 70 years of selective mutation and screening to increase its yield. (The original wild *P. chrysogenum* synthesized 60 mg/ml of medium, and the latest isolate yields 85,000 mg/ml.) The semisynthetic penicillin derivatives are produced by introducing the assorted side-chain precursors to the fermentation vessel during the most appropriate phase of growth. Currently, a semisynthetic form of the antimalaria drug artemisinin is being produced by bioengineered *Saccharomyces cerevisiae*.

Several steroid hormones used in therapy are produced industrially. Corticosteroids of the adrenal cortex, cortisone and cortisol (hydrocortisone), are invaluable for treating inflammatory and allergic disorders, and female hormones such as progesterone or estrogens are the active ingredients in birth control pills. For years, the production of these hormones was tedious and expensive because it involved purifying them from slaughterhouse animal glands or chemical syntheses. In time, it was shown that, through biotransformation, various molds could convert a precursor compound called diosgenin into cortisone. By the same means, stigmasterol from soybean oil could be transformed into progesterone.

Some vaccines are also adaptable to mass production through fermentation. Vaccines for *Bordetella pertussis*, *Salmonella typhi*, *Vibrio cholerae*, and *Mycobacterium tuberculosis* are produced in large batch cultures. *Corynebacterium diphtheriae* and *Clostridium tetani* are propagated for the synthesis of their toxins, from which toxoids for the DT vaccines are prepared.

27.1 MAKING CONNECTIONS

The Bioterrorism-Biotechnology Connection

Our increasing use of genetic technology to manipulate organisms, combined with an extensive knowledge of the genomes of many pathogens, brings to mind a question. Could terrorists use these same techniques and information to create more effective weapons of bioterrorism? The answer is troubling but is fortunately tempered by some good news as well.

Startlingly effective pathogens have been created by accident in the laboratory. In one incident, what started as a contraceptive vaccine to help control Australia's mouse population resulted in a recombinant mousepox virus that, by inactivating part of the immune system, quickly killed infected mice, even those that had been previously vaccinated against the virus. As mousepox is related to smallpox, it wasn't a great leap to imagine creating a smallpox virus that was even more virulent than wild-type smallpox.

Another easily imagined scenario is the incorporation of antibiotic-resistance genes into highly virulent bacterial pathogens. The anthrax scare of late 2001 was tempered somewhat by the fact that anthrax is easily treated with the antibiotic ciprofloxacin. If the anthrax had been a strain engineered to carry a gene for ciprofloxacin resistance, its power both to kill and to induce fear would have been much greater. This is not idle speculation; when several scientists from Biopreparat, a network of laboratories in Russia and Kazakhstan, defected to the West, they claimed they had created a form of *Yersinia pestis*, the bacterium responsible for plague, that was resistant to 16 different antibiotics.

Several companies have developed techniques to engineer a wide variety of bacteria with traits such as production of new antibiotics. A California company used this technology to create a strain of *E. coli* that was 32,000 times **less** sensitive to the antibiotic cefotaxime. After this persuasive demonstration of its new technology, the company destroyed the resultant strain at the request of the American Society for Microbiology, which was concerned about the potential of the resistant strain falling into the wrong hands.

But all is not lost. Pathogens engineered in the laboratory would probably struggle to survive in the outside world. It is extremely difficult to engineer a pathogen that can retain its newly enhanced (or acquired) virulence yet remain transmissible. Any new trait would soon be lost unless it conferred some selective advantage on its bearer. The questions then become: How quickly will the pathogen lose its virulence, and how many people will be infected before that happens? Clearly, the rapid discovery of pathogens is a key aspect of keeping people safe.

Beginning in 2003 the BioWatch system was implemented to provide just such rapid detection. Relying on air samplers in more than 30 cities to collect air in public places like train stations and airports, some samplers even sat atop public buildings. As air traveled through filters in the sampler, microbes would be trapped. Once a day, the filters were collected and screened for the presence of plague, tularemia, smallpox, and other pathogens. Unfortunately BioWatch was prone to false alarms, with over 50 recorded since the system was first put into service. Based on testing carried out secretly at the Pacific Northwest National Laboratory

A BioWatch air sampler in the Washington, D.C. subway Courtesy of Lawrence Livermore National Laboratory

in Washington State, the assays used to detect pathogens as part of BioWatch were found to be unsuitable for the task and the search began for more specific methods.

In 2010 a highly advanced technology that screens for pathogens was introduced by the Lawrence Livermore National Laboratory. This device, called the Microbial Detection Array, is loaded with nearly 400,000 known DNA probes that interact with more than 2,000 viruses and about 900 bacteria. Its plan is similar to the microarrays described in chapter 10 for identifying genes.

In practice, DNA is extracted from a sample of interest and labeled with a fluorescent dye. The processed sample is loaded onto the array chip, which is about the size of a glass slide. After hybridization, the chip is scanned and analyzed by computers that detect any of the probes that are adhering to the sample DNA and provide a readout of that sample's identity. This versatile technology has numerous benefits and applications. Most results will be available in about 24 hours and can be focused on detecting just those pathogens with the highest bioterrorism potential. To illustrate the detection array's accuracy and sensitivity, when its makers used it to screen a new rotavirus vaccine, they were able to detect a pig virus that had contaminated the vaccine. Right now, its potentials for use in biodefense, law enforcement, diagnosis, and industry seem almost unlimited.

What are some of the major ethical and medical concerns surrounding the development of harmful technologies? *Answer available on Connect.*

Miscellaneous Products

An interesting use of the powers of certain microbes has been the development and industrial production of natural *biopesticides* using *Bacillus thuringiensis*. During sporulation, these bacteria produce intracellular crystals that can be toxic to certain insects. When the insect ingests this endotoxin, its digestive tract breaks down and it dies, but the material is relatively nontoxic to other organisms. Commercial dusts are available to suppress caterpillars, moths, and worms on various agricultural crops and trees. A strain of this bacterium is also being considered to control the mosquito vector of malaria (chapter 23) and the black fly vector of onchocerciasis (river blindness; chapter 23).

Enzymes are critical to chemical manufacturing, the agriculture and food industries, textile and paper processing, and even laundry and dry cleaning. The advantage of enzymes is that they are very specific in their activity and are readily produced and released by microbes. Mass quantities of proteases, amylases, lipases, oxidases, and cellulases are produced by fermentation technology (see table 27.3). The wave of the future appears to be custom designing enzymes to perform a specific task by altering their amino acid content. Other compounds of interest that can be mass-produced by microorganisms are amino acids, organic acids, solvents, and natural flavor compounds to be used in air fresheners and foods.

In exploring the unlimited possibilities for applications of this technology, biotechnology-based industries have even ventured into developing products related to bioterrorism (**27.1 Making Connections**).

CASE STUDY Part 2

The outbreak at the military lunch revolved around a dish called perlo, which contained chicken, sausage, and rice. The day before the lunch, chicken was cooked in a pot of boiling water; the meat was removed from the bones, by hand, and combined with cooked sausages, onions, seasonings, and rice. The pot of cooked perlo was placed in an unheated oven overnight. The following day the perlo, which was still warm, was transferred to a slow cooker and reheated before being served. Most likely, *Staphylococcus aureus* was present on the hands of one of the persons who removed the cooked chicken from the bones (gloves were not worn during this process). *S. aureus* growth and toxin production is optimal at 34°C to 41°C (93°F to 106°F), and storing the dish in an unheated oven overnight provided

a perfect environment for both growth and toxin production. Staphylococcal enterotoxins are resistant to heat, and though the *S. aureus* bacteria may have been killed when the perlo was reheated, the toxins were still fully active. The speed with which staphylococcal intoxication occurs (as early as 2 hours after lunch, in this case) is always a clue as to the offending organism. Further, the halotolerance of *Staphylococcus* makes it a prime suspect when a dish is highly salty (containing ham or sausage, for instance). Fortunately food intoxication due to *S. aureus* generally passes quickly and has no lingering effects.

The botulism case was traced to homemade potato salad. Every ill person reported having eaten some at the potluck, and leftover potato salad tested positive for the presence of botulinum toxin. The person who prepared the potato salad used home-canned potatoes that had been prepared in a boiling water canner, which does not kill endospores of *Clostridium botulinum*. Acidic foods, like tomatoes or pickles, with a pH below 4.6 inhibit germination of *C. botulinum* endospores, but potatoes are a low-acid food and don't possess this inhibitory property. Further, the home canning process creates an anaerobic environment, and if endospores of *C. botulinum* (an obligate anaerobe) are present, they will germinate, grow, and produce toxins during storage of the food. Finally, in contrast to staphylococcal enterotoxin, botulinum neurotoxin is heat labile and boiling the potatoes for 10 minutes prior to making the potato salad would have inactivated the toxins. Fortunately no other patients died, but 29 were hospitalized.

The Chipotle outbreak may never be solved. The slower pace of an *E. coli* infection compared to the intoxications seen in the other two cases make epidemiological investigation far more difficult. In the week to 10 days it took for most patients to present to a physician, restaurant trash had been thrown away, supplies of meat and vegetables had been exhausted and reordered several times, and countertops, refrigerators, and work surfaces had been cleaned many times over. The fact that several different Chipotle locations were involved in the outbreak indicated that the source of infection was probably a food ingredient delivered to many restaurants from a single supplier and not a sick Chipotle employee or other isolated source. By the end of 2015 the outbreak seemed to have run its course, and it was thought that whatever had caused the problem was no longer in the restaurant's supply chain. On February 1, 2016, the CDC declared the outbreak to be over.

- Why would potatoes be a common vehicle for botulism?
- Food safety guidelines recommend that large batches of food be transferred to shallow containers prior to refrigeration. Why is this?

To learn more about these three cases, search the Internet for “Large Outbreak of Botulism Associated with a Church Potluck Meal,” “Outbreak of Staphylococcal Food Poisoning from a Military Unit Lunch Party,” or “Multistate Outbreaks of Shiga Toxin-Producing *Escherichia coli* O26 Infections Linked to Chipotle Mexican Grill Restaurants.”

Chapter Summary with Key Terms

27.1 Applied Microbiology and Biotechnology

Biotechnology is the practical application of microbiology in the manufacture of food, industrial chemicals, drugs, and other products. Many of these processes use mass, controlled microbial **fermentations** and bioengineered microorganisms.

- A. Microorganisms in Water and Wastewater Treatment
1. Drinking water is rendered safe by a purification process that involves storage, sedimentation, settling, aeration, filtration, and disinfection.
 2. Sewage or used wastewater can be processed to remove solid matter, dangerous chemicals, and microorganisms.
 3. Microbes biodegrade the waste material or sludge. Solid wastes are further processed in **anaerobic digesters**.

27.2 The Microbiology of Food

- A. Microbes and humans compete for the rich nutrients in food. Many microbes are present on food as harmless contaminants; some are used to create flavors and nutrients; others may produce unfavorable reactions.
1. The beneficial effects of microorganisms on food are based mainly on their ability to ferment or chemically change it to alter flavor, taste, or texture. Microbes can also serve as food themselves.
 2. The detrimental effects of microorganisms are their ability to cause food-borne illness and to spoil food, making it unsuitable for consumption.
 3. Microbes in or on food may result in no consequences at all. In that case, their effect on food is considered neutral.

27.3 Microbial Fermentations in Food Products from Plants

- A. Microbes can impart desirable aroma, flavor, or texture to foods. Bread, alcoholic beverages, some vegetables, and some dairy products are infused with pure microbial strains to yield the necessary fermentation products.
1. Baker's yeast, *Saccharomyces cerevisiae*, is used to **leaven** bread dough by giving off CO₂.
 2. Beer making involves the following steps: Barley is sprouted (**malted**) to generate digestive enzymes, transformed to **mash**, and heated with **hops** to produce a **wort**. Wort is fermented by yeast and **lagered** in large tanks before it is carbonated and packaged.

3. Wine is started by fermentation of **must** (fruit juices). Whiskey, vodka, brandy, and other alcoholic beverages are distilled to increase their alcohol content.
4. Vegetable products, including sauerkraut, pickles, and soybean derivatives, can be pickled in the presence of salt or sugar.
5. Vinegar is produced by fermenting plant juices first to alcohol and oxidizing the alcohol to acetaldehyde and acetic acid.
6. Most dairy products are produced by microbes acting on nutrients in milk. In cheese production, milk proteins are coagulated to a solid **curd** that separates from the watery **whey**.
7. Mass-cultured microbes such as yeasts, molds, and bacteria can serve as food. Proteins derived from microbes are currently added to animal feeds.

27.4 Microbial Involvement in Food-Borne Disease

- A. A number of bacteria, protozoa, and viruses cause spoilage and food poisoning.
- B. Prevention Measures
1. Microbial growth that leads to spoilage and food poisoning can be avoided by high temperature and pressure treatment (canning) and **pasteurization** for disinfecting milk and other heat-sensitive beverages.
 2. Refrigeration and freezing inhibit microbial growth.
 3. Irradiation sterilizes or disinfects foods for longer-term storage.
 4. Alternative preservation methods include additives (salt, nitrites), treatment with ethylene oxide gas, and drying.

27.5 General Concepts in Industrial Microbiology

- A. Industrial microbiology involves the large-scale commercial production of organic compounds such as antibiotics, vitamins, amino acids, enzymes, and hormones using specific microbes in carefully controlled fermentation settings.
- B. Microbes are chosen for their production of a desired **metabolite**; several different species can be used to biotransform raw materials in a stepwise series of metabolic reactions.
- C. Fermentations are conducted in massive culture devices called **fermentors** that have special mechanisms for adding nutrients, stirring, oxygenating, altering pH, cooling, monitoring, and harvesting product.

Level I. Knowledge and Comprehension

These questions require a working knowledge of the concepts in the chapter and the ability to recall and understand the information you have studied.

? Multiple-Choice Questions

Select the correct answer from the answers provided. For questions with blanks, choose the combination of answers that most accurately completes the statement.

1. Which of the following is *not* a stage in purification of drinking water?
 - a. filtration
 - b. chlorination
 - c. activated sludge
 - d. sedimentation
2. Milk is usually pasteurized by
 - a. the high-temperature short-time method
 - b. ultrapasteurization
 - c. batch method
 - d. electrical currents

3. Substances given off by yeasts during fermentation are
 - a. alcohol
 - b. carbon dioxide
 - c. organic acids
 - d. all of these
 4. Which of the following is added to facilitate milk curdling during cheese making?
 - a. lactic acid
 - b. salt
 - c. *Lactobacillus*
 - d. rennin
 5. Secondary metabolites of microbes are formed during the _____ phase of growth.
 - a. exponential
 - b. stationary
 - c. lag
 - d. death
 6. The dried, presprouted grain that is soaked to activate enzymes for beer is
 - a. hops
 - b. malt
 - c. wort
 - d. mash
 7. A food maintenance temperature that generally will prevent food poisoning is
 - a. below 4°C
 - b. above 60°C
 - c. room temperature
 - d. both a and b
 8. Most cases of food intoxication are caused by
 - a. *Salmonella enteritidis*
 - b. *Staphylococcus aureus*
 - c. *Bacillus cereus*
 - d. *Giardia lamblia*
 9. The large tanks used in industrial production of antibiotics are termed
 - a. digesters
 - b. fermentors
 - c. spargers
 - d. biotransformers
 10. Which of the following microbes produces a natural biopesticide?
 - a. *Penicillium chrysogenum*
 - b. *Saccharomyces cerevisiae*
 - c. *Bacillus thuringiensis*
 - d. *Lactobacillus bulgaricus*
-

Case Study Review

1. Chopped garlic often contains *C. botulinum* endospores and is commonly sold submerged in olive oil, which creates an anaerobic environment. What is required to be added to garlic sold in this manner?
 - a. sodium chloride
 - b. citric acid
 - c. water
 - d. A warning label describing the symptoms of botulism.
 2. During the Chipotle outbreak, some people were sickened with *E. coli*, but a DNA profile of the bacterium in their feces showed that it was not the outbreak strain. What conclusion can be drawn from this information?
 - a. The person was not sickened by *E. coli*.
 - b. The person is not part of the outbreak.
 - c. *Escherichia coli* mutates frequently, making DNA profiling unreliable.
 - d. The person has already begun to recover from the disease.
 3. If the bacterium in question during the perlo outbreak had been *E. coli* instead of *S. aureus*, how might the outbreak have changed?
-

Writing Challenge

For each question, compose a one- or two-paragraph answer that includes the factual information needed to completely address the question. Check Your Progress questions can also be used for writing-challenge exercises.

1. Every year, supposedly safe municipal water supplies cause outbreaks of enteric illness.
 - a. How in the course of water analysis and treatment might these pathogens be missed?
 - b. Why is there less tolerance for a fecal coliform in drinking or recreational water than for other bacteria?
 2. Summarize the basic processes in food fermentations, using examples from beer, wine, and dairy products.
 3. Outline the major methods used to prevent foodborne illness and spoilage. Explain the adage “When in doubt, throw it out” from a microbiological perspective.
 4. Explain the differences between primary and secondary metabolites as they relate to industrial microbiology.
-

Concept Mapping

On Connect you can find an Introduction to Concept Mapping that provides guidance for working with concept maps along with concept mapping activities for this chapter.

Level II. Application, Analysis, Evaluation, and Synthesis

These problems go beyond just restating facts and require higher levels of understanding and an ability to interpret, problem solve, transfer knowledge to new situations, create models, and predict outcomes.

Critical Thinking

Critical thinking is the ability to reason and solve problems using facts and concepts. These questions can be approached from a number of angles, and in most cases, they do not have a single correct answer.

- Describe three important potential applications of bacteria that can make methane.
- Describe four food-preparation and food-maintenance practices in your own kitchen that could expose people to food poisoning, and explain how to prevent them.
 - What is a good general rule to follow concerning food of questionable quality?
- What is the purpose of boiling the wort in beer preparation?
 - What are hops used for?
 - If fermentation of sugars to produce alcohol in wine is anaerobic, why do winemakers make sure that the early phase of yeast growth is aerobic?
- Predict the differences in the outcome of raw milk that has been incubated for 48 hours versus pasteurized milk that has been incubated for the same length of time.
- Explain the ways that biotransformation by synergistic microorganisms is harnessed in industrial microbiology.
 - Outline the steps in the production of an antibiotic, starting with a newly discovered mold.
 - Review chapter 10 and locate examples of recombinant DNA technology being applied to industrial processes.
- Log on to <http://www.cdc.gov/pulsenet/> to learn about the PulseNet system and explain how it would have been applied in the three outbreaks described in this chapter's Case Study.

Visual Challenge

- From **chapter 7, figure 7.6**. What method of food preservation exploits the principles that are illustrated here?

Hypotonic Solution

Hypertonic Solution

- From **chapter 8, figure 8.23**. Correlate the stages in this figure with corresponding steps in wine making, starting with grapes (figure 27.6). Where do champagne bubbles come from? What causes wine to go sour?

Appendix A

Detailed Steps in the Glycolysis Pathway

Steps in the Glycolysis Pathway The first portion of glycolysis involves activation of glucose, which is followed by oxidation reactions of the glucose fragments, the synthesis of ATP, and the formation of pyruvic acid. *Although each step of metabolism is catalyzed by a specific enzyme, we will not mention it for most reactions.* The following outline lists the principal steps of glycolysis. To see an overview of glycolysis, refer to figure 8.17.

1. **Glucose** is phosphorylated by means of an **ATP** acting with the enzyme hexokinase. The product is glucose-6-phosphate. (Numbers in chemical names refer to the position of the phosphate on the carbon skeleton.) This is a way of “priming” the system and keeping the glucose inside the cell.

2. Glucose-6-phosphate is converted to its isomer, fructose-6-phosphate, by phosphoglucisomerase.

3. Another ATP is spent in phosphorylating the first carbon of fructose-6-phosphate, which yields fructose-1,6-diphosphate.

Up to this point, no energy has been released, no oxidation-reduction has occurred, and, in fact, 2 ATPs have been used. In addition, the molecules remain in the 6-carbon state.

4. Now doubly activated, fructose-1,6-diphosphate is split into two 3-carbon fragments: glyceraldehyde-3-phosphate (G-3-P) and dihydroxyacetone phosphate (DHAP). These molecules are isomers, and DHAP is enzymatically converted to G-3-P, which is the more reactive form for subsequent reactions.

The effect of the splitting of fructose diphosphate is to double every subsequent reaction, because where there was once a single molecule, there are now two to be fed into the remaining pathways.

5. Each molecule of glyceraldehyde-3-phosphate becomes involved in the single oxidation-reduction reaction of glycolysis, a reaction that sets the scene for ATP synthesis. Two reactions occur simultaneously and are catalyzed by the same enzyme, called glyceraldehyde-3-phosphate dehydrogenase. The coenzyme **NAD⁺** picks up electrons and a proton from G-3-P, forming **NADH**. This step is accompanied by the addition of an inorganic phosphate (**PO₄³⁻**) to form an unstable bond on the third carbon of the G-3-P substrate. The product of these reactions is diphosphoglyceric acid.

In aerobic organisms, the NADH formed during step 5 will undergo further reactions in the electron transport system, where the final electron acceptor will be oxygen, and an additional 3 ATPs will be generated per NADH. In organisms that ferment glucose anaerobically, the NADH will be oxidized back to NAD⁺, and the hydrogen acceptor will be an organic compound.

6. One of the high-energy phosphates of diphosphoglyceric acid is donated to ADP via substrate-level phosphorylation, resulting in a molecule of ATP. The product of this reaction is 3-phosphoglyceric acid.

7,8. During this phase, a substrate for the synthesis of a second ATP is made in two substeps. First, 3-phosphoglyceric acid is converted to 2-phosphoglyceric acid through the shift of a phosphate from the third to the second carbon. Then, the removal of a water molecule from 2-phosphoglyceric acid produces phosphoenolpyruvic acid, which is charged to release a high-energy phosphate.

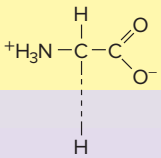

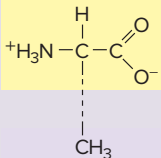

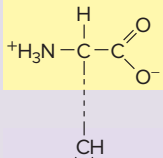

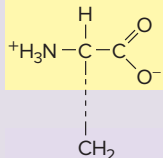

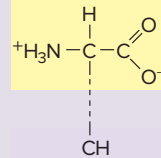

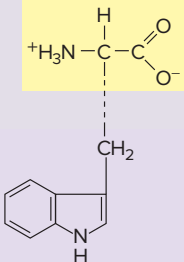

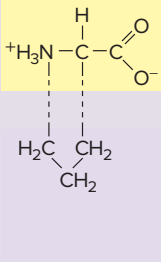

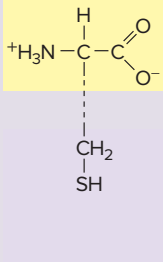

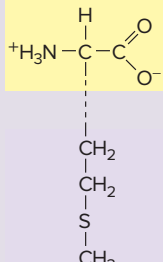

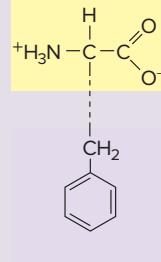

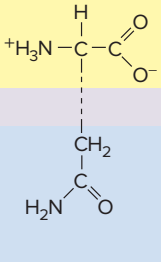

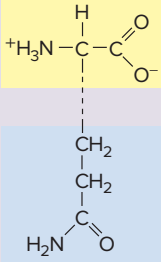

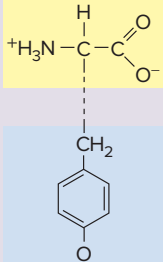

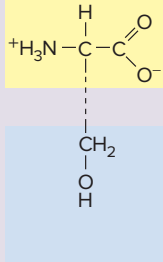

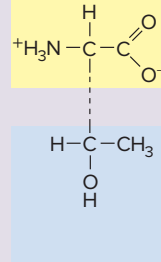

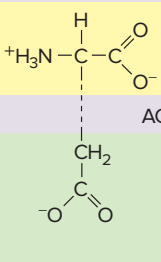

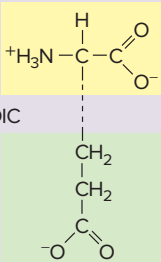

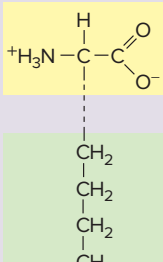

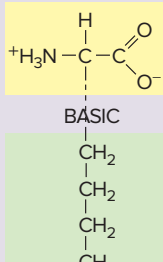

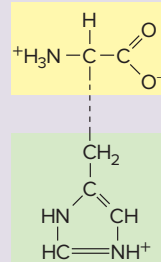

9. In the final reaction of glycolysis, phosphoenolpyruvic acid gives up its high-energy phosphate to form a second ATP via substrate-level phosphorylation. This reaction, catalyzed by pyruvate kinase, also produces pyruvic acid (pyruvate), a compound with many roles in metabolism.

The 2 ATPs formed during steps 6 and 9 are examples of substrate-level phosphorylation, in that the high-energy phosphate is transferred directly from a substrate to ADP. These reactions are catalyzed by kinases. Because both molecules that arose in step 4 undergo these reactions, an overall total of 4 ATPs is generated in the partial oxidation of a glucose to 2 pyruvic acids. However, 2 ATPs were expended for steps 1 and 3, so the net number of ATPs available to the cell from these reactions is 2.

TABLE A.1 Twenty Amino Acids and Their Abbreviations*

Nonpolar							
	Glycine (Gly)	Alanine (Ala)	Valine (Val)	Leucine (Leu)	Isoleucine (Ile)		
							
	Tryptophan (Trp)	Proline (Pro)	Cysteine (Cys)	Methionine (Met)	Phenylalanine (Phe)		
	Polar						
		Asparagine (Asn)	Glutamine (Gln)	Tyrosine (Tyr)	Serine (Ser)	Threonine (Thr)	
		Electrically Charged					
			Aspartic Acid (Asp)	Glutamic Acid (Glu)	Arginine (Arg)	Lysine (Lys)	Histidine (His)

*The basic skeleton is in yellow; R groups are in purple, blue, or green, depending on the nature of their composition.

Appendix B

Tests and Guidelines

Methods for Testing Sterilization and Germicidal Processes

Most procedures used for microbial control in the clinical setting are either physical methods (heat, radiation) or chemical methods (disinfectants, antiseptics). These procedures are so crucial to the well-being of patients and staff that their effectiveness must be monitored in a consistent and standardized manner. Particular concerns include the time required for the process, the concentration or intensity of the antimicrobial agent being used, and the nature of the materials being treated. The effectiveness of an agent is frequently established through controlled microbiological analysis. In these tests, a biological indicator (a highly resistant microbe) is exposed to the agent, and its viability is checked. If this known test microbe is destroyed by the treatment, it is assumed that the less resistant microbes have also been destroyed. Growth of the test organism indicates that the sterilization protocol has failed. The general categories of testing include:

Heat The usual form of heat used in microbial control is steam under pressure in an autoclave. Autoclaving materials at a high temperature (121°C) for a sufficient time (15–40 minutes) destroys most bacterial endospores. To monitor the quality of any given industrial or clinical autoclave run, technicians insert a dried test strip of *Bacillus stearothermophilus*, a spore-forming bacterium with extreme heat resistance. After autoclaving, the ampule is incubated at 56°C (the optimal temperature for this species) and checked for growth.

Radiation The effectiveness of ionizing radiation in sterilization is determined by placing special strips of dried spores of *Bacillus sphaericus* (a common soil bacterium with extreme resistance to radiation) into a packet of irradiated material.

Filtration The performance of membrane filters used to sterilize liquids may be monitored by adding *Pseudomonas diminuta* to the liquid. Because this species is a tiny bacterium that can escape through the filter if the pore size is not small enough, it is a good indicator of filtrate sterility.

Gas sterilization Ethylene oxide gas, one of the few chemical sterilizing agents, is used on a variety of heat-sensitive medical and laboratory supplies. The most reliable indicator of a successful sterilizing cycle is the sporeformer *Bacillus subtilis*, variety *niger*.

Germicidal assays U.S. hospitals and clinics commonly employ more than 250 products to control microbes in the environment, on inanimate objects, and on patients. Controlled testing of these products' effectiveness is usually performed not in the clinic itself but by the chemical or pharmaceutical manufacturer. A number of standardized in vitro tests are currently available to assess the effects of germicides. Most of them use a non-sporeforming pathogen as the biological indicator.

The Phenol Coefficient (PC)

The older disinfectant phenol has been the traditional standard by which other disinfectants are measured. In the PC test, a water-soluble phenol-based (phenolic) disinfectant (Amphyl, Lysol) is tested for its bactericidal effectiveness as compared with phenol. These disinfectants are serially diluted in a series of *Salmonella choleraesuis*, *Staphylococcus aureus*, or *Pseudomonas aeruginosa* cultures. The tubes are left for 5, 10, or 15 minutes and then subcultured to test for viability. The PC is a ratio derived by comparing the following data:

$$PC = \frac{\text{Greatest dilution of the phenolic that kills test bacteria in 10 min but not in 5 min}}{\text{Greatest dilution of phenol giving same result}}$$

The general interpretation of this ratio is that chemicals with lower phenol coefficients have greater effectiveness. The primary disadvantage of the PC test is that, because it is restricted to phenolics, it is inappropriate for the vast majority of clinical disinfectants.

Use Dilution Test

An alternative test with broader applications is the use dilution test. This test is performed by drying the test culture (one of those species used in the PC test) onto the surface of small stainless steel cylindrical carriers. These carriers are then exposed to varying concentrations of disinfectant for 10 minutes, removed, rinsed, and placed in tubes of broth. After incubation, the tubes are inspected for growth. The smallest concentration of disinfectant that kills the test organism on 10 carrier pieces is the correct dilution for use.

Filter Paper Disc Method

A quick measure of the inhibitory effects of various disinfectants and antiseptics can be achieved by the filter paper disc method. First, a small (½-inch) sterile piece of filter paper is dipped into a disinfectant of known concentration. This is placed on an agar medium seeded with a test organism (*S. aureus* or *P. aeruginosa*), and the plate is incubated. A zone devoid of growth (zone of inhibition) around the disc indicates the capacity of the agent to inhibit growth (**figure B.1**). Like the antimicrobial sensitivity test (see figure 12.18), this test measures the minimum inhibitory concentration of the chemical. In general, chemicals with wide zones of inhibition are effective even in high dilutions.

Guidelines for Universal Precautions in the Clinical Setting

The significance of these procedures for infection control is introduced in chapter 13.

1. Barrier precautions, including masks and gloves, should be taken to prevent contact of skin and mucous membranes with patients' blood or other body fluids. Because gloves can

FIGURE B.1 A filter paper disc containing hydrogen peroxide produces a broad clear zone of inhibition in a culture of *Staphylococcus aureus*.

Source: © Kathy Park Talaro

develop small invisible tears, double gloving further decreases the risk. For protection during surgery, venipuncture, or emergency procedures, gowns, aprons, and other body coverings should be worn. Dental workers should wear eyewear and face shields to protect against splattered blood and saliva.

2. More than 10% of health care personnel are pierced each year by sharp (and usually contaminated) instruments. These accidents carry risks not only for AIDS but also for hepatitis B, hepatitis C, and other diseases. Preventing inoculation infection requires vigilant observance of proper techniques.
 - All disposable needles, scalpels, or sharp devices from invasive procedures must immediately be placed in puncture-proof containers for sterilization and final discard.
3. Dental handpieces should be sterilized between patients, but if this is not possible, they should be thoroughly disinfected with a high-level disinfectant (peroxide, hypochlorite). Blood and saliva should be removed completely from all contaminated dental instruments and intraoral devices prior to sterilization.
4. Hands and other skin surfaces that have been accidentally contaminated with blood or other fluids should be scrubbed immediately with a germicidal soap. Hands should likewise be washed after removing rubber gloves, masks, or other barrier devices.
5. Because saliva can be a source of some types of infections, barriers should be used in all mouth-to-mouth resuscitations.
6. Health care workers with active, draining lesions of the skin or mucous membrane must refrain from handling patients or equipment that will come into contact with other patients. Pregnant health care workers risk infecting their fetuses and must pay special attention to these guidelines. Personnel should be protected by vaccination whenever possible.

Isolation procedures for known or suspected infections should still be instituted on a case-by-case basis. See table 13.11.

An additional consideration with regard to infectious agents is covered by the biosafety levels of microbes being handled in the laboratory, ranging from 1 (least level of pathogenicity) up to 4 (highest level of pathogenicity). This topic is also discussed in chapter 13. An overview of the containment levels and concerns are presented in **table B.1**.

TABLE B.1 Primary Biosafety Levels and Agents of Disease

Personnel handling infectious agents in the laboratory must be protected from possible infection through special risk management or containment procedures.		
Biosafety Level	Facilities and Practices	Risk of Infection and Class of Pathogens
1	Standard, open bench, no special facilities needed; typical of most microbiology teaching labs; access may be restricted.	Low infection hazard; class 1 microbes not generally considered pathogens and will not invade the bodies of healthy persons; <i>Micrococcus luteus</i> , <i>Bacillus megaterium</i> , <i>Lactobacillus</i> , <i>Saccharomyces</i> .
2	At least Level 1 facilities and practices; plus personnel must be trained in handling pathogens; lab coats and gloves required; safety cabinets may be needed; biohazard signs posted; access restricted.	Agents with moderate potential to infect; class 2 pathogens can cause disease in healthy people but can be contained with proper facilities; pathogens that belong to class 2 include <i>Staphylococcus aureus</i> , <i>Escherichia coli</i> , <i>Salmonella</i> spp.; pathogenic helminths; hepatitis A, B, and rabies viruses; <i>Cryptococcus</i> and <i>Blastomyces</i> ; HIV.
3	Minimum of Level 2 facilities and practices; manipulation performed in safety cabinets with special containment features; all personnel require protective clothing; no unsterilized materials can leave the lab; personnel are monitored and vaccinated.	Agents can cause severe or lethal disease especially when inhaled; spp. 3 microbes include <i>Mycobacterium tuberculosis</i> , <i>Francisella tularensis</i> , <i>Yersinia pestis</i> , <i>Brucella</i> spp., <i>Coxiella burnetii</i> , <i>Coccidioides immitis</i> , yellow fever, and western equine encephalitis.
4	Minimum of Level 3 facilities and practices; facilities have highest levels of controlled access; clothing changes and showers required for all people entering and leaving; materials must be autoclaved or gas-sterilized prior to entering and leaving lab.	Agents being handled are highly virulent microbes that pose extreme risk for morbidity and mortality when inhaled in droplet or aerosol form; class 4 microbes include flaviviruses, arenaviruses (Lassa fever virus), and filoviruses (Ebola and Marburg viruses).

TABLE B.2 Most Probable Number Chart for Evaluating Coliform Content of Water

The Number of Tubes in Series, with Positive Growth at Each Dilution							
10 ml	1 ml	0.1 ml	MPN* per 100 ml of Water	10 ml	1 ml	0.1 ml	MPN* per 100 ml of Water
0	1	0	0.18	5	0	1	3.1

5	0	0	2.3	5	5	4	160.0

*Most probable number of cells per sample of 100 ml.

Tests for Water Analysis

Figure B.2 and table B.2 provide standards used in analyzing water samples using the most probable number (MPN) method, as described in chapter 26. The figure indicates the steps in the laboratory procedure, and the table provides estimated counts for coliforms, based on the number of tubes with growth.

FIGURE B.2 The most probable number (MPN) procedure for determining the coliform content of a water sample. In the presumptive test, each set of tubes of broth is inoculated with a water sample reduced by a factor of 10. After incubation, the sets of tubules are examined and rated for gas production (for instance, 0 means no tubes with gas, 1 means one tube with gas, 2 means two tubes with gas). Applying this result to Table C.2 will indicate the probable number of cells present in 100 ml of the water sample. Confirmation of coliforms can be achieved by confirmatory tests on additional media, and complete identification can be made through selective and different media and staining (Chapter 20).

Appendix C

General Classification Techniques and Taxonomy of Bacteria

TABLE C.1 Summary of Techniques Used in Bacterial Identification and Classification, Chapter 4, Section 4.6

<ul style="list-style-type: none"> • Microscopic Morphology Traits that can be valuable aids to identification are combinations of cell shape and size, Gram stain reaction, acid-fast reaction, and special structures, including endospores, granules, and capsules. Electron microscope studies can pinpoint additional structural features (such as the cell wall, flagella, pili, and fimbriae). • Macroscopic Morphology Appearance of colonies, including texture, size, shape, pigment, speed of growth and patterns of growth in broth and gelatin media. • Physiological/Biochemical Characteristics Enzymes and other biochemical properties of bacteria are fairly reliable and stable expressions of the “chemical identity” of each species. Diagnostic tests determine the presence of specific enzymes and assess nutritional and metabolic activities. Examples include fermentation of sugars; digestion of complex polymers such as proteins and polysaccharides; presence of catalase, oxidase, and decarboxylases; sensitivity to antimicrobial drugs. • Chemical Analysis Analyzing the types of specific structural substances that the bacterium contains, such as the chemical composition of peptides in the cell wall and lipids in membranes. • Serological Analysis Bacteria display molecules called antigens that are recognized by the immune system. One immune response to antigens is to produce antibodies that are designed to bind tightly to the antigens. This response is so specific that antibodies can be used as a means of identifying bacteria in specimens and cultures. • Genetic and Molecular Analysis Examining the genetic material itself has revolutionized the identification and classification of bacteria. 	<p>G + C Base Composition The overall percentage of guanine and cytosine (the G + C content as compared with A + T content) in DNA is a general indicator of relatedness because it is a trait that does not change rapidly. Bacteria with a significant difference in G + C percentage are less likely to be genetically related. See the revised classification scheme that is partly based on this percentage (table C.2).</p> <p>DNA Analysis Using Genetic Probes It is possible to identify a bacterial species by analyzing its genetic material. This uses small fragments of DNA (or RNA) called probes that are complementary to the specific sequences of DNA from a particular microbe. Unknown test DNA from specimens or cultures is bound to a special surface. After several different probes have been added, the plate is observed for visible signs that the probes have become fixed to the test DNA. The binding of probes onto areas of the test DNA indicates close correspondence and makes identification possible.</p> <p>Nucleic Acid Sequencing and rRNA Analysis One of the most valuable indicators of evolutionary relatedness is the sequence of nitrogen bases in ribosomal RNA, a major component of ribosomes. Ribosomes have the same function (protein synthesis) in all cells, and they tend to remain stable in their nucleic acid content over long periods. Thus, any major differences in the sequence, or “signature,” of the rRNA is likely to indicate some distance in ancestry.</p> <p>This technique is effective for differentiating general group differences (it was used to separate the three superkingdoms of life discussed in chapter 1), and it can identify species. Elements of these and other identification methods are presented in more detail in chapters 10, 16, and 17.</p>

Case Study 27 Questions

1. b
2. b
3. Answer appears in Connect

Glossary

- abiogenesis** The belief in spontaneous generation as a source of life.
- abiotic** Nonliving factors such as soil, water, temperature, and light that are studied when looking at an ecosystem.
- ABO blood group system** Developed by Karl Landsteiner in 1904; the identification of different blood groups based on differing isoantigen markers characteristic of each blood type.
- abscess** An inflamed, fibrous mass enclosing a core of pus.
- abyssal zone** The deepest region of the ocean; a sunless, high-pressure, cold, anaerobic habitat.
- acid-fast** A term referring to the property of mycobacteria to retain carbol fuchsin even in the presence of acid alcohol. The staining procedure is used to diagnose tuberculosis.
- acidic** A solution with a pH value below 7 on the pH scale.
- acidic fermentation** An anaerobic degradation of pyruvic acid that results in organic acid production.
- acquired immunodeficiency syndrome** See **AIDS**
- acquired immunodeficiency syndrome/AIDS** The complex signs and symptoms of immune system destruction seen during the late phase of human immunodeficiency virus (HIV) infection.
- acquired or adaptive immunity** Refers to specific immunity developed by lymphocytes responding to antigens.
- actin** Fine protein fibers within cells that contribute to structure and support.
- actinomycetes** A group of filamentous, funguslike bacteria.
- active immunity** Immunity acquired through direct stimulation of the immune system by antigen.
- active site** The specific region on an apoenzyme that binds substrate. The site for reaction catalysis.
- active transport** Nutrient transport method that requires carrier proteins in the membranes of the living cells and the expenditure of energy.
- acute** Characterized by rapid onset and short duration.
- acyclovir** A synthetic purine analog that blocks DNA synthesis in certain viruses, particularly the herpes simplex viruses.
- adapt/adaptation** The act of successfully adjusting to a new environment, often made possible by random genetic changes that provide an advantage under changed environmental conditions.
- adenine (A)** A purine nitrogen base found in DNA and RNA that pairs with the pyrimidine thymine.
- adenosine deaminase (ADA) deficiency** An immunodeficiency disorder and one type of SCIDS that is caused by an inborn error in the metabolism of adenine. The accumulation of adenine destroys both B and T lymphocytes.
- adenosine triphosphate (ATP)** A nucleotide that is the primary source of energy for cells.
- adenovirus** Nonenveloped DNA virus that causes colds; transmissible via respiratory and ocular secretions.
- adhesion** The process by which microbes gain a stable foothold at the portal of entry; often involves a specific interaction between the molecules on the microbial surface and the receptors on the host cell.
- adjuvant** In immunology, a chemical vehicle that enhances antigenicity, presumably by prolonging antigen retention at the injection site.
- adsorption** A process of adhering one molecule onto the surface of another molecule.
- aerobe** A microorganism that lives and grows in the presence of free gaseous oxygen (O₂).
- aerobic respiration** Respiration in which the final electron acceptor in the electron transport chain is oxygen (O₂).
- aerosols** Airborne suspensions of fine dust or moisture particles that contain live pathogens.
- aflatoxin** From *Aspergillus flavus* toxin, a mycotoxin that typically poisons moldy animal feed and can cause liver cancer in humans and other animals.
- agammaglobulinemia** The absence of functioning antibodies in serum. A related term, hypogammaglobulinemia, means there is a reduced level of antibodies, rather than a complete absence.
- agar** A polysaccharide found in seaweed and commonly used to prepare solid culture media.
- agglutination** The aggregation caused by antibodies when they cross-link cells or large particles into clumps that settle.
- agranulocyte** One form of leukocyte (white blood cell), having globular, nonlobed nuclei and lacking prominent cytoplasmic granules.
- AIDS-defining illness** A group of serious and life-threatening diseases that occur primarily in HIV-positive people. When a person acquires one of these illnesses, he or she is diagnosed with the advanced stage of HIV infection known as AIDS.
- alcoholic fermentation** An anaerobic degradation of pyruvic acid that results in alcohol production.
- algae** Photosynthetic, plantlike organisms that generally lack the complex structure of plants; they may be single-celled or multicellular and inhabit diverse habitats such as marine and freshwater environments, glaciers, and hot springs.
- allergen** A substance that provokes an allergic response.
- allergy** The altered, usually exaggerated, immune response to an allergen. sometimes used interchangeably with hypersensitivity.
- alloantigen** Antigens that vary in exact composition among the members of the same species, which is what causes incompatibilities in blood types.
- allograft** Relatively compatible tissue exchange between nonidentical members of the same species. Also called homograft.
- allosteric** Pertaining to the altered activity of an enzyme due to the binding of a molecule to a region other than the enzyme's active site.
- amastigote** The rounded or ovoid nonflagellated form of the *Leishmania* parasite.
- Ames test** A method for detecting mutagenic and potentially carcinogenic agents based upon the genetic alteration of nutritionally defective bacteria.
- amination** The addition of an amine (—NH₂) group to a molecule.
- amino acids** The building blocks of protein. Amino acids exist in 20 naturally occurring forms that impart different characteristics to the various proteins they compose.
- aminoglycoside** A complex group of drugs derived from soil actinomycetes that impair ribosome function and have antibiotic potential. Example: streptomycin.
- ammonification** Phase of the nitrogen cycle in which ammonia is released from decomposing organic material.
- amphibolism** Pertaining to the metabolic pathways that serve multiple functions in the breakdown, synthesis, and conversion of metabolites.
- amphipathic** Relating to a compound that has contrasting characteristics, such as hydrophilic-hydrophobic or acid-base.
- amphitrichous** Having a single flagellum or a tuft of flagella at opposite poles of a microbial cell.
- anabolism** The energy-consuming process of incorporating nutrients into protoplasm through biosynthesis.
- anaerobe** A microorganism that grows best, or exclusively, in the absence of oxygen, and which does not use oxygen in its metabolism.
- anaerobic digesters** Closed chambers used in a microbial process that converts organic sludge from waste treatment plants into useful fuels such as methane and hydrogen gases. Also called bioreactors.
- anaerobic respiration** Respiration in which the final electron acceptor in the electron transport chain is an inorganic molecule containing sulfate, nitrate, nitrite, carbonate and other salts, rather than molecular oxygen gas.
- analog** In chemistry, a compound that closely resembles another in structure.
- anamnestic response** In immunology, an augmented response or memory related to a prior stimulation of the immune system by antigen. It boosts the levels of antibodies.
- anaphylaxis** An exaggerated systemic allergic reaction to antigen that leads to severe respiratory and cardiac complications.
- anion** A negatively charged ion.
- anoxygenic** Any reaction that does not produce oxygen; usually in reference to the type of photosynthesis occurring in anaerobic photosynthetic bacteria.
- anthrax** A zoonotic disease of herbivorous livestock. The anthrax bacillus is a facultative parasite and can infect humans in a number of ways. In its most virulent form, it can be fatal.
- antibiotic** A chemical substance produced by one microorganism that can inhibit or kill another microbe, even in minute amounts.
- antibody** A large protein molecule evoked in response to an antigen that interacts specifically with that antigen.
- anticodon** The triplet sequence in transfer RNA that is complementary to the triplet sequence of messenger RNA (the codon).
- antigen** Any cell, particle, or chemical that has properties that allow it to stimulate a specific immune response by B cells or T cells. See the related term **immunogen**.
- antigen binding site** Specific regions at the ends of the antibody molecule that recognize specific antigens. These sites have numerous shapes to fit a wide variety of antigens.
- antigen-presenting cell (APC)** A macrophage or dendritic cell that ingests and degrades an antigen and subsequently places the antigenic determinant molecules on its surface for recognition by CD4 T lymphocytes.
- antigenic drift** Minor antigenic changes in the influenza virus due to mutations in the spikes' genes.
- antigenic shift** Major changes in the influenza virus due to recombination of viral strains from two different host species.

- antigenicity** The property of a substance to stimulate a specific immune response such as antibody formation.
- antihistamine** A drug that counters the action of histamine and is useful in allergy treatment.
- antiseptics/antiseptic** Use of a growth-inhibiting agent (antiseptic) on tissues to prevent infection.
- antiserum** Antibody-rich serum derived from people who have recovered from specific infections such as hepatitis; sometimes taken from the blood of animals deliberately immunized against an infectious or toxic antigen. Used in passive immune therapy.
- antitoxin** Globulin fraction of serum that neutralizes a specific toxin. Also refers to the specific antitoxin antibody itself.
- apoenzyme** The protein part of an enzyme, as opposed to the nonprotein or inorganic cofactors.
- appendages** Accessory structures that sprout from the surface of bacteria. They can be divided into two major groups: those that provide motility and those that enable adhesion.
- aquifer** A subterranean water-bearing stratum of permeable rock, sand, or gravel.
- arboviruses** Arthropod-borne viruses including togaviruses, reoviruses, flaviviruses, and bunyaviruses. These viruses generally cause mild, undifferentiated fevers and occasionally cases of severe encephalitis and hemorrhagic fever.
- archaea** Prokaryotic single-celled organisms of primitive origin that have unusual anatomy, physiology, and genetics, and live in harsh habitats; when capitalized (**Archaea**), the term refers to one of the three domains of living organisms as proposed by Woese.
- arthropod** A phylum of invertebrate animals with jointed exoskeletons. Includes insects such as mosquitoes and arachnids such as ticks that may be vectors of infectious diseases.
- Arthus reaction** An immune complex phenomenon that develops after repeat injection. This localized inflammation results from aggregates of antigen and antibody that bind, complement, and attract neutrophils.
- artificial immunity** Specific protection acquired through medical means.
- ascospore** A spore formed within a saclike cell (ascus) of Ascomycota following nuclear fusion and meiosis.
- ascus** Special fungal sac in which haploid spores are created.
- asepsis** A condition free of viable pathogenic microorganisms.
- aseptic technique** Methods of handling microbial cultures, patient specimens, and other sources of microbes in a way that prevents infection of the handler and others who may be exposed.
- asthma** An allergic respiratory disease marked by extreme sensitivity to allergens.
- asymptomatic** An infection that produces no noticeable symptoms even though the microbe is active in the host tissue.
- asymptomatic carrier** A person with an inapparent infection who shows no symptoms of being infected yet is able to pass the disease agent on to others.
- atmosphere** That part of the biosphere that includes the gaseous envelope up to 14 miles above the earth's surface. It contains gases such as carbon dioxide, nitrogen, and oxygen.
- atom** The smallest particle of an element to retain all the properties of that element.
- atomic number (AN)** A measurement that reflects the number of protons in an atom of a particular element.
- atomic weight** The average of the mass numbers of all the isotopic forms for a particular element.
- atopy** Allergic reaction classified as type I, with a strong familial relationship; caused by allergens such as pollen, insect venom, food, and dander; involves IgE antibody; includes symptoms of hay fever, asthma, and skin rash.
- ATP synthase** A unique enzyme located in the mitochondrial cristae, bacterial cell membrane, and chloroplast grana that harnesses the flux of hydrogen ions to the synthesis of ATP.
- attenuate** To reduce the virulence of a pathogenic bacterium or virus by passing it through a nonnative host or by long-term subculture.
- autoantibody** An antibody formed by a person against his own self molecules, called autoantigens, that are part of his cells.
- autoantigen** Molecules that are inherently part of self but are perceived by the immune system as foreign.
- autoclave** A sterilization chamber that allows the use of steam under pressure to sterilize materials. The most common temperature/pressure combination for an autoclave is 121°C and 15 psi.
- autograft** Tissue or organ surgically transplanted to another site on the same subject.
- autoimmune disease/autoimmunity** Literally, an immune reaction that targets self. This pathologic condition arises from the production of antibodies against autoantigens, for example in rheumatoid arthritis and multiple sclerosis.
- autotroph** A microorganism that requires only inorganic nutrients and whose sole source of carbon is carbon dioxide.
- axenic** A sterile state such as a pure culture. An axenic animal is born and raised in a germ-free environment. See **gnotobiotic**.
- axial filament** A type of flagellum (called an endoflagellum) that lies in the periplasmic space of spirochetes and is responsible for locomotion. Also called periplasmic flagellum.
- azoles** Five-ringed compounds used in antifungal therapy. They are usually recognized by their *-azole* suffix, e.g., ketoconazole, clotrimazole.
- bacillus** Bacterial cell shape that is basically cylindrical (longer than it is wide); plural is bacilli.
- back-mutation** A mutation that counteracts an earlier mutation, resulting in the restoration of the original DNA sequence.
- bacteremia** The presence of viable bacteria in circulating blood.
- bacteria** (plural of *bacterium*) Category of prokaryotes with peptidoglycan in their cell walls and a single, circular chromosome. This group of small cells is widely distributed in the earth's habitats.
- bacterial chromosome** A circular body in bacteria that contains the primary genetic material. Also called **nucleoid**.
- bacterial meningitis** Inflammation of the meninges as a result of bacterial infection.
- bactericide** An agent that kills bacterial vegetative cells.
- bacteriophage** A virus that specifically infects bacteria; phage means "to eat."
- bacteriostatic** Any process or agent that inhibits bacterial growth.
- barophile** A microorganism that thrives under high (usually hydrostatic) pressure.
- basement membrane** A thin layer (1–6 μm) of protein and polysaccharide found at the base of epithelial tissues.
- basic** A solution with a pH value above 7 on the pH scale.
- basidiospore** A sexual spore that arises from a basidium. Found in basidiomycota fungi.
- basidium** A reproductive cell created when the swollen terminal cell of a hypha develops filaments (sterigmata) that form spores.
- basophil** A motile polymorphonuclear leukocyte that binds IgE. The basophilic cytoplasmic granules contain mediators of anaphylaxis and atopy.
- benign tumor** A self-contained growth within an organ that does not spread into adjacent tissue.
- benthic zone** The sedimentary bottom region of a pond, lake, or ocean.
- beta oxidation** The degradation of long-chain fatty acids. Two-carbon fragments are formed as a result of enzymatic attack directed against the second or beta carbon of the hydrocarbon chain. Aided by coenzyme A, the fragments enter the tricarboxylic acid (TCA) cycle and are processed for ATP synthesis.
- beta-lactamase** An enzyme secreted by certain bacteria that cleaves the beta-lactam ring of penicillin and cephalosporin and thus provides for resistance against the antibiotic. See **penicillinase**.
- binary fission** The formation of two new cells of approximately equal size as the result of parent cell division.
- binomial system** Scientific method of assigning names to organisms that employs two names to identify every organism—genus name plus species name.
- biochemistry** The study of organic compounds produced by (or that are components of) living things. The four main categories of biochemicals are carbohydrates, lipids, proteins, and nucleic acid.
- bioenergetics** The study of the production and use of energy by cells.
- bioethics** The study of biological issues and how they relate to human conduct and moral judgment.
- biofilm** A complex aggregate of interacting microbial cells that adhere to each other and to surfaces by means of a polysaccharide matrix. Biofilms permit communication among participants, which facilitates their survival and adaptation.
- biogenesis** Belief that living things can only arise from others of the same kind.
- biogeochemical cycle** A process by which matter is converted from organic to inorganic form and returned to various nonliving reservoirs on earth (air, rocks, and water) where it becomes available for reuse by living things. Elements such as carbon, nitrogen, and phosphorus are constantly cycled in this manner.
- bioinformatics** A field that uses computer technology to manage and analyze large sets of biological data, including genome and protein sequences.
- biological vector** An animal that not only transports an infectious agent but plays a role in the life cycle of the pathogen, serving as a site in which it can multiply or complete its life cycle. It is usually an alternate host to the pathogen.
- biomes** Particular climate regions in a terrestrial realm.
- bioremediation** The use of microbes to reduce or degrade pollutants, industrial wastes, and household garbage.
- biosphere** Habitable regions comprising the aquatic (hydrospheric), soil-rock (lithospheric), and air (atmospheric) environments.
- biotechnology** The use of organisms (microbes, plants, animals) or their products in the commercial or industrial realm.
- biotic** Living factors such as parasites, food substrates, or other living or once-living organisms that are studied when looking at an ecosystem.
- blocking antibody** The IgG class of immunoglobulins that competes with IgE antibody for allergens, thus blocking the degranulation of basophils and mast cells.

- blood cells** Cellular components of the blood consisting of red blood cells, primarily responsible for the transport of oxygen and carbon dioxide, and white blood cells, primarily responsible for host defense and immune reactions.
- bradykinin** An active polypeptide that is a potent vasodilator released from IgE-coated mast cells during anaphylaxis.
- broad spectrum** A term to denote drugs that affect many different types of bacteria, both gram-positive and gram-negative as well as atypical bacteria such as rickettsias and chlamydias.
- brucellosis** A zoonosis transmitted to humans from infected animals or animal products; causes a fluctuating pattern of severe fever in humans as well as muscle pain, weakness, headache, weight loss, and profuse sweating. Also called **undulant fever**.
- bubo** The swelling of one or more lymph nodes due to inflammation.
- bubonic plague** The form of plague in which bacterial growth is primarily restricted to the lymph and is characterized by the appearance of a swollen lymph node referred to as a bubo.
- budding** See **exocytosis**.
- bulbar poliomyelitis** Complication of polio infection in which the brain stem, medulla, or cranial nerves are affected. Leads to loss of respiratory control and paralysis of the trunk and limbs.
- calculus** Dental deposit formed when plaque becomes mineralized with calcium and phosphate crystals. Also called **tartar**.
- Calvin cycle** The recurrent photosynthetic pathway characterized by CO₂ fixation and glucose synthesis. Also called the dark reactions.
- cancer** Any malignant neoplasm that invades surrounding tissue and can metastasize to other locations. A carcinoma is derived from epithelial tissue, and a sarcoma arises from proliferating mesodermal cells of connective tissue.
- capsid** The protein covering of a virus' nucleic acid core. Capsids exhibit symmetry due to the regular arrangement of subunits called capsomers. See **icosahedron**.
- capsomer** A subunit of the virus capsid shaped as a triangle or disc.
- capsule** In bacteria, the loose, gel-like covering or slime made chiefly of simple polysaccharides. This layer is protective and can be associated with virulence.
- carbohydrate** A compound containing primarily carbon, hydrogen, and oxygen in a 1:2:1 ratio.
- carbon cycle** That pathway taken by carbon from its abiotic source to its use by producers to form organic compounds (biotic), followed by the breakdown of biotic compounds and their release to a nonliving reservoir in the environment (mostly carbon dioxide in the atmosphere).
- carbon fixation** Reactions in photosynthesis that incorporate inorganic carbon dioxide into organic compounds such as sugars. This occurs during the Calvin cycle and uses energy generated by the light reactions. This process is responsible for the vast majority of productivity on earth.
- carbuncle** A deep staphylococcal abscess joining several neighboring hair follicles.
- carotenoid** Yellow, orange, or red pigments that are accessories that trap light for photosynthesis.
- carrier** In epidemiology, a person who asymptotically harbors infectious agents and inconspicuously spreads them to others. In chemistry, a chemical that can accept an atom, chemical radical, or electron from one compound and pass it to another chemical.
- caseous lesion** Necrotic area of lung tubercle superficially resembling cheese. Typical of tuberculosis.
- catabolism** The chemical breakdown of complex compounds into simpler units to be used in cell metabolism.
- catalyst** A substance that alters the rate of a reaction without being consumed or permanently changed by it. In cells, enzymes are catalysts.
- catalytic site** The niche in an enzyme where the substrate is converted to the product (also active site).
- cation** A positively charged ion.
- cecum** The intestinal pocket that forms the first segment of the large intestine. Also called the appendix.
- cell** An individual membrane-bound living entity; the smallest living unit capable of an independent existence.
- cell-mediated immunity** The type of immune responses brought about by T cells, such as cytotoxic, regulatory, and helper effects. An activated T cell interacts directly with antigen-bearing cells in order to bring about its end result.
- cellulose** A long, fibrous polymer composed of β -glucose; one of the most common substances on earth.
- cephalosporins** A group of antibiotics isolated from the fungus *Cephalosporium* that block the synthesis of the cell wall and can be used for a variety of infections.
- cercaria** The free-swimming larva of the schistosome trematode that emerges from the snail host and can penetrate human skin, causing schistosomiasis.
- cestode** The common name for tapeworms that parasitize humans and domestic animals.
- chancre** The primary sore of syphilis that forms at the site of penetration by *Treponema pallidum*. It begins as a hard, dull red, painless papule that erodes from the center.
- chancroid** A lesion that resembles a chancre but is soft and is caused by *Haemophilus ducreyi*.
- chemical bond** A link formed between molecules when two or more atoms share, donate, or accept electrons.
- chemical mediators** Small molecules that are released during inflammation and specific immune reactions that allow communication between the cells of the immune system and facilitate surveillance, recognition, and attack.
- chemiosmotic theory** An explanation for ATP formation that is based on the formation of a proton (H⁺) gradient across a membrane during electron transport. Movement of the protons back across an ATP synthase causes the formation of ATP.
- chemoautotrophs** An organism that relies upon inorganic chemicals for its energy and carbon dioxide for its carbon. Also called a chemolithotroph.
- chemokines** Chemical mediators (cytokines) that stimulate the movement and migration of white blood cells.
- chemostat** A growth chamber with an outflow that is equal to the continuous inflow of nutrient media. This steady-state growth device is used to study such events as cell division, mutation rates, and enzyme regulation.
- chemotaxis** The tendency of cells to move in response to a chemical gradient (toward an attractant or to avoid adverse stimuli). In inflammation, it refers to the movement of blood cells in reaction to chemical signals.
- chemotherapy** The use of chemical substances or drugs to treat or prevent disease.
- chemotroph** An organism that oxidizes compounds to feed on nutrients.
- chickenpox** A papulo-pustular rash caused by infection by varicella-zoster virus.
- chimera** A product formed by the fusion of two different organisms.
- chitin** A polysaccharide similar to cellulose in chemical structure. This polymer makes up the horny substance of the exoskeletons of arthropods and certain fungi.
- chlamydias** Tiny gram negative bacteria that are obligate parasites inside the vacuoles of host cells; members cause a type of STD and pneumonia.
- chlorophyll** A group of mostly green pigments that are used by photosynthetic eukaryotic organisms and cyanobacteria to trap light energy to use in making chemical bonds.
- chloroplast** An organelle containing chlorophyll that is found in photosynthetic eukaryotes.
- cholesterol** Best-known member of a group of lipids called steroids. Cholesterol is commonly found in cell membranes and animal hormones.
- chromatin** The genetic material of the nucleus. Chromatin is made up of nucleic acid and stains readily with certain dyes.
- chromophore** The chemical radical of a dye that is responsible for its color and reactivity.
- chromosome** The tightly coiled bodies within cells, composed of DNA, that are the primary locations for genetic material.
- chronic infection** An infection that persists over a long duration, with symptoms being mild or absent.
- cilium** (plural: *cilia*) Eukaryotic structure similar to flagella that propels a protozoan through the environment.
- class** In the levels of classification, the division of organisms that follows phylum.
- clonal selection theory** A conceptual explanation for the development of lymphocyte specificity and variety during maturation of the immune system.
- clone** A colony of cells (or group of organisms) derived from a single cell (or single organism) by asexual reproduction. All units share identical characteristics. Also used as a verb to refer to the process of producing a genetically identical population of cells or genes.
- cloning host** An organism such as a bacterium or a yeast that receives and replicates a foreign piece of DNA inserted through genetic engineering techniques.
- cluster of differentiation (CD)** Receptors on mature T cells that serve in cell communication; react with MHC receptors for immune recognition by antigen processing cells.
- coagulase** A plasma-clotting enzyme secreted by *Staphylococcus aureus*. It contributes to virulence and is involved in forming a fibrin wall that surrounds staphylococcal lesions.
- coagulase-negative staphylococci** Opportunistic species that are usually part of the normal flora of the skin and mucous membranes. They cause infection when host defenses are low and lack many virulence factors such as coagulase.
- coccobacillus** An elongated coccus; a short, thick, oval-shaped bacterial rod.
- coccus** A spherical-shaped bacterial cell; plural is cocci
- codon** A specific sequence of three nucleotides in DNA or mRNA that constitutes the genetic code for a particular amino acid.
- coenzyme** A complex organic molecule, several of which are derived from vitamins (e.g., nicotinamide or niacin, riboflavin). A coenzyme operates in conjunction with an enzyme. Coenzymes serve as transient carriers of specific atoms or functional groups during metabolic reactions.

- cofactor** An enzyme accessory. It can be organic, such as coenzymes, or inorganic, such as Fe^{2+} , Mn^{2+} , Zn^{2+} , or other metallic ions.
- cold sterilization** The use of nonheating methods such as radiation or filtration to sterilize materials.
- coliform** A collective term that includes normal enteric bacteria that are gram-negative and lactose-fermenting.
- colony** A macroscopic cluster of cells appearing on a solid medium, each arising from the multiplication of a single cell.
- colostrum** The clear yellow early product of breast milk that is very high in secretory antibodies. Provides passive intestinal protection.
- commensalism** An unequal relationship described as one member (A) deriving benefit from another member (B), without harming or benefiting (B).
- common (seed) warts** Painless, elevated rough growths on the fingers or occasionally other parts of the body.
- communicable infection** Capable of being transmitted from one individual to another.
- community** The interacting mixture of populations in a given habitat.
- competitive inhibition** The blockage of microbial growth through a metabolic analog drug that inserts on the active site of an essential metabolic enzyme and prevents further action of that enzyme.
- complement/complement fixation** In immunology, protein components that act in a defined sequence (cascade) when set in motion either by an antigen-antibody complex or by factors from the lectin or alternative pathways. When complement adheres to a certain antibody or receptor, it is said to be fixed.
- complementary DNA (cDNA)** DNA created by using reverse transcriptase to synthesize DNA from RNA templates.
- complex (nonsynthetic) medium** Culture medium containing at least one component that is chemically undefined.
- compounds** Molecules that are a combination of two or more different elements.
- concentration** The expression of the amount of a solute dissolved in a certain amount of solvent. It may be defined by weight, volume, or percentage.
- condylomata acuminata** Extensive, branched masses of genital warts caused by infection with human papillomavirus.
- congenital rubella** Transmission of the rubella virus to a fetus *in utero*. Injury to the fetus is generally much more serious than it is to the mother.
- conidia** Asexual fungal spores shed as free units from the tips of fertile hyphae.
- conjugation** In bacteria, the contact between donor and recipient cells associated with the transfer of genetic material such as plasmids. Can involve special (sex) pili. Also a form of sexual recombination in ciliated protozoans.
- conjunctivitis** Sometimes called “pinkeye.” A *Haemophilus* infection of the subconjunctiva that is common among children, easily transmitted, and treated with antibiotic eyedrops.
- constitutive enzyme** An enzyme present in bacterial cells in constant amounts, regardless of the presence of substrate. Enzymes of the central catabolic pathways are typical examples.
- consumer** An organism that feeds on producers or other consumers. It gets all nutrients and energy from other organisms (also called **heterotroph**). May exist at several levels, such as primary (feeds on producers), and secondary (feeds on primary consumers).
- contagious** Very readily communicable; transmissible by direct contact with infected people and their fresh secretions or excretions.
- contaminant** An impurity; any undesirable material or organism. A culture into which unknown microbes have been introduced is contaminated.
- convalescence** Recovery; the period between the end of a disease and the complete restoration of health in a patient.
- corepressor** A molecule that combines with an inactive repressor to form an active repressor. The resultant combined molecule attaches to the operator gene site and inhibits the activity of structural genes in line with the operator.
- covalent bond** A chemical bond formed by the sharing of electrons between two atoms.
- Creutzfeld-Jakob disease (CJD)** A spongiform encephalopathy caused by infection with a prion. The disease is marked by dementia, impaired senses, and uncontrollable muscle contractions.
- crista** The infolded inner membrane of a mitochondrion that is the site of the respiratory chain and oxidative phosphorylation.
- culture** The visible accumulation of microorganisms in or on a nutrient medium. Also, the propagation of microorganisms with various media.
- curd** The coagulated milk protein used in cheese making.
- cutaneous** Second level of skin, including the stratum corneum and occasionally the upper dermis.
- cutaneous anthrax** The mildest form of anthrax, caused by the entrance of bacterial spores into small nicks or openings in the skin, their germination, and the formation of a dark necrotic lesion called an eschar.
- cutaneous candidiasis** A mycosis occurring in the skin and membranes of compromised patients and neonates as a result of infection by *Candida albicans*.
- cyanobacteria** Widespread and ecologically important photosynthetic bacteria; evidence indicates their role in the evolution of chloroplasts in eukaryotic cells.
- cyst** The resistant, dormant, but infectious form of protozoans. Can be important in spread of infectious agents such as *Entamoeba histolytica* and *Giardia lamblia*.
- cysteine** Sulfur-containing amino acid that is essential to the structure and specificity of proteins.
- cytochrome** A group of heme protein compounds whose chief role is in electron and/or hydrogen transport occurring in the last phase of aerobic respiration.
- cytokine** A chemical substance produced by white blood cells and tissue cells that regulates development, inflammation, and immunity.
- cytopathic effect** The degenerative changes in cells associated with virus infection. Example: the formation of multinucleate giant cells (Negri bodies), the prominent cytoplasmic inclusions of nerve cells infected by rabies virus.
- cytoplasm** Dense fluid encased by the cell membrane; the site of many of the cell’s biochemical and synthetic activities.
- cytosine (C)** One of the nitrogen bases found in DNA and RNA, with a pyrimidine form.
- cytoskeleton** A fine intracellular network of fibers, filaments, and other strands that function in support and shape of cells.
- cytotoxic/cytotoxicity** Having the capacity to destroy specific cells. The cytotoxic class of T cells attacks cancer cells, virus-infected cells, and eukaryotic pathogens.
- death phase** A dramatic downturn in numbers occurs due to lack of nutrition, adverse environmental factors, and accumulation of wastes. A greater number of cells are dying in this phase.
- debridement** Trimming away devitalized tissue and foreign matter from a wound.
- decomposer** A consumer that feeds on organic matter from the bodies of dead organisms. These microorganisms feed from all levels of the food pyramid and are responsible for recycling elements (also called saprobes).
- decomposition** The breakdown of dead matter and wastes into simple compounds that can be directed back into the natural cycle of living things.
- decontamination** The removal or neutralization of an infectious, poisonous, or injurious agent from a site.
- definitive host** The organism in which a parasite develops into its adult or sexually mature stage. Also called the **final host**.
- degeneracy** The property of the genetic code that allows an amino acid to be specified by several different codons.
- degerm/degermation** To physically remove surface oils, debris, and soil from skin and wounds to reduce the microbial load.
- degranulation** The release of cytoplasmic granules, as when cytokines are secreted from mast cell granules.
- dehydration synthesis** During the formation of a carbohydrate bond, the step in which one carbon molecule gives up its OH group and the other loses the H from its OH group, thereby producing a water molecule. This process is common to all polymerization reactions.
- denature/denaturation** The loss of normal characteristics (shape, configuration) resulting from some molecular alteration. Used in reference to loss of normal activity by proteins when their 3-D structure has been altered by heat or chemicals.
- dendritic cell** A large, antigen-processing cell characterized by long, branchlike extensions of the cell membrane.
- denitrification** The end of the nitrogen cycle when nitrogen compounds are returned to the reservoir in the air.
- dental caries** A mixed infection of the tooth surface that gradually destroys the enamel and may lead to destruction of the deeper tissue.
- deoxyribonucleic acid (DNA)** The nucleic acid often referred to as the “double helix.” DNA carries the master plan for an organism’s heredity.
- deoxyribose** A 5-carbon sugar that is an important component of DNA.
- dermatophytoses** Superficial mycoses such as athlete’s foot and ringworm associated with certain fungi with an affinity for the skin, hair, and nails. These fungi are called **dermatophytes**.
- desensitization/hyposensitization** A therapeutic exposure to known allergens designed to build tolerance and eventually prevent allergic reaction. Hyposensitization is gaining in use because it emphasizes that the allergy is reduced not completely removed.
- desiccate/desiccated** To dry thoroughly. To preserve by drying.
- diabetes mellitus** A disease involving compromise in insulin function. In one form, the pancreatic cells that produce insulin are destroyed by autoantibodies, and in another, the pancreas does not produce sufficient insulin.
- diapedesis** The migration of intact blood cells between endothelial cells of a blood vessel such as a venule.
- differential medium** A single substrate that discriminates between groups of microorganisms on the basis of differences in their appearance due to different chemical reactions.

- differential stain** A technique that utilizes two dyes to distinguish between different microbial groups or cell parts by color reaction.
- diffusion** The passive dispersal of molecules, ions, or microscopic particles propelled down a concentration gradient by spontaneous random motion to achieve a uniform distribution.
- DiGeorge syndrome** A genetic defect that causes the loss of thymus function; results in abnormally low or absent T cells and other developmental abnormalities.
- dimer** A molecule that is composed of two monomers bound together.
- dimorphic** In mycology, the tendency of some pathogens to alter their growth form from mold to yeast in response to rising temperature.
- diphtheria** Infection by *Corynebacterium diphtheriae*. It is transmitted by human carriers or contaminated milk, and the primary infection is in the upper respiratory tract. Several forms of this infection may be fatal if untreated. Vaccination on the recommended schedule can prevent infection.
- diphtherotoxin** Exotoxin responsible for the effects seen in diphtheria. The toxin affects the upper respiratory system, peripheral nervous system, and the heart.
- diplococcus** Spherical or oval-shaped bacteria, typically found in pairs.
- direct, or total, cell count** 1. Counting total numbers of individual cells being viewed with magnification. 2. Counting isolated colonies of organisms growing on a plate of media as a way to determine population size.
- disaccharide** A sugar containing two monosaccharides. Example: sucrose (fructose + glucose).
- disinfection/disinfectant** The destruction of pathogenic nonsporulating microbes or their toxins, usually on inanimate surfaces. A disinfectant is a chemical used for this purpose.
- division** In the levels of classification, an alternate term for *phylum*.
- DNA polymerase** Enzyme responsible for the replication of DNA. Several versions of the enzyme exist, each completing a unique portion of the replication process.
- DNA profiling, DNA fingerprinting** A method of identifying patterns of specific genetic markers unique to an individual for the purpose of identification. Used in forensics, medicine, anthropology, and microbial identification.
- DNA sequencing** A process of determining the exact order of nucleotides in a segment of DNA, ranging from small pieces to whole chromosomes or genomes. The newest technologies are rapid machine-based methods that use lasers, cameras, or microscopes to read fluorescent nucleotides on a strand of DNA.
- DNA vaccine** A newer vaccine preparation based on inserting DNA from pathogens into host cells to encourage them to express the foreign protein and stimulate immunity.
- domain** In the levels of classification, the broadest general category to which an organism is assigned. Members of a domain share only one or a few general characteristics.
- droplet nuclei** The dried residue of fine droplets produced by mucus and saliva sprayed while sneezing and coughing. Droplet nuclei are less than 5 μm in diameter (large enough to bear a single bacterium and small enough to remain airborne for a long time) and can be carried by air currents.
- drug resistance** An adaptive response in which microorganisms begin to tolerate an amount of drug that had previously been inhibitory.
- dry heat** Air with a low moisture content that has been heated from 160 to several thousand degrees Celsius.
- dysentery** Infectious diarrhea characterized by blood and mucus in the feces.
- dyspnea** Difficulty in breathing.
- ecosystem** A collection of organisms together with its surrounding physical and chemical factors existing in a given place and time.
- eczema** An acute or chronic allergy of the skin associated with itching and burning sensations. Typically, red, edematous, vesicular lesions erupt, leaving the skin scaly and sometimes hyperpigmented.
- edema** The accumulation of excess fluid in cells, tissues, or serous cavities. Also called swelling.
- electrolyte** Any compound that ionizes in solution and conducts current in an electrical field.
- electron** A negatively charged subatomic particle that is distributed around the nucleus in an atom.
- electrophoresis** The separation of molecules by size and charge through exposure to an electrical current.
- element** A substance comprising only one kind of atom that cannot be degraded into two or more substances without losing its chemical characteristics.
- ELISA** Abbreviation for enzyme-linked immunosorbent assay, a very sensitive serological test used to detect antibodies in diseases such as AIDS. Two types are **indirect ELISA** and **capture ELISA**.
- emerging disease** Newly identified diseases that are becoming more prominent.
- endemic disease** A native disease that exists continuously in a geographic region. This pattern may reflect a vector or environmental source.
- endergonic reaction** A chemical reaction that occurs with the absorption and storage of surrounding energy. Antonym: **exergonic**.
- endocytosis** The process whereby solid and liquid materials are taken into the cell through membrane invagination and engulfment into a vesicle.
- endoenzyme** An intracellular enzyme that functions primarily within the cell compartment, as opposed to enzymes that are secreted.
- endogenous** Originating or produced within an organism or one of its parts.
- endoplasmic reticulum (ER)** An intracellular network of flattened sacs or tubules with or without ribosomes on their surfaces.
- endospore** A small, dormant, resistant derivative of a bacterial cell that germinates under favorable growth conditions into a vegetative cell. The bacterial genera *Bacillus* and *Clostridium* are typical sporeformers.
- endosymbiosis** The evolutionary process through which prokaryotic cells came together in a mutually beneficial association that gave rise to eukaryotic cells during billions of years of coevolution.
- endotoxin** A bacterial intracellular toxin that is not ordinarily released (as is exotoxin). Endotoxin is composed of a phospholipid-polysaccharide complex that is an integral part of gram-negative bacterial cell walls. Endotoxins can cause severe shock and fever.
- energy of activation** The minimum energy input necessary for reactants to form products in a chemical reaction.
- energy pyramid** An ecological model that shows the energy flow among the organisms in a community. It is structured like the food pyramid, but shows how energy is reduced from one trophic level to another.
- enriched medium** A nutrient medium supplemented with blood, serum, or some growth factor to promote the multiplication of fastidious microorganisms.
- enterohemorrhagic *E. coli* (EHEC)** A strain of *E. coli*, type O157: H7, that secretes toxins that provoke secretory diarrhea and intestinal hemorrhage.
- enteroinvasive** Predisposed to invade the intestinal tissues.
- enteropathogenic** Pathogenic to the alimentary canal.
- enterotoxigenic *E. coli* (ETEC)** Strains of *E. coli* that produce toxins that attack the GI tract; effects are similar to cholera.
- enterotoxin** A bacterial toxin that specifically targets intestinal mucosal membrane cells. Enterotoxigenic strains of *Escherichia coli* and *Staphylococcus aureus* are typical sources.
- enveloped virus** A virus whose nucleocapsid is enclosed by a membrane derived in part from the host cell. It usually contains exposed glycoprotein spikes specific for the virus.
- enzyme** A protein biocatalyst that facilitates metabolic reactions.
- enzyme induction** One of the controls on enzyme synthesis. This occurs when enzymes are synthesized only when suitable substrates are present.
- enzyme repression** The inhibition of enzyme synthesis by the end product of a catabolic pathway.
- eosinophil** A leukocyte whose cytoplasmic granules readily stain with red eosin dye. Eosinophils function primarily in the destruction of large parasites and in allergy and inflammation.
- epidemic** A sudden and simultaneous increase in the number of cases of a certain disease in a community.
- epidemic parotitis (mumps)** Disease caused by infection with *Paramyxovirus* and marked by swelling in and around the parotid salivary glands.
- epidemiology** The study of the factors affecting the prevalence and spread of disease within a community.
- epimastigote** The trypanosomal form found in the tsetse fly or reduviid bug vector. Its flagellum originates near the nucleus, extends along an undulating membrane, and emerges from the anterior end.
- epitope** The portion of a foreign cell or virus that is the precise stimulus for an immune response. Also called the **antigenic determinant**.
- Epstein-Barr virus (EBV)** Herpesvirus linked to infectious mononucleosis, Burkitt lymphoma, and nasopharyngeal carcinoma.
- erysipelas** An acute, sharply defined inflammatory disease specifically caused by hemolytic *Streptococcus*. The eruption is limited to the skin but can be complicated by serious systemic symptoms.
- erysipeloid** An inflammation resembling erysipelas but caused by *Erysipelothrix*, a gram-positive rod. The self-limited cellulitis that appears at the site of an infected wound, usually the hand, comes from handling contaminated fish or meat.
- erythrocytes (red blood cells)** Blood cells involved in the transport of oxygen and carbon dioxide.
- erythrogenic toxin** An exotoxin produced by lysogenized group A strains of β -hemolytic streptococci that is responsible for the severe fever and rash of scarlet fever in the nonimmune individual. Also called a pyrogenic toxin.
- eschar** A dark, sloughing scab that is the lesion of anthrax and certain rickettsioses.
- essential nutrient** Any ingredient such as a certain amino acid, fatty acid, vitamin, or mineral that cannot be formed by an organism and must be supplied in the diet. A growth factor.
- ester bond** A covalent bond formed by reacting carboxylic acid with an OH group:
- $$\text{(R}-\overset{\text{O}}{\parallel}\text{C}-\text{O}-\text{R}')\text{}$$
- Olive and corn oils, lard, and butter are examples of triacylglycerols—esters formed between glycerol and three fatty acids.

- ethylene oxide** A potent, highly water-soluble gas invaluable for gaseous sterilization of heat-sensitive objects such as plastics, surgical and diagnostic appliances, and spices. Potential hazards are related to its carcinogenic, residual, and explosive nature. Ethylene oxide is rendered nonexplosive by mixing with 90% CO₂ or fluorocarbon.
- etiologic agent** The microbial cause of disease; the pathogen.
- Eukarya** One of the three domains (sometimes called superkingdoms) of living organisms, as proposed by Woese; contains all eukaryotic organisms.
- eukaryotic cell** A cell that differs from a prokaryotic cell chiefly by having a nuclear membrane (a well-defined nucleus), membrane-bounded subcellular organelles, and mitotic cell division.
- eutrophication** The process whereby dissolved nutrients resulting from natural seasonal enrichment or industrial pollution of water cause overgrowth of algae and cyanobacteria to the detriment of fish and other large aquatic inhabitants.
- evolution** Scientific principle that states that living things change gradually through hundreds of millions of years, and these changes are expressed in structural and functional adaptations in each organism. Evolution presumes that those traits that favor survival are preserved and passed on to following generations, and those traits that do not favor survival are lost.
- exanthem** An eruption or rash of the skin.
- exergonic** A chemical reaction associated with the release of energy to the surroundings. Antonym: endergonic.
- exfoliative toxin** A poisonous substance that causes superficial cells of an epithelium to detach and be shed. Example: staphylococcal exfoliatin. Also called an epidermolysin.
- exocytosis** The process that releases enveloped viruses from the membrane of the host's cytoplasm.
- exoenzyme** An extracellular enzyme chiefly used to hydrolyze nutrient macromolecules that cannot readily enter the cell. This enzyme is secreted into the environment, where it may function in saprobic decomposition of organic debris or support the invasion of tissues by pathogens.
- exogenous** Originating from outside the body.
- exon** A section of eukaryotic DNA coding for a corresponding portion of mRNA that is translated into proteins. Intervening stretches of DNA that are not expressed are called introns. During transcription, exons are separated from introns and are spliced together into a continuous mRNA transcript.
- exotoxin** A toxin (usually protein) that is secreted and acts upon a specific cellular target. Examples: botulin, tetanospasmin, diphtheria toxin, and erythrogenic toxin.
- exponential** Pertaining to the use of exponents, numbers that are typically written as superscripts to indicate how many times a factor is to be multiplied. Exponents are used in scientific notation to render large, cumbersome numbers into small, workable quantities.
- extrapulmonary tuberculosis** A condition in which tuberculosis bacilli have spread to organs other than the lungs.
- extremophiles** Organisms capable of living in harsh environments, such as extreme heat or cold.
- facilitated diffusion** The passive movement of a substance across a plasma membrane from an area of higher concentration to an area of lower concentration utilizing specialized carrier proteins.
- facultative** Pertaining to the capacity of microbes to adapt or adjust to variations; not obligate. Example: The presence of oxygen is not required for a facultative anaerobe to grow, even though it can use oxygen if it is present.
- family** In the levels of classification, a mid-level division of organisms that groups more closely related organisms than previous levels. An order is divided into families.
- fastidious** Requiring strict, narrow nutritional or environmental conditions for growth. Said of bacteria.
- fecal coliforms** Any species of gram-negative lactose-positive bacteria (primarily *Escherichia coli*) that live primarily in the intestinal tract and not the environment. Finding evidence of these bacteria in a water or food sample is substantial evidence of fecal contamination and potential for infection (See **coliform**).
- fermentation** The extraction of energy through anaerobic degradation of substrates into simpler, reduced metabolites. In large industrial processes, fermentation can mean any use of microbial metabolism to manufacture organic chemicals or other products.
- fermentor** A large tank used in industrial microbiology to grow mass quantities of microbes that can synthesize desired products. These devices are equipped with means to stir, monitor, and harvest products such as drugs, enzymes, and proteins in very large quantities.
- fertility (F) factor** Donor plasmid that allows synthesis of a pilus in bacterial conjugation. Presence of the factor is indicated by F⁺, and lack of the factor is indicated by F⁻.
- filament** A helical structure composed of proteins that is part of bacterial flagella.
- fimbria, fimbriae** Short, numerous surface appendages on some bacteria that provide adhesion but not locomotion.
- final electron acceptor** A molecule that receives the electrons (is reduced) at the end of a pathway where electrons are being transported. For example, in aerobic organisms, the final acceptor in the electron transport chain is O₂, whereas in organisms with anaerobic respiration, it is some other compound such as SO₂²⁻, or NO₃⁻.
- flagellum** (Plural: *flagella*) A long appendage used to propel an organism through a fluid environment. Flagella of bacteria and eukaryotes are similar in general function but differ significantly in structure.
- fluid mosaic model** A conceptualization of the molecular architecture of cellular membranes as a bilipid layer containing proteins. Membrane proteins are embedded to some degree in this bilayer, where they float freely about.
- fluorescence/fluorescent antibodies** The property possessed by certain minerals and dyes to emit visible light when excited by ultraviolet radiation. One application is to combine a fluorescent dye with a specific antibody to detect the presence of an unknown antigen.
- focal infection** Occurs when an infectious agent breaks loose from a localized infection and is carried by the circulation to other tissues.
- folliculitis** An inflammatory reaction involving the formation of papules or pustules in clusters of hair follicles.
- fomite** Virtually any inanimate object an infected individual has contact with that can serve as a vehicle for the spread of disease.
- food chain** A simple straight-line feeding sequence among organisms in a community.
- food fermentations** Addition to and growth of known cultures of microorganisms in foods to produce desirable flavors, smells, or textures. Includes cheeses, breads, alcoholic beverages, and pickles.
- food infection** A form of food-borne illness associated with ingesting living pathogenic microbes that invade the intestine. The damage caused by microbes growing in the body cause the main symptoms, which are usually gastroenteritis (example is salmonellosis).
- food intoxication** A form of food-borne illness that is the result of ingesting microbial toxins given off by bacteria growing in the food. The toxins cause the main symptoms (example is botulism).
- food poisoning** Any form of illness acquired from ingesting foods; sources include microbes, chemicals, plants, and animals (also food-borne disease).
- food web** A complex network that traces all feeding interactions among organisms in a community (see **food chain**). This is considered to be a more accurate picture of food relationships in a community than a food chain.
- formalin** A 37% aqueous solution of formaldehyde gas; a potent chemical fixative and microbicide.
- frameshift mutation** An insertion or deletion mutation that changes the codon reading frame from the point of the mutation to the final codon. Almost always leads to a nonfunctional protein.
- fructose** One of the carbohydrates commonly referred to as sugars. Fructose is commonly fruit sugars.
- functional group** In chemistry, a particular molecular combination that reacts in predictable ways and confers particular properties on a compound. Examples: —COOH, —OH, —CHO.
- fungicide** A chemical that can kill fungal spores, hyphae, and yeast.
- fungus/fungi** Heterotrophic unicellular or multicellular eukaryotic organism that may take the form of a larger macroscopic organism, as in the case of mushrooms, or a smaller microscopic organism, as in the case of yeasts and molds.
- furuncle** A boil; a localized pyogenic infection arising from a hair follicle.
- Gaia theory** The concept that biotic and abiotic factors sustain suitable conditions for one another simply by their interactions. Named after the mythical Greek goddess of earth.
- GALT** Abbreviation for **gut-associated lymphoid tissue**. Includes **Peyer's patches**.
- gamma globulin** The fraction of plasma proteins high in immunoglobulins (antibodies). Preparations from pooled human plasma containing normal antibodies make useful passive immunizing agents against pertussis, polio, measles, and several other diseases.
- gas gangrene** Disease caused by a clostridial infection of soft tissue or wound. The name refers to the gas produced by the bacteria growing in the tissue. Unless treated early, it is fatal. Also called **myonecrosis**.
- gastroenteritis** Inflammation of the lining of the stomach and intestine. May be caused by infection, intestinal disorders, or food poisoning.
- gene** A site on a chromosome that provides information for a certain cell function. A specific segment of DNA that contains the necessary code to make a protein or RNA molecule.
- gene probe** Short strands of single-stranded nucleic acid that hybridize specifically with complementary stretches of nucleotides on test samples and thereby serve as a tagging and identification device.

- gene therapy** The introduction of normal functional genes into people with genetic diseases such as sickle-cell anemia and cystic fibrosis. This is usually accomplished by a virus vector.
- generation time** Time required for a complete fission cycle—from parent cell to two new daughter cells. Also called **doubling time**.
- genetic engineering/bioengineering** A field involving deliberate alterations (recombinations) of the genomes of microbes, plants, and animals through special technological processes.
- genetics** The science that studies inheritance of biological characteristics.
- genital warts** A prevalent STD linked to some forms of cancer of the reproductive organs. Caused by infection with human papillomavirus.
- genome** The complete set of chromosomes and genes in an organism.
- genotype** The genetic makeup of an organism as inherited from parents. The genotype is ultimately responsible for an organism's phenotype, or expressed characteristics.
- genus** In the levels of classification, the second most specific level. A family is divided into several genera.
- germ theory of disease** A theory first originating in the 1800s that proposed that microorganisms can be the cause of diseases. The concept is so well established in the present time that it is considered a fact.
- germicide** An agent lethal to non-endospore-forming pathogens.
- giardiasis** Infection by the *Giardia* flagellate. The most common mode of transmission is contaminated food and water. Symptoms include diarrhea, abdominal pain, and flatulence.
- gingivitis** Inflammation of the gum tissue in contact with the roots of the teeth.
- glomerulonephritis** An inflammatory autoimmune condition in response to streptococcal toxins.
- gluconeogenesis** The formation of glucose (or glycogen) from noncarbohydrate sources such as protein or fat. Also called glyconeogenesis.
- glucose** One of the carbohydrates commonly referred to as sugars. Glucose is characterized by its 6-carbon structure.
- glutaraldehyde** A yellow acidic liquid used in antimicrobial control. Because glutaraldehyde kills spores, it is considered a sterilant.
- glycan** A polysaccharide.
- glycerol** A 3-carbon alcohol, with three OH groups that serve as binding sites.
- glycocalyx** A filamentous network of carbohydrate-rich molecules that coats cells.
- glycogen** A glucose polymer stored by cells.
- glycolysis** The energy-yielding breakdown of glucose to pyruvic or lactic acid (occurs in fermentation). It is often called anaerobic glycolysis because no molecular oxygen is consumed in the processes.
- glycosidic bond** A bond that joins monosaccharides to form disaccharides and polymers.
- gnotobiotic** Literally means known (gnoto) and life (bios). Referring to experiments performed on germ-free animals that have been inoculated with known species of microbes.
- Golgi apparatus** An organelle of eukaryotes that participates in packaging and secretion of molecules. Also known as **Golgi complex**.
- gonococcus** Common name for *Neisseria gonorrhoeae*, the agent of gonorrhea.
- graft versus host disease (GVHD)** A condition associated with a bone marrow transplant in which T cells in the transplanted tissue mount an immune response against the recipient's (host) normal tissues.
- graft/graft rejection** Live tissues or organs taken from a donor and transplanted into a recipient to replace damaged or missing tissues such as skin, bone, blood vessels, heart, bone marrow. When the donor displays antigens that are recognized and trigger an immune attack, the grafted tissue or organ may be lost.
- Gram stain** A differential stain for bacteria useful in identification and taxonomy. Gram-positive organisms appear purple from crystal violet-mordant retention, whereas gram-negative organisms appear red after loss of crystal violet and absorbance of the safranin counterstain.
- grana** Discrete stacks of chlorophyll-containing thylakoids within chloroplasts.
- granulocyte** A mature leukocyte that contains noticeable granules in a Wright stain. Examples: neutrophils, eosinophils, and basophils.
- granuloma** A solid mass or nodule of inflammatory tissue containing modified macrophages and lymphocytes. Usually a chronic pathologic process of diseases such as tuberculosis or syphilis.
- granzymes** Cytotoxic enzymes produced by cytotoxic T cells and natural killer cells that participate in cell death.
- Graves' disease** A malfunction of the thyroid gland in which autoantibodies directed at thyroid cells stimulate an overproduction of thyroid hormone (hyperthyroidism).
- greenhouse effect** The capacity to retain solar energy by a blanket of atmospheric gases that redirects heat waves back toward the earth.
- group translocation** A form of active transport in which the substance being transported is altered during transfer across a plasma membrane.
- growth curve** A graphical representation of the change in population size over time. This graph has four periods known as lag phase, exponential or log phase, stationary phase, and death phase.
- growth factor** An organic compound such as a vitamin or amino acid that must be provided in the diet to facilitate growth. An essential nutrient.
- guanine (G)** The purine nitrogen base found in DNA and RNA that pairs with cytosine.
- Guillain-Barré syndrome** A neurological complication of influenza vaccination. Approximately 1 in 100,000 recipients of the vaccine will develop this autoimmune disorder, which is marked by varying degrees of weakness and sensory loss.
- gumma** A nodular, infectious granuloma characteristic of tertiary syphilis.
- gyrase** An enzyme that functions in packaging of DNA in bacterial chromosomes by preventing excess distortion of the molecule as it is coiling.
- HAART** Short for highly active antiretroviral therapy, the drug cocktail that is used as a treatment for HIV infection and AIDS.
- habitat** The environment to which an organism is adapted.
- halogens** A group of related chemicals with antimicrobial applications. The halogens most often used in disinfectants and antiseptics are chlorine and iodine.
- halophile** A microbe that needs a high concentration of salt for growth or one that tolerates high salt concentrations.
- hapten** An incomplete or partial antigen. Although it constitutes the determinative group and can bind antigen, hapten cannot stimulate a full immune response without being carried by a larger protein molecule.
- Hashimoto's thyroiditis** An autoimmune disease of the thyroid gland that damages the thyroid follicle cells and results in decreased production of thyroid hormone (hypothyroidism).
- hay fever** A form of atopic allergy marked by seasonal acute inflammation of the conjunctiva and mucous membranes of the respiratory passages. Symptoms are itching, coughing, and runny nose.
- health care-associated/nosocomial infection** An infection not present upon admission to a hospital, clinic, or care home, but incurred while being treated there.
- helical** Having a spiral or coiled shape. Said of certain virus capsids and bacteria.
- helminth** A term that designates parasitic worms such as roundworms and flatworms.
- hemagglutinin (H)** A molecule that causes red blood cells to clump or agglutinate. A major surface receptor on the influenza virus needed for entry.
- hemolysin** Any biological agent that is capable of destroying red blood cells and causing the release of hemoglobin. Many bacterial pathogens produce exotoxins that act as hemolysins.
- hemolytic disease of the newborn** Incompatible Rh factor between mother and fetus causes maternal antibodies to enter the fetus and trigger complement-mediated destruction of fetal RBCs (hemolysis).
- hemolytic uremic syndrome (HUS)** A kidney disease caused by infection with *E. coli* O157:H7.
- hemopoiesis** The process by which the various types of blood cells are formed by stem cells in the bone marrow. Also called hematopoiesis.
- hepadnavirus** Enveloped DNA viruses with a predisposition to affect the liver. Hepatitis B is the most serious form.
- hepatitis** Inflammation and necrosis of the liver, often the result of viral infection.
- hepatitis A virus (HAV)** Enterovirus spread by contaminated food responsible for short-term (infectious) hepatitis.
- hepatitis B virus (HBV)** Hepadnavirus that is the causative agent of serum hepatitis.
- hepatitis C virus (HCV)** A blood-borne RNA virus that is the third most common cause of hepatitis.
- hepatocellular carcinoma** A liver cancer associated with infection with hepatitis B virus.
- herd immunity** A collective acquired immunity in a population that reduces the incidence of a pathogen and makes it less likely that nonimmune individuals will contract and spread infection. One aim of vaccination is to induce herd immunity.
- heredity** Genetic inheritance.
- hermaphroditic** Containing the sex organs for both male and female in one individual.
- herpes zoster** A recurrent infection caused by latent chickenpox virus. Its manifestation on the skin tends to correspond to dermatomes and to occur in patches that "girdle" the trunk. Also called **shingles**.
- herpetic keratitis** Corneal or conjunctival inflammation due to herpesvirus type 1.
- heterotroph** An organism that relies upon organic compounds for its carbon and energy needs.
- hexose** A 6-carbon sugar such as glucose and fructose.
- hierarchies** Levels of power. Arrangement in order of rank.
- histamine** A cytokine released when mast cells and basophils release their granules. An important mediator of allergy, its effects include smooth muscle contraction, increased vascular permeability, and increased mucus secretion.
- histone** Proteins associated with eukaryotic DNA. These simple proteins serve as a scaffolding to compact and condense DNA into chromosomes, while also enhancing or preventing the expression of certain genes.

- holoenzyme** An enzyme complete with its apoenzyme and cofactors.
- hops** The ripe, dried fruits of the hop vine (*Humulus lupulus*) that is added to beer wort for flavoring.
- host range** The limitation imposed by the characteristics of the host cell on the type of virus that can successfully invade it.
- human diploid cell vaccine (HDCV)** A vaccine made using cell culture that is currently the vaccine of choice for preventing infection by rabies virus.
- human herpesvirus-6 (HHV-6)** The herpesvirus that causes roseola and may possibly be linked to chronic neurological diseases.
- human immunodeficiency virus (HIV)** A retrovirus that causes acquired immunodeficiency syndrome (AIDS).
- human papillomavirus (HPV)** A group of DNA viruses whose members are responsible for common, plantar, and genital warts.
- humoral immunity** Protective molecules (mainly antibodies) carried in the fluids of the body.
- hybridization** A process that matches complementary strands of nucleic acid (DNA-DNA, RNA-DNA, RNA-RNA). Used for locating specific sites or identifying exact sequences of nucleic acids.
- hybridoma** An artificial cell line that produces monoclonal antibodies. It is formed by fusing (hybridizing) a normal antibody-producing cell with a cancer cell, and it can produce pure antibody indefinitely.
- hydrogen bond** A weak chemical bond formed by the attraction of forces between molecules or atoms—in this case, hydrogen and either oxygen or nitrogen. In this type of bond, electrons are not shared, lost, or gained.
- hydrologic cycle** The continual circulation of water between hydrosphere, atmosphere, and lithosphere.
- hydrolysis** A process in which water is used to break bonds in molecules. Usually occurs in conjunction with an enzyme.
- hydrophilic** The property of attracting water. Molecules that attract water to their surface are called hydrophilic.
- hydrophobic** The property of repelling water. Molecules that repel water are called hydrophobic.
- hydrosphere** That part of the biosphere that encompasses water-containing environments such as oceans, lakes, rivers.
- hypertonic** A solution that, when compared to a reference solution, has a higher concentration of solute and less water; Placed opposite a hypotonic solution, it will cause water to diffuse more rapidly from the hypotonic solution, thus creating a greater osmotic pressure.
- hyphae** The tubular threads that make up filamentous fungi (molds). This web of branched and intertwining fibers is called a mycelium.
- hypogammaglobulinemia** An inborn disease in which the gamma globulin (antibody) fraction of serum is greatly reduced. The condition is associated with a high susceptibility to pyogenic infections.
- hypothesis** A tentative explanation of what has been observed or measured.
- hypotonic** A solution that, when compared with a reference solution, is less concentrated, i.e. has more water and less solute. When a membrane is placed between this solution and a hypertonic solution, water will move from the hypotonic side to the hypertonic side at a higher rate.
- icosahedron** A regular geometric figure having 20 surfaces that meet to form 12 corners. Some virions have capsids that resemble icosahedral crystals.
- immune complex reaction** Type III hypersensitivity of the immune system. It is characterized by the reaction of soluble antigen with antibody, and the deposition of the resulting complexes in basement membranes of epithelial tissue.
- immune surveillance** The continual function of macrophages, cytotoxic T cells, and natural killer cells in identifying and destroying cancer cells within the body.
- immune tolerance** The ability of the immune system to remain nonreactive to normal cell molecules.
- immunity** An acquired resistance to an infectious agent due to prior contact with that agent.
- immunoassays** Extremely sensitive tests that permit rapid and accurate measurement of trace antigen or antibody.
- immunocompetence** The ability of the body to recognize and react with multiple foreign substances.
- immunodeficiency** Immune function is incompletely developed, suppressed, or destroyed.
- immunogen** Any antigen molecule that, after being processed by the immune system, will stimulate protective T and B cell responses.
- immunoglobulin (IG)** The chemical class of proteins to which antibodies belong.
- immunology** The study of internal body defenses that protect against infection. This includes phagocytosis, inflammation, and acquired immunities.
- immunopathology** A disease state initiated by incorrect or harmful immune responses. Some immune diseases are caused by overreactions (allergies) and others are due to the lack of a functional immune response (immunodeficiencies).
- immunotherapy** Preventing or treating infectious diseases by administering substances that produce artificial immunity. May be active or passive.
- impetigo** Contagious skin infection marked by pustules and vesicles; caused by *S. aureus* and *S. pyogenes*. Also known as **pyoderma**.
- IMVIC** Abbreviation for four identification tests: indole production, **methyl red test**, **Voges-Proskauer test** (i inserted to concoct a wordlike sound), and citrate as a sole source of carbon. This test was originally developed to distinguish between *Enterobacter aerogenes* (associated with soil) and *Escherichia coli* (a fecal coliform).
- in vitro** Literally means “in glass,” signifying a process or reaction occurring in an artificial environment, as in a test tube or culture medium.
- in vivo** Literally means “in a living being,” signifying a process or reaction occurring in a living thing.
- incidence** In epidemiology, the number of new cases of a disease occurring during a time period.
- incineration** Destruction of microbes by subjecting them to extremes of dry heat. Microbes are reduced to ashes and gas by this process.
- inclusion** A relatively inert body in the cytoplasm such as storage granules, glycogen, fat, or some other aggregated metabolic product. Also called **inclusion body**.
- incubate** To isolate a sample culture in a temperature-controlled environment to encourage growth.
- incubation period** The period of time from the initial contact with an infectious agent to the appearance of the first symptoms.
- indicator bacteria** In water analysis, any easily cultured bacteria that may be found in the intestine and can be used as an index of fecal contamination. The category includes coliforms and enterococci. Discovery of these bacteria in a sample means that pathogens may also be present.
- induced mutation** Any alteration in DNA that occurs as a consequence of exposure to chemical or physical mutagens.
- inducible operon** A system of gene regulation in which a gene is ordinarily repressed unless the substrate of the structural proteins is present and induces it to become active; otherwise the operon is blocked and the RNA polymerase cannot transcribe.
- induction** Process by which an individual accumulates data or facts and then formulates a general hypothesis that accounts for those facts.
- infection** The entry, establishment, and multiplication of pathogenic organisms within a host.
- infectious disease** The state of damage or toxicity in the body caused by an infectious agent.
- infectious dose** The estimated number of microbial cells or units required to establish an infection.
- inflammation** A natural, nonspecific response to tissue injury that protects the host from further damage. It stimulates immune reactivity and blocks the spread of an infectious agent.
- inoculation** The implantation of microorganisms into or upon culture media.
- inorganic chemicals** Molecules that are composed of elements other than the basic framework of carbon and hydrogen, and which are usually much simpler chemically than organic molecules.
- interferon (IFN)** Naturally occurring polypeptide produced by fibroblasts and lymphocytes that can block viral replication and regulate a variety of immune reactions.
- interleukin** Molecules (interleukin-1, or IL-1) secreted by macrophages that stimulate lymphocyte function. In response to IL-1 T cells release yet another interleukin (IL-2), which amplifies T-cell response by activating additional T cells. T helper cells stimulated by IL-2 stimulate B-cell proliferation and promote antibody production.
- intermediate host** The organism in which the larval development of a parasite occurs.
- intoxication** Poisoning that results from the ingestion of a toxin and the subsequent effects of that toxin as it spread into body tissues.
- intron** A contracted version of “intrinsic regions.” These are segments on split genes of eukaryotes that do not code for polypeptide. They serve other functions. See **exon**.
- iodophor** A combination of iodine and an organic carrier that is a moderate-level disinfectant and antiseptic.
- ionic bond** A chemical bond in which electrons are transferred and not shared between atoms.
- ionization** The aqueous dissociation of an electrolyte into ions.
- ionizing radiation** Radiant energy consisting of short-wave electromagnetic rays (X ray) or high-speed electrons that cause dislodgement of electrons on target molecules, which creates create ions.
- irradiation** The application of radiant energy for diagnosis, therapy, disinfection, or sterilization.
- irregular (in shape)** Refers to bacteria that stain unevenly or display cell to cell variation in size and/or shape (pleomorphic) within a single species.
- isograft** Transplanted tissue from one monozygotic twin to the other; transplants between highly inbred animals that are genetically identical.
- isolation** The separation of microbial cells by serial dilution or mechanical dispersion on solid media to create discrete colonies.
- isotonic** Solutions having the same osmotic pressure, such that, when separated by a semipermeable membrane, show no net movement of solvent in either direction.

- isotope** A version of an element that is virtually identical in all chemical properties to another version except that their atoms have slightly different atomic masses.
- jaundice** The yellowish pigmentation of skin, mucous membranes, sclera, deeper tissues, and excretions due to abnormal deposition of bile pigments. Jaundice is associated with liver infection, as with hepatitis B virus and leptospirosis.
- Kaposi's sarcoma** A malignant or benign neoplasm that appears as multiple hemorrhagic sites on the skin, lymph nodes, and viscera and apparently involving the metastasis of abnormal blood vessel cells. It is a clinical feature of AIDS.
- keratoconjunctivitis** Inflammation of the conjunctiva and cornea.
- killed or inactivated vaccine** A whole cell or intact virus preparation in which the microbes are dead or preserved and cannot multiply but are still capable of conferring immunity.
- kingdom** In the levels of classification, the second division from more general to more specific. Each domain is divided into kingdoms.
- Koch's postulates** A procedure to establish the specific cause of disease. In all cases of infection: (1) The agent must be found; (2) inoculations of a pure culture must reproduce the same disease in animals; (3) the agent must again be present in the experimental animal; and (4) a pure culture must again be obtained.
- Koplik's spots** Tiny red blisters with central white specks on the mucosal lining of the cheeks. Symptomatic of measles.
- Krebs cycle** Metabolic cycle that is linked to glycolysis and receives acetyl groups generated when pyruvic acid is decarboxylated; it provides NADH₁, FADH₂, and ATP; also known as TCA cycle and citric acid cycle.
- L form** L-phase variants; wall-less forms of some bacteria that are induced by drugs or chemicals. These forms can be involved in infections.
- labile** In chemistry, molecules or compounds that are chemically unstable in the presence of environmental changes.
- lactose** One of the carbohydrates commonly referred to as sugars. Lactose is commonly found in milk.
- lactose (*lac*) operon** Control system that manages the regulation of lactose metabolism. It is composed of three DNA segments, including a regulator, a control locus, and a structural locus.
- lag phase** The early phase of population growth during which little sign of growth occurs. It is this period that readies the cells for the rapid expansion to come.
- lager** The maturation process of beer, which is allowed to take place in large vats at a reduced temperature.
- lagging strand** The newly forming DNA strand that is discontinuously replicated in short segments (Okazaki fragments) because the template cannot be continuously read by the DNA polymerase.
- latency** The state of being inactive and not multiplying. Example: a latent virus or latent infection.
- leading strand** The newly forming DNA strand that is replicated in a continuous fashion without fragments because it is oriented in the correct 3' to 5' direction for the DNA polymerase.
- leaven** To lighten food material by entrapping gas generated within it. Example: the rising of bread from the CO₂ produced by yeast or baking powder.
- legionellosis/legionnaire's disease** Pulmonary infection by *Legionella* bacteria. Gram-negative rods survive inside amoebas in aquatic habitats. Some conditions may be fatal.
- leprous leprosy** Severe, disfiguring leprosy characterized by widespread dissemination of the leprosy bacillus in deeper lesions.
- leprosy** A chronic progressive disease of the skin and nerves caused by a slow growing, strictly parasitic bacterium, *Mycobacterium leprae*. Also known as **Hansen disease**.
- lesion** A wound, injury, or some other pathologic change in tissues.
- leukocidin** A heat-labile substance formed by some pyogenic cocci that impairs and sometimes lyses leukocytes.
- leukocytes** White blood cells. The primary infection-fighting blood cells.
- leukocytosis** An abnormally large number of leukocytes in the blood, which can be indicative of acute infection.
- leukopenia** A lower-than-normal leukocyte count in the blood, which can be indicative of blood infection or disease.
- leukotriene** An unsaturated fatty acid derivative of arachidonic acid. Leukotriene functions in chemotactic activity, smooth muscle contractility, mucus secretion, and capillary permeability.
- ligase** An enzyme required to join nucleotides together to complete the final attachment of the ends of two fragments of DNA; this enzyme also works in DNA technology to attach sticky ends of DNA pieces during splicing.
- light-dependent reactions** The series of reactions in photosynthesis that are driven by the light energy (photons) absorbed by chlorophyll. They involve splitting of water into hydrogens and oxygen, transport of electrons by NADP, and ATP synthesis.
- light-independent reactions** The series of reactions in photosynthesis that can proceed with or without light. It is a cyclic system that uses ATP from the light reactions to incorporate or fix carbon dioxide into organic compounds, leading to the production of glucose and other carbohydrates (also called the Calvin cycle).
- limnetic zone** The deep-water region beyond the shoreline.
- lipid** A term used to describe a variety of substances that are not soluble in polar solvents such as water but will dissolve in nonpolar solvents such as benzene and chloroform. Lipids include triglycerides, phospholipids, steroids, and waxes.
- lipopolysaccharide** A molecular complex of lipid and carbohydrate found in the bacterial cell wall. The lipopolysaccharide (LPS) of gram-negative bacteria is an endotoxin with generalized pathologic effects such as fever.
- listeriosis** Infection with *Listeria monocytogenes*, usually due to eating contaminated dairy products, poultry, or meat. It is usually mild in healthy adults but can produce severe symptoms in neonates and immunocompromised adults.
- lithosphere** That part of the biosphere that encompasses the earth's crust, including rocks and minerals.
- littoral zone** The shallow region along a shoreline.
- lobar pneumonia** Infection involving whole segments (lobes) of the lungs, which may lead to consolidation and plugging of the alveoli and extreme difficulty in breathing.
- localized infection** An infection in which a microbe enters a specific tissue, infects it, and remains confined there.
- locus (plural, loci)** The specific site on a DNA molecule where a particular gene or sequence of nucleotides is located. In diploid organisms, the locus is occupied by two allele copies, one on each of the chromosome pairs.
- logarithmic or log phase** Maximum rate of cell division during which growth is geometric in its rate of increase. Also called **exponential growth phase**.
- lophotrichous** Describing bacteria having a tuft of flagella at one or both poles.
- lumen** The cavity within a tubular organ.
- lymphadenitis** Inflammation of one or more lymph nodes. Also called lymphadenopathy.
- lymphatic or lymphoid system** A system of vessels and organs that serve as sites for development of immune cells and immune reactions. It includes the spleen, thymus, lymph nodes, and GALT.
- lymphocyte** The second most common form of white blood cells.
- lyophilization** Freeze-drying; the separation of a dissolved solid from the solvent by freezing the solution and evacuating the solvent under vacuum. A means of preserving the viability of cultures.
- lysin** A complement-fixing antibody that destroys specific targeted cells. Examples: hemolysin and bacteriolysin.
- lysis** The physical rupture or deterioration of a cell.
- lysogeny** The indefinite persistence of bacteriophage DNA in a host without bringing about the production of virions. A lysogenic cell can revert to a lytic cycle, the process that ends in lysis.
- lysosome** A cytoplasmic organelle containing lysozyme and other hydrolytic enzymes.
- lysozyme** An enzyme that attacks the bonds on bacterial peptidoglycan. It is a natural defense found in tears and saliva.
- macromolecules** Large, molecular compounds assembled from smaller subunits, most notably biochemicals.
- macronutrient** A chemical substance required in large quantities (phosphate, for example).
- macrophage** A white blood cell derived from a monocyte that leaves the circulation and enters tissues. These cells are important in nonspecific phagocytosis and in regulating, stimulating, and cleaning up after immune responses.
- macroscopic** Visible to the naked eye.
- major histocompatibility complex (MHC)** See **HLA**.
- major histocompatibility complex/human leukocyte antigen** Major histocompatibility complex (MHC) and human leukocyte antigen (HLA). These alternate terms refer to a closely linked cluster of genes that program cell surface glycoprotein markers that control immune interactions between cells and are involved in immune recognition and some hypersensitivities, transfusion reactions, and graft rejections.
- malignant tumor** Cancerous growth characterized by uncontrolled growth or abnormal cells within normal tissue.
- malt** The grain, usually barley, that is sprouted to obtain digestive enzymes and dried for making beer.
- MALT (Mucosal-Associated Lymphoid Tissue)** Active lymphocytes distributed within the mucosal surfaces of respiratory and other systems.
- maltose** One of the carbohydrates referred to as sugars. A fermentable sugar formed from starch.
- Mantoux test** An intradermal screening test for tuberculin hypersensitivity. A red, firm patch of skin at the injection site greater than 10 mm in diameter after 48 hours is a positive result that indicates current or prior exposure to the TB bacillus.
- marker** Any trait or factor of a cell, virus, or molecule that makes it distinct and recognizable. Example: a genetic marker.

- mash** In making beer, the malt grain is steeped in warm water, ground up, and fortified with carbohydrates to form mash.
- mass number (MN)** Measurement that reflects the number of protons and neutrons in an atom of a particular element.
- mast cell** A nonmotile connective tissue cell implanted along capillaries, especially in the lungs, skin, gastrointestinal tract, and genitourinary tract. Like a basophil, its granules store mediators of allergy.
- matrix** The dense ground substance between the cristae of a mitochondrion that serves as a site for metabolic reactions.
- matter** All tangible materials that occupy space and have mass.
- maximum temperature** The highest temperature at which an organism will grow.
- mechanical vector** An animal that transports an infectious agent but is not infected by it, such as houseflies whose feet become contaminated with feces.
- medium** (plural, **media**) A nutrient used to grow organisms outside of their natural habitats.
- membrane, cell** A molecular “skin” surrounding the cytoplasm of cells that functions in protection, transport, communication, and secretion.
- memory cell** A long-lived progeny of a sensitized lymphocyte that remains in circulation and is genetically programmed to react rapidly the next time it encounters its antigen.
- meningitis** An inflammation of the membranes (meninges) that surround and protect the brain. It is often caused by bacteria such as *Neisseria meningitidis* (the meningococcus) and *Haemophilus influenzae*.
- merozoite** The motile, infective stage of an apicomplexan parasite that comes from a liver or red blood cell undergoing multiple fission.
- mesophile** Microorganisms that grow at intermediate temperatures—usually between 20 and 40 degrees C.
- messenger RNA (MRNA)** A single-stranded transcript that is a copy of the DNA template that corresponds to a gene; it generally carries the genetic code for a protein.
- metabolic analog** A chemical, usually a drug, that mimics the natural substrate of an enzyme and vies for its active site. This reaction, called competitive inhibition, can block the metabolic pathway that requires that enzyme.
- metabolism** A general term designating the totality of chemical processes occurring in a cell.
- metabolites** Small organic molecules that are intermediates in the stepwise biosynthesis or breakdown of macromolecules.
- metagenomics** The analysis of genomes recovered from mixed environmental samples that provides information on the diversity of microbe types without isolating or culturing them.
- methanogens** Microbes that produce methane gas.
- MIC** Abbreviation for minimum inhibitory concentration. The lowest concentration of antibiotic needed to inhibit bacterial growth in a test system.
- microaerophile** An aerobic bacterium that requires oxygen at a concentration less than that in the atmosphere.
- microbe** See **microorganism**.
- microbial loop** A process occurring in natural aquatic habitats that maintains the cycling of nutrients from producers to consumers and back to producers. It is powered primarily by mineralizing and decomposing bacteria and protozoa.
- microbiology** A specialized area of biology that deals with living things ordinarily too small to be seen without magnification, including bacteria, archaea, fungi, protozoa, and viruses.
- microbiota** The native types of bacteria, fungi, and viruses that normally reside on the body. An older term is normal flora.
- microfilaments** Cellular cytoskeletal element formed by thin protein strands that attach to cell membrane and form a network through the cytoplasm. Responsible for movement of cytoplasm.
- micronutrient** A chemical substance required in small quantities (trace metals, for example).
- microorganism** A living thing ordinarily too small to be seen without magnification; an organism of microscopic size.
- microscopic** Invisible to the naked eye.
- microscopy** Science that studies structure, magnification, lenses, and techniques related to use of a microscope.
- microtubules** Long tubular structures made of protein that function in the structure, shape, and movement of eukaryotic cells.
- mineralization** The process by which decomposers (bacteria and fungi) convert organic debris into inorganic and elemental form. It is part of the recycling process.
- minimum inhibitory concentration (MIC)** The smallest concentration of drug needed to visibly control microbial growth.
- minimum temperature** The lowest temperature at which an organism will grow.
- miracidium** The ciliated first-stage larva of a trematode. This form is infective for a corresponding intermediate host snail.
- missense mutation** A mutation in which a change in the DNA sequence results in a different amino acid being incorporated into a protein, with varying results.
- mitochondrion** A double-membrane organelle of eukaryotes that is the main site for aerobic respiration. It contains its own chromosome and ribosomes.
- mitosis** Somatic cell division that preserves the somatic chromosome number.
- mixed acid fermentation** An anaerobic degradation of pyruvic acid that results in more than one organic acid being produced (acetic acid, lactic acid, succinic acid, etc.).
- mixed culture** A container growing two or more different, known species of microbes.
- mixed infection** Occurs when several different pathogens interact simultaneously to produce an infection. Also called a synergistic infection.
- moist heat** Heat combined with some form of water, including hot water, boiling water, or steam, generally ranging from 60°C to 135°C.
- molds** The filamentous fungi, composed of elongate hyphae.
- molecule** A distinct chemical substance that results from the combination of two or more atoms.
- molluscum contagiosum** Poxvirus-caused disease that manifests itself by the appearance of small lesions on the face, trunk, and limbs. Often associated with sexual transmission.
- monoclonal antibody** An antibody produced by a clone of lymphocytes that respond to a particular antigenic determinant and generate identical antibodies only to that determinant. See **hybridoma**.
- monocyte** A large mononuclear leukocyte normally found in the lymph nodes, spleen, bone marrow, and loose connective tissue. This type of cell makes up 3% to 7% of circulating leukocytes.
- monomer** A simple molecule that can be linked by chemical bonds to form larger molecules.
- mononuclear phagocyte system** A collection of monocytes and macrophages scattered throughout the extracellular spaces that function to engulf and degrade foreign cells and substances.
- monosaccharide** A simple sugar such as glucose that is a basic building block for more complex carbohydrates.
- monotrichous** Describing a microorganism that bears a single flagellum.
- morbidity** A diseased condition.
- morphology** The study of organismic structure.
- mortality rate** Total number of deaths in a population attributable to a particular disease.
- most probable number (MNP)** Coliform test used to detect the concentration of contaminants in water supplies.
- motility** Self-propulsion.
- MRSA/methicillin-resistant *Staphylococcus aureus*** This refers to a strain of *S. aureus* that resists not only methicillin but a wide variety of nonpenicillin drugs such as cephalosporins, gentamycin, tetracycline, and erythromycin. These “superbugs” are common in the hospital and are increasingly found in community settings.
- Multibacillary** Containing many bacilli.
- multinucleate giant cell** A cytopathic effect that arises from the fusion of the cytoplasmic membranes of several infected cells. Characteristic of infection with paramyxoviruses.
- mumps** See **epidemic parotitis**.
- must** Juices expressed from crushed fruits that are used in fermentation for wine.
- mutagen** Any agent that induces a change in the composition of DNA. Examples: certain chemical substances, ultraviolet radiation, radioactive elements.
- mutant strain** A subspecies of microorganism that has undergone a mutation, causing expression of a trait that differs from other members of that species.
- mutation** A permanent inheritable alteration in the DNA sequence or content of a cell.
- mutualism** Organisms living in a close, mutually beneficial relationship.
- mycelium** The filamentous mass that makes up a mold. Composed of hyphae.
- mycetoma** A chronic fungal infection usually afflicting the feet, typified by swelling and multiple draining lesions. Example: maduromycosis or Madura foot.
- mycoplasma** Species of mycoplasma are among the smallest self-replicating microorganisms. Mycoplasma naturally lack a cell wall. Most species are parasites of animals and plants.
- mycorrhizae** Various species of fungi adapted in an intimate, mutualistic relationship to plant roots.
- mycosis** Any disease caused by a fungus.
- mycotoxicosis** Illness resulting from eating poisonous fungi.
- myonecrosis** Another name for **gas gangrene**.
- nanobes** Cell-like particles, found in sediments and other geologic deposits, that some scientists speculate are the smallest bacteria. Short for **nanobacteria**.
- narrow spectrum** Denotes drugs that are selective and limited in their effects. For example, they inhibit either gram-negative or gram-positive bacteria but not both.
- nasopharyngeal carcinoma** A malignancy of epithelial cells that occurs in older Chinese and African men and is associated with exposure to Epstein-Barr virus.
- natural immunity** Specific protection from disease acquired through normal, nonmedical life processes.

- necrosis** A pathologic process in which cells and tissues die and disintegrate.
- necrotizing fasciitis** Severe invasive disease of skin, muscle, and connective tissue, usually caused by group A streptococci.
- negative feedback** Enzyme regulation of metabolism by the end product of a multienzyme system that blocks the action of a “pacemaker” enzyme at or near the beginning of the pathway.
- negative stain** A staining technique that renders the background opaque or colored and leaves the object unstained so that it is outlined as a colorless area.
- nematode** A common name for helminths called roundworms.
- neoplasm** A synonym for tumor.
- neuraminidase** A glycoprotein found in the envelope of influenza virus that facilitates release of new viruses from the host cell.
- neurotropic** Having an affinity for the nervous system. Most likely to affect the spinal cord.
- neutralization** In immunology, a type of antibody-antigen reaction which results in the blockage of a virus receptor or toxic protein by an antibody. In chemistry, the process of combining an acid and a base until they reach a balanced proportion, with a pH value close to 7.
- neutron** An electrically neutral particle in the nuclei of all atoms except hydrogen.
- neutrophil** A mature granulocyte present in peripheral circulation, exhibiting a multilobular nucleus and numerous cytoplasmic granules that retain a neutral stain. The neutrophil is an active phagocytic cell in bacterial infection.
- niche** In ecology, an organism’s biological role in or contribution to its community.
- Nicotinamide adenine dinucleotide/NAD/NADH** Abbreviations for the oxidized/reduced forms of nicotinamide adenine dinucleotide, an electron carrier. Nicotinamide is another name for the vitamin niacin.
- nitrification** Phase of the nitrogen cycle in which ammonium is oxidized.
- nitrogen cycle** The pathway followed by the element nitrogen as it circulates from inorganic sources in the nonliving environment to living things and back to the nonliving environment. The longtime reservoir is nitrogen gas in the atmosphere.
- nitrogen fixation** A process occurring in certain bacteria in which atmospheric N_2 gas is converted to a form (NH_4) usable by plants.
- nitrogenous base** A ringed compound of which pyrimidines and purines are types.
- nomenclature** A set system for scientifically naming organisms, enzymes, anatomical structures, etc.
- noncoliforms** Lactose-negative enteric bacteria in normal flora.
- noncommunicable** An infectious disease that is not established through transmission of an infectious agent via another infected host.
- nonionizing radiation** Method of microbial control, best exemplified by ultraviolet light, that causes the formation of abnormal bonds within the DNA of microbes, increasing the rate of mutation. The primary limitation of nonionizing radiation is its inability to penetrate beyond the surface of an object.
- nonpolar** A term used to describe an electrically neutral molecule formed by covalent bonds between atoms that have the same or similar electronegativity.
- nonself** Cells or molecules recognized by the immune system as containing foreign markers. Nonself can stimulate the immune system to react and eliminate the foreign substances.
- nonsense codon** A triplet of mRNA bases that does not specify an amino acid but signals the end of a polypeptide chain. Also called **stop codon**.
- nonsense mutation** A mutation that changes an amino acid-based codon into a stop codon, leading to premature termination of a protein during translation.
- Norwalk agent** One of a group of Caliciviruses, Norwalk agent causes gastrointestinal distress and is commonly transmitted in schools, camps, cruise ships, and nursing homes.
- nucleocapsid** In viruses, the close physical combination of the nucleic acid with its protective covering.
- nucleoid** The undifferentiated space or region in the cytoplasm that contains the bacterial genetic material. It is naked and not enclosed in a membrane.
- nucleolus** A granular mass containing RNA that is contained within the nucleus of a eukaryotic cell.
- nucleosome** Structure in the packaging of eukaryotic DNA formed when the DNA strands wrap around histone proteins, forming an arrangement that looks like beads on a chain.
- nucleotide** The basic structural unit of DNA and RNA; each nucleotide consists of a phosphate, a sugar (ribose in RNA, deoxyribose in DNA), and a nitrogenous base such as adenine, guanine, cytosine, thymine (DNA only), or uracil (RNA only).
- nucleus** 1) In chemistry, the central core of an atom, composed of protons and neutrons. 2) In cell structure, a prominent spherical organelle that is encased by a double membrane or envelope; it is the site where the majority of a cell’s DNA is housed.
- numerical aperture (NA)** In microscopy, a measure of the light passing from the object and into the objective to maximize optical clarity and resolution.
- nutrient** Any chemical substance that is acquired from the environment and used for metabolism and growth. Macronutrients are required in large amounts, and micronutrients in small amounts.
- nutrition** The acquisition of chemical substances by a cell or organism for use as an energy source or as building blocks of cellular structures.
- obligate/strict** Without alternative; restricted to a particular way of life. Example: An obligate parasite survives and grows only in a host; an obligate aerobe must have oxygen to grow; an obligate anaerobe is destroyed by oxygen.
- Okazaki fragment** In replication of DNA, a segment formed on the lagging strand where biosynthesis is conducted in a discontinuous manner as required by the DNA polymerase orientation.
- oligodynamic action** A chemical having antimicrobial activity in minuscule amounts. Example: Certain heavy metals are effective in a few parts per billion.
- oligotrophic** Nutrient-deficient ecosystem.
- oncogene** A naturally occurring type of gene that when activated can transform a normal cell into a cancer cell.
- oncology** The study of neoplasms, their cause, disease characteristics, and treatment.
- onychomycosis** A fungal infection of the nail and nailbed. Also called tinea unguium.
- operator** In an operon sequence, the DNA segment where transcription of structural genes is initiated.
- operon** A genetic operational unit that regulates metabolism by controlling mRNA production. In sequence, the unit consists of a regulatory gene, inducer or repressor control sites, and structural genes.
- opportunistic infection** A situation where ordinarily nonpathogenic or weakly pathogenic microbes cause disease in an immunologically compromised host.
- opportunistic pathogen** A microbe that infects a host when the body’s defense system is vulnerable, causing an **opportunistic infection**.
- opsonization** The process of stimulating phagocytosis by affixing molecules (opsonins such as antibodies and complement) to the surfaces of foreign cells or particles.
- optimum temperature** The temperature at which a species shows the most rapid growth rate.
- orbitals** The pathways of electrons as they rotate around the nucleus of an atom.
- order** In the levels of classification, the division of organisms that follows class. Increasing similarity may be noticed among organisms assigned to the same order.
- organelle** A small component of eukaryotic cells that is bounded by a membrane and specialized in function.
- organic chemicals** Molecules that are structured with a basic framework of the elements carbon and hydrogen; usually these are larger than inorganic molecules and contain additional elements as well.
- ornithosis** Worldwide zoonosis carried in the latent state in wild and domesticated birds; caused by *Chlamydia psittacosis*.
- osmophile** A microorganism that thrives in a medium having high osmotic pressure.
- osmosis** The diffusion of water across a selectively permeable membrane in the direction towards lower water concentration and higher solute concentration.
- osteomyelitis** A focal infection of the internal structures of long bones, leading to pain and inflammation. Often caused by *Staphylococcus aureus*.
- otitis media** Acute infection of the middle ear, usually by the pneumococcus, that causes severe pain and drainage.
- outer membrane** A structure made of lipids in the outer layer of the cell wall of gram-negative bacteria.
- oxidation** In chemical reactions, the loss of electrons by one reactant. An oxidizing agent is a molecule that causes electron loss or removes electrons from a substrate.
- oxidation-reduction** Redox reactions, in which paired sets of molecules participate in electron transfers.
- oxidative phosphorylation** The synthesis of ATP using energy released during the electron transport phase of respiration.
- oxygenic** Any reaction that gives off oxygen; usually in reference to the result of photosynthesis in eukaryotes and cyanobacteria.
- palindrome** In the DNA code, a short segment of paired nitrogen bases that have the same sequence when read in opposite directions. Palindromes have significance as transposable elements, regulatory protein targets, and in DNA splicing. In ordinary language, a palindrome is a word, verse, number, or sentence that reads the same forward or backward.
- palisades** The characteristic bacterial arrangement resembling a row of fence posts created by cells snapping together.
- pandemic** An epidemic that has spread across a wide geographic area, including more than one continent or international border, and can extend to a worldwide occurrence.
- papilloma** Benign, squamous epithelial growth commonly referred to as a wart.
- parainfluenza** A respiratory disease (croup) caused by infection with Paramyxovirus.
- parasitism/parasite** A close interaction in which one organism (the parasite) lives on or within another organism (the host), from which it obtains nutrients and receives protection. The parasite produces some degree of harm to the host.

- parenteral** Administering a substance into a body compartment other than through the gastrointestinal tract, such as via intravenous, subcutaneous, intramuscular, or intramedullary injection.
- passive carrier** Persons who mechanically transfer a pathogen without ever being infected by it, such as health care workers who don't wash their hands adequately between patients.
- passive immunity** Specific resistance that is acquired indirectly by donation of preformed immune substances (antibodies) produced in the body of another individual.
- passive transport** Nutrient transport method that follows basic physical laws and does not require direct energy input from the cell.
- pasteurization** Heat treatment of perishable fluids such as milk, fruit juices, or wine to destroy heat-sensitive vegetative cells, followed by rapid chilling to inhibit growth of survivors and germination of spores. It prevents infection and spoilage.
- pathogen** Any agent—usually a virus, bacterium, fungus, protozoan, or helminth—that infects body tissues and causes disease.
- pathogen-associated molecular pattern (PAMP)** Molecules on the surfaces of pathogenic microbes that are recognized by phagocytes and trigger immune responses against the microbes.
- pathogenicity** The capacity of microbes to cause disease.
- Paucibacillary** Containing just a few bacilli.
- pelvic inflammatory disease (PID)** An infection of the uterus and fallopian tubes that has ascended from the lower reproductive tract. Caused by gonococci and chlamydiae.
- penicillinase** An enzyme that hydrolyzes penicillin; found in penicillin-resistant strains of bacteria.
- penicillins** A large group of naturally occurring and synthetic antibiotics produced by *Penicillium* mold and active against the cell wall of bacteria.
- pentose** A monosaccharide with five carbon atoms per molecule. Examples: arabinose, ribose, and xylose.
- peptide** Molecule composed of short chains of amino acids, such as a dipeptide (two amino acids), a tripeptide (three), and a tetrapeptide (four).
- peptide bond** The covalent union between two amino acids that forms between the amine group of one and the carboxyl group of the other. The basic bond of proteins.
- peptidoglycan** A network of polysaccharide chains cross-linked by short peptides that forms the rigid part of bacterial cell walls. Gram-negative bacteria have a smaller amount of this rigid structure than do gram-positive bacteria.
- perforin** A protein secreted by cytotoxic and natural killer cells that attacks the cell membrane of infectious agents and forms pores.
- period of invasion** The period during a clinical infection when the infectious agent multiplies at high levels, exhibits its greatest toxicity, and becomes well established in the target tissues.
- periplasmic space** An open area between the cell wall and cell membrane in the cell envelopes of bacteria. Gram-negative bacteria have a more extensive space than do gram-positive bacteria.
- peritrichous** In bacterial morphology, having flagella distributed over the entire cell.
- pertussis** Infection by *Bordetella pertussis*. A highly communicable disease that causes acute respiratory syndrome. Pertussis can be life-threatening in infants, but vaccination on the recommended schedule can prevent infection. Also called **whooping cough**.
- petechiae** Minute hemorrhagic spots in the skin that range from pinpoint- to pinhead-size.
- Peyer's patches** Oblong lymphoid aggregates of the gut located chiefly in the wall of the terminal and small intestine. Along with the tonsils and appendix, Peyer's patches make up the **gut-associated lymphoid tissue** that responds to local invasion by infectious agents.
- pH** The symbol for the negative logarithm of the H ion concentration; p (power) or $[H^+]_{10}$. A system for rating acidity and alkalinity.
- phagocytosis** A type of endocytosis in which the cell membrane actively engulfs large particles or cells into vesicles. A **phagocyte** is a cell specialized for doing this.
- phagolysosome** A body formed in a phagocyte, consisting of a union between a vesicle containing the ingested particle (the phagosome) and a vacuole of hydrolytic enzymes (the lysosome).
- phenetic** Based on phenotype, or expression of traits.
- phenotype** The observable characteristics of an organism produced by the expression of its genetic potential (genotype). Includes any morphological and physiological traits.
- phlebotomine** Pertains to a genus of very small midges or blood-sucking (phlebotomous) sand flies and to diseases associated with those vectors such as kala-azar, Oroya fever, and cutaneous leishmaniasis.
- phosphate** An acidic salt containing phosphorus and oxygen that is an essential inorganic component of DNA, RNA, and ATP.
- phospholipid** A class of lipids that compose a major structural component of cell membranes.
- phosphorylation** Process in which inorganic phosphate is added to a compound.
- photic zone** The aquatic stratum from the surface to the limits of solar light penetration.
- photoautotroph** An organism that utilizes light for its energy and carbon dioxide chiefly for its carbon needs.
- photolysis** Literally, splitting water with light. In photosynthesis, this step frees electrons and gives off O_2 .
- photon** A subatomic particle released by electromagnetic sources such as radiant energy (sunlight). Photons are the ultimate source of energy for photosynthesis.
- photophosphorylation** The process of electron transport during photosynthesis that uses captured light energy to synthesize ATP from ADP and phosphate.
- photosynthesis** A process occurring in plants, algae, and some bacteria that traps the sun's energy and converts it to ATP in the cell. This energy is used to fix CO_2 into organic compounds.
- phototroph** A microbe that uses sunlight for energy and CO_2 as a carbon source.
- phylogenetic** A classification system based on evolutionary relationships. Also called phyletic.
- phylum** In the levels of classification, the third level of classification from general to more specific. Each kingdom is divided into numerous phyla. Sometimes referred to as **division**.
- physiology** The study of the function of an organism.
- pili (singular, pilus)** Small, stiff filamentous appendages in gram-negative bacteria that function in DNA exchange during bacterial conjugation.
- pinocytosis** The engulfment, or endocytosis, of liquids by extensions of the cell membrane.
- plague** Zoonotic disease caused by infection with *Yersinia pestis*. The pathogen is spread by flea vectors and harbored by various rodents.
- plankton/planktonic** Minute animals and protozoa (zooplankton) or algae (phytoplankton) that float and drift in the limnetic zone of bodies of water.
- plantar warts** Deep, painful warts on the soles of the feet as a result of infection by human papillomavirus.
- plaque** In virus propagation methods, the clear zone of lysed cells in tissue culture or chick embryo membrane that corresponds to the area containing viruses. In dental application, the filamentous mass of microbes that adheres tenaciously to the tooth and predisposes to caries, calculus, or inflammation.
- plasma** The carrier fluid element of blood.
- plasma cell** A progeny of an activated B cell that actively produces and secretes antibodies against a specific microbe.
- plasmids** Extrachromosomal genetic units characterized by several features. A plasmid is a double-stranded DNA that is smaller than and replicates independently of the cell chromosome; it bears genes that are not essential for cell growth; it can bear genes that code for adaptive traits; and it is transmissible to other bacteria.
- platelets** Formed elements in the blood that develop when megakaryocytes disintegrate. Platelets are involved in hemostasis and blood clotting.
- pleomorphism** Normal variability of cell shapes in a single species; bacteria having diverse shapes are called pleomorphic.
- pneumococcus** Common name for *Streptococcus pneumoniae*, the major cause of bacterial pneumonia.
- pneumonia** An inflammation of the lung leading to blockage of the respiratory tract that compromises breathing.
- pneumonic plague** The acute, frequently fatal form of pneumonia caused by *Yersinia pestis*.
- polar** Term to describe a molecule with an asymmetrical distribution of charges. Such a molecule has a negative pole and a positive pole.
- Polar flagellum** Description of flagella that are attached at one or both ends of the cell.
- poliomyelitis** An acute enteroviral infection of the spinal cord that can cause neuromuscular paralysis.
- polyclonal antibodies** In reference to a collection of antibodies with mixed specificities that arose from more than one clone of B cells.
- polymer** A macromolecule made up of a chain of repeating units. Examples: starch, protein, and DNA.
- polymerase** An enzyme that produces polymers through catalyzing bond formation between building blocks (polymerization).
- polymerase chain reaction (PCR)** A technique that amplifies segments of DNA for testing. Using denaturation, primers, and heat-resistant DNA polymerase, the number can be increased several million-fold.
- polymyxin** A mixture of antibiotic polypeptides from *Bacillus polymyxa* that are particularly effective against gram-negative bacteria.
- polypeptide** A relatively large chain of amino acids linked by peptide bonds.
- polyribosomal complex** An assembly line for mass production of proteins composed of a chain of ribosomes involved in mRNA transcription.
- polysaccharide** A carbohydrate that can be hydrolyzed into a number of monosaccharides. Examples: cellulose, starch, and glycogen.
- population** A group of organisms of the same species living simultaneously in the same habitat. A group of different populations living together constitutes the community level.
- porin** Transmembrane proteins of the outer membrane of gram-negative cells that permit transport of small molecules into the periplasmic space but bar the penetration of larger molecules.

- portal of entry** Characteristic route of entry for an infectious agent; typically a cutaneous or membranous route.
- portal of exit** Characteristic route through which a pathogen departs from the host organism.
- positive stain** Technique in which dye affixes to a specimen and imparts color to it. It takes advantage of the ready binding of bacterial cells to dyes.
- potable** Describing water that is relatively clear, odor-free, and safe to drink.
- pox** The thick, elevated pustular eruptions of various viral infections. Also spelled *pocks*.
- poxvirus** A group of large complex DNA viruses that create pox skin lesions. Agents of smallpox and molluscum contagiosum.
- prevalence** The total cumulative number of cases of a disease in a certain area and time period.
- primary infection** An initial infection in a previously healthy individual that is later complicated by an additional (secondary) infection.
- primary pulmonary infection (PPI)** Disease that results from the inhalation of fungal spores and their germination in the lungs. This may serve as a focus of infection that spreads throughout the body.
- primary response** The first response of the immune system when exposed to an antigen.
- primary structure** Initial protein organization described by type, number, and order of amino acids in the chain. The primary structure varies extensively from protein to protein.
- primers** Short segments of RNA that serve as binding sites for DNA polymerase to start adding nucleotides to the new strand of DNA.
- prion** A concocted word to denote “proteinaceous infectious agent”; a cytopathic protein associated with the slow-virus spongiform encephalopathies of humans and animals.
- probes** Small fragments of single-stranded DNA (or RNA) that are known to be complementary to a specific sequence of DNA being studied.
- probiotic** A microbe or mixture of microbes that may be used to balance the normal microbiota and improve gastrointestinal health.
- prodromium** A short period of nonspecific symptoms at the end of the period of incubation that is usually the earliest indication of an infection.
- producer** An organism that synthesizes complex organic compounds from simple inorganic molecules. Examples would be photosynthetic microbes and plants. These organisms are solely responsible for originating food pyramids and are the basis for life on earth (also called autotroph).
- proglottid** The egg-generating segment of a tapeworm that contains both male and female organs.
- progressive multifocal leukoencephalopathy (PML)** An uncommon, fatal complication of infection with JC virus (polyomavirus).
- prokaryotic cell** Small cell lacking special structures such as a nucleus and organelles. All prokaryotes are microorganisms.
- promastigote** A morphological variation of the trypanosome parasite responsible for leishmaniasis.
- prophage** A lysogenized bacteriophage; a phage that is latently incorporated into the host chromosome instead of undergoing viral replication and lysis.
- prophylactic/prophylaxis** Any device, method, or substance that prevents a disease from developing.
- prostaglandin** A hormonelike substance that regulates many body functions. Prostaglandin comes from a family of organic acids containing 5-carbon rings that are essential to the human diet.
- protein** Predominant organic molecule in cells, formed by long chains of amino acids.
- proton** An elementary particle that carries a positive charge. It is identical to the nucleus of the hydrogen atom.
- protoplast** A bacterial cell whose cell wall is completely lacking and that is vulnerable to osmotic lysis.
- protozoa** A group of single-celled, eukaryotic organisms that feed on other cells and usually have a locomotor organelle.
- pseudohypha** A chain of easily separated, spherical to sausage-shaped yeast cells partitioned by constrictions rather than by septa.
- pseudomembrane** A tenacious, noncellular mucous exudate containing cellular debris that tightly blankets the mucosal surface in infections such as diphtheria and pseudomembranous enterocolitis.
- pseudopods** Appendages responsible for motility of protozoa such as amoebas. Also called “false feet.”
- psychrophile** A microorganism that thrives at low temperatures (0°C–20°C), with a temperature optimum of 0°C–15°C.
- pulmonary** Occurring in the lungs. Examples include pulmonary anthrax and pulmonary nocardiosis.
- pulmonary anthrax** The more severe form of anthrax, resulting from inhalation of spores and resulting in a wide range of pathological effects, including death.
- pure culture** A container growing a single species of microbe whose identity is known.
- purine** A nitrogen base that is an important encoding component of DNA and RNA. It is composed of a basic two-ring structure and is larger than a pyrimidine. The two most common purines are adenine and guanine.
- pus** The viscous, opaque, usually yellowish matter formed by an inflammatory infection. It consists of serum exudate, tissue debris, leukocytes, and microorganisms. *Purulent* refers to a puslike condition.
- pyogenic** Pus-forming; especially pertaining to the pyogenic cocci: pneumococci, streptococci, staphylococci, and neisseriae.
- pyrimidine** A nitrogen base that helps form the genetic code on DNA and RNA. It is composed of a single-ring structure and is smaller than a purine. Thymine, cytosine, and uracil are the most important pyrimidines.
- pyrimidine dimer** The union of two adjacent pyrimidines on the same DNA strand, brought about by exposure to ultraviolet light. It is a form of mutation.
- pyrogen** A substance that causes a rise in body temperature. It can come from infectious agents (exogenous) or from polymorphonuclear leukocytes and macrophages (endogenous pyrogens).
- Q fever** A disease first described in Queensland, Australia, initially dubbed Q for “query” to denote a fever of unknown origin. Q fever is now known to be caused by a rickettsial infection.
- quaternary ammonium compounds** See **quats**.
- quaternary structure** The most complex protein structure, characterized by the formation of large, multiunit proteins by more than one of the polypeptides. This structure is typical of antibodies and some enzymes that act in cell synthesis.
- quats/quaternary ammonium compounds** A family of surfactants called **quaternary ammonium compounds**, termed **quats** for short. These detergents are weakly microbicidal and are used as disinfectants, sanitizers, and preservatives.
- quorum sensing** A phenomenon occurring among microbes in a biofilm in which the members signal each other and coordinate their functions.
- rabies** The only rhabdovirus that infects humans. Zoonotic disease characterized by fatal meningoencephalitis.
- radiation** Electromagnetic waves or rays given off from an energy source. Includes gamma rays, X rays, ultraviolet, visible light, and others.
- reactants** Molecules entering or starting a chemical reaction.
- reactive oxygen intermediate (ROI)** Any charged oxygen radical (e.g. superoxide ions, peroxide) given off during oxygen metabolism that can be toxic to microbial and other cells.
- real image** An image formed at the focal plane of a convex lens. In the compound light microscope, it is the image created by the objective lens.
- recombinant DNA technology** A technology, associated with genetic engineering, that deliberately modifies the genetic structure of an organism to create novel products, microbes, animals, plants, and viruses.
- recombination** A type of genetic transfer in which DNA from one organism is donated to another. The resultant cell is termed *recombinant*.
- recycling** A process that converts unusable organic matter from dead organisms back into their essential inorganic elements and returns them to their nonliving reservoirs to make them available again for living organisms. This is a common term that means the same as *mineralization* and *decomposition*.
- redox** Denoting an oxidation-reduction reaction.
- reduction** In chemistry, the gain of electrons. A reducing agent is one that causes the addition of electrons to a substrate.
- reemerging disease** Previously identified disease that is increasing in occurrence.
- refraction** In optics, the bending of light as it passes from one medium to another with a different index of refraction.
- regular (in shape)** Refers to bacteria with uniform staining properties and that are consistent in shape from cell to cell within a particular species.
- regulator** DNA segment that codes for a protein capable of repressing an operon.
- rennin** The enzyme casein coagulase, which is used to produce curd in the processing of milk and cheese.
- reovirus** Respiratory enteric orphan virus. Virus with a double-stranded RNA genome and both an inner capsid and an outer capsid. Not a significant human pathogen.
- replication** In DNA synthesis, the semiconservative mechanisms that ensure precise duplication of the parent DNA strands.
- replication fork** The Y-shaped point on a replicating DNA molecule where the DNA polymerase is synthesizing new strands of DNA.
- reportable disease** Any disease that needs regular and frequent monitoring of individual cases so that it can be managed and prevented. These are diseases that must be reported to health authorities by law.
- repressible operon** A system of gene regulation that is normally active but can be blocked when a build-up of the operon’s product occurs; this causes transcription by the RNA polymerase to be stopped, i.e. *repressed*.
- repressor** The protein product of a repressor gene that combines with the operator and arrests the transcription and translation of structural genes.
- reservoir** In epidemiology, the natural host or habitat of a pathogen that is its long-term origin.
- resident microbiota** The deeper, more stable microflora that inhabit the skin and exposed mucous membranes, as opposed to the superficial, variable, transient population.

- resistance (R) factor** Plasmids, typically shared among bacteria by conjugation, that provide resistance to the effects of antibiotics.
- resolving power** The capacity of a microscope lens system to accurately distinguish between two separate entities that lie close to each other. Also called resolution.
- respiratory chain** In cellular respiration, a series of electron-carrying molecules that transfers energy-rich electrons and protons to molecular oxygen. In transit, energy is extracted and conserved in the form of ATP.
- respiratory syncytial virus (RSV)** An RNA virus that infects the respiratory tract. RSV is the most prevalent cause of respiratory infection in newborns.
- restriction endonuclease** An enzyme present naturally in bacteria that cleaves specific locations (palindromes) on DNA. It is an important means of inactivating viral genomes, and it is also used in genetic engineering to splice genes.
- reticuloendothelial system (RES)** A network of fibers and phagocytic cells (macrophages) that permeates the tissues of all organs. Examples: Kupffer cells in liver sinusoids, alveolar phagocytes in the lung, and microglia in nervous tissue. Also known as the mononuclear phagocyte system.
- retrovirus** A group of RNA viruses (including HIV) that have the mechanisms for converting their genome into a double strand of DNA that can be inserted on a host's chromosome.
- reverse transcriptase (RT)** The enzyme possessed by retroviruses that carries out the reversion of RNA to DNA—a form of reverse transcription.
- Reye's syndrome** A sudden, usually fatal neurological condition that occurs in children after a viral infection. Autopsy shows cerebral edema and marked fatty change in the liver and renal tubules.
- Rh factor** An isoantigen that can trigger hemolytic disease in newborns due to incompatibility between maternal and infant blood factors.
- rhabdovirus** Family of bullet-shaped viruses that includes rabies.
- rheumatic fever** Chronic group A *Streptococcus*-associated syndrome that damages the heart valves.
- rhinoviruses** Picornaviruses associated with the common cold. Transmission is through human-to-human contact, and symptoms typically are short-lived. Most effective control is effective hand washing and care in handling nasal secretions.
- rhizobia** Bacteria that live in plant roots and supply supplemental nitrogen that boosts plant growth.
- rhizosphere** The zone of soil, complete with microbial inhabitants, in the immediate vicinity of plant roots.
- ribonucleic acid (RNA)** The nucleic acid responsible for carrying out the hereditary program transmitted by an organism's DNA.
- ribose** A 5-carbon monosaccharide found in RNA.
- ribosome** A bilobed macromolecular complex that coordinates the codons of mRNA with tRNA anticodons and, in so doing, constitutes the protein assembly site. It is composed of ribosomal RNA (rRNA) and protein.
- ribozyme** An RNA-containing catalyst that serves to cut and splice RNA during gene processing, protein synthesis, and other RNA-based functions.
- rickettsias** Medically important family of tiny, intracellular parasitic bacteria, commonly carried by ticks, lice, and fleas. Cause of Rocky Mountain spotted fever and typhus.
- Rifampin** An antibiotic used primarily in the treatment of mycobacterial infection.
- ringworm** A superficial mycosis caused by various dermatophytic fungi. This common name is actually a misnomer.
- RNA polymerase** The enzyme that converts the genetic code provided by DNA into a complementary RNA molecule.
- root nodules** Small growths on the roots of legume plants that arise from a symbiotic association between the plant tissues and bacteria (Rhizobia). This association allows fixation of nitrogen gas from the air into a usable nitrogen source for the plant.
- roseola** Disease of infancy, usually self-limiting, caused by infection with human herpesvirus-6.
- Rotavirus** Virus with a double-stranded RNA genome and both an inner capsid and an outer capsid. Transmitted by fecal contamination, it is common in areas with poor sanitation. *Rotavirus* typically causes diarrheal disease and can be fatal.
- rough endoplasmic reticulum (RER)** Microscopic series of tunnels that originates in the outer membrane of the nuclear envelope and is used in transport and storage. Large numbers of ribosomes, partly attached to the membrane, give the rough appearance.
- rubella** Commonly known as German measles. Rubella is caused by *Rubivirus*, a member of the togavirus family. Postnatal rubella is generally a mild condition; congenital rubella poses a risk of birth defects and results when virus passes from infected mother to fetus.
- rubeola (red measles)** Acute disease caused by infection with *Morbivirus*.
- saccharide** Scientific term for sugar. Refers to a simple carbohydrate with a sweet taste.
- salmonellosis** Illnesses caused by infection of the noncoliform *Salmonella* pathogens. The cause of typhoid fever, *Salmonella* food poisoning, and gastroenteritis.
- salpingitis** Inflammation of the fallopian tubes.
- sanitize/sanitization** To clean inanimate objects using soap and degerming agents so that they are safe and free of high levels of microorganisms.
- saprobe** A microbe that decomposes organic remains from dead organisms. Also known as a saprophyte or saprotroph.
- sarcina** A cubical packet of 8, 16, or more cells; the cellular arrangement of the genus *Sarcina* in the family Micrococcaceae.
- saturation** The complete occupation of the active site of a carrier protein or enzyme by the substrate.
- scarlet fever** Serious group A *Streptococcus* infection that causes redness, shedding of the skin, and high fever.
- schistosomiasis** Infection by blood fluke, often as a result of contact with contaminated water in rivers and streams. Symptoms include fever, chills, diarrhea, and cough. Infection may be chronic.
- schizogony** A process of multiple fission whereby first the nucleus divides several times, and subsequently the cytoplasm is subdivided for each new nucleus during cell division.
- scientific method** Principles and procedures for the systematic pursuit of knowledge, involving the recognition and formulation of a problem, the collection of data through observation and experimentation, and the formulation and testing of a hypothesis.
- scolex** The anterior end of a tapeworm characterized by hooks and/or suckers for attachment to the host.
- secondary infection** An infection that complicates a preexisting primary infection.
- secondary response** The rapid rise in antibody titer following a repeat exposure to an antigen that has been recognized from a previous exposure. This response is brought about by memory cells left behind after the primary exposure.
- secondary structure** Protein structure that occurs when the functional groups on the outer surface of the molecule interact by forming hydrogen bonds. These bonds cause the amino acid chain either to twist, forming a helix, or to pleat into an accordion pattern called a β -pleated sheet.
- selectively toxic** Property of an antimicrobial agent to be highly toxic against its target microbe while being far less toxic to other cells, particularly those of the host organism.
- self** Natural markers of the body that are recognized by the immune system and generally do not stimulate an immune response.
- semiconservative replication** In DNA replication, during the synthesis of new DNA strands (the daughter DNA), the parent strand template DNA is retained in the final molecule.
- semisolid media** Nutrient media with a firmness midway between that of a broth (a liquid medium) and an ordinary solid medium; motility media.
- semisynthetic** Antibiotics that have been isolated as natural products of bacteria, fungi, or other living sources, and are then chemically modified in the industrial setting to achieve a desired action.
- sensitizing dose** The initial effective exposure to an antigen or an allergen that stimulates an immune response but not symptoms.
- sepsis** The state of putrefaction; the presence of pathogenic organisms or their toxins in tissue or blood.
- septic shock** Blood infection resulting in a pathological state of low blood pressure accompanied by a reduced amount of blood circulating to vital organs. Endotoxins of all gram-negative bacteria can cause shock, but most clinical cases are due to gram-negative enteric rods.
- septicemia** Systemic infection associated with microorganisms multiplying in circulating blood.
- septum** A partition or cellular cross wall, as in certain fungal hyphae.
- sequela** A morbid complication that follows a disease.
- serology** The branch of immunology that deals with *in vitro* diagnostic testing of serum.
- seropositive** Showing the presence of specific antibodies in a serological test. Indicates ongoing or recent infection.
- serotonin** A vasoconstrictor that inhibits gastric secretion and stimulates smooth muscle.
- serotyping** The subdivision of a species or subspecies into an immunologic type, based upon antigenic characteristics.
- serum** The clear fluid expressed from clotted blood that contains dissolved nutrients, antibodies, and hormones but not cells or clotting factors.
- serum sickness** A type of immune complex disease in which immune complexes enter circulation, are carried throughout the body, and are deposited in the blood vessels of the kidney, heart, skin, and joints. The condition may become chronic.
- severe acute respiratory syndrome (SARS)** A severe respiratory disease caused by infection with a newly described Coronavirus.
- severe combined immunodeficiencies** A collection of syndromes occurring in newborns caused by a genetic defect that knocks out both B- and T-cell types of immunity. There are several versions of this disease, termed SCIDS for short.
- sewage** Liquid runoff or wastewater from communities.
- sexually transmitted disease (STD)** An infection resulting from pathogens that enter the body via sexual intercourse or intimate, direct contact.

- shigellosis** An incapacitating dysentery caused by infection with *Shigella* bacteria.
- shingles** A skin condition occurring on the trunk or head that is caused by the reactivation of a latent varicella-zoster virus. Also known as **herpes zoster**.
- side effects** Unintended, usually harmful consequences of chemotherapy, including damage to organs, allergy, and disruption of normal microbiota.
- sign** Any abnormality uncovered upon physical diagnosis that indicates the presence of disease. A sign is an objective assessment of disease, as opposed to a symptom, which is the subjective assessment perceived by the patient.
- silent mutation** A mutation that, because of the degeneracy of the genetic code, results in a nucleotide change in both the DNA and mRNA but not the resultant amino acid and thus, not the protein.
- simple stain** Type of positive staining technique that uses a single dye to add color to cells so that they are easier to see. This technique tends to color all cells the same color.
- smallpox** Disease caused by infection with variola virus. Smallpox has been eradicated worldwide, and variola virus exists today only in a few government laboratories.
- smooth endoplasmic reticulum (SER)** A microscopic series of tunnels lacking ribosomes that functions in the nutrient processing function of a cell.
- solution** A mixture of one or more substances (solutes) that cannot be separated by filtration or ordinary settling.
- solvent** A dissolving medium.
- somatic (O or cell wall) antigen** One of the three major antigens commonly used to differentiate gram-negative enteric bacteria.
- source** The person, location, or object that supplies the pathogen in an infection. This is different from the reservoir, which is where the pathogen lives.
- Southern blot** A technique that separates fragments of DNA using electrophoresis and identifies them by hybridization.
- species** In the levels of classification, the most specific level of organization.
- specificity** Limited to a single, precise characteristic or action.
- spheroplast** A gram-negative cell whose peptidoglycan, when digested by lysozyme, remains intact but is osmotically vulnerable.
- spike** A receptor on the surface of certain enveloped viruses that facilitates specific attachment to the host cell.
- spirillum** A type of bacterial cell with a rigid spiral shape and external flagella; plural is spirilla.
- spirochete** A coiled, spiral-shaped bacterium that has endoflagella and flexes as it moves.
- spontaneous generation** Early belief that living things arose from vital forces present in nonliving, or decomposing, matter.
- spontaneous mutation** A mutation in DNA caused by random mistakes in replication and not known to be influenced by any mutagenic agent. These mutations give rise to an organism's natural, or background, rate of mutation.
- sporadic** Description of a disease that exhibits new cases at irregular intervals in unpredictable geographic locales.
- sporangium** A fungal cell in which asexual spores are formed by multiple cell cleavage. This division results in sporangiospores.
- spore** A differentiated, specialized cell form that can be used for dissemination, for survival in times of adverse conditions, and/or for reproduction. Spores are usually unicellular and may develop into gametes or vegetative organisms.
- sporicide** A chemical agent capable of destroying bacterial endospores.
- sporotrichosis** A subcutaneous mycosis caused by *Sporothrix schenckii*; a common cause is the prick of a rose thorn.
- sporozoite** One of many minute elongated bodies generated by multiple division of the oocyst. It is the infectious form of the malarial parasite that is harbored in the salivary gland of the mosquito and inoculated into the victim during feeding.
- sporulation** The process of spore formation.
- staphylococci** (singular, **staphylococcus**) Coccus-shaped bacteria arranged in irregular clusters due to their division in several different planes.
- start codon** The nucleotide codon AUG that codes for the first amino acid in protein sequences.
- starter culture** Pure cultures of bacteria, molds, or yeasts inoculated into substrates for bulk processing, as in the preparation of fermented foods, beverages, and pharmaceuticals.
- stationary growth phase** Survival mode in which cells either stop growing or grow very slowly and the population number evens out.
- stem cells** Undifferentiated cells found in the bone marrow and other organs that have the capacity to develop or differentiate into the lines of blood cells (pluripotential).
- sterile** Completely free of all microbial life forms, including spores and viruses.
- sterilization** Any process that completely removes or destroys all viable microorganisms, including viruses, from an object or habitat. Material so treated is sterile.
- STORCH** Acronym for common infections of the fetus and neonate. STORCH stands for Syphilis, Toxoplasmosis, Other diseases (hepatitis B, AIDS and chlamydia), Rubella, Cytomegalovirus, and Herpes simplex virus.
- strain** In microbiology, a set of descendants cloned from a common ancestor that retain the original characteristics. Any deviation from the original is a different strain.
- streptococci** (singular, **streptococcus**) Coccus-shaped bacteria arranged in chains due to their division in one plane.
- streptolysin** A hemolysin produced by streptococci.
- strict, or obligate, anaerobe** An organism that does not use oxygen gas in metabolism and cannot survive in oxygen's presence.
- stroma** The matrix of the chloroplast that is the site of the dark reactions.
- subacute endocarditis** An infection of the heart lining due to invasion of the blood by oral streptococci.
- subacute sclerosing panencephalitis (SSPE)** A complication of measles infection in which progressive neurological degeneration of the cerebral cortex invariably leads to coma and death.
- subcellular vaccine** A vaccine against isolated microbial antigens rather than against the entire organism.
- subclinical** A period during an infection when no noticeable manifestations occur.
- subculture** To make a second-generation culture from a well-established colony of organisms.
- subcutaneous** The deepest level of the skin structure.
- substrate** The specific molecule upon which an enzyme acts.
- subunit vaccine** A vaccine preparation that contains only antigenic fragments such as surface receptors from the microbe. Usually in reference to virus vaccines.
- sucrose** One of the carbohydrates commonly referred to as sugars. Common table or cane sugar.
- sulfonamide** Antimicrobial drugs that interfere with the essential metabolic process of bacteria and some fungi. Also known as **sulfa drugs**.
- superantigens** Microbial toxins and proteins that can activate T cells nonspecifically and often lead to an overpowering reaction such as toxic shock.
- superficial mycosis** A fungal infection located in hair, nails, and the epidermis of the skin.
- superinfection** An infection occurring during antimicrobial therapy that is caused by an overgrowth of drug-resistant microorganisms.
- surfactant** An agent that reduces surface tension and forms a water-soluble interface. Derived from **surface-active** agent. Examples: detergents, soaps, wetting agents, and dispersing agents.
- sylvatic** Denotes the natural presence of disease among wild animal populations. Examples: sylvatic (sylvan) plague, and rabies.
- symbiosis/symbionts** An intimate association between two or more individuals that are termed symbionts; is sometimes used incorrectly as a synonym for mutualism.
- symptom** The subjective evidence of infection and disease as perceived by the patient.
- syncytium** A multinucleated protoplasmic mass formed by consolidation of individual cells.
- syndrome** The collection of signs and symptoms that, taken together, paint a portrait of the disease.
- synergism** The coordinated or correlated action by two or more drugs or microbes that results in a heightened response or greater activity.
- syphilis** A sexually transmitted bacterial disease caused by the spirochete *Treponema pallidum*.
- systemic infection** *Systemic* means occurring throughout the body; said of infections that invade many compartments and organs via the circulation.
- T helper cell/helper T cell** A class of thymus-stimulated lymphocytes that facilitate various immune activities such as assisting the activation of B cells and macrophages. Also called **T_H** or **helper T cell**.
- T-even phages** A group of related bacterial viruses (T-2, T-4, and T-6) that infect *Escherichia coli* bacteria.
- taxa** Taxonomic categories.
- taxonomy** The formal system for organizing, classifying, and naming living things.
- temperate phage** A bacteriophage that enters into a less virulent state by becoming incorporated into the host genome as a prophage instead of in the vegetative or lytic form that eventually destroys the cell.
- template** The strand in a double-stranded DNA molecule that is used as a model to synthesize a complementary strand of DNA or RNA during replication or transcription.
- teratogenic** Causing abnormal fetal development.
- tertiary structure** Protein structure that results from additional bonds forming between functional groups in a secondary structure, creating a three-dimensional mass.
- tetanus toxin** The neurotoxin of *Clostridium tetani*, the agent of tetanus. Its chief action is directed upon the inhibitory synapses of the anterior horn motor neurons.
- tetanus** A neuromuscular disease caused by infection with *Clostridium tetani*. Usual portals of entry include puncture wounds, burns, umbilical stumps, frostbite sites, and crushed body parts. Vaccination repeated at the recommended times can prevent infection. Also called lockjaw.

- tetracyclines** A group of broad-spectrum antibiotics with a complex 4-ring structure.
- tetrads** Groups of four.
- theory** A collection of statements, propositions, or concepts that explains or accounts for a natural event.
- therapeutic index (TI)** The ratio of the toxic dose to the effective therapeutic dose that is used to assess the safety and reliability of the drug.
- thermal death point** The lowest temperature that achieves sterilization in a given quantity of broth culture upon a 10-minute exposure. Examples: 55°C for *Escherichia coli*, 60°C for *Mycobacterium tuberculosis*, and 120°C for spores.
- thermal death time** The least time required to kill all cells of a culture at a specified temperature.
- thermal dimorphism** A property of certain fungal pathogens of converting from hyphal to yeast form in response to increased temperature.
- thermocline** A temperature buffer zone in a large body of water that separates the warmer water (the epilimnion) from the colder water (the hypolimnion).
- thermoduric** Resistant to the harmful effects of high temperature.
- thermophile** A microorganism that thrives at a temperature of 50°C or higher.
- thrush** *Candida albicans* infection of the oral cavity.
- thylakoid** Vesicles of a chloroplast formed by elaborate folding of the inner membrane to form “discs.” Solar energy trapped in the thylakoids is used in photosynthesis.
- thymine (T)** One of the nitrogen bases found in DNA but not in RNA. Thymine is a pyrimidine that pairs with adenine.
- thymus** Butterfly-shaped organ near the tip of the sternum that is the site of T-cell maturation.
- tincture** A medicinal substance dissolved in an alcoholic solvent.
- tinea** Ringworm; a fungal infection of the hair, skin, or nails.
- tinea versicolor** A condition of the skin appearing as mottled and discolored pigmentation as a result of infection by the yeast *Malassezia furfur*.
- titer** In immunochemistry, a measure of antibody levels in a patient’s serum or specimen, as determined by agglutination methods.
- toll-like receptors (TLRs)** Small surface receptors on phagocytes that are specialized to bind and react to pathogens.
- topoisomerases** Enzymes that can add or remove DNA twists and thus regulate the degree of supercoiling.
- toxemia** An abnormality associated with certain infectious diseases. Toxemia is caused by toxins or other noxious substances released by microorganisms circulating in the blood.
- toxic shock syndrome** Toxemia caused by *Staphylococcus aureus* and associated with use of tampons.
- toxigenicity** The tendency for a pathogen to produce toxins. It is an important factor in bacterial virulence.
- toxin** A specific chemical product of microbes, plants, and some animals that is poisonous to other organisms.
- toxinoses** Disease whose adverse effects are primarily due to the production and release of toxins.
- toxoid** A toxin that has been rendered nontoxic but is still capable of eliciting the formation of protective antitoxin antibodies; used in vaccines.
- trace elements** Micronutrients (zinc, nickel, and manganese) that occur in small amounts and are involved in enzyme function and maintenance of protein structure.
- transcription** mRNA synthesis; the process by which a strand of RNA is produced against a DNA template.
- transduction** The transfer of genetic material from one bacterium to another by means of a bacteriophage vector.
- transfection** Introduction of genetic material into an animal or plant cell using a viral or bacterial vector.
- transfer RNA (tRNA)** A transcript of DNA that specializes in converting RNA language into protein language.
- transformation** In microbial genetics, the transfer of genetic material contained in “naked” DNA fragments from a donor cell to a competent recipient cell.
- transfusion** Infusion of whole blood, red blood cells, or platelets directly into a patient’s circulation.
- transgenic organisms/ genetically modified organisms (GMOs)** Cells or organisms into which foreign DNA has been introduced. Includes recombinant plants, animals, and microbes created through genetic engineering.
- transients** In normal microbiota, the assortment of superficial microbes whose numbers and types vary depending upon recent exposure. The deeper-lying residents constitute a more stable population.
- translation** Also termed protein synthesis; the process of decoding a messenger RNA code into a polypeptide.
- transmissible spongiform encephalopathies (TSEs)** Progressive brain infections caused by unusual pathogens called prions, leading to loss of brain structure and function.
- transposon** A DNA segment with an insertion sequence at each end, enabling it to migrate to another plasmid, to the bacterial chromosome, or to a bacteriophage.
- trematode** A fluke or flatworm parasite of vertebrates.
- trichomoniasis** Sexually transmitted disease caused by infection by the trichomonads, a group of protozoa. Symptoms include urinary pain and frequency and foul-smelling vaginal discharge in females or recurring urethritis with a thin milky discharge in males.
- triglyceride** A type of lipid composed of a glycerol molecule bound to three fatty acids.
- triplet** A grouping of three nucleotides that serves as the genetic code for protein synthesis. Synonymous with codon.
- trophozoite** A vegetative protozoan (feeding form) as opposed to a resting (cyst) form.
- true pathogen** A microbe capable of causing infection and disease in healthy persons with normal immune defenses.
- trypanomastigote** The infective morphological stage transmitted by the tsetse fly or the reduviid bug in African trypanosomiasis and Chagas disease.
- tubercle** In tuberculosis, the granulomatous well-defined lung lesion that can serve as a focus for latent infection.
- tuberculin reaction** A diagnostic test in which an intradermal injection of a purified protein (tuberculin) extract from *M. tuberculosis* elicits an immune response, seen as a small red bump, in those persons previously exposed to tuberculosis.
- tuberculoid leprosy** A superficial form of leprosy characterized by asymmetrical, shallow skin lesions containing few bacterial cells.
- tularemia** Infection by *Francisella tularensis*. A zoonotic disease of mammals common to the northern hemisphere. Occasionally called rabbit fever. Portal of entry and symptoms are varied.
- turbid** Cloudy appearance of nutrient solution in a test tube due to growth of microbe population.
- tyndallization** Fractional (intermittent) sterilization designed to destroy spores indirectly. A preparation is exposed to flowing steam for an hour, followed by incubation to permit spore germination. The resultant new vegetative cells are destroyed by repeated steaming and incubation.
- typhoid fever** A form of salmonellosis. It is highly contagious. Primary symptoms include fever, diarrhea, and abdominal pain. Typhoid fever can be fatal if untreated.
- typhus** Rickettsia infection characterized by high fever, chills, frontal headache, muscular pain, and a generalized rash within 7 days of infection. In more severe cases, a personality change, low urine output, hypotension, and gangrene can cause complications. Mortality is high in older adults.
- ubiquitous, ubiquity** The state of being everywhere at the same time; omnipresent. Said of microbes which are known to live in the vast majority of the habitats on earth.
- ultraviolet (UV) radiation** Radiation with an effective wavelength from 240 nm to 260 nm. UV radiation induces mutations readily but has very poor penetrating power.
- undulant fever** See **brucellosis**.
- universal donor** In blood grouping and transfusion, blood whose erythrocytes bear no A nor B antigens and so may be given to any person in an emergency.
- universal precautions (UPs)** Centers for Disease Control and Prevention guidelines for health care workers regarding the prevention of disease transmission when handling patients and body substances.
- uracil (U)** The only nitrogen base existing in RNA but not in DNA. It is a pyrimidine and the mate of adenine during transcription.
- urban plague** Plague passed to humans through contact with domestic animals or other humans.
- vaccination** The process of inoculation with a selected microbial antigen (vaccine) in order to stimulate an immunity to that microbe.
- vaccine** Originally used in reference to inoculation with the cowpox or vaccinia virus to protect against smallpox. In general, the term now pertains to injection of whole microbes (killed or attenuated), toxoids, or parts of microbes as a prevention or cure for disease.
- vacuoles** In the cell, membrane-bounded sacs containing fluids or solid particles to be digested, excreted, or stored.
- valence** The combining power of an atom based upon the number of electrons it can either take on or give up.
- variable (v) region** The antigen-binding fragment of an immunoglobulin molecule, consisting of a combination of heavy and light chains whose molecular conformation is specific for the antigen.
- varicella** See **chickenpox**.
- varicella-zoster virus** Herpesvirus responsible for the diseases chickenpox and shingles.
- variolaion** A hazardous, outmoded process of deliberately introducing smallpox material scraped from a victim into the nonimmune subject in the hope of inducing resistance.
- VDRL** A flocculation test that detects syphilis antibodies. An important screening test. The abbreviation stands for Venereal Disease Research Laboratory.
- vector** An animal that transmits infectious agents from one host to another, often a biting or piercing

- arthropod such as the tick, mosquito, or fly, but it can also include birds and mammals. Vectors convey infectious agents mechanically by simple contact or biologically, with the parasite developing in the vector.
- vector₂** A genetic element such as a plasmid or a bacteriophage used to introduce genetic material into a cloning host as a part of recombinant DNA technology.
- vehicle** An inanimate material (solid object, liquid, or air) that serves as a transmission agent for pathogens.
- verruca** A flesh-colored wart. This self-limited tumor arises from accumulations of growing epithelial cells. Example: papilloma warts.
- vesicle** A blister characterized by a thin-skinned, elevated, superficial pocket inflated with serum.
- vibrio** A curved, rod-shaped bacterial cell.
- viremia** The presence of viruses in the bloodstream.
- virion** An elementary virus particle in its complete morphological and thus infectious form. A virion consists of the nucleic acid core surrounded by a capsid, which can be enclosed in an envelope.
- viroid** An infectious agent that, unlike a virion, lacks a capsid and consists of a closed circular RNA molecule. Although known viroids are all plant pathogens, it is conceivable that animal versions exist.
- virtual image** In optics, an image formed by diverging light rays; in the compound light microscope, the second, magnified visual impression formed by the ocular from the real image formed by the objective.
- virucide** A chemical agent that inactivates viruses, especially on living tissue.
- virulence** In infection, the relative capacity of a pathogen to invade and harm host cells.
- virulence factor** A product of microbes such as an enzyme or toxin that increases the microbe's invasiveness or pathogenicity.
- virus** Microscopic, acellular agent composed of nucleic acid surrounded by a protein coat.
- vitamins** Components of coenzymes critical to nutrition and the metabolic function of coenzyme complexes.
- vulvovaginal candidiasis (VC)** Vaginal STD caused by *Candida albicans* and often associated with disruption of the normal vaginal flora.
- wart** An epidermal tumor caused by papillomaviruses. Also called a **verruca**.
- Western blot test** A procedure for separating and identifying antigen or antibody mixtures by two-dimensional electrophoresis in polyacrylamide gel, followed by immune labeling.
- wheal/flare** A welt; marked, slightly red, usually itchy bumps on the skin that change in size and shape as they spread. It is surrounded by a red patch (the flare). The reaction is triggered by cutaneous contact or intradermal injection of allergens in sensitive individuals.
- whey** The residual fluid from milk coagulation that separates from the solidified curd.
- white piedra** A fungus disease of hair, especially of the scalp, face, and genitals, caused by *Trichosporon beigeli*. The infection is associated with soft, mucilaginous, white-to-light-brown nodules that form within and on the hair shafts.
- whitlow** A deep inflammation of the finger or toe, especially near the tip or around the nail. Whitlow is a painful herpes simplex virus infection that can last several weeks and is most common among health care personnel who come in contact with the virus in patients.
- whole blood** A liquid connective tissue consisting of blood cells suspended in plasma.
- whooping cough** See **pertussis**.
- Widal test** An agglutination test for diagnosing typhoid fever and determining the antibody titer.
- wild type** The natural, nonmutated form of a genetic trait.
- wort** The clear fluid derived from soaked mash that is fermented for beer.
- xenograft** The transfer of a tissue or an organ from an animal of one species to a recipient of another species.
- yaws** A tropical disease caused by *Treponema pertenue* that produces granulomatous ulcers on the extremities and occasionally on bone but does not produce central nervous system or cardiovascular complications.
- yeasts** Single-celled, budding fungi.
- yellow fever** Best-known arboviral disease. Yellow fever is transmitted by mosquitoes. Its symptoms include fever, headache, and muscle pain that can proceed to oral hemorrhage, nosebleeds, vomiting, jaundice, and liver and kidney damage.
- zoonosis** An infectious disease indigenous to animals that humans can acquire through direct or indirect contact with infected animals.
- zooplankton** The collection of nonphotosynthetic microorganisms (protozoa, tiny animals) that float in the upper regions of aquatic habitat and together with phytoplankton comprise the plankton.
- zygospore** A thick-walled sexual spore produced by the zygomycete fungi. It develops from the union of two hyphae, each bearing nuclei of opposite mating types.

Index

Note: In this index entries followed by a lower-case f refer to figures, entries followed by a lower-case t refer to tables, and entries printed in **boldface** type indicate definitions or introductory discussions.

 Varicella-zoster virus (VZV), 749, 750t, 754, 758–59, 759t
 Variolation, 492
 Variola virus, 492, 750t, 752. *See also* Smallpox
 Varivax (chickenpox vaccine), 759
 Vascular changes, and inflammation, 451–52, 452f
 Vasculitis, 648
 Vasoactive mediators, 451, 453f, 454
 Vasodilation, 452
 VDRL (Venereal Disease Research Laboratory) test, 545, 653
 Vectors. *See also* Carriers; Reservoirs
 arthropods as, 740–43, 741f, 742t, 789–92, 790f, 791f
 arthropods in rickettsias, 663, 664t
 for bubonic plague, 639–41, 640f
 for cloning, 309–10
 for disease, 152, 423–24
 disease and, 12
 Vegetation, and biofilms, 572
 Vegetative cells, 105–7, 106f, 330t, 336
 Vegetative hyphae, 141, 141f
 Vehicles, and transmission of disease, 424–26, 425f

Venenivibrio, 195f
 Venter, Craig, 314
 Vent polymerase, 308
 Verruca (wart), 767
 Verrucous lesions, 694
 Vertical transmission, of disease, 424
 Vesicles, 132, 132f, 133, 133f
 Vesicular rash, 749
 Vetter, David (SCID child), 527, 527f
 Viable but nonculturable (VBNC) microbes, **75**
 Viable plate count, **214**, **214f**
 Vibrio, as bacterial shape, 107, 108f
Vibrio spp., 551
 V. cholerae, 75f, 95, 108f, 179, 413t, 649t, 658–60, 659f (*See also* Cholera)
 V. parahaemolyticus, 649t, 660–61, 848t, 850 (*See* Paralytic shellfish poisoning)
 V. vulnificus, 660–61
 Viking Explorer (space vehicle), 29
 VIM (Verona Integron-mediated Metallo-beta-lactamase), 634
 Vincent disease (NUG), 675

 Vinegar, 248, 846
 Viral encephalitis, 410t
 Viral envelope, 167
 Viral persistence, 179t, 751, 751f
 Viremia, 419
 Viricide, 331
 -Viridae (suffix), 170, 752
Viridans streptococci, 557t, 572
 Virion, 176
 Viroids, 184
 Virtual image, 63
 Virulence, 409
 Virulence factors, 409, 412–14, 413f, 416, 629–31, 639, 650. *See also specific diseases*
 -Virus (suffix), 752
 Virus(es), 162. *See also* Active viruses; Complex viruses; DNA viruses; Inactive viruses; Live, attenuated viruses; Naked viruses; Neurotropic viruses; Oncogenic viruses; Reoviruses; Retroviruses; RNA viruses
 antibacterial drugs, 391
 antimicrobial drugs, 183, 365t, 377–79, 378f, 379t, 388t, 458–59, 459f
 aquatic habitats, 832
 autoimmune diseases, 523
 bacteriophages, 177–79
 beneficial roles of, 164
 classification and nomenclature, 170
 clinical microbiology, 551, 552f
 cultivation and identification, 179–81
 defined, **7**, **7**
 discovery of, 162–63
 emerging and reemerging as global threat, 779
 genetic engineering, 314
 genetics of, 292–93
 hepatitis, 763–66
 infectious disease, 171t–172t, 181–82, 750–52, 750t, 751f
 as microbiota, 400–402, 403f
 multiplication, 172–77, 292–93
 non-living, **92**
 position of in biological spectrum, 162–63
 properties of, 162t
 structure of, 164–71
 VISA (vancomycin intermediate *Staphylococcus aureus*), 564

Zygomycota, phylum, **144t**
Zygospores, **142**, 142f

LIST OF CASE STUDIES (Chapter openings)

- 01 Microbes Find A Way
- 02 Following the Water and Carbon on Mars
- 03 Battling a Brain Infection
- 04 Heart Valves and Biofilms
- 05 Neglected Tropical Diseases
- 06 A Killer Virus (H5N2)
- 07 A Creature of Habitat
- 08 Recipe for a Toxic Brew
- 09 At War with an Emerging Pathogen
- 10 Nicholas's Story: A New Frontier in Genomic Medicine
- 11 The Billion Dollar Medical Error
- 12 An Ounce of Prevention and a Pound of Cure
- 13 Fatal Filaments from Faraway Africa (Ebola)
- 14 When Phagocytes Fail
- 15 A Tale of Two Bat Bites
- 16 A Deadly Transfusion Reaction
- 17 A Hospital Outbreak of Seafood Sickness
- 18 A Rapidly Advancing Pathogen Deserves an Equally Rapid Response
- 19 Three Patients
- 20 The More Things Change, the More They Stay the Same
- 21 A Different Kind of Tourism
- 22 Sun, Fun, and Fungi
- 23 Keep Your Head Above Water
- 24 Childhood Diseases
- 25 This Can't Be From That
- 26 May I Get a Glass of Water?
- 27 Something You Can Really Sink Your Teeth Into
