Exchange interactions in materials with localized 5f states can be seen as analogous to the lanthanides, for which the indirect exchange of the RKKY-type (oscillatory) is a good approximation. The other limit, systems with strongly itinerant 5f states can be understood in terms of the Stoner–Edwards–Wohlfarth theory for itinerant magnets (one band model), in which the ordering temperature is proportional to the ordered moment. For intermediate delocalization, when the direct 5f–5f overlap is negligible, two types of states have to be considered. 5f states are dominant for the moment formation, but their interaction is mediated by the hybridization with broadband states. Thus a dual role of the 5f–ligand hybridization has to be considered. It destabilizes the 5f magnetic moments, but because the spin information is conserved in the hybridization process, it leads to an indirect exchange coupling. The maximum ordering temperatures consequently can be expected for a moderate strength of hybridization, because a strong hybridization completely suppresses magnetic moments, whereas a weak one leaves moments intact, but their coupling is weak. Cooper and coworkers, on the basis of the Coqblin–Schrieffer approach, have given a model leading to realistic results (Cooper *et al.*, 1985). The mixing term in the Hamiltonian of the Anderson-type is treated as a perturbation, and the hybridization interaction is replaced by an effective f-electron–band-electron resonant exchange scattering. If the ion–ion interaction is considered to be mediated by different covalent-bonding channels, each for a particular magnetic quantum number m_l, then the strongest interaction is for those orbitals, which point along the ion–ion bonding axis, and which represents the quantization axis of the system. The two 5f ions maximize their interaction by compression of the 5f charge towards the direction of the nearest 5f ion. This has serious impacts on magnetic anisotropy, because it means a population of the 5f states with orbital moments perpendicular to the bonding axis. This interaction results in a strong ferromagnetic coupling of actinide atoms along the bonding direction. There is no special general tendency to ferro- or antiferromagnetism in the perpendicular direction, where the interaction is much weaker, and can be comparable to the 'background' isotropic exchange interaction of the standard RKKY-type. Unlike such two-ion hybridization-mediated anisotropy, crystal field (single-ion) effects control the type

and strength of magnetic anisotropy for materials with the localized 5f states, in analogy to lanthanide systems.

The two-ion anisotropy, for which orbital moments are a necessary prerequisite, has been observed in numerous U compounds especially when single-crystal magnetization data exist. The tendency for moments to orient perpendicular to the U—U bonding links leads to a uniaxial anisotropy in crystal structures with U atoms organized in planes with a short in-plane U–U spacing and larger inter-plane spacing, whereas the case of U linear chains leads to a planar type of anisotropy (see Fig. 21.19). The strength of anisotropy, which is observable both in magnetically ordered and paramagnetic phases, can be estimated in some cases from the difference between paramagnetic Curie temperatures when the susceptibility is measured with the magnetic field along different crystallographic directions. Other estimates can be obtained from the extrapolated magnetic field at which magnetization curves along different directions would intersect each other. Typically values of 10^2–10^3 K or 10^2–10^3 Tesla (assuming the anisotropy is energy expressed in $k_B T$ and $\mu_B H$, respectively, where k_B is the Boltzmann constant and μ_B the Bohr magneton) are obtained in this way; see Figs. 21.20 and 21.21).

For large groups of isostructural compounds, the same type of anisotropy is, as a rule, found irrespective of the non-actinide components. The strong generally uniaxial anisotropy of compounds UTX (with the hexagonal structure of the ZrNiAl-type) or tetragonal UT_2X_2, both with strong U bonding within

planes perpendicular to the hexagonal (tetragonal) axis, and U-moments (or higher susceptibility) along this axis are examples (Sechovsky and Havela, 1998).

21.9.7 Magnetic structures

The specific mechanisms of magnetic anisotropy and exchange interactions both affect the types of magnetic structures in light-actinide materials. Strong anisotropy leads frequently to collinear modulated structures (spin-density

waves), which are preferred over non-collinear equal-moment structures. The reason is that the anisotropy energy is typically stronger than the exchange coupling energies. Non-collinear magnetic structures are stable if the easy-magnetization directions on different sites are non-collinear, as in U_2Pd_2Sn, where they are orthogonal. Also for those cases in which the lattice symmetry imposes no special requirements on the directions of the moments (see Sandratskii, 1998) do non-collinear equal-moment structures appear (e.g. UPtGe). The types of magnetic structures are also affected by the strong ferromagnetic coupling along strong bonding directions (see the hybridization-induced exchange model in Section 21.9.6). For example, the UTX compounds with the hexagonal structure of the ZrNiAl-type tend to magnetic structures consisting of ferromagnetic basal-plane sheets, whereas the inter-sheet exchange interaction is weaker and can be of the ferromagnetic or antiferromagnetic type, leading to a variety of stacking sequences along the hexagonal axis. In this case, ferromagnetic-like alignment can be obtained in moderate magnetic fields applied along the antiferromagnetic stacking direction.

21.9.8 Relation of electronic transport and magnetism – giant magnetoresistance phenomena

The situation in which magnetic moments are strongly coupled to the crystal lattice due to the strong spin–orbit coupling and large orbital moments, and the 5f states are strongly hybridized with other conduction-electron states, is especially favorable to observe any variations of magnetism projected onto electrical resistivity and other transport properties.

The frequently observed anisotropy of exchange coupling (see subsection 21.9.7) often leads to a striking anisotropy in the resistivity. In single crystals of tetragonal, hexagonal, or orthorhombic materials not only the magnitude of resistivity is dependent on the direction of electrical current, but often different directions yield different types of temperature-dependent behavior. In certain directions, antiferromagnetic correlations can be broken by an external magnetic field and a giant magnetoresistance effect can be observed at the critical field. The residual resistivity ρ_0 typically reaches smaller values in ferromagnets. The much larger ρ_0 values observed in antiferromagnets can be understood as due to a gapping of part of the Fermi surface due to an additional periodicity. If, for example, the magnetic structure consists of two sublattices with antiparallel sublattice magnetization, the magnetic unit cell is doubled compared to the crystallographic unit cell (assuming a simple case with one actinide atom in the unit cell). The size of the Brillouin zone is therefore reduced by a factor of 2. As quantum states of electrons must have a gap at every Brillouin zone boundary, a gapping of the Fermi surface will occur if it is cut by the new, inserted, Brillouin zone boundary. This does not bring an extra scattering mechanism, but the effective number of electrons available for the charge transport is reduced, and resistivity therefore increases. This effect is parametrized by the expression:

$$\rho = (\rho_0 + \rho_{e-ph} + \rho_{e-e} \ldots)/[1 - g\ m(T)], \tag{21.18}$$

where $m(T)$ is the temperature dependence of sublattice magnetization and g is a truncation factor modifying the Fermi surface. ρ_0, $\rho_{e-ph,}$ ρ_{e-e} represent individual resistivity terms due to impurity, electron–phonon, and electron–electron scattering, respectively.

The situation can be illustrated by the example of UNiGa (see Fig.21.21), which has an antiferromagnetic ground state. It crystallizes in a layered hexagonal structure (ZrNiAl-type), in which U–Ni and Ni–Al layers alternate along the *c*-axis. Strong ferromagnetic exchange is found within the U–Ni basal planes, where the U-atoms are close together. Magnetic moments are locked along the *c*-axis. The exchange along *c* is weak and antiferromagnetic, and ferromagnetic alignment can be achieved by a magnetic field below 1 T if applied along *c*. The resistivity for current along the *ab*-plane has the character of a ferromagnet, as mostly electrons with the wave vector along *ab* contribute to the conduction. Residual resistivity is low. For current along *c* electrons respond to the antiferromagnetic coupling, and the resistivity is very high. The magnetic unit cell is six times larger than the crystallographic cell along *c*, because the stacking of layers can be described as (++—+–). Fig. 21.21 shows how the high resistivity is suppressed in the metamagnetic state in UNiGa. ρ_0 drops by about 90%. The minimum in $\rho(T)$ for *i*//*c* is due to antiferromagnetic correlations above T_N, which can be suppressed by the magnetic field (Sechovsky and Havela, 1998).

21.10 COHESION PROPERTIES – INFLUENCE OF HIGH PRESSURE

The variable nature of the 5f electronic states in actinide metals is reflected in cohesion properties. Crystal structures of elemental actinide metals are complex and of low symmetry for the earlier actinides (up to Pu), and they show also relatively higher bulk moduli and few (if any) phase transitions under pressure. In contrast, the transplutonium metals do not have the 5f electrons involved in bonding, their atomic volumes are much higher, and they are softer, i.e. with lower bulk moduli. Application of pressure induces a sequence of structural phase transitions, eventually reaching states with itinerant 5f states with corresponding low atomic volumes and low-symmetry structures. In Fig. 21.22, the phase diagram for Ac through Cf as a function of pressure is shown from a more detailed discussion by Lindbaum *et al*. (2003). The reason why the 5f bonding leads to smaller atomic volumes can be seen from two points of view. One is the smaller spatial extent of the 5f states even in bonding situations, when compared to the other bonding states (6d, 7s), as described in section 21.4.1. The bonding energy minimum evaluated for the separate 5f states appears at much smaller inter-atomic spacing than for the 6d–7s states. The real equilibrium volume, obtained by summing both contributions, corresponds

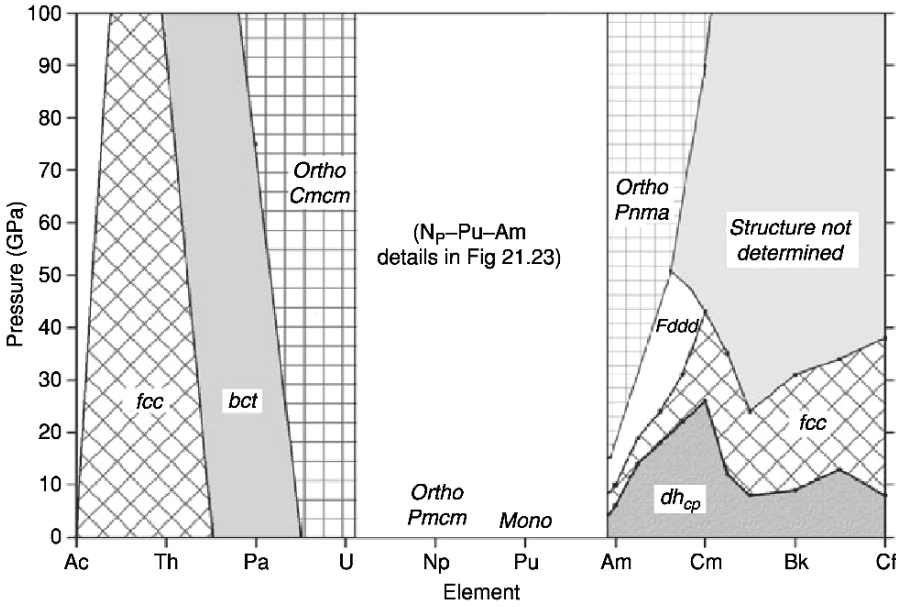

Fig. 21.22 *Phase diagram of the actinides* (*Ac through Cf*) *vs pressure. The complexity of the pressure phase diagram depends in large part on the role of the 5f electrons in bonding and variations in bonding as the interatomic distances are decreased under pressure* (*after Lindbaum* et al., 2003).

then to a compromise between the smaller 5f and larger 6d–7s bonding distance. Releasing the 5f states from bonding leads to the 6d–7s bonding only, with its larger bonding length. The second reason for the volume expansion is the different screening of the ionic potential, attracting the outer (6d–7s) electrons to the ion core. When withdrawn from bonding, the 5f charge density redistributes more towards the ion core, which screens more effectively the attractive potential, and the less attracted 6d and 7s states expand.

The existence of the low-symmetry structures for itinerant 5f electronic states can be caused by an electronic Jahn–Teller effect. In this situation, when the density of electronic states in the vicinity of the Fermi level reaches appreciable values, the total energy can be minimized by redistributing some of the 5f band states towards lower energies, using the degrees of freedom offered by all possible exotic crystal structures. For these high densities of states, such distortions can compensate the loss of the Madelung energy, which favors high-symmetry structures. One can compare this situation with e.g. the late 3d transition metals, similarly characterized by high $N(E_F)$ values. In such a case, the Stoner criterion $U.N(E_F) > 1$ is fulfilled, which leads to magnetic order. Thus the ground state for high $N(E_F)$ values can be either magnetic (in case of sufficient high U) or a low-symmetry crystal structure, if U is not large enough.

The latter case holds in the early actinide metals and in the late actinides in the high-pressure phases. An interesting insight is provided by *ab initio* electronic structure calculations in different structure types (see for example, Wills and Eriksson, 1992 or 2000).

Although specialized review chapters exist covering the structural aspects of actinides at high pressures (Benedict, 1987; Benedict and Holzapfel, 1993), the enormous progress in the last decade has brought numerous new data (extended pressure ranges led to discovery of new phases, improved hydrostatic conditions yield much more precise values of bulk moduli), so that it is worthwhile to provide a more detailed overview for the individual metals. Thorium crystallizes in the fcc structure, but at very high pressure (between 75 and 100 GPa), it undergoes a transition to a body-centered tetragonal structure (Vohra and Akella, 1991). Calculations show that the high-pressure structure can be associated with a population of the 5f band of about 0.6 electrons (Rao *et al*., 1992). This structure is the same as adopted by protactinium at ambient pressure. Pa bulk modulus value, 118(2) GPa obtained from a recent experiment (Le Bihan *et al*., 2003), is much closer to the value of 100 GPa predicted by calculations (Söderlind and Eriksson, 1997) than previous data (Benedict *et al*., 1982). The new experiment also revealed a structural phase transition at 77(5) GPa identified as the α-U structure (Haire *et al*., 2003). The reason for this structure change can be seen in somewhat varying (increasing) 5f occupancy at lower volume.

The same argument, i.e. higher 5f occupancy, is why the orthorhombic α-U structure (*Cmcm* space group) stabilizes in uranium. Its bulk modulus 104(2) GPa (Le Bihan *et al*., 2003) is similar to the value for Pa. Some authors, though, give higher values. For a review of older data, see Benedict (1987) and Benedict and Holzapfel (1993). The α-U structure is stable to at least 100 GPa, in agreement with theory (Le Bihan *et al*., 2003). The ground state structure of neptunium (orthorhombic, space group *Pmcn*) was found to be similarly stable to at least 52 GPa (Dabos *et al*., 1987). The bulk modulus of 118(2) GPa is comparable with the value of 110 GPa obtained from calculations (Johansson and Skriver, 1982).

The qualitative difference of cohesion properties in transplutonium materials is well illustrated by the case of americium (Heathman *et al*., 2000; Lindbaum *et al*., 2001). The initial bulk modulus of 30 GPa leads to a rapid decrease of the volume with applied pressure. A sequence of structural phase transitions starts at 6.1 GPa, at which pressure the dhcp ground-state structure (the same as for Cm, Bf, and Cf) transforms into a fcc structure. The next transition at 11 GPa, accompanied by a volume collapse of 2%, leads to an orthorhombic structure, which is identical with the γ-Pu structure. It has been proposed that this structure already shows 5f bonding. An even larger volume collapse of 7% appears at 16 GPa, and brings Am into an orthorhombic structure with a low compressibility, similar to the α-U-type, and thus confirming the itinerant nature of the 5f states. The volume collapse and 5f bonding was predicted also by theory, although one type of calculation preferred the α-Pu structure as the high-pressure phase (Söderlind *et al*., 2000). On the other hand, calculations of

Pénicaud (2002) are not only consistent with the real orthorhombic structure, but suggest that this so-called Am(IV) structure is also one of the high-pressure structures of Pu. Although Pu has been studied thoroughly, information is lacking in the open literature for the high-pressure range, clearly due to nuclear non-proliferation concerns. But the data available confirm the stability of the α-Pu phase up to 40 GPa (Benedict and Holzapfel, 1993 and Dabos-Seignon *et al.*, 1993). On the other hand, the expanded-volume δ-phase collapses again under a pressure of several few kbar (1 kbar = 0.1 GPa). The opposite experiment, i.e. imposing a negative pressure by doping larger Am atoms, shows that the δ-Pu phase is stabilized over a large concentration range and corresponds actually to the Am(II) fcc structure. Recent results for Cm indicate a lattice structure stabilized by magnetism (Heathman *et al.*, 2005). The interplay between pressure and alloy substitution is shown very nicely in Fig. 21.23 for the Np, Pu, Am solid solution series. The inset in the upper left corner of Fig. 21.23 shows elemental Pu as a function of pressure. There is a strong resemblance to the phases obtained from alloys of Pu with Np, which effectively increases the pressure in the Pu lattice (Hecker, 2000).

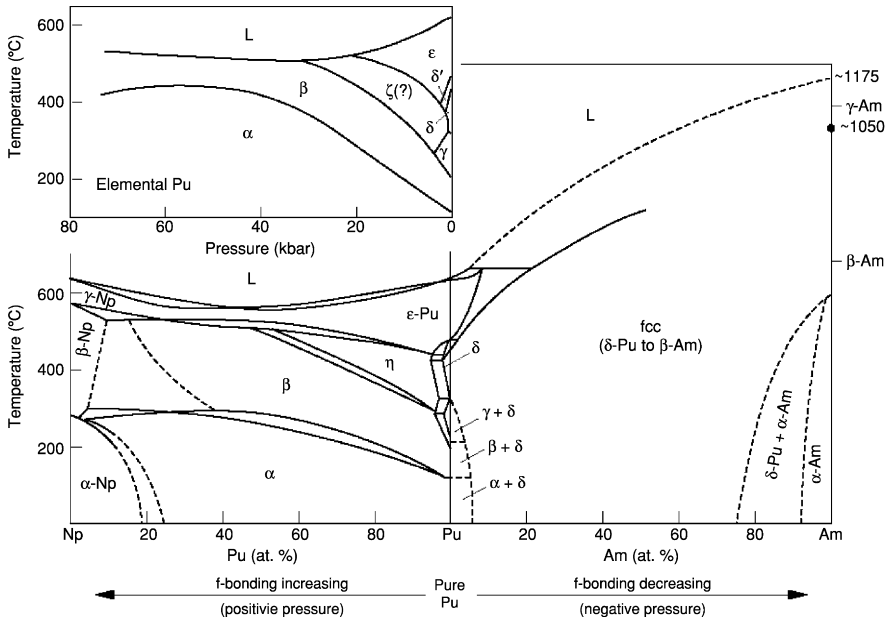

Fig. 21.23 *The binary phase diagram for Np through Am as a function of temperature. The inset in the upper left shows the temperature vs pressure phase diagram for Pu metal. The similarity between the Pu pressure diagram and the Np–Pu binary gives clear indication of how atomic substitution may create effective pressure in metallic solids* (*after Hecker,* 2000).

21.11 CONCLUDING REMARKS

There remains a great deal of uncertainty regarding the understanding of the actinides in the metallic state. For the late actinide metals, much of the uncertainty arises from sample size and purity limitations. For the early actinides (through Pu), the uncertainty is centered on the understanding of the 5f electrons and the nature of the narrow bands in actinide metals. The literature presents many models for treating the 5f electrons from Th through Pu with no clear consensus model for the electronic structure, which is universally applicable. In many cases, it appears that the 5f electrons form narrow bands, which hybridize with the conduction electrons to some extent and give rise to many of the interesting properties of actinides in the metallic state. By expanding the phase space of investigation to include alloys, compounds, and pressure one finds some systematics in the properties of actinide metals. Indeed, Fig. 21.23 demonstrates how pressure and alloying may be considered equivalent knobs to adjust in tuning the properties of metallic actinides. The propensity for rich electronic structure in the metallic actinides is highlighted by the frequent occurrence of correlated electron ground states including magnetism (both local moment and band magnetism), enhanced mass, superconductivity, and charge-density waves. The rich electronic structure is indicative of nearly degenerate energy scales and competing processes to lower the free energy. In the most complex systems, one finds competing ordered ground states such as enhanced mass and superconductivity in UPt_3 and UBe_{13} with truly exceptional characteristics in materials like UPd_2Al_3, which exhibits enhanced mass, magnetism, and superconductivity. The discovery of superconductivity at 18 K in $PuCoGa_5$ in 2002 (Sarrao *et al.*, 2002) ushers in a new era for actinide superconductivity spanning the gap between low-temperature spin-fluctuators and the high temperature oxides exhibiting charge fluctuations. While an uncontested explanation for the electronic properties of metallic actinides is still in the future, the broader understanding of actinide alloys and compounds, along with increased range in pressure and temperature phase space, gives us a better understanding of the intricacies of the elemental actinides in the metallic state such as the charge-density waves in uranium metal as well as the multiple phases, crystal structures, and volumes of plutonium metal.

ABBREVIATIONS

Å	Angström
AF	anti-ferromagnetic
An	actinide
ARPES	angle resolved photoemission
bcc	body-centered cubic
bct	body-centered-tetragonal

T_c	critical temperature
T_C	Curie temperature
DFT	density functional theory
dhcp	double hexagonal close-packed
dHvA	de Haas–van Alpen
DOS	density of states
DMFT	Dynamical Mean Field Theory
m^*	Effective mass
fcc	face-centered cubic
E_F	Fermi Energy
FL	Fermi Liquid
FM	Ferromagnetic
γ	low temperature specific heat coefficient
GGA	generalized gradient approximation
hcp	hexagonal close-packed
LDA	local density approximation
χ	magnetic susceptibility
mono	monoclinic
T_N	Néel temperature
NFL	Non-Fermi-Liquid
orth	Orthorhombic
PAM	Periodic Anderson Model
PES	photoelectron spectroscopy
RKKY	Ruderman-Kittel-Kasuya-Yosida
SC	Superconducting
SIM	single impurity model

ACKNOWLEDGMENTS

Thanks to James L. Smith for a great deal of assistance in figures and scientific input, and in general to John Wills, Jim Smith, Olle Eriksson, and Mike Boring for discussions and previous work which J.J. and A.A. relied heavily upon in writing this review. This work was supported by the U.S. Department of Energy, Office of Science. The work of L.H. at the Charles University was part of the research program MSM 002160834 financed by the Ministry of Education of the Czech Republic.

CHAPTER TWENTY TWO

ACTINIDE STRUCTURAL CHEMISTRY

Keith E. Gutowski, Nicholas J. Bridges, and Robin D. Rogers

22.1 INTRODUCTION

This chapter focuses on the solid state structural chemistry of actinide materials as determined by single-crystal X-ray diffraction, single-crystal neutron diffraction, powder X-ray diffraction, and powder neutron diffraction techniques. Since Burns' chapter, Structural Chemistry, was published in the 1986 edition of this work, significant improvements in crystallographic technology and instrumentation have advanced the field of solid state chemistry. Some of the most dramatic changes have been in computer technology and software, making the data collection, reduction, and refinement processes highly automated and simplified. As a consequence, X-ray diffractometers have become nearly ubiquitous in research departments globally and neutron-scattering resources have become more advanced and accessible, resulting in the elucidation and publication of a greater number of additional actinide structures since the last edition; these structures are the focus for this chapter.

In the past, the structural study of actinide compounds using diffraction techniques had often entailed complications, many of which were inherent difficulties attributable to the composition (very heavy and very light elements) and radioactivity of the samples themselves. However, modern advances and insights have made the study of actinide-containing compounds almost a routine process. For example, X-ray diffraction of actinide–organic complexes can be complicated by the scattering due to the heavy atoms, which often dominates

that of light atoms; however, the complementary use of neutron diffraction techniques allows for the accurate placement of lighter atoms, particularly hydrogen, along with the heavy atoms (Suortti, 2002). In instances where the growth of sufficiently large single crystals for analysis has been an obstacle, powder diffraction, particularly when coupled with sophisticated refinement techniques, has allowed for the determination of positional and thermal parameters of samples containing randomly oriented crystallites with nearly the same degree of precision as single-crystal techniques (Rietveld, 1967). In addition, advances in the growth of single crystals from melts, solutions, and vapors have enabled many difficulties in this area to be overcome (Spirlet *et al.*, 1991). For many actinide isotopes, radioactive decay can cause defects and dislocations in single-crystal samples. However, substitution of less radioactive isotopes alleviates the rate at which lattice deterioration occurs, creating more stable samples for study. For short-lived isotopes available in larger quantities, self-heating or irradiation problems are encountered; for example, ^{242}Cm ($t_{1/2} = 162.8$ days) produces 122 W/g although substituting ^{244}Cm ($t_{1/2} = 8.1$ years) or ^{248}Cm ($t_{1/2} = 3.4 \times 10^5$ years) reduces that aspect of the problem (Haire and Eyring, 1994).

While our treatment is by no means exhaustive (in the sense that we do not include every actinide structure published in the literature), it is intended to represent a large number of important structures, to illustrate how advances in solid state techniques have led to the generation of larger numbers of structures, and to offer an appreciation for solid state actinide structures in general. In addition, this overview of actinide structural and coordination chemistry has the aim to establish an understanding of how the unique electronic properties of the actinide elements influence chemical bonding in their inorganic, coordination, and organometallic compounds.

22.2 SOLID STATE STRUCTURAL TECHNIQUES

Recent advances in crystallography and structure determination focus on improvements in instrumentation because the theory and preparatory steps (i.e., crystal growing, unit cell/orientation matrix determination) remain the same. Although many actinide inorganic structures were solved several decades ago, the use of state-of-the-art instrumentation for the determination of new structures or the refinement of old ones will be highlighted whenever possible throughout this chapter.

22.2.1 X-ray diffraction techniques

X-ray crystallography as a technique is based on the diffraction of X-rays by electron density that resides in defined planes within the crystalline lattice; the nature of the diffraction is governed by Bragg's law ($n\lambda = 2d\sin\theta$). Thus, X-ray diffraction yields information regarding the distribution of electrons in a crystalline solid. The application of X-ray crystallography to actinide science is

met with a unique challenge; because X-rays are diffracted by electron density, the large, dense actinides can easily overshadow smaller atoms with less electron density. The study of heavy elements in this manner has become routine, however, through use of techniques to circumvent this problem (Deschamps and Flippen-Anderson, 2002).

In most small-scale X-ray diffractometers (i.e., non-synchrotron), X-ray tubes are used to accelerate electrons toward a target material (Mo or Cu), resulting in the generation of X-rays which are then filtered, collimated, and focused through an aligned single crystal that is subsequently rotated through space by a goniometer; the diffracted X-rays are then registered by an area detector, such as a charge coupled device (CCD), resulting in a diffraction pattern that is then interpreted. Current X-ray diffractometers are controlled by computers and software that assist in refining the data and aid in solving the crystal structure, making the method so attractive that it is regarded as an essential analytical instrument in many research departments. In fact, tasks that used to require several months of effort are now easily accomplished in minutes with modern day computational and graphical resources (Suortti, 2002).

The advent of the synchrotron has revolutionized the ways in which X-rays are generated and used for research purposes. Synchrotron radiation is emitted when light, charged particles (e.g., electrons or positrons) moving at relativistic speeds undergo radial acceleration. Unlike laboratory diffractometers, synchrotrons are large-scale facilities that are designated for the production of synchrotron radiation. Small synchrotrons of the past have paved the way for the development of third-generation synchrotron facilities; in the latter, electrons emitted by an electron gun are first accelerated in a linear accelerator (linac) and then transmitted to a circular accelerator (booster synchrotron) where they are accelerated to energy levels of several gigaelectron volts (GeV). These high-energy electrons are then injected into a large storage ring where they circulate in a vacuum environment, at a constant energy, for many hours. Magnets are used to deflect the particles, causing them to change direction and emit synchrotron radiation, which is then directed toward a beamline for use in experiments (Suortti, 2002).

The radiation produced is extremely bright over a broad spectral range; in fact, it is several orders of magnitude brighter than that produced by a conventional X-ray tube. The X-rays produced in this manner are collimated to a narrow beam, polarized, and pulsed (subnanosecond). Synchrotron radiation offers the advantage of being able to analyze very small crystals because 10^{10}–10^{11} photons sec^{-1} can be focused on a sample 10 μm in diameter (Suortti, 2002).

Powder X-ray diffraction refers to the use of a collimated monochromatic beam of X-rays to analyze a sample containing a large number of crystals with random orientations. Diffraction intensity is measured as a function of 2θ, thus allowing a simple application of Bragg's law to determine d-spacings within the lattice. The resulting set of d-spacings is a 'fingerprint' that can uniquely determine crystal symmetry and can identify a crystalline material or a mixture of crystalline materials, typically by comparisons with standards. Powder X-ray

diffraction has become an important tool in the study of actinide compounds because it is often impossible to obtain sufficiently large single crystals for some classes of compounds (Suortti, 2002).

22.2.2 Neutron diffraction techniques

In X-ray diffraction, the scattering power of a given atom for a given reflection, or the 'scattering factor', is strongly dependent on the type of atom, the scattering angle, and thermal motion, thus drastically affecting the resolution and the determination of the position of lighter atoms in the presence of heavy ones. However, scattering in neutron diffraction occurs primarily from the nucleus; since the diameter of the nucleus is small relative to the wavelength of the neutrons, the 'scattering factor' is characteristic of the particular nucleus and independent of scattering angle. As a result, neutron diffraction offers the ability to distinguish among near neighbors in the periodic table, or determine the position of light atoms with the same degree of accuracy as the heavy elements. For example, the scattering amplitudes for ^{2}D and ^{238}U with X-rays are 0.28 and 25.92, respectively, while with neutrons, these values are 0.67 and 0.84, respectively. In this regard, X-ray diffraction and neutron diffraction are often thought of as complementary techniques (Deschamps and Flippen-Anderson, 2002).

Currently, monochromatic neutrons for scattering experiments are produced at large facilities because there is no laboratory-size instrument comparable to the X-ray diffractometer. Nuclear reactors offer a source of steady (i.e., not pulsed) neutrons; high-energy neutrons (1 MeV) from continuous self-sustained fission reactions in ^{235}U are moderated to thermal energies near 40 meV and extracted through holes that penetrate the moderator. Alternatively, pulsed (spallation) sources use short bursts of 1 GeV protons to generate a large number of neutrons by being spalled ('chipped') from target nuclei (e.g., 25 neutrons per incident photon for ^{238}U). The resulting neutrons are moderated (using hydrogenous materials) to a pulse of neutrons with energies less than 10 eV (Suortti, 2002).

Spallation-based neutron scattering has emerged as comparable and complementary to reactor-based neutron scattering, although there are fundamental differences between the experiments. Neutrons from a reactor are separated with a monochromator to provide a small energy band for use in diffraction experiments in a manner similar to the beam from an X-ray tube. Spallation neutrons have a wide energy distribution and diffraction patterns are analyzed as a function of the neutron wavelength by employing time-of-flight diffraction (Suortti, 2002).

Powder neutron diffraction, like its X-ray analog, is an important tool for analyzing samples containing randomly oriented crystallites. However, in recent years, powder X-ray and neutron diffraction have become more widely used due to the advantages offered by the Rietveld refinement technique, originally developed for analyzing neutron diffraction data; here, positional and thermal

parameters can be determined from powder data. In fact, precision comparable to single-crystal X-ray diffraction data is achievable for positional parameters, but thermal parameters are less reliable (by a factor of 2 or 3) (Deschamps and Flippen-Anderson, 2002).

22.3 METALS AND INORGANIC COMPOUNDS

22.3.1 Actinide metals

The temperature-dependent phase diagrams of actinide metals are usually complicated by a variety of allotropic forms as illustrated in Fig. 22.1. As the temperature is increased, the metallic forms of the light actinides, in many cases, go through a series of allotropic changes, the most complicated of which is observed in plutonium metal (Smith and Kmetko, 1983). In general, as the metals approach melting, they take on the body-centered cubic (bcc) form, almost universally observed for high-temperature forms of lanthanide metals; however, this bcc form is predicted to be unstable for the later actinides (Sari *et al*., 1972/73). This change in crystal structure is caused by intricate differences in the electronic nature of the early actinides, while these differences in the later actinides become less clear due to lack of research. In a paper by Wills and Eriksson (1992), predictions of the crystal structure properties of thorium, protactinium, and uranium metal were made based on electronic considerations which successfully reproduced the experimentally observed crystal structures.

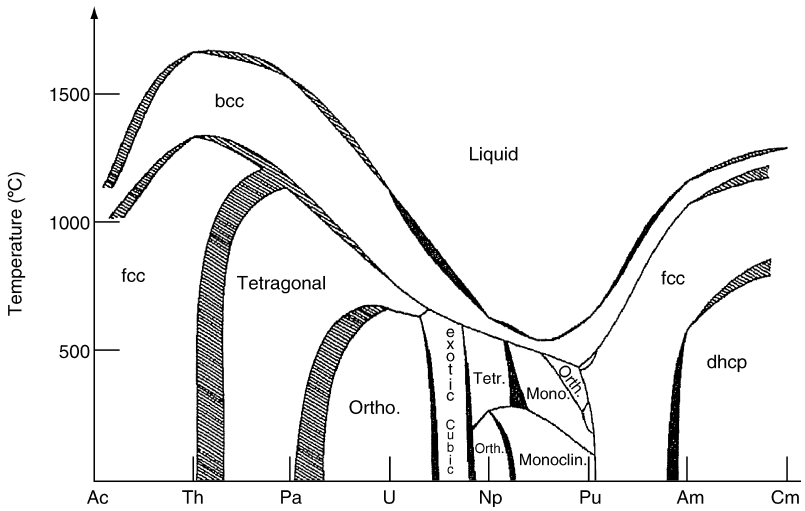

Fig. 22.1 *Binary phase diagram of the light actinides* (*bcc: body-centered cubic; fcc: face-centered cubic; ortho.: orthorhombic; mono.: monoclinic; dhcp: double hexagonal close packed*) (*Smith and Kmetko,* 1983. *Reproduced with permission from Elsevier*).

Described below are the different structural forms of the actinide metals from actinium through einsteinium. The transition temperatures listed reflect the widely agreed upon values from Chapters 2–12, 15, 19, and 21, although may not be reflective of the primary references listed, which have been included for completeness.

(a) Actinium

Actinium metal has a crystal structure identical to that of β-La, the high-temperature form of lanthanum. Actinium metal is a face-centered cubic (fcc) system with unit cell dimensions of 5.31(1) Å as determined by X-ray powder diffraction. Despite the existence of low-temperature α-La, a corresponding α-Ac has not been detected (Farr *et al.*, 1961).

(b) Thorium

Thorium metal exhibits two allotropic forms; at temperatures below 1360°C, the fcc form is present, after which it transforms into a bcc form. The bcc phase is present until the melting point of thorium is reached at 1750°C (Chiotti, 1954).

(c) Protactinium

Low-temperature protactinium metal (less then 1170°C) is a body-centered tetragonal crystal system. Upon heating, the axial ratio (c/a) increases exponentially from 0.8260(7) to 1.00, causing the structure to tend toward bcc at high temperature (up to 1572°C) (Marples, 1965).

(d) Uranium

Uranium metal has three temperature-induced allotropic forms. The room temperature allotropic form, α-phase (below 668°C), was the first to be discovered. This phase was originally reported by Wilson as having a monoclinic structure (Wilson, 1933). Within 4 years, it had been reindexed as an orthorhombic structure (Jacob and Warren, 1937). The last phase to be discovered was the β-phase which belongs to the tetragonal crystal system (Thewlis, 1951). This phase is present over the smallest temperature range, 668–776°C. X-ray single-crystal results are found in an article by Tucker (1951). The high-temperature γ-phase has a bcc crystal structure and is present until the melting point of uranium is reached (1135°C). Tucker (1950) also summarizes structural aspects of the allotropic forms of uranium in detail.

(e) Neptunium

Room-temperature neptunium metal belongs to the orthorhombic crystal system, known as the α-phase, and is different from that of uranium. In the α-phase, two different neptunium environments are present, only one of which

resembles the environment of the atoms observed in α-uranium (Zachariasen, 1952a). The α-phase is stable up to about 280°C, after which it transforms into the β-phase, a tetragonal crystal system. The final phase, present above 576°C, is known as the γ-phase (bcc crystal system) and exists until the metal melts at 639°C (Zachariasen, 1952b).

(f) Plutonium

Plutonium metal, by far the most complex of the actinide metals, has six different temperature-dependent allotropic forms with a wide range of physical properties and crystal structures. The α-phase, present at room temperature, is monoclinic and exists up to 124.4°C, after which it transforms into the β-phase (Zachariasen and Ellinger, 1963a). The α-phase is the densest and has the largest positive thermal expansion coefficient of all the plutonium allotropes (Zachariasen and Ellinger, 1957). A comprehensive list of densities and thermal expansion coefficients for plutonium metal is available from Choppin and Stout (1991). The β-phase is body-centered monoclinic and is stable up to about 214.8°C. The α–β phase transition has no simple geometry transformation, thus making the change sluggish (Zachariasen and Ellinger, 1959, 1963b). Between 214.8 and 320.0°C, the orthorhombic γ-phase is present and is unlike any other metal, having ten close plutonium neighbors at an average distance of 3.157 Å. The mean linear thermal expansion coefficients of the metal are positive along the [010] and [001] crystallographic direction and negative along the [100] direction (Zachariasen and Ellinger, 1955). The δ and the δ′ allotropic forms of plutonium are the only two that exhibit negative thermal expansion, thus introducing special concerns during casting of plutonium metal. The δ-phase is present between 320.0 and 462.9°C and belongs to the fcc crystal system. The δ′-phase is only present in the small range of 462.9–482.6°C and possesses, in magnitude, the largest thermal expansion coefficient of all the plutonium allotropic forms. At temperatures higher then 482.6°C (up to the melting point of plutonium metal at 640°C), the bcc ε-phase is present (Ellinger, 1956). The changes in the thermal expansion coefficients with respect to the allotropic forms of plutonium are shown graphically in Fig. 22.2. A summary of all the physical and crystallographic properties of plutonium metal is presented in greater detail elsewhere (Jette, 1955).

(g) Americium

At room temperature, americium metal, like α-La, belongs to the double hexagonal closed-packed (dhcp) crystal system (Graf *et al*., 1956; McWhan *et al*., 1962). At temperatures between 600 and 700°C, it was originally reported that a dhcp to fcc change occurs; however, a later report by Sari *et al*. refuted the existence of this change and suggested evidence for a solid-solid transition around 1075°C (before melting at 1173°C), although the exact nature of the

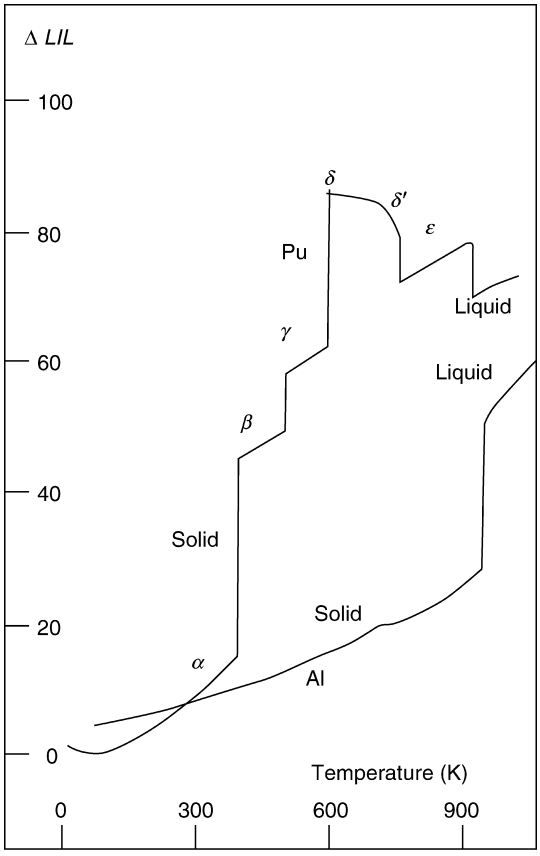

Fig. 22.2 *Dilation of aluminium and plutonium metals as a function of temperature. The allotropes are designated by their symbols* (*Choppin and Stout*, 1991. *Reproduced with permission from The Royal Society of Chemistry*).

modification could not be determined (Sari *et al*., 1972/73). Further evidence supports the α to β-phase at 769°C, β to γ-phase 1077°C with melting occurring at 1176°C, (see chapter 8).

(h) Curium

The crystal structure of curium metal as reported by Cunningham and Wallmann indicates a dhcp form at low temperatures (below 1295°C) that is isostructual with α-La and dhcp americium (1964). A later report by Smith *et al*. saw no evidence for the dhcp form, but rather a cubic close-packed structure. In their study, however, they reported broadened lines indicative of damaged curium structures, as well as weak curium lines compared to the tungsten lines. Also reported was a high-temperature phase (1295–1346°C) with fcc

symmetry where the metallic radius of curium (1.54 Å) is consistent with the 4+ oxidation state (Smith *et al.*, 1969).

(i) Berkelium

X-ray powder diffraction of berkelium metal revealed the existence of two stable room-temperature crystallographic modifications: dhcp and fcc . In preparation of the metal, annealing at 800°C with slow cooling tended to favor the dhcp structure, while annealing at 900°C resulted primarily in the fcc structure (Peterson *et al.*, 1971). Current studies place the α-phase below 977°C while the β-phase exists until melting at 1050°C (see Chapter 10).

(j) Californium

Californium metal was also observed to exist in two allotropic forms at room temperature: fcc and hexagonal close-packed (hcp). Upon heating in a vacuum, the fcc structure usually changed to the hcp structure, but would not revert back to the fcc, even at liquid nitrogen temperatures (Haire and Baybarz, 1974). A subsequent study by Zachariasen (1975) called into question these results, and concluded that the hcp and fcc structures were attributable to Cf_2O_2S and CfS, respectively. Further studies by Haire and Asprey (1976) later showed the existence of two dhcp structures present as a mixture. Analysis of the data and comparisons with previous results suggest that californium metal is one of the most complex transplutonium metals, existing in both a divalent and higher valent form with dhcp, and fcc structures. Current evidence supports the dchp phase below 700°C and the fcc phase between 700 and 900°C (see Chapter 11).

(k) Einsteinium

Einsteinium metal has been investigated through the reduction of a thin film of Es_2O_3 by lanthanum. The metallic einsteinium has a fcc structure and at the present time is the only known allotropic form (Haire and Baybarz, 1979).

22.3.2 Oxides

Actinide oxides (An_xO_y) are refractory materials, indicating their collective resistance to decomposition at high temperatures. For example, ThO_2 has the highest melting point of any oxide (3378°C) (Ronchi and Hiernaut 1996). Research has focused on the use of appropriate actinide oxides as nuclear fuels, although the chemistry associated with the actinide elements tends to be complex and includes polymorphism, non-stoichiometric compounds, and intermediate phases. The oxides are basic in character (they are weak Lewis bases, able to donate electron pairs). Their chemical reactivity is usually influenced by their thermal history; actinide oxides are significantly more inert after they have been ignited (Greenwood and Earnshaw, 2001).

Several early studies of actinide monoxides reported structural data for Th through Am, although definitive evidence is lacking. A later study with plutonium oxides, however, contested their existence and presented data supporting the existence of plutonium oxycarbide rather than monoxide as a phase on plutonium metal surfaces (Larson and Haschke, 1981). Studies of lanthanides (La–Nd, Sm) under high-temperature and high-pressure conditions supported the formation of NaCl-type monoxides, but noted their instability in condensed form under standard conditions. This suggests that PuO may be attainable by similar high-pressure techniques (Leger *et al.*, 1981). Despite this evidence against plutonium monoxide under standard conditions, structural data for the remaining actinide monoxides will be presented herein for completeness.

Structural studies of other actinide oxides have largely been by means of powder diffraction techniques due to the refractory nature of the materials and the difficulty in obtaining single crystals. Actinide dioxides are known for the elements thorium through californium. All are isostructural and adopt the common face-centered cubic (fcc) fluorite structure (CaF_2). The unit cell constants for the dioxides from thorium to Californium are shown in Table 22.1. In the CaF_2 structure, the cations occupy the cubic closest packing sites and the anions fill the remaining tetrahedral holes, resulting in a coordination number (CN) of eight for each cation. Thus, the overall structure is three-dimensional with a strong covalent component due to the high formal charge on the cation, resulting in compounds with unusually high melting points. The dioxides, with the exception of PaO_2, tend to lose oxygen at high temperature and form substoichiometric compounds with oxygen vacancies in the anion part of the lattice; the protactinium and uranium dioxides can form superstoichiometric compounds at room temperature (Keller, 1973).

Actinide sesquioxides (An_2O_3) become increasingly stable progressing from the lighter to the heavier actinide elements. Their structures are analogous to those formed for rare earths and adopt three structures commonly classified according to the following types:

Table 22.1 *Unit cell constants for actinide dioxides.*

Compound	*Cell constant, a* (Å)	*Reference*
ThO_2	5.597	Sellers *et al.* (1954); Leigh and McCartney (1974)
PaO_2	5.505	Sellers *et al.* (1954)
UO_2	5.4704	Grønvold (1955); Hutchings (1987)
NpO_2	5.4334	Fahey *et al.* (1976)
PuO_2	5.396	Gardner *et al.* (1965)
AmO_2	5.373	Hurtgen and Fuger (1977)
CmO_2	5.359	Peterson and Fuger (1971)
BkO_2	5.3315	Fahey *et al.* (1974)
CfO_2	5.310	Baybarz *et al.* (1972a)

A-type: hexagonal structure, with AnO_7 units in capped octahedral arrangement (CN = 7);

B-type: monoclinic structure, with two AnO_7 units in capped trigonal prism arrangement and third in capped octahedral arrangement (CN = 7, possibly 6);

C-type: cubic structure (related to fluorite), where one-quarter of anions have been removed to reduce coordination number to 6, but not octahedral (CN = 6).

As with the lanthanides, the smaller actinides favor the C-type structure (Greenwood and Earnshaw, 2001). However, none of the actinide sesquioxides have been studied using single-crystal X-ray diffraction techniques, thus making precise structural characterization (i.e., atomic positions, bond lengths) impossible. The chemistry of this class of compounds may be further complicated by temperature or pressure dependence on the structures, as detailed by Haire and Eyring (1994).

More complex and less common actinide oxides, including AnO_3, An_3O_8, and An_2O_5, will be discussed on a case by case basis, where appropriate. For example, AnO_3 compounds are known, but typically exist in a hydrated state; the only known anhydrous trioxide is UO_3. Anhydrous uranium trioxide has been isolated in seven polymorphic forms, reflecting the ability of uranium(VI) to exist in a variety of low symmetry, high coordination environments with similar energies (Weller *et al.*, 1988).

(a) Actinium

Only one actinium oxide has been reported. Fried *et al.* (1950) reported that actinium sesquioxide, Ac_2O_3, can be obtained through decomposition of actinium oxalate at 1100°C. The compound has hexagonal symmetry and is isomorphous with certain lanthanide sesquioxides, including those of lanthanum, cerium, and praseodymium (A-type). It is interesting to note that the sample was prepared from less than 10 μg of actinium to minimize fogging of the X-ray film due to high gamma radiation encountered during structural data collection.

(b) Thorium

Two binary oxides have been reported for thorium. Metastable thorium monoxide has been reported to form on the surface of thorium metal exposed to air and subsequent crystallographic analysis revealed an fcc structure with a lattice parameter of 5.302 Å (Ackermann and Rauh, 1973). ThO_2, also with fcc symmetry (CaF_2 structure), is stable up to its melting point of 3390°C, although extensive heating to 1800–2000°C in a vacuum results in a blackened material due to loss of oxygen (Haire and Eyring, 1994).

(c) Protactinium

The oxides of protactinium are more complex than those of the two earlier actinide elements, ascribable to its more complex electronic structure. Three binary oxides are known: PaO, PaO_2, and Pa_2O_5. Several intermediate oxides of variable stoichiometry also exist between PaO_2 and Pa_2O_5, in addition to seven crystal modifications of Pa_2O_5 (Haire and Eyring, 1994).

Crystallographic analysis of the monoxide, PaO, showed the NaCl structure with a lattice cell length of 4.961 Å. This material, like ThO, has been reported to exist as a coating on metal. Its existence is further ascribed as PaO because the substance is slowly oxidized by air to form PaO_2 (Sellers *et al.*, 1954).

The white binary oxide Pa_2O_5 is formed by heating the hydrated oxide ($Pa_2O_5 \cdot nH_2O$), as well as several other protactinium compounds (hydroxide, nitrate, etc.), in air or oxygen above 650°C. The crystalline modification that is obtained (there are seven total, including fcc, tetragonal, hexagonal, orthorhombic, and rhombohedral forms) depends on the temperature to which the starting material is heated. The black dioxide, PaO_2, can be prepared by the reduction of Pa_2O_5 with H_2 at 1550°C and has a fluorite fcc structure (Sellers *et al.*, 1954).

Intermediate compounds with O/Pa ratios between 2.0 and 2.5 are obtained by selective oxidation of PaO_2 or reduction of Pa_2O_5. These compounds have been identified as $PaO_{2.18}$–$PaO_{2.21}$, $PaO_{2.33}$, $PaO_{2.40}$–$PaO_{2.42}$, and $PaO_{2.42}$–$PaO_{2.44}$, having fcc, tetragonal, tetragonal, and rhombohedral symmetries, respectively (Roberts and Walter, 1966).

(d) Uranium

The complexity of uranium oxides is due to the ability of uranium to exist in several valence states, both exclusively and simultaneously. Many uranium oxides are known, including UO_2, U_2O_5, U_3O_8, U_4O_9, and UO_3, each showing a range of content. Diffraction data for the monoxide have been reported and, like the analogous thorium compound, UO is unstable with respect to disproportionation (Ackermann and Rauh, 1973). The compound U_3O_8 is the most stable oxide of uranium under ambient conditions.

Uranium dioxide is the most widely studied of the dioxides due to its use in the nuclear industry. The room-temperature fcc fluorite crystal structure of stoichiometric UO_2 was first determined by Goldschmidt and Thomassen (1923) and they showed that the uranium atoms occupy the face-centered sites, while the oxygen atoms occupy the corners of a cube centered within the unit cell. Earlier, however, Hillebrand established the isomorphism of UO_2 with ThO_2 (Hillebrand, 1893). The fluorite structure possesses two types of lattice holes per unit cell: three positioned in the middle of the unit cell edges at (½, 0, 0), (0, ½, 0), and (0, 0, ½), and one large hole in the cube center at (½, ½, ½). The openness of the structure allows the anions to move toward the holes and causes anharmonic motion of the oxygen atoms (Rouse *et al.*, 1968).

In addition, the holes allow for the addition of oxygen atoms up to a composition of $UO_{2.25}$ without changing the cubic structure of the cell. Several studies have been performed to determine the exact positions of oxygen atoms in UO_{2+x} using X-ray (Belbeoch *et al.*, 1961; Willis, 1978) and neutron diffraction (Willis, 1964). Neutron diffraction on polycrystalline UO_2 has also been reported (Knowles *et al.*, 1981).

Hyperstoichiometric UO_{2+x}, resulting from the addition of oxygen to the dioxide lattice, has been thoroughly investigated using neutron diffraction (Willis, 1963, 1964). Willis showed that the additional oxygen atoms are not exactly on the (½, ½, ½) positions, but are slightly displaced around these holes. Vacancies are also still present in the oxygen sublattice. Electron diffraction of $UO_{2.19}$ revealed a superstructure composed of $4 \times 4 \times 1$ basic cells of UO_2 (fluorite); the oxygen atoms were displaced slightly from ideal locations with local accumulations of three oxygen atoms (Steeb and Mitsch, 1965). The structure of $UO_{2.25}$ (or U_4O_9) has also been thoroughly investigated using X-ray (Belbeoch *et al.*, 1961), neutron (Masaki and Doi, 1972), and electron diffraction (Blank and Ronchi, 1968). The superlattice is cubic with a cell dimension that is four times that of UO_2. The structures, dislocations, and defects in anion-excess uranium oxides are described in detail elsewhere (Vollath, 1984; Willis, 1987).

The three crystalline forms of U_2O_5 exist only at elevated temperature and pressure. The powder pattern of the α-form was not successfully indexed at first, but was observed as the predominant form below 800°C and between 10 and 60 kbar of pressure (Hoekstra *et al.*, 1970). It was later indexed as a monoclinic cell (Haire and Eyring, 1994). The β- and γ-forms exist mainly above 800°C and between 30 and 60 kbar of pressure; they are hexagonal and monoclinic, respectively. Samples prepared at the highest pressure (60 kbar) and above 800°C sometimes appeared as the β-form, and other times as the γ-form (Hoekstra *et al.*, 1970).

The most stable uranium oxide, U_3O_8, has two common polymorphs (α and β) that exist independently. Using neutron diffraction, Loopstra (1964) was able to model the two phases, both of which are orthorhombic. The most stable polymorph is α-U_3O_8 in which the oxygen atoms are all located at the corners of a pentagonal bipyramid around the central uranium. Generation of the β-U_3O_8 polymorph is accomplished by extended heating of α-U_3O_8 to 1350°C in air or oxygen, followed by slow cooling over about 2 weeks. The β-U_3O_8 polymorph exhibits two uranium coordination environments forming two distinct uranium polymeric chains along the *c*-axis. The first set of chains has uranium surrounded by oxygen atoms at the corners of a pentagonal bipyramid, while the remaining chains have the uranium surrounded by both pentagonal bipyramidal and octahedral oxygen atoms in an alternating fashion. Here, all neighbors of octahedrally coordinated uranium are pentagonal bipyramids (Loopstra, 1970). Other uncommon polymorphs include the γ-U_3O_8 which is formed from α-U_3O_8 at pressures and temperatures greater then 16,000 atm and

400°C (Herak and Jovanovic, 1969). If the α-U_3O_8 polymorph is exposed to an oxygen atmosphere for a prolonged time at 1350°C, the lattice converts to δ-U_3O_8 (Amirthalingam, 1966). Another form, p-U_3O_8, was discovered when α-U_3O_8 was held at room temperature and pressures greater than 50 kPa. This polymorph is not stable at temperatures greater then 1100°C in air or an argon atmosphere, and converts back to α-U_3O_8 (Steeb and Brucklacher, 1966).

Seven forms of UO_3, both crystalline and amorphous, have been characterized. Their methods of preparation are illustrated in Fig. 22.3. The amorphous form of the oxide is referred to as A-UO_3 (Hoekstra and Siegel, 1961). The structure of α-UO_3 has gone through many refinements, the latest of which corrects several discrepancies in previous studies. Here, Greaves and Fender (1972)

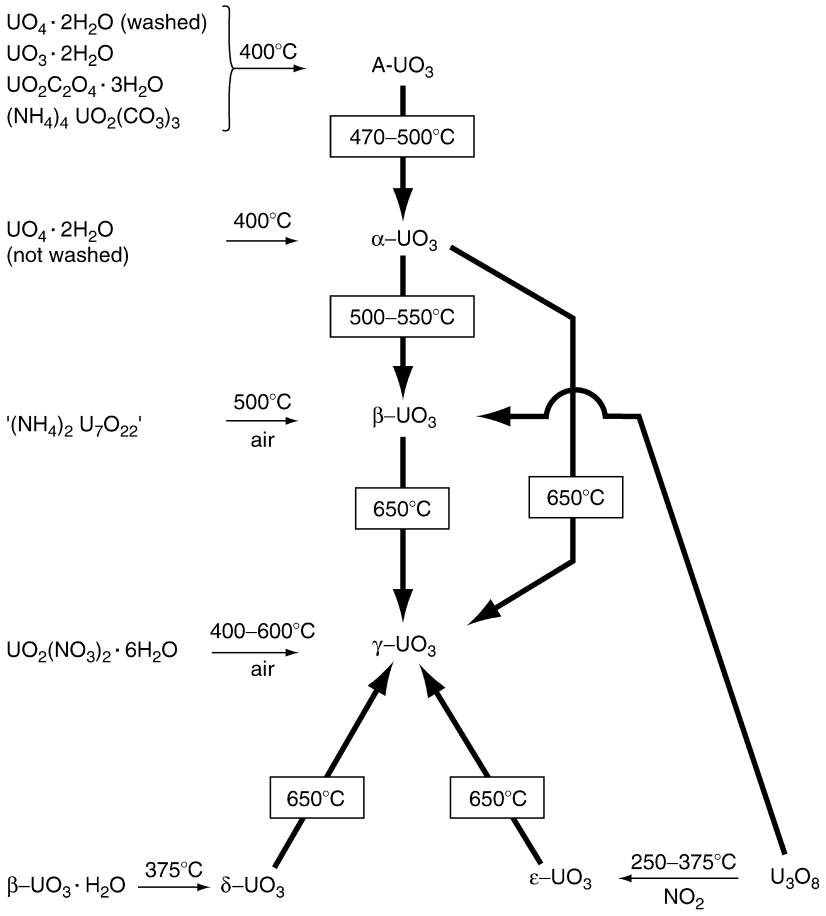

Fig. 22.3 *Uranium trioxide polymorphs and means of preparation* (*Weigel,* 1986. *Reproduced with permission from Chapman and Hall*).

based the structure on uranium-deficient α-U_3O_8; the loss of uranium atoms is countered by the shortening of some U–O distances from 2.1 to 1.6 Å, thus explaining the existence of some uranyl-like bonds. The diffraction pattern of β-UO_3 revealed three different environments for uranium with coordination numbers of 6, 6, and 7. The overall structure may be visualized as layers interconnected by distorted uranyl groups (Debets, 1966). The most recent neutron powder profile of γ-UO_3 shows the existence of three closely related phases between 373 and 77 K. At 373, 323, and 77 K, tetragonal, orthorhombic, and orthorhombic structures are observed, respectively. Of all the UO_3 crystalline phase, γ-UO_3 is the most thermodynamically stable (Loopstra *et al.*, 1977). Cubic δ-UO_3 has an unusual regular octahedral uranium environment and is isostructural with ReO_3. The structure has been confirmed with both powder X-ray diffraction (Wait, 1955), and powder neutron diffraction techniques (Weller *et al.*, 1988). Structural data for ε-UO_3 shows a triclinic cell (Hoekstra and Siegel, 1961). The last form isolated at high pressure, η-UO_3, is seven-coordinate with two *trans* oxygen atoms at 1.80 and 1.85 Å forming the uranyl group, and the remaining five oxygen atoms distributed equatorially in a puckered pentagon (Siegel *et al.*, 1966).

(e) Neptunium

Neptunium monoxide has been reported as having the NaCl structure type with a lattice parameter of 5.00(1) Å (Zachariasen, 1949a). However, like the other actinide monoxides, its existence is a point of debate except as a vapor phase species at high temperature and pressure.

The first neptunium compound to be identified by X-ray powder diffraction was NpO_2 and is isostructural with other actinide dioxides (Zachariasen, 1949a). NpO_2 can be prepared by calcining nitrates, hydroxides, or oxalates of the metal in air or oxygen at 700–1000°C.

Neptunium(v) oxide, Np_2O_5, is prepared by bubbling ozone through a solution of Np(v) in molten $LiClO_4$ at 260°C and displays a very narrow compositional range with limited stability (Cohen, 1963). Anhydrous neptunium oxides above Np_2O_5 are not known. The pentoxide is monoclinic; however, the β angle is nearly 90°, allowing poor crystalline samples to be mistakenly indexed as orthorhombic (Cohen, 1963).

A hydrated oxide, $NpO_3 \cdot 2H_2O$, has been prepared by ozone oxidation of Np(v) in a $LiNO_3$–KNO_3 eutectic at 150°C (Cohen, 1963).

(f) Plutonium

The monoxide of plutonium, previously reported as belonging to the NaCl structure type, is actually a plutonium oxide carbide of the form PuO_xC_y. It is very similar to the samarium oxide carbide analog, thus aiding in its characterization. Due to these similarities, it is suggested that PuO likely exists in

the vapor phase under high temperature and pressure (Larson and Haschke, 1981).

Two sesquioxides of plutonium have been identified. Interestingly, two forms of α-Pu_2O_3 have been observed, both of which are sub-stoichiometric compounds due to loss of oxygen from the dioxide. The first, α-form, is prepared by heating PuO_2 in a vacuum at 1650–1800°C in a tantalum crucible. This compound has a C-type bcc structure and exists at an O/Pu ratio of 1.515. An alternate form of α-Pu_2O_3, referred to as α'-Pu_2O_3, has also been observed at a O/Pu ratio of 1.61, although its classification as fcc is ambiguous. The only purely stoichiometric form, β-Pu_2O_3, is prepared by reducing PuO_2 with 20% excess of Pu metal at 1500°C and adopts an A-type, hexagonal structure. A more comprehensive analysis of plutonium oxide sub-stoichiometric behavior as a function of temperature is available (Gardner *et al.*, 1965).

Crystals of PuO_2, the most stable plutonium oxide, can be obtained by careful temperature control during decomposition in a molten salt (Schlechter, 1970), reaction of Pu with O_2 (Akimoto, 1960), or other methods, including the calcination of plutonium oxalate (or other salts) in air or oxygen to 800–1000°C for several hours. The dioxide is isostructural with other actinide dioxides and adopts the fluorite-type structure (Phipps and Sullenger, 1964).

(g) Americium

Although its existence is questionable, the monoxide of americium (NaCl type) has been reported by Zachariasen (1949b) and Akimoto (1967). Furthermore, the presence of certain X-ray powder diffraction lines from americium metal are possibly attributable to fcc AmO with a lattice parameter of 5.05 Å (McWhan *et al.*, 1960).

Two modifications of americium sesquioxide have been reported. The bcc (C-type) structure is the low-temperature form, prepared by heating the dioxide in H_2 at 600°C. The high-temperature hexagonal (A-type) structure was prepared by ignition of the metal oxalate at 850°C, followed by reduction in H_2 at 800°C (Templeton and Dauben, 1953). Chikalla and Eyring (1968) reported that samples with O/Am ratios between 1.54 and 1.51, when quenched from 800°C or above, gave several weak diffraction lines of neither C-type nor A-type origin. These lines compared reasonably well with those for monoclinic B-type Sm_2O_3 and were assigned as B-type Am_2O_3. The B-type sesquioxide was only found in quenched samples and it exists only at elevated temperatures; its upper temperature limit of stability lies between 950 and 1000°C. It is likely not stable as a dominant phase. The lattice constants for the americium sesquioxides are listed in Table 22.2.

Phase relations of americium oxides in the O/Am range of 1.5–2.0 have also been investigated. The cubic sesquioxide was observed to dissolve excess oxygen at room temperature up to a stoichiometry of $AmO_{1.67}$. In this range, there was either a single phase of continually variable composition or there were several

narrow regions separated by miscibility gaps. For stoichiometries between $AmO_{1.67}$ and AmO_2, an intermediate phase is thought to exist, likely from O/Am ratios between 1.67 and 1.80 (Chikalla and Eyring, 1968).

AmO_2 was the first reported americium compound (Zachariasen, 1948a, 1949b) and was shown to crystallize in the fluorite structure. It can be prepared in a variety of ways, including ignition of the nitrate or oxalate in air or oxygen up to 900°C (Templeton and Dauben, 1953). Self-irradiation effects in americium oxides are quite significant. Crystalline AmO_2 expands due to these effects, resulting in an enlargement of the lattice constant, an effect that was unaccounted for in early reports of the structure. Interestingly, lattice expansion varied between those samples stored under vacuum and those stored under O_2, with the latter occurring at a slightly slower rate. Likewise, self-irradiation of the low-temperature cubic form of the sesquioxide caused a transformation to the hexagonal form over the time span of about 3 years (Hurtgen and Fuger, 1977).

(h) Curium

The monoxide of curium has been reported during the study of curium metal, where three extra lines in the diffraction pattern were indexed as fcc CmO with a lattice constant of 5.09 Å (Cunningham and Wallmann, 1964).

Three crystalline forms of Cm_2O_3 have been characterized and the lattice constants are summarized in Table 22.3. The low-temperature bcc (C-type) structure is formed from the hydrogen reduction of a higher curium oxide (Wallmann, 1964). Heating the C-type structure between 800 and 1300°C irreversibly generates the monoclinic (B-type) structure (Mosley, 1972) and is

remarkably stable with respect to self-irradiation (Haug, 1967). The reversible hexagonal (A-type) structure can be prepared in two ways: heating the B-type sesquioxide above 1600°C (Mosley, 1972) or from gradual self-irradiation of the C-type form at room temperature (Wallmann, 1964). In addition, it has been discovered that heating the A-type form to 500°C results in the B-type structure (Noé *et al.*, 1970).

The dioxide of curium can be prepared in several ways, including calcining of salts (i.e., oxalates, hydroxides) in oxygen followed by slow cooling (Asprey *et al.*, 1955) or by oxidation of the cubic sesquioxide at 400°C in air or oxygen for several days (Haug, 1967). Alternatively, CmO_2 can be prepared by thermally decomposing a resin loaded with Cm^{3+} (Hale and Mosley, 1973). The dioxide has the fluorite structure with a lattice parameter of 5.357(1) Å at room temperature, but in the case of ^{244}Cm, can undergo significant lattice damage due to self-irradiation, resulting in a swelling of the lattice parameter to 5.373 Å within 3 days (Mosley, 1972). A powder neutron diffraction study of the dioxide with Rietveld refinement yielded a stoichiometry of $CmO_{1.970 \pm 0.034}$; thus the material is probably hypostoichiometric. In fact, magnetic susceptibility measurements gave an effective moment of 3.36 μ_B, indicative of substantial Cm^{3+} impurity, thus favoring a nominal composition of $CmO_{1.91}$. The discrepancy between neutron diffraction data and thermogravimetric analysis (TGA) data (indicating CmO_2), and magnetic susceptibility data that favor the non-stoichiometric material, is yet to be resolved (Morss *et al.*, 1989).

Thermal decomposition of the dioxide has revealed two intermediate systems, $CmO_{1.81}$, with fluorite symmetry, and Cm_7O_{12}, with rhombohedral symmetry, finally ending with the C-type sesquioxide (Mosley, 1972). The complex nature of the curium–oxygen system bears some resemblance to the analogous plutonium system, and its intricacies are outlined elsewhere (Chikalla and Eyring, 1969).

(i) Transcurium elements

The monoxide of berkelium has been reported as having the NaCl structure type, although its existence is debatable (Fahey *et al.*, 1972).

Three berkelium sesquioxides have been identified as having A-, B-, and C-type structures and their lattice parameters are listed in Table 22.4. The low-temperature cubic C-form is produced by hydrogen reduction of the higher oxide, BkO_2 (Peterson and Cunningham, 1967a; Baybarz, 1968). Irreversible conversion of the C-type sesquioxide to the monoclinic, B-type structure occurs upon heating in the range 1200–1700°C. Further heating of the B-type sesquioxide to temperatures above 1750°C results in the hexagonal, A-type sesquioxide. The melting point occurs at 1920°C (Baybarz, 1973a).

The oxygen dissociation pressure of non-stoichiometric oxides of the form BkO_x, where $1.5 < x < 2.0$, have been investigated, resulting in the identification of three phases, $BkO_{1.5–1.77}$, $BkO_{1.81–1.91}$, and $BkO_{1.93–2.00}$

Table 22.4 *Lattice constants for Bk_2O_3* (*Peterson and Cunningham,* 1967a*; Baybarz,* 1968, 1973*a*).

C – Cf_2O_3	cubic	10.839	–	–	–

(Turcotte *et al.*, 1971). A follow-up investigation of the phase behavior was consistent with previous studies, resulting in a phase diagram of the non-stoichiometric area at high temperatures. Two regions were indexed for BkO_x compounds in the non-stoichiometric range: a bcc region for $1.5 < x \leq 1.70$ and a fcc region for $1.78 < x < 2.0$ (Turcotte *et al.*, 1980). A more comprehensive investigation of the phase diagram in the temperature range from 200 to 900°C and from 59 to 67 atomic % oxygen is available from Okamoto (1999).

The stoichiometric dioxide of berkelium is obtained by calcination of berkelium salts (nitrate, oxalate, hydroxide, etc.) in air or oxygen, resulting in a fcc structure. The first structural determination of the dioxide was performed in 1962 using only 4 ng of sample; the diffraction pattern showed four lines that were indexed on the basis of a fcc cell (Peterson and Cunningham, 1967a). Subsequent studies used larger samples (μg) of ^{249}Bk that had been loaded onto an ion exchange resin, calcined, and indexed (Peterson and Cunningham, 1967a; Baybarz, 1968). BkO_2 also undergoes thermal expansion in 1 atm of oxygen, although the phenomenon is reversible with a decrease in temperature (Fahey *et al.*, 1974).

The three known sesquioxides of californium are the A-, B-, and C-type structures and their lattice constants are provided in Table 22.5. The first discovered was the monoclinic, B-type sesquioxide (Green and Cunningham, 1967) followed by the discovery of the cubic, C-type sesquioxide (Copeland and Cunningham, 1969). The hexagonal, A-type sesquioxide was the most difficult to obtain due to its small range of existence between the monoclinic form and the melting point. The low-temperature B-type sesquioxide is transformed to the C-type upon heating between 1200 and 1700°C, followed by a transformation to the A-type sesquioxide above 1700°C and melting at 1750°C (Baybarz, 1973a).

Table 22.6 *Lattice constants for Es_2O_3* (*Haire and Baybarz,* 1973*; Haire and Eyring,* 1994).

Formula	*Symmetry*	*a* (Å)	*b* (Å)	*c* (Å)	*β* (°)
A – Es_2O_3	hexagonal	3.7	–	–	–
B – Es_2O_3	monoclinic	14.1	3.59	8.80	100
C – Es_2O_3	cubic	10.766	–	–	–

An intermediate between the sesquioxide and the dioxide was identified as Cf_7O_{12}. This rhombohedral structure can be prepared by heating the cubic sesquioxide in air or oxygen, at which time the sesquioxide takes up oxygen to an O/Cf ratio of 1.7; its existence is limited to a very narrow range of O/Cf values. It can also be prepared by heating the nitrate, oxalate, or nitrate salts in air or oxygen to 750°C, after which oxygen is lost to form the sesquioxide (Baybarz *et al.*, 1972a).

Californium dioxide has been prepared by the oxidation of the cubic sesquioxide with high-pressure molecular oxygen and by atomic oxygen. The dioxide has the fluorite structure with a lattice parameter of 5.310(2) Å, which has been corrected for expansion due to swelling. Preparation of CfO_2 can also be achieved through self-irradiation of lower californium oxides via the generation of active oxygen species from alpha decay (Baybarz *et al.*, 1972a).

The only characterized oxides of einsteinium have been the sesquioxides, the lattice parameters for which are provided in Table 22.6. The cubic C-type sesquioxide was prepared from the calcination of submicrogram amounts of the metal nitrate and analyzed by electron diffraction (Haire and Baybarz, 1973). The monoclinic B-type sesquioxide was produced from the oxidation of einsteinium metal under oxygen at elevated temperatures (800–1000°C). The hexagonal A-type sesquioxide is produced as a result of the self-irradiation of the monoclinic form. Both the B- and A-types were characterized by electron diffraction (Haire and Eyring, 1994). The rapid appearance of the highly radioactive daughter ^{249}Bk from the parent ^{253}Es (3% per day) has made the study of these compounds quite challenging.

Crystal structures for the oxides of transeinsteinium elements are not available due to limitations in abundance and their short half-lives.

22.3.3 Actinyl compounds

Actinide elements in the hexavalent oxidation state commonly exist as the actinyl (AnO_2^{2+}) ion in both aqueous solutions and solid state. The linear geometry of the uranyl ion with its *trans* oxo ligands (O=U=O) was first elucidated by Fankuchen (1935) from the space group symmetry of sodium uranyl acetate. The stability of the uranyl ion is evident in the hundreds of structural characterizations that have since been published, many of which were

included by Burns in Chapter 20 of the previous edition (pre-1986) as well as Chapter 5 of the current edition. The ubiquity of the hexavalent uranyl moiety in both solution and the solid state has led to numerous studies in a variety of environments, including inclusion into the cavity of macrocyclic ligands (see Section 22.4.2) for separations applications, the interaction with ligands such as carbonate (Morse *et al.*, 1984), and citrate (Pasilis and Pemberton, 2003) to understand environmental mobility and/or immobilization, elucidation of the Lewis base properties of the oxo ligands with respect to ligand exchange, substitution, and cation–cation interactions (Sarsfield and Helliwell, 2004), and computational studies of the role of 5f electrons in bonding, electronic, and structural properties to understand the origin of its linearity (Zhang and Pitzer, 1999).

Hexavalent actinyl ions are also known for transuranic actinides Np (neptunyl), Pu (plutonyl), and Am (americyl). The entire series is isostructural although structural details are limited compared to uranyl. The An–O bond strength, as well as the resistance to reduction, decreases in the order U > Np > Pu > Am. Whereas uranyl salts are highly common, formation of AmO_2^{2+} requires the use of strong oxidizing agents such as peroxodisulfate. The An=O bond length in hexavalent actinyl compounds generally ranges between 1.7 and 2.0 Å. In all cases, the bond is very strong, while in uranyl, it appears that the bond order may be even greater than two as evidenced by the short bond length (Greenwood and Earnshaw, 2001).

The linearity of the uranyl and other hexavalent actinyl ions (Np, Pu, Am) has been the subject of many theoretical inquiries that sought to elucidate the relative contributions of orbitals from the actinide and oxygen atoms. Wadt (1981) noted that the difference in the gas-phase geometries of isoelectronic UO_2^{2+} and ThO_2 is due to the relative ordering of the 5f and 6d levels. In uranium, the 5f orbitals are lower in energy, thus favoring a linear geometry upon interaction with oxygen 2p orbitals. In thorium, however, the 6d orbitals are lower, resulting in a bent geometry. Furthermore, Tatsumi and Hoffmann (1980) and Pyykkö *et al.* (1989) have added that 6p interactions with oxygen are significant in uranium; this repulsive interaction activates the 5f orbitals of uranium in a coorperative manner through a 'pushing from below' mechanism, leading to short, linear oxo bonds. A review of the electronic structure of several actinide-containing molecules is available from Pepper and Bursten (1991).

It is estimated that 98% of all crystal structures have O=U=O angles in the range 174–180° (Sarsfield *et al.*, 2004). Despite the prevalence of the linear dioxo cation, nonlinear uranyl species have been observed. For example, the structure of $UO_2[(SiMe_3N)CPh(NSiMe_3)]_2THF$ contains a uranyl unit with a O=U=O angle of 169.7(2)° (Sarsfield and Helliwell, 2004). While this bend is a dramatic example of nonlinearity, more common deviations are observed in the structures of $UO_2(O\text{-}2,6\text{-}{}^{i}Pr_2C_6H_3)_2(pyr)_2$ (Barnhart *et al.*, 1995a) and $[UO_2(OCH({}^{i}Pr)_2)_2]_4$ (Wilkerson *et al.*, 2000); the O=U=O angles in these examples are 173.4(2)° and 172.6(2)°, respectively.

Accurate determination of the uranium–oxygen bond length of uranyl in its compounds by X-ray diffraction have traditionally been difficult due to the large difference in scattering power (proportional to the number of electrons) between the two atoms. However, advances in neutron diffraction techniques and their wider availability have eliminated this problem. The nuclear cross sections of uranium and oxygen are comparable, thus allowing accurate atomic placement using neutrons.

In general for hexavalent actinyl ions, several factors have been identified that can lead to variations in the U=O bond length. The most significant is the bonding of ligands in the equatorial plane, perpendicular to the O=An=O axis. Actinyls readily form complexes with halides, such as F^- and Cl^-, oxygen donors such as OH^-, SO_4^{2-}, NO_3^-, PO_4^{3-}, and carboxylates, as well as neutral donors, such as H_2O or pyridine. Coordination numbers between four and six from monodentate and bidentate ligands are common in the equatorial plane and generate octahedral, pentagonal bipyramidal, and hexagonal bipyramidal geometries. In uranyl, the formal charge on uranium is 2+, although other evidence suggests that it may be closer to 3+ (the formal charge is different from oxidation state); thus, depending on the extent of orbital overlap from equatorial ligands, the electron density withdrawn from the axial oxygen atoms greatly affects the M=O bond lengths (Sarsfield and Helliwell, 2004). Another factor is the local environment provided by the rest of structure, sometimes resulting in U=O bond lengths that vary within the same compound. For example, in the compound $UO\{OB(C_6F_5)_3\}[(SiMe_3N)CPh(NSiMe_3)]$, the interaction of one oxo ligand (Lewis base) with the borane (Lewis acid) results in an elongated U=O bond (1.898(3) Å) compared to the uncoordinated one (1.770(3) Å) (Sarsfield and Helliwell, 2004). Finally, reduction of the actinide oxidation state from 6+ to 5+ results in a lengthening, and hence weakening, of the oxo bond. Additional information on actinyl structures and structural changes with correlations to vibrational spectra has been compiled by Hoeskstra (1982).

Actinide elements in the pentavalent oxidation state form a less common type of actinyl represented by the formula AnO_2^+. This species is known for U, Np, Pu, and Am. Like AnO_2^{2+}, the AnO_2^+ ion is linear and symmetric, although the low charge on AnO_2^+ prevents the formation of very stable complexes. These compounds are very susceptible to disproportionation into An(IV) and An(VI). The most notable pentavalent actinyl is NpO_2^+; it has recently been observed to form an inclusion complex with the porphyrin, hexaphyrin(1.0.1.0.0.0). Here, the environment around the linear cation results in two different Np=O bond lengths: 1.762(1) and 1.826(1) Å. These distances are unusually short for the neptunyl ion where 1.85 Å is common in simple inorganic salts (Sessler *et al.*, 2001b).

Differences in the An=O bond length are also significantly influenced by the oxidation state of the metal; changing from a hexavalent to a pentavalent actinyl results in a bond length increase of about 0.14 Å (Burns and Musikas, 1977). This change in the bond length implies a weakening of the bond and is

attributed to the additional non-bonding electrons in each AnO_2^+ ion compared to the corresponding AnO_2^{2+} ion. Both AnO_2^+ and AnO_2^{2+} exhibit the actinide contraction where incremental increases in the atomic number result in a lengthening of the An=O bond by about 0.01 Å (Zachariasen, 1954; Musikas and Burns, 1976). Self-assembled uranyl peroxide nanosphere clusters of 24, 28, and 32 polyhedra (some containing neptunyl) that crystallize from alkaline solution have been characterized (Burns *et al*., 2005).

22.3.4 Hydrides, borohydrides, borides, carbides, and silicides

(a) Hydrides

A majority of the actinide hydrides attain either the $AnH_{2\pm x}$ or AnH_3 composition through direct reaction of the metal in a H_2 atmosphere. Structural information is available for hydrides of thorium through californium. The resulting actinide hydrides react readily with oxygen and all are pyrophoric.

(*i*) *Thorium*

Thorium dihydride was originally studied by Rundle *et al*. (1952) using neutron diffraction and was indexed as a body-centered tetragonal (bct) lattice; it is also isomorphous with ZnH_2. However, several weak maxima were observed in the X-ray diffraction pattern that were presumably due to unidentified impurities. An X-ray diffraction study by Korst (1962) examined sub-stoichiometric samples of thorium hydride in the overall composition range $ThH_{1.93}$ to $ThH_{1.73}$. Samples richest in hydrogen ($ThH_{1.93}$ and $ThH_{1.88}$) gave diffraction patterns corresponding to the bct lattice of Rundle *et al*., while the other samples ($ThH_{1.84}$, $ThH_{1.79}$, and $ThH_{1.73}$) contained bct lines as well as face-centered cubic lines in their diffraction patterns. As a result, Korst reindexed all samples as face-centered tetragonal, for which the preferred setting is body-centered tetragonal.

The higher thorium hydride, Th_4H_{15}, was studied by X-ray diffraction and assigned a bcc lattice based on a H/Th ratio of 3.62 (representing the lower limit due to impurities) (Zachariasen, 1953). The structure of Th_4H_{15} was also confirmed by Korst (1962) with a H/Th ratio as high as 3.73.

(*ii*) *Protactinium*

X-ray diffraction studies of the complicated Pa–H system revealed the existence of four protactinium hydride phases during the hydriding process as a function of temperature and pressure. Phase I is present in mixtures with Phase II (>500 K) or Phase IV (<500 K) at H/Pa ratios less than 1.3 and has a body-centered tetragonal structure. Phase II exists solely at temperatures above 500 K in the range corresponding to Pa_3H_4–Pa_3H_5 and has a fcc structure. After a narrow two-phase region above 500 K, Phase III becomes dominant with a wide

composition range corresponding to $2.0 \leq H/Pa \leq 3.0$. This phase has a cubic structure that is isostructural with β-UH_3, which will be described later. Phase IV forms rapidly below 500 K and exhibits an extremely wide composition range corresponding to $1.3 \leq H/Pa \leq 3.0$. This phase also has a cubic structure and is isostructural with α-UH_3 (Ward *et al.*, 1984).

(*iii*) *Uranium*

Two crystalline modifications of uranium trihydride have been characterized and are denoted α-UH_3 and β-UH_3. The first to be discovered was the β-form of the trihydride and was studied using both X-ray (Rundle, 1947) and neutron diffraction (Rundle, 1951). Neutron diffraction of UD_3 shows that each hydrogen atom lies in a distorted tetrahedron, surrounded by four uranium atoms at a distance of 2.32 Å. There are two types of uranium atoms in the lattice; each is surrounded by 12 hydrogens at this distance. Uranium atoms of the first type are surrounded by hydrogen atoms at the corners of an icosahedron (of T_d symmetry), while the uranium atoms of the second type are surrounded by sets of three hydrogen atoms, each forming the face of a different icosahedron. The absence of metallic U–U bonds indicates that the structure is held together solely by U–H interactions.

The less stable α-UH_3 was structurally characterized in 1954 and was found to be a metastable form of UH_3.The crystal structure of α-UH_3 is simple cubic with a lattice parameter of 4.160(5) Å and has U–H distances identical to the β-form. Interestingly, the reaction of hydrogen with uranium powder at the lowest temperatures (–80°C) produced mixtures of the α- and β-forms with the greatest percentage of α-UH_3. Heating of mixtures of known composition at 250°C resulted in total conversion to the β-form, but heating of the same mixture at 100°C resulted in no change in the diffraction pattern. Thus, the appearance of the α-form is only by virtue of it being formed more rapidly than it decomposes at low reaction temperatures (Mulford *et al.*, 1954).

(*iv*) *Transuranium*

The Np–H and Pu–H systems are the most thoroughly studied of the transuranium hydride systems. Two studies of the Np–H system have been performed, the latter of which used ultra-pure metal to confirm the existence of two structural forms, a cubic form and a hexagonal form as well as a two-phase region. An unusually sharp phase boundary is observed at a H/Np ratio of 2.13 marking the disappearance of neptunium metal. At temperatures below 400°C and a H/Np ratio above about 2.3, a cubic region is observed where the dihydride lattice expands upon addition of hydrogen, a phenomenon which has not been observed in any other systems. The transition to a hexagonal/cubic two-phase system occurs at a H/Np ratio of about 2.6, followed by a very narrow hexagonal NpH_{3-x} region, both of which were only observed upon dehydriding. Increasing the H/Np ratio to 3.0 resulted in a hexagonal trihydride

structure with very weak indications of cubic artifacts due to decomposition (Mulford and Wiewandt, 1965; Ward *et al.*, 1987).

The Pu–H system is very complex. A recent study by Haschke *et al.* (1987) indicated the existence of five phases in the range $1.9 \leq \text{H/Pu} \leq 3.0$ during the dehydriding process as a function of temperature. At lower temperatures (75–100°C), only the cubic (fcc) dihydride exists for H/Pu values less than 2.7. In the range of $2.7 < \text{H/Pu} < 2.9$, a two-phase region exists that has both cubic and hexagonal (hcp) structural features. In the small region of H/Pu values between 2.9 and 2.95, only the hexagonal trihydride is present, but the region from 2.95 to 3.0 has not been structurally characterized. A neutron diffraction study describing the occupancy of hydrogen atoms in tetrahedral versus octahedral sites is also described. See Chapter 7, especially section 7.8.1 of this work, for further discussion of Pu hydrides.

X-ray diffraction studies of the americium–hydrogen system revealed both fcc AmH_{2+x} and a hexagonal AmH_3 phases, thus resembling the Np–H and Pu–H systems. The cubic dihydride was observed until a composition of $AmH_{2.7}$ was reached, after which a transition to the hexagonal AmH_3 occurred. As in the Pu–H system, the lattice constant decreases in the cubic region as hydrogen content increases (Olson and Mulford, 1966; Roddy, 1973).

Curium and berkelium hydrides, like their transuranium predecessors, also exhibit both fcc MH_{2+x} (dihydride) and hexagonal MH_3 phases (Gibson and Haire, 1985a,b). Structural data on the cubic californium dihydride has also been collected, but a trihydride has not yet been observed (Gibson and Haire, 1987).

(b) Borohydrides

The limitations of single-crystal X-ray diffraction techniques were evident in the study of $U(BH_4)_4$ as evidenced by an inherent inability to locate hydrogen atoms against the extreme electron density of the actinide (Bernstein *et al.*, 1972a). This problem was easily overcome with neutron diffraction (Bernstein *et al.*, 1972b). Whereas X-ray diffraction only revealed the interaction of uranium with boron atoms of the four bridging and two terminal groups, neutron diffraction data showed that, in actuality, the four bridging BH_4^- groups each donate two hydrogen atoms to the uranium polyhedron (resulting in a helical polymer), and the terminal groups donate three hydrogen atoms, resulting in a uranium coordination number of 14.

Similar borohydride compounds with dimethyl ether, $U(BH_4)_4 \cdot O(CH_3)_2$, and diethyl ether $U(BH_4)_4 \cdot O(C_2H_5)_2$ (Fig. 22.4), show slight variations in the structural trends due to metal–ether bonding. In both cases, the coordination number of 14 is maintained due to 13 hydrogen atoms (4 bridging, 9 terminal) and one ether oxygen atom contributing to the coordination polyhedron (Rietz *et al.*, 1978a). A coordination number of 14 was also observed in the borohydride/tetrahydofuran (THF) compound, $U(BH_4)_4 \cdot (OC_4H_8)_2$ due to 12 hydrogen atoms from borohydride and two oxygen atoms from THF. This is a unique

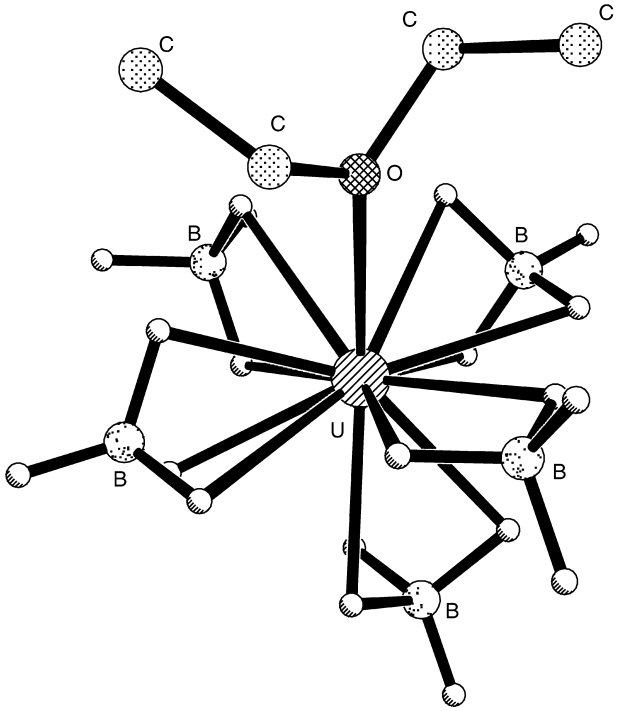

Fig. 22.4 *Crystal structure of* $U(BH_4)_4 \cdot O(C_2H_5)_2$ *with ether hydrogen atoms omitted* (*Rietz* et al., 1978*a*).

example in which all the borohydride groups are terminal, resulting in a monomeric solid state complex (Rietz *et al.*, 1978b). Interestingly, coordination numbers of 13 and 14 are observed for two different uranium atoms in the solid state structure of $U(BH_4)_4 \cdot (n\text{-}C_3H_7)_2$, resulting in an unsymmetrical dimer (Zalkin *et al.*, 1978a).

The stability of the $An(BH_4)_4$ (where An = Th, Pa, U, Np and Pu) compounds of the actinides decreases going from thorium to plutonium; the latter two decompose readily. Structural analyses using X-ray powder diffraction indicate that the Th, Pa, and U compounds are isomorphous tetragonal polymers. The Np and Pu compounds are also isomorphous, but have a different tetragonal structure and are monomeric in the solid state (Banks *et al.*, 1978).

(c) Borides, carbides, and silicides

The structures for actinide borides, carbides, and silicides are summarized in Table 22.7. In general, borides, carbides, and silicides are less chemically reactive relative to the hydrides and are refractory materials, enabling their consideration as nuclear fuels (Naito and Kamegashira, 1976). In general,

their stoichiometries are highly varied. The monocarbides, AnC, are semi-metallic and primarily ionic, but with supernumerary electrons in a delocalized conduction band.

Actinide borides (in actuality, metal borides in general) are interstitial compounds through inclusion of the small boron atoms into the lattice holes of the metallic structure which becomes expanded, but maintain their simple structure. Metal borides are characterized by the fact that boron atoms can form direct B–B bonds in the lattice (Vegas *et al.*, 1995). This catenation increases with the concentration of boron atoms in the lattice, where the boron atoms rest at the centers of trigonal prisms of metal atoms (Greenwood and Earnshaw, 2001). Structural details of metal diborides, tetraborides, and hexaborides where the structure of the parent metal is retained are described elsewhere (Vegas *et al.*, 1995).

Actinide borides all contain either two- or three-dimensional lattices of covalent B–B bonds with lengths from 1.72 to 1.83 Å and these bond lengths are typically invariant with respect to changes in the metal atom type. The actinide–boron bonds show a range of distances depending on the crystal structure. They appear to adjust to the more rigid framework of the boron atoms and can be found in several compositions. The hexagonal UB_2 has been characterized by X-ray diffraction (Brewer *et al.*, 1951; Dancausse *et al.*, 1992). The structure contains triangular nets of boron atoms that alternate with similar layers of uranium to form a hexagonal stacking sequence. Alternatively, the structure can be described in terms of boron atoms at the center of trigonal prisms of uranium atoms. Thus, each uranium atom has 12 boron neighbors (Post *et al.*, 1954). The formation of AnB_4 is common and, as detailed for UB_4, the synthesis can be achieved through several methods, including floating zone melting, the tri-arc Czochralski method, and from a molten metal flux (Menovsky *et al.*, 1984). Like ThB_4, the structure of UB_4 consists of B_6 octahedra linked along the *z*-axis and joined in the *xy* plane by pairs of B_2 atoms. The resulting three-dimensional structure has tunnels along the *z*-axis that are filled by metal atoms; thus the B_6 and B_2 units are surrounded by metal cubes and metal trigonal prisms, respectively. Each metal has 18 nearest boron neighbors (Vegas *et al.*, 1995).

The structure of ThB_6 is a three-dimensional array of interconnected B_6 octahedra with An atoms in the lattice holes, forming a primitive cubic structure

expanded by the B_6 clusters; this gives Th a coordination number of 24. The An–An distances in AnB_6 usually are similar to the An–An bond distances in the parent metal. Dodecaborides, AnB_{12}, can be described as a cubic closest packed structure of B_{12} units with actinide cations located in the octahedral lattice holes. The metal is coordinated with 24 boron atoms (Vegas *et al*., 1995).

Heating AnO_2 with excess carbon usually leads to the formation of AnC_2, which may also be prepared by direct reaction of the metal with carbon (Troost, 1893). Three polymorphs of ThC_2 have been detected using both X-ray and neutron diffraction: monoclinic α-ThC_2 at room temperature (Hunt and Rundle, 1951; Bowman *et al*., 1968), tetragonal β-ThC_2 at temperatures between 1430 and 1480°C, and cubic γ-ThC_2 at temperatures above 1480°C (Bowman *et al*., 1968). The dicarbide of uranium has two polymorphs. The α-form is tetragonal (CaC_2-type) at 1700°C and differs from the tetragonal β-form of thorium dicarbide. The β-form of uranium dicarbide is cubic at 1900°C and is analogous to γ-ThC_2 (Bowman *et al*., 1966). The α- and β-forms of PuC_2 are tetragonal (Chakraburtty and Jayadevan, 1965) and fcc (Harper *et al*., 1968), respectively. The tetragonal form adopts the CaC_2 structure type. PaC_2 (Lorenz *et al*., 1969) and NpC_2 (Sheft and Fried, 1953) have been observed with cubic and tetragonal structures, respectively. Careful control of the conditions for preparing AnC_2 can also be used to produce AnC. Structural information on AnC and An_2C_3 structures can be located in Table 22.7.

Of the actinide silicides, the uranium and thorium compounds are the most thoroughly characterized. The α-form of $ThSi_2$ was first identified in 1942 (Brauer and Mitius, 1942); the β-form readily transforms to α-$ThSi_2$ above 1350°C, and is reversible below 1250°C. A defect structure of the non-stoichiometric composition $ThSi_{1.67}$ is also known (Brown, 1961). The structure of USi was the most recent to be determined. Le Bihan *et al*. (1996) describe the synthesis of USi and assign a tetragonal symmetry to this compound despite previous reports of an orthorhombic cell. The unit cell has 68 uranium atoms. The plutonium–silicon binary system contains at least five different compounds, with Pu_5Si_3 being one of the few actinide silicide structures determined from single crystal X-ray diffraction (Cromer *et al*., 1964). The structural determination of AmSi and $AmSi_2$ was first reported by Weigel *et al*. (1984) using X-ray powder diffraction. Further work produced a range of americium silicides between room temperatures and 900°C. Curium silicides were first prepared by Weigel and Marquart (1983) through the reduction of CmF_3 with stoichiometric amounts of elemental Si at 1260°C. The X-ray diffraction data was compared to X-ray data from known analogous compounds of uranium, neptunium, plutonium, and americium. However, the authors caution that, because of the use of ^{244}Cm in the structures, the large amount of self-irradiation that occurs can destroy the lattice and cause inaccuracies due to broadening of and intensity changes in the X-ray lines, although the destruction could be reduced by a factor of 20000 if ^{248}Cm were used in its place (Weigel and Marquart, 1983).

22.3.5 Pnictides and chalcogenides

Actinide pnictides (compounds with N, P, As, Sb, and Bi) and chalcogenides (compounds with S, Se, and Te) are of interest to solid state chemists because these compounds display interesting electronic properties based upon the degree of localization or delocalization of the 5f electrons, resulting in compounds that are not purely ionic. In most cases, the delocalized nature of the 5f electrons in thorium through plutonium (although the transuranium elements become weakly delocalized) allows them to participate in bonding, while the localized nature of these electrons in americium and beyond makes them non-bonding (Damien *et al.*, 1986). In general, the nature of the bonding in these compounds is considered to be semimetallic.

For example, the monopnictides are face-centered cubic (fcc) compounds with lattice parameters decreasing from Th to U, increasing through Cm, and then decreasing again (Damien and de Novion, 1981). This behavior reflects metallic character in ThN, delocalized 5f electrons in UN, less delocalization in NpN, PuN, and AmN, and localized lanthanide-like behavior in CmN and BkN (due to the prevalence of the trivalent oxidation state in the later actinides). Similar behavior is observed in other pnictides; when there is a direct comparison with lanthanide compounds, transamericium compounds show slightly larger lattice parameters than do isoelectronic lanthanides. The delocalized nature of UN, NpN, and PuN 5f electrons is indicative of band formation and metallic conduction. The variation in lattice parameters of monochalcogenides follows a similar trend, but transcurium elements are unknown.

Several structural lattice types are common within these compounds. A list of known actinide–pnictide and actinide–chalcogenide compounds are provided in Tables 22.8 and 22.9, respectively.

The majority of the structures listed in these tables were determined by X-ray powder diffraction (lattice parameters and structural type) because the compounds are sensitive to oxidation in air, are unstable at high temperature due to the considerable partial pressures of the nonmetal elements over the crystalline phases, and have high chemical reactivity at elevated temperatures. Common methods used for growing single crystals of the monopnictides involve considerable difficulties, including selecting sufficiently inert materials for the high-temperature sample container. While some single crystals have been grown for certain compounds in both classes, little has been done in terms of structure determination. Efforts to facilitate the synthesis have been detailed by Horyn *et al.* (1983).

The structural types adopted by actinide pnictides and chalcogenides are quite diverse. All monopnictides and monochalcogenides are NaCl fcc structures except for ThTe which has a CsCl structure. A thorough summary of the structural types of higher pnictides and chalcogenides is available (Damien *et al.*, 1986). Some interesting examples include the body-centered cubic (bcc) form of Th_3P_4

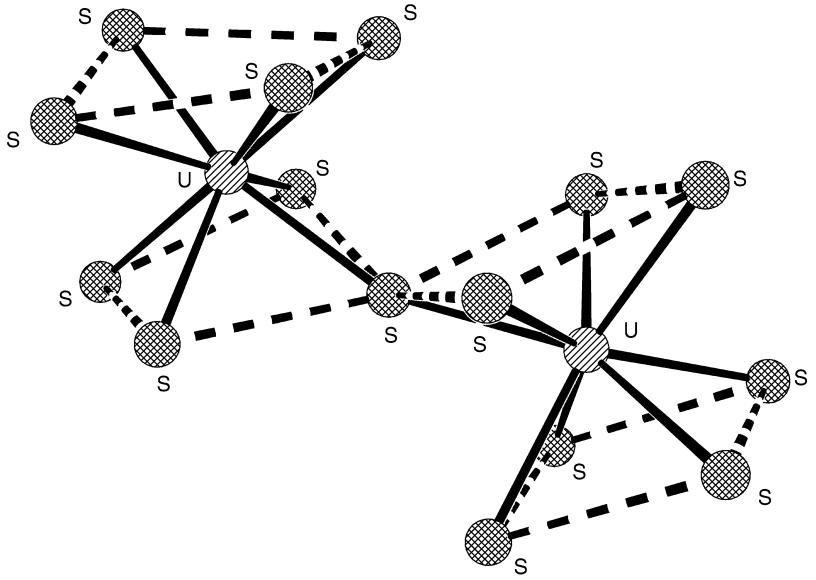

Fig. 22.5 *The two crystallographically independent uranium centers in the crystal structure of α-US_2. Dashed lines are used to delineate square antiprisms* (*Noël and Le Marouille,* 1984).

and the reverse structure, anti-Th_3P_4, adopted by pnictides such as Pu_4Sb_3 and Am_4Sb_3, which are different from hexagonal U_4Sb_3. The dichalcogenides are characterized by a variety of sub-stoichiometric phases that can either crystallize in different forms (i.e., tetragonal $PuS_{1.9}$ vs monoclinic PuS_2) or retain their structures (i.e., transuranium ditellurides). Fig. 22.5 shows the crystal structure of the α-form of the dichalcogenide, US_2. Finally, the sesquichalcogenides (An_2X_3) can take on up to five polymorphic forms, including α (orthorhombic), β (orthorhombic), γ (body-centered cubic), η (orthorhombic), and ξ (orthorhombic). Interestingly, berkelium is the first transuranic element to exhibit the ξ-type modification and an identical $\eta \rightarrow \xi$ transition occurs in the lanthanides at terbium, the homolog of berkelium (Damien *et al.*, 1979b). The existence of the β-modification in the actinides, although widely reported, may in fact be an oxychalcogenide (Damien *et al.*, 1986).

22.3.6 Halides and oxyhalides

The halides are the most widely examined of the actinide compounds from the point of view of structural determination. A review by Taylor (1976) noted that over 70 binary actinide halides, 60 actinide oxyhalides, and 70 binary

transition metal fluorides were known as of 1976. Despite the large number of compounds, their structural study is simplified by the isostructural nature of the series due to common structural types. Thus, powder diffraction data are often sufficient for obtaining adequate structural information about these compounds.

The bonding in actinide halides is largely ionic in nature. In general, the structures of these compounds may be approximated as consisting of positive actinide cations surrounded by negative anions. The shape of the anionic polyhedron around the actinide cation is controlled by many factors, including significant size effects. For a given oxidation state of the metal, coordination number usually decreases in the order F > Cl > Br > I due to increasing size of the anion. In addition, coordination number for a given ligand (i.e., F) typically increases as the oxidation state of the metal decreases due to size effects as in UF_6 (CN = 6) and UF_3 (CN = 11). This variability in size results in a large number of potential polyhedral types, significantly more diverse than those observed in transition metal halides. Further comprehensive structural reviews on actinide and lanthanide halides (Brown, 1968) as well as actinide fluorides (Penneman *et al.*, 1973) are available elsewhere. Important structural types and tables of known structures will be described herein.

In addition to size effects based on ligand type and metal oxidation state, clear trends are often also observed due to the actinide contraction. As one moves from left to right across the actinide series, the cation becomes smaller, resulting in an increasing occurrence of actinide halide polyhedra of lower coordination number. When polymorphism is observed for a given element, the high-temperature polymorph is typically the one of lower coordination number due to the generation of a more open lattice structure. Polymorphism is more common in the lower oxidation states due to larger size of the cation and enhanced ionic bonding (Taylor, 1976).

Dihalides are known for only a few of the actinides due to the instability of the An^{2+} oxidation state. Thorium diiodide was first prepared by the reaction of ThI_4 with Th metal at elevated temperatures and characterized in an X-ray powder pattern by Clark and Corbett (1963). A subsequent single-crystal X-ray diffraction study by Guggenberger and Jacobson (1968) confirmed the prediction by Clark and Corbett that the compound is not a true Th(II) salt, but rather contains Th(IV) with two supernumerary electrons. Thus, ThI_2 should be formulated as $Th^{4+}(I^-)_2(e^-)_2$. The structure contains four two-dimensionally infinite layers that alternate between trigonal prismatic and trigonal antiprismatic layers.

Americium dichloride, dibromide, and diiodide, each of which was prepared by reacting americium metal with the appropriate mercuric halide, have also been indexed using X-ray diffraction. The chloride and bromide belong to orthorhombic and tetragonal crystal systems, respectively (Baybarz, 1973b). The diiodide, AmI_2, has a monoclinic structure (Baybarz *et al.*, 1972b). Some

dihalides of californium(II) have also been characterized; $CfBr_2$ (Peterson and Baybarz, 1972) and CfI_2 (Hulet *et al.*, 1976) are tetragonal and hexagonal, respectively.

The actinide trihalides are the most structurally complete series of all the actinide halides and they form a series of compounds showing strong similarities to the lanthanide trihalides. The trifluorides (through curium) exhibit a nine-coordinate LaF_3-type structure; however, berkelium trifluoride is dimorphic with its low-temperature modification being the eight-coordinate YF_3-type (Brown, 1973). The same type of change occurs in californium trifluoride above 600°C (Stevenson and Peterson, 1973). An analogous structural change occurs in the lanthanide trifluorides between promethium and samarium (Thoma and Brunton, 1966). These structural observations have been related to the actinide contraction in a paper by Brown *et al.* (1968a).

The actinide trichlorides follow a similar trend. At californium, there is a structural change as a consequence of the actinide contraction. The earlier actinides possess the nine-coordinate UCl_3 structure type. Californium trichloride is dimorphic and exhibits both a nine-coordinate UCl_3 modification, and an eight-coordinate $PuBr_3$-type modification. The structural change observed in the trichlorides occurs earlier in the tribromides; Ac through α-$NpBr_3$ are nine-coordinate UCl_3 types, while β-$NpBr_3$ through $BkBr_3$ are eight-coordinate $PuBr_3$ types. The triiodides are quite different altogether. The triiodides from protactinium through americium (α-modification) are $PuBr_3$-type structures, while the compounds from americium (β-modification) through californium are six-coordinate BiI_3-type structures (Brown, 1973). The trichlorides, tribromides, and triiodides are also moisture-sensitive materials and easily form hydrated compounds. The trihalides of the actinides are listed in Table 22.10.

The actinide tetrafluorides (Th–Cf) have been the most extensively characterized class of tetrahalides due to their isostructural nature (all are monoclinic); each eight-coordinate actinide is surrounded by a square antiprism of fluorine ligands (Keenan and Asprey, 1969). Structural details of the remaining tetrahalides are far less available (Table 22.11). The tetrachlorides (Th through Np) are also isostructural and have tetragonal crystal lattices. In $ThCl_4$, thorium is eight-coordinate and the ligands are arranged in a dodecahedron around the actinide. Both β-$ThBr_4$ and $PaBr_4$ are isostructural with the tetrachlorides. Few structural details are available for α-$ThBr_4$, UBr_4, and $NpBr_4$ other than them being orthorhombic, monoclinic, and monoclinic, respectively. Of the tetraiodides, structural data are only available for ThI_4 and UI_4. The former has an eight-coordinate distorted square antiprismatic geometry, while the latter is six-coordinate octahedral (Brown, 1973).

The pentahalides are quite uncommon; the only actinide for which all four pentahalides are known is protactinium, and none are known past neptunium (only NpF_5 is known). These compounds are extremely moisture sensitive and the hydrolysis of some is further complicated by disproportionation. PaF_5 and

β-UF_5 are isostructural (Brown, 1973), while the powder data from NpF_5 appears to be similar to that of α-UF_5 (Malm *et al.*, 1993); each has tetragonal crystal symmetry. PaF_5 and β-UF_5 are both seven-coordinate with pentagonal bipyramidal geometry. The structure of α-UF_5, however, is six-coordinate and octahedral. $PaCl_5$ is also seven-coordinate with infinite chains of edge-fused pentagonal bipyramids (Fig. 22.6). Of the remaining pentahalides, α-$PaBr_5$ and UBr_5 are isostructural, β-$PaBr_5$ and α-UCl_5 (cubic close-packed) both form edge-sharing dimers, β-UCl_5 dimers are based on hexagonal close-packing of anions, and PaI_5 is believed to be structurally similar to TaI_5 (Brown *et al.* 1976; Müller, 1979). The pentahalides are listed in Table 22.12.

Some intermediate compounds of the stoichiometries An_2X_9 and An_4X_{17} have also been discovered, including Pa_2F_9, U_2F_9, U_4F_{17}, and Pu_4F_{17}. The former two compounds are isostructural with bcc symmetry. In the nine-coordinate U_2F_9, it is believed that its black color results from resonance between oxidation states four and five. The latter two compounds are structurally uncharacterized (Brown, 1973).

Structural information for only four actinide hexahalides is available (Table 22.13). The hexafluorides of U, Np, and Pu are volatile solids obtained

from AnF_4 fluorination, and UCl_6 is obtained from the reaction of $AlCl_3$ with UF_6. AmF_6 has been claimed as the result of oxidation of AmF_3 by KrF_2 in anhydrous HF at 40–60°C, although no structural data is available (Drobyshevskii *et al.*, 1980). All are powerful oxidizing agents and extremely sensitive to moisture; contact with water results in the formation of AnO_2X_2 and HX compounds. The hexafluoride of uranium is important in gaseous diffusion processes for the enrichment of uranium. The hexafluorides are isostructural compounds that form discrete octahedra, although in the case of UF_6, neutron diffraction data suggests that there are significant deviations from the ideal parameters of Hoard and Stroupe due to strong U–U repulsions (Taylor *et al.*, 1973). The hexachloride of uranium (the only other actinide hexahalide) contains a hexagonal crystal lattice with perfect octahedral geometry around uranium. It is isostructural with β-WCl_6 (Taylor, 1976).

Actinide oxyhalides of the type An(VI)O_2X_2, An(V)O_2X, An(IV)OX_2, and An(III)OX are known although less thoroughly characterized than the halides themselves. In general, the higher oxidation state compounds are favored by the early actinides, while the lower oxidation states are favored by the later actinides. The trivalent actinide oxyfluorides are limited to AcOF, ThOF, PuOF, and CfOF. With the exception of PuOF, these oxyhalides have CaF_2 fluorite-type structures with the oxygen and fluorine atoms randomly distributed in the anion sites. The PuOF lattice is a tetragonal modification of the fluorite structure, probably stabilized by excess fluoride (Brown, 1973).

The remaining trivalent actinide oxychlorides, oxybromides, and oxyiodides (where structural data are available) are strictly of the tetragonal PbFCl structure type, thus making their characterization rather straightforward. In this arrangement, the metal atom has four oxygen neighbors and five halide neighbors. It is rather remarkable that compounds formed from both large and small cations ranging in size from Ac^{3+} to Es^{3+} and anions from Cl^- to I^- can all adopt this structure type. The known compounds are listed in Table 22.14.

Tetravalent actinide oxyhalides are very limited in number; none are known beyond neptunium (Table 22.15). With the exception of $ThOF_2$, all adopt the $PaOCl_2$ structure type. This rather unusual structure consists of infinite

polymeric chains along the *c*-direction with cross-linking in the *ab* plane. The protactinium environments are diverse and can be either seven-, eight-, or nine-coordinate with three- or four-coordinate oxygen atoms. The LaF_3 structure type of $ThOF_2$ is orthorhombic but is largely structurally uncharacterized (Taylor, 1976).

The pentavalent actinide oxyhalides can be of An(v)OX_3, An(v)O_2X, or An(v)$_2OX_8$ composition. In general, structural data are few, if available at all (Table 22.16). The most thoroughly characterized of these oxyhalides are the isostructural $PaOBr_3$ and $UOBr_3$ systems. The structure of the former compound is composed of endless double chains (with random terminations) with pentagonal bipyramidal polyhedra around the Pa atoms. Four out of every five pentagonal edges of the polyhedra are shared (Brown *et al.*, 1975).

Hexavalent actinide oxyhalides are typically of the form An(VI)O_2X_2 (actinyl) or An(VI)OX_4. The actinyl fluorides, UO_2F_2, NpO_2F_2, PuO_2F_2, and AmO_2F_2, are isostructural and have the rhombohedral UO_2F_2 structure type. Here, the linear uranyl cation is surrounded equatorially by six fluorides, generating a coordination number of 8 for uranium. The U–O bond distance of 1.74(2) Å is common for the uranyl cation. Neutron diffraction of UO_2Cl_2 reveals a linear uranyl cation surrounded equatorially by five atoms, four of which are chlorides and the fifth is an oxygen atom from a neighboring uranyl group. Uranyl bromide, UO_2Br_2, is also known structurally, but the last in the series, UO_2I_2, is as of yet unknown. Known compounds are listed in Table 22.17 (Taylor, 1976).

Actinide halo-complexes containing alkali, ammonium, or other cations will not be discussed here. The reader is referred elsewhere for comprehensive reviews of structural characterizations (Brown, 1973).

22.3.6 Carbonates, nitrates, phosphates, arsenates, and sulfates

In general, a limited number of anhydrous binary compounds of actinides and these ligands are reported in the literature. This is due to the greater stability of the hydrated compounds and higher order complexes. In most examples, the common structural feature is that the anions all provide oxygen atoms that surround the actinide cation. Coordination numbers for the metal atom in these compounds can be as high as eight to 12 for tetravalent thorium, but typically decrease across the series to between six and nine due to the actinide contraction. A coordination number of six is observed in a few uranyl structures. The high coordination numbers are predominantly due to the ability of these ligands to act in both monodentate and bidentate (symmetric and asymmetric) coordination modes. Bidentate coordination is most common because of the small 'bite' distance (O $\cdots$ O distance) of the ligand.

(a) Carbonates

Structures of actinide carbonates number very few in the literature and mostly contain the actinyl cation, thus restricting ligand bonding to the equatorial region. Carbonates typically bond in a bidentate fashion, but instances of monodentate bridging carbonate are also known. Actinide carbonates are sometimes geologically occurring minerals such as rutherfordine. Rutherfordine is the naturally occurring form of the mineral UO_2CO_3 and its structure has been investigated both as the natural mineral (Christ *et al.*, 1955) and a synthetic compound (Cromer and Harper, 1955). The crystal structure of the natural mineral has reccently been refined (Finch *et al.*, 1999). In both cases, UO_2CO_3 crystallizes as an orthorhombic lattice and there are six oxygen atoms bound in the equatorial plane. Two carbonate groups act in a symmetrical bidentate fashion, while the remaining two oxygens are from monodentate carbonate groups, resulting in hexagonal bipyramidal geometry. Other instances of uranyl carbonate compounds are listed in Table 22.18. While the hexagonal bipyramidal geometry is common in several uranyl carbonates, slight differences in the U=O actinyl bond length are still observed; for example, 1.67(9), 1.79(1), and 1.80(1) Å distances are observed in UO_2CO_3, $(NH_4)_4UO_2(CO_3)_3$ (Graziani *et al.*, 1972), and $Tl_4UO_2(CO_3)_3$ (Mereiter, 1986b), respectively.

Simple carbonates of the transuranium actinyls (AnO_2^{2+}) are known for both neptunium and plutonium. NpO_2CO_3 (Thévenin *et al.*, 1986; Kato *et al.*, 1998) and PuO_2CO_3 (Navratil and Bramlet, 1973) are both isostructural with the uranium analog and have orthorhombic lattices. The tetraammonium tricarbonate compounds of neptunyl and plutonyl, $(NH_4)_4NpO_2(CO_3)_3$ and

$(NH_4)_4PuO_2(CO_3)_3$, are also isostructural with the corresponding uranium compound and crystallize in monoclinic crystal systems. Only bidentate coordination of the carbonate ion is observed. Pentavalent actinyl (AnO_2^+) carbonate compounds containing americium have also been studied; the compounds $KNpO_2CO_3$, $KPuO_2CO_3$, and $KAmO_2CO_3$ (Ellinger and Zachariasen, 1954; Keenan and Kruse, 1964) are isostructural with hexagonal symmetry.

Tetravalent thorium and plutonium carbonate compounds include $Na_6Th(CO_3)_5 \cdot 12H_2O$ (Voliotis and Rimsky, 1975b) and $Na_6[Pu(CO_3)_5]_2 \cdot Na_2CO_3 \cdot 33H_2O$ (Clark *et al.*, 1998a); the crystal structure of the latter is shown in Fig. 22.7. In both structures, the actinides are ten coordinate and all the carbonate groups are bidentate. The geometry of each has been described as a modified hexagonal bipyramid; two *trans* carbonate ligands occupy axial positions analogous to the *trans* oxo ligands in an actinyl ion, while the remaining carbonates occupy the equatorial sites, thus forming the hexagon. An example of a trivalent actinide carbonate can be seen in the structure of $Am_2(CO_3)_3 \cdot 2H_2O$ (Weigel and ter Meer, 1967).

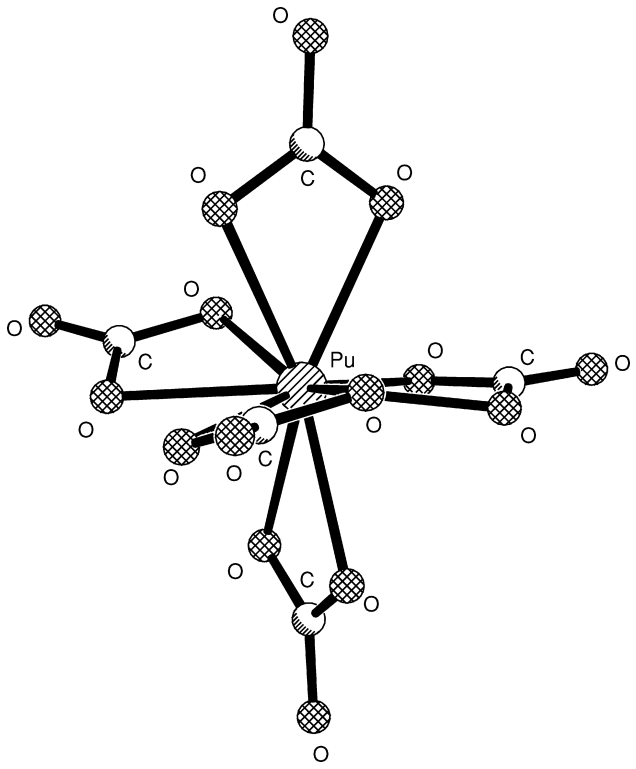

Fig. 22.7 *Coordination geometry of* $[Pu(CO_3)_5]^{6-}$ *anion* (*showing axial and equatorial carbonate ligands*) *in the crystal structure of* $[Na_6Pu(CO_3)_5]_2 \cdot Na_2CO_3 \cdot 33H_2O$ (*Clark* et al., 1998*a*).

(b) Nitrates

Structures of simple actinide nitrates containing only actinide/actinyl cations and nitrate anions are unknown. All known structures are hydrated, contain additional non-actinide monovalent or divalent cations, or contain various donor ligands. Actinide nitrate compounds are limited mainly to Th(VI) and uranyl cations, although a few neptunium and plutonium structures exist. In the tetravalent thorium and plutonium compounds, the nitrate anions are typically bidentate, thus allowing for extraordinarily high coordination numbers ranging from eight to as high as 12. In actinyl compounds, the *trans* oxo ligands enforce equatorial nitrate coordination, thus causing both bidentate as well as monodentate coordination in the case of four equatorial nitrate ligands. Hexagonal bipyramidal geometry is common in this case. Examples of actinide nitrate compounds are available from the previous edition of this work or Brown (1973).

Thorium(IV) nitrate pentahydrate has been investigated using both X-ray and neutron diffraction (Taylor *et al.*, 1966; Ueki *et al.*, 1966). The structure as determined by neutron diffraction is shown in Fig. 22.8. Four bidentate nitrate groups and three of the five water molecules are coordinated to the metal center, resulting in a coordination number of 11. Water–water and water–nitrate hydrogen bonds are significant in terms of stabilizing the overall structure, with the latter being slightly longer than the former by about 0.2 Å. The plutonium analog, $Pu(CO_3)_4 \cdot 5H_2O$, is isostructural with the thorium compound, both of which have orthorhombic symmetry (Staritzky, 1956).

The dihydrate (Dalley *et al.*, 1971), trihydrate (Hughes and Burns, 2003), and hexahydrate (Hall *et al.*, 1965) of uranyl nitrate each exhibit eight-coordinate uranium centers of hexagonal bipyramidal geometry. In each compound, both nitrates are bidentate and two waters are coordinated through oxygen. Once again, extensive hydrogen bonding is present between hydrogen atoms of water molecules and unbound oxygen atoms of the nitrate groups (Hall *et al.*, 1965; Dalley *et al.*, 1971). The U=O bond lengths are shorter in the dihydrate (1.754(4) and 1.763(5) Å) than in the hexahydrate (1.85 and 1.87 Å), presumably due to the greater effects of hydrogen bonding in the latter.

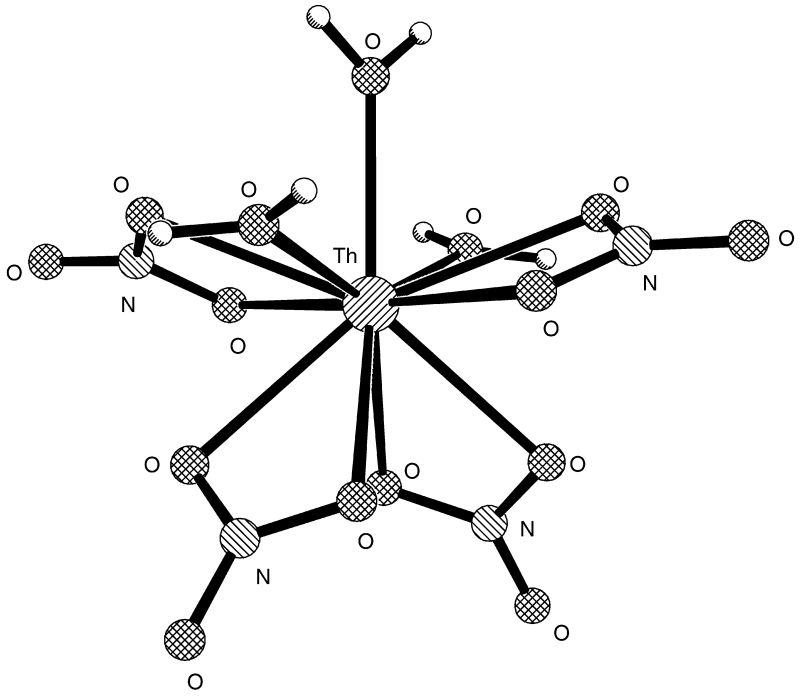

Fig. 22.8 *Coordination environment of thorium in the neutron diffraction crystal structure of* $Th(NO_3)_4 \cdot 5H_2O$ (*Taylor* et al., 1966).

Neptunyl nitrate hexahydrate, $NpO_2(NO_3)_2 \cdot 6H_2O$, has orthorhombic symmetry and appears to be isostructural with the uranium analog. X-ray powder data are also available for the compounds $NpO_2NO_3 \cdot H_2O$ and $Np(NO_3)_4 \cdot N_2O_5$, but structural details are inconclusive (Laidler, 1966).

The series of tetravalent thorium nitrates having the formula M(II)Th$(NO_3)_6 \cdot 8H_2O$ [M(II) = Mg, Mn, Co, Ni, Zn] are isomorphically related. Further studies of the Mg compound have shown that the coordination is best described by the formula $[Mg(H_2O)_6] \cdot [Th(NO_3)_6] \cdot 2H_2O$. All the nitrates bond in a bidentate fashion, leading to a coordination number of 12 for thorium (Šćavničar and Prodić, 1965). In some cases, anhydrous nitrate compounds can be obtained such as $RbUO_2(NO_3)_3$. All the nitrate groups are bidentate to the metal, thus resulting in hexagonal bipyramidal geometry around the uranium atom (Barclay *et al.*, 1965). Also included in the anhydrous uranyl compounds are $KUO_2(NO_3)_3$ (Krivovichev and Burns, 2004) and $CsUO_2(NO_3)_3$ (Zivadinovic, 1967), as well as the tetranitrate $Rb_2[UO_2(NO_3)_4]$ (Irish *et al.*, 1985).

(c) Phosphates and arsenates

Phosphate and arsenate compounds containing the following actinides have been the subject of a series of extensive articles: uranium(VI) (Weigel and Hoffmann, 1976a), neptunium(VI) (Weigel and Hoffmann, 1976b), ammonium–americyl(VI)–phosphate (Weigel and Hoffmann, 1976c), plutonium(VI) (Fischer *et al.*, 1981), americium(VI) (Lawaldt *et al.*, 1982), thorium(IV), uranium(IV), and neptunium(IV) (Bamberger *et al.*, 1984a), and plutonium(III) and plutonium(IV) (Bamberger *et al.*, 1984b). Representative examples of actinide phosphates will be presented herein (Table 22.19).

The structural chemistry of actinide phosphates and arsenates is important on a number of levels. Uranyl phosphates and arsenates in particular are found geologically in large numbers as naturally occurring minerals, which include autenite, tobernite, metazeunerite, and uranocircite. Additionally, the long-term stability of the rare-earth phosphate mineral monazite has led to studies involving the immobilization of actinides in synthetic monazites for long-term storage. Phosphate chemistry is also critically important for understanding the behavior of actinides in the environment as well as in separations schemes.

Actinide phosphate compounds typically contain the orthophosphate (PO_4^{3-}), metaphosphate (PO_3^-), or pyrophosphate ($P_2O_7^{4-}$) anions; arsenate structures are typically limited to the former type. The tetrahedral PO_4^{3-}ion lends itself to both monodentate and bidentate metal bonding, as illustrated in Fig. 22.9. The pyrophosphate anion contains two tetrahedral centers, each of which can be monodentate or bidentate. The various types of phosphate coordination modes in the solid state are exemplified in the structure of $Th_4(PO_4)_4P_2O_7$. Each heavy thorium atom is bound to eight oxygen atoms from five PO_4^{3-} groups and one $P_2O_7^{4-}$ group. One of the former groups is bidentate and the remaining four are monodentate; the pyrophosphate

group donates two oxygen atoms, one from each tetrahedral center (Bénard *et al*., 1996).

Actinide pyrophosphates can adopt two different structural modifications: the orthorhombic β-form and the cubic α-form. Structural details of the former type are scarce, but the latter modification is known for structures including the actinides Th, Pa, U, Np, and Pu. These pyrophosphates are all isostructural and lattice parameters decrease with increasing atomic number. Six oxygen atoms are coordinated to the metal center in each instance (Le Cloarec and Cazaussus, 1978). The β-UP_2O_7 modification has orthorhombic symmetry (Douglass and Staritzky, 1956). Simple metaphosphates of tetravalent Th, Pa, U, and Pu of the composition $An(PO_3)_4$ are all isostructural and have orthorhombic symmetry

(Douglass, 1962; Le Cloarec and Cazaussus, 1978). Structural details for the simple arsenates of $AmAsO_4$ and $PuAsO_4$ (monoclinic symmetry) are available elsewhere (Keller and Walter, 1965).

(d) Sulfates

Actinide sulfates enjoy a unique place in the history of nuclear chemistry; it was A. H. Becquerel who, in 1896, discovered radioactivity in the uranyl double sulfate $K_2UO_2(SO_4)_2 \cdot 2H_2O$. He simply noticed that in the absence of sunlight (actually, in the total darkness of laboratory drawer), the salt will darken a photographic plate and so must spontaneously emit its own type of radiation (Becquerel, 1896).

Additionally, sulfates have traditionally played an important role in the mining of uranium ores. Uranium is leached from crushed ores using sulfuric acid, resulting in soluble ionic species such as $UO_2(SO_4)_3^{4-}$. Despite its prevalence in actinide chemistry, structural characterizations of actinide sulfates are relatively few (Table 22.20).

Actinide sulfate compounds are usually found in hydrated form where as few as one to as many as ten water molecules are present in the structural formula.

Water molecules can be directly bonded to the metal or take on a non-bonding role in the lattice. In the case of thorium(IV) sulfates, the number of water molecules in the lattice is variable by controlling the temperature of crystallization. The octahydrate is crystallized from neutral aqueous solution at 20–25°C, lower hydrates are obtained by drying at 100–110°C, and the anhydrous form is formed at 400°C. In the octahydrate, the coordination sphere around thorium is occupied by four oxygen atoms from two chelating sulfate groups and the oxygen atoms of six water molecules, resulting in bicapped square antiprismatic geometry. These polyhedra are linked by hydrogen bonding (Habash and Smith, 1983).

Protactinium sulfates are rare, probably due to the difficulties in handling this element. One example is $H_3PaO(SO_4)_3$ which has hexagonal symmetry, but decomposes to amorphous $H_3PaO(SO_4)_3$ at 375°C (Bagnall *et al.*, 1965). Uranyl sulfate structures, however, are more common because they constitute a widespread class of minerals. For example, in the cluster compound $Na_{10}[(UO_2)(SO_4)_4](SO_4)_2 \cdot 3H_2O$, the $[(UO_2)(SO_4)_4]^{6-}$ anion (Fig. 22.10) is composed of a uranyl pentagonal bipyramid that shares an edge with one sulfate tetrahedron and vertices of three tetrahedra (Burns and Hayden, 2002). Polymorphism is displayed in $2UO_2SO_4 \cdot 7H_2O$; the α and β forms are similar, but differ in the

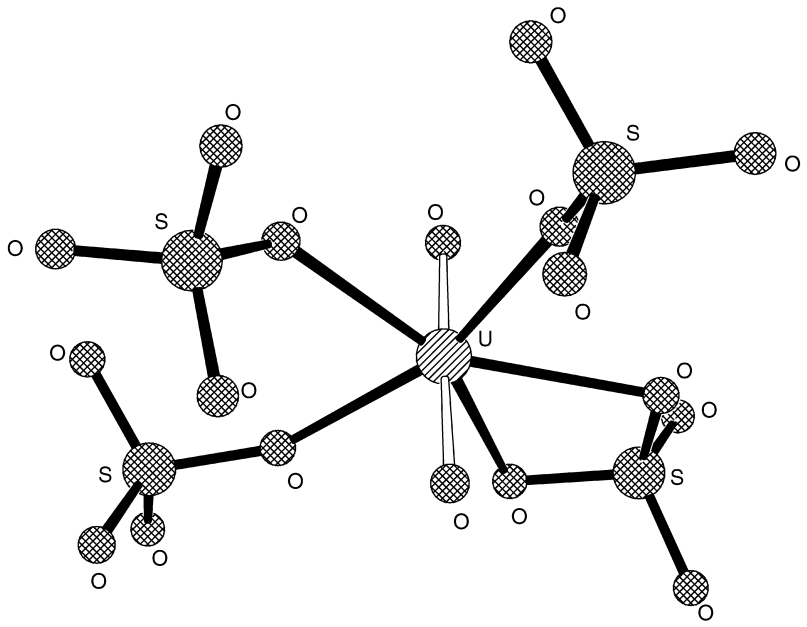

Fig. 22.10 *The uranyl sulfate cluster in the crystal structure of* $Na_{10}[(UO_2)(SO_4)_4](SO_4)_2 \cdot 3H_2O$ (*Burns and Hayden,* 2002).

way in which their chains are repeated and the orientation of their polyhedra (Zalkin *et al.*, 1978b).

Examples of neptunium and plutonium sulfate structures are also available. The compound $(NpO_2)_2SO_4 \cdot H_2O$ is a rare example of cation–cation interactions. Each linear NpO_2^+ unit is coordinated equatorially by three oxygen atoms from three sulfate groups as well as two oxygen atoms from two neighboring neptunyl groups, resulting in pentagonal bipyramidal polyhedra (Grigor'ev *et al.*, 1993a). Higher hydrated forms are also known, depending on the conditions of preparation (Budantseva *et al.*, 1988). The hexavalent actinide compounds of the composition $AnO_2SO_4 \cdot 2.5H_2O$ (An = U, Np, Pu) are isostructural with monoclinic symmetry. Two structural modifications are known for $Pu(SO_4)_2 \cdot 4H_2O$ (α and β), both of which are monoclinic; the latter modification has a lattice constant (*a*-axis) nearly twice as large as the former (Weigel and Hellmann, 1986).

The compound $Am_2(SO_4)_3 \cdot 8H_2O$, a rare americium sulfate, was studied using single-crystal X-ray diffraction. Each trivalent americium atom is coordinated by four oxygen atoms from four sulfate groups and by four water molecules; the resulting polyhedron is intermediate between an antiprism and a dodecahedron. Extensive hydrogen bonding links the polyhedra and the structure is isomorphous with the neodymium analog (Burns and Baybarz, 1972).

22.4 COORDINATION COMPOUNDS

Structural studies of coordination compounds of actinides in the solid state are quite numerous and diverse. Crystallographic information generated from X-ray and neutron diffraction techniques regarding the structural details of such compounds is too extensive to be comprehensively discussed herein. Thus, the following section comprising actinide coordination compounds will focus on two major areas: (1) structures containing carboxylic acid-derived acyclic ligands and (2) structures containing macrocyclic ligands including crown ethers, calixarenes, and porphyrins/phthalocyanines. Organoactinide compounds will be treated separately.

Actinide complexes with acyclic ligands are by no means limited to those involving carboxylic acids; a large number of crystal structures are available for those containing amides, phosphine oxides, and carbonyls, just to name a few. Due to the great diversity in this area, carboxylic acids were chosen owing to their extensive employment as actinide extraction ligands, ion-exchange media, and as agents in other practical applications. Their ability to act in both monodentate and bidentate modes and yield complexes of high coordination number has resulted in a plethora of structural characterizations, which will be illustrated in Section 22.4.1.

Macrocyclic ligands, including crown ethers, calixarenes, and porphyrins/phthalocyanines, have received a lot of attention due to their cyclic arrangement of donor atoms (including oxygen, nitrogen, and sulfur) for coordination to both lanthanide and actinide cations. The ability to vary the ring size of the macrocycle, as well as to alter the identity of the donor atoms (to tune hard/soft properties), has resulted in the generation of a large number of crystal structures that exhibit tremendous diversity, particularly with regard to the role of counter-ions for the generation of inclusion versus exclusion complexes. Examples of structurally characterized actinide/macrocycle complexes will be presented in Section 22.4.2.

Organoactinide structures involving cyclopentadienyl ligands, their derivatives, and related ligands, on account of their distinction from both acyclic and macrocyclic actinide complexes, will be the focus of Section 22.5. In addition, the chemistry of organoactinide complexes, including both synthesis and characterization, is the focus of Chapter 25.

22.4.1 Complexes with carboxylic acids

Carboxylic acids typically form stable coordination complexes with the large actinide ions via monodentate or bidentate donation through the carboxylate oxygen atoms, yielding complexes of high coordination number. Representative carboxylate ligands include monocarboxylate species such as formates, acetates, glycolates, and salicylates, dicarboxylate species such as oxalates and malonates, and pyridine or benzene derivatives containing three or more carboxylate functionalities. Several coordination modes are possible in carboxylic acid complexes with actinides, the major types of which are represented in Fig. 22.11 (for monocarboxylic acids). Carboxylic acid ligands can engage in both monodentate and bidentate coordination modes, as well as provide more than one bonding site per molecule. These features make carboxylic acids highly versatile ligands as evidenced in the high number of structural characterizations that have been made (Tables 22.21–22.23). Structural characteristics of representative examples will be described.

While a large number of carboxylic acid ligands exhibit the potential to chelate actinide cations, crystal structures have been most commonly determined of formates, acetates, oxalates, and malonates. This is due to the small O···O 'bite' distances and the overall relative compactness of the molecules, resulting in easy packing in the crystal lattice. Large or bulky chains attached to the (mono- or di-) carboxylate functionality tend to make crystallization and subsequent structural characterization difficult (Casellato *et al.*, 1978).

Formates are the simplest type of carboxylic acid, where the the R_1 group is a hydrogen atom. Actinide formates are typically prepared in solution using formic acid or a formate salt. Uranium(VI) diformate monohydrate crystallizes in the orthorhombic space group with the uranyl ion coordinated equatorially by five oxygen atoms, resulting in pentagonal bipyramidal geometry around the

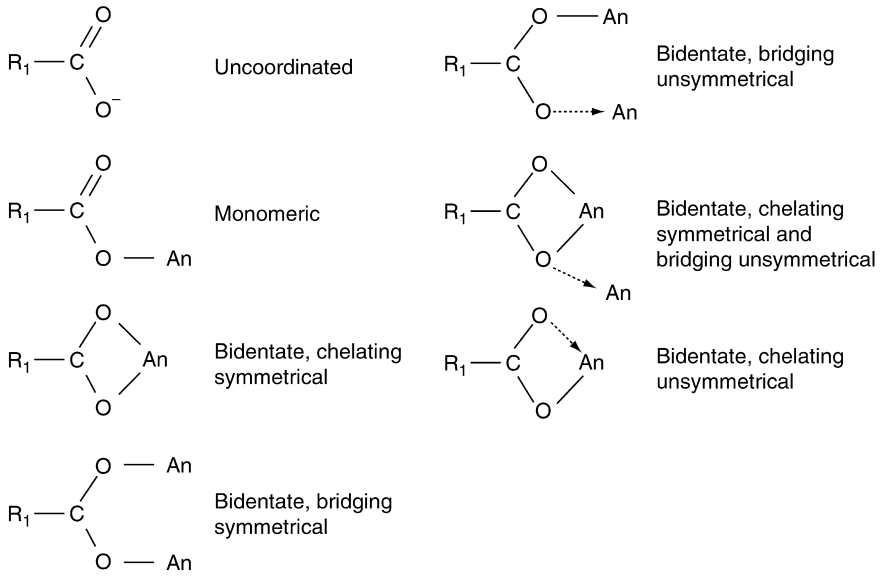

Fig. 22.11 *Summary of possible monocarboxylic acid bonding modes. R_1 can be a hydrocarbon radical or a proton* (*Casellato* et al., 1978).

uranium atom. The equatorial coordination is assigned to one oxygen atom from bound water and four oxygen atoms from the formate ligands, with these nodes forming infinite formate–uranium–formate chains, further stabilized by hydrogen bonding through bound water (Mentzen *et al.*, 1977).

The monoclinic $NaUO_2(HCOO)_3 \cdot H_2O$ lattice contains an interesting combination of structural motifs with two distinct types of formate bonding (Fig. 22.12). First, the uranyl motif contains equatorial pentagonal coordination through five formate oxygen atoms. The two uranyl oxygen atoms reside axially, resulting in a pentagonal bipyramid about uranium. The second motif has hexa-coordination around Na^+ using two oxygen atoms from water and four from formate ligands. Each uranium polyhedron is formed from three types of formate ligands. First, one type of formate bridges adjacent uranium centers, resulting in infinite formate–uranium–formate chains. Second, two infinite chains are bridged by a second type of formate, resulting in a uranium polyhedra 'layer'. Third, layers of sodium polyhedra and uranium polyhedra are bridged by a third type of formate ligand, resulting in an ..ABABA.. layering scheme (Claudel *et al.*, 1976, Mentzen, 1977).

Formate complexes with Th(IV) have also have been structurally investigated. For example, $Th(HCOO)_4 \cdot 3H_2O$ contains a central thorium atom with coordination number of ten, formally described as $[Th(HCOO)_4 \cdot 2H_2O]H_2O$. Each thorium is coordinated to eight oxygen atoms of eight separate bridging formate

ligands, resulting in a distorted Archimedic antiprism. The remaining two coordination sites are occupied by oxygen atoms from two water molecules located in the square faces of the antiprism (Chevreton *et al.*, 1968).

Acetate ligands are carboxylates where R_1 is a methyl group, making them compact for packing in a crystal. The uranyl acetate dihydrate lattice contains a uranyl cation equatorially coordinated to an oxygen from a water molecule, two oxygen atoms from a chelating acetate ligand, and two oxygen atoms from two bridging acetate ligands, resulting in a distorted pentagonal bipyramidal geometry around the uranium center. The bridging acetates link the uranium centers together to form propagating chains, and adjacent chains are associated with one another through a lattice water molecule; this water participates in hydrogen bonding to the bound water of one chain and two acetate ligands of the neighboring chain (Howatson *et al.*, 1975).

Acetate complexes with uranyl incorporating phosphine oxides have also been structurally characterized and are significant with regards to separations processes. Certain types of phosphine oxides exhibit functional extractive abilities for actinides such as uranium and plutonium, making them invaluable for remediating acidic media and waste streams. The compound $UO_2(CH_3COO)_2(Ph_3PO)_2$ and the related arsine oxide analog $UO_2(CH_3COO)_2(Ph_3AsO)_2$ were found to be isomorphous by single-crystal X-ray diffraction (Graziani *et al.*, 1967; Bandoli *et al.*, 1968). The related compounds $[UO_2(CH_3COO)_2(Ph_3PO)]_2$ (Panattoni *et al.*, 1969) and $[UO_2(CH_3COO)_2(Ph_3AsO)]_2$ (Bandoli *et al.*, 1968) have also been isolated. The former structure consists of two seven-coordinate uranium centers. Each uranium has two axial uranyl

oxygen atoms and pentagonal equatorial coordination provided by a chelating acetate group, two oxygen atoms from bridging acetate groups, and an oxygen atom from a triphenyl phosphine oxide moiety. It is isomorphous with the arsenic-containing analog.

An example of a pentavalent actinide complex is illustrated (Fig. 22.13) in the single-crystal X-ray diffraction structure of $BaNpO_2(CH_3COO)_3 \cdot 2H_2O$. The anion contains a linear NpO_2^+ unit surrounded equitorially by three bidentate acetate groups, resulting in a hexagonal bipyramidal geometry around the neptunium center. The Ba^{2+} cation acts a crosslinker with shared coordination between six acetate oxygen atoms of three different neptunium polyhedra and the oxygen atoms of two lattice water molecules, resulting in a dodecahderal/square antiprism polyhedron. Neptunyl Np–O bond distances are 1.85(2) Å, while $Np–O_{acetate}$ distances range from 2.52(2) to 2.56(2) Å (Burns and Musikas, 1977).

Tetravalent thorium forms an anhydrous complex with four acetate ligands, $Th(CH_3COO)_4$, that is structurally isomorphous (Eliseev *et al.*, 1967) with the uranium(IV) analog (Jelenić *et al.*, 1964). Each thorium center is ten-coordinate;

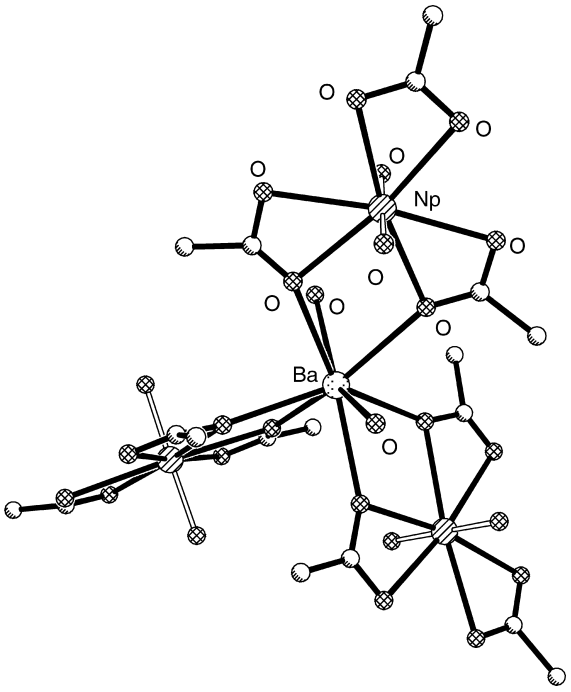

Fig. 22.13 *Crystal strucuture of $BaNpO_2(CH_3COO)_3 \cdot 2H_2O$ with hydrogen atoms omitted* (*Burns and Musikas,* 1977). *The coordinates were obtained from the Cambridge Structural Database* (*refcode BNPTAC*) (*Allen*, 2002).

eight oxygen atoms are provided by eight acetate ligands that bridge between adjacent thorium centers and the remaining two coordination sites are occupied by two of these acetate ligands acting in a tridentate manner (i.e., both oxygen atoms close to the metal center).

Dicarboxylate complexes with actinides are well studied, as evidenced by the large number of crystal structures present in the literature (Table 22.22). Crystallographic information for complexes with the simplest dicarboxylate, the oxalate ligand, is abundant, primarily due to its high affinity for actinides, the ability to form both four- and five-membered rings, and its potential to chelate in a tetradentate manner. An example of the tetradentate ability of oxalate is illustrated in $UO_2(C_2O_4) \cdot 3H_2O$. Each oxalate ligand, through its four oxygen donors, bridges two uranyl ions yielding five-membered rings; additional coordination is provided by the oxygen of a water molecule, making each uranium center hepta-coordinate and pentagonal bipyramidal. The remaining two water molecules, while not participants in direct uranium bonding, engage in hydrogen bonding to further stabilize the complex (Jayadevan and Chackraburtty, 1972).

The crystal structure of monoclinic $K_2(UO_2)_2(C_2O_4)_3 \cdot 4H_2O$ shows the association of three separate oxalate ligands with a single uranyl cation (Fig. 22.14). Each linear uranyl fragment has six oxygen atoms bound equatorially from three oxalate ligands, forming three five-membered rings, with an average

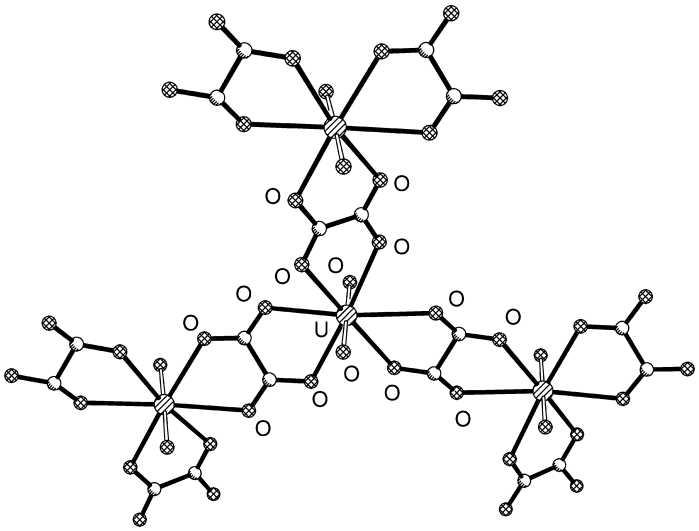

Fig. 22.14 *Crystal strucuture of anionic portion of* $K_2(UO_2)_2(C_2O_4)_3 \cdot 4H_2O$ *with* K^+, H_2O, *and hydrogen atoms omitted* (*Jayadevan* et al., 1975). *The coordinates were obtained from the Cambridge Structural Database* (*refcode KUROXT*).

U–O bond distance of 2.45(4) Å. The geometry around each uranium atom is hexagonal bipyramidal, with the equatorial hexagon being slightly puckered. Each oxalate group takes on a tetradentate role while associated with two uranyl cations, yielding infinite polymeric anions in the crystal lattice; the K^+ cations are associated with eight oxygen atoms from the oxalate ligands and the lattice water molecules within a sphere of about 3.2 Å (Jayadevan *et al.*, 1975).

Bridging oxalate coordination and the absence of uranium-bound water is observed in $K_6[(UO_2)_2(C_2O_4)_5] \cdot 10H_2O$; each uranyl cation in the dinuclear hexavalent anion is five-coordinate equatorially. Two oxalate ligands coordinate in a bidentate manner, forming two five-membered rings, and one oxalate bridges symmetrically, donating one oxygen atom to each uranium center. The pentagonal bipyramidal polyhedron around uranium has an average equatorial U–O bond distance of 2.38 Å (Legros and Jeannin, 1976).

Pyridine-2,6-dicarboxylic acid (pdca) can be multidentate through oxygen only or heteronuclear oxygen/nitrogen donation, and can form monomeric or polymeric metal-templated complexes. A repeating helical pattern is found in the single-crystal X-ray diffraction structure of $[UO_2\{C_5H_3N(COO)_2\} \cdot H_2O]_n$ where pseudo-planar pentagonal equatorial coordination around the linear uranyl ion is provided by two oxygens and one nitrogen from the pdca ligand, oxygen from a water molecule, and oxygen from a neighboring pdca ligand (Fig. 22.15). The bridging provided by the neighboring pdca ligand results in a polymeric structure that takes on a helical shape. In the crystal, all helices are of the same sense and possess a diameter of about 21 Å. Each helix is surrounded

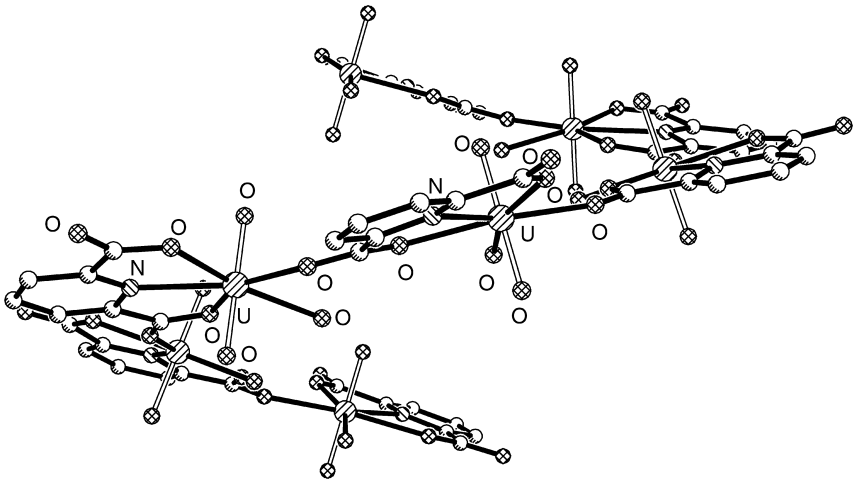

Fig. 22.15 *Crystal strucuture of* $[UO_2\{C_5H_3N(COO)_2\} \cdot H_2O]_n$ *with hydrogen atoms omitted* (*Immirzi* et al., 1975). *The coordinates were obtained from the Cambridge Structural Database* (*refcode PYDCUO*).

by six other helices that are associated with one another via hydrogen bonding between bound water and dangling C–O groups (Immirzi *et al.*, 1975).

Malonate ligands are dicarboxylates, structurally related to oxalates, where the caboxylate functionalities are joined by a methylene group. Several Th(IV) and U(VI) malonato complexes have been structurally characterized, once again taking advantage of the relatively compact nature of the malonate ligand for crystal packing. Malonate ligands have the ability to coordinate with actinides in bidentate, tridentate, and tetradentate modes, examples of which will be shown when available.

The structure of the bispiperazinium complex, $(C_4H_{12}N_2)_2[Th(CO_2CH_2CO_2)_4] \cdot H_2O$, contains an eight-coordinate thorium atom with four 1,5-bidentate malonate ligands, resulting in a monomeric anionic complex (Fig. 22.16). The geometry around the thorium is distorted square antiprismatic, with the Th–O bond distances ranging from 2.337(2) to 2.450(2) Å. The lattice water molecule is uncoordinated. The compounds $(C_2H_{10}N_2)_2[Th(CO_2CH_2CO_2)_4(H_2O)]$, $(C_4H_{12}N_2)_2[Th(CO_2CH(CH_3)CO_2)_4] \cdot 2H_2O$, and $(C_2H_{10}N_2)_2[Th(CO_2C(CH_3)_2\ CO_2)_4] \cdot 5H_2O$ have similar coordination around the thorium center with the exception that the former compound has a bound water, giving

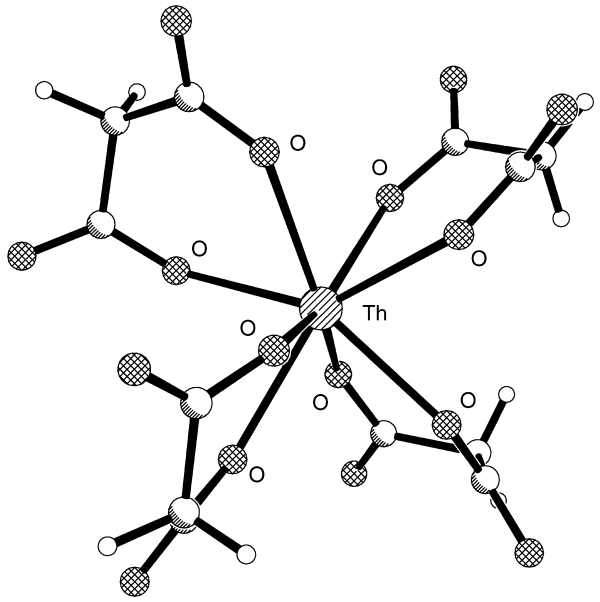

Fig. 22.16 *Crystal strucuture of anioic portion of* $(C_4H_{12}N_2)_2[Th(CO_2CH_2CO_2)_4] \cdot H_2O$ *with* $(C_4H_{12}N_2)^{2+}$ *and* H_2O *omitted* (*Zhang* et al., 2000). *The coordinates were obtained from the Cambridge Structural Database* (*refcode WONKUF*).

the thorium a coordination number of nine and a mono-capped distorted square antiprismatic geometry. The latter two structures contain methylmalonate and dimethylmalonate ligands, respectively (Zhang *et al.*, 2000).

The structure of $[U(CO_2CH_2CO_2)_2(H_2O)_3]_n$, however, contains uranium with a coordination number of nine in a mono-capped square antiprismatic geometry. The coordination sphere is achieved through two 1,5-bidentate malonate ligands, each also bridging to an adjacent uranium through a carbonyl oxygen (thus the malonate ligands are tridentate) and oxygen atoms from three water molecules. The bridging character of the malonate ligands results in the formation of infinite chains. Chelating U–O bond distances are 2.315(4) and 2.434(4) Å, while the bridging U–O distance is 2.420(4) Å (Zhang *et al.*, 2000).

Two other types of malonate binding have also been observed using single-crystal X-ray diffraction. The structure of $(C_6H_{16}N_2)[(UO_2)_3(CO_2C(CH_3)_2CO_2)_4(H_2O)_2]\cdot 3H_2O$ (involving dimethylmalonate), has two distinct uranium sites. The first site shows hexagonal bipyramidal geometry around a single uranium center from two axial uranyl oxygen atoms, two *trans* equatorial water molecules, and two equatorial 1,3-bidentate malonate ligands. The second site shows two crystallographically equivalent uranium atoms, each also with hexagonal bipyramidal geometry. This geometry results from two axial uranyl oxygen atoms, a 1,3-bidenate malonate ligand that bridges the uranium atom at the first site, and two malonate ligands in a μ_2-1,3- and 1,5-bidentate arrangement. The malonate that bridges the two uranium sites is coordinated in a bis(1,3-bidentate) manner, making the ligand tetradenate and the overall structure infinite (Zhang *et al.*, 2002b).

Higher order carboxylate ligands (tetracarboxylate and hexacarboxylate) are shown in Table 22.23, the details of which will not be discussed here.

22.4.2 Complexes with macrocyclic ligands

(a) Crown ethers

Traditional crown ethers are cyclic polyether molecules that interact with the actinide cations in one of two fashions: either through an inner-sphere coordination mode, resulting in direct metal ion inclusion into the crown ether cavity, or through an outer-sphere coordination mode involving hydrogen bonds with the uranyl cation where the metal–crown interaction results in sandwich or polymeric structures. Crown ether derivatives where oxygen has been replaced with nitrogen (azacrowns) or sulfur (thiacrowns) have also been studied, thus taking advantage of the softer character of these elements. The complexation characteristics of crown ethers depend on a variety of factors, including size of cavity (size-fitting effect), nature of the heteroatoms present, as well as the type of counter ions, all of which are critical in obtaining inclusion versus exclusion complexes.

For inclusion complexes, the diameter of the crown ether molecule, and thus the ability for an actinide cation to fit within the cavity, increases from 12-crown-4, to 15-crown-5, to 18-crown-6. Crown ethers are neutral molecules; crystal structures showing metal ion complexation that results in inclusion usually have one or more poorly coordinating anions present to balance the charge on the cation. The formation of crown ether inclusion complexes, as indicated by the few structures available in the literature, takes careful matching of solvent and counter-ions to suitable macrocyclic cavity sizes (Bradshaw *et al.*, 1996). Representative structures of actinide inclusion complexes are shown in Table 22.24.

In UO_2(18-crown-6)$(CF_3SO_3)_2$, an inclusion complex between UO_2^{2+} and 18-crown-6, the trifluoromethanesulfonate anion is not directly bound to the complex, but rather effectively balances the overall charge (Deshayes *et al.*, 1994a). The linear uranyl fragment is perpendicular with respect to the crown plane and the six crown ether oxygen atoms coordinate the uranium atom equatorially, resulting in an overall hexagonal bipyramidal geometry. The average equatorial U–O bond distance is 2.50(5) Å. In the related structure (Fig. 22.17), UO_2(dicyclohexyl-18-crown-6)$(CF_3SO_3)_2$, uranyl insertion into dicyclohexano-18-crown-6 results in a similar 1:1 UO_2:crown inclusion complex where the geometry about the uranium atom is a hexagonal bipyramid (Deshayes *et al.*, 1994a). Here, the average equatorial U–O bond distance is slightly longer at 2.58(7) Å, indicating that the dicyclohexane rings of the crown ether result in a less flexible coordination environment.

The uranyl cation in the related inclusion complex UO_2(18-azacrown-6)$(CF_3SO_3)_2$ is bonded to all six nitrogen atoms of the crown in a hexagonal bipyramidal manner. The six nitrogen atoms in the azacrown ring are in a puckered plane with the uranium atom lying 0.066(1) Å out of this plane. The average U–N bond distance is 2.66(6) Å, indicating the relative weakness of

the U–N bond compared to the U–O bond in the above complexes (Nierlich *et al*., 1994).

The compound $[U(BH_4)_2$dicyclohexyl-18-crown-6$]_2[UCl_5(BH_4)]$ contains U(III) macrocyclic coordination along with the coexistence of U(IV) in the same crystal. In the cationic portion, the $U(III)(BH_4)_2^+$ moiety resides in the crown ether cavity and the two BH_4 groups assume axial positions (B–U–B = 173(5)°). All six equatorial oxygen atoms participate in bonding, resulting in hexagonal bipyramidal geometry around uranium. The anion, $(UCl_5BH_4)^{2-}$ contains uranium in the 4+ oxidation state in a pseudo-octahedral environment (Dejean *et al*., 1987). Other crown ether inclusion complexes of uranium include $U(BH_4)_3$(18-crown-$6)_{3/4}$, for which only marginal crystallographic data exist due to crystal disorder, making further structural characterization necessary (Moody *et al*., 1979).

A rare example of a transuranium inclusion compound is $[NpO_2$(18-crown-6)$](ClO_4)$. The NpO_2^+ cation resides within the crown ether cavity and the Np center is equatorially coordinated by the six coplanar oxygen atoms at an average distance of 2.594(10) Å, yielding a hexagonal bipyramidal coordination polyhedron (Fig. 22.18). The average Np–O distances of the *trans* oxo ligands are 1.800(5) Å, unusually short for the NpO_2^+ cation (Clark *et al*., 1998b).

Despite the potential to favorably match crown ether cavities containing five and six donors to the UO_2^{2+} ion that prefers such equatorial coordination

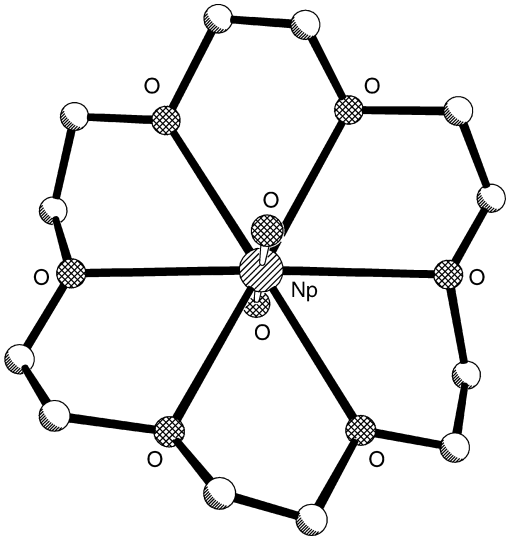

Fig. 22.18 *Crystal strucuture of* [NpO_2(18-*crown*-6)](ClO_4) *with* ClO_4^- *and hydrogen atoms omitted* (*Clark* et al., 1998*b*). *The coordinates were obtained from the Cambridge Structural Database* (*refcode NICFUA*).

environments, the majority of actinide structures in the literature exhibit second sphere/outer sphere exclusion motifs (Thuéry *et al.*, 1995d). The result is the formation of 'supermolecules' usually involving complex hydrogen-bonded networks. Hydrogen bonding between the crown ether oxygen atoms and water molecules coordinated to the metal is commonly observed (but not always) (Rogers *et al.*, 1988). Table 22.25 summarizes representative second sphere/outer sphere actinide-crown ether exclusion complexes.

An interesting example of mistaken identity was observed in the case of $UO_2(NO_3)_2(H_2O)_2 \cdot$(12-crown-4). An initial study by Armağan (1977) contended, based on crystallographic data, that the compound was of the inclusion type. However, all previous and subsequent attempts to place uranyl in the relatively small cavity of 12-crown-4 were unsuccessful. Due to anomalies within the reported results, a follow-up study was done that established the structure as an exclusion complex; $UO_2(NO_3)_2$ nodes are connected to 12-crown-4 molecules through a hydrogen-bonded network enabled by the lattice water molecules (Ritger *et al.*, 1983).

One of the first examples of a hydrogen bonding-stabilized exclusion complex is that of $UO_2(NO_3)_2(H_2O)_2 \cdot 2H_2O \cdot$(18-crown-6). Discrete $UO_2(NO_3)_2(H_2O)_2$ units are separated by crown ether molecules and linked together by hydrogen bonding through intermediary water molecules. Each uranium atom is coordinated to the *trans* uranyl oxygen atoms, two water molecules, and two bidentate nitrate groups (Eller and Penneman, 1976).

The crystal lattice of the compound $[(H_5O_2)\{(NO_2)_2$benzo-15-crown-5$\}_2]_2[\{UO_2(NO_3)_2\}_2C_2O_4]$ contains discrete cation and anion pairs. The anion consists of two $UO_2(NO_3)_2$ groups (each nitrate is bidentate) bridged by a tetradentate oxalate group (forming two five-membered rings); each uranium center is surrounded by a hexagonal bipyramidal polyhedron of ligands. A single $H_5O_2^+$ ion resides between two 15-crown-5 molecules and is stabilized by hydrogen bonding to the ethereal oxygen atoms of the crown ether (Rogers *et al.*, 1991).

Inclusion of H_3O^+ is observed in the structure of $[(H_3O)(18\text{-crown-}6)]_2[\{UO_2(NO_3)_2\}_2C_2O_4]$; the H_3O^+ species resides in the cavity of the crown ether molecule, stabilized by hydrogen bonding (Fig. 22.19). This hydrogen bonding likely occurs with three crown ether oxygen atoms, giving the hydronium a pseudo-pyramidal geometry, residing 0.4 Å out of the plane. The discrete uranyl-containing anion adopts the same conformation as the former molecule, with alternate cation–anion–cation stacking (Rogers *et al.*, 1991).

In $UO_2(SO_4)(H_2O)_2 \cdot (12\text{-crown-}4)_{0.5} \cdot H_2O$, two *trans* uranyl oxygen atoms, two water molecules, and one oxygen each from three sulfate atoms coordinate each uranium atom, generating a pentagonal bipyramid. The sulfate anions bridge each uranium atom to two neighbors, thus forming polymeric double chains. Furthermore, the 18-crown-6 molecule and the uncoordinated water molecule form an organic layer that separates the layers of the uranium polymeric double chains; the layers are stabilized by a hydrogen-bonding network (Rogers *et al.*, 1991).

A series of five alkali metal/crown ether/uranyl halide sandwich exclusion complexes have been structurally characterized and each displays square

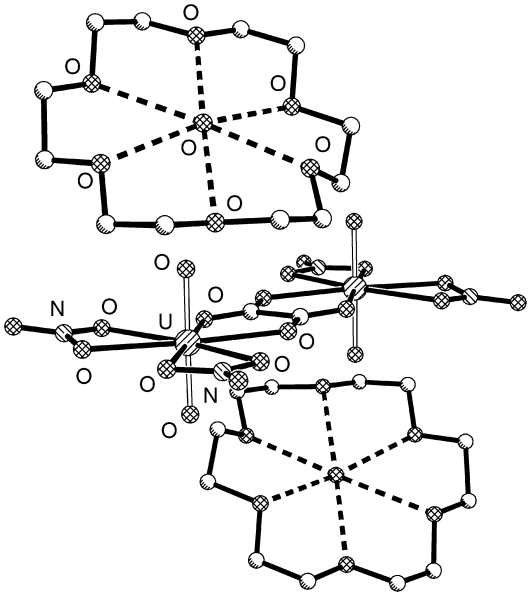

Fig. 22.19 *Crystal strucuture of* $[(H_3O)(18\text{-}crown\text{-}6)]_2[\{UO_2(NO_3)_2\}_2C_2O_4]$ *with hydrogen atoms omitted* (*Rogers* et al., 1991). *The coordinates were obtained from the Cambridge Structural Database* (*refcode SODFUM*).

bipyramidal $[UO_2X_4]^{2-}$ anions sandwiched between two $[A(\text{crown ether})]^+$ cations (X = Cl, Br and A = Li, Na, K). Crown ethers of varying cavity size were investigated, including 18-crown-6, 15-crown-5, and 12-crown-4. The $[K(18\text{-crown-}6)]_2[UO_2Cl_4]$ and $[K(18\text{-crown-}6)]_2[UO_2Br_4]$ complexes display Type I bonding behavior where the K^+ cations form inclusion complexes with the crown ethers. Two uranium-bound halides coordinate in a bridging manner to each K^+ ion and the anionic unit is tilted with respect to the plane of the crown ether toward the K^+ ions to varying degrees (56° for Cl and 63° for Br) (Danis *et al.*, 2001).

The $[Na(15\text{-crown-}5)]_2[UO_2Cl_4]$ has two crystallographically unique anionic units, one of which is Type I bonding, as described above, and the other Type II where only one uranium-bound chloride interacts with each Na^+ ion. Significant tilt of the anionic unit (31°) also occurs. In the Type I bonding, the linear uranyl unit of the anion is aligned parallel to the crown ether plane. If the halide in the aforementioned complex is changed from Cl to Br, a structural shift occurs to Type III bonding. Here, each crown-encapsulated Na^+ ion is bridged by one uranyl bromide and one uranyl oxygen. The linear unbound Br–U–Br unit is aligned parallel to the crown ether plane. Finally, $[Li(12\text{-crown-}4)]_2[UO_2Cl_4]$ and $[Li(12\text{-crown-}4)]_2[UO_2Br_4]$ both exhibit Type IV bonding and are both nearly isostructural. In both complexes, the bonding to each crown-

encapsulated Li^+ is solely through the two uranyl oxygen atoms, resulting in a plane defined by uranium and its four halide atoms that separates the cationic units. The type of bonding exemplified in these structures can be described in terms of hard–soft acid–base theory; in the latter two complexes, the 'hard' Li^+ ion prefers exclusive interaction with the 'hard' uranyl oxygen atoms (Danis *et al.*, 2001).

Exclusion crown ether complexes of uranyl incorporating ligands that are important in uranium chemistry are also known. For example, thenoyl (trifluoroacetone) (HTTA), a β-diketone extractant that acts synergistically with crown ethers in extraction schemes, interacts directly with uranium in $[UO_2\ (TTA)_2H_2O]_2$(benzo-15-crown-5) and $[UO_2(TTA)_2(\mu\text{-}H_2O)]_2(H_2O)_2$(dibenzo-18-crown-6), where the crown ethers are second-sphere and third-sphere ligands, respectively (Fig. 22.20). In both complexes, each uranium attains pentagonal bipyramidal geometry, with equatorial coordination provided by two bidentate HTTA groups and a water molecule. In the former, the bound water hydrogen bonds to the crown ether, making it second sphere. In the latter, intermediate water molecules generate a hydrogen-bonding network (Kannan *et al.*, 2001).

Various forms of phosphate also play significant roles in both processing and environmental aspects of uranium chemistry. The structure of $[UO_2(H_2PO_4)_2(H_2O)]_2 \cdot (18\text{-crown-6}) \cdot 5H_2O$ once again shows pentagonal bipyramidal geometry around uranium, as well as infinite, one-dimensional $[UO_2(H_2PO_4)_2(H_2O)]$ chains that are hydrogen-bonded to uncomplexed crown ether molecules

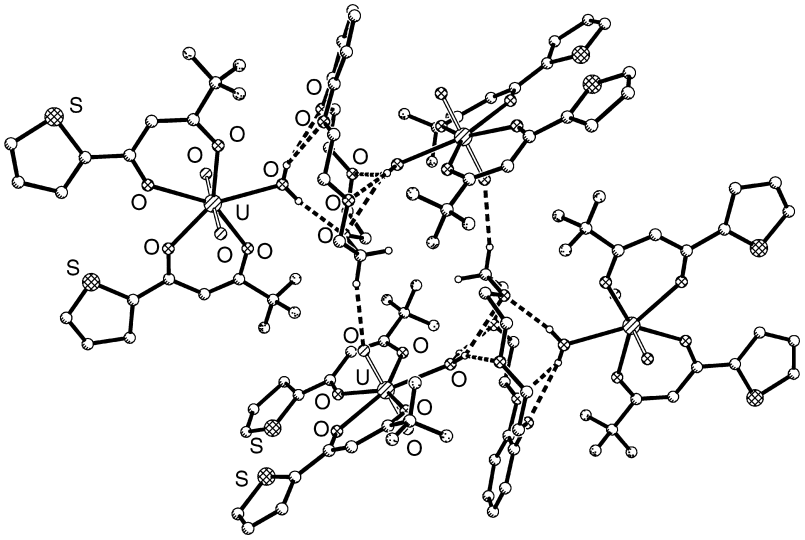

Fig. 22.20 *Crystal strucuture of* $[UO_2(TTA)_2H_2O]_2$(*benzo*-15-*crown*-5) *with hydrogen atoms omitted* (*Kannan* et al., 2001). *The coordinates were obtained from the Cambridge Structural Database* (*refcode RORXIF*).

through solvate lattice water molecules. Each of four $H_2PO_4^-$ units is bound $\mu-\eta^1$ to uranium. A similar situation is observed in the crystal structure of $UO_2(H_2PO_4)_2(H_2O) \cdot (18\text{-crown-6}) \cdot 3H_2O$ (Danis *et al*., 2000).

Although fewer in number, thorium exclusion-type crown ether structures are also known. For example, the crystal structure of $[(H_3O)(\text{dicyclohexano-18-crown-6})]_2[Th(NO_3)_6]$ reveals the thorium atom resting at a center of symmetry and unbound to the crown ether donor atoms. The thorium is 12-coordinate due to bidentate coordination of the six nitrate anions, thus giving it a nearly perfect icosahedral geometry. The Th–O bond distances in this anionic unit range from 2.551 to 2.587 Å. Each H_3O^+ cation rests in the cavity of the crown ether molecules, stabilized by three hydrogen bonds, as well as ion–dipole interactions (Ming *et al*., 1988).

(b) Calixarenes

The class of macrocyclic ligands known as calixarenes is structurally recognized by phenolic subunits joined in a cyclic fashion via methylene linkages; derivatives based on CH_2–X–CH_2 linkages are also commonly used, where X is O, NH, or S. Substitutions at the pendant phenol oxygen site are also possible. The latter types are of interest due to their less rigid character and larger number of potential donor sites. Calixarenes are highly diverse in terms of available ring sizes, making them excellent candidates for systematic analyses concerning their donor properties in binding to groups of metal ions, including lanthanides and actinides. Traditional calixarene chemistry allows for substitutions at either the lower or upper rim of the calixarene and the tuning of their physical properties. The lower rim of a calixarene comprises the cyclic arrangement of alcohol functionalities of the phenol unit. Typically, substitution is directed to the upper rim, leaving the lower rim unsubstituted, thus comprising the class of 'phenolic calixarenes'. Due to the variety of ring sizes available, actinide complexes with calixarenes can be either inclusion or exclusion complexes with the coordination based on considerations such as ligand type, ring diameter, and metal ion radius. For a general overview of phenolic calixarene f-element coordination chemistry, the reader is referred to a review from Thuéry *et al*. (2001d); representative single-crystal X-ray diffraction structures from the literature will be reviewed herein, the likes of which are summarized in Table 22.26.

The complexes formed between $UO_2^{2+}$and triply deprotonated *p-tert*-butylhexahomotrioxacalix[3]arene, studied by Thuéry *et al*. (1999a) show the lowest coordination number (five) observed for a uranyl complex (Fig. 22.21). In the presence of the deprotonating agents triethylamine and DABCO, two isomorphous inclusion-type complexes are formed where the uranyl is located in the center of the lower rim of the calixarene. The uranyl cation is bound in the equatorial plane to the three deprotonated phenolic oxygen atoms with an average $U–O_{eq}$ bond distance of 2.20(3) Å, yielding pseudo-trigonal

bipyramidal geometry around the uranium atom. The oxa-linkages that connect the phenolic units do not take part in the bonding; thus, the five-coordinate environment around uranium is the lowest ever observed. The overall conformation of the calixarene ligand is cone-shaped, and the uranyl is slightly displaced from the plane formed by the three bonding phenolic oxygen atoms. This displacement is counter-ion-dependent, with triethylamine and DABCO resulting in 0.186(4) and 0.248(3) Å displacements, respectively (Thuéry *et al.*, 1999a).

The trigonal equatorial coordination environment around uranium in the two aforementioned complexes changes with alterations to the upper rim as well as the deprotonating agent. Maintaining the *tert*-butyl substitution at the upper rim and changing the deprotonation agent to H_2NBu preserves the trigonal equatorial coordination around uranium; however, in the presence of NPr_3, a distorted tetragonal coordination is observed, with an ether oxygen also taking part in the bonding. Distorted tetragonal coordination is also observed with a methyl substitution and triethylamine. Higher degrees of equatorial coordination are also possible. A *tert*-butyl substitution with 4-methylpiperidine as

the deprotonating agent results in distorted pentagonal coordination aided by the participation of two ether oxygen atoms; an intermediate coordination environment (between tetragonal and pentagonal) occurs with $HNBu_2$ (Masci *et al.*, 2002a).

Calix[4]arene-based actinide complexes are plentiful in the literature, owing to the larger cavity size of the ligand and larger number of potential donor sites. Tetrahomodioxa- and tetrahomodiazacalix[4]arene uranyl structures typically show 1:1 complexes with different complexation modes. The complexation of UO_2^{2+} with *p-tert*-butyltetrahomodioxacalix[4]arene in the presence of triethylamine yields an inclusion complex where the uranyl is bound equatorially in the plane of four deprotonated phenolic oxygen atoms, with the two calixarene ether oxygen atoms taking on a non-bonding role (3.832(4) and 3.820(4) Å from uranium). The geometry around uranium is square bipyramidal with an average $U–O_{eq}$ bond distance of 2.28(3) Å (Thuéry *et al.*, 2001a).

The uranyl/*p*-methyl-*N*-benzyltetrahomodiazacalix[4]arene complex, on the other hand, is of the exclusion type. Interestingly, the complex forms in the absence of base, resulting in a neutral 1:1 complex, where the uranyl is bound to two phenolic oxygens (zwitterionic form) of the calixarene and to two nitrate counter-ions. The uranyl cation rests above the plane of the four phenolic oxygen atoms at a distance of 1.543(8) Å, with the two bound $U–O_{phenol}$ distances at 2.234(9) and 2.269(8) Å. The nitrate anions have different coordination modes, one being mondentate and the other bidentate. The differences observed between the dioxa- and diaza-complexes are presumably due to electrostatic repulsion between the uranyl and the ammonium groups of the diazacalixarene (Thuéry *et al.*, 2001a).

A unique inclusion complex between *p*-methyloctahomotetraoxacalix[4]arene and two uranyl cations has also been structurally characterized (Fig. 22.22). The doubly bridged dinuclear cation rests in the calixarene cavity with the bridging provided by a hydroxide and one oxygen atom from a water molecule. Pentagonal bipyramidal geometry around each uranium results from the two axial uranyl oxygen atoms, the two bridging oxygen atoms, two deprotonated phenolic oxygen atoms, and a single ether oxygen atom. The mean $U–O_{phenoxide}$ bond distances are 2.25(2) Å, while the mean $U–O_{ether}$ distances are significantly longer at 2.67(2) Å (Thuéry *et al.*, 2001b).

The reaction of UO_2^{2+} with *p-tert*-butycalix[5]arene in the presence of triethylamine generates an inclusion complex. The uranyl is bound equatorially to the five phenolic oxygen atoms of the lower rim of the calixarene, generating an overall pentagonal bipyramidal geometry around the uranium atom. Interestingly, only four of the five phenolic sites are deprotonated, suggesting that uranyl ion has an acid-enhancing effect. The $U–O_{eq}$ bond distances vary greatly; three in the range 2.25–2.30 Å, a fourth at 2.571(7) Å, and the longest at 2.836(8) Å. The large variation in the range of $U–O_{eq}$ bond lengths may be due to the calixarene cavity being too large for ideal coordination of the uranyl ion. Finally, the calixarene itself takes on the common cone conformation and

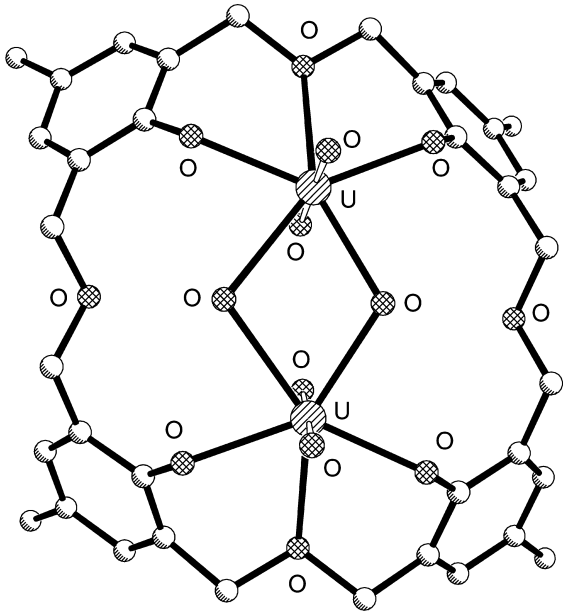

Fig. 22.22 *Crystal strucuture of* [*Hpyr*][$(UO_2)_2$(p-*methyloctahomotetraoxacalix*[4]*arene*–4*H*)(*OH*)(H_2O)] · 2.5*pyr with Hpyr, pyr, and hydrogen atoms omitted* (*Thuéry* et al., 2001*b*). *The coordinates were obtained from the Cambridge Structural Database* (*refcode QOPMIR*).

one of the protonated triethylamine molecules sits in the cavity of the cone, coordinated with an axial uranyl oxygen atom (Thuéry and Nierlich, 1997).

Single crystals of larger calix[*n*]arenes, where $n = 6$, 7, 8, 9, or 12, complexed with actinides have also been isolated and their structures determined. While uranium–calixarene complexes are the most common in the literature, a novel Th(IV) structure with *p-tert*-butylcalix[8]arene has also been solved (DMSO solvate). The structure contains two different calixarene ligands, each with varying degrees of deprotonation (both seven and six protons), bound to four thorium atoms. While the structure itself is very complicated, it is obvious that the two calixarenes attain two different conformations, with one being in a 'propeller' conformation and the other a 'crown'. The two calixarenes form four cone-shaped cavities, the apices of which are defined by a plane of four phenolic oxygen atoms; each cavity is subsequently associated with a single thorium atom. Each thorium center is associated with five phenolic oxygen atoms, three of which are mondentate while the remaining two take on bridging interactions. DMSO and hydroxide molecules also contribute to the bonding (Harrowfield *et al.*, 1991b).

A related uranyl complex incorporating *p-tert*-butylcalix[8]arene is bimetallic and contains only a single calixarene ligand (Fig. 22.23). Here, each uranyl ion

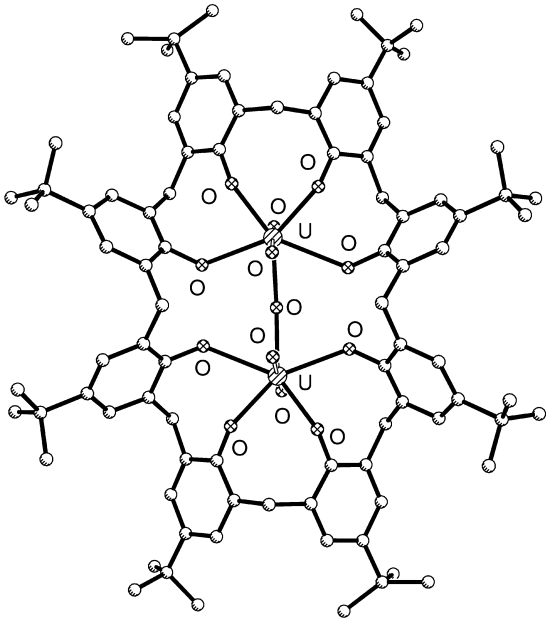

Fig. 22.23 *Crystal strucuture of* $[(HNEt_3)_2(OH)][(UO_2)_2$(p-tert-*butylcalix*[8]*arene*–4*H*)$(OH)] \cdot 2NEt_3 \cdot 3H_2O \cdot 4MeCN$ *with* $[(HNEt_3)_2(OH)]^+$, NEt_3, H_2O, *MeCN, and hydrogen atoms omitted* (*Thuéry* et al., 1995*c*). *The coordinates were obtained from the Cambridge Structural Database* (*refcode ZAMJIG*).

resides in the cavity of the calixarene, making it an inclusion complex, and each is bound equatorially to four phenolic oxygen atoms, two of which are deprotonated. The uranyl ions are also linked via a bridging hydroxide, thus making the overall geometry around each heptacoordinate uranium atom distorted pentagonal bipyramidal. The equatorial U–O bond lengths at the protonated sites are 2.619(9) and 2.476(9) Å, while the corresponding lengths at the deprotonated sites are 2.218(9) and 2.20(1) Å. Two protonated triethylamine molecules are also associated with the complex, each being hydrogen-bonded to a separate axial uranyl oxygen atom. The overall conformation of the bound calixarene has been described as a 'pleated loop' (Thuéry *et al*., 1995c).

The largest calixarene complex of an actinide to date for which a single-crystal X-ray diffraction structure is known is that between *tert*-butylcalix[12]arene and UO_2^{2+} (Fig. 22.24). The resulting inclusion complex contains two uranyl bimetallic units; the uranyl ions in each unit are bridged by a tridentate nitrate ligand. Each bimetallic unit is bound to five phenolic oxygen sites, four of which are deprotonated. One uranyl in each unit is bound to three of the oxygen atoms, while the second is bound to the remaining two and a pyridine molecule (through nitrogen). The resulting geometry around each uranium atom is pentagonal bipyramidal. The four shorter $U–O_{eq}$ bond lengths at each bimetallic

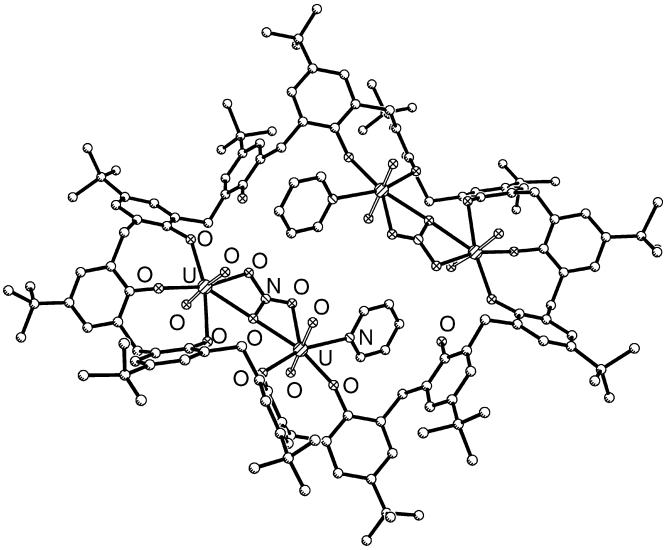

Fig. 22.24 *Crystal strucuture of* $[HNEt_3]_2[\{(UO_2)_2(NO_3)(pyr)\}_2$(tert-*butylcalix*[12]*arene*–8H)$]\cdot 9pyr$ *with* $[HNEt_3]^+$, *pyr*(*unbound*), *and hydrogen atoms omitted* (*Leverd* et al., 2000). *The coordinates were obtained from the Cambridge Structural Database* (*refcode MALGEL*).

unit are about 2.2 Å and correspond to the four deprotonated phenolic sites; the fifth longer bond length at the protonated site is 2.62(3) Å (Leverd *et al*., 2000).

(c) Porphyrins/phthalocyanines

The macrocyclic ligands commonly referred to as porphyrins are ubiquitous in nature. They are structurally described as an arrangement of four pyrrole units linked together in a cyclic manner at the 2- and 5-positions by methine bridges, forming an aromatic, 22-π electron system. The iron-containing porphyrin, commonly known as heme, comprises the primary binding site in hemoglobin that is responsible for dioxygen transport throughout the body. While traditional porphyrins contain only nitrogen-donor atoms, pyrrole-derived macrocycles have also been synthesized that contain pyrrole, furan, and thiophene subunits solely, or combinations thereof. In addition, extensive chemistries have been developed in the synthesis of expanded, contracted, and isomeric porphyrins, the details of which have been described elsewhere. Expanded porphyrins will hereafter be defined as containing at least 17 atoms in a conjugated manner and three pyrrole or pyrrole-like subunits (Sessler and Weghorn, 1997). Porphyrins have been extensively studied as templates for metal ion coordination; the addition of base, such as triethylamine, for the deprotonation of nitrogen sites allows for tetradentate or higher coordination to the metal

centers, often times facilitating electronic transitions in the visible portion of the electromagnetic spectrum that give rise to a wide range of observable color changes. In addition, traditional nitrogen-containing porphyrins give rise to unique coordination complexes with metals that prefer oxygen or sulfur atom donation (Girolami *et al.*, 1994).

Traditionally, oxygen and sulfur atoms, when incorporated into ligand support molecules, have been the atoms of choice for coordination to metal centers; thus, the use of pyrrole-derived porphyrins provides a unique opportunity to study the binding to actinide ions in a non-traditional manner (i.e. all nitrogen atoms) and the subsequent effect on electronic and structural (using X-ray crystallography) motifs. Only a small number of porphyrin–actinide crystal structures have been reported in the literature, indicative of the inherent difficulty in synthesizing these kinds of complexes (as well as the precursors). These structures contain the expanded porphryins, characterized by a bigger core size to accommodate the actinide cations that are considerably larger in diameter than the more commonly used transition metals (Sessler *et al.*, 2001a).

Crystallographic studies of porphyrin- and polypyrrolic-derived ligands with actinides have been limited to tetravalent, pentavalent, and hexavalent cations, including Th(IV), U(IV), Np(V), and U(VI). Table 22.27 lists representative structurally characterized actinide phthalocyanine/porphyrin complexes. The claimed 'first' structural determination of an actinide porphyrin complex was

for U(tpp)Cl_2(THF) with U(IV) and doubly deprotonated tetraphenylporphyrin (tpp). X-ray analysis indicates an exclusion complex, where the U(IV) rests above the plane of the porphyrin (defined by four nitrogen atoms) by 1.29 Å; the two chloride ions and a THF molecule are bound to the metal. The porphyrin itself is not rigorously planar, but rather 'saucer-shaped' to promote bonding of the four nitrogens to uranium. Overall, the coordination geometry about uranium consists of what may be described as a 4:3 piano-stool configuration, with the porphyrin comprising the base of the stool. The U–N bond lengths are 2.41(1) Å, while the U–Cl and U–O bond distances are 2.63(1) and 2.50(1) Å, respectively (Girolami *et al.*, 1987). The structure of Th(octaethylporphyrin)(acetylacetonate)$_2$, incidentally, was reported by Dormond *et al.* in 1986.

The structure of UO_2(pentaphyrin) contains an expanded pentadentate porphyrin that takes on a characteristic saddle-shaped geometry with a uranyl ion located at the center. The uranyl ion is bound symmetrically through uranium to all five nitrogen atoms of the ligand, resulting in a nearly ideal, centrally coordinated pentagonal bipyramid, with U–N and U–O bond distances averaging 2.541(3) and 1.756(5) Å, respectively. Distortions from planarity are due to the oversized diameter of the ligand cavity, thus yielding to the bonding requirements of the uranyl ion (Burrell *et al.*, 1991a).

The complexes of both UO_2^{2+} and NpO_2^+ with hexaphyrin(1.0.1.0.0.0) contain the ligand in its oxidized, aromatic form; the crystal structure of the latter is provided in Fig. 22.25. The linear uranyl ion is completely encapsulated within the porphyrin and is oriented perpendicularly to the plane of the six nitrogen atoms; each nitrogen participates in bonding to the uranium, resulting in a distorted hexagonal bipyramid due to non-centered placement of uranium within the macrocycle cavity. The average U–N bond distance is 2.63(1) Å (considerably longer than U–N distances observed in the former pentaphyrin structure) and U–O distances are 1.760(2) Å (typical for the uranyl cation) (Sessler *et al.*, 2001b).

The analogous NpO_2^+ structure reveals less distortion in the ligand geometry as compared to the uranyl complex, presumably due to a better intrinsic 'fit' between the larger NpO_2^+ cation and the hexaaza ligand core. The geometry around the neptunium center, as in the uranium complex, is roughly a hexagonal bipyramid. The two Np–O bond distances [1.762(1) and 1.826(1) Å] are short for the NpO_2^+ cation (1.85 Å in simple metal salts); the difference in length of these bonds is presumably due to a short-contact interaction between a triethylammonium cation nitrogen atom and a neptunyl oxygen atom. In addition, Np–N bond distances average 2.77(2) Å, nearly 0.14 Å longer than in the corresponding uranyl complex (Sessler *et al.*, 2001b).

Thorium–porphyrin compounds are also relatively common in the literature; for example, Th(IV) and octaethylporphyrin (oep) in the presence of acetylacetonate yield Th(oep)(acac)$_2$. The geometry about the Th(IV) center in the crystal structure is described as a nearly ideal octa-coordinated Archimedean antiprism

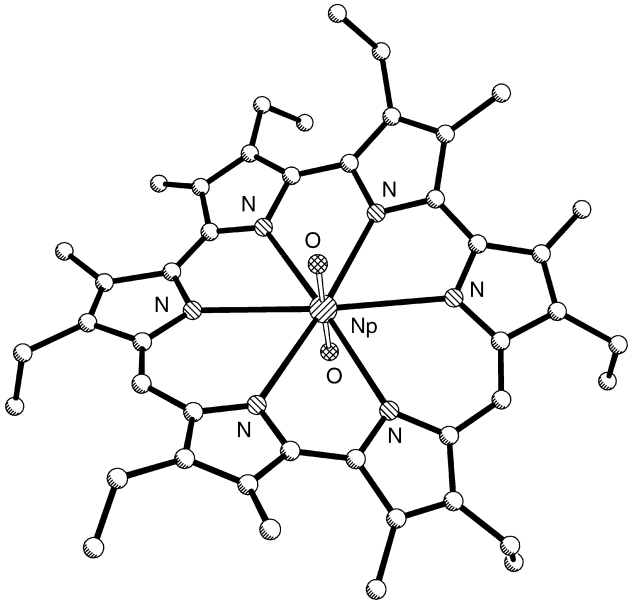

Fig. 22.25 *Crystal strucuture of* $[HNEt_3]NpO_2$[*hexaphyrin*(1.0.1.0.0.0)] *with* $[HNEt_3]^+$ *and hydrogen atoms omitted* (*Sessler* et al., 2001*b*). *The coordinates were obtained from the Cambridge Structural Database* (*refcode QIVCON*).

provided by the four pyrrolic nitrogen atoms and the four oxygen atoms of the two acetylacetonato ligands. The Th(IV) ion is observed to rest closer to the acteylacetonato oxygen atoms than the nitrogen atoms of the porphyrin, making it an exclusion complex. The Th–N and Th–O bond distances average 2.50 and 2.40 Å, respectively, and the geometry of the acetylacetonate ligand is consistent with known carboxylic acid complexes of related type (Dormond *et al*., 1986).

The neutral Th(tetraphenylporphyrin)$_2 \cdot C_7H_8$ and its oxidized π-radical cation in the form of $[Th(tpp)_2][SbCl_6]$ are quite similar and have average Th–N bond distances of 2.55(1) and 2.52(2) Å, respectively. Both metal centers are displaced from the mean plane formed by the pyrrolic nitrogen atoms with an average displacement distance of 1.47 Å for the neutral and 1.45 Å for the cation. The overall geometry around thorium in both the neutral and cationic species may be described as distorted square antiprismatic. Slight differences in the interplanar spacings and twists angles further distinguish the two (Girolami *et al*., 1988).

Phthalocyanines are porphyrin-like macrocycles (aza rather than methine bridge) and may be described as tetrabenzo-tetraazaporphyrins that, unlike porphyrins, are typically prepared via a metal-templated condensation using phthalonitrile and its derivatives (Sessler and Weghorn, 1997). The

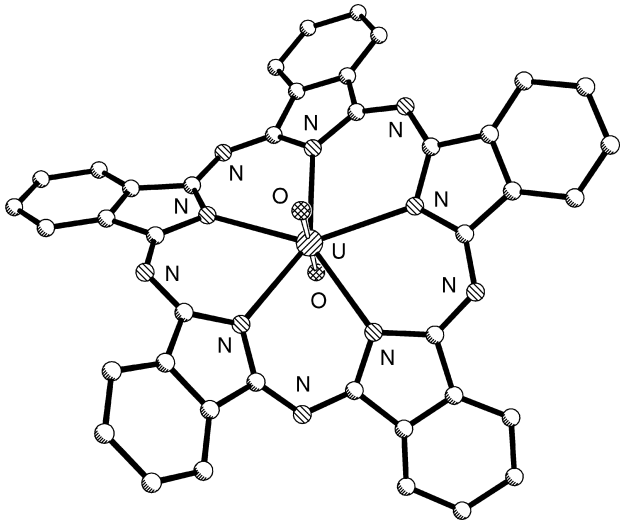

Fig. 22.26 *Crystal strucuture of UO_2(superphthalocyanine) with hydrogen atoms omitted* (*Day* et al., 1975). *The coordinates were obtained from the Cambridge Structural Database* (*refcode CIMINU10*).

uranyl-templated condensation reaction with *o*-dicyanobenzene has yielded an expanded, cyclic five-subunit complex with uranyl known as a 'uranyl superphthalocyanine' (Fig. 22.26). The crystal structure of the UO_2(superphthalocyanine) complex reveals a linear uranyl ion pentacoordinated to the five nitrogen donors of the ligand, creating a near ideal compressed pentagonal bipyramid. The linear [179(1)°] uranyl fragment has an average U–O bond distance of 1.744(8) Å, consistent with other uranyl structures. The average U–N bond distance is 2.524(9) Å and is consistent with other seven-coordinate uranyl/nitrogen complexes. A side-profile of the complex reveals severe distortions from planarity, inherently due to steric strain within the ligand upon metal binding (Day *et al.*, 1975).

22.5 ORGANOACTINIDE COMPOUNDS

Historically, organoactinide chemistry had its origins in the era of the Manhattan Project with unsuccessful attempts to synthesize volatile compounds such as tetraethyl uranium for isotopic enrichment in the gaseous diffusion operations. The synthesis of the unique sandwich compound, uranocene, in 1968, more than previous strides in actinide chemistry with cyclopentadienyl ligands, truly marked the beginning of the organoactinide era, evidenced by the exponential growth thereafter. The subsequent exploration

of organoactinide complexes has mainly focused on π-electron interactions with the cyclopentadienyl and cyclooctatetraenyl ligands and their derivatives, resulting in complexes that take advantage of the potential for high coordination numbers as compared to d-block elements. In addition to the π-bonding ability of these ligands, coordinative saturation of the actinide center can be approached with a variety of other σ- or π-donating ligands (including halides, alkyls, and others), thus introducing a seemingly endless number of possibilities for studying coordination, ligand activation, or reactivity (Marks, 1982a).

Organometallic complexes of lanthanide ions are largely ionic in nature, due to poor overlap between the 4f orbitals and ligand molecular orbitals. As a result, all the lanthanides favor the trivalent oxidation state and display similar chemical reactivity, with differences being primarily due to differences in ionic radii. The 5f electrons of the early actinides, however, are not completely shielded by the 6s and 6p electrons, resulting in a significant radial extension of the 5f orbitals that allows for overlap with ligand orbitals and a covalent bonding contribution. Despite this small covalent contribution, ionic character predominates; in fact, in the later actinides, contraction of the 5f orbitals due to increased nuclear charge results in less metal–ligand orbital overlap and in the predominance of the trivalent oxidation state (Bombieri *et al*., 1998).

The interest surrounding organoactinide chemistry is based on the unique properties of actinide ions (e.g., larger size) that cause them to interact with ligands to produce chemistry that is wholly different from that observed with the d-elements. The larger size of the actinide ions permits coordination numbers (as high as 12) and polyhedra that are unknown or highly unusual for d-elements. This implies a greater control over coordinative unsaturation and a greater number of reactive species can be coordinated and maintained in spatially unusual orientations (Marks, 1982a).

The tremendous growth of organoactinide chemistry since 1968 has resulted in the structural characterization of a wide range of complexes, far too many to be comprehensively presented in this section. The following sections present representative examples, primarily organized in a tabular form, that give the reader an idea of the classes of bonding, as well as the diversity and complexity of organoactinide structural chemistry with brief synopses of select complexes where appropriate. For a more comprehensive treatment of the chemistry and characterization of these compounds, the reader is referred to Chapter 25 of this work, or the annual lanthanide/actinide surveys that are listed in Table 22.28.

22.5.1 Cyclopentadienyl–actinide compounds

Organoactinide complexes of the cyclopentadienyl ligand (η^5-C_5H_5 or Cp) commonly occur as An(η^5-C_5H_5)$_4$, An(η^5-C_5H_5)$_3$X, An(η^5-C_5H_5)$_2$X$_2$, and An(η^5-C_5H_5)X$_3$ where X is a halogen atom, an alkyl, hydride, or alkoxy group, NCS, BH_4, or other ligands with oxygen, nitrogen, or phosphorus donor sites of varying denticity. Typically, the aromatic nature of the Cp ring

lends itself to a η^5 (pentahapto) bonding mode to the actinide metal via its π-electrons. The following discussion will focus on structural motifs present in representative compounds of mono-, bis-, tris-, and tetrakis-cyclopentadienyl organoactinide complexes (Marks, 1979b).

(a) Tetrakis–cyclopentadienyl complexes

The Cp_4An complexes, shown in Table 22.29, are very few in number and are prepared by heating $AnCl_4$ with KCp. A single-crystal X-ray diffraction study of Cp_4U revealed four identical Cp rings arranged in a tetrahedral fashion around the uranium atom with an average U–C distance of 2.538 Å (Burns, 1974). The single-crystal structure of Cp_4Th is isostructural with the uranium analog with a slightly longer average Th–C distance of 2.606 Å (Maier *et al*., 1993). The arrangement of Cp ligands around the thorium center is illustrated in Fig. 22.27. Furthermore, powder X-ray diffraction techniques have confirmed the isostructural nature of the Th, U, and Np complexes (Kanellakopulos and Bagnall, 1972).

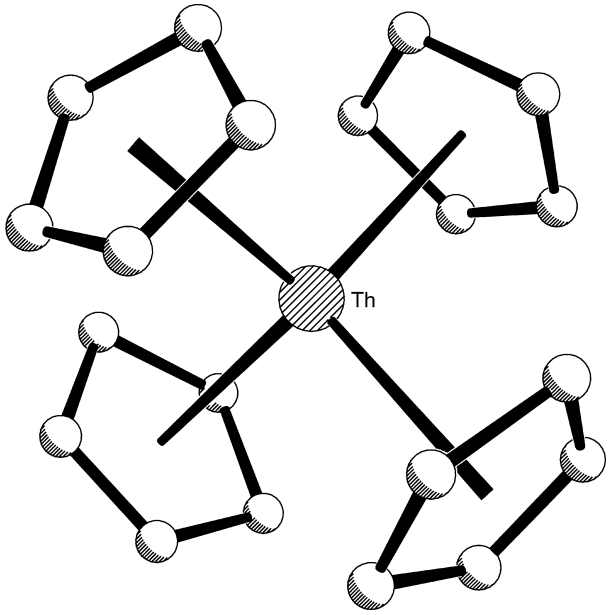

Fig. 22.27 *Crystal strucuture of Cp_4Th with hydrogen atoms omitted* (*Maier* et al., 1993). *The coordinates were obtained from the Cambridge Structural Database* (*refcode LANTEZ*).

(b) Tris-cyclopentadienyl complexes

The tris-cyclopentadienyl complexes of the actinides are known for Th, U, Pu, Am, Cm, Bk, and Cf, but not all have been structurally characterized. The uranium and thorium compounds can be prepared by different methods, including reduction of the tetravalent derivatives or photo-induced β-hydride elimination reactions of Cp_3An–alkyl compounds (Bruno *et al.*, 1982a). The thorium version is a unique example of thorium in the rare trivalent oxidation state and some structural data are available (Kanellakopulos *et al.*, 1974). The uranium complex is a strong Lewis acid and readily favors the formation of adducts with a variety of Lewis bases (Marks, 1982a). Powder diffraction data are available for the Cm, Bk, and Cf compounds, evidence that the trivalent oxidation state is preferred for the heavier actinide elements (Cm, Bk, Cf) (Laubereau and Burns, 1970a,b).

The predominance of Cp_3AnX compounds over Cp_3An (where An is U or Th and X is an anion, Lewis base, or another Cp ring) in organoactinide chemistry depicts the degree to which the tetravalent oxidation state of the metal is preferred over the trivalent state in these complexes, or in cases where the trivalent oxidation state is maintained, the high Lewis acid character of the

precursor (Bombieri *et al.*, 1998). In all the Cp_3AnX compounds, the Cp rings are bound in the traditional η^5 (pentahapto) mode to the actinide cation(s) and the complexes have irregular tetrahedral structure (although there are exceptions). Structural analysis has confirmed that this molecular arrangement exists for other complexes in which the X is varied, revealing not only the retention of the irregular tetrahedral structure, but also the aromatic nature of the Cp rings and the regularity of the An–C bond length.

A series of tris-cyclopentadienyl actinide complexes are tabularized in Table 22.30. The series of Cp_3UX complexes, where X is a halide (F, Cl, Br, I), have been structurally characterized (Wong *et al.*, 1965; Ryan *et al.*, 1975; Spirlet *et al.*, 1989; Rebizant *et al.*, 1991). While each has the same distorted tetrahedral environment around the uranium center, none are isostructural, despite the chloride and bromide being geometrically equivalent (both monoclinic, $P2_1/n$). A neutron diffraction structure of the chloride is also available which shows disorder of the Cp rings as well as a crystallographic phase transition between 80 and 100 K (Delapalme *et al.*, 1988). A structure of the iodide derivative is shown in Fig. 22.28.

A large number of compounds exhibit σ-bonding at the fourth site, such as $Cp_3U(n\text{-}C_4H_9)$, $Cp_3U(p\text{-}CH_2C_6H_4Me)$ (Perego *et al.*, 1976), or $Cp_3U[MeC(CH_2)_2]$ (Halstead *et al.*, 1975), with U—C_σ bond distances of 2.426(23), 2.541(15), and 2.48(3) Å, respectively. In the latter complex, while π-bonding of the methylallyl group is possible, the structure clearly indicates σ-type interactions with the metal center. The result is a distorted tetrahedral geometry with approximate C_{3v} symmetry. An interesting case exists with $[Cp_2Th(\eta^5{:}\eta^1\text{-}C_5H_4)]_2$, where the two Cp_2Th centers are bridged by two $\eta^5{:}\eta^1\text{-}C_5H_4$ ligands, each pentahapto to one thorium and monohapto (σ-bonded) to its neighbor (Baker *et al.*, 1974).

Another interesting situation arises in the pyrazolate complex, $Cp_3U(N_2C_3H_3)$, where endo-bidentate η^2-coordination through both nitrogen atoms to the uranium center is observed; the U–N distances are 2.40 and 2.36 Å (Fig. 22.29). In this compound, the ionic nature of the U–N bond suggests that the N–N bond is involved in a non-directional association with the uranium atom; the resulting geometry may be described as a flattened tetrahedron with bonds joining the uranum atom with the center of the three Cp ligands and the midpoint of the N–N pyrazolate bond (Eigenbrot and Raymond, 1981).

The reaction of $Cp_3U \cdot THF$ with the potentially bidentate phosphine ligand, $Me_2P(CH_2)_2PMe_2$, yields the complex $(Cp_3U)_2[Me_2P(CH_2)_2PMe_2]$ where the phosphine ligand adopts an unusual role (Zalkin *et al.*, 1987a). Here, the phosphine acts as a bridging ligand between each Cp_3U fragment rather that chelating in a bidentate mode through each phosphorus atom. In doing so, the steric repulsions are minimized and the coordination number of the uranium is reduced by one, resulting in an 'economical arrangement'. The U–P bond distance is 3.022(2) Å and the U–$Cp_{centroid}$ distance is 2.52(1) Å, both of which

are comparable to the distances observed in the $(MeCp)_3U(PMe_3)$ complex of 2.972(6) and 2.52(1) Å, respectively (Brennan and Zalkin, 1985).

Several novel tris-cyclopentadienyl complexes have also been studied structurally. In the anionic portion of $[Ph_4As][Cp_3U(NCS)_2]$, the uranium center is surrounded by a trigonal planar arrangement of Cp ligands in the equatorial plane, and the thiocyanate ligands occupy axial positions with U–N bond distances of 2.46 and 2.50 Å (Bombieri *et al.*, 1983a). The first example of the opposite situation, a cationic organoactinide species, was observed in $[Cp_3U(NCMe)_2]_2[UO_2Cl_4]\cdot(C_4H_6)_2$, formed from the reaction of Cp_3UCl in MeCN with gaseous butadiene and traces of O_2 (Fig. 22.30). The cation contains uranium in the tetravalent oxidation state with trigonal bipyramidal geometry (D_{3h}), while the anion has hexavalent uranium with approximate D_{2h} symmetry (Bombieri *et al.*, 1983b). Another cationic organoactinide species is evident in $[Cp_3U(NCMe)_2][CpThCl_4(NCMe)]$ with the familiar trigonal bipyramidal geometry. An interesting aspect of this structure is the simultaneous presence of tetravalent thorium in the anion with octahedral coordination (Rebizant *et al.*, 1987).

In the compound $Cp_3U(NPh)(O)CCHPMe_2Ph$, η^2 coordination of the oxygen and nitrogen atoms of the neutral ligand creates a four-membered ring. The U–N and U–O bond lengths are 2.45(1) and 2.34(1) Å, respectively, indicating the presence of single bonds which are typical for donor atoms carrying a partial negative charge. Due to the sterically crowded nature of the uranium center, the formation of this *cis*-Cp_3UXY-type compound is quite rare; its highly crowded nature is evident in the small ligand bite distance (2.22(2) Å), elongated $U–C_{Cp}$ bonds (average 2.84(2) Å vs 2.72 Å for Cp_3UBr), and compressed $Cp_{centroid}–U–Cp_{centroid}$ angles (Cramer *et al.*, 1987b).

A rare instance of a neptunium-containing organometallic complex (with tetravalent neptunium) is $Cp_3Np(OPh)$. Considering the oxygen atom and the centers of the three Cp ligands as vertices, the structure has flattened tetrahedral geometry and near C_{3v} symmetry (De Ridder *et al.*, 1996a). The Np–O bond

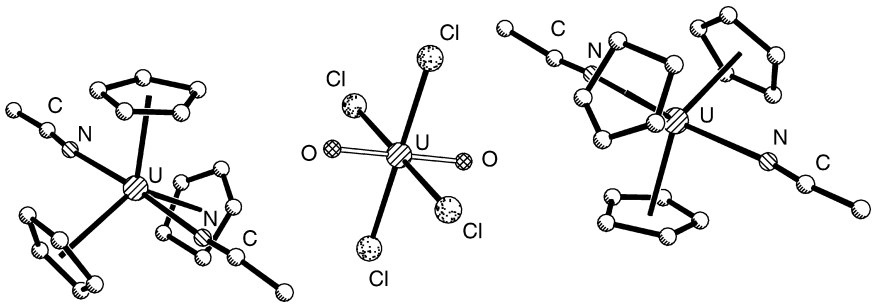

Fig. 22.30 *Crystal strucuture* $[Cp_3U(NCMe)_2]_2[UO_2Cl_4]\cdot(C_4H_6)_2$ *with* (C_4H_6) *and hydrogen atoms omitted* (*Bombieri* et al., 1983*b*). *The coordinates were obtained from the Cambridge Structural Database* (*refcode BUJPOL*).

distance is 2.136(7) Å, considerably shorter than that in $CpNpCl_3(OPMePh_2)_2$ of 2.277(6) Å (Bagnall *et al.*, 1986). $Cp_3Np(OPh)$ is isostructural with its uranium analog $Cp_3U(OPh)$; the U–O bond distance is slightly shorter, however, at 2.119(7) Å, and the flattened tetrahedral geometry is maintained (Spirlet *et al.*, 1990a).

The structure of $[(MeCp)_3U]_2[\mu\text{-}S]$ shows sulfur occupying a bridging role between two $(MeCp)_3U$ moieties, with an average U–S distance of 2.60(1) Å, one of the shortest ever observed. The most interesting aspect of this structure is the bent U–S–U angle of 164.9(4)°. These observed structural features are consistent with a class of bridging sulfur transition metal complexes with nearly linear M–S–M angles (159–180°) and M–S bond lengths shorter than expected for a M–S single bond. This trend suggests that the bridging sulfur may act as a π-donor or π-acceptor towards the metal center; an alternative explanation, however, is an electrostatic one, where steric repulsion due to the bulky $(MeCp)_3U$ groups accounts for the observed structural features (Brennan *et al.*, 1986b).

The first example of end-on binding of N_2 has been observed in the structure of $(Cp^*)_3U(\eta^1\text{–}N_2)$. A solution of $(Cp^*)_3U$ under N_2 at 80 psi darkens with the precipitation of hexagonal crystals of the desired compound. Binding is reversible, with quantitative regeneration of $(Cp^*)_3U$ upon lowering the pressure to 1 atm. The three Cp* ligands are bound pentahapto to the uranium center, with the remaining coordination site filled by N_2, resulting in a trigonal pyramidal geometry (Evans *et al.*, 2003b). The U–N bond distance of 2.492(10) Å is comparable to the 2.485(9) Å $U\text{–}C_{CO}$ distance observed in $(Cp^*)_3U(CO)$. Here, the C≡O ligand is isoelectronic with N_2 and also binds end-on to the uranium center through carbon (Evans *et al.*, 2003a). The isostructural nature of the two compounds is illustrated in Fig. 22.31.

(c) Bis-cyclopentadienyl complexes

Like the tris-compounds, the prevalance of $Cp_2(Th,U)X_2$ compounds over $Cp_2(Th,U)X$ compounds reveals the large preference for the tetravalent oxidation state in these complexes. However, the $Cp_2(Th,U)X_2$ are considerably unstable compared to transition metal and lanthanide analogs towards intermolecular ligand redistribution (Bombieri *et al.*, 1998). For example, Cp_2UCl_2, produced by the reaction of TlCp and UCl_4 in the presence of 1,2-dimethoxyethane (DME), is actually a mixture of Cp_3UCl and $CpUCl_3(DME)$ (Ernst *et al.*, 1979).

The pentamethylcyclopentadienyl ligand (Cp*) has been utilized in organoactinide chemistry to circumvent many of the problems encountered with the unstable $Cp_2(Th,U)X_2$ compounds. As compared to the unsubstituted analog (Cp), Cp* provides increased covalent character of the Cp–M bond, stronger π-donor ability, kinetic stabilization due to steric shielding of the metal, and increased thermal stability. In addition to inhibiting the formation of polymeric structures, the Cp* improves many solution chemistry properties, including

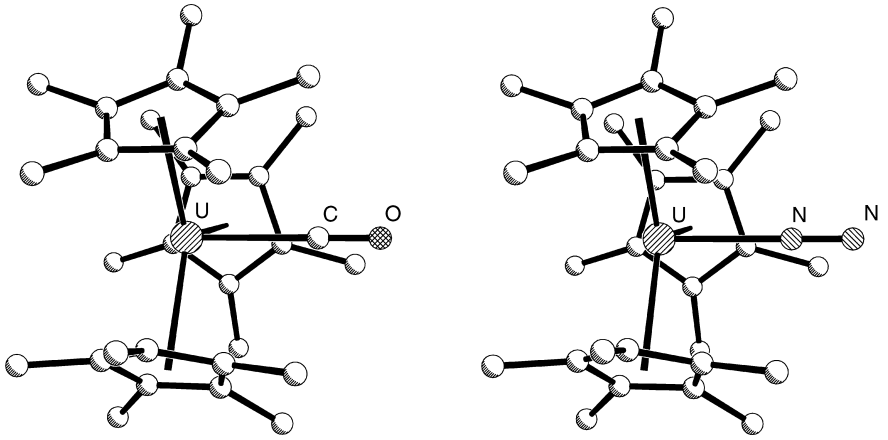

Fig. 22.31 *Crystal strucutures of* $(Cp^*)_3U(CO)$ (*Evans* et al., 2003*a*) *and* $(Cp^*)_3U(\eta^1\text{-}N_2)$ (*Evans* et al., 2003*b*) *with hydrogen atoms omitted. The coordinates were obtained from the Cambridge Structural Database* (*refcodes IMUVAN and ENABUQ*).

crystallizability, thus promoting its widespread use in organoactinide chemistry (Bombieri *et al*., 1998).

The addition of methyl groups to the Cp rings promotes coordinative unsaturation of the actinide metal by preventing the binding of other sterically demanding ligands. In addition, the methyl groups stabilize the organoactinide complexes with respect to ligand redistribution reactions, a feature that dominates the solution chemistry of unsubstituted f-element metallocenes. Ligand rearrangement prevents the cystallization of the Cp_2UCl_2 and $(Cp^*)(Cp)UCl_2$, as well as $[(^t\text{Bu})Cp]_2UCl_2$ and $(Cp')_2UCl_2$ (Lukens *et al*., 1999). In contrast, the $(Cp^*)_2UCl_2$ complex (Fig. 22.32) has normal, monomeric pseudotetrahedral 'bent-sandwich' configuration and has no tendency to undergo ligand redistribution to form the unknown $(Cp^*)_3UCl$ (Spirlet *et al*., 1992a).

A large number of representative bis-cyclopentadienyl actinide complexes are listed in Table 22.31, again illustrating the magnitude and diversity of organoactinide structural chemistry. The list is dominated by Cp* ligands (and other Cp derivative with bulky substituents), a tribute to its prevalence in organometallic chemistry and its usefulness in preventing ligand redistribution.

The series of compounds $Cp_2ThX_2(Me_2P(CH_2)_2PMe_2)$, where X = Cl, Me, or $CH_2C_6H_5$, have been synthesized and structurally characterized. The chloro derivative (Fig. 22.33) was synthesized from the reaction of sodium cyclopentadienide with $ThCl_4 \cdot (CH_3)_2PCH_2CH_2P(CH_3)_2$ in THF at 203 K. The latter two derivatives were synthesized from the reaction of the chloro derivative with methyllithium and benzyllithium, respectively, at 228 K. In accordance with Keppert's rules, the monodentate ligand with the shortest bond distance in each

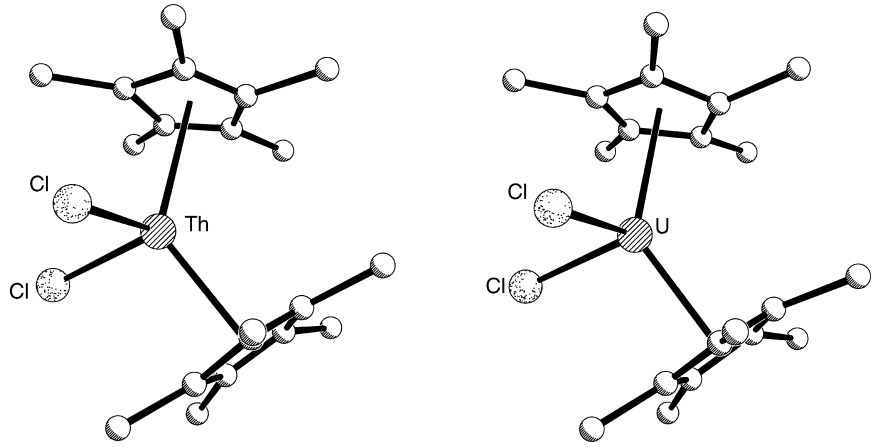

Fig. 22.32 *Crystal strucutures of* $(Cp^*)_2ThCl_2$ *and* $(Cp^*)_2UCl_2$ *with hydrogen atoms omitted* (*Spirlet* et al., 1992*a*). *The coordinates were obtained from the Cambridge Structural Database* (*refcodes VUJRAT and VUJPUL*).

structure (the Th–$Cp_{centroid}$ bond) occupies the site *trans* to the bidentate $Me_2P(CH_2)_2PMe_2$ ligand, thus making the bulky Cp ligands *cis* to one another. This is, in many ways, counter-intuitive in that the bulky Cp ligands should prefer a *trans* configuration to each other to lessen steric hindrance. The average Th–P bond lengths in the above three compounds are 3.147(1), 3.121(1), and 3.19(3) Å, respectively (Zalkin *et al*., 1987b,c).

The compounds $(Cp^*)_2UCl_2(C_3H_4N_2)$, $(Cp^*)_2UCl(C_3H_3N_2)$, and $(Cp^*)_2U(C_3H_3N_2)_2$ exhibit two bonding modes for the pyrazole/pyrazolate ligand. In the first compound, the pyrazole ligand acts as a neutral donor, with donation to the uranium center occurring through only a single nitrogen atom. In the latter two complexes, the pyrazole ligand is in the form of the pyrazolate anion and donates two nitrogen atoms per ligand to the uranium center. In the mono-chloro complex, the geometry can be approximated as tetrahedral by considering the two Cp* centroids, the chloride, and the midpoint of the N–N bond as corners. The U–N nitrogen bond length trend is supported by the nature of the ligand: the longest U–N bonds (2.607(8) Å average) occur for the neutral pyrazole ligand, while the anionic ligand yields the shortest U–N bonds. In the monopyrazolate complex, the two U–N bond lengths are 2.351(5) and 2.349(5) Å, while the dipyrazolate distances are 2.403(4), 2.360(5), 2.363(9), and 2.405(5) Å. Interestingly, in the latter case, the two 'internal' U–N bonds are shorter (greater crowding) than the two 'external' bonds. The pyrazolate U–N bond lengths are consistent with the $Cp_3U(N_2C_3H_3)$ structure (1.36, 1.40 Å) (Eigenbrot and Raymond, 1982).

* Semicolons used to differentiate coordination to different metal centers or different structures.

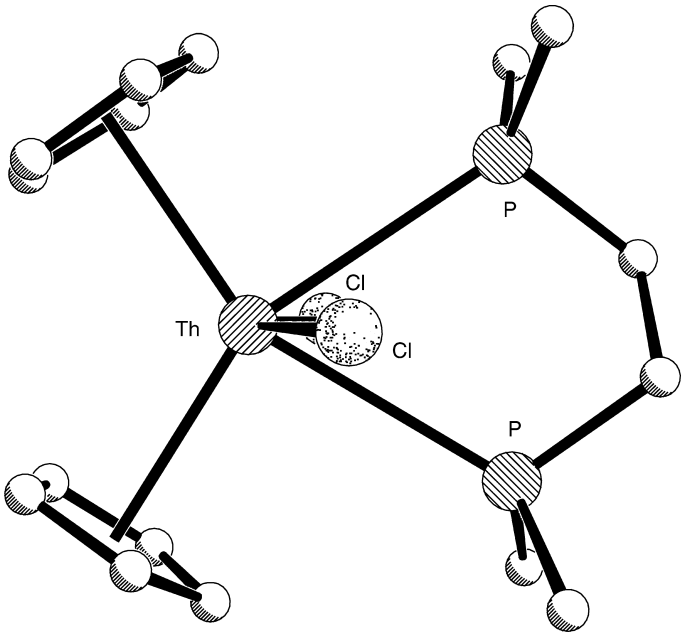

Fig. 22.33 *Crystal strucuture of* $Cp_2ThCl_2(Me_2P(CH_2)_2PMe_2)$ *with hydrogen atoms omitted* (*Zalkin* et al., 1987*b*). *The coordinates were obtained from the Cambridge Structural Database* (*refcode BIXVOT10*).

The first example of an organoactinide polysulfide reveals the unique twist-boat conformation of a ThS_5 ring, generated by the reaction of $(Cp^*)_2ThCl_2$ with Li_2S_5. The crystal structure of $(Cp^*)_2ThS_5$ (Fig. 22.34) is unique compared to transition metal analogs, such as Cp_2TiS_5, Cp_2ZrS_5, and Cp_2HfS_5, which strictly exhibit a MS_5 chair conformation. This anomaly in conformation is likely due to the coordination of four ring sulfur atoms to the uranium center, rather than two. Two types of bonding are thought to occur: two Th–S bonds at 2.768(4) Å are ionic in nature and two at 3.036(3) Å are dative in nature (Wrobleski *et al*., 1986b).

Many polynuclear bis-organoactinide complexes with bridging hydride, halide, and oxo groups are known. For example, the single-crystal neutron diffraction structure of the dimeric compound $[(Cp^*)_2Th(H)(\mu\text{-}H)]_2$, one of the first examples of an actinide hydride complex, contains both bridging and terminal hydrides. Two $(Cp^*)_2Th(H)$ moieties, each containing a terminal hydride, are connected by two bridging hydrides; the terminal and bridging Th–H distances are 2.03(1) and 2.29(3) Å, respectively, with a Th–Th separation of 4.007(8) Å (Broach *et al*., 1979).

The trimeric bridging halide complex, $[(Cp^*)_2U(\mu\text{-}Cl)]_3$, contains three $(Cp^*)_2U$ units, each connected by a bridging chloride and pseudotetrahedral

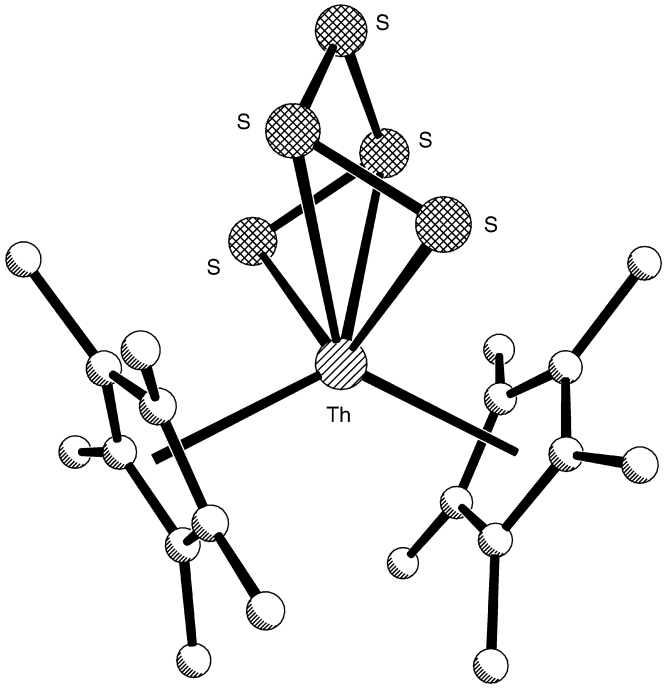

Fig. 22.34 *Crystal strucuture of* $(Cp^*)_2ThS_5$ *with hydrogen atoms omitted* (*Wrobleski* et al., 1986*b*). *The coordinates were obtained from the Cambridge Structural Database* (*refcode DIJRET*).

geometry around each uranium. The cyclic –U–Cl–U–Cl–U–Cl– moiety comprises a nearly planar six-membered ring, with average U–Cl, U–C, and U–U distances of 2.901(5), 2.76(3), and 5.669(2) Å, respectively (Manriquez *et al*., 1979). Finally, the bridging oxo complex, $[(Cp'')_2U(\mu\text{-}O)]_2$, contains two $(Cp'')_2U$ units connected by two bridging oxo ligands and a geometry similar to the chloro complex (Fig. 22.35). The average U–O and U–C distances are 2.213(8) and 2.77(4) Å, respectively. The average $U\text{–}Cp_{centroid}$ distance is 2.496 Å (Zalkin and Beshouri, 1988). For further examples of bridging complexes, the reader is referred to Table 22.31.

(d) Mono-cyclopentadienyl complexes

Mono-cyclopentadienyl organoactinide complexes, while less common, are typically Lewis-base adducts of the type $CpAnX_3L_n$. These complexes are usually sterically and electronically unsaturated, making their synthesis and subsequent crystallization quite challenging. Representative complexes for which structural data are available are listed in Table 22.32. The structures of

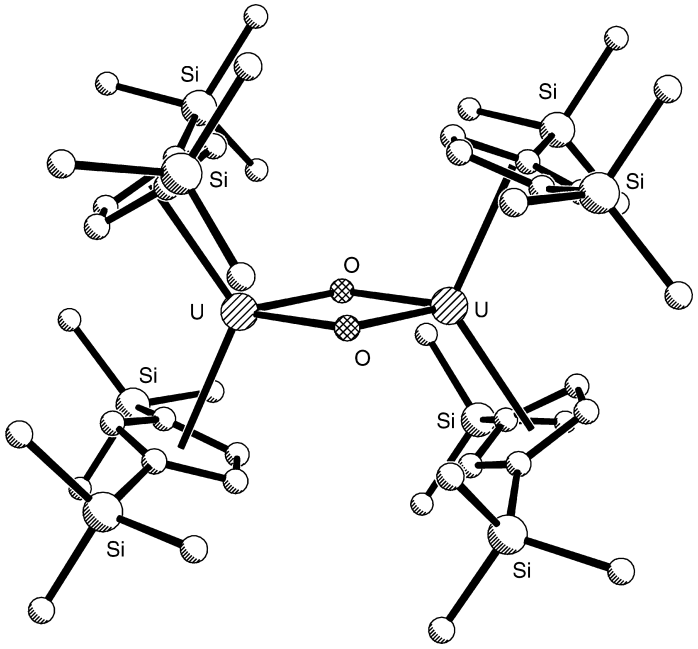

Fig. 22.35 *Crystal strucuture of* $[(Cp'')_2U(\mu\text{-}O)]_2$ *with hydrogen atoms omitted* (*Zalkin and Beshouri,* 1988). *The coordinates were obtained from the Cambridge Structural Database* (*refcode GIFNIS*).

$CpUCl_3(OPPh_3)_2 \cdot THF$ (Bombieri *et al.*, 1978c; Bagnall *et al.*, 1984) and $CpUCl_3[OP(NMe_2)_3]_2$ (Bagnall *et al.*, 1984) show an octahedral environment around the uranium centers with the neutral ligands occupying the *cis* coordination sites. In addition, the chlorine ligands are arranged in a *mer* fashion (as opposed to a *fac* arrangement) and the Cp ligands are *trans* to one of the neutral ligands. One of the few neptunium-containing organoactinide complexes, $CpNpCl_3(OPMePh_2)_2$, is analogous to the uranium structures described above (Fig. 22.36) (Bagnall *et al.*, 1986).

The compound $[CpU(CH_3COO)_2]_4O_2$ has four seven-coordinate uranium centers, each with distorted pentagonal bipyramidal geometry. The pentagonal arrangement around a given uranium center is defined by five oxygen atoms from four different acetate ligands. Two bridging acetates are monodentate simultaneously with respect to two neighboring uranium atoms. The remaining two bridging acetate groups take on a more complex role, each joining two neighboring uranium centers, with one oxygen being mondentate toward one uranium and the other oxygen being bidentate toward both uranium atoms. The remaining coordination sites are occupied by bridging oxo ligands (joining two pairs of uranium atoms), providing the apex of each pentagonal bipyramid,

and each pentahapto Cp ligand occupies the remaining apex (Rebizant *et al.*, 1992).

A cyclic hexameric thorium organoactinide complex (Fig. 22.37) is evident in the structure of $[CpTh_2(O\text{–}^iPr)_7]_3$. Interestingly, the Cp ligands in this structure take on a bridging role between three $[Th_2(O\text{–}^iPr)_7]$ units, each pentahapto to its neighboring thorium atoms. Each thorium center has distorted octahedral geometry provided by a Cp ligand and five $O\text{–}^iPr$ groups, two of which are bound to a thorium atom and the remaining three bridge between two thorium atoms (Barnhart *et al.*, 1995b).

The two thorium atoms in the triflate-bridged compound isolated by Butcher *et al.* (1995) have different coordination numbers (Fig. 22.38). Each thorium atom has one Cp* ligand bound in a pentahapto fashion and the two centers are

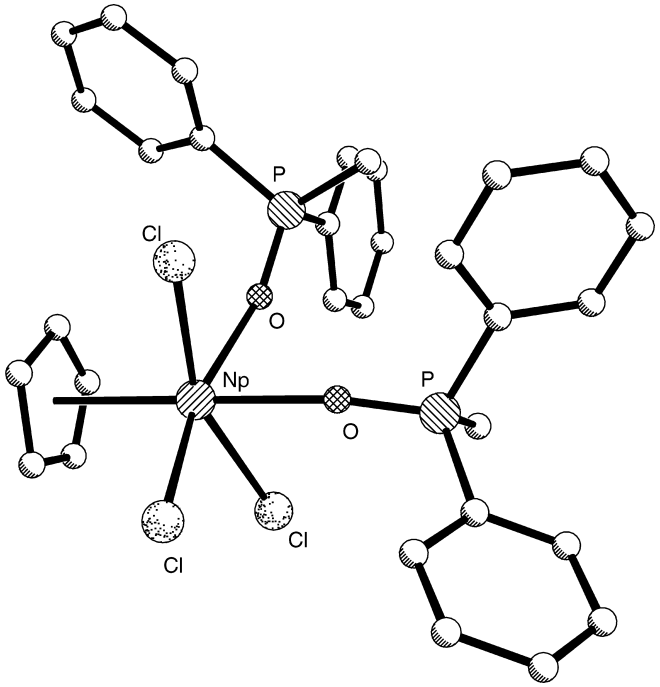

Fig. 22.36 *Crystal strucuture of* $CpNpCl_3(PMePh_2O)_2$ *with hydrogen atoms omitted* (*Bagnall* et al., 1986). *The coordinates were obtained from the Cambridge Structural Database* (*refcode DIXCOC*).

joined by three bridging triflate ligands. One thorium center is coordinated to a cyclometalated amide ligand in a bidenate manner through both nitrogen, and interestingly, carbon, resulting in a hexacoordinate thorium atom (Th–N= 2.26(4) Å, Th–C=2.43(5) Å). The remaining thorium center has a bis-(trimethylsilyl)amide ligand bound in a monodentate fashion only through the nitrogen atom (Th–N=2.24(3) Å), resulting in pentacoordinate thorium.

22.5.2 Cyclooctatetraene–actinide compounds

A milestone in the field of organometallics that effectively marked the beginning of organoactinide chemistry was the synthesis (Streitweiser and Müller-Westerhoff, 1968) and subsequent structural characterization of uranocene. The pursuit of uranocene was a direct result of the idea that it would be analogous to ferrocene with the additional benefit of studying the contribution of f-orbitals to the bonding. Like ferrocene, uranocene is a sandwich complex of D_{8h} symmetry in which the uranium(IV) ion is positioned between two octahapto (η^8-C_8H_8) cyclooctatetraene (COT) dianions. Although eclipsed in

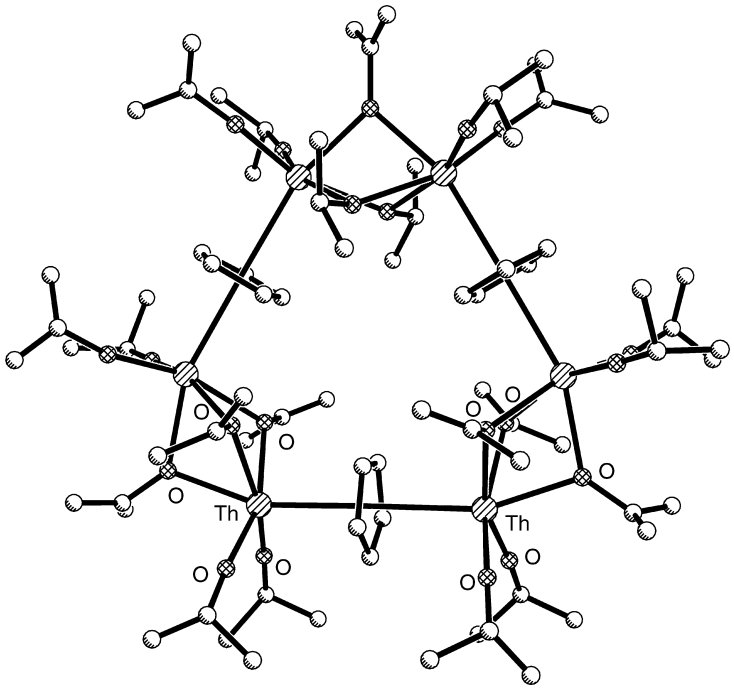

Fig. 22.37 *Crystal strucuture of* $[CpTh_2(O\text{-}^iPr)_7]_3$ *with hydrogen atoms omitted* (*Barnhart* et al., 1995*b*). *The coordinates were obtained from the Cambridge Structural Database* (*refcode ZEJYES*).

uranocene, the COT rings have the potential of being either eclipsed or staggered (Zalkin and Raymond, 1969; Avdeef *et al*., 1972). The thorium analog of uranocene, commonly referred to as thorocene, is isostructural, and both are extremely air-sensitive (Avdeef *et al*., 1972). Both structures consist of the central metal atom participating in symmetrical π-bonding to the COT ligands, related by a crystallographic inversion center. The average Th–C and U–C bond distances are 2.701(4) and 2.647(4) Å, respectively; the corresponding metal-to-centroid distances are 2.004 and 1.924 Å. Spectroscopic studies with uranocene seem to indicate at least some π-interactions between the molecular orbitals of the COT ligands and the 5f orbitals of the metal.

Neptunocene, a transuranic metallocene, is isostructural with both thorocene and uranocene, with an average Np–C bond distance of 3.630(3) Å (De Ridder *et al*., 1996b). Powder diffraction data are available for both $(COT)_2Pa$ and $(COT)_2Pu$ that indicate protactinocene is isostructural with the lower actinide analogs and plutonocene is isomorphous with the series (Karraker *et al*., 1970; Starks *et al*., 1974). Incorporation of the COT ligand is not limited to metallocenes. In fact, a host of other examples containing COT are listed in Table 22.33.

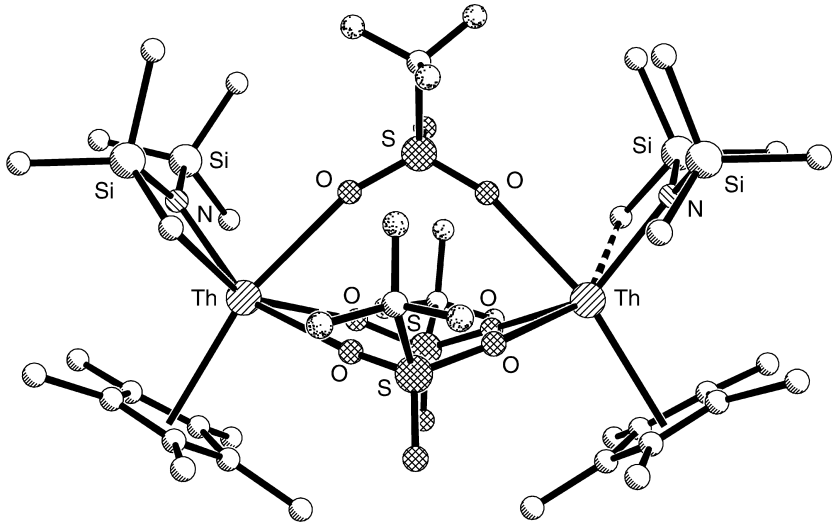

Fig. 22.38 *Crystal strucuture of* $Cp^*[(Me_3Si)_2N]Th(\mu_2\text{-}OSO_2CF_3)_3Th[N(SiMe_3)(SiMe_2CH_2)]Cp^*$ *with hydrogen atoms omitted* (*Butcher* et al., 1995). *The coordinates were obtained from the Cambridge Structural Database* (*refcode ZANJIH*).

A mixed cyclopentadiene/cyclooctatetraene complex is observed in the crystal structure of (COT)(Cp*)U(Me_2bpy) (Schake *et al.*, 1993). The binding of the COT and Cp* rings are η^8 and η^5, respectively, and the bipyridine adduct is bidentate through both nitrogen atoms. The resulting geometry around the uranium is a distorted tetrahedron with a Cp*–U–COT bond angle (from centroids of ligands) of 138.2°, comparable to what is observed in the thorium complexes, (COT)Cp*Th[$CH(SiMe_3)_2$] and (COT)Th(Cp*)(μ-Cl)$_2$Mg($CH_2{}^t$Bu)(THF) · 0.5PhMe (Gilbert *et al.*, 1989).

Butenouranocene, $[C_8H_6(CH_2)_2]_2U$, contains a cyclooctatetraene derivative appended with a cyclobuteno ring (Fig. 22.39). The uranium ion is sandwiched between the two eclipsed rings, but centered on the cyclooctatetraene rings, with an overall C_{2h} symmetry. The average U–C distance of 2.64(2) Å (Zalkin *et al.*, 1979) is comparable to uranocene (2.65 Å) and similar structures.

22.5.3 Other (indenyl, arene, etc.) compounds

Representative organoactinide complexes containing ligands not covered in previous sections are listed in Table 22.34 and include various indenyl, arene, and miscellaneous structures, including bridged Cp ligands. The indenyl ligand, $C_9H_7^-$, is formally analogous to $C_5H_5^-$, yet is more sterically demanding (both substituted and unsubstituted) and can coordinate in pentahapto, trihapto, and monohapto modes (Bombieri *et al.*, 1998).

The π-bonding of indenyl ligands to the Th(IV) center in $(C_9H_7)_4Th$ occurs in an η^3 manner, where the five-membered rings of each indenyl ligand form the apices of a distorted tetrahedron. The indenyl bonding occurs through the three non-bridging carbons of each five-membered ring, giving thorium a

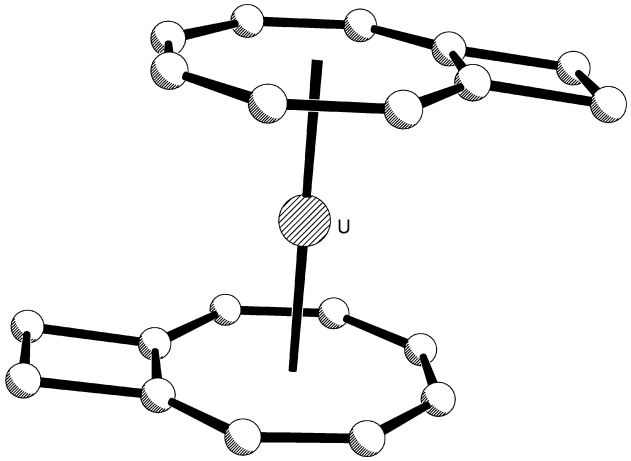

Fig. 22.39 *Crystal strucuture of* $[C_8H_6(CH_2)_2]_2U$ *with hydrogen atoms omitted* (*Zalkin* et al., 1979). *The coordinates were obtained from the Cambridge Structural Database* (*refcode CBOCTU*).

coordination number of 12. The lengthening of the distance between thorium and the remaining two bridging carbons of the five-membered ring is likely a consequence of localization of charge at these sites (Rebizant *et al*., 1986a,b). This is similar to what is observed in $(C_{12}H_{13})_3ThCl$ (containing a trimethyl indenyl ligand) (Spirlet *et al*., 1982) and $(C_9H_7)_3UCl$. In the latter case, the three shorter U–C bond distances range from 2.67(1) to 2.77(1) Å, while the two longer bonds are in the range of 2.79(1)–2.89(1) Å, suggesting trihapto bonding. However, the authors suggest the possibility of pentahapto bonding if one considers steric interferences from chloride and the six-membered ring (Burns and Laubereau, 1971). The trihapto indenyl coordination mode is also reported in the bromide and iodide analogs of the uranium complex (Spirlet *et al*., 1987b; Rebizant *et al*., 1988).

Pentahapto coordination of the indenyl ligand is apparent in the structures of several complexes, including $(C_9H_7)_3U$ (Meunier-Piret *et al*., 1980a), $(C_9H_7)_2U(BH_4)_2$ (Rebizant *et al*., 1989), and $(C_9H_7)UBr_3(THF)(OPPh_3)$ (Meunier-Piret *et al*., 1980b). In the tri-indenyl uranium complex (Fig. 22.40), the $U–C_{indenyl}$ bond distances to the five-membered ring are very similar; for instance, these distances for one of the indenyl rings are 2.846, 2.802, 2.845, 2.833, and 2.804 Å, with no bridging/non-bridging correlation. The first example of monhapto indenyl coordination is in the structure of $(C_{15}H_{19})_3ThCl$, where the hexamethyl indenyl ligand is σ-bonded through one carbon of each five-membered ring to thorium (Spirlet *et al*., 1992b).

Arene complexes of the actinides are very few (and limited to uranium); those for which structures are available show η^6 π-bonding of the aromatic ring

* Semicolons used to differentiate coordination to different metal centers or different structures.

(C_6H_6) to the metal center. For example, in the complexes $(C_6H_6)U(AlCl_4)_3$ (Cesari *et al.*, 1971) and $(C_6Me_6)U(AlCl_4)_3$ (Cotton and Schwotzer, 1987), the hexahapto arene ligands are bound to the uranium centers along with three bidentate $AlCl_4$ ligands (through chlorine), resulting in pentagonal bipyramidal structures (Fig. 22.41). In the case of $[(C_6Me_6)UCl_2]_2(\mu\text{-}Cl)_3(AlCl_4)$, as well as other U(III)–benzene complexes, the U–benzene (centroid) distances are considerably longer than in traditional anionic π-ligands. This is a strong indication of the relatively weak bonds that form in these types of complexes with the neutral arene ligand (Cotton and Schwotzer, 1985).

22.6 SUMMARY

The actinide structures that have been presented herein represent a fraction of known f-element compounds that have been studied by neutron and X-ray diffraction techniques. However, this treatment is by no means exhaustive as it

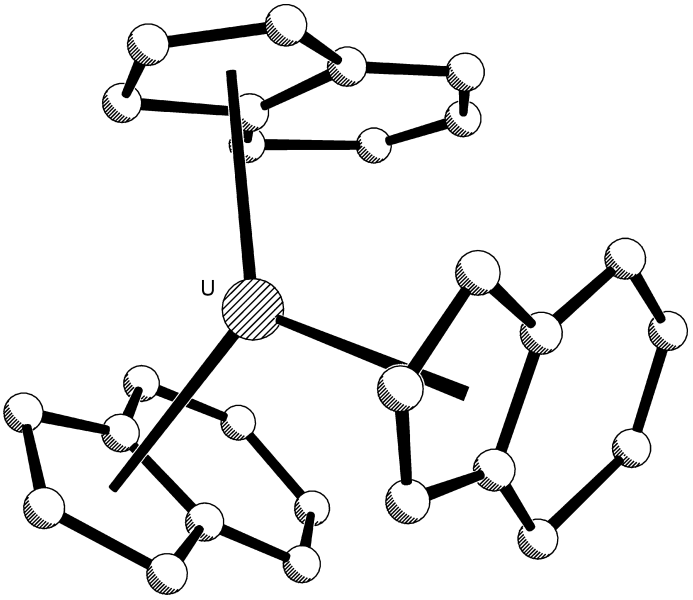

Fig. 22.40 *Crystal strucuture of* $(C_9H_7)_3U$ *with hydrogen atoms omitted* (*Meunier-Piret* et al., 1980*a*). *The coordinates were obtained from the Cambridge Structural Database* (*refcode TRINUR*).

would require several more chapters of comparable length. It should be apparent that the study and structural characterization of actinide compounds continues to play an important role in understanding the nature of this fascinating row of elements. While it is true that most simple and fundamental actinide compounds have been structurally characterized over the past 50 years, these studies are only the 'tip of the iceberg' in terms of what can and has yet to be discovered.

Due to the complex nuclear wastes that exist at many sites, the intricacies of environmental actinide migration and interaction phenomena, the task-specific nature of fuel processing schemes for the recovery of heavy elements, and a continued fundamental academic interest in these elements, advances in actinide chemistry will continue to be increasingly important into the foreseeable future. These advances must necessarily be accompanied by more complex structural analyses that will achieve a more thorough understanding of the chemical behavior of the actinides.

The development of more advanced X-ray and neutron diffraction instrumentation, along with the use of more exotic techniques such as extended X-ray absorption fine-structure (EXAFS) spectroscopy and even highly advanced *ab initio* quantum mechanics tools based on relativistic theory, will be

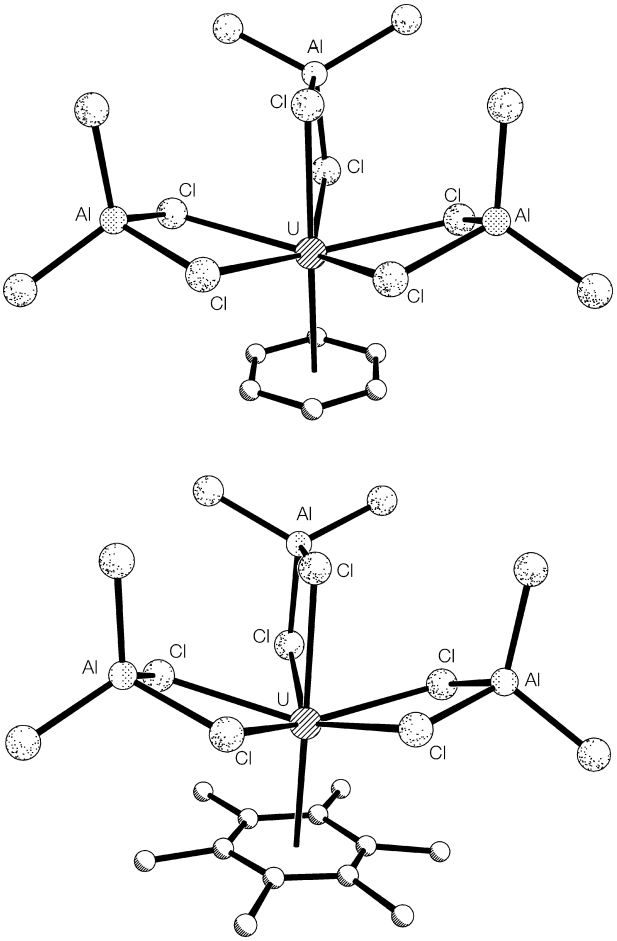

Fig. 22.41 *Crystal strucutures of* $(C_6H_6)U(AlCl_4)_3$ (*Cesari* et al., 1971) *and* $(C_6Me_6)U(AlCl_4)_3$ (*Cotton and Schwotzer,* 1987) *with hydrogen atoms omitted. The coordinates were obtained from the Cambridge Structural Database* (*refcodes BNZUAL and FODRUL*).

paramount in moving forward. These techniques will continue to assist in the elucidation of the critical aspects of actinide electronic structure and bonding, such as the role of 5f electrons in covalent interactions, that are still widely studied and debated. Nonetheless, the actinides are a series of elements unlike any other that will continue to provide ample challenges for chemists worldwide and push the limits of existing technology, particularly in the area of structural determination.

CHAPTER TWENTY THREE

ACTINIDES IN SOLUTION: COMPLEXATION AND KINETICS

Gregory R. Choppin and Mark P. Jensen

23.1 INTRODUCTION

The solution chemistry of the actinide elements has been explored in aqueous and organic solutions. While the relative stabilities of the actinide oxidation states and the types of complexes formed with the actinide cations in these states vary between solvents, the fundamental principles governing their redox reactions and their complexation strengths are the same regardless of the solvent. This chapter focuses on aqueous actinide chemistry, reflecting the wide variety of studies on actinide reactions in aqueous solutions. However, three factors that are important for actinides in non-aqueous solvents should be noted. First, in non-aqueous solvents, the formation of neutral cation–anion ion pairs is often dominant due to the lower (as compared to water) dielectric constants of the solvents. Second, non-aqueous conditions also allow the formation of complexes between actinide cations and ligands containing soft Lewis base groups, such as sulfur. Third, non-aqueous solvents are often useful for

stabilizing redox-sensitive actinide complexes, as oxidation states that are unstable in aqueous solution may be stable in non-aqueous solutions (Mikheev *et al.*, 1977; Hulet *et al.*, 1979).

Actinide cations can exist in a variety of oxidation states (2+ to 7+) in aqueous solution, with trivalent, tetravalent, pentavalent, and hexavalent actinides being the most common. However, there is wide variability in the stability of a particular oxidation state across the actinide series and for some actinides several oxidation states can coexist in the same solution. This is most evident for plutonium as there are small differences in the redox potentials of Pu(III), Pu(IV), Pu(V), and Pu(VI) over a range of pH values (Fig. 23.1).

The divalent oxidation state is the most stable form of nobelium in acidic aqueous solution. It is strongly stabilized, relative to the trivalent state, by the formation of a closed, $5f^{14}$ shell, as reflected in the large reduction potential of the No^{3+} aquo ion [E°(No(III)/No(II)) = +1.45 V vs NHE] (see Chapter 19).

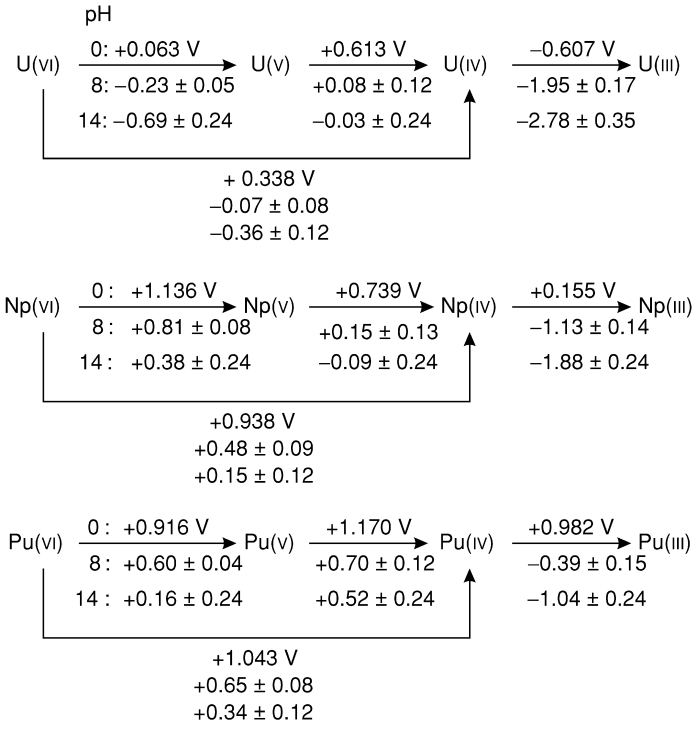

Fig. 23.1 *Reduction potential diagrams for uranium, neptunium, and plutonium for* 1 M $HClO_4$, *pH* 8, *and* 1 M *NaOH* (*Choppin* et al., 2002). *Values for* 1 M $HClO_4$ *are formal potentials for that medium.*

This is in direct contrast to nobelium's lanthanide homolog, ytterbium, which is significantly more stable as E°(Yb(III)/Yb(II)) = –1.05 V vs NHE (Morss, 1985). The stability of No(II) suggests that isoelectronic Md(I) might be expected in aqueous solution. However, while Md(I) has been reported (Mikheev *et al.*, 1980), its existence has not been confirmed (Hulet *et al.*, 1979; Samhoun *et al.*, 1979). Md(II) is moderately stable in acidic solution [E°(Md(III)/Md(II)) = −0.15 V vs NHE], and can be produced through the reduction of Md(III) by Cr(II), Eu(II), or metallic zinc. Nobelium and mendelevium are the only actinides stable as divalent cations in aqueous solution but Am(II), Cm(II), and Cf(II) can be produced transiently in aqueous acidic solutions by pulse radiolysis (Gordon *et al.*, 1978). Trivalent californium, einsteinium, and fermium also can be reduced to the divalent oxidation state by Sm(II) or Yb(II) in 85% ethanol/water.

The trivalent oxidation state is the most stable form of actinium and the transplutonium actinide ions, americium to mendelevium and lawrencium, in aqueous solution. Pu(III) is readily produced by reduction, but it is slowly oxidized to Pu(IV) by the radiolysis products from the α-decay if more than tracer amounts of ^{238}Pu or ^{239}Pu are present. Solutions of the long-lived plutonium isotopes ^{242}Pu and ^{244}Pu in 1 M perchloric acid show little oxidation of Pu(III) after storage for weeks. Np(III) is less stable than Pu(III) but its oxidation to Np(IV) is very slow in the absence of oxygen. U(III) is a strong reducing agent, oxidizing in water. Trivalent thorium and protactinium are not stable in solution.

All the actinides from thorium to californium form tetravalent species in aqueous solution. Th(IV) is the only oxidation state of thorium that is stable in solution. Pa(IV), U(IV), and Np(IV) are stable in the absence of oxygen. Low concentrations of Pu(IV) are stable in acidic aqueous solutions even in the presence of oxygen, but the similarity of the potentials of the Pu(IV)/Pu(V), Pu(V)/Pu(IV), and Pu(IV)/Pu(III) redox couples can make it difficult to prepare and maintain high concentrations of plutonium in a single oxidation state because of the resulting tendency of plutonium to undergo disproportionation reactions (see Section 23.10). Tetravalent americium, curium, berkelium, and californium are much less stable than the other An(IV) species, but they can be prepared in aqueous solution with strong oxidants in the presence of fluoride, phosphate, or polyoxometallate ligands, which form strong complexes with the tetravalent actinides. Bk(IV) is the most stable of the tetravalent transplutonium species with a Bk(IV)/Bk(III) reduction potential similar to that of Ce(IV) [E°(Ce(IV)/Ce(III)) = +1.6 V vs NHE] (Antonio *et al.*, 2002).

The actinides from protactinium to americium can be prepared in the pentavalent oxidation state. Pa(V) and Np(V) are the most stable oxidation states of these elements in aqueous solution, though NpO_2^+ disproportionates to Np(IV) and Np(VI) at high neptunium concentrations and acidities (>8 M HNO_3). UO_2^+ and PuO_2^+ are very susceptible to disproportionation, but become more stable as the uranium or plutonium concentration is decreased or the pH is increased.

PuO_2^+ becomes the predominant dissolved form of plutonium in natural waters (Nelson and Lovett, 1978). AmO_2^+ is a strong oxidant and is reduced to Am(III) by alpha radiolysis.

The hexavalent oxidation state of the actinides, which is present as AnO_2^{2+} ions in aqueous solution, is known for the actinides from uranium to americium. UO_2^{2+} is the most stable form of uranium in solution and is the most stable of the actinyl(VI) cations. The stability of the actinyl(VI) cations decreases in the order $UO_2^{2+} >> PuO_2^{2+} > NpO_2^{2+} > AmO_2^{2+}$. Np(VI) can be reduced by cation exchange resin to Np(V) (Sullivan *et al*., 1955).

The heptavalent actinides, Np(VII) and Pu(VII), are unstable in acidic solution. The reduction of Np(VII) and Pu(VII) to the hexavalent oxidation state is very slow in alkaline solutions (Spitsyn *et al*., 1968; Sullivan and Zielen, 1969), and is reversible in 1 M NaOH (Zielen and Cohen, 1970). The structure of the Np(VII) anion, $NpO_4(OH)_2^{3-}$, is the same in the solid state (Burns *et al*., 1973; Tomilin *et al*., 1981; Grigor'ev *et al*., 1986) and in solution (Appelman *et al*., 1988; Williams *et al*., 2001). The existence of Am(VII) (Krot *et al*., 1974; Shilov, 1976) is still a matter of controversy.

Given the stabilities of the various oxidation states, as well as the limited availability and high specific activity of many of the actinide nuclides, there are comparatively few solution studies of the complexes of actinium, protactinium, and the transplutonium elements from berkelium to lawrencium. Quantitative information about the complexation of actinide ions in the less common oxidation states, An(II) and An(VII), also is very scarce. The lack of data on these species can often be filled by extrapolation from the behavior of other, better studied actinide cations.

Stability constants provide a measure of the resistance of a metal–ligand complex to dissociation in solution, and are directly related to the Gibbs energy of complexation. It is often difficult to measure the chemical activities of actinide ions, ligands, and complexes, so concentrations are used commonly in place of activities for calculations of stability constants. Such concentration stability constants are valid for only a limited range of conditions due to their dependence on the ionic strength of the solution. The concentration stability constant, β_{nq}, for the reaction of an actinide cation, An, with a ligand, L, according to the equation,

$$n\mathrm{An} + q\mathrm{L} \rightleftarrows \mathrm{An}_n\mathrm{L}_q$$

is

$$\beta_{nq} = [\mathrm{An}_n\mathrm{L}_q]/[\mathrm{An}]^n[\mathrm{L}]^q \tag{23.1}$$

This notation is used throughout this chapter to identify stability constants, Gibbs energies (ΔG_{nq}), enthalpies (ΔH_{nq}), and entropies (ΔS_{nq}) of complexation of n actinide cations by q ligands.

23.2 HYDRATION OF ACTINIDE CATIONS

The hydration of an actinide cation is a critical factor in the structural and chemical behavior of the complexes. Although f-element salts generally have large lattice energies, many are fairly soluble in water, reflecting the strength of the interactions between the metal cations and water molecules. Once an actinide cation is dissolved in an aqueous solution, the formation of inner sphere complexes involves displacement of one or more water molecules by each ligand. In the reaction with simple ligands to form inner sphere complexes, the release of water molecules from the hydration spheres of the ligand and actinide ion to the bulk solvent contributes to the thermodynamic strength of the complexes formed by increasing the entropy, but some of this gain is offset by a positive enthalpy contribution.

The size and structure of the hydration sphere of a metal ion have been probed by direct and indirect methods. Direct methods include X-ray and neutron diffraction, X-ray absorption fine structure (XAFS) measurements, luminescence decay, and nuclear magnetic resonance (NMR) relaxation measurements, while the indirect methods involve compressibility, NMR exchange, and optical absorption spectroscopy. Theoretical and computational studies are also becoming important in understanding the coordination geometry and coordination number (CN) of actinide ion hydrates (e.g. Spencer *et al*., 1999; Hay *et al*., 2000; Tsushima and Suzuki, 2000; Antonio *et al*., 2001).

23.2.1 Trivalent actinides

Much of the initial hydration data reported for trivalent actinide cations were derived by analogy to the experimental data for the trivalent lanthanide ions. In the lanthanide studies, the data is consistent with formation of an isostructural series with nine water molecules coordinated to the early members of the lanthanide series that transitions to an isostructural series containing eight water molecules over the middle members of the lanthanide series. This reflects the decrease in radius with increasing atomic number; i.e. the lanthanide (and actinide) contraction. The transition between CN = 9 and 8 occurs between Pm(III) and Dy(III) for the Ln(III) series. The trivalent cations of both the An(III) and Ln(III) series have similar cationic radii, and a similar decrease in hydration number from nine to eight is observed for the trivalent actinide elements between Am(III) and Es(III) (Table 23.1), which span the same range of cationic radii as Pm(III)–Dy(III).

Initial measurements of the hydration of the trivalent actinides involved electrophoretic and diffusion methods in which it is difficult to differentiate between the total hydration (all of the water molecules that feel the effect of a cation over several concentric hydration spheres) and first sphere or primary hydration (i.e. the water molecules directly coordinated to the cation).

Table 23.1 *Hydration radii, R_b, hydration numbers, h, and primary sphere hydration, N_{H_2O}, of trivalent actinide ions obtained by electrophoresis and diffusion measurements* (*Lundqvist* et al., 1981; *Fourest* et al., 1984; *David*, 1986).

[a] Data obtained from diffusion measurements.

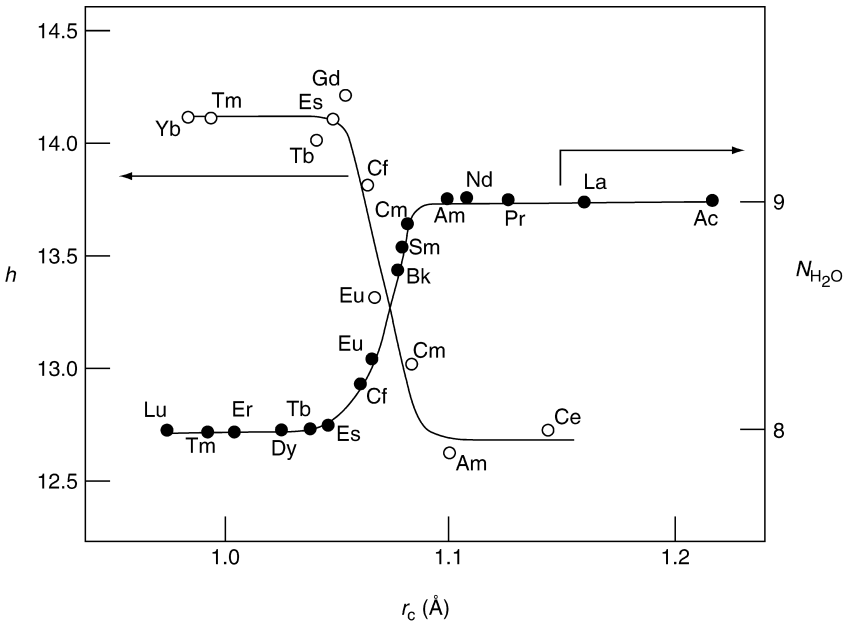

Fig. 23.2 *Total hydration (h) and number of water molecules in the primary coordination sphere(N_{H_2O}) of Ln^{3+} and An^{3+} cations* (*Rizkalla and Choppin,* 1994).

Fourest *et al.* (1984) estimated the primary, inner sphere coordination numbers, N_{H_2O} of the trivalent actinides by interpolation using the values of the lanthanide elements (Habenschuss and Spedding, 1979a, 1979b, 1980). The two sets of hydration numbers for Ln(III) and An(III) cations are presented in Fig. 23.2.

These values show that the primary hydration number, N_{H_2O}, of the trivalent metal ions as a function of cationic radius for coordination number 8 is, in both cases, sigmoidal with smaller primary hydration for the smaller, heavier cations. By contrast the opposite trend is seen for the total hydration number, h, which is smaller for the lighter cations. This was attributed by Fourest's group to the increase in the cationic charge density as the atomic number increases. It should be noted that the break in the properties of the two series also is observed in other physical data such as apparent molal volume, relative viscosity, heat of dilution, and electrical conductivity.

The coordination geometry in the first hydration sphere has been obtained primarily from neutron diffraction measurements and is consistent with formation of nona-coordinate lanthanides with a tricapped trigonal prismatic (TCTP) structure. X-ray crystal structures of nona-coordinate Ln(III) and Pu(III) triflates also show this geometry in the solid state (Chatterjee *et al.*, 1988; Matonic *et al.*, 2001). Similarly, the data for the heavier members of the series, with coordination number 8, are consistent with a square prismatic structure. The ions that are intermediate between these two extremes (Pm–Dy or Am–Es) show an equilibrium mixture of the structures for $N_{H_2O} = 8$ and $N_{H_2O} = 9$. Optical spectroscopy indirectly confirms that the solid state structures of the hydrated An(III) ions persist in solution as well (Carnall, 1989; Matonic *et al.*, 2001), and fluorescence lifetime measurements of Cm(III) solutions give a direct primary hydration number of (9.2 ± 0.5) (Kimura and Choppin, 1994).

While it cannot give the coordination geometry, XAFS measurements are useful for determining the average actinide–oxygen bond distances of the first hydration sphere and N_{H_2O} in liquid samples at concentrations much lower than those accessible by X-ray or neutron diffraction. An–OH_2 bond distances and coordination numbers have been determined by XAFS for all of the An(III) from U(III) to Cf(III) at concentrations of $0.5-20 \times 10^{-3}$ M. The An–O bond distances are all consistent with octa- or nona-coordination, and the average coordination number reported across the actinide series is (9 ± 1). As is the case with the other oxidation states, some investigators report hydration numbers 10–20% higher than this, but this is within the generally accepted absolute uncertainty of XAFS-based coordination number determinations and there are a number of factors that could explain systematic deviations from the true coordination number, as discussed by Allen *et al.* (2000).

23.2.2 Tetravalent actinides

Information relating to the hydration numbers of tetravalent actinide ions is somewhat limited. From NMR peak areas, an estimate of the primary hydration number of Th(IV) in an aqueous acetone solution of $Th(ClO_4)_4$ at $-100°C$ indicated a hydration number of 9 (Butler and Symons, 1969; Fratiello *et al.*, 1970a) whereas an indirect, NMR line width method gave $N_{H_2O} = 10$ (Swift and Sayre, 1966). However, the direct and accurate method of solution X-ray

diffraction gave $N_{H_2O} = (8.0 \pm 0.5)$ for acidic, 1–2 M $Th(ClO_4)_4$ and $ThCl_4$ solutions (Johansson *et al.*, 1991). Other reported values are: Th(IV) (10.8 ± 0.5) and U(IV) (10 ± 1) (Moll *et al.*, 1999), Np(IV) (11.2 ± 0.4) (Allen *et al.*, 1997), Th(IV) 11.0, U(IV) 10.65, Np(IV) 10.2, and Pu(IV) 10.0 (David and Vokhmin, 2003).

An entirely different method for the estimation of total hydration numbers from conductivity measurements has been proposed and developed by Gusev (1971, 1972, 1973). This method gave a value of $h = 20$ for the total hydration number of Th(IV), which can be compared to the values of 22 obtained from compressibility measurements (Bockris and Saluja, 1972a,b) that are based on the lower compressibility of a solvate's solvent molecules as a result of electroconstriction (Passynskii, 1938).

Reviews of the available evidence pertaining to hydration numbers of U(IV) and Np(IV) have suggested that two forms of each of these aquo ions may exist, differing in geometry and possibly coordination number (Rykov *et al.*, 1971; Sullivan *et al.*, 1976). Radial distribution functions from X-ray measurements on 2 M uranium(IV) perchlorate solutions indicate a primary hydration number of $N_{H_2O} = (7.8 \pm 0.3)$ with no perchlorate in the primary coordination sphere (Pocev and Johansson, 1973). XAFS measurements of Np(IV) and Bk(IV) aquo cations gave $N_{H_2O} = (9 \pm 1)$ and (7.9 ± 0.5), respectively (Antonio *et al.*, 2001, 2002). The An–O bond distances derived from XAFS for the An(IV) hydrates, which are more accurate than the coordination numbers, also are most consistent with a primary hydration number of 8. Changes in the optical absorption spectra of U(IV), Np(IV), and Pu(IV) also have been interpreted as consistent with $N_{H_2O} = 8$ (Rykov *et al.*, 1973).

23.2.3 Pentavalent and hexavalent actinides

The hydration of pentavalent actinyl cations has been studied less than any of the other common oxidation states, but the findings are quite consistent from study to study. In the solid state, neptunyl(V) perchlorate has a total equatorial coordination number of 5. Four oxygens come from inner sphere water molecules and a fifth oxygen comes from the '-yl' oxygen of a neighboring NpO_2^+ ion (Grigor'ev *et al.*, 1995), as discussed in Section 23.9. In solutions, where the AnO_2^+ concentration is usually quite small, cation–cation complexes (Section 23.9) of AnO_2^+ are not important, and fully hydrated AnO_2^+ cations are expected. Optical absorption spectra of AnO_2^+ in solution are consistent with a primary hydration number of 5, based on symmetry considerations and comparison with the spectra of solid state complexes of known structures (Garnov *et al.*, 1996). XAFS measurements on solutions containing 1×10^{-3} to 2×10^{-2} M NpO_2^+ agree well with this, consistently giving a hydration number of 5 and Np–O equatorial bond distances that suggest the coordination of 5 water molecules (Combes *et al.*, 1992; Allen *et al.*, 1997; Antonio *et al.*, 2001).

Hydration numbers of the hexavalent actinyl cations have received more attention, particularly for UO_2^{2+}. The Raman spectra of aqueous uranyl

solutions were interpreted to show the presence of six inner sphere water molecules in the plane perpendicular to the O=U=O axis (Sutton, 1952). However, similar hydration numbers have been obtained by methods that are influenced by the second hydration shell. For example, activity coefficient measurements suggest a hydration number of 7.4 relative to an assumed hydration number of zero for Cs(I) (Hinton and Amis, 1971). Similarly, a hydration number of 7 has been derived from conductivity measurements (Gusev, 1971, 1972, 1973).

In the solid state, $UO_2(ClO_4)_2 \cdot 7H_2O$ contains discrete pentagonal bipyramidal $UO_2(H_2O)_5^{2+}$ cations and ClO_4^- anions (Alcock and Esperås, 1977), an indication that, like the actinyl(V) cations, penta hydration may be preferred by actinyl(VI) cations in solution. Garnov *et al.* (1996) also deduced a hydration number of 5 for AnO_2^{2+} from absorption spectra of PuO_2^{2+}. It seems likely that this is correct since XAFS measurements of AnO_2^{2+} solutions also give average hydration numbers of ranging from 4.5 to 5.3 and An–O equatorial bond distances that are close matches for those of pentacoordinate $UO_2(H_2O)_5^{2+}$ in $UO_2(ClO_4)_2 \cdot 7H_2O$ (Allen *et al.*, 1997; Wahlgren *et al.*, 1999; Antonio *et al.*, 2001). In agreement with this, a study of uranyl(VI) perchlorate solutions by X-ray diffraction concluded that the hydration number of UO_2^{2+} could be either 4 or 5 (Åberg *et al.*, 1983a).

23.2.4 Solvation and hydration in non-aqueous media

Solvation numbers of actinide cations in non-aqueous media have been measured for only a few systems. FTIR investigations of the homologous lanthanide solvates $[Ln(NO_3)_3(DMSO)_n]$ in anhydrous acetonitrile (Bünzli *et al.*, 1990) indicated a change in coordination number in the middle of the series near Eu(III) from nine to eight with increasing atomic number. NMR spectroscopy, stoichiometric, and XAFS measurements gave a solvation number of 2 for uranyl nitrate salts in tri(*n*-butyl)phosphate (TBP) solutions. The total coordination number would include two for TBP coordination and four for the bidentate nitrate coordination (Siddall and Stewart, 1967; Den Auwer *et al.*, 1997).

A commonly used extractant ligand in actinide separation science is thenoyltrifluoroacetone, TTA. The luminescent lifetimes of the Cm(III) complex with TTA in various organic solvents was 130–140 μs which gives $N_{H_2O} = (3.8 \pm 0.5)$. This indicates the formation of a Cm–TTA complex with a total CN = 10 (Dem'yanova *et al.*, 1986).

Solvation of UO_2^{2+} ions in water–acetone and water–dioxane mixtures were studied by ultrasound (Ernst and Jezowska-Trzebiatowska, 1975a,b). The resulting hydration numbers are listed in Table 23.2. The data show a decrease in the hydration numbers with increasing dioxane concentration. This can be attributed to a partial replacement of waters of hydration by the organic

Table 23.2 *Hydration numbers of AnO_2^{2+} ions in aqueous and mixed solvents.*

solvent although inner sphere complexation by the anion would also reduce the hydration number.

This result is in agreement with low-temperature ^{1}H-NMR measurements for both UO_2X_2 (X is ClO_4^-, Cl^-, or NO_3^-) (Fratiello *et al.*, 1970b; Shcherbakov and Shcherbakova, 1976) and NpO_2^{2+} (Shcherbakov *et al.*, 1974) compounds (Table 23.2). For uranyl, the average number of bound waters was shown to increase with increasing molar ratio, $[H_2O]/[UO_2^{2+}]$, to a limiting value of six for ratios from 40 to 70 depending on the anion (Shcherbakov and Shcherbakova, 1976). The stronger the complexing ability of the anion, the higher the ratio required to reach maximum hydration. More recent high-field NMR measurements of UO_2^{2+} and NpO_2^{2+} hydration report $N_{H_2O} = 4.7–4.9$ for a range of $[H_2O]/[AnO_2^{2+}]$ ratios (Åberg *et al.*, 1983a; Bardin *et al.*, 1998).

23.2.5 Measurements of N_{H_2O} by TRLF technique

Beitz and Hessler (1980) reported the first study of aqueous Cm(III) photophysics, including measurement of the emission spectrum and lifetimes of aqueous of Cm^{3+} in H_2O and D_2O. Beitz (1994) reported a value of $N_{H_2O} = 9$ for the hydrated Cm^{3+} cation and smaller residual inner sphere hydration numbers for a number of Cm(III) complexes in a review of the theoretical and experimental aspects of such studies to 1994. Studies by time-resolved laser fluorescence (TRLF) with Cm(III) have proven very valuable for understanding the hydration of trivalent actinides. Measurement of the Cm fluorescence decay constant, k(Cm), as a function of residual hydration in crystals of lanthanide complexes of known structure and hydration doped with Cm(III) resulted in equation (23.2) for calculation of the residual hydration numbers (Kimura and Choppin, 1994):

$$N_{H_2O} = 0.65k(\mathrm{Cm}) - 0.88 \tag{23.2}$$

where k(Cm) is expressed in ms^{-1}. This equation assumes no contribution from the ligand to the deexcitation of the luminescence excited state and that quenching of the excitation results only from interaction with the OH vibrators of the water in the first coordination sphere. The absolute uncertainty in the hydration numbers calculated from equation (23.2) is ± 0.5. Use of equation (23.2) gives a value for N_{H_2O} of Cm^{3+} in water of (9.2 ± 0.5).

The residual hydration in the primary coordination sphere of Cm(III) in a number of aminopolycarboxylate complexes (Kimura and Choppin, 1994) is plotted in Fig. 23.3 and shows the variation of the measured hydration number, N_{H_2O}, as a function of pH. These data indicate that the complexation is initiated around pH 2–4 and the hydration number remains constant until pH values of 10 and higher are reached. This constancy over the medium pH range is consistent with the formation of very strong 1:1 complexes. The two plateaus in the data for the NTA complex reflects the successive formation of 1:1 and 1:2 complexes for this smaller ligand. In Table 23.3, the calculated hydration numbers reported for the different complexes are listed for Am(III) and Nd(III) (Kimura and Kato, 1998) and Cm(III) and Eu(III) (Kimura *et al.*, 1996). In these systems, the total coordination number (i.e. the sum of the average number of ligand donor groups and primary water molecules) was (9.3 ± 0.4) for Cm(III), (10.7 ± 0.5) for Am(III), (8.8 ± 0.5) for Eu(III) and (9.9 ± 0.5) for Nd(III) complexation.

The TRLF technique has been used to characterize Cm(III) complexation in natural waters by ligands such as OH^-, CO_3^{2-}, NO_3^- and humic acids (Table 23.4). While the aqueous Cm^{3+} ion has nine water molecules in the primary coordination sphere, $N_{H_2O} = 8.5$, 8.0, 7.0, 5.0, and 3.0 are expected for monohydroxide, dihydroxide, monocarbonate, dicarbonate, and tricarbonate complexes, respectively, from the assumptions that OH vibrators of coordinated water molecules act independently in the de-excitation process and a carbonate ion coordinates with Cm(III) as a bidentate ligand. The N_{H_2O} for each

species calculated from the lifetime in Table 23.4 agrees with each expected value within the experimental uncertainty. The lifetimes measured for Cm(III) humate and fulvate complexes involves two components, which indicates the presence of two types of complexes. The first component gives an N_{H_2O} of 8.2–8.4 and the second, 3.6–3.7.

All of the N_{H_2O} values calculated using equation (23.2) from the fluorescence lifetimes in the literature are chemically reasonable. The determination of the hydration number from fluorescence lifetimes makes it possible to characterize Cm(III) species in aqueous solution at high sensitivity, providing valuable insight into the primary structure of ions in solution.

23.2.6 Hydration in concentrated solutions

Data from luminescence studies in more concentrated media must be evaluated carefully. An example of this is shown in Fig. 23.4 in which the measured hydration number for the trivalent europium ion increases as the perchloric acid concentration increases. This presumably reflects the fact that as the electrolyte concentration increases, the number of water molecules in the

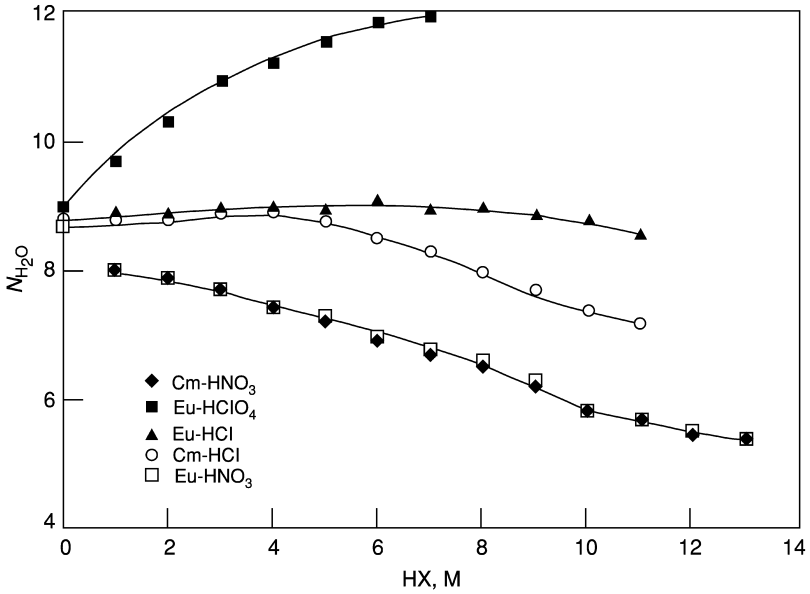

Fig. 23.4 *Variation of the number of water molecules in the primary hydration sphere of trivalent europium and curium ions as determined by TRLF.*

secondary hydration sphere decreases and, consequently, there is a tightening of the bond between the trivalent europium and the hydrate waters in the inner sphere. This tightening allows for more efficient quenching of the fluorescence by the hydroxyl groups of the H_2O. NMR studies (Choppin, 1997) have shown that inner sphere complexation by perchlorate ions does not occur below approximately 8–10 M. Obviously, this calculated increase in hydration number does not represent greater hydration nor does it represent an effect of complexation by perchlorate; rather, it is due to the tighter bonding.

The data in Fig. 23.4 show that the hydration number of the Eu(III) remains relatively constant in hydrochloric acid up to approximately 6–8 M, after which it decreases. The same is true for the Cm(III) hydration number in HCl, which begins a decline at about 5 M HCl. This difference presumably reflects greater complexation of the actinide trivalent ion by the relatively soft anion Cl^-. In fact, this difference in complexation has been used for over 40 years to provide efficient separation of trivalent actinides from trivalent actinides in concentrated HCl solutions by passage through columns of cation exchange resin. Independent studies (Rizkalla and Choppin, 1994) have shown that complexation does occur with the chloride anions for both trivalent actinides and lanthanides in 1.0 M HCl. The constancy of the hydration number in Fig. 23.4 for both

cations to concentrations of ca. 4 M HCl indicates that up to this concentration, only outer sphere complexes are formed and, therefore, the primary hydration sphere is not affected. At higher concentrations, however, there is greater complexation by the soft donor Cl^- with the actinide, which has been interpreted as reflecting an enhanced covalent interaction of trivalent actinide ions relative to that of lanthanide ions of the same ionic radius (Diamond *et al.*, 1954, see Section 23.4). By contrast, in Fig. 23.4 it is seen that the Cm(III) and Eu(III) behavior as a function of nitric acid concentration is very similar from dilute acid to $\geq$12 M. Nitrate ions begin to form inner sphere complexes at lower concentrations than chloride anions do, as reflected in the decreased hydration number even at relatively lower concentrations. However, the oxygens of the nitrate are hard donors and, therefore, there is no evidence of any covalent enhancement in its bonding as is seen with the chloride anions for the trivalent actinide cations relative to the lanthanide cations.

23.2.7 Thermodynamic properties

As Chapter 19 of this work is devoted to the thermodynamic properties of the actinides, their ions and compounds, this section focuses only on the hydration behavior of the actinides to minimize overlap. The values used for the calculations of the thermodynamic properties in this section are taken from literature references, which are sometimes different from those accepted in recent critical assessments of the thermodynamic properties of the actinides (Grenthe *et al.*, 1992; Silva *et al.*, 1995; Lemire *et al.*, 2001; Guillaumont *et al.*, 2003) or those in Chapter 19.

The thermodynamic properties of the actinide ions in the oxidation states III–VI have been reviewed by Morss (1976), Fuger and Oetting (1976), Fuger (1982), and David (1986). Calorimetric measurements of the heats of formation of the trivalent cations are limited to the actinides up to californium that are available in macroscopic quantities and with isotopes of sufficiently low specific radioactivity. Entropies of Pu(III) (Hinchey and Cobble, 1970; Fuger and Oetting, 1976), Th(IV) (Morss and McCue, 1976), and the actinyl ions UO_2^{2+} (Coulter *et al.*, 1940), NpO_2^+ and NpO_2^{2+} (Brand and Cobble, 1970) also have been reported. Data on other actinide species have been estimated across the entire actinide series using various models.

David *et al.* (1985) proposed a general expression for the calculation of the absolute enthalpy of hydration, ΔH°_{hyd}, based on the semiempirical model of Bockris and Reddy (1970). The hydration enthalpy of a cation can be related to the crystallographic radius, R, the hydration number, N_{H_2O}, and the ionic charge, $+Z$, by the equation:

$$\begin{aligned} \Delta H^{\circ}_{hyd} = {} & \alpha Z^2 (R + 2R_W)^{-1} + \beta Z N_{H_2O} (R + R_W)^{-2} \gamma Z N_{H_2O} (R + R_W)^{-3} \\ & + \sigma Z^2 N_{H_2O} (R + R_W)^{-4} + N_{H_2O} W + P(-1)^Z \end{aligned} \tag{23.3}$$

where W is the hydration energy of one water molecule and R_w is the radius of a water molecule, 1.38 Å. The numerical values of the coefficients (α, β, etc.) of equation (23.3) were computed using hydration enthalpies (which included contributions from the hydration of halide anions) of 35 monovalent, divalent, trivalent, and tetravalent ions (David *et al.*, 1985) assuming $N_{H_2O} = 4$ for monovalent, 6 for divalent, and 8 for trivalent and tetravalent cations. The estimated uncertainty between the experimental and calculated enthalpies is 0.4–0.5%.

Bratsch and Lagowski (1985a,b, 1986) proposed an ionic model to calculate the thermodynamics of hydration ΔG°_{hyd}, ΔH°_{hyd}, and ΔS°_{hyd} using standard thermochemical cycles. The model uses the values of the enthalpy of formation of the monoatomic gas $[\Delta H^{\circ}_f(M_g)]$, the ionization potential for the oxidation state under consideration, and the crystal ionic radius of the metal ion. Since the ionization potentials for the actinide ions are not all available, the authors 'back-calculated' an internally consistent set of ionization potentials from selected thermodynamic data (Bratsch and Lagowski, 1986). The general set of equations used are:

$$\Delta H^{\circ}_{hyd}(M^{Z+}) = \Delta H^{\circ}_f(M^{Z+}_{aq}) - \Delta H^{\circ}_f(M^{z+}_g) + Z[\Delta H^{\circ}_f(H^+_g) + \Delta H^{\circ}_{hyd}(H^+_{aq})] \tag{23.4a}$$

$$\Delta S^{\circ}_{hyd}(M^{Z+}) = S^{\circ}(M^{Z+}_{aq}) - S^{\circ}(M^{Z+}_g) + Z[S^{\circ}(H^+_g) + \Delta S^{\circ}_{hyd}(H^+_{aq})] \tag{23.4b}$$

$$\Delta G^{\circ}_{hyd}(M^{Z+}) = \Delta G^{\circ}_f(M^{Z+}_{aq}) - \Delta G^{\circ}_f(M^{Z+}_g) + Z[\Delta G^{\circ}_f(H^+_g) + \Delta G^{\circ}_{hyd}(H^+_{aq})] \tag{23.4c}$$

The calculated Gibbs energies and enthalpies of hydration for the actinide ions are listed in Tables 23.5 and 23.6.

The absolute entropies for the gaseous ions are calculated with the equation (Johnson, 1982):

$$S^{\circ}(M^{Z+}_g) = 1.5R \ln(\text{at wt.}) + R \ln(2J + 1) + 108.75 \tag{23.5}$$

The values of the entropies of the trivalent aquo actinide ions were obtained by interpolation from the dependence of the corrected (structural) entropy term, S°_c (see Chapter 19, equation (19.6)), of the lanthanides on ionic radii (Fig. 23.5) These corrected entropy values are only dependent on the structure of the aquo ion (David *et al.*, 1985). Justification of this approach is provided by the agreement of the calculated value of S°_c of Pu(III) with that from experimental data (Fuger and Oetting, 1976). The entropies are listed in Table 23.7. Similarly, the entropies of the tetravalent actinides were obtained from pertinent data on Th(IV) (Morss and McCue, 1976) and Ce(IV) (Morss, 1976).

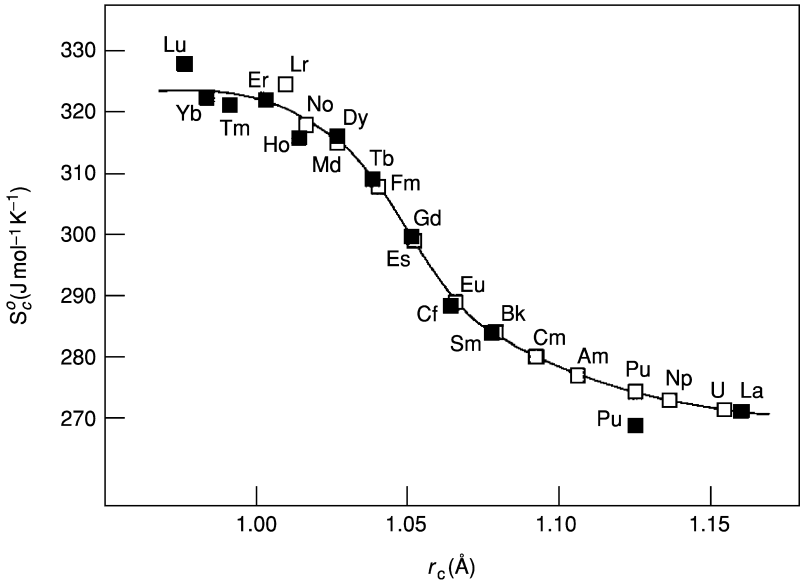

Fig. 23.5 *Variation of the corrected entropy,* S_c^o, *with the crystallographic radius of the trivalent lanthanides and actinides with CN* = 8. (■) *experimental data* (□) *extrapolated data.*

Differences in lanthanide and actinide hydration thermodynamics have been attributed by Bratsch and Lagowski (1986) to relativistic effects in the actinides which perturb the energies of the s, p, d, and f orbitals. The first and second ionization potentials of the 7s electrons of the actinides are higher than those of the 6s electrons of the lanthanides whereas the third ionization potentials are similar for both groups and the fourth ionization potential is lower for the actinides than the lanthanides. A small decrease in IP_3 and IP_4 for the f^7 configuration in the actinides results in smoother variations in the relative stabilities of the adjacent oxidation states across the actinide series while the greater spatial extension of the 5f orbitals increases the actinides' susceptibility to environmental effects (Johnson, 1982).

Nugent *et al*. (1973a,b) proposed equation (23.6) as a basis for comparison of the actinide and lanthanide thermodynamics:

$$P(\mathrm{M}) = \Delta H_\mathrm{f}^\mathrm{o}(\mathrm{M_g}) + \Delta E(\mathrm{M}) - \Delta H_\mathrm{f}^\mathrm{o}(\mathrm{M_{aq}^{3+}}) \qquad (23.6)$$

where ΔE(M) is the promotion energy from the ground state electron configuration to the $f^q d^1 s^2$ configuration where q varies from 0 (La and Ac) to 14 (Lu and Lr). ΔE(M) is approximately zero or near zero for La, Ce, Gd,

and Lu, and for Ac, Pa, U, Np, Cm, and Lr. For the other f-elements, ΔE(M) is positive with accurately known values from spectroscopic measurements (Bratsch, 1983). Fig. 23.6 shows a graph of P(M) for lanthanide (4f) and actinide (5f) ions.

Only for UO_2^{2+} is there extensive data for the actinyl cations. Comparison of ΔH^o_{hyd} and ΔS^o_{hyd} with other 2+ and 3+ cations indicate that the enthalpy of hydration of actinyl(VI) cations is comparable to those of dipositive ions whereas the entropy of hydration is somewhat between that of dipositive and tripositive ions (Marcus and Loewenschuss, 1986). These authors assigned the increase in entropy to the large effective charge on the uranium center, +3.3. The non-spherical symmetry of the uranium atom caused by the shielding effect of the axial uranyl oxygens results in a lower hydration entropy than those of the typical trivalent cations. However, the strong primary sphere interactions from the charge–dipole effects causes more extensive but weaker secondary hydration. As a result, the net enthalpy of hydration is more similar to that of divalent than to trivalent cations.

23.3 HYDROLYSIS OF ACTINIDE CATIONS

Hydrolysis reactions occur for the f-elements in weakly acidic to alkaline solutions in the 3+, 4+, and 6+ oxidation states and often predominate over other complexation reactions in neutral and basic solutions. Hydrolysis of the pentavalent actinides occurs for pH $\geq$ 8. The hydrolysis reactions can be expressed by the general reaction

$$n\mathrm{An}^{z+} + q\mathrm{H_2O} \rightleftarrows \mathrm{An}_n(\mathrm{OH})_q^{nz-q} + q\mathrm{H}^+ \quad (\mathrm{An} = \mathrm{An(III)},\ \mathrm{An(IV)},\ \mathrm{AnO_2^+},\ \mathrm{AnO_2^{2+}}) \tag{23.7}$$

$$^*\beta_{nq} = [\mathrm{An}_n(\mathrm{OH})_q^{nz-q}][\mathrm{H}^+]^q/[\mathrm{An}^{z+}]^n$$

where $^*\beta_{nq}$ increases with increasing cationic charge density. Such hydrolysis reactions can be described as due to the positive charge of the metal ion polarizing the water molecule(s) sufficiently to release the proton(s). They are related to hydroxide complexation reactions:

$$n\ \mathrm{An}^{z+} + q\ \mathrm{OH}^- \rightleftarrows \mathrm{An}_n(\mathrm{OH})_q^{nz-q} \tag{23.8}$$

$$\beta_{nq} = [\mathrm{An}_n(\mathrm{OH})_q^{nz-q}]/[\mathrm{An}^{z+}]^n[\mathrm{OH}^-]^q$$

by $K_\mathrm{W} = [\mathrm{H}^+][\mathrm{OH}^-]$, making $\beta_{nq} = {}^*\beta_{nq}/K_w^q$. The strength of hydrolysis follows the order:

$$\mathrm{An}^{4+} > \mathrm{AnO_2^{2+}} > \mathrm{An}^{3+} > \mathrm{AnO_2^+}$$

This is consistent with most thermodynamic data and reflects the effective charges on the actinide atoms in the actinyl(V) and actinyl(VI) ions (Section 23.4). Hydroxide-bridged polynuclear complexes have been observed for actinide cations and the tendency toward polymer formation (Fig. 23.7) is a function of the charge density of the actinide cation. In the case of Th^{4+} and U^{4+}, X-ray measurements indicate the formation of clusters built of units with an An–An distance in range 3.95–4.00 Å. The kinetics of polymerization–depolymerization becomes more complicated for Pu^{4+}. The slower rate of

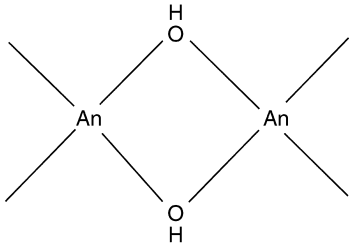

Fig. 23.7 *Structure of hydroxyl bridged actinide hydroxide polymers.*

depolymerization compared with the rate of polymer formation is due to an equilibrium between hydroxo and oxo bridge formation with aging.

23.3.1 Trivalent actinides

With a few exceptions, quantitative hydrolysis measurements of the actinide ions are complicated since the actinide hydroxides are quite insoluble and sorb to surfaces. The increasing pH required for hydrolysis also can result in significant changes in the oxidation state equilibria (e.g. for plutonium). Of the common oxidation states, the trivalent actinides have been the most intensively studied species. Solubility experiments (Rai *et al.*, 1983), solvent extraction (Caceci and Choppin, 1983a), spectroscopy (Stadler and Kim, 1988), and other techniques (Shalinets and Stepanov, 1972) have been used. The low solubility of $An(OH)_3$ in neutral/basic solutions prevents use of conventional absorption spectroscopy. However, time-resolved laser fluorescence spectroscopy allows measurements at the very low concentrations present in neutral/alkaline solutions (Stadler and Kim, 1988).

This laser spectroscopy technique was used to study the hydrolysis of Cm(III) at concentrations as low as 3×10^{-9} M. Values obtained for formation of the 1:1 and 1:2 species at 25°C in 0.10 M ($NaClO_4$) solutions are:

$$\log \beta_{11} = (6.67 \pm 0.18)$$

$$\log \beta_{12} = (12.6 \pm 0.28)$$

The laser fluorescence method has been used by Fanghänel and Kim (1994) to measure the values of $\log \beta_{11}$ and $\log \beta_{12}$ for Cm(III) over a range of ionic strengths from 0.011 to 6.15 M in NaCl solution at pH 8.6.

An evaluation of An(III) hydrolysis has been made by Rai *et al.* (1983). Table 23.8 lists the $\log {}^*\beta_{nq}$ and $\log K_{sp}$ values for the hydrolytic reactions of Am(III) from this reference. In carbonate-free environments, $Am(OH)^{2+}$ and $Am(OH)_2^+$ are the major species at pH 8.2, while, in carbonate-rich waters, $Am(CO_3)^+$ and $Am(CO_3)_2^-$ may also be significant components (Fig. 23.8). Because of the strong sorption characteristics of the hydroxide species, Am(III) is frequently removed from solution onto colloids, sediments, and humic substances. Stadler and Kim (1988) and the OECD-NEA (Silva *et al.*, 1995, Guillaumont *et al.*, 2003) have reviewed americium hydrolysis, while the hydrolysis of trivalent actinides has been reviewed by Fuger *et al.* (1992) and Rizkalla and Choppin (1994).

Polynuclear hydroxides of the formula $An_2(OH)_2^{4+}$ have been reported for Np(III) (Allard *et al.*, 1980) and Pu(III) (Allard and Rydberg, 1983) with values for $\log {}^*\beta_{22}$ of ca. −15 (Np) and −16 (Pu). Values for the $AnOH^{2+}$ hydrolysis formation constants for the trivalent actinide ions are listed in Table 23.9.

Table 23.8 *Hydrolysis constants for Am(III), $I = 0$ M; $T = 22°C$ (Rai* et al., 1983; *Felmy* et al., 1990).

23.3.2 Tetravalent actinides

Study of the aqueous chemistry of tetravalent actinides can be difficult due to the very strong tendency of the cations to hydrolyze even in acidic solutions (pH $\leq$ ca. 2). Moreover, An(IV) cations of elements from protactinium through americium can undergo redox reactions relatively easily if the pH is not very low or in the absence of a strong complexant, making it difficult to ensure that only the tetravalent oxidation state is present.

Thorium is found in aqueous solution only in the 4+ oxidation state and is often used as a model for Np(IV) and Pu(IV) behavior. However, it has a smaller ionic charge density than these cations, due to its larger ionic radius, that results

in significant differences in the extent of the hydrolytic reactions. The hydrolysis of Th^{4+} involves extensive formation of polynuclear complexes. In the earlier stages of the hydrolysis in perchlorate media, when the number of hydroxide ions per thorium atom in the complexes is ≤ 2, the hydrolytic reactions are fully reversible and equilibrium is quickly reached (Hietanen, 1954; Kraus and Holmberg, 1954; Baes *et al.*, 1965). The first extensive measurements of the hydrolysis behavior were interpreted (Hietanen, 1954) as indicating the formation of an infinite series of 'core + links' complexes, $Th((OH)_3Th)_n^{4+n}$. However, other measurements over large pH and Th(IV) concentration ranges could be satisfactorily fitted with three polymers, $Th_2(OH)_2^{6+}$, $Th_4(OH)_8^{8+}$, and $Th_6(OH)_{15}^{9+}$, and two monomers, $ThOH^{3+}$ and $Th(OH)_2^+$ (Kraus and Holmberg, 1954; Baes *et al.*, 1965). In Table 23.10, the constants ${}^{*}\beta_{nq}$ are listed for the reactions:

$$n\mathrm{Th}^{4+} + q\mathrm{H_2O} \rightleftarrows \mathrm{Th}_n(\mathrm{OH})_q^{4n-q} + q\mathrm{H}^+$$

Of the complexes mentioned, $\mathrm{Th_2(OH)_2^{6+}}$ is significant in chloride media (Hietanen and Sillen, 1968; Baes and Mesmer, 1976; Milic, 1981) as well as $\mathrm{Th_2(OH)_3^{5+}}$ and $\mathrm{Th_6(OH)_{14}^{10+}}$. In nitrate media, the complexes $\mathrm{Th_2(OH)_2^{6+}}$, $\mathrm{Th_6(OH)_{15}^{9+}}$ and $\mathrm{Th_3(OH)_5^{7+}}$ predominate (Milic and Suranji, 1982). Constants for the hydroxo complexes are somewhat smaller in chloride and nitrate than in perchlorate media (Table 23.10).

For values $n \geq 2$ (equation (23.7)), equilibrium is more slowly attained than for mononuclear complex formation, resulting in formation of larger polymers before precipitation takes place. Direct structural determinations by X-ray diffraction on hydrolyzed thorium nitrate solutions confirmed the existence of the dimer $\mathrm{Th_2(OH)_2^{6+}}$ (Johansson, 1968). The Th–Th distance is 3.99 Å, i.e. exactly the same as in the solid $\mathrm{Th_2(OH)_2(NO_3)_6(H_2O)_8}$ that contains dimers joined by double hydroxo bridges. As the hydrolysis reaction proceeds, complexes of higher nuclearity become prominent although the Th–Th distance stays almost the same, approximately 3.94 Å. The hydrolytic complexes formed in concentrated nitrate solutions also contain nitrate ions coordinated as bidentate ligands. As expected, the number of nitrate ions coordinated per thorium decreases as hydrolysis becomes more extensive. Diffraction measurements by Johansson (1968) on hydrolyzed solutions of thorium perchlorate and chloride give the same Th–Th distance 3.94 Å, implying that the same type of hydroxo-bridged complexes are formed in these media.

Rai *et al.* (1997) have reported a value of $\log K_{sp}^0 = -45.5$ for amorphous $\mathrm{Th(OH)_4}$ while Neck and Kim (2001) have proposed for a value of $\log K_{sp}^0$ of $-(47.0 \pm 0.8)$ (Table 23.11). The values of $\log K_{sp}^0$ of Th(IV) are larger than for

the other An(IV) ions, presumably due to inclusion of polynuclear species of Th(IV) in the concentration of the soluble fraction (Neck and Kim, 2001).

Evidence is scarce and conflicting on the hydrolysis of Pa^{4+}. Values of $\log {}^{*}\beta_{11} = -0.14$ and $\log {}^{*}\beta_{12} = -0.52$ have been measured for the first two mononuclear complexes in a 3 M $(Li,H)ClO_4$ medium, by means of a solvent extraction method (Guillaumont, 1968). This would lead to about 50% of the protactinium present as unhydrolyzed Pa^{4+} in 1 M perchloric acid; however, other extraction measurements indicate that $Pa(OH)_2^{2+}$ is the predominant species in 1 M acid (Lundqvist, 1974). The mononuclear complexes are predominant only in extremely dilute solutions. Polymers become significant at protactinium concentrations as low as 10^{-5} M.

Hydrolysis of U(IV) is of concern only in reducing solutions as UO_2^{2+} is the form present in oxic waters. The hydrolysis of U(IV) increases with increasing ionic strength and increasing temperature. Polynuclear hydrolytic species form readily and are likely to be present except in strongly acidic solutions or at very low concentrations of U(IV). Hydrolysis constant values were reported for a series of polynuclear $U_{(n+1)}(OH)_{3n}^{(4+n)+}$complexes in 3 M $(H,Na)ClO_4$ by Hietanen (1956) using a 'core+links' model of thread-like chains of $U(OH)_2U$ links. However, this model has fallen out of favor and reevaluation of these experiments showed that only $U(OH)^{3+}$ and one polynuclear species, $U_6(OH)_{15}^{9+}$, were required to reproduce the data with $\log {}^{*}\beta_{11} = -2.1$ and $\log {}^{*}\beta_{6,15} = -16.9$ (Baes and Mesmer, 1976) except at the highest $q{:}n$ ratios. This suggests that dinuclear or tetranuclear hydroxide complexes are less important for U(IV) than for Th(IV), but that hexanuclear $U_6(OH)_{15}^{9+}$ and higher oligomers of U(IV) with $n > 6$ and $q/n > 2.5$ do form in millimolar solutions of U(IV) when the pH exceeds 1.5.

As can be seen in the data in Table 23.11, the hydrolysis of Np(IV) is quite similar to that of Pu(IV) but greater than that of Th(IV) and U(IV). The ease of oxidation of Np(IV) to NpO_2^+ in non-reducing solutions results in Np(V) being the dominant neptunium species in oxic waters. Although there has been little research on hydrolytic polymers of Np(IV), it is very probable that the same polymers observed for Th(IV), U(IV), and Pu(IV) are formed by Np(IV).

Similar to the situation for Np(IV), the hydrolysis of Pu(IV) is difficult to investigate. At pH $\geq$ 1.0, tetravalent plutonium experiences hydrolysis and also oxidizes to PuO_2^+. Disproportionation reactions also occur in these acid solutions to form Pu(III) and PuO_2^{2+}. Preparation and maintenance of a solution with only Pu(IV) present is a challenge in any investigation of Pu(IV) behavior. This is reflected in the inconsistent data in a number of publications on Pu(IV) hydrolysis. The tendency of hydrolyzed plutonium(IV) to form intrinsic colloids or to sorb on other colloids is also a complicating factor. It has been demonstrated that colloidal Pu(IV) can be present at pH = 0 to 1 and total Pu(IV) concentrations smaller than 10^{-3} M (Kim and Kanellakopulos, 1989). Ultrafiltration removes such colloids if a sufficiently small filter size is used. However, without filtration, the solubility data used to calculate solubility product constants may be more than an order of magnitude too large due to the presence of colloids. Hydrolyzed plutonium species also have a strong tendency to sorb to surfaces. The surfaces of equipment used for plutonium experimentation must be treated to minimize sorption in solubility and extraction measurements (Caceci and Choppin, 1983b).

Freshly precipitated $Pu(OH)_4 \cdot xH_2O$, dehydrates over time with the hydroxo bridges between neighboring plutonium ions converting to an oxo bridged structure (Fig. 23.9). The resulting crystalline PuO_2 has a value of $\log K^{o}_{sp(cr)} = -64$ (Table 23.11), compared to the value of the amorphous hydrate of $\log K^{o}_{sp(am)} = -58.5$. The measured value of $\log K^{o}_{sp(cr)}$ (−64.0) reflects the reduced solubility of the aged precipitate; but measured solubilities in solutions of pH $\geq$ 7 are those of the amorphous solid, independent of whether $An(OH)_{4(am)}$ or $AnO_{2(cr)}$ were used for the initial solid phase. This can be attributed to the bulk crystalline solid being covered by a surface layer of the amorphous species. The amorphous form dissolves readily in strong acid but dissolution of the aged PuO_2 precipitate is very difficult due to the strength of

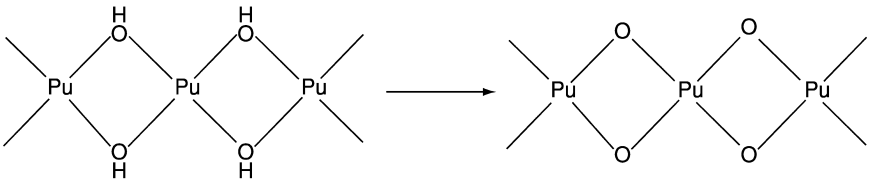

Fig. 23.9 *Conversion of amorphous $Pu(OH)_4$ into crystalline PuO_2 by loss of H_2O.*

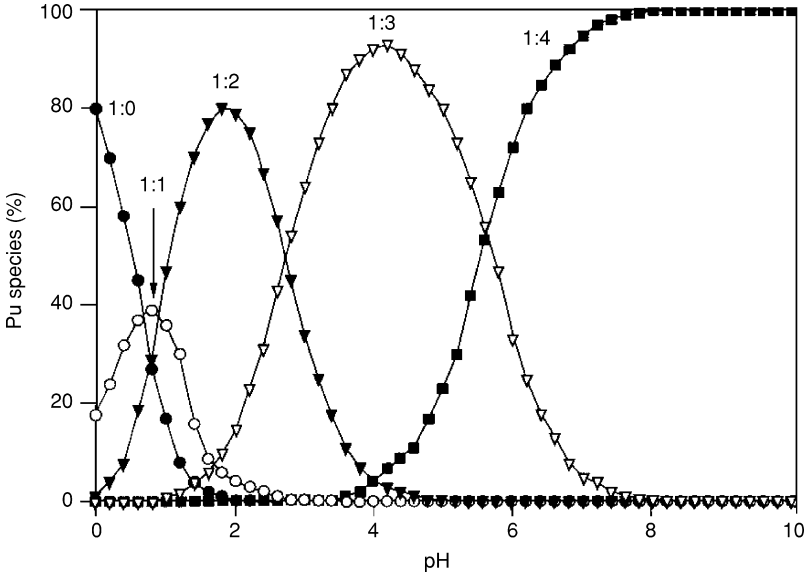

Fig. 23.10 *Fraction of mononuclear plutonium(IV) hydrolysis products as a function of pH in* 1 M $NaClO_4$ *solution* (*Choppin,* 2003).

the Pu–O bonding. Generally, aged $PuO_{2(cr)}$ must be contacted with an acidic oxidizing solution which converts the Pu(IV) to the much more soluble PuO_2^{2+} species.

The variation of mononuclear Pu(IV) hydrolytic species with pH is shown in Fig. 23.10. At pH 1.0, there are almost equal concentrations of Pu^{4+}, $Pu(OH)^{3+}$, and $Pu(OH)_2^{2+}$, demonstrating strong hydrolysis of Pu(IV). The fraction of polynuclear species present increases as the plutonium and/or the pH concentration increases. The hydrolysis constants of Pu(IV) indicate an extremely low value for soluble plutonium in neutral solutions. However, the net plutonium solubility is much larger than predicted ($\leq 10^{-6}$ M) by the constants in Table 23.11, as it is due to the relatively high concentration of PuO_2^+ ($\sim 10^{-6}$ to 10^{-7} M) in redox equilibrium with the ultratrace concentrations of soluble Pu(IV).

23.3.3 Pentavalent actinides

The protactinium(V) ion is a much stronger acid than other pentavalent actinides with $\log {}^*\beta_{11} = -4.5$ in 3.5 M (Li, H)ClO_4 (Guillaumont, 1968). In both the tetravalent and pentavalent states, protactinium hydrolyzes much more readily than do the other actinides. A structure different from the other actinyl(V) ions, e.g. $PaO(OH)_2^+$, with a strongly covalent protactinium–oxo bond has been proposed (Guillaumont *et al.*, 1968).

The tendency of UO_2^+ and PuO_2^+ to disproportionate and the strong oxidation properties of AmO_2^+ have led to few hydrolytic studies of these cations. NpO_2^+ is relatively stable, however, and is the most studied actinyl(V) species. Pentavalent neptunium does not hydrolyze in solutions with pH less than 8. Sullivan *et al.* (1991), Itagaki *et al.* (1992), and Neck *et al.* (1992) have discussed neptunium hydrolysis in some detail. A value of $\log {}^*\beta_{11}$ for NpO_2^+ (ca. -8.85 at $I = 0$) was reported by Baes and Mesmer (1976) and Schmidt *et al.* (1980). The stability of NpO_2^+ has led to its use as a chemical analog for pentavalent plutonium since PuO_2^+ is environmentally important at low concentrations of plutonium (Nelson and Lovett, 1978).

A study of the thermodynamics of NpO_2^+ hydrolysis (Sullivan *et al.*, 1991) in a solution of $I = 1.0$ M $(CH_3)_4NCl$ at $T = 25°C$ gave the following values for the reaction $NpO_2^+ + OH^- \rightleftarrows NpO_2OH$:

$$\log {}^*\beta_{11} = -(9.26 \pm 0.06)$$

$$\Delta H_{11} = -(22.10 \pm 0.04)\,\text{kJ mol}^{-1}$$

$$\Delta S_{11} = (16 \pm 5)\,\text{J K}^{-1}\,\text{mol}^{-1}$$

This value for ${}^*\beta_{11}$ indicates that at pH 9.26, NpO_2^+ is 50% hydrolyzed.

Sullivan *et al.* (1991) estimated that $\log \beta_{11}$ for PuO_2^+ would be ca. 4.5, which indicates that PuO_2^+ does not form a significant fraction of hydroxide species until pH 9. Of all the plutonium oxidation states, the pentavalent state has the least tendency to hydrolyze (Choppin, 1991) and is most stable in basic solution (Peretrukhin *et al.*, 1994). Unlike the case of NpO_2^+, the redox potential of Pu(V)/Pu(IV) and the strong hydrolysis of Pu(IV) limit the concentration of $PuO_2{}^+$ in marine waters. Plutonium redox and sorption have been reviewed by Morse and Choppin (1991) and plutonium hydrolysis by Clark *et al.* (1995).

23.3.4 Hexavalent actinides

The hydrolysis of the uranyl cation, UO_2^{2+}, has been studied more intensely than that of any other actinide cation, partially because the lower level of radioactivity of natural uranium allows use of a wider variety of techniques than for shorter lived actinides. Also, the hydrolysis of U(VI) forms a wide variety of polynuclear hydrolytic species, resulting in a quite complex chemistry (Table 23.12 and Fig. 23.11).

The hydrolysis of the cations of the actinyl(VI) species decreases in the order $UO_2^{2+} > NpO_2^{2+} > PuO_2^{2+}$, with a larger difference between NpO_2^{2+} and PuO_2^{2+} (Table 23.13). The actinide radial contraction with atomic number would lead to the opposite trend. The pattern is different also from that for the actinide(IV) ions where the order of acidities is $U^{4+} > Np^{4+} < Pu^{4+}$. For these ions, the unexpected decrease between U^{4+} and Np^{4+} is followed by a marked reversal at Pu^{4+}.

In very dilute solutions, $\leq 10^{-6}$ M U(VI), the hydrolysis of UO_2^{2+} first forms mononuclear $UO_2(OH)_q^{2-q}$ species, but above this concentration UO_2^{2+} exists mainly in polynuclear species. Within wide ranges of pH and C_M (metal concentration), the predominant complex is the dimer ($(UO_2)_2(OH)_2^{2+}$). As the pH increases, the trimer $(UO_2)_3(OH)_5^+$ becomes prominent (Fig. 23.12). In chloride solutions $(UO_2)_3(OH)_4^{2+}$ is also formed. In concentrated solutions of low pH, $(UO_2)_2OH^{3+}$ may be present. Other complexes which have been proposed to form are $(UO_2)_3(OH)_7^-$, $(UO_2)_3(OH)_{10}^{4-}$, $(UO_2)_4(OH)_6^{2+}$, $(UO_2)_4(OH)_7^+$,

and $(UO_2)_5(OH)_8^{2+}$. The variation of the hydrolysis constant of $UO_2(OH)^+$ as a function of ionic strength is shown in Table 23.14.

The existence of the dimer $(UO_2)_2(OH)_2^{2+}$ has been confirmed by direct determination of the species present in hydrolyzed uranyl(VI) chloride solutions (Åberg, 1970). Even in the concentrated solutions ($C_M = 3$ M) used in these diffraction studies, the dimer is an important species at the lower ligand numbers investigated.

The average U–U distance in this concentrated solution is 3.88 Å, which is close to the distance of 3.94 Å found in the solids $[(UO_2)_2(OH)_2Cl_2(H_2O)_4]$ and $[(UO_2)_2(OH)_2(NO_3)_2(H_2O)_3]H_2O$ (Åberg, 1969; Perrin, 1976).

23.4 BONDING IN ACTINIDE COMPLEXES

Actinide ions in all common solution oxidation states (2+ to 6+) are hard Lewis acids, and actinide–ligand bonds are predominantly ionic, as expected from the electropositive nature of the actinides. This is manifested in kinetically labile, non-directional bonds, and a marked preference for binding to ligands via hard Lewis base donor atoms like fluorine or oxygen. The thermodynamic bond strengths of actinide–ligand complexes are determined primarily by electrostatic attraction and steric constraints. The electrostatic attraction between an actinide cation and a ligand is proportional to the product of the effective charges of the metal and ligand divided by the actinide–ligand distance. The steric constraints may arise from the properties of the actinide cation (ion size and presence or absence of actinyl oxygen atoms) or of the ligand (number and spatial relationship of donor atoms, size of the chelate rings, and flexibility of ligand conformations).

23.4.1 Ionicity of f-element bonding

As a consequence of the predominantly ionic nature of the metal–ligand bonding in actinide complexes, the strength of the complexes and the associated chemistry are determined primarily by the effective charge of the actinide cation and of the coordinating ligands. Similar to the lanthanide 4f orbitals, the actinide 5f orbitals are well shielded from environmental influences and have little influence on bonding energies of the outer 6d orbitals, which dominate the radii values. The orbital energies and the radii of actinide ions in a given oxidation state vary slowly and smoothly across the actinide series. As a result, the types of actinide complexes formed and the strength of those complexes, as reflected by the stability constants, are relatively uniform within an oxidation state in comparison to transition metal complexes where covalence and ligand field stabilization energies can cause significant variations (Fig. 23.13). An important exception to the regularities of complex formation within an actinide oxidation state is Pa(v), which is the only pentavalent actinide that does not form the linear transdioxo actinyl(v) moiety, and whose chemistry is closer to that of pentavalent niobium and tantalum (Kirby, 1959) than that of AnO_2^+ cations.

23.4.2 Thermodynamics of bonding

The predominantly ionic nature of actinide–ligand bonding also accounts for the enthalpies and entropies of actinide complexation. The formation of inner sphere 1:1 actinide–ligand complexes in aqueous solution is characterized

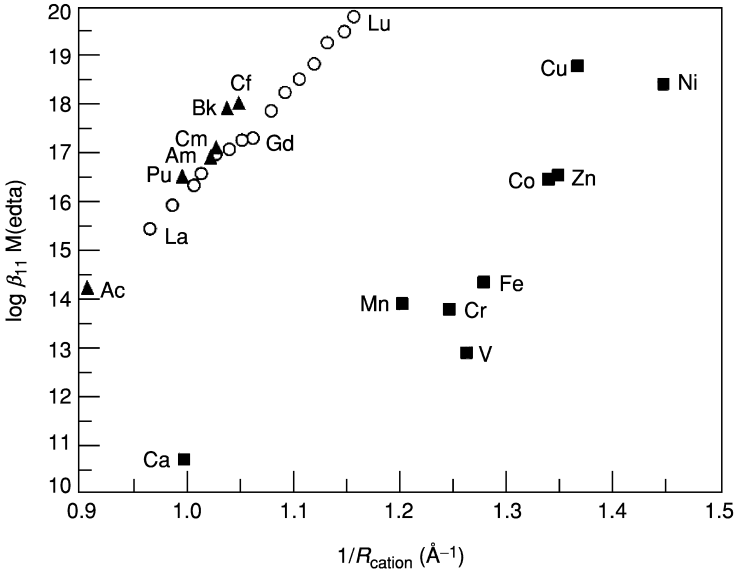

Fig. 23.13 *Variation of the stability constants of metal complexes with ethylenediaminetetraacetate* ($edta^{4-}$) *with ion size for the trivalent actinide* (▲), *trivalent lanthanide* (○), *and divalent fourth row metal cations* (■). *Stability constant data from Martell* et al. by positive values of the formation entropies, ΔS_{11}, and of the values of the formation enthalpies, ΔH_{11}, that vary from moderately endothermic (positive and unfavorable) to moderately exothermic (negative and favorable) depending on the charge and coordination number of the ligand. For simple ligands, the entropic component of the Gibbs energy tends to be the more important in determining the magnitude of the Gibbs energy change (ΔG) upon complexation and, hence, of the equilibrium constant. In aqueous media, the entropy changes (ΔS) for formation of 1:1 lanthanide and actinide complexes arise primarily from the partial dehydration of the metal and ligand that is associated with the formation of an inner sphere complex. For a given ligand, the ΔS values tend to increase as the effective charge of the actinide ion increases, as expected for electrostatic bonding (Laidler, 1956). Also, since the complexation entropies are linked to dehydration of the metal and ligand, characteristic values of $\Delta S/n$ exist for a given actinide oxidation state and a particular class of ligands, as shown for actinide carboxylate complexation in Table 23.15 (n can be either the number of donor groups bound to the cation or the number water molecules displaced from the inner coordination sphere of the cation).

23.4.3 Coordination numbers

Typical coordination numbers of transition metal ions, where d-orbitals participate in the formation of directional covalent bonds, range from four to six, with well-defined stereochemistry (tetrahedral, square planar, octahedral, etc.). In contrast, most actinide–ligand bonds are characterized by a very small degree of covalence, if any, and the coordination geometry of the complexes is not determined by the directionality of the bonding overlap of the actinide and ligand orbitals. Combined with the somewhat larger size of actinide cations relative to the 3d and 4d transition metal cations, this results, for actinide cations, in larger and variable coordination numbers, which are determined by the maximum number of ligands (including Lewis base solvent molecules) that can fit around the actinide. Increasing oxidation state decreases the ionic radii of the actinide ions (Shannon, 1976), thus favoring lower coordination numbers than are observed for actinides in the lower oxidation states. In water, or in other oxygenated solvents with similar steric demands, typical inner sphere coordination numbers of actinide ions range between seven and nine (including the -yl oxygen atoms of the actinyl cations) with coordinated solvent molecules filling space not occupied by other ligands.

The size and shape of the ligands are very important in determining the exact coordination number of actinide cations. Coordination numbers as low as four or five, for example in $U(NPh_2)_4$ (Reynolds *et al.*, 1977) or UO_2(*p-tert*-butylhexahomotrioxacalix[3]arene)$^-$ (Masci *et al.*, 2002), are observed for bulky ligands in low polarity media. In contrast, coordination numbers of 10 or 12 are not uncommon in solid state and solution-phase complexes containing small, bidentate ligands, such as CO_3^{2-} and NO_3^- [e.g. ten-coordinate $An(CO_3)_5^{6-}$ (Clark *et al.*, 1995) and 12-coordinate $An(NO_3)_6^{2-}$ (Ryan, 1960; Ščavnicar and Prodic, 1965)].

The constraints imposed by the presence of the two oxo groups in the linear, pentavalent AnO_2^+ and hexavalent AnO_2^{2+} cations provide an inherent, steric limitation on the number of ligand donor groups that can form bonds to the actinyl cations. The stability constants of the complexes of actinide cations in

each of the common oxidation states with a series of carboxylate and amino-carboxylate ligands are presented as a function of the number of potential donor groups present in each ligand in Fig. 23.14. For the spherical An(III) and An(IV) cations, which lack the -yl oxygen atoms of the higher actinide oxidation states, the stability constants of the metal–ligand complexes increase regularly with the increased number of donor groups in the ligand. The size, spherical symmetry, and lack of strong, directional covalent bonding in these complexes allow An(III) and An(IV) cations to accommodate polydentate ligands that form multiple chelate rings. In contrast, the linear dioxo structure of AnO_2^+ and AnO_2^{2+} cations constrains the interactions with ligands to the

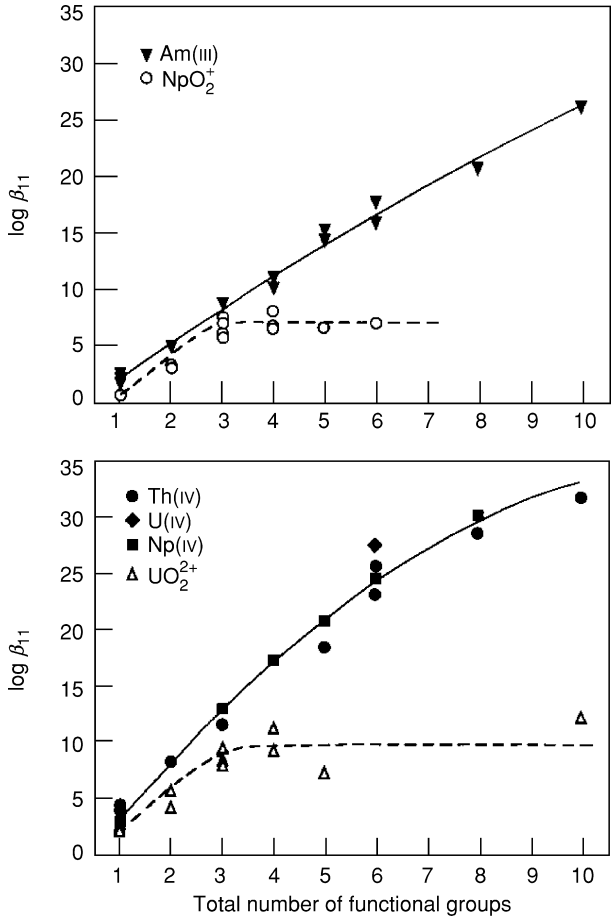

Fig. 23.14 *Effect of the steric constraints imposed by actinyl oxygen atoms of neptunyl(V) and uranyl(VI) on the stability constants of the carboxylate and aminocarboxylate ligands as compared to trivalent and tetravalent actinides. Data from Martell* et al. (1998), *Rizkalla* et al. (1990*a*), *and Tochiyama* et al. (1994).

plane perpendicular to the actinyl oxygens (referred to as the equatorial plane hereafter). Generally, this limits the number of bound donor groups in a single ligand to three or four for the actinyl ions. As shown in Fig. 23.14, the thermodynamic stability of the complexes of AnO_2^+ and AnO_2^{2+} cations increases regularly until three donor groups are present in a given ligand. The presence of additional (more than three) donor groups causes no significant increase in the stability constants of the actinyl complexes because the additional donors do not form bonds with the actinyl cation. Interesting exceptions to this general observation are the pentacoordinate calixarene-based ligands (Shinkai *et al.*, 1987; Guilbaud and Wipff, 1993a), which have the proper geometry to be strong and highly selective complexants for the actinyl(VI) ions.

23.4.4 Steric effects in actinyl bonding

The '-yl' oxygen atoms can interfere with the complexation of rigid ligands, even if the ligand contains three or fewer donor atoms, by restricting ligand donor atoms to bonding only in the equatorial plane of the actinyl ion. In rigid ligands this restriction can cause torsional strain within a bound ligand, or, if the ligand is too large to be contained in the equatorial plane, portions of the ligand and the actinyl oxygens may come into steric conflict. This was reported for the uranyl(VI) complexes of the relatively rigid ligand tetrahydrofuran-2,3,4,5-tetracarboxylic acid, for which the stability constant of the uranyl complex is two orders of magnitude smaller than expected from the stability constants of the complexes of the ligand with the sterically undemanding trivalent lanthanide cations or the uranyl complexes of similar, but more flexible, ligands (Morss *et al.*, 2000).

When steric constraints are not important, the strength of actinide–ligand interactions are primarily governed by electrostatic attraction. Increasing effective charge and decreasing ion size (i.e. increasing charge density) of either the actinide cation or the ligand favor stronger bonds, as discussed in Section 23.6. For a given oxidation state, the radii of actinide ions become progressively smaller with increasing atomic number, imparting a larger charge density to the actinide cation and, generally, making the complexes of the heavier actinides progressively more stable. Unfortunately, little data is available for elements heavier than curium, but the measured stability constants support such correlations.

23.4.5 Relative strength of complexation

For a given ligand, the strength of the actinide complexes usually increases in the order

$$AnO_2^+ < An^{3+} \lesssim AnO_2^{2+} < An^{4+}$$

when steric effects are not important. Obviously the order tracks neither the oxidation state nor the formal charge of the actinide cations. While the overall, formal charges of the actinyl(V) and actinyl(VI) cations are +1 and +2,

respectively, the order of the stability constants implies that the effective charge (Z_{eff}) felt by a ligand bound to the actinyl cations in the equatorial plane is considerably larger. This suggests that the -yl oxygen atoms of the actinyl(v) and actinyl(vi) cations retain a partial negative charge. Assuming completely electrostatic bonding (except for the actinyl oxygens) and that the effective charges of Ca^{2+}, Nd^{3+}, Am^{3+}, and Th^{4+} are equal to their formal charges, the effective charge felt by ligands bound to pentavalent and hexavalent actinyl cations were estimated empirically. For NpO_2^+, Z_{eff} was estimated as $+(2.2 \pm 0.1)$ (Choppin and Rao, 1984). For AnO_2^{2+} (An = U, Np, Pu), cations this approach estimated Z_{eff} between +3.0 and +3.3, depending on the cation and the estimation procedure (Choppin and Unrein, 1976; Choppin, 1983; Choppin and Rao, 1984). In the series of AnO_2^{2+}–fluoride complexes, the derived value of Z_{eff} decreases with increasing atomic number. These experimental Z_{eff} values agree with those from theoretical calculations (Walch and Ellis, 1976; Matsika and Pitzer, 2000), providing theoretical foundations for the observed order of actinide complex stabilities.

The stability constants of a few carboxylate complexes of No^{2+} have been reported (McDowell *et al.*, 1976). They are smaller than those of the actinyl(v) cations, and are similar to those observed for Ca^{2+} or Sr^{2+}. This suggests that the divalent actinides have the lowest effective charge and form the weakest complexes of any actinide oxidation state.

23.4.6 Covalent contribution to bonding

Although an ionic model adequately describes most actinide complexes in solution, measurable covalent bonding is present in the actinide–ligand bonds of some compounds. The most prevalent example of covalence in actinide bonding comes from actinide–ligand multiple bonds (Kaltsoyannis, 2000; Denning *et al.*, 2002), particularly the short (ca. 1.7–1.8 Å) O=An=O bonds in the linear dioxo actinyl ions of the pentavalent and hexavalent light actinides, AnO_2^+ and AnO_2^{2+} (An = U, Np, Pu, Am). Other well-characterized examples of actinide–ligand bonds with some degree of covalence are found in actinide–organometallic complexes (Cramer *et al.*, 1983; Brennan *et al.*, 1987, 1989). More surprising examples come from computation (Pepper and Bursten, 1991) and experiments that suggest that a measurable covalent contribution is present even in An–F bonds, the actinide–ligand bonds expected to be the most strongly ionic. Bleaney *et al.* (1956) and Kolbe and Edelstein (1971) observed superhyperfine splitting, attributable to covalence, in the EPR of trivalent uranium and plutonium fluorides, which are present as cubic AnF_8^{5-} in a fluorite host. In contrast, superhyperfine splitting was not observed for the equivalent compounds of the trivalent lanthanides doped in fluorite, implying that the An–F bonds have measurably greater covalent character than Ln–F bonds. However, the presence of some covalence in the actinide–ligand bonds does not diminish the overarching importance of ionic interactions in the formation of these bonds.

In solution, the best evidence for some degree of covalence in actinide–ligand bonds comes from the thermodynamic differences in the complexes of the trivalent lanthanides and the trivalent actinides with soft donor ligands (i.e. ligands containing N, S, or halide donors other than F^-). The complexes formed by An^{3+} cations and Ln^{3+} cations with hard donor, oxygen-based, ligands (carboxylates, organophosphates) are nearly indistinguishable for Ln^{3+} and An^{3+} ions with similar ionic radii (e.g. Am^{3+} and Pm^{3+}). However, as first observed by Diamond *et al*. (1954), An^{3+} cations form thermodynamically more stable complexes with soft donor ligands than the equivalent Ln^{3+} cations do. This deviation from predictions based solely on electrostatic bonding has been interpreted as indicating slightly greater covalence in the actinide–soft donor ligand bond. The stability constants of aqueous complexes of trivalent lanthanide and actinide cations with some representative hard and soft donor ligands, as well as ligands containing both hard and soft donor groups, are summarized in Table 23.16.

23.4.7 Soft ligand bonding

A greater degree of covalence in the bonds between an actinide ion and soft donor ligand should also be reflected in more exothermic complexation enthalpies, relative to the equivalent lanthanide complexes. Significant differences in the enthalpies of metal–nitrogen bonds were not observed in the aminocarboxylate complexes of americium, curium, and europium (Rizkalla *et al*., 1989). However, large differences in the complexation enthalpies of trivalent lanthanide and actinide cations consistent with enhanced covalence in actinide–soft donor bonds have been reported for ligands containing only soft donor atoms in both aqueous and organic solutions (Zhu *et al*., 1996; Jensen *et al*., 2000a; Miguirditchian, 2003).

The preference of actinide ions for softer donor ligands is the common basis for successful chemical separations of the trivalent actinides from the trivalent lanthanides (Nash, 1993a). Although actinide–soft donor bonds are thermodynamically stronger than the corresponding lanthanide–soft donor bonds, neither series of f-element cations forms particularly strong complexes with ligands containing only soft donors, as illustrated by the stability constants in Table 23.16. The likelihood of observing complexes between actinide ions and soft donor ligands is further reduced in aqueous solution by the high background concentration of the hard Lewis base H_2O, 55 mol L^{-1}. Thus, forming actinide complexes with soft donor ligands in aqueous solution requires either high concentrations of the soft ligand, multiple soft donor sites within a single ligand, or the presence of both hard and soft donors within the same ligand. Soft donor binding in aqueous solution is also encouraged when the soft donor groups are relatively acidic, which allows the soft donor ligand to compete with hydrolysis reactions. As a result, actinide soft donor reactions are most easily observed in non-aqueous solvents.

Table 23.16 *Stability constants of trivalent lanthanide and actinide cations of similar ionic radius with oxygen donor and nitrogen donor ligands in aqueous $NaClO_4$, $T = 25°C$. In summary, actinide–ligand bonding, though primarily ionic, should be considered as intermediate between the strongly ionic bonding observed in lanthanide complexes and the more covalent bonding found in transition metal complexes. The exact behavior of an actinide ion is determined by its oxidation state, the hard or soft characteristics of the ligand, and the position of an actinide element within the actinide series, with the actinides becoming more lanthanide-like with increasing atomic number.

23.5 INNER VERSUS OUTER SPHERE COMPLEXATION

Although the concept of outer sphere complexation was introduced by Werner (1913) and the theory first given a mathematical base by Bjerrum (1926) progress in understanding the factors involved in the competition between inner and outer sphere complexation was slow.

The term 'outer sphere complex' refers to species in which the ligand does not enter the primary coordination sphere of the cation but remains separated by at least one solvent molecule. Such species are known also as 'solvent separated' ion pairs to distinguish them from inner sphere complexes in which the bonding involves direct contact between the cation and the ligand. Some ligands cannot displace the water and complexation terminates with the formation of the outer sphere species. Actinide cations have been found to form both inner and outer sphere complexes and for some ligands, both types of complexes may be present simultaneously.

For labile complexes, it is often quite difficult to distinguish between inner and outer sphere complexes. Adding to this confusion is the fact that stability constants for such labile complexes determined by optical spectrometry are often lower than those of the same system determined by other means such as potentiometry, solvent extraction, etc. This has led some authors to identify the former as 'inner sphere' stability constants and the latter as 'total' stability constants. However, others have shown that this cannot be correct even if the optical spectra of the solvated cation and the outer sphere complex are the same (Beck, 1968; Johansson, 1971). Nevertheless, the characterization and knowledge of the formation constants of outer sphere complexes are important as such complexes play a significant role in the Eigen–Tamm mechanism for the formation of labile complexes (Eigen and Wilkins, 1965). The Eigen–Tamm mechanism assumes rapid formation of an outer sphere association complex (i.e. an ion pair) and the subsequent rate-determining step in which the ligand displaces one or more water molecules,

$$M(H_2O)_q^{z+} + L^{x-} \rightarrow M(H_2O)_q^{z+}\text{- - -}L^{x-} \rightarrow M(H_2O)_{q-1}L^{z-x} + H_2O$$

The conversion of the outer sphere complex to the inner sphere complex is the rate-determining step and is dependent on the equilibrium concentration of the outer sphere complex. Consequently, calculations of rate constants by the Eigen model involve estimation of the stability constants of the outer sphere species. Actinide cations form labile, ionic complexes of both inner and outer sphere character and serve as useful probes to study the competition between inner and outer sphere complexation due to ligand properties.

It has been proposed (Choppin and Strazik, 1965; Choppin and Ensor, 1977; Khalili *et al*., 1988) that the thermodynamic parameters of complexation can be used as a criterion for evaluation of inner versus outer sphere complexation. For outer sphere complexes, the primary hydration sphere is minimally perturbed. As a result, an exothermic enthalpy results from the cation–ligand interaction while the entropy change can be expected to be negative since the ordering of ionic charges is not accompanied by a compensatory disordering of the hydration sphere. By contrast, when inner sphere complexes are formed, the primary hydration sphere is sufficiently disrupted that this contribution to the entropy and enthalpy of complexation frequently exceeds that of the cation–ligand

interaction and the result is an endothermic enthalpy and a positive entropy change. These considerations have led, for trivalent lanthanides and actinides in their 1:1 complexes (i.e., ML), to assignment of predominately outer sphere character to the Cl^-, Br^-, I^-, ClO_3^-, NO_3^- and sulfonate complexes and of inner sphere character to the F^-, IO_3^- and SO_4^{2-} complexes (Choppin, 1971).

The experimental, total, stability constant, β^{exp} is related to β_{os} and β_{is} by

$$\beta^{exp} = \beta_{is} + \beta_{os}$$

where β_{is} and β_{os} are the stability constants for inner and outer sphere formation, respectively. The effect of cationic charge on the equilibrium between inner and outer sphere complexation by the halate and chloroacetate anions has been investigated (Rizkalla *et al.*, 1990b; Choppin *et al.*, 1992b). In the case of halate systems, the entropy change for the complexation with monochlorate ($pK_a(HClO_3) = -2.7$) was considered to indicate 100% outer sphere character while that of the monoiodate ($pK_a(HIO_3) = 0.7$) led to the assignment of a predominately inner sphere character. The data for the 1:1 europium bromate ($pK_a(HBrO_3) = -2.3$) complex was interpreted to show a mixed nature with the outer sphere character more dominant. For thiocyanate complexes, stepwise stability constant patterns are reported for An(III) (Harmon *et al.*, 1972a) and AnO_2^{2+} (Ahrland and Kullberg, 1971a) to be $K_1 > K_2 < K_3$, indicating predominant outer sphere nature of the 1:1 and 1:2 complexes which changes to inner sphere for the 1:3 system. For An(IV), the pattern (Laubscher and Fouché, 1971) is $K_1 > K_2 > K_3 < K_4$, indicating that inner sphere complexation occurs only in the 1:4 species.

A series of related ligands, acetate and chloroacetates (Ensor and Choppin, 1980), was studied by solvent extraction and calorimetry to ascertain the relationship of ligand pK_a and inner versus outer sphere character. The relationship of experimental values of $\log \beta_{11}$ with the ligand pK_a as well as the relationships of the calculated values of $\log \beta_{is}$ and $\log \beta_{os}$ is shown in Fig. 23.15. Acetate (ac^-, $pK_a = 4.8$) formed inner sphere complexes and trichloroacetate (Cl_3ac^-, $pK_a = -0.5$), outer sphere complexes. The inner sphere nature increased with pK_a (Rinaldi *et al.*, 1979) with estimates for inner character of 100% $La(ac)^{2+}$, 50% $La(Clac)^{2+}$, 22% $La(Cl_2ac)^{2+}$, and 0% $La(Cl_3ac)^{2+}$. These values agreed satisfactorily with calculations using a modified Born equation (Choppin and Strazik, 1965). For the uranyl(VI) system, similar calculations (Khalili *et al.*, 1988) provided the following values for the percent inner sphere character: $UO_2(ac)^+$, 100%; $UO_2(Clac)^+$, 42%; $UO_2(Cl_2ac)^+$, 9%; $UO_2(Cl_3ac)^+$, 4%.

The data are consistent with an increased tendency to outer sphere complexation for the same cation as the ligand pK_a values decrease since the more acidic ligand is less competitive with hydration. Conversely, there is a stronger tendency to outer sphere complexation with increased charge on the metal cation, reflecting the increased hydration strength for higher cation charge. From acetate/haloacetate 1:1 complexation data with An^{3+} and AnO_2^{2+}, it

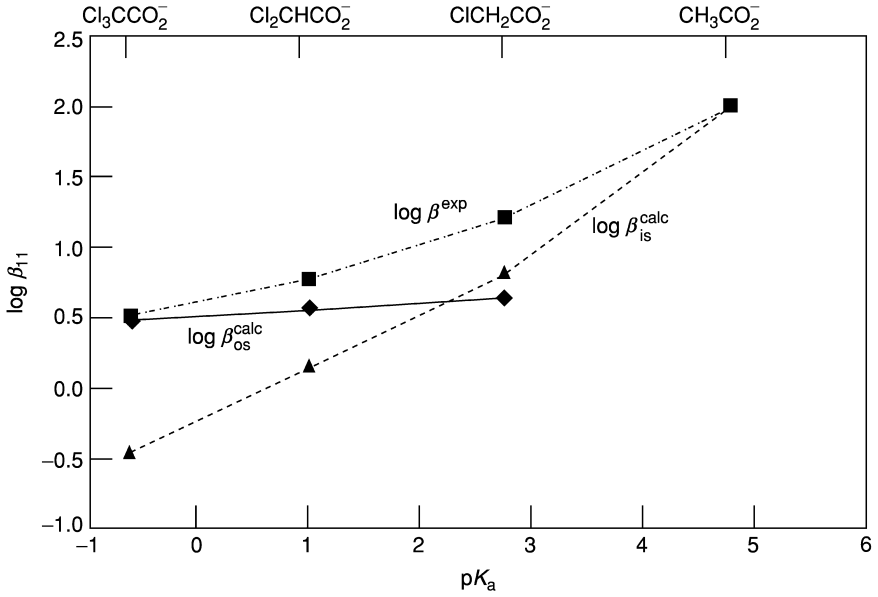

Fig 23.15 *Dependence of the experimentally measured total stability constant,* β^{exp}, *and the calculated inner* (β_{is}) *and outer* (β_{os}) *sphere stability constants for Am*(III) *complexes on the acidity of* $Cl_{3-n}H_nCCO_2H$ *ligands.*

was estimated that equal amounts of inner and outer sphere complexation would be observed for carboxylate ligands of p$K_a \sim 2.8-3.0$ (Khalili *et al.*, 1988). For NpO_2^+ and Th^{4+} cations, equal amounts of inner and outer sphere complexes would be present in 1:1 complexes with carboxylate ligands of p$K_a \sim$ 1.1 and 4.2, respectively (Choppin and Rizkalla, 1994).

The thermodynamic data of Eu(halate)$^{2+}$ and Th(halate)$^{3+}$ complexation are listed in Table 23.17. The entropy for the monochlorate (pK_a $HClO_3 = -2.7$) was interpreted as indicating 100% outer sphere character with Eu(III) and a predominance of it with Th(IV). The values for the monoiodate (pK_a $HIO_3 = 0.7$) complexes led to assignment of a predominately inner sphere character for both Eu(III) and Th(IV) (Choppin and Ensor, 1977). The data for the 1:1 europium complex with bromate (pK_a $HBrO_3 = -2.3$) were interpreted as showing a mixed nature with more outer sphere character. Values of 70, 80, and 85% ($\pm$10%) were estimated as the percent of outer sphere nature in the $EuBrO_3^{2+}$, $UO_2BrO_3^+$, and $ThBrO_3^{3+}$ complexes (Rinaldi *et al.*, 1979; Ensor and Choppin, 1980; Khalili *et al.*, 1988). This is consistent with increased outer sphere nature with larger effective charge of U in UO_2^{2+}. This pattern is likely due to the increase in hydration strength as the cationic charge increases.

Table 23.17 *Thermodynamic parameters for halate complexation.*

23.6 CORRELATIONS

Actinide cations interact with hard Lewis bases through strongly ionic bonds whose thermodynamic strength is dependent of the charges of the actinide cations and of the ligands and on any steric constraints imposed by the actinide ion or ligand (see Section 23.4). In the absence of steric effects, the predominance of ionic bonding in actinide complexes and the regular decrease in the size of actinide ions within an oxidation state as the atomic number increases are the basis for the systematics of actinide–ligand complexation, which can be exploited for important predictive capabilities. The stoichiometries, structures, and stability constants of actinide–ligand complexes in solution can often be predicted from the chemistry of related ligands or of other metal ions, including those in other oxidation states. Such empirical correlations can provide fairly accurate estimates of the properties of actinide–ligand complexes, although no correlation is universally applicable to all ligands, actinide ions, or actinide oxidation states because of electronic effects (e.g. covalency) or steric constraints. Given the large number of potential ligands, the ability to use such correlations to predict the strength of the interaction between a metal ion and a ligand accurately is very useful. The difficulties in working with radioactive materials further increase the value of these correlations.

The interactions of H^+ and An^{z+} with ligands are governed primarily by the same physical forces, electrostatics. Consequently, ligand basicity is often a good predictor of the relative thermodynamic strength of the interactions of ligands with actinide cations. In practice, ligand basicity may be expressed either in the Brønsted sense as the affinity of a ligand for protons or, more generally, as the affinity of a ligand for Lewis acids (i.e. other metal cations). Since both the pK_a and the logarithmic stability constant of a metal–ligand complex (M_nL_q), $\log \beta_{nq}$, are directly proportional to the Gibbs energy of reaction,

$$\Delta G_{\text{protonation}} = -2.303RT\,pK_a \tag{23.9}$$

$$\Delta G_{\text{complexation}} = -2.303RT \log \beta_{nq} \tag{23.10}$$

the correlation of stability constants with ligand basicity falls in the general category of linear Gibbs energy correlations.

The database of ligand pK_a values is the most extensive set of data available for correlating and interpreting actinide–ligand bonding. The logarithm of the stability constant for actinide–ligand complexation is expected to be directly proportional to the basicity of the ligand, expressed as the pK_a, within a series of ligands containing a single bonding functionality where variations in steric effects are negligible. Examples of this type of correlation for the formation of 1:1 UO_2^{2+}:monocarboxylate complexes and of both 1:1 and 1:2 NpO_2^+:β-diketonate complexes are shown in Fig. 23.16. The monocarboxylic acids could behave as monodentate or bidentate ligands (Howatson *et al.*, 1975; Denecke *et al.*, 1998; Rao *et al.*, 2002), while the β-diketonate ligands form bidentate six-membered chelate rings with the neptunyl(V) ion. The deviation of the $UO_2(O_2CCHCl_2)^+$ complex from the correlation likely arises from the formation of a mixture of inner and outer sphere dichloroacetate complexes (Section 23.5), while the other ligands form only inner sphere complexes with the uranyl(VI) cation.

Using the pK_a to represent ligand basicity is straightforward for simple ligands, such as monocarboxylate and β-diketonate ligands (Fig. 23.16), where all of a ligand's donor atoms are available for coordination once the single ionizable proton is removed from the ligand. The correlation of actinide complexation constants to ligand basicity is more complicated when the ligand contains multiple basic sites or can form more than a single chelate ring. Summing the pK_a values for each of a ligand's donor groups yields a single parameter representing an effective, total basicity. These values, ΣpK_a, usually correlate fairly well with the stability constants, log β_{11}, of an actinide ion, as shown in Fig. 23.17. Such correlations between stability constants and ΣpK_a values is the strongest within groups of related ligands, as similarity of the structural features of the complex is more likely. In some cases, all of the

potential donor atoms represented by the individual pK_a values do not bind the metal ion, either because of actinide- or ligand-based steric considerations, or because the donor atoms are not well matched to actinide chemistry (e.g. sulfur donors in aqueous solution). For such complexes, the actual An–L stability constant is smaller than predicted. In other cases, the assumption of An–L bonds being primarily ionic may be invalid, or the presence of a ligand containing donor atoms that are Lewis bases without appreciable Brønsted basicity (e.g. ether oxygens), would result in an An–L stability constant that is greater than that predicted by the ΣpK_a correlation.

Deviations from the expected correlation between a *measured* stability constant and ΣpK_a for a particular An–L pair can be a useful diagnostic for determining the denticity or coordination modes of ligands in actinide complexes (Jensen and Nash, 2001). The complexation of Np(v) by thiodiacetic acid (H_2tda) in 0.5 M $NaClO_4$ solution (Rizkalla *et al.*, 1990a) is a good example of this approach. Thiodiacetic acid (Fig. 23.18), is a potentially tridentate ligand, capable of forming two five-membered –S–C–C–O– chelate rings with metal ions of the proper size. However, the low affinity of actinide ions for ligands with sulfur donor atoms and the low effective charge of the neptunyl(v) cation, +2.2, combine to keep the ligand from forming such chelate rings. Based on the ΣpK_a (3.07 + 4.00 = 7.07), the correlation predicts a stability constant for $NpO_2(tda)^-$ of $\log\beta_{11} = 3.0$. A favorable Np–S interaction yielding a tridentate complex with two –S–C–C–O– chelate rings would make the stability constant still larger. However, the reported stability constant is much smaller ($\log\beta_{11} = 1.2$), indicating that the complex is not tridentate. The magnitude of the stability constant does match those of NpO_2^+ complexes with monofunctional carboxylic acid ligands ($\log\beta_{11} = 0.7$–1.3), and is only slightly larger than

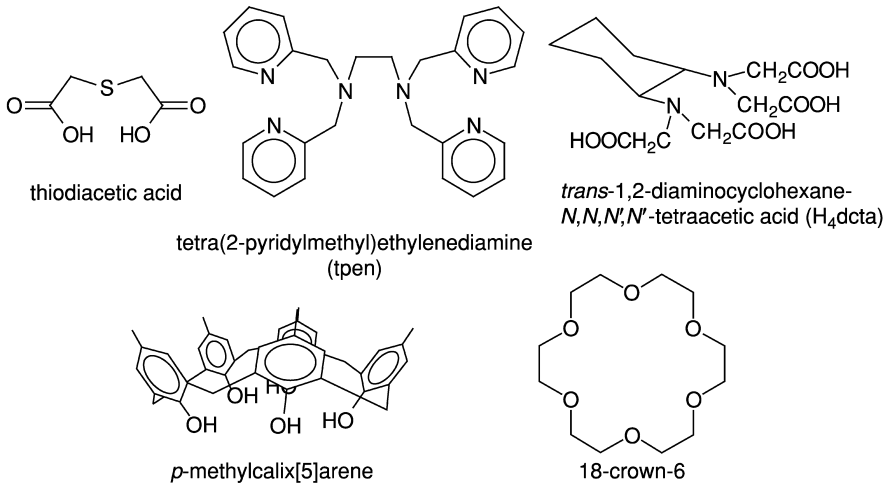

Fig. 23.18 *Ligand structures.*

the value predicted, $\log \beta_{11} = 0.8$, by considering NpO_2^+ complexation only at the most acidic site where $pK_a = 3.07$. The agreement of the experimental stability constant with that for a single ligand pK_a leads to the conclusion that there is no significant Np–S interaction and that tda^{2-} binds to NpO_2^+ only through a single carboxylate group. The lack of a Np–S bond also is consistent with the crystal structure of $NaNd(tda)_2$, in which only Nd–O bonds are observed (Kepert *et al.*, 1999).

The uncertainty in the nature of the interactions of certain actinide ions with particular ligands can make it difficult to understand or predict actinide complexation chemistry based solely on the basicity of a ligand, as the size and charge of the proton are very different from those of the actinide ions in solution. Using the Gibbs energies of complexation for other metal ions instead of pK_a values can overcome this limitation if the Lewis acids (metal ions) used for the correlations impose steric constraints, electrostatic fields, and degrees of covalency similar to those of the actinide ions under consideration. Since the lanthanide cations form metal–ligand bonds that are predominantly ionic and are of approximately the same size as actinide cations, they often are good models for actinide–ligand complexes. Hard transition metal cations, such as Fe^{3+} or Zn^{2+} (Hancock and Martell, 1989; Jarvis and Hancock, 1991), and alkaline earth cations, such as Ca^{2+} (Choppin *et al.*, 1992a), also can be used, with care, in some actinide–ligand bonding correlations. Figs. 23.18 and 23.19 compare the stability constants of actinide–ligand complexes of actinide cations in each of the common solution oxidation states (3+, 4+, 5+, and 6+) with the stability constants of the complexes formed by the same ligands with the trivalent lanthanide cations Nd^{3+} or Sm^{3+}. The correlations are considerably better than for the stability constants of the UO_2^{2+} –ligand or Th^{4+}–ligand complexes with the ΣpK_a values depicted in Fig. 23.17. However, as discussed in Section 23.4, the correlation fails when the assumption of similar steric constraints is incorrect for the complexes of actinyl ions with polydentate ligands containing more than three donor groups per ligand (Figs. 23.19a and 23.20a). In contrast, when the $Np(V)O_2^+$ complexes are compared to the complexes of $An(VI)O_2^{2+}$ cations, which are subject to similar steric constraints, the stability constants of polydentate ligands track the correlation well (Fig. 23.19b).

The stability constants of An(IV) cations, represented by Th^{4+}, and of An(III) cations, represented by Am^{3+}, track the Gibbs energies of trivalent lanthanide (Nd^{3+} or Sm^{3+}) complexation well (Fig. 23.20), indicating that any steric constraints imposed on the ligands by the trivalent and tetravalent actinide cations are similar to those of the lanthanide cations. However, one complex obviously deviates from the correlation. The stability constant of the $Am(tpen)^{3+}$ complex (Ligand #39, tetra(2-pyridylmethyl)ethylendiamine, Fig. 23.18) is two orders of magnitude larger than expected based on the stability constant of the $Sm(tpen)^{3+}$ complex, even though the larger radius of Am^{3+} suggests that the stability constant should be smaller for $Am(tpen)^{3+}$.

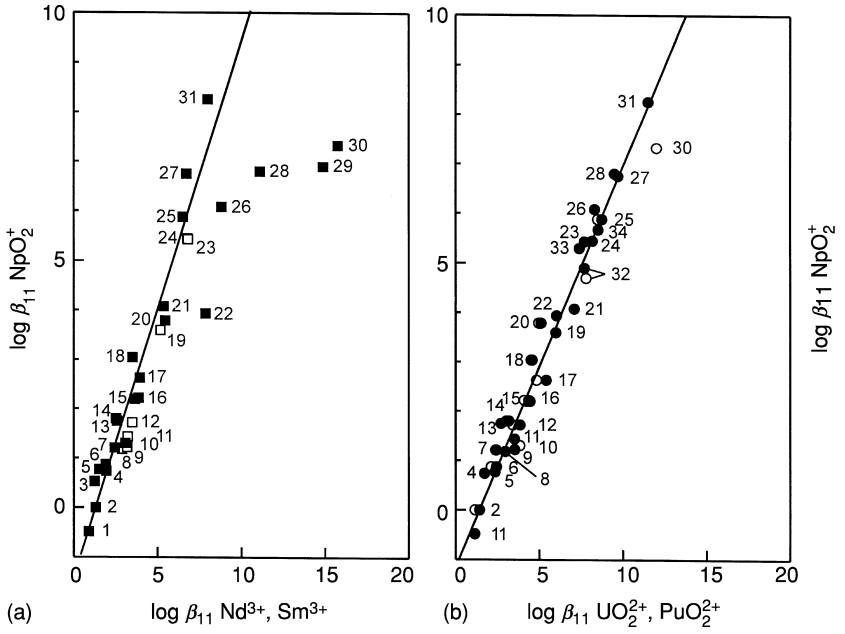

Fig. 23.19 *Correlation between the stability constants of neptunyl(v) complexes and the stability constants of the complexes of (a) the trivalent lanthanides* Nd^{3+} (■) *and* Sm^{3+} (□), *and (b) the hexavalent actinides* UO_2^{2+} (●) *and* PuO_2^{2+} (○). *See Fig.* 23.17 *for the ligands' numerical identities.*

(The crystal radius of Am^{3+} is 1.230 Å for coordination number 8, while for Sm^{3+} it is 1.219 Å under the same conditions [Shannon, 1976].) All six of the potential nitrogen donor atoms in the tpen ligand appear to be coordinated to both Ln^{3+} and An^{3+} cations, with some coordinated water molecules remaining in the inner coordination sphere of the metal ions in aqueous solution (Jensen *et al.*, 2000a). Based on the similar size and coordination environment of the two cations, steric constraints would be expected to play no role in this deviation of the Am^{3+}–Ln^{3+} correlation. The greater stability of the Am^{3+}–tpen complex most likely arises from an enhanced degree of covalence in the An–N bonds as compared to the Ln–N bonds (Choppin, 1983).

The size of the ligand chelate rings can also affect the stability of actinide–ligand complexes. Examining the Gibbs energy relationships for the complexes of two different ligands with numerous different metal ions can be instructive for understanding the interactions of actinide ions with ligands (Jensen and Nash, 2001). Five-membered chelate rings are the most stable ring size for complexes of actinide-sized cations (Hancock, 1992), and the strength of actinide–ligand interactions for chelating ligands usually decreases with ring size in the order $5 > 6 \gg 7 \sim 8$ for all actinide oxidation states (Stout *et al.*, 1989). If the

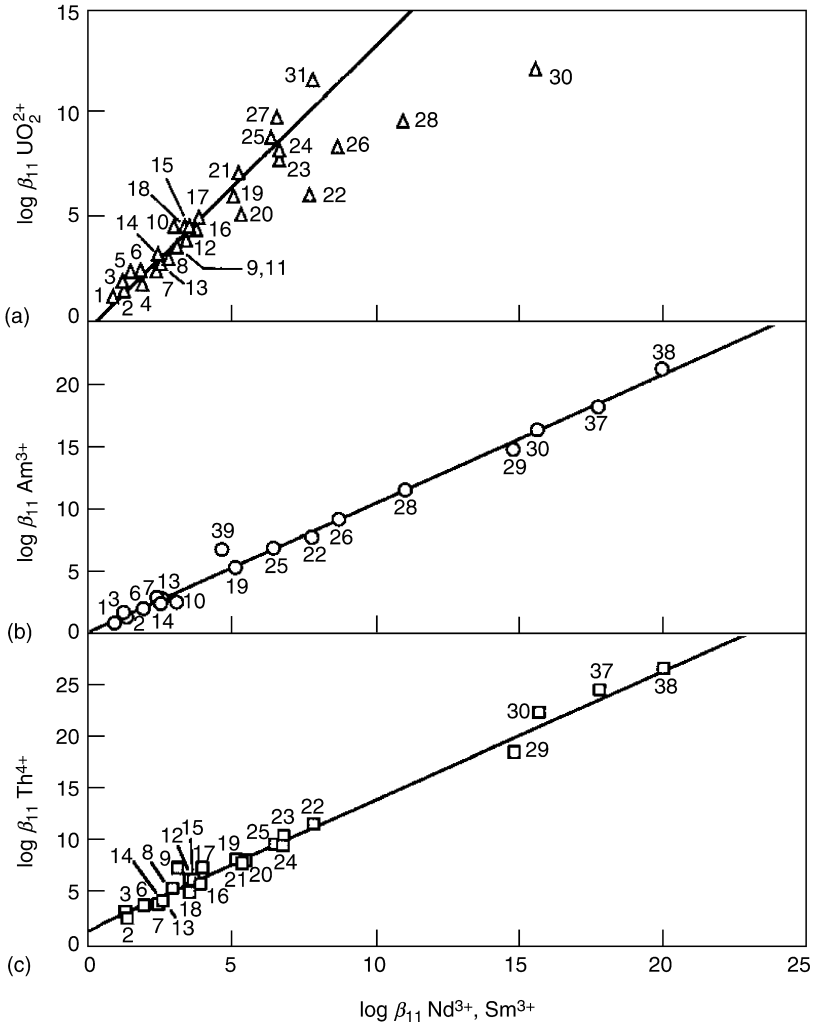

Fig. 23.20 *Correlation between the stability constants of trivalent lanthanide complexes and the stability constants of the complexes of* (*a*) *a hexavalent actinide,* (*b*) *a trivalent actinide, and* (*c*) *a tetravalent actinide. See Fig.* 23.17 *for the ligands' numerical identities.*

donor groups are strongly basic, ligands that form seven-membered rings can be quite stable. Presumably this is because the large size and non-directional electrostatic bonding of the actinide cations can accommodate the larger chelate ring (Rapko *et al.*, 1993). Complexes with eight-membered chelate rings formed by inter-ligand hydrogen bonding also are important species in non-aqueous

media, most notably for phosphoric acid based extractants such as bis(2-ethylhexyl)phosphoric acid (Ferraro and Peppard, 1963).

The basis for the empirical correlations between the stability constants of the actinide ion complexes with the acid constants of ligands or the stability constants of other metal ions is the strongly ionic character of the bonding in these systems. Born (1920) calculated the solvation energy of an ion in solution (M^{Z+}) from a model of a sphere of charge $+Z$ and radius R in a system with a dielectric constant, D, by the equation

$$\Delta G_{\text{solvation}}(M^{Z+}) \propto Z^2/DR \tag{23.11}$$

Modifications to the Born equation (Münze, 1972) have formed a useful basis for estimating and comparing actinide–ligand complexation constants (Choppin, 1983; Rizkalla *et al.*, 1990b), and may be useful for describing the entropies of complexation as well (Manning, 1996). For cations of the same charge (Z), the modified Born equation predicts a linear relationship between the logarithmic stability constant and $1/R_{\text{cation}}$, the reciprocal of the cation radii. This relationship holds over a range of cationic radii for numerous metal–ligand complexes, as shown for trivalent lanthanides and for trivalent and tetravalent actinides in Fig. 23.21. In systems where an approximately linear relationship does not hold for f-element complexes, such as citrate complexes (Fig. 23.21), significant steric effects or specific interactions (metal–solvent, ligand–solvent, complex–solvent, or ligand–ligand) are likely. However, it is not known if the order of magnitude deviation of the $Fm(dcta)^-$ and $Md(dcta)^-$ ($dcta^{4-}$ = *trans*-1,2-diaminocyclohexane-*N*,*N*,*N*′,N′-tetraacetate, Fig. 23.18) complexes from the correlation with $1/R_{\text{cation}}$ in Fig. 23.21 arises from such chemical factors or from the higher uncertainties associated with stability constant measurements of complexes involving high specific activity radionuclides.

The cationic charge used in the Born equation, Z, could be taken to be equal to the formal charge of An(III) and An(IV) cations, but it is less clear what the value of Z should be for AnO_2^+ and AnO_2^{2+} species since the oxo ligands appear to retain a partial negative charge. As discussed in Section 23.4, electrostatic correlations based on the Born equation for actinyl–fluoride complexes, suggest that the effective cationic charge experienced by a ligand bound to NpO_2^+ is $+2.2$, and for ligands bound to UO_2^{2+} is $+3.3$ (Choppin and Unrein, 1976; Choppin and Rao, 1984).

Defining the ligand charge in the cases of neutral ligands, polydentate ligands, or ligands containing both anionic functional groups (e.g., CO_2^- or PO_3^{2-}) and neutral donor sites (e.g. –N= or –O–) is also difficult. Effective anionic charges have been estimated for some organic ligands by assuming that the Born equation is valid for ligand protonation (Choppin, 1983), which results in a linear relationship between ΣpK_a and the effective anionic charge of a ligand,Z_{an},

$$Z_{an} = 0.208 \cdot \Sigma pK_a$$

The Born approach has been useful in describing actinide–ligand complexation in solution, but there has been much discussion over the years about the proper form that an equation describing general electrostatic bonding interactions should take. This debate eventually waned due to the understanding that the general function, Z^n/r^m, is suitable (Huheey, 1976). The Brown–Sylva–Ellis equation, a semiempirical correlation using a complicated function of Z^2/r^2 coupled to a number of electronic corrections appears very successful for describing metal–ligand interactions for a wide range of metal ions, including the actinides (Brown *et al.*, 1985). Other electrostatic models that incorporate corrections for inter-ligand repulsion (Moriyama *et al.*, 1999, 2002; Neck and

Kim, 2000) into the general Born framework have been able to reproduce the stability complexes for higher mononuclear complexes of the actinides (i.e. β_{1q} with $q > 1$).

Inter-ligand interactions are not important for 1:1 An^{z+}:L^- complexes and the metal–ligand interactions can be represented by the simplest form of the coulombic attraction between a metal ion and a monovalent L^- ligand with $\log \beta_{11} \propto Z/d_{M-L}$ (d_{M-L} = the distance between the center of the metal ion and the ligand donor atom). Fig. 23.22 depicts this correlation for the 1:1 complexes of hydroxide and fluoride anions with neptunium in the trivalent, tetravalent, pentavalent, and hexavalent oxidation states, using estimates of the actinide–ligand bond distances derived from extended X-ray absorption fine structure measurements of aqueous actinide complexes (Allen *et al.*, 1997, 2000; Moll *et al.*, 1999; Vallet *et al.*, 2001) and effective charges of +2.2 and +3.2 for NpO_2^+ and NpO_2^{2+} cations, respectively. The correlation also holds for more complicated inorganic and organic ligands.

Correlations based on electrostatic considerations are important for understanding actinide–ligand bonding, but other correlations could also be used. Drago and Wayland (1965) used an empirical, four-parameter equation,

$$-\Delta H_{11} = E_A E_B + C_A C_B \tag{23.12}$$

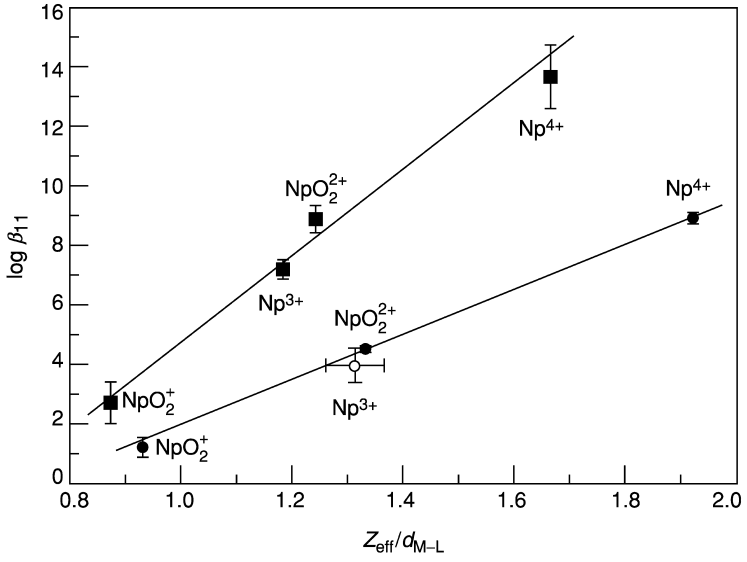

Fig. 23.22 *Dependence of the stability constants of neptunium fluoride* (●) *and neptunium hydroxide* (■) *on the effective ionic potential at* I = 0 M *and* 25°C. *Data from Lemire* et al. (2001) *with the value for* NpF^{2+} (○) *estimated from the* LnF^{2+} *stability constants of Martell* et al. (1998).

to describe the enthalpy of adduct formation between a Lewis acid (the E_A and C_A terms) and a Lewis base (the E_B and C_B terms). E_A and E_B are related to the tendency of an acid and base to form electrostatic bonds and C_A and C_B are related to their tendency to form covalent bonds. The equation was subsequently related to the molecular orbitals of the complexes formed (Marks and Drago, 1975). Hancock and Marsicano (1980) extended this approach to Gibbs energies of complexation using two additional parameters to include the steric constraints of the Lewis acid and base. Stability constants of aqueous Pu(IV) and U(VI) complexes with a number of ligands were estimated in this way (Hancock and Marsicano, 1980; Jarvis *et al.*, 1992; Jarvis and Hancock, 1994). This parameterization also has been used to understand bonding in lanthanide–ligand systems (Choppin and Yao, 1988; Carugo and Castellani, 1992). For a given lanthanide ion, the stability constants with oxygen donor ligands, which form strongly ionic bonds, were found to be well correlated to E_B, the ligand electrostatic parameter. In contrast, the stability constants of the complexes of the softer, nitrogen donor ligands were correlated with the ligand-based covalent parameter, C_B. Ionization potentials and electronegativities have also been used in correlations with the Gibbs energies of complexation of other families of metal ions (Hefter, 1974; Hancock and Martell, 1996).

The success of such correlations, whether based on linear Gibbs energy relationships of stability or protonation constants, on the Born solvation model, or on empirical parameterization is a reflection of the regularity of the solution chemistry of actinide cations and the strongly electrostatic nature of the bonding of their complexes.

23.7 ACTINIDE COMPLEXES

The complexes formed by actinide ions have been the focus of much research because of the importance of separating individual actinide elements from each other or from other elements in the nuclear fuel cycle, and of understanding the environmental chemistry of the actinide elements. A wide variety of experimental methods have been used to identify the stoichiometry or quantify the appropriate equilibrium constants of kinetically labile actinide complexes in solution. The accuracy of these studies depends strongly on the oxidation state purity of the actinide, which can be a problem for less stable oxidation states [e.g. U(III), U(V), Pu(V), Pu(VII), Am(IV), Am(V), or Am(VI)] and when multiple oxidation states can coexist in the same solution as is the case for neptunium and plutonium. The stoichiometry and strength of the actinide complexes with a given ligand are similar within a fairly narrow range for a particular oxidation state due to the predominantly ionic nature of the actinide–ligand bonds and the small differences in cationic radii. The consistent exception to this is Pa(V), which does not exist as an actinyl(V) cation.

23.7.1 Complexes with inorganic ligands

The reactions of actinide ions with halide and pseudohalide anions have been studied extensively. The complexes are, with the exception of the fluoro complexes, moderately weak in aqueous solution. As a consequence, measurements of the complexation constants often require high ligand concentrations (>1 M) and acidic media to allow sufficient amounts of the complexes to form and to avoid interference from hydrolysis reactions. This is most necessary for the tetravalent actinides which can undergo hydrolysis even when pH $\leq$ 1. Many of the halide complexes are sufficiently weak that outer sphere complexes are formed, particularly for the 1:1 (M:L) complexes.

Aqueous fluoro complexes of the actinide ions are known for the trivalent through the hexavalent oxidation states. The fluoride ligand has a much higher affinity for actinide cations than the heavier halides and all actinide fluoro complexes are inner sphere complexes. The neutral fluoro complexes of trivalent and tetravalent actinides, AnF_3 and AnF_4, are insoluble in aqueous solution ($pK_{sp} = 16.4$ for PuF_3 and 26.7 for PuF_4 at $I = 0$ M [Lemire *et al.*, 2001]). In contrast, all of the aqueous actinyl(V) and actinyl(VI) fluoro complexes are soluble. Separation of actinyl species from actinides in the lower oxidation states by fluoride precipitation is an effective method for determining the oxidation state speciation of trace actinides (Kobashi and Choppin, 1988). Cationic complexes formed in the equilibria

$$An^{z+} + qF^- \rightleftarrows AnF_q^{(z-q)+}$$

(An^{z+} = An(III), An(IV), An(V), and An(VI), and $q < z$) have been identified. Anionic complexes of AnO_2^+ and AnO_2^{2+} have also been studied (Ahrland and Kullberg, 1971b; Inoue and Tochiyama, 1985), and pentagonal bipyramidal $UO_2F_5^{3-}$ forms at high fluoride concentrations (Vallet *et al.*, 2002). Stability constants and thermodynamic parameters for the formation of the fluoro complexes of actinides in various oxidation states are summarized in Table 23.18. The stability constants of the 1:1 An:F complexes vary in the order $UO_2^{2+} > NpO_2^{2+} > PuO_2^{2+}$ for hexavalent actinides [see Section 23.4, and Choppin and Rao (1984)], $Th^{4+} < U^{4+} > Np^{4+} \geq Pu^{4+}$ for tetravalent actinides, and $Am^{3+} < Cm^{3+} < Bk^{3+} < Cf^{3+}$ for trivalent actinides (Chaudhuri *et al.*, 1999). Stability constants for the fluoro complexes of the pentavalent actinides have been reported only for protactinium (Guillaumont, 1966; Kolarich *et al.*, 1967) and neptunium (as assessed by Lemire *et al.*, 2001). The reversal in the sequence of the stability constants from the order expected based on the cationic radii of the tetravalent actinides is small, and the expected order is observed for AnF_2^{2+} and AnF_3^+. In each of these oxidation states, the stability of the actinide fluoro complexes is due to the highly favorable entropy contribution while the complexation enthalpies either oppose complex formation or are weakly favorable (Table 23.18). These ΔH and ΔS values reflect the importance of ion dehydration in the formation of inner sphere actinide complexes.

Table 23.18 *Stability constants, and Gibbs energies, enthalpies, and entropies of complexation for the reactions* $An^{z+} + qF^- \rightleftarrows AnF_q^{z-q}$ *and* $AnO_2^{z+} + qF^- \rightleftarrows AnO_2F_q^{z-q}$ *at* 25°C.

The actinide complexes of the heavier halides are much weaker than those of the fluoro complexes. They also are quite soluble. To the extent that equilibrium constants are available, the strength of the monohalogeno complexes decreases in the order $Cl^- > Br^- > I^-$ (Grenthe *et al.*, 1992) and they appear to be outer sphere under most circumstances (Section 23.2.6). Data on aqueous bromide complexation is scarce and the reducing power of iodide as well as the weakness of the complexes formed have limited studies of the iodide complexes to U(IV), Np(IV), and Pu(III) species (Vdovenko *et al.*, 1963; Khopkar and Mathur, 1974; Patil *et al.*, 1978). Stability constants for actinide complexation with chloride anions in aqueous solution are available for 1:1 and usually 1:2 species for trivalent (Ac, Pu–Es), tetravalent (Th–Pu), pentavalent (Np), and hexavalent

(U–Pu) actinides (Fuger *et al.*, 1992). For actinyl(VI) cations the complexation enthalpies for formation of the monochloro and dichloro complexes are endothermic in 2 M $HClO_4$ at 25°C ($\Delta H_{11} = +[9.2 \pm 0.5]$ and $\Delta H_{12} = +[18 \pm 1]$ kJ mol^{-1} for UO_2^{2+} and $\Delta H_{11} = +[14 \pm 2]$ kJmol^{-1} for PuO_2^{2+} (Rabideau and Masters, 1961; Awasthi and Sundaresan, 1981)). The values of the corresponding complexation entropies range from +26 to +50 $JK^{-1}mol^{-1}$.

Anionic chloro complexes are often used for separations purposes. Reliable stability constants are not known for these species, but anion exchanging resins or solvent extraction reagents promote the formation of these inner sphere complexes. The trivalent actinides form anionic $AnCl_4^-$ complexes in the resin or organic phase when the concentration of hydrochloric acid exceeds 8 M. Tetravalent uranium, neptunium, and plutonium form anionic chloro complexes with increasing ease, though anionic Th(IV) chloro complexes were reported as being only minor species in 12 M LiCl/0.1 M HCl (Kraus *et al.*, 1956). The actinyl(VI) cations also form anionic chloro complexes that absorb on anion exchange resins. Both the tetravalent and hexavalent actinides absorb as the doubly charged anionic complexes, $AnCl_6^{2-}$ and $AnO_2Cl_4^{2-}$, in 12 M HCl, while $AnCl_5^-$ and $AnO_2Cl_3^-$ are the likely species at lower chloride concentrations (Ryan, 1961; Allen *et al.*, 1997). Although anionic complexes form in the resin phase, in non-aqueous solvents (Marcus and Bomse, 1970) and in the solid state (Brown, 1972), anionic actinide chloro, bromo, and iodo complexes are not present in appreciable amounts in the aqueous phase, except at the highest halide concentrations (Marcus, 1966; Allen *et al.*, 2000). The stability constants for formation of the 1:1 complexes at $I = 1.0$ M are listed in Table 23.19.

The pseudohalides azide (N_3^-)and nitrogen-coordinated thiocyanate (NCS^-) form complexes with actinide cations that are moderately stronger than the equivalent chloro complexes (Table 23.19). The greater stability of the An(III) complexes with these softer ligands (i.e. Cl^-, N_3^-, and NCS^-) relative to that of the Ln(III) complexes has been the basis for group separations of the trivalent 5f elements from the 4f elements (Diamond *et al.*, 1954; Sekine, 1965; Starý, 1966; Musikas *et al.*, 1983; Borkowski *et al.*, 1994). Despite the greater strength of the pseudohalide complexes, spectroscopic measurements indicate that the 1:1 and, probably, the 1:2 An(III):SCN^- complexes are outer sphere complexes (Harmon *et al.*, 1972b). Strong evidence for the aqueous anionic complexes, $An(SCN)_4^-$, $AnO_2(SCN)_3^-$, and $AnO_2(N_3)_3^-$ and $AnO_2(N_3)_4^{2-}$ also have been reported (Ahrland, 1949; Sherif and Awad, 1961; Sekine, 1965; Kinard and Choppin, 1974; Chierice and Neves, 1983).

23.7.2 Complexes with inorganic oxo ligands

Actinides in the common oxidation states form complexes with inorganic oxo ligands. The complexes of the most common of these ligands, H_2O and OH^- are discussed in Sections 23.2 and 23.3, while the complexes of the halate ligands are considered in Section 23.5.

The stabilities of the actinide complexes with inorganic oxo anions vary in the order $NO_3^- < SO_4^{2-} \ll CO_3^{2-} < PO_4^{3-}$, as expected from the increasing charge and basicity of the ligands. The actinide nitrato complexes are important in the processing of nuclear reactor fuel, especially in separations where the neutral actinide nitrates can be extracted into organic solvents and the anionic, hexanitrato actinide(IV) complexes are used in anion exchange separations. The reported stability constants of the 1:1 $An:NO_3^-$ complexes are slightly larger than those of the analogous chloro complexes, and the anionic nitrato species form more readily than the corresponding chloro complexes. For the actinides, nitrate ions usually act as bidentate chelating ligands with two oxygen atoms from each nitrate coordinated to an actinide.

Sulfate, carbonate, and phosphate complexes can be important in actinide processing, and, along with silicates, are important ligands in determining the environmental behavior of actinide cations. Normally, the stability constants of the complexes with these ligands increase in the usual sequence of $AnO_2^+ < An^{3+} < AnO_2^{2+} < An^{4+}$.

The trivalent actinides have been shown to form 1:1 and 1:2 $An:SO_4^{2-}$ complexes, while the trisulfato complexes also form for the tetravalent and hexavalent actinides. For the weakly complexing actinyl(V) cations, only $NpO_2SO_4^-$ has been reported (Halperin and Oliver, 1983). Stability constants for some actinide–sulfate complexes are summarized in Table 23.20. The thermodynamics of actinide–sulfate complexation are consistent with the formation of inner sphere

Table 23.20 *Stability constants of actinide sulfate complexes at* I = 2 M *and* 25°C (*De Carvalho and Choppin,* 1967*; Ahrland and Kullberg,* 1971*a; Halperin and Oliver,* 1983*; Nash and Cleveland,* 1983*; Martell* et al.*,* 1998) *and carbonate complexes at* I = 0 M *and* 25°C (*Grenthe* et al., 1992; *Silva* et al., 1995; *Lemire* et al., 2001).

complexes. The endothermic enthalpies of complexation vary little between actinides in different oxidation states and the strength of a particular actinide–sulfate complex relative to that of other actinide–sulfate species is determined mainly by the complexation entropies (Table 23.21). Sulfate complexes of uranyl(VI) can form polynuclear, ternary hydroxo-sulfato complexes in weakly acidic solutions (Grenthe and Lagerman, 1993; Moll *et al.*, 2000).

Carbonate complexes of the actinides have been investigated often, as reviewed by Newton and Sullivan (1985) and Clark *et al.* (1995). Although the solubility of neutral $AnO_2(CO_3)$ is low, the triscarbonato uranyl(VI) complex, $UO_2(CO_3)_3^{4-}$, is responsible for the relatively high concentration of uranium in seawater (Spence, 1968). The complexes $NpO_2(CO_3)_3^{4-}$ and $PuO_2(CO_3)_3^{4-}$ are less important in the environment because the stability constants of the actinyl (VI) triscarbonato complexes decrease by four orders of magnitude from UO_2^{2+} to PuO_2^{2+} as the effective charge on the actinide decreases (Table 23.20). Similar to nitrate, the carbonate ligands are bidentate, binding in the equatorial plane of the actinyl cations, forming triscarbonato actinyl complexes with hexagonal bipyramidal geometry. Carbonate complexes also are among the few soluble complexes of uranyl(V), plutonyl(V), and americyl(V) that have been quantitatively studied (Bennet *et al.*, 1992; Giffaut and Vitorge, 1993; Docrat *et al.*, 1999). The stabilities of the triscarbonato actinyl(V) complexes are roughly 13 orders of magnitude smaller than the corresponding actinyl(VI) complexes (Lemire *et al.*, 2001). Nevertheless, carbonate ligands stabilize actinyl(V) ions, especially in the solid state (Keenan and Kruse, 1964; Madic *et al.*, 1983a). Few measured stability constants for $An(IV)-CO_3^{2-}$ complexes have been reported, but those of the limiting solution species, $An(CO_3)_5^{6-}$ (Clark *et al.*, 1998), are large, exceeding 10^{35} M^{-5}. Well-characterized polynuclear complexes of the actinyl(VI) cations with bridging and terminal carbonate ligands have an $AnO_2^{2+}:CO_3^{2-}$ stoichiometry of 3:6 (Åberg *et al.*, 1983b; Allen *et al.*, 1995). Carbonate complexes of Np(VII) also have been proposed (Shilov *et al.*, 1976).

The actinide complexes of highly charged inorganic ligands, such as phosphates, arsenates, or silicates, can precipitate in a variety of different solid phases. Soluble, protonated complexes of these ligands, for example $AnO_2(HPO_4)_n^{2-2n}$, have lower stability constants than complexes of the fully deprotonated ligands because of the reduced charge of the protonated ligand. The actinyl(V) and actinyl(VI) cations form soluble 1:1 complexes with PO_4^{3-} that are strong enough to compete with carbonate complexation (Sandino and Bruno, 1992; Brendler *et al.*, 1996; Morgenstern and Kim, 1996).

Singly deprotonated orthosilicic acid, $H_3SiO_4^-$, forms complexes with trivalent and hexavalent actinides in solutions that are weakly acidic to neutral (Yusov and Fedoseev, 2003 and references therein), and the stability constants of the orthosilicate complexes are proportional to the hydrolysis constants of the metal cations (Jensen and Choppin, 1998).

Multicharged, complex inorganic oxides, such as polyphosphates, polymeric silicates, and polyoxometallates, with properties intermediate between those of simple ligands and of oxide or mineral surfaces also form complexes with actinide cations. Stability in acidic solution and the ability to create soluble, well-defined structures with extensive redox activity make the actinide polyoxometallates interesting complexes (Yusov and Shilov, 1999). The rich chemistry of polyoxometallates results in the complexation and stabilization of

transplutonium actinides in oxidation states usually not stable in aqueous solutions, for example Am(IV), Cm(IV), and Cf(IV) (Kosyakov *et al.*, 1977). Many common polyoxometallate anions, such as $SiW_{12}O_{40}^{4-}$, $P_2W_{18}O_{62}^{6-}$, $Nb_6O_{19}^{8-}$, and $NaP_5W_{30}O_{110}^{14-}$, form complexes with actinide cations, and both 1:1 and 1:2 complexes have been identified. The stability constants for the Th^{4+} complexes of $SiW_{12}O_{40}^{4-}$ are $\log \beta_{11} = 11.3$ and $\log \beta_{12} = 17.8$, and are characterized by large positive complexation entropies, $\Delta S_{11} = 232\ JK^{-1}mol^{-1}$ and $\Delta S_{12} = 356\ JK^{-1}mol^{-1}$ (Choppin and Wall, 2003). The binding sites on the surfaces of some polyoxometallate ligands can accommodate the steric requirements of the actinyl cations as well as the simple actinide cations (Gaunt *et al.*, 2002). Certain polyoxometallates, like the Preyssler anion $P_5W_{30}O_{110}^{15-}$, also can encapsulate actinide cations internally, forming inert, but soluble, compounds (Creaser *et al.*, 1993; Antonio *et al.*, 1998).

23.7.3 Complexes with organic ligands

The variety and strength of organic ligands that form complexes with actinide ions in aqueous solution are limited by the preference of the actinides for hard donor ligands and by the tendency of actinide cations toward hydrolysis. Consequently, ligands that bind actinide cations in aqueous solution usually contain some hard base, oxygen donor sites because the strength and basicity of organic ligands containing only softer donor groups, generally, are insufficient to suppress the precipitation of actinide hydroxides. In organic solvents, where actinide hydrolysis is not important, organic ligands with softer donors such as dithiophosphinic acids (Pinkerton *et al.*, 1984; Jensen and Bond, 2002), thiacrown ethers (Karmazin *et al.*, 2002), ethylenediamine (Cassol *et al.*, 1990), or tripyrazine (Drew *et al.*, 2000) form actinide complexes that are stable, although weaker than complexes of similar oxygen donor ligands.

The most commonly studied actinide–organic ligand complexes involve ligands bearing carboxylic acid groups. Actinide complexes with simple monocarboxylate ligands (i.e. those that contain no other actinide-binding groups) are not among the stronger actinide complexes (Table 23.22). Compared to common inorganic ligands, the actinide complexes of simple monocarboxylates are somewhat stronger than the equivalent SO_4^{2-} complexes, but weaker than the OH^- or CO_3^{2-} complexes. For acetic acid, the stability constants of the first and second acetate complexes, β_{11} and β_{12}, follow the expected order of effective cation charge and ionic radii for actinides in the different oxidation states. However, the 1:3 acetate complexes of the actinyl(VI) ions are stronger than expected from the stability constants of the An(III) and An(IV) complexes. The thermodynamics of actinide–monocarboxylate complexation are, like those of the simple inorganic ligands, entropy driven, with weakly positive or negative complexation enthalpies. Monocarboxylates with low pK_a values (e.g. dichloroacetate [$pK_a = 1.1$] and trichloroacetate [$pK_a = -0.5$]), form outer sphere complexes with the actinides (Section 23.5).

Multifunctional ligands such as polycarboxylates, hydroxycarboxylates, and aminocarboxylates tend to form stronger actinide complexes than simple monocarboxylates due to the formation of chelate rings through coordination of multiple functional groups. This occurs because the affinity of carboxylate (or phosphonate) groups for actinide ions, and their very favorable complexation entropies, provide an anchor for the complexation of amines, ether oxygens, or other less effective donor atoms within the same ligand. For instance, simple

alcohols are not good ligands for actinides in aqueous solution. However, the stability constants of the 1:1 An:L complexes of α-hydroxycarboxylates like glycolate (Table 23.22) and α-hydroxyisobutyrate are stronger than that of acetate because of chelation via the α-hydroxy group (Ahrland, 1986; Stumpf *et al.*, 2002; Toraishi *et al.*, 2002), even though the pK_a values of the carboxylic group would indicate that they are less basic ligands.

Multifunctional ligands also form polynuclear complexes by bridging actinide ions, though this behavior is not unique to actinide cations. In some cases, for example $(UO_2)_2$(edta), $(UO)_2(\text{citrate})_2^{2-}$, or $Th_4(\text{glycolate})_n$ ($n = 8 \pm 1$) (Kozlov and Krot, 1960; Rajan and Martell, 1965; Fraústo da Silva and Simoes, 1968; Toraishi *et al.*, 2002), the polynuclear complexes are well defined and soluble, making measurement of the formation constants of the polynuclear species possible. The likelihood of polynuclear complex formation is usually favored by increasing metal concentrations and decreasing ligand:metal ratios. As the size of the polynuclear complexes increase, their precipitation becomes more likely.

Ethylenediaminetetraacetic acid (H_4edta) and the related multifunctional polyaminocarboxylate ligands are strong, but not very selective, complexants for An(III) and An(IV) cations. Steric constraints make them much poorer ligands for actinyl(V) and actinyl(VI) cations as discussed in Section 23.6. This has led to the use of polyaminocarboxylates as masking agents for interfering An(III) or An(IV) cations in the chemical analysis of actinyl ions. When fully coordinated, the most commonly used polyaminocarboxylate ligands, hexadentate edta^{4-} and dcta^{4-}, and octadentate dtpa^{5-} only partially envelope actinide cations, leaving one or more coordination sites for water molecules (Carey and Martell, 1968; Fried and Martell, 1971; Kimura and Choppin, 1994), or for other small ligands (Pachauri and Tandon, 1975). The strongest polyaminocarboxylate ligands complex An(III) and An(IV) cations over a wide range of acidities (Fig. 23.23). In moderately acidic media (pH 1–3), protonated actinide–polyaminocarboxylate complexes, for example An(Hedta), form. As the pH is increased, fully deprotonated complexes, such as An(edta)$^-$ form first, followed by the formation of ternary actinide–hydroxy-polyaminocarboxylate complexes, such as An(OH)(edta)$^{2-}$, in basic solutions. Increasing the hydroxide concentration further will eventually displace the organic ligand, but for strong polyaminocarboxylate ligands like edta^{4-} this occurs only in the most caustic solutions (>1 M NaOH) (Wang *et al.*, 2003).

Table 23.23 shows that the strength of actinide-polyaminocarboxylate complexes is principally due to large, positive complexation entropies, in common with other inner sphere actinide complexes. However, in contrast to the actinide complexes of inorganic or carboxylate ligands, most actinide–polyaminocarboxylate complexes are strengthened by substantially exothermic complexation enthalpies, which are commonly observed in metal–amine complexation.

Organophosphorus ligands with low water solubility are used widely in organic solvents for chemical separation or purification of the actinides by

solvent extraction. Water-soluble organophosphorus ligands based on phosphoric and phosphonic acids, $ROPO_3H_2$ and RPO_3H_2, are also important actinide complexants in nature (Panak *et al.*, 2002a,b) and in chemical separations (see Chapter 24). Compared to carboxylic acids, the phosphonic acids usually form f-element complexes with Gibbs energies of complexation that are larger than expected from the ligand basicity (Nash, 1993b), even when the ligands are partially protonated (e.g. RPO_3H^-) as illustrated in Table 23.22. The methane-1,1-diphosphonic acids, $RCH(PO_3H_2)_2$, analogs of malonic acid,

$CH_2(CO_2H)_2$, form quite strong complexes. Partially protonated complexes are believed to be a key factor in the strength of these diphosphonate complexes, stabilizing the 1:2 actinide:phosphonate complexes through inter-ligand, intra-complex hydrogen bonding (Nash *et al.*, 1995). The larger anionic charge of the fully deprotonated phosphonic acids, the presence of inter-ligand hydrogen bonding, and the enhanced dehydration of the metal cations on complexation (Jensen *et al.*, 2000b), contribute to the stability of actinide–diphosphonate complexes, as does the strength of the An–O=P bond. Complexation of An(IV) cations by neutral, fully protonated methanediphosphonic acid, $CH_2(PO_3H_2)_2$, persist in 2 M nitric acid at ligand concentrations as low as 0.05 M (Nash, 1991b).

Since monophosphonate and diphosphonate ligands form complexes with actinide ions more readily than the corresponding carboxylates, methylenephosphonic acid derivatives of H_4edta might be expected to be extremely powerful complexants. However, replacing the four acetic acid groups of H_4edta with

methylenephosphonic acid groups (H_8edtmp) yields slightly weaker An(III) complexes (Fig. 23.23), although the stability constants indicate that a range of $AnH_n edtmp^{n-5}$ complexes exist in 1 M NaOH for a concentration of 1×10^{-4} M edtmp (Shalinets, 1972b). Inter-ligand hydrogen bonding between the amines and the phosphonates (Jensen *et al.*, 2000b) and steric constraints (Shalinets, 1972c) apparently resist the formation of complexes in these aminomethylenephosphonates.

Anionic carboxylate and organophosphorus-based ligands are among the most studied organic actinide complexants in aqueous solution, but the actinide complexes of a variety of other organic ligands also have been studied. Stable actinide complexes form in weakly acidic aqueous solution (pH 3–6) with neutral ligands like tpen (Fig. 23.18), or polyamino(2-hydroxyalkyl) ligands (Jarvis *et al.*, 1992; Jarvis and Hancock, 1994; Jensen *et al.*, 2000a). The pK_a values of these neutral ligands are low enough that An(III), An(IV), or An(VI) cations can effectively compete with protons for the ligand binding sites in acidic solutions. However, the hydroxide concentration in nearly neutral solutions is sufficient to displace these neutral organic ligands and precipitate actinide hydroxides.

Competition of protons for the actinide binding sites is not a hindrance to the binding of crown ether ligands (e.g. 15-crown-5 or 18-crown-6, Fig. 23.18). Yet without chelating by other complexing groups such as carboxylic acids incorporated into the crown ether, these ligands are weak actinide complexants in aqueous solution (Brighli *et al.*, 1985), most likely forming outer sphere complexes (Guilbaud and Wipff, 1993b). In contrast, even the simplest phenol-based calix[5]- and calix[6]-arene macrocyclic ligands (Fig. 23.18) form strong actinyl(VI) complexes ($\log\beta_{11} = 19$ for UO_2^{2+} at 25°C, $I = 0.1$ M) with a selectivity ratio for UO_2^{2+} over divalent transition metal cations that exceeds 10^{10} (Shinkai *et al.*, 1987).

Naturally occurring ligands that efficiently bind metal cations are found throughout the biosphere. Hard transition metal cations are vital for many biological processes and there are many natural ligands that regulate their biochemistry. The actinides are also hard cations and the charge to radius ratio of the tetravalent actinides is similar to that of one of the most biologically important metal ions, Fe(III). Consequently, ligands that efficiently bind iron are expected to be efficient ligands for actinides. Desferrioxamine siderophores, a class of polyhydroxamic acid ligands used by microbes to scavenge and transport Fe(III), have proven to be equally efficient ligands for Pu(IV) (Jarvis and Hancock, 1991). X-ray crystallography of the Pu(IV) complex of desferrioxamine E shows that the Pu is nine-coordinated with three water molecules and six desferrioxamine oxygens in the inner coordination sphere (Neu *et al.*, 2000). Interestingly, the ligand is only slightly deformed when it complexes Pu(IV) rather than Fe(III), despite the 0.08 Å difference in ionic radii (CN = 6).

The complexing strength of naturally occurring hydroxamic and catechol (1,2-dihydroxybenzene) groups that siderophores use to sequester Fe(III) have

led to the design of catecholamide and hydroxypyridone ligands that strongly complex An(III) and An(IV) cations (Raymond, 1985). These ligands are highly selective for An(IV) over Fe(III) both *in vitro* (Romanovski *et al.*, 1999; Zhao *et al.*, 1999) and *in vivo* (Stradling *et al.*, 1992; Xu *et al.*, 1995), and are more efficient reagents for Pu decontamination than the polyaminocarboxylate, diethylenetriaminepentaacetate ($dtpa^{5-}$).

Humic and fulvic acids are naturally occurring polyelectrolytes resulting from the decay of natural matter. Their composition varies with the local geology, hydrology, and biology, resulting in fulvic acids with molecular weights as low as 300 and humic acids with molecular weights in excess of 100 000 (Choppin and Allard, 1985). These materials contain alcoholic, phenolic, and carboxylic acid groups, which result in an affinity for metal ion complexation. Actinide ions may interact with these ligands either through binding in specific sites (Marinsky, 1976) or through a generalized 'territorial' binding where the cation is attracted by multiple functional groups within one area of the ligand (Manning, 1979). Different modeling approaches have been proposed to calculate the stability constants for metal ions bound by these ligands (Choppin and Labonne-Wall, 1997). Stability constants of certain humic and fulvic acid complexes have been reported for the most common actinides (Choppin and Allard, 1985; Kim and Sekine, 1991; Moulin *et al.*, 1992; Kim *et al.*, 1993; Marquardt and Kim, 1998). In addition to complexation of actinide cations, humic and fulvic acids can also be redox active, reducing the hexavalent NpO_2^{2+} and PuO_2^{2+} (Dahlman *et al.*, 1976; Choppin, 1988; Jainxin *et al.*, 1993; Yaozhong *et al.*, 1993), and pentavalent PuO_2^{+} (André and Choppin, 2000) and NpO_2^{+} (Marquardt *et al.*, 1996). Both their redox and complexation properties can lead to significant effects on actinide behavior in environmental systems.

23.8 TERNARY COMPLEXES

In aqueous solution, most actinide–ligand complexes could be considered ternary complexes, as they have three components, an actinide ion (component 1), one or more ligands (component 2) and some number of inner sphere water molecules (component 3). It is common, however, to consider such metal cation + ligand anion + coordinated water complexes as a binary metal–ligand complexes. Therefore, our discussion of ternary (or mixed) complexes is limited to three-component complexes, such as AnX_qY_p or $AnO_2X_qY_p$, where X and Y are different ligands but not H_2O. Such ternary complexes may also have coordinated water molecules and varying degrees of protonation of the ligands. Bimetallic complexes, $An_nM_mX_q$ also are considered ternary complexes, but solution studies on such bimetallic complexes of actinide cations are rare (Stemmler *et al.*, 1996; Dodge and Francis, 1997). Despite the large literature on actinide–ligand complexation and the large number of possible complexes of

actinide ions in their various oxidation states, with two different ligands, the number of detailed experimental studies on ternary actinide complexation is limited.

The combination of the low polarity and hydrophobicity of organic solvents often results in the formation of ternary complexes in these solvents. As a consequence, the best documented and most extensively studied actinide ternary complexes are those present in the organic phases of liquid–liquid (solvent) extraction systems, which are described in detail in Chapter 24. In organic solvents, the ternary actinide complexes often form with neutral organophilic ligands, required to provide solubility, and anions, required to balance the positive charge of the actinide cations, in the inner coordination sphere. However, complexes containing different anions and no neutral ligands are also well known in such solvents (Ferraro and Peppard, 1963).

Ternary complexes of actinide salts have been important in actinide separations for more than a century, since the initial use of the extraction of $UO_2(NO_3)_2(Et_2O)_2$ into diethylether to purify uranium (Péligot, 1842). Industrial scale processing of the tetravalent and hexavalent actinides was built on this foundation, substituting methylisobutylketone, dibutylcarbitol (dibutoxydiethylene glycol), or tri(*n*-butyl)phosphate (and similar organophosphate-based ligands) for diethylether. The tri(*n*-butyl)phosphate (TBP) systems are particularly important since they have been adopted internationally for processing nuclear fuel in the PUREX process (Choppin *et al*., 2002). When actinides are extracted from nitric acid solutions into organic solutions containing TBP, the complexes $AnO_2(NO_3)_2(TBP)_2$ are formed in the organic phase for the hexavalent actinides, while the tetravalent actinides have the form $An(NO_3)_4(TBP)_p$ ($p = 2$ or 3). The nitrate groups are directly coordinated to the central actinide cation as bidentate ligands.

Given the propensity of the actinides to undergo hydrolysis reactions (Section 23.3), the single largest class of ternary complexes in aqueous solution are the mixed hydroxides, $An(OH)_qL_p$, which are readily encountered even in weakly acidic solutions for some species. This class of complexes was first reported almost 50 years ago (Hök-Bernström, 1956). The most extensively studied ternary actinide complexes remain the hydroxycarbonates, $An(OH)_q(CO_3)_p$ and $AnO_2(OH)_q(CO_3)_p$. The structural features and the formation constants of An^{3+}, An^{4+}, AnO_2^+, and AnO_2^{2+} hydroxycarbonates have been reported (Clark *et al*., 1995). The hydroxycarbonates of the pentavalent and hexavalent actinyl ions (Neck *et al*., 1997; Szabó *et al*., 2000) exhibit some solubility. In contrast, the neutral hydroxycarbonates, $An(OH)(CO_3)$, are the solubility-limiting species in near neutral aqueous solutions in equilibrium with atmospheric carbon dioxide when other ligands are absent (Bernkopf and Kim, 1984; Silva and Nitsche, 1984; Standifer and Nitsche, 1988; Felmy *et al*., 1990). Neutral 1:1:1 $An(OH)(CO_3)$ species do not exist in significant amounts in the solution phase (Felmy *et al*., 1990; Meinrath and Kim, 1991). Simple, mononuclear hydroxycarbonate complexes, as well as polynuclear species with average

stoichiometries of $Th_{16}(OH)_{20}(CO_3)_{16}^{12+}$ and $Th_8(OH)_{20}(CO_3)_2^{8+}$ have been reported at low metal concentrations (Grenthe and Lagerman, 1991).

Ternary U(VI)–fluoride–carboxylate ligand complexes have been used for systematic studies of the rates and mechanisms of intermolecular and intramolecular exchange reactions. Multinuclear NMR and potentiometric investigations of the complexes revealed a variety of stoichiometries and structures that depend on the nature of the carboxylic acid (Smith, 1959; Szabó *et al.*, 1997; Aas *et al.*, 1998; Szabó and Grenthe, 2000; Szabó, 2002). The presence of two types of ligands ($X = F^-$, $Y = RCOO^-$) and a variety of coordination geometries usually gave rise to a number of different ternary complexes that were simultaneously present in the solutions. In the presence of carbonate or glycolate ligands, the formation of dinuclear ternary complexes, $(UO_2)_2F_q(gly)_p^{4-q-p}$ and $(UO_2)_2F_q(CO_3)_p^{4-q-2p}$, was reported. Although a variety of species were present in the solutions studied, the rate constants and the activation parameters for fluoride exchange were not strongly dependent on the identity of the carboxylate ligand, even for chelating ligands containing other coordinating groups (e.g. picolinic acid, glycine, and *N*-(phosphonomethyl) glycine). Coordination of negatively charged carboxylate ligands (Y^{z-}) has little effect on the equilibrium constants for fluoride complexation by $UO_2Y_q^{2-qz}$ in contrast to fluoride complexation by $UO_2(H_2O)_q^{2+}$ (Aas *et al.*, 1998).

The small amount of quantitative information regarding ternary complexes in aqueous solution limits attempts to model the chemical speciation of actinides in chemical systems when many different ligands are present. Nevertheless, the regularity of electrostatic bonding in actinide complexes (Section 23.4) makes estimation of the formation constants possible, allowing evaluation of the possible importance of a hypothesized species to determine if additional experimental work would be justified. The thermodynamic parameters for the formation of simple 1:1:1 An(X)(Y) ternary complexes often can be estimated from the parameters of the binary AnX and AnY complexes (Grenthe and Puigdomenech, 1997); however, the uncertainty in an estimated formation constant for these complexes can approach an order of magnitude. The most accurate estimated equilibrium constants for the formation of ternary complexes should include corrections for the appropriate change in the effective charge of the actinide caused by the complexation of the first ligand and for the decrease in the number of available coordination sites, which is an entropic (statistical) factor.

23.9 CATION–CATION COMPLEXES

Most studies of actinide complexation have involved interaction of actinide cations with neutral or anionic ligands as nearly all of the known complexes are with such ligands. However, the cationic, *trans*-dioxoactinide(v) (i.e. actinyl(v)),

species form weak complexes with polyvalent metal cations in non-complexing, acidic solutions, as first observed for the complexes of NpO_2^+ with UO_2^{2+} (Sullivan *et al*., 1961). Cation–cation complexes of UO_2^+ (Newton and Baker, 1962), PuO_2^+ (Newton and Burkhart, 1971), and AmO_2^+ (Rykov and Frolov, 1975) with various cations have also been reported. Actinyl(v) cations are not the only dioxocation species that form cation–cation complexes. A complex of pentavalent *cis*-dioxovanadium(v), VO_2^+, with oxovanadium(IV), VO^{2+}, also has been reported (Madic *et al*., 1983b).The formation of cation–cation complexes is not an inherent property of all actinyl ions. The presence of a pentavalent actinyl(v) cation is required to form cation–cation complexes. The actinyl(VI) cations, which have the same structure as the actinyl(v) cations, form cation–cation complexes only with an actinyl(v) cation.

The nature of the species formed in cation–cation complexes has been a focus of investigation since their discovery. Three different models have been proposed. In one model, cation–cation complexes were treated as products of incomplete redox reactions accompanied by the formation of electron–hole pairs in the solvent (Rykov and Frolov, 1972a, 1974). However, this model postulated the formation of solvated electrons, which are not observed in the EPR spectrum of the Np(v)−U(VI) complex (Madic *et al*., 1979). Another model proposed that the cation–cation complexes are polynuclear, ligand-bridged complexes (Guillaume *et al*., 1982; Nagasaki *et al*., 1992) by analogy with oligomeric AnO_2^{2+} hydroxides such as $(UO_2)_2(OH)_2$. However, cation–cation complexes are stable in acidic solutions (2 M $HClO_4$), and it is not apparent why water molecules or perchlorate anions would be effective bridging ligands for polynuclear species requiring participation of AnO_2^+ cations, as these cations generally form comparatively weak complexes with normal ligands.

In the model most used, the cation–cation complexes are the result of bonding between AnO_2^+ cations either as inner sphere (Sullivan, 1962) or outer sphere complexes (Stout *et al*., 1993). Although the actinyl(v) cations possess a formal +1 charge, the effective charge of the actinide atom is approximately +2.2 (Choppin and Rao, 1984). This observation implies that each of the -yl oxygen atoms has a residual negative charge of ca. –0.6 that allows them to form moderately weak electrostatic bonds with other cations (Vodovatov *et al*., 1979). Relativistic spin–orbit configuration interaction calculations on NpO_2^+ resulted in a value for the residual negative charge of −0.48 on each of the neptunyl(v) oxygens while the calculated residual charge on the oxygen atoms of neptunyl(VI) was −0.17 (Matsika and Pitzer, 2000). If the residual negative charge on the oxygen atoms of actinyl(VI) cations is indeed so much smaller than it is for the actinyl(v) cations, the formation of cation–cation complexes by actinyl(v) ions but not by actinyl (VI) ions can be understood.

However, a different explanation for the lack of actinyl(VI) cation–cation complexes is required if the empirical effective positive charges on the actinyl (VI) (ca. +3.2) and actinyl(v) (ca. +2.2) cations are more accurate reflections of the electron distribution in the actinyl cations than are these theoretically

computed electron distributions. The effective positive charges measured for the pentavalent and hexavalent actinyl cations (Choppin and Rao, 1984) predict that the -yl oxygen atoms of actinyl cations carry approximately the same partial negative charge, –0.6, regardless of the oxidation state of the actinyl cation. Therefore, the attractive electrostatic force between the negatively charged -yl oxygen atoms and a given cation would be the same for both oxidation states. Under this model, the lack of actinyl(VI) cation–cation complexes must be attributed to the cancellation of the attractive electrostatic force between the cation and the -yl oxygen atoms by the larger repulsive force between the effective +3.2 charge of the central hexavalent actinide atom and the positive charge of the other cation.

Regardless of which mechanism is correct, the formally cationic actinyl(V) ions can assume the normal role of ligands, forming electrostatic bonds with other cations through the actinyl oxygen atoms, which carry a substantial, partial negative charge.

The actual structures of cation–cation complexes in solution can be surmised from the combination of several different lines of structural evidence. The magnetic splitting of the Np Mössbauer spectra of $NpO_2^+ - Cr^{3+}$ and $NpO_2^+ - Rh^{3+}$ adsorbed on cation exchange resin were interpreted as being consistent with axially symmetric NpO_2^+ (Karraker and Stone, 1977). Wide angle X-ray scattering measurements of solutions containing either $NpO_2^+ - NpO_2^+$ or $NpO_2^+ - UO_2^{2+}$ cation–cation complexes show a peak at 4.2 Å in the radial distribution function, which was assigned as the distance between nearest neighbor actinide atoms in the cation–cation complexes (Guillaume *et al.*, 1983). Also, inner sphere NpO_2^+–NpO_2^+ cation pairs have been observed in a number of crystalline neptunyl(V) complexes (Cousson *et al.*, 1984; Tomilin *et al.*, 1986; Grigor'ev *et al.*, 1993a–c, 1995). In the solid state, two structural motifs for $NpO_2^+ - NpO_2^+$ complexes, the staggered and the 'T-shaped' dimers (Fig. 23.24), with significantly different cation–cation distances, have been observed. The Np–Np distances of the T-shaped dimers, like those observed in $NpO_2ClO_4 \cdot 4H_2O$, 4.20 Å (Grigor'ev *et al.*, 1995), are excellent matches for the X-ray scattering results from aqueous solutions of $NpO_2^+ - NpO_2^+$ complexes (Guillaume *et al.*, 1983). Polymeric NpO_2^+ cation–cation structures have not been observed in solution. Taken together, these experiments confirm the T-shaped solution phase coordination geometry initially suggested by Sullivan (1962) and imply that these are inner sphere complexes.

The stability constants for the formation of cation–cation complexes are invariably small. Typical constants reported for the equilibrium

$$AnO_2^+ + M^{z+} \rightleftarrows AnO_2M^{(z+1)+}$$

range from 0.1 to 16 M^{-1} in aqueous solution, depending on the cations involved and the ionic strength. In organic media the equilibrium constants may be much larger (Rykov and Frolov, 1972b; Musikas, 1986). The enthalpies and entropies

NpO_2^+	−0.9	0	+3	6.0

of complexation in aqueous solutions also are relatively small (Table 23.24). Such small or negative ΔH and ΔS values often indicate outer sphere complexation (Choppin, 1997). However, the reported ΔH and ΔS values also would be in agreement with the accumulated structural data and the formulation of the complexes as inner sphere, $O{=}An{=}O^+{-}M^{z+}$, complexes if the hydration sphere about the resulting complex is more ordered than the hydration spheres of the individual cations are (Stout *et al.*, 1993).

The redox reaction rates of AnO_2^+ ions are often influenced by complex formation with other cations present in the solution. Despite the small stability constants of these complexes (<10), the oxidation of AnO_2^+ by several agents is slowed by the formation of cation–cation complexes. The stabilities of the complexes of AnO_2^+ with UO_2^{2+} decrease in the sequence $UO_2^+ > NpO_2^+ > AmO_2^+ > PuO_2^+$, with a stability constant of $\beta = 16$ for the most stable complex, $UO_2^+ - UO_2^{2+}$. The complexes $NpO_2^+ - UO_2^{2+}$ and $NpO_2^+ - NpO_2^{2+}$ have about the same stability (Madic *et al.*, 1979). Because the $UO_2^+ - UO_2^{2+}$ complex undergoes redox disproportionation at a much slower rate than the simple UO_2^+ aquo ion, solutions of the relatively unstable uranium(v) are significantly stabilized in the presence of UO_2^{2+}.

23.10 KINETICS OF REDOX REACTIONS

The redox reactions of the lighter actinides, which often have several oxidation states of almost equal reduction potentials (e.g. plutonium, Fig. 23.1) are particularly challenging systems. The An(IV)–An(III) and the An(VI)–An(V) couples involve simple electron loss or gain (Newton, 1975; Sullivan and Nash, 1986). The An(VI)–An(IV) and An(V)–An(IV) redox half-reactions include metal–oxygen bond formation or rupture, as well as electron gain or loss, because of the dioxo structure of the actinyl(V) and actinyl(VI) cations. The redox behavior of the actinides is complicated further by the possibility of disproportionation reactions at macro (but not at micro) concentrations.

23.10.1 Electron exchange reactions

Examples of reactions where the An–O bonds in the actinyl ions are not broken are processes such as

$$An(1)^{3+} + An(2)O_2^{2+} \rightleftarrows An(1)^{4+} + An(2)O_2^{+}$$

where An(1) and An(2) denote actinide ions that retain their structures (e.g. $An(1)^{z+}$ or $An(2)O_2^{z+}$). A number of such reactions, involving uranium, neptunium, and plutonium as reductants and oxidants, have been carefully studied (Table 23.25) (Fulton and Newton, 1970). Though these reactions are fast, the rates vary within wide limits; for example, the oxidation of U^{3+} by UO_2^{2+} or Np^{3+} by NpO_2^{2+}, respectively, are extremely fast while that of Np^{3+} by UO_2^{2+} or of Pu^{3+} by NpO_2^{2+} are much slower. The difference is not due to the fact that the latter reactions involve different actinides, since the oxidation of Pu^{3+} by $PuO_2{}^{2+}$ is even slower than the $Np^{3+} + UO_2^{2+}$ and the $Pu^{3+} + NpO_2^{2+}$ reaction rates.

The rates of reaction are closely connected with the Gibbs energies, enthalpies, and entropies of activation (ΔG^*, ΔH^*, and ΔS^*). These have been determined from the temperature dependence of the rate constants and are listed in Table 23.25 for the formation of the activated complex $[An(1)An(2)O_2^{5+}]^*$ along with the equilibrium thermodynamic reaction values ΔG°, ΔH°, and ΔS° for the redox reaction.

The equilibrium values of the entropy changes, ΔS°, are practically the same in all the reactions. This is because the hydration of the actinide ions in a particular oxidation state is fairly independent of the particular element involved. The values of ΔS° are very negative, implying that the formation of strongly hydrated M^{4+} ions brings about a considerable net increase of order in the solutions. However, the values of ΔH°, and, consequently, the values of ΔG°, differ considerably between the various systems in such a way that the fastest reactions are also the most exothermic. The reactions rate constants, k, do not decrease monotonically as the reactions become less exothermic.

The activation parameters provide insight into the source of the large differences in the reaction rates. The three reactions $U^{3+} + UO_2^{2+}$, $Np^{3+} + NpO_2^{2+}$, and $Pu^{3+} + PuO_2^{2+}$ are all first order in each of the reactants and independent of H^+ in the range of acidities measured (0.04–0.6 M, 0.01–0.1 M, and 0.1–1.0 M perchloric acid, respectively, at constant ionic strength) (Newton and Fulton, 1970). This implies that the reactions proceed via an activated complex $[An(1)An(2)O_2^{5+}]^*$. The reaction $Pu^{3+} + NpO_2^{2+}$, also progresses through formation of this activated complex. Since the rate depends upon the acidity, a parallel reaction path via a hydrolyzed complex $[Pu(OH)NpO_2^{4+}]^*$ was proposed (Fulton and Newton, 1970). In the case of $Np^{3+} + UO_2^{2+}$, the conditions are complicated by the presence of two parallel reactions following the initial reaction (Newton, 1970):

$$Np^{3+} + UO_2^+ + 4H^+ \rightarrow Np^{4+} + U^{4+} + 2H_2O$$

and

$$2UO_2^+ + 4H^+ \rightarrow UO_2^{2+} + U^{4+} + 2H_2O$$

At high acidities, these reactions are fast, despite the need to break the U–O -yl bonds in UO_2^+. As the reaction proceeds in 1.0 M acid, the concentration of uranyl(V) reaches a maximum, then decreases, while the concentration of uranium(IV) produced by the reaction of Np^{3+} with UO_2^+ steadily increases after a slow beginning. The activation parameters listed in Table 23.25 refer to the activated complexes $[An(1)An(2)O_2^{5+}]^*$.

The rates of the two fastest reactions are due to different causes. For $U^{3+} + UO_2^{2+}$, the rate is due to the less negative activation entropy while for $Np^{3+} + NpO_2^{2+}$, it is due to the less endothermic enthalpy. The values of ΔH^* are not very different for $U^{3+} + UO_2^{2+}$ and $Pu^{3+} + PuO_2^{2+}$, but the values of ΔS^* are quite different. The faster rates of the mixed systems $Np^{3+} + UO_2^{2+}$ and $Pu^{3+} + NpO_2^{2+}$ compared to $Pu^{3+} + PuO_2^{2+}$ are due primarily to the favorable values of ΔH^*.

23.10.2 Reactions of An–O bond breakage

Redox reactions in which An–O bonds are broken or formed are represented by

$$An(1)^{4+} + An(2)O_2^{2+} + 2H_2O \rightleftarrows An(1)O_2^+ + An(2)O_2^+ + 4H^+$$

in Table 23.26. Analogous to the oxidation of An^{3+} (Table 23.25), the rates have a first-order dependence on the concentrations of each of the actinide reactants. However, the rates of the An^{4+} oxidations also depend upon the H^+ concentrations with exponents that vary from –1 to –3. For some reactions, a non-integral exponent is found, indicating alternative paths with different orders of dependence on the acidity. The apparent second-order rate constants are generally much smaller than the rate constants of the An^{3+} oxidation reactions.

Table 23.25 *Rate constants* ($M^{-1}\ s^{-1}$), *activation parameters, and thermodynamic equilibrium parameters for the reaction* $An(1)^{3+} + An(2)O_2^{2+} \rightarrow An(1)^{4+} + An(2)O_2^{+}$ *in* 1.0 M $HClO_4$ *at* 25°C *from Fulton and Newton* (1970).

[a] Order of the hydrogen ion dependence; if more than one reaction path was observed, the order of the less important path is given in parentheses.
[b] $T = 30$°C.

The strong tendency for hydrolysis of An^{4+} sets a lower limit on the acidity of the solutions which can be investigated, ca. 0.1 M.

Inverse acidity dependence is displayed by the reactions $U^{4+} + UO_2^{2+}$ and $Pu^{4+} + PuO_2^{2+}$, which have similar slow rates and almost equal activation parameters, indicating they proceed along analogous paths. By contrast, $U^{4+} + NpO_2^{2+}$ and $U^{4+} + PuO_2^{2+}$, which also display inverse linear acidity dependence, are the fastest of these reactions with similar values for the activation parameters. The large increase in the rate is due to the much more favorable values of ΔH^*. The values of ΔS^* are less favorable, reducing somewhat the influence of the more favorable values of ΔH^*.

Generally, the slow rates of An^{4+} oxidation are due to very positive values of ΔH^*. Positive values of ΔS^* favor the process but are insufficient to compensate for the influence of ΔH^*. Both the ΔH^* and ΔS^* values of An^{4+} oxidation differ significantly from those of An^{3+} oxidations (Table 23.25).

These trends are even more marked in the thermodynamic equilibrium parameters in Tables 23.25 and 23.26 for the two types of reactions. The values of ΔS^o are negative in An^{3+} oxidation reactions due to the formation of the strongly hydrated An^{4+} ions but they are positive for the oxidation reactions in the An^{4+} systems as this reaction is accompanied by release of water from the inner coordination sphere of the tetravalent cation. By contrast, the An^{3+} oxidations are exothermic, while the An^{4+} oxidations are endothermic. Thus, ΔH^o opposes ΔS° in both sets of reactions and the result is a mixture of values for the Gibbs energy changes of these oxidation reactions.

23.10.3 Redox disproportionation reactions

The disproportionation of actinyl(v) ions, AnO_2^+, is the reverse of the $An^{4+} + AnO_2^{2+}$ oxidation–reduction reactions. In Table 23.27, the rates and activation parameters of the disproportionation reactions of UO_2^+, NpO_2^+, and PuO_2^+ are listed. These rates vary from UO_2^+ reacting quite rapidly to NpO_2^+

Table 23.27 *Apparent second order rate constant and activation parameters for the disproportionation reaction* $2AnO_2^+ + 4H^+ \rightarrow An^{4+} + AnO_2^{2+} + 2H_2O$ *in perchlorate media,* $[H^+] = 1.0$ M *at* 25°C *from Ahrland* (1986).

	I (M)	n[a]	k ($M^{-1}\,s^{-1}$)	ΔG^* ($kJ\,mol^{-1}$)	ΔH^* ($kJ\,mol^{-1}$)	ΔS^* ($J\,K^{-1}\,mol^{-1}$)
UO_2^+	2	1	4×10^2	60	46	−46
NpO_2^+	2	2	9×10^{-9}	119	72	−159
PuO_2^+	1	1	3.6×10^{-3}	87	79	−24

[a] Acid dependence of the rate constant.

reacting extremely slowly. The fast reaction rate of UO_2^+ is due to a low value of ΔH^* while the slow rate of $NpO_2{}^+$ is due, to a large negative value of ΔS^*.

For both the redox and the disproportionation reactions, the lower the charge of the activated complex, the lower the ΔS^* value. For the formation of AnO_2^+ ions, the more negative the exponent of the hydrogen dependence, the more positive the ΔS^* value. For the disproportionation reactions, the more positive the exponent of the hydrogen dependence, the more negative the ΔS^* value. All of the AnO_2^+ ions listed disproportionate at a faster rate in D_2O (Rabideau, 1957; Hindman *et al.*, 1959). Also, the reaction rates of MO_2^+ ions are often influenced by complex formation with cations present in the reaction. These cation–cation complexes are discussed in Section 23.9. Their formation results in a slower rate of oxidation of the AnO_2^+ species by a number of oxidizing agents.

23.10.4 Effect of complexation

All reactions discussed so far take place between hydrated metal ions in non-complexing perchlorate media. In the presence of complex formation with anions, the reaction rates usually increase significantly. This was noticed initially for chloride and sulfate solutions. For example, plutonium(IV) disproportionates about five times faster in hydrochloric acid than in perchloric acid of the same concentration (Rabideau and Cowan, 1955). A study of sulfate media containing Np(IV), Np(V), and Np(VI) revealed that the rate of formation of neptunium(V) depends upon the concentration of the complexes $NpSO_4^{2+}$ and NpO_2SO_4, while disproportion depends upon the concentration of HSO_4^- (Sullivan *et al.*, 1957). For both reactions, the rate laws are not simple. With increasing sulfate concentration, the rate of formation initially increases, reaches a maximum, then decreases. The maximum coincides with the maximum concentration of $NpSO_4^{2+}$ as the higher sulfate complexes have no catalytic effect. The rate of disproportionation, by contrast, is a monotonically increasing function of the concentration of HSO_4^-. Table 23.28 lists the parameters for the reduction reactions of NpO_2^{2+} by complexing anions.

In the disproportionation of americium(V), analogous catalytic effects have been observed (Coleman *et al.*, 1963). In perchloric acid, the reaction

$$3AmO_2^+ + 4H^+ \rightleftarrows 2AmO_2^{2+} + Am^{3+} + 2H_2O$$

occurs, with a rate dependence on the hydrogen ion between 2 and 3. At 76°C, and an acidity of 2 M, the rates in nitric, hydrochloric, and sulfuric acids are 4, 4.6, and 24 times as great as that in perchloric acid. Similar effects have also been found for several other systems.

Comparison of the rate constants for the reaction of $[(NH_3)_6Co]^{3+}$ and $[(NH_3)_5CoX]^{2+}$ ($X = N_3^-, F^-, Cl^-, ac^-, Br^-, CN^-$, or NCS^-) with U^{3+} indicate that these reactions proceed by an inner sphere mechanism. The activation parameters for the analogous reaction of Np^{3+} with $(NH_3)_5RuX^{3+}$ ($X = H_2O$

Table 23.28 *Rate constant and activation parameters for the reduction of Np(VI). Data from Rao and Choppin* (1984), *Kim and Choppin* (1988), *and Choppin and Kim* (1989).

and NH_3) (Espenson and Wang, 1970; Lavallee *et al.*, 1973) supported this proposal, indicating formation of a seven-coordinate Ru(III) intermediate. Other bridging ligands such as SO_4^{2-}, ClO_4^-, Cl^-, etc. have an accelerating effect on the reaction rate. This was attributed to a reduction in the cation–cation electrostatic repulsion through the formation of the intermediate $An^{3+}{-}X^{x-}{-}M^{z+}$.

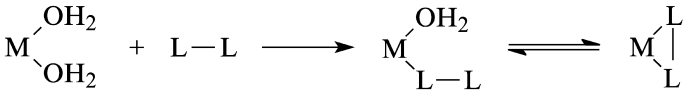
23.11 KINETICS OF COMPLEXATION REACTIONS

The complexation and dissociation of actinide cations with anions of simple structure are more rapid than the analogous rates of reaction of the d-transition cations. These fast reaction rates are due to the strongly ionic nature of most actinide–ligand bonds, which results in a wide range of hydration and coordination numbers and symmetries. This structural versatility arises from the lack of strong crystal-field effects in 5f electronic configurations as well as from the relatively large ionic radii of these cations as the coordination numbers and symmetries are determined by steric and electrostatic factors (see Sections 23.4 and 23.6).

The complexation reactions usually proceed by the Eigen mechanism (Diebler and Eigen, 1959; Eigen and Tamm, 1962; Eigen, 1963). This mechanism involves two steps, the rapid formation of an outer sphere association complex (i.e. an ion pair) and the subsequent rate-determining step in which the ligand displaces one or more water molecules.

$$M(H_2O)_q^{m+} + L^{z-} \rightleftarrows M(H_2O)_q^{m+}{-}L^{z-} \rightleftarrows M(H_2O)_{q-1}L^{(m-z)} + H_2O$$

The actual ligand-interchange step may be dissociative or associative in character. For multidentate ligands, the associative steps with replacement of two-coordinated water can be represented as



In the absence of any steric constraints, formation of the first M–L bond, generally, but not always, leads to rapid ring closure. As the chain distance separating the two donor atoms of the ligand increases, the rate (or probability) of ring closure decreases (Wilkins, 1974, Burgess, 1978). This is reflected in a decrease in $\log\beta_{11}$ and a deviation from linearity in plots of $\log\beta_{11}$ versus ΣpK_a (see Section 23.6). In some systems it is uncertain whether this increase in donor separation is accompanied by a change from chelation to monodentation. Microscopic reversibility requires that complex dissociation reactions follow the formation pathway in reverse. Complex dissociation is typically investigated by addition of a competing metal ion or of a chelating agent that binds more strongly to the cation. Complex dissociation reactions are often catalyzed by H^+ in acidic solution. A variety of experimental techniques have been used to study actinide complexation kinetics. These include stopped-flow spectrophotometry, pulse radiolysis, temperature-jump, NMR, solvent extraction separation methods, and conventional spectrophotometry.

According to the Eigen mechanism for complexation, the rate of solvent water exchange represents an upper limit to the rate of complex formation. Such rates are not available for the trivalent actinides but have been discussed for the chemically analogous lanthanides. Cossy *et al.* (1989) have reported that the second-order rate constants for water exchange are directly proportional to the cation radii of trivalent lanthanides. The water exchange rates for Am(III)–Cf(III) are estimated to range from 1×10^9 to 1×10^8 M^{-1} s^{-1} assuming a linear correlation with the lanthanides based on cation radius (Nash and Sullivan, 1998). Kiener *et al.* (1976) report that the water exchange rates for UO_2^{2+} are complex. Exchange rates for tetravalent and for pentavalent actinide cations have neither been reported, nor can they be estimated reliably. Bardin *et al.* (1998) have reported NMR data that give a first order rate constant for water exchange by UO_2^{2+} in d_6-acetone of 1×10^6 s^{-1} at 25°C.

The complexation kinetics of multidentate ligands are slower than for monodentate ligands due to the changes in ligand structural characteristics during the reactions. The aminopolycarboxylates have been used commonly in actinide separations, and, as a result, their kinetics of complexation with the An(III) cations have been studied in more depth than for any other An(III)–ligand system. Such studies usually involve metal exchange in which the An(III) cation displaces a trivalent lanthanide from complexation with an aminopolycarboxylate complex. For the reaction of An(III) with the Eu(III)–ethylenediaminetetraacetate complex (D'Olieslager *et al.*, 1970; Williams and Choppin, 1974), the rate was shown to be described by the equation:

$$\begin{aligned}\text{Rate} = {} & (k_a[\text{Eu(edta)}][\text{H}][\text{An}]/[\text{Eu}] + k_b[\text{Eu(edta)}][\text{An}]) \\ & - (k_c[\text{An(edta)}][\text{H}] + k_d[\text{An(edta)}][\text{Eu}])\end{aligned} \tag{23.14}$$

in which the ionic charges are omitted for simplicity. The specific rate constants k_a and k_c are associated with the hydrogen ion catalyzed forward and reverse terms, while k_b and k_d are specific rate constants for the respective acid-independent terms.

Below about pH 6 the hydrogen-catalyzed paths dominate the reaction. In these paths, the metal complex is protonated in a series of proton additions, leading ultimately to the decomposition of the complex and hence to metal exchange. The alternate acid-independent path in the exchange mechanism has been described by a metal ion-catalyzed decomposition of the complex in which the ligand serves as a bridge between the entering and exiting metal ions. The exchange reactions can be represented as follows ($Y = edta^{4-}$).

(A) *Acid-dependent mechanism*

$$\begin{array}{ccccccc} & & \overset{\text{Fast}}{} & & \overset{\text{Slow}}{} & & \overset{\text{Fast}}{} \\ \text{EuY} + \text{H} & \rightleftharpoons & \text{EuYH} & \rightarrow & [\text{EuYH}]^* & \rightleftharpoons & \text{Eu} + \text{H}_x\text{Y} + \text{An} \\ & & & & & & \downarrow\uparrow \text{ Fast} \\ & & \overset{\text{Fast}}{} & & & & \overset{\text{Slow}}{} \\ \text{AnY} + \text{H} & \rightleftharpoons & \text{AnYH} & & & \leftarrow & [\text{AnYH}]^* \end{array}$$

(B) *Acid-independent mechanism*

$$\begin{array}{ccccc} & & \overset{\text{Fast}}{} & & \overset{\text{Slow}}{} \\ \text{EuY} + \text{An} & \rightleftharpoons & \text{EuY–An} & \rightarrow & [\text{EuYAn}]^* \\ & & & & \downarrow \text{ Fast} \\ & & & \overset{\text{Fast}}{} & \\ & & \text{AnY} + \text{Eu} & \rightleftharpoons & \text{Eu-YAn} \end{array}$$

The formation and dissociation reactions of other aminopolycarboxylate complexes of Ln and An cations follow these general mechanisms. The rates of metal ion exchange for the trivalent actinides (Am, Cm, Bk, Cf) with $Eu(edta)^-$ indicate a similar dependence on acidity and, in cases where an acetate buffer was used, an additional dependence on free acetate concentration (Choppin and Williams, 1973; Williams and Choppin, 1974).

The rates of formation and dissociation of the Am(III) complex with $dcta^{4-}$ (*trans*-1,2-diaminocyclohexane-*N*,*N*,*N*′,*N*′-tetraacetate, Fig. 23.18) were determined using stopped-flow spectrophotometry to study the formation reaction and conventional spectrophotometry for the decomposition reaction (Sullivan *et al.*, 1978). The experimental results are consistent with the interpretation that a precursor between Am(III) and the ligand is formed. The rate-determining step in the reaction was postulated to be the formation of a bond between Am(III) and an imino nitrogen of $dcta^{4-}$.

The dissociation of the $Am(dcta)^-$ complex was studied by the metal ion exchange technique using Cu^{2+}, as was reported in an analogous study of the

$Ln(dcta)^-$ chelates (Nyssen and Margerum, 1970). No dependence on the copper concentration was observed, implying that any reaction rates measured were pertinent to either acid-induced or spontaneous dissociation of the complex. The results agree with studies on the rate of dissociation of trivalent actinides with a variety of aminopolycarboxylate complexants studied by solvent extraction or ion exchange separation techniques at radiotracer concentrations of the metal ion (D'Olieslager *et al.*, 1970; Choppin and Williams, 1973; El-Rawi, 1974; Williams and Choppin, 1974; Muscatello *et al.*, 1989). The rate-determining step for complex formation is an acid-dependent intramolecular process that appears to be limited by the rate of formation of An(III) bonding to the amine nitrogen. The activation parameters for the reaction were reported to be $E_a = +59.0\ kJ\,mol^{-1}$ and $\Delta S^* = -19\ JK^{-1}\,mol^{-1}$ (Sullivan *et al.*, 1978).

The rate of dissociation of trivalent actinide (Am, Cm, Bk, Cf) complexes with the aminopolycarboxylate ligands $hedta^{3-}$ (*N*-hydroxyethylethylenediaminetriacetate) and $tmdta^{4-}$ (trimethylenediaminetetraacetate) have been measured (El-Rawi, 1974; Muscatello *et al.*, 1989). As in the case for the edta complexes, the rate of the acid-catalyzed dissociation decreases with increasing cation atomic number (Fig. 23.25), which is consistent with a simple electrostatic model for the interactions of both lanthanides and actinides. The dissociation rate of $Am(dcta)^-$ was observed to be more similar to that of the isoelectronic $Eu(dcta)^-$ than to the dissociation rate of $Nd(dcta)^-$, whose cationic radius (and, hence, electrostatic attraction for the ligand) is closest to that of Am^{3+}.

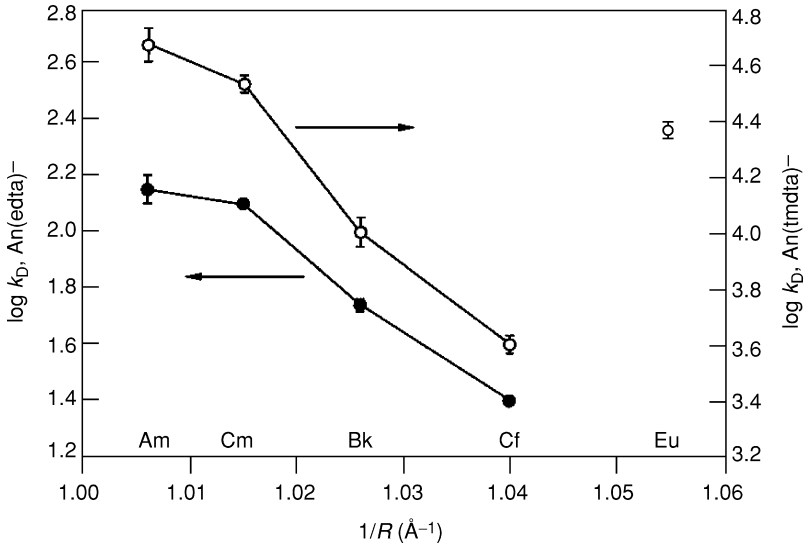


Fig. 23.25 *Correlation of the rate constant of the acid dependent dissociation pathway,* k_D, *of* MY^- ($Y = edta^{4-}$ *or* $tmdta^{4-}$) *and the reciprocal of the cation radius* ($CN = 6$).

This result suggests a possible minor covalent contribution in the binding of Am(III) to the amine (Nash and Sullivan, 1998).

The dissociation rate constants for the trivalent actinide complexes with tmdta^{4-}, as seen in Fig. 23.25, are about two orders of magnitude larger than for the corresponding An(edta)$^{-}$ complexes. This is most probably due to the greater lability of the Am–N bonds in the six member N–Am–N ring of the tmdta complex when compared to the lability of the Am–N bonds in the five-membered N–Am–N ring of the edta chelate.

In contrast to the tmdta complex, the acid-dependent rate constant for the acid dissociation of the Am(dcta)$^{-}$ complex is $\log k_D = 0.64$, which is two orders of magnitude smaller than that for Am(edta)$^{-}$ (Sullivan *et al.*, 1978). This was attributed to the structural effect of the rigidity of the cyclohexyl ring. Table 23.29 lists the values for both the formation and dissociation rate constants for actinide(III) complexes of tmdta^{4-}, dcta^{4-}, and edta^{4-} from Muscatello *et al.* (1989).

23.12 SUMMARY

Although the aqueous complexes of the actinide elements has been a topic of continual interest for over half a century, puzzles remain to be solved and opportunities abound because such complexes are central to understanding the environmental, biological, and separations chemistry of the actinides. Historically, most of this work has involved studies of complexation strength, and to a lesser extent, studies of the kinetics of reactions. Many different techniques have been used. Unfortunately, the utility of such thermodynamic and kinetic measurements diminishes the farther system conditions deviate from those used in the laboratory measurements. The presence of new kinetic pathways, unforeseen equilibria, or solid phases that were not encountered in the laboratory studies can dominate the aqueous speciation when the concentrations of

the solution components or pH values are significantly different from the conditions that have been studied. For instance, the U–O bonds of the UO_2^{2+} cation are quite inert in acidic aqueous solutions with a half-life for oxygen exchange of 4×10^4 h in 1 M perchloric acid (Gordon and Taube, 1961), but in 3.5 M tetramethylammonium hydroxide, the exchange is complete in minutes (Clark *et al*., 1999). As a result, other techniques for studying actinide complexes, such as NMR, fluorescence spectroscopy, and EXAFS have become increasingly important sources of extra-thermodynamic information on dissolved actinide complexes in recent years.

While the information available on the solution complexation of the actinide elements covers a range of actinide ions, oxidation states, and ligands, it can usually be understood by several straightforward principles. The actinide cations are hard Lewis acids that interact preferentially with ligands that are hard Lewis base donors, in aqueous solution, forming strongly electrostatic bonds. Thus, the complexes generally become more stable as the effective charge of the actinide cation or ligand increases and as the size of the actinide cation decreases, if metal- or ligand-centered steric constraints are not important. This is best characterized for the An(III) and An(IV) oxidation states. However, the limited number of actinide cations that are stable in several of the oxidation states from 3+ to 6+, and the short half-lives of the *trans*-californium elements limit the number of actinide species that can be studied by many techniques for use in systematic, empirical comparisons of the metal ion properties. The electrostatic model of actinide–ligand bonding can be very useful despite its simplicity. However, accurate, quantitative, and non-empirical predictions of the strength and structure of actinide complexes are currently only possible for the simplest ligands because of ligand- and solvent-centered effects.

Many areas of actinide complexation chemistry remain relatively unexplored. Topics in actinide complexation which are only beginning to be defined include actinide complexation by neutral ligands in aqueous solutions, the formation of ternary complexes, and the behavior of actinide complexes in alkaline solutions. In addition, studies of ligands that are capable of stabilizing difficult to attain oxidation states; studies of ligands with well defined, pre-organized actinide binding sites; and studies of actinide–selective soft donor ligands have the potential to create new perspectives in actinide chemistry.

ACKNOWLEDGMENTS

This chapter incorporates portions of Chapter 21, Solution Chemistry and Kinetics of Ionic Reactions by Sten Ahrland from *The Chemistry of the Actinide Elements*, second edition. Preparation of this chapter was supported by the U.S. Department of Energy, Office of Basic Energy Sciences, Division of Chemical Sciences, Geosciences, and Biosciences at Argonne National Laboratory (Contract No. W-31-109-ENG-38) and at Florida State University.

CHAPTER TWENTY FOUR

ACTINIDE SEPARATION SCIENCE AND TECHNOLOGY

Kenneth L. Nash, Charles Madic, Jagdish N. Mathur, and Jérôme Lacquement

24.1 INTRODUCTION

Both the science and technology of the actinides as we know them today owe much to separation science. Conversely, the field of metal ion separations, solvent extraction, and ion exchange in particular, would not be as important as it is today were it not for the discovery and exploitation of the actinides. Indeed, the synthesis of the actinides and the elucidation of their chemical and physical features required continuous development and improvement of chemical separation techniques. Furthermore, the diverse applications of solvent extraction and ion exchange for metal ion separations as we know them today received significant impetus from Cold War tensions (and the production of metric tons of plutonium) and the development of nuclear power for peaceful uses.

Solvent extraction, precipitation/coprecipitation, and ion exchange procedures have played a central role in the discovery and characterization of the 5f transition elements. Each of these separations techniques likewise has shaped progress in technological applications of actinides for electricity production and for nuclear weapons. Recent decades have seen the rise of pyroelectrometallurgical separations, wherein the long-term future of actinide separations may lie.

Efficient chemical separations are an essential feature of actinide science and technology because (1) aside from U and Th there are no primordial transuranic actinides and so no natural mineral deposits from which to isolate them and (2) the nuclear techniques employed to create actinides also induce fission in the heavy metal target atoms producing mixtures that can include up to one-third of the periodic table. Whether for scientific purposes or technological applications, high degrees of purification of actinides from diverse solid solutions containing small amounts of the desired material in a complex solid matrix are required. This chapter addresses the details of these chemical separation processes and describes what the exercise of these separation processes has taught us about the chemistry of the actinides.

Four specific separation tasks had to be accomplished to enable the discovery of the 5f elements and then to support creation of sufficient amounts of these elements to sustain their practical application: isolation of natural uranium from its mineral sources, isotope enrichment to increase the relative percentage of fissile ^{235}U above that of natural uranium, separation of actinides from a diverse mixture of fission products, and separation of individual members of the series. The accomplishment of these tasks required innovative solutions to demanding problems. Setting aside the technologically essential process of isotope enrichment (not discussed in this chapter), separations of actinides can be considered at two scales: analytical-scale separations conducted at low concentrations or with small amounts of the analyte, and large-scale separations conducted on kilogram quantities of materials in large shielded facilities. Each of these carries unique opportunities and challenges. Analytical separations are best served by reagents that are both highly specific and very efficient (i.e. capable of quantitatively separating the target species in a single (or small number of) contact(s)). Plant-scale separations also perform best with highly specific reagents, but extremely high phase-transfer efficiency typically is not preferred because materials must also be readily recovered from the separation matrix. Weak chemical separations processes can be overcome at plant scale by adding more repeat contacts (stages) of reagents.

In a once through nuclear fuel cycle, there are no large-scale separations subsequent to the preparation of the enriched uranium fuel. However, in the operation of a closed loop fuel cycle, it is necessary to separate the transuranium actinides individually or as a group from uranium and fission products. For the purpose of scientific discovery, it was (and is) necessary to isolate individual members of the series. The diverse redox chemistry of uranium, neptunium, and plutonium is the primary feature of processes for their isolation and purification. For the actinides beyond americium and in most applications for americium as well, the trivalent oxidation state predominates. The trivalent oxidation state is also prevalent in the lanthanides, which are produced in about one-third of thermal neutron-induced fission events in ^{235}U and ^{239}Pu. Most features of the chemistries of the trivalent transplutonium actinides and lanthanides are nearly identical.

Aside from the unique demands of trivalent actinide/lanthanide group separations, the discussions of separations systems below will consider features of lanthanide separations as representative of the behavior of trivalent actinides. The separation of individual trivalent actinides relies on the predominantly electrostatic bonding characteristics of the ions and on the steady reduction that is seen in the trivalent cation radii with increasing atomic number, a behavior paralleling that of the lanthanides. This small but (more-or-less) regular decrease in cationic radii provides an adequate driving force for ion exchange-based separations of the individual members of the series, as will be described below.

The actinides are as a group readily separated from most fission products, based on their unique chemistry as compared with the great diversity of species present. Typically, only Ru, Mo, Zr (under some circumstances), and the ubiquitous lanthanides represent a significant separations challenge. The isolation of individual trivalent transplutonium actinides from trivalent lanthanides can be readily achieved if the species to be separated are sufficiently differentiated based on cation radii. Specifically, the transplutonium elements can be readily separated from the light lanthanides, but with greater difficulty from those in the middle of the series. For an effective separation of the trivalent actinides from the lanthanides as a group or for ions having similar cation radii, it has proven essential to incorporate into the separation scheme donor atoms 'softer' than oxygen or fluoride. Poly-aza ligands of complex geometries, chloride ions, thiocyanate ions, or species containing sulfur donor atoms have proven the most viable candidates. These soft-donor reagents can appear in the separation schemes either as lipophilic extractant molecules or as water-soluble complexing agents.

Nearly 60 years of industrial scale implementation of aqueous processing schemes has produced both considerable insight into the ways and means of conducting these separations, and large waste disposal/environmental restoration challenges at the sites where such large-scale processing has been conducted. The legacy of the massive volume of waste generated during these many years of aqueous processing to recover actinides from spent fuel has spurred efforts to develop radically different approaches. In particular, separations developed conceptually in the 1960s based on molten salts, molten metal, including electrochemical processing in these media, have received considerable attention in recent years for their potential as alternative large-scale separations methods for spent fuel processing. Such methods tend to strongly favor reduced actinide species and radically different (though fundamentally simple) coordination chemistry for the actinide species in these media. Far less is known about the chemistry of actinides in supercritical fluids, room-temperature ionic liquids, or other non-conventional media, but any of these methods could play a central role in future nuclear fuel cycles. Processes based on volatility of certain actinide compounds have also received some attention and possess some interesting features. However, each of these concepts is far behind aqueous processing,

both because of the number of years of experience that have been accumulated for the aqueous option, and the unknowns always attendant to developing new science and technology.

24.1.1 Prior literature reviews/useful reference volumes

There are two categories of previous studies each serving a complementary role in describing actinide separation science: those providing 'recipes' for conducting separations of radioactive materials and those explaining the underlying principles. In the beginning, the chemical properties of the transuranium elements were a matter of informed speculation, so underlying principles were not known except by inference. Their discovery and the ultimate elucidation by Seaborg of the actinide hypothesis was a clear demonstration of the correctness (and utility) of Mendeleev's periodic table. The chemical separation procedures that enabled actinide science as we know it today were based on belief in chemical periodicity. One remarkable aspect of actinide separation science is the enduring quality of many of the separations developed during the days of actinide discovery. This is a tribute to the talents and abilities of those early practitioners of actinide separation science.

Perhaps the most useful (even today 40 or more years after their publication) detailed experimental separation procedures are those found in the National Academy of Science Series on radioanalytical chemistry. This series, published in the 1950s and 1960s, still constitutes a useful primary reference for formula separation schemes for the entire periodic table, including the actinides. Though individual bound volumes of these separation procedures are widely available, the series is long out of print. These volumes are however presently available online (http://lib-www.lanl.gov/radiochemistry/elements.htm).

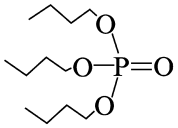
Of course, the insights gained from these initial explorations have allowed the development of more general reference works and a better understanding of the chemical features of the processes. The classic reference book for aqueous separations chemistry (both ion exchange and solvent extraction) has long been *Ion Exchange and Solvent Extraction of Metal Complexes* by Marcus and Kertes (1969). In this book, the theory and practice of separation science is discussed in great detail. Solvent extraction chemistry has been reviewed by Sekine and Hasegawa (1977). In addition to concentrating on solvent extraction, this work differs from the Marcus and Kertes volume in that it has references to many more specific examples. Helfferich (1962) published a volume that is generally considered as the most authoritative discussion of the unique theoretical aspects of ion exchange-based separations. Two 'how-to' manuals have been published which describe in detail useful ion exchange separation procedures for the lanthanides and actinides (Korkisch, 1986a,b).

Updates on the state of the art of f-element separations have appeared in the literature at regular intervals. Jenkins (1979, 1984) reviewed ion exchange applications in the atomic energy industry. Symposium volumes entitled

Actinide Separations (Navratil and Schulz, 1980), *Lanthanide/Actinide Separations* (Choppin *et al.*, 1985) and *Separations of f Elements* (Nash and Choppin, 1995) are collections of papers from several authors covering various aspects of lanthanide and actinide separations. Additional specialized reviews of specific topics have also appeared frequently. Most of these are considered below.

The subject of lanthanide/trivalent actinide separations has been reviewed previously (Weaver, 1974; Nash, 1993a). Weaver's review is an excellent source for a comprehensive discussion of solvent extraction separations of the lanthanides and trivalent actinides. Weaver discusses many of the historical aspects of lanthanide/actinide separations, and considers both the successes and failures in the separation of trivalent lanthanides and actinides. Nash's review complements and updates the observations of Weaver, emphasizing the critical role played by soft-donor ligands in the development of efficient processes for the selective separations of the trivalent 4f and 5f elements.

Arguably, the most important reagent for actinide separations is tri(*n*-butyl) phosphate (TBP – structure a). This compound is the subject of a four-volume handbook entitled *The Science and Technology of Tributyl Phosphate* (Schulz *et al.*, 1990). Many chapters in this collection address important features of the application of TBP for nuclear fuel processing and actinide recovery. On the subject of large-scale separations of actinides, the current state of the art in hydrometallurgical processing of actinides from spent fuel or radioactive wastes has been reviewed recently (Horwitz and Schulz, 1999; Mathur *et al.*, 2001).



Structure a

These reports describe and critically evaluate water-based actinide partitioning research activities being conducted around the world. The diversity of activities being pursued worldwide is in some respects surprising. However, it does reflect the increasingly important nature of these separations. In truth, aqueous separations still dominate the actinide separations landscape. Contemporary research attempts to take a 21st century perspective on nuclear fuels processing, emphasizing the importance of closing the fuel cycle while minimizing the generation of wastes requiring geological disposal.

24.1.2 Scope of the chapter

The space available to this chapter simply does not allow for a comprehensive treatment of all aspects of the subject of actinide separations. Some selectivity will therefore be applied in the following discussion. All essential features of actinide separations will be discussed, but it will not be possible to include detailed step-by-step descriptions of all of the well-known separation systems.

The reader will find such information among the several reviews noted above. Greater emphasis will be placed on the details of newer science and technologies, those currently being considered for advanced applications, and on those most appropriate methods to preserve long-term options for nuclear fuels recycling in the 21st century.

Because chemical separations have played such an important role in the discovery of the actinides, the chapter begins with a discussion of the early history of actinide separations. This discussion will be followed by some consideration of the fundamental chemistry of separation systems and of actinide behavior in phase transfer systems. The fundamental chemistry of actinides in aqueous solutions has been described in the previous chapter. It will therefore not be necessary to address the details of actinide behavior in solution in detail here. However, some aspects of the aqueous chemistry of actinides (redox, solvation, complexation) do play an important role in actinide separations, and so will receive an appropriate emphasis wherever needed in this chapter. The general features of phase transfer reactions will be discussed briefly, focusing on the differences between the classic solvent extraction, ion exchange, and precipitation methods. Unconventional techniques, those still at the developmental/exploration stage, including those related to the use of supercritical fluids (mainly CO_2), molten metals/molten salts, and more exotic (and less extensively tested) techniques like those based on the use of room temperature ionic liquids (RTILs) or volatility will then be addressed. The issue of scale will be considered with coverage of analytical separations followed by a detailed description of the current state of the art in hydrometallurgical (industrial-scale) separations for actinide recovery, recycle, and transmutation. The chapter concludes with some consideration of future directions.

24.2 HISTORICAL DEVELOPMENT OF ACTINIDE SEPARATIONS

Actinide separations had its beginnings with the discovery of radioactivity. Crookes and Becquerel found that the addition of carbonate to a solution containing uranium caused the formation of a precipitate that contained the beta, gamma radioactivity while the uranium remained in the solution phase. Rutherford and Soddy made a similar observation for thorium. Marie and Pierre Curie began a program to separate the components of pitchblende. In 1898, they announced the discovery of the new element polonium, ''While carrying out these operations (separations by precipitation), more active products are obtained. Finally, we obtained a substance whose activity was 400 times larger than that of uranium. We therefore believe that the substance whose activity we have isolated from pitchblende is a hitherto unknown metal. If the existence of this metal can be affirmed, we suggest the name polonium'' (Choppin *et al.*, 2002). The separation method used by these pioneers was precipitation/coprecipitation, which remained the predominant

separation technique through the Manhattan Project of World War II. A historical perspective on the development of this science and technology through the end of World War II is available in *The Making of the Atomic Bomb* (Rhodes, 1986).

Between 1934 and 1939, about 50 research papers claimed the discovery and reported studies of transuranium elements with $Z = 93$, 94, 95, 96. In 1939, Hahn and Strassmann conducted very careful separations on neutron-irradiated uranium samples and proved that these 'transuranium elements' were, in fact, products of nuclear fission with atomic numbers below 60. This led to new experiments in 1940 in which neptunium ($Z = 93$) and plutonium ($Z = 94$) were synthesized and separated. These new elements were isolated using an oxidation–reduction cycle (with BrO_3^- as the oxidizing agent) followed by precipitation of the reduced metal ions with crystalline LaF_3, establishing a link with the 4f elements.

Within the context of world politics in the 1930s and 1940s (and as it turned out the following decades), it was perhaps inevitable that the discovery of fission would be first valued for its potential military applications. Two approaches to the assembly of a critical mass were immediately recognized: isotope enrichment to increase the atom percentage of the fissile uranium isotope ^{235}U and transmutation of ^{238}U by neutron capture and β^- decay to produce ^{239}Pu. The former option required a many theoretical plate isotope separation process wherein the stage-wise efficiency is limited by the small difference in mass of the two principal isotopes. Plutonium production instead relies on neutron capture in a reactor fueled by uranium (the ratio of ^{239}Pu production to fission of ^{238}U after capture of a thermalized neutron is about 14 to 1 (Choppin and Rydberg, 1980) and chemical separation of different elements. Differences in the redox chemistries of uranium and plutonium facilitate their mutual separation. Neither isotope enrichment nor plutonium production were considered to have an advantage in the race to produce a critical mass for the first nuclear weapon in time to affect the outcome of the war, so both methods were pursued with equal vigor in the Manhattan Project.

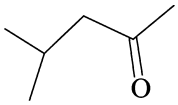
Two approaches to uranium isotope enrichment were proposed for full investigation and process development: electromagnetic isotope separation, proposed by E. O. Lawrence at Berkeley, and gaseous diffusion, championed by John Dunning at Columbia University (Rhodes, 1986). The latter was considered the more likely to succeed on an industrial scale because it was based on technology that was better established. It also offered the advantage of continuous operation, which was not deemed possible in the electromagnetic separation option. Electromagnetic isotope separation received equal consideration because of the greater per-stage separation potential of the technique. Each method relied on the low-temperature volatility of UF_6 (Cotton and Wilkinson, 1988).

As research continued on both approaches, groundbreaking occurred on the Clinch River in eastern Tennessee in 1942, leading to the establishment of the Clinton Engineering Works in Oak Ridge. The Gaseous Diffusion Plant (K-25)

required the co-siting of a dedicated coal-fired power plant and occupied about 0.2 sq. km under a four-stories-high roof. The electromagnetic isotope separations plant (Y-12) occupied half that space and required 13 tons of silver (borrowed from the U.S. Treasury) for the electromagnets. In the end, K-25 provided feedstock of up to 50% enriched ^{235}U to the Y-12 plant for completion of the high enrichment needed for weapons production. These two plants working in tandem produced the ^{235}U for the Hiroshima weapon (Rhodes, 1986).

Industrial scale plutonium production was first accomplished at the Hanford site on the Columbia River near Richland, Washington (Anonymous, 1996). It began with commissioning of B reactor in September 1944 and continued through the lifetimes of eight single-pass reactors, N reactor (the only dual-use Hanford reactor that produced both usable steam and Pu), and the fast flux test facility (FFTF) ending in the early 1980s. The isolation of plutonium from uranium and fission products was initially accomplished by precipitation with $BiPO_4$. The process, pioneered by S. G. Thompson (Thompson and Seaborg, 1956, 1957; Seaborg and Thompson, 1960), involves coprecipitation of Pu(IV) by $BiPO_4$ followed by oxidation to Pu(VI), which does not carry on $BiPO_4$. The process was repeated several times and followed by a LaF_3 precipitation to increase the purity of the product. This batch process is inherently inefficient and has the additional disadvantage of losing uranium to the waste stream. At the time, the loss of uranium to the waste stream was particularly damaging to process efficiency because of the limited amount of purified uranium that was available. However, precipitation/coprecipitation was the only viable technology that could be readily scaled up to production plant dimensions within the demanding time constraints of the Manhattan Project. In fact, the $BiPO_4$ coprecipitation process was first demonstrated using microgram quantities of plutonium, hence the scale-up was by a factor of 10^9. Because of the consistency and reproducibility of the chemistry involved, this scale-up occurred without significant complications. After the war, additional separations of $BiPO_4$ wastes were conducted to recover the rejected uranium for recycle to reactors.

$BiPO_4$ was eventually replaced at Hanford by solvent extraction processes based on the use of methyl(isobutyl)ketone (hexone, Structure b) for extraction of uranium and plutonium from slightly acidic $Al(NO_3)_3$ solutions (REDOX process) and later using TBP to selectively extract (and mutually separate) uranium and plutonium from nitric acid solutions (PUREX process). Great improvements in efficiency were achieved with each successive development, though the PUREX process produced a far smaller volume of secondary wastes than the REDOX process. Fifty years later, PUREX remains the principal method for processing of spent nuclear fuel.



Structure b

In the spirit of scientific discovery and at several laboratories around the world, though primarily at Berkeley and under the supervision of Glenn Seaborg, research in the 1950s and 1960s continued to extend the actinide series from plutonium and americium towards the final element of the series ($Z = 103$). The identification of new elements demands satisfaction of "...The basic criterion for the discovery of a new element is the experimentally verified proof that the atomic number of the new element is different from the atomic numbers of all previous elements. Establishment of the atomic number can be by chemical means, by identification of the characteristic X-rays in the decay of the new species, or by establishment of genetic decay relationships through α-particle decay chains in which the new element is identified by the observation of previously known decay products" (Seaborg and Loveland, 1990). To respond to the demand for predictable chemistry, it was essential that the separations process behave in a systematic fashion.

As the postwar research on actinide syntheses progressed, it was quickly learned that the rich redox chemistry of the light actinides, which was central to most of the successful separations of the light members of the series, did not persist beyond americium. In aqueous solutions, the elements beyond americium behaved chemically more like the 4f analog lanthanides than the light members of the series, strongly preferring to remain in the trivalent oxidation state.

Because synthesis of successive members of the series (beyond Cm) required the isolation and irradiation of a previous member of the series, the task of identifying the later members of the series was hindered not only by the ability to analyze for new species produced, but also by the rate at which target elements could be produced (and how quickly they decayed). The difficulty is demonstrated in Table 24.1 in which the nuclear reaction, target element, and product are noted. The process was further complicated by the increasingly short half-lives of the elements produced, and the low efficiency of the reactions leading to their production. For the elements beyond einsteinium, only a few atoms at a time were created and detected. The procedures of one-atom-at-a-time chemistry have been described in some detail by Seaborg and Loveland (1990) and can be found in Chapters 13 and 14 of this work.

The particle capture reactions that yielded new elements were also always accompanied by some fission. Yields for lanthanides in heavy element fission are high thus the dissolution of irradiated targets led to the creation of solutions that contained not only small amounts of the target transamericium elements but also significant concentrations of lanthanides. This complication impacted both the identification of new elements and the creation of appropriate target materials.

Two challenging separation problems resulted from this circumstance: the need for mutual separation of the two groups (5f from 4f), and of adjacent metal ions (in the 5f series) of identical charge and similar cationic radii. Because

[b] Heavy ion linear accelerator.

of the minute amounts of materials being used as targets and produced in irradiations, and the absence of multiple oxidation states, many standard separation procedures (e.g. precipitation/coprecipitation) were simply not useful. The emergence of polymeric ion exchange materials proved essential to accomplishing both of these separations.

Though cation exchange resins bearing readily deprotonated sulfonic acid groups adsorbed the trivalent f-elements strongly, even from moderately acidic solutions, these sorbents exhibited little inherent facility for accomplishing either separation, i.e. there was insufficient differentiation between cations of similar size. Lanthanides and trivalent actinides were absorbed by the resin under the same conditions and with most inorganic eluants exited the column together. The secret to attaining selectivity was proper choice of the eluting solution. Two distinctly different classes of eluting agents were applied to these separation problems, soft-donor ligands, and hydroxycarboxylate complexants. Their use enabled the positive identification of the remaining members of the series thus confirming the basic correctness of the actinide hypothesis. Each of these separations methods is discussed in greater detail in Section 24.3.3.

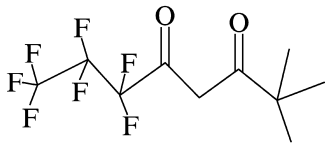
24.3 FUNDAMENTAL FEATURES OF ACTINIDE SEPARATION SYSTEMS

To isolate an actinide ion from a complex mixture, some procedure must be devised to transport the target metal ion from its starting condition into a separate phase and then recover the target metal ion from that separate phase. For analytical-scale separations, a highly efficient process that can be

accomplished in a single (or small number of) contact(s) between the phases is most desirable. For large-scale separations, complex series of processes are typically combined to accomplish the separation. As a result, less efficient single-stage chemical processes are acceptable (and in fact often preferred) for hydrometallurgical applications. Selectivity becomes a more important feature than extractant strength. The key features needed for large-scale separations of nuclear materials are: (1) reversibility of phase transfer (mass transport) reactions with a shift in extraction conditions, (2) sufficient reliability to be readily adaptable to remote (i.e. no human contact) operations, (3) rapid chemical reaction and phase-transfer kinetics, and (4) the ability to operate in a continuous rather than batch fashion. The first three features are absolutely essential; the fourth is highly desirable. Materials must also demonstrate physical and chemical stability in contact with strongly acidic aqueous solutions and in a high radiation environment. General features of selected separation techniques will be discussed in the following sections.

24.3.1 Volatility-based separations methods

Choppin (2002) has provided an overview of the subject of separation processes based on the volatility of actinides and selected fission products. He suggests possible approaches to selective removal of Zr, Tc, and Ru fission products (or cladding material) through their volatile oxides (Tc, Ru) or chlorides (Zr). There are also reports on the potential use of volatile β-diketone complexes of trivalent lanthanides for gas phase based separations. For example, tetra- and hexavalent actinide cations are known to form volatile compounds with FOD (6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedione, Structure c), which could form the basis for a separation of uranium and plutonium from americium (Anonymous, 1995). This same reagent will appear again in the discussion of actinide separations methods based on supercritical CO_2 (Section 24.3.10). No separation system based on the volatility of either fission product oxides or β-diketonate complexes has received extensive development at the process scale.



Structure c

The most extensively researched system for volatility separations is based on the same volatile fluorides that are the basis of isotope separations. A separation based on the volatility of uranium and plutonium fluorides was demonstrated by Hyman *et al.* (1956) and investigated in greater detail at Oak Ridge National Laboratory for reprocessing as a part of the molten salt reactor project (Rosenthal *et al.*, 1972). The overall effectiveness of the process is limited

principally by the simultaneous production of volatile fluorides of fission products Tc, Te, and I. The volatile fluorides can be separated by distillation, though the lower volatility of PuF_4 (arising from the decomposition of PuF_6) leads to Pu deposition problems. In principle, this approach should produce minimal volumes of wastes, though operations combining fluorine compounds and radioactive materials always present challenging materials handling and safety issues. The application of fluorinated compounds to volatility separations is mimicked in many separations that rely on supercritical CO_2, as will be discussed in Section 24.3.10.

24.3.2 Precipitation/coprecipitation methods

In the laboratory, precipitation and coprecipitation processes are a regular and accepted feature of radioanalytical chemistry. Several applications of precipitation and coprecipitation techniques for conducting investigations of the redox speciation of actinides at radiotracer concentrations are discussed in Section 24.4.1a. For the cleanup of aqueous media containing low concentrations of actinides, ultrafiltration has also been employed to collect ultrafine actinide-containing solids (Cecille *et al.*, 1987; Senentz and Liberge, 1998; Smith *et al.*, 1998, 1999; Bisset *et al.*, 2003). Though a number of precipitation processes have been advanced over the years to assist in selected actinide separation scenarios (Bertozzi *et al.*, 1976; Mousty *et al.*, 1977; Pietrelli *et al.*, 1987; Spurny and Heckmann, 1987; Grossi *et al.*, 1992a,b; Sinha *et al.*, 1992; Strnad and Heckmann, 1992; Felker *et al.*, 1995; Tomiyasu and Asano, 1995; Harada *et al.*, 2001), precipitation is no longer practiced as the primary means of separations for large-scale actinide production purposes.

Because the actinides are acidic cations, they readily undergo hydrolysis and precipitate as hydroxides. If complexing agents are kept from the solution, actinide hydroxides can be readily precipitated in the trivalent ($K_{sp} \approx 10^{-20}$), tetravalent ($K_{sp} \approx 10^{-54}$), pentavalent ($K_{sp} \approx 10^{-10}$), and hexavalent ($K_{sp} \approx 10^{-25}$) oxidation states (Martell and Smith, 1998). Hydroxides are generally avoided at the production scale and are unreliable for radioanalytical purposes, but often prove quite convenient avenues to the purification of actinide ions at the milligram to gram level for research purposes. Their most notable feature is the ready reversibility of the precipitation through the addition of mineral acid solutions, thus hydroxide precipitation can be used to readily convert from (for example) chloride to nitrate salts. The cautionary note here is to avoid the formation of tetravalent plutonium hydroxide, which has an extremely low K_{sp} and is redissolved only with difficulty, and often not cleanly, particularly if the precipitate is aged. The presence of carbonate or strong complexing agents (e.g. aminopolycarboxylates) can seriously interfere with hydroxide precipitation processes.

Other species that are readily precipitated are the phosphates of actinide ions in any oxidation state and under a wide range of conditions, and the fluorides

and the oxalates of trivalent and tetravalent actinide ions. The latter two reagents can be employed for oxidation state-based separations, as the pentavalent or hexavalent actinide cations do not form insoluble species under most conditions with these anions while both the trivalent and tetravalent ions precipitate readily from acidic solutions. In the remanufacture of plutonium from nuclear weapons pits (fission core of a thermonuclear device), the selective precipitation of tetravalent plutonium as the peroxide was an essential feature of operations at the Rocky Flats Plant (Cleveland, 1970).

The most technologically important coprecipitation process (no longer used in practice) is that based on bismuth phosphate, as noted above in Section 24.2 and again later in more detail in the discussion of process chemistry. For actinide oxidation state speciation in radioanalytical applications, the actinides themselves are present at concentrations too low to challenge solubility limits in a reliable fashion. The introduction of cations and anions that combine to form insoluble species that carry the actinides down are useful analytical or laboratory-scale purification procedures. This is the case of lanthanum fluoride (LaF_3) whose solubility product is reported as about $10^{-18.7}$ (Martell and Smith, 1998). This compound is readily precipitated from comparatively dilute acidic fluoride solutions. LaF_3 (actually, most any lanthanide will serve) quantitatively carries trivalent and tetravalent actinide ions. Care must be exercised for quantitative LaF_3 carrier precipitation to avoid excess HF, as the resultant formation of soluble metal fluoride complexes can interfere with the efficiency of precipitation. Partly as a result of the unique coordination geometry of the dioxo actinide (V) and (VI) cations, there are no reliable coprecipitation procedures for their analysis or macroscale separation, though there are a number of insoluble adsorbents that will remove these ions from solutions (though with limited selectivity). These adsorption reactions will be discussed in Section 24.4.1.

24.3.3 Ion exchange methods

The development of solid materials capable of capturing and reversibly releasing the metal ions back into the contacting solution, ion exchange materials, was a great step forward in separating elements with similar properties. The earliest non-crystallization separation processes for individual trivalent lanthanide ions based on inorganic ion exchangers demonstrated separation factors for adjacent ions of 1.01–1.05, barely acceptable for chromatographic separations using large columns. For the production of actinides in microscopic amounts, such separation factors are simply too low to be useful. The selectivity limitations of inorganic ion exchange materials were only slightly improved with the development of polymeric organic ion exchange materials, though the latter offered superior reproducibility and resistance to dissolution. Radiation stability is an issue for either class of sorbents, but more problematic for the polymeric

materials. Clearly, more efficient procedures were required to cope with submicroscopic amounts of the new transplutonium elements being produced.

The separation of trivalent actinides from lanthanides was first achieved by cation exchange from concentrated chloride media. Street and Seaborg (1950), Diamond *et al.* (1954), and later Choppin and Chetham-Strode (1960) demonstrated that the behavior of lanthanides and actinides on cation exchange columns was identical below 6 M HCl, but diverged between 6 and 12 M (as shown in Fig. 24.1). Separation factors of about 10 were achieved at 12 M HCl. Separation efficiency was increased when the separation was carried out from salt solutions (dilute acid) or from alcohol–water mixtures of HCl. Diamond and coworkers proposed that the separation of promethium and americium at high concentrations of HCl was a manifestation of f-orbital covalency to the bonding of Am^{3+} to Cl^{-} (which is not present in the Pm system). The origin of the effect is still a matter of discussion and debate, but it has become abundantly clear over the intervening decades that the most effective trivalent actinide and lanthanide separations are based on the contribution of ligand donor atoms softer (i.e. more polarizable) than oxygen.

Separation efficiency was slightly greater when anion exchange was employed. Thompson *et al.* (1954) found actinide/lanthanide separation factors above 10 for anion exchange separation from 10 M LiCl aqueous solutions.

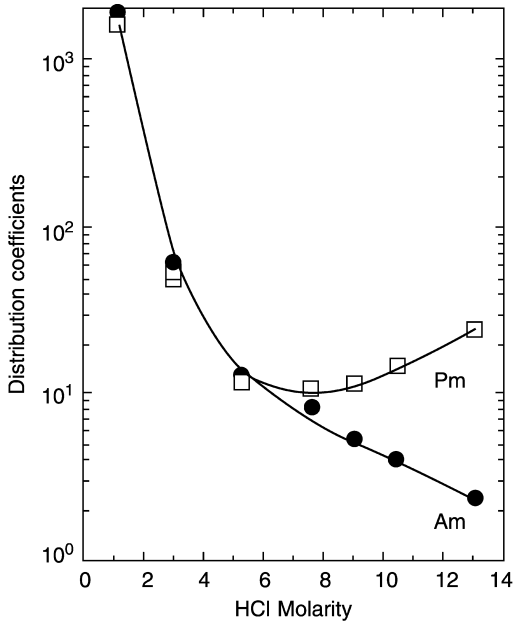


Fig. 24.1 *Distribution of Pm(III) and Am(III) onto Dowex* 50 *cation exchange resin as a function of hydrochloric acid concentration* (*Diamond* et al., 1954).

In this case, higher order (anionic) actinide chloride complexes are formed which preferentially associate with the resin. Introduction of 20% ethanol improved the separation factor, presumably through a modification of the hydration characteristics of the metal ions or their complexes. In this system, the actinides were eluted within a few column volumes while the lanthanides required much larger volumes. In another procedure using a Dowex 1 anion exchange resin column and eluting with 9.9 M LiCl (0.11 M HCl), Hulet *et al.* (1961) achieved an excellent separation of Ln–An. Surls and Choppin (1957) reported that similar results could be achieved in thiocyanate solution at significantly lower concentrations than is required for chloride (Fig. 24.2). This is a result of the increased interaction strength of the actinide with the 'less-soft' nitrogen donor atom of SCN^- relative to the very soft Cl^- anion. The LiCl anion exchange process is still used for actinide/lanthanide separation at Oak Ridge National Laboratory for actinide production (King *et al.*, 1981).

The results of Guseva and Tikhomirova (1972) indicate a significant improvement in the group separation from 4% cross-linked Dowex 50 using 10.5 M HCl

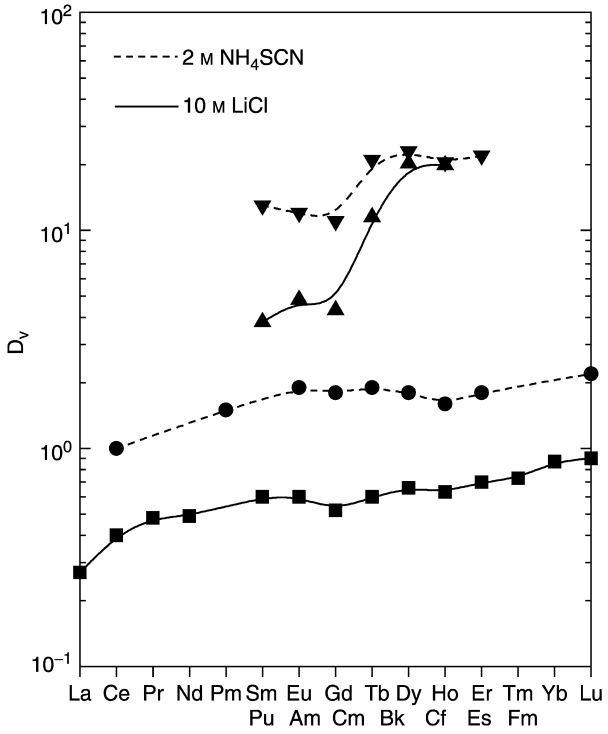

Fig. 24.2 *Partitioning of trivalent actinides and lanthanides onto Dowex* 1 *anion exchange resin from* 10 M *lithium chloride* (*Hulet* et al., 1961) *and* 2 M *ammonium thiocyanate* (*Surls and Choppin*, 1957) *solutions* (▼, ▲, *actinides*, ●, ■, *lanthanides*).

in 40% ethanol as the eluant as compared with 12.5 M HCl in water. Guseva *et al*. (1987a,b) subsequently demonstrated an efficient separation of trivalent actinides from all matrix elements (lanthanides and other fission products) with both cation and anion exchange from aqueous–ethanol solutions of sulfuric acid. Usuda and coworkers (Usuda, 1987, 1988; Usuda *et al*., 1987) have proposed a separation scheme for trivalent actinides using a three-step ion exchange partition from light actinides and fission products. Though little fundamental solution chemistry research has been done to probe the impact of alcohol–water mixtures on actinide separations, the effects cited above clearly indicate an important role for the interactions between solvent and solute molecules in these systems.

The separation of adjacent trivalent actinides represented an even more challenging task. The inherent selectivity of Dowex 50 cation exchange resin for adjacent lanthanide cations (in this case, behaving analogously with the trivalent actinides under all conditions) is demonstrated in Fig. 24.3. Separation factors for adjacent lanthanide cations average about 1.007. The coupling of water-soluble chelating agents (also demonstrated in Fig. 24.3) with the ion

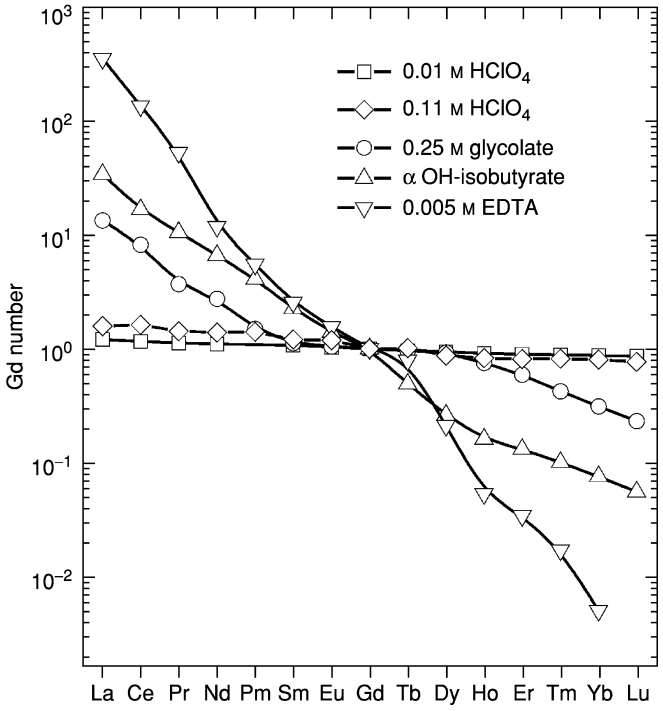

Fig. 24.3 *Partitioning of trivalent lanthanide ions onto Dowex* 50 *cation exchange resin from various aqueous acid solutions.* (*Gd number is the distribution ratio of the element normalized relative to* $D_{Gd} = 1.0$, *created from data in Marcus*, 1983.)

exchange systems by Thompson and coworkers (Thompson *et al.*, 1950, 1954; Choppin *et al.*, 1956) was the enabling science that made the identification of the new transplutonium elements possible.

The combination of a buffered solution of, in particular, a hydroxycarboxylic acid with a strong acid cation exchange resin like Dowex 50 made it possible to take advantage of the relative stability of the aqueous complexes of the actinide ions (which generally increase in proportion to those of the analogous lanthanide complexes across the series). This effect can be readily understood given a little consideration of the monophasic and biphasic equilibria involved in the process. Assuming that the water-soluble metal complexes present in the eluant are not sorbed by the resin, the distribution of the metal ion onto the acidic resin phase is governed by the following equilibrium (taking a trivalent cation as the example):

$$M^{3+} + 3H(\text{Resin}) \rightleftarrows M(\text{Resin}) + 3H^{+} \tag{24.1}$$

In the aqueous phase the metal complexation equilibria with a ligand HY can be written as:

$$M^{3+} + nHY \rightleftarrows MY_n^{(3-n)^+} + nH^{+} \tag{24.2}$$

The distribution ratio (D) for the metal ion is the ratio of the amount of metal species in the resin phase, $[M]_R$ to that in the aqueous phase $[M]_a$. Most commonly, these values are normalized to 1 ml of solution and 1 g of resin, respectively.

$$D = [M]_R/[M]_a = [M(\text{Resin})]/([M^{3+}] + \Sigma_1^n(MY_n^{(3-n)^+})) \tag{24.3}$$

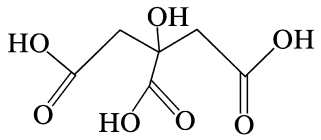
The distribution ratio is directly proportional to the resin's affinity for the metal ion and inversely proportional to the degree of complex formation in the aqueous phase. In general, the separation factor (S), the ratio of distribution ratios, determines whether a separation of two species is successful or not. Written in terms of the respective one- and two-phase complexation equilibria, the separation factor is:

$$S_{M'}^{M} = \frac{D_M}{D_{M'}} = \frac{K_{ex}^{M}\ \cancel{[HR]^3}/\cancel{[H^+]^3}(1+\Sigma\ \beta_i^{M'}[Y]^i)}{K_{ex}^{M'}\ \cancel{[HR]^3}/\cancel{[H^+]^3}(1+\Sigma\ \beta_i^{M'}[Y]^i)} \tag{24.4}$$

wherein $K_{ex}^{M,M'}$ represents the equilibrium coefficient for the partitioning of the cation onto the resin phase, and $\beta_i^{M,M'}$ represents the complexation equilibrium constants for species present in the eluant solution. In fact, multiple complexants can be used in the aqueous phase to enhance separations, in which case additional complexation equilibria can be used to predict separation performance.

First attempts relied on citric acid (Structure d) as the eluant. As the synthesis of new actinides proceeded across the series, the product nuclides had progressively shorter half-lives, and in passing the middle of the series, the actinide equivalent of a gadolinium break (differentiation of the stability constants of

adjacent actinide complexes, predominant at the beginning and end of the lanthanide series, disappeared in the middle of the series) reduced the effectiveness of citrate as an eluant. These combined features resulted in smaller separation factors between the newest nuclides and in their early exit from the column, hampering analysis and detection. Substitution of lactic acid for citric acid improved performance. The comparative elution positions of Am, Cm, Bk, Cf, Es, and Fm from Dowex 50 cation exchange resin when the eluting solution was 0.25 M ammonium citrate or 0.4 M ammonium lactate are shown in Table 24.2.



Structure d

Ultimately, the demands of the chemistry and the radiochemistry required a 'better' eluant (i.e. one yielding more consistent (i.e. linear) trends of elution with decreasing radii while retaining rapid kinetics). To satisfy this demand, Choppin and Silva (1956) introduced α-hydroxyisobutyric acid (Structure e), α-HIBA, which also came to be known colloquially as the 'BUTT' eluant. This complexant differs from lactate in the substitution of a second methyl group for H at the alpha position. The α-hydroxyisobutyric acid provides average separation factors for adjacent lanthanides or trivalent actinides of about 1.3–1.5 and very consistent elution positions even through the middle of the series where many reagents fail to give acceptable results. Parallel performance between trivalent lanthanides and actinides in cation exchange separations was a key factor in the identification of most of the transplutonium actinides. Fig. 24.4 shows the elution profile of trivalent actinides and lanthanides with ammonium α-hydroxyisobutyrate and shows the consistency in separation factors for adjacent cations across the series. It should be noted that if the data were plotted in terms of cationic radii rather than atomic number, the lanthanide and actinide results would overlap. Table 24.3 compares $S_M^{M'}$ of adjacent actinides with lactic acid, α-hydroxyisobutyrate, ethylenediamine-*N*,*N*,*N*′,*N*′-tetraacetic acid (EDTA) and further relates those data to the separation factors observed for

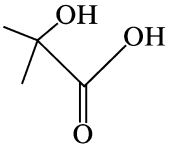
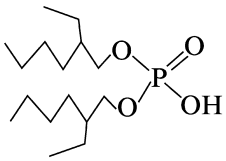
solvent extraction separations using bis(2-ethylhexyl)phosphoric acid (HDEHP, Structure f), which will be considered further in Section 24.3.4a



Structure e



Structure f

Improvements in separations have been achieved with cation exchange systems of this type using very finely divided resin beds and high-pressure elutions (Campbell, 1970). Kilogram amounts of americium and gram amounts of curium have been purified from each other by using nitrilotriacetic acid (NTA) and diethylenetriamine-*N*,*N*,*N*′,*N*″,*N*″-pentaacetic acid (DTPA, Structure g) as

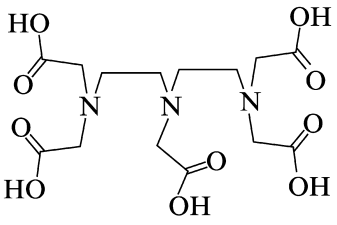
the eluants (Baybarz, 1970). The kinetics of the metal complexation/ion exchange equilibration on the Dowex 50 column with α-hydroxyisobutyrate eluant was also found to be superior to that for the several other ligands that had been previously employed. For example, aminopolycarboxylic acid ligands like EDTA demonstrated comparable or even superior separation factors (to α-hydroxyisobutyrate; see Fig. 24.3), but slower equilibration rates, which required longer residence times for the solutions on the column. The need for longer equilibration times on the column was a definite handicap in the search for short-lived actinide species. Like TBP and PUREX, the BUTT column remains today one of the most effective ion exchange separation method for trivalent f-elements from a mixture of like elements (Nash and Jensen, 2000).

It should be noted that the intrinsic affinity of cation exchange resins increases for actinides in the order An(V) < An(III) < An(VI) < An(IV), in accord with the comparative electrostatic attraction of the cations for the anionic sulfonate functional groups of the resin. The differences are sufficiently large to allow the mutual separation of the ions in different oxidation states; however, all but the pentavalent oxidation state are bound too strongly for effective separation procedures to be routinely used. Where necessary and possible, sorption of strongly bound ions is generally reversed using oxidation state adjustment or chelating agents.



Structure g

To avoid the elution difficulties of the cation exchange resins, ion exchange separations for the purification of the tetravalent and hexavalent actinides more frequently rely on anion exchange techniques. A variety of separation methods based on the use of tetraalkylammonium or methyl pyridinium polymeric resins have been developed. Introduction of the Reillex resins, based on methylpyridinium functional groups, is among the more significant recent advances in anion exchange separations for actinides (Abney *et al.*, 1995). Perhaps the most important application of anion exchange resins is in the purification of plutonium. Pu(IV) is selectively sorbed onto Dowex 1 from 8 M HNO_3, allowing the passage of other contaminants through the resin. Pu(IV), which is retained on the resin as the hexanitrato complex ($Pu(NO_3)_6^{2-}$), is readily eluted using more dilute nitric acid. Anion exchange separations for An(IV) and An(VI) are facile because these cations readily form anionic complexes with simple inorganic anions like NO_3^- and Cl^-. However, higher order complexes are formed in the presence of the resin than are observed in the same solution in its absence. This is due to the superposition of the phase transfer equilibrium upon the typical aqueous phase complexation reactions, which tends to drive the process. In essence, anionic complexes are sorbed to the resin whether or not they are present in the aqueous solution phase contacting the resin.

A new chelating ion exchange resin (Diphonix) that exhibits high affinity for actinide cations in all oxidation states from strongly acidic solutions has been developed jointly at Argonne National Laboratory and the University of Tennessee as a spinoff of the development of the transuranium extraction (TRUEX) solvent extraction process (Alexandratos *et al.*, 1993; Chiarizia *et al.*, 1993, 1994, 1996, 1997; Horwitz *et al.*, 1993, 1994; Chiarizia and Horwitz, 1994, 2000; Trochimczuk *et al.*, 1994). Diphonix resin combines a methylenediphosphonic acid chelating group with carboxylic and benzene sulfonic acid groups in a styrene–divinylbenzene matrix. This combination results in a chelating resin that exhibits good metal ion uptake kinetics (Chiarizia *et al.*, 1994) and effectively sorbs actinide metal ions in all oxidation states from moderate to strong acid solutions and even in the presence of moderately strong complexants. The hexavalent and tetravalent species are so strongly retained by the resin even from 10 M HNO_3 that they can only be removed upon elution with a moderately concentrated solution of a structurally related diphosphonate chelating agent (1-hydroxyethane-1,1-diphosphonic acid, HEDPA; Structure h) or by applying a reducing agent. The distribution ratios for Am(III), U(VI), Pu(IV), Np(IV), and Th(IV) onto Diphonix as a function of [HNO_3] are shown in Fig. 24.5. The acid dependence for Am(III) uptake indicates normal cation exchange behavior while that for Th(IV) and U(VI) has been interpreted in terms of coordination of these cations by the phosphoryl oxygens of the fully protonated methylenediphosphonate groups. The principal feature of the Diphonix resin is the strength of cation uptake rather than selectivity, though the resin demonstrates significant selectivity for Pu(IV) and U(VI) over Am(III) from concentrated nitric acid media. The principal advantage of this resin may

be in the separation of actinides from less-strongly-bound fission product and cations present as a result of matrix dissolution.

24.3.4 Solvent extraction methods

Successful solvent extraction processes depend on the *selective* transport of the target metal ion (or group of metal ions) from an aqueous solution containing contaminants into an immiscible organic solution. When the target metal ion is removed from that organic phase, it will have undergone some degree of purification, often characterized in terms of a 'decontamination factor' (D_f). Additional purification processes may subsequently be engaged, depending on the D_f required for the product. Strongly acidic, extensively hydrated metal ions like actinides and most of their complexes with typical mineral acid anions or other hydrophilic complexants have minimal intrinsic tendency to partition spontaneously from aqueous into non-polar organic solutions. The driving force for phase transfer is provided by the introduction of a lipophilic complexant (extractant) into the organic phase. Usually, new complexes possessing a hydrophobic external 'shell' are formed at the oil–water interface and transferred to the non-polar (or less polar) organic phase. Chemical reactions occurring in the aqueous phase, including oxidation–reduction, hydrolysis, and the formation of water-soluble complexes, all affect the phase transfer equilibrium position as well.

Of all separation techniques that have been applied for actinide separations, solvent extraction offers the greatest number of options and adjustable parameters to finetune performance. Further, it is perhaps the separations technique best adapted to the continuous operations, high throughput, and remote handling that are essential to the processing of nuclear fuels. Of course, this flexibility can also introduce complications, including rather long development time for the creation of a new solvent extraction-based process. Historically, industrial scale aqueous processes have also produced waste streams noteworthy for both their complexity and volume.

It is important at this stage to make the clear distinction between the chemistry of actinides in the organic media relevant to solvent extraction and the chemistry generally termed as organoactinide chemistry, which is covered in Chapters 25 and 26. In solvent extraction, metal ions in organic solutions *never* engage in bonding to *carbon* atoms, as they do in most true organometallic complexes. Direct bonding interactions between actinide ions and lipophilic complexants *do* play an important role in most solvent extraction systems, except for those based on molecules that organize in organic solutions to form reverse micelles. For the actinides in extraction processes, bonding is always to oxygen, nitrogen, or occasionally sulfur donor atoms in organic compounds or to chloride or thiocyanate anions, sometimes in combinations.

In solvent extraction, some dissolved water molecules are always present in the organic phase. For actinide separations, these solutions will often also bear mineral acid molecules that have been extracted by the same lipophilic reagents that remove the actinides from the aqueous phase. In some systems, a specific interaction can occur between the metal cation and solvent molecules, but only

with compounds like methyl(isobutyl)ketone (MIBK) or (neat) tri(*n*-butyl) phosphate (TBP) which are moderately strong Lewis bases and so capable of competing with adventitious water molecules in the organic phase of solvent extraction systems.

It would be impossible to catalog all of the various reagents whose actinide extraction properties have been investigated in the space allocated for this overview. In the following discussion, the general characteristics of the classes of selected extraction systems are considered. The objective here is to illustrate the general features of the techniques. There are at least five different classes of solvent extraction systems that have been employed for actinide separations. The classes and representative biphasic extraction equilibria are:

Liquid cation exchangers/chelating agents,

$$M^{3+}_{aq} + nHL_{org} \rightleftarrows ML_{n,org} + 3H^{+}_{aq} \tag{24.5}$$

Micellar extractants,

$$M^{3+}_{aq} + (HL)_{n,org} \rightleftarrows MH_{n-3}L_{n,org} + 3H^{+}_{aq} \tag{24.6}$$

Solvating extractants,

$$M^{3+}_{aq} + 3X^{-}_{aq} + nS_{org} \rightleftarrows MX_3S_{n,org} \tag{24.7}$$

Ion pair forming extractants (or liquid anion exchangers),

$$M^{3+}_{aq} + 3X^{-}_{aq} + A^{+}X^{-}_{org} \rightleftarrows MX_4A_{org} \tag{24.8}$$

Synergistic extractants,

$$M^{3+}_{aq} + 3HL_{org} + nS_{org} \rightleftarrows ML_3S_{n,org} + 3H^{+}_{aq} \tag{24.9}$$

Species present in the aqueous and organic solutions are designated by the subscripts aq and org, respectively. In solvent extraction systems, the metal ion distribution ratio is a dimensionless quantity defined as $D = [M]_{org}/[M]_{aq}$. D is not a species-specific term but rather defines the analytical concentrations of the metal ion in the aqueous and organic phases. The stoichiometric features of the equilibria outlined above are most relevant at low concentrations of the metal ions. Under conditions near the stoichiometric limits of concentrations, the phase transfer equilibria can be substantially more complex than these simple equilibria indicate.

Each class of extraction system accomplishes the phase transfer by a slightly different chemical process. However, these systems share the following general characteristic: while the high dielectric constant of water readily supports the presence of charged ionic species as discrete molecules, the low polarity of organic solutions demands close contact between cations and anions. Most solutes in most organic solvents are expected to be discrete electroneutral entities. The liquid cation exchangers, chelating agents, and micellar extractants each exchange a number of monovalent cations (usually H^{+}) equivalent to the

formal charge on the cation extracted to maintain electroneutrality in both phases. In these systems, transfer of the metal ion into the organic phase is favored by low acidity, implying that the metal ion can be stripped from the loaded organic solution into concentrated acid solutions (as H^+ competes with the metal ion for the extractant). Some acidic extractants have a tendency to self organize (aggregate), even in the absence of the extracted metal ion, to form dimers or higher order aggregates. Sulfonic acid extractants in particular behave in this manner, forming reverse micelles in the organic phase.

Solvating extractant systems are technologically the most important for actinide purification. They accomplish phase transfer by solvating electroneutral metal complexes with mineral acid anions, hence the net phase transfer reaction includes the necessity to dehydrate and resolvate in the organic phase both the metal ion and a sufficient number of conjugate base anions of mineral acids to neutralize the cation charge. In solvating extraction systems, the phase transfer reaction is favored by high concentrations of the counter-ion (preferably introduced as an acid solution to minimize the generation of secondary wastes) and stripped from the loaded organic solution by contact with dilute acid solutions, a change in oxidation state, or washing with a water-soluble complexant.

Primary among the solvating extractant systems that are technologically the most important actinide separations systems in operation today are those based on the solvating ability of TBP. More than 50 years of cumulative industrial scale experience exists on the PUREX process. This solvent extraction process accomplishes the selective removal of both plutonium [as Pu(IV)] and uranium [as U(VI)] from dissolved spent fuel solutions (3–6 M HNO_3) as their electroneutral nitrate salts with minimal complication (Fig. 24.6). Most fission products and the trivalent and pentavalent actinides [Am(III), Cm(III), Np(V)] are rejected by TBP.

Plutonium is selectively recovered from the extractant phase through its reduction to the trivalent oxidation state in which its extraction performance is comparable to that of Am(III). In PUREX processing, changes in neptunium oxidation state speciation causes partitioning of this element to undesirable locations within the process flow scheme. Until recent years, it has been most advantageous to try to maintain Np(V) in the aqueous phase so that it remains with the fission product raffinate. The emergence of full recycle fuel cycles for actinide transmutation in recent years has brought greater attention to the means of controlling Np speciation in PUREX-style separations. The details of neptunium's speciation complexity are discussed in Section 24.4.4f.

Synergistic systems generally combine acidic extractants, usually and most effectively multidentate chelating agents, with solvating extractants, hence they share some features of both liquid cation exchangers and solvating extractant molecules. Ion pair-forming extractants tend to be micellar in most organic solutions and to exchange simple anions for negatively charged metal coordination complexes. For actinide extraction by liquid anion exchangers, the

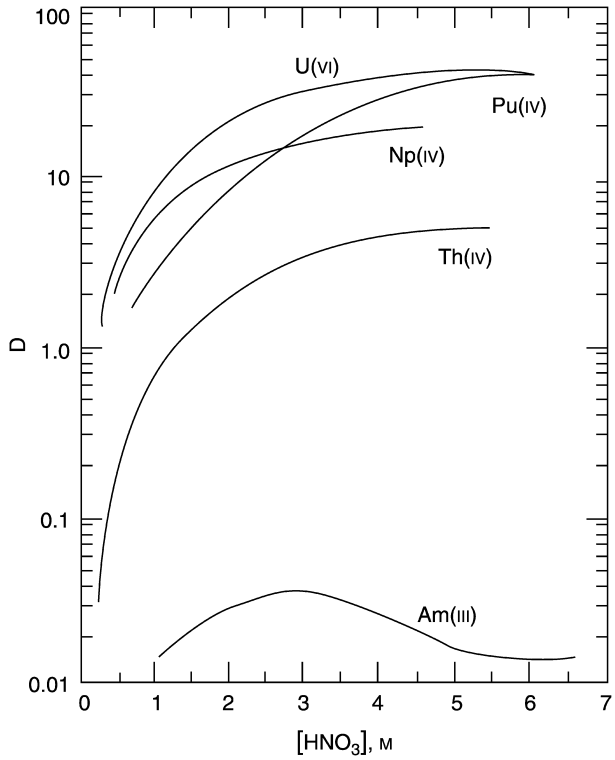

Fig. 24.6 *Extraction of actinides into tri*(n-*butyl*)*phosphate/dodecane as a function of nitric acid concentration*.

anionic complex (e.g. $AmCl_4^-$) exists only in the organic phase in the presence of the lipophilic counter-ion and is usually not an important species in the aqueous phase. These extractants are the soluble analogs of anion exchange resins and so exhibit relative actinide affinities in the order: An(IV) > An(VI) > An(III) > An(V).

As a general (though not universal) rule, the greatest selectivity for metal ions having similar properties (like adjacent trivalent lanthanides or actinides) is seen in acidic extractant systems, particularly those involving the formation of multidentate complexes. Solvating extractant systems tend to exhibit their greatest selectivity only for metal ions differing in charge (for interactinide separations, this implies the presence of the metal ions in different oxidation states), but extract chemically similar species without much selectivity. Such behavior is also generally seen for micellar reagents, i.e. minimal selectivity is demonstrated for series of closely related metal ions. Synergistic systems achieve increased extraction strength, usually at the price of decreased selectivity (though there are some exceptions).

The organic molecule almost always used to solubilize or dilute the extractant[1] is commonly considered to be 'inert', but, as the data in Table 24.4 indicates, this inertness is relative. Considering a single extractant system that transfers the metal ion in a straightforward equilibrium process, several orders of magnitude variation in extraction efficiency can be seen to result simply from a change in the diluent. For analytical separations, different classes of diluents can be employed, though many techniques favor volatile species like chloroform. For hydrometallurgical separations, issues of phase compatibility at high solute loading, low flammability, and low toxicity are primary considerations in the selection of a diluent.

Phase modifiers, secondary solute molecules that may or may not enter into specific interaction with the metal ion, the extracted complex, or the extractant itself are often employed simply to improve solubility characteristics. In hydrometallurgical separations of actinides, the phenomenon of third phase formation (also known as phase splitting), in which the biphasic system

[1] Typically this organic compound is referred to as the diluent for historic reasons – the solution containing the extractant molecule in a diluent is referred to as the "solvent" in solvent extraction.

becomes a ternary liquid system, complicates process operations under conditions of high solute loading of the organic phase. This phenomenon has been most extensively studied in the TBP–PUREX system from an operational perspective (Rao and Kolarik, 1996) and empirical correlations have been developed. More recent work by Chiarizia and coworkers (Borkowski *et al.*, 2002, 2003; Jensen *et al.*, 2002a; Chiarizia *et al.*, 2003a,b, 2004) and by Tondre and coworkers (Erlinger *et al.*, 1998; Lefrancois *et al.*, 2001a,b) has attempted to provide a more fundamental understanding of the physical chemistry of the phenomenon.

Subtle variations in the properties of the aqueous phase can alter both extraction efficiency and selectivity patterns, as illustrated by the work of Sekine on the TBP extraction of Am^{3+} and Eu^{3+} by tri(*n*-butyl)phosphate from thiocyanate and mixed thiocyanate/perchlorate solutions [Fig. 24.7 (Sekine, 1965)]. The salting out effect of added perchlorate reduces the degree of order in the aqueous solution, which leads to a more efficient phase transfer process. However, the penalty paid is a reduction in the selectivity of the thiocyanate extractant system for Am over Eu. This system is discussed in more detail in Section 24.3.9. Note that in this example, Am(III) and Eu(III) are extractable into TBP solution because the aqueous acid solution has been replaced by a salt solution of higher pH.

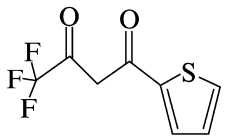
(a) Acidic extractants

The extraction of actinides (and lanthanides) by thenoyltrifluoroacetone (TTA, Structure i) was one of the first solvent extraction methods for the isolation of individual An(III) ions (Stary, 1966). The separation factors for adjacent ions are slightly greater than in α-HIBA elution, but they are less constant throughout the series. TTA extraction from 1 M acid solutions is highly specific for tetravalent actinide ions, and is often employed in studies of oxidation state speciation of actinides in environmental samples (Choppin and Bond, 1996; Choppin and Wong, 1998; Nash *et al.*, 1988a; Rollin, 1999). Because of the photolytic instability of TTA and its appreciable solubility in aqueous solutions, it is employed almost exclusively in research rather than in hydrometallurgical separations. For analytical applications, this reagent should be prepared fresh frequently and always protected from ambient light and air. Structurally similar pyrazolone compounds extract actinide ions in patterns similar to those demonstrated by the β-diketones represented by TTA. They differ from β-diketones in that they are slightly more acidic, thus able to accomplish actinide phase transfer from more acidic solutions.



Structure i

Acidic organophosphorus extractant molecules have been used extensively in actinide separations. The first important acidic organophosphorus extractant was dibutylphosphoric acid (HDBP), which is produced spontaneously during the use of TBP (solvating-class extractant) for nuclear fuel processing. In TBP-based extraction systems, the presence of HDBP in the extractant phase caused considerable difficulty in the stripping of actinides from loaded and degraded TBP solutions into dilute acid solutions. From the above extraction equilibrium equations, it is clear that conditions needed for stripping of metal complexes from solvating extractants favor the phase transfer of the acidic analog, hence the simultaneous presence of both solvating and acidic extractants can have an important negative impact on the efficiency of solvent extraction separations. In the case of HDBP, the complications introduced by its presence were readily overcome by the development of careful procedures for removing HDBP from the TBP-extractant phase as its water-soluble sodium salt by scrubbing of recycled process solvent with sodium carbonate (Schulz *et al.*, 1990).

Realization of the special features of HDBP extraction touched off efforts to develop similar extractants less prone to degradation or able to function under different sets of conditions. One of the current principal methods for isolation of individual lanthanides commercially is solvent extraction with HDEHP mentioned above (Structure f), a reagent first reported by Peppard *et al.* (1957).

Adjacent lanthanide separation factors are up to twice as high for HDEHP separations as for α-hydroxyisobutyrate cation exchange. Trivalent actinides likewise are separated from one another by this reagent. A representative plot of actinide extraction in the most common oxidation states is shown in Fig. 24.8. This extractant is the phase transfer reagent for the TALSPEAK process for lanthanide/trivalent actinide separation (Weaver and Kappelmann, 1964, 1968).

Many long years of research were invested in systematic studies of monofunctional acidic organophosphorus extractants containing different alkyl groups designed to alter both the solubility of the reagent and the basicity of the functional group. Dialkylphosphoric acids like HDEHP [$(RO)_2P(O)(OH)$] are characterized by the presence of two alkyl ester bonds. The P–O–C linkage is far more susceptible to hydrolytic and radiolytic degradation than P–C bonds. To increase the long-term stability of the extractant (and its suitability for application to the separation of radioactive materials) while simultaneously modifying its basicity (and so the effective range of pH operation), phosphonic [$(RO)(R)P(O)(OH)$] and phosphinic [$(R)_2P(O)(OH)$] acids replace alkoxide groups with alkyl groups, resulting in reagents of steadily increasing hydrolytic stability and greater basicity of the functional groups. Higher basicity translates into stronger metal ion bonding but typically forces operation under less acidic conditions due to the increased affinity of the extractants for H^+.

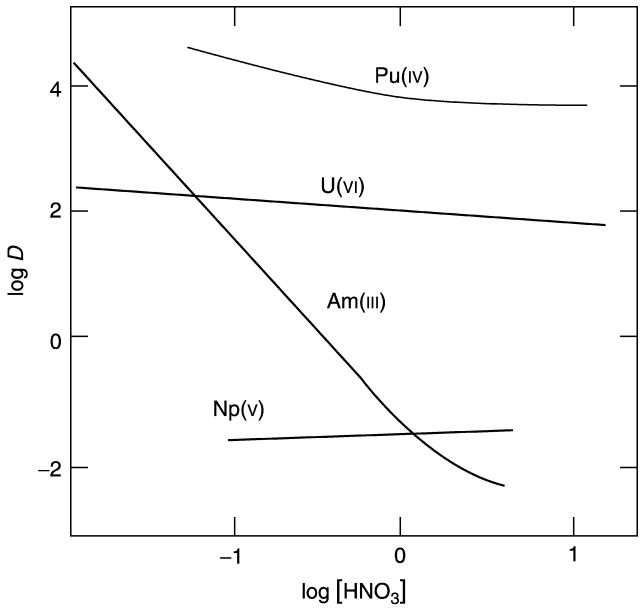


Fig. 24.8 *Dependence of extraction of Pu(IV), U(VI), Am(III), and Np(V) into* 0.5 M *HDEHP/iso-octane on nitric acid concentration* (*Myasoedov* et al., 1974).

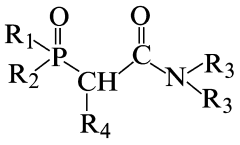
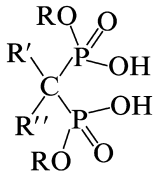
Many variations on these general structures are commercially available. They have found application for actinide/lanthanide separation and for actinide partitioning, as will be described in Section 24.3.9.

If one acidic organophosphorus binding site is good, might not two be better? In the 1960s, work in the water-treatment/detergent industry led to the production of alkyldiphosphonic acid complexing agents as substitutes for pyrophosphates in detergent formulations (Irani and Moedritzer, 1962; Carroll and Irani, 1967, 1968; Elesin *et al.*, 1972; Wada and Fernando, 1972). These complexants followed the same operational philosophy as the extractant development activity discussed in the previous paragraph: replacement of P–O–C bonds with P–C bonds increases hydrolytic stability and thereby utility of this arrangement of ligand donor groups. During the development of CMPO (most typically referring to octyl(phenyl)-*N*,*N*-diisobutylcarbamoylmethylphosphine oxide, but the term CMPO is used to refer to carbamoylmethylphosphine oxide extractants generally; generic Structure j) and the TRUEX process, research at Argonne National Laboratory addressed the use of diphosphonate complexants as efficient actinide-stripping reagents (Nash and Horwitz, 1990; Nash, 1991, 1993b). An additional feature of these compounds is that selected representatives were devised to be readily decomposable to minimize waste volumes in process applications. The latter ligands were given the acronym TUCS, meaning thermally unstable complexants (Schulz and Kupfer, 1991; Horwitz *et al.*, 1992; Nash and Rickert, 1993).



Structure j

Chiarizia and coworkers (Chiarizia *et al.*, 1998; McAlister *et al.*, 2002; Otu and Chiarizia, 2002; Otu *et al.*, 2002) have prepared and characterized a number of dialkyl diacidic actinide extractants based on diphosphonic acids, derived from symmetric partial esterification of water-soluble diphosphonates (Structure k). These extractants have proven uniquely capable actinide sequestrants, finding unique application in analytical separations. Neutron scattering and osmometric studies of these extractants reveal unexpected patterns of extractant aggregation and cation size selectivity as the length of the alkyl chain bridging the phosphonate monoester groups changes from 1 to 6.

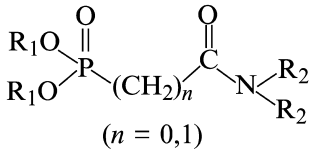


Structure k

(b) Solvating extraction systems

The ability of TBP to reject the so-called minor actinides (Np, Am, Cm) present in dissolved spent fuel was recognized as a desirable feature of this extractant system when maximizing production of plutonium and recovery of uranium were the primary motivations for processing spent nuclear fuels. However, for actinide separations in the 21st century, minimizing the toxicity of the wastes exiting a production facility must become an equally important factor in process operations. In most countries operating a closed loop nuclear fuel cycle today, recovery of the minor actinides for isolation or transmutation has become more desirable. To recover americium and curium from spent nuclear fuel using TBP would demand reduction of the acidity of the aqueous feed and the addition of salting out reagents like $NaNO_3$. Both of these actions will increase the volume of wastes and therefore are unacceptable. Neptunium can in principle be recovered as either Np(IV) or Np(VI), but neither oxidation state has adequate stability in nitric acid to prevent its dispersal to undesirable portions of the process under the ambient conditions prevailing in a process facility (i.e. moderate concentrations of nitric acid, radiolysis). Within the structure of a modern processing facility, what is needed is a reagent that will complement TBP (most probably a solvating extractant) by accomplishing the complete and selective recovery of the minor actinides from strongly acidic solutions. A significant fraction of research on actinide separations today seeks to develop such reagents and processes for their use.

In the early 1960s, a few bidentate carbamoyl phosphonate compounds (Structure l) were synthesized (Siddall, 1963a, 1964) and their utility for the extraction of trivalent americium, cerium, and promethium from moderately acidic solutions demonstrated. The bifunctional nature of the extractant reduces the impact of competition between HNO_3 and the target metal ion for the primary extractant binding site (P=O). Schulz and coworkers (Schulz and McIsaac, 1975; Schulz and Navratil, 1982) revived interest in synthesis of new compounds of this class and in their utilization for the extraction of actinides and lanthanides. Since that time, several groups in the United States (of greatest note, the Horwitz group at Argonne National Laboratory) and other parts of the world have synthesized numerous derivatives of CH_2-bridged (CMPs) and unbridged (CPs) extractants and studied the extraction behavior of hexavalent, tetravalent, and trivalent actinides and a few lanthanides using the extractant alone (Martella and Navratil, 1979; Navratil and Thompson, 1979; Petrzilova *et al.,* 1979; Horwitz *et al.*, 1981, 1982; Kalina *et al.*, 1981b; Hugen *et al.*, 1982; McIsaac, 1982; McIsaac and Baker, 1983; Kalina and Horwitz, 1985; Akatsu and Kimura, 1990; Rapko, 1995) or in combination with TBP in various diluents (Mathur *et al.*, 1991, 1992a).



Structure 1

Slope analysis studies at radioanalytical concentrations established the stoichiometry of the extracted complexes of trivalent actinides and lanthanides from NO_3^- and SCN^- media, and those of U(VI) and Th(IV) from the NO_3^- medium by CMP from the equilibria:

$$M^{3+}_{aq} + 3NO^-_{3\,aq} + 3CMP_{org} \rightleftarrows M(NO_3)_3 \cdot 3CMP_{org} \tag{24.10}$$

$$M^{3+}_{aq} + 3SCN^-_{aq} + 4CMP_{org} \rightleftarrows M(SCN)_3 \cdot 4CMP_{org} \tag{24.11}$$

$$UO^{2+}_{2\,aq} + 2NO^-_{3\,aq} + 2CMP_{org} \rightleftarrows UO_2(NO_3)_2 \cdot 2CMP_{org} \tag{24.12}$$

$$Th^{4+}_{aq} + 4NO^-_{3\,aq} + 3CMP_{org} \rightleftarrows Th(NO_3)_4 \cdot 3CMP_{org} \tag{24.13}$$

where M^{3+} = trivalent actinides and lanthanides. In the case of the Am system, the slope of the straight line for log D vs log [CMP] plot was only 3.6 in the thiocyanate system implying the presence of both tri- and tetra-solvate complexes. However, while using the mixture of CMP and TBP, americium and promethium were extracted from a NO_3^- medium as $M(NO_3)_3 \cdot (2.6)$ CMP·0.4 TBP. Complete coordination of all possible ligand donor atoms (bidentate nitrate and CMP molecules) would require unusually large complex coordination numbers. It is believed in general that the denticity of the CMP ligands is less than two in most of these species with the P=O group preferentially coordinated.

Ultimately, the CMP and CP extractants proved inadequate for the task of trivalent actinide recovery from nitric acid solutions of moderate concentration as are encountered in the raffinate from the first stages of PUREX processing. Ligand development procedures conducted over an extended period led Horwitz and coworkers to conclude that the extractant CMPO represents the best combination of features around which to build an effective industrial-scale process for total actinide recycle, including their extraction in the trivalent oxidation state. The greater basicity of the phosphine oxide overcomes the principal weakness of the CP and CMP class of ligands.

The nature of U(VI) and Pu(IV) species extracted into the organic phase from NO_3^- medium with CMPO can be given by the following equilibria:

$$UO_{2\,aq}^{2+} + 2NO_{3\,aq}^{-} + 2CMPO_{org} \rightleftarrows UO_2(NO_3)_2 \cdot 2CMPO_{org} \quad (24.14)$$

$$Pu_{aq}^{4+} + 4NO_{3\,aq}^{-} + 2CMPO_{org} \rightleftarrows Pu(NO_3)_4 \cdot 2CMPO_{org} \quad (24.15)$$

There has been a lot of interest in the extraction of Am(III) and Eu(III) by CMPO from aqueous media containing NO_3^-, SCN^-, ClO_4^- or $NO_3^- + ClO_4^-$. The extraction equilibria can be given as:

$$M_{aq}^{3+} + 3NO_{3\,aq}^{-} + 3CMPO_{org} \rightleftarrows M(NO_3)_3 \cdot 3CMPO_{org} \quad (24.16)$$

$$M_{aq}^{3+} + 3SCN_{aq}^{-} + 3CMPO_{org} \rightleftarrows M(SCN)_3 \cdot 3CMPO_{org} \quad (24.17)$$

$$M_{aq}^{3+} + 3\,ClO_{4\,aq}^{-} + 3\,CMPO_{org} \rightleftarrows M(ClO_4)_3 \cdot 3CMPO_{org} \quad (24.18)$$

$$M_{aq}^{3+} + NO_{3\,aq}^{-} + 2ClO_{4\,aq}^{-} + 3CMPO_{org} \rightleftarrows M(NO_3)(ClO_4)_2 \cdot 3CMPO_{org} \quad (24.19)$$

The thermodynamic features of these reactions will be discussed in Section 24.3.5. The work of Dozol and coworkers (Delmau *et al*., 1998, 1999; Arduini *et al*., 2000; Dozol *et al*., 2000; Garcia-Carrera *et al*., 2001; Gruener *et al*., 2002; Teixidor *et al*., 2002; Arnaud-Neu *et al*., 2003; Schmidt *et al*., 2003) and of Scott (Peters *et al*., 2002) has sought to introduce an element of molecular recognition into CMPO–actinide coordination complexes with the creation of polydentate podand structures based on rigid alkyl backbones and calixarenes. These intriguing structures have yet to produce startling advances in actinide separations.

The process based on the use of CMPO is the TRUEX process (Vandegrift *et al*., 1984, 1993; Horwitz and Schulz, 1990; Horwitz and Chiarizia, 1996). The TRUEX process solvent consists of 0.2–0.25 M CMPO and 1.0–1.4 M TBP (depending on the nature of the diluent, with a normal paraffinic hydrocarbon preferred). Because this solvent can simultaneously extract the actinides in the oxidation states important in technological processes, it could have significant impact in the reduction of the volume of high-level waste requiring burial in a geological repository. There has been one report that proposes an oxidation state selective separation of actinides based on the use of TRUEX extraction and a diphosphonic acid complexant (Nash and Rickert, 1993).

The neutral bifunctional extractants (CMPs, CMPOs, and related compounds) have been applied to a few analytical-scale separations as well. Horwitz *et al*. (1981) studied the separation of the trivalent actinides from Am to Fm (Table 24.5) using dihexyl-*N*,*N*-diethylcarbamoylmethylphosphonate (DHDECMP) and aqueous nitrate solutions. Steadily decreasing distribution ratios are observed for the lanthanides, but a much smaller decrease is found for the trivalent actinides. These results suggest possible interlanthanide

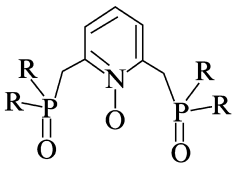
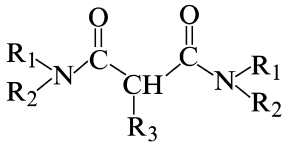
(but probably not interactinide) separations. The adaptation of CMPOs to extraction chromatography has led to the development of additional selective separations methods based on these reagents, to be discussed in Section 24.4.4b. Continued development of phosphine oxide ligand types and processes based on their use has produced a simplified version of the CMPO ligands (and an alternative TRUEX process, discussed in Sections 24.4.4b(i)–(iv)) and tridentate pyridine-*N*-oxide bisphosphine oxide reagents (Structure m) that exhibit useful actinide separations properties (Paine, 1995; Bond *et al.*, 1997, 1998; Nash *et al.*, 2002). Chmutova *et al.* (1975) have demonstrated that alkylene phosphine dioxides exhibit some ability to enhance the separation of californium from americium ($S_{Cf}^{Am} \approx 25$), and berkelium from curium ($S_{Bk}^{Cm} \approx 10$).

A considerable body of research has been developed by Karandashev and coworkers (Turanov *et al.*, 2000, 2002, 2004) on the subject of lanthanide extraction by bisphosphine oxide (and structurally similar) podands that should have strong analogies to actinide separations, though this latter opportunity has not been extensively investigated.



Structure m

A new class of solvating extractants has been introduced during the past decade as non-phosphorus-containing alternatives to CMPO for total actinide recycle. Amidation of the well-studied lanthanide/actinide complexant malonic acid yields lipophilic complexants that exhibit affinity for actinides in the trivalent, tetravalent, and hexavalent oxidation states. Malonamide extractants (Structure n) were proposed initially by Musikas and coworkers in the 1980s and have seen extensive investigation during the intervening years (Musikas, 1987; Cuillerdier *et al.*, 1991a; Nakamura *et al.*, 1995; Nigond *et al.*, 1995; Berthon *et al.*, 1996, 2001; Delavente *et al.*, 1998, 2001, 2003; Erlinger *et al.*, 1998, 1999; Mahajan *et al.*, 1998; Iveson *et al.*, 1999; Madic *et al.*, 2002). These extractants, functionalized at the α-carbon atom with either long chain alkyl groups or alkoxides to improve phase compatibility, compare favorably with CMPO in many respects. The process built around these extractants is referred to as the DIAMEX process.



Structure n

The DIAMEX system has a steeper nitric acid dependence than is seen for CMPO, requiring that the aqueous feed be maintained above 3 M HNO_3 for adequate phase transfer. However, a steep acid dependence also implies more facile stripping of the actinides from the loaded organic phase. The primary advantage of this class of reagents, containing only carbon, hydrogen, oxygen, and nitrogen (CHON), is their ability to be completely incinerated leaving no ash behind when the end of their useful lifetime arrives. A further and in some respects equally important advantage of the malonamides is the innocuous character of the degradation products of diamides. Unlike the phosphinic acid, compounds that are produced as CMPO is degraded (to be discussed in Section 24.4.4b(iv)) or the dibutylphosphoric acid from TBP, the carboxylates

and amines resulting from the degradation of diamides do not appear to interfere appreciably with the ease of stripping of actinides from the loaded extractant phase. This positive feature is counterbalanced by a slightly faster rate of radiolytic degradation than is seen for CMPO or TBP. Phase compatibility issues in large-scale tests to date have indicated a moderate tendency toward (third-phase formation) and led to adjustments in both the extractant and diluent.

Extraction of Am(III), U(VI), Np(IV), Fe(III), Sr(II), and Cs(I) from solutions of different HNO_3 concentrations using 1 M dimethyldibutyltetradecylmalonamide (DMDBTDMA in *n*-dodecane and that of americium from a synthetic PHWR–HLW (pressurized heavy water reactor–high level waste) has been reported (Mahajan *et al.*, 1998). It is suggested that this amide is very promising for the extraction of americium and other actinides from 3–4 M HNO_3, particularly under high loading of Nd or a mixture of Nd and U. The extraction of trivalent, tetravalent, and hexavalent actinides from HNO_3 medium by DMDBTDMA/*n*-dodecane can be represented by the equilibria:

$$Am^{3+}_{aq} + 3NO^{-}_{3\,aq} + 2A_{org} \rightleftarrows Am(NO_3)_3 \cdot 2A_{org} \tag{24.20}$$

$$Pu^{4+}_{aq} + 4NO^{-}_{3\,aq} + 3A_{org} \rightleftarrows Pu(NO_3)_4 \cdot 3A_{org} \tag{24.21}$$

$$UO^{2+}_{2\,aq} + 2NO^{-}_{3\,aq} + 2A_{org} \rightleftarrows UO_2(NO_3)_2 \cdot 2A_{org} \tag{24.22}$$

These species have very similar stoichiometries to those observed for CMPO. The same diamide when adsorbed on an inert support is also efficient for the uptake of trace quantities of actinide ions from 3–5 M HNO_3. Batch studies show reasonable uptake of actinides from synthetic PHWR–HLW, only when it has been given two contacts with 20% TBP/*n*-dodecane (Mohapatra *et al.*, 2000).

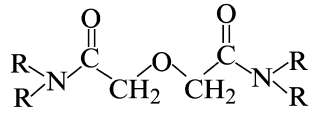
Hydrolytic and radiolytic degradation of *n*-dodecane solutions of three malonamides, DMDBTDMA, *N*,*N*′-dimethyl-*N*,*N*′-dibutyldodecyloxyethyl malonamide (DMDBDDEMA), and *N*,*N*′-dimethyl-*N*,*N*′-dioctylhexyloxyethyl malonamide (DMDOHEMA), in the presence of HNO_3 have been conducted (Berthon *et al.*, 2001). The results of a similar investigation of *N*,*N*,*N*′,*N*′-tetraoctyl-3-oxapentane-1,5-diamide (TODGA) has also been reported (Sugo *et al.*, 2002). Degradation products were identified using gas chromatography coupled to Fourier transform infrared spectroscopy (FTIR) or mass spectrometry. The primary degradation products are a variety of amide–acid species and secondary amines R′–CH_3NH. The amide–acids are thermally unstable and decarboxylate to form monoamides. The other products such as amide–lactone, diamides, carboxylic acids, and alcohol are formed but their concentrations in the organic phase are much lower than the three mentioned above. It has been observed that D_{Am} and D_{Ln} values decrease with increasing irradiation doses. In a comparative study on the radiolysis of 1 M solution of

TBP, DMDBTDMA, and DMDOHEMA in TPH (hydrogenated tetrapropene or 4,4-dipropyl heptane) in contact with 4 M HNO_3 with an integrated dose of 0.7 M Gy, the concentrations found after radiolysis were respectively 0.95, 0.68, and 0.57 M. For these process representative conditions, the stability of malonamides is lower than that of TBP by a factor of 6–9.

DMDBTDMA/*n*-dodecane has been used as carrier in supported liquid membranes (SLM) studies for the facilitated transport of Am(III) using 1–5.5 M of HNO_3 as the feed solution and 0.01 M HNO_3 as the strip solution (Sriram *et al.*, 2000). It is interesting to note that under similar conditions, the permeability of Fe(III) was significantly lower than that of Am(III). In another study (Sriram and Manchanda, 2002), several other diluents apart from *n*-dodecane were used to prepare solutions of DMDBTDMA and the transport of U(VI), Pu(IV), Am(III), and Eu(III) from HNO_3 medium using a SLM technique was carried out. The stripping agent containing a mixture of 0.4 M formic acid, 0.4 M hydrazine hydrate, and 0.1 M DTPA was most promising.

Madic and coworkers (Spjuth *et al.*, 2000) have synthesized seven new compounds in the malonamide series by introducing an ether oxygen into the alkyl chain attached to the bridging methylene group or of phenyl substituents on the nitrogen. These modifications reduce the basicity of the new derivatives to less than that of DMDBTDMA. The extraction of Am from HNO_3 by different malonamides in *t*-butylbenzene diluent has shown that the D_{Am} is higher for the malonamides with low basicity than that for DMDBTDMA.

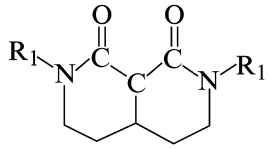
Taking the cue from the malonamide work, researchers at the Japan Atomic Energy Research Institute (JAERI) have synthesized six diglycolamides (Structure o) having the generic formula R,R–N–CO–CH_2–O–CH_2–CO–N–R,R where R is an alkyl group having carbon atoms ranging from 3 to 10 (Sasaki *et al.*, 2001). Of these, only two compounds, namely, *N*,*N*,*N*′,*N*′-tetra(octyl)-3-oxapentanediamide (TODGA) and *N*,*N*,*N*′,*N*′-tetradecyl-3-oxapentanediamide (TDDGA) showed adequate solubility in *n*-dodecane to be useful for process development. Using TODGA the *D* values of actinides increased with increasing HNO_3 concentrations and the number of diglycolamide molecules attached to the extracted actinide ions (derived from slope analysis at radioanalytical concentrations of the metal ions) were three for Th(IV), U(VI), and Pu(IV) and four for Am(III) and Cm(III). TODGA in *n*-dodecane has been shown to extract both actinides and lanthanides completely from HNO_3 solutions.



Structure o

Additional basic work continues on this class of reagents on many fronts in France, in Japan with the development of diglycolamide extractants (Sasaki *et al.*, 2001; Sasaki and Tachimori, 2002) and in the U.S., with the report of a

structurally–hindered diamide (Lumetta *et al.*, 2002, 2003) that exhibits greater affinity for trivalent actinides than the free rotation analogs (Structure p). Work also progresses on monoamides as possible replacements for TBP in a PUREX-like extraction system. The ultimate potential of this class of extractant molecules has perhaps not yet been reached.



Structure p

(c) Ion pair formation systems

Two classes of alkyl amine extraction systems are known, tertiary and quaternary amines. Tertiary amines are electroneutral species that are readily protonated to form lipophilic salts ($R_3NH^+X^-$) while quaternary amines are tetraalkylammonium ions (R_4N^+) bearing a permanent positive charge and always associated with an anion in the organic phase. Both extractant classes have a tendency toward the formation of reverse micelles in organic solutions.

Tertiary amines require preequilibration with concentrated acid to create the ion pair. However, this protonation reaction introduces an additional means of adjusting the extraction chemistry of such systems. The efficiency of this class of extractants is impacted by both the salt concentration in the aqueous contacting solution and its acid concentration. Quaternary ammonium extractants are analogous to tetraalkylammonium based anion exchange resins and bear some kinship to the room temperature ionic liquids that will be discussed in Section 24.3.10.

Moore (1964) first applied quaternary amines to lanthanide/actinide group separations examining the system Aliquat 336[2]/xylene/H_2SO_4–NH_4SCN.

A principal advantage of this method is the relatively low concentration of salts required to attain a usable separation. Several other applications of the method have been summarized (Weaver, 1974). This class of extractants can be immobilized on an inert support to create extraction chromatographic materials that combine the best features of the extractants with the increased efficiency of extraction chromatography. Horwitz *et al.* (1995) have reported the application of the effect of thiocyanate for the selective separation of actinides from lanthanides using such resins (Fig. 24.9). When loaded from a solution 1.0 M NH_4SCN/0.1 M HCO_2H, trivalent actinides (represented by Am^{3+}) are quantitatively sorbed while lanthanides (from La to Eu) are rejected. Americium can be eluted from the column with 0.25 M HCl for a very selective actinide/lanthanide separation.

[2] Aliquat 336-nitrate is tri(C8-10 alkyl)methylammonium nitrate

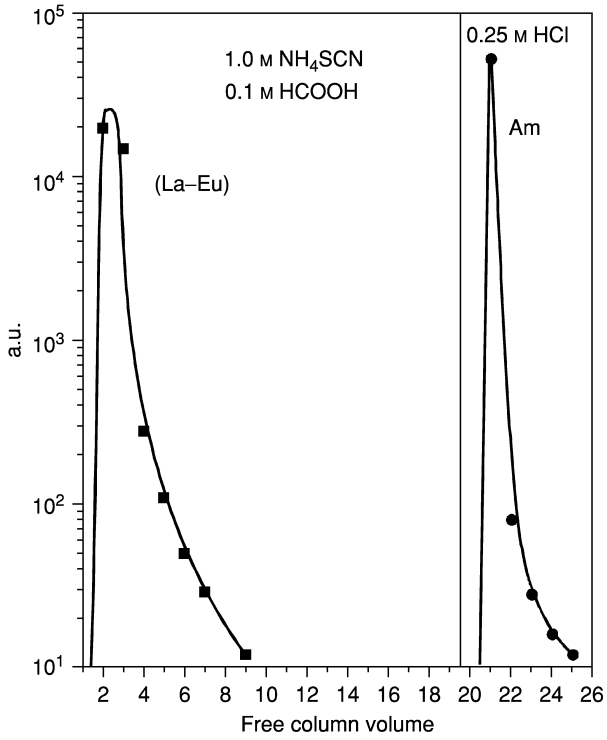


Fig. 24.9 *Partitioning of trivalent lanthanides and actinides on U-TEVA resin™* (*Horwitz* et al., 1995).

(d) Synergistic systems

The principal feature of synergistic extraction systems is increased extraction strength. Improved extraction efficiency often comes at the expense of selectivity. This is seen in the extraction of lanthanides from xylene solutions of TTA and TTA/TBP mixtures for which the separation factors (normalized to Lu^{3+}) are shown in Fig. 24.10. A linear correlation is observed between the separation factors and the position of the lanthanide ions through the series for the extraction of $Ln(TTA)_3$, whereas for extraction of $Ln(TTA)_3(TBP)_2$ separation of adjacent cations is observed for the light lanthanides only but not for the latter members of the series. The relevant literature on trivalent lanthanide/actinide separations by synergistic systems was reviewed by Mathur (1983).

Extensive investigations of 1-phenyl-3-methyl-4-benzoyl-5-pyrazolone (PMBP, Structure q) by Chmutova *et al.* (1973) indicate that the synergistic enhancement for TBP and TOPO adducts (in benzene) of the trivalent actinides (extracted from nitric acid) increase in the order Am < Cm < Bk < Cf. However, Khopkar and Mathur (1982) do not observe any particular order in

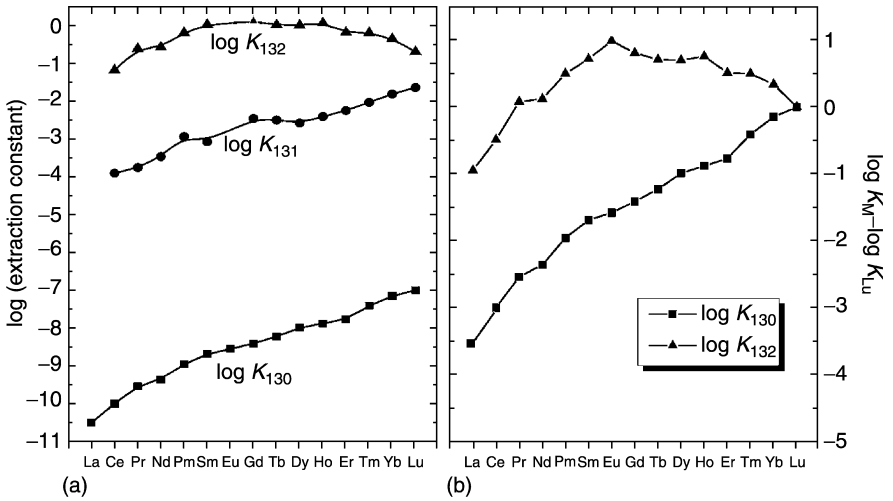

Fig. 24.10 *The effect of adding a synergist on extraction efficiency and comparative extraction of trivalent lanthanides in the TTA–TBP system*: (*a*) *extraction equilibrium constants for the reactions* $M^{3+} + 3\ HTTA \rightleftarrows M(TTA)_3 + 3\ H^+$ (K_{130}) (*Poskanzer and Foreman*, 1961), $M(TTA)_3 + TBP \rightleftarrows (M(TTA)_3TBP$ (K_{131}), *and* $M(TTA)_3 + 2\ TBP \rightleftarrows M(TTA)_3(TBP)_2$ (K_{132}) (*Farbu* et al., 1974). (*b*) *Comparative data normalized to log* $K_{Lu} = 0$.

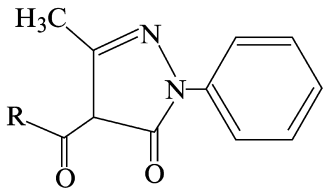
the extraction of these metal ions from hydrochloric acid solutions into the same extractant mixtures with xylene as diluent.



Structure q

While such reagents possess interesting cation coordination properties, ligands designed for size-selective metal ion coordination, the crown ethers (CE), calixarenes, and related species have been employed primarily as synergists for An(III) separations. As yet, no important separations of actinides have been developed based on the application of such species as a primary extractant. The use of benzo-15-crown-5 (Bz15-C-5), and dicyclohexano-18-crown-6 (DCH18-C-6) as synergists for lanthanide and actinide extraction with 1-phenyl-3-methyl-4-trifluoroacetyl-5-pyrazolone (PMPFT)/chloroform suggest some potential for such mixtures to accomplish certain specific group and inter-actinide separations (Mathur and Khopkar, 1988). Aly *et al.* (1985) studied synergistic extraction using TTA and 15-crown-5 synergist for lanthanide and trivalent actinide extraction. They found significant enhancement of the extraction, but

little separation of individual ions. The extracted complex is $M(TTA)_3(CE)_2$ for the 15-crown-5 synergist and $M(TTA)_3(CE)$ for the 18-crown-6.

There is also evidence that non-cyclic polyethers can function as synergists in lanthanide/actinide separations. Ensor and Shah (1983, 1984) report that 1,13-bis[8-quinolyl]-1,4,7,10,13-pentaoxatridecane (Kryptofix-5, or K-5) enhances the extraction of Ce(III), Eu(III), Tm(III), Am(III), Cm(III), and Bk(III) into chloroform solutions of TTA. The extracted complex has the stoichiometry $R(TTA)_3 \cdot K\text{-}5$, and the synergistic enhancement is comparable to that of TBP under the conditions studied. The separation factors reported for TTA alone are $S_{Am}^{Cm} = 1.1$, $S_{Am}^{Bk} = 5.25$, $S_{Am}^{Cf} = 11$, while for the mixture of TTA and K-5 the values are $S_{Am}^{Cm} = 0.87$, $S_{Am}^{Bk} = 3.4$, $S_{Am}^{Cf} = 2.5$, clearly indicating a decrease in separation efficiency.

24.3.5 Thermodynamic features of actinide solvent extraction reactions

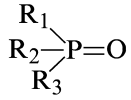
The transfer of a metal ion from an aqueous medium to an organic extractant solution and back is governed by the relative positions of several competing reversible equilibria. In the aqueous phase, hydration and protonation equilibria of metal cations, chelating agents, and metal complexes, as well as the complexation equilibria of metal ions and ligands control the relative extractability of metal ions. In the organic phase, metal–ligand bonding, non-specific and specific solvation of complexes, and ligand–ligand interactions are the most important processes contributing to the net thermodynamics of phase transfer (Nash, 2001). Because solvent extraction reactions are fundamentally mass-transfer processes, they can be driven against an unfavorable Gibbs energy gradient by manipulation of phase transfer conditions, as will be demonstrated in the discussion of trivalent ion extraction by Cyanex 301 below.

Most investigations of the thermodynamics of f-element solvent extraction reactions have been performed relying on the change in the extraction equilibrium constant (K_{ex}) as a function of temperature with application of the Van't Hoff relationship $[\partial(\ln K_{ex})/\partial(1/T) = -\Delta H/R]$. Second order thermodynamic effects resulting from changes in ΔC_p generally do not complicate the application of this technique, as the temperature range is restricted by solubility and volatility considerations to the region of 0–60°C, often significantly less. There have been several reports of enthalpy changes measured calorimetrically in synergistic systems. In these experiments, measured enthalpies describe the addition of a co-extractant to the primary chelate complex of the extracted metal ion in a homogeneous organic phase. The experimental results described below are derived from a variety of literature reports. The reader is referred to the original references for details of the experimental procedures.

The most thoroughly investigated synergistic extraction systems involving f-elements are those in which TTA is the primary extractant. Neutral organophosphorus compounds, aliphatic amines, crown ethers, bipyridyl, phenanthroline, and aliphatic sulfoxide extractants have all been investigated

thermochemically as synergistic reagents for lanthanide and actinide extraction by TTA. Most of the thermodynamic data were determined using the temperature variation method, some were investigated by calorimetry, and a few systems have been studied using both techniques. Adduct formation reactions are generally exothermic (ΔH between –20 and –70 kJ mol^{-1}) while the entropies cover a wide range of both favorable and unfavorable contributions to the net equilibrium, dependent primarily on the nature of the synergist (Nash, 2001).

The tris-TTA complex of the lanthanides is a dihydrate or trihydrate in most organic diluents, thus the entropy change upon formation of the adduct partly reflects the ability of the synergist to displace this residual hydration. Using calorimetry, Choppin and coworkers (Caceci *et al.*, 1985) studied the addition of both TBP and trioctylphosphine oxide (TOPO, Structure r, where $R_1 = R_2 = R_3 =$ *n*-octyl) to the neutral TTA complexes of UO_2^{2+}, Nd^{3+}, and Th^{4+} in benzene. The enthalpies of adduct formation were 10–20 kJ mol^{-1} more exothermic in the dry solvent than the water-saturated equivalent. The corresponding variations in the entropy changes almost fully compensated the variations in enthalpy changes, resulting in a constant Gibbs energy of adduct formation. Crown ether adducts on the corresponding TTA complexes (Mathur and Choppin, 1993) were characterized by negligible entropy changes in the trivalent lanthanide adducts, but moderately unfavorable entropy changes for the UO_2^{2+} and Th^{4+} complexes.

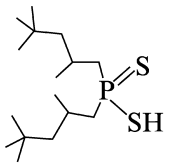


Structure r

Addition of pyridine-based donors like bipyridyl to lanthanide TTA complexes or dipivaloylmethane (also a β-diketone) is characterized by a strongly exothermic enthalpy (–40 to –70 kJ mol^{-1}) partially compensated by an unfavorable entropy change (Kassierer and Kertes, 1972; Kertes and Kassierer, 1972; Dakternieks, 1976). The synergistic extraction of lanthanides by mixtures of TTA and trialkyl amines exhibits no temperature dependence implying that the formation of the adduct from $Ln(TTA)_3$ is characterized by an enthalpy change of the same magnitude but opposite in sign to that of the extraction of the lanthanide by TTA alone. This curious observation has been made for the combination of tertiary amines and pyrazolone extractants as well.

The greater affinity of actinides for donor atoms softer than oxygen is at the heart of all successful separations of the trivalent ions of the transplutonium elements from the lanthanides (Nash, 1994). This difference in interaction strength has been attributed to a greater tendency for the actinides towards covalency in their bonding, which should, in principle, be manifested thermodynamically by exothermic complexation heats. Dithiophosphinic acid extractants [e.g. Cyanex 301, bis(2,4,4-trimethylpentyl)dithiophosphinic acid, Structure s] have been shown to exhibit separation factors of greater than 10^3 for

trivalent actinide ions over lanthanides of comparable size. Cyanex 301 when purified and used for the extraction of Am(III) and Eu(III) from nitrate medium gave an S_{Eu}^{Am} of 5.9×10^3 (Zhu *et al.*, 1996). The $S_M^{M'}$ for other lanthanides was found to be Am/La ~3500, Am/Ce ~1000, Am/Pr ~1000, Am/Nd ~1900, Am/Sm ~4500. The average Am/Ln $S_M^{M'}$ being greater than 2300.



Structure s

The work of Tian *et al.* (2001) has demonstrated that Am/Eu separation factors above 10^3 can be seen even in partially degraded solvents when excess lanthanides are present in the aqueous phase. Excess non-radioactive lanthanides tend to mask the deleterious effect of degradation products of Cyanex 301 (oxygenated phosphinic acid extractant molecules in particular) on Am/Eu separation factors by competing more strongly than Am for the oxygenated species. Lanthanide saturation of the oxygenated degradation products allows the soft-donor interaction between Am and the thio phosphinates to be maintained.

These authors also have calculated thermodynamic parameters based on the measurement of distribution ratios as a function of temperature the enthalpy associated with extraction of Am^{3+} and Eu^{3+} from 1.0 M Na/HNO_3 by purified Cyanex 301. Tian *et al.* report $\Delta H_{Am} = +18.1$ kJ mol^{-1}, $\Delta H_{Eu} = +43.6$ kJ mol^{-1} with corresponding entropy changes of $\Delta S_{Am} = -87$ J K^{-1} mol^{-1}, $\Delta S_{Eu} = -66$ J K^{-1} mol^{-1}. Though both phase transfer reactions are characterized by unfavorable endothermic enthalpic effects and negative entropies, analysis of the data indicates that the enthalpy difference between the americium and the europium extraction is the principal source of the greater selectivity of Cyanex 301 for Am^{3+} [$(\Delta H_{Am} - \Delta H_{Eu}) = -25.5$ kJ mol^{-1}; $-T(\Delta S_{Am} - \Delta S_{Eu}) = +6.3$ kJ mol^{-1}]. Both the more exothermic heat and greater order implicit in the entropy contribution are consistent with increased strength of the Am–S bonding relative to that of Eu–S.

Jensen and Bond (2002a,b) have concluded based on a combination of EXAFS, osmometry, Karl Fisher titration, and UV–visible spectrophotometry that the complexes of lanthanide and trivalent actinide ions extracted into Cyanex 301 in xylene are octahedral containing no inner sphere water molecules. They interpret this result as indicating that the difference in thermodynamic parameters is most likely a result of increased Cm–S bonding strength relative to that of Sm. Tian *et al.* (2003) argue based on EXAFS, FTIR, and MS data for the presence of eight-coordination lanthanide and actinide complexes with Cyanex 301. The lanthanide complex contains an inner-sphere water molecule that is not present in the corresponding eight-coordinate Am complex.

The most common neutral extractants for f-elements are trialkyl-phosphates, -phosphonates, -phosphinates, and -phosphine oxides. As shown in equation (24.7) describing the extraction process for systems of this class, both an appropriate number of aqueous anions to neutralize the cation charge and a variable number of extractant molecules to make the complex lipophilic are needed. This assembly of a number of components to form a single product species suggests that the net extraction entropy for such reactions should be consistently negative. In fact, for extraction of trivalent lanthanides, actinides, Th^{4+}, and UO_2^{2+} by simple monodentate or complex bidentate organophosphorus extractants (which represent the bulk of such neutral extractant systems) the extraction entropies range between –40 and –150 J K^{-1} mol^{-1}independent of the nature of the counter ion X^-. Extraction enthalpies are exothermic and in the range of –30 to –90 kJ mol^{-1}, implying a net increase in bonding strength for the phase transfer reaction (though the origin of the increased bonding strength cannot be established from such investigations) (Nash, 2001).

The relative extraction of trivalent lanthanides and actinides in neutral systems has been examined by comparing Am^{3+} and Eu^{3+} extraction by CMPO (Mathur and Nash, 1998; Suresh *et al*., 2001) and DHDECMP (Horwitz *et al*., 1981; Muscatello *et al*., 1982). The stoichiometries of the extraction equilibria are as described above. The thermodynamic data (ΔG, ΔH, and ΔS) for the extraction of Am(III) and Eu(III) species from NO_3^- and SCN^- media with CMP and NO_3^-, SCN^-, ClO_4^-, and $ClO_4^- + NO_3^-$ media with CMPO are given in Table 24.6. The thiocyanate systems demonstrate a greater selectivity for americium corresponding to an increased Gibbs energy change of 4–5 kJ mol^{-1} (a separation factor of 5–7). Substantially more exothermic extraction enthalpies are observed in both the Eu^{3+} and Am^{3+} thiocyanate systems than is seen in the corresponding nitrate reactions. This difference has been attributed, based on data tabulated by Marcus (1997), to the greater exothermicity of the transfer three SCN^- ions from the aqueous to a normal alkane organic phase as compared with the transfer of three nitrate anions (Mathur and Nash, 1998). Differences in the enthalpy of extraction of americium relative to europium are not substantial or consistent enough to attribute the enhanced extraction of the actinide to a soft donor-effect.

24.3.6 Aqueous biphasic systems

Some research has been done on liquid–liquid extraction systems that seek to eliminate hydrophobic organic materials. For example, polyethylene glycols can produce two-phase systems (called aqueous biphases) when equilibrated with concentrated salt solutions of water-structuring anions (Rogers *et al*., 1993). The key characteristic of these systems is that the immiscible phases are both largely aqueous in nature. Myasoedov and Chmutova (1995) have reported conditions for the separation of transplutonium elements from uranium, thorium, and lanthanides. The aqueous biphase itself does not extract actinides

strongly, but Arsenazo III (2,7-bis(2,2′-arsonophenylazo)-1,8-dihydroxy-naphthalene-3,6-disulfonic acid) is a highly effective carrier for these metal ions. A method for preparation of an isotope generator for ^{239}Np from ^{243}Am using an ammonium sulfate solution containing potassium phosphotungstate has also been reported (Molochnikova *et al*., 1995). Overall, while the aqueous biphasic extraction approach brings forward some interesting features, the high salt concentrations needed to generate the biphase work against its utility for large-scale separations. Polyethylene glycols remain useful compounds when employed as phase modifiers in conventional solvent extraction.

24.3.7 Actinide separations from Alkaline Solutions

Alkaline conditions tend, in general, to lead to the precipitation of actinide hydroxides. However, much of the actinide inventory within the waste system in the U.S. is found in (or in contact with) such solutions, and the tendency of actinides to precipitate from alkaline solutions can be overcome by

water-soluble chelating agents. There are a few examples of the separation of lanthanides and actinides from alkaline and carbonate solutions, as reviewed by Karalova *et al*. (1988). Both solvating and chelating extractants have been used in these studies. Ternary and quaternary amines, alkylpyrocatechols, β-diketones, pyrazolones, and *N*-alkyl derivatives of aminoalcohols are the extractants indicated as useful for alkaline extraction processes. A variety of diluents have been used, but their nature seems to have little effect on the extraction efficiency or separation factors.

The factors contributing to a successful separation procedure in alkaline media are not different from those relevant in acidic solutions, i.e. the efficiency is dependent on the nature of the extractant and the aqueous complexant, the pH of the aqueous solution, and the strength of aqueous complexes. Two advantages provided by this approach are the relative ease of back extraction (contact with neutral salt solutions is usually sufficient) and the potential for separations based on relative rates of phase transfer reactions. The disadvantage (from a practical standpoint) is the requirement of working with concentrated salt solutions, which creates waste disposal problems. However, the potential for reducing the transuranium element (TRU) content of alkaline wastes justifies a search for viable separation schemes based on alkaline solutions.

Extraction from alkaline and carbonate solutions is characterized by an unusual sequence of the distribution ratios favoring the trivalent oxidation state [in carbonate solutions the order of extraction is M(III) > M(IV) > M(V) > M(VI)]. A further benefit of operation in alkaline solutions is the greater tendency for air oxidation of some trivalent metal ions. Group separation factors for the trivalent actinides and lanthanides are about 2 for extraction by Aliquat 336-EDTA in contact with an alkaline EDTA aqueous solution (Bukina *et al*., 1983). Eu–Am separation factors of 70 have been reported for a non-equilibrium extraction in the system 4-(α,α-dioctylethyl)-pyrocatechol/NaOH/DTPA (or DTPMPA, diethylenetriamine-*N*,*N*,*N*′,*N*″,*N*″-pentamethylenephosphonic acid) (Karalova *et al*., 1982). In contrast with most acid-medium separation systems, the separation factors are based mainly on the difference in the *rates* of the metal–DTPA (or DTPMPA) complexation reactions for europium and americium rather than chemical equilibria. They are, therefore, highly dependent on the contact time. A principal limitation to the practical application of separation schemes based on alkaline solutions is the relatively long contact times (more than 10 min) required for extraction.

24.3.8 Separations of actinides involving natural agents

Several natural agents present in plants (Dushenkov *et al*., 1997; Huang *et al*., 1998; Thulasidas *et al*., 1999) or more generally biomass (Anonymous, 1951; Dhami *et al*., 1998a,b; Banaszak *et al*., 1999), jimson weeds (Anonymous, 1995), tannin biomolecules (Sakaguchi and Nakajima, 1987, Nakajima and Sakaguchi,

1990), siderophores (Whisenhunt *et al*., 1993), chitosan (a natural biopolymer derivative of chitin) (Anonymous, 1995; Park *et al*., 1999; Srinivasan *et al*., 2001) etc. have been considered for actinide separations from very dilute solutions. Our emphasis here will be on non-living microbial biomass, a common fungus *Rhizopus arrhizus* (*RA*), which has chitin chains inside its cell walls, and chitosan which is a natural biopolymer derivative of chitin extracted from crab shell.

A detailed study on the biosorption of uranium and thorium by *RA* has been carried out by Tsezos and coworkers (Tsezos and Volesky, 1981, 1982; Tsezos, 1983) where they have reported very high uptake of uranium from aqueous solutions to the extent of 180 mg U per gram of *RA*. The highest uptake of the metal ions was between pH 4 and 5. The presence of Cu^{2+}, Zn^{2+}, and Fe^{2+} ions interfered in the biosorption of uranium and thorium. The mechanism of uranium sequestering by *RA* has been studied by using techniques like electron microscopy, X-ray energy dispersion analysis, and IR spectroscopy. It has been proposed that the total sorption of uranium is the cumulative effect of three processes: formation of uranium coordination compounds with the amine nitrogen of the chitin chains, adsorption of uranium to the polyalcohol surface of the chitin matrix, and hydrolysis of the U–chitin complex formed, resulting in the precipitation of the hydrolysis product in the cell wall (Tsezos and Volesky, 1982). Sorption of radionuclides ^{233}U, ^{239}Pu, ^{241}Am, ^{144}Ce, ^{147}Pm, $^{152,154}Eu$, and ^{95}Zr from aqueous nitrate medium (pH 2–11) has been studied with *RA*: it was suggested that *RA* is an effective biomass for the removal of actinides and trivalent fission product lanthanides from low-level waste streams generated in PUREX process and also in the secondary wastes generated from the TRUEX process (Dhami *et al*., 1998a,b).

The adsorption of uranyl ion on powdered chitosan is characterized by a high affinity in neutral pH range; however the adsorption capacity of chitosan at relatively high pH decreases due to the presence of negatively charged uranyl species in the solution (Park *et al*., 1999). Chitosan has been found to be a good natural material for the sorption of ^{241}Am at a pH of 3 (Srinivasan *et al*., 2001).

24.3.9 Trivalent actinide/lanthanide separation systems

The classic historical methods of separating trivalent actinides from fission product lanthanides are based on ion exchange, as discussed in Section 24.2.4. However, as is seen in Section 24.3.4, solvent extraction techniques have a wider range of applications. One approach to accomplishing trivalent actinide/lanthanide separation by solvent extraction is to apply consecutively two unrelated separation processes in a complementary fashion. Sekine and Dyrssen (1964) reported Eu/Am separation factors for 12 acidic extractants covering the spectrum of available materials (Table 24.7 is adapted from their work). Based on their separation factors, one can envision a counter-current separation procedure involving first extraction by dibutylphosphoric acid (HDBP) to

Table 24.7 *Europium/americium separation factors for a series of acidic extractants* (*Sekine and Dyrssen,* 1964).

Extractant	*Diluent*	S_{Am}^{Eu}
dibutylphosphoric acid	$CHCl_3$	22.9
dioctylphosphoric acid	$CHCl_3$	14.1
1-phenyl-3-methyl-4-acetylpyrazolone-5	$CHCl_3$	3.47
thenoyltrifluoroacetone	$CHCl_3$	3.02
neocupferron	$CHCl_3$	1.74
N-benzoylphenylhydroxylamine	$CHCl_3$	1.66
N-2,4-dichlorobenzoylphenylhydroxylamine	$CHCl_3$	1.32
β-isopropyltropolone	$CHCl_3$	0.98
1-hydroxy-2-napthoic acid	hexone	1.07
2-hydroxy-1-napthoic acid	hexone	1.02
3-hydroxy-2-napthoic acid	hexone	0.95
5,7-dichloroxine	$CHCl_3$	0.10

preferentially remove americium, followed by contact of the aqueous phase with 5,7-dichloroxine to extract europium. Substituting bis(2-ethylhexyl)phosphoric acid (HDEHP) for HDBP, Kasting *et al*. (1979) suggest that such a separation procedure could give actinide/lanthanide separation factors of several thousand.

From a process-scale application perspective, combinations of extraction systems are generally considered undesirable because of the complexity they introduce into the separations process. The more widely accepted approach to the separation of trivalent actinides from lanthanides is to rely upon the slightly stronger interaction that the trivalent actinides exhibit with ligands containing soft-donor bases (S, Cl, or N), as reported by Diamond *et al*. (1954). The soft-donor atoms may be present as free ions (SCN^-, Cl^-) or in a complexant/extractant molecule either water-soluble or lipophilic. This condition was recognized early in the race to produce new actinides, and formed the basis of separations techniques developed between 1945 and 1960, several of which still constitute the 'state-of-the-art' in actinide separations. Both ion exchange and solvent extraction techniques figure prominently in these separations.

The efficiency of lanthanide/actinide separations through the agency of soft-donor complexants is highly dependent on the strength of the interaction between the hydrated metal cation and the bulk water structure in the aqueous phase as well. The results reported by Sekine (1965) illustrate this in showing the combined effect of soft-donor ligands (SCN^-) and of water-structure disrupting anions (both SCN^- and ClO_4^-) on Am/Eu separation using a solvating extractant (Fig. 24.7). Both the extraction and mutual separation of americium and europium with 5% TBP in hexane from 5.0 M $NaClO_4$/NaSCN, and from NaSCN solutions without supporting electrolyte (pH 4–5) exhibit strong dependence on the concentration of SCN^-. In each case, separations factors (S_{Eu}^{Am}) decline with increasing thiocyanate concentration, though they are

lower throughout the range of observation in the mixed salt system than in the thiocyanate-only system. However, in the thiocyanate-only system, distribution ratios overall are significantly lower for both metal ions, particularly at low total thiocyanate.

Distribution ratios are significantly higher in the mixed salt system due to the 'perchlorate effect' (Marcus and Kertes, 1969). The Gibbs energy for extraction of either Am or Eu in the presence of perchlorate (for example, at 1 M NaSCN) is 12–17 kJ mol^{-1} more favorable than when perchlorate is absent. At the highest SCN^- concentrations, separation factors are about unity because the disrupting effect of SCN^- and ClO_4^- on the water structure essentially diminishes the importance of the effect of the soft-donor interaction in actinide binding to the SCN^-. It appears that cation/complex solvation effects dominate the relative interactions under these conditions. Effectively, water activity is increased by the disruptive effect of the large anions and thus the soft-donor thiocyanate can no longer effectively distinguish between Am and Eu (as it clearly does at lower salt concentrations).

The bifunctional extractants (CMPs and CMPOs discussed in Section 24.3.4b) are designed for process applications to permit complete recovery of all actinides in oxidation states 3+, 4+, and 6+ from nitric acid solutions. Their extraction strength does not readily lend itself to selective separations. However, Muscatello *et al.* (1982) reported that substitution of dilute NH_4SCN for HNO_3, in the extraction of trivalent f-elements from 0.244 M DHDECMP (dihexyl)diethylcarbamoylmethylphosphonate) yielded americium/europium separation factors as high as 10.8. The thermodynamic features of these and related systems have been discussed in Section 24.3.5.

A more efficient, but considerably more complex, approach to actinide/lanthanide separation was developed by Weaver and Kappelmann (1964). If the normal mineral acid aqueous phase is replaced by a 1 M carboxylic acid (pH 1.8) solution, HDEHP extraction of Am is depressed relative to that for the lanthanides. At higher pH values (~3.0), the separation factors are increased, with the most consistent enhancement observed for lactic acid. Addition of only 0.05 M DTPA to the solutions of carboxylic acids at pH 3 resulted in dramatically improved separation factors. For extraction from 1 M lactic acid/0.05 M DTPA at pH 3 with 0.3 M HDEHP/diisopropylbenzene, the worst actinide/lanthanide separation factor is for $S_{Cf}^{Nd} \approx 10$. Separation factors for lanthanides over americium and curium were greater than 100. In this system, up to one lactic acid molecule appears in the extracted complex. The DTPA complexes remain in the aqueous phase.

This separation process has acquired the acronym TALSPEAK (Trivalent Actinide Lanthanide Separation by Phosphorus reagent Extraction from Aqueous Komplexes). The generic applicability of the concept is demonstrated by the work of Baybarz (1965), who finds only slightly reduced efficiency upon substitution of 2-ethylhexyl(phenyl)phosphonic acid/diethyl benzene (H(EH(Φ)P)/DEB) for HDEHP/DIPB. The impact of substitution of DTPA

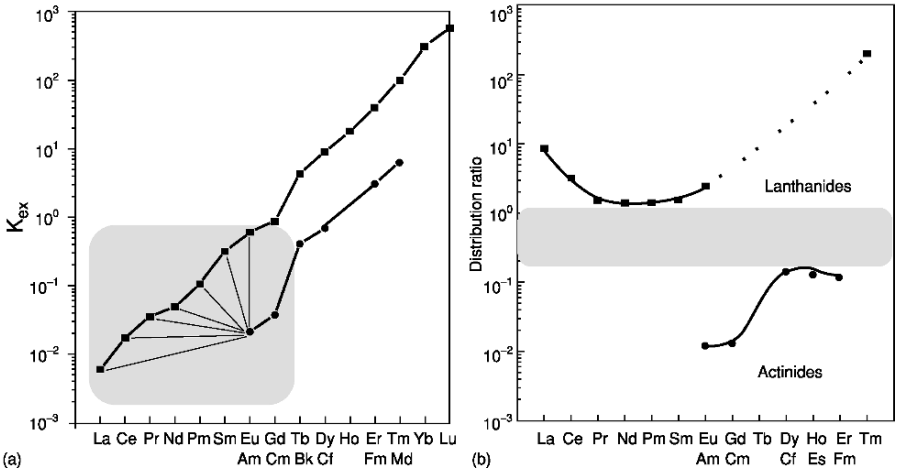

Fig. 24.11 *Distribution of lanthanide* (▪) *and trivalent actinide* (●) *cations between* (*a*) *nitric acid and* 0.5 M *HDEHP* (*Peppard* et al., 1957) *and* (*b*) 0.3 M *HDEHP/DIPB*, 1 M *lactic acid*, 0.05 M *DTPA at pH* 3 (*Weaver and Kappelmann*, 1964).

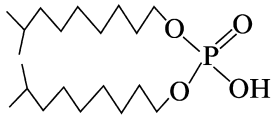
and lactate for nitric acid on group separations (as compared with HDEHP alone) is illustrated in Fig. 24.11. In a modification of the TALSPEAK process, known as the Reverse TALSPEAK process, trivalent actinides and lanthanides together are extracted by 1 M HDEHP from the 0.1 M HNO_3 feed solution. Americium and curium are then selectively stripped from the organic phase with a mixture of 0.05 M DTPA and 1.5 M lactic acid at a suitable pH adjusted with ammonia (Persson *et al*., 1984).

A number of other reports have discussed applications, process experience, and modifications of TALSPEAK. Kosyakov and Yerin (1980) report that for curium extraction with TALSPEAK-type aqueous solutions using HDEHP/decane solutions both extractant (HDEHP) and acid dependencies (i.e. the number of extractant molecule dimers in the complex and the number of H^+ ions released to the aqueous solution) decreased from 3 to 2. This reduction indicates the extraction of a 1:1 M–lactate complex for the aliphatic diluent. Similar extractant dependencies were reported for Bk, Eu, and Ce. Bourges *et al*. (1980) report a comparison of TALSPEAK with TBP-nitrate and trilauryl ammonium nitrate extraction for Am/Cm separations using DTPA as aqueous complexing agent (in extraction chromatographic mode). Though TALSPEAK gives higher lanthanide/actinide separation factors, these authors cite favorable chromatographic kinetics and improved Am/Cm separation as justification for the choice of TBP/DTPA over TALSPEAK. Ishimori finds higher distribution ratios in a TALSPEAK type system using di-isodecylphosphoric acid (DIDPA, Structure t) in place of HDEHP (Ishimori, 1980). Bond and Leuze (1980) describe a lanthanide/actinide removal and separation scheme using a 1 M lactic

acid–0.05 M DTPA stripping solution to separate trivalent actinides from the lanthanides.



Structure t

The TALSPEAK process is adaptable to liquid membrane separations (Novikov and Myasoedov, 1987). These authors report the use of a 'supported liquid membrane' impregnated with HDEHP for the separation of Am/Cm, Eu/Tb, and Am/Eu using DTPA, citric acid, and the potassium salt of a heteropolyacid ($K_{10}P_2W_{17}O_{61}$) as aqueous complexants. The optimum separation factors reported are $S_{Cm}^{Am} = 5.0$, $S_{Tb}^{Eu} = 10.8$, and $S_{Am}^{Eu} > 10^2$. Elements of the TALSPEAK (or reverse) still get periodic consideration in process chemistry of actinide recycle, as will be discussed in Section 24.4.4 g.

French researchers have investigated the use of soft-donor extractants and complexants to enhance actinide/lanthanide group separations (Musikas *et al.*, 1980; Musikas, 1985; Vitorge, 1985). The relative stability constants for lanthanide and actinide azide complexes reported by Musikas *et al.* (1980) suggest that hydrazoic acid (HN_3) could function as a useful reagent for this separation. This is confirmed in a later report on Am/Eu separation (Musikas, 1985) in which americium extraction is suppressed by complex formation with azide. The separation factors are similar to those reported by Sekine (1965) using SCN^- as the complexant in TBP extraction. As to the thermodynamic factors describing this system, Choppin and Barber (1989) find that, while the trivalent actinide–azide stability constants are somewhat larger than those of the trivalent lanthanides, the complexation enthalpies (calculated from the temperature coefficient of the stability constants) do not support the existence of a covalent bonding contribution.

A soft-donor extractant system, mixtures of *o*-phenanthroline and nonanoic acid (Musikas, 1985), extracts americium in order of magnitude more strongly than europium from 0.1 M $NaNO_3$ solutions at pH 4.5–5.1 [$S_{Eu}^{Am} = (17.4 \pm 0.9)$]. To accomplish the separation at higher acidity, research has been conducted on the complexant/extractant 2,4,6-tris(2-pyridyl)-1,3,5-triazine (TPTZ, Structure u), used in conjunction with carboxylate and sulfonate co-extractants. The latter is necessary because of the hydrophilicity of the $Am(NO_3)_3TPTZ$ complex. Replacement of nitrate by α-bromocaprate (with decanol as diluent) gives group separation factors ≈ 10 with little apparent variation in the distribution ratios for the members of the groups (Am, Cm, or Eu, Nd, Tb, and Yb) (Table 24.8) in the pH range of 2–3. Substitution of dinonylnaphthalenesulfonic acid (HDNNS) for α-bromocapric acid gives similar performance at 0.1 M acid.

Table 24.8 *Extraction of selected trivalent actinides and lanthanides by* 2,4,6-*tris* (2-*pyridyl*)-1,3,5-*triazine* (*TPTZ*)/1 M α-*bromocapric acid* (*ABCA*)/*decanol*, *and TPTZ/HDNNS/t-butylbenzene*(*TBB*) *nitric acid* (*Musikas*, 1985).

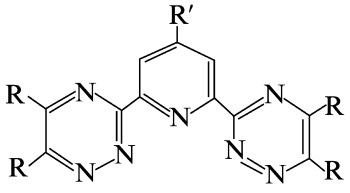
Structure u

Structurally, TPTZ is perhaps not ideally suited as an extractant for this separation. Though there are a number of nitrogen donor atoms present in TPTZ, the planar nature of the ligand demands that no more than three nitrogen atoms be coordinated to a metal ion, leaving three additional potential donor atoms available for interactions (quite probably non-productive interactions) with other solutes in the organic phase. Continued research on the design, synthesis, and characterization of polyaza extractants led ultimately to the development by Kolarik *et al*. (1999) of the bistriazinylpyridine (BTP) class of ligands (Structure v). Work continues on the adjustment of the structure and properties of these ligands (Hägstrom *et al*., 1999; Hudson *et al*., 2003; Drew *et al*., 2004a, b).

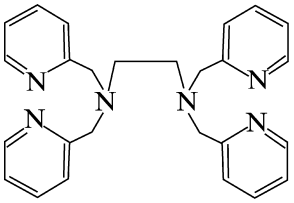


Structure v

In this ligand, pyridine rings have been substituted by triazines, in a geometry that favors at least tridentate coordination of the metal ion. Actinide/lanthanide

separation factors as high as 100 have been reported. This ligand is receiving considerable attention as a candidate for process-scale lanthanide/actinide reagent (Madic *et al.*, 2002). To date, 75 derivatives of this class of reagents have been prepared and have undergone some degree of characterization. Lipophilic co-extractants (carboxylic or organophosphoric acids) and/or long-chain alcohol diluents are often employed to minimize partitioning of the BTP extractant to the aqueous phase.

Another polyaza ligand that has received some attention for its potential to accomplish actinide/lanthanide separation is the EDTA structural analog *N*,*N*,*N*′,*N*′-tetra(methylpyridyl)ethylenediamine (TPEN, Structure w). Investigations of the structure of lanthanide complexes (Morss and Rogers, 1997) and the thermochemistry (Jensen *et al.*, 2000) of the corresponding aqueous species confirm the existence of a hexadentate coordination mode and an apparent 100-fold selectivity for actinides over lanthanides in aqueous solutions. Separation-specific studies have been conducted by Takeshita and coworkers (Watanabe *et al.*, 2002). These authors have reported separation factors greater than 70 in a synergistic extraction system analogous to that employed in the BTP system. As with all polyaza ligands, extractant partitioning to the aqueous phase is a complication in these systems.



Structure w

In general, f-elements are poorly extracted by simple sulfur donor extractants. Furthermore, extractant molecules that incorporate sulfur as a donor atom are often plagued by poor stability when contacted with acidic (particularly nitrate) aqueous solutions. Certain types of extractants are more vulnerable to such attack, as results presented by Musikas (1985) indicate. His reports of good actinide/lanthanide separation factors for solvent extraction by thio derivatives of HDEHP were later dismissed (Freiser, 1988) as being the result of hydrolysis of the extractant to produce the oxygenated derivative. Because the oxygenated analogs of thiophosphorus ligands extract trivalent lanthanide/actinide cations very strongly, even very low concentrations of these degradation products profoundly compromise the ability of the soft-donor extractant to accomplish the separation.

Thiophosphinic acids like Cyanex 301 are slightly more resistant to hydrolytic degradation than the dialkyldithiophosphates though the oxygenated products of their hydrolysis are as damaging to a successful lanthanide/actinide separation as HDEHP is in the thiophosphate system. This extractant when employed for separations of d-transition metals (e.g. Cd^{2+}) is often used in a de-aerated

environment to reduce the impact of degradation of the extractant on separation efficiency. Unfortunately, for separations of radioactive materials, the effect of radiolysis (and the oxygenated by-products of water radiolysis) cannot be eliminated and degradation of the extractant will be problematic in process applications.

Other derivatives of dialkyl dithiophosphinic acids have also been prepared and evaluated as potential actinide/lanthanide separation reagents. Results from Jarvinen *et al.* (1995) indicate moderate separation factors for americium from europium using dithiophosphinic acid extractants (R_2PS_2H) Cyanex 301, dicyclohexyldithiophosphinic acid, and diphenyldithiophosphinic acids. Wang *et al.* (2001) have synthesized several dialkylthiophosphinic acids where 2,4,4-trimethylpentyl group present in Cyanex 301 was replaced with *n*-octyl, 1-methylheptyl, 2-ethylhexyl, heptyl, or hexyl groups. It has been observed that by using 0.5 M solution of the thiophosphinic acids, the pH for 50% extraction ($pH_{1/2}$) of americium and europium from 1 M sodium nitrate is 2.58, 2.63, 2.67, 3.19, and 3.94, 3.99, 4.06, 4.52, respectively, for R = *n*-octyl, 1-methylheptyl, 2-ethylhexyl, or 2,4,4-trimethylpentyl groups. The Am/Eu separation factors for the four extractants are $\sim 1 \times 10^4$. These authors suggest that di(2-ethylhexyl)dithiophosphinic acid is the most promising of these extractants because of its lower $pH_{1/2}$ and higher loading capacity of extraction of americium as compared to Cyanex 301 (Tian *et al.*, 2001). More data on extractions at macro concentrations of the lanthanides, S_{Eu}^{Am} mixer–settler or centrifugal contactor runs will be required to substantiate these studies.

In an attempt to lower the $pH_{1/2}$ of this class of extractants, Modolo and Odoj (1999) prepared bis(*p*-chlorophenyl)dithiophosphinic acid. This extractant in a process solvent that includes tri(*n*-butyl)phosphate or trioctylphosphine oxide as a co-extractant is able to selectively extract trivalent actinides from lanthanides with separation factors acceptable for process applications. This extractant is receiving attention for possible process application, as will be discussed in Section 24.4.5b.

The higher $S_M^{M'}$ between americium and europium has been suggested by Ionova *et al.* (2001) as being due to the strong coordination of M(III) to soft-donor sulfur atoms of Cyanex 301, covalent effect being significantly higher for Am–S as compared with Eu–S bonds. These authors have further shown that while using a mixture of Cyanex 301 and neutral O-bearing co-extractants, the extraction of M(III) and S_{Eu}^{Am} can be correlated with the effective charge on O atom of the neutral organophosphorus extractant molecule. The S_{Eu}^{Am} reported are 3200 for Cyanex 301 alone, 4700 for Cyanex 301 and TBP, 9100 for Cyanex 301 and tri-*tert*-butyl phosphate, 16 000 for Cyanex 301 and triphenyl phosphate, 0.45 for Cyanex 301 and TOPO/CMPO, 95 for Cyanex 301 and *N*, *N*′-dimethyl-*N*,*N*′-dibutyltetradecylmalonamide, and 17 000 for Cyanex 301 and *N*, *N*′-di (ethyl-2-hexyl)dimethyl-2,2-butanamide.

Other classes of sulfur donor extractants appear to be more resistant to hydrolysis, and have demonstrated some potentially useful selectivity for

Table 24.9 *Distribution ratios and separation factors for americium/europium extraction by 4-benzoyl-2,4-dihydro-5-methyl-2-phenyl-3H-pyrazol-3-thione/toluene* (0.0297 M)/0.1 M $NaClO_4$ *as a function of* 4,7-*diphenyl*-1,10-*phenanthroline* (*synergist*) *from* (*Ensor* et al., 1988).

[DPPHEN]	D_{Am}	S_{Eu}^{Am}
0.00269	25.3	183
0.00215	21.9	196
0.00144	14.8	192
0.00108	10.3	174
0.000718	6.1	156
0.000359	2.7	129

actinides over lanthanides. For example, the mixture of 0.3 M 4-benzoyl-2, 4-dihydro-5-methyl-2-phenyl-3H-pyrazol-3-thione (BMPPT)/0.01 M TOPO/benzene extracts (from 0.1 M $LiClO_4$, pH 3) americium preferentially over europium ($S_{Eu}^{Am} = 68$) (Smith *et al.*, 1987). The analogous system based on the oxygen-donor analog and TOPO (Chmutova and Kochetkova, 1970) gave stronger extraction but no significant separation of curium from europium. Further substitution of the soft-donor synergist 4,7-diphenyl-1,10-phenanthroline (DPPHEN, Structure x) for TOPO (Ensor *et al.*, 1988), results in even greater selectivity for americium ($S_{Eu}^{Am} = 190$, pH 3.7, 0.03 M HBMPPT/0.0027 M DPPHEN). The extracted species is $M(BMPPT)_3(DPPHEN)$ (Table 24.9). This is the only known example of a system that contains soft-donor atoms in both the primary extractant and in the synergist. Choppin *et al.* (1995) have reported on the separation of americium from europium using various combinations of thiothenoyltrifluoroacetone, tri(*n*-butyl)phosphate, tributylphosphine sulfide, and *N*,*N*-dimethyl-*N*,*N*′-dihexyl-3-oxapentanediamide as coextractant ligands in a synergistic extraction system. In this case, the soft-donor ligands show little enhancement of Am/Eu separation factors.

24.3.10 Supercritical fluid extraction of actinides

The field of supercritical fluid extraction (SFE) of metal ions has been developed during the past decade. Among the first papers published, those by Wai and coworkers were the most important. In 1991, this group (Laintz *et al.*, 1991)

published a paper describing the solubility of fluorinated metal dithiocarbamates in supercritical carbon dioxide (sc-CO_2) wherein they demonstrated that the solubility of the fluorinated dithiocarbamates were two to three orders of magnitude higher than those of the corresponding non-fluorinated compounds. This technique was thus recognized as a promising new extraction method for metal ions from various sources. A year later, Wai and co-workers published a second paper (Laintz *et al.*, 1992) related to the SFE of metal ions from aqueous solutions and solid materials, and in 1993 they demonstrated the possibility of extracting lanthanide (Ln) and actinide (An) ions from solid materials with a fluorinated β-diketone (Lin *et al.*, 1993).

The rationale for the use of SFE of metal ions as an alternative to conventional liquid–liquid extraction (LLE) was mainly to minimize the generation of the secondary organic waste often encountered in LLE processes. Carbon dioxide was chosen as the most appropriate supercritical fluid because: (i) the values of the critical point (Darr and Poliakoff, 1999) were appropriate for a SFE application: $P_c = 72.9$ atm, $T = 304.2$ K, $\rho_c = 0.47$ g mL^{-1}; (ii) CO_2 can be considered as a green solvent for the environment; (iii) (aside from asphyxiation hazards) CO_2 is harmless to workers; (iv) CO_2 is almost inert with respect to radiolysis; (v) CO_2 is inexpensive. Moreover, the high diffusivity of sc-CO_2 means that rapid extraction of the metal ions from their sources can be expected. Since 1991, about 80 reports related to the SFE of metal ions have been published, most of them related to actinides. The most studied actinide ion is U(VI), with about 50 papers. This field was recently reviewed by Darr and Poliakoff (1999) and by Wai (2002). The sections to follow present the most important aspects of the SFE of actinide ions contained within various sources: (i) aqueous solutions, (ii) solid materials, (iii) pure actinide oxides. As most of the information available in the literature is related to U(VI), the examples discussed will predominantly concern this ion.

(a) Experimental setup and SFE procedures

Fig. 24.12 is a schematic of an experimental setup proposed by Tomioka *et al.* (2001a) for the SFE of metal ions from a metal oxide. A similar apparatus has been described by Wai and Laintz (1999). The carbon dioxide passes first through a vessel where it dissolves the contained ligand (solid or liquid). In the second vessel, the sc-CO_2 ligand solution then comes into contact with the actinide oxide to be extracted. Trofimov *et al.* (2001) recently showed that the use of ultrasound increases the solid dissolution rate. After extraction, the metal ion complex can be recovered by reducing both the pressure and temperature of the sc-CO_2 solution, leading to the precipitation of the metal ion complex and of the excess ligand. The CO_2 can subsequently be recycled. To perform this reduction of pressure and temperature, the loaded sc-CO_2 solution passes through a capillary restrictor made of silica or stainless steel. Wai *et al.* (1998) noted some drawbacks to using this technique, such as clogging of the capillary

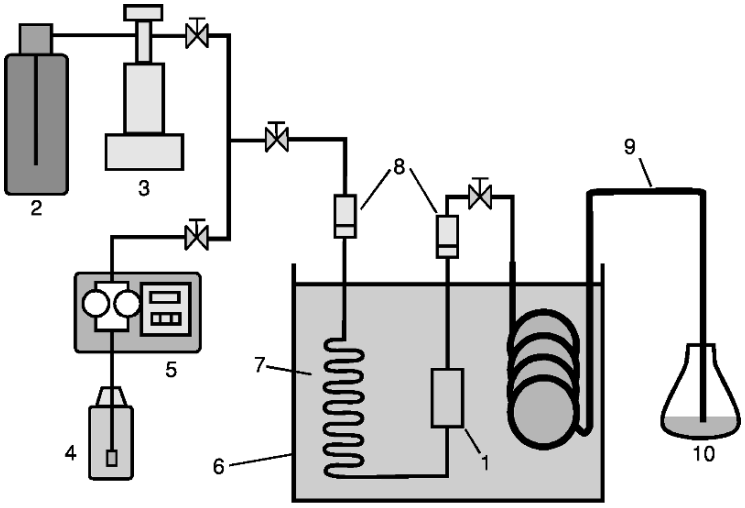

Fig. 24.12 *Apparatus for the dissolution of uranium oxide powder with supercritical CO_2 containing the HNO_3–TBP complex* (*adapted from Tomioka* et al., 2001*a*).

by the solutes, or breaking of the silica capillary in case of the use of sc-CO_2 modified with methanol. They therefore proposed an improved stripping method to eliminate these drawbacks by passing the loaded sc-CO_2 solution through an acidic aqueous solution while maintaining the pressure and temperature conditions of the SFE. Extraction of metal ions from aqueous solutions can be performed in such an apparatus with minor modifications.

Several systems have been developed to measure the concentration of the metal ion extracted into the sc-CO_2. The most popular uses a UV–visible spectrophotometric cell to measure colored metal ion complexes, as in the case of U(VI) (Furton *et al.*, 1995; Addleman *et al.*, 1998; Sasaki *et al.*, 1998). Recently, Wai and co-workers (Carrott and Wai, 1998; Hunt *et al.*, 1999) proposed sophisticated UV–visible measurement cells, with several light path lengths (38 μm, 733 μm, and 1 cm) coupled with optical fibers, the spectra being measured with a charge–coupled device array UV–visible spectrophotometer. In the case of SFE of U(VI), the same research group also proposed the use of a Raman measurement cell (Addleman *et al.*, 1998) or of a time-resolved laser-induced fluorescence spectrometry cell (TRLIFS) (Addleman *et al.*, 1998, 2000a,b; Addleman and Wai, 1999, 2000). The latter technique permits the measurement of U(VI) complexes under a wide range of concentrations.

The pressure and temperature conditions often chosen for SFE of metal ions are the following: pressure in the range 150–300 atm, temperature in the range 60–120°C. Frequently used conditions are 150 atm and 60°C. SFE of metal ions can be carried out in two modes:

(1) Static mode: The actinide containing sample and the sc-CO_2 fluid are placed in contact and stirred until the actinide distribution equilibrium is obtained. The actinide-loaded sc-CO_2 fluid is then removed from the extraction vessel.
(2) Dynamic mode: The sc-CO_2 fluid containing the extractant is continuously fed to the extraction vessel and the actinide-loaded sc-CO_2 fluid is then stripped online.

(b) SFE properties of actinide ions

(*i*) *Ligands*

Numerous ligands can be used for the SFE of actinide ions, most of which have also been used (or are structurally similar to reagents that have been used) in conventional solvent extraction. The most important ones are as follows.

β-Diketones

A ligand of this type, 2,2-dimethyl-6,6,7,7,8,8,8-heptafluoro-3,5-octanedione (FOD), was used by Wai and coworkers in the first article related to the SFE of actinide ions (Lin *et al.*, 1993). It was shown that about 99% of 10 μg of uranyl ion contained within uranyl acetate solutions at pH 1.0 or deposited on cellulose-based filter paper from a solution at pH 6.5, can be extracted under the following SFE conditions: 80 μg of FOD, sc-CO_2 containing 5% methanol, wet paper, 60°C; 150 atm. In another article, the same group (Lin *et al.*, 1994) studied the SFE efficiency of several β-diketones for Th(IV) and U(VI); the following ligands were studied: acetylacetone (AA), trifluoroacetylacetone (TAA), hexafluoroacetylacetone (HFA), thenoyltrifluoroacetone (TTA), and FOD. In the absence of methanol in the sc-CO_2 and all other SFE conditions being identical to those mentioned above, the extraction efficiency observed for U(VI) and Th(IV) were the following, respectively: 10 and 12% (AA), 15 and 22% (TAA), 40 and 69% (HFA), 51 and 80% (FOD), and 70 and 82% (TTA). The fluorinated β-diketones are the most effective ligands and among them TTA seems to be the best. Note that Th(IV) is slightly more strongly extracted than U(VI) under these conditions.

Neutral organophosphorous compounds

Organophosphates and phosphine oxides were the most studied neutral organophosphorous compounds for SFE of actinide ions. Work has principally focused on the use of TBP for the extraction of uranyl nitrate (Lin *et al.*, 1994, 1995; Iso *et al.*, 1995, 2000; Meguro *et al.*, 1996, 1997, 1998b, 2002;

Toews *et al*., 1996; Smart *et al*., 1997b; Carrott *et al*., 1998; Sasaki *et al*., 1998; Addleman *et al*., 2000a; Addleman and Wai, 2000, 2001; Enokida *et al*., 2000; Park *et al*., 2000; Tomioka *et al*., 2000, 2001a,b, 2002; Clifford *et al*., 2001; Shamsipur *et al*., 2001) This was certainly related to the observation of Toews *et al*. (1996) that of the three extractants TBP, tri-*n*-butylphosphine oxide (TBPO) and tri-*n*-octylphosphine oxide (TOPO), TBP was by far the most effective ligand for sc-CO_2 extraction and transport of uranyl nitrate. This is primarily a result of the greater solubility of TBP in sc-CO_2 relative to the phosphine oxides (Lin *et al*., 1995). Only a few reports concern the TBP-mediated SFE of other actinide ions: Th(IV) (Lin *et al*., 1995) and Pu(IV) (Iso *et al*., 2000). SFE of actinide ions (mostly U(VI) and Th(IV) by phosphine oxides has been the subject of a few reports (Lin *et al*., 1995; Toews *et al*., 1996; Wai *et al*., 1999; Addleman *et al*., 2000a; Shamsipur *et al*., 2001).

It should be noted that most of the research on the extraction of actinide ions by neutral organophosphorous ligands has been done by Wai (U.S.), Yoshida (Japan) and their coworkers. Some of the results related to the extraction of uranyl nitrate by TBP are presented here; other results related to this system will be presented later in this section. The extracted complex in sc-CO_2 has the same stoichiometry $[UO_2(NO_3)_2(TBP)_2]$ as is observed in conventional solvent extraction. The identity of the complex was established by Meguro *et al*. (1996) and confirmed by Wai *et al*. (1999) using the classical slope analysis method. This complex was characterized by UV–visible spectrophotometry (Addleman *et al*., 1998; Carrott *et al*., 1998; Sasaki *et al*., 1998), Raman spectrometry (Addleman *et al*., 1998), and TRLIFS (Addleman *et al*., 1998, 2000a,b; Addleman and Wai, 1999, 2000, 2001). TRLIFS was used in particular by Addleman and coworkers to determine the solubility of the U(VI) complex (Addleman *et al*., 2000a) and the $D_{U(VI)}$ values (Addleman and Wai, 2001), and for online measurement of the extracted U(VI) (Addleman *et al*., 2000b). The extraction kinetics of uranyl nitrate by TBP in sc-CO_2 are rapid (Wai *et al*., 1999) ($\sim$45 min) if the U(VI) source consists of aqueous solutions. With solid samples (tissue paper, soil, sand, etc.), the extraction of U(VI) requires more time. An efficient model for interpreting the kinetic aspects of the SFE extraction of uranyl nitrate by TBP in sc-CO_2 in dynamic mode was recently proposed by Clifford *et al*. (2001).

The value of $D_{U(VI)}$ is 2.0, for extraction by 0.3 mol L^{-1} TBP in sc-CO_2 at 60°C and 15 MPa from an aqueous solution of 3 mol L^{-1} HNO_3 (Iso *et al*., 2000). Under the same experimental conditions, the distribution ratio for Pu(IV) was found to be 3.1 (Iso *et al*., 2000). Other thermodynamic aspects of the extraction of uranyl nitrate by TBP are considered below in the discussion of the influence of pressure and temperature on the SFE of metal ions. Uranyl nitrate can be effectively extracted from various sources, such as aqueous solutions, whether acidic or neutral, and solid waste (cellulosic paper, contaminated soil or sand, metallic waste). The solubility of $UO_2(NO_3)_2(TBP)_2$ in sc-CO_2 was found to be the highest of all the metallic complexes studied so far (Meguro *et al*., 1996):

~0.43 mol L^{-1} at 40°C and 225 atm (Carrott *et al.*, 1998). This moderate solubility warrants consideration of process development for spent nuclear fuel reprocessing. Only a few reports have considered the use of bidentate neutral organophosphorous extractants. This is certainly due to the low solubility of these ligands in sc-CO_2, as shown by Meguro *et al.* (1998a) for dihexyl (*N,N,*-diethylcarbamoyl)methylphosphonate and for the octyl(phenyl)(*N,N*-diisobutyl)carbamoylmethylphosphine oxide (OΦCMPO).

Synergistic mixtures

In 1994, Lin *et al.* (1994) were the first to report the existence of synergistic phenomena for the SFE of U(VI) and Th(IV) ions. For example, with TTA and TBP extractants at 60°C and 150 atm, SFE was carried out in dynamic mode on samples consisting of sand (200 mg) contaminated with 10 μg of U and 10 μg of Th with the following results (U and Th extracted, respectively): TTA (80 μmol) = 72 and 74%; TBP (80 μmol) = 15 and 10%; TTA + TBP (40 μmol + 40 μmol) = 94 and 93%. A net synergistic effect was thus observed for the extraction of both actinide ions. Several papers related to SFE of actinide ions by diketones and neutral organophosphorous compound synergistic mixtures have been published since (Furton *et al.*, 1995; Lin *et al.*, 1998, 2001; Murzin *et al.*, 1998; Addleman *et al.*, 2000a, 2000b; Geertsen *et al.*, 2000).

(*ii*) *Modifiers*

The addition of a modifier can be an effective means of enhancing the extraction efficiency of sc-CO_2 extractant solutions. Methanol is the most widely used modifier. The use of methanol as an sc-CO_2 modifier was often reported when the ligands were β-diketones and their synergistic mixtures, but modifiers are not ordinarily used in the case of TBP alone. The following example illustrates the efficiency of methanol as an sc-CO_2 modifier. Lin *et al.* (1994) studied the SFE of U(VI) and Th(IV) with the β-diketones: AA, TAA, HFA, FOD, and TTA, with neat or 5% methanol-modified sc-CO_2. The following experimental conditions were chosen: 60°C, 150 atm, cellulose-based filter contaminated with 10 μg of U and 10 μg of Th, 80 μmol of ligand, dynamic extraction. The actinide ion extraction yields obtained for neat and 5% methanol-modified sc-CO_2, respectively, were as follows: AA (U = 10 and 45%; Th = 12 and 58%), TAA (U = 15 and 98%; Th = 22 and 95%), HFA (U = 40 and 95%; Th = 69 and 92%), FOD (U = 51 and 98%; Th = 80 and 97%), TTA (U = 70 and 96%; Th = 82 and 91%). The presence of methanol thus induces a net increase in uranium and thorium extraction efficiency, and this is certainly correlated to the increased polarity of the sc-fluid due to the presence of the modifier.

With SFE of solid samples, such as soil, sand or paper, it is also observed (Lin *et al.*, 1993) that a small amount of water must be added to obtain satisfactory metal ion extraction efficiency.

(c) Influence of pressure and temperature on SFE of actinide ions

The SFE efficiency of actinide ion complexes can be tuned by modifying the pressure and temperature conditions as well. To illustrate these properties, consider the TBP SFE of U(VI) and Pu(IV) nitrates from aqueous nitric acid solutions, as studied by Yoshida and coworkers (Iso *et al.*, 2000). At constant temperature and TBP concentration in sc-CO_2, an increase in pressure induces a decrease in $D_{U(VI)}$ and $D_{Pu(IV)}$ correlated with the higher density of the sc-fluid. A simple linear correlation between $D_{U(VI)}$ or $D_{Pu(IV)}$ and ρ is observed in log–log plots:

$$\log D = a \log \rho + b \qquad \text{(I)}$$

in which a is a proportionality constant related to the solvation characteristics of the metal complexes in sc-CO_2. The slopes a of the relationships were equal to $-(2.7 \pm 0.5)$ for U(VI) and $-(1.6 \pm 0.1)$ for Pu(IV). The differences in D as well as in the slope a between U(VI) and Pu(IV) make it possible to design a SFE scheme to separate uranium from plutonium. In the case of U(VI), for a temperature increase from 313 to 353 K and for a pressure of 40 MPa, $D_{U(VI)}$ decreases by a factor of about 2, as shown by Yoshida and coworkers (Meguro *et al.*, 1997; Iso *et al.*, 2000). Conversely, the same group (Iso *et al.*, 2000) has shown that $D_{Pu(IV)}$ increases with T, and the lower the pressure the greater the temperature effect.

The increase in the pressure of sc-CO_2 that induces an increase in the density of the sc-fluid has a large impact on the solubility of solutes. Chrastil (1982) demonstrated that the solubility S (g L^{-1}) of an organic solute in a sc-fluid is correlated with the density (g L^{-1}) of the sc-fluid by the following empirical relation

$$\ln S = \kappa \ln \rho + C \qquad \text{(II)}$$

where the value of k is related to the solute–solvent interactions and that of C to the volatility of the solute. Since then, equation (II) has also been found to represent variations of the solubility of metal ion complexes in sc-CO_2. A review of the solubility of chelating agents and their metal complexes has been published by Smart *et al.* (1997a). This equation was also shown to be usable to represent the solubility of actinide ion extractants and their complexes (Meguro *et al.*, 1998b). This is the case in particular for $UO_2(NO_3)_2(TBP)_2$ (Carrott *et al.*, 1998; Addleman *et al.*, 2000a) which, as noted above, is the metallic complex with the highest solubility in sc-CO_2.

(d) Sources of actinide ions for SFE

Several sources of actinide ions can be treated by SFE, including:

(1) Aqueous solutions: Acetate-buffered solution are often used when the extractants are β-diketones (Lin *et al.*, 1994), nitric acid, and nitric acid and alkali nitrate solutions (Lin *et al.*, 1995; Meguro *et al.*, 1996, 1997,

1998b; Smart *et al*., 1997b; Iso *et al*., 2000), uranium mine water (Lin *et al*., 1994).

(2) Solid matrices (surrogates or genuine wastes): Cellulosic filter paper (Lin *et al*., 1993, 1994; Brauer *et al*., 1994; Shamsipur *et al*., 2001; Kumar *et al*., 2002), sand (Tomioka *et al*., 2002), soil (Fox *et al*., 1999), kaolin (Furton *et al*., 1995), glass wool (Furton *et al*., 1995), metals (Murzin *et al*., 1998; Shadrin *et al*., 1998), asbestos (Murzin *et al*., 1998), rubber (Murzin *et al*., 1998), plastics (polyethylene, polyester) (Furton *et al*., 1995), contaminated with solid actinide compounds, such as nitrates or oxides,

(3) Actinide oxides: This case is particularly important in the light of the potential future applications, and is considered here in greater detail. Wai *et al*. (1997) filed a patent related to the SFE of metal ions directly from their oxides. They proposed as ligands numerous acidic compounds including β-diketones, phosphinic acids, and carboxylic acids. Better performance was seen for fluorinated derivatives. In 2000, Tomioka and coworkers (Enokida *et al*., 2000; Tomioka *et al*., 2000) described the dissolution of gadolinium and neodymium ions from their sesquioxides M_2O_3 (M=Gd and Nd) by the complex TBP–HNO_3 dissolved in sc-CO_2. Wai and Waller (2000) also demonstrated the efficiency of the SFE extraction of uranium from UO_3 by TTA or TTA + TBP synergistic mixtures. Several papers related to the dissolution of uranium oxides (UO_2, U_3O_8, and UO_3) by the TBP–HNO_3 complex have been published since then (Enokida *et al*., 2000; Samsonov *et al*., 2001; Tomioka *et al*., 2001a,b; Trofimov *et al*., 2001). The dissolution of UO_2 was less rapid than those of the two other oxides, but it is possible to increase the dissolution rates of oxides if the HNO_3/TBP molar ratio in sc-CO_2 is greater than 1. In a recent conference paper, Samsonov *et al*. (2002) reported the SFE of actinides from their oxides using TBP–HNO_3; the studied oxides were: ThO_2, UO_2, U_3O_8, and UO_3, NpO_2, and PuO_2. Under the experimental conditions [65°C, 250 atm, TBP–HNO_3 reagent in sc-CO_2, thrice-repeated alternation of static (10 min) and dynamic (15 min) extractions] it was shown that the extraction yields of U oxides were good (> 85% for the lowest value) while those of the oxides of Th, Np, and Pu were almost nil.

(e) Possible applications

(*i*) *Industrial processes*

(1) Spent nuclear fuel reprocessing: Smart and Clifford (2001) from BNFL (UK) filed an international patent in 2001 in which they claimed that the reprocessing of spent nuclear fuel will be possible using the SFE method. The several steps of the conceptual process flow sheet are the following: (i) oxidize decladding of spent fuel under oxygen at 600°C, (ii) SFE of uranium by treatment of the oxidized fuel with a sc-CO_2 solution containing

an acidic ligand like a β-diketone, (iii) separation of U from the other extracted ions in fractionation columns, and (iv) reduction of the volatile uranium complex by hydrogen to precipitate UO_2. Probably the most interesting reagent for such application is TBP–HNO_3 as noted by the teams of Wai and Yoshida.

(2) Actinide waste decontamination: As noted above, the efficiency of SFE extraction of actinides from miscellaneous solid wastes has been demonstrated. An interesting case was the demonstration by Shadrin *et al*. (1998) of the efficiency of SFE for decontamination (U, Np, Pu, and Am) of 'real-world' contaminated stainless steel. This could be a basis for further industrial developments.

(*ii*) *Analytical applications*

SF-chromatography has been used to develop analytical methods. Examples include the work of Martin-Daguet *et al*. (1997) and Geertsen *et al*. (2000) for the analysis of U(VI).

(f) Conclusions

SFE of actinide ions has been a very active research field since its inception a decade ago. Important nuclear applications may some day be developed, particularly in spent nuclear fuel reprocessing and nuclear waste decontamination. The observation by Wai *et al.* on dissolution of uranium oxides by sc-CO_2 solutions of HNO_3–TBP solutions is noteworthy. The Wipff group is examining the system using the techniques of computational chemistry (Baaden *et al*., 2002; Schurhammer and Wipff, 2003). However, fundamental understanding of the basic chemistry of actinide interactions in supercritical media lags far behind practical demonstrations. Considerable basic research and development studies are still required, but it is safe to say that the interest in this field is likely to increase in the future.

24.3.11 Actinides in room-temperature ionic liquids (RTILs)

Room temperature ionic liquids (RTILs) were discovered by Hurley and Wier (1951), who found that a mixture of $AlCl_3$ and ethylpyridinium bromide (EPB) in a 2:1 molar ratio melted at $-40°C$ and that this liquid is suitable for the electrodeposition of aluminum metal at room temperature. Research in this area has been pursued with two main objectives: the development of electrolytes for batteries, and the use of RTILs as 'green' liquids for the design of industrial processes for the synthesis of organic compounds. Though continuing research has established that this class of RTILs can indeed be quite toxic, these liquids are considered 'green' compared with traditional organic solvents used in the industry because they have no vapor pressure, hence no gaseous emissions, at

least from intact RTIL formulations. However, it should further be noted that many RTIL formulations are based on the use of hydrolytically unstable inorganic anions like PF_6^- (reacts with water to produce HF). For more information on the properties of these materials, see reviews by Hussey (1983) and Welton (1999). The interest in using RTILs to develop separation processes for metals, for example liquid–liquid extraction with hydrophobic RTILs, is quite recent, as noted in a review by Visser *et al.* (2002). This subject became a hot topic in the late 1990s.

The first paper dealing with an actinide in an RTIL, published in 1982 by De Waele *et al.* (1982), examined the electrochemical behavior of uranium(IV) in a Lewis acidic $AlCl_3$ + *N*(*n*-butyl)pyridinium chloride (BPC) RTIL. Since that time, about 20 papers including patents for separation applications related to the chemistry of actinides within RTILs have been published, most of them (16) being related to uranium. In this short review, after a brief presentation of RTILs, the main chemical properties of actinides in RTILs will be described and the possible uses of RTILs for actinide separation presented.

(a) A brief description of RTILs

RTILs (Carpio *et al.*, 1979; Hussey, 1983; Visser *et al.*, 2002) are salts made of organic cations, such as: (i) *N*-alkyl quaternary ammonium, R_4N^+, (ii) *N*-alkyl pyridinium, (iii) *N*-alkylisoquinolinium, (iv) 1-*N*-alkyl-3-methylimidazolium, (v) *N*-alkyl quaternary phosphonium, R_4P^+, associated with various anions, e.g. halides (Cl^-, Br^-), haloaluminates (chloro or bromo), chlorocuprate ($CuCl_2^-$), tetraalkylborides (R_4B^-), NO_3^-, $CF_3CO_2^-$, BF_4^-, PF_6^-, and $N(SO_2CF_3)_2^-$. With the anions BF_4^-, PF_6^-, $N(SO_2CF_3)_2^-$, the RTILs are most often hydrophobic and can be used, for example, for the development of liquid–liquid extraction separation processes (Visser *et al.*, 2002). Nevertheless, most of the work related to actinides concerns RTILs of $AlCl_3$ and *N*-alkylpyridinium or *N*-alkylmethylimidazolium chlorides (called APC and AMIC, respectively). Both classes are highly sensitive to moisture. Recent work concerning the use of RTILs for nuclear fuel reprocessing is based on an RTIL made of *N*-alkylmethylimidazolium nitrate (Thied *et al.*, 1999). RTILs with nitrate anions were mentioned for the first time by Lane (1953).

The physical properties, such as the density, viscosity, or electric conductivity of RTILs consisting of mixtures of $AlCl_3$ and APC or AMIC have been the subject of numerous measurements (Carpio *et al.*, 1979; Hussey, 1983; Fannin *et al.*, 1984). The density of these melts exceeds 1 kg dm^{-3}; although most of them are quite viscous, their conductivity is suitable for electrochemical applications. The chemistry of these melts is dominated by the Lewis chloro-acidity. Depending on the molar ratio (M_r) of $AlCl_3$ versus APC or AMIC, the chloro-acidity (which can be expressed as pCl^- with low and high pCl^- for basic and acidic melts, respectively) of the melts varies. For $M_r = 1, > 1$, and < 1, the melts are neutral, acidic, and basic, respectively. The main reactions between

aluminum chloride and the chloride ion occurring in these melts that control pCl^- are the following:

$$AlCl_3 + Cl^- \rightleftarrows AlCl_4^- \tag{24.23}$$

$$AlCl_4^- + AlCl_3 \rightleftarrows Al_2Cl_7^- \tag{24.24}$$

For these melts, pCl^- can vary between ~0 and 15 for highly basic and highly acidic melts, respectively, as shown by Schoebrechts and Gilbert (1985) for RTILs containing mixtures of $AlCl_3$ and *n*-butylpyridinium chloride. If oxygen-bearing compounds such as water are present in these melts, aluminum oxochloro complexes, e.g. $AlOCl_3^{2-}$, are formed that can influence the chemistry of the other metallic solutes. An ^{17}O NMR study of water in these melts was carried out by Zawodzinski and Osteryoung (1987a,b). One of the main advantages of these RTILs is the large electrochemical window available. For example, for melts made of mixtures of $AlCl_3$ and 1-ethyl-3-methylimidazolium chloride (EMIC), Gray *et al.* (1995) noted the following values for the electrochemical window (ΔV):

(i) neutral melt: $\Delta V = 4.7$ V, between the anodic $4\,AlCl_4^- \rightleftharpoons 2Al_2Cl_7^- + Cl_2 + 2\,e^-$ and cathodic $Na^+ + e^- \rightleftharpoons Na$ or ($EMI^+ + ne^- \rightarrow$ unknown coompound) reactions,

(ii) acidic melt: $\Delta V = 2.5$ V, between the anodic $4\,AlCl_4^- \rightleftharpoons 2Al_2Cl_7^- + Cl_2 + 2\,e^-$ and cathodic $4\,Al_2Cl_7^- + 3\,e^- \rightleftharpoons Al + 7AlCl_4^-$ reactions,

(iii) basic melt: $\Delta V = 3.3$ V, between the anodic $2\,Cl^- \rightleftharpoons Cl_2 + 2\,e^-$ and cathodic $Na^+ + e^- \rightleftharpoons Na$ (or $EMI^+ + ne^- \rightarrow$ unknown compound) reactions.

(b) Basic actinide properties in RTILs

Almost all studies of actinide chemistry in RTILs have been done in materials obtained by mixing $AlCl_3$ with APC or AMIC. The only exception is the work reported by Mohammed (1987) who also studied the properties of uranium within RTILs made of mixtures of $AlBr_3$ and EMI bromide. Most of the published work (16 papers) concerns uranium. Neptunium and plutonium were the subjects of only one and three papers, respectively. No work related to other actinides was found in the literature.

(c) Uranium chemistry in RTILs made of mixtures of $AlCl_3$ and APC or AMIC

The chemistry of uranium within these melts has been studied using electrochemical and spectrochemical methods. The most detailed spectrometric study by Costa and coworkers (Hopkins *et al.*, 2000, 2001) concerned the U(VI) chloro complex, $UO_2Cl_4^{2-}$, in basic ($AlCl_3$ + EMIC) RTIL, carried out by

UV–visible–NIR, Raman, and one-photon and two-photon excitation spectroscopy, and by luminescence lifetime measurements. As will appear from the references in the next sections, many research groups have been involved in the study of the properties of actinides in RTILs. A brief summary of the properties of U in basic or acidic ($AlCl_3$ + EMIC) RTILs, used as an example of this type of RTIL, is presented below.

(*i*) *Basic* (*$AlCl_3$ + EMIC*) *RTILs*

Uranium can exist in these basic ($AlCl_3$ + EMIC) RTILs as U(III), U(IV), and U(VI). U(V) was not stable in these basic melts as noted by Dai *et al.* (1997b). The chemical forms for the stable uranium solutes are the following: UCl_6^{3-} for U(III), UCl_6^{2-} for U(IV), and $UO_2Cl_4^{2-}$ for U(VI). These species have been characterized mainly by UV–visible–NIR spectroscopy. In the case of U(VI) species, Dai *et al.* (1997a) observed that it is certainly stabilized in the medium by establishing a hydrogen bond with the H born by the carbon in position 2 on the heterocycle ring of the EMI^+ cation.

The diffusion coefficients of U(III) and U(IV) chloro complexes have been determined electrochemically and both values were found to be similar (1.61 and 1.85×10^{-7} $cm^2\ s^{-1}$, respectively) and compatible with the 1:6 stoichiometry between U(III) or U(IV) ions and the Cl^- ligand within the complexes. The electrochemical reaction $UCl_6^{2-} + e^- \rightleftharpoons UCl_6^{3-}$ was found to be reversible. Conversely, no reduction of U(IV) to U(III) was observed in basic RTILs made of mixtures of $AlCl_3$ and BPC, as shown by Heerman *et al.* (1985). This difference is a result of the reduction potential of BP^+ being higher than that of EMI^+. Thus, BP^+ can oxidize U(III) to U(IV). The U(VI)/U(IV) electrochemical conversion in [$AlCl_3$ + EMIC] RTILs is irreversible. Moreover, no reduction of U(III) to U metal was observed.

(*ii*) *Acidic* (*$AlCl_3$ + EMIC*) *RTILs*

Owing to the large decrease of the concentration of Cl^- in the acidic ($AlCl_3$ + EMIC) RTILs compared with the basic melts, the chloro complexes of U(III), U(IV), U(VI) are destabilized. Note that U(VI) is not chemically stable in these media. It is converted to U(V) species, the ultimate complex being UCl_6^-, after reduction and loss of oxide ions (Anderson *et al.*, 1999). The UCl_6^- complex was also observed by Sinha (1986) in ($AlCl_3$ + BPC) RTIL. It should be noted that U(V) was found to be stable in these RTILs. Moreover, if oxide ions are present in these RTILs, mixed oxo-chloro complexes can be formed. The chemistry of these RTILs is thus more complex than for the basic melts. After extensive electrochemical and spectrochemical work, Costa *et al.* (2000) proposed a general scheme (Fig. 24.13) for the inter-conversion of U(VI), U(V), U(IV), and U(III) species by chemical and electrochemical equilibria in acidic ($AlCl_3$ + EMIC) RTILs.

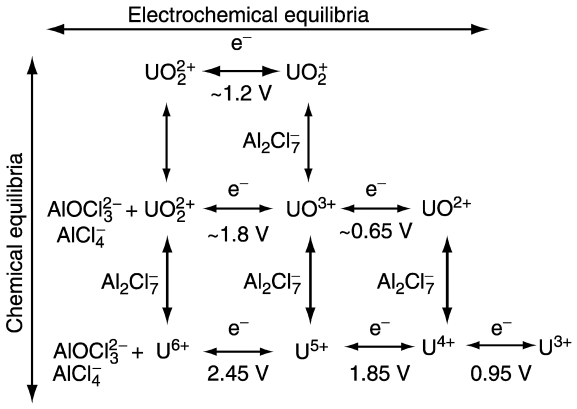

Fig. 24.13 *Mechanism for the inter-conversion of the different chemical forms of uranium within acidic RTILs* (*Costa* et al., 2000) (*note that the* Cl^- *ligands bound to the U ions are not shown for clarity*).

(d) Neptunium chemistry in basic and acidic ($AlCl_3$ + BPC) RTILs

Schoebrechts and Gilbert (1985) published the only paper on neptunium chemistry in ionic liquids. In acidic as well as in basic RTILs, the electrochemical reduction of Np(IV) to Np(III) is quasi-reversible on a glassy carbon electrode. UV–visible and Raman spectra indicated that Np(IV) and Np(III) both exist as hexachloro complexes in basic media. For acidic melts, these complexes are destabilized and Np(III) was found to lose more Cl^- ligands than Np(IV). These results are close to those observed for U in ($AlCl_3$ + EMIC) RTILs mentioned above.

(e) Plutonium chemistry in basic and acidic ($AlCl_3$ + EMIC) RTILs

Costa *et al*. (2000) published the only fundamental paper related to plutonium chemistry in basic and acidic ($AlCl_3$ + EMIC) RTILs. In basic RTIL, the reversible redox couple Pu(IV)/Pu(III) was observed at +0.37 V [the reference electrode being an aluminum metal wire in a 40/60 basic ($AlCl_3$ + EMIC) RTIL]. For acidic melts, the electrochemical behavior of plutonium resembles that described above for uranium, with the involvement of the plutonium oxidation states 6+, 5+, 5+, and 3+, and the existence of chloro and oxo-chloro complexes (Fig. 24.13). Further work is required for a more precise understanding of the chemistry of plutonium in these RTILs.

(f) Possible separation techniques for actinides using RTILs

The potential interest of using RTILs in the industrial processing of actinide nuclear materials is being tested by a team led by Costa at Los Alamos National Laboratory (USA) which studied plutonium processing (Costa *et al*., 2000;

Harmon *et al*., 2001). Another team in UK led by Seddon supported by British Nuclear Fuels Plc, proposes the use of RTILs for the reprocessing of commercial spent nuclear fuels and the treatment of nuclear wastes. In recent years, this team filed several patents in this area (Fields *et al*., 1998, 1999; Thied *et al*., 1999, 2001). Several techniques that could be used in processing nuclear materials within RTILs are briefly described in the following sections.

(*i*) *Dissolution*

Dissolution of solid actinide compounds in RTILs has been established. UO_3 readily dissolves in basic ($AlCl_3$ + BPC, Heerman *et al*., 1985; $AlCl_3$ + EMIC) RTILs (Anderson, 1990; Anderson *et al*., 1991). As shown by the patent of Fields *et al*. (1998), UO_2 dissolves in RTIL made of nitrates of BP^+ or EMI^+. This requires the presence of an oxidant to convert U(IV) (from UO_2) into soluble U(VI). Suitable oxidants include HNO_3, H_2SO_4, and $[NO][BF_4]$. These nitrate-based RTILs are the main new media proposed by BNFL for nuclear spent fuel reprocessing: in their patent, Thied *et al*. (2001) have shown that uranium and plutonium *metals* can be dissolved by anodic electrochemical oxidation in BMI nitrate (for U at room temperature) and EMIC (for Pu at 90°C).

(*ii*) *Precipitation*

U(VI) can be precipitated from an RTIL of BMI nitrate in the form of a crystalline compound (Bradley *et al*., 2002) with the formula $[\{(UO_2)(NO_3)_2\}_2(C_2O_4)][BMI]_2$. The source of the oxalate anion that induces the precipitation of U(VI) can be acetone, being oxidized to oxalate by the medium.

(*iii*) *Electrodeposition of metals*

Thied *et al*. (2001) claimed the feasibility of electrorefining uranium in molten hexylethylimidazolium (HEI) chloride at 70°C using a uranium metal rod anode and a copper cathode. During the experiment described, for a total of 236 Coulombs passed in the electrochemical cell, 193 mg of uranium metal was dissolved from the anode as U(III) species in the melt and 18.7 mg of uranium was deposited on the copper cathode. Solid material was found at the bottom of the cell, indicating that deposited uranium does not adhere well to copper. An identical experiment was performed for plutonium, but no plutonium deposit was observed on the cathode.

More work is necessary in the domain of electrodeposition of actinide metals from RTILs. The experience accumulated in the field of electrodeposition of metals could be used to select suitable systems. RTILs made of AMI^+ cations are preferable owing to the low potential required for the reduction of AMI^+. For example, in melts made of neutral ($AlCl_3$ + EMIC), the electrodeposition of

lithium and sodium metals can be performed if the solutes HCl (Gray *et al.*, 1995) or SO_2Cl_2 (Fuller *et al.*, 1995) are present in the melts. Tsuda *et al.* (2001, 2002) also studied the electrodeposition of lanthanum metal or Al–La alloy from ($AlCl_3$ + EMIC) RTIL.

(*iv*) *Liquid–liquid extraction*

Liquid–liquid extraction of metal ions is possible with hydrophobic RTILs based on the use of the anions: BF_4^-, PF_6^-, and $N(SO_2CF_3)_2^-$. The first work was published by Dai *et al.* (1999) who showed that Sr(II) can be very efficiently extracted from aqueous solutions by a crown ether dissolved in RTILs made of AMI^+ cations and the anions PF_6^- or $N(SO_2CF_3)_2^-$. Subsequent investigations (Jensen *et al.*, 2002b, 2003) have established that the elevated distribution ratios and resistance to back extraction exhibited by this system are at least in part a result of extraction occurring by a cation exchange mechanism in which the AMI^+ cation is transferred (irreversibly) to the aqueous phase. Since then, Rogers and his co-workers published several important papers in this field (Visser *et al.*, 2000a,b, 2001a,b) including a review paper (Visser *et al.*, 2002).

A few reports address features of the partitioning of actinides into RTILs (Davis, 2002; Visser and Rogers, 2002; Visser *et al.*, 2003). This system likewise is impacted by the problem of undesirable partitioning of the hydrophobic cation to the aqueous and irreversibility of the phase transfer reaction (Jensen *et al.*, 2003). Much additional work is required before this simple solvent-substitution approach to improving actinide separations with RTILs can be established.

(g) Conclusions

The chemistry of the actinides in RTILs is still in its infancy. Due to the recent impetus given by several research teams in the U.S. and UK, growing interest can be expected worldwide in this field owing, in particular, to the interesting practical applications that could be designed for the nuclear industry. Issues related to biphasic instability, generation of HF, the expense and toxicity of the RTILs may prove a significant obstacle to any efforts for an early implementation of these compounds in actinide process chemistry.

24.3.12 Pyrochemical processes

Pyrochemical processing involves the conduct of dry chemical reactions at high temperature in which the reactions occur in solid, liquid, and gas phases. Oxidation–reduction, volatilization (of halide or metal), slagging (melt refining, molten salt extraction, carbide slagging), liquid metal (melt refining, liquid metal extraction, liquation, precipitation), and electrolytic processes are the most common types.

Molten salts – or fused salts – lead to operating conditions that are constraining: high temperatures are required and corrosion effects are common, making identification of appropriate containers quite difficult. However, metallurgists use molten salts for electrolytic production of some metallic products, notably for refining very electropositive elements and strong reducing agent such as alkali metals. Potassium and sodium metals were first prepared in 1807 by using melt electrolysis of respectively potash and soda (Davy, 1808). Today melt electrolysis (alkali chloride) remains the only process for production of metallic sodium or lithium. Molten salt refining is also appropriate for aluminum, which is obtained by electrolytic decomposition of aluminum oxide in molten cryolite (Hall–Héroult process) (Grojtheim *et al.*, 1982).

Essential to the examples above, molten salts also have some properties which make them attractive for nuclear applications: (i) they are less subject to radiolytic degradation than aqueous media due to their ionic liquid structure; (ii) criticality concerns and problems are reduced due to the absence of neutron moderating elements and organic solvents. These properties in particular enable the processing of materials producing high radiation loadings, for example, high concentrations of fissile materials like spent nuclear fuels after a short cooling interval. In addition, it is possible to reduce the number of chemical conversion steps compared to those needed for aqueous processes. The first significant attempts at actinide metal production in molten salts started with the Manhattan Project in the 1940s (Rhodes, 1986). Significantly, Kolodney (1982) confirmed that uranium and plutonium could be electrodeposited from molten chlorides. The literature on U and Pu electrorefining in molten salts has been reviewed by Willit *et al.* (1992). Basic chemistry and technologies developed in Russia have been described by Bychkov and Skiba (1999).

Today, molten alkali and alkaline earth chlorides have been most extensively studied for plutonium conversion and separation. Three processes are in use throughout the world at significant scale-up (Moser and Navratil, 1983): (i) direct oxide reduction (DOR) process which consists of PuO_2 reduction by calcium in Ca-based chloride salt; (ii) molten salt extraction (MSE) process for ^{241}Am removal from weapon-grade plutonium by $MgCl_2$ in alkali chloride salt; (iii) electrorefining (ER) process for high plutonium purification using molten alkali and/or alkaline earth chloride electrolyte.

Pyroprocessing has also been proposed and developed for reducing the cost of fuel fabrication and fuel reprocessing (Motta, 1956). Between 1964 and 1969, a rudimentary process without molten salts – melt refining – was first demonstrated in Idaho Falls to recycle metallic fuel from the second experimental breeder reactor (EBR-II) (Trice and Chellew, 1961; Stevenson, 1987).

At the same time in the former USSR, emerged a concept of vibropacked fuel fabrication for fast reactors and pyroelectrochemical reprocessing based on electrolysis of oxide fuel in molten alkali chlorides. After being applied to UOX fuel, the Dimitrovgrad Dry Process (DDP) process has been adapted today for

MOX fuel reprocessing and weapon-grade plutonium conversion into plutonium oxide for civilian use in Russian fast reactors (Bychkov *et al.*, 1995; Skiba and Ivanov, 1995).

Due to the low burn-ups that have been achieved with EBR-II and for safety considerations, the interest in metal fuels declined in the U.S. for the next 15 years while ceramic fuel development, mainly oxides, increased (Burris, 1986). Consequently, molten salt process development slowed in the U.S. In the mid-1980s, interest of molten salts was renewed by the integral fast reactor concept proposed by Argonne National Laboratory (Till and Chang, 1988; Chang, 1989; Hannum, 1997). A combination of the electrometallurgical technology (EMT) and a set of molten salt/liquid alloy extractions was selected for overall actinide management purposes in the IFR fuel cycle (metallic alloy of U, Pu, and Zr) (Burris *et al.*, 1987). EMT consists of electrorefining the reactor fuel in LiCl–KCl melt at 500°C in an inert atmosphere: (i) the fuel in metallic form is dissolved at the anode, (ii) uranium, plutonium, and other transuranium elements are selectively deposited on solid or liquid cathode (e.g. cadmium), (iii) cladding material and fission products are left at the anode and/or in the electrolyte. In parallel, a pyrometallurgical process for the recovery of the transuranium elements from irradiated oxide fuels was initiated as a means of providing a source of plutonium for the start-up of additional IFRs (Pierce, 1991).

After the IFR program was stopped in 1994, EMT development was sufficiently advanced to be proposed for new applications: DOE spent nuclear fuel reconditioning (Laidler, 1994). A demonstration campaign (1996–1999) on spent EBR-II fuel in Idaho Falls used EMT for converting the fuel to a safe configuration by eliminating the sodium seal and recovering high enriched uranium for interim storage.

EMT is now being considered around the world for various fuel cycle concepts. Japan calls for the development of: (i) a global fuel cycle combining oxide fuel in pressurized water reactors (PWR) with transmutation of actinides as metal fuel in fast neutron reactors and (ii) a ^{15}N-enriched nitride fuel cycle involving molten salt reprocessing for ^{15}N management. For both projects, spent fuel reprocessing should take place in a LiCl–KCl melt using previous separation techniques: DOR process (lithium substituting calcium), ER process on solid or liquid cathode, and MSE process (Inoue *et al.*, 1991; Arai and Yamashita, 1997; Takano *et al.*, 1998).

Researchers in the U.S. recently have proposed a baseline process combining aqueous and pyrochemical processes in the framework of the preparation of a technology development roadmap for the accelerator transmutation of waste (ATW) Technology (ATW Separations, 1999). The process begins with an aqueous 'UREX' process that would produce from light water reactor (LWR) spent fuel a pure U stream for waste, technetium, and iodine streams for target fabrication and a transuranium elements–fission product oxide stream. Using pyroprocessing, this oxide stream would be treated for converting TRU elements to a metallic form suitable for fabrication of ATW fuel (based on Zr).

The pyroprocessing should involve two steps: (i) DOR process with Li in LiCl melt to reduce the actinide oxides to the metallic form and (ii) EMT in LiCl–KCl melt to separate transuranium elements from the remaining fission products. The baseline option for ATW irradiated fuel processing would rest on a chloride volatility process for zirconium separation coupled to an electrowinning process in LiCl–KCl for TRU and fission product separation.

Since the mid-1990s, countries of the European Community (Great Britain, France, Spain, Italy), the European Institute for Transuranium Elements (Karlsruhe, Germany), and the Czech Republic have launched research programs for the development of molten salt chemistry and technology for various applications (Partitioning & Transmutation, future fuel cycles). At present, these programs only involve work at the laboratory scale on fundamental aspects or small pilot projects.

Finally, a fused medium in which fuel and reprocessing are strongly connected concerns molten fluorides. In the past, molten fluorides have been developed as fuel and coolant in molten salt reactor systems. The development was largely carried out at Oak Ridge National Laboratory in the 1960s for the molten salt breeder reactor concept, using molten $LiF–BeF_2$ solutions. Today molten salt reactor development has been stopped, though some countries continue isolated investigations (e.g. Czech Republic or Russia).

(a) Chemistry of actinides in major salts – general considerations

As noted above, all the significant pyrochemical technology developments for plutonium conversion and for oxide, metal, or nitride fuel reprocessing call essentially for halide systems: molten chlorides of alkaline and alkaline earth metals, molten fluorides of different cation compositions. Other salt systems, based on oxy-anion salts, have been proposed as backup process or for exotic fuel processing. The most common salts of alkali metals are nitrates, sulfates, molybdates, and tungstates.

Both fundamental and technological progress was reported at the beginning of the 1990s. In this section, after a presentation of the main chemical properties of actinides in molten salts, the principles of separation techniques will be described and main ongoing work on pyroreprocessing in the nuclear industry will be presented. For more detailed information, the reader is referred to the literature cited herein. Molten salt chemistry of actinides has been reviewed previously by Martinot (1991).

(b) Molten chlorides

(*i*) *Thorium*

Anhydrous $ThCl_4$ is colorless and is prepared, among other techniques, by reacting a mixture of $CCl_4 + Cl_2$ gases on ThO_2 at 600°C (Cuthbert, 1958). Dissolved in a KCl melt, thorium exists in the tetravalent oxidation state.

The existence of Th(II) has been reported (Smirnov and Ivanovskii, 1957), but this conclusion also has been disputed (Martinot, 1991). Apparent standard potentials of Th(IV)/Th(0) (relative to the Cl_2/Cl^-, mole fraction couple) are –2.52, –2.50, and –2.47 V at 673, 723, and 773 K, respectively, in LiCl–KCl eutectic (Martinot *et al.*, 1977) and $-3.109 + 6.3810^{-4}T$ (923–973 K) (in volts) in NaCl–KCl eutectic (Srinivasan and Flengas, 1964). Activity coefficient at infinite dilution in LiCl–KCl and NaCl–KCl, solubility product of ThO_2 in LiCl–KCl and NaCl–KCl, potential–pO^{2-} diagram in LiCl–KCl with $[Th(IV)] = 10^{-2}$ M are given by Martinot (1986, 1991).

(*ii*) *Protactinium*

Anhydrous $PaCl_4$ is prepared from PaO_2 by reacting with CCl_4 at 300°C (Stein, 1964) while $PaCl_5$ is obtained from Pa_2O_5 reactions with $SOCl_2$ at 400°C (Brown and Jones, 1966; Hendricks *et al.*, 1971). Pa(V) is reduced in chloride melts to Pa(IV). Apparent standard potential of Pa(IV)/Pa(0) (referred to Cl_2/Cl^-, mole fraction) are –2.35, –2.32, and –2.29 V at 673, 723, and 773 K, respectively, in LiCl–KCl eutectic (Martinot *et al.*, 1980). Activity coefficient at infinite dilution, solubility product of PaO_2 and potential–pO^{2-} diagram in LiCl–KCl with $[Pa(IV)] = 10^{-2}$ M are given by Martinot and Fuger (1986, 1991).

(*iii*) *Uranium*

A great deal of work has been done in the past in binary melts (NaCl–KCl, LiCl–KCl, NaCl–CsCl), in NaCl–KCl–$BaCl_2$, NaCl–KCl–$MgCl_2$, LiCl–NaCl–$CaCl_2$–$BaCl_2$, and the results have been reviewed (Martinot, 1991; Willit *et al.*, 1992; Bychkov and Skiba, 1999). Some results in LiCl–KCl have been published as well (Roy *et al.*, 1996; Sakamura *et al.*, 1998; Shirai *et al.*, 1998). The reader is referred to these papers for more detailed information. Only values related to melts in use in the current EMT development are reported hereafter. It essentially concerns three alkali chloride eutectics: NaCl–KCl, NaCl–2CsCl, and 3LiCl–2KCl.

Uranium in NaCl–KCl

The first EMF measurements, referred to Ag/AgCl (5 mol%) or Cl_2/Cl^- electrodes, have been made from 700 to 850°C (Flengas, 1961; Smirnov and Skiba, 1963). These authors reported only the U(III)/U(0) and U(IV)/U(III) couples. Martinot and coworkers gave the temperature dependence of the several apparent standard potentials (referred to Cl_2/Cl^- electrode). At 700°C (Martinot and Ligot, 1989; Martinot, 1991), $E°[U(III)/U(0)] = -2.49$ V, $E°[U(IV)/U(III)] = -1.33$ V, and $E°[U(V)/UO_2] = -0.80$ V. A recent review (Bychkov and Skiba, 1999) reports 'formal electrode potential' at 727°C (referred to Cl_2/Cl^- electrode): $E°[U(III)/U(0)] = -2.19$ V, $E°[U(IV)/U(III)] = -1.39$ V, and $E°[U(VI)/UO_2] = -0.40$ V. Willit *et al.* (1992) report that the formal potential

incorporates both standard potential and ratio of activity coefficients of the oxidized and reduced species.

Activity coefficients for U(IV) and U(III) are available at various temperatures (Flengas, 1961; Martinot *et al.*, 1975; Martinot, 1991). Diffusion coefficients for U(IV) and U(III) at 700°C have been determined (Willit *et al.*, 1992). Martinot and Ligot (1989) and Martinot (1991) also report the temperature dependence of the solubility product of UO_2; a potential–pO^{2-} diagram has been calculated for [U(V)] = [U(IV)] = [U(III)] = 10^{-2} M. These authors claim that U(VI) does not exist at equilibrium and that the stability area of U(V) is very wide in comparison with the other chloride melts.

Uranium in NaCl–2CsCl

Investigations in the eutectic have been made in the framework of the DDP process development. Few data are available in the open literature. Formal electrode potentials (referred to Cl_2/Cl^- electrode) are given at 727°C: $E°$[U(III)/U(0)] = –2.39 V, $E°$[U(IV)/U(0)] = –1.45 V, and $E°$[U(VI)/UO_2] = –0.65 V (Bychkov and Skiba, 1999).

Uranium in 3LiCl–2KCl

U(III), U(IV), and U(VI) have been identified spectrophotometrically in LiCl–KCl melt (Gruen *et al.*, 1960). At present, the existence of U(V) is no longer considered in dispute (Martinot, 1991). As for the NaCl–KCl eutectic, historic background and basic data have been reported in previous reviews (Martinot, 1991; Willit *et al.,* 1992; Bychkov and Skiba, 1999). Several apparent standard potentials (referred to Cl_2/Cl^-, molar fraction) are available from Martinot (1991): at 450°C, $E°$[U(III)/U(0)] = –2.59 V, $E°$[U(IV)/U(III)] = –1.49 V, $E°$[U(VI)/U(V)] = –0.84 V, and $E°$[U(VI)/UO_2] = –0.81 V. Data from Russian studies are summarized at 500°C by Bychkov and Skiba (1999): $E°$[U(III)/U(0)] = –2.31 V, $E°$[U(IV)/U(III)] = –1.40 V, and $E°$[U(VI)/UO_2] = –0.50 V, all referred to Cl_2/Cl^-. Recent results on the U(III)/U(0) couple (Roy *et al.*, 1996; Sakamura *et al.*, 1998) give at 450°C $E°$ = –1.287 V vs Ag/AgCl (–2.498 V vs Cl_2/Cl^-), which is consistent with other reports.

Activity coefficients at infinite dilution for U(IV) and U(III) are given as a function of temperature (Martinot, 1975, 1991). New calculations have been made recently by Roy *et al.* (1996) and by Betchel and Storvick (1999). Roy and coworkers indicate non-ideal solution behavior for U(III) (activity coefficient is 3.1×10^{-3} at 450°C). Diffusion coefficients for U(IV), U(III) and U(VI) have been determined by Caligara *et al.* (1968) for the range of temperature 400–550°C; other studies of U(III) and U(IV) have been reviewed by Willit *et al.* (1992). $D_{U(III)}$ is typically between 4.1 and 10.3 $\times$ 10^{-3} cm^2s^{-1}. Using the values of UO_2 solubility product (Martinot and Fuger, 1986), Martinot (1991) has calculated potential–pO^{2-} diagram at 450°C (Fig. 24.14). The stability area of U(V) is rather narrow in comparison with NaCl–KCl eutectic.

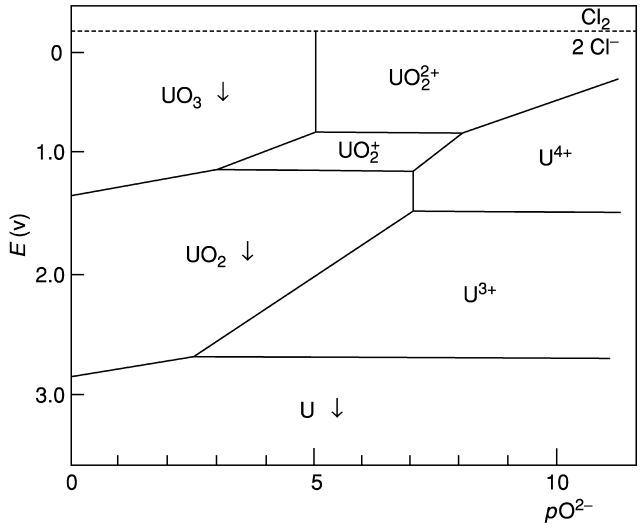

Fig. 24.14 *Potential–pO^{2-} diagram for* [*U*(*IV*)] = [*U*(*III*)] = [*U*(*IV*)] = [*U*(*V*)] = 10^{-2} M *in* 3*LiCl–2KCl at* 450°C (*Martinot*, 1991).

(*iv*) *Neptunium*

Neptunium has been the subject of fewer investigations than uranium. Its chemical behavior has been most extensively studied in alkali chloride melts. In the eutectic (3LiCl–2KCl), the 3+, 4+, and 5+ oxidation states have been identified spectrophotometrically (Gruen *et al.*, 1960). Np(IV), Np(III), and Np(V) are stable species while Np(VI) does not exist as a stable species. Np(VI) is reduced by chloride ions to Np(V) (Martinot, 1991). Standard potentials for Np(III)/Np(0), Np(IV)/Np(III), and Np(V)/NpO_2 have been measured (vs Cl_2/Cl^-, molar fraction) at various temperatures by Martinot and coworkers (Martinot *et al.*, 1967; Martinot and Duyckaerts, 1969a,b). At 450°C, the standard potentials are: E°[Np(III)/Np(0)] = –2.41 V, E°[Np(IV)/Np(III)] = –0.70 V, and E°[Np(V)/NpO_2] = –0.32 V (Martinot, 1991). Bychkov and Skiba (1999) report formal potentials (vs Cl_2/Cl^-, molar fraction) at 500°C: E°[Np(III)/Np(0)] = –2.315 V, E°[Np(IV)/Np(III)] = –1.51 V, and E°[Np(V)/NpO_2] = –0.32 V (450°C). The latest reports from Roy and coworkers (Roy *et al.*, 1996; Sakamura *et al.*, 1998) give for Np(III)/Np(0) E° = –1.487 V vs Ag/AgCl (i.e. –2.698V vs Cl_2/Cl^-). Discrepancies in the results could possibly be explained by the variety of experimental arrangements.

Activity coefficient of Np(III) and diffusion coefficients of Np(III), Np(IV), and Np(V) are available in the literature (Martinot, 1975, 1986, 1991). $D_{Np(III)}$ is equal to $(4.6 \pm 0.2) \times 10^{-6}$ cm^2 s^{-1} at 400°C. The solubility product of NpO_2 has also been measured as a function of temperature by Martinot and

Fuger (1986). Potential–pO^{2-} diagram has been calculated for [Np(V)] = [Np(IV)] = [Np(III)] = 10^{-2} M at 450°C (Martinot, 1986, 1991).

(*v*) *Plutonium*

The electrochemistry of plutonium in molten chlorides was studied early driven by the belief that electrorefining could be a method of purification of plutonium notably for military applications (Brodsky and Carleson, 1962; Mullins and Leary, 1965). Willit *et al*. (1992) have published a useful review on the technological aspects. The melts investigated include LiCl–KCl, NaCl–KCl, $BaCl_2$–KCl, $BaCl_2$–$CaCl_2$–LiCl—NaCl, and NaCl–$CaCl_2$. The most stable oxidation state of plutonium in alkali chloride melts is the trivalent state. Chronopotentiometric and potentiometric studies carried out in the 1960s and 1970s to understand the mechanism of Pu(III) reduction (Campbell and Leary, 1966; Nissen, 1966; Martinot, 1991; Bychkov and Skiba, 1999) have been recently repeated (Roy *et al*., 1996; Sakamura *et al*., 1998, 2001; Shirai *et al*., 1998, 2001). Campbell and Leary (1966) measured the standard potential of Pu(III)/Pu in 3LiCl–2KCl as a function of temperature using a Ag/AgCl reference electrode. Recent results with the same kind of reference electrode agree with the previous value within the uncertainties of the Ag/AgCl electrode potentials due certainly to the membrane potential: E°[Pu(III)/Pu(0)] = –2.204 + 0.000845T (vs Ag/AgCl, molar fraction, AgCl 1 wt%) (Sakamura *et al*., 2001). When adjusted to the Cl_2/Cl^- reference, the standard potential should be –2.775 V at 500°C (Roy *et al*., 1996). Bychkov and Skiba (1999) reports a similar result (–2.82 V) while Martinot (1991) gave a more positive potential.

The activity coefficient of Pu(III) in 3LiCl–2KCl is between 1.0×10^{-3} and 4.1×10^{-3} from 400 to 500°C (Roy *et al*., 1996). Diffusion coefficient $D_{Pu(III)}$ is equal to 12×10^{-6} cm^2 s^{-1} (Nissen, 1966; Willit *et al*., 1992). These data are similar to those of UCl_3. The Pu(IV)/Pu(III) couple has been investigated (Martinot and Duyckaerts, 1970, 1973; Landresse and Duyckaerts, 1974; Bychkov and Skiba, 1999). In common alkali chloride melts, the standard potential of the Pu(IV)/Pu(III) couple is very close to that of Cl_2/Cl^-. For example, in 3LiCl–KCl at 500°C, E°[Pu(IV)/Pu(III)] = +0.01 V, in NaCl–KCl at 727°C E°[Pu(IV)/Pu(III)] = +0.09 V, in NaCl–2CsCl at 600°C, E°[Pu(IV)/Pu(III)] = –0.05 V (Bychkov and Skiba, 1999).

In the presence of a chlorine–oxygen gas mixtures, oxygen-free trivalent and tetravalent forms of plutonium disappear while oxygenated ions of Pu(V) and Pu(VI) appear (Martinot, 1991; Bychkov and Skiba, 1999). The potential–pO^{2-} diagram in 3LiCl–2KCl at 450°C is available from Martinot and coworkers (Martinot and Duyckaerts, 1973; Martinot, 1991) but the authors indicate that it must be considered as a tentative diagram due to large uncertainties in solubility products of plutonium oxides. The NaCl–2CsCl eutectic has been well investigated and temperature dependencies of standard potentials of Pu(VI)/PuO_2 and Pu(V)/PuO_2 couples are known. A potential–pO^{2-}

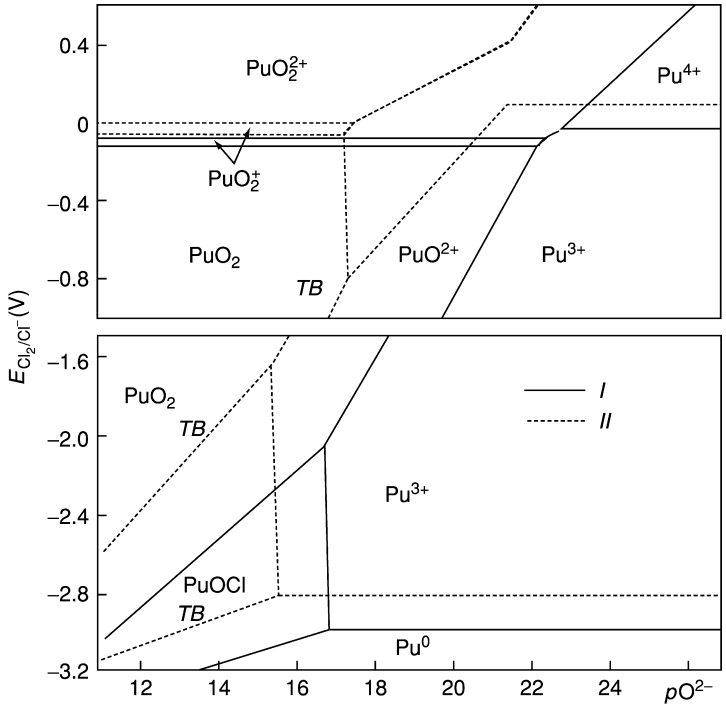

Fig. 24.15 *Potential–pO^{2-} diagram for* $[Pu(IV)] = [Pu(III)] = [PuO_2^+] = [PuO_2^{2+}] = [PuO^{2+}] = 10^{-3}$ M *in NaCl–2CsCl at* 600°C (*solid line*) *and* 800°C (*dashed line*). *Insoluble species are indicated with the TB notation.* (*Vavilov* et al., 1985).

diagram (Fig. 24.15) has been calculated for the medium NaCl–2CsCl (Vavilov *et al.*, 1985).

(*vi*) *Americium*

The existence of both trivalent and divalent americium in alkali chloride melts has been claimed. Initially, similarity in the spectrum of $AmCl_3$ dissolved in 3LiCl–KCl at 450°C obtained by Gruen *et al.* (1960) and the spectrum of Am(III) in concentrated HCl establish the existence of Am(III). Later, chronopotentiometric studies by Martinot *et al.* (1973) in the same eutectic confirmed the existence of the Am(III)/Am(0) couple. Leary and Mullins (1973) argued the existence of Am(II) in NaCl–KCl eutectic, while Kolesnikov *et al.* (1976), using measurements of polarization of various cathodes in $AmCl_3$–NaCl–KCl melts ($AmCl_3$ 1.1 wt%) at 700°C, just showed the wave of discharging of Am(III) to the metal. More recently, based on cyclic voltammetry at 450°C in 3LiCl–2KCl, Grimmett *et al.* (1994) proposed that deposition of Am proceeds in two steps: reduction of Am(III) to Am(II) and then Am(II) into Am metal. The two oxidation states have been confirmed by Lambertin *et al.* (2000).

Standard potentials vs Cl_2/Cl^- for Am(III)/Am(II) and Am(II)/Am(0) in 3LiCl–2KCl between 450 and 500°C reported by several authors (Bychkov and Skiba, 1999; Fusselman *et al.*, 1999; Lambertin *et al.*, 2001) are internally consistent. At 450°C, $E°$[Am(III)/Am(II)] = –2.83 V, $E°$[Am(II)/Am(0)] = –2.852 V (Fusselman *et al.*, 1999). The existence and solubility products of AmO^+, AmOCl, and Am_2O_3 in 3LiCl–2KCl have been determined by potentiometric titration and cyclic voltammetry; a potential–pO^{2-} diagram has been calculated at 470°C for [Am(III)] = [Am(II)] = 10^{-2} M (Lambertin *et al.*, 2000). Lambertin also reports disproportionation of divalent americium in 3LiCl–2KCl can be induced by addition of fluoride anion.

(*vii*) *Curium and transcurium elements*

There have been few studies on the chemistry of curium in chloride melts. Trivalent curium has been identified in 3LiCl–2KCl and NaCl–KCl (Martinot *et al.*, 1975; Kolesnikov *et al.*, 1976). In NaCl–KCl at 750°C, Kolesnikov and coworkers showed, as for americium, that the potential of discharging Cm(III) to Cm(0) is close to the potential of deposition of the alkali metal (difference 0.25–0.3 V) and claimed use of a liquid cathode for alloying americium or curium during recovery by electrolysis. Attempts have been carried out with a zinc cathode (Kolesnikov *et al.*, 1976). In their investigations on the lowest oxidation states of lanthanides and actinides, Kulyukhin *et al.* (1997) show that californium, einsteinium, and fermium in LiCl–$NdCl_2$–$NdCl_3$ melt can be reduced only to the 2+ oxidation state. This is also true for americium.

(c) Molten fluorides

The chemical development carried out in support of the molten salt breeder reactor (MSBR) at Oak Ridge National Laboratory (ORNL) has produced a quantitative description of the chemistry and thermodynamics of actinide and fission-product fluorides in molten LiF–BeF_2 solutions (Baes, 1966). The molten-salt technology was based on the concept of a high-temperature, thermal-neutron breeder reactor that operated on the ^{233}U–^{232}Th fuel cycle with ^{7}LiF–BeF_2–ThF_4–UF_4 (71.7–16–12–0.3 mol%) as reference fuel (Hightower, 1975). In that case, the nature of the fuel logically implies on-site reprocessing involving molten phases to minimize the number of conversion steps and to have low reprocessing costs. The processes that have been developed are described in numerous reports from ORNL. The chemistry of the actinides in molten fluorides has been reviewed (Martinot, 1991). We refer the reader to this comprehensive review as a source for quantitative data – in particular for solubility products, apparent standard potentials, and activity coefficients – of the actinides in molten fluorides. The basic chemical properties of actinides in MSBR melt and the principles of molten salt reactor processing are briefly described in the following sections.

(*i*) *Thorium and protactinium*

In $LiF–BeF_2$ (67–33 mol%), $LiF–BeF_2–ThF_4$ (72–16–12 mol%), and LiF–NaF–KF (46.5–11.5–42 mol%) melts, only the tetravalent oxidation state is observed for thorium. Coordination complexes are formed depending on the excess of free fluoride ions in the melt. The activity coefficient for ThF_4 has been measured as a function of the LiF mole fraction in various $LiF–BeF_2–ThF_4$ melts (Baes, 1974). In the MSBR fuel cycle, ^{233}Pa is formed as a result of neutron capture by ^{232}Th. In such a medium, tetravalent and pentavalent protactinium are potentially coexisting species. By controlling the pO^{2-} and the redox potential of the melt (i.e. U(IV)/U(III) ratio, if the MSBR operating conditions this ratio is ~100), it is possible to have protactinium only in the tetravalent oxidation state (Ross *et al.*, 1973; Tallent and Ferris, 1974).

(*ii*) *Uranium and plutonium*

Trivalent and tetravalent uranium are stable in MSBR melt. Apparent standard potentials have been experimentally measured in $LiF–BeF_2$ (67–33 mol%) as a function of temperature (Martinot, 1975). The chemistry of uranium has been largely investigated and equilibrium constants of interest have been determined in MSBR melt (Baes, 1969; Long and Blankenship, 1969; Toth and Gilpatrick, 1972) to control the redox potential of the fuel and undesirable reactions (e.g. corrosion). By fixing the ratio of U(IV)/U(III) to about 100, only the trivalent oxidation state is stable. Quantitative data (apparent standard potential of Pu(III)/Pu(0), solubility of PuF_3 and PuO_2) are available in $LiF–BeF_2$ (67–33 mol%) and $LiF–BeF_2–UF_4$ (70–10–20 mol%) (Baes, 1969; Toth and Gilpatrick, 1972).

(d) Processing requirements

If a thorium–uranium reactor is to operate as a breeder, ^{233}Pa must be isolated from the region of high neutron flux during its decay to ^{233}U. Also, the fission products must be removed in order to minimize neutron absorptions. The rare earths and zirconium are the principal fission products that must be removed. It also is necessary to remove the excess uranium that is produced to maintain the proper redox potential of the fuel salt and to maintain oxide and corrosion product concentrations at acceptable levels (Long and Blankenship, 1969).

(e) Molten-salt reactor processing

The reference flow sheet has been described (Bell and McNeese, 1971; Hightower, 1975) and was based upon a fluorination-reductive extraction and a metal-transfer process. The fuel salt containing 0.3 mol% of UF_4 and approximately 0.0035 mol% of PaF_4 is withdrawn from the reactor on a 10-day cycle. Uranium is first

removed as volatile UF_6 in a continuous fluorinator. The U-free salt is then fed to an extraction column where protactinium, zirconium, and the remaining uranium are extracted into a bismuth stream containing a reductant.

Subsequently, the bismuth stream is hydrofluorinated in the presence of a second salt stream, which results in transfer of the extracted materials to the salt. Reductant is added to recovered bismuth, and the resulting metal stream is recycled to the extraction column. The secondary salt stream is circulated through a hydrofluorinator, a fluorinator, and a protactinium decay tank. The fluorinator is used to maintain an acceptably low uranium concentration in the protactinium decay tank. The salt is withdrawn from the decay tank periodically to remove zirconium and other fission products that accumulate in the tank. The salt is held for a sufficient period before final discard to allow ^{233}Pa to decay to ^{233}U, which is recovered from the salt by batch fluorination.

Salt leaving the protactinium extraction column is essentially free of uranium and protactinium but contains the rare earths. It is fed to the metal transfer process (McNeese, 1971). This process for removal of rare earths and separating them from thorium is based upon the selective extraction of rare earths from bismuth into LiCl (Ferris *et al.*, 1970, 1972). Rare earths and thorium are extracted into bismuth containing elemental lithium reductant (0.2 at.%) and the rare earths are selectively removed from the bismuth by contact with LiCl. Divalent and trivalent rare earths are removed separately from the LiCl by extraction into Bi–Li streams containing 50 and 5 at.% Li, respectively. The bismuth stream used for the isolation of protactinium is actually fed to the recirculating bismuth stream in the rare earth removal system.

Uranium is returned to the fuel salt in a fuel reconstitution step before the salt is sent back to the reactor. The uranium addition is performed by absorbing the UF_6 stream coming from the fluorinators into a recycle salt stream containing dissolved UF_4. UF_6 reacts with UF_4 to give non-volatile UF_5, which is reduced by hydrogen gas into UF_4. At last a purification step is necessary to remove traces of bismuth before the salt is returned to the reactor.

(f) Molten oxy-anion salts

(*i*) *Molten molybdates*

Investigations of molten molybdates focus on recrystallization of uranium and plutonium oxides (Bychkov and Skiba, 1999). A MoO_3–Na_2MoO_4 melt could be a potential candidate. Ustinov (1995) studied various phase diagrams of binary and ternary systems: UO_2–MoO_3, PuO_2–MoO_3, UO_3–MoO_3, CeO_2–MoO_3, ZrO_2–MoO_3, BaO–MoO_3, RuO_2–MoO_3, UO_2–MoO_3–Na_2MoO_4, PuO_2–MoO_3–Na_2MoO_4 in the temperature range 1000–1200°C. Practically all the oxides are dissolved in molten MoO_3 except for RuO_2. The solubility of the oxides of fission products in MoO_3 is higher than those of oxides of uranium and plutonium. On the other hand, oxides of uranium and

plutonium have a low solubility in Na_2MoO_4. The solubility of molybdates of U and Pu increases with the temperature. From the experimental phase diagrams, various recrystallization methods are proposed for the production of: (i) UO_2, (ii) PuO_2, (iii) homogeneous solid solution of $(U–Pu)O_2$, and (iv) uranium molybdates.

(*ii*) *Molten tungstates*

Molten tungstates, M_2WO_4–$M_2W_2O_7$ where M = Li, Na, K, and Cs have some interesting physical properties: (i) high thermal stability, (ii) low volatility, (iii) relatively low melting points, and (iv) high values of decomposition voltage (Afonichkin and Komarov, 1995). Common working temperatures are in the range 700–900°C and an inert atmosphere is required (Afonichkin *et al*., 2001). Nevertheless, there have been few experiments on actinides. Afonichkin and coworkers investigated the electrodeposition of uranium oxide from Na_2WO_4–UO_2WO_4 and Na_2WO_4–$Na_2W_2O_7$–UO_2WO_4 melts. In the binary melt, an ionic model has been proposed to explain the dissolution of uranium oxide and the formation of UO_2, UO_{2+x}, U_4O_{9-y}, and U_3O_8 phases on the cathode (Afonichkin *et al*., 2001):

$$U_3O_8 + 2Na_2WO_4 + \frac{1}{2}O_2 \rightleftarrows Na_2[UO_2(WO_4)_2] + Na_2U_2O_7 \tag{24.25}$$

$$Na_2[UO_2(WO_4)_2] \rightleftarrows 2Na^+ + [UO_2(WO_4)_2]^{2-} \tag{24.26}$$

$$[UO_2(WO_4)_2]^{2-} \rightleftarrows UO_2^{2+} + 2WO_4^{2-} \tag{24.27}$$

$$2UO_2^{2+} + 2WO_4^{2-} \rightleftarrows U_2O_5^{2+} + W_2O_7^{2-} \tag{24.28}$$

and, in concentrated UO_2WO_4 solutions,

$$UO_2^{2+} + U_2O_5^{2+} + 2WO_4^{2-} \rightleftarrows U_3O_8^{2+} + W_2O_7^{2-} \tag{24.29}$$

Electrolysis:

$$UO_2^{2+} + 2e^- \rightleftarrows UO_2 \tag{24.30}$$

$$U_3O_8^{2+} + 2e^- \rightleftarrows U_3O_8 \tag{24.31}$$

$$(1-2x)UO_2^{2+} + xU_2O_5^{2+} + 2(1-x)e^- \rightleftarrows UO_{2+x} \tag{24.32}$$

$$2(1+y)UO_2^{2+} + (1-y)U_2O_5^{2+} + 2(3+y)e^- \rightleftarrows U_4O_{9-y} \tag{24.33}$$

If the ternary system allows a lower melting point, the resulting addition of $Na_2W_2O_7$ in the melt decreases the potential of the melt decomposition. However, it has been shown that the transition from the binary to the ternary melt

has minimal effect on the oxygen coefficient and on the main parameters of electrolysis. Current efficiency does not exceed 65% of theoretical value (Afonichkin and Komarov, 1995; Afonichkin *et al.*, 2001), indicating chemical interactions of the cathodic product with the electrolyte. With increasing temperature and $W_2O_7^{2-}$ concentration, the current efficiency decreases.

(*iii*) *Nitrates and sulfates*

Several authors (Morgan *et al.*, 1980; Martinot, 1991; Bychkov and Skiba, 1999) have prepared comprehensive reviews of pyroprocessing of actinides in nitrate and sulfate media. Such media create awkward operating conditions since nitrate melts are particularly hazardous and processes in molten sulfates involve corrosive gaseous phases. A distinctive feature of the molten alkali nitrate melts (300–450°C) is the ability to dissolve uranium oxide while PuO_2 remains insoluble. In molten sulfates (450–650°C), both uranium and plutonium oxides can be dissolved using gaseous sulfur oxides or vapor of sulfuric acid (Brambilla, 1984; Bychkov and Skiba, 1999). Uranium oxide could be recovered by electrolysis though PuO_2 is precipitated by decomposition of its sulfate at high temperature (Brambilla, 1984; Bychkov and Skiba, 1999).

(g) Separation techniques: principles, performances, and limitations

(*i*) *Oxide–oxide processes*

Since the 1960s, Research Institute of Atomic Reactors (RIAR, Dimitrovgrad), has been developing fabrication and reprocessing processes for oxide fast reactor fuel (Bychkov *et al.*, 1995; Skiba and Ivanov, 1995). It combines vibropacking fabrication of fuel rods and pyroelectrochemical technology of spent fuel in molten alkali chlorides. Original studies conducted at Hanford within the framework of the Salt Cycle Process development (for UO_2–PuO_2 fuel reprocessing) involved LiCl–KCl melts (Benedict *et al.*, 1963). Changing the melt composition and the electrolysis atmosphere allowed production of various oxides. For instance, highly enriched UO_2 was dissolved in equimolar LiCl–KCl with chlorine sparging and UO_2Cl_2 was then electroreduced at 550–800°C to UO_2 on the cathode, leaving plutonium and fission products in the melt. If one wanted a PuO_2–UO_2 solid solution, electrolysis was done in the same melt at 475–675°C under chlorine–oxygen gaseous mixture. If it was only necessary to recover plutonium, dissolution was performed in 2.5:1 LiCl–KCl melt and plutonium was precipitated as dioxide with chlorine–oxygen sparging. Since that time, RIAR has developed a similar process, named Dimitrovgrad dry process (DDP), at the semi-industrial scale, for spent UO_2 or MOX fuel reprocessing, in two other alkali melts: NaCl–2CsCl or NaCl–KCl–UO_2Cl_2 (Bychkov and Skiba, 1999).

(*ii*) *Basis of the DDP*

Dissolution

First, spent oxide fuel is dissolved in the melt by a strong oxidizing agent, chlorine gas at 650–700°C. Actinides are present either as chlorides or oxychlorides (see Section 24.3.12b). Uranium and plutonium behaviors can be explained by the following chemical reactions and equilibria:

$$UO_2 + Cl_2 \rightleftarrows UO_2Cl_{2\ melt} \tag{24.34}$$

$$PuO_2 + Cl_2 \rightleftarrows PuO_2Cl_{2\ melt} \tag{24.35}$$

$$PuO_2Cl_2 \rightleftarrows PuO_2Cl_{melt} + \frac{1}{2}Cl_2 \tag{24.36}$$

$$PuO_2Cl_2 + Cl_2 \rightleftarrows PuCl_{4\ melt} + O_2 \tag{24.37}$$

$$PuCl_4 \rightleftarrows PuCl_{3\ melt} + \frac{1}{2}Cl_2 \tag{24.38}$$

U(VI) present as uranyl species UO_2^{2+} is stable; treating the melt with chlorine–oxygen gaseous mixture will stabilize the highest oxidation states of plutonium, respectively PuO_2^+ and PuO_2^{2+}. The temperature dependence of equilibrium constants for plutonium species in NaCl–2CsCl is known for various partial pressures of chlorine gas (Vavilov *et al*., 1985).

Uranium and plutonium recovery

The recovery of uranium and plutonium as oxides at high temperature (> 400°C) works because UO_2 and PuO_2 conduct electricity and can be electrodeposited at a cathode like a metal. According to the formal potentials listed in Table 24.10, UO_2 and PuO_2 are reduced at more positive potentials than all the fission products, except for noble metals (Bychkov and Skiba, 1999; Bychkov *et al*., 2000). If plutonium recovery is not necessary, UO_2Cl_2 is electroreduced to UO_2 at the pyrolytic carbon cathode, leaving plutonium and the majority of fission products in the melt. Recovery efficiency is 99.0–99.5% (Bychkov and Skiba, 1999). At the anode, chloride ions are oxidized to chlorine gas.

Table 24.10 *Formal electrode potentials of actinides and fission products* (*vs* Cl_2/Cl^-, *molar fraction*) *in NaCl–2CsCl eutectic at* 600°C (*in* volts) (*Bychkov and Skiba*, 1999).

Sm(II)/Sm	–3.58	Pu(III)/Pu	–2.83	U(VI)/UO_2	–0.65
Eu(II)/Eu	–3.39	U(III)/U	–2.39	Pd(II)/Pd	–0.48
Ce(III)/Ce	–3.08	Zr(IV)/Zr	–2.17	Rh(III)/Rh	–0.44
		Fe(II)/Fe	–1.48	Ru(III)/Ru (510°C)	–0.413
		U(IV)/U(III)	–1.45	Np(V)/NpO_2	–
		Mo(III)/Mo	–0.97	Pu(IV)/Pu(III)	–0.05
		Ag(I)/Ag	–0.932	Pu(VI)/PuO_2	+0.12

If both uranium and plutonium recovery is desired, electrolysis must be carried out while sparging the melt with an oxygen–chlorine gaseous mixture (Bychkov and Skiba, 1999). The cathodic products are quasi-homogeneous (U, Pu)O_2 with two-phase composition: solid solution of PuO_2 in UO_2 crystals and solid solution of UO_2 in PuO_2 crystals. UO_2 deposition rate is pre-set by current density while PuO_2 deposition rate is limited by the diffusion of plutonyl ions to the cathode (Bychkov *et al.*, 2000). If it should be necessary to recover only PuO_2, dissolution is performed in NaCl–KCl and plutonium oxide is precipitated by oxygen gas (Bychkov and Skiba, 1999).

Behavior of minor actinides

(Np, Am, and Cm). After the dissolution step, neptunium is present in the melt as NpO_2^+. As a result, neptunium is electroreduced to NpO_2 and is co-deposited with uranium oxide (see Table 24.11). The behavior of americium and curium is not similar to that of neptunium; they remain as soluble species in the melt like other soluble fission products (alkaline elements, alkaline earth elements, and rare earth elements) (Kormilitzyn *et al.*, 1999).

Separation of americium and curium from the soluble fission products by carbonate precipitation has been proposed. Sodium carbonate is added to the spent melt (NaCl–2CsCl or NaCl–KCl) for fractional precipitation of americium and curium, probably as sesquioxides M_2O_3 (M = Am and Cm). Similar results were obtained for both media in terms of the possible separation of minor actinides and rare-earth elements (hereafter REE) (Kormilitzyn *et al.*, 1999, Fig. 24.16). Unfortunately, americium precipitates between lanthanide(III) and lanthanide(II), which makes it difficult to separate Am from REE. Even if a small part of the americium sesquioxide could be recovered by filtration at high temperature, the remaining americium precipitates as mixed oxide with REE. If the separation of americium from REE is not necessary, the melt can be purified by adding phosphate to precipitate americium (and curium) and fission products. Fission products in the trivalent oxidation state precipitate as insoluble double phosphates $Na_3M(PO_4)_2$, while many fission products in the divalent

oxidation state, including alkaline earth elements, also precipitate (Kormilitzyn *et al.*, 1999).

(h) Applications, separation efficiency in the DDP

A chlorinator–electrolyzer has been designed that will accommodate a volume of 40 L. It can reprocess a loading of about 30 kg of material. All the internal surfaces that come into contact with the salt and gaseous phases (anode-crucible, cathode, gas tube) are crafted of pyrolitic graphite. After pyroelectrochemical treatment, the cathodic deposits are crushed, purified from salts by distillation, dried, and classified for vibropac fabrication of fuel rods (Bychkov and Skiba, 1999). Since the 1970s about 3 metric tons of UO_2, 100 kg of PuO_2, and 1600 kg of $(U–Pu)O_2$ have been produced in molten alkali chlorides for BOR60, BN350, and BN600 reactors. From 1968 to 1973, 5.8 kg of spent UO_2 coming from VK-50 and BOR60 reactors were reprocessed while spent MOX fuel reprocessing began in the 1990s with 4.1 kg from BN350 (burn-up 4.7%) and 3.5 kg from BOR60 (burn-up 21–24%) (Bychkov and Skiba, 1999). For example, reprocessing of MOX fuel from BOR60 involved: (i) dissolution of the fuel in LiCl–4.53NaCl–4.88KCl–0.66CsCl; (ii) electrolysis to remove part of UO_2 free from Pu; (iii) PuO_2 precipitation; (iv) additional electrolysis for removing residual uranium as UO_2, and (v) melt purification by phosphates.

Mass balances give information on the behavior of actinides and fission products. It has been found that (Bychkov and Skiba, 1999; Bychkov *et al.*, 2000): (i) Zr, Nb, Ru, Rh, Pd, and Ag were located in the first UO_2 deposit; (ii) U/Pu separation factor in the first electrolysis is 120–140; (iii) most of the

Np is distributed between the two UO_2 deposits; (iv) Am is present in UO_2 deposits (~3.5 wt%), in PuO_2 precipitate (~18 wt%) and in phosphates (~73 wt%); (v) practically all the Cm is in phosphates though it has also been detected in the second UO_2 deposit; (vi) representatives of REE (Ce and Eu) are concentrated in phosphates, and (vii) Cs, Rb, and partially Sr remain in melt.

If a (U, Pu)O_2 deposit is desired, it will be necessary to perform a preliminary electrolysis for the removal of Ru, noble metals and Zr, before carrying out the main electrolysis under a chlorine–oxygen atmosphere. In tests on simulated materials in NaCl–2CsCl, the separation factors observed were: ~ 1000 for Cs, >100 for REE, ~1 for Ru and Zr without preliminary electrolysis, and ~10 with preliminary electrolysis (Kormilitzyn *et al.*, 1999).

DDP is currently used for oxide fuel reprocessing and for producing three oxides: UO_2, PuO_2, and (U–Pu)O_2. The latter one is mainly dedicated to MOX fuel fabrication for BOR-60 reactor. Research programs are now focused on conversion of weapon-grade plutonium into MOX fuel, development of a process for complete recycle of Pu, Np, Am and Cm (*D*ry reprocessing, *O*xide fuel, *V*ibro-compact, *I*ntegral, *T*ransmutation of *A*ctinides, DOVITA program) (Bychkov and Skiba, 1999).

(i) Metal–metal processes

(*i*) *Melt refining* (*or oxide slagging process*)

Early pyrometallurgical processes which have been developed for minimizing the cost of recycling were rudimentary. One example is the melt refining process, which was proposed to reprocess the metallic uranium fuel alloy used in the core of the second experimental breeder reactor (EBR-II) (Motta, 1956; Burris *et al.*, 1964). The fuel was an enriched uranium alloy (~52 wt% ^{235}U) containing 5 wt % *fissium* (mixture of molybdenum, ruthenium, rhodium, palladium, zirconium, and niobium) with sodium used as a thermal bond (Burris *et al.*, 1964; Steunenberg *et al.*, 1970). Melt refining is also named oxide slagging or oxide drossing. Fission products were removed by combining volatilization and selective oxidation.

After the mechanical removal of cladding and sodium bonds, the separation process consisted simply in melting the fuel at 1300–1400°C in a lime-stabilized zirconia crucible. Volatile fission products that are condensable, such as iodine and cesium, were trapped on alumina–silica fibers while gaseous fission products (krypton, xenon) were stored to allow decay of 5.3 day ^{133}Xe before being released into the atmosphere. Elements more electropositive than zirconium (see Table 24.11: alkali metals, alkaline earth, and rare earth elements) reacted with the zirconia to form an insoluble oxide slag. The other fission products (noble metals comprising the *fissium*) and the actinides remained with the uranium in the metallic form to be recycled. At this stage, the uranium recovery yield ranged from 90 to 95 wt% (Trice and Chellew, 1961; Burris *et al.*, 1964).

The melt refining process leaves a residue or skull (mixture of oxides and unpoured metal) at the bottom of the crucible, which represented about 5–10% of the loading. An auxiliary process had been proposed to recover uranium from the skull. After preliminary oxidation of the skull under oxygen–argon mixture at 700°C, the resulting oxides were dissolved into a chloride flux. Contact with liquid zinc between 700 and 800°C allowed the removal of noble metals (Ru, Mo, Rh, Pd) and Ag. Uranium was then extracted from the chloride flux by using Mg–Zn alloy (magnesium being the reducing agent and zinc the alloying agent). Combining this process with the melt refining increased the uranium recovery yield to about 99.5 wt%. The fission product removals that had been achieved (rare earths: 90%, Ru: 80%, Mo: 90%, Pd: >99%, Zr: 75%, Ba, and Sr: >99%) were sufficient to maintain the desired concentrations of the *fissium* alloying elements in the EBR-II fuel (Burris *et al*., 1964). The complementary process, named the skull reclamation process, has been studied only at the laboratory scale (Burris *et al*., 1964; Steunenberg *et al*., 1970).

Oxide slagging was also investigated for plutonium reactor fuels, for example with the proposed LAMPRE fuel (Los Alamos Molten Plutonium Reactor Experiment, 10 wt% Fe–Pu alloy) (Mullins *et al*., 1960). Tests on synthetic spent plutonium fuel have been performed in magnesia and zirconia crucibles. But this approach was rapidly abandoned because of numerous drawbacks: high temperature, slow reaction rates, and the creation of a plutonium-bearing residue.

(j) Melt refining under molten salts (or halide slagging processes)

In the halide slagging process, in particular chloride slagging, the active fission products were rapidly removed from the molten fuel as a result of chemical reactions occurring at the interface between two liquid phases. Moreover, the plutonium transfer was less than 1 wt%. The process consisted of contacting the molten fuel at 600–700°C with molten alkali chloride salts containing plutonium chloride or magnesium chloride as an oxidant. Used slags were $PuCl_3$–NaCl, $MgCl_2$–LiCl—KCl, or $MgCl_2$–NaCl–KCl (Leary *et al*., 1958; Mullins *et al*., 1960). Gibbs energies of formation of selected halides are shown in Table 24.12.

Results were in agreement with thermodynamic predictions: electropositive fission products (alkali and alkaline earth elements, rare earths) were oxidized and dissolved in the chloride slag. But, as in every melt refining process, the noble metal fission products were not removed from the spent fuel. Mullins *et al*. (1960) gave for $MgCl_2$–NaCl–KCl at 700°C the percentage transferred into the salt phase for the following elements: Pu 0.92, Fe 0.04, Zr < 0.04, Mo < 0.15, Ru < 0.20, Ce 98, La 100, Mg 26. In these experiments, the $MgCl_2$ exceeded by 10% the stoichiometric quantity needed to remove the rare earths. A similar process has been tested on (10–20 wt% plutonium)–uranium alloys with $BaCl_2$–$CaCl_2$ and $MgCl_2$ as oxidant (Glassner, 1957). The effect of the slag

composition is minor. The criteria for slag selection must be melting point and high stability of halide components (alkali or alkaline earth elements).

(k) Molten metal-salt extraction processes

By combining liquid metal (or alloy) solvent with molten salts and using oxidation–reduction reactions, it is possible to accomplish separations that could not be achievable by melt refining. The elements are distributed in the two-phase solvent system and the distribution coefficients depend on the nature of the oxidizing and reducing agents and on the activities of the reacting species in solution. In general, chlorides are preferred because of their lower volatility, their compatibility with many containers, and favorable solubility relationships. Such separation techniques in various biphasic systems have been proposed in the past by several American laboratories: Brookhaven National Laboratory investigated Bi/$MgCl_2$–NaCl–KCl to reprocess bismuth–uranium fuel (Bennett *et al.*, 1964); the Hanford Works studied the actinide distribution in Al/$AlCl_3$–KCl (Dwyer, 1956); the Ames Laboratory examined the same in Zn/LiCl–KCl (Moore and Lyon, 1959); Los Alamos National Laboratory tested Hg/RbCl–LiCl–$FeCl_2$ for the reprocessing of LAMPRE fuel (Chiotti and Parry, 1962); Argonne National Laboratory proposed various applications in $MgCl_2$-based salt with Cu–Mg or Zn–Mg alloy. One of them is the Argonne salt transport process for the reprocessing of LMFBR fuels (Steunenberg *et al.*, 1970).

(*i*) *Argonne salt transport process*

The partitioning of element M between magnesium alloy and $MgCl_2$-based salt can be expressed by:

$$\mathrm{M(alloy)} + \tfrac{1}{2}n\mathrm{MgCl_2(salt)} \rightleftharpoons \mathrm{MCl}_n\mathrm{(salt)} + \tfrac{1}{2}n\mathrm{Mg\ (alloy)} \qquad (24.39)$$

If K_a is the equilibrium constant, a_i and γ_i respectively the activity and the activity coefficient of the reactants, the distribution ratio D_M for a metal M

(ratio of mole fraction of MCl_n in salt to atom fraction of M in alloy) will be expressed by:

$$\log D_M = (-\Delta G^\circ/2.3RT) + (-\tfrac{1}{2}n \log a_{Mg} + \log \gamma_M) - (-\tfrac{1}{2}n \log a_{MgCl_2} + \log \gamma_{MCl_n}) \quad (24.40)$$

where $\Delta G^\circ = -RT \ln K_a = \Delta G_f^\circ(MCl_n, T) - \frac{1}{2}n\Delta G_f^\circ(MgCl_2, T)$. The first term in brackets in equation (24.40) depends on temperature via the Gibbs energy of formation of MCl_n and $MgCl_2$. The second term depends on temperature and composition of the alloy while the third depends on temperature and composition of salt. Importance of these terms on D_M decreases from left to right when salt with $MgCl_2$ is used as the oxidizing agent (Bowersox and Leary, 1960).

The halides of the noble-metal fission products and the metals used for cladding (like Fe), have a less negative Gibbs energy of formation (see Table 24.12) the first term dominates the distribution ratio and they should be easily separated from actinides by remaining in the alloy. For actinides and rare earth elements, the two following terms cannot be ignored. Johnson (1974) has explained their effect on distribution coefficients.

Distribution ratios of actinides and rare earth elements between molten $MgCl_2$ and Mg-alloy (Mg–Zn, Mg–Cu) have been measured over a wide range of magnesium content (Knighton and Steunenberg, 1965; Knighton, 1969). They are at a minimum when a Zn–Mg alloy is used (Mg content is about 10 wt%). A similar effect is not observed when Cu–Mg alloy is used. These two alloys have been proposed by Argonne National Laboratory to separate uranium and plutonium from fission products. Salt transport separation is based on the selective transfer of uranium and plutonium from a donor alloy to an acceptor alloy via a saline phase (see Fig. 24.17):

$$Pu(\text{donor alloy}) + \tfrac{3}{2}MgCl_2(\text{salt}) \rightarrow PuCl_3(\text{salt}) + \tfrac{3}{2}Mg\ (\text{donor alloy}) \quad (24.41)$$

$$PuCl_3(\text{salt}) + \tfrac{3}{2}Mg(\text{acceptor alloy}) \rightarrow Pu(\text{acceptor alloy}) + \tfrac{3}{2}MgCl_2(\text{salt}) \quad (24.42)$$

When uranium and plutonium are salt-transported from the donor alloy to the acceptor alloy, noble fission product metals remain in the donor alloy and rare earth fission product are stabilized in the salt phase. Using 50 mol% $MgCl_2$–30 mol% NaCl–20 mol% KCl and Mg–44 at% Cu alloy at 650°C, the separation factor for Ce from Pu is about 1000.

Typical phase compositions for plutonium recovery and purification are: for the donor alloy, Cu–33wt% Mg; for the salt, 50 mol% $MgCl_2$–30 mol% NaCl–20 mol% KCl; for the acceptor alloy, Zn–5 wt% Mg. The solubility of the transported material in the donor alloy must be high enough to have a significant transfer rate. For example, the solubility of uranium at 600°C in Cu–33 wt% Mg alloy is very low (50 ppm) while it can reach 3.8 wt% in

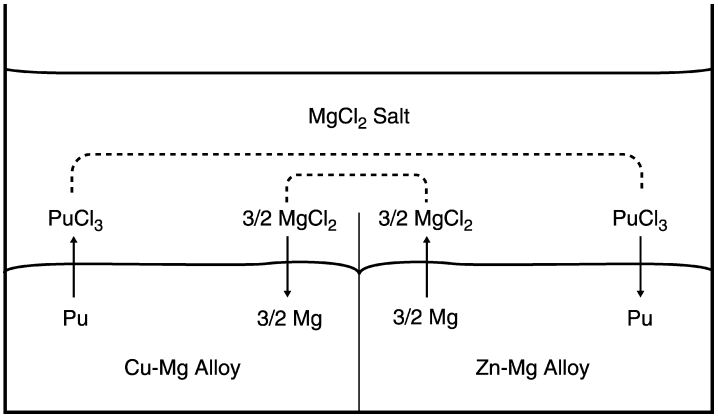

Fig. 24.17 *Scheme of salt transport process for plutonium* (*Steunenberg* et al., 1970).

Cu–6.5 wt% Mg alloy (Steunenberg *et al.*, 1970). Salt transport process has been developed at the laboratory scale, but no full scale application has yet been developed, though it was proposed in the mid-1990s in a conceptual flow sheet for recovering actinides from LWR fuels (Pierce *et al.*, 1993; Johnson *et al.*, 1994) (see Section 24.3.12n).

(*ii*) *Other applications of molten salt-metal extraction*

Development of this separation technique in molten fluorides has been carried out largely at Oak Ridge National Laboratory, in support of the molten salt breeder reactor (MSBR) concept for the reprocessing of fuel based on molten $LiF–BeF_2$ solutions (see Section 24.3.12**c**). In chlorides, molten salt-metal extraction has been proposed for enhanced recovery of actinides from spent salt generated during electrorefining of metallic fuel (see Section 24.3.12.l). It has also been developed as one process stage for actinide recovery from HLLW coming from PUREX (see Section 24.3.12m(i)).

(l) Electrorefining

Early work on electrorefining from molten salts was done to prepare either high-purity metallic uranium or plutonium separately. It began with investigations on uranium at small scale (Driggs and Lilliendahl, 1930; Marzano and Noland, 1953), at larger scale (Anonymous, 1951; Chauvin *et al.*, 1962, 1964), then with plutonium. A significant application is the recovery and purification of plutonium developed at Los Alamos National Laboratory (Mullins *et al.*, 1962) and used at Rocky Flats, Hanford and in various countries (Moser and Navratil, 1983). There has been little research and development related to the application of electrorefining techniques to the recovery and purification of spent fuels.

Investigations on irradiated uranium (Chauvin *et al*., 1964) and on Los Alamos Molten Plutonium Reactor Experiment (LAMPRE) fuel (Leary *et al*., 1958) have been carried out.

Interest in electrorefining was revived with the proposed advanced fast reactor concept called the integral fast reactor (IFR) (Burris, 1986; Till and Chang, 1988; Chang, 1989; Hannum, 1997) whose primary feature was an integral fuel cycle in which the core and blanket materials after discharging are to be processed and refabricated in an onsite facility. The fuel cycle was based on electrorefining with a molten salt electrolyte (LiCl–KCl–UCl_3/$PuCl_3$) at 500°C in an inert atmosphere. An abundant literature has appeared on the chemistry and technology of IFR (see in particular Burris *et al*., 1987; Willit *et al*., 1992; Hannum, 1997; Anonymous, 2000). In the discussion below, the following features of this system will be presented: (i) a brief description of the main steps of the pyro-process; (ii) the chemical basis for partitioning of actinides and fission products between metallic (solid or liquid) and salt phases; and (iii) the separation efficiencies obtained at laboratory scale and in the only engineering scale application (EBR-II spent fuel treatment demonstration) completed to date.

(*i*) *Reprocessing in the IFR fuel cycle*

After discharging the spent core fuel (alloy of U, Pu, and Zr) in its stainless cladding, the fuel is chopped and placed in an anode basket. The anode basket containing the chopped fuel is put into an electrorefiner containing molten LiCl–KCl electrolyte and a liquid cadmium pool under inert atmosphere. $CdCl_2$ is added in the electrolyte to oxidize electropositive fission-product metals (alkali, alkaline earths, and a large fraction of the rare earth metals) to their chlorides (see Table 24.12). The amount of oxidizing agent to be added is adjusted to maintain 2 mol% actinide chlorides in the salt phase. The basket is made anodic and the following sequence occurs: (i) nearly pure uranium is electro-transported to a solid mandrel cathode and (ii) transuranium elements and some uranium are transferred by electro-transport to a liquid cadmium cathode. Noble metal fission products remain in an unoxidized form and are removed from the basket with the cladding hulls, although some portion falls into the cadmium pool at the bottom of the electrolyzer. Electropositive fission products remain in the salt and build-up during the successive reprocessing batches and progressively modify the electrochemical and physical properties of the electrolyte. Periodic treatment is thus required to remove them and recycle the electrolyte.

The molten metal-salt extraction (using Li–Cd alloys) has been proposed for reduction and removal of transuranium elements (TRUs) from the electrolyte salt and for TRU reoxidation back into the salt to start the next electrorefining campaign. Moreover, the use of UCl_3 as oxidant makes it possible to avoid the introduction of cadmium in the electrorefiner and thus the lower cadmium pool can be eliminated. This approach avoids the deposition of cadmium and

makes easier the removal of solids that accumulate at the bottom of the electrolyzer.

Both types of cathode products are processed to distill off adhering salt and cadmium (in case a liquid cadmium cathode is used). Such a process produces three waste streams: fission product gases, metal waste stream that contains cladding hulls, and noble metal fission products, and salt waste stream (alkali, alkaline earth fission products). The treatment, the immobilization, and the disposal of these wastes are challenging, but their discussion is not within the scope of this chapter. These features have largely evolved during the laboratory-scale and engineering-scale developments depending on the applications. The lone large-scale feedback is the demonstration campaign on the treatment of spent metal fuel from the EBR-II fast reactor commenced in 1996 at the Argonne-West site in Idaho. Processes and results obtained are discussed in reference Anonymous (2000).

(*ii*) *Chemical basis of electro-transport in LiCl–KCl*

Johnson (1988) and Ackerman and coworkers (Ackerman, 1991, Tomczuk *et al*., 1992; Ackerman and Johnson, 1993) have described the chemistry that controls the electro-transport in LiCl–KCl electrolyte on solid or liquid cathode. The transfer of the element of interest (for example U or Pu) is done by electrolyzing (electrochemical oxidation) this element into the salt (electrolyte) at the anode and electrodepositing it as metal at the cathode. The element must be initially present in the electrolyte before starting electrolysis. Dissolution is facilitated by addition of a chemical oxidizing agent (i.e. a chemical agent whose the chloride is less stable than the chloride of the element one wishes to electro-transport). For uranium electro-transport, the oxidizing agent can be $CdCl_2$ (see Table 24.12).

In the electrorefiner, the salt is well stirred and is in contact with both metal (electrode) phases. When a predetermined number of moles of metal (of given composition) are removed from the anode to the cathode, the compositions of both electrodes and the salt change until the salt is in equilibrium. For both elements M and M′, the following equilibrium exists at each electrode:

$$n1(\mathrm{MCl}_{n2}) + n2(\mathrm{M}')_{\mathrm{alloy}} \rightleftarrows n1(\mathrm{M})_{\mathrm{alloy}} + n2(\mathrm{M}'\mathrm{Cl}_{n1})\mathrm{salt} \tag{24.43}$$

Equilibrium constant K_a can be expressed using mole fraction x_i and activity coefficient γ_i of M and M′ in metal phase(s) and salt by:

$$K_a(T) = [(\gamma\mathrm{M})^{n1}(\gamma\mathrm{M}'\mathrm{Cl}_{n1})^{n2}]/[(\gamma\mathrm{M}')^{n2}(\gamma\mathrm{MCl}_{n2})^{n1}] \cdot [(\mathrm{xM})^{n1}(\mathrm{xM}'\mathrm{Cl}_{n1})^{n2}]/[(\mathrm{xM}')^{n2}(\mathrm{xMCl}_{n2})^{n1}] \tag{24.44}$$

where $\Delta G^{\circ}(T) = -RT \ln K_a(T) = n_2 \Delta G_f^{\circ}(\mathrm{MCl}_{n1}, T) - n_1 \Delta G_f^{\circ}(\mathrm{M}'\mathrm{Cl}_{n2}, T)$. By writing donor alloy = anode and acceptor alloy = cathode (Johnson, 1988), the equations are similar to those written for salt transport description

(see Section 24.3.12.**k**). The metal (electrode) phases need not to be in equilibrium with each other in the classical sense which would mean that activity of each metal would be the same in all phases (Anonymous, 1951; Tomczuk *et al.*, 1992; Ackerman and Johnson, 1993).

Concentrations in the salt phase at equilibrium depend on activity coefficients in metal phases (solid or liquid) and salt. As the salt is diluted, the activity coefficients of MCl_{n2} and $M'Cl_{n1}$ are assumed to be constant. However, activity coefficients of M and M′ in metal phases can vary greatly when changing the metal phase and they can be greatly reduced by the formation of intermetallic compounds. For instance, the plutonium activity is reduced in cadmium by formation of $PuCd_6$ (Johnson *et al.*, 1965). A similar decrease for rare earth activity coefficients is observed with Cd (Johnson and Yonco, 1970). Uranium does not form intermetallic compounds with cadmium at the electrorefining temperature (500°C) (Martin *et al.*, 1961).

A reduction in the activity coefficient of an element (e.g. Pu) is equivalent to a reduction in the stability of the corresponding chloride. In presence of cadmium, plutonium behaves as its trichloride was about 3.3 kJ (equiv.)$^{-1}$ more stable than uranium trichloride whereas it is 30.1 kJ (equiv.)$^{-1}$more stable in absence of cadmium (Ackerman, 1991, see Table 24.12). This result also implies that the difference between the reduction potential of Pu(III)/Pu(0) and U(III)/U(0) is less negative at the liquid cadmium cathode than at the solid cathode. Sakamura *et al.* (1999) have summarized the reduction potential of actinide and rare earth elements in LiCl–KCl salt when the nature of the cathode change (see Fig. 24.18). These data are compiled from the literature (Martin *et al.*, 1961; Lebedev *et al.*, 1968, 1969; Krumpelt *et al.*, 1974; Ackerman and Johnson, 1993; Kurata *et al.*, 1996; Kinoshita *et al.*, 1999).

The removal of pure uranium on a solid mandrel electrode is possible because the reduction potential of U(III)/U(0) is far from those of the other actinides (see Fig. 24.18). The range of $PuCl_3/UCl_3$ ratios in the electrolyte within which pure uranium can be removed at a solid cathode has been determined by Tomczuk *et al.* (1992). At a liquid cadmium cathode, the reduction potentials of actinides are very similar and such a cathode should be suitable for recovery of all actinides together. However, the potentials are too close to those of rare earth elements to be suitable for an actinide/rare earth separation. The gap between actinides and rare earth elements is increased if bismuth is substituted for cadmium. This change could enable an actinide/RE separation (see Section 24.3.12 m(i)). The principal drawback of bismuth as an electrode material (compared to cadmium) is that it is not distillable and therefore difficult to purify.

(*iii*) *Separation efficiencies in EBR-II demonstration campaign* (2000)

From 1996 to 1999, a hot demonstration was conducted in the Fuel Conditioning Facility at Idaho Falls where 100 spent driver assemblies (410 kg of highly enriched uranium alloyed with ~10 wt% Zr, plus stainless steel cladding) and

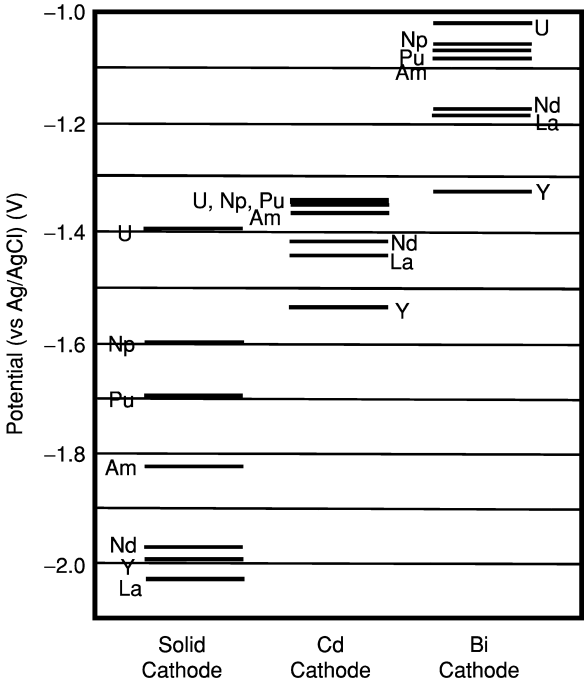

Fig. 24.18 *Reduction potential of actinide and rare earth elements at solid cathode, liquid cadmium cathode, and liquid bismuth cathode in LiCl–KCl eutectic salt at* 500°C, $x_{M\ in\ salt} = x_{M\ in\ Cd} = x_{M\ in\ Bi} = 0.001$. (*Figure created from information in Sakamura* et al., 1999.)

25 spent blanket assemblies (1200 kg of depleted-uranium with stainless steel cladding) from the Experimental Breeder Reactor-II have been treated by the electro metallurgical technology (EMT) developed by Argonne National Laboratory. The metallic fuel was separated into three components: metallic uranium, a metallic waste form from the anode, and a highly radioactive salt mixture. The global process involved the following steps: (i) chopping the fuel elements; (ii) electrorefining; (iii) removing entrained salt (about 20 wt%) from uranium deposits and consolidating dendritic deposits in a cathode processor; (iv) casting into ingots the uranium metal from the cathode; (v) casting into ingots the metal residue from the anode; and (vi) mixing, heating, and pressing the salt electrolyte with zeolite to form a ceramic waste.

The core of the process is the electrorefining step in LiCl–KCl melt at 500°C: the metallic fuel is selectively dissolved at the anode while nearly pure uranium metal is deposited at the cathode, leaving fission products, fuel cladding material, plutonium, and other transuranium elements partially at the anode and partially in the molten salt. In addition, the process neutralizes the reactive components (e.g. sodium-bonds) of the fuel. The distribution of actinides

(U, Np, and Pu) and some fission products in each flux has been calculated from material balance given by Mariani and coworkers (Anonymous, 2000; Mariani *et al.*, 2000) for spent driver fuel treatment (Table 24.13).

Two electrorefiners have been designed and developed. The first, Mark-IV, was used for driver elements and contained a cadmium pool. This pool was not used as cathode but acted as neutron absorber and corrosion-resistant barrier. $CdCl_2$ was added into the electrolyte to oxidize some of the U and other active metals before starting electrotransport. The anode assembly (four baskets) could hold about 8 kg of uranium. An overall anode batch size of 16 kg was achieved by using dual anode assemblies with a single cathode. Steel scrapers were placed near the cathode to control the growth of the uranium dendritic deposit and to allow the removal of the deposit through the cathode port. During the demonstration campaign, Mark-IV was used to treat 12 driver assemblies at an average rate of 24 kg of uranium per month over a 3-month period.

The second electrorefiner, Mark-V, cadmium free, was used for blanket elements (large quantities of depleted uranium). The throughput has been increased by using anode–cathode modules (ACMs) with a capacity of 37 kg per ACM. The overall anode batch size was about 150 kg when four ACMs are used. Each ACM would be able to produce about 87–100 kg of uranium per month. During the demonstration campaign, Mark-V was used to treat 4.3 blanket assemblies at an average rate of 206 kg of U per month over one month.

(m) Oxide–metal processes

A pyrometallurgical partitioning technology for the recovery of uranium and transuranium elements from high-level liquid waste (HLLW) has been developed by the Japanese Central Research Institute of Electric Power Industry (CRIEPI) (Inoue *et al.*, 1991), as described below.

(*i*) *Recovery of actinides from denitrated HLLW*

The process begins with a denitration step in which dehydration by heating converts all the elements in water to insoluble oxides (except for alkali metals which are removed by rinsing with water). The resulted oxides are chlorinated in molten LiCl–KCl eutectic melt. Kurata *et al.* (2000) argue that Cr, Fe, Zr, Mo, and Te are separated during the chlorination step. This is followed by a set of reductive extraction steps.

(*ii*) *Reductive extraction of noble metals*

The purpose of the first reductive extraction is to remove as much of the noble metals as possible while carrying less than 0.1% of each actinide into the reductive extraction product. Extraction step is performed by adding Cd–Li alloy. Laboratory-scale tests show that the amounts of neptunium, plutonium,

and americium extracted in cadmium alloy is less than 0.1% while a larger fraction of uranium is transferred to the alloy. The zirconium removal from the salt ranges from 50 to 95% (Fusselman *et al.*, 1997).

(*iii*) *Reductive extraction of actinides and rare earth elements*

The purpose of the second reductive extraction is to separate the actinides from alkaline earth elements with a recovery yield of each actinide higher than 99.9%. Uranium, transuranium elements are reduced by adding Cd–Li and transferred into Cd alloy, leaving alkaline earth elements in the salt phase. Laboratory-scale experiments indicate that the removal of U, Np, Pu, and Am from the melt is more than 99.9% but most of the rare earth elements are also reduced and so not separated from the actinides (Fusselman *et al.*, 1997).

(*iv*) *Separation of actinides from rare earth elements*

The cadmium phase coming from the second extraction step serves as an anode in an electrorefining step. The goal is to extract the actinides and rare earths from the cadmium alloy for recycling it and to deposit uranium onto the cathode as solid metal (Fusselman *et al.*, 1997, see also Section 24.3.12k). The salt coming from the electrorefining step is then introduced in a multistage extraction step for separating the transuranium elements (TRUs) from rare earths (REs). Distribution coefficients for actinides and rare earths in LiCl–KCl/Li–Cd system have been measured by numerous workers (Sakata *et al.*, 1991; Koyama *et al.*, 1992; Ackerman and Settle, 1993; Hijikata *et al.*, 1993; Sakamura *et al.*, 1994). The LiCl–KCl/Li–Bi system has been investigated by Kurata *et al.* (1995).

Liquid bismuth is used instead of cadmium because the LiCl–KCl/Li–Bi system provides better TRU/RE separation factors than the LiCl–KCl/Li–Cd system (see Table 24.14). Separation factors obtained in laboratory-scale tests performed as described in Fig. 24.19 at 500°C are constant at each extraction stage and are in good agreement with those given in the literature, except for uranium and zirconium whose separation factors vary and are higher than expected. This result could be explained by transfer of a part of uranium and zirconium to the salt phase as soluble oxygenated species due to traces of oxygen in the salt (Uozumi *et al.*, 2001).

(*v*) *Actinide electrorecovery*

Contrary to extraction in the LiCl–KCl/Cd system wherein the actinides can be recovered from the final metallic product (An–Cd alloy) by cadmium distillation, in the LiCl–KCl/Bi system bismuth is not easily distillable, as was noted above. It is therefore necessary to carry out a complementary oxidation–reduction step to separate actinides from bismuth and to recover them as metal.

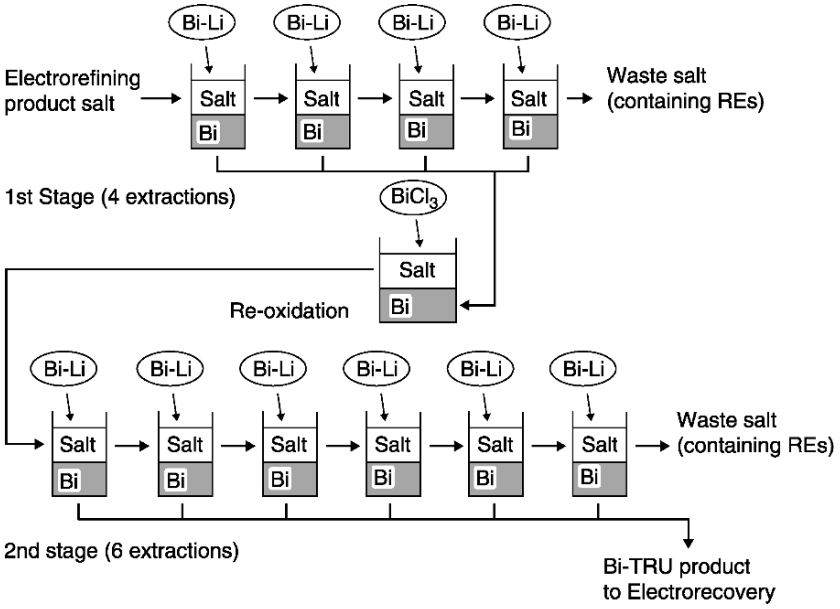

Fig. 24.19 *Schematic flow sheet tested for TRUs/REs separation.* (*Figure created from information in Uozumi* et al., 2001).

An electrolytic recovery in which actinides are stripped from bismuth used as anode and collected on a cathode has been proposed (Uozumi *et al.*, 2001). All the actinides are well stripped (97% for U and more than 99% for TRUs) from Bi. During the electrodeposition, 91–93% of each actinide – U, Np, and Pu – whose lowest stable oxidation state is 3+, are collected on a tantalum cathode. Americium exhibits a more complex behavior because of its two possible oxidation states (3+ and 2+). The recovery of americium is limited by the reproportionation reaction $2Am(III) + Am(0) \rightleftharpoons 3Am(II)$ (see Section 24.3.12b) and only 25% of the total is recovered. Reuse of the americium-bearing salt in the previous step has been proposed to avoid sending it to waste.

Laboratory-scale demonstration tests show that, by combining electrorefining and reductive extraction as described above, less than 0.1% of uranium and individual TRUs are transferred to waste salt. The weight ratio between TRUs and REs in the final product is 2.01 (larger than 1.0, the minimal value required ratio for transmutation strategies).

(n) Recovery of actinides from LWR fuels

Argonne National Laboratory has developed (and is still developing) oxide pyroprocessing compatible with the pyrochemical processes for metal fuels. One purpose is to recover actinides from spent light water reactor fuels to

introduce them into an integral fast reactor fuel cycle. Basically the process for oxide fuel involves the reduction of the oxides to metallic form, followed by either: (i) a combination of the salt transport and halide slagging for separation of fission products and the separation of the uranium from the transuranic elements (see Section 24.12k, (Pierce *et al.*, 1993; Johnson *et al.*, 1994) or (ii) the standard electrorefining process (see Section 24.3.12l) for the same purpose (Pierce, 1991; Laidler, 1994). Typically, the reducing agent is calcium or lithium.

(*i*) *Calcium reduction*

In the 1960s, the production of plutonium metal by direct calcium reduction of plutonium dioxide (direct oxide reduction or DOR process) was investigated. These efforts were reviewed by Moser and Navratil (1983). First attempts showed that molten salts were necessary for dissolving the CaO produced and for allowing plutonium metal consolidation. The first used salt was $CaCl_2$ at 800°C but the binary melt $CaCl_2$–CaF_2 with lower working temperature is efficient for minimizing corrosion and product contamination. Calcium reduction has been adapted for LWR fuel reduction when salt transport is used. The oxide fuel is reduced by a Ca–Mg–Cu alloy in contact with $CaCl_2$–CaF_2. Calcium plays the role of reducing agent while Mg–Cu alloy is the donor alloy for salt transport as described in Section 24.3.12k. Most of the reduced uranium and noble metals are insoluble in Mg–Cu alloy and thus precipitate while TRUs and trivalent REs are solubilized in the alloy. Alkali metals, alkaline earth elements, Sm, Eu, Se, Te, Br, and I remain in the salt phase (Pierce *et al.*, 1993; Johnson *et al.*, 1994).

Reduction experiments at laboratory scale have been carried out on high-fired UO_2, powders of PuO_2 and NpO_2, several representative fission product oxides, and simulated fuel pellets with non-radioactive fission products. Reduction yields obtained for the actinides are more than 99%. Neptunium coprecipitates with uranium (Pierce *et al.*, 1993; Johnson *et al.*, 1994). The salt is electrochemically treated for CaO decomposition and calcium regeneration. Oxygen is liberated at the carbon anode as CO and CO_2 and the calcium that is produced is dissolved in a liquid cathode of recycled Mg–Cu alloy. The feasibility of the electrochemical regeneration of the spent salt has been established at the laboratory scale. Current efficiency of 70% is reached when Mg–Cu alloy is used as cathode, but the current density of about 170 mA cm^{-2} is low for a full-scale process (Pierce *et al.*, 1993).

(*ii*) *Lithium reduction*

Reduction by lithium in chloride melts has been proposed when the objective of the process is electrorefining in LiCl–KCl melt (Johnson *et al.*, 1994; Laidler, 1994). In such reduction no metallic solvent is required and the temperature is

lower so that common construction materials can be used. The reduction produces lithium oxide in the salt. Lithium is a less effective reducing agent than calcium, thus the progress of the reduction depends greatly on the activity of Li_2O (i.e. its concentration in the salt) (Johnson *et al*., 1994). Moreover, it is necessary to maintain Li_2O dissolved in salt to avoid physical interactions between the reduced oxides and Li_2O. Reductions on UO_2 in various chloride melts between 500 and 750°C showed that reductions were complete, but Li_2O solubility was exceeded when low-temperature melts were used (Johnson *et al*., 1994). Pure LiCl, whose the melting point is 602°C, has been chosen as the medium for the reduction and Li_2O solubility has been measured in the range 600–750°C (Johnson *et al*., 1994; Usami *et al*., 2002). Johnson *et al*. (1994) gives 8.7 wt% at 650°C and 11.9 wt% at 750°C.

Experiments on mock fuel with TRU oxides in LiCl at 650, 700, and 750°C have shown poor reduction efficiencies for TRUs. The reduction efficiency decreases with increasing temperature. For instance, the amount of plutonium remaining in salt varies from 0.004 to 37.7% in the range 500–750°C while the americium remaining in the salt varies from 0.06 to 29.6%. To prevent this, LiCl–KCl (60–40 wt%) melt has been proposed as the medium for reduction at lower temperature (500°C) (Johnson *et al*., 1994). It has been claimed that PuO_2 is completely reduced by lithium at 650°C in LiCl with no intermediate product formation, even if Li_2O concentration is just below the solubility limit (Usami *et al*., 2002). In reduction tests performed at 500°C, alkaline earth elements and europium are in the salt presumably as chlorides while the other REs probably remain as precipitated sesquioxides in the salt phase (Pierce *et al.*, 1993). Laboratory-scale (50 to 100 g of simulated fuel) and engineering-scale (3.7 to 5.2 kg of simulated fuel) experiments are currently performed to determine and to master the parameters for process scale-up, taking into account the electrorefiners developed at Argonne National Laboratory (Karell *et al*., 2001). As was the case in calcium reduction, the spent reduction salt is decomposed electrochemically to recover the salt and the lithium metal. Laboratory-scale experiments showed that platinum is a suitable oxygen-evolving electrode that can be operated at high current densities (2 to 3 A cm^{-2}). Current efficiencies are reported at 50–80% (Karell *et al*., 2001).

(o) Nitride–nitride process

In the early 1990s, the Japan Atomic Energy Research Institute (JAERI) proposed a double strata fuel cycle concept for partitioning–transmutation strategies in which the minor actinides from the commercial fuel cycle go into a second-stratum transmutation ('actinide-burner') cycle. Dense fuel is preferable in the second-stratum and nitride fuel is regarded as the reference fuel (metallic fuel remaining an alternative) by JAERI (Mukaiyama *et al*., 1995; Ogawa *et al*., 1995). Having a high electrical conductivity, the molten salt

electrolytic process developed for metallic fuel (see Section 24.3.12l) can be applicable to mononitride fuel (Arai *et al.*, 1995).

(*i*) *Dissolution step*

The actinide nitrides are anodically dissolved in molten LiCl–KCl eutectic at 773 K as follows:

$$UN + 3Cl^- \rightleftarrows 3e^- + UCl_3 + \tfrac{1}{2}N_2 \qquad (24.45)$$

Actinides and most of fission products (except for zirconium) behave almost the same as in metallic fuel (Arai *et al.*, 1995; Kobayashi *et al.*, 1999). According to the above chemical reaction, nitrogen escapes from salt bath as N_2 gas so that such dissolution should facilitate the recycling of ^{15}N-enriched nitrogen, which would have to be used in nitride fuel to minimize the generation of ^{14}C (Ogawa *et al.*, 1995). The release of nitrogen has been studied during NdN dissolution by chemical oxidation (with $CdCl_2$). About 90% of the nitrogen is evolved as N_2 gas (Arai *et al.*, 1999; Kobayashi *et al.*, 1999).

The feasibility of the anodic dissolution has been demonstrated at the laboratory scale for UN (Kobayashi *et al.*, 1995), for NpN and PuN (Arai *et al.*, 1999; Shirai *et al.*, 2000). During the dissolution, a by-product (UNCl) can be formed at the anode. The stability diagram of the U–N–Cl system has been determined. This by-product can be decomposed by heating to high temperatures (Ogawa *et al.*, 1997). The chemistry of AnN in molten LiCl–KCl is still in its infancy and several unknowns remain: (i) the effect of partial pressure of released N_2 on the redox potential of AnN/An(III); (ii) the formation of AnNCl, and (iii) the behavior of transplutonium elements.

(*ii*) *Actinide nitride recovery*

Fission products and actinides are dissolved in the bath as chlorides. The actinides can be recovered as nitrides by either direct or indirect methods (Ogawa *et al.*, 1997):

(i) the actinide chlorides are directly converted to actinide nitrides in molten LiCl–KCl by using Li_3N (Lithium Nitride Extraction of actinides (LINEX process),
(ii) the actinide chlorides are first electro-reduced as actinide metals on a liquid cadmium cathode and then they are converted to nitrides in the liquid cadmium (with either N_2 gas or Li_3N).

The LINEX process is based on the comparable stability of mononitrides of actinides and lanthanides. As the Gibbs energies of formation of the lanthanide trichlorides are more negative than those of the actinide trichlorides

(see Table 24.12), the actinide nitrides should be preferentially formed and the following equilibrium should be displaced to the right:

$$AnCl_3 + Li_3N \rightleftarrows AnN + 3LiCl \tag{24.46}$$

In LiCl–KCl eutectic, the equilibrium constant must be expressed by taking into account the chemical activities of the various species. First attempts of nitridation by Li_3N have been performed on a $LiCl–UCl_3–NdCl_3$ mixture where preferential nitridation of UCl_3 has been observed (Ogawa *et al.*, 1997).

Nitridation in liquid cadmium has been tried on 2 wt%U–1 wt%Gd–1 wt% Ce–Cd mixtures with N_2 gas over the temperature range of 773–873 K (Akabori *et al.*, 1997). Uranium was preferentially nitrided to form U_2N_3, while almost all of Ce remained in the liquid Cd phase as $CeCd_{11}$. Gadolinium behavior is more complex and a small portion of Gd is precipitated (nitride or metallic forms). Nitridation in liquid cadmium appears efficient for light lanthanides (La–Nd).

24.4 APPLICATIONS OF SEPARATIONS IN ACTINIDE SCIENCE AND TECHNOLOGY

24.4.1 A question of scale and more – analytical separations and hydrometallurgical processing

Previous sections of this chapter have dealt with actinide separations emphasizing the basics of actinide solution chemistry in aqueous/organic media and molten salt/metallic phases, historical background, and emerging techniques that may figure prominently in future developments of actinide separations options. In this section, the focus will be on applications of the most extensively developed methods for analysis and industrial-scale processes.

(a) Separation techniques for actinide speciation in the environment

Development and validation of thermodynamic models for actinide behavior in nature require accurate information on oxidation state distribution of the actinides in natural samples. A major difficulty in the determination of (for example) plutonium oxidation states in groundwater samples is the relative ease of interconversion among the oxidation states. Because of the typically very low concentrations involved (generally below 10^{-8} M and often far less), conventional techniques (e.g. spectrophotometry) are not useful, except for the unique case of curium, which can be determined at extremely low concentrations through its fluorescence emissions (discussed in Chapter 9). For most laboratories, separation chemistry combined with radiometric or mass spectrometric analysis are the most appropriate techniques for such speciation at these

low concentrations. The key challenge is to determine the oxidation state using procedures that do not alter this oxidation state during the measurement. Time of analysis and efficient separation procedures are clearly the most important aspect of separation for this purpose. Several complementary separation methods can (and should) be applied to insure accuracy. Some examples of actinide oxidation state speciation methods based on sorption or solvent extraction are:

- LaF_3 coprecipitation in which a lanthanide fluoride carries An(III) and An(IV), leaving An(V) or An(VI) in the solution phase, a technique that traces its roots to the dawn of discovery of transuranium actinides. Care must be exercised during the application of this technique, as excess fluoride can promote reduction during the precipitation process (Choppin and Nash, 1996). Samples must be acidified as well, thus risking the chance of oxidation state change during analysis.
- Silica gel (SiO_2) selectively sorbs An(IV) and An(VI) from basic media leaving An(V) in solution (Inoue and Tochiyama, 1977).
- $CaCO_3$ selective sorbs An(V) and An(IV), leaving An(VI) in solution as the tris carbonato complex (Kobashi *et al.*, 1988).
- Thenoyltrifluoroacetone (TTA, 0.5 M in xylene) selectively extracts An(IV) from 0.25 to 1.0 M acid. The same extractant can then be used to extract An (VI) from acetate buffer at pH 4 (Bertrand and Choppin, 1982). Photolysis of this solution can be used to produce comparatively pure samples of Pu(V) in neutral solutions (Saito *et al.*, 1985).
- The β-diketone dibenzoylmethane (DBM, 0.2 M in xylene) selectively extracts An(IV) at pH<2.5, An(VI) at pH 5, An(III) at pH 7. An(V) is not extracted (Saito and Choppin, 1983).

Filtration of the sample should always be conducted prior to conducting the analysis to determine whether some portion of the material is being transported as colloidal material. Most of the analytical procedures require that the ambient conditions of the solution be altered. It has been suggested that acidification of the sample may be undesirable, as redox-active metals like Pu can undergo oxidation state change with a change in pH. However, there are situations under which acidification might be desirable, for example when appreciable concentration of organic complexing agents are present. In these cases, acidification can reduce the stability of the actinide complex, releasing the cation, and improving the accuracy of the analysis. The guiding principle in conducting such analyses is to never rely on a single observation by one technique to establish actinide oxidation state speciation in natural water samples. Multiple methods should be applied in tandem and some of the methods applied should include alteration of the solution conditions.

As discussed more extensively in Chapter 30, quantitative analysis of actinide concentrations in environmental or bioassay samples by standard methods requires extensive treatment to promote the release of the radionuclides from

the complex matrix. For such quantitative analysis, preserving the ambient condition of the sample is a less important consideration than assuring complete recovery of the sample and applying internal standards to trace yields of the separation processes. Analyses of such samples have required up to 24 h processing time. Standard ion exchange and solvent extraction have been used for these analyses. The recent development of more selective extraction chromatographic materials and the development of procedures for their use have greatly shortened the time required for these analyses (Horwitz *et al*., 1995). These extraction chromatographic materials are based on well-known solvent extraction methods, as follows:

- TRU® resin for selective sorption of An(III), An(IV), An(VI), Ln(III). The extractant is 0.75 M CMPO in TBP.
- TEVA® resin for sorption of An(IV). The extractant is $(C_{10}H_{21})_2(C_8H_{17})(CH_3)N^+$ (Aliquat 336, neat i.e. without diluent present).
- U/Teva® resin for sorption of U(VI), An(VI). The extractant is $(C_5H_{11}O)_2(C_5H_{11})P{=}O$ DP[PP], neat.

An example of an element-specific separation scheme of actinides using TRU® resin is as follows:

- load sample from 2 M HNO_3, rinse off non-TRUs with 1.0 M HNO_3 then 9 M HCl,
- elute Am^{3+} with 4 M HCl,
- elute Pu^{4+} with 4 M HCl/0.1 M hydroquinone,
- elute Th^{4+} with 2 M HCl,
- elute Np^{4+} with 1 M HCl/0.03 M oxalate,
- elute UO_2^{2+} with 0.1 M $NH_4HC_2O_4$,
- analyze fractions radiometrically.

Analytical methods of this sort are seeing increasing application for bioassay. In addition, instrumental analysis methods suitable for quantitation of lanthanides (Nash and Jensen, 2000) would be suitable for application to samples containing actinides at higher concentrations, but there are few examples of these techniques having been applied for actinide analysis.

24.4.2 Hydrometallurgy – industrial scale separations of actinides

The production of electricity by nuclear fission is, at present, nearly 366 gigawatts electric (GW_e), generated from 438 operating nuclear reactors. The spent fuel from power production reactors contains moderate amounts of transuranium (TRU) actinides and fission products in addition to the still slightly enriched uranium. As we noted previously, there are three choices for the management of the spent fuel: (a) recycle to recover valuable components; (b) direct geologic disposal as waste, or (c) long-term monitoring after stabilization for surface or near-surface storage. At present, both byproduct recycle and 'short-term'

monitoring are being practiced worldwide. After more than 30 years of continuous investigation, no repositories have been fully licensed to receive commercial reactor fuels. Yet safe disposal of either spent fuel or the high-level waste (HLW) generated during reprocessing of spent fuel is a matter of great environmental concern (Baetsle, 1992). The question of waste disposal has become the largest single issue standing in the way of further development of this otherwise environmentally friendly technology. Furthermore, a recent analysis projecting how fission-based nuclear power could favorably impact greenhouse gas emissions emphasizes the need for breeding additional fuel to satisfy a projected long-term shortage (Hoffert *et al.*, 2002). Satisfying this demand can only be accomplished by closing the loop of the fuel cycle by reprocessing spent fuel.

Though the pyrometallurgical processes described in Section 24.3.12 may ultimately prove the most efficient method for actinide recycle and transmutation, the nearly 60 years of industrial-scale experience that has been accumulated worldwide on aqueous-based processing of nuclear fuels clearly qualify these methods as the best approach to actinide recycle during at least the next 20 years. In this section, the ongoing research seeking new approaches to hydrometallurgical processing of nuclear fuels will be outlined.

(a) Statement of the problem

At present, half of the world's spent nuclear fuel is produced in a 'once-through cycle'. The other half is reprocessed to recycle uranium and plutonium. A deep geological repository is still considered the best option for the sequestration of either spent fuel or high-level waste by-products of reprocessing from the environment. Without actinide partitioning and transmutation, radioactivity levels in a repository will remain above natural backgrounds for several hundred thousand to several million years. How to accomplish long-term surveillance of a geologic repository to make reliable predictions on the projected lifetime of the engineered and natural barriers beyond a period of 10000 years (which time exceeds, that of all human history) and, above all, public acceptance of such repositories are key questions that impact the future of nuclear power.

The option of partitioning actinides from HLW represents an opportunity to reduce the uncertainties associated with geologic disposal. Partitioning followed by geologic disposal of the transplutonium actinides and long-lived fission products can reduce the volume of materials requiring this most expensive form of sequestration, allowing less expensive near-surface burial of shorter-lived fission products. Homogeneous feed streams for waste form production (for example, containing only actinides) would enable the use of waste forms specifically designed to accommodate the class of waste being sequestered (as opposed to demanding that one waste form be compatible with the largest part of the periodic table of species present in wastes). The long-term stability of such tailored waste forms would be easier to assure based on analogies with natural systems.

Table 24.15 *Long-lived actinides in HLW solution and their half-lives.*

Nuclide	^{237}Np	^{238}Pu	^{239}Pu	^{240}Pu	^{241}Am	^{243}Am	^{246}Cm
$t_{½}$ (yr)	2.144×10^6	87.74	24 411	8550	432.2	7370	4760

Exercise of the partitioning and transmutation (P&T) option seeks to convert all long-lived nuclides into short-lived radioactive (or stable) species. Successful application of this approach to radioactive waste management could substantially reduce the requirement for geologic repository capacity. The trade-offs are that a P&T approach to radioactive waste management could increase opportunities for Pu proliferation and will increase the *volumes* of some categories of high-level, intermediate-level, and low-level wastes. However, even if the cost of P&T exceeds the gain in energy from actinide incineration, the added safety margin for the repository could justify the expense. The important actinides from a waste management perspective are given in Table 24.15.

It should be noted that there are different degrees of difficulty associated with different processing options. Spent fuel freshly discharged from the reactor (or allowed only a short cool-down interval) is the most demanding because of the radiation, thermal heat, and diversity of materials to be separated. Long-term storage of these materials prior to reprocessing reduces these problems, as heat and the most intense radiation decline at a moderate rate. In plants designed to recycle purified materials that have not been irradiated (for example, decommissioned weapons), the radiation effects are significantly diminished and heat loads are minimal thus the processes are less damaging to materials and reagents. The aqueous processing of waste materials may approach either situation depending on the source. For tank wastes like those found in the DOE complex in the U.S., their long-term storage implies that most of the fission product radioactivity has decayed and heat loads are significantly reduced (though not eliminated). But for such materials, chemical diversity remains and challenging solid–liquid separations are needed prior to any processing.

24.4.3 Actinide production processes with considerable industrial experience

There are several coprecipitation and solvent extraction procedures that have been utilized to separate and recover actinides from different solutions including the dissolver solutions (resulting from dissolution of the spent fuel). Among the coprecipitation reagents, lanthanum fluoride and bismuth phosphate were widely used in the earlier times. As has been noted previously, bismuth phosphate has been used for plant-scale separation of Pu from dissolver solutions. Among the solvent extraction processes, REDOX, BUTEX, TLA, and PUREX processes have been demonstrated to the production scale, mainly for the separation of uranium and plutonium. A brief description of these processes,

and why they cannot be used for the recovery of minor actinides from high level waste or TRU waste solutions will be discussed below.

(a) Bismuth phosphate process

Bismuth phosphate is a highly specific carrier for Pu in the trivalent and tetravalent oxidation states. Pu(IV) is more efficiently carried on $BiPO_4$ than Pu(III). For separating Pu from dissolver solutions, free of UO_2^{2+} and with high D_f from the fission products, $BiPO_4$ precipitation from moderate HNO_3 solutions containing sulfuric acid can be used. Under such conditions, UO_2^{2+} is sufficiently complexed by sulfate ion to prevent precipitation of uranyl phosphate (Perlman, 1946; Lawroski, 1955; Thompson and Seaborg, 1956; Hill and Cooper, 1958; Stoller and Richards, 1961; Wick, 1967; Cleveland, 1970; Schulz and Benedict, 1972). Pu can be redissolved in ~10 M HNO_3. A few cycles of $BiPO_4$ precipitation and dissolution followed by a final LaF_3 precipitation considerably increases the concentration of Pu in the solution and final recovery can be accomplished by plutonium peroxide and then oxalate precipitations.

For large-scale isolation of plutonium at the Hanford site, the $BiPO_4$ process was employed by adding sodium nitrite in the dissolver solution to adjust the valency of plutonium to the 4+ state, while neptunium remains in the 5+ and uranium in the 6+ state. Plutonium is co-precipitated with $BiPO_4$, leaving behind all the actinides and fission products. $BiPO_4$ product precipitate is dissolved in ~10 M nitric acid and plutonium oxidized to 6+ state by strong oxidizing agents like $K_2Cr_2O_7$, $KMnO_4$, or sodium bismuthate. PuO_2^{2+} remains in the filtrate. It can then be reduced to Pu(IV) with Fe^{2+}. This cycle can be repeated several times. The flow sheet developed at Hanford gave an overall D_f of 10^7. This process was employed during the Manhattan Project because it was the only separation technology reliable enough to be scaled up quickly to meet wartime production demands. The inability to operate the process continuously (separations are made batch-wise) and its rejection of the still-useful enriched uranium caused the discontinuation of its application in favor of the solvent extraction processes, which overcame both of these limitations.

(b) REDOX process

This process, developed at the Argonne National Laboratory, utilizes methyl (isobutyl)ketone (hexone) as the extractant and dissolver solution as the aqueous phase. Plutonium is oxidized to the hexavalent state with $Na_2Cr_2O_7$. High nitrate salt concentrations are generated by addition of $Al(NO_3)_3$ under acid-deficient conditions. PuO_2^{2+} and UO_2^{2+} are extracted into the organic phase, leaving behind most of the fission products, corrosion products, and trivalent actinides in the raffinate (Anonymous, 1951; Merrill and Stevenson, 1955; Stoller and Richards, 1961). Uranium and plutonium are stripped from the hexone phase by water containing small amounts of $Na_2Cr_2O_7$ (to maintain

oxidizing conditions). This cycle is repeated two or three times to get a high D_f from the fission products. Finally, the feed solution containing uranium, plutonium, $Al(NO_3)_3$, acid, and $Na_2Cr_2O_7$ in the required quantity (for feed adjustment and keeping metal ions as PuO_2^{2+} and UO_2^{2+}) are contacted with the hexone solution. From the loaded organic phase, plutonium is stripped by an aqueous solution of $Al(NO_3)_3$ and ferrous sulfamate, which reduces Pu(VI) to Pu(III). Uranium is subsequently stripped with water. To obtain uranium and plutonium in high purity and with high D_f from the fission products, the entire cycle is repeated several times. The ability to run this process as a continuous operation and to recover uranium marked a major improvement for production efficiency over the $BiPO_4$ process. However, the process generated enormous volumes of moderately difficult wastes containing mixed fission products and minor actinides, and demanded procedures to accommodate the toxicity and flammability of the extractant. At Hanford, the process-generated aqueous wastes were made basic and stored in underground tanks. The Al_2O_3 that was generated as a by-product of this process complicates current efforts to remediate tank wastes.

(c) BUTEX process

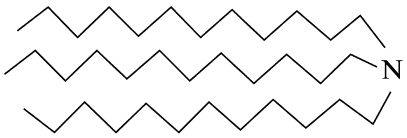
This process, developed in the UK, utilizes the triether dibutylcarbitol, 'Butex' (C_4H_9O–$(C_2H_4O)_2$–C_4H_9; Structure y) as the main extracting agent. The primary advantage of this process as compared with REDOX is that it is possible to extract uranium and plutonium from HNO_3 solutions without the addition of a salting out agent (Howells *et al.*, 1958). The extraction order for actinides and a few fission products is $UO_2^{2+} > PuO_2^{2+} > Pu^{4+} > U^{4+} > Zr^{4+} > Ce^{4+} > Ru(NO)^{3+}$. Like the REDOX and $BiPO_4$ processes, BUTEX rejected neptunium and the transplutonium actinides to the waste stream. Because of several limitations including the high viscosity and density of the extractant, and the formation of crystalline uranyl nitrate–Butex compounds, this process was discontinued as more efficient processes emerged.

Structure y

(d) TLA process

Trilaurylamine (TLA, Structure z) is a highly specific extractant for Pu(IV) while the extration of U(VI) is very low. Thus the TLA process was suggested for a second-stage plutonium recovery process (Auchapt *et al.*, 1968). A solution of 7–20% TLA in diethylbenzene has been used to extract Pu from 1.25–3 M HNO_3. Plutonium was stripped with 3–4 M acetic acid (Coleman, 1964). From a solution formed as zircaloy-clad fuel element is dissolved in nitric acid, plutonium extraction has been shown to be highly effective by using 10% TLA in

t-butylbenzene (Haeffner *et al.*, 1965; Hultgren, 1967). With certain modifications, the TLA process has generated a $D_{f\,Pu}$ of 1.75×10^7 from uranium and of 8×10^7 from β and γ activities.



Structure z

(e) PUREX process

The PUREX (originally Plutonium Uranium Extraction but also found in the literature as Plutonium Uranium Recovery by Extraction or Plutonium Uranium Reduction Extraction) process used TBP dissolved in an inert aliphatic diluent as the extractant for uranium and plutonium from dissolver solution (Anonymous, 1951, 1955; McKay, 1956; Cooper and Walling, 1958; Mathieson and Nicholson, 1968; Koch *et al.*, 1977). Normally a solution of 20–30% TBP in *n*-dodecane, odorless kerosene, or another normal (or branched) paraffinic hydrocarbon (or mixture of hydrocarbons) is used as the diluent. This process was first developed at the Oak Ridge National Laboratory (Flanary, 1954). It has been employed at the industrial scale for nearly 50 years and remains the cornerstone of nuclear fuel reprocessing for both defense and power reactor fuels around the world. One of the major advantages of this process is that it selectively extracts $Pu(NO_3)_4$ and $UO_2(NO_3)_2$ from dissolved spent nuclear fuels from solutions of moderate nitric acid concentrations (2–3 M), requires no addition of any salts, and is plagued by few co-extracted impurities.

Both Pu(IV) and Pu(VI) are readily extracted into the organic phase, whereas Pu(III) extraction is comparable to that of americium (see Fig. 24.6). In the hexavalent state, the order of distribution ratio is U(VI) > Np(VI) > Pu(VI). Neptunium, normally maintained in the pentavalent oxidation state in PUREX processing, is extracted even less than the trivalent actinides. Neptunium redox chemistry in nitric acid solutions generally causes some more extractable neptunium species to be present, hence there is often 'leakage' of neptunium into undesirable process streams in a PUREX plant (Drake, 1990), as will be discussed further in Section 24.4.4f. As the detailed description of the PUREX flow sheet is given elsewhere, only the practical steps involved with this process are listed here:

(1) Feed preparation – fuel is decladded and dissolved, nitric acid concentration is adjusted to 2–3 M and plutonium valency is adjusted to 4+, most commonly with H_2O_2 or HNO_2.
(2) Co-decontamination cycle – U(VI) and Pu(IV) are co-extracted into the TBP phase leaving behind the fission products, trivalent actinides, and Np(V) in the aqueous raffinate.

(3) Partition cycle – Pu(IV) is reduced to Pu(III) using ferrous sulfamate, U(IV), or hydroxylamine, resulting in Pu(III) being stripped into the aqueous phase while uranium remains in the TBP phase; U(VI) is subsequently stripped with very dilute nitric acid solution; final cleanup of remaining traces of U(VI) occurs during extractant reconditioning with Na_2CO_3.
(4) A second uranium and plutonium extraction cycle follows step (3) for both the aqueous phases separately after feed adjustments to improve recovery.
(5) Final purification of plutonium is done in modern PUREX plants using additional TBP solvent extraction steps. Historically, pure plutonium has been prepared using anion exchange chromatography, as follows: the feed is adjusted to 7.1 M HNO_3 and the plutonium anionic species $Pu(NO_3)_6^{2-}$ is adsorbed strongly onto the column; remaining contaminants like U, Zr–Nb, Ru, and Fe are not adsorbed; after adequate washings, plutonium is eluted from the anion exchange resin with 0.5 M nitric acid.

The improved PUREX (IMPUREX) process operated at temperatures higher than 50°C suggests several advantages such as prevention of plutonium accumulation in the extractors, improvement in fission products and neptunium separations, etc. (Schmeider and Petrich, 1989) and is worth considering.

All of the processes mentioned above, particularly PUREX, have been operated on a production scale. However, none of these processes can be used to separate and recover trivalent actinides or Np(V) neither from HLW solutions nor from various TRU containing waste solutions, which are often moderately concentrated nitric acid solutions (2–4 M). TBP can be employed to extract trivalent actinides (as was indicated in the work of Sekine, 1965, discussed in Section 24.3.4), but only with the reduction of acidity of the aqueous stream and addition of salting out agents. Diluting the HLW solutions, decreasing the acidity by denitration, or partial neutralization to obtain dilute acid salt solutions will increase the volumes of by-product wastes and increase the difficulty of their disposal. If the so-called minor actinides are to be transmuted, there clearly is a need for developing full-fledged processes for recovery of these minor actinides from HLW and TRU wastes.

(f) THOREX process

In the 1960s and 1970s, great interest developed in the thorium fuel cycle as a supplement to limited uranium reserves. The slightly harder neutron spectrum of heavy water and gas-cooled/graphite-moderated reactors make such reactors reasonable centerpieces of a uranium–thorium breeder reactor cycle, though it has been shown that thorium can be used practically in any type of existing reactor. For example, Stewart *et al.* (1971) have described a thorium–uranium breeder fuel cycle designed around the now-decommissioned Fort St. Vrain gas-cooled reactor. Molten salt reactors have a similar favorable neutron spectrum

for this fuel cycle. These initiatives have been virtually brought to a halt for various reasons, except in India, where research has continued with its exploration of the thorium–uranium fuel cycle (Lung and Gremm, 1998).

The initial ^{233}U to operate this fuel cycle must be produced in a ^{235}U-fueled reactor, or with an initial ^{235}U or ^{239}Pu charge surrounded by a ^{232}Th breeding blanket. Two fundamental limitations of the U–Th fuel cycle are the creation of ^{228}Th ($t_{1/2} = 1.912$ years, 5.42 MeV α) and ^{232}U ($t_{1/2} = 68.9$ years, 5.32 MeV α) and their daughters as by-products, and the creation of ^{233}Pa ($t_{1/2} = 27$ days, 0.3 MeV γ, 0.6 MeV β^-) as parent of the desired ^{233}U product. The build-up of isotopic contaminants during successive irradiations of recycled ^{233}U–Th fuels can greatly affect the handling procedures used in fuel-element refabrication. Reactor-fuel elements containing ^{233}U may be fabricated semi-remotely provided that complete fabrication can be accomplished in 2 weeks or less. If ^{233}U contains more than 200 ppm ^{232}U, or if refabrication of fuel elements requires longer than 2 weeks, a shielded refabrication facility is necessary. Thorium fuels must be allowed to decay for 12 years if unshielded refabrication procedures are to be used (Arnold, 1962; Schlosser and Behrens, 1967). The fuel cycle has been advocated as non-proliferating on the basis of the presence of ^{232}U isotope and the energetic γ activity of its ^{208}Tl and ^{212}Bi daughters (Ragheb and Maynard, 1980). Another significant advantage of this fuel cycle is the reduced production of long-lived transuranium actinides.

Several approaches to fuel dissolution have been developed for this fuel cycle dependent in part on the reactor type used to breed ^{233}U. The oxide fuel and the breeding blanket used for gas-cooled reactor fuels are imbedded in a graphite matrix. In this cycle, the spent fuel is crushed and the carbon typically burned out prior to fuel reprocessing.

Stainless steel cladding from water-moderated reactors is easily dissolved with 4–6 M H_2SO_4 (Sulfex process) or 5 M HNO_3–2M HCl (Darex process) in low-carbon nickel alloy or titanium equipment, respectively. Uranium losses to the decladding solutions are readily recovered from the Darex decladding solutions in the acid THOREX extraction process. The ThO_2–UO_2 core can be dissolved in 13 M HNO_3–0.04 M NaF–0.1 M $Al(NO_3)_3$. Uranium and thorium can be recovered from graphite-based fuels by: (a) disintegration and leaching with 90% HNO_3; (b) grinding and leaching with 70% HNO_3; or (c) combustion followed by dissolution in fluoride-catalyzed HNO_3 (Blanco *et al.*, 1962). Irradiated Al-clad Th metal slugs are dissolved in HNO_3 containing Hg^{2+} and F^- as catalysts (Bruce, 1957).

The separation of thorium from uranium is most typically accomplished using the same basic chemistry that drives the PUREX process, i.e. extraction of Th(IV) and U(VI) from nitric acid solutions into TBP solutions with aliphatic hydrocarbon diluents. The use of an acid-deficient feed (0.15 M) induces high decontamination while injection of HNO_3 at the fourth extraction stage provides high salting strength and insures quantitative uranium and thorium extraction. Because thorium is extracted by TBP less effectively than Pu(IV) or

U(VI), the introduction of $Al(NO_3)_3$ (Oliver, 1958) or $Be(NO_3)_2$ (Farrell *et al.*, 1962) as salting out reagent has been demonstrated.

In the acid THOREX process, three solvent extraction cycles are used. In the first cycle, uranium and thorium are extracted away from most fission products by 30% TBP from 5 M HNO_3. Both are stripped into a dilute acid phase. In the second cycle, acid conditions are controlled for selective extraction of uranium while thorium remains in the aqueous raffinate. The extracted uranium is further purified by solvent extraction or ion exchange while the thorium is concentrated and stored for recycle.

The processing of short-cooled thorium metal results in the collection of a first cycle extraction column raffinate that contains 20–30% of the mass 233 as ^{233}Pa. Ultimate recovery of ^{233}U requires storage of the raffinate for decay of ^{233}Pa. During a THOREX pilot plant short-cooled scouting run, an estimated 27 g of ^{233}Pa was collected and stored as extraction column raffinate. A one-cycle solvent extraction flow sheet was used to separate ^{233}U from fission products and other contaminants contained in the raffinate. ^{233}U was extracted into 6% TBP in Amsco 125–82 and subsequently stripped into dilute HNO_3 (McDuffee and Yarbro, 1957, 1958).

Five thorium processing campaigns were conducted at the Savannah River Plant. Two different flow sheets were used and a total of about 240 metric tons of thorium and 580 kg of uranium was processed. In the first two campaigns on thorium oxide, uranium was recovered with a dilute 3.5% TBP flow sheet and the thorium was sent to waste. ^{232}U concentrations in these two campaigns were 40–50 ppm and 200 ppm. In the third campaign, thorium metal and thorium oxide were processed. ThO_2 was processed in the final two THOREX campaigns. The three THOREX campaigns used 30% TBP to recover both uranium and thorium. Irradiation conditions were set to produce a concentration of 4–7 ppm ^{232}U. Dissolving rates for thorium metal exceeded 4 metric tons per day and with thorium sent to waste, solvent extraction rates increased, and posed no limits. When Th oxide feed was used dissolving and THOREX solvent extraction rates were $\approx$1 metric ton per day. Satisfactory flow sheets were developed, losses were acceptable, and decontamination from fission products and Pa were adequate. Th–DBP precipitates did appear in the second Th cycle during the first THOREX campaign (Orth, 1978). Rainey and Moore (1962) demonstrated a laboratory-scale THOREX separation in which good decontamination factors were obtained, and U and Th losses were less than 0.01 and 0.3%. Watson and Rainey (1979a,b) have demonstrated a THOREX computer code.

When the fuel being irradiated contains appreciable amount of ^{238}U, the plutonium thus formed requires that a combination of the THOREX and PUREX processes must be applied. The THOREX process is technologically less advanced and principally hindered by the much lower distribution coefficient of Th nitrate relative to uranium and plutonium. To drive thorium into the

TBP phase, a strong salting agent is required. Aluminum nitrate is replaced by nitric acid to reduce the amount of radioactive waste. However, high acid concentrations are counter-effective in achieving high fission product decontamination. Therefore, several flow sheet variants with acid and acid-deficient feed solutions, respectively, have been investigated (Merz and Zimmer, 1984). To achieve high decontamination factors, a dual cycle THOREX process was developed. This process uses an acid feed solution in the first cycle and an acid-deficient feed in the second cycle. An immediate separation of thorium and uranium appears advisable in view of both fuel cycle strategy and process feasibility.

To test the separation of thorium, uranium, and plutonium from each other, Grant *et al.* (1980) developed a modified THOREX solvent extraction flow sheet using 30% TBP. Not surprisingly, the inclusion of plutonium in the fuel cycle increases complexity. The first and second stages are used as a decontamination cycle to remove most of the fission products from the actinides. After intermediate concentration and adjustment of plutonium valency [to Pu(III)], the next three stages comprise the primary separation system and are used to recover Pu(III), Th, and ^{233}U separately.

Finally, several alternative extractants and even extractant types have also been suggested as a means of separating ^{233}U from irradiated thorium. To overcome the comparatively weak extraction of Th by TBP, Siddall (1958, 1963b) suggests that diamyl(amyl)phosphonate (DAAP) should be considered as a replacement for TBP in Th processing. The separation factor between thorium and zirconium is at least ten times greater with DAAP than with TBP. A high degree of complexing of DAAP by thorium occurs even in dilute HNO_3. This extractant is also less prone to third phase formation.

The extraction behavior of 1 M solutions of tri-2-ethylhexyl phosphate (TEHP), di-2-ethylhexyl isobutyramide (D2EHIBA), and di-*n*-hexyl hexanamide (DHHA) in *n*-dodecane towards U(VI), Th(IV), and Pa(V) in the presence of 220 g L^{-1} of thorium from nitric acid medium also has been studied (Pathak *et al.*, 2000). Separation factors for U(VI) over Th(IV) consistently varied in the order: D2EHIBA > DHHA > TEHP > TBP under most conditions. The quantitative extraction of ^{233}U from a synthetic mixture containing $^{233}U(10^{-5}$ M), ^{233}Pa (10^{-11} M), and thorium (220 g L^{-1}) at 1 M HNO_3 using a 1 M solution of D2EHIBA in *n*-dodecane is achieved in three stages.

Detailed studies on the processing of irradiated thorium using an amine solvent at pilot plant scale have been reported (Awwal, 1971). In this process, the ^{233}U and thorium are coextracted with 0.1 M methyldidecylamine from a feed solution of 5.8 g Th L^{-1} having 2.5×10^{-3} M H_2SO_4. The extracted thorium is selectively stripped with 1M H_2SO_4 and ^{233}U is stripped with 0.5 M HNO_3. The final product is purified by anion exchange. The decontamination factor from fission products for ^{233}U and thorium are 3.2×10^4, 3.8×10^4, respectively, for the single cycle solvent extraction process. The separation factor of ^{233}U from thorium is 2×10^4.

24.4.4 Actinide production processes at the design and pilot stages

During the last two decades, concerted and mission-oriented research conducted around the world has identified a number of promising extractant systems for actinide separations using solvent extraction, extraction chromatography, supported liquid membrane, magnetically assisted chemical separations, or pyro-reprocessing. The pyrometallurgical options have been discussed in Section 24.3.12. Plant-scale demonstrations are yet to occur, partly because of materials/corrosion issues. Most aspects of separations in the IFR project have been demonstrated at the pilot scale. In the following discussion, the performance of the new extraction systems that have been developed for actinide partitioning will be compared. Many of the new extractant systems under development are based on bifunctional (or multifunctional) reagents, whose unique nature will become apparent in the discussion to follow. The chemical features of many of these systems have been considered above (see Section 24.3.4b). The emphasis in this section will be more on the status of process development. The reader is referred to the cited literature for detailed information on the chemistry of the extraction systems.

(a) Dihexyl-*N*,*N*-diethylcarbamoylmethylphosphonate (DHDECMP or CMP)

Navratil and coworkers (Martella and Navratil, 1979; Navratil and Thompson, 1979) conducted a preliminary feasibility study for separation of actinides from synthetic acidified waste solutions likely to be produced during nuclear fuel fabrication and reprocessing. The initial solution contained large quantities of Na_2CO_3, Na_3PO_4, NaCl, Na_2SO_4, and the actinides, plutonium, americium, and uranium. A first contact with 30% TBP/*n*-dodecane removed more than 99.99% of uranium and most of the plutonium. The aqueous raffinate was then contacted with 20–30% CMP/CCl_4 which removed more than 99.91% of americium and all the residual plutonium and other actinides.

Rapko and Lumetta (1994) have reported the extraction of U(VI), Pu(IV), Am (III), and important competing metal ions (e.g. Fe(III), Zr(IV), Bi(III)) from HNO_3 solutions using a mixture of CMP (0.75 M) and TBP (1.05 M) in an aliphatic diluent [normal paraffinic hydrocarbon (NPH) or isoparaffinic hydrocarbon (ISOPAR)]. Above 2M HNO_3, this organic phase splits into heavy and light fractions (third phase formation) even in the presence of $\sim$ 1 M TBP. Adjustment to about 2.0 M $NaNO_3$ is indicated as necessary to prevent third phase formation. At about 2 M (HNO_3, NO_3^-) in the absence of any aqueous complexing agent, a distribution ratio D_{Am} of about 5 is reasonably good. Though 0.1 M HF has no effect on D_{Am}, 0.05 M oxalic acid decreases D_{Am} to about 1. Salting out with $NaNO_3$ increased this value. D_{Pu} at radiotracer concentrations and D_U at 0.05 M ($\sim$12 g L^{-1} total uranium) have been reported. D_{Am} decreases in the presence of such moderate concentrations of uranium, presumably as a

result of the tying up of the free extractant by the macroscopic quantities of uranium present. Degradation products and acidic impurities in the CMP extractant can inhibit stripping of plutonium and uranium. The increased volume of wastes in all categories that would result from the introduction of a salting-out reagent required to maintain extraction efficiency and phase compatibility is a significant drawback to the application of this class of reagents.

(b) Octyl(phenyl)-*N*,*N*-di-isobutylcarbamoylmethylphosphine oxide (OϕDiBCMPO or CMPO)

To overcome the comparative weakness of the CMP-class extractants, structurally similar extractants containing the phosphine oxide functional group were prepared. Compounds with different substituents at the phosphoryl group and the amide nitrogen have been synthesized (Kalina *et al.*, 1981a; Chmutova *et al.*, 1983) and studied for extraction of transplutonium metal ions. Alterations have also been made at the bridge between the P=O and C=O groups (Rapko, 1995). Two detailed papers describe the synthesis and purification (Gatrone *et al.*, 1987) and the spectral properties of the carbamoylmethylphosphine oxides (Gatrone and Rickert, 1987). The extraction behavior of mainly trivalent actinides, lanthanides, and a few other metal ions has been studied with all the reagents synthesized in this class. Actinide extraction properties and phase compatibility varied significantly with the nature of the alkyl substituents on the carbamoylmethylphosphine oxide core. Of the compounds investigated, OΦCMPO was found to possess the best combination of properties for actinide extraction in a PUREX-compatible diluent system. The CMPO-type compounds have received the greatest attention of all potential actinide partitioning reagents developed over the past 20 years and as a result represent the best-understood hydrometallurgical reagents for total actinide partitioning from wastes.

Numerous investigations have attempted to demonstrate quantitative phase transfer of americium from HNO_3 or HCl solutions by CMPO into diluents like diethylbenzene, CCl_4, C_2Cl_4, and paraffinic hydrocarbons (Horwitz *et al.*, 1981, 1983, 1986; Kalina *et al.*, 1981a; Horwitz and Kalina, 1984). Extraction of Eu(III) from HNO_3 or HCl with CMPO alone or a mixture of CMPO and TBP in mesitylene or *n*-dodecane has been reported (Liansheng *et al.*, 1990) as has the extraction of neptunium and plutonium (Kolarik and Horwitz, 1988; Mincher, 1989; Nagasaki *et al.*, 1992) and Pm, U, Pu, Am, Zr, Ru, Fe, and Pd (Mathur *et al.*, 1992b) from HNO_3 into a mixture of CMPO and TBP in *n*-dodecane. Basic studies of CMPO have reported its activity coefficients (Diamond *et al.*, 1986), complexes formed with trivalent actinides and lanthanides (Mincher, 1992), electrochemistry of Ce(III) nitrate complex (Jiang *et al.*, 1994), and numerical modeling to predict operations in the TRUEX process (Regalbuto *et al.*, 1992; Vandegrift *et al.*, 1993; Vandegrift and Regalbuto, 1995) and for co-extraction of Tc(VII) with U(VI) (Takeuchi *et al.*, 1995).

The now well-known TRUEX process for the recovery of all the actinides from various types of highly acidic nuclear waste solutions is based on CMPO as the principal extractant. The TRUEX process solvent is 0.2–0.25 M CMPO + 1.0–1.4 M TBP in paraffinic hydrocarbon (linear or branched, though the process has been demonstrated in chlorinated diluents as well) (Vandegrift *et al.*, 1984; Horwitz *et al.*, 1985; Schulz and Horwitz, 1988; Horwitz and Schulz, 1990; Mathur and Nash, 1998; Suresh *et al.*, 2001). TBP hinders third-phase formation, contributes to better acid dependencies for D_{Am}, improves phase compatibility, and reduces hydrolytic and radiolytic degradation of CMPO. The basic actinide solvent extraction chemistry of TRUEX has been discussed in Sections 24.3.4b and 24.3.5. The ability to efficiently extract trivalent, tetravalent, and hexavalent actinides from solutions of moderate acid concentration and with good selectivity over *most* fission products (except lanthanides) is a key feature of this extractant. From an engineering perspective, the more-or-less constant D values of Pu(IV), U(VI), and Am(III) between about 1 and 6 M HNO_3 is important, as it allows efficient extraction of actinides from wastes or dissolved fuels with little or no need to adjust the acidity of the feed solution. This particular feature of TRUEX distinguishes this extraction system from other methods for TRU isolation. A sufficient volume of process-relevant thermodynamic data on CMPO extraction chemistry has been developed to support the existence of a computational model, the generic TRUEX model (GTM) that can be used to predict system performance over a wide range of conditions (Regalbuto *et al.*, 1992; Vandegrift *et al.*, 1993; Vandegrift and Regalbuto, 1995).

Russian chemists have independently developed a TRU extraction process based on a somewhat simpler (thus, less expensive) derivative of CMPO (diphenyl-*N*,*N*-di-*n*-butyl CMPO, DΦDBuCMPO) employing a fluoroether diluent (Fluoropol-732) (Myasoedov *et al.*, 1993). This process behaves similarly to the TRUEX process in terms of its efficiency for actinide extraction, shows little tendency toward third-phase formation, and avoids the interferences caused by degradation of TBP. It has been tested in centrifugal contactors and found to recover actinides with greater than 99.5% efficiency. The corrosive nature of aqueous effluents derived from degraded solvent (i.e. containing HF) is a potential drawback for this process.

Continuing exploration of this extractant has suggested a *un*iversal solvent *ex*traction (UNEX) process for the separation of cesium, strontium, and the actinides from nitric acid solutions and from actual acidic radioactive waste solutions (Law *et al.*, 2001, 2002; Romanovskiy *et al.*, 2001a,b, 2002; Herbst *et al.*, 2002, 2003; Romanovskiy, 2002a,b; Todd *et al.*, 2003). The composition of the UNEX solvent is 0.08 M chlorinated cobalt dicarbollide, 0.5 vol.% polyethylene glycol-400 (PEG-400) and 0.02 M DΦDBuCMPO in a phenyltrifluoromethyl sulfone (FS-13) diluent. Cobalt dicarbollide $[Co(B_9C_2H_8Cl_3)_2^-]$ is a lipophilic substitution-inert Co(III) complex that exhibits significant affinity for Cs^+. Using the Idaho National Engineering and Environmental Laboratory

(INEEL) tank waste, removal efficiencies of 99.4, 99.995, and 99.96% for ^{137}Cs, ^{90}Sr, and the actinides, respectively, have been demonstrated. Possible limitations of the process include corrosive products of diluent degradation (e.g. HF), difficult back extraction due to the requirement of very low acidity for low D_{Am}, and possibly complex solvent cleanup prior to recycle of the extractant (Horwitz and Schulz, 1999).

(*i*) *TRUEX demonstrations with HLW and simulants*

Decontamination of four types of actinide-bearing wastes (or waste simulants) from the Hanford site, plutonium finishing plant (PFP), complexant concentrate (CC), neutralized cladding removal waste (NCRW), and single-shell tank (SST) waste have been the subject of either bench-scale experiments or pilot-scale demonstrations using TRUEX with results as follows:

- The removal of americium and plutonium from the plutonium finishing plant (PFP) aqueous acidic waste [$HNO_3/Al(NO_3)_3$ at 3 M total nitrate with 0.09 M HF, 0–0.2 M U, 10^{-5} to 10^{-4} M Pu, 10^{-6} to 10^{-5} M Am, less than 6×10^{-4} M Be, Cr, Ni, Zn, Pb] was accomplished using the TRUEX solvent (0.25 M CMPO, 0.75 M TBP in C_2Cl_4). The first two highly successful counter-current runs with actual PFP waste employed a cross-flow microfilter unit to remove finely divided solids and 4 cm diameter centrifugal contactor equipment for the solvent extraction of TRU elements. Duplicate runs were completed with 10 L of the clarified waste in about 40 min. The α-activity of the aqueous raffinate was 1–2 $n\text{Ci} \cdot \text{g}^{-1}$ and a TRU D_f of 10^4 was obtained. A generic flow sheet of the TRUEX process for the removal of americium and plutonium from PFP waste is given in Fig. 24.20. A larger-scale demonstration using a 20-stage centrifugal contactor configuration achieved α-decontamination factors up to 6.5×10^4 (Chamberlain *et al.*, 1997).
- The CC waste is alkaline and contains high concentrations of Na^+, NO_3^-, NO_2^-, $Al(OH)_4^-$, CO_3^{2-}, organic complexants (EDTA, HEDTA, citric acid, and their radiolytic and hydrolytic degradation products), and moderate concentrations of Cs^+ and Sr^{2+}. After acidification, bench-scale batch extraction tests with synthetic and actual CC waste demonstrated that the $D_{f\ TRU}$ was on the order of 10^2 (Schulz and Horwitz, 1988). The TRU concentration in the effluent was 1 $n\text{Ci g}^{-1}$.
- NCRW consists of solids (principally $ZrO_2 \cdot xH_2O$) generated while treating Zircaloy-clad fuels. It contains moderate amounts of TRU elements. A preliminary test with actual NCRW dissolved in HNO_3 or HNO_3–HF solutions using the TRUEX solvent was reported to result in satisfactory uptake of the actinides (Schulz and Horwitz, 1988). At the Pacific Northwest National Laboratory (PNNL), highly encouraging results have been reported for actinide removal by TRUEX treatment of NCRW sludge and of PFP sludge (Swanson, 1991a–c; Lumetta and Swanson, 1993a–c).

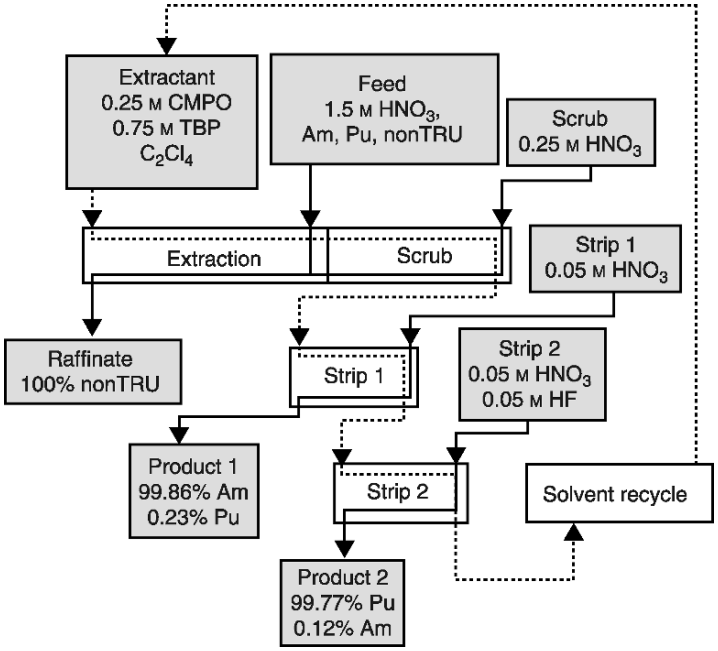


Fig. 24.20 *Generic flow sheet for TRUEX processing of plutonium finishing plant (PFP) wastes.*

- SST waste, a mixture of solid salt cake (e.g. water-soluble sodium salts), solid sludge [primarily hydrated Fe(III) oxide], and a small volume of interstitial liquid containing TRU elements, can also be treated and TRU removed from the acidic solutions, as has been demonstrated using TRUEX on simulated dissolved sludge waste (Schulz and Horwitz, 1988).

The most extensive pilot-scale testing of the TRUEX process has been done at the Idaho National Engineering and Environmental Laboratory under the auspices of the Lockheed Martin Idaho Technologies Co. Several TRUEX demonstration runs have been made on sodium-bearing wastes (Law *et al.*, 1998), a secondary acidic HLW. An optimized TRUEX flow sheet was tested in shielded hot cells at the Idaho Chemical Processing Plant (ICPP) Remote Analytical Laboratory using a 20-stage bank of 2 cm centrifugal contactors.

Stripping of actinides from the loaded process solvent was accomplished with 99.79% efficiency (99.84% for Am, 99.97% for Pu, 99.80% for U) using 1-hydroxyethane-1,1-diphosphonic acid (HEDPA) as the stripping agent. A second demonstration using a dissolved zirconium calcine feed recovered 99.2% of Am (Law *et al.*, 1998). In this case, the HEDPA stripping was less efficient due to problems created by precipitation of zirconium phosphate. The phosphate is believed to be present as an impurity in the HEDPA solution.

Literature reports indicate that such impurities are readily removed by recrystallization of HEDPA from glacial acetic acid (Nash and Horwitz, 1990). The radiolytic stability of this reagent has not been tested, but it is stable in acidic aqueous solutions.

At the Los Alamos National Laboratory (LANL) substantial amounts of waste chloride salts containing moderate concentrations of Pu and Am are generated. These salts, dissolved in HCl, can serve as feed for the separation of actinides using high concentration of CMPO (0.5 M) in C_2Cl_4. If the feed contains large amounts of metal ion impurities that are appreciably extracted by CMPO [e.g. U(VI)], a preceding solvent extraction process employing TBP, TOPO, quaternary ammonium compounds, or some other process must be applied. The D values of Th(IV), U(VI), Np(IV), Pu(IV), and Am(III) at varying HCl concentrations in contact with 0.5 M CMPO in tetrachloroethylene have been reported previously (Horwitz *et al.*, 1987). Initial counter-current studies using TRUEX solvent indicated the need for moderate chloride ion concentration in the feed solution for satisfactory extraction of plutonium and americium (Schulz and Horwitz, 1988). Flow sheet for the generic TRUEX process for the removal of actinides from aqueous chloride solutions is given in Fig. 24.21.

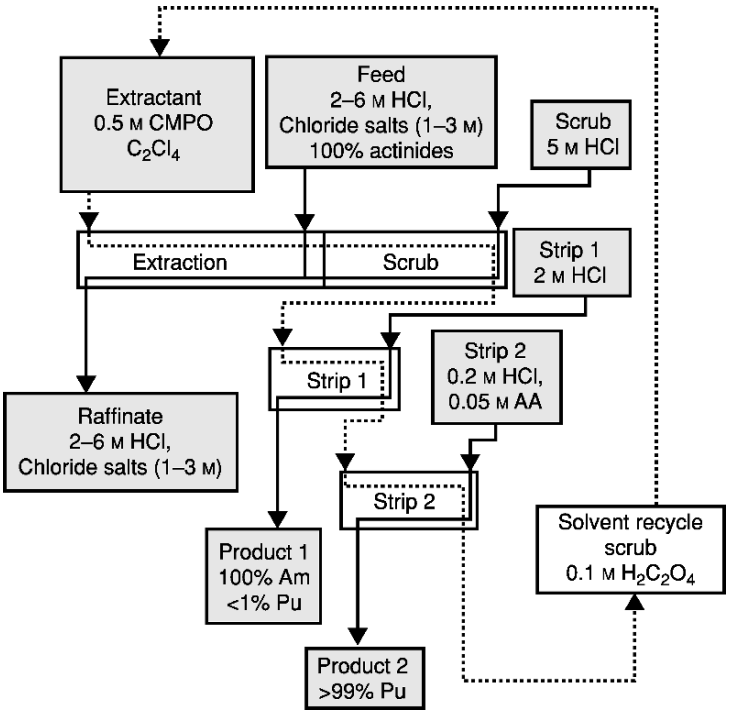

Fig. 24.21 *Generic flow sheet for TRUEX processing of chloride wastes.*

In the European Community R&D program on the management and disposal of radioactive wastes, the Fuel Cycle Dept. ENEA, Rome, Italy, reported that the mixture of TBP and CMPO in chlorinated or aliphatic hydrocarbons achieves a very high D_f for actinides. Batch and counter-current extraction experiments were performed with MOX fabrication liquid wastes. Only batch studies were conducted with simulated solutions of aluminum MTR CANDU high-level wastes of the EUREX reprocessing plant and with analytical wastes from control laboratories of a MOX fabrication plant. Very high D_f values for actinides were obtained without requiring any salting agents and in the presence of many potentially complexing anions (Casarci *et al.*, 1988, 1989).

At Japan's Power Reactor and Nuclear Fuel Development Corporation (PNC), batch and counter-current runs with real high-active raffinate from FBR spent fuel reprocessing have been carried out without adjusting acidity, using 0.2 M CMPO + 1.2 M TBP in *n*-dodecane. The mixer–settler employed in this study had 19 stages for extraction-scrubbing and 16 stages for stripping. The rare earths were extracted along with actinides and some fraction of ruthenium. The D_f for actinides was greater than 10^3. Oxalic acid was added in the feed and scrubbing solutions to improve ruthenium decontamination and effectively lower the D values of zirconium and molybdenum (Ozawa *et al.*, 1992). In another communication from the same laboratory, Ozawa *et al.* (1998) suggested improvements in the TRUEX process flow sheet, specifically, increasing the acidity of the feed to about 5 M to improve Ru decontamination in the actinide fraction, and using salt-free reagents like hydrazine oxalate, hydrazine carbonate, and tetramethylammonium hydroxide for stripping and cleanup steps to obtain a final raffinate that is α-inactive and salt-free. The improved TRUEX flow sheet utilized at PNC is given in Fig. 24.22.

A numerical simulation code for the TRUEX process has been developed to determine the optimum operational conditions for the separation and recovery of TRU elements (Takanashi *et al.*, 2000). With a view to minimize radioactive organic/inorganic waste released from TRUEX process, the electro-redox technique and mediatory electrochemical oxidation using Ag(II)/Ag(I) or Co(III)/Co(II) couples have shown great promise (Ozawa *et al.*, 2000).

At the Bhabha Atomic Research Centre in India, basic data were generated for the extraction of actinides and a few fission and corrosion products using TRUEX solvent (0.2 M CMPO + 1.2 M TBP in *n*-dodecane) (Mathur *et al.*, 1992b). Subsequent studies examined the extraction and separation of actinides from synthetic and actual high-level aqueous raffinate waste (HAW), sulfate-bearing high-level waste solutions (SBHLW) at low acidity of about 0.3 M, non-sulfate wastes originating from pressurized heavy water reactor (PHWR), and fast breeder reactor (FBR) both in about 3 M HNO_3, and actual HLW solutions generated from the reprocessing of research reactor fuels at this center. In each study, the compositions of the synthetic waste solutions were reported (Deshingkar *et al.*, 1993, 1994; Mathur *et al.*, 1993a, 1995, 1996a; Gopalakrishnan *et al.*, 1995). The results of batch studies on actual waste solutions are given below:

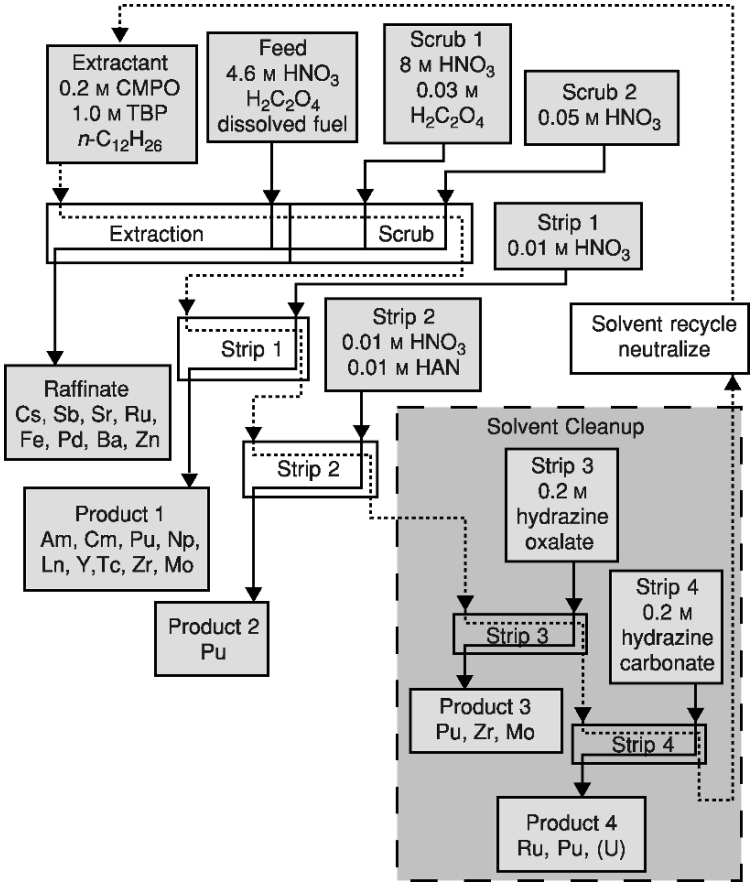

Fig. 24.22 *Generic TRUEX flow sheet for actinide partitioning at JNC.*

- Unmodified HAW was contacted twice with fresh lots of 0.2 M CMPO + 1.2 M TBP in *n*-dodecane in 1:1 ratio. After two contacts, 99.8% of the α-activity was found in the organic phase. The rare earths (Ce, Pm, Eu, etc.) followed americium, and ruthenium was partially extracted while cesium and strontium were not (Mathur *et al.*, 1993a).
- For extraction of HLW, the feed contains at least ten times higher concentration of uranium, fission and corrosion products than those in HAW. Therefore, one contact with 30% TBP/*n*-dodecane was made to deplete the uranium content. After this, four contacts were made with 0.2 M CMPO + 1.4 M TBP. The raffinate was found to contain $\sim$ 0.06% of the total α-activity (Mathur *et al.*, 1993a).

- With SBHLW, two contacts were made with 30% TBP followed by four contacts with 0.2 M CMPO + 1.2 M TBP in *n*-dodecane. Even at the low acidity of 0.3 M and ~ 0.16 M SO_4^{2-}, about 99.6% of the total α-activity was removed from the HLW solutions (Gopalakrishnan *et al*., 1995).

Mixer–settler experiments employing a six-stage unit with synthetic SB- and PHWR-HLW have been reported. After pretreatment with 30% TBP to reduce the concentrations of uranium, neptunium, and plutonium, the raffinate containing the remaining uranium, neptunium, and plutonium and the trivalent actinides and lanthanides (at total acidity of about 3 M) was the feed for a subsequent mixer–settler experiment using 0.2 M CMPO + 1.2 M TBP in *n*-dodecane. In all cases, the HLW raffinate leaving the extraction section showed α-activity near background level. Final analysis indicated that nearly 99.7% of the rare earths are extracted along with the actinides and with about 30% of the ruthenium (Deshingkar *et al*., 1993, 1994; Chitnis *et al*., 1998b). The combined flow sheet using 30% TBP and the TRUEX solvent (Fig. 24.23) has been tested with actual HAW solutions generated from the reprocessing of research reactor fuels.

In the first step, with 30% TBP U, Np, and Pu were recovered from HAW and then minor actinides left in the raffinate were extracted with the TRUEX solvent in the second step. Plutonium and neptunium extracted in TBP were stripped together using a mixture of H_2O_2 and ascorbic acid in 2 M HNO_3 and later uranium was stripped from the TBP phase with dilute HNO_3. Actinides extracted in TRUEX solvent were stripped together using a mixture of formic acid, hydrazine hydrate, and citric acid. The final raffinate analysis showed no alpha activity (Chitnis *et al*., 2000).

(*ii*) *Recovery of Pu from oxalate supernatant*

The solutions resulting from Pu oxalate precipitation (oxalate supernatants) are among the final liquid waste streams in conventional PUREX processing. This waste typically contains ~30 mg $L^{-1}$of plutonium in 3 M HNO_3 and about 0.1 M oxalic acid. TRUEX solvent has proven highly efficient for almost quantitative recovery of plutonium from such a solution in batch solvent extraction studies. Plutonium is stripped from the loaded CMPO phase by 0.5 M acetic acid or by a mixture of oxalic acid, calcium nitrate, and sodium nitrite (Mathur *et al*., 1994). Plutonium also could be recovered from such solutions utilizing the extraction chromatographic technique in which CMPO adsorbed on Chromosorb-102 (CAC) was used for batch and column studies (Mathur *et al*., 1993b). When the oxalate supernatant contained large amounts of uranium (10–12 g L^{-1}) along with plutonium, a TBP extraction step followed by TRUEX process solvent step has recovered uranium and plutonium almost quantitatively (Michael *et al*., 2000).

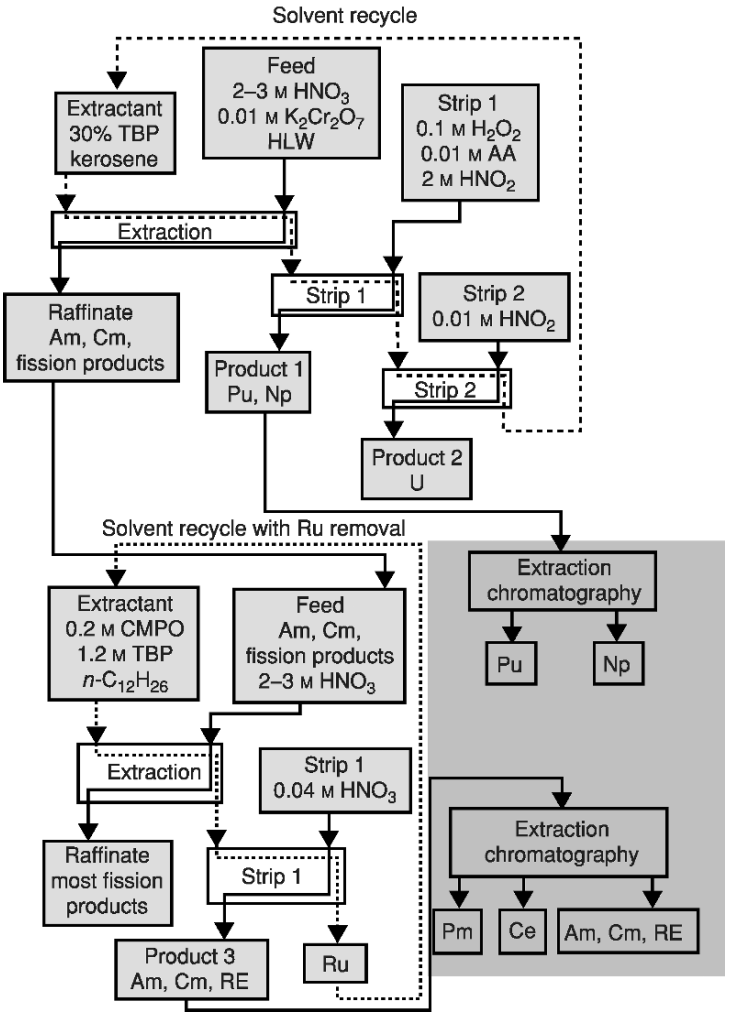

Fig. 24.23 *Generic TRUEX flow sheet for actinide partitioning at BARC.*

(*iii*) *Stripping of actinides from TRUEX solvent*

Oxidation state-specific stripping of actinides from loaded TRUEX solvent can be done in three steps: 0.04 M HNO_3 to remove trivalent actinides, dilute HNO_3–HF mixture (0.05M each), or dilute oxalic acid for selective stripping of tetravalent actinides, and 0.25 M Na_2CO_3 for uranium recovery (and simultaneous reconditioning of solvent for recycle). Horwitz and Schulz (1990)

recommend that a solution of either vinylidene-1,1-diphosphonic acid (VDPA) or HEDPA be used for stripping TRUs when they are directly to be vitrified. In similar fashion, coprecipitation of actinides, lanthanides, and a few other fission and corrosion products extracted into the TRUEX process solvent was achieved by using iron(III)ferricyanide as a carrier precipitant. The volume of the precipitate was very small and suitable for vitrification of TRUs (Rizvi and Mathur, 1997). In other reports (Chitnis *et al.*, 1999a,b), a mixture of formic acid, hydrazine hydrate, and citric acid have shown promise for efficient stripping of Am and Pu from TRUEX solvent loaded with simulated HLW in both batch and counter-current modes. Ozawa *et al.* (1998) report that hydrazine oxalate, hydrazine carbonate, and tetramethylammonium hydroxide for stripping of actinides from loaded TRUEX solvent and its cleanup will lead to a salt-free effluent.

(*iv*) *Degradation, cleanup, and reusability of TRUEX solvent*

The hydrolytic and radiolytic degradation of CMPO has been studied in CCl_4 and decahydronaphthalene (decalin) (Chiarizia and Horwitz, 1986), TCE, or a mixture of TBP and TCE (Nash *et al.*, 1988b). Hydrolytic and radiolytic degradation of TRUEX process solvent (0.2 M CMPO + 1.2 M TBP in *n*-dodecane) has been investigated in the presence of 5 M HNO_3 (Chiarizia and Horwitz, 1990) and under dynamic conditions in contact with 3 M HNO_3 or synthetic PHWR-HLW (Mathur *et al.*, 1988). The *G* values (molecules/100 eV deposited) for the disappearance of CMPO in CMPO–TBP mixture are (1.2 ± 0.3) in *n*-dodecane, (4.5 ± 0.3) in TCE, and (16.4 ± 1.7) in CCl_4 (Nash *et al.*, 1989; Chiarizia and Horwitz, 1990), indicating that more reactive conditions are created upon radiolysis of chlorinated diluents. Hydrolysis generates only acidic compounds while radiolysis produces both acidic and neutral compounds. The degradation products reported are methyl(octyl)phenylphosphine oxide, octyl(phenyl)-*N*-monoisobutylcarbamoylmethyl phosphine oxide, dibutylphosphoric acid, octyl(phenyl)phosphinic acid, octyl(phenyl)phosphinyl acetic acid (Chiarizia and Horwitz, 1990), methyl(phenyl)-*N*,*N*-diisobutylcarbamoylmethylphosphinic acid, and phenyl(diisobutyl) carbamoylnitromethylphosphine oxide (Mathur *et al.*, 1988).

The presence of the acidic extractants as degradation products increases D_{Am} under stripping conditions. Such impurities must be nearly completely removed from the used TRUEX solvent prior to recycle of the extractant. Table 24.16 gives the D_{Am} with an irradiated CMPO mixture under static conditions in contact with 5 M HNO_3 (Chiarizia and Horwitz, 1990) and under dynamic conditions in contact with 3 M HNO_3 (Mathur *et al.*, 1988). The *D* values at pH 2.0 are quite high and increase with absorbed dose. They also increase in the same fashion at 0.04 M HNO_3, but up to a dose of 200 kGy ($\sim$55 W h L^{-1} or 20 Mrad absorbed dose), *D* is less than 1, hence stripping with 0.04 M HNO_3 should still be possible. Up to an absorbed dose of about 200 kGy, primary cleanup

Table 24.16 *Partitioning of americium (D_{Am}) between* 0.2 M *CMPO* + 1.2 M *TBP in* n-*dodecane* and *HNO_3 as a function of absorbed gamma dose.*

	D_{Am}				
	Static condition 5.5 M *HNO_3 Chiarizia and Horwitz* (1990)			*Dynamic condition* 3 M *HNO_3 Mathur* et al. (1988)	
Dose (kGy)	pH 2.0	0.04 M	*Dose* (kGy)	pH 2.0	0.04 M
0	0.011	0.13	0	0.016	–
~70	0.87	0.72	~50	0.55	0.23
~130	0.91	0.61	~110	2.77	0.38
~200	1.33	0.59	~210	16.4	0.81
~280	1.42	0.58	~260	32.7	1.21

D_{Am} only after the wash with respective aqueous phase, no sodium carbonate or alumina treatment.

with 0.25 M Na_2CO_3 will remove most of the acidic impurities. Although the D_{Am} at pH = 2.0 may not match the reference condition, D_{Am} at 0.04 M HNO_3 suggests that continuous counter-current stripping of americium will be efficient. However, at high radiation doses, a secondary cleanup with macroporous anion exchange resin (Chiarizia and Horwitz, 1990) or with basic alumina (Mathur *et al.*, 1988) will restore TRUEX process solvent to near reference condition.

(*v*) *CMPO for extraction chromatography separation of actinides*

Extraction chromatography is fundamentally solvent extraction in which the extractant phase is 'immobilized' on a non-reactive solid support. The technique is generally considered to be most applicable for analytical purposes due to the tendency of the immobilized extractant to 'bleed' from the solid as the aqueous effuent transits the column. However, process-scale applications have been suggested.

The feasibility of using TRU-Resin™ (CMPO + TBP adsorbed on Amberchrom-CG-71 from Eichrom Industries Inc., Darien, Illinois, USA) for separating TRU elements from actual neutralized decladding waste solution (resulting from the removal of zirconium cladding from irradiated fuel) from the Hanford Waste tank has been demonstrated (Lumetta *et al.*, 1993). Actinides (U, Pu, Am) and lanthanides (Ce, Eu) were separated from nitric acid solutions using a column of 0.75 M CMPO in TBP adsorbed on XAD-7. They were subsequently eluted from the column with HCl, oxalic acid, and nitric acid solutions (Yamaura and Matsuda, 1999). Highly encouraging results have been reported for the separation of americium, plutonium, and uranium from acidic waste solutions using several types of extraction chromatographic supports

impregnated with CMPO (Barney and Covan, 1992; Schulte *et al.*, 1995a,b, 1996; Barr *et al.*, 2001).

Batch uptake studies have been carried out on the extraction chromatographic behavior of U(VI), Pu(IV), Am(III), and several fission and corrosion products from HNO_3 media using CMPO adsorbed on Chromosorb-102 (CAC) (Mathur *et al.*, 1995). Very high *D* values of actinides and lanthanides as compared to other fission products were obtained. For example, a small CAC column (containing 9.5 g of CAC) was prepared and about 0.5 L of the uranium depleted actual HAW at an acidity of ~1.7 M was passed through it. No α-activity was detected in the effluent. An americium and RE fraction, plutonium fraction, and uranium fraction were subsequently eluted with 0.04 M HNO_3, 0.01 M $H_2C_2O_4$, and 0.25 M Na_2CO_3, respectively. Comparable results were obtained while using a similar column and a synthetic SBHLW (Gopalakrishnan *et al.*, 1995).

A novel silica-based extraction chromatographic support has been prepared by immobilizing styrene–divinylbenzene copolymer in porous silica particles (SiO_2-P) (Wei *et al.*, 2000). Separation experiments using a CMPO/SiO_2–P resin packed column have given good separation of trivalent actinides and lanthanides from fission products like Cs, Sr, and Ru in simulated HLW solutions containing concentrated HNO_3. Also, it has been shown that, using a column packed with freshly purified Cyanex-301/SiO_2–P, americium was completely adsorbed by the resin and only about 1–2% of the Ln(III) were adsorbed from a 1 M $NaNO_3$ solution at pH 3.99 containing trace amounts of ^{241}Am, ^{153}Gd, ^{152}Eu (and 10^{-2} M Eu carrier), and ^{139}Ce. Americium was then eluted in a pure form with 0.1 M HNO_3.

(*vi*) *CMPO in supported liquid membrane separation of actinides*

Supported liquid membrane (SLM) is a technique wherein a microporous film (either as flat sheets or hollow tubes) is impregnated with an extractant and the transport of target metal ions is facilitated from the feed to the stripping solution. A simple schematic description of the SLM system is shown in Fig. 24.24. The salient features of the SLM processes are (1) extractant needed is in small quantities, (2) high feed/strip volume ratio, and (3) very simple

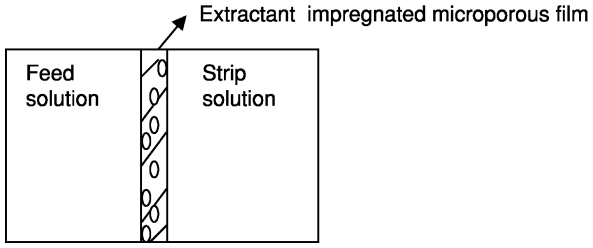

Fig. 24.24 *Schematic description of a supported liquid membrane (SLM) system.*

operation systems. Danesi *et al.* (1983) have used a solution of CMPO/DEB adsorbed onto a 48-μm thick microporous polypropylene film to facilitate the transport of Am(III) from aqueous nitrate solutions to the strip section containing formic acid solution. The transport mechanism suggested consists of a diffusion process in the feed compartment through an aqueous diffusion film followed by a fast interfacial chemical reaction and finally diffusion through the membrane itself to the stripping compartment. The membrane permeability coefficient has been correlated with the diffusional parameters and to the chemical composition of the system.

In another study from the same group (Danesi *et al.*, 1985), an SLM consisting of a mixture of 0.25 M CMPO and 0.75 M TBP in decalin adsorbed on thin microporous polypropylene supports in flat-sheet and hollow-fiber configurations was used for the selective separation and concentration of actinides (Am, Pu, U, and Np) and lanthanides from synthetic acidic nuclear wastes. It has been shown that actinides can be efficiently removed at a level sufficient to characterize the resulting solution as a non-TRU waste. An adjustment developed by Danesi *et al.* (1985) suggested an improvement in the efficiency of actinide removal from waste solutions. Incorporation of a double liquid membrane system, wherein a second SLM containing a primary amine that extracts only HNO_3 from the strip solution, allows near complete removal of actinide and lanthanide metal ions from the feed solution (Chiarizia and Danesi, 1987).

Ramanujam *et al.* (1999) have reported the transport of actinides from nitric acid and uranium-lean simulated samples as well as the actual HLW using CMPO/*n*-dodecane as a carrier and polytetrafluoroethylene as the support. The receiving phase was a mixture of citric acid, formic acid, and hydrazine hydrate. Very good transport of U(VI), Np(VI), Np(IV), Pu(IV), Am(III), and Ce (III) has been achieved. The TRUEX solvent (0.2 M CMPO + 1.2 M TBP/*n*-dodecane) has also been used as a carrier for the transport of Am(III) from nitrate–nitric acid solutions using track-etched polycarbonate plastic membranes (Pandey *et al.*, 2001). For Am(III) transport, these membranes performed at a level comparable to that obtained using commercial membranes.

(*vii*) *CMPO in magnetically assisted chemical separation of actinides*

Pioneering work on the separation and recovery of actinides from waste solutions using magnetically assisted chemical separation (MACS) was performed at the Argonne National Laboratory by Nunez *et al.* (1995a,b). This process gives a selective and efficient separation by chemical sorption followed by magnetic recovery. Magnetic particles (ferrite, magnetite, etc.) are coated with extractants and added to the treatment tank containing dilute TRU waste. The solution can be stirred mechanically or by any other method. Finally, the particles are magnetically separated by imposing a magnetic field around the tank, pumping the solution through a magnetic filter, or introducing a magnet into the tank. Actinide ions can be stripped from the loaded particles with small

volumes of suitable stripping agents. This process of recovery of actinides (or any other metal ions) from the waste streams seems to be very simple, compact and, in the proper application, is likely to be cost-effective. Like membrane-based separations, this approach does not involve large amounts of organic solvents and will not produce large volumes of secondary wastes. A conceptual diagram of the MACS process could be visualized as given in Fig. 24.25.

Nunez *et al.* (1995a,b) have used TRUEX solvent (CMPO in TBP) as the active coating on the magnetic particles. The extraction of americium and plutonium from HNO_3 solutions ranging in concentration from 2 to 8 M was found to decrease slowly with increasing acid concentration. The range of K_d values was between 400 and 3000 for americium and between 3900, and 46000 for plutonium. The uptake of the same nuclides was tested using synthetic dissolved sludge waste equivalent to the Hanford site waste. It was concluded that the MACS process could be applied to remediation problems at the Hanford site and other sites only if the waste streams contained low concentrations of TRU elements and lanthanides.

Kaminiski and Nunez (2000) have further studied the separation of U(VI) from HNO_3 and HCl solutions using extractants like CMPO, TBP, TOPO, and HDEHP employing the MACS technique. When magnetic particles were coated with TBP or a mixture of TOPO and HDEHP, partitioning of U(VI) was most efficient from dilute acid environments typical of contaminated ground water. From 2 to 8 M HNO_3, the 1.0 M CMPO in TBP-coated

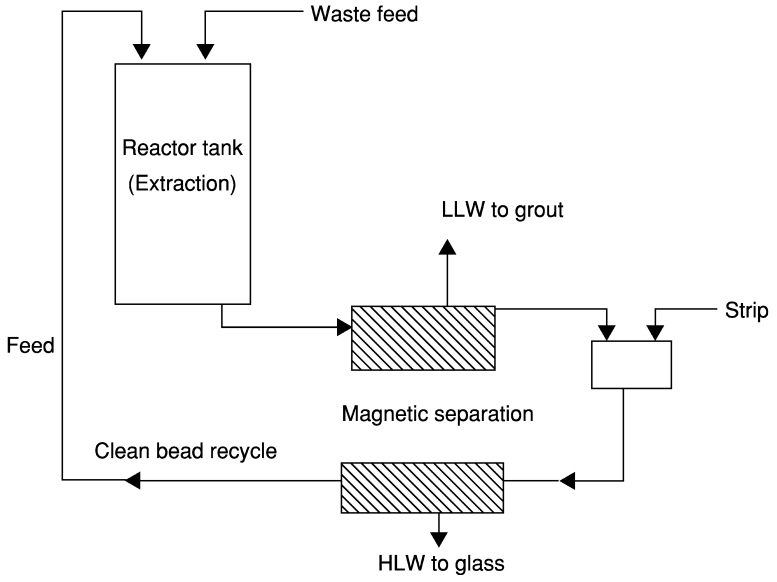

Fig. 24.25 *Schematic diagram of a magnetically assisted chemical separation system (MACS).*

particles gave the highest K_d values for U(VI). From these collected observations, it seems likely that MACS has potential for separating actinides from different actinide-bearing acidic waste solutions using various extractants coated on magnetic particles. Further studies are needed to demonstrate a full-scale operation. The same group has also shown a very high separation between Co and Ni while coating the magnetic particles with a mixture of 0.5 M Cyanex 272 and 0.5 M HDEHP (Kaminski and Nunez, 1999). The other uses of the MACS technique were in pre-analysis separation and concentration of actinides in groundwater (Navratil, 2001), capture of 0.2–0.8 μm PuO_2 particles from very dilute solutions (Worl *et al.*, 2001), and removal of Pu and Am from pH 12 waste waters using magnetic polyamine–epichlorohydrin (Ebner *et al.*, 1999).

(c) Trialkylphosphine oxide (TRPO)

Trialkylphosphine oxide, a mixture of seven alkyl phosphine oxides (Structure r), R being heptyl and octyl alone and a mixture of hexyl, heptyl, and octyl groups[3], has been tested initially in China at the Institute for Nuclear Energy and Technology (Tsinghua University) (Zhu *et al.*, 1983). Tests were continued in a collaborative effort with the European Institute for Transuranium Elements (Karsruhe, Germany) (Apostolidis *et al.*, 1991; Zhu and Song, 1992; Glatz *et al.*, 1993, 1995; Song *et al.*, 1994, 1996; Song and Zhu, 1994; Zhu and Jiao, 1994) for the extraction of actinides, lanthanides, and other fission products from HNO_3 and HLW solutions. The extraction equilibria for the actinide metal ions in their different valency states from nitrate solutions by TRPO can be represented as follows:

$$M^{3+}_{aq} + 3NO^{-}_{3\,aq} + 3TRPO_{org} \rightleftarrows M(NO_3)_3 \cdot 3TRPO_{org} \tag{24.47}$$

$$M^{4+}_{aq} + 4NO^{-}_{3\,aq} + 2TRPO_{org} \rightleftarrows M(NO_3)_4 \cdot 2TRPO_{org} \tag{24.48}$$

$$MO^{+}_{2\,aq} + NO^{-}_{3\,aq} + TRPO_{org} \rightleftarrows MO_2(NO_3) \cdot TRPO_{org} \tag{24.49}$$

$$MO^{2+}_{2\,aq} + 2NO^{-}_{3\,aq} + 2TRPO_{org} \rightleftarrows MO_2(NO_3)_2 \cdot 2TRPO_{org} \tag{24.50}$$

From studies in HNO_3 medium with 30% TRPO in *n*-dodecane as the extractant (Zhu and Song, 1992), it was observed that D_{Am} was less than 1 at 3 M and about 10 only at 1 M HNO_3. To achieve an acceptable D_f for Am, the acidity of HLW (typically 3–6 M) must be reduced to less than 1 M. Neptunium extraction is accomplished after electrolytic reduction to Np(IV) in HNO_3 and in simulated HAW solutions. During all of the experiments with concentrated wastes initially 3 M HNO_3, the waste was diluted ten times and the acidity

[3] Zhu and Song (1992) report approximate composition of 10% hexyl, 50% heptyl and 40% octyl.

then adjusted between 0.7 and 1.0 M. Under such conditions, the recovery of U, Np, Pu, Am, and Cm from HAW using a seven-stage mixer–settler was highly efficient (Zhu and Jiao, 1994). Centrifugal contactor runs (Glatz *et al.*, 1993, 1995; Song *et al.*, 1996) using a battery of 12 extractors with actual diluted HLW has given $D_{f\ \text{actinides}}$ between 10^3 and 10^5. The actinides have in all cases been stripped with 5 M HNO_3 (Am, Cm, rare earths), 0.5 M oxalic acid (Np, Pu), and 5% Na_2CO_3 (U).

Subsequent investigations applied the process to highly saline actual HLW from a Chinese reprocessing plant using 30% TRPO-kerosene. The feed was diluted 2.7 times and the HNO_3 concentration maintained at 1.08 M. This run using miniature centrifugal contactors gave a D_f for total α and ^{99}Tc activities of 588 and 125, respectively. It is claimed that after partitioning the HLW is a non-α waste (Jianchen and Chongli, 2001). The study of γ-irradiation of a 30% TRPO solution in kerosene has shown that above a dose of 2×10^6 Gy phosphonic and phosphinic acids are produced as the radiolytic degradation products along with the formation of polymeric products in the molecular weight range of 500–900 g mol^{-1}. The polymer forms strong complexes with plutonium from which the plutonium is not back-extracted even after five contacts with 0.6 M oxalic acid. This leads to the retention of plutonium in the organic phase (Morita and Kubota, 1987, 1988; Morita *et al.*, 1995; Zhang *et al.*, 2001).

Studies have been carried out with the commercially available TRPO (Cyanex-923, Cytec, Canada Inc., a mixture of four alkyl phosphine oxides R_3PO, R'_3PO, $R_2R'PO$ and RR'_2PO where R = hexyl and R′ = octyl group) to evaluate the effect of phase modifier, TBP, on the extraction of actinides from HNO_3 and synthetic PHWR-HLW solutions (Murali and Mathur, 2001). A series of experiments carried out under various conditions indicated that a mixture of 30% TRPO/20% TBP in *n*-dodecane, when contacted with PHWR-HLW containing ~18 g L^{-1} U at 1 M acidity and an organic to aqueous phase ratio of 5:1, gave highly encouraging results in batch studies. In these experiments, acidity was adjusted with ammonia (a 0.1 L solution of HLW required ~0.02 L of liquid ammonia).

The suitability of TRPO for the partitioning of actinides from HLW solutions has been summarized in Table 24.17. A generic flow sheet is shown in Fig. 24.26. A significant weakness of employing TRPO for actinide partitioning is its comparatively limited capacity and narrow range of nitric acid concentrations that will enable acceptable extraction of trivalent actinides. The dilution of HLW and adjustment of acidity increase waste volume that will create many problems when handling large volumes of HLW.

(d) Diisodecylphosphoric acid (DIDPA)

At the Japan Atomic Energy Research Institute, separation of metal ions from the HLW solutions has been classified into four groups: transuranium elements, Tc–platinum group metals, Sr–Cs, and other elements. For the separation of

Table 24.17 *Suitability of TRPO for the partitioning of actinides from HLW.*

HLW, condition	*Reagent composition*	*Inference*
In ~3.0 M acidity, as such	30% TRPO/*n*-dodecane	third phase formation, cannot be used
Zhu and Song (1992) 10 times diluted, $[H^+]$ adjusted, 0.7–1.0 M	30% TRPO/*n*-dodecane	extraction, reported satisfactory
Murali and Mathur (2001) $[H^+] = \sim 1.0$ M	30% TRPO + 20% TBP/*n*-dodecane, org:aq = 5:1	up to six successive contacts, no reflux, reasonably high *D*
Murali and Mathur (2001) $[H^+] = \sim 1.0$ M HLW, diluted in the ratio 1:2 with 1 M HNO_3	30% TRPO + 20% TBP/*n*-dodecane org:aq = 2:1	up to six successive contacts, no reflux, reasonably high *D*

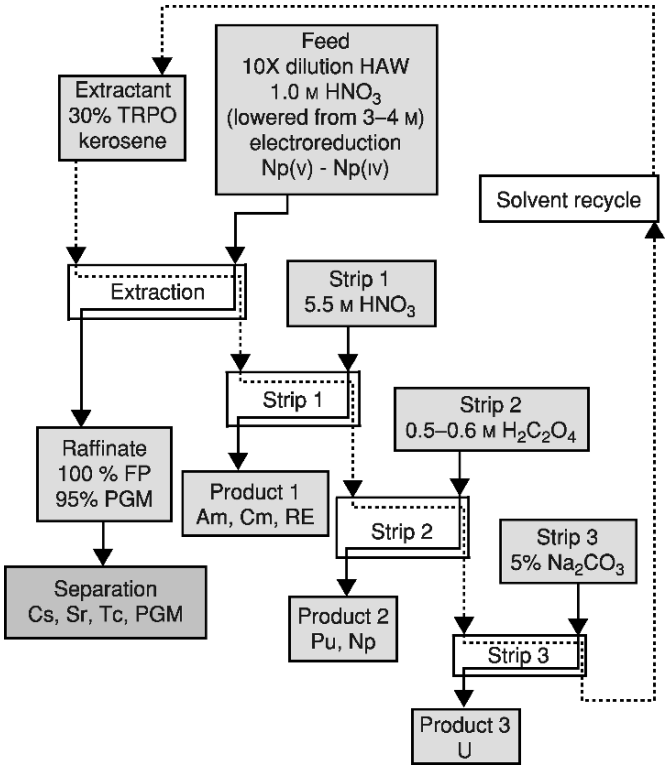

Fig. 24.26 *Generic flow sheet for actinide partitioning using TRPO.*

TRU elements, a mixture of 0.5 M DIDPA + 0.1 M TBP in *n*-dodecane has been proposed with the acidity of the HLW reduced to 0.5 M. Neptunium is reduced from Np(V) to Np(IV) using H_2O_2 and co-extracted with Pu(IV). DIDPA being in the dimeric form (H_2A_2) in *n*-dodecane, the species of the trivalent tetravalent, pentavalent and hexavalent actinides extracted in the organic phase are most likely the electroneutral complexes $M(HA_2)_3$, $M(HA_2)_4$, $MO_2(HA_2)$, and $MO_2(HA_2)_2$, respectively.

Batch as well as counter-current tests using a 16-stage miniature mixer–settler with conditioned synthetic HLW have given very high extraction of actinides including neptunium (flow sheet in Fig. 24.27). During stripping, batch studies with DTPA as a stripping agent gave an Am/rare earths separation factor of greater than 10. After selectively stripping trivalent actinides with DTPA, rare earths could be quantitatively removed with 4 M HNO_3. Neptunium and plutonium are stripped with 0.8 M oxalic acid (Morita and Kubota, 1987, 1988; Morita *et al.*, 1995). In this process, reduction of acidity to about 0.5 M

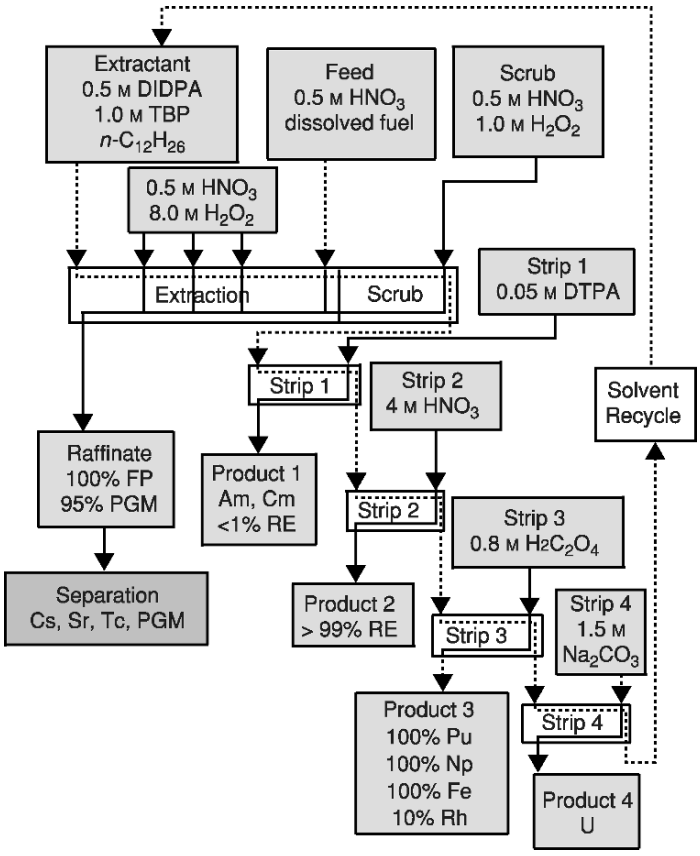

Fig. 24.27 *Generic flow sheet for actinide partitioning in the DIDPA process.*

is accomplished using formic acid. At such low acidity, molybdenum and zirconium precipitate out, carrying about 93% of the plutonium. Filtration units are needed to get a clean HLW solution.

(e) *N*,*N*′-Dimethyl-*N*,*N*′-dibutyltetradecylmalonamide (DMDBTDMA)

One drawback of using organophosphorus extractants is the solid residue that results upon their incineration at the end of their useful life. French researchers have championed the CHON (carbon, hydrogen, oxygen, nitrogen) principle of extractant design (avoiding the use of S or P containing reagents) to minimize the generation of wastes from extractant destruction. This approach to extractant design has generated a much interesting research on a diverse group of reagents.

Among the numerous diamides synthesized and employed for extraction of actinides from nitric acid solutions (Musikas and Hubert, 1983; Musikas, 1987, 1991, 1995; Cuillerdier *et al.*, 1991a,b, 1993; Nigond *et al.*, 1994a,b; Baudin *et al.*, 1995), *N*,*N*-dimethyl-*N*′,*N*′-dibutyl-2-tetradecylmalonamide (DMDBTDMA) has shown the greatest promise. This diamide dissolves in *n*-dodecane, does not give a third phase when in contact with 3–4 M HNO_3, and a 1 M solution gives a D_{Am} of about 10 at 3 M HNO_3. In France, this extractant has been strongly promoted for the partitioning of actinides from HLW solutions (the DIAMEX process).

Investigations of the extraction of uranium, plutonium, americium, and iron by DMDBTDMA at varying HNO_3 concentrations from medium activity liquid waste has given encouraging results. However, some problems have been reported while using this process on tests with high-activity liquid wastes (Baudin *et al.*, 1995). A counter-current centrifugal extractor experiment using a 16-stage battery has been carried out to investigate the hydraulic and extraction behavior of the DIAMEX process using a synthetic HLW solution (Courson *et al.*, 2000) and then finally used for the genuine HLW solution (Malmbeck *et al.*, 2000). With six extraction stages, decontamination factors between 100 and 230 were obtained for lanthanides and above 300 for minor actinides. For back-extraction, four stages were sufficient to recover more than 99.9% of both lanthanides and actinides. The kinetics of lanthanide/actinide extraction (Weigl *et al.*, 2001) and both transient and steady-state concentration profiles in DIAMEX counter-current processing (Facchini *et al.*, 2000) have also been studied. Detailed characterization of these materials and further development of the DIAMEX process continue under the auspices of the PARTNEW European Program (Madic *et al.*, 2002).

(f) Neptunium partitioning during processing

In PUREX processing, consistent control of the flow of neptunium through the system is much more difficult than that of uranium, plutonium, or the trivalent actinides. Dissolution of spent reactor fuel by nitric acid under reflux conditions yields a solution containing principally Np(V) and Np(VI). Flow of neptunium in

PUREX depends on what initial oxidation state adjustments are made to the feed and what steps are taken subsequently to partition plutonium and uranium. Drake (1990) has summarized both the chemistry and process aspects of neptunium control in PUREX. The distribution of neptunium remains a topic of interest in actinide partitioning.

At the Bhabha Atomic Research Centre, the recovery of neptunium from the HLW along with uranium was attempted using a 30% TBP extraction step. The sample was pretreated with 0.01 M $K_2Cr_2O_7$ to oxidize both neptunium and plutonium to the hexavalent state. Both are subsequently co-extracted with U (VI) into 30% TBP. The extraction behavior of neptunium was tested with three types of synthetic wastes and finally with an actual HLW solution. More than 90% of uranium, neptunium, and plutonium could be removed in a single contact. Stripping of neptunium was achieved using a mixture of 0.01 M ascorbic acid and 0.1 M H_2O_2 in 2 M HNO_3 (Mathur *et al.*, 1996b). The kinetics of Np(VI) extraction and stripping under the above conditions while taking synthetic PHWR-HLW as the feed using the AKUFVE technique (Andersson *et al.*, 1969; Johansson and Rydberg, 1969; Reinhardt and Rydberg, 1969; Rydberg, 1969) has demonstrated that the reaction kinetics are fast enough to avoid problems in mixer–settler contacts (Chitnis *et al.*, 1998a). A counter-current study using PHWR-HLW has confirmed the entire process of neptunium extraction and stripping (Chitnis *et al.*, 1998b).

Recent work at the British Nuclear Fuels Limited (BNFL) has focused on the development of an advanced PUREX process. Control of neptunium partitioning in such a system can be accomplished through its interactions with hydroxamic acids. Taylor *et al.* (1998, 2001a,b) report that both formo- and acetohydroxamic acids selectively complex tetravalent actinides and rapidly reduce Np(VI) to Np(V). These characteristics could be used to separate neptunium from plutonium or uranium depending on the approach taken for neptunium extraction. Selected alkyl hydroxylamine species have also been evaluated as reductants for Np(VI) and Pu(IV).

A similar approach to neptunium selectivity using reduction of Np(VI) by butyraldehydes has been suggested by Uchiyama *et al.* (1998). In the partitioning conundrum (PARC), process, the separation of neptunium from plutonium and uranium is proposed in steps prior to Pu/U partitioning in the first extraction cycle of PUREX. Np(VI) is rapidly reduced to Np(V) by *n*-butyraldehyde. This reagent has no effect on the oxidation state of either Pu(IV) or U(VI). Flow sheet development demonstrated partial success in neptunium, technetium, and uranium partitioning. Further work is required to optimize the process.

(g) Trivalent actinide/lanthanide group separation

As noted in Section 24.3.9, separation of trivalent actinides as a group from the lanthanides has been a topic of great interest since the time of discovery of the transplutonium elements. However, setting aside waste volume minimization

considerations, this separation is most important as a problem for hydrometallurgical separations only if the actinides are to be transmuted. Neutron economy in transmutation requires the substantial removal of neutron-absorbing lanthanides. In the PUREX process, as in most new processes being developed for actinide partitioning from HLW, the stripped fraction containing the trivalent actinides (Am and Cm) also contains the trivalent lanthanides. If all actinides are to be recycled as fuel (or targets for transmutation) in a current generation reactor, it is essential to separate americium and curium from trivalent lanthanides to avoid the strong absorption of thermalized neutrons by the lanthanides. Due to the similarities in chemical properties and behavior of Am(III) and Ln(III) reagents, extractants or complexing agents containing soft-donor atoms such as N, S, Cl, etc. are required for reliable group separations (Nash, 1994). A number of techniques and reagents have been developed to achieve separation of trivalent actinides and lanthanides. Among these, a few important existing methods and those being newly developed will be discussed.

(*i*) *TRAMEX process*

Solution of concentrated LiCl at an acidity of 0.02 M HCl in contact with a tertiary amine solution in kerosene or diethyl benzene is the basis of the TRAMEX process for plant-scale separation of trivalent actinides from fission-product lanthanides (Baybarz *et al*., 1963). In this process, the feed solution is 11 M LiCl (0.02 M HCl) containing trivalent actinides and the fission products; the organic phase employed is 0.6 M Alamine 336 (a mixture of tertiary C6–C8 alkyl amines) in diethyl benzene. The scrubbing solution is 11 M LiCl (0.02 M HCl). Trivalent actinides are extracted into the organic phase, while the trivalent lanthanide fission products remain in the raffinate. The actinides are subsequently stripped from the organic phase with 5 M HCl. The TRAMEX process flow sheet is shown in Fig. 24.28. In a single extraction contact, trivalent actinides (Am, Cm, Bk, Cf, Es, and Fm) as a group have a separation factor of about 100 from the trivalent lanthanides (Ce, Nd, Eu, Tb, Ho, and Tm). The order of extraction for the actinides is reported to be Cf > Fm > Es > Bk > Am > Cm.

Several tertiary amines also have been investigated for the extraction of americium and europium from 8 M LiCl/2 M $AlCl_3$/0.02 M HCl using 0.5 M amine in diethyl benzene. The separation factor between americium and europium followed the order: triisoheptyl- (151.7) > triisooctyl- (124.5) ~ trilauryl- (124.1) > Alamine 336 (108). The distribution ratios of americium and europium increased with a decrease in the carbon chain length of the amines. Although separation factor between americium and europium was lowest with Alamine 336, this extractant was preferred because of its easy availability and satisfactory extraction characteristics.

In another study, extraction of trivalent Pu, Am, Cm, Cf, Eu, and Tm from 11.9 M LiCl at pH 2.0 was done with quaternary amines (Aliquat-336 and

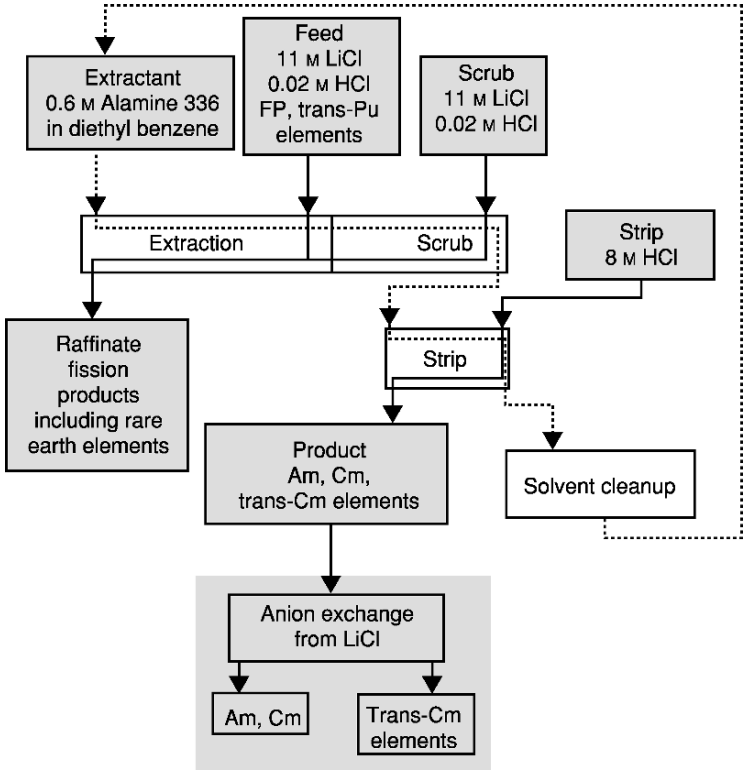

Fig. 24.28 *Generic flow sheet for the TRAMEX process* (*adapted from King* et al., 1981).

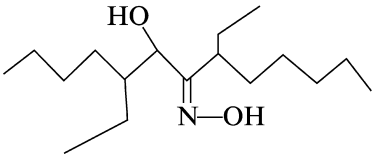
tetraheptyl ammonium chloride) and tertiary amines (triisooctyl amine, tri-*n*-octyl amine, Alamine-336 and trilauryl amine) in xylene (Khopkar and Mathur, 1981). The authors have obtained very low separation factors between trivalent actinides and lanthanides when quaternary amines were used whereas they are moderately high while using the tertiary amines. From the absorption spectra of americium and neodymium extracted by the above amines, it was established that the higher separation factors between actinides and lanthanides with tertiary amines are a result of the formation of octahedral hexachloro complexes as compared to the predominantly lower chloro-complexes extracted by the quaternary amines.

(*ii*) *Separation using LIX-63*

The extractant 5,8-diethyl-7-hydroxydodecane-6-one oxime (LIX 63, Structure aa) gave a separation factor (D_{Am}/D_{Eu}) of 2.9 in a batch extraction study (Hoshi *et al.*, 2001). Using this extractant, separation of americium from lighter

lanthanides has been achieved using high-speed counter-current chromatography with a small-coiled column. The coiled column was filled with polytetrafluoroethylene impregnated with a hexane solution of LIX 63. The mobile phase (0.1 M $NaNO_3$/0.01 M morpholinoethane sulfonic acid) contained neodymium and europium (each 10^{-5} M) and radiotracer ^{241}Am. The sample gave a very clear peak for lanthanides when the pH of the mobile phase was 5.60. ^{241}Am was eluted at a pH of 4.60.The authors claim that separation of micro amounts of americium from macro amounts of lanthanides (Hoshi *et al.*, 2001) is possible using this technique. Further work needs to be done to complete the evaluation of the method.



Structure aa

(*iii*) *TALSPEAK process*

The chemistry of the TALSPEAK process has been discussed in detail in Section 24.3.9. Though not deployed as such for accomplishing lanthanide–trivalent actinide separations at process scale, the critical reagent in TALSPEAK, aminopolycarboxylic acids, have repeatedly been employed in the conceptual development of actinide–lanthanide hydrometallurgical separation processes. In the DIDPA and SETFICS processes (described in the next section), the separation of 4f and 5f elements is accomplished in a reverse-TALSPEAK stripping with 0.05 M DTPA (see Fig. 24.11). In the context of modern process design, the aminopolycarboxylates are acceptable reagents, as they are composed of only C, H, O, and N, and hence are fully incinerable. It should be noted, however, that this class of compounds are known to cause difficulties in storage, as hydrogen generation in waste tanks at Hanford has taught (Babad *et al.*, 1991; Meisel *et al.*, 1991; Pederson *et al.*, 1992).

24.4.5 Methods under development

The considerable knowledge that has been developed during decades of fundamental studies of actinide separations supports a number of fresh approaches to important separations processes. It is expected that future efforts to minimize the volume of wastes derived from spent-fuel processing will benefit from this scientific legacy as well. An example of the use of well-understood science being applied in process development is the use of DTPA for La/An partitioning in the DIDPA extraction process for the TRU elements (Morita *et al.*, 1995, 2002). In this case, the stripping of trivalent actinides from the loaded 0.5 M

DIDPA + 0.1 M TBP solvent gave in a batch experiment (after adjustment to pH 3.6) a separation factor of americium from the lanthanides of 10.

A report from JNC has suggested the separation of trivalent actinides and lanthanides applying DTPA in a TRUEX-based process known as SETFICS (Solvent Extraction for Trivalent F-elements Intragroup Separation in CMPO-Complexant System) (Koma *et al*., 1998, 1999; Ozawa *et al*., 1998). Using this process, a counter-current experiment was done with an actual TRUEX product solution employing 0.05 M DTPA/4 M $NaNO_3$ (pH 2.0) as the strippant. Americium and curium were successfully recovered using SETFICS. $^{144}Ce/^{241}Am$ decontamination factor has been reported to be 72. Though 80% of the lanthanides were rejected from the Am–Cm fraction, samarium and europium were poorly separated from the actinide fraction (Koma *et al*., 1998).

(a) Employing soft-donor extractants

By comparison with oxygen donor extactants, soft-donor extractant molecules offer greater potential for more efficient trivalent actinide–lanthanide group separations. For example, Ensor *et al.* (1988) reported Am/Eu separation factors of greater than 100 using the synergistic combination of 4-benzoyl-2,4-dihydro-5-methyl-2-phenyl-3H-pyrazol-3-thione (BMPPT) and 4,7-diphenyl-1,10-phenanthroline (DPPHEN). Independently, neither extractant is particularly effective for the extraction of americium or europium. Musikas and Hubert (1983) reported a high $S_{Am}^{M'}$ between americium and rare earths for their extraction from dilute nitric acid into an extractant mixture of TPTZ and dinonylnaphthalenesulfonic acid (HDNNS) in CCl_4. It was further proposed that HDNNS could be replaced by α-bromocapric acid in an aliphatic diluent. Work on solvent extraction procedures using TPTZ (and related complexants) continues (Cordier *et al*., 1998; Drew *et al*., 1998, 2000).

To overcome the considerable aqueous solubility of TPTZ while conforming to the CHON principle, development of nitrogen-containing extractant molecules continues. In a multinational effort funded by the European Commission's research program on nuclear fuels reprocessing for the future (NEWPART), polyaza ligands, BTPs, have been characterized for selective extraction of trivalent actinides from 1.9 M HNO_3/NH_4NO_3 solutions (Kolarik *et al*., 1999). The extracted complexes have the stoichiometry $M(NO_3)_3 \cdot HNO_3 \cdot 3BTP$ and the Am/Eu separation factors average 100–120. The extraction and separation efficiency is strongly dependent on the diluent. The *n*-propyl derivative self-associates (forming dimers and trimers) in a solution of branched alkanes with 2-ethyl-1-hexanol present as a phase modifier. Counter-current testing of the SANEX-BTP process with real radioactive materials at the Atalante facility in France demonstrated that the *n*-propyl derivative was susceptible to air oxidation with HNO_2 catalysis. Branching in the hydrocarbon side chain improves stability.

(b) Employing Cyanex 301 and other dialkyldithiophosphinic acids

Though Musikas (1985) indicated potential for effective separation of trivalent actinides from lanthanides using thiophosphoric acid extractants, the instability of such extractants towards hydrolysis reduced their utility. However, dithiophosphinic acids, represented by the commercially available extractant Cyanex 301, are somewhat more stable (Sole *et al.*, 1993). Basic features of these systems have been discussed in Sections 24.3.5 and 24.3.9. In a counter-current fractional process having three extraction and two scrubbing stages, more than 99.99% of americium can be separated from a trace amount of europium with less than 0.1% extraction of the latter (Zhu, 1995; Zhu *et al.*, 1996; Chen *et al.*, 1997; Hill *et al.*, 1998).

In another study, a mixture of 0.5 M purified Cyanex 301 and 0.25 M TBP/kerosene has been used in a counter-current experiment to separate americium from lanthanides (Pr, Nd, and Eu) at concentrations of 0.1–0.6 M. A separation factor of around 200 between americium and the lanthanides has been obtained and the extraction can be performed at a pH of 2.7–2.8. This pH value is about 1 unit lower than that needed when Cyanex 301 is used alone. Americium was successfully (>99.998%) separated from macro amounts of lanthanides with only less than 0.04% lanthanides co-extracted (Wang *et al.*, 2001).

The alternative to the SANEX-BTP process that relies instead on dialkyldithiophosphinic acid extractants has been examined as the SANEX-DTP or ALINA process. Initial investigations with a solvent composed of Cyanex 301 in combination with TBP or TOPO as phase modifiers proved inadequate in testing due to the instability of Cyanex 301 under representative conditions. Aromatic derivatives were synthesized in an effort to enable the separation from more acidic media and improve radiation stability. The bis(*p*-chlorophenyl) dithiophosphinic acid (DClDPDTPA) synthesized by Modolo and Odoj (1999) accomplishes both of these objectives. The SANEX-IV process currently under development relies on DClDPDTPA in combination with TOPO as phase modifier. This solvent is reported to extract trivalent actinides from 0.5 to 1.5 M nitric acid.

Apart from the solvent extraction technique for the separation of trivalent actinides from the lanthanides employing Cyanex 301, other techniques like supported liquid membrane and column chromatography have also been utilized (Hoshi *et al.*, 2000; Mimura *et al.*, 2001). A selective and preferential transport of americium across a supported liquid membrane containing highly purified Cyanex 301 has been achieved in the product solution while most of europium remained in the feed solution (Hoshi *et al.*, 2000). Also, microcapsules enclosing Cyanex 301 were prepared by employing a biopolymer gel, alginic acid, as an immobilization matrix. The chromatographic separation of americium and europium was accomplished by gradient elution with 0.1 M (H, Na)NO_3 (pH 2.0) for europium and 0.1 M HNO_3 for americium while using the column packed with the above micro-capsule (Mimura *et al.*, 2001).

Although Cyanex 301 has not yet been used for the separation of americium and curium from the rare earths in the fraction stripped by 0.04 M HNO_3 in the TRUEX process, this process appears to have great potential, though radiation stability and the nature of degradation products represent a concern.

24.4.6 Comparison of extractants being proposed for actinide partitioning

A comparison of the different extractants, their concentration, diluent, phase modifier, best conditions for extraction and stripping of americium is given in Table 24.18. Each system has both positive and negative features. Based on cost of the extractant, the DIDPA and TRPO are clearly superior. However, processes based on the TRPO and DIDPA extractants require, respectively, a ten-fold dilution of the aqueous feed and/or denitration with formaldehyde impacting the volume of wastes generated. Only the DMDBTDMA extractant is completely incinerable. Furthermore, degradation products of DMDBTDMA do not interfere with stripping of americium, while those of CMP and CMPO can. However, the malonamide requires higher concentrations of HNO_3 for efficient extraction of americium, has a comparatively steep nitric acid dependence on the extraction side, and a lower radiolytic stability than that of TBP. Phase modifiers (TBP) are required for both CMP and CMPO extraction systems to prevent third-phase formation, but the TBP apparently increases the stability of the primary extractant. Extraction in the CMPO/TRUEX system is moderately independent of the concentration of HNO_3, simplifying feed preparation. As a complement to PUREX, TRUEX has an advantage, as no adjustment of the aqueous raffinate from PUREX would be required to

Table 24.18 *Comparative features of partitioning of actinides* (*with data for Am*(III)) *with various extractants.*

Extractant concentration (M)	*Diluent*	*HNO_3 conc., for extraction* (M)	*HNO_3 concentration for stripping* (M)
CMP, 0.75	aliphatic hydrocarbon + 0.5 M TBP	>2	<0.15
DIDPA, 0.5	*n*-dodecane + 0.1 M TBP	0.5, denitration or dilution of HLW	4
CMPO, 0.2	*n*-dodecane + 1.2 M TBP	2–3, any HLW as such	0.04
TRPO, 30% (V/V)	*n*-dodecane	0.7–1.0 M, HLW diluted 10 times	>4
TRPO, 30% (V/V)	*n*-dodecane + 20% TBP	~1.0 M, no major dilution	>4
DMDBTDMA, 1.0	*n*-dodecane	>2	<0.5

make successive TRUEX extraction stages compatible. Several new options for trivalent actinide/lanthanide separations by solvent extraction are also emerging. It is clear that, like the decision of whether to process irradiated fuels or not, countries having irradiated nuclear fuels clearly have numerous viable options for processing those fuels should the P&T option be pursued.

Actinide partitioning if and when incorporated at the back-end of the nuclear fuel cycle will considerably reduce the long-term radiological risks and therefore increase the safety of the disposal of nuclear wastes in a geologic repository. Whether actinides are recycled to a reactor (or accelerator) for transmutation or disposed of in a repository, a significant reduction in the hazard associated with the wastes (with transmutation) or the cost (without transmutation) can be achieved through the deployment of actinide partitioning technologies. Though there is no universal consensus on the desirability of actinide partitioning for radioactive waste disposal, continuing research around the world offers an ever-increasing number of potentially viable options for accomplishing partitioning based on solvent extraction, extraction chromatography, supported liquid membranes, or magnetically assisted chemical separations. The continued development of more options relying on the proven technology of solvent extraction may assist immeasurably in securing the public acceptability of nuclear power as the most viable strategy for combating global warming. More advanced options may emerge as work progresses on alternative media like supercritical fluids, room temperature ionic liquids, or the various pyrometallurgical processing options.

24.4.7 Actinide separations around the world – past, present, and future

In the last 20 years, significant emphasis has been put on partitioning and transmutation (P&T) of actinides present in TRU waste generated from various operations involving actinides and also from the HLW solution generated from the reprocessing of nuclear reactor fuels. The International Atomic Energy Agency (IAEA, Vienna) held several advisory group meetings and coordinated research programs on the P&T option. These meetings served as a forum for discussion among several participating countries regarding various extractants, processes developed earlier, or those being developed for partitioning of actinides from HLW solutions. Some of the extractants and developed processes have been discussed above. Here the work that has been carried out and brought to mixer–settler or centrifugal contactor stage of testing will be discussed emphasizing the status of activities in those countries involved in the process, noting that international collaboration is important in this field

(a) United States

In the U.S. after a large amount of work on the extraction of trivalent actinides and lanthanides with several carbamoylmethylphosphonate and phosphine oxides, OΦCMPO was adjudged as the best extractant for this purpose.

For process applications, a mixture of 0.2–0.25 M ОФCMPO and 1–1.4 M TBP in *n*-dodecane, called the TRUEX solvent has been judged as optimum. Although actual HLW generated from the fuel reprocessing plants have not been treated with TRUEX solvent on a large scale in the U.S., different TRU wastes generated have been treated. For example, large volumes of waste generated at the Argonne National Laboratory and the New Brunswick Laboratory have been treated. At Lockheed Martin Idaho Technologies Co., the TRUEX process has been evaluated for the separation of actinides from sodium-bearing waste and calcine waste. At the Oak Ridge National Laboratory, separation and recovery of macro quantities of americium and curium from highly irradiated (> 87% fission) ^{242}Pu targets has been achieved employing the TRUEX process. Other TRU wastes treated with TRUEX solvent at different laboratories in the U.S. are neutralized cladding removal waste (Pacific Northwest National Laboratory), plutonium finishing plant waste (Westinghouse Hanford Co.), and TRU wastes containing chloride salts (Los Alamos National Laboratory). Successful demonstration of a very high efficiency of recovery of TRU elements from the above-mentioned types of wastes is a unique feature for CMPO as an extractant.

Recently, new work has been initiated in the U.S. on the evaluation of possible future nuclear fuel cycles with the commencement of the Advanced Fuel Cycle Initiative. This program is progressing more-or-less in tandem with work on future reactor designs (Generation IV program). In addition, a considerable amount of work has been done in the U.S. investigating pyrometallurgical processing of spent nuclear fuels. Though much work remains to be done to fully enable pyroprocessing, there is no denying that this option has some attractive features and additional work to improve the process is justified.

(b) Japan

At the Japan Atomic Energy Research Institute, 0.5 M DIDPA + 0.1 M TBP in *n*-dodecane has been proposed for the separation of TRU elements from HLW solutions. To employ this acidic extractant for spent fuel reprocessing, the acidity must be reduced to 0.5 M to obtain an efficient recovery of actinides. Work has been done in batch and counter-current tests using synthetic HLW. At Power Reactor and Nuclear Fuel Development Corporation, the TRUEX solvent, i.e. 0.2 M CMPO + 1.2 M TBP in *n*-dodecane, has been utilized for actinide partitioning in batch and counter-current runs with a real high-active raffinate from FBR spent fuel reprocessing. Pyroprocessing and supercritical fluids extraction are also under active consideration in Japan, as are alternatives to the DIAMEX process.

(c) Russia

At the Khlopin Radium Institute, St. Petersburg, efforts have been directed towards using a modified PUREX process to recover actinides such as neptunium

and the other actinides, possibly including the trivalent ions by using a neutral organophosphorus extractant like isoamyldialkylphosphine oxide. Scientists in this laboratory have developed a Russian TRUEX process, based on diphenyl-*N*,*N*-dibutyl CMPO which is less expensive and gives higher D_{Am} values as compared to O(Φ)CMPO. It does not need TBP as the phase modifier but the diluent used is a fluoroether. Very high recoveries and separations of trivalent actinides have been achieved from waste solutions. A variation on this process has been incorporated by scientists in the U.S. at the Idaho National Engineering and Environmental Laboratory in the development of the UNEX process for radioactive waste processing.

(d) China

In China, the main emphasis has been on the extractant trialkylphosphine oxide (TRPO), which is easily synthesized and inexpensive. Actinide recovery and separation from HLW solutions carried out within international collaborations had to be done at acidity of $\leq$1 M and the HLW diluted considerably in this process. However, batch studies, mixer–settler, and centrifugal contactor runs have given highly encouraging results.

(e) France

French chemists have concentrated on the CHON (carbon, hydrogen, oxygen, and nitrogen) principle to design the new extractants of the class amides and diamides. After significant efforts in synthesizing various diamides with different combinations of substituents at R_1, R_2, and R_3 (Structure n), the compound DMDBTDMA was prepared, which is soluble in aliphatic diluent like *n*-dodecane and has respectable *D* values for trivalent actinides and lanthanides at 3–4 M HNO_3. More recently, the tetradecyl backbone substituent has been replaced (in the baseline process) by an ethoxy hexyl (ether) group to improve phase compatibility characteristics. Batch studies, mixer–settler, and centrifugal contactor runs with synthetic as well as actual high-active wastes have given satisfactory results for the recovery of actinides. A great deal of effort has been expended in France on new reagents and processes for minor actinide partitioning and lanthanide/actinide separations and on investigating phase compatibility issues in solvent extraction. Creativity and innovation highlight both the technology and R&D efforts in France on the closed-loop nuclear fuel cycle.

(f) India

Scientists at Bhabha Atomic Research Centre have tested the TRUEX solvent for batch and mixer–settler runs using synthetic high-active waste, stored sulfate bearing waste, and PHWR-HLW. A uranium depletion step with 30% TBP/*n*-dodecane followed by TRUEX process has been suggested for highly efficient

separation and recovery of all the actinides. Batch studies with actual HAW and HLW of research reactor fuels and mixer–settler runs with actual HAW of research reactor fuels have been performed. The raffinate from the mixer–settler runs with synthetic as well as actual wastes had α-activities at the background level. Also, work has been done with Cyanex 923 (a commercially available TRPO) and its mixture with TBP in *n*-dodecane. The batch studies suggest that even with the combination of Cyanex 923 and TBP, the acidity has to be brought down to about 1 M but it may not be necessary to dilute the HLW to a great extent for achieving high separation efficiencies of the actinides. Preliminary studies have been carried out on the extraction of Am(III), U(VI), and Pu(IV) with DMDBTDMA from nitric acid and PHWR-HLW solutions.

(g) Sweden

The research group at Chalmers University developed a three-stage process called CTH (Chalmers Tekniska Hogskola) for separation and recovery of all the actinides from HLW solutions (Svantesson *et al.*, 1979, 1980; Liljenzin *et al.*, 1980). In the first step, acidity of HLW is adjusted to 6 M and uranium, neptunium, and plutonium are extracted with 1 M HDEHP/kerosene. This step also extracts most of the Fe, Zr, Nb, and Mo. In the second step, the acidity of the raffinate is considerably reduced by contacting with 50% TBP/kerosene. Finally in the third step, americium, curium, and rare earths are extracted with 1 M HDEHP. From all the loaded organic phase, the actinides are stripped with suitable reagents. The entire process has been tried with synthetic waste using small-scale mixer–settlers. Because of the problems associated with significant acidity adjustment in the entire process, this may not be cost-effective on a plant scale.

(h) Other countries

In the UK, though British Nuclear Fuels Ltd. actively reprocesses commercial fuels to recover uranium and plutonium, little has been done in the field of actinide partitioning. It appears likely that if the United Kingdom ultimately decides to partition actinides, an appropriate process from the variety of options being developed elsewhere will most probably be adopted. Among the other countries, at the European Commission Joint Research Centre–Ispra Establishment, Italy, a process has been developed by first extracting uranium, neptunium, and plutonium with TBP or HDEHP, diluting the raffinate to a pH of 2 and extracting trivalent americium, curium, and rare earths with a mixture of 0.3 M HDEHP + 0.2 M TBP in *n*-dodecane (Cecille *et al.*, 1980). This process has the same limitations mentioned above for the CTH process. Within Europe, wide international collaboration on actinide partitioning is supported by the European Commission in the frame of its successive Research Framework Programs.

24.5 WHAT DOES THE FUTURE HOLD? FUTURE DIRECTIONS IN ACTINIDE SEPARATIONS

Actinide separations for plutonium processing (in connection with either weapons production or as a part of a plutonium recycle program) and uranium recovery involve primarily solvent extraction processes operating on acidic aqueous solutions. As a consequence of 50 years of both research and process experience, this technology must be considered mature, and has proven to be reliable, though its application has generated complex wastes. Partly as a result of this maturity, but also due to changes in world politics, acid processing to recover plutonium is no longer the principal driving force for development in actinide separations. The challenges attendant to the present status of actinide separations are determined by renewed interest in closing the fuel cycle and by the need for waste cleanup and environment restoration for legacy materials. Current issues in actinide separations are defined by the physical and chemical state of actinides as they occur and the motivation for carrying out the separation.

24.5.1 Alkaline wastes in underground storage tanks

One legacy of 50 years of plutonium production for defense purposes is a large volume of mixed wastes (containing TRUs, long-lived fission products, and non-radioactive but chemically hazardous materials) (Horwitz *et al.*, 1982). Their presence in underground waste tanks or storage bins represents a potential threat to the surrounding environment and so demands attention. These wastes take the form of sludges, solids, alkaline, or acidic solutions, and slurry phases in which actinides coexist with long-lived fission products and non-radioactive constituents. In the face of this complexity, how can the volume of waste going to a repository be minimized? Two potentially important areas for development are: improving sludge washing procedures that can selectively remove actinides from the solids or sludges (solid–liquid separation), and separation procedures suitable for plant-scale development which can operate in alkaline media.

24.5.2 Actinide burnup strategies

A 'permanent' remedy to the long-term hazard of actinides is to 'incinerate' them in advanced reactors or accelerators and thus transform them into short-lived fission products. An added advantage of this approach is the potential for recovery of the energy value of the actinides. Clearly, transmutation also eliminates weapons proliferation concerns as well. Because lanthanides have high cross sections for neutron capture and thus interfere with the neutron physics of actinide burnup, robust Ln/An separation methods are demanded, in particular, processes resistant to radiolysis effects. Two areas of actinide separations research relevant to this problem are the continued development

of fast reactor concept and pyrometallurgical separation process, and the development of new soft-donor extractants and aqueous complexants for actinide/lanthanide separations. Some of the less developed unconventional materials and techniques (RTILs and sc-CO_2, and volatility-based methods in particular) may ultimately have an important role to play in solving this challenging problem.

24.5.3 Actinides and the environment

Minor concentrations of actinides are present in the terrestrial environment as a result of atmospheric weapons testing, the Chernobyl accident, and actinide production activities (including both planned and accidental releases). Accurate speciation techniques, environment decontamination methods, and *in-situ* immobilization techniques are needed. Three generic areas for research, all of which involve some form of separation science, are pertinent to this subject: the development of reliable speciation techniques and thermodynamic models; solid-solution separation methods for removal of actinides from soils, contaminated process equipment, etc.; and solution–mineral conversion techniques to fix residual actinides *in-situ* and inhibit their entry into the hydrosphere/biosphere.

In the earliest days of actinides separations, discovery and plutonium production dominated the landscape. Sixty years later as we approach the end of the age of fossil fuels, actinide separation could play a central role in the preservation and restoration of the planetary environment. The major change in emphasis does not mean the end of the need for actinide separations, it indicates a shift toward new horizons. Many opportunities exist for improvements in existing procedures or the development of new methods for actinide isolation.

CHAPTER TWENTY FIVE

ORGANOACTINIDE CHEMISTRY: SYNTHESIS AND CHARACTERIZATION

Carol J. Burns and Moris S. Eisen

25.1 INTRODUCTION

The advent of modern organometallic chemistry has often been cited as the report of the preparation of ferrocene, $(\eta^5\text{-}C_5H_5)_2Fe$, the first metallic complex containing a π-complexed ligand (Pauson, 1951). It was not long after the report of this compound that comparable analogs of the lanthanides and actinides were reported (Reynolds and Wilkinson, 1956). Since that time, the organometallic chemistry of the actinides has lagged in comparable developments to the chemistry of the transition metals. Recent years, however, have witnessed a resurgence of interest in the non-aqueous chemistry of the actinides, in part due to the availability of a much wider array of ancillary ligands capable of stabilizing new compounds and introducing new types of reactivity. Equally important in stimulating new interest has been the realization by numerous researchers that the organometallic chemistry of these elements provides types of chemical environments that effectively probe the metals' ability to employ valence 6d and 5f orbitals in chemical bonding. Modern organoactinide chemistry is now characterized by the existence not only of actinide analogs to many classes of d-transition metal complexes (particularly those of Groups 3 and 4), but increasingly common reports of compounds (and types of reactions) unique to the actinide series. Most developments in the non-aqueous chemistry of the

actinides have involved the use of thorium and uranium, both due to their lower specific activity, and to the apparent chemical similarity these elements bear to Group 4 metals in organometallic transformations. Uranium has further demonstrated the ability to access a wide range of oxidation states (3+ to 6+) in organic solvents, providing for greater flexibility in effecting chemical transformations.

The earliest technological interest in organometallic actinide chemistry focused on its potential for application in isotope separation processes (Gilman, 1968). More recent reports continue to discuss the volatility of organoactinide compounds as a possible benefit in separation processes (gas chromatography, fractional sublimation) or in chemical vapor deposition processes (Mishin *et al.*, 1986). At the same time, interest has emerged in the behavior of the actinide elements in stoichiometric and catalytic transformations, particularly in comparison to d-transition metal analogs. The relatively large size and abundance of valence orbitals associated with the actinide metals can facilitate transformations of substrates at the metal center, or enable new types of reactions. These reactions will be discussed further in Chapter 26.

This chapter will provide an overview of the preparation and properties of the major classes of actinide complexes; the material will be organized by major ancillary ligand type. Within a class of ligands, compounds will be discussed based upon assigned formal oxidation states. While earlier definitions of organometallic chemistry would restrict consideration to compounds exclusively containing metal–carbon σ- or π-bonds, for the purposes of this treatise we will briefly consider select classes of ancillary ligands based principally coordination of the metal center by elements of Group 15 or Group 16, particularly where these ligand sets serve to support novel molecular transformations at the metal center.

25.2 CARBON-BASED ANCILLARY LIGANDS

25.2.1 Cyclopentadienyl ligands

(a) Trivalent chemistry

The most common class of organoactinide complexes is that containing the cyclopentadienyl ligand ($C_5H_5^-$), or one of its substituted derivatives. The use of variants of the cyclopentadienyl ligand has dominated the field of organometallic chemistry over the past 50 years, given their ability to stabilize a wide variety of oxidation states and coordination environments (Cotton *et al.*, 1999). The cyclopentadienyl ligand itself dominated the early development of organoactinide chemistry. The coordination environment that likely has been reported for the largest number of the actinide elements is the homoleptic compound $(\eta^5\text{-}C_5H_5)_3An$ (An = actinide). This ligand set support most members of the actinide series from thorium to californium (Table 25.1).

A number of synthetic routes have been reported to generate these species and their tetrahydrofuran (THF) adducts, including direct metathesis with alkali

metal salts (Crisler and Eggerman, 1974; Kanellakopolus *et al.*, 1974a, 1980; Moody and Odom, 1979; Wasserman *et al.*, 1983), or transmetallation with Be $(\eta^5\text{-}C_5H_5)_2$ or $Mg(\eta^5\text{-}C_5H_5)_2$ (Fischer and Fischer, 1963; Baumgärtner *et al.*, 1965, 1966, 1967, 1970; Laubereau and Burns, 1970a,b). In addition, the trivalent compounds may be obtained from chemical (Crisler and Eggerman, 1974) or photochemical (Kalina *et al.*, 1977; Bruno *et al.*, 1982) reduction of suitable tetravalent actinide precursors (Karraker and Stone, 1972; Chang *et al.*, 1979; Zanella *et al.*, 1980). Examples of these preparations are given in equations (25.1)–(25.5).

$$UCl_3 \cdot n\text{THF} + 3Na(C_5H_5) \xrightarrow{\text{THF}} (\eta^5\text{-}C_5H_5)_3U(\text{THF}) + 3\text{NaCl} \quad (25.1)$$

$$2AnCl_3 + 3Be(C_5H_5)_2 \xrightarrow{70^\circ C} (\eta^5\text{-}C_5H_5)_3An + 3BeCl_2 \quad An = Pu,\ Am,\ Cm,\ Bk,\ Cf \quad (25.2)$$

$$2PuCl_3 + 3Mg(C_5H_5)_2 \xrightarrow{\text{THF}} (\eta^5\text{-}C_5H_5)_3Pu + 3MgCl_2 \quad (25.3)$$

$$(\eta^5\text{-}C_5H_5)_3U[(CH(CH_3)_2] \xrightarrow{h\nu, C_6H_6} (\eta^5\text{-}C_5H_5)_3U\text{-H} + CH_2{=}CHCH_3$$
$$(\eta^5\text{-}C_5H_5)_3U\text{-H} + (\eta^5\text{-}C_5H_5)_3U[CH(CH_3)_2] \longrightarrow (\eta^5\text{-}C_5H_5)_3U + CH_3CH_2CH_3 \quad (25.4)$$

$$Cs_2PuCl_6 + Mg(C_5H_5)_2 \xrightarrow{\text{THF}} (\eta^5\text{-}C_5H_5)_3Pu + \text{unknown} \quad (25.5)$$

More recently, a study was conducted on reduction products of $(\eta^5\text{-}C_5H_5)_3UCl$ with a variety of reducing agents (Le Marechal *et al.*, 1989). It was found that the composition of the product was a function of the reducing agent [equations (25.6)–(25.8)].

$$(\eta^5\text{-}C_5H_5)_3UCl + Na/Hg \xrightarrow{THF} (\eta^5\text{-}C_5H_5)_3U(THF) \quad (25.6)$$

$$(\eta^5\text{-}C_5H_5)_3UCl + Na/Hg + 18{-}crown{-}6 \xrightarrow{THF} [(18{-}crown{-}6)Na][(\eta^5\text{-}C_5H_5)_3UCl] \quad (25.7)$$

$$(\eta^5\text{-}C_5H_5)_3UCl + NaH \longrightarrow [Na(THF)_2]\{[(\eta^5\text{-}C_5H_5)_3U]_2(\mu\text{-}H)\} \quad (25.8)$$

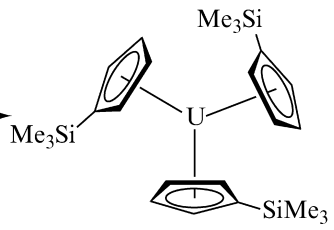
Perhaps the most useful development in the synthetic chemistry of trivalent actinide complexes in recent years has been the development of the more soluble iodide starting materials (Karraker, 1987; Clark *et al.*, 1989) AnI_3L_4 (An = U, Np, Pu; L = THF, pyridine, DMSO). These species, generated from actinide metals and halide sources in coordinating solvents, are readily soluble in organic solvents, and serve as convenient precursors to a variety of trivalent actinide species [equations (25.9)–(25.10)] (Zwick *et al.*, 1992).

$$An + 3/2I_2 \xrightarrow[L = THF,\ pyridine,\ DMSO]{L} AnI_3L_4 \quad (25.9)$$

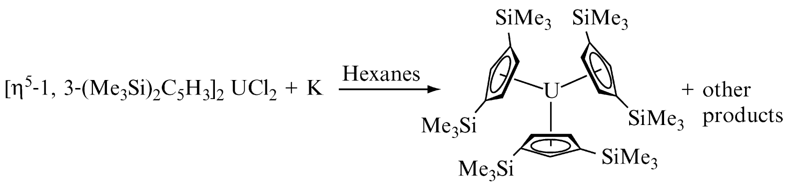
$$PuI_3(THF)_4 + Li(C_5H_5) \xrightarrow{THF} (\eta^5\text{-}C_5H_5)_3Pu(THF) + 3LiI \quad (25.10)$$

The solubility of the parent tris(cyclopentadienyl)actinide complexes is limited in non-polar media, presumably due to oligomerization through bridging cyclopentadienyl ligands. The molecular structures of these species have only been inferred by comparison of powder diffraction data with that obtained from known tris(cyclopentadienyl)lanthanide complexes. In response, a number of groups have explored the chemistry of substituted analogs of the cyclopentadienyl ligand for the light actinides (Th, U), including those with alkyl or silyl substituents, as well as the indenyl ligand. Tris(ligand) complexes have been reported and several examples have been structurally characterized. Tris(indenyl) complexes of thorium and uranium have been reported, and the complex $(\eta^5\text{-}C_9H_7)_3U$ was structurally characterized (Goffart, 1979; Meunier-Piret *et al.*, 1980). Several other trivalent substituted cyclopentadienyl complexes have been prepared by reduction of tetravalent precursors (Brennan *et al.*, 1986a; Zalkin *et al.*, 1988a; Stults *et al.*, 1990), as shown in equation (25.11).

$$(\eta^5\text{-}Me_3SiC_5H_4)_3UCl + {}^tBuLi \xrightarrow{Toluene} \quad (25.11)$$



The complexes $[\eta^5\text{-}(Me_3Si)_2C_5H_3]_3U$ and $(\eta^5\text{-}C_5Me_4H)_3U$ have also been prepared by reduction of tetravalent precursors (del Mar Conejo *et al.*, 1999), although in the synthesis of $[\eta^5\text{-}(Me_3Si)_2C_5H_3]_3U$, ligand redistribution also takes place [equation (25.12)].



(25.12)

One of the more interesting members of the series of trivalent homoleptic cyclopentadienyl complexes is the well-characterized thorium example, $[\eta^5\text{-}(RMe_2Si)_2C_5H_3]_3Th$ (R = Me, ${}^tBu$) (Blake *et al.*, 1986a, 2001). This complex was prepared in a manner similar to that shown in equation (25.12), by reduction of the metallocene dichloride or the tris(cyclopentadienyl) chloride in toluene by Na–K alloy. The compound is isolated in good yield as a dark blue crystalline material, which has been structurally characterized (Fig. 25.1).

As for most base-free tris(cyclopentadienyl)actinide complexes, the compound crystallizes in a pseudo-trigonal planar structure, with averaged ligand centroid–thorium–centroid angles near 120°, and averaged $Th\text{–}C_{ring}$ distances of 2.80(2) Å. A particular element of interest for this complex has been its electronic structure. One of the most investigated aspects of actinide–cyclopentadienyl chemistry has been the nature of bonding between the metal and the ligand (Burns and Bursten, 1989). Most experimental studies of tris(cyclopentadienyl)actinide complexes, including ^{237}Np Mössbauer studies of $(\eta^5\text{-}C_5H_5)_3Np$ (Karraker and Stone, 1972) and infrared and absorption spectroscopic studies of plutonium, americium, and curium analogs (Baumgärtner *et al.*, 1965; Pappalardo *et al.*, 1969; Nugent *et al.*, 1971) suggest that while the bonding is somewhat more covalent than that in lanthanide analogs, the interaction between the metal and the cyclopentadienyl ring is still principally ionic. Theoretical treatments have suggested that the 6d orbitals are chiefly involved in interactions with ligand-based orbitals. While the 5f orbital energy drops across the series, creating an energy match with ligand-based orbitals, spatial overlap is poor, precluding strong metal–ligand bonding (Strittmatter and Bursten, 1991). Thorium lies early in the actinide series and the relatively high energy of the 5f orbitals (before the increasing effective nuclear charge across the series drops the energy of these orbitals) has lead to speculation that a Th(III) compound could in fact demonstrate a $6d^1$ ground state. In support of this, Kot *et al.* (1988) have reported the observation of an EPR spectrum with *g* values close to 2 at room temperature.

Despite the common use of the permethylated cyclopentadienyl ligand $(C_5Me_5^-)$ in actinide and lanthanide chemistry, it is only recently that a tris (cyclopentadienyl) actinide complex has been prepared with this ligand

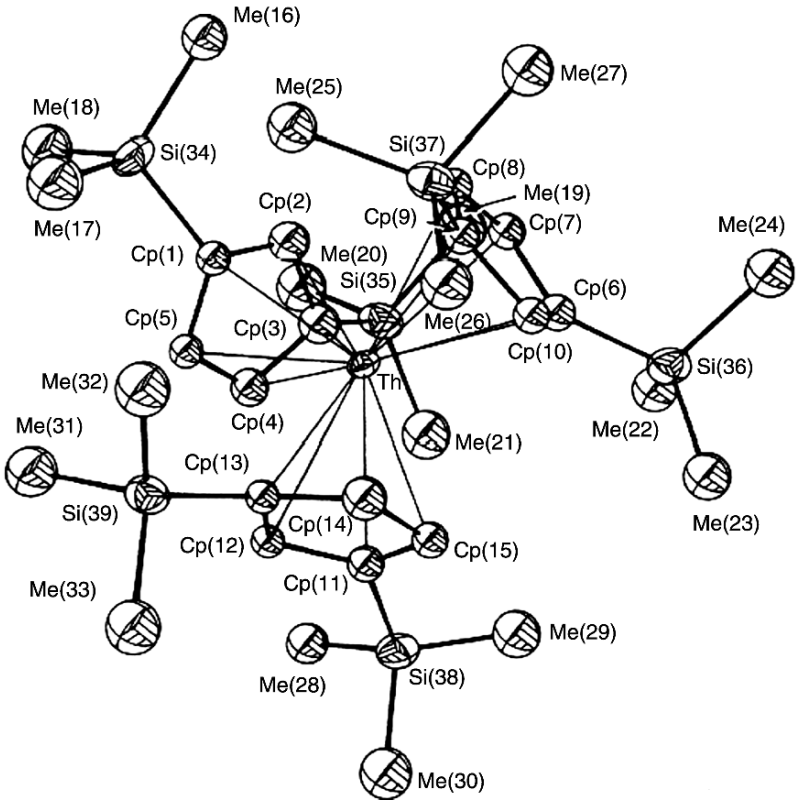


Fig. 25.1 *Crystal structure of* $[\eta^5\text{-}(Me_3Si)_2C_5H_3]_3Th$ (*Blake* et al., 1986a). (*Reproduced by permission of The Royal Society of Chemistry*.)

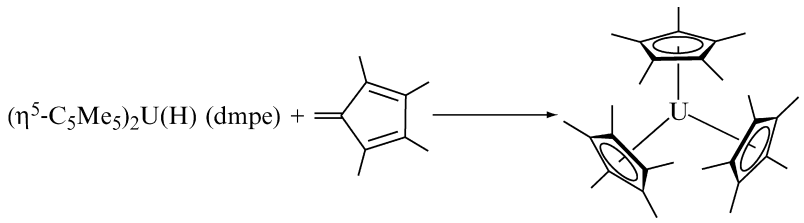
(Evans *et al.*, 1997). It was previously anticipated that the large steric bulk associated with this ligand would preclude incorporation of three pentamethylcyclopentadienyl groups in the coordination sphere of an actinide, and in fact direct metathesis routes had not proven successful. The complex $(\eta^5\text{-}C_5Me_5)_3U$ was instead initially prepared by reaction of a trivalent hydride complex with tetramethylfulvene [equation (25.13)].



(25.13)

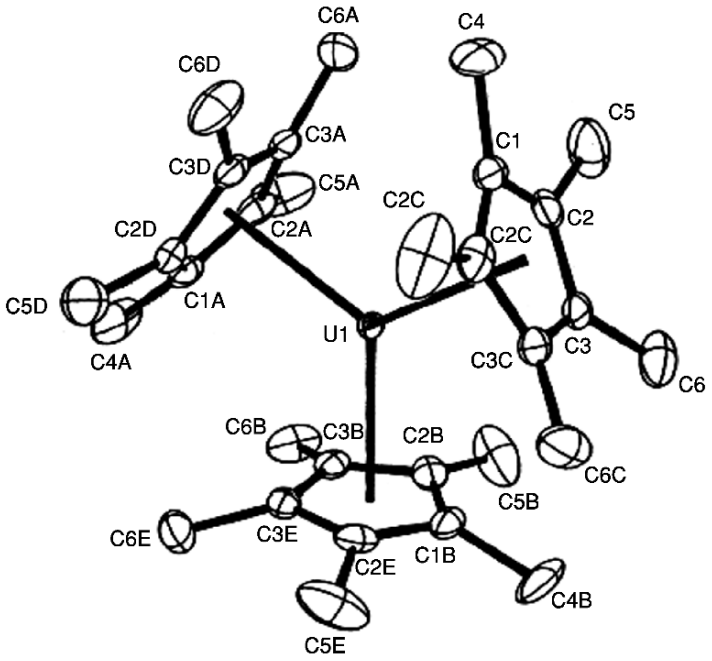


Fig. 25.2 *Crystal structure of* $(\eta^5\text{-}C_5Me_5)_3U$ (*Evans* et al., 1997). (*Reproduced with permission from John Wiley & Sons, Inc.*)

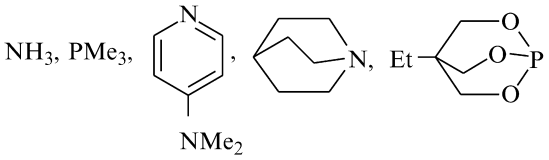
Since that time, however, several other routes have been reported to generate the compound (Evans *et al.*, 2002). The molecular structure is shown in Fig. 25.2.The average $U–C_{ring}$ bond distance in this compound [2.858(3) Å] is much larger than in other crystallographically characterized U(III) pentamethylcyclopentadienyl complexes (*ca.* 2.77 Å), suggesting a significant degree of steric crowding.

The tris(cyclopentadienyl)actinide complexes display a rich coordination chemistry, and one which sheds light on the nature of metal orbital participation in chemical bonding. Actinide metals generally are acidic and coordinate Lewis bases. As previously discussed, many of the tris(cyclopentadienyl)actinide complexes can be isolated as THF adducts directly from reactions carried out in that solvent. In addition, these complexes will coordinate other simple N-, O-, or P-donor bases. In most instances the complexes form simple 1:1 adducts [equation (25.14)] (Brennan and Zalkin, 1985; Brennan *et al.*, 1986b, 1988a; Zalkin and Brennan, 1987; Rosen and Zalkin, 1989; Adam *et al.*, 1993), while in select cases complexes have been isolated where two metal centers are bridged by a bidentate base [equation (25.15)] (Zalkin *et al.*, 1987b).

$$(\eta^5\text{–}MeC_5H_4)_3U + L \longrightarrow (\eta^5\text{–}MeC_5H_4)_3U\text{–}L \quad L=Ph_3P=O, \tag{25.14}$$



$$(\eta^5\text{-}C_5H_5)_3U(THF) + dmpe \xrightarrow{THF} Cp_3U\text{—}P \quad P\text{—}UCp_3 \tag{25.15}$$

Similarly, reaction of tris(cyclopentadienyl) complexes with anionic reagents has been shown to produce either anionic [equation (25.16)] or anion-bridged bimetallic complexes [equation (25.17)] (Stults *et al.*, 1989; Berthet *et al.*, 1991a, 1992a):

$$2(\eta^5\text{-}(SiMe_3)C_5H_4)_3U + NaN_3 + 18\text{-crown-6} \longrightarrow [Na(18\text{-crown-6})]\,[(\eta^5\text{-}(SiMe_3)C_5H_4)_3U\text{–}N{=}N{=}N\text{–}U(\eta^5\text{-}(SiMe_3)C_5H_4)_3U] \tag{25.16}$$

$$2(\eta^5\text{-}(SiMe_3)C_5H_4)_3U + NaH + 18\text{-crown-6} \longrightarrow [Na(18\text{-crown-6})]\,[(\eta^5\text{-}(SiMe_3)C_5H_4)_3U\text{–}H\text{–}U(\eta^5\text{-}(SiMe_3)C_5H_4)_3U] \tag{25.17}$$

Determination of the relative affinities of tris(cyclopentadienyl) complexes for various classes of ligands has been used to suggest the extent of metal-to-ligand π-back-donation. In order to compare the properties of actinides with lanthanides, ligand displacement series have been evaluated for the compounds $(RC_5H_4)_3M$ (M = U, Ce) (Brennan *et al.*, 1987). Both uranium and cerium complexes were found to have a preference for 'softer' phosphine donor ligands over 'harder' amine ligands, although in direct competition between the two metals, uranium always prefers the softer donors over cerium. Examination of the crystal structures of comparable uranium and cerium compounds reveals a slight shortening of the U–P bond (corrected for differences in metal radii); it has been suggested that this is a consequence of metal π-back-donation to phosphorus.

Another indication of the ability of low-valent early actinides to engage in π-back-donation may be found in the coordination of carbon monoxide to $(R_nC_5H_{5-n})_3U$ (Brennan *et al.*, 1986c; Parry *et al.*, 1995; del Mar Conejo *et al.*, 1999). Both structural and spectroscopic studies indicate that a strong degree of metal-to-ligand back donation occurs. The molecular structure of $(\eta^5\text{-}C_5Me_4H)_3U(CO)$ (Fig. 25.3) evidences a short $U\text{–}C_{CO}$ bond distance of 2.383(6) Å.

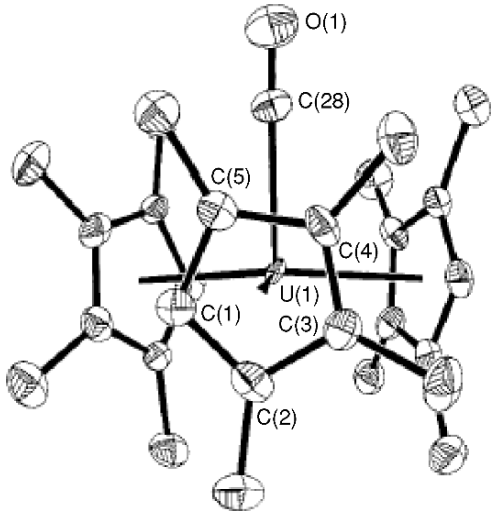


Fig. 25.3 *Crystal structure of* $[\eta^5\text{-}C_5Me_4H]_3U(CO)$ (*del Mar Conejo* et al., 1999). (*Reprinted with permission from John Wiley & Sons, Inc.*)

Table 25.2 *IR data of* $(\eta^5\text{-}R_nC_5H_{5-n})_3U(CO)$ *complexes.*

Compound	ν_{CO} (cm^{-1})
$(\eta^5\text{-}C_5Me_4H)_3U(CO)$	1880
$(\eta^5\text{-}Me_3CC_5H_4)_3U(CO)$	1960
$(\eta^5\text{-}Me_3SiC_5H_4)_3U(CO)$	1976
$[\eta^5\text{-}(Me_3Si)_2C_5H_3]_3U(CO)$	1988

Comparison of the ν_{CO} stretching frequencies for a series of compounds with varying ligand substituents (Table 25.2) demonstrates that electron-donating substituents on the ring contribute to increasing the electron density at the metal center, increasing metal-to-ligand back donation.

There is little comparable data for the heavier actinides, although the above bonding arguments would suggest that as the 6d orbital energy drops across the series, metal–ligand interactions would be weaker. Consistent with this picture, it has been reported that plutonium forms less robust adducts. While the complex $(\eta^5\text{-}C_5H_5)_3Pu(THF)$ can be isolated from solution, the THF is removed upon sublimation (Crisler and Eggerman, 1974); the analogous uranium compound remains intact upon sublimation (Wasserman *et al.*, 1983).

The early trivalent actinide cyclopentadienyl complexes are susceptible to one- and two-electron oxidation reactions. As an example, reaction of the tris (cyclopentadienyl) complexes have been reported to yield the corresponding U(IV) thiolate or selenolate complexes [equation (25.18)] (Leverd *et al.*, 1996).

$$\begin{aligned} &Cp_3U + R-E-E-R \longrightarrow Cp_3U-ER \\ &Cp = (\eta^5\text{-}C_5H_5),\ (\eta^5\text{-}C_5H_4Me),\ (\eta^5\text{-}C_5H_4SiMe_3); \\ &E = S,\ R = Me,\ Et,\ {}^{i}Pr,\ {}^{t}Bu,\ P;\ E = Se,\ R = Me \end{aligned} \tag{25.18}$$

Alkyl halides are similarly capable of oxidizing U(III) to generate equimolar mixtures of U(IV)–R and U(IV)–X as shown in equation (25.19) (Villiers and Ephritikhine, 1990).

$$2(\eta^5\text{-}C_5H_5)_3U(THF) + R-X \longrightarrow (\eta^5\text{-}C_5H_5)_3U-R + (\eta^5\text{-}C_5H_5)_3U-X \tag{25.19}$$

In the presence of sodium amalgam to reduce the uranium halide formed, the reaction can be made to be quantitative for formation of the alkyl species.

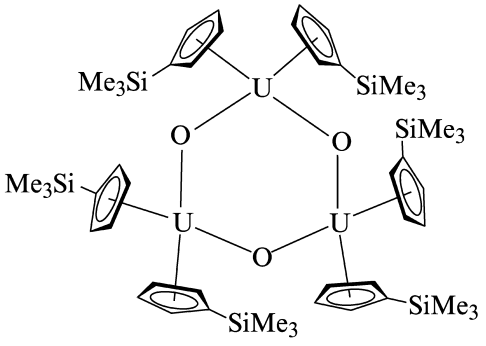
Reaction of $(\eta^5\text{-}C_5H_5)_3U(THF)$ with dioxygen produces the bridged bimetallic complex $[(\eta^5\text{-}C_5H_5)_3U]_2(\mu\text{-}O)$ (Spirlet *et al.*, 1996). The analogous μ-sulfido complex was produced by reaction of $(\eta^5\text{-}C_5H_5)_3UCl$ with freshly prepared K_2S. Chalcogen transfer reagents also oxidize tris(cyclopentadienyl) uranium complexes to yield bridged bimetallic species [equation (25.20)]; while most phosphine chalcogenides react readily, phosphine oxide does not oxidize U(III), but rather yields a base adduct (Brennan *et al.*, 1986b).

$$\begin{aligned} &(\eta^5\text{-}C_5H_4Me)_3U(THF) + E=PR_3 \longrightarrow \\ &(\eta^5\text{-}C_5H_4Me)_3U-E-U(\eta^5\text{-}C_5H_4Me)_3 \\ &\quad E = Se,\ Te,\ R = Bu;\ E = S,\ R = Ph \end{aligned} \tag{25.20}$$

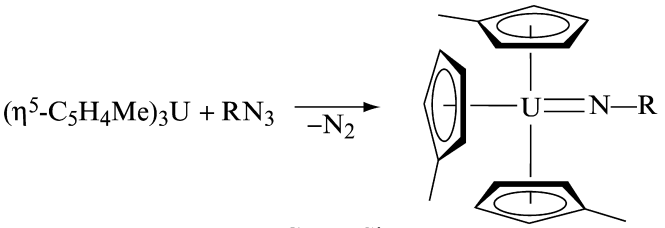
An analogous bridging oxo complex has been generated by the reaction of $(\eta^5\text{-}C_5H_4SiMe_3)_3U$ with CO_2 or N_2O [equation (25.21)] (Berthet *et al.*, 1991b).

$$\begin{aligned} &(\eta^5\text{-}C_5H_4SiMe)_3U + CO_2 \text{ or } N_2O \longrightarrow \\ &(\eta^5\text{-}C_5H_4SiMe_3)_3U-O-U(\eta^5\text{-}C_5H_4SiMe_3)_3 \end{aligned} \tag{25.21}$$

This complex can also be prepared by the reaction of $(\eta^5\text{-}C_5H_4SiMe_3)_3U(OH)$ with $(\eta^5\text{-}C_5H_4SiMe_3)_3UH$ (Berthet *et al.*, 1993); pyrolysis of the hydroxide complex generates instead the trinuclear complex $[(\eta^5\text{-}C_5H_4SiMe_3)_2U(\mu\text{-}O)]_3$.

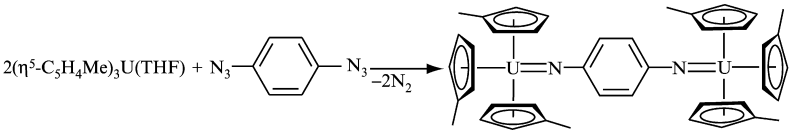


There are also a limited number of examples of two-electron oxidation reactions of tris(cyclopentadienyl)uranium compounds. Reaction of $(\eta^5\text{-}C_5H_4Me)_3U(THF)$ with organic azides (Brennan and Andersen, 1985) results in elimination of dinitrogen and formation of U(v) organoimido derivatives [equation (25.22)].



(25.22)

The related reaction with 1,3- or 1,4-diazidobenzene gives rise to bimetallic pentavalent products [equation (25.23)] (Rosen *et al.*, 1990).



(25.23)

The product generated from 1,4-diazidobenzene supports electronic communication between the metal centers through an aromatic ligand conjugation-based superexchange pathway; antiferromagnetic coupling is observed between the unpaired spins on the two metal centers (Fig. 25.4). The compound derived from 1,3-diazidobenzene, however, cannot undergo similar conjugation, and the susceptibility data show no interaction between the metal centers.

There exist relatively fewer examples of trivalent actinide complexes with two cyclopentadienyl rings. Compounds of the parent cyclopentadienyl ion are somewhat rare. Examples include the reported compounds $(\eta^5\text{-}C_5H_5)_2ThCl$ (Kanellakopulos *et al.*, 1974a) and $(\eta^5\text{-}C_5H_5)_2BkCl$ (Laubereau, 1970), thought to exist as dimers. The compounds $(\eta^5\text{-}C_5H_4Me)_2NpI(THF)_3$ and $(\eta^5\text{-}C_5H_4Me)NpI_2(THF)_3$ were prepared by reactions of $NpI_3(THF)_4$ with $Tl(C_5H_4Me)$ in tetrahydrofuran (Karraker, 1987). Given the propensity of sterically smaller ligands to redistribute and generate multiple species in solution, most complexes have been generated with more highly substituted cyclopentadienyl ligands, particularly $(\eta^5\text{-}C_5Me_5)$, $[\eta^5\text{-}(Me_3Si)_2C_5H_3]$, and $[\eta^5\text{-}(Me_3C)_2C_5H_3]$. One of the most investigated of these complexes is the chloride-bridged trimeric complex $[(\eta^5\text{-}C_5Me_5)_2U(\mu\text{-}Cl)]_3$ (Manriquez *et al.*, 1979; Fagan *et al.*, 1982). The complex can be prepared by a number of routes as shown in equations (25.24)–(25.26).

$$(\eta^5\text{-}C_5Me_5)_2U(Cl)(R) + 3/2\ H_2 \longrightarrow 1/3[(\eta^5\text{-}C_5Me_5)_2U(\mu\text{-}Cl)]_3 + 3RH \quad (25.24)$$

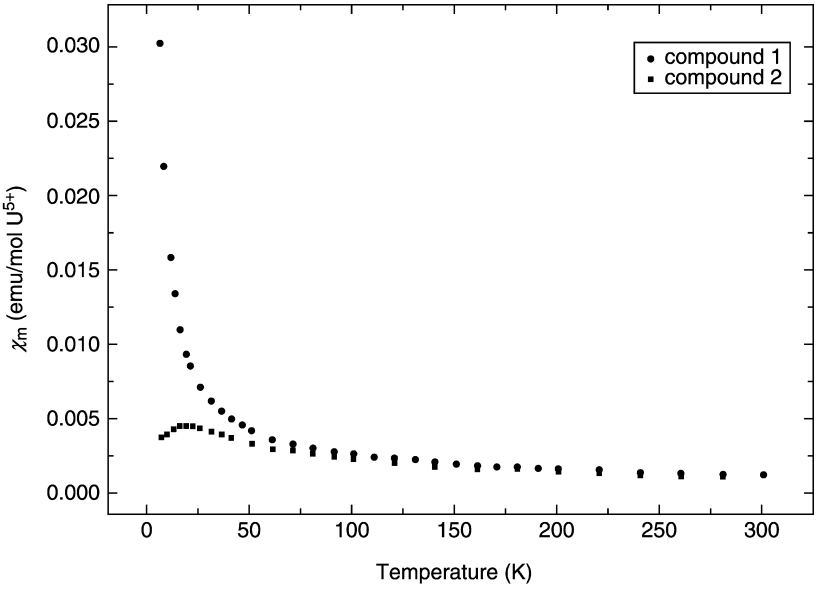


Fig. 25.4 *Magnetic susceptibility data for* 1,4-[(η^5-$C_5H_4Me)_3U$](=*N*-C_6H_4-*N*=)[*U*(η^5-$C_5H_4Me)_3$] (*compound* 1) *and* 1,3-[(η^5-$C_5H_4Me)_3U$](=*N*-C_6H_4-*N*=)[*U*(η^5-$C_5H_4Me)_3$] (*compound* 2). (*Reprinted with permission from Rosen* et al. (1990). *Copyright* 1990 *American Chemical Society.*)

$$(\eta^5\text{-}C_5Me_5)_2UCl_2 + {}^t\text{BuLi} \longrightarrow 1/3\ [(\eta^5\text{-}C_5Me_5)_2U(\mu\text{-}Cl)]_3 + \text{LiCl} + \text{organic products} \quad (25.25)$$

$$(\eta^5\text{-}C_5Me_5)_2UH_2 + (\eta^5\text{-}C_5Me_5)_2UCl_2 \longrightarrow 1/3[(\eta^5\text{-}C_5Me_5)_2U(\mu\text{-}Cl)]_3 \quad (25.26)$$

The reduction reaction shown in equation (25.24) has been extended to bis (alkyl) complexes to generate a stable mononuclear hydride complex stabilized by added ligand (Duttera *et al.*, 1982), as depicted in equation (25.27).

$$(\eta^5\text{-}C_5Me_5)_2UR_2 + 3/2\ H_2 + \text{dmpe} \longrightarrow (\eta^5\text{-}C_5Me_5)_2\ U(H)(P,P) + 2RH \quad (25.27)$$

The complex [(η^5-$C_5Me_5)_2U(\mu$-Cl)]$_3$ reacts with a variety of Lewis bases to generate monomeric adducts, and will undergo metathesis reactions (Fig. 25.5).

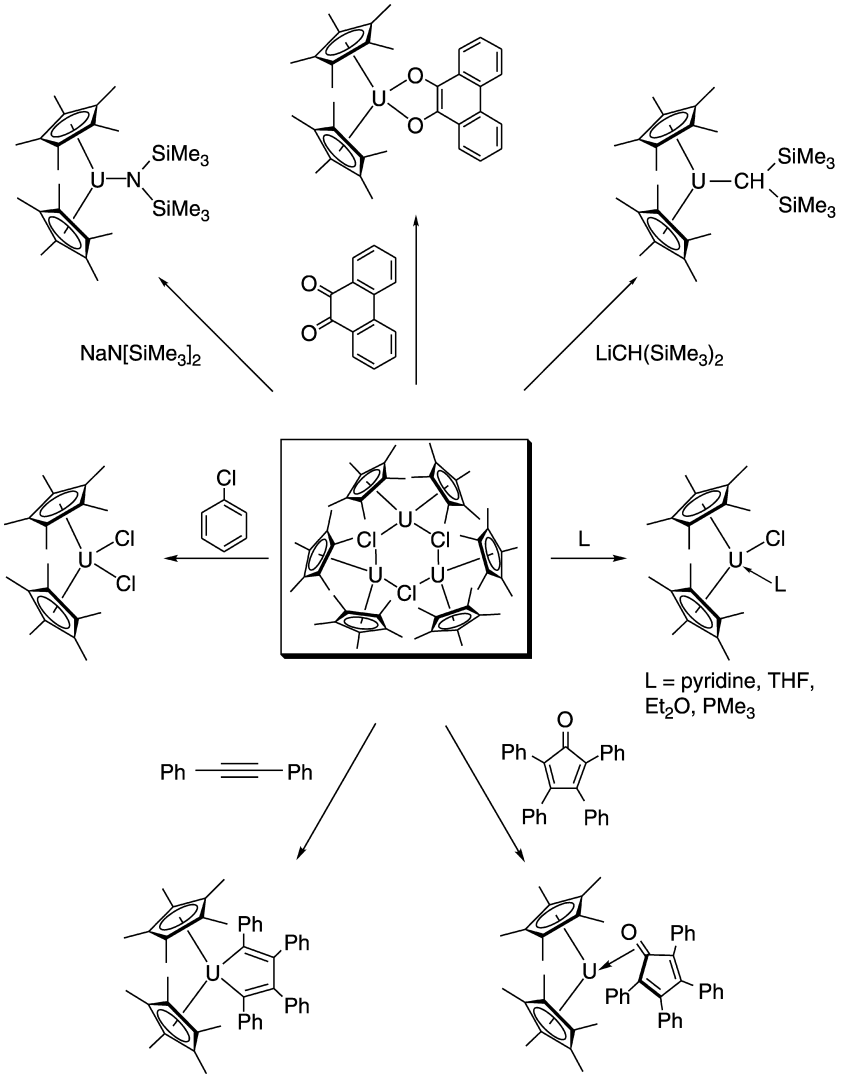

Fig. 25.5 *Reactions of* $[(\eta^5\text{-}C_5Me_5)_2U(\mu\text{-}Cl)]_3$ (*Fagan* et al., 1982).

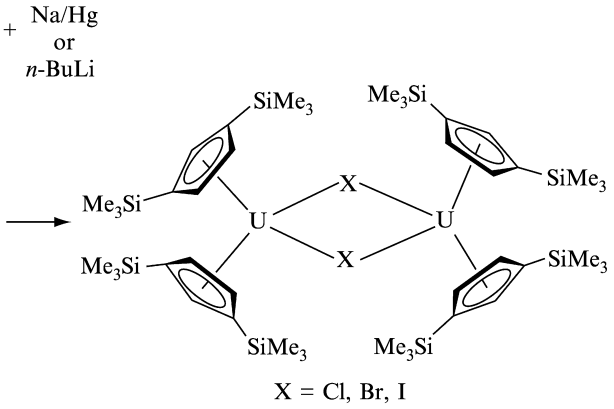
Alkyl complexes have been prepared by reaction with alkyllithium reagents, but are unstable at room temperature, except for $R = CH(SiMe_3)_2$. One of the most interesting reactions is that of $[(\eta^5\text{-}C_5Me_5)_2U(\mu\text{-}Cl)]_3$ with unsaturated substrates such as diphenylacetylene. In an apparent disproportionation, the reaction products include the metallacycle complex resulting from coupling of two alkyne ligands, as well as an equivalent amount of $(\eta^5\text{-}C_5Me_5)_2UCl_2$. Finke *et al.* (1981a,b) have examined the oxidation of the base adduct

$(\eta^5\text{-}C_5Me_5)_2UCl(THF)$ with alkyl halides. Kinetic evidence supports an atom-abstraction oxidative addition mechanism to the coordinatively unsaturated $(\eta^5\text{-}C_5Me_5)_2UCl$. The rate of reaction is 10^4–10^7 faster than any known isolable transition metal system reacting by atom abstraction.

A cationic bis(pentamethylcyclopentadienyl)uranium(III) complex has been reported (Boisson *et al.*, 1997). The complex $[(\eta^5\text{-}C_5Me_5)_2U(THF)_2][BPh_4]$ is generated by protonation of the complex $(\eta^5\text{-}C_5Me_5)_2U[N(SiMe_3)_2]$ with $[NH_4][BPh_4]$.

A number of U(III) complexes containing the $[\eta^5\text{-}1,3\text{-}(Me_3Si)_2C_5H_3]$ ligand have been prepared (Blake *et al.*, 1986b, 1987) by reduction of U(IV) precursors with Na–Hg or *n*-BuLi in toluene or hexanes [equation (25.28)].



(25.28)

In the presence of a coordinating ligand (e.g. TMEDA), a uranate salt ($[\eta^5\text{-}(Me_3Si)_2C_5H_3](\mu\text{-}Cl)_2U(L)$) (L = ligand) is isolated (Blake *et al.*, 1988).

An expanded synthesis of these and related $[\eta^5\text{-}1,3\text{-}(Me_3C)_2C_5H_3]$ complexes has been reported involving reduction of tetravalent precursors by *t*-BuLi in hexanes (Lukens *et al.*, 1999b,c). A number of the dimeric complexes have been structurally characterized (Fig. 25.6) (Lukens *et al.*, 1999a). The solution behavior of a number of members of the class $[\{\eta^5\text{-}1,3\text{-}R_2C_5H_3\}_2U(\mu\text{-}X)]_2$ (R = Me_3Si or Me_3C) have been examined by variable temperature NMR (Lukens *et al.*, 1999b). The complexes exist as dimers in solution at all temperatures examined. The dimers react with Lewis bases to yield monomeric mono- or bis-ligand adducts (Blake *et al.*, 1987; Beshouri and Zalkin, 1989; Zalkin and Beshouri, 1989); these serve as reagents in subsequent metathesis reactions (Blake *et al.*, 1987).

The complexes $[\{\eta^5\text{-}1,3\text{-}R_2C_5H_3\}_2U(\mu\text{-}OH)]_2$ (R = Me_3Si or Me_3C) have been prepared by reaction of one equivalent of water with $[\eta^5\text{-}1,3\text{-}(Me_3Si)_2C_5H_3]_3U$ and $[\eta^5\text{-}1,3\text{-}(Me_3C)_2C_5H_3]_2UH$, respectively (Lukens *et al.*, 1996).

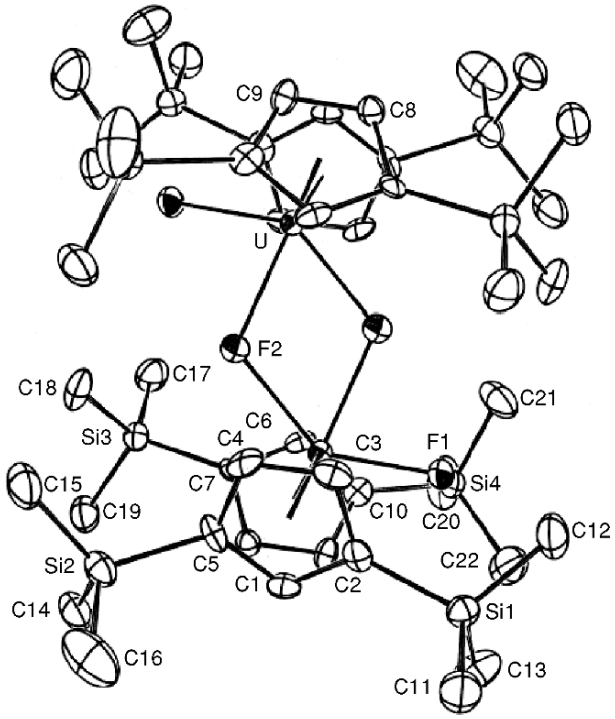


Fig. 25.6 *Crystal structure of* $[\{\eta^5\text{-}1,3\text{-}(Me_3Si)_2C_5H_3\}_2U(\mu\text{-}F)]_2$. (*Reprinted with permission from Lukens* et al. (1999a). *Copyright* 1999 *American Chemical Society*.)

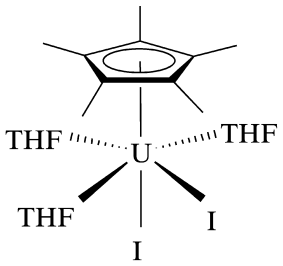
Upon heating, these complexes have been observed to undergo an unusual 'oxidative elimination' to yield the corresponding μ-oxo complexes [equation (25.29)].

$$[\{\eta^5\text{-}1,3\text{-}R_2C_5H_3\}_2U(\mu\text{-}OH)]_2 \xrightarrow[-H_2]{100^\circ C} [\{\eta^5\text{-}1,3\text{-}R_2C_5H_3\}_2U\{\mu\text{-}O)]_2 \qquad (25.29)$$
$$R = Me_3Si \text{ or } Me_3C$$

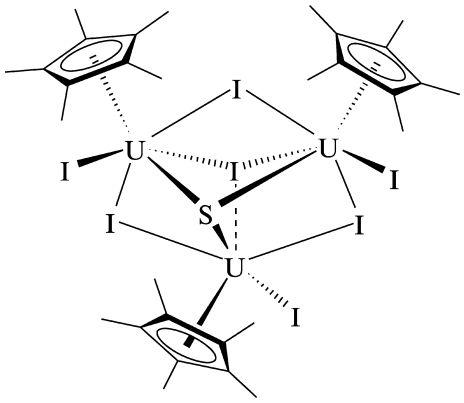
The kinetics of this process have been examined, and the reaction is found to be intramolecular, probably involving a stepwise α-elimination process.

The reagent $UI_3(THF)_4$ has proven valuable in generating mono(cyclopentadienyl) uranium(III) complexes (Avens *et al.*, 2000). Reaction of one equivalent of $UI_3(THF)_4$ with $K(C_5Me_5)$ results in the formation of the complex $(\eta^5\text{-}C_5Me_5)UI_2(THF)_3$. In the solid state this complex exhibits a pseudo-octahedral *mer*, *trans* geometry, with the cyclopentadienyl group occupying the axial position.



In the presence of excess pyridine, this complex can be converted to the analogous pyridine adduct, $(\eta^5\text{-}C_5Me_5)UI_2(py)_3$. $(\eta^5\text{-}C_5Me_5)UI_2(THF)_3$ will react further with $K(C_5Me_5)$ to generate the bis(ring) product, $(\eta^5\text{-}C_5Me_5)_2UI$ (THF), or will react with two equivalents of $K[N(SiMe_3)_2]$ to produce $(\eta^5\text{-}C_5Me_5)U[N(SiMe_3)_2]_2$. The solid state structure of the bis(trimethylsilyl)amide derivative reveals close contacts between the uranium center and two of the methyl carbons [2.80(2), 2.86(2) Å].

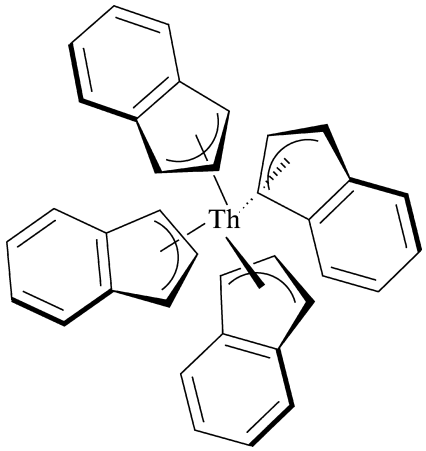
Oxidation of $(\eta^5\text{-}C_5Me_5)UI_2(THF)_3$ with CS_2 or ethylene sulfide produces a complex of the formula $[(\eta^5\text{-}C_5Me_5)UI_2(THF)_3]_2(S)$. This species undergoes slow decomposition in solution to yield a polynuclear complex (Clark *et al.*, 1995):



(b) Tetravalent chemistry

The tetravalent oxidation state dominates the cyclopentadienyl chemistry of the early actinide elements. Tetrakis(cyclopentadienyl) complexes were among the earliest actinide complexes prepared, and the complexes $(\eta^5\text{-}C_5H_5)_4An$ are known for Th (Fischer and Treiber, 1962), Pa (Baumgärtner *et al.*, 1969), U (Fischer and Hristidu, 1962), and Np (Baumgärtner *et al.*, 1968). Although only the uranium and thorium compounds have been structurally characterized (Burns, 1974; Maier *et al.*, 1993), IR spectral and X-ray powder data confirm

that all four complexes are isostructural. $(\eta^5\text{-}C_5H_5)_4U$ is found to be psuedo-tetrahedral, with a mean $U\text{–}C_{ring}$ bond distance of 2.81(2) Å. This is somewhat longer than average $U\text{–}C_{ring}$ distances for other U(IV) cyclopentadienyl complexes, reflecting the degree of steric crowding. The related tetrakis(indenyl) thorium compound has also been reported (Rebizant *et al.*, 1986). The thorium atom is bonded to the carbons of the five-membered ring portion of the indenyl ligand, although not in a η^5 fashion. The shortest Th–C bond distances [Th–C average = 2.83(3) Å vs 3.09(3) Å] are to the three non-bridging carbon atoms, leading to the overall designation of the rings as trihapto.



The first reported organoactinide complex was $(\eta^5\text{-}C_5H_5)_3UCl$ (Reynolds and Wilkinson, 1956), a member of the extensive class of complexes represented as Cp_3AnX. The complex was first prepared by the reaction of uranium tetrachloride with sodium cyclopentadienide in tetrahydrofuran. Comparable routes have been used to prepare $(\eta^5\text{-}C_5H_5)_3NpCl$ (Karraker and Stone, 1979), although this complex has also been prepared by reaction of $NpCl_4$ with $(C_5H_5)_2Be$ (Fischer *et al.*, 1966). Alternative routes have since been reported for the generation of $(\eta^5\text{-}C_5H_5)_3UCl$ (Marks *et al.*, 1976). Tris(indenyl)uranium and tris(indenyl)thorium complexes have been prepared by metathesis reactions with $K(C_9H_7)$ in THF (Burns and Laubereau, 1971; Laubereau *et al.*, 1971; Goffart *et al.*, 1975, 1981; Goffart and Duyckaerts, 1978).

Since the first report of cyclopentadienyl complexes, attempts have been made to assess the nature of the bonding in these complexes from their chemical reactivity. In contrast to complexes of lanthanides and Group 3 metals, $(\eta^5\text{-}C_5H_5)_3UCl$ does not react with $FeCl_2$ to produce ferrocene, and it decomposes relatively slowly in water. Although this is taken as some indication of increased covalency in chemical bonding, these complexes are still believed to be more ionic than the majority of d-transition metal cyclopentadienyl complexes (Burns and Bursten, 1989). The molecular structure of several Cp_3AnX complexes have

been determined, as well as several structures of closely related tris(indenyl) actinide halide complexes. Some comparative structural information is provided in Table 25.3, and a typical structure represented by $(\eta^5\text{-}C_5H_5)_3UBr$ is presented in Fig. 25.7.

Table 25.3 *Structural information for Cp_3AnX complexes.*

All complexes possess pseudo-tetrahedral geometry, with the halide ligand on an approximate three-fold axis of symmetry. The An–C and An–X bond lengths are consistent for most of the complexes; Th–C and Th–X values are slightly larger, as would be expected for the larger ionic radius. The average U–C_{ring} and U–X bond lengths are longer than would be expected in complexes $(\eta^5\text{-}C_5Me_5)_3UX$ (X = Cl, F); the U–Cl bond length in $(\eta^5\text{-}C_5Me_5)_3UCl$ is >0.15 Å longer than that for related complexes. The origin of this difference appears to be significant steric crowding in the molecule. Interligand repulsions between the bulky pentamethylcyclopentadienyl ligands results in the most signficant distortion from tetrahedral geometry; the cyclopentadienyl rings lie within a crystallographic plane of symmetry, requiring the angle X–U–$C_{centroid}$ to be rigorously 90°. This in turn results in repulsion between the rings and the halide, lengthening the bond.

As observed in the $An(indenyl)_4$ complexes, the tris(indenyl) complexes all evidence a 'slip' of the rings towards a trihapto bonding, resulting in two separate sets of U–C distances. The compound $(C_9HMe_6)_3UCl$ possesses a highly substituted hexamethylindenyl ligand (Spirlet *et al.*, 1992a). The steric encumbrance associated with this ligand induces a further slippage of the ring; the resulting complex has indenyl rings that are essentially monohapto towards the metal center, with mean U–C bonds of 2.622(6) Å (Fig. 25.8).

A number of approaches have been employed to generate derivatives of Cp_3AnX (von Ammon *et al.*, 1969; Kanellakopulos *et al.*, 1974b; Marks and Kolb, 1975; Fischer and Sienel, 1976, 1978; Bagnall *et al.*, 1982a,b; Spirlet *et al.*, 1996). Prototype reactions include protonation of $(\eta^5\text{-}C_5H_5)_4U$ [equation (25.30)] and metathesis [equation (25.31)].

$$(\eta^5\text{-}C_5H_5)_4U + HCN \longrightarrow (\eta^5\text{-}C_5H_5)_3U{-}CN + C_5H_6 \qquad (25.30)$$

$$(\eta^5\text{-}C_5H_5)_3An{-}Cl + KX \longrightarrow (\eta^5\text{-}C_5H_5)_3An{-}X + KCl \qquad (25.31)$$
$$An = U,\ Np,\ Pu;\ X = CN^-,\ CNBH_3^-,\ NCS^-$$

Reactions such as that between $(\eta^5\text{-}C_5H_5)_3UCl$ and KCN may be carried out in water (Bagnall *et al.*, 1982b), indicating the stability of the metal–ligand bonding in these complexes. In fact, it has been suggested that $(\eta^5\text{-}C_5H_5)_3UCl$ ionizes in water to yield the five-coordinate adduct $[(\eta^5\text{-}C_5H_5)_3U(H_2O)_2]^+$ (Fischer *et al.*, 1982). This spurred further interest in investigating other five coordinate species, e.g. $[(\eta^5\text{-}C_5H_5)_3UXY]^-$. The anionic complexes $[(\eta^5\text{-}C_5H_5)_3An(NCS)_2]^-$ (An = U, Np, Pu) can be isolated, provided that the cation is sufficently large (Bagnall *et al.*, 1982b). Spectrophotometric and other evidence indicates a trigonal–bipyramidal geometry for these species. The assignment of the geometry of these species is further supported by structural characterization of neutral base adducts $(\eta^5\text{-}C_5H_5)_3AnXL$, such as $(\eta^5\text{-}C_5H_5)_3U(NCS)(NCMe)$ (Fischer *et al.*, 1978; Aslan *et al.*, 1988) or $(\eta^5\text{-}C_5H_5)_3U(NCBH_3)(NCMe)$ (Adam *et al.*, 1990);

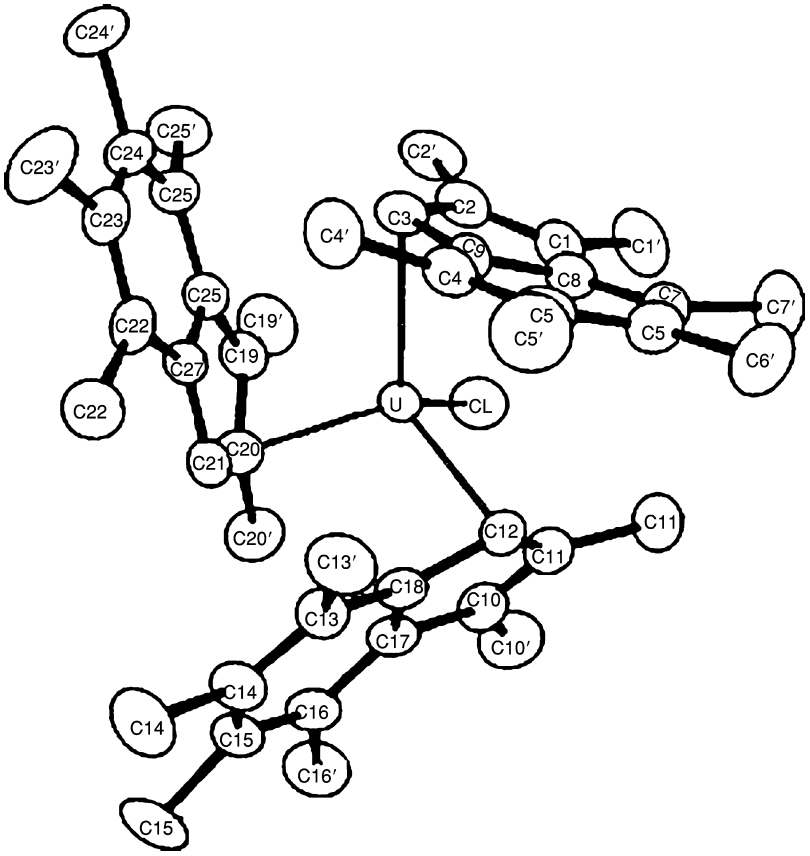

Fig. 25.8 *Crystal structure of* $(C_9HMe_6)_3UCl$ (*Spirlet* et al., 1992a). (*Reprinted with permission of the International Union of Crystallography*.)

these complexes exibit a trigonal-bipyramidal geometry, with the smaller ligands adopting the axial positions.

Cationic species can also be produced. The compound $[(\eta^5\text{-}C_5H_5)_3U(NCMe)_2]^+$ has been isolated as a $[BPh_4]^-$ salt by the reaction of $(\eta^5\text{-}C_5H_5)_3UCl$ and $NaBPh_4$ in water/acetonitrile mixtures (Aslan *et al.*, 1988). The cationic complex $[(\eta^5\text{-}C_5H_5)_3U(THF)]BPh_4$ was generated by protonation of the neutral amide precursor with $[NHEt_3]^+$ as illustrated in equation (25.32) (Berthet *et al.*, 1995).

$$(\eta^5\text{-}C_5H_5)_3U-NR_2 + [HNEt_3][BPh_4] \xrightarrow{THF} [(\eta^5\text{-}C_5H_5)_3U(THF)][BPh_4] + HNR_2 + NEt_3 \quad R = Me, Et \tag{25.32}$$

Similarly, treatment of precursor alkyl or amide complexes with pyridinium triflate gives rise to the triflate complex $(\eta^5\text{-}C_5H_5)_3U(O_3SCF_3)$ (Berthet *et al.*, 2002).

The crystal structure of the ^{t}BuCN adduct has also been determined (Berthet *et al.*, 1998).

Metathesis and protonation routes have been used to generate L_3An(IV) (L = cyclopentadienyl, indenyl) complexes containing alkoxide (OR), amide (NR_2), phosphide (PR_2), and thiolate (SR) ligands (Jamerson *et al.*, 1974; Goffart *et al.*, 1977; Karraker and Stone, 1979; Arduini *et al.*, 1981; Paolucci *et al.*, 1985; Leverd *et al.*, 1996; De Ridder *et al.*, 1996). Both magnetic susceptibility measurements and ^{237}Np Mössbauer spectroscopy have been employed to assess the qualitative order of ligand field strengths for a variety of ligands in the complexes $(\eta^5\text{-}C_5H_5)_3NpX$ (Karraker and Stone, 1979). The identified order of donor strength from this study is $X = Cl^- \sim BH_4^- > OR^- > R^- > C_5H_5^-$.

One of the best studied classes of $(\eta^5\text{-}C_5H_5)_3AnR$ (Th, U, Np) complexes is that containing alkyl or aryl ligands. The literature on alkyl complexes is extensive (e.g. Brandi *et al.*, 1973; Calderazzo, 1973; Gabala and Tsutsui, 1973; Marks *et al.*, 1973; Tsutsui *et al.*, 1975; Marks, 1979). The complexes are most often prepared by reaction of $(\eta^5\text{-}C_5H_5)_3AnX$ (X = halide) with Grignard [equation (25.33)] or alkyllithium [equation (25.34)] reagents.

$$(\eta^5\text{-}C_5H_5)_3An-X + RMgX' \longrightarrow (\eta^5\text{-}C_5H_5)_3An-R + MgXX' \quad (25.33)$$

$$(\eta^5\text{-}C_5H_5)_3An-X + LiR \longrightarrow (\eta^5\text{-}C_5H_5)_3An-R + LiX \quad (25.34)$$

Comparable indenylactinide derivatives have also been prepared (e.g. Goffart *et al.*, 1977). While there is a dearth of thermally stable U(IV) hydride complexes, the complexes $[\eta^5\text{-}(Me_3Si)C_5H_4]_3UH$ and $[\eta^5\text{-}(Me_3C)C_5H_4]_3UH$ can be obtained by reaction of the corresponding chlorides with $KBEt_3H$ (Berthet *et al.*, 1992b).

The molecular structures of several $(\eta^5\text{-}C_5H_5)_3AnR$ complexes have been determined; compounds display pseudo-tetrahedral geometries. Typical metal–carbon bond lengths for the alkyl ligand are 2.40 Å. All three cyclopentadienyl ligands are pentahapto, which nearly saturates the coordination environment of the metal center, as evidenced by the observation that allyl ligands can only be accomodated in a simple σ-bonded fashion (Halstead *et al.*, 1975) as shown in Fig. 25.9.

This monohapto geometry is also the low-temperature limiting structure for $(\eta^5\text{-}C_5H_5)_3U$(allyl) in solution (Marks *et al.*, 1973) although at room temperature the allyl ligand is fluxional, presumably interconverting sites by means of a π-bound intermediate. The relative coordinative saturation is reflected in the thermal stabilities of alkyl derivatives: primary > secondary > tertiary. Primary alkyl ligands are resistant to β-hydride elimination; thermal decomposition is presumed to take place through U–C bond homolysis and abstraction of a ring proton by the caged alkyl radical (although metal-containing products have not been definitively identified).

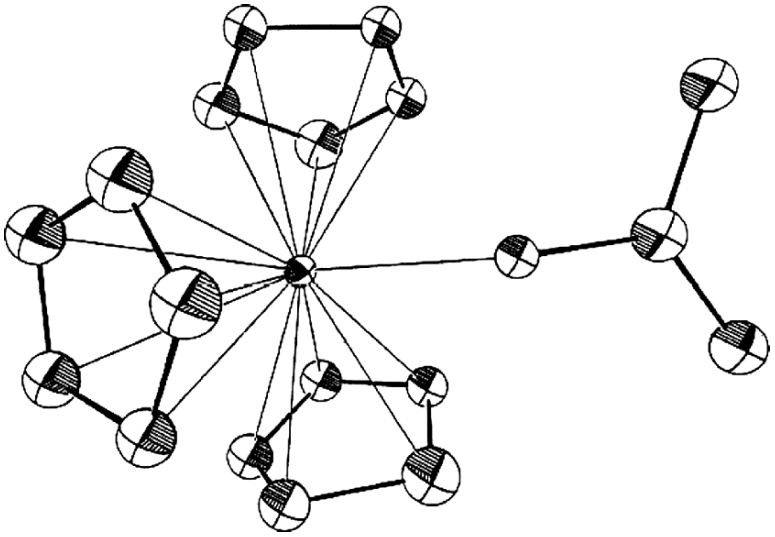

Fig. 25.9 *Crystal structure of* $(\eta^5\text{-}C_5H_5)_3U[CH_2C(CH_3)_2]$. (*Reprinted with permission from Halstead* et al. (1975). *Copyright* 1975 *American Chemical Society*.)

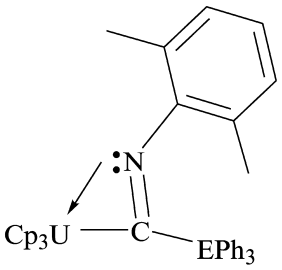
Further indication of the steric saturation of the complex may be found in the observation that reaction of $(\eta^5\text{-}C_5H_5)_3UR$ with excess alkyllithium does not result ultimately in the formation of anionic bis(alkyl) complexes. Rather, reaction products either result from alkyl exchange (Tsutsui *et al.*, 1975) or reduction of the metal center (Arnaudet *et al.*, 1983, 1986) as shown in equation (25.35).

$$(\eta^5\text{-}C_5H_5)_3U\text{–}R + LiR \longrightarrow Li[(\eta^5\text{-}C_5H_5)_3U\text{–}R] + \text{organic products} \tag{25.35}$$

It has been reported that the complex $[(\eta^5\text{-}C_5H_5)_3UMe_2]^-$ can be observed as an intermediate in solution by NMR spectroscopy (Villiers and Ephritikhine, 1991).

Other derivatives of the Group 14 elements have been prepared. Reaction of $(\eta^5\text{-}C_5H_5)_3UCl$ with $Li(EPh_3)$ affords the silyl- and germyluranium derivatives $(\eta^5\text{-}C_5H_5)_3U(EPh_3)$ [E = Si (Porchia *et al.*, 1986, 1989), E = Ge (Porchia *et al.*, 1987)], whereas the stannyl analog $(\eta^5\text{-}C_5H_5)_3U(SnPh_3)$ was best made from a the reaction of $(\eta^5\text{-}C_5H_5)_3U(NEt_2)$ with $HSnPh_3$. It can also be made from the transmetallation reaction of $HSnPh_3$ with $(\eta^5\text{-}C_5H_5)_3U(EPh_3)$ (E = Si, Ge) (Porchia *et al.*, 1989). The silyl compound is very reactive; under a number of conditions it can be transformed into $(\eta^5\text{-}C_5H_5)_3U(OSiPh_3)$. Insertion of xylylisocyanide into U–E bonds generates the corresponding η^2-iminoacyl complexes $[(\eta^5\text{-}C_5H_5)_3U\{C(EPh_3) = N(xylyl)\}]$ (E = Si, Ge).



E = Si, Ge

Several groups have conducted investigations of the thermochemistry of organoactinide complexes in order to determine the enthalpies of metal–ligand bonds, and thereby shed light on the nature of bonding and the anticipated reaction patterns. An excellent overview of available data on organouranium complexes has appeared recently (Leal *et al.*, 2001). Data compiled for tris (cyclopentadienyl)uranium(IV) complexes are presented in Table 25.4. Values tabulated in Leal *et al.* (2001) are based upon several types of measurements: solution titration experiments involving reaction with iodine or alcohols, static bomb combustion calorimetry, or gas-phase or solution equilibrium experiments. A few general trends may be noted. The enthalpy values for all U–C (sp^3) bonds are relatively consistent; U–C(sp^2) and U–C(sp) bonds increase in strength, as might be expected for a bond involving a higher degree of s-orbital involvement. While the bonds involving all Group 14 element bonds are reasonably close in energy, uranium bonds to Group 16 or Group 17 elements are somewhat stronger. The reason for the disparity between D(U–S) for the EtS^- and $^tBuS^-$ may be due to the greater steric bulk associated with the latter.

Comparable experiments have been carried out for the complexes (η^5-$C_5H_5)_3$ThR (Sonnenberger *et al.*, 1985); results of these measurements are found in Table 25.5. The thorium–carbon bond strengths are found to be overall higher than for comparable uranium species. This has been rationalized in terms of the greater stability of the U(III) complexes, resulting from homolytic loss of an alkyl radical.

The reaction of carbon monoxide with (η^5-$C_5H_5)_3$AnR (An = Th, U; R = alkyl, hydride) yields an acyl complex as shown in equation (25.36).

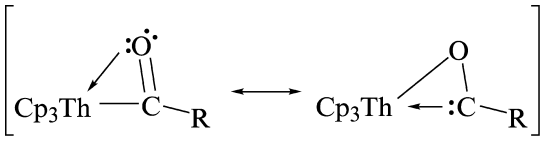
[a] Determined using reaction–solution calorimetry unless otherwise indicated.
[b] Mean bond dissociation enthalpy.
[c] Static bomb combustion calorimetry.
[d] This notation means that the bond is the stated amount stronger or weaker than the first bond dissociation enthalpy in $U(\eta^5\text{-}C_5H_5)_4$.

These reactions have been studied mechanistically (Sonnenberger *et al.*, 1984) for a series of thorium deriatives (R = *i*-Pr, *s*-Bu, *neo*-C_5H_{11}, *n*-Bu, $CH_2Si(CH_3)_3$, Me, and $CH_2C_6H_5$). Under the conditions employed, insertion is first order in thorium complex and first order in CO. The relative rates of insertion for

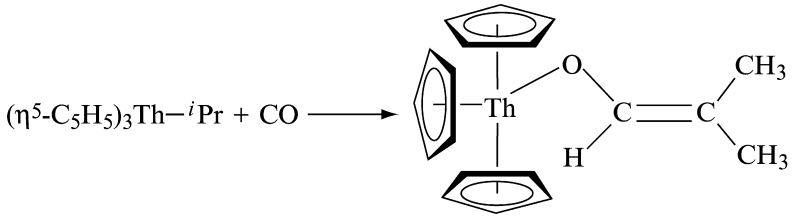
Table 25.5 *Bond dissociation enthalpies for Cp_3ThR complexes.*

Compound	*R*	*D*(*Th–R*) (kJ mol^{-1})
$(\eta^5\text{-}C_5H_5)_3ThR$	CH_3	374.9 (4.6)
	$CH(CH_3)_2$	342.2 (10.9)
	$CH_2C(CH_3)_3$	333.0 (11.7)
	$CH_2Si(CH_3)_3$	367.8 (15.1)
	$CH_2C_6H_5$	315.1 (9.2)

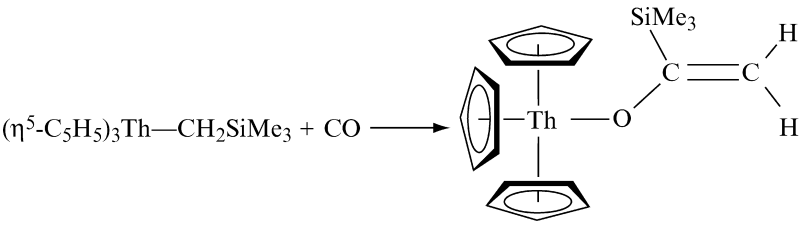
the ligands was found to be *i*-Pr > *s*-Bu > *neo*-C_5H_{11} > *n*-Bu > $CH_2Si(CH_3)_3$ > Me > $CH_2C_6H_5$. The relative rates of insertion correlate reasonably well with the bond enthalpies reported in Table 25.5, and as expected, were accelerated by photolysis. Where R = *s*-Bu, *neo*-C_5H_{11}, *n*-Bu, Me, and $CH_2C_6H_5$, the chief isolated product was the insertion (η^2-acyl) product shown in equation (25.36). This complex has been discussed as having a 'carbene-like' resonance form:



In the case of *i*-Pr and $CH_2Si(CH_3)_3$, however, the only products that could be isolated were those arising from 1,2-rearrangement [equations (25.37)–(25.38)].



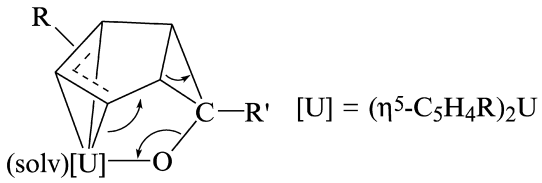
(25.37)



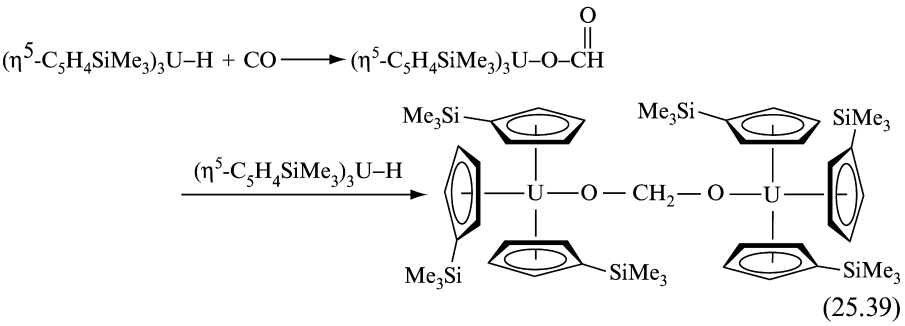
(25.38)

A comparative study of CO_2 insertion to generate carbonate complexes showed that carboxylation is significantly slower than carbonylation, and exhibits different trends in the dependence of rate on the alkyl ligand (Sonnenberger *et al.*, 1984).

Similar insertion reactions of carbon monoxide have been investigated for complexes of the type $(\eta^5\text{-}C_5H_4R)_3UR'$ (Paolucci *et al.*, 1984; Villiers and Ephritikhine, 1994). Villiers and Ephritikhine performed mechanistic studies, which showed that the insertion reaction appears first order under conditions of excess CO. The rate of insertion varies as a function of the cyclopentadienyl ring, with the rate decreasing in the order R = H > Me > ^{i}Pr > ^{t}Bu, as might be expected from steric considerations. The rate also depends on the identity of the alkyl ligand in the unusual order R′ = *n*-Bu > ^{t}Bu > Me > ^{i}Pr. The resulting η^2-acyl product was not stable and rearranged to yield alkylbenzenes C_6H_4RR', suggested to arise from ring enlargement of the cyclopentadienyl ligand by incorporation of the CR′ fragment. The reaction was observed to follow first-order kinetics, with the rate varying with the alkyl ligand in the order R′ = Me > *n*-Bu > ^{i}Pr > ^{t}Bu. In benzene solvent, the rates varied with R in the order ^{t}Bu > ^{i}Pr > Me > H, while the opposite order was observed in THF solvent. For a given solvent, the relative proportions of *meta*- and *para*-isomers were invariant with R and R′. The proposed mechanism involved a cyclopropyl intermediate, resulting from addition of the oxycarbene group to the cyclopentadienyl ligand.

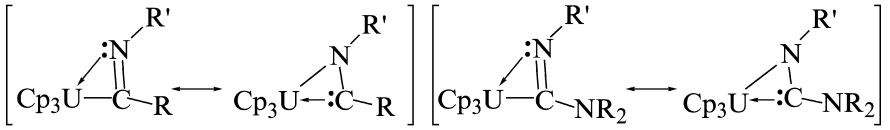


Carbon monoxide will also insert into the U–H bond of $(\eta^5\text{-}C_5H_4SiMe_3)_3UH$ (Berthet and Ephritikhine, 1992). As shown in equation (25.39), the initial product is believed to be a formate complex, which reacts further with the hydride to yield a dioxymethylene species.



(25.39)

Isoelectronic isocyanide ligands will also undergo insertion into uranium–carbon or uranium–nitrogen bonds (Dormond *et al.*, 1984; Zanella *et al.*, 1987) to yield η^2-iminoalkyl and η^2-iminocarbamoyl adducts.



η^2-Iminoalkyl η^2-Iminocarbamoyl

A unique class of $(\eta^5\text{-}C_5H_5)_3AnR$ complexes has been generated by Cramer *et al.* (1981, 1983, 1988). Reaction of $(\eta^5\text{-}C_5H_5)_3AnCl$ with lithium ylide or phosphine imide salts yields the following species [equations (25.40) and (25.41)]:

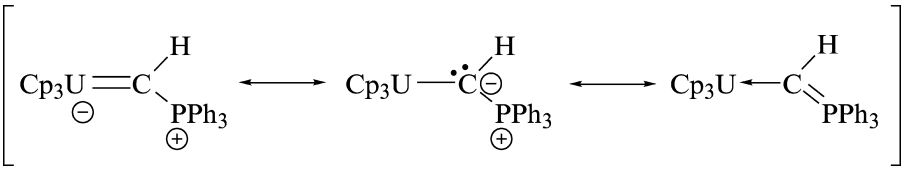
$$(\eta^5\text{-}C_5H_5)_3U\text{–}Cl + Li[(CH_2)_2P(CH_3)(C_6H_5)] \longrightarrow (\eta^5\text{-}C_5H_5)_3U[(CH)P(CH_3)_2(C_6H_5)] \quad (25.40)$$

$$(\eta^5\text{-}C_5H_5)_3An\text{–}Cl + Li[NP(C_6H_5)_3] \longrightarrow (\eta^5\text{-}C_5H_5)_3An[NP(C_6H_5)_3] \quad (25.41)$$

An = Th, U

The molecular structure of the uranium phosphine imide complex is shown in Fig. 25.10.

While the overall geometry of these complexes is similar to most $(\eta^5\text{-}C_5H_5)_3AnX$ compounds, these species are characterized by unusually short U–C(N) bonds. The U–C(1) bond distance in the ylide complex is 2.29(3) Å [significantly shorter than the average uranium–alkyl bond in $(\eta^5\text{-}C_5H_5)_3UR$ complexes, *ca.* 2.43 Å], and the U–N bond distance in the phosphine imide complex is 2.07(2) Å. Two useful descriptions have been presented for the bonding in these complexes, consistent with the resonance forms depicted for the phosphoylide complex:



One model would suggest that a multiple bond is formed between the metal and the carbon. This is supported by theoretical calculations at the extended Hückel level (Tatsumi and Nakamura, 1984; Cramer *et al.*, 1988) that reveal an important overlap population in the U–C bond of the phosphoylide complex and U–N bond of the phosphine imine complex. A second description would

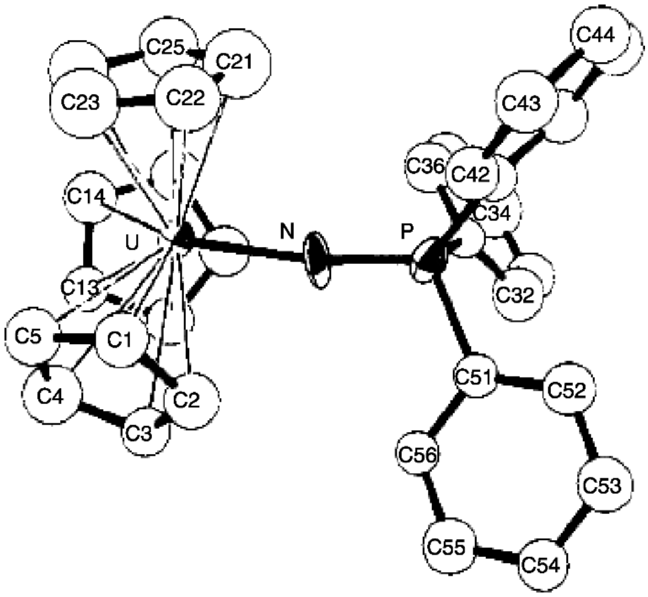


Fig. 25.10 *Crystal structure of* (η^5-C_5H_5)$_3$*U*[*NP*(C_6H_5)$_3$]. (*Reprinted with permission from Cramer* et al. (1988). *Copyright* 1988 *American Chemical Society.*)

suggest that the compounds are principally ionic, with the short U–C bond attributed to the Coulombic attraction between the electropositive metal and the residual charge on the ligand, as well as the smaller radial extent of the sp^2-hybridized ligand-based orbital. In reality, these models are probably merely extreme descriptions of the true bonding situation, and both are valid.

Unlike other complexes with metal–ligand multiple bonds (*vide infra*), the phosphoylide complex reacts as a U(IV) alkyl, however, undergoing a variety of insertion reactions (Cramer *et al.*, 1982, 1984a,b, 1986, 1987a,b) as shown in Fig. 25.11.

Complexes of the general formula (η^5-C_5H_5)$_2$AnX_2 have proven very difficult to synthesize, given the instability of the metallocene complex with respect to ligand redistribution to yield mono- and tris(ring) species (Kanellakopulos *et al.*, 1974c). Alternative approaches to generate complexes of this formula have generally involved introduction of the cyclopentadienyl ligands in the presence of other ligands that inhibit redistribution, as in equations (25.42)–(25.45) (Jamerson and Takats, 1974; Zanella *et al.*, 1977, 1987).

$U(NEt_2)_4$ + 2  $\longrightarrow$ (η^5-C_5H_5)$_2$U(NEt_2)$_2$ + 2 $HNEt_2$ (25.42)

$$UCl_4 + NaBH_4 \longrightarrow (BH_4)_2UCl_2 + 2NaCl \qquad (25.43)$$

$$(BH_4)_2UCl_2 + 2Tl(C_5H_5) \longrightarrow (\eta^5\text{-}C_5H_5)_2U(BH_4)_2 + 2TlCl \qquad (25.44)$$

$$(dmpe)ThCl_4 + 2Na(C_5H_5) \longrightarrow (\eta^5\text{-}C_5H_5)_2Th(Cl)_2(dmpe) + 2NaCl \qquad (25.45)$$

The bis(indenyl) complex $(\eta^5\text{-}C_9H_7)_2U(BH_4)_2$ has been generated by the reaction of $Na(C_9H_7)$ with $U(BH_4)_2$, and the structure reported (Spirlet *et al.*, 1989b). Peralkylated indenyl ligands have also been used to produce metallocene derivatives. Reaction of $ThCl_4$ with $Li(C_9Me_7)$ yields the dichloride complex $(\eta^5\text{-}C_9Me_7)_2ThCl_2$ (Trnka *et al.*, 2001). This species serves as a reagent for the synthesis of a number of derivatives, including $(\eta^5\text{-}C_9Me_7)_2ThMe_2$, $(\eta^5\text{-}C_9Me_7)_2Th(NMe_2)_2$, $(\eta^5\text{-}C_9Me_7)_2Th(NC_4H_4)_2$, and $(\eta^5\text{-}C_9Me_7)_2Th(\eta^3\text{-}H_3BH)_2$. The permethylindenyl ligand in all of these derivatives binds with nearly an idealized η^5-coordination mode, with the Th–C bonds for the five-membered ring of the indenyl ligands varying by no more than 0.05 Å. The indenyl rings are not entirely planar, indicating that there are steric repulsions between the proximal methyl groups of the two $(\eta^5\text{-}C_9Me_7)$ ligands, although these distortions are smaller than in related zirconium compounds, consistent with the larger radius of the thorium ion.

The principal synthetic means employed to stabilize bis(cyclopentadienyl) actinide complexes against ligand redistribution has been to use substituted cyclopentadienyl ligands. The first reports of successfully stabilizing bis(cyclopentadienyl) complexes involved the use of peralkylated derivatives (C_5Me_5: Manriquez *et al.*, 1978; Fagan *et al.*, 1981a; C_5Me_4Et: Green and Watts, 1978). The pentamethylcyclopentadienyl ligand has come to be one of the most widely used ligands in organoactinide chemistry due to the thermal stability, solubility, and crystallinity of its compounds. Initial synthetic routes involved alkylation of the metal tetrahalides by Grignard [equation (25.46)] or tin [equation (25.47)] reagents:

$$AnCl_4 + 2(C_5Me_5)MgCl \cdot THF \longrightarrow (\eta^5\text{-}C_5Me_5)_2AnCl_2 + 2MgCl_2 \quad An = Th, U \qquad (25.46)$$

$$UCl_4 + 2(C_5Me_4Et)SnBu_3 \longrightarrow (\eta^5\text{-}C_5Me_4Et)_2UCl_2 + 2Bu_3SnCl \qquad (25.47)$$

The molecular structure of $(\eta^5\text{-}C_5Me_5)_2UCl_2$ has been determined (Spirlet *et al.*, 1992b; Fig. 25.12), as have those of $(\eta^5\text{-}C_5Me_5)_2ThX_2$ (X = Cl, Br, I) (Spirlet *et al.*, 1992b; Rabinovich *et al.*, 1997, 1998).

All exist as monomeric complexes with a pseudo-tetrahedral, 'bent metallocene' geometry. The complex $(\eta^5\text{-}C_5Me_5)_2NpCl_2$ was generated in a manner similar to that in equation (25.46) (Sonnenberger and Gaudiello, 1986); reaction of the tetrahalide with $Tl(C_5Me_5)$ had previously been reported to yield a THF

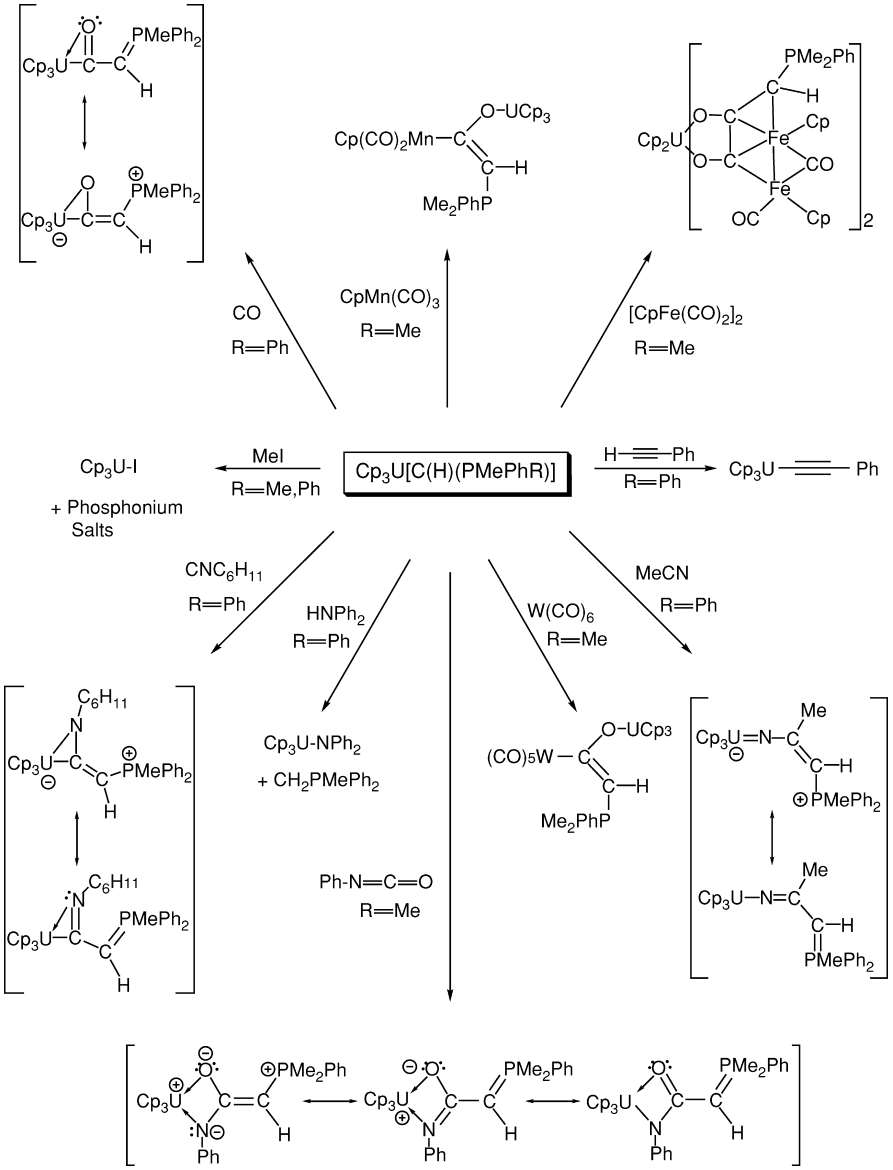

Fig. 25.11 *Reactions of* $(\eta^5\text{-}C_5H_5)_3U[(CH)P(CH_3)(C_6H_5)(R)]$, *where* $R = CH_3$, C_6H_5.

adduct (Karraker, 1983). The electrochemistry of $(\eta^5\text{-}C_5Me_5)_2NpCl_2$ reveals a reversible one-electron reduction wave at –0.68 V versus a ferrocene internal standard. A one-electron reversible reduction is also reported for $(\eta^5\text{-}C_5Me_5)_2UCl_2$ at –1.30 V (Finke *et al.*, 1982). Interestingly, the difference in

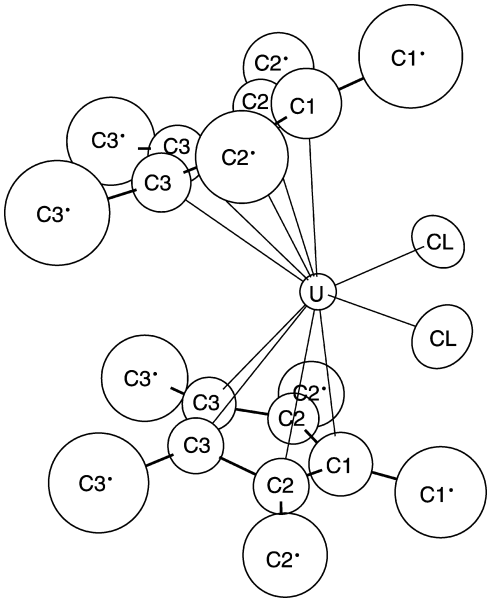

Fig. 25.12 *Crystal structure of* $(\eta^5\text{-}C_5Me_5)_2UCl_2$ (*Spirlet* et al., 1992b). (*Reprinted with permission of the International Union of Crystallography*.)

the U and Np non-aqueous reduction potentials is very close to the difference in their aqueous reduction potentials.

Other substituted cyclopentadienyl ligand sets have been generated and used to stabilize tetravalent metallocenes, particularly [1,3-$(Me_3Si)_2C_5H_3$] and [1,3-$(Me_3C)_2C_5H_3$]. The metal complexes have been prepared by reaction of the metal tetrahalides with either cyclopentadienyllithium reagents [equation (25.48)] (Blake *et al.*, 1995) or the substituted magnesocenes [equation (25.49)] (Lukens *et al.*, 1999a).

$$\mathrm{AnCl_4 + 2Li[1,3\text{-}(Me_3Si)_2C_5H_3] \longrightarrow [\eta^5\text{-}1,3\text{-}(Me_3Si)_2C_5H_3]_2AnCl_2 + 2LiCl} \quad \mathrm{An = Th,\ U} \tag{25.48}$$

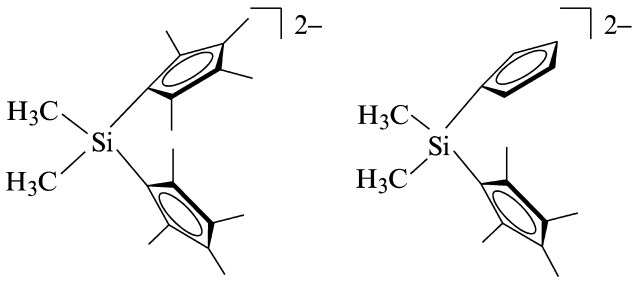
$$\mathrm{UCl_4 + (1,3\text{-}R_2C_5H_3)_2Mg \longrightarrow (\eta^5\text{-}1,3\text{-}R_2C_5H_3)_2UCl_2 + MgCl_2} \quad \mathrm{R = SiMe_3,\ CMe_3} \tag{25.49}$$

In the latter case, all metatheses were performed with the chloride salt, and the chloride product was subsequently converted to other halides by reaction with $XSiMe_3$ (X = Br, I) or $BF_3 \cdot Et_2O$. The molecular structures of the complexes $[\eta^5\text{-}1,3\text{-}R_2C_5H_3]_2UX_2$ ($R = SiMe_3$, X = F, Cl, Br; R = ^{t}Bu, X = F, Cl) have

been reported, as has the structure of $[\eta^5\text{-}1,3\text{-}(Me_3Si)_2C_5H_3]_2ThCl_2$. All exist as monomers in the solid state, except for $[\{\eta^5\text{-}1,3\text{-}(Me_3Si)_2C_5H_3\}_2UF(\mu\text{-}F)]_2$, which is a dimer (see Fig. 25.6). A detailed study of the solution behavior of the complexes has been conducted (Lukens *et al.*, 1999a). Both fluoride complexes are found to display a monomer–dimer equilibrium in solution. The ^1H NMR chemical shifts and magnetic susceptibility data for the complexes further suggest that the ligands $[1,3\text{-}(Me_3Si)_2C_5H_3]$ and $[1,3\text{-}(Me_3C)_2C_5H_3]$ produce significantly different electronic environments at the metal center.

Despite the kinetic stability that the sterically larger cyclopentadienyl ligands provide, in a limited number of cases base adducts have been generated. The complex $(\eta^5\text{-}C_5Me_5)_2UCl_2(pz)$ (pz = pyrazole) has been reported (Eigenbrot and Raymond, 1982), as has the chelating phopshine adduct $[\eta^5\text{-}1,3\text{-}(Me_3Si)_2C_5H_3]_2ThCl_2(dmpe)$ (Edelman *et al.*, 1995). The complex $(\eta^5\text{-}C_5Me_5)_2U(OTf)_2(H_2O)$ (OTf = trifluoromethylsulfonate) was isolated in low yield from the reaction of $(\eta^5\text{-}C_5Me_5)_2UMe_2$ with triflic acid (Berthet *et al.*, 1998). In compounds of the formula $(\eta^5\text{-}C_5Me_5)_2UX_2(L)$ (L = neutral ligand), the coordinated base generally occupies the central position in the equatorial wedge.

A second strategy for kinetically stabilizing actinide metallocenes against redistribution reactions is to employ the chelate effect by linking the two cyclopentadienyl rings (*ansa* metallocenes). The most common of these ligands are the *ansa* ligand sets.



The molecular structure of $[(\eta^5\text{-}C_5Me_4)_2(\mu\text{-}SiMe_2)]U(\mu\text{-}Cl)_4[Li(TMEDA)]_2$ (TMEDA = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine) is shown in Fig. 25.13.

As for most *ansa* metallocenes, the complex is characterized by a more acute centroid–metal–centroid angle (114.1°) than non-linked metallocenes (133–138°). This leaves more room in the equatorial wedge, accounting for the ability to accommodate four bridging chloride ligands. The more open coordination environment generated by 'tying' back the cyclopentadienyl ligands also enhances the reactivity of the resulting metal complex. The complex $[(\eta^5\text{-}C_5Me_4)_2(\mu\text{-}SiMe_2)]Th(n\text{-}Bu)_2$, generated by reaction of the structurally characterized precursor $[(\eta^5\text{-}C_5Me_4)_2(\mu\text{-}SiMe_2)]Th(\mu\text{-}Cl)_4[Li(DME)]_2$ with *n*-BuLi, was found to be a very active catalyst for the dimerization of terminal alkynes and the hydrosilylation of terminal alkynes or alkenes with $PhSiH_3$ (Dash *et al.*, 2001).

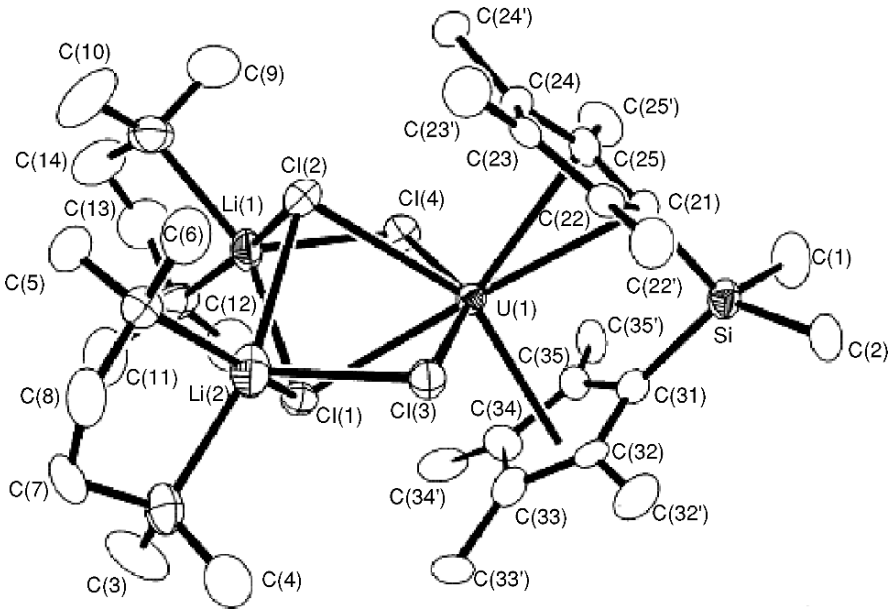


Fig. 25.13 *Crystal structure of* $[(\eta^5\text{-}C_5Me_4)_2(\mu\text{-}SiMe_2)]U(\mu\text{-}Cl)_4[Li(TMEDA)]_2$ (*Schnabel* et al., 1999). (*Reprinted with permission from Elsevier*.)

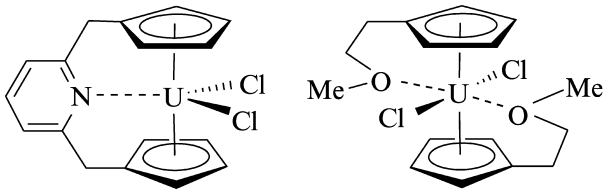
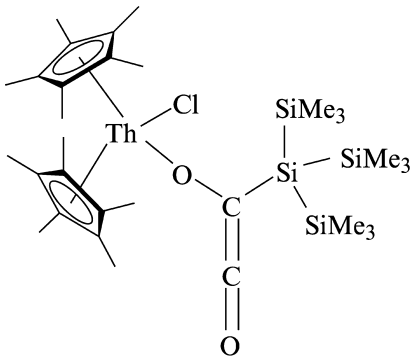
Other ligand sets have been explored that append Lewis base groups to the ring that will coordinate to the metal center to help prevent ring redistribution. A bis(cyclopentadienyl) substituted pyridine ligand has been used to generate the complex $[\eta^5\text{-}C_5H_4(CH_2)]_2(C_6H_5N)UCl_2$ (Paolucci *et al.*, 1991), and the pendant ether complex $[\eta^5\text{-}C_5H_4(CH_2CH_2OCH_3)]_2UCl_2$ has also been reported (Deng *et al.*, 1996):



Metathesis and protonation reactions have been employed to produce a wide array of derivatives of the metallocene unit. A limited number of complexes exist with bonds to Group 14 elements other than carbon. Reaction of $(\eta^5\text{-}C_5Me_5)_2ThCl_2$ with the bulkyl silyl salt $(THF)_3Li[Si(SiMe_3)_3]$ yields an unstable complex $(\eta^5\text{-}C_5Me_5)_2Th(Cl)[Si(SiMe_3)_3]$ that could be trapped by reaction with two equivalents of carbon monoxide to produce a ketene complex $(\eta^5\text{-}C_5Me_5)_2Th(Cl)[O\text{–}C(=C=O)Si(SiMe_3)_3]$.



The analogous silyl compound $(\eta^5\text{-}C_5Me_5)_2ThCl(Si^tBuPh_2)$ could be isolated and its reaction with CO gave a similar silylthoroxyketene compound, and in this case the transient η^2-acyl complex $(\eta^5\text{-}C_5Me_5)_2ThCl[\eta^5\text{-}CO(Si^tBuPh_2)]$ could be detected (Radu *et al.*, 1995).

Metathesis [equations (25.50), (25.52), and (25.53)] and protonation [equations (25.42) and (25.51)] reactions are the most widely used routes to generate metallocene amide complexes (Fagan *et al.*, 1981a,b; Eigenbrot and Raymond; 1982).

$$(\eta^5\text{-}C_5Me_5)_2AnCl_2 + 2\,LiNMe_2 \xrightarrow[-2\ LiCl]{} (\eta^5\text{-}C_5Me_5)_2U(NMe_2)_2 \quad (25.50)$$
$$An = Th, U$$

$$(\eta^5\text{-}C_5Me_5)_2AnR_2 + 2\ HNEt_2 \xrightarrow[-2\ RH]{} (\eta^5\text{-}C_5Me_5)_2U(NEt_2)_2 \quad (25.51)$$
$$An = Th, U$$

$$(\eta^5\text{-}C_5Me_5)_2UCl_2 + Na(pz) \longrightarrow (\eta^5\text{-}C_5Me_5)_2U(Cl)(pz) + NaCl \quad (25.52)$$
$$pz = pyrazolate$$

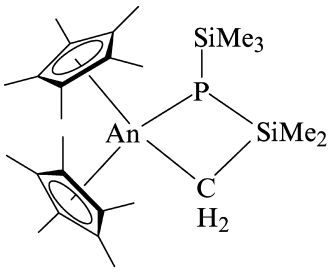
$$(\eta^5\text{-}C_5Me_5)_2UCl_2 + 2\ Na(pz) \longrightarrow (\eta^5\text{-}C_5Me_5)_2U(pz)_2 + 2\ NaCl \quad (25.53)$$
$$pz = pyrazolate$$

Metallocene phosphide complexes have been generated by metathesis routes [equations (25.54) and (25.55)] (Wrobleski *et al.*, 1986a; Hall *et al.*, 1993).

$$(\eta^5\text{-}C_5Me_5)_2ThCl_2 + 2\ LiPR_2 \longrightarrow (\eta^5\text{-}C_5Me_5)_2Th(PR_2)_2 + 2\ LiCl \quad (25.54)$$
$$R = Ph, Cy, Et$$

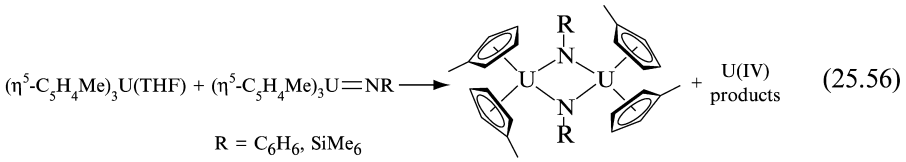
$$(\eta^5\text{-}C_5Me_5)_2An(X)(Cl) + KP(SiMe_3)_2 \longrightarrow (\eta_5\text{-}C_5Me_5)_2An(X)[P(SiMe_3)_2] + KCl \quad (25.55)$$
$$An = Th, U;\ X = Cl, Me$$

For the bis(trimethylsilyl)phosphide substituent, a bis(phosphido) complex cannot be produced. Solution ^{1}H NMR spectra indicate that there is restricted rotation about the An–P bond at room temperature. The complexes $(\eta^5\text{-}C_5Me_5)_2AnMe[P(SiMe_3)_2]$ decompose thermally by elimination of methane to generate a metallacyclic complex:



An = Th, U

The metallocene framework has also been integral to the isolation of organoimido and phosphinidene complexes. Comproportionation of U(III) and U(V) metallocenes results in the formation of uranium(IV) organoimido complexes [equation (25.56)] (Brennan *et al.*, 1988b).

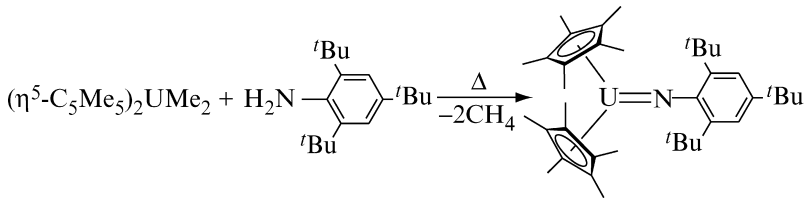


(25.56)

The molecular structure of $[(\eta^5\text{-}MeC_5H_4)_2U(\mu\text{-}NPh)]_2$ is shown in Fig. 25.14.

The complexes exist as centrosymmetric dimers with asymmetric bridging organoimido ligands; the degree of asymmetry in the U–N bonds depends on the identity of the imido substituent.

It is only recently that terminal organoimido complexes of U(IV) have been isolated (Arney and Burns, 1995). α-Elimination reactions have been employed to generate the monoimido complex $(\eta^5\text{-}C_5Me_5)_2U(=N\text{-}2,4,6\text{-}{}^tBu_3C_6H_2)$ [equation (25.57)].



(25.57)

The complex is isolated even from ethereal solvents as a base-free species. The complex displays a very short U–N bond distance [1.95(1) Å], and a large

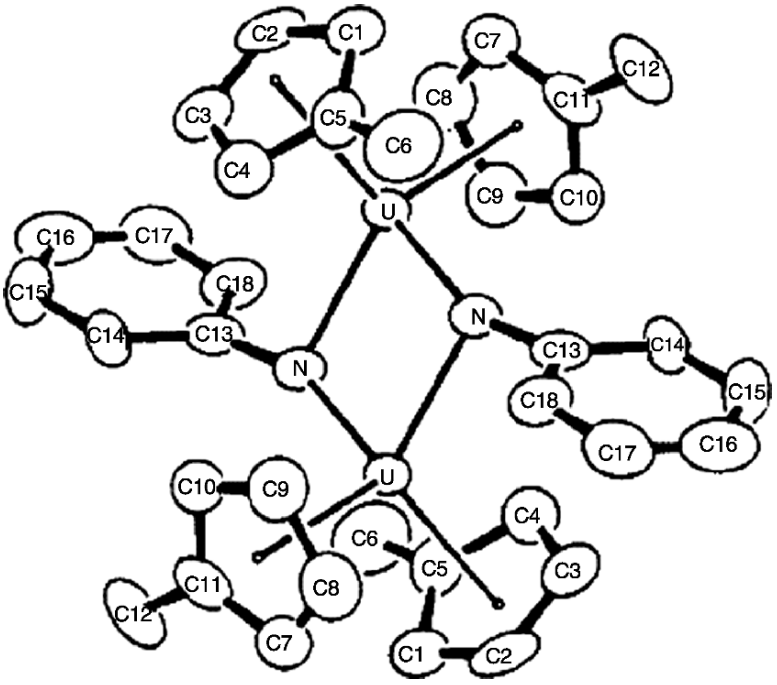


Fig. 25.14 *Crystal structure of* $[(\eta^5\text{-}MeC_5H_4)_2U(\mu\text{-}NPh)]_2$. (*Reprinted with permission from Brennan* et al. (1988b). *Copyright* 1988 *American Chemical Society.*)

U–N–C angle [162.3(10)°]. Unlike the phosphoylide and phosphine imide complexes described previously, the organoimido complex is relatively inert; it does not undergo insertion reactions, suggestive of a bond order greater than 1. The steric bulk of the aryl group is important in stabilizing a base-free organoimido complex; the smaller $(\eta^5\text{-}C_5Me_5)_2U(=N\text{-}2,6\text{-}{}^iPr_2C_6H_3)$ is best isolated as the THF adduct, and the parent phenylimido has only been isolated as a uranate salt, $[Li(TMEDA)][(\eta^5\text{-}C_5Me_5)_2U(=NC_6H_5)Cl]$. Organoimido complexes of U(IV) and Th(IV) have been implicated as intermediates in the catalytic intermolecular hydroamination of terminal alkynes (Straub *et al.*, 1996, 2001). It has been proposed that monoimido derivatives of the formula $(\eta^5\text{-}C_5Me_5)_2An(=NR')$ are formed in the reaction of $(\eta^5\text{-}C_5Me_5)_2AnMe_2$ with primary amines $R'NH_2$. These undergo metathesis reaction with alkynes to yield four-membered azametallacyclic intermediates, which can undergo subsequent amine protonation (with isomerization) to yield the product imines. The mechanism of this reaction is discussed further in Chapter 26. Although the organoimido intermediates involving aliphatic amines have not been isolated, analogs such as $(\eta^5\text{-}C_5Me_5)_2Th(=N\text{-}2,6\text{-}Me_2C_6H_3)(THF)$ have been structurally

characterized (Haskel *et al.*, 1996; Straub *et al.*, 2001). As in the case of the uranium organoimido complex, the thorium complex displays a short Th–N bond [2.045(8) Å] and a near-linear Th–N–C_{ipso} angle (171.5(7)°).

Similarly, bridging actinide phosphinidene complexes predated their terminal counterparts. The hydride complex $[(\eta^5\text{-}C_5Me_5)_2UH_2]_2$ reacts with $P(OMe)_3$ to generate a bridging phosphinide complex $[(\eta^5\text{-}C_5Me_5)_2U(OMe)]_2(\mu\text{-}PH)$ by P–O cleavage with sacrificial formation of $(\eta^5\text{-}C_5Me_5)_2U(OMe)_2$ [equation (25.58)] (Duttera *et al.*, 1984).

$$[(\eta^5\text{-}C_5Me_5)_2UH_2]_2 + P(OMe)_3 \longrightarrow (\eta^5\text{-}C_5Me_5)_2U(MeO)\text{–}P(H)\text{–}U(OMe)(\eta^5\text{-}C_5Me_5)_2 + (\eta^5\text{-}C_5Me_5)_2U(OMe)_2 \quad (25.58)$$

A terminal phosphinidene complex has also been reported (Arney *et al.*, 1996). Reaction of $(\eta^5\text{-}C_5Me_5)_2U(Me)Cl$ with $KPH(2,4,6\text{-}{}^tBu_3C_6H_2)$ in the presence of trimethylphosphine oxide yields the base adduct of the phosphinidene complex $(\eta^5\text{-}C_5Me_5)_2U(=P\text{-}2,4,6\text{-}{}^tBu_3C_6H_2)(OPMe_3)$ (Fig. 25.15).

The complex displays a short U–P distance [2.562(3) Å]. The U–P–C angle 143.7(3)°; the nonlinear angle is not unusual in comparison to d-transition metal terminal phosphinidene complexes. No product is isolated in the absence of coordinating base, except for when the ancillary ligand set is $[(\eta^5\text{-}C_5Me_4)_2(\mu\text{-}SiMe_2)]$. In the case of the less congested *ansa*-metallocene; a phosphinidene-bridged dimer $[\{(\eta^5\text{-}C_5Me_4)_2(\mu\text{-}SiMe_2)\}U(\mu\text{-}PR)]_2$ (R = 2,4,6-${}^tBu_3C_6H_2$) is generated.

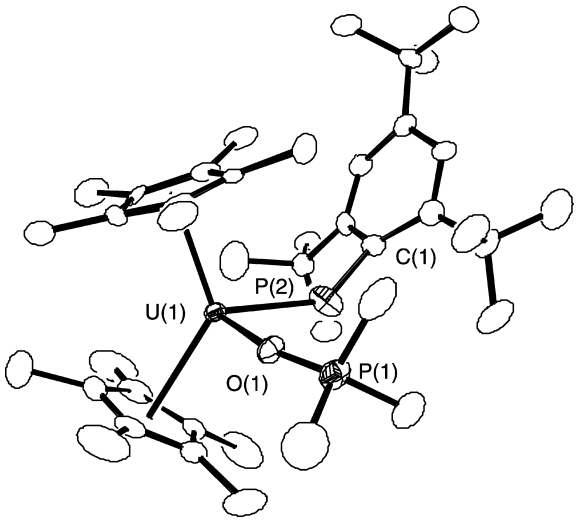

Fig. 25.15 *Crystal structure of* $(\eta^5\text{-}C_5Me_5)_2U(=P\text{-}2,4,6\text{-}t\text{-}Bu_3C_6H_2)(OPMe_3)$. (*Reprinted with permission from Arney* et al. (1996). *Copyright* 1996 *American Chemical Society*.)

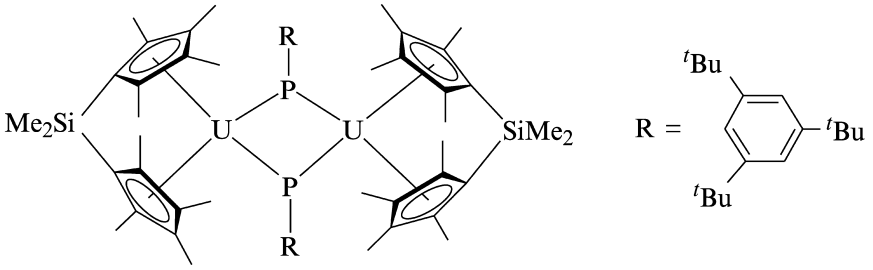
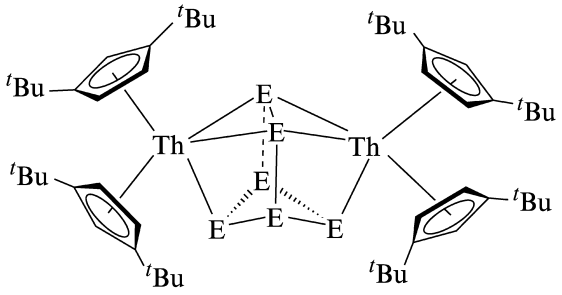
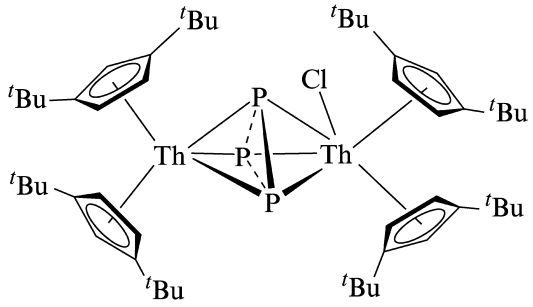


An interesting series of polypnictide complexes have been generated by the reaction of $(\eta^5\text{-}1,3\text{-}^t\text{Bu}_2\text{C}_5\text{H}_3)_2\text{Th}(\eta^4\text{-}\text{C}_4\text{H}_6)$ with P_4 or As_4. The main group elements react to generate a hexapnictide complex: $[(\eta^5\text{-}1,3\text{-}^t\text{Bu}_2\text{C}_5\text{H}_3)_2\text{Th}]_2(\mu,\eta^3,\eta^3\text{-}\text{E}_6)$ (E = P, As) (Scherer *et al.*, 1991, 1994).



E = P, As

In the presence of magnesium chloride, however, only the complex: $[(\eta^5\text{-}1,3\text{-}^t\text{Bu}_2\text{C}_5\text{H}_3)_2\text{Th}](\mu,\eta^3\text{-}\text{P}_3)[\text{Th}(\text{Cl})(\eta^5\text{-}1,3\text{-}^t\text{Bu}_2\text{C}_5\text{H}_3)_2]$ is formed in the reaction with phosphorus.

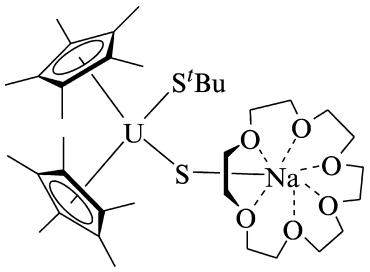


One of the earliest descriptions of metallocene thiolate complexes involved reactions of $(\eta^5\text{-}\text{C}_5\text{H}_5)_2\text{U}(\text{NEt}_2)_2$ with monothiols and dithiols (Jamerson and Takats, 1974). While compounds with the chelating thiols are stable (generally dimers), compounds of monodentate thiols $(\eta^5\text{-}\text{C}_5\text{H}_5)_2\text{U}(\text{SR})_2$ were reported to

be unstable and decomposed to form $(\eta^5\text{-}C_5H_5)_2U(SR)$. Two other reports of bis (pentamethylcyclopentadienyl) metallocene dithiolates have been appeared: $(\eta^5\text{-}C_5Me_5)_2Th(SPr)_2$ (Lin *et al.*, 1988) and $(\eta^5\text{-}C_5Me_5)_2U(SR)_2$ (R = Me, ^{i}Pr, ^{t}Bu, Ph) (Lescop *et al.*, 1999).

Two reports have appeared featuring cyclopentadienyl-supported actinide chalcogenide complexes. Reaction of $(\eta^5\text{-}C_5Me_5)_2ThCl_2$ with Li_2S_5 generates the compound $(\eta^5\text{-}C_5Me_5)_2Th(S_5)$ (Wrobleski *et al.*, 1986b); the molecular structure of this complex shows that the six-membered ring formed by the S_5 ligand and the Th has a twist-boat conformation. Bonding of the ligand was characterized as η^4 on the basis of close contacts between the β-sulfides and the metal center. Variable temperature NMR data show that the ligand is fluxional at room temperature.

The complex $(\eta^5\text{-}C_5Me_5)_2U(S^tBu)_2$ is reported to undergo reduction by Na–Hg with cleavage of a C–S bond (Ventelon *et al.*, 1999). The product was isolated with 18-crown-6 and proved to be a complex with a terminal sulfido ligand bound to the sodium counter-ion. The complex [Na(18-crown-6)][$(\eta^5\text{-}C_5Me_5)_2U(S^tBu)(S)$] possesses a short U–S bond distance [2.462(2) Å], which is significantly shorter than typical U–SR bond distances (*ca.* 2.64 Å).



Given the relative importance of d-transition metal metallocene alkyl chemistry in Group 4 organometallic chemistry, it is to be expected that the alkyl chemistry of the actinide metallocene complexes would also be extensively studied. The majority of this chemistry has employed the more highly substituted ligand sets, although less sterically hindered metallocene frameworks can be alkylated in the presence of a stabilizing base as shown in equation (25.59) (Zalkin *et al.*, 1987a):

$$(\eta^5\text{-}C_5H_5)_2ThCl_2(dmpe) + 2LiR \longrightarrow (\eta^5\text{-}C_5H_5)_2ThR_2(dmpe) + 2LiCl \quad R = CH_3,\ CH_2Ph \tag{25.59}$$

Complexes employing the pentamethylcyclopentadienyl ligand can be prepared for a wide range of alkyl and aryl groups (Fagan *et al.*, 1981a; Erker *et al.*, 1986; Smith *et al.*, 1986), where the alkylating agents can be either alkyllithium, Grignard, or dialkylmagnesium reagents [equation (25.60)].

$$(\eta^5\text{-}C_5Me_5)_2AnCl_2 + 2R^- \longrightarrow (\eta^5\text{-}C_5Me_5)_2AnR_2 + 2Cl^-$$
$$An = Th,\ U;\ R = CH_3,\ CH_2SiMe_3,\ CH_2CMe_3,\ C_6H_5,\ CH_2C_6H_5 \qquad (25.60)$$

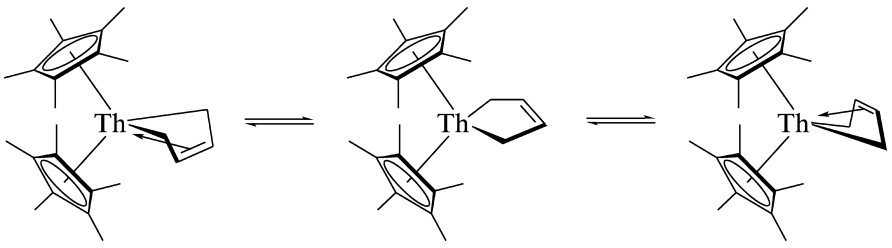
The corresponding mixed alkyl halide complexes can be prepared in most cases by reaction of $(\eta^5\text{-}C_5Me_5)_2AnCl_2$ with one equivalent of alkylating agent, although the methyl chloride complex is best prepared by redistribution from the dichloride and dimethyl complexes [equation (25.61)].

$$(\eta^5\text{-}C_5Me_5)_2AnCl_2 + (\eta^5\text{-}C_5Me_5)_2AnMe_2 \longrightarrow 2(\eta^5\text{-}C_5Me_5)_2An(Me)(Cl)$$
$$An = Th,\ U \qquad (25.61)$$

The complexes are generally thermally stable, although some undergo elimination reactions at elevated temperatures (*vide infra*). The dimethyl complexes react with acetone, alcohols, and iodine to produce the corresponding *t*-butoxide, alkoxides (with generation of methane), and iodides (with generation of methyl iodide) (Fagan *et al.*, 1981a). Competition experiments at –78°C indicate that the thorium complexes are more reactive than those of uranium, consistent with its larger ionic radius.

Two alternate descriptions have appeared for the complex $(\eta^5\text{-}C_5Me_5)_2Th(\eta^4\text{-}C_4H_6)$. The complex and its derivatives have been termed both butadiene and 2-buten-1,4-diyl complexes, although the latter description is generally favored. The molecular structure of $(\eta^5\text{-}C_5Me_5)_2Th(\eta^4\text{-}C_4H_6)$ is shown in Fig. 25.16.

The crystal structure supports the η^4-hapticity of the organic ligand, given that the average Th–C distance to the terminal carbon atoms of the ligand [2.57(3) Å] is only slightly smaller than that to the internal carbon atoms [2.74(2) Å], and are comparable to those found in other thorium alkyl complexes. The C(1)–C(2) and C(3)–C(4) average distances (average of four independent molecules in the unit cell) is 1.46(5) Å, and the average C(2)–C(3) distance is 1.44(3) Å. The complex displays fluxional behavior in solution, with equilibration of the cyclopentadienyl and α-methylene protons occurring via the intermediacy of a planar metallacyclopentene structure.



The actinide–carbon bonds in these complexes appear to be reasonably polar; they undergo hydrogenolysis under one atmosphere of dihydrogen to yield the dihydride complexes [equation (25.62)]:

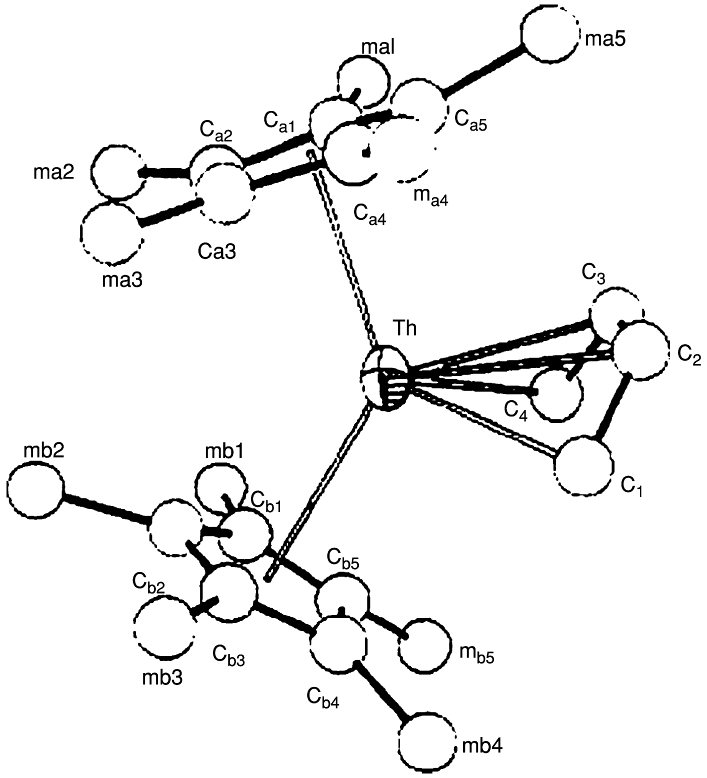


Fig. 25.16 *Crystal structure of* $(\eta^5\text{-}C_5Me_5)_2Th(\eta^4\text{-}C_4H_6)$. (*Reprinted with permission from Smith* et al. (1986). *Copyright* 1986 *American Chemical Society.*)

$$(\eta^5\text{-}C_5Me_5)_2AnR_2 + 2H_2 \longrightarrow \tfrac{1}{2}(\eta^5\text{-}C_5Me_5)_2An(H)(\mu\text{-}H)_2An(H)(\eta^5\text{-}C_5Me_5)_2 + 2RH \qquad (25.62)$$

An = Th, U

The dimeric formulation of the dihydride complexes is supported both by cryoscopic molecular weight determinations and a single-crystal neutron diffraction structure of the thorium compound (Broach *et al.*, 1979); ^{1}H NMR experiments indicate that the bridge and terminal hydrides exchange rapidly in solution to –85°C. Under an atmosphere of D_2, H/D exchange in the hydride positions is very rapid. In the case of uranium, the ring methyl protons appear to interchange rapidly with the hydrides, resulting in isotopic scrambling. The thorium complex is thermally stable; in contrast, the uranium complex loses dihydrogen at room temperature *in vacuo* over a period of 3 h to generate a U(III) hydride.

Dialkyl complexes of an *ansa*-metallocene [$(\eta^5\text{-}C_5Me_4)_2(\mu\text{-}SiMe_2)$]$ThR_2$ (R = CH_2SiMe_3, CH_2CMe_3, C_6H_5, *n*-C_4H_9, and $CH_2C_6H_5$) have also been reported (Fendrick *et al.*, 1988). The ring centroid-metal-centroid angle (118.4°) is again much reduced from that typically found in non-linked metallocene complexes (135–138°). The dialkyl complexes undergo rapid hydrogenolysis under H_2 to yield a light-sensitive dihydride complex [$\{(\eta^5\text{-}C_5Me_4)_2(\mu\text{-}SiMe_2)\}ThH_2]_2$. IR spectroscopy and structural data [a short Th···Th distance of 3.632(2) Å] are evidence cited in support of a formulation of the compound as one with four bridging hydride ligands.

Thermochemical investigations have tabulated the bond disruption enthalpies for a number of metallocene alkyl halide and dialkyl complexes; these values are given in Table 25.6 (Bruno *et al.*, 1983, 1986b). As noted previously, the Th–R bond enthalpies are uniformly larger than those for U–R. It has also been noted (Leal *et al.*, 2001) that there appears to be significantly different values for certain bond enthalpy values (e.g. U–Me in Tables 25.4 and 25.6). The authors note that these values are based upon different reactions (alcholysis vs reaction with iodine), and therefore are based upon different assumed enthalpy values for product species. A potential correction was proposed, leading to a more self-consistent description of uranium bond enthalpies.

A further observation from the thermochemistry of thorium complexes is that the bond dissociation enthalpy for Th–H in [$(\eta^5\text{-}C_5Me_5)_2Th(\mu\text{-}H)H]_2$ (407.9 ± 2.9 kJ/mol), while somewhat larger than typical Th–C values (300–380 kJ mol^{-1}), is not larger enough to produce as strong a driving force for the

Table 25.6 *Mean bond dissociation enthalpies for* $(\eta^5\text{-}C_5Me_5)_2AnR_2$ *and* $(\eta^5\text{-}C_5Me_5)_2AnRX$ *complexes* (*Bruno et al.,* 1983, 1986*b*).

Compound	*R*	*D*(*An–R*) (kJ mol^{-1})

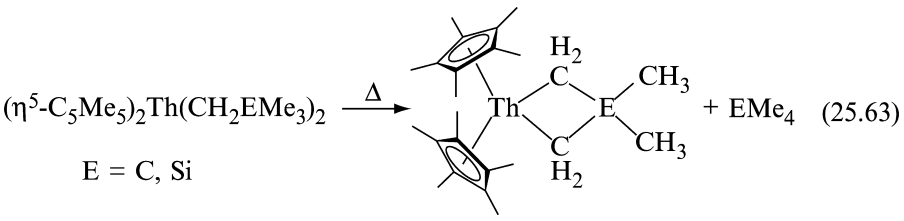
	Ph	380.8 ± 16

formation of hydrides. Therefore, unlike mid- to late-transition metal compounds, reactions such as β-hydride elimination will not be strongly favored. This energetic situation, similar to that found for early transition metals, makes actinide metallocenes suitable species to effect C–C bond forming reactions, such as olefin polymerization (see Chapter 26).

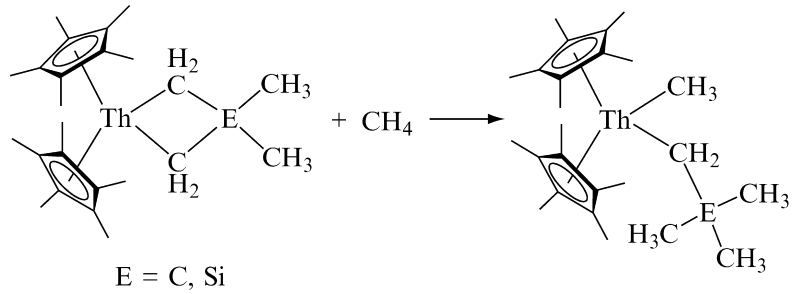
One of the predominant reaction patterns of bis(cyclopentadienyl)actinide complexes is insertion chemistry. Insertion of unsaturated substrates such as CO, CNR, CO_2, and CS_2 into U–C, U–Si, U–N, and U–S bonds has been observed (Fagan *et al.*, 1981a,b; Erker *et al.*, 1986; Porchia *et al.*, 1989; Lescop *et al.*, 1999). The products of insertion generally display η^2-C(R) =E bonding. As an example, insertion of CO into An–R bonds yields η^2-acyl derivatives. Theoretical studies (Tatsumi *et al.*, 1985) have been conducted, both to explain the geometry of the η^2-complexes, as well as to understand the origin of the 'carbene-like' reactivity (Fig. 25.17).

A second common reaction pattern observed in metallocene complexes is thermally induced intramolecular elimination reactions. The dominant classes of elimination reactions are those involving formation of four-membered metallacyle complexes [equation (25.63)] (Bruno *et al.*, 1986a).



(25.63)

Kinetic and labeling studies in the cyclometallation reactions indicate that intramolecular γ-C–H activation is the rate-limiting step. It is believed that the reaction is chiefly entropically driven, with some driving force coming from relief of steric strain associated with the thorium dialkyl complex. The cyclometallated products have extensive reaction chemistry that is characterized by insertion of unsaturated substrates into Th–C bonds, as well as intermolecular activation of C–H bonds of other substrates, even saturated hydrocarbons such as methane [equation (25.64)] (Fendrick and Marks, 1986).



(25.64)

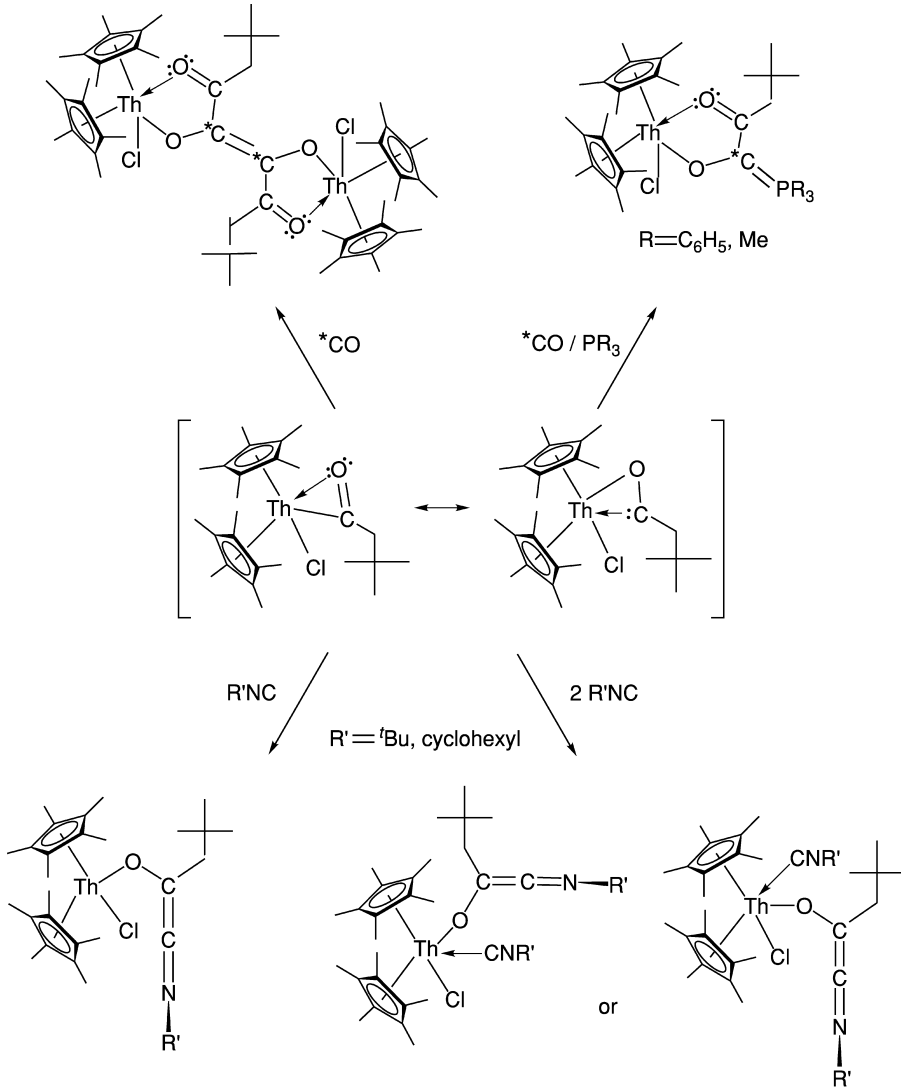


Fig. 25.17 *Reactivity of actinide η^2-Acyl complexes* (*Moloy* et al., 1983).

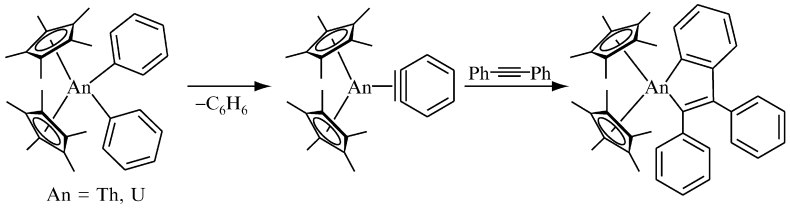
A second class of reactions is the elimination of benzene from diaryl complexes to form *o*-diphenylene, or benzyne-type complexes [equation (25.65)] (Fagan *et al.*, 1981a).



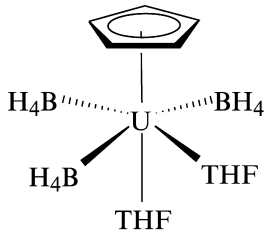
(25.65)

The uranium complexes undergo this *ortho*-activation process ($k_U \gg k_{Th}$); although the intermediate benzyne complex is not stable, it can be trapped with diphenylacetylene to yield a metallacyclopentadiene product.

Despite the early report of mono-ring complexes of the formula (η^5-C_5H_5)UCl_3(DME) (DME = 1,2-dimethoxyethane) (Doretti *et al.*, 1972), there are far fewer reports of compounds containing a single cyclopentadienyl ring. The complex was initially prepared by reaction of UCl_4 with $Tl(C_5H_5)$ in DME [equation (25.66)].

$$UCl_4 + Tl(C_5H_5) \xrightarrow{DME} (\eta^5\text{-}C_5H_5)UCl_3(DME) \qquad (25.66)$$

Since that time, a number of other base adducts of the uranium mono-ring compound have been prepared using both monodentate (Bagnall and Edwards, 1974; Bagnall *et al.*, 1978a; Bombieri *et al.*, 1978) and bidentate bases (Ernst *et al.*, 1979). The complex $U(BH_4)_4$ similarly reacts with $Tl(C_5H_5)$ to yield (η^5-C_5H_5)$U(BH_4)_3$ (Baudry and Ephritikhine, 1988), although base adducts of this compound are reported to redistribute to generate (η^5-C_5H_5)$_2U(BH_4)_2$ (Baudry *et al.*, 1988). The structure of the (η^5-C_5H_5)$U(BH_4)_3(THF)_2$ complex has been proposed to be *mer*-octahedral with *cis* THF ligands on the basis of solution NMR investigations with a pentahapto cyclopentadienyl ring; this structure was confirmed for the complex (η^5-MeC_5H_4)$UCl_3(THF)_2$.



A later NMR study (Le Marechal *et al.*, 1986) reported an equilibrium between two isomers in solution for a variety of base adducts of (η^5-C_5H_5)UCl_3. Analogous compounds of the formula (η^5-C_5H_5)AnX_3L_2 (X = halide, NCS^-) have been produced for thorium (Bagnall and Edwards, 1974), neptunium (Karraker and Stone, 1972; Bagnall *et al.*, 1986), and plutonium (Bagnall *et al.*, 1985).

A variety of substituted cyclopentadienyl ligands have been introduced to generate cyclopentadienylthorium and cyclopentadienyluranium compounds by reaction with Grignard or alkali metal reagents. Indenyl complexes of the formula $(\eta^5\text{-}C_9H_7)AnX_3L$ (X = halide, L = base) can be prepared as shown in equations (25.67) and (25.68) (Goffart *et al.*, 1980; Meunier-Piret *et al.*, 1980).

$$AnX_4 + K(C_9H_7) \xrightarrow{THF} (\eta^5\text{-}C_9H_7)AnX_3(THF)_2 + KX \qquad (25.67)$$

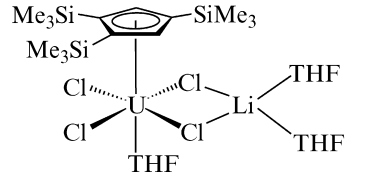
An = Th, U, Np; X = Cl, Br

$$(\eta^5\text{-}C_9H_7)AnX_3(THF)_2 + Ph_3P{=}O \longrightarrow (\eta^5\text{-}C_9H_7)AnX_3(THF)(O{=}PPh_3) + THF \qquad (25.68)$$

An = Th, U, Np; X = Cl, Br

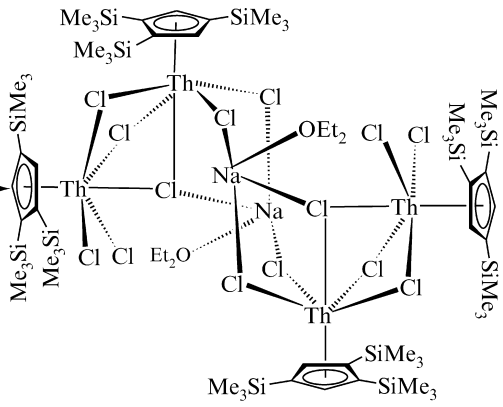
The use of alkali metal cyclopentadienyl reagents can lead to the formation of uranate-type complexes [equations (25.69) and (25.70)] (Edelman *et al.*, 1987, 1995):

$$UCl_4 + Li[1,2,4\text{-}(Me_3Si)_3C_5H_2] \xrightarrow{THF}$$



(25.69)

$$ThCl_4 + Na[1,2,4\text{-}(Me_3Si)_3C_5H_2] \xrightarrow{Et_2O}$$



(25.70)

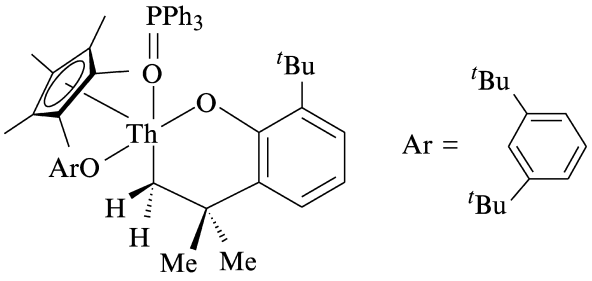
Mono-ring pentamethylcyclopentadienyl thorium and pentamethylcyclopentadienyl uranium complexes can also be synthesized from reaction of the tetrahalides with $(C_5Me_5)MgCl$ (Mintz *et al.*, 1982; Butcher *et al.*, 1996), and their base adducts prepared. Spectroscopic data would again indicate a meridional disposition of the chloride ligands in a pseudo-octahedral geometry. As described in equation (25.71), these complexes can be alkylated with either organolithium or Grignard reagents to yield a limited number of stable alkyl derivatives (Mintz *et al.*, 1982; Cymbaluk *et al.*, 1983a; Marks and Day, 1985; Marks, 1986).

$$(\eta^5\text{-}C_5Me_5)AnX_3(THF)_2 + RLi \text{ or } RMgX \longrightarrow (\eta^5\text{-}C_5Me_5)AnR_3$$

An = Th; R = allyl, $CH_2C_6H_5$, CH_2CMe_3, *o*-$C_6H_4NMe_2$ (25.71)

An = U; R = allyl, 2-methylallyl, $CH_2C_6H_5$

One study has been conducted of the metathesis chemistry of $(\eta^5\text{-}C_5Me_5)ThBr_3(THF)_3$ with aryloxide salts (Butcher *et al.*, 1996). Both the mono(aryloxide) and bis(aryloxide) complexes $(\eta^5\text{-}C_5Me_5)ThBr_2(OAr)(THF)$ and $(\eta^5\text{-}C_5Me_5)ThBr(OAr)_2$ (OAr = O-2,6-^{t}Bu$_2$C$_6$H$_3$) may be produced by reaction with one or two equivalents of KOAr. The dibromide complex may be further alkylated to generate $(\eta^5\text{-}C_5Me_5)Th(CH_2SiMe_3)_2(OAr)$. Thermolysis of this compound in the presence of triphenylphosphine oxide permits the isolation of a rare example of an f-element compound with a cyclometallated aryloxide ligand.



(c) Pentavalent chemistry

Pentavalent complexes of the actinides containing organic ligands are rare. They are anticipated to be limited to uranium, given the increasing stability of lower oxidation states for the later actinides. Most pentavalent organouranium complexes are supported by multiply bonded functional groups, such as those present in the complexes $(\eta^5\text{-}C_5H_4Me)_3U{=}NR$ previously described [see equation (25.22)]. The complex $[\eta^5\text{-}1,3\text{-}(Me_3Si)_2C_5H_3]_2UCl(THF)$ has been reported to react with Me_3SiN_3 to liberate N_2 and generate the U(v) organoimido complex $[\eta^5\text{-}1,3\text{-}(Me_3Si)_2C_5H_3]_2U(=NSiMe_3)(Cl)$ (Blake *et al.*, 1987). Oxo transfer has also been effected to a U(III) precursor; the complex $(\eta^5\text{-}C_5Me_5)U(OAr)(THF)$ (Ar = 2,6-^{i}Pr$_2$C$_6$H$_3$) reacts with pyridine *N*-oxide to yield the oxo derivative $(\eta\text{-}C_5Me_5)U(=O)(OAr)$ (Arney and Burns, 1993). The molecular structure of this complex has been determined. The complex exists as a typical pseudo-tetrahedral metallocene complex, with a U–O (oxo) bond length of 1.859(6) Å, slightly longer than that common for a mutliply-bonded oxo group in the uranyl ion (UO_2^{2+}).

Attempts to prepare U(VI) dioxo complexes supported by cyclopentadienyl groups has recently generated another rare example of a pentavalent oxo complex. Reaction of $(\eta^5\text{-}^t Bu_3C_5H_2)_2UCl_2$ with KC_8, followed by oxidation with pyridine N-oxide, results in the formation of the complex $(\eta^5\text{-}^t Bu_3C_5H_2)_4U_6O_{13}(bipy)_2$ (Duval *et al.*, 2001) (Fig. 25.18).

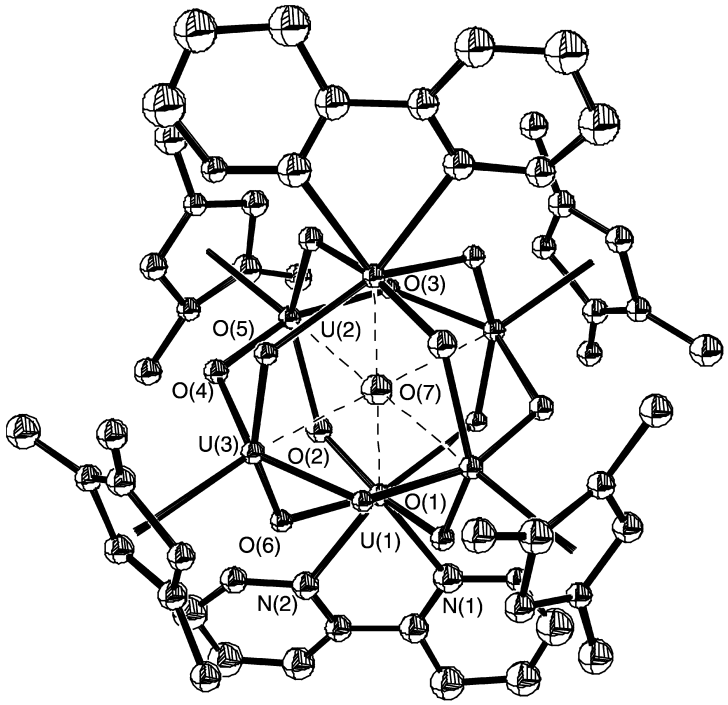


Fig. 25.18 *Crystal structure of* $(\eta^5\text{-}^t Bu_3C_5H_2)_4U_6O_{13}(bipy)_2$ (*methyl carbons of* tert-*butyl groups are omitted for clarity*) (*Duval* et al., 2001). (*Reprinted with permission from John Wiley & Sons, Inc.*)

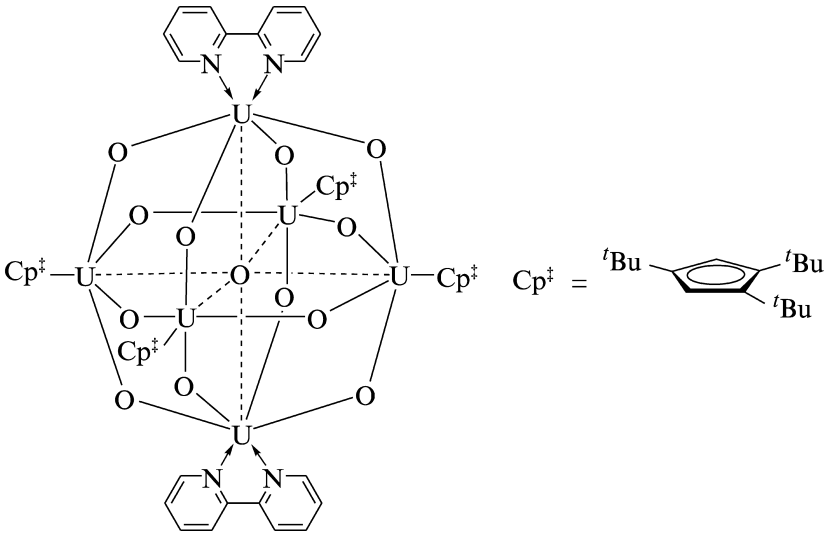

The core of the complex is a U_6O_{13} aggregate. Four uranium atoms in an equatorial plane are capped with a tri-*tert*-butylcyclopentadienyl ligand, while the two apical uranium atoms are ligated by 2,2′-bipyridine ligands, apparently derived from the by-product pyridine. The proposed mechanism for the formation of the aggregate is the generation and assembly of 'UO_2' and '$(\eta^5\text{-}^t Bu_3C_5H_2)_2UO_2$' fragments from homolytic ring loss. Although the central metal oxo unit is structurally similar to the Lindqvist class of polyoxometallate anions, there is no indication of electronic delocalization in the complex. Magnetic susceptibility measurements suggest that the uranium centers behave as independent U(v) f^1 paramagnets.

Another approach to U(v) organometallic complexes has recently been reported. Oxidation of neutral precursors $(\eta^5\text{-}C_5Me_5)U(NMe_2)_3(THF)$ and $(\eta^5\text{-}C_5Me_5)_2U(NEt_2)_2$ with $AgBPh_4$ gives rise to the corresponding cationic derivatives $[(\eta^5\text{-}C_5Me_5)U(NMe_2)_3(THF)][BPh_4]$ and $[(\eta^5\text{-}C_5Me_5)_2U(NEt_2)_2][BPh_4]$ (Boisson *et al.*, 1995). The electronic structure of these complexes was subsequently examined by EPR in frozen solution (Gourier *et al.*, 1997). It was shown that the interaction of the metal 5f orbitals with the cyclopentadienyl and amido ligands are sufficiently small and that the $J = 5/2$ ground state quantum number for U(v) remains a good quantum number for the complexes; the 5f orbitals are essentially nonbonding, and any covalent bonding interaction must therefore involve metal 6d orbitals.

(d) Hexavalent chemistry

Historically, there have been extremely few examples of non-aqueous compounds of hexavalent actinides, despite the prevalence of the actinyl ion (AnO_2^{2+}) for the elements U to Am. Attempts to prepare alkyl- or cyclopentadienyl compounds of the actinyl ions were met with reduction of the metal center (Seyam, 1982). In the last 10 years, a class of formally hexavalent cyclopentadienyluranium complexes has been prepared that is alternatively stabilized by the presence of organoimido substituents. The complex $(\eta^5\text{-}C_5Me_5)_2U(=NC_6H_5)_2$ was first prepared by the oxidation of $[Li(TMEDA)][(\eta^5\text{-}C_5Me_5)_2U(=NC_6H_5)Cl]$ with phenyl azide (Arney *et al.*, 1992; Arney and Burns, 1995), although other routes have since been devised (Fig. 25.19). The structure of the complex is shown in Fig. 25.20.

The complex has a pseudo-tetrahedral bent metallocene geometry, with a N–U–N angle of 98.7(4)°. This bent E=U=E moiety is quite different from the linear O=U=O angle found in the uranyl ion, and may be attributed to the strong donor character of the pentamethylcyclopentadienyl groups. The short uranium–nitrogen distances [1.952(7) Å], and the near-linear U–N–C bond angle [177.8(6)°] are consistent with the formulation of the ligands as organoimido groups. The organoimido ligands are remarkably unreactive in comparison with their Group 4 d-transition metal counterparts (Walsh *et al.*, 1988, 1992, 1993; Baranger *et al.*, 1993), showing no reaction with unsaturated

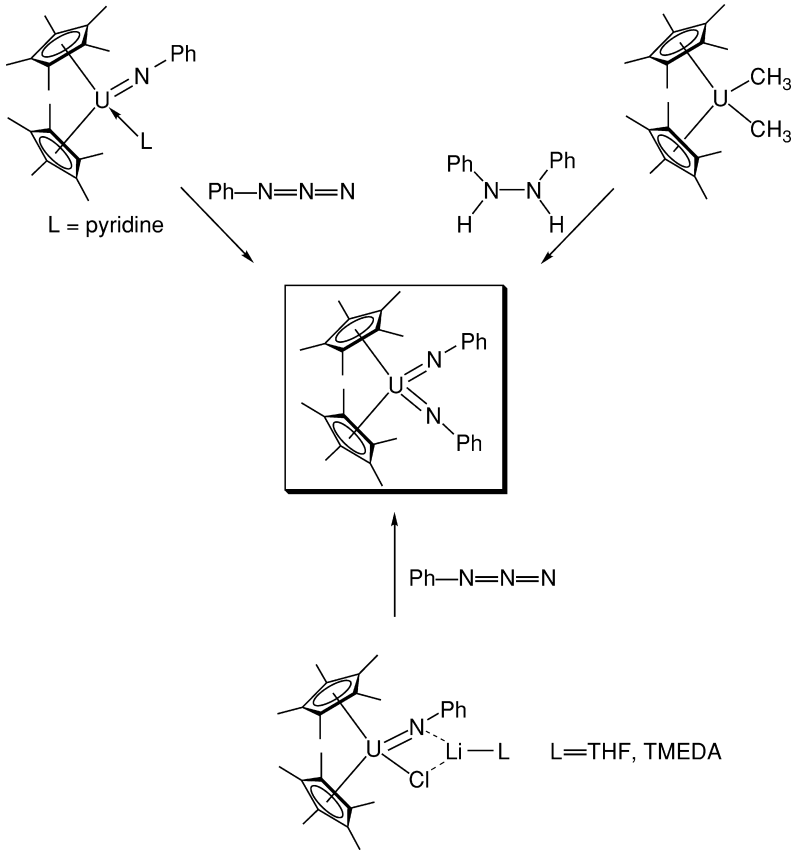

Fig. 25.19 *Synthetic pathways to* $(\eta^5\text{-}C_5Me_5)_2U(=NC_6H_5)_2$ (*Arney* et al., 1995).

substrates, MeI, or ammonia. This, coupled with the observation that the U–C_{ring} bond distances [2.72(1)–2.75(1) Å] are comparable with those found in typical U(IV) metallocenes, argues for some degree of covalency in the U–N bonding. In order to invoke a higher bond order, it is necessary to suggest the involvement of 5f orbitals in stabilizing the nitrogen 2p lone pair electrons, as there is no 6d orbital of the appropriate symmetry. The U(VI) character of the complex is demonstrated in the lack of observable metal-based electronic transitions (f–f, f–d) in the near-IR spectrum, as well as the observation in the ^{1}H NMR spectrum that the complex appears to act as a temperature-independent paramagnet (Arney *et al.*, 1992).

Since the initial report, other U(VI) bis(imido) compounds have been prepared with substituted arylimido and trimethylsilylimido ligands. In addition, U(VI) imido-oxo complexes $(\eta^5\text{-}C_5Me_5)_2U(=NAr)(=O)$ (Ar = 2,4,6-$Me_3C_6H_2$, 2,4,6-$^t Bu_3C_6H_2$, 2,6-$^i Pr_2C_6H_3$) have been synthesized (Arney and Burns, 1995). These complexes have similar geometries to the bis(imido)

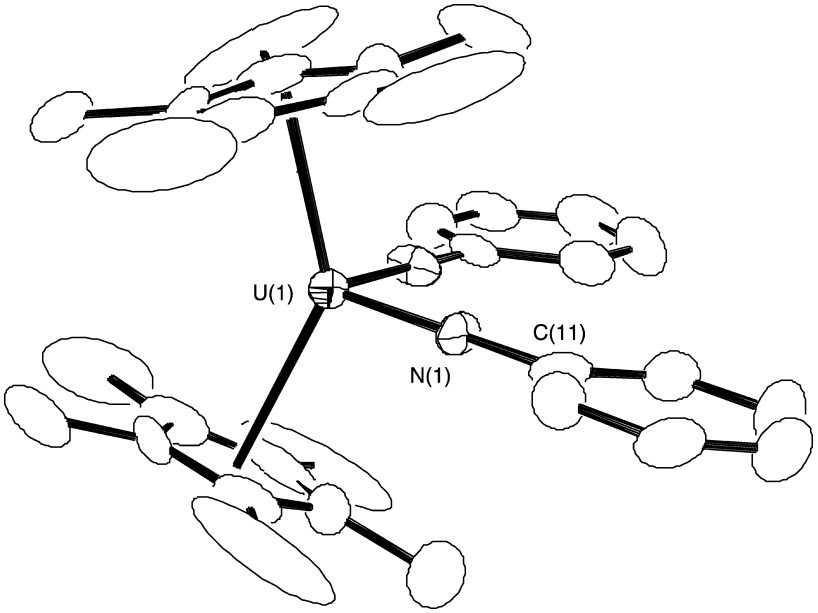

Fig. 25.20 *Crystal structure of* $(\eta^5\text{-}C_5Me_5)_2U(=NC_6H_5)_2$. (*Reprinted with permission from Arney* et al. (1992). *Copyright* 1992 *American Chemical Society*.)

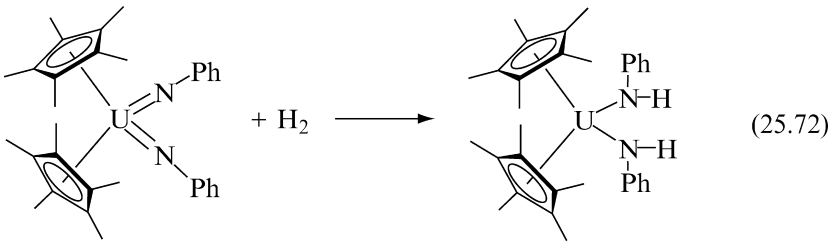
derivatives, with a U–O bond length of 1.844(4) Å for the complex $(\eta^5\text{-}C_5Me_5)_2U(=N\text{-}2,6\text{-}{}^iPr_2C_6H_3)(=O)$. This bond length is significantly longer than that observed for uranyl ions, which may reflect a reduced bond order.

The ancillary ligand appears to make a difference in the accessibility of the U (VI) oxidation state. Complexes of uranium with the chelating ligand sets $[Me_2Si(\eta^5\text{-}C_5Me_4)_2]^{2-}$ and $[Me_2Si(\eta^5\text{-}C_5Me_4)(\eta^5\text{-}C_5H_4)]^{2-}$ have been prepared and employed in analogous reactions to prepare organoimido complexes (Schnabel *et al.*, 1999). While the bis(tetramethylcyclopentadienyl) *ansa*-metallocene successfully produces a bis(imido) compound, reaction of $[Me_2Si(\eta^5\text{-}C_5Me_4)(\eta^5\text{-}C_5H_4)]U(CH_2C_6H_5)_2$ with *N*,*N*′-diphenylhydrazine yields only the tetravalent bridging imido complex and $[\{Me_2Si(\eta^5\text{-}C_5Me_4)(\eta^5\text{-}C_5H_4)\}U(\mu\text{-}NPh)]_2$. Electrochemical investigations of the chloride compounds $[Me_2Si(\eta^5\text{-}C_5Me_4)_2]UCl_2 \cdot 2LiCl \cdot 4(Et_2O)$ and $[Me_2Si(\eta^5\text{-}C_5Me_4)(\eta^5\text{-}C_5H_4)]UCl_2 \cdot 2LiCl \cdot 4(THF)$ suggest that the ancillary ligands have the capacity to significantly alter the redox activity of the metal center; $[Me_2Si(\eta^5\text{-}C_5Me_4)(\eta^5\text{-}C_5H_4)]UCl_2 \cdot 2LiCl \cdot 4(THF)$ is more difficult to oxidize than $[Me_2Si(\eta^5\text{-}C_5Me_4)_2]UCl_2 \cdot 2LiCl \cdot 4(Et_2O)$ by ~ 0.24 V (vs $[Cp_2Fe]^{0/+}$). It has also been proposed that *ansa* bis(cyclopentadienyl) ligands sets generate more electrophilic metal centers (Lee *et al.*, 1998; Shin *et al.*, 1999).

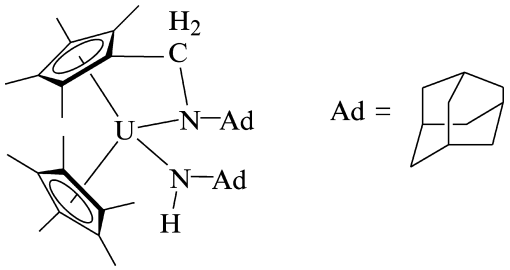
As mentioned previously, the uranium imido complexes are generally unreactive, although a limited number of bond activation reactions have been

reported. The complex $(\eta^5\text{-}C_5Me_5)_2U(=NC_6H_5)_2$ will effect the homolytic cleavage of dihydrogen to yield a bis(amide) compound [equation (25.72)].

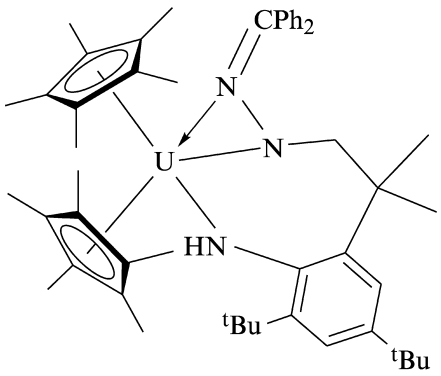


(25.72)

In an attempt to prepare more reactive organoimido functional groups, the more electron-rich adamantylimido complex $(\eta^5\text{-}C_5Me_5)_2U(=NAd)_2$ (Ad = Adamantyl) was prepared (Warner *et al.*, 1998). This complex undergoes decomposition under thermolysis to generate a complex derived from C–H activation of a pentamethylcyclopentadienyl methyl group (Peters *et al.*, 1999).



More reactive uranium–nitrogen multiple bonds may be generated by heteroatom substitution. The reaction of tetravalent $(\eta^5\text{-}C_5Me_5)_2U(=N\text{-}2,4,6\text{-}{}^tBu_3C_6H_2)$ with diphenyldiazomethane generates the mixed bis(imido) complex $(\eta^5\text{-}C_5Me_5)_2U(=N\text{-}2,4,6\text{-}{}^tBu_3C_6H_2)(=N\text{-}N{=}CPh_2)$, which undergoes a cyclometallation reaction upon mild thermolysis to generate a uranium(IV) bis(amide) complex that results from net addition of a C–H bond of an ortho *tert*-butyl group across the N=U=N core (Kiplinger *et al.*, 2002).



In select cases, U(VI) will catalyze chemical transformations; these will be discussed further in Chapter 26.

25.2.2 Cyclooctatetraenyl ligands

The chemistry of the cyclooctatetraenyl ligand and its substituted variants is significant in the development of actinide organometallic chemistry, and highlights differences between the f-elements and transition metals. The recognition that the lanthanides and actinides possess f-orbitals of the appropriate symmetry to interact with this carbocyclic ligand led to the theoretical prediction that a 'sandwich' compound could be prepared (Fischer, 1963). This prediction was subsequently validated by the preparation of $(\eta^8\text{-}C_8H_8)_2U$ (or 'uranocene') by the reaction of UCl_4 and the potassium salt of the dianion of cyclooctatetraene, $K_2(C_8H_8)$ [equation (25.73)] (Streitwieser and Müller-Westerhoff, 1968). Since that time, other synthetic routes to bis(cyclooctatetraenyl) complexes of the actinides have appeared [equations (25.74) and (25.75)] (Starks and Streitwieser, 1973; Starks *et al.*, 1974; Chang *et al.*, 1979; Rieke and Rhyne, 1979):

$$UCl_4 + 2K_2(C_8H_8) \xrightarrow{\text{THF}} (\eta^8\text{-}C_8H_8)_2U + 4KCl \qquad (25.73)$$

$$U\ (\text{powder}) + 2C_8H_{10} \xrightarrow{\text{Hg(cat.)}} (\eta^8\text{-}C_8H_8)_2U + 2H_2 \qquad (25.74)$$

$$UF_4 + 2Mg(C_8H_8) \longrightarrow (\eta^8\text{-}C_8H_8)_2U + 2MgF_2 \qquad (25.75)$$

Bis(cyclooctatetraenyl) complexes of a number of other actinide elements have also been prepared, including Th (Streitwieser and Yoshida, 1969; Goffart *et al.*, 1972; Starks and Streitwieser, 1973), Pa (Goffart *et al.*, 1974; Starks *et al.*, 1974), Np (Karraker *et al.*, 1970), and Pu (Karraker *et al.*, 1970). Most are prepared by the methods of equations (25.73) and (25.74), although the plutonium compound was prepared from Cs_2PuCl_6.

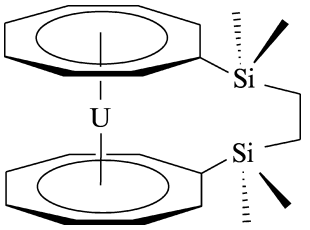
A large number of substituted (cyclooctatetraenyl) complexes have also been reported. The addition of substituents has been employed to improve solubility, alter electronic properties, or investigate the dynamics of ring rotation reactions. The largest class of these are the 1,1′-disubstituted derivatives (Harmon *et al.*, 1977; Spiegl, 1978; Miller and DeKock, 1979; Spiegl and Fischer, 1979) prepared by the method of equation (25.76):

$$UCl_4 + 2K_2(C_8H_7R) \longrightarrow (\eta^8\text{-}C_8H_7R)_2U + 4KCl \qquad (25.76)$$

R = Me, Et, *n*-Bu, cyclo-C_3H_5, $CH{=}CH_2$, C_6H_5, OMe, OEt, O^{t}Bu, CO_2Et, *p*-C_6H_4R, NR_2, *p*-$C_6H_4NMe_2$, PR_2, $SiMe_3$, $SnMe_3$

1,1′-Disubstituted derivatives (R = Et, *n*-Bu) of neptunium and plutonium have also been prepared (Karraker, 1973). A number of uranocene derivatives with higher degrees of substitution have been reported (Streitwieser *et al.*, 1971;

Streitwieser and Harmon 1973; Streitwieser and Walker, 1975; Solar *et al.*, 1980; LeVanda and Streitwieser, 1981; Miller *et al.*, 1981; Lyttle *et al.*, 1989), including several with exocyclic ligands (Luke *et al.*, 1981; Zalkin *et al.*, 1982; Streitwieser *et al.*, 1983). The silylated derivatives $[\eta^5\text{-}1,3,5\text{-}(SiMe_3)_3C_8H_5]_2An$ have been prepared for An = Th, U, and Np (Apostolidis *et al.*, 1999). There is also one example of a bridged, or linked uranocene, [η^8:η^8-1,2-bis(cyclooctatetraenyldimethylsilyl)ethane]uranium (Streitwieser *et al.*, 1993).



The molecular structure of many uranocene derivatives have been determined; the molecular structure of $(\eta^8\text{-}C_8H_8)_2U$ is shown in Fig. 25.21 (Zalkin and Raymond, 1969, Avdeef *et al.*, 1972).

The molecule possesses rigorous D_{8h} symmetry, with the eight-membered rings arranged in an eclipsed conformation. The averaged $U\text{–}C_{ring}$ bond distance is 2.647(4) Å; all atoms of the cyclooctatetraene ligand lie within the plane

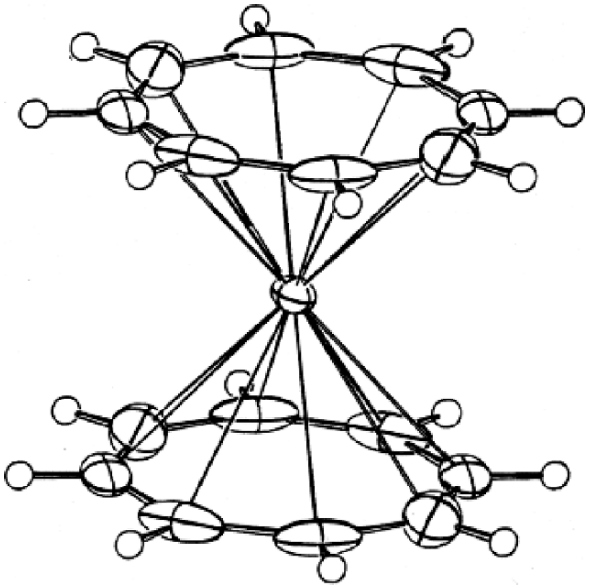


Fig. 25.21 *Crystal structure of* $(\eta^8\text{-}C_8H_8)_2U$. (*Reprinted with permission from Zalkin and Raymond* (1969). *Copyright* 1969 *American Chemical Society.*)

to 0.02 Å. A comparison of the average C–C bond lengths for alternate sets of four bonds within the rings [1.396(5) and 1.388(27) Å] confirms the aromatic nature of the ligand. Substituted uranocene derivatives can show staggered ring geometries in the solid state; the rings in the complex bis(η^8-1,3,5,7-tetraphenylcyclooctatetraene)uranium are eclipsed (Templeton *et al.*, 1976), while the structure of bis(η^8-1,3,5,7-tetramethylcycloctatetraene)uranium reveals two symmetry-independent molecules in the asymmetric unit: one with staggered rings and one in which the rings are nearly eclipsed (Hodgson and Raymond, 1973).

The bonding in these highly symmetric compounds has been studied extensively by theoretical and experimental methods. The first theoretical treatments assumed that the principal metal–ligand interactions occurred through 5f orbitals, and that 6d orbitals would be too high in energy to interact with ligand-based orbitals. Improvement in computation methods (such as the inclusion of spin–orbit coupling) and inclusion of relativistic corrections have amended this bonding description. An *ab initio* calculation on uranocene incorporating relativistic core potentials and spin–orbit CI calculations suggests a significant degree of covalency in metal–ligand bonding; the 6d orbitals play a primary role in these interactions, and the 5f orbital involvement is secondary (Chang and Pitzer, 1989). A qualitative molecular orbital diagram is shown in Fig. 25.22.

The principal bonding interaction involves the metal 6dδ and ligand $3e_{2g}$ orbitals, as well as the metal 5fδ and ligand $3e_{2u}$ combination. Minimal interaction also exists between the metal 5fϕ orbitals and the ligand-based e_{3u} orbitals. The dashed line in the figure shows the impact of including relativistic effects in the calculations, further stabilizing a d_{z^2} orbital, making it the lowest unoccupied molecular orbital, housing any unpaired metal electrons (the orbital is essentially metal–ligand nonbonding).

Experimental probes of bonding in actinocenes have included chemical reactivity, magnetism, NMR spectroscopy, optical spectroscopy, Np-237 Mössbauer spectroscopy, and photoelectron spectroscopy (PES) (Burns and Bursten, 1989, and references therein). The initial observation of the stability of (η^8-$C_8H_8)_2U$ to hydrolysis (relative to (η^8-$C_8H_8)_2Th$) suggested a higher degree of covalency in bonding in the uranium complex. Attempts have been made to derive the magnetic moment for bis(cyclooctatetraene) complexes of U, Np, and Pu. For example, (η^8-^{t}Bu$C_8H_7)_2Pu$ is reported to have a $J = 0$ ground state and exhibits temperature-independent paramagnetism (Karraker, 1973). The first predictions of the magnetism were based on the assumption of ionic bonding (weak crystal-field perturbations) and simple *L–S* coupling models (Karraker *et al.*, 1970). Deviations of the calculated moments from the observed were corrected by application of an empirical 'orbital reduction factor' described as a measure of covalency in bonding. Later non-relativistic calculations provided a better fit to experimentally observed magnetic moments between 10 and 80 K (Hayes and Edelstein, 1972). These calculations suggested a significant degree of covalency, but it was pointed out that the high value assumed for the

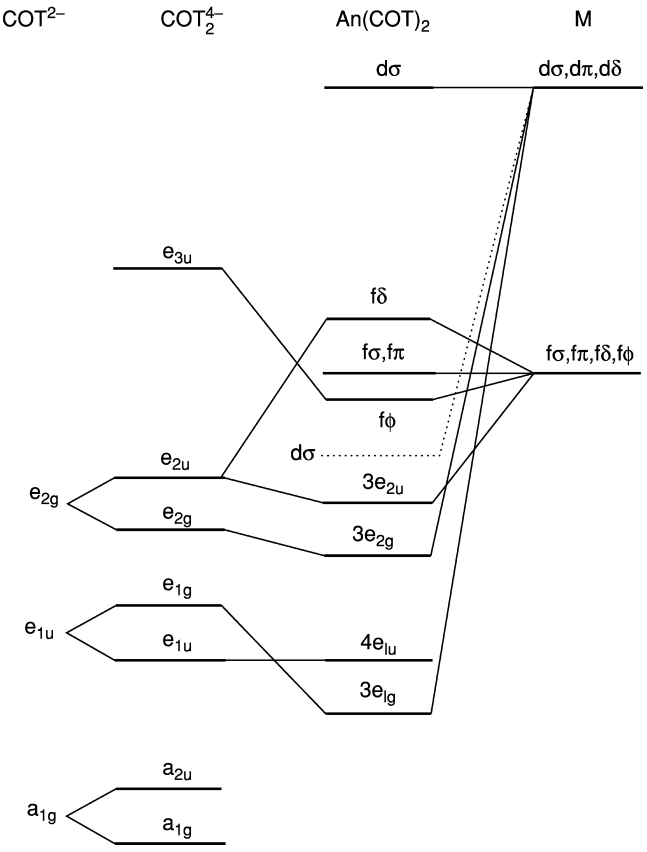

Fig. 25.22 *Molecular orbital diagram of* $(\eta^8\text{-}C_8H_8)_2U$. (*Reprinted with permission from Parry* et al. (1999). *Copyright* 1999 *American Chemical Society*.)

5f valence state ionization potential could cause an overestimation of the covalence in bonding.

Some of the most compelling evidence for the degree of covalency in uranocene (and particularly for a 5f orbital role) comes from variable energy photoelectron spectroscopy (Brennan *et al.*, 1989). In general, metal-based electrons are known to have an energy-dependent cross section. In $(\eta^8\text{-}C_8H_8)_2U$ (over the energy range 24–125 eV), the f-band shows cross-section features attributable to 5f resonant photoemission in the vicinity of the 5d–5f giant resonant absorption ($h\nu = 101$ and 110 eV). The e_{2g} and e_{2u} bands also show small cross-section maxima at these energies; that for the e_{2u} ionization being the more intense. The mapping of the intensity changes of the f-band by the e_{2u} band provides strong evidence for f-orbital contribution to valence orbitals in this molecule (Fig. 25.23).

Ring dynamics (rotation and exchange) have been studied by means of variable-temperature NMR spectroscopy for substituted derivatives. It is

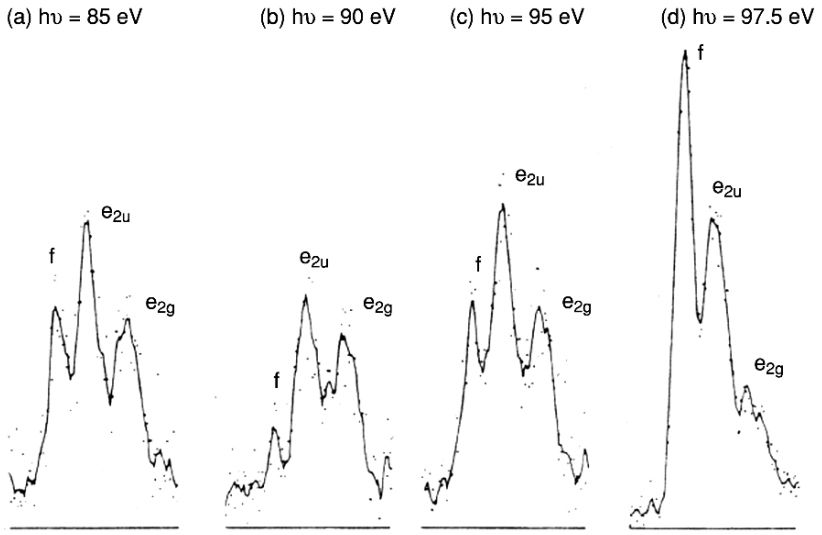

Fig. 25.23 *Variable energy photoelectron spectrum of* $(\eta^5\text{-}C_8H_8)_2U$. (*Reprinted with permission from Brennan* et al. (1989). *Copyright* 1989 *American Chemical Society*).

found that uranocenes undergo rapid ligand exchange with cyclooctatetraene dianions (LeVanda and Streitwieser, 1981). The barrier to ring rotation has been estimated at 8.3 kcal mol^{-1} for $(\eta^8\text{-}1,4\text{-}{}^t Bu_2C_8H_6)_2U$; this compares with a value of 13.1 kcal mol^{-1} for a d-transition metal metallocene analog $(\eta^5\text{-}1,3\text{-}{}^t Bu_2C_5H_3)_2Fe$ (Luke and Streitwieser, 1981).

In addition to the neutral tetravalent actinocenes, synthetic routes have been devised to anionic trivalent derivatives, $[(\eta^8\text{-}C_8H_8)_2An]^-$, either by treatment of trivalent precursors with $K_2(C_8H_8)$ [equation (25.77)], or by reduction of the actinocene [equation (25.78)] (Karraker and Stone, 1974; Billiau *et al.*, 1981; Eisenberg *et al.*, 1990).

$$\begin{aligned} &AnI_3 + 2K_2(C_8H_8) \xrightarrow{\text{THF}} K[(\eta^8\text{-}C_8H_8)_2An] \cdot 2THF \\ &An = Np, Pu \end{aligned} \tag{25.77}$$

$$\begin{aligned} &(\eta^8\text{-}C_8H_8)_2An + K/\text{Naphthalene} \longrightarrow K[(\eta^8\text{-}C_8H_8)_2An] \\ &An = U,\ Np,\ Pu \end{aligned} \tag{25.78}$$

The Mössbauer spectrum of the neptunium compound $[(\eta^8\text{-}C_8H_8)_2Np]^-$ confirms that the metal is in the trivalent oxidation state, and suggests a lower overall degree of covalency in metal–ligand bonding than in tetravalent derivatives. Most recently, the reduction route has been extended to generate trivalent actinocenes $K(DME)_2[\{\eta^8\text{-}1,4\text{-}({}^t BuMe_2Si)_2C_8H_6\}_2An]$ (An = Th, U), wherein the bulky silyl substituents are proposed to provide both kinetic and

thermodynamic stabilization of the Th(III) compound (Parry *et al.*, 1999). The complexes display asymmetric An–C_{ring} distances, owing to the 'capping' of one ring by close association with the potassium counter-ion. The observed magnetic moment for the thorium compound is $1.20\mu_B$ at 293 K, which is low when compared to the spin-only value for one unpaired electron ($1.73\mu_B$). It has been proposed that the low moment is due to mixing of the ground state magnetic component with low-lying excited states.

Intermolecular electron-transfer rates have been studied for uranocene and substituted derivatives of uranium, neptunium, and plutonium (Eisenberg *et al.*, 1990) by examining the variable-temperature NMR spectra of mixtures of $(\eta^8\text{-}C_8H_8)_2An$ and $[(\eta^8\text{-}C_8H_8)_2An]^-$. In all cases, electron transfer rates are rapid. Specific rates could not be derived for uranium and plutonium derivatives due to the small chemical shift differences between analogous An(IV) and An(III) compounds, but in the case of $(\eta^8\text{-}^tBuC_8H_7)_2Np$, the rate has been estimated to be of the same order of magnitude as comparable lanthanide cyclooctatetraene compounds ($\sim 10^7$ $M^{-1}s^{-1}$).

The chemistry of actinide complexes containing a single cyclooctatetraenyl ring began with a report of $(\eta^8\text{-}C_8H_8)NpI\cdot xTHF$, prepared by reaction of $NpI_3(THF)_4$ and $K_2(C_8H_8)$ in THF (Karraker and Stone, 1977). The first structurally characterized examples of this class of compounds included both derivatives of uranium [$(\eta^8\text{-}C_8H_8)UCl_2(pyridine)_2$ and $(\eta^8\text{-}C_8H_8)U(MeCOCHCOMe)_2$; Boussie *et al.*, 1990] and thorium [$(\eta^8\text{-}C_8H_8)ThCl_2(THF)_2$; Zalkin *et al.*, 1980]. Since these initial reports, other entries into mono-ring chemistry have been established, principally those involving redistribution [equations (25.79) and (25.80)] (LeVanda *et al.*, 1980; Gilbert *et al.*, 1988; Baudry *et al.*, 1990a), halogenation [equation (25.81)] (Berthet *et al.*, 1990), and metathesis [equations (25.82) and (25.83)] (Boisson *et al.*, 1996a).

$$\tfrac{1}{2}(\eta^8\text{-}C_8H_8)_2Th + ThCl_4 \longrightarrow (\eta^8\text{-}C_8H_8)ThCl_2 \qquad (25.79)$$

$$\tfrac{1}{2}(\eta^8\text{-}C_8H_8)_2U + \tfrac{1}{2}U(BH_4)_4 \longrightarrow (\eta^8\text{-}C_8H_8)U(BH_4)_2 \xrightarrow{L} (\eta^8\text{-}C_8H_8)U(BH_4)_2(L) \qquad L = THF,\ Ph_3P{=}O \qquad (25.80)$$

$$(\eta^8\text{-}C_8H_8)_2U + I_2 \xrightarrow{THF} (\eta^8\text{-}C_8H_8)UI_2(THF)_2 \qquad (25.81)$$

$$(NEt_2)_2UCl_2 + K_2(C_8H_8) \xrightarrow{THF} (\eta^8\text{-}C_8H_8)U(NEt_2)_2(THF) + 2KCl \qquad (25.82)$$

$$(\eta^8\text{-}C_8H_8)_2U + 3LiNEt_2 \longrightarrow Li[(\eta^8\text{-}C_8H_8)U(NEt_2)_3] \qquad (25.83)$$

Collectively, these complexes further serve as precursors to a variety of mono (cyclooctatetraenyl) derivatives, including alkyl (Berthet *et al.*, 1994), alkoxide (Arliguie *et al.*, 1992), amide (Gilbert *et al.*, 1988; Le Borgne *et al.*, 2000), and

thiolate (Leverd *et al.*, 1994; Arliguie *et al.*, 2000) complexes. Mixed-ring derivatives containing both cyclooctatetraenyl and cyclopentadienyl ligands have similarly been prepared by metathesis reactions (Gilbert *et al.*, 1989; Berthet *et al.*, 1994, Boisson *et al.*, 1996b). The complex $(\eta^8\text{-}C_8H_8)(\eta^5\text{-}C_5Me_5)Th[CH(SiMe_3)_2]$ undergoes hydrogenolysis to yield the hydride compound $(\eta^8\text{-}C_8H_8)(\eta^5\text{-}C_5Me_5)ThH$ (Gilbert *et al.*, 1989).

An interesting example of the introduction of a bridging cyclooctatetraenyl ligand is found in the reaction of $(\eta^5\text{-}C_5Me_5)_3U$ with cyclooctatetraene (Evans *et al.*, 2000). As previously discussed, the bulky tris(pentamethylcyclopentadienyl) complex can act as a multi-electron reductant. Reaction with C_8H_8 produces the complex $[(\eta^8\text{-}C_8H_8)(\eta^5\text{-}C_5Me_5)U]_2(\mu\text{-}C_8H_8)$, along with $(C_5Me_5)_2$. The complex consists of two mixed-ring U(IV) units coordinated to a bridging $C_8H_8^{2-}$ ligand (Fig. 25.24). The bridging ring is non-planar and appears bound to the two metal centers in an unusual $\eta^3{:}\eta^3$ manner, with one carbon in common.

Cationic derivatives of the formula $[(\eta^8\text{-}C_8H_8)U(NEt_2)(THF)_2][BPh_4]$ and $[(\eta^8\text{-}C_8H_8)U(BH_4)(THF)_2][BPh_4]$ may be produced by protonation of the respective tetravalent precursors $(\eta^8\text{-}C_8H_8)UX_2(THF)$ with $[NEt_3H][BPh_4]$ (Boisson *et al.*, 1996b; Cendrowski-Guillaume *et al.*, 2000). Reaction of the latter with additional ammonium salt in the presence of hexamethylphosphoramide (HMPA) yields the unique dicationic species $[(\eta^8\text{-}C_8H_8)U(HMPA)_3][BPh_4]_2$. The U–N bond in the complex $[(\eta^8\text{-}C_8H_8)U(NEt_2)(THF)_2][BPh_4]$ is susceptible to protonation by alcohols and thiols, and will insert CO_2, CS_2, or MeCN to generate the complexes $[(\eta^8\text{-}C_8H_8)U(E_2CNEt_2)(THF)_2][BPh_4]$ (E = O, S) and $[(\eta^8\text{-}C_8H_8)U(NC(Me)NEt_2)(THF)_2][BPh_4]$.

Few trivalent derivatives of mono(cyclooctatetraenyl)uranium have been isolated, likely due to the facile ligand redistribution and disproportionation

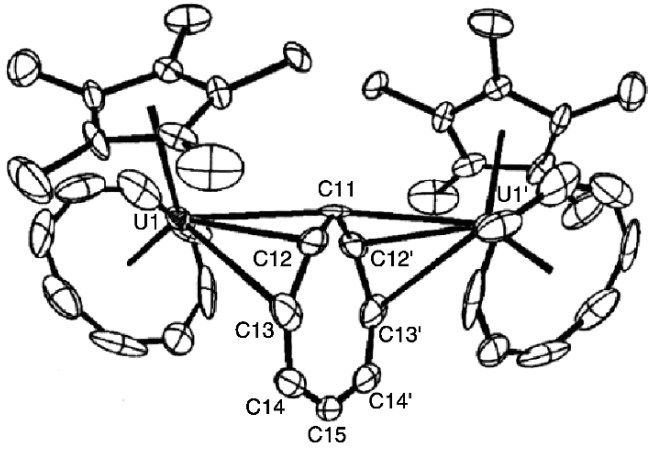

Fig. 25.24 *Crystal structure of* $[(\eta^8\text{-}C_8H_8)(\eta^5\text{-}C_5Me_5)U]_2(\mu\text{-}C_8H_8)$ (*Evans* et al., 2000). (*Reprinted with permission from John Wiley & Sons, Inc.*)

reactions that give rise to uranocene. The complex $(\eta^8\text{-}C_8H_8)(\eta^5\text{-}C_5Me_5)U(THF)$ is produced by reaction of $(\eta^5\text{-}C_5Me_5)UI_2(THF)$ with $K_2(C_8H_8)$ (Schake *et al.*, 1993); the 4,4′-dimethyl-2,2′-bipyridine adduct has been structurally characterized. The complex exists as a bent metallocene with a ring centroid–uranium–ring centroid angle of 138.2°. The average $M\text{–}C_{ring}$ distances are consistent with the larger ionic radius of U(III). The aforementioned dication $[(\eta^8\text{-}C_8H_8)U(HMPA)_3][BPh_4]_2$ can be reduced by sodium amalgam to generate a monocation $[(\eta^8\text{-}C_8H_8)U(HMPA)_3][BPh_4]$ (Cendrowski-Guillaume *et al.*, 2001).

An interesting new class of pentavalent complexes supported by the cyclooctatetraenyl ligand has recently been developed. Oxidation of anionic U(IV) mono-ring amide complexes with $TlBPh_4$ or $AgBPh_4$ generates the corresponding pentavalent amide complexes as shown in equations (25.84) and (25.85) (Berthet and Ephritikhine, 1993; Boisson *et al.*, 1995).

$$[(\eta^8\text{-}C_8H_8)U(NEt_2)_3]^- + TlBPh_4 \longrightarrow (\eta^8\text{-}C_8H_8)U(NEt_2)_3 \qquad (25.84)$$

$$(\eta^8\text{-}C_8H_8)U(NEt_2)_2(THF) + AgBPh_4 \longrightarrow [(\eta^8\text{-}C_8H_8)U(NEt_2)_2(THF)][BPh_4] \qquad (25.85)$$

The molecular structure of $[(\eta^8\text{-}C_8H_8)U(NEt_2)_2(THF)][BPh_4]$ has been determined (Boisson *et al.*, 1996a). The amide ligands are susceptible to protonation by alcohols to yield alkoxide complexes. Pentavalent cyclooctatetraenyluranium compounds have been studied by EPR (Gourier *et al.*, 1997) and X-ray absorption spectroscopy (Den Auwer *et al.*, 1997). Analysis of EPR spectra suggested that (as for cyclopentadienyl ligands) chemical bonding with the cyclooctatetraenyl ligand occurs principally with the uranium 6d orbitals, except in the case of the tris(*iso*-propoxide) complex $(\eta^8\text{-}C_8H_8)U(O^iPr)_3$. In this complex, it was proposed that the 5f–O interaction is strong, so that J is no longer a good quantum number, and the weak-field approximation can no longer be considered valid.

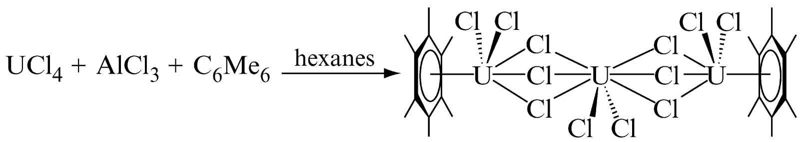
25.2.3 Other carbocyclic ligands

(a) Arene ligands

Although arene compounds of the d-transition metals were prepared early in the 20th century, their identity as η^6-ligands was not recognized until many years later. All previous carbocyclic ligands discussed in this article may be regarded to have a formal charge (e.g. $C_5H_5^-$, $C_8H_8^{2-}$), and so therefore may bind more strongly to actinide centers via Coulombic forces. In contrast, arenes are often regarded as neutral ligands, and so any interaction with a metal center might best be regarded as one involving significant electrostatic polarization of the ligand π-electrons, or alternatively, covalent bonding. Given the propensity of the later actinides to engage principally in ionic bonding, it is therefore not

surprising that arene complexes are restricted to the early actinides. Only uranium has been found to generate arene complexes. This suggests a greater propensity for uranium to engage in covalent bonding, consistent with the observation that U–C bonding in uranocene appears to be more covalent than in its thorium analog.

The initial method employed to prepare π-arene complexes of d-transition metals was the reducing Friedel–Crafts route developed by Fischer and Hafner (1955), involving reduction of a metal salt with aluminum powder, followed by reaction with an arene ligand. Extension of this method to reaction with UCl_4 produced the first π-arene complex, the trivalent species $(\eta^6\text{-}C_6H_6)U(AlCl_4)_3$ (Cesari *et al.*, 1971). The molecular structure of the complex consists of a pseudotetrahedral arrangement of the four ligands about uranium, with two bridging chlorides between each aluminum and uranium. The benzene ring was refined as an idealized model, with uranium–carbon distances of 2.91–2.92 Å. Toluene and hexamethylbenzene analogs have also been described (Cotton and Schwotzer, 1987; Garbar *et al.*, 1996). Subsequently, two polymetallic tetravalent complexes were prepared by a variant of this procedure as depicted in equation (25.86) (Cotton and Schwotzer, 1985; Campbell *et al.*, 1986):



(25.86)

The complex $[(\eta^6\text{-}C_6Me_6)Cl_2U(\mu\text{-}Cl)_3UCl_2(\eta^6\text{-}C_6Me_6)][AlCl_4]$ was isolated by further reduction with zinc powder. Once isolated, the compounds are insoluble in non-coordinating solvents. The cation of the molecule $[(\eta^6\text{-}C_6Me_6)Cl_2U(\mu\text{-}Cl)_3UCl_2(\eta^6\text{-}C_6Me_6)][AlCl_4]$ is shown in Fig. 25.25.

The arene ligands in these complexes are all found to be weakly bound, and are readily displaced by other bases such as THF or acetonitrile. Detailed structural studies have been conducted on these arene complexes. In no case does the arene ring appear to significantly deviate from planarity. The $U\text{–}C_{arene}$ bond distances in these complexes are long for actinide–carbocyclic ligands; they fall in the range 2.89(2)–2.96(2) Å.

η^6-Arene complexes of trivalent uranium have also been isolated from the thermolysis of $U(BH_4)_4$ in aromatic solvents (Baudry *et al.*, 1989a). The mesitylene complex $(\eta^6\text{-mesitylene})U(BH_4)_3$ was initially isolated from that solvent. The weakly coordinated arene is readily displaced by other aromatic substrates, however, and the hexamethylbenzene complex is reported to be more stable to displacement in toluene solution.

More recently, reduction of tetravalent actinide amide complexes has been found to give rise to an interesting series of 'inverted sandwich', or bridging arene complexes (Diaconescu *et al.*, 2000; Diaconescu and Cummins, 2002). Reduction of $[N(^tBu)Ar]_3UI$ ($Ar = 3,5\text{-}Me_2C_6H_3$) by KC_8 in toluene generates the complex $[N(^tBu)Ar]_2U(\mu\text{-}\eta^6,\eta^6\text{-}C_7H_8)U[N(^tBu)Ar]_2$. The related compound

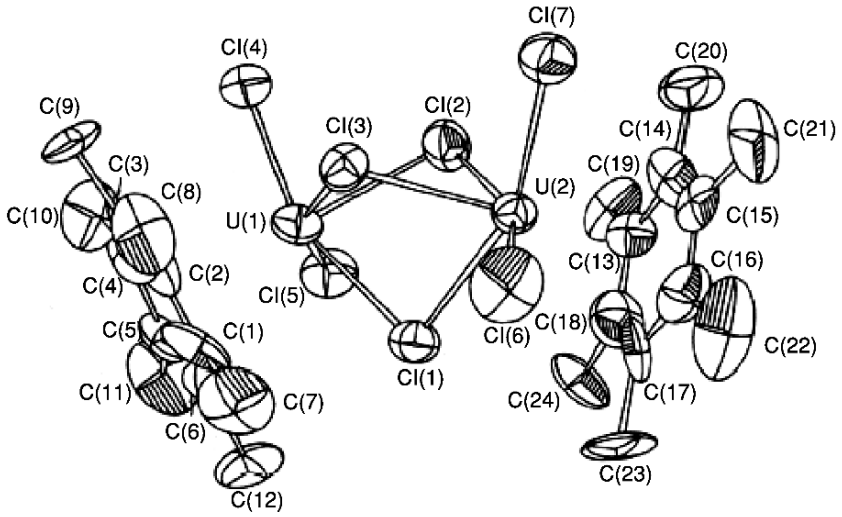


Fig. 25.25 *Molecular structure of* $[(\eta^6\text{-}C_6Me_6)Cl_2U(\mu\text{-}Cl)_3UCl_2(\eta^6\text{-}C_6Me_6)]^+$. (*Reprinted with permission from Campbell* et al. (1986). *Copyright* 1986 *American Chemical Society*.)

$[N(R)Ar]_2U(\mu\text{-}\eta^6,\eta^6\text{-}C_7H_8)U[N(R)Ar]_2$ (R = adamantyl; Ar = 3,5-$Me_2C_6H_3$), could also be generated in low yield by reaction of $UI_3(THF)_4$ with $(Et_2O)LiN(R)Ar$ in toluene. Structural characterization reveals that the complex contains a bridging toluene molecule bound symmetrically to the two metal centers (Fig. 25.26).

The U–C_{ring} distances are short relative to other η^6-arene complexes, ranging from 2.503(9) to 2.660(8) Å. In addition, there is a slight distortion in the bound toluene ligand; the average C–C distances increase by approximately 0.04 Å from that in free toluene. Density functional calculations carried out on the molecule suggest that four electrons are engaged in the formation of two δ-symmetry back-bonds involving U 6d and 5f orbitals and the LUMO of the bridging arene molecule. The complex acts as a 'uranium(II)' reagents in subsequent reactions, and can effect four-electron reduction of substrates.

(b) Other carbocyclic ligands (cycloheptatrienyl, pentalene, endohedral metallofullerenes)

Complexes of actinides with five-, six-, and eight-membered rings have already been described. It is only recently that this series has been completed with the preparation of complexes employing the cycloheptatrienyl ligand. Unlike the other members of this series, the first complex to be prepared was not the sandwich complex, but rather the 'inverse sandwich' compound $[X_3U(\mu\text{-}\eta^7,\eta^7\text{-}C_7H_7)UX_3]^-$ (X = NEt_2, BH_4), formed in the reaction of $U(NEt_2)_4$ or

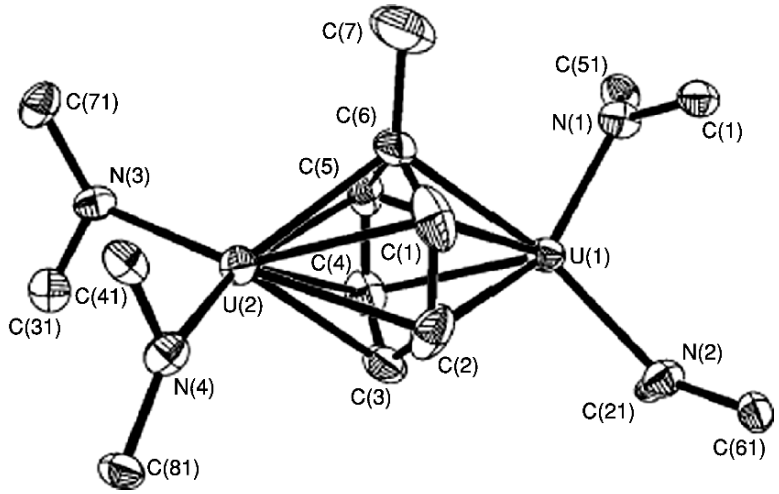

Fig. 25.26 *Molecular structure of* $[N(R)Ar]_2U(\mu\text{-}\eta^6,\eta^6\text{-}C_7H_8)U[N(R)Ar]_2$ (R = *adamantyl, Ar* = 3,5-$Me_2C_6H_3$). *Bulky peripheral substituents omitted for clarity*. (*Reprinted with permission from Diaconescu* et al. (2000). *Copyright* 2000 *American Chemical Society*.)

$U(BH_4)_4$ with $K(C_7H_9)$ (Arliguie *et al.*, 1994). The sandwich complex [K(18-crown-6)][$(\eta^7\text{-}C_7H_7)_2U$] has subsequently been prepared [equations (25.87) and (25.88)] (Arliguie *et al.*, 1995).

$$UCl_4 + K + \text{xs} \quad \xrightarrow[\text{18-crown-6}]{\text{THF}} \quad [K(18\text{-crown-6})][(\eta^7\text{-}C_7H_7)_7U] \tag{25.87}$$

$$UCl_4 + 4K(C_7H_7) \xrightarrow[18-\text{crown}-6]{\text{THF}} [K(18\text{-crown-6})][(\eta^7\text{-}C_7H_7)_2U] \tag{25.88}$$

The molecular structure of the anion $[(\eta^7\text{-}C_7H_7)_2U]^-$ is shown in Fig. 25.27.

The complex consists of a sandwich of crystallographic C_{2h} symmetry. The cycloheptatrienyl ligands are planar to within 0.02 Å, and display a regular heptagonal geometry. The two rings are staggered. The uranium–carbon bond distances average 2.53(2) Å, significantly shorter than those found for typical tetravalent uranium cyclopentadienyl and cyclooctatetraenyl complexes. Similar bond shortening has been observed in M–C bonds in early transition metal cycloheptatrienyl complexes, and has been explained as reflecting electron transfer from the metal to the ligand, with an increase in metal valency. Some attention has therefore been given to the assignment of oxidation state in this complex. A density functional study examined the question of bonding in the complexes $(\eta^7\text{-}C_7H_7)_2An$ (Li and Bursten, 1997). It was found that the 5f δ-symmetry orbitals not only participate in the bonding with e_2'' pπ orbitals of the C_7H_7 rings, but are as important as the

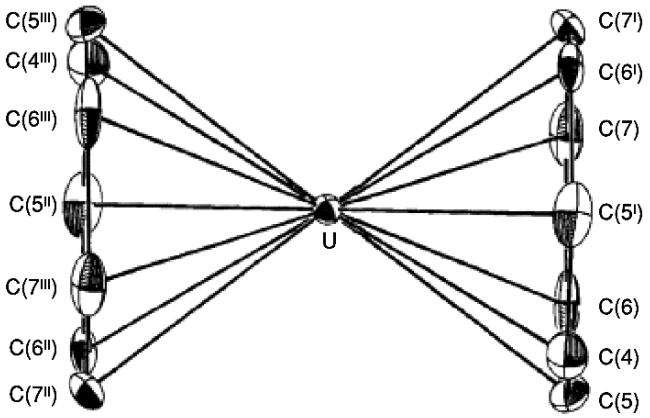

Fig. 25.27 *Molecular structure of* $[(\eta^7\text{-}C_7H_7)_2U]^-$ (*Arliguie* et al., 1995). (*Reproduced by permission of The Royal Society of Chemistry*.)

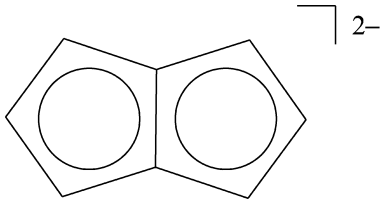
symmetry-appropriate 6d orbitals in stabilizing the ligand-based fragment orbitals. The 5f percentage in frontier e_2 molecular orbitals increases across the series, although not the energetic stabilization. The most important bonding interactions are shown in Fig. 25.28.

Although only one valence electron resides in a principally 5f localized orbital in the known uranium complex, a formal oxidation state of +3 ($5f^3$) was assigned to uranium, based on the fact that the $3e_2''$ molecular orbitals (occupied by four electrons) are nearly 50% 5f in character, and so two of these electrons were assigned to the metal. EPR and ENDOR studies of $[(\eta^7\text{-}C_7H_7)_2U]^-$ suggest that the complex could be treated as $5f^1$, with a ground state molecular orbital comprised of both $5f_\pi$ and $5f_\sigma$ orbitals (Gourier *et al*., 1998).

Although the cyclooctatetraenyl dianion has been extensively employed in actinide organometallic chemistry, another C8 ligand, the pentalene dianion ($C_8H_6^{2-}$) has been far less studied, due to the difficulty inherent in its preparation. The ligand may be considered to be derived from $C_8H_8^{2-}$ by removal of two hydrogen atoms with generation of a C–C bond to yield two fused five-membered rings.



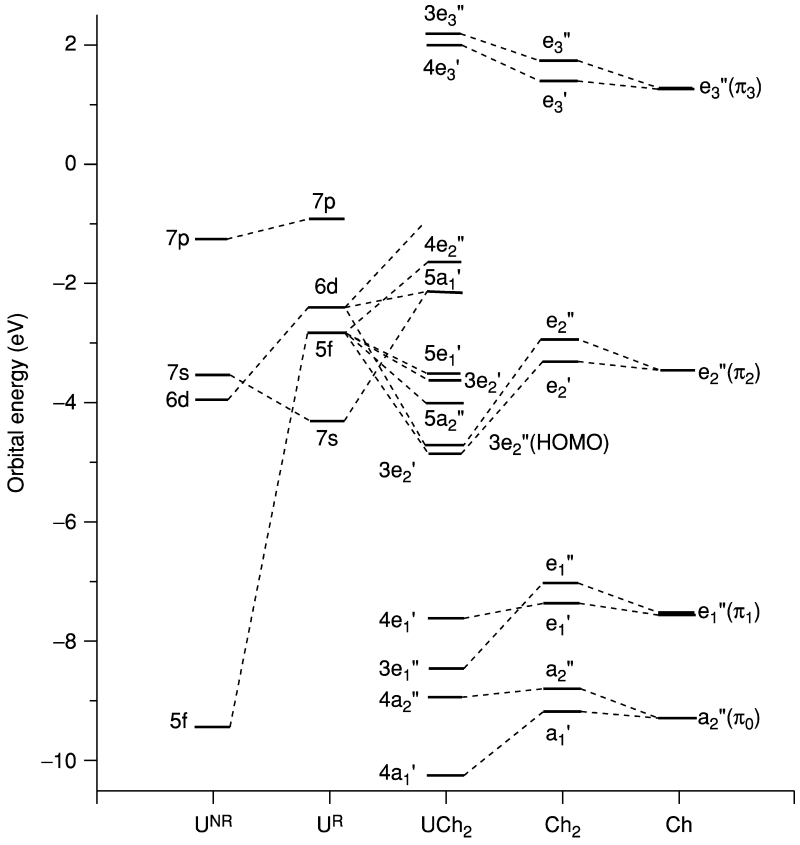


Fig. 25.28 *Bonding interactions in* $[(\eta^7\text{-}C_7H_7)_2U]^-$ *under* D_{7h} *symmetry.* U^{NR} *and* U^{R} *indicate atomic orbital energies at the nonrelativistic and relativistic levels, respectively.* $Ch = \eta^7\text{-}C_7H_7$. (*Reprinted with permission from Li and Bursten* (1997). *Copyright* 1997 *American Chemical Society.*)

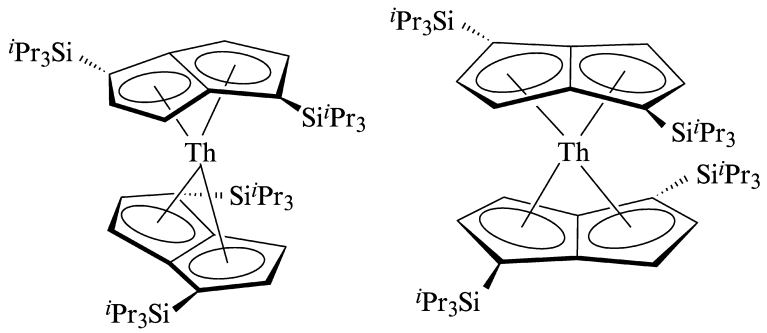
A substituted derivative of the pentalene ligand, $[1,5\text{-}(Si^iPr_3)_2C_8H_4]^{2-}$, has been employed to generate the neutral bis(ligand) uranium and thorium compounds $[\eta^8\text{-}1,5\text{-}(Si^iPr_3)_2C_8H_4]_2Th$ and $[\eta^8\text{-}1,5\text{-}(Si^iPr_3)_2C_8H_4]_2U$, which are rare examples of η^8-coordinated pentalene ligands (Cloke and Hitchcock, 1997; Cloke *et al.*, 1999). The molecular structure of the thorium compound revealed it to be a near-equal mixture of staggered and eclipsed sandwich isomers in a disordered structure. The two isomers are generated by thorium binding to two different prochiral faces of the ligand; as such the isomers are not found in NMR studies to interconvert on any timescale in solution.



The larger actinide ion accommodates a smaller bending, or 'folding' angle about the bridgehead C–C bond (24°, compared to 33° in a related tantalum compound). The Th–C_{ring} bond lengths vary from 2.543(10) to 2.908(11) Å. Photoelectron spectroscopy studies and density functional calculations present a consistent picture of the bonding in these complexes. Metal–ligand bonding takes place chiefly through four molecular orbitals with both 6d and 5f orbital involvement (although 6d orbitals again make a larger contribution); the uranium compound further houses two unpaired electrons in 5f-based orbitals. Both the f-ionization and the highest lying ligand orbitals have lower ionization energies than uranocene or $(\eta^5\text{-}C_5H_5)_4U$, suggesting that the pentalene dianion is a stronger donor ligand than other carbocyclic groups.

Among the largest discrete organometallic ligands that could be identified would be fullerenes, and many metal-encapsulated derivatives, or endometallofullerene complexes have been identified. The first reports of possible uranium encapsulation (Haufler *et al.*, 1990; Guo *et al.*, 1992) suggested that the principal products from laser vaporization experiments with graphite and UO_2 in a supersonic cluster beam apparatus included $U@C_{60}$ and the product of the unusually small cage $U@C_{28}$. XPS studies of the bulk product suggested a uranium valence of 4+ in the complex. A subsequent report identified $U@C_{60}$ and $U@C_{82}$ in the sublimed soot (Diener *et al.*, 1997). Most recently, metallofullerenes of uranium, neptunium, and americium have been produced via arc-discharge using a carbon rod containing lanthanum as a carrier with ^{237}U, ^{239}Np, and ^{240}Am as radiotracers (Akiyama *et al.*, 2001). The metallofullerenes were purified by CS_2 extraction and toluene HPLC elution. The dominant products identified for neptunium and americium were $An@C_{82}$. Two uranium-containing metallofullerenes were identified, $U@C_{82}$ and $U_2@C_{80}$. Based upon comparison with the optical spectra of lanthanide analogs, it was suggested that the oxidation state in these complexes might best be regarded as +3.

Electronic structure calculations have been carried out on $U@C_{60}$, $U@C_{28}$, and $Pa@C_{28}$ (Chang *et al.*, 1994; Zhao and Pitzer, 1996). The ground state of $Pa@C_{28}$ was found to have one electron in a cage π^* orbital, suggested a higher overall oxidation state for the metal. Similarly, $U@C_{28}$ had a $(\pi^*)^1(5f)^1$

diamagnetic ground state. In all cases, the complexes show extensive mixing of π-orbitals with both 6d and 5f orbitals, suggesting strong bonding.

25.2.4 Allyl, pentadienyl and related π-ligands

Allyl complexes with associated cyclopentadienyl ligands have been discussed previously. There are, however, several classes of complexes reported for thorium and uranium that contain allyl or other 'open' π-system ligands. Tetrakis (allyl) and substituted allyl complexes of thorium and uranium can be prepared by the reaction of the tetrachloride complexes with the appropriate Grignard reagent (Wilke *et al.*, 1966; Lugli *et al.*, 1969; Brunelli *et al.*, 1973), although they are thermally unstable and decompose at temperatures greater than –20°C [equation (25.89)].

$$AnCl_4 + 4C_3H_5MgX \longrightarrow \text{An(allyl)}_4 + 4MgXCl \qquad (25.89)$$

An = Th, U

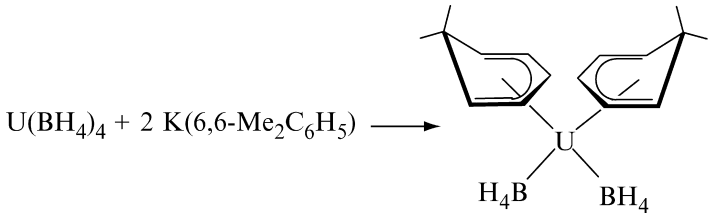
Mixed-ligand complexes are known to be somewhat more stable. As an example, the reaction of $(\eta^5\text{-}C_3H_5)_4U$ with aliphatic alcohols has been reported to generate the mixed-ligand complexes $[(\eta^5\text{-}C_3H_5)_2An(OR)_2]_2$ (Brunelli *et al.*, 1979); the structure of the isopropoxide derivative has been determined. The complex exists as a dimer in the solid state, with two bridging alkoxide ligands, although they are proposed to be monomeric in THF solution. The allyl ligands are bound trihapto, which is consistent with the proposed mode of coordination for allyl ligands in the homoleptic compounds, as determined by solution NMR studies. A further example is provided by the reaction of $(\eta^5\text{-}C_3H_5)_4U$ with 2,2′-bipyridine. The product generated is more thermally stable, likely due to the incorporation of three Lewis bases into the coordination sphere of the metal. It is proposed that this is made possible by the transfer of two of the allyl groups to one or more of the bipyridine ligands (Vanderhooft and Ernst, 1982).

A more stable 'open' π-system is provided by the pentadienyl ligand. Since pentadienyl complexes are generally considered to be more reactive than cyclopentadienyl ligands, it has often proven necessary to employ substituted derivatives. The 2,4-dimethylpentadienyl ligand was first used in the generation of a homoleptic compound of U(III) [equation (25.90)] (Cymbaluk *et al.*, 1983b).

$$UCl_3 \cdot n\text{THF} + 3K(2,4\text{-}Me_2C_5H_5) \longrightarrow \text{U(dienyl)}_3 + 3KCl \qquad (25.90)$$

The mixed-ligand complex [K(18-crown-6)][(η^5-2,4-$Me_2C_5H_5$)$_2$U(BH_4)$_2$] has been prepared either by reaction of (η^5-mesitylene)U(BH_4)$_3$ with K(2,4-$Me_2C_5H_5$), or by reaction of (η^5-2,4-$Me_2C_5H_5$)$_3$U with KBH_4 (Baudry *et al.*, 1989b). The reaction of (η^5-2,4-$Me_2C_5H_5$)$_3$U with [Et_3NH][BPh_4] has been reported to generate a cationic complex [(η^5-2,4-$Me_2C_5H_5$)$_2$U][BPh_4]. The tetravalent derivatives (η^5-2,4-$Me_2C_5H_5$)$_2$U(BH_4)$_2$ and (η^5-2,4-$Me_2C_5H_5$)U(BH_4)$_3$ have been generated by the reactions of (η^5-2,4-$Me_2C_5H_5$)$_3$U with $TlBH_4$ or U(BH_4)$_4$ with K(2,4-$Me_2C_5H_5$), respectively (Baudry *et al.*, 1989c).

Comparable reactions have also been carried out with the related 6,6-dimethylcyclohexadienyl ligand. Reaction of U(BH_4)$_4$ with K(6,6-$Me_2C_6H_5$) generates the bis(ligand) compound, (η^5-6,6-$Me_2C_6H_5$)$_2$U(BH_4)$_2$ as shown in equation (25.91) (Baudry *et al.*, 1990b).



(25.91)

In order to generate the mono(ligand) compound, (η^5-6,6-$Me_2C_6H_5$)U(BH_4)$_3$, it is necessary to react U(BH_4)$_4$ with (η^5-6,6-$Me_2C_6H_5$)$_2$U(BH_4)$_2$ in a ligand redistribution reaction (Baudry *et al.*, 1990b). The anionic compounds [K(18-crown-6)][(η^5-6,6-$Me_2C_6H_5$)$_2$UX_2] (X = Cl, BH_4) were synthesized by treatment of UCl_4 or (η^6-mesitylene)U(BH_4)$_3$ with K(6,6-$Me_2C_6H_5$).

Although no alkyne coordination complex of an actinide has been isolated, alkyne complexes have been proposed as intermediates in the catalytic dimerization of terminal alkynes by cationic amide complexes, based upon spectroscopic evidence (Wang *et al.*, 1999; Dash *et al.*, 2000).

25.2.5 Alkyl ligands

Early attempts to prepare homoleptic alkyl complexes of the actinides resulted only in the formation of organic decomposition products and uranium metal, suggesting thermal instability (Gilman, 1968). Various methods of steric stabilization have been employed to enhance the stability of alkyl complexes, including reactions designed to generate uranate complexes, and the introduction of ancillary bases to block the elimination reactions believed to occur during decomposition.

The reactions of uranium and thorium tetrachlorides with excess alkyllithium reagents yield isolable products [equations (25.92) and (25.93)] (Andersen *et al.*, 1975; Sigurdson and Wilkinson, 1977; Lauke *et al.*, 1984).

$$\begin{aligned} &UCl_4 + XS\,RLi \xrightarrow{xs\,L} [Li(L)_n]_2[UR_6] \\ &R = CH_3,\ C_6H_5,\ CH_2(SiMe_3)_2 \\ &L = Et_2O,\ THF,\ n = 4;\ L = TMEDA,\ n = 3.5 \end{aligned} \tag{25.92}$$

$$ThCl_4 + xs\,CH_3Li + xs\,TMEDA \longrightarrow [Li(TMEDA)]_3[TH(CH_3)_7] \cdot TMEDA + 4LiCl \tag{25.93}$$

While the uranium compounds are reported to decompose above room temperature, the thorium compound is stable for hours at room temperature, and the crystal structure has been determined. The thorium is hepta-coordinate, with a monocapped trigonal prismatic geometry. Six of the methyl groups also bridge to the three lithium counter-ions [Th–C = 2.667(8)–2.765(9) Å], while the seventh methyl group is terminal [Th–C = 2.571(9) Å].

The other proven route to stabilization of alkyl complexes involves the use of coordinating phosphines to sterically saturate the coordination sphere. The bis (1,2-dimethylphosphino)ethane (dmpe) complexes of uranium and thorium tetrachloride have been prepared; metathesis reactions with these precursors yield thermally stable alkyl complexes [equations (25.94) and (25.95)] (Edwards *et al.*, 1981, 1984):

$$\begin{aligned} &(dmpe)_2AnCl_4 + 4RLi \longrightarrow (dmpe)_2AnR_4 \\ &An = Th,\ U \\ &R = CH_3,\ CH_2C_6H_5 \end{aligned} \tag{25.94}$$

$$(dmpe)_2AnCl_4 + 3Li(CH_2C_6H_5) + LiCH_3 \longrightarrow (dmpe)_2An(CH_3)(CH_2C_6H_5)_3 \quad An = Th,\ U \tag{25.95}$$

The only neutral homoleptic actinide complex characterized to date is $U[CH(SiMe_3)_2]_3$, produced by the reaction of $U(O\text{-}2,6\text{-}{}^tBu_2C_6H_3)_3$ with $Li[CH(SiMe_3)_2]$ in hexane (Van Der Sluys *et al.*, 1989). The molecular structure is shown in Fig. 25.29.

Unlike comparable first-row transition metal tris(alkyl) complexes, the compound has a pyramidal geometry, with a C–U–C angle of 107.7(4)°, and a U–C bond distance of 2.48(2) Å. The complex is thermally stable in the solid state at room temperature, but decomposes with loss of alkane at temperatures greater than 60°C. Reaction of $UCl_3(THF)_x$ with three equivalents of $Li[CH(SiMe_3)_2]$ does not generate the neutral complex, but rather an ionic complex formulated as $[Li(THF)_3][(Cl)U\{CH(SiMe_3)_2\}_3]$. The neptunium and plutonium analogs $An[CH(SiMe_3)_2]_3$ have been reported (Zwick *et al.*, 1992), although not fully characterized.

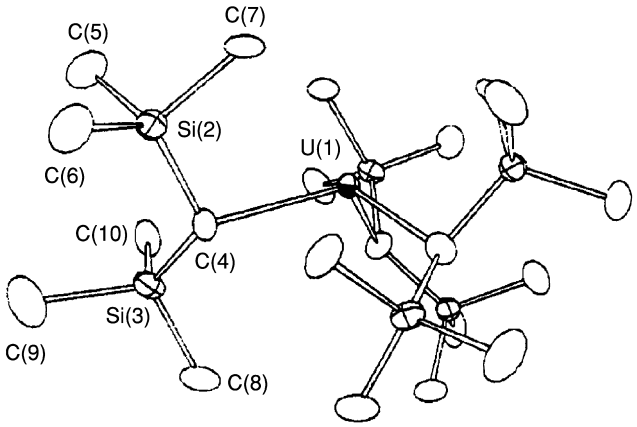


Fig. 25.29 *Molecular structure of* $[CH(SiMe_3)_2]_3U$. (*Reprinted with permission from Van Der Sluys* et al. (1989). *Copyright* 1989 *American Chemical Society*.)

25.3 HETEROATOM-CONTAINING π-ANCILLARY LIGANDS

25.3.1 Dicarbollide ligands

Although not strictly carbocyclic ligands, 1,2-dicarbollide groups ($C_2B_9H_{11}^{2-}$) have been employed as ancillary ligands in organoactinide chemistry, and deserve inclusion owing to their structural analogy to cyclopentadienyl groups. This ligand has been used in the synthesis of a number of mono- and bis-ligand analogs of cyclopentadienyl complexes. The first report of a dicarbollide complex was the generation of an anionic 'bent metallocene analog' [equation (25.96)] (Fronczek *et al.*, 1977).

$$UCl_4 + 2Li_2(C_2B_9H_{11}) \xrightarrow{\text{THF}} [Li(THF)_4]_2[(\eta^5\text{-}C_2B_9H_{11})_2UCl_2] + 2LiCl \tag{25.96}$$

The complex has a geometry analogous to a typical metallocene complex, with pentahapto dicarbollide ligands. The two carbons of the capping face could not be definitively distinguished, although a model was suggested that placed the carbon atoms closest to the coordinated chloride ligands. The U–B(C) bond distances range from 2.64(3) to 2.86(3) Å. The average value of 2.73(2) Å is similar to that found in typical U(IV) cyclopentadienyl complexes. A uranium(IV) dibromide analog has since been reported (Rabinovich *et al.*, 1996), as have thorium complexes $[Li(THF)_4]_2[(\eta^5\text{-}C_2B_9H_{11})_2ThX_2]$ (X = Cl, Br, I) (Rabinovich *et al.*, 1997). The uranium(IV) dibromide complex can be chemically reduced to generate a uranium(III) complex, $[Li(THF)_x]_2[(\eta^5\text{-}C_2B_9H_{11})_2UBr(THF)]$ (de Rege *et al.*, 1998). Trivalent mono-ligand complexes can also be generated by metathesis reactions with $UI_3(THF)_4$ [equation (25.97)]

(Rabinovich *et al.*, 1996):

$$UI_3(THF)_4 + 2Li_2(C_2B_9H_{11}) + TMEDA \xrightarrow{THF} [Li(TMEDA)][(\eta^5\text{-}C_2B_9H_{11})UI_2(THF)_2] + LiI \quad (25.97)$$

A single report has appeared on the complexation of uranium by another carborane anion [equation (25.98)] (Xie *et al.*, 1999).

$$UCl_3 + 12K + 4o\text{-}C_2B_{10}H_{12} \xrightarrow{THF} [\{K_2(THF)_5\}\{(\eta^7\text{-}C_2B_{10}H_{12})(\eta^6\text{-}C_2B_{10}H_{12})U\}]_2 + 8KCl \quad (25.98)$$

25.3.2 Phospholyl ligands

The closest π-ligand analogs to cyclopentadienyl groups in this class are phosphole compounds and their derivatives. Of these potential ligands, the tetramethylphospholyl group has been employed to generate actinide complexes. The initial report involved introduction of the phospholyl ligand to the metal center by metathesis [equations (25.99) and (25.100)] (Gradoz *et al.*, 1992a):

$$U(BH_4)_4 + 2K(Me_4C_4P) \longrightarrow (\eta^5\text{-}Me_4C_4P)_2U(BH_4)_2 \quad (25.99)$$

$$U(BH_4)_4 + K(Me_4C_4P) \longrightarrow (\eta^5\text{-}Me_4C_4P)U(BH_4)_3 \quad (25.100)$$

Reduction of these complexes in THF by sodium amalgam affords trivalent uranate anions. Reaction of trivalent uranium precursors with the phospholyl salt also yields the uranate species. The molecular structure of the U(IV) product $(\eta^5\text{-}Me_4C_4P)_2U(BH_4)_2$ has been described and is presented in Fig. 25.30 (Baudry *et al.*, 1990c).

The complex is structurally very similar to a bis(cyclopentadienyl) metallocene. The phospholyl ring remains planar upon coordination to the uranium center, and coordinates in a pentahapto manner. The average metal–carbon bond distance is 2.81(4) Å, comparable to that found in U(IV) metallocene complexes, and the U–P distance is 2.905(8) Å. The complex $(\eta^5\text{-}Me_4C_4P)_2UCl_2$ was subsequently generated from the reaction of UCl_4 with the potassium salt of the phospholyl (Gradoz *et al.*, 1994a).

The tris(phospholyl) complexes have been produced from uranium tetrachloride [equation (25.101)] (Gradoz *et al.*, 1992b):

$$UCl_4 + 3K(Me_4C_4P) \longrightarrow (\eta^5\text{-}Me_4C_4P)_3UCl + 3KCl \quad (25.101)$$

The chloride may be further substituted to generate alkyl, hydrido, and alkoxide species.

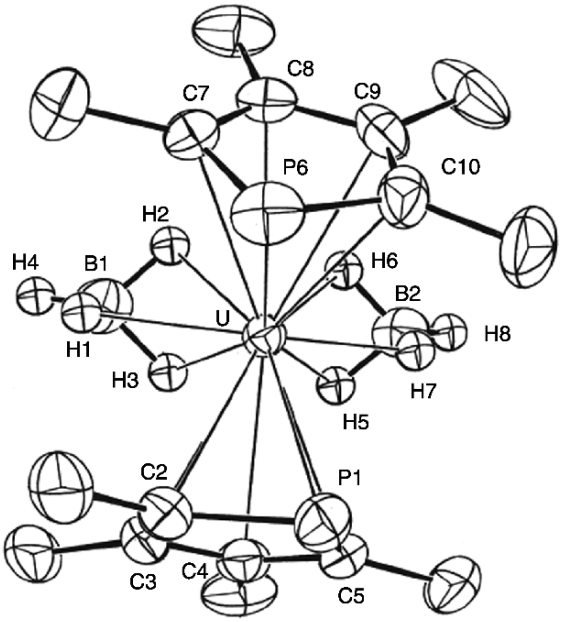

Fig. 25.30 *Molecular structure of* $(\eta^5\text{-}Me_4C_4P)_2U(BH_4)_2$ (*Baudry* et al., 1990*c*). (*Reprinted with permission from John Wiley & Sons, Inc.*)

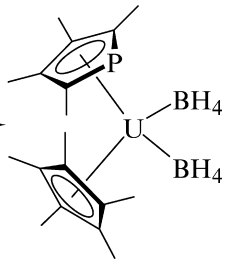
Mono-ring complexes of the formula $(\eta^5\text{-}Me_4C_4P)UCl_3(DME)$ and $(\eta^5\text{-}Me_4C_4P)UCl_3(THF)_2$ are prepared by the reaction of UCl_4 and $K(Me_4C_4P)$ in the appropriate solvent (Gradoz *et al.*, 1994a). It is the borohydride derivative $(\eta^5\text{-}Me_4C_4P)U(BH_4)_3$ and its pentamethylcyclopentadienyl analog $(\eta^5\text{-}C_5Me_5)U(BH_4)_3$ that serve as reagents in most reported subsequent metathesis reactions as illustrated in equation (25.102) for the preparation of the mixed-ring complex $(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}Me_4C_4P)U(BH_4)_2$:

$$(\eta^5\text{-}C_5Me_5)U(BH_5)_3 + K(Me_4C_4P) \longrightarrow \quad (25.102)$$



The complexes $(\eta^5\text{-}Me_4C_4P)_2U(BH_4)_2$, $(\eta^5\text{-}Me_4C_4P)U(BH_4)_3$, and $(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}Me_4C_4P)U(BH_4)_2$ serve as precursors for a number of alkyl and alkoxide derivatives (R = Me, CH_2SiMe_3, OEt, O^{i}Pr, and O^{t}Bu).

The mixed-ring compounds $(\eta^8\text{-}C_8H_8)(\eta^5\text{-}Me_4C_4P)U(BH_4)(THF)$ and $K[(\eta^8\text{-}C_8H_8)(\eta\text{-}Me_4C_4P)_2U(BH_4)(THF)_x]$ can be generated by the reaction of

(η^8-C_8H_8)U(BH_4)$_2$(THF) or [(η^8-C_8H_8)U(BH_4)(THF)$_2$][BPh_4], respectively, with K(Me_4C_4P). The cationic complex [(η^8-C_8H_8)U(η^5-Me_4C_4P)(HMPA)$_2$][BPh_4] is isolated from the reaction of [(η^8-C_8H_8)U(HMPA)$_3$][BPh_4] with the potassium phospholyl salt (Cendrowski-Guillaume *et al.*, 2002).

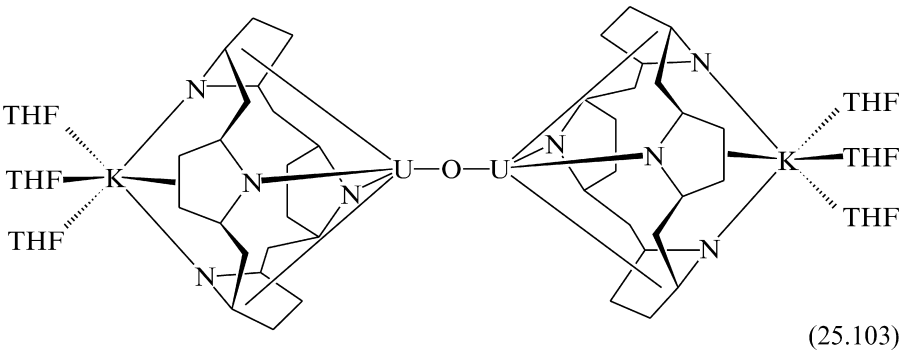
The dimeric trivalent compound [(η^5-Me_4C_4P)(μ,η^5,η^1-Me_4C_4P)U(BH_4)]$_2$ constitutes a rare example of a dimeric phospholyl complex, in which each phospholyl ligand phosphorus atom serves as a donor to the other uranium atom (Gradoz *et al.*, 1994b). The molecular structure of the complex reveals pseudo-tetrahedral uranium coordination, with the borohydride ligands on the same side of the U_2P_2 plane (Fig. 25.31).

The metrical data indicate no apparent strain introduced by the dimer formation; U-ring atom bond distances and centroid-metal-centroid angles are not significantly distorted from the values found for (η^5-Me_4C_4P)$_2$U(BH_4)$_2$ [U–C_{ave} = 2.84(3) Å, U–P_{ave} = 2.970(3) Å] (Fig. 25.30). The bridging P→U distance is 2.996(3) Å. Although it has been suggested that the phosphorus lone pair of the phospholyl group should lie in the ring plane, the P→U-ring centroid angle in this complex is 159.0(3)°, suggesting that U_2P_2 'ring closure' imposes a steric requirement for bending about the donor phosphorus atom.

25.3.3 Pyrrole-based ligands

The nitrogen-based analog, the pyrrole ligand, has not been found by itself to support pentahapto coordination to actinide centers, presumably due to the relative 'hard' basic character of the nitrogen in the heterocycle. Examples of (η^5-C_4N) coordination may instead be found in the reaction products of uranium halides with the tetraanion of the macrocycle [{(–CH_2–)$_5$}$_4$-calix[4]tetrapyrrole] (Korobkov *et al.*, 2001a). As described in equation (25.103), the reaction of $UI_3(THF)_4$ with the potassium salt of the tetrapyrrolide in THF generates a dinuclear U(IV) complex, [{[{(–CH_2–)$_5$}$_4$-calix[4]tetrapyrrole]UK(THF)$_3$}$_2$(μ-O)]·2THF; the oxo group is proposed to come from deoxygenation of a THF molecule.

$UI_3(THF)_4$ + [$K(THF)_4$] [calix-[4]-tetrapyrrole] ⟶



(25.103)

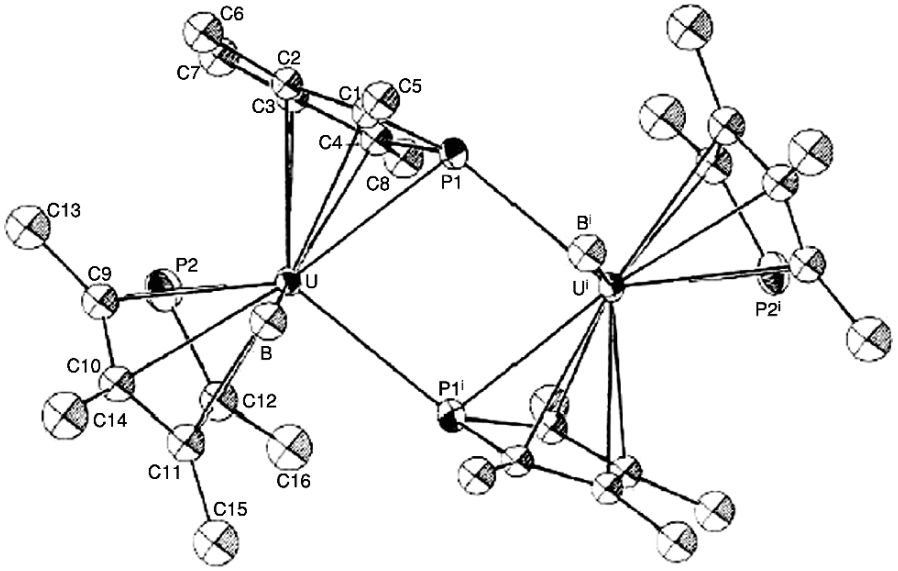


Fig. 25.31 *Molecular structure of* $[(\eta^5\text{-}Me_4C_4P)(\mu\eta^5\eta^1\text{-}Me_4C_4P)U(BH_4)]_2$. *The H atoms of the* BH_4 *ligand have been omitted for clarity* (*Gradoz* et al., 1994b). (*Reprinted with permission from Elsevier*.)

Reaction of $UI_3(THF)_4$ with the corresponding lithium tetrapyrrolide salt in a 1:2 ratio generates instead $[\{[(-CH_2-)_5]_4\text{-calix[4]tetrapyrrole}\}ULi(THF)_2]_2 \cdot$ hexane, in which the β-carbon of one of the pyrrole rings has undergone a metallation reaction (Fig. 25.32).

Reaction of the potassium salt with $UI_3(DME)_4$ avoids the complication of THF activation, and the simple trivalent uranate complex, $[\{[(-CH_2-)_5]_4\text{-calix[4]tetrapyrrole}\}U(DME)][K(DME)]$, is generated. The geometry about the metal center in these compounds is qualitatively similar to a metallocene complex. The ligand adopts a σ/π-bonding mode, in which two of the four pyrrole rings in the macrocycle are η^5-bonded to the uranium, and the other two rings are σ-coordinated only through the pyrrole nitrogen. The U–N (σ) bond lengths for the tetravalent derivatives range from 2.39 to 2.47 Å; these distances are slightly longer in the trivalent derivative (*ca*. 2.53 Å). The π-coordination of the pyrrole ring yields somewhat longer U–N bond distances (*ca*. 2.65 Å in tetravalent compounds, 2.74 Å in the trivalent compound), and $U-C_{pyrrole}$ bond distances that range from 2.68 to 2.88 Å.

Reaction of $UI_3(THF)_4$ with $[Li(THF)]_4\{[(-CH_2-)_5]_4\text{-calix[4]tetrapyrrole}\}$ in a substoichiometric (2:1) ratio generates the dinuclear complex $[Li(THF)_4]_2[U_2I_4\{[(-CH_2-)_5]_4\text{-calix[4]-tetrapyrrole}\}]$ (Fig. 25.33) in moderate yield (Korobkov *et al*., 2001b).

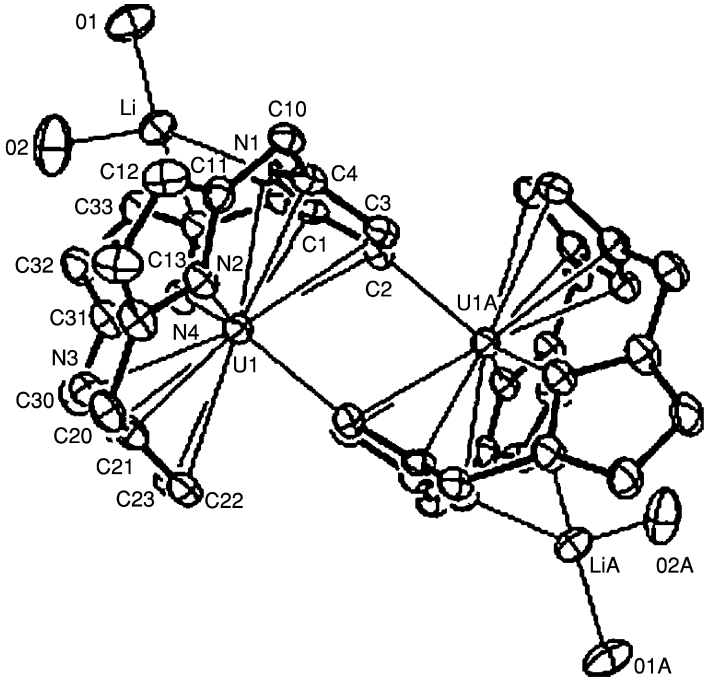

Fig. 25.32 *Molecular structure of* [{(–CH_2–)$_4$-*calix*[4]-*pyrrole*}*ULi*(*THF*)$_2$]$_2$. (*Reprinted with permission from Korobkov* et al. (2001*a*). *Copyright* 2001 *American Chemical Society*.)

Partial reduction of UCl_4, followed by reaction with one half of an equivalent of the lithium salt is reported to generate the mixed-valence compound [Li(THF)$_2$](μ-Cl)$_2${U$_2$[(–CH_2–)$_5$]$_4$-calix[4]tetrapyrrole}Cl$_2$·THF. Both of these complexes display alternate σ/η^5, π-coordination to opposite pairs of pyrrole ligands in a single tetrapyrrole group. The bridging nature of the macrocyclic ligand brings the uranium centers into relatively close proximity (3.4560(8) and 3.365(6) Å, respectively); magnetic susceptibility measurements on the U(III)/U(III) dimer suggests weak antiferromagnetic coupling occurs between metal centers.

25.3.4 Other nitrogen-containing π-ligands

Amidinate ligands have been employed as ancillary ligands in the generation of organometallic compounds of tetravalent uranium and thorium, as well as complexes with the uranyl ion. Reaction of Li[N(SiMe$_3$)$_2$] and Na[N(SiMe$_3$)$_2$] with *para*-substituted benzonitriles yields the benzamidinate ligands M[4-RC$_6$H$_4$C(NSiMe$_3$)$_2$] (M = Li, Na; R = H, Me, OMe, CF$_3$).

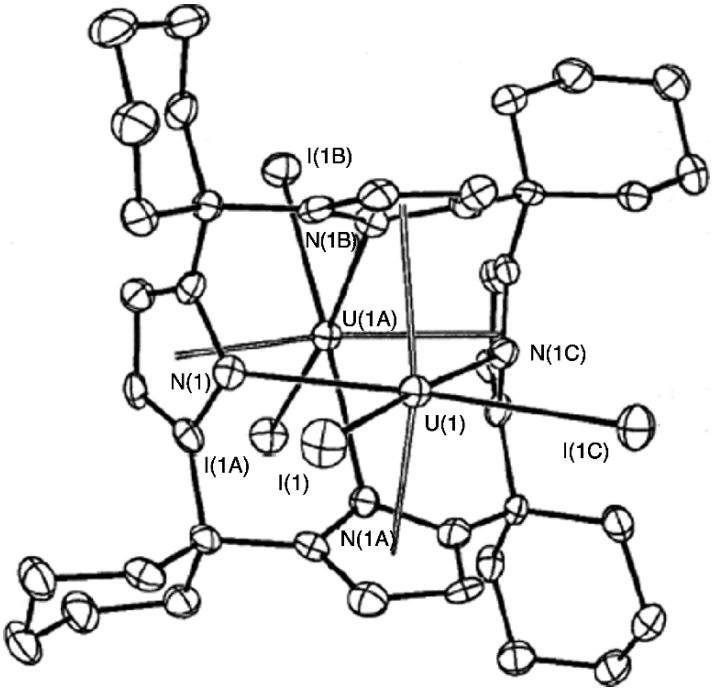

Fig. 25.33 *Molecular structure of* $[Li(THF)_4]_2[U_2I_4\{[(-CH_2-)_5]_4$-*calix*[4]-*tetrapyrrole*$\}]$. (*Reprinted with permission from Korobkov* et al. (2001b). *Copyright* 2001 *American Chemical Society*.)

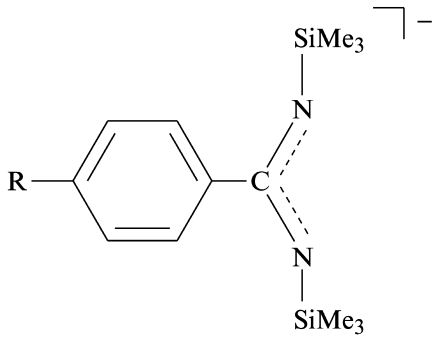
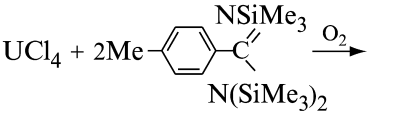
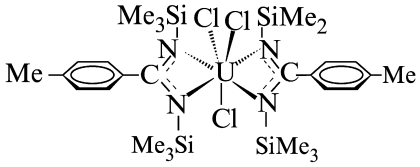


Alternatively, more substituted ligands $Li[2,4,6\text{-}R_3C_6H_2C(NSiMe_3)_2]$ (R = CF_3, Me) are generated by the addition of aryllithium reagents to $Me_3SiN{=}C{=}NSiMe_3$. The amidinate ligands (L) have been used to generate complexes of the formula L_2AnCl_2 (An = Th, U) and L_3AnCl (for less

sterically demanding substituents) by metathesis reactions (Wedler *et al.*, 1990). Substitution of the halide precursors has been reported to generate methyl and borohydride derivatives (Wedler *et al.*, 1992a). The molecular structure of the complex $[C_6H_5C(NSiMe_3)_2]_3UMe$ has been determined. The benzamidinate ligands coordinate to the metal center in a η^3-manner; the relatively long U–C σ bond of 2.498(5) Å is taken as an indication of steric crowding in the complex.

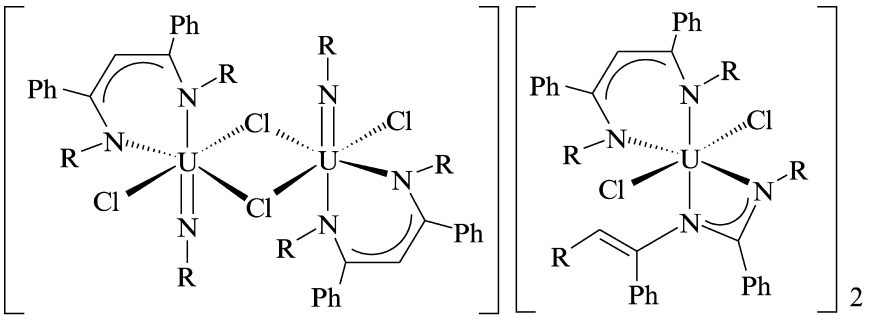
The benzamidinate ligands have been found to support a range of oxidation states in uranium chemistry. The uranyl complex $[C_6H_5C(NSiMe_3)_2]_2UO_2$ complex was prepared by a metathesis reaction with UO_2Cl_2 (Wedler *et al.*, 1988), and the interesting pentavalent derivative $[4\text{-}MeC_6H_4C(NSiMe_3)_2]_2UCl_3$ was produced by adventitious aerobic oxidation during reaction of UCl_4 with the corresponding silylated benzimidine [equation (25.104)] (Wedler *et al.*, 1992b).





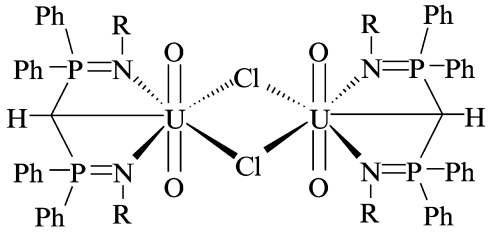
(25.104)

Related amidinate and 1-aza-allyl ligands also have been shown to generate bis(ligand)thorium dichloride complexes (Hitchcock *et al.*, 1997), as well as an interesting mixed-valence U(III)/U(VI) complex (Hitchcock *et al.*, 1995).



R = $SiMe_3$; Ph = C_6H_5

A rare example of a U–C interaction in hexavalent actinide chemistry is found in the isolation of a bis(iminophosphorano)methanide uranyl complex (Sarsfield *et al.*, 2002). Reaction of $[UO_2Cl_2(THF)_2]_2$ with $Na[CH(Ph_2P{=}NSiMe_3)_2]$ generates the dimer $[UO_2(\mu\text{-}Cl)\{CH(Ph_2P{=}NSiMe_3)_2\}]_2$.



R = $SiMe_3$

The U–C distance is 2.691(8) Å; the length indicates a very weak interaction, although it falls within the sum of the van der Waals radii of the two atoms.

25.4 HETEROATOM-BASED ANCILLARY LIGANDS

Although complexes containing primarily heteroatom-donor ligands are less likely to be regarded as organometallic species, these ligands are playing an increasing important role in the development of non-aqueous f-element chemistry. The flexible steric and electronic characteristics of these ligands can stabilize unusual oxidation states and promote novel substrate activation reactions at actinide centers, making their study more attractive. Although not all 'inorganometallic' chemistry will be comprehensively reviewed here, discussion is warranted for certain classes of ligands that have played a significant role in the development of non-aqueous actinide chemistry.

25.4.1 Bis(trimethylsilyl)amide

As an ancilliary ligand, the bis(trimethylsilyl)amide ligand $[N(SiMe_3)_2]^-$ has been shown to support a wide array of oxidation states of uranium. It has further been used in tetravalent actinide chemistry (An = U, Th) to support metal centers that can effect a number of organic transformations.

Trivalent homoleptic complexes $[(SiMe_3)_2N]_3An$ have been prepared for uranium, neptunium, and plutonium (Andersen, 1979; Clark *et al.*, 1989; Zwick *et al.*, 1992) by metathesis reactions [equations (25.105) and (25.106)].

$$UCl_3 \cdot (THF)_x + 3Na[N(SiMe_3)_2] \xrightarrow{THF} [(SiMe_3)_2N]_3U \qquad (25.105)$$

$$AnI_3(THF)_4 + 3Na[N(SiMe_3)_2] \xrightarrow{THF} [(SiMe_3)_2N]_3An \qquad (25.106)$$
$$An = U, Np, Pu$$

The molecular structure of $[(SiMe_3)_2N]_3U$ has been determined (Stewart and Andersen, 1998). The geometry about the uranium center is trigonal pyramidal, with a U–N distance of 2.320(4) Å, and a N–U–N angle of 116.24(7)°. The

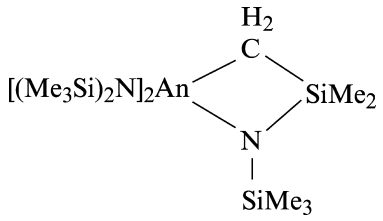
magnetic susceptibility shows that the complex has effective moments comparable to those determined for trivalent metallocenes and halides ($\mu_{eff} = 3.354(4)$, $\theta = -13$ K at 5 kG), consistent with a $5f^3$ electronic configuration. This is confirmed by the photoelectron spectroscopy, which demonstrates a low-energy 5f ionization band (Green *et al.*, 1982). The steric congestion about the metal center prohibits isolation of stable base coordination compounds.

Tetravalent complexes of the formula $[(SiMe_3)_2N]_3AnCl$ (An = Th, U) have been prepared (Turner *et al.*, 1979a) from the 3:1 reaction of $NaN(SiMe_3)_2$ with $AnCl_4$ [(equation (25.107)], and the complex $[(SiMe_3)_2N]_2UCl_2(DME)$ can be generated from a 2:1 reaction of ligand:halide salt (McCullough *et al.*, 1981).

$$AnCl_4 + 3Na[N(SiMe_3)_2] \xrightarrow{THF} [(SiMe_3)_2N]_3An-Cl \quad (25.107)$$
$$An = Th, U$$

Substituted complexes of the formula $[(SiMe_3)_2N]_3AnR$ (An = Th, U; R = Me, Et, ^{i}Pr, Bu, BH_4) are formed by the reaction of $[(SiMe_3)_2N]_3AnCl$ with the appropriate lithium or magnesium reagent (Turner *et al.*, 1979a; Dormond *et al.*, 1988). Unlike comparable cyclopentadienyl analogs, the methyl compound does not undergo ready insertion of CO, although a number of other insertion and protonation reactions have been reported, including insertion of ketones, aldehydes, isocyanides, and aliphatic nitriles (Dormond *et al.*, 1987b, 1988). The methyl ligand is further susceptible to removal by protic reagents such as secondary amines.

The hydride compounds $[(SiMe_3)_2N]_3AnH$ (An = Th, U) are the sole products of attempts to introduce an additional equivalent of the bis(trimethylsilyl) amide ligand to $[(SiMe_3)_2N]_3AnCl$ (Turner *et al.*, 1979b). Pyrolysis of the hydride results in the loss of dihydrogen and the formation of an unusual metallacycle (Simpson and Andersen, 1981a).



The metallacycles of uranium and thorium have been shown to undergo a large number of insertion and protonation reactions (Simpson and Andersen, 1981b; Dormond *et al.*, 1985, 1986a,b, 1987a,b, 1989a,b; Baudry *et al.*, 1995), as shown in Fig. 25.34.

In some cases these reactions (such as reduction of carbonyl-containing organic compounds) have been found to be stereoselective.

As in the case of substituted cyclopentadienyl complexes, the bis(trimethylsilyl)amide ligand is capable of supporting the formation of organoimido

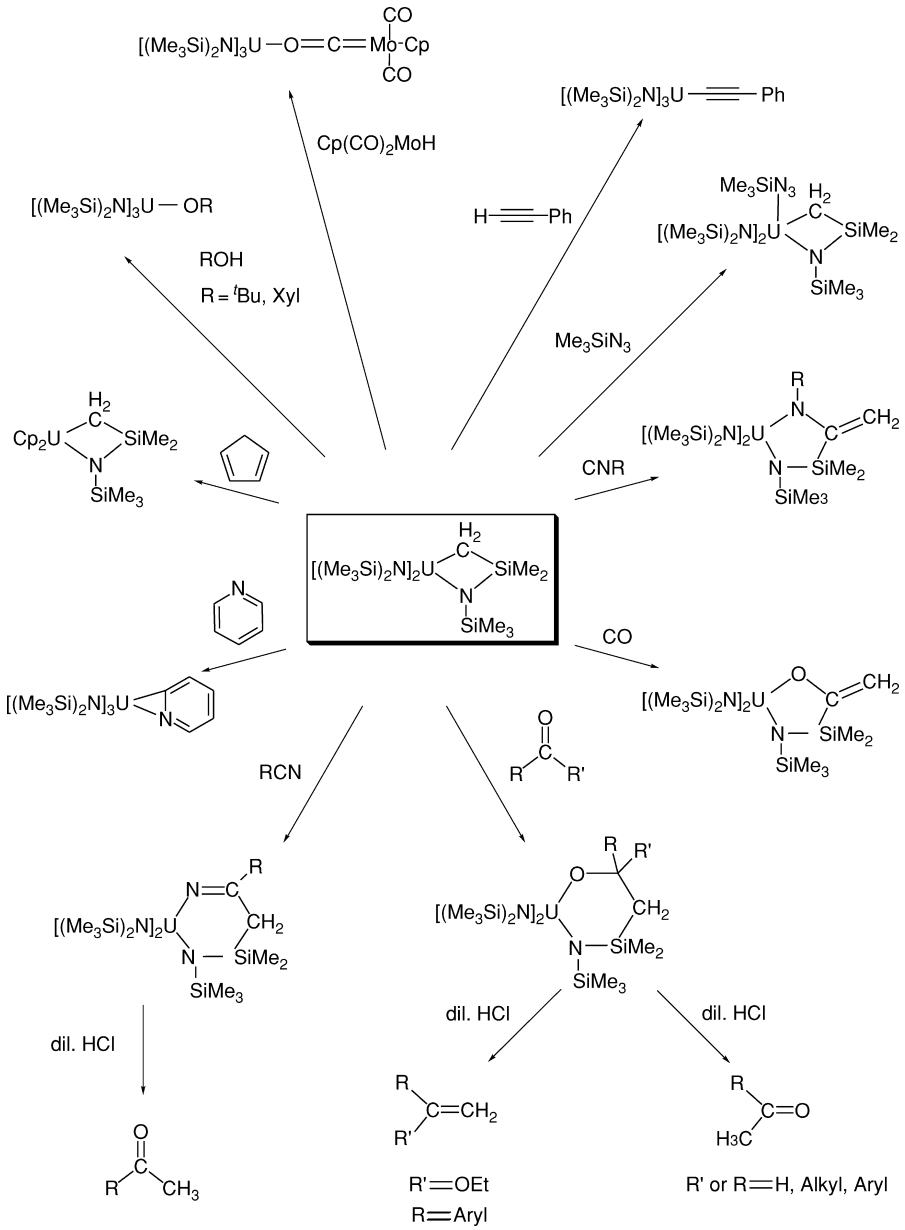


Fig. 25.34 *Reactions of uranium metallacycle.*

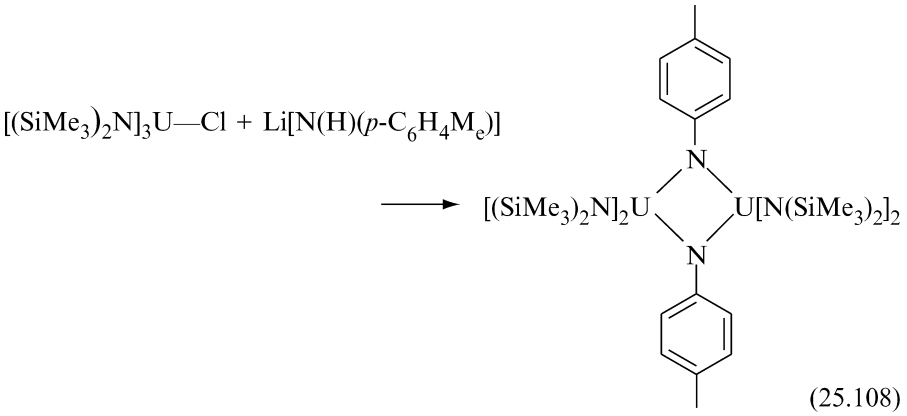
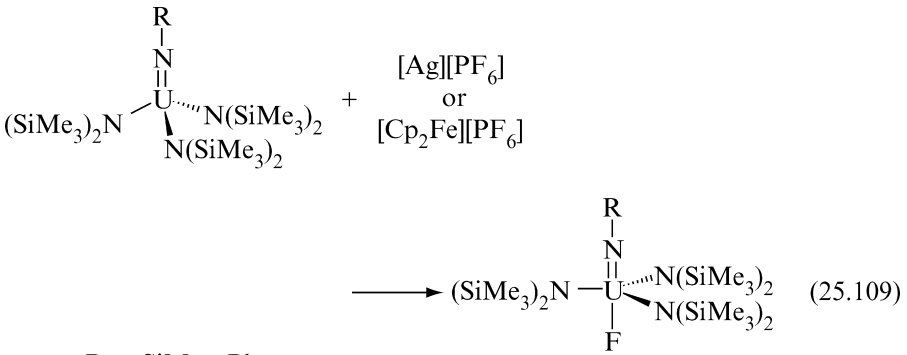
complexes. The tetravalent uranium dimer $[\{(SiMe_3)_2N\}_2U(\mu\text{-}N\text{-}p\text{-}C_6H_4Me)]_2$ was prepared by reaction of $[(SiMe_3)_2N]_3UCl$ with $Li[N(H)(p\text{-}C_6H_4Me)]$ [equation (25.108)] (Stewart and Andersen, 1995), presumably by α-elimination of $HN(SiMe_3)_2$ from an intermediate amide complex:



(25.108)

As in the case of the related cyclopentadienyl compound, the arylimido ligand bridges the two metal centers in an asymmetric fashion, with U–N bond distances of 2.378(3) and 2.172(2) Å.

Reaction of $[(SiMe_3)_2N]_3U$ with Me_3SiN_3 generates the uranium(V) organoimido complex $[(Me_3Si)_2N]_3U(=NSiMe_3)$ (Zalkin *et al.*, 1988b). Both this and the related phenylimido complex are oxidized by mild oxidants such as $AgPF_6$ or $[Cp_2Fe][PF_6]$ to generate the U(VI) imido fluoride complexes $[(Me_3Si)_2N]_3U(=NR)F$ (R = $SiMe_3$, Ph) as shown in equation (25.109) (Burns *et al.*, 1990).



(25.109)

R = $SiMe_3$, Ph

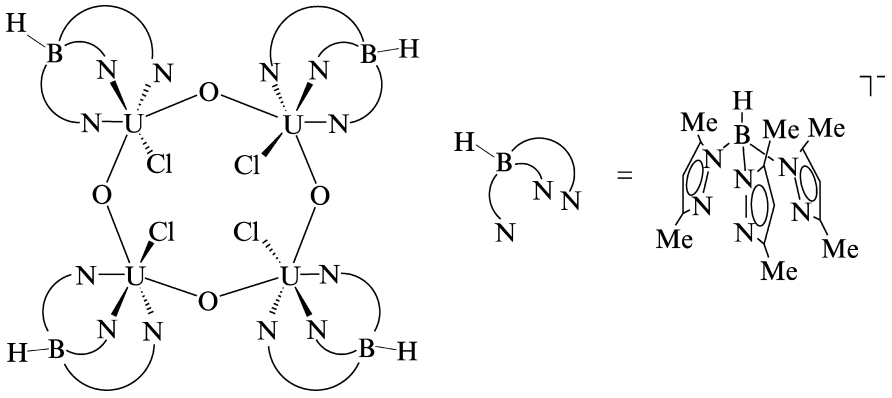
Both U(VI) complexes are trigonal bipyramidal with the bis(trimethylsilyl) amido groups occupying the equatorial positions. The F–U–N_{imido} angles are near linear, as are the U–N–Si(C) angles. The U=N_{imido} bond lengths are 1.85 (2) and 1.979(8) Å, respectively, for the silylimido and phenylimido complexes.

25.4.2 Pyrazolylborate

Monoanionic poly(pyrazolyl)borate ligands ($B(pz)_4^-$, $HB(pz)_3^-$, $H_2B(pz)_2^-$, and substituted derivatives, pz = pyrazol-1-yl) have found broad application as ancillary ligands in d-transition metal chemistry as substitutes for cyclopentadienyl ligands (Trofimenko, 1993). Their σ-donor strength is comparable to that of a cyclopentadienyl ligand, although the precise ordering depends on the metal (Tellers *et al.*, 2000). These ligands most commonly bind to f-elements in either a trihapto or dihapto geometry through nitrogen atoms in the pyrazolyl substituents.

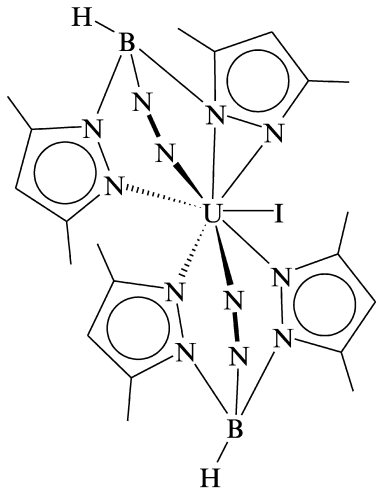
The first report of an actinide complex employing a poly(pyrazolyl)borate ligand was the preparation of complexes of the formula $[H_2B(pz)_2]_4U$, $[HB(pz)_3]_4U$, and $[HB(pz)_3]_2UCl_2$ by reaction of UCl_4 with the potassium salt of the appropriate ligand (Bagnall *et al.*, 1975). On the basis of ^{13}C NMR spectroscopy, the $HB(pz)_3$ ligands were assigned as bidentate in the complex $[HB(pz)_3]_2UCl_2$, while the complex $[HB(pz)_3]_4U$ was speculated to have two bidentate and two tridentate ligands (Bagnall *et al.*, 1976).

Since the initial identification of these compounds, the chemistry of poly(pyrazolyl)borate ligands has expanded to include representatives involving trivalent actinides, most encompassing the substituted ligand $HB(3,5\text{-}Me_2pz)_3$. The complex $[HB(3,5\text{-}Me_2pz)_3]UCl_2$ has been generated either by metathesis reaction of UCl_3 with $K[HB(3,5\text{-}Me_2pz)_3]$ (Santos *et al.*, 1985, 1986) or reduction of the U(IV) precursor $[HB(3,5\text{-}Me_2pz)_3]UCl_3$ with sodium naphthalenide (Santos *et al.*, 1987). The complex is somewhat unstable, and upon recrystallization can be oxidized to generate the tetravalent oxo complex $[\{HB(3,5\text{-}Me_2pz)_3\}UCl(\mu\text{-}O)]_4$ (Domingos *et al.*, 1992a).



Recently, the use of uranium triiodide has become more common in the synthesis of trivalent complexes. Reaction of $UI_3(THF)_4$ with $M[HB(3,5\text{-}Me_2pz)_3]$ (M = Na, K) in a 1:1 or 1:2 ratio results in the formation of the compounds $[HB(3,5\text{-}Me_2pz)_3]UI_2(THF)_2$ and $[HB(3,5\text{-}Me_2pz)_3]_2UI$, respectively (McDonald *et al.*, 1994; Sun *et al.*, 1994). In the monoligand compound,

the pyrazolylborate ligand is tridentate, while the bis(ligand) compound demonstrates two different coordination modes for the two [$HB(3,5\text{-}Me_2pz)_3$] groups.



One of the ligands is η^3-coordinated to the metal center, while in the second ligand, one of the pyrazolyl rings appears to coordinate in a 'side-on' type of arrangement with the N–N bond of the ring within a bonding distance to the uranium atom. Upon abstraction of the iodide ligand with $TlBPh_4$, however, this ligand reverts to a conventional tridentate geometry; the uranium center is seven-coordinate in $[\{HB(3,5\text{-}Me_2pz)_3\}_2U(THF)]^+$, with the tetrahydrofuran ligand occupying the seventh site (McDonald *et al.*, 1994).

A limited number of U(III) complexes have been reported with other pyrazolylborate ligands. Uranium trichloride or triiodide reacts with the bis(pyrazolyl) borate ligands $H_2B(3,5\text{-}Me_2pz)_2$ and $H_2B(pz)_2$ to generate the species $[H(\mu\text{-}H)B(3,5\text{-}Me_2pz)_2]_3U$ and $[H(\mu\text{-}H)B(pz)_2]_3U(THF)$ (Carvalho *et al.*, 1992; Sun *et al.*, 1995). The coordinated tetrahydrofuran may be removed from the latter to yield the base-free complex $[H(\mu\text{-}H)B(pz)_2]_3U$. The solid state structure of $[H(\mu\text{-}H)B(3,5\text{-}Me_2pz)_2]_3U$ reveals that the metal lies in a trigonal prismatic arrangement of six pyrazole nitrogen atoms, with the three rectangular faces of the trigonal prism capped by three B–H bonds (Fig. 25.35).

When a related ligand devoid of B–H bonds is employed ($Ph_2B(pz)_2$), the resulting tris(ligand) complex $[Ph_2B(pz)_2]_3U$ contains a six-coordinate uranium center (Maria *et al.*, 1999). The lower coordination number is considered to be the origin of slightly shorter U–N bond distances (2.53(3) Å versus 2.59(3) or 2.58(3) Å in the ten- and nine-coordinate complexes, respectively). A mixed-alkyl substituted bis(pyrazolyl)borate complex has been produced by the reaction of $UI_3(THF)_4$ with $K[H_2B(3\text{-}^t\!Bu,5\text{-}Mepz)_2]$. The complex $[H_2B(3\text{-}^t\!Bu,5\text{-}Mepz)_2]UI_2(THF)_2$ reacts with $Ph_3P{=}O$ to yield the base adduct $[H_2B(3\text{-}^t\!Bu,5\text{-}Mepz)_2]UI_2(O{=}PPh_3)_2$ (Maria *et al.*, 1999).

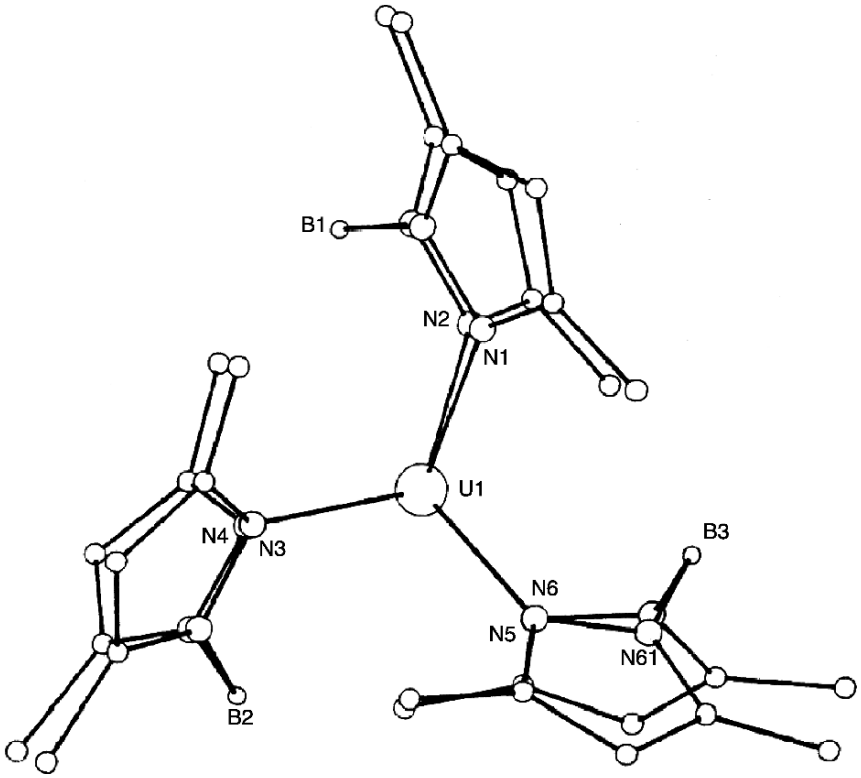


Fig. 25.35 *Molecular structure of* $[H(\mu\text{-}H)B(3,5\text{-}Me_2pz)_2]_3U$. *The PLUTO view is in the plane of one of the triangular faces of the trigonal prism* (*Carvalho* et al., 1992). (*Reprinted with permission from Elsevier.*)

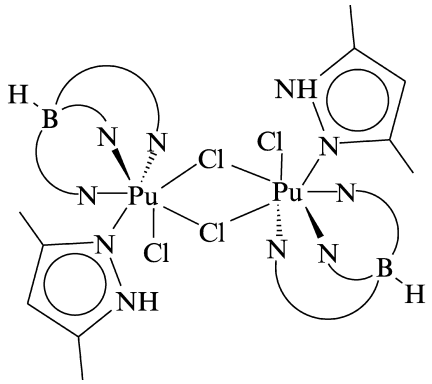
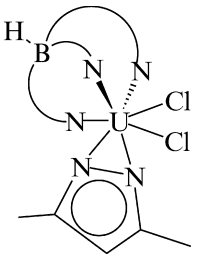
Only one complex of a trivalent transuranic metal has been reported; reaction of $PuCl_3$ with $K[HB(3,5\text{-}Me_2pz)_3]$ in refluxing THF generates the dimeric complex $[PuCl(\mu\text{-}Cl)\{HB(3,5\text{-}Me_2pz)_3\}(3,5\text{-}Me_2pzH)]_2$ (Apostolidis *et al.*, 1991, 1998).



The chemistry of tetravalent actinides with poly(pyrazolyl)borates has been explored more extensively. The first report of metathesis reactions with thorium involved the preparation of the compounds $[HB(pz)_3]_{4-n}ThX_n$ ($n = 2$, X = Cl, Br; $n = 1$, X = Cl), $[HB(3,5\text{-}Me_2pz)_3]_2ThCl_2$, $[B(pz)_4]_2ThBr_2$, and base adducts of the complexes $[HB(pz)_3]ThCl_3$ and $[HB(pz)_3]_4Th$ (Bagnall *et al.*, 1978b), although subsequent reports have appeared describing other derivatives, including $[HB(3,5\text{-}Me_2pz)_3]ThCl_3$ (Ball *et al.*, 1987). The larger ionic radius of thorium enables higher coordination numbers; unlike the uranium complexes, the thorium derivatives $[HB(pz)_3]_2ThX_2$ (X = Cl, Br) were shown spectoscopically to possess tridentate pyrazolylborate ligands.

Several routes have been identified to produce $[HB(pz)_3]_2UI_2$, including reaction of UI_4 with two equivalents of $K[HB(pz)_3]$ in CH_2Cl_2 (Campello *et al.*, 1994), oxidation of $[HB(pz)_3]_2UI(THF)_2$ with iodine, and reaction of the tetravalent alkyl $[HB(pz)_3]_2U(CH_2SiMe_3)_2$ with iodine (Campello *et al.*, 1993). The reaction of UI_4 with two equivalents of $K[HB(pz)_3]$ in THF does not yield the same compound, however. Instead, the iodobutoxide complex $[HB(pz)_3]_2U(I)[O(CH_2)_4I]$ was isolated, presumably generated by ring-opening of solvent (Collin *et al.*, 1993; Campello *et al.*, 1994). The smaller size of the U(IV) ion, combined with the larger steric size of the $[HB(3,5\text{-}Me_2pz)_3]$ ligand, inhibits formation of bis(ligand) complexes of the substituted poly(pyrazolyl)borate; reaction of UCl_4 with two equivalents of $K[HB(3,5\text{-}Me_2pz)_3]$ leads to ligand degradation and the formation of $[HB(3,5\text{-}Me_2pz)_3]UCl_2(3,5\text{-}Me_2pz)$ [equation (25.110)] (Marques *et al.*, 1987a).

$$UCl_4 + 2K[HB(3,5\text{-}Me_2Pz)_3] \longrightarrow \quad (25.110)$$



The complex $[HB(3,5\text{-}Me_2pz)_3]UCl_3(THF)$ contains a relatively weakly coordinated solvent molecule; the base-free complex can be isolated, and has been crystallographically characterized (Domingos *et al.*, 1990). The THF is also readily replaced by a number of other coordinating bases, permitting comparisons of relative ligand affinity. The relative affinities of a series of bases for $[HB(3,5\text{-}Me_2pz)_3]UCl_3$ was found to be

$$O{=}PPh_3 > C_6H_{11}NC > PhCN > MeCN > O{=}P(OEt)_3 > O{=}P(O{-}n\text{Bu})_3 > C_5H_5N > THF$$

Attempts to introduce a larger poly(pyrazolyl)borate ligand have established the steric limits of this system. Reaction of UCl_4 with one equivalent of the thallium salt of $[HB(3\text{-}Mspz)_3]^-$ (Ms = mesityl) generates only the product containing an isomerized ligand, $[HB(3\text{-}Mspz)_2(5\text{-}Mspz)]UCl_3$ (Silva *et al.*, 2000).

A variety of metathesis reactions have been carried out with the bis(ligand) actinide species $[HB(pz)_3]_2AnCl_2$ (An = Th, U) to generate complexes containing oxygen, nitrogen, or sulfur donors (Santos *et al.*, 1987; Domingos *et al.*, 1989a, 1992b,c), as depicted in Fig. 25.36.

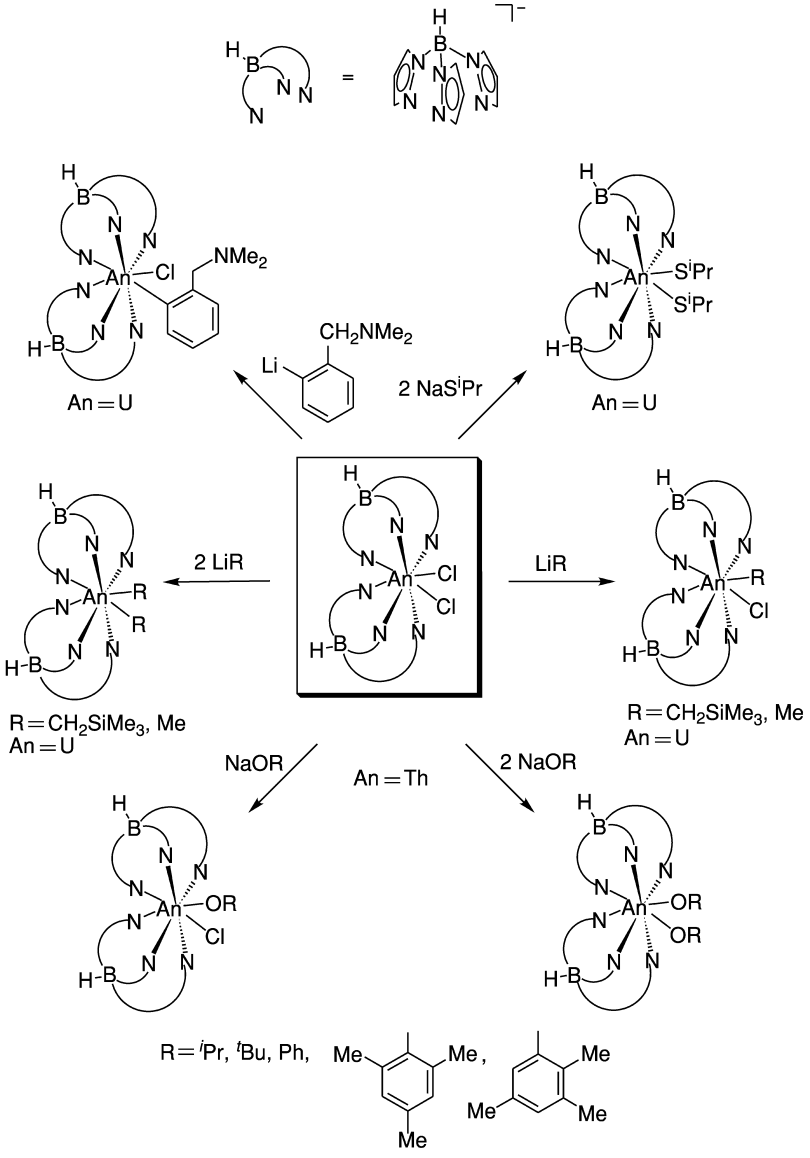


Fig. 25.36 *Chemical reactions of* $[HB(pz)_3]_2AnCl_2$ *(An = Th, U).*

Steric factors can be significant in these reactions. For example, reaction of bulky alkylamides with $[HB(pz)_3]_2UCl_2$ generates only the monoamide complexes $[HB(pz)_3]_2UCl(NR_2)$. These complexes display restricted rotation about the U–N bond at room temperature, indicating a significant degree of steric saturation. Relatively few complexes have been isolated containing alkyl ligands. Many reactions of U(IV) with alkyllithium reagents result in reduction of the metal center. The complexes $[HB(pz)_3]_2Th(CH_2SiMe_3)_2$, $[HB(pz)_3]_2U(R)Cl$ (R = Me, CH_2SiMe_3, *o*-$NMe_2CH_2C_6H_4$) and $[HB(pz)_3]_2UR_2$ (R = Me, CH_2SiMe_3) have been reported (Domingos *et al.*, 1992c; Campello *et al.*, 1997).

In an attempt to reduce the steric constraints of the ancillary ligand, derivatives of the mono(pyrazolylborate) complexes $[HB(3,5\text{-}Me_2pz)_3]AnCl_3(THF)$ (An = Th, U) have also been prepared (Marques *et al.*, 1987b; Domingos *et al.*, 1989b, 1992d; Leal *et al.*, 1992). As before, the degree of substitution is often dependent on the size of the ligand introduced; tris(amide) derivatives such as $[HB(3,5\text{-}Me_2pz)_3]An(NR_2)_3$ can be produced for R = Et, Ph, whereas for the larger ligand $[N(SiMe_3)_2]^-$, only a monoamide complex can be isolated. The monoalkoxide and monoaryloxide complexes of thorium have been reported to be unstable; uranium mono(phenoxide) and bis(phenoxide) complexes are only stable in the presence of a coordinating molecule of THF (Domingos *et al.*, 1989b). The complex $[HB(3,5\text{-}Me_2pz)_3]UCl_3(THF)$ is also susceptible to reduction by alkyllithium reagents; the full range of $[HB(3,5\text{-}Me_2pz)_3]U(Cl)_{3-x}(R)_x$ complexes have been prepared only for R = CH_2SiMe_3. Reaction of $[HB(3,5\text{-}Me_2pz)_3]UCl_3(THF)$ with phenyllithium results in the formation of U(III) species (Silva *et al.*, 1995), but the use of aryllithium reagents with bulky ortho-substituents permits isolation of mono(aryl) products, $[HB(3,5\text{-}Me_2pz)_3]UCl_2R$. The reactivity of $[HB(3,5\text{-}Me_2pz)_3]UCl_2(CH_2SiMe_3)$ and $[HB(3,5\text{-}Me_2pz)_3]UCl_2[CH(SiMe_3)_2]$ toward unsaturated substrates has been investigated (Domingos *et al.*, 1994); insertion similar to that reported in other alkyl complexes is observed. As an example, $[HB(3,5\text{-}Me_2pz)_3]UCl_2(CH_2SiMe_3)$ reacts with stoichiometric amounts of aldehydes, ketones, nitriles, and isonitriles to yield the corresponding secondary and tertiary alkoxide, azomethine, and iminoalkyl products.

The neptunium derivatives $[HB(pz)_3]_2NpCl_2$ and $[HB(3,5\text{-}Me_2pz)_3]NpCl_3(THF)$ have been produced from $NpCl_4$ (Apostolidis *et al.*, 1990).

The reaction of uranium tetrachloride with two equivalents of the bulky ligand $[B(pz)_4]^-$ as the potassium salt yields the complex $[B(pz)_4]_2UCl_2$ (Campello *et al.*, 1999). Although a limited number of derivatives of this compound could be produced, in general the ligand set provided less thermal stability than comparable complexes of the '$[HB(pz)_3]_2U$' fragment. The complex $[B(pz)_4]_2UCl_2$ displays eight-coordinate geometry in the solid state, in a distorted square antiprismatic arrangement of ligands (Fig. 25.37).

The complex is fluxional in solution; ^1H NMR spectra demonstrate that all coordinated pyrazolylborate rings are equivalent. For the derivatives $[B(pz)_4]_2UCl(O^tBu)$, $[B(pz)_4]_2UCl(O\text{-}2,4,6\text{-}Me_3C_6H_2)$, $[B(pz)_4]_2U(S^iPr)_2$, and

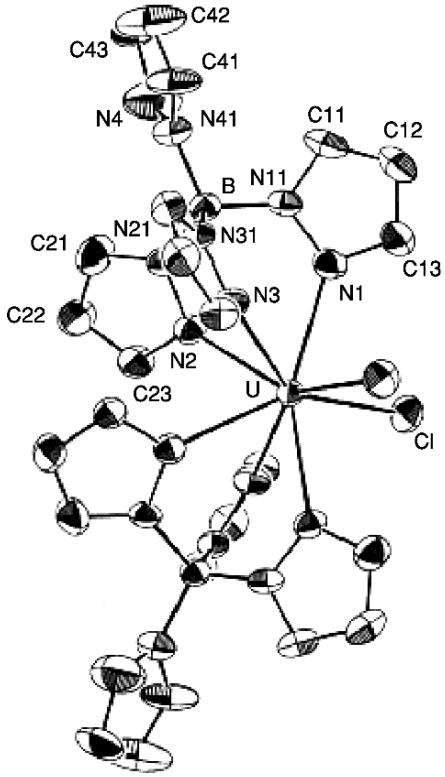

Fig. 25.37 *Molecular structure of* $[B(pz)_4]_2UCl_2$ (*Campello* et al., 1999). (*Reprinted with permission from Elsevier*.)

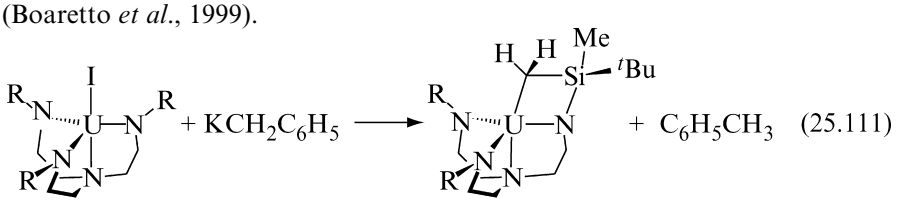
$[B(pz)_4]_2U(O^tBu)_2$, it is possible to slow down the interconversion of the typical eight-coordinate polyhedra (square antiprism ↔ dodecahedron ↔ bicapped trigonal prism). At higher temperatures, it was possible for some of these compounds to reach a regime where all pyrazolyl groups were equivalent on the NMR timescale, indicating dissociative exchange of free and coordinated rings.

25.4.3 Tris(amidoamine)

As in the case of early transition metals, the tris(amido)amine class of ligands, $[N(CH_2CH_2NR)_3]^{3-}$ (R = trialkylsilyl), has proven to be a versatile ligand set that supports unusual reactivity in the early actinides. Complexes of both thorium and uranium have been generated by metathesis reactions involving both the ligands $[N(CH_2CH_2NSiMe_3)_3]^{3-}$ and $[N(CH_2CH_2NSi^tBuMe_2)_3]^{3-}$. The complexes $[\{N(CH_2CH_2NSiMe_3)_3\}AnCl]_2$ (An = Th, U) were the first to be reported (Scott and Hitchcock, 1994); the molecular structure of the uranium complex demonstrated it was dimeric in the solid state. The chloride ligand may

be substituted, and derivatives incorporating cyclopentadienyl, borohydride, alkoxide, amide, and diazabutadiene derivatives have been characterized (Scott and Hitchcock, 1995a,b; Roussel *et al.*, 1997a, 1999). Attempts to alkylate the complex $[N(CH_2CH_2NSi^tBuMe_2)_3]UI$ with alkyllithium or alkylpotassium reagents resulted in the isolation of a metallacyclic product resulting from intramolecular activation of a methyl group, as shown in equation (25.111) (Boaretto *et al.*, 1999).

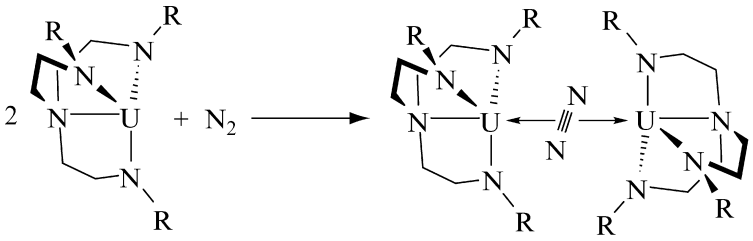


(25.111)

R = Si^tBuMe_2

The U–C bond length in the metallacyclic unit is unusually long [2.752(11) Å], and is susceptible to protonation by alcohols, amines, and terminal alkynes; reaction with pyridine leads to the generation of a η^2-pyridyl complex.

Initial attempts to reduce the complex $[N(CH_2CH_2NSi^tBuMe_2)_3]UCl$ resulted in the formation of a mixed-valence complex $[\{N(CH_2CH_2NSi^tBuMe_2)_3\}U]_2(\mu\text{-Cl})$ (Roussel *et al.*, 1996, 1997b). The complex is thought to possess electronically distinct U(III) and U(IV) centers. Fractional sublimation results in the isolation of a purple species, identified as the trivalent $[N(CH_2CH_2NSi^tBuMe_2)_3]U$ (Roussel *et al.*, 1997b). This complex can also be produced by reduction of $[N(CH_2CH_2NSi^tBuMe_2)_3]UI$ by potassium in pentane. A variety of base adducts of this complex have been reported (Roussel *et al.*, 2002). The U(III) complex can similarly be oxidized by trimethylamine *N*-oxide, trimethylsilyazide, and trimethylsilyldiazomethane to yield μ-oxo, imido, and hydrazido derivatives, respectively (Roussel *et al.*, 2002). One of the most unusual adducts isolated in this system is prepared by the reaction of the U(III) complex with dinitrogen [equation (25.112)].



(25.112)

R = Si^tBuMe_2

The molecular structure of the complex has been reported (Roussel and Scott, 1998) (Fig. 25.38). The N–N distances in the dinitrogen unit are essentially unperturbed. Metrical data, along with magnetic data, suggest that the complex

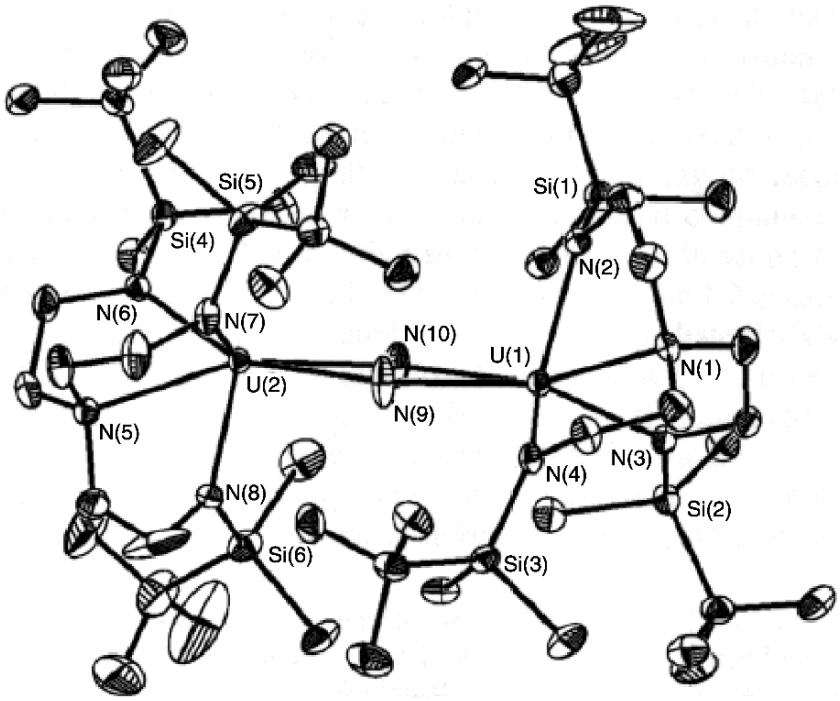


Fig. 25.38 *Molecular structure of* $[\{N(CH_2CH_2NSi^tBuMe_2)_3\}U](\mu^2\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$. (*Reprinted with permission from Roussel and Scott* (1998). *Copyright* 1998 *American Chemical Society.*)

may be best formulated as a U(III) species. The electronic structure of this complex has been investigated; the only significant U–N_2–U interaction was found to consist of U→N_2 π-backbonding (Kaltsoyannis and Scott, 1998).

25.4.4 Other

Few other ligands have been developed with the steric bulk and solubility to stabilize mononuclear actinide complexes and support organometallic chemistry. A bulky amide ligand set has been developed for uranium that supports novel coordination complexes of lower valent uranium. Complexes of the formula $(NRAr)_3UI$ (R = ^{t}Bu, adamantyl; Ar = 3,5-$Me_2C_6H_3$) may be prepared by the reaction of $UI_3(THF)_4$ with Li[NRAr] (Odom *et al.*, 1998); oxidation of the uranium center is presumed to be accompanied by sacrificial generation of U(0). A limited number of tetravalent derivatives of this ligand set have been reported, including the silyl complex $(N^tBuAr)_3U[Si(SiMe_3)_3]$ (Diaconescu *et al.*, 2001) and the bridging cyanoimide complex $(N^tBuAr)_3U{=}N{=}C{=}N{=}U(N^tBuAr)_3$ (Ar = 3,5-$Me_2C_6H_3$) (Mindiola *et al.*, 2001).

Reduction of the uranium (IV) complex by sodium amalgam results in the isolation of $(N^tBuAr)_3U(THF)$ (Ar = 3,5-$Me_2C_6H_3$). Reaction of the trivalent complex with $Mo[N(Ph)(R')]_3$ (R′ = ^{t}Bu, adamantyl) under dinitrogen results in the formation of $[N^tBuAr]_3U(\mu\text{-}N_2)Mo[N(Ph)(R')]_3$, which contains a linear Mo–N–N–U unit. It is suggested that both metals are best regarded as tetravalent. As previously mentioned, reduction of $(N^tBuAr)_3UI$ also provides entry into an interesting class of μ-arene complexes (*vide supra*).

25.5 BIMETALLIC COMPLEXES

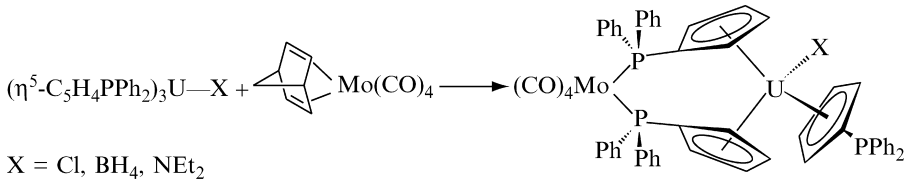
One of the least explored aspects of the non-aqueous chemistry of the actinides is that of complexes containing other metals. Bimetallic complexes have been studied with the intent of creating complexes with two centers of reactivity for effecting chemical transformations. In addition, interest has grown in creating true metal–metal bonds. These complexes are rare; metal–metal bonding is disfavored in the f-elements with respect to d-transition metals, perhaps due to the limited radial extent of valence d- and f-orbitals most likely to be employed in bonding between two metal centers.

Many of the early attempts to generate bimetallic complexes focused on metathesis reactions involving the introduction of anionic metal carbonylate ligands onto actinide cations (Bennett *et al.*, 1971; Dormond and Moise, 1985). These reactions invariably resulted in the isolation of isocarbonyl species in which the actinide was bound by the oxygen atom of one or more carbonyl ligands [equation (25.113)].

$$UCl_4 + 4Na[Mn(CO)_5] \xrightarrow{THF} U[Mn(CO)_5]_4 + 4NaCl \qquad (25.113)$$

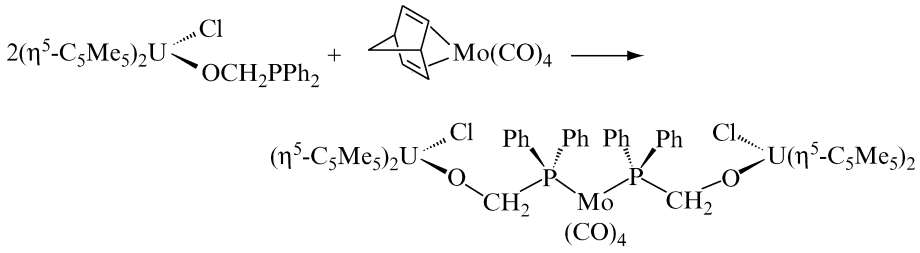
More recently, synthetic efforts have been further expanded to include several classes of compounds in which bridging ligands hold two metal centers in close proximity, but no evidence exists for a metal–metal interaction. Bridging hydride complexes $(\eta^5\text{-}C_5H_5)_3UH_6ReL_2$ (L = PPh_3, P(*p*-F-C_6H_4)$_3$) have been prepared by the reaction of $(\eta^5\text{-}C_5H_5)_3UCl$ with $[K(THF)_2][L_2ReH_6]$ in THF (Baudry and Ephritikhine, 1986). The compounds are fluxional at room temperature in solution, judging from the equivalence of all hydride ligands in the ^{1}H NMR spectrum, but it has been hypothesized that the Re and U centers are bridged by multiple hydride ligands. Ring-substituted analogs $(\eta^5\text{-}C_5H_4R)_3UH_6Re(PPh_3)_2$ could not be prepared directly from $(\eta^5\text{-}C_5H_4R)_3UCl$; rather, the cationic reagent $[(\eta^5\text{-}C_5H_4R)_3U][BPh_4]$ was employed (Cendrowski-Guillaume and Ephritikhine, 1996). Reaction of $(\eta^5\text{-}C_5Me_5)_2UCl(THF)$ with $[K(THF)_2][(PPh_3)_2ReH_6]$ does not result in simple metathesis. Instead, an anionic product of the formula $[K(THF)_2][(\eta^5\text{-}C_5Me_5)_2U(Cl)H_6Re(PPh_3)_2]$ is obtained (Cendrowski-Guillaume *et al.*, 1994; Cendrowski-Guillaume and Ephritikhine, 1996). NMR data suggest that three hydride ligands bridge the two metal centers.

Other examples of bimetallic complexes are generated using ligands on the actinide center that have pendant phosphine groups capable of binding transition metal centers. The diphenylphosphidocyclopentadienyl ligand acts as an electron-poor carbocyclic ligand in the synthesis of bis- and tris-cyclopentadienyl uranium complexes $(\eta^5\text{-}C_5H_4PPh_2)_3UX$ and $(\eta^5\text{-}C_5H_4PPh_2)_2UX_2$ (X = Cl, OR, R, NEt_2, BH_4) (Dormond *et al.*, 1990; Baudry *et al.*, 1993). In reactions with suitable transition metal reagents, complexes can be prepared in which the diphenylphosphide group binds to a second metal center (Dormond *et al.*, 1990; Baudry *et al.*, 1993; Hafid *et al.*, 1994) (equation (25.114)).



(25.114)

A second approach involves the use of cyclopentadienyl complexes in which the other substituents have pendant phosphine groups. A series of alkoxyphosphido complexes of uranium have been prepared for both bis- and tris-cyclopentadienyl frameworks: $(\eta^5\text{-}C_5Me_5)_2UCl[O(CH_2)_nPPh_2]$, $(\eta^5\text{-}C_5Me_5)_2U[O(CH_2)_nPPh_2]_2$, and $(\eta^5\text{-}C_5H_5)_3U[O(CH_2)_nPPh_2]$ (n = 0,1) (Dormond *et al.*, 1994). These species react with (norbornadiene)$M(CO)_4$ (M = Mo, W) to yield bimetallic compounds. The complexes $(\eta^5\text{-}C_5Me_5)_2U[O(CH_2)_nPPh_2]_2$ generate 1:1 (U:M) products in which both phosphorus atoms are bound to a single transition metal. As illustrated in equation (25.115), the complexes $(\eta^5\text{-}C_5Me_5)_2UCl[O(CH_2)_nPPh_2]$ and $(\eta^5\text{-}C_5H_5)_3U[O(CH_2)_nPPh_2]$ react to form 2:1 (U:M) adducts in which the metal carbonyl fragment is bound to one 'arm' of each of the uranium units:

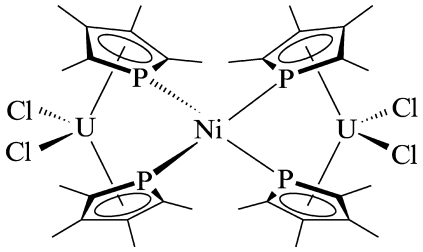


(25.115)

The compounds containing the sterically less hindered OCH_2PPh_2 ligand react more quickly in substitution reactions that their counterparts containing $OPPh_2$.

The phospholyl ligand has also demonstrated the ability to bridge two metal centers in a $\mu\text{-}\eta^5,\eta^1$ manner. Reduction of $NiCl_2$ in the presence of the previously mentioned uranium phospholyl compound $(\eta^5\text{-}C_5Me_4P)_2UCl_2$ yields the complex $Cl_2U(\mu\text{-}\eta^5,\eta^1\text{-}C_5Me_4P)_2Ni(\mu\text{-}\eta^5,\eta^1\text{-}C_5Me_4P)_2UCl_2$ in which the

central nickel atom is bound in a near-tetrahedral fashion by four phosphorus atoms from the four phospholyl ligands (Arliguie *et al.*, 1996).



The dimeric nickel phospholyl complex $(\eta^5\text{-}C_5Me_4P)Ni(\mu\text{-}\eta^1\text{-}C_5Me_4P)_2Ni(\eta^5\text{-}C_5Me_4P)$ can also be prepared; reduction of this in the presence of two equivalents of $(\eta^5\text{-}C_5Me_4P)_2UCl_2$ yields a tetrametallic complex $[Cl_2U(\mu\text{-}\eta^5,\eta^1\text{-}C_5Me_4P)_2Ni(\mu\text{-}\eta^1\text{-}C_5Me_4P)_2Ni(\mu\text{-}\eta^5,\eta^1\text{-}C_5Me_4P)_2UCl_2]$ (Fig. 25.39). In these complexes, long U···Ni distances (>3.3 Å) preclude direct metal–metal interaction.

Select compounds have been prepared in which the bridging ligands appear to coexist with a direct metal–metal interaction. The phosphido-bridged complexes $(\eta^5\text{-}C_5Me_5)_2Th(\mu\text{-}PPh_2)_2ML_n$ [ML_n = $Ni(CO)_2$, $Pt(PMe_3)$] are prepared by the reaction of the thorium phosphide precursor, $(\eta^5\text{-}C_5Me_5)_2Th(PPh_2)_2$ with an olefin complex of the appropriate transition metal species in the presence of additional ligand [equations (25.116) and (25.117)] (Ritchey *et al.*, 1985; Hay *et al.*, 1986).

$$(\eta^5\text{-}C_5Me_5)_2\,Th(PPh_2)_2 + Ni(COD)_2 + 2CO \longrightarrow (\eta^5\text{-}C_5Me_5)_2Th\begin{array}{c}Ph_2\\P\\\diagup\quad\diagdown\\Ni(CO)_2\\\diagdown\quad\diagup\\P\\Ph_2\end{array} \qquad (25.116)$$

$$(\eta^5\text{-}C_5Me_5)_2Th(PPh_2)_2 + Pt(COD)_2 + PMe_3 \longrightarrow (\eta^5\text{-}C_5Me_5)_2Th\begin{array}{c}Ph_2\\P\\\diagup\quad\diagdown\\Pt\text{—}PMe_3\\\diagdown\quad\diagup\\P\\Ph_2\end{array} \qquad (25.117)$$

Calculations performed on both complexes suggest the presence of a direct M–Th interaction (Hay *et al.*, 1986; Ortiz, 1986). This contention appears to be supported both by ^{31}P NMR and structural evidence. The thorium–metal distance in each compound is shorter than that expected on the basis of metal radii derived from related structures without metal–metal nonbonded distances [Th–Ni = 3.206(2) Å, Th–Pt = 2.984(1) Å]. Furthermore, the Th–M–P_2 unit is 'folded' about the phosphide ligands in each case to bring the two metal atoms

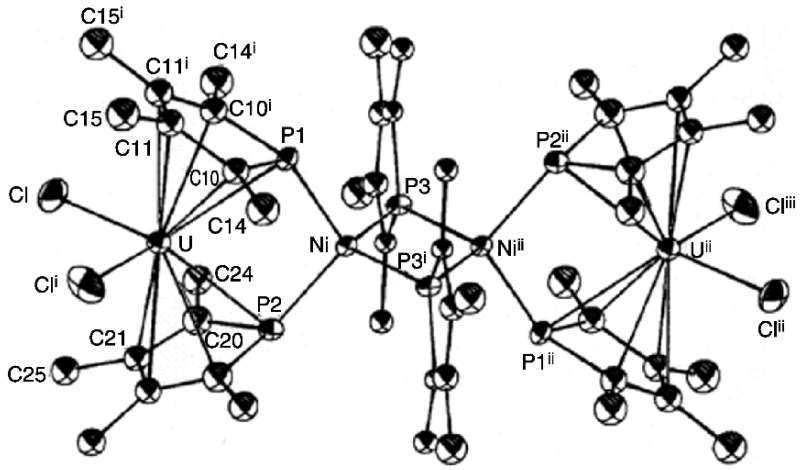


Fig. 25.39 *Molecular structure of* $[Cl_2U(\mu\text{-}\eta^5,\eta^1\text{-}C_5Me_4P)_2Ni(\mu\text{-}\eta^1\text{-}C_5Me_4P)_2Ni(\mu\text{-}\eta^5,\eta^1\text{-}C_5Me_4P)_2UCl_2]$ (*Arliguie* et al., 1996). (*Reprinted with permission from Elsevier.*)

in closer proximity. Theoretical examination of these compounds suggest that the interaction is essentially a M→Th (M = Ni, Pt) dative donor–acceptor bond, involving principally metal d-orbitals.

One class of compounds exist which possess an unsupported metal–metal interaction. Reaction of $(\eta^5\text{-}C_5Me_5)_2ThX_2$ (X = Cl, I) with $Na[(\eta^5\text{-}C_5H_5)Ru(CO)_2]$ produces the complexes $(\eta^5\text{-}C_5Me_5)_2Th(X)Ru(\eta^5\text{-}C_5H_5)(CO)_2$ [equation (25.118)] (Sternal *et al.*, 1985). This synthetic methodology has also been extended to include derivatives of the tris(cyclopentadienyl) framework [equation (25.119)] (Sternal and Marks, 1987).

$$(\eta^5\text{-}C_5Me_5)_2ThX_2 + Na[(\eta^5\text{-}C_5H_5)Ru(CO)_2] \longrightarrow (\eta^5\text{-}C_5Me_5)_2Th(X)Ru(CO)_2 + NaX \qquad X = Cl, I \qquad (25.118)$$

$$(\eta^5\text{-}C_5H_5)_3AnCl \; (An = Th, U) + Na[(\eta^5\text{-}C_5H_5)M(CO)_2] \; (M = Fe, Ru) \longrightarrow (\eta^5\text{-}C_5H_5)_3An\text{–}M(CO)_2 + NaX \qquad (25.119)$$

The molecular structure of $(\eta^5\text{-}C_5Me_5)_2Th(I)Ru(\eta^5\text{-}C_5H_5)(CO)_2$ has been determined (Fig. 25.40); it confirms the presence of a direct metal–metal interaction, with a Th–Ru bond length of 3.0277(6) Å.

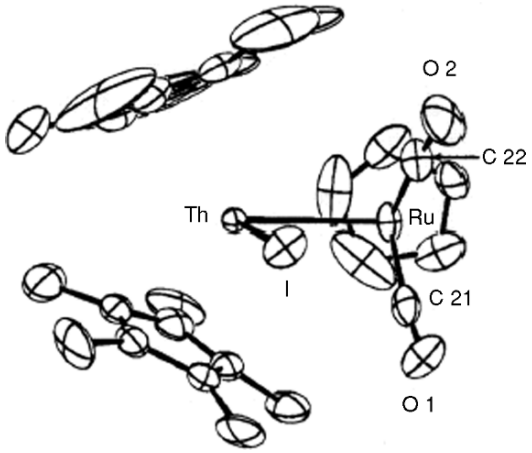

Fig. 25.40 *Molecular structure of* (η^5-C_5Me_5)$_2$*Th*(*I*)*Ru*(η^5-C_5H_5)(*CO*)$_2$. (*Reprinted with permission from Sternal* et al. (1985). *Copyright* 1985 *American Chemical Society*.)

The bond distance is sensitive to the identity of the metal; the Th–Fe distance in the complex (η^5-C_5H_5)$_3$ThFe(η^5-C_5H_5)(CO)$_2$ is 2.940(5) Å. Variable temperature NMR data for the complexes (η^5-C_5H_5)$_3$AnM(η^5-C_5H_5)(CO)$_2$ (M = Fe, Ru) suggest rotation about the metal–metal bond is hindered in solution at room temperature. Thermochemical measurements have determined U–M bond disruption enthalpies for the derivatives (η^5-C_5H_5)$_3$UM(η^5-C_5H_5)(CO)$_2$ [M = Fe, 30.9 (3.0) kcal/mol; M = Ru, 40.4 (4.0) kcal/mol], indicating relatively weak metal–metal interactions (Nolan *et al.*, 1991). Consistent with this observation, the An–M interactions are easily disrupted by protic reagents. In addition, reaction of (η^5-C_5Me_5)$_2$Th(Cl)Ru(η^5-C_5H_5)(CO)$_2$ with coordinating bases (such as ketones or acetonitrile) generates (η^5-C_5H_5)Ru(CO)$_2$H, along with thorium products arising from C–H activation of the Lewis base substrate, followed by insertion of a second (and third) equivalent of the Lewis base (Sternal *et al.*, 1987). Theoretical examination of the bonding (η^5-C_5Me_5)$_2$Th(I)Ru(η^5-C_5H_5)(CO)$_2$ (Bursten and Novo-Gradac, 1987) demonstrates that once again, the bonding is best described as a Ru→Th dative donor–acceptor bond, involving principally Th 6d and Ru 4d orbitals.

25.6 NEUTRAL CARBON-BASED DONOR LIGANDS

One of the most common ligands in d-transition metal organometallic chemistry, the carbonyl ligand, is virtually unknown in actinide chemistry. Aside from the carbon monoxide adducts of tris(cyclopentadienyl)uranium previously described (see Section 25.2.1.1), there are no actinide carbonyl complexes that are

isolable at room temperature and pressure. Uranium carbonyl complexes U $(CO)_n$ ($n = 1$–6) were first reported to form in matrix isolation experiments and were produced by the condensation of thermally generated uranium vapor with carbon monoxide in an argon matrix at 4 K (Slater *et al.*, 1971; Sheline and Slater, 1975). More recent studies indicate that thermal and pulsed-laser evaporated uranium atoms undergo reaction with CO in argon matrices to generate the linear triatomic species CUO (Tague *et al.*, 1993). Tague *et al.* (1993) indicate that higher uranium carbonyls ($n > 2$) are only produced upon subsequent annealing of the matrices to 15—30 K. Photolysis was reported to regenerate CUO from the carbonyls.

The most recent class of Group 14 donor ligands to be employed in actinide chemistry is that of *N*-heterocyclic carbenes. These ligands act as σ-donor bases toward a number of metals in coordination chemistry. Reaction of $[UO_2Cl_2(THF)_2]_2$ with 1,3-dimesitylimidazole-2-ylidene and its 4,5-dichloro-substituted derivative generate 1:2 (uranium:carbene) adducts $UO_2Cl_2(L)_2$ (Oldham *et al.*, 2001). Crystallographic characterization reveals an octahedral metal center with *trans* oxo, chloro, and carbene ligands. The uranium–carbon bond distances in these species are long at 2.626(7) and 2.609(4) Å, consistent with the formulation of the C–U bond as a dative interaction.

CHAPTER TWENTY SIX

HOMOGENEOUS AND HETEROGENEOUS CATALYTIC PROCESSES PROMOTED BY ORGANOACTINIDES

Carol J. Burns and Moris S. Eisen

26.1 INTRODUCTION

During the last two decades, the chemistry of organoactinides has flourished, reaching a high level of sophistication. The use of organoactinide complexes as stoichiometric or catalytic compounds to promote synthetically important organic transformations has matured due to their rich, complex, and

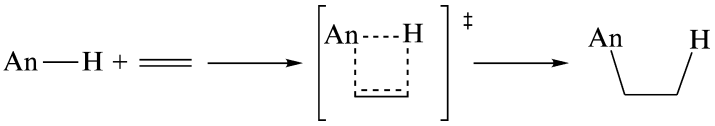
uniquely informative organometallic chemistry. Compared to early or late transition metal complexes, the actinides sometimes exhibit parallel and sometimes totally different reactivities for similar processes. In many instances the regiospecific and chemical selectivities displayed by organoactinide complexes are complementary to that observed for other transition metal complexes. Several recent review articles (Edelman *et al.*, 1995; Edelmann and Gun'ko, 1997; Ephritikhine, 1997; Hitchcock *et al.*, 1997; Berthet and Ephritikhine, 1998; Blake *et al.*, 1998; Edelmann and Lorenz, 2000), dealing mostly with the synthesis of new actinide complexes, confirm the broad and rapidly expanding scope of this field.

The aim of this chapter is to survey briefly and in a selective manner the catalytic chemistry of organoactinide complexes in homogeneous and heterogeneous catalytic reactions. A comprehensive review of the reactivities of actinide compounds has been published covering the literature until 1992 (Edelmann, 1995). This chapter reviews the new literature for the last decade. The treatment of this chapter is necessarily concise. We encourage the reader to seek the recent review articles and additional references given as an integral part of the subchapters for additional details and background material.

26.2 REACTIVITY OF ORGANOACTINIDE COMPLEXES

26.2.1 Modes of activation

Interest in the reactivity of organoactinide complexes is based on their ability to effect bond-breaking and bond-forming of distinctive moieties. The factors influencing these processes are both steric and electronic. A number of articles have been devoted to the steric control in organo-5f-complexes. Xing-Fu *et al.* (1986a) have proposed a model for steric saturation, suggesting that the stability of a complex is governed by the sum of the ligand cone angles (Xing-Fu *et al.*, 1986a,b; Xing-Fu and Ao-Ling, 1987). In this model, highly coordinated 'oversaturated' complexes will display low stability. An additional model concerning steric environments has been proposed by Pires de Matos (Marçalo and Pires de Matos, 1989). This model assumes pure ionic bonding, and is based on cone angles defining the 'steric coordination number'. A more important and unique approach to the reactivity of organo-5f-complexes regards the utilization of thermochemical studies. The knowledge of the metal–ligand bond enthalpies is of fundamental importance to allow the estimation of new reaction pathways (Marks *et al.*, 1989; Jemine *et al.*, 1992, 1993; King *et al.*, 1992; Leal *et al.*, 1992; Leal and Martinho Simões, 1994; King and Marks, 1995; Leal *et al.*, 2001). In addition, neutral organoactinides have been shown to follow a four-center transition state in insertion reactions [equation (26.1)], suggesting that prediction of new actinide patterns of reactivity is possible taking into account the negatives entropies of activation (Marks and Day, 1985).



(26.1)

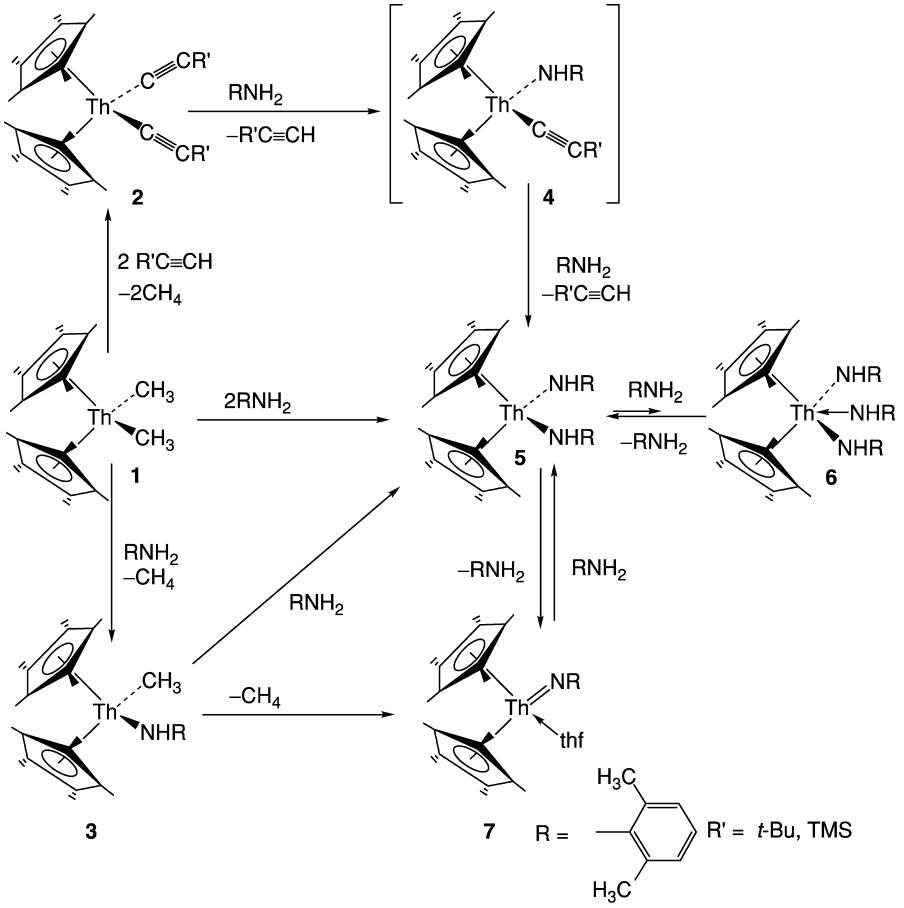
This chapter deals with the reactions of organoactinide complexes that comprise intermediate and key steps in catalytic processes, whereas the preceding chapter focuses in a more detailed and comprehensive fashion on the synthesis and characterization of similar complexes.

26.2.2 Stoichiometric reactions of organoactinide complexes of the type $(C_5Me_5)_2AnMe_2$

The different catalytic reactivity found for similar organoactinides, previously unprecedented in the chemistry of organoactinides, was the driving force for Haskel *et al.* (1999) to study the stoichiometric reactivity of organoactinide complexes of the type $(C_5Me_5)_2AnMe_2$ (An = Th, U). These complexes have been widely used for the hydrogenation of olefins under homogeneous conditions (Fagan *et al.*, 1981a; Fendrick *et al.*, 1988; Lin and Marks, 1990). The reactivity of the actinide complexes towards alkynes and/or amines is outlined in Schemes 26.1 and 26.2 for Th and U, respectively.

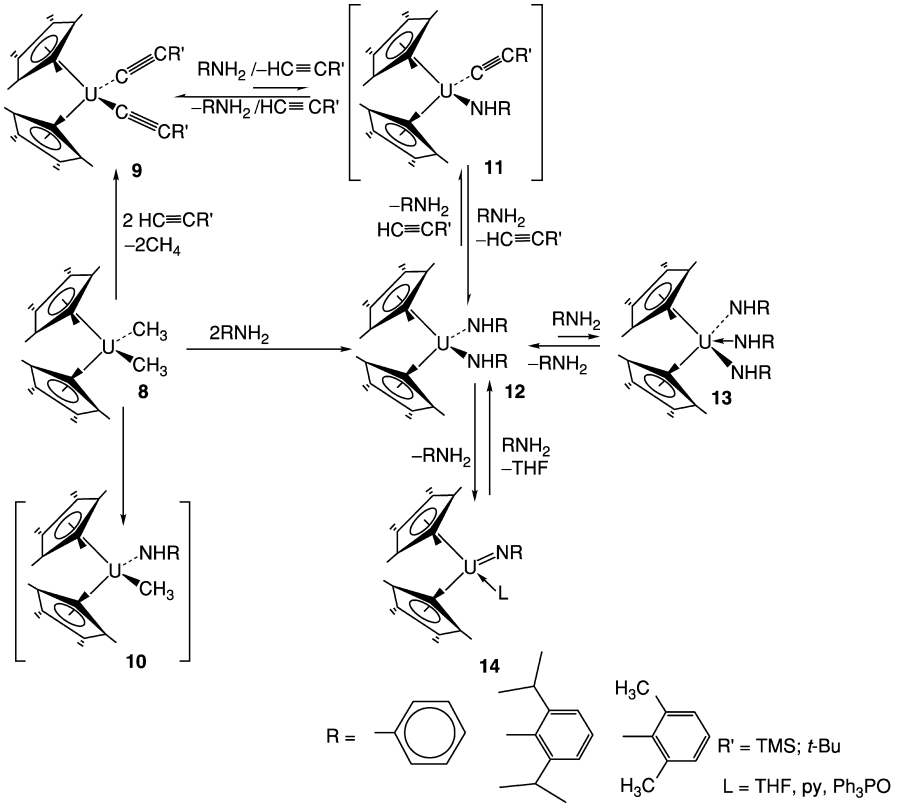
$(C_5Me_5)_2ThMe_2$ (**1**) was found to react with terminal alkynes producing the bisacetylide complexes $(C_5Me_5)_2Th(C{\equiv}CR)_2$ (**2**) (R = ^{t}Bu, TMS). The reaction of these bisacetylide complexes **2** with equimolar amounts of amine yielded half of an equivalent of the corresponding bisamido complexes $(C_5Me_5)_2Th(NHR)_2$ (**5**) and half of an equivalent of the starting bisacetylide complex, indicating that the second amine insertion into the thorium monoamido monoacetylide complex **4** was faster than the first insertion. The reaction of $(C_5Me_5)_2Th(CH_3)_2$ (**1**) with an equimolar amount of amine resulted in the formation of the monoamido thorium methyl complex **3**, which upon subsequent reaction with another equivalent of amine produced the bisamido complex **5**. Heating complex **5**, in THF, allowed the elimination of an amine molecule producing the formation of the thorium–imido complex **7**. This complex also was formed by eliminating methane by heating complex **3** (Haskel *et al.*, 1996). In the presence of an excess of amine, the bisamido complex **5**, was found to be in rapid equilibrium with the bisamido–amine complex **6** (Straub *et al.*, 1996), resembling lanthanide complexes (Gagné *et al.*, 1992a,b; Giardello *et al.*, 1994) though the equilibrium was investigated and found to lie towards the bisamido complex.

Similar reactivity has been found for the corresponding uranium complex, **8** (Scheme 26.2). The reaction with alkynes produced the bisacetylide complexes $(C_5Me_5)_2U(C{\equiv}CR)_2$ (**9**) (R = Ph, TMS) but in contrast to the thorium species, these bisacetylide complexes are extremely stable and the bisamido complex **12** can be formed only by adding large excess of the amine, indicating that the

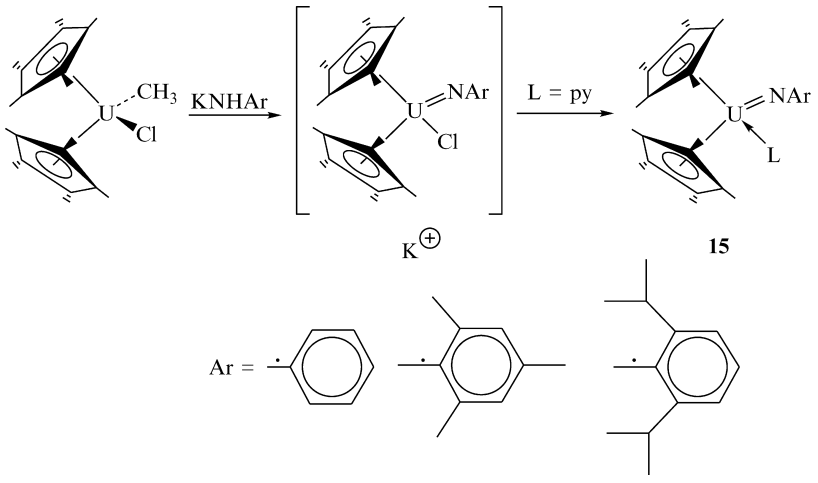


Scheme 26.1 *Stoichiometric reactions of the complex* $(C_5Me_5)_2ThMe_2$ *with amines and terminal alkynes.*

equilibrium between complexes **9** and **12** lies preferentially towards the bisacetylide complexes, instead of either the monoamido monoacetylide **11** or the bisamido complexes **12**. Attempts to isolate the monomethyl–amido complex **10**, by reacting one equivalent of amine with complex **8**, yielded only half of an equivalent of the bisamido complex **12**. Similar to the reactivity of the thorium complex, in the presence of an excess of amine, complex **12** was found to be in fast equilibrium with complex **13**, with the equilibrium favoring the bisamido complex. By heating the bisamido complex **12** in THF, elimination of an amine molecule was observed allowing the formation of the corresponding uranium–imido complex **14** (Eisen *et al.*, 1998). The U(IV) arene–imido complexes have also been prepared following a parallel pathway through a potassium salt [equation (26.2)] (Arney and Burns, 1995).

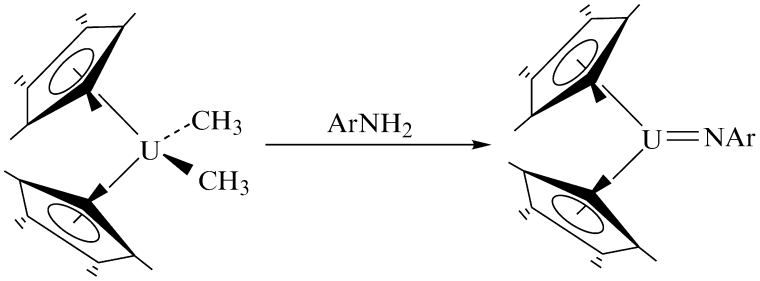


Scheme 26.2 *Stoichiometric reactions of the complex* $(C_5Me_5)_2UMe_2$ *with amines and terminal alkynes.*



(26.2)

The only base-free monomeric organo-imido complex of U(IV) has been obtained for the bulky tris-*tert*-butyl phenyl amine derivative [equation (26.3)] [32].



(26.3)

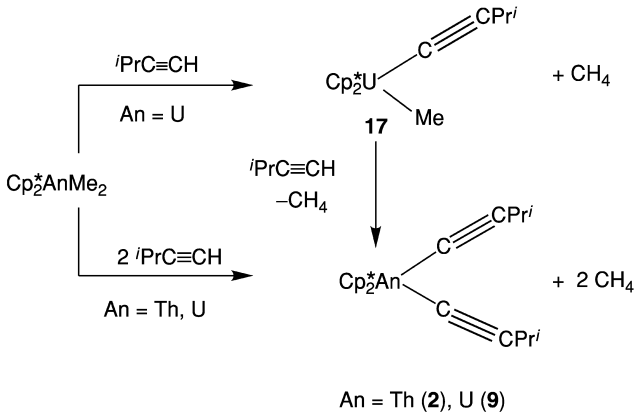
Ar = 2,4,6-^{t}Bu$_3$C$_6$H$_2$

16

The crystal structure of this coordinatively unsaturated organoimido uranium (IV) complex (**16**) exhibits almost a linear U–N-*ipso*-C linkage with and almost C_2 symmetry along the U–N bond. The U–N-*ipso*-C angle is 162.30(10), with the aryl substituent canted towards the uranium through the methyl group in the *ortho*- position of the aromatic ring. Interestingly, besides this close disposition, no chemical evidence was found regarding any agostic interactions. The remarkable feature in this complex was found to be the extremely short U–N bond length of 1.952(12) Å resembling the distance of aryl–imido complexes of U(V) and U(VI) (Brennan and Andersen, 1985; Burns *et al.*, 1990; Arney and Burns, 1993) when the differences in ionic radii due to the variation in the U oxidation states were taken into account (Shannon, 1976). Thus, it was suggested that in this aryl–imido uranium (IV) complex **16**, there is a high formal bond order presumably formed by donation of a lone pair of electrons from the nitrogen to the uranium center.

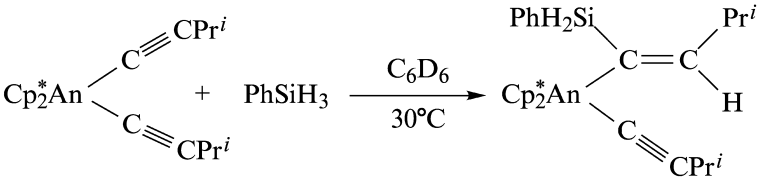
26.2.3 Stoichiometric reactions between $(C_5Me_5)_2AnMe_2$ (An = Th, U), alkynes and silanes

In order to detect the key organometallic intermediates in the hydrosilylation process (*vide infra*), a consecutive series of stoichiometric reactions were investigated, using the organoactinide precursor $(C_5Me_5)_2AnMe_2$ (An = Th, U), reacting with ^{t}PrC≡CH and $PhSiH_3$. The stoichiometric reaction of $PhSiH_3$ with $(C_5Me_5)_2UMe_2$ induced the dehydrogenative coupling of the silane ($PhSiH_3$) to give oligomers, but the reaction $PhSiH_3$ with $(C_5Me_5)_2ThMe_2$ produced only the dimer and the corresponding $[(C_5Me_5)_2ThH(\mu\text{-}H)]_2$, as described in the literature (Fagan *et al.*, 1981b; Aitken *et al.*, 1989). The reaction of the organoactinide complexes $(C_5Me_5)_2AnMe_2$ (An = Th, U) with alkynes in stoichiometric amounts allowed the preparation and characterization of monoacetylide and bisacetylide complexes of organoactinides as described in Scheme 26.3.



Scheme 26.3 *Stoichiometric reactivity of the organoactinide complexes* $(C_5Me_5)_2AnMe_2$ *(An = Th, U) with terminal alkynes.*

In stoichiometric reactions of ^{i}PrC≡CH with $(C_5Me_5)_2UMe_2$, methane gas was evolved leading to the formation of the orange (mono)acetylide methyl complex, $(C_5Me_5)_2U(C{\equiv}CPr^i)(Me)$ (**17**). This transient species was found to be very reactive, and the addition of a second equivalent of ^{i}PrC≡CH converted complex **17** rapidly into the deep red brown bisacetylide complex $(C_5Me_5)_2U(C{\equiv}CPr^i)_2$ (**9**). Addition of one equivalent of $PhSiH_3$ at room temperature to a benzene solution of any of the bisacetylide organoactinide complexes resulted in the quantitative formation of the silylalkenyl acetylide actinide complexes $(C_5Me_5)_2An(PhSiH_2C{=}CH^iPr)(C{\equiv}C^iPr)$ (An = Th (**18**), U (**19**)), which were found to be intermediates in the catalytic cycle for the hydrosilylation reactions [equation (26.4)].

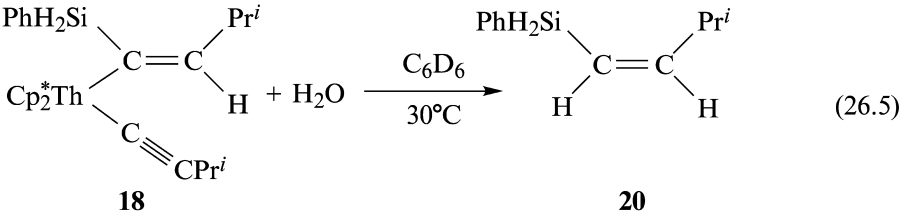


(26.4)

An = Th (**2**), U (**9**) An = Th (**18**), U (**19**)

Formation of the intermediate was indicated by the change in color of the reaction from pale yellow to dark red for **18**, and orange to dark orange brown for complex **19**. The structure of **18** and **19** were unambiguously confirmed by ^{1}H-, ^{13}C-, ^{29}Si-NMR spectroscopy as well as by nuclear overhauser effect (NOE) experiments. The silyl group was found to be in the *cis*-configuration with respect to the *iso*-propyl group in the organometallic

complex. Corroboration of this stereochemistry of the organometallic intermediate **18** was found by the quenching of **18** with H_2O producing the corresponding *cis*-vinylsilane product **20** [equation (26.5)].



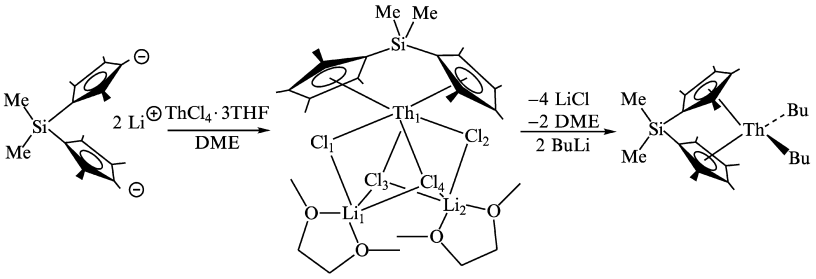
18 **20** (26.5)

Intriguingly, no further reaction was observed with an excess of $PhSiH_3$ with complexes **18** or **19**, strongly suggesting that at room temperature, neither the silane nor the alkyne is able to induce the σ-bond metathesis or the protonolysis of the hydrosilylated alkene or the alkyne. The addition of an excess of alkyne at room temperature to complex **18** in the presence of $PhSiH_3$ yielded the unexpected *trans*-hydrosilylated alkyne, in addition to the corresponding alkene, silylalkyne, and the bis(acetylide) complex.

26.2.4 Synthesis of *ansa*-organoactinide complexes of the type $Me_2Si(C_5Me_4)_2AnR_2$

Stoichiometric and catalytic properties of organo-f-element complexes are profoundly influenced by the nature of the π ancillary ligands (Bursten and Strittmatter, 1991; Edelmann, 1995a,b; Anwander, 1996; Anwander and Herrmann, 1996; Edelmann, 1996; Molander, 1998). It has proven possible to generate a more open coordination sphere at the metal center by introducing a bridge metallocene ligation set as in the complex *ansa*-$Me_2SiCp''_2MR_2$ ($Cp'' = C_5Me_4$) (Fendrick *et al.*, 1984; Jeske *et al.*, 1985a,b; Fendrick *et al.*, 1988). The effect of opening the coordination sphere of organolanthanides in some catalytic processes resulted in an increase (10-fold to 100-fold) in rates for the olefin insertion into the M–R bond (Jeske *et al.*, 1985a,b; Gagné and Marks, 1989; Giardello *et al.*, 1994). In organoactinides, this modification was shown to cause an increase (10^3-fold) in their catalytic activity for the hydrogenation of 1-hexene (Fendrick *et al.*, 1984). The syntheses of the complexes $Me_2Si(C_5Me_4)_2ThCl_2$ (**21**) and $Me_2Si(C_5Me_4)_2Th^nBu$ (**22**) have been reported as presented in equation (26.6) (Gagné and Marks, 1989; Dash *et al.*, 2001). The complex $Me_2Si(C_5Me_4)_2ThCl_2$ was isolated in 82% yield as a lithium chloride adduct. The single-crystal X-ray diffraction revealed a typical bent metallocene complex. The ring–centroid–Th–centroid angle (113.3°) is smaller than that observed in unbridged bis(pentamethylcyclopentadienyl) thorium complexes (130–138°) (Bruno *et al.*, 1986), and slightly smaller than the angle determined for the bridged thorium dialkyl complex $Me_2Si(C_5Me_4)_2Th$

$(CH_2Si(CH_3)_3)_2$ (118.4°) (Fendrick *et al.*, 1984). The thorium–carbon (carbon = cyclopentadienyl ring carbons) bond lengths are not equidistant; the complex displays a shorter distance between the metal and the first carbon adjacent to the silicon bridge because of the strain generated by the Me_2Si-bridge, similar to that reported for other *ansa* types of complexes (Bajgur *et al.*, 1985).

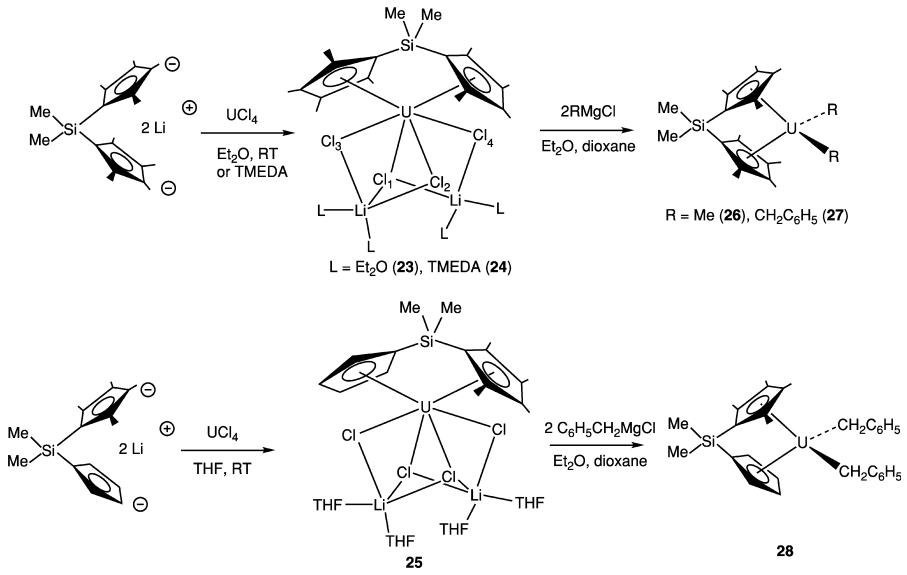


(26.6)

21 **22**

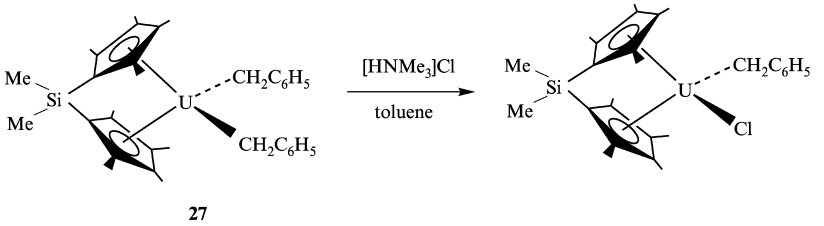
The X-ray analysis of complex **21** showed that two of the thorium–chloride bonds are shorter than the other two Th(1) – Cl(1) = 2.770(2)Å, Th(1) – Cl(2) = 2.661(2)Å, Th(1) – Cl(3) = 2.950(2)Å, and Th(1) – Cl(4) = 2.918(2)Å. The longer Th–Cl distances are those corresponding to the chlorine atoms disposed in the three-fold bridging positions and coordinated to both lithium atoms. Each of the other two chlorine atoms is coordinated only to one lithium atom. All the Th–Cl distances are longer than those observed for terminal Th–Cl distances (Th–Cl = 2.601Å for $Cp^*_2ThCl_2$ or 2.65Å for $Cp^*_2Th(Cl)Me$). *ansa*-Chelating bis(cyclopentadienyl) complexes of uranium have been prepared as presented in Scheme 26.4. Schnabel *et al.* (1999) have described an effective high yield procedure for these desired U(IV) complexes (Schnabel *et al.*, 1999).

The uranium complexes (**23–25**) were obtained as dark-red air- and moisture-sensitive materials. The complexes are soluble in aromatic solvents but insoluble in hexane. In solution, these complexes have shown no dynamic behavior. The molecular structure of complex **23** reveals a normal bent metallocene with an angle of 114.1° for the ring centroid–metal–ring centroid. This angle is smaller as compared to the non-bridged uranium complexes (133–138°) (Fagan *et al.*, 1981b; Eigenbrot and Raymond, 1982; Duttera *et al.*, 1984; Cramer *et al.*, 1989a,b). The uranium atom is bound to four bridging chloride ligands; two bonds are much longer than the others U–(Cl(1)) = 2.885(3), U–(Cl(2)) = 2.853(3), U–(Cl(3)) = 2.760(3), U–(Cl(4)) = 2.746(3)Å, the longer U–Cl bonds are those associated with chlorides that bridge to one lithium atom. For the preparation of the dialkyl complexes, the corresponding chloride–TMEDA complex **24** was used as a precursor. The alkylation of the halide precursors with Grignard reagents produced the corresponding alkyl complexes using a large excess of dioxane as the precipitating solvent for the magnesium salts.



Scheme 26.4 *Synthetic pathway for the preparation of* ansa*-organouranium complexes.*

Interestingly, complex **28** is very stable in comparison to the corresponding dimethyl thorium complex (Fendrick *et al.*, 1984). The dimethyl complex of the mixed cyclopentadienyl precursor **25** could not be isolated. Instead, the precipitation of insoluble material and the evolution of gas were observed. In contrast, the dibenzyl complexes **27** and **28** were obtained in high yields. The mixed benzyl–chloride complex was obtained by protonation of the dibenzyl complex **27** with $[HNMe_3]Cl$ as described in equation (26.7).



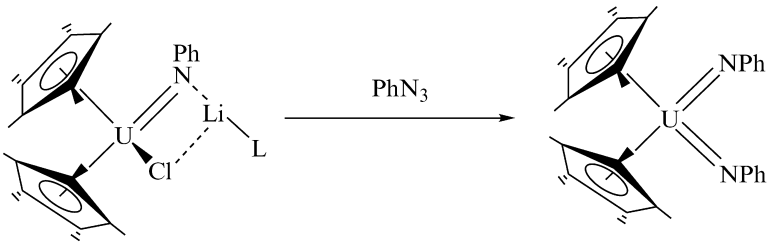
(26.7)

26.2.5 Synthesis of high-valent organouranium complexes

The reactivity of organoactinide (IV) alkyl, amido, or imido complexes towards unsaturated organic substrates such as olefin, alkynes, and nitriles follows a four-center transition state as described in equation (26.1). These complexes

display this type of reactivity due to the high-energy orbital impediment to oxidative addition and reductive elemination. Consequently, the synthesis, characterization, and reactivity studies of high-valent organouranium complexes are of primary importance. The ability to transform U(IV) to U(VI) and vice versa can create complementary modes of activation inducing unique and novel reactivities.

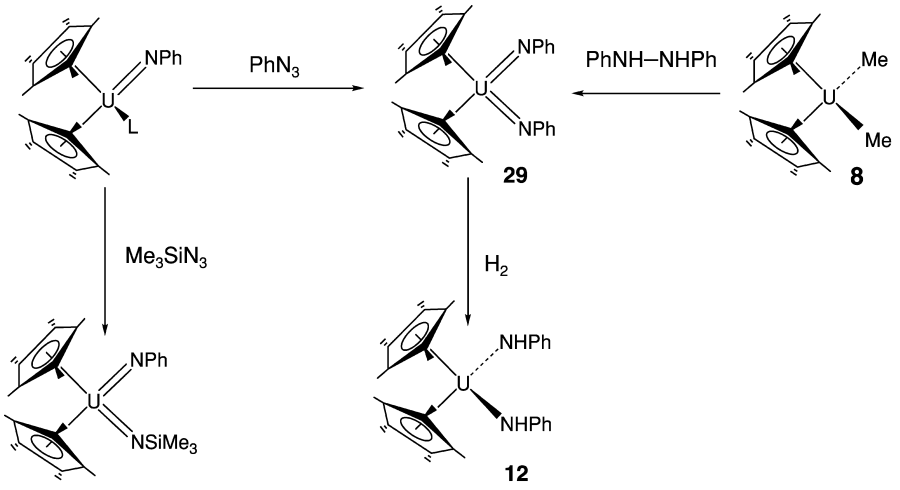
The first high-valent organouranium(VI) bis(imido) complex **29** was prepared by Arney *et al.* (1992) by the oxidation of a lithium salt of an organoimido uranium chloride complex with phenylazide [equation (26.8)] (Arney *et al.*, 1992).



(26.8)

29

Other bis(imido) organouranium (VI) complexes have been prepared as described in Scheme 26.5. The reactions involve the oxidation of uranium (IV)



Scheme 26.5 *Alternative synthetic pathways for the preparation of high-valent organouranium–imido complexes and their reactivity with dihydrogen.*

bis(alkyl) or uranium (IV) imido complexes with the two-electron atom transfer reagents in high yield (Brennan and Andersen, 1985).

A very elegant and simple procedure for the generation of high-valent bis (imido) organouranium (VI) complexes has been described starting from an organometallic uranium (III) species. The reaction involves the direct reduction of diazenes or azides [equation (26.9)] (Warner *et al.*, 1998). Complex **30** was found to react at elevated temperature activating one methyl of the cyclopentadienyl ring (Peters *et al.*, 1999a) [equation (26.10)].

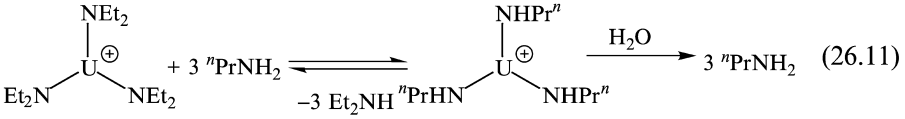
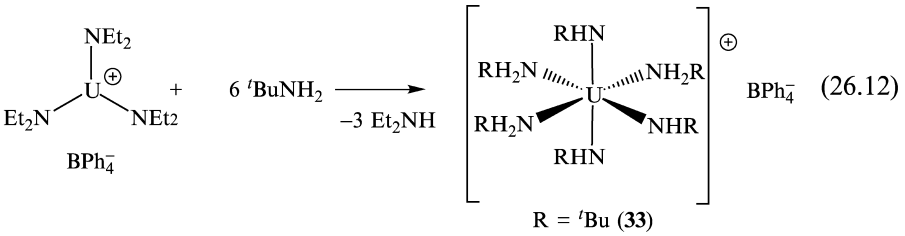
26.2.6 Reactivity of the cationic complex $[(Et_2N)_3U][BPh_4]$ with primary amines

As will be presented in the course of this chapter, a large amount of work has been dedicated towards catalytic reactions using the cationic complex $[(Et_2N)_3U][BPh_4]$ (Berthet *et al.*, 1995). In order to tailor the possibilities of such cationic complexes, stoichiometric reactions with amines have been studied. Under mild conditions (room temperature in benzene), the amido ligands of $[(Et_2N)_3U][BPh_4]$ were straightforwardly activated. The reaction of $[(Et_2N)_3U][BPh_4]$ with *n*-propylamine yielded an organoactinide intermediate that upon consecutive quenching reaction with water, after all volatiles were removed, yielded *n*-propylamine with no traces of Et_2NH. This result indicated that all three amido groups were easily transaminated [equation (26.11)] (Wang *et al.*, 2000). NMR spectroscopy has indicated that complexes

of the type $[(R_2N)_3U][BPh_4]$ normally adopts a zwitterionic structure in non-coordinating solvents, with two phenyl groups of BPh_4 coordinated to the metal center (Wang *et al.*, 2002a).



(26.11)

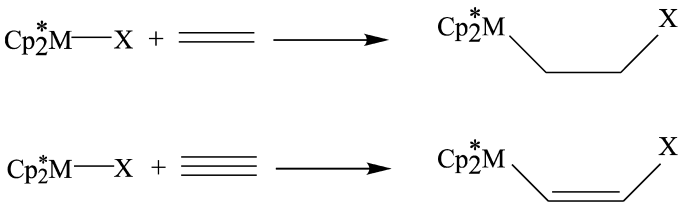


(26.12)

Similarly reaction of $[(Et_2N)_3U][BPh_4]$ with ^{t}butylamine allowed the formation of the complex $[(t\text{BuNH}_2)_3(t\text{BuNH})_3U][BPh_4]$ (**33**) [equation (26.12)]. The X-ray diffraction analysis of **33** revealed a uranium atom in a slightly distorted octahedral environment, with the three amido and three amine ligands arranged in a *mer* geometry. The U–N(amido) bond lengths average 2.20(2)Å and were similar to those determined in the distorted facial octahedral cation $[(Et_2N)_3(THF)_3U]^+$ (mean value of 2.18(1)Å) (Wang *et al.*, 2002a). The complex $[(t\text{BuNH}_2)_3(t\text{BuNH})_3U][BPh_4]$ is a unique uranium(IV) complex with primary amine ligands that have been crystallographically characterized (Wang *et al.*, 2002a). The mean U–N(amino) bond distance of 2.67(3)Å can be compared with the average U–N bond length of 2.79(2)Å in $[UCl_4(Me_2NCH_2CH_2NMe_2)_2$ (Zalkin *et al.*, 1986). The shorter U–N(amido) bond length (U–N = 2.185(7) Å) and the longer U–N(amine) bond length (U–N = 2.705(8) Å) were found to be those which are in *trans* positions. The small octahedral distortion was manifested in the different angles between the amine–amido, amine—amine, and amido–amido groups.

26.3 OLIGOMERIZATION OF ALKYNES

The last decade has witnessed an intense investigation of the chemistry of electrophilic d^0/f lanthanide and actinide metallocenes (Edelmann, 1995a,b). A substantial impact was encountered in diverse catalytic areas, where the key step is an insertion of an olefinic (alkene or alkyne) functionality into a metal–alkyl, metal—hydride, or metal–heteroatom moiety [equation 26.13; $Cp^* = \eta^5$-C_5Me_5; X = alkyl, H, NR_2).



(26.13)

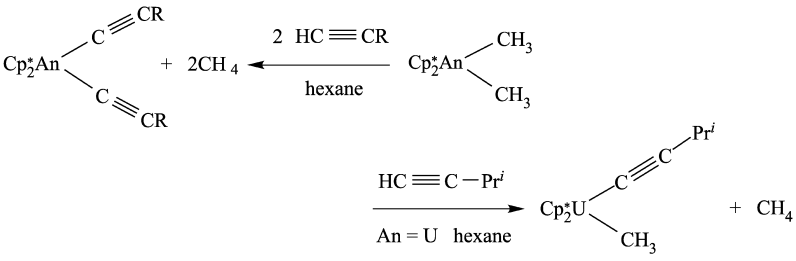
For organolanthanides, such processes include hydrogenation (Molander and Hoberg, 1992; Giardello *et al.*, 1994; Haar *et al.*, 1996; Molander and Winterfeld, 1996; Roesky *et al.*, 1997a,b), dimerization (Heeres *et al.*, 1990), oligomerization/polymerization (Jeske *et al.*, 1985c; Watson and Parshall, 1985; Heeres and Teuben, 1991; Schaverien, 1994; Fu and Marks, 1995; Ihara *et al.*, 1996; Mitchell *et al.*, 1996), and other related reactions that will be discussed later in this chapter, whereas for organoactinides, until 1991 C–H activation (Smith *et al.*, 1986a; Fendrick *et al.*, 1988) and hydrogenation (Fagan *et al.*, 1981a,b; Fendrick *et al.*, 1988; Lin and Marks, 1990) comprised all such processes. Mechanistically, these insertion reactions are not in general well understood and are certainly more efficient in very different metal–ligand environments than the more extensive studied analogs of the middle- and late-transition metals (Collman *et al.*, 1987; Elschenbroich and Salzer, 1989; Hegedus, 1995). Hence, the d^0/f metal ions are likely to be in a high formal oxidation state, and in neutral complexes are expected to be electronically unsuitable for π-back-donation. In addition, these types of complexes are unlikely to form stable olefin/alkyne complexes, due to the relatively polar metal–ligand bonding with strong affinity for 'hard' ligands, and to feature startling M–C/M–H bond disruption enthalpy patterns as compared with those of the late transition elements (Marthino Simões and Beauchamp, 1990; Nolan *et al.*, 1990; King and Marks, 1995).

26.3.1 Bisacetylide organoactinide complexes

Organometallic complexes containing an acetylide moiety have played an important role in the development of organolanthanide chemistry (Evans *et al.*, 1983, 1989; Den Haan *et al.*, 1987; Shen *et al.*, 1990). A number of synthetic routes applicable to the preparation of this class of compounds have been developed, examples of which include the salt metatheses between lanthanide halides with main group acetylides, and the σ-bond metatheses between lanthanide alkyl or hydrides and terminal alkynes.

Bisacetylide organoactinide complexes can be synthesized at room temperature by the reaction of $(C_5Me_5)_2AnMe_2$ (An = Th, U) with either stoichiometric or excess amounts of the corresponding terminal alkynes (Schemes 26.1 and 26.2). The reaction is faster for the organoactinide uranium complex than for the corresponding thorium complex. In all cases, the bisacteylide complexes

were obtained instead of the uranium methyl acetylide complex (**34**) [equation (26.14)], indicating that the metathesis substitution of the second methyl ligand by the terminal alkyne is normally much faster than the first σ-bond metathesis.



(26.14)

An = Th (**2**), U (**9**)

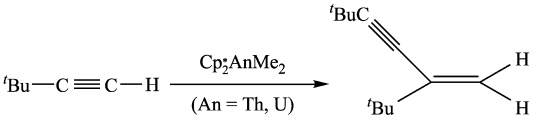
34

$An = Th, R = TMS, {}^{i}Pr; An = U, R = Ph, {}^{t}Bu, {}^{i}Pr$

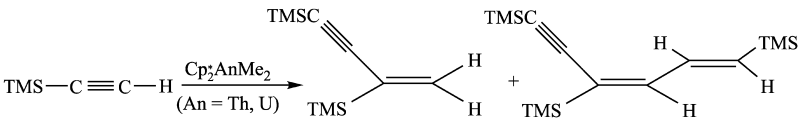
Due to the paramagnetism of the $5f^2$ uranium (IV) center and its rapid electron spin–lattice relaxation times, the chemical shifts of the magnetically non-equivalent ligand protons were found to be generally sharp, well-separated, and readily resolved in the ^{1}H-NMR spectra.

26.3.2 Oligomerization of terminal alkynes catalyzed by neutral organoactinide complexes of the type $(C_5Me_5)_2AnMe_2$

The reaction of $(C_5Me_5)_2AnMe_2$ (An = Th, U) with an excess of *tert*-butylacetylene yielded the regioselective catalytic formation of the head-to-tail dimer, 2,4-di-*tert*-butyl-1-butene-3-yne (Th = 99%; U = 95%), whereas with trimethylsilylacetylene the head-to-tail geminal dimer, 2,4-bis(trimethylsilyl)-1-butene-3-yne (Th = 10%; U = 5%), and the head-to-tail-to-head trimer, (*E,E*)-1,4,6-tris(trimethylsilyl)-1-3-hexadiene-5-yne (Th = 90%; U = 95%), were the exclusive products [equation (26.15)] (Straub *et al.*, 1995):



(26.15)



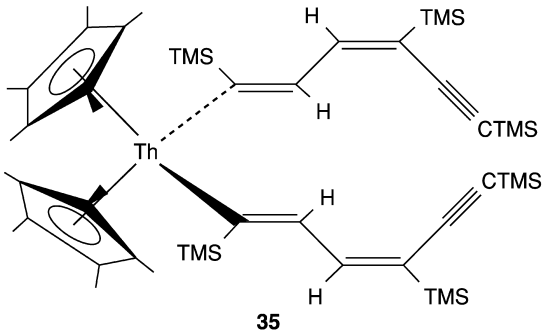
head-to-tail dimers and the formation of higher oligomers with no specific regio-selectivity and chemo-selectivity. For the bulky 4-Me-PhC≡CH, a different reactivity was found for the different organoactinide complexes. Whereas $(C_5Me_5)_2ThMe_2$ generated a mixture of dimers and trimers, the corresponding $(C_5Me_5)_2UMe_2$ afforded *only* the head-to-head *trans*-dimer. In contrast to the reactivity of lanthanide complexes, the organoactinides did not induce the formation of allenic compounds. Although the turnover frequencies for both of the organoactinide complexes were in the range of the 1–10 h^{-1}, the turnover numbers were found to be higher, in the range of 200–400.

26.3.3 Key intermediate complex in the oligomerization of terminal alkynes promoted by neutral $(C_5Me_5)_2AnMe_2$ organoactinides

When the reaction of TMSC≡CH with $(C_5Me_5)_2ThMe_2$ was followed spectroscopically, two different compounds were observed. The first compound observed at room temperature was the bisacetylide complex. The oligomerization reaction started only upon heating the reaction mixture to 70°C, whereupon the bisacetylide complex disappeared and the new complex **35** (Fig. 26.1) was spectroscopically characterized, indicating that both acetylide positions at the metal center were active sites.

26.3.4 Kinetic, thermodynamic, and thermochemical data in the oligomerization of terminal alkynes promoted by neutral $(C_5Me_5)_2AnMe_2$ organoactinides

A kinetic study of the trimerization of TMSC≡CH with $Cp^*_2UMe_2$ was monitored *in situ* by ^{1}H-NMR spectroscopy. From the kinetic data, the empirical rate law for the organoactinide-catalyzed oligomerization of TMSC≡CH is given by equation (26.16). The derived rate constant at 70°C for the production



35

Fig. 26.1 *Bis*(*dienyne*) *organoactinide complex* **35** *found in the linear oligomerization of terminal alkynes.*

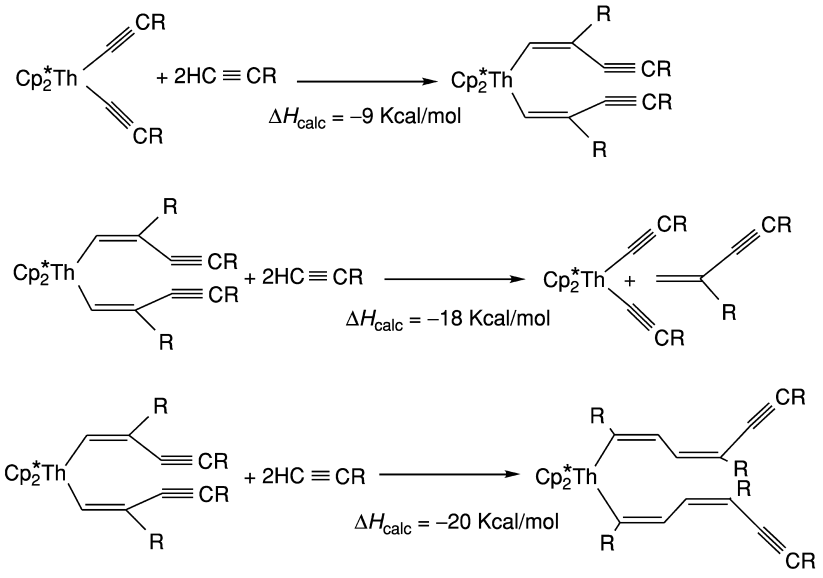
of the corresponding trimer was found to be $k = 7.6 \times 10^{-4}$ (6) s^{-1}.

$$v = k[\text{alkyne}]^1[\text{U}]^1 \tag{26.16}$$

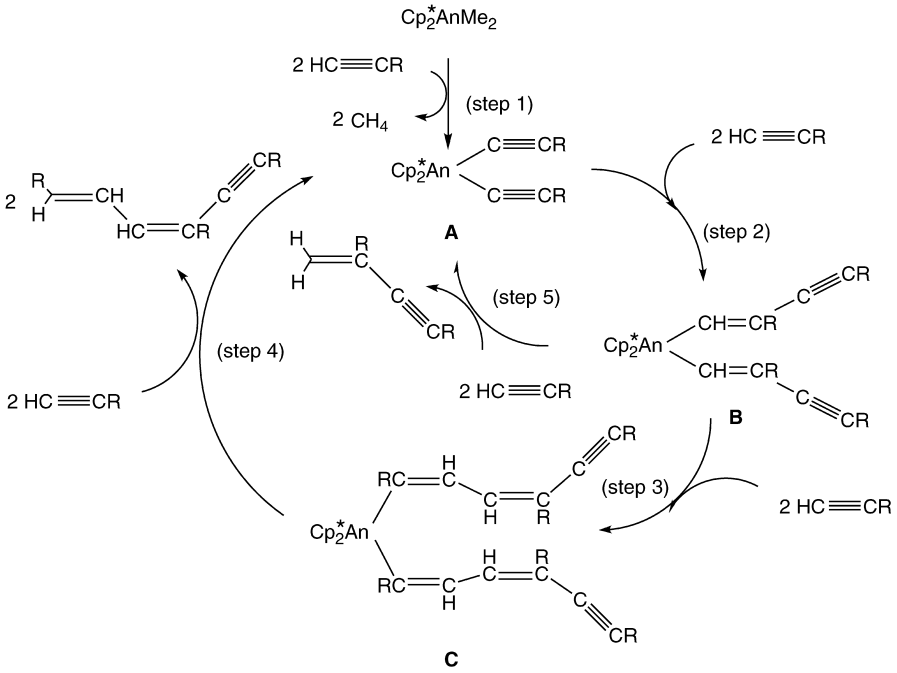
A similar kinetic dependence on alkyne and catalyst concentration was observed over a range of temperatures permitting the derivation of the activation parameters from the corresponding Eyring analysis. The values measured were $E_a = 11.8(3)$ kcal mol^{-1}, $\Delta H^{\ddagger} = 11.1(3)$ kcal mol^{-1}, and $\Delta S^{\ddagger} = -45.2(6)$ eu, respectively (Straub *et al.*, 1999).

Thermodynamically, higher oligomers and even polymers were expected (Ohff *et al.*, 1996; Wang and Eisen, 2003). The reaction of either the Th or U organoactinide complex with acetylene (HC≡CH) resulted in the precipitation of black *cis*-polyacetylene. The *cis*-polyacetylene was thermally converted to the corresponding *trans*-polyacetylenes at 80°C. The enthalpies of reaction may be calculated for the addition of triple bonds in a conjugated manner (Scheme 26.6), The ΔH_{calc} for the dimer formation is exothermic by 27 kcal mol^{-1}, whereas additional insertions are calculated to be exothermic by an additional 20 kcal mol^{-1}. Thus, ΔH_{calc} for the trimer formation is exothermic by 47 kcal mol^{-1}, supporting the results in which non-bulky terminal alkynes were oligomerized with no chemoselectivity.

A plausible pathway was proposed for the organoactinide-oligomerization of terminal alkynes, presented in Scheme 26.7. The mechanism is a sequence of well-established reactions such as insertion of an alkyne into a M–C σ-bond and



Scheme 26.6 *Calculated enthalpies of reaction for the oligomerization of terminal alkynes.*

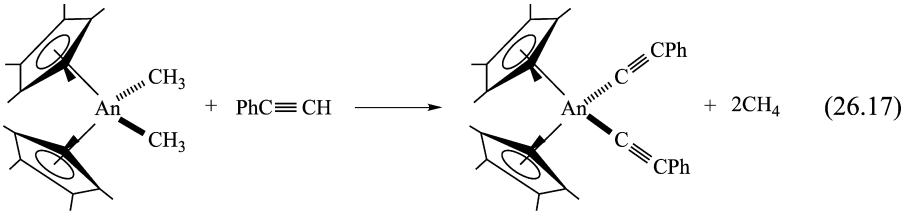


Scheme 26.7 *Proposed mechanism for the linear oligomerization of terminal alkynes catalyzed by organoactinide bisacetylide complexes.*

σ-bond metathesis. The first step in the catalytic cycle involves the protonation of the alkyl groups in the organoactinide precatalyst at room temperature, yielding the bisacetylide complexes $(C_5Me_5)_2An(C{\equiv}CR)_2$ (**A**), with the concomitant elimination of methane (step 1). In general, this is a very rapid reaction extremely exothermic as calculated for the reaction of the organoactinides with PHC≡CH [equation (26.17)]

The 1,2-head-to-tail-insertion of the alkyne into the actinide–carbon σ-bond was proposed to yield the plausible bisalkenyl actinide complex **B** (step 2). Complex **B** may undergo either a σ-bond metathesis with the C–H bond of another alkyne producing the corresponding geminal dimer and **A** (step 5), or an additional 2,1-tail-to-head-insertion of an alkyne, with the expected regioselectivity (for TMSC≡CH), into the organoactinide alkenyl complex **B**, yielding the bis(dienyl)organoactinide complex **C** (step 3). The reaction of complex **C** with an incoming alkyne was proposed to yield the corresponding trimer and regenerating the active actinide bisacetylide complex **A** (step 4). The turnover-limiting step for the catalytic trimerization was identified to be the elimination of the organic trimer from the organometallic complex **C**. This result indicated that the rate for σ-bond metathesis between the actinide–carbyl and the alkyne and the rate of insertion of the alkyne into the metal–acetylide (steps 1 and 2)

were much faster than the rate for σ-bond metathesis of the alkyne with the metal–dialkenyl bond in the catalytic cycle (step 4).



$\Delta H_{\text{Th (calc)}} = -18$ kcal mol^{-1}
$\Delta H_{\text{U (calc)}} = -48$ kcal mol^{-1}

26.3.5 Cross oligomerization of ^{t}BuC≡CH and TMSC≡CH promoted by $(C_5Me_5)_2UMe_2$

In the oligomerization of ^{t}BuC≡CH with $(C_5Me_5)_2UMe_2$, the geminal dimer was found to be the major product, indicating that the addition of the alkyne to the metal acetylide was regioselective with the bulky group pointing away from the cyclopentadienyl groups (Fig. 26.2).

The reaction of equimolar amounts of ^{t}BuC≡CH and TMSC≡CH with $(C_5Me_5)_2UMe_2$ produced two dimers (14%) and three specific trimers (86%). The dimers generated in the reaction were characterized to be the geminal dimer **36** (10%) and the cross geminal dimer **37** (4%), resulting from the insertion of a ^{t}BuC≡CH with the same regioselectivity as observed in Fig. 26.2 into the uranium bis(trimethylsilylacetylide) complex. The trimers obtained were the head-to-tail-to-head trimer, (*E,E*)-1,4,6-tris(trimethylsilyl)-1-3-hexadiene-5-yne (**38**), as the major product (43%), the trimer **39** (15%), resulting from the insertions of two TMSC≡CH into the *tert*-butylacetylide complex, and the unexpected trimer **40** (27%) [equation (26.18)]. Trimer **40** was

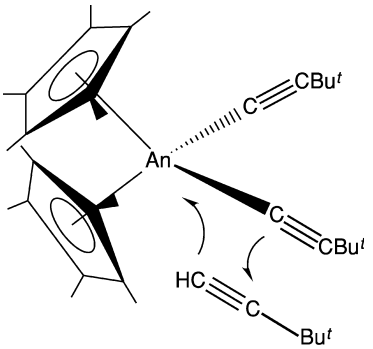


Fig. 26.2 *Regioselectivity of the insertion of* ^{t}*BuC≡CH into an organoactinide acetylide bond.*

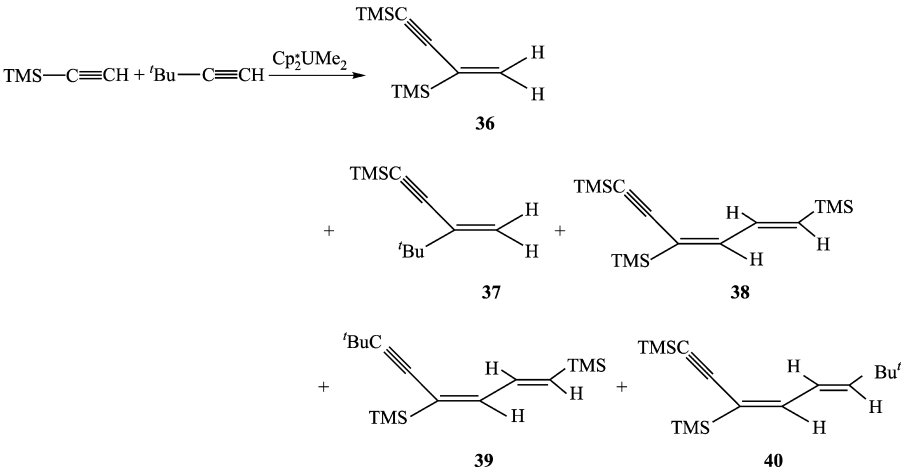
formed by the consecutive insertion of ^{t}BuC≡CH after the TMSC≡CH insertion. These results indicated that in the formation of trimers, the last insertion rate must be fast and competitive for both alkynes, and that the metathesis of the free alkyne is the rate-determining step.



(26.18)

26.4 DIMERIZATION OF TERMINAL ALKYNES

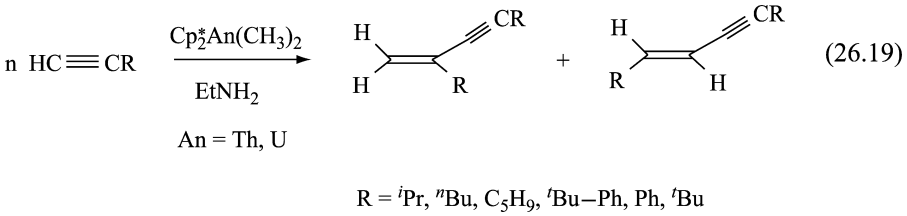
Due to the different reactivities displayed in the selective dimerization of terminal alkynes by different neutral and cationic organo-5f-complexes, this topic will be divided based on the nature of the catalytic species.

26.4.1 Dimerization of terminal alkynes promoted by neutral $(C_5Me_5)_2AnMe_2$ complexes in the presence of amines

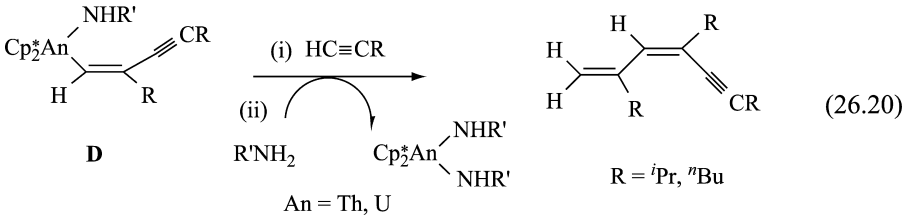
An interesting rationale has been presented in connection with the proposed mechanism, suggesting the means to permit the formation of a specific dimer while limiting the formation of higher oligomers. This would, in effect block steps 3 and 4 in Scheme 26.7 and restrict the reaction to follow steps 2 and 5. Haskel *et al.* (1999) have reported a principle for the selective control over the extent of the oligomerization of terminal alkynes by using an acidic chain-transfer agent. The basic approach employs a chain transfer reagent not ending up in the product and not involving subsequent elimination from the product to release the unsaturated oligomer (in contrast to e.g. ethene oligomerization by metallocene catalysts or magnesium reagents) (Samsel, 1993; Pelletier *et al.*, 1996). The dimerization was performed in the presence of an amine (primary or

secondary); this resulted in minimal alteration of the turnover frequencies compared with the non-controlled process. The selectivity control (i.e. the amount of the different oligomers obtained by the different complexes (Th, U)) of the new catalytic cycle is explained by considering the difference in the calculated bond-disruption energies between an actinide–alkenyl- and an actinide–amido-bond, and combining non-selective catalytic pathways with individual stoichiometric reactions.

Organoactinide complexes of the type $(C_5Me_5)_2AnMe_2$ (An = Th, U) reacted with terminal alkynes in the presence of primary amines yielding preferentially alkyne dimers [equation (26.19)] and for certain alkynes small amounts of regioselective trimers [equation (26.20)]. This selectivity was opposite to that found in the oligomerization of alkynes under the same conditions in the absence of amines. In general, the initial reaction of $(C_5Me_5)_2AnMe_2$ (An = Th, U) with an alkyne yielded the bisacetylide complex, though in the presence of amines, for the thorium complex, the corresponding $(C_5Me_5)_2Th(NHR)_2$ (**5**) was formed. For the uranium complex, no bisamido complex is observed unless large excess of the amine was used.



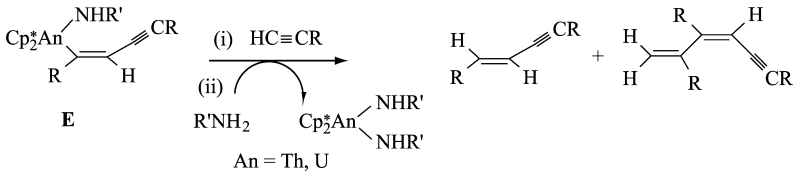
(26.19)



(26.20)

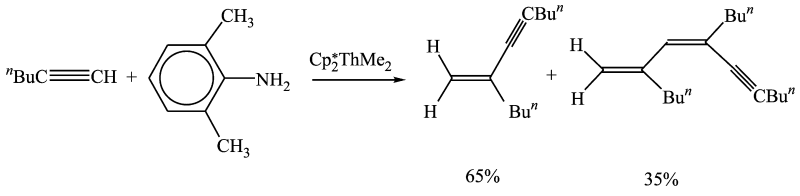
When comparing the oligomerization of terminal alkynes promoted by the thorium complex in the presence of amines as to the results obtained without amines, a dramatic reduction in the extent of oligomerization was observed. When $EtNH_2$ or other primary amines were used with aliphatic alkynes, mixtures of the corresponding *geminal* and *trans* dimer were produced, while for aromatic alkynes, just the *trans* dimer was formed. Increasing the bulkiness of the primary amine for aliphatic alkynes allowed only the formation of the *geminal* dimer, and the specific trimer as represented in equation (26.20). These results indicated that the insertion of the second alkyne into the metalla–eneyne **D** complex and the trimer elimination [equation (26.20)] are faster than either the insertion of an alkyne into the intermediate complex **E**,

and/or the protonolysis of **E** by either the alkyne or the amine, eliminating the corresponding isomeric trimer and/or dimer, respectively [equation (26.21)]. Reactions of the thorium precursor with secondary amines allowed the formation of higher oligomers (up to pentamers), however in lower yields, as compared with the results obtained in the reactions in the absence of amines. It was proposed that for secondary amines, the protonolysis of the growing oligomer from the metal was much slower as compared to the insertion of the alkynes and cutting the oligomer chain by the alkyne itself.

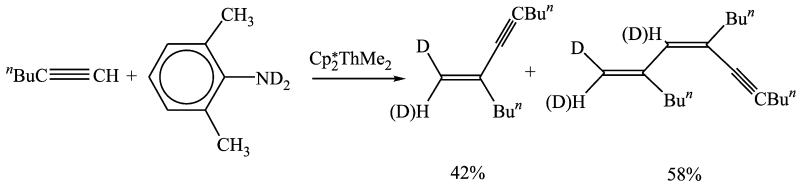


(26.21)

For uranium, the oligomerization of non-bulky alkynes with secondary amines showed no control whereas for primary amines ($R'NH_2$), the intermolecular hydroamination product obtained was exclusively ($RCH_2CHN{=}R'$) (Haskel *et al.*, 1996). While the dimerization of ^{t}BuC≡CH produced the *geminal* dimer, in the presence of ^{t}BuNH$_2$, a mixture of both dimers were obtained, which suggested the attachment of the amine to the metal center at the time of the alkyne insertion allowing different regioselectivities. Previously, for the non-controlled oligomerization reactions, the actinide–bisacetylide complex was proposed as the active species in the catalytic cycle. In the controlled oligomerization reaction, the formation of the organoactinide bisamido complex, which was the predominant species, provided strong evidence that the amine was the major protonolytic agent. A novel strategy was implemented in support of the protonolytic theory to increase the selectivity towards the trimeric isomer. Enhanced selectivity was attained by providing a kinetic delay for the fast protonolysis using deuterated amine. The kinetic effect allowed more trimer formation, in a reaction producing both dimer and trimer [equation (26.22)]. The strategy biased the chemoselectivity of the oligomerization increasing the trimer:dimer ratio.



(26.22)



When the product formation was followed as a function of time, the first deuterium was observed at the geminal position, but at higher conversions, more olefinic positions were deuterated, suggesting that the alkyne and the deuterated amine were in equilibrium through a metal complex only exchanging hydrogen/deuterium atoms.

(a) Kinetic, thermodynamic, and mechanistic studies of the controlled oligomerization of terminal alkynes

Kinetic measurements of the controlled oligomerization reaction of ^{n}BuC≡CH with ^{i}BuNH$_2$ promoted by $(C_5Me_5)_2ThMe_2$ revealed a first-order dependence of the catalytic rate on substrate concentration, an inverse first-order in amine and first-order dependence in precatalyst. Thus, the rate law for the controlled oligomerization of terminal alkynes promoted by organoactinides can be written as presented in equation (26.23).

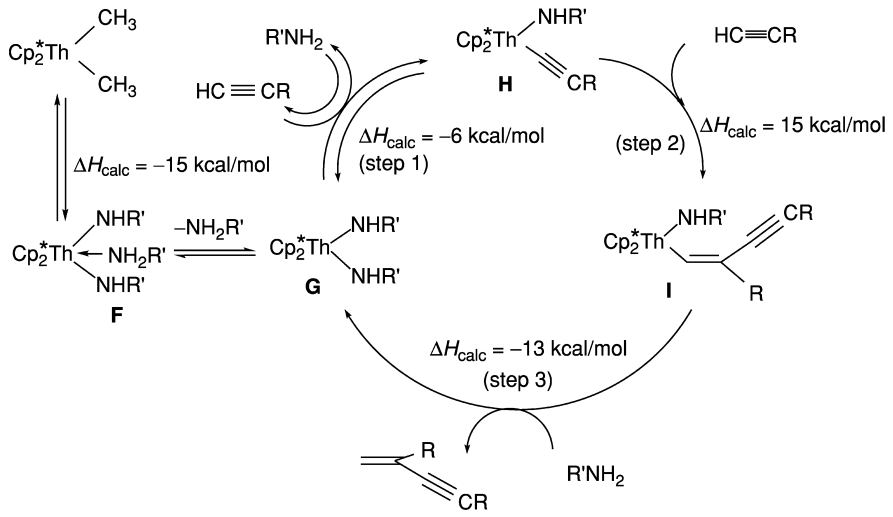
$$v = k\,[\mathrm{Th}]^1\ [\mathrm{alkyne}]^1\ [\mathrm{amine}]^{-1} \tag{26.23}$$

The derived $\Delta H^{\dagger}$ and $\Delta S^{\dagger}$ values from an Eyring analysis were measured to be 15.1(3) kcal mol^{-1} and –41.2(6) eu, respectively.

An inverse proportionality in catalytic systems is consistent with a rapid equilibrium before the rate-limiting step. For this reaction, it was consistent with the equilibrium between the bisamido complex and a bisamido–amine complex, as found in the hydroamination of terminal alkynes promoted by early transition complexes (Walsh *et al.*, 1992; Baranger *et al.*, 1993) and in the hydroamination of olefins promoted by organolanthanide complexes (Gagné *et al.*, 1992a,b; Molander and Hoberg, 1992).

A reasonable mechanism for the controlled oligomerization of terminal alkynes is described in Scheme 26.8.

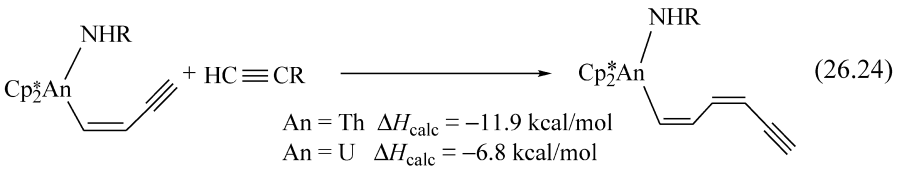
The mechanism presented in Scheme 26.8 consists of a sequence of simple reactions, such as insertion of acetylene into an M–C σ-bond, and σ-bond metathesis. The starting complex $(C_5Me_5)_2ThMe_2$ reacts fast with amines to the bisamido complex **G** and the bisamido–amine complex **F**. These complexes were found to be in rapid equilibrium and responsible for the inverse proportionality in the kinetic dependence of the amine (Straub *et al.*, 1996). Complex **G**, which was found to be the resting state for the catalytic species, reacted with one equivalent of alkyne in the rate-limiting step, producing complex **H** (step 1). Comparison of the results obtained for the oligomerization of phenylacetylene in the absence of amines (with amines only a dimer was obtained), in which both dimers and higher oligomers were obtained, indicated that an amido acetylide and not the bisacetylide complex was responsible for the regio-differentiation. Complex **H** reacts with an alkyne, yielding the actinide–alkenyl amido complex **I** (step 2), which may undergo either a σ-bond protonolysis with the amine to yield the corresponding dimer and the bisamido complex **G** (step 3), or another



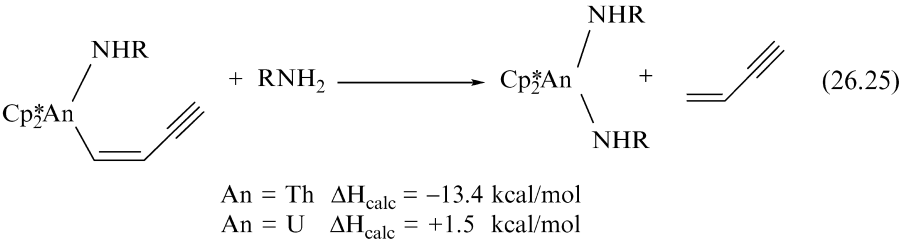
Scheme 26.8 *Plausible mechanism for the oligomerization of terminal alkynes, in the presence of amines, promoted by organothorium complexes.*

insertion of an alkyne and concomitant σ-bond protonolysis by the amine, yielding the oligomeric trimer and the bisamido complex **G**. Thus the reaction rate law presented in equation (26.23) was compatible with rapid, irreversible alkyne insertion (step 2), rapid σ-bond protonolysis of the oligomer by the amine (step 3), a slow pre-equilibration involving the bis-amido **G** and the mono amido-acetylide complex (**H**) (step 1), and a rapid equilibrium between the bisamido complex **G** and the bisamido–amine complex **F**.

Control over the oligomerization was accomplished by a kinetic competition between the insertion reaction of a new alkyne molecule into the metal–alkenyl bond [equation (26.24)] and the protonolysis by the amine [equation (26.25)]. The insertion reaction produces a larger metalla–oligomer complex, whereas the competing protonolysis produces the organic product and the bisamido organometallic complex. The difference in selectivity found for the thorium and uranium complexes was corroborated using bond disruption energy data (Bruno *et al.*, 1983; Smith *et al.*, 1986b; Marthino Simões and Beauchamp, 1990; Giardello *et al.*, 1992). For thorium, both reactions [equations (26.24) and (26.25)] were calculated to be exothermic by almost equal amounts generating control over the extent of oligomerization. For the corresponding uranium complex, where no control over chain length was observed, the formation of the bisamido complex was calculated to be endothermic, limiting the control over the degree of oligomerization.



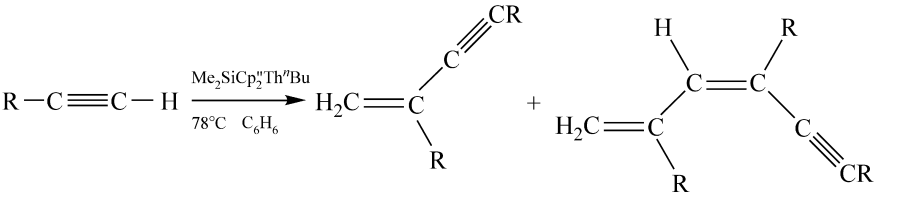
(26.24)



(26.25)

26.4.2 Dimerization of terminal alkynes promoted by the *ansa*-organothorium complex $Me_2Si(C_5Me_4)_2ThBu_2$

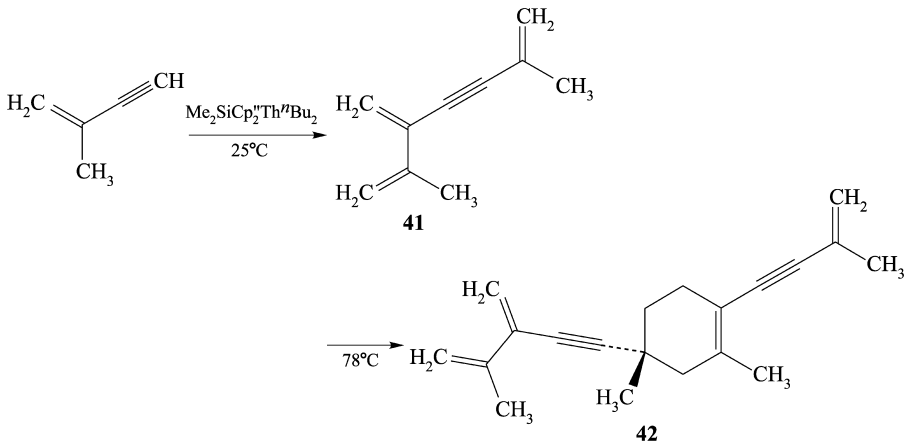
The *ansa*-bridged organoactinide complex $Me_2Si(C_5Me_4)_2Th^nBu_2$ was found to be an excellent precatalyst for the chemo- and regio-selective dimerization of terminal alkynes. At room temperature, head-to-tail geminal dimers were obtained, whereas at higher temperature (78°C), the geminal dimer and some minor amounts of the specific head-to-tail-to-tail trimer (up to 5%) were also observed particularly for the specific alkynes ^{i}PrC≡CH and ^{n}BuC≡CH [equation (26.26)] (Dash *et al.*, 2001). Although no large difference was observed among similar alkyne substituents, the dimerization reaction of either ^{i}PrC≡CH or ^{n}BuC≡CH with $Me_2Si(C_5Me_4)_2Th^nBu_2$ was much faster and more selective than the dimerization with $Cp^*_2ThMe_2$. The most striking result regarding the dimerization/oligomerization of terminal alkynes was found for TMSC≡CH (TMS = Me_3Si). No catalytic reaction was observed by using the *ansa*-bridged complex (butane was evolved), in contrast to the results obtained in the reaction of TMSC≡CH with $Cp^*_2ThMe_2$, in which the geminal dimer (10%) and the head-to-tail-to-head trimer (90%) were obtained with high regioselectivity (Straub *et al.*, 1995).



R = ^{t}Bu, ^{i}Pr, H_2C=C(Me), ^{n}Bu, Me R = ^{i}Pr, ^{n}Bu

(26.26)

A domino reaction was observed in the dimerization of the alkene-functionalized alkyne producing dimer **41**, which undergoes a quantitative intermolecular Diels–Alder cyclization to produce compound **42** [equation (26.27)].



(26.27)

(a) Kinetic studies of the dimerization of terminal alkynes promoted by $Me_2Si(C_5Me_4)_2Th''Bu_2$

The kinetics for the dimerization of $^{i}PrC{\equiv}CH$ promoted by $Me_2Si(C_5Me_4)_2Th''Bu_2$ were studied. The reaction displayed a first-order dependence in precatalyst, and two different kinetic domains were observed, with differing alkyne dependence (Fig. 26.3). At low concentrations of alkyne, an inverse proportionality was observed indicating that the reaction is in an inverse first-order, but at higher concentrations, the reaction exhibited a zero order in alkyne (Eisen *et al.*, 1998). The change from an inverse rate to a zero rate was rationalized by invoking two equilibrium processes. In one of these equilibrium processes, the complex was removed from the catalytic cycle (inverse order), whereas the second equilibrium was found to be the rate-determining step in the dimer formation. The latter was measured only at high alkyne concentrations. The derived activation parameters E_a, $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$ from an Eyring analysis were 11.7(3) kcal mol^{-1}, 11.0(3) kcal mol^{-1}, and 22.6(5) eu, respectively.

Given that the stereochemical approach of the alkyne to the organometallic moiety is likely side-on, the highly regioselective production of the geminal dimers was rationalized by suggesting that the insertion of the alkyne occurs with the substituent away from the metal center. The methyl groups of the cyclopentadienyl spectator ligand also disfavor the disposition of the alkyne substituent facing the metal center.

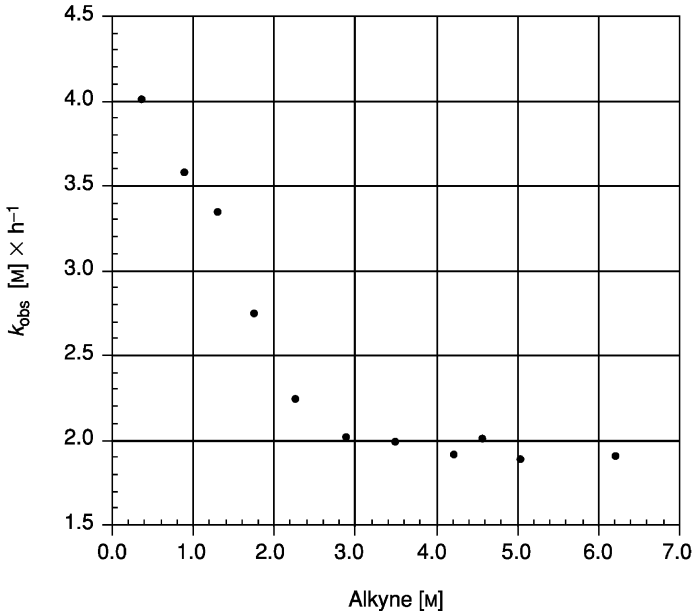


Fig. 26.3 *Alkyne dependence in the dimerization of* $^{i}PrC{\equiv}CH$ *promoted by* $Me_2Si(C_5Me_4)_2Th^{n}Bu_2$.

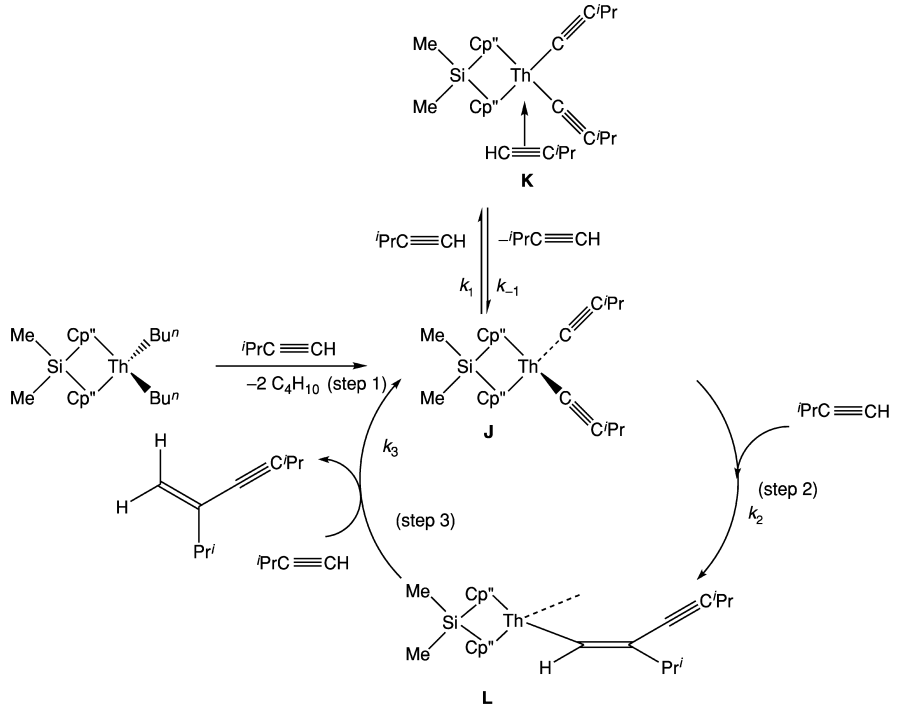
A plausible mechanism for the selective dimerization of $^{i}PrC{\equiv}CH$ promoted by $Me_2Si(C_5Me_4)_2Th^{n}Bu_2$ is presented in Scheme 26.9. The initial step in the catalytic cycle is the alkyne C–H activation by the complex $Me_2Si(C_5Me_4)_2Th^{n}Bu_2$ and the formation of the bisacetylide complex **J** together with butane (step 1). Complex **J** is proposed to be in equilibrium with an alkyne, forming the proposed π-alkyne acetylide complex **K**, which removes the active species from the catalytic cycle (inverse rate dependence). Alternatively, **J** undergoes a head-to-tail insertion with another alkyne into the thorium–carbon σ-bond, producing the substituted alkenyl complex **L** (step 2). Complex **L** goes through a σ-bond protonolysis with an additional alkyne (step 3), yielding the corresponding dimer and regenerating the active acetylide complex **J.** In contrast to the general expectations for organoactinides, complex **K** was the first π-olefin intermediate complex (*vide infra*) exhibiting new rich and versatile reactivity for actinide complexes.

The turnover-limiting step for the catalytic dimerization was measured to be the insertion of the alkyne into the thorium–acetylide complex **J** (step 2). Thus, the derived rate law based on the mechanism proposed in Scheme 26.9 for the oligomerization of terminal alkynes promoted by the complex $Me_2SiCp''_2Th^{n}Bu_2$ is given by equation (26.28), fitting the kinetic performances of the alkyne and catalysts.



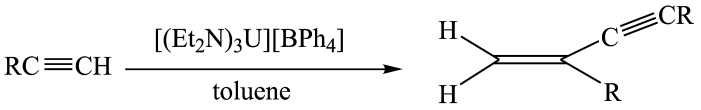
Scheme 26.9 *Proposed mechanism for the dimerization of terminal alkynes promoted by* $Me_2SiCp''_2Th^nBu_2$.

$$v = \frac{k_{-1}k_2[\text{Cat}]}{k_1 + k_2 - \frac{k_2k_{-2}}{k_3[\text{alkyne}]}} \tag{26.28}$$

26.4.3 Catalytic dimerization of terminal alkynes promoted by the cationic actinide complex $[(Et_2N)_3U][BPh_4]$. First f-element alkyne π-complex $[(Et_2N)_2U(C{\equiv}C^tBu)(\eta^2\text{-}HC{\equiv}C^tBu)][BPh_4]$

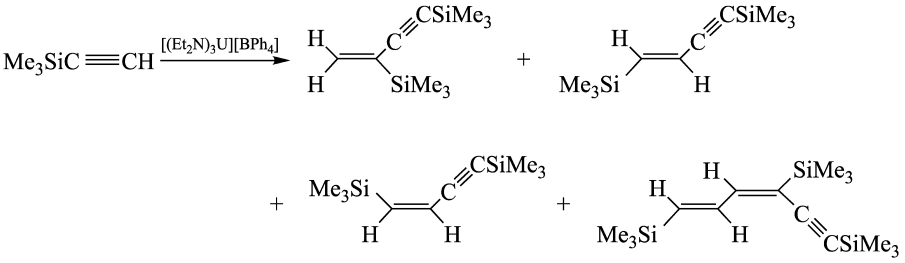
Unlike neutral organoactinide complexes, homogeneous cationic d^0/f^n actinide complexes have been used as catalysts for the polymerization of α-olefins (Jia *et al.*, 1997; Chen *et al.*, 1998), as have their isolobal group 4 complexes. The alkyne oligomerization reaction has been mentioned as a useful probe for the insertion and σ-bond metathesis reactivity of organoactinide complexes. For the corresponding cationic actinide complexes, little was known regarding their reactivity with terminal alkynes (Wang *et al.*, 1999). Reaction of the cationic complex $[(Et_2N)_3U][BPh_4]$ (Berthet *et al.*, 1995) with the terminal alkynes RC≡CH, (R = Me, ^{n}Bu, ^{i}Pr) resulted in the chemo- and regio-selective catalytic formation of the head-to-tail *gem*-dimers without the formation of the *trans* dimer or any other major oligomers [equation (26.29)]. For PhC≡CH, the

reaction was less chemoselective, allowing the formation of some trimers (dimer:trimer ratio = 32:58). For TMSC≡CH, besides the formation of the geminal head-to-tail dimer, the *trans*-head-to-head dimer, and the regioselective head-to-tail-to-head-trimer (*E,E*)-1,4,6-tris(trimethylsilyl)1-3-hexadien-5-yne, the unexpected head-to-head *cis* dimer was also formed [equation (26.30)]. For ^{t}BuC≡CH, besides the geminal dimer also the unexpected *cis*-dimer was formed [equation (26.31)].

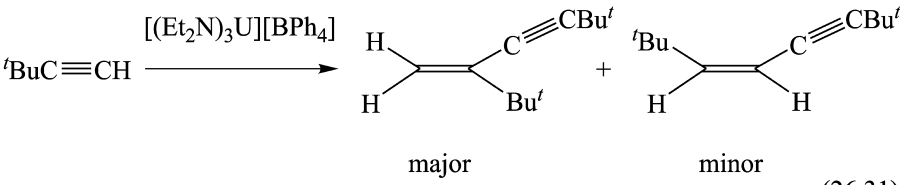


(26.29)

R = Me, ^{n}Bu, ^{i}Pr



(26.30)



(26.31)

As already mentioned, mechanistically, the relatively polar metal–ligand bonds, the absence of energetically accessible metal oxidation states for oxidative addition/reductive elimination processes and the presence of relatively low-lying empty σ-bonding orbitals, implicate a 'four-center' heterolytic transition state in the metal–carbon bond cleavage (Marks and Day, 1985; Marks, 1986a,b). The reaction of the metal acetylide with a terminal alkyne occurs in a *syn* mode and the σ-bond protonolysis of the resulting alkenyl complex will be expected to maintain the *cis*-stereochemistry at the product (Fig. 26.4).

Hence, the formation of the *trans* dimers [equations (26.30) and (26.31)] argued for an isomerization pathway before the products were released from the metal center. For comparison, in the oligomerization of terminal alkynes promoted by the cationic complexes $[Cp^*_2AnMe][B(C_6F_5)_4]$ (An = Th, U), the

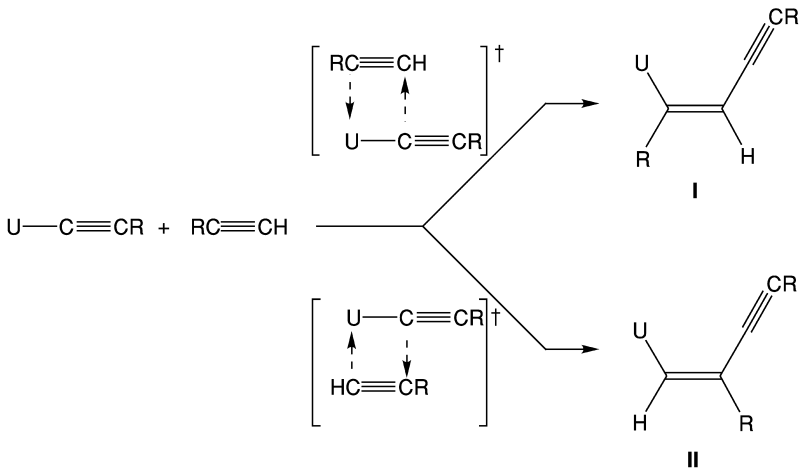


Fig. 26.4 *Modes of activation of an actinide–acetylide complex with an alkyne through a* syn *four-centered transition state pathway towards the formation of the intermediates* I *or/and* II.

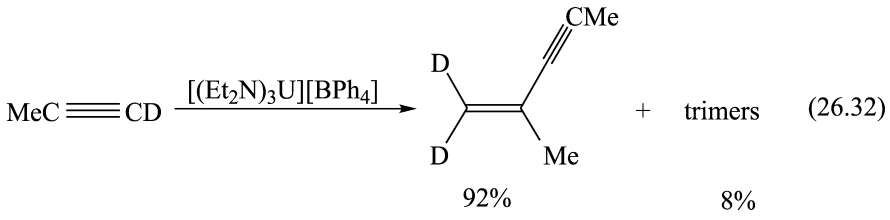
geminal dimer was chemoselectively formed with no trace formation of either *cis* or *trans* dimers (Haskel *et al*., 1999).

Mechanistically, in the reaction of $[(Et_2N)_3U][BPh_4]$ with terminal alkynes, one equivalent of the Et_2NH amine was released in solution, forming the bisamido acetylide cationic complex $[(Et_2N)_2U–C{\equiv}CR][BPh_4]$. This reaction was shown to be a slow equilibrium, and the addition of different equimolar amounts of external Et_2NH to the reaction mixture led to a linear lowering of the reaction rate (Fig. 26.5).

Considering that in the reactions with alkynes, the amount of the released free amine was stoichiometric, it was deduced that the free terminal alkyne was also the major protonolytic agent. The confirmation of this protonolytic hypothesis was obtained by generating a kinetic delay for the presumed fast protonolysis by the alkyne to allow trimer formation, through replacement of the terminal hydrogen with deuterium [equation (26.32)]. By using that strategy, the chemoselectivity of the oligomerization was altered allowing formation of the deuterated geminal dimer, and some trimer (Dash *et al*., 2000).



The kinetics of the dimerization reaction of $^{n}BuC{\equiv}CH$ was studied, indicating that the reaction behaved with a first-order dependence in precatalyst, and as

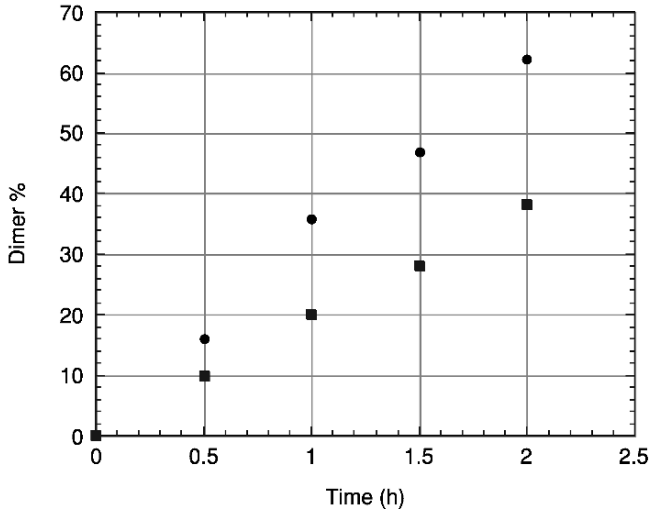


Fig. 26.5 *Following the dimer formation as a function of time in the reaction of* $^{i}PrC{\equiv}CH$ *catalyzed by* $[(Et_2N)_2U{-}C{\equiv}CR][BPh_4]$. *Absence of external amine* (●), *presence of one equivalent of external* Et_2NH (▪).

a function of alkyne, the kinetic plots showed two domains (Fig. 26.6). At low alkyne concentrations, an inverse proportionality was observed, indicating that the reaction was inverse first-order, and at higher concentrations, the reaction exhibits a zero-order in alkyne, similar to the behavior displayed in Fig. 26.3.

The activation parameters derived for the dimerization of ^{n}BuC≡CH were characterized by a small enthalpy of activation ($\Delta H^{\dagger} = 15.6(3)$ kcal mol^{-1}) and a negative entropy of activation ($\Delta S^{\dagger} = -11.4(6)$ eu). The proposed mechanism for the dimerization of ^{n}BuC≡CH is presented in Scheme 26.10. The initial step in the catalytic cycle is the alkyne C–H activation by the cationic uranium amide complex and the formation of the bisamido carbyl complex $[(Et_2N)_2U\text{-}C{\equiv}C^{n}Bu][BPh_4]$ (**M**) together with Et_2NH. Complex **M** can be in equilibrium with an alkyne forming the π-alkyne acetylide uranium complex **N**, which drives the active species out of the catalytic cycle (inverse rate dependence), or undergoes with an alkyne a head-to-tail insertion into the uranium–carbon σ-bond, yielding the substituted uranium alkenyl complex **O**. Complex **O** may undergo a σ-bond metathesis with an additional alkyne, leading to the corresponding dimer and regenerating the active carbyl complex **M**.

Complex **N** (for R = ^{t}Bu) was trapped and its structure spectroscopically determined. The ^{1}H- and ^{13}C-NMR spectra of complex **N** showed sharp lines as found for other actinide-IV type of complexes. The ^{1}H-NMR spectrum exhibited the acetylide signal (≡C–H) at $\delta = -2.14$ which correlated in the distortionless enhancement by polarization transfer (DEPT) and in the 2D C–H correlation NMR experiments to the carbon having the signal at $\delta = -19.85$

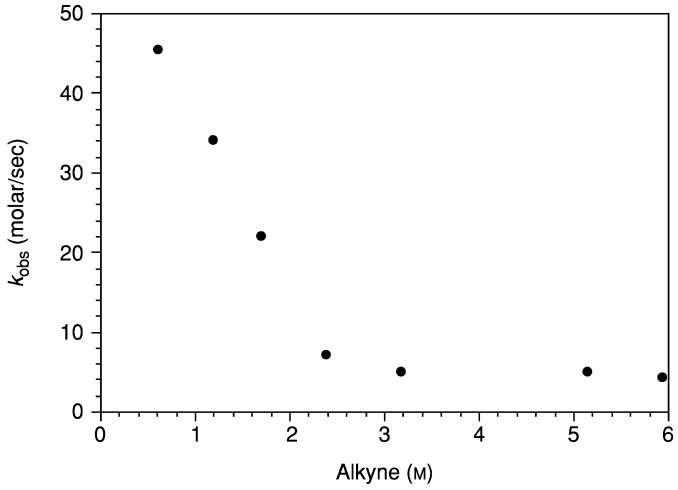

Fig. 26.6 *Alkyne dependence in the dimerization of* $^{n}BuC{\equiv}CH$ *promoted by* $[(Et_2N)_3U][BPh_4]$.

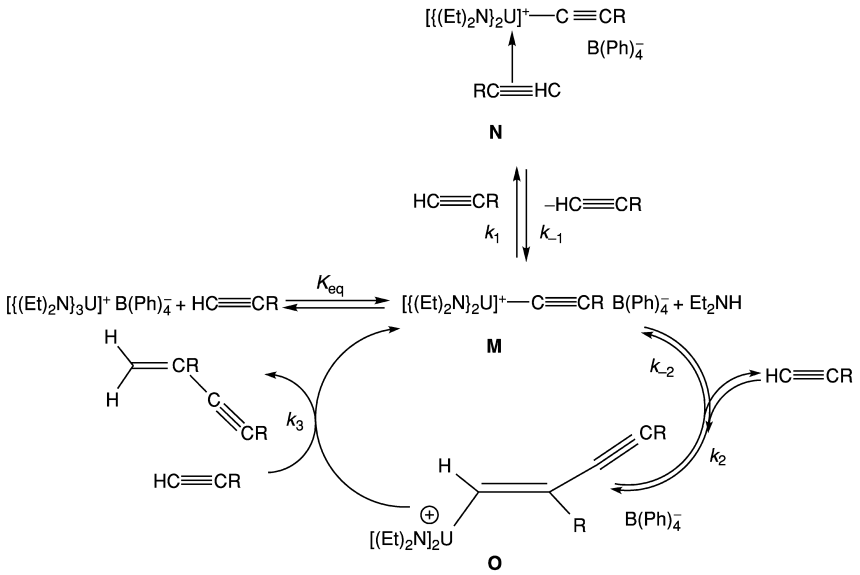
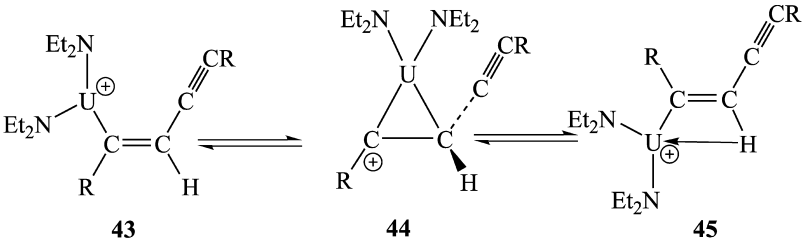


Scheme 26.10 *Proposed mechanism for the dimerization of terminal alkynes promoted by* $[(Et_2N)_3U][BPh_4]$.

ppm, with a coupling constant of $^{1}J = 250$ Hz. A confirmation of the formation of an alkyne η^2-complex, as compared to an acetylide complex or to a free alkyne was also obtained by FT-IR spectroscopy. The C≡C stretching of the free alkyne (2108 cm^{-1}) disappeared, giving rise to two signals at lower

frequencies, as expected for η^2-transition metal complexes, one at 2032 cm^{-1} similar to acetylide lanthanides, and the second one at 2059 cm^{-1}. The turnover-limiting step for the catalytic dimerization was found to be the insertion of the alkyne into the uranium–carbyl complex **M**. The proposed mechanism also agreed with the formation of trimer oligomers, which are only expected if a kinetic delay in the protonolysis was operative [equation (26.32)].

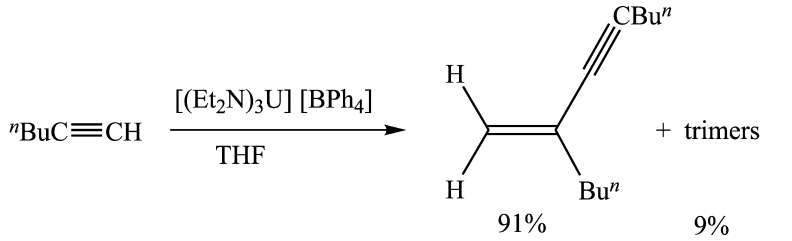
For sterically demanding alkyne substituents (TMS, ^{t}Bu), it was proposed that the rate of the protonolysis step is lower than that of the isomerization of the metalla–alkenyl complex **43**, producing the unexpected *cis*-dimer **45**, probably through the metalla–cyclopropyl cation (**44**), via the 'envelope isomerization' [equation (26.33)] (Faller and Rosan, 1977). The preference for the *cis*-isomer was suggested to arise from an agostic β-hydrogen interaction to the metal center (Wang *et al.*, 1999; Dash *et al.*, 2000).



(26.33)

(a) Effect of external amines in the dimerization of alkynes promoted by the cationic complex $[(Et_2N)_3U][BPh_4]$

Since the formation of the cationic complex **M** is an equilibrium reaction (Scheme 26.10), it was possible to tailor the regiochemistry of the dimerization by using external amines. The expectation was that the amine would be bonded to the cationic metal center, causing a kinetic delay, but also allowing unique regiochemistry. As presented above in the reaction of 1-hexyne with a catalytic amount of the cationic complex $[(Et_2N)_3U][BPh_4]$ [equation (26.29)] the geminal dimer was chemoselectively obtained. However, when the reaction was carried out in a polar solvent like THF, the reaction was much slower, yielding besides the dimer a mixture of trimers [equation (26.34)]. The result was rationalized by the lower reactivity of the THF adduct $[(Et_2N)_3(THF)_3U]^+$ resulting in slower protonolysis of the corresponding alkenyl intermediate $[(Et_2N)_2(THF)_3U(C{=}C(H)C{\equiv}CR)]^+$ (R = ^{n}Bu), and allowing further alkyne insertion with the formation of trimers, but with a total lack of regioselectivity.

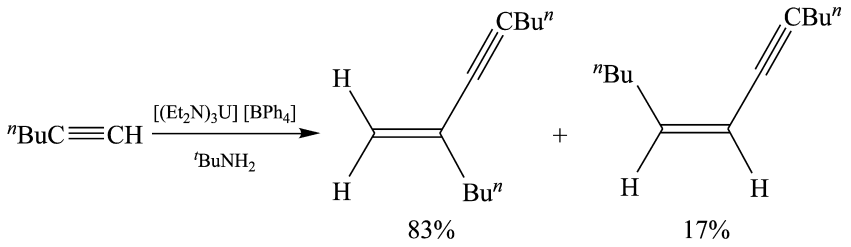


(26.34)

For 1-hexyne, the addition of equimolar amounts of the external amine $EtNH_2$ (alkyne:amine = 1:1) to the reaction mixture impeded the occurrence of the dimerization process. The same behavior was found for propyne [equation (26.35)]. This lack of reactivity for these alkynes was proposed to be a consequence of either their inability to engage in the equilibrium reaction (Scheme 26.10), resulting in the formation of the acetylide complex **M** in the presence of external $EtNH_2$, or the formation of an inactive π-alkyne complex, similar to **N** in Scheme 26.10. When 1-hexyne was reacted in the presence of an equimolar amount of the bulkier amine $^{t}BuNH_2$, the *gem* dimer and the unexpected *cis* dimer were obtained [equation (26.36)], indicating that the bulky amine probably allowed the formation of the acetylide intermediate $[(^{t}BuNH_2)_x(^{t}BuNH)_2U(C{\equiv}C^{n}Bu)]^{+}$ by the reaction of $^{n}BuC{\equiv}CH$ with the trisamido cation $[(^{t}BuNH_2)_3(^{t}BuNH)_3U]^{+}$. This acetylide would then undergo insertion of an alkyne molecule to give the corresponding alkenyl species and dimerization products.

$$RC{\equiv}CH + EtNH_2 \xrightarrow[\text{benzene}]{[(Et_2N)_3U]\,[BPh_4]} \text{no reaction} \qquad (26.35)$$

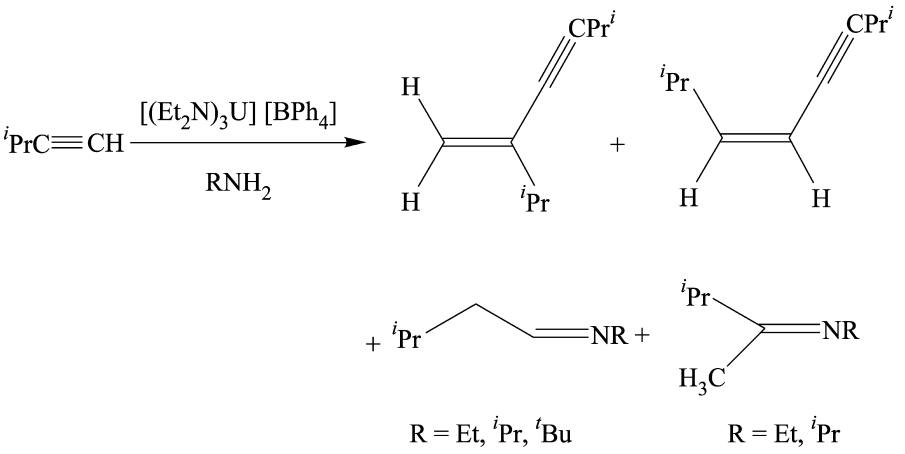
$R = CH_3,\ ^{n}Bu$



(26.36)

(b) Dimerization and hydroamination of $^{i}PrC{\equiv}CH$ and $^{t}BuC{\equiv}CH$ catalyzed by $[(Et_2N)_3U][BPh_4]$ in the presence of amines

Unpredictably, the reactions of $^{i}PrC{\equiv}CH$ and $^{t}BuC{\equiv}CH$ followed a quite distinct course. These alkynes were found to be more reactive than 1-hexyne or propyne in the presence of different amines. The nature of the diverse products were found to be strongly dependent on the size or steric encumbrance of the amine. The reaction of $^{i}PrC{\equiv}CH$ with $[(Et_2N)_3U][BPh_4]$ in the presence of $EtNH_2$ or $^{i}PrNH_2$ afforded the *cis* dimer, trace amounts of the *gem* dimer, and depending on the amine, one or both of the two corresponding hydroamination products were generated. By using the bulkier amine $^{t}BuNH_2$ both dimers and only one hydroamination product were observed [equation (26.37)] (Wang *et al.*, 2002a).

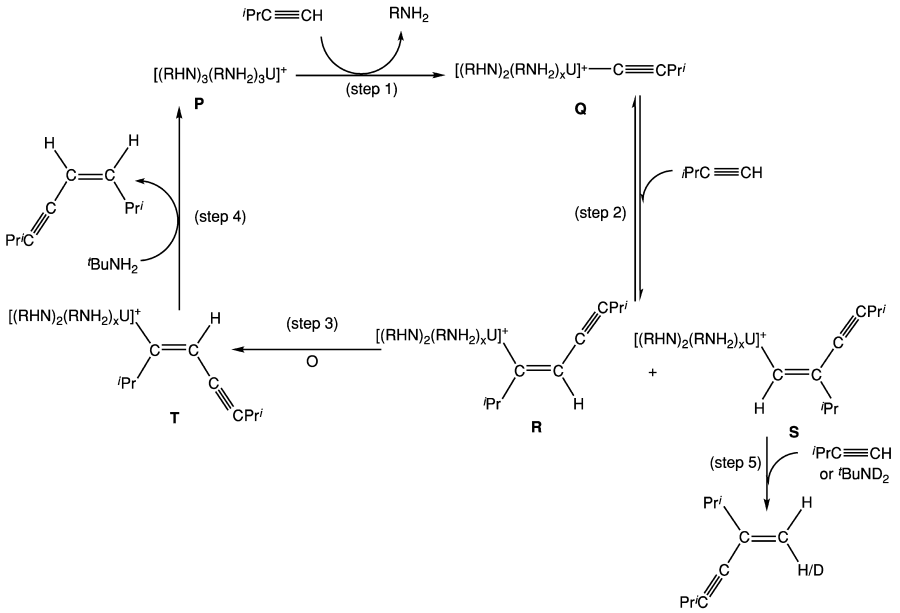


(26.37)

The rather large effect of alkyne concentration on the distribution of the products was revealed by the relative proportions of the dimers (*gem* to *cis*), which vary from 40:24 in the reaction of ^{t}BuND$_2$ with two equivalents of ^{i}PrC≡CH to 70:8 in the reaction of ^{t}BuNH$_2$ with one equivalent of ^{i}PrC≡CH. The results agreed with a dimerization mechanism such as that in Scheme 26.11. The mechanism consists of the formation of complex **Q** by the reaction of the cationic complex **P** with the alkyne (step 1). The acetylide complex reacts with an additional alkyne, producing the mixture of alkenyl compounds **R** and **S** (step 2). Isomerization of complex **R** through an envelope mechanism [equation (26.33)] allowed the formation of complex **T** (step 3) that by protonolysis yielded the unexpected *cis*-dimer (step 4). The addition of a large amount of alkyne in combination with a source of deuterium (as ^{t}BuND$_2$) removed complex **S** from the catalytic cycle as the *geminal* product (step 5). This latter species was found partially deuterated since the alkyne served also as a protonolytic reagent. The rate-determining step in the reaction was proposed to be the isomerization reaction (step 3).

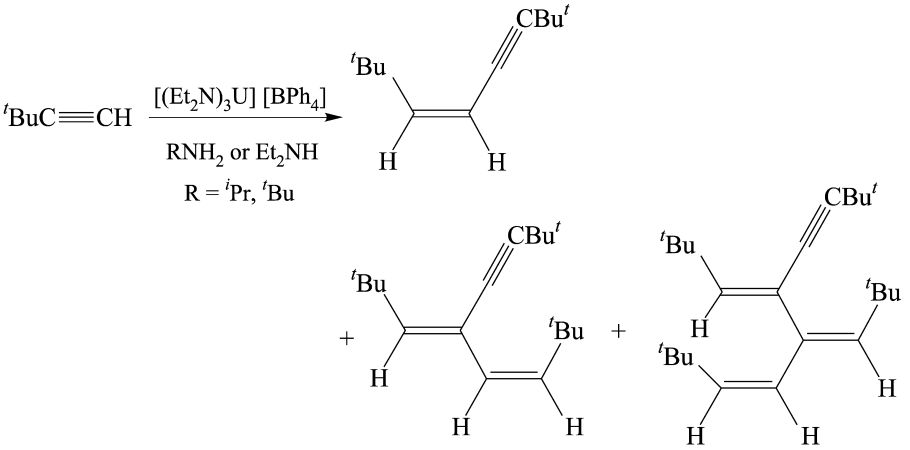
(c) Regioselective oligomerization of ^{t}BuC≡CH promoted by [(Et$_2$N)$_3$U][BPh$_4$] in the presence of amines

Reaction of the bulkier alkyne ^{t}BuC≡CH with the cationic uranium complex [(Et$_2$N)$_3$U][BPh$_4$] in the presence of ethylamine gave mainly the *cis* dimer and small amounts of the *gem* isomer (up to 2%), showing the remarkable influence of the nature of the amine on the dimerization reaction, by transposing the regioselectivity [see equation (26.31)]. With other primary or secondary amines, the *cis* dimer was the major product although the concomitant formation of one regiospecific trimer and one regiospecific tetramer were also observed.



Scheme 26.11 *Proposed mechanisms for the formation of the* gem- *and* cis-*dimers, promoted by the cationic complex* $[(Et_2N)_3U][BPh_4]$ *in the reaction of* $^{i}PrC{\equiv}CH$ *with primary amines.*

The most remarkable result, aside from the formation of only one trimer and one tetramer, was the fact that the regiochemistry of these oligomers was unpredictable, regardless of amine [equation (26.38)]. The trimer and the tetramer corresponded to the consecutive insertions of an alkyne molecule into the vinylic CH bond *trans* to the bulky *tert*-butyl group.



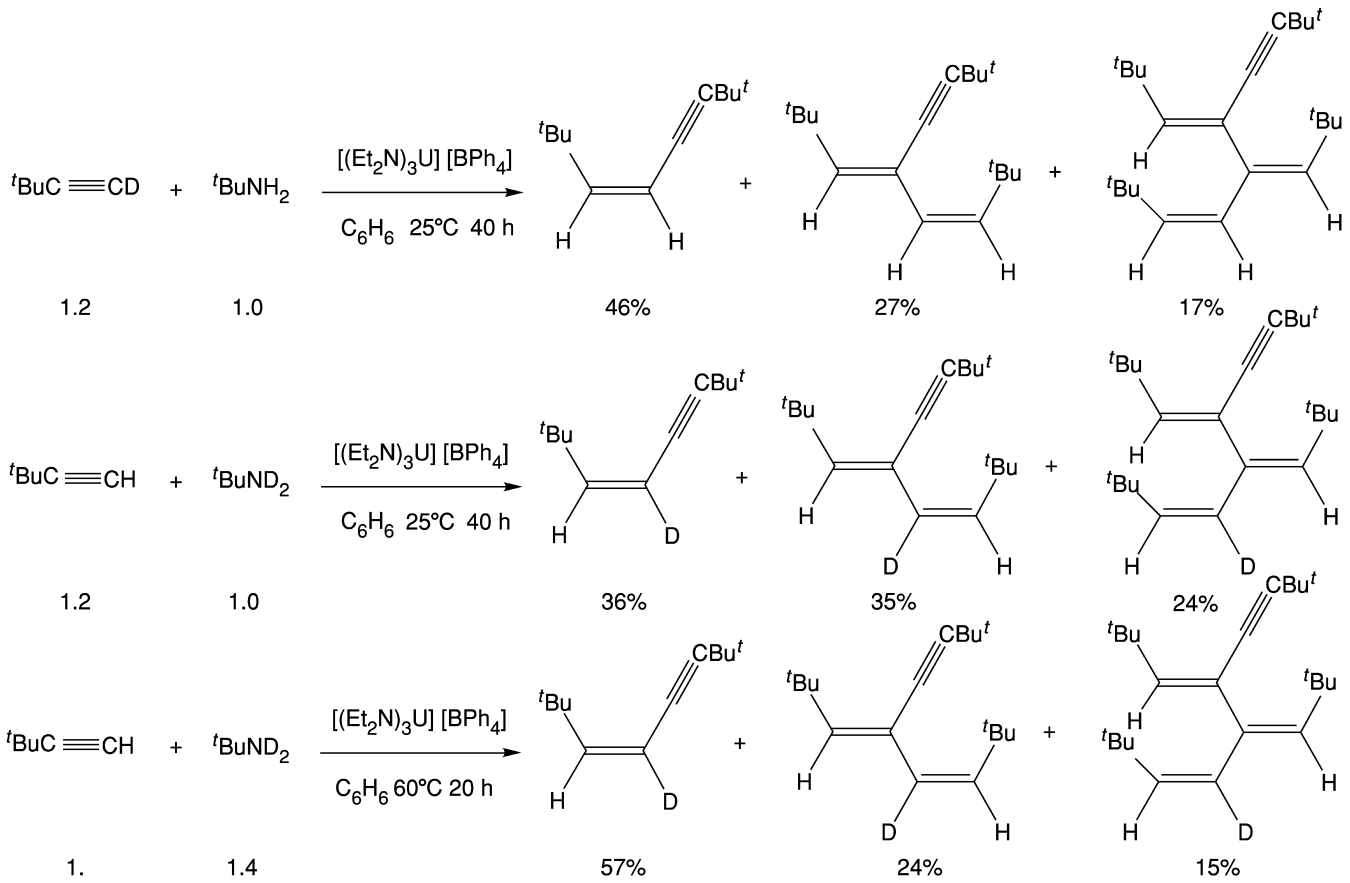
(26.38)

To reveal the role of the amine, and to examine the possibility that the initially *cis* isomer was reactivated to yield the regioselective trimer and tetramer, the reactions with deuterated amine ^{t}BuND$_2$ and deuterated alkyne ^{t}BuC≡CD were performed (Scheme 26.12). The reaction of ^{t}BuC≡CD with ^{t}BuNH$_2$ gave the products with *no* deuterium, indicating that ^{t}BuC≡CD was transformed into ^{t}BuC≡CH. The reaction for the H/D exchange between ^{t}BuC≡CH and ^{t}BuND$_2$ was found to be active in the presence of the catalyst, to give ^{t}BuC≡CD and ^{t}BuNHD. These compounds were also observed at early stages of the catalytic oligomerization of ^{t}BuC≡CH in the presence of ^{t}BuND$_2$, which afforded the *cis* dimer as a mixture of mono- and non-deuterated compounds. The amount of the non-deuterated dimer was always larger than that of the mono-deuterated dimer. The deuterium atom in the dimer was found only in the *trans* position relative to the ^{t}Bu group. Mixtures of non- and mono-deuterated compounds were also obtained for the trimer and tetramer having the deuterium atom always in the internal position, *trans* to the ^{t}Bu group. The presence of only one deuterium atom in the oligomers, in unique positions, strongly suggested that this D atom was introduced during the protonolysis steps of the catalytic cycle. In agreement with this hypothesis was the increasing proportion of the trimer and dimer, which likely results from the slower cleavage of the alkenyl intermediate by the deuterated amine or alkyne, permitting further insertion of an alkyne molecule into the U–C bond.

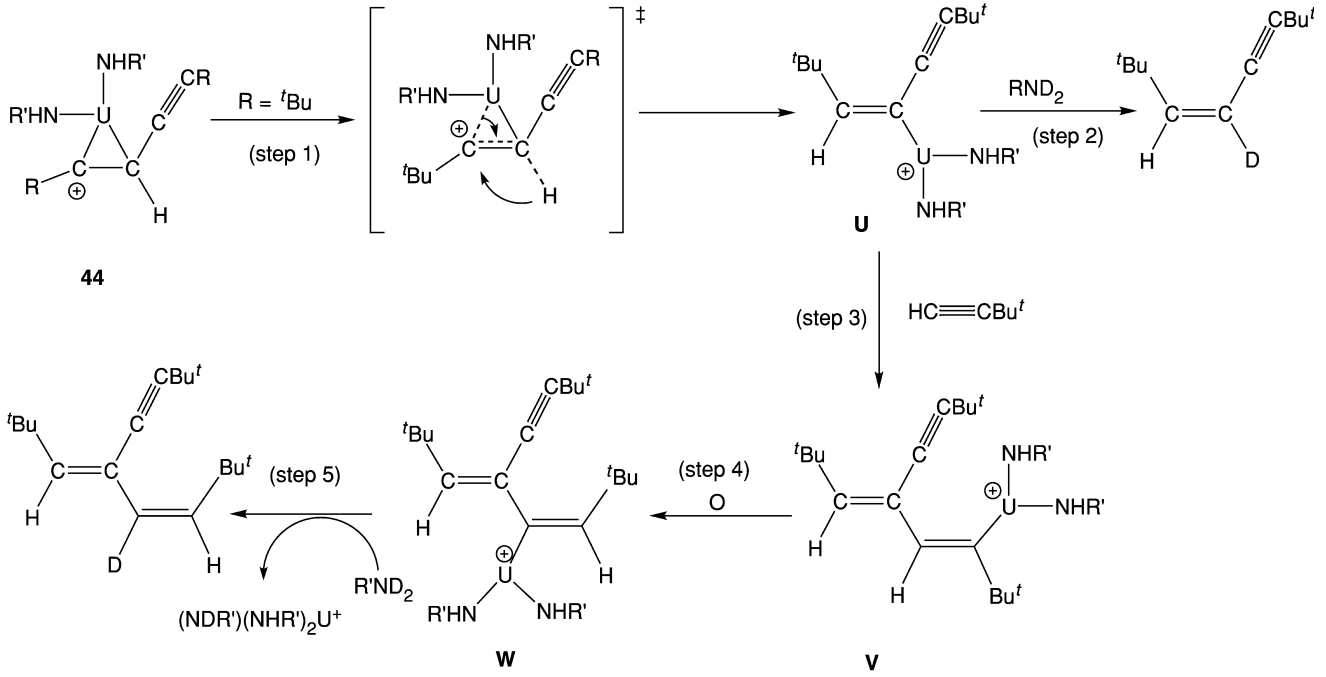
The proposed mechanism for the regiospecific formation of the trimer and tetramer is described in Scheme 26.13. The same intermediate **44**, which was proposed to explain the *trans–cis* isomerization of the alkenyl intermediate by the envelope mechanism [equation (26.33)] was proposed to explain conceptually the regiospecific formation of one trimer and one tetramer. The mechanism is based on the 1,2-hydride shift isomerization of the metal–alkenyl complex **44**, leading to the isomeric compound **U** (step 1). Deuterolysis at this stage liberates the deuterated dimer regioselectively (step 2). Insertion of an alkyne molecule into the U–C bond of **U** leads to the formation of complex **V**. The regioselectivity of this insertion (step 3) results from the steric hindrance between the alkyne substituent at the α-position of the metal–alkenyl chain and the incoming alkyne. The same isomerization process as before converts complex **V** into the *syn* complex **W** (step 4). Protonolysis of **W** regenerates the catalyst and produces the specific trimer (step 5), whereas the additional insertion of the alkyne, envelope isomerization, and protonolysis yielded the specific tetramer.

26.5 CROSS DIMERIZATION OF TERMINAL ALKYNES CATALYZED BY $[(Et_2N)_3U][BPh_4]$

Based on the different regioselectivities observed for the cationic complex $[(Et_2N)_3U][BPh_4]$, it was proposed that selective cross dimerization of alkynes could be induced. In the reaction of an equimolar mixture of ^{t}BuC≡CH

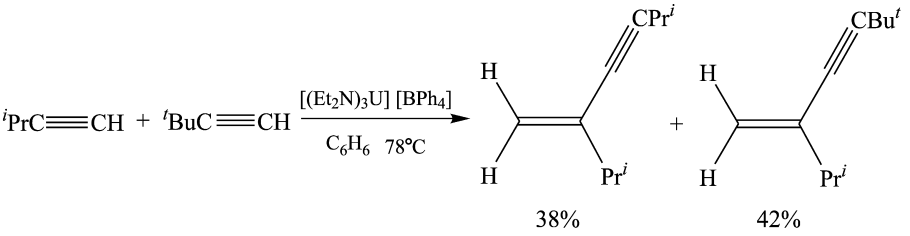


Scheme 26.12 *Deuterium labeling experiments in the oligomerization of* $^{t}BuC{\equiv}CH$ *with* $^{t}BuND_2$ *and* $^{t}BuC{\equiv}CD$ *with* $^{t}BuNH_2$ *promoted by* $[(Et_2N)_3U][BPh_4]$.



Scheme 26.13 *Proposed mechanism for the regioselective dimerization and trimerization of* $^{t}BuC{\equiv}CH$ *promoted by* $[(Et_2N)_3U][BPh_4]$ *in the presence of* $^{t}BuNH_2$.

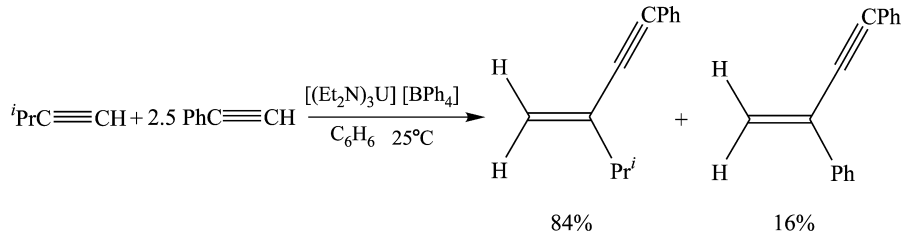
and ^{i}PrC≡CH with [$(Et_2N)_3U$][BPh_4], the *gem*-dimer of ^{i}PrC≡CH and the *gem*-codimer were obtained [equation (26.39)] (Wang *et al.*, 2002b).



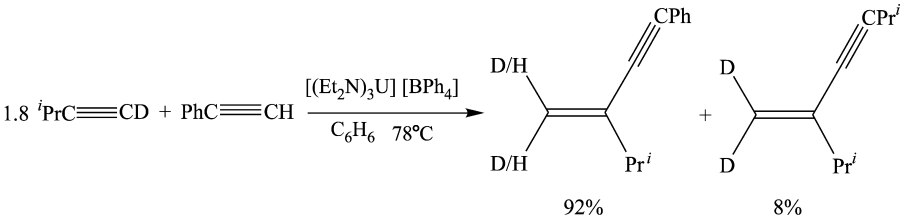
(26.39)

This result was extremely important, since it pointed out that the formation of both metal–acetylide complexes, M–C≡CR (R = ^{i}Pr, ^{t}Bu), was rapid and of comparable rates, although the insertion of ^{i}PrC≡CH into both M–C≡CR (R = ^{i}Pr, ^{t}Bu) moieties was much faster than that of ^{t}BuC≡CH. The lack of any trimer formation implied that the protonolysis of the metal–alkenyl fragments by either one of the terminal alkynes was faster than any additional alkyne insertion.

When a mixture of ^{i}PrC≡CH and PhC≡CH was reacted at room temperature (to avoid trimers), the *gem*-codimer was obtained. This codimer was the result of the protonolysis of the metal–alkenyl fragment produced from the insertion of ^{i}PrC≡CH into the M–C≡CPh moiety. Along with the codimer, a small amount of the *gem*-dimer of PhC≡CH was also produced by the insertion of PhC≡CH into the M–C≡CPh moiety before the protonolysis [equation (26.40)]. This result showed that PhC≡CH preferentially reacted with the precatalyst [$(Et_2N)_3U$][BPh_4] forming the acetylide complex U–C≡CPh into which ^{i}PrC≡CH inserted faster as compared with the aromatic alkyne. To shed light on which of the alkynes is the major protonolytic reagent the reaction of a mixture of ^{i}PrC≡CD and PhC≡CH was performed [equation (26.41)].

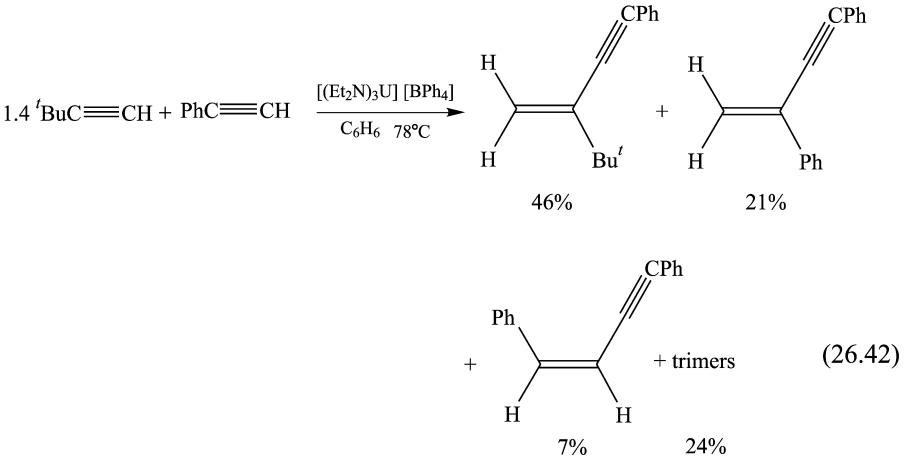


(26.40)



(26.41)

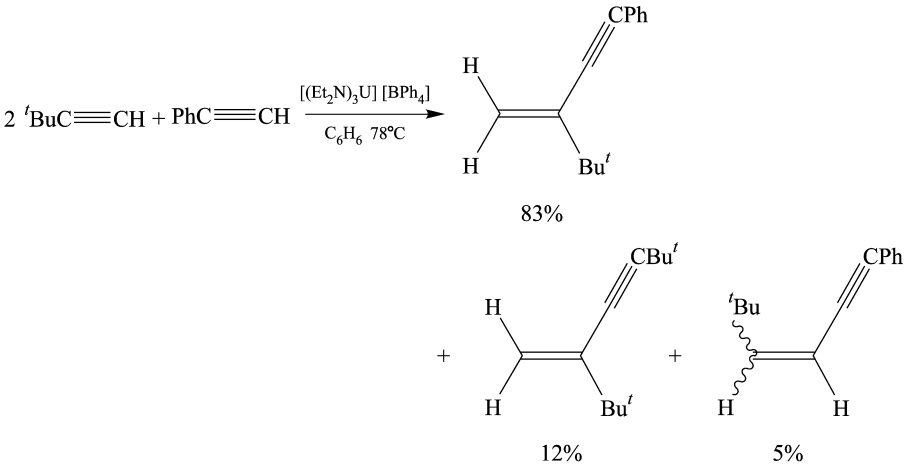
The favored formation of the codimer was substantiated with the following observations: (i) the aromatic metal–acetylide moiety was initially formed; (ii) ^{i}PrC≡CD inserted faster than the corresponding aromatic alkyne; (iii) the protonolysis by PhC≡CH was faster than that of the aliphatic alkyne; (iv) the formation of the deuterated *gem*-dimer was obtained due to some excess of the aliphatic alkyne that was present in the reaction. The scrambling of the deuterium atom at the geminal position (only one deuterium at each dimer) was the result of the exchange of acidic H/D atoms between the two aliphatic and aromatic alkynes through the metal center. With an excess of the aliphatic alkyne, the deuterolysis of the most stable U–C≡CPh by ^{i}PrC≡CD produced PhC≡CD and U–C≡CPr^{i} that reacted again with the aromatic alkyne yielding back U–C≡CPh and ^{i}PrC≡CH. The intermediate U–C≡CPr^{i} was the fragment responsible for the formation of the *gem* unlabelled dimer when the aliphatic alkyne was present in excess. The absence of trimers was an indication that the protonolysis by the PhC≡CH/D was much faster than any alkyne insertion, aromatic or aliphatic, into the metal–alkenyl complex.



(26.42)

As mentioned above, when the bulkier alkyne ^{t}Bu≡CH was dimerized, the *cis* product was formed in addition to the *geminal* dimer [equation (26.31)]. Thus, in the codimerization of ^{t}Bu≡CH with PhC≡CH [equation (26.42)], the

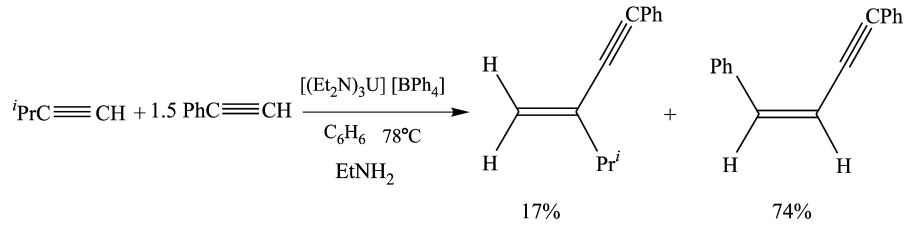
gem-codimer and the two dimers (*gem* and *cis*) of the aromatic alkyne were characterized as products. This result argued once more for the preferred formation of the aromatic metal–acetylide U–C≡CPh into which both ^{t}BuC≡CH or PhC≡CH are able to insert. PhC≡CH inserted in this codimerization with low regioselectivity and the protonolysis was found to be not as fast as the insertion, since mixtures of trimers of PhC≡CH were also found in trace quantities.



(26.43)

To avoid the trimers and to allow a better regioselectivity a larger excess (two equivalent) of ^{t}BuC≡CH and one equivalent of PhC≡CH were used in the cross dimerization [equation (26.43)] producing the *gem*-codimer as the major isomer (83%), the *gem*-dimer of the aliphatic alkyne (12%), and small amounts of the codimer (5%). This result indicated again that the U–C≡CPh moiety was the first intermediate formed. To this acetylide intermediate, ^{t}BuC≡CH inserts preferentially in the head-to-tail manner to obtain the precursor of the codimer.

The effect of external amines in the cross dimerization of terminal alkynes with the cationic complex $[(Et_2N)_3U][BPh_4]$ was investigated by the reaction of an excess of PhC≡CH with ^{i}PrC≡CH in the presence of $EtNH_2$. The reaction generated low yields of the codimer $CH_2{=}C(^{i}Pr)C{\equiv}CPh$ (17%), as compared with the reaction without external amine, and remarkably the *cis* aromatic dimer, was the major product [equation (26.44)].



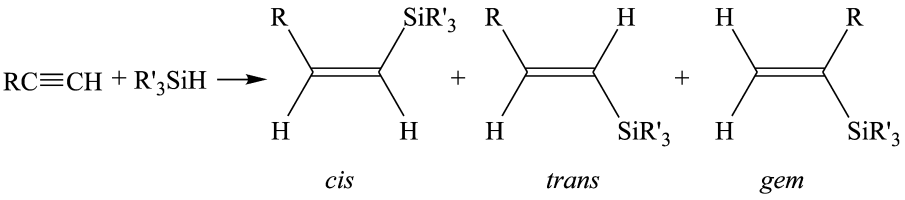
(26.44)

26.6 CATALYTIC HYDROSILYLATION OF OLEFINS

26.6.1 Catalytic hydrosilylation of terminal alkynes promoted by neutral organoactinides

The metal-catalyzed hydrosilylation reaction, which is the addition of a Si–H bond across a carbon–carbon multiple bond, is one of the most important reactions in organosilicon chemistry and has been studied extensively for half a century. The hydrosilylation reaction is used in the industrial production of organosilicon compounds (adhesives, binders, and coupling agents), and in research laboratories, as an efficient route for the syntheses of a variety of organosilicon compounds, silicon-based polymers, and new type of dendrimeric materials. The versatile and rich chemistry of vinylsilanes has attracted considerable attention in recent years as they are considered important building blocks in organic synthesis (Chan, 1977; Colvin, 1988; Fleming *et al.*, 1989).

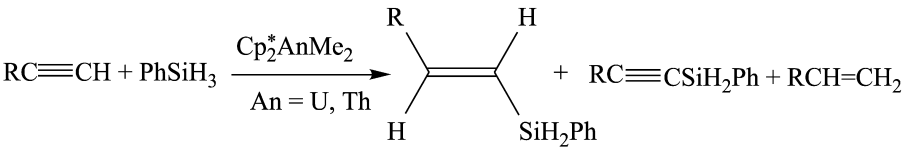
The syntheses of vinylsilanes have been extensively studied and one of the most convenient and straightforward methods is the hydrosilylation of alkynes (Esteruelas *et al.*, 1993; Takeuchi and Tanouchi, 1994; Asao *et al.*, 1996). In general, hydrosilylation of terminal alkynes produces the three different isomers, *cis*, *trans*, and *geminal*, as a result of both 1,2 (*syn* and *anti*) and 2,1 additions, respectively, as shown in equation (26.45). The distribution of the products is found to vary considerably with the nature of the catalyst, substrates, and the specific reaction conditions.



(26.45)

(a) Hydrosilylation of terminal alkynes: scope at room temperature by $(C_5Me_5)_2AnMe_2$ complexes

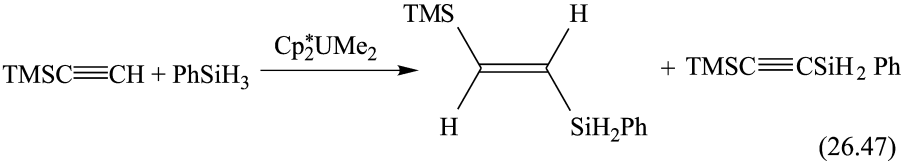
The room temperature reaction of $(C_5Me_5)_2AnMe_2$ (An = Th, U) with an excess of terminal alkynes RC≡CH (R = ^{t}Bu, ^{i}Pr, ^{n}Bu) and $PhSiH_3$ resulted in the catalytic formation of the corresponding *trans*-vinylsilanes RCH = $CHSiH_2Ph$, the dehydrogenative silylalkyne RC≡$CSiH_2Ph$ and alkenes RCH=CH_2 (R = ^{t}Bu, ^{i}Pr, ^{n}Bu) [equation (26.46)] (Dash *et al.*, 1999).



$R = {}^{t}Bu, {}^{i}Pr, {}^{n}Bu$ (26.46)

Irrespective of the alkyl substituents and the metal center, the major product in the hydrosilylation reaction was the regio- and stereoselective *trans*-vinylsilane without any trace formation of the other two hydrosilylation isomers (*geminal* or *cis*). For bulky alkynes (^{t}BuC≡CH), the product distribution was nearly the same for both catalytic systems, whereas for other terminal alkynes, it varies from one catalytic system to another. In the hydrosilylation reaction of the alkynes with $(C_5Me_5)_2ThMe_2$ and $PhSiH_3$, similar amounts of the alkene and the silylalkyne were obtained. This result suggested a mechanistic pathway involving two organometallic complexes formed possibly in a consecutive manner, each species being responsible for each one of the products.

The reaction of $(C_5Me_5)_2UMe_2$ with TMSC≡CH (TMS = Me_3Si) and $PhSiH_3$ was slow producing the *trans*-TMSCH = $CHSiH_2Ph$ and the silylalkyne $TMSC{\equiv}CSiH_2Ph$ respectively, whereas for the analogous $(C_5Me_5)_2ThMe_2$, no hydrosilylation or dehydrogenative coupling products were observed [equation (26.47)].

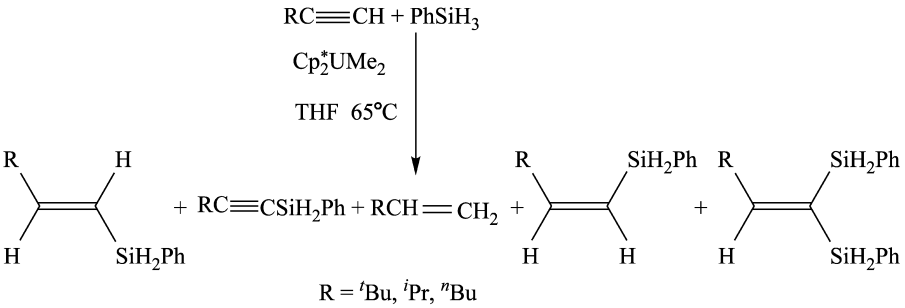


(26.47)

(b) Hydrosilylation of terminal alkynes: scope of catalysis at high temperature by $(C_5Me_5)_2AnMe_2$ complexes

The chemoselectivity and the regioselectivity of the vinylsilanes formed in the organoactinide-catalyzed hydrosilylation of terminal alkynes with $PhSiH_3$ at high temperature (65–78°C) were found to be diverse, as compared to the hydrosilylation results obtained at room temperature. The hydrosilylation of RC≡CH (R = ^{t}Bu, ^{i}Pr, ^{n}Bu) with $PhSiH_3$ catalyzed by $(C_5Me_5)_2UMe_2$, produced in addition to the hydrosilylation products at room temperature [equation (26.46)] the corresponding *cis*-hydrosilylated compounds, *cis*-$RCH{=}CHSiH_2Ph$, and small to moderate yields of the *unexpected* double hydrosilylation products $RCH{=}C(SiH_2Ph)_2$ (R = ^{t}Bu, ^{i}Pr, ^{n}Bu), in which the

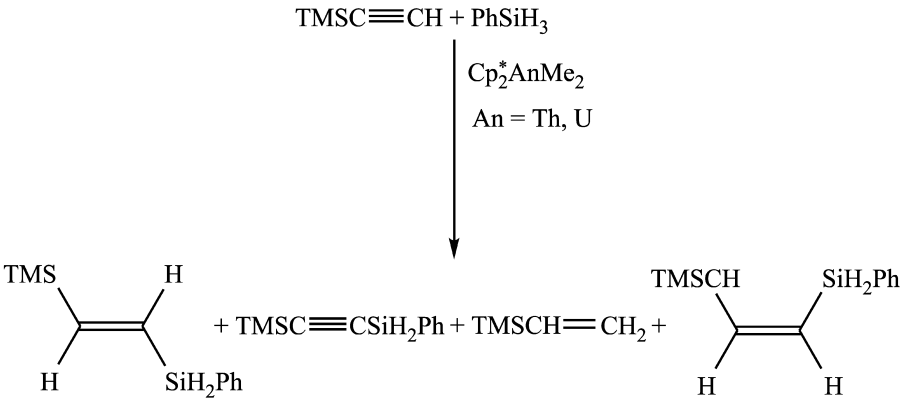
two silyl moieties are attached to the same carbon atom [equation (26.48)] (Dash *et al.*, 1999).



(26.48)

Whereas $(C_5Me_5)_2UMe_2$ catalyzed the hydrosilylation yielding a mixture of both *cis*- and *trans*-vinylsilane, remarkably, $(C_5Me_5)_2ThMe_2$ afforded only the *trans*-vinylsilane.

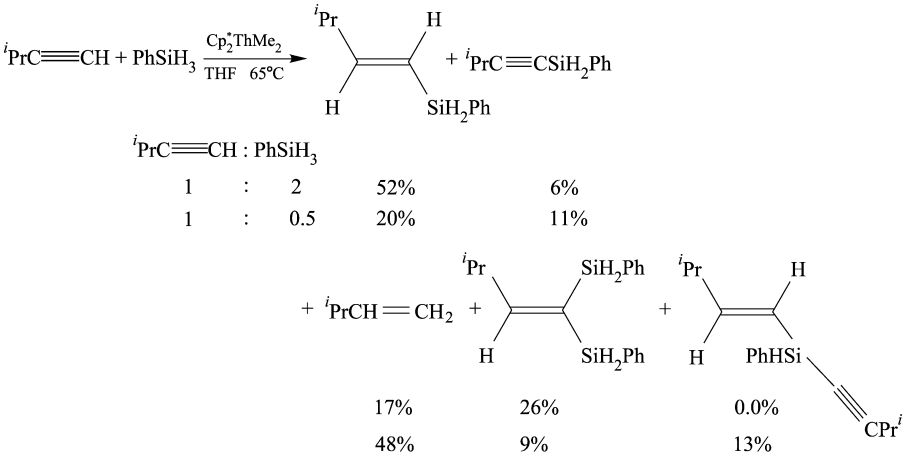
In the hydrosilylation reaction of TMSC≡CH with $PhSiH_3$ catalyzed by $(C_5Me_5)_2UMe_2$, besides the *trans*-vinylsilane and the silylalkyne products, which were also obtained at room temperature [equation (26.47)], the *cis*-vinylsilane and the olefin $TMSCH{=}CH_2$ were also observed [equation (26.49)]. For $(C_5Me_5)_2ThMe_2$, the same products as in the hydrosilylation reaction promoted by $(C_5Me_5)_2UMe_2$ were formed except for the *cis*-vinylsilane, in contrast to the room temperature reaction, in which no products were found.



(26.49)

(c) Effect of the Ratio Alkyne:Silane and the Silane Substituent in the Hydrosilylation Reaction

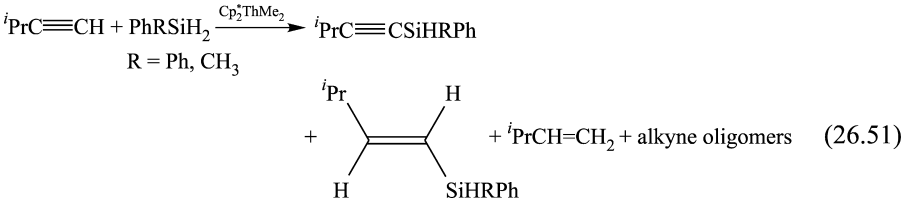
The effect of $PhSiH_3$ on the formation of the different products was studied by performing comparative experiments. Large chemoselectivity and regioselectivity dependence of the products on the silane concentrations was observed [equation (26.50)].



(26.50)

When the hydrosilylation reaction was carried out using a 1:2 ratio of $^{i}PrC{\equiv}CH$:$PhSiH_3$ with $(C_5Me_5)_2ThMe_2$, the *trans*-vinylsilane was found to be the major product. When the reaction was conducted with the opposite ratio between the substrates ($^{i}PrC{\equiv}CH$:$PhSiH_3 = 0.5$), the olefin $^{i}PrCH{=}CH_2$ was found to be the major product, in addition to the other products (*trans*-$^{i}PrCH{=}CHSiH_2Ph$, $^{i}PrC{\equiv}CSiH_2Ph$, the double hydrosilylated olefin, and the tertiary silane *trans*-$^{i}PrCH{=}CHSiH(Ph)(C{\equiv}C^{i}Pr)$). The tertiary silane was obtained by the dehydrocoupling metathesis between the *trans*-alkenylsilane and the metal acetylide complex.

The replacement of a hydrogen atom on $PhSiH_3$ by either an alkyl or a phenyl group generated a reduction in the hydrosilylation reaction rate when compared to the rate obtained utilizing phenylsilane. The selectivities of the products were appreciably different when compared to those obtained using $PhSiH_3$ as the hydrosilylating agent [equation (26.51)].



(26.51)

(d) Kinetic studies on the hydrosilylation of ^{i}PrC≡CH with $PhSiH_3$ catalyzed by $(C_5Me_5)_2ThMe_2$

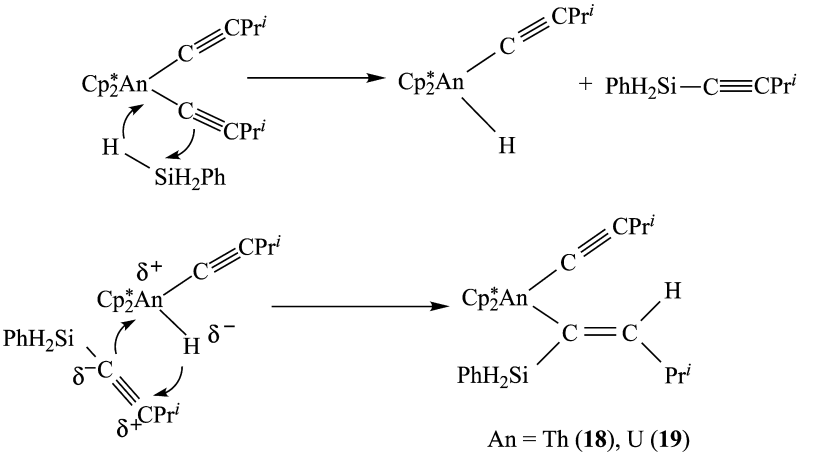
The kinetic study of the hydrosilylation of ^{i}PrC≡CH with $PhSiH_3$ catalyzed by $(C_5Me_5)_2ThMe_2$ shows a first-order dependence in alkyne, silane, and catalyst. The empirical rate law expression for the $(C_5Me_5)_2ThMe_2$ catalyzed hydrosilylation of ^{i}PrC≡CH with $PhSiH_3$ is given by equation 26.52.

$$v = k[^{i}\mathrm{PrC}{\equiv}\mathrm{CH}][\mathrm{PhSiH_3}][(\mathrm{C_5Me_5})_2\mathrm{ThMe_2}] \qquad (26.52)$$

From the Eyring analysis, the derived activation parameters, E_a, $\Delta H^{\dagger}$, and $\Delta S^{\dagger}$ values are 6.9 (3) kcal mol^{-1}, 6.3(3) kcal mol^{-1}, and 51.1(5) eu, respectively.

(e) Formation of active species, mechanism, and thermodynamics in the hydrosilylation of alkynes

We have already seen that in the reaction of either bisacetylide organoactinide complex with $PhSiH_3$ the quantitative isolation of complexes **18** and **19**, for thorium and uranium, respectively, was observed [equation (26.4)]. These complexes were formed by the σ-bond metathesis with the silane forming the corresponding actinide hydrides and the silylalkyne, which rapidly reinsert producing **18** or **19 [**equation (26.53)].



(26.53)

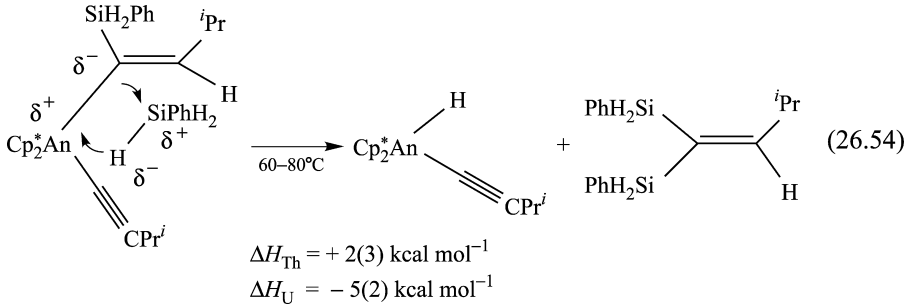
The regioselectivity of the insertion of $PhSiH_2C{\equiv}CPr^i$ into the actinide hydride bond is electronically favored, driven by the polarity of the organoactinides and the π* orbital of the alkyne (Apeloig, 1989). In addition, since the insertion occurs through a four-center transition state mechanism, the *cis*-stereochemistry is expected, as corroborated by the H_2O poisoning experiment and the high-temperature reactions with alkyne or silane [equation (26.5)]. The same regioselective insertion of TMSC≡CH into an organothorium

alkenyl complex Th–C bond was observed in the organoactinide-catalyzed oligomerization of alkynes (Straub *et al.*, 1995, 1999).

The formation of an organoactinide–silane intermediate **46** as described in Scheme 26.14 was shown to be not operative by the following experiments: (1) quenching experiments with water gave exclusively the *cis* vinylsilane; (2) under stoichiometric conditions, the addition of silane did not induce the protonolysis of the acetylide–alkenylsilane complex (**18** or **19**), to yield complex **46**; (3) no geminal hydrosilylated products were obtained (as would be expected were complex **48** an intermediate); (4) no *cis* hydrosilylated products can be obtained from complex **46**, and (5) no *cis* double hydrosilylated product was observed (if σ-bond metathesis occurred from complex **47** or **48**) (Dash *et al.*, 1999).

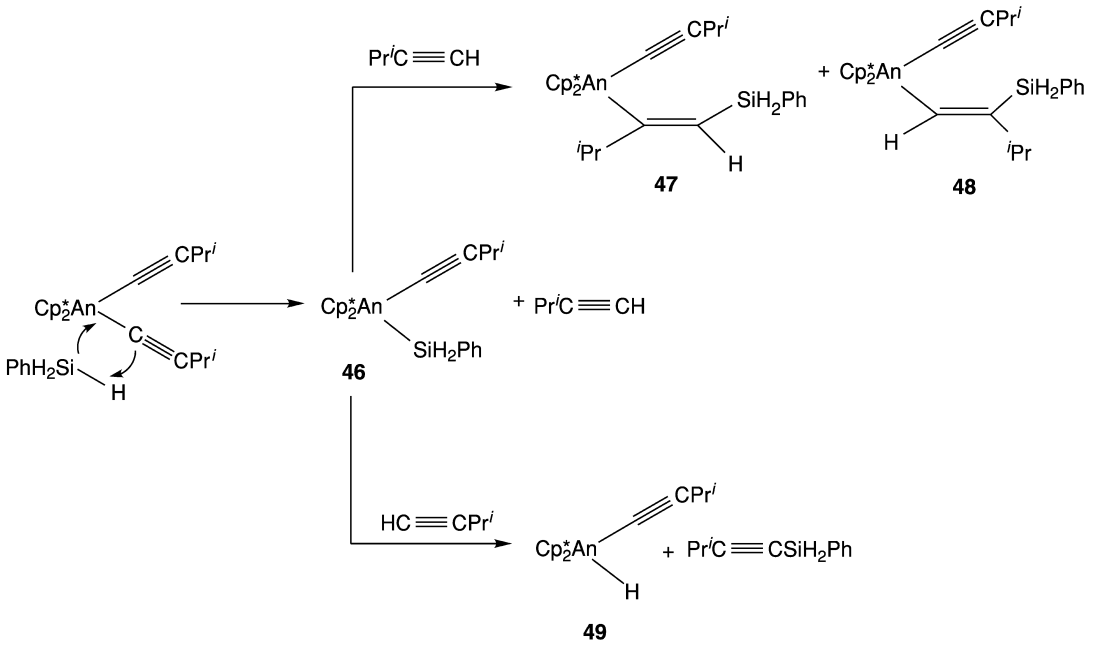
The reactions of complexes **18** or **19** yielding the double hydrosilylated product [equation (26.54)] were proposed to be stereoselectively favored, due to the assumed polarization of the $PhSiH_3$ towards the metal center, as well as the preferred thermodynamics, as compared to the protonolysis by the silane producing complex **46** and the *cis* hydrosilylated product ($\Delta H_{(Th)} = +15$ (4) kcal mol^{-1}; $\Delta H_{(U)} = -3$ (2) kcal mol^{-1}).

The most remarkable observation concerned the reaction products of complexes **18** or **19** with alkyne at either low or high temperatures. At elevated temperatures, the expected *cis*-hydrosilylated product was obtained, but at low temperatures, the unexpected *trans* isomer was achieved. These results have been explained through a competitive mechanism in which an equilibrium gives the different hydrosilylation products at different temperatures.

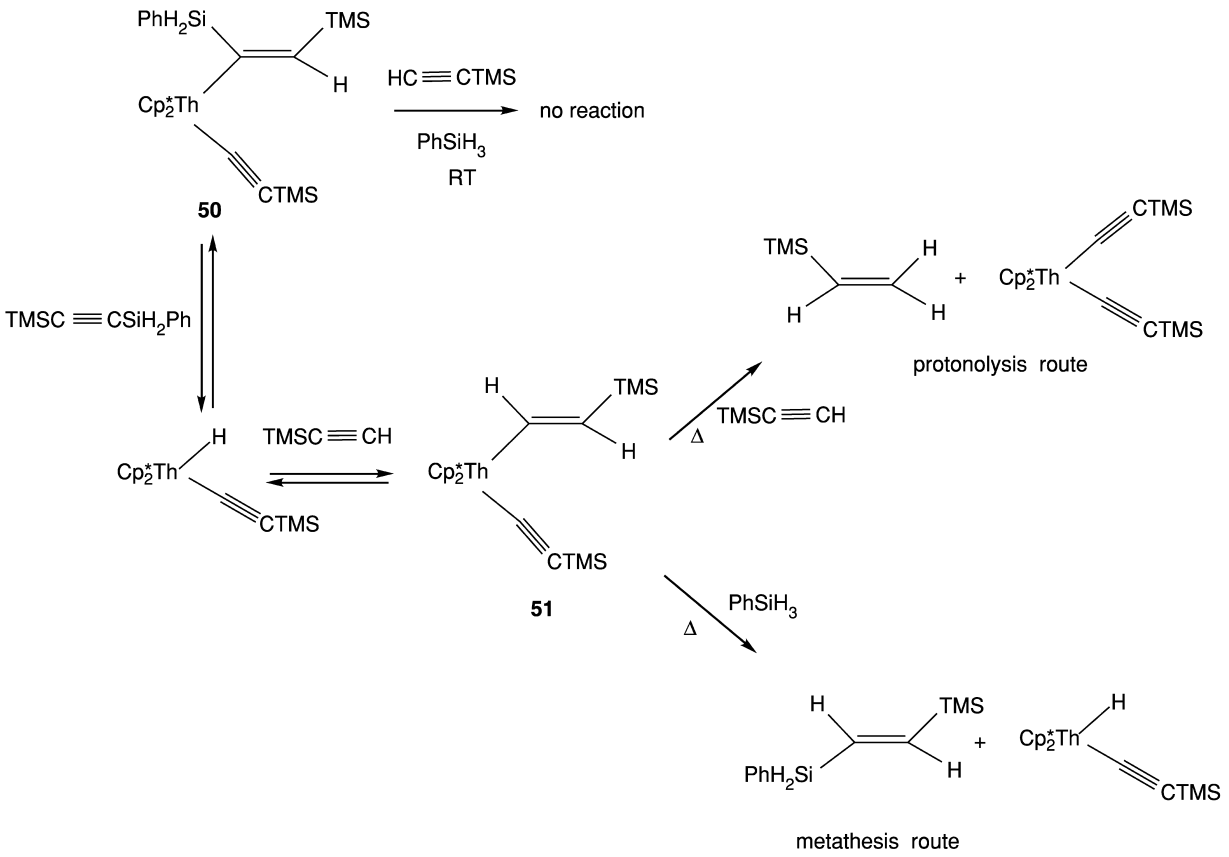


(26.54)

Different alkynes displayed different reactivities. TMSC≡CH exhibited a total lack of reactivity with $PhSiH_3$ in the presence of $(C_5Me_5)_2ThMe_2$ at room temperature. However, at high temperature, the *trans* vinylsilane, the silylalkyne, and the alkene were obtained. This type of reactivity was explained, in general, as the result of a kinetic effect suggesting also an equilibrium between the organometallic complexes **50** and **51** (Scheme 26.15). Complex **51** was obtained by the insertion of the silylalkyne into a hydride complex. Complex **51** is able to react with another alkyne, yielding the alkene and the bis(acetylide) complex (protonolysis route) or react with a silane producing the organometallic hydride and the *trans*-product (σ-bond metathesis route). The low activity



Scheme 26.14 *Expected organoactinide intermediates in the stoichiometric hydrosilylation of terminal alkynes through a transient organoactinide–silicon bond.*



Scheme 26.15 *Protonolysis and σ-bond metathesis routes for the high-temperature hydrosilylation of TMSC≡CH with $PhSiH_3$ catalyzed by $(C_5Me_5)_2ThMe_2$.*

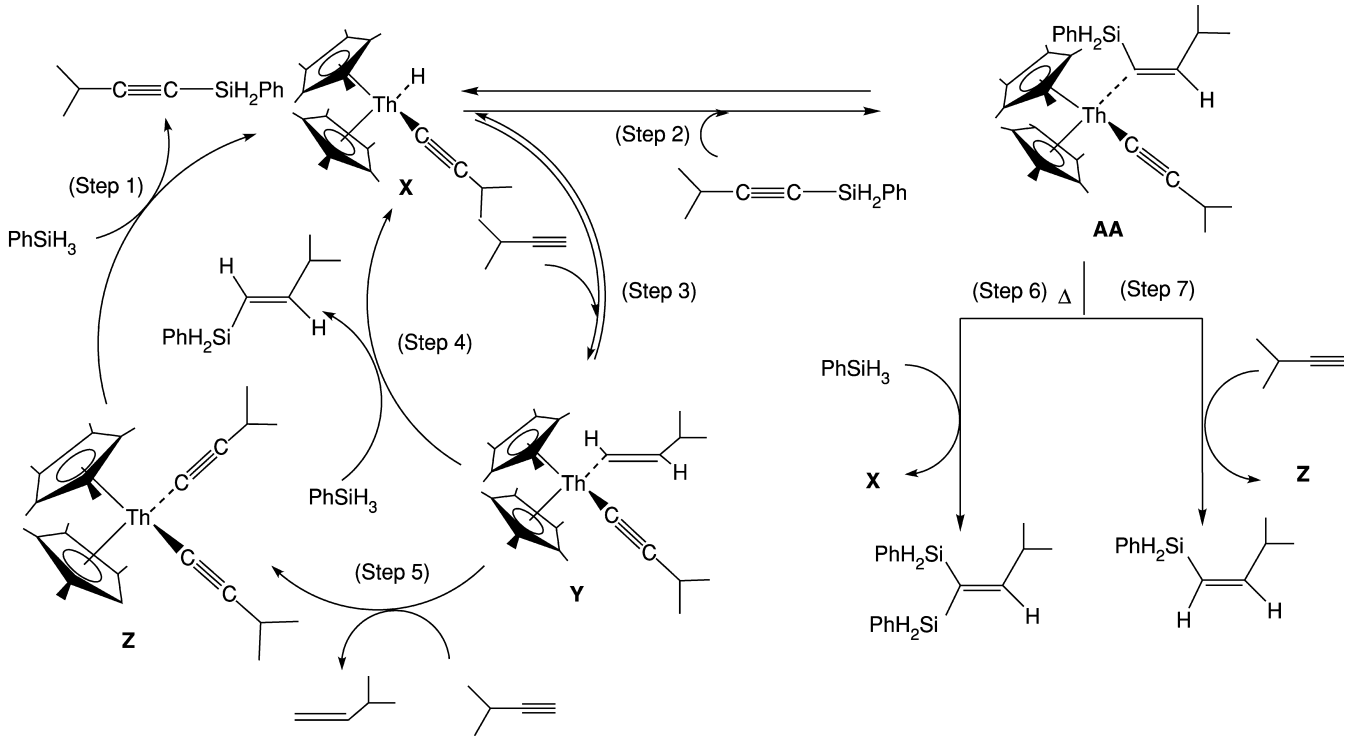
obtained for TMSC≡CH was explained by an elevated activation energy to perform both the metathesis or protonolysis of complex **51**, as compared with other alkynes (Dash *et al.*, 1999).

The ratio between the silane and the alkyne were found to govern the kinetics leading to the different products. Thus, when the $PhSiH_3$:$^{i}PrC{\equiv}CH$ ratio was two, the *trans*- and the double-hydrosilylation products were the major products (metathesis route). Increasing the alkyne concentration routed the reaction towards the alkene and the bis(acetylide) complex (protonolysis route).

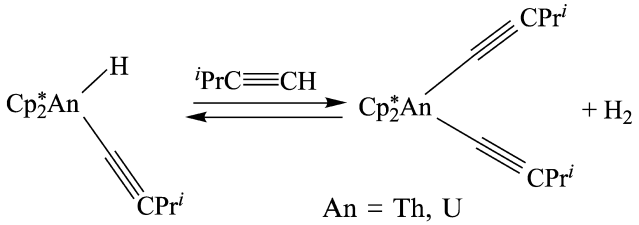
A likely mechanism for the hydrosilylation of terminal alkynes catalyzed by $Cp^{*}_{2}ThMe_2$ was proposed and described in Scheme 26.16.

The mechanism presented in Scheme 26.16 consists of insertion of acetylene into a metal–hydride σ-bond, σ-bond metathesis by a silane, and protonolysis by an acidic alkyne hydrogen. The precatalyst $(C_5Me_5)_2ThMe_2$ in the presence of alkyne was converted to the bis(acetylide) complex **Z**. Complex **Z** reacts with $PhSiH_3$ towards the silylalkyne and the organoactinide hydride **X** (step 1), which was found to be in equilibrium with the intermediate **AA** after reinsertion of the silylalkyne with the preferential stereochemistry (step 2). Complex **AA** was found to be the principal complex under silane and alkyne starvation. Complex **X** will react with an alkyne producing the alkenyl acetylide organothorium complex **Y** (step 3), which is presumably in equilibrium with complex **X** (first-order in alkyne). Complex **Y** was proposed to react with $PhSiH_3$, as the rate-determining step, regenerating the hydride complex **X** and the *trans*-hydrosilylated product (step 4). Under the catalytic conditions, complex **Y** may also react with a second alkyne producing the alkene and the bis (acetylide) complex **Z** (step 5). A similar insertion of the alkene into complex **X** with the concomitant reaction with an additional alkyne produced the double hydrogenated product, as found for isopropylacetylene. At high temperature, complex **AA** may react with a silane (step 6), yielding complex **X** and the double hydrosilylation product or with an alkyne (step 7), yielding complex **Z** and the *cis*-isomer. Thus, the reaction rate law [equation (26.52)] was rationalized with rapid irreversible phenylsilane metathesis with complex **Z**, rapid pre-equilibrium involving the hydride, and alkenyl complexes **X** and **Y**, and a slow metathesis by the $PhSiH_3$. For the thorium complex, step 6 was found to be much faster than step 7 since the amounts of the *cis*-product were obtained in trace amounts.

The mechanistic pathway as proposed, takes into the account comparable yields for the alkene and silylalkyne even when the alkyne concentration was in excess (the sum of the silylated products must equal the amount of the alkene). For the thorium or uranium complexes, the amount of the hydrosilylated product was always similar to or larger than that of the alkene, indicating that a competing equilibrium should be operative, responsible for the transformation of the hydride complex back to the bisacetylide complex, allowing the production of the silylalkyne without producing the alkene [equation (26.55)].

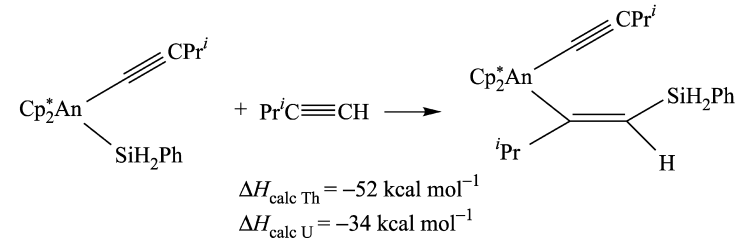


Scheme 26.16 *Proposed mechanism for the room- and high-temperature hydrosilylation of isopropylacetylene with* $PhSiH_3$ *promoted by* $(C_5Me_5)_2ThMe_2$.



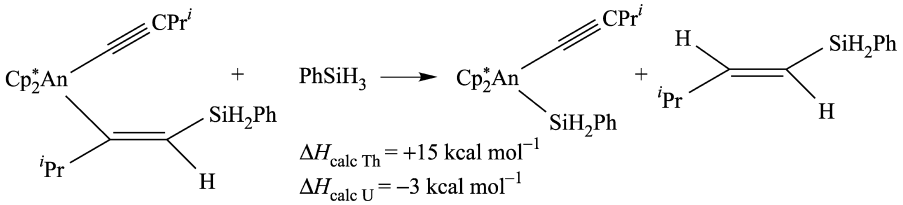
(26.55)

Thermodynamically, it is very interesting to compare the possible mechanistic silane and hydride intermediates towards the possible hydrosilylation *trans*-product as presented in equations (26.56) and (26.57), respectively.



$\Delta H_{\text{calc Th}} = -52$ kcal mol^{-1}

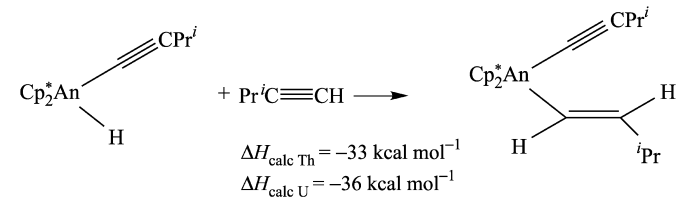
$\Delta H_{\text{calc U}} = -34$ kcal mol^{-1}



$\Delta H_{\text{calc Th}} = +15$ kcal mol^{-1}

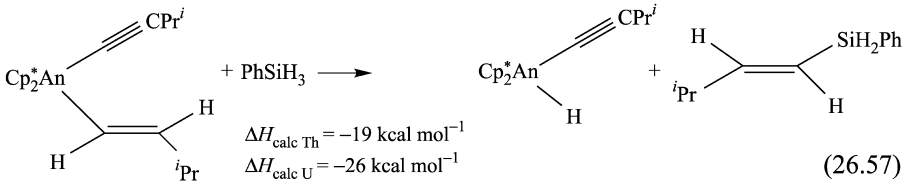
$\Delta H_{\text{calc U}} = -3$ kcal mol^{-1}

(26.56)



$\Delta H_{\text{calc Th}} = -33$ kcal mol^{-1}

$\Delta H_{\text{calc U}} = -36$ kcal mol^{-1}



$\Delta H_{\text{calc Th}} = -19$ kcal mol^{-1}

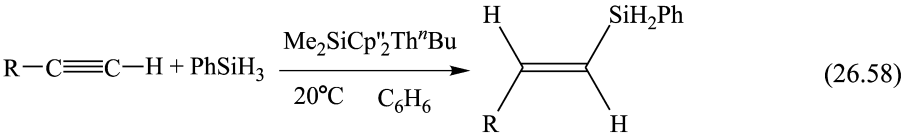
$\Delta H_{\text{calc U}} = -26$ kcal mol^{-1}

(26.57)

The calculated enthalpy of reaction for the insertion of an alkyne into an actinide–silane bond [equation (26.56)] ($\Delta H_{Th} = -52$ kcal mol^{-1}, $\Delta H_U = -34$ kcal mol^{-1}) or into an actinide hydride bond [equation (26.57)] ($\Delta H_{Th} = -33$ kcal mol^{-1}, $\Delta H_U = -36$ kcal mol^{-1}) was expected to be exothermic. However, the protonolysis by the silane yielding the An-Si bond and the *trans*-product [equation (26. 56)] was for thorium an endothermic process ($\Delta H_{Th} = +15$ kcal mol^{-1}), as compared to the exothermicity of the σ-bond metathesis [equation (26.57) of the thorium alkenyl complex with the silane ($\Delta H_{Th} = -19$ kcal mol^{-1}), yielding the corresponding Th–H bond and the *trans*-product. For the corresponding uranium complexes, the latter processes were calculated to be exothermic although the σ-bond metathesis route [equation (26.57)] was more exothermic ($\Delta H_U = -26$ kcal mol^{-1}) than the protonolysis route [equation (26.56)] ($\Delta H_U = -3$ kcal mol^{-1}).

26.6.2 Catalytic hydrosilylation of terminal alkynes promoted by the bridged complex $Me_2SiCp''_2Th^nBu_2$

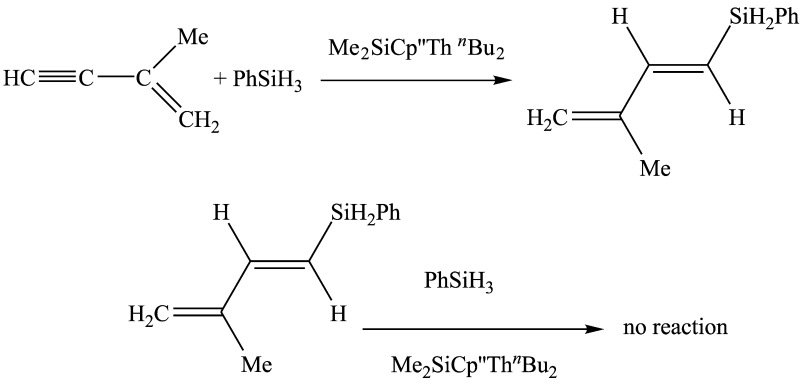
The hydrosilylation reaction of terminal alkynes and $PhSiH_3$ catalyzed by $Me_2SiCp''_2Th^nBu_2$ resulted in the speedy and regioselective formation of the hydrosilylated *trans*-vinylsilane as the unique product regardless of the alkyne substituent [equation (26.58)].



(26.58)

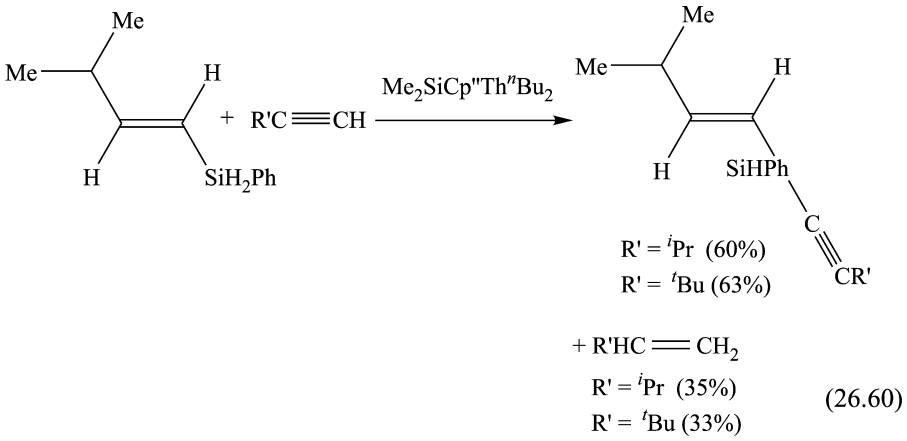
R = ^{t}Bu, ^{i}Pr, ^{n}Bu, Ph, 4-^{t}Bu-Ph

When an olefin-functionalized alkyne was used for the reaction with $PhSiH_3$, the alkyne moiety was regioselectively hydrosilylated to yield the corresponding *trans*-diene [equation (26.59)]. Addition of an excess of $PhSiH_3$ did not induce any subsequent hydrosilylation.



(26.59)

The addition of an excess of $PhSiH_3$ to any of the vinylsilane products did not induce further hydrosilylation. However, addition of a second equivalent of an alkyne to a hydrosilylation product allowed the formation of the corresponding alkene and the dehydrogenative coupling of the alkyne with the *trans*-vinylsilane [equation (26.60)] (Forsyth *et al.*, 1991; Harrod, 1991; Corey *et al.*, 1993; Tilley, 1993).



(26.60)

(a) Kinetic and thermodynamic studies for the hydrosilylation of terminal alkynes with primary silanes promoted by the bridged complex $Me_2Si(C_5Me_4)_2Th^nBu_2$

Kinetic measurements on the hydrosilylation ^{i}PrC≡CH with $PhSiH_3$ catalyzed by $Me_2Si(C_5Me_4)_2Th^nBu_2$ indicated that the reaction behaved with a first-order dependence in precatalyst and silane, and exhibited an inverse proportionality (inverse first-order) in alkyne [equation (26.61)]. The inverse proportionality was consistent with a rapid equilibrium before the turnover limiting-step, removing one of the key organoactinide intermediates from the catalytic cycle.

$$v = k[Me_2Si(C_5Me_4)_2Th^nBu_2][\text{silane}]^1[\text{alkyne}]^{-1} \qquad (26.61)$$

The derived $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ parameter values from a thermal Eyring analysis were measured to be 10.07(5) kcal mol^{-1} and –22.06(5) eu, respectively (Dash *et al.*, 2001).

It is important to note the difference between the kinetic behavior of the alkyne in the hydrosilylation reaction and that in the dimerization process (*vide supra*). In the latter process, the alkyne was involved in two parallel routes, both sensitive to the alkyne concentration. In one route, the alkyne exhibited an inverse kinetic order (removing one of the active compounds from catalytic cycle), whereas in the second pathway the alkyne was involved in the rate-determining step. Thus, at high alkyne concentrations the overall dependence

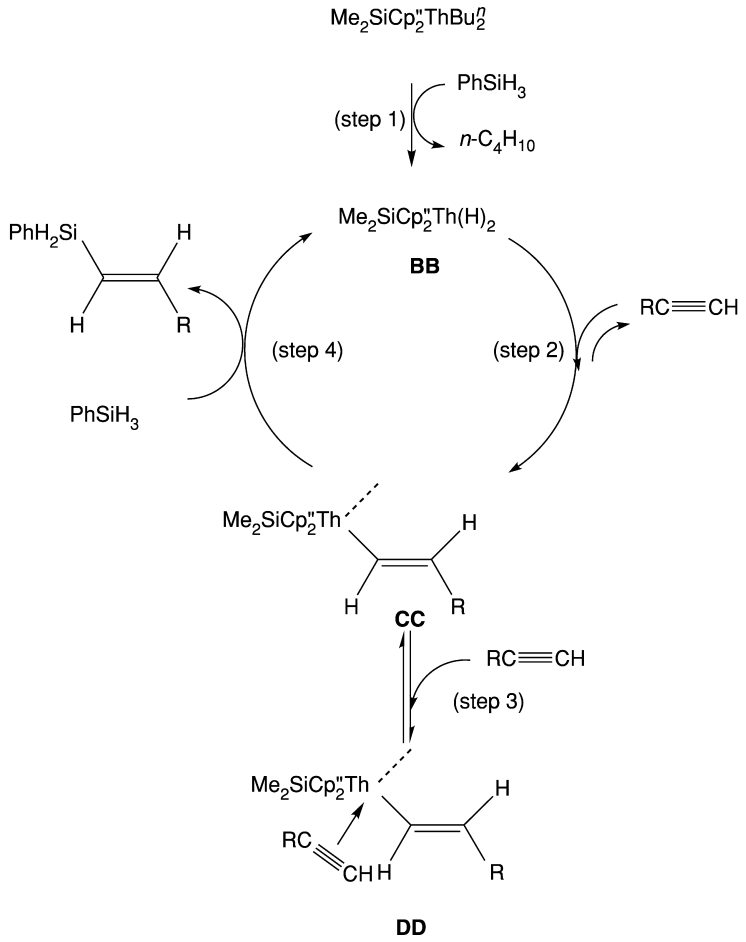
on alkyne is cancelled out. In the hydrosilylation process, the alkyne was proposed to be only involved in routing an active compound out of the catalytic cycle, with the silane presumably reacting in the rate-limiting step. Thus, modification of the alkyne order was observed.

In the hydrosilylation reactions of organo-f-element complexes, two Chalk–Harrod mechanisms have been proposed as plausible routes, differing in the inclusion of a σ-bond metathesis instead of the classical oxidative addition–reductive elimination processes. The two mechanisms differ in the reactive intermediates; the hydride (M–H) route and the silane ($M–SiR_3$) route (Chalk and Harrod, 1965; Harrod and Chalk, 1965; Ruiz *et al.*, 1987; Seitz and Wrighton, 1988; Tanke and Crabtree, 1991; Duckett and Perutz, 1992; Marciniec *et al.*, 1992; Takeuchi and Yasue, 1996; Bode *et al.*, 1998; Ojima *et al.*, 1998; Reichl and Berry, 1998; Sakaki *et al.*, 1998). The use of terminal alkynes with bridged organoactinides was an excellent probe to investigate which of the two routes was the major pathway followed. Thus, taking into account that the alkyne was expected to insert with the substituent group pointing away from the metal center (as observed in the dimerization) the following mechanistic insights were obtained. If the hydrosilylation reaction goes through a $M–SiR_3$ intermediate, the *gem*-hydrosilylated vinyl isomer will be formed, whereas only the *trans*-isomer will be obtained via the M–H route (if the insertion stereochemistry is not maintained, the *cis* product will be observed). The exclusive selectivity obtained for $Me_2Si(C_5Me_4)_2Th^nBu_2$ towards the *trans* hydrosilylated isomer argued that the hydride route was acting as the major mechanistic pathway.

(b) Hydrosilylation of terminal alkynes with primary silanes promoted by the bridged complex $Me_2Si(C_5Me_4)_2Th^nBu_2$: scope and mechanism

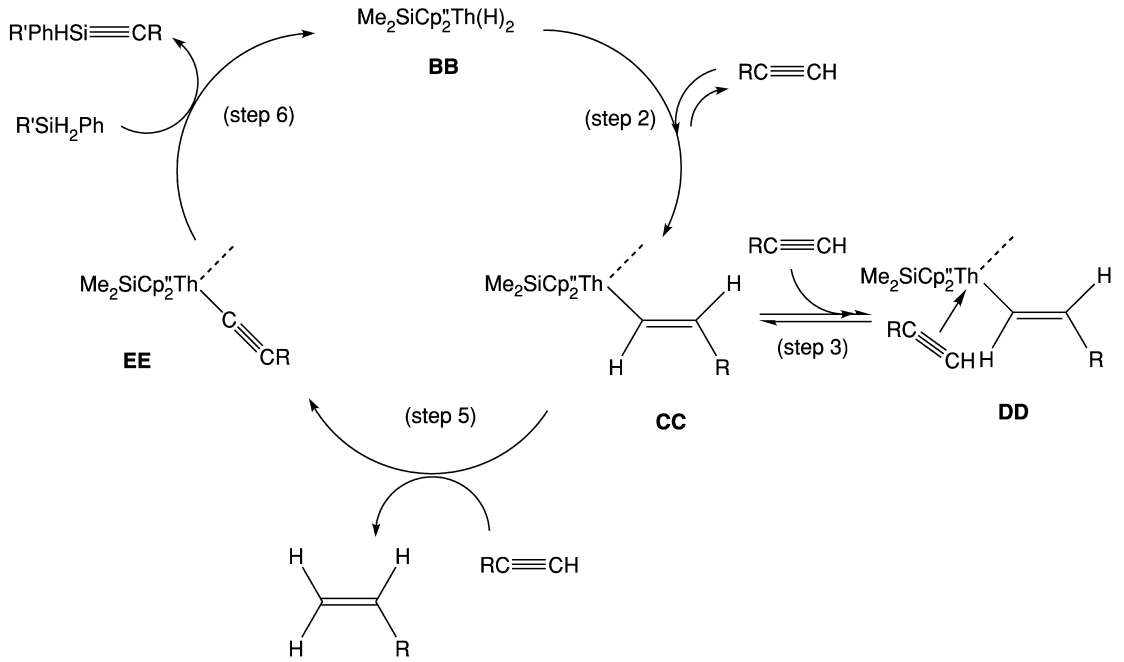
The hydrosilylation of terminal alkynes with $PhSiH_3$ promoted by the bridged complex $Me_2Si(C_5Me_4)_2Th^nBu_2$ produced regioselectively and chemoselectively the *trans*-hydrosilylated vinylsilane without any other by-products. The lack of silylalkynes, the dehydrogenative silane coupling products, or any other geometrical isomer of the vinylsilane strongly indicated that the Th–H pathway was the major operative route in the hydrosilylation reaction. A plausible mechanism for the hydrosilylation of terminal alkynes towards *trans*-vinylsilanes was proposed and is presented in Scheme 26.17.

The precatalyst $Me_2Si(C_5Me_4)_2Th^nBu_2$ in the presence of silane and alkyne was converted into the hydride complex **BB** (step 1), as observed by the stoichiometric formation of n-$BuSiH_2Ph$. Rapid insertion of an alkyne into complex **BB** allows the formation of the vinylic complex **CC** (step 2). Complex **CC** was found to be in rapid equilibrium with the proposed π-complex **DD** (step 3), responsible for the inverse order in alkyne, and undergoes a σ-bond metathesis with $PhSiH_3$, as the rate-determining step (step 4), producing selectively the *trans*-hydrosilylated vinyl product and regenerating complex **BB**. Since no



Scheme 26.17 *Proposed mechanism for the hydrosilylation of terminal alkynes with* $PhSiH_3$ *promoted by the bridged complex* $Me_2Si(C_5Me_4)_2Th^nBu_2$.

geometrical isomers or different products were observed by adding an excess of $PhSiH_3$ to any of the vinylsilanes, neither the hydride complex **BB** nor the alkenyl complex **CC** were found to be the resting catalytic state, indicating complex **DD** is the resting state. However, the subsequent addition of a second equivalent of an alkyne to the reaction mixture formed the corresponding alkene and the silylalkyne. The formation of these two compounds was proposed to follow the mechanistic pathway as shown in Scheme 26.18. Complex **CC** reacts, in the absence of a primary silane, with another alkyne (step 5) producing the corresponding alkene and the acetylide complex **EE.** A σ-bond metathesis with the Si–H bond of the vinylsilane (step 6) formed the



Scheme 26.18 *Proposed mechanism for the formation of alkene and silylalkyne in the presence of vinylsilanes and terminal alkynes promoted by* $Me_2Si(C_5Me_4)_2Th^nBu_2$. *Only one of the equatorial ligations at the metal center is shown for clarity.*

dehydrogenative coupling product and regenerated the hydride complex **BB** (Dash *et al*., 2001).

The yield of the alkene was found to be lower than that of the silylalkyne product. Therefore, an additional equilibrium reaction was proposed to exist, responsible for the transformation of complex **BB** into the acetylide complex **EE**, allowing the formation of the silylalkyne without forming the alkene. This pathway was also observed for non-bridged organoactinides [equation (26.55)] (Dash *et al*., 1999, 2001). Examination of the measured rates of the hydrosilylation process catalyzed by the bridged complex revealed larger turnover frequencies as compared to $(C_5Me_5)_2YCH_3 \cdot THF$ or other lanthanide complexes (Schumann *et al*., 1999). The yttrium complex was found to induce the hydrosilylation reaction of internal alkynes preferentially towards the *E*-isomer, although in some case the *Z*-isomer was found in comparable amounts. Mechanistically, the active species for the yttrium hydrosilylation of internal alkynes was proposed to be the corresponding hydride (Molander and Knight, 1998). It is well known that the hydrosilylation of alkynes is induced either by radical initiators (Selin and West, 1962) or by transition metal catalysts (Weber, 1983; Hiyama and Kusumoto, 1991; Sudo *et al*., 1999). The radical procedure often provides a mixture of *trans*- and *cis*-hydrosilylation products. In contrast, the transition metal catalyzed reaction proceeds with high stereoselectivity via a *cis*-hydrosilylation pathway usually producing a mixture of two regio-isomers (terminal and internal adducts). Thus, the organoactinide process seems to contain a unique chemical environment allowing the production of the *trans*-vinylsilane, complementing the chemistry of other transition metal complexes.

26.6.3 Catalytic hydrosilylation of alkenes promoted organoactinide complexes

The organoactinide complexes $(C_5Me_5)_2ThMe_2$ and $Me_2Si(C_5Me_4)_2Th^nBu_2$ were also found to be good precatalysts for the highly regio-selective hydrosilylation of alkenes. The chemoselectivity of the reactions was moderate since the hydrogenated alkane was always encountered as a concomitant product. The reactions of $(C_5Me_5)_2ThMe_2$ and $Me_2Si(C_5Me_4)_2Th^nBu_2$ with an excess of an alkene and $PhSiH_3$ resulted in the formation of the regioselective 1,2-addition hydrosilylated alkene and the alkane with no major differences between the two organoactinides [equation (26.62)] and Table 26.1 (Dash *et al*., 2001).

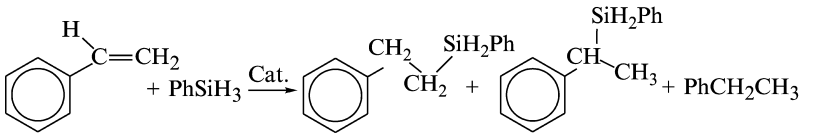
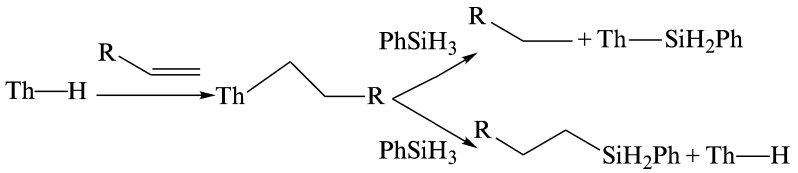
[c] Turnover frequency for the hydrosilylation process.
[d] The number in parentheses corresponds to the 2,1-addition hydrosilylation product, 2-(phenylsilyl)ethylbenzene.

Since for the substrate allyl benzene only one hydrosilylated product was formed, a comparison of the effect of distance between the aromatic ring and the metal center was performed. In the hydrosilylation of styrene with each of the organoactinides [equation (26.63)], both 1,2- and 2,1-hydrosilylation products were obtained, in addition to ethylbenzene. For $(C_5Me_5)_2ThMe_2$, a small amount of the branched silane was obtained whereas for the coordinatively unsaturated complex $Me_2Si(C_5Me_4)_2Th^nBu_2$ equal amounts of both (linear and branched) isomers were found (entries 9,10 in Table 26.1).



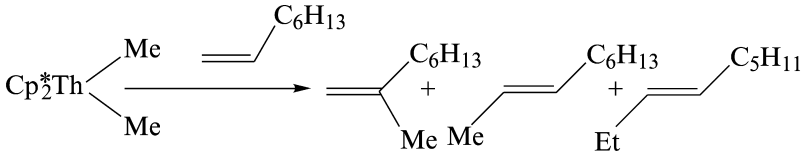
(26.63)

The presence of the two major products (hydrosilylation and hydrogenation) indicated the existence of two parallel catalytic pathways. The formation of the hydrogenation products required considering the possibility that intermediates with Th–Si/Th–H bonds were formed [equation (26.64)]. Thus, the production of alkanes might be considered, to some extent, as indirect evidence of the existence of complexes containing an actinide–Si bond. Protonolysis of a Th–alkyl by the silane will yield the Th–Si bond and the hydrogenation product, whereas metathesis of the Th–alkyl by the silane will produce the hydrosilylated compound regenerating the hydride complex.



(26.64)

Another pathway to obtain a hydrogenation product from a Th–alkyl complex may be proposed, consisting of cutting the alkyl chain with an additional alkene, forming a transient vinyl complex. Therefore, the reaction between $(C_5Me_5)_2ThMe_2$ and an excess of 1-octene was studied. Although no hydrogenation product was observed, ruling out the protonolysis by an alkene, a stoichiometric reaction, resulting in the production of 2-methyl-1-octene, 2-nonene, and 3-nonene in almost equal amounts, and the additional slow catalytic isomerization of the starting 1-octene to *E*-4-octene (3.8%), *E*-3-octene (39.4%), *E*-2-octene (13.0%), and *Z*-2-octene (41.8%), was observed [equation (26.65)] (Dash *et al.*, 2001).



(26.65)

This result indicated that the Th–Me bond underwent insertion by the alkene moiety, forming a Th–alkyl complex, followed by a β-hydrogen elimination to the corresponding metal–hydride (Th–H) and equimolar amounts of all three isomeric nonenes. The hydride was proposed to be the active species in the isomerization of 1-octene. The same reaction with 2-octene showed a slower reaction and different product ratios (*E*-3-octene (11.2%), *E*-2-octene (82.2%), and *Z*-2-octene (6.6%)), indicating a non-equilibrium process between 1-octene and 2-octene. In order to study the resting state of the organoactinide catalyst given that only two complexes with either a thorium hydride (Th–H) or a thorium–alkyl (Th–R) were expected, the isomerization reaction was followed until full conversion of 1-octene (>98%) was obtained. All the volatiles were removed under vacuum and new solvent was reintroduced. The ratio between the products that remained in the reaction mixture was measured by gas chromatography, demonstrating the disappearance of 1-octene. Quenching of the reaction mixture with a slight excess of D_2O at low temperatures, and analysis of the solution showed the presence of a mono-deuterated 1-*d*-octane, indicating that the Th–alkyl moiety was the resting organoactinide. The most astounding result was the presence of equimolar amounts of 1-octene, based on the metal complex. This result indicated that a *π-alkene thorium–alkyl* complex (**HH** in Scheme 26.19) was the resting catalytic state of the organoactinide complex; addition of D_2O liberated the alkene and the alkane from the metal.

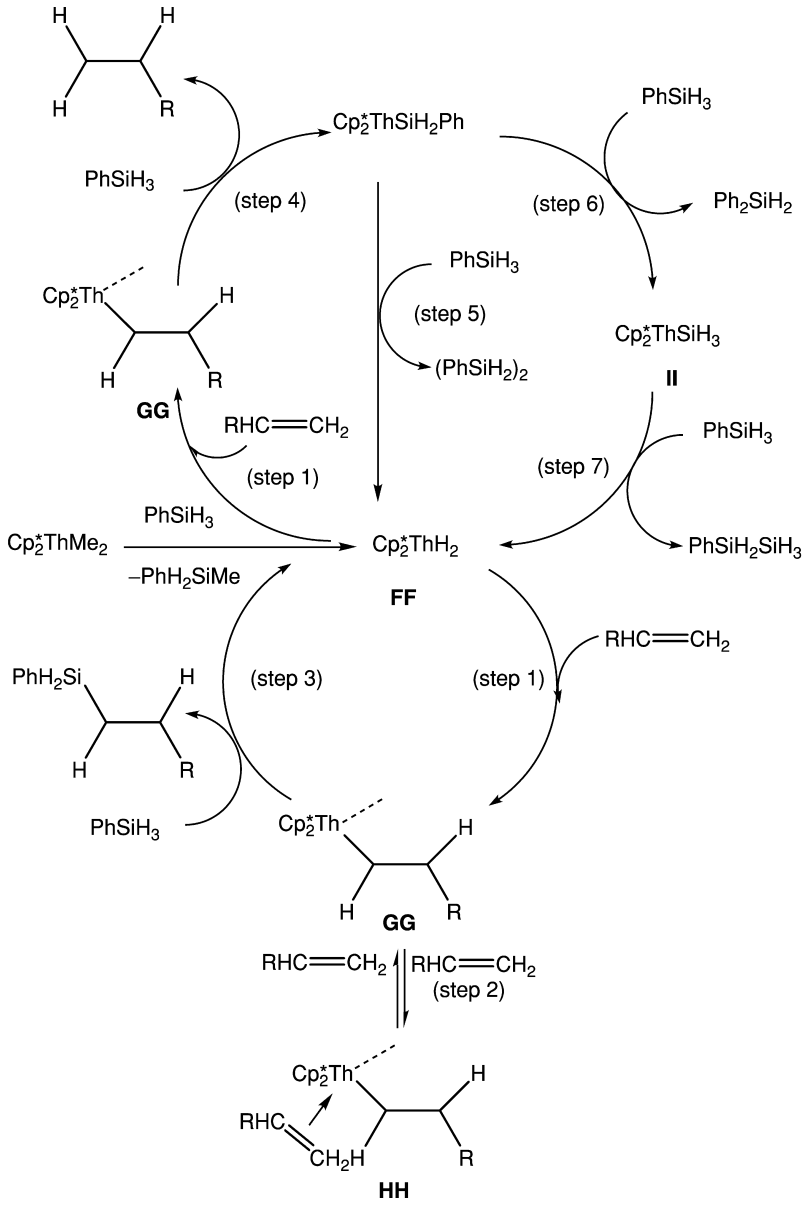
(a) Kinetic studies of the hydrosilylation of alkenes with $PhSiH_3$

Kinetic measurements of the hydrosilylation of allylbenzene with $PhSiH_3$ catalyzed by $(C_5Me_5)_2ThMe_2$ were performed. The reaction was found to follow a first-order dependence in precatalyst and silane, and exhibits an inverse first-order dependence in alkene. The inverse proportionality as described for alkynes is consistent with a rapid equilibrium before the rate-determining step, steering an intermediate out of the catalytic cycle. Thus, the rate law for the hydrosilylation of alkenes with $PhSiH_3$ promoted by $(C_5Me_5)_2ThMe_2$ can be expressed as presented in the following equation:

$$v = k[(C_5Me_5)_2ThMe_2][\text{silane}]^1[\text{alkene}]^{-1} \tag{26.66}$$

The derived E_a, $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$ parameter values from an Arrhenius and a thermal Eyring analysis were measured to be 11.0(4) kcal mol^{-1}, 10.3(4) kcal mol^{-1}, and –45 eu, respectively.

A comparison of the product distribution for both bridged and non-bridged organoactinides revealed that no special effects were introduced by increasing the coordinative unsaturation of the organothorium complex. The presence of double hydrosilylation products suggested the presence of two parallel interconnecting competing pathways. The formation of the alkane required the presence of the intermediate Th–H/Th–Si moieties (Eisen, 1997, 1998). The only evidence available so far for the formation of a Th–Si bond was obtained



Scheme 26.19 *Proposed mechanism for the hydrosilylation of alkenes with $PhSiH_3$ promoted by $(C_5Me_5)_2ThMe_2$ or $Me_2Si(C_5Me_4)_2Th^nBu_2$. The scheme depicts the mechanism for the unbridged metallocene. Only one of the equatorial ligations at the metal center is shown for clarity.*

from the formation of a metalloxy ketene via the double insertion of carbon monoxide into a Th–Si bond (Radu *et al.*, 1995). The proposed mechanism for the hydrosilylation of alkenes promoted by organoactinides is described in Scheme 26.19.

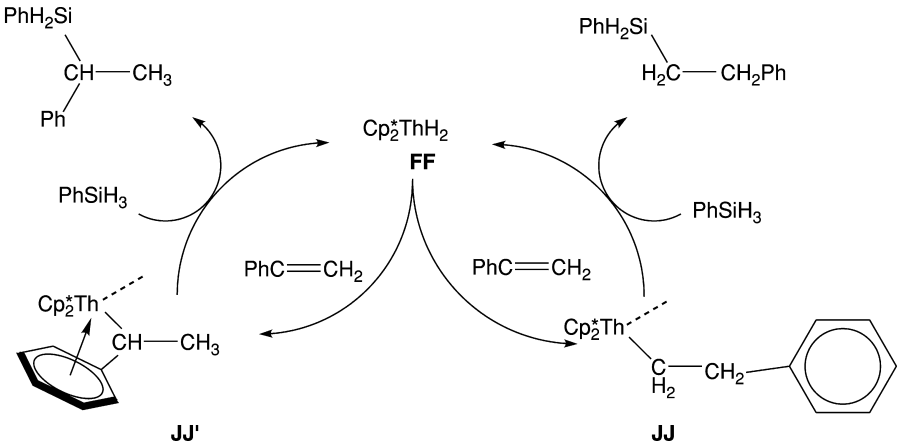
The first step in the proposed mechanism is the reaction of the precatalyst $(C_5Me_5)_2ThMe_2$ with $PhSiH_3$, yielding the hydride complex **FF** and $PhSiH_2Me$. Complex **FF** may react with an alkene producing the alkyl complex **GG** (step 1), which can undergo three parallel pathways. The first route is a reaction with an alkene, to produce a π-alkene complex **HH**, removing the complex **GG** from the catalytic cycle (step 2), and giving rise to the inverse order in alkene. The second and third paths are metathesis and protonolysis reactions between the Th–alkyl fragment and the Si-H moiety, yielding in the former case the substituted silane and regenerating complex **FF** (step 3), and yielding in the latter process the Th–SiH_2Ph complex and the alkane (step 4). The proposed scheme also takes into account the formation of materials in trace amounts.

For styrene, the formation of both hydrosilylation products in similar amounts indicates comparable activation energy for both processes, differing only in the disposition of the silane with respect to the thorium alkyl complex. The Th–SiH_2Ph bond can be activated by two different paths. The metathesis reaction with the Si–H bond in $PhSiH_3$ produces the dehydrogenative dimer and the hydride **FF** (step 5), whereas in the reaction with a Si–Ph bond, Ph_2SiH_2, and a complex containing the Th–SiH_3 (**II**) moiety will be obtained (step 6), which will then rapidly react with an additional silane yielding the oligomeric dehydrogenative coupling of silanes (step 7). In the hydrosilylation of styrene, the formation of the branched isomer was rationalized by the stereochemistry of the insertion reaction of the styrene with the metal hydride complex (Scheme 26.20); the alkyl formed is presumably stabilized by the π-arene interaction (**JJ′**).

For alkenes, the hydrosilylation reaction promoted by organolanthanides of the type $(C_5Me_5)_2LnR$ (Ln = Sm, La, Lu) or $Me_2Si(C_5Me_4)_2SmR$ are much faster (by one order of magnitude) than those obtained with organoactinides. The major difference is found for linear α-alkenes, which lanthanides will hydrosilylate forming both isomers, whereas actinides will exclusively yield the 1,2-adduct product (Harrod, 1991; Ojima *et al.*, 1998; Schumann *et al.*, 1999). Mechanistically, the lanthanide hydrides have been proposed as the primary pathway towards the hydrosilylated products. Thus, organoactinides represent again complementary catalysts to organolanthanides and other transition metal complexes for the regioselective hydrosilylation of α-olefins.

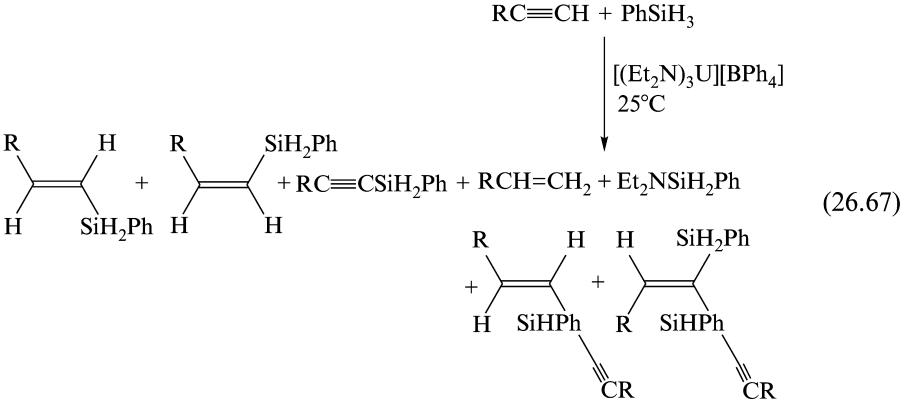
26.6.4 Catalytic hydrosilylation of alkynes promoted by the cationic complex $[(Et_2N)_3U][BPh_4]$

The hydrosilylation reactions of terminal alkynes promoted by neutral organoactinides has motivated similar studies whose goal is the formation of a cationic hydride complex as an intermediate in the catalytic hydrosilylation of

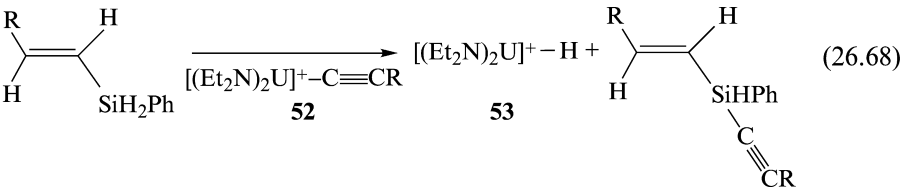


Scheme 26.20 *Proposed mechanism for the hydrosilylation of styrene and $PhSiH_3$ promoted by $(C_5Me_5)_2ThMe_2$ or $Me_2Si(C_5Me_4)_2Th^nBu_2$.*

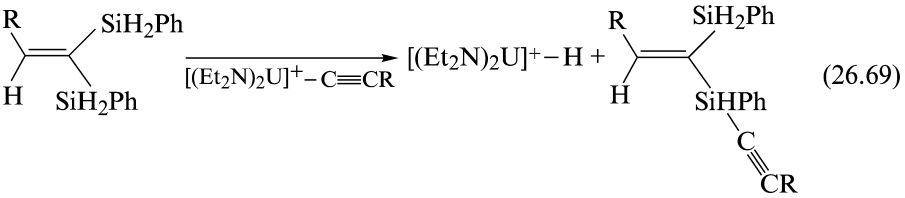
terminal alkynes. Reactions promoted by the cationic complex $[(Et_2N)_3U][BPh_4]$ were studied (Dash *et al.*, 2000). The reaction of $[(Et_2N)_3U][BPh_4]$ with terminal alkynes RC≡CH (R = ^{i}Pr, ^{t}Bu) and $PhSiH_3$ resulted in the catalytic formation of a myriad of products. The observed products *cis*- and *trans*-vinylsilane ($RCH{=}CHSiH_2Ph$), the dehydrogenative silylalkyne ($RC{\equiv}CSiH_2Ph$), alkenes ($RCH{=}CH_2$) (R = ^{i}Pr, ^{t}Bu), and the aminosilane Et_2NSiH_2Ph were found to account for 100% conversion with respect to the alkyne. For the bulky ^{t}BuC≡CH, the tertiary silanes *trans*-^{t}BuCH=CHSi(HPh)(C≡C^{t}Bu), and ^{t}BuCH=C(SiH_2Ph)Si(HPh)(C≡C^{t}Bu) were also observed [equation (26.67)]. Formation of the tertiary silanes can be accounted for by metathesis reactions of the *trans*-alkenylsilane and the double hydrosilylated compound with the metal acetylide complex **52**, respectively, as shown in equations (26.68) and (26.69).



(26.67)



(26.68)



(26.69)

At high temperatures (65–78°C), the chemoselectivity and regioselectivity of the products formed in the cationic organouranium-catalyzed hydrosilylation of terminal alkynes with $PhSiH_3$ were found to be different in comparison to those obtained at room temperature. The hydrosilylation of RC≡CH (R = ^{n}Bu, ^{i}Pr, ^{t}Bu) with $PhSiH_3$ catalyzed by $[(Et_2N)_3U][BPh_4]$ produced, in addition to the hydrosilylation products at room temperature [equation (26.67)], the corresponding double hydrosilylated compounds: $RCH{=}C(SiH_2Ph)_2$ (R = ^{n}Bu, ^{i}Pr, ^{t}Bu), and small amounts of the corresponding geminal dimers and trimers. A similar type of mechanism as observed for the neutral organoactinides was proposed, based on kinetic data and product distributions.

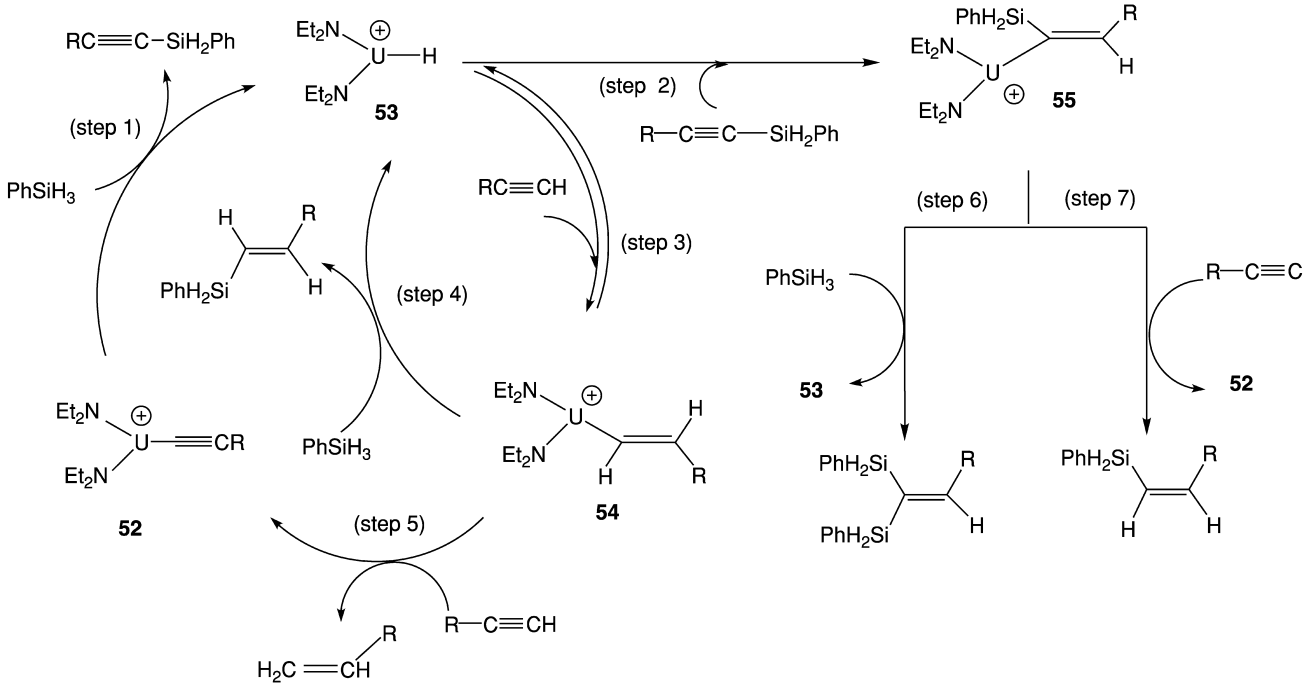
The formation of an active uranium hydride complex **53** was proposed to occur either by the reaction of the cationic complex with a silane molecule, giving the corresponding aminosilane, and/or by the reaction of the acetylide complex **52** with a silane, producing the corresponding silylalkyne [equations (26.70) and (26.71), respectively).

$$[(Et_2N)_3U]^+ \xrightarrow{PhSiH_3} [(Et_2N)_2U]^+{-}H + PhSiH_2NEt_2 \qquad (26.70)$$

$$\underset{\mathbf{52}}{[(Et_2N)_2U]^+{-}{\equiv}CR} \xrightarrow{PhSiH_3} \underset{\mathbf{53}}{[(Et_2N)_2U]^+{-}H} + RC{\equiv}CSiH_2Ph \qquad (26.71)$$

The proposed mechanism, which takes into account the formation of all products, is described in Scheme 26.21 (Dash *et al.*, 2000).

The precatalyst $[(Et_2N)_3U][BPh_4]$ in the presence of alkyne was converted to the acetylide complex **52** by removal of one of the amido ligands. Complex **52** was proposed to react with $PhSiH_3$ to give the silylalkyne and the actinide hydride **53** (step 1). The hydride **53** may reinsert the silylalkyne forming complex **55** (step 2) or react with the alkyne to produce the alkenyl uranium complex **54** (step 3). Complex **54** is then proposed to react with $PhSiH_3$, regenerating the organouranium hydride complex **53** and the *trans*-hydrosilylated product



Scheme 26.21 *Proposed mechanism for the room- and high-temperature hydrosilylation of terminal alkynes promoted by* $[(Et_2N)_3U][BPh_4]$. *The transformation of the starting complex into the acetylide complex* $[(Et_2N)_2U{-}C{\equiv}CR][BPh_4]$ (**52**) *was described in Scheme* 26.10, *and is omitted here for clarity.*

(step 4). Under catalytic conditions, complex **54** may also react with a second alkyne giving the alkene and the acetylide complex **52** (step 5). Complex **55** may react with a silane (step 6) yielding complex **53** and the double hydrosilylation product, or with an alkyne (step 7) yielding complex **52** and the *cis*-isomer.

This mechanistic scenario took into account the higher yields observed for the alkene compound as compared with those obtained for the silylalkyne. For TMSC≡CH and ^{i}PrC≡CH at high temperature, the amount of the hydrosilylated products is larger than that of the alkenes, indicating that a competing equilibrium route was present. This would again involve the transformation of the hydride **53** back into the acetylide complex **52** by reaction with the alkyne [equation (26.72)], allowing the production of more silylalkyne without producing the alkene. The hydride **53** could alternatively react with $PhSiH_3$ to give the organometallic silyl compound $[(Et_2N)_2USiH_2Ph][BPh_4]$ [equation (26.73)], which would further react with $PhSiH_3$ or RC≡CH to regenerate the hydride **53** and $PhH_2Si\text{-}SiH_2Ph$ or $PhH_2SiC{\equiv}CR$, respectively.

$$\underset{\mathbf{53}}{(Et_2N)_2U^{\oplus}\text{—}H} \underset{}{\overset{HC{\equiv}CTMS}{\rightleftharpoons}} \underset{\mathbf{52}}{(Et_2N)_2U^{\oplus}\text{—}C{\equiv}CTMS} + H_2 \qquad (26.72)$$

$$(Et_2N)_2U^{\oplus}\text{—}H \xrightarrow{PhSiH_3} (Et_2N)_2U^{\oplus}\text{—}SiH_2Ph + H_2$$

$$\xrightarrow{PhSiH_3} PhH_2Si\text{—}SiH_2Ph + (Et_2N)_2U^{\oplus}\text{—}H$$

$$\xrightarrow{HC{\equiv}CTMS} (Et_2N)_2U^{\oplus}\text{—}H + PhH_2SiC{\equiv}CTMS \qquad (26.73)$$

In the hydrosilylation reaction of ^{t}BuC≡CH at high temperature, a small amount of the dehydrogenative coupling of phenylsilane was observed. This product argued for the formation of a compound with an uranium–silicon bond, although not as a major intermediate. The compound $[(Et_2N)_2USiH_2Ph][BPh_4]$ can be theoretically postulated instead of the hydride complex **53** either from steps 1, 4, or 6 in the catalytic cycle (Scheme 26.21). In these steps, the silane would act as the protonolytic source.

26.7 DEHYDROCOUPLING REACTIONS OF AMINES WITH SILANES CATALYZED BY $[(Et_2N)_3U][BPh_4]$

The catalytic processes involving the cationic uranium amide complex, $[(Et_2N)_3U][BPh_4]$, have been found to be particularly efficient in the controlled dimerization of terminal alkynes and in the hydrosilylation reactions of terminal alkynes and alkenes with $PhSiH_3$. These processes have been characterized

through the activation of the corresponding amido uranium–acetylide or the amido uranium–hydride species that were the active intermediates, respectively. A conceptual question that arose from those studies concerned the possibility of activating the amido ancillary ligands in $[(Et_2N)_3U][BPh_4]$ with a silane molecule producing the corresponding aminosilane and an organometallic hydride complex. The ability to transform the hydride into the starting amido complex using another amine with the attendant elimination of dihydrogen would give a way to perform the catalytic dehydrogenative coupling of amines and silanes. Thermodynamic calculations have predicted this process as plausible (King and Marks, 1995). The dehydrogenative coupling of amines and silanes has been performed by either late transition metal catalysts (Blum and Laine, 1986; Biran *et al*., 1988; Wang and Eisenberg, 1991) or early transition metal complexes (Liu and Harrod, 1992; He *et al*., 1994; Lunzer *et al*., 1998). These reactions are an alternate route to silazanes, which are precursors for the synthesis of silicon nitride materials. The reaction of $^{n}PrNH_2$ and $PhSiH_3$ promoted by the cationic complex $[(Et_2N)_3U][BPh_4]$ produced dihydrogen and the aminosilanes $PhSiH(NHPr^{n})_2$ and $PhSi(NHPr^{n})_3$ [equation (26.74)]. The use of a large excess of amine allowed for full conversion of the silane into the di- and tri-aminosilanes. The monoaminosilane, $PhSiH_2(NHPr^{n})$, was not detected, indicating that in this compound the Si–H hydride bonds were more reactive than those in the starting $PhSiH_3$ (Wang *et al*., 2000).

The reaction of $^{i}PrNH_2$ and $PhSiH_3$ gave dihydrogen together with $PhSiH_2NHPr^{i}$ (33%) and $PhSiH(NHPr^{i})_2$ (56%) with a total conversion of 89% for $PhSiH_3$. The use of large amine excess promoted the reaction towards the bisaminosilane $PhSiH(NHPr^{i})_2$. The bulky $^{t}BuNH_2$ reacted with $PhSiH_3$ producing $PhSiH_2NHBu^{t}$ quantitatively. This monoaminosilane reacted further with an excess of amine to produce an additional equivalent of dihydrogen and exclusively the bisaminosilane $PhSiH(NHBu^{t})_2$. This latter compound was transformed back slowly into the mono aminosilane, $PhSiH_2NHBu^{t}$, after the addition of one equivalent of $PhSiH_3$ [equation (26.75)], which indicated that the production of aminosilanes promoted by the cationic complex $[(Et_2N)_3U][BPh_4]$ was in equilibrium.

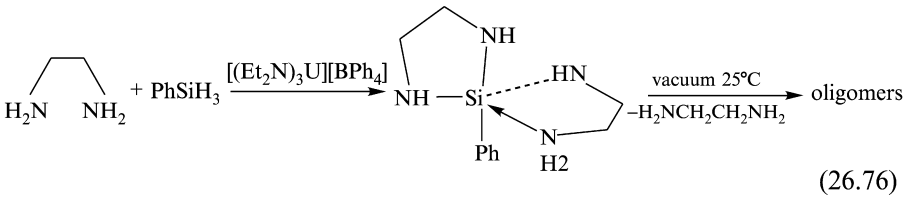
$$RNH_2 + PhSiH_3 \xrightarrow[-H_2]{[(Et_2N)_3U][BPh_4]} PhSiH_2NHR$$

$$R = {}^{n}Pr;\ {}^{i}Pr;\ {}^{t}Bu$$

$$PhSiH_2NHR \xrightarrow[-H_2]{[Cat]\ RNH_2} PhSiH(NHR)_2 \xrightarrow[-H_2]{[Cat]\ RNH_2} PhSi(NHR)_3 \qquad (26.74)$$

$$PhSiH_2(NHBu^{t}) \underset{[(Et_2N)_3U][BPh_4]\ PhSiH_3}{\overset{[(Et_2N)_3U][BPh_4]\ {}^{t}BuNH_2}{\rightleftharpoons}} PhSiH(NHBu^{t})_2 \qquad (26.75)$$

Ethylenediamine $H_2NCH_2CH_2NH_2$ reacted with $PhSiH_3$ in the presence of the catalyst, yielding dihydrogen and the spiro chelated complex $PhSi(\eta^2\text{-}NHCH_2CH_2NH)(\eta^2\text{-}NHCH_2CH_2NH_2)$ quantitatively. When the spiro product was heated at 25°C under vacuum, ethylenediamine was removed and $PhSi(\eta^2\text{-}NHCH_2CH_2NH)(\eta^2\text{-}NHCH_2CH_2NH_2)$ was transformed into a mixture of oligomers [equation (26.76)].



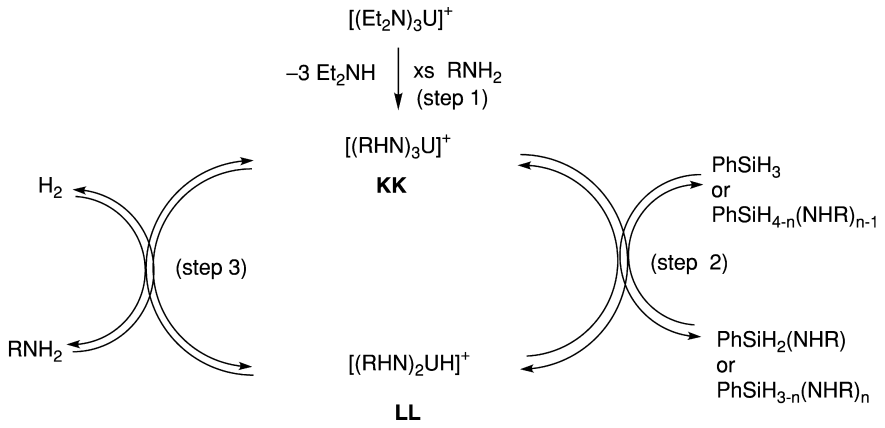
(26.76)

From these results it was concluded that the reactivity of primary amines RNH_2 in the formation of aminosilanes with $PhSiH_3$ catalyzed by the cationic uranium complex $[(Et_2N)_3U][BPh_4]$ follows the order primary > secondary > tertiary.

Secondary amines and secondary silanes were found to be less reactive than the corresponding primary amine and silanes. The reaction of Et_2NH with $PhSiH_3$ produced H_2 and a mixture of $PhSiH(NEt_2)_2$ and $PhSiH_2NEt_2$. No reaction was observed between $(^{i}Pr)_2NH$ and $PhSiH_3$, presumably because of the steric hindrance of the amine. The bulk of the silane was also found to have an effect. $^{n}PrNH_2$ reacted with the secondary silane $PhSiMeH_2$, generating H_2, $PhSiHMe(NHPr^{n})$ and $PhSiMe(NHPr^{n})_2$.

$[(Et_2N)_3U][BPh_4]$ reacted directly with stoichiometric or excess amounts of $PhSiH_3$, creating in both cases one equivalent of the corresponding aminosilane $PhSiH_2NEt_2$ and $[(Et_2N)UH][BPh_4]$; when an excess of silane was used, trace formation of the homodehydrogenative coupling product of the silane was observed. These results identified the monohydride complex as the active intermediate, since no other amido moieties were found to react with the phenylsilane. Therefore, the synthesis of a uranium hydride was accomplished by treatment of the corresponding amide with a silane, as has been reported in zirconium chemistry. Similar exchange reactions with boranes, alanes, and stannanes have been observed (Lappert *et al.*, 1980; Hays and Fu, 1997; Liu *et al.*, 1999).

A plausible mechanism for the dehydrocoupling of amines with silanes promoted by the cationic complex $[(Et_2N)_3U][BPh_4]$ is described in Scheme 26.22. The first step of the mechanism was proposed to be the transamination reaction of $[(Et_2N)_3U][BPh_4]$ with RNH_2 giving $[(NHR)_3U][BPh_4]$ (**KK**) (step 1). Complex **KK** may react with $PhSiH_3$ to afford the monoaminosilane $PhSiH_2NHR$ and the corresponding hydride $[(NHR)_2UH][BPh_4]$ (**LL**) (step 2). The last step of the catalytic cycle (step 3) is the reaction of **LL** and the amine, regenerating **KK** with the concomitant elimination of dihydrogen.



Scheme 26.22 *Proposed mechanism for the coupling of amine with silanes promoted by* $[(Et_2N)_3U][BPh_4]$.

The different polyaminosilanes $PhSiH_{3-n}(NHR)_n$ are obtained by replacing $PhSiH_3$ with $PhSiH_{4-n}(NHR)_{n-1}$ ($n \geq 1$) in step 2.

Since in the presence of an excess of amine the reactive hydrogen atoms were found to be those of the silane, a study of the reactivity of the aminosilane products towards a silane was conducted. The reaction of $PhSi(NHPr^n)_3$ with an excess of $PhSiH_3$ in the absence of amine was considered in order to determine a possible equilibrium and/or a tailoring approach to specific products by activation of the amine hydrogen atoms of the aminosilane. $PhSi(NHPr^n)_3$ reacted with an excess of $PhSiH_3$ in the presence of $[(Et_2N)_3U][BPh_4]$ to give a mixture of four compounds (**MM, NN, OO, PP)** (Scheme 26.23).

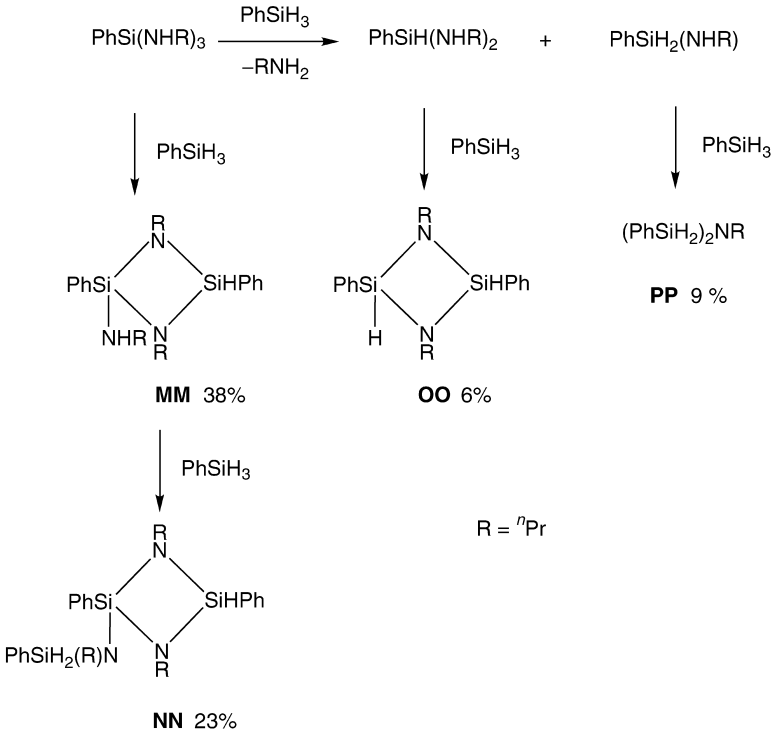
The explanation of how only four compounds were obtained may be found by consideration of the formation of all possible compounds as outlined in Scheme 26.24.

These results show how a cationic organoactinide complex offered an alternative route for the dehydrogenative coupling of amines with silanes by a mechanism consisting of activation of an amido ligand by a silane, producing the aminosilane and an organometallic hydride, which was recycled by addition of amine.

26.8 INTERMOLECULAR HYDROAMINATION OF TERMINAL ALKYNES

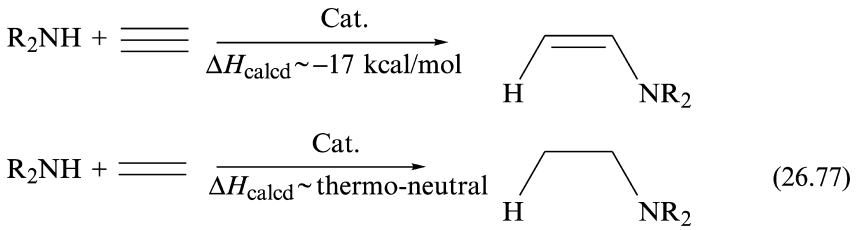
26.8.1 Intermolecular hydroamination of terminal alkynes catalyzed by neutral organoactinide complexes: scope and mechanistic studies

Catalytic C–N bond formation is a process of cardinal importance in organic chemistry, and the hydroamination of unsaturated substrates by the catalytic addition of a N–H moiety epitomizes a desirable atom-economic transformation



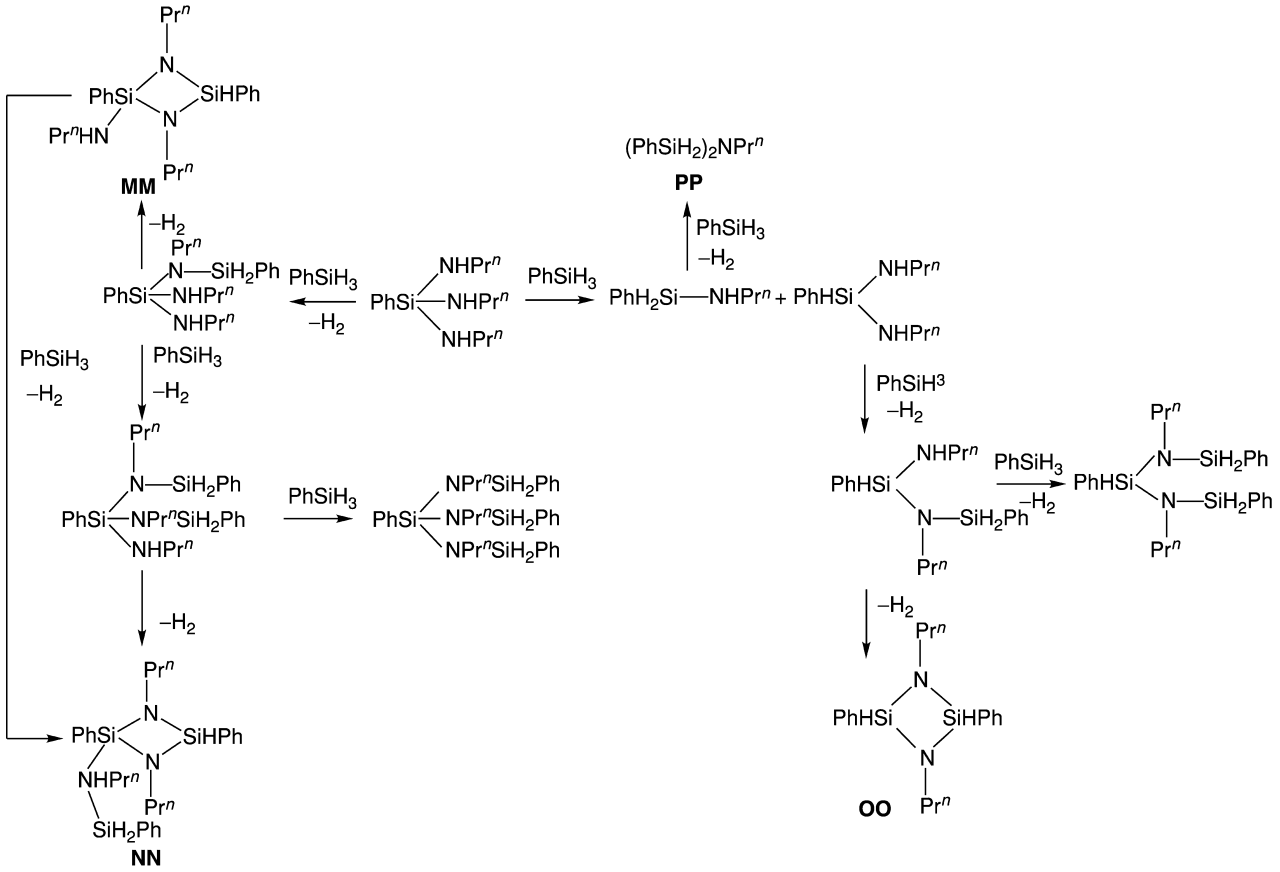
Scheme 26.23 *Reactivity of PhSi(NHPr^n)$_3$ with an excess of PhSiH$_3$ in the presence of* [$(Et_2N)_3U$][BPh_4].

with no by-products. This reaction remains a challenge [equation (26.77)] and current catalytic research activities in this area is widespread and spans to the entire periodic table (Nobis and Driessen-Hölscher, 2001; Molander and Romero, 2002; Pohlki and Doye, 2003; Seayad *et al.*, 2003; Trost and Tang, 2003; Utsunoyima *et al.*, 2003). The intermolecular functionalization of olefins and alkynes with amines has been mentioned as one of the ten most important challenges in catalysis (Haggin, 1993).



(26.77)

Thermodynamically, the addition process of amines to alkenes is close to thermoneutral whereas the addition to alkynes is more enthalpically favored.

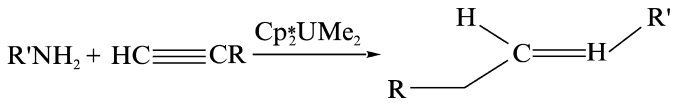


Scheme 26.24 *Formation of compounds **MM, NN, OO**, and **PP** in the coupling of amine and silanes catalyzed by* $[(Et_2N)_3U][BPh_4]$.

Because of the mode of activation of these organoactinides, the negative entropy of the reaction thwarts the use of high temperatures. Organolanthanide complexes have been found to be extremely good catalysts for the intramolecular hydroamination/cyclization of aminoalkenes, aminoalkynes, and aminoallenes (Gagné *et al.*, 1992a,b; Li and Marks, 1996; Roesky *et al.*, 1997b; Buergstein *et al.*, 1998; Li and Marks, 1998; Arredondo *et al.*, 1999a,b; Molander and Dowdy, 1999; Tian *et al.*, 1999; Ryu *et al.*, 2001; Douglass *et al.*, 2002; Hong and Marks, 2002; O'Shaughnessy *et al.*, 2003), and enantioselective intramolecular amination reactions have been performed using chiral organolanthanide precatalysts (Gagné *et al.*, 1992a).

The organoactinide complexes $(C_5Me_5)_2AnR_2$ (An = Th, U, R = Me, NHR′ R′ = alkyl) were found to be excellent precatalysts for the intermolecular hydroamination of terminal aliphatic and aromatic alkynes in the presence of primary aliphatic amines yielding the corresponding imido compounds (Haskel *et al.*, 1996; Straub *et al.*, 2001). The reactivity exhibited for the uranium complexes was different, depending on the alkynes, when compared to organothorium complexes [equations (26.78) and (26.79)].

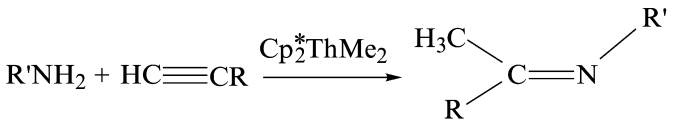
The intermolecular process [equations (26.78) and (26.79)] showed two hydroamination regioselectivities depending on the precatalyst. The intermolecular hydroamination catalyzed by the uranium compound exhibited large regioselectivity and chemoselectivity with the *E*-isomer of the imine usually formed. For the thorium catalyst, the methyl alkyl-substituted imines were obtained. In the latter case, the imines were produced in moderate yields with the concomitant formation of the alkyne *gem* dimer.



R = TMS, ^{t}Bu; R' = Me, Et, ^{n}Pr, ^{i}Pr, ^{n}Bu, ^{i}Bu
R = ^{n}Bu; R' = Me, Et, ^{n}Pr, ^{i}Pr, ^{i}Bu
R = Ph; R' = Me, Et
R = ^{i}Bu; R' = Et
R = C_5H_{11}; R' = Et

(26.78)

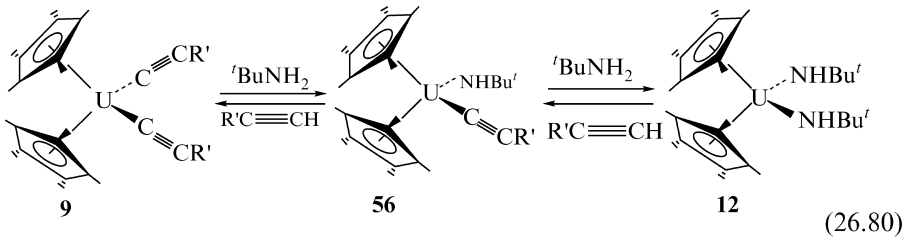
For R = TMS the imines are obtained as mixtures of E and Z isomers.



R = H; R' = Et
R = ^{n}Bu; R' = Me, Et
R = Ph; R' = Et
R = ^{i}Pr; R' = Ph

(26.79)

When the alkyne reactions catalyzed by the uranium complexes were performed using the bulky $^{t}BuNH_2$ as the primary amine, no hydroamination products were obtained. The products observed were only the selective *gem* dimers corresponding to the starting alkyne. This result has indicated that with $^{t}BuNH_2$, the proposed active species responsible for the intermolecular hydroamination was not generated. Using this bulky amine, the observed organouranium complexes in solution were the corresponding uranium bis(acetylide) (**9**) and the uranium bis(amido) (**12**) complexes. These two compounds were found to be in rapid equilibrium with the monoamido acetylide complex (**56**), responsible for the oligomerization of alkynes in the presence of amines [equation (26.80)].



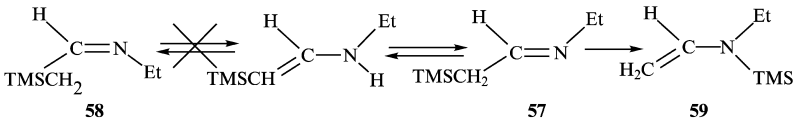
9 **56** **12** (26.80)

When comparing the hydroamination rates for a specific alkyne utilizing the various amines, the bulkier the amines, the lower the turnover frequency, and when comparing the hydroamination rates for a particular amine ($MeNH_2$) using various alkynes, similar turnover frequencies were observed. The lack of effect on the turnover frequency suggested no steric effect of the alkynes on the hydroamination process.

The intermolecular hydroamination catalyzed by the analogous organothorium complex $(C_5Me_5)_2ThMe_2$ exhibited similar reactivities with TMSC≡CH and $MeNH_2$ or $EtNH_2$ [equation (26.78)]. However, in the intermolecular hydroamination with ^{n}BuC≡CH or PhC≡CH and $MeNH_2$ or $EtNH_2$ a dramatic change in the regioselectivity was obtained, generating the unexpected imines [equation (26.79)]. For all the organoactinides, no hydroamination products were formed by using either secondary amines or internal alkynes. With secondary amines, the chemoselective alkyne dimers and in some cases trimers were obtained.

The catalytic hydroamination of ^{n}BuC≡CH or TMSC≡CH with $EtNH_2$ with either the organothorium complexes **1** or **5** gave identical results (rate, yields, stereochemistry of the products, and kinetic curves) indicating that both reactions occurred through a common active species, in a similar manner to that observed for the uranium complexes. It is interesting to point out that when the mixture of imines **57** and **58** were obtained, **57** was found to undergo a noncatalyzed Brook silyl rearrangement to form the corresponding enamine **59** [equation (26.81)] (Brook and Bassindale, 1980). The rearrangement followed

first-order kinetics with direct conversion of **57** to **59**, leaving the concentration of **58** unaffected:

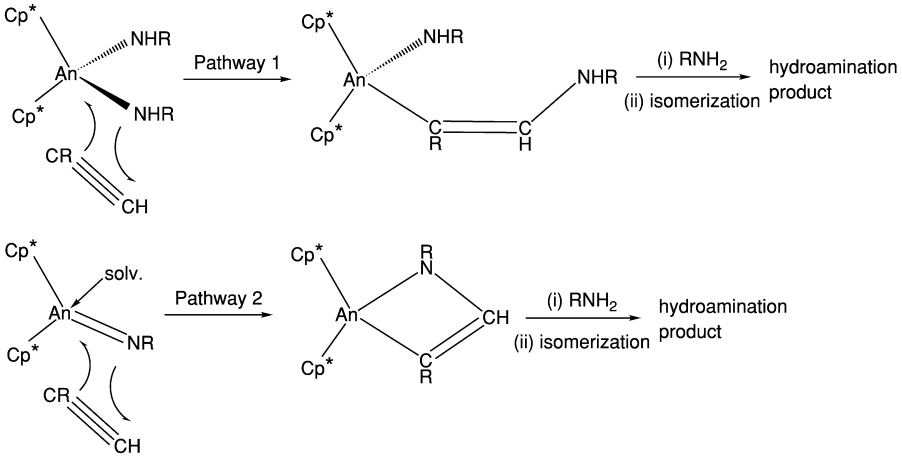


(26.81)

The formation of the corresponding oligomers in the hydroamination reactions catalyzed by the thorium complexes indicated that two different complexes were active in solution, possibly interconverting, resulting in two parallel processes. It was possible to discriminate between the two most probable mechanistic pathways to find the key organometallic intermediate responsible for the hydroamination process (Scheme 26.25). The first route proposed involved the insertion of an alkyne into a metal–amido bond, as found in lanthanide chemistry (Gagné *et al.*, 1992a,b; Roesky *et al.*, 1997a,b; Tian *et al.*, 1999). The second route consisted of insertion of an alkyne into a metal–imido (M=N) bond, as observed for early transition metal complexes (Walsh *et al.*, 1992, 1993).

26.8.2 Kinetic studies of the hydroamination terminal alkynes with primary amines

Kinetic measurements of the hydroamination of TMSC≡CH with $EtNH_2$ revealed that the reaction has a inverse first-order dependence in amine, first-order dependence in precatalyst, and zero-order dependence in alkyne



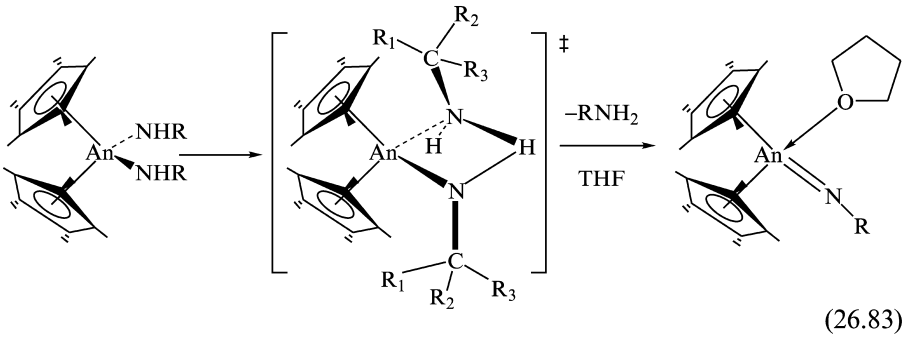
An = U;
For An = Th, the stereochemistry approach for some alkynes was inverted before insertion

Scheme 26.25 *Expected pathways for the organoactinide-catalyzed intermolecular hydroamination of primary amines with terminal alkynes.*

concentration. Thus, the rate law for the hydroamination of terminal alkynes promoted by organoactinides can be formulated as presented in equation (26.82). The derived $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ parameter values (in the range 60–120°C) (error values are in parenthesis) from a thermal Eyring analysis were 11.7(3) kcal mol^{-1} and –44.5(8) eu, respectively.

$$v = k[\mathrm{An}][\mathrm{amine}]^{-1}[\mathrm{alkyne}]^{0} \tag{26.82}$$

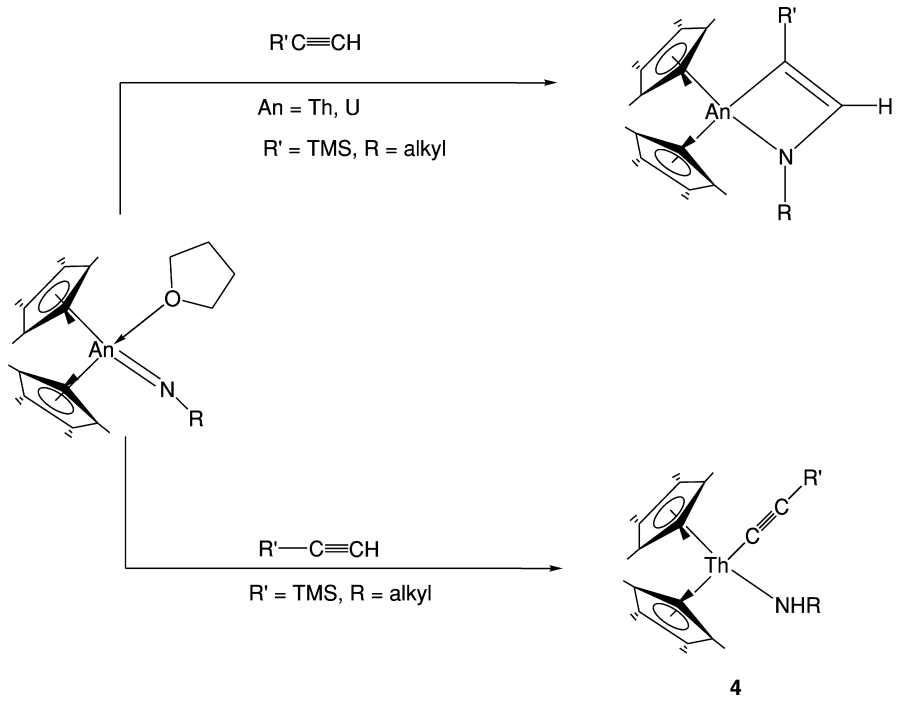
Since the approach of either alkyne or an amine to the organometallic catalyst is expected to occur in a side-on manner in the metallocene, the lack of alkyne concentration dependence in the kinetic hydroamination rate suggested that the proposed pathway 1 (Scheme 26.25) was not a major operative route. The zero kinetic order on alkyne suggests pathway 2 (Scheme 26.25) is consistent with the high coordinative unsaturation of the imido complexes that allows a fast insertion of the different alkynes with indistinguishable rates. When bulky amines were utilized, the formation of the corresponding imido complexes was hindered due to the encumbered transition state [equation (26.83)], reaching the highest steric hindrance with $^{t}BuNH_2$



(26.83)

The different activation mode for the two organoactinides is very unusual. For both organoactinide–imido complexes, a selective metathesis with the π-bond of the alkyne was found to exist (demonstrated by the production of hydroamination products), whereas for the thorium complex a protonolysis reaction was observed as a competing reaction. The competing reaction was found to be responsible for the selective dimerization of the terminal alkynes (Scheme 26.26).

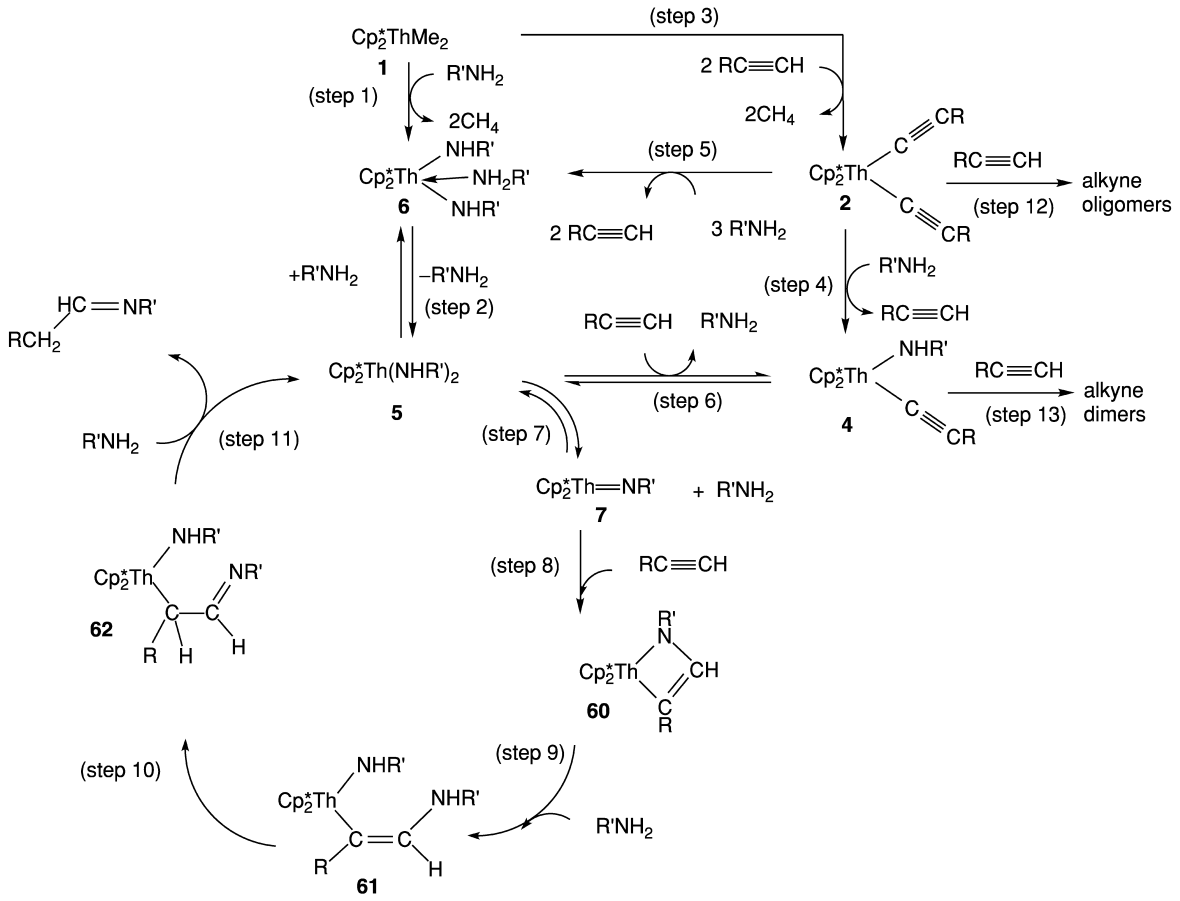
A likely scenario for the intermolecular hydroamination of terminal alkynes promoted by the organothorium complex is shown in Scheme 26.27. The first step in the catalytic cycle involved the N–H σ-bond activation of the primary amine by the starting organoactinide, yielding methane and the bisamido–amine complex $(C_5Me_5)_2Ac(NHR')_2 \cdot H_2NR'$ **6** (step 1), which was found to be in rapid equilibrium with the corresponding bis(amido) complex **5** (step 2) (Straub *et al.*, 1996; Eisen *et al.*, 1998) An additional starting point



4

Scheme 26.26 *Distinctive modes of activation for organoactinide–imido complexes in the presence of terminal alkynes.*

involved a similar C–H activation of an alkyne with the organoactinide yielding methane and the bis(acetylide) complex **2** (step 3). This complex may react rapidly in the presence of amines either in equivalent amounts (step 4) or with an excess (step 5) yielding complexes **4** or **6**, respectively. Complex **5** followed two competitive equilibrium pathways. The σ-bond metathesis with a terminal alkyne yielded complex **4** (step 6), which induced the production of selective dimers (step 13). The second pathway (step 7), as the rate-limiting step, involves elimination of an amine molecule producing the corresponding imido complex **7**. The imido complex participated in a rapid π-bond metathesis with an incoming alkyne, yielding the metallacycle **60** (step 8). Rapid protonolytic ring opening of complex **60** by an amine yielded the actinide–enamine amido complex **61** (step 9). Complex **61** rapidly isomerized to the actinide–alkyl(imine) amido, **62**, by an intramolecular 1,3 sigmatropic hydrogen shift (step 10), which upon a subsequent protonolysis by an additional amine (step 11) produced the imine and regenerates the bis(amido) complex **5**.



Scheme 26.27 *Proposed mechanism for the intermolecular hydroamination of terminal alkynes and primary amines promoted by neutral organoactinide complexes.*

The preferential formation of the *E* imine isomer as compared to that of the *Z* isomer may be explained by the steric hindrance of the amine substituents in the isomerization pathway as described in Scheme 26.28.

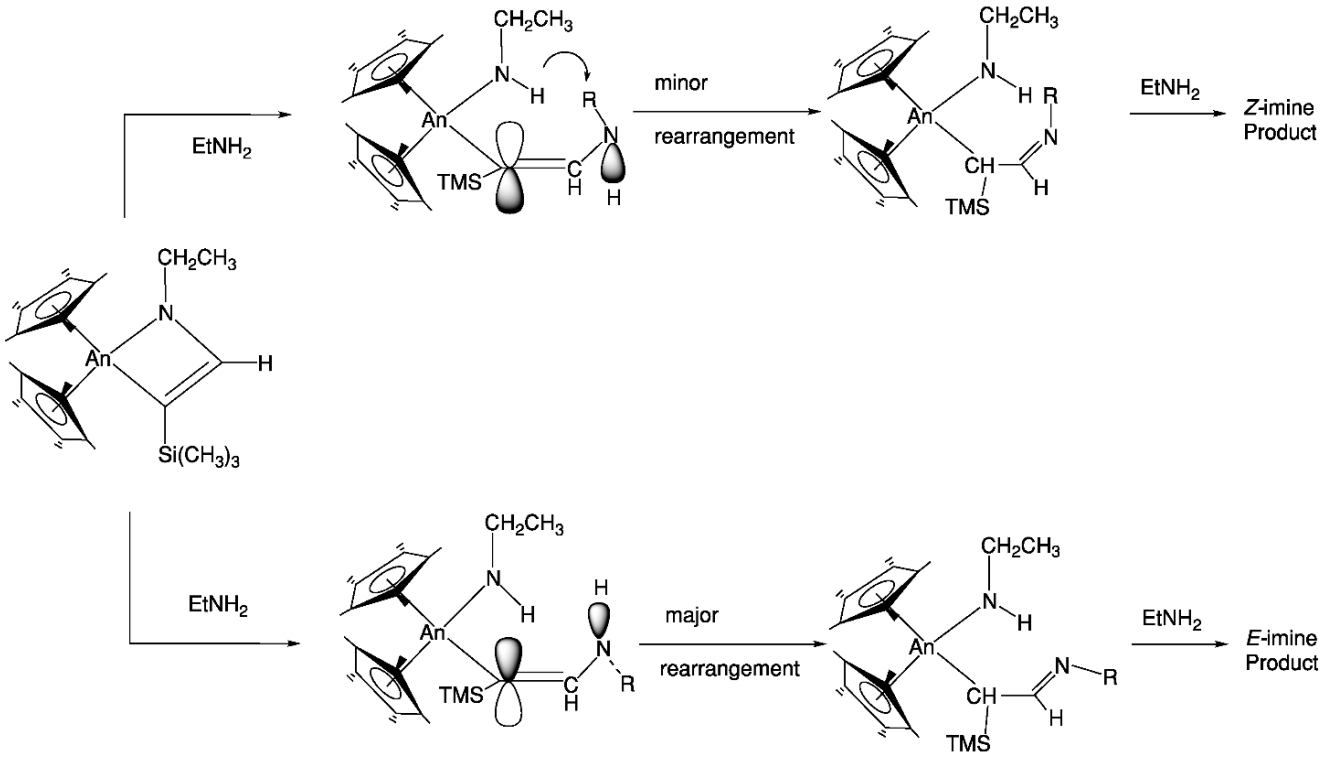
The distinct products formed by the two organoactinide catalysts in the hydroamination reaction are a result of a stereochemical difference in the approach of the alkyne to the imido complex (Scheme 26.29). It has been proposed that the regiochemistry of the intermolecular hydroamination between U and Th is driven by the differences in their electronic configurations, rather than the difference in their thermochemistry (potentially the f^2 electronic configuration of the uranium complex).

26.9 INTRAMOLECULAR HYDROAMINATION BY CONSTRAINED-GEOMETRY ORGANOACTINIDE COMPLEXES

Recently novel types of constrained-geometry actinide complexes were synthesized by the amine elimination syntheses using a protic ligation and the corresponding homoleptic amido-actinide precursor (Scheme 26.30) (Stubbert *et al.*, 2003). The equilibrium position of the elimination reaction was controlled by the dialkylamine concentration, whereas the removal of this by-product was the key step to obtain good yields for both actinide metals (Th, U). A slight excess of the ancillary ligand was used to obtain the complexes under mild conditions in up to 77% yield.

All three uranium complexes were crystallized as well as the $(CGC)Th(NMe_2)_2$ ($CGC{=}Me_2Si(\eta^5\text{-}Me_4C_5)\text{-}(^t BuN)$). The observed trends for the Cp(centroid)–metal–nitrogen angles for the actinide complexes and their respective comparison to lanthanides are Th > U > Sm > Yb, indicating a more open coordination for the 5f elements (Tian *et al.*, 1999; Stubbert, *et al.*, 2003). The *tert*-butylamido-metal bond length in all the complexes was found to be larger than the corresponding metal–NR_2 bond. The longer bonds are plausibly due to the lower basicity of the (Me_2Si *tert*-ButylN) as compared to that of the NR_2 moieties. Table 26.2 shows the turnover frequency for the hydroamination/cyclyzation of aminoalkenes and aminoalkynes. In addition, a nice comparison for the different abilities of the constrained geometry complexes with organoactinide metallocenes $Cp^*_2AnMe_2(An = Th, U)$ in the hydroamination is illustrated.

Kinetic studies on the hydroamination/cyclization reaction shows similar behavior as found for lanthanides. The kinetic rate law exhibits a first-order dependence on the precatalyst and zero order on the substrate i.e. rate α $[precatalyst]^1[substrate]^0$. This result argues that the protonolysis of the precatalyst amido moieties by the substrate is rapid, and that the rate determining step of the reaction is the olefin (alkene or alkyne) insertion into the An–NHR bond. For aminoalkenes, faster reactions are observed for the organoactinide



Scheme 26.28 *Formation of imines* E *and* Z *by a* 1,3*-sigmatropic hydrogen shift from the two possible organoactinide complexes. The curved arrow shows the steric interaction between the amine substituents present in the top route as compared to the bottom route.*

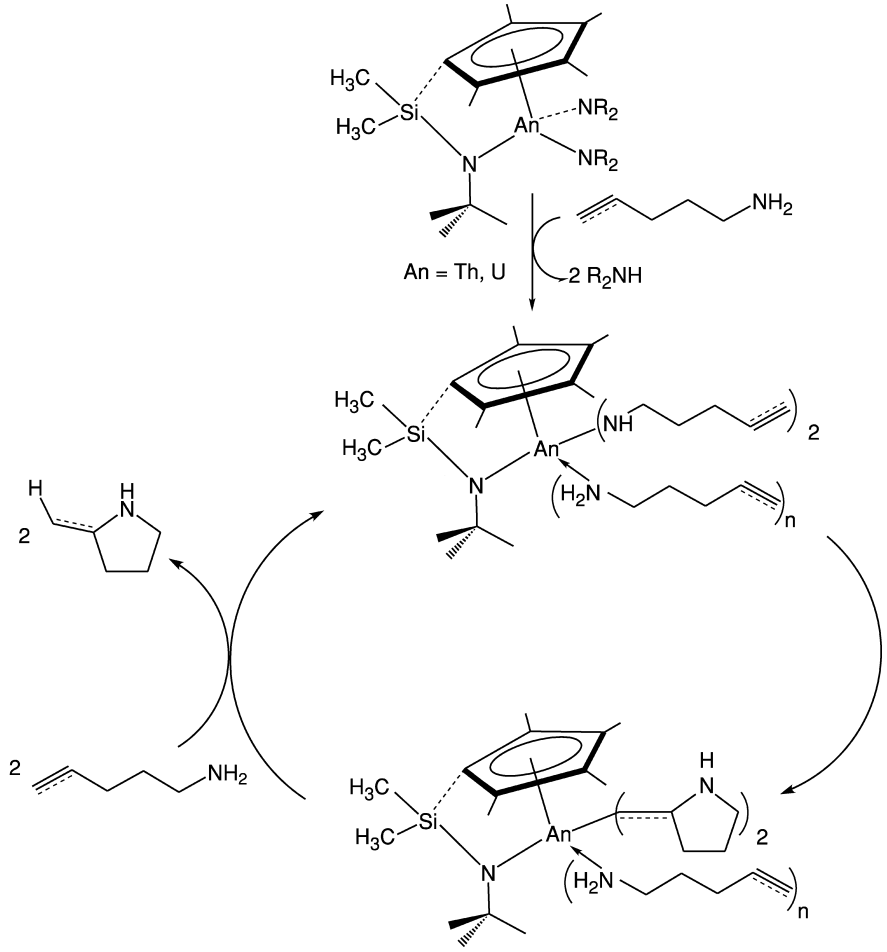
with a larger ionic radius, while for aminoalkynes, the faster reactions are observed for the organoactinide with the smaller ionic radius. A plausible mechanism for the hydroamination/cyclization is presented in Scheme 26.31.

It can be seen that the more sterically open environment of the constrained geometry complexes induces to a greater turnover frequencies for the aminoalkene substrates by allowing a greater access to the metal center without interfering with the kinetics and the stability of the complexes. For both aminoalkene and aminoalkynes, the constrained geometry complexes react much faster than the corresponding organoactinide metallocenes.

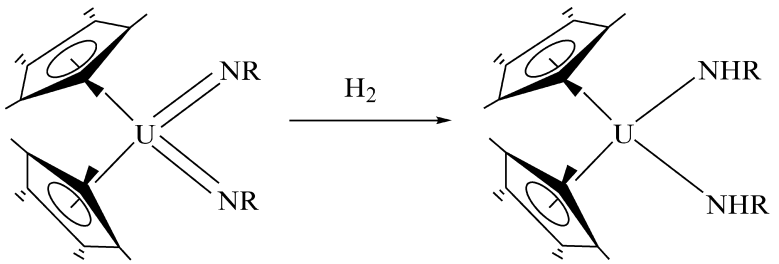


Scheme 26.31 *Plausible mechanism for the intramolecular hydroamination/cyclization of aminoolefins promoted by constrained geometry organoactinide complexes.*

26.10 THE CATALYTIC REDUCTION OF AZIDES AND HYDRAZINES BY HIGH-VALENT ORGANOURANIUM COMPLEXES

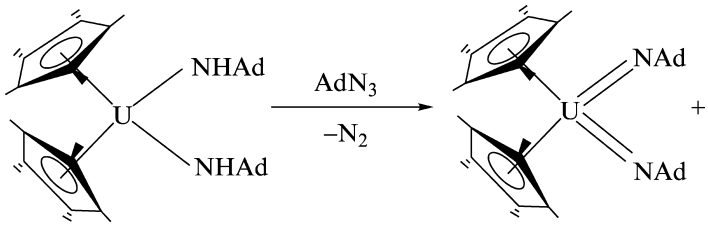
U(IV) metallocene compounds frequently show reactivities comparable to lanthanide and group IV transition metal metallocenes. Common types of processes among these metals (as demonstrated above) include olefin insertion, σ-bond metathesis, and protonolysis. In contrast to the lanthanides and group IV metals, however, uranium can also access the 6+ oxidation state, giving rise to the possibility of two-electron (4+/6+) redox processes. When the complexes $(C_5Me_5)_2U(=NR)_2$ (R = Ph, **29**; R = Ad = 1-adamantyl), **30**; are exposed to an

atmosphere of hydrogen, they are reduced to the corresponding bis(amide) complexes $(C_5Me_5)_2U(NHR)_2$ (**12**) (R = Ph, Ad,) [equation (26.84)]. The rate of hydrogenation of complex **30** was found to be much faster than that of complex **29**. When AdN_3 was added to a solution of the bis(amide) **12**, the bis (imido) **30** and $AdNH_2$ were formed [equation (26.85)]. Therefore, when complex **12** (R = Ad) was reacted with AdN_3 under an atmosphere of dihydrogen, catalytic hydrogenation of AdN_3 to $AdNH_2$ was observed (Scheme 26.32) (Peters *et al.*, 1999b).



(26.84)

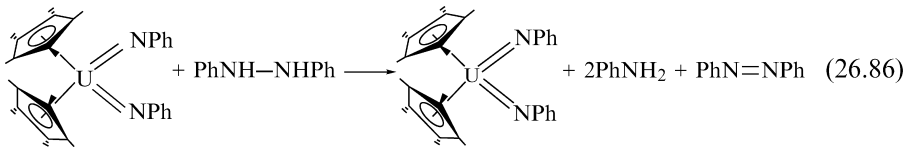
R = Ph, Ad



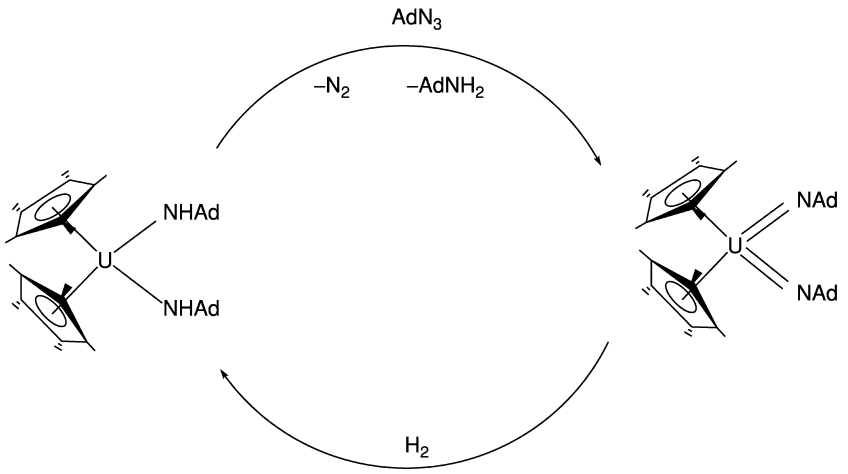
+ $AdNH_2$ (26.85)

30

N,*N*′-diphenylhydrazine was also used as the oxidant converting $(C_5Me_5)_2UMe_2$ (**8**) to **29**. This reaction was shown to occur by the protonation of the methyl groups, liberating methane. When $(C_5Me_5)_2U(=NPh)_2$ was treated with an excess of *N*,*N*′diphenylhydrazine in the absence of hydrogen, the substrate was entirely consumed, and aniline and azobenzene were observed to form in a 2:1 ratio [equation (26.86)]. This disproportionation indicated that the *N*,*N*′-diphenylhydrazine functioned as both oxidant and reductant. The formation of aniline during this reaction suggested that the U(IV) bis(amide) **12** is formed and serves to reduce the hydrazine, although the only observed uranium species in solution throughout the reaction was $(C_5Me_5)_2U(=NPh)_2$, indicating that the oxidation from U(IV) to U(VI) is faster than the subsequent reduction (Peters *et al.*, 1999b).



(26.86)



Scheme 26.32 *Catalytic reduction of azides by organouranium complexes.*

This reaction is favored both enthalpically and entropically. The calculated ΔH_f for converting two molecules of *N*,*N*'-diphenylhydrazine to two molecules of aniline and one molecule of azobenzene is –14.6 kcal/mol. Entropy considerations also qualitatively favor product formation; two molecules of starting material are converted to three molecules of product.

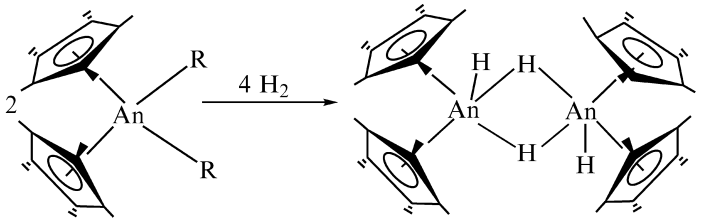
The catalytic activity of $(C_5Me_5)_2U(=NAd)_2$ (**30**) was also examined. The expectation was that if the mechanism of catalysis proceeds by protonation of the U(IV) bis(amide) by *N*,*N*′-diphenylhydrazine, similar to the reaction of *N*,*N*′-diphenylhydrazine with $(C_5Me_5)_2UMe_2$, initial product formation would include adamantylamine and azobenzene, with the concomitant formation of $(C_5Me_5)_2U(=NPh)_2$. However upon performing that reaction, $(C_5Me_5)_2U(=NAd)_2$, aniline and azobenzene were the only products observed, indicating that the imido ligands plausibly operated as sites for mediating H-atom transfer. No reaction was observed in the stoichiometric reaction of **29** with 1-adamantanamine ruling out the possibility of U–N bond rupture in which compound **29** is formed and undergoes subsequent rapid reaction with 1-adamantanamine regenerating **30** (Peters *et al.*, 1999a,b).

The catalytic transformations of substrates by two-electron processes are a novel type of reactivity for f-element complexes. The involvement of U(VI) species strongly argued for the requirement of f-orbital participation.

26.11 HYDROGENATION OF OLEFINS PROMOTED BY ORGANOACTINIDE COMPLEXES

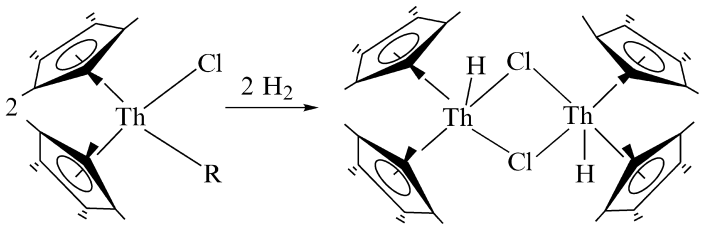
The insertion of olefinic functionalities into metal–hydride bonds is an important step in various stoichiometric and homogeneous catalytic processes. A rich and versatile chemistry of organoactinide hydride complexes has been observed

for the complexes $(C_5Me_5)_2AnR_2$ (An = Th, U; R = alkyl). The formation of the hydride complexes has been obtained by hydrogenolysis of the corresponding organoactinide hydrocarbyl bonds [equations (26.87) and (26.88)] (Fagan *et al.*, 1981a,b; Marks, 1982, 1986a,b).



(26.87)

An = Th, U; R = alkyl



(26.88)

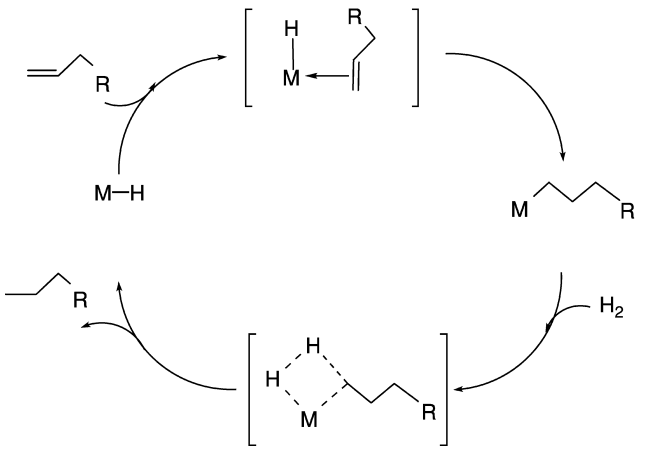
R = alkyl

These reactions have been studied thoroughly, mechanistically following a four-center transition state. Kinetic studies show that the reaction displays a first-order dependence in both actinide complex and in dihydrogen (Lin and Marks, 1987, 1990).

The organoactinide hydrides of the type $[(C_5Me_5)_2AnH_2]_2$ react rapidly and quantitatively with olefins yielding the corresponding 1,2-addition product. For example, the hydride complex $[(C_5Me_5)_2UH_2]_2$ catalyzes the hydrogenation of 1-hexene at 25°C and 1 atm of H_2 in toluene with a turnover frequency of 63000 h^{-1}. Scheme 26.33 shows the proposed hydrogenation mechanism of alkenes. The mechanism was derived from kinetic investigations similar to the hydrogenations promoted by the organolanthanide hydride $[(C_5Me_5)_2Lu(\mu\text{-}H)]_2$.

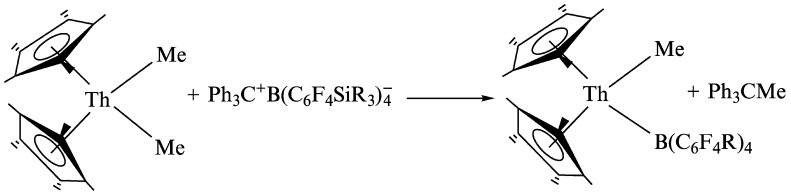
26.12 POLYMERIZATION OF α-OLEFINS BY CATIONIC ORGANOACTINIDE COMPLEXES

The synthesis of the cationic actinide complexes $[(C_5Me_5)_2ThMe][BPh_4]$ and $[(C_5Me_5)_2ThMe][B(C_6F_5)_4]$ has led to their study for the polymerization of ethylene and 1-hexene (Yang *et al.*, 1991). Mechanistically, the complexes $(C_5Me_5)_2AnMe_2$ (An = Th, U) react with a strong Lewis acid, like methylalumoxane (MAO), resulting in the formation of a cationic complex of the type $[(C_5Me_5)_2AnMe]^+[MAO\text{–}Me]^-$. These cationic complexes insert α-olefins many



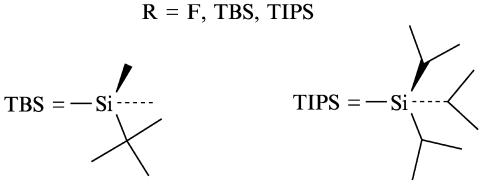
Scheme 26.33 *Proposed mechanism for the catalytic hydrogenation of alkenes promoted by* $[(C_5Me_5)_2UH_2]_2$.

times before a β-hydrogen elimination or a β-methyl elimination occurs, producing polymers. For ethylene, high-density polyethylene has been obtained whereas for propylene, atactic polypropylene was the product. The search for different cocatalysts (instead of MAO) has brought the development of new and versatile perfluoroaromatic boron compounds. These highly coordinative unsaturated cationic organothorium complexes have been recently prepared and found active for the polymerization of olefins [equation (26.89)] (Jia *et al.*, 1994, 1997).



(26.89)

R = F, TBS, TIPS



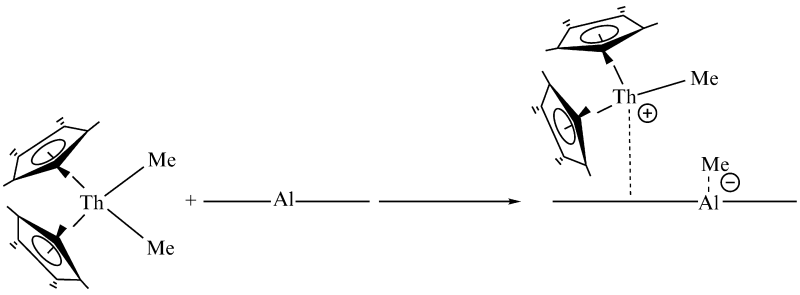
The reactivity of the organothorium complexes for the polymerization of ethylene follows the order: $[(C_5Me_5)_2ThMe][B(C_6F_5)_4] > [(C_5Me_5)_2ThMe]$

$[B(C_6F_4TIPS)_4] > [(C_5Me_5)_2ThMe][B(C_6F_4TBS)_4]$; however, their activity is an order of magnitude lower that observed for the corresponding zirconium complexes.

26.13 HETEROGENEOUS SUPPORTED ORGANOACTINIDE COMPLEXES

26.13.1 Hydrogenation of arenes by supported organoactinide complexes, kinetic, and mechanistic studies

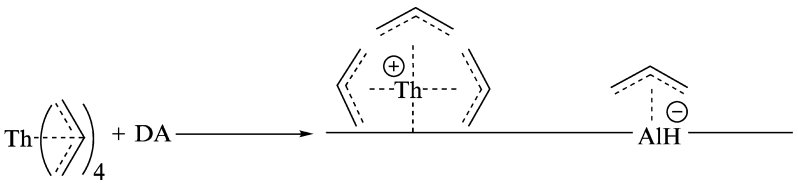
Supporting homogeneous complexes on metal oxides creates a substantial alteration in their activity as compared to that observed in solutions (Iwasawa and Gates, 1989). For early transition metals (Yermakov *et al.*, 1981) and actinide alkyl complexes (Burwell and Marks, 1985; Finch *et al.*, 1990; Gillespie *et al.*, 1990; Marks, 1992) adsorbed upon metal oxide (e.g. alumina), large enhancements in the activities for catalytic hydrogenation were observed. The increase in coordinative unsaturation in metallocene organometallic-f-complexes generates a remarkable increase in the reactivity of these adsorbed complexes towards polymerization and hydrogenation of simple olefins, rivaling the activity of supported rhodium (He *et al.*, 1985; Marks, 1992), although these complexes are inefficient for the hydrogenation of arenes. Chemisorption of organoactinides involves the transfer of an alkyl group to the Al^{3+} (coordinatively unsaturated surfaces) sites and the formation of a 'cation–like' organothorium center as shown schematically in equation (26.90) (Jia *et al.*, 1997).



(26.90)

To address the question of how coordinatively unsaturated an organometallic-f-element complex was needed for the efficient reduction of arenes, a series of complexes of the type $R^1R^2_3Th(R^1 = \eta^5 - (CH_3)_5C_5; R^2 = CH_2C_6H_5; R^1 = R^2 = 1,3,5 - (CH_3)_3C_6H_2, R^1 = R^2 = \eta^3 - C_3H_5)$chemisorbed on highly dehydroxilated γ-alumina (DA) were prepared (Eisen and Marks, 1992a). Presumably, the adsorption of these organometallic-f-complexes is similar as displayed in equation (26.90), transferring an allyl group from the

thorium coordination to the strong Lewis acid site at the surface [equation (26.91)].



(26.91)

The hydrogenation reactivity of the latter complexes towards the hydrogenation of arenes (Table 26.3) shows that faster rates of hydrogenation are observed for less sterically hindered substrates.

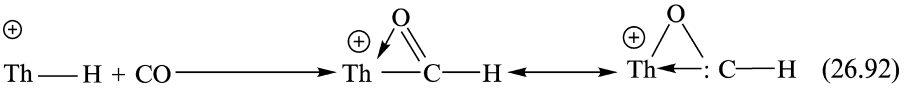
26.13.2 Assessment of the percentage of $Th(\eta^3\text{-}C_3H_5)_4$/DA active sites

The percentage of supported organoactinide sites active in the olefin hydrogenation was estimated by dosing the catalyst with measured quantities of CO in a H_2 stream, measuring the amount of CO adsorbed by the catalyst, and determining the effect on subsequent catalytic activity. Similar results were found for H_2O/D_2O, and CH_3Cl poisoning experiments. The CO poisoning chemistry presumably involved migratory insertion equation (26.92) to produce surface η^2-formyl, which may then undergo various possible subsequent reactions.

Table 26.3 *Product and kinetic data for the $Th(\eta^3\text{-}C_3H_5)_4$/DA catalyzed hydrogenation of various arenes*[a]

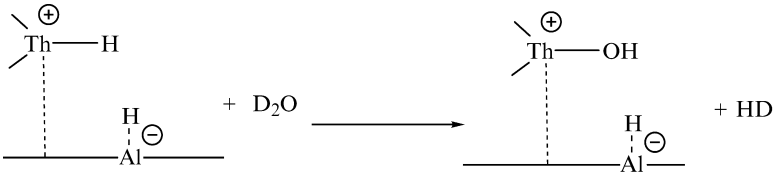
Substrate	*Product*	*Turnover frequency* (s^{-1})
C_6H_6	C_6H_{12}	6.80
C_6D_6	$C_6H_6D_6$	6.78
$CH_3C_6H_5$	$CH_3C_6H_{11}$	4.05[b]
$CD_3C_6D_5$	$CD_{3-x}H_xC_6H_6D_5$	3.98[b]
1,4-$(CH_3)_2C_6H_4$	 3 : 1	0.65[b]
Naphthalene	 5 : 1	8.3×10^{-3}

[a] pH_2 = 190 psi; [arene] = 10 mmol. Temp = 90°C.
[b] = values at 100% yield.



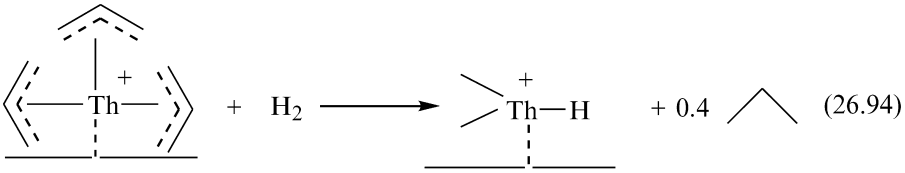
(26.92)

Additional confirmation of the estimated number of active sites was provided by measurement of the metal–hydride content by adding aliquots of D_2O, and studying the catalytic activity after each addition. This stepwise titration of active sites indicated that $8 \pm 1\%$ of the total $Th(\eta^3\text{-}C_3H_5)_4/DA$ sites present on the support were responsible for the majority of the catalysis [equation (26.93)].



(26.93)

Another additional complementary experiment for measuring the number of hydrides was undertaken by reacting the adsorbed $Th(\eta^3\text{-}C_3H_5)_4/DA$ with hydrogen and measuring the amount of organic gas recovery from the reaction. The amount of propane per thorium was found to be only 10% of the total amount expected [equation (26.94)]. No propylene was released from the reaction, indicating that the hydrogenation of propylene was extremely fast, and indeed, the turnover frequency for the hydrogenation of propylene was measured separately to be ($N_t(25^\circ C) = 25\ s^{-1}$).



(26.94)

The number of thorium hydride sites formed was confirmed to be the same by reaction with methyl chloride and measurement of the amount of methane per Th that was evolved from the reaction [equation (26.95)].

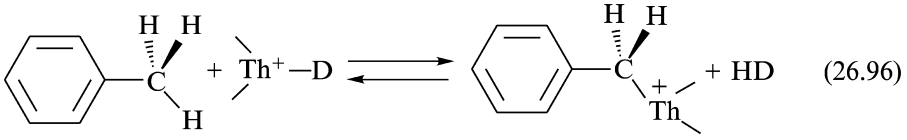
(26.95)

The importance of these poisoning experiments is that they indicate that only a very small fraction of the organothorium adsorbate sites on dehydroxylated alumina were responsible for the bulk of the catalytic reactivity. It is likely that one or more different structures of the suggested 'cation-like' organothorium moieties constitute the catalytic sites on alumina, but the exact structural characteristics defining these structures remain to be elucidated.

For arene hydrogenation, the kinetic data can be accommodated by three repetitions of a two-step sequence: (i) arene insertion (olefin insertion for the subsequent step) into a Th–H bond; (ii) hydrogenolysis of the resulting Th–alkyl bond. The kinetic data measured for benzene conforms to the rate law $N_t = k$ [benzene]^0[pH_2]^1[Th]^1 (Th = tetraallyl complex). The kinetic isotope measurements for the hydrogenation of benzene indicated $N_t(H_2)/N_t(D_2) = 3.5 \pm 0.3$ at 90°C and 180 psi of H_2. In the hydrogenation reaction of benzene with D_2, the product $C_6H_6D_6$ was obtained as a mixture of two geometric isomers as refers to the disposition of the deuterium atoms: *all cis* and *cis*, *cis*, *trans*, *cis*, *trans* in a ratio of 1:3 respectively. The Arrhenius activation energies for the catalytic hydrogenation of benzene was measured to be 16.7 ± 0.3 kcal mol^{-1} and the corresponding thermodynamic activation parameters were $\Delta H^{\ddagger} = 16.0 \pm 0.3$ kcal/mol and $\Delta S^{\ddagger} = 32.3 \pm 0.6$ eu (Eisen and Marks, 1992).

The mechanism proposed for the hydrogenation of arenes is described in Scheme 26.34. The process takes into account the lack of facial selectivity by which the ratio 1:3 among the geometrical isomers were formed. As a function of substrate, the relative rates of Th(η^3-C_3H_5)$_4$/DA-catalyzed hydrogenation of arenes was found to be in the order benzene > toluene > *p*-xylene > naphthalene.

In the hydrogenation of benzene no H/D scrambling is observed during the process but H/D scrambling is observed after complete hydrogenation of the starting material. In the reaction between toluene-d_8 and H_2 or toluene and D_2 significant C–H/C–D exchange at the benzylic positions was observed during the hydrogenation. Significant incorporation of deuterium atoms into the starting toluene and subsequently into the cyclohexane product was observed at partial conversions. The C–H/C–D exchange was suggested to occur through a benzylic activation as shown in equation (26.96).

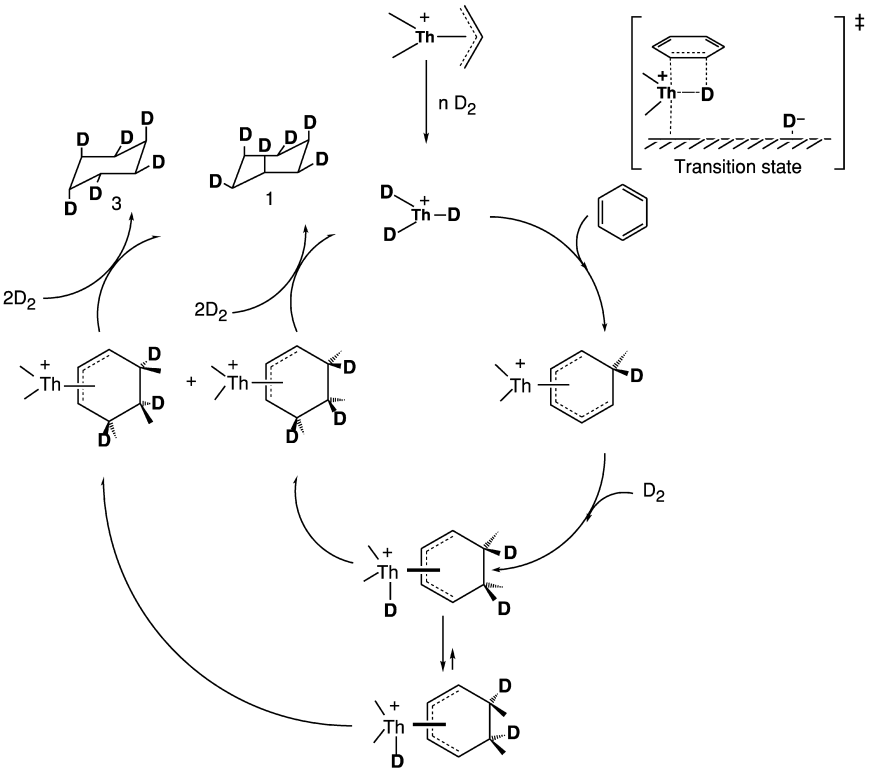


(26.96)

Competition experiments confirmed the large kinetic discrimination for the different arenes. The hydrogenation reaction of equimolar quantities of *p*-xylene and benzene yielded cyclohexane with almost complete selectivity (97%) and a mixture of 3:1 *cis*:*trans* 1,4-dimethylcyclohexane (3%).

26.13.3 Facile and selective alkane activation by supported tetraallylthorium

C–H activation processes involving alkanes are considered high-energy demanding transformations. Although significant advances have been made in the functionalization of C–H bonds by f- and early transition complexes (Shilov, 1984; Gillespie *et al.*, 1990; Ryabov, 1990; Watson, 1990; Basset *et al.*, 1998;



Scheme 26.34 *Proposed mechanism for the hydrogenation of arenes by cationic supported organoactinide complexes.*

Schneider *et al.*, 2001), the catalytic intermolecular activation of inert alkane molecules with favorable rates and selectivities is still a major challenge. As noted above, studies on benzene reduction with D_2 revealed C–H/C–D exchange in the cyclohexane product only after benzene conversion was complete. This observation prompted detailed studies of the activation of hydrocarbons. The results from slurry reaction studies of C–H/C–D exchange for a variety of alkanes catalyzed by thorium tetraallyl complex/DA under a D_2 atmosphere are summarized in Table 26.4 (Eisen and Marks, 1992b).

Rapid C–H/C–D exchange was promoted by the tetraallyl complex/DA, with turnover frequencies comparable to or exceeding those of conventional group 9 heterogeneous alkane activation catalysts (Butt and Burwell, 1992). C–H functionalization occurred with substantial selectivity and in an order which does not parallel the C–H bond dissociation energies: primary > secondary > tertiary,

Table 26.4 *Kinetic and product structure/deuterium distribution data for Th(η^3-C_3H_5)$_4$/DA catalyzed C–H/C–D fuctionalization.*

Substrate	*Deuterium distribution in product* (%)	*Turnover frequency* (h^{-1})

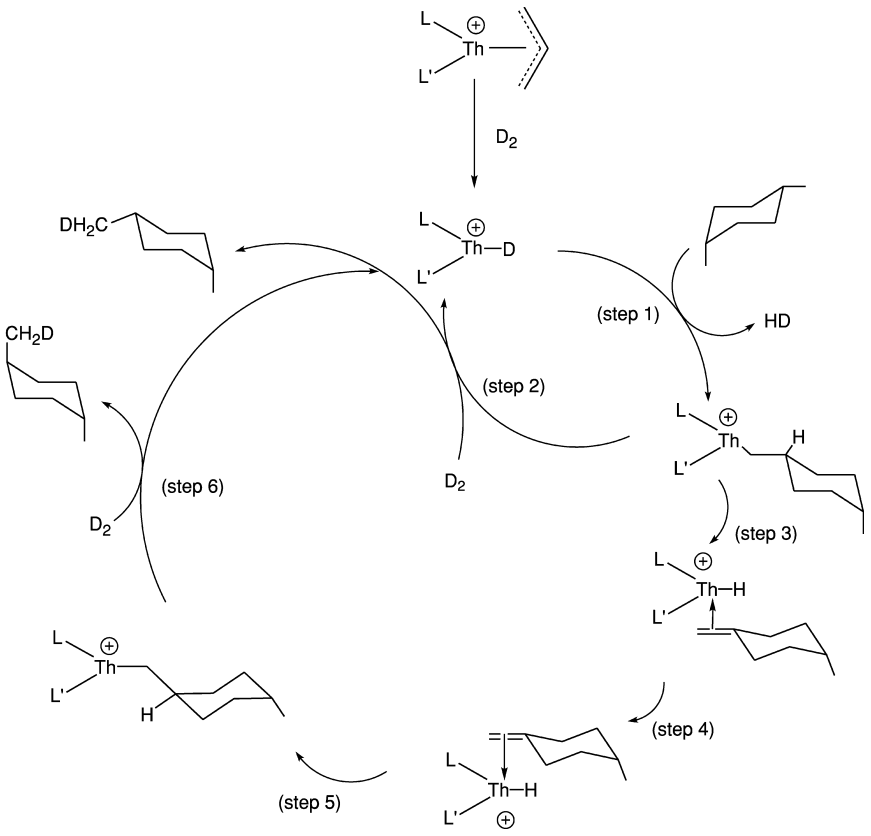
	 	834

and sterically less hindered > sterically more hindered. NMR and GC-MS measurements as a function of conversion indicated single C-H exchanges, with no evidence for multiple exchange processes (e.g. non-statistical amounts of RD_2 species). Unexpectedly, the CH/CD exchange reaction of *cis*-dimethylcyclohexanes produced isomerization towards a *cis–trans* mixture. Based on the same two reasonable assumptions as for the arene hydrogenation, a plausible mechanistic scenario for the activation and isomerization of alkanes was proposed and summarized in Scheme 26.35. The mechanistic sequence invokes presumably endothermic Th–C bond formation and HD elimination via a 'four- center', heterolytic 'σ-bond metathesis' (step 1), followed by deuterolysis

(step 2). Cycloalkane skeletal isomerization would then occur via a β-H elimination (step 3) and re-addition of the Th^{+}–H to the opposite face of the double bond (step 4). This process would involve the rapid dissociation and re-addition of the alkene, although other mechanisms have been proposed as conceivable. Insertion (step 5) and deuterolysis (step 6) produced the isomerized cycloalkane. The isotopic labeling experiments revealed little D incorporation at the dimethylcyclohexane tertiary carbon centers and negligible differences in the D label distribution of the isomerized and un-isomerized hydrocarbons. These results indicated that the ancillary ligands L and L′ in Scheme 26.35 are either non-D in identity (e.g. η^3-allyl or oxide), or that such Th–D functionalities were chemically and stereochemically inequivalent to that formed in a β-H abstraction, since they do not compete for olefin addition.



Scheme 26.35 *Proposed scenario for the Th(η^3-allyl)$_4$/DA-catalyzed C–H activation and isomerization of alkanes.*

In summary, these results demonstrate that supported organo-f-complexes are extremely active catalysts for a number of high-energy organic chemistry transformations.

CHAPTER TWENTY SEVEN

IDENTIFICATION AND SPECIATION OF ACTINIDES IN THE ENVIRONMENT

Claude Degueldre

27.1 BACKGROUND

All actinide isotopes are radioactive. Since the middle of the last century, new actinide and transactinide isotopes have been artificially produced and the use of several of the naturally occurring actinide isotopes has increased. This production is due to the nuclear power industry and the military fabrication and use of nuclear weapons. These activities have created anxiety about the introduction of actinide elements into the environment. Consequently, environmental systems that contain or are exploited for natural actinides, or, are potentially contaminated by anthropogenic actinides, must be investigated. The analytical techniques introduced in this chapter are used, after sampling when required, to identify and quantify the actinide isotopes and to determine the species in which they are present.

The amounts or concentrations of actinide elements or isotopes in the environmental samples need to be identified and quantified. Moreover, since transport properties and bioavailability are closely linked to species and atomic environment of the actinide elements, both radiotoxicity and speciation of actinides in the studied phases must be determined to understand the behavior of these elements in the environment (Livens, 2001). In this chapter, analysis of a broad range of environmental systems are considered such as fluid phases from air or waters from surface to subsurface, samples from terrestrial

to oceanic, and samples from rocks to organic or bio-related phases. These samples range from depleted to rich in actinides and from inorganic to organic or bioorganic. The actinides are either dissolved in solid or liquid solutions, or associated with particles dispersed in the sample phase: in air or water, or in heterogeneous solids. Actinide species may also be located at phase boundaries such as rock–water or dispersed *in vivo*, associated with biofunctional environments. The phases of interest range from the nanometer to the kilometer in size, in surface or in volume.

In all cases, accurate or quantifiable sampling is required, together with identification, quantification, and determination of the redox states or of the complexes in the phases or at the interfaces, as well as characterization of the molecular environment, or emphasis on the crystalline or the amorphous phases that contain actinide isotopes, elements, or species. This information is required to understand how actinide species will behave in the environment and the way in which actinides can migrate or be retained. However, contamination may concentrate via bioaccumulation mechanisms (Holm and Fukai, 1986; Skwarzec *et al.*, 2001) or a geochemical process specific to a local hydrogeochemical environment (Bundt *et al.*, 2000). Spatial information is needed, ranging from the subnanometer to the micrometer size to understand migration behavior from the microscopic to the geographic scale, and temporal information is needed, ranging from second fractions to millions of years.

Figure 27.1 schematizes the source, location, or occurrence of natural actinides and of present or potential contamination including man-made actinide elements in the environment. The actinide elements and isotopes considered are the natural ones, with Th and U (primordial nuclides formed in the buildup of the terrestrial matter and still present today) being the major elements at the 10^{13} ton level in the Earth's crust (Wasserburg *et al.*, 1964) and with Ac and Pa being the trace elements formed by decay of the major natural actinide isotopes. Naturally occurring Np and Pu are present at the ultratrace level generated by nuclear reactions in the environment, and are also residual traces of primordial actinides, or produced man-made, as discussed below.

Natural actinide isotopes are present in rocks or minerals, e.g. phosphates containing uranium or thorium (^{232}Th and ^{235}U, ^{238}U) (Heier and Rogers, 1963; Khater *et al.*, 2001). The minor components (^{227}Ac, ^{228}Ac, ^{227}Th, ^{228}Th, ^{230}Th, ^{231}Th, ^{234}Th, ^{231}Pa, ^{234m}Pa, ^{234}U) are produced by decay of the major actinide isotopes (e.g. Murray *et al.*, 1987; Arslanov *et al.*, 1989). Natural ^{236}U has been detected at an atomic ratio, ^{236}U/^{238}U, of 6×10^{-10} in uranium deposits such as at the Cigar Lake, Saskatchewan, Canada (Zhao *et al.*, 1994). It may be generated by neutron capture on ^{235}U. Similarly, a long-lived actinide such as ^{237}Np was found in ultratrace levels (^{237}Np/^{238}U: 2×10^{-12}) in uranium ores from Katanga (Myers and Lindner, 1971). Ultratrace components such as ^{239}Np or ^{239}Pu are also generated by neutron capture (Curtis *et al.*, 1987; Barth *et al.*, 1994), with typical concentrations in the order of 10^{-12} g Pu per gram sample

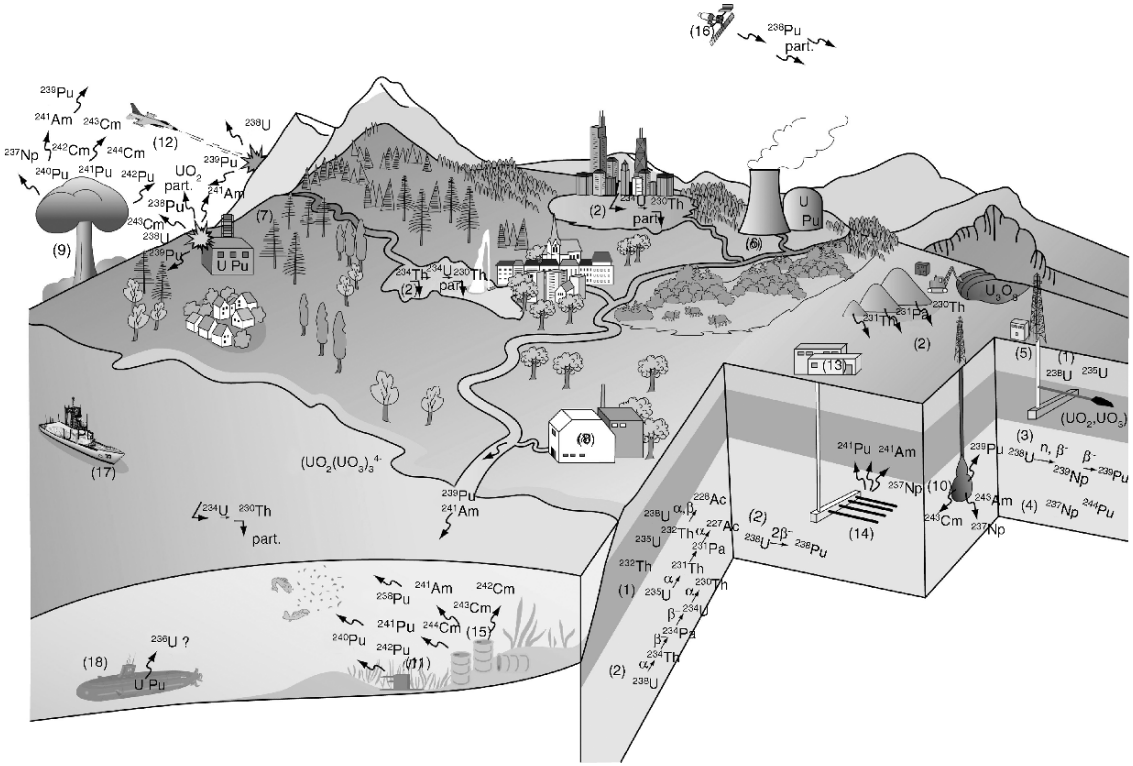

Fig. 27.1 *Natural and anthropogenic actinide species in the environment.* (1) *Natural major actinides,* (2) *minor actinides,* (3) *actinides at the ultratrace level generated from the majors by neutron capture in environment,* (4) *actinides of primordial origin,* (5) *natural actinide contamination around uranium mining and milling plants. Anthropogenic actinides:* (6) *released intentionally below legal norms from nuclear power plants,* (7) *by accident, or* (8) *reprocessing facilities. Actinides released from military activities, e.g. weapons production:* (9) *atmospheric tests,* (10) *underground detonations, or* (11) *objects from nuclear naval vessels, or* (12) *depleted uranium warheads. Waste management activities:* (13) *intermediate or* (14) *geologic and* (15) *oceanic disposal. Unexpected events from nuclear power sources, e.g.* (16) *satellite reentry in atmosphere,* (17) *nuclear icebreaker, or* (18) *nuclear submarine sinking; 'part' stands for colloidal particles.*

in pitchblende, 10^{-14} g Pu per gram U ore, and maximum concentrations in the order of 5×10^{-15} g Pu per gram lava (Hawaiian), 10^{-15} to $3 \times 10^{—17}$ g Pu per gram granite (Kontinentales Tiefbohrprogramm). ^{244}Pu, which was found in a rare earth mineral to the extent of 1 part per 10^{18}, is likely to have been produced during Earth formation (Hoffman *et al.*, 1971). As identification techniques become increasingly sensitive, it may be possible that specific isotopes such as heavy curium isotopes may be found at the ultratrace level as natural components as it was targeted in a study about supernova producing long-living radionuclides in terrestrial archives (Wallner *et al.*, 2000).

The specific case of the natural fossil reactors in the Oklo region (e.g. Oklo, Oklobonde, Bagombe), which underwent spontaneous chain neutronic reaction some 2×10^9 years ago, was studied extensively and revealed the buildup of large quantities of transuranium elements during chain reactions. However, most of them have now decayed. Natural plutonium has been produced and has remained in the environment even before it was produced artificially. It remains the heaviest natural element found in the environment at the level of milligrams per 100 tons of uranium ore residues (Peppard *et al.*, 1951).

Artificial or anthropogenic actinides are those generated by civilian and military activities. Actinide isotopes that have been artificially produced in significant amounts are ^{233}Pa, ^{233}U, ^{236}U, ^{237}Np, ^{238}Pu, ^{239}Pu, ^{240}Pu, ^{241}Pu, ^{242}Pu, ^{241}Am, ^{243}Am, ^{242}Cm, ^{243}Cm, and ^{244}Cm (Mitchell *et al.*, 1995b; Lujaniene *et al.*, 1999), with about 2000 tons Pu produced until now, which some groups would like to reuse in a very pragmatic way (Degueldre and Paratte, 1999). The amount of artificially produced actinides is larger than that occurring naturally. Actinide isotopes such as ^{239}Np and ^{239}Pu belong to both classes and are qualified as natural or anthropogenic according to their origin. Recently, attention has also been drawn to depleted uranium and its use in projectiles. Its dispersal in the environment has been the subject of investigations with regard to its toxic potential.

Natural processes typically disperse, transport, and dilute contaminants. Some local geophysical, hydrochemical, or bioorganic processes can concentrate them. Usually, however, atmospheric flow transports particulate contaminants through the atmosphere or the stratosphere. Water flows allow contaminants to migrate to the geosphere or at its surface. In these systems, naturally occurring actinides may be used as tracers to estimate element residence time in particulate form in air or in water systems. For example, ^{234}Th is used as a natural marker to study particles in Lake Michigan (Nelson and Metta, 1983) or Lake Geneva (Dominik *et al.*, 1989). Similarly, Th isotopes may be used to investigate their scavenging by colloidal mechanisms in seawater (Baskaran *et al.*, 1992). Similar studies may be applied to study actinides in particulate phases, or aerosols, in the atmosphere (Salbu, 2001). The naturally occurring actinides U and Th, as well as Ra, may be utilized in studies of paleoclimate, dating old groundwaters, rock–water interaction processes (Ivanovich, 1994), and geochronology systems (Balescu *et al.*, 1997), using

$^{234}U/^{238}U$ or $^{230}Th/^{234}U$ ratios. Anthropogenic actinides may also be used as markers; for example, the use of $^{239+240}Pu$ to replace ^{137}Cs as an erosion tracer in agricultural landscapes contaminated with the Chernobyl fallout (Schimmack *et al.*, 2001) was recently suggested.

Actinides from human activities have also been occasionally released into the environment. The potential of contamination begins at the uranium mine with tailings and the problems associated with, for example, the release of U and Th, and their daughter products (e.g. Winkelmann *et al.*, 2001); hazards continue all along the nuclear fuel cycle with research, commercial, or military activities and the potential for real spread and contaminations of the environment, as for example, the Irish Sea, Semipalatinsk, and Maralinga (Kim *et al.*, 1992; Cooper *et al.*, 1994; Kazachevskiy *et al.*, 1998), due to commercial or military activities or accidental events. Actinides may be dispersed, at restricted levels and below legal limits, from electric power utilities during operations (Mátel *et al.*, 1993), or may be instantaneously dispersed in large doses, for example, as a consequence of an accident involving a reactor (Holm *et al.*, 1992), an aircraft carrying nuclear weapons (Mitchell *et al.*, 1995a; Rubio Montero and Martin Sánchez, 2001a,b), or during nuclear bomb testing (Wolf *et al.*, 1997; Kudo, 1998). These actinide releases contaminate the environment, such as desert (Church *et al.*, 2000) or forest soil, but contaminate flora specimens such as mushrooms insignificantly (Mietelski *et al.*, 1993). However, diluted in water, actinides undergo bioaccumulation, e.g. in a marine environment (Baxter *et al.*, 1995), within phytoplankton and macro algae (Holm and Fukai, 1986), crustacean (Swift and Nicholson, 2001a,b), and fish (Skwarzec *et al.*, 2001). The reentry of a satellite equipped with a ^{238}Pu power source in the atmosphere and its disintegration through the stratosphere has been a source of contamination. In the ocean the leakage of objects from naval reactor pressure vessels in submarines (Mount *et al.*, 1995) or waste dumping on the seabed (Rastogi and Sjoeblom, 1999) are also potential sources of actinide contamination. In the geosphere, contaminants may affect the saturated or the unsaturated zones (Penrose *et al.*, 1990). All these cases schematized in Fig. 27.1 depict situations for which actinides are present as a main or a diluted phase. They also may be in a 'dissolved' state or present as colloidal particles in the liquid or gas environment. Consequently, the analytical techniques used range from major component quantitative analysis to detection at the ultratrace level. The analytical methods used to identify and characterize, i.e. provide speciation information for the actinides, must be efficient, accurate, very sensitive, and able to provide information on the chemical characterization of the environment of the actinide. This allows the reconstruction of the history of the actinide-loaded phases and consequently the prediction of actinide behavior in the environment to be made. For example, an oxide phase produced at low temperature will dissolve faster in water than a high-temperature oxide phase. Size distribution of these particles is a relevant parameter to estimate dissolution or transport behavior.

Before analysis, sampling and/or sample treatment, with separation if needed, must be utilized when the analytical technique is not applied *in situ*.The investigated analytical techniques are classified according to the interaction (if any) between irradiation particles or reagent and the analyzed sample, and for the signal detected or recorded (see Table 27.1). For passive techniques, excitations are absent. For interactive techniques, irradiations or reagent additions are made with phonons, photons, electrons, neutrons, or ions with a known energy, flux, chemical affinity, or mass. The irradiation or injection is done locally while the reception may be carried out in a given space at a given angle from the stimuli direction or the incident beam, instantaneously or after a certain time after irradiation. The detection tools are spectroscopy (S), microscopy (M), or radiography (RAD) instruments. The reaction takes place within or without a specific field such as electrical and magnetic flow or mechanical acceleration. The detected signal may be the same in nature as the incident one, with the same energy, or a signal with lower energy, with particles being phonons, photons, electrons, neutrons, or ions. In addition to these analytical tools or techniques, neutral species such as atoms or molecules may also be used to interrogate the material. They are treated in this chapter as ions (from a mass point of view). The techniques are classified according to increasing energy of reagents or incident particles. The combination of all excitation or reagent addition and reception or product detections makes the analytic potential very rich for identification of elements or isotopes, quantitative determination, and spatial speciation in a broad way.

The sensitivity κ (units of $M \cdot au^{-1}$, with M: $mol \cdot L^{-1}$, and au: arbitrary unit), and detection limit DL of the concentration C(M) of isotope, element, or species, or their amount N(mol) must be discussed at both theoretical and experimental levels. From the experimental side these concentration and amount limits are given by:

$$C_{DL} = 3\sigma\kappa \tag{27.1}$$

$$N_{DL} = V_{min} C_{DL} \tag{27.2}$$

where σ(au) is the standard deviation of the limiting noise and V_{min}(L) is the minimum volume that can be analyzed (e.g. 1 mL). From the theoretical side, a detection limit may be evaluated from the physical–chemical process and from the performance of the analytical unit, while it remains usually an experimental limit.

For all analyses, sample volume, mass, or amount, the flux of the reagent, the size of the analyzed part of the sample, and the acquisition time or time of analysis are key parameters linked to the detection limit. The nature and origin of the environmental sample dictate the size of the sample. However, the size of the sample is also coupled with the analytical technique for which time and detection limits (DLs) are key parameters for its application. DL is a function of the number

Table 27.1 *Analytical techniques including excitation (if any) and detection for isotope, element, or species characterization (see list of abbreviations in the glossary). Note: excitation or detection is performed with phonons, photons, electrons, neutrons, ions (or atoms or molecules) considering the particles (plain, solvated, or cluster) or their associated waves.*

Detection / *Excitation*	*Phonon*	*Photon*	*Electron*	*Neutron*	*Ion*
–	–	XS, γS, MBES	EHE, RAD, LSC, βS	NS	GRAV, ISE RAD, LSC, αS

Ion	–	ICPOES, PIXE, PIGE	–	NRA	VOL, AFM ICPMS, SIMS, AMS, RBS, ERDA, NRA

of actinide atoms, the volume of the sample, the subsample excitation conditions (see Section 27.2), and the acquisition quality of the detector, and interferences such as quenching or peak overlapping. It may, however, be desirable to split the speciation range according to 'macro concentration' $> 10^{-6}$ M $>$ 'trace concentration'. Analysis may be performed in-line, on-line, on a flow bypass with direct detection of activity, for example, or at-line with intermediate samples, or off-line with the transfer of the sample in the laboratory. The analysis may be carried out *in situ*, for example using an atmospheric balloon, or in an underground rock laboratory in the considered phase, or *ex situ* with transfer of the sample and separation. To complete the picture it must be mentioned that separation techniques such as filtration, centrifugation, diffusion, electrodiffusion, electroplating, partitioning (liquid–liquid or solid–liquid) may also be applied, making the analysis more specific or efficient.

Information required such as activity (chemical, radioisotopic), amount (mass), concentration (fraction), and structures of the actinides in the studied phases have to be determined at the nuclear (pm), atomic, molecular (nm), microscopic (μm), macroscopic structural (mm), bulk scale (cm), at the component or system scale (m), or at environmental or geographic scale (km) according to the requirements of the study. Identification concerns the actinide elements and isotopes, but speciation may be understood not only at the molecular scale but also in a broader sense such as at the environmental scale. Understanding in the macroscopic scale by plain washing, leaching, or extraction tests would be a step for remediation investigations. In many types of soil the mitigation approach could be some type of soil washing to remove selectively the contaminating species (Burnett *et al.*, 1995). The selective extraction tests are also discussed in this chapter; the phases are, however, analyzed using the techniques discussed below.

Passive and active analytical methods will be reviewed (Table 27.1) through Sections 27.2 and 27.3, with examples of their utilization in transmission, injection diffusion, or reflective modes. The sampling area, beam size, and reagent quantities are macroscopic, microscopic, or nanoscopic in nature, while spatial–temporal conditions make excitation vs detection direction through solid angle, with synchronous detection or with temporal delay, possible. In Section 27.4, combinations of techniques are discussed. For example, seismic reflection (SR), which cannot be used by itself for identifying thorium or uranium, can be used in combination with other techniques as a prospecting tool. Atomic force microscopy (AFM) morphological studies also provide useful information; however, they must be complemented with other technique results to provide the required identification result (e.g. Walther, 2003). Similarly, *Eh* electrode (EHE) measurements may contribute to the speciation of redox-sensitive actinides such as U, Np, or Pu in waters. They are, however, generally completed by spectroscopic investigations. Chromatography, which is basically a separation technique, must be combined with detectors and is also studied in this chapter.

Separation of elements of interest, which are later analyzed by different analytical techniques, is an important prerequisite of any analytical method, as discussed in Section 27.2. The analytical procedure typically includes sampling or sample preparation (e.g. decomposition), separation, and/or enrichment before analysis in either a passive or an interactive way.

27.2 SAMPLING, HANDLING, TREATMENT, AND SEPARATION

In environmental systems, actinides may sometimes be analyzed on site. This requires a probe or detector installation *in situ* and direct detection or measurement of actinide concentration, activity, or amount. This is an ideal case. Because of interferences, low levels of concentrations, or difficulties in transporting the analytical unit, sampling is generally the best solution, with transfer of samples or subsamples to the laboratory for further analysis. The sampling and sample handling are performed taking into account (Salbu, 2000):

- representative samples and fractionation of samples,
- treatment *in situ*, at-site, or shortly after sampling, and
- dilution or pre-concentration, and chemical yield (efficiency of handling).

Sampling, pretreatment, shipment to laboratory, and analysis are areas where contaminations, losses, or speciation changes can occur (Harvey *et al.*, 1987). Corrections for these artifacts must be applied by using isotopic tracers or specific handling conditions.

27.2.1 Sample and data collection of compounds

The two main strategies are either to make measurements on site without sampling and adapting the probe *in situ* or to collect samples and then perform the analysis *ex situ*, as discussed below.

Sample amounts and collection techniques are dependent on the nature of the sample and on its actinide content. Samples with high actinide contents do not generally need enrichment phases, while very dilute actinide samples may require treatment, enrichment, and other time-consuming protocols. The strategy may be very different for fluids (such as air or water) than for solids (such as rock or biospecimen).

In air samples, actinides are usually present as liquid aerosols or particles since their partial pressure as gaseous species is insignificant. A particulate phase must be characterized in terms of size distribution and nature, because its behavior in the environment may be function of production mode and history, which have a direct impact on composition, nature, specific size distribution, and actinide-release properties.

In water samples, the actinides may be present as truly dissolved species, as separate particulate, and/or as colloidal phases. Here again the particle structure and size distribution must be determined to understand the actinide migration potential.

In solid samples, actinides are either present as constituents of solid solutions or as phases that are heterogeneously dispersed within the matrix phases. This is also valid for biospecimens. The sample in all cases must be preserved from degradation, contamination, or other physicochemical changes. Specific protocols such as collection under a controlled atmosphere, a preservative reagent, and storage in the dark and at a reduced temperature may be required. The larger the sample volume and the corresponding contact area of the vessel, the smaller will be the loss by sorption on the vessel wall and the shorter the storage time, and the less will be degradation of the sample by contamination or particle aggregation.

As an example, typical air sample volumes range over several hundred meters (Iwatschenko-Borho *et al.*, 1992). Rainwaters, for example, require collectors of $\sim$1 m^2 active surface, and water samples of the order of 100 L (Rubio Montero and Martin Sánchez, 2001b). Analysis of river water may also require some 100 L (Garcia *et al.*, 1996) for Pu and Am determination. Seawater sampling also requires very large volumes, processed up to 6000 L (Livingston and Cochran, 1987; Robertson, 1985), in order to achieve concentration measurements of trace level of Th, Pu, and Am isotopes. Rock samples may be as large as the 100 kg amount that was required for the detection of ^{244}Pu (Hoffmann *et al.*, 1971) in nature.

27.2.2 Sample treatment and separation

Sample preparation and separation of ions or other species of interest, which are later analyzed by different analytical techniques, are usually important prerequisite steps of any analytical method. Radiotracer techniques may be applied for each step of the separation: sample decomposition, trace–matrix separation (precipitation, ion exchanger, solvent extraction), volatilization, and other treatment without any restriction on the chemical and physical forms of sample. All these techniques may be quantitatively applied using isotope dilution, e.g. with ^{235}Np, ^{236}Pu (Bellido *et al.*, 1994), or ^{244}Pu spikes according to the specific requirements.

Air samples are generally treated in a way such that their particulate content may be collected on filters or impactors (Iwatschenko-Borho *et al.*, 1992). Aerosol analysis generally requires treatment of a very large volume of air.

Aqueous solutions are generally filtered, typically through a 0.45 μm pore membrane, followed by a series of ultrafiltration (Orlandi *et al.*, 1990; Francis *et al.*, 1998) or centrifugation (Kim *et al.*, 1997; Dominik *et al.*, 1989; Itagaki *et al.*, 1991) steps. Centrifugation requires larger instrumentation compared to filtration. This limits the use of centrifugation on site and

furthermore *in situ*. The two new samples produced are: (1) single particle or colloid cake on the collector surface, or colloid concentrate; and (2) the filtered liquid phase with its soluble content. Treatments of restricted volumes of water are required, depending on the level of contamination of the water. For example, observation of chemical speciation of plutonium was carried out after filtration of Irish Sea and western Mediterranean Sea waters (Mitchell *et al.*, 1995). The redox state distribution of ^{239,240}Pu and ^{238}Pu in these waters shows little variation with 87% as Pu(V). Pu(IV) is mostly associated with particles.

In situ dialysis has also been applied to concentrate the colloid phase associated with actinides. Extraction of an actinide from the particulate phase or from a rock sample may be carried out by applying a successive leaching technique (e.g. Szabó *et al.*, 1997; Nagao *et al.*, 1999), with reagents successively more and more aggressive such as, for example, the following:

1. water at 25°C to desorb exchangeable actinides;
2. sodium acetate at pH 5 and 25°C to dissolve carbonate phases;
3. ammonium oxalate at pH 3 and 25°C to separate reducible phases, i.e. (Fe, Mn);
4. sodium hydroxide 0.3 M at 60°C to leach actinide associated with organics;
5. hydrogen peroxide at pH 1 and 60°C to dissolve sulfide phases;
6. nitric acid 8 M at 80°C to leach mineralized phases including actinide oxides.

Each step must be characterized by a reagent, a pH value, a temperature, a sample/reagent volume or mass ratio, and a given time. Each extraction step may be repeated several times before the next extraction step in order to follow the reversibility of the desorption or leaching process (Salbu, 2000). Sequential leaching has been applied to perform speciation of uranium associated with particulates in seawater (Hirose, 1994). The major species consists of an insoluble complex that dissolves by leach test at pH 1.

Co-precipitation is usually applied as an enrichment technique of an actinide from an aqueous solution with $Fe(OH)_3$ (Morello *et al.*, 1986), LaF_3 (Nelson and Lovett, 1978), or $Ba(SO_4)$ for Ac assay on Ra (Niese, 1994), as a carrier phase, followed by dissolution and separation.

Electroplated sources are very useful for alpha spectroscopy (αS). Electroplating is the preparation of very thin and uniform actinide films obtained by electrodeposition onto stainless steel disks. The literature on electrodeposition describes the procedure (see Chapter 30), which remains empirical, perhaps because electrodeposition is a multiparametric process that includes the electrolyte solution (concentration, pH), the hydrodynamic profile in the cell, the nature and geometry of the electrodes, the deposition current and potential, and the electrodeposition time. The electrodeposition of americium was reviewed with emphasis on the physicochemical behavior of the solution (Becerril-Vilchis *et al.*, 1994). The use of a tracer may be required to evaluate losses by adsorption of the studied actinides, or a quantitative method is

followed such as the use of a hydrogen sulfate–sodium sulfate buffer (Bajo and Eikenberg, 1999). The effect of a counter-ion was also studied in detail (Zarki *et al.*, 2001). Recently, however, specific microprecipitation followed by ultrafiltration has been used as an alternative for source preparation.

The separation and/or concentration of elements or species as soluble entities may be performed by applying partitioning between two phases such as:

- liquid–liquid, with specific complexes soluble in an organic phase: e.g. 2,4-pentanedione (Haa) in toluene (Engkvist and Albinsson, 1992), thenoyltrifluoroacetone (TTA) in xylene for Np extraction (Dupleissis *et al.*, 1974), tri-*n*-octylphosphine oxide (TOPO) in toluene for Pu, Am, and Cm extraction (Kosyakov *et al.*, 1994), and solvent liquid extraction can be used for the analytical determination of actinides in urine (Harduin *et al.*, 1993);
- liquid–solid, with specific polymers: anionic or cationic, organic (Qu *et al.*, 1998) or inorganic (Kobashi *et al.*, 1988). For example, actinides from contaminated soil samples can be separated by use of anion-exchanger columns for Am, Cm, and Pu spectroscopy (Michel *et al.*, 1999), and uranium from waters may be pre-concentrated using an ion exchanger and filtered off before desorption in small aliquot acidic solution and analyzed using inductively coupled plasma optical emission spectroscopy (ICPOES) (Van Britsom *et al.*, 1995).

Chromatography is discussed in combination with detections in Section 27.4.

The separation of colloidal species may be performed by applying specific techniques such as:

- field-free techniques: ultrafiltration, gel permeation, or size exclusion chromatography (Taylor and Farrow, 1987; Hafez and Hafez, 1992), or
- within a controlled field: flow-field fractionation (Bouby *et al.*, 2002), density gradient fractionation (Mohan *et al.*, 1991), or capillary or gel electrophoresis.

The latter technique has been performed for actinide separation by applying an electrical field during liquid–solid distribution. Speciation and solubility of neptunium has been studied in an underground environment by paper electrophoresis, ion exchange, and ultrafiltration (Nagasaki *et al.*, 1988). Gradient gel electrophoresis was used to characterize 13 kDa polysaccharide ligands complexing ^{234}Th from marine organic matter (Quigley *et al.*, 2002). Capillary electrophoresis is growing in importance as a versatile assay for speciation; however, there are still major challenges that limit the practical acceptance of the technique. The potential problems are inadequate attention to sample preparation (species stability, matrix effect), ignoring possible change in speciation during electrophoresis, inappropriate treatment on method validation and system suitability, and no sample enrichment methodology. Recommendations have recently been suggested (Timerbaev, 2001).

27.3 IDENTIFICATION AND SPECIATION

27.3.1 Passive techniques

Radiometric techniques dominate the analyses of short- and medium-lived actinide nuclides. The passive techniques currently used for actinide detection are summarized in Table 27.2. They include spectroscopy (S) or RAD of X-rays or gamma photons, along with Mössbauer emission spectroscopy (MBES), conversion electrons or β^-, neutrons, and ions such as alpha or spontaneous fission products that are emitted during decay of actinide nuclides. The investigated systems range from geographic to microscopic in size and the detection tool may also be adapted to these scales. The actinide isotopes considered in the environmental studies are not β^+ emitters; they may be neutron emitters that can consequently be detected by neutron spectroscopy (NS). Nothing is reported so far for the detection of the phonons generated by the actinide decays. Ion-selective electrodes (ISEs) may be used to detect actinide elements in a passive way, while gravimetry (GRAV) may be applied for concentrated phases.

The passive techniques and more especially the radiometric techniques remain widely used for the analysis of actinides because they utilize low-cost instrumentation, are simple to operate, achieve low-cost of analysis per sample, and have the possibility to perform non-destructive sample analysis.

In X-ray spectroscopy (XS) and γ-ray spectroscopy (γS), the most important developments include the production of high-efficiency coaxial and well-type detectors operating with anti-cosmic ray or anti-Compton shielding. Detection is currently carried out using a semiconductor crystal or by scintillation. Typical analytes include natural actinides such as ^{234}Th or anthropogenic actinides with detection limits of the order of 1 mBq. Based on this activity limit, the detection limits for actinide isotope amounts are calculated for relevant isotopes in Table 27.2. Sample preparation may require classical specific treatments before radioanalysis, such as separation or enrichment, as treated in Section 27.2.

Measurements of transuranics, in particular several isotopes of plutonium, are especially difficult to carry out due to the low-penetrating nature of their radiations (α- and X-rays). Direct alpha detection is difficult; therefore thin scintillators that rely on the detection of L-shell X-rays (13–21 keV) are used for survey work (Miller, 1994). These instruments may be used for environmental detection and for X-ray astronomical measurements in space. Theoretical detection limits for thin-layer samples are given in Table 27.2. Determination of actinides in solution may also be carried out by using a high-purity germanium crystal detector, allowing for plutonium a detection limit near 10^{-10} mol (Gatti *et al.*, 1994).

Classically, ^{227}Ac may be determined in environmental samples from the beta or gamma activity of its daughter products (Khokhrin and Denisov, 1995). Gamma-ray spectroscopy was used *in situ* and in the laboratory to determine

^{228}Ac activities in eight sites around the proposed Yucca Mountain repository in Nevada (Benke and Kearfott, 1997). The *in situ* determined specific activities were consistently within the ±15% of the laboratory soil sample results. Despite the good correlation between field and laboratory results, *in situ* counting with calibrated detector was recommended.

Gamma-ray spectroscopy has been systematically used to detect ^{232}Th or ^{238}U from environmental samples. The detection of these isotopes may be done using gamma photons from daughter nuclides. *In situ* determination of uranium in surface soil was performed by gamma spectroscopy measuring ^{234}Th and ^{234m}Pa using a high-resolution γ-ray spectrometer and assuming secular equilibrium (Miller *et al*., 1994). On the other hand, uranium and thorium were also detected in soil samples by measuring ^{208}Tl and ^{214}Bi (LaBreque, 1994), respectively, which were as well assumed to be in secular equilibrium with their respective parents. The determination of the specific activity of these major natural actinides may be carried out by airborne gamma spectroscopy using the above key nuclides, or other nuclides, e.g. U by Ra (Kerbelov and Rangelov, 1997). This method enables analysis during fixed-wing aircraft or helicopter flight (Guillot, 2001). The sensitivity of the spectral analysis of windows at 2615 and 1764 keV for ^{232}Th (by ^{208}Tl) and ^{238}U (by ^{214}Bi), respectively, was optimized by subtraction of the Compton continuum in the detection window. The detection of ^{232}Th and ^{238}U is possible in their natural background of 33 Bq kg^{-1} in a large-volume NaI detector (16 L) and a short sampling time (1–5 s) at 40 m ground clearance. The calculation of the concentrations is then simple and reliable. A quantitative estimate of radioactive anomalies can also be obtained easily. The spectral profile analysis is of great interest and has been applied within the framework of environmental monitoring studies. Fig. 27.2(a) shows a map obtained for ^{232}Th during a mapping exercise. Similarly, aerial measurements above uranium mining and milling area have also been reported (Winkelmann *et al.*, 2001).

A gamma-logging (γS) probe has been used to monitor thorium and uranium as a function of depth in a borehole (Nagra, 1991; Mwenifumbo and Kjarsgaard, 1999), as presented in Fig. 27.2(b). The technique is used for uranium exploration; it discriminates between valuable uranium ore and other radioactive material of little value. Here again, lateral resolution is linked to detector geometry and improvements, e.g. coaxial logging cables are suggested (Conaway *et al.*, 1980). Gamma logging has been used recently in a well contaminated with plutonium (Hartman and Dresel, 1998). In addition, the use of gamma spectroscopy for identifying and measuring plutonium isotopes in contaminated soil samples has been reported (Kadyrzhonov *et al.*, 2000).

The application of marine γ-ray measurements follows similar principles. The difference from the aerial technique is that water absorbs γ-rays rather strongly and that the detector must move at the surface of the seabed while being towed. The emitters are detectable if they are present in sufficient quantities and have energies above 100 keV. Consequently, if ^{238}U and ^{232}Th are

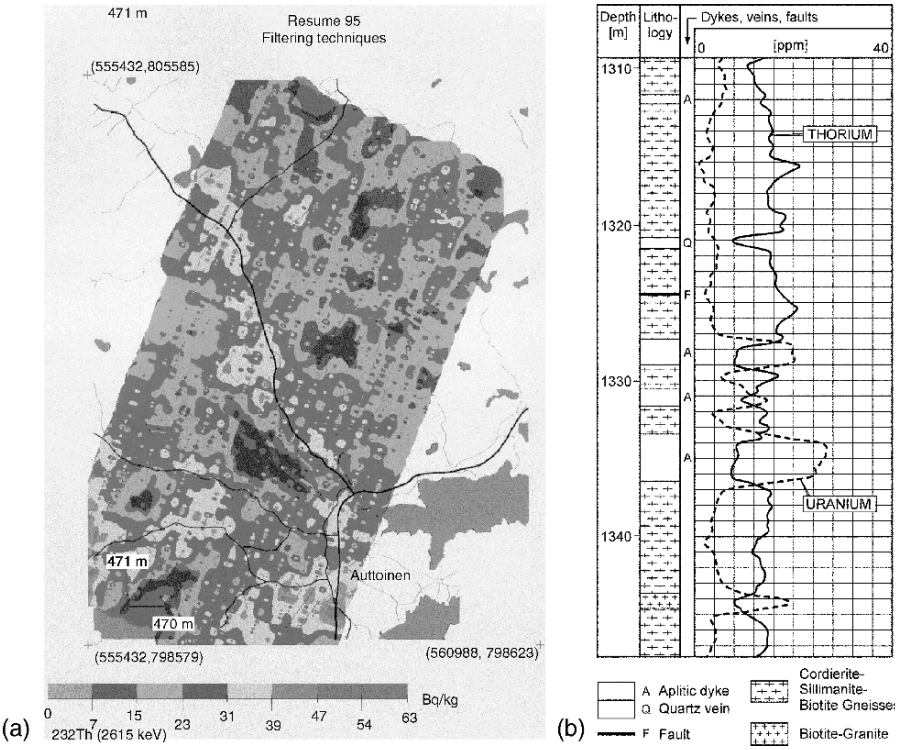

Fig. 27.2 (*a*) ^{232}*Th maps* (*from exercise in Finland, Area* 2) *processed by the filtering and window methods* (*Guillot,* 2001). detectable with daughter isotopes, low-energy γ emitters such as ^{241}Am and the plutonium isotopes are very difficult to measure by applying this *in situ* technique (Jones, 2001).

The radiometric technique alone is not effective for speciation. Only MBES, a resonant emission of gamma photons, can provide information. Among the actinide isotopes, ^{231}Pa, ^{232}Th, ^{238}U, ^{237}Np, and ^{243}Am are active as the Mössbauer nucleus. While ^{237}Np is an excellent Mössbauer nuclide, little speciation has been done for environmental samples, perhaps because Mössbauer spectroscopy requires macroconcentrations.

In the field of beta spectroscopy (βS), introduction of a very low background liquid scintillation counting (LSC) spectrometer enables the analysis of soft β emitters such as ^{241}Pu with detection limits of the order of 10 mBq (Yu-fu *et al.*, 1990). This makes it possible to estimate the detection limit for beta

spectroscopy in Table 27.2. However, since the beta spectrum is continuous, application of beta spectroscopy cannot be directly used for the identification of actinides in environmental samples without the use of specific separation techniques. The counting yield of beta scintillation counting is always smaller than 100%.

NS can be applied in a plain counting mode to detect spontaneously fissile actinides in the environment and in the framework of trafficking. Plutonium-239 is hard to detect by means of its α-, x-, or γ-rays, but neutrons are more penetrating and can be specifically detected. Recently, sensitive neutron detectors including ^{3}He proportional counter tubes moderator and integrated electronic have been developed to detect ^{239}Pu down to the gram (5×10^{-3} mol) level at 20 cm in 5 s (Klett, 1999).

GRAV belongs to the last class of passive techniques. Actinide GRAV, e.g. from ore samples, may be carried out after dissolution and separation with, for example, oxalate or oxinates at pH 5–9. Uranium in neutral conditions gives a red precipitate with oxine, $UO_2(C_9H_6NO)_2 \cdot (C_9H_7NO)$ (Hecht and Reich-Rohrwig, 1929), which should be washed with oxine solution (Claassen and Vissen, 1946). However, this technique suffers from a lack of specificity.

ISEs belong to the class of electron detection passive tools for species analysis, and while the hydrated electrons themselves are not detected, the electronic exchange remains the driving force. Poly(vinyl chloride) matrix membrane uranyl ion-sensitive electrodes based on organophosphorous sensors were successfully tested (Moody *et al.*, 1988). Recently, multi-sensors were developed for the determination of Fe(II), Fe(III), U(VI), and U(IV) in complex solutions (Legin *et al.*, 1999). Twenty-nine different sensors (selective electrodes) with various solid-state crystalline and vitreous materials with enhanced electronic conductivity and redox and ionic cross-sensitivity have been incorporated into the sensor array. The system was tested for Fe(II) and Fe(III) concentrations in the range 10^{-7} to 10^{-4} M, as well as for U(VI) and U(IV), the latter being determined with a precision of 10–40%, depending on the concentration. The developed multi-sensor system could be applied in the future for the analysis of mining and borehole waters, and other contaminated natural media; it can include on-site measurements.

For alpha spectroscopy, the high-resolution silicon detectors have proved to be sensitive down to 10 μBq levels for analysis of both natural Th and U isotopes and daughter nuclides, as well as for the anthropogenic actinides. The isotope ^{227}Ac was quantitatively determined in environmental samples after sample treatment and electrodeposition: a first alpha count at 4.85–4.95 MeV for the 1.38% alpha decay of ^{227}Ac and a second at 5.5–6.1 MeV after ^{227}Th buildup to equilibrium (Bojanowski *et al.*, 1987) were obtained. After sample treatment ^{232}Th and ^{238}U from environmental samples are better characterized by alpha spectroscopy than by gamma spectroscopy as, for example, in urine analysis (Eikenberg *et al.*, 1999) (Fig. 27.3(a)). Natural (U, Th) and anthropogenic (Pu, Am) actinides were, for example, determined and their

speciation determined in Venice canal sediment samples (Testa *et al.*, 1999). Here sequential extraction was applied before extraction chromatography, followed by electroplating and alpha spectroscopy. Pu and Am were found at the 1.0 and 0.3 Bq kg^{-1} level, respectively, with a ^{241}Am/$^{239+240}$Pu ratio of 0.3,

while Th and U were at the 20 and 30 Bq kg^{-1} levels. These isotopic analyses show that the sediments were not affected by the Chernobyl fallout but have been contaminated by nuclear weapon test fallout.

An activity may be measured after separation of the sample on a membrane after filtration or ultrafiltration. This may be applied for electrolytic fluids, solutions, or gas. Activity measurements on size-fractionated aerosols indicate different transport mechanisms for I and Ru, Cs (gaseous), or actinides (particulate) released during the Chernobyl accident. A hot particle found by autoradiography on an air filter sample was measured with a surface barrier detector (Gäggeler *et al.*, 1986). Its alpha activity was identified to be mainly due to ^{242}Cm (Fig. 27.3(b)).

Alpha LSC is attractive because it offers a nearly 4π geometry and because the counting yield for an actinide α emitter is about 100%, but with a lower energy resolution than for alpha spectroscopy. Improvements for alpha energy resolution and background reduction are key needs. An improvement of alpha energy resolution for determining low-level plutonium has been achieved using combined solvent extraction low-level liquid scintillation counter (Yu-fu *et al.*, 1990) and can also be applied for $^{239+40}$Pu and ^{241}Pu activity measurements in seawater (Irish Sea and North Sea) and soils (Cumbria and Belorussia) (Yu-fu *et al.*, 1990). Resolution of the order of 275 keV for liquid scintillation spectra can be achieved, which allows low-level determination of plutonium (see Fig. 27.4(a)).

Autoradiography (RAD) consists of using a photographic film or an organic-sensitive polymer to record tracks induced by the decay products from hot spots or contaminated phases in seawater, sediments, or marine organisms (Wong, 1971; Baxter *et al.*, 1995) (e.g. Fig. 27.4(b)) or, for example, natural rock samples sorbed with uranium and americium (Smyth *et al.*, 1980). After development, quantification of the tracks can be performed by counting the tracks or using a densitometer. Extensive work has also been performed with rock samples contacted with actinide solutions or simply contaminated (e.g. Fig. 27.4(c)). ^{241}Am and ^{233}U sorbed onto the rock cause tracks in the autoradiographic emulsions, which may be revealed and observed with an optical microscope. Direct detection with a grid detector and an image reconstruction of the source can also be carried out (Ward *et al.*, 1998).

In all passive techniques, geometrical parameters such as size of the system analyzed, size of the detector, and object–detector distance are key parameters, which, together with acquisition time, rule the detection limit for actinide identification.

Radon and helium contents in groundwater, rock, or soil may be analyzed as actinide by-products to identify uranium- or thorium-rich phase locations. Radon and uranium contents may be correlated (Virk, 1997). However, radon data need to be correlated with helium to yield more accurate results (Virk *et al.*, 1998). It must be noted that radon emanations and helium data are controlled not only by the uranium content of the rock and soil but also by structural zones (thrust, fault, etc.) that help in the easy migration of helium and radon from

deeper parts of the Earth's crust. Consequently, for uranium prospection, the use of helium and radon data must be verified by combining other techniques, as discussed in Section 27.4.

27.3.2 Interactive photon–photon techniques

The techniques derived from the interaction of photons with a sample and subsequent detection and spectral analysis of photons are numerous, taking advantage of the potential of the large energy spectrum available. They are listed by increasing energy of the incident photon beam as follows: nuclear magnetic resonance (NMR), electron paramagnetic resonance (EPR), infrared Fourier transform spectroscopy (IRFT), diffuse reflection spectroscopy (DRS), near-infrared and visible spectroscopy (NIR-VIS), or spectrophotometry, or colorimetry (COL), Raman spectroscopy (RAMS), atomic absorption spectroscopy (AAS), laser ablation inductively coupled plasma optical emission spectroscopy (LAICPOES), time-resolved laser-induced fluorescence spectroscopy (TRLIFS), phosphometry (PHOS), ultraviolet spectroscopy (UVS), X-ray absorption spectroscopy (XAS), X-ray fluorescence spectroscopy (XRF), X-ray tomography (TOM), Mössbauer absorption spectroscopy (MBAS), and photoactivation (PHOTA). Table 27.3 depicts the way in which these techniques may be used in spatial (transmission, reflection) and temporal (with or without delay) modes when applied to actinide identification or speciation.

In transmission mode, single- or double-beam techniques are applied, the second technique subtracting automatically the blank. In reflection or scattering mode the axis along the detection probe forms an angle with the incident beam. In the delayed mode, detection is carried out at a specific time after excitation of the sample.

NMR is a radiofrequency spectroscopy method that utilizes the interaction of a nuclear magnetic dipole or an electric quadrupole moment with an external or internal magnetic field. Information collected from these investigations characterizes chemical atomic environments. Actinide isotopic species such as ^{229}Th(IV), ^{233}U(VI), and ^{235}U(VI) are active in NMR (Fisher, 1973) at concentration above 10^{-2} M, and for ^{231}Pa(V) and ^{237}Np(VII) above 10^{-4} M. However, very little NMR is done in actinide environmental science except using the NMR signals of actinide neighbor nuclides (^{1}H, ^{17}O,...). EPR is a spectroscopy involving the interaction of electrons in magnetic field, allowing magnetic characterization and indirectly speciation. This technique has been mostly used to study the effect of actinide decay on the magnetic properties dictated by the paramagnetic center concentration of the sample, e.g. soil matrix (Rink and Odom, 1991; Li and Li, 1997; Kadyrzhanov *et al.*, 2000).

Infrared spectroscopy (IRS) has occasionally been used for the study of actinides under environmental conditions. It has been used in the transmission mode as well as in the diffuse reflectance mode, both with and without the

application of the Fourier transform. IRS may provide useful information on the speciation of an actinide when present in relatively large concentrations. For example the complexation and reduction of uranium by lignite was determined with site-specific material (Nakashima, 1992). An alternative way to determine actinide speciation may be obtained applying RAMS. The vibrational frequencies concerned are assigned to AnO_2^{i+}, which yields a peak near 870 nm for U(VI) to 860 nm for Np(VI), 767 nm for Np(V), and 835 for Pu(VI) and for actinide concentrations above 10^{-3} M (Basile *et al.*, 1978; Maya and Begun, 1981). The speciation of uranyl in water and sorbed on a smectite (see Fig. 27.5 (a) and (b)) was investigated by Raman vibrational spectroscopy (Morris *et al.*, 1994). The uranium loading was from 0.1 to about 50% of the cation-exchange capacity. The spectral peaks varied in shape and morphology, suggesting speciation changes during the loading. RAMS may be applied at the macroscale (cubic millimeter) as well as at the microscale (cubic micrometer).

NIR-VIS of the 5f elements is a powerful technique for the characterization of oxidation state (e.g. Gauthier *et al.*, 1983) for Np and complexes (e.g. Runde *et al.*, 1997) of actinides. Molar absorptivities (ε) of actinide ions are however smaller than 500 M^{-1} cm^{-1}, limiting the detection limit of the actinide solutions to ~10^{-5} M. Consequently, for actinide ion speciation in natural waters ((An) $<10^{-6}$ M), classical NIR-VIS is not sufficiently sensitive. Addition of a specific complexing dye is required, as described in the next paragraph.

COL, which is a specific application of absorption spectroscopy, has been applied to analyze actinide ions. This technique remains a powerful one despite the emergence of new techniques. This method requires in principle addition of an absorbent specific complex before spectrochemical analysis in the domain 300–1000 nm. Arsenazo-III has been used in the past for the determination of Th and U after extraction (Keil, 1979, 1981) with DL = 7 ng·mL^{-1} (3×10^{-11} mol·mL^{-1}) and 10 ng·mL^{-1} (4×10^{-11} mol·mL^{-1}), respectively. Pyrocatechol violet (3,3′,4′-trihydroxyfuchson–2″-sulfonic acid) has been used recently in a competitive complexation to derive speciation data of uranyl with respect to orthosilicic acid (Jensen and Choppin, 1998). Silicate complexes of uranyl are derived from these tests, allowing estimate of uranyl in silica-rich groundwaters such as those found in the tuff formations in Nevada. (Hydroxy-2-disulfo-3-6-naphtylazo-1)-2 benzene arsonic acid (Thoron) was used at 540 nm for Th quantification in various waters and rocks, e.g. sand (Bhilare and Shinde, 1994). Recently, the use of coumarine azo dyes was suggested for the determination of thorium by spectrophotometry (El-Ansary *et al.*, 1998). DRS has been used to detect uranium down to 35 ng (1.5×10^{-11} mol) on gel by specific complex with 2-(5-bromo-2-pyridylazo)-5-(diethylamino)phenol (5Br-PADAP) in a 10 mL volume of solution (Ivanov *et al.*, 1995).

Actinide colloids may be characterized by photon correlation spectroscopy (PCS). This technique makes use of the light scattered from a laser beam in a colloidal suspension and of dynamic analysis of the scattered light by

deconvolution. Little has been done with actinide colloids apart from analysis of their size as reported for thorium colloids (Walther, 2003) or for plutonium colloids (Triay *et al.*, 1991).

AAS is based on the metal-ion absorption of light in a flame or furnace atmosphere. AAS has occasionally been applied for uranium analysis but the detection limit is relatively high, e.g. 7 ppm in flame or 31 ppb in furnace (Goltz *et al.*, 1995).

LAICPOES applies the combination of sample vaporization by a laser ablation process followed by ICPOES (see Section 27.3.5). LAICPOES has been applied in the field in a mobile laboratory for the *in situ* determination of uranium in soil from sites suspected to contain uranium (Zamzow *et al.*, 1994). The optical emission spectroscopy (OES) detection uses the U line at 409.014 nm, with a detection limit for uranium around 5 ppm. Concentration of uranium determined for 15 sites ranged from <20 to 285 ppm. For these concentrations, uncertainty is very large (2σ: 85 ppm). It is, however, reduced

when performing the analysis in the laboratory (2σ: 10 ppm). For 10 ppm C (DL) and a 10 μm^3 crater the N(DL) is around 10^{-18} mol.

UVS may occasionally be used for actinide analysis, but has poor detection limits. It has however been used for speciation studies with Np(V) in carbonate solutions (Neck *et al.*, 1994) and with Am(III) in the micrometer range (Kim *et al.*, 1993).

Detection in a fluorescence mode improves the speciation method and allows trace analysis in liquid or solid samples. Classically, the excitation is carried out in the UV domain, around 340 nm, e.g. with a mercury lamp or with a laser, and the detection performed in the visible region, e.g. from 490 to 570 nm for U(VI), and near 600 nm for Cm(III). Although this technique may be applied to aqueous solutions, it was developed for pellet samples of fluorite salt solid solutions. Salt mixtures, e.g. NaF–LiF, as fluxes with the sample (an aliquot containing U) are melted, e.g. at 1000°C, and examined with a fluorimeter (fluorometer) after cooling at room temperature (Price *et al.*, 1953; Veselsky and Ratsimandresy, 1979). This technique, which is not limited by the interference effect of organics, is however limited by the quenching effect due to the presence of absorbing elements (e.g. Veselsky and Ratsimandresy, 1979; Veselsky and Degueldre, 1986). Structural characterization of Cm(III) on phosphate mineral surfaces was carried out using laser spectrofluorimetry (Cavellec *et al.*, 1998). This technique also allows characterizing the surface complexes of Cm on the mineral surface. Future improvements may include the use of microchip lasers and *in situ* measurements.

TRLIFS, like kinetic PHOS, applies detection temporal windows during fluorescence decay after decrease of organic impurities fluorescence. Pioneering studies demonstrated the powerfulness of this technique for actinide analysis in aqueous solutions (Beitz and Hessler, 1980; Beitz *et al.*, 1988). It is a very versatile tool to achieve speciation of actinides such as uranium and curium (see Fig. 27.6). It has been used successfully to characterize U(IV) hydroxide complexes in environmental conditions (Moulin *et al.*, 1995), occasionally doped with phosphates (Eliet *et al.*, 1995), and for uranium speciation in waters from different mining areas (Bernard *et al.*, 1998). Direct speciation of Cm(III) in natural aquatic system shows that the method is applicable at concentrations down to 7×10^{-9} M (Wimmer *et al.*, 1992) (see Fig. 27.6). The technique can also be applied to gain surface speciation information.

XAS today takes advantage of third-generation high-brilliance synchrotron radiation sources fitted with insertion devices such as wigglers and undulators. This technique has revived interest in the field of hard X-rays in macro- and microprobes. Recent developments are based on the use of Fresnel zone plates and containment techniques such as taped glass capillaries and plastic films, which allow microanalysis to be performed. Typical performance of synchrotron microprobes corresponds to a photon flux of 10^{10} $s^{-1} \cdot \mu m^{-2}$, with minimum

detection limits ~10^{-15} g (~4×10^{-18} mol). Analyses are performed by X-ray absorption near-edge spectroscopy (XANES) methods to map elemental distribution and to determine the oxidation states, and extended X-ray absorption fine structure spectroscopy (EXAFS) method to determine the coordination environment of the atoms in question.

Several authors (Nitsche, 1995; Hess *et al.*, 1997; Antonio *et al.*, 2001) suggested recently the use of X-rays provided by synchrotron beams in absorption spectroscopy (XAS) as a new tool for actinide speciation in solids (soils) and liquid (waters) as well as at their interface. This technique is quasi non-destructive, element-specific (L edges for actinides), and very attractive for actinide speciation and for the definition of their atomic environment (Conradson, 1998; Degueldre *et al.*, 2004) and redox state (see Fig. 27.7). It makes use of monoenergetic beams in the range up to (100 keV, focusing a very intense beam over a small area. The micro X-ray absorption beam may be used to focus on local details, for example to better understand the sorption of uranium in soil sediments (Bertsch *et al.*, 1994). In addition, comparison of fine structure for various valence state of uranium (IV) and (VI) was for example recently reported (Hunter and Bertsch, 1998).

XRF is based on the measurement of the fluorescent characteristic radiation emitted by an element when its inner shell electrons are excited. Technically the method is applied in two different spectroscopy modes called wavelength-dispersive spectrometry (WDS) and energy-dispersive X-ray spectroscopy (EDS) modes. The energy-dispersive system is a multielemental technique that can determine the elements in a wide range of concentration from 10^{-6} to 1 $g \cdot g^{-1}$ (ppm). It is non-destructive, with minimum spectral interference. The analysis is very fast and in many cases the sample preparation requires only grinding and pelletizing. The recent use of detectors with better energy resolution down to 10 eV (superconducting tunnel junction) makes this technique even more promising. XRF is also a technique that can be applied in the field with portable units. It may be applied for mineral exploration, mining, monitoring of polluted areas, and other environmental studies.

Aerosol deposits on a filter create homogeneous and thin layers, which result in negligible matrix effects during XRF analysis. The most recent advances are the application of synchrotron-induced XRF. In water, suspended matter can be separated on a filter and analyzed by XRF. Actinides in samples like soils, sediments, rocks, minerals, fly ash, and solid waste are often detected at the 10^{-6} $g \cdot g^{-1}$ level when applying an XRF method. This technique has been applied for analysis of particles from waters, sediments, and waste phases. (see Fig. 27.8) and may also be applied for determination in biological tissues, analysis of airborne particles, and foodstuffs (Akopov *et al.*, 1988; Misaelides *et al.*, 1995; Hunter and Bertsch, 1998). Uranium can be determined in water by precipitation with a non-specific chelating reagent and collection on a filter, which is analyzed by XRF (Civici, 1997). The detection limit is 0.15 μg U (6×10^{-10} mol) or 10^{-9} mol for a 500 mL sample. It can be improved with a microbeam.

X-ray TOM investigations have been carried out to identify and locate the spatial extension of phases. When used with dichromatic or dual-energy mode for the element discrimination, the irradiation is first performed below the element edge and then above the edge. This mode of TOM allows analyzing a specific

element by comparing the intensity of X-ray absorption below and above the edge. Since the actinide atomic number is high, the energy of the X-ray absorption K edge is rather high too. The sample is placed on a rotation table; the beam is several millimeters in size, with photon intensity of the order of 10^8 mm^{-2} s^{-1}. The detector is a charge-coupled device (ccd) camera that records the image obtained on an X-ray converter screen. Images collected are translated into a 3D tomogram of the element considered, visualizing the element densities. Fig. 27.9 presents

MBAS is a resonant absorption of gamma photons that may be applied to provide information on several actinide isotopes: ^{231}Pa, ^{232}Th, ^{238}U, ^{237}Np, and ^{243}Am. Recently, preparation details of source and sealed absorption holders for ^{237}Np and ^{238}U Mössbauer measurements were reported (Nakada *et al.*, 1998). However, little has been done for actinide speciation of environmental samples, perhaps because this technique requires macro quantities. However, the study of the interaction of Pu(IV) and Np(IV,V,VI) with iron hydroxides has been performed by Fe Mössbauer spectroscopy in order to predict the behavior of actinides in environmental media (Grigoriev *et al.*, 2001).

PHOTA, which involves γ-ray absorption by nuclides, has not yet been used for actinide characterization so far.

27.3.3 Interactive photon–phonon, –electron, –neutron, –ion techniques

Interactive techniques implying photon irradiation and detection of other signals such as phonons, electrons, neutrons, and ions are also used to identify or analyze the actinides. The techniques described below are laser-induced photoacoustic spectroscopy (LIPAS), laser-induced thermal lensing, laser-induced photothermal displacement spectroscopy (LIPDS), laser-induced breakdown detection (LIBD), ultraviolet photoelectron spectroscopy (UPS), X-ray photoelectron spectroscopy (XPS), secondary electron X-ray absorption spectroscopy (SEXAS), laser ablation micro mass analysis (LAMMA), laser ablation inductively coupled plasma mass spectroscopy (LAICPMS), resonance-induced mass spectroscopy (RIMS), and neutron photoactivation (NPHOT), the latter being only occasionally used. They are listed in Table 27.4 on the basis of the particle detected.

Photoacoustic spectroscopy (PAS) is based on the detection of the acoustic signal during photon absorption in the system. PAS has been applied for speciation studies of uranium and transuranium species in aqueous solution as well as in precipitates. LIPAS has been adapted for the UV–VIS and NIR photon energy, as well as for the infrared, domain. The technique applies the absorption of light that creates locally a thermal shock wave, which is detected through a piezoelectric crystal using a dual-beam system (Pollard *et al.*, 1988; Klenze *et al.*, 1991). LIPAS permits identification of U, and its speciation may be performed down to 10^{-6} M. It may be used to achieve speciation of uranium ions in mill tailing water (Geispel *et al.*, 1998). This technique may be used for the speciation of uranium in solution or in precipitates (Kimura *et al.*, 1992). LIPAS has also been used to characterize plutonium species as Pu(VI) in slightly acidic solutions (Okajima *et al.*, 1991) and in neutral solutions (Neu *et al.*, 1994), as well as to generate americium colloids (Buckau *et al.*, 1986). This was carried out for various actinide speciation tests in solution that simulate environmental conditions (see Fig. 27.10). Using an optical heterodyne interferometer, the

LIPAS unit can be modified in a photothermal displacement instrument (LIPDS), which can be used for the speciation of lanthanides and actinides (Kimura *et al.*, 1998).

When the laser intensity is increased, phase breakdown occurs. Instead of a simple thermal shock, the material is atomized (breaks down). Laser-induced breakdown spectroscopy (LIBS) is used to detect colloidal particles (Gutmacher *et al.*, 1987) and allows the detection of actinide colloids or actinide-associated particles. LIBS was applied to determine the solubility product of Th(IV) colloids (Bundschuh *et al.*, 2000; Bitea *et al.*, 2003).

UPS and XPS applies to spectroscopy of electrons excited by UV or X-ray photons from samples under vacuum. UPS was not applied to environmental samples but to thin-layer actinide research only (Gouder, 1998).

XPS techniques have occasionally been used to characterize actinides associated with environmental samples. They help to understand how uranium is sorbed onto phosphate (Drot *et al.*, 1998) or calcite (Geipel *et al.*, 1997) surfaces, as well as how actinides behave in contaminated soil (Dodge *et al.*, 1995) in the presence of microbes (Francis *et al.*, 1994). In all cases XPS allows redox and spatial speciation of the actinides by the use of energy shifts. For XPS, the detection limit may be estimated as 4×10^{-11} mol for a sample of 1 cm^2 with a 10 nm thickness and a density of 1 g cm^{-3} and 1% actinide mass. This detection limit can be upgraded for microbeam units.

SEXAS could be used to study particles on filters, but nothing has been reported on actinide investigations with this technique. In this case a layer of the order of 100 nm is analyzed and the DL for a 1 to a 10 μm size XAS would be 10^{-11} to 10^{-19} mol, respectively.

Other photon–particle interactive techniques include production of neutrons or ions. Photoneutron logging (PHOTN) was discussed for uranium detection in boreholes in the frame of rock and ore analysis in their occurrence site (Burmistenko, 1986).

Thermal ionization mass spectroscopy (TIMS) applies thermal ionization by evaporating a sample from a heated metal surface and simultaneous measurement of all isotopes of an actinide, using up to nine Faraday detectors. These conditions lead to high precision of isotope ratio measurements ($\leq$0.01%). Due to isobaric interferences, a chemical separation of the interfering elements must be performed before analysis. Therefore, isotopic dilution analysis mass spectroscopy coupled with TIMS represents one of the most accurate methods for the determination of the content of actinides and their isotopic composition. TIMS is currently applied to analyze actinide isotopic composition. The analysis of ^{230}Th distribution in the waters of a North Atlantic site (Vogler *et al.*, 1998), as well as the study of the origin of initial Th from Lake Lahontan, Nevada (Lin *et al.*, 1996), was performed by TIMS. The isotopic measurements of rock samples from the Oklo uranium ore deposit (Ohnuki *et al.*, 1996), as well as a wide variety of environmental samples (Buesseler, 1989), were analyzed by TIMS. Isotope dilution can provide for concentration determination down to the 10^{-15} to 10^{-18} g (4×10^{-18} to 4×10^{-21} mol) range.

LAMMA could be used to study particles on filters or directly on solid samples, but very little has been reported on actinide investigations with this technique. As an example, LAMMA has been applied to fingerprinting coal constituents in bituminous coal. Uranium phases were detected (Lyons *et al.*, 1987). Laser desorption ionization mode of matrix-assisted laser desorption ionization (MALDI) time-of-flight mass spectrometry (TFMS) analysis of U(VI) leads to the formation of uranium oxide clusters (Soto-Guerrero *et al.*, 2001). The formation of clusters can be eliminated using selected matrices, and a more sensitive uranium determination with a detection limit down to 10^{-12} M is possible.

LAICPMS has been used for determination of elemental concentration (in ppm range) and their isotopic composition in solid samples (conducting or not

conducting). It can be done without time-consuming sample preparations. The beam diameter can vary from ~10 to 300 μm. The method allows a depth profile analysis in the range from about 10 μm to several millimeters. The inductively coupled plasma mass spectroscopy (ICPMS) technique is described and illustrated in Section 27.3.5. LAICPMS has been applied for the *in situ* determination of thorium and uranium in silicate rocks and soils (Perkins *et al.*, 1993). Powdered geological materials have been prepared both as pressed powder disks and as fused glasses. Detection limits are better than routine XRF, but comparable with instrumental neutron activation analysis (NAA). For a 10 μm^3 crater and a 1 ppm C(DL) the N(DL) would be 10^{-19} mol. Uranium was analyzed successfully by LAICPMS in various geological samples such as in Neo-Proterozoic or older zircons or baddeleyite with U contents $\geq$65–270 ppm (Horn *et al.*, 2000), in a coral colony (*Porites lobata*) (Fallon *et al.*, 1999) and in the chalcopyrite wall of a black smoker chimney (Butler and Nesbitt, 1999). Dating of the normal faulting along the Indus Suture in the Pakistan Himalayas has also been performed by analyzing ^{231}Pa–^{235}U disequilibrium by LAICPMS (Anczkiewicz *et al.*, 2001).

In resonance ionization spectroscopy (RIS), atoms or molecules are excited stepwise from a defined state, normally the ground state, to highly excited states by resonant absorption of photons followed by an ionization process. An additional mass separation step completes the method of resonance ionization mass spectroscopy (RIMS). Spectroscopic study of thorium using continuous-wave RIMS with ultraviolet ionization provided sufficient signal for isotopic analysis of volcanic-like samples containing as little as 1–5 ng of thorium. The ability to determine accurately and precisely the ^{230}Th/^{232}Th isotopic ratios for 1 ng samples represented an improvement over TIMS (Johnson and Feary, 1993). Detection and speciation of trace amounts of neptunium and plutonium is possible by RIMS, with a three-step photoionization in combination with TFMS (Trautmann, 1992). The detection efficiency allows analysis of 10^7 atoms (2×10^{-17} mol) of an actinide, allowing identification at very low concentrations (see Fig. 27.11). RIMS has been applied to plutonium and transplutonium elements and should allow detection down to 10^6 atoms (3×10^{-18} mol) (Trautmann *et al.*, 1986; Erdmann *et al.*, 1998).

27.3.4 Interactive electron–photon, –electron, –ion techniques

Several techniques using electrons as incident beam or reagent are also applied to identify or characterize actinides. They are summarized in Table 27.5: electron–photon, such as EDS or wavelength-dispersed spectroscopy (electron microprobe analysis, EMPA); electron–electron, such as scanning electron microscopy (SEM) or transmission electron microscopy (TEM), Auger electron spectroscopy (AES), and electron energy loss spectroscopy (EELS); electron–ion, such as electrospray ionization mass spectroscopy (ESMS), and spark

source mass spectroscopy (SSMS). Electron–phonon methods such as scanning electron acoustic microscopy (SEAM) have not been reported for the identification of actinides. Electroanalytical techniques such as differential pulse voltammetry (DPV) or differential pulse polarography (DPP) may also be applied to characterize the actinides and are treated below.

In the field of structural analysis, microscopic techniques such as TEM, SEM, and high-resolution electron microscopy (HREM) are powerful imaging techniques with nano-scale resolution as well as microprobe capabilities using electron excitation and XS, electron loss spectroscopy, or time-of-flight atom probing. With EDS, high-resolution semiconductor detectors capable of spectral resolution of X-ray lines of neighboring elements made possible the construction of energy-disperse systems. SEAM studies of actinide-doped samples are not reported so far in the literature.

EMPA applies a WDS of the X-rays produced by interaction in the sample. Radiation from the sample is resolved by crystal diffraction, and the monochromatic photons are measured at different angles, assuming a very good resolution of the lines. EMPA is well established and used mainly for elemental analysis in industrial and environmental fields. This technique is used for actinide characterization in environmental samples with a lateral resolution better than 1 μm (Berry *et al.*, 1989, 1994).

Inhalation of respirable particles of uranium is a radiological concern. An investigation of some exposures to low enriched uranium indicated that intakes occurred from the inhalation of surface oxide (UO_x) particles, for example, above low enriched uranium metal plates. Measurements of the size distributions of these particles were made by SEM image analysis (Linauskas *et al.*, 1996). The size distribution analysis from 0.05 to 50 μm allowed a better understanding of the inhalation properties of these uranium oxide particles. As is known, inhaled particles with size <1 μm may be retained in the lungs. SEM allows excellent morphological analysis, which can be completed by backscattered electron analysis to complement the phase study, such as the actinide-doped phase (uranpyrochlore) vs the actinide-depleted phase (baddeleyite), as presented in Fig. 27.12.

X-ray analyses by EDS associated with SEM or TEM enable the investigation at the subcellular level. Since actinides have been introduced in marine environments, their bioavailability to marine organisms is of economic and ecological interest. Cellular and subcellular distributions of ^{238}U, ^{239}Pu, and ^{241}Am have been examined by means of microanalytical techniques, i.e. EDS in organisms: oysters, mussels, shrimps, crabs, and sea spiders (Chassard-Bouchaud and Galle, 1988). Actinide bioaccumulation was detected in target organs, cells, and organelles for every species. The process of the physiological strategies involved in the uptake, storage, and elimination of these actinides was elucidated. The concentration factors range from 10 to 2×10^3. If detection is performed in a cubic micrometer phase with 2% actinide doping, the detection limit DL calculated is reported in Table 27.5. This detection limit is reduced by

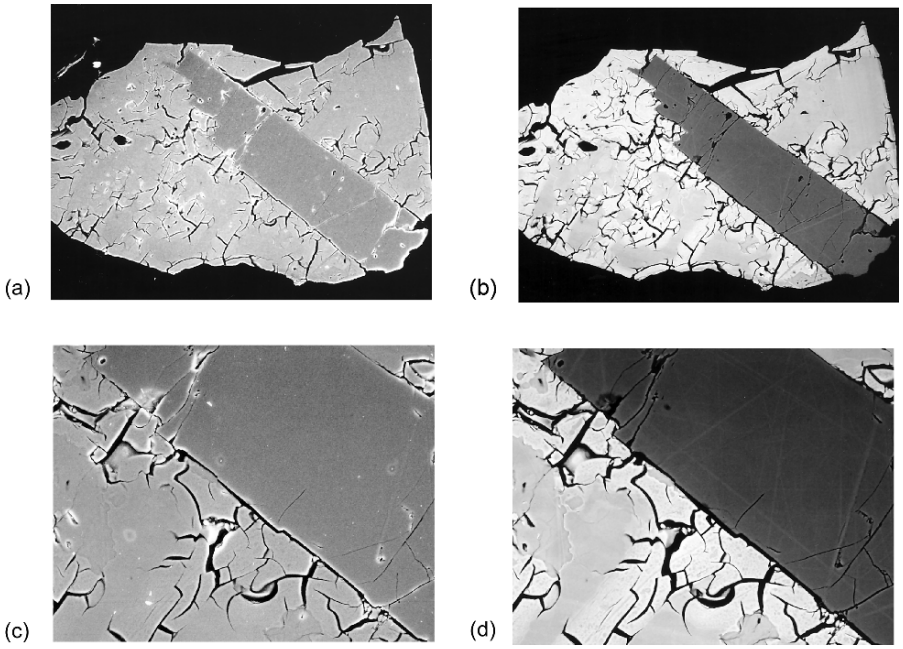

Fig. 27.12 *SEM comparison of secondary* (*a,c*) *and backscattered* (*b,d*) *electron images* (*Lumpkin,* 1999). *Conditions: pairs of intergrowth between uranpyrochlore and baddeleyite from Jacupiranga carbonatite complex, Brazil. a factor of 10^3 in a 10^6–10^7 nm^3 phase for an EDS adapted to a TEM unit. However, overlapping of peaks from L and K edges of elements may reduce the accuracy of the analysis.

AES is a technique yielding results similar to XPS. However, AES makes use of the electron as an excitation tool. AES has not been utilized for characterizing actinides in environmental samples. The only AES studies in this field concern the oxygen states in the oxides of uranium and their Auger spectra (Teterin *et al.*, 1997; Gouder, 1998).

EELS may be coupled to TEM or to scanning transmission electron microscopy (STEM) analysis. It is based on spectroscopy of the electron energy after passing through the microscopic specimen. EELS allows study of the oxidation state and the chemical coordination of lanthanides and actinides to be performed in host materials. The speciation may be derived from the M4/M5 edges position and structure. Low levels of transuranics may be characterized with a lateral resolution of the order of 1 nm and concentrations of <200 ppm (Buck and Fortner, 1997). This was applied to redox studies in glasses for plutonium

immobilization (Fortner *et al.*, 1997), in uranium pyrochlore and uraninite as natural analogs of Pu- and U-bearing waste forms (Xu and Wang, 1999), as well as to test the role of alveolar macrophages in the dissolution of different industrial uranium oxide phases (Henge Napoli *et al.*, 1996). The characterization of zirconia–thoria–urania ceramics by X-ray and electron interaction has recently been performed, bridging for actinides EELS and X-ray absorption fine structure spectroscopy (XAFS) potential (Curran *et al.*, 2003). The comparison of EELS spectra collected for these ceramics with spectra recorded for UO_2 and U_3O_8 reference materials also allows assessing U oxidation state at the nanometer-size level in these samples.

Because of its excellent lateral resolution ($2 \times 2 \times 10$ nm) and high sensitivity (1–0.1%), EELS has a demonstrated superior detection limit vs EDS for elements with absorption edges <1000 eV (see Table 27.5).

DPV and DPP are based on electron exchanges between polarizable electrodes and a solution containing redox-sensitive actinides such as U, Np, and Pu (Fig. 27.13). Uranium can be analyzed in U–Fe mixtures by DPV routinely at the 20 μg mL^{-1} (10^{-4} M) level in phosphate solution (Sreenivasan and Srinivasan, 1995) and down to 0.3 μg mL^{-1} (10^{-6} M) level without a preconcentration step in the processing and waste streams of a uranium plant (Sawant *et al.*, 1996). Submicrogram quantities of neptunium and plutonium may be determined by potentiometric voltammetry down to 2×10^{-8} M (Kuperman *et al.*, 1989). Investigations of the redox behavior and the speciation of plutonium in concentrated NaCl solutions with respect to an intermediate-level waste repository were carried out with a rotating disk electrode (Marx *et al.*, 1992). Concentrations of Pu(IV) may be determined quantitatively from the peak height while the shifts in potential are due to speciation changes (complexation) within the solution. In addition, simultaneous determination of U(VI), Pu(VI), and Pu(V) in 0.5–4.0 M NaOH was reported by DPV (Abuzwida *et al.*, 1991). U(VI) is detected at the dropping mercury electrode in the range 10^{-7} to 3×10^{-3} M. Pu(VI) and Pu(V) at the platinum electrode were analyzed at concentrations from 4×10^{-6} to 10^{-3} M even in the presence of various potential interfering ions such as Mo(VI), W(VI), V(V), and Cu(II) in salts such as $NaNO_3$, $NaNO_2$, and NaI.

On non-polarizable electrodes, quantitative electroanalytical methods can also be applied, taking advantage of the rich redox chemistry of the actinide elements. Numerous controlled potential coulometry (COUL) studies have been reported in the literature. For example, neptunium determination is possible at as low as the 2 mg level with a precision of 0.2% (Kasar *et al.*, 1991), even in the presence of interfering elements such as Pu, U, Ce, Cr, Fe, or Mn (1000-fold) (Karelin *et al.*, 1991).

ESMS is a recently developed analytical technique that seems promising for speciation studies. This technique applies a spray of electrons on a material surface followed by mass spectrometry of the cluster ions formed in 'soft conditions'. First developed for biological samples, it is now used for direct

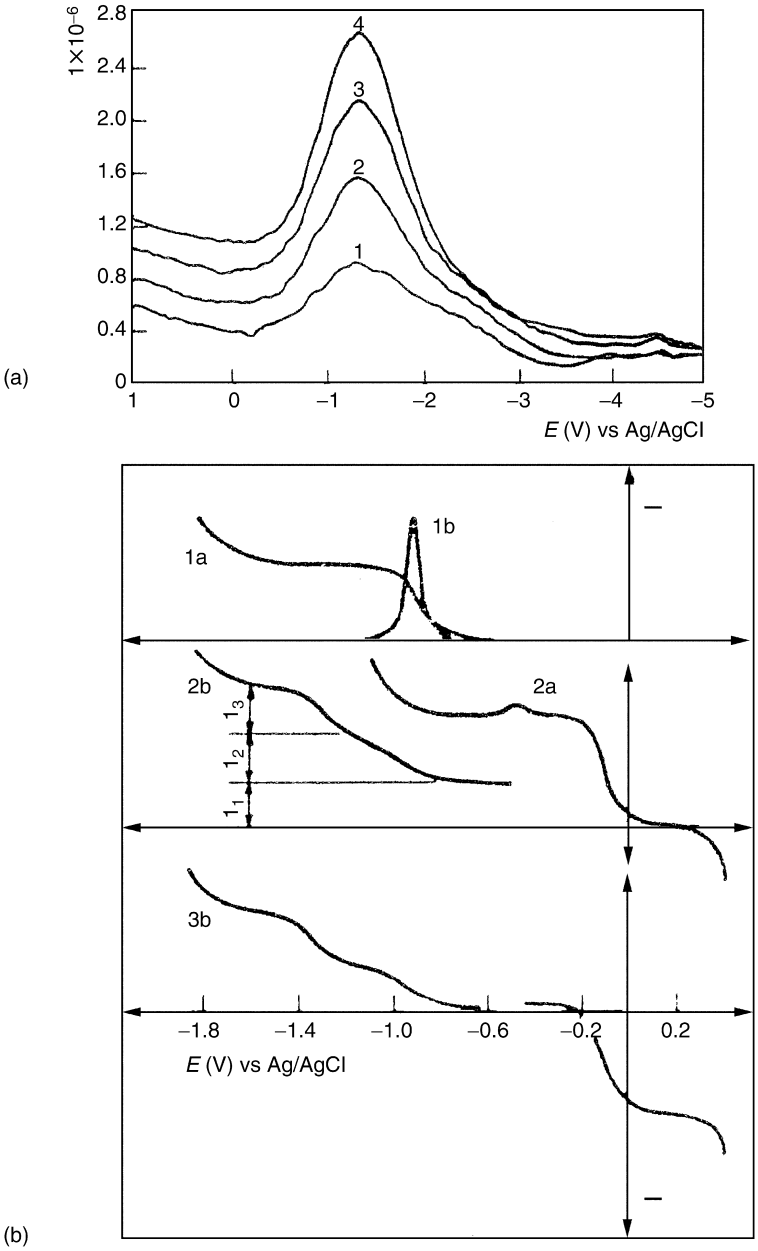

Fig. 27.13 (*a*) *Differential pulse polarogram* (*DPP*) *of U* 1.5 *to* 6×10^{-5} M *at dropping mercury electrode* (*Sawant* et al., 1996)*, possible down to* 10^{-6} M *level without a pre-concentration step in the processing and waste streams of a uranium plant, and* (*b*) *DPV of U and Pu* 10^{-4} M *on Pt electrode* (*Abuzwida* et al., 1991) *in* 1 M *NaOH.*

speciation studies in solution. It is now possible to directly couple a liquid at atmospheric pressure to mass detection at reduced pressure, even if the mechanisms taking place are rather complex. ESMS investigations were adapted for the speciation of Th(IV) hydrolysis species (Moulin *et al.*, 2001) and U(VI) in neutral solutions (Moulin *et al.*, 2000). Fig. 27.14 shows a typical spectrum obtained

for a uranyl solution at pH 3.5. Peaks can be interpreted for the species $((UO_2)_i(OH)_j\,(H_2O)_n)^{(2i-j)+}$.

Increasing the energy of the electronic stimuli permits the technique to be extended from molecular to atomic analysis. SSMS is similar to the former technique but the source of electrons is driven at higher potential. This allows direct quantitative analysis of elements and isotopes of the material. SSMS was used to determine trace elements in the U_3O_8 standard (Li *et al.*, 1991) as well as in other actinide oxides. In a complementary way SSMS may be used to analyze uranium from environmental samples.

27.3.5 Interactive neutron–photon, –electron, –neutron, –ion techniques

Neutron-interactive techniques make use of neutron scattering or absorption in the studied environmental samples. Absorption may be specific to actinide isotopes. The nuclide generated by neutron capture may be detected for its emission of gamma photon, neutron, or ion (fission products or alpha). Its detection is performed as described in Section 27.3 using spectrometric (S) or radiographic (RAD) techniques such as fission track (FT) techniques. Analytical data are given in Table 27.6.

Neutrons are ideal probes for the study of condensed matter, having important advantages over other radiation types. The outstanding feature of neutrons as probes is their high penetration (~10 cm) in materials, while the non-systematic variation of scattering length and absorption cross section from element to element makes its use versatile for actinide analysis. However, neutron RAD has not found applications for actinide speciation in environmental samples but may be used to characterize nuclear fuel pellets in segments of rods (e.g. Groeschel *et al.*, 2003).

NAA, being essentially an isotopic and not an elemental method of analysis, is capable of determining a number of actinide nuclides of radioecological interest by transformation of a nuclide into a radionuclide more quantifiable. The nuclear characteristics that favor this technique may be summarized in an advantage factor relative to radiometric analysis of the original radioanalyte. NAA can be performed by means of several kinds of sources such as nuclear reactors for cold, thermal, epithermal, and fast neutrons, portable isotopic sources such as Am–Be neutron sources, actinide (^{252}Cf) sources, and accelerator/generator or spallation sources with which originally fast neutrons can be thermalized. After activation, the nuclides that are produced are detected by gamma, beta, or alpha spectrometry. Its advantage is that NAA is a multielement, very highly sensitive, not handling intensive, efficient, instrumental, quasi non-destructive, and isotopic technique. On the other hand, it suffers from high costs, nuclear interferences, and residual radioactive wastes. NAA is a sensitive and accurate method for bulk analysis. NAA has been widely used for actinide analysis, in particular in the field of uranium prospecting. Nowadays it

is applied to determine concentrations in environmental, geological, and biological samples. NAA has also the advantage of being well suited for routine analysis.

Since neutrons activate almost all elements present in the sample, it is necessary to resolve the activity generated by actinides from activities of other elements. Separations are achieved through instrumentation or chemical methods.

The application of NAA to determine ^{230}Th, ^{232}Th, ^{235}U, ^{238}U, and ^{237}Np quantitatively provides an independent quantification that complements the conventional radiometric techniques (Byrne, 1993). NAA was used to determine, in the presence of other elements, Th distribution in geological material (Castillo *et al.*, 1996), ^{231}Pa in environmental and biological samples (Byrne and Benedik, 1999), ^{235}U and ^{238}U in geological samples (Sheng *et al.*, 1985), and ^{237}Np in sediments (Byrne, 1986) (Fig. 27.15) and in biological samples (May *et al.*, 1987), the latter with detection limits down to 5×10^{-13} g Np (2×10^{-15} mol) corresponding to 2.5×10^{-9} mg kg^{-1} for a 200 mL seawater sample.

NAA is currently used for solid samples. However, it has also been successfully applied to the analysis of waters. For example, the effect of humic material on the dissolution of natural trace elements, especially of actinide homologs, and on the sorption behavior of Np, Pu, Am, and Cm has been determined (Probst *et al.*, 1995). The groundwater constituents have been analyzed by applying NAA as well as other analytical techniques. Fractions of fluid samples were obtained by ultrafiltration and by ultracentrifugation. The study showed that trace actinides were associated with the colloidal phase (Kim *et al.*, 1987).

Delayed neutron activation analysis (DNAA) applies delayed neutron detection (see Section 27.3.1) after nuclide activation by neutrons. This technique is very sensitive to the detection of fissile isotopes. It has been compared to other techniques for ^{232}Th, ^{238}U, ^{239}Pu, and ^{240}Pu analysis (Alfassi, 1990; Jaiswal *et al.*, 1994). DNAA was performed for isotopic analysis of uranium in safeguard studies (Papadopulos and Tsagas, 1994), and was applied to uranium analysis in sediments (Noller andHart, 1993), in vegetal specimens (Apps *et al.*, 1988), and in human tissues (Gonzales *et al.*, 1988).

Track-etching is a form of RAD that may also be applied for localizing phases rich in fissile actinides (Fernandez-Valverde *et al.*, 1988). This technique has been applied for ^{235}U and ^{238}U quantification. Different kinds of polycarbonates were used as fission fragment detectors. Sample solutions, with U at the ppm level, dried on the detector are neutron irradiated for a given fluence and fission fragment tracks are microscopically counted (Berry *et al.*, 1989). FT detection is appropriate for the detection of ^{239}Pu in, for example, biological and environmental samples (Johansson and Holm, 1996). The lower detection limit is a few microbecquerel ($2\ \mu$Bq $= 4 \times 10^{-18}$ mol), which is comparable to the detection limit of mass spectroscopy and more sensitive than the alpha spectroscopic method. It must, however, include a removal of uranium from the sample.

27.3.6 Interactive ion–photon, –electron, –neutron, –ion techniques

The techniques derived from the ion reaction/interaction with sample particle detection make use of the large potential of the spectrum of particles produced or reemitted. They are listed as follows: ion–photon, ion–phonon, ion—electron, and ion–ion (Table 27.7). The ion–photon techniques are LAICPOES,

proton (particle)-induced X-ray emission spectroscopy (PIXE), and particle (proton)-induced gamma radiation emission (PIGE). Both ion–phonon and ion–electron techniques have not been applied so far. However, the ion–ion analytical mode is adapted by several powerful techniques such as ICPMS, secondary ion mass spectroscopy (SIMS), accelerator mass spectroscopy (AMS), Rutherford backscattering (RBS), elastic recoil detection analysis (ERDA), and nuclear reaction analysis (NRA). Finally, volumetry (VOL) is added as representative for the ion reaction with ions in solution.

The methods that utilize low-energy ions are dominated by inductively coupled plasma (ICP) techniques. In ICP an inductively coupled argon plasma is used to ionize an aerosol from the finely dispersed matrix and an optical emission spectrometer (ICPOES) detects the emitted light intensities. ICPOES allows, in principle, analysis of actinides at ~2 to 20 ppb levels (~10^{-8} to 10^{-7} M) (Van Britsom *et al.*, 1995; Huff and Bowers, (1990)). It has been used to analyze uranium (at 385.96 nm) at low levels (<100 ppm) in raw phosphoric acid from leachate of phosphate rocks (Waqar *et al.*, 1995). High-resolution (HR) ICPOES has also been used in the nuclear field to analyze fuel burn-up and to analyze samples for major uranium isotopes. The determination of the $^{235}U/^{238}U$ isotopic ratio demonstrates the versatility of the HR-ICPOES technique (Johnson *et al.*, 1998).

Other methods that employ high-energy ions use accelerator-based techniques to generate these ions. The ion accelerators provide a variety of ion beams with energies from a few keV to a few hundred MeV, and beam size ranges from the nanometer to the millimeter scale. Ion beams are applied to trace element determination using X-rays produced in the ionization process or nuclear reactions, including elastic or inelastic scattering or Coulomb excitation to measure actinides or isotopes in the sample. Detection limits are typically of the order of 10^{-6} g g^{-1} mass ratio (~4×10^{-9} mol g^{-1}), or much lower when detection is performed by mass spectroscopy. Ion microbeam analysis uses an ion beam focused to micrometer dimensions for elemental imaging at sample surfaces. This can be performed by measuring secondary radiation induced by the primary ion beam, such as X-rays and nuclear reaction products, or by measuring the energy loss of transmitted primary ions. This technique is very powerful in combination with electron microscopy for investigations of dust and soil particles, particularly those loaded with actinides.

PIXE is typically based on the use of MeV protons and allows the quantification of trace elements ranging from Na to actinides with sensitivities in the range from 10^{-6} – to 10^{-3} $g \cdot g^{-1}$, depending on element and matrices. The μPIXE detection limit is about 5×10^{-16} mol for a $5 \times 5 \times 5$ μm phase depending on the actinide detected. PIXE was, for example, used to determine qualitatively and quantitatively the distribution of uranium and plutonium sorbed onto a variety of rocks and their constituent minerals (Berry *et al.*, 1994). Both surface and subsurface concentrations of actinides were measurable. This identified which minerals are important for the sorption of uranium and plutonium for a given

rock. U and Pu were detected by PIXE in particle grains from contaminated soils (Kadyrzhanov *et al.*, 2000).

PIGE is normally used to detect light elements but cannot be applied to detect actinides.

NRA may be applied with neutron detection, e.g. (d,n). This method is used for elements for which PIXE analysis is unfavorable (e.g. $Z < 20$) but is not applicable to actinides, perhaps because of their larger Coulomb barrier.

VOL analyses such as complexometry and redox titration are two methods in which actinide ions react with other ions in solution to determine the actinide element concentration. For example, Th(IV) can be titrated by ethylenediaminetetracetic acid (EDTA) for the estimation of thorium concentration in low-grade ores (Strelow, 1961), or thorium-rich minerals. This complexation titration is carried out at pH 9–9.5, using Eriochrome Black T as an indicator (Negi and Malhotra, 1980). EDTA complexometry for Np(IV) was reported at pH from 1.3 to 2.0 with xylenol orange as indicator (Rykov *et al.*, 1975). Plutonium and uranium may also be titrated by the same complexation reagent.

Redox titrations are only possible for U, Np, and Pu. Volumetric determination of uranium is classically carried out by reduction using titanous sulfate as reducing reagent before oxidimetric titration (Wahlberg *et al.*, 1957). Ce(IV) (Moss, 1960) or AgO (Godbole and Patil, 1979) may be used to oxidize Np(V) to Np(VI), and Fe(II) to titrate Np(VI) to Np(V). Assay of uranium and plutonium in the same aliquot is possible by potentiometric titration (Nair and Kumar, 1986). The Macdonald method, rescaled down to milligrams of plutonium, was applied using an electrochemical process for each step; the end point of the final titration was determined potentiometrically (Kuvik *et al.*, 1992). Here again, as for GRAV, chemical separation may be required in order to avoid specific complexometric or redox interferences.

In ICPMS the analysis of assayed ions generated in an argon-ion plasma torch is carried out in a quadrupole or a magnetic mass spectrometer. The low detection limits for a large number of elements and the possibility to measure isotopic ratios have established ICPMS as a powerful analytical tool. The advantages are clearly a large dynamic range, 10^{-6} to 10^{-12} g·g^{-1} (4×10^{-14} M: see Table 27.7), occasionally down to 10^{-14} g·g^{-1} (4×10^{-16} M), and the use of various sample introduction techniques with the possibility to measure liquid or solid samples. Nevertheless, the numerous molecular and isobaric overlaps restrict the direct analysis of some elements. The latter problem may be overcome by using a higher-resolution unit (sector spectrometer) or separation (see Section 27.4). Precise and accurate analysis and isotope ratio measurement of long-lived actinides at trace and ultratrace concentration levels in environmental samples can be carried out by ICPMS. This technique allows the analysis of isotopic ratio variation in environmental materials and can provide evidence of contamination from radioactive wastes. The technique is widely used today and is routinely applied for age dating, as well as characterization of samples from the environment and from nuclear reactor materials. The determination of

precise isotopic ratio of uranium, thorium, and plutonium samples with relative standard deviation of the order of 0.05% can be achieved by utilizing a quadrupole mass spectrometer, a direct-injection high-efficiency nebulizer (Becker and Dietze, 1999a), and optimal isotope analysis (Becker and Dietze, 1999b). For actinides, ICPMS has been used to analyze Th and U in soil and plants (e.g. Yukawa *et al.*, 1999), neptunium (Kim *et al.*, 1989) in contaminated soil (Igarashi *et al.*, 1990), and transuranium elements (Agarande *et al.*, 2001) up to Cm (Barrero Moreno *et al.*, 1996). In addition to the large variety of injector, nebulizer, and torch design, electrothermal vaporization (ETV) allows direct introduction of solid samples (such as in a fine suspension) in the plasma. The advantage of the ETV is that there is no need for dilution. ETV–ICPMS was used to determine $^{240}Pu/^{239}Pu$ atomic ratios and ^{237}Np concentrations in marine sediments (Sampson *et al.*, 1991). Determination of a small volume of Am solution, e.g. 20 μl, can be performed using a micronebulizer and a minicyclonic spray chamber (Becker and Dietze, 1999a). Recently ICPMS has been used to analyze colloids in a single-particle mode. This method was applied for the analysis of thorium colloids (Degueldre and Favarger, 2004) and uranium colloids (Degueldre *et al.*, 2005).

SIMS is used for isotopic analysis with high sensitivity and micron-size space resolution. It makes use of a sputter-ion source and a mass spectrometer for analysis and detection of keV secondary particles (positive, negative, or neutral) produced. SIMS may be used in a static way for ion imaging of a surface or in a dynamic way by sputtering for depth profiling. The use in a SIMS system of an accelerator mass spectrometer improves the detection limit for many elements by several orders of magnitude. This technique is sometimes referred to as super-SIMS. Super-SIMS systems that allow bulk sensitivities of 10^{13} atoms per cm^3 (2×10^{-11} mol per cm^3) have been developed, which may be used for both bulk and depth profile measurements.

Micro-SIMS was used to characterize and map actinides ingested in marine organisms, allowing isotopic measurement and cellular images (Chassard-Bouchaud and Galle, 1988) (see Fig. 27.16). Concentrations of uranium and plutonium sorbed onto minerals can be routinely determined with sensitivities down to 1 ng cm^{-2}. Data obtained have been used to identify the minerals in a rock that are relevant to actinide sorption. The age determination of Pu particles was demonstrated by SIMS images (Wallenius *et al.*, 2001). This age is highly important in view of the pending cut-off treaty for nuclear weapon materials. By collecting particles from the vicinity of or inside the nuclear facilities and determining their ages, it is possible to monitor the observance of the agreement. SIMS was also used to measure qualitatively the distribution of sorbing actinides and their penetration rates into minerals after sorption tests (Berry *et al.*, 1993). SIMS has excellent spatial resolution (less than micrometer scale) and achieves some depth profiling to a few micrometers beneath a surface.

AMS incorporates an ion accelerator and its beam transport system as elements of an ultrasensitive mass and charge spectrometer. Isotopic ratios of

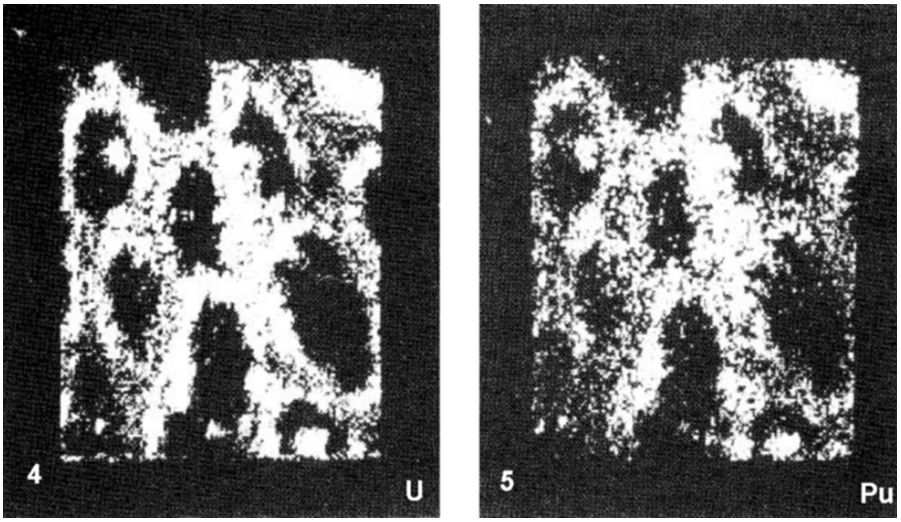

Fig. 27.16 *SIMS pictures of U and Pu from subcellular features of a mussel* Mytilus edulis *digestive gland* (*Chassard-Bouchaud and Galle,* 1988) (200 mm *full horizontal scale*).

less than 1 part in 10^{15} can be measured for some actinide isotopes. This is four or five orders of magnitude smaller than possible with conventional mass spectroscopy. Negative ions produced by a sputter-ion source (e.g. Cs or Ga) can be detected using an AMS system. AMS assay of ^{229}Th, ^{230}Th, ^{233}U, ^{236}U, ^{237}Np, ^{239}Pu, and ^{244}Pu are reported (Zhao *et al.*, 1994a,b; Purser *et al.*, 1996; Zhao *et al.*, 1997). The theoretical detection limit is determined by the overall efficiency of the system: the product of the AnO^- negative ion formation, which ranges from 0.15 for ThO^- to 1.0% for PuO^- (Fifield *et al.*, 1997), multiplied by the transmission efficiency through the accelerator to the detector. The overall efficiency is 1×10^{-6}, so that the sensitivity is 1 count for 1.7×10^4 atoms or 2.8×10^{-20} mol with an extremely small background (virtually zero). Among the lowest-level samples analyzed recently were the river waters downstream from the Mayak plant (Oughton *et al.*, 2000). A sample containing 6×10^7 atoms of ^{239}Pu yielded 63 counts in 15 min in a sample of 3 mg Fe_2O_3. The extreme case was described recently (Wallner *et al.*, 2000) for the detection of supernova-produced long-lived actinide nuclei.

RBS measures the composition profile of a material near the surface. Conventional RBS is performed using helium ions, while heavy-ion RBS has the advantage of a better mass resolution for heavy elements, being able to separate isotopes in some cases. Sensitivity increases for higher masses. Depth resolutions down to 1 nm can be obtained with Si surface barrier detectors in optimized setups, leading to quantitative studies of surface interface mixing and interdiffusion (see Fig. 27.17). The scavenging properties of inorganic particles towards heavy elements such as actinides may be studied by RBS

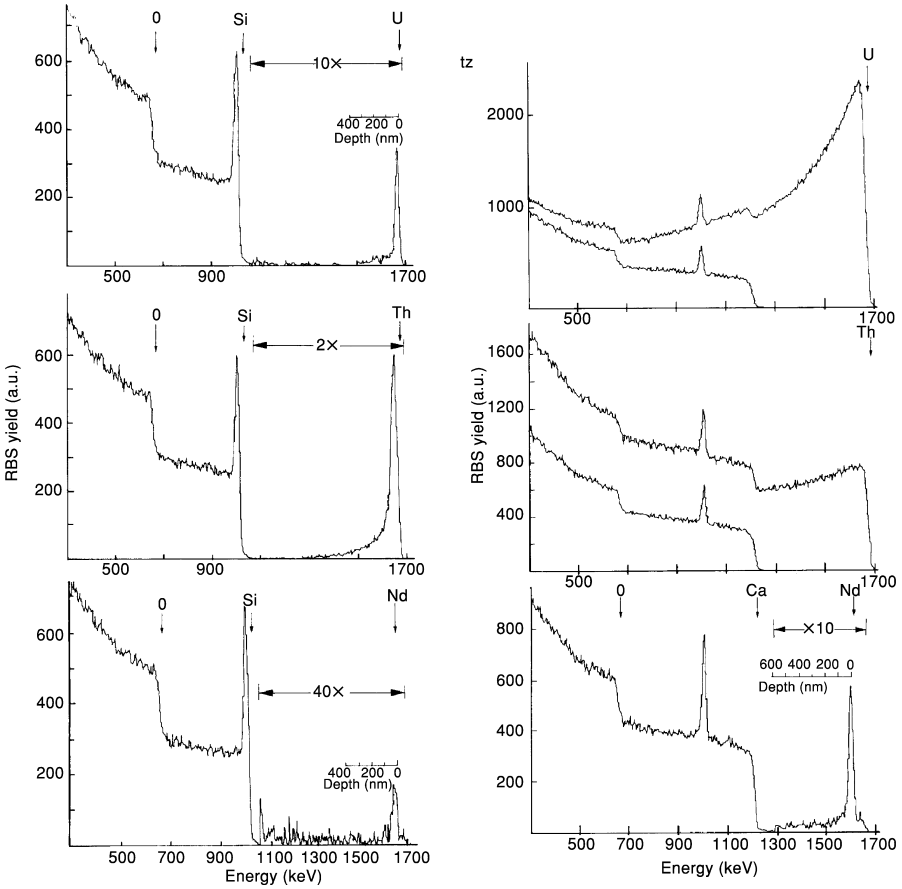

Fig. 27.17 *RBS spectra of U and Th sorbed* (*a*) *on quartz on the surface at* 100°C *and* (*b*) *on calcite at* 50°C *with diffusion in the bulk* (*below the spectra of calcite leached with DI-water*). *Conditions:* 2.2 MeV $^4He^{2+}$. *Note the thin actinide layer on quartz and the diffuse profile in calcite* (*Dran* et al., 1988).

(Della Mea *et al.*, 1992). The interactions of U(VI) and Th(IV) at the calcite–solution interface have been investigated by RBS; it was observed that uranium forms a solid solution while Th yields precipitates (Carroll *et al.*, 1992). Sorption of these actinides was also studied on silica and granite by this technique (Dran *et al.*, 1988). Further sorption work was carried out with uranium and plutonium on minerals with loadings of the order of 1 ng cm^{-2} (Berry *et al.*, 1993). This technique remains a very powerful tool for the identification of the actinides on light-element matrices (soil, bioorganic material).

ERDA makes use of glancing angle heavy-ion irradiation to extract light-element ions from a matrix. This technique is not used to identify actinides but to contribute to light element speciation studies in actinide compounds. ERDA was used to quantitatively measure hydration and hydrogen profiles in the near surface of UO_2 for spent nuclear fuel direct storage, and for a tailor-made titanium-based ceramic that was developed to incorporate radioactive waste for safe and long-term underground storage (Matzke *et al.*, 1990; Matzke and Turos, 1991). In these specimens, no hydrogen uptake was observed at temperatures below 100°C, but for higher leaching temperatures up to 200°C and for longer times, hydrogen profiles could be measured for both materials.

With NRA, specific (d,p), (d,α), (p,α), and other nuclear reactions are used to make sensitive determination of many specific isotopes. In general this method is used for elements for which PIXE analysis is unfavorable (e.g. $Z < 20$) but is not applied for actinides, perhaps because of their larger Coulomb barrier.

27.4 COMBINING AND COMPARING ANALYTICAL TECHNIQUES

The sequential and comparative use of analytical techniques is an important way to improve the quality of any analytical investigations. This has been widely applied to actinide characterization. Combination of techniques is a useful strategy to optimize and confirm information on species. Physical or chemical separation followed by applying one or several identification or speciation techniques is a key route for performing specific and accurate analysis.

SR has become a valuable tool for uranium ore body prospecting. SR is applied in a high-resolution mode, by the action of vibroseis (acoustic source emitters) at a low frequency (10–80 Hz) that are separated by, for example, 10 m, and an array of receivers (geophones) (Phelps and Davis, 1981). Seismic waves can respond specifically to uranium-bearing ore deposits (Liu *et al.*, 1985). SR data incorporate the mapping of geophysical features with radon/helium detection, transient electromagnetic (EM) sounding (Rozenberg and Hoektra, 1982), gravity anomalies, airborne gamma spectroscopy, and gamma logging, to identify high-grade uranium deposits (Dong, 1990; Poty and Roux, 1998). Often the confidential aspect of seismic studies does not allow their use to be made public. Uranium deposit exploration requires, consequently, extensive studies of empirical regional parameters including relationship to geophysical and geochemical records. X-ray diffraction (XRD) and IRS in a reflective mode provide useful lithogeochemical data. These need also to be combined with an EM survey that can be obtained by airborne scanning. Conductive zones that could be key indicators and uranium-rich features may be detected in these bodies. Radiometric survey, gravity mapping, and resistivity measurements complete the later studies. Geochemical and geophysical signatures are correlated in a semiempirical way to guide exploration before uranium ore body identification (Matthews *et al.*, 1997).

AFM has been used to characterize thorium oxyhydroxide colloids (Walther, 2003). This technique, being non-specific for an element, must be combined with others such as SEM/EDS and TEM/EDS to identify the actinide colloidal species. However, AFM is very powerful for determining the morphology and the size of these actinide colloids. The derived techniques such as acoustic AFM (aAFM) and electrochemical AFM (eAFM) allow characterization of specific properties. The latter was recently applied for nanoscopic observation of U(IV) oxide surface dissolution and remineralization (Römer *et al.*, 2003).

EHE may be used for speciation of redox-sensitive actinides such as U, Np, or Pu in waters. Groundwater redox conditions and oxidation state of dissolved uranium were studied in natural water samples from the Palmottu uranium deposit, Finland (Ahonen *et al.*, 1994). Good correlations were observed between the dissolved U(IV)/U(VI) ratio and the measured redox value. The latter, however, requires careful measurements, as recently reported (Degueldre *et al.*, 1999).

The technique of alpha and beta counting by a phoswich detector for simultaneous counting of α- and β-ray (including γ-ray) and determination of actinides is feasible by multi-interface (ZnS(Ag)/NE102A) detectors. Such systems have been developed for complementary actinide α- and β-emitter analysis (Usuda *et al.*, 1997, 1998) and are applicable for actinide identification under high background conditions.

The combination of chemical separation and radioanalysis is classical. Sequential separation combined with photon electron rejecting alpha liquid scintillation (PERALS™) is currently applied for measuring ^{228}Th, ^{230}Th, ^{232}Th, ^{234}U, and ^{238}U in soil samples without tracers (Füeg *et al.*, 1997) (see Fig. 27.18). The minimal detectable concentration ranges between 0.2 and 0.8 Bq kg^{-1} for a 1 g aliquot and 80 000 s counting time. Determination of ^{239}Pu + ^{240}Pu, and ^{241}Pu in environmental samples has been achieved (Yu-fu *et al.*, 1990). After pretreatment of the sample, the plutonium nuclides are co-precipitated with iron(III) hydroxide and calcium oxalate and isolated further from impurities by means of anion-exchange chromatography. Plutonium isotopes are extracted before spectrometric measurement with an ultra low-level liquid scintillation spectrometer. Counting efficiency of plutonium for 100 L of seawater or 40 g of soil sample was about 50%. The detection limit was 0.2 mBq (4×10^{-16} mol) for ^{239,240}Pu.

Extraction may also be used as a separation and a pre-concentration step before polarographic investigations of uranium. This protocol was applied for the determination of U(VI) (Degueldre and Taibi, 1996): the actinide was quantitatively extracted in a hydrocarbon–diethyl-2-hexyl phosphoric acid–TOPO or in hydrocarbon –tri-*n*-octylamine, the organic phase was diluted into the same volume of alcohol and spiked with H_2SO_4 (0.1 M) before electroanalytical investigation by direct current polarography and by DPP. The pulse polarographic peak allowed determination of U(VI) down to 10^{-6} M in the organic phase, which would be impossible without pre-concentration by

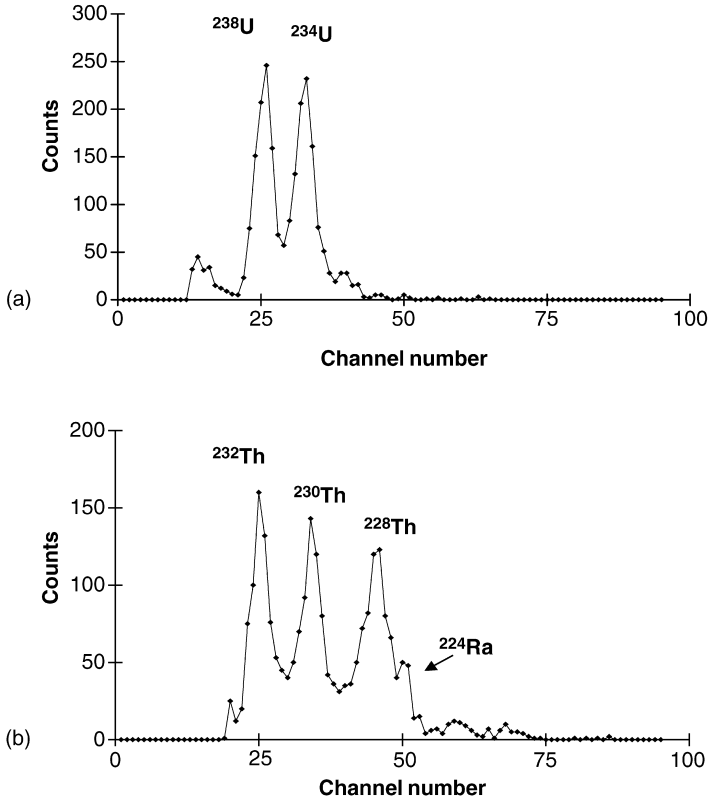

Fig. 27.18 *Typical PERALS™ spectra for the determination of uranium and thorium by extraction and counting.* (*a*) *U in reference soil IAEA*-375, (*b*) *Th in reference soil IAEA*-375*; data from* (*Füeg* et al., 1997).

extraction. This protocol of extraction and analysis is currently applied, for example, with ICPOES for the determination of uranium and thorium in apatite minerals after solvent extraction into diisobutyl ketone using 1-phenyl-3-methyl-4-trifluoroacetyl-5-pyrazolone (Fujino *et al.*, 2000).

Chromatography is basically a separation technique that needs to be completed by applying analytical sensors after the separation step. Chromatography may be performed with an ion-exchange column or by extraction with partitioning onto a liquid phase; spectroscopy and conductivity sensors are generally used for detection. Extraction chromatography was applied for the determination of plutonium and americium in soil samples from Semipalatinsk (Kazachevskij *et al.*, 1999). Ion chromatography was used to perform speciation of plutonium in natural groundwater using anion-exchange resin (Cooper *et al.*, 1995). In most cases actinides are detected using alpha spectroscopy (e.g. Morello *et al.*, 1986). Occasionally, UVS–VIS has been applied to identify actinides eluted.

The determination of actinides (U, Np, Pu, Am, and Cm) is very sensitive and accurate by combining high-performance ion chromatography and ICP quadrupole mass spectrometric detection (Garcia Alonso *et al.*, 1995; Röllin *et al.*, 1996) (see Fig. 27.19). This separation technique followed by mass spectroscopic detection allows the elimination of isobaric interferences such as from one

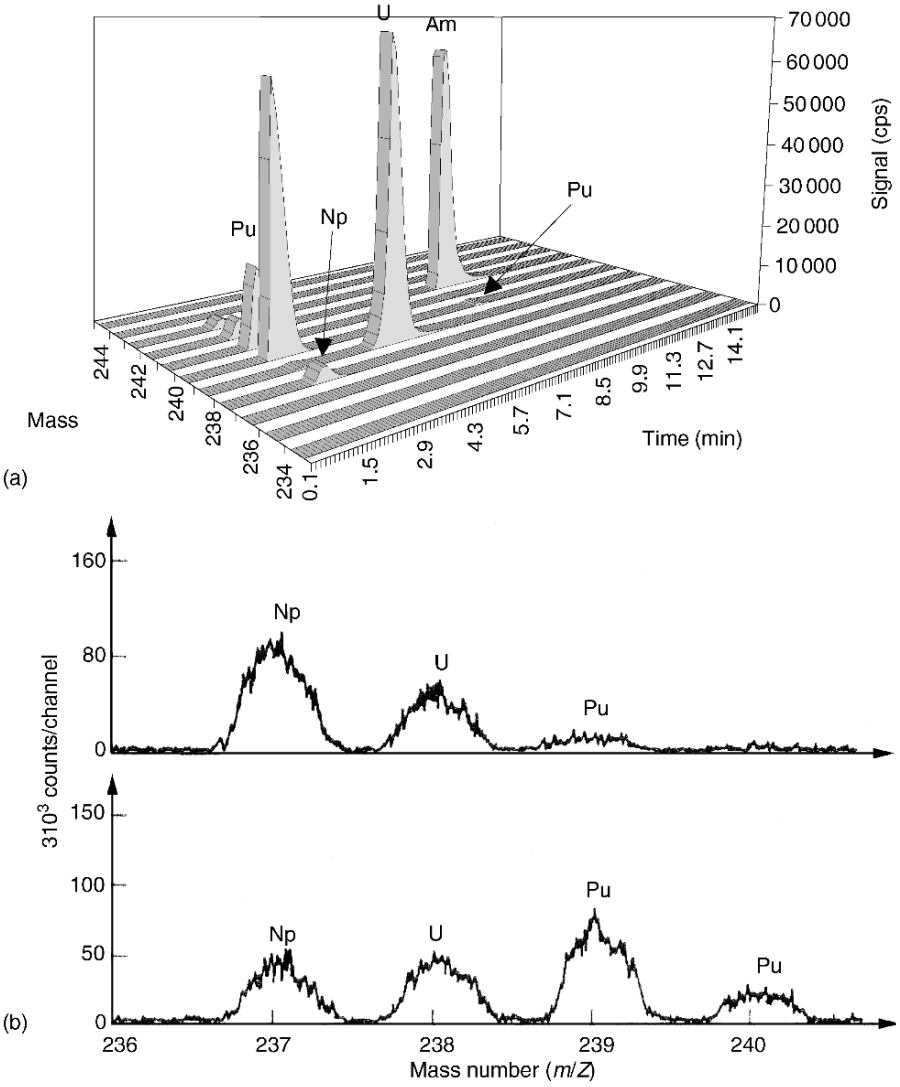

Fig. 27.19 (*a*) *Separation of U, Np, Pu, and Am in* 200 µl *of* 1% HNO_3 *solution containing* 100 ng mL^{-1} *U, Pu, and Am by HPLC-ICPMS* (*Röllin* et al., 1996). actinide element, e.g. ^{243}Am and ^{243}Cm, or from cluster ions, e.g. $^{155}Gd^{40}Ar_2^+$ or $^{207}Pb^{16}O^{12}C^+$ for $^{235}U^+$, $^{238}U^1H^+$ for $^{239}Pu^+$ (Moreland *et al.*, 1970), $^{232}Th^{12}C^+$ for $^{244}Cm^+$ (e.g. from ETV), or $^{232}Th^{16}O^+$ for $^{248}Cm^+$ (Becker *et al.*, 1999c).

Physical separation techniques such as filtration or ultracentrifugation may be used to enhance actinide speciation. Ultrafiltration or dialysis may be used with alpha spectroscopy for actinides associated with particles or colloids (Degueldre *et al.*, 1994). Combination of ultrafiltration and ICPMS offers also a very sensitive means for colloid analysis, as was the case for groundwater sampling around the fossil reactor of Bagombé (Pedersen, 1996).

Recently, capillary electrophoresis was coupled to ICPMS in order to combine the good performance of this separation technique with the high sensitivity of the ICPMS for the analysis of plutonium and neptunium states (Kuczewski *et al.*, 2003). It was possible to separate a model element mixture containing NpO_2^+, UO_2^{2+}, La^{3+}, and Th^{4+} in 1 M acetic acid. All separations were obtained in less than 15 min and a detection limit of 2×10^{-7} M was achieved. To verify the good speciation performances for plutonium and neptunium during the separation, capillary electrophoresis ICPMS was compared with the result of UV-VIS.

Combining XRF with micro-Raman and IR spectroscopies is a powerful experimental approach in providing information on components present in highly heterogeneous materials, which contain or have been in contact with actinides (Schoonover and Havrilla, 1999). XRF mapping allows identification of plutonium-contaminated regions, while vibrational microspectroscopy provides information on molecular species present and their spatial distribution. This approach provides insight into very complex samples and provides a technique capable of exploring the interaction of molecular components with actinides in complex environmental media. For example, XANES and XPS are combined to confirm uranium reduction from VI to IV by *Clostridium* sp. (Francis *et al.*, 1994). Speciation of uranium complexes in solutions at low ionic strength containing phosphate such as those of seepage waters from old uranium mill tailings was performed by combining data provided by potentiometric and spectroscopic investigations (Brendler *et al.*, 1996).

The feasibility of using the combination of PIXE and RBS to measure uranium and thorium in environmental and biological samples has been demonstrated for environmental studies (Paschoa *et al.*, 1987). The microdistribution of uranium-bearing particles in biological tissues was performed in order to evaluate local irradiation doses in the lungs of former and present uranium miners and millers. These particles have been localized in lungs using neutron-induced uranium FTs registered in solid-state nuclear track detectors in association with a microPIXE and RBS combination. Similarly, RBS and microPIXE have been recently used combined for the study of uranium diffusion in granitic rock matrices analyzing the effect of the presence of bentonite clay (Alonso *et al.*, 2003).

The analysis of the structure of layers on UO_2 leached in H_2O was performed by combining nuclear techniques including RBS-channeling, resonance

scattering, and ERDA using energetic He ions (Matzke, 1996). They were used for the analysis of a UO_2 single crystal leached in demineralized water with different pH values at temperatures up to 200°C. For growth of a U_3O_7 layer, the rate law for layer growth followed a $t^{1/2}$ trend for temperatures between 150 and 200°C and pH in the range 6–10.

Experiments investigating the migration behavior of Th, U, Np, Pu, and Am and the influence of smectite colloids by *in situ* tracer experiment in fractured rock have been performed in dipole mode (Möri *et al.,* 2003). The colloid determination was carried out by LIBD, PCS, and single-particle counting (SPC), while the actinides were determined by the radiochemical techniques after physical separation. Colloid recovery was comparable for these detection techniques.

A comparison of techniques for the analysis of uranium from uraniferrous coal-bearing clays has been reported (Ochsenkuehn Petropulu and Parissakis, 1993). It was carried out using separation techniques, including leaching in carbonate solution, enrichment through an ion exchanger, and elution of Mo and V with EDTA. Uranium is quantitatively eluted by HNO_3 and precipitated by NH_4OH. DPP, atomic absorption analysis (AAS), XRF, instrumental NAA, and ICPMS have been used to determine the uranium content in the raw materials and to investigate the various steps of the process.

Comparison of sensitive techniques such as ICPMS and radiometric alpha and beta spectroscopy has been systematically explored by authors (e.g. Solatie *et al.*, 2000). ICPMS remains very sensitive for the long-lived actinides while radiometric techniques are more suited for short-lived actinides. The half-lives of actinides that are appropriate for analysis by ICPMS may be estimated from Table 27.2 (DL = 10 μBq) and Table 27.7. The detection limits for ICPMS range from 4×10^{-17} to 4×10^{-19} mol in 1 mL depending on the methodology, which correspond to half-lives of 10^4 to 10^2, respectively.

Table 27.8 presents a summary of detection limits estimated for a large number of the sensitive techniques discussed in this chapter. The passive radioanalytical techniques are very sensitive to short-lived nuclides. Alpha spectroscopy has better performance than gamma spectroscopy because of the more efficient detection yield and better background conditions. NAA may improve the sensitivity but its use becomes increasingly limited. Visible spectrophotometry (VIS) is less sensitive than COL but fluorescence (TRLIFS) techniques, allowing speciation, are much more powerful. DPP and XAS provide data for actinide speciation in solution, the latter method in the solid phase also at the 10^{-9} mol level (upgraded to ~4×10^{-18} mol for microXAS, see Section 27.3.2). ICPMS, SIMS, RIMS, and AMS are all very sensitive. The latter reaches DLs better than 10^{-20} mol. Finally, EELS associated with STEM is the most sensitive identification and speciation technique. The detection limit is estimated to be of the order of 10^{-22} mol but it applies to specific small specimens in vacuum, which require extensive preparation and time-consuming analysis and interpretation. EELS has however proved its superior detection.

27.5 CONCLUDING REMARKS

For the past 50 years, actinide identification and speciation in environmental samples has been a topic of growing interest. Techniques required to perform the characterization of actinides that will have better performance in terms of capacity, realization, precision, and detection limit are needed. This will remain a challenge for this century. Detection limits are compared in Tables 27.2–27.7 and summarized in Table 27.8.

Since most of the actinides are α emitters, development of separation techniques coupled with highly sensitive alpha spectroscopy or LSC allows their detection below the 10 mBq level. LSC allows a fast analysis while alpha spectroscopy requires more experimental efforts but permits higher resolution and more sensitive analysis (10 μBq). An alternative to conventional alpha spectrometry may be NAA for which limitations of low counting rates on the non-activated actinide-bearing samples should be improved by their activation; the background is, however, also enhanced. NAA has been found to be particularly prone to interference especially from uranium nuclides.

The trend today is to use advanced ICPMS techniques instead of separation, electroplating, and alpha spectroscopy because ICPMS uses less material and is a less time-consuming technique. ICPMS may, however, require the use of a separation technique, as discussed in Section 27.4, which may advantageously be performed on-line because ICPMS is fast enough, compared to NAA or alpha spectroscopy, to analyze the eluant on-line. Evaluation of NAA and ICPMS methods for the assay of neptunium and other long-lived actinides in environmental matrices has been discussed (Hursthouse *et al.*, 1992). ICPMS offers suitable sensitivity, precision, and accuracy compared to other techniques, with considerably faster sample throughput relative to radiometric and activation approaches. Added advantages of ICPMS include the abilities to determine concentrations of several long-lived actinides simultaneously and to quantify $^{239}Pu/^{240}Pu$ ratios.

ICPMS, NAA, and alpha spectrometry were compared (Kim *et al.*, 1989) for the determination of ^{237}Np in environmental samples. The accuracy and precision of ICPMS was assessed by comparison with that obtained by NAA and alpha spectrometry. Results are in good agreement at a relative deviation of 2–9%. The routine analysis detection limit is 0.02 mBq mL^{-1} or 4×10^{-15} mol (comparable with the estimated data in Table 27.8) calculated with the specific activity of 26 Bq per ng of ^{237}Np.

Plutonium is somewhat difficult to analyze quantitatively by γ-ray spectroscopy because all the commonly encountered isotopes ^{236}Pu, ^{238}Pu, ^{239}Pu, ^{240}Pu, ^{242}Pu, and ^{244}Pu have very low γ-ray abundance emissions, making conventional 4π α-γ coincidence counting techniques impractical. ^{241}Pu is a low-energy β emitter with low (20 keV) end point energy and no associated γ-ray. ^{241}Pu is best analyzed using LSC by calibration with ^{3}H with some corrections for differing end-point energies and beta spectrum shapes.

Several of the advanced analytical techniques described in this chapter are very powerful methods for the determination and characterization of actinides in environmental systems. Better standards and reference materials, as well as intercomparison exercises, are required. For some techniques, standards are occasionally unavailable, for example for SIMS, EMPA, LAICPMS, XRF, and some surface analyses. Other techniques such as RBS, AMS, and EELS under vacuum and XAS in solution require internal calibrations; the sensitivity of the latter is expected to improve in the future. However, the techniques presented are often complementary; in many cases they provide unique information that cannot be obtained with alternative methods. Consequently, their continued and expanded utilization is required for actinide identification and speciation in the environment. Development of analytical techniques such as MBE/AS or EPR, which is more sensitive than NMR for actinide identification and speciation, may be suggested in future research programs.

As far as the environment is concerned, one has to think the way the analyst and the environmental scientist would collaborate together to produce data that can be used by modelers or authorities. The challenge is however to understand the behavior of actinide elements in the environment. Biogeochemical pathways have to be described, quantified, and understood. The contaminated systems interact with the local environment that may modify actinide speciation by physical–chemical processes, which need to be studied. Simple processes such as actinide association with biofilm, bioaccumulation, specific co-precipitation, or sorption onto soil or rock require detailed and full quantification and speciation for the understanding of process mechanism. Transport of actinides in fluids such as air or water includes particulate or colloidal phases. These analyses must be integrated in the analytical strategy as specific species for modeling their biogeochemical affinity.

The challenge will be to find and develop direct analytical probes for actinide speciation at very low concentration to provide data that will better characterize the actinide species to predict their behavior in heterogeneous and complex natural systems.

GLOSSARY

aAFM	Acoustic AFM
AAS	Atomic absorption spectroscopy
AES	Auger electron spectroscopy
AFM	Atomic force microscope
AMS	Accelerator mass spectroscopy
COL	Colorimetry
COUL	Coulometry
DNAA	Delay neutron activation analysis
DPP	Differential pulse polarography

DPV	Differential pulse voltammetry
DRS	Diffuse reflection spectroscopy
eAFM	Electrochemical AFM
EDS	Energy-dispersive X-ray spectroscopy
EELS	Electron energy loss spectroscopy
EMPA	Electron microprobe analysis
EPR	Electron paramagnetic resonance
ERDA	Elastic recoil detection analysis
ESMS	Electrospray ionization mass spectroscopy
ETV	Electrothermal vaporization
EXAFS	Extended X-ray absorption fine structure spectroscopy

MBAS	Mössbauer absorption spectroscopy
MBES	Mössbauer emission spectroscopy
MS	Mass spectroscopy
NAA	Neutron activation analysis
NIRS	Near-infrared spectroscopy
NMR	Nuclear magnetic resonance
NPHOT	Neutron photolysis
NRA	Nuclear reaction analysis
NS	Neutron spectroscopy
PAS	Photoacoustic spectroscopy
PCS	Photon correlation spectroscopy
PERALS	Photon electron-rejecting alpha liquid scintillation
PHOS	Phosphometry
PHOTA	Photoactivation
NPHOT	Neutron photoactivation
PIGE	Particle (proton)-induced gamma emission

PIXE	Proton (particle)-induced X-ray emission
RAD	Radiography, autoradiography
RAMS	Raman spectroscopy
RBS	Rutherford backscattering
RIS	Resonance ionization spectroscopy
RIMS	Resonance ionization mass spectroscopy
RMA	Raman microprobe analysis
SEAM	Scanning electron acoustic microscopy
SEM	Scanning electron microscopy
SEXAS	Secondary electron X-ray absorption spectroscopy
SIMS	Secondary ion mass spectroscopy
SNMS	Sputtered neutral mass spectroscopy
SPC	Single-particle counting
SR	Seismic reflection
SSMS	Spark source mass spectroscopy
STEM	Scanning transmission electron microscopy
TEM	Transmission electron microscopy
TFMS	Time-of-flight mass spectroscopy
TIMS	Thermal ionization mass spectroscopy
TOM	Tomography
TRLIFS	Time-resolved laser-induced fluorescence spectroscopy
VIS	Visible spectroscopy
UPS	Ultraviolet photoelectron spectroscopy
UVS	Ultraviolet spectroscopy
VOL	Volumetry
WDS	Wavelength-dispersive spectrometry
XANES	X-ray absorption near-edge spectroscopy
XAS	X-ray absorption spectroscopy
XPS	X-ray photo-electron spectroscopy
XRF	X-ray fluorescence spectroscopy
XS	X-ray conversion spectroscopy
αS	Alpha spectroscopy
βS	Beta spectroscopy
γS	Gamma spectroscopy

CHAPTER TWENTY EIGHT

X-RAY ABSORPTION SPECTROSCOPY OF THE ACTINIDES

Mark R. Antonio and Lynda Soderholm

28.1 INTRODUCTION

The recent availability of synchrotron radiation has revolutionized actinide chemistry. This is particularly true in environmental studies, where heterogeneous samples add to the already multifaceted chemistry exhibited by these ions. Environmental samples are often inhomogeneous, chemically diverse, and amorphous or poorly crystalline. Even surrogates prepared in the laboratory to simplify the natural complexity are plagued by multiple oxidation state and varied coordination polyhedra that are a reflection of inherent 5f chemistry. For example, plutonium can be found as Pu^{3+}, Pu^{4+}, $Pu(V)O_2^+$, and $Pu(VI)O_2^{2+}$ within naturally occurring pH–Eh conditions, consequently complex equilibria are found between these oxidation states in one solution. In addition, dissolved actinides have significant affinities for various mineral surfaces, to which they can adsorb with or without concomitant reduction–oxidation (redox) activity, depending on details of the solution and surface conditions.

A molecular level understanding of this diverse chemistry is necessary if predictive modeling of the fate and transport of these biohazardous ions is to be attained. Synchrotron studies are rapidly becoming a workhorse in the effort to chemically characterize 5f, actinide pollutants, their speciation, and their complexation at a molecular level. Synchrotrons are proving ideal for the task for several reasons: (1) they provide a high flux of tunable, high-energy

radiation; (2) highly focused beams allow for small (<1 mg) sample sizes; (3) the energy range permits excitation of the M- and L-adsorption edges of the actinides; (4) the penetrating nature of X-rays allows sample encapsulation and containment; and (5) a wide variety of spectroscopy, scattering, and imaging experiments are available.

Most of the synchrotron studies published to date have focused on X-ray absorption spectroscopy (XAS). This technique has found widespread use as a speciation probe for several reasons: (1) it is a single-ion probe that can be used to study one element from a complex mixture; (2) it is sensitive to both the oxidation state and to the coordination environment of the ion, and (3) it can be used for solution, surface, or solid samples. As a result, XAS has been able to answer a variety of important fundamental chemistry questions about actinide-ion speciation in solution and in the solid-state that have direct relevance to environmentally germane problems. Very recent trends indicate that these studies will expand to include other X-ray techniques and that more studies will focus on transuranics as the scientific community becomes more aware of the vast potential of synchrotron radiation as a molecular-level probe.

XAS itself is often artificially divided into two experiments, X-ray absorption near-edge structure (XANES), and extended X-ray absorption fine structure spectroscopy (EXAFS) because of the two different modes employed for analyses (Koningsberger and Prins, 1988; Bertagnolli and Ertel, 1994; Zubavichus and Slovokhotov, 2001). From a practical perspective they both arise from the same response about an absorption edge as a function of energy, as shown in Fig. 28.1. The absorption about the edge, or XANES data, provides information about the valence of the central ion by comparison to standards of known oxidation states. Often there is a shift of the absorption edge to higher energy that can be correlated to an increase in valence. This shift can be quite pronounced, as seen for example in Fig. 28.2a for Eu, which shows a 8 eV difference in absorption energy between Eu^{2+} and Eu^{3+} (Antonio *et al.*, 1997; Rakovan *et al.*, 2001). Shifts with oxidation state are often less definitive for the actinides and are complicated by the significant change in coordination environment that occurs in the 4+/5+ couple with the formation of the actinyl ion for U–Am (Ankudinov *et al.*, 1998; Conradson *et al.*, 1998; Antonio *et al.*, 2001) as shown in Fig. 28.2b. The dioxo coordination manifests itself as a predominant shoulder on the high-energy side of the absorption edge (Hudson *et al.*, 1995a) and a shift to somewhat lower energy (Soderholm *et al.*, 1999). This feature is even more enhanced for tetraoxo coordination, as seen in $[Np(VII)O_4]^-$ (Williams *et al.*, 2001) and demonstrated in Fig. 28.2c. Therefore, although XANES is primarily used for determining oxidation states, in specific situations it can be used to infer something about the absorbing ion's coordination environment.

Detailed coordination information is determined by fitting the EXAFS oscillations above the absorption edge (Lee *et al.*, 1981; Teo, 1986; Filipponi, 2001). The discovery of EXAFS was made in the 1920s (Lytle, 1999); however, it was

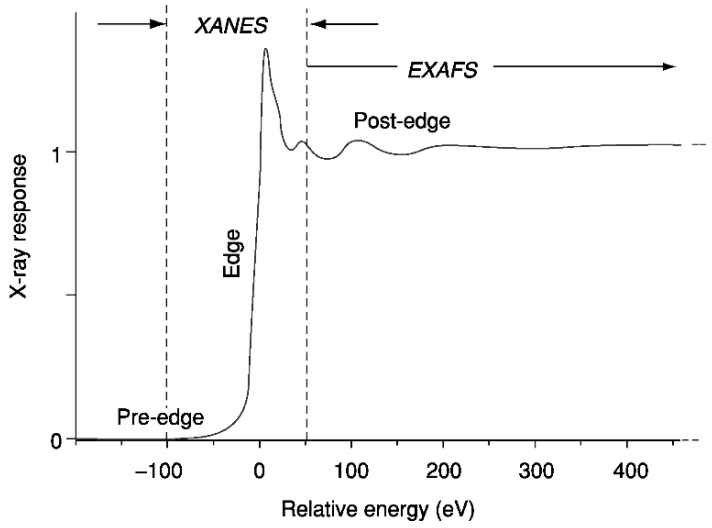

Fig. 28.1 *A* X*-ray absorption spectrum after background subtraction and normalization. The XANES region is usually considered to be the data from about* 100 eV *below the absorption edge to about* 50 eV *above the edge. The higher-energy data are considered to be the EXAFS spectrum. This distinction is somewhat arbitrary and reflects the different methods used to analyze the data. The XANES are considered to be electronic in origin and are often plotted as their derivative in order to clearly define the absorption edge for use in oxidation state assignment. The EXAFS data are re-configured into momentum space* ($Å^{-1}$) (*Teo,* 1986) *and then may be Fourier transformed to obtain a real-space* (Å) *spectrum. Data are fit for distances from the central absorbing ion and number of coordinating ligands using either* k*-space or FT data, as shown in Fig.* 28.3.

not until the 1970s that three pivotal developments set the foundation for the practice and acquisition of EXAFS. The first was the direct application of Fourier transform (FT) analysis to invert experimental data to obtain structural information about the near-neighbor coordination environment of a selected absorbing element in amorphous and crystalline materials alike (Sayers *et al.*, 1971). The second was the advent of intense synchrotron radiation of X-ray wavelengths that immensely facilitated the collection of data. Throughout the past three decades, the unique properties of synchrotron radiation available at some 30 operational facilities (as of 2003) throughout the world (Winick and Nuhn, 2003) has been exploited for EXAFS experiments that would be impossible to perform with conventional sources of x-radiation.

One important property – polarization – of the synchrotron radiation, was exploited for what was the first publication (Templeton and Templeton, 1982) about X-ray experiments with an actinide-bearing material, rubidium uranyl nitrate, $RbUO_2(NO_3)_3$, at a synchrotron facility. U L_3- and L_1-edge XANES

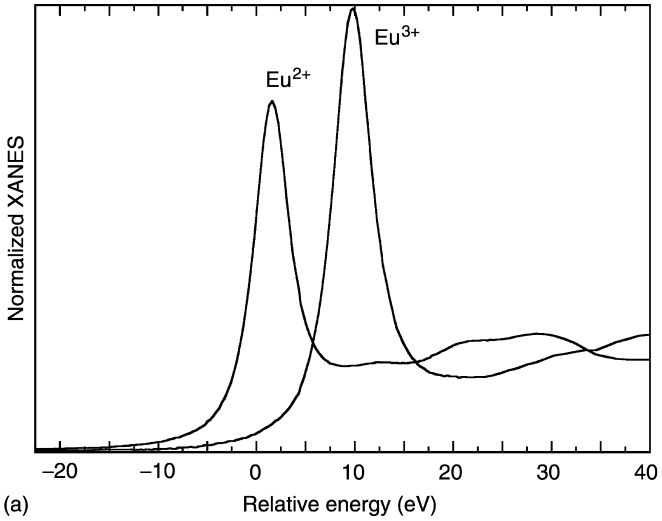

Fig. 28.2 (a) *Eu L_3-edge XANES demonstrating the* 8 eV *difference between the divalent and trivalent absorption maximum. Less obvious from the spectra is the slightly different FWHMs and integrated intensities of the two spectra, which is important to take into account when determining relative oxidation states from XANES* (*Antonio* et al., 1997; *Newville* et al., 1999).

data were acquired for a single-crystal with the electric vector of the linearly polarized synchrotron radiation both parallel and perpendicular to the linear, *trans*-dioxo uranyl {O–U–O} axis. At the time, the interpretation of the 'substantial dichroism' effects posed "...a challenge which we hope will stimulate further theoretical work" (Templeton and Templeton, 1982). This theoretical challenge, and the third pivotal development of EXAFS, was largely met in the 1990s with the release of the general-purpose XAS *ab initio* code known as FEFF (de Leon *et al*., 1991; Rehr *et al*., 1991, 1992; Zabinsky *et al*., 1995). The theoretical algorithms available with FEFF6 were first brought to bear upon spectroscopic features in U L_3-edge XANES of oxides and intermetallics (Hudson *et al*., 1995a). Together with other results, this benchmark study established the origin – a localized multiple-scattering resonance attributable to the linear $[O{=}U{=}O]^{2+}$ group – of the absorption resonance observed some 15 eV above the U edge peak in uranyl fluoride, UO_2F_2, in particular, and for uranyl compounds, in general. The calculations provided the initial successful interpretation of the substantial linear X-ray dichroism effects observed some 13 years earlier in the original U L_1- and L_3-eges XANES (Templeton and Templeton, 1982) and the subsequent U L_3-edge XANES and EXAFS of uranyl acetate dihydrate, $[UO_2(OOCCH_3)_2]\cdot 2H_2O$ (Hudson *et al*., 1996).

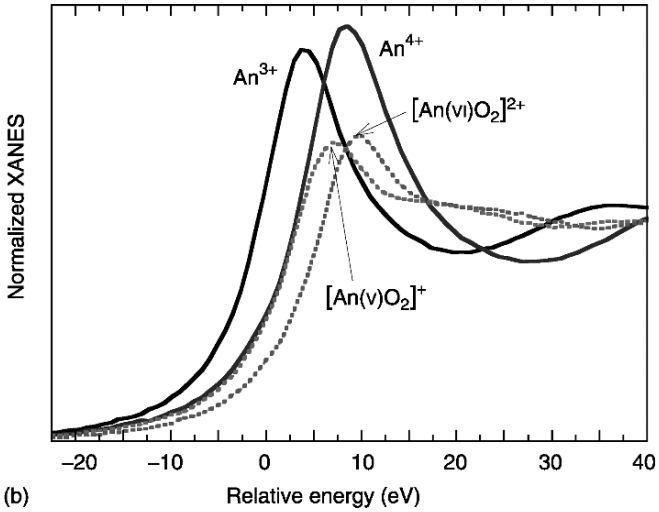

Fig. 28.2 (b) *Representative XANES data as a function of oxidation state and coordination environment. The trivalent and tetravalent spectra show about a* 4 eV *difference in the edge energy, as do the pentavalent and hexavalent dioxo moieties. However, a comparison of tetravalent with pentavalent dioxo spectra show very small, sometimes negative shifts in the edge energies, as shown. In addition, the shapes of the spectra are different. The trivalent and tetravalent species tend to have a larger white-line feature whereas the dioxo coordination of the higher oxidation states produces multiple-scattering that results in the shoulder to higher energy of the edge peak itself* (*Hudson* et al., 1995a).

Today EXAFS is widely used to determine the coordination environment of an actinide in a non-crystalline sample. All measurements of the EXAFS response, including the use of both primary (e.g. transmission, fluorescence, electron-yield) and secondary (e.g. optical luminescence, ion-yield, photoconductivity, photoacoustic) detection schemes, are made as a function of incident X-ray energy, E, in electron volts. Following a number of data reduction treatments, the EXAFS signal, χ, is plotted as a function of the photoelectron wave vector k (Å^{-1}), which is obtained according to:

$$k = \frac{2\pi}{\lambda_e} = \sqrt{\frac{2m}{\hbar^2}(E - E_0)} = \sqrt{0.263(E - E_0)} \tag{28.1}$$

Here, E_0 is the experimental energy threshold chosen to define the energy origin of the EXAFS spectrum in k-space. That is, $k = 0$ Å^{-1} when the X-ray energy E equals E_0, and the photoelectron of wavelength λ_e has no kinetic energy. Examples of representative data, $\chi(k)$ vs k, and their corresponding FTs are shown in Fig. 28.3. Under favorable conditions, the number, distance, and identity of the coordinating ion can be determined and, together with XANES

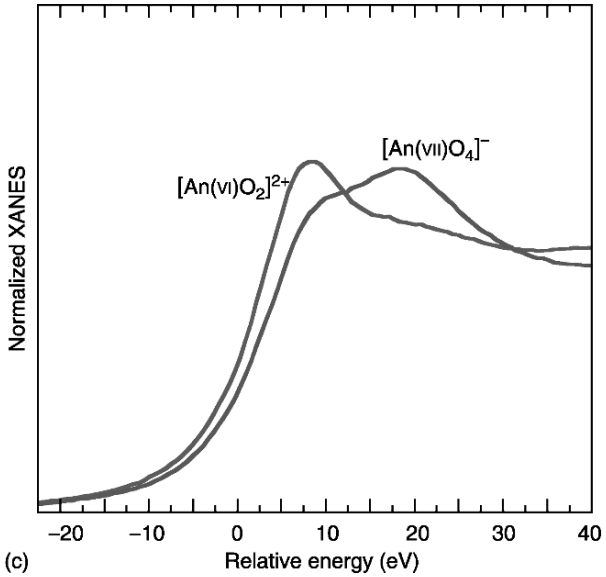

Fig. 28.2 (c) *A comparison of XANES spectra from an An(VI) dioxo-coordinated ion with that of a tetraoxo An(VII)-coordinated ion. The increased shoulder intensity for the latter coordination is presumed to arise from an increased number of multiple-scattering pathways.*

data, provide metrics on actinide-ion speciation. FEFF plays a very important role by providing element-specific phase and amplitude functions, thereby eliminating the need for obtaining these quantities from standard compounds. Until FEFF was in common use, the need for standard compounds to study actinides was a significant problem because of the very limited number of transuranic compounds with well-known structures and because of the radically different coordination environments, including dioxo coordination, which was difficult to resolve well enough experimentally to obtain adequate independent phase and amplitude functions.

In most cases, non-linear least squares minimization techniques are applied to fit the EXAFS or FT data with a semiempirical, phenomenological model of short-range, single-scattering according to (Teo, 1986):

$$\chi(k) = S_0^2 \sum_{i=1}^{n} \frac{N_i F_i(k, r_i)}{k r_i^2} \exp\left(-2k^2\sigma_i^2\right) \exp\left(\frac{-2r_i}{\lambda_e(k)}\right) \sin\left(2kr_i + \varphi_i(k, r_i) + \varphi_c(k)\right) \tag{28.2}$$

The backscattering amplitude, $F_i(k, r_i)$, and phase, $\varphi_i(k, r_i)$, as well as the central atom phase, $\varphi_c(k)$, are typically obtained from the FEFF and used as input for the iterative refinement procedures. An overall amplitude reduction

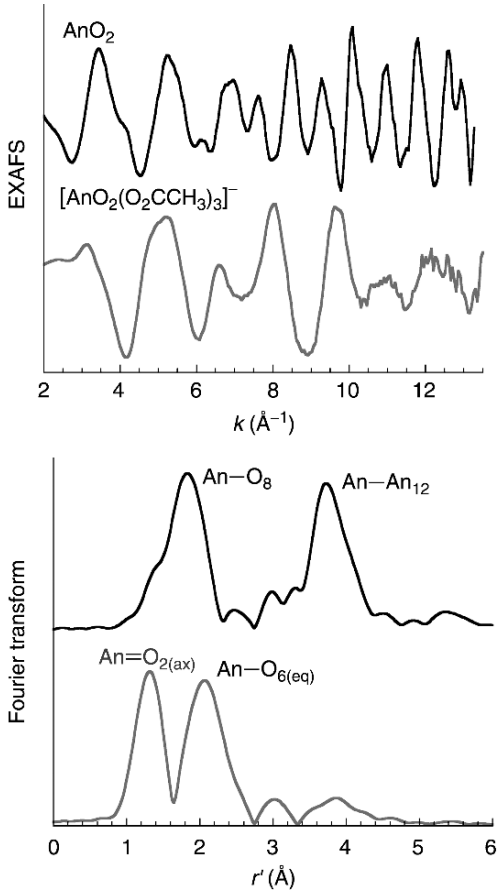

Fig. 28.3 *Representative L_3 EXAFS data comparing tetravalent and dioxo-hexavalent absorbers. Data are plotted as $k^3\chi(k)$, and their corresponding Fourier transforms (FTs) for a tetravalent oxide, AnO_2, and a hexavalent actinyl absorber with acetate ligation, $[AnO_2(O_2CCH_3)_3]^-$. The FT data for the dioxide shows a singe peak at* 1.83 Å (*before phase shift correction*) *due to O backscattering, whereas the dioxo complex anion shows two strong peaks due to O at* 1.32 *and* 2.07 Å (*before phase shift correction*) *that are diagnostic of the axial* (*ax*) *and equatorial* (*eq*) *backscattering, beyond which there is little response. In contrast, the strong, distant peak at* 3.73 Å (*before phase shift correction*) *observed in the FT data for the dioxide is diagnostic of An–An backscattering.*

factor, S_0^2, is normally a fixed input parameter too. The exponential term that includes the photoelectron mean free path, $\lambda_e(k)$, is not explicitly used for a standard analysis. The three principal structure parameters obtained from the fitting include the coordination number, N_i, interatomic distance, r_i, and the Debye–Waller factor, σ_i, for each of the i-th scattering shells about the central absorbing ion out to about 4 Å. An energy scale (ΔE_0) parameter is also fitted to

account for differences between the experimental and theoretical values of E_0. The distances and energy scale both depend on the period of EXAFS oscillations and are therefore correlated, as are the coordination number and Debye–Waller factor, which both depend on the amplitude of the oscillations. The number of parameters that can be determined from a data set, N_p depend on the k- and r-ranges over which the data are fit, and can be calculated according to: $N_p = 2\Delta k \Delta r/\pi$ (Teo, 1986). A rule-of-thumb error estimate is that the fitted distances are precise to about $\pm 1\%$ whereas the coordination numbers can be quoted to ± 1.

It has been understood for some time that correlations exist between the bond distance, coordination number, and oxidation state for a metal species, M^{n+}. A quantitative, electrostatic model for coordination environments in complex ionic solids was proposed in 1929 (Pauling, 1929). Improvements in X-ray diffraction techniques have allowed significant refinement of this original model, and the development of an empirical correlation between valence and the length of a bond (Brown, 1981, 1987, 2002). This correlation, built up by examining the published X-ray structures now available, has been approximated by a simple, two-parameter expression for the experimental bond-valence, S_{ij} :

$$S_{ij} = \exp\left(\frac{R_0 - R_{ij}}{B}\right)$$

where R_{ij} is the distance between atoms i and j. R_0 is an empirically derived parameter, determined such that it represents the length of the bond of unit valence. Its value is dependent on the two ions involved in the bond, and has been tabulated for a variety of bond pairs (Brown, 1996, 2002). Unless otherwise noted, B is generally assumed to be very close to 37 pm. The valence sum rule:

$$V_i = \sum S_{ij}$$

states that the sum of the experimental bond-valences around ith atom is equal to the atomic valence (Brown, 2002). In this way, the bond distance, coordination number, and metal-ion valence can all be correlated.

This concept has been nicely realized for the hexavalent uranyl ion (Burns *et al.*, 1997), for which Brown's R_0 and B parameters have been established from a wide range of X-ray single-crystal structural refinements. A representative plot of bond-valence sum (BVS) versus bond distance is shown in Fig. 28.4, for which the BVS for hexavalent U has been optimized to six. These results can be used in several ways, including confirmation of a coordination number from EXAFS data when a bond distance has been determined. This concept is a useful added tool because the coordination numbers are often not adequately determined from EXAFS alone to answer a question in hand. Likewise, confirmation of oxidation state can come from correlations between bond distances

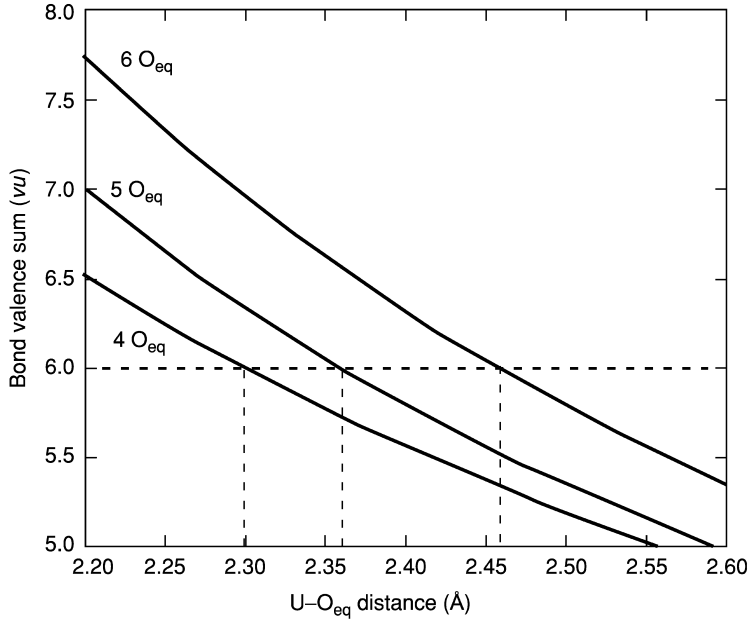

Fig. 28.4 *Bond-valence sums* (*Brown,* 2002) *calculated for the uranyl*(*VI*) *ion with ligating oxygen ions. Parameters used in the calculation* (*Burns* et al*.,* 1997) *were derived from an extensive analysis of available single-crystal structures. Whereas O=U=O bonds are seen to be invariant to changes in coordination environment, the distances to the* O_{eq} *are seen to be dependent on the number of coordinating ions in the equatorial plane. For* $U(VI)O_2^{2+}$ *the average bond distances are* 2.29(5), 2.37(9), *and* 2.47(12) Å *for* 4, 5, *and* 6 *equatorial ligation. These distances can be compared with those obtained from fitting EXAFS data to support a determination of the equatorial coordination environment. Unfortunately, the good quality, single-crystal X-ray structural data necessary to determine a similar plot for transuranic ions is not currently available.*

and XANES data. Interpretation of the XAS data can be further checked by comparison with a variety of published data on similar systems. Published compendia of XAS spectra and analyses for a variety of Th- and U-containing mineral and related phases facilitate these comparisons (Farges, 1991; Thompson *et al*., 1997; Hanchar, 1999). Unfortunately, the use of well-established trends in bond distances and oxidation states or coordination numbers for transuranic studies is limited by the paucity of well-determined single-crystal structures for these ions.

XAS is a single-ion probe that can be tuned to an energy that selects the absorption edge of an ion of interest, an essential attribute when studying an ion's speciation in chemically complex samples. Unfortunately, the spectrum that is obtained is the sum of all the oxidation states and coordination

environments that occur in the sample. This can be particularly problematic for actinide-containing samples in which multiple redox states and coordination environments often occur within one sample. Although difficult to ascertain from simple data analysis, there are two recent developments that are proving to be powerful tools to assess and overcome this problem. The increased brightness afforded by the newer generation synchrotrons has made microsynchrotron-X-ray fluorescence (μ-SXRF) particularly valuable for examining inhomogeneous natural samples. The utility of this technique was clearly demonstrated in seminal experiments examining Pu speciation when adsorbed onto natural tuff samples (Duff *et al.*, 1999a). The results of the experiments demonstrated that Pu was preferentially associated with Mn phases, as opposed to Fe-bearing phases as had been hypothesized, and that some of the Pu had been oxidized. The observation of Pu in multiple oxidation states, and its association with Mn phases were made possible by the use of a very small, focused beam. The second development is the application of principal component analysis (PCA) to XAS data (Wasserman, 1997; Wasserman *et al.*, 1999). PCA can be used on a series of data to determine how many different independent species are required to account for all of the spectra. This mathematical approach provides an estimate of the number of species present in the samples, information that is not otherwise available. Together with model compound spectra, PCA can suggest which of a variety of chemically possible species are present in different samples.

This chapter presents an overview of synchrotron studies on actinide species in environmentally relevant samples. The discussion is organized into solution studies in aqueous acid and base media, sorption studies onto mineral, natural soil, and bacterial surfaces. With the exception of selected experiments on μ-SXRF, almost all of the work has involved XAS studies.

28.2 THE TERRESTRIAL AQUATIC ENVIRONMENT

Since the discovery of the anthropogenic transuranium elements in the 1940s to 1950s, massive efforts have been directed at preventing the despoliation of the environment, particularly the ground- and surface-water supplies, fresh and saline alike, with radionuclide ions. Because of the legacy of the Cold War, the fate and migration of actinide (An) ions presently in the geosphere is a subject of intense interest (Lieser, 1995; Silva and Nitsche, 1995; Nitsche, 1997; Sterne *et al.*, 1998). In terms of its sheer abundance and essentially isotropic distribution on Earth, water is viewed as the principal dispersant of radionuclide pollution. Moreover, because potable water is vital to humanity and all its activities, especially agriculture and aquaculture, fundamental research about An speciation in aqueous media is of historical and contemporary significance.

From a science perspective too, water is the single-most important system with dual benchmark properties of solvent and coordinating ligand. Insofar as both hydration and coordination influence reactivity as well as spectro- and electrochemical responses of 5f-ions in aquatic environments, information about An aquo ions is pivotal to a thorough and predictive understanding of basic chemical phenomena involving migration, absorption, solvation, complexation, exchange, electron transfer, and hydrolysis behaviors, just to name a few, pertinent to hydrologic and geochemical processes. By comparison with the extent of knowledge about An oxidation states and their well-known redox activity (Morss, 1994), metrical details about the coordination of water with the trans-uranium elements are generally sparse. Despite the availability of potential–pH (Pourbaix) equilibrium diagrams for Th, U, Np, Pu, and Am in aqueous solutions at 25°C (Pourbaix, 1974), these do not provide quantitative information about bond lengths and coordination numbers as a function of oxidation state, the so-called An redox speciation. Nor do these diagrams apply to ligands other than H_3O^+, H_2O, and OH^-, and no diagrams are available to describe the redox equilibrium behavior of Ac, Pa, and the trans-Am elements in aqueous solution.

To build a foundation for a thorough understanding of An redox speciation in aqueous media containing environmentally relevant ligands that are known An complexants, e.g. HCO_3^-, CO_3^{2-}, Cl^-, NO_3^-, and SO_4^{2-}, it is first important to understand the structure of the pure molecular An aquo ions and the nature of the An–OH_2 interactions in each of their accessible oxidation states without other interference. In order to suppress and eliminate possible complicating effects of hydrolysis, disproportionation, oligomerization, precipitation, etc., experiments have been routinely performed at low pH in aqueous non-complexing mineral acids. Perchloric acid is the system of choice because the ClO_4^- anion does not participate in direct, inner-sphere interactions with An ions, thereby providing immediate access to the hydrated An species in the absence of competitive binding effects.

Within the domain of the thermodynamic stability of water, which consists of a small (1.229 V) polarization window (Bratsch, 1989), all An electrochemical equilibria are limited by the pH-dependent reduction and oxidation of water itself. Under standard conditions at 25°C that include no complexing ions and 1 atm partial pressures of H_2 and O_2, the potential limits of water with respect to the standard hydrogen electrode (SHE) are imposed by the following reactions:

$$\text{Reduction of } H^+(\text{and } H_2O) \text{ to } H_2 - E^\circ(\text{V}) = 0.000 - 0.0591 \times \text{pH}$$
$$H^+ + e^- \rightarrow {}^1\!/_2H_2 \uparrow \quad \text{and} \quad H_2O + e^- \rightarrow {}^1\!/_2H_2 \uparrow + OH^- \tag{28.3}$$

$$\text{Oxidation of } H_2O \text{ (and } OH^-) \text{ to } O_2 - E^\circ(\text{V}) = +1.229 - 0.0591 \times \text{pH}$$
$${}^1\!/_2H_2O \rightarrow {}^1\!/_4O_2 \uparrow + H^+ + e^- \quad \text{and} \quad OH^- \rightarrow {}^1\!/_4O_2 \uparrow + {}^1\!/_2H_2O + e^- \tag{28.4}$$

The linear and parallel potential, E° (V), dependencies for the reactions (28.3) and (28.4) as a function of pH are conveniently visualized in the Pourbaix diagrams for all elements from $Z=1$ to 95 (Am) such as is illustrated in Fig. 28.5 for Fe. As can be seen from Table 28.1, there are a number of solution-stable An species under both acid and alkaline conditions that exhibit redox activity within the electrochemical window afforded by water. In fact, some transuranium ions, notably Np and Pu, are known to have a remarkable variety of solution species as well as intricacies and ambiguities of valence with five accessible oxidation states – III, IV, V, VI, and VII. In this regard, electrochemical research has played a central role in the advancement of actinide science. And, in the field of equilibrium electrochemistry, the cornerstone of all practical, thermodynamic applications of electroanalytical techniques, e.g. potentiometry and polarography, is the Nernst equation (28.5). (Archer, 1989):

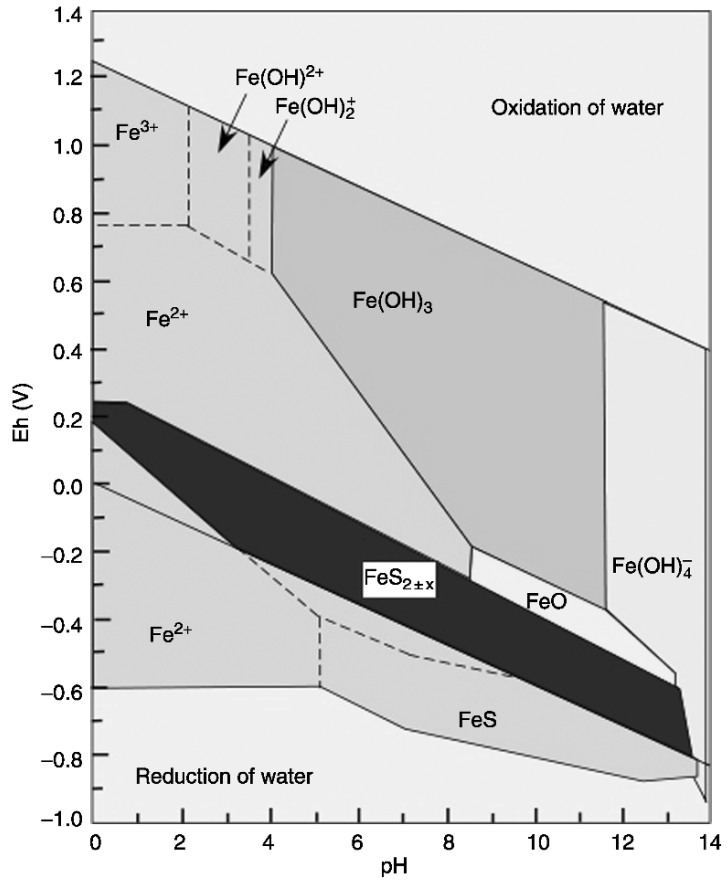

Fig. 28.5 *The complex behavior of iron in an aqueous environment, showing both changes in oxidation state and ligation as a function of solution Eh and pH* (*Hem*, 1985).

Table 28.1 *The standard reduction potentials (E°, V vs SHE) for some one- and two-electron half-reactions of selected ions. The more positive the potential, the more favored the reaction as written. Except where noted, all values are from Bratsch* (1989).

$$E_p = E^{\circ\prime} + \frac{RT}{nF}\ln\frac{[\Re_{ox}]}{[\Re_{rd}]} \tag{28.5}$$

Derived in 1888 by W. H. Nernst (1864–1941), his eponymous equation establishes the equality between an electrode potential, E_p, and the formal electrode potential, $E^{\circ\prime}$, which is a thermodynamic value, for a redox reaction, such as shown in Table 28.1, under any conditions of pH, electrolyte, ionic strength, etc. In general, for a reversible electrode couple involving n electrons, as illustrated by equation (28.6), the extent of the forward and reverse redox reactions can be manipulated by the application of an applied potential in the vicinity, typically ± 0.20 V, of $E^{\circ\prime}$:

$$\Re_{ox} + ne^- \leftrightarrows \Re_{rd} \tag{28.6}$$

Through measurement of the solution concentrations of both the oxidized and reduced ions, $[\Re_{ox}]$ and $[\Re_{rd}]$, respectively, at a series of selected potentials, a so-called Nernst plot can be prepared in the form of E_p vs $\ln([\Re_{ox}]/[\Re_{rd}])$. An example of a Nernst plot for the one-electron reaction of equation (28.7) for the neptunium redox couple is shown in Fig. 28.6:

$$Np^{4+} + e^- \leftrightarrows Np^{3+} \tag{28.7}$$

For this so-called Nernstian process, meaning that the reaction (28.7) is thermodynamically reversible, wherein the reactant, Np^{4+}, and electrogenerated product, Np^{3+}, maintain equilibrium concentrations at the electrode surface with variation of E_p, a linear plot results. The x-axis intercept is obtained when $[\Re_{ox}]=[\Re_{rd}]$ and provides the formal potential, $E^{\circ\prime}$. The slope, RT/nF, of the plot provides the number of electrons, n, transferred in the redox reaction. For measurements at room temperature, $T=298.15$ K, it is a matter of convenience to simplify equation (28.5) with numerical substitutions for the constants, where R is the universal gas constant, 8.314570 J K^{-1} mol^{-1}, and F is the Faraday constant, 96485 C mol^{-1}, and by conversion from the natural logarithm, ln, to the common logarithm, log, as shown in the following equation:

$$E_p = E^{\circ\prime} + \frac{0.05915}{n} \log \frac{[\Re_{ox}]}{[\Re_{rd}]} \tag{28.8}$$

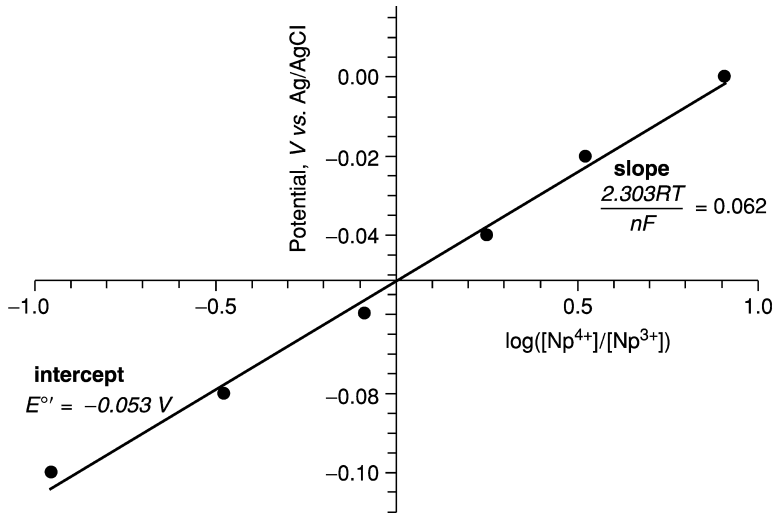

Fig. 28.6 *Nernst plot for the* Np^{4+}/Np^{3+} *redox reaction* (28.7). *The experimental data* (*circles*) *were obtained through use of XANES spectroelectrochemistry*. (*Soderholm* et al., 1999) *The linear least-squares fit shown as a line* ($R^2 = 0.994$) *provides a slope that corresponds to a* 1 e^- *couple, and an intercept of* –0.053 V, *which compares favorably with published values* (*Cohen and Hindman*, 1952*; Riglet* et al., 1989*; Li* et al., 1993).

In the plot of Fig. 28.6, the relative concentrations of the oxidized and reduced Np species were determined by use of XANES spectroscopy (Soderholm *et al.*, 1999). Optical, vibrational, and nuclear magnetic resonance (NMR) probes of concentration are more typically employed in experimental combinations of spectroscopy and electrochemistry, shortened to spectroelectrochemistry in common usage, than are X-ray techniques (Gale, 1988). Regardless of the method, a range of controlled electrochemical potentials must be selected at which the forward and reverse reactions provide sufficient concentration variations of admixtures of $\Re_{ox}$ and $\Re_{rd}$ to perform a Nernst analysis. A typical abscissa range extends between log values of –1 and +1, corresponding to concentration ratios, $[\Re_{ox}]/[\Re_{rd}]$, of 1/10 and 10/1, respectively.

In 1980, XAS, consisting of the methods of XANES and EXAFS, was first brought to bear upon the issue of An speciation in aqueous solutions. This section contains a review of the results published since then for the An aquo species of Th and U–Cf, inclusive (there are no published reports for Ac, Pa, Es, and beyond) with particular emphasis on hydration numbers and inner-sphere An–O interatomic distances with the neutral water molecule. The results are discussed in Section 28.2.2. The interactions of An ions in solution and as solid-state complexes with anionic ligands of mono- and multidentate organic anions are treated separately in Section 28.3.4.

28.2.2 Acid redox speciation

Because of their high charge, small size, and oxophilicity, the 5f-elements are especially prone to hydrolysis reactions and precipitation in neutral and alkaline media. Their solubility and stability in aqueous acid media of $pH \leq 2$ facilitates spectroscopic research, especially the EXAFS work reviewed here whose origins can be attributed to the study of what is now considered to be a concentrated (0.2 M) hexavalent U sample dissolved in 0.2 M HNO_3 (Karim *et al.*, 1980). The L_3-edge EXAFS was acquired with a rotating anode X-ray source and, despite the low signal-to-noise (S/N) quality, provided 'striking' information about the uranyl moiety, $[UO_2]^{2+}$, in solution. The two resolved peaks of the FT data, which are immediately recognized in modern EXAFS research, were attributed to a combination of backscattering from the O nearest atoms of the linear *trans*-dioxo cation, $[O{=}U^{6+}{=}O]^{2+}$, and the next-nearest O atoms of an equatorial arrangement of ligands typical of a hydrolysis complex or, alternatively, the H_2O molecules of a hydration shell. The comparison of the solution FT with that for crystalline UO_2F_2 (a known structure) confirmed the existence of the 'ubiquitous' uranyl group upon dissolution of the solid. At the time in 1980, the theoretical central atom phase function for U was not available. As a result, the functions of Teo and Lee (1979) were extrapolated to simulate the U L_3 $k\chi(k)$ EXAFS with two O atoms at 1.77 Å and five O atoms at 2.38 Å. As shown in Table 28.2, these distances, especially that for the close O atoms of the

Table 28.2 *Uranium redox speciation for U(III), U(IV), U(V), and U(VI). For the spherical ions, the hydration numbers* (n, n′, *coordinated* H_2O) *and U–*OH_2 *interatomic distances are listed. uranyl group, are precisely comparable with numerous subsequent synchrotron radiation measurements.

In the historic work of Karim *et al.* (1980), the exact extent of equatorial O coordination could not be determined because of S/N complications and the imprecise knowledge of Debye–Waller factors and electron mean-free-path terms. Now, decades later, and despite remarkable advances in the theory of EXAFS (Rehr and Albers, 2000), similar problems with scattering losses, amplitude reduction effects, etc. continue to plague aspects of the precision and accuracy of coordination numbers extracted from EXAFS data by curve-fitting methods (Allen *et al.*, 2000). This is especially true for distant, next-nearest neighbors in multi-shell systems wherein spectral congestion and phase cancellation effects can make analyses difficult. Uncertainties can also arise in the determination of the coordination numbers for the simple trivalent and tetravalent hydrated cations, $An^{3+}\cdot nH_2O$ and $An^{4+}\cdot n'H_2O$, where n and n' are the numbers of water molecules directly bound to the An ions in the immediate hydration sphere. The case in point is illustrated by the results of Table 28.3 for the Th^{4+} aquo ion in 1–1.5 M $HClO_4$.

(a) The monatomic spherical An(III) and An(IV) ions

Under conditions that pertain to most ecological habitats, the low-valent 3+ oxidation states of the 5f-elements would not be stable until Am ($Z=95$) and beyond. This is one of the obvious contrasts with lanthanide coordination chemistry wherein stability is dominated by the spherical, monatomic, tripositive ions. Actinide coordination chemistry in natural systems may, however, be influenced by the 4+ oxidation states that are stabilized in anoxic, subsurface aquifers and lacustrine and marine basins wherein redox processes are mediated by species other than O_2, such as S-bearing entities. Under such reducing conditions, An(IV) interactions with H_2O are largely driven by classical, electrostatic forces. This facilitates various approaches in the modeling of thermodynamic properties for the aquo species of the two spherical, monatomic

An(III) and An(IV) cations (David and Vokhmin, 2003). These efforts incorporate or rely upon the significant body of metrical information obtained from the An EXAFS reviewed below.

(*i*) *Thorium*(*IV*)

The initial analysis of Th L_3 EXAFS for a 0.055 M solution of Th^{4+} in 1 M $HClO_4$ provided an O coordination number of 11.0 ± 0.7, which at the 95% confidence level means that hydration numbers of 10, 11, and 12 are statistically equivalent (Moll *et al*., 1998). In a more rigorous follow-up study with two solutions – 0.03 and 0.05 M – of Th^{4+} in 1.5 M $HClO_4$, hydration numbers of 11.0 ± 0.9 and 11.2 ± 0.9 and corresponding distances of 2.43 and 2.45 Å, respectively, were obtained from curve-fitting analyses of the L_3-edge EXAFS with and without the use of cumulant methods, which account for an asymmetrical distribution of distances about Th^{4+} (Moll *et al*., 1999). Despite the evidence for an asymmetric distribution of H_2O about Th^{4+}, the effects of pair asymmetry on the Th–OH_2 interatomic distance were small, 0.01–0.02 Å, and of approximately the same magnitude as the experimental error itself.

Based upon a combination of results from the primary (Th EXAFS) data and a variety of other metrical comparisons, Moll *et al*. (1999) concluded that the EXAFS results were compatible with hydration numbers of 9–11, and they ultimately "...selected 10 ± 1 as the most likely coordination number" for the Th^{4+} (and U^{4+}) aquo ion in perchloric acid. The addition of fluoride ion in the form of NaF at the same concentration (0.05 M) as that for Th^{4+} in the acid solution was shown to have a significant effect on the coordination environment, but not on the total coordination number. The EXAFS data were analyzed to reveal a pair distribution (Th–F and Th–O) asymmetry with 1 F^- at 2.14 Å and 10 H_2O at 2.48 Å. The subsequent Th L_3-edge results (Neck *et al*., 2002; Rothe *et al*., 2002) for a 0.055 M Th^{4+} solution in 1.5 M $HClO_4$ indicate that the aqueous speciation consists of 12.7 O atoms at an average distance of 2.45 Å about Th^{4+}. Although the interstudy agreement of Th–O distances is better than 1%, there is an approximately 25% study-to-study variation of coordination number. Because of the experimental conditions employed and the interatomic distances obtained, the results of the four studies (Moll *et al*., 1998, 1999; Neck *et al*., 2002; Rothe *et al*., 2002) are essentially the same. Thus the coordination number discrepancy may not arise from genuine variations of sample condition. Rather, it appears to stem from different approaches to the curve-fitting analyses including, in addition to a host of other factors, the choice of amplitude reduction factor, S_0^2, which has direct impact on the absolute accuracy of EXAFS determinations of coordination numbers (Allen *et al*., 2000).

A final comment about the nature of the Th^{4+} aquo ion in these different experiments is necessary. The EXAFS results in each of the three aforementioned studies (Moll *et al*., 1999; Neck *et al*., 2002; Rothe *et al*., 2002) on the

dilute and similar Th^{4+} solutions as summarized in Table 28.3 are contrasted with those from large-angle X-ray scattering studies (Johansson *et al.*, 1991) that reveal a less populated hydration sphere of 8.5 ± 0.5 water molecules at an average distance of 2.485 ± 0.010 Å. In the extremely concentrated solutions, ≈ 1 M Th^{4+}, required for the scattering measurements, it is reasonable to expect that inter-ion aggregation phenomena can lead to a different form of the aquo ion from the significantly less concentrated (18–33 times less) solutions of the EXAFS studies (Moll *et al.*, 1999). At high concentration, the Th^{4+} cations may be partially dehydrated because of an insufficient number of H_2O molecules to satisfy their own solvation requirements as well as those for the (5 M) $[ClO_4]^-$ anions. There is also the possibility for some degree of nucleation and contact through cation–anion and cation–cation interactions. Until one (or both) of the experiments can be repeated under identical conditions, comparisons are not reliable, and it certainly is not obvious that either one (or more) of the studies is in error. In the interim, results from DFT calculations indicate that the first hydration shell about Th^{4+} contains 9 H_2O molecules with Th–O bond lengths of 2.54–2.55 Å (Yang *et al.*, 2001).

(*ii*) *Uranium*(*IV*)

The first U L_3-edge EXAFS results for a dilute, acidic (pH = 2) solution of the U^{4+} aquo ion revealed a hydration number of nine with an average U–O interatomic distance of 2.42 Å (Charpin *et al.*, 1985). The earliest structure report using X-ray scattering was ultimately interpreted to show that the coordination number of U^{4+} in $HClO_4$ was "not significantly different from eight" (Pocev and Johansson, 1973). The indefinite nature of this phrase may reflect the variations in coordination number (between six and ten) obtained with different analysis procedures, especially data set length, and numerical modeling treatments of the data for the acid solution of concentrated (2.044 M) U^{4+} in which about 2% (0.035 M) was present as uranyl(VI). The low-limit value of the reported range of U–O distances, 2.42–2.52 Å (Pocev and Johansson, 1973) is the same as the EXAFS-determined distance (Charpin *et al.*, 1985). The initial work on a dilute (0.05 M) solution of U^{4+} in 1.5 M $HClO_4$ revealed an O coordination number of 11 ± 1 and, moreover, that the hydration numbers of U^{4+} and Th^{4+} are the same (Moll *et al.*, 1998). In a subsequent and more extensive paper on the subject of the tetravalent aquo ion, including the effects of fluoride ion, an EXAFS-determined value of 10.8 ± 0.5 water molecules about U^{4+} at an average distance of 2.41–2.42 Å was reported (Moll *et al.*, 1999). The presence of F^- at concentrations equal to (0.055 M) and greater than that for $[U^{4+}]$ (0.09 M) was shown to affect the speciation, wherein the immediate coordination environment was shown to consist of ca. one F^- at 2.10 Å and 8.2–8.7 H_2O at 2.45–2.46 Å.

Additional insights about the magnitude of the 10.8 ± 0.5 hydration number for the pure aquo ion were provided by comparison of the U–O interatomic

distance with the previously reported Er–O distance (2.36 Å) (Johansson and Wakita, 1985) for the Er^{3+} aquo ion, which has an exact hydration number of eight. The comparison is appropriate because the ionic radii of U^{4+} and Er^{3+} (1.00 and 1.004 Å, respectively, for CN 8) (Shannon, 1976) are essentially identical. Because An–OH_2 bond lengths are mainly influenced by electrostatic effects, the extent of such interatomic interactions is known to increase with increasing coordination number. It is argued that the 0.06 Å longer distance for the U^{4+} aquo species "...can only be explained by a coordination number larger than eight" (Moll *et al.*, 1999). Based upon this and other comparisons with available U–O distances in solid-state crystal structures, they suggested that coordination numbers of either nine or ten are possible and ultimately selected ten as the most likely one. The fact that the larger value (≈ 11) obtained from the actual analyses of the data can be so readily disregarded with sound arguments based upon EXAFS-determined distances further underscores the generally recognized problems with the accuracy of EXAFS coordination number determinations mentioned above. Similar selections of coordination numbers other than those obtained from analysis of the primary data are scattered throughout the literature reviewed here for aqueous An species.

(*iii*) *Neptunium*(*IV*)

Neptunium is considered to be the most problematic of the transuranium elements for waste storage because of its high solubility in groundwater (Viswanathan *et al.*, 1998; Kaszuba and Runde, 1999) and the projected dose commitments to the public that would arise from its breach of long-term containment (Hursthouse *et al.*, 1991). The aquo ion of tetravalent ^{237}Np has been the subject of three independent EXAFS investigations (Allen *et al.*, 1997; Reich *et al.*, 2000; Antonio *et al.*, 2001). Well before these, optical data were interpreted to reveal a hydration number of eight (Rykov *et al.*, 1973). Neptunium L_3-edge measurements of dilute (0.005 M) Np^{4+} were originally obtained in various concentrations of HCl from 1–10 M (Allen *et al.*, 1997). No inner-sphere Cl^- complexation was noted for the solution of Np^{4+} in 1 M HCl, and the EXAFS data for the aquo ion were analyzed to reveal 11.2 O neighbors at an average distance of 2.40 Å. Comparisons of this interatomic distance with a selection of related Np^{4+} and Pu^{4+} species suggested "...that the number of waters around the Np^{4+} ion lies in the range of 9–11." On increasing HCl concentrations from 5 to 10 M, the data analysis revealed a systematic replacement of inner-sphere H_2O molecules by inner-sphere Cl^- ions (reaching values of 7.7 and 2.0, respectively) that was accompanied by a 0.04 Å elongation of the Np–O bond length. The trends were interpreted to indicate the formation of a mixture of multi-aquo-chloro complexes of the general form $[Np(OH_2)_xCl_y]^{4-y}$, for $y \geq 2$.

In the second study (Reich *et al.*, 2000), a dilute (0.05 M) solution of Np^{4+} in 0.1 M HNO_3 was stabilized by the addition of 2 M H_2SO_4 to suppress the

spontaneous oxidation reaction,

$$Np^{4+} + 2H_2O \rightarrow [Np^{5+}O_2]^+ + e^- + 4H^+. \quad (28.9)$$

Analysis of the L_3-edge EXAFS revealed an O coordination number of 11 with an average Np–O distance of 2.39(1) Å, both of which bear close resemblance to the initial results (Allen *et al.*, 1997). Upon further analysis of distant features in the FT data, evidence was found for the inner-sphere coordination that contains two $[SO_4]^{2-}$ groups bound to Np^{4+} in a bidentate fashion (Reich *et al.*, 2000). So, the total O coordination number of 11 is the sum of four O from two sulfate groups and seven from H_2O molecules and, despite the agreement with the earlier work (Allen *et al.*, 1997), the mixed sulfate–hydrate of Np^{4+} species is not a pure aquo ion.

In order to avoid such troublesome effects of complexation as well as those from oxidation, hydrolysis, disproportionation, and precipitation reactions, a dilute (0.0047 M) solution of Np in the non-complexing, supporting electrolyte of perchloric acid (1 M) was used for *in situ* L_2-edge EXAFS spectroelectrochemical measurements of all four – III, IV, V, and VI–aquo ion species (Antonio *et al.*, 2001). The *in situ* technique eliminates interferences from chemical reductants/oxidants that may be required to produce and maintain a specific Np oxidation state during the time required to perform a conventional *ex situ* experiment. Moreover, the use of the non-complexing, supporting electrolyte of perchloric acid further assures that all inner-sphere Np–O bonding is free of interferences from Np–$[ClO_4]^-$, Np–$[SO_4]^{2-}$, Np–$[Cl]^-$, etc., interactions. The EXAFS analyses of the data for the Np^{4+} aquo ion revealed a coordination number of 9(1) O atoms at an average distance of 2.37(2) Å. Comparison of this solution Np^{4+}–O distance with the corresponding distance for crystalline NpO_2, containing eight-coordinate Np^{4+}, reveals that the average distance for the aquo ion is 0.02 Å longer. Insofar as interatomic distances can be used to estimate coordination numbers, it was concluded that "...hydration numbers of either 8 or 9 are more realistic than hydration numbers of either 10 or 11" for the Np^{4+} aquo ion (Antonio *et al.*, 2001). In support of this conclusion, a simple numerical model, based upon an adaptation of the original method of Egami and Aur (1987) used previously with success for metal-ions in glass matrices, was introduced for estimating An ion coordination numbers. The number calculated for Np^{4+} was eight.

The *in situ* X-ray absorption technique was further developed as a means to determine the formal electrode potential ($E^{\circ\prime}$) of Np redox reactions (Soderholm *et al.*, 1999), including the Np^{4+}/Np^{3+} couple of equation (28.7). As discussed previously, for reversible reduction–oxidation reactions of An ions in general, the measurement of thermodynamic formal potentials is important from fundamental and practical perspectives concerning An mobility and reactivity in the geosphere. Whereas the equipment and methods of X-ray absorption spectroelectrochemistry have evolved since the first description of its use (Smith *et al.*, 1984), none of the myriad of multipurpose cell designs (Sharpe *et al.*, 1990;

Igo *et al.*, 1991; Farley *et al.*, 1999) were directly suitable to achieve the application-specific containment and safety standards necessary for *in situ* experiments with radionuclides. This led to the design of a purpose-built system (Antonio *et al.*, 1997), which by facilitating the simultaneous combination of electrochemistry and XANES, provides direct access to the formal electrode potentials of redox reactions of An ions. For example, by use of a series of controlled electrochemical potentials (E_p) at which the forward and reverse reactions of equation (28.7) provide concentration variations of Np^{4+} and Np^{3+}, sufficient XANES data were acquired (Soderholm *et al.*, 1999) to perform a Nernst analysis according to equation (28.8). The spectra for the admixtures of the two solution species were analyzed using standard linear regression analysis as well as PCA with the valence-pure Np^{4+} and Np^{3+} spectra to provide the relative partial concentrations used for the Nernst plot of potential, E_p, vs $\log[Np^{4+}]/[Np^{3+}]$ shown in Fig. 28.6. In this analysis, the slope (0.062 V) corresponds to $n = 1$ e^-. The x-axis intercept provides the formal potential, $E^{\circ\prime} = -0.053$ V. Besides the Np^{4+}/Np^{3+} reaction of equation (28.7), the method was successfully applied to the Bk^{4+}/Bk^{3+} (Antonio *et al.*, 2002) and Np^{6+}/Np^{5+} (Soderholm *et al.*, 1999) aquo ion redox reactions as well as with the IV/III couples of Np and Pu in complexes with the electroactive, Wells–Dawson heteropolyoxoanion ligand, $[P_2W_{17}O_{61}]^{10-}$, which obscures the optical and electrochemical response of the An-ion itself (Chiang *et al.*, 2003). In this situation, the *in situ* XANES approach provides information about formal electrode potentials that is not obtainable from conventional spectrophotometric measurements, cyclic voltammetry, or potentiometric titrations alone.

(*iv*) *Plutonium*(IV)

Metrical aspects of the speciation of the $^{242}Pu^{4+}$ aquo ion came to light in three papers (Ankudinov *et al.*, 1998; Conradson, 1998; Conradson *et al.*, 1998). The experimental Pu XANES at the L_1 (Ankudinov *et al.*, 1998) and L_3 (Conradson *et al.*, 1998) edges for a 0.10 M Pu^{4+} solution in 1 M $HClO_4$ were compared with theoretical spectra obtained from multiple-scattering XANES calculations using the *ab initio* code known as FEFF (Rehr and Albers, 2000). Although these efforts provided no quantitative information about the Pu^{4+} coordination environment in terms of bond distances and hydration numbers, structural parameters for Pu^{4+} as well as for the three other Pu aquo ions were provided in an appendix (Ankudinov *et al.*, 1998). The primary source of the supplementary results was attributed to, at that time, an unpublished study. These structure details appear to be the same as those subsequently published in the review article (Conradson, 1998), which shows the FT data and the results from the curve-fitting analysis of the L_3 EXAFS. The Pu^{4+} aquo ion in 1 M $HClO_4$ was shown to consist of eight or nine water molecules at an average distance of 2.39 Å. A similar hydration structure was found for the Np^{4+} aquo ion species that was also studied in 1 M $HClO_4$ (Antonio *et al.*, 2001).

Independent EXAFS measurements of aqueous solutions of 0.05 M $^{239}Pu^{4+}$ in 3 and 8 M HNO_3 revealed an O coordination number of 11 with best fit Pu–O distances of 2.41 and 2.45 Å, respectively (Allen *et al*., 1996b). Analysis of the distant peaks in the FT data revealed N backscattering that increased with the HNO_3 concentration. The N coordination numbers and Pu–N interatomic distances, in combination with results from ^{15}N NMR and optical spectroscopies (Veirs *et al*., 1994), revealed the formation of di- and tetra-nitrato complexes with decreasing water content, $[Pu(NO_3)_2(H_2O)_7]^{2+}$ and $[Pu(NO_3)_4(H_2O)_3]$, respectively, wherein each $[NO_3]^-$ acts as a bidentate ligand. At 13 M HNO_3, the Pu coordination sphere was fully dehydrated, consisting of a 12 O coordinate hexanitratro complex, $[Pu(NO_3)_6]^{2-}$, with an average Pu–O distance of 2.49 Å for the bidentate $[NO_3]^-$ bonds (Veirs *et al*., 1994; Allen *et al*., 1996b).

The discovery of significant oxygen hyperstoichiometry in the binary Pu^{4+}–O system, e.g., PuO_{2+x} for $0.0 \leq x \leq 0.27$ (Haschke *et al*., 2000), has sparked something of a revolution in the oxide chemistry of plutonium. Even though similar hyperstoichiometry is well-known and of considerable practical importance in the binary fluorite-type oxygen-excess uranium oxides, a similar situation was not recognized with plutonium oxides. It is only now clear that the fluorite lattice of PuO_2 ($Fm3m$) can accommodate excess O as well (Haschke *et al*., 2001; Haschke and Allen, 2002; Haschke and Oversby, 2002). Considerable international interest in the PuO_{2+x} system has arisen vis-à-vis actinide environmental science because of the possibility that the oxidized Pu ions, either Pu^{5+} and/or Pu^{6+} required for charge compensation, might be easily leached out of the otherwise water-insoluble PuO_2. Although the precise location of the excess O^{2-} in these materials is still open to question, the Pu L_3-edge X-ray absorption work (Conradson *et al*., 2003, 2004) provides valuable insights about the Pu valence and speciation. Most important, and contrary to initial suggestions (Haschke *et al*., 2000), the XANES and EXAFS "...results indicate that the excess O in PuO_2 occurs as localized Pu^{5+}–oxo moieties" with distances of 1.83–1.91 Å, and not as localized Pu^{6+} sites (Conradson *et al*., 2003). Also contrary to initial concern, the unusual stability of the PuO_{2+x} system suggests that the Pu^{5+} ions in the bulk solid of PuO_{2+x} may not have any higher solubility than the Pu^{4+} ions (Conradson *et al*., 2003). Still, many pieces of this new puzzle in plutonium chemistry remain, and until the time that additional definitive and conclusive evidence is reported, many of the issues opened up in the landmark publication (Haschke *et al*., 2000) will continue to fuel contemporary research interests.

(*v*) *Berkelium*(*IV/III*)

Of the trans-plutonium elements, only Bk has a comparatively stable, tetravalent aquo ion. Because of their spontaneous reactivity with water ($E^\circ > +2.6$ V), (Bratsch, 1989) the tetravalent aquo ions of Am, Cm, and Cf have, as yet, to be

stabilized for detailed physical, spectroscopic, and structure characterization. In comparison to the extensive volume of results for the aquo ions of Th, U, Np, and Pu (see Tables 28.2–28.5), there are significantly fewer metrical details about the coordination of water with the trans-plutonium elements (cf. Tables 28.2 to 28.6). For example, despite significant research in the years since the discovery of Bk in 1949, no direct structural information about the aquo ion of Bk^{4+} as well as that of Bk^{3+} was available until 2002. At that time, the simultaneous combination of XAS and electrochemical methods was used to probe the redox speciation of ^{249}Bk (Antonio *et al.*, 2002). Through use of *in situ* L_3-edge measurements of a dilute (0.47 mM) Bk solution in a non-complexing aqueous mineral acid electrolyte (1 M $HClO_4$) the inner-sphere hydration environments were found to undergo reorganization, with regard to the average Bk–OH_2 interatomic distances and the number of coordinated H_2O molecules, corresponding to controlled variation of redox state. Bk^{4+} was found to be eight-coordinate with an average Bk–O distance of 2.32(1) Å, whereas Bk^{3+} was found to be nine-coordinate with an average Bk–O distance of 2.43(2) Å. The change in hydration was shown to have a number of parallels with the well-recognized change between the aquo ions of the large, light trivalent lanthanide ions, e.g. La–Pm, and the small heavy ones, e.g. Tb–Lu (Habenschuss and Spedding, 1980; Cossy *et al.*, 1995).

(*vi*) *Curium*(III)

The trivalent aquo ions of ^{248}Cm and ^{249}Cf, the elements adjacent to Bk, have been independently investigated in HCl media through use of L_3-edge EXAFS. The spectrum for a 0.01 M solution of Cm^{3+} in 0.25 M HCl was fit to reveal 10.2 O at an average distance of 2.45 Å (Allen *et al.*, 2000). The single sinusoidal-like variation of the EXAFS data was interpreted to indicate an inner-sphere coordination of water molecules without interference from Cl^- complexation. No compelling evidence for inner-sphere Cm–$[Cl]^-$ interactions was obvious from the FT data and the curve-fitting results until surprisingly high LiCl concentrations, $\geq$ 8.7 M. Although the EXAFS data suggest that little chloride complexation occurs at low $[Cl^-]$ ($\sim$5 M or less), this absence of evidence may reflect, in part, general problems with the method itself concerning resolution and detection limitations of Cl backscattering in a dilute admixture of one (or more) chloro complex(es) in an aquo ion system.

(*vii*) *Californium*(III)

In the highest Z (98) EXAFS yet reported, a multinational effort on a dilute (0.007 M) solution of $^{249}Cf^{3+}$ in 1 M HCl led to the publication of two reports (David *et al.*, 1998; Revel *et al.*, 1999). The initial one (David *et al.*, 1998) contained metrical results from EXAFS analyses that revealed 9.5(9) O around

Cf^{3+} at an average distance of 2.44(1) Å. For ensuing calculations of the molecular radius of H_2O and comparison with that obtained from an ionic model, the authors selected 8.5 as the O coordination number, which is the value inferred from previous conductivity measurements (Fourest *et al.*, 1995) because the EXAFS-determined coordination number was "measured with insufficient accuracy." The second note (Revel *et al.*, 1999) contains, in addition to the $L_{1,2,3}$-edge Cf XANES data, the $k^3\chi(k)$ EXAFS curve-fitting results for a single shell of 8.5 ± 1.5 O atoms at 2.42(2) Å. It is not clear if the coordination number, which is described as an indicative value, was refined in the fitting procedure. Despite the concentration (1 M) of the HCl solution, there was no evidence for the formation of an inner-sphere chloro complex of Cf^{3+}. This result is consistent with the aforementioned EXAFS conclusions (Allen *et al.*, 2000) for Cm^{3+} in chloride media of < 5 M.

(*viii*) *Americium*(*III*)

The aquo ions of the trivalent actinides have been of particular interest for comparison with those of the trivalent lanthanides in order to address fundamental issues about the nature of An–O bonding, i.e. the comparative extent of 5f versus 4f orbital overlap with O orbitals. Because the ionic radius (IR) of Am^{3+} (1.09 Å for CN = 8) (Shannon, 1976) is intermediate of those for Nd^{3+} (1.109 Å) and Sm^{3+} (1.079 Å), this similarity facilitates direct comparisons of the coordination environments of the Am^{3+} aquo ion and the nine-coordinate Nd^{3+} and Sm^{3+} aquo ions. Although no metrical details were reported, the FT data obtained from the EXAFS for an Am^{3+} solution of unspecified concentration in 1 M $HClO_4$ indicate that the Am^{3+}–OH_2 bond distance for the pure aquo ion decreases slightly with the addition of Cl^-, suggesting a subtle reorganization of either of its inner- and/or outer-hydration sphere (Runde *et al.*, 1997). The results of the analysis of the EXAFS data for an Am^{3+} solution (also of unspecified concentration) in 1 M HCl were reported to reveal 9.5(9) O atoms at 2.51(1) Å (David *et al.*, 1998). For subsequent modeling and calculations of the molecular radius of H_2O, the coordination number of nine was selected largely on the basis of other indirect measurements (Fourest *et al.*, 1995). The L_3-edge EXAFS data of a 0.01 M solution of ^{243}Am in 0.25 M HCl were fit to show that the aquo ion has 10.2 O at 2.45 Å (Allen *et al.*, 2000). The O coordination number decreases to 8.9 and 6.4 at Cl^- concentrations of 8 and 12.5 M, respectively, as the number of Am–Cl interactions simultaneously grow in, reaching a maximum of ca. 2. Remarkably, there is essentially no effect on the Am–O interatomic distances, which range from 2.48–2.51 Å in no particular order with $[Cl^-]$, which is qualitatively different from the preliminary observations of Am^{3+} (Runde *et al.*, 1997).

(*ix*) *Uranium*(*III*)

The significant amount of work on the tripositive aquo ions of Np and Pu (Tables 28.4 and 28.5) stands in obvious contrast with the sole study of the U^{3+} aquo ion in 1 M HCl (David *et al.*, 1998; see Table 28.2). Although the concentration is not specified and despite the notorious instability of U^{3+} to oxidation upon contact with air, EXAFS data were acquired and analyzed to provide a coordination number of 8.7(9) and an average U–O distance of 2.56(1) Å, which sets the benchmark as the longest one of the entire An^{3+} series for which data are available. This result is consistent with the effects of the contraction of 5f-element IR with increasing Z, where near the beginning of the series, i.e. U^{3+}, the interatomic distances are longer than for those ions near the end of the series, for example Cf^{3+} mentioned above, which has a distance of 2.42–2.44 Å (David *et al.*, 1998; Revel *et al.*, 1999) for its aquo ion. Curiously, the experimental An^{3+}–O bond length variation between U ($Z=91$) and Cf ($Z=98$) of 0.12–0.14 Å is nearly twice (1.6 to 1.9 times) the difference between their ionic radii, 0.075 Å, for CN = 6.

Concurrent with the measurements of the U^{3+} aquo ion and in the same manner, EXAFS data were collected and analyzed for the aquo ions of Np^{3+} and Pu^{3+}, which were also of unspecified concentration in 1 M HCl and of considerable reactivity with respect to oxidation (David *et al.*, 1998). The metrical details were reported as, in order of Np^{3+} and Pu^{3+}, 9.8(9) O at 2.52 (1) Å and 9.9(9) O at 2.51(1) Å. As expected, both interatomic distances are within the aforementioned scale and, moreover, are near to that for U^{3+}–O. The collective results of David *et al.* (1998) indicate that the trivalent aquo ions of U, Np, Pu, Am, and Cf are either nine or ten-coordinate with O atoms of water molecules. For the most part, the results of the comparable studies of Tables 28.2 and 28.4–28.6 as discussed separately in sections above and below bear this out.

(*x*) *Neptunium*(*III*)

The *in situ* L_3 EXAFS data for the aquo ion of Np^{3+} (0.0047 M in 1 M $HClO_4$), in which the oxidation state was precisely maintained by electrochemical methods, were best fit with 9(1) O atoms at 2.48(2) Å (Antonio *et al.*, 2001). The corresponding results from density functional theory (DFT) methods, including relativistic effects, indicate that coordination numbers of either eight or nine lead to the most stable conformations. In addition, the coordination number calculated from a simple geometric model was eight. The combination of the EXAFS, DFT, and modeling results led to the conclusion that Np^{3+} has a coordination number of eight or nine in aqueous perchloric acid. The same conclusion was obtained for Np^{4+}. The 0.04 Å difference in the experimental, average Np^{3+}–O distances of 2.48(2) Å (Antonio *et al.*, 2001) and 2.52 Å (David *et al.*, 1998) may reflect the influence of the (1 M) chloride ion on the hydration sphere in the solution of the latter experiment. The perchlorate anion is known

to be significantly less interacting, essentially non-complexing, with cations than is Cl^- and, moreover, $[ClO_4]^-$–H_2O interactions are less well-defined than those for $[Cl]^-$–H_2O (Neilson *et al.*, 1985).

(*xi*) *Plutonium*(*III*)

The speciation of the Pu^{3+} aquo ion and the surprising results about the effects of Cl^- on the Pu hydration sphere were addressed in two provocative reports (Allen *et al.*, 1997, 2000). In the first, for a solution of 0.02 M $^{242}Pu^{3+}$ in dilute (0.01 M) LiCl at pH = 3, the L_2-edge EXAFS was best fit to show an environment that consisted of 10.2 ± 1 O at 2.51 Å. In the subsequent work, the value of the O coordination number was refined to 9.2 by use of a larger amplitude reduction factor than fixed previously. The independent investigation (David *et al.*, 1998) for an aqueous Pu^{3+} solution of unspecified concentration in 1 M HCl confirmed the original Pu–O distance exactly and, within the error of the measurement, the O coordination numbers too (see Table 28.5). A remarkable aspect of the results is that the Pu EXAFS "...showed no evidence for the formation of inner-sphere chloro complexes up to a Cl^- concentration of 12.3 M" (Allen *et al.*, 1997). Although the O coordination number was shown to decrease from 9.2 to 5.2 with increasing $[Cl^-]$, there was no systematic change in the Pu–O distance, which held constant at 2.50–2.51 Å. The apparent dehydration of the Pu^{3+} aquo ion was not simultaneously compensated by the addition of Cl^-, thereby leading to the formation of some type of coordinately unsaturated Pu^{3+} aquo ion in the 12.3 M $[Cl^-]$ medium. What seems odd about this behavior is the insensitivity of the Pu–O bond length to the significant change in O coordination number. The combination of this observation with the contradictory behavior noted for the effects of Cl^- on the aquo ions of Am^{3+} and Cm^{3+} presents something of a quandary. There is the possibility that the EXAFS method itself may be the source of inherently misleading information for this Pu^{3+} system, wherein, for example, the apparent absence of Pu–Cl backscattering and the reduction of the Pu–O backscattering arise from cancellation effects. The confluence of coincidental phase and amplitude differences relating to the O and Cl interatomic distances, their Debye–Waller factors, and their coordination numbers, may lead to a significant degree of destructive interference and, ultimately signal cancellation. Such problems with EXAFS have been noted beforehand with multi-shell systems (Antonio *et al.*, 1983; Goulon *et al.*, 1983; Martens *et al.*, 1985; Roehler, 1992; Zhang *et al.*, 1998). Whether it applies to the Pu^{3+} system described here is, of course, unknown and requires independent confirmation of the experimental results.

Two other associated EXAFS studies of the Pu^{3+} aquo ion provide experimental results, i.e. eight to nine O at 2.48–2.49 Å (Ankudinov *et al.*, 1998; Conradson, 1998) that are in reasonable accord with the aforementioned ones (see Table 28.5) obtained in chloride media. Although details about the composition of the Pu^{3+} specimen were not included in either report, the EXAFS data

are likely to have been collected on the very same sample, 0.10 M Pu^{3+} in the non-complexing aqueous mineral acid solution of 1 M $HClO_4$, from which the XANES was acquired (Conradson *et al.*, 1998). If true, the shorter bond lengths (2.48–2.49 Å) for the Pu^{3+} aquo ion in the perchlorate solution compared with that (2.51 Å) for the chloride-containing solutions are consistent with subtle differences in the hydration of Pu^{3+}. Additional studies would be beneficial in this regard. Nevertheless, all of the EXAFS metrical information (Allen *et al.*, 1997; Ankudinov *et al.*, 1998; Conradson, 1998; David *et al.*, 1998; Allen *et al.*, 2000) are in reasonable accord with the relativistic DFT investigation (Blaudeau *et al.*, 1999) showing that the first solvation shell of Pu^{3+} contains eight or possibly nine H_2O molecules with Pu–O bond lengths of 2.51–2.55 Å.

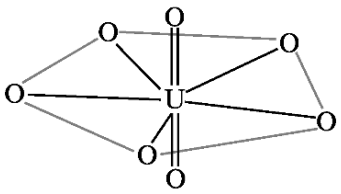
(b) The triatomic An(V) and An(VI) ions

Up to this point, the discussions have focused on the spherical, monatomic trivalent and tetravalent An ions involving only An–OH_2 bonding. We now turn attention to the penta- and hexavalent An ions, which in acidic aqueous solution invariably take the form of the linear, triatomic *trans*-dioxocations, $[O{=}An^{5+}{=}O]^{+}$ and $[O{=}An^{6+}{=}O]^{2+}$. In these so-called actinyl cations, the terminal O interactions with the An ions have double bond character as indicated and, moreover, the An ions are coordinately unsaturated. Their coordination spheres are completed by the complexation of H_2O molecules that encircle the An ions in an equatorial plane perpendicular to the axial O=An=O moiety. The exact degree of hydration of the actinyl cations $[AnO_2]^{+}$ and $[AnO_2]^{2+}$ has been the subject of decades-long study and debate. The extent that the results from An EXAFS experiments have provided insights into the structure of these hydrated ions is summarized below. Additional aspects of actinyl electronic properties and coordination in molecular complexes as probed by XAS have been reviewed elsewhere (Den Auwer *et al.*, 2003b).

(*i*) *Uranyl*(VI)

The aqueous uranyl ion, $[UO_2]^{2+}$, with formally hexavalent U is the most studied system, whereas its pentavalent homolog, $[UO_2]^{+}$ is the least studied because of its limited stability and susceptibility to disproportionation. Even before the first U EXAFS measurements were recorded with a laboratory spectrometer (Karim *et al.*, 1980), the consensus from a number of structural experiments was that, in the solid-state, the $[UO_2]^{2+}$ ion exhibits a preference for five equatorial ligands thereby forming a pentagonal bipyramid (Evans, 1963). More contemporary compilations of structural data bear this out (Burns *et al.*, 1997). In the solid-state, the pentagonal bipyramidal polyhedron of $[UO_2]^{2+}$ is more common than either of the square or hexagonal bipyramidal coordination polyhedra. From the survey of solution EXAFS results presented in Table 28.2, the consensus is clear. The *trans*-dioxo $[UO_2]^{2+}$ cation exists in acidic aqueous

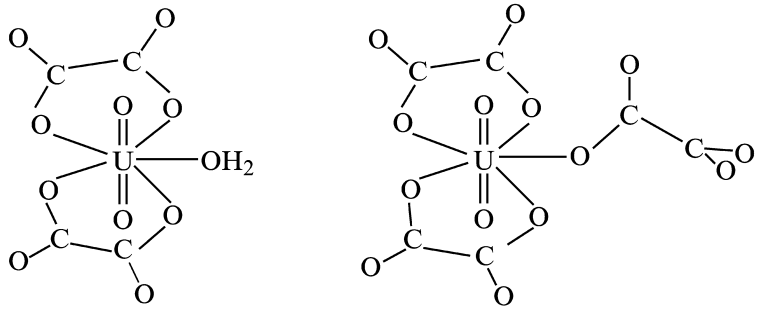
solution just as it does in the solid-state and that it has a hydration number of five. It is generally assumed that the U coordination geometry in dilute (<0.25 M) solutions is the same as that in the solid-state with an equatorial arrangement of five H_2O molecules between the two axial O atoms, wherein U^{6+} is seven-coordinate in the form of a pentagonal bipyramid, which is illustrated below. The selection of results shown in Table 28.2 from a number of theoretical calculations and other spectroscopic measurements are in agreement about the structure of the $[UO_2]^{2+} \cdot 5H_2O$ aquo ion.



For the uranyl cation, the EXAFS-determined axial U=O distances of Table 28.2, 1.75–1.78 Å, have a small (0.03 Å) dispersion, and are essentially independent of differences in experimental conditions. By comparison, the 1.702(5) Å U=O bond length obtained for a concentrated (1 M) $[UO_2]^{2+}$ solution through use of X-ray scattering is anomalously short (Aberg *et al.*, 1983). The bond length dispersion is more than twice as large (0.08 Å) for the EXAFS-determined U–OH_2 distances, which for the synchrotron radiation studies exhibit a range of 2.40–2.48 Å. This suggests that the equatorial hydration of $[UO_2]^{2+}$ is sensitive to experimental variations, such as pH as well as the nature and concentration of the anion in the inorganic and organic acids.

To address aspects of these issues, an exhaustive series of U L_3-edge EXAFS measurements have demonstrated that the perchlorate anion does not coordinate directly to the $[UO_2]^{2+} \cdot 5H_2O$ aquo cation even in 11.5 M $HClO_4$ (Sémon *et al.*, 2001). The average, equatorial U–OH_2 distances (2.40–2.43 Å) for the $[UO_2]^{2+}$ aquo ions in perchloric acid are independent of concentration, and are at the short end of the range of distances for the mineral acid aquo ion systems of Table 28.2. In contrast, the systematic U L_3 EXAFS studies of the $[UO_2]^{2+}$ ion in 0–10 M solution concentrations of HCl reveal inner-sphere Cl^- complexation at and above 4 M, which is accompanied by expansion of the U–OH_2 bond lengths (Allen *et al.*, 1997). The total equatorial coordination number remained constant at five, suggesting a simple replacement of H_2O with Cl^- as the concentration of HCl increased. Subsequent treatments of the ten EXAFS spectra in the $[Cl^-]$ series through principal component (factor) analysis revealed the presence of three distinct species (Wasserman *et al.*, 1999). Two of these reflect the inner-sphere replacement of H_2O by Cl^- at the equatorial position in the 1–10 M HCl solutions. The third species, significant only for the $[UO_2]^{2+}$ ion in 12 and 14 M solutions of LiCl, was attributed to a product resulting from the use of the Dowex anion-exchange resin for the preparative chemistry.

In acidic solutions (pH ≈ 5) of 0.052 M $[UO_2]^{2+}$ with excess fluoride ion (0.21 and 0.45 M), the equatorial coordination number was also found to be five, consisting of a combination of U–F and U–OH_2 interactions that were not resolved in the FT data (Vallet *et al.*, 2001). The F^- and H_2O coordination numbers were determined from the combined results of equilibrium measurements and the U L_3-edge EXAFS analysis to reveal tri- and tetrafluoride complexation, $[UO_2F_3(H_2O)_2]^-$ and $[UO_2F_4(H_2O)]^{2-}$, with average U–F and U–OH_2 distances of 2.25–2.26 and 2.47–2.48 Å, respectively. At 3 M [F^-], water does not participate in the equatorial coordination, which was shown to consist of five F^- anions at 2.26 Å, of the uranyl(VI) pentafluoride complex, $[UO_2F_5]^{3-}$ (Vallet *et al.*, 2001). Solution EXAFS and quantum chemical methods have been brought to bear upon the nature of aqueous uranyl(VI) complexes with fluoride and oxalate, $[C_2O_4]^{2-}$, ligands (Vallet *et al.*, 2003). At pH = 4.2 in the absence of F^-, the equatorial bonding in the $[UO_2(O_2C_2O_2)_2H_2O]^{2-}$ complex was determined to consist of five O atoms of which four are attributable to the two symmetric oxalate ligands, wherein each carboxylate group chelates to U in a monodentate fashion with one O, and the fifth is from H_2O. In this molecular complex, whose structure is illustrated below (left), the average equatorial U–O distance is 2.38 Å. Upon the addition of F^- at a concentration slightly in excess of that (0.06 M) for $[UO_2]^{2+}$, the fluoride ion displaces the water molecule without any effect on the nature of the oxalate chelation, thereby maintaining the five-coordinate equatorial ligation, $[UO_2(O_2C_2O_2)_2F]^{3-}$. With excess (1.68 M) oxalate at pH = 6.5, a five-coordinate complex with three oxalate ligands, $[UO_2(O_2C_2O_2)_3]^{4-}$, is formed. In this structure (illustrated below, right) two of the oxalates are chelate-bonded exactly as in the aquo and fluoride complexes and the third is bound to U through a single carboxylate O.



The early EXAFS experiments indicated that the dissolution of solid uranyl nitrate, $UO_2(NO_3)_2 \cdot 6H_2O$, and sodium uranyl acetate, $NaUO_2(CH_3CO_2)_3$, at concentrations of 0.25 M and less in acidic media leads to their complete dissociation and formation of the pentahydrate aquo ion, $[UO_2]^{2+} \cdot 5H_2O$ (Charpin *et al.*, 1985). In subsequent concentration- and temperature-dependent U L_3-edge EXAFS measurements (Schofield *et al.*, 1999), no evidence was found for equatorial ligand replacement of H_2O with $[NO_3]^-$ in acidic solutions of 1 M nitrate and less at 150°C and below. In related *in situ*,

temperature-dependent U L_3-edge EXAFS studies of the uranyl ion speciation in acidic acetate solutions with different concentration ratios, $[CH_3CO_2^-]$: $[UO_2^{2-}]$, (Mosselmans *et al.*, 2001), little direct evidence was apparent in the FT data for $[CH_3CO_2]^-$ coordination to the pentahydrate $[UO_2]^{2+}$ cation at low ratios. Whereas the equatorial coordination number was also found to be five at high ratios, the evidence for distant U–C backscattering suggests the coordination of at least two bidentate acetate ligands even at temperatures as high as 250°C. The presence of one H_2O molecule is presumed to complete the equatorial O coordination in a neutral aquo species, $[UO_2(CH_3CO_2)_2H_2O]$.

For the binary, aqueous $[UO_2]^{2+}$–$[SO_4]^{2-}$ system in acidic solution pH$\leq$2, bidentate O coordination of the sulfate ligand to $[UO_2]^{2+}$ was evident through observation of distant S backscattering in the U L_3-edge EXAFS data for each of two solution species identified as UO_2SO_4(aq) and $[UO_2(SO_4)_2]^{2-}$ in the equilibrium distribution diagram (Moll *et al.*, 2000a). Both were shown to have an equatorial O coordination number of five, meaning that in addition to the two O atoms from the bidentate $[SO_4]^{2-}$ groups, the former has three H_2O molecules, i.e. $[UO_2SO_4(H_2O)_3]$, and the latter has one H_2O molecule, i.e. $[UO_2(SO_4)_2H_2O]^{2-}$, in the inner-sphere equatorial coordination environment of $[UO_2]^{2+}$. At the higher pH of 5.25, obtained by adjustment with NaOH, the EXAFS metrical results showing bidentate sulfate chelation in the $[UO_2]^{2+}$–$[SO_4]^{2-}$–$[OH]^-$ system were used to verify the previously proposed structure models for the tri- and pentanuclear complex anions, $[(UO_2)_3O(OH)_2(SO_4)_3(H_2O)_2]^{4-}$ and $[(UO_2)_5O_3(OH)_2(SO_4)_4(H_2O)_2]^{6-}$, respectively. For a related sulfur-bearing oxoanion in acidic aqueous solutions, the triflate anion, $[CF_3SO_3]^-$, was found to act as a monodentate ligand by inner-sphere coordination to U through one O atom at high (>8 M) concentrations of the anion (Sémon *et al.*, 2001). The total equatorial O coordination number is approximately five, suggesting the displacement of one H_2O molecule from the pentahydrate aquo species and the formation of $[UO_2(CF_3SO_3)_1(H_2O)_4]^+$.

(*ii*) *Neptunyl*(*v*)

Although there are, as yet, no experimental structural details for the aqueous uranyl ion of U^{5+}, $[UO_2]^+$, the calculated structure (Hay *et al.*, 2000) using DFT methods is, not surprisingly, a pentagonal bipyramid with U=O and U–OH_2 bond lengths of 1.810 and 2.616 Å, respectively. Unlike U, the most stable form of Np in acidic aqueous solution is the pentavalent neptunyl ion, $[NpO_2]^+ \cdot n''H_2O$. It can be conveniently and reversibly interconverted to the hexavalent form, $[NpO_2]^{2+} \cdot n'''H_2O$, by electrochemical means, suggesting that the one-electron redox reaction is either independent of possible differences in the hydration of Np or, alternatively, that the hydration numbers n'' and n''' for $[Np^{5+}O_2]^+$ and $[Np^{6+}O_2]^{2+}$, respectively, are equivalent. This has been an issue of some controversy since the 1970s, when original work involving NMR

studies of perchlorate salt solutions of $[NpO_2]^{2+}$ was interpreted to provide a mean number of six-coordinated water molecules (Shcherbakov *et al.*, 1974; Mashirov *et al.*, 1975; Shcherbakov and Iorga, 1975). Similarly, based upon ^1H NMR experiments, a hydration number of six was proposed for $[NpO_2]^+$ (Glebov *et al.*, 1977). Recent interpretations of electronic absorption spectra suggest that the hydration number for both neptunyl species, $[NpO_2]^+$ and $[NpO_2]^{2+}$, is five and, furthermore, that their coordination polyhedra are pentagonal bipyramids (Garnov *et al.*, 1996). This interpretation is consistent with the accepted coordination of the pentahydrate, hexavalent uranyl ion, $[UO_2]^{2+} \cdot 5H_2O$.

As shown in Table 28.4, the first Np L_3-edge EXAFS brought to bear upon the $[NpO_2]^+ \cdot n''H_2O$ ion indicated that $^{237}Np^{5+}$ has an equatorial coordination of five H_2O molecules at 2.52(2) Å (Combes *et al.*, 1992). Two subsequent, independent EXAFS investigations (Allen *et al.*, 1997; Antonio *et al.*, 2001) as well as the results from two theoretical calculations (Hay *et al.*, 2000; Tsushima and Suzuki, 2000) confirmed the hydration number of five. A lower value of four H_2O molecules was extracted from the analysis of the EXAFS data for an aqueous solution of 0.05 M $[NpO_2]^+$ in 0.1 M HNO_3, the sole exception (Reich *et al.*, 2000). Although the exact reasons for the variance are not known, the complex hydrolytic behavior of Np^{5+}, particularly at pH $\approx$ 1, might have some bearing upon this as well as the unusually large (0.08 Å) range of average interatomic distances, 2.44–2.52 Å, involving the equatorial coordination of water molecules. Alternatively, it may suggest that the hydration sphere of $[NpO_2]^+$ has substantial sensitivity to experimental conditions, such as pH, counter-anion, ionic strength, etc., whereas the axial Np=O interactions (1.80–1.85 Å) are less sensitive. In either case, complicating chemical behaviors, e.g. hydrolysis, disproportionation, complexation, oligomerization, precipitation, etc., are generally suppressed in a highly acidic (pH $\approx$ 0) non-complexing perchloric acid medium. The EXAFS experimental conditions cover a range of pH values starting from effectively 0 in 1 M $HClO_4$ (Antonio *et al.*, 2001) to pH $\approx$ 1 in 0.1 M HNO_3 (Reich *et al.*, 2000), to pH $\approx$ 2 in perchloric acid (Combes *et al.*, 1992) and, finally, to pH $\approx$ 3 in hydrochloric acid with excess (3 M) chloride as LiCl (Allen *et al.*, 1997). At Cl^- concentrations of ca. 6 M and above, the equatorial coordination number remains constant at five, but whereas one (or more) Cl^- ions displace and replace an equal number of H_2O molecules about $[NpO_2]^+$ (Allen *et al.*, 1997). This is accompanied by an elongation of the Np–OH_2 bond lengths.

(*iii*) *Neptunyl*(*VI*)

The two independent Np L_3-edge EXAFS studies (Reich *et al.*, 2000; Antonio *et al.*, 2001) and the two independent theoretical studies (Hay *et al.*, 2000; Tsushima and Suzuki, 2000) of the hexavalent neptunyl ion are in consensus

about the hydration number (five). The EXAFS results reveal axial Np=O bond lengths (1.73–1.75 Å) and equatorial Np–OH_2 bond lengths (2.36–2.41 Å) that are consistently shorter (ca. 0.03–0.16 Å) than the corresponding interactions for the pentavalent neptunyl aquo ion $[NpO_2]^+ \cdot 5H_2O$. The shorter bond distances for the hexavalent species $[NpO_2]^{2+} \cdot 5H_2O$ are consistent with the expected decrease in the Np IR with increasing oxidation state. The well-known ionic radii (IR) tabulations of Shannon (1976) are limited to the comparison between Np^{5+} (0.75 Å) and Np^{6+} (0.72 Å) for CN = 6. The 0.03 Å difference is considerably smaller than the corresponding IR contraction of 0.14 Å between Np^{3+} (1.01 Å) and Np^{4+} (0.87 Å), which is clearly borne out in the Np–OH_2 distances of Table 28.4 for the $Np^{3+} \cdot nH_2O$ and $Np^{4+} \cdot n'H_2O$ systems. The absence of experimental detail for the pentavalent uranyl aquo ion prevents the analogous metrical comparisons between it and the hexavalent uranyl aquo ion. Because the Pu aquo system has stable pentavalent and hexavalent plutonyl ions, additional comparisons, both absolute and relative, can be drawn with regard to the data of Table 28.5.

(*iv*) *Plutonyl*(*VI/V*)

Two reports of Pu L_3-edge EXAFS measurements (Ankudinov *et al.*, 1998; Conradson, 1998) constitute the full extent of experimental investigation of the $[Pu^{5+}O_2]^+ \cdot n''H_2O$ system and the majority of that for $[Pu^{6+}O_2]^{2+} \cdot n'''H_2O$. For plutonyl(V), the curve-fitting analysis furnished axial Pu=O bond lengths of 1.81–1.84 Å and an equatorial coordination number of four with Pu–OH_2 bond lengths of 2.45–2.47 Å. This hydration number (four) stands in contrast to that (five) obtained from the results of two different levels of calculation with DFT (Hay *et al.*, 2000) and Hartree–Fock (Tsushima and Suzuki, 2000) methods. The theoretical investigations of the hexavalent plutonyl aquo ion reach the same conclusion, namely that $[PuO_2]^{2+}$ forms the most stable and strongly bound complexes with five H_2O molecules in the equatorial coordination (Spencer *et al.*, 1999; Hay *et al.*, 2000; Tsushima and Suzuki, 2000). Whereas the optical spectroscopy (Garnov *et al.*, 1996) and the early EXAFS experiments (Runde *et al.*, 1997) are in agreement, showing an O coordination number of five, the later EXAFS work (Ankudinov *et al.*, 1998; Conradson, 1998) provides an O coordination number of six. The fact that the average Pu–OH_2 distances of 2.45 Å (Runde *et al.*, 1997) for the pentahydrate plutonyl(VI) and 2.40–2.45 Å (Ankudinov *et al.*, 1998; Conradson, 1998) for the hexahydrate plutonyl(VI) species are overlapping despite the unit difference in hydration number remains something of a quandary. In strongly acidic (1 M $HClO_4$ and 1 M HCl) $[PuO_2]^{2+}$ solutions with aqueous chloride concentrations of 5 M and above, Pu EXAFS data reveal the formation of plutonyl(VI) chloro complexes, wherein some number of inner-sphere H_2O are replaced by Cl^- ions (Runde *et al.*, 1997). Although the exact extent of the

Cl^- substitution was not determined, the effects include a weakening and elongation (0.01 to 0.06 Å) of the remaining equatorial Pu–OH_2 interactions as well as the axial Pu=O bonds.

According to the data of Table 28.5, the axial Pu–O interatomic distance contraction between the plutonyl(v) and (vi) aquo ions amounts to 0.06–0.10 Å. This is more than twice that expected based upon the difference in the Pu^{5+} (0.74 Å) and Pu^{6+} (0.71 Å) IR for CN=6 (Shannon, 1976). As mentioned previously, the same phenomenon was observed for the neptunyl(v) and (vi) aquo ions. This behavior is to be contrasted with that between the aquo ions of Pu^{3+} and Pu^{4+}, which exhibit a 0.09–0.12 Å Pu–OH_2 interatomic distance contraction that is consistent in magnitude with the 0.14 Å difference of IR for CN = 6. In view of the apparent difference in the equatorial coordination number between $[PuO_2]^+$ and $[PuO_2]^{2+}$, it is difficult to ascribe any significance to the 0.0–0.07 Å difference between the Pu–OH_2 distances of Table 28.5. Comparisons with corresponding Am species, $[AmO_2]^+$ and $[AmO_2]^{2+}$, would be informative but are not possible because of the present lack of metrical information for these two aquo ions.

28.2.3 Base redox speciation

The aqueous actinide chemistry of the four oxidation states – iii, iv, v, and vi – described above for acidic solutions have been complemented by studies, albeit far fewer in number, of the same four states plus the heptavalent (vii) one in alkaline and carbonate solutions (Shilov and Yusov, 2002). In particular, the An^{7+} ions of Np, Pu, and Am are extremely unstable species under all but the most alkaline of conditions. Concentrated carbonate solutions too have been shown to facilitate studies of the otherwise unstable Am^{4+}, Cf^{5+}, and Cm^{6+} ions. Aspects of An redox speciation in hydroxide and carbonate media as obtained by use of EXAFS spectroscopy are surveyed in this section.

(a) Hydroxide solution systems

(*i*) *Neptunium*(*vii/vi*)

A longstanding problem in actinide science about the nature of the Np^{7+} species in aqueous, basic solutions was resolved through use of EXAFS and quantum chemistry. Since the first report of its preparation (Krot and Gelman, 1967), the coordination environment of Np^{7+} has remained controversial, in part because of the technical difficulties associated with the stabilization of the high-valent ion. The existence of an anionic species of Np^{7+} in alkaline solution was proposed early on (Spitsyn *et al.*, 1969), "...and its formula is believed by most researchers to be NpO_5^{3-}" (Fahey, 1986). Still, equally probable trianionic

forms include $[NpO_4(OH)_2]^{3-}$ (Burns *et al.*, 1973) and $[NpO_2(OH)_6]^{3-}$, among others. In order to address this speciation issue, Np L_3-edge EXAFS was brought to bear upon a 0.03 M solution of Np^{7+} in 2.5 M NaOH prepared by ozonation of the neptunyl(VI) hydroxide, $NpO_2(OH)_2$ (Clark *et al.*, 1997). The analysis provided evidence for a linear, *trans*-dioxo species of Np^{7+}, which has an overall pentagonal bipyramidal coordination consisting of the two axial O atoms at 1.85(2) Å and five equatorial O atoms attributed to four OH^- at 2.18(3) Å and one H_2O at 2.43(3) Å. This environment is consistent with the formation of a monoanionic neptunyl(VII) species, $[NpO_2(OH)_4(H_2O)]^-$, whose coordination polyhedron is similar, albeit with different Np–O distances, to those for the *bona fide* dioxo species of $[Np^{5+}O_2]^+$ and $[Np^{6+}O_2]^{2+}$ that are ubiquitous in acid solution.

In contrast, two subsequent Np EXAFS and DFT studies (Bolvin *et al.*, 2001; Williams *et al.*, 2001) of the coordination geometry of Np^{7+} in alkaline solution came to the conclusion that Np^{7+} has a tetraoxo square planar coordination environment. The presence of two distant, axial O atoms, presumably hydroxide ligands, completes the coordination sphere, which has a square bipyramid structure. In one study (Williams *et al.*, 2001), bulk electrolysis techniques in simultaneous combination with ozonation were utilized to control the Np valence in a freshly prepared suspension of Np^{5+} (0.0065 M) in 1 M NaOH for *in situ* Np L_3-edge EXAFS of the Np^{7+} and Np^{6+} ions, whose electrochemical interconversion is facile (Zielen and Cohen, 1970). The Np^{6+} EXAFS was fit to reveal a typical *trans*-dioxo species with two close, axial O atoms at 1.82(2) Å and an equatorial coordination of four distant O atoms at 2.21(3) Å, in what would likely be a square bipyramidal polyhedron, $[NpO_2(OH)_4]^{2-}$. Geometry optimizations at the B3LYP level using a CPCM solvent model confirm this neptunyl(VI) structure and stoichiometry (Bolvin *et al.*, 2001). In contrast, the Np^{7+} EXAFS was fit to reveal four close O atoms at 1.87(1) Å and two distant ones at 2.24(4) Å, consistent with a polyhedron that could also be a square bipyramid. The accompanying DFT calculations predicted a slightly distorted square-planar geometry for the tetraoxo, $[NpO_4]^-$, anion (Williams *et al.*, 2001). The geometry was further elucidated at the DFT level using the hybrid functional B3LYP and a CPCM solvent model to reveal a six-coordinate Np^{7+} in the square bipyramid polyhedron, $[NpO_4(OH)_2]^{3-}$ (Bolvin *et al.*, 2001). The associated Np L_3-edge EXAFS acquisition and analysis for a solution of Np^{7+} (0.015 M) in 2.5 M NaOH revealed a coordination of 3.6 ± 0.3 O atoms at 1.89 Å and 3.3 ± 1.3 O atoms at 2.33 Å. The large error on the distant O coordination number was attributed to the low backscattering amplitude and the interference from the four close O atoms. From the combination of theoretical results and experimental data (including solid-state structural and solution electrochemical information) (Shilov, 1998), it was concluded "...that the predominant Np(VII) complex found in solutions with high concentration of OH^- is indeed $NpO_4(OH)_2^{3-}$" (Bolvin *et al.*, 2001).

(*ii*) *Plutonium*(*VII/VI*)

Although no EXAFS results have been published about the corresponding Pu^{7+}/Pu^{6+} and Am^{7+}/Am^{6+} redox speciation in alkaline solutions, the plutonium electrochemical behavior as a function of hydroxide ion activity is very much like that for neptunium, except for the more positive electrode potentials for Pu (Shilov, 1998). This suggests that the six O, tetragonal bipyramidal coordination environments for both Np^{7+} and Np^{6+} are likely to be obtained for the corresponding Pu species. In these, the absence of a substantial structural rearrangement between the hexa- and heptavalent species would explain the reversible and generally facile redox reaction:

$$[An^{7+}O_4(OH)_2]^{3-} + 2H_2O + e^- \leftrightarrow [An^{6+}O_2(OH)_4]^{2-} + 2OH^- \qquad (28.10)$$

The formulas shown in this equation are presently accepted by actinide electroanalytical chemists in general (for An ≡ Np, Pu, and Am) and this An^{7+}/An^{6+} redox speciation appears, exactly as written, in contemporary compilations of standard electrode potentials (Bratsch, 1989). The estimated potential for the Pu^{8+}/Pu^{7+} couple (>3V) (Shilov and Yusov, 2002) is well beyond the polarization window of aqueous solutions. The existence of Pu^{8+} will have to be confirmed in other solvents, such as newly designed ionic liquids with immense (ca. 5V) polarization windows (Quinn *et al.*, 2002), or in the solid-state.

(*iii*) *Uranyl*(*VI*)

Because of practical and technological issues in nuclear waste storage and processing, the speciation and structure of U^{6+} complexes in strongly alkaline solutions has been investigated with U L_3-edge EXAFS, quantum chemical calculations, and other spectroscopic and physical methods (Moll *et al.*, 1998; Schreckenbach *et al.*, 1998; Clark *et al.*, 1999; Wahlgren *et al.*, 1999; Moll *et al.*, 2000b; Vallet *et al.*, 2001). Driven by implications of serious environmental concern, i.e. aging tanks of alkaline high-level waste, the original work (Clark *et al.*, 1999) on $[UO_2]^{2+}$ (≈0.10 M) in a 3.5 M tetramethylammonium hydroxide, $[(CH_3)_4N]OH$, solution sparked interest of theoretical, applied, and fundamental importance. The FT data revealed a single asymmetric peak, which was shown to include backscattering contributions from axial and equatorial O coordination. The $k^3\chi(k)$ EXAFS was fit to expose two nearest O atoms at 1.79(1) Å, attributed to axial U=O bonding, and 5.2(5) O atoms at 2.22(1) Å, attributed to equatorial U–OH bonding. This seven O pentagonal bipyramidal coordination of U^{6+} is not unusual on its own and, except for the relatively long and short axial and equatorial bonds, respectively, it is the prevalent structure in acid solution. Yet, comparison of the solution environment with that for the solid uranyl(VI) salt, $[Co(NH_3)_6]_2[UO_2(OH)_4]_3 \cdot H_2O$, crystallized from 3.5 M $[(CH_3)_4N]OH$ revealed unexpected detail that has been the source of multinational debate. The single-crystal structure shows a six O pseudo-octahedral

coordination of U^{6+} with two *trans*-oxo atoms at 1.82(1) Å and four OH^- ligands at 2.26(2) Å. The corresponding EXAFS data for the crystalline compound, collected and analyzed in the same manner as for the solution sample, are in agreement with the X-ray diffraction data. The $k^3\chi(k)$ EXAFS were best fit with two O atoms with an average U=O distance of 1.81(1) Å and 3.9(5) O atoms with an average U–O distance of 2.21(1) Å (Clark *et al.*, 1999). The pivotal difference between the solid and solution structures is the OH^- coordination number, which is four in the solid and five in solution.

Although such differences in coordination upon dissolution of a solid are not extraordinary, the remarkable aspect here is the observation of essentially identical, within experimental error, average U=O and U–OH distances despite the coordination number difference in the solution (7) and solid (6) uranyl hydroxide complexes. Based upon a comparison of the U^{6+} IR for CN=6 and 7 (0.73 and 0.81 Å, respectively) (Shannon, 1976), the U–O distances for the seven-coordinate solution sample are anticipated to be 0.08 Å longer than those for the corresponding six-coordinate solid sample. An expansion of this magnitude is not evident, suggesting that a simple ionic, electrostatic model of the U=O and U–OH interactions is inappropriate for these systems. Alternatively, it may be an indication of some degree of covalency and the participation of f-electrons in the U–O bonding, or that the solution coordination number is in error because of, for example, the effects of an equilibrium distribution of two monomeric uranyl(VI) species, a pentahydroxide, $[UO_2(OH)_5]^{3-}$, and a tetrahydroxide, $[UO_2(OH)_4]^{2-}$ (Clark *et al.*, 1999). These intriguing results, in particular, the equatorial coordination number (5) in highly alkaline solution conditions, have been experimentally confirmed through EXAFS (Moll *et al.*, 1998; Wahlgren *et al.*, 1999). Yet, remarkably, and as developed below, the EXAFS-determined value was set aside in favor of that (4) from bond length comparisons and theoretical and geometrical optimizations.

Uranium L_3-edge EXAFS was used to elucidate the coordination of $[UO_2]^{2+}$ (0.055 M) in solutions of $[(CH_3)_4N]OH$. The results obtained from the curve-fitting analyses are indistinguishable and reveal two axial O atoms at 1.82 Å as well as 5.0 ± 0.5 and 5.2 ± 0.5 equatorial O atoms at 2.24 Å in 1 and 3 M $[(CH_3)_4N]OH$, respectively (Moll *et al.*, 1998; Wahlgren *et al.*, 1999). This latter coordination number was subsequently reevaluated to be 4.6 ± 0.6 (Moll *et al.*, 2000b). A number of factors combine to cast doubt on the EXAFS result for the equatorial coordination number, including the general difficulty and large uncertainty associated with such determinations for uranyl complexes at ambient temperature. (Thompson *et al.*, 1995, 1997; Barnes *et al.*, 2000) Insofar as bond lengths generally increase with coordination number (Shannon, 1976), it is also peculiar that the average U–OH distance (2.24 Å) for a purportedly five-coordinate hydroxo anion of $[UO_2]^{2+}$ in solution is the same as that (2.26(2) Å) for the four OH^--coordinated $[UO_2]^{2+}$ complex anion, $[UO_2(OH)_4]^{2-}$, in a crystallographically characterized solid (Clark *et al.*, 1999). Despite the higher coordination number indicated by the EXAFS data, it was concluded "...that

the coordination number of uranyl(VI) ion in strongly alkaline solution is four, not five. . .'' and that the mononuclear, tetrahydroxide species, $[UO_2(OH)_4]^{2-}$, is the dominant complex in strongly alkaline solutions (Wahlgren *et al.*, 1999). This suggestion was corroborated by the results of geometry optimizations obtained through a number of *ab initio* quantum chemical calculations (Moll *et al.*, 1998; Schreckenbach *et al.*, 1998; Wahlgren *et al.*, 1999; Vallet *et al.*, 2001).

At the time of this publication, issues about the form of $[UO_2]^{2+}$ in alkaline solution were most recently revisited with regard, again, to its speciation in 0.5 and 3 M $[(CH_3)_4N]OH$ by use of U L_3-edge EXAFS and ^{17}O NMR (Moll *et al.*, 2000b). The results serve to resolve, in part, the controversy generated by the watershed report (Clark *et al.*, 1999), whose experimental evidence indicated the formation of a pentahydroxide species, and the approximately coincident work (Wahlgren *et al.*, 1999), whose evidence was interpreted in favor of a tetrahydroxide species. The latest research has found evidence for the latter, $[UO_2(OH)_4]^{2-}$, species from the primary EXAFS analysis of data obtained in a dilute (0.05 M) solution of $[UO_2]^{2+}$ in 0.5 M $[(CH_3)_4N]OH$ at pH = 13.7 (Moll *et al.*, 2000b). The pseudo-octahedral environment of U^{6+} was shown to consist of 1.8 ± 0.3 O atoms at 1.83 Å and 4.2 ± 0.6 O atoms at 2.26 Å. In the concentrated, 3 M solution of $[(CH_3)_4N]OH$ of the original studies (Clark *et al.*, 1999), the presence of a fifth OH^- ligand in association with $[UO_2(OH)_4]^{2-}$ was unambiguously established by use of ^{17}O NMR (Wahlgren *et al.*, 1999). A $[UO_2(OH)_5]^{3-}/[UO_2(OH)_4]^{2-}$ ratio of ≈ 0.3 in a 3 M solution of $[(CH_3)_4N]OH$ was calculated based upon an estimation of the equilibrium constant for the aqueous reaction,

$$[UO_2(OH)_4]^{2-} + OH^- \leftrightarrow [UO_2(OH)_5]^{3-} \qquad (28.11)$$

The EXAFS results for this mixture of solution species provide a site-averaged coordination environment of 1.8 ± 0.3 O at 1.83 Å and 4.6 ± 0.6 O at 2.25 Å (Wahlgren *et al.*, 1999).

Since the publication of the results from the pioneering X-ray scattering experimentation (Aberg, 1970; Musikas and Narten, 1978), metrical details about the solution structures of polynuclear hydrolysis products of uranyl(VI) have been few and far between. At least, there is a dearth of EXAFS research, other than the investigation of an acidic solution (pH = 4.1) of dilute (0.05 M) $[UO_2]^{2+}$ in 0.05 M $[(CH_3)_4N]OH$ (Moll *et al.*, 2000b). In these conditions, the formation of the triangular, trinuclear complex, $[(UO_2)_3(OH)_5]^+$, was confirmed on the basis of the 3.80 Å U–U interatomic distance. The U coordination number for a pure specimen of this trinuclear hydrolysis complex is two. The lower, EXAFS-determined values of $1.3–1.4\pm0.4$ are consistent with an admixture of the trinuclear complex and the binuclear one, $[(UO_2)_2(OH)_2]^{2+}$, whose structure has been optimized at several levels of theory (Tsushima and Reich, 2001) and which is presumed to have the core structure of the solid-state hydroxo compound $[(UO_2)_2(OH)_2Cl_2(H_2O)_4]$, with a U coordination number of one and a U–U interatomic distance of 3.94 Å (Aberg, 1970).

The EXAFS-measured distribution of equatorial U–O interactions, which involve a combination of bridging as well as terminal oxo and hydroxide ligation and bond lengths, are also consistent with a mixed speciation of polynuclear complexes. The site- and species-averaged, axial U=O bond length of the uranyl ion was 1.79 Å (Moll *et al.*, 2000b).

(*iv*) *Thorium*(IV)

The hydrolysis of the tetravalent actinides leads to a complicated distribution of species with different degrees of aggregation, the exact extent of which hinges upon the solution conditions (Neck and Kim, 2001). For example, even below the onset of oligomerization, in the narrow (2 unit) pH range of 3–5, the calculated Th^{4+} speciation already indicates appreciable amounts of bi- and tetranuclear species, such as $[Th_2(OH)_2]^{6+}$ and $[Th_4(OH)_8]^{8+}$, in addition to the mononuclear ones, e.g. $[Th(OH)]^{3+}$, $[Th(OH)_2]^{2+}$, $[Th(OH)_3]^{+}$ (Neck *et al.*, 2002). In view of the complexity for such an assortment of multi-site, polynuclear complexation, the use of EXAFS for studies of the aqueous speciation of suspended colloids above the onset of hydrolysis has been limited. The available studies concern the use of Th L_3-edge EXAFS for coulometrically titrated solutions (pH = 1.38–3.67) of 0.0043–0.028 M Th^{4+} in 0.5 M NaCl (Neck *et al.*, 2002; Rothe *et al.*, 2002). The FT data for the aqueous solutions of pH $\leq$ 3 (below the onset of colloid formation) exhibit a strong, nearly symmetric peak due to O backscattering, fit as 11.6–12.7 O at 2.45–2.46 Å, that is typical of the Th^{4+} aquo ion. In contrast, the FT data for the aqueous suspension of colloidal species at pH = 3.50 and 3.62 exhibit a weak, highly asymmetric peak due to O backscattering, fit as 10.5–10.6 O at 2.51 Å, that is expected for a broad distribution of Th–O interactions arising from the presence of a mixture of ultrafine (i.e. nanosize), polynuclear species and amorphous Th^{4+} colloids. The EXAFS data for the aqueous suspension at pH = 3.67 also reveals a weak, distant peak attributed to Th–Th interactions. The structural parameters and Th^{4+} coordination environment for this specimen are similar to those for the carefully prepared amorphous hydrated oxyhydroxide solid, $ThO_n(OH)_{4-2n} \cdot xH_2O$ (Neck *et al.*, 2002; Rothe *et al.*, 2002).

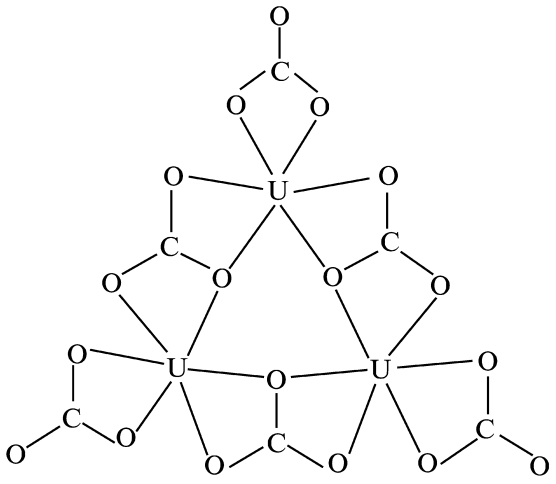
(b) Carbonate solution systems

A large part of the interest and activity in environmental and molecular sciences of the actinide elements concerns their interactions with carbonate, $[CO_3]^{2-}$, and bicarbonate, $[HCO_3]^{-}$, anions in hydrologic and geochemical processes. Besides H_2O (including hydroxide) itself, these are the predominant ligands for An-ion complexation found in fresh and saline waters alike. Of the Earth's estimated total water volume, approximately 97% or 317×10^6 mi^3 is attributed to seawater alone (Nace, 1967), which is known to contain an essentially uniform, worldwide distribution of uranium at $3.35 \pm 0.2 \times 10^{-9}$ g/cm^3 (Ku *et al.*, 1977).

An estimate of the total amount of dissolved U in the oceans (4.43×10^{12} kg) provides a glimpse of the enormity of scale and the correspondingly keen interest in its aqueous speciation. From decades of experimental study, it is generally accepted that U takes the form of the mononuclear anionic, uranyl(VI) tris(carbonato) complex, $[UO_2(CO_3)_3]^{4-}$, in the slightly alkaline (pH$\approx$8) ocean waters (Djogic and Branica, 1991). Despite comprehensive studies of actinide carbonate chemistry, which are very well reviewed elsewhere (Clark *et al.*, 1995), the field of synchrotron radiation research of An carbonate complexes was late to break open with the report on uranyl carbonate complexes in near-neutral aqueous solution (Allen *et al.*, 1995). In this section, we describe the results obtained from EXAFS studies of the carbonate solution chemistry of the trivalent and tetravalent An ions as well as for the actinyl, $[AnO_2]^{n+}$, carbonates of the pentavalent ($n=1$) and hexavalent ($n=2$) An ions.

(*i*) *Uranyl*(VI)

The apparent simplicity of the $[CO_3]^{2-}$ anion belies its flexibility in the formation of coordination compounds with $[UO_2]^{2+}$ in various degrees of polynuclear association. In addition to serving conventional mono- and symmetrical bidentate structural roles, it may serve to bridge and link metal-ions. Although some 14 modes of carbonate ligation with two, three, four, and six metal-ions are known (Cotton *et al.*, 1999), its service as a molecular bridge between uranyl cations is relatively rare (Allen *et al.*, 1995; Clark *et al.*, 1995). To elucidate aspects of such aggregation behavior, a multipronged approach was taken to unravel the solution species distribution of the monomeric tris(carbonato) complex, $[UO_2(CO_3)_3]^{4-}$, and the trimeric complex, $[(UO_2)_3(CO_3)_6]^{6-}$. The unusual structure of the trimer, schematically illustrated below without the axial O atoms, is built up of three bis(carbonato) monomers of empirical formula



$[UO_2(CO_3)_2]^{2-}$ with three bridging carbonate ligands linking three U^{6+} ions in a fashion (i.e. six-bond $-(U-O)_3-$ ring) not depicted in Cotton *et al.* (1999).

A 0.2 M aqueous solution (pH = 5.7) of this crystallographically characterized triangular, trinuclear uranyl(VI) carbonate, $[(UO_2)_3(CO_3)_6]^{6-}$ as the guanidinium salt $[C(NH_2)_3]^+$, was studied by U L_3-edge EXAFS (Allen *et al.*, 1995). The data analysis provided O, C, and U coordination numbers and interatomic distances consistent with the trimeric structure of the solid salt, $[C(NH_2)_3]_6[(UO_2)_3(CO_3)_6]\cdot 6.5H_2O$, suggesting that the oligomeric anionic unit is maintained upon dissolution of the solid under the selected conditions. The analysis was confirmed by the presence of a distant, 4.92 Å U–U interaction that was not evident in the EXAFS data for the corresponding monomeric species, $[UO_2(CO_3)_3]^{4-}$, which has an otherwise identical, eight O coordination of U^{6+} in a hexagonal bipyramid polygon (Reeder *et al.*, 2000). The two closest, axial O atoms are bonded at 1.79 Å in both the monomeric and trimeric anions. The six equatorial O atoms arise from the symmetrical bidentate coordination of three carbonate groups, with an average U–O distance of 2.42 Å for the monomer and 2.45–2.46 Å for the trimer. The EXAFS data for the trimer and the monomer alike provide evidence for distant backscattering that was fit to reveal three C at 2.89–2.90 Å as well as three O at 4.12 Å (monomer) and at 4.16–4.17 Å (trimer), which are attributed to the terminal O atoms of the three carbonate ligands.

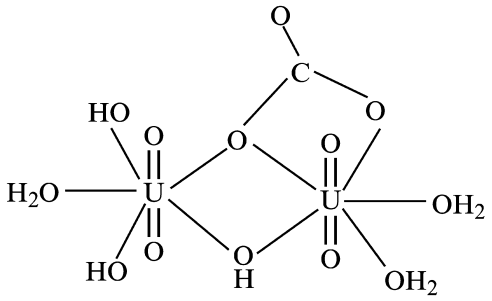
The recent discovery and characterization of the aqueous, neutral dicalcium uranyl(VI) tris(carbonato) complex, $[Ca_2UO_2(CO_3)_3]$, in natural, mining-related waters (Bernhard *et al.*, 1996) reinvigorates interest with the ages-old anionic species, $[UO_2(CO_3)_3]^{4-}$, particularly with regard to issues of ion-pairing. The combination of experimental (Bernhard *et al.*, 2001) and theoretical (Tsushima *et al.*, 2002) results reveal that counter-cations can play a significant role in the aqueous speciation and structure of the otherwise ordinary $[UO_2(CO_3)_3]^{4-}$ complex anion. The solution (pH = 8) U L_2- and L_3-edge EXAFS for $[Ca_2UO_2(CO_3)_3]$ (0.0005 M) and $[UO_2(CO_3)_3]^{4-}$ (0.001 M) do not differ significantly and, moreover, the carbonate coordination of uranyl(VI) in both is the same as that for the natural mineral liebigite, $Ca_2UO_2(CO_3)_3\cdot 10H_2O$, which has two axial O at 1.78 Å, six equatorial O at 2.43 Å, three C at 2.86, and three O at 4.12 Å. In addition, the crystallographic structure of liebigite reveals a 4.07 Å U–Ca interaction arising from two Ca–O polyhedra in the equatorial plane. These distant Ca interactions are difficult to identify in the U EXAFS data of the $[Ca_2UO_2(CO_3)_3]$ aqueous species and solid mineral specimens at ambient temperature because of spectral congestion and overlap with the nearly equidistant interactions of the terminal O atoms (3) of the symmetrical, bidentate carbonate ligands. Nevertheless, based upon a rigorous analysis of the available EXAFS and in combination with other physical and spectroscopic evidence, Bernhard *et al.* (2001) concluded "...that the calcium atoms are likely to be in the same positions both in the solution complex and in the solid." Structure optimizations of the neutral $[Ca_2UO_2(CO_3)_3]$ aquo species were subsequently

calculated at different levels (HF, MP2, and B3LYP) of theory with and without Ca^{2+}, i.e., $[UO_2(CO_3)_3]^{4-}$, and with and without hydration (Tsushima *et al.*, 2002). The calculated structure that included two Ca^{2+} and ten H_2O molecules is in good agreement with that deduced by EXAFS measurement and, thereby, demonstrates the need to explicitly incorporate counter-cations and water molecules to obtain accurate geometrical structures from theory.

Uranium L_3-edge EXAFS was used to probe the coordination environment of the uranyl(VI) tris(carbonato) complex, $[UO_2(CO_3)_3]^{4-}$, before and after a stoichiometric, one-electron electrochemical reduction (Docrat *et al.*, 1999). In aqueous electrolytes of 1 M Na_2CO_3 at pH = 11.95 (Docrat *et al.*, 1999) and 0.1 M Na_2CO_3/0.1 M $NaNO_3$ at pH = 11.3 (Morris, 2002), the cyclic voltammetry data for $[UO_2(CO_3)_3]^{4-}$ (0.0022–0.010 M) show one electrochemically irreversible couple attributed to U^{6+}/U^{5+} redox activity. The metastable reduced species formed by controlled potential coulometry was ascribed to the uranyl(V) tris (carbonato) complex, $[UO_2(CO_3)_3]^{5-}$. The U L_3-edge position for the reduced species was 2.4 eV lower than that for the oxidized form, consistent with the reduction of $[U^{6+}O_2]^{2+}$ to $[U^{5+}O_2]^{+}$. The EXAFS analysis revealed that the basic geometry of the U coordination environment is essentially the same for both solution complexes, except for the expected variation of interatomic distances with change of U oxidation state. The average axial dioxo distance increases by 0.10 Å from 1.80(2) to 1.90(2) Å upon reduction. Elongations of similar magnitude (0.05–0.10 Å) are found for the six equatorial O bonds, the three C, and the three terminal O interactions with the carbonate ligands. These three distances increase, in order, from 2.43(2), 2.89(4), and 4.13(4) Å in the oxidized form to 2.50(2), 2.94(4), and 4.23(4) Å, respectively, in the reduced form. The absence of significant conformational variation between $[UO_2(CO_3)_3]^{4-}$ and $[UO_2(CO_3)_3]^{5-}$ makes it difficult to rationalize the less than ideal electrochemical response and the relative instability of the reduced species (Docrat *et al.*, 1999).

Four different isomers have been proposed for the binuclear complex anion, $[(UO_2)_2(CO_3)(OH)_3(H_2O)_n]^-$, in solution (Szabo *et al.*, 2000). This variety of bridge isomers is largely attributable to the assortment of different carbonate bonding modes (Cotton *et al.*, 1999) that can be envisioned to link the two $[UO_2]^{2+}$ groups in this ternary species. Although the use of U EXAFS alone is not sufficient to provide an unambiguous identification of the predominant isomer, the EXAFS results in combination with multinuclear (^{13}C and ^{17}O) NMR measurements have provided conclusive insight about the speciation. The U L_3-edge EXAFS of a 0.05 M solution of $[(UO_2)_2(CO_3)(OH)_3(H_2O)_n]^-$ (pH $\approx$ 7–8) was analyzed with multi-shell models of axial and equatorial O, U–C, and U–U interactions (Szabo *et al.*, 2000). The pivotal aspect of the analyses was the identification of terminal, equatorial OH^- bonding (1.3 ± 0.3 at 2.26 Å) and distant U interactions (0.5 ± 0.1 at 3.90 Å). The equatorial coordination sphere is completed by 3.9 ± 0.6 O atoms at 2.47 Å. This is consistent with a pentagonal bipyramidal uranyl(VI) environment, wherein the two axial O atoms are bonded

at 1.81 Å. The isomer structure consistent with the combined EXAFS and NMR data is suggested to consist of two $[UO_2]^{2+}$ groups that are bridged by two O atoms, one from hydroxide and one from the lone carbonate ligand that is in bidentate coordination with one uranyl unit. The terminal equatorial coordination is completed by a combination of the two remaining hydroxide ligands and three water molecules, $[(H_2O)(OH)_2UO_2(OH)(CO_3)UO_2(H_2O)_2]^-$, as illustrated below.



(*ii*) *Neptunyl*(V)

The study of neptunium in aqueous carbonate solutions provides fundamental information that can be applied to intricate environmental problems and to solving difficult issues with regard to the treatment of alkaline, high-level tank waste. Concerns about pentavalent neptunyl carbonate complexation, particularly the aqueous speciation, solubility, redox, and sorption behaviors, also relate to its fate and transport in subsurface geologic repositories (Efurd *et al.*, 1998; Kaszuba and Runde, 1999).

Three environmentally relevant neptunyl(V) carbonato complexes of general composition $[NpO_2(CO_3)_n]^{(2n-1)-}$ for $n=1$ $[NpO_2(CO_3)]^-$, $n=2$ $[NpO_2(CO_3)_2]^{3-}$, and $n=3$ $[NpO_2(CO_3)_3]^{5-}$, have long been of interest. Information about their molecular structures and the extent of hydration became available through Np L_3-edge EXAFS and complementary spectroscopic work on single-component solutions of the anions with unprecedented solubilities (0.001 M) achieved by use of the large, bulky tetra-*n*-butylammonium, $[(n\text{-}Bu)_4N]^+$, counter-cations in place of alkali-metal cations (Clark *et al.*, 1996a,b). For the tris(carbonato) complex ($n=3$) in a Na_2CO_3 solution (of unspecified concentration), the EXAFS spectra show "...unequivocally that the carbonate ligands must be coordinated in a bidentate fashion due to the combination of six Np–O and three Np–C distances of 2.52 and 2.98 Å", (Clark *et al.*, 1996a) respectively. The overall eight-coordinate geometry of Np^{5+} is hexagonal bipyramidal, in which the two *trans*-neptunyl O atoms at 1.86(2) Å occupy the usual axial positions with respect to the six equatorial O atoms. Much less definitive information about the equatorial coordination was provided for the mono- and bis

(carbonato) species, $n=1$, and 2, respectively, in $[(n\text{-Bu})_4N]_2CO_3$ solutions (unspecified concentrations) because of curve-fitting difficulties and metrical uncertainties. What seems clear "... is a distinct change in coordination geometry about the neptunyl ion, from six O atoms in the tris- and bis-carbonato complexes, to five O atoms in the mono(carbonato) complex" (Clark *et al.*, 1996b). The five O atoms of the equatorial ligation for the mono(carbonato) complex are attributed to the coordination of three H_2O molecules and two O atoms from the $[CO_3]^{2-}$ anion in a symmetrical bidentate mode. The overall stereochemistry of Np^{5+} is expected to be a pentagonal bipyramid that has an average Np–O equatorial distance of 2.49(3) Å. This bond length is shorter than that (2.53(3) Å) for the 6-O equatorial coordination of the tris(carbonato) species, a detail that is consistent with the 5-O equatorial coordination of $[NpO_2]^+$ in $[NpO_2(CO_3)(H_2O)_3]^-$. Similarly, the six O atoms of the equatorial ligation for the bis(carbonato) complex are attributed to the coordination of two H_2O molecules and four O atoms from the two bidentate $[CO_3]^{2-}$ anions, as $[NpO_2(CO_3)_2(H_2O)_2]^{3-}$, with an average distance of 2.48(3) Å. It seems counter-intuitive that the higher coordination number for the bis(carbonato) complex does not correlate with a larger average equatorial Np–O distance, e.g. like that for the unequivocally characterized tris(carbonato) neptunyl(v) complex with six O atoms in the equatorial plane.

(*iii*) *Plutonyl*(*VI*)

The aqueous speciation of the plutonyl and americyl cations, $[AnO_2]^{n+}$ for $n=1$ and 2, in carbonate media has not been examined through XAS. Solid-state EXAFS studies of actinyl carbonates are similarly absent, except for the sole work in which $^{239}Pu^{6+}$ was precipitated from an acid solution of pH=4 with CO_2 over the course of 3–5 days (Runde *et al.*, 1999). The washed solids, identified as PuO_2CO_3 from powder X-ray diffraction measurements, were examined by Pu EXAFS to reveal the typical FT data with contributions from axial (1.74 Å) and equatorial O atoms (2.45 Å) as well as a distant, 4.2 Å Pu–Pu interaction. No coordination numbers were reported for this monocarbonate phase.

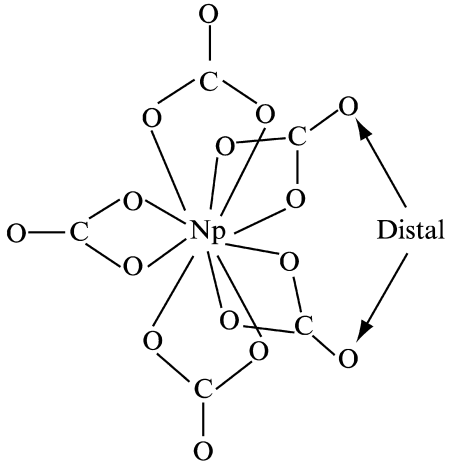
(*iv*) *Tetravalent An*

The tetravalent An carbonate series, $[An(CO_3)_n]^{4-2n}$ for An ≡ Th, U, Np, and Pu, has been the subject of systematic and comprehensive EXAFS investigations. In this collection of results, the predominant aqueous species is, by far, the pentacarbonato ($n=5$) complex, $[An(CO_3)_5]^{6-}$. For example, the extensive L_3-edge EXAFS measurements of U^{4+}, Np^{4+}, and Pu^{4+} in the aqueous $K^+ - HCO_3^- - CO_3^{2-} - OH^- - H_2O$ system (Rai *et al.*, 1998, 1999a,b) can be succinctly summarized as follows: The aqueous An^{4+} complexes in carbonate (5.4–6.0 M K_2CO_3) and bicarbonate (0.9–1.0 M) solutions were found to be

$[An(CO_3)_5]^{6-}$. Despite the excess concentrations of $[HCO_3]^-$, with respect to $[An^{4+}]$, no evidence was ever found for its complexation. This may reflect an inherent limitation of the technique, wherein the effects of protonation on the average An–O and An–C distances would be insignificant in comparison with the measurement error, and therefore extremely difficult to determine. In this regard, the detection of appreciably more coarse and substantial structural variations, especially the equatorial O coordination number, can be problematic and fraught with uncertainty. This, in turn, can make it difficult to determine the exact number of bicarbonate and carbonate groups, as well as their identity, involved in the complexation of tetravalent An ions.

(*v*) *Neptunium*(*IV*)

A case that illustrates this complicated issue as regards An^{4+} EXAFS in general concerns the investigation of the pure Np^{4+} ion (of unspecified milli-molar concentration) in 0.93 M $KHCO_3$ (Rai *et al.*, 1999a). In the FT data, the Np–O and Np–C interactions are not resolved, and correlation effects in the curve-fitting leads to metrical parameters that are not diagnostic of a unique structure. For example, from the nearest O and C coordination numbers, 11.0 ± 2.8 and 5.8 ± 1.8, respectively, alone, it is difficult to establish the presence of tetra-, penta-, hexa-, or heptacarbonato complexation. In this situation, fortunately, the magnitude of the average Np–O and Np–C interatomic distances, 2.43(2) and 2.84(2) Å, respectively, is known to be diagnostic of bidentate carbonate coordination (Denecke *et al.*, 1997b). To provide added quantitative insights about the Np carbonate species, a distant and well-resolved peak in the FT data attributed to the distal O atoms of the bidentate $[CO_3]^{2-}$ groups was subjected to analysis. The coordination number obtained, 5.4 ± 1.6 O atoms, is a conclusive indicator "...that five carbonate groups were involved, and the complexed Np^{4+} species therefore is $Np(CO_3)_5^{6-}$" in 0.93 M $KHCO_3$ (Rai *et al.*, 1999a).



The structure is illustrated above in which two of the five distal O atoms at 4.16 (2) Å are identified. For the corresponding 5.4 M K_2CO_3 solution, the unintended, partial oxidation of Np^{4+} leads to neptunyl(V) contamination and additional uncertainties with the EXAFS analyses. Nevertheless, the data are consistent with the suggestion that $[Np(CO_3)_5]^{6-}$ is the dominant species in carbonate solution.

(*vi*) *Uranium*(*IV*) *and plutonium*(*IV*)

From EXAFS acquisition and analyses (Rai *et al.*, 1998, 1999b), the speciation of U^{4+} and Pu^{4+} (of unspecified milli-molar concentrations) in 0.9 and 1.0 M $KHCO_3$ solutions, respectively, was shown to be like that for Np^{4+}. Namely, the three An^{4+} solution species are the anionic (6–) penta(carbonato) complexes, wherein the five carbonate groups are in bidentate coordination consisting of 9.5 O at 2.46 Å and 5.2 C at 2.90 Å for U (Rai *et al.*, 1998) and 9.8 ± 2.5 O at 2.41(2) Å and 5.5 ± 1.7 C at 2.88 Å for Pu (Rai *et al.*, 1999b). The corresponding distal O interactions consist of 4.1 O at 4.18 Å for U and 5.0 ± 1.5 O at 4.14(2) Å for Pu. Because of the presence of oxidation state impurities, e.g. uranyl(VI) and plutonyl(V), and the low S/N ratio of the primary data due to minuscule solubility, the EXAFS spectra for the U^{4+} and Pu^{4+} carbonate species in 5.4–6.0 M solutions of K_2CO_3 were not adequate for detailed analysis. Despite the uncertainties with the available EXAFS, it was concluded largely based upon other comparisons that $[An(CO_3)_5]^{6-}$ is the dominant An^{4+} species in concentrated carbonate solutions. Other complementary research (Clark *et al.*, 1998) provides thorough and convincing evidence in this regard. The Pu L_3-edge EXAFS of the limiting $^{242}Pu^{4+}$ (ca. 0.1 M) ion in an aqueous solution of 2.5 M Na_2CO_3 was fit to reveal 10.0 ± 1.2 O atoms at 2.42(1) Å; 5.0 ± 0.6 C atoms at 2.88(2) Å; 5.0 ± 0.6 O atoms at 4.16(2) Å. These values are consistent with the formation of a monomeric penta(carbonato) anion, $[Pu(CO_3)_5]^{6-}$, that is essentially identical to the one found in the solid-state, single-crystal X-ray structure of $[Na_6Pu(CO_3)_5]_2 \cdot Na_2CO_3 \cdot 33H_2O$ (Clark *et al.*, 1998). In this anion, each of the five $[CO_3]^{2-}$ groups has bidentate coordination in a pseudo-hexagonal bipyramid polygon about Pu^{4+} with three in equatorial positions and two in axial ones. This definitive structure sets to rest a decade-long debate about the molecular structure of the limiting complex in the Pu^{4+} carbonate system under high $[CO_3^{2-}]$ in both solution- and solid-states.

(*vii*) *Thorium*(*IV*)

EXAFS investigations of the Th^{4+} carbonate system show that a penta(carbonato) $[Th(CO_3)_5]^{6-}$ solution species is obtained at high concentrations of carbonate (1–2 M Na_2CO_3 with 0.1–1.0 M NaOH) and bicarbonate (0.17–1.0 M $NaHCO_3$) (Felmy *et al.*, 1997; Hess *et al.*, 1997). Curve-fitting analysis of Th

L_3-edge EXAFS data for solutions of 0.001–0.009 M Th^{4+} reveals ten O atoms at 2.49–2.50 Å, a distance that is consistent with bidentate coordination of $[CO_3]^{2-}$. Because the C backscattering is weaker than that for the nearer O and because the Th–C peak cannot be resolved from the Th–O peak in the FT data, the Th–C metrical parameters are subject to large uncertainties. For example, coordination numbers of 3.1–5.2 and distances of 2.97–3.01 Å make it difficult to be specific about the character of the carbonate complexation. The number of coordinated carbonate groups was determined through the analysis of the signal for the well-resolved distal O peak in the FT data to reveal 5 ± 1 O atoms at 4.21–4.26 Å, as expected for the $[Th(CO_3)_5]^{6-}$ anion. In contrast, for solutions with a bicarbonate concentration of 0.1 M and less, "...the thorium speciation changes dramatically" (Felmy *et al.*, 1997; Hess *et al.*, 1997). The specific and exact nature of this change was not conclusively established from the EXAFS analysis because of data quality limitations, i.e. low S/N ratio, of the primary spectra for the dilute (≤ 0.0001 M) Th^{4+} solutions at pH = 9.39–9.43. Although the issue is open to question, the initial EXAFS results suggest a contraction of the Th–O bond length (from ca. 2.50 Å for $[Th(CO_3)_5]^{6-}$ to 2.46 Å) accompanied by a decrease in the number of nearest O atoms (from 10 for $[Th(CO_3)_5]^{6-}$ to 8). Based upon this information, a mixed carbonate hydroxide species was proposed (Felmy *et al.*, 1997), wherein three $[CO_3]^{2-}$ groups are in bidentate coordination around Th^{4+} along with two OH^- groups (Hess *et al.*, 1997).

28.2.4 Organic acids

EXAFS analyses provide an average structure of all the element-selected An ions in solution, regardless of their state of speciation – monomer, dimer, trimer, ..., polymer – and their possible combined and simultaneous presence as hydrolysis products, intermediates, non-complexed aquo ions, etc. As such, the short-range metrical results for An materials containing an assortment of bonding sites and mixtures of phases are difficult to use for definitive comparisons with individual structures proposed in speciation diagrams. In these cases, additional spectroscopic information, such as from, for example, NMR, optical, vibrational, fluorescence, etc., experiments is necessary to confirm the available EXAFS results. For example, the use of EXAFS alone to study the coordination and binding stoichiometry of An ions in natural materials like organic macromolecules known as humic substances, which contain multiple coordination sites, different functional groups (i.e. carboxyl, carbonyl, hydroxyl, thiol, amido, etc.), and bonding modes, can be a difficult and intricately complicated problem. Fortunately, the carboxylate anions, $-COO^-$, of organic acids are the most important and widespread functional group for An complexation in the surface-waters and in the subsurface geologic fluids of the terrestrial aquatic environment (Pittman and Lewan, 1994). Moreover, the use of EXAFS has been developed for such challenging environmental research thorough analysis and understanding of the spectra for smaller, molecularly characterized

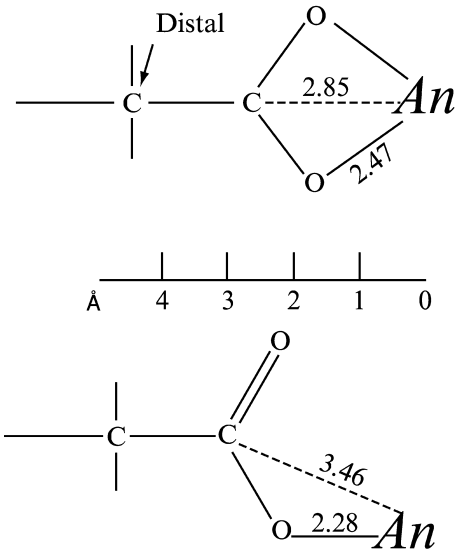
An carboxylate complexes of common organic, carboxylic acids both aliphatic (R-COOH) and aromatic (Ar-COOH), including the di- and tricarboxylic acids.

Tables 28.7 and 28.8 contain the structures of the mono-, di-, and tricarboxylate ligands as well as several phenolate ligands that are relevant with regard to their presence in natural waters and materials. Except for two publications, one about Th^{4+} (Denecke *et al*., 1999) and the other on Np^{4+} (Denecke *et al*., 2002), the EXAFS research available in time for this publication is exclusively focused on the uranyl(VI) ion, $[UO_2]^{2+}$, complexes of these organic anions. Though large, the extent of the EXAFS structure investigations is dwarfed by the number of crystal and molecular structures studies that have been completely reviewed and discussed in the light of the complexation of radionuclides with humic substances, particularly the humic and fulvic acids, elsewhere (Leciejewicz *et al*., 1995; Denecke *et al*., 1997a).

(a) Model systems

Despite early success at probing the bonding of $[UO_2]^{2+}$ with the aliphatic, monobasic acetate ligand through use of U L_3-edge EXAFS (Charpin *et al*., 1985), research on An complexes of organic acids was not immediately impacted by the method. More than a decade later, three EXAFS studies were reported (Allen *et al*., 1996a; Pompe *et al*., 1996; Reich *et al*., 1996a) with results for uranyl(VI) solutions and solids containing organic carboxylate ligands that set the groundwork for EXAFS measurements that continue today. A pivotal development was realized when the results from EXAFS were demonstrated to be diagnostic of carboxylate coordination (Denecke *et al*., 1997a,b, 1998a,b). In particular, the distinction between mono- and bidentate O coordination is plainly reflected in the U–O interatomic distance, wherein long U–O distances of ca. 2.5 Å are indicative of bidentate coordination and shorter ones of ca. 2.3 Å suggest monodentate coordination. Oftentimes, the bidentate mode of coordination is corroborated by the appearance of either one or two U–C interactions. The first one with a U–C interaction of ca. 2.85 Å arises from the nearest C atom that is bonded to the two O atoms and the second oftentimes weak one at ca. 4.4 Å arises from the next nearest, the so-called distal C atom that is collinear with the nearest C and absorbing An atoms. Because these two U–C interactions occur at significantly longer distances for the monodentate-bonding mode, e.g. the first and closest U–C distance is ca. 3.5 Å, they are rarely observed in the FT data of An EXAFS. A schematic representation of these two binding forms is shown below. Similar schemes and interatomic distances apply for the bidentate and monodentate coordination of the carbonate ligand discussed above.

Despite the extensive research with the model ligands (L) of Tables 28.7 and 28.8, the results from EXAFS are not sufficient on their own to provide conclusive speciation information about the equatorial coordination of $[UO_2]^{2+}$ and other An moieties. The An:L complexation ratio, e.g. 1:1, 1:2,



1:3, and 2:2, 2:3, etc., is especially difficult to determine from one-dimensional metrical information largely because of spectral congestion. For example, the identification of typically weak and distant U–U interactions that are expected for the 2:2 complexes is oftentimes complicated. Peaks that are purported to arise from U–U interactions can be essentially identical to the O–O peak (i.e. the U–O–U–O–U backscattering pathway) that arises from multiple-scattering within a single uranyl group, which is a common structural feature of the monomeric (1:1, 1:2, ...) and dimeric (2:2, 2:3, ...) complexes. Fortunately, in this regard, the U–U assignment can be convincingly made by use of low-temperature EXAFS (Thompson *et al.*, 1995, 1997; Barnes *et al.*, 2000; Hennig *et al.*, 2001b). Another difficulty arises in the identification of all of the equatorial O ligands in the molecular complexes of $[UO_2]^{2+}$ that contribute to the total coordination number of which five is the most common one of all the entries of Tables 28.7 and 28.8. For example, the O equatorial responses from carboxylate, phenolate, water, and hydroxide are difficult, oftentimes impossible, to distinguish from EXAFS alone. The use of vibrational spectroscopies, particularly FT-infrared, is especially useful with regard to information about the coordination of $R–COO^-$ and $Ar–COO^-$ moieties.

(b) Natural systems

Both humic and fulvic acids play key roles that are not very well understood in the biological and environmental sciences. Humic acid is, in large part, responsible for the immobilization of An ions and heavy metals in soils. The complexation of metals with reactive functional groups is an important regulatory

process of the solubility and fate of soil contaminants. As such, the identity of potential binding sites of 'hard' and 'soft' functional groups, including ligands of N (e.g. amino), O (e.g. hydroxyl, carboxyl, carbonyl), and S (e.g. thiol, sulfide, thiol-ether, sulfonyl) on the outer and inner surfaces of humic acid that would accommodate An ions with different charge/IR ratios has been a subject of practical concern. The difficulties in this area of research stem from uncertainties about the nature of humic acid itself. The diversity of the chemical building blocks that combine in their assembly to form humic acid is well-known and remains a matter of significant interest (Giordano, 1994; Silva and Nitsche, 1995; Nitsche, 1997; Paciolla *et al.*, 1999). In particular, the primary and secondary molecular and crystal structures of humic acid and its conformers, which are believed to vary with ancestry, are not known. Yet, despite the existing gap in knowledge about the specific formula and stereochemistry of humic acid, in general, and about the metal-binding sites of humic acid, in particular, the obvious strength of the EXAFS work is that it provides direct insight about the An coordination. The results of exhaustive U L_3-edge EXAFS data acquisition and analysis of humic and fulvic acids of both natural and synthetic origin, and under the neutral to slightly acidic conditions of pH and Eh that are of environmental relevance, are in consensus (Denecke *et al.*, 1997a, 1998a,b; Reich *et al.*, 1998a; Nitsche *et al.*, 1999; Schmeide *et al.*, 2003). The bonding of the uranyl ion is predominantly associated with carboxylate functional groups. Moreover, the U–O interatomic distances are consistent with the monodentate coordination structure shown above. Under alkaline conditions, the bonding appears to involve some degree of interaction with phenolic –OH groups (Reich *et al.*, 1996a), which are deprotonated at $8 \leq \text{pH} \leq 10$. The pH-dependent bonding of $[UO_2]^{2+}$ to carboxylate and phenolate functionalities has been demonstrated in several model systems (Rossberg *et al.*, 2000, 2003; Moll *et al.*, 2003). Additional work has been proposed to clarify this possibility with natural humic acids (Reich *et al.*, 1996a; Schmeide *et al.*, 2003).

28.3 SORPTION STUDIES

Chemical reactions that take place at the particle–water interface play a large role in controlling environmental speciation, bioavailability, and transport of ions. For example, adsorption/desorption equilibria and redox reactions can be significantly influenced by the nature of the surfaces seen by the solution. Simple solution solubilities may be altered in the presence of a mineral surface that can preferentially adsorb, and thereby concentrate and precipitate metal-ions at solution concentrations well below their solubility limits. In addition, surface redox reactions can also reduce metal solubility and result in mineral incorporation or crystallization reactions that would not occur in the absence of the active surface (Breit, 1995). In this manner, the mobility of radionuclides through the environment is strongly influenced by their interactions at water–mineral

interfaces. For example, uranium mobility in oxic groundwater is dominated by adsorption of U(VI) onto mineral surfaces. The sorption of uranyl on to organic and inorganic surfaces plays a major role in preconcentrating low-temperature sedimentary uranium and the formation of uranium-bearing minerals, such as uraninite, through reduction following adsorption from groundwater. To predict mobility, it is necessary to have a fundamental understanding of interaction processes including surface complexation and precipitation as well as radionuclide incorporation into mineral phases. Among physical factors that influence partitioning between solution and metal surface are the specific actinide involved, its concentration, coordinating ligands such as dissolved carbonate, phosphate, and other complexing ions, solution pH, and mineral surface contamination.

Published synchrotron studies examining actinide interactions on mineral surfaces focus on valence and structural details of binding. Questions to be answered have centered on the valence state of the actinide and its coordination environment, including the presence of mineral-phase atoms visible in the coordination sphere that may help to distinguish inner- from outer-sphere interactions. The presence of actinide–actinide interactions may indicate clustering or the formation of oligomers on the mineral surface. Such oligomers may represent precursors to mineral-phase formation.

Synchrotron work to date has focused on XAS and microprobe studies of U, Np, or Pu adsorption onto silicate, phosphate or iron-based mineral phases and onto more complex soil samples. Work has also been published that looks at sorption onto bacterial surfaces as well as incorporation into mineral phases. These topics will be reviewed in the following subsections.

28.3.1 Silicates

Silicates are the largest and most complicated class of minerals, with estimates that as much as 90% of the Earth's crust is composed of silicates. These complicated structures can form as single units, double units, chains, sheets, rings, and frameworks. Phyllosilicates are a silicate subclass in which rings of tetrahedra are linked by shared oxygens to other rings in a two-dimensional plane that produces a sheet-like structure. The silicon to oxygen ratio is generally 2:5, with the sheets typically connected to each other by cation layers. The cation layers are weakly bound and often have water and other moieties trapped between the sheets. Clays are a group of phyllosilicates that contain large percentages of water trapped between the silicate sheets. Most clays are chemically and structurally analogous to other phyllosilicates but contain varying amounts of water and allow facile ion-exchange of interlayer ions. It is the physical characteristics of clays, more so than their chemical and structural characteristics, which defines this group.

Clay minerals are further divided into four groups, one of which is the montmorillonite/smectite group. Montmorillonites differ mostly in chemical

content. The general formula is $(Ca,Na,H)(Al,Mg,Fe,Zn)_2(Si,Al)_4O_{10}(OH)_2 \cdot nH_2O$. The water content is variable, and in fact when water is absorbed, the crystals tend to swell to several times their original volume. The effect of montmorillonite is to slow the progress of water through soil or rocks.

There have been several studies of the adsorption of actinide ions onto silicate surfaces, as summarized in Table 28.9. These studies are driven by the realization that the surfaces of these mineral phases have a discernable influence on the migration of ions in natural environments. Silicates have been proposed to have two surface sites onto which an adsorbed ion can bind. Numerous experiments explore specific models which address these two broad classes of binding sites: external amphoteric 'edge' sites whose properties are pH-dependent, and fixed-charge, basal-plane 'exchange' sites whose reactivity is independent of pH (Sposito, 1984, 1990; Weiland *et al.*, 1994). Unlike many transition-metal mineral phases, the silicate surface itself shows no redox chemistry. This simplifies the types of interactions that can be expected on the surface to complexation,

precipitation, and incorporation, and thereby providing simple model for study. The main question that has been addressed to date is the mechanism by which the ion binds to a silicate surface. As demonstrated in Fig. 28.7 for an actinyl ion, surface binding can include mononuclear or polynuclear inner- or outer-sphere complexation. Inner-sphere complexes can bind with either monodentate or bidentate ligation with surface sites.

The simplest of the silica phases to be studied are silica gels, amorphous $SiO_2 \cdot nH_2O$. Non-porous pyrogenic silica samples, consisting of spherical particles amorphous by X-ray diffraction, were used in a study of Th adsorption in order to determine the molecular details of the adsorption (Oesthols *et al.*, 1997). Wet samples of Th sorbed onto amorphous silica were studied using Th L_3-edge EXAFS. Solution pH values in the study were in the range of 2.8–4.0, which corresponded to the adsorption edge in the pH region of 2–3 that had previously been determined potentiometrically (Oesthols, 1995). Th surface coverages were

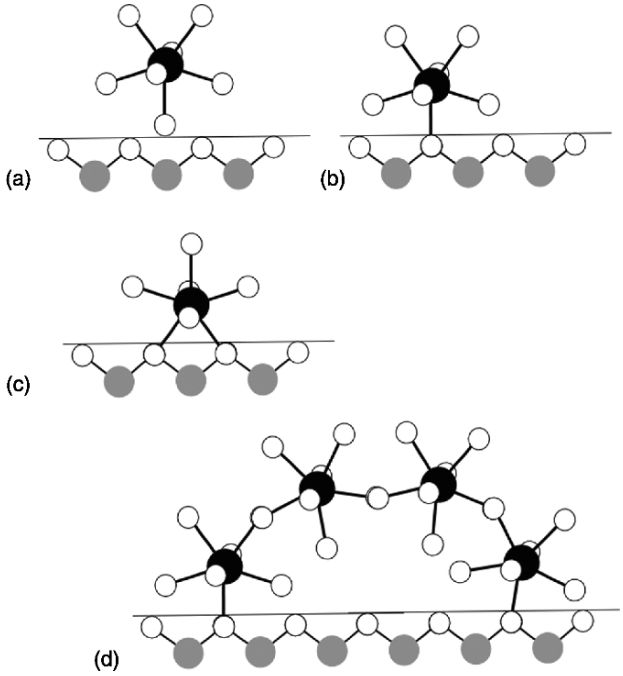

Fig. 28.7 *Binding modes for a metal-ion to a mineral surface. The binding can be* (*a*) *outer sphere, in which the metal ion's first coordination sphere is not a bulk-surface ion;* (*b*) *a mononuclear, monodentate, inner-sphere complex, in which the metal-ion's first coordination sphere includes an ion from the bulk-surface;* (*c*) *mononuclear, bidentate coordination, in which the complexing metal-ion shares two ligands with the surface; and* (*d*) *polynuclear, bidentate coordination, in which the metal-ion has coordination to other metal-ions as well as the surface.*

determined to be 3.8–230%. The spectra showed a decrease in structural order with increasing surface coverage. For lower surface coverage, 3.8–75.5%, two oxygen coordination shells were seen at approximately 2.28 and 2.54 Å with coordination numbers of about 2–2.7 and 5, respectively. These samples also showed about 2(1) Th–Si interactions at 3.85 Å. Samples with higher Th surface coverage, that is 92.7 and 230%, also showed two oxygen shells, with about two O at 2.33 Å and 4.5 O at 2.54 Å and 2.3 and 1.3 Th–Si interactions at 3.84 and 3.79 Å, respectively. None of the samples showed evidence of any Th–Th interactions, even the sample reported to have 230% surface coverage, suggesting that the surface layer resembles amorphous thorium hydroxide, which also shows no significant Th–Th correlations. The absence of Th–Th correlations, even in amorphous $Th(OH)_4$ was attributed to a high degree of disorder (Oesthols *et al.*, 1997). The EXAFS data were consistent with Th adsorption onto the amorphous silica surface via bidentate inner-sphere complexation, in which Th has a double corner-sharing bond with two different SiO_4 surface tetrahedra. Four to eight oxygen atoms are shared with coordinated solution–water molecules, which account for the longer Th–O correlations at 2.55 Å.

Uranium sorption by silica gels has also been shown to be pH sensitive (Michard *et al.*, 1996), increasing with increasing pH over the range of about 3–5. This pH interval corresponds approximately to that over which there are hydrolyzed uranyl species present in solution. A two-phase process has been proposed that involves an external mass transfer and an intra-particle mass transfer, of which only the former is strongly pH-dependent. Earlier, Raman studies had suggested that uranyl sorbs as an inner-sphere surface complex (Maya, 1982). This suggestion has been confirmed by EXAFS studies of UO_2^{2+} sorption products for samples prepared at pH 3 and 5 (Dent *et al.*, 1992), which were noted to be indistinguishable, but no detailed analysis was provided. Coordination information of uranyl sorbed to silicic acid and silica gel samples prepared at pH 4 was determined by EXAFS (Reich *et al.*, 1996b). The two materials are distinguished by different surface areas, 80 vs 470 mg/g for silicic acid and silica gel respectively, as determined by BET measurements. An analysis of EXAFS data showed the expected dioxo coordination with a $U–O_{ax}$ distance of 1.78 Å for both samples. Two silicic acid samples, prepared with different solution uranyl concentrations, were examined. The sample, obtained from a 0.01 M UO_2^{2+} solution, has two resolvable O coordination shells in the equatorial plane with 2.6(4) O at a distance of 2.27 Å and 1.8 O at a distance of 2.50 Å. The sample obtained from a more concentrated uranyl solution, 0.05 M, has 2.1(4) equatorial O at a distance of 2.27 Å and 2.25 O at a distance of 2.48 Å. Both samples show a total equatorial O coordination of slightly less than 5. These results compare to those determined for silica gel samples obtained from a 0.05 M uranyl solution, which also have two equatorial O shells, one with 4(1) O at 2.29 Å and the other with 1.6(7) O at a distance of 2.50 Å, for a total O coordination greater than five. Similar results were determined for a sample prepared at pH 3.4 (Sylwester *et al.*, 2000).

The observation of two O coordination shells separated by about 0.2 Å, coupled by the absence of an EXAFS feature attributable to U–U interactions, is strong evidence that, at pH values 3.4 and 4, uranyl undergoes inner-sphere, mononuclear, bidentate surface complexation (Reich *et al*., 1996b; Sylwester *et al*., 2000). In contrast, samples prepared at higher pH values show additional U–Si and U–U coordination shells (Allard *et al*., 1999; Sylwester *et al*., 2000). For example, at pH 6.24 additional coordination shells are observable in the data, with one Si at 3.1 Å and about two U at 4 Å (Sylwester *et al*., 2000). This result indicates some form of oligomeric uranyl phase, either a surface complex or a precipitate. The U–Si atomic distance and coordination number would imply a surface adsorption via bidentate complexation to two surface O associated with the same Si. Monodentate complexation with surface O would be expected to result in a longer U–Si distance of about 3.8 Å (Burns *et al*., 1997).

EXAFS spectra of uranyl-loaded montmorillonite, which contains aluminol as well as silanol sites, are clearly different from that of the metal adsorbed onto silica (Chisholm-Brause *et al*., 1992, 1994; Thompson *et al*., 1997; Sylwester *et al*., 2000; Hennig *et al*., 2002). The degree of complexation at the edge aluminol or silanol sites should rise with increasing pH because these sites become increasingly deprotonated and therefore available for cation complexation. In studies with pH values in the range of about 3 (Chisholm-Brause *et al*., 1994) to 5 (Dent *et al*., 1992; Sylwester *et al*., 2000), the data contain an unresolvable single-shell structure similar to those seen in aqueous solution and consistent with outer-sphere coordination. The observed $U–O_{eq}$ bond distances of 2.41–2.43 Å support this finding. In contrast, studies at higher pH (5–7) indicate that an inner-sphere complexation process dominates the sorption. Although the short data range (3.1–11.4 $Å^{-1}$) prohibited the observation of a splitting in the shell attributed to equatorial ligation, large Debye–Waller factors (0.013–0.017 $Å^2$) together with much shorter bond distances observed at higher pH, 2.34–2.38 Å, were used to support models for binding to amphoteric surface hydroxyl sites (Hennig *et al*., 2002).

Another interesting study was published concerning the role of montmorillonite surface coverage on the local structure about the uranyl (Chisholm-Brause *et al*., 1994). There were three samples studied whose final pH values decreased with increasing surface coverage, from 5.6 to 4.4 and finally to 3.4. At low surface coverage, 0.0103 mmol/g, the ratio of the integrated EXAFS amplitude from the equatorially bound O to that found in solution is only 0.58. The bond distance is also short at 2.391 Å. As the solution concentration was increased, the surface coverage also increased from 0.044 to 0.208 mmol/g, there was a higher ratio of uranyl ligation in the equatorial plane (0.65 and 0.77) and these O occurred at longer distances, specifically 2.414 and 2.444 Å, respectively. This same observation has been previously quantified in terms of significant differences in equatorial O coordination as a function of solution U concentration (Chisholm-Brause *et al*., 1992; Dent *et al*., 1992). The authors argue that these data suggest that uranyl forms at least three distinct sorption

complexes on montmorillonite, a result that is consistent with previously published modeling (Zachara and McKinley, 1993). Using simple bond-length to coordination-number correlations, it was also argued that the observed increase in amplitude of the EXAFS spectra with increasing surface coverage must be due, at least in part, to decreasing disorder, and not just an increase in the number of coordinating ligands (Chisholm-Brause *et al*., 1994). An independent study (Hennig *et al*., 2002) on samples with uranium loading of 1751–2473 ppm did not support this finding. These EXAFS data show no evidence of U–U interactions, even at pH values >5.4, where thermodynamic modeling predicts the formation of solid-hydrated uranyl oxides, indicating that surface complexation may be kinetically favored relative to precipitation under the conditions employed. It should be noted that molecular dynamics simulations of uranyl sorption onto a quartz surface find that water oxygen atoms and surface oxygen atoms are equidistant to the metal-ion. Equatorial splitting of the bond distances is caused not by inner-sphere coordination, but instead by the presence of other ligands in the first coordination sphere of the UO_2^{2+}, such as the carbonate anion (Greathouse *et al*., 2002).

Uranyl sorption complexes on two related phyllosilicates, vermiculite, which is a montmorillonite, and hydrobiotite, which is a mica, were studied to gain further information on binding to different surface sites (Hudson *et al*., 1999). Samples were prepared that favored fixed-charge, ion-exchange sites, or amphoteric surface hydroxyl sites. Samples made under conditions that significantly favored the ion-exchange sites had EXAFS spectra with one resolvable equatorial O distance, consistent with outer-sphere uranyl complexation. Upon dehydration, the EXAFS data are consistent with inner-sphere uranyl coordination. In addition to the standard EXAFS experiments, the local structure about the uranyl ion in the hydrated sample was also studied using polarized L_1- and L_3-edge XANES. Polarized X-ray absorption data have been demonstrated to yield information about the spatial orientation of the linear dioxo group (Hudson *et al*., 1996). Polarization data were used to probe the orientation of the linear dioxo-groups with respect to the silicate surface in the vermiculite sample (Hudson *et al*., 1999). The ion-exchanged sites, with outer-sphere coordination, showed a preferred orientation of the dioxo moiety parallel to the silicate layers. Samples that significantly favored the hydroxy sites have EXAFS spectra that show the uranyl ion in a highly distorted equatorial shell with the detection of a U–U interaction, which suggests the formation of surface precipitates and/or oligomeric complexes.

The reports on sorption onto montmorillonite have been extended by experiments on uptake at initial Th concentrations representing undersaturation (pH 2 and 3) and oversaturation (pH 5) with respect to amorphous ThO_2 (Daehn *et al*., 2002). The sorption experiments were conducted with Th concentrations in the range of 2.7×10^{-6} to 4×10^{-4} M and under an N_2 atmosphere. At low and intermediate surface coverage, 1–34 and 157 μmol/g, two coordinating oxygen shells were observed, with about three O at 2.24 Å, six to

eight O at 2.45–2.48 Å, and one Si shell at 3.81–3.88 Å. Any attempt to include Th–Th interactions into the fit failed. The same coordination environment was observed for both pH values. The pH = 5 samples had Th–O coordination similar to those observed at the lower pH. For the samples with lower Th loading (14 and 40 μmol/g), data analyses suggested a reduced number of Th–Si pairs, 1.4–1.7 at a distance of 3.87 Å, compared to the sorption samples prepared at pH = 3, which had 2.5–2.9 Si at 3.83 Å. The reduced Th–Si coordination number at the higher pH could be explained by assuming that a fraction of Th is no longer directly bonded to the montmorillonite surface, but instead forms an outer-sphere complex. It could also indicate destructive interference with the EXAFS generated by the Th–Si pairs at 3.9 Å (Daehn *et al.*, 2002). This latter hypothesis is supported by the data from the pH = 5 sample with the highest Th loading (166 μmol/g), which was satisfactorily fit with neither a Th–Si nor a Th–Th interaction. However, the similarity of EXAFS data from this sample with those obtained from a Th amorphous precipitate suggests the surface formation of similar precipitates at high Th concentrations and high pH.

Polarized EXAFS measurements were also obtained from Th-treated oriented films, prepared at pH values of 2 and 3, to investigate whether the sorbed Th was oriented with respect to the octahedral sheets of the clay (Daehn *et al.*, 2002). The spectra were recorded with an electric field vector at 10°, 35°, 55°, and 80° with respect to the clay-film plane. No significant polarization effects were observed in the spectra obtained from the pH = 2 or 3 samples. It was postulated that Th adsorbs to the montmorillonite at its edge sites, by sharing double corners with Si tetrahedra, and that these sites are saturated when the concentration of Th is greater than 32 μmol/g. This hypothesis is supported by the observed difference in EXAFS spectra of the lower concentration samples compared with the higher surface-coverage samples, which look more similar to solution Th spectra. This result may indicate that Th is sorbed as an outer-sphere complex after the clay edge sites are saturated.

Studies on Th- (Giaquinta *et al.*, 1997a) and uranyl-exchanged bentonite (Giaquinta *et al.*, 1997a,b), a smectite clay, and zeolite (Wasserman *et al.*, 2000) samples extended previous work on two aspects: (1) the exchanged clays were coated with hydrophobic silanes in order to inhibit interlayer-water exchange and (2) uranyl-exchanged samples were subjected to hydrothermal conditions. The uranyl-ion-exchanged samples were thoroughly washed in an effort to produce samples with single-interlayer binding sites. The EXAFS from the simple, untreated samples were analyzed, assuming only one site. The results from Th L_3-edge EXAFS (Giaquinta *et al.*, 1997a) showed that Th had a single hydration sphere with approximately 11 O at a distance of 2.49 Å and 2.7(6) O at 3.66 Å. In contrast, EXAFS spectra from the hydrothermally treated samples were similar to that obtained from ThO_2. The first O shell shifted to a slightly shorter distance, 2.39 Å and there were two additional peaks present. The peak at 3.93 Å, present only in the treated sample, was attributed to a Th–Th

interaction and consistent with the formation of a thoria-like hydrous polymer (Baes and Mesmer, 1976). The EXAFS from the UO_2^{2+} exchanged sample, before treatment, was analyzed with 2.2 O at 1.77 Å, 5 O at 2.43 Å, and 2.6 O at 3.45 Å (Giaquinta *et al*., 1997b). This result is consistent with outer-sphere uranyl complexation as seen for other montmorillonite samples.

In contrast to the Th samples, the uranyl-loaded clays from hydrothermally treated samples produced EXAFS spectra that were different from those obtained before treatment. The silane-treated uranyl samples also showed no change to the uranyl environment compared to those obtained before hydrothermal treatment, except that the spectra showed that the coordination shells were at longer distances. The methoxysilane data revealed dramatic changes in the uranium environment. The dioxo coordination environment disappeared and was replaced by a single oxygen shell at 2.33 Å. There was also an additional peak observed at 3.36 Å and another at 3.92 Å, determined to be a U–U interaction. This coordination is suggestive of small particle uraninite formation, which implies the reduction of U(VI) to tetravalent U. This suggestion was confirmed by U L_3 XANES experiments. The observation of uranyl reduction in the presence of an organic and under elevated temperature and pressure is important in terms of uranium migration under geological conditions.

Dissolved CO_2 is also believed to significantly influence uranium adsorption on mineral surfaces with a maximum at near-neutral pH, and decreasing sharply toward more acidic (pH $<$ 6) and more alkaline (pH $>$ 7) conditions. The mechanism behind this influence was studied using EXAFS to probe uranyl sorption onto the clay-mineral kaolinite (Thompson *et al*., 1998). The combination of uranium concentrations and pH values used in these experiments were such that complex uranyl oxyhydroxides would be expected. Indeed U–U interactions were observed.

In addition to the work on the aluminosilicate clays, there have been limited EXAFS studies of actinide sorption onto aluminates, specifically uranyl onto γ-Al_2O_3 and α-Al_2O_3. The former study was done on two samples with contact solution pH values of 3.48 and 6.50 (Sylwester *et al*., 2000). EXAFS data from both samples demonstrated the standard dioxo uranium(VI) coordination at 1.78 Å. There were also two equatorial shells, the first with about 2.8 O at 2.37 Å and about 2.0 O at 2.53 Å, whereas the second had about 2.6 O at 2.34 Å and 3.1 O at 2.50 Å. The splitting of the equatorial coordination shell is again used as evidence for inner-sphere coordination to the alumina surface. The sample at near-neutral pH also showed a U–U interaction at 4.10 Å corresponding to about 0.5 U near-neighbors, which indicated the coordination of a mixture of mononuclear and polynuclear surface complexes. The study of uranyl sorption on α-Al_2O_3 (Denecke *et al*., 2003) examined the polarization dependence of uranyl ions sorbed onto a single-crystal (110) surface under different loading conditions. Although the authors indicate the potential of polarization experiments, no definitive information about uranyl coordination to the α-Al_2O_3 surface was provided.

28.3.2 Carbonate incorporation

Carbonate minerals are among the most common secondary phases that form in near-surface environments. There are three main sedimentary carbonate minerals: calcite, aragonite, and dolomite, as listed in Table 28.10. Of these mineral phases, calcite is one of the most abundant of the non-silicate minerals, comprising about 4% by weight of the Earth's crust. Aragonite is a less common polymorph of calcite and is a major constituent of invertebrate skeletons that, in most environments, eventually converts to calcite. Carbonate minerals are known to incorporate trace amounts of uranium, an attribute that has been utilized for the U-series age determinations of ancient calcites and as marine paleoenvironmental (Brannon *et al.*, 1996) and diagenetic indicators (Russell *et al.*, 1994). In addition, the carbonate mineral class itself includes a variety of stable uranyl carbonates (Reeder, 1983). The studies of actinide interactions with carbonate phases have focused on incorporation studies.

It is important to develop a molecular level understanding of the speciation of actinides sequestered in carbonate phases in order to assist in the assessment of these ubiquitous minerals in actinide mobility and sequestration. The mechanism(s) of actinide incorporation into carbonates, particularly calcium carbonates, for which the actinide can substitute for Ca^{2+}, has been the source of significant recent study when the substituting ion is uranium (Shen and Dunbar, 1995). The structural work published to date has focused on uranium substitution and has not directly addressed the issue of transuranic substitution into a calcium carbonate lattice. U^{4+} is approximately the right size to substitute for Ca^{2+} in the calcite lattice, but there are two problems to this simple ion replacement. First, the substitution of a tetravalent ion for a divalent one requires some stable charge-balance mechanism available in the lattice. Second, U^{4+} has a low groundwater solubility because of the precipitation of insoluble uranous phases and as a result U is present in most natural waters as the dioxo uranium(VI) ion. Although $U(VI)O_2^{2+}$ is divalent, its configuration and size would be expected to cause significant local structural disruption if it were to substitute directly for Ca^{2+} (Langmuir, 1978; Reeder, 1983).

Table 28.10 *Carbonate mineralogy. The common carbonate mineral phases studied for actinide incorporation using synchrotron radiation.*

Mineral	*Formula*	*Crystallographic group*	*References*
calcite	$CaCO_3$	trigonal ($R\bar{3}c$)	Effenberger *et al.* (1981)
aragonite	$CaCO_3$	orthorhombic (Pmcn)	Dal Negro and Ungaretti (1971); de Villiers (1971)
dolomite	$CaMg(CO_3)_2$	trigonal ($R\bar{3}$)	Effenberger *et al.* (1981)
strontianite	$SrCO_3$	orthorhombic (Pmcn)	de Villiers (1971)
siderite	$FeCO_3$	trigonal ($R\bar{3}c$)	Effenberger *et al.* (1981)

The structural details of uranium incorporation into calcite and dolomite were first probed by performing EXAFS experiments on powdered samples exposed to a uranyl perchlorate solution (Geipel *et al.*, 1997). The adsorption experiments were done with no external pH control and under atmospheric conditions, that is, without excluding CO_2. The final solution pH values, after equilibration, were measured to be between 8 and 9 and the final samples had loadings of about 12.8 to 66.3 mg U/g. XPS studies on the samples indicated that the uranyl ions displace Ca at the mineral surface. There was no chlorine-containing surface species detected, indicating that the perchlorate anion did not participate in the surface reaction. The U EXAFS of all the samples studied were indistinguishable and consistent with uranyl coordination. The uranyl equatorial shell was characterized by a broad distribution of U–O distances, with an average of 2.34(2) Å. These results support conclusions of earlier studies that uranyl carbonates and hydroxides form at the grain surfaces of calcite (Carroll and Bruno, 1991; Carroll *et al.*, 1992).

More recent studies have focused on the incorporation of uranyl into synthetic aragonite (Reeder *et al.*, 2000) and calcite (Reeder *et al.*, 2000, 2001). Several previous studies have shown uranyl to be preferentially taken up by aragonite relative to calcite (Kitano and Oomori, 1971; Meece and Benninger, 1993), which points to underlying important mechanistic or structural differences for its incorporation into these two polymorphs. This issue was directly examined by comparing synthetic samples of the two phases (Reeder *et al.*, 2000) that were formed under similar conditions, that is U concentrations were held in the range 10–82 mM, the pH values were maintained at about 8.2–8.3, and air was bubbled through the solutions. Because of the deleterious effects of Sr incorporation on XAS data collection, efforts were made to ensure its exclusion during sample preparation. The final aragonite samples had 985 and 10810 ppm U whereas the calcite samples had 700 and 1890 ppm U in agreement with previous findings that uranyl is preferentially taken up by the orthorhombic phase. U L_3 XANES data indicate the presence of uranyl(VI) in the samples. Fits to the EXAFS data for all uranyl-containing aragonite and calcite samples showed the typical dioxo-coordination environment.

The results of a detailed analysis of the EXAFS data are given in Table 28.11. The most significant differences between U in the two mineral phases were evident in the first equatorial shell. For the aragonite sample, a fit to the data determined that the uranyl ion in aragonite has the same coordination environment as the uranyl triscarbonato solution complex, which was also measured during the same experiment (Reeder *et al.*, 2000, 2001). The O_{eq} distances from aragonite compare to the U–O average distance of 2.47 Å determined for the uranyl coordination by six equatorial oxygens (Burns *et al.*, 1997). In addition to oxygen scattering, a correlation attributed to U–C_3, from carbonate at 2.89 Å is in the range characteristic of bidentate coordination by three carbonate groups (Allen *et al.*, 1995). A further correlation attributed to distal oxygens of carbonate groups at 4.1 Å was also observed, as was a linear

Table 28.11 *Comparisons of coordination numbers (CN), distance from uranium (R), and Debye-Waller factor (σ^2) determined for the best fits of U L_3 EXAFS data from synthetic aragonite and calcite that were precipitated from solutions containing the uranyl ion (Reeder* et al.*, 2000). Multiple values for one parameter indicate fits from different samples. Underlined values indicate that the parameter was fixed during fitting.*

three-legged multiple-scattering path (O_{dist}–C–U) at essentially the same distance. The observation of bidentate coordination of U by three carbonate ions was supported by Raman and luminescence spectroscopies. There was no unambiguous evidence of any U–U interactions that would indicate clustering or co-precipitation of a uranyl mineral phase. In addition, evidence of U–Ca correlation was observed that was dependent on U concentration.

The same basic structural unit was determined for the uranyl incorporation into aragonite as was observed in the growth solution, which was also measured and analyzed (Reeder *et al.*, 2000). The EXAFS results, supported by Raman data, were used to postulate an incorporation mechanism for uranyl into aragonite. EXAFS show that the predominant aqueous uranyl species is $UO_2(CO_3)_3^{4-}$ and that this configuration is preserved in aragonite. The authors suggest that the entire solution species is incorporated into the mineral phase essentially intact (Reeder *et al.*, 2000).

In contrast to the well-defined coordination environment observed for uranyl in aragonite, the coordination environment of uranyl in calcite appears significantly more disordered (Reeder *et al.*, 2000, 2001). The second FT peak from the U EXAFS data, attributable to U–O_{eq}, is significantly less intense and at a smaller U–O distance, relative to the dioxo peak, in the calcite sample. This observation is manifested in the fit, which has fewer, about five, equatorial O with significantly larger Debye–Waller factors (0.009–0.010 Å^2). Weak peaks in the FT suggest that there are carbon atoms coordinated at 2.9 and 3.2 Å with more than one type of U coordination by carbonate, indicating both mono and bidentate interactions. The luminescence data are also different for calcite, indicating the possibility of uranyl hydroxide formation on mineral surfaces, a postulate previously made from an independent study (Geipel *et al.*, 1997).

The work on powder-samples of calcite has been augmented by further work, on single-crystals, designed to address the issue of whether incorporation occurs at structurally distinct surface sites (Reeder *et al.*, 2001). The single crystals were grown at slightly lower pH values (7.5–7.6) than were the powder samples. Luminescence lifetime measurements indicated that more than one solution species was present in the growth solution. The average U concentrations in the crystals were rather low, about 15 and 225 ppm. Micro synchrotron X-ray fluorescence (μ-SXRF) and micro X-ray absorption near-edge structure (μ-XANES) data were obtained from the single-crystals using a monochromatic beam with spot size 15×15 μm^2 or 5×6 μm^2. The as-grown $(10\overline{1}4)$ face was examined, and had a single, polygonized growth hillock composed of four uniform vicinal faces that differed by the orientation of their growth steps and the direction of their advancement during growth. The presence of this hillock is significant because uranyl species can become incorporated into structurally distinct steps of the non-equivalent vicinal faces during crystal growth processes. The μ-SXRF data reveal a striking difference in the distribution of uranium corresponding precisely to the non-equivalent vicinal faces. The $[4\overline{4}1]_+$ and $[4\overline{4}1]_-$ surfaces were highly enriched in uranium relative to the $[48\overline{1}]_+$ and $[48\overline{1}]_-$ surfaces. The magnitude of differential uptake was approximately a factor of 6 to 10. The implications of these findings are that surface controls are significant and therefore that the relative proportions of crystal surface morphologies can strongly influence uranyl incorporation. Polarized μ-XANES revealed neither a discernible difference between the spectra obtained from the non-equivalent vicinals nor any orientational dependence. Fits to the EXAFS data were similar to those from the powder samples, listed in Table 28.11, with two axial O at 1.80 Å, 5.7 O at 2.36 Å, and 3.2 C at 2.92 Å. Weak features observed at higher *r* could be fit with minor contributions from a distal oxygen and a multiple-scattering path at 4.15 and 4.18 Å, respectively. The results indicate that there is no preferred orientation of the uranyl moiety within the single-crystal, and would be consistent with multiple uranium species, as suggested by luminescence and supported by the apparent disorder seen by EXAFS beyond the first coordination shell.

The uranyl concentrations in the synthetic calcite and aragonite samples far exceed that normally found in natural samples, raising the possibility that the obtained coordination environments do not reflect the environments seen in natural samples, which equilibrate over long time frames, and may undergo repeated dissolution/precipitation or structural transformations. Unfortunately, the low concentrations of U typically found in natural calcium carbonate mineral samples, combined with the presence of large amounts of Sr^{2+}, either substituting directly for Ca^{2+} ion in the lattice or as partially segregated into stronitianite (Greegor *et al.*, 1997) complicate the acquisition of EXAFS data with adequate statistics for useful analyses. One study looked at U incorporation into natural coral skeletal aragonite (Pingitore *et al.*, 2002). Two live coral samples, collected from the Galapagos Islands, and one dead sample,

obtained from an exposed reef terrace on Guadeloupe were used in the study. Radiocarbon dating from nearby reefs yielded the age of the Guadeloupe sample as about 25000–30000 years old. The U content, determined from inductively coupled plasma-mass spectrometry (ICP-MS) was low, approximately 3 ppm. In contrast, the Sr concentrations were approximately 7000 ppm in all three samples, requiring XAS data acquisition at the U L_2-edge. XANES edge energies and shapes were used to infer that the U in the two live samples was present as uranyl(VI) whereas that in the dead sample from the exposed reef on Guadeloupe was predominately U^{4+}. Unfortunately, the EXAFS data were not of sufficient quality to confirm this observation and furthermore it should be noted that XANES data can sometimes be misleading when distinguishing between tetra- and hexavalent U (Eller *et al.*, 1985; Calas *et al.*, 1987; Greaves *et al.*, 1989; Biwer *et al.*, 1997; Hess *et al.*, 1998; Sturchio *et al.*, 1998).

There have been two reports published on natural calcite samples that contain uranium. The first looked at a natural sample of spar calcite from a Mississippi Valley-type zinc ore deposit (Sturchio *et al.*, 1998). This sample has a relatively high U concentration (5–35 ppm). The sample also included a high concentration of Sr, necessitating data collection at the U L_2-edge. The XANES data are inconclusive with respect to the U oxidation state. In contrast, the EXAFS data fit well with a single coordination environment. The missing peak at 1.8 Å in the FT confirms the absence of a uranyl ion and the overall coordination environment confirms the incorporation of tetravalent U into the calcite lattice. Although the EXAFS results show an important difference for the U coordination over that of Ca^{2+}, it is clear that the U does directly substitute for Ca^{2+} in the lattice. In calcite, the Ca^{2+} has a first coordination shell of octahedral O about Ca^{2+} at a distance of 2.36 Å (Effenberger *et al.*, 1981). In contrast the incorporated U is best fit with two shells: one at 2.21 and one at 2.78 Å. More distant shells were also observed, including six C at 3.26 Å, six Ca^{2+} at 4.02 Å, and six Ca^{2+} at 4.98 Å. These distances are indistinguishable from those observed in calcite itself. An X-ray synchrotron microprobe analysis of the same sample confirms the substitution of U into the calcite structure and is inconsistent with inclusions of distinct U-rich phases. The simultaneous presence of sulfide minerals and hydrocarbon inclusions indicates that this calcite sample was formed in a reducing environment. This may explain the high concentration of U in this sample, and indicates that U^{4+} is preferentially incorporated into calcite in such environments. In contrast, U^{6+} is generally excluded from calcite. These results provide insight into the geochemical cycle of U in deep groundwater aquifers and anoxic lacustrine and marine basins. The incorporation of U into calcite gives a potentially stable host for dispersed U^{4+} over geological time scales.

The second report of an XAS study of uranium in natural calcite (Kelly *et al.*, 2003) involved the use of XAS and X-ray microprobe to look at a sample relatively rich in U (about 360 μg/g) from a 13700-year-old speleothem deposit

in northern Italy (Spoetl *et al.*, 2002). X-ray fluorescence (XRF) mapping was done with a monochromatic beam (17.3 keV) focused to 5×5 μm^2. Fluorescence emission from U, Sr, and Ca were monitored. XRF mapping indicated that uranium concentrations vary between 80 and 500 ppm that were homogeneous on the 100-μm scale. The data were considered consistent with a dilute solid solution. It is interesting to note that there is petrographic evidence that this natural sample of calcite formed by recrystallization of a U-rich aragonite sample, which may explain the high uranium substitution. In contrast to the previous data on the natural calcite sample from the Mississippi valley, the XANES data from the northern Italy calcite sample indicated uranium is predominately hexavalent. The EXAFS data confirmed a hexavalent, dioxouranyl coordination that is monodentate to four carboxylates with U–O distances from the EXAFS fit of 2.41 Å. These results are similar, although more detailed, than those previously reported for synthetic calcite samples (Reeder *et al.*, 2000, 2001) but the interpretation is different. The authors of the paper, reporting uranyl incorporation into natural calcite (Kelly *et al.*, 2003), propose a direct substitution into the calcite lattice that involves the replacement by UO_2^{2+} of one Ca and two carbonate anions. Charge balance then requires the non-local substitution of excess Na^+, which is observed in the chemical analysis. Overall, the reported EXAFS analyses are not inconsistent with their proposed model, although the complexity of the uranyl site requires eight scattering contributions with 19 variable parameters to adequately fit the data. Considering the reported *k*-range, only 15 parameters should have been used in the fit (Teo, 1986). Thus, although the proposed model for uranyl substitution into calcite is interesting, further experimental work is required for its confirmation.

The overall conclusion that the uranyl ion is more effectively incorporated into the aragonite than the calcite structure raises an environmental issue (Reeder *et al.*, 2000). Prevalent geological conditions at or near the Earth's surface favor the transformation of aragonite, which is metastable, into calcite. However, the uranyl ion does not fit into the calcite lattice as well as it does into the aragonite lattice. The UO_2^{2+} coordination environment is more clearly defined in the latter material, which is known to incorporate a significantly higher concentration of uranyl. Therefore the transformation of aragonite into calcite destabilizes the uranyl incorporated into the phase. As a result, $CaCO_3$ may not be an effective sequestering agent for U(VI) under geologic conditions and over long timescales.

28.3.3 Fe-bearing mineral phases

Iron and its compounds play an important environmental role in both biotic and abiotic processes. Its complex redox and solubility behavior is a function of solution Eh and pH, as sketched in Fig. 28.5 (Hem, 1985). Fe^{2+} is generally soluble in groundwater systems whereas most iron minerals and insoluble complexes contain Fe^{3+}. Iron oxides in particular are ubiquitous in soils and

sediments where they play an important, although not well understood, role in regulating metal-ion distribution through chemical, adsorption, and redox mechanisms. Iron sulfides also play a role in more anoxic environments. Oxidation state properties of Fe can play an important role in actinide speciation and transport, especially in reducing environments. Simple solution redox reactions may be directly affected by the presence of a redox-active surface, or they may be altered in the presence of a mineral surface that can preferentially adsorb, and thereby concentrate metal-ions at solution concentrations that are well below their solubility limits.

In order to understand the results of experiments designed to study actinide speciation on Fe surfaces, which are conducted at a macroscopic level, it is necessary to elucidate a molecular level model for the solid/surface reactivity. Several studies, using EXAFS spectroscopy, have been undertaken to probe actinide speciation on carefully prepared Fe samples, as listed in Table 28.12. Most, although not all of these experiments have focused on uranyl adsorption onto mineral phases, although the occlusion of U by Fe-oxide mineral coatings has also been reported (Jenne, 1977). In the absence of high solution concentrations of complexing ligands, U has been shown to complex to Fe minerals such

Table 28.12 *Published studies of uranium and neptunium binding to Fe mineral surfaces. These studies focus on inner- versus outer-sphere coordination of actinide with mineral surface as well as any evidence of redox chemistry.*

as hematite and goethite over a wide range of solution pH conditions (Hsi and Langmuir, 1985; Waite *et al.*, 1994; Duff and Amrhein, 1996), making these reactions of significant importance to its environmental behavior. For the most part, these studies involve Fe(III) phases and are therefore unlikely to involve redox activity because the studies have utilized the fully oxidized UO_2^{2+} ion in solution.

Among the relevant experiments are those that probe the interaction of uranyl with hydrous ferric oxide (HFO) because the enrichment factor for uranyl on the HFO surface is about 500 times greater than on well-crystallized goethite, and about 10^5 times greater than on clay surfaces (Szalay, 1991). EXAFS data, obtained from samples prepared at pH 5 with an 8.2% surface coverage (Manceau *et al.*, 1992), show uranyl coordination with about five equatorial oxygens at 2.2–2.4 Å and an additional broad peak corresponding to one Fe at about 3.4 Å and another 0.5 Fe at about 3.3 Å. These distances are consistent with uranyl bonding as a mononuclear bidentate inner-sphere complex, sharing edges with the Fe–O, OH surface octahedra. The authors note the excellent match between the unshared edges of the Fe–O octahedra and of the O–O distance of the equatorial uranyl ligands. They use this match to explain the unusually high affinity of uranyl for HFO as compared to crystalline phases such as goethite. The structural relationship between the sorbent and the sorbate is used to explain, at a molecular level, why uranyl complexes inhibit the HFO to crystalline oxide transformation (Manceau *et al.*, 1992).

A related study involved U L_3-XAFS studies of U(VI) adsorption onto ferrihydrate over a wide range of solution and adsorption conditions (Waite *et al.*, 1994). Ferrihydrate is an amorphous or poorly crystalline hydrous Fe(III) oxide that exhibits a stoichiometry near $Fe_2O_3 \cdot H_2O$. EXAFS experiments were performed on ferrihydrite samples that had been aged for 65 h at 25°C and pH 6, after which the pH was adjusted to 5 or 5.5 and held for a further 24 h before adding U(VI). There were two samples made with U/Fe molar ratios of 0.044 and 0.077. Data, collected over a k-range of 3–16 $Å^{-1}$, required three U–O and one U–Fe shells to obtain the best fit. The results, using integral coordination numbers for the U–O fits, were two axial O at 1.80 Å, three equatorial O at 2.34 Å, two O at 2.52 Å, and about 0.5–1 Fe at a distance of approximately 3.4 Å. The authors conclude from their fits that the O at 2.52 Å is an inner-sphere O sorbed to the ferrihydrate surface. The Fe is coordinated in a bidentate fashion with the U, and, within a 10% error margin, there are no sorbed multinuclear uranyl complexes. These results are very similar to those reported in the previous study (Manceau *et al.*, 1992), although the latter study shows a split equatorial oxygen shell. The EXAFS results, supported by model simulations, suggest that the major U(VI) species at the ferrihydrite surface in the acidic pH range is an inner-sphere, bidentate complex that involves two surface hydroxyls of an Fe octahedral edge and the uranyl cation. Later work on very similar samples (Reich *et al.*, 1998b) failed to confirm the split oxygen shells at 2.34 and 2.52 Å, but instead found a single shell with five O coordinating at 2.36–2.39 Å

with a large Debye–Waller factor, consistent with the earlier work (Manceau *et al.*, 1992). Despite the absence of evidence for a split equatorial oxygen shell, inner-sphere complexation was proposed (Reich *et al.*, 1998b), and the authors noted that the difference in the equatorial oxygen coordination cannot be explained by the shorter *k*-range of their data.

Uranium uptake was studied from solutions at various pH values in the presence of the iron-bearing mineral phases goethite, lepidocrocite, and mackinawite (Moyes *et al.*, 2000). Refinements of EXAFS data show the U coordination at the surface to be very similar to those reported previously for U bound to other Fe–O and Fe–S mineral surfaces (Waite *et al.*, 1994; Reich *et al.*, 1998b). Binuclear, bidentate surface complexes are present together with monodentate, mononuclear coordination to the structural sulfate for the $FeSO_4$ oxide, schwertmannite (Walter *et al.*, 2003).

The EXAFS results from uranyl adsorbed on HFO and other mineral samples, together with modeling, show that the adsorbed complex is a unique product of the coordination environment at the surface, and appears independent of the predominant U(VI) speciation in solution, as was previously suggested (Waite *et al.*, 1994). A diffuse double-layer, two-site model with two proposed surface species provided excellent agreement with all data over a range of pH, U(VI) concentration, and two dissolved CO_2 concentrations. This conclusion contradicts several previously published modeling approaches to uranyl surface speciation (Hsi and Langmuir, 1985).

It has been previously reported that dissolved carbonate, ubiquitous in groundwater, plays a crucial role in the distribution of U(VI) between solution and Fe oxide surfaces (Ho and Doern, 1985; Hsi and Langmuir, 1985). EXAFS studies have focused on the molecular influence of carbonato complexation on U sorption onto Fe oxide surfaces. U complexed to ferrihydrite shows a U–C distance of 2.93(2) Å (Reich *et al.*, 1998b), which matches the U–C distance previously reported for a bidentate coordination of the CO_3^{2-} group to uranyl (Coda *et al.*, 1981; Allen *et al.*, 1995), and is consistent with the proposed formation of $(\equiv FeO_2)UO_2CO_3^{2-}$ (Waite *et al.*, 1994), an inner-sphere structure. U coordinated to hematite shows a similar behavior (Bargar *et al.*, 1999a,b). EXAFS fits indicate that U(VI) has five to six equatorial oxygens. Since two of these should be hematite-surface oxygens, it is argued that there are at most two carbonate ligands and the complex should have a composition similar to $FeO_2UO_2(CO_3)_x$, where $x \leq 2$. The absolute coordination numbers for carbonate in all samples imply that $\geq$ 50% of adsorbed U was complexed, even at pH 4.75. This finding contradicts predictions that U(VI)–carbonato ternary complexes should predominate only above pH 6 (Waite *et al.*, 1994). In addition, at pH values $\leq$ 6.5, there was no evidence from the EXAFS data for second-neighbor U(VI), indicating that the adsorbates were monomeric (Bargar *et al.*, 2000).

Also ubiquitous in the environment is the citrate anion. EXAFS was used to characterize the coordination environment of uranyl adsorbed onto goethite in

the presence of citrate under aqueous conditions where uranyl is strongly sorbed (Reddon *et al.*, 2001). A PCA showed that two major constituents should account for all the data. Unlike other Fe-mineral adsorption studies, there was no evidence of a Fe-neighbor in the U EXAFS. The authors concluded that the adsorption of uranyl does not follow a simple, stoichiometric relationship between the total U and citrate in the sample, and that under the conditions employed the adsorption of citrate on goethite appears to be favored over the formation of a uranyl–citrate–goethite complex.

In addition to the adsorption of uranyl onto mineral phases, EXAFS structural data were reported for U trapped in Fe-rich gels that are formed during the oxidative weathering of a granitic U deposit in the context of acid-mine drainage (Allard *et al.*, 1999). These natural samples, from the Massif Central in France, were in water that was close to saturation with respect to amorphous silica and crystalline-hydrated U-hydroxides and silicates. This effort addressed the elementary processes implied in U sorption and the trapping mechanism of U by natural short-range ordered phases. They investigated samples obtained at the fissure outlets on the walls of the galleries. These include hydrated amorphous products that are referred to as gels. XANES data confirm that the U was found to be present as hexavalent uranyl. The EXAFS on the Fe-rich gels found that uranyl is mainly present either as an outer-sphere complex or as an inner-sphere complex unresolved by EXAFS. No U–Fe, U–Si/Al, or U–U interactions were evident from the gel samples. The absence of U–Fe contributions to the data, despite the high affinity of uranyl for hydrous Fe oxides, suggests that U may be trapped in a two-step process involving the early complexation of U and Si/Al followed by the transport of Fe as ferrous in fissure water, with the ultimate precipitation of Fe in Si/Al-containing solutions at a redox front.

Green rusts, which are mixed Fe(II)/Fe(III) hydroxides, are formed by a number of abiotic and biotic processes under circumneutral to alkaline conditions in suboxic environments. The interaction of hydroxysulfate green rust, in which SO_4^{2-} is an interlayer anion was studied to examine its influence on the redox behavior of U(VI) (O'Loughlin *et al.*, 2003). L_3-edge XANES spectra show that U(VI) was readily reduced to U(IV) at a pH of 7.3 in the presence of green rust. EXAFS data indicate an average U local environment similar to that in UO_2. The decreased FT amplitude in the green rust sample compared to a UO_2 standard probably indicates small particle size and/or increased disorder.

The co-precipitation of uranium with iron-oxide minerals was studied with a series of co-precipitates with mole fractions of U in the range of 0.35–5.4% (Duff *et al.*, 2002). Although the XANES spectra are consistent with U(VI), EXAFS results show U to be in a highly distorted environment, in agreement with XRD, FT-infrared, XANES, and luminescence studies. Fits to the data for samples with <1 mol% U indicate no axial O, instead there are about four O at 2.21–2.36 Å. The model fits also indicate that at least one Fe atom exists in the uranium second-coordination shell at 3.19 Å. However, details of the fit suggest that there are multiple shell environments. Overall, the results are interpreted as

consistent with the incorporation of U(VI), minus the dioxo coordination, into the Fe oxides. This situation does not apply for co-precipitated samples with > 1 mol% U, which exhibit uranyl coordination and evidence of a second shell U backscatterer. These data are consistent with XRD, FT-infrared and luminescence data, which taken together show evidence of a U(VI) oxide hydrated phase such as schoepite, $UO_2(OH)_2 \cdot 2H_2O$.

There have been few reports of synchrotron studies centered on the sorption of transuranics onto Fe-bearing mineral phases. Despite its low affinity for complexation, Np(V) has been reported to sorb onto mineral surfaces with the decreasing affinity: calcite > goethite >> $MnO_2 \approx$ clays. The sorption of Np(V) onto these phases may involve its reduction to yield the much less soluble Np^{4+}, which has much high binding affinities and generally lower solubility. An early study of Np(V) on an iron-bearing mineral involved goethite, which has fully oxidized Fe (Combes *et al.*, 1992). XANES spectra confirm the presence of neptunyl groups. Fitting the EXAFS data results in 2.2 O at 1.85 Å and 5.5 O at 2.51 Å for Np adsorbed onto goethite, compared with the fit obtained from Np (V) in solution of 1.6 O at 1.83 Å and 5.2 O at 2.52 Å. This coordination environment for solution Np(V) compares with more recent comparative studies of Np coordination in solution, which are listed in Table 28.4. The only observed difference between the spectra obtained directly from solution and the goethite-sorbed spectrum is the presence of high-amplitude structure between 2.5 and 4 Å in the FT of the latter. Although these data may indicate Np–Fe interactions, the short *k*-range prohibits a full analysis. The authors claim that their data rule out diffusion into the solid and precipitation or coprecipitation of ordered solids onto the goethite surface. A more recent study (Moyes *et al.*, 2002) looked at solution Np(V) sorption onto microcrystalline mackinawite (FeS) at pH values in the range 7–8 and 3, and Np solution concentrations of 0.27, 0.68, and 2.74 mM. XANES spectra indicate limited sorption coupled with a reduction to Np(IV) that is confirmed by EXAFS. The coordination environment of Np in all samples is indistinguishable, with four O at 2.25 Å, three S at 2.63 Å, two Fe at 3.92 Å, and six Fe at 4.15 Å. The absence of two axial O atoms at about 1.85 Å supports the XANES finding for the reduction of Np(V). The short Np–S distances suggest a direct coordination with mineral surface S.

28.3.4 Phosphates

The phosphate class of minerals are made up of $(MO_4)^{3-}$ units in which M^{5+} can be P, As, Sb, or V (Deer *et al.*, 1992). Although apatites are the most common subclass of the phosphates, monazites are important here because of the insolubility of rare-earth and actinide phases. Thorium and uranium are common impurity phases in monazite.

Uranium sorption on the surface of hydroxyapatite, $Ca_5(PO_4)_3OH$, was studied as a removal mechanism for heavy metals from groundwater, either

by precipitating as a phosphate or by ion-exchange for Ca^{2+} (Fuller *et al*., 2002). Samples with less than 4700 ppm surface-sorbed uranium(VI) were studied by EXAFS and found to have the standard axial dioxo coordination. In addition, a broad equatorial shell was observed that, for two of the three samples studied could not be resolved by the fit. The single, unresolved shell was fit to a distance of about 2.313 Å by employing large Debye–Waller factors and fixing the coordination number to six. The most concentrated sample (4700 ppm) showed a resolvable two-shell equatorial coordination with 3.6(6) O at 2.338(8) Å and 2.1(2) O at 2.51 Å. Two of the three samples also had U–Ca interactions that fit to about one Ca at 3.8 Å, a distance consistent with bidentate edge sharing and/or monodentate corner-sharing coordination between the equatorial oxygens of the uranyl ion and the Ca–O polyhedra on the hydroxyapatite surface. In contrast, the U(VI) coordination environment is inconsistent with its incorporation into the mineral phase. One of the samples, exposed to dissolved carbonate, showed a U–C interaction implying U–carbonate ternary complexes. There were also indications of a more distant coordination shell that was fit as either a Ca atom at 4.55 Å or a U atom at 4.09 Å, with no independent evidence presented that could distinguish between the two fits. As the uranyl coverage on the hydroxyapatite surface increased above 4700 ppm, the EXAFS spectra began to resemble that of a U(VI) phosphate, notably chernikovite, $(H_3O)_2(UO_2)_2(PO_4)_2 \cdot 6H_2O$. The uranyl uptake at the onset of chernikovite precipitation corresponds to a surface coverage of about 6% of a monolayer.

An independent study was also conducted on the incorporation of U(VI) into synthetic fluorapatite (Rakovan *et al*., 2002). XAS together with luminescence and diffuse reflectance were used to determine the local structure of U(VI) in a powder sample. The sample had a concentration of 2.3 wt% U. Optical luminescence data, including lifetime measurements, combined with diffuse reflectance data indicate that although the U appears hexavalent in the fluorapatite sample, it does not have the standard dioxo coordination environment. This finding is supported by U L_3-edge XANES spectra, which confirms that uranium is hexavalent. However, the XANES data do not show the small shoulder feature indicative of dioxo coordination about uranium (Hudson *et al*., 1995a), but instead are similar to the spectra observed for U(VI) in Li_4UO_5 (Locock and Burns, unpublished) and Np(VII) in solution (Williams *et al*., 2001). Both of these ions exhibit an unusual tetraoxo coordination environment of four short and two longer oxygen distances. This coordination environment is confirmed by a simple inspection of the U EXAFS data, which are also inconsistent with a dioxo coordination environment. An analysis revealed that U is coordinated to six equidistant oxygens at 2.06 Å. With respect to the host fluorapatite sample, the U EXAFS fit shows a similarity to the coordination environment of the Ca1 site (space group $P6_3/m$, No 176; Wyckoff position 4*f*; 3 symmetry) (Comodi *et al*., 2001). Attempts to fit the data assuming Ca2 substitution (Wyckoff position 6*h*, *m* symmetry) were unsuccessful. The finding of 6 oxygen at 2.06 Å is in agreement with the average U–O distances for

six-coordinate, tetraoxo- (Hoekstra and Siegel, 1964) or near-cubic (Bawson *et al*., 1956) coordination. This work clearly demonstrates that fluorapatite can accommodate large concentrations of U(VI) into the lattice, with a coordination environment that is very similar to that found in perovskites, another common mineral class. Therefore, the determination of significant uranium incorporation into fluorapatite may point to an important sequestration mechanism for high-valent actinides in the environment.

Uranyl sorption onto the lanthanide phosphates $LaPO_4$ and $La(PO_3)_3$ has also been studied as a function of pH (Ordonez-Regil *et al*., 2002). The study included pH values of 1, 2, and 3, which compare to the isoelectric point of about 4 for $LaPO_4$ and 3 for $La(PO_3)_3$. The fitted parameters for the EXAFS spectra from the two samples were statistically indistinguishable. In addition to the dioxo-shell, there were two equatorial O shells, with 2.4 O at 2.31 Å, and 1.8 O at 2.47 Å, distances consistent with bidentate, inner-sphere coordination. The observation of a U–P interaction at 2.74 Å is used to argue that the uranyl is complexed to a single surface phosphate group.

28.3.5 Natural soil samples

The understanding and prediction of actinide speciation in natural soil samples comes from a synthesis of the published studies of actinide speciation and coordination under laboratory conditions. The challenge encountered when characterizing naturally occurring samples is the length scale of potential inhomogeneities. Depending on their origins, soil samples can have fine grain sediments that present chemical inhomogeneities on the micron or smaller length scale. Micro techniques that have been used to study such samples, including scanning tunneling microscopy (STM) (Yanase *et al*., 2002) uranyl fluorescence (Joergensen, 1977) and micro-Raman (Allen *et al*., 1987; Biwer *et al*., 1990; Palacios and Taylor, 2000) that produce important, but limited, information about uranium speciation.

Until the development of specialized μ-XAS and μ-SXRF capabilities, synchrotron-based spectroscopic studies were limited by beam sizes on the order of mm^2 or larger. Various micro-focusing techniques have reduced the beam size to about 50×50 μm^2 or larger, depending on energy ranges and flux requirements. Unfortunately, the focusing optics work over limited energy ranges, so that for work on the actinide L_3-edges, XAS energy scans are limited to 200–300 eV, sufficient only for XANES spectroscopy. Nevertheless, information has been obtained by these μ-XAS techniques that have significantly broadened the knowledge of actinide speciation in these complex samples.

A conventional XAS study on uranium-contaminated soil samples showed the potential for XAS to contribute information necessary to the development of a rational remediation scheme (Morris *et al*., 1996). This study examined samples from the Fernald Environmental Restoration Management Company, a U.S. DOE facility that once served as one of the principal processing centers

for uranium. The soil matrix consists primarily of quartz, calcite, dolomite, and the clay minerals illite and chlorite, with the pH of the topsoils in the range of about 5.4–6.3 (Elless and Lee, 1994). Background levels of U in uncontaminated reference topsoils near the production facility are typically about 3–5 ppm. There were many different source terms for the contaminants including both aqueous waste and airborne particulate. U concentrations from production range from about 10 to 8000 ppm at pH values of 7–8.5. Only about the top 0.25–0.3 m were contaminated.

XANES studies of both bulk and size-selected samples showed that most of the U exists in the hexavalent oxidation state, a finding that was confirmed by EXAFS. EXAFS data showed that the equatorial uranyl coordination varied significantly between samples and indicated variation in speciation. Independent optical, microscopy, and diffraction (Elless and Lee, 1994) data indicated the presence of autunite-like, $Ca(UO_2)_2(PO_4)_2 \cdot 2–6H_2O$, and schoepite-like, $UO_3 \cdot 2H_2O$, phases in the samples, consistent with the variation in EXAFS coordination. The goethite (FeOOH) that is naturally present in the soil should require U(VI) if equilibrium is reached because the Fe(III)/Fe(II) reduction potential is considerably lower than the corresponding U(VI)/U(IV) potential. The XAS used in this study, together with other spectroscopies, confirmed that 75–95% U was hexavalent. Based on this speciation, the authors were able to make specific recommendations about site remediation, including the need for near-term action based on the solubility and mobility of U(VI). A later study, in which U was added to natural subsurface soil samples from Hanford, SRS, and Oak Ridge produced similar results (Bostick and Fendorf, 2002).

Micro-XAS and synchrotron X-ray fluorescence (SXRF) studies on soil and sediment samples from Fernald and the Savannah River Site (SRS) offer a different perspective (Bertsch *et al.*, 1994; Hunter and Bertsch, 1998). The samples from the SRS differ from those of Fernald in that the U contamination was discharged as aqueous waste. This study used a micro-focused synchrotron beam with spot sizes that varied from 50×50 to 300×300 μm^2. The focusing optics utilized limit the energy range over which data was collected to approximately 200–300 eV, which restricted spectra to the XANES region only. Under the experimental configuration employed, it was possible to simultaneously collect a full SXRF spectrum to provide specific information on associated elemental distributions that is coupled to speciation data from XAS. The objective of the study was to determine U speciation in localized regions within inhomogeneous samples. XANES of clay fractions from both sites indicated $> 90\%$ hexavalent U, with no evidence of spatial variability of the U speciation within the clay fraction. This result was expected because the beam size was much bigger than individual clay particles and was consistent with the large number of size-fractionated sediment samples from SRS even though some of these latter samples were collected in seasonally reduced environments from wetland areas. No observation of significant biotic or abiotic U reduction was observed, as had been previously suggested (Lovley *et al.*, 1991; Nagy *et al.*, 1991), from samples

with high organic content that were in reducing environments. In contrast, sand and sediment fractions showed significant spatial variation using a 50 μm beam. The XRF signal was monitored, looking for areas concentrated in U, and then XANES spectra collected. Two types of populations were discernable: (1) those highly enriched in U and depleted in other elements such as Fe and Mn. For Fernald soil samples, U-rich regions were often relatively enriched in Ca, Cu, and Zn, whereas for SRS sediment these regions were highly enriched in Ni, and (2) U was concentrated and co-associated with regions relatively enriched in Fe and Mn. The U-rich region represented about 25% of the observations and may represent discrete U-containing phases either originally deposited as a component of the source term, or subsequently precipitated as a secondary phase. The zones of lower U concentration may represent either U co-precipitated with or sorbed to the Fe, Al, and Mn oxyhydroxides indigenous to the samples. XANES data, obtained using a 50 μm beam, from various regions within the sand fraction of Fernald soils provided evidence of varying oxidation states. Two of the 22 regions sampled showed predominantly U(IV) whereas other regions showed U(VI). There appeared to be discrete regions of U(IV) surrounded by a larger number of U (VI)-containing particles or surface-associated U(VI) phases. In contrast, when operating with a beam size of 300 μm, there was no evidence of pure or predominantly U(VI) speciation because of spatial averaging, pointing out the clear advantage of microprobe studies of natural, spatially inhomogeneous samples. The sand fractions from SRS did not display spectral differences indicative of varying oxidation states and were consistent with U(VI). However, post edge features indicated significant differences in the coordination environments within various regions of the sample.

During the 1999 global conflicts in the Balkan states, ammunitions were expended containing large amounts of depleted uranium (DU) that remains as an environmental pollutant with unknown health risks (Fetter and von Hippel, 1999; Priest, 2001; Bleise *et al.*, 2003). A series of studies was devised to investigate the oxidation state of particles dispersed into the geosphere in order to assess the fate and transport of this introduced pollutant (Shaughnessy *et al.*, 2003). The samples used in the analyses were collected at Ceja Mountain, Kosovo. Analytical results revealed U in soils with concentrations exceeding 2–3 ppm. Scanning electron microscopy (SEM) showed that most of the particles were present in the respiratory fraction, that is less than 5 μm (Danesi *et al.*, 2003). Micro-XANES data from the samples, obtained over an energy range of 300 eV using an X-ray beam spot size of 20×20 μm^2, were compared with U standards. SXRF data indicated the simultaneous presence of U and Ti, in accord with other analytical techniques and the known sample histories. The U L_3-edge data from the samples indicated that the U was oxidized, i.e. that there was no metal present. Depending on sample details, the U was consistent with either tetravalent U, as UO_2, or U_3O_8, or mixed samples. Hexavalent U was not observed. This finding is interpreted as DU particles with tetravalent

cores and oxidized surfaces, indicating weathering. This study revealed important factors for further assessing the environmental and health impacts of munitions-generated depleted U.

Elevated levels of U occur in natural soils and evaporation ponds that are associated with agricultural irrigation activities in the southwestern U.S. Evaporation ponds are periodically filled and evaporated to dryness, a process that can significantly influence redox processes. Most soils in the area are derived from marine Cretaceous shale that is known to contain high levels of U, with total concentrations as high as 280 ppm. A synchrotron-based study has been published that focuses on natural uranium speciation in evaporation ponds located in the San Joaquin Valley (SJV), CA (Duff *et al.*, 1997). Sediment samples, obtained from depths of 0–5 cm, were collected on two different occasions, one when the pond was nearly dry and the other when it was partially filled with drainage water. Suspension pH and Eh measurements were obtained at the time of sampling. There were no observable trends in U concentration with depth of sample, however the aqueous concentrations of U(IV) decreased with increasing Eh whereas dissolved U(VI) concentrations increased greatly with increasing Eh.

Micro-XANES data were obtained over a 130 eV range with a $200 \times 200\ \mu m^2$ beam size and SXRF data were collected at the U L_3-edge energy. XANES spectra were fitted using those obtained from standard spectra to assess relative ratios of reduced to oxidized U. These data showed that the amount of reduced U relative to oxidized U increases with increasing sample depth. The deepest samples (about 5 cm) showed that about 25% of the U in the measured samples was tetravalent. No changes were observed in the U concentration as the beam was scanned across the sample. Whereas the samples did not appear to contain any U hotspots, it should be noted that the particle sizes less than 2 μm were considerably smaller than the beam size, which was about 200 μm. A scenario for the fate of U in the SJV evaporation pond was proposed based on XANES and SXRF data that were complemented by other analytical techniques. It was proposed that U enters the pond in the drainage water, probably as a carbonate anionic species. Some of the U is accumulated by algae that creates a biomass with reducing conditions in which U(VI) reduction takes place. The precipitation of mixed U(VI)/U(IV) in organic matter then brings the U into the sediment. Over time, with increasing burial, the increasingly anoxic environment further reduces the U(VI). As the ponds drain, the soil aerates and the reduced U is reoxidized, resolublized, and thus remobilized. A follow-up study was published that addressed samples obtained over a wider depth range, 0–40 cm (Duff *et al.*, 2000). Microprobe (300 μm^2 spot size) XANES measurements, over a 140 eV range, were used to infer the relative amount of U(VI) by comparing edge position with known standards. This study found that the relative percentage of U(VI) appeared to decrease with increasing sampling depth and correlated with a decreasing total organic content.

The power of synchrotron-based microprobe spectroscopies to provide unique speciation information was clearly demonstrated in a series of experiments designed to probe plutonium adsorbed to natural tuff samples from the Yucca Mountain site (Duff *et al.*, 1999a,b, 2001). Tuff is rock composed of compacted volcanic ash that varies in size from fine particulate to gravel. These studies were performed to assist in the modeling of Pu speciation and groundwater transport in the event of a release of stored radioactive waste into the environment. The solubility of Pu in groundwater varies greatly, with 3+ and 4+ states being significantly more sorptive and less soluble than their higher valent counterparts. This discrepancy occurs because the higher valent ions form dioxo moieties, which have lower overall ionic charges. Under acidic conditions, Pu(v) undergoes disproportionation, to form Pu(iv) and Pu(vi), whereas in neutral to basic oxic solutions $Pu(v)O_2^+$ dominates speciation. The synchrotron microprobe studies were designed to determine what Pu species are adsorbed to natural tuff samples using spatially resolved μ-SXRF to determine Pu distribution and μ-XANES to determine oxidation states. All oxidation states of Pu have been reported to sorb to smectites and iron- and manganese-bearing oxyhydroxides (Keeney-Kennicutt and Morse, 1985; Sanchez *et al.*, 1985). A question addressed by these studies is whether minerals, particularly those with redox-active surfaces, can influence the redox chemistry of Pu in solution. The tuff samples, analyzed by X-ray diffraction, were predominantly zeolitic phases, specifically clinoptilolite 80 wt%, smectite 2%, opal 8%, feldspar 7%, and quartz 3%. Further work on the smectite isolates showed them to contain rancieite, a mineral with mixed manganese content, (Ca, Mn^{2+}) $Mn_4^{4+}O_9 \cdot 3H_2O$.

Information on the average oxidation state of sorbed Pu on tuff was obtained on the spatial scale of about 140 μm^2. The Pu-sorbed samples were prepared using 10^{-4} M, $^{239}Pu(v)$ spiked, synthetic groundwater meant to mimic deep tuffaceous aquifers such as those found below Yucca Mountain. About 92–98% of the initial Pu(v) in solution was sorbed to the samples. SXRF was done for elements with absorption energies below 18.5 keV. The problem in resolving the Pu and Sr signals was circumvented by obtaining one elemental map just below the Pu L_3-edge and another just above the edge. The Pu elemental map was then obtained by subtracting the images. Contrary to expectations based on previous work (Triay *et al.*, 1997), the mapping showed that Pu is predominately associated with manganese oxides, specifically rancieite, and smectites but not with iron oxides. Fractures and pore spaces from Yucca Mountain tuff samples contain highly reactive surfaces that can sorb a variety of differently charged and sized ions from fracture- and pore-space fluids. Rancieite comprises less than a percent of the mineral distribution in the tuff, but its presence at primary flow paths makes it highly accessible to dissolved species in the groundwater (Duff *et al.*, 2001). Several other elements in addition to Pu were co-associated with the manganese oxide and not with hematite. It is postulated that the iron mineral surfaces appear to be passivated and thus inaccessible to sorption.

Why the iron oxide, and not the manganese oxide, surfaces were passivated is not understood. Modeling and surface calculations based on experimentally determined concentrations suggest that multiple binding sites are present on the Mn–O/smectite phase.

μ-XANES was obtained from the same samples at two different 10×15 μm^2 spots that appeared to contain the highest level of Pu as determined by the SXRF mapping. Unfortunately, XANES was not definitive in determining the oxidation state. Although the Pu L_3-edge position indicates the presence of primarily Pu(VI), the post edge feature associated with multiple-scattering from the plutonyl was not observed. The FT of a short EXAFS spectrum ($k_{max} = 8$ Å^{-1}) did not show evidence of the two-shell first coordination sphere that is expected for plutonyl coordination (Duff *et al*., 1999b). A single peak at 1.65 Å (uncorrected for phase shift) was observed but not fit. In addition, there was no evidence of a Pu–Pu interaction, which would have signaled Pu precipitation on the tuff surface. The authors conclude only that there may have been some oxidation of their Pu upon sorption to the Mn^{4+}-rich phase. It should be noted that tuff samples have been shown to oxidize Ce(III) to Ce(IV) (Vaniman *et al*., 2002), an oxidation that was attributed to its association with rancieite, which contains an oxidized fraction of Mn.

These seminal papers clearly demonstrate the importance of a molecular level understanding of sorption on natural samples. That Pu should sorb preferentially to a Mn-oxide phase was not expected. Such information is very important in modeling actinide migration through the geosphere. In addition, it supports previous findings that actinide sorption is governed by the solid–water interface rather than solution speciation (Waite *et al*., 1994). The results show that predictive remediation requires a more comprehensive understanding of Mn–Pu interactions.

Toward this end, a study was undertaken (Shaughnessy *et al*., 2003) of interfacial reactions between aqueous Pu(VI) species and Mn oxyhydroxide mineral surfaces, notably manganite (MnOOH) and hausmannite (Mn_3O_4), which serve as representative examples of Mn phases typically found in the vadose zone. Note that manganite has a rutile-related structure, with trivalent Mn whereas hausmannite is a spinel-related structure with mixed di- and trivalent Mn. These two phases were from commercial stock and size selected for particles in the range of 63–212 μm. The pH of the point of zero surface charge (pH_{pzc}) was determined to be 7.4(3) for manganite and greater than 10 for hausmannite. Sorption studies were done as a function of pH over the range 3–10, a function of Pu concentration, and as a function of solution exposure time at a fixed pH. Pu solution concentrations ranged from 1×10^{-7} to 1×10^{-4} M. There was an initial rapid sorption step that occurred within the first 24 h of contact, followed by a much slower sorption process. This two-step process for actinide adsorption onto mineral phases has been previously reported (Keeney-Kennicutt and Morse, 1985; Waite *et al*., 1994). All XAS data reported in the Mn work were limited to samples that had a 24 h contact time with the soak-Pu

solutions. The sorbed Pu oxidation states were determined by a combination of optical absorption methods and XAS. A comparison of the Pu L_3-edge XANES data from the mineral-adsorbed phase with those from oxidation-state specific solution phases showed that the Pu sorbed to the Mn phases had been reduced from Pu(VI) in the initial solutions to Pu(IV) on the sorbed surface. Optical spectra on the remaining solutions determined the presence of Pu(V). In other words, all of the initial solution phase Pu(VI) had been reduced to either Pu(V), which remained in solution, or Pu(IV), which remained sorbed on manganite or hausmannite. There was no reduction observed for a blank Pu(VI) solution over the same time frame. The reductant in this redox reaction was not clearly evident from the experiment, but the authors conjecture that there may have been dissolved Mn(II) in solution. It should be noted that the reduction of Pu(VI) observed in this study is in contrast to the work on natural tuff, in which Pu (V) was seen to oxidize (Duff *et al*., 1999a,b, 2001). The similarity in redox couples for Pu(IV), Pu(V), and Pu(VI) clearly complicates the chemistry in these redox-active mineral systems. EXAFS data from the same Mn samples (Shaughnessy *et al*., 2003) were analyzed to determine the Pu coordination onto the mineral surfaces. The data were analyzed over a short *k*-range (2.5–10 $Å^{-1}$), significantly limiting the allowable number of variable parameters in the fitting. The data do not indicate dioxo coordination of the Pu, supporting the XANES interpretation of Pu reduction to tetravalent. The best fit was consistent with a single O shell at distances of 2.28–2.36 Å and with coordination numbers in the range of 7–9. The values may vary with the pH of the soak solution used for the sorption experiments. The fitted distances compare well with those expected for Pu(IV)–O interactions, as exemplified by the 2.337 Å one found in PuO_2 (Haschke *et al*., 2000). In addition, Pu–Mn interactions were observed at about 3.37 Å for all samples, indicating that, like other adsorbed actinides, the sorbed Pu has an inner-sphere coordination with the mineral surface. These results support the finding that Mn-based mineral phases may serve to sequester Pu under natural groundwater conditions.

28.3.6 Bacterial interactions

It has been recently realized that microbes can actively influence actinide chemistry in the environment. Although much less studied than processes involving inorganic constituents, biotic interactions can have a marked influence on actinide speciation. Microbes are ubiquitous in the environment and therefore their influence must be included when developing predictive modeling for actinide fate and transport. Microbial processes can cause either mobilization or immobilization of radionucludes, that is actinides may be stabilized in solution or precipitated by direct processes, such as respiration, or indirect processes, such as the biotic modification of solution constituents.

XAS is developing into a cornerstone technique for discerning the influence of bacteria on actinide speciation, as indicated by the published work referenced in

Table 28.13. XAS is often used together with other physical techniques, such as optical and/or infrared spectroscopies, X-ray diffraction, microscopy (TEM, SEM), EDS (energy dispersive X-ray spectroscopy). These results augment the standard chemical analyses, such as titrations and solvent extraction. The advantage afforded by XAS is that it can probe metal-ion speciation *in situ*, that is in the presence of bacterial cells, cell growth media, and other metal-ions, with no necessity for chemical pretreatment. Its sensitivity to oxidation state is particularly important for probing redox effects of microbial interactions. Among its most significant disadvantages are its sensitivity, often requiring ppm or higher concentrations for meaningful data acquisition, and the propensity for beam-induced redox chemistry (Skanthakumar *et al.*, 2004) that can vitiate speciation, especially at low metal concentrations.

There are several questions that arise concerning microbial influence on actinide speciation. These all center on solubility and transport issues, and include precipitation, adsorption to the bacterial surface, incorporation into the cell, and solubilization of mineral phases. Precipitation can occur either through a change in redox state or through chelation. Generally, the higher oxidation states, including U(VI), Np(V), and Pu(V), (VI) are soluble in acidic and near-neutral pH, whereas their tetravalent analogs are relatively insoluble. Therefore, processes that control oxidation state are particularly important to quantify. Compounds or ions in solution may be used as electron acceptors in energy metabolism, a process referred to as dissimilative metabolism. The reduced species is excreted in the environment. Microbes are known to involve metal-ions, such as Fe(III) or Mn(III,IV), directly in their respiratory processes as electron acceptors. Aerobic respiration involves O_2 as the electron acceptor. Some microbes are capable of anaerobic respiration, in which they use nitrate, sulfate, carbonate, ferric iron or even certain organic compounds as the electron acceptor. Because these ions have lower reduction potentials than O_2, less energy is released. However, the use of alternate electron acceptors in their respiratory process allows microorganisms to live in environments that contain too little oxygen to support life.

Dissimilatory metal-reducing bacteria (DMRB) are able to couple the oxidation of organic matter to the reduction of Fe(III) or Mn(III/IV). Under anoxic conditions, DMRB have been shown to readily reduce U(VI) to precipitate UO_2 solid (Lovley *et al.*, 1991; Gorby and Lovley, 1992). XANES spectroscopy was used to probe U(VI) reduction, either as an aqueous species $[UO_2(CO_3)^{4-}_{3(aq)}]$ or as metaschoepite $[UO_3 \cdot 2H_2O_{(s)}]$ (Fredrickson *et al.*, 2000). The results showed that the DMRB bacterium *Shewanella putrefaciens* reduced UO_2^{2+} in complex mineral suspensions via a combination of direct enzymatic or indirect mechanisms to insoluble U(IV) species. U reduction occurred whether the U(VI) was in solution or associated with a solid phase. The studies further showed that *S. putrefaciens* could reduce U(VI) in complex suspensions that included Fe(III) as an alternative electron acceptor, despite the lower standard potential of the U (VI) couple, as shown in Table 28.1. Further experiments, involving Mn K-edge

XANES, showed that the presence of Mn(III/IV) oxides may impede the reduction of U(VI), by *S. putrefaciens* (Fredrickson *et al*., 2002), in soils. Independent studies use U L_3 XANES to determine that *Desulfosporosinus* ssp, a Gram positive sulfate reducer, is able to reduce U(VI) to U(IV) (Suzuki *et al*., 2002, 2003). These studies used organic substrates to create anaerobic conditions to stimulate growth of *Desulfosporosinus* ssp in natural U-contaminated sediments from the Midnite Mine, WA, USA. After 1 month, the U concentrations were reduced from 20 to 0.3 ppm. EXAFS-determined coordination numbers were used to infer an average particle size of about 1.5 nm. XAS, together with TEM data show the particles to be uraninite. The authors conclude that the small particle size of biogentic UO_2 may not significantly limit its mobility. This has important implications for the use of bacteria in environmental remediation.

A review of the standard reduction potentials listed in Table 28.1 shows that both Np(V) and Pu(VI), (V) are more easily reduced than is U(VI), suggesting that microbial reduction may play an important role in the aquatic environmental chemistry of dissolved or sorbed actinide ions. In addition, bacteria can be viewed as generating a biopotential through their surfaces and through enzymes, such as siderophores, that they excrete into their environment. In this way, bacteria compete with dissolved ions to influence the solution's effective reduction potential, or Eh. There are very few studies focused on their microbial reduction, even though Pu(VI) and (V) are both more easily reduced than Fe(III). Published work investigating Np(V) reduction by *Desulfovibrio desulfuricans* (Soderholm *et al*., 2000) and by an anaerobic methanogenic microcosm (Banaszak *et al*., 1999) indicate that Np(V) is reduced abiotically in the growth medium necessary to sustain the organism.

The solubility and mobility of actinide ions can also be significantly influenced by biosorption. In addition to living cells and spores, dead and decomposed cells are present in natural systems, and can play a role in complexation. Actinides can be complexed with the amino, carboxylate, hydroxyl, and phosphate functional groups that are present on the cell surface. These negatively charged groups are capable of complexation with actinide cations to form biocolloids that have their own chemistry and transport properties. EXAFS spectroscopy has been used to develop an understanding of the functional groups responsible for complexation. XAS studies of actinide biocolloid formation are largely limited to L_3-edge U data. EXAFS of biocolloids formed in brine by halophilic bacteria (WIPP 1A) indicate that bulk samples contain more than one U-containing phase (Francis *et al*., 1998). TEM and EDS analyses supported this result, showing that U was accumulated intracellularly in addition to being bound to the cell surface. In another study (Hennig *et al*., 2001a), Gram-positive strains of *Bacillus cereus* and *Bacillus sphaericus* were recovered from a U waste pile, the 'Haberlandhalde' in Germany. The vegetative cells and spores of these isolates were compared with cells and spores of two reference strains, *B. cereus* 4415 and *B. sphaericus* 9602. The structure of the spore coat is completely different from that of the cell wall. The studies showed that the

bacteria selectively accumulate a large variety of heavy metals, specifically these strains accumulate large amount of U. L_3- and L_2-edge XANES spectra obtained from all the bacilli samples were consistent with U(VI). The EXAFS parameters from all the samples, including both vegetative cells and spores, were very similar, indicating that a structurally similar U complex is formed in all cases. The structural parameters exclude the presence of hydrolysis species but coordination numbers and bond lengths compare well with inorganic 1:1 uranyl phosphate phases. U–P interactions at 3.61–3.63 Å in all samples, which are typical distances for monodentate-bound phosphate phases. After 8 weeks, vegetative cells of *B. sphaericus*, lysing cells, and the activity of enzymes lead to the release of $H_2PO_4^-$ that caused quantitative precipitation of bacterial U(VI) as $UO_2(H_2PO_4)_2$ (Panak *et al.*, 2002b). This complex differs significantly from those of the bacterial surface complexes. The results confirm that surface complexes are formed without metabolic activity.

Similar results were obtained from studies of U complexes formed by *Acidithiobacillus ferrooxidans* (Merroun *et al.*, 2002a), which accumulate U as phosphate compounds. EXAFS data, supported by EDX and infrared spectroscopy (Merroun *et al.*, 2002b) were used to suggest that U accumulates within extracellular polysaccharides and as dense granules in the cell cytoplasm. On the basis of these results it was suggested that these bacteria use polyphosphates to detoxify and remove U when it enters the cells and is present at toxic levels.

In order to quantitatively assess the effects of changing chemical conditions on actinide adsorption/desorption on bacterial surfaces, a surface complexation model for U complexation for Gram-positive cells has been developed (Fein *et al.*, 1997). This model treats surface complexation as a series of thermodynamic equilibria that are dependent on binding geometry and may be pH-dependent. XAS spectroscopy has been used to test this uranyl–bacterial surface speciation model (Kelly *et al.*, 2002). In general, the data are consistent with the model, although a large number of parameters were used to treat the EXAFS data.

Np(V) was determined to adsorb on the facultative, gram negative soil bacterium *Pseudomonas fluorescens* without significant reduction (Songkasiri *et al.*, 2002). The adsorption of 15–20% of the available NpO_2^+ onto the bacterial surface at pH 7 is contrary to expectations based on solution Np(V) chemistry. The situation is more complex for Pu. Sorption studies with Pu(VI) on aerobic soil bacteria showed the reduction of Pu upon complexation, as determined by optical absorption spectroscopy and solvent extraction techniques (Panak and Nitsche, 2001). Follow-up studies, employing XANES spectroscopy in conjunction with solvent extraction, showed that after 9 days of contact with *B. sphaericus*, 32(10)% of the Pu(VI) remained, whereas 28(12)% and 40(6)% were reduced to Pu(V) and Pu(IV), respectively (Panak *et al.*, 2002a). EXAFS data were used to show that Pu(VI) forms strong surface complexes with *B. sphaericus*. These complexes mainly involve phosphate groups, similar to earlier U work (Panak *et al.*, 2000). These results are consistent with a model of

the different interaction processes of Pu(VI) with aerobic soil bacteria (Panak and Nitsche, 2001). This process involves (i) the complexation of Pu(VI) with phosphate groups on the cell wall, (ii) reduction of Pu(VI) followed by the dissolution of Pu(V), and (iii) disproportionation of Pu(V) to tetravalent and hexavalent Pu, followed by the complexation of Pu(IV) with the biomass. These interactions may have important implications for the migration behavior of Pu in natural systems.

Overall, the role of bacteria on the chemistry of actinides and their impact on speciation and transport remains unclear. There is certainly evidence of actinide reduction and precipitation; it remains unclear if these small particles remain mobile through some biocolloid transportation mechanisms. In addition, the particles are so small that re-dissolution reactions may be important. The development of predictive models for the mechanisms of actinide complexation with bacterial surfaces (Fein *et al.*, 1997) and actinide redox reactions (Panak and Nitsche, 2001) are important steps toward a predictive understanding of bacterial influences on actinide mobility. XAS is playing a crucial role in the development and testing of these models.

28.4 FUTURE DIRECTION

XAS and μ-SXRF capabilities have proven to be important synchrotron tools applied to the study of actinide chemistry. The information obtained has significantly improved, and is still improving, our understanding of environmental actinide chemistry. The direction of future actinide studies is closely tied with the operation of existing synchrotrons and with the development of the so-called fourth generation facilities. The availability of new beamlines will open scientific vistas heretofore unavailable with regard to time, energy, and spatial resolution, including the study of dynamic processes and reactions with unprecedented temporal sensitivity; high-energy resolution measurements throughout the electromagnetic spectrum from the infrared through the visible, vacuum ultraviolet, and deep into the X-ray region; and microanalysis of materials on the nanometer length scale.

There are a variety of other synchrotron techniques that are currently under development and are beginning to find use for answering outstanding issues in environmental science (Fenter *et al.*, 2002). Although XAS and microprobe experiments are expected to continue playing a central role in discerning actinide speciation, several relatively new synchrotron techniques, including small-angle X-ray scattering (SAXS), high-energy X-ray scattering (HES), standing wave, and reflectivity measurements are expected to play a growing role in unraveling ever more complex problems posed by actinides in the environment.

Although it is always more convenient to conduct experiments in one's own laboratory than at a synchrotron radiation facility, conventional tube-sources

of X-rays do not provide properties, such as polarization and pulsed-time structure to name just two, that arise naturally from the continuum radiation produced at bending magnets and from the tuned radiation produced from insertion devices. Without exception, synchrotron light is a probe with which actinide science will advance in ways that would be impossible otherwise.

ACRONYMS, ABBREVIATIONS, AND SYMBOLS

An	actinide
Ar	aromatic/aryl functional group
ATCC	American-Type Culture Collection
B	empirical constant, 0.37, in Brown's BVS equation
B3LYP	hybrid Hamiltonian of Becke's 3 parameter exchange functional and correlation functional of Lee-Yang-Parr
BET	Brunauer-Emmett-Teller, adsorption method for surface area measurement
BVS	bond-valence sum
COSMO	conductor-like screening model
CPCM	conductive polarizable continuum model
CN	coordination number
DFT	density functional theory
DMRB	dissimilatory metal-reducing bacteria
DU	depleted uranium
e^-	electron
E	X-ray energy, eV
E_p	applied/controlled electrode potential, V
E°	standard electrode potential, V
E°'	formal electrode potential, V
E_0	energy threshold for k-space conversion, eV
ΔE_0	energy scale parameter
Eh	redox potential
EDS	energy dispersive X-ray spectroscopy
EDX	energy dispersive X-ray analysis
EXAFS	extended X-ray absorption fine structure
F	Faraday's constant
$F(k, r)$	back-scattering amplitude function
FEFF	effective curved-wave scattering amplitude, $F_{\text{eff}}(k, r)$, computer code
FT	Fourier transform
$\hbar$	Planck's constant
HES	high-energy X-ray scattering
HFO	hydrous ferric oxide

ICP-MS	inductively coupled plasma-mass spectrometry
IR	ionic radius/radii
k	photoelectron wave vector, $Å^{-1}$
λ_e	photoelectron wavelength
m	electron mass
MCD	magnetic circular dichroism
MP2	2^{nd} order Moller Plesset perturbation theory
n	number of electrons
N	coordination number
N_p	number of independent parameters
μ-SXRF	micro synchrotron-X-ray fluorescence
μ-XANES	micro X-ray absorption near-edge structure
$\varphi(k, r)$	backscattering atom phase function
$\varphi_c(k)$	central atom phase function
pH	negative log of the hydrogen ion concentration
PCA	principal component analysis
R	aliphatic/alkyl functional group
r	interatomic distance
R	gas constant
R_0	empirical radius parameter in Brown's BVS equation
$\Re_{ox}$	oxidized form of reagent
$\Re_d$	reduced form of reagent
σ	Debye–Waller factor
S_0^2	amplitude reduction factor
SJV	San Joaquin Valley
SRS	Savannah River Site
SEM	scanning electron microscopy
S/N	signal to noise
SAXS	small-angle X-ray scattering
SHE	standard hydrogen electrode
SXRF	synchrotron X-ray fluorescence
T	temperature
TEM	transmission electron microscopy
WIPP	waste isolation pilot plant
XANES	X-ray absorption near-edge structure
XAS	X-ray absorption spectroscopy
$\chi(k)$	EXAFS signal

CHAPTER TWENTY NINE

HANDLING, STORAGE, AND DISPOSITION OF PLUTONIUM AND URANIUM

John M. Haschke and Jerry L. Stakebake

29.1 INTRODUCTION

The need to address topics of handling, storage, and disposal of plutonium and uranium is driven by concern about hazards posed by the element and by the worldwide quantity of civilian and military materials. The projected inventory of separated civilian plutonium for use in fabricating mixed-oxide (MOX) reactor fuel during initial decades of this century is constant at about 120 metric tons and a comparable amount of excess military plutonium is anticipated from reductions in nuclear weapon stockpiles (IAEA Report, 1998). Although inventories of civilian material are in oxide form, Pu from weapons programs exists primarily as metal. Plutonium is a radiological toxin (Voelz, 2000); its management in a safe and secure manner is essential for protecting workers, the public, and the environment.

The focus of this chapter is on plutonium handling and storage, which are operations required for both civilian and weapons materials. Plutonium dioxide for MOX fabrication is processed and stored on an interim basis. The spent fuel formed during power generation is considered suitable for disposal. Excess Pu from military sources must be extracted, prepared, and stored until disposal options are investigated and evaluated. Storage periods of several decades may

be required until disposal methods are selected and implemented. This chapter centers on handling and storage of plutonium metal and oxide, and where information is available, on handling and storage of uranium metal and oxide.

Hazards associated with Pu and U strongly depend on the material form and are substantially altered by chemical reaction. Atmospheric dispersal of particles is the primary mechanism for large-scale environmental distribution of actinide-containing materials such as oxide (Mishima and Pinkston, 1994). Entrainment and dispersal of oxide particles with geometric dimensions less than 10 μm is anticipated under normal aerodynamic conditions. The source term for environmental release is determined by the mass fraction of particles within the aerosolizable size range. Oxide particles in the respirable fraction have geometric dimensions less than 3 μm and are retained in a human respiratory system if inhaled. Metal is not highly dispersible, but its release is facilitated by corrosion reactions that transform metal into powdered forms and contribute to loss of containment by generating heat and pressure. Therefore, corrosion reactions of Pu and U are important considerations, especially in light of pyrophoric tendencies exhibited by metal fines and corrosion products such as the hydrides.

In addition to an inherent source term for dispersal, oxides of Pu and U chemically interact with environmental gases during handling and storage in ways that significantly alter the potential hazard. This statement conflicts with the widely held view that PuO_2 is stable and unreactive. Because oxides and other compounds exist as adherent layers on the surfaces of Pu and U, a thorough understanding of the chemistry is necessary to determine their properties and influence on behavior of the metals. Some product layers are protective and slow the corrosion of the metal, but others catalyze rapid reaction. Such a 'runaway' reaction occurred during a seemingly routine operation in which a failed storage vessel containing a Pu casting was examined in a gloved box filled with a nitrogen-rich atmosphere normally used for handling metal (Haschke and Martz, 2000). After the partially disassembled package had been exposed to that atmosphere for 3 h, workers discovered that the vessel was hot and that its diameter had increased by 50% in the region around the metal. Subsequent investigation showed that a spontaneous reaction had advanced into the metal at more than 1 cm h^{-1}, a rate that is 10^{10} faster than normal corrosion of Pu in dry air at room temperature.

Unanticipated behavior is a consistent feature of plutonium chemistry. As described in a review by Waber (1980) early experience with handling and storage of plutonium and uranium revealed perplexing and unexplained observations. Reports suggest that corrosion rates of metal are markedly enhanced by moisture, by storage in Ar, or other inert gases with low oxygen content, and by confinement in a sealed vessel, but are slow in open air or a large amount of oxygen. Pyrophoric products are often present on Pu after extended storage in a closed container. Metal pyrophoricity and ignition behavior are unpredictable.

In a later review (Stakebake, 1971), proposed corrosion mechanisms and possible involvement of hydrogen are described, as well as instances of container pressurization that correlate with adsorption of atmospheric gases such as H_2O and CO_2 and with their subsequent radiolysis or thermal desorption. Other reviews describe kinetics (Colmenares, 1975) and mechanisms (Colmenares, 1984) of U and Pu oxidation, as well as physicochemical properties of the oxides. Material properties and kinetics, as well as conditions for safe handling and storage of plutonium metal and oxide, are discussed in more recent reviews (Haschke and Martz, 1998a; IAEA Report, 1998).

In this chapter, we describe relevant chemistry of plutonium metal, oxide, hydride, and other compounds and apply observations in interpreting the complex behavior of Pu and PuO_2 during handling and storage. Recent identification of key gas–solid and solid-state reactions that were not recognized in early studies show the importance of both rapid and slow reactions. Processes occurring over periods of years form highly catalytic surfaces that promote metal corrosion. The importance of minor chemical constituents such as water, of catalytic cycles, and of synergistic reactions is recognized. We describe and evaluate incidents involving containment failure and release of nuclear material with the objective of identifying conditions that alter chemical reactivity and the potential hazard. Existence of multiple hazards and multiple paths to the same potentially hazardous state suggests that unrecognized pathways probably exist and that knowledge is incomplete. Although current understanding of behavior is adequate for recommending procedures that significantly increase safety during handling and extended storage of metals and oxides, definition of general comprehensive requirements is precluded by substantial uncertainty about behavior of Pu-containing residues.

29.2 KINETIC CONSIDERATIONS

29.2.1 Scope of concerns

Chemical reactions that create hazards during handling differ in one important way from those encountered during storage. Reactions during handling are typically of concern only if they are rapid enough to create a direct hazard, such as pyrophoric ignition, during that operation. In contrast, reactions of concern during extended storage may occur slowly with cumulative effects resulting in a hazard such as progressive pressurization and containment failure over time. Gas–solid and liquid–solid reactions are of primary concern because rates of solid–solid reactions are typically insignificant, but exceptions to this general rule cannot be excluded.

The scope of the review is confined to hazards associated with separated plutonium and uranium, not those posed by spent fuel. Three material

categories are identified and addressed: metals, oxides, and residues. Metallic forms are typically from weapons sources. They generally include unalloyed and Ga-containing alloys of typical weapons-grade Pu (initially 0.04% ^{238}Pu, 93.3% ^{239}Pu, 6.0% ^{240}Pu, 0.6% ^{241}Pu, 0.04% ^{242}Pu) (IAEA Report, 1998), as well as highly enriched (>90% ^{235}U) and depleted (<0.72% ^{235}U) U. Oxides are derived from both weapons and civilian sources. The isotopic distribution of Pu depends on the level of fuel burnup and is typically about 1% ^{238}Pu, 60–70% ^{239}Pu, 20–25% ^{240}Pu, 5–10% ^{241}Pu, and 1–5% ^{242}Pu for civilian sources (IAEA Report, 1998). Unirradiated MOX fuel for light-water reactors typically contains 5–7% Pu. Residues are poorly defined and include a broad spectrum of wastes produced by processing activities.

29.2.2 Rate-controlling factors and mechanisms

A negative Gibbs energy change is necessary for any reaction, either rapid or slow. The potential hazard existing during handling depends on both the rate and the enthalpy of reaction. Factors that determine the reaction rates of liquids and gases with metals or ionic compounds are suggested by consideration of likely mechanistic steps. Reacting molecules must (1) reach the solid interface, (2) adsorb on that surface, and (3) dissociate to form a monatomic anion by interaction with electrons from the solid. Resulting anions must (4) enter the solid lattice, (5) be transported through the layer of product solid while electrons move toward the surface, and (6) ultimately react at the product–reactant interface. The rate of reaction is determined by the slowest step or the combined effect of steps.

A general expression for the rate, R, of a gas–solid reaction includes dependencies on temperature and on partial pressures $P_1, P_2, P_3, \ldots$ of gaseous reactants $1, 2, 3, \ldots$.

$$R = k \exp(-E_a/R^*T)(P_1)^{n_1}(P_2)^{n_2}(P_3)^{n_3} \ldots .$$

This equation includes the proportionality constant (k) and an Arrhenius term defined by the activation energy (E_a), the gas constant (R^*), and temperature. The rate is normalized for surface area of the reacting solid using geometric areas of massive solids or molecular-scale (BET) areas of powders. Dependencies of R on gas concentrations are described by the pressure exponents $n_1, n_2, n_3, \ldots$. Experimental valuation of k, E_a, and n are important in identification of rate-determining steps.

Different rate-controlling steps are encountered during corrosion of solids at different conditions (Haschke *et al.*, 2000a). During reaction of a mixture of reactive and inert gases, the rate may be controlled by transport of reactive gas through a layer of unreactive gas that accumulates at the gas–solid interface. In some cases, the rate is determined by the concentration of reactant molecules adsorbed on the surface. In other cases, R is determined by diffusion of the reacting anion through an adherent product layer on the reacting solid, as

indicated by a parabolic time dependence of the extent of reaction. Parabolic dependence is observed only as long as the product adheres and the thickness of the diffusion barrier increases. If spallation of product particles begins, the layer is thin in some locations and the rate increases at those sites. Although rates vary across the surface, continuing reaction and spallation maintain a constant average thickness and results in a linear dependence of extent on time. The combined process of parabolic and linear steps is described as 'paralinear' behavior. In the linear step, the diffusion-controlled rate is constant at fixed temperature and reactant pressure. The diffusion rate is usually increased by increasing temperature or by increasing pressure until the surface becomes saturated with reactant molecules. The reaction rate is dramatically increased and becomes temperature independent if the surface layer catalytically dissociates and transports reactant to the product–reactant interface. In that case, the rate is determined solely by the concentration of adsorbed reactant and depends only on gas pressure.

The preceding discussion of rate-controlling processes implies that the product layer on the surface of a reacting solid may be protective or catalytic depending on its ability to form and transport the diffusing species. The structure of the product formed on the reacting solid (metal or compound) is important in determining its nature. A surprising feature of plutonium compounds formed by atmospheric constituents is the pervasive presence of plutonium in cubic ($Fm3m$ symmetry) structures in which Pu occupies face-centered cubic (fcc) positions (Haschke *et al.*, 2000a). The fcc cation lattice has two tetrahedral interstitial sites per cation and one interstitial octahedral site per cation, features that allow for a variety of compositions and accommodation of up to three anions per Pu. Maintenance of charge balance in the lattice is enhanced by the ability to include anions with different charges and Pu cations in different oxidation states in solids.

This structural flexibility facilitates formation of various products at low temperature by decreasing or increasing the anion/cation ratio or by replacing existing anions. Such reactions of solid phases usually occur at elevated temperatures because of the high activation energies associated with rearrangement of the cationic lattice. The NaCl-type structure is formed by anion occupation of octahedral sites in the fcc lattice, the CaF_2-type structure is formed by occupation of the tetrahedral sites, and the anti-Fe_3Al structure is formed by occupation of both sites. Extended solid solutions form as the anion/cation ratio and the average oxidation state of Pu progressively change.

Transport rates of reactant ions in the product layer appear strongly dependent on deviations from ideal stoichiometry (Haschke *et al.*, 2000a). At low temperatures, transport of ions through a rigid CaF_2-type lattice like PuO_2 or UO_2 occurs by hopping of reactant ions between octahedral sites. Vacant tetrahedral sites formed in substoichiometric compounds share faces with normally vacant octahedral sites and create channels that facilitate anion movement. In a similar way, occupation of octahedral sites in compositions with

anion:cation ratios greater than 2 tends to hinder anion movement because diffusion channels are occupied. However, markedly different behavior is encountered with superionic conductors in which the cation lattice is rigid and the anions (e.g. O^{2-}, F^-, Cl^-, I^-) are highly mobile (Boyce and Huberman, 1979). These solids frequently have NaCl-type, CaF_2-type, or related structures; their ionic conductivities are comparable to those of molten salts and typically exceed those of ordinary ionic solids by more than 10^8.

In large measure, plutonium reactivity and its perplexing behavior are determined by fundamental properties of the product compound(s) existing on the metal surface, not by the properties of Pu. The only important property of plutonium is its chemical potential that drives reaction. Interpretation of Pu corrosion hinges on understanding the behavior of hydride, oxide, and other surface compounds. Therefore, relevant fundamental properties of these materials are reviewed as a basis for describing reactivities of metals and compounds.

29.3 FORMATION AND PROPERTIES OF COMPOUNDS

29.3.1 Plutonium hydrides

As shown by the phase diagram in Fig. 29.1, the complex plutonium–hydrogen system is dominated by the existence of a fcc PuH_x solid solution that is stable from $PuH_{1.95}$ to $PuH_{2.7}$ at room temperature and extends to PuH_3 above 300°C. This simplified diagram does not indicate regions of apparent structural ordering outlined in comprehensive reviews of hydride properties (Flotow *et al.*, 1984; Haschke *et al.*, 1987; Ward and Haschke, 1994). At high compositions, the fcc CaF_2-related hydride coexists with the PuH_y ($2.8<y<3.0$ at 25°C) solid solution, a substoichiometric phase derived from the hexagonal LaF_3-related PuH_3 phase by formation of anion vacancies. Hydrides are obtained by reaction of metal with H_2 or with elemental hydrogen derived from other sources. Hexagonal hydride is formed by reaction of Pu with H_2 at several bar pressure and temperatures above 400°C (Haschke *et al.*, 1987) and its appearance is unlikely unless these conditions exist. Transformation of the Pu cations from the fcc arrangement of PuH_x to the hcp arrangement of PuH_y at low temperatures is apparently precluded by a high activation energy. Therefore, metastable PuH_x forms beyond the $PuH_{2.7}$ composition as hydrogen occupies vacant octahedral sites in the cubic structure. The value of x exceeds 2.9 as the H_2 pressure is increased to 1 bar (Haschke *et al.*, 1980). The cubic PuH_x powder formed by slow reaction at low temperatures is pyrophoric in air at room temperature, but the hexagonal PuH_y only ignites in air when heated above 270°C (Haschke *et al.*, 1987).

Stoichiometric PuH_2 is frequently formulated as a distinct binary phase, but reference to Fig. 29.1 shows that the dihydride exists only as a composition within the PuH_x continuum. The hydride at the lower phase boundary has a

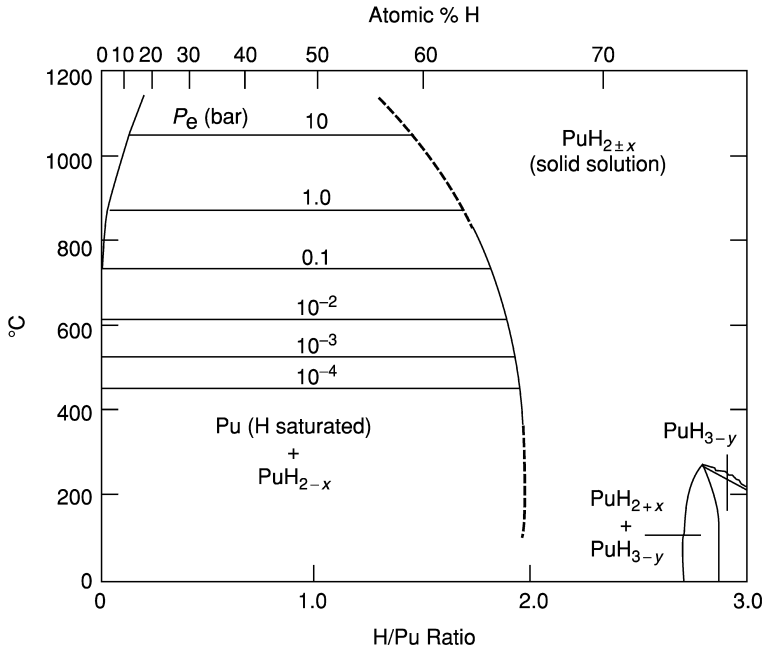

Fig. 29.1 *Proposed phase diagram of the Pu–H system. Data are from Flotow* et al. (1984).

progressively decreasing x with increasing temperature and coexists with hydrogen-saturated metal (Allen, 1991). Temperatures and corresponding equilibrium H_2 pressures within the two-phase region (Fig. 29.1) show that the hydride decomposes to metal upon heating in vacuum. The extrapolated equilibrium hydrogen pressure at room temperature is 10^{-21} bar (Flotow *et al.*, 1984) and the estimated H/Pu ratio in the metal is 10^{-9} (Allen, 1991). ΔH_f° (298 K) and ΔG_f° (298 K) for cubic PuH_x vary regularly with x between values for terminal compositions in Table 29.1 (Flotow *et al.*, 1984).

Electrical properties of PuH_x are inconsistent with those of ionic insulators having CaF_2-type structures (Haschke *et al.*, 1987; Ward and Haschke, 1994). Whereas compositions less than PuH_2 are consistent with forming vacancies on anion sites, x values in the 2–3 range are apparently attained by progressive occupation of additional anion sites by H^-. The PuH_2 formula implies that plutonium is present as the divalent cation, an unknown oxidation state of Pu in solids. The color of PuH_x changes from silver at $x = 2$ to black at high x; hydride conductivity is comparable to that of α-phase Pu at x near 2 and decreases to the semiconductor range at high x. Magnetic data show that Pu in PuH_x is present in the trivalent state. PuH_2 is most easily viewed as a Pu(III) lattice in which anion sites are occupied by H^- in a 2:1 H/Pu ratio and a

conduction band is occupied by one electron per Pu (Haschke *et al*., 1987). The hydride color changes from silver to black with increasing PuH_x composition as conduction electrons are progressively bound as H^- on anion sites.

High mobility of hydrogen in PuH_x is indicated by proton nuclear magnetic resonance (NMR) data showing that resonance lines are motionally narrowed and the diffusion of hydrogen is 'too fast' for measurements at room temperature (Cinader *et al*., 1976). At and below 190 K (–83°C), line shapes of PuH_x correspond to a rigid lattice with hydrogen occupying all tetrahedral sites and the appropriate fraction of octahedral sites required by x. A previously unexplained broad peak in the C_p curve for hydride (Flotow *et al*., 1984) at 200–270 K coincides with freezing-in of H^- on lattice sites. This peak is identified as the transition from ionic to superionic conduction above 0°C (Haschke and Allen, 2001) and implies that hydrogen transport in PuH_x is extremely rapid at 25°C and higher temperatures.

29.3.2 Plutonium oxides

The partial plutonium–oxygen phase diagram in Fig. 29.2 is based on phase relationships presented in prior reviews of oxide chemistry (Colmenares, 1975; Weigel *et al*., 1986) and in a more recent assessment of high-temperature data (Wriedt, 1990). Three oxides are stable at room temperature: hexagonal La_2O_3-type sesquioxide (identified as β-Pu_2O_3), bcc Mn_2O_3-related $PuO_{1.515}$ (identified as α-Pu_2O_3), and PuO_2. According to the diagram, β-Pu_2O_3 coexists with oxygen-saturated Pu and α-Pu_2O_3 coexists with PuO_2 below 335°C with a narrow two-phase region separating the $PuO_{1.50}$ and $PuO_{1.515}$ compositions at low temperatures. Assignment of this unusual relationship is based on coexistence of the two phases, failure to observe the hexagonal to cubic transition, and a reported lack of overlap in their compositions (Wriedt, 1990). This basis seems tenuous because dimorphic relationships of hexagonal and cubic oxides exist for

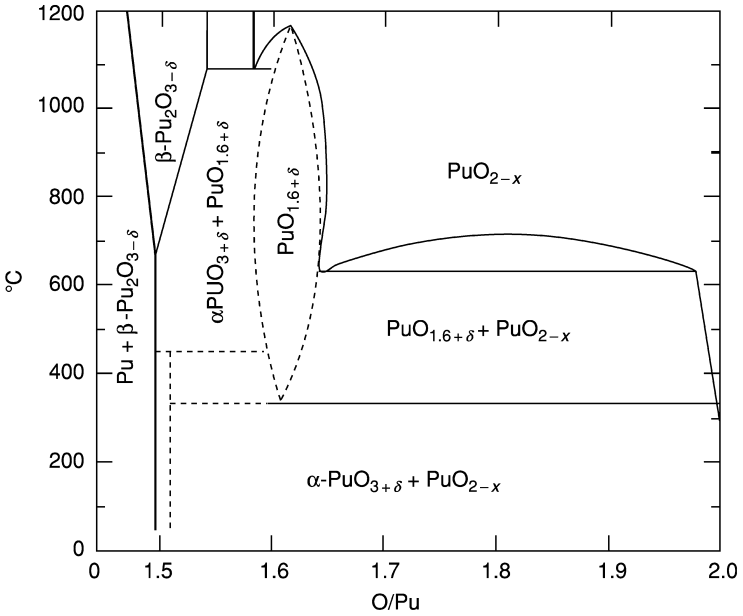

Fig. 29.2 *Partial Pu–O phase diagram based on high-temperature studies with O_2.*

lanthanide analogs (Eyring, 1979) and transformation is likely to be slow at low temperatures. The composition of the cubic oxide ($PuO_{1.46 \pm 0.04}$) formed during slow oxidation of Pu by water at room temperature (Haschke *et al.*, 1983) suggests that composition ranges of the two oxides are not significantly different. A reason to expect enhanced stability for a stoichiometric Mn_2O_3-related phase at the Pu_2O_3 composition with 3% occupancy of the cation sites by Pu(IV) is not apparent. In addition, both α- and β-forms of the sesquioxide are reportedly prepared by carbon reduction of PuO_2 at 1500–2000°C (Haire and Haschke, 2001), a temperature range in which α-Pu_2O_3 is unstable (Fig. 29.2) (Weigel *et al.*, 1986; Wriedt, 1990).

Concern about the precise phase relationships of sesquioxide may seem unmerited, but the nature of the oxide layer on Pu is apparently a key factor in determining metal reactivity. Data in Fig. 29.2 imply that β-Pu_2O_3 should exist on the metal surface, but analysis of Pu surfaces shows that only PuO_2 is detectable after exposure to air at room temperature (Terada *et al.*, 1969; Stakebake, 1971; Colmenares, 1984). Kinetic control of oxidation is implied (Haschke, 1992a) and supported by X-ray diffraction (XRD) measurements showing that heating of dioxide-coated Pu in vacuum results in reduction of the PuO_2 surface layer to α-Pu_2O_3 by the underlying metal (Terada *et al.*, 1969). The α-Pu_2O_3 readily appears at 150°C, is completely formed within minutes at 200°C, and persists when heated at 420°C. Appearance of a NaCl-type phase

at higher temperatures is attributed to formation of PuO (Cleveland, 1979). Subsequent X-ray photoelectron spectroscopy and atomic emission spectroscopy (XPS/AES) investigation confirms the facile reduction of PuO_2 to Pu_2O_3 at 200°C, but shows that the product observed at high temperatures is an oxide carbide (nominally $Pu(III)O_{0.5 \pm 0.1}C_{0.5 \pm 0.1}$) formed by reaction of free carbon with oxide and metal (Larson and Haschke, 1981). The spectroscopic data also show that plutonium oxide is extensively contaminated with unbound C after exposure to air or CO_2 and that the C(1s) peak shifts to a lower binding energy characteristic of carbide (C^{4-}) at temperatures in the range reported for PuO formation. Although plutonium monoxide is frequently reported in the literature, those products are most likely ternary compounds stabilized by carbon or nitrogen (Larson and Haschke, 1981; Weigel *et al.*, 1986).

Formation of an α-Pu_2O_3 layer on Pu at 200°C does not agree with phase relationships in Fig. 29.2, but is consistent with facile movement of oxide ions in fcc Pu cations lattice. The bcc Mn_2O_3-type structure (Wells, 1975) is derived by ordered removal of O^{2-} from one-fourth of the tetrahedral sites of CaF_2-type PuO_2 and occupation of all cation sites by Pu(III). The superstructure of anion vacancies results in a doubled cubic cell (a_0 bcc $= 2\ a_0$ fcc). Electrons move into the PuO_2 layer and reduce Pu(IV) to Pu(III) as O^{2-} ions move from the oxide layer to the oxide–metal interface and form additional α-Pu_2O_3.

In air or O_2, the steady-state chemical composition of the oxide layer on the Pu surface is determined by the relative rates of competing reactions (Haschke and Allen, 2001). Formation of α-Pu_2O_3 at the oxide–metal interface is countered by its oxidation to PuO_2 by oxygen. The relatively rapid rate of PuO_2 formation at 25°C yields a layer that is primarily dioxide, even though a thin sesquioxide layer must exist at the oxide–metal interface. These reactions have different activation energies and the rate of reduction increases more rapidly with increasing temperature than the rate of oxidation, as demonstrated by XRD and XPS analysis of the product layer formed in water vapor at 250°C (Stakebake *et al.*, 1993). The α-Pu_2O_3 layer is detectable beneath a relatively thin double layer composed of an inner PuO_2 layer and an outer layer of a previously unidentified higher oxide with a CaF_2-related structure. The dominant oxide layer on Pu surface in air progressively changes from PuO_2 at 25°C to α-Pu_2O_3 with increasing temperature (Haschke and Allen, 2001). The rate reduction becomes increasingly rapid with increasing temperature and formation of sesquioxide is kinetically favored above 500°C.

Additional complexity of the Pu–O phase diagram is suggested by results of water titration measurements in which Pu was submerged in salt solution at room temperature (Haschke *et al.*, 1983; Haschke, 1992a). Ionic radii of Pu(III) and Pu(IV) and relative free energies of Pu_2O_3 and PuO_2 correspond closely with those of Pr, suggesting that stable mixed-valence intermediate oxides like the CaF_2-related phases in the Pr–O system (Eyring, 1979) are to be expected for Pu. The titration (Haschke *et al.*, 1983), which is monitored by measuring hydrogen production, shows that the H_2 generation rate progressively decreases

Table 29.2 *Sequence of reactions derived from cumulative H_2/Pu ratios at intersection points of linear segments during reaction of Pu with water at* 23°C (*Haschke*, 1992*a*).

Reaction	*Cumulative H_2/Pu ratio*[a]

[a] Uncertainties in measured values are given in parenthesis.

over a year-long period in a sequence of constant-rate steps with intersection points at well-defined molar ratios of H_2:Pu associated with completion points of successive reactions. Intersection points corresponding to changes in rate (Table 29.2) are assigned to formation of oxide hydrides (PuOH and $Pu_7O_9H_3$), Pu_2O_3, members of the Pu_nO_{2n-2} homologous series with $n = 7$, 9, 10, and 12, and PuO_2. Continued generation of pure H_2 beyond the dioxide composition could not be explained. XRD data for initial and terminal products show CaF_2-related structures and imply that all intermediate products have fcc Pu lattices that do not transform at 25°C. Members of the homologous series presumably have CaF_2-related structures like those of intermediate praseodymium oxides (Eyring, 1979).

Formation of a high-composition plutonium oxide, PuO_{2+x}, by reaction of PuO_2 with H_2O or with O_2 in the presence of water is indicated by microbalance and pressure–volume–temperature measurements at 25–250°C (Haschke *et al.*, 2000b). The oxide–water reaction proceeds with H_2 formation and a mass increase corresponding to stoichiometric incorporation of oxygen in the solid:

$$PuO_2(s) + xH_2O(l, g) \rightarrow PuO_{2+x}(s) + xH_2(g).$$

Dry O_2 (air) does not react with PuO_2 at a detectable rate, but is preferentially consumed in forming PuO_{2+x} via a water-catalyzed cycle if water is present. Catalyzed reaction of O_2 forms PuO_{2+x} at the same rate as the oxide–water reaction, but H_2 is not formed. The catalytic cycle is established as water reacts with the oxide at its characteristically more rapid rate and atomic H formed on the surface combines with dissociatively adsorbed oxygen to re-form water. In the absence of O_2, high-purity (>99.99%) H_2 is produced according to the above reaction as H atoms associate and desorb.

XRD data for solid products of the oxide–water reaction show a single CaF_2-related phase with a lattice parameter that increases by 0.4 pm as reaction

initiates and thereafter has a linear dependence on composition, a_0 (nm) = 0.53643 + 0.001764(2+x), consistent with the formation of an extended solid solution. Results account for earlier observations of H_2 generation beyond the PuO_2 composition in liquid water (Haschke *et al.*, 1983; Haschke, 1992a) and show that oxide stoichoimetries approach $PuO_{2.3}$ (Haschke *et al.*, 2000b), but do not define the upper phase boundary of PuO_{2+x}. The area-normalized rate of H_2 formation by the PuO_2–water reaction is temperature-dependent (E_a = 39.3 kJ mol^{-1}), implying that the reaction is chemical, not radiolytic. Self-induced radiation damage does not account for the expansion of a_0 (Haschke and Allen, 2002) and radiolysis of H_2O fails to account for either the observed H_2 formation rate or for absence of O_2 as a gaseous product (Haschke *et al.*, 2001a).

As implied by extended X-ray absorption fine structure (EXAFS) and X-ray absorption near edge structure (XANES) results showing Pu(V) in PuO_{2+x} (Conradson *et al.*, 2003, 2004; Paffett *et al.*, 2003a), formation of this UO_{2+x} analog occurs by substitution of Pu(V) for Pu(IV) on cation lattice sites and accommodation of additional O^{2-} on octahedral interstices of the lattice (Haschke *et al.*, 2000b). EXAFS results show nearest-neighbor Pu–O distances of 0.183–0.193 nm for a range of PuO_{2+x} compositions (Conradson *et al.*, 2003, 2004). This value is significantly shorter than the characteristic Pu–O distance of 0.233 nm for O in tetrahedral sites of PuO_2. Evaluation of parameters affecting XANES edge energies indicates that observations are most consistent with the presence of Pu(V) in PuO_{2+x}.

The highest PuO_{2+x} possible composition is identified as $PuO_{2.5}$, the maximum attainable stoichiometry of the $Pu(IV)_{1-2x}Pu(V)_{2x}O_{2+x}$ solid solution (Haschke and Allen, 2002). Lattice parameters of steady-state solids formed after placing Pu(IV) hydrous oxide in aqueous solution are consistent with formation of cubic PuO_{2+x} with x-values that vary from 0 near pH 10 to 0.5 near pH 3 (Haschke and Oversby, 2002). Stability of PuO_{2+x} is demonstrated by extraction of oxygen from water during formation and is supported by thermodynamic assessment (Haschke and Allen, 2002). Results indicating that the phase is stable to $x = 0.5$ in air at temperatures of 350–400°C and that x approaches zero at 600°C are not confirmed by experiment. ΔH_f°(298 K) and ΔG_f°(298 K) for α-Pu_2O_3, PuO_2, and selected PuO_{2+x} compositions are given in Table 29.1.

Further EXAFS investigation of hydrothermal products and other compounds formed by aging precipitates from neutral Pu(IV) and Pu(VI) solutions shows the 0.183–0.193 nm Pu–O distances characteristic of PuO_{2+x} (Conradson *et al.*, 2004). These compounds, as well as those formed by reaction of PuO_2 with water vapor, have slightly increased fcc lattice parameters relative to PuO_2 and are identified as $PuO_{2+x-y}(OH)_{2y}$. Interpretation of EXAFS and XANES results leads to a structure described as a conglomeration of oligomerized Pu(IV) and PuO_2^+ oxo-hydroxide-aquo moieties with the same average Pu sublattice locations as in PuO_2. Other workers suggest that additional oxygen is

accommodated in the lattice predominately as hydroxyls, not as oxide and describe the phase as $PuO_{2+x} \cdot H_2O$ (Paffett *et al.*, 2003a).

Results of thermal decomposition and chemical analyses (Haschke, 1992a) of the product subsequently identified as $PuO_{2.27}$ on the basis of H_2 generation (Haschke *et al.*, 2000b) are most consistent with an anhydrous product, but stabilization of the higher oxide by hydroxide cannot be excluded. A first-principles quantum mechanical calculation of the PuO_{2+x} electronic structure (Petit *et al.*, 2003) indicates that a delicate energy balance does not favor PuO_{2+x} formation, but might be altered if interstitial species other than O^{2-} are present. The predicted composition dependence of the cubic PuO_{2+x} lattice parameter is consistent with the observed insensitivity of a_0 to x. Incorporation of hydroxyl in the lattice during exposure of oxide to moisture may account for the mass loss observed above 700°C during calcination (Stakebake, 1973).

Although behavior of plutonium oxides is generally consistent with a recently proposed Pu–O phase diagram (Haire and Haschke, 2001), the alternative diagram in Fig. 29.3 shows overlapping compositions for α-Pu_2O_3 and β-Pu_2O_3. Transformation of α into β near 450°C (Wriedt, 1990) is consistent with behavior of lanthanide oxides (Eyring, 1979). Thermodynamic data do not resolve the issue because the difference in free energies of formation of the two oxides is small. The $\Delta G_f^\circ(298\ K)$ of –1580 kJ mol^{-1} recommended for β-Pu_2O_3

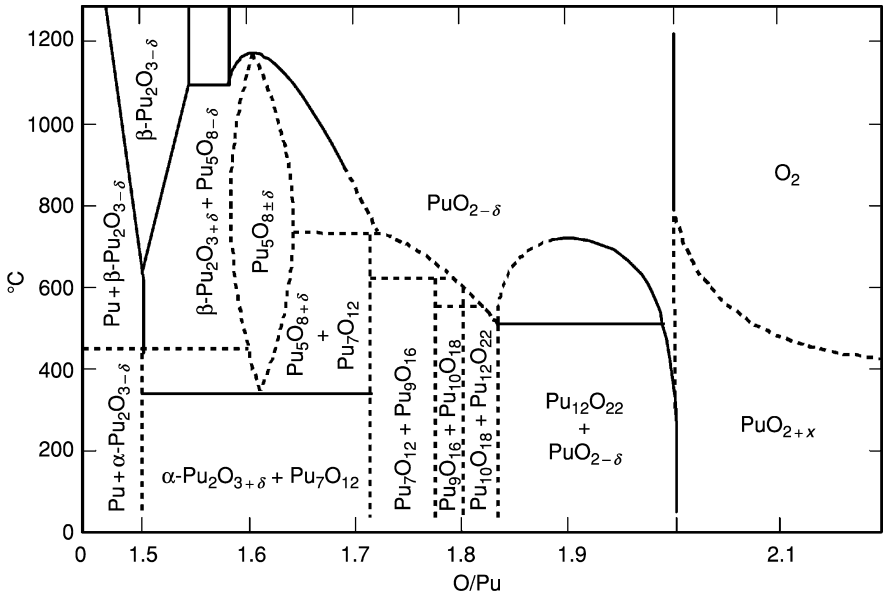

Fig. 29.3 *Partial PuO–phase diagram based on studies with O_2 at high temperatures and on studies with H_2O at low temperatures.*

(Morss, 1986) overlaps with the composition-adjusted value (–(1574 ± 11) kJ mol^{-1}) for stoichiometric α-Pu_2O_3. Formation of α-Pu_2O_3 in water at low temperatures may result from favorable kinetics of a preexisting fcc Pu lattice, but the reported preparation of bcc $PuO_{1.515}$ by reduction of PuO_2 above 1600°C (Weigel *et al.*, 1986) cannot be explained because that composition is within the phase field of β-Pu_2O_3 (Figs. 29.2 and 29.3), a solid that apparently does not transform into α-Pu_2O_3 on cooling (Wriedt, 1990).

A major difference between Figs. 29.2 and 29.3 is the existence of homologous series oxides containing fixed ratios of Pu(III) and Pu(IV) (Haschke, 1992a). Observed compositions correspond to those of Pr–O (Eyring, 1979) plus an additional member at $n = 5$ ($PuO_{1.6}$). Intermediate oxides apparently form during reaction of α-Pu_2O_3 with water at room temperature because rates of the oxide–water reactions are sufficiently slow that conditions are isothermal and differences in rates of successive reactions are resolved (Haschke *et al.*, 1983; Haschke, 1992a). Failure to observe intermediate oxides in studies with O_2 is attributed to the catalytic nature of α-Pu_2O_3 and rapid exothermic reaction of the bcc oxide with oxygen (Haschke and Allen, 2001). Rapid reaction heats the oxide beyond the stability ranges of the Pu_nO_{2n-2} phases and terminates at PuO_2. Unlike the dioxides of Ce, Pr, and Tb (Eyring, 1979), PuO_2 does not desorb oxygen and equilibrate with $Pu_{12}O_{22}$ when heated to 500°C, but vaporized incongruently at 1500–2000°C with the formation of PuO_2 (g), PuO (g), O (g), and O_2 (g) (Cleveland, 1979; Weigel *et al.*, 1986).

As defined by estimated equilibrium oxygen pressures (Haschke and Allen, 2001), the phase boundary of the PuO_{2+x} solid solution is indicated in Fig. 29.3. Data suggest that the stable solution extends to $PuO_{2.5}$ at temperatures up to 400°C and imply that a very narrow two-phase region exists between PuO_2 and PuO_{2+x}. Behavior is uncertain and additional work is needed to resolve the controversy over existence of PuO_{2+x} (Ronchi *et al.*, 2000) and define equilibria in the Pu–O and Pu–O–H systems.

29.3.3 Other plutonium compounds

As the major constituent of air, nitrogen is an important potential reactant in corrosion. The only binary compound of plutonium is the mononitride, PuN, which has a variable composition ($PuN_{1-\delta}$) attributed to formation of anion vacancies in the fcc NaCl-type structure (Cleveland, 1979; Weigel *et al.*, 1986). Reaction of N_2 with Pu initiates at about 300°C, but is slow and only 80% complete after 17 h at 1000°C (Brown *et al.*, 1955). The nitriding rate is markedly increased by reacting N_2 with PuH_x in a process that initiates at temperatures as low as 230°C. A rapid initial reaction is about 60% complete and followed by a slower second step that results in 97% of theoretical PuN formation after several hours. Nitriding of Pu is promoted if the metal is coated with hydride and then exposed to N_2 at 250°C (Cleveland, 1979). The reaction apparently proceeds as nitrogen displaces hydrogen in the fcc Pu lattice of PuH_x

and as product H atoms advance into the metal to re-form hydride (Haschke and Allen, 2001). Values of $\Delta H_f^\circ(298\ K)$ and $\Delta G_f^\circ(298\ K)$ for PuN are given in Table 29.1 (Lemire *et al.*, 2001).

Reaction of plutonium metal with water in near-neutral solutions at room temperature proceeds by a stoichiometric reaction that forms 0.5 mol H_2 per mol of Pu and a hydridic black solid identified as plutonium monoxide monohydride, PuOH (Haschke *et al.*, 1983; Haschke, 1992a). Formation of this compositional analog of PuOCl is suppressed at high pH (Haschke, 1995) and catalyzed by chloride and other salts in solution, but those anions are not incorporated in the solid (Haschke, 1992a). The product forms an adherent layer on the metal and spalls as particles with average dimensions of about 7 nm (Haschke *et al.*, 1983). PuOH crystallizes in a CaF_2-related structure and XPS data indicates that plutonium is trivalent, implying that cation sites are occupied by Pu(III) and anion sites are occupied by O^{2-} and H^-. Thermal decomposition of PuOH at 105–195°C in vacuum results in stoichiometric loss of hydrogen and formation of a violently reactive solid at the PuO composition. The oxide hydride is insoluble in dilute HCl and continued exposure to liquid water produces additional H_2 and a sequence of solid products identified in Section 29.3.2.

29.3.4 Plutonium alloys

As shown by phase diagrams for binary and higher systems of plutonium (Ellinger *et al.*, 1968), formation of intermetallic compounds is an extensive and important aspect of Pu chemistry. Alloying of Pu with 3–9 at% (1–3 wt%) Ga expands the thermal stability range of the fcc δ-phase from the 310–452°C span of pure metal to a range extending from about 100 to 600°C (Hecker, 2001) and substantially reduces the corrosion rate in air (Waber, 1980). Although the Ga alloy is apparently unstable at room temperature, the rate of transformation is extremely slow. Addition of Al has comparable effects on δ-phase stability and corrosion, and forms a $PuAl_2$ intermetallic compound that melts congruently at 1540°C (Ellinger *et al.*, 1968). Alloying with Fe forms a eutectic composition (10 at% Fe) that melts at 410°C and Pu_6Fe, an intermetallic phase that melts at 428°C (Ellinger *et al.*, 1968). Other metals, such as Nb and V, do not form compounds with Pu and are relatively insoluble in molten Pu (Ellinger *et al.*, 1968). At 1200–1300°C, the saturated Pu-rich liquid contains about 10 at% of these metals.

29.3.5 Uranium compounds

Like plutonium, uranium forms compounds with constituents of the atmosphere and of environments for handling and storage. A single stoichiometric hydride, UH_3, formed by reaction of the elements exists in two cubic modifications (Ward, 1985). The low-temperature α-UH_3 is difficult to prepare and is not expected to form during routine operations. The β-UH_3 phase crystallizes in a

structure identified as β-tungsten-type, but the correct structure is apparently anti-type W_3O (Wells, 1975). All H-atoms occupy distorted tetrahedral sites that are formed by four U-atoms and share a face with another occupied tetrahedron and edges with three occupied tetrahedra. Edge-shared octahedral vacancies formed by six edge-shared tetrahedra provide the most likely pathway for H-transport. The measured activation energy for hydrogen self-diffusion in β-UH_3 is (30 ± 5) kJ mol^{-1} (Ward and Haschke, 1994). The electrical conductivity at 25°C (1×10^{-3} ohm^{-1} cm^{-1}) indicates metallic behavior. The hydride is highly reactive and ignites spontaneously when exposed to air. Thermodynamic properties of the hydride are reviewed (Flotow *et al.*, 1984; Grenthe *et al.*, 1992): $\Delta H_f^\circ(298\ K)$ and $\Delta G_f^\circ(298\ K)$ for β-UH_3 are –127 and –73 kJ mol^{-1}, respectively.

The U–O_2 system is also complex (Keller, 1973; Colmenares, 1975). Studies cited in these reviews indicate that reaction of U with O_2 successively forms UO_2, UO_{2+x} ($x < 0.2$), U_4O_9, U_3O_7, U_2O_5, and U_3O_8, the stable oxide in air with U in U(IV) and U(VI) oxidation states. UO_2 is prepared by reducing higher oxides with H_2 (Anderson *et al.*, 1955). The highest oxide, UO_3, is obtained in five crystallographic forms by heating U_3O_8 in 40 bar O_2 at 500°C or in NO_2 at (115 ± 60)°C and by ignition of oxygen-rich precipitates such as the hydrated nitrate ($UO_2(NO_3)_2 \cdot 6H_2O$) at 400–600°C (Hoekstra *et al.*, 1961). UO_{2+x} forms by accommodating oxygen on octahedral sites of CaF_2-type UO_2. UO_{2+x} is stable only at temperatures above 300°C, but may form as a metastable phase at lower temperatures. The CaF_2-related structure of U_4O_9 results from long-range ordering of oxygen on octahedral sites. The structure of low-temperature orthorhombic α-U_3O_8 (Wells, 1975) contains chains of vertex-shared pentagonal–bipyramidal (UO_7) coordination polyhedra. The structure, which is formed by sharing edges of polyhedral chains, has narrow channels that may restrict oxygen transport (Haschke *et al.*, 2001b). $\Delta H_f^\circ(298\ K)$ and $\Delta G_f^\circ(298\ K)$ for UO_2, U_4O_9, and U_3O_8 are –1085 and –1032 kJ mol^{-1}, –4511, and –4276 kJ mol^{-1}, and –3575 and –3369 kJ mol^{-1}, respectively (Grenthe *et al.*, 1992).

Hydrothermal studies indicate that U_3O_7, U_2O_5, and $UO_3 \cdot nH_2O$ form by spontaneous reaction of UO_2 with water at 130–200°C (Matzke and Turos, 1991). Rutherford backscattering (RBS) and elastic recoil detection analysis (ERDA) show that a layer of hydrogen-free higher oxide forms on the dioxide surface and imply that H_2 is produced.

$$3UO_2(s) + H_2O(l) \rightarrow U_3O_7(s) + H_2(g).$$

Experimental conditions preclude the presence of significant amounts of O_2. Hydrated UO_3 ($UO_3 \cdot nH_2O$) apparently forms at 200°C via a complex process involving oxidation of UO_2, leaching of U(VI) from the higher oxide product, and precipitation of hydrated UO_3. However, thermodynamic data for uranium oxides (Grenthe *et al.*, 1992) indicate that oxidation of UO_2 by H_2O is unfavorable at standard conditions. Because changes in heat capacities are small over a limited temperature range, ΔG° for the reaction at 130°C is approximately equal

to that for 25°C (+92 kJ mol^{-1}) and ΔG at 2.7 bar H_2O pressure remains positive unless the H_2 pressure is less than 10^{-12} bar, a condition that is difficult to maintain in an autoclave system as H_2 is apparently produced. Behavior parallels that for PuO_2–H_2O (see Section 29.3.2) and additional work is needed.

Uranium reacts with N_2 or NH_3 to form sesquinitride, U_2N_3, at temperatures above 400°C (Dell, 1973). The phase is non-stoichiometric with compositions typically ranging from $UN_{1.6}$ to $UN_{1.7}$. Below 1100°C, the α-U_2N_3 product has the bcc Mn_2O_3-related structure like that of α-Pu_2O_3 (Wells, 1975). The NaCl-type mononitride, UN, obtained by decomposing the sesquinitride in vacuum above 1100°C has a room-temperature conductivity (6.7×1^{-3} ohm^{-1} cm^{-1}) similar to that of Bi and Pb (Keller, 1973). The tendency to form sesquinitride during reaction of the elements is consistent with autocatalysis of nitriding by UN. Behavior appears similar to autocatalysis of hydriding by PuH_x and to the catalyzed oxidation of α-Pu_2O_3 by O_2. Values of $\Delta H_f^\circ(298\ K)$ and $\Delta G_f^\circ(298\ K)$ for UN and α-$U_2N_{3.18}$ are –290 and –265 kJ mol^{-1} and –758 and –676 kJ mol^{-1}, respectively (Grenthe *et al.*, 1992).

29.4 REACTION KINETICS OF PLUTONIUM COMPOUNDS

29.4.1 Hydride reactions

(a) Relevant hydride properties

Reaction rates of PuH_x ($1.95<x<3$) with gases and liquids depend on the size distribution of hydride particles and are proportional to surface area (Haschke, 1991). Size distributions of PuH_x vary with preparative conditions; fine powders are formed during slow reaction at low temperatures (Stakebake, 1981a,b) and coarse particles with dimensions up to 1 cm are produced during rapid reaction at temperatures above 400°C (Haschke *et al.*, 1980). Specific surface areas of the low-temperature hydride are in the 0.15–0.25 m^2 g^{-1} range and equal those (0.1–0.2 m^2 g^{-1}) of Pu powders prepared by thermal dehydriding of the powder (Stakebake, 1981c). Therefore, the size distribution of metal particles prepared by a hydride–dehydride process is adopted for low-temperature PuH_x (Haschke, 1992b). Geometric areas of a few cm^2 per gram for hydride prepared at high temperatures are comparable to those of massive Pu.

(b) Reaction of PuH_x with hydrogen

The reaction of PuH_x with H_2 is an important process in ignition and corrosion of Pu metal, but has not been extensively studied. Compositions measured by microbalance methods at constant pressures in the 1–400 mbar range as PuH_x was heated at 2°C min^{-1} in the 25–500°C range agree with isothermal x-values at equilibrium (Haschke, 1981). In addition to indicating that the rates of

hydrogen absorption and desorption by cubic PuH_x are rapid, these results imply that formation of atomic H at the gas–solid interface and transport of hydrogen in the hydride are facile, even at room temperature. The rate of hydrogen absorption by PuH_x is comparable to the rate of the Pu–H_2 reaction and is essentially constant for compositions in the $PuH_{1.9}$–$PuH_{2.7}$ range (Haschke *et al.*, 1980). After adjustment of the surface area to account for a two- to three-fold increase during hydriding, the area-normalized rate at 1 bar H_2 pressure is 1–3 mmol H_2 cm^{-2} min^{-1} (geometric area).

Accommodation of additional hydrogen in the hydride structure is facile and has important kinetic consequences (Haschke and Allen, 2001). Product hydrogen accumulates in the solid and is released as H_2 after x of the PuH_x cores inside reacting hydride particles approach 3. Therefore, reactions of PuH_x with liquids and gases initiate without counter-current flow of hydrogen out of the solid or formation of H_2 at the gas–solid interface.

(c) Reaction of PuH_x with oxygen

Because exposure of hydride to oxygen is expected to result in pyrophoric reaction, observations made during microbalance studies in which PuH_x ($2.0<x<2.7$) at 50–360°C was exposed to O_2 at 13.3 mbar are perplexing (Stakebake, 1981a,b). Reaction initiated immediately at 50°C, essentially ceased after 2 min (20% completion), and completely transformed the hydride to PuO_2 only after the temperature was increased to 315°C in several steps. After each step, the microbalance system was evacuated and the sample temperature was increased before O_2 was reintroduced. During the initial stage of each step, the oxidation rate of oxide-coated hydride was similar to that observed during initial exposure of PuH_x to O_2. Within each step, the rate progressively decreased during an intermediate stage and continued at a slow temperature-dependent rate after entry into a final stage. Results show that reaction at 360°C proceeds via these stages with 95% transformation to PuO_2 after 90 min. XRD data verify that PuO_2 is the product layer on the hydride during the final stage. Kinetic analysis shows that E_a for the initial spontaneous PuH_x–O_2 reaction is negative (–9 kJ mol^{-1}), a result that is inconsistent with the expectation of high activation energies for autothermic processes. Evaluation of linear rates R, in mg O_2 (mg PuH_x)$^{-1}$ min^{-1}, for the final stage shows an Arrhenius dependence ($\ln R = 8.75 - 5050/T$) and an E_a (42 kJ mol^{-1}) consistent with diffusion control of oxygen through a protective PuO_2 film.

In a more recent study of hydride pyrophoricity and catalysis (Haschke and Allen, 2001), the stages of PuH_x oxidation observed in earlier work (Stakebake, 1981a,b) are correlated with chemistry of the oxide layer on the hydride. During heating in vacuum, PuH_x spontaneously reduces the PuO_2 layer to α-Pu_2O_3, a product that rapidly dissociates O_2, and transports oxygen to the oxide–hydride interface. The initial linear oxidation rates of PuH_x and α-Pu_2O_3-coated PuH_x form a single data set with values (88 μg Pu cm^{-2} min^{-1} at 50°C to

21 μg Pu cm^{-2} min^{-1} at 360°C, BET area) and yield an E_a of –8 kJ mol^{-1}. Results imply that α-Pu_2O_3 and PuH_x are equally reactive toward O_2. A negative E_a is consistent with a decrease in concentration of adsorbed reactant on a catalytic ($E_a = 0$) solid as temperature increases at constant pressure. Oxidation of the Pu_2O_3 surface to PuO_2 competes with reduction of PuO_2 by hydride during the intermediate stage, a process apparently triggered as x in PuH_x approaches 3 and product hydrogen flows out of the solid. The diffusion-controlled final stage is entered as the surface is covered by protective PuO_2.

The PuH_x–O_2 reaction is not autothermic, but is controlled by the oxygen pressure, P_{O_2} (Haschke and Allen, 2001). The rate equation is based on data for a range of temperatures because E_a is essentially zero:

$$R \text{ (in g Pu cm}^{-1}\text{min}^{-1}) = 0.37(P_{O_2})^2 \text{ (BET area, } P \text{ in bar)}.$$

The reason for a squared pressure dependence is unknown. The equation accurately predicts temperature-independent rates and is applied in interpreting hydride pyrophoricity and its dependence on temperature. Oxidation is rapid when the hydride is covered by α-Pu_2O_3 and is markedly slowed by a layer of PuO_2. Contrary to expectation, increasing the O_2 pressure does not favor formation of PuO_2. As with the oxide layer on Pu, high temperatures result in reduction of PuO_2 to α-Pu_2O_3 on PuH_x instead of PuO_2 formation (see Section 29.3.2). The large increase in the rates of oxidation and heat generation induced by a small increase in P_{O_2} drives up the temperature, promotes transformation of the oxide surface into catalytic α-Pu_2O_3, and results in continued oxidation at a rate equal to that of freshly prepared PuH_x. E_a for the PuH_x–O_2 reaction is zero, but pyrophoric oxidation of hydride depends indirectly on temperature as the pressure-dependent reaction heats the solid and maintains the catalytic surface.

Consistent failure of PuH_x to oxidize completely upon exposure to 13 mbar O_2 (Stakebake, 1981b) suggests that this P_{O_2} is below a threshold ignition pressure required for generating heat at a rate sufficient to form Pu_2O_3 and sustain rapid oxidation (Haschke and Allen, 2001). Complete oxidation of hydride within minutes at 0.13 bar O_2 (Stakebake, 1981a) implies that the threshold ignition pressure is 13–130 mbar, a range consistent with spontaneous ignition in air (0.21 bar O_2). The estimated threshold O_2 pressure for ignition of PuH_x is 40 mbar.

(d) Reaction of PuH_x with N_2

A facile PuH_x–N_2 reaction is implied by the use of hydride as an intermediate in preparing PuN (see Section 29.3.3), but kinetic data are limited. In an early study, nitriding initiated abruptly at 230°C during heating at 2.7°C min^{-1} in 1 bar N_2, transformed 60% of the PuH_x to PuN within minutes, and continued in a slow stage that approached completion (97%) after several hours (Brown *et al.*, 1955). XRD analysis of PuN products showed the presence of PuO_2 that

may have formed on the PuH_x before nitriding or on the nitride during handling. Effects of surface oxide in preventing reaction at temperatures below 230°C are uncertain.

A microbalance investigation of the PuH_x–N_2 reaction (Muromura and Ouchi, 1974) shows that rapid initial reactions of PuH_2 and PuH_3 at 282°C and 1 bar N_2 pressure are followed by progressively slower reactions that are about 60% complete after 2 h. Data for the initial stage at 225–268°C and 10^{-3}–1 bar N_2 are evaluated using a model based on rate control by chemisorption of nitrogen or hydrogen. Results indicate that the initial rate is controlled by slow association of product H-atoms at the gas–solid interface, a conclusion that seems inconsistent with measured E_a values of 150–297 kJ mol^{-1} for the initial stage of reaction.

Subsequent microbalance results for PuH_x–N_2 at 67 mbar (Stakebake, 1988) are consistent with early observations (Brown *et al.*, 1955). Mass–time data for reaction at 275°C show an initial linear rate (0.2 mg Pu cm^{-2} min^{-1}, BET area) stage resulting in 30% reaction, an intermediate stage in which the rate became progressively slower over time, and a slow constant-rate final stage entered after 85% reaction. Linear rates for the slow stage at 270–445°C (0.14–0.37 μg Pu cm^{-2} min^{-1}, BET area) yield an activation energy of 18 kJ mol^{-1}. Each temperature increase was followed by a brief, but rapid initial reaction. The initial rate at 275°C (1.6 mg Pu cm^{-2} min^{-1}) is comparable to that for the α-Pu_2O_3-catalyzed PuH_x–O_2 reaction at 67 mbar.

(e) Reaction of PuH_x with air

Exposure of PuH_x to air at 25°C results in spontaneous reaction of O_2 and N_2 and a thermal spike (Haschke *et al.*, 1998a). PuH_x was exposed to air supplied from a reservoir connected to a reactor. After reaction ceased, the residual gas was 50–75% H_2 plus 25–50% N_2. Product mole fractions in the solid were 0.80–0.95 PuH_x, 0.03–0.15 PuN, and 0.20–0.5 Pu_2O_3. N_2 and O_2 were consumed in a (1.6 ± 0.5) ratio (3.71 N_2/O_2 ratio in air) during reaction, showing that temperatures generated by hydride oxidation were sufficient to initiate the PuH_x–N_2 reaction. Product hydrogen accumulated in the hydride cores of reacting particles until x approached 3 and was thereafter released as H_2, a product that pressurized the reactor and subsequently prevented access of additional O_2.

The preceding results show that pyrophoric PuH_x–air reaction involves both O_2 and N_2, but are skewed by an experimental configuration in which accumulation of H_2 prevents continuing access of air (O_2) to the sample. Experience shows that unconfined reaction of hydride in air typically continues to completion and is accompanied by burning of H_2 as a pale flame above the solid. Water may have existed as a transient species in the closed system, but is probably formed in open systems. Unlimited access to air may also result in a secondary reaction in which the Pu_2O_3 and PuN products are oxidized to PuO_2.

(f) Reaction of PuH_x with H_2O

Reaction of PuH_x with liquid water at 25°C proceeds at a surprisingly slow rate (Haschke, 1995). The proposed reaction is based on simultaneous generation of H_2 and increase in composition of hydride cores of reacting particles until $x+\delta$ approaches 3:

$$PuH_x(s) + y\ H_2O(l) \rightarrow y\ PuOH(s) + (1-y)\ PuH_{x+\delta}(s) + (y(1+x+\delta)-\delta)/2\ H_2(g).$$

Production of H_2 is observed and XRD data for the product show an increase in hydride composition, but the oxidation product is not identified. Formation of PuOH is assumed by analogy to the reaction of liquid water with Pu metal.

Measurements of the H_2 formation rate show that a moderately rapid reaction occurs during the 0.5 h period after immersion of PuH_2 in 1 M $CaCl_2$ solution (Haschke, 1995). This initial stage is followed by one in which the rate has a parabolic time dependence, characteristic of a diffusion-controlled reaction. Based on H_2 generation and the above equation, the derived linear rate for the initial stage (0.3 μg Pu cm^{-2} min^{-1}, BET area) is 100-fold less than that for corrosion of Pu in 1 M $CaCl_2$ (Haschke, 1992a).

29.4.2 Oxide reactions

(a) Reactions of α-Pu_2O_3

Contrary to early reports that describe the bcc sesquioxide as protective and the source of parabolic oxidation kinetics during metal corrosion (Schnizlein and Fischer, 1967; Lindsay *et al.*, 1972), recent studies suggest that α-Pu_2O_3 is highly reactive and catalyzes reactions of Pu with H_2, O_2, and N_2 (Haschke and Allen, 2001). Kinetic data are available for the reaction of sesquioxide with liquid water (Haschke *et al.*, 1983; Haschke, 1992a). During formation of Pu_7O_{12} at 25°C, α-Pu_2O_3 reacts with H_2O at a slow constant rate of 10 nmol H_2 per g Pu_2O_3 per min or about 2 pg Pu_2O_3 cm^{-2} min^{-1} (BET area) according to the reaction shown in Table 29.2.

(b) Reactions of PuO_2

Reactions of PuO_2 with liquids and gases also depend on surface area, a property that varies substantially depending on the oxide source and preparative conditions (Haschke and Ricketts, 1995). Specific areas of oxides obtained by firing oxygenated precipitates at 400–500°C vary from 10 m^2 g^{-1} for nitrate to as much as 60 m^2 g^{-1} for oxalate and those from oxidation of Pu are 5–15 m^2 g^{-1}. Specific areas decrease upon firing above 600°C and consistently fall to 1–5 m^2 g^{-1} during calcining at 950°C.

Chemical behavior of plutonium dioxide is altered over broad ranges of temperature and humidity by chemisorption and physisorption of water

(Stakebake and Steward, 1973; Benhamou and Beraud, 1980, Haschke and Ricketts, 1997). Dissociative chemisorption occurs at low humidity by reaction of H_2O with O^{2-} ions to form two OH^- ions that bind strongly to the surface (Haschke and Ricketts, 1997). This reaction occurs at low H_2O concentrations (<300 ppm or <0.3 mbar H_2O) via two first-order steps that each adds one monolayer of hydroxide corresponding to a mass gain of 0.11 mg H_2O m^{-2} of oxide surface (3 μmol H_2O m^{-2}) and transforms the surface stoichiometry to $PuO(OH)_2$. Measurements with $U_{0.75}PuO_{0.25}O_{2-x}$ ($0.02<x<0.05$) suggest that the oxide surface is saturated by chemisorbed water at a gas-phase concentration of 10–20 ppm H_2O (Woodley and Gibby, 1973). Adsorbate-free (calcined) oxide tenaciously getters water and maintains a low H_2O pressure at 25°C and 10–15% coverage by the initial hydroxide layer (Haschke *et al*., 2001b). The chemisorption rate in air at 25°C and 0.3 mbar H_2O (1% relative humidity at 25°C) is approximately 10 μmol H_2O m^{-2} h^{-1} (Haschke *et al*., 2001a).

Additional water physisorbs on the $PuO(OH)_2$ surface of the oxide at progressively slower rates in discrete first-order steps corresponding to layers of molecular H_2O (0.22 mg H_2O m^{-2} per layer) as water pressure increases (Haschke and Ricketts, 1997). At 25°C and relative humidities in the 10–60% range, the equilibrium water concentration, $[H_2O]$, is (0.4 ± 0.1) mg H_2O m^{-2}, corresponding to two OH^- layers plus approximately one H_2O layer. The $[H_2O]$ increases sharply above 70% relative humidity and approaches a total of ten layers at saturation. The water content of oxide equilibrated with moist air at a given temperature and relative humidity is readily estimated if the specific surface area of the oxide is known. Although the distribution of water between adsorbed and gaseous states in a closed container depends on specific conditions, more than 99% of available H_2O resides on the oxide surface in a typical storage configuration at 25–75°C (Haschke *et al*., 2001a).

Thermal studies show that water desorbs from PuO_2 in two temperature ranges (Stakebake, 1973). Desorption enthalpies derived from kinetic data for removal of water in the 100–150 and 300–350°C ranges are 84 and 285 kJ mol^{-1}, respectively, if reversible adsorption is assumed to be a nonactivated process. Gravimetric data show a third mass loss above 700°C, but that process is not characterized. Adsorption–desorption measurements in a closed system at 25–260°C indicate that desorption is complete within that temperature range (Paffett *et al*., 2003b). Desorption enthalpies derived from non-isothermal adsorption data vary from 51 to 44 kJ mol^{-1} depending on adsorbate coverage and are consistent with values for UO_2 and other metal oxides. Further work is needed to resolve the differences between results of these studies and to account for a significant mass loss at 700–1000°C (Stakebake, 1973).

Slow reaction of PuO_2 with liquid or gaseous water forms PuO_{2+x} and H_2 via a temperature-dependent process (see Section 29.3.2). The rate of H_2 formation (or oxygen accommodation in the dioxide structure) is described by an Arrhenius equation derived from data for gaseous and liquid water at 25–350°C (Haschke *et al*., 2000b):

$$\ln R \text{ (mol } H_2 \text{ m}^{-2} \text{ h}^{-1}) = -6.441 - (4706/T) \text{ (BET area)}.$$

This reaction also defines R (in mol O m^{-2} h^{-1}) for PuO_{2+x} formation by water-catalyzed reaction of O_2. The rate is independent of water concentration at room temperature (Haschke *et al.*, 2001b), but behavior at high temperatures is unknown.

Radiolytic decomposition of adsorbed water by alpha particles from decay of Pu isotopes occurs simultaneously with the formation of PuO_{2+x} and H_2. As with gamma radiolysis of liquid water (Draganić and Draganić, 1971), alpha radiolysis (Christensen, 1998) proceeds with formation of free radicals such as hydroxyl (OH) and atomic hydrogen (H). Association of radicals leads to formation of H_2 and H_2O_2, a product that accumulates in solution and decomposes with the formation of O_2. The radiochemical yield (G_{H_2}) for hydrogen production is 0.45 H_2 per 100 eV of energy absorbed by water for gamma radiation and approximately 1.3 H_2 per 100 eV of energy absorbed by water for alpha particles. If water is irradiated in a closed system, a steady-state pressure of 1–2 atm is established as rates of radiolysis and re-formation of water become equal (Allen *et al.*, 1952). Similar dissociation reactions occur during radiolysis of adsorbed water, but differences are expected because absence of a liquid phase prevents formation and accumulation of products in solution. A review of observations during gamma irradiation of water adsorbed on non-radioactive oxides (Haschke *et al.*, 2001a) shows variable behavior and imbalance in the hydrogen–oxygen inventory, a condition attributed to reaction of gaseous product (usually loss of oxygen) with substrate solids. Radiochemical yields of adsorbed H_2O are reduced by factors of 10^3 in some cases and increased by up to 10^2 in others. Difficulties in balancing the radiolytic inventory and determining the radiolysis rate for H_2O on PuO_2 are likely because radiolytic oxygen is scavenged by PuO_{2+x} formation and because H_2 is independently produced by the oxide–water reaction (Haschke *et al.*, 2001a).

Studies of alpha-particle radiolysis of water by ^{244}Cm in solution show a H_2/O_2 ratio of 1.86 in the product gas (Kalinichenko *et al.*, 1987). Results of companion studies with $^{238}PuO_2$ immersed in water or exposed to steam at 60–140°C (0.2–3.6 bar H_2O pressure) imply that H_2 is the only gaseous product because G_{H_2} values for alpha radiolysis of water (1.05 and 5.8 H_2/100 eV absorbed by liquid and vapor, respectively) are based on measured (total) rates of gas evolution. The chemical fate of oxygen is not addressed. H_2 generation rates measured during exposure of mixed residues containing PuO_2 and MgO, $Ca(OH)_2$, or CaF_2 to moist air in closed containers at ambient temperature and 90°C are compared with predictions based on the rate of energy release by alpha decay, G_{H_2}, and composition-weighted stopping powers of water in the mixture (Livingston, 1999). On average, observed rates exceed predictions by a factor of 10. Evaluation (Haschke *et al.*, 2001a) of data from tests with only PuO_2 (Livingston, 1999) shows consumption of O_2, formation of N_2, and a temperature-dependent process that is inconsistent with radiolysis.

An estimate of the radiolysis rate ((9 ± 4) pmol H_2 m^{-2} h^{-1}) for oxide exposed to 50% humid air at 25°C (Haschke *et al.*, 2001a) indicates that radiolysis neither accounts for observed H_2 generation rates during exposure of PuO_2 to H_2O nor for a temperature dependence of the rate (Haschke *et al.*, 2000b). Particle-size distribution and self-absorption of alpha energy by the oxide, specific area of the oxide, thickness and alpha particle range of the absorbed water layer, and G_{H_2} for liquid H_2O are included in the derivation. Observed rates exceed estimated values by factors of 10 at 25°C and 10^5 at 350°C. A rate equation is derived assuming a linear dependence on water concentration and a zero rate in the absence of water:

$$R\ (\text{pmol H}_2\ \text{m}^{-2}\ \text{h}^{-1}) = 0.37\ (\text{mol H}_2\ (\text{mol H}_2\text{O})^{-1}\ \text{h}^{-1})[\text{H}_2\text{O}](\mu\text{mol H}_2\text{O}\ \text{m}^{-2}).$$

Observations with CeO_2–H_2O show that G_{H_2} is strongly dependent on $[H_2O]$ if less than—two to three water layers are adsorbed and remains essentially constant if more than three layers are adsorbed (LaVerne and Tandon, 2002). Therefore, proportionality of R and $[H_2O]$ may be limited to water concentrations less than 15 μmol H_2O m^{-2}.

Exposure of H_2–O_2 mixtures to calcined (water-free) PuO_2 at 25–300°C results in surface-catalyzed combination as H_2O (Haschke *et al.*, 1996, 2001b; Morales, 1998). The spontaneous reaction apparently proceeds by dissociative adsorption of H_2 and O_2 and combination of the atomic species. Behavior at 25°C is consistent with first-order kinetics controlled by the concentration of active sites on the oxide surface and progressive blockage of those sites by chemisorption of product water as OH^- (Haschke *et al.*, 2001b), but R is less sensitive to $[H_2O]$ at 100–300°C (Morales, 1998). Combination rates on water-free PuO_2 at 25 and 100–300°C are 30 nmol H_2O m^{-2} h^{-1} and 50 μmol m^{-2} h^{-1} (BET areas), respectively (Haschke *et al.*, 2001a). Adsorption of product H_2O sharply reduces the rate at 25°C, but only causes a 50-fold reduction above 100°C. The combination rate on stainless steel at 25°C (100 nmol H_2O m^{-2} h^{-1}, geometric area) is comparable to that for PuO_2 (Haschke *et al.*, 2001a). The combination reactions on both solids compete with radiolytic decomposition of water, but the extent of reaction on the relatively small area of steel in a typical storage configuration is negligible compared to that on calcined oxide ((3 ± 2) m^2 g^{-1}).

29.4.3 Nitride reactions

Plutonium nitride is readily oxidized to hydrous oxide ($PuO_2 \cdot xH_2O$) by water and reacts more slowly with oxygen to form dioxide (Brown *et al.*, 1955). The oxidation rate in O_2 is increased by moisture (Cleveland, 1979). Reaction with O_2 in air initiates below 100°C and rapidly goes to completion by 150°C with apparent formation of a hydrous intermediate that decomposes on heating above 800°C (Brown *et al.*, 1955). An effect of residual hydrogen on the reactivity of PuN formed via hydride is suggested by absence of pyrophoric

behavior after the product was heated in vacuum and N_2 at 700°C (Leary *et al.*, 1967). This result is confirmed by a study in which nitride from a PuH_x–N_2 reaction was heated at 700°C in N_2 atmospheres that were repeatedly replaced until H_2 could not be detected (<0.01%) in the static gas (Allen, 2001). The product was unreactive in 1 bar O_2 at temperatures up to 700°C, suggesting that residual hydrogen or moisture formed by hydrogen is involved in promoting oxidation of PuN.

29.5 CORROSION KINETICS OF PLUTONIUM METAL

29.5.1 Reaction of Pu with hydrogen

As with the U–H_2 reaction (Haschke, 1991), hydriding of PuO_2-coated Pu proceeds through several stages that culminate in rapid corrosion of the metal (Haschke *et al.*, 2000a). Pu is inherently coated with oxide unless the surface is prepared in ultra-high vacuum by abrasion/scraping or sputter etching. At room temperature, a variable induction period, during which reaction is not detected, is followed by nucleation and growth of reactive hydride sites that ultimately cover the metal surface and induce the maximum hydriding rate. Kinetic studies are facilitated using Pu samples that are covered by PuH_x before testing (Ogden *et al.*, 1980; Haschke and Allen, 2001). Uncertainty is inherent in rate measurements because variation in x of the PuH_x product alters the amount of Pu consumed by a given quantity of H_2. Although PuH_2 is not a distinct phase, use of that hydride composition facilitates evaluation.

Data from pressure–volume–temperature (PVT) in Fig. 29.4 show the dependence of the Pu hydriding rate, R, on H_2 pressure between –18 and 300°C (Haschke and Allen, 2001). The $\ln R - \ln P_{H_2}$ slopes define the pressure exponents, n, of H_2 (see Section 29.2.2). The dependence of R on temperature and P_{H_2} are described by a general rate equation:

$$R\,(\text{g Pu cm}^{-2}\ \text{min}^{-1}) = 0.0567\exp(805/T)(3.75P_{H_2})^n\ (\text{geometric area},\ P \text{ in bar}).$$

The pressure exponent is 1 for P_{H_2} less than 0.27 bar and 0.5 for higher pressures. These pressure exponents are consistent with the Langmuir model and control of the rate by the concentration of adsorbed hydrogen at the gas–hydride interface. The progressive decrease in the rate with increasing temperature in Fig. 29.4 gives an E_a of –7 kJ mol^{-1}, a result attributed to a decrease in the concentration of adsorbed hydrogen with increasing temperature at constant P_{H_2}. The hydriding rate is 1–2 g Pu cm^{-2} min^{-1} or 4–8 mmol H_2 cm^{-2} min^{-1}at 1 bar H_2 (geometric area), a value that is close to the rate (1–3 mmol H_2 cm^{-2} min^{-1}) of the PuH_x–H_2 reaction.

Results for reaction of H_2 with metal powder (0.1–0.3 m^{-2} g^{-1}) from unalloyed Pu (Stakebake, 1992a) and the δ-phase Ga alloy (Stakebake, 1981c) are consistent with findings for massive metal. The pressure exponent is 1 at low

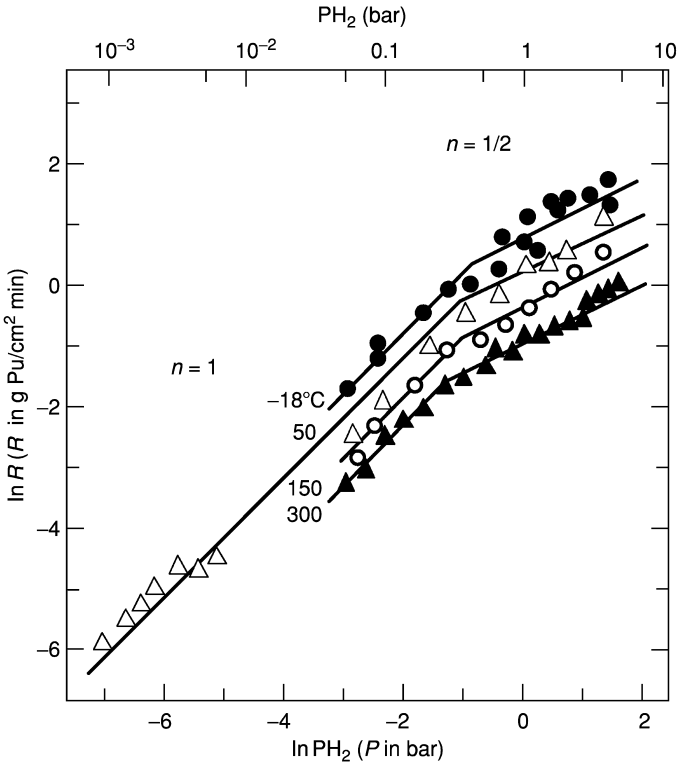

Fig. 29.4 *Dependence of* ln R *on* ln P_{H_2} *for the Pu–H_2 reaction at selected temperatures between* –18 *and* 300°C.

P_{H_2}, but the transition to $n = 1/2$ occurs near 5 mbar H_2. Activation energies are negative (–0.2 to –0.6 kJ mol^{-1}). The initial linear hydriding rate at 30°C and 10.6 mbar H_2 (1.7 mg Pu cm^{-2} min^{-1}, BET area) is less than calculated for massive Pu (32 mg cm^{-2} min^{-1}, geometric area) by the above equation. The ratio of the rates implies that the true (BET) area of hydride surface on massive metal is 20 times greater than the geometric area (Haschke and Allen, 2001).

In early hydriding rate measurements, massive metal was attached to heat sinks and the extent of reaction was controlled in an effort to limit thermal excursion and minimize error in the E_a determination. Pressure exponents of 0.6 (Bowersox, 1977) and 0.7 (Ogden *et al.*, 1980) are determined for experimental P_{H_2} ranges spanning the transition pressure from $n = 1$ to 0.5 in Fig. 29.4, but Arrhenius evaluations give positive E_a values of 8 kJ mol^{-1} (Ogden *et al.*, 1980) and 25 kJ mol^{-1} (Bowersox, 1977) inconsistent with negative values obtained without thermal control. A negative activation energy cannot result from autothermic effects. Self-heating always drives E_a to more positive values regardless

of its sign and cannot cause E_a to be negative, only less negative. Mass–time data for an extended test at 40°C and 9.0 bar H_2 (Ogden *et al.*, 1980) are inconsistent with a positive E_a. The temperature of the sample and sink rose by about 100°C during the measurement. Although a two-fold rate increase is anticipated if E_a is 8 kJ mol^{-1} as a result of the temperature increase, microbalance data show a two-fold rate decrease consistent with –8 kJ mol^{-1}.

Kinetics of the Pu–H_2 reaction are altered by the type of oxide on the metal surface (Haschke and Allen, 2001). Induction periods are absent and maximum hydriding rates are observed immediately upon exposure of the metal to H_2 at all temperatures if the PuO_2 layer is reduced to α-Pu_2O_3 by heating to 200°C in vacuum before reaction. Catalytic properties of PuH_x and α-Pu_2O_3 are implied by the rates at which those materials dissociate and transport hydrogen. At room temperature and 1 bar H_2, the corrosion rates of unalloyed and alloyed Pu are about 1.7 g Pu cm^{-2} min^{-1} and correspond to advancement of the reaction front into the metal at about 6 cm h^{-1}, a rate that is unusually rapid for a gas–solid reaction. The rate is essentially independent of temperature, but goes to zero if equilibrium conditions in the Pu–PuH_x two-phase region (Fig. 29.1) are satisfied. As indicated by curve 11 in Fig. 29.5, corrosion of Pu by H_2 at 1 bar ceases at the 850°C equilibrium point (Flotow *et al.*, 1984).

29.5.2 Reaction of Pu with oxygen, water, and air

(a) Overview of kinetic behavior

Plutonium ignites in air and oxidizes via a self-sustaining reaction if the temperature exceeds 500°C or the corrosion rate exceeds 0.07 g Pu cm^{-2} min^{-1}, the approximate R required for self-heating of Pu to that autothermic temperature (Haschke and Allen, 2001). The Arrhenius evaluation of Pu corrosion reactions in Fig. 29.5 shows three sets of rate curves. Curves 1–7 show strong temperature dependence characteristic of rate control by diffusion of reactant through a protective PuO_2 layer. Curves 8 and 9 are consistent with onset of self-sustaining oxidation at high temperatures. Reaction becomes self-sustaining when the metal is heated above the ignition temperature, T_i, by an external or internal heat source. The set formed by curves 10–12 are independent of temperature and rates of these catalyzed reactions inherently exceed that required for ignition, regardless of initial temperature. Equations (Haschke *et al.*, 1998a; Haschke and Allen, 2001) for the curves in Fig. 29.5 are given in Table 29.3.

A variety of parameters participate in controlling the corrosion rate of thermally driven processes described by curves 1–6 in Fig. 29.5 (Haschke *et al.*, 1996, 1998a). Reactions in this set are temperature-dependent and exhibit paralinear behavior, implying that rates are controlled by diffusion of reactant through the product layer on the metal (Haschke *et al.*, 2001b). Parabolic kinetics are observed only during the formation of the initial oxide layer at temperatures below 400°C and are typically not encountered during routine

handling and storage. Rates indicated by curves 1–6 in Fig. 29.5 are for the linear (constant-rate) stage of corrosion maintained by continuous spallation of product and diffusion of reactant through a product layer of constant average thickness. Assessment of behavior in air is facilitated by normalization of data to 0.21 bar oxidant (O_2 or H_2O) pressure.

Influence of parameters other than temperature is shown by effects of moisture and alloying on corrosion rates described by curves 1–6. Therefore, corrosion kinetics of unalloyed and alloyed Pu in dry air, water vapor, and moist air are discussed separately. Attainment of moisture levels at which the corrosion

[a] Equations are for the linear stage of corrosion and have the form $\ln R$ (g Pu cm^{-2} min^{-1}) $= A - B/T$ (geometric area of Pu).
[b] The oxidant pressure is 0.21 bar O_2 or H_2O, unless otherwise specified.
[c] References: A, Haschke *et al.* (1998a); B, Stakebake and Saba (1990); C, Stakebake and Lewis (1988); D, Haschke and Martz (1998b); E, Martz and Haschke (1998); F, Haschke and Allen (2001).
[d] Dry conditions are less than 0.5 ppm H_2O at 1 bar pressure.
[e] P_e is the equilibrium pressure of H_2O at T.
[f] The value of A has been changed to correct an error (Haschke *et al.*, 1996).
[g] The Pu surface is coated with PuH_x or a double layer of α-Pu_2O_3 and PuH_x.

rate of unalloyed Pu in air or oxygen is insensitive to water concentration at low temperatures is difficult. Results of many studies with 'dry' gases appear inaccurate because residual H_2O concentrations exceeded the 0.5 ppm level required to avoid moisture enhancement of corrosion (Haschke *et al.*, 1996).

(b) Dry oxidation of unalloyed and alloyed Pu

Linear oxidation of unalloyed Pu in dry (<0.5 ppm H_2O) air or 0.21 bar O_2 proceeds as described by curve 1 in Fig. 29.5 and Table 29.3 (Haschke *et al.*, 1996, 1998a). Behavior is defined by a single Arrhenius curve for temperatures up to 400°C, implying that the same reaction occurs over that range (Haschke *et al.*, 2001b). Oxidation of Pu in dry air forms PuO_2 (Colmenares, 1984), a product that persists at the gas–solid interface even though the thickness of the α-Pu_2O_3 layer at the product–metal interface increases with increasing temperature. The E_a for oxidation is 75 kJ mol^{-1} (Haschke *et al.*, 1996), but the temperature dependence for autoreduction at the interface is unknown. The penetration rate by oxidation in dry air at 25°C is about 20 pm h^{-1}.

Control of oxidation by the rate of O^{2-}-ion diffusion through the dioxide layer is supported by paralinear kinetics and agreement of E_a values for oxidation and oxygen self-diffusion in nonstoichiometric dioxide (Haschke *et al.*, 1996, 2001b). Dependence of electrical conductivity on P_{O_2}, positron annihilation data for UO_2 (Colmenares, 1984), and close correspondence of the Pu and

U systems suggest that the oxidation is a concerted process in which electrons move toward the gas–solid interface as Pu(v) ions simultaneously migrate toward the product–metal interface. Data suggest that O^{2-} ions form clusters by associating with Pu(v) and move by hopping between octahedral sites in the fluorite structure. Migration of O^{2-} through the oxide layer is driven by the gradient in oxygen concentration between the gas–oxide and oxide–metal interfaces.

Arrhenius results for oxidation of δ-phase Ga alloy in dry air or O_2 are shown by curve 2 in Fig. 29.5 and Table 29.3 (Stakebake and Saba, 1990; Haschke *et al.*, 1998a). The pressure exponent of O_2 varies from near zero to 0.5 (Stakebake and Lewis, 1988). The activation energy (79 kJ mol^{-1}) agrees with that (75 kJ mol^{-1}) for unalloyed Pu, suggesting that the oxidation mechanism is essentially identical for the two metals. The only obvious difference is that oxidation of the alloy is a factor of 70 slower than that of unalloyed Pu. Because the rate is apparently controlled by diffusion of oxygen through the oxide layer in both cases, the slower oxidation rate of the alloy apparently results from a reduced rate of oxygen transport through PuO_2 formed by that metal. The chemical fate of gallium during oxidation of the alloy is uncertain. Ga may occupy octahedral anion sites in the PuO_2 structure and slow diffusion of oxygen or reside on cation sites and restrict the flow of electrons to the surface.

In addition to the parabolic and linear stages of reaction, a second linear stage appears after 1–2 days during oxidation of alloyed Pu at 275–300°C (Stakebake, 1986; Stakebake and Lewis, 1988). A similar rapid third stage is observed for unalloyed Pu (Stakebake, 1992b). This more rapid corrosion results in 1.5- to three-fold rate increases and is attributed to the formation of cracks in the adherent surface layer of oxide.

(c) Oxidation of unalloyed and alloyed Pu by water vapor

As shown by curves 3–5 in Fig. 29.5, the corrosion rate of unalloyed Pu in water vapor at temperatures below 200°C is more rapid than that in dry air (Haschke *et al.*, 1996, 1998a; Haschke and Allen, 2001). Curves 3 and 4 differ slightly because P_{H_2O} is fixed at 0.21 bar above 61°C and equals the value for liquid–gas equilibrium at lower temperatures. As shown by curve 5, the progressive decrease in R between 110 and 200°C is consistent with a mechanism change in which effects of moisture enhancement are lost (Haschke and Allen, 2001). At temperatures above 200°C, the corrosion rate in water at 0.21 bar is indistinguishable from that in dry air. Moisture enhancement of the Pu corrosion rate is confined to the envelope bounded by curves 1, 3, and 5. Relative to dry oxidation, R is increased by 10^2 at room temperature and by 10^4 at 100°C.

Kinetic data show that the corrosion rate of unalloyed Pu by water depends on temperature and is proportional to $(P_{H_2O})^{1/2}$ (Haschke *et al.*, 1996). As shown by data in Table 29.4, experimental E_a values are a linear function of $\ln P_{H_2O}$. The systematic set of Arrhenius equations derived from these data

Table 29.4 *Arrhenius equations*[a] *for reaction of unalloyed Pu with water vapor at selected pressures or with air at* 1 bar *pressure and the corresponding partial pressures of water* (*Haschke* et al., 1996).[b]

P_{H_2O} (bar)	*H_2O concentration* (ppm)	E_a (kJ mol^{-1})	*A*	*B*
4.7×10^{-7}	0.46	75	8.90	9050
1×10^{-6}	1	79	10.72	9480

0.1	10^5	132	37.89	15850
1	10^6, $(P_{H_2O})_e$[c]	142	42.76	17130

[a] The form of the Arrhenius equations is $\ln R$ (g Pu cm^{-2} min^{-1}) $= A - B/T$ (T in K, geometric area of Pu). Note that rate units are mg O cm^{-2} min^{-1} in the original report, but are reported here as g Pu cm^{-2} min^{-1} to facilitate comparison with data in Table 29.3.
[b] Each equation is valid for T between 383 K and the point at which P_{H_2O} equals the equilibrium pressure $(P_{H_2O})_e$.
[c] The maximum P_{H_2O} at each T is $(P_{H_2O})_e$ below 373 K and equals 1 bar at higher temperatures.

describes the dependence of R on T within the envelope. Curves a, b, c, and d in Fig. 29.5 indicate behavior at 0.01, 0.1, 1, and 10 mbar H_2O, respectively. Rate equations for any water concentration within the envelope are readily derived by interpolation of equations in Table 29.4. Values in the region of decreasing rates between 110 and 200°C may be estimated using curves in the figure.

Although formation of PuO_2 and PuH_2 is reported in early studies of the Pu–H_2O reaction, PuO_2 and H_2 are the only detectable products below 100°C (Stakebake, 1971; Colmenares, 1984). Because production of hydride is thermodynamically favorable in the presence of metal, formation of H_2 implies that hydrogen is not readily transported through the oxide product layer at low temperatures (Haschke *et al.*, 2001b). Increasingly larger amounts of hydrogen are apparently transported with increasing temperature, but the observed product fraction of about 0.15 PuH_x after extended reaction of H_2O at 250°C (Stakebake *et al.*, 1993) is substantially less than the 0.67 fraction expected for complete reaction of hydrogen. As described in Section 29.5.2(d), stoichiometric amounts of PuH_x form at all temperatures via a secondary reaction if excess metal and H_2O are confined in a closed system for an extended period.

The oxide product of the Pu–H_2O reaction is chemically identical to that formed by dry O_2 and kinetics are paralinear, implying diffusion control of O^{2-} transport through an oxide layer (Haschke *et al.*, 2001b). The rapid oxidation rate (curve 3) relative to that by dry air/O_2 (curve 1) is attributed to the combined effect of a high concentration of chemisorbed OH^- at the gas–solid

interface, to facile formation of O^{2-} by interaction of OH^- ions with electrons, and the resulting increase in oxide concentration that produced PuO_{2+x} at the surface (Stakebake *et al.*, 1993). The oxidation rate is enhanced by H_2O because the steady-state oxygen gradient across the constant thickness oxide layer is larger than with dry oxygen. Whereas O^{2-} is formed by transferring one electron to OH^-, the probability of transferring two electrons to dissociatively adsorbed O atoms is low and results in slow oxidation. Enhancement of the Pu oxidation rate by H_2O is attributed to the relatively rapid rates of forming oxide ions from hydroxide ions at the gas–oxide interface. Closure of the rate–temperature envelope (curve 5) is consistent with progressive desorption of water at 110–200°C.

Comparison of curves 6 and 2 in Fig. 29.5 shows the oxidation rate of δ-phase Ga alloy in 0.21 bar water vapor is about a factor of 10 faster than in dry air (Stakebake and Saba, 1990; Haschke *et al.*, 1996). Kinetics of the alloy–water reaction are paralinear and the linear stage is followed by a third stage. At 305°C, the third-stage rate progressively increases by 100 fold and results in complete reaction of 1-mm-thick unalloyed Pu over a 10 h period (Stakebake, 1992b). At that temperature and 20 mbar H_2O, the maximum rate is about 0.01 g Pu cm^{-2} min^{-1} (geometric area). The activation energy (65 kJ mol^{-1}) and the pressure exponent ($n = 0.15$–0.23) of the linear stage are similar to those for oxidation in dry conditions, but E_a is low (11 kJ mol^{-1}) and $n = 1$ for the third stage. Behavior parallels that encountered with hydride-catalyzed oxidation of metal by air (see Section 29.4.1b), suggesting that more rapid diffusion of hydrogen through the oxide layer at elevated temperatures results in the accumulation of hydride at the product–metal interface and catalytic enhancement of reaction by α-Pu_2O_3 and PuH_x layers (Haschke and Allen, 2001). Formation of cracks in the oxide product should enhance this process.

Mixtures of oxide and hydride are formed during reaction of Pu skulls and turnings with flowing mixtures of 25% steam and 75% Ar at 400–800°C (Smith, 1960). After initiation by external heating, reaction becomes self-sustaining and is controlled by adjusting the steam–argon ratio at 1 bar total pressure. The reported corrosion rate of 250 g Pu h^{-1} and the approximate specific area (10 cm^2 g^{-1}) of turnings (Martz *et al.*, 1994) yield an area-normalized value of 0.4 g Pu cm^{-2} min^{-1} (geometric area). Prediction of the third-stage rate at 0.25 bar H_2O pressure using the rate based on data for at 305°C (Stakebake, 1992b) and first-order dependence on P_{H_2O} (Stakebake and Saba, 1990) yields 0.1 g Pu cm^{-2} min^{-1}. Similarity of the rates suggests that the self-sustaining process corresponds to the third stage of the Pu–H_2O reaction, that E_a is zero, and that rate is controlled by P_{H_2O} after a hydride layer is formed at the product–metal interface. As observed during oxidation of PuH_x, a protective PuO_2 layer apparently forms unless the water pressure, heat-generation rate, and resulting temperature are adequate to maintain an α-Pu_2O_3 surface that catalyzes the reactions of H_2 and O_2.

(d) Oxidation of unalloyed Pu by moist air

At a given water pressure and temperatures less than 110°C, the corrosion rate of unalloyed Pu in moist air is more rapid than in dry air and indistinguishable from that observed during oxidation in water vapor at corresponding conditions (Haschke *et al.*, 1996). The pressure exponent for H_2O is 0.5; activation energies and Arrhenius equations vary with humidity as defined by data for water vapor in Table 29.4. Curves a, b, c, and d in Fig. 29.5 indicate corrosion behavior in 1 bar air at 10, 100, 10^3, and 10^4 ppm H_2O. The effect of 1 ppm water is clearly evident and reliability of many kinetic studies at 'dry' conditions appears doubtful.

Although corrosion kinetics in moist air and water vapor are indistinguishable, the chemistry of moisture-enhanced oxidation in moist air below 110°C is different from that for water vapor because O_2 is consumed and H_2 is not produced. Failure to observe H_2 has apparently resulted in proposal of various mechanisms to account for moisture enhancement of corrosion in air. As discussed in a review of proposed mechanisms (Haschke *et al.*, 2001b), two primary explanations are suggested: (1) disruption of the protective oxide layer by formation of hydride or hydrogen at the product–metal interface and (2) rapid transport of oxygen through the oxide as OH^- or H_2O. The validity of such mechanisms is questioned because formation of PuO_2 as the only product at low temperatures requires that product H either form PuH_x or return to the gas–solid interface and re-form H_2O. Because hydride is not observed and decomposition back to metal and hydrogen is prevented by thermodynamic stability of PuH_x, mechanisms involving migration of hydrogen or hydrogen-containing species through the oxide layer appear unlikely.

Modification of the mechanisms for oxidation in dry air and water vapor (see Sections 29.5.2(b) and 29.5.2(c)) accounts for all observations with moist air, including appearance of linear kinetics and absence of physical disruption of the oxide layer (Haschke *et al.*, 2001b). As shown by the following sequence of reactions, chemical behavior is described by a water-catalyzed cycle like that for formation of PuO_{2+x} in air (Haschke *et al.*, 2000b):

$$\begin{aligned}
&Pu(s) + 2H_2O(ads) \rightarrow PuO_2(s) + 4H(ads)\\
&O_2(g) \leftrightarrow 2O(ads)\\
&\underline{4H(ads) + 2O(ads) \rightarrow 2H_2O(ads)}\\
&Pu(s) + O_2(g) \rightarrow PuO_2(s)
\end{aligned}$$

Adsorbed water reacts at the relatively rapid rate of Pu–H_2O reaction. In the presence of O_2, product H-atoms combine with dissociative adsorbed oxygen to re-form H_2O instead of associating as H_2. The net reaction accounts for the disappearance of O_2, formation of PuO_2, and absence of PuH_x or H_2 products. As with reaction of Pu with water vapor, adsorption of H_2O and formation of PuO_{2+x} at the gas–solid interface apparently create an oxygen gradient that

enhances corrosion by driving more rapid transport of oxide ions through the PuO_2 layer.

Mixtures of oxide and hydride are formed by reaction of Pu (and U) with water vapor or moist air at low temperatures if three conditions are satisfied: the system is closed, the time period is sufficiently long, and excess metal is present. In moist air, O_2 is first consumed by the above cycle and H_2O then reacts via the second step to form additional oxide and H_2 (Haschke *et al.*, 2001b). Oxide is formed at equal rates during those reactions. If the system remains closed, H_2 produced by the second step reacts with available Pu (U) to form hydride after H_2O is depleted. Hydriding of Pu is facile if the oxide surface on the metal is transformed to α-Pu_2O_3 by autoreduction.

(e) Thermal ignition and self-sustained oxidation of Pu

As shown by curves 1, 2, and 6 in Fig. 29.5, all effects of water vapor and alloying cease abruptly near 400°C (Haschke *et al.*, 1996; Haschke and Allen, 2001). The origin of the rate decrease for unalloyed Pu and of the convergence of Arrhenius curves for all metal forms is uncertain. A reasonable suggestion consistent with the sharpness of the step is the stoichiometry-dependent transition of $PuO_{2-\delta}$ from n-type to p-type semiconduction (Stakebake and Lewis, 1988). The ensuing rate increase indicated by curve 7 leads to self-sustained oxidation reactions defined by curves 8 and 9.

A sharp increase in corrosion rate at 400–500°C is shown by measurements with the Ga alloy in 0.67 bar air (Stakebake and Lewis, 1988). High E_a values (205–226 kJ mol^{-1}) are observed during both the second and third stages of reaction. As indicated by the average oxide thickness at which kinetic behavior deviates from parabolic behavior, the PuO_2 diffusion barrier progressively decreases in thickness over the 400–450°C range and is not discernable at higher temperatures. Behavior implies that the rate of sesquioxide formation by the Pu–PuO_2 reaction at the product–metal interface approaches and exceeds that for dioxide formation at the gas–solid interface as temperature increases (Haschke and Allen, 2001). The proposed transformation of surface oxide to α-Pu_2O_3 near 500°C is consistent with the onset of self-sustained corrosion in air at (500 ± 25)°C (Martz *et al.*, 1994). The high E_a (298 kJ mol^{-1}) for curve 7 (Fig. 29.5 and Table 29.3), which is based on well-defined rates at 400 and 500°C (Haschke *et al.*, 1998a), agrees with measured results and reflects the change from a protective to a catalytic surface.

Ignition and onset of self-sustained oxidation of unalloyed and alloyed Pu at 500°C are shown by results of several studies cited in a review of plutonium pyrophoricity (Martz *et al.*, 1994). If determined under conditions of dynamic heating, the ignition temperature, T_i, is correlated with geometric specific area, S, of the metal as shown in Fig. 29.6. Whereas Pu powder, chips, turnings ignite at (150 ± 50)°C, foil and bulk metal with thicknesses greater than 0.2 mm ignite at (500 ± 25)°C. As outlined in the preceding paragraph, T_i apparently corresponds

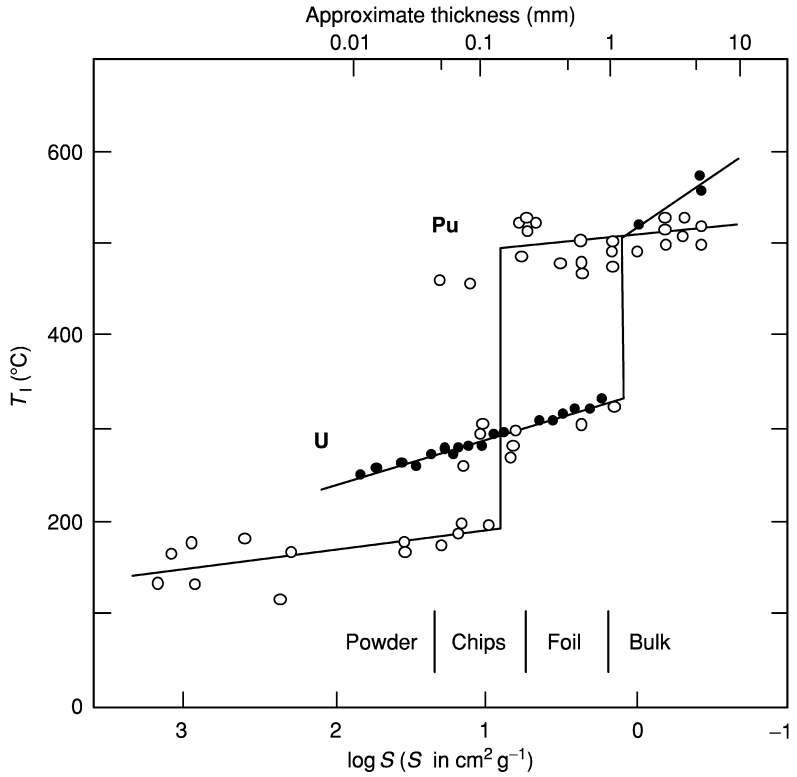

Fig. 29.6 *Correlation of reported ignition temperatures, T_i, for Pu and U with specific surface area, S, of the metal.*

to the temperature at which autoreduction transforms the oxide layer to α-Pu_2O_3, but low-temperature ignition of powder and turnings seems inconsistent with that interpretation. Appearance of large pre-ignition exotherms at 200–300°C during studies with bulk metal samples (Pitts, 1968; Schnizlein and Fischer, 1968) suggests that substantial amounts of heat are generated by a rapid chemical reaction at the Pu surface. If a fixed amount of heat is produced per unit area of metal, the self-heating effect is much larger for powders and turnings with high specific area than for massive pieces of Pu. A likely exothermic source is rapid re-oxidation of the Pu_2O_3 layer at the oxide–metal interface. A thermal model based on this concept and retention of all heat by the metal and reaction products predicts ΔT for rapid reoxidation of the Pu_2O_3 layer (5 μm thick) formed in the oxide–metal interface at 150°C (Martz *et al.*, 1994). ΔT values equaling or exceeding the 350° increment required to reach 500°C are predicted for spherical Pu particles with diameters less than 0.25 mm and foils

with thicknesses less than 0.088 mm, agreeing with the observed specific area for transition from $T_i = 150°C$ to $T_i = 500°C$ in Fig. 29.6.

The thermal model for low-temperature ignition (Martz *et al.*, 1994) accounts for unanticipated observation of lower T_i values in air than in 1 bar O_2 (Schnizlein and Fischer, 1968). Although conventional logic suggests that foils and powders should oxidize more readily in oxygen than in air, an increase in P_{O_2} favors formation of protective PuO_2 while suppressing Pu_2O_3 formation and onset of ignition. This explanation seems to contradict the conclusion that increasing P_{O_2} promotes Pu_2O_3 formation during oxidation of PuH_x (see Section 29.4.1(b)) and PuH_x-coated Pu (see Section 29.5.2(f)), but differences in the dependence of rate on P_{O_2} must be considered. Rates of reaction and heat production are proportional to $(P_{O_2})^n$ with $n = 2$ for the PuH_x–O_2 reaction and with $0<n<0.5$ for the Pu–O_2 reaction (see Section 29.5.2(b)). If PuH_x is present, increasing P_{O_2} from 0.2 to 1 bar increases the rate of heat production by a factor of 25. In the absence of PuH_x, the resulting rate change is less than two-fold.

Effects of other counter-intuitive observations (Pitts, 1968) are also consistent with Pu_2O_3 formation at the ignition point. T_i values for Pu powder (100–250 μm diameter) are 392, 189, and 152°C for 0.03, 0.12, and 0.60 g specimens, respectively. The steady-state O_2 concentration within the porosity of a powder bed decreases with increasing sample size because the area of reactive surface is larger and oxygen diffusion into the powder is increasingly restricted. Low P_{O_2} in the bed promotes formation of catalytic α-Pu_2O_3 and reduces T_i. Similar decreases in T_i of foil (0.06 mm thick) after folding and compressing are probably not due to stress in the metal, but to fracture of the PuO_2 layer during deformation and to reduction of the O_2 concentration within folds of the sample. A decrease in T_i with increasing extent of surface oxidation before testing is consistent with formation of a thicker Pu_2O_3 layer and a larger ΔT during reoxidation (Martz *et al.*, 1994).

The 500°C ignition point of Pu is observed under dynamic conditions in which heat is supplied at a rate that causes a temperature increase in excess of 10°C min^{-1} (Pitts, 1968; Schnizlein and Fischer, 1968; Musgrave, 1971). Studies show that T_i of massive Pu is progressively decreased by reducing the heating rate and reaches 355°C at about 0.1°C min^{-1} (Pitts, 1968). During constant-temperature experiments, samples ignited after 0.5 h at 400°C and after 3 h at 375°C, but oxidized completely without igniting at 350°C. Results are consistent with thermal calculations indicating that the static ignition point of massive Pu is near 300°C, the temperature at which the rates of heat generation by the Pu oxidation in air and heat loss from the metal surface are equal (Haschke *et al.*, 2000c). Autothermic behavior is possible above 300°C, but experiments suggest that static ignition is likely to occur only at above 350°C.

As indicated by curve 8 in Fig. 29.5, self-sustained oxidation of Pu in static air is independent of temperatures above 500°C (Haschke and Martz, 1998b). The average rate at 500–1000°C is (0.14 ± 0.07) g Pu cm^{-2} min^{-1}, corresponding to a

linear corrosion rate of about 5 mm Pu per hour. E_a for the process ((9.6 ± 6.3) kJ mol^{-1}) is effectively zero, but the dependence on P_{O_2} is unknown. The zero E_a is attributed to the formation of an O_2-depleted boundary layer of unreactive N_2 that controls the oxidation rate by limiting the O_2 flux to the metal surface, causing the burning metal to glow with a steady charcoal-like orange color during reaction (Haschke *et al.*, 2000a). However, analogy to results for other reactions involving catalytic α-Pu_2O_3 (Haschke and Allen, 2001) suggests that the rate might be invariant because E_a is zero and P_{O_2} of air is constant.

Curve 9 in Fig. 29.5 shows the Arrhenius relationship derived for dynamic Pu in air after ignition (Martz and Haschke, 1998). The kinetic assessment is based on studies in which laser-ignited metal particles (0.07–0.6 mg) incandesced with increasing brightness and ultimately 'exploded' during free fall in air (Nelson, 1980). The time in free fall before explosion increased with increasing particle mass. Vaporization and oxidation of residual Pu during the nonviolent explosions produced hollow oxide spherules with one or more vent holes plus an aerosol that accounted for up to 77% of the Pu. Conceptually, oxide-coated metal spheres form upon melting of the Pu at 640°C and react at an increasing rate during free fall because an O_2-depleted layer cannot form (Martz and Haschke, 1998). Progressive heating increases the particle temperature, melts the oxide coat at 2300–2400°C, and results in venting of residual metal as vapor above the 3230°C boiling point of Pu. The 'explosion' results from rapid oxidation of vented Pu vapor in air.

A quantitative thermal model based on the above concept includes correction for thermal losses by the falling particle and fitting of the activation energy (Martz and Haschke, 1998). The model accurately predicts time intervals to explosion and fractions of aerosolized Pu as a function of Pu particle size. The effective E_a (40 kJ mol^{-1}) for reaction of ignited Pu in free fall suggests a temperature-dependent process that is evident for dynamic conditions in which the N_2 boundary layer is swept away. However, self-sustained oxidation of α-Pu_2O_3-coated PuH_x by O_2 (see Section 29.4.1(b)) and of Pu by H_2O (see Section 29.5.2(c)) has zero activation energy. Because α-Pu_2O_3-coated Pu may behave in a similar way, the apparent E_a might be a consequence of P_{O_2} dependence and the increasing O_2 impingement rate as the particle accelerates during free fall.

Ignition studies with samples of Pu powder are relevant to anecdotal reports that kilogram-sized pieces (Martz *et al.*, 1994), as well as chips and turnings (Stakebake, 1992c), spontaneously ignite in air at room temperature. Specimens of Pu powder (50–100 μm size) used in ignition studies were prepared by filing metal and sieving the fines in dried (200–700 ppm H_2O) air (Musgrave, 1971). If fine Pu particles were pyrophoric, they would ignite during this preparation. The filings apparently oxidized slowly in air at room temperature and ignited only upon heating to 175–200°C, suggesting that other reactive materials such as α-Pu_2O_3 and PuH_x participate in initiation of self-sustained reactions of both finely divided and massive metal at room temperature (see Section 29.8.4b).

(f) Catalyzed ignition and self-sustained reaction of Pu

Involvement of reactive materials in initiating self-sustained oxidation of Pu is supported by results of kinetic studies with Ga alloy coated with PuH_x or a double layer of α-Pu_2O_3 and PuH_x (Haschke *et al.*, 1998a; Haschke and Allen, 2001). Oxidation of a 1.5 mm thick Pu sample coated with the double layer was complete in less than 1 s and produced gas-phase temperatures in excess of 1000°C after exposure to O_2 at a median pressure of 3.2 bar (Haschke *et al.*, 2000a). The solid product expanded in the shape of the Pu sample during reaction and consisted of a PuH_x core surrounded by a thick Pu_2O_3 layer. Product hydrogen was accommodated as PuH_x during advancement of oxidation into the metal and was not detectable in the gas phase after reaction. As with the PuH_x–O_2 reaction, oxidation of hydride-coated metal has zero activation energy, a property that allows the dependence of rate on P_{O_2} to be evaluated without regard for the temperature.

Rate data for oxidation of Pu coated with the α-Pu_2O_3–PuH_x double layer are consistent with those for reaction of O_2 with PuH_x and α-Pu_2O_3-coated PuH_x (Haschke and Allen, 2001). If the factor of 20 between geometric and BET areas of the metal is included, evaluation shows that the oxidation rate of hydride-coated Pu with O_2 is proportional to P_{O_2} squared as indicated by the following equation.

$$R \text{ (in g Pu cm}^{-2} \text{ min}^{-1}) = 7.4(P_{O_2})^2 \text{ (geometric area, } P \text{ in bar).}$$

The rate in 1 bar O_2 is indicated by curve 12 in Fig. 29.5. Hydride-catalyzed oxidation is apparently independent of alloying and penetrates the metal at more than 25 cm h^{-1} at 1 bar O_2 and by almost 3 m h^{-1} at 3 bar O_2, a value corresponding to the interfacial hydriding rate expected for the metal–hydrogen reaction at 1 kbar H_2. Rapid oxidation of Pu is attributed to a two-part catalytic process in which α-Pu_2O_3 dissociatively adsorbs and transports oxygen to the oxide–hydride interface and PuH_x transports product hydrogen to the hydride–metal interface. Transport of anions in the fixed fcc Pu lattice of product compounds and formation of PuH_x at the product–metal interface are extremely rapid. Zero activation energy and the dependence of R on P_{O_2} imply that the corrosion rate is controlled by dissociative adsorption of O_2.

Exposure of PuH_x-coated Pu or PuOH-coated Pu to air at room temperature results in rapid corrosion that parallels behavior of the PuH_x–air reaction (see Section 29.4.1c) and indiscriminately consumes N_2 and O_2 at the 3.7:1 ratio of air (Haschke *et al.*, 1998a; Haschke and Allen, 2001). Stoichiometry data show that reaction is described by formation of PuN:Pu_2O_3 in a 5.57:1 ratio plus PuH_x with x near 3 and consumes 1.86 moles of Pu per mol of air. The solid product may be a mixture of nitride and sesquioxide or contain a NaCl-related oxide nitride, $PuN_{1-v}O_v$, having a maximum v of 0.13 (Jain and

Ganguly, 1993). Reaction continues until all Pu is consumed and forms solids with PuH_x cores similar to those observed during reaction of O_2. H_2 is produced if spalled hydride powder is present (Haschke *et al.*, 1998a). Reaction of PuOH-coated metal apparently proceeds through an initial stage in which the surface layer reacts with metal to form α-Pu_2O_3 and PuH_x (Haschke and Allen, 2001).

Kinetic data for substantial ranges of air pressure, P_a, and temperature show that the corrosion rate of Pu coated by the α-Pu_2O_3–PuH_x double layer is independent of temperature and proportional to P_a squared (Haschke and Allen, 2001).

$$R \text{ (in g Pu cm}^{-2} \text{ min}^{-1}) = 1.72(P_a)^2 \text{ (geometric area, } P_a \text{ in bar)}.$$

Behavior is indicated by curve 11 in Fig. 29.5. Fortuitously, the corrosion rate in 1 bar air is coincident with that for the Pu–H_2 reaction at 1 bar pressure (see Section 29.5.1) and advances into the metal at about 6 cm h^{-1}. Dissociation and transport of nitrogen and oxygen are catalyzed by the PuN–α-Pu_2O_3 corrosion product covering the PuH_x layer. Involvement of PuH_x in catalyzing the Pu–N_2 reaction is evident because N_2 does not react with Pu_2O_3-coated Pu following thermal ignition (see Section 29.5.2(e)). Reactions of PuH_x-coated Pu and PuH_x in air are similar and suggest that involvement of N_2 is contingent on generation of sufficient heat by the initial PuH_x–O_2 reaction to form Pu_2O_3 and to initiate the PuH_x–N_2 reaction. Both the amount and partial pressure of O_2 are important factors in hydride-catalyzed ignition of self-sustained corrosion in air.

The importance of O_2 in initiating and sustaining catalyzed corrosion of Pu in air is shown by derivation of the rate equation for reaction in air from that for oxidation of PuH_x in O_2 (Haschke and Allen, 2001). That relationship is obtained by assuming that the oxidation kinetics of hydride (see Section 29.4.1(c)) and hydride-coated plutonium by O_2 are identical. If reaction of N_2 is driven by the thermal effect of O_2 reaction, the squared dependence of R on P_a arises only from the partial pressure of O_2, while the pressure exponent for N_2 is zero. The rate equation for air is derived from that for oxidation in O_2 by including the metal consumption ratio (5.57:1) for indiscriminate reaction of air and by substituting $0.21P_a$ for P_{O_2}.

$$R \text{ (in g Pu cm}^{-2}\text{min}^{-1}) = 1.8(P_a)^2 \text{ (geometric area, } P_a \text{ in bar)}.$$

Agreement of this derived equation with the experiment result presented above supports the conclusion that the kinetics the PuH_x–air and hydride-catalyzed Pu–air reactions are controlled by the O_2 partial pressure. As with the PuH_x–O_2 reaction, oxygen pressures below a threshold value have an insufficient heat generation rate for maintaining a catalytic α-Pu_2O_3 surface and result in the formation of a protective PuO_2 layer.

(g) Salt-catalyzed corrosion of Pu in liquid water

Formation of PuOH by reaction of Pu with water is strongly dependent on the anion concentration, [X], in solution (Haschke, 1992a). Data for [X] in the 10^{-7} ($[OH^-]$ in distilled H_2O) to 2 M ($[Cl^-]$ in $CaCl_2$ solution) at 25°C (Haschke, 1995) show that $\ln R$ is a linear function of ln[X] as described by the dependence of corrosion rate, R, on salt concentration in moles per liter.

$$R \text{ (in g Pu cm}^{-2}\text{ h}^{-1}) = 0.0073[\text{X}]^{0.43} \text{ (geometric area)}.$$

Measured corrosion rates in distilled water, typical tap water, and synthetic seawater are 7×10^{-3}, 0.52, and 6.3 mg Pu cm^{-2} h^{-1}, respectively. If a 1 mm thick piece of Pu is submerged in seawater at room temperature, corrosion on both surfaces results in transformation to PuOH powder within 5–6 days. The dependence of R on salt concentration suggests that anions catalyze the reaction by facilitating electron transfer at the surface.

Data indicate that the corrosion rate in water is sensitive to pH and temperature (Haschke, 1995). The corrosion rate at pH 10 is 10^4 slower than at pH 7 and freshly burnished metal is untarnished after 3 weeks in solution at pH 13.7. Relative to the corrosion rate in 1 M $CaCl_2$ solution, the 50-fold more rapid rates in 1 M $FeCl_3$ and $NiCl_2$ solutions are attributed to H^+ formation by cation hydrolysis. Evaluation of limited data gives an E_a of 25 kJ mol^{-1} for corrosion in near-neutral solutions.

29.5.3 Reaction of Pu with steel

Molten plutonium aggressively dissolves all types of iron and steel (Haschke and Martz, 1998a). If excess Pu is present, corrosion penetrates a 1.5 mm thick stainless steel barrier within a few minutes at 700–900°C. Although a eutectic near the Pu_6Fe composition melts at 410°C, the Pu–Fe reaction is slow below the 640°C melting point of Pu because reaction proceeds by inter-diffusion of the solid metals. The intimate contact required for that process is further hindered by the presence of oxide layers on the metals.

The extent of corrosion at temperatures below the 1230°C melting point of $PuFe_2$ is limited by the equilibrium composition of the Pu-rich liquid coexisting with that intermetallic compound (Ellinger *et al.*, 1968). At 1000°C, the iron-saturated solution contains 33 at% Fe, the composition formed by reaction of 6.8 g Pu with a 1 cm^2 area of 1 mm thick steel. Complete dissolution of Fe is expected at 1000°C if the thickness-normalized ratio of g Pu per cm^2 of steel surface approaches or exceeds 6.8 at any point of contact. The corrosion rate decreases as the molar ratio of Fe:Pu exceeds 1:2 (33 at% Fe) and reaction of residual Fe is slowed by formation of a protective $PuFe_2$ layer. The likelihood of penetration is low if the Fe:Pu ratio exceeds 2:1, but failure of a steel container is possible at high Fe:Pu ratios if corrosion of the steel is localized. In typical storage configurations, the Fe:Pu ratio is low and rapid loss of containment is likely if the temperature exceeds 700°C.

29.6 CORROSION KINETICS OF URANIUM COMPOUNDS AND URANIUM METAL

29.6.1 Reaction of UO_2 with water

Formation of higher-oxide layers on the surface of UO_2 during exposure to water and aqueous solutions in the absence of O_2 at 130–200°C (Matzke and Turos, 1991) implies that H_2 is produced by chemical reaction. The kinetics in pH 10 solution are parabolic over the 170–200°C range as indicated by proportionality of the product layer thickness (τ in nm) to the square root of reaction time (t in hours) at constant temperature: $\tau = kt^{1/2}$. Arrhenius evaluation of published data shows that $2\ln k$ (nm $h^{-0.5}$) = 31.75 –(10100/T) and that E_a (84 kJ mol^{-1}) is consistent with self-diffusion of oxygen in the oxide. If the product layer is U_3O_7, each nm of oxide thickness formed by reaction of H_2O corresponds to generation of 1.4 nmol H_2 per cm^2 of oxide (BET area).

The corrosion rate and the mechanism of the UO_2–H_2O reaction are sensitive to solution pH and temperature (Matzke and Turos, 1991). The rate is apparently not controlled by diffusion below 170°C or in neutral solutions because the layer growth is linear with time at those conditions. Although kinetic data are not reported for the linear regime, reaction apparently proceeded with formation of higher oxide and H_2 over a broad parametric range. Consequences of the UO_2–H_2O reaction during storage of uranium oxide merit consideration and further evaluation even though thermodynamic data indicate that the process is not favorable.

29.6.2 Reaction of U with hydrogen

Kinetics of the U–H_2 reaction are outlined in earlier reviews describing quantitative rate data and models for hydriding are proposed (Haschke, 1991; Ward and Haschke, 1994). Hydriding of oxide-coated U proceeds sequentially through induction, nucleation, and acceleration stages as localized hydride sites initiate and grow. Under certain conditions, a parabolic stage appears in the window bounded by complete surface coverage by UH_3 and onset of the final linear (constant-rate) stage. As with Pu, nucleation of hydride sites on U is slowed by oxide on the metal surface and preferential site growth implies that hydriding is promoted by UH_3. Appearance of a parabolic stage indicates the rate is controlled by diffusion of hydrogen through a UH_3 layer and that the hydriding mechanisms of U and Pu differ.

Adequate kinetic data are available only for the terminal constant-rate stage of hydriding with a fully active surface covered by UH_3. The $\ln R$–$\ln P_{H_2}$ isotherms in Fig. 29.7 derived (Ward and Haschke, 1994) from measurements at low (10^{-7}–0.1 bar) (Powell *et al.*, 1991) and high (0.01–50 bar) (Block and Mintz, 1981) H_2 pressures show that the area-normalized rate during the linear stage of the U–H_2 reaction depends on both T and P_{H_2} as described by $R = k\exp(-E_a/R^*T)(P_{H_2})^n$. Three regions with distinctly different pressure

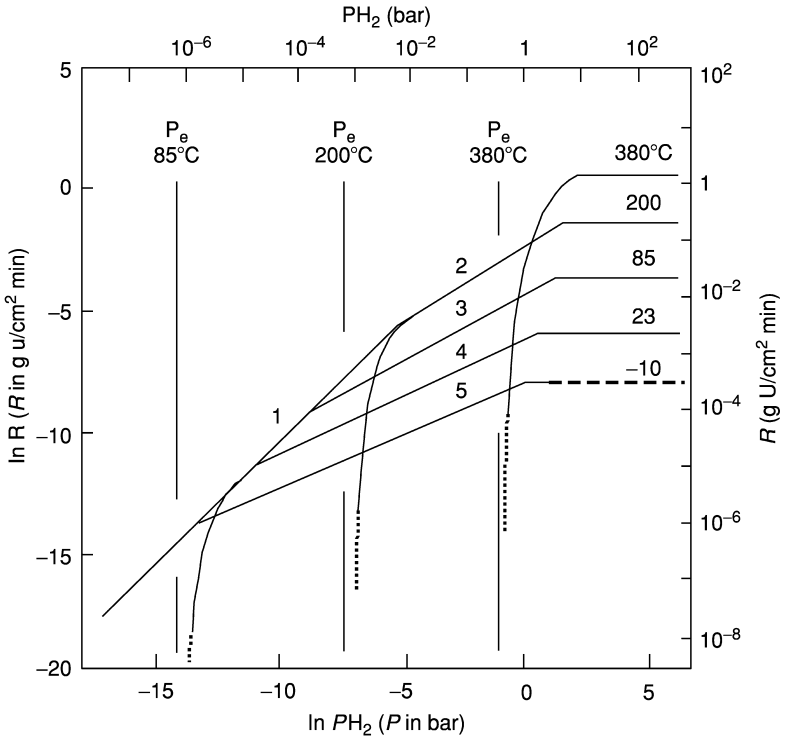

Fig. 29.7 *Dependence of* ln R *on* ln P_{H_2} *for the U–H_2 reaction at selected temperatures between* –10 *and* 380°C.

exponents consistent with Langmuir adsorption theory are identified: a low-pressure region in which the surface concentration of adsorbed hydrogen, θ, is negligible and proportional to P_{H_2} ($n = 1$); an intermediate-pressure region in which θ is proportional to $(P_{H_2})^n (n = 0.5 \pm 0.1)$, and a high-pressure region in which θ is 1 and independent of $P_{H_2} (n = 0)$. At low P_{H_2} and temperatures below 200°C, rates for all temperatures converge to a single line with a slope of 1 (curve 1 in Fig. 29.7) consistent with rate control by impingement of H_2 on the surface. In the absence of a dependence on T, $E_a = 0$ and $R = kP_{H_2}$. As shown by data in Table 29.5, the general equation also applies to curves 2–5 with n values near 0.5, implying that R depends on the concentration of adsorbed H_2 and that reaction involves dissociation into atomic H. Pressure independence at high P_{H_2} is attributed to hydrogen saturation of the surface.

Arrhenius results in Table 29.6 show that the hydriding rate is dependent on temperature at intermediate and high P_{H_2} (Ward and Haschke, 1994). In the pressure-independent ($n = 0$) region, R depends only on temperature. As shown by E_a values in Table 29.6, activation energies coincide with the

Table 29.5 *Rate equations describing the dependence of the U hydriding rate on H_2 pressure for curves in Fig.* 29.7.[a]

Curve	T (°C)	*Applicable* P_{H_2} *range* (bar)	k	n
1	<200	–[b]	0.75	1.0
2	200	5×10^{-3}–5	0.067	0.61
3	85	2×10^{-4}–3	0.012	0.53
4	23	2×10^{-5}–1	1.7×10^{-3}	0.46
5	–10	2×10^{-6}–0.7	3.2×10^{-4}	0.40

[a] Rate equations have the form R(in g U cm^{-2} min^{-1}) $= k(P_{H_2})^n$ (P_{H_2} in bar, geometric area of U). Reference to Fig. 29.7 may be necessary to verify validity of the equation.
[b] The applicable P_{H_2} range of curve 1 depends on temperature and expands to higher pressures with increasing temperature. Curve 1 is not applicable above 200°C because the required P_{H_2} approaches P_e for UH_3 formation. Reference to a detailed analysis of applicable kinetic regimes (Ward and Haschke, 1994) may be necessary.

Table 29.6 *Arrhenius equations*[a] *for hydriding of U along selected H_2 isobars in Fig.* 29.7 (*Haschke*, 1998).

P_{H_2} (bar)	*Applicable* T *range*[b] (°C)	E_a (kJ mol^{-1})	A	B

10^{-2}	<200	24	0.82	2865
10^{-3}	<70	23	–0.49	2730

[a] Rate equations have the form $\ln R$ (R in g U cm^{-2} min^{-1}) $= A-(B/T)$ (T in K, geometric area of U).
[b] Temperature limits are based on kinetic regimes defined in a $P_{H_2} - T$ diagram (Ward and Haschke, 1994).

(30 ± 5) kJ mol^{-1} E_a for hydrogen self-diffusion in UH_3 (see Section 29.3.4), implying that R is controlled by diffusion of hydrogen through the adherent hydride layer at high P_{H_2} and is determined by the combined effects of the adsorbed H_2 concentration and diffusion at intermediate pressures. Rates in the intermediate-pressure ($n \sim 0.5$) region vary with T, as well as with P_{H_2}, showing that R depends on both parameters. Systematic variations of n with T (Table 29.5) and E_a with P_{H_2} (Table 29.6) suggest that parameters are not independent. In part, the dependence of E_a on P_{H_2} accounts for the large range of activation energies (8–33 kJ mol^{-1}) cited in early studies (Haschke, 1991); the observed value depends on the isobaric H_2 pressure present during measurement.

Involvement of thermodynamic rate control is shown in Fig. 29.7 by abrupt decreases in rate as P_{H_2} approaches the equilibrium pressure, P_e, for UH_3 formation at 85, 200, and 380°C. Values of R consistently deviate from control by other parameters for $P_{H_2} < 10P_e$. Values of P_e are defined by $\ln P_e$ (in bar) $= 14.54-(10233/T)$ (Flotow *et al.*, 1984). A diagram identifying the

$P_{H_2} - T$ regimes in which different parameters determine the rate of U–H_2 reaction (Ward and Haschke, 1994) shows that impingement control is not possible above 200°C because the P_{H_2} required to drive that process is greater than P_e. In a similar way, existence of the regime involving combined effects of P_{H_2} and T is precluded by thermodynamic control above 400°C. The 85°C isotherm in Fig. 29.7 exhibits all four types of control. Although several models have been proposed to describe and predict the hydriding kinetics of U (Haschke, 1991), results suggest that accounting for behavior over the full parametric range with a single model is unlikely unless all control mechanisms and their relationships are included.

Kinetic studies with high surface area (0.5–3 $m^2\ g^{-1}$) U prepared by hydriding and dehydriding cycles (Condon and Larson, 1973; Stakebake, 1979) suggest that reaction of H_2 with powdered metal differs from that of massive uranium. Studies with U-powder at 75–200°C and 5×10^{-4}–0.13 bar H_2 show that $n = 0.5$ (Condon and Larson, 1973), that E_a is –7 kJ mol^{-1} (Condon and Larson, 1973; Stakebake, 1979), and that R depends on the amount of unreacted metal, not on the surface area. Proposed models in both studies are based on rapid diffusion of hydrogen and formation of hydride within the U-particles. Mass–time data for reaction of U-powder (0.6 $m^2\ g^{-1}$) with H_2 at 0.13 bar and 100°C (Stakebake, 1979) yield a linear rate of 2×10^{-4} g U $cm^{-2}\ min^{-1}$ (BET area). The value of R calculated for massive U at 100°C using the equation for 0.1 bar in Table 29.6 and a specific area that is 10–20 times the geometric value yields a rate of $(2 \pm 1) \times 10^{-4}$ g U $cm^{-2}\ min^{-1}$ (BET area), suggesting that hydriding kinetics of powdered and massive U are similar.

Compared to the penetration rate of Pu by H_2 at 1 bar and 25°C (6 cm h^{-1}), corrosion of massive U by H_2 at those conditions is relatively slow (40 μm h^{-1}) and is consistent with differences in hydrogen-transport properties of the hydrides. Although the corrosion rate of finely divided uranium appears to be indistinguishable from that of massive metal, the rate of heat generation is enhanced because of the larger surface area. The UH_3 product has a specific area of about 1 $m^2\ g^{-1}$ (Condon and Larson, 1973) and is pyrophoric in air. Studies of the reaction between UH_3 and saturated H_2O vapor at 100°C show that UO_2 and H_2 form at a constant rate until the process is approximately 65% complete after 20 h (Baker *et al.*, 1966). Subsequent reaction continues at a progressive slower rate and becomes immeasurably slow at about 80% completion after 50–60 h.

29.6.3 Reaction of U with oxygen, water, and air

As shown in a recent review (Haschke, 1998), oxidation kinetics of U in dry air and water vapor closely parallel those of Pu, but diverge in moist air below the ignition point and in static air at temperatures above the ignition point. The kinetic behavior of U (Fig. 29.8) is similar to that of unalloyed Pu in Fig. 29.5. Arrhenius curves for U form an envelope bounded by slow rates in dry air and

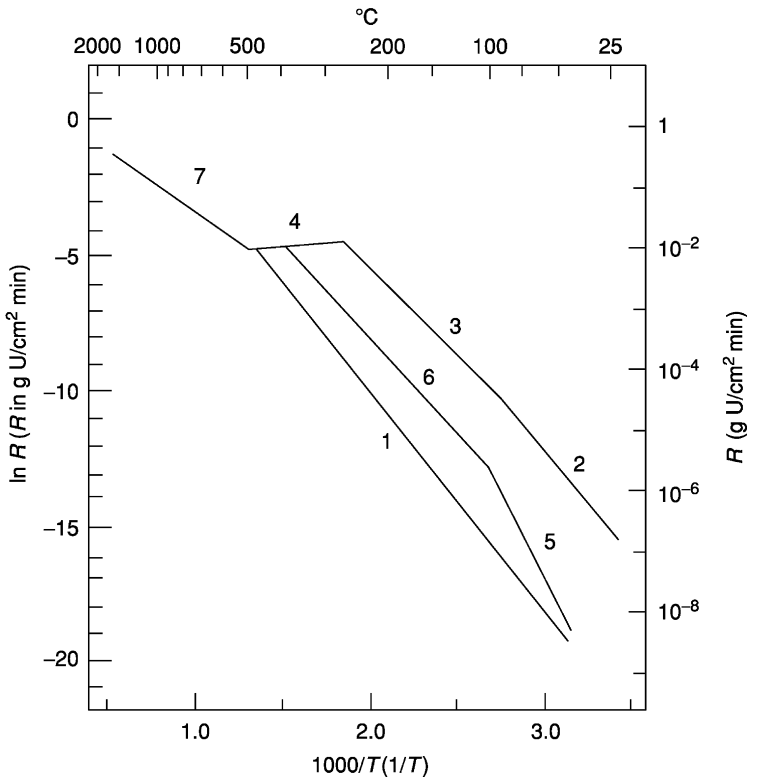

Fig. 29.8 *Arrhenius curves for corrosion of U in air and water vapor. Curve* 1 *describes behavior in dry air. rapid rates in water vapor at low temperatures and closed by convergence of rates at high temperatures. Respective rates for U and Pu in dry air at 25°C are 8 and 5 ng metal cm^{-2} min^{-1}. The oxidation rates of both metals in saturated water vapor are approximately 250 times faster than in dry air at room temperature.

Oxidation of uranium in dry air proceeds with formation of an adherent product layer on the metal surface and with paralinear kinetics (Haschke *et al.*, 2001b). The chemical composition of the layer during the linear stage was identified as UO_2 below 275°C and an outer layer of U_3O_8 was observed in air at higher temperatures (Colmenares, 1975). Spalled oxide continues to react and form U_3O_8 in air. Curve 1 in Fig. 29.8 for the constant-rate stage of oxidation (Haschke, 1998) is based on measurements in dry air at 40–350°C (McGillivray

Table 29.7 *Arrhenius equations*[a] *for corrosion of U in air and H_2O vapor.*

		Applicable range				
Curve	*Reaction*	*T* (K)	P_{H_2O} (bar)	*A*	*B*	*References*[b]
1	U + dry air	<773	0	6.19	8 077	A,B
2	U + H_2O vapor	<373	P_e[c]	10.64	7 725	A,C
3	U + H_2O vapor	373–623	1.01	8.33	6 860	A,D
4	U + H_2O vapor	623–773	1.01	–4.92	0	A,D
5	U + humid air	<373	0.003–0.5	22.96	13 285	A,C,E
6	U + humid air	372–673	0.053[d]	5.09	6 765	A,B,C
7	U + dry/humid air	>773	1.01	1.21	4 655	A,F

[a] Arrhenius equations have the form R (in g U cm^{-2} min^{-1}) = $A - B/T$ (T in K, geometric area).
[b] References: A, Haschke (1998); B, McGillivray *et al.* (1994); C, Colmenares (1984); D, Huddle (1953); E, Ritchie *et al.* (1986); F, Hilliard (1958).
[c] P_e is the H_2O pressure in equilibrium with water at T.
[d] The 0.053 bar H_2O pressure corresponds to a median value of the measurements. Rates at other conditions are derived using the temperature-dependent exponent of P_{H_2O}, n, which varies from 0 at 100°C to a maximum of 1 at 250°C and decreases to 0.6 at 350°C (Haschke, 1998).

et al., 1994). The Arrhenius equation describing curve 1 appears in Table 29.7. E_a (67 kJ mol^{-1}) is consistent with rate control by diffusion of oxygen through the adherent oxide layer. As shown by curves 2 and 3 in Fig. 29.8, corrosion of uranium in water vapor is more rapid than in dry air (curve 1). Contrary to reports that UH_3 is formed by the U–H_2O reaction, products are identified as H_2 and UO_{2+x} with values of x varying from 0 to 0.2 (Haschke *et al.*, 2001b). Curve 2 (Table 29.7) describes the reaction rate for equilibrium vapor pressures, P_e, of water at temperatures up to 100°C (Haschke, 1998). The pressure exponent is 0.5 and E_a is 64 kJ mol^{-1}, implying that the rate is controlled by diffusion of oxygen through the product layer of constant average thickness (Haschke *et al.*, 2001b). The derived rate equation for 100–250°C given by curve 3 in Fig. 29.8 and Table 29.7 is derived using R at 100°C and 1.01 bar H_2O and on experimental data (curve 4) for the uranium-steam reaction at 200–500°C (Huddle, 1953). Those data describe a temperature-independent process that results in closure of the rate envelope near 500°C and absence of moisture-enhanced corrosion above that point.

Curves 5 and 6 in Fig. 29.8 and Table 29.7 describe the corrosion of uranium in moist air (Ritchie *et al.*, 1986; McGillivray *et al.*, 1994; Haschke, 1998). At 100°C, R for U at O_2 concentrations less than 20 ppm is proportional to $(P_{H_2O})^{0.5}$(Colmenares, 1984). This behavior is like that observed for Pu at all O_2 pressures (see Section 29.5.2(c)). If P_{O_2} exceeds 0.15 mbar (150 ppm), R exceeds the rate in dry air, but remains fixed as P_{H_2O} is varied from 3 to 130 mbar. Curve 5 describes the humidity-independent corrosion rate (E_a = 110 kJ mol^{-1}) in air at 40–100°C. At 100–400°C, the corrosion rate is dependent on H_2O pressure with values of n increasing linearly from 0 at 100°C to a maximum

of 1 at 250°C and decreasing linearly to 0.6 at 350°C (Haschke, 1998). Curve 6 defines R for a median H_2O pressure of 0.053 bar and an E_a equal to 56 kJ mol^{-1}. Rates, $R(P_{H_2O})_T$, at other values of T and P_{H_2O} are derived using $R(0.053)_T$ from curve 6 and the equation: $R(P_{H_2O})_T = R(0.053)_T((P_{H_2O})^n/0.053^n)$. Enhancement of the rate in moist air is attributed to the same water-catalyzed cycle as proposed for plutonium (see Section 29.5.2d) (Haschke *et al.*, 2001b). Attenuation of enhancement by O_2 suggests that the oxide surface is chemically altered by the formation of a higher oxide or other change that reduces the rate of O^{2-} formation or transport. Convergence of curves 5 and 1 at 35–40°C indicates that corrosion of U in air is insensitive to humidity at room temperature or that curve 1 describes the corrosion rate in air with significant residual moisture.

At temperatures above 500°C, the corrosion rate of U is humidity-independent and described by curve 7 (Hilliard, 1958; Haschke, 1998). The convergence of curves 1, 4, and 7 in Fig. 29.8 at this temperature suggests that measurements are consistent and implies a significant change in chemical behavior. Corrosion rates exceed that required to form a N_2-rich boundary layer with Pu (curve 8, Fig. 29.5) (Haschke and Martz, 1998b), are insensitive to an increase of 10^4 in the flow rate of air during reaction, and show that reaction slows slightly after O_2 is depleted from static air at 805°C (Hilliard, 1958). Unlike Pu, corrosion of U at high temperatures apparently proceeds with facile reaction of both O_2 and N_2. E_a (39 kJ mol^{-1}) is comparable to that (40 kJ mol^{-1}) observed for ignited Pu during free fall in air.

29.6.4 Thermal ignition and self-sustained oxidation of U

The ignition behavior of U is uncertain because of conflicting observations. Reported ignition temperatures of U in air (Fig. 29.6) indicate that the ignition behavior is similar to that of Pu. Ignition temperatures, T_i, extracted from an early review (Wilkinson, 1962) show that powder, chips, and foils with dimensions less than 1 mm ignite at 250–325°C and that pieces with larger dimensions ignite at 500–600°C. Behavior suggests that rapid reoxidation of a UO_2 layer at the oxide–metal interface to U_3O_8 might provide sufficient heat to raise the temperatures of powder and chips to the ignition point in a process similar to that described for Pu (see Section 29.5.2(e)).

Questions about the T_i data in Fig. 29.6 are raised by results of other studies (Hilliard, 1958). Exposure of burnished and preheated U samples to flowing air resulted in three types of behavior depending on initial temperature. At temperatures below 400°C, attainment of a stable temperature after 1–2 h is followed by a continuing reaction at a constant rate. At temperatures of 400–650°C, an initial thermal spike is followed by a period in which the sample temperature remained near the furnace temperature. Successive periods (0.3–0.5 h) of such slow reaction were followed by a thermal spike that exceeded 1000°C in some cases. This cyclic process continued until the metal was consumed.

At initial temperatures above 650°C, a sharp initial thermal spike was followed by a period (0.5–1 h) in which the sample temperature remained relatively constant at a value above the furnace temperature.

Thermal excursions attributed to ignition may correspond to spikes induced by periodic spallation of a thick oxide layer (Hilliard, 1958), not with onset of autothermic reaction. That possibility is supported by failure of samples at 1250°C to continue reacting in air after removal from the furnace (Hilliard, 1958). Corrosion rates derived for isothermal reactions during extended (>1 h) tests at 440 (365°C furnace) and 810°C (710°C furnace) are 0.006 and 0.05 g U cm^{-2} min^{-1}, respectively. The corresponding rates calculated for curves 1 and 7 (Table 29.7) are 0.0059 and 0.045 g U cm^{-2} min^{-1}. Observation of a stable rate over a long time period at 810°C is inconsistent with onset of autothermic behavior at 500–600°C. The autothermic behavior of U remains uncertain.

29.6.5 Reactions of U and UH_3 with water

A review and assessment of chemistry and reaction kinetics for reactions of U and UH_3 with water (Haschke, 1995) suggest that the solid products may be oxide hydrides ($UO_{1.5 \pm 0.3}H_{0.5 \pm 0.2}$), not mixtures of UO_2 and UH_3. The corrosion rate of U in distilled water at 25°C (0.5 μg U cm^{-2} min^{-1}, geometric area) is similar to that for Pu, but the U–H_2O rate in synthetic seawater is a factor of 20 slower than in distilled water. The reaction rate of UH_3 (2 μg U cm^{-2} min^{-1}, BET area) is modest for small samples, but violent exothermic reaction is reported for samples greater than 25 g (Newton *et al.*, 1949).

29.7 RADIOLYTIC REACTIONS

Radiolysis of organic and molecular compounds in close proximity to radioactive materials provides an important source of chemical reactants capable of altering properties and behavior of materials, especially during periods of extended storage. The extent of radiolysis is a function of specific alpha activity, which is negligible for ^{238}U and varies significantly for the common Pu isotopes (IAEA Report, 1998). Respective values for ^{238}Pu, ^{239}Pu, ^{240}Pu, ^{241}Pu, and ^{242}Pu are 600, 2, 8, 3700 (beta decay), and 0.1 GBq g^{-1}. The alpha activity of ^{241}Am formed by beta decay of ^{241}Pu is 120 GBq g^{-1}. The isotopic distribution of Pu varies markedly with the level of fuel burnup. An activity of 8×10^{-5} GBq g^{-1} for ^{235}U indicates that radiolytic processes are relatively insignificant for highly enriched uranium.

Formation of H_2, CH_4, and other gaseous products by alpha-induced radiolytic decomposition of hydrocarbons (–CH_2–) and other organic materials is especially important:

$$-CH_2- \ (s, l, g) + \alpha\text{-particle energy} \rightarrow C(s) + H_2(g).$$

Hydrocarbon oils polymerize and polyethylene plastics are embrittled by this reaction. Alpha radiolysis of oxygenated organic compounds also generates CO and CO_2 (Kazanjian, 1976). Radiolysis of polyvinyl chloride (PVC) and chlorinated solvents produces HCl. Rates progressively decrease over time from 'burnout' as a layer of carbon-rich residue forms adjacent to the Pu-containing source. Studies in which liquid and solid organic materials (oil, ethylene glycol, silicone rubber) were placed in contact with oxide-coated Pu show that H_2 is the primary (>99%) gaseous product and that gas generation rates are surprisingly similar for all organic materials in the tests (Haschke *et al*., 2001c). Respective rates after 0.01, 0.5, and 2.5 years are 4, 0.07, and 0.04 nmol H_2 cm^{-2} min^{-1} (geometric Pu area). Corresponding H_2-generation rates for plutonium oxide powders in contact with organic materials are expected to vary from 0.2 to 0.002 nmol H_2 cm^{-2} min^{-1} (BET area).

Formation of gaseous products is reported for tests in which cellulose, plastics, hydrocarbon oils, latex rubber, and chlorocarbon solvents were exposed to $^{238}PuO_2$ or $^{239}PuO_2$ in closed containers with air atmospheres (Kazanjian, 1976). Derived *G*-values for total gas generation vary from 0.4 to 3 molecules per 100 eV of absorbed energy. As shown by a linear time dependence of moles H_2 produced, rates of hydrogen production were essentially constant over 1-year test periods and show no evidence for decreases associated with burnout. O_2 was consumed at a constant rate over a period of 20–60 days, suggesting that observed rates of H_2 production during the initial period were reduced by formation of H_2O. These results and consistent evidence for water in gas analyses indicate that H_2 does not accumulate as predicted by *G*-values if O_2 is present, but that water is formed by surface-catalyzed combination of the elements. Continuing formation of CO_2 after depletion of O_2 suggests a radiolytic or catalytic reaction of H_2O with C-rich residues.

Radiolytic reactions of Pu also form highly reactive and corrosive products in other systems. In the absence of organic compounds, radiolysis of air in a confined volume produces mixtures containing up to 10% N_2O and NO_2 within 2–3 years (Haschke and Martz, 1998a). NO_2 is corrosive to steel at moisture levels above 3% relative humidity. Radiolysis of air-exposed aqueous solutions produces HNO_3 (Rai *et al*., 1980; Rai and Ryan, 1982). The pH of a solution containing about 1 mg $^{238}PuO_2$ per ml decreased from neutral to 1.5 within a 3.5-year period. N_2 atmospheres are not inert if aqueous solutions are present because HNO_3 is formed from oxygen produced by radiolysis of water. Radiation-promoted nitration of organic materials such as ion-exchange resins in nitric acid solution forms solids that may react violently when dry (Cleveland, 1979).

Mention of an important nonradiolytic process related to alpha decay of Pu isotopes is merited because of its apparent involvement in movement of submicrogram-size oxide particles. Observation indicates that spreading of radioactive contamination occurs spontaneously during operations with oxide. Movement of $^{238}PuO_2$ is noticeably more rapid than in similar operations with $^{239}PuO_2$. The unquantified process, which is attributed to air entrainment

of small particles by recoil energy from alpha decay, is apparently an important factor in transport of finely divided powders and spread of contamination over time.

29.8 HAZARD ASSESSMENT

29.8.1 Synergistic reactions

The chemistry of Pu metal and oxide, and to a lesser extent that of U, is unusually complex and reactivities of systems containing those materials may be dramatically altered by changes in surface chemistry. Slow processes that normally do not merit consideration may become important during an extended storage period. Trace amounts of hydrogen, water, and other gases are important constituents because of their chemical properties. For example, H_2 reacts with O_2 to form water and with Pu to form hydride. Both products catalyze specific reactions. In some cases, transport of oxide particles is a key step in radiolytic formation of H_2. Entrainment of submicrogram-size particles is promoted by alpha recoil. Synergistic convergence of several processes like these may produce unanticipated behavior.

Synergistic interaction is demonstrated by considering a hypothetical storage configuration in which oxide-coated Pu metal and a high-purity Ar atmosphere are sealed for an extended period in a steel container with an elastomeric *o*-ring closure. A potentially hazardous situation is created by occurrence of parallel and sequential reactions. In the absence of oxygen, the oxide layer is reduced to α-Pu_2O_3 over time. Small oxide particles entrained by alpha recoil are simultaneously dispersed throughout the container via thermal currents created by heat from radioactive decay. Hydrogen formed by radiolytic decomposition of elastomer by alpha particles from oxide particles deposited on the *o*-ring reacts with the sesquioxide-coated Pu to form a Pu_2O_3–PuH_x double layer. Catalytic initiation of self-sustained oxidation and nitriding (see Section 29.5.2(f)) is possible and likely upon exposure of the metal to air.

A significant constraint on assessment of hazards for Pu exists because all pathways that lead to potentially hazardous situations are not defined. In light of limited understanding of synergistic interactions, subsequent discussions of hazards cannot be considered exhaustive.

29.8.2 Potential hazards

(a) Formation of gases

Concern focuses on the formation of potentially explosive gases and generation of static pressures that might result in loss of containment and dispersal of Pu-containing particles. H_2 produced by chemical or radiolytic processes is

highly reactive and forms explosive mixtures with O_2. Gas pressures generated by chemical reaction, radiolysis, or thermal decomposition may rupture a container.

Contrary to widely held views that PuO_2 is inert and the ideal storage form for plutonium, observations (see Sections 29.3.2 and 29.4.2) show that dioxide tenaciously adsorbs water and reacts with H_2O to form PuO_{2+x} and H_2. If air or O_2 is sealed in the storage container with moisture-equilibrated oxide, the water-catalyzed PuO_2–O_2 reaction (Haschke *et al.*, 2000b) proceeds via a mechanism like that for water-catalyzed oxidation of Pu by O_2 (see Section 29.5.2d).

$$\begin{aligned}
&PuO_2(s) + x\ H_2O(ads) \rightarrow PuO_{2+x}(s) + 2x\ H(ads)\\
&x/2\ O_2\ (g) \leftrightarrow x\ O(ads)\\
&\underline{2x\ H(ads) + x\ O(ads) \rightarrow x\ H_2O(ads)}\\
&PuO_2(s) + x/2\ O_2(g) \rightarrow PuO_{2+x}(s)
\end{aligned}$$

Occurrence of this process in storage is shown by initial disappearance of O_2 from air-filled storage containers at the rate predicted for kinetic control by the first step of this cycle (Haschke *et al.*, 2001a). Calculations indicate that O_2 in a typical air-filled container is consumed after about 1.5 years. After O_2 is depleted, H_2O reacts via the initial step with association of H atoms as H_2.

The maximum H_2 pressure from chemical reaction of water in a closed, air-filled system is determined by several factors: amount of oxide, specific area of the oxide, initial concentration of adsorbed water, oxide mass, free volume of the container, and rate of the oxide–water reaction. These factors are included in a quantitative model for calculating the time dependence of pressure in a sealed oxide container (Haschke *et al.*, 2001a). Thermodynamic assessment indicates that reaction of water is not limited by attainment of the equilibrium H_2 pressure and that the oxide–water reaction proceeds to completion (Haschke and Allen, 2002).

An important consequence of the water-catalyzed cycle is the sequential nature of the catalytic cycle. Depletion of O_2 before onset of H_2 formation is observed for water-enhanced oxidation of Pu and U, implying that corrosion is controlled by the oxide surface. Therefore, formation of H_2–O_2 mixtures by chemical reaction is apparently precluded. That assessment is tempered by the requirement that formation of H_2 by radiolysis of H_2O or some other process is slow relative to the rate of O_2 consumption (Haschke *et al.*, 2001a). Although formation of H_2 by weapons-grade plutonium oxide appears sufficiently slow, the radiolysis rate must be considered in each case because rapid formation of H_2 may result in the formation of a transient explosive mixture.

As implied by preceding discussion, H_2 is produced by radiolysis of organic materials in close proximity to oxide or metal. The process is under kinetic control and is capable of generating high pressures. Formation of H_2 is limited only by the amount of organic material available, but its rate of formation is slowed by kinetic factors such as 'burnout' around the radiation source

(see Section 29.7) and by formation of H_2O in the presence of O_2. The rates at which H_2 and O_2 dissociatively adsorb and form H_2O on various surfaces are unknown, but may be important in determining the H_2 inventory and pressure.

H_2 is also generated by reaction of H_2O with metallic Pu and U. Measurements with Pu in moist air show that the pressure in a sealed container decreases as O_2 is consumed and then increases at essentially the same rate as H_2 is formed (Haschke *et al.*, 2001b). However, as discussed in Section 29.5.2d, hydrogen is a transient species in the presence of Pu and is expected to ultimately react with available metal to form PuH_x. Measurements show that the reaction proceeds as expected if H_2O is the only source of H_2 or if solid organic materials are radiolyzed. Hydride formation does not initiate immediately and the H_2 pressure may continue to increase over time if volatile organic liquids are present.

The course of the Pu–H_2O reaction in low-O_2 atmospheres is altered and the rate of H_2 generation is increased if small amounts of gaseous HCl are present (Haschke *et al.*, 1998b). $PuCl_3$ formed by rapid Pu–HCl reaction is deliquescent, forms a concentrated chloride solution on the metal surface, and apparently catalyzes the formation of PuOH plus H_2, as observed in aqueous chloride solution (see Section 29.5.2(g)). Chloride catalysis increases the H_2 formation rate of alloyed Pu by approximately 10^3 at room temperature.

Thermodynamic data derived for PuO_{2+x} suggest that the higher oxide is a thermally activated source of high-O_2 pressure (Haschke and Allen, 2002). Results indicate that $PuO_{2.2}$ is the equilibrium composition formed by calcination of oxalate, peroxide, nitrate, or other oxygenated solids at 400–450°C in air and that PuO_2 is stable above 650°C. Predictions are consistent with formation of $PuO_{2.3}$ during heating of $PuO_3 \cdot 0.7H_2O$ in vacuum at 200–250°C. Pressurization of storage containers may result from decomposition of PuO_{2+x} upon heating to 450–500°C (Bagnall and Laidler, 1964), as well as from generation of gases by pyrolysis of anion residues in low-fired solids (see Section 29.8.3(b)). Generation of O_2 pressures approaching 50 bar is possible if a typical sealed storage vessel containing low-fired (400–450°C) $PuO_{2.2}$ is heated above 650°C. Formation of O_2–H_2 mixtures is possible during heating if higher oxide was formed *in situ* by reaction of adsorbed H_2O.

Other possible methods of generating O_2 and other noncondensable gases exist if the storage container for low-fired oxide is involved in a fire. Pressurization may occur as gases are formed by thermal decomposition of residual oxygen-containing anions or anion fragments remaining in the oxide.

A minor contribution to the pressure is made by accumulation of helium produced by alpha decay in oxide. For short time periods (several hundred years) compared to the half-life of ^{239}Pu, the He production rate is approximately constant at 0.10 mmol He per kg $^{239}PuO_2$ per year. Although a comparable rate of 0.11 mmol He per kg ^{239}Pu per year exists for Pu, He is retained in the metal (Hecker and Martz, 2000) and is released only upon heating. Results

indicate that, except for a near surface layer from which alpha particles escaped, all He produced in bulk ^{239}Pu over a 40 year period remains in the metal.

Although generation of gas pressures during storage of UO_2 has not been of concern, questions are raised by the reported reaction of UO_2 with liquid water and solutions (Matzke and Turos, 1991). Additional investigation is needed to determine if uranium dioxide reacts with water vapor and adsorbed water, to define kinetic behavior over a broad range of conditions, and to assess potential consequences for handling and storage.

(b) Thermal hazards

In addition to the thermal hazard posed by reaction of hydrogen from radiolytic and chemical interactions, large amounts of heat are produced over short time periods by rapid, self-sustained corrosion of Pu metal. As described in Sections 29.5.2e and 29.5.2f, autothermic reactions are initiated in two ways: thermally and catalytically. Thermal sources may be external or exist within the chemical system. As discussed in Section 29.5.2e, Pu powder does not spontaneously ignite in air at room temperature, implying that spontaneous ignition of the metal at 25°C is driven by reaction of coexisting pyrophoric or catalytic materials. Formation of catalytic surface layers on Pu may result in spontaneous ignition upon exposure to air at room temperature. Self-sustained reaction during both thermal and catalytic processes is apparently contingent on attainment of a temperature required to maintain an α-Pu_2O_3 surface, but PuH_x is also necessary for catalyzed reaction and results in simultaneous reaction of both O_2 and N_2.

Highly reactive and pyrophoric compounds of plutonium are potential thermal sources for heating Pu above the 500°C ignition point. The α-Pu_2O_3 layer formed on Pu by autoreduction of the oxide surface is identified as the ignition source for Pu chips and fines (Martz *et al.*, 1994). PuH_x is considered pyrophoric because of its unique ability to accommodate product H_2 and consume N_2 (Haschke and Allen, 2001). In concert, these processes promote pyrophoric reaction by facilitating transport of O_2 to the hydride surface and preventing formation of a N_2/H_2 boundary layer at the hydride surface. The heat-generation rate of 10–15 kJ g^{-1} PuH_x per min for the hydride–air reaction is substantially larger than the 0.1–0.5 kJ g^{-1} Pu per min rate required for self-sustained reaction of massive metal in air because the hydride surface area is relatively high. Thermal calculations show that more than 30 mass% of a hypothetical mixture containing substoichiometric dioxide ($PuO_{1.98}$), 5% hydride, and 0.5% Pu powder must be present and react to adiabatically heat the co-existing metal (70 mass%) to 500°C (Haschke and Allen, 2001).

Catalyzed corrosion of Pu by H_2 is initiated by an α-Pu_2O_3 surface layer, as well as by a layer of PuH_x. As discussed in Section 29.5.2f, Pu coated with an α-Pu_2O_3–PuH_x double layer spontaneously reacts with O_2 and N_2 upon exposure

to air at room temperature. The catalytic double layer forms on the Pu surface via several pathways, including exposure of PuH_x-coated metal to air or O_2. Other known routes to the catalytically active surface include exposure of α-Pu_2O_3-coated Pu to a small amount of H_2 and formation of a PuOH precursor by immersion of the metal in water (Haschke and Allen, 2001). When altered by traces of gaseous HCl, the water vapor–metal reaction also produces a reactive PuOH surface (see Section 29.8.2a). Existence of additional routes to the catalytically active surface is likely. On the basis of rate equations and enthalpy data, rates of heat generation by self-sustained oxidation of static Pu in air, by the autocatalytic Pu–H_2 (1 bar H_2) reaction, and by the catalyzed Pu–air reaction are 0.5, 1.1, and 2.7 kJ cm^{-2} min^{-1}, respectively. If the surface of a 2 kg Pu casting (5 cm diameter, 1.3 cm high) is fully active and all heat is retained in the metal, a 1.0 kJ cm^{-2} min^{-1} generation rate produces a temperature increase of 490° per min.

Secondary consequences of thermal excursions of internal or external origin are also of concern because temperatures frequently exceed the 640°C melting point of Pu. If the metal is in a steel container, rapid corrosion of the vessel by molten Pu (see Section 29.5.3) may result in catastrophic release to the environment (Haschke and Martz, 1998a). A substantial increase in the surface area of the metal is possible upon release and may cause a noticeable increase in the corrosion rate.

As discussed in Section 29.6.2, the ignition characteristics of U are uncertain. Behavior seems most consistent with rate control by a protective UO_2 product layer that is not capable of forming a catalytic oxide like α-Pu_2O_3. If sharp thermal spikes are caused by periodic spallation of the uranium oxide, onset of self-sustained reaction of massive metal is unlikely. However, exposure of UH_3 powder to air is likely to result in pyrophoric ignition and a large thermal excursion.

(c) Release and dispersal of nuclear material

For humans, the primary health hazard of plutonium is radiation exposure from small Pu-containing particles retained in the respiratory system (Voelz, 2000). Airborne particles with aerodynamic diameters, D_A, less than 10 μm are deposited in significant quantities in the lungs (Luna *et al.*, 1971). D_A is the diameter of a unit-density (1 g cm^{-3}) sphere with the same terminal velocity in air as a particle of arbitrary size, shape, and density. Because effects of shape and air resistance are small, $D_A \sim (\rho_p)^{0.5} D_G$, where D_G is the geometric diameter of a particle with density ρ_p (Mishima and Pinkston, 1994). The density of PuO_2 is 11.46 g cm^{-3} and the combined mass of oxide particles with geometric diameters less than 3 μm constitutes the respirable release fraction (RRF) of an oxide powder. The aerosol release fraction (ARF) is the mass fraction of powder comprised of particles that are likely to become airborne. Because aerodynamic diameters of particles in ARF are less than 30 μm, PuO_2 particles

in this mass fraction typically have geometric diameters less than 10 μm, but entrainment studies during metal oxidation suggest that D_G may extend to 20 μm (Stewart, 1963).

The source term (ST) for the airborne release of respirable particles is usually defined by the source strength of aerosolizable particles in units of grams (Luna *et al.*, 1971). ST is a function of the quantity, Q, of material at risk, ARF, and RF, the respirable fraction of ARF:

$$\mathrm{ST} = Q \times \mathrm{ARF} \times \mathrm{RF} = Q \times \mathrm{RRF}.$$

Note that RF is a fraction of ARF and that RRF is a fraction of Q because these quantities are easily confused.

The risk of releasing and dispersing respirable particles is significantly enhanced by corrosion reactions that simultaneously transform metal into powder and promote loss of containment (Haschke *et al.*, 1998a). Reactions of oxide do not detectably alter the source term, but generate gases that pressurize the container. Consequences of solid expansion during metal corrosion are surprising because solid products do not move to occupy free volume within the container. After the solid product expands to the container wall, further reaction compresses the product, prevents movement that would relieve radial pressure, and leads to rupture of the container (Haschke and Martz, 1998a).

Assessment of the dispersal hazard is contingent on availability of source-term data, and in some cases, on the corrosion rate, R, of metal at conditions of interest (Haschke and Martz, 1998b). If corrosion continues during the dispersal incident, the material at risk increases as metal is progressively transformed into product. The dependence of ST on R, surface area of metal involved, and time period of the incident are incorporated into the above source-term equation by replacing Q with the product of R, surface area, and time. Values of R are defined for Pu and U in Sections 29.5 and 29.6. Alternatively, the measured airborne release rate, which inherently equals $R \times$ ARF, may be included along with SA and time to define the source term for a dynamic event.

Cumulative mass fractions of particles with geometric sizes less than 3, 10, and 30 μm for oxides from corrosion of Pu and calcination of precipitates are listed in Table 29.8 (Pritchard *et al.*, 1963; Stewart, 1963; Stakebake and Robinson, 1977; Giacomini, 1985; Ricketts, 1995; Machuron-Mandard and Madic, 1996; Haschke *et al.*, 1998a; Martz and Haschke, 1998c; Szempruch, 2001). Respirable release fractions are indicated by cumulative fractions for 3 μm size particles. Because RRF varies by as much as 10^5 depending on preparative method, reliable assessment of the dispersal hazard is unlikely unless the oxide source is considered. RRF for oxide from corrosion of metal is decreased by increasing temperature and humidity or by the presence of hydride catalyst, but is increased by alloying (Stewart, 1963; Haschke *et al.*, 1998a). These correlations suggest that the size distribution of a spalled corrosion product is determined by the relative rates of corrosion and crack formation in the density-stressed product layer on the metal surface (Haschke *et al.*, 1998a). Nucleation

and propagation of cracks appear rather insensitive to parameters that increase the corrosion rate; slow reaction at room temperature promotes formation of small particles by allowing time for extensive crack formation and spallation before a thick product layer is formed. Size distributions of products formed at temperatures above the 500°C ignition point of Pu and by rapid catalyzed reactions are bimodal, suggesting that particles form by two processes (Haschke, 1992b). A second distribution of small fragments is apparently produced during spallation of large particles. A bimodal distribution also results from formation of small oxide particles during oxidation of PuH_x.

The RRF for ignited Pu droplets (Table 29.8) is approximately 0.7 for all droplets with diameters greater than 100 μm if the free-fall period is sufficient for the temperature to exceed the boiling point of Pu (Martz and Haschke, 1998). Electron micrographs of oxide formed by oxidation of the vapor show a fume aerosol containing web-like chains of particles with diameters of 5–100 nm (Raabe *et al.*, 1978). *In vitro* dissolution rates of the fume aerosol are higher than normally observed for PuO_2. Data from tests to simulate dispersal of Pu by accidental detonation of high explosive show that particles collected in downwind air samplers were primarily spheres or spheroids with average densities of ~2.8–4.9 g cm^{-3} (Friend and Thomas, 1965), suggesting that metal particles

were heated above the melting point during detonation and that hollow oxide spherules were formed by venting of metal vapor (see Section 29.5.2(e)). Size distribution data for collected particles show that RRF is approximately 0.2 and that the mass fraction of particles with aerodynamic diameters below 0.1 μm (geometric diameter <0.03 μm) is less than 0.005 (Friend and Thomas, 1965; Luna *et al*., 1971; Stephens, 1995). Trimodal distributions correlate with three size-determining processes: fragmentation of metal, surface oxidation of fragments, and oxidation of Pu vapor. Average spherule densities of 3–5 g cm^{-3} correspond to release of 55–75% of the mass as fume aerosol and suggest that the aerosol release fraction may far exceed the 0.5% value derived from collection data.

RRF values for PuO_2 prepared by calcination of precipitates such as oxalate and peroxide in Table 29.8 vary by a factor of 10^2, even for the same chemical process. Although differences are inherently introduced by different methods of size measurement, that possibility is unlikely to account for these observations and suggests that specific preparative procedures are important in determining the source term of the oxide product. Adoption of a single conservative value of RRF for all situations seems inappropriate. Characterization of the specific material at risk appears necessary for a meaningful assessment of the dispersal hazard.

Uranium oxide particles produced by oxidation of U in a fuel fire are significantly larger than those from oxidation of Pu under similar conditions (Stewart, 1961; Haschke, 1998). Size data are described by a bimodal distribution and estimated cumulative mass fractions with dimensions less than 3, 10, and 30 μm are 1×10^{-4}, 5×10^{-4}, and 5×10^{-3}, respectively.

(d) Uncertainty of chemical properties

A serious hazard associated with the variety of Pu-containing materials is uncertainty about chemical composition and reactivity. Certain process residues such as chloride-rich pyrochemical salts have been characterized (Haschke and Phillips, 2000) and their chemical reactivity has been evaluated (Haschke *et al*., 2000c). However, numerous potential vulnerabilities cited in an assessment of weapons-related facilities (DOE Report, 1994) derive from lack of knowledge about properties of residues containing several metric tons of Pu. Vulnerabilities are likely to exist worldwide for residues from both military and civilian operations.

(e) Nuclear criticality

Radiation levels produced by fission of ^{239}Pu or ^{235}U in a nuclear chain reaction present a severe potential hazard during operations involving these isotopes. Criticality is controlled by complex relationships that depend on the amount, density, and geometry of fissionable isotopes, as well as on moderation and

reflection of neutrons and interactions with other neutron sources. Criticality assessment is beyond the scope of this review and must be made by expert evaluation for each specific handling or storage configuration.

29.8.3 Case studies

(a) Incidents with metal

Several incidents involving spontaneous ignition and reaction of kilogram-size Pu metal castings have resulted in contamination of workers and facilities by nuclear materials (Haschke and Martz, 1998a, 2000). In at least two cases, storage of metal in unsealed storage containers and sealed plastic contamination barriers resulted in rupture of the container by expansion of the solid and release of material to the environment. Assessment of the previously mentioned incident (see Section 29.1) (Haschke *et al*., 2000a) is especially useful because the package involved in the incident appeared stable over an 11-year storage period. The package consisted of an inner cylindrical steel container with 2.5 kg of rod-shaped Pu castings and welded closures at both ends, two sealed plastic contamination barriers, and an outer steel can with a slip-lid closure covered by plastic tape. A worker became highly contaminated with Pu-containing particles during routine handling of the package.

Inspection of the package in a nitrogen-rich gloved box atmosphere routinely used for handling Pu metal showed that the outer can contained a fine oxide-like powder, that the plastic barriers had embrittled and failed surrounding the lower weld, and that the end of the inner can had been torn open by formation and expansion of a solid reaction product around the Pu castings. Product particles had apparently been released as air was expelled by flexing and volume change as the can was handled. During a 3 h period after exposure of the inner container to the gloved box atmosphere, a rapid reaction caused significant bulging and heating of the inner container. Reaction ceased after the container was transferred to an argon-filled gloved box.

Assessment suggests the occurrence of two important processes: (1) autoreduction of oxide on the metal surface to α-Pu_2O_3 over a period of years and (2) simultaneous transport and deposition of oxide particles on the plastic bagging, resulting in radiolytic production of H_2 and embrittlement of the plastic. Movement of oxide from the inner container, through the constriction of a faulty weld, and onto the plastic barrier is attributed to recoil entrainment of small particles and pumping of gas by action of atmospheric pressure changes on the plastic bagging. Reaction of hydrogen with the activated metal surface produced a Pu_2O_3–PuH_x double layer and resulted in catalyzed reaction of O_2 and N_2 after the plastic failed and air entered the package. This reaction led to failure of an inner metal container. The rate of rapid corrosion observed after the inner container was placed in a reduced-oxygen gloved box corresponds to that for indiscriminate reaction of Pu with air (Haschke *et al*., 1998a).

Formation of the catalytic double layer by different pathways is suggested by observations with other massive samples (Martz *et al.*, 1994). Spontaneous ignition of a massive Pu casting in air after exposure to hydrocarbon oil in a closed container is consistent with reaction of radiolytic H_2 to form a PuH_x surface layer followed by catalyzed reaction upon exposure to air. Similar reaction of Pu after opening of a container that had been immersed in water during criticality measurements is consistent with formation of PuOH on the metal surface and ignition in air (see Section 29.5.2(f)). Water apparently entered the steel container through a faulty seal.

Involvement of catalytic surfaces is also suggested by exothermic reaction of a Ga alloy casting during annealing in a N_2 atmosphere at temperatures in the δ-phase stability range (Haschke, 1986). As the alloy was heated during the initial processing operation in a newly constructed annealing furnace, the temperature greatly exceeded the programmed value and continued to rise after the furnace had been shut down. Exothermic reaction ceased after the casting was consumed, but resumed when the furnace was opened to air. The initial exothermic reaction is attributed to PuH_x-catalyzed nitriding. Surface hydride was apparently formed by high-temperature reaction of water driven from a furnace hearth plate of asbestos fiberboard containing hydrated aluminosilicates. The second exotherm resulted from oxidation of the nitride. In addition to showing that hydrogen originates from unexpected sources, these observations demonstrated that N_2 is not an inert gas for operations with Pu metal at elevated temperatures. Inertness is unlikely even at room temperature where nitriding of PuH_x-coated metal is documented (Haschke *et al.*, 2001c).

(b) Incidents with oxide

The hazard associated with organic material in contact with oxide is shown by violent rupture of a sealed container with only 225 g of PuO_2 after less than 2 years in storage (Haschke and Martz, 1998a). The oxide compact was contaminated with a die lubricant containing aluminum stearate and dodecane. When the package failed, it was propelled out of a criticality well and onto the floor of the storage vault, resulting in extensive contamination of the facility. Examination of a companion container showed that high H_2 pressures were generated by radiolysis of the organic material.

In another incident (Haschke and Martz, 1998a), a storage container of oxide with a relatively high ^{238}Pu content ruptured during transport in an insulated shipping container certified for the existing heat load. The multi-kilogram charge had been prepared by calcination of plutonium nitrate. Alpha contamination was discovered in the shipping container during unpacking. Inspection showed that an inner slip-lid container, a sealed plastic contamination barrier, and an outer rim-seal can had all failed due to internal pressure. Pressurization was attributed to thermal desorption of water and other gases from the oxide, but a high adsorbate concentration would have been necessary. As outlined in

Section 29.8.2a, formation of O_2 by thermal decomposition of PuO_{2+x} and of anion residues may also have contributed to pressurization.

The possibility for PuO_{2+x} involvement in pressurization is supported by analytical data for the Pu and O content of oxides prepared by calcination of oxalate, peroxide, and nitrate precipitates using production procedures (Moseley and Wing, 1965). Materials were heated to the indicated temperatures, but heating periods are not specified. Results (Table 29.9) derived from reported analytical data show that O/Pu ratios in the products generally decrease with increasing temperature and that mass fractions of Pu plus O approach 1.00, suggesting that other constituents remain after calcination at low temperatures. Oxide compositions in excess of the PuO_2 are consistently indicated and are likely to be present unless oxides are thoroughly calcined at high temperature.

(c) Incidents with residues

Although photographs of numerous corroded and failed containers of Pu metals and compounds are presented in a U.S. DOE vulnerability study (DOE Report, 1994), information and documentation of the failures are unavailable. The difficulty associated with residues is demonstrated by severe bulging of rim-seal cans containing reacted ash, a residue produced by firing hydroxide precipitates of Pu and other metals with filter paper and other organic materials at 400–450°C (Van Konynenburg *et al.*, 1996). Residues prepared over a period of 20 years before repackaging were removed from storage in unsealed containers with plastic contamination barriers, homogenized by blending in air, and sealed in food-pack cans. Bulging of cans was observed after 13 months and subsequent analysis of several containers showed that pressure increases up to 5 bar resulted from two distinctly different processes (Haschke and Martz,

Table 29.9 *Analytical data for oxides prepared by calcination of plutonium-containing precipitates* (*Moseley and Wing*, 1965).[a,b]

Initial precipitate	*Calcination temperature* (°C)	(g *Pu* + g *O*)/g	*O/Pu ratio*
Pu(III) oxalate	400	0.893	3.21
	600	0.983	2.48
	800	0.991	2.06
	1000	1.000	2.09
Pu peroxide	400	0.961	2.33
	600	0.983	2.17
	1000	1.000	2.04
Pu nitrate	600	0.997	2.06
	800	0.974	2.18
	1000	0.999	2.14

[a] Calcination times are not specified and may vary.
[b] Pu contents were determined by Ce titration and emission spectrography; O contents were determined by vacuum fusion with carbon.

1998a). For cases in which large amounts of free C was apparently present, N_2 appeared stable, O_2 was depleted, H_2 and CO_2 were formed, and a pH of 4 was measured after the solid residue was placed in water. In other cases, N_2 plus O_2 were formed and the observed pH was 10. A qualitative explanation for some observations is proposed (Van Konynenburg *et al.*, 1996), but proposed processes do not account for production of N_2 and O_2. Formation of N_2 parallels that observed with air-exposed oxide in radiolysis studies (Livingston, 1999) and suggests involvement of radiolytic nitrogen oxides that form on the oxide surface during exposure to air (Stakebake *et al.*, 1970).

Large variations in the chemistry of a relatively well-characterized residue such as reacted ash are surprising. Confidence in estimation of the potential hazard must be tempered by recognition of uncertainty and lack of knowledge. Assessment of hazards for poorly characterized plutonium-bearing residues is especially difficult.

29.9 MITIGATION OF HAZARDS

29.9.1 Atmospheres for safe handling of plutonium

Control of oxygen and moisture levels in the gloved box atmosphere is essential for preventing excessive corrosion of Pu metal and adsorption of water on the oxide. As shown by retention of H_2O formed by combination of H_2 and O_2 on PuO_2 (Haschke *et al.*, 2001b), water tenaciously adsorbs on oxide and oxide-coated metal. Use of an argon atmosphere is desirable because radiolytic formation of nitrogen oxides and nitrates is curtailed, but maintenance of low ($<$10 ppm) O_2, H_2O, and N_2 concentrations is challenging. Use of nitrogen atmospheres is less desirable because N_2 is not radiolytically (see Section 29.7) or chemically (see Sections 29.4.1(e) and 29.8.3(a)) inert at room temperature.

A perplexing observation reported by early workers is that corrosion of Pu by moisture is as much as 60 times more rapid in argon or helium than in air at the same humidity level (Waber, 1980). Suggestions that this behavior parallels that of U and that H_2O corrosion is suppressed by O_2 are not supported by results for the Pu–H_2O reaction (Haschke *et al.*, 1996). Another possibility is suggested by enhancement of Pu corrosion by traces of HCl in an Ar atmosphere (Haschke *et al.*, 1998b). At 25°C, the estimated corrosion rate of alloyed Pu in saturated H_2O is 0.2 ng Pu cm^{-2} min^{-1}; the derived rate with ppm levels of HCl and P_{H_2O} less than 0.1 mbar is 0.5 μg Pu cm^{-2} min^{-1} (Haschke *et al.*, 2001c). The likely source of HCl is radiolysis of polymerized residues formed during prolonged use of chlorinated organic solvents in the gloved box. Enhanced corrosion in He or Ar atmospheres during early studies may have resulted from a similar synergistic interaction.

Dry air is suitable for handling plutonium metal and oxide if adequate controls are exercised. Metal powder and chips do not spontaneously ignite in

air at room temperature (see Section 29.5.2e) and corrosion of Pu is suppressed by formation of a protective PuO_2 layer, but ignition is likely if reactive and catalytic compounds such as PuH_x and Pu_2O_3 are present. Effects of water concentration on the corrosion rate of unalloyed Pu are evident at 1 ppm H_2O and maintenance of 0.5 ppm is apparently necessary to prevent moisture enhancement (Haschke *et al.*, 1996). The water-catalyzed cycle for the Pu–O_2 reaction (see Section 29.5.2d) is almost insidious. H_2O is not consumed during corrosion as long as O_2 is present, but remains tenaciously adsorbed and accumulates on the oxide surface over time at low equilibrium pressure. The surface of freshly calcined PuO_2 has a stronger affinity for water than many commonly used desiccants (molecular sieves, $CaSO_4$, and $CaCl_2$) and will extract water from them.

Use of dry N_2-enriched atmospheres containing less than 3–5% O_2 is advantageous because pyrophoric materials such as PuH_x do not spontaneously ignite at this condition (Haschke and Allen, 2001). Experiments show that preheated (>500°C) Pu specimens rapidly cool instead of oxidizing when exposed to N_2–O_2 mixtures with 7–9% O_2, but burn in a self-sustaining reaction when exposed to mixtures containing 10% or more O_2 (Musgrave, 1971). Predictions based on corrosion rates show that thermal ignition of Pu is prevented by maintaining the O_2 percentage below 9.6% and that pyrophoric reactions of PuH_x and PuH_x-coated Pu are prevented by maintaining the O_2 percentage below 4.2% (Haschke and Allen, 2001). Results are consistent with observations indicating that the threshold O_2 pressures for self-sustained reactions of Pu and PuH_x are 90 and 40 mbar, respectively.

29.9.2 Conditions for safe storage of metals and oxides

(a) Packaging and storage of plutonium

General requirements for storage of plutonium metals and oxides are outlined in safety guidelines (IAEA Report, 1998) and in a recent review (Haschke and Martz, 1998a). Specific recommendations for storage periods up to 50 years are presented in a U.S. DOE standard (DOE Standard, 2000a). In addition to outlining criteria for design, construction, and testing of storage containers, the DOE publication includes recommendations for material stabilization, packaging, quality assurance, documentation, and surveillance. The standard applies to Pu-containing metals and oxides containing at least 30 mass% Pu plus U and unirradiated MOX fuel, but not to residues, wastes, spent nuclear fuels, radiation sources, or solutions.

Packaging recommendations in the DOE standard include double confinement of materials in nested cylindrical containers constructed of a durable, corrosion-resistant metal such as 300 series stainless steel (Fig. 29.9) and sealed by welding (DOE Standard, 2000a). An unsealed convenience can be used to facilitate loading without contamination of the inner container or the weld

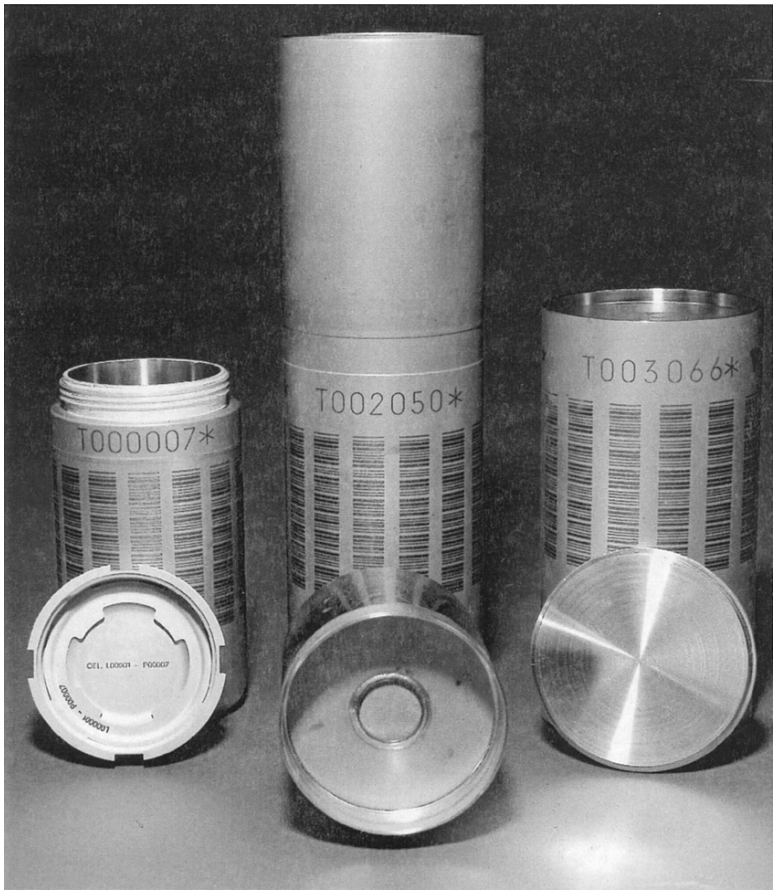

Fig. 29.9 *Plutonium storage containers fabricated in accordance with DOE Standard* 3013. *Convenience can* (*left*), *inner welded can* (*center*), *and outer welded can* (*right*) *are shown.*

zone. The inner container is designed to deform if the internal pressure reaches 8 bar; the minimum design pressure of the outer container is 50 bar. Welds are certified to have leak rates less than 10^{-7} std cm^3 s^{-1} using standard leak-test procedures. Rigorous exclusion of organic materials such as elastomeric gaskets, organic coatings, and plastic contamination barriers from the storage package is essential to prevent formation of radiolytic gases during storage.

Recommendations for stabilization of metals are simple compared to those for oxides (DOE Standard, 2000a). Metal pieces weighing more than 50 g are considered suitable for storage because ignition at 150–200°C is unlikely (see Section 29.5.2(e)). Metal surfaces should be visibly free of non-adhering corrosion products (including oxide) and organic materials. Stabilization of oxides is

accomplished by calcination at 950°C in an oxidizing atmosphere such as air for a minimum of 2 h or until the loss-on-ignition (LOI) criterion or other suitable method indicates that residual moisture level is sufficiently low. LOI is a gravimetric analysis that measures the loss of volatile species from a calcined oxide sample during heating at 1000°C for 1 h. The acceptance criterion for oxide at the time of packaging is a maximum LOI of 0.5 mass%, a level that limits the H_2 pressure from the oxide–water reaction (see Sections 29.3.2 and 29.4.2b) to a value below the design pressure of the package. In addition to removing moisture, calcination at 950°C consistently reduces the specific area of PuO_2 to below 5 $m^2\ g^{-1}$ (Haschke and Ricketts, 1995; Machuron-Mandard and Madic 1996), an area that prevents re-adsorption of H_2O in excess of the 0.5 mass% criterion during exposure to air (Haschke and Ricketts, 1997).

The combined mass of Pu and other fissile materials such as ^{235}U stored as metal or oxide in each package is limited to 4.40 kg (DOE Standard, 2000a). The container may be filled with any gas (air, argon, or a He-rich mixture for leak testing) that does not react adversely with the container or contained materials. Surveillance is based on initial and periodic measurements of package properties. Onset of pressurization may be detected by radiographic indication of a deformed inner container. Recommended non-destructive surveillance activities also include periodic verification of package mass and leak rate.

(b) Packaging and storage of uranium

The standard for storage of ^{233}U (DOE Standard, 2000b) is similar to that for plutonium, but is much less restrictive.

29.10 DISPOSITION OPTIONS

29.10.1 Issues

Reduction in nuclear arsenals and dismantlement of nuclear weapons creates the problem of what to do with excess plutonium and enriched uranium. In addition to issues of environmental aspects, safety, and health, the proliferation risk posed by surplus nuclear material is of concern. An ideal disposition method would eliminate the possibility of reusing such materials in weapons applications. Because total elimination is unrealistic, the U.S. National Academy of Sciences has proposed the 'spent-fuel standard' as a concept for minimizing accessibility to plutonium and uranium (National Academy of Sciences Report, 1994). The concept, which has been accepted by the U.S., Russia, and seven other stakeholder nations, defines 'minimized accessibility' as equivalent to that of Pu in spent reactor fuel. In cooperative agreements endorsed by other countries, the U.S. and Russia will investigate and demonstrate disposition technologies for use in subsequent disposal of 68 metric tons of weapons-grade Pu.

Studies to define the best disposal options for excess fissile materials are concentrated in three main areas:

- immobilization with high-level waste (HLW) (treating plutonium as waste);
- conversion to a mixed oxide (MOX) for burning in existing reactors;
- use in fueling fast-neutron reactors.

Russia, for example, is focusing on disposal of surplus Pu by burning MOX fuel in reactors. The hybrid United States strategy attempts to insure against possible difficulties by including both irradiation of MOX and immobilization (DOE, 1996, 1997a,b). The approach allows for immobilization of some relatively impure Pu in glass or ceramic material and disposal in a geologic repository, as well as for burning MOX in existing commercial reactors with subsequent geologic disposal as spent fuel. Low-grade Pu-containing materials may be disposed of as nuclear waste. As implied in following sections, implementation of disposal options will require extensive processing capability to separate and prepare materials for disposal. Construction of dedicated facilities to accomplish these tasks will probably be necessary.

29.10.2 Disposition of metals and oxides

(a) Disposition of plutonium metal

Implementation of disposal options requires that Pu metal be converted to oxide. Consideration has been given to pyrochemical processes in which preparation of plutonium hydride is followed by direct conversion to the oxide or by a two-step method involving formation of nitride and subsequent oxidation to PuO_2. In an alternative method, oxide can be produced directly by somewhat slower oxidation of metal, but hazards associated with handling hydrogen and plutonium hydride are avoided. An intriguing one-step process for separation and oxidation employs formation of the α-Pu_2O_3–PuH_x double layer on the metal and controlled oxidation with O_2 (see Section 29.5.2f). An advanced recovery and integrated extraction system (ARIES) is being developed to demonstrate requisite process technologies (Rofer *et al.*, 2000).

(b) Disposition as plutonium as MOX fuel

One disposal pathway for plutonium is irradiation of MOX fuel ($\sim$5% PuO_2) in commercial light-water reactors. The fissile content is similar to that of enriched uranium fuels in which the Pu content reaches about 1% during normal operation. Civilian plutonium is currently being recycled in European light-water reactors in this way, and MOX usage is expected to expand to Japan and other countries. Burning military plutonium as MOX fuel minimizes accessibility in two important ways: (1) formation of the Pu-containing matrix of highly

radioactive fission products and (2) alteration of the isotopic distribution from weapons-grade to reactor-grade plutonium.

Opponents of using military Pu in MOX fuels contend that substantial proliferation risk exists because the plutonium is considered 'weapons-usable' after irradiation. As noted in Section 29.2.1, weapons-grade plutonium typically contains 93–94% of the fissile ^{239}Pu isotope, whereas reactor-grade plutonium usually contains less than 70% ^{239}Pu. Irradiation of 'weapons-grade' plutonium as MOX fuel increases the difficulty of using high-burnup material in weapons applications by increasing the fraction of non-fissile Pu isotopes. Burning weapons Pu as MOX has limited effect on the proliferation risk because extensive spent-fuel sources of Pu exist worldwide.

(c) Plutonium immobilization

Immobilization of plutonium oxide in a suitable glass or ceramic material and placement in a geological repository achieves the spent-fuel standard by encapsulating plutonium in a waste form with a radiological barrier to reduce accessibility. The radiological barrier can be either internal or external to the plutonium packages. 'Homogeneous' and 'can-in-can' (CIC) are two types of immobilization packaging concepts that have been evaluated (Gray and Gould, 1997). In both concepts the fission products in the canister generate a radiation barrier of at least 100*R* per hour at a distance of 1 m from the package over 30 years and would mimic the characteristics of spent fuel.

The homogeneous package is formed by incorporating HLW or ^{137}Cs as an internal radiation barrier along with Pu in a glass or ceramic. In a batch process, plutonium oxide is melted directly with fission products such as ^{137}Cs or HLW to form a single highly radioactive glass product that is placed in a large stainless steel canister. This type of package may also be prepared in a two-stage process that first forms a Pu-containing glass. In the second step, glass and fission products are heated and the molten mixture is poured into the storage canister.

The CIC package has a radiation barrier that is external to the plutonium-bearing material (Gray and Gould, 1997). Small cans of Pu-containing glass or ceramic matrix are placed in a rack within a large (0.6 m in diameter, 3 m high) stainless steel canister that is then filled with HLW glass as an external radiation barrier. Although the homogeneous concept has a slight advantage from a non-proliferation standpoint because of the intimate mixing of the plutonium with fission products, the CIC option is preferred over the homogeneous designs from an operational perspective because of higher technical viability and ease of implementation. Both concepts meet the 'spent fuel' criterion, but extensive fabrication facilities and potentially hazardous process operations are required to produce a form that is inherently obtained by burning MOX fuel.

(d) Immobilization of plutonium by vitrification

Vitrification of HLW and placement in a packaging configuration is a disposal option that has been extensively studied and evaluated for 30 years (McKibbon and Wicks, 1995). Early studies show that plutonium can be safely incorporated into a high-level plutonium borosilicate glass at concentrations up to at least 4–5 wt% (Matzke and van Geel, 1995). Another candidate matrix is an alkali–tin–silicate (ATS) glass for incorporating ^{137}Cs as an internal radiation barrier. However, work on this glass has essentially stopped because of interest in the CIC option.

The glass proposed for the CIC option is similar to commercial Löffler optical glasses that contain up to 55 wt% rare-earth oxide. This glass is a single-phase lanthanide borosilicate (LaBS) formulated to accommodate up to 16 wt% actinide (Gould *et al.*, 1988). Highly volatile cesium cannot be incorporated as an internal radiation barrier because of the high melting temperature (1500°C) of these glasses (Science and Technology Review, 1997). Leaching tests show that LaBS is more durable than typical borosilicate glass and has outstanding chemical resistance. Excellent performance of glass systems and general improvement with time were observed in laboratory tests and actual field experiments in Sweden, Belgium, England, and the U.S. (Wicks, 1999).

(e) Immobilization of plutonium by ceramification

Ceramic waste forms have been considered for use in immobilizing HLW since the late 1970s. The most advanced ceramic formulation to date is a synthetic rock (Synroc) developed by the Australian Nuclear Science and Technology Organization (ANSTO) in 1978 (Jostons, 1994). A demonstration plant completed in 1987 operated at a commercial scale of approximately 10 kg of Synroc per hour. The proposed plutonium immobilization ceramic form is Synroc-F, a pyrochlore-rich ceramic that also contains zirconolite, brannerite, and rutile as secondary and tertiary phases (Gould *et al.*, 1988). This titanate ceramic was chosen for Pu immobilization to accommodate high loadings of plutonium and uranium, as well as the neutron absorbers gadolinium and hafnium that are added to ensure criticality control in the repository. Plutonium and uranium are interchangeable in pyrochlore with nominal actinide loadings of 10 wt% Pu and 20 wt% U. The preferred titanate-based ceramic can be formulated as $ABTi_2O_7$ where Ca and half of the Gd are in the A-position, and Pu, U, Hf, and the remainder of the Gd occupies the B-position. Calcium and titanium oxide are the mineral formers. Natural pyrochlore is calcium zirconate titanate ($CaZrTi_2O_7$), but the pyrochlore selected for immobilizing Pu has the chemical formula: $(Ca_{0.89}Gd_{0.11})(Hf_{0.23}U_{0.44}Pu_{0.22}Gd_{0.11})Ti_2O_7$. The molar ratio of neutron poison to Pu is 1:1; the molar ratio of U to Pu is 2:1 (Rankin and Gould, 1999).

Assessment of current information indicates that both ceramic and glass are acceptable forms for Pu immobilization. Ceramic technology is recommended for the CIC packaging option because of superior proliferation resistance, repository performance and acceptability, potential worker dose, and cost effectiveness (Cohran *et al.*, 1997; Macfarlane, 1998).

29.10.3 Interim storage

At the present time, the path forward for disposition of weapons plutonium is uncertain. In some cases, the method of disposition has not been conclusively determined and/or requisite processing facilities do not exist. Placing these materials in a final disposition condition (either by immobilization or burning as MOX fuel) will most likely take longer than weapons dismantlement. Therefore, safe interim storage of excess plutonium must be considered for both short and extended periods.

Likewise, interim storage of highly enriched uranium and separated reactor-grade plutonium oxide for use in MOX fuel fabrication will be necessary. It is hoped that use of the fundamental and applied information presented in this chapter will facilitate safe handling, storage, and disposition of these nuclear materials.

CHAPTER THIRTY

TRACE ANALYSIS OF ACTINIDES IN GEOLOGICAL, ENVIRONMENTAL, AND BIOLOGICAL MATRICES

Stephen F. Wolf

30.1 INTRODUCTION

Actinide elements are ubiquitous in nature. Uranium and thorium are present in the Earth's crust with average concentrations of 1–10 μg g^{-1}, making them more abundant than Ag, Sb, Cd, or Hg. While U and Th can even be found as major or minor mineral constituents in a variety of geochemical environments, typically they are highly dispersed and present only at trace or ultra-trace concentrations in most natural materials. Because ^{238}U, ^{235}U, and ^{232}Th are the parents of the three naturally occurring non-extinct radioactive decay chains, they are always accompanied by lower concentrations of their radioactive progeny, many of which are also actinides (Table 30.1). The chemical behavior of ^{238}U, ^{235}U, ^{232}Th, and their progeny have been studied for years because accurate determination of their relative abundances can provide geochronological information on a variety of geological/environmental processes. Careful analyses have revealed that trace amounts of the transuranic actinides ^{237}Np and ^{239}Pu occur naturally and are present in U ores with mass ratios of

Table 30.1 *Nuclear data for naturally occurring actinides, their decay products, as well as nuclides used as analytical isotopic tracers. The abundances, half-life* ($t_{1/2}$)*, and primary decay mode data are taken from Firestone and Shirley* (1996)*. The thermal-neutron cross section* (σ_n) *data are taken from Erdtmann* (1976).

$<2 \times 10^{-12}$ and $<1 \times 10^{-11}$ for ^{237}Np/U and ^{239}Pu/U, respectively (Levine and Seaborg, 1951; Peppard *et al.*, 1952). Once considered extinct, the long-lived plutonium isotope ^{244}Pu was first proposed to have existed in the early solar system by Kuroda (1960). The presence of this nuclide in the early solar system was first confirmed via its signature of fissiogenic Xe isotopes (Rowe and Kuroda, 1965). The nuclide was eventually found to be non-extinct by direct detection in Precambrian bastnasite (Hoffman *et al.*, 1971).

Although the existence of some of the naturally occurring actinides has been known for more than two centuries, the use of actinides reached a new era with the discovery of nuclear fission in 1938. The development of nuclear fission as an energy source and weapon have led to the production and subsequent global spread of both natural and artificial actinide elements in the environment at ultra-trace levels. Fallout from nuclear weapon testing represents the highest contributor to the global spread of transuranic actinides with cumulative levels of the most abundant transuranic actinide Pu averaging approximately 1 mCi km^{-2} (Kim, 1986, and references therein). For the transuranic actinides, of particular concern are the nuclides that will linger in the environment due to long half-lives (Table 30.2). The more than 50 years of nuclear weapons production, testing, and energy generation has left a worldwide legacy of environmental contamination. As strategies for environmental remediation and disposal of actinide-contaminated materials are developed and implemented, the ability to perform accurate and precise determinations of trace level actinides in a variety of natural matrices has become increasingly important.

Accurate determination of trace actinides in geological, environmental, and biological materials represents a significant challenge due to their extremely low concentrations and the diverse matrix chemistry of these samples. Concentrations of the environmental transuranic actinides are frequently <1 fg g^{-1} sample and require accurate determination of less than 10^6 atoms of actinide. To perform these types of measurements, the modern analytical chemist can select from a variety of procedures and techniques encompassing sample decomposition, chemical separation, as well as analytical instruments, and calibration methods for the determination of concentration. The specific approach selected is dependent on several factors: sample matrix, sample size, analyte concentration, the need to determine multiple analytes, cost of analysis, time of analysis, equipment available, and the skill and training of the analyst. Any of these factors can influence the selection of an analytical method. The purpose of this chapter is to review and assess those procedures and techniques that are currently the state-of-the-art for trace actinide determination in geological, environmental, and biological matrices. This chapter emphasizes the procedures and techniques that are used specifically for the determination of the naturally occurring actinides and the long-lived environmental transuranic actinides at concentrations <1 μg g^{-1}.

30.2 CHEMICAL PROCEDURES

30.2.1 Sample decomposition

Most modern instrumental analytical techniques first require the preparation of a homogeneous, stable, aqueous solution that possesses a known matrix. For aqueous samples, the actinides may be present as dissolved species or adsorbed on the surfaces of suspended solid materials. In many cases these actinides can be solubilized and stabilized via acidification. Environmental aqueous samples such as natural waters are simply acidified with HNO_3 or HCl soon after collection to eliminate and/or prevent the formation of Fe or Al hydroxides (Lally, 1992). Simple acidification, however, may not decompose all suspended solid materials. Urine samples are acidified and decomposed with heat after addition of an inactive carrier and isotopic spikes (Wyse *et al*., 1998). For solid samples, complete decomposition of the sample matrix is typically performed; this requires more aggressive chemical treatment. Samples possessing organic matrices are typically dried thermally and ashed as a first step. Complete dissolution of actinides in solid samples may be complicated due to the presence of refractory oxide actinide phases. Selection of the appropriate sample decomposition method is an important factor in performing an accurate determination of actinide concentration. Selection of a sample decomposition method is dependent on the sample matrix, the chemical state of the actinide, and the chosen method of actinide determination. The decomposition step may be followed by separation, purification, and conversion of the actinide to a chemical form that is appropriate with the requirements of the method of determination. Decomposition of solid materials can be accomplished by either fusion or acid decomposition.

(a) Fusion decomposition

Fusion decomposition is extremely aggressive and is used primarily for decomposition of geological and solid environmental materials. Fusions are performed by heating a mixture of the sample with a flux reagent at atmospheric pressure in a graphite, zirconium, or platinum crucible. The method is well suited for large samples (several grams). The wide variety of sample matrices in each case requires a careful selection of the flux reagent. Selection of the appropriate flux material can result in both acid–base and oxidation–reduction-based decompositions (Dolezal *et al*., 1968). Common fluxes are hydroxides, peroxides, carbonates, bisulfates, hydrosulfates, pyrosulfates, tetraborates, and metaborates (Dean, 1995). For fusion decompositions, 0.1–10 g of a dried, homogenized, and powdered solid sample is mixed with flux at a sample to flux ratio ranging from 1:2 to 1:20. Isotopic spikes and elemental carriers, if required, are added at this stage. The mixture is heated to a temperature above the melting point of the flux over a Meker burner or in a muffle furnace until the

mixture forms a well-mixed molten mass. After cooling, the resulting fusion bead is dissolved with a dilute acid such as HNO_3 or HCl.

Fusion with $NaOH–Na_2O_2$ is a standard geochemical procedure that is extremely effective in decomposing silica-containing matrices. The effectiveness of the method is due to the high temperatures and oxidizing conditions that can be achieved. This method was used to decompose gram quantities of U-ore materials for determination of naturally produced Pu and Tc (Dixon *et al.*, 1997). The oxidizing conditions of the fusion mixture ensured reproducible decomposition and equilibration of a ^{242}Pu isotopic spike. The method yielded a precision of 1.6% and a blank of (0.17 ± 0 .15) pg for ^{239}Pu in Canadian Reference Material BL-5. Comparison of ^{239}Pu results with results from acid-decomposed samples (Attrep *et al.*, 1992) indicates that the fusion method may be more effective in totally dissolving trace Pu in U ore samples than acid decomposition. Croudace *et al.* (1998) used a metaborate–tetraborate flux for fusion of soil and sediments contaminated with weapons Pu and U. The American Society for Testing and Materials (ASTM) has published a standard procedure for fusion decomposition of solid materials (ASTM C1342-96, 1996b).

The major disadvantage to fusion decomposition is that the large mass of flux material yields a solution with high total dissolved solids (TDS). Chemical separation of the analyte from the dissolved flux material is typically required. Additionally, trace analysis of naturally occurring actinides may be complicated due to trace impurities in the flux. The aggressiveness of the reaction can also result in the attack of the mass of the crucible, leading to contamination of the sample. Despite these disadvantages, fusion decomposition is one of the most effective methods of decomposing refractory mineral phases in geological and environmental samples.

(b) Acid decomposition

Acid decompositions have been adapted for virtually all sample matrices. Acid decompositions yield solutions with low TDS that can be used for direct determination of many elements, including actinides, without subsequent chemical treatment. The availability of ultrahigh purity acids makes acid decomposition ideal for determination of trace U and Th. Acid decompositions are performed in a chemically resistant beaker on a hotplate at atmospheric pressure or in a closed digestion bomb at elevated pressures and temperatures in a convection or microwave oven.

For open-vessel acid decompositions a dried, homogenized, and powdered solid sample is mixed with several milliliters of one or more concentrated acids in a glass, polytetrafluoroethylene (PTFE), or perfluoroalkoxy (PFA) beaker and heated in a fume hood on a hotplate at atmospheric pressure. Several grams of material can be decomposed in an open vessel. For closed-vessel acid decompositions, the sample and acids are mixed in a PTFE-lined pressure vessel.

Water can be added to increase the solubility and prevent temperature spikes due to exothermic reactions. The vessel is sealed tightly and heated in a convection oven. The effectiveness of closed-vessel system results from the higher pressures and temperatures under which the decomposition takes place. Closed-vessel decompositions are typically restricted to <1 g of inorganic material or <0.1 g of organic material for a 23 mL closed vessel (Dean, 1995).

The types of acids selected depend on the chemical properties of the sample matrix as well as the elements to be determined. Actinides are soluble in HNO_3 and HCl so most procedures for the decomposition of actinide-containing samples utilize these acids. The ASTM has published a set of standard procedures for hotplate and convection-oven digestion of water and solid samples with HNO_3 and HCl (ASTM D1971-95, 1995a). These procedures are applicable to wastewaters, sludges, river and lake waters, and plant and animal tissues.

A HF–HNO_3 mixture is required for acid decomposition of silicates. After decomposition, HF must be removed so that insoluble actinide fluorides are converted to a soluble form either by fuming with $HClO_4$ or H_2SO_4 or by complexation with H_3BO_3. Beasley *et al.* (1998) used open vessels for the decomposition of soil samples for U, Np, and Pu determinations. Samples weighing 1–3 g were ash dried at 600°C to remove organic matter and were dissolved in a mixture of HF–HCl. The residue was fumed to dryness in an open vessel three times to remove residual HF and then dissolved in 6 M HCl–H_3BO_3 mixture to solubilize actinide fluorides.

The addition of H_2O_2 in small or catalytic quantities aids in oxidizing organic matter. A HNO_3–H_2O_2 mixture has been used for decomposition of plant material (Testa *et al.*, 1998) as well as animal and human whole organs and bones (USTUR 100, 1995; Glover *et al.*, 1998b).

Recently, specially designed microwave sample decomposition systems have become a routine analytical tool for decomposition of geological, environmental, and biological samples (Lamble and Hill, 1998). Microwave systems provide high-heating efficiency and programmability for unattended operation. The resulting decomposition procedures are reproducible and rapid. Specially designed closed PTFE or PFA vessels minimize sample contamination. Standard procedures for microwave-heated, closed-vessel decomposition with HCl and HNO_3 for the determinations of metals in groundwater have been published (ASTM D4309-91, 1991a). These procedures are applicable for digestion of suspended solids in water and leaching elements from most solid materials but would not yield total dissolution of silica-containing materials. The United States Environmental Protection Agency (U.S. EPA) has developed Method 3052 (U.S. EPA, 1996) for total microwave-heated, closed-vessel decomposition of ashes, biological tissues, oils, oil-contaminated soils, sediments, sludges, and soils. This method has been validated for U determinations on the Standard Reference Material (SRM) 2704 Buffalo River Sediment. Attrep *et al.* (1992) used a microwave system for the decomposition of U-ore materials for the determination of naturally produced Pu and Tc. Alvarado *et al.* (1996) have

developed a microwave procedure for the rapid decomposition of plant tissue for the purpose of actinide analysis using a $HNO_3-H_2O_2$ mixture. An overview of microwave digestion techniques can be found in Kingston and Haswell (1997).

30.2.2 Chemical separation

The accuracy and precision of most methods of actinide determination are influenced both by nonspecific interferences from more abundant sample matrix species and by specific spectroscopic or isobaric interferences from other actinides. These interferences often necessitate chemical separation of the actinide from the interfering species before determination. Additionally, chemical separations preconcentrate the analyte. Preconcentration is especially useful for actinides because of their ultralow concentrations in the environment. Chemical separations can enhance the sensitivity, accuracy, and precision of the overall analytical method.

Actinides are amenable to a variety of chemical separation methods including: coprecipitation, adsorption, chelation, liquid–liquid extraction, column ion-exchange chromatography, column extraction chromatography, or a combination of two or more of these methods. Procedures for the separation and purification of environmentally important actinides have been compiled (Kirby, 1959; Hyde, 1960; Penneman and Keenan, 1960; Stevenson and Nervik, 1961; Gindler, 1962; Coleman, 1965; Burney and Harbour, 1974). Many of these methods are applicable here. Recently, flow injection (FI) analysis and high-performance liquid chromatography (HPLC) have been utilized for online actinide separation with radiometric or mass spectrometric detection. In this section, we review the methods that have been used specifically for analytical-scale separations of trace actinides for the purpose of concentration determination. Because of the common desired goal, i.e. separation of the actinide from more abundant matrix elements and/or other actinides, most of the procedures below can be adapted to geological, environmental, and biological samples.

(a) Coprecipitation

Actinides can be preconcentrated from a large solution volume by coprecipitation. The most frequently used anions for actinide coprecipitation are fluorides, hydroxides, and phosphates. Actinides in the trivalent and tetravalent states are efficiently scavenged from solution by addition of a rare-earth element carrier with precipitation as a fluoride (Magnusson and LaChapelle, 1948). Actinides can also be coprecipitated as a group with $Fe(OH)_3$ (Lally, 1992) from a carbonate-free solution. Carbonate must be removed by boiling under acidic conditions due to its ability to complex with actinides and prevent quantitative precipitation. Coprecipitation is performed by adding a macroscopic amount of $FeCl_3$ to an acidified sample digest solution and adjusting the solution pH to basic by the addition of NH_4OH. The precipitate can then be filtered, washed,

and dissolved with HCl or HNO_3 before further separation and purification of the actinides. Coprecipitation of actinides can also be performed with Ca(II) as $Ca_3(PO_4)_2$ from an acidic digest solution with the addition of NH_4OH to a pH 8–9. This procedure is used for group actinide precipitation from digested soils (Kim *et al.*, 2000) and from urine for bioassay (Maxwell and Fauth, 2000). Direct coprecipitation with MnO_2(s) and adsorption onto MnO_2(s) have been extensively used for preconcentration of actinides from large-volume freshwater and seawater samples (Wong *et al.*, 1978; Bowen *et al.*, 1980). Sidhu and Hoff (1999) describe a procedure in which Pu was preconcentrated *in situ* from 2001 samples of fresh- and seawater. In this method, $KMnO_4$ solution was added to an acidified water sample and MnO_2(s) was precipitated with the addition of $NaHSO_3$. The resulting solid was filtered and the Pu was further purified before determination.

(b) Liquid–liquid extraction

Liquid–liquid extraction of actinides can be accomplished with a wide range of organic acids, ketones, ethers, esters, alcohols, and phosphoric acid derivatives (Lally, 1992). Methyl isobutyl ketone has been used to extract U(VI) from aqueous solutions. U(IV) can be extracted with ethyl acetate after treatment of an acidified solution with $Al(NO_3)_3 \cdot 9H_2O$ (Guest and Zimmerman, 1955). U(VI) can be extracted with 25% tributylphosphate (TBP) in toluene (Mair and Savage, 1986). A standard test method for the determination of U in water by high-resolution α-liquid-scintillation spectrometry utilizes a selective extractive scintillator solution containing dialkylphosphoric acid (ASTM D6239-98, 1998). Interfering radionuclides (Am, Pu, Po, Ra, Rn, and Th) are masked from extraction by diethylenetriaminepentaacetic acid (DTPA). Attrep *et al.* (1992) described a method for the determination of ultralow levels of natural ^{239}Pu in U ores in which Pu was extracted with 0.5 M thenoyltrifluoroacetone (TTA) in *o*-xylene and back-extracted into 8 M HNO_3. Bis(2-ethylhexyl)phosphoric acid (HDEHP) in toluene and dibutyl-*N*,*N*-diethylcarbamylphosphonate (DDCP) have both been used to separate Am from Pu for bioassay measurements (Filipy *et al.*, 1998). Triisooctylamine (TIOA) in xylene has been used to selectively extract Np from U and Pu (Novikov *et al.*, 1972). Whereas liquid–liquid extraction methods are very effective, in general they are being replaced due to the volume and classification of waste products that are produced by their use.

(c) Ion exchange

Ion-exchange resins are typically high-molecular-weight organic polymers containing a large number of functional groups that provide the basis for the separation of the analyte from undesired species. Cation exchange can be performed on resins possessing functional groups such as the strongly acidic

sulfonate group $-SO_3^-$. A cation-exchange resin composed of spherical polystyrene–divinylbenzene polymer substrate containing geminally substituted diphosphonic and sulfonic groups capable of selectively binding actinides and lanthanides from common matrix elements has been developed. This resin, Diphonix, allows preconcentration of actinides from large samples (Horwitz *et al.*, 1993a). Actinides can be recovered from Diphonix resin by elution with 1-hydroxyethylidenediphosphonic acid (HEDPA) or by complete decomposition of the resin (Chiarizia *et al.*, 1997). This method has been applied to separations of transuranic radionuclides in urine (Eikenberg *et al.*, 1999a) and for separation of Th from dietary samples, urine, and feces (Eikenberg *et al.*, 1999b).

Most ion-exchange methods for the separations of actinides utilize anion exchange. Anion exchange is performed on resins possessing functional groups such as the strongly basic quaternary ammonium salt $-NR_3^+$. Uranium can be separated from a variety of ions by the use of basic anion-exchange resins such as Bio-Rad AG1X8. Uranyl ions form strong anionic sulfate and chloride complexes that can be the basis for U separations. A standard test method for the determination of U in water uses coprecipitation of U spiked with ^{232}U-tracer with $Fe(OH)_3$ (ASTM D3972-90, 1990). After dissolution of the precipitate, U is separated from Th, Po, Pu, and Am by adsorption from a HCl solution onto an anion-exchange resin. Separation of ^{231}Pa is not achieved by this method and this nuclide could potentially cause spectroscopic interference with ^{234}U when alpha spectrometry is employed for U determination.

Anion exchange is also used for the separation of Pu from solution. Determination of Pu in water can be performed by coprecipitation of Pu and ^{242}Pu-tracer with Fe(III) as $Fe(OH)_3$ (ASTM D3865-97, 1997a). After dissolution of the precipitate, Pu is separated from Th and Am by anion exchange. Separation of ^{238}Pu from ^{228}Th and ^{241}Am is necessary due to α-spectroscopic interference.

A specialized anion-exchange resin called TEVA·Resin (EIChroM Industries Inc., Darien, IL, USA) is capable of separating actinides in different oxidation states from common matrix elements. The resin is composed of a liquid aliphatic quaternary amine incorporated onto an inert polymeric substrate, Amberchrom CG-71ms. Specifically, this resin allows the separation of the tetravalent actinides Pu(IV), Np(IV), and Th(IV) from hexavalent U(VI) and trivalent Am(III) in HNO_3 solutions (Horwitz *et al.*, 1995). Th(IV) that has sorbed onto TEVA·Resin can be preferentially eluted with 3 M HCl. Separation of Pu from Np is also feasible with this material. Addition of hydroquinone reduces Pu(IV) to Pu(III), allowing Pu elution with 9 M HCl whereas Np is retained. Np can then be eluted with 0.5 M HCl or 0.02 M HNO_3–0.02 M HF. Lanthanide elements are difficult to separate from Am(III) and may interfere with preparation of a sample for α-spectrometric analysis. Am can be separated from lanthanide elements on TEVA·Resin by complexation with thiocyanate.

(d) Extraction chromatography

Several extraction chromatographic resins have been developed specifically for the separation and preconcentration of actinides from acidic matrices such as acid-stabilized groundwaters and dissolved environmental and geological solids. These resins are composed of an inert support material that has been impregnated with an actinide-selective organic extractant. Whereas these resins function by passing actinide-containing solutions down to an exchange column containing the material, the separation is based on liquid–liquid extraction. These commercially available extraction resins named Actinide-CU, UTEVA·Spec, and TRU·Spec (EIChroM Industries Inc.) provide an extremely valuable tool for the preconcentration and separation of actinide elements from elements common to natural matrices and for separation of individual actinide elements from each other.

Preconcentration of Am and Pu from human tissue samples has been performed using Actinide-CU resin (Qu *et al.*, 1998). This resin is composed of bis(2-ethylhexyl)methanediphosphonic acid (H_2DEH[DMP] or DIPEX) supported by an inert polymeric substrate, Amberlite XAD-7. This resin has a strong affinity for actinides in strongly acid solutions and, thus, stripping of the actinide–organophosphonate complex with isopropanol is required to recover the actinides. This resin is appropriate only for preconcentration of actinides and not separation of individual elements.

The resin U/TEVA·Spec demonstrates specificity for U and tetravalent actinides. It is composed of diamylamylphosphonate (DAAP) sorbed on Amberlite XAD-7 (Horwitz *et al.*, 1992). Preconcentration and separation of U from common geological and environmental matrix elements such as Fe, Ca, Al, Na, and K and other actinides can be achieved from HNO_3 solutions. Separation of U from Th can be accomplished with a 2 M HNO_3 whereas separation of U from Np or Pu can be accomplished with a HNO_3–oxalic acid mixture.

TRU·Spec resin demonstrates high retention of tri-, tetra-, and hexavalent actinides. It is composed of octyl(phenyl)-*N*,*N*-diisobutylcarbamoylmethylphosphine oxide (CMPO) in TBP supported by Amberlite XAD-7 (Horwitz *et al.*, 1993b). In HNO_3 solutions, preconcentration and separation of all actinides from matrix elements common to geological and environmental samples can be achieved with TRU·Spec. Additionally, TRU·Spec allows for sequential elution of Am, Pu, Th, Np, and U using a scheme that incorporates HNO_3 and HCl rinse steps in combination with complexation and oxidation-state adjustments. Common matrix elements can be eluted before the actinides, providing for separation of these matrix elements. A method for preconcentration and separation of actinides from urine by this method was first described by Horwitz *et al.* (1990). Separations with applications to geochemistry have also been developed. TRU·Spec resin has been used for the separation of Th and U from geological samples (Pin and Zalduegui, 1997) and for the separation of

U and Th, from Pa in shells and minerals for geochronological measurements (Burnett and Yeh, 1995).

Many highly effective, flexible, and efficient methods for the separation of actinides from their sample matrix, as well as from each other, have been devised by combining anion exchange with one or more extraction chromatography steps. Croudace *et al.* (1998) described a procedure for the determination of Pu and U in soils and sediments that utilizes a combination of anion exchange and extraction chromatography (U/TEVA·Spec) to isolate Pu and Th from U and purify the U fraction. Maxwell (1997) devised a rapid-actinide separation method for environmental samples that utilizes anion exchange with TEVA·Spec resin and extraction chromatography with U/TEVA·Spec resin for the separation of U, Np, Pu, Am, and Cm.

Yokoyama *et al.* (1999) used extraction chromatography with U/TEVA·Spec resin and anion exchange with TEVA·Spec resin to separate Th and U before mass spectrometric determination of Th/U isotopic content of silicate rock samples. The recovery yields for Th and U were >90% and the total blanks were <19 pg for Th and <10 pg for U. Dual sequential columns and vacuum extraction were used to increase sample throughput. Separations by anion exchange with TEVA·Spec resin and extraction chromatography with TRU·Spec have been applied to separation of actinides from urine (Maxwell and Fauth, 2000), soil (Smith *et al.*, 1995), and soft human tissue (Moody *et al.*, 1998). A general radiochemical method that utilizes anion exchange and extraction chromatography for separating Th, U, Np, Pu, and Am from each other and matrix elements is shown in Fig. 30.1.

The use of extraction chromatographic resins configured as a continuous low-pressure FI or HPLC system, in series with the appropriate detector, can potentially enhance the selectivity, sensitivity, and speed of the detection method. Egorov *et al.* (1998) have developed a multieluant FI scheme utilizing TRU·Spec resin and off-line radiometric counting for quantitation. This system is capable of performing automated separations of Am from Pu including on-column Pu oxidation and reduction. FI has also been used with mass spectrometric detection of actinides (ASTM C1310-95, 1995c).

(e) Speciation separations

The most commonly used method for the determination of concentrations of actinides with oxidation-state specificity is direct spectrometric analysis in the visible and near IR spectral regions (see Chapter 27, section 27.3.2, of this book). Spectroscopic methods, however, typically require actinide concentrations that are higher than those found in most environmental and biological samples. To solve the problem of low concentration, indirect methods have been developed. These indirect methods use oxidation-state selective chemical separation of actinide species followed by radiometric or mass spectrometric

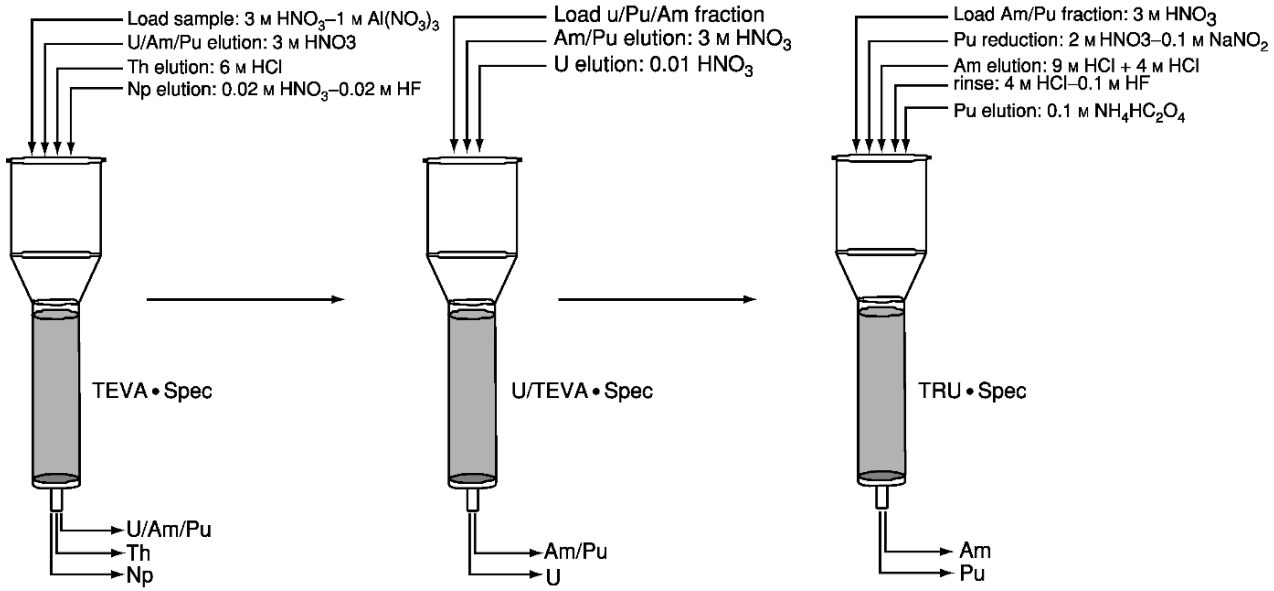

Fig. 30.1 *Schematic representation of a method for sequential separation of Th, Np, U, Am, and Pu using sequential anion exchange and extraction chromatography (after Horwitz* et al.*, 1995). In this procedure analyte and yield tracers are initially co-precipitated as a group from a dissolved or digested sample using one of the common carriers such as Ca(II). The precipitate is separated, washed, and dissolved with* 3 M HNO_3–1.0 M $Al(NO_3)_3$ *and loaded on the first column. The method is applicable to geological, environmental, and biological materials.*

determination. These chemical separation methods are based on the same fundamental principles of actinide separation used for interference removal.

Solvent extraction has been used for separating trace actinides possessing different oxidation states (Foti and Freiling, 1964). Saito and Choppin (1983) developed a solvent extraction-based methodology for the separation of trace level actinide elements in the III, IV, V, and VI oxidation states in solutions possessing pH 6–8. Dibenzoylmethane (DBM) in benzene was used as an extractant for actinides in 0.7 M NaCl aqueous solutions. The pH dependence of the extraction was determined for Am(III), Th(IV), Np(V), U(VI), and the method was demonstrated on systems containing mixtures of Pu(IV) and Pu (VI). The solvent extraction method can be applied to solutions possessing pH < 4 by using thenoyltrifluoroacetone (TTA) as the extractant (Bertrand and Choppin, 1982). Actinides in the V oxidation state were extracted from 0.1 M acetate buffer whereas actinides in the VI state were extracted from 0.6 M perchloric acid.

Oxidation state-specific adsorption has been used for separating trace actinide species. Inoue and Tochiyama (1977) used adsorption on silica gel to distinguish between Np(V) and Np(VI). Bondietti and Trabalka (1980) used differential adsorption to TiO_2 as a method to determine Pu(V) in natural waters with pH 9–11. Orlandini *et al*. (1986) used selective adsorption of Pu(VI) on silica gel and adsorption of Pu(V) on $CaCO_3$ for the determination of Pu oxidation state in Lake Michigan Water.

Coprecipitation has also been used to separate actinides possessing different oxidation states. The most widely used adsorption and coprecipitation method is the rare-earth fluoride technique that was adapted from the classical separation of reduced Pu(III + IV) from oxidized Pu(VI) by the coprecipitation of the former on a rare-earth fluoride (Magnusson and LaChapelle, 1948). This method was used for the determination of the oxidation state of Pu in filtered and unfiltered seawater samples from the Irish Sea (Nelson and Lovett, 1978a; Nelson *et al*., 1984) and the Pacific Ocean (Nelson and Lovett, 1978b). Samples were made 0.8 M in HNO_3, 0.25 M in H_2SO_4, 0.5 mM in $K_2Cr_2O_7$, and 0.7 mM in $Nd(NO_3)_3$. Sufficient HF was added to raise the total fluoride concentration to 0.25 M and the precipitated NdF_3, along with the coprecipitated Pu(III + IV), was filtered. The unprecipitated Pu(V) and Pu(VI) was treated with $(NH_4)_2SO_4 \cdot FeSO_4 \cdot 6H_2O$ to reduce the remaining Pu and a second NdF_3 step was performed. The Pu in each fraction was purified by anion exchange and Pu isotopes were quantified by alpha spectrometry.

The association of actinides with organic and inorganic aqueous colloidal materials is an important factor that controls the mobility of the actinide in the environment. The determination of the concentrations of actinides associated with aqueous colloids is typically performed by physically separating aqueous colloids by ultrafiltration with subsequent analysis of the filtrate. Ultrafiltration separation of actinide-associated colloidal materials in natural waters has been performed by passing solutions through flat membrane filters possessing specific nominal pore sizes (Nelson and Lovett, 1978a; Nelson *et al*., 1984), by

tangential-filtration with hollow-fiber cartridge filters (Marley *et al.*, 1991; Kaplan, *et al.*, 1994), and by size-exclusion chromatography (SEC) (Cooper *et al.*, 1995). Porcelli *et al.* (1997) used the tangential-flow hollow-fiber technique to separate U and other elements associated with colloids >10 kDa and >3 kDa in a study of the transport of U isotopes through the Kalix River watershed and Baltic Sea. Kersting *et al.* (1999) characterized Pu-associated colloidal material in groundwater from the Nevada Test Site by sequentially filtering aqueous samples with 1000, 50, and approximately 7 nm pore size filters. Tangential filtration was employed for the 7 nm size filtration. The $^{240}Pu/^{239}Pu$ ratio of the collected particulate material (>1000 nm), two colloidal fractions (1000–50 nm and 50–7 nm), and the ultrafiltrate (<7 nm) was determined by mass spectrometry. The measurements had a reported precision of ±1.5% and a procedural blank of <2 pg Pu. The Pu isotopic signature allowed the identification of the source of the Pu as a specific nuclear event. The authors noted, however, that the high pumping rates employed could potentially generate higher colloidal concentrations due to shear stress. The chemical form of the colloid could not be identified by this method.

30.3 NUCLEAR TECHNIQUES

The radioactive properties intrinsic to all actinides allow their direct detection by using radiometric techniques. In principle, the α-particles, β-particles, and γ-rays emitted by any radionuclide can be used for quantitative analysis (see Chapter 27, section 27.3.1, of this book). An examination of the radioanalytical literature reveals that a variety of mathematical criteria have been used to establish levels at which a radionuclide can be considered to be qualitatively detected or quantitatively determined with a given relative standard deviation (RSD). The minimum concentration level that leads to detection is generally defined as the minimum detection limit (MDL). The minimum concentration level that leads to quantitative determination with satisfactory precision is generally defined as the limit of quantitation (LOQ). Currie (1968) developed working expressions for the MDL as 3.29σ and the LOQ as 10σ where σ is the statistically defined standard deviation for the well-determined blank of the method. The confidence limits are assumed to be 95% for these values. These expressions have been widely adopted by the analytical community.

The natural abundances, half-lives ($t_{1/2}$), specific activities, modes of decay, and thermal-neutron capture cross sections (σ_n) for the naturally occurring actinides, their decay products, and several isotopic tracer nuclides are given in Table 30.1. The half-lives, specific activities, modes of decay, and thermal-neutron capture cross sections, for the environmental transuranic actinides and several of their tracers are given in Table 30.2.

Neutron activation analysis (NAA) techniques are based on the transmutation of nuclei to radionuclei or excited nuclear states by capture of neutrons.

Qualitative and quantitative analysis can be performed by detecting the α-particles, β-particles, γ-rays, delayed neutrons, or fission products that are produced as the excited nuclei relax. The emitted radiation or particles can be measured during irradiation or after a delay. Because all actinides are already radioactive the objective of NAA is to produce radionuclides with higher activities thus, improving the measurement sensitivity relative to alpha, beta, or gamma spectrometry of the unirradiated actinide.

Because quantitative analysis using radiometric and NAA techniques are based on the measurement of disintegration rates of radionuclides, the MDL is related to the specific activity of the determined radionuclide, the number of atoms of the radionuclide, counting time, and detection efficiency. The long half-lives and, therefore, low specific activities of the parents of the three non-extinct natural decay chains as well as several of the environmental transuranic nuclides complicates determination using radiometric techniques. Samples containing low concentrations of an actinide need to be counted for relatively long times on extremely stable spectrometers possessing low backgrounds to obtain precision adequate for detection and accurate determination. Whereas there are many radiometric procedures that are amenable to the determination of actinides at trace concentrations, the procedures that are the most generally applicable and commonly used are high-resolution alpha and gamma spectrometries.

30.3.1 Alpha spectrometry

Alpha spectrometry allows the analyst to identify and quantify individual α-emitting radionuclides based on the detection of emitted α-particles and determination of α-particle energies specific to the radionuclide of interest. Detection of α-particles with specific energies allows isotopic discrimination for most actinides. Nuclear data for naturally occurring actinides, environmental transuranic actinides, as well as nuclides utilized as isotopic tracers in α-spectrometric determinations are given in Table 30.3.

Despite the short range of α-particles through matter, analyses based their detection possess advantages as compared to the detection of β-particles and γ-rays due to the extremely low backgrounds that are achievable. However, accurate and precise α-spectrometric analysis typically requires chemical separation of actinide to eliminate sources of α-particles with energies similar to the analyte, correction for the recovery of the chemically separated actinide with an isotopic spike, and preparation of a thin source. Despite the necessity of these chemical procedures, alpha spectrometry is one of the most frequently utilized techniques for the routine determination of actinides in geological, environmental, and biological samples. The requirement of chemical separations can be used to the analyst's advantage by performing preconcentration from large samples. The instrumentation used in high-resolution alpha spectrometry is not extremely complex or expensive and

Table 30.3 *Nuclear data for naturally occurring actinides, environmental transuranic actinides, as well as nuclides utilized as isotopic tracers in alpha-spectrometric determinations. The principal α-particle energies (E_α) and yields (I_α) are taken from Firestone and Shirley* (1996).

can be used on a routine basis. Alpha spectra are reasonably simple and allow straightforward quantitative analysis.

(a) Alpha-spectrometry fundamentals

Alpha spectrometry can be performed using ionization chambers, magnetic spectrometers, scintillation detectors, and semiconductor detectors. Because of the combination of high resolution, sensitivity, compactness, and relative ease of use, alpha spectrometry is most frequently performed utilizing spectrometers that incorporate ion-implanted Si semiconductor detectors.

A typical alpha spectrometer with a 450 mm^2 ion-implanted Si detector has an energy resolution $<$20 keV, an efficiency $>$25% for source-to-detector spacing $>$1 cm, an energy range from 3 to 8 MeV, and a background $<1 \times 10^{-4}$ Bq. The detector is part of an integrated spectrometer that includes a vacuum chamber, bias supply for the detector, complete amplification system (preamplifier and amplifier), and calibration pulser. Data acquisition is controlled by a personal computer equipped with a multichannel analyzer for pulse height analysis along with data acquisition and processing software. A schematic diagram of a typical alpha-spectrometry system is illustrated in Fig. 30.2. A more detailed discussion of the theory and operation of alpha spectrometers can be found in Ehman and Vance (1991) and in Ivanovich and Murray (1992).

For accurate determination by high-resolution alpha spectrometry the α-emitting radionuclide must be prepared as a thin, flat, uniform source. To minimize the inelastic scattering of α-particles that degrade peak resolution the ideal source consists of a monolayer of the actinide. Three methods have generally been used for source preparation: evaporation, microprecipitation with a rare-earth fluoride, and electrodeposition (ASTM D3084-95, 1995b). The method most often employed is electrodeposition. In this method actinides are electrochemically deposited quantitatively from an electrolyte solution onto a polished stainless steel or platinum cathode planchet. The deposition is non-selective. Prior chemical separation of the actinides from matrix elements may be required so that the total mass of electrodeposited material is $<$10 $\mu g\ cm^{-2}$. Additionally, chemical separation of the analyte from other

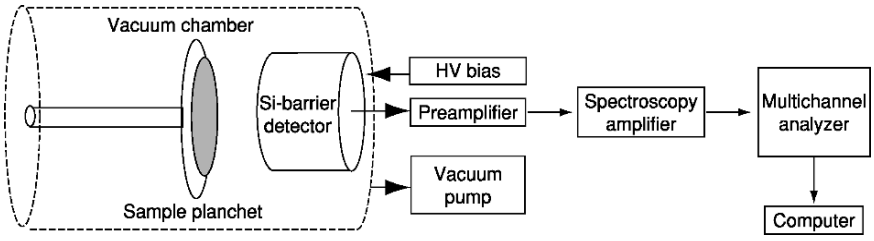

Fig. 30.2 *Schematic diagram of a alpha-spectrometry system.*

actinides that decay with similar α-particle energies is required to minimize spectroscopic interferences. A variety of electrolytes have been used in the preparation of electrodeposited actinide sources: $NaHSO_4$–Na_2SO_4, KOH–KCO_3, NH_4HCOO_2, NH_4Cl–HCl, NH_4Cl–NH_4I, NH_4Cl–$H_2C_2O_4$, $(NH_4)_2SO_4$, $(NH_4)_2SO_4$–H_2SO_4–NH_4OH, isopropanol, and dimethyl sulfoxide (DMSO) (Kressin, 1977 and references therein). The anode is typically Pt wire or gauze. Rotating the anode provides stirring for a more uniform deposit. Electrodeposition is performed at a constant current density (0.5 A cm^{-2}) and low voltage for approximately 2 h. Recent work on optimizing the $(NH_4)_2SO_4$–H_2SO_4–NH_4OH buffer system by Glover *et al.* (1998c) has demonstrated nearly 100% recoveries of Th, U, Pu, and Am in only 1 h. A standard procedure for electrodeposition of actinides from a solution of $(NH_4)_2SO_4$ has been published (ASTM D1284-00, 2000b).

Alpha-spectrometric measurement is performed by placing the actinide-containing planchet in a vacuum chamber at a fixed distance from a detector with a known background and efficiency. The air in the chamber is evacuated and the sample is counted for a time sufficient to attain desired statistical uncertainty. A total of 10000 counts would be required for 1% uncertainty (1σ) due to counting statistics alone (Friedlander *et al.*, 1981). The background is determined by separately counting a chemically prepared experimental blank. The efficiency of the detector for a given geometry is determined by counting a calibrated source at the same geometry that samples are counted. After counting the sample, the alpha spectrum is corrected for background and detector efficiency. Correction for losses incurred during radiochemical procedures are made based on the recovery of the isotopic spike. Spike recovery can be determined as determined from the alpha spectrum or by separate alpha-spectrometric analysis. The number of counts per second (cps) of each nuclide can then be related to the activity of the sample according to the following equation:

$$a = \frac{N}{\varepsilon_d r t_s d_s} \tag{30.1}$$

where a is the activity of the nuclide of interest (Bq), N is the total number of counts in the energy region of interest, ε_d is the detector efficiency, r is the fraction of isotopic tracer recovered, t_s is the analysis live-time (s), and d_s is the sample decay fraction from the time of sample collection to the midpoint of the counting period.

(b) Alpha-spectrometry applications

Because the analyte elements have typically been chemically separated (see Section 30.2.2) and prepared as a thin-layer source on a planchet before alpha-spectrometric analysis, the details of the actual analysis by alpha-spectrometric measurement are essentially independent of the initial source

matrix material. The nature of the source of the actinides (natural and/or anthropogenic) will dictate what spectral interferences may be present in the sample. There are numerous examples in the literature of applications of alpha spectrometry for the determination of trace actinide content in a variety of matrices. The following examples describe some specific details of these applications and give an overview of the breadth of applications.

Alpha spectrometry has historically been one of the most frequently utilized techniques for uranium-series disequilibria measurements particularly for ^{234}U and ^{238}U (Ivanovich and Murray, 1992). Complete isotopic analysis of the naturally occurring isotopes ^{238}U, ^{235}U, and ^{234}U can be performed with ion-implanted Si detectors because of complete resolution of their peaks. Uranium-232, a commonly used recovery spike, can also be completely resolved. ^{236}U has also been used as a recovery spike. However, tailing from the higher energy ^{236}U α-particles can potentially overlap with those of ^{235}U and a correction for this contribution may need to be performed. Samples must be counted soon after chemical separation due to the ingrowth of short-lived daughters whose α-particle energies overlap with U isotopes. To achieve a 1% counting uncertainty U isotope determination using a 7 day count and a 25% efficiency detector would require a sample containing 5.3 μg, 830 ng, and 290 pg of ^{238}U, ^{235}U, and ^{234}U, respectively. Alpha-spectrometric determination of U in geological and environmental samples require, therefore, long counting times and/or preconcentration from large samples to obtain sufficient amounts of U (see Section 30.2.2). For these reasons there has been great impetus for development of mass spectrometric methods for U isotopic analysis.

Maxwell and Fauth (2000) have recently demonstrated that alpha spectrometry possesses the sensitivity and low background sufficient for U isotope bioassay. By utilizing appropriate chemical procedures and a ^{232}U spike, they demonstrated analytical biases of +7.8% and +1.5% for ^{234}U and ^{238}U, respectively. Typical U levels in urine were found to be 0.003–0.03 Bq L^{-1} and 0.002–0.05 Bq L^{-1} for ^{234}U and ^{238}U, respectively. The method demonstrated blanks of 0.1 mBq L^{-1} for ^{234}U and 0.4 mBq L^{-1} for ^{238}U, sufficiently low for routine assay.

The determination of Th isotopes, specifically ^{230}Th and ^{232}Th, is an important component of uranium-series disequilibria measurements (Ivanovich and Murray, 1992). For the determination of ^{230}Th and ^{232}Th, chemical separation of Th from U is required due to the spectral interference between ^{230}Th and ^{234}U (Table 30.3). As with U, complete isotopic analysis of the naturally occurring Th isotopes ^{232}Th, ^{230}Th, and ^{228}Th can be performed because their peaks can be completely resolved using an ion-implanted Si detector. ^{229}Th, a commonly used recovery spike, can also be completely resolved. Alpha-spectrometric determination of Th isotopes can be complicated due to the ingrowth of ^{224}Ra interfering with ^{228}Th determination (Ivanovich and Murray, 1992). This parent–daughter relationship can be exploited for the determination of ^{224}Ra via alpha-spectrometric determination of ^{228}Th (Noyce, 1981). Eikenberg *et al.* (1999b) have recently utilized alpha spectrometry for the determination of Th

isotopic ratios in human diet as well as urine and feces achieving MDLs as low as 0.04 mBq L^{-1} for ^{232}Th, ^{230}Th, and ^{228}Th.

Protactinium-231 is a daughter product of ^{235}U that is used in soil and sediment dating (Ivanovich *et al.*, 1992). ^{231}Pa is typically determined via isotope dilution with ^{233}Pa followed by chemical separation and alpha-spectrometric determination. Chemical recovery is determined via by gamma-spectrometric determination of ^{233}Pa (Lally, 1992). High radiochemical purity is required to minimize spectral interferences from the typically more abundant ^{230}Th and ^{234}U (Table 30.3).

High-resolution alpha spectrometry is one of the most common methods for the determination of the environmental transuranic actinides in environmental and biological samples. When chemically separated as a group, the transuranic actinides can be determined with only a few spectral interferences, most notably: ^{240}Pu–^{239}Pu, ^{238}Pu–^{241}Am, and ^{243}Cm–^{244}Cm. Fig. 30.3 shows an alpha spectrum from a sample containing long-lived actinide and transuranic nuclides produced by the irradiation of UO_2 nuclear fuel.

Neptunium-237 is essentially free of spectral interferences from other transuranic actinides although separation from U and Th isotopes is required due to potential spectral interferences (Table 30.3). Neptunium-237 determination is complicated because it possesses a long half-life and is typically at much lower concentrations in nuclear fuel cycle source materials (Wolf, 1998). The general

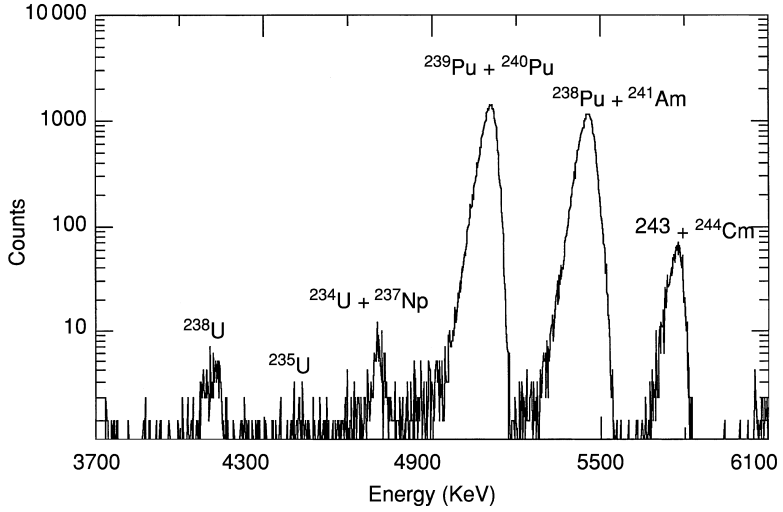

Fig. 30.3 *An alpha spectrum from the author's laboratory of an electrodeposited source containing actinides with E_α between* 3700 and 6100 keV *that are present in irradiated UO_2 nuclear fuel after a cooling period of* 20 years. *The spectrum contains prominent peaks from $^{243}Cm+^{244}Cm$, $^{238}Pu+^{241}Am$, and $^{240}Pu+^{239}Pu$ (listed from high to low energy). Also detectable at lower energies are minor contributions from long-lived nuclide $^{234}U+^{237}Np$, ^{235}U, and ^{238}U.*

reverse relationship between radionuclide half-life and α-particle energy (the Geiger–Nuttall relationship) complicates ^{237}Np determination when higher activities of high-energy α-emitters are present. High-accuracy alpha-spectrometric determination of ^{237}Np can be achieved via isotope dilution with ^{239}Np followed by chemical separation (Horwitz *et al.*, 1995). Chemical recovery is determined via by gamma-spectrometric determination of ^{239}Np. Examples of the routine application of alpha spectrometry to the determination of ^{237}Np in environmental and biological samples are given by Maxwell (1997) and Maxwell and Fauth (2000). Levels as low as 0.017 mBq of ^{237}Np were measured in Irish Sea sediment (Yamamoto *et al.*, 1998). Analogous to natural U and Th isotopes, the low specific activity of ^{237}Np complicates determination via alpha spectrometry and this has led to an effort to develop mass spectrometric methods of determination.

Alpha spectrometry is routinely used for the determination of Pu isotopes in environmental and biological samples. Plutonium-238 is particularly amenable to alpha-spectrometric determination because of its relatively high specific activity (for example, Cooper *et al.*, 2000). Chemical separation of Pu from Am must be performed due to spectral interferences between ^{238}Pu and ^{241}Am (Table 30.3). Thorium-228 will also interfere if present at sufficient concentrations. Unambiguous determination of both ^{240}Pu and ^{239}Pu cannot be performed due to near identical α-particle energies. For this reason it is common to report the combined $^{240+239}$Pu activity. Determination of individual ^{239}Pu and ^{240}Pu activities from an alpha-spectrometric measurement requires an independent mass spectrometric analysis determination of the ^{240}Pu/^{239}Pu atom ratio. Complete resolution of the ^{236}Pu, ^{238}Pu, $^{240+239}$Pu, and ^{242}Pu can be achieved with ion-implanted Si detectors. Plutonium-241 is not determined via alpha spectrometry because it does not decay by α-emission (Table 30.2). Standard methods for the determination of Pu in water (ASTM D3865-97, 1997a) and soil (ASTM C1001-00, 2000a) by alpha spectrometry have been published. These methods utilize either ^{236}Pu or ^{242}Pu as isotopic spikes. The procedure for determination of Pu in water demonstrates biases of less than ±10% whereas the procedure for determination of Pu in soil demonstrates biases of less than ±26% for soil samples containing 0.00188–0.150 Bq Pu g^{-1}.

Americium-241 is similar to ^{238}Pu in that it also possesses a relatively high specific activity compared to many of the environmental transuranic actinides. Frequently, Americium-241 is determined concurrently in a chemically separated aliquot of a sample. Americium-241 must be separated chemically from ^{238}Pu and ^{228}Th to remove spectral interferences. Accurate and precise determination of ^{241}Am via alpha spectrometry is performed using ^{243}Am as an isotopic spike. A routine procedure for ^{241}Am determinations in soil has been published (ASTM C1205-97, 1997b). Alpha spectrometry has been used extensively for the determination of anthropogenic Pu and Am isotopes in the environment including seawater (see for example, Nelson and Lovett, 1978a,1978b; Bowen *et al.*, 1980; Nelson *et al.*, 1984; Plutonium in the Environment, 1995), Antarctic

snow (Holm and Persson, 1978), and plant samples grown in a contaminated lake bed (Whicker *et al.*, 1999). Alpha spectrometry has been used for the determination of Pu and Am isotopes in biological samples such as human tissue (Moody *et al.*, 1998; Qu *et al.*, 1998), and urine (Maxwell and Fauth, 2000). It has also been used to determine concentrations of natural ^{239}Pu in geological samples (Ganz *et al.*, 1991).

The short half-lives of ^{243}Cm and ^{244}Cm essentially preclude their determination by any method other than alpha spectrometry at environmental levels. Spectral deconvolution is required to separate the ^{243}Cm and ^{244}Cm α-peaks due to low concentrations and similar energies (Mitchell *et al.*, 1998). Studies have utilized alpha spectrometry to search for ^{242m}Am via detection of daughter ^{242}Cm as well as ^{243}Cm and ^{244}Cm in lichen samples (Murray *et al.*, 1979).

A recent study of the application of alpha spectrometry to the transuranic actinides by Wolf (1998) achieved 10σ LOQ for ^{237}Np, ^{239}Pu, ^{241}Am, and ^{244}Cm of 40, 0.4, 0.008, and 0.0003 pg, respectively (1 mBq). These analyses were performed using relatively short counting periods (<48 h) under routine conditions with 450 mm^2 ion-implanted Si detectors possessing 25% relative efficiency and backgrounds (1×10^{-4} Bq). Activities over an order of magnitude have been quantified with dedicated low-level detectors and extremely long (>30 days) counting periods (Yamamoto *et al.*, 1998; Eikenberg *et al.*, 1999b; Cooper *et al.*, 2000; Maxwell and Fauth, 2000). The U.S. EPA and ASTM have published standard methods for the determination of actinides in water (U.S. EPA, 1979; ASTM D3084-95, 1995b).

30.3.2 Gamma spectrometry

Gamma spectrometry allows the analyst to identify and quantify individual actinide nuclides based on the detection of emitted γ-rays possessing energies that are specific to nuclear transitions in the actinide of interest. γ-Rays are highly penetrating and their measurement is relatively straightforward because essentially all γ-ray peaks can be individually resolved by high-resolution detectors. X-ray spectrometry is a related technique in which X-rays produced by a daughter atom after decay is detected. These X-rays are element-specific. Lower photon energies, sample self-shielding, lack of isotope specificity, and difficulty in calibrating efficiency curves at low energies complicate X-ray spectrometric determination. For these reasons, gamma spectrometry is a more commonly used than X-ray spectrometry for quantitation of specific actinide nuclides.

Gamma spectrometry requires minimal sample preparation, particularly when compared to the chemical procedures required for the preparation of a source for alpha spectrometric analysis. Gamma spectrometry is non-destructive and multiple radionuclides can be measured simultaneously. In some cases quantitation of actinides by gamma spectrometry can be performed based on the activity of one or more daughter products of the parent actinide. Quantitation based on daughter product activity requires an assumption of

radioactive equilibrium in the sample. However, daughter product analysis is the only route for determining ^{238}U and ^{232}Th by gamma spectrometry at their naturally occurring concentrations. Gamma spectrometry is frequently employed to measure recovery of long-lived actinides by way of spiking with a short-lived, γ-ray-emitting isotope. The sensitivity of the technique is dependent primarily on the half-life of the radionuclide and the percent γ-ray intensity (I_γ). Nuclear data for naturally occurring actinides, environmental transuranic actinides, as well as nuclides utilized as isotopic tracers in gamma-spectrometric determinations are given in Table 30.4.

(a) Gamma-spectrometry fundamentals

Several types of detectors can be used for gamma spectrometry. They can be classified as gas-filled, scintillation, and semiconductor. Gas-filled detectors are essentially a chamber filled with a gas mixture, such as 90% Ar–10% CH_4, that contains a positively biased anode. Depending on the bias voltage of the anode, gas-filled detectors can function as ionization chambers, proportional counters, or Geiger–Müller counters. Ionization chambers are used for high-radiation fluxes and are typically not suitable for trace analysis. Proportional counters are used for X-ray measurements where only moderate resolution is required (>1 keV at 5.9 keV). Geiger–Müller counters do not allow the energy of the γ-ray to be determined. Scintillation detectors function because γ-rays interacting with a scintillator produce a pulse of light that can be detected by a photomultiplier tube. A variety of plastics as well as Tl-activated NaI and CsI crystals are capable of detecting γ-rays with energies >1000 keV and have found applications as γ-ray detectors. The 7.6 × 7.6 cm NaI(T1) detector is the benchmark standard for the calculation of efficiency of γ-ray detectors. These detectors possess absolute efficiencies between 20 and 40% for the energies typical for most actinide γ-rays. Most analytically important actinide γ-rays and X-rays are in the 3–300 keV region. The low cost-to-size ratio of NaI and its ability to be configured into extremely large detector systems has enabled its use as anti-coincidence shields. One such environmental radionuclide detector system is described by Wogman (1970). However, the energy resolution of scintillator detectors (>10 keV at 100 keV) is typically insufficient to allow deconvolution of complex actinide γ-ray spectra.

Because of their superior resolution, most gamma-spectrometry systems currently utilize a high-purity germanium (HPGe) detector biased with a power supply, a preamplifier, spectroscopy amplifier, and pulse height analyzer. Most HPGe detectors are configured as a junction between n- and p-type semiconductor materials and come in a variety of geometries, sizes, and shapes. The selection of a specific detector depends on the types of samples measured. The most common geometry is a coaxial HPGe detector. Typical HPGe detectors used in geochemical and environmental analysis have volumes 100–200 cm^3, possess efficiencies of approximately 30–40% relative to a 7.6 × 7.6 cm NaI

Table 30.4 *Nuclear data for naturally occurring actinides, environmental transuranic actinides, as well as daughter nuclides and isotopic tracers utilized as in γ-spectrometric determinations. The principal γ-ray energies (E_γ) and yields (I_γ) are taken from Firestone and Shirley (1996).*

(Tl) detector, and have resolutions <1 keV at 122 keV. These systems are useful for a wide spectrum of applications and are normally calibrated in the range from approximately 50 to 2000 keV. Larger detectors with relative efficiencies >150% are available but at the expense of slightly lower relative resolutions (<2 keV at 122 keV). These high-efficiency detectors are useful for counting larger-volume, low-activity environmental samples. Another approach to high-efficiency gamma spectrometry is to use a well-type HPGe. Well-type detectors offer the ultimate absolute counting efficiency for small samples. The name 'well type' is given because this type of detector possesses a cavity that can surround a small sample. A typical well only has an available volume of <10 cm^3, which precludes the analysis of very large-volume samples. Finally, thin planar HPGe detectors equipped with a beryllium window offer high resolutions for the measurement of γ-rays and X-rays with energies between 3 and 300 keV. The thin beryllium window minimizes attenuation of these low-energy photons. These thin detectors have the additional benefit of being transparent to higher energy γ-rays and thus possess lower background from Compton scattering of high-energy γ-rays.

HPGe detectors are required to be at liquid-nitrogen temperature when they are under high-voltage bias and are connected to a liquid N_2-containing Dewar via a cryostat. The detector and sample are normally shielded with alternating layers of lead, copper, and a low-Z material such as plastic. This graded shielding system minimizes the X-rays scattered from the lead shielding and shields the detector from external sources. Data acquisition and spectral analysis can be controlled by a personal computer equipped with data acquisition and processing software for quantitative analysis. A schematic diagram of a typical gamma-spectrometry system is illustrated in Fig. 30.4. A more detailed discussion of gamma-spectrometry systems can be found in Friedlander *et al.* (1981) and Ehman and Vance (1991).

Typically, all that is required is that the sample be placed in front of the detector of a calibrated gamma-spectrometry system. The detector needs to be

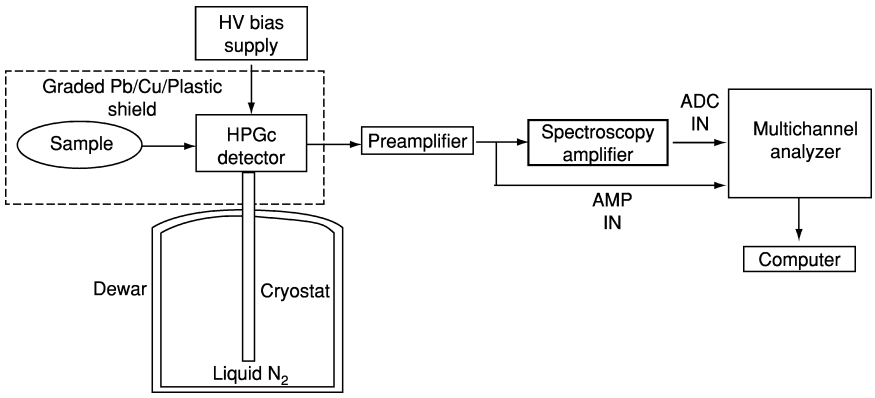

Fig. 30.4 *Schematic diagram of a gamma-spectrometry system* (*after Wolf,* 1999).

calibrated for energy and efficiency at the geometry at which the sample is counted. Additionally, the sample size and matrix of the sample need to be similar to that of the standardization source. This is typically achieved by preparing a mock-up sample that has been spiked with known amounts of radionuclides that emit γ-rays with energies comparable to those of interest.

(b) Gamma-spectrometry applications

Extensive work has been performed to develop gamma-spectrometric analysis methods for the determination of the naturally occurring long-lived actinides ^{238}U, ^{235}U, ^{232}Th, and their progeny for both environmental and geochemical studies. A review of this application of gamma spectrometry to U-series disequilibria has been published (Ivanovich and Murray, 1992).

In the ^{238}U-series nuclides, determination of ^{238}U is usually based on the measurement of short-lived daughter ^{234}Th due to the lack of an intense γ-ray for ^{238}U (Harbottle and Evans, 1997). ^{234}Th is essentially always in equilibrium with ^{238}U in geological and environmental samples such as minerals and soils unless the material has been recently chemically treated or the U has been recently deposited. Determination is typically based on the measurement of the 92.6 or the 63.3 keV γ-ray doublets. Measurement of the 63.3 keV γ-ray generally can be improved by using a planar HPGe with a thin Be window. A gamma spectrum of a UO_2 sample collected on a high-resolution planar HPGe detector is given in Fig. 30.5. Determination of ^{238}U can also be performed by measurement of the 1001 keV γ-ray from the decay of ^{234m}Pa. The low I_γ for this γ-ray precludes its use for samples with U concentrations $<10\ \mu g\ g^{-1}$. A recently published example of the application of gamma spectrometry for the determination of actinides is that of Gu *et al*. (1997). In a study of the deposition of dust in the Chinese loess plateau, activities of ^{238}U, as well as ^{232}Th and several of their daughter products were determined non-destructively using a low background well-type HPGe detector. Uranium-234 can potentially be determined by measuring its 53.23 keV γ-ray; however, this line is weak and spectral interference from ^{214}Pb at 53.2 keV essentially precludes direct determination of ^{234}U via gamma spectrometry. Determination of the ^{238}U daughter ^{230}Th can be accomplished by measuring its 67.8 keV emission. The low I_γ of this transition precludes its measurement in samples with only trace ^{238}U content. Harbottle and Cumming (1994) report a MDL of 4.4 μg for ^{238}U in 3 g environmental samples using a Compton suppression well counter.

In the ^{235}U-series, identification and quantitation can be performed directly on the parent nuclide via measurement of its strong 185.7 keV γ-ray. A correction for interference from the ^{238}U daughter ^{226}Ra is required for samples in secular equilibrium. However, this interference can be corrected by indirectly determining the contribution of ^{226}Ra based on measurement of γ-rays from ^{214}Pb and ^{214}Bi. The α-decay of ^{226}Ra produces ^{222}Rn ($t_{1/2}$ = 3.8235 days), which rapidly establishes equilibrium with both ^{214}Pb and ^{214}Bi. The short

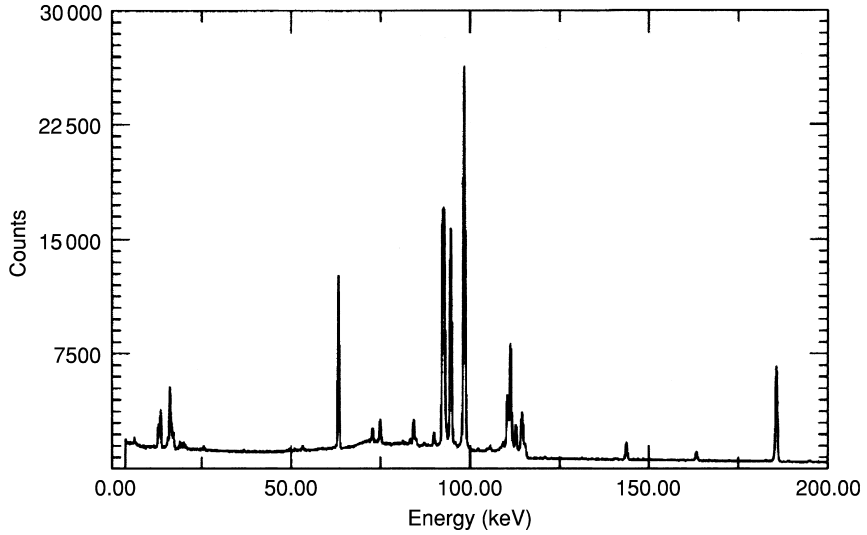

Fig. 30.5 *Gamma spectrum of an isotopically enriched U sample counted for 1 day. The spectrum was collected on a high-resolution planar HPGe detector possessing a thin Be window. The spectrum illustrates prominent peaks from* ^{234}*Th and* ^{235}*U* (*after Wolf,* 1999).

half-lives and abundance of γ-rays emitted by these two progeny make it possible to correct for ^{226}Ra in samples containing total U at concentrations <1 μg g^{-1} when secular equilibrium can be assumed (Harbottle and Evans, 1997). The total mass of U in the sample can be calculated from the determination of ^{235}U if a natural or other known isotopic distribution is assumed. Harbottle and Cumming (1994) report a MDL of 50 ng for ^{235}U in 3 g environmental samples using a Compton suppression well counter.

Direct determination of ^{231}Pa is difficult due to its complex γ-ray spectrum at relevant higher energies (280–300 keV). Indirect determination via the 50.14 keV γ-ray of short-lived daughter ^{227}Th is complicated due to sample shielding at lower energies. The availability of commercially available gamma-spectrometry software to enable the deconvolution of the 235.97 keV ^{227}Th peak from a quartet of peaks due to the presence of ^{212}Pb, ^{224}Ra, and ^{214}Pb (Harbottle and Evans, 1997). ^{233}Pa, an isotopic tracer for ^{231}Pa determinations, can be quantified directly by gamma spectrometry.

In the ^{232}Th-series, ^{232}Th cannot be determined directly via gamma spectrometry due to its long half-life and lack of an intense γ-ray. ^{232}Th can be determined indirectly by measuring one of several γ-rays emitted by short-lived daughters ^{228}Th, ^{228}Ac, or ^{212}Pb provided that equilibrium can be assumed.

In the transuranic actinides ^{237}Np, ^{239}Pu, ^{240}Pu, and ^{241}Am, typically only ^{241}Am is determined via gamma spectrometry. Americium-241 is a daughter of

^{241}Pu, a minor isotope of weapons-grade Pu, and has been used as a convenient qualitative signature for the presence of Pu (Burns *et al.*, 1995; Jerome *et al.*, 1995; Wolf *et al.*, 1997). Americium-241 can be readily be determined directly through measurement of its 59.54 keV γ-ray. Use of ^{241}Am as a signature for Pu, however, requires subsequent laboratory determination of Pu by other techniques to ensure that chemical fractionation of Am and Pu has not occurred in the environment.

Neptunium-237 can be determined directly via measurement of a pair of low-energy γ-rays at 29.4 and 86.5 keV or indirectly via daughter product ^{233}Pa after secular equilibrium has been achieved. The low specific activity of ^{237}Np essentially precludes its determination in environmental samples by gamma spectrometry. Chemical recovery of ^{237}Np can be monitored with the isotope spike ^{239}Np. Neptunium-239 can be determined directly by gamma spectrometry via any of its relatively intense γ-rays.

Plutonium isotopes ^{239}Pu and ^{240}Pu have numerous γ-rays that potentially allow their determination by gamma spectrometry (Gunnick, 1991). Most of these γ-rays have $I_\gamma < 1 \times 10^{-3}$, making their direct determination in environmental samples impossible. Alternatively, Pu can be determined by measuring U L-shell X-ray emissions associated with its decay. This method has been applied to chemically pure Pu standards achieving MDLs of 20 pg (Nitsche *et al.*, 1992). A recent study of the application of gamma spectrometry to the transuranic actinides by Wolf (1998) achieved LOQs for ^{237}Np, ^{239}Pu, and ^{241}Am of 100 ng, 1500 ng, and 5 pg, respectively. These analyses were performed under routine conditions using a 104% relative efficiency HPGe detector. These results correspond to LOQs of 1.0, 3500, and 0.5 Bq and MDLs of 0.3, 1100, and 0.2 Bq for ^{237}Np, ^{239}Pu, and ^{241}Am, respectively.

A standard method for the determination of γ-ray emitters in water has been published (ASTM D3649-91, 1991c). This method reports that with typical gamma spectrometers activities of approximately 40 Bq can be measured under routine conditions and activities of 0.4 Bq can be determined for many nuclides. Application of gamma spectrometry to most naturally occurring actinides and the environmentally important transuranic actinides, however, are limited by typical long half-lives and/or low intensities for emitted γ-rays. The limitations of radiometric determination via gamma spectrometry are particularly apparent when sensitivity is considered on a mass basis.

30.3.3 Neutron activation analysis

(a) NAA fundamentals

Analysis of trace actinide content by NAA has been performed on the naturally occurring actinides as well as on transuranic actinides (see Chapter 27, section 27.3.5, of this book). The most frequently used method of NAA is activation with thermal neutrons. Typically, NAA is performed using neutrons produced in a nuclear reactor or by an isotopic source such as ^{252}Cf and subsequently

thermalized (most probable energy of 0.025 eV). Samples and flux monitor standards are typically irradiated simultaneously and analyzed for high-precision quantitative analysis. After the irradiation, measurement of the α-particles, β-particles, γ-rays, delayed neutrons, or fission products are performed using an appropriate spectrometer. If no chemical treatment is performed after irradiation, the technique is called instrumental neutron activation analysis (INAA). If chemical separations are performed after irradiation, the technique is called radiochemical neutron activation analysis (RNAA). If chemical methods are used to preconcentrate the element of interest before activation the technique is called preconcentration neutron activation analysis (PCNAA). NAA employing epithermal neutrons, i.e. neutrons with energies of 0.1–1 eV, is called epithermal neutron activation analysis (ENAA). Finally, if the concentration of the nuclide is determined by using an isolated solid detector to quantify the number of tracks produced by neutron-induced fission, the method is known as fission track analysis (FTA).

The basic equation that governs all NAA methods is:

$$R = \frac{m}{M} N\phi\, \sigma_n \varepsilon (1 - \mathrm{e}^{-\lambda t}) \tag{30.2}$$

where R (Bq) is the count rate of a sample containing a mass m (g) of a given nuclide with molecular weight M (g mol^{-1}) at the end of irradiation, and N is Avogadro's constant. The thermal-neutron flux density (ϕ) is the number of thermal neutrons incident on a unit area of sample per unit time (n cm^{-2} s^{-1}). The thermal-neutron capture cross section (σ_n) is a measure of the probability that the nuclide of interest will capture a neutron and be activated and has unit surface area (cm^2). The term ε is the efficiency of the detector measuring the count rate (absolute number of decays per number of decays counted) for the decaying radionuclide. The final set of terms in parentheses corrects the activity for the duration of irradiation t (s) and the decay constant λ (s^{-1}) of the specific nuclide. This equation is valid for samples thin enough that attenuation of the neutron flux can be ignored. Examination of equation (30.2) shows that the absolute sensitivity of NAA is dependent on the flux ϕ, the cross section σ_n for the nuclear reaction, the decay constant λ of the nuclide of interest, and the irradiation duration t. An overview of the fundamentals of NAA can be found in texts such as Friedlander *et al.* (1981) and Ehman and Vance (1991).

(b) INAA applications

Non-destructive INAA determination of U in geological and environmental materials can be performed in several ways (Parry, 1991). One approach is NAA with subsequent detection of delayed neutrons. This method possesses a high specificity for U and has been used for many years in the exploration of U ores. The method is based on the measurement of delayed neutrons following a short irradiation with thermal neutrons. Uranium-235 undergoes thermal-neutron-induced fission. The resulting neutron-rich fission products undergo β^- decay.

While most of the fissiogenic daughter nuclei are in excited states and relax via γ-ray emission, some daughter nuclei possess sufficient energy for relaxation to occur via delayed-neutron emission. The delayed neutrons are emitted instantaneously after β^--decay with the half-life of the β^--decaying parent. The neutrons are detected with polyethylene-moderated BF_3 proportional counter systems. The BF_3 detector is extremely sensitive to neutrons and insensitive to the γ-rays and β^--particles emitted by other activated elements in the sample. The technique, therefore, is highly selective with respect to ^{235}U. If the sample is irradiated with a neutron flux possessing an appreciable fast-neutron component, there will be a contribution from fast-neutron fissions of ^{238}U. This condition is not problematic because this nuclide is still U. If the sample contains significant amount of ^{232}Th, a correction for fast-neutron fissions is required for accurate U determination. The dominant ^{235}U fission products that decay via delayed-neutron emission are ^{89}Br ($t_{1/2} = 4.4$ s), ^{87}Br ($t_{1/2} = 55.6$ s), ^{94}Rb ($t_{1/2} = 2.8$ s), ^{137}I ($t_{1/2} = 24.5$ s), and ^{135}Sb ($t_{1/2} = 1.7$ s). For example, the decay scheme for ^{87}Br is

$$^{87}_{35}\mathrm{Br} \xrightarrow{55.60\ \mathrm{s}} {}^{87}_{36}\mathrm{Kr} + {}^{0}_{-1}\beta^- + \bar{\nu} \xrightarrow{76.3\ \mathrm{min}} {}^{86}_{36}\mathrm{Kr} + {}^{1}_{0}n + {}^{0}_{-1}\beta^- + \bar{\nu}$$

NAA with delayed-neutron detection can be automated for online and unattended determination of U content in solid and liquid samples. A system described by Rosenberg *et al.* (1977) determines the U content in 10 g samples that have been packed in polyethylene containers and irradiated for 60 s in a flux of 10^{16} *n* cm^{-2} s^{-1}. Samples are counted for 60 s after a 20 s decay. Even though natural U is only 0.720% ^{235}U, and less than 1% of the neutrons released in the fission are from delayed-neutron emitters, the thermal cross section of ^{235}U is so large that the technique possesses sufficient sensitivity for routine analysis of U-containing materials with a reported MDL of 0.6 μg g^{-1}. This method can also be coupled with gamma spectrometry for the determination of additional elements in the sample.

A second and more common pathway for INAA of U is use of the (n,γ) reaction. For ^{238}U this method consists of determining the intensity of the 105 keV γ-ray from the decay of ^{239}Np. ^{239}Np is produced from the decay of ^{239}U that results from thermal-neutron capture by ^{238}U according to the following reaction:

$$^{238}_{92}\mathrm{U} + {}^{1}_{0}\mathrm{n} \longrightarrow {}^{239}_{92}\mathrm{U} \xrightarrow{23.5\mathrm{min}} {}^{239}_{93}\mathrm{Np} + {}^{0}_{-1}\beta^- + \bar{\nu} \xrightarrow{2.33\ \mathrm{days}} {}^{239}_{93}\mathrm{Pu} + {}^{0}_{-1}\beta^- + \bar{\nu}$$

The amount of ^{239}U and ^{239}Np produced is directly related to, and therefore a measure of, the amount of ^{235}U present in the original sample. At high concentrations U can be determined by measurement of the 74 keV γ-ray from the decay of ^{239}U immediately after sample irradiation. MDLs are enhanced with the use of a detector sensitive to low-energy photons such as a planar HPGe with a thin Be window. Both of these methodologies are enhanced with a higher ratio of epithermal neutrons. INAA of ^{232}Th is based on gamma-spectrometric

determination of ^{233}Pa produced by the following reaction:

$$^{232}_{90}\mathrm{Th} + ^{1}_{0}\mathrm{n} \longrightarrow ^{233}_{90}\mathrm{Th} \xrightarrow{22.3\mathrm{min}} ^{233}_{91}\mathrm{Pa} + ^{0}_{-1}\beta^{-} + \bar{\nu} \xrightarrow{27.0\ \mathrm{days}} ^{233}_{92}\mathrm{U} + ^{0}_{-1}\beta^{-} + \bar{\nu}$$

INAA determination of trace U and Th is that the analysis can be performed simultaneously with a suite of other elements. Routine applications of INAA for the determination of trace elements including U and Th in the recent literature include the analysis of oceanic basalts (Joron *et al*., 1997) and precious and common opals (McOrist and Smallwood, 1997). Joron *et al*. (1997) reported detection limits of 6.9 and 1.7 ng g^{-1} for U and Th, respectively. Samples weighing 150 mg were irradiated for 8–15 h at a flux of 1.1×10^{13} *n* cm^{-2} s^{-1} followed by a 1-week sample cooling and 3000 s count time for U determination. Samples were counted second time for 40000 s after a 30-day cooling period for the Th determination.

The high sensitivity of INAA makes this technique ideal for the analysis of minute amounts of material such as individual phases, minerals, and crystals separated from bulk material. Schrauder *et al*. (1966) used INAA to determine U and Th along with a suite of trace elements in 13 micro-inclusion-bearing fibrous diamonds from Botswana to constrain the composition of fluids in the mantle (Schrauder *et al*., 1996). Raimbault *et al*. (1997) developed a technique to extract single crystals and perform multielemental analysis, including U and Th, with INAA. The INAA technique required only a few micrograms of mineral and facilitated the measurement of more than 30 elements in multiple samples from the Oklo U deposit in Gabon. This work utilized the presence of epithermal neutrons in the reactor flux producing (n,p) reaction products, extending the number of elements determined. This methodology was able to detect low μg g^{-1} concentrations of U and Th in single-crystal samples in a variety of minerals.

A non-destructive method for the determination of ^{239}Pu by INAA in contaminated soils has been developed by Fuller *et al*. (1965). This method utilized the fission product ^{140}La to quantify ^{239}Pu. Because ^{140}La is produced by the fission of both ^{239}Pu and ^{235}U, the ^{235}U contribution needs to be subtracted from the total activity. This was accomplished by first directly determining the ^{235}U content of the unirradiated soil via gamma spectrometry. Soil samples were irradiated with thermal neutrons for 60 s and counted twice after decay periods of 3–4 and 10–14 days. The ^{238}U content was determined after the first cooling period via the ^{239}Np 74 keV γ-ray. Lanthanum-140 was determined after the second cooling period by measuring its 1.6 MeV γ-ray. The MDL for ^{239}Pu in soil sample was reported to be 5 ng.

(c) RNAA applications

With respect to NAA techniques, RNAA offers lower MDLs for actinides than INAA due to virtual elimination of activated matrix elements. RNAA has traditionally been used for trace U and Th determinations in a variety of

matrices (Parry, 1991) from the first lunar samples (Wänke *et al.*, 1970) to biological materials (Picer and Strohal, 1968). Typically, the irradiated sample is decomposed and equilibrated with a milligram amount of the element of interest known as the carrier. The carrier element, along with the radionuclide produced during sample irradiation, is then chemically separated and purified. The amount of radionuclide recovered from the chemical separation is determined gravimetrically from the amount of carrier element recovered. For RNAA determination of U, the quantitation is based on the radiochemical analysis of one or more fission products arising from the thermal-neutron-induced fission of ^{235}U. RNAA determination of ^{232}Th is complicated due to lack of a stable isotopic carrier for the determination of the recovery yield. In this case, ^{231}Pa can be used as a recovery tracer for the activation product ^{233}Pa (Glover *et al.*, 1998a and references therein). The purified elemental sample can then be radiometrically assayed by gamma spectrometry. RNAA is a destructive technique that is more time-consuming and requires greater analytical and chemical laboratory skills than does INAA. The chemical separation of the element of interest, however, results in a sample possessing a gamma spectrum with virtually no background from other γ-ray-emitting species. Procedures for the determination of trace U in geological materials via the ^{235}U(n,f)^{132}Te reaction are given in Anders *et al.* (1988). Using a thermal-neutron flux of 1×10^{14} *n* cm^{-2} s^{-1}, this methodology can achieve MDLs as low as 10 pg g^{-1} for U. Filby (1975) used the ^{235}U(n,f)^{135}I reaction to determine U in human lung samples, coal dust, coal filters, rat lung tissue, animal diets, and minerals. The reported MDLs for U in these matrices were as low as 5 ng g^{-1} depending on the sample matrix and final radiochemical purity.

A comparison of INAA and RNAA analyses for ^{232}Th show that up to two orders of magnitude improvement in MDLs can be achieved when RNAA is employed. RNAA has been used for the analysis of ^{232}Th in human tissue samples with a MDL of 10 pg (Picer and Strohal, 1968).

Recently, a procedure for PCNAA of ^{232}Th in human tissues has been developed (Glover *et al.*, 1998a). The method used ^{227}Th to determine the yield of the preconcentration process. Removal of the matrix elements before irradiation greatly lowers the dose to the radiochemist processing the sample. This method resulted in a MDL of 10^{-4} Bq per sample ($\sim$20 ng ^{232}Th), an order of magnitude lower than the MDL for direct alpha-spectrometric determination. PCNAA has the advantage in that very large samples can be processed. Th isotopic composition (^{228}Th, ^{230}Th, and ^{232}Th) can be determined when this PCNAA procedure is combined with alpha spectrometry (Glover *et al.*, 1998b). Thorium isotopes ^{228}Th and ^{230}Th can be determined before irradiation by electroplating the separated Th onto a V planchet and counting it on a alpha spectrometer. The electroplated sample can then be irradiated for ^{232}Th determination. This method has been used to measure the Th isotopic composition of human tissues with MDLs of 1×10^{-8}, 4×10^{-4}, and 1 ng for ^{228}Th, ^{230}Th, and

^{232}Th, respectively. A PCNAA method has been adapted for the determination of ^{237}Np via the ^{237}Np(n,γ) ^{238}Np reaction (Byrne, 1986). This method was used to determine ^{237}Np in contaminated sediments from the Esk estuary and the foreshore at Grange-over-Sands, Cumbria. The sediment samples were ashed and the Np separated by ketone extraction. Recovery of the ^{237}Np was monitored with a ^{239}Np isotopic spike. The reported MDL for ^{237}Np was 4 pg g^{-1} for a 5 g sample. This MDL could be improved to $<$0.4 pg g^{-1} if higher neutron fluences were used.

(d) FTA applications

If a sample is irradiated in close proximity to a glassy or plastic material, the heavy nuclides generated from thermal-neutron-induced fission will produce submicroscopic tracks in the material. The measurement of these tracks after etching is the basis for FTA and was first reported in 1958 by Young (1958). Moorthy *et al*. (1988) describe the application of FTA to the analysis of ^{239}Pu in urine. Because ^{235}U will also undergo thermal-neutron-induced fission the Pu is first isolated by anion-exchange chromatography. An aliquot of the separated sample was transferred to a fused silica slide. Samples and standards were irradiated for 10 min for a neutron fluence of 10^{17} *n* cm^{-2}. After cooling for 2 days the slide is washed and etched with HF. Fission track density is determined under a bright-field microscope. The reported LOQ was 5 fg ^{239}Pu per sample. Recently FTA has been used for the measurement of U in pore water (Barnes and Cochran, 1990). The FTA method can be performed with small samples but generally only gives precisions of 6–15%. Love *et al*. (1998) recently have described a novel approach to determine ^{240}Pu/^{239}Pu ratios in human tissue samples by combining alpha spectrometry and FTA.

30.4 ATOMIC SPECTROMETRIC TECHNIQUES

Atomic spectrometric techniques are based on the absorption and emission of electromagnetic radiation from atoms or ions. Information specific to the electronic structure of individual elements is manifested in the ultraviolet and X-ray regions (see Chapter 27, section 27.3.2, of this book) of the electromagnetic spectrum. Each element possesses a unique electronic structure and, therefore, unique atomic spectra. The absorption and emission of electromagnetic radiation of a wavelength specific to an electronic transition of a particular element can serve as the basis for analysis and determination of that element. The actinides are amenable to analysis and determination via several atomic absorption/emission-based techniques including atomic absorption spectrometry (AAS), atomic emission spectrometry (AES), flame emission spectrometry (FES), and inductively coupled plasma atomic emission spectrometry (ICPAES). The

application of these techniques for U determination has recently been reviewed (Wolf, 1999). The application of these techniques to trace analysis of actinides has been limited due to the complexity of actinide ultraviolet absorption/emission spectra, lack of sensitivity, and lack of isotopic specificity. Atomic spectrometric methods based on fluorescence or phosphorescence generally possess lower MDLs. The actinides U, Am, and Cm are relatively unique among most elements in that they can be determined directly via fluorometry without the addition of a fluorescent chelating agent. Even lower MDLs can be achieved by utilizing the ability of uranyl ions to phosphoresce when excited to a triplet state. Because of this, the techniques of fluorometry, and phosphorimetry, have been employed for trace U determination.

30.4.1 Fluorometry

(a) Fluorometry fundamentals

In the fluorometric determination of U, an aliquot of a decomposed solid sample or digested aqueous liquid sample is pipetted onto a Pt disk containing a NaF–LiF flux and is evaporated and fused in a furnace. The fused disk is then exposed to an ultraviolet source such as a mercury-arc lamp in combination with a filter or monochromator at 365 nm. Laser excitation with time-resolved detection can increase the sensitivity of the technique by two orders of magnitude. The intensity of the fluorescence is measured at 560 nm. The presence of ionic species of Cd, Cl, Cr, Co, Cu, Fe, Mg, Mn, Ni, Pb, Pt, Si, Th, and Zn quench U fluorescence and lower the sensitivity of the technique. Nb and Ta are reported to enhance U fluorescence. In samples containing significant quantities of these elements, analyses can be performed after chemical separation of the U or dilution of the sample if sufficient concentrations of U are present. The fluorometric method is a single-element method dedicated to the determination of U.

(b) Fluorometry applications

Fluorometry has also been applied to the determination of U in geological, environmental, and biological materials. The ASTM has published a standard test method for determining traces of U in water by fluorometry (ASTM D2907-91, 1991b). This method can determine U concentrations as low as 5 ng mL^{-1}. A procedure has recently been developed for the determination of trace U rocks, minerals, and soils by laser fluorometry after low-temperature dissolution with a HF–HNO_3 mixture for economical high-throughput analyses (Ramdoss *et al.*, 1997). Time-resolved laser fluorometry can attain MLDs as low as 50 pg mL^{-1} (Ghods-Esphahani *et al.*, 1990 and references therein).

30.4.2 Phosphorimetry

(a) Phosphorimetry fundamentals

The uranyl ion can be directly determined phosphorimetrically in a H_3PO_4 or H_2SO_4 solution. The acid is added to protect the uranyl ion from various intermolecular mechanisms that quench luminescence. The sample is excited at 254 nm, and the intensity of the yellow-green emission can be measured in a fluorimeter and related to concentration. Use of a pulse-laser excitation source can increase the sensitivity of this method greatly. In the pulsed-laser phosphorimetric method, an aliquot of sample is pipetted into a glass vial, mixed with HNO_3 and H_2O_2, and taken to dryness. The residue is dissolved in HNO_3 and a complexant such as H_3PO_4. The phosphorimetric method is a single-element method dedicated to the determination of U. The technique determines total U concentration independent of the specific isotopic composition of U.

(b) Phosphorimetry applications

The ASTM has published a standard test method for determining trace U in water by pulsed-laser phosphorimetry (ASTM D5174-91, 1991d). This technique can be used to determine U concentrations as low as 50 pg mL^{-1}.

30.5 MASS SPECTROMETRIC TECHNIQUES

In contrast to radiometric techniques, quantitative analysis by mass spectrometry is based only on counting the number of atoms of the nuclide of interest as opposed to counting randomly occurring radioactive decay events (see Chapter 27, section 27.3.3, of this book). The precision of the measurement is, therefore, independent of the specific activity of the radionuclide. The long half-lives and low specific activities of the parents of the three non-extinct natural decay chains and several of the environmental transuranic nuclides (^{231}Pa, ^{237}Np, ^{239}Pu, ^{240}Pu) make them ideal candidates for determination by mass spectrometry. Mass spectrometric techniques are based on the separation of gas-phase analyte ions (either molecular or atomic) on the basis of their mass-to-charge ratio (m/z) so that they can be separately detected. The technique can, therefore, provide isotopic information of the element of interest. The first mass spectroscopic measurement of a U compound was demonstrated by F. W. Aston in 1931 (Aston, 1931). The first accurate mass spectrometric measurement of the isotopic composition of U was performed by A. O. Nier in 1939 (Nier, 1939). Technological advancements have since resulted in highly automated, commercially available inorganic mass spectrometers that, in many laboratories, have

replaced radiometric and other nuclear-based techniques for the trace analysis of actinides.

Mass spectrometric measurements require the atomization and ionization of the analyte from a solid sample or solution in the ion source. Ions are electrostatically extracted from the source and focused with a system of electrostatic ion lenses into the mass analyzer. The mass analyzer disperses the ions in space or time based on m/z. Several types of mass analyzers have been utilized for inorganic mass spectrometry including single focusing static magnetic sectors, double focusing tandem magnetic/electrostatic sectors, dynamic time-of-flight (TOF) mass analyzers, and quadrupole mass analyzers (Becker and Dietze, 1998). A limitation to the magnetic-sector mass analyzer is that it does not focus on the basis of velocity for an ion with a given mass. Velocity focusing can be achieved with the addition of an electrostatic sector to form a double focusing tandem magnetic/electrostatic sector mass analyzer. The dynamic TOF mass analyzer functions by accelerating all ions to the same kinetic energy and allowing ions with different masses to disperse along a flight tube. Quadrupole mass analyzers function as a high-pass, low-pass mass filter. This is achieved by placing a direct current (dc) voltage and a radiofrequency (rf) voltage on two pairs of parallel rods. For a given set of dc and rf voltages, only ions with a specific m/z possess a stable path through the filter. A m/z scan can be performed by varying the dc and rf voltages. After dispersion by the mass analyzer ions are detected. High precision can be achieved on systems that disperse the ions in space by configuring multiple detectors to simultaneously detect ions with different m/z (multicollector systems). The detector and mass analyzer are both pumped to a very low pressure so that collisions with gas molecules are minimized. More details of the various configurations of sources, mass analyzers, and detectors can be found in Platzner *et al*. (1997).

Mass spectrometric techniques are defined primarily by the ion source. Mass spectrometers utilized for inorganic trace analysis include the spark source mass spectrometer (SSMS), the glow discharge mass spectrometer (GDMS), the laser ablation mass spectrometer (LAMS), the resonance ionization mass spectrometer (RIMS), the accelerator mass spectrometer (AMS), the secondary ion mass spectrometer (SIMS), the thermal ionization mass spectrometer (TIMS), and the inductively coupled plasma mass spectrometer (ICPMS). Mass spectrometric determination of trace actinides requires the spectrometer to produce actinide ions with high efficiency, and the capability of selectively separating the nuclide of interest from interfering isobars, molecules, and backgrounds caused by higher abundance isotopes. The most commonly used mass spectrometric techniques for trace actinide analysis are TIMS and ICPMS. AMS, and RIMS, although less routine than TIMS and ICPMS, have the potential for ultrahigh-sensitivity determination of actinides. Fundamentals and application of TIMS, AMS, RIMS, and ICPMS for trace actinide determinations are discussed below.

30.5.1 Thermal ionization mass spectrometry

Thermal ionization sources produce an extremely stable, relatively intense supply of ions with a minimal energy spread, and minimal molecular and atomic interferences. When coupled with an appropriate mass analyzer and multicollector detector system, the resulting TIMS instrument is capable of measuring elemental isotopic ratios with precisions $<0.01\%$ while requiring only nanograms of material (Becker and Dietze, 1998). However, the high first ionization potential for the actinides complicates their determination by TIMS due to the lower efficiency of the thermal ionization process. Despite this, methods have been developed so that as little as 40 fg of an actinide can be determined (Chen and Wasserburg, 1981). The main disadvantage of TIMS is that extensive sample preparation is required. Whereas the thermal ionization source is moderately selective with respect to some interfering atomic and organic molecular species, chemical procedures are required to separate individual actinides to minimize the presence of interfering isobars. Additionally, TIMS is typically used to determine only one element per prepared sample. Despite these disadvantages, TIMS has been used nearly exclusively in geochronological studies where high-precision isotope ratio determinations are required (Chen *et al.*, 1992). In some cases TIMS has been replacing alpha spectrometry in environmental studies where extremely low concentrations of long-lived transuranic actinides are being determined (Cooper *et al.*, 2000). TIMS analysis of actinides is also applicable for the purpose of bioassay (Maxwell, 1997).

(a) TIMS fundamentals

TIMS instruments that are used for actinide analysis consist of the following principal components: a thermal ionization source that produces positively charged actinide ions; ion extraction and focusing optics and source slit; mass analyzer; collector slit and detection system (Platzner *et al.*, 1997). These components and their arrangement are illustrated in Fig. 30.6.

Trace analysis of an element by TIMS first requires sample dissolution and chemical separation of the analyte element from sample matrix components as well as potentially interfering isobars (see Section 30.2.2). A small aliquot of solution containing the chemically separated actinide (typically <1 μg of actinide) is deposited onto a filament composed of a clean, degassed refractory metal such as Re or W that possesses a high-electron work function. The most frequently used method utilizes two filaments arranged opposite to each other. Single, double, and triple filament designs have been utilized. In a double filament configuration, one filament is used for evaporative heating of the atoms and the second for ionization. Arden and Gale (1974) and Chen and Wasserburg (1981) have developed a method using graphite to enhance U^+ emission by loading an aqueous colloidal suspension of graphite onto a Re filament. The solution is evaporated, producing a thin graphite film. The

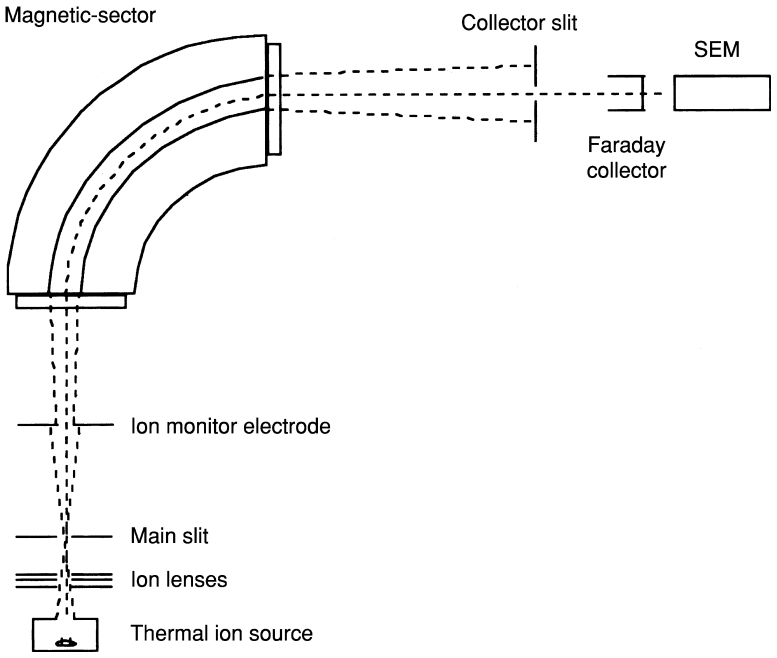

Fig. 30.6 *Schematic representation of a* 90° *single-collector TIMS* (*after Platzner* et al., 1997).

separated U sample is loaded onto the filament, evaporated, and a second graphite film is applied. The geometry of the filament was either V-shaped or dimpled. The ionization efficiencies with this method were determined to be 0.6–1.2% for standards and the source produced very stable ion beams. This method has also been utilized for the preparation of a ^{231}Pa source yielding efficiencies of 0.7% (Pickett *et al.*, 1994). A second method of source preparation directly uses an anion-exchange resin bead onto which U, Th, or Pu has been adsorbed (Walker *et al.*, 1974). This resin bead source has also been used for the determination of Am and Cm by TIMS (Poupard and Jouniaux, 1990). Perrin *et al.* (1985) developed a surface ionization-diffusion-type ionization (SID) source for the analysis of Pu, which uses a Re filament onto which Pu has been electroplated followed by an overplating with Pt.

Ions produced in the source are accelerated to approximately 10 kV, focused with a series of ion lenses, and pass through a source slit to enter the mass analyzer. The most common method of mass analysis for TIMS measurements of actinides is the single-focusing static magnetic sector (Chen *et al.*, 1992). The magnetic-sector mass analyzer disperses ions by m/z according to the following equation:

$$\frac{m}{z} = \frac{H^2 r^2}{2V} \tag{30.3}$$

where m is the ion mass, z is the ion charge, V is the potential to which the ion has been accelerated, H is the strength of the magnetic field, and r is the radius of the circular path followed by the ion. A magnet with a radius of 30 cm requires a field strength of 0.7 T to achieve beam separation of 0.255 cm for m/z 236 and 235 (Platzner *et al*., 1997). Double focusing tandem magnetic/electrostatic sector instruments (Palacz *et al*., 1992) as well as three-stage instruments (Lagergren and Stoffels, 1970) have also been utilized for actinide determination. In a single detector system, after dispersion by the magnetic sector, the ion beam is scanned across the collector slit so that only one isotope reaches the detector at any one time. Because of the low ion currents generated during trace analysis a detector that enhances the signal at each m/z such as a secondary electron multiplier (SEM) or Daly detector is used. Larger currents from major isotopes are measured with Faraday ion collectors. On a typical modern system, instrument control, data acquisition and analysis are computer-controlled.

Quantitative trace analysis by TIMS is typically performed via isotope dilution (ID). Accurate results require corrections for time-dependent and time-independent biases in the ion source, mass analyzer, and detector system. The rate of evaporation of isotopes of an element from any thermal ionization source is mass dependent so bias corrections are required. These mass fractionation discrimination effects limit the accuracy of determination. Correction for biases can be made in part by the use of internal isotopic standards and performing analysis of well-determined standards.

(b) TIMS applications

The analysis of trace concentrations of actinides by TIMS has been demonstrated for essentially all of the long-lived actinides including ^{234}U, ^{235}U, ^{238}U, ^{230}Th, ^{232}Th, ^{231}Pa, ^{237}Np, ^{239}Pu, ^{239}Pu, ^{240}Pu, ^{241}Pu, and ^{241}Am and has been utilized for measurements of geological, environmental, and biological samples. TIMS is currently one of the most frequently utilized techniques for U-series disequilibria measurements. Procedures and applications of TIMS to U measurements are summarized in Chen *et al*. (1992) and references therein. Chen and Wasserburg (1981) utilized their graphite-coated filament in a methodology for the determination of ^{238}U abundances, ^{238}U/^{235}U ratios, and ^{234}U/^{238}U ratios in small cosmochemical samples. The method utilized a ^{233}U–^{236}U double spike to correct for instrumental fractionation, high-yield, low-background chemical separation procedures, and filament-loading techniques. This methodology could determine ^{234}U/^{238}U ratios with a precision of 0.5% (2σ) for a sample size of 5×10^9 ^{234}U atoms and accurate U concentration measurements could be made with as little as 20 fg of U. This method has also been adapted for the determination of Th isotopes (Cheng *et al*., 2000). The high-precision and

sensitivity of TIMS has been used to redetermine the half-lives of ^{234}U and ^{230}Th by precisely determining $^{234}U/^{238}U$ and $^{230}Th/^{238}U$ ratios in many geological materials that have behaved as closed systems $>10^6$ years (Bourdon *et al*., 1999).

Naturally occurring ^{231}Pa, a nuclide that has traditionally been determined radiometrically, has recently been determined in geological and seawater samples by TIMS. Pickett *et al*. (1994) determined ^{231}Pa in geological samples by ID–TIMS. ^{233}Pa was separated from a ^{237}Np source and was utilized as the isotopic spike. The authors estimated that as little as 30 fg of ^{231}Pa under routine analysis conditions and achieved an external reproducibility better than $\pm 1\%$. The preferred sample size was stated to be >100 fg ^{231}Pa. A similar method has been developed by Bourdon *et al*. (1999) that utilizes a ^{233}Pa spike produced *in situ* from neutron activation of ^{232}Th. The application of TIMS to ^{231}Pa, ^{230}Th, and ^{232}Th determination in seawater yielded decreased sample size (100–1000-fold), increased precision (5–10% vs. 20–40%), and decreased measurement time (hours vs. weeks) when compared to traditional alpha-spectrometric determination (Edmonds *et al*., 1998).

A typical TIMS system and method used for the determination of transuranic actinides has been described by Perrin *et al*. (1985). The method utilized a modified instrument developed at the National Bureau of Standards (NBS, currently National Institute of Standards and Technology, NIST). This spectrometer is a 30.5 cm radius 90° deflection magnetic-sector mass analyzer equipped with a 17-stage electron multiplier. The dark current of the detector system is 0.05 cps. Application to Pu isotopic determination demonstrated the capability of measuring the $^{240}Pu/^{239}Pu$ atom ratio in samples of 0.5–2 ng with 0.07% precision and accuracy at the 95% confidence level. Chemical separation of Pu from U and Am is required to minimize isobaric interferences from ^{238}U and ^{241}Am on ^{238}Pu and ^{241}Pu, respectively. Plutonium-242 (Cooper *et al*., 2000) is typically used as an isotope spike in the ID–TIMS determination of Pu. Plutonium-244 has also been used as an isotope spike in an investigation of sources of transuranic elements in artic marine sediments where ^{242}Pu was one of the target analytes (Curtis *et al*., 1999). When combined with the appropriate analytical separations and clean room techniques the TIMS methodology has a ^{239}Pu blank of (17 ± 0.15) pg and MDL of 440 fg (Cooper *et al*., 2000). This method has been used to determine concentrations of naturally occurring ^{239}Pu in U ores (Attrep *et al*., 1992; Dixon *et al*., 1997) as well as measure colloidal transport of Pu in groundwater that originated from the testing of nuclear weapons at the Nevada Test Site (Kersting *et al*., 1999). The groundwater measurements had a reported precision of $\pm 1.5\%$ and a procedural blank of <2 pg Pu. These figures of merit allowed the identification of the source of the Pu as a specific nuclear event. A related ID–TIMS procedure for ^{237}Np in soil and in human tissue samples has been developed (Efurd *et al*., 1986). This ID–TIMS method used ^{236}Np was used as an isotope spike and is optimized for samples containing 100 pg ^{237}Np. Although ^{237}Np does not possess any isobaric interferences, chemical separation must be performed to

minimize the amount of ^{238}U in the sample due to the tail of the ^{238}U peak adding counts at $m/z = 237$. This type of interference results from limitations in a performance characteristic called abundance sensitivity. Abundance sensitivity is defined as the ratio of the signal at the mass of interest resulting from the presence of a major abundance peak to the signal of the major peak. This characteristic is inherent to each individual mass spectrometer. Interference is caused when ions possessing a higher m/z inelastically scatter with components of the spectrometers or residual gas in the spectrometer. This scattering causes ions to have decreased kinetic energies and produces a signal in the low m/z region of tail of the higher-mass isotope peak. The contribution of this signal becomes increasingly significant as the ratio of the minor to the major isotope decreases. Lagergren and Stoffels (1970) describe a three-stage TIMS that has been used for the low-level determination of actinides. This instrument is equipped with a sliding-shaft vacuum lock for precise positioning of the ion source, two magnetic sectors followed by an electrostatic sector, and a pulse-counting ion detection system. The instrument has good sensitivity for minor isotope determination and is capable of determining even the minor Pu isotopes ^{241}Pu and ^{242}Pu in environmental samples. This TIMS instrument has been used to assess the production of ^{237}Np from above-ground nuclear testing by determining $^{237}Np/^{239}Pu$ ratios in northern hemisphere soil samples. An essential component to this work is that it was performed in a dedicated low-level laboratory. Laboratory blank levels did not exceed approximately 10^4 atoms. Highly reproducible and accurate results were achieved at $<10^6$ atoms of transuranic actinide (^{237}Np, ^{239}Pu, ^{240}Pu, ^{241}Pu, ^{242}Pu).

Extremely high sensitivity and the capability of providing isotopic information makes TIMS an extremely effective tool for trace actinide determination. In general TIMS can be applied to actinide determination in geological, environmental, and biological samples. The technique can also be applied to routine actinide bioassay determination (Maxwell, 1997) although alpha spectrometry and ICPMS are typically used due to their greater cost effectiveness. The technique is highly selective due primarily to chemical procedures performed before analysis. The technique is applicable to isotopes of all the naturally occurring actinides and environmental transuranic actinides. Calculations based solely on counting statistics indicate that under routine conditions radionuclides with half-lives $\sim$70 years and greater can be determined more precisely by TIMS (Chen *et al.*, 1992). These calculations indicate that ^{238}Pu is the actinide with the half-life that is the lower limit for which TIMS is more precise than alpha spectrometry.

30.5.2 Accelerator mass spectrometry

Accurate determination of trace concentrations of any nuclide by mass spectrometric techniques requires the ability to discriminate between the analyte signal and the signal from interfering species possessing near-identical m/z ratios.

These interfering species may either be molecules, isobars, or species resulting from inelastic scattering of ions possessing higher m/z ratios. Theoretically, discrimination of molecules and isobars possessing near-identical m/z ratios may be achieved by increasing the resolution of the spectrometer to a level sufficient for discrimination on the basis of m/z. This approach, however, decreases ion transmission efficiency and thus, instrumental sensitivity. The determination of a minor isotope can be complicated if it possesses a lower mass than the most abundant isotope due to limitations in abundance sensitivity. All of these interferences result in limiting the ability of a mass spectrometer to precisely and accurately determine concentrations of trace elements and trace isotopes of elements. Acceleration of analyte ions to potentials >1 MV offers several unique mechanisms that together allow for the elimination of both of these types of interfering species. The utilization of high-energy accelerators for ultrahigh-sensitivity mass spectrometric analysis is called AMS.

(a) AMS fundamentals

The high sensitivity and specificity of AMS is achieved with control and manipulation of a combination of experimental parameters depending on mass (m), charge (z), and energy (E) of the analyte ion combined with unique advantages that high-energy acceleration introduces. The first significant experiment using AMS was reported by Alvarez and Cornog (1939) who used a cyclotron to assist in the discovery of ^{3}He in He. The AMS technique was reintroduced in the 1970s and developed for the measurement of long-lived ($t_{1/2}$ = 2.73 y – 16 My) cosmogenically produced radionuclides such as ^{3}H, ^{10}Be, ^{14}C, ^{26}Al, ^{32}Si, ^{36}Cl, ^{41}Ca, ^{53}Mn, ^{55,60}Fe, ^{59,63}Ni, ^{81,85}Kr, and ^{129}I (Vogel *et al.*, 1995). The primary strength of the AMS technique is the ability to measure the abundance of minor isotopes in the presence of major isotopes in the range 10^{-12} to 10^{-15}. Modern AMS instruments that have used for actinide analysis typically consist of the following components: a pre-accelerator system consisting of a negative ion source, pre-accelerator, and a mass analyzer; a tandem-based accelerator with a gas-based or foil-based electron stripper; and a post-accelerator analysis and detection system (Litherland, 1987). These components and their arrangement are illustrated in Fig. 30.7. Negative ions, either atomic or molecular, are extracted from the ion source at a potential of several kV. This potential allows the initial energy distribution of the ions extracted from the source to be sufficiently overwhelmed so that unit mass resolution analysis of the ions may be achieved before introduction into the accelerator. The ions accelerate toward the terminal of the accelerator that is at a high-positive electrostatic potential of several MV. At the terminal the ions pass through either a low-pressure gas or thin foil that strips one or more electrons from the ions. Typically beam conditions are optimized so that two or more electrons are stripped from the analyte ions. Multiply charged molecular ions fragment due to coulombic repulsion. Thus, essentially all molecules can be destroyed. These positively charged ions now

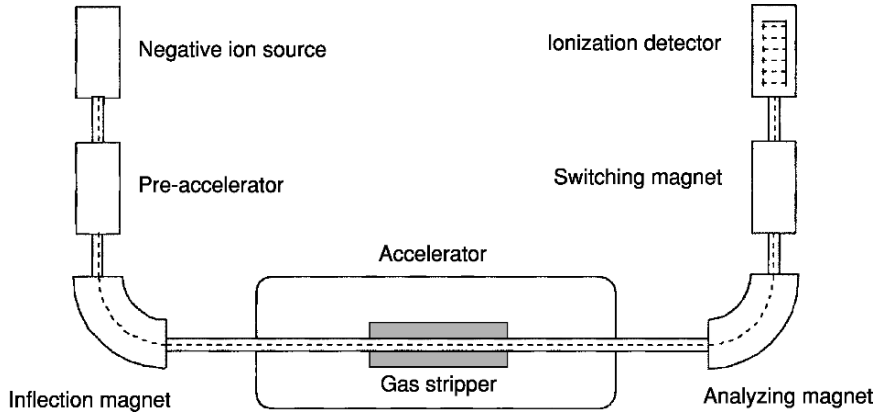

Fig. 30.7 *Schematic representation of the AMS based on the* 14UD *Pelletron accelerator at the Australian National University* (*after Fifield* et al., 1996).

accelerate away from the terminal with an increased energy. These ions, which can possess energies as high as several GeV, are subjected to further mass analysis and detection. The high energies that can be achieved in such a system allows utilization of rate of energy loss-range detection, a detection system that allows separation of isobars due to differing average nuclear charge as ions pass through a gas.

An important requirement for an AMS ion source is the ability to produce an intense beam of negative ions (>1 μA) with low memory effect. The most common ion source utilized for AMS is a Cs sputter ion source. Zhao *et al.* (1994a) studied the production of negative atomic and molecular ions from a Cs sputter ion source for introduction of ions into the accelerator for subsequent analysis and detection of the isotopes of interest. Samples were prepared as compressed as either mixtures of original sample material (Th metal or U ore); mixtures of actinide, C, and Al; or a mixture of actinide oxide and Nb. The authors concluded that a dicarbide was an effective molecule for the analysis of Th and Pa whereas a monoxide was superior for U and Pu.

Many of the facilities that developed AMS for the determination of these radionuclides utilized tandem-based accelerators originally constructed for nuclear physics experiments. However, the analysis of actinides by AMS was initially restricted due to limitations in the maximum achievable terminal potential of most tandem-based accelerators. Lower terminal potentials result in substantially higher backgrounds due to the higher cross sections of both elastic scattering and charge-changing collisions at these energies. Background can be particularly problematic for actinide analysis due to the large number of mass combinations of lighter atoms at heavier masses. Lower terminal potentials also result in decreased transmission efficiencies due to the lower yield of higher

charge states of heavier ions during charge-changing collisions. However, several instrumental advances resulting in improved background control now allow the analysis of actinides with tandem-based accelerators at moderate (1–3 MeV) energies (Kilius *et al*., 1990).

(b) AMS applications

AMS has been demonstrated for several actinide elements, in particular Th, Pa, U, and Pu. The first detection of the naturally occurring U isotope ^{236}U by AMS was achieved by Zhao *et al*. (1994b) at the IsoTrace Laboratory in Ontario, Canada. This nuclide is produced by the (n,γ) reaction on ^{235}U in U ore deposits. The production of ^{236}U can be significantly increased in U ore deposits saturated with water due to the production and subsequent thermalization of MeV neutrons from the fission of ^{238}U. Analysis of ^{236}U by conventional low-energy mass spectrometric methods is problematic due to the background resulting from elastic scattering of the intense ^{238}U signal and the molecular species ^{235}UH. The AMS instrument used in this work was composed of a Cs sputter source; an injection system consisting of a 45° electrostatic analyzer ($E/\Delta E \sim 400$) and a 90° magnet ($m/\Delta m \leq 400$); a tandem accelerator operating at a potential of $\leq$2MV; a post-accelerator system consisting of a 15° electrostatic analyzer ($E/\Delta E \sim 300$), a 90° magnet ($m/\Delta m \leq 2600$), a 45° electrostatic analyzer ($E/\Delta E \leq 900$); and an ionization chamber detection system. Molecular interferences were minimized by selecting an ion charge state of +5. This system determined a ^{236}U/^{234}U ratio of $(1.0 \pm 0\ .27) \times 10^{-5}$ in a sample of U ore from Cigar Lake, Saskatchewan, Canada. This ratio corresponds to a ^{236}U/^{238}U ratio of $(5.6 \pm 0\ .15) \times 10^{-10}$ under the assumption of secular equilibrium. This measurement demonstrated the capability of small tandem-based AMS systems for analyzing actinides.

Purser *et al*. (1996) proposed the configuration of a broad-range precision AMS system for the measurement of ^{229}Th, ^{230}Th ^{233}U, and ^{236}U. The authors proposed using ^{236}U as a thermal-neutron monitor with an integration period >100 My. The AMS instrument proposed by the authors consists of a Cs sputter source; an injection system consisting of a 90° magnet ($m/\Delta m \sim 800$) and a 90° electrostatic analyzer ($E/\Delta E \sim 120$); a tandem accelerator with a terminal stripping tube operating at a potential of 3 MV; a post-accelerator system consisting of two electrostatic analyzers, a second stripper to remove E/z ambiguities, a 90° magnet ($m/\Delta m > 1000$) equipped so that the energy of the ions can be bounced at the source to select individual masses, and a focal-plane detection system.

The measurement of Pu isotopes by AMS has been demonstrated by Fifield *et al*. (1996). A simplified schematic representation of the AMS system is shown in Fig. 30.7. The instrument consisted of a high-intensity negative ion source that produced PuO^-; an injection system consisting of a 125 kV preaccelerator and a 90° magnet; a 14 UD Pelletron accelerator operating with a terminal

voltage of 3.5 MV with a gas stripper; a post-accelerator system consisting of a 90° magnet and a switching magnet; and a longitudinal-field ionization heavy-ion detector. This instrument had a limit of detection of approximately 10^6 atoms of Pu and was capable of determining $^{240}Pu/^{239}Pu$ ratios.

The ability to measure isotopic ratios in the range 10^{-12} to 10^{-15} potentially makes AMS an extremely powerful technique, particularly for the determination of naturally occurring minor actinide isotopes such as ^{230}Th in the presence of ^{232}Th and ^{236}U as well as in the presence of the more abundant isotope ^{238}U. Despite the demonstrated high sensitivity of AMS it has not become a widely used method for the determination of trace levels of actinide elements. AMS requires dedicated accelerator facilities and personnel. Whereas several AMS user facilities exist, none of these facilities perform trace actinide analyses routinely.

30.5.3 Resonant ionization mass spectrometry

High ionization efficiency and extremely low interferences from isobars and molecular ions are important factors for the measurement of low concentrations of actinides by mass spectrometric techniques. The availability of high-intensity narrow-bandwidth tunable lasers has enabled the application of laser spectroscopic techniques for highly efficient and selective ionization of specific elements. RIMS is the name given for the technique in which photons from laser light sources are used to selectively excite and ionize atoms before mass spectrometric analysis. The resonant ionization process is theoretically achievable for every actinide element (Hurst, 1987).

(a) RIMS fundamentals

Ambartzumian and Letokhov (1972) were the first to describe the process by which neutral atoms are selectively excited and ionized via a two-step photon absorption process. The primary strength of this technique as a source of ions for mass spectrometric analysis is the high selectivity in which atoms of a selected element are ionized. A laser is tuned to a wavelength that will promote a valence electron in a Z-selected atom from its ground state to an excited state. Additional resonance or non-resonance steps are then used to achieve nearly 100% ionization efficiency. Hence, by selecting a laser or lasers with energies matching specific bound electronic transitions of the atoms of interest, saturated resonant excitation and ionization can be achieved provided that the sum of the energies of the photons exceed the ionization potential of the element. Two simplified resonance ionization schemes that have been used for RIMS analysis of actinides are illustrated in Fig. 30.8. These discrete resonant transitions are critical for the RIMS technique because they are highly specific and extremely efficient processes, as high as 10^9 times as that for non-resonant background

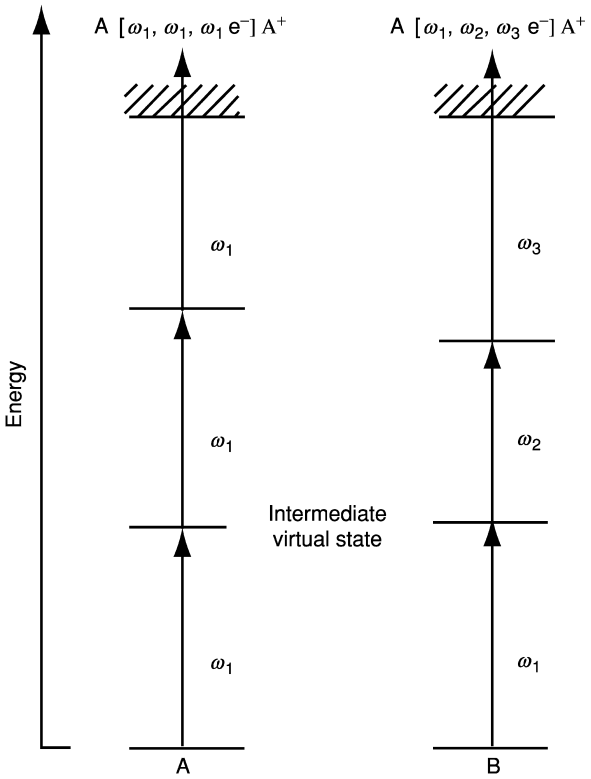

Fig. 30.8 *Simplified energy diagrams for two pathways that have used for RIMS analysis of actinide elements* (*after Krönert* et al., 1985*; Peuser* et al., 1985*; Trautmann,* 1992). *Pathway A is a two-photon transition followed by photoionization by a photon of the same energy. This resonance ionization pathway has been demonstrated for U* (*Krönert* et al., 1985). *Pathway B shows a three-step excitation and photoionization process using three photons possessing different energies. Pathway B has been demonstrated for Pu* (*Peuser* et al., 1985) *and Np* (*Trautmann,* 1992).

nuclides (Fassett *et al.*, 1983). In a typical two-photon process, an atom is first resonantly excited from the ground state to an excited electronic state and then subsequently ionized by absorbing a second photon. Some elements require a three-photon process: two photons for excitation to consecutive excited electronic states followed by a third photon for ionization. Multiple isotopes of a given element may be excited and ionized simultaneously, but not equally, by selecting broad bandwidth lasers. In RIMS, ionization is followed by mass spectrometric analysis for unambiguous identification on the basis of m/z. Mass analysis is typically performed using either magnetic sector or TOF mass spectrometers. Detection of ions is typically performed by a secondary electron multiplier or channel plate detectors.

(b) RIMS applications

Analysis by RIMS has been demonstrated for several actinides including Th, U, Np, and Pu. Detection of Pu isotopes by RIMS was first demonstrated by Donohue and Young (1983). A sample consisting of a mixture of NBS SRM 947e (^{238}Pu, ^{239}Pu, ^{240}Pu, and ^{241}Pu) and a ^{242}Pu standard was loaded onto a single Re thermal ionization source filament, atomized, and then excited and ionized with a nitrogen pumped dye-laser system. Several potential two-photon RIMS-active wavelengths in the excitation range of 431–451 nm were identified. After ionization, Pu ions were analyzed with a single-stage magnetic sector mass spectrometer that was scanned across the 238–250 amu mass range. The mass spectrum of this sample appeared with approximately the same abundances as it did when ionized by thermal ionization demonstrating that resonance ionization of Pu. This initial work with Pu did not, however, have sufficient sensitivity to achieve precision sufficient for analysis within a reasonable time. Further development of this method resulted in a methodology that, in addition to virtually eliminating isobaric interferences, demonstrated the potential of being at least as precise as TIMS (Donohue *et al.*, 1984). Improvements included the use of a single-wavelength RIMS process that used low-energy photons in the 590 nm region for resonant ionization of both U and Pu. A pulsed-heated filament synchronized with a 30 Hz pulsed-laser system resulted in a ten-fold improvement in sensitivity. Analysis was performed with a high-sensitivity tandem magnetic sector mass spectrometer.

Continued development and improvements in pulsed-laser systems have resulted in the ability to detect trace amounts of Pu by RIMS (Krönert *et al.*, 1985; Peuser *et al.*, 1985). Sensitivity was improved by applying a high-repetition pulsed-laser three-photon excitation and ionization scheme. A laser system was developed that consisted of a 6.5 kHz 30 ns pulse width Cu vapor laser for simultaneously pumping of three dye lasers. The dye lasers were scanned for the first two steps $\lambda_1 = 586.5$ nm and $\lambda_2 = 688.2$ nm using wavelength intervals of 0.05 nm whereas the third was made with part of the laser pump beam at $\lambda_3 = 578.2$ nm. TOF mass spectrometry was used for mass analysis and to minimize the background from non-resonantly produced ions. These improvements resulted in the ability to detect as few as 10^8 Pu atoms by RIMS and also demonstrated the capability to detect ^{237}Np (Trautmann, 1992). More recently RIMS has been applied to Pu and transplutonium elements with the potential of detecting 10^6 atoms in environmental samples (Erdmann *et al.*, 1998).

The RIMS method has been used for the measurement of U isotope ratios in several NBS standards. The ^{234}U/^{235}U ratio of NBS U930 and ^{235}U/^{238}U ratios of natural U, NBS U930, NBS U500, and NBS U750 were measured via resonant ionization followed by TOF mass spectrometry with a gated pulse counter designed specifically for the processing transient signals generated by the pulsed multiphoton ionization process. Replicate measurements of ^{235}U/^{238}U ratios in NBS U500 demonstrated accuracy and precision of 0.4%

(Green and Sopchyshyn, 1989). This work, however, was performed on relatively high concentrations of pure U samples.

Fearey *et al*. (1992) have developed a RIMS method for the determination of $^{230}Th/^{232}Th$ ratios for application in U-disequilibrium dating of geological samples. The use of both a broadband standing wave dye laser to excite both isotopes simultaneously and a scanned narrowband Ti:sapphire laser for excitation of each individual isotope was investigated. Mass spectrometry was performed with a single magnetic sector mass analyzer. Results indicated that the superior frequency stability of the narrowband Ti:sapphire laser compared to the broadband dye laser resulted in both higher accuracy and precision of the $^{230}Th/^{232}Th$ ratio determination. The method demonstrated a higher ionization efficiency than thermal ionization.

The extremely high efficiency and specificity of the resonant ionization process possesses enormous potential for high-sensitivity analysis of actinide elements. Single atom counting would be possible providing that suitably sensitive detection technologies could be developed and applied. The primary drawback of the technique is that ion signals generated by pulsed multiphoton ionization processes are inherently difficult to quantify with high precision. Despite its potential for high sensitivity RIMS has not become a widely used method for the determination of trace levels of actinide elements. The instrumentation for RIMS analysis is complex and is not well suited for routine analysis of geological, environmental, and biological samples. Further development of laser technologies may provide for less complex and less expensive RIMS instruments for routine analysis in the future. Application to complex geological, environmental, and biological samples will require utilization of chemical sample preparation procedures.

30.5.4 Inductively coupled plasma mass spectrometry

The ICP source is an effective and efficient atomization and ionization source that allows convenient introduction of aqueous samples. The high temperature of the ICP source efficiently ionizes actinide elements. When coupled with a quadrupole mass analyzer, the large dynamic range, nominal resolution, high-sample throughput and relatively simple spectra make ICPMS an extremely useful analytical tool for performing rapid trace analysis with <1 pg of an actinide. ICPMS instruments equipped with quadrupole mass analyzers became commercially available in the early 1980s and have since gained wide acceptance as a sensitive and accurate method for geoanalytical and environmental chemists. Actinides can be determined along with a suite of other trace elements simultaneously. Most aqueous samples can be analyzed with minimal pretreatment. ICPMS has rapidly emerged as one of the most versatile analytical techniques for trace actinide analysis.

(a) ICPMS fundamentals

Analysis by ICPMS typically requires a liquid sample. Bulk elemental analysis of solid materials by ICPMS requires the dissolution of the material followed by direct analysis. Acid dissolutions are usually performed so that the TDS values do not exceed 0.2%. In many cases ICPMS analysis can be performed directly on aqueous samples such as water and urine. Chemical preconcentration and separation of the actinides of interest from matrix elements can also be performed before analysis. Laser ablation (LA) has been used for direct sampling of solid materials. The analytical capabilities of LA–ICPMS have been described in Longerich *et al.* (1996). The focus of this section is aqueous sample ICPMS.

In ICPMS, a solution of the sample is introduced as an aerosol into the ICP source by a nebulizer in combination with spray chamber. Nebulization converts the liquid sample to an aerosol with a stable and reproducible size distribution. Because instrumental sensitivity and background values in ICPMS are dependent on the method of sample introduction, a variety of approaches have been designed to increase efficiency, reduce sample volume requirements, and reduce the effect of solvent loading on the plasma (Montaser *et al.*, 1998). Several types of nebulizers have been utilized with ICPMS including pneumatic, ultrasonic (USN), and electrothermal vaporization (ETV). Matrix reduction methods include FI as well as desolvation. The most common sample introduction method is pneumatic nebulization. Crain and Mikesell (1992) demonstrated that the higher efficiency of the USN system yielded improved sensitivity of ICPMS for the determination of U in industrial wastewater by an order of magnitude. FI preconcentrates analyte elements and reduces matrix effects. FI–ICPMS has been demonstrated for U analysis in environmental samples (Aldstadt *et al.*, 1996).

The aerosolized sample is swept into the ICP with a stream of Ar called the sample carrier gas. A typical ICP source contains a torch that is configured as three concentric quartz tubes through which Ar is flowing. The diameter of the largest tube is approximately 2 cm, and the Ar that flows through it at a rate of approximately 14 L min^{-1} is called the cooling gas. The middle tube contains Ar flowing at a rate of 0–1 L min^{-1}. This auxiliary flow can be used to affect the shape of the plasma and extend the torch life. The aerosol sample and carrier gas is introduced into the center tube with a flow of approximately 1 L min^{-1}. The torch is surrounded by a water-cooled induction coil that is powered by a radio frequency generator that creates the plasma. Typical frequencies are 27.5 and 40 MHz with a power of 1.3 kW. An impedance matching circuit is used to maintain a stable plasma. The source is called an inductively coupled plasma because the coil acts as an inductor. The ICP atomizes molecular species and ionizes the atoms.

The most critical component of an ICPMS is the interface that samples these ions and allows their transfer to a lower pressure region without significant bias.

Sampling is achieved by a sampling cone with an orifice approximately 1 mm in diameter. Ions flow through this orifice into an expansion chamber that is mechanically pumped to lower the pressure. The sampled material forms a supersonic jet. The jet flows through a skimmer cone also with an approximately 1 mm diameter orifice. Ions are extracted and focused toward the mass analyzer with a series of electrostatic ion lenses. Most commercial ICPMS instruments use a fast-scanning quadrupole mass analyzer operated at nominal mass resolution. Typical multielemental survey scan rates are 100 ms for a continuous scan from ^{6}Li to ^{238}U. Dedicated trace actinide analysis use programmed peak jumping with longer dwell times. Ions transmitted through the mass analyzer are typically detected with a channel electron multiplier. A schematic diagram of typical ICPMS instrumentation is given in Fig. 30.9. A thorough description of the principles of ICPMS operation and instrumentation can be found in Jarvis *et al.* (1991). Instrument control and data acquisition is controlled with a personal computer equipped with a software interface. For transuranic actinide analysis, the ion source or the entire instrument may be contained in a fume hood or gloved box.

Spectra generated by ICPMS are relatively simple, primarily singly charged ions with some additional doubly charged ions, oxides, and hydrides. The doubly charged ions, hydrides, and oxides can be minimized to approximately $<1\%$ of the parent ion. Actinide determination is straightforward due to the virtual absence of isobaric or molecular interferences in typical environmental and geological samples. Modern state-of-the-art ICPMS instruments possess 100 MHz μg^{-1} mL^{-1} sensitivity with backgrounds <0.5 cps. These figures correspond to a MDL <100 fg mL^{-1} for an actinide in solution, approximately 2.5×10^{8} atoms in a 1 mL sample, or 50 pg g^{-1} in solid samples assuming a typical 0.2% TDS sample dissolution. Equivalent MDLs are readily achievable for all other actinides.

Perhaps the technique that shows the most promise for improvements in routine actinide analysis is high resolution (HR)-ICPMS. This technique

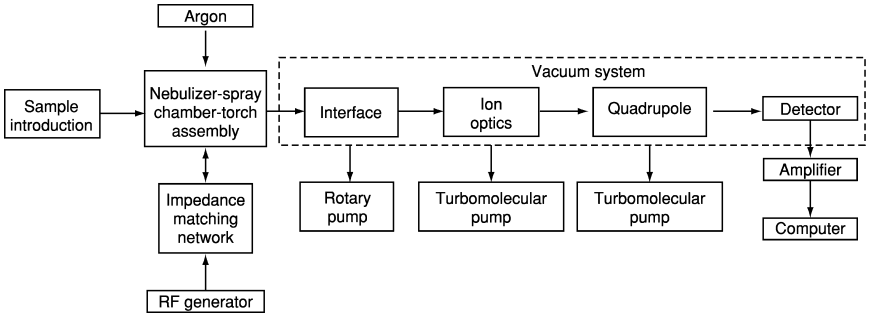

Fig. 30.9 *Schematic diagram of an ICPMS* (*after Wolf,* 1999).

combines an ICP source with a high-precision, double-focusing, mass analyzer. A review of HR-ICPMS instrumentation and applications has been published by Moens and Jakubowski (1998). The technique was first introduced in 1988 and the availability of commercial second- and third-generation HR-ICPMS instruments has made a significant impact on planetary, earth, and environmental chemistry. Commercial HR-ICPMS instruments, when operated at resolutions >2000, are capable of separating many interfering polyatomic ions from isotopes of interest. However, when operated at lower resolutions, a HR-ICPMS equipped with a single detector is capable of measurement with higher sensitivities, lower backgrounds, and higher precisions than typical quadrupole-based ICPMS instruments. A mass spectrum of a 1 ng mL^{-1} U- and Th-containing solution measured on a VG Elemental Axiom HR-ICPMS is given in Fig. 30.10. The spectrum was collected by the author using instrumental resolution setting of 460. Essentially all of the U and Th isotopes are isobar-free; however, ^{232}ThH and ^{238}UH can potentially bias ^{233}U and ^{239}Pu determinations if high ^{232}Th and ^{238}U concentrations are present. This instrument possesses a 2 GHz μg^{-1} mL^{-1} sensitivity and a <0.1 cps background corresponding to a MDL of <1 fg mL^{-1} for U in solution, approximately 2.5×10^{6} atoms of

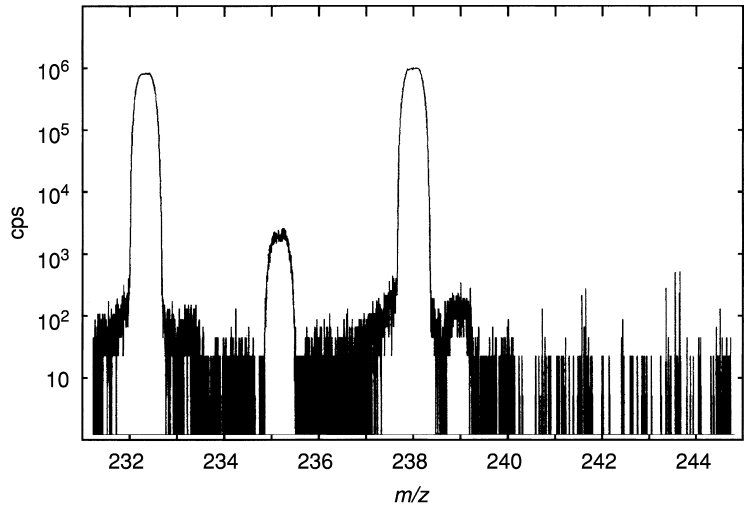

Fig. 30.10 *Spectrum of a* 1 ng mL^{-1} *U- and Th-containing sample. The spectrum was analyzed using conventional liquid sample introduction, pneumatic nebulization and a HR-ICPMS in the author's laboratory. The sample was prepared from NIST SRM* 3164 *and NIST SRM* 3159. *Note that even at these low concentrations, peaks from naturally occurring minor U isotopes* ^{234}U *and* ^{236}U *are evident. Also apparent is the contribution from the major* ^{238}U *peak to m/z* = 237 *and the contribution of* ^{238}UH *to m/z* = 239.

U in a 1 mL sample, or 1 pg g^{-1} in solid samples with assuming a typical 0.2% TDS sample dissolution. Equivalent MDLs are readily achievable for all other actinides. In addition to higher sensitivities, superior precisions can be achieved on HR-ICPMS instrumentation designed in a multicollector (MC) configuration. In this configuration, the precision of MC-ICPMS is comparable to TIMS.

(b) ICPMS applications

ICPMS can be used to determine total actinide element concentration, concentration of individual nuclides, and isotope ratios. The technique has been applied to the analysis of all of the long-lived naturally occurring actinides and environmental transuranic actinides. Elemental analysis of U and Th in geological samples with ICPMS requires the determination of the concentration of at least one isobar-free isotope and known isotopic distribution for the element. This is accomplished by direct determination of $m/z = 232$ for Th and $m/z = 238$ for U. Total U is calculated using the natural isotopic composition of U. Quantitative trace analysis of U and Th can be performed using internal standardization, external calibration, or isotope dilution. The most common approach to calibration is external calibration followed by linear regression. Internal standards such as ^{209}Bi (for ^{235}U, ^{238}U) (Wolf, 1998), another actinide (i.e. ^{232}Th for U analysis) (Crain and Mikesell, 1992), or an isotopic spike (i.e. ^{233}U, ^{235}U, or ^{236}U for U analysis) (Eggins *et al*., 1997) have been used to compensate for variations in instrumental response. These calibration methods typically yield uncertainties less than $\pm 10\%$ for a wide variety of matrices even at ultra-trace concentrations.

Isotope dilution (ID) is commonly employed to improve the accuracy of elemental ICPMS determinations. The suitability of ID-ICPMS analysis was evaluated for U determinations (Joannon *et al*., 1997). Uranium concentrations were measured in two separate solutions of six international rock reference materials, and the results differed by 1–3% for concentrations in the range of 10–400 ng g^{-1}. Isotope dilution ICPMS analysis can yield uncertainties less than $\pm 1\%$ in a wide variety of matrices.

Uranium and thorium isotope ratio measurements for U-disequilibrium studies using ICPMS and HR-ICPMS are straightforward because of the availability of the isobar-free nuclides ^{230}Th, ^{232}Th, ^{234}U, ^{235}U, and ^{238}U. Typical precisions for quadrupole-based ICPMS instruments range from 0.1 to 1.0%. These precisions limit its usefulness for measurement of many of the geologically important isotopic systems. Despite these limitations, the ease at which ICPMS is able to measure isotope ratios makes it useful for a few selected isotopic systems that do not require precisions better than approximately 0.1%. Superior precision can be achieved on HR-ICPMS instrumentation designed in a multicollector (MC) configuration. When used in the MC configuration, the precision of ICPMS is comparable to that of TIMS. A review of MC-ICPMS

instrumentation and applications including U and Th isotopic analysis has been reported (Halliday *et al*., 1998). This paper reviews results of replicate analysis of NIST SRM-906 measured by TIMS and MC-ICPMS. Precisions of approximately 1δ unit (2σ), comparable to the best achievable TIMS precision, were achieved. The external reproducibility of MC-ICPMS was superior to TIMS. Multicollector ICPMS will undoubtedly be established as the preferred method for U and Th isotopic determinations due to its high precision, ease of sample introduction, high sample throughout, and user-friendly interface.

ICPMS has been used to determine concentrations of U and Th in geological, environmental, and biological materials. A review of applications of ICPMS to geological materials has been published (Lipschutz *et al*., 2001). Environmental matrices such as wastewaters (Crain and Mikesell, 1992) and soils (Crain *et al*., 1995) have been analyzed by ICPMS. Biological materials studied include plant tissues (Alvarado *et al*., 1996), urine and lung fluid (Wyse *et al*., 1998), and fecal material (Twiss *et al*., 1994). Standard methods for the determination of ^{238}U and ^{232}Th in water (ASTM D5673-96, 1996a) and in soils (ASTM C1345-96, 1996c) have been published. The estimated MDLs for ^{238}U and ^{232}Th in water by ICPMS are 20 and 30 pg mL^{-1}, respectively. The ICPMS MDL for ^{238}U and ^{232}Th in soil are both 500 ng g^{-1}. These MDLs take into consideration a dilution factor of 200 from the soil dissolution procedures. A standard method for the determination of ^{234}U and ^{230}Th in soil by FI-ICPMS has also been published (ASTM C1310-95, 1995c). The estimated FI-ICPMS MDL for ^{234}U and ^{230}Th in soil are 2 and 5 pg g^{-1}, respectively.

The capabilities of both ICPMS and HR-ICPMS can easily be expanded to the determination of the transuranic actinides. In contrast to TIMS, direct analysis of actinides can be performed without any chemical separations. This approach can be complicated due to backgrounds caused by limitations in the mass analyzer, molecular interferences, and isobars. Chemical separation of U must be performed to minimize the contribution of ^{238}U to $m/z = 237$ during ^{237}Np determinations. ^{238}UH can interfere with trace determinations of ^{239}Pu particularly when the U/Pu ratio is $>10^6$. Chemical separation of U from Pu minimizes this effect. Isobaric interferences complicate total Pu isotopic analysis: ^{238}U interferes with ^{238}Pu, and ^{241}Am interferes with ^{241}Pu. Essentially all of these interferences can be minimized by utilizing one of the chemical separation procedures outlined in Section 30.2.2.

Vance *et al*. (1998) have recently assessed and reviewed the application of ICPMS for the routine determination of ^{237}Np in a variety of matrices and found that ICPMS achieves MDLs 1–2 orders of magnitude lower than alpha spectrometry. Yamamoto *et al*. (1994) used HR-ICPMS to measure fallout ^{237}Np in soil samples with concentrations as low as 15 fg g^{-1} of soil. Chemical separations were used to preconcentrate ^{237}Np from 10–40 g samples and ^{239}Np was used as a recovery spike. Crain *et al*. (1995) used ICPMS to determine concentrations of several long-lived actinides including ^{237}Np and ^{239}Pu in soil leachates with MDLs of 20 fg mL^{-1} of solution sample. These MDLs were

achieved using an USN and peak jumping for maximum sensitivity. ICPMS has also been used for the determination of ^{239}Pu in urine for bioassay (Wyse *et al.*, 1998). A recent study of the application of IDMS to the transuranic actinides achieved LOQs for ^{237}Np, ^{239}Pu, ^{239}Pu, ^{241}Am, and ^{244}Cm of 20 pg for each nuclide (Wolf, 1998). These analyses were performed using pneumatic nebulization on a quadrupole-based ICPMS designed in a containment hood. Considering the sensitivities of modern state-of-the-art instruments, MDLs of $<$100 fg in a 1 mL sample are readily attained for isobar-free actinides by ICPMS (Brenner *et al.*, 1998). If 1 mBq is assumed to be the MDL for routine alpha-spectrometric actinide determination, then ICPMS should possess higher sensitivities than alpha spectrometry for actinides with $t_{1/2} > 1400$ years.

HR-ICPMS and MC-ICPMS are capable of even greater sensitivities and precisions for trace transuranic actinide determination. HR-ICPMS has been used for the determination of ^{239}Pu, ^{240}Pu, and ^{242}Pu isotope ratios in soils from the former Semipaltinsk nuclear test site in the former USSR (Yamamoto *et al.*, 1996). Ratio measurements with precision of 5% could be achieved with as little as 100 fg mL^{-1} of solution. However, to discriminate between different source materials on the basis of Pu isotopic ratios requires precisions $<$1% at ultra-trace concentrations. Taylor *et al.* (2001) have determined Pu isotope ratios in solutions containing $<$100 fg mL^{-1} with precisions of 1.4% (2σ). These high precisions were achieved utilizing a MC-ICPMS along with a ^{236}U/^{233}U double spike to correct for instrument drift. High sensitivity of MC-ICPMS allowed the determination of ^{242}Pu/^{239}Pu ratios. MDLs $<$1 fg mL^{-1} that can be attained for isobar-free actinides by HR-ICPMS and MC-ICPMS. The addition of USN or other low-flow nebulizers to such systems could lower these MDLs by an order of magnitude. Again, if 1 mBq is assumed to be the MDL for routine alpha-spectrometric actinide determination, then HR-ICPMS should possess higher sensitivities than alpha spectrometry for actinides with $t_{1/2} > 14$ years.

30.6 SUMMARY

The development of standard methods, improvements in chemical procedures, and technological advances in instrumentation have significantly enhanced capabilities in trace actinide determination. There are many methods available for the determination of trace concentrations of actinides in geological, environmental, and biological materials. A substantial database of standard analytical methods for actinide determinations has been compiled and is maintained by the ASTM. In the area of chemical procedures, the development of actinide-specific anion and extraction chromatographic resins has greatly simplified actinide chemical separations. These procedures are used in most laboratories that specialize in the determination of actinides in geological,

environmental, and biological samples. The impact that improved chemical procedures have on the sensitivity, precision, and accuracy of analytical methods cannot be underestimated.

Because of the numerous and complex factors involved in the overall quality of an analytical approach, direct comparison of the different techniques is difficult. A few general observations can be made. The actinides are the only family of elements whose concentrations can be determined entirely by direct radiometric counting techniques. Gamma spectrometry has the advantage of being the only non-destructive radiometric technique but it is limited in general applicability to all the actinides due to the absence of intense γ-rays. Essentially all but a few of the naturally occurring actinides and environmental transuranic actinides can be determined by gamma spectrometry. Alpha spectrometry can provide complete isotopic information for U and Th. However, alpha spectrometry, like all radiometric techniques, is fundamentally limited by the low specific activity of most of the naturally occurring actinides and environmental transuranic. Despite this limitation, alpha spectrometry has been one of the most frequently utilized techniques for the routine determination of actinides in geological, environmental, and biological samples. The principal reasons for this are experimentally adequate sensitivity and selectivity as well as instrumentation well adapted to high-throughput routine analyses. In cases where higher sensitivity and higher precision are required, TIMS has typically been employed. The primary drawback to routine utilization of TIMS is that the instrumentation is more complex than in alpha spectrometry and is less suited to routine high-throughput analysis. In theory, both AMS and RIMS have the potential for improved sensitivity and selectivity over TIMS. In practice, however, the complexity of the instrumentation required for actinide determination by AMS and RIMS have so far prevented their adaptation as routine methods.

Perhaps the most significant technological advancement in the area of trace element analysis has been the continuing development of ICPMS and its application to actinide determinations. The strength of ICPMS resides in its high sensitivity, multielement capability, and high-sample throughput. ICPMS has replaced INAA as the standard method for trace element analysis of geological materials. Commercially available quadrupole-based ICPMS instruments are well suited for routine determination of actinides in a variety of sample matrices. The sensitivity and precision of ICPMS is comparable to that of alpha spectrometry for all but the shortest-lived actinides. When configured as a multicollector instrument the sensitivity and precision of MC-ICPMS is comparable to TIMS. The sensitivity of MC-ICPMS is comparable to, or superior to that of RNAA, for the determination of ultra-trace elements. Both ICPMS and MC-ICPMS are supplanting other methods in laboratories that need to determine trace actinide concentrations with isotopic specificity. Further development of applications of the more recently available HR-ICPMS and

MC-ICPMS instruments for ultra-trace actinide determinations will certainly improve our understanding of the chemistry of the actinide and transuranic actinide elements in the environment.

LIST OF ABBREVIATIONS

AAS	atomic absorption spectrometry
AES	atomic emission spectrometry
AMS	accelerator mass spectrometry
ASTM	American Society for Testing and Materials
Bq	Becquerel
CMPO	octyl(phenyl)-*N*,*N*-diisobutylcarbamoylmethylphosphine oxide
cps	counts per second
Da	Dalton, unified atomic mass unit
DAAP	diamylamylphosphonate
DBM	dibenzoylmethane
dc	direct current
DDCP	dibutyl-*N*,*N*-diethylcarbamylphosphonate
DTPA	diethylenetriaminepentaacetic acid
ENAA	epithermal neutron activation analysis
EPA	Environmental Protection Agency
ETV	electrothermal vaporization
FES	flame emission spectrometry
FI	flow injection
FTA	fission track analysis
GDMS	glow discharge mass spectrometry
HDEHP	bis(2-ethylhexyl)phosphoric acid
H_2DEH[DMP]	bis(2-ethylhexyl)methanediphosphonic acid
HEDPA	1-hydroxyethylidenediphosphonic acid
HPGe	high-purity germanium
HPLC	high-performance liquid chromatography
HR-ICPMS	high resolution-inductively coupled plasma mass spectrometry
ICPAES	inductively coupled plasma atomic emission spectrometry
ICPMS	inductively coupled plasma mass spectrometry
ID	isotope dilution
ID-ICPMS	isotope dilution-inductively coupled plasma mass spectrometry
ID-TIMS	isotope dilution-thermal ionization mass spectrometry
INAA	instrumental neutron activation analysis

LA	laser ablation
LA-ICPMS	laser ablation-inductively coupled plasma mass spectrometry
LAMS	laser ablation mass spectrometry
LOQ	limit of quantitation
MC-ICPMS	multicollector-inductively coupled plasma mass spectrometry
MDL	minimum detection limit
NAA	neutron activation analysis
NBS	National Bureau of Standards
NIST	National Institute of Standards and Technology
PCNAA	preconcentration neutron activation analysis
PFA	perfluoroalkoxy
PTFE	polytetrafluoroethylene
rf	radio frequency
RIMS	resonance ionization mass spectrometry
RNAA	radiochemical neutron activation analysis
RSD	relative standard deviation
SEC	size exclusion chromatography
SEM	secondary electron multiplier
SID	surface ionization diffusion
SIMS	secondary ion mass spectrometry
SRM	standard reference material
SSMS	spark source mass spectrometry
TBP	tributyl phosphate
TDS	total dissolved solids
TIMS	thermal ionization mass spectrometry
TIOA	triisooctylamine
TOF	time-of-flight
TTA	thenoyltrifluoracetone
USN	ultrasonic nebulization
USTUR	United States Transuranium and Uranium Registries

ACKNOWLEDGMENTS

The author would like to thank his colleagues at Argonne National Laboratory for many informative discussions on the chemistry of actinide elements and his colleagues at Indiana State University for encouragement and support during the writing of this work. The author is especially grateful to his wife Heather for her assistance and support through the many evenings and weekends that were used to produce this work.

CHAPTER THIRTY ONE

ACTINIDES IN ANIMALS AND MAN

Patricia W. Durbin

31.1 INTRODUCTION

Protection of workers and the public has been the main objective of actinide biology research since its beginning in early 1942. It was recognized even before the fission chain reaction was demonstrated that nearly all of the isotopes of the newly created elements heavier than radium would be radioactive and emit alpha particles, and that, if taken into the body, they would be as damaging in the tissues as radium (Stone, 1951). Biological research with the actinides concentrated on quantifying their uptake and retention in tissues after introduction into the body by ingestion, inhalation, or injection (biokinetics, metabolism); identifying the nature of the radiation and/or chemical damage in the tissues with the greatest initial uptake, concentration, and longest retention; defining the radiation dose-dependent relationships between toxicity and actinide intake to blood.

Actinide biokinetics studies now include many species and the actinide sequence from $^{227}Ac^{3+}$ to $^{253}Es^{3+}$. Whole-body retention of several actinides has been measured in long-lived animals, in some cases for life span. Microscopic localization of actinides in the tissues has been investigated autoradiographically. Significant advances in the methods of aerosol preparation and inhalation exposure allowed quantification of deposition and retention of inhaled actinide particles in the lungs. Most of the biological investigations of internally

deposited actinides were undertaken to define their dose-dependent chronic radiotoxicity, which is manifested mainly as functional impairment and/or cancer induction in bone, liver, kidneys, and lung (when actinide aerosols are inhaled). Many of the actinide biology studies have been summarized (Zirkle, 1947; Voegtlin and Hodge, 1949, 1953; Thompson, 1962, 1989; Stover and Jee, 1972; Thompson and Bair, 1972; Hodge *et al.*, 1973; Nenot and Stather, 1979; Stannard, 1988; Lloyd *et al.*, 1993, 1994). As they became available, the data generated by those investigations were used to set and refine protection limits for actinide intakes into the body, both for workers and the public (Chalk River, 1949; NBS, 1953; ICRP, 1959, 1979, 1980, 1986, 1993, 1995). An introduction to the actinide biology literature is provided as an Appendix.

The biokinetic and toxicological data have generally been considered sufficient for radiation protection purposes, and with the exception of uranyl ion, less attention was given to understanding the chemical reactions of the actinides in the special chemical environments of the blood, tissue fluid, and tissues of the mammalian body.

Some of the aspects of actinide chemistry relevant to their uptake, distribution, and retention in the tissues of mammals have been reviewed (Durbin, 1962, 1975; Gindler, 1973; Taylor, 1973a,b; Bulman, 1978, 1980; Raymond and Smith, 1981; Duffield and Taylor, 1986; Katz *et al.*, 1986).

The chemical reactions of actinide ions in warm (37°C), nearly neutral (pH 7.4), dilute saline fluids of the mammalian body are dominated by hydrolysis and complexation (ICRP, 1972, 1986; Durbin, 1975; Duffield and Taylor, 1986; Taylor, 1998). After intake of an actinide in solution into the blood, ligand competition and exchange, in some cases facilitated by changes in local pH, determine its distribution among the tissues, presumably favoring those tissues or structural elements that contain or display the most stably binding bioligands on their surfaces.

31.2 INITIAL DISTRIBUTION OF ACTINIDES IN MAMMALIAN TISSUES

Access of foreign metal ions, in this case actinides, is most likely to occur by absorption from inhaled particles deposited in the lungs and from ingested food and water. Less likely modes of intake are through a contaminated wound or the broken skin. Once solubilized and transported into the blood, deposition in tissues and excretion of the absorbed actinides are essentially independent of the route of entry, for example, tissue deposition is equivalent for injected, inhaled, or ingested $^{239}Pu^{4+}$ citrate (Ballou *et al.*, 1972) and for a wide variety of uranium compounds (Voegtlin and Hodge, 1949, 1953; Tannenbaum, 1951b; Durbin and Wrenn, 1975). Parenteral injection (intravenous, iv; intraperitoneal, ip; intramuscular, im; subcutaneous, sc) has been a useful tool for investigating the chemically related factors that determine the disposition of actinides in the animal body. By placing solutions of actinide salts or complexes directly into the

blood or tissue fluid the experimental variables introduced by the efficient lung and gastrointestinal (GI) tract barriers are avoided. Comparable studies of the same actinide in several animal species help to differentiate between the chemical factors that are common across species and the biological factors that are species- or age-specific.

The initial distribution and excretion of soluble forms of the first ten actinides (Th through Es) plus Ac have been defined, in some cases in several animal species. Those basic biological data are collected in Tables 31.1–31.6; seven trivalent actinides including Pu^{3+} (rats, Table 31.1); five actinides injected in oxidation states greater than trivalent (rats, Table 31.2); actinide ions representing the four major oxidation states (mature female mice, Table 31.3); seven actinides considered to be long-term health hazards or with special radiological characteristics (young adult beagle dogs, Table 31.4); actinides in four major

Table 31.1 *Initial distribution of injected trivalent actinides in rats.*[a]

			Fractions of absorbed actinide (%)[b]				
			Tissues			*Excreta*	
Nuclide	*Mass injected* ($\mu g\ kg^{-1}$)	*Time* (days)	*Skeleton*	*Liver*	*Other tissues*[c]	*Urine*	*Feces and GI tract*
$^{227}Ac^{3+}$[d]	0.019	4	27	56	4	5	8
$^{239}Pu^{3+}$[e]	67	4	51	23	9	1	17
$^{241}Am^{3+}$[f]	0.12	4	35	42	3	10	10
$^{242}Cm^{3+}$[g]	1.6×10^{-3}	4	31	36	8	1	24
$^{249}Bk^{3+}$[h]	4×10^{-3}	5	54	16	9	15	6
$^{249,252}Cf^{3+}$[i]	0.02	4	64	14	4	7	11
$^{253}Es^{3+}$[j]	2.2×10^{-3}	7	69	7	2	11	11

[a] Investigators in the different laboratories used several strains of Wistar-derived albino rats. Ages at the time of injection were rarely stated; however, the reported body weights indicate a range of age from 60 to 150 days. For some incompletely reported studies, sex and body weight and/or age were obtained from archived data. Rats of both sexes are sexually mature at about 60 days, but this species does not achieve skeletal maturity. Because active growth centers remain at the ends of some long bones and vertebrae after 150 days of age, the skeletons of the rats used in these studies must be considered to be still growing (Simpson *et al.*, 1950).

[b] Data are normalized to 100% absorption and 100% material recovery; discrepancies are due to rounding.

[c] Includes kidneys, range 0.6 to 2.2%; ^{249}Bk and ^{253}Es studies also include full GI tract.

[d] Hamilton (1956); 180 g females; im injection of $^{227}Ac^{3+}$ in 0.1 M Na citrate (73% absorbed).

[e] Carritt *et al.* (1947); 225 g young males; iv injection of $^{239}Pu^{3+}$ in 0.14 M NaCl.

[f] Durbin *et al.* (1969); Durbin (1973); 240 g, 110-day-old females; im injection of $^{241}Am^{3+}$ in 0.1 M Na citrate (99% absorbed).

[g] Scott *et al.* (1949b); 190 g females; im injection of $^{242}Cm^{3+}$ in 0.14 M NaCl, pH 5 (92% absorbed).

[h] Hungate and Baxter (1972); 400 g males; iv injection of $^{249}Bk^{3+}$ in 0.01 M HCl.

[i] Durbin (1973); 250 g, 130-day-old females; im injection of $^{249,252}Cf^{3+}$ in 0.1 M Na citrate (98% absorbed).

[j] Smith (1972); 300 g females; iv injection of $^{253}Es^{3+}$ in HNO_3, pH 2.

$^{230}UO_2^{2+}$[i]	3×10^{-5}	4	11	0.2	12	0.9	76	–
$^{233}UO_2^{2+}$[j]	200	4	21	0.2	20	2	56	–
$^{238}PuO_2^{2+}$[k]	0.04	15	64	7	1	4	5	19
$^{239}PuO_2^{2+}$[l]	67	4	66	10	2	8	8	6

[a] Investigators in the different laboratories used several strains of Wistar-derived albino rats. Ages at the time of injection were rarely stated; however, the reported body weights indicate a range of age from 60 to 150 days. For some incompletely reported studies, sex and body weight and/or age were obtained from archived data. Rats of both sexes are sexually mature at about 60 days, but this species does not achieve skeletal maturity. Because active growth centers remain at the ends of some long bones and vertebrae after 150 days of age, the skeletons of the rats used in these studies must be considered to be still growing (Simpson *et al.*, 1950).

[b] Data are normalized to 100% absorption and 100% material recovery; discrepancies are due to rounding.

[c] Hamilton (1953); 215 g females; im injection of $^{227}Th^{4+}$ in 0.05 M Na citrate (94% absorbed).

[d] Hamilton (1948a); 190 g females; im injection of $^{233}Pa^{5+}$ in 0.14 M NaCl, pH 1.9 (42% absorbed).

[e] Lanz *et al.* (1946); 270 g males; im injection of $^{239}Np^{4+}$ in 0.14 M NaCl, pH 2.6 (64% absorbed).

[f] Talbot *et al.* (1990); 300 g, 140-day-old males; iv injection of $^{237}Pu^{4+}$ plus 30 Bq of other alpha-emitting Pu isotopes, 'impure ^{237}Pu', in citrate buffer.

[g] Carritt *et al.* (1947); 225 g, young males; iv injection of $^{239}Pu^{4+}$ in citrate buffer.

[h] Morin *et al.* (1973); 275 g, sex not specified; im injection of $^{237}NpO_2^{+}$ in HNO_3, pH 1.5 (43% absorbed).

[i] Hamilton (1948b); 190 g females; im injection of $^{230}UO_2^{2+}$ in 0.14 M NaCl (94% absorbed).

[j] Hamilton (1947a); 180 g males; im injection of $^{233}UO_2^{2+}$ in 0.14 M NaCl (97% absorbed).

[k] J. G. Hamilton (unpublished data); 200 g females; im injection of $^{238}PuO_2^{2+}$ in 0.1 M Na citrate and 0.01 M Na bromate (71% absorbed).

[l] Carritt *et al.* (1947); 225 g, young males; iv injection of $^{239}PuO_2^{2+}$ in dilute HNO_3.

oxidation states (mature Macaque monkeys, Table 31.5; mature Kenya baboons, Table 31.6); isotopes of industrially important Pu^{4+} and UO_2^{2+} and results from a $^{241}Am^{3+}$ accident case (adult human males, Table 31.7).

The data sets selected for inclusion in Tables 31.1–31.7 met the following criteria: The actinide studied was injected as an ultrafilterable citrate complex or a chloride or nitrate solution sufficiently acidic to avoid hydrolysis and colloid

Table 31.3 *Initial distribution of intravenously injected actinides in mice.*[a]

		Fraction of injected actinide at 1 day (%)[b]					
		Tissues				*Excreta*	
Nuclide	*Mass injected* ($\mu g\ kg^{-1}$)	*Skeleton*	*Liver*	*Kidneys*	*Other tissues*	*Urine*	*Feces and GI tract*
$^{241}Am^{3+}$[c]	0.23	27	50	1	6	14	3
$^{238}Pu^{4+}$[c]	0.09	31	50	2	8	4	5
$^{237}NpO_2^+$[d]	200	37	14	2	6	39	2
$^{232,234,235}UO_2^{2+}$[e]	100	17	1	19	3	58	2

[a] Sexually and skeletally mature female Swiss-Webster mice 90 to 160 days old (35 g body weight) (Durbin *et al.*, 1992).
[b] Data are normalized to 100% material recovery; discrepancies are due to rounding.
[c] Durbin *et al.* (1994); $^{241}Am^{3+}$ or $^{238}Pu^{4+}$ in 0.008 M Na citrate and 0.14 M NaCl, pH 3.5.
[d] Durbin *et al.* (1994); $^{237}NpO_2^+$ in 0.14 M NaCl, pH 3.5.
[e] Durbin *et al.* (1994); $^{232}UO_2^{2+}$ plus $^{234,235}UO_2^{2+}$ in 0.14 M NaCl, pH 3.5.

Table 31.4 *Initial distribution of intravenously injected actinides in beagle dogs.*[a]

			Fraction of injected actinide (%)[b]					
			Tissues				*Excreta*	
Nuclide	*Mass injected* ($\mu g\ kg^{-1}$)	*Time* (days)	*Skeleton*	*Liver*	*Kidneys*	*Other tissues*	*Urine*	*Feces*
$^{241}Am^{3+}$[c]	0.54	1–21	31	52	0.7	5	10	1
$^{243,244}Cm^{3+}$[d]	0.042	6–20	44	38	0.7	6	8	4
$^{249}Cf^{3+}$, $^{252}Cf^{3+}$[e]	0.0005–0.7	1–21	49	18	1	10	16	7
$^{253}Es^{3+}$[f]	10^{-4}	21	54	12	0.6	7	19	7
$^{228}Th^{4+}$[g]	3×10^{-3}	1–23	66	4	3	15	10	2
$^{239}Pu^{4+}$[h]	2.2	1–22	51	34	0.5	2	5	8
$^{233}UO_2^{2+}$[i]	300	7	8	1	7	2	83	~0

[a] Beagle dogs were bred and raised in the University of Utah colony (Rehfield *et al.*, 1972; Stover and Stover, 1972). Both sexes, 15 to 18 months old (mean body weight 10 kg), were sexually mature at the time of injection. Skeletal growth centers were united except in the ribs, but bone remodeling was still active in the spongy (trabecular) bone sites at the ends of some long bones and in the ribs and vertebrae (Dougherty, 1962).
[b] All actinides were injected iv in 0.08 M Na citrate buffer, pH 3.5; data are normalized to 100% material recovery.
[c] Lloyd *et al.* (1970); average dosage shown for dogs given 0.26 to 0.81 $\mu g\ kg^{-1}$.
[d] Lloyd *et al.* (1974).
[e] Lloyd *et al.* (1972a, 1976); Atherton *et al.* (1972); injected either $^{249}Cf^{3+}$ or $^{252}Cf^{3+}$.
[f] Lloyd *et al.* (1975).
[g] Stover *et al.* (1960), Lloyd *et al.* (1984a).
[h] Stover *et al.* (1959, 1972); average dosage shown for dogs given 0.25 to 4.85 $\mu g\ kg^{-1}$.
[i] Stevens *et al.* (1980).

Table 31.5 *Initial distribution of injected actinides in Macaque monkeys.*[a]

			Fractions of absorbed actinide (%)[b]					
			Tissues				*Excreta*	
Nuclide	*Mass injected* ($\mu g\ kg^{-1}$)	*Time* (days)	*Skeleton*	*Liver*	*Kidneys*	*Other tissues*	*Urine*	*Feces and GI tract*
$^{241}Am^{3+}$[c]	0.12	8	25	56	0.6	7	9	2
$^{238}Pu^{4+}$[d]	0.04	8	28	61	0.6	5	3	2
$^{237}NpO_2^+$[e]	42	4	42	10	1	3	43	0.5
$^{233}UO_2^{2+}$[f]	18	3	3	0.5	9	2	84	1

[a] Macaque monkeys (*Macaca mulatta*, *Macaca fasicularis*) were caught in the wild. Both sexes were used (about 80% were females), and injected at 5 to 15 years of age (2.5–11 kg body weight). They were sexually and skeletally mature; skeletal maturity was verified roentgenographically (Van Wagenen and Asling, 1958).
[b] Data are normalized to 100% absorption and 100% material recovery; discrepancies are due to rounding.
[c] Durbin (1973); im injection of $^{241}Am^{3+}$ in 0.08 M Na citrate buffer, pH 3.5 (98% absorbed); average dosage shown for monkeys given 0.03 to 0.17 $\mu g\ kg^{-1}$.
[d] Durbin *et al.* (1985); iv or im injection of $^{238}Pu^{4+}$ in 0.08 M Na citrate buffer, pH 3.5 (91% absorbed); average dosage shown for monkeys given 0.017 to 0.112 $\mu g\ kg^{-1}$.
[e] Durbin *et al.* (1987); im injection of ^{237}Np in 0.08 M Na citrate buffer, pH 3.5, probably a mixture of NpO_2^+ and Np^{4+} (99% absorbed).
[f] P. W. Durbin and N. Jeung unpublished data; im injection of $^{233}UO_2^{2+}$ in 0.14 M NaCl (100% absorbed).

formation in the medium; values were reported for the actinide content of all soft tissues, the whole skeleton, and the separated urine and feces; the fraction retained at the wound site was reported for im injection studies.

The skeleton is a major deposition site for the actinides in all of the oxidation states that have been administered to animals. Liver is the most important soft tissue deposition site for all of the actinides except UO_2^{2+}. Shortly after intake to blood, the skeleton and liver (skeleton and kidneys in the case of UO_2^{2+}) account for about 90% of the actinide in the body (Tables 31.1–31.6; ICRP, 1972). It is clear that both bone and liver possess appropriate binding sites and ligands with high affinities for actinide ions, but the partitioning of the individual actinides between deposition in bone and liver varies with their chemical properties, most importantly electronic charge and ionic radius.

The initial partitioning of an actinide between deposition in bone and liver is likely to depend primarily on the relative affinities of the ligands on the anatomical surfaces of bone and on liver cell membranes for binding that actinide in competition with the ligands that transport it in the blood. The outcome of those competitions will be modulated by the relative abundances of ligands (binding sites) on the bone surfaces and hepatic cell membranes that are exposed

[e] Includes kidneys.
[f] Ralston *et al.* (1986); iv injection of $^{239}NpO_2^{2+}$ in 0.01 M $NaHCO_3$.
[g] Lipsztein (1981); iv injection of $^{237}UO_2^{2+}$ in HNO_3, pH 1.6.

to the circulating fluids, the relative rates of blood flow through those tissues, and the concentrations of the transport ligands.

31.2.1 Trivalent actinides

The initial distributions of Am^{3+} in the tissues of the six mammals (Tables 31.1–31.7) agree well with one another, as do the overall distributions of Cm^{3+} in the rats, dogs, and baboons (Tables 31.1, 31.4, and 31.6), and those of Cf^{3+} and Es^{3+} in the rats and dogs (Tables 31.1 and 31.4). Bone and liver are the major initial deposition sites. The larger animals (dog, baboon) retained more Am^{3+}, Cm^{3+}, Cf^{3+}, and Es^{3+} in the bulk soft tissues, mainly muscle and pelt, than did the rats and mice. Renal excretion of the trivalent actinides is limited. It tended to be somewhat greater for the heavier than for the lighter members of the series, and to be greater for the dogs, who were given iv injections of actinide solutions containing large excesses of citrate buffer. Impeded filtration through the kidneys into urine indicates that uptake of the trivalent actinides in the target tissues is rapid and/or that the major fraction of circulating actinide is bound to nonfilterable protein.

In both the rats (Table 31.1) and the dogs (Table 31.4), and similarly to the behavior of the lanthanides, the initial skeletal deposition of the trivalent actinides increases and the partitioning between deposition in bone and liver

[a] Robinson *et al.* (1983); 64-year-old man; accidental high-level skin burns and abrasions contaminated with ~3 mCi of ^{241}Am in hot 7 M HNO_3; 10 μCi absorbed and retained as estimated from external photon measurements.
[b] Talbot *et al.* (1993); two male volunteers, average age 66 years, average body weight 73 kg; iv injection of $^{237}Pu^{4+}$ in 0.03 M Na citrate; tissue distribution estimated from collected excreta and external photon measurements.
[c] Includes kidneys.
[d] Original data of Bernard and Struxness (1957) normalized to 100% material recovery; bedridden terminally ill adult males with inoperable brain tumors; tissue distributions estimated from autopsy specimens. Case 6, iv injection of $UO_2(NO_3)_2$ enriched with $^{234,235}UO_2^{2+}$, age 60 years, body weight 57 kg. Case 8, iv injection of UCl_4 enriched with $^{234,235}U^{4+}$in in 0.2 M acetate buffer, pH 4.7, age 56 years, body weight 63 kg; most of the U detected in 'other tissues' was in the spleen (6.7%).

shifts from favoring liver to favoring bone with the decrease in ionic radius (r) that accompanies the addition of f-shell electrons (Durbin, 1962, 1973). Within each series, that is also the trend of increasing stability of complexes.

Within the lanthanide and actinide series, the stabilities of complexes with the same ligand increase with decreasing ionic radius (Cotton and Wilkinson, 1980), as illustrated for the actinide oxalate and citrate complexes in Table 31.8. It is reasonable to expect that the stabilities of their complexes with other biologically important ligands such as phosphate, for which stability constants are unavailable, will exhibit a similar trend. For the same ligand, complexes of the trivalent actinides tend to be more stable than those of their lanthanide analogs with the same ionic radii. For example, the EDTA complexes of the trivalent actinides are, on average, one to two orders of magnitude greater than those of the EDTA complexes with lanthanides of the same ionic radii (Sillen and Martell, 1964; Ahrland, 1986; Hulet, 1986).

For the purposes of this discussion, initial skeletal deposition is expressed as the skeletal fraction of the initial body burden ($BB_{0,\%}$ of injected amount), where BB_0=skeleton + soft tissue + $liver_{max}$=100% – Σ (urine). Skeleton, soft tissue, and urine are the measured amounts of actinide in those specimens (Table 31.1), and $liver_{max}$ is the sum of the measured amounts of actinide in the liver, GI tract plus contents, and passed feces. Biliary excretion of liver actinide into the GI tract and feces will be discussed in the context of actinides in

the liver. The initial skeletal fraction, skeleton/BB_0, normalizes the data by accounting for the somewhat variable early urinary excretion. Initial skeletal fractions of the trivalent lanthanides and actinides in rats are plotted vs ionic radius in Fig. 31.1. The straight-line segments were fitted by linear regression analysis to serve as eye guides. The initial skeletal fraction of Pu^{3+} lies so far

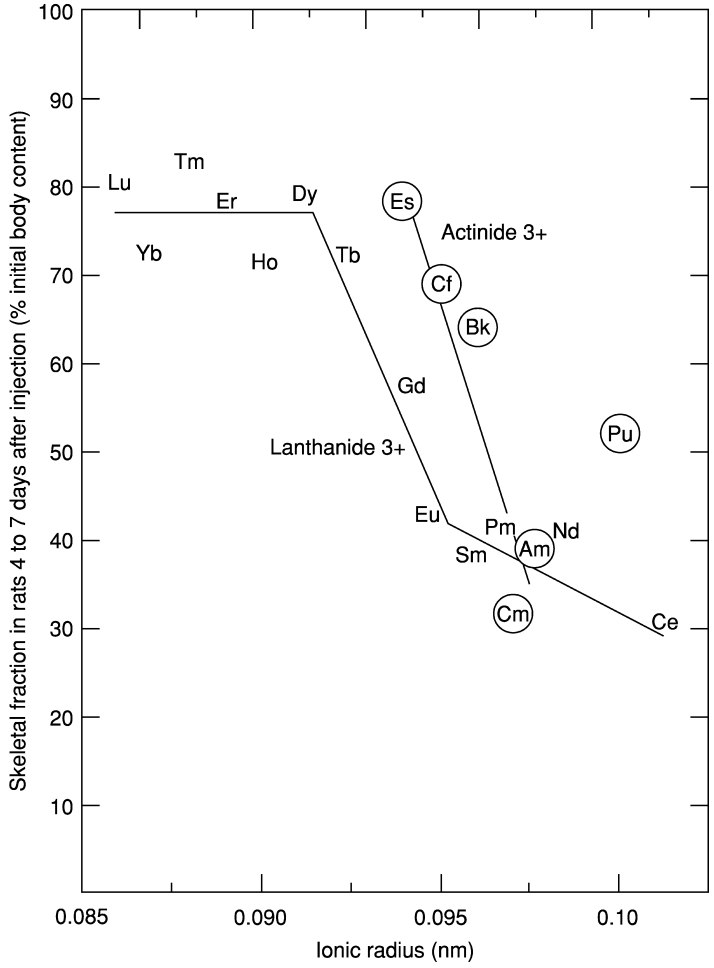

Fig. 31.1 *Deposition of trivalent actinides and lanthanides in the skeleton of rats at* 4 *to* 7 *days after injection, expressed as percent of initial body content* (%BB_0), *and shown as functions of their six-coordinate ionic radii. from the trend line for the other trivalent actinides that it was not included in determining the regression line for the trivalent actinides. The aberrant behavior of Pu^{3+} supports the view that Pu^{3+} will be oxidized to Pu^{4+} *in vivo* (Carritt *et al.*, 1947; Scott *et al.*, 1948b).

The plot of initial skeletal fraction vs ionic radius for the trivalent actinides and lanthanides in rats (Fig. 31.1) is discontinuous. Six-coordinate ionic radii are those reported by Shannon (1976). Fig. 31.1 exhibits three distinct regions,

as follows: For the lanthanides, there is a plateau from Lu^{3+} to Tb^{3+} ($r < 0.0925$ nm), followed by a steeply declining region from Tb^{3+} to Eu^{3+} ($r = 0.0925$–0.095 nm), and a less steeply declining segment from Eu^{3+} to Ce^{3+} ($r \geq 0.095$ nm). For the trivalent actinides, Es^{3+} to Am^{3+} ($r = 0.094$–0.0975 nm), only the steeply declining central region was observed.

The initial skeletal fractions of Am^{3+} and Cm^{3+} in rats lie in the region defined by the larger lighter lanthanides; they resemble Pm^{3+}, which has about the same ionic radius, but two less f-shell electrons. The initial skeletal fraction of Es^{3+} lies within the region defined by the smaller heavier lanthanides; the initial skeletal fractions of Bk^{3+}, Cf^{3+}, and Es^{3+} most closely resemble the lanthanides, Gd^{3+}, Tb^{3+}, and Dy^{3+}, respectively, which have ionic radii 0.0025 nm smaller, on average, and one less f-shell electron.

If the increase in initial skeletal fraction with decreasing ionic radius found for the lanthanides and trivalent actinides depended only on their affinities for bone surface ligands (bone mineral and/or protein), a more gradual trend would be expected. The discontinuous pattern observed resembles the relationship between the size of a multivalent cation and its ability to occupy both of the similar but unequal metal-binding sites of transferrin (Tf), the iron-transport protein of mammalian blood plasma (Pecoraro *et al.*, 1981). The combined data for the skeletal deposition of the trivalent actinides and lanthanides in rats and metal binding to Tf suggest that the stabilities of their Tf complexes strongly influence the skeletal deposition of these trivalent metal ions.

Studies in several animal species show that a number of soft tissues other than liver accumulate radiologically significant concentrations of trivalent actinides (Lloyd *et al.*, 1970, 1974, 1975, 1976; Atherton and Lloyd, 1972; Durbin, 1973; Guilmette *et al.*, 1980). Autoradiographs of soft tissues of rats, dogs, monkeys, and baboons show that the initial actinide deposits are located extracellularly in the connective tissue components (Taylor *et al.*, 1969a,b, 1972a; Lloyd *et al.*, 1970; Durbin, 1973; Guilmette *et al.*, 1980). The connective tissue at most, but not all, of the sites of actinide deposition was shown histochemically to contain substances that react positively to the periodic-acid Schiff (PAS) stain for mucins, glycogen, and glycoproteins (Pearse, 1961; Taylor *et al.*, 1972a). The trivalent actinides were found deposited in the intertubular connective tissue of the kidneys of all of the species, and in the dogs, also in the capillary tufts and in or on the basement membrane of the glomerular capsule.

The most widely distributed deposition site identified in all of the tissues examined from all of the animals studied is the medial layer of the small arterioles, where the nuclides appeared to be localized in the connective tissue and not the smooth muscle layers. There was also some selective localization in specialized connective tissue components of the aorta, coronary arteries, and heart valves. Skeletal muscle and pelt contribute 43 and 14%, respectively, of the body weight of the study animals (Tables 31.1–31.6). Although the concentrations of the trivalent actinides in those tissues are low (0.5–2.5% per kg), most of the actinide in the body, apart from liver and skeleton, is associated with those

large tissue masses. Actinides in the walls of their abundant blood vessels can account for much of the early actinide content of these tissue masses.

All of the investigated trivalent actinides concentrated in the interfollicular connective tissue of the thyroid glands of the dogs, but not the primates. The stability of that binding was demonstrated by prolonged retention of $^{241}Am^{3+}$ (Lloyd *et al.*, 1970) and $^{249}Cf^{3+}$–$^{249}Bk^{3+}$ (Taylor *et al.*, 1972a) and by the recovery with the insoluble connective tissue fraction of 95% of ^{241}Am in a homogenate of the thyroid of a $^{241}Am^{3+}$ injected dog (Stevens *et al.*, 1969). Combined, all of these observations suggest that the trivalent actinides bind to glycoprotein in the connective tissue ground substance, a hypothesis supported by the affinity of purified bone glycoprotein for $^{241}Am^{3+}$ *in vitro* (Chipperfield and Taylor, 1968, 1972).

31.2.2 Tetravalent and pentavalent actinides

Thorium, protactinium, and plutonium were injected in animals as Th^{4+}, Pa^{5+}, and Pu^{4+}, respectively, their most stable states in biological systems (dilute saline solution, mild redox conditions, nearly neutral pH). The biological data indicate that Np^{4+} and U^{4+} tend to be unstable *in vivo* (Tables 31.2 and 31.7).

(a) Th^{4+}

Tracers of citrate complexes of two shorter-lived Th isotopes were injected im in rats ($^{227}Th^{4+}$, Table 31.2) and iv in dogs ($^{228}Th^{4+}$, Table 31.4). Absorption of Th^{4+} from the im injection site in the rats was nearly complete in 8 days. There was no evidence of intravascular colloid formation in the iv-injected dogs. The initial distributions of Th^{4+} in the rats and dogs agreed well. Bone is the predominant deposition site of Th^{4+}. Liver deposition is low, but soon after injection, kidneys and other soft tissues account for a substantial fraction of the body content (13 to 18% at 1 to 23 days). About 10% of the injected Th^{4+} is excreted in the urine, mainly in the first 24 h. Fecal excretion is low for the rats and negligible for the dogs.

Autoradiographs were prepared from the soft tissues of a dog that died 10 days after sc injection of a lethal dose of $^{228}Th^{4+}$ (10 μCi kg^{-1} of $^{228}ThCl_4$, pH 4–5) (Erleksova, 1960). The published autoradiographs are overexposed, and the distribution of the $^{228}Th^{4+}$ is obscured by tracks from the ingrown $^{224}Ra^{2+}$ and ^{220}Rn daughters. There is phagocytized radiation-damaged cell debris in many of the tissues. However, the general pattern of Th^{4+} distribution in the soft tissues can be discerned, and it is nearly the same as that described above for Am^{3+} and Cf^{3+} in dogs (Taylor *et al.*, 1969b, 1972a; Lloyd *et al.*, 1970). Some Th^{4+} in the liver was contained within hepatic cells. In the kidneys, Th^{4+} was associated with the tubular epithelium and with cell debris in collecting tubules. Combined, these observations were taken as evidence for the intratubular dissociation of an ultrafilterable low molecular weight Th^{4+} complex present

in the plasma. The $^{228}Th^{4+}$ alpha tracks appeared mainly, if not entirely, to be located in the connective tissue components of the organs examined, including thyroid, testis, and adrenal glands, and in the medial layers of arterioles. In the lungs, the Th^{4+} was accumulated in the bronchiolar cartilages. Slow release of $^{228}Th^{4+}$ from the soft tissues of the dogs (Stover *et al.*, 1960) and the great affinity of bone glycoproteins for Th^{4+} *in vitro* (Chipperfield and Taylor, 1972) suggest that Th^{4+} can bind stably to PAS-positive proteins in connective tissue.

(b) U^{4+}

The initial distribution of U after iv injection of U^{4+} has been reported for rats (Neuman, 1949) and an adult man (Bernard and Struxness, 1957). The details of the human study are given in Table 31.7. The rats (63 days old males and 112 days old females, 200 g body weight) were injected iv with natural UCl_4 in 0.2 M acetate buffer, pH 4.6, at doses ranging from 1.5 to 3 mg U per kg. Excreta and all tissues were analyzed for U by a fluorometric method (Flagg, 1949). In the female rats killed at 5 days, the injected U was distributed as follows [original data of Neuman (1949) normalized to 100% material recovery]: liver and spleen 59%, kidneys 4%, skeleton 7%, urine 21%, feces 6%.

The initial distributions of U injected iv as U^{4+} in the rats and the man can be compared with those of soluble Pu^{4+} and UO_2^{2+} (Tables 31.2 and 31.7). The initial urinary excretion of the U was much greater than for Pu^{4+}, but much less than for UO_2^{2+}. Deposition of the U in bone was much less than for Pu^{4+} and about the same as for UO_2^{2+}. Deposition of the U in the kidneys was much less than would be expected for UO_2^{2+}. The U retained in the liver and spleen of the man was less than for Pu^{4+}, but much greater than for UO_2^{2+}; in the rats, retention of the U in liver and spleen was much greater than would be expected for either soluble Pu^{4+} or UO_2^{2+}.

Several U compounds, including UCl_4, are unstable *in vivo*, and are slowly oxidized to UO_2^{2+} in 0.025 M HCO_3^- pH 7.4 (Dounce, 1949). If, similarly to Th^{4+} and Pu^{4+}, U^{4+} circulated as a nonfilterable plasma protein complex that was cleared slowly from the plasma, only a small amount would be excreted by the kidneys. However, an important fraction of the U injected as U^{4+} was excreted in the urine during the first day (14 and 24% by the rats and the man, respectively). The presence of filterable U in the circulation is evidence that some of the U^{4+} was oxidized to UO_2^{2+} within minutes after the injection. The rats excreted an additional 7% of the U in the urine in days 2 to 5 (Neuman, 1949), and the man excreted an additional 44% in the interval 2 to 21 days, (Table 31.7), providing evidence of slow continuous oxidation to UO_2^{2+} of U^{4+} initially sequestered in the tissues. Parenterally injected UCl_4 is only about one-tenth as toxic to the kidneys of rats as $UO_2(NO_3)_2$; the LD_{50s} at 14 to 21 days are 25 and 2.5 mg U per kg body weight, respectively (Yuile, 1973). *In vivo* oxidation of U^{4+} and release of UO_2^{2+} into the circulation apparently proceed sufficiently slowly that the kidneys are not exposed to a toxic level of UO_2^{2+}.

(c) Np^{4+}

Tetravalent $^{239}Np^{4+}$ and $^{237}Np^{4+}$ have been studied in rats (Table 31.2; Moskalev *et al.*, 1979; Paquet *et al.*, 1996; Ramounet *et al.*, 1998). The biological behavior of Np^{4+} would be expected to resemble Pu^{4+}, based on similar chemical properties. Deposition of Np^{4+} in the skeleton is about the same as that of Pu^{4+} and within the range of values reported for initial skeletal Pu^{4+} content of rats (ICRP, 1972). However, the Np^{4+} content of the liver was well below that expected based on similarity to Pu^{4+}. Urinary excretion of Np^{4+} was 24% in 4 days, more than 10 times that found for Pu^{4+}, but less than the early urinary excretion of NpO_2^+ (36% in 3 days, Table 31.2). Uptake of iv-injected $^{237}Np^{4+}$ citrate in the skeleton was significantly faster than for $^{238}Pu^{4+}$, but significantly slower than for $^{237}NpO_2^+$ (Ramounet *et al.*, 1998).

(d) Pu^{4+}

Most of the biological studies of Pu have been performed with $^{239}Pu^{4+}$, however, other Pu isotopes have been used to take advantage of their special physical properties – the photon emissions of $^{237}Pu^{4+}$, the greater specific radioactivity of $^{238}Pu^{4+}$, and the beta particle emissions of ^{241}Pu. In addition to the numerous studies of injected Pu^{4+}, various chemical forms of Pu^{4+} have been administered to animals by inhalation to measure absorption into the body and assess the local radiotoxicity of the Pu alpha particles in the tissues of the respiratory tract, and by mouth to measure absorption from the GI tract. Chemical forms of Pu that have been investigated in those studies range from soluble complexes to insoluble PuO_2 particles. In addition to the animal species represented in Tables 31.1–31.7, distribution, retention, and toxicity of injected Pu^{4+} have also been studied in rabbits, chinchillas, swine, and sheep (Buldakov *et al.*, 1969; Taylor, 1969; ICRP, 1972, 1986; Bair *et al.*, 1973; Vaughan *et al.*, 1973).

Overall, the initial distributions of injected Pu^{4+} in rats, mice, dogs, monkeys, and human adults are similar (Tables 31.1–31.5 and 31.7). On average, skeleton plus liver accounts for 85% of the injected Pu^{4+}, and soft tissues other than liver and early urinary and fecal excretion, for 7, 4, and 5%, respectively. The initial Pu^{4+} distributions in the rats and dogs are nearly the same as those of the heavier trivalent actinides, Bk^{3+}, Cf^{3+}, and Es^{3+}, whereas the Pu^{4+} distributions in the mice, monkeys, and human adults closely resemble Am^{3+}. The combined data for the initial Pu^{4+} distributions in the five species may be compared to those for the trivalent actinide(s) they resemble most closely. The Pu^{4+} contents of the soft tissues other than liver, as well as the early fecal Pu^{4+} excretion are nearly the same as the best matched trivalent actinide(s). About 10% more of the injected Pu^{4+} is deposited in the skeleton plus liver (85%) than is found for the matched trivalent actinide(s) (75%), and that difference is accounted for by the smaller amount of early Pu^{4+} excretion in urine (4%, on average) compared with an average early excretion of 15% for the matched trivalent actinides.

Although the initial Pu^{4+} content of skeleton plus liver is nearly the same for all five species, the partitioning of the Pu^{4+} between those two tissues favors skeletal deposition in the rats and dogs, and liver in the mice, monkeys, and human adults. That species difference may be attributed in part to the less mature and/or more reactive skeletons of the rats and dogs at the time of Pu^{4+} injection (Durbin, 1975). The male rat skeleton grows slowly until late in life (Simpson *et al.*, 1950). In dogs, the degree of skeletal maturity (age at the time of Pu^{4+} injection) alters the proportions of Pu in the skeleton and liver in a reciprocal manner, favoring deposition in bone of juvenile dogs (3 months old) and young adult dogs (18 months old) and in the liver in older dogs (5 years old) (Bruenger *et al.*, 1983).

Autoradiographs of soft tissues of several species show that initially, soluble Pu^{4+} is prominently deposited in hepatic cells and to a lesser degree in the renal papillae, on nonskeletal mineralized structures both physiological (calcifying tracheal cartilages) and ectopic (calcified renal stones and scar tissue), and occasionally in involuting ovarian follicles and corpora lutea. Low concentrations are seen in the medial layer of arteries and arterioles and in the connective tissue of all tissues and organs examined, including bronchiolar cartilages, heart, testis, and thyroid gland (Painter *et al.*, 1946; Bloom, 1948; Erleksova, 1960; Cochran *et al.*, 1962; Jee and Arnold, 1962; Durbin, 1975; Green *et al.*, 1977; Miller *et al.*, 1980; Durbin *et al.*, 1985). Concentrations of Pu^{4+} in connective tissue are much less than those found for the heavier trivalent actinides. Those observations suggest that Pu^{4+} complexes with connective tissue glycoproteins are not as stable as the circulating Pu^{4+} complexes with plasma proteins, particularly Tf, or the complexes that Pu^{4+} forms at binding sites on the surfaces of hepatic cells and bone.

Carritt *et al.* (1947) studied groups of rats injected iv with $^{239}Pu^{4+}$ citrate at doses ranging from 0.14 to 231 μg kg^{-1} (data for the 0.14 and 67 μg kg^{-1} groups are included in Table 31.2), and Talbot *et al.* (1990) injected rats iv with 0.04 μg kg^{-1} of $^{237,238}Pu^{4+}$ citrate. The results are essentially the same over the entire range of iv-injected Pu^{4+} doses indicating that, although limited in quantity, a sufficient number of Tf-binding sites were available to accommodate the largest amount of $^{239}Pu^{4+}$ (0.97 μmo1 kg^{-1}) injected.

(e) Pa^{5+}

The stable state of this poorly studied actinide appears to be Pa^{5+} *in vivo*. The eight-coordinate ionic radius of Pa^{5+}, 0.091 nm (Shannon, 1976), is smaller and the charge/radius ratio is larger than those of its quadrivalent neighbors, and it is more acidic and hydrolyzes at a lower pH (Smith and Martell, 1976; Katz *et al.*, 1986). Stability constants are not available for Pa^{5+} complexes with the low molecular weight ligands shown in Table 31.8, but complexes with those ligands and with Tf and tissue and bone glycoproteins should be as stable, if not more stable, than those formed by Pu^{4+}. Complete distribution and excretion

studies of Pa^{5+} have been conducted only in rats (Table 31.2). Distribution of the absorbed fraction of im-injected $^{233}Pa^{5+}$ in the tissue of rats – predominant deposition in the skeleton and low uptake in liver – closely resembles that of Th^{4+}. These results in rats are similar to those reported by others for im-injected $^{233}PaCl_5$ (Lanz *et al.*, 1946) or iv-injected, ultra filtered $^{233}Pa^{5+}$ citrate (Schuppler *et al.*, 1988).

There are incomplete data for the tissue distribution in baboons of iv-injected $^{233}Pa^{5+}$ (10^{-6}μg kg^{-1}) in 0.08 M citrate buffer, pH 3.2 (Ralston *et al.*, 1986). Initial excretion in urine was low (6% in 24 h). At 24 h, the Pa^{5+} content of the skeleton is estimated to be about 50% of the amount injected. Because plasma clearance of the Pa^{5+} is slow (Cohen and Ralston, 1983), much of the Pa^{5+} associated with soft tissue at early times can be accounted for by contained blood. By 21 days, when the plasma Pa^{5+} has been reduced to about 2% of the amount injected, measurements of excreta and *in vivo* γ-ray counting of the whole body indicate the following distribution of Pa^{5+} in this large animal: cumulative urine and feces 15 and 3%, respectively, skeleton 65%, all soft tissue 13%.

Ralston *et al.* (1986) reported that they also prepared an injection solution similar to the $^{233}Pa^{5+}$ described above, in which Pa was in the 6+ oxidation state. There is no evidence for the existence of a stable state of Pa higher than Pa^{5+} (Kirby, 1986b; Katz *et al.*, 1986), so it is reasonable to conclude that the procedures used to prepare the second solution made no change, and the oxidation state was Pa^{5+} in both injection media. Furthermore, the plasma clearances and whole-body retentions of the two preparations were identical, indicating that the oxidation state was the same, Pa^{5+}, in both cases.

31.2.3 The dioxo ions

(a) UO_2^{2+}

Hexavalent uranium, UO_2^{2+}, is the most stable state of U in the animal body. Many U compounds with broad ranges of composition and solubility have been fed to or inhaled by animals, and U metal fragments have been implanted in wounds. The fractions of the U that dissolve and are absorbed to blood are distributed in the tissues (skeleton and kidneys) and excreted in the urine similarly to injected $UO_2(NO_3)_2$ (Hodge, 1949; Maynard and Hodge, 1949; Stokinger *et al.*, 1949; Stradling *et al.*, 1985a,b, 1987, 1988; Hahn *et al.*, 2002).

Kidney is the only organ in which histopathological changes are seen consistently in U-poisoned animals. The nature and location of the renal injury (predominantly in the last third of the proximal tubules) are diagnostic of intake of UO_2^{2+} to blood (Voegtlin and Hodge, 1949, 1953; Hodge, 1949; Yuile, 1973). All of the U compounds studied that have any degree of dose-dependent toxicity exhibit the renal injury typical of UO_2^{2+}. The similarities to UO_2^{2+} (tissue distribution, urinary excretion, and kind and site of renal pathology) led to

the conclusion that the absorbed fractions of U compounds are converted to UO_2^{2+} under physiological conditions (Hodge, 1949; Dounce and Flagg, 1949).

The initial tissue distributions of U injected as UO_2^{2+} in the six mammalian species shown in Tables 31.2–31.7 agree well with one another, even though the sampling (postinjection) time ranged from 1 to 7 days and the UO_2^{2+} dose ranged from 2×10^{-6} μg kg^{-1} of $^{237}UO_2^{2+}$ (baboon) to 300 μg kg^{-1} of $^{233}UO_2^{2+}$ (dog). Skeleton and kidneys are the main sites of UO_2^{2+} deposition. They each contain about 12% at 4 days, on average, 3.5% is present in all other soft tissues; about 73% has been excreted, almost entirely in the urine. Linear regression analysis indicates weak correlations of tissue deposition and urinary excretion with UO_2^{2+} dosage; weakly positive for U deposition in skeleton and kidneys and weakly negative for urinary excretion. Linear regression analysis of tissue deposition and urinary excretion with time after injection predicts that at 24 h after a UO_2^{2+} injection, the U will be distributed, as follows: skeleton 15%, kidneys 18%, other tissues 5%, and urine 63%. That predicted distribution is in essential agreement with the parameters of the biokinetic model for U most recently adopted by the ICRP (1995).

The U initially deposited in the kidneys passes into the urine with a half-time of about 7 days (ICRP, 1995), until nearly all of the original U deposit has been eliminated. Nearly all of the long-retained U in the body is in the skeleton (Neuman, 1949; Yuile, 1973; Stevens *et al.*, 1980; Wrenn *et al.*, 1985).

In young rapidly growing rats, UO_2^{2+} is less toxic to the kidneys than in adults, and it is less toxic in adult male rats than in females of the same age (Haven and Hodge, 1949). Neuman (1949) observed that growing rats stored more U administered as UO_2^{2+} in their skeletons than adults and that the incomplete skeletons of adult male rats took up more U than adult females. The relative proportion of the U dose deposited in the kidneys varied inversely with U storage in bone; the kidneys of the growing rats and adult male rats were spared by diversion of larger fractions of the injected U to the skeleton.

(b) NpO_2^+, NpO_2^{2+}

The initial distributions in the tissues of im- or iv-injected $^{237}NpO_2^+$ in rats, mice, and monkeys agree well with one another (Tables 31.2, 31.3, and 31.5). Skeleton is the main site of Np deposition. Filtration into urine is the main excretory pathway, but little Np is deposited in the kidneys. At 1 to 4 days after injection, on average, 41% of the Np is in the skeleton, and the remainder is distributed as follows: liver 10%, kidneys 2%, other soft tissues 5%, urine 39%, and feces 2%. The initial distribution of circulating NpO_2^+ in the animals appears to be the result of competition between skeletal uptake and urinary excretion.

The initial distribution of Np in the tissues of a baboon-injected iv with $^{239}NpO_2^{2+}$ in 0.01 M $NaHCO_3$ was reported by Ralston *et al.* (1986), and those data are included in Table 31.6. The initial distributions of tracer quantities of $^{239}NpO_2^{2+}$ and $^{237}UO_2^{2+}$ in the baboon can be compared directly; the early

urinary excretion of the Np is much less, the skeletal deposition of Np is much greater, and Np deposition in the kidneys is much less than UO_2^{2+}. Distributions in the tissues and early urinary excretion of the dioxo Np ions are nearly the same regardless of the animal (rat, mouse, monkey, baboon), the reported valence state of the Np (NpO_2^+, NpO_2^{2+}), the injected dose of Np (range, 4×10^{-7} μg kg^{-1} of $^{239}NpO_2^{2+}$ or $^{239}NpO_2^+$ in baboons to 360 μg kg^{-1} of $^{237}NpO_2^+$ in rats), or the chemical composition of the injection medium (dilute nitric acid, isotonic saline, or citrate or bicarbonate buffer). Combined, these observations indicate that NpO_2^{2+} is unstable *in vivo* with respect to reduction to NpO_2^+.

Under the conditions of poorly oxygenated, slowly flowing tissue fluid at an im wound site in rats, 200 μg kg^{-1} of $^{233}UO_2^{2+}$ was rapidly and quantitatively absorbed (Table 31.2). In contrast, absorption of 360 μg kg^{-1} of $^{237}NpO_2^+$ injected im was slow (22% at 1 day and 62% at 30 days, Morin *et al.*, 1973). Those results suggest some reduction to Np^{4+} at the wound site.

(c) PuO_2^{2+}

In several early studies of Pu distribution in animal tissues, mice, rats, rabbits, and dogs were injected iv or im with $^{239}PuO_2^{2+}$ (Finkle *et al.*, 1946; Painter *et al.*, 1946; Van Middlesworth, 1947; Carritt *et al.*, 1947; Kisieleski and Woodruff, 1948, Scott *et al.*, 1948b). Complete data sets are available only for rats, and those shown in Table 31.2 are representative for rats injected im with $^{238}PuO_2^{2+}$ citrate or iv with $^{239}PuO_2(NO_3)_2$. The deposition pattern of PuO_2^{2+} in rats (Table 31.2) can be compared with data for both Pu^{4+} and UO_2^{2+} in several animal species (Tables 31.2–31.7). The initial tissue distribution of Pu given as PuO_2^{2+} does not resemble that of its analog UO_2^{2+}, but is nearly the same as that of Pu^{4+}.

The early association of about 5% of iv-injected PuO_2^{2+} with red blood cells (Painter *et al.*, 1946) resembles UO_2^{2+} (Lipsztein, 1981), but not Pu^{4+} (Stover *et al.*, 1959). Urinary excretion of PuO_2^{2+} in the first 24 h was much less than for PuO_2^{2+} and only somewhat greater than for Pu^{4+}. Retention of Pu in the kidneys after injection of PuO_2^{2+} was much less than for UO_2^{2+} and about the same as that of Pu^{4+}. Absorption of Pu after im injection of $^{239}PuO_2Cl_2$ was slower and much less efficient than for UO_2^{2+}, but faster than for the same mass of im-injected $^{239}PuCl_4$ (Scott *et al.*, 1948b). Combined, these results indicate that PuO_2^{2+} is unstable *in vivo* with respect to reduction to Pu^{4+}.

31.3 ACTINIDE TRANSPORT IN BODY FLUIDS

31.3.1 Composition of mammalian plasma and tissue fluid

The concentrations of the major electrolytes in normal human blood plasma listed in Table 31.9 include cations that compete with actinide ions for circulating bioligands and low molecular weight anions with the potential for actinide

Table 31.9 *Concentrations of low molecular weight electrolytes in human plasma and urine, and estimated concentrations in fluid entering last third of proximal ural tubules.*

	Concentration (mM)		
Electrolyte	*Plasma and tissue fluid*	*Late proximal tubule fluid*[a]	*Bladder urine*[b]
Na^+	140[b]	140	130
K^+	5[b]	5	44
Ca^{2+}	1.5[c]	2	4
Cl^-	110[b]	110	140
HCO_3^-	25[b]	8.8	1.6
HPO_4^{2-}[d]	1[d]	0.5	20
Citrate	0.1[d]	0.1[e]	4
pH	7.4	6.5[e]	6.0

complexation. The concentrations of the major electrolytes in the plasma of the laboratory animals used in the studies of tissue distribution (Tables 31.1–31.7) differ little from each other or from those in human plasma (Altman and Dittmer, 1971; Loeb and Quimby, 1999).

Table 31.10 lists the fluid volumes (plasma, interstitial fluid) and the concentrations of proteins and iron in the plasma of the laboratory animals and human adults. Even though there is a 2000-fold range of body weight from mouse to man, their fractional plasma and tissue fluid volumes are similar. The mean fractional plasma and tissue fluid volumes of the animals are 43 ± 8 and 210 ± 39 mL kg^{-1} body weight, respectively, similar to those of human adults. The concentrations of albumin, globulins, and Tf, the iron-transport protein of mammalian plasma, do not vary greatly among the animals and man. However, the concentration of plasma iron and the numbers of Tf-binding sites normally occupied by iron (saturation) differ among the species. Tf Fe-saturation, which ranges from 33 to 44% for the larger animals (beagle, nonhuman primates, man) and from 59 to 74% for the small rodents, is inversely correlated with body weight (Table 31.10) and directly correlated with metabolic rate (Brody, 1945).

31.3.2 Circulation of extracellular fluid

Foreign ions taken into the mammalian body are transported in the circulating extracellular fluid (ECF), which is actually two communicating compartments. The plasma is the fluid phase of the blood, and it is confined within the blood

Table 31.10 *Fluid volumes and protein and iron concentrations in plasma of mature laboratory animals and human adults.*

	Mouse	*Rat*	*Beagle dog*	*Macaque monkey*	*Human adult*

vessels. The interstitial (tissue) fluid is outside the vascular system, and it bathes the body cells and their supporting connective tissue.

Mammalian plasma is a steadily flowing, well-mixed, nearly neutral (pH 7.4), dilute saline solution containing numerous solutes (electrolytes and proteins) at closely regulated concentrations. The plasma water and filterable (low molecular weight, nonprotein constituents) are in steady-state exchange with the tissue fluid by outward diffusion though the arterial ends of the capillaries and inward diffusion at the venous ends, at a rate in human adults of about one plasma volume per min. The capillary walls are not completely impermeable, and between 50 and 100% of plasma proteins escape through the capillaries and reenter the blood via the lymphatic circulation daily (Cronkite, 1973). The composition of the tissue fluid approximates an ultrafiltrate of the plasma. It contains small molecules and electrolytes at about the same concentrations as the plasma, but the protein concentration is less than 20% of that in the plasma. The tissue fluid is the medium that transports the filterable dissolved solutes of the plasma to the body cells, and it transports cell products and wastes back into the plasma.

More tissue fluid is produced at the arterial ends of the capillaries than is withdrawn by diffusion back into the venous capillaries. That excess fluid and

the escaped protein are drained away and returned to the plasma by colocated lymph capillaries. The concentration of protein in lymph is somewhat greater than that in the tissue fluid.

31.3.3 Loose connective tissue

Tissue fluid does not flow freely; it penetrates and is confined within the loose connective tissue that fills the spaces between the capillaries and the cells of most tissues and organs. Loose connective tissue is composed of fine collagen and elastin fibers embedded in a colloidal gel hydrated by the tissue fluid. The solids of the gel are hydrated high molecular weight mucopolysaccharides (hyaluronic and chondroitin sulfuric acids) and glycoprotein. Both the structural proteins and the components of the connective tissue gel contain potential metal-binding sites – the carboxyl groups of the mucopolysaccharides, the carboxyl (aspartic and glutamic acid) and hydroxyl (tyrosine) side chains of the proteins, and the sialic acid side chains of the glycoproteins (Dounce and Lan, 1949; Passow *et al.*, 1961; Rothstein, 1961; Taylor, 1973a,b; Ham, 1974; Luckey and Venugopal, 1977; Pecoraro *et al.*, 1981).

31.3.4 Distribution of actinides in plasma

Trace quantities of multivalent cations circulate in the body fluids as complexes (Taylor, 1972, 1998; Luckey and Venugopal, 1977). Any complexing species such as citrate ion injected with a foreign cation is rapidly diluted and removed from the circulation, and the cation must form new complexes with the filterable low molecular weight plasma constituents (Table 31.9) or with nonfilterable plasma proteins (Table 31.10) or both.

Distribution of actinide ions among the constituents of mammalian blood plasma has been studied in plasma and serum (plasma minus fibrinogen and clotting factors) of rats and dogs injected iv with soluble actinides (*in vivo*) and in whole blood, plasma or serum of rats, dogs, and human adults and purified plasma constituents incubated with actinide solutions (*in vitro*).

The analytical techniques have included: ultrafiltration, electrophoresis, electrodialysis, size exclusion and ion-exchange chromatography, immunochromatography, immunoprecipitation, protein precipitation, and spectroscopy. The information provided by those studies is mainly semiquantitative, because each procedure tends to disturb the natural speciation of the system (reviewed by Taylor, 1998). Furthermore, in the living animal competition for injected actinide ions among the plasma constituents and between the plasma constituents and the tissue ligands continually shifts the chemical speciation in the plasma compartment in favor of the most stable complex(es) (Dounce, 1949; Stevens *et al.*, 1968; Turner and Taylor, 1968a,b; Durbin *et al.*, 1972; Durbin, 1973; Ramounet *et al.*, 1998).

(a) Filterable low molecular weight ligands

The stabilities of actinide complexes with a given ligand, including the OH of water, increase in the order: $MO_2^+ < MO_2^{2+} \sim M^{3+} < M^{4+}$. For actinides of the same electric charge, e^-, the stabilities of complexes with the same ligand generally increase with decreasing ionic radius, r. The net effect is increased stabilities of complexes with the increasing ratio of electric charge to ionic radius, e/r. The most stable complexes formed by the 'hard' actinide ions are those with ligands that contain oxygen as the electron donor group. In general, the stabilities of the actinide complexes with such groups are in the order: $SO_4^{2-} < CO_2^- < CO_3^{2-} \sim PO_4^{3-}$ (Ahrland, 1986).

Most of the actinide ions introduced into mammalian plasma *in vivo* or *in vitro* tend to associate predominantly with plasma proteins, but in all cases an ultrafilterable low molecular weight fraction has been identified, ranging from small (<10%) for the trivalent, tetravalent, and pentavalent actinides (Stevens *et al.*, 1968; Popplewell and Boocock, 1968; Turner and Taylor, 1968a,b; Bruenger *et al.*, 1971a) to large (≥50%) for UO_2^{2+} and NpO_2^+ (Dounce, 1949; Bruenger *et al.*, 1971b; Stevens *et al.*, 1980; Guilmette *et al.*, 1982).

Stability constants (log K_1) of one-to-one complexes with several of the low molecular weight ligands present in mammalian plasma are shown in Table 31.8 for the actinides that have been studied in animals and humans (Tables 31.1–31.7). Table 31.8 also includes the ionic radii of those actinide species (Shannon, 1976), assigning coordination number 6 (CN 6) for the trivalent actinides and the dioxo actinide cations, MO_2^+ and MO_2^{2+}, and CN 8 for the tetravalent and pentavalent actinides. The ionic radii are included to emphasize the relationships among ionic charge and ionic radius (charge–radius ratio, e/r) and the tendencies of the metal ions to hydrolyze and form stable complexes. The first hydrolysis constants for the actinides are shown for comparison with the other ligands, because at the nearly neutral pH of mammalian plasma, in the absence of stable complexing ligands, all of the actinides that have been administered to animals, with the possible exception of NpO_2^+, would be expected to hydrolyze and form colloidal hydroxides intravascularly.

(*i*) *Citric and other alpha-hydroxy dicarboxylic acids*

Citrate ion is the only low molecular weight ligand in mammalian plasma that is competitive with OH^- for all of the actinides studied (Table 31.9), and it is the only competitive ligand for the trivalent actinides. Dicarboxylic acids and phosphate may also compete with OH^- for the tetravalent actinides, and carbonate is competitive for the MO_2^{2+} dioxo actinide ions.

In addition to citrate, other alpha-hydroxy 3- and 4-carbon dicarboxylic acids (malic, oxaloacetic, tartaric) stably bind UO_2^+. These tridentate ligands bind

metal ions through the alpha OH group as well as the two carboxylate groups, forming stable five- and six-membered chelate rings. Those ligands form UO_2^{2+} complexes that are stable enough to prevent and to reverse the inhibitory binding of UO_2^{2+} to protein enzymes (Singer *et al.*, 1951). Low concentrations of three alpha-hydroxy dicarboxylic acids (malic, oxaloacetic, isocitric) are present in human plasma (Table 31.9), and their combined concentration is about the same as that of citrate ion. Those organic acids may also participate in actinide complexation in the plasma.

A small fraction of the filterable plasma Ca^{2+} circulates as a citrate complex (concentration about 7×10^{-5} M, Neuman and Neuman, 1958). The concentration of plasma citrate is about 10^{-4} M (Table 31.9), so nearly 70% of the circulating citrate ion is bound to Ca^{2+}. The stabilities of the citrate complexes with trivalent and tetravalent actinides (Table 31.8) are several orders of magnitude greater than that of Ca-citrate (log K_f=3.2, Martell and Smith, 1977), and they can be expected to compete with Ca^{2+} for citrate *in vivo*.

When citrate complexes of the tri- and tetravalent actinides are injected iv, the subsequent behavior of the metal ion demonstrates that the injected complexes are transient and less stable than the complexes that the metal ions can form with plasma protein(s) and tissue ligands. In rats and dogs within 2 h after iv injection of the Pu–citrate complex, 90% of the Pu^{4+} in the plasma was found by gel chromatography to be bound to nonfilterable protein(s); by 24 h after the injection less than 5% of the circulating Pu^{4+} was associated with filterable low molecular weight species. Concurrently, excretion of Pu^{4+} in the urine, which is a modified, concentrated ultrafiltrate of plasma, declined rapidly demonstrating the disappearance of the originally ultrafilterable citrate complex from the plasma (Stevens *et al.*, 1968; Turner and Taylor, 1968a; Durbin *et al.*, 1972).

The presence of low concentrations of ultrafilterable citrate complexes of Pu^{4+}, Am^{3+}, and Cm^{3+} in plasma was shown indirectly through identification of their citrate complexes as the major, if not the only, species of those actinides in urine (Popplewell *et al.*, 1975; Stradling *et al.*, 1976). It is reasonable to assume that small amounts of other actinides and foreign metal ions circulate as citrate complexes that can be ultrafiltered by the kidneys and excreted in the urine.

Citrate ion, injected locally soon after Pu^{4+} is deposited in an im wound, is capable of complexing and hastening Pu^{4+} absorption (Volf, 1975).

(*ii*) *Carbonate and bicarbonate*

Most carbonates are sparingly soluble, but the actinide dioxo ions form stable carbonate complexes at physiological pH (Smith and Martell, 1976; Ahrland, 1986). The special cases of *in vivo* transport of UO_2^{2+} and NpO_2^{+} as carbonate complexes are discussed below.

3.4.2 Nonfilterable plasma proteins

(a) Albumin and the globulins

Serum albumin and globulin are globular proteins that are soluble in dilute saline. In normal human plasma, albumin transports about 26% of Ca^{2+} and globulins transport about 7%. Ca^{2+} has low affinity for amino groups and monocarboxylic acids like acetate, but it is strongly chelated by polycarboxylic and hydroxycarboxylic acids like citrate (Neuman and Neuman, 1958). The serum proteins contain abundant amino acids with –COOH side chains (aspartic acid, glutamic acid, cystine), –OH side chains (serine, threonine, hydroxyproline), and phenolic side chains (tyrosine) (Hawk *et al.*, 1947). However, only carboxylate or hydroxyl side chains of the amino acids in close proximity to one another in the protein structure are able to bind Ca^{2+} and other multivalent cations.

The affinities of the serum proteins for cations depend on both their amino acid composition and the spatial arrangement of those amino acids and the binding units of their residues. The globular structures of the serum proteins are determined and maintained by the continuous coiling, bending, and folding of the polypeptide chains, which provide close approach of amino acid side chains that are widely separated in the primary (elongated) structure. That folded lattice-like three-dimensional structure provides numerous carboxyl and hydroxyl groups positioned suitably for metal binding (Schwartz and Fien, 1973). Nonspecific binding to serum proteins has been described for UO_2^{2+}, the trivalent lanthanides, and other multivalent metal ions (Painter *et al.*, 1946; Dounce and Lan, 1949; Gurd and Wilcox, 1956; Clarkson, 1961; Passow *et al.*, 1961; Rothstein, 1961; Kyker, 1962; Stevens *et al.*, 1965, 1968; Popplewell and Boocock, 1968; Stover *et al.*, 1968a; Bruenger *et al.*, 1969b, 1971b; Taylor, 1973a,b; Ham, 1974; Luckey and Venugopal, 1977).

The total concentrations of Ca^{2+} and Mg^{2+} in normal human plasma are about 2.5 and 1.0 mM, respectively. Assuming that Ca^{2+} and Mg^{2+} are distributed similarly among the constituents of plasma and that the strengths of their binding to the plasma proteins are similar, the fractions of the metal-binding sites of the plasma proteins normally occupied by the alkaline earth elements can be estimated. In human plasma, about 0.65 mM of Ca^{2+} is bound to albumin and about 0.17 mM is bound to the globulins; 0.26 and 0.07 mM of plasma Mg^{2+} are assumed to be associated with albumin and the globulins, respectively. The maximum Ca^{2+} and Mg^{2+} binding capacities of the plasma albumin and globulins are, on average, 11 and 6 moles of metal per 10^5 g of protein, respectively (Neuman and Neuman, 1958). The concentrations of albumin and the globulins in plasma are 6.5×10^{-4} and 21.0×10^{-4} M, respectively (Table 31.8). The mean molecular weights of serum albumin and the globulins are about 67 000 and 160 000, respectively (Hawk *et al.*, 1947). Calculations suggest that about 22% of the potential metal-binding sites of the plasma

proteins are normally occupied. Thus, binding sites are available for occupancy by foreign cations without need to displace their normal loads of Ca^{2+} and Mg^{2+}.

Nonspecific binding of the actinides by the plasma proteins is likely to be stronger than that of the alkaline earths, but weaker than specific binding to Tf (see below). The abundances of the plasma proteins and their potential binding sites may favor nonspecific actinide binding strong enough to withstand renal filtration, but too weak to compete with the ligands in liver, bone, and connective tissue.

(b) Transferrin

(*i*) *Structure*

Iron is transported in the plasma of mammals as Fe^{3+} bound to Tf, a specialized glycoprotein of molecular weight 79.6 kDa that migrates electrophoretically with the β-globulins. The amino acid sequence of transferrin has been defined. Each end of the Tf molecule has a globular sialoprotein moiety at which one Fe^{3+} atom may be bound in association with one bicarbonate molecule. The two iron-binding sites of Tf differ slightly. The C-terminal site is larger and binds Fe^{3+} more tightly than the smaller N-terminal site. At pH 7.4, the C-terminal site has an affinity for Fe^{3+} about five times greater than that of the N-terminal site. However, the weaker N-terminal site is preferentially occupied by Fe^{3+}, so kinetic and/or access factors may be more important than thermodynamic effects. Iron binding by Tf is pH-dependent, and Fe^{3+} is released at pH < 7.4.

(*ii*) *Function*

Tf is a true carrier molecule in that it is conserved for many cycles of Fe^{3+} delivery to the erythroblasts and reticulocytes (early and late stages of developing red cells) in the red bone marrow. Iron-bearing Tf, preferentially diferric Tf, binds to cell surface Tf receptors, forming clusters in surface pits, and these are internalized by endocytosis. Inside the developing red cells, the Fe–Tf receptor complex is contained in coated vesicles, which fuse with endosomes. Within the endosomes, the low pH ($\sim$5) releases one Fe^{3+} presumably from the N-terminal site. Release of a second Fe^{3+} may be mediated by other molecules and may involve reduction of Fe^{3+} to Fe^{2+}. Neither the Tf nor the Tf-receptor is degraded in the process. The Tf–Tf-receptor complex minus one or two Fe^{3+} atoms is returned to the cell membrane where, at pH 7.4, apotransferrin (iron-free Tf, apoTf) and/or monoferric Tf are released to the interstitial fluid and ultimately reenter the plasma to take up more Fe^{3+}. In addition to the developing red blood cells, hepatic cells and to a lesser degree most other cells possess surface Tf receptors and are able to endocytose Tf. When Tf is fully saturated with iron,

the iron absorbed from the GI tract is deposited in the liver (Katz, 1970; Aisen and Listowsky, 1980; Fairbanks and Beutler, 1995).

Tf is synthesized mainly in the parenchymal cells of the liver. At any time about 50% of the exchangeable Tf is located extravascularly in interstitial fluid, and it is returned to the plasma compartment with a half-time of about 17 h. As is the case with the other serum proteins, Tf is destroyed at a first-order rate. Its survival half-time of about 9 days is significantly shorter than that of serum albumin. The sites of Tf destruction are believed to be liver and kidneys (Katz, 1970).

(*iii*) *Binding of foreign metal ions*

Tf binds Fe^{3+} ($r = 0.0645$ nm, $e/r = 46.5$ e nm^{-1}) in preference to other biologically essential metal ions. Iron binding at both sites involves deprotonation of two tyrosine moieties and the association of one bicarbonate molecule. If a foreign multivalent cation is to occupy either binding site, it must be small enough to fit into the Fe-binding cavity, and have sufficient charge density (e/r) to deprotonate both of the two tyrosine phenols required for stable binding (Luk, 1971; Harris *et al.*, 1981).

Metal coordination with apoTf was investigated by spectrophotometric titration of the Tf complexes of metal ions with a broad range of electric charge and ionic radius. Two tyrosines were coordinated at both binding sites by the small transition metal ions and the smaller lanthanides; each Tf molecule bound two metal ions and released four tyrosine protons (Fig. 31.2, Pecoraro *et al.*, 1981). The larger lanthanide ions were able to fit only into one Fe-binding site, presumably the larger C-terminal site, and the number of coordinated tyrosines per Tf molecule decreased from four to two. Because of the size difference in the two sites, the larger Th^{4+} ion is bound stably at one site and weakly at the other, whereas the smaller Zr^{4+} and Pu^{4+} ions are expected to be bound stably at both sites. Europium appears to be an indicator of the maximum size (0.095 nm) of a multivalent cation that can fit into and bind stably at both Tf-binding sites, whereas the larger La^{3+}, Am^{3+}, and Cm^{3+} ions are expected to bind only at the larger C-terminal site.

(c) Actinide binding by transferrin

Under appropriate experimental conditions all of the actinides investigated, except NpO_2^+ form variably stable complexes with plasma Tf (Popplewell and Boocock, 1968; Stevens *et al.*, 1968; Stover *et al.*, 1968a; Turner and Taylor, 1968a,b; Bruenger *et al.*, 1969b, 1971b; Taylor, 1970, 1998; Stevens and Bruenger, 1972; Durbin *et al.*, 1976; Cooper and Gowing, 1981; Peter and Lehmann, 1981; Guilmette *et al.*, 1982; Wirth *et al.*, 1985; Taylor and Farrow, 1987; Paquet *et al.*, 1996). The apparent stabilities of those actinide Tf

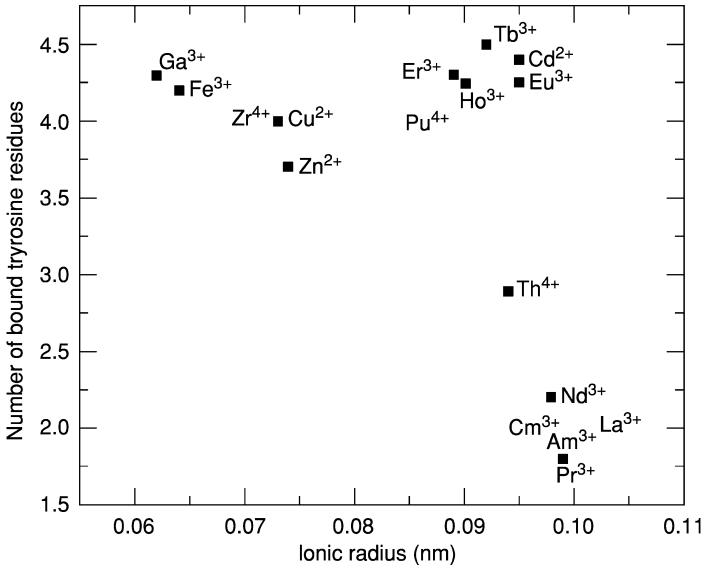

Fig. 31.2 *Number of tyrosine moieties engaged in binding metal ions as related to their six-coordinate radii* (*Shannon*, 1976). *Data of Harris* et al. (1981) *and Pecoraro* et al. (1981). *Not measured but noted by their elemental abbreviations are* Zr^{4+} *and* Pu^{4+}, *which are small enough to fit into both Fe-binding sites and displace four tyrosine protons, and* La^{3+}, Am^{3+}, *and* Cm^{3+}, *which are too large to occupy the smaller N-terminal site and would be expected to displace only two tyrosine protons per transferrin molecule.*

complexes is in the order expected based on their tendencies to form stable complexes:

$$Pa^{5+} > Pu^{4+} > Th^{4+} > Np^{4+} \gg UO_2^{2+} > Cf^{3+} > Am^{3+} > Cm^{3+}$$

Each Tf molecule possesses only two Fe-binding sites, and the concentrations of Tf in mammalian plasma are low (Table 31.10). Thus, the capacity of circulating Tf for transporting actinide ions is limited by both the total number of binding sites and the number of sites not already occupied by Fe^{3+}, that is, the degree of Fe saturation of the Tf. Stover *et al.* (1968a,b) showed that Tf binding of Pu^{4+} in plasma varied inversely with Fe–Tf saturation, and that relationship has also been demonstrated for Th^{4+} and Np^{4+} (Peter and Lehmann, 1981; Wirth *et al.*, 1985).

The actinide Tf complexes, with the possible exception of Pa^{5+}–Tf, are less stable than Fe–Tf, and the actinides are readily displaced from Tf by adding Fe^{3+} to the reaction medium (Popplewell and Boocock, 1968; Stover *et al.*, 1968a; Peter and Lehmann, 1981; Wirth *et al.*, 1985). Similarly to Fe–Tf, the Pu^{4+}, Th^{4+}, and UO_2^{2+} Tf complexes are pH-dependent and they begin to dissociate at pH < 7 (Bruenger *et al.*, 1971b). Presumably, the stabilities of the

Tf complexes with the other actinides are similarly pH-dependent (Popplewell and Boocock, 1968; Bruenger *et al.*, 1971b; Stevens *et al.*, 1980).

(d) Association of actinides with erythrocytes

The trivalent and tetravalent actinides form variably stable complexes with the Fe-transport protein, Tf, and the iron storage protein, ferritin, but they are not incorporated into hemoglobin or associated with the stroma of erythrocytes (red blood cells).

The primary function of Tf is delivery of iron to the developing erythroblasts in the red bone marrow for synthesis of hemoglobin. Iron-bearing Tf binds to specific Tf-receptors on the erythroblast surfaces, and the complete complex, Fe–Tf–Tf-receptor, is internalized by endocytosis. Within the erythroblasts, the complex is taken up by lysosomes, where the reduced pH (5 to 5.5) causes dissociation of the complex and release of Fe^{3+}. The released Tf is extruded from the cells for reuse (Aisen and Listowsky, 1980).

The simplest explanation for the absence from the interior of the erythroblasts of actinides and other multivalent cations that bind to Tf is that the foreign metal ions bound to Tf induce a conformational change in the protein structure that is not recognized by the erythroblast Tf-receptor. It is possible, but less likely, that foreign metal ions like Pu^{4+}, freed from their pH-dependent Tf complexes at the low lysosomal pH, are rapidly shuttled out of the erythroblasts, bound to new Tf molecules, extruded at the cell surface, and recirculated. However, because the latter mechanism probably would be imperfect, small amounts of residual foreign metal ions could be left in the red cells, perhaps bound to the stroma, and that is not observed.

There is evidence that some actinides can bind transiently to the red cell membrane. Actinides in the 3+, 4+, 5+, MO_2^+, and MO_2^{2+} oxidation states were equilibrated with aliquots of whole blood *in vitro*. Except for $^{239}Pu^{3+}$ and UO_2^{2+}, the actinide concentrations in the washed red cells were $\leq$10% of those in the plasma (Chevari and Likhner, 1968; Bruenger *et al.*, 1971b; Stevens *et al.*, 1980).

Small fractions ($\leq$4%) of iv-injected UO_2^{2+} and PuO_2^{2+} are transiently associated with the red cell membrane (Painter *et al.*, 1946; Lipsztein, 1981; Durbin *et al.*, 1997a). Clearance of UO_2^{2+} from the plasma volume is much faster than the rate of release of UO_2^{2+} from the red cell membrane. Consequently, most of the U in samples of whole human blood from individuals in equilibrium with their normal daily intakes of U in drinking water and foods is associated with the red cells (Hursh and Spoor, 1973; Wrenn *et al.*, 1985).

Evaluation of the clearance of iv-injected $^{228}Th^{4+}$ citrate from the blood of beagles included measurements of the Th^{4+} bound to centrifugally separated red cells (Lloyd *et al.*, 1984a). The association of the Th^{4+} with red cells is

greater and somewhat more persistent than, but otherwise similar to, that of UO_2^{2+}. The red cell associated Th^{4+} rose rapidly from zero at the time of the injection to about 8% at 1 min and 30% at 6 h; at that time the blood Th^{4+} was about equally divided between plasma and cells. From 6 to 48 h, red cells accounted for as much as two-thirds of the Th^{4+} in whole blood, and the red cell fraction was being cleared with a half-time of about 14 h, one-half of the plasma clearance rate. By 30 days, the Th^{4+} associated with red cells was nearly 100 times that of the plasma. Between 2 and 30 days, a small fraction of the Th^{4+} was released from the red cells (3.5%) with a half-time of about 15 days. In the special case of Th^{4+}, binding to the red cell membrane is competitive with complexation by plasma Tf. Binding to the membrane is the most likely mechanism for the association of actinides with red cells. If, for example, Th^{4+} had entered the red cell interior, a much larger fraction of the 6 h maximum amount of the Th^{4+} associated with red cells would be expected to remain with the circulating red cells for a longer time (the life span of mammalian red cells is about 90 days (Cronkite, 1973)).

31.4 CLEARANCE OF ACTINIDES FROM THE CIRCULATION

Data for plasma clearances and early urinary excretion of the actinides in laboratory animals and man can be combined with the information developed for their reactions with the plasma constituents to assess their status in the circulation.

Plasma clearances of nine actinides injected iv in soluble form have been investigated in at least one mammalian species (data are not available for Ac^{3+} or Bk^{3+}). Industrially important UO_2^{2+}, Pu^{4+}, and Am^{3+} have been studied in several species. Plasma clearance data are available for two valence states of U (U^{4+}, UO_2^{2+}), two of Pu (Pu^{4+}, PuO_2^{2+}), and three of Np (Np^{4+}, NpO_2^{+}, NpO_2^{2+}). Plasma clearance curves of the actinides are shown in Figs. 31.3–31.7, in rats, mice, beagles, nonhuman primates, and human adults, respectively. The plasma clearances of iv-injected Pu^{4+}, Am^{3+}, and UO_2^{2+} in the laboratory animals and human adults are compared in Figs. 31.8, 31.9, and 31.10, respectively.

The rates of clearance of the several actinides from mammalian plasma are determined largely by their chemical properties, in particular by their tendencies to form stable complex(es) with plasma Tf. The actinides that form the most stable Tf complexes are cleared slowly, whereas those that form only weak Tf complexes are cleared at much faster rates. The order of disappearance of the actinides introduced into mammalian plasma is independent of the animal used for study (Figs. 31.3–31.7). Combining the data for all of the animals, and based

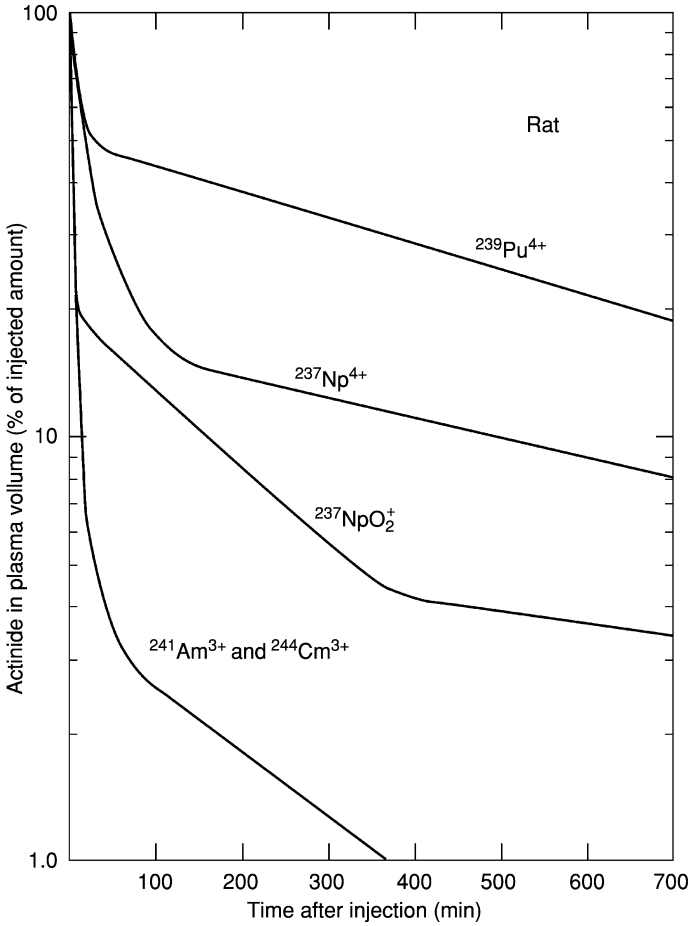

Fig. 31.3 *Clearance of iv-injected actinides from plasma volume of rats:* $^{239}Pu^{4+}$ (*Durbin* et al., 1972); $^{241}Am^{3+}$ *and* $^{244}Cm^{3+}$ (*Turner and Taylor*, 1968a); $^{237}Np^{4+}$ *and* $^{237}NpO_2^+$ (*Ramounet* et al., 1998).

on the time (min) required to clear 90% of the iv-injected actinide from the plasma volume, plasma clearance rates are in the order:

$$[UO_2^{2+}, Am^{3+}, Cm^{3+}, NpO_2^+] > [Cf^{3+}, Es^{3+}] \gg [Th^{4+}, Np^{4+}, Pa^{5+}, Pu^{4+}].$$

Note that the 90% plasma clearance measure does not differentiate among the rapidly clearing lighter trivalent actinides and the actinide dioxo ions, which are all cleared at about the same rate, but by different mechanisms.

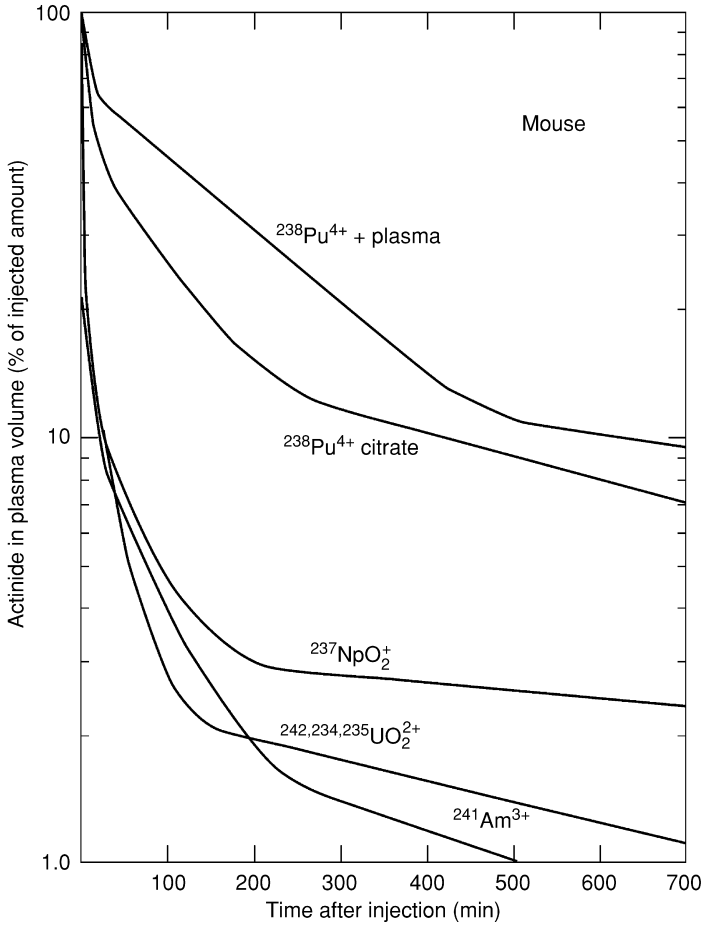

Fig. 31.4 *Clearance of iv-injected actinides from plasma volume of mice*: $^{238}Pu^{4+}$ *citrate* (*Durbin* et al., 1997b); $^{237}NpO_2^+$ (*Durbin* et al., 1998b); $^{232,234,235}UO_2^{2+}$ (*Durbin* et al., 1997a); $^{241}Am^{3+}$ and $^{238}Pu^{4+}$ + *plasma* (*P. W. Durbin and B. Kullgren, unpublished data*).

Plasma clearance of the actinides is modulated by the physiology of the animals used for study. Plasma retention of Pu^{4+}, Am^{3+}, and UO_2^{2+} in the different animals, as illustrated in Figs. 31.8–31.10, is in the order:

$$\text{adult man} > \text{dog} > \text{baboon} \geq \text{monkey} > \text{rat} > \text{mouse}.$$

Plasma actinide retention among the different animals is directly related to body size and inversely related to metabolic rate, renal filtration rate, and the degree of Fe saturation of the plasma Tf (Brody, 1945; Durbin *et al.*, 1997b; Table 31.10).

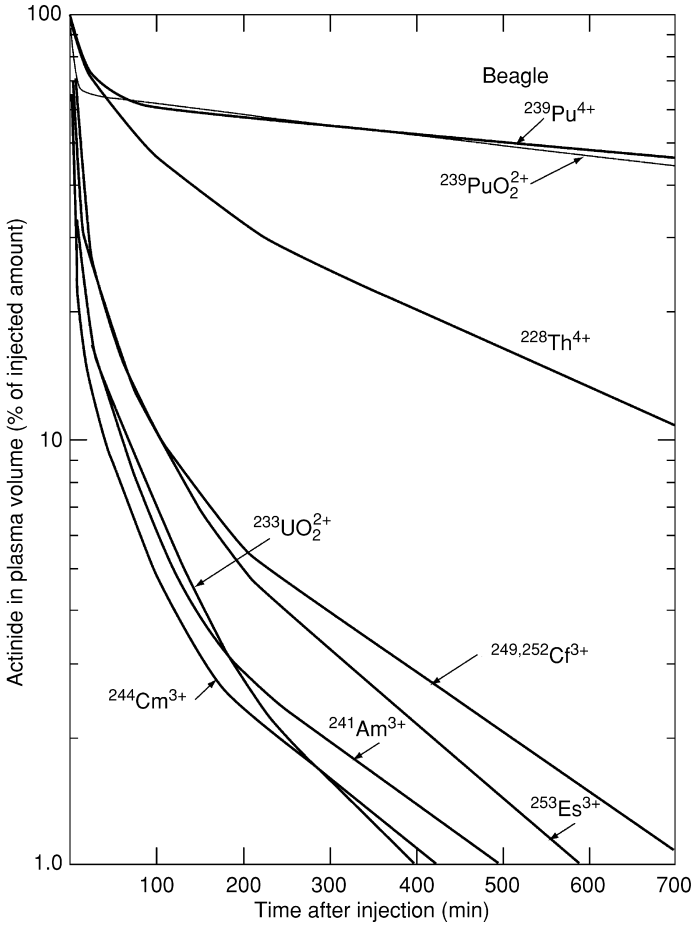

Fig. 31.5 *Clearance of iv-injected actinides from plasma volume of beagles:* $^{239}Pu^{4+}$, $^{228}Th^{4+}$, $^{241}Am^{3+}$, $^{249}Cf^{3+}$, and $^{252}Cf^{3+}$ (*Stevens and Bruenger,* 1972); $^{244}Cm^{3+}$ (*Atherton* et al., 1973); $^{253}Es^{3+}$ (*Atherton* et al., 1974); $^{233}UO_2^{2+}$ (*Stevens* et al., 1980); $^{239}PuO_2^{2+}$ (*Painter* et al., 1946).

31.4.1 Trivalent actinides

(a) Ac^{3+}

Timed plasma data for Ac^{3+} injected iv in rats are insufficient to define a clearance curve, however, the pattern of disappearance of $^{227}Ac^{3+}$ from the plasma is similar to Am^{3+} and Cm^{3+} in the same animals (Fig. 31.3). Clearance was 90% complete in about 50 min and 99% complete in about 400 min. Also

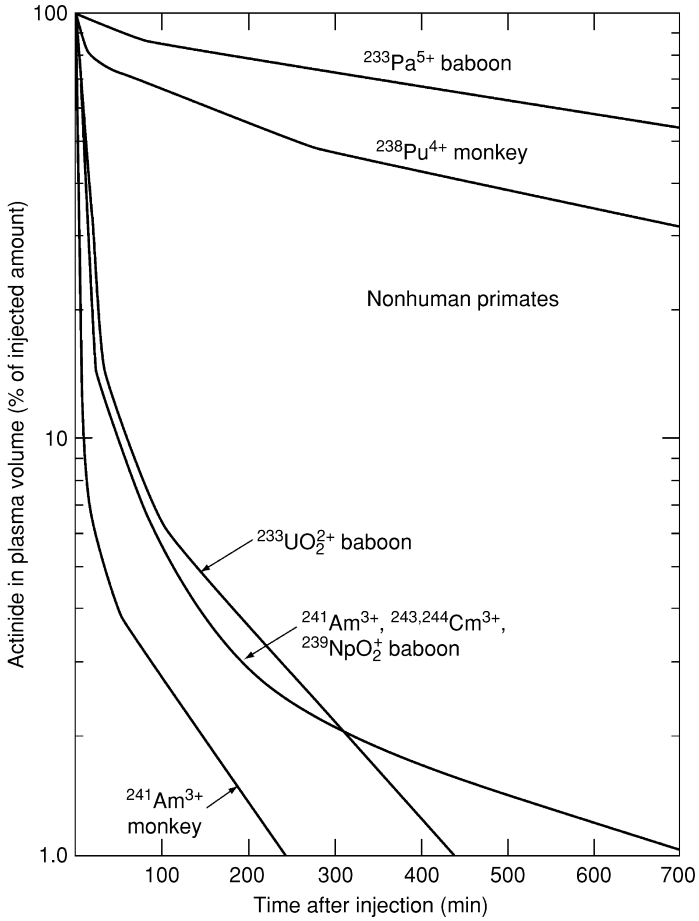

Fig. 31.6 *Clearance of iv-injected actinides from plasma volume of nonhuman primates: monkey* – $^{238}Pu^{4+}$ (*Durbin* et al., 1985), $^{241}Am^{3+}$ (*Durbin,* 1973); *baboon* – $^{241}Am^{3+}$ (*Guilmette* et al., 1980), $^{243,244}Cm^{3+}$ (*Lo Sasso* et al., 1981), $^{233}UO_2^{2+}$ (*Lipsztein,* 1981), $^{239}NpO_2^{+}$ and $^{233}Pa^{5+}$ (*Ralston* et al., 1986). (*Note: The curves for* $^{241}Am^{3+}$, $^{243,244}Cm^{3+}$, and $^{239}NpO_2^{+}$ *in the baboons coincide, and a single curve is shown for all three nuclides.*)

similarly to Am^{3+} and Cm^{3+}, tissue uptake was fast, and early urinary excretion was negligible (Taylor, 1970).

(b) Am^{3+}, Cm^{3+}, Cf^{3+}, Es^{3+}

Plasma clearances of iv-injected $^{241}Am^{3+}$ citrate or nitrate have been studied in five laboratory animals (Figs. 31.3–31.6, 31.9), and $^{243}Cm^{3+}$ or $^{244}Cm^{3+}$ citrate have been studied in three (Figs. 31.3, 31.5, and 31.6). Separate plasma curves

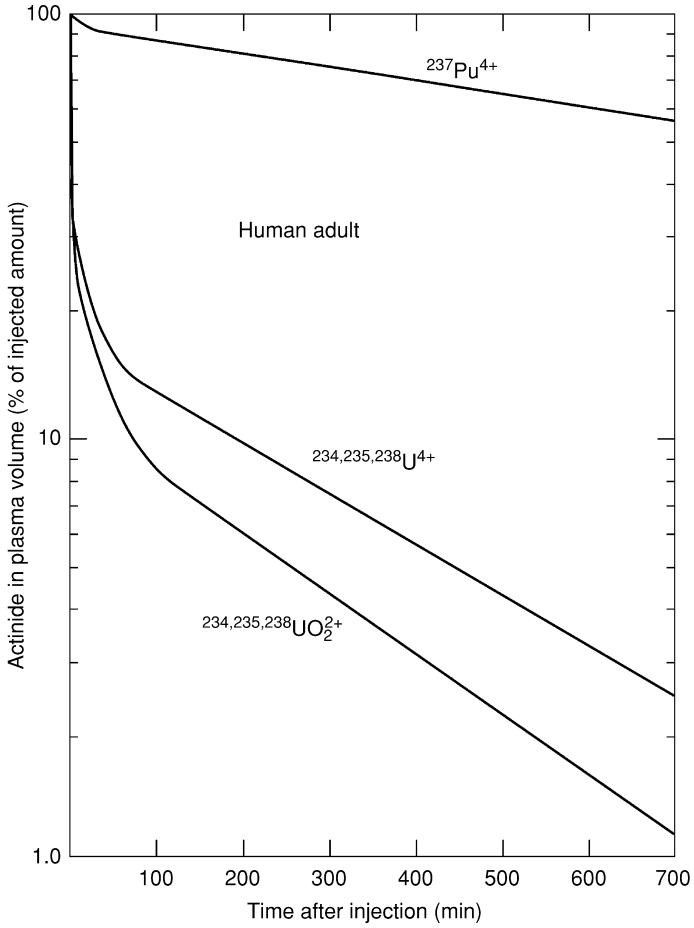

Fig. 31.7 *Clearance of iv-injected actinides from blood volume of adult human males:* $^{237}Pu^{4+}$ (*Talbot* et al., 1993); $^{234,235,238}U^{4+}$ *and* $^{234,235,238}UO_2^{2+}$ (*Bernard and Struxness*, 1957).

are not shown for Cm^{3+} in the rats (Fig. 31.3) or the baboons (Fig. 31.6), because they are indistinguishable from those for Am^{3+} in those animals. Clearances of Am^{3+} and Cm^{3+} from the plasma are fast: in all of the animals studied, they were 90% complete in 60 min and 99% complete in $\leq$600 min. Tissue uptake of both trivalent actinides is fast, and only small amounts are excreted in urine in the first 24 h (Taylor, 1962; Turner and Taylor, 1968a; Belyayev, 1969; Durbin, 1973).

Clearances of $^{249,252}Cf^{3+}$ and $^{253}Es^{3+}$ from the plasma of beagles was 90% complete in about 100 min, compared with 60 min for the two lighter larger

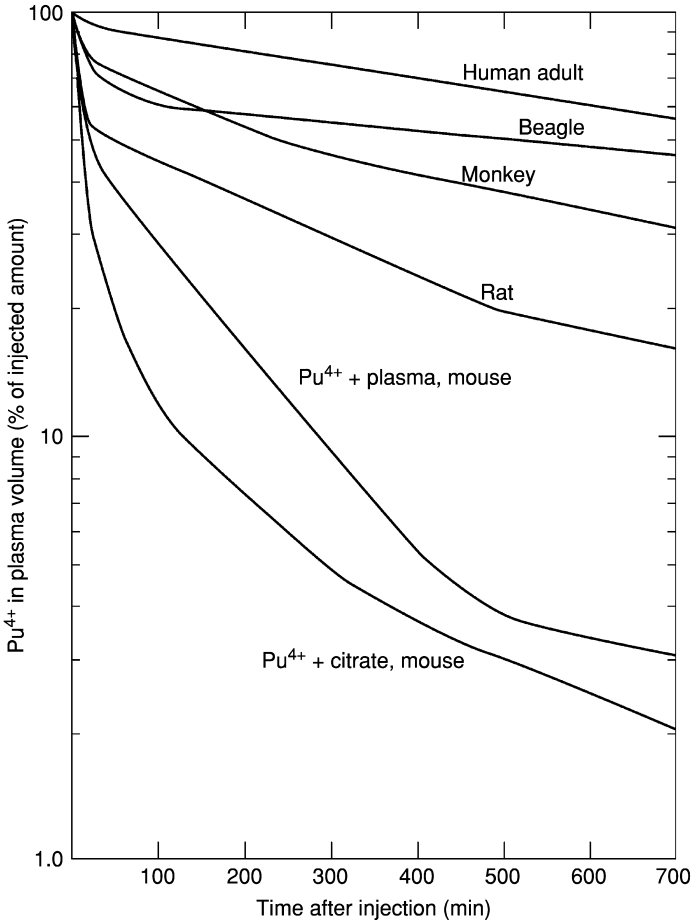

Fig. 31.8 *Clearance of iv-injected* Pu^{4+} *from plasma volume of animals and man:* $^{239}Pu^{4+}$, *rat* (*Durbin* et al., 1972); $^{238}Pu^{4+}$, *mouse* (*Durbin* et al., 1997b); $^{239}Pu^{4+}$, *beagle* (*Stevens and Bruenger,* 1972); $^{238}Pu^{4+}$, *monkey* (*Durbin* et al., 1985); $^{237}Pu^{4+}$, *adult human male* (*Talbot* et al., 1993); $^{238}Pu^{4+}$ + *plasma, mouse* (*P. W. Durbin and B. Kullgren, unpublished data*).

trivalent actinides, and the time required for 99% clearance of Cf^{3+} and Es^{3+} was about 200 min longer (Fig. 31.5). The slower plasma clearances of Cf^{3+} and Es^{3+}, compared with Am^{3+} and Cm^{3+}, confirmed the expectation that the two heavier smaller trivalent actinides would form more stable plasma protein complexes (Stevens and Bruenger, 1972; Atherton *et al.*, 1974).

Immediately after iv injection, the plasma contains rapidly declining fractions of the trivalent actinides in the form of the filterable low molecular weight complex injected (Turner and Taylor, 1968a). The major fraction apparently

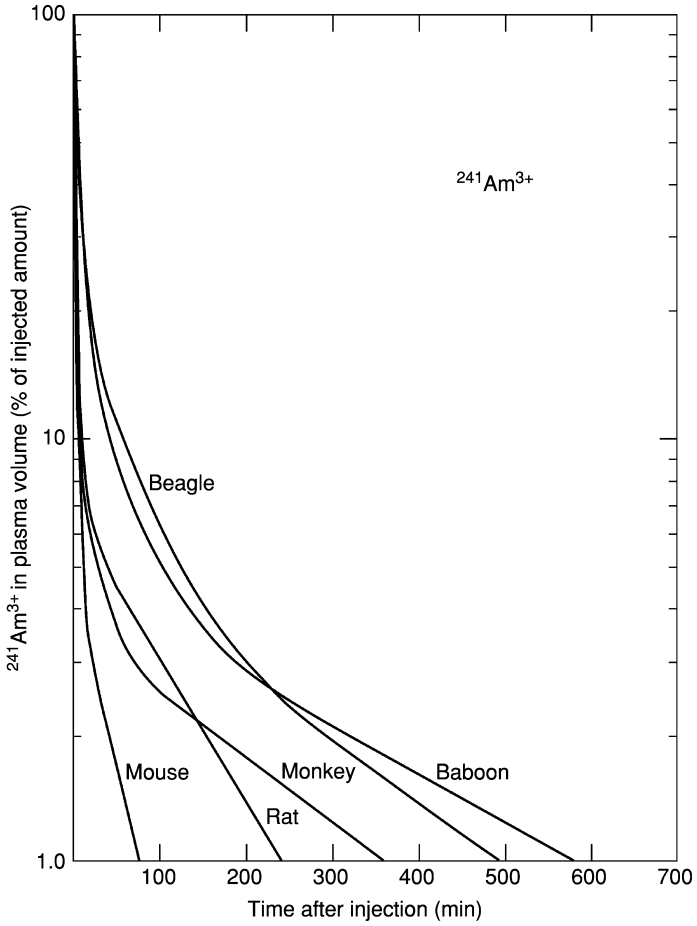

Fig. 31.9 *Clearance of iv-injected* $^{241}Am^{3+}$ *from the plasma volume of animals: rat* (*Turner and Taylor,* 1968a); *mouse* (*P. W. Durbin and B. Kullgren, unpublished data*); *beagle* (*Stevens and Bruenger,* 1972); *monkey* (*Durbin,* 1973); *baboon* (*Guilmette* et al., 1980).

forms weak nonfilterable complex(es) with Tf and other plasma proteins, which prevent renal filtration into urine, but are much less stable than the complexes that the trivalent actinides can form with ligands on hepatic cell and bone surfaces and in connective tissue.

In rats injected iv with Am^{3+} or Cm^{3+} citrate, about 50% was protein bound at 1 min and 95% was bound at 60 min (Turner and Taylor, 1968a). *In vivo* and *in vitro* studies of the associations of Ac^{3+}, Am^{3+}, Cm^{3+}, and Cf^{3+} with plasma proteins show that Tf is a major carrier of the trivalent actinides in mammalian plasma, however, those complexes are weak, and they do not survive the more

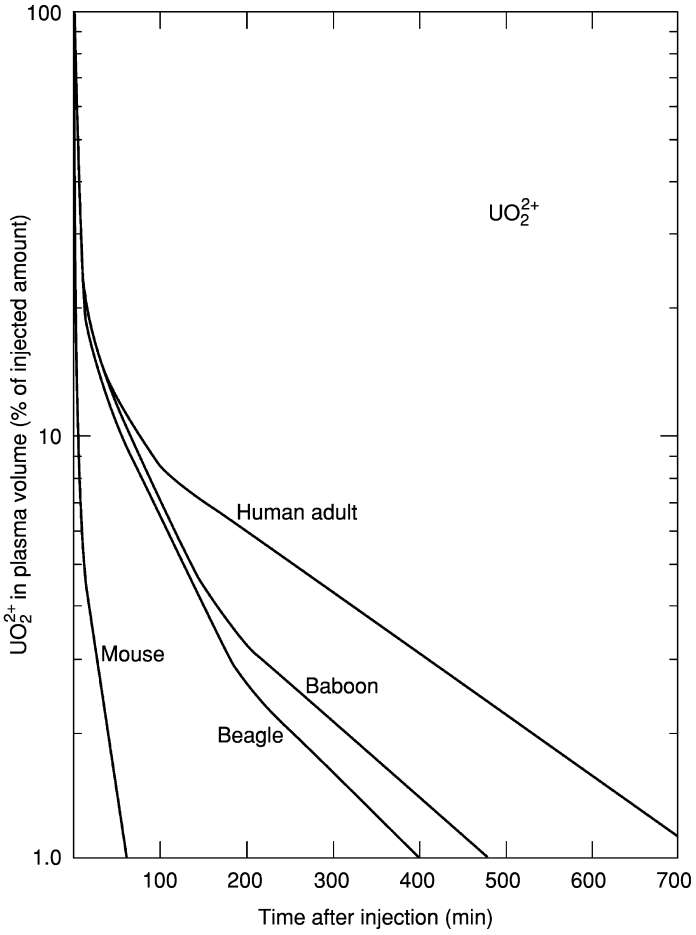

Fig. 31.10 *Clearance of iv-injected* UO_2^{2+} *from the plasma volume of animals and man:* $^{232}UO_2^{2+}$ *mouse* (*Durbin* et al., 1997a); $^{233}UO_2^{2+}$ *beagle* (*Stevens* et al., 1980); $^{233}UO_2^{2+}$ *baboon* (*Lipsztein,* 1981); $^{234,235,238}UO_2^{2+}$ *adult human male* (*Bernard and Struxness,* 1957).

rigorous analytical procedures (Popplewell and Boocock, 1968; Turner and Taylor, 1968a; Bruenger *et al.*, 1969b, 1971b; Taylor, 1970; Stevens and Bruenger, 1972; Cooper and Gowing, 1981). Provisional formation constants (log K_1) have been calculated, 5.3 and 6.5 for Am^{3+} and Cm^{3+}, respectively (Taylor, 1998), and these are similar to the value of the apparent stability constant for binding of Gd^{3+} to the C-terminal site of human Tf (Zak and Aisen, 1988).

Binding of Am^{3+} by Tf is reduced when Fe^{3+} saturation of Tf is high and eliminated altogether by addition of Fe^{3+} in excess of the Tf iron-binding

capacity (Popplewell and Boocock, 1968; Bruenger *et al.*, 1969b). The trivalent actinides also bind to plasma proteins other than Tf. Depending on the experimental conditions and the analytical methods, variable fractions of the trivalent actinides in plasma associate with the heaviest proteins and with albumin (Turner and Taylor, 1968a; Bruenger *et al.*, 1969b, 1971b; Stevens and Bruenger, 1972).

31.4.2 Tetravalent and pentavalent actinides

(a) Th^{4+}

Clearance of iv-injected $^{228}Th^{4+}$, studied only in beagles, is somewhat faster than, but comparable to that of $^{239}Pu^{4+}$ in the same animal (Fig. 31.5). Reduction to 10% occurred in 0.5 day, and 99% of the injected Th^{4+} had disappeared from the plasma in 1.5 days. A larger fraction of the Th^{4+} was excreted in 21 days than was found for Pu^{4+} (Table 31.4).

Transferrin is the main protein carrier of Th^{4+} in the plasma. The larger Th^{+} ion forms a Tf complex that appears to be less stable than the Pu^{4+}–Tf complex. Similarly to Pu^{4+}, the Th^{4+}–Tf complex is destabilized by excess Fe^{3+}. Binding of Th^{4+} to Tf is suppressed in Fe^{3+}-saturated plasma, permitting formation of less stable complexes with the heavier plasma proteins and small filterable ligands (Bruenger *et al.*, 1971a; Peter and Lehmann, 1981; Pecoraro *et al.*, 1981).

(b) U^{4+}

Clearance from the blood of iv-injected $^{234,235,238}U^{4+}$ was studied in rats (data not shown, Neuman, 1949) and an adult man (Table 31.7, Fig. 31.7; Bernard and Struxness, 1957). Based on their similar properties, the disposition of U^{4+} *in vivo* would be expected to resemble Th^{4+} and Pu^{4+}, with stable binding to plasma protein and delayed blood clearance (Tables 31.4, 31.7; Figs. 31.5, 31.7). However, disappearance from the blood of both the rats and man of U injected iv as U^{4+} was fast. In humans, it was 90% complete in 200 min and 99% complete in 24 h. During the first hour after injection, clearance from the blood of U injected as U^{4+} was nearly the same as that of UO_2^{2+} (Fig. 31.7). Thereafter, U in the blood declined at nearly the same rate as UO_2^{2+}, but the U concentration in the blood was about 1.7 times greater that of UO_2^{2+}. Overall, the clearance of U^{4+} from human blood closely resembled that of UO_2^{2+} and differed markedly from the plasma clearances of Th^{4+} and Pu^{4+} in the dogs and Pu^{4+} in adult men.

By analogy to Th^{4+} and Pu^{4+}, binding of U^{4+} by circulating Tf would be expected, but there is little evidence for such stable binding *in vivo*. The absence from the U^{4+} blood curve of a major rapidly forming and slowly clearing component argues against formation of a stable U^{4+}–Tf complex *in vivo*.

When $^{233}U^{4+}$ citrate was added to plasma *in vitro* and chromatographed on G-25 Sephadex, <10% of the U eluted with the plasma proteins (Bruenger *et al.*, 1971b).

(c) Np^{4+}

Plasma clearance of Np^{4+} was studied in rats injected iv with about 310 μg kg^{-1} (0.4 μmol per rat) of $^{237}Np^{4+}$ citrate, and plasma was sampled at 1, 2, 6, and 24 h (Fig. 31.3, Ramounet *et al.*, 1998). Paquet *et al.* (1996) injected rats iv with a tracer of $^{239}Np^{4+}$ citrate (17 pg kg^{-1}) or 1.2 mg kg^{-1} (1.1 μmol per rat) of $^{237}Np^{4+}$ citrate. Blood was sampled only at 24 h, at which time the plasma volumes of both groups contained 4 to 5% of the injected Np, in good agreement with the data of Fig. 31.3. Because no blood samples were taken sooner than 60 min after injection, the earliest phases of the plasma clearance curve for Np^{4+} are poorly defined. Renal excretion of Np at 24 h was about 20% of the amount injected regardless of the mass of Np^{4+} injected.

Based on their similar chemical properties, plasma clearances of Np^{4+} and Pu^{4+} would be expected to be similar, that is, slow clearance accompanied by slow tissue uptake and little early urinary excretion (Table 31.2). In the rats, plasma clearances of Np^{4+} and Pu^{4+} were 90% complete in 500 and 1150 min, respectively. After 2 h, their clearance rates were similar, and 99% of both actinides disappeared from the blood in 2 days. Extrapolation of the terminal slope of the Np^{4+} plasma curve (Fig. 31.3) to $t = 0$ suggests that about 16% of the injected Np^{4+} circulated bound to nonfilterable protein, compared with stable protein binding of ≥50% of the Pu^{4+}.

Sephacryl S-300 and DEAE-cellulose chromatography were used to investigate protein binding of Np in the plasma taken from rats 30 min after iv injection of 10 μCi of $^{239}NpO_2^+$ nitrate. At 30 min after injection, based on the plasma clearances of NpO_2^+ in other animals (Figs. 31.3, 31.4, and 31.6), it may be estimated that about 5% of the injected Np would still be in the plasma, most likely bound to protein. Both chromatographic techniques showed that ≥95% of the Np applied to the columns colocated with the Fe–Tf peak. Results were essentially the same when $^{239}NpO_2^+$ was incubated with rat serum *in vitro*, except that the fraction of Np applied to the columns eluting with the Tf peak was reduced to about 70%. Specific Np binding to Tf was confirmed by manipulation of the Fe saturation of the Tf; the association of the Np with the Tf peak decreased as the iron saturation of the Tf was increased. In highly Fe^{3+}-saturated preparations, larger fractions of the Np tended to be associated with both the heavier plasma proteins and with the low molecular weight solutes (Wirth *et al.*, 1985). These studies demonstrated binding of Np to Tf, but as Wirth *et al.* (1985) and Taylor (1998) suggest, it is likely to be complexation of Np^{4+} rather than of the weakly complexing NpO_2^+. These results also imply that some of the $^{239}NpO_2^+$ injected in the rats or added to rat serum *in vitro* was reduced to Np^{4+}.

(d) Pu^{4+}

Plasma clearances of iv-injected Pu^{4+} citrate are shown in Figs. 31.3–31.7 for rats, mice, beagles, monkeys, and human adults, respectively, and Fig. 31.8 compares the clearances of Pu^{4+} in all of these animals. Clearance of Pu^{4+} from the plasma is slow in all of the mammals studied. It was 90% complete in 0.2 to 0.75 day in mice and rats and 1.5 to 5 days in monkeys, beagles, and human adults. Reduction of plasma Pu^{4+} to 1% of its initial value required from 0.7 to 1 day in the rodents and 2.5 to 21 days in the larger animals and man.

Delayed clearance from the plasma of rats and dogs of iv-injected $^{239}Pu^{4+}$ or $^{239}PuO_2^{2+}$ and minimal amounts of urinary Pu excretion in the first 24 h were indications that Pu introduced into mammalian plasma was rapidly and almost quantitatively bound to nonfilterable plasma protein (Finkle *et al.*, 1946; Painter *et al.*, 1946; Muntz and Guzman-Barron, 1947; Stevens *et al.*, 1968). Slow plasma clearance of Pu^{4+} along with minimal renal excretion is evidence for rapid formation of a stable Pu^{4+} complex with plasma protein and for the slow kinetics of the exchanges of Pu^{4+} between Tf and the tissue ligands.

Transferrin is the main, if not the only, protein carrier of Pu^{4+} in normal mammalian plasma (Popplewell and Boocock, 1968; Stevens *et al.*, 1968, 1975; Stover *et al.*, 1968a; Turner and Taylor, 1968a,b; Bruenger *et al.*, 1971a; Durbin *et al.*, 1976; Lehmann *et al.*, 1983; Taylor, 1998). A provisional stability constant derived for Pu^{4+}–Tf (log K_1=21.8, Taylor, 1998) is close to but less than that derived for Fe^{3+}–Tf (log K_1=24; Raymond *et al.*, 1980). Pu–Tf is destabilized by reduction of the pH, by addition of excess Fe^{3+}, and by increasing the concentration of citrate ion to ten times that of normal plasma. The latter two reactions may contribute to the release of Pu^{4+} from Tf to competing tissue ligands.

A small fraction ($\leq$5%) of circulating Pu^{4+} is associated with low molecular weight plasma ligands, suggesting that an equilibrium exists between those ligands and the Tf-bound fraction of circulating Pu^{4+}. In highly Fe^{3+}-saturated plasma, Pu^{4+} can bind to the heavier proteins, and a larger than usual fraction associates with the low molecular weight ligands (Popplewell and Boocock, 1968; Stover *et al.*, 1968a).

(e) Pa^{5+}

Baboons were injected iv with 10^{-6} μg kg^{-1} of $^{233}Pa^{5+}$ in 0.08 M Na citrate pH 3.2, and blood was sampled frequently for 21 days (Fig. 31.5, Cohen and Ralston, 1983; Ralston *et al.*, 1986). Clearance of the Pa^{5+} from the plasma was slower than that of $^{239}Pu^{4+}$ citrate in beagles (Figs. 31.5 and 31.8), and comparable to that of $^{237}Pu^{4+}$ in adult men (Figs. 31.7 and 31.8). Plasma clearance was 90% complete in 6 days and 99% complete in 21 days. It was as slow as the plasma clearances of Pu^{4+} and Th^{4+} in the beagles, and along with low early urinary excretion, a good indication of the formation of a stable Pa^{5+} plasma protein complex.

Pa^{5+}, incubated with normal human plasma *in vitro*, was associated with the Tf peak, indicating that the stable complex was Pa^{5+}–Tf (Bruenger *et al.*, 1971b). Taylor and Farrow (1987) prepared a solution for animal injection by diluting a stock solution of $^{233}Pa^{5+}$ in 8 M HCl with normal saline and adjusting to pH 7 with $NaHCO_3$. The distribution of the Pa^{5+} in the serum from rats killed and bled at 5 and 50 min after injection was investigated by gel and ion-exchange chromatography and electrophoresis. In all procedures, the $^{233}Pa^{5+}$ was associated only with the Tf fraction of the serum proteins.

In normal mammalian plasma, Tf binds Th^{4+}, Np^{4+}, and Pu^{4+} (Peter and Lehmann, 1981; Lehmann *et al.*, 1983; Wirth *et al.*, 1985). Binding of those tetravalent actinides by Tf is reduced in Fe-saturated serum, and they are all released from their Tf complexes by treatment with excess Fe^{3+}. These findings are regarded as evidence that Fe^{3+}–Tf is more stable than the actinide^{4+}–Tf complexes. In contrast, Tf binding of Pa^{5+} was not prevented by presaturation of Tf with Fe^{3+}, nor was it reversed by addition *in vitro* of excess iron to rat serum containing Pa^{5+} (Taylor and Farrow, 1987). Those findings suggest that the Pa^{5+}–Tf complex is more stable than the Tf complexes of the tetravalent actinides and also more stable than Fe^{3+}–Tf.

(f) Summary

The charge/radius ratios of ferric iron and the tetra- and pentavalent actinides are, in units of e nm^{-1}, as follows: Pa^{5+}, 54.9; Fe^{3+}, 46.2; Pu^{4+}, 41.7; Np^{4+}, 40.8; Th^{4+}, 38.1 (eight-coordination is assumed for the actinides, six-coordination is assumed for Fe^{3+}, Table 31.8) (Shannon, 1976). Based on the positive correlation of the stabilities of actinide complexes and their charge/radius ratios, the stabilities of their Tf complexes would be predicted to be in the above order. The apparent stabilities of their Tf complexes in normal mammalian plasma relative to one another and to Fe^{3+} are in that expected order.

31.4.3 The dioxo ions

(a) UO_2^{2+}

Plasma clearance of iv-injected UO_2^{2+} has been studied in mice, beagles, baboons, and human adults (Figs. 31.4–31.7, 31.10). It was fast in all of the species studied; clearance was 90% complete in 10 to 80 min, and 99% was cleared in 60 to 700 min. Urinary excretion and uptake of UO_2^{2+} in the tissues are fast, as illustrated by measurements in mice (Durbin *et al.*, 1997a). Both processes begin immediately after the UO_2^{2+} is introduced into the blood and continue until the plasma is cleared (about 100 min). Diffusion of filterable low molecular weight complexes between the plasma and tissue fluid and weak binding to plasma protein briefly delay, but do not otherwise interfere with renal filtration of UO_2^{2+} or its deposition in the skeleton.

During the first few days after intake to blood about 85% of absorbed UO_2^{2+} is filtered through the kidneys, about 85% of the filtered fraction is eliminated in passed urine, but about 12% of the injected UO_2^{2+} is deposited in the kidneys (Tables 31.2–31.7). The UO_2^{2+} retained in the kidneys is bound mainly to the brush border of the luminal surfaces of the cells that line the proximal tubules, the site of the renal injury (Tannenbaum, 1951a,b). Binding of UO_2^{2+} to cell membranes is the presumed cause of the cell damage, but the mechanism – conformational changes, blockage of ion channels that interfere with the cell's absorptive functions, and/or inhibition of membrane enzymes required for cell respiration – is not certain (Dounce, 1949; Kirschbaum and Oken, 1979; Kirschbaum 1982; Leggett, 1989).

The large fraction of circulating UO_2^{2+} that is rapidly excreted in urine is indicative of formation of ultrafilterable UO_2^{2+} complexes with low molecular weight ligands in the plasma. Uranyl ion is rapidly and quantitatively absorbed from an im or sc injection site (Tables 31.2 and 31.5), even though formation of *in situ* poorly transportable hydrolysis products is expected at physiological pH, indicating that sufficient concentrations of ligands for UO_2^{2+} are also present in tissue fluid. Bicarbonate was presumed to be the dominant ligand for UO_2^{2+} in the body fluids; UO_2^{2+} complexes with phosphate and organic acids were considered to be of lesser importance (Dounce and Flagg, 1949; Muntz and Guzman-Barron, 1951).

The evidence for bicarbonate as the principal low molecular weight ligand for UO_2^{2+} in body fluids was indirect. Addition of HCO_3^- greatly increased the ultrafilterability of UO_2^{2+} added to blood serum. Protein precipitated with UO_2^{2+} redissolved, and enzymes inhibited with UO_2^{2+} were reactivated by addition of HCO_3^-. The urinary pH of cats and rabbits was lowered or raised by manipulation of their diets: acidification of the urine reduced UO_2^{2+} excretion and increased UO_2^{2+} deposition in the kidneys. Conversely, alkalinization increased urinary UO_2^{2+} excretion and reduced UO_2^{2+} deposition in the kidneys. Infusion of excess HCO_3^- in rabbits injected iv with UO_2^{2+} resulted in more and more rapid urinary UO_2^{2+} excretion and even less UO_2^{2+} retention in the kidneys than increasing urinary pH alone. The stability of the filtered UO_2^{2+} complex was more dependent on the concentration of HCO_3^- in the filtrate than on the pH (Dounce, 1949; Dounce and Flagg, 1949; Wills, 1949; Muntz and Guzman-Barron, 1951).

The abundance of HCO_3^- in both plasma and tissue fluid greatly exceeds those of the other low molecular weight ligands (phosphate, organic acids, Table 31.9). Uranyl carbonate complexes are more stable than those with phosphate and citric acid (Table 31.8; Grenthe *et al.*, 1992). The circulating filterable UO_2^{2+} complex is pH-dependent, whereas UO_2 citrate is stable over the physiological pH range (Dounce and Flagg, 1949).

About 40% of circulating UO_2^{2+} is bound to nonfilterable plasma protein. Based on estimated molecular weight and electrophoretic properties, the protein that bound UO_2^{2+} was originally thought to be serum albumin (Dounce, 1949;

Dounce and Flagg, 1949; Muntz and Gurman-Barron, 1951). Stevens *et al.* (1980) demonstrated that the protein that binds UO_2^{2+} in plasma is Tf. The UO_2^{2+}–Tf complex is demonstrably weaker than the complexes that UO_2^{2+} forms with carbonate. As the plasma UO_2^{2+} is depleted by glomerular filtration of the low molecular weight complexes, the equilibrium between the filterable and nonfilterable complexes is continuously reestablished by dissociation of the nonfilterable protein complex and shift to the filterable complex until UO_2^{2+} has been cleared from the plasma by renal filtration and binding to bone.

As the plasma ultrafiltrate formed by the renal glomeruli is converted to bladder urine >99% of the water and electrolytes are reabsorbed, mainly in the proximal tubules, and the pH is reduced. Bicarbonate and phosphate are preferentially reabsorbed as the fluid passes through the proximal tubule, and by the time the tubular fluid enters the last third of the proximal tubule (the site of UO_2^{2+} deposition and renal injury), their concentrations are 0.35 and 0.50, respectively, of those in the plasma (Wong *et al.*, 1986). Under these conditions UO_2^{2+} carbonate complexes formed in the plasma will become less stable.

The concentration of HCO_3^- in bladder urine is usually <1% of that in plasma, and the pH is about 6, whereas the concentrations of phosphate and citrate are slightly greater than in the plasma (Table 31.9). The UO_2^{2+} carbonate complexes formed in the plasma cannot survive the transit through the entire renal tubule system to the bladder, and the chemical form of UO_2^{2+} in urine is not likely to be the same as in the circulating fluids.

Speciation calculations can be used to identify and provide estimates of the relative concentrations of the UO_2^{2+} complexes that are likely to form in biological fluids. Concentrations of the important constituents of human plasma and bladder urine are shown in Table 31.9. The concentrations of these constituents in the fluid entering the last third of the proximal renal tubules (site of UO_2^{2+} deposition and renal injury) were estimated from the renal micropuncture data of Wong *et al.* (1986) (Table 31.9). Concensus values are available for the formation constants of the UO_2^{2+} complexes with the ligands in biological fluids at $T = 25°C$ and ionic strength $I = 0.1$ M, the closest match to the conditions in biological fluids. A very stable soluble neutral dicalcium uranyl triscarbonate complex, $Ca_2UO_2(CO_3)_3(aq)$, was shown to influence the speciation of UO_2^{2+} in the region pH 6 to 10 of calcite-rich U mining waters (Bernhard *et al.*, 2001). That complex was included in the present calculations, because the chemical conditions in the mine waters resemble those in blood plasma and renal tubular fluid, both of which are nearly neutral and contain significant concentrations of Ca^{2+} and HCO_3^-.

(*i*) *Complexes in plasma*

The conditions for the plasma calculations were, as follows: Data for the human UO_2^{2+} injection case (Table 31.7) were combined with human data for fluid volumes and Tf concentrations (Table 31.10) to calculate an initial UO_2^{2+}

concentration in plasma of 10^{-5} M and a concentration of available Tf-binding sites of 3.6×10^{-5} M. The partitioning of UO_2^{2+} in the plasma was set at 60% associated with ultrafilterable ligands and 40% bound to nonfilterable Tf (Stevens *et al.*, 1980). No correction was made for the small fraction of newly injected UO_2^{2+} ($\leq$4%) that is transiently associated with red blood cells (Dounce, 1949; Stevens *et al.*, 1980; Lipsztein, 1981; Durbin *et al.*, 1997a).

The set of equations for the competing reactions was solved simultaneously. The predominant filterable UO_2^{2+} complex in the plasma, identified as $Ca_2UO_2(CO_3)_3(aq)$, can account for 86% of the filterable UO_2^{2+}, with 13% in the form of the triscarbonate complex, and about 1% as the biscarbonate (Table 31.11). The selected concentration of Tf-binding sites and fraction of UO_2^{2+} bound to Tf yielded a value for the formation constant of UO_2^{2+}–Tf, $\log K_f = 14.5$, which agrees reasonably well with a reported value of $\log K_f = 16$ determined in a solution much more dilute than 0.1 M NaCl (Ansoborlo *et al.*, 2003).

(*ii*) *Complexes in proximal renal tubular fluid*

Only a crude estimate can be made of the speciation of the UO_2^{2+} complexes that exist in the chemical milieu of the fluid flowing through the late proximal renal tubules, because the fluid in the last third of the proximal tubules is not accessible to micropuncture sampling. The composition of the tubular fluid shown in

Table 31.11 UO_2^{2+} *complexes with the low molecular weight ligands of biological fluids as identified by speciation calculations.*[a,b]

	Distribution of UO_2^{2+} *complex species* (% *of total*)			
UO_2^{2+} *complex*	$\log K_f$	*Plasma ultrafiltrate*	*Late proximal tubule fluid*[c]	*Bladder urine*
$UO_2(CO_3)_2^{2-}$	16.2[c]	0.6	7.0	0.2
$UO_2(CO_3)_3^{4-}$	21.6[c]	13	6.3	<0.1
$Ca_2UO_2(CO_3)_3(Aq)$	28.1[d]	86	73	0.4
UO_2HPO_4	7.2[c]	<0.1	0.3	77
UO_2 citrate	7.4[e]	<0.1	0.5	22
'Tubule protein'[f]	–	–	13	–

[a] Values for formation constants at T=25°C and ionic strength I=0.1 used as best match to 0.14 M NaCl in biological fluids.

[c] NEA (1992). Calculated from composition of fluid entering last third of proximal tubules.
[d] Bernhard *et al.* (2001).
[e] Martell and Smith (1977).
[f] Membrane of proximal tubule microvilli.

Table 31.9 is the set of measurements made closest to the beginning of the last third of the proximal tubules (Wong *et al.*, 1986). The concentration of HCO_3^- and the tubular fluid pH continue to be reduced during the traverse of the last portion of the proximal tubule, but by how much before the fluid enters the more distal nephron cannot be estimated, because Wong *et al.* (1986) did not report measurements of the concentration of HCO_3^- in the distal tubules.

Specification of chemical conditions for the tubular fluid calculations introduces additional uncertainty. During its transit through the last third of the proximal tubules, about 13% of the injected UO_2^{2+} is lost from the fluid phase and is deposited on the membrane of the brush border microvilli. To take account of that loss to protein binding, it was assumed that the contact between the tubular fluid and the membrane of the microvilli was so intimate that the membrane protein could be considered to be 'virtually' in solution. The concentration of membrane protein-binding sites was set at 10^{-4} M, assuming that the binding sites for UO_2^{2+} were three times more abundant than those of Tf. The concentrations of the UO_2^{2+} complexes calculated for the plasma ultrafiltrate were used as starting conditions for the UO_2^{2+} content of the tubular fluid.

The dominant complex is still $Ca_2UO_2(CO_3)_3(aq)$ (Table 31.11), which can account for 73% of the UO_2^{2+} entering the system, 13% is bound to kidney protein (fixed by starting conditions), the biscarbonate (7%) is more important than in the plasma, whereas the triscarbonate (6.3%) is less important than in plasma. In addition, about 1% of the UO_2^{2+} in this system is predicted to be associated with phosphate and citrate. The selected concentration and fractional binding of UO_2^{2+} to tubule membrane protein yielded a value for a 'formation constant' of UO_2^{2+}-membrane protein, $\log K_f = 9.6$. The fixed protein 'concentration' and $\log K_f$ are coupled, and both are uncertain.

(*iii*) *Complexes in bladder urine*

The conditions for the urine calculations were as follows: The human UO_2^{2+} injection case (Table 31.7) excreted 59% of the injected UO_2^{2+} (14 μmol) in 1.4 L of urine in the first 24 h (Hursh and Spoor, 1973), and the concentration of UO_2^{2+} in urine was 10^{-5} M. The concentrations of the constituents of urine of humans consuming an ordinary diet are those given in Table 31.9. The speciation calculations indicate that only 1% of the excreted UO_2^{2+} would still be a carbonate complex, and 99% would be present as phosphate and citrate complexes (Table 31.11). Diets that raise the pH and/or increase HCO_3^- in urine and HCO_3^- infusion, which increases both the HCO_3^- concentration and the pH of the urine, would allow survival of greater fractions of the carbonate complexes filtered from plasma and their excretion in the urine.

Two questions that have received little attention are the near absence at low UO_2^{2+} intakes to blood of significant UO_2^{2+} deposition in portions of the renal tubular system distal to the proximal tubules and the spreading out of the renal injury at toxic UO_2^{2+} doses. The degree and extent of renal injury

caused by UO_2^{2+} are dose-dependent. At low to moderately toxic intakes to blood, cell damage is limited to the later portion of the proximal tubules, seen in microscopic sections as occupying the region near the cortico-medullary junction. With increasing doses of UO_2^{2+}, the cellular injury becomes progressively more widespread, extending proximally to the earlier portions of the proximal tubules and the distal tubules in the cortical region and distally to the loops of Henle in the medulla (Barnett and Metcalf, 1949). Autoradiographs of the kidneys of rodents given low doses of $^{232}UO_2^{2+}$ or $^{233}UO_2^{2+}$ verified that deposition of the UO_2^{2+} coincided with the zone of low-dose cellular injury. When the shorter-lived U isotopes were given augmented with toxic amounts of $^{238}UO_2^{2+}$, autoradiographs showed more U deeper in the cortex (earlier portions of the proximal tubules and distal tubules) and deeper into the medulla (loops of Henle) than were seen with the lower doses of UO_2^{2+}.

In chemical terms, when high concentrations of UO_2^{2+} (10^{-3} M) were circulating, the carbonate complexes filtered from the plasma apparently begin to destabilize at the conditions of the earlier portions of the proximal tubules (Table 31.9), and the concentrations of phosphate and citrate are insufficient to prevent UO_2^{2+} binding to the presumably lower affinity proteins of the membrane of the later segments of the renal tubule system.

The microvilli of the proximal tubule brush border are specialized for absorption, and the brush border presents a surface area many orders of magnitude greater than the luminal surface of the more distal portions of the renal tubule system (Berliner, 1973). Combined, the lower concentrations of potential UO_2^{2+} binding sites and lower affinities for UO_2^{2+} of these sites (less than those of phosphate and citrate) could account for the apparent lack of binding of low doses of UO_2^{2+} in the more distal tubule segments.

(b) NpO_2^+

Plasma clearance of iv-injected $^{237}NpO_2^+$ was studied in rats and mice (Figs. 31.3 and 31.4). Clearance of NpO_2^+ from mouse plasma was fast, with 90% clearance in 10 min and 99% clearance in 60 min. At 100 min, skeletal uptake and urinary excretion accounted for 80% of the injected Np (Table 31.3). Plasma clearance of Np was also investigated in baboons injected iv with 1 ng kg^{-1} of ^{239}Np or 100 μg kg^{-1} of ^{237}Np reported as NpO_2^+ or NpO_2^{2+} in solutions of Na citrate, $NaHCO_3$, or $NaNO_3$ (Ralston *et al.*, 1986). No differences were found in the plasma clearances, urinary excretion rates, or whole-body retentions of the differing masses of Np or Np oxidation states or chemical compositions of the injection media. Those findings indicate that either NpO_2^{2+} had not been formed or that it was promptly reduced to NpO_2^+ *in vivo*. Plasma clearance of NpO_2^+ was fast in the baboons; it was 90% complete in about 45 min and 99% complete in about 300 min (Fig. 31.6).

The plasma clearance of iv-injected $^{237}NpO_2^+$ nitrate in the rats differs somewhat from those of the other animals (Figs. 31.3, 31.4, and 31.6). About 80% of

the injected Np was cleared from the plasma as rapidly as in the mice and baboons (in about 20 min, Figs. 31.4 and 31.6), but clearance of the remaining 20% was slow and resembled that of Np^{4+} in the same animal models. Overall clearance was slow; it was 90% complete in 160 min and 99% complete only after 1.7 days. In the three animals, a small fraction of the iv-injected NpO_2^+ was cleared from the plasma as slowly as Pu^{4+} (0.5% in the mice, 2% in the baboons, and 5.5% in the rats). The complexes of NpO_2^+ are weak (Table 31.8), and it is reasonable to consider that these small slowly clearing fractions of the injected Np had been reduced to Np^{4+} *in vivo* and were circulating complexed with serum proteins.

Human plasma was incubated with ^{237}Np as Np^{4+}, NpO_2^+, or NpO_2^{2+} in 0.08 M Na citrate buffer pH 3.2. Chromatography on G-25 Sephadex indicated that about 20% of the Np in all these preparations was associated with serum proteins. Chromatography on G-100–200 Sephadex indicated that the ^{237}Np, applied as NpO_2^+, was distributed among the heavy proteins (22%), the albumin-Tf peak (33%), and low molecular weight species (44%). Re-chromatography of the albumin-Tf peak on DEAE-Sephadex showed only a moderate tendency of the Np to be associated with the Tf peak (Bruenger *et al.*, 1971b).

Protein precipitation, dialysis, ultrafiltration, and gel chromatography (150-Sephadex) were used to study protein binding of $^{239}NpO_2^+$ incubated with dog serum. All of those procedures indicated that about 50% of the Np was associated with protein, but no specific protein(s) could be identified. Protein binding was weak, and gel chromatography showed that about 20% of the applied Np was associated with the heaviest proteins and 80% eluted with the low molecular weight species in the same fraction as NpO_2NO_3 (Guilmette *et al.*, 1982).

Intravenously injected NpO_2^+ is rapidly cleared from the plasma of mice, rats, and baboons, mainly to urinary excretion and uptake in bone (Tables 31.2, 31.3, 31.5, and 31.6; Figs. 31.3, 31.4, and 31.6). There is little evidence for protein binding of NpO_2^+ in the plasma. Combined, these observations are good indicators that, in accord with its tendency to form only weak complexes, NpO_2^+ does not form stable complexes with plasma protein (Bruenger *et al.*, 1971b; Guilmette *et al.*, 1982). Stable binding of Np to Tf apparently requires that the injected NpO_2^+ be reduced *in vivo* to Np^{4+}, which forms complexes as stable as those of Pu^{4+}. *In vivo* reduction of NpO_2^+ to Np^{4+} is likely to be slow, because it involves the breaking of M–O bonds, but as Durbin *et al.* (1998b) and Taylor (1998) point out, at pH 7.4 in the presence of ligands with great affinity for Pu^{4+} and Np^{4+} but little affinity for NpO_2^+ and an average eH in mammalian plasma of about 270 mV (Van Rossum and Schamhart, 1991), such reduction is theoretically possible.

The low molecular weight NpO_2^+ species transported in the plasma, filtered by the kidneys into the urine, and rapidly deposited in bone (Tables 31.2, 31.3, and 31.5) have not been identified. Hydrolysis of NpO_2^+ is not expected at physiological pH. Some of the NpO_2^+, which behaves like a large monovalent

cation, may exist as a hydrated ion, and carbonate is known to stabilize NpO_2^+ (Ahrland, 1986). Both an aqueous ion and a NpO_2^+ carbonate complex should be ultrafilterable and excreted by the kidneys into the urine.

The identities of the NpO_2^+ species that may be expected in mammalian plasma can be calculated for the specific set of conditions in the plasma volume of a 6.2 kg monkey immediately after iv injection of 42 μg kg^{-1} of $^{237}NpO_2^+$ (Table 31.5); the concentration of the NpO_2^+ would be 4.5×10^{-6} M in 0.025 M HCO_3^- at pH 7.4 (Tables 31.8 and 31.9). The stability constants of the NpO_2^+ carbonate, phosphate, and citrate complexes are as shown in Table 31.8.

The speciation calculations predict that in mammalian plasma hydrolysis of NpO_2^+ is negligible, and about 20% of the injected NpO_2^+ circulates as a hydrated ion, $NpO_2^+(aq)$, 50% as $NpO_2CO_3^-$, 20% as $NpO_2HPO_4^-$, and 10% as a NpO_2^+ citrate complex. The concentration of HCO_3^- and the pH are too low to allow formation of a biscarbonate.

The $NpO_2CO_3^-$ complex is unstable at the reduced HCO_3^- and pH in the renal tubules (Table 31.9). In the urine, NpO_2^+ is likely to be about equally divided between its HPO_4^{2-} and citrate complexes.

The fraction of iv-injected NpO_2^+ that deposits in the kidneys is $\leq$3% (Tables 31.2, 31.3, and 31.6), the tendency of NpO_2^+ to bind to kidney tissue protein is apparently much less than that of UO_2^{2+}. However, if the amount of Np injected (oxidation state not certain) is in the toxic range ($\geq$6 mg kg^{-1}), even that small fractional kidney deposit will result in renal tubular injury of the same nature at the same anatomical location that is typically seen with much smaller doses of UO_2^{2+} (Maynard and Hodge, 1949; Ballou *et al.*, 1962; Mahlum and Clarke, 1966).

(c) PuO_2^{2+}

A dog was injected iv with 0.84 μg Pu per kg of $^{239}PuO_2^{2+}$ in a solution containing 0.01 M Na citrate and 0.14 M NaCl, pH 7 (Painter *et al.*, 1946). About 35% of the injected Pu was cleared from the plasma in the first 20 min, but in contrast to its analog, UO_2^{2+}, clearance of about 65% of the injected PuO_2^{2+} from the plasma was as slow as that of Pu^{4+} in beagles (Fig. 31.5). Comparisons of the plasma clearance pattern and early urinary excretion in the dog and the tissue distributions in rats of Pu injected as PuO_2^{2+} with those of Pu^{4+} and UO_2^{2+} in the same animals (Tables 31.2 and 31.4) show that the disposition of PuO_2^{2+} does not resemble that of UO_2^{2+}, but is similar to that of Pu^{4+}. Combined, these observations indicate reduction of PuO_2^{2+} to Pu^{4+} *in vivo*. Where in the body that reduction occurs is not known, but because it is rapid, it is likely to take place in the circulating fluids.

The stabilities of the biscarbonate complexes of UO_2^{2+} and PuO_2^{2+} are similar (Table 31.8). However, after iv injection of $^{239}PuO_2^{2+}$ in rats little Pu was excreted in the urine, and the distribution of the Pu was nearly the same as that of iv-injected $^{239}Pu^{4+}$ citrate (Table 31.2; Carritt *et al.*, 1947). These results

also suggest that PuO_2^{2+} is rapidly reduced to Pu^{4+} in the circulation (Table 31.2). However, when $^{239}PuO_2Cl_2$ was injected im in rats, Pu absorption was greater and faster than when the same mass of Pu was injected im as $^{239}PuCl_4$ or $^{239}PuCl_3$, suggesting that some PuO_2^{2+} was mobilized from the wound site in a transportable form before it could be reduced to Pu^{4+} and hydrolyzed *in situ* (Scott *et al.*, 1948b).

31.5 TISSUE DEPOSITION KINETICS

The kinetics of the tissue uptake of some actinides and lanthanides have been studied to relate differences in their biological behavior to their chemical properties, to aid in developing procedures for the therapeutic removal of actinides from the body, to identify the biological processes underlying the several components of the plasma clearance curves, and to determine whether the target tissues take up actinide bound to plasma protein or complexed by low molecular weight plasma ligands or both. The experimental design of the kinetic studies, which as a practical matter have been conducted only in rats and mice, involves killing groups of animals at intervals from 1 min to 24 h after iv injection of an actinide and measuring the nuclide content of the blood, and/or plasma, tissues, and excreta.

31.5.1 Tissue deposition kinetics in rats

Tissue uptake data have been reported for iv-injected $^{241}Am^{3+}$ by Belyayev (1969), for $^{239}Pu^{4+}$ by Schubert *et al.* (1950) and Rosenthal and Schubert (1957), and for four representative lanthanides (Durbin *et al.*, 1955). Taylor (1962) reported that the pattern of uptake of iv-injected $^{241}Am(NO_3)_3$ or $^{241}Am^{3+}$ citrate in the bones of growing rats more closely resembled that of Ca^{2+} than Pu^{4+}. The data from those studies were recalculated to account for nuclide in the contained plasma of the tissues (Durbin *et al.*, 1972; Durbin, 1973). Within the first 5 min after iv injection of Ca^{2+}, Ce^{3+}, Eu^{3+}, Am^{3+}, or Pu^{4+} in rats, as much as 50% of the injected nuclide disappeared from the plasma, but could not be accounted for by excretion or uptake in bones and liver. Material balance studies with Ca^{2+} and four lanthanides demonstrated that at that time 75 to 90% of the missing nuclide was present transiently in the bulk soft tissue, indicating association with interstitial water (ISW) rather than with cellular components. The light lanthanides, Ce^{3+} and Eu^{3+}, Ca^{2+}, and Am^{3+} bind weakly to plasma proteins, and 50 to 60% of the injected amounts of those nuclides had diffused into ISW (Durbin, 1973). Plasma Tf binds stably to Pu^{4+}, and only 20 to 40% of iv-injected Pu^{4+} diffused into ISW, depending on whether the Pu^{4+} was administered as the nitrate or complexed with citrate (Durbin *et al.*, 1972).

The fraction of iv-injected nuclide diffusing into ISW depends on the stability of its protein complex(es). The less stable the protein binding, the more slowly the complex forms, and the larger is the fraction that promptly leaves the plasma by diffusion into ISW or immediate uptake by bone and/or liver or urinary excretion.

These kinetic studies of Am^{3+} and lanthanides demonstrated that the initial fast decline in the plasma clearance curves (first exponential component) was the combined result of rapid early deposition in the target tissues and urinary excretion and diffusion of filterable nuclide from the plasma to ISW, most of which is associated with the bulk soft tissues. Delayed return to the plasma compartment from ISW contributes to the second and third components of the plasma clearance curves and supports continued, but slower, uptake in the tissues. The multiexponential equations that describe the uptake of Am^{3+} in the bone and liver of rats have rate terms in common with each other and with the equations of clearance from the plasma and the soft tissues (ISW). Common terms in the transport equations are expected for two communicating fluid compartments (Durbin *et al.*, 1997b). The common rate terms in the liver and skeleton uptake equations indicated that Am^{3+} was being accumulated in both tissues from common pools – initially, from complexes with low molecular weight plasma ligands, and later from the weak plasma protein complexes (Durbin, 1973).

The recalculated data for Pu^{4+} clearance from the plasma and the uptake kinetics of Pu^{4+} in rat skeleton and liver (Schubert *et al.*, 1950; Rosenthal and Schubert, 1957) were combined with data for protein binding of Pu^{4+} in rat and dog plasma measured at times from a few minutes to 24 h after injection of Pu^{4+} citrate (Stevens *et al.*, 1968; Turner and Taylor, 1968a). These data were used to solve a biokinetic compartment model of circulatory transport and tissue uptake (Durbin *et al.*, 1972). The Pu^{4+} complexed with Tf and the Pu^{4+} complexed with filterable low molecular weight plasma ligands were designated as bound or free, respectively. The model structure consisted of four interconnecting transport compartments – plasma-bound, plasma-free, ISW-bound, and ISW-free. The plasma-bound and plasma-free compartments communicated with four effectively nonreturning sinks – liver, skeleton, soft tissue, and excreta. The numerical solutions of the model implied the following: Pu^{4+}-free binds to protein, mainly to Tf, in the ISW as well as in the plasma; little, if any Pu^{4+}-bound is excreted or deposited in the liver; which suggests that Tf binding is not a necessary precondition for liver uptake of Pu^{4+}; both Pu^{4+}-bound and Pu^{4+}-free are taken up by bone.

31.5.2 Tissue deposition kinetics in mice

Detailed studies of tissue uptake kinetics were conducted in mice injected iv with $^{232,235}UO_2Cl_2$ (Fig. 31.11, Durbin *et al.*, 1997a) , $^{237}NpO_2Cl$ (Fig. 31.12, Durbin *et al.*, 1998b) , $^{241}Am^{3+}$ citrate (Fig. 31.13, P. W. Durbin and B. Kullgren,

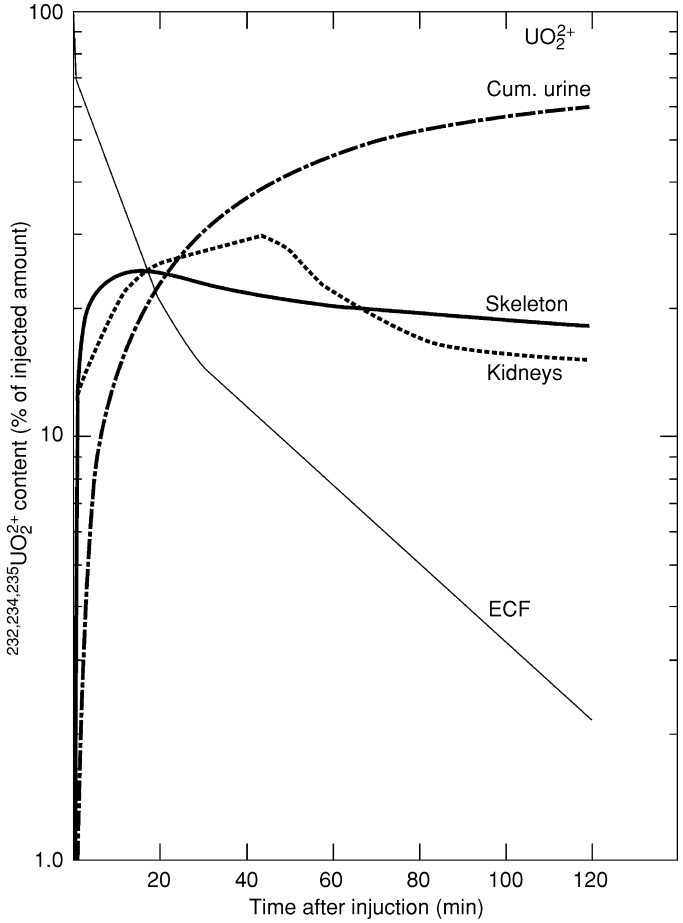

Fig. 31.11 *Clearance from extracellular fluid* (*ECF*) of mice, uptake in EFC-free skeleton and ECF-free kidneys, and cumulated urinary excretion of iv-injected $^{232,234,235}UO_2Cl_2$ (100 μg kg^{-1} *of U*). *Data of Durbin* et al. (1997a).

unpublished data) , or $^{238}Pu^{4+}$ citrate (Fig. 31.14, Durbin *et al.*, 1997b, P. W. Durbin and B. Kullgren unpublished data) . These studies provide useful comparisons of the deposition kinetics of actinides in their four biologically important oxidation states that form complexes with plasma constituents ranging in stability from very weak to strong. In all of these studies, female mice of the same strain and age were used. Nuclides were injected iv, and data were taken from groups of five mice killed at 16 timed intervals from 1 min to 24 h. Actinide content of plasma and all tissues of each mouse (including its entire skeleton) and pooled excreta of each five-mouse group were determined by

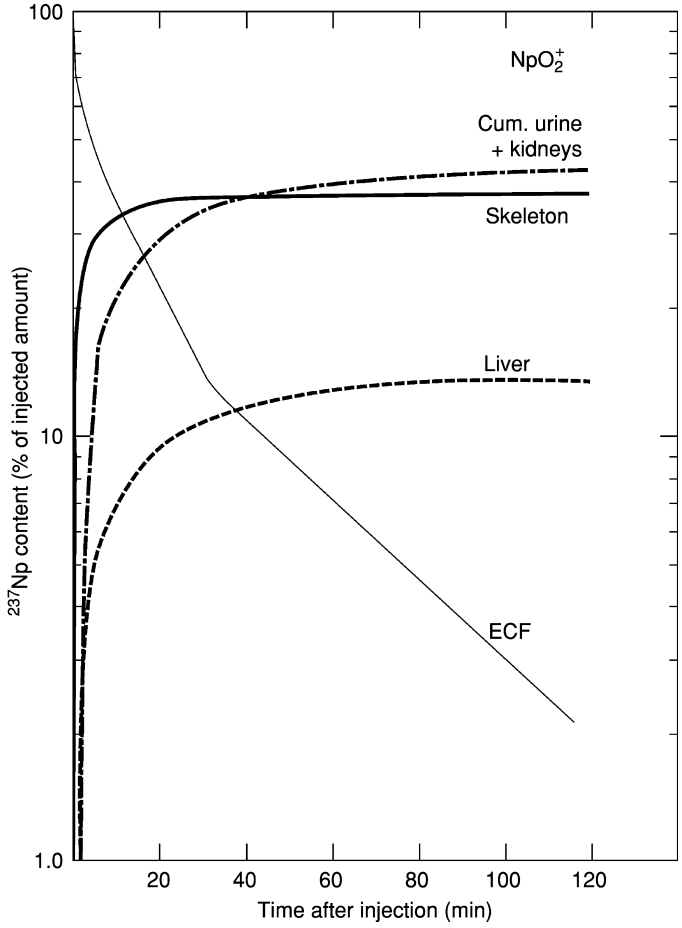

Fig. 31.12 *Clearance from extracellular fluid (ECF) of mice, uptake in ECF-free skeleton and ECF-free liver, and cumulated urinary excretion plus ECF-free kidneys of iv-injected* $^{237}NpO_2Cl$ (200 μg kg^{-1} *of Np*). *Data of Durbin* et al. (1998b).

scintillation counting. On average, 95% of the injected actinide was recovered in these material balance studies.

The fractional volumes of plasma and ECF in the tissues and whole body had been measured in similar mice (Durbin *et al.*, 1992). Those fluid distributions were used to calculate and apportion among its tissues the actinide removed in the plasma sample of each mouse, approximately recreating the total in-life actinide content of each tissue. The amounts of actinide deposited in the target tissues at each time (t), ECF-free tissue (t), was estimated by subtracting the amount of actinide calculated to be in their contained plasma [P(t)] and

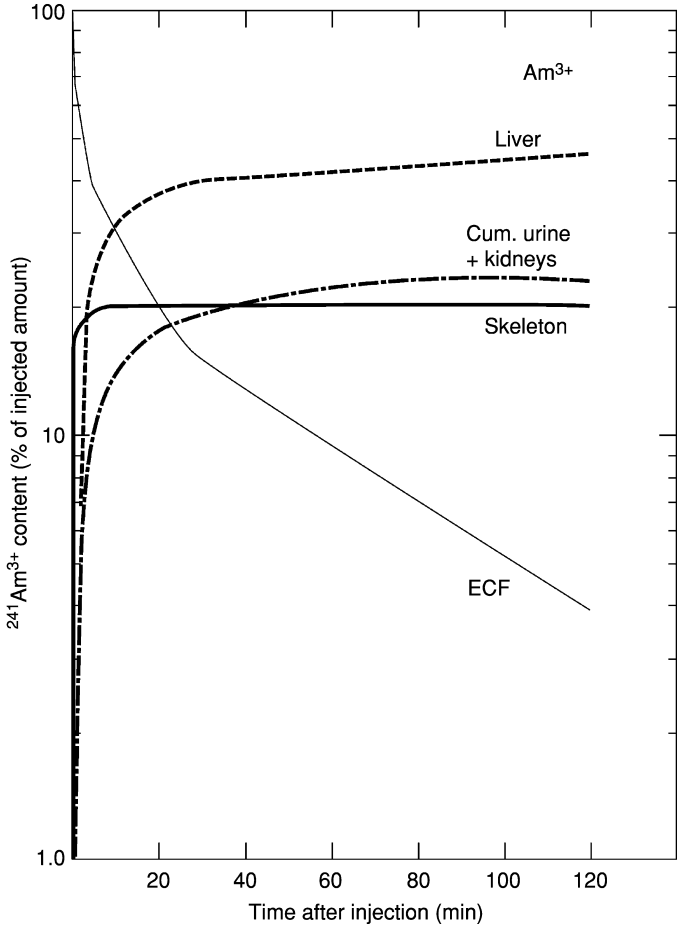

Fig. 31.13 *Clearance from extracellular fluid (ECF) of mice, uptake in ECF-free skeleton and ECF-free liver, and cumulated urinary excretion plus ECF-free kidneys of iv-injected* $^{241}Am^{3+}$ *citrate* (0.23 μg kg^{-1} *Am*). *Unpublished data of P. W. Durbin and B. Kullgren.*

ISW [I(t)] from their measured values that had been corrected for blood loss; skeleton [Sk(t)], liver [L(t)], and kidneys [K(t)] (Durbin *et al.*, 1992, 1997a,b, 1998b),

$$\text{ECF-free skeleton} = [\text{Sk}(t) - \text{P}_{\text{Sk}}(t) - \text{I}_{\text{Sk}}(t)]$$
$$\text{ECF-free liver} = [\text{L}(t) - \text{P}_{\text{L}}(t) - \text{I}_{\text{L}}(t)]$$
$$\text{ECF-free kidneys} = [\text{K}(t) - \text{P}_{\text{K}}(t) - \text{I}_{\text{K}}(t)].$$

The tissue uptake data (deposited fractions), expressed as percent of injected actinide in ECF-free tissues, are plotted vs time to 120 min after injection in Figs. 31.11–31.14. Those curves and the parameters of their multiexponential

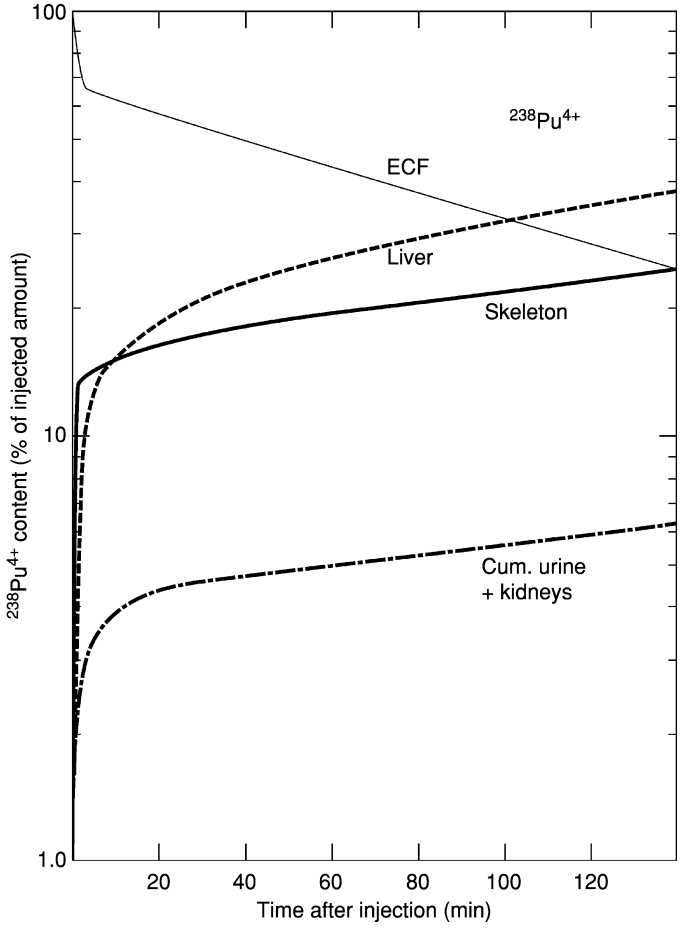

Fig. 31.14 *Clearance from extracellular fluid (ECF) of mice, uptake in ECF-free skeleton and ECF-free liver, and cumulated urinary excretion plus ECF-free kidneys of iv-injected* $^{238}Pu^{4+}$ *citrate* (0.09 μg kg^{-1} *Pu*). *Data of Durbin* et al. (1997b) *and unpublished data of P. W. Durbin and B. Kullgren.*

equations were obtained by log-linear regression analysis. The curves were plotted for clearance of actinides from the plasma (Fig. 31.4) and ECF (Figs. 31.11–31.14) of mice, and their equations were calculated to 120 min after injection for UO_2^{2+}, NpO_2^{+}, and Am^{3+} and to 480 min for Pu^{4+}. Each has three exponential components,

Plasma (t) or ECF(t) = $\sum A_i e^{-\lambda_i t}$(% of amount injected), t is min after injection.

Maximum actinide accumulations in the ECF-free tissues and urinary excretion were estimated from the tabular data. Equations were derived to describe

the actinide uptake in the target tissues and cumulated urinary excretion using published methods (Comar, 1955; Durbin, 1973). The exponential tissue uptake equations were calculated to 120 min for UO_2^{2+}, NpO_2^{+}, and Am^{3+} and to 480 min for Pu^{4+}. Nearly all of the tissue uptake equations also have three negative exponential terms,

Tissue(t) or cum. urine(t) $= \sum A_i(1 - e^{-\lambda_i t})$ (% of injected amount), t is min after injection.

The parameters, coefficients (A_i,%), and rate constants (λ_i, min^{-1}) of the plasma and ISW clearance equations and the equations describing actinide uptake in the ECF-free tissues and cumulated urinary excretion are collected in Table 31.12. Table 31.12 also includes the maximum values of the ECF-free tissue deposits and total urinary excretion and the approximate postinjection times of maximum accumulation. This table also includes, for comparison, the parameters of the two-component plasma clearance curves determined in similar mice for the organic tracers, $CaNa_3$–^{14}C–DTPA and ^{3}H-inulin, which are freely diffusible, do not accumulate in any tissue, and are quantitatively filtered into the urine (Durbin *et al.*, 1997b). The deposition kinetics studies of Am^{3+} and Pu^{4+} in the mouse confirmed the findings for those actinides in rats, and deposition kinetic studies were extended to include UO_2^{2+} and NpO_2^{+}.

In the mice, the first two exponential terms of the plasma clearance equations of Am^{3+}, UO_2^{2+}, and NpO_2^{+} are similar to those of the diffusible tracers, $CaNa_3$–^{14}C–DTPA and ^{3}H-inulin (Table 31.12). Within 5 min, about 85% of those injected actinides and the organic molecules have diffused into ISW, been filtered by the kidneys, and, for the actinides, been taken up by the skeleton and liver.

Immediate diffusion of large fractions of these three injected actinides into ISW and some early urinary excretion show that upon introduction into the plasma they exist mainly as 'free' filterable complexes with small ligands (either plasma constituents or, in the case of Am^{3+} with the injected excess citrate). Initially, large fractions of these actinides are taken up in the liver or kidneys and skeleton at very fast rates. The coefficients of the first components of their uptake equations (A_1) account for accumulation of 40–80% of the maximum deposits in the skeleton and about 30% of the maximum liver deposits. The rate constants (λ_1) imply uptake half-times of 0.3 to 0.8 min in bone and 1 to 1.4 min in liver (Table 31.12). Tissue uptake and urinary excretion persist, but more slowly at times longer than 5 min postinjection as is shown by the rate constants of the second and third components of their uptake equations (λ_2 and λ_3).

The deposition kinetics of Pu^{4+} differ quantitatively from those of the other three actinides of differing oxidation state, mainly because Pu^{4+} forms a stable complex with plasma Tf, while the complexes that NpO_2^{+}, UO_2^{2+}, and Am^{3+} form with Tf and other plasma proteins are very weak. In the mice, about 75% of Fe-binding sites of plasma Tf are occupied by Fe^{3+} (Table 31.10). During the first few minutes after iv injection of Pu^{4+} citrate, about one-half of the Pu^{4+} appeared to be 'free' and circulating as a filterable low molecular weight species.

* % of injected nuclide and minutes (min) is time after injection.

[a] Data sources are as follows: $^{232,234,235}UO_2Cl_2$, Durbin *et al.* (1997a); $^{237}NpO_2Cl$, Durbin *et al.* (1998b); $^{241}Am^{3+}$ citrate, P. W. Durbin and B. Kullgren (unpublished data); $^{238}Pu^{4+}$ citrate, Durbin *et al.* (1997b) and P. W. Durbin and B. Kullgren (unpublished data).

[b] Equations for plasma and ISW clearance were fitted from $t(0)$ to $t(120$ min), and those for tissue accumulation and urinary excretion were fitted from $t(0)$ to t(maximum). Maximum tissue accumulation and cumulated urinary excretion values and the postinjection times at which those maxima were attained were estimated from Figs. 31.11–31.14.

[c] Clearance equations are of the form, plasma(t) or ISW(t)$=\sum A_i e^{-\lambda_i t}$, and those for accumulation in the tissues and cumulated urinary excretion are of the form, tissue(t) or cum. urine(t)$=\sum A_i(1-e^{-\lambda_i t})$, where plasma ($t$), ISW ($t$), tissue($t$), and cum. urine($t$) are expressed as % of injected actinide and t is min. after injection.

[d] Actinide calculated to have diffused into interstitial water (ISW).

[e] ECF-free kidneys (t) are combined with cum. urine (t) to account for all actinide filtered by the kidneys.

[f] Durbin *et al.* (1997b).

Only about 25% of the injected Pu^{4+} diffused into ISW, and skeleton and liver uptakes were about 30% of their maximum accumulated amounts (Table 31.12). The initial rates of Pu^{4+} deposition in liver and skeleton were about the same as those for the other study actinides (half-times 0.4 and 1.7 min, respectively, for skeleton and liver).

Subsequently, return of Pu^{4+} from ISW was slower than for the other actinides. Plasma Pu^{4+} retention was prolonged, renal excretion was negligible, and uptake in the target tissues proceeded at rates 1/3 to 1/10 as fast as those observed for the other actinides. Skeletal uptake persisted for about 24 h or until nearly all of the Pu^{4+} had been cleared from the plasma, during which time nearly all of the Pu^{4+} in the plasma was likely to be bound to Tf (components 2 and 3). Renal filtration, although small, also persists, indicating the continuous presence of a small fraction of 'free' Pu^{4+}. Net uptake in liver essentially stops when the 'free' Pu^{4+} has been reduced to a low level.

31.5.3 Summary

Bone and liver cell surfaces have great affinities for actinides (except that liver does not accumulate UO_2^{2+}), and those tissues take up (bind) actinides rapidly during the first few minutes after iv injection, when substantial fractions of the actinides are likely to be circulating as weak complexes with small filterable ligands. The reduced rates of tissue uptake and renal filtration that emerged in the mice at postinjection times longer than 5 min were not likely to be caused by sudden changes in the tissue affinities for actinides or the saturation of metal-binding sites. Alteration of the renal filtration rate is scarcely possible, because that rate is a species-specific constant (Smith, 1951; Durbin and Schmidt, 1989; Durbin *et al.*, 1997b). The reductions in tissue uptake and renal excretion rates and their related plasma clearance rates appear to be due to changes taking place in the transport system. Rapid diffusion of actinides from plasma to ISW and slow return reduce the rate at which the actinides are presented to the tissues. Protein binding, most importantly for Pu^{4+}, decreases the differences between the stabilities of the actinide complexes with the tissue ligands and those with the plasma ligands, effectively reducing the competitiveness of the tissue ligands and delaying or preventing the transfer of actinide from plasma ligands to tissue ligands.

31.6 ACTINIDES IN THE LIVER

Large fractions of injected soluble trivalent and tetravalent actinides are taken up by the liver, and their retention in liver has been studied because of its importance for tumor induction and radiation dosimetry (Tables 31.1–31.7; Finkle *et al.*, 1946; Painter *et al.*, 1946; Hamilton, 1947b, 1948c; ICRP, 1959,

1972, 1986; Durbin 1960, 1962, 1973; Cochran *et al.*, 1962; Stover *et al.*, 1968b, 1971; Taylor and Bensted, 1969; Mewhinney *et al.*, 1972; McKay *et al.*, 1972; Lloyd *et al.*, 1972b, 1984b; Taylor *et al.*, 1972b; Guilmette *et al.*, 1980; Lo Sasso *et al.*, 1981; Durbin *et al.*, 1985; NCRP, 2001).

Autoradiographic studies show that the actinides initially are distributed nearly uniformly in liver cells. With the passage of time after injection, actinide retained in the liver of rats, dogs, and monkeys tends to be located mainly in the Kupffer cells as aggregates associated with hemosiderin (Cochran *et al.*, 1962; Durbin, 1973, 1975; Durbin *et al.*, 1985).

31.6.1 Liver microanatomy

The initial binding sites in the liver for soluble blood-borne metal ions including the tri- and tetravalent actinides are the two sinusoidal membrane surfaces of the one-cell thick sheets of hepatocytes. The membranes facing the sinusoidal blood spaces possess numerous microvilli that project into the fluid-filled space. The microvilli are rich in receptors, enzymes, and transport proteins, and they provide an enormous surface area for absorption of blood-borne substances. Bile is secreted at the canalicular hepatic surfaces between the cells into minute ducts that ultimately coalesce and empty into the common bile duct (Ham, 1974; Ballatori, 1991).

31.6.2 Liver blood supply

The liver has an abundant blood supply; it receives about 20% of the cardiac output (Detweiler, 1973). Two-thirds of liver blood is delivered by the portal vein, which transports blood from the GI tract. The hepatic artery supplies the remainder. The two sets of blood vessels branch into capillaries that end in blood-filled spaces (sinusoids), where the venous and arterial blood mix. The thin flat lining cells that separate the sinusoidal hepatic cell surfaces from the sinusoidal blood are porous (pore size about 0.1 μm in diameter), thereby excluding red blood cells and larger particles while allowing access of the whole plasma to the hepatocyte microvilli. The sinusoidal lining contains fixed phagocytes (Kupffer cells) that recognize and ingest colloidal particles (Ham, 1974; Ballatori, 1991).

31.6.3 Transport of metals into liver cells

Entry of metal ions into hepatic cells may be via facilitated diffusion and/or by liquid phase, adsorptive, and receptor-mediated endocytosis, followed by temporary residence in the cytosol as complexes formed with binding proteins or in the lysosomes. In endocytosis, a vesicle of membrane envaginates into a sac, which sinks into the cytoplasm matrix. These vesicles fuse with each other or with other vesicles or with lysosomes. It has recently been shown that the liver

cell internalizes more than 20% of its volume and between 5 and 50% of its surface area each hour by a process termed membrane recycling. Rapid membrane recycling is likely to be a major contributor to the hepatic intake of metals that have high affinities for membrane-binding sites (Ballatori, 1991).

Iron is transported into hepatocytes by at least two independent pathways. The dominant mechanism is receptor-mediated endocytosis in which Fe–Tf binds to specialized Tf-receptors on the hepatocyte surface. Membrane binding is followed similarly to the delivery of Fe–Tf to developing erythrocytes, by endocytosis, and internalization of the Fe–Tf–Tf-receptor complex, fusion of the endocytotic vesicle with other vesicles, release of the Fe within the acidic vesicles, and extrusion of the iron-depleted Tf (Ballatori, 1991). Hepatic uptake of the normally very small fraction of Fe^{3+} circulating as a low molecular weight complex has been shown to occur by direct binding to integral membrane protein. Membrane binding is probably followed by internalization in the energy-dependent membrane recycling process (Planas-Bohne *et al.*, 1985, 1989; Planas-Bohne and Duffield, 1988; Planas-Bohne and Rau, 1990).

31.6.4 Iron storage

(a) Ferritin

Ferritin serves as a source of stored iron that can be mobilized for red cell production. It is a large water-soluble complex of protein (apoferritin, molecular weight about 450 kDa) and ferric oxyhydroxide. At the usual level of iron saturation (18%), the weight of the complex is about 620 kDa. The protein forms a shell within which crystals of iron hydroxide and phosphate are dispersed in a lattice-like relationship. Apoferritin is synthesized in response to intracellular iron by the ribosomes of nearly all mammalian cells, but liver, spleen, and bone marrow are especially rich in stored ferritin. At low iron levels, new iron is incorporated into existing apoferritin molecules, particularly those with a partially iron-filled core. Elevated iron stimulates production of apoferritin, which rapidly takes up excess iron. The residence time of ferritin in the cell cytosol is brief, and it tends to accumulate within lysosomes.

Iron is incorporated into and stored in ferritin as Fe^{3+}, but to break the coordination bonds and be released from the ferritin complex, the iron must be reduced to Fe^{2+}. It is then reoxidized in the cytosol and bound by intracellular Tf (Aisen and Listowsky, 1980; Fairbanks and Beutler, 1995).

(b) Hemosiderin

The other iron storage compound, hemosiderin, is found mainly in the macrophages of the bone marrow, the Kupffer cells of the liver, and phagocytic cells in the spleen. It is not water-soluble. It is composed of ferritin partially stripped of the protein component and contains 25 to 35% iron by weight. Much

hemosiderin appears to consist of ferric hydroxide core crystals (Fairbanks and Beutler, 1995).

31.6.5 Actinide association with stored iron

Investigations of actinide retention in the whole liver were extended to include identification of the constituents of hepatic cells that bind and store them (Taylor, 1972; Duffield and Taylor, 1986). Preliminary analysis of clear, particle-free homogenates of the livers of dogs injected iv with $^{239}Pu^{4+}$ citrate indicated that the Pu^{4+} was associated with ferritin (Bruenger *et al.*, 1969a). Competitive binding studies showed that the ferritin complexes of Pu^{4+} and Am^{3+} are more stable than their Tf complexes (Bruenger *et al.*, 1969a; Stover *et al.*, 1970).

The subcellular distributions of soluble iv-injected actinides in the livers of several animal species have been investigated using a variety of techniques. The actinides ($^{227}Ac^{3+}$,$^{233}Pa^{5+}$,$^{238}Pu^{4+}$,$^{239}Pu^{4+}$,$^{241}Am^{3+}$,$^{244}Cm^{3+}$,$^{249}Cf^{3+}$, $^{237}NpO_2^+$, and $^{239}NpO_2^+$) were studied in rats, mice, dogs, rabbits, baboons, and/or hamsters. Homogenates were prepared from the livers, and the subcellular organelles were separated from each other and from the filterable cytosol by means of differential centrifugation and centrifugation through sucrose or salt density gradients into nuclei plus cell debris, mitochondria, lysosomes, microsomes, and cytosol. Marker enzymes were used to identify mitochondria and lysosomes, and ^{59}Fe was used to identify ferritin. The nature of the actinide-binding protein(s) in the cytosol was investigated using gel chromatography and electrophoresis (Taylor, 1969, 1970, 1972; Taylor *et al.*, 1969a,b; Boocock *et al.*, 1970; Stover *et al.*, 1970; Bruenger *et al.*, 1971a, 1972, 1976; Grube *et al.*, 1978; Schuppler *et al.*, 1988; Paquet *et al.*, 1995, 1996, 1998). These methods did not provide clear separation of 'iron-rich' heavy lysosomes from the mitochondria.

In more recent studies, actinide-injected animals were pretreated with Triton WR 1339, which causes liver lysosomes to imbibe water and swell, thus reducing their density enough to allow clean separation from the mitochondria (Gruner *et al.*, 1981; Winter and Seidel, 1982; Sutterlin *et al.*, 1984). Carrier-free electrophoresis has also been used to obtain a clear separation of lysosomes from all other organelles (Seidel *et al.*, 1986). Most of those studies were conducted using liver material from rats injected with ultrafilterable $^{239}Pu^{4+}$ citrate, and the results agree with supporting studies of liver material from rats and other animals injected iv or im with other soluble actinides and $^{141}Ce^{3+}$.

Combined, all of the studies of subcellular distribution of actinides in the liver show that ferritin is the predominant actinide-binding protein within the hepatocytes, and the lysosomes are the main subcellular storage organelles. Actinides that have entered the hepatocytes are initially mainly associated with the soluble lighter 'apoferritin-rich' ferritin in the cytosol, and to a lesser degree, they are sequestered in lysosomes. With time, the actinide associated with the soluble ferritin in the cytosol declines and the lysosomal actinide fraction, which includes the heavier 'iron-rich' ferritin, increases (Boocock *et al.*, 1970; Bruenger

et al., 1971a; Grube *et al.*, 1978; Seidel *et al.*, 1986). That is the same time-dependent pattern followed by newly acquired hepatic iron – initial incorporation into freshly synthesized apoferritin in the cytosol followed by gradual accumulation in lysosomes of ferritin that has acquired more iron (Aisen and Listowsky, 1980; Fairbanks and Beutler, 1995). At times longer than 70 days in dogs injected iv with $^{239}Pu^{4+}$ citrate, the concentration of the Pu^{4+} in the nuclei-cell debris fraction increased, and it was shown autoradiographically that the Pu^{4+} was contained in the Kupffer cells in association with hemosiderin (Cochran *et al.*, 1962; Taylor *et al.*, 1969a,b; Bruenger *et al.*, 1971a).

In addition to their presence in the cytosol and lysosomes in association with ferritin, and depending on the mass injected or used to incubate cultured hepatocytes, lower specific activity $^{237}NpO_2^+$, and $^{239}Pu^{4+}$ localized in the hepatic cell nuclei in association with an as yet unidentified nuclear matrix protein (Schuler and Taylor, 1987; Paquet *et al.*, 1995, 1996).

31.6.6 Actinide uptake by liver cells

The multivalent lanthanides and actinides, particularly Pu^{4+}, share some metabolic properties of iron. They form variably stable complexes with Tf in the plasma and are stored in the liver associated with ferritin. It was reasonable to postulate that, like iron, these metals would be bound to and be taken into hepatic cells by a Tf-mediated receptor mechanism. However, in a series of elegant experiments using cultured liver cells (primary rat hepatocytes and human hepatoma Hep-G2 cells) and isolated rat hepatocyte membrane, Planas-Bohne and coworkers demonstrated that the mechanism by which Pu^{4+} (and presumably other trivalent and tetravalent metals) are bound to and taken into liver cells is not only independent of, but is actually hampered by, Tf binding (Planas-Bohne *et al.*, 1985, 1989; Schuler and Taylor, 1987; Schuler *et al.*, 1987; Planas-Bohne and Duffield, 1988; Planas-Bohne and Rau, 1990).

Uptake of Pu^{4+} from a medium containing Pu^{4+} citrate into liver cells was not influenced substantially by the Pu^{4+} concentration or the molar ratio, citrate: Pu^{4+}, suggesting a nonspecific nonsaturatable mechanism. Cell uptake of Pu^{4+} was much reduced at 4°C, compared with 37°C, suggesting that transport into the cells was energy dependent. Cells incubated with $^{239}Pu^{4+}$–^{14}C-citrate did not bind or take in the ^{14}C-citrate suggesting ligand exchange between the Pu^{4+} citrate and the Pu^{4+} receptor complex(es). If the Pu^{4+} was prebound to Tf, uptake of Pu^{4+} into the cells and by isolated perfused rat liver was very low, only about 10% of the uptakes from Pu^{4+} citrate.

Liver cell intake of Pu^{4+} from its citrate complex requires a high activation energy and can be prevented by inhibition of oxidative phosphorylation; other processes seem not to be important. Uptake of Pu^{4+} by liver cells from the Pu^{4+} citrate complex can be prevented by chelators (EDTA, DFO) and by unsaturated Tf suggesting that the Pu^{4+} reacts directly with constituents of the liver cell

membrane. The stabilities of the Pu^{4+} receptor complex(es) appear to be greater than that of Pu^{4+} citrate but less than that of Pu^{4+}–Tf or Pu^{4+}–EDTA.

Fragments of purified rat hepatocyte membrane were incubated with Pu^{4+} citrate. Binding of Pu^{4+} to the membrane was pH-dependent (optimal at pH 7.4), saturatable, and independent of temperature, suggesting direct binding of Pu^{4+} at a limited number of sites. Binding of Pu^{4+} was prevented by the presence of unsaturated Tf, EDTA, or DFO, indicating that membrane binding of Pu^{4+} involved Pu^{4+} complexation with a spatially suitable arrangement of amino acid residues at the binding sites. The two kinds of binding sites found for Pu^{4+} were shown not to be phospholipids or glycoproteins, but large integral membrane proteins (molecular weight between 150 and 400 kDa), and they are different from the two kinds of binding sites identified with direct uptake of iron. When membrane was incubated with Pu^{4+}–^{125}I–Tf and then solubilized and subjected to gel filtration, the Pu^{4+} eluted in fractions different from those containing ^{125}I–Tf bound to membrane protein receptors or unbound ^{125}I–Tf, indicating dissociation of the Pu^{4+}–Tf complex.

31.6.7 Summary

From the standpoint of actinide biology, the most important results are that Pu^{4+} can bind directly to a limited number of sites on the hepatic cell membrane and be internalized, that transport of the Pu^{4+} into hepatic cells is not mediated by Tf, and that complexation of Pu^{4+} by Tf suppresses Pu^{4+} binding to hepatic cell membrane. It is reasonable to assume that the elements of group III and subgroup IV and the lanthanides and other actinides can also bind directly, possibly at the same or similar hepatocyte-binding sites as Pu^{4+}. Direct metal binding in the liver and its suppression by competition with Tf suggest an explanation for the observed direct correlation between the fractional deposition of the lanthanides and actinides in the liver and the instabilities of their Tf complexes (for which increasing ionic radius and plasma clearance rates are crude proxies) (Tables 31.1–31.7; Figs. 31.3–31.7; Durbin, 1962, 1973). The hepatic cell metal-binding sites compete successfully with bone surfaces for multivalent cations like Ce^{3+} and Am^{3+} that circulate complexed with small plasma ligands like citrate or as weak complexes with Tf or other plasma proteins. However, competition for metals that form more stable Tf complexes, like Th^{4+} and Pu^{4+}, favors bone, and the source of the uptake in liver may be mainly the small fraction that circulates as low molecular weight complexes (Durbin *et al.*, 1972; Planas-Bohne *et al.*, 1989).

31.7 ACTINIDES IN BONE

The defining characteristic of the biological behavior of the actinides in mammals, and the chemically similar elements of group III, subgroup IV, and the lanthanides, is their intraskeletal distribution. As soon as suitable radioisotopes

became available, autoradiographs were prepared from undecalcified sections of the femora of rats injected with fission products ($^{91}Y^{3+}$, $^{95}Nb^{3+}$, $^{95}Zr^{4+}$, $^{144}Ce^{3+}$, $^{147}Pm^{3+}$, $^{152,154}Eu^{3+}$) and five actinides ($^{227}Ac^{3+}$, $^{234}Th^{4+}$, $^{239}Pu^{4+}$, $^{241}Am^{3+}$, $^{242}Cm^{3+}$) (Axelrod, 1947; Hamilton, 1947b). Autoradiographs of five representative radioelements were included in the original reports; the remainder was published later as a complete set (Durbin, 1962).

The deposition patterns of $^{45}Ca^{2+}$ and $^{89}Sr^{2+}$ in rat bones had already been studied autoradiographically, and it was shown that the alkaline earth elements penetrated into and were nearly uniformly distributed throughout the bone mineral volume (Hamilton, 1941; Pecher, 1942). The internal distribution of the multivalent cations was markedly different. None was initially incorporated into the bone volume. The tetravalent elements (Zr^{4+}, Th^{4+}, and Pu^{4+}) were deposited at endosteal surfaces, particularly on the trabeculae of the spongy bone and beneath the periosteum. The distribution patterns of the trivalent cations generally resembled the tetravalent elements, but there was also substantial spotty deposition in the compact bone, which was later shown to be on the mineralized walls of vascular channels.

The radioisotopes of all of the trivalent and tetravalent elements have been classified for the purposes of radiation dosimetry as 'bone surface seekers'. The methods used for calculating radiation doses to the bone cells and marrow surrounding the deposits of these nuclides in the skeleton have taken into account their nonuniform intraskeletal distribution (ICRP, 1959, 1967, 1979).

Actinide binding to the calcified bone surfaces is the net result of several biological and chemical processes: the nature of the bone mineral crystals and the organic bone matrix, the relative affinities of the individual actinides for the mineralized surface and the plasma ligands, the ability of the circulating actinide complexes to pass through or between the cells on resting surfaces and penetrate the osteoid and active osteoblasts on growing surfaces, and the richness of the blood supply and its proximity to the bone surfaces.

31.7.1 Bone surfaces

Detailed descriptions of the microanatomy of the skeleton and of bone growth and maintenance remodeling are available in specialized works (Bourne, 1956; Frost, 1963; Ham, 1974). The periosteal surface is beneath the outer tissue layer that envelops the whole bones. The endosteal surface is the inner aspect of whole bones plus the much larger surface of the three-dimensional interconnected network of the fine bony bars, rods, and plates of the spongy (trabecular) bone. The vascular (Haversian) surface is the cylindrical lining of the numerous vascular channels that penetrate and nourish the compact (cortical) bone. The large anatomical surface of the mammalian skeleton – about 12 m^2 in an adult human male – is about equally divided between the endosteal and Haversian surfaces (Spiers, 1968; Lloyd and Marshall, 1972; ICRP, 1979).

Three general bone surface types are recognizable histologically: actively growing, resting, and resorbing. Depending on age and stage of skeletal maturity, the abundances of the three surface types vary in individual bones and in the whole skeleton. New bone is laid down at the active surfaces, which are recognized by the presence of regular rows of tall columnar cells (active osteoblasts) located just above a variably thick layer of uncalcified or poorly calcified bone matrix (osteoid). A thin strongly PAS-positive margin marks the line of calcification. The cell and osteoid layers covering sites of active bone formation make these sites the least accessible to circulating metal ions. Resting surfaces are covered with a layer of thin flattened cells, which line the adjacent calcified surface. The bone beneath the resting cells is usually more calcified than that beneath the cells on the growing surfaces. The mineral–organic interface stains PAS-positive. Resting bone surface sites, which are predominant in human adults, are well mineralized, but their accessibility is somewhat hindered by the overlying cell layer. Resorbing surfaces are recognized by their irregular outline, their high degree of mineralization, the intense PAS-positive stain at the calcified margin, the absence of covering cells, and the presence of the large multinuclear osteoclasts that dissolve and digest bone. The resorbing sites are exposed directly to the circulating blood and/or tissue fluid, making them the most accessible.

The vascular channels of cortical bone (horizontal Volkmann's canals and longitudinal Haversian systems) are short cylindrical tunnels in the well-mineralized compact bone. They are lined with a layer of flattened endosteal cells, so their inner aspect resembles resting bone surface. The central space is filled with loose connective tissue and one large capillary or two small arterial and venous capillaries.

31.7.2 Bone blood supply

The blood supplies to the periosteum, the internal skeletal sites containing fatty marrow, and the vascular channels of cortical bone are closed capillary beds that effectively retain the red cells and nearly all of the plasma protein and allow only filterable low molecular weight plasma constituents and filterable metal complexes access to the bone surfaces. Erythropoietic marrow contains large vascular sinusoids with a discontinuous lining that permits whole plasma to pass into the extravascular space. The bony trabeculae embedded in the red marrow are exposed not only to metal ions complexed with the low molecular weight constituents of tissue fluid but also their nonfilterable complexes with plasma proteins (Ham, 1974; Wronski *et al.*, 1980; Miller *et al.*, 1982).

31.7.3 Intraskeletal distribution of actinides

More refined and definitive autoradiographic techniques confirmed the early observations of the surface-limited deposition of actinides in bone. Sectioning and autoradiography of undecalcified bone are difficult, and later studies

focused on $^{233}UO_2^{2+}$,$^{239}Pu^{4+}$,$^{241}Am^{3+}$, and most recently ^{237}Np. In addition to revealing important details of the initial distribution of these actinides in bone, they have helped to define the mechanisms of release of actinides bound to bone and the kinds and extent of local radiation damage.

(a) $^{241}Am^{3+}$

The initial intraskeletal distribution of $^{241}Am^{3+}$ was investigated autoradiographically in rats (Taylor *et al.*, 1961; Durbin *et al.*, 1969; Durbin, 1973; Priest *et al.*, 1983), dogs (Herring *et al.*, 1962; Lloyd *et al.*, 1972b; Polig *et al.*, 1984), and monkeys (Durbin, 1973, 1975). $^{241}Am^{3+}$ is initially deposited nearly uniformly on all types of bone surfaces – endosteal, periosteal, and Haversian canals. Deposition is somewhat more intense on resorbing and resting surfaces than on actively growing surfaces. No $^{241}Am^{3+}$ was found initially as a diffuse distribution in the bone volume (Herring *et al.*, 1962; Priest *et al.*, 1983). Results for $^{249,252}Cf^{3+}$ in rats were essentially the same as for $^{241}Am^{3+}$ (Durbin, 1973).

(b) Pu^{4+}

Initial intraskeletal distribution of Pu^{4+} ($^{238}Pu^{4+}$ or $^{239}Pu^{4+}$) was studied autoradiographically in rats (Arnold and Jee, 1957; Taylor *et al.*, 1961; Priest and Giannola, 1980), dogs (Arnold and Jee, 1959, 1962; Herring *et al.*, 1962; Wronski *et al.*, 1980), and monkeys (Durbin, 1975). Soluble Pu^{4+} is initially deposited almost entirely on endosteal surfaces, in particular, the surfaces of the trabeculae of spongy bone closest to the sinusoidal circulation of the erythropoietic marrow that surrounds them. In the beagles, the initial surface concentrations of $^{239}Pu^{4+}$ on the fine trabeculae in vertebral bodies, pelvis, and proximal humerus (sites in spongy bone containing red marrow) were four to eight times greater than on the coarser trabeculae in the proximal ulna and distal humerus (sites containing fatty marrow) (Wronski *et al.*, 1980). Endosteal deposition is not uniform, and Pu^{4+} concentrations on endosteal surfaces decrease generally in the order: resorbing > resting > actively growing. Deposits of Pu^{4+} on periosteal surfaces are less intense, and those on Haversian canal surfaces are very low. There is no initial diffuse distribution of Pu^{4+} in the bone volume.

(c) UO_2^{2+}

The initial intraskeletal distribution of UO_2^{2+} ($^{232}UO_2^{2+}$ or $^{233}UO_2^{2+}$) was studied autoradiographically in rats (Priest *et al.*, 1982) and dogs (Rowland and Farnham, 1969; Stevens *et al.*, 1980). Uranyl ion is initially deposited on all bone surface types, but it is found preferentially on actively growing surfaces that are laying down new bone. Similarly to Ra^{2+}, UO_2^{2+} is deposited in the calcifying zones of skeletal cartilage. In the dogs, a detectable fraction diffused into the bone volume.

(d) $^{237}NpO_2^+$

The intraskeletal distribution of ^{237}Np, injected iv as $^{237}NpO_2NO_3$, was investigated autoradiographically in rats (Wirth and Volf, 1984; Sontag, 1993). The initial distribution appears to be nearly uniform on all endosteal and periosteal surfaces and the vascular canal surfaces of compact bone. There is no evidence for early diffusion of Np into the bone volume.

(e) $^{91}Y^{3+}$, $^{144}Ce^{3+}$, $^{170}Tm^{3+}$

The initial intraskeletal distribution of these three trivalent metal ions was studied autoradiographically in growing dogs (Jowsey *et al.*, 1958), and $^{91}Y^{3+}$ was also investigated in rachitic young dogs and weanling rabbits (Herring *et al.*, 1962). The distributions of these trivalent elements in bone were similar to $^{241}Am^{3+}$. They were located on all bone surfaces, with the greatest concentrations associated with highly mineralized surfaces of resorbing or resting bone. There was little or no deposition in areas of active bone formation, and no deposition in osteoid tissue. All three radioisotopes were deposited on the mineralized surfaces of the resting and resorbing Haversian systems in cortical bone, but at intensities less than on the endosteal surfaces.

(f) Summary

Within the skeleton, deposition of multivalent cations is initially limited to the anatomical surfaces in the order: endosteal > periosteal >cortical vascular channels, and among the bone surfaces in the order: resorbing >resting > actively growing.

The intensities of the local surface deposits are positively correlated with accessibility to the blood supply, the nature of the local blood supply, the degree of mineralization of the surface, and the instability of the complexes formed with Tf and other plasma proteins.

31.7.4 Retention – remodeling and redistribution

Prolonged skeletal retention is a distinguishing feature of the actinides (ICRP, 1959, 1972, 1979, 1993, 1995; Leggett, 1985, 1989, 1992a,b). The actinides (except UO_2^{2+}), once deposited on bone surfaces, appear to be released only when the bone containing them is physically destroyed (Arnold and Jee, 1957, 1959). There are long-term skeletal retention data for several actinides in beagles. The terminal slope of the skeletal retention function for UO_2^{2+} in the beagles has a half-time of about 3 years: UO_2^{2+} is lost from bone by chemical processes as well as by structural remodeling, and because it is efficiently excreted in the urine, little is redeposited in bone (Rowland and Farnham, 1969; Stevens *et al.*, 1980; Leggett, 1989). Retention of the trivalent and tetravalent actinides in the

beagle skeleton is much more prolonged. The half-times of the terminal slopes of the skeletal retention equations for $^{241}Am^{3+}$, $^{249}Cf^{3+}$, and $^{228}Th^{4+}$ are 15 to 18 years (Stover *et al.*, 1960; Lloyd *et al.*, 1972b, 1976, 1984a,b). About 56% of the initial skeletal deposit of $^{239}Pu^{4+}$ is cleared with a half-time of about 1.6 years; later measurements of $^{239}Pu^{4+}$ in the skeletons of individual dogs at postinjection times as long as 4400 days yielded a curve with a slope that could not be distinguished from zero (Stover *et al.*, 1962, 1972; Stover and Atherton, 1974).

The mature mammalian skeleton is not static, and it undergoes much internal structural change throughout the life span. During growth, structural remodeling (both resorption and accretion) is vigorous and extensive, and there is a net increase in bone mass. After skeletal growth is complete, remodeling and bone turnover involve only small fractions of the skeleton at any time, and there is little change in skeletal mass. During the last years of life of some mammals, resorption exceeds replacement leading to a slow decrease in skeletal mass (Bourne, 1956; Frost, 1963).

Bone resorption and accretion are surface-limited processes (Bourne, 1956; Ham, 1974). In the mature skeleton, turnover of bone (resorption and accretion) at the surfaces of the fine trabeculae of spongy bone is faster than at the surfaces of the larger trabeculae in the flat and membranous bones and in the distal ends of the long bones and the surfaces of the cortical bone vascular channels (about eight times faster in young adult beagles and four times faster in human adults) (Arnold and Jee, 1962; Arnold and Wei, 1972; ICRP, 1973; Wronski *et al.*, 1980).

Actinide-labeled bone surfaces may be resorbed by osteoclasts or be buried beneath new bone in the course of structural remodeling, or they may remain unaltered (Copp *et al.*, 1946; Arnold and Jee, 1962; Durbin *et al.*, 1969; Durbin, 1973; Wronski *et al.*, 1980; Sontag, 1993). The actinide content of the resorbed bone is eventually dissolved by the osteoclasts and/or marrow macrophages, released into the circulation, and redistributed among the target tissues (Arnold and Jee, 1962; Priest and Giannola, 1980; Priest *et al.*, 1983; Durbin and Schmidt, 1985; Durbin *et al.*, 1985). There is evidence indicating that solubilized actinide released from bone (or any other body site) is complexed and transported by the same plasma ligands (mainly Tf) and distributed among the same target tissues in the same proportions as the soluble form originally injected (Arnold and Jee, 1962; Durbin *et al.*, 1969; Jee, 1972a,b; Durbin, 1973; Priest and Giannola, 1980; Leggett, 1985, 1989, 1992a,b).

Redeposition in the skeleton can occur on both old (preinjection) surfaces augmenting their existing actinide concentrations and on new (postinjection) surfaces, which will acquire a lighter more diffuse label than those labeled immediately after the injection. With the passage of time, resorption of actinide-labeled bone surfaces (mainly trabeculae at red marrow sites) and redeposition of substantial fractions of the released and solubilized actinide will reduce the concentrations at the bone surfaces and increase the concentration in the

bone volume, tending to equalize the concentration in bones containing red marrow sites (vertebral bodies, ribs, sternum, pelvis, proximal ends of humerus and femur) and those that are mainly cortical bone (Durbin, 1973; Durbin *et al.*, 1985; Durbin and Schmidt, 1985; Sontag, 1993).

31.7.5 Summary

Prolonged retention of actinides deposited in the skeleton is the combined result of redeposition in bone of actinide released from soft tissues, removal from bone only by the relatively slow process of bone resorption, recirculation after release bound mainly to plasma proteins (which severely impedes excretion), and redeposition at new bone sites of large fractions of the actinide released from initially labeled bone sites.

31.8 ACTINIDE BINDING IN BONE

The specific nature of the initial chemical reactions underlying the fixation of actinides in living bone is incompletely understood.

31.8.1 Composition of bone

The compositions of mature mammalian cortical and trabecular bone are, on average, about 61, 26, and 13% by weight and 40, 35, and 27% by volume, mineral, organic matrix, and water, respectively (Gong *et al.*, 1964). The mineral phase [hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$] exists as minute tablet-shaped crystals 2 to 2.5 μm wide, 3.5 μm long, and 0.25 to 0.5 μm thick, and these are aligned parallel to the longitudinal direction of the collagen fibers of the matrix (Neuman and Neuman, 1958). At the microscopic level, bone is not homogeneous, but it is reasonable to assume that the proportions of mineral and matrix on fully mineralized bone surfaces are about the same as the bulk volume composition, that is, that the exposed surface area is about equally divided between mineral crystals and organic matrix along with some bound water. By the same reasoning, bone that is not fully developed would be expected to have a smaller proportion of mineral exposed on the surface.

31.8.2 Actinide binding to bone *in vivo*

There is good, if inferential, evidence for *in vivo* actinide binding to bone mineral. In living mammals, the initial skeletal binding site of the actinides and their trivalent and tetravalent chemical analogs is at the mineral–organic interface. Actinide deposition is greatest on bare, fully mineralized resorbing surfaces and least on growing surfaces covered by a layer of bone matrix

(osteoid) (Jowsey *et al.*, 1958; Herring *et al.*, 1962). In rachitic animals, bone continues to grow but is very poorly mineralized: In such animals, Pu^{4+} passed through the nonmineralized osteoid and deposited on the first available mineralized structures (Jee and Arnold, 1962). Actinides also accumulate on calcified nonskeletal structures such as renal calculi, calcified scar tissue, and calcified tracheal and bronchial cartilage (Painter *et al.*, 1946; Jee and Arnold, 1962; Durbin, 1973; Durbin *et al.*, 1985).

31.8.3 Actinide binding to bone mineral *in vitro*

Neuman (1953) demonstrated that binding of UO_2^{2+} by bone mineral *in vitro* was a reversible ion-exchange process: One UO_2^{2+} displaced two Ca^{2+} ions and immobilized two PO_4^{3-} moieties. *In vivo*, UO_2^{2+} deposits at growth sites in the skeleton, and it accompanies hydroxyapatite crystal growth *in vitro*. However, the evidence indicates that UO_2^{2+} is limited to the crystal surfaces, presumably because it is too large and too polar to 'fit' into the crystal lattice (Neuman and Neuman, 1958).

Jowsey *et al.* (1958) prepared solutions of $^{91}Y^{3+}$, $^{144}Ce^{3+}$, and $^{170}Tm^{3+}$ in human plasma reconstituted with water or with 0.0034 M sodium citrate. Bovine cortical bone was used to prepare the following dry powders (particle size not specified): fat-free whole bone, ED-bone (bone powder heated in ethylenediamine to digest the organic matrix); bone ash (heated at 600°C to destroy the organic matrix); EDTA-bone (bone powder treated with EDTA to remove the mineral fraction). Calcium phosphate [$Ca_3(PO_4)_2$] was included as a bone mineral surrogate, and charcoal and glass wool were included as nonspecific particulate controls. The dry powders (250 mg each) were placed in small paper thimbles, a solution of lanthanide in plasma or in citrated plasma was percolated through the solids, and two rinses of isotope-free media were applied. On average, uptake of the lanthanides by ED-bone, whole bone, $Ca_3(PO_4)_2$, and bone ash was 42, 40, 33, and 19% respectively, of the amounts present in the plasma media. Uptakes were about 30% greater from citrated plasma. The powdered organic matrix, charcoal, and glass wool did not take up the lanthanides from plasma, with or without added citrate. Thin sections of bone embedded in methylmethacrylate were incubated in a solution containing $^{91}Y^{3+}$, and autoradiographs showed that all of the calcified surfaces took up the lanthanide.

Foreman (1962) prepared a solution of $^{239}Pu^{4+}$ in 0.05 M lactate buffer pH 7. Bovine cortical bone was used to prepare the following dry powders (particle size not specified in most cases): fat-free whole bone, bone ash (700°C, 100–200 mesh), coarse bone ash (>100 mesh); KOH-bone (bone powder heated in KOH and ethylene glycol to digest the organic matrix); EDTA-bone (decalcified organic matrix). Carborundum, alundum, and pumice were included as particulate controls. Samples of each powder were shaken for 24 h with 100 to 200 mL of the Pu^{4+}-lactate buffer solution, and the clear supernatant was sampled periodically after allowing the solids to settle. After 24 h, the four particulates

containing bone mineral had taken up $\geq$95% of the Pu^{4+} in the medium. The initial uptake rates of the bone mineral samples were in the order: bone ash (fine) > bone ash (coarse) $\gg$ KOH-bone $\gg$ whole bone. At equilibrium, the EDTA-decalcified organic fraction took up $\leq$10% of the available Pu^{4+}. The Pu^{4+} did not adhere to the three inert mineral powders. Addition of 0.2 M Ca^{2+} or 0.2 M Na^{+} to the buffer medium did not change either the rates or 24 h uptakes of Pu^{4+} by the whole bone or bone ash powders.

Foreman (1962) also prepared whole rat femora, as follows: fresh bone cleaned of adhering soft tissue; bone ash (700°C furnace); KOH-bone; and EDTA-bone. Four replications of each femur preparation were sealed in cellophane bags and surgically implanted in the peritoneal cavities of 'host' rats. The 'host' rats were injected iv with $^{239}Pu^{4+}$ citrate 24 h later and killed 48 h after the Pu^{4+} injection. Uptake of the Pu^{4+} in the living femora of the 'host' rats was reproducible, on average, 164 400 $\pm$ 66 000 cpm per whole bone. Uptakes of Pu^{4+} in the implanted femora that had been heat or chemically ashed were nearly the same, about 40% of that in the living bone of their 'hosts', while Pu^{4+} uptakes in the implanted fresh bone and EDTA-decalcified bone were 15 and 6%, respectively. The chemically or heat ashed bone preparations that were essentially free of organic tissue barriers had the greatest affinities for the Pu^{4+}, while the affinity of the decalcified bone matrix was the least. An important outcome of this experiment was the demonstration of the passage of Pu^{4+} through the semipermeable cellophane membrane, implying the presence of a filterable Pu^{4+} complex in the interstitial fluid of the peritoneal cavity.

Chipperfield and Taylor (1972) prepared dilute solutions of $^{239}Pu^{4+}$, $^{241}Am^{3+}$, and $^{244}Cm^{3+}$ nitrates, each of these was mixed with 3 mL of solutions of tris buffer pH 7.2 containing chelators, including: 3.4×10^{-4} M sodium citrate, 3.2×10^{-4} M EDTA, 2.4×10^{-4} M DTPA, 3.4×10^{-6} M Tf, or 4×10^{-6} M bone sialoprotein or bone chondroitin sulfate–protein complex. Fine cortical bone ash powder (200–300 mesh) was added (10 mg) to each actinide-chelator solution and stirred vigorously for 1 h. Supernatant containing unbound actinide and solids containing bound actinide were separated by centrifugation. In the absence of a chelator, all three actinides were quantitatively associated with the bone mineral fraction. The fractions bound to the bone mineral (100% – reported solution content) for Pu^{4+}, Am^{3+}, and Cm^{3+}, respectively, were as follows: Tf (98, 99, 84); citrate (73, 100, 100); bone glycoproteins, on average (79, 92, 92); EDTA (91, 70, 61); DTPA (14, 0, 0). Effectiveness for preventing actinide binding to bone mineral, which can be viewed as the stabilities of their complexes with the chelators relative to those formed with the bone ash is in the order: Tf $\leq$ citrate < bone glycoproteins < EDTA < DTPA. Binding of Am^{3+} and Cm^{3+} to bone mineral was the same in this test system and nearly quantitative in the presence of Tf, citrate, or the bone glycoproteins; it was partially prevented by EDTA and completely prevented

by DTPA. Binding of Pu^{4+} to bone mineral was nearly quantitative in the presence of Tf, partially prevented by EDTA, the bone glycoproteins, or citrate, and incompletely prevented by DTPA.

Guilmette *et al.* (1998, 2003) prepared solutions of $^{238}Pu^{4+}$, $^{239}Pu^{4+}$, and $^{241}Am^{3+}$ in 0.0034 to 0.005 M sodium citrate. Finely ground bovine bone ash and synthetic bone mineral (hydroxyapatite, HAP) were characterized by X-ray diffraction, and their measured specific surface areas were 10.7 and 65 $m^2\ g^{-1}$, respectively. Each actinide was stirred for 24 h with 10 mg of a mineral powder in 0.1 M HEPES buffer pH 7.2. The solid and supernatant were separated by ultrafiltration. Under these conditions $\geq$99% of the actinide was bound to the minerals. Varying masses of $^{238}Pu^{4+}$ and $^{239}Pu^{4+}$ (0.001–100 μg) and $^{241}Am^{3+}$ (0.001–1.0 μg) were added to 10 mg of bone ash or HAP to characterize the relationships between actinide binding and mineral surface area, that is, the binding capacity. For Pu^{4+}, masses $\leq$10 μg, and for all $^{241}Am^{3+}$ masses studied, binding to both minerals was $\geq$99% in 24 h. However, when the mass of $^{239}Pu^{4+}$ was 100 μg, more than 50% incubated with bone ash and 20% incubated with HAP remained unbound at 24 h. The data are consistent with the larger specific surface area of HAP presenting more binding sites, and they may also be interpreted as signifying that the mineral surfaces contain a saturatable number of potential metal-binding sites per unit area. The DTPA chelates of $^{238}Pu^{4+}$ and $^{241}Am^{3+}$ were incubated with 10 mg of HAP. There was no indication that the $^{241}Am^{3+}$–DTPA complex dissociated in favor of mineral binding. In contrast, 50% of the $^{238}Pu^{4+}$–DTPA complex dissociated in 24 h in favor of binding to the bone mineral. The stability of $^{241}Am^{3+}$–DTPA is evidently greater, while that of $^{238}Pu^{4+}$–DTPA is somewhat less, than the stabilities of their respective bone mineral complexes.

Guilmette *et al.* (2003) investigated removal of $^{238}Pu^{4+}$ and $^{241}Am^{3+}$ from bone mineral by 24 h incubation of those actinides prebound to HAP by chelators in solutions of 0.1 M HEPES buffer pH 7.2. Binding of $^{238}Pu^{4+}$ and $^{241}Am^{3+}$ by HAP is sufficiently stable that $ZnNa_3$–DTPA removed only 1.4% of the Am^{3+} and $\leq$0.1% of the Pu^{4+} sorbed to the mineral. Actinide removal from HAP was tested with a set of tetra-, hexa-, and octadentate ligands with linear or branched backbones containing bidentate catecholate (CAM) or hydroxypyridinonate (HOPO) metal-binding groups. Removal of Pu^{4+} (4–54%) was achieved only by the linear octadentate CAM and HOPO ligands. Removal of Am^{3+} (5–21%) was achieved with several linear or branched tetra-, hexa-, or octadentate ligands.

Bostick *et al.* (2000), Moore *et al.* (2003), and Thomson *et al.* (2003) conducted investigations in support of the management and remediation of actinide-contaminated groundwaters, sediments, and wastewaters. Batch sorption and column tests demonstrated the great affinities of UO_2^{2+}, NpO_2^{+}, Pu^{4+}, Am^{3+}, and stable Ce^{3+} for natural and synthetic apatites, including hydroxyapatite, $Ca_3(PO_4)_2$, and bone ash.

31.8.4 Actinide binding by bone glycoproteins

A case can be made for the participation of some low abundance organic matrix constituents in the binding of actinides in living bone (reviewed by Duffield and Taylor, 1986). *In vitro* complexation of Th^{4+} and Pu^{4+}, and to a lesser degree, Am^{3+} and Cm^{3+} by isolated mucoprotein substituents of bone matrix has been demonstrated.

All of the multivalent lanthanides and actinides studied autoradiographically deposit most intensely on fully mineralized bone surfaces, anatomical sites that also stain positively with PAS for the presence of mucosubstances (Jowsey, 1956; Herring *et al.*, 1962; Williamson and Vaughan, 1964; Vaughan *et al.*, 1973). Paraphrasing Jowsey (1956) in response to a conference participant's question: In areas of bone resorption, the PAS staining is the result of the depolymerized state of the mucopolysaccharides in the ground substance (matrix). In such state there are presumably free side chains of the mucopolysaccharide molecules (containing potentially chelating 1,2-hydroxy groups), which are oxidized by the periodic acid to aldehydes and take up the Schiff stain.

Nearly 90% of the organic bone matrix is collagen, which contributes about 20% of the weight of native bone. Five distinct glycoprotein fractions were extracted from bovine cortical bone. Their designations and weight fractions of native bone (% by weight) are, as follows: bone sialoprotein, 0.25%; bone chondroitin sulfate–protein complex, 0.18%; three less well-characterized glycoprotein fractions – glycoprotein I and II, 1.57% combined; cetylpyridonium chloride (cpc) soluble glycoprotein, 0.1%. While not regarded as conclusive, supporting experiments indicate that the sialoprotein content (and perhaps also the other mucosubstances) of bone are formed and laid down in the matrix during bone formation. The functions of the mucosubstances of mature bone are not known (Herring, 1964). Bone sialoprotein contains large proportions of sialic, glutamic, and aspartic acids; 15, 20, and 15 moles of acids per mole of protein, respectively.

Chipperfield and Taylor (1968, 1970, 1972) used gel filtration (Sephadex G-25 and G-50) to investigate the bonding of ultrafiltered dilute solutions of $^{228}Th^{4+}$, $^{239}Pu^{4+}$, $^{241}Am^{3+}$, and $^{244}Cm^{3+}$ nitrates incubated with the isolated bone glycoproteins noted above. The proteins were dissolved in tris buffer pH 7.2, and the protein:metal molar ratios were 1:1 for Pu^{4+} and 10:1 for the higher specific activity radionuclides. The results of those studies are collected in Table 31.13. Those results, although variable and regarded by the authors as semiquantitative, indicate that at physiological pH the isolated glycoprotein fractions of bone matrix can form complexes with Th^{4+} and Pu^{4+}, and to a lesser degree, with Am^{3+} and Cm^{3+}. Under these experimental conditions, the affinities of the bone glycoprotein fractions for Th^{4+} and Pu^{4+} apparently exceed the affinities for these actinides of reconstituted human Tf or apo-Tf. Two of the bone glycoproteins, bone sialoprotein and bone chondroitin sulfate–protein

complex, were about as effective as EDTA in competing with bone ash for Pu^{4+}, Am^{3+}, and Cm^{3+}.

Supporting studies demonstrated that actinide binding by the bone glycoproteins was pH dependent; maximum binding of Pu^{4+} by bone sialoprotein is at pH 6, and of Am^{3+} and Cm^{3+} at pH 8. These results were interpreted by the authors to mean that Pu^{4+} was bound by the abundant carboxyl groups of the protein's amino acid side chains, but that those carboxyl groups were less important for binding the trivalent actinides. Binding of Pu^{4+} by bone sialoprotein was reduced, but not abolished, by mild acid hydrolysis (removal) of the terminal sialic acid moieties, which suggests that the sialic acid groups may also participate in metal binding.

31.8.5 Summary

Actinide binding in bone is a surface phenomenon. However, except for UO_2^{2+}, binding of the trivalent and tetravalent actinides and NpO_2^+ to bone surfaces is so stable that those metals neither migrate into the bone volume via the canaliculi nor are released back into the circulation by ion exchange or complexation with the ligands of the constantly flowing plasma and tissue fluid.

At physiological pH, trivalent and tetravalent lanthanides and actinides, UO_2^{2+} and NpO_2^+, bind stably to native and synthetic bone mineral *in vitro*. Actinide uptake by various bone mineral preparations was nearly quantitative

from buffered solutions (lactate, tris, HEPES, pH 7–7.4) even from those solutions that also contained 0.3 to 0.5 mM citrate, whole plasma, or human Tf. In general, actinide uptake by the crystalline bone mineral preparations (synthetic HAP, chemically ashed KOH-glycol bone, or ED-bone) was faster than for bone ash, $Ca_3(PO_4)_2$, or powdered defatted whole bone, in which about one-half of the exposed particle surface is organic matrix. Actinide uptake by bone mineral is positively correlated with the surface area of the particles and appears to be saturable, indicating a fixed number of binding sites per unit surface area.

Hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$] presents an organized Ca^{2+}-poor negatively charged surface with unsatisfied negative charges on adjacent phosphates. If Ca^{2+} is replaced, as is the case for UO_2^{2+}, there is access to the oxygens of two and perhaps three phosphates. The complexes of Th^{4+} and Pu^{4+} with bone mineral are more stable than the complexes that these metal ions form with $ZnNa_3$-DTPA, indicating that the crystals themselves provide spatially suitable multidentate binding sites.

The PAS-positive staining at the organic–mineral interface of bone surfaces, which are the actinide deposition sites in the skeleton, suggested that bone glycoproteins may participate in actinide binding, even though powdered decalcified bone matrix does not bind actinides. Five isolated low abundance bone glycoproteins form variably stable actinide complexes. The binding units of these proteins are considered to be mainly free sialic acid, the monodentate carboxyl groups of glutamic acid, and the bidentate alpha-hydroxy-carboxyl groups of aspartic acid.

The mineral crystals of native bone are sandwiched between layers of matrix collagen fibers, and the exposed bone surfaces do not present as many metal-binding sites as isolated bone mineral crystals. The most stable complexes of the trivalent lanthanides and actinides are six-coordinate (six M–O bonds), and those of the tetravalent actinides are eight-coordinate (eight M–O bonds). It would seem that *in situ* the number and configuration of the exposed potential binding groups of the glycoproteins alone would be insufficient to provide enough suitably arranged binding groups for stable actinide complexation. However, in living bone, both the mineral crystals and the neighboring matrix constituents (glycoproteins) combined may furnish sufficient numbers of binding groups suitably arranged in three-dimensional space for rapid stable actinide complexation *in situ*.

31.9 *IN VIVO* CHELATION OF THE ACTINIDES

The potential hazards to human health of the radioactive fission products and new heavy elements created by nuclear fission were recognized early, stimulating the search for effective ways to remove internally deposited radioelements

from the body (Schubert, 1955; Voegtlin and Hodge, 1949, 1953; Stone, 1951). Chemical agents that form stable excretable actinide complexes were soon recognized as the only practical therapy for internal contamination (decorporation) (Voegtlin and Hodge, 1949, 1953; Schubert, 1955; Rosenthal, 1956; Catsch, 1964). Such agents should have greater affinity for actinides at physiological pH than the biological ligands, low affinities for essential divalent metals, and low toxicity at effective dose. Reviews and proceedings of conferences on the development of chelators suitable for removal of internally deposited actinides have dealt with the chemistry of metal chelates, animal studies to determine ligand effectiveness for reducing actinide burdens in the tissues and amelioration of actinide-induced chemical and radiation damage, ligand toxicity, and clinical applications (Rosenthal, 1956; Seven and Johnson, 1960; Kornberg and Norwood, 1968; Volf, 1978; NCRP, 1980; Raymond and Smith, 1981; Taylor, 1991; Bhattacharyya *et al.*, 1992; Durbin *et al.*, 1997a, 1998a,b; Stradling *et al.*, 2000a,b; Wood *et al.*, 2000; Gorden *et al.*, 2003).

31.9.1 Polyaminopolycarboxylic acids

The first chelating agent investigated was ethylenediaminetetraacetic acid (H_4-EDTA). Its Ca^{2+} salt, $CaNa_2$–EDTA, was introduced to avoid toxic depletion of serum Ca^{2+}. It enhanced excretion of $^{91}Y^{3+}$, $^{144}Ce^{3+}$, and $^{239}Pu^{4+}$ in rats (Foreman and Hamilton, 1951; Hamilton and Scott, 1953). But $CaNa_2$–EDTA is a poor actinide decorporation agent: it is renally toxic at effective dose; it depletes essential Zn^{2+} and other divalent metals; its efficacy cannot be improved except by increasing the administered dose.

Pentacarboxyl diethylenetriaminepentaacetic acid (H_5-DTPA) and its Ca^{2+} and Zn^{2+} salts ($CaNa_3$–DTPA introduced in 1957 and $ZnNa_3$–DTPA introduced in 1965) improved lanthanide and actinide decorporation compared with $CaNa_2$–EDTA (Catsch and Lê, 1957; Kroll *et al.*, 1957; Smith, 1958; Catsch and von Wedelstaedt, 1965). Those clinically approved DTPA salts are effective decorporation agents for the trivalent lanthanides and actinides, less effective for Pu^{4+} and Th^{4+}, and nearly ineffective for reducing the body content of UO_2^{2+} or NpO_2^+. [See references cited in Volf, 1978; Durbin *et al.*, 1997a, 1998a,b; Gorden *et al.*, 2003]. Although nominally octadentate, $CaNa_3$–DTPA appears not to coordinate fully with Pu^{4+}, and it does not remove Pu^{4+} bound to bone mineral *in vitro* (Raymond and Smith, 1981; Guilmette *et al.*, 2003).

Several variants and derivatives of DTPA have been prepared and tested in animals, including polyaminopolycarboxylic acids with longer central bridges or additional carboxyl groups (Catsch, 1964); a dihydroxamic acid derivative, ZnNa–DTPA–DX (Durbin *et al.*, 1989b; Stradling *et al.*, 1991; Volf *et al.*, 1993); lipophilic derivatives containing long alkane side chains (Volf, 1978; Raymond and Smith, 1981; Miller *et al.*, 1993). None of those DTPA-based

ligands was substantially more effective for *in vivo* chelation of lanthanides or Pu^{4+} or less toxic than native $CaNa_3$–DTPA, and most have been abandoned.

31.9.2 Desferrioxamine

Desferrioxamine (DFO), a linear tris-hydroxamate ligand, is a member of a class of compounds (siderophores) elaborated by microorganisms to obtain iron from the environment (Raymond and Smith, 1981). *In vivo* Pu^{4+} chelation is hampered by the weak acidity of the hydroxamic groups, which are not ionized at pH < 8; they are deprotonated only slowly at pH 7.4 by Fe^{3+} and Pu^{4+} but not by trivalent actinides (Taylor, 1967; Durbin *et al.*, 1980, 1989b; Rodgers and Raymond, 1983).

31.9.3 Siderophores as model chelators

Investigations of the siderophores and their structures and coordination chemistry identified the powerful hexadentate iron-sequestering agent, enterobactin (EB). EB is produced by enteric bacteria (*E. coli*) to obtain Fe^{3+} from the nearly neutral contents of the mammalian intestine (see references in Raymond and Smith, 1981 and Gorden *et al.*, 2003). It contains three bidentate catecholate binding groups attached through amide linkages to a cyclic 1-serine backbone and is preorganized for binding. The properties and structure of EB and similarities in the coordination properties of Pu^{4+} and Fe^{3+} provided the basis for rational design of highly selective multidentate actinide chelators that would be effective at physiological pH.

(a) Catecholate ligands

Multidentate catecholate ligands based on the EB model (denticity 4–8) were prepared containing catechol (CAM), sulfocatechol [CAM(S)], carboxycatechol [CAM(C)], or catecholamide (TAM) metal-binding groups (Fig. 31.15) attached through amide linkage to linear (LI-), cyclic (CY-), aromatic (ME-), or branched (TREN-, H(2,2)-) backbones. Syntheses and structures of the CAM ligands are collected in Gorden *et al.* (2003). All of those ligands were evaluated for promotion of excretion of $^{238}Pu^{4+}$ from mice (30 μmol kg^{-1} ligand ip 1 h after iv injection of $^{238}Pu^{4+}$ citrate, kill at 24 h). Catecholate ligands of denticity <8 and those containing only CAM groups were marginally effective for *in vivo* Pu^{4+} chelation. The water-soluble octadentate ligands with flexible linear backbones based on spermine were more effective than octadentate ligands with attached lipophilic side chains or those with cyclic backbones. Reduction of skeleton Pu^{4+} by 3,4,3-LICAM(S) and of liver Pu^{4+} by 3,4,3-LICAM(C) were greater than obtained with an equimolar amount of $CaNa_3$–DTPA (Durbin *et al.*, 1980, 1984, 1989a,b, 1996; Lloyd *et al.*, 1984c). Those

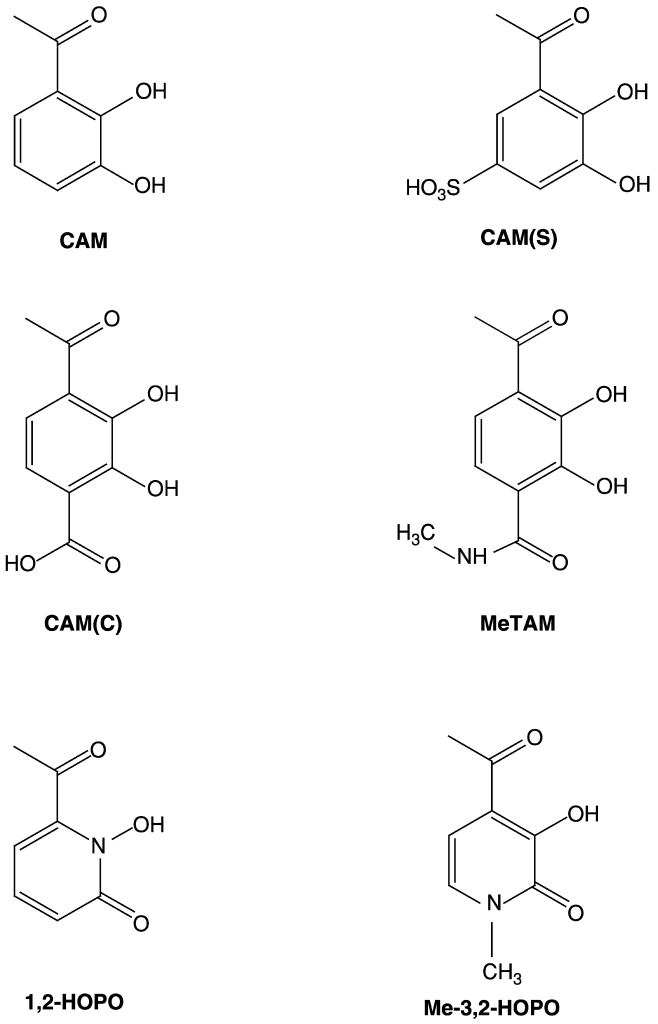

Fig. 31.15 *Catecholate and hydroxypyridonate metal-binding units incorporated into multidentate ligands for* in vivo *chelation of actinides. Catechol* (*CAM*), 5-*sulfocatechol* (*CAM*(*S*)), 4-*carboxycatechol* (*CAM*(*C*)), *methylterephthalamide* (*METAM*), 1,2 *hydroxypyridinone* (1,2-*HOPO*), *Me*-3,2-*hydroxypyridinone* (*Me*-3,2-*HOPO*).

ligands were much more effective than $CaNa_3$–DTPA at doses $\leq$30 μmol kg^{-1}, and they were orally active.

Although some of the *in vivo* properties of the two octadentate catecholate ligands are favorable, both are defective. *In vivo* chelation of Am^{3+} (and presumably other trivalent actinides and lanthanides) was significantly less than with $CaNa_3$–DTPA (Lloyd *et al.*, 1984c; Stradling *et al.*, 1986, 1989;

Volf, 1986; Volf *et al.*, 1986). The specific electric charge (e/r) of Am^{3+} is not great enough to deprotonate more than three of the eight OH groups of the tetracatecholate ligands at pH 7.4 (Kappel *et al.*, 1985). Furthermore, both of these nominally octadentate ligands are only functionally hexadentate at pH < 12. As the pH is reduced below 7.4, binding of Pu^{4+} by the more lipophilic 3,4,3-LICAM(C) becomes progressively less stable, and at pH 6 to 6.5 (the ambient pH of the lungs and renal tubules), the tetradentate species of the Pu^{4+}–3,4,3-LICAM(C) complex dominates (Kappel *et al.*, 1985; Durbin *et al.*, 1989a). Chelation of inhaled Pu^{4+} deposited in the lungs is weak and less effective than with $CaNa_3$–DTPA. The Pu^{4+} complex with 3,4,3-LICAM(C) that formed in the blood at pH 7.4 partially dissociates at the reduced pH of the kidneys depositing Pu^{4+} residues (Stradling *et al.*, 1986, 1989; Volf, 1986; Volf *et al.*, 1986; Durbin *et al.*, 1989a). 3,4,3-LICAM(S) was found to be renally toxic in dogs at the effective dose (Lloyd *et al.*, 1984c).

At pH 7.4, methylterephthalamide (MeTAM) forms a more stable ferric complex than any other catecholate-binding group (Durbin *et al.*, 1996). MeTAM was introduced into three octadentate ligands with differing backbones; the MeTAM group was attached to the N-terminal of DFO, and four MeTAM groups were incorporated into linear spermine (3,4,3-LIMeTAM) and branched PENTEN [H(2,2)-MeTAM]. Reductions of body Pu^{4+} by these octadentate ligands were similar to each other, somewhat greater than for 3,4,3-LICAM(C), and significantly greater than for $CaNa_3$–DTPA. Their Pu^{4+} complexes are stable over the physiological pH range, and no Pu^{4+} residues were left in the kidneys. These lipophilic ligands are sparingly soluble at pH < 8, their solutions are rapidly air oxidized, and their reductions of body Pu^{4+} in mice, similar to that obtained with 3,4,3-LICAM(C), suggested that they were also functionally hexadentate at pH 7.4.

(b) Hydroxypyridinonate ligands

Bidentate metal-binding groups more acidic than derivatized catechol and were required to achieve full eight-coordination with Pu^{4+} and to stably bind trivalent actinides in dilute aqueous solution at physiological pH. Highly selective HOPO metal-binding units occur in a few siderophores. The 1,2-HOPO and Me–3,2-HOPO isomers (Fig. 31.15) are structural and electronic analogs of hydroxamic acid and catechol, respectively. Their Fe^{3+} complexes are exceptionally stable, and both isomers are deprotonated and ready for metal binding at physiological pH (Scarrow *et al.*, 1985).

The 1,2-HOPO and Me–3,2-HOPO binding units were derivatized by attaching a carboxyl group adjacent to the OH group on the pyridinone ring; the COOH group can then be attached to amines on the selected molecular backbones through amide linkages. An important feature of the 1,2-HOPO and Me–3,2-HOPO complexes is that, as is observed in the catecholamide complexes, strong hydrogen bonds between the amide proton and the adjacent oxygen

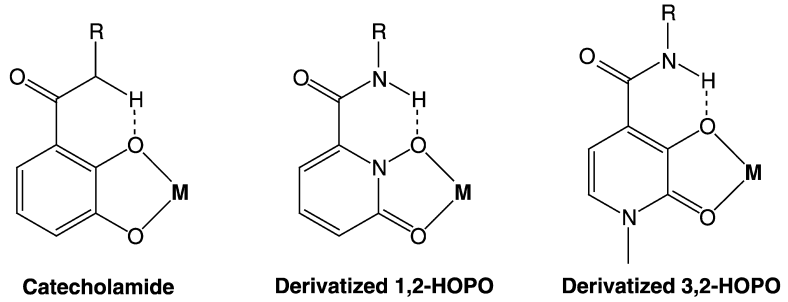

Fig. 31.16 *Strong hydrogen bonds between the amide proton and the adjacent oxygen donor enhance the stabilities of the metal complexes of the catecholate and hydroxypyridinonate ligands* (*Xu* et al., 2001).

donor increase the stabilities of their metal complexes (Fig. 31.16) (Xu *et al.*, 1995, 2001). Sets of multidentate 1,2-HOPO and Me–3,2-HOPO ligands were prepared, as follows: tetradentate with linear backbones (α-ω-alkanediamines – 3-LI-, 4-LI-, 5-LI- 6-LI- and 2-aminoethylether, 5-LIO-); hexadentate with a linear spermidine backbone (3,4-LI-) or with a tripodal branched backbone triethyleneamine (TREN-); octadentate with a linear spermine backbone (3,4,3-LI-), or through attachment of one HOPO group to the N-terminal of DFO (DFO-), (Fig. 31.17) (White *et al.*, 1988; Xu *et al.*, 1995; Xu and Raymond, 1999; Durbin *et al.*, 2000b).

Ligand efficacies were assessed for *in vivo* Pu^{4+} chelation by administering them to mice that had been injected iv with $^{238}Pu^{4+}$ citrate, as follows: ligand injected ip (30 μmol kg^{-1}) at 1 h (prompt injection), variable ligand dose at 1 h (dose effectiveness), ligand ip at 24 h (delayed effectiveness), ligand given orally at 5 min (oral activity). The ferric complexes of some ligands were administered promptly by ip injection or orally to assess competition between the ferric and Pu^{4+} complexes. Mice were killed 24 h after the ligand administration, and all tissues and excreta were radioanalyzed for Pu^{4+} (White *et al.*, 1988; Xu *et al.*, 1995; Durbin *et al.*, 2000b; Gorden *et al.*, 2003). Selected ligands were also assessed for *in vivo* chelation of $^{241}Am^{3+}$,$^{232}UO_2^{2+}$ or $^{233}UO_2^{2+}$, and $^{237}NpO_2^{+}$ (Durbin *et al.*, 1994, 1997a, 1998b, 2000a).

(c) Ligands for Pu^{4+}

1,2-HOPO and Me–3,2-HOPO ligands (tetradentate with 4-LI-, 5-LI-, 5-LIO-backbones, hexadentate with a TREN- backbone, and octadentate with a 3,4,3-LI- or H(2,2)- backbone) given ip or orally after the Pu^{4+} iv injection at doses ranging from 0.1 to 100 μmol kg^{-1} were significantly and markedly superior to equimolar amounts of $CaNa_3$–DTPA for promoting Pu^{4+} excretion. Promotion of Pu^{4+} excretion by ip injection of 30 μmol kg^{-1} of the linear 1,2-HOPO ligands (injected ip 1 h after the Pu^{4+} injection) was positively correlated with

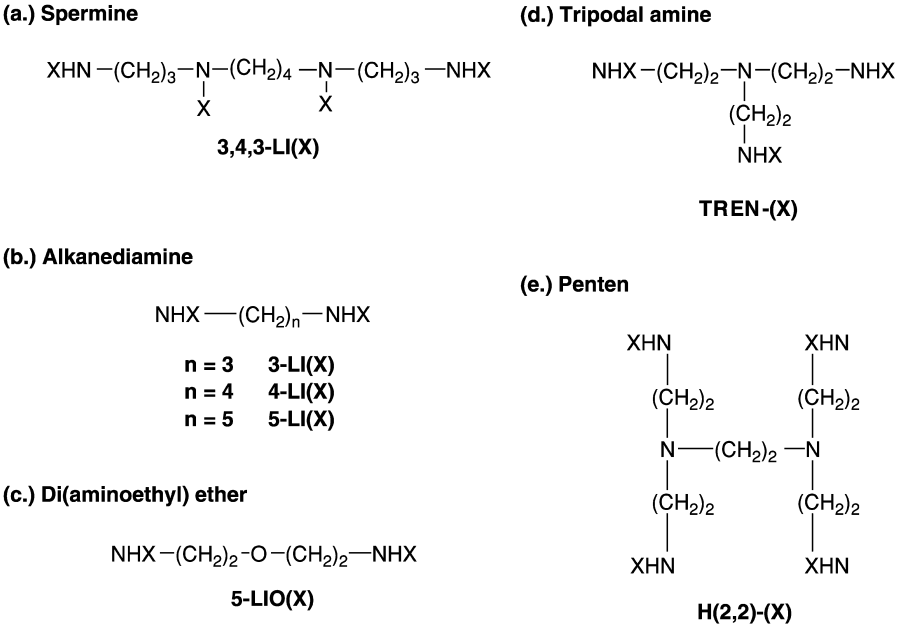

Fig. 31.17 *Linear and branched molecular backbones used for multidentate actinide chelating agents: tetradentate* (*b, alkanediamines; c, di*(*aminoethyl*)*ether*); *hexadentate* (*d, tripodal amine*); *octadentate* (*a, spermine; e, penten*).

ligand denticity, indicating formation of a complete eight-coordinate complex with octadentate 3,4,3-LI(1,2-HOPO) (White *et al.*, 1988; Gorden *et al.*, 2003).

At the standard 30 μmol kg^{-1} dose given to mice ip at 1 h after the Pu^{4+} injection, the tetra-, hexa-, and octadentate Me–3,2-HOPO ligands all promoted nearly the same amount of Pu^{4+} excretion. Apparently, the stabilities of the Pu^{4+} complexes with the tetradentate and hexadentate Me–3,2-HOPO ligands and the ligand concentrations established in the blood at this dose level are large enough to allow those ligands to compete for Pu^{4+} with the bioligands. However, when the Me–3,2-HOPO ligands were given orally, at lower doses, or as ferric complexes, the octadentate ligands, which have 1:1 stoichiometry for binding Pu^{4+}, were clearly more effective for *in vivo* Pu^{4+} chelation than the ligands of lesser denticity (Durbin *et al.*, 1989b, 2000b; Xu *et al.*, 1995; Gorden *et al.*, 2003).

The efficacies of the structurally analogous pairs of 1,2-HOPO and Me–3,2-HOPO ligands were compared in several Pu^{4+} removal protocols in mice. Overall, the Me–3,2-HOPO ligands were more effective for *in vivo* Pu^{4+} chelation than their structural 1,2-HOPO analogs (Durbin *et al.*, 2000b). The greater affinity of Me–3,2-HOPO for Pu^{4+} *in vivo* agrees with the greater stabilities of

the Me–3,2-HOPO complexes with other 'hard' metal ions like Fe^{3+} and Th^{4+} (Scarrow *et al.*, 1985; Veeck *et al.*, 2004).

Both octadentate HOPO ligands with the branched H(2,2)-backbone were highly effective for *in vivo* Pu^{4+} chelation, but they were considered to be too toxic to warrant further investigation (Durbin *et al.*, 1997a, 2000b). Low-toxicity DFO-(1,2-HOPO) given by ip injection is about as effective as 3,4,3-LI(1,2,-HOPO) for *in vivo* Pu^{4+} chelation, and it is moderately effective when given orally or at low dose (White *et al.*, 1988; Durbin *et al.*, 1989b). However, the weak acidity of the three hydroxamate groups prevents that ligand from competing effectively for inhaled Pu^{4+} deposited in the lungs and from stably binding Am^{3+} (Stradling *et al.*, 1991; Volf *et al.*, 1993, 1996a). *In vivo* Pu^{4+} chelation by DFO-(Me-3,2-HOPO) was significantly poorer than was obtained with its analog, DFO-(1,2-HOPO), but better than with native DFO. The lower than expected efficacy of DFO-(Me-3,2-HOPO) may be attributed to its lower aqueous solubility and the instability of its Pu^{4+} complex at the lower end of the physiological pH range (Xu *et al.*, 1995).

Among the ligand sets, the most effective for *in vivo* Pu^{4+} chelation is linear octadentate 3,4,3-LI(1,2-HOPO). Although it contains the less stably binding 1,2-HOPO unit, it has good aqueous solubility, and the flexible linear spermine backbone apparently confers advantages for Pu^{4+} binding by allowing a more favorable spatial arrangement of the four binding groups around the Pu^{4+} center. The 3,4,3-LI(1,2-HOPO) ligand is markedly superior to $CaNa_3$–DTPA for reducing Pu^{4+} in all tissues when given by injection, oral administration, or subcutaneous infusion after an iv or im injection or inhalation of Pu^{4+} nitrate or citrate in rats and mice (White *et al.*, 1988; Durbin *et al.*, 1989b, 2000b; Stradling *et al.*, 1992, 1993; Volf *et al.*, 1993, 1996a,b; Gray *et al.*, 1994). It is effective at doses as low as 0.03 μmol kg^{-1} in mice. When injected or infiltrated into an im wound site, it is more effective than $CaNa_3$–DTPA for reducing the body and wound site content of Th^{4+} (Stradling *et al.*, 1995a).

It was considered that the effectiveness of the octadentate 3,4,3-LI(1,2-HOPO) ligand might be improved, if the thermodynamically more potent Me-3,2-HOPO were introduced. Concerns about toxicity, lipophilicity, and aqueous solubility of a tetra-Me-3,2-HOPO ligand led to the synthesis of the mixed ligand, 3,4,3-LI(1,2-Me-3,2-HOPO). Two 1,2-HOPO units occupy the central secondary amines and two Me-3,2-HOPO units are attached to the terminal primary amines of spermine. Substitution of the two Me-3,2-HOPO groups for 1,2-HOPO slightly increased the stability of the Pu^{4+} complex at pH 7.4 and the lipophilicity and oral activity of the ligand, while somewhat reducing acute toxicity at high dose (Xu *et al.*, 2002). However, the modest thermodynamic gain was offset by the reduction in hydrophilicity, which appears to be an important property of 3,4,3-LI(1,2-HOPO), most likely facilitating its access to Pu^{4+} in the skeleton (Durbin *et al.*, 2000b, 2003).

Crystals have been prepared from water of structurally analogous Ce^{4+}[5-LI-(Me–3,2-HOPO)$_2$] and Pu^{4+}[5-LIO-(Me–3,2-HOPO)$_2$] complexes (Fig. 31.18).

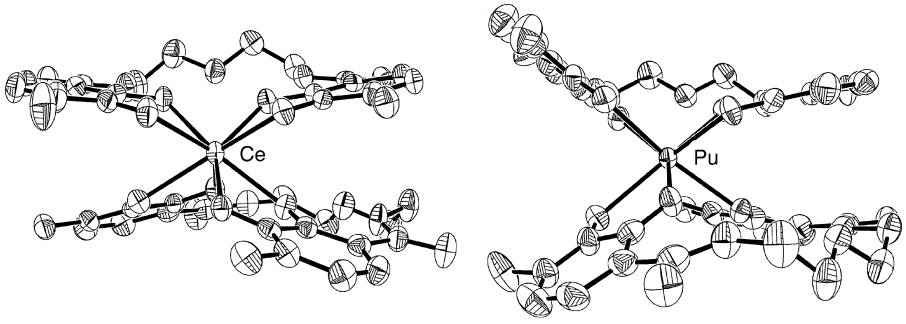

Fig. 31.18 *Molecular structures* (*viewed from the side*) *of Ce*(IV)[5-*LIO*(*Me*-3,2-*HOPO*)]$_2$ (*left side, Xu* et al., 2000) *and Pu*(IV)[5-*LIO*(*Me*-3,2-*HOPO*)]$_2$ (*right side, Gorden* et al., 2005).

In both cases the 2:1 structure is demonstrated. The overall ligand geometries resemble sandwich structures that are defined by the oxygen atoms coordinating to the Ce^{4+} and Pu^{4+} centers (Xu *et al.*, 2000; Gorden *et al.*, 2005). Solution thermodynamic studies of the Ce^{4+} complex system gave an overall formation constant of the complex (log β_2) of 41.6, and the formation constant of the analogous Pu^{4+} complex is expected to be essentially the same.

(d) Ligands for Am^{3+}

The efficacies of ligands containing HOPO groups for *in vivo* chelation of Am^{3+} and for removing Am^{3+} from bone mineral are generally in the order: octadentate > hexadentate > tetradentate (Guilmette *et al.*, 2003). The octadentate ligands more than satisfy the requirement for six-coordination preferred by Am^{3+}, and if three of their bidentate metal-binding units can bind to Am^{3+} without steric hindrance, the extra binding group appears to enhance the stabilities of their Am^{3+} complexes. As noted above, *in vivo* chelation of Am^{3+} by the octadentate ligands containing carboxy- or sulfocatechol [CAM (C), CAM(S)] or by hydroxamate (as in the octadentate ligands with the DFO-backbone) is weak because too few of the hydroxyl groups of those ligands can be deprotonated by Am^{3+} (and presumably other trivalent actinides) to form stable complexes at physiological pH (Lloyd *et al.*, 1984c; Kappel *et al.*, 1985; Stradling *et al.*, 1986, 1989; Volf, 1986; Volf *et al.*, 1986; Zhu *et al.*, 1988).

Four HOPO ligands have been investigated in rats and mice for *in vivo* chelation of Am^{3+}: octadentate 3,4,3-LI(1,2-HOPO), hexadentate TREN-(Me–3,2-HOPO), tetradentate 5-LI(Me–3,2-HOPO), and 5-LIO(Me–3,2-HOPO). When given by injection or orally (30 μmol kg^{-1}) to rats or mice contaminated with $^{241}Am^{3+}$ by injection or infiltration into a wound, all four of those ligands were more effective than an equimolar amount of

$CaNa_3$–DTPA. Octadentate 3,4,3-LI(1,2-HOPO) was about as effective as $CaNa_3$–DTPA, while the other HOPO ligands of lesser denticity were less effective than $CaNa_3$–DTPA for reducing body and lung Am^{3+} when the Am^{3+} had been inhaled (Stradling *et al.*, 1992; 1993, 1995b; Volf *et al.*, 1993, 1996; Durbin *et al.*, 1994; Gray *et al.*, 1994; Volf, 1996; Gorden *et al.*, 2003).

(e) Ligands for UO_2^{2+}

Soluble uranyl ion, UO_2^{2+}, is nephrotoxic, and because bone is the major storage organ for UO_2^{2+}, the high specific activity uranium isotopes also induce bone cancer (Voegtlin and Hodge, 1949, 1953; Finkel and Biskis, 1968; Hodge, 1973). Although sought since the 1940s, no multidentate ligand was identified that would efficiently bind UO_2^{2+} *in vivo*, promote its excretion, and reduce deposits in kidneys and bone (reviewed by Durbin *et al.*, 1997a). The modest reductions of acute UO_2^{2+} poisoning obtained with tiron, a bidentate sulfocatecholate, suggested that multidentate ligands containing similar binding groups would be effective *in vivo* UO_2^{2+} chelators.

Representative tetra-, hexa-, and octadentate ligands with linear or branched backbones containing CAM(S), CAM(C), MeTAM, 1,2-HOPO, or Me-3,2-HOPO groups (20 in all) were evaluated in mice for *in vivo* chelation of UO_2^{2+}. Experimental conditions were: $^{232\,+\,235}UO_2Cl_2$ or $^{233}UO_2Cl_2$ pH 4 injected iv, 30 μmol kg^{-1} of ligand injected ip at 5 min (see Fig. 31.11), ligand: U molar ratio 75 to 91, kill at 24 h. All of the test chelators were screened for acute toxicity. Except for the two tetradentate 1,2-HOPO ligands and $CaNa_3$–DTPA, all of the injected test chelators significantly reduced UO_2^{2+} in the kidneys compared with controls, and ligands containing CAM(S), CAM(C), or MeTAM groups also significantly reduced UO_2^{2+} in the skeleton. Administered orally at molar ratios from 90 to 300, the linear tetradentate ligands containing Me-3,2-HOPO, CAM (S), or CAM(C) and 3,4,3-LI(1,2-HOPO) significantly reduced UO_2^{2+} binding in the kidneys, but not in the skeleton. The combined assessments of ligand efficacy and acute toxicity identified tetradentate 5-LIO(Me-3,2-HOPO) and 5-LICAM(S) as the most effective low toxicity agents for UO_2^{2+}. They efficiently removed circulating UO_2^{2+} at molar ratios as low as 20, removed useful amounts of newly deposited UO_2^{2+} from kidneys and/or bone at molar ratios $\geq$100, and reduced kidney UO_2^{2+} significantly when given orally at molar ratios $\geq$100. 5-LIO(Me-3,2-HOPO) has greater affinity for UO_2^{2+} in the kidneys, 5-LICAM(S) has greater affinity for UO_2^{2+} in bone, and a 1:1 mixture of the two ligands (total ligand: U molar ratio 91) reduced kidney and bone UO_2^{2+} to 15 and 58% of control, respectively – more than an equimolar amounts of either ligand alone (Durbin *et al.*, 1989b; 1997a, 2000a; Gorden *et al.*, 2003).

Crystals of uranyl chelates with the set of linear tetradentate Me–3,2-HOPO ligands demonstrate a 1:1 structure and show that those ligands bind in a nearly planar ring perpendicular to the plane of the dioxo oxygens (Fig. 31.19) (Xu and Raymond, 1999).

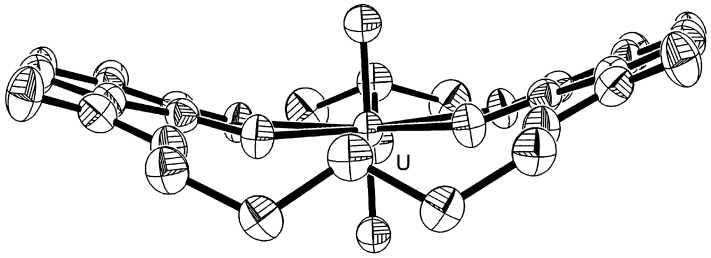

Fig. 31.19 *Molecular structure of* UO_2[5-*LI*(*Me*-3,2,-*HOPO*)] (*Xu and Raymond*, 1999).

(f) Ligands for NpO_2^+

As noted above in the sections dealing with tissue distribution, circulatory transport, and tissue uptake kinetics, the oxidation state of Np *in vivo* is uncertain and probably variable. Rapid plasma clearance and substantial urinary excretion of NpO_2^+ resemble the behavior of UO_2^{2+}, while the deposition in the skeleton of nearly one-half of Np taken into blood and its prolonged retention resemble Pu^{4+}. Redox conditions *in vivo* range from an oxidizing environment in the lungs to more reducing environments in the tissues. Depending on the oxidation state of the Np introduced into the blood (Np^{4+}, NpO_2^+, NpO_2^{2+}), the local conditions in the blood and tissues, and the availability of stabilizing bioligands, both reduction of NpO_2^+ and oxidation of Np^{4+} may be expected (Duffield and Taylor, 1986; NCRP, 1988; Taylor, 1998). The complexes formed by NpO_2^+ are weak, while those of Np^{4+} are about as stable as those of Pu^{4+} with the same ligands (Table 31.8).

$CaNa_3$–DTPA was injected ip at ligand:Np molar ratios $\geq$50 in rats that had been injected iv with ^{237}Np or ^{239}Np citrate solutions (oxidation states uncertain). Excretion of both Np isotopes was increased, the Np content of liver and kidneys was reduced, but there was little reduction in skeleton Np (Smith, 1972b). Effective reduction of ^{239}Np in the body of rats was achieved by ip injection of octadentate 3,4,3-LICAM(C), given at very large ligand:Np molar ratios 1 h after iv injection of $^{239}NpO_2NO_3$. But similarly to the experience with *in vivo* chelation of Pu^{4+} by that ligand, the Np complex formed in the blood partially dissociated leaving a residue of Np in the kidneys (Volf and Wirth, 1986). These observations were taken as an indication of the presence *in vivo* of chelatable Np^{4+}.

Based on that encouraging result, a systematic investigation was undertaken of the *in vivo* chelation of Np by a set of representative multidentate ligands. The ligands assessed for Np chelation were tetra-, hexa-, and octadentate with linear or branched backbones containing CAM(C), CAM(S), 1,2-HOPO, or Me-3,2-HOPO binding groups. Mice were injected ip with a ligand (30 μmol kg^{-1},

ligand:Np molar ratio 22) 5 min after the iv injection of $^{237}NpO_2Cl$ (see Fig. 31.12) and killed at 24 h. All 10 test ligands, but not $CaNa_3$–DTPA, significantly reduced body Np, regardless of denticity or the identity of the binding group. Most ligands significantly reduced Np in the liver, and except for 3,4,3-LICAM (C), also in the kidneys. Significant reduction of Np in the skeleton was also achieved with tetradentate 5-LIO(Me-3,2-HOPO) and 5-LI(Me-3,2-HOPO), and octadentate H(2,2)-(1,2-HOPO), H(2,2)-(Me-3,2-HOPO), and 3,4,3-LICAM(C). Except for tetradentate 5-LI(Me-3,2-HOPO), which was orally active at lower dose, ligand:Np molar ratios $\geq$22 were required to obtain significant reductions in body Np, when the test ligands were given orally at 5 min (Durbin *et al.*, 1994, 1998a,b).

Experiments were undertaken to examine the efficacy of 3,4,3-LI(1,2-HOPO) for *in vivo* chelation of ^{237}Np in contaminated wounds in rats. Ligand:Np molar ratios ranged from 4.3 to 285. Early infiltration of the wound site with the ligand was effective, but delayed treatments were progressively less effective. 3,4,3-LI (1,2-HOPO) was able to complex the Np at the wound site before it was translocated to blood, but Np deposited in the tissues became progressively less accessible to the ligand (Paquet *et al.*, 1997, 2000).

Based on the combined considerations of ligand efficacy and acute ligand toxicity, the most promising ligands for *in vivo* chelation of Np are in order: tetradentate 5-LIO(Me-3,2-HOPO) and 5-LI(Me-3,2-HOPO), octadentate 3,4,3-LI(1,2-HOPO), and hexadentate TREN-(Me-3,2-HOPO).

ACKNOWLEDGMENTS

The author wishes to thank the following members of the Lawrence Berkeley National Laboratory, Chemical Sciences Division, for their essential contributions to the preparation of this manuscript: Dr. Wayne W. Lukens, Jr. for the speciation calculations for UO_2^{2+} and NpO_2^+ in blood plasma; Lindarae M. Aubert and Lynne A. Dory for manuscript preparation; and Dr. Norman M. Edelstein for his patience and assistance. Flavio Robles of the Creative Services Group and Dr. Jide Xu of the U. C. Department of Chemistry provided the illustrations.

APPENDIX: SOURCES OF MATERIALS ON ACTINIDE BIOLOGY

The pioneering biological studies with actinides conducted during World War II (1942–1946) encompassed the following: pharmacology and toxicology of injected, ingested, and inhaled uranium compounds (Tannenbaum, 1951a,b; Voegtlin and Hodge, 1949, 1953); biokinetics of injected and ingested fission products, plutonium, and actinide fission by-products (Lanz *et al.*, 1946; 1947a,b, 1948a,b, 1949b; Carritt *et al.*, 1947; Finkle *et al.*, 1946; Hamilton,

1947b, 1948c); acute toxicity of injected fission products and plutonium (Painter *et al.*, 1946; Bloom, 1948; Fink, 1950); biokinetics and acute toxicity of inhaled or intratracheally intubated fission products and plutonium (Abrams *et al.*, 1946a,b, 1947; Scott *et al.*, 1947b, 1949a). Stannard (1988) summarized the designs and major findings of those studies and provided the tables of contents for the otherwise unpublished Plutonium Project documents and reports.

Actinide biology summaries and reviews include: General reviews – (Durbin, 1960, 1962), Finkel and Biskis (1968), Stover and Jee (1972), Nenot and Stather (1979), ICRP (1972, 1986), Duffield and Taylor (1986), Stannard (1988), Thompson (1989); Element-specific reviews, uranium – Hursh and Spoor (1973), Yuile (1973), Durbin and Wrenn (1975); neptunium – Thompson (1982), NCRP (1988); plutonium – Bair *et al.* (1973), Vaughan *et al.* (1973), Bair (1974), Durbin (1975); transplutonium elements – Durbin (1973); conference proceedings – Rosenthal (1956), Dougherty *et al.*, 1962), Thompson (1962), Mays *et al.* (1969), Thompson and Bair (1972), Healy (1975), Wrenn (1975), Jee (1976), Wrenn (1981), Gerber *et al.* (1989), Stather and Karaoglou (1994), Métivier *et al.* (1998), Stather *et al.* (2003); databases compiled for radiation protection guidance – ICRP (1959, 1972, 1979, 1980, 1986).

The bibliographies of three reports dealing with the deposition and biological effects of plutonium and other selected radionuclides provide an introduction to the large research program on internally deposited radionuclides undertaken in the USSR (Buldakov *et al.*, 1969; Moskalev *et al.*, 1969; Moskalev, 1972).

APPENDIX I

NUCLEAR SPINS AND MOMENTS OF THE ACTINIDES

Nuclear spins and nuclear moments are used to test the single-particle models and nuclear quadrupole moments provide the deformation of the nucleus. In the following table, we present measured values of ground state spin in units of $\hbar$, magnetic dipole moment (μ) in units of nuclear magneton, and spectroscopic quadrupole moment (Q) in units of barns. The data have been taken from Raghavan (1989) and Firestone and Shirley (1996).

Nuclide	*Nuclear spin* ($\hbar$)	*Nuclear magnetic moment* (nuclear magneton)	*Electric quadrupole moment* (barns)
^{217}Ac	9/2	+3.825(45)	
^{227}Ac	3/2	+1.1(1)	+1.7(2)
^{229}Th	5/2	+0.46(4)	+4.3(9)
^{228}Pa	3	+3.48(33)	
^{230}Pa	2	+2.00(29)	
^{231}Pa	3/2	+2.01(2)	–1.72(5)
^{233}Pa	3/2	+3.39(70)	−3.0
^{233}U	5/2	0.59(5)	3.663(8)
^{235}U	7/2	−0.38(3)	4.936(6)

APPENDIX II

NUCLEAR PROPERTIES OF ACTINIDE AND TRANSACTINIDE NUCLIDES

Irshad Ahmad

DISCUSSION

In this appendix, an elementary discussion of the nuclear properties of heavy elements is presented. For a better understanding of the subject, the reader should refer to nuclear chemistry textbooks (Krane, 1988; Choppin *et al*., 2002) and for the information on decay data, the *Table of Isotopes* (Firestone and Shirley, 1996) or the *Table of Radioactive Isotopes* (Browne and Firestone, 1986) or *Nuclear Data Sheets* (Tuli, 2004) should be consulted.

Isotopes of all elements with $Z \geq 89$ are radioactive. The most common mode of decay for these nuclei is by the emission of alpha particles (^{4}He ions). Alpha decay energies have been experimentally measured (Browne and Firestone, 1986; Firestone and Shirley, 1996) for most nuclides and these can also be calculated from atomic masses (Wapstra *et al*., 2003). The α decay of a nucleus with atomic number Z and atomic mass A produces a daughter nucleus with atomic number Z–2 and atomic mass A–4. During the α decay, about 2% of the available decay energy is imparted to the recoiling daughter nucleus and the remaining energy is carried off by the fast moving α-particle. Several groups of α-particles are emitted by a sample of a nuclide, each with a definite energy. For the actinide nuclides, α-particle energies range from about 4 to 11 MeV. As a rule, α-particle energy increases with increasing Z, and for a given element, it decreases with increasing mass number.

The α-decay half-life decreases exponentially with increasing energy. As a guide, every 50 keV increase in the decay energy reduces the half-life by a factor of ~2. The dependence of the α-decay half-life on the decay energy is given by the well-known Geiger–Nuttall law and more recently by Viola–Seaborg formula. A very useful quantity that facilitates the understanding of the mechanism of α-decay is the concept of hindrance factor. It is defined as the ratio of the experimental partial α-decay half-life to the theoretical half-life calculated on the assumption that the α-particle pre-exists in the nucleus and during its emission, it carries no angular momentum. An alpha transition in which the

ground state configuration of the parent nucleus remains unchanged is called 'favored transition'. All alpha transitions between the ground states of even–even nuclei are favored transitions and are assigned a hindrance factor of one.

Like elements of lower Z, each actinide element has one or more β-stable isotopes. Isotopes heavier than the β-stable isotope decay by the emission of β^- particles (electrons) and isotopes lighter than the β-stable isotopes decay by electron capture (EC). Electron capture decay is usually accompanied by the emission of K x-rays of the daughter nuclide. These x-rays provide a signature of the decaying nuclide. In heavy nuclei, β^+/EC ratio is very small and, as a consequence, positron (β^+) emission has been observed only in a few nuclei. The β-decay energy increases as the mass of the isotope gets further away from the line of β-stability. A quantity denoted by log ft is very useful in classifying the β transitions and estimating the β-decay half-lives of unknown nuclei. The ft value, also called the reduced β transition probability, is the energy-independent transition rate.

Spontaneous fission is a decay process in which a nucleus breaks up into two almost equal fragments. Each fission event is accompanied by the release of about 200 MeV energy and the emission of two to four neutrons. More than hundred nuclides are produced in fission of a nuclide sample and the mass yields and charge distributions have been measured for many fissioning systems (Wahl, 1989; Ahmad and Phillips, 1995). The fission half-life depends on the fissility parameter Z^2/A and is the major decay mode for many isotopes of element 100 and beyond. Nuclides with reasonable fission branch and available for experiments and industrial use are ^{248}Cm ($t_{1/2} = 3.40 \times 10^5$ years) and ^{252}Cf ($t_{1/2} = 2.64$ years). The isotope ^{252}Cf is widely used as a neutron source in industry and research.

Another rare mode of decay for heavy elements is the decay by the emission of intermediate mass fragments. These fragments are heavier than α particles but smaller than fission fragments. The branching ratio for this kind of radioactivity is extremely small ($\sim 10^{-10}$). Examples of such radioactivity are the ^{24}Ne emission by ^{231}Pa and ^{232}U (Price, 1989).

Alpha and β transitions usually populate excited states in addition to the ground states of the daughter nuclei. The excited states then decay to the ground state by emission of γ rays and conversion electrons. Typical half-lives of the excited states range from 10^{-9} to 10^{-14} s. However, in some cases, the decay of an excited state is forbidden for fast magnetic dipole ($M1$), electric dipole ($E1$), or electric quadrupole ($E2$) transitions because of the angular momentum selection rule. Such states have half-lives between nanoseconds and years. An excited state that has a half-life value greater than a nanosecond is called a 'metastable' state or 'isomer'. The isomeric state either de-excites to the ground state of the same nucleus by an internal transition (IT) or it decays by the usual mode of disintegration.

Most isomers occur because of the large difference between the spins of the excited state and the ground state. However, there are isomers which result not

by the difference in the spins of the states but by the difference in the shapes. These isomers decay by fission and are called 'fission isomers' or 'shape isomers' and have half-lives between 10^{-9} and 10^{-3} s. These isomers have deformations that are twice as large as the deformations of the ground states. More than 50 fission isomers have been discovered (Vandenbosch, 1977).

Very neutron-deficient nuclides decay predominantly by electron capture (EC). In some of these nuclei, the EC decay energy is quite large (> 4 MeV) and hence states at high excitation energy are populated in the daughter nucleus and a small fraction of these excited states decay by fission. Delayed fission of many nuclei has been observed (Hall and Hoffman, 1992).

Nuclear structure studies of actinide nuclides have been performed using a variety of techniques. These include high-resolution alpha, electron and gamma-ray spectroscopy, charged-particle transfer reaction spectroscopy, and Coulomb excitation studies. These investigations have provided significant information on the shape, size, and single-particle potential of actinide nuclei. The available data establish a spheroidal shape for nuclei with $A \geq 225$, with major to minor axes ratio of $\sim$1.25. The intrinsic quadrupole moments of actinide nuclei have been measured to be about 10^{-23} e cm^2 and the nuclear radii are about 10^{-12} cm.

Although most actinide nuclei have spheroidal shapes, there are indications that some neutron-deficient Ac and Pa nuclei have small octupole deformation in their ground states. These nuclei are pear-shaped and are axially symmetric but they are reflection asymmetric. Examples of such nuclei are ^{229}Pa and ^{225}Ac (Ahmad and Butler, 1993).

In nuclei, nucleons (neutrons and protons) move in orbits under the influence of the central nuclear potential. Nilsson (1955) and others (Chasman *et al.*, 1977) have calculated the eigenvalues and eigenfunctions of nucleons in a deformed potential as a function of the deformation β. Plots of the eigenvalues versus the deformation, commonly known as Nilsson diagrams, are extremely useful in understanding the single-particle properties of actinide nuclei. Each Nilsson state is characterized by a set of quantum numbers Ω π, N, N_z, and Λ. The quantum number Ω is the projection of the single-particle angular momentum on the nuclear symmetry axis and π is the parity of the wavefunction. The asymptotic quantum numbers N, N_z and Λ denote the oscillator shell number, the number of the oscillator quanta along the symmetry axis, and the projection of the orbital angular momentum on the symmetry axis, respectively. In heavy nuclei, neutrons (protons) fill each orbital above the closed shell of 126 (82) pairwise and thus the ground state of an odd-mass nucleus is simply the orbital occupied by the last unpaired nucleon. All even–even nuclei have ground state spin-parity of 0^+.

A spheroidal nucleus rotates about an axis perpendicular to the nuclear symmetry axis. The projection, K, of the total angular momentum, I, on the symmetry axis is the same as Ω. The rotation of a spheroidal nucleus generates a rotational band with spin sequence K, $K+1$, $K+2, \ldots$. The

rotational energy E_I of a level with spin I is given by the expression

$$E_I = \frac{\hbar^2}{2\Im} I(I+1),$$

where $\hbar$ is Planck's constant and $\Im$ is the nuclear moment of inertia. Typical values of $\hbar^2/2\Im$ are 7.0 keV for even–even actinide nuclei and 6.0 keV for odd-mass nuclei. The ground state band of an even–even nucleus has spin-parity sequence 0^+, 2^+, 4^+ . . .; odd spin values are not allowed.

Qualitative and quantitative analysis of actinide samples can be performed by using a variety of techniques (Knoll, 2000). Gross counting with a 2π (50%) geometry gas proportional counter can be used to determine the α or β^- count rate in a sample. These counters have very low background for α particles but somewhat higher background for electrons. Background of $\sim$0.1 α count per minute can be easily achieved for these counters.

Alpha pulse height analysis can be used to identify nuclides in a sample. Alpha spectra are measured either by Au–Si surface barrier detectors or passivated implanted planar silicon (PIPS) detectors. For best resolution (full width at half maximum), which can be as low as 9.0 keV, extremely thin sources are required. Precise energies and intensities of alpha groups have been tabulated by Ritz (1991).

Gamma-ray spectroscopy with high-resolution germanium spectrometers provides a powerful technique for qualitative and quantitative analysis of actinide samples. For high-energy γ rays in the range of 200 keV to 1.5 MeV, large volume Ge detectors provide the best sensitivity. Resolutions (FWHM) of less than 2.0 keV at the ^{60}Co 1332.5 keV line are easily achieved. In actinide nuclei, K x-ray energies lie in the 80–160 keV range and can be measured with high-resolution low-energy planar spectrometers (LEPS). K x-rays are produced when a vacancy in the K shell of an atom, created by electron capture or internal conversion, is filled by an electron from a higher shell. These K x-rays energies depend on the atomic number and there is sufficient separation between the energies of adjacent elements for them to be clearly identified. The Cm K x-ray spectrum produced in the alpha decay of ^{251}Cf and measured with a high-resolution LEPS is displayed in Fig. A.2.1. The resolution (FWHM) of the spectrometer is about 500 eV. Measurements of gamma ray spectrum and K x-ray spectrum are very useful in identifying and quantifying odd-mass nuclei.

L x-rays of actinide nuclei, which are produced when a vacancy in the L subshell of an atom is filled by an electron from a higher shell, have energies in the 10–30 keV range. Spectra of L x-rays can be measured with lithium-drifted silicon, Si(Li), detectors with resolutions (FWHM) of $\sim$300 eV. A Np L x-ray spectrum from ^{241}Am alpha decay, measured with a Si(Li) spectrometer, is shown in Fig. A.2.2. These spectra are also characteristic of the element but are more complex. The definition of x-ray components is given in (Firestone and Shirley, 1996). Even–even nuclei decay to excited levels of daughter nuclei which de-excite by highly L converted transitions generating L x-rays. Thus even–even

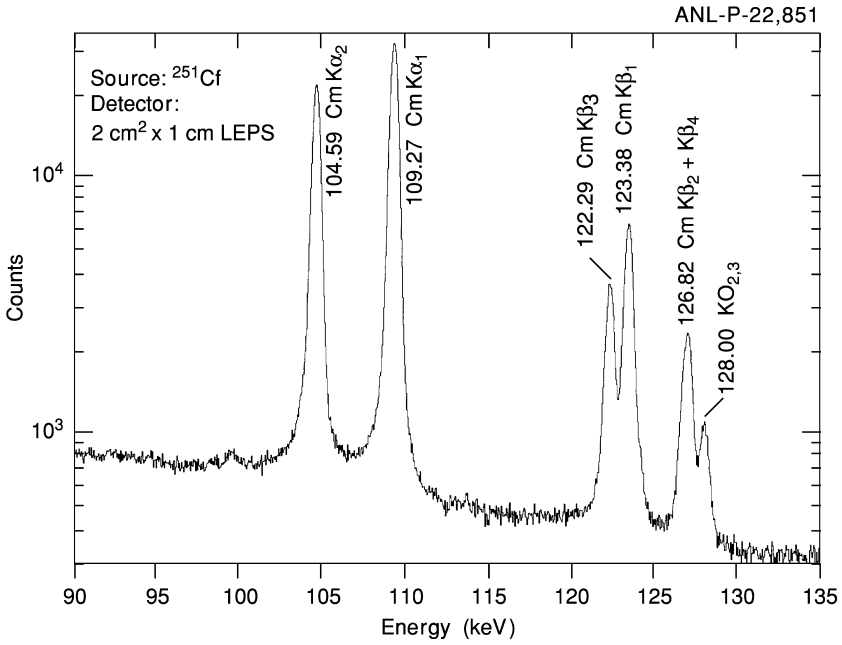

Fig. A.2.1 *K X-ray spectrum of Cm, produced in the alpha decay of* ^{251}*Cf, measured with a* 2 cm^2 × 1 cm *LEPS spectrometer.*

nuclei, which do not have any intense γ rays, can be analyzed by L X-ray spectroscopy.

Fissioning nuclides like ^{252}Cf can be assayed by measuring the gamma-ray spectrum with large-volume Ge detectors and using the intensities of gamma rays emitted in the decay of the abundant fission fragments (Ahmad *et al.*, 2003).

Some actinide nuclides have very long half-lives and hence they occur in nature. These include ^{232}Th, ^{235}U and ^{238}U which decay through a series of isotopes terminating at stable Pb isotopes. Isotopes of Ac, Th, and Pa are usually separated from the parent nuclides and used in the chemical and nuclear studies of these elements.

Transuranium isotopes are produced by long irradiations in nuclear reactors. In the US, there is a national program for the production and isolation of transuranium isotopes utilizing the High Flux Isotope Reactor (HFIR) at the Oak Ridge National Laboratory. The heaviest nuclide produced in this program is the 100 day ^{257}Fm. Neutron-deficient actinide isotopes are usually produced by nuclear reactions in charged particle accelerators.

All data in the tables of nuclear properties given in the preceding chapters and in this appendix have been taken from Browne and Firestone (1986), Firestone and Shirley (1996), Nuclear Data Sheets (Tuli, 2004) and from the

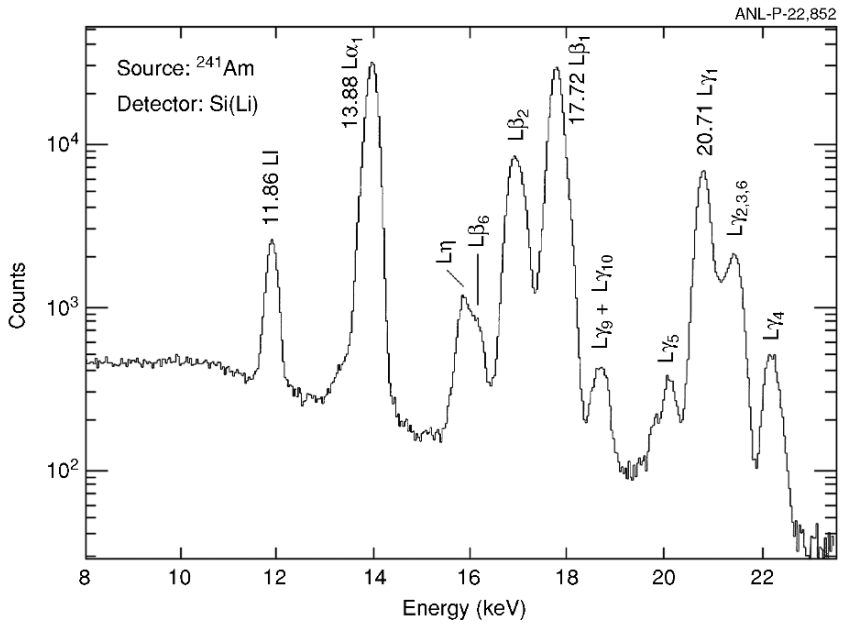

Fig. A.2.2 *L X-ray spectrum of Np, produced in the alpha decay of* ^{241}*Am, measured with a* 1 cm *diameter and* 5 mm *thick Si*(*Li*) *detector*.

web sites at the Isotope Project, Lawrence National Berkeley Laboratory (http://www.lbl.gov) and at the Nuclear Data Center, Brookhaven National Laboratory (http://www.nndc.bnl.gov). For the heaviest elements, data were taken from Armbruster (2000) and Hofmann and Münzenberg (2000). The cut-off date for literature survey was June 2004.

The notations for decay modes in the tables are: α for alpha decay, β^- for β^- decay, β^+ for positron decay, EC for electron capture decay, IT for isomeric transition, and SF for spontaneous fission. The letter m after a mass number represents an isomer. Isomers with half-lives of less than 1 s (except for the heaviest elements) and fission isomers are omitted from the tables. Energies and intensities are given for the most abundant α groups and most intense γ rays; for β^- particles, the maximum energy β_{max} is given. In the last column of Table A2.1, only the convenient methods of production are given; 'nature' denotes that the nuclide occurs in nature and 'multiple neutron capture' means that the nucleus is produced by multiple neutron capture in a high-flux reactor such as HFIR.

The specific activity S in disintegrations per minute per microgram was calculated using the expression

$$S = \frac{4.17449 \times 10^{17}}{t_{1/2}A},$$

where $t_{1/2}$ is half-life of the nuclide in minutes and A is the atomic mass in atomic mass units. The half-lives and atomic masses were taken from the references mentioned earlier in this text.

[a] Decay modes are denoted by: α for alpha decay, β^- for beta decay, EC for electron capture, IT for isomeric transition, and SF for spontaneous fission. The decay mode given in this column represents either the major decay mode or the only observed decay mode.
[b] 1 year = 365.243 days.
[c] Specific activity is given in units of disintegrations per minute per microgram and contains one more significant figure than the half-life in order to avoid rounding-off errors.
[d] For commonly used isotopes, specific activities are also given in units of Curies per gram. 1 Ci = 2.22×10^{12} disintegrations per minute = 3.7×10^{10} Bq.
