some 4 μg of it can be obtained essentially free of ^{253}Es. The latter isotope is highly desirable for nuclear syntheses but is of more limited value for physiochemical work, despite its longer half-life. This is due not only to the smaller amounts of it but also to the highly penetrating radiation field generated from its short-lived ^{250}Bk daughter ($t_{1/2}$ = 3.217 h with β^- decay having a 45% branching ratio for a ~1 MeV gamma emission) in equilibrium with it. Thus, decisions must be made regarding the needs and the different choices available for the einsteinium products generated.

More detailed discussions on the nuclear properties, preparation of einsteinium isotopes, and their decay schemes are provided in the references. The K-series X-ray energies of einsteinium isotopes are discussed in Dittner and Bemis (1972). The electron-capture delayed fission processes of neutron-deficient isotopes, ^{242}Es and ^{244}Es, have also been reported, and highly asymmetric mass distributions have been noted (Kosyakov *et al.*, 1974). Average pre-neutron total kinetic energies of (183 ± 18) and (186 ± 9) MeV, respectively, were found. The probability of delayed fission was determined to be (6 ± 2) × 10^{-3} and (1.2 ± 0.4) ×10^{-4}, respectively; smaller probabilities were given for the ^{246}Es and ^{248}Es isotopes.

12.3 PURIFICATION AND ISOLATION

The techniques used for the isolation, recovery, and purification of einsteinium isotopes are very dependent on the method of production. Accelerator production often involves thin foils or targets, where the einsteinium products are either recovered simply (washed off) from the target or from 'catcher' foils located behind a thin target. Recovery from 'catcher' foils can be straightforward, and recovery of products may only involve dissolution or washing of the foil followed by a minor purification of the einsteinium product.

In contrast, recovery of einsteinium following a neutron irradiation process can be rather complex. Larger quantities of very radioactive materials are involved in this process and it requires hot cell operations. The actinide targets are placed in some form of 'container' for the reactor irradiation (normally in aluminum rods), which must then be removed mechanically or chemically to reach the irradiated starting and product materials. At that point, one is faced with the starting material (i.e. curium oxide) and various fission products, in addition to the desired transcurium products (i.e. berkelium, californium, einsteinium, and some fermium). The purification and recovery of einsteinium then involves: (1) separation from lanthanide fission products; and (2) separation from curium, berkelium, and the adjacent actinides, californium and fermium. The major obstacle is the great similarity in the chemical properties of their trivalent actinide ions in solution, given their similar ionic radii.

There is only a small contraction in radii with increasing atomic number in the case of transplutonium elements, which provides a small increase in covalency

and complexing ability, but these are sufficient to allow chromatographic methods to be used for separations. An advantage is acquired in the case of berkelium (which is also a daughter product of einsteinium), as this element can be oxidized to a tetravalent state and separated from the curium through fermium trivalent elements. Separation of einsteinium from its berkelium daughter product can be accomplished by solvent extraction. If solvent extraction is used to remove tetravalent berkelium, the extraction can then leave trivalent californium, einsteinium, and fermium ions together. These elements would have to be separated by subsequent ion exchange or chromatography techniques. A schematic for the separation of einsteinium is given in Fig. 12.3, parts A and B.

The details of various chemical separation processes have been published and presented as reviews. Two earlier reviews cover the approaches in the U.S. (Hulet and Bodé, 1972) and in Russia (Myasoedov *et al.*, 1974). A more general overview for separation of the transuranium elements is also available (Hyde *et al.*, 1964), and individual accounts of procedures used worldwide have been published (Müller, 1967; Bigelow, 1974; Ishimori, 1980; King *et al.*, 1981; Collins *et al.*, 1981). The early scheme used for products from the HFIR at ORNL has also been published in separate reports (Baybarz *et al.*, 1973; Benker *et al.*, 1981). Many of these procedures have not changed significantly over the years.

The removal of lanthanides from the actinides can be accomplished in different ways. An early method, suited for laboratory separations of smaller quantities, was through the use of alcoholic hydrochloric acid as an elutant for the

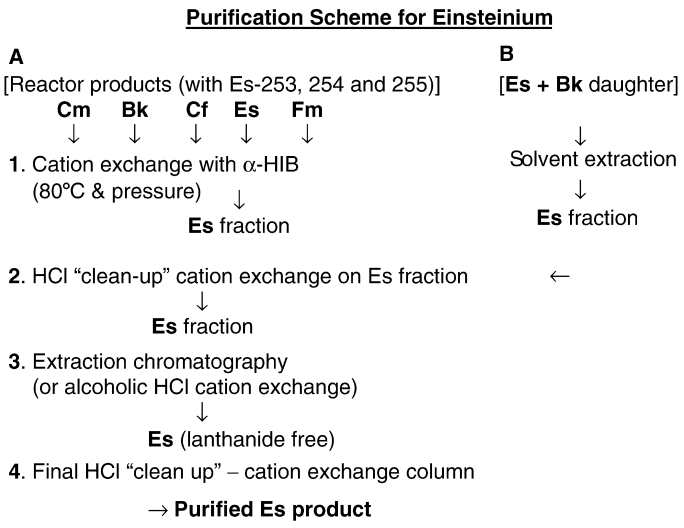

Fig. 12.3 *Einsteinium purification scheme.*

transcurium elements sorbed on cation resin (Street and Seaborg, 1950), where the greater complexing ability of the actinides allowed their desorption as chloride complexes ahead of the lanthanides. A preferred method for larger-scale operations is a lithium chloride anion-exchange process (Shoun and McDowell, 1980), which partitions the actinides from the lanthanides. For small amounts of lanthanides from einsteinium (i.e. the final removal of trace amounts of lanthanides of similar ionic radii) an extraction chromatography column employing ammonium thiocyanate and formic acid can be used (TEVA™ columns; see Horwitz *et al*., 1994; Porter *et al*., 1997). These special columns are also available commercially and give excellent separations between the lanthanide and actinide groups.

When the three elements californium, einsteinium, and fermium are considered, the individual elements can be separated by cation-exchange processes. One method that has been used for several decades is to sorb the three ions on a cation resin from dilute acids (i.e. 0.1 M hydrochloric acid) and selectively elute them with ammonium alpha-hydroxyisobutyrate (α-HIB) solutions at a pH in the range 3.8–4.2 (Choppin and Silva, 1956; Baybarz *et al*., 1973; Bigelow *et al*., 1980; Myasoedov *et al*., 1980; Shoun and McDowell, 1980; Campbell, 1981). The elution order is fermium, einsteinium, and then californium; a high-pressure, ion-exchange column operated at 80°C gives the best results. Separation factors are not great but sufficient, ranging from 1 to 2 for different conditions. Details of using high-pressure columns for separation of f-elements have been given by Campbell (1981). However, even when working with only 10–20 μg of ^{253}Es, care must be exercised, as its radiation level is sufficient to char the resin upon standing and makes it difficult to recovery fully the einsteinium from the resin.

Another approach employs extraction chromatography, where either bis(2-ethylhexyl)phosphoric acid (HDEHP) or 2-ethylhexylphenylphosphonic acid (HEMΦP) are placed on an inert (i.e. fine glass particles) support. The actinides are loaded on this column and eluted with a dilute 0.3 M nitric acid solution (Hulet and Bodé, 1972). Separation factors for these actinide elements are again between 1 and 2. Ion-exchange separations of einsteinium from irradiated californium have also been discussed by Elesin *et al*. (1986).

The extraction chromatography behavior of einsteinium with a quaternary ammonium nitrate has been discussed (Horwitz *et al*., 1966), and extraction of einsteinium with bis(2-ethylhexyl)phosphoric acid was also reported (Horwitz *et al*., 1969). The extraction of einsteinium by bis(2-ethylhexyl)phosphoric acid and the stability constants for hydroxycarboxylic acids is reported by Aly and Latimer (1970a). The extraction of Es by dibutyl *N*,*N*,-diethyl carbamyl phosphate is also discussed (Aly and Latimer, 1970b). The current separation procedure for einsteinium from neutron-irradiated targets at ORNL dates back many years and has been summarized by Campbell (1970). Other separation methods for einsteinium have been provided by Horwitz *et al*. (1994).

12.4 ELECTRONIC PROPERTIES AND STRUCTURE

Chapter 16 is concerned with spectra and electronic structure of free actinide atoms and ions, and these topics are only touched upon here. As einsteinium belongs to the actinide series of elements it can be considered a 5f electron element, which has localized (non-bonding) 5f electrons, and potentially a 'dsp' or an 's^2' type of bonding. In addition, both non-relativistic and relativistic approaches (appropriate because of its high atomic number einsteinium) should be considered with regard to its behavior.

From non-relativistic considerations, the radial probability distributions of the 5f electrons are well within the principal confines of the 6d, 7s, and 7p orbitals, although there is some 'tailing' to the outer regions. This tailing or extension relative to the 7s and 7p orbitals lends itself to a slightly greater degree of covalency than found for the lanthanide's 4f electrons. With the transplutonium elements, the degree of covalency increases slightly when moving to elements with increased atomic number for a given ionic state.

For the relativistic situation, the binding of the electrons becomes greater with higher atomic numbers, which can affect the energies for the different electronic states. Also, potential effects may be found with regard to radii and energies of certain orbitals, spin–orbit splitting, and the expansion of the d- and f-orbitals, all of which can affect chemical behavior. An overview of this electronic picture has been given (Seaborg and Loveland, 1990).

The electronic configurations of einsteinium in neutral and singly ionized gaseous atoms have been analyzed via emission spectra (Gutmacher *et al.*, 1967; Conway, 1979), although full characterization of the ~20000 lines collected is still incomplete. Worden *et al.* (1974) have provided term assignments to a small number of these lines, and Brewer (1971a,b) had estimated energies for the lower spectroscopic terms. Brewer estimated that for a singly ionized atom the $f^{10}s^2$, f^{12}, and $f^{11}d$ levels should be lower in energy than the $f^{11}p$ level reported by Worden *et al.* (1974).

For the gaseous atom of einsteinium, a $5f^{11}7s^2$ ground state is assumed, and the successively ionized neutral gaseous atom loses first one, then two 7s electrons, while the third and even fourth electron lost are 5f electrons, to give a $5f^9$ configuration for the potential ion. It must be remembered that the gaseous atom configurations are different from those encountered in the metals, which are influenced by other factors including crystal energies.

Brewer (1971a,b) has calculated that for einsteinium metal the bonding configuration could be $5f^{10}$dsp, where the 6d and 7p orbitals play important roles. In this case, einsteinium would have three bonding electrons in its conduction band. Alternative configurations would be $5f^{11}$sp or $5f^{11}s^2$, where only two bonding electrons are present, and in this case, einsteinium would be the first divalent actinide metal. The latter configuration appears to be the correct configuration for einsteinium metal. The reason for the divalency of einsteinium metal can be found in the promotion energy for changing an f-electron to a

d-electron, which would then provide three electrons rather than two electrons for the metallic bonding.

A plot of promotion energies for the actinide is shown in Fig. 12.4 (Haire, 1994), which shows einsteinium's promotion energy as being just above the border between divalent and trivalent metal bonding. This 'borderline' energy relates to the crystal energy recovered when the metal atoms crystallize. Thus, when gaseous atomic einsteinium ($5f^{11}7s^2$) condenses to form a crystal, promotion of a 5f electron must occur to provide three rather than two bonding electrons in the solid if a trivalent metal (i.e. with a ds^2 configuration) is to form. For the earlier transplutonium metals, this promotion energy is provided from the greater crystal energy acquired, but with einsteinium, the promotion

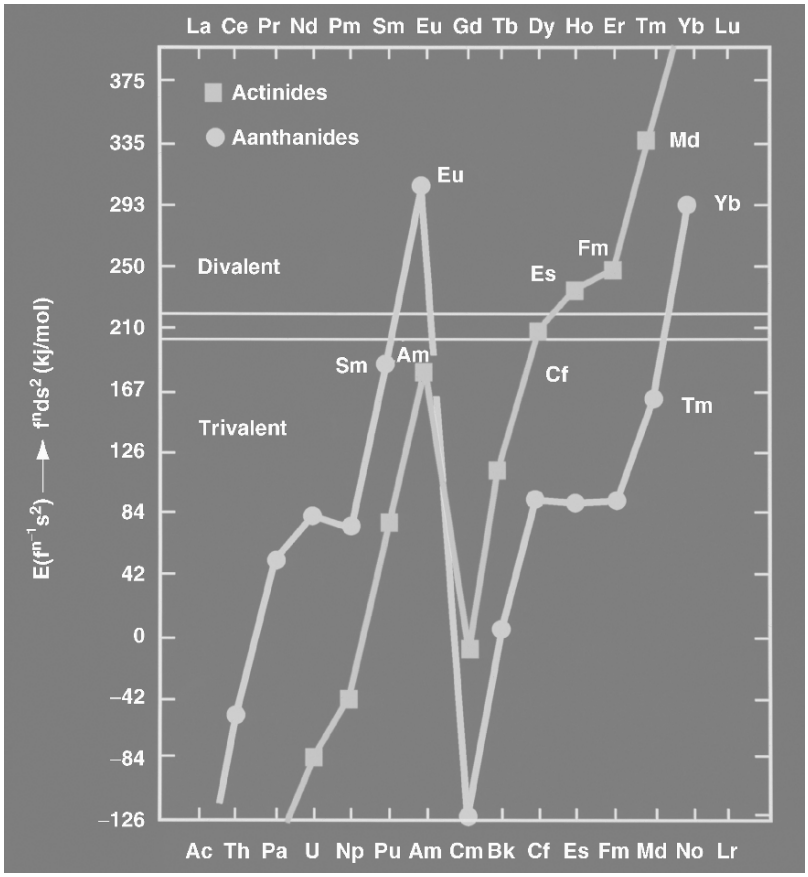

Fig. 12.4 *The f→d promotion energies for the f-elements* (*bar across figure is estimate of crystal energy needed to compensate for promotion of an electron from an f to a d level*).

energy needed exceeds the crystal energy recovered. Thus, einsteinium remains a divalent metal, as do the next three metals in the series.

Recent gas-phase studies of einsteinium have also provided important new insights into its chemistry. The behavior of einsteinium ions in the gas phase is discussed in Section 12.6.6 and the concept of f→d promotion energy again is seen as being important for the different gas species and their reactions.

Blaise and Wyart (1992) have provided tabulated values for einsteinium's energy levels and atomic spectra. Tabulated values for the newer values are given in Table 12.2 for Es(I). The reader is referred to Blaise and Wyart (1992) or Wyart *et al.* (2005) for more extensive data and values for Es(II). Some other atomic values for einsteinium and its ionization potentials are also given in Table 12.3. Estimations of the first ionization potential for einsteinium were earlier given to be 6.42(3) eV (Rajnak and Shore, 1978) but the ionization potential has now been determined accurately by resonance ionization mass spectroscopy using some 10^{12} atoms of ^{254g}Es in an atomic beam (Erdmann *et al.*, 1998; Peterson *et al.*, 1998). The method used is based on measuring photoionization thresholds as a function of an applied electric field, followed by an extrapolation to a zero electric field. The first ionization potential determined experimentally was found to be to be 6.367(5) eV (see Table 12.3). Goodman *et al.* (1975) also examined the nuclear and quadrupole moments of einsteinium. Table 12.3 provides some basic values for Es, but the reader may find more details in the references.

12.5 THE METALLIC STATE

The scarcity and the high specific radioactivity of einsteinium isotopes have in general impeded the investigation of its chemistry, but particularity so for its metallic state. The self-radiation and accompanying heat are imposing factors, and the former rapidly destroys the metal's crystal lattice. The transplutonium elements are all electropositive metals, and react with water and the oxygen in air, but einsteinium metal is even more reactive. Strong reducing agents are needed to convert einsteinium oxide or its halides to the metal. Einsteinium is the most volatile of all the actinides preceding it, which dictates the preparative methods that can be used. It has been concluded that einsteinium is the first divalent actinide metal, in the sense that there are two bonding electrons in its conduction band compared to three or higher for the preceding actinide metals (see Section 12.4). It is followed by divalent fermium metal, and presumably divalent mendelevium and nobelium metals. The last member of the series, lawrencium, is presumably again a trivalent metal. It is likely to have a filled 5f level and a single d-electron; therefore, the promotion of an f-electron is not necessary for it to become trivalent. Thus, einsteinium is divalent like europium and ytterbium metals, but not trivalent like its homolog holmium, the other lanthanide metals, or the americium through californium metals.

Small quantities of transplutonium metals have traditionally been prepared by different methods, two of which are mentioned here (Haire, 1982). The first is reduction of an actinide halide by an active metal (alkali or alkaline earth), and the desired actinide metal is left as a product. This is a suitable technique if the actinide has a lower volatility than the reductant or its halide product (i.e. lithium and lithium fluoride, which are both sufficiently volatile). The second approach is to reduce the actinide oxide with thorium or lanthanum metal and distill away the actinide product. The choice frequently depends on the volatility of the actinide metal. In the case of einsteinium, the latter technique is the most appropriate given its higher volatility. If einsteinium fluoride was reduced with lithium metal, it would be difficult to obtain the metal free of lithium fluoride in the distilled/condensed product.

The first reported attempt to prepare einsteinium metal (Cunningham and Parsons, 1971) used less than 1 μg of einsteinium, and involved distilling lithium metal onto EsF_3. The temperature was raised to 800°C and the sample than quench-cooled to give a material contaminated with lithium fluoride. Thin films of pure einsteinium were prepared subsequently by reducing Es_2O_3 with lanthanum metal followed by collecting the einsteinium metal distillate on electron microscopy grids (Haire and Baybarz, 1979). This reduction approach has become the normal preparative route for einsteinium metal, and has provided the first diffraction data from pure einsteinium metal.

Electron diffraction data for the metal prepared by oxide reduction consisted of over 14 diffraction lines and were obtained from 10–200 ng deposits. The very thin films reduced effects from both self-irradiation damage and self-heating in the metal from the ^{253}Es isotope, and they also allowed diffraction powder patterns to be obtained in a few seconds versus the 30–120 min often needed

for X-ray powder analysis. The diffraction data obtained showed a face-centered cubic (fcc) (*Fm*3*m*) symmetry and generated a lattice parameter of 5.75(1) Å, which corresponds to a metallic radius of 2.03 Å. This radius compares with radii of 2.042 and 1.940 Å (Topp, 1965) for divalent europium and ytterbium metals, respectively, compared to much smaller radii (i.e. 1.734–1.877 Å) for the trivalent lanthanide metals and 1.691–1.725 Å for the trivalent americium through californium metals (Haire, 1990). The radii of Ba, Eu, Es, and Yb form a smooth curve, if radii are plotted versus atomic number (see Fig. 12.1 for the volume behavior of the latter three elements). These findings led to the conclusion that einsteinium is indeed the first divalent actinide metal, and this was subsequently supported by studies of the enthalpy of sublimation of einsteinium (see subsequent discussion) and thermochromatography studies with tracer levels of einsteinium. Selected data for einsteinium and selected f-element metals are given in Tables 12.4 and 12.5.

The elements americium through californium are trivalent metals and exhibit a double hexagonal close-packed (dhcp) room-temperature and an

[a] Note: Am, Cm, and Bk metal values are similar to those for Cf; all four are 'trivalent' metals, while Es is a 'divalent' metal.

elevated-temperature fcc structure. The densities of the four trivalent transplutonium metals range from 13.6 to 15.1 g cm^{-3}, while einsteinium has a density of 8.84 g cm^{-3} (Haire, 1990). The cubic structure of einsteinium should be considered as reflecting its electronic bonding configuration rather than being a high-temperature form, as are the room temperature structures of europium (body-centered cubic, bcc) and ytterbium (fcc) in the lanthanide series. Europium remains bcc down to 5 K, even with 'cold working' of the material. In contrast, ytterbium transforms from its fcc structure to a hcp form below 270 K, which can be retained at room temperature. Einsteinium metal has been examined at liquid nitrogen temperature (Haire, 1980), where evidence for a hexagonal structure was obtained. However, it was not resolved in that work whether this was a temperature-induced change (comparable to ytterbium metal) or reflected a change from the effects of radiation damage to the einsteinium lattice.

Alloys of einsteinium with europium and with ytterbium (~1 mol%) have also been prepared by co-distilling the metals (Haire, 1982) from mixed oxides (einsteinium–europium and einsteinium–ytterbium) after reacting the oxide mixtures with lanthanum metal. With 100 μg of ^{253}Es, the self-heating/radiation in an Es–Yb alloy was sufficient to give rise to partial sublimation of the einsteinium product when it was isolated in vacuum.

A value for the melting point of einsteinium was obtained by observing the heating of deposits in an electron microscope (Haire and Baybarz, 1979). The melting point was taken as the point where ''micro-puddles'' were formed, in conjunction with calibration studies with other known metals done in a similar fashion. A value of (1133 ± 50) K was reported for the melting point of einsteinium metal. This value can be compared to the melting points of 1099 and 1097 K for europium and ytterbium metals, respectively, while the values for the trivalent lanthanide and americium through californium metals are higher, being (1173–1620) K (Haire, 1990).

At the tracer level, einsteinium–calcium metal mixtures were prepared and studied via thermochromatographic metal columns, where their sorption/condensation behaviors were monitored (Hübener, 1980). Data from this work supported the divalency of einsteinium metal. It was determined that ytterbium, einsteinium, fermium, and mendelevium all condensed at the same column length (~700 K), but deviations were found for europium, samarium, and calcium, where their behaviors were intermediate to the divalent and trivalent metals. One aspect of this thermochromatographic technique has been variation in results when different metals are used for the sorbers or columns.

Volatilities of these metals are correlated with f-electron promotional energies and the number of bonding electrons – the fewer the bonding electrons the higher the volatility. Estimates have been given by Nugent *et al.* (1969a) for the enthalpy of sublimation of these metals via extrapolations. Kleinschmidt *et al.* (1984, 1985) and Haire and Gibson (1989) have also reported experimental data for the enthalpies of sublimation and entropies of einsteinium metal.

The enthalpy for einsteinium also supports that it is a divalent metal. The enthalpy of sublimation of einsteinium is given as 133 kJ $mol^{-1}$and was found to agree closely with that for fermium (143 kJ mol^{-1}) (Haire and Gibson, 1989), the second divalent actinide metal. In the latter work on fermium, the enthalpy for einsteinium was reevaluated, and a value of 134 kJ mol^{-1} was determined for einsteinium, this value being slightly lower than that for fermium. However, this difference is not significant, given that error bars were estimated at $\pm$ 12 kJ mol^{-1}. In essence, the two values for einsteinium and that for fermium can be considered the same.

Subsequent studies of heavy elements (including einsteinium) via thermochromatography have been performed (Hübener *et al.*, 1994; Taut *et al.*, 1997, 1998) and results varied significantly with the metal of the columns used – five different metals were used in the work. With iron columns, californium, einsteinium, and fermium behaved the same; with niobium columns, einsteinium was intermediate to positions for californium and fermium, and in titanium columns, einsteinium and fermium behaved similarly (Hübener *et al.*, 1994). It was concluded that einsteinium and fermium were acting as divalent actinide metals while californium was 'borderline' between divalent and trivalent. Subsequently, similar studies with californium, einsteinium, and fermium tracers estimated einsteinium's enthalpy of sublimation to be 167 kJ mol^{-1} (Taut *et al.*, 1997), a significantly higher value than reported earlier by more direct methods (134 kJ mol^{-1}) but still lower than the enthalpy for californium determined by this technique (close to 200 kJ mol^{-1}). It was stated in Taut *et al.*'s work (1997) that the value for einsteinium is still typical for a divalent metal, although it was higher than that for fermium. Additional discussions on einsteinium thermochromatography are given together with the work on nobelium, where the two models are discussed in conjunction with *ab initio* calculations for actinide adsorption enthalpies (Eichler *et al.*, 2002), and in diffusion studies into tantalum (Legoux and Merinis, 1986).

The crystal entropy of einsteinium has been calculated using a correlation (Ward and Hill, 1976; Ward *et al.*, 1980; Ward, 1986) based on ytterbium metal, and a value of (89.4 $\pm$ 0.8) J K^{-1} mol^{-1} at 298 K was determined. For the 1133 K melting point of einsteinium (Haire and Baybarz, 1979), the enthalpy of melting was calculated to be 9.40 kJ mol^{-1} and the entropy as 8.30 J K^{-1} mol^{-1} by Ward and Hill (1976). The magnetic entropy for a $5f^{11}$ configuration gives a total angular momentum of $J = 15/2$ for the divalent einsteinium. A boiling point of 1269 K was also calculated (Kleinschmidt *et al.*, 1984) for the metal. One additional piece of information has been reported for the metal; its thermal conductivity has been estimated to be 10 W m^{-1} K^{-1} at 300 K (Ho *et al.*, 1972). The bulk modulus of einsteinium was estimated to be similar to those for europium and ytterbium metals. See Tables 12.4 and 12.5 for selected properties and values of einsteinium.

More recent work on the preparation of einsteinium metal provided the first isolated piece of pure einsteinium metal ($\sim$100 μg) and a 60 μg deposit ($\sim$200 μm

in diameter) on platinum. These efforts were in conjunction with attempts to study the high-pressure behavior of the metal (Haire and Heathman, 2000) by energy-dispersive X-ray diffraction using high-intensity tungsten radiation. The pressure behavior of einsteinium metal is very interesting, as it could become a trivalent metal under pressure, where pressure provides the energy necessary to promote an f-electron to a bonding state. In essence, the volume of einsteinium may be reduced under pressure to force additional bonding, similar to that found in the trivalent Am through Cf metals. It was anticipated that applying additional pressure on a potential trivalent einsteinium product could even lead to a further reduction in volume and result in the formation of an einsteinium metal product with itinerant 5f electrons (Haire *et al.*, 2004). This can be understood by examining the volume curves shown in Fig. 12.1, where the volume reduction induces greater bonding. However, the intended study of einsteinium under pressure was not successful, as the intense self-irradiation of einsteinium destroyed both its crystal lattice and the platinum pressure marker present within a few minutes. But the recent preparative effort with einsteinium allowed a new level to be reached in obtaining elemental einsteinium – namely, an einsteinium metal product free of a supporting substrate (i.e. a 100 μg 'bulk form' of pure einsteinium metal).

12.6 COMPOUNDS OF EINSTEINIUM

12.6.1 Crystal data

Once the existence of a new element has been established, scientists strive to determine its chemical and physical properties. The extent to which this is possible depends on the availability and nature of the material, and the techniques that are or can be established to study it. With the availability of multiple micrograms of einsteinium it became feasible to prepare and examine 'bulk forms' of its compounds, although not without perturbations and limitations caused by its short half-life, high self-radiation field, and the heat associated with the decay (^{253}Es alpha decay corresponds to 15312 kJ mol^{-1} min^{-1}). For the preparation of compounds, one normally uses the ^{253}Es isotope (see earlier discussion on isotopes), given its greater availability. Some of the techniques used for microgram-sized samples of einsteinium have been discussed (Haire, 1981, 1982).

Only a few compounds of einsteinium have been prepared and have had their crystal structures identified. In this realm, there are induced changes or destruction of crystal lattices by the isotope's self-irradiation (alpha emission plus nucleus recoil) and the rapid ingrowth of the berkelium daughter (~3% per day, berkelium 'impurity'). For diffraction studies, the accompanying penetrating radiation (L, M and N X-rays, the gamma emissions from ^{254g}Es and its short-lived daughter, ^{250}Bk, also have serious effects on both X-ray

detectors and/or X-ray film in a short time frame (the film is often used for small 1–2 μg sized samples).

Even with rotating anode-type generators with higher X-ray intensities, these difficulties with einsteinium are not overcome. Electron diffraction techniques do afford major advantages, as only small, very thin samples (which can be smaller than the alpha particle's range, where a minimum amount of its energy is transferred) are needed. This technique requires very short exposure times (seconds) and that the detection mode is located approximately 1 m from the sample, which avoids film or detector problems from the einsteinium radiations.

Although synchrotron radiation can supply more intense radiation for diffraction studies with einsteinium samples, two difficulties are encountered: (1) the destruction of the crystal lattice during the time of 'transportation' to the synchrotron beamline; (2) the difficulty of obtaining approvals to use the activity levels from the einsteinium at the synchrotron, or for setting up an apparatus for *in situ* preparation of the compounds on the beamline. Yet, the latter remains an option for dealing with some of the experimental problems with einsteinium's rapid radioactive decay.

As with many of the transuranium compounds, halides and oxides were among the first compounds of einsteinium to be prepared and studied, which is in accord with the fact that these have frequently been among the first to be prepared for new elements. These are also used often as a starting platform for synthesizing other materials. To overcome the experimental difficulties encountered with diffraction analysis of ^{253}Es or ^{254g}Es compounds, three approaches have been successful. One has been constant resynthesis of the compound during X-ray analysis, while another has been the use of very thin films, especially in conjunction with electron diffraction. The third has been to use very short exposures as can be accomplished by electron diffraction. Crystal data have been collected for the following materials: $EsCl_3$, EsOCl, Es_2O_3, $EsBr_3$, and EsI_3 (See Table 12.6). A discussion of X-ray diffraction techniques for einsteinium compounds is also available (Haire and Peterson, 1979).

The first crystal data for einsteinium compounds were obtained for the trichloride and the oxychoride via the constant synthesis technique (Fujita *et al*., 1969a,b). The approach was to resynthesize these materials *in situ* at ~430°C. The trichloride was found to be hexagonal, isostructural with the actinium through californium trichlorides and the lanthanum through gadolinium trichlorides (UCl_3-type, space group $C^2_{6h}-C6_3/m$). The oxychloride was found to crystallize in the tetragonal PbFCl structure (space group $D^7_{4h}-P4/nmm$) and is isostructural with the trivalent lanthanum through erbium oxychlorides and the known actinium through californium oxychlorides. The lattice parameters, corrected to 298 K, are given in Table 12.6.

Einsteinium sesquioxide was the next compound for which diffraction data were acquired, and this involved the use of the electron diffraction technique. The samples were prepared by calcining an einsteinium nitrate salt *in situ* on

0.928 Å) for this oxide were intermediate to those for Gd_2O_3 and Tb_2O_3, and just smaller than those for Cf_2O_3 (see Table 12.7).

Lattice parameters and ionic radii for the cubic sesquioxides of the f-elements are shown in Fig. 12.6, where a smooth relationship can be seen. These behaviors differ from the volume behaviors of the metals (see Fig. 12.1). The properties of einsteinium oxide and a comparison of its properties are also discussed in reviews (Baybarz and Haire, 1976; Haire and Eyring, 1994). As opposed to the metal, compounds of einsteinium (i.e. the oxide here) display lattice parameters and ionic radii similar to the comparable transplutonium and lanthanide compounds. All of the first five transplutonium sesquioxides form this cubic crystal form, but some may also exist in a monoclinic structure (Sm_2O_3-type, space group $C2/m$) or a hexagonal form (La_2O_3-type, space group $P3m1$), depending on the thermal history and the particular element in question (see Haire and Eyring, 1994).

Self-irradiation may also convert one structural form of the sesquioxide to another; this radiation effect has been discussed in an earlier review (Fuger, 1975). For einsteinium sesquioxide, both a monoclinic and a hexagonal form have been recorded (Haire *et al*., 1985; Haire and Eyring, 1994). The monoclinic form was observed during oxidation of metal films below 1273 K, and this effect has also been observed with gadolinium metal films. The hexagonal oxide was observed in 'aged' cubic einsteinium sesquioxide. It could not be ascertained whether the monoclinic and/or hexagonal forms of Es_2O_3 resulted from being heated, from self-heating, or from self-irradiation damage. It is probable that the hexagonal form resulted from one of both of the latter two consequences; the hexagonal form of Es_2O_3 would be expected from systematics to be formed

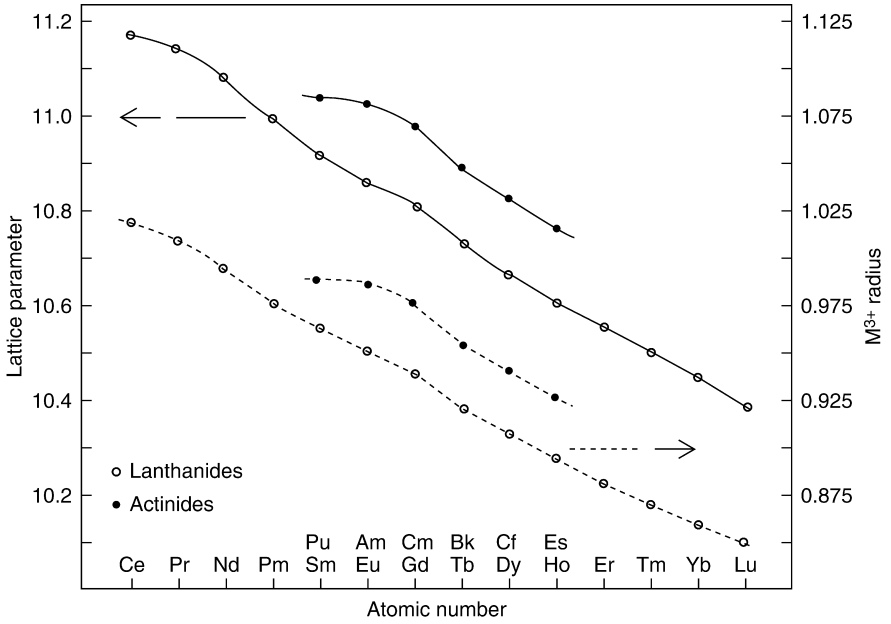

Fig. 12.6 *Lattice parameters and calculated radii for the cubic sesquioxides. A regular trend is observed with Es(III), as opposed to the different behavior observed with Es metal (Haire and Eyring, 1994). Parameters and radii are given in Å.*

only near its melting point (Baybarz and Haire, 1976; Haire and Eyring, 1994). Lattice parameters for the monoclinic and/or hexagonal structural forms of einsteinium sesquioxide must also be considered in this context. The monoclinic form of einsteinium sesquioxide was obtained after heating at temperatures lower than would be expected to bring about the thermal transformation from its cubic form. The values for the lattice parameters of the monoclinic and hexagonal forms of Es_2O_3 are however reasonable, based on ionic systematics for the lanthanide and first four transplutonium sesquioxides (Haire and Eyring, 1994), and allowing for some lattice expansion due to self-irradiation.

X-ray data were also obtained for $EsBr_3$ (Fellows *et al.*, 1975, 1977) and EsI_3 (Peterson, 1979; Haire, 1980). The $EsBr_3$ data were acquired from very small ($\sim$1 μg) pieces immediately after annealing at 400°C. Fifteen diffraction lines were obtained and indexed as a monoclinic $AlCl_3$-type structure, which is isostructural with $BkBr_3$ and $CfBr_3$ (Burns *et al.*, 1975). The information for EsI_3 was obtained from freshly sublimed films formed in a quartz capillary. The diffraction lines were indexed as belonging to a hexagonal BiI_3-type structure, which is also formed by the transneodynium triiodides and the five transplutonium triiodides. The first four lanthanide triiodides form a $PuBr_3$-type structure (Brown, 1968). Important factors in obtaining these diffraction data were the very small samples or thin films and some luck.

12.6.2 Spectrometry – solids

Another important technique for characterizing einsteinium compounds was the use of absorption spectrometry of solids (as well as for actinides in solution, see Section 12.6.3). Divalent compounds of einsteinium were characterized entirely by this technique, given the difficulties in obtaining diffraction data. A great aid in this technique was incorporation of a 'fingerprint' approach, where correlations between spectra and short-range local environment ('crystal environment'; X-ray diffraction requires 'longer-range order') allowed important conclusions to be drawn for the einsteinium compounds. This technique depends partly on the changes in metal ion coordination in the structures. One advantage of this technique is it allows samples to be prepared, annealed, and/or chemically converted in quartz capillaries, while permitting spectral analyses of intermediate products to follow the completeness of the changes being sought (i.e. reduction of a trihalide with hydrogen) in the same system. This approach was particularly suited to halides, as they had modest melting points, and with care, the melts can be solidified to transparent solids or even single crystals. The technique employed a microscope–spectrometer system, which has been described (Young *et al.*, 1976, 1978, 1981). The einsteinium solid-state absorption spectra are characterized normally by sharp electronic f–f transitions. In addition, luminescence spectra have been obtained but the self-radiation of einsteinium also excites trace amounts of impurities and the quartz envelopes containing it, producing an additional source of luminescence that must be considered. Some of the solid-state absorption spectra for einsteinium compounds are shown in Fig. 12.7.

As discussed in Section 12.6.5, potentials ranging from –1.6 to –1.2 V are reported for the Es^{3+}–Es^{2+} couple in aqueous solutions; a value of –1.3V is adopted in Chapter 19. This potential offers an explanation for the ability to reduce einsteinium trihalides with hydrogen at elevated temperatures. This potential for einsteinium contrasts with the more negative $Am^{3+} - Am^{2+}$ through $Bk^{3+} - Bk^{2+}$ potentials, whose trihalides cannot be reduced by hydrogen. This smaller potential is in accord with the greater tendency for obtaining divalency with einsteinium (also see Section 12.6.5).

Several halide materials have been prepared and their solid-state absorption spectra obtained: $EsCl_2$ (Fellows *et al.*, 1975, 1977; Peterson *et al.*, 1977, 1979; Peterson, 1979; Young *et al.*, 1981); $EsBr_2$ and EsI_2 (Young *et al.*, 1976, 1978; Peterson *et al.*, 1979); for EsF_3 (Ensor *et al.*, 1981); and $EsBr_3$ and $EsCl_3$ (Fellows *et al.*, 1975, 1977; Peterson *et al.*, 1979; Young *et al.*, 1981). Efforts to prepare EsF_2 have not been successful and attempts to prepare EsI_3 have encountered difficulties involving the thermal reduction to EsI_2. The spectra obtained for the three divalent halides of einsteinium and that for $EsBr_3$ are shown in Fig. 12.7 (Peterson *et al.*, 1979). The distinct differences between the spectra of $EsBr_2$ and $EsBr_3$ are obvious, while the similarities in the spectra for the three dihalides are also evident. The cutoff in the near UV for the diiodide reflects charge transfer occurring in this sample. The absorption spectrum of

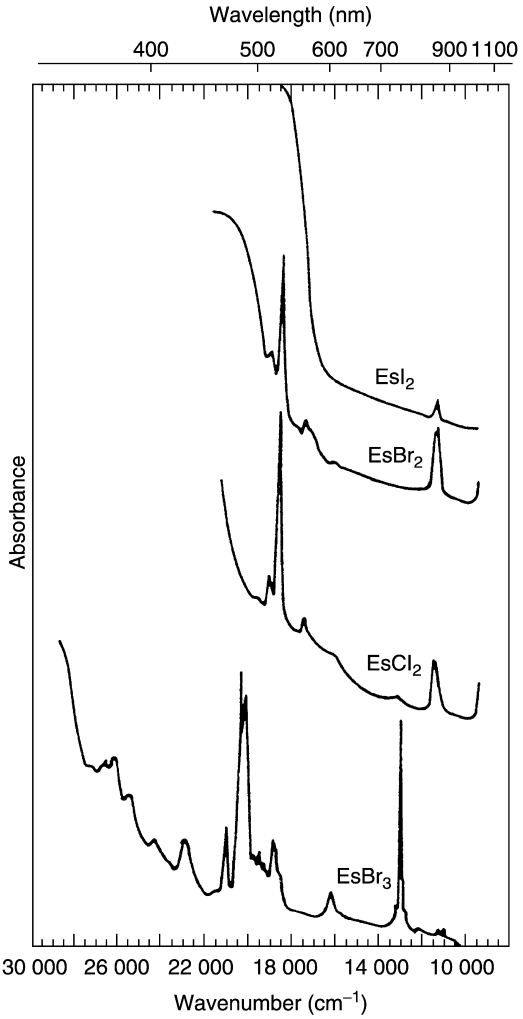

Fig. 12.7 *Solid-state absorption spectra for Es halides* (*Peterson* et al., 1979).

EsOBr is similar to that of $EsBr_3$, but it is sufficiently different to differentiate between the spectra of the two compounds and identify them.

Absorption spectrometry has also been used to study EsF_3 (Ensor *et al.*, 1981) and to then follow the decay products (^{249}Bk and ^{249}Cf, daughter and granddaughter) as they formed in the solid-state sample. From the spectrometric data, it was concluded that EsF_3 initially formed as a LaF_3-type trigonal phase.

Silicate matrices containing ^{253}Es have also been prepared. Results of recent spectroscopic investigations of their properties have been reported (Assefa *et al.*, 1999; Assefa and Haire, 2000, 2001). These studies concentrated on

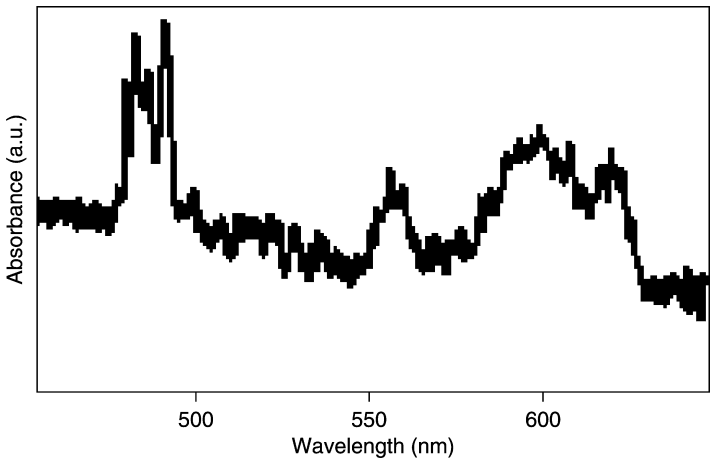

Fig. 12.8 *Absorption spectrum of Es in a borosilicate glass: absorption bands correspond to Es(III)* (*Assefa and Haire*, 2001).

self-luminescence from the materials, and examined the effects of the excitation source used, power of excitation, sample age, and nature of the sample matrix. Also obtained in that work were the absorption spectra of the einsteinium in this host matrix. The self-luminescence arising from einsteinium in these matrices was attributed to defect centers within the Si–O–Si network, nonbonding oxygen holes and Si cluster sites. It was determined that Es(III) was present; evidence for Es(II) was not found. The different spectra obtained for einsteinium in silicate matrices are shown in Figs. 12.8 and 12.9.

12.6.3 Other results – solids

Electron paramagnetic resonance spectra have been obtained for einsteinium placed in single-crystal hosts of CaF_2 (Edelstein *et al.*, 1970; Edelstein, 1971), in BaF_2 and SrF_2 (Bouissières *et al.*, 1980), and in BaF_2 and $SrCl_2$ (Boatner *et al.*, 1976). The spectra of Es^{2+} were similar in CaF_2 and BaF_2. The immediate reduction of Es(III) to Es(II) in the matrix from electron displacement via the alpha radiation field was suggested as the cause of the einsteinium reduction observed in these efforts. A $5f^{11}$ configuration with a ground state close to the $^4I_{15/2}$ (with a small admixture of a $^2K_{15/2}$ state) state was assigned to einsteinium. This indicated that only a minor perturbation of the inner 5f orbitals occurred from the crystal fields in the solids. A value of $\mu_n = 3.62(50)$ nm was reported for einsteinium.

Some information has also been acquired for the magnetism of einsteinium compounds. Preliminary magnetic measurements on einsteinium metal did not show a low temperature transition (Huray *et al.*, 1983). Studies on Es_2O_3 and EsF_3 indicated moments of 10.2(1) and 10.5(1) Bohr magetons, respectively. When corrected for the berkelium ingrowth present in the oxide sample, a value

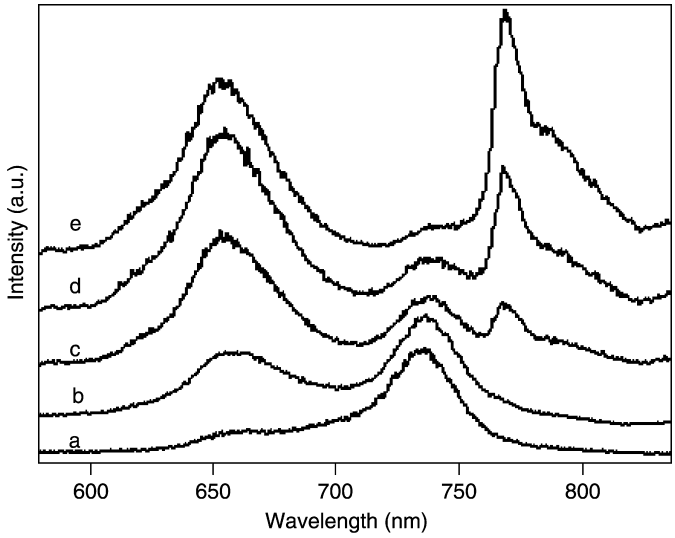

Fig. 12.9 *Photoluminescence spectra from a borosilicate glass doped with Es: excitation was with* 488 nm. *Spectra were recorded at laser powers of* (*a*) 100; (*b*) 310; (*c*) 600; (*d*) 800*; and* (*e*) 1000 mW (*Assefa and Haire*, 2001).

of 10.6(1) is obtained, which is in excellent agreement with a calculated $5f^{10}$ free-ion value (Huray *et al*., 1983; Huray and Nave, 1987).

Preliminary information for the vaporization behavior of Es_2O_3 has been reported (Haire, 1994). The primary mode of vaporization for this oxide is the generation of atomic metal vapor, rather than via a monoxide (Es/EsO in the vapor was greater than 10:1). This situation arises as a result of the lower dissociation energy of EsO, which was estimated to be 460 kJ mol^{-1}. More recent calculations and work (Gibson, 2003; Gibson and Haire, 2003) discuss the electronic states, dissociation energies, and gaseous behavior of einsteinium. A brief discussion on these topics is given in Section 12.6.6.

The thermal behavior of einsteinium sesquioxide and the reduced formation of EsO(g) compares closely to the behaviors of europium and ytterbium oxides. The sesquioxides of europium and ytterbium also decompose mainly to atomic europium and ytterbium rather than form monoxides. A calculated estimate for the standard Gibbs energy of formation of Es_2O_3 at 298 K has been given as –1605 kJ mol^{-1}, and that for EsO_2 as –701 kJ mol^{-1} (Chapter 19). A tentative value for the Gibbs energy of formation for Es_2O_3 based on experimental behavior was given to be between –1650 and –1700 kJ mol^{-1} (Haire, 1994). Attempts to form EsO_2 or other compounds containing Es(IV) (i.e. $BaEsO_3$ or other materials that might help stabilize Es(IV)) have produced negative results (Haire and Bourges, 1980). Several estimated values for thermodynamics of formation of Es_2O_3, EsO_2, EsF_3, EsF_4, $EsCl_2$, and $EsCl_3$ are also given in Chapter 19.

12.6.4 Spectrometry – solutions

Spectrometry of einsteinium in solution has also been pursued, but only its trivalent state has been observed. The solution properties of the trivalent state are similar to those of the previous four transplutonium elements, and coordination number is an important variable. Given that the trivalent ion is present, bonding with ligands is often due to electrostatic effects. But as covalence for a given oxidation state increases across the series, second-order contributions from covalent interactions are possible. The ionic radius of einsteinium in solution should be only slightly smaller than that of californium(III). The free-ion energy levels for trivalent actinides have been given by Blaise and Wyart (1992) and Wyart *et al.* (2005). The ground state of einsteinium (Es(I)) is given as $^5I_8$, with the first excited state appearing at $\sim 10 \times 10^3$ cm^{-1} higher in energy (see Table 12.2).

The first observation of a solution spectrum was for $EsCl_3$ in hydrochloric acid by Cunningham *et al.* (1967), which was obtained by a special technique, where the micro-sized volume of the solution was kept constant by 'pumping' in liquid to overcome evaporation/radiolysis effects. Superior results were obtained subsequently with larger amounts of einsteinium, and 18 peaks between 370 and 1060 nm were obtained in a later work (Fujita *et al.*, 1969b). Electronic energy level and intensity correlations have also been made for Es(III) aquo ion, using data from dilute perchloric acid solutions (Carnall *et al.*, 1973). The absorption spectrum of Es(III) in solution, as demonstrated by Carnall *et al.*, is shown in Fig. 12.10. The band structure and intensities of einsteinium have also been discussed (Nugent *et al.*, 1969b, 1970; Varga *et al.*, 1973a,b).

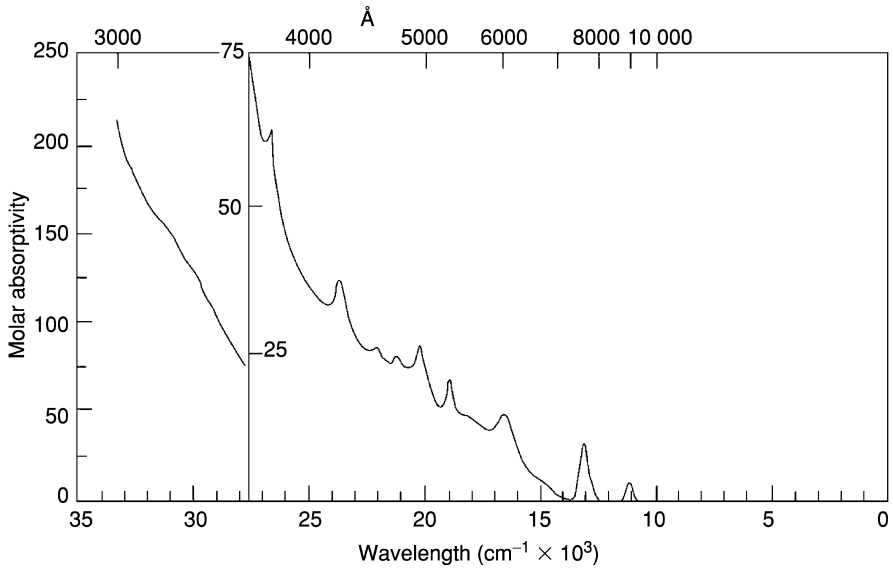

Fig. 12.10 *Solution spectrum of Es(III) in dilute perchloric acid* (*Carnall* et al., 1973).

The spectra fit the behavior expected for an Es(III) free ion, where the f–f transitions were believed to arise from mixed eigenstates, due to coupling that was intermediate between LS and jj.

Photoelectron spectrometry of einsteinium oxide provided spectra of the 4f lines obtained with MgKα excitation (Krause *et al.*, 1988). Binding energies for $4f_{5/2}$ (569.3(4) eV) and $4f_{7/2}$ (550.8(3) eV) of einsteinium were reported and compared to values for other actinides. These values compared well (within –1.0 and –0.1 eV, respectively) with theoretical binding energies The spin–orbit splitting for the 4f level was also measured and compared to the values obtained from theory. Beitz *et al.* (1992, 1998) have reported on the spectrometry and dynamics of the 5f electron states in Es(III) placed in a LaF_3 matrix.

The consequences of self-irradiation from einsteinium on selected clay minerals for waste isolation have also been probed employing ^{253}Es in solution. The einsteinium was sorbed from aqueous solution using two different clay minerals (kaolin and attapugite) and the morphology of the clay was followed with time using electron microscopy (Haire and Beall, 1979). The conclusion reached was that although the clay structure became damaged, einsteinium was still retained by the clay debris and not released to the solution.

12.6.5 Related studies in solution

The complex-ion chemistry of einsteinium has often been studied in conjunction with an examination of the stabilities of other trivalent actinide ions in solution, and often at the tracer level. Although einsteinium exhibits oxidation states of II, III with a potential for IV in the solid state, its solution chemistry is essentially that of a trivalent ion, and is often comparable to the actinide and lanthanide ions having similar radii. A list of the reported stability constants for einsteinium is given in Table 12.8. It has been concluded that chloride and possibly some thiocyanate complexes are the only outer-sphere complexes (water of hydration found between the ligand and the metal ion). The majority of the complexes are instead the inner-sphere type, which has been inferred from an increased stability constant as a function of increased atomic number, and from the enthalpy and entropy values for the formation of the complexes. Several different complexes have been studied, and these are shown in Table 12.8.

The radii and hydration numbers for actinide(III) ions have been derived from the Stokes' law approach using migration rates in electric fields or diffusion coefficients of tracers in electrolytes (Lundqvist *et al.*, 1981; Latrous *et al.*, 1982; Fourest *et al.*, 1983). David (1986) have also discussed the radii of actinides. In line with an expected greater covalent nature when progressing across the series, the Es(III) and Fm(III) hydrated ions are larger than those for earlier members of the series. A value of 0.492 nm (with up to $\sim$16 molecules of water in the hydration sphere) has been estimated for the radius of einsteinium(III).

Several thermodynamic values have also been reported for einsteinium: (1) the molar activity coefficient in sodium nitrate solutions (Chudinov and Pirozhkov,

1973); and (2) the Gibbs energy, enthalpy, and entropy of formation (Nugent, 1975; David *et al.*, 1978, 1986; Lebedev, 1978). The following values given were: enthalpy of formation, $\Delta_f H^0 = -603\,\text{kJ mol}^{-1}$; the entropy of formation, $\Delta_f S^0 = -100\,\text{J K}^{-1}\,\text{mol}^{-1}$; and the Gibbs energy, $\Delta_f G^0 = -573\,\text{kJ mol}^{-1}$.

Morss (1986) has provided estimates for several thermodynamic properties of einsteinium, ranging from the formation of aqueous ions, the activity products for the trihydroxide and dioxide, hydration enthalpies and ionization energies, and the enthalpies of formation and solution for the sesquioxide and dioxide. Also given are the calculated enthalpies of formation and solution for the dichlorides and trihalides (fluoride, chloride, bromide, and iodide) and the enthalpy of formation of the four tetrahalides.

Electrode potentials and diffusion coefficients for einsteinium were measured by radiopolarography using solutions and a dropping mercury cathode (Samhoun and David, 1979). A single half-wave for the III to 0 standard potential for reduction/amalgamation was reported as –1.460(5) V and a diffusion coefficient of $6 \times 10^{-6}\,\text{cm}^2\,\text{s}^{-1}$. Nugent (1975) suggested a corrected, more negative value (−1.98(7) V; after correcting for the amalgamation energy) as given in

Chapter 19. David (1986) discussed other values and gave selected ionic radii for several actinides, including einsteinium.

The amalgamation behavior of einsteinium and other actinide elements had been investigated earlier, where it was noted that amalgams of californium, einsteinium, and fermium displayed an anomalous behavior (Maly, 1969). This work suggested that these three elements may display a divalent state, given their preference to form amalgams in comparison to other actinides. Radiopolarography frequently employs mercury as one phase but phase diagrams for mercury alloys or dilute amalgams are not available for many of the transplutonium elements. One report (Guminski, 1996) has tabulated information from pre-1970 publications that contained incorrect data, which makes this publication of limited value.

Although einsteinium is the first element in the series to be divalent, the divalent ionic states of americium and californium have also been reported (see Chapters 8 and 11). The III→II reduction potential for einsteinium was initially estimated to be –1.6V, based on the lowest state for electron transfer (Nugent *et al*., 1969b; Nugent, 1975), but was later suggested to be –1.21 V (from work with chloroaluminate salts (Duyckaerts and Gilbert, 1977)) and –1.18 V from radiopolarographic experiments (David *et al*., 1978). Using a method of co-crystallization of einsteinium tracer with $SmCl_2$, Mikheev *et al*. (1972a,b) and Mikheev and Rumer (1972) had suggested einsteinium's reduction potential should be close to that for samarium (−1.55(6) V). A value of −1.3 V is adopted in Chapter 19 for the standard potential of the $Es^{3+}-Es^{2+}$ couple.

A series of papers over several years have dealt with Es^{2+} in selected solutions. These have been tracer-level studies involving different facets of the co-crystallization technique and of complexation studies. One of these papers (Mikheev *et al*., 1986) investigated the cocrystallization of divalent ions of californium, einsteinium, fermium, samarium, europium, and ytterbium with SrI_2 (18-crown-6) using tetrahydrofuran as a solvent. The Tm^{2+} ion controlled the oxidation potential of the solution. Cocrystallization coefficients relative to strontium were given as close to 1, where the coefficients of the three actinides fell between values of 1.10 for samarium and 0.83 for ytterbium.

The behavior of einsteinium (together with other Am, Cf, and Fm) in $LiCl–NdCl_2–NdCl_3$ and in $LiI–PrI_2$ systems was examined (Kulyukhin *et al*., 1997a,b). In the first molten salt, Nd(II) reduced Cf and Fm to a divalent state. In the second salt system, it was not clear if these actinides were reduced to their divalent or monovalent states. Ratios of the actinide distribution coefficients to those of samarium were reported for both salt systems. Mikheev *et al*. (2004) have reviewed the lower oxidation states of actinides with regard to cocrystallization coefficients in melts, and provided a distribution coefficient for einsteinium versus strontium ($D_{Es/Sm} = 0.94$).

Complexation and cocrystallization of einsteinium with 18-crown-6 in water and water–ethanol mixtures were reported by Mikheev *et al*. (1993a,b). Log K values measured for water and the water–ethanol mixtures were 2.64

and 4.70, respectively. The solvent effects on cocrystallization of Es^{2+} with $SrCl_2$ were reported by Mikheev *et al.* in the 1993b reference. Mikheev *et al.* (1986) had also looked at cocrystallization of Es^{2+} with SrI_2–18-crown-6 complexes, and the effects of water on the cocrystallization and solubility of einsteinium in $Sr(Sm)SO_4$ systems (Mikheev *et al.*, 1987). In the latter work, hydration values could be estimated for Es^{2+} from radii considerations of the different ions. Solubility products for einsteinium complexes with 18-crown-6, boron tetrafluoride, and boron tetraphenyl in tetrahydrofuran were discussed by Kulyukin and Mikheev (1997a,b). The distribution of einsteinium in molten salts containing reductants was described by Kulyukin *et al.* (1997). Veleshko *et al.* (1993) discussed the complexation of Es^{2+} with tetraphenylborate in acetonitrile, and Mikheev *et al.* (1988b) reported the data for the latter with water–ethanol mixtures.

Another study examined the effects of water on the cocrystallization of divalent europium, ytterbium, and einsteinium ions in the $Sr(Sm)SO_4$–ethanol system (Mikheev *et al.*, 1988a,b). Water affected the Es^{2+} coefficients up to 10 M water. The Gibbs energies of hydration were given for Eu^{2+}, Yb^{2+}, and Sr^{2+} ions and were assumed to extend to Es^{2+}. Values ranged from 1361 to 1461 kJ mol^{-1}. The coordination of these three ions was also examined with sodium tetraphenylborate in water–ethanol solutions (Mikheev *et al.*, 1988b). The coordination constants, β_1 and β_2, were determined and the observed trend suggested that the hydrated Es^{2+} ion was smaller than the two divalent lanthanide ions. The β_1 and β_2 values were given as log values: 6.2 and 106.4 for Es^{2+}; 1.7 and 52.7 for Eu^{2+}; and 6.5 and 25.7 for Yb^{2+}.

The effect of the solvent on the cocrystallization of Es^{2+} complexed with tetraphenylborate in acetonitrile and tetrahydrofuran was reported (Mikheev *et al.*, 1993a,b), where the einsteinium was complexed in the acetonitrile but not in the other solvent. The stability constants of the Es^{2+} complexes in acetonitrile were given as $\log \beta_1 = 6.6$ and $\log \beta_2 = 16.0$. Additional work on the complexation of Eu^{2+}, Yb^{2+}, and Es^{2+} with this reagent in different solvents suggested that outer sphere complexes are formed due to electron tunneling from the cation into the unsaturated π-bonds of the anion to form a single-electron bond (Mikheev *et al.*, 1993). The β_1 and β_2 values were given for the three divalent ions in water–ethanol mixtures, acetonitrile, and tetrahydrofuran. From the complexation of Es^{2+} in ethanol–water, acetonitrile, and tetrahydrofuran with the tetraphenylborate ion, it was concluded that complexes are not formed in tetrahydrofuran, as the solvent molecule is too large (Veleshko *et al.*, 1993). In the other two solvents, the smaller solvent molecule is inner sphere and complexes are formed.

The complexation of Es^{2+} with 18-crown-6 in aqueous ethanol and in water was studied, and the stability constants of the complex were determined (Mikheev *et al.*, 1993a,b). The log K values for einsteinium were given as 2.70 in water and 4.70 in ethanol–water (10 M). In both solvents, the log k varied in the order: $Eu^{2+} > Es^{2+} > Yb^{2+}$. The effect of perchlorate, tetrafluoroborate,

and tetraphenylborate ions on the crystallization behavior of Es^{2+} with Sr–10-crown-6)I in tetrahydrofuran was reported (Kulyukhin and Mikheev, 1997a,b). The first two ions affected the cocrystallization constants but the tetraphenylborate ion did not, as it did not form complexes with the metal ion in this solvent. The stability constants were found to increase in going from the tetrafluoroborate to the perchlorate ions.

12.6.6 Compounds in the vapor state

The chemistry of elemental einsteinium in the vapor state was covered in Section 12.5. Elemental einsteinium vapor was generated by direct vaporization of it while ions as Es^+ or EsO^+ were produced by laser ablation of solid matrices or by heating oxides.

Recent gas-phase studies of einsteinium have provided important new insights into its chemistry. The concept of f→d promotion energy is also very important for different gas species and their reactions. The promotion energies for einsteinium's 5f electrons in the elemental state and in different ions are given in Figs. 12.11–12.13, which are taken from Gibson and Haire (2003). One plot is for the promotion energies for An^+ and Ln^+ ions from their ground state electronic configuration to the lowest-lying configurations that have two unpaired non-f valence electrons (i.e. $5f^{n-2}6d7s$), where the value for einsteinium requires some 150 kJ mol^{-1} more energy than its homolog, holmium. The second plot in Fig. 12.12 compares promotion energies for an An^+ ion from the ground state to a configuration having two non-5f valence electrons, a $5f^{n-2}6d7s$ versus a $5f^{n-2}7s^2$ state. The promotion energy for an einsteinium ion having two unpaired 7s electrons is lower. The third comparison in

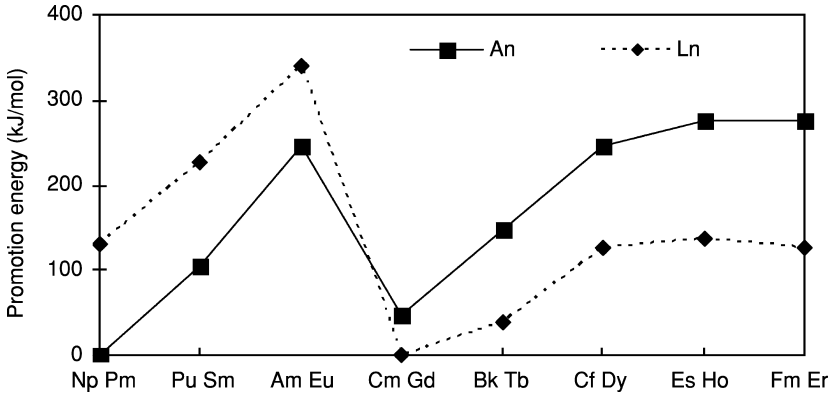

Fig. 12.11 *Promotion energies for An^+ and Ln^+ from ground states to the reactive lowest lying onfiguration having two unpaired, non-f electrons.* (*Gibson and Haire*, 2003). *Note the different trend with the higher members of each series.*

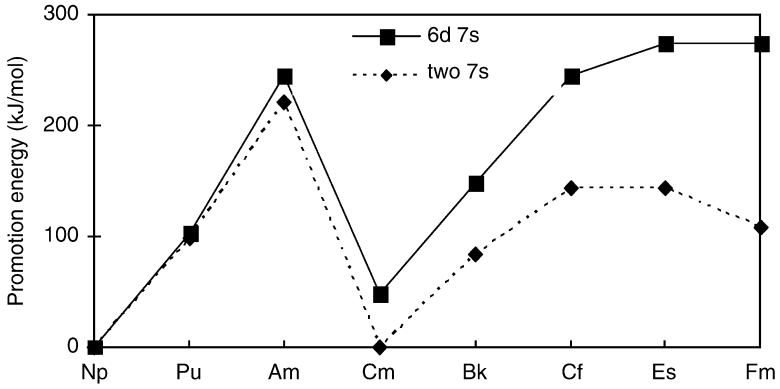

Fig. 12.12 *Promotion energies for An^+ ground state to produce a reactive state with two unpaired f electrons and a 6d7s* state (*solid line*) *versus a paired $7s^2$ state* (*dashed line*). *Additional energy is needed to acquire the 6d7s reactive state.* (*Gibson and Haire*, 2003).

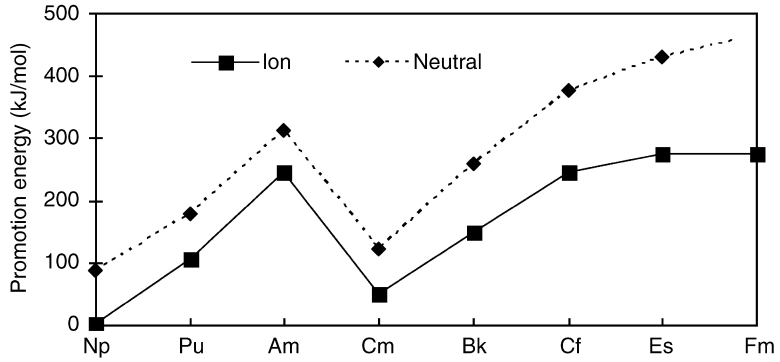

Fig. 12.13 *Promotion energies for An^+ for atomic ions and for An neutral atoms. The energies are for excitation from the ground states to 6d7s "divalent" configurations for An^+ and for 6d7s "trivalent" configurations for the atoms.* (*Gibson and Haire*, 2003).

Fig. 12.13 is made for the promotion energies from the ground state to the neutral atom ('trivalent' configuration, $5f^{n-3}$ $6d^27s$) and the Es^+ ion ('divalent' configuration, $5f^{n-2}6d7s$), where the neutral atom has a promotion energy twice that for forming the An^+ ion.

Important information has been acquired from gas-phase studies of einsteinium, where laser ablations were used in conjunction with mass spectrometry (Gibson and Haire, 2003). The small yields of EsO^+ obtained relative to Es^+ ions indicated that the Es^+–O bond is significantly weaker than that for the earlier actinides.

Fluorination of Es^+ by extraction of fluorine atoms from hexafluoropropene demonstrated the stability of the divalent state of einsteinium. Using this technique, the first organometallic complex of einsteinium was observed ($EsC_4H_8^+$) in the gas phase. From this work the bond dissociation energy for EsO^+ was established and it was found to be smaller than those for EuO^+ and YbO^+, being more similar to that for TmO^+.

Systematic trends of einsteinium's chemistry terms of electronic structure and the energetics of the actinides and lanthanides were developed in this work (Gibson and Haire, 2003). The bond dissociation energy for Es^+–O was estimated to be (470 ± 60) kJ mol^{-1}, higher than the values for Eu^+−O (389 kJ mol^{-1}) and Yb^+−O (372 kJ mol^{-1}), but similar to that for Tm^+–O (478 kJ mol^{-1}) (Gibson and Haire, 2003). The dissociation energy for EsO was earlier reported to be 443 kJ mol^{-1} (Haire, 1994), smaller than dissociation energies for the americium through californium monoxides but similar to those for europium and ytterbium. Thus, einsteinium sesquioxide at high temperatures produces mainly elemental einsteinium rather than a monoxide, where the latter is found when heating curium sesquioxide to very high temperatures.

An important finding was that for einsteinium to become a reactive species, it was necessary to promote the Es^+ ion's ground state electronic configuration to the lowest-lying configuration having two unpaired non-5f valence electrons (i.e. 6d7s rather than $7s^2$). The Es^+ ion was found to be the least efficient of the Th^+ through Cf^+ ions at the dehydrogenation of organic materials, although it was only slightly less efficient than Am^+ and Cf^+ ions (Gibson and Haire, 2003).

In conjunction with the proposal that a hexavalent state of einsteinium could exist based on the added stability acquired from formation of a half-filled 5f orbital (i.e. $[Rn]5f^{11}7s^2 \rightarrow [Rn]5f^7$ for Es(VI)); Liebman, 1978), a potential compound could be the hypothetical EsF_6. As a molecular material, it would be expected to be volatile like UF_6 and PuF_6. From limited attempts to make this material, there is no experimental evidence to support its existence. Attempts to prepare AmF_6 have also proven it to be an elusive material, and far less stable than UF_6 or PuF_6. Therefore, it is unlikely that EsF_6 would be stable.

Studies have also been performed on the formation of volatile molecules using the concepts of thermochromatography (see Section 12.5), and the idea that a molecule in an unusual oxidation state may have a greater potential to form or to exist in the vapor state. From tracer experiments with ^{254}Es, evidence was claimed to support the existence of EsF_4 (Bouissières *et al.*, 1980). The technique consisted of treating EsF_3 with flowing fluorine and determining the temperature where the einsteinium's activity was deposited. This temperature was correlated with deposition temperatures for five other (Pu–Cf) actinide materials, also assumed to be transported as tetrafluorides. The volatility of fluorides should increase with higher oxidation states, so that the order of volatility would be expected to be hexafluoride > tetrafluoride > trifluoride. A point of concern with einsteinium may be the ability to form a tetrafluoride from its trifluoride at temperatures above the expected

decomposition temperature of the tetrafluoride, as estimated from the behaviors of other actinide tetrafluorides.

Thermochromatography of ^{254g}Es in chlorinating carrier gas was used to estimate the adsorption of $EsCl_3$, and was found to be in agreement with a Monte Carlo model for its behavior (Eichler *et al*., 2002). Volatile einsteinium hexafluoroacetylacetonate (HHFA) complexes have also been reported (Fedoseev *et al*., 1987a,b). At the tracer level, these materials can form by passing vapors of the HHFA over einsteinium chloride solids at 200°C. A thermochromatographic study was then used to follow the reaction products. Mixed ligand complexes and lanthanide complexes were also studied. Solvated complexes of HHFA (as well as other organic materials) and the oxychlorides were found to be less volatile in the system. It was concluded that the complexes contained Es(III) rather than Es(II), the latter having a lower volatility.

The gas-phase chemistry of Es^+ and EsO^+ ions has been studied by a laser ablation technique (Gibson and Haire, 2003). The behavior of the Es^+ ion was found to be comparable to that of other actinide ions. The yield of EsO^+ ions suggests that the Es^+–O bond energy is significantly lesser that that of other such actinide ions (i.e. Bk^+–O). By performing chemical reactions in the gas phase between these einsteinium ions and other materials (halogenated organics, alkenes, etc.), it was possible to ascertain important aspects of the chemical behavior of einsteinium in the gas phase, and the ability to form organometallic compounds of einsteinium.

12.7 ATOMIC AND IONIC RADII, AND PROMOTION ENERGIES – THEIR IMPORTANCE IN EINSTEINIUM'S OVERALL SCIENCE

The radii of ions, molecules, and atoms are important in the chemistry and physics of materials as well as for estimation/interpolation of their behaviors. For einsteinium there is a considerable difference in its atomic radius compared to the four previous transplutonium elements, and this is reflected in its properties and science. For divalent and trivalent einsteinium ions, much of their solid and solution behaviors reflect their radii, and in these states einsteinium often behaves similarly to the comparable oxidation states of the other transplutonium and lanthanide ions. In the gas state, bonding energies and potentials (oxidation and promotion) are also of major chemical importance.

The atomic and ionic radii for a given number of bonding electrons or for an oxidation state of the f-elements, in principle, should decrease in a uniform manner across each series (well-established f-element contraction phenomena). This contraction with atomic number has been found to be is in good agreement with multidimensional Dirac–Fock calculations (Desclaux and Freeman, 1984). Ionova *et al*. (1978) have also calculated einsteinium's radius via Hartree–Fock approximations. Thus, these radii are often useful for extrapolations of behavior and properties.

In the case of atomic radii, one observes that einsteinium's radius compares well with radii of europium and ytterbium; as a result of it being a divalent rather than a trivalent metal (see Section 12.5 and Fig. 12.1). The divalent atomic radii of these elements are considerably larger than the trivalent atomic radii of these f-elements, as expected from one less bonding electron. This comes about in part due to the larger promotion energy for changing an f-electron in einsteinium to a 'd' state to enable additional bonding. As a result, einsteinium is the first divalent actinide metal.

With ionic compounds, many are found to form similar, isostructural phases, which is well established in oxide systems (Haire and Eyring, 1994). The ion-exchange behavior of the trivalent ions in solution also shows this correlation (Seaborg and Loveland, 1990). The ionic radius of Es(III), which varies with the coordination number, has been determined from different compounds. From sesquioxide lattice parameters for the actinides and lanthanides (Haire and Eyring, 1994), the ionic radius of Es^{3+} (0.928 Å) is slightly smaller than that of Cf^{3+}, and midway between the radii for Tb^{3+} (0.920 Å) and Gd^{3+} (0.938 Å). Another set of ionic radii has been given by David (1986), which shows a similar relationship. Thus, similar oxide-phase behavior is expected for these ions. The relative behaviors of the sesquioxide lattice parameters and the ionic radii are shown in Fig. 12.6 and Table 12.7, including calculated radii for Es(II) ions. Values are also given for potential Es(IV) ions; these ions would have different coordination numbers and show somewhat different behaviors than the Es(II) and Es(III) ions.

Einsteinium's sesquioxide and trivalent halide-phase behaviors in several solid compounds are found to be comparable to the lanthanides discussed above. In the case of cation-exchange behavior, the elution behavior from ion-exchange columns for a given oxidation state is generally in the order of the radii of the hydrated ions, with the largest or more readily complexed ions eluting first (einsteinium before californium). With elution from a cation column using α-HIB, einsteinium is found at a position between dysprosium and holmium (einsteinium's lanthanide homolog; Seaborg and Loveland, 1990).

Thus, einsteinium's atomic and ionic radii are important factors in the science of einsteinium. They often serve as useful information to understand, predict, and/or extrapolate the behavior of einsteinium. And the f→d electron promotion energy is also very important to understanding elemental einsteinium, as well as several facets of einsteinium's gas-phase chemistry.

CHAPTER THIRTEEN

FERMIUM, MENDELEVIUM, NOBELIUM, AND LAWRENCIUM

Robert J. Silva

13.1 GENERAL

Because of conflicting claims, the International Union of Pure and Applied Chemistry (IUPAC) recently reviewed the names of all the trans-fermium elements; Münzenberg (1999) has published a detailed discussion of the problems and the resolution. First, a Transfermium Working Group decided the priority of discoveries. Next, the discoverers proposed names to the IUPAC and names were officially accepted by that body. The names for the elements mendelevium, nobelium, and lawrencium were retained as originally proposed at the time of their discoveries.

As of this writing, the number of known isotopes of Fm, Md, No, and Lr is 58, ranging in half-life from as short as 0.25 ms for ^{250}No to as long as 100.5 days for ^{257}Fm. Relativistic effects have been predicted to affect ground state electronic configurations, ionic radii, and oxidation state for the heavier actinides. While the 3+ oxidation state remains a dominant feature of the heavier actinides, a tendency toward the formation of lower oxidation states has emerged. Divalency had been observed in solution for fermium through nobelium, in fact, the elements Fm, Md, and No are divalent in the metallic state. Due to increased 5f electron binding of the filled $5f^{14}$ shell, the 2+ oxidation state is the most stable in aqueous solution for nobelium. However, lawrencium, the last member of the actinide series, returns to the 3+ oxidation state as the most stable in aqueous solution, as predicted (Seaborg, 1949).

Due to the short half-lives and low production yields of Fm–Lr, all available chemical information has been obtained from experiments with tracer quantities. In fact, in many cases, chemical experiments were performed with only a few atoms or even one atom at a time. These experiments have necessarily been rather simple in principle, aimed primarily at making comparative studies with elements of known chemical properties. Nevertheless, all available experimental and theoretical evidence supports the original prediction of an actinide series (Seaborg, 1945) involving filling of the 5f electron shell, analogous to the lanthanide series resulting from the filling of the 4f electron shell, and that element 103 is the last member of this series of elements (Seaborg, 1949). The next element, atomic number 104, would be expected to fall into the next chemical group, i.e. Group IVB, of the periodic table.

13.2 FERMIUM

13.2.1 Introduction

The first isotope of element 100 was discovered in heavy-element samples obtained after the 'Mike' thermonuclear explosion of 1952, during the same set of experiments that resulted in the discovery of element 99. A joint effort by the researchers from the Lawrence Berkeley National Laboratory, the Argonne National Laboratory, and the Los Alamos National Laboratory resulted in the chemical isolation and identification of the 20 h half-life isotope ^{255}Fm (Ghiorso *et al*., 1955a). The production involved rapid, multiple neutron capture by uranium nuclei in the nuclear device to form neutron-rich uranium isotopes of heavy mass followed by beta decay to elements of higher atomic number. The ^{255}Fm in the samples, produced from the beta decay of the longer-lived ^{255}Es, was purified and chemically identified by cation-exchange chromatography and detected through the use of alpha particle energy analysis. The name, fermium, was proposed in 1955 in honor of the leader in nuclear science, Enrico Fermi, and the name was subsequently accepted by the IUPAC.

13.2.2 Isotopes of fermium

As can be seen in Table 13.1, there are 19 known isotopes of element 100, ranging from atomic masses 242 through 260. Isotopes with masses 254 through 257 have been identified in samples of plutonium or elements of higher atomic number following neutron irradiation in nuclear reactors. All the other isotopes can only be produced by charged-particle bombardments of targets of elements of lower atomic number at charged-particle accelerators, e.g. cyclotrons, linear accelerators, etc.

The isotope that can be produced in largest quantities on an atomic basis is ^{257}Fm. This isotope is also the nuclide of highest atomic and mass number ever

Table 13.1 *Nuclear properties of fermium isotopes.*

Mass number	*Half-life*	*Mode of decay*	*Main radiations* (MeV)	*Method of production*
242	0.8 ms	SF		^{204}Pb(^{40}Ar,2n)
243	0.18 s	α	α 8.546	^{206}Pb(^{40}Ar,3n)
244	3.3 ms	SF		^{206}Pb(^{40}Ar,2n)

isolated from either reactor or thermonuclear-produced materials. The neutron capture production chain essentially terminates at mass 257 owing to the very short spontaneous fission half-lives of the heavier isotopes. The current annual reactor production rate is in the picogram range (Porter *et al.*, 1997). However, in the thermonuclear explosion of 1969 called 'Hutch,' about 10^8 higher production was achieved (Hoff and Hulet, 1970), but only one

part in 10 million of the total number of atoms of ^{257}Fm imbedded in tons of geologic debris was recovered, i.e. a 10 kg sample of debris yielded about 10^{10} atoms.

Though ^{257}Fm is produced in larger amounts, ^{255}Fm has been more available on a regular basis from the beta decay of reactor-produced ^{255}Es ($t_{1/2} = 38.3$ days) and is more frequently used for chemical studies at the tracer level. Radioactivity levels in excess of 10^8 alpha disintegrations per minute of ^{255}Fm can be obtained from periodic chemical separations of Fm, 'milkings,' from purified Es samples.

13.2.3 Preparation and purification

Because of their strong chemical similarity, the only satisfactory methods of separation of the trivalent actinides are by cation exchange or solvent extraction chromatography. The procedure most often selected is separation by elution from a cation-exchange resin column, e.g. Dowex 50 × 8 or × 12 resin, using an aqueous solution of the chelating agent ammonium α-hydroxyisobutyrate (α-HIB) as eluant. This combination, developed in 1956 (Choppin *et al.*, 1956) primarily for the isolation and identification of new actinide elements, remains the main process method for the separation of trivalent actinides (Porter *et al.*, 1997). The actinides exhibit increasing complexation strength with the organic ligand with increasing atomic number, attributed to the decreasing ionic radii due to the actinide contraction (Katz *et al.*, 1986) and are eluted from the column in a regular sequence with the higher atomic number elements eluting first. Fig. 13.1 shows a typical separation of trace amounts of trivalent actinides using this method.

Vobecký *et al.* (1991) have obtained similar sequential elution and separation of 3+ actinides from a column of the spheroidal cation exchanger OSTION using a solution of ammonium α-hydroxy-α-methylbutyrate as the eluant.

Porter *et al.* (1997) have described a process method for the isolation and purification of fermium from other actinides and from rare earth fission produce from reactor target material. In addition to the standard series of transcurium actinide separations through the use of ammonium α-HIB eluant and cation-exchange resin, final purification of the fermium from small amounts of rare earth impurities that could contribute to the mass of the sample was accomplished using a solvent extraction chromatographic resin (the quaternary amine, Aliquat-336, impregnated into Amberchrom CG-71 ms support resin) that is marketed under the trade name TEVA.

Mikheev *et al.* (1983) have developed a rapid method for the separation of fermium from californium, einsteinium, and lanthanide elements based on the cocrystallization of reduced ^{254}Fm(II) with sodium chloride in aqueous ethanol solutions containing Yb(II). The coefficient of separation of Fm

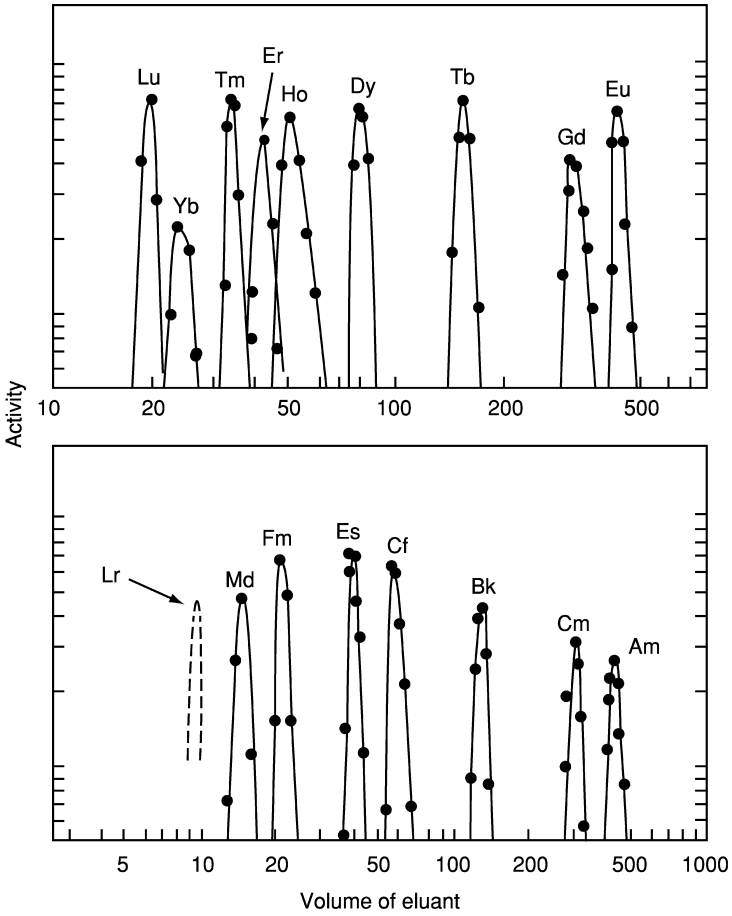

Fig. 13.1 *Elution of homologous trivalent actinides and lanthanides from a Dowex* 50 *cation-exchange resin column at* 87°C *with ammonium α-hydroxyisobutyrate as eluant. The broken curve for element* 103 (*Lr*) *is an estimate based on its predicted radius.*

from its elemental analogs in one cocrystallization step is 10^3 to 10^4 and the separation takes about 10 min.

Fermium has also been separated rapidly from the other transplutonium elements via chromatography using strongly basic anion-exchange resin and mixtures of nitric acid and methyl alcohol at elevated temperatures for the elutions (Usuda *et al.*, 1987).

Volatile hexafluoroacetylacetonates of Md and Fm have been prepared and could be the bases for chemical isolation by thermochromatography (Fedoseev *et al.*, 1990).

13.2.4 Atomic properties

Goodman *et al.* (1971) have used the atomic-beam magnetic resonance technique, adapted to the measurement of radioactive samples, to determine the magnetic moment, g_j, of the atomic ground state of neutral atoms of ^{254}Fm to be 1.16052 ± 0.00014. A comparison of the experimentally measured value with values obtained from intermediate coupling calculations for several likely electron configurations was made. The measured value of g_j was found to be in close agreement only with that calculated for the $^3H_6$ level of the $5f^{12}7s^2$ electronic configuration. This agreement was taken as a conclusive evidence for the assignment of this configuration to the ground state of fermium.

The inner-shell binding energies and X-ray energies for the heavy elements have been estimated from total energies obtained from a Dirac–Fock computer code of Desclaux by Carlson and Nestor (1977). In these calculations, small empirical corrections were added as a result of comparing calculations with experimentally determined binding energies for elements of $Z > 95$. Where comparisons have been made for higher Z elements, the results of the calculations have agreed well with the experimentally measured values. Fricke *et al.* (1972) have also published electron binding energies in fermium obtained from Dirac–Fock calculations and compared them to the values of Porter and Freedman (1971) measured experimentally via spectroscopic measurements of internal conversion electrons emitted following the beta decay of ^{254m}Es to ^{254}Fm. Das (1981) calculated the binding energies in fermium by using a relativistic local density functional theory. Porter and Freedman (1978) have recommended atomic binding energies of the K, L, M, N, O, and P shells for heavy elements from $Z = 84$ to 103. A table of electron binding energies based on the latter is given by Firestone *et al.* (1996). The values for Fm differ slightly from their earlier experimental values (Porter and Freedman, 1971). The results of the three theoretical calculations are compared with the recommended values of Porter and Freedman in Table 13.2. The agreement is quite good and demonstrates that these types of theoretical calculations are consistent and quite useful for predictive purposes.

Dittner *et al.* (1971) have measured the K-series X-rays of ^{251}Fm emitted following the alpha decay of ^{255}No. The K-series X-ray energies derived experimentally from these studies are compared with the values calculated using the binding energies of Porter and Freedman (1978) in Table 13.2.

13.2.5 The metallic state

Fermium metal has not been prepared, however, measurements have been performed on alloys with rare earth metals and a number of predictions about it have been made.

Johansson and Rosengren (1975) have correlated the measured and predicted cohesive energies of the lanthanide and actinide elements in both the divalent and trivalent metallic states. They concluded that the gain in energy of binding

of the $5f^n6d^17s^2$ (trivalent) configuration over the $5f^{n+1}7s^2$ (divalent configuration) is less than the energy necessary to promote one 5f electron to the 6d state in the final members of the actinide series. Therefore, Es, Fm, Md, and No prefer a divalent metallic state similar to Eu and Yb rather than a trivalent one. However the energy difference is small for Es and Fm and, at modest compression, the divalent metallic state may convert to the trivalent one.

The sublimation enthalpy, a fundamental metallic property, is connected directly with the valence electronic structure of the metal. The enthalpy of sublimation of fermium has been determined directly by measuring the partial pressure of Fm over Fm–Sm and Fm, Es–Yb alloys for the temperature range 642–905 K (Haire and Gibson, 1989). Based on their combined second law and third law measured values for the enthalpy of sublimation of Fm, they reported a value of (142 ± 13) kJ mol^{-1} for ΔH_{298}. Because the enthalpy of sublimation

of Fm was similar to those of divalent Es, Eu, and Yb, it was concluded that Fm is divalent in the metallic state. Comparisons with radii and melting points of Eu, Yb, and Es metals have yielded estimated values of 0.198 nm and 1125 K for Fm by these authors. David *et al.* (1978) have estimated a divalent metallic radius of 0.194 nm for Fm, in close agreement.

Because the heaviest actinides are available only in trace amounts, innovative experimental approaches must be used in order to characterize their elemental state properties. Zvara and coworkers (Zvara *et al.*, 1976) compared the evaporation rates of trace amounts of Es, Fm, and Md from molten La with those of Ce, Eu, Yb, Am, and Cf to obtain information on their metallic states. Hübener (1980) compared the thermochromatographic behavior of Es, Fm, and Md evaporated from molten La in titanium columns with those of Na, Sc, Sm, Eu, Yb, Bk, and Cf. The conclusion reported in both of these papers supported the idea that Es, Fm, and Md prefer the divalent metallic state. The adsorption behavior of Cf, Es, Fm, and Md on titanium and molybdenum thermochromatographic columns was compared to a number of monovalent, divalent, and trivalent elements and enthalpies of adsorption determined (Hübener and Zvara, 1982). From the data, the authors also concluded that Es, Fm, and Md are divalent in the metallic state and that the position of the f-energy levels relative to the Fermi-energy is lower than in the cases of Cf and Yb. A nearly linear correlation was found between the experimental enthalpies of adsorption of the heavy actinides and their predicted enthalpies of sublimation.

Thermochromatographic studies of the adsorption of Cf, Es, and Fm on several metals were conducted by Taut *et al.* (1997) and enthalpies of sublimation inferred from the measured enthalpies of adsorption. The results support the value of the enthalpy of sublimation of Fm published by Haire and Gibson (1989).

13.2.6 Solution chemistry

The chemical properties of fermium have been studied only with trace quantities. The chemical properties of Fm have been discussed by Thompson *et al.* (1954). Under conditions not strongly reducing, fermium behaves in aqueous solution as expected for a trivalent actinide ion. Fermium coprecipitates with rare earth fluorides and hydroxides. The elution of fermium just before einsteinium from cation-exchange resin columns with hydrogen ion and the complexing ligands citric acid, lactic acid, and α-HIB is consistent with the existence of a trivalent ion (Katz and Seaborg, 1957). In concentrated hydrochloric acid, nitric acid, and ammonium thiocyanate solutions, fermium forms anion complexes with these ligands that can be adsorbed onto and subsequently eluted from anion-exchange columns (Thompson *et al.*, 1954). In this case, fermium follows einsteinium in the elution sequence. Both types of column results indicate that Fm forms a slightly stronger complex with the ligands than Es, which is due to the slightly smaller ionic radius of Fm as a result of the actinide contraction

(Katz *et al.*, 1986). Fermium also exhibits a more acidic behavior than the preceding actinides in aqueous solution, having a first hydrolysis constant of 1.6×10^{-4} (Hussonnois *et al.*, 1972).

David *et al.* (1978) have estimated some thermodynamic properties of the 5f elements obtained from theoretical considerations and empirical correlations drawn from observed trends in the 4f series. They proposed an ionic radius of 0.0922 nm for Fm^{3+}. From the linear correlation of log distribution coefficients with ionic radius obtained from elution positions from α-HIB/cation-exchange column separations, a value of 0.0911 nm was calculated for the ionic radius of Fm^{3+} (Brüchle *et al.*, 1988). Lundqvist *et al.* (1981) have studied the migration rates of Fm^{3+} in an electrical potential gradient using paper electrophoresis and reported a hydrated radius of 0.495 nm and a hydration number of 16.9 in aqueous perchlorate solutions.

Fermium readily forms complexes with a variety of organic ligands, e.g., β-diketones (Hussonnois *et al.*, 1972), hydroxycarboxylic acids (Thompson *et al.*, 1954; Choppin *et al.*, 1956; Baybarz, 1965, 1966; Ermakovl and Stary, 1967; Hubert *et al.*, 1974), organophosphorus esters (Baybarz, 1963; Stary, 1966; Horwitz *et al.*, 1969), and alkylamines (Müller, 1967). α-HIB has long been used as the eluant for inner series separation of trivalent actinides by cation-exchange chromatography as stated above. However, bis(2-ethylhexyl)phosphoric acid (HDEHP) (Horwitz and Bloomquist, 1973) and Alamine 336 (a mixed *n*-octyl and *n*-decyl tertiary amine) (Leuze *et al.*, 1963) have also been used for similar separations of Fm by solvent extraction column chromatography. Gorski *et al.* (1990) have investigated the complex formation of several transplutonium elements, including Fm, with 1,2-diaminocyclohexane tetraacetic acid (DCTA) and shown the correlation of ionic radii with the values of the log of the complex stability constants. A linear dependence is observed for lanthanides while it deviates from linearity for the heavy actinides. The author's postulate that, since the stability of chelate complexes are determined by the positive change of entropy of the reaction, the change in stability constants of the heavy actinides is due to an entropy effect rather than to the change in the ionic radii.

The behavior of Sr, Y, Sm, Eu, Am, Cf, Es, and Fm in the molten salt mixtures LiCl–$NdCl_2$–$NdCl_3$ and LiI–PrI_2 have been studied (Kulyukhin, 1997). In the presence of Nd^{2+}, Cf, Es, and Fm are reduced to the 2+ oxidation state. The results obtained in the LiI–PrI_2 system were ambiguous as to whether the actinides Cf–Fm were reduced to the 1+ or 2+ oxidation states.

The tendency of Fm to form a divalent ion under strong reducing conditions was first suggested by the work of Maly (1967). Mikheev *et al.* (1972) reported the reduction of Fm^{3+} to Fm^{2+} in 1972 from the results of reduction/cocrystallization experiments with $SmCl_2$. The reduction of Fm^{3+} to Fm^{2+} with $SmCl_2$ has also been observed by Hulet *et al.* (1979). Mikheev *et al.* (1977) were able to estimate the reduction potential to be very nearly the same as the $Yb^{3+} \rightarrow Yb^{2+}$ couple or −1.15 V. This value is in reasonably good

agreement with the value of $-(1.1 \pm 0.2)$ V calculated by Nugent (1975) using refined electron-spin-pairing theory.

Using a refined radiopolarographic technique, Samhoun and David (1976) measured the half-wave potential for the $Fm^{2+} \rightarrow Fm(Hg)$ reduction at a dropping mercury electrode as $-(1.47 \pm 0.01)$ V. By applying an estimated amalgamation potential correction of 0.90 V obtained from correlations of other divalent ions, a value for E° ($Fm^{2+} \rightarrow Fm^0$) of $-(2.37 \pm 0.1)$ V was reported. Using this latter value of Samhoun and David, combined with Mikheev's value of -1.15 V for the $Fm^{3+} \rightarrow Fm^{2+}$ couple, a value of $-(1.96 \pm 0.13)$ V can be calculated for E° ($Fm^{3+} \rightarrow Fm^0$). Nugent (1975) has estimated $E^\circ(Fm^{4+} \rightarrow Fm^{3+})$ to be $+4.9$ V. These values (Table 13.8) are consistent within uncertainties with those in Chapter 19 (Fig. 19.9).

Unless otherwise indicated, all electrode potentials in this chapter are with reference to the normal hydrogen electrode (NHE) and the 1969 IUPAC convention, i.e. the more positive the potential the more stable the reduced form (McGlashan, 1970).

13.3 MENDELEVIUM

13.3.1 Introduction

The first isotope of element 101 was produced in 1955 by Ghiorso *et al*. (1955b). It was synthesized in the bombardment of approximately one billion atoms of ^{253}Es with 41 MeV alpha particles and produced at a rate of only about two atoms per 3 h bombardment. A chemical identification was made on the basis of its elution position just before Fm from a cation-exchange resin column using ammonium α-HIB as eluant in a series of repetitive experiments. It was not detected directly but by the observation of spontaneous fission events arising from its electron-capture daughter ^{256}Fm. Additional analysis of the data, coupled with further experimentation, showed the isotope to have mass 256 and to decay by electron capture with a half-life of 1.5 h. The name mendelevium was proposed for the element in honor of Dimitri Mendeleev, in recognition of his contributions to the development of the chemical periodic system, and it was accepted by IUPAC.

13.3.2 Isotopes of mendelevium

Sixteen isotopes of mendelevium from mass 245 to 260 are known (see Table 13.3) . All of its isotopes can only be produced through charged-particle irradiations at accelerators. Although ^{258}Md, with a half-life of 51 days, is the longest-lived isotope, ^{256}Md remains the isotope most often used in chemical experiments because it can be produced in relatively larger quantities. Using microgram amounts of ^{253}Es presently available, more than a million

atoms per hour of ^{256}Md can be produced by alpha-particle bombardments (Hulet *et al.*, 1967).

13.3.3 Preparation and purification

The isotope ^{256}Md can best be produced for chemical study by the ^{253}Es(α,n) or ^{254}Es(α,2n) reactions at cyclotrons or linear accelerators. The isotope ^{254}Es would be the target material of choice if available. It has a half-life of 276 days compared to only 20.5 days for ^{253}Es and thus it would have a longer usable target lifetime.

The discovery experiments on mendelevium were the first in which the recoil momentum imparted by the bombarding ion to a product atom during its formation was used to carry out an instantaneous physical separation of the product atom from the target material (Seaborg, 1963). The recoil atoms were collected on a thin metal foil placed behind the target in an evacuated reaction chamber. This eliminated the time needed to separate the product atoms from the target atoms, previously accomplished by chemical means, and made it possible to use the same valuable target in repeated bombardments. A few years later, it was found that the recoil atoms could be slowed down and stopped in a gaseous atmosphere, frequently helium. The gas could be pumped out of the reaction chamber through a small orifice to form a 'gas-jet.' If this jet was impinged onto the surface of a foil, some fraction (frequently 75% or more) of the nonvolatile product atoms carried along with the gas were deposited permanently on the foil surface (Ghiorso, 1959; Macfarlane and Griffioen, 1963). The foil could be removed periodically for processing and a new foil installed. A good description of this system has been giving by Hoffman (1994).

After removal of the Md atoms from the collector foil by acid etching or following total dissolution of the thin metal foil, they can be purified and isolated from other product activities by several other techniques.

Md can be separated from the dissolved 'catcher' foil material, e.g. Be, Al, Pt, or Au, and most fission-product activities by coprecipitation with lanthanum fluoride. Subsequent separation of trivalent actinides from lanthanide fission products and La carrier can be accomplished with a cation-exchange resin column using a 90% water/10% ethanol solution saturated with HCl as eluant (Thompson *et al.*, 1954). When a very thin gold foil is used as the 'catcher' foil, after dissolution with aqua regia, a rapid separation of the Md from the Au can be made by anion-exchange chromatography using 6 M HCl as eluant. The gold remains on the column while the Md and other actinides pass through.

Final isolation of Md^{3+} from other trivalent actinides can be accomplished by selective elution from a cation-exchange resin column using ammonium α-HIB (Choppin *et al.*, 1956). When using the gas-jet system, the first two steps can frequently be eliminated.

In more recent years, it was found that, using the 'gas-jet' method, the recoil product atoms could be transported many meters with the stopping gas through a long capillary tube to the chemistry/counting area (Macfarlane and McHarris, 1974). In this case, effective transport over long distances requires the presence of large clusters, frequently KCl aerosols, in the 'carrier' gas. By this method, it is possible to transport and collect individual product atoms in a fraction of a second some tens of meters away from the target area. This method is quite generally used nowadays in the production and isolation of transeinsteinium elements.

A good separation of Md and Fm has been performed on a spheroidal cation-exchanger OSTIN using ammonium α-hydroxy-α-methylbutyrate (Vobecký *et al.*, 1991). The isotope ^{256}Md is most easily detected through the measurement

of the spontaneous fission activity of its daughter ^{256}Fm; however, in the presence of other fissioning nuclides, the detection of alpha particles of the characteristic energy of ^{256}Md associated with the 10% alpha decay branch can be used for identification.

Intragroup separation of the 3+ actinides has also been achieved by solvent extraction chromatography using HDEHP as the stationary organic phase and HNO_3 as the mobile aqueous phase (Horwitz and Bloomquist, 1969). Here, the actinide elution sequence is reversed from that of the cation-exchange resin column. This method gives a somewhat better final separation of Md from Fm than the cation-exchange resin column. It has the advantage that the final solution containing the Md is free of organic complexing agents compared to the resin column but has the disadvantage that Md elutes after Fm late in the sequence.

Following the discovery that Md can form a divalent state, extraction chromatography using HDEHP was used to show that the elution behavior of Md^{2+} is dissimilar to that of Es^{3+} and Fm^{3+} (Hulet *et al.*, 1967). This became the basis for a rapid separation method for the isolation of Md (Hulet *et al.*, 1979; Lundqvist *et al.*, 1981). After the initial steps of dissolution from the 'catcher' foil and coprecipitation with terbium fluoride, the mendelevium and 50 mg of Cr (added as a holding reductant) in 0.1 M HCl are co-reduced with Zn(Hg). The solution is passed through a solvent extraction column containing HDEHP on an inert support as the stationary organic phase. The actinides in the trivalent and tetravalent states as well as the trivalent lanthanides are extracted by the HDEHP and are retained on the column while the divalent Md is not appreciably extracted and appears in the 0.1 M HCl washes of the column. After reoxidation of the Md and Cr to the trivalent states with H_2O_2, the residual impurities, including the Cr, are separated from the Md by selective elution with 2 M (to remove the impurities) and 6 M HCl (to remove the Md) from a small column of Dowex 50 $\times$ 12 colloidal resin. Guseva *et al.* (1988) have reported a similar method for isolating Md where, using one column with cationite and zinc amalgam and a solution of 1 M HCl as the eluant, Md is reduced and washes through the column with the alkaline earth elements.

Volatile hexafluoroacetylacetonates of Md and Fm have been prepared and could be the bases for chemical isolation by thermochromatography (Fedoseev *et al.*, 1990).

13.3.4 Atomic properties

The electronic structure of the ground state of gaseous mendelevium atoms has been predicted to be the $^2F_{7/2}$ level of the $5f^{13}7s^2$ configuration (Martin *et al.*, 1974). An experimental confirmation has not yet been made. No experimental measurements of inner-shell binding energies or X-ray energies have been reported but estimated values have been reported by Firestone *et al.* (1996)

Table 13.4 *Estimated electron binding and X-ray energies for mendelevium, nobelium, and lawrencium.*

	Binding energy (−eV)				*X-ray energy* (keV)

$5f_{7/2}$	10.5	11.1	17.0				

based on the values recommended by Porter and Freedman (1978). The results are given in Table 13.4.

13.3.5 The metallic state

While mendelevium metal has not been prepared, Johansson and Rosengren (1975) predicted that, for the same reasons as discussed above for Fm, Md would prefer a divalent metallic state similar to Eu and Yb rather than a trivalent one.

As was the case with Fm, thermochromatographic studies conducted with trace amounts of Md by Zvara *et al*. (1976), Hübener (1980), and Hübener and Zvara (1982) led to the conclusion that Md forms a divalent metal. If the enthalpies of sublimation determined for Es and Fm from alloys are accepted, then, using the measured enthalpies of adsorption and the established correlation between the sublimation and adsorption enthalpies, Haire and Gibson (1990) estimated that Md has an enthalpy of sublimation in the range of

134–142 kJ mol^{-1}. Using empirical correlation methods, David *et al.* (1978) have estimated a divalent metallic radius of (0.194 ± 0.010) nm.

13.3.6 Solution chemistry

Before mendelevium was discovered, the trivalent state was predicted to be the most stable in aqueous solution and, therefore, it was expected to exhibit a chemical behavior similar to the other 3+ actinides and lanthanides (Seaborg and Katz, 1954). The elution of Md just before Fm in the elution sequence of trivalent actinides from a cation-exchange resin column observed in the discovery experiments appeared to confirm this prediction. Later, Md was indeed found to form insoluble hydroxides and fluorides that are quantitatively coprecipitated with trivalent lanthanides (Hulet *et al.*, 1967). Both the cation-exchange resin column (Choppin *et al.*, 1956) and HDEHP solvent extraction column (Horwitz and Bloomquist, 1969) elution data are consistent with a trivalent state for Md and an ionic radius slightly smaller than Fm.

Using empirical correlations, David *et al.* (1978) have estimated an ionic radius of 0.0912 nm (coordination number (CN) 6) for Md^{3+}. In addition to the ionic radius, a number of enthalpies and entropies of formation and sublimation were also estimated for Md. Hoffman *et al.* (1988) and Brüchle *et al.* (1988) compared the distribution coefficients for Lr, Md, and Fm with those of Tm, Er, and Ho obtained from ammonium α-HIB elutions from cation-exchange resin columns. Using the known ionic radii for the trivalent rare earths and the linear correlation of log distribution coefficient with ionic radius (for the same coordination number), an average ionic radius of 0.0896 nm was estimated for Md^{3+} and a heat of hydration of $-(3654 \pm 12)$ kJ mol^{-1} calculated using empirical models and the Born–Haber cycle.

Gorski *et al.* (1990) have studied the extraction behavior of Md with trioctylphosphine oxide in the presence of complexing agents and compared it to other transplutonium elements. They have also investigated the complex formation of several transplutonium elements, including Md, with DCTA and shown the correlation of ionic radii with the values of the log of the complex stability constants. The observed deviation from linearity by the heavy actinides is discussed in Section 13.2.5.

Hulet *et al.* (1967) first observed an anomalous chemical behavior for Md in certain chemical systems involving reducing conditions. With 10^5 to 10^6 atoms per experiment, coprecipitation with $BaSO_4$ and solvent extraction chromatography experiments using HDEHP were carried out in the presence of a number of different reducing agents. These experiments showed that Md^{3+} could be easily reduced to a stable Md^{2+} in aqueous solution. An estimate was made for the standard potential of the half-reaction $E^\circ(Md^{3+} \rightarrow Md^{2+})$ of approximately −0.2 V. Maly and Cunningham (1967) also produced the divalent state of Md and, from experiments similar to Hulet *et al.*, estimated $E^\circ(Md^{3+} \rightarrow Md^{2+})$ at −0.1 V. David (1986a) estimated $E^\circ(Md^{3+} \rightarrow Md^{0})$ to be −1.74 V. David

et al. (1981, 1990a) measured $-(1.51 \pm 0.01)$ V for the polarographic $E_{1/2}$ of the couple $Md^{2+} \rightarrow Md^{0}$ which (with correction for amalgamation potential of 1.0 V) yields an estimated $E^{\circ}(Md^{2+} \rightarrow Md^{0}) = -2.5$ V (SHE). These values (Table 13.8) are consistent with those in Chapter 19 (Fig. 19.9).

Guseva *et al.* (1988) compared the elution behavior of Md^{2+} with Sr^{2+} and Eu^{2+} from a cationite and zinc amalgam ion-exchange column using 1 M HCl. On the basis of the elution peak position of Md relative to the Sr and Eu and the known ionic radii of the latter two elements, a value for the ionic radius of Md^{2+} was estimated to be 0.115 nm. Using this value for the radius, the enthalpy of hydration of Md^{2+} was calculated to be -1413 kJ mol^{-1}.

In 1973, Mikheev *et al.* reported that a stable monovalent Md ion could be produced in neutral water–ethanol solutions and that it cocrystallized with CsCl (Mikheev *et al.*, 1973). However, studies of the overall reduction of Md^{3+} to Md^{0} (Hg) using controlled potential radiocoulometry (Samhoun *et al.*, 1979) and radiopolarography (David *et al.*, 1981) led to the conclusion that Md could not be considered as a cesium-like element and no evidence was obtained consistent with the formation of a monovalent state. Electrode reduction proceeded in two steps, $3+ \rightarrow 2+$ and $2+ \rightarrow 0$. Hulet *et al.* (1979) repeated some of the cocrystallization experiments of Mikheev and performed a series of new experiments in an attempt to prepare Md^{+} by reduction with Sm^{2+} in ethanol solutions and also in fused KCl. In these experiments, the coprecipitation behavior of Md was compared to tracer quantities of Es, Fm, Eu, Sr, Y, and Cs. Md consistently followed the behavior of Fm^{2+}, Eu^{2+}, and Sr^{2+} rather than Cs^{+}. They concluded that Md could not be reduced to a monovalent state with Sm^{2+} as claimed by Mikheev. However, on the basis of the results of further thermodynamic studies of the cocrystallization process of mendelevium with chlorides of alkali metals, the Russian investigators maintain that Md can be reduced to the monovalent state in water–ethanol solutions and that the cocrystallization of Md^{+} with salts of divalent ions can be explained as being due to the formation of mixed crystals (Mikheev *et al.*, 1980, 1981a; Spitsyn *et al.*, 1982). An ionic radius of 0.117 nm was calculated for Md^{+} from the results of the cocrystallization studies (Mikheev *et al.*, 1981b, 1982).

Unsuccessful attempts have been made to oxidize Md^{3+} to Md^{4+} using the strong oxidant sodium bismuthate (Hulet *et al.*, 1967). Thus, Md^{3+} is not readily oxidized as would be expected from the value of $+5.4$ V predicted by Nugent (1975) for the $E^{\circ}(Md^{4+} \rightarrow Md^{3+})$ couple.

13.4 NOBELIUM

13.4.1 Introduction

The discovery of element 102 was first reported in 1957 by an international research team working at the Nobel Institute in Stockholm, Sweden (Fields *et al.*, 1957). During the bombardment of a ^{244}Cm target with ^{13}C ions from the

Nobel Institute cyclotron, an 8.5 MeV alpha particle activity was produced which decayed with a half-life of approximately 10 min. The alpha activity eluted just before Es and Fm from a cation-exchange resin column using ammonium α-HIB as eluant and also appeared in the trivalent actinide fraction along with Cf and Fm, also produced in the irradiations, from a cation-exchange resin column using 6 M HCl as eluant. This behavior was taken as chemical evidence for the production of an isotope of element 102. From half-life systematics and reaction energetics, an isotope with a mass number of 253 or 255 was thought to have been produced. The name, nobelium, was proposed in honor of Alfred Nobel, in recognition of his support of the natural sciences, and in honor of the Nobel Institute where the experiments were conducted.

During the following 10 years, researchers at both the Lawrence Berkeley National Laboratory and the Dubna Research Center, Russia, attempted to repeat the Nobel Institute experiments, but were unsuccessful. However, the Berkeley group did succeed in identifying an alpha-emitting isotope of element 102 in 1958 using a newly developed method called the 'double recoil technique' (Ghiorso *et al.*, 1958) and assigned a mass of 254. Where the same isotopes have been studied, the Dubna and Berkeley groups are in substantial agreement (Ghiorso and Sikkeland, 1967). The results of the efforts of both groups exclude the likelihood of any isotope of element 102 having a half-life of 10 min with the emission of 8.5 MeV alpha particles. Further, chemical studies by Maly *et al.* (1968) showed that, because of its divalency in aqueous solutions, element 102 could not have exhibited the trivalent cation-exchange column elution behavior attributed to the 10 min activity. On the basis of their 1958 and later work, the Berkeley group claimed discovery of element 102 and, because of the wide use of the name over many years, suggested that nobelium be retained as the name of element 102 (Ghiorso and Sikkeland, 1967).

Because No is normally a divalent ion in aqueous solution and is difficult to oxidize and hold in the trivalent state, it has not been possible to make a chemical identification of the atomic number in the same manner as the preceding 3+ actinides, i.e. identification by their unique positions in the elution sequence from a cation-exchange resin column. However, in 1971, the atomic number of ^{255}No was unequivocally determined through the observance of characteristic K-series X-rays from the daughter isotope ^{251}Fm in coincidence with the alpha particles from the decay of the parent, ^{255}No (Dittner *et al.*, 1971).

13.4.2 Isotopes of nobelium

The known isotopes of nobelium range from mass 250 through 262, with the exception of 261 (Table 13.5) . The isotope ^{259}No is the longest-lived with a half-life of 58 min. However, the isotope ^{255}No has a considerably higher production rate and is most often used for chemical studies.

Table 13.5 *Nuclear properties of nobelium isotopes.*

Mass number	*Half-life*	*Mode of decay*	*Main radiations* (MeV)	*Method of production*
250	0.25 ms	SF		$^{233}U(^{22}Ne,5n)$

260	106 ms	SF, α		$^{254}Es(^{18}O,x)$
262	5 ms	SF		^{262}Lr daughter

13.4.3 Preparation and purification

The isotope ^{255}No can be produced for chemical study via the ^{249}Cf ($^{12}C,\alpha 2n$) reaction; about 1200 atoms were produced in a 10 min irradiation of a 350 μg cm^{-2} target of ^{249}Cf with 3×10^{12} particles per second of 73 MeV ^{12}C ions (Dittner *et al.*, 1971).

As with Md, the physical separation of the nobelium atoms from the target material can be made using the recoil-atom catcher foil technique. It is preferable to combine this with the 'gas-jet' technique since the product atoms can be deposited on the 'catcher' foil in a chemistry area separate from the bombardment area. The nearly monolayer of collected atoms can then be easily rinsed off the surface of the foil with dilute acid without dissolution of the foil. Isolation of the No from other actinides produced in the bombardment and from any target material transferred to the foil can be readily made using schemes based on the separation of divalent ions from trivalent ones, e.g. selective elution by solvent extraction chromatography using HDEHP as the stationary organic phase and 0.05 M HCl as the mobile aqueous phase (Silva *et al.*, 1969). Under these conditions, No passes through the column in the first few column volumes while the trivalent actinides are strongly adsorbed on the column. Selective

elution from a cation-exchange resin column, e.g. Dowex 50 × 4, can also be made using 3 M HCl as eluant. Here, No again elutes in a few column volumes and the trivalent actinides remain on the column (Silva *et al.*, 1973). When using a direct 'catcher' foil, e.g. gold, a more elaborate scheme involving separation of the gold by anion-exchange chromatography is necessary (David *et al.*, 1990b). This can be followed by selective isolation of the No from contaminants by elution from a chromatographic extraction column using HDEHP.

13.4.4 Atomic properties

The electronic ground state of gaseous nobelium atoms has been predicted to be the $^1S_0$ level of the $5f^{14}7s^2$ configuration (Martin *et al.*, 1974). No experimental information is available. No experimental measurements of inner-shell binding energies have been reported but estimated values have been published by Firestone *et al.* (1996), along with X-ray energies, based on the values recommended by Porter and Freedman (1978). The results are given in Table 13.4.

The characteristic K-series X-rays of ^{253}No emitted following the alpha decay of ^{257}Rf have been measured in alpha/X-ray coincidence experiments by Bemis *et al.* (1973). Values for $K_{\alpha 2}$ and $K_{\alpha 1}$ were reported as (120.9 ± 0.3) and (127.2 ± 0.3) keV, respectively.

13.4.5 The metallic state

Nobelium metal has not been prepared; however Johansson and Rosengren (1975) predicted that, for the same reasons as discussed above for Fm, No would prefer a divalent metallic state similar to Eu and Yb rather than a trivalent one. An estimate of 126 kJ mol^{-1} for the enthalpy of sublimation of No has been reported (David, 1986a). This value is similar to that of Es, Fm, and Md and supports the suggestion that No would form a divalent metal (Haire and Gibson, 1990). David (1986a) estimated a divalent metallic radius of 0.197 nm.

13.4.6 Solution chemistry

Before discovery, nobelium was expected to be a trivalent ion in aqueous solution and to exhibit a chemical behavior similar to the elements preceding it in the actinides series. However, in 1949, Seaborg (1949) predicted that a relatively stable 2+ state might exist for element 102 due to the special stability of the filled $5f^{14}$ shell in the $5f^{14}7s^2$ electronic configuration. Twenty years later, this prediction was confirmed.

In over 600 experiments, Maly *et al.* (1968) subjected about 50000 atoms of ^{255}No to cation-exchange chromatography and coprecipitation experiments. These tracer experiments showed that nobelium exhibits a chemical behavior substantially different from the trivalent actinides but similar to the divalent alkaline earth elements, Sr, Ba, and Ra. Thus, the divalent ion of nobelium was

shown to be the most stable species in aqueous solution in the absence of strong oxidizing agents.

Chuburkov *et al.* (1967) have compared the behavior of nobelium to those of Tb, Cf, and Fm during experiments where the atoms were first chlorinated and subsequently were carried by gas along a tube with a thermal gradient. From the position of deposition of atoms along the tube, they concluded that the chloride of No undergoes strong adsorption on solid surfaces and therefore is not very volatile; its volatility is close to the chlorides of Tb, Cf, and Fm. The chloride of either divalent or trivalent nobelium would be expected to exhibit a low volatility.

Silva *et al.* (1974) have conducted solvent extraction and cation-exchange chromatography studies of nobelium. Its complexing ability with chloride ions were compared with that of divalent mercury, cadmium, copper, cobalt, and barium in a tri-*n*-octylamine chloride/HCl liquid extraction system, and it was found to be most similar to the relatively weakly complexed alkaline earth element. The elution behavior of nobelium was also compared with that of Be, Mg, Ca, Sr, Ba, and Ra in a cation-exchange resin column/4 M HCl system and found to elute with Ca^{2+}. Further, comparison with these alkaline earth elements in an HDEHP/HCl liquid chromatography system showed nobelium to elute between Ca^{2+} and Sr^{2+}. The ionic radius of No^{2+} was estimated as 0.11 nm from a linear correlation of ionic radius with log distribution coefficient for several divalent ions obtained using an HDEHP/HNO_3 liquid–liquid extraction system. Using a similar correlation, a value of 0.10 nm was obtained from the cation-exchange chromatography data. From the results of relativistic Hartree–Foch–Slater calculations (Lu *et al.*, 1971), a value of 0.11 nm was suggested for the ionic radius of No^{2+}. The single-ion heat of hydration, calculated using an empirical form of the Born equation (Phillips and Williams, 1966) was 1486 kJ mol^{-1}. From correlations of ionic radii of actinides and lanthanides with atomic number, an ionic radius for No^{3+} of 0.90 and 1.02 Å for CNs 6 and 8, respectively, have been estimated. (David *et al.*, 1978; David, 1986b).

The formation of divalent nobelium complexes with citrate, oxalate, and acetate ions in aqueous solution of 0.5 M NH_4NO_3 have been studied by McDowell *et al.* (1976) using solvent extraction techniques. In general, the complexing tendency of nobelium with these ligands is between that of Ca and Sr, being somewhat more like Sr.

Silva *et al.* (1969) have studied the reduction potential of the No(III)–No(II) couple in aqueous solution with 50–100 atoms per experiment using HDEHP extraction column chromatography to distinguish between No^{2+} and No^{3+}. By comparing the extraction of nobelium from dilute acid solutions containing oxidants of differing potentials with the extraction behavior of tracer quantities of Cf, Cm, Ra, Tl, and Ce, the standard potential $E^{\circ}(No^{3+} \rightarrow No^{2+})$ was estimated to be between +1.4 and +1.5 V.

Meyer *et al.* (1976) used a modified radiopolarographic technique and ^{255}No to measure the half-wave potential for the reduction of nobelium at a mercury electrode and reported a value for $E^{\circ}(No^{2+} \rightarrow No^{0}(Hg))$ of −1.6 V. After

applying an estimated amalgamation potential correction, a value of −2.6 V was calculated for the standard potential of the $No^{2+} \rightarrow No^0$ couple. More recently David *et al.* (1990b) have measured amalgamation potentials of nobelium using radiocoulometry with the isotope ^{259}No. From the data, they estimated the $No^{2+} \rightarrow No^0$ couple standard potential as $-(2.49 \pm 0.06)$ V. This couple, combined with the measured $3+ \rightarrow 2+$ potential of 1.45 V (Silva *et al.*, l969) resulted in an estimated value for E° ($No^{3+} \rightarrow No^0$) of −1.18 V by David *et al.* (1990b). David (1986a, 1986b) estimated E° ($No^{3+} \rightarrow No^0$) to be −1.26 V, which leads to a calculated E° ($No^{2+} \rightarrow No^0$) = −2.61 V; these values were selected for Table 13.8 and Fig. 19.9 because of the consistent systematics (David, 1986a, 1986b) among many actinide species. David *et al.* (1990b) also estimated Gibbs energies of formation of −480 and −342 kJ mol^{-1} for No^{2+} (aq) and No^{3+} (aq), respectively. From a semiempirical technique for the linearization of actinide and lanthanide electrode potentials, Nugent (1975) has calculated a value of +6.5 V for $E^\circ(No^{4+} \rightarrow No^{3+})$.

13.5 LAWRENCIUM

13.5.1 Introduction

In 1961, Ghiorso, Sikkeland, Larsh, and Latimer of the Lawrence Berkeley National Laboratory reported the discovery of element 103 (Ghiorso *et al.*, 1961). An alpha particle activity of 8.5 MeV energy with a half-life of 8 s was produced in bombardments of a Cf target with both ^{10}B and ^{11}B ions. Owing to the short half-life, a chemical identification was not possible but the alpha activity was attributed to an isotope of element 103 on the basis of convincing nuclear evidence, i.e. the results of cross-bombardments with other targets and projectiles. However, because the target consisted of a mixture of californium isotopes, masses 249 through 252, an unambiguous mass assignment was not possible. Though isotopes of masses 255–259 could have been produced, based on cross-section considerations, the highest yield was expected for mass 257. The discoverers suggested the name lawrencium, symbol Lw, for the new element in honor of E. O. Lawrence, inventor of the cyclotron and founder of the Lawrence Berkeley National Laboratory. The name was accepted by IUPAC, but the symbol was changed to Lr.

The results of subsequent studies on the production and identification of ^{255}Lr, ^{256}Lr, and ^{257}Lr by researchers at the Joint Institute for Nuclear Research (JINR) at Dubna, Russia, appeared to conflict with the Berkeley mass assignment because none of the above isotopes had the decay properties of the original Berkeley alpha activity (Druin, 1971). However, in 1971, six alpha particle emitting isotopes of lawrencium, masses 255–260, were identified at Berkeley in bombardments of nearly isotopically pure targets of ^{248}Cm with ^{14}N and ^{15}N and ^{249}Cf with ^{10}B and ^{11}B ions, respectively, and an explanation for the discrepancy was suggested (Eskola *et al.*, 1971). From the Berkeley experiments, ^{257}Lr was found to emit

alpha particles of 8.8 MeV with a half-life of only 0.6, but ^{258}Lr was found to have a half-life of 4.2 s with the emission of 8.62 MeV alpha particles. Thus, Ghiorso and associates considered that the mass assignment made in 1961 should have been 258. The difference in the new half-life value compared to the 1961 value was attributed to relatively poor counting statistics resulting from the small number of alpha particle events observed in the earlier work.

13.5.2 Isotopes of lawrencium

Twelve isotopes of lawrencium are known with masses ranging from 252 through 262 (Table 13.6). The longest-lived isotope is ^{262}Lr, with a half-life of 3.6 h. The isotope ^{256}Lr, half-life of 26 s, was used in the early chemical studies; however, the longer-lived isotope ^{260}Lr ($t_{1/2} = 3$ min) has been used in more recent experiments.

13.5.3 Preparation and purification

The production of ^{256}Lr is best accomplished through the ^{249}Cf(^{11}B,4n) reaction using 70 MeV boron ions while ^{260}Lr is produced via the ^{249}Bk(^{18}O, α3n) reaction using 117 MeV oxygen ions.

As with Md and No, the physical separation of the Lr atoms from the target material and subsequent rapid collection is best accomplished using a recoil-atom gas-jet system coupled to a capillary transport system of some type (Hoffman *et al.*, 1988).

Because of their short half-lives, there is insufficient time to obtain a rigorous chemical purification of ^{256}Lr or ^{260}Lr. The isotope, ^{256}Lr was first isolated from

reaction products by a rapid solvent extraction technique using the chelating agent thenoyltrifluoroacetone (TTA) dissolved in methyl isobutyl ketone (MIBK) as the organic phase and buffered acetate solutions as the aqueous phase (Silva *et al.*, 1970). This method did not separate individual trivalent actinides so identification of Lr was made on the basis of its unique alpha particle energy of 8.24 MeV.

When the capillary transport system is used, the longer-lived isotope, ^{260}Lr, can be washed from the 'catcher' foil along with the small amount of aerosol carrier particles with 0.05 M HCl. Kept to a few drops of volume, this solution can be placed on the top of a cation-exchange resin column and isolation of Lr^{3+} from other trivalent actinides can be accomplished by selective elution with ammonium α-HIB (Hoffman *et al.*, 1988). An automated system called Automated Rapid Chemistry Apparatus (ARCA) has been developed and used to carry out this separation (Brüchle *et al.*, 1988).

13.5.4 Atomic properties

The electronic structure of the ground state of neutral atoms of Lr was predicted in 1970 as the $^2D_{3/2}$ level of the $5f^{14}6d^17s^2$ configuration (Moeller, 1970) similar to the rare earth homolog Lu, $4f^{14}5d^16s^2$, as one would expect from a simple extrapolation from the chemical periodic table. This prediction was brought into question in 1971 by Brewer who calculated, by a semiempirical method, a configuration of $5f^{14}7s7p^1$ (Brewer, 1971). Later the results of relativistic Dirac–Hartree–Fock calculations by Nugent *et al.* (1974) concluded that the energy difference between these two configurations was quite small and either configuration could be the ground state. On the basis of the results of multiconfiguration Dirac–Fock calculations, Desclaux and Fricke (1980) predicted the $5f^{14}7s^27p^1$ configuration as the ground state. Later, multiconfiguration Dirac–Hartree–Fock calculations by Wijesundera *et al.* (1995) and relativistic Fock-space coupled-cluster method by Eliav *et al.* (1995) led to a similar conclusion, i.e. the s^2p $J = 1/2$ is energetically favored over the s^2d $J = 3/2$ state. This result is due to the relativistic mass increase of the electrons that are strongly accelerated near the highly charged nucleus. This effect is strongest for the spherical s and $p_{1/2}$ orbitals that have high densities near the nucleus.

In 1988, Eichler and coworkers proposed gas adsorption chromatography experiments to distinguish between the two ground state configurations s^2d and s^2p. They calculated that there should be a measurable difference in the enthalpies of adsorption on metal surfaces for the two different configurations (Eichler *et al.*, 1988). The s^2p was predicted to be less volatile, perhaps similar to the p-element Pb, than the s^2d configuration with estimated sublimation energies of about 134 and 400 kJ mol^{-1}, respectively. Online gas chromatography was applied to study the volatility of Lr by Jost *et al.* (1988) and to determine the enthalpy of adsorption. No evidence for Lr as a volatile element was found under reducing conditions at a temperature of about 1000°C. Their

$L_{\alpha 1}$ ($3d_{5/2} \rightarrow 2p_{3/2}$)	17.48	17.57 (12)
L_l ($3s \rightarrow 2p_{3/2}$)	14.43	14.43 (20)

[a] Firestone *et al.* (1996).
[b] Bemis *et al.* (1977).
[c] Error in last two digits.

results gave a lower limit for the adsorption enthalpy for Lr on quartz and Pt surfaces at 290 kJ mol^{-1}, significantly higher than the estimated values for Lr (s^2p). The configuration of the ground state of lawrencium is still in doubt.

No experimental measurements of inner-shell binding energies have been reported but estimated values have been published by Firestone *et al.* (1996), along with X-ray energies, based on the values recommended by Porter and Freedman (1978). The results are given in Table 13.4.

The characteristic L-series X-rays of ^{256}Lr have been observed in coincidence with alpha particles of the parent ^{260}Db by Bemis *et al.* (1977). The results are presented in Table 13.7. They agree very well with those given by Firestone *et al.* (1996).

13.5.5 Metallic state

Lawrencium metal has not been prepared. An estimate of 352 kJ mol^{-1} for the enthalpy of sublimation of Lr has been reported (David *et al.*, 1978). This value is similar to that of Lu and supports the suggestion that Lr would prefer the formation of a trivalent metal as expected for the last member of the actinide series. Systematic properties of heats of vaporization, bulk modulus, and atomic volumes suggest that Lr would be a trivalent metal with a volume similar to that of Lu (Haire and Gibson, 1990). David *et al.* (1978) estimated a trivalent metallic radius of 0.171 nm.

13.5.6 Solution chemistry

In 1949, element 103 was predicted by Seaborg (1949) to be the last member of the proposed actinide or 5f series of elements and to be similar to lutetium with respect to the stability of the 3+ oxidation state in aqueous solution. It required nearly 20 years to finally synthesize this element and to conduct chemical experiments to confirm this prediction.

Silva *et al.* (1970) employed a fast solvent extraction procedure using MIBK containing the chelating agent TTA as the organic phase and buffered acetate solutions of differing pH as the aqueous phase to distinguish between the 2+, 3+, and 4+ oxidation states. In over 200 separate experiments, approximately 1500 atoms of ^{256}Lr were produced for study and the extraction behavior of Lr was compared with a number of tetravalent (Th, Pu), trivalent (Fm, Cf, Cm, Am, Ac), and divalent ions (No, Ba, Ra). In these experiments, lawrencium was found to extract into the organic phase over the pH range of 3+ ions along with Fm and Cf. Thus, it was concluded that the 3+ oxidation state is the most stable oxidation state for Lr in aqueous solution. Unfortunately, because of the short half-life, there was insufficient time to perform a cation-exchange resin column separation to confirm its predicted elution position just ahead of Md^{3+}.

From studies comparing the retention times of chlorinated atoms of several different actinides and transactinides as they passed through a heated glass column, Chuburkov *et al.* (1969) concluded that the chloride of element 103 has an adsorbability on solid surfaces, and hence volatility, similar to the chlorides of Cm, Fm, and No and to be much less volatile than the chlorides of element 104, Rf.

Because Lr is a trivalent ion in aqueous solution, it should exhibit a chemical behavior similar to the other 3+ actinides and lanthanides, e.g. insoluble fluoride and hydroxide. One would expect Lr^{3+} to have a slightly smaller ionic radius than Md^{3+}, due to the actinide contraction, and to elute just before Md from a cation-exchange resin column using ammonium α-HIB as eluant (see Fig. 13.1). From correlations of ionic radius with atomic number for actinide and lanthanide elements, David *et al.* (1978) estimated an ionic radius of 0.0893 nm for Lr^{3+}.

By 1987, a longer-lived isotope of lawrencium, ^{260}Lr, with a half-life of 3 months and alpha particle energy of 8.03 MeV, was available for chemical studies. Hoffman *et al.* (1988) repeated the solvent extraction experiments of Silva *et al.* (1970) and confirmed the trivalent nature of Lr in aqueous solution. Further, elutions of Lr from a cation-exchange resin columns using ammonium α-HIB as eluant were conducted and compared with the elution behavior of Md and the rare earths Tm, Er, and Ho (Hoffman *et al.*, 1988). Lr was found to elute between Ho and Tm, and approximately with the Er tracer. Seven alpha events attributable to Lr^{260} were detected. The distribution coefficients were determined from the elution positions and, using the linear correlation of ionic radius with log distribution coefficient, an ionic radius was calculated for each Lr event. The average Lr^{3+} radius was found to be 0.0886 ± 0.0003 nm assuming an ionic radius of 0.0881 nm for Er for CN 6 (Templeton and Dauben, 1954). This result was surprising to the authors because it gave a difference of only 0.0015 nm for the step of 2 in atomic number between Md, with an ionic radius of 0.0896 nm, and Lr. This is substantially smaller than the 2Z difference of 0.0021 for the analogous trivalent rare earth ions Tm and Lu and indicates

an ionic radius for Lr larger than expected. Therefore, Lr elutes later than predicted in Fig. 13.1.

In later experiments, a German–American collaboration (Brüchle *et al.*, 1988) used the ARCA (Automated Rapid Chemistry Apparatus) system to check the earlier results of Hoffman *et al.* (1988) and to increase the number of Lr atoms studies and thus the statistical significance. The earlier work was confirmed and a value of 0.0881 ± 0.0001 nm was obtained from the elution data for Lr. A heat of hydration of $-(3685 \pm 13)$ kJ mol^{-1} was calculated from the radius using empirical models and the Born–Haber cycle. Brüchle *et al.* (1988) pointed out that the difference between the radii of Md^{3+}, Fm^{3+}, and Es^{3+} is 0.0016 nm while this difference is 0.0012 nm for the analogous lanthanide ions. This suggests that the contraction at the end of the actinides series is larger than the analogous lanthanide contraction, perhaps due to relativistic effects (Seth *et al.*, 1994), with the exception of the last member of the actinide series, Lr.

It is possible that relativistic effects could stabilize the $7s^2$ closed shell so that only the $7p_{1/2}$ or 6d electron would be ionized under reducing conditions to give a monovalent Lr. Several attempts have been made to reduce Lr^{3+} to a divalent or monovalent ion in aqueous solution. Hoffman *et al.* (1988) used a solvent extraction column with HDEHP as the stationary organic phase and dilute HCl as the mobile aqueous phase to separate 1+ and 2+ ions from 3+ and 4+ ions, the former passing through the column while the latter remain fixed. Solutions containing $^{260}Lr^{3+}$ were passed through the column where the Lr remained fixed. The reducing agent hydroxylamine hydrochloride was added to the HCl and the resulting solution passed through the column for 20 s at 80°C in an attempt to reduce and elute any Lr. The attempt was unsuccessful, however, as the authors noted, the kinetics of the reduction are slow. In companion experiments, Scherer *et al.* (1988) used the HDEHP solvent extraction column

method, with the ARCA system, to attempt reductions of Lr to di- or monovalent ions (Scherer *et al.*, 1988). In a series of experiments using the reducing agents V^{2+} and Cr^{2+} in the dilute HCl-eluting solutions, there was no evidence for the reduction of Lr^{3+} to either the 2+ or 1+ oxidation state. From the results, a limit of <-0.44 V was estimated for the $Lr^{3+} \rightarrow Lr^{2+,\ 1+}$ reduction potential. Using the newly discovered Lr^{262} ($t_{1/2} = 3.6$ h), Lougheed *et al.* (1988) attempted to reduce Lr with Sm^{2+}, $E^{\circ}(Sm^{3+} \rightarrow Sm^{2+}) = -1.55$ V, and coprecipitate Lr^{1+} with Rb using sodium tetraphenylborate or chloroplatinic acid but were unsuccessful. The 2+ and 3+ actinide ions do not coprecipitate under these conditions. On the basis of 20 Lr events, they calculated an upper limit of -1.56 V for $E^{\circ}(Lr^{3+} \rightarrow Lr^{1+})$ and concluded that it is unlikely that Lr^{1+} can exist in aqueous solutions. Nugent (1975) has calculated values of -2.06 V for $E^{\circ}(Lr^{3+} \rightarrow Lr^{0})$ and $+7.9$ V for $E^{\circ}(Lr^{4+} \rightarrow Lr^{3+})$.

A summary of some of the chemical properties of fermium, mendelevium, nobelium, and lawrencium is given in Table 13.8.

CHAPTER FOURTEEN

TRANSACTINIDE ELEMENTS AND FUTURE ELEMENTS

Darleane C. Hoffman, Diana M. Lee, and Valeria Pershina

14.1 INTRODUCTION

This chapter gives a brief summary of the reported discoveries, confirmation, and nuclear properties of the claimed and confirmed transactinide elements through the year 2004. However, the primary emphasis is on the chemical properties – experimental, theoretical, and predicted – of the transactinides and a comparison of measured properties with theoretical predictions. The experimental studies of chemical properties are especially challenging because of the low production rates and the short half-lives and the need for very special facilities and the use of atom-at-a-time chemistry. The discovery of a new element must furnish evidence that its atomic number is different from those of all the currently known elements and first claims to discovery often lacked such positive identification. As a result, there were uncertainties and controversies over priority of discovery, nuclear and chemical properties, and assignment of names. The first *positive identification* of the atomic number of all these elements was accomplished using 'physical' rather than chemical techniques.

The authors of this chapter have made a conscientious effort to present a balanced view of research on the properties of the transactinides. The chapter also includes predictions of the nuclear and chemical properties of the

SuperHeavy Elements (SHEs). The term originally referred to an 'island of nuclear stability' around the predicted closed spherical shells at 112 to 114 protons and 184 neutrons. Revisions due to recent experiments and theoretical calculations are discussed.

As of 1997, discoveries of the transactinide elements 104 through 109 had been recognized by the International Union of Pure and Applied Chemistry (IUPAC) and the International Union of Pure and Applied Physics (IUPAP). The names and symbols for these elements as finally approved by IUPAC in 1997 (CNIC, 1997) and the year of discovery are given in Table 14.1.

Claims to the discovery of element 110 were made by researchers at the Lawrence Berkeley National Laboratory (LBNL) (Ghiorso *et al*., 1995a,b), by researchers at the Gesellschaft für Schwerionenforschung (GSI) in Darmstadt, Germany (Hofmann *et al*., 1995a), and by a Dubna/Livermore group working at the Joint Institute for Nuclear Research (JINR) in Dubna, Russia (Lazarev *et al*., 1996).

The published analysis of these claims by a Joint Working Party (JWP) of IUPAC/IUPAP (Karol *et al*., 2001) gave credit for the synthesis of element 110 to the GSI group and invited them to propose a name. They proposed the name 'Darmstadtium' with the symbol Ds after the place in Germany where the element 110 discovery experiments were conducted. The IUPAC Commission on Nomenclature of Inorganic Chemistry (CNIC) considered the proposal and in March 2003 (Corish and Rosenblatt, 2003) recommended to the IUPAC Bureau that it be accepted. It was officially approved by the IUPAC Council at the 42nd General Assembly in Ottawa, Canada, on August 16, 2003.

The discovery of elements 111 and 112 was reported by the GSI group in 1995 (Hofmann *et al*., 1995b, 1996) and confirmatory experiments were reported in 2002 (Hofmann *et al*., 2002). In mid-2003 the JWP assigned credit for discovery of element 111 to the GSI group and asked them to propose a name (Corish and Rosenblatt, 2003; Karol *et al*., 2003), but judged that the evidence for assigning

Table 14.1 *CNIC/IUPAC compromise recommendation for names of transactinide elements. Approved by IUPAC, August* 30, 1997, *Geneva, Switzerland.*

Element	*Name*	*Symbol*	*Discovery year*
104	Rutherfordium	Rf	1969
105	Dubnium (Hahnium)[a]	Db (Ha)[a]	1970
106	Seaborgium	Sg	1974
107	Bohrium	Bh	1981
108	Hassium	Hs	1984
109	Meitnerium	Mt	1982

[a] Many publications of chemical studies before 1997 use hahnium (Ha) for element 105.

credit for the discovery of element 112 was insufficient. The element 111 discovery team proposed the name 'Roentgenium' with symbol Rg after Wilhelm Conrad Roentgen, the discoverer of X-rays. A provisional recommendation for approval of the proposal was sent (Corish and Rosenblatt, 2004) to the IUPAC Bureau and Council and was approved in late 2004. A modern periodic table showing elements through $Z = 154$ is given in Fig. 14.1.

Evidence for elements 112 through 116 has been reported from 1999 to early 2004 by groups working at Dubna (Oganessian, 1999a–c, 2001, 2002; Lougheed *et al.*, 2000; Oganessian *et al.*, 2000a,b, 2002, 2004a–c). However, it should be emphasized that as yet there is no confirmation by other groups of the isotopes of these elements and their decay products. Nuclear properties of the transactinide elements including half-life, mode of decay, main radiations, and method of production based on reports published through early 2004 are given in Table 14.2 and in Appendix II. Nuclides for which only one decay chain has been reported are not listed. Charts of the isotopes of Lr (the last of the actinides) through 109 and for 110 through 116 are shown in Fig. 14.2(a) and (b).

The transactinide elements begin with element 104 (rutherfordium) and include all the elements beyond lawrencium, the element that ends the actinide series with the filling of the 5f electron shell. According to results of atomic relativistic calculations (Fricke, 1975), the filling of the 6d shell takes place in the

first nine of the transactinide elements ($Z = 104$ through 112). In elements 113 through 118 the 7p shell is being filled and element 118 is the heaviest member of the noble gas group. Filling of the 8s shell is expected to occur with elements 119 and 120, making them homologs of elements in groups 1 and 2. Accurate relativistic calculations (Eliav *et al.*, 1998a) show that element 121 will have an 8p electron in its ground state configuration in contrast to the 7d electron expected from simple extrapolation of the members of group 3 in the periodic table. A 7d electron will be added in element 122 to give it the [118] $8s^2 7d 8p$ configuration (Eliav *et al.*, 2002), in contrast to thorium, which has the configuration $[Rn]7s^2 6d^2$.

No accurate calculations exist beyond element 122 (Eliav *et al.*, 1992), where the situation becomes more complicated because the energy spacings for the 7d, 6f, and 5g levels and later on for the 9s, $9p_{1/2}$, and $8p_{3/2}$ become so close that in the region of $Z = 160$ the usual classification on the basis of a simple electronic configuration may become invalid. Clear structures on the basis of pure p-, d-, f-, and g-blocks are no longer distinguishable. Chemical properties of the elements influenced by these mixed electronic shells will then be so different from anything currently known that classification on the basis of the known periodic table will be impossible.

In order to positively identify a new element and place it in its proper position in the periodic table, its atomic number (proton number) must be determined or deduced in some way. For transactinide elements it became necessary to develop new methods for positive identification of atomic number. One widely used technique is that of correlation of the unknown element's decay to a known daughter and/or granddaughter, which can be identified either chemically or by its decay characteristics. The method of $\alpha-\alpha$ correlations has been widely used for elements that decay by alpha emission to subsequent known α emitters. Another definitive method is measurement of the characteristic X-rays of the new element. This technique was used by Bemis *et al.* (1973, 1977) to confirm the discovery and reported properties of elements 104 and 105, but it requires considerably larger samples than the α–α correlation method. Although detection of spontaneous fission (SF) is a very sensitive technique, determination of the Z of the parent fissioning nuclide is extremely difficult and depends on some other indirect method such as excitation functions, half-life systematics, production in other reactions, or determination of the atomic number of *both primary fragments* from the same SF event in order to add them together to get the Z of the fissioning new element. Detection of only SF decay has led to many controversies concerning discoveries of the transactinide elements.

In 1974, IUPAC and IUPAP appointed an *ad hoc* committee of neutral experts, consisting of three members from the USA, three from the USSR, and three from other countries (including the chairman), to consider the claims of priority to discovery of elements 104 and 105 and attempt to get agreement between the research groups at Berkeley (USA) and Dubna (USSR). The

committee was finally disbanded without finishing the report, but the American members eventually published their own in-depth report (Hyde *et al*., 1987) that summarized the claims and counterclaims together with a critical assessment of both the physical and the chemical evidence relating to discovery of these elements during the period 1960–77. Reference tables with all the known information for each element, a comprehensive bibliography including internal laboratory reports from Dubna and Berkeley, and all articles published in refereed journals related to the first synthesis and identification of the isotopes of elements 104 and 105, and a summary and conclusions were presented. They concluded that the information published for element 104 (Ghiorso *et al*., 1969) and element 105 (Ghiorso *et al*., 1970, 1971) was correct and fully met the criteria for discovery of new elements stated by Harvey *et al*. (1976) and Flerov and Zvara (1971) and that priority for discovery of elements 104 and 105 clearly belonged to the Berkeley group and endorsed their proposal that they be named rutherfordium (Rf) and hahnium (Ha).

However, the combined IUPAC and IUPAP Transfermium Working Group (TWG) came to different conclusions in their reports (Barber *et al*., 1991, 1992, 1993) on the final assignment of credit for discovery of elements 101 through 109. An immediate rebuttal to the initial assignments of credit for discovery (Barber *et al*., 1991) of element 102 to Dubna, and assignment of shared credit to Berkeley/Dubna for elements 104 and 105, and to GSI/Dubna for element 107 was sent in 1991 in a message from Ghiorso and Seaborg to the chairman of the joint IUPAC/IUPAP TWG. A longer response is found in Ghiorso and Seaborg (1993a), as part of the responses invited from Berkeley, Dubna (Oganessian and Zvara, 1993), and GSI (Armbruster *et al*., 1993). These were published immediately following the TWG report (Barber *et al*., 1993). The response from Ghiorso and Seaborg (1993b) was also published in *Progress in Particle and Nuclear Physics* because IUPAP had given them no opportunity to respond to the companion 'discovery' article published there (Barber *et al*., 1992). A long period of dissent ensued after the CNIC resolved that 'an element could not be named after a living person' and, therefore, the name seaborgium for element 106 already approved by the American Chemical Society could not be accepted. The names for elements 101 through 103 were accepted as mendelevium, nobelium, and lawrencium, but dubnium (Db), joliotium (Jl), rutherfordium (Rf), bohrium (Bh), hahnium (Ha), and meitnerium (Mt) were recommended for elements 104 through 109 by IUPAC/CNIC and approved by the IUPAC Bureau in September 1994. This resulted in protest and criticism from around the world as names that had been in common use were scrambled and the historical right of discoverers of a new element to name it was ignored. A long period of negotiation ensued and resulted in 1995 in the suggestion of still another 'compromise' set of names. This time nobelium (102) was replaced with the name flerovium (Fl), and dubnium, joliotium, seaborgium, nielsbohrium, hahnium, and meitnerium were suggested for elements 104 through 109. This slate did not meet with any more approval than the previous one and in an

unprecedented step the IUPAC Bureau rescinded the previously approved names and solicited comments over a 5-month period. Finally, the CNIC/IUPAC compromise recommendation shown in Table 14.1 was approved by the IUPAC Bureau on August 30, 1997. The long negotiations and final compromise that resulted in the naming of elements 104 through 106 as rutherfordium, dubnium, and seaborgium, and elements 107 through 109 as bohrium, hassium, and meitnerium have been described in detail in the book *The Transuranium People* (Hoffman *et al.*, 2000a).

14.2 NUCLEAR PROPERTIES OF THE TRANSACTINIDE ELEMENTS

All known isotopes of the transactinides are radioactive. The longest known confirmed half-life for these elements ranges from 75 s for ^{261}Rf to only 42.7 ms for ^{268}Mt, the daughter of ^{272}111 (see Fig. 14.2). No transactinide elements have been found in nature although early predictions (Myers and Swiatecki, 1966; Meldner, 1967) that an 'island of SHEs' well beyond uranium might exist around elements with atomic numbers 114 or 126 raised the tantalizing possibility that very long-lived SHEs might still exist on Earth after having been formed during the last nucleosynthesis in our solar system some 5 billion years ago. Later theoretical studies based on new theories of nuclear structure (Strutinsky, 1966; Nilsson *et al.*, 1969a,b; Fiset and Nix, 1972; Randrup *et al.*, 1974) confirmed that an island of nuclear stability stabilized by spherical nuclear shells should be centered around 110 to 114 protons and 184 neutrons. Some calculations even indicated that element 110 with 184 neutrons (^{294}110) should be the longest-lived, with a half-life in the range of hundreds of thousands to a billion years. These predictions sparked a host of experimental investigations to try to detect SHEs in a wide variety of natural sources, but by 1987 no credible evidence for SHEs in nature remained (Hoffman *et al.*, 2000b).

14.3 ONE-ATOM-AT-A-TIME CHEMISTRY

14.3.1 Challenges

Special challenges are involved in studying the chemical properties of the transactinide elements because of their short half-lives, low production rates, the presence of many other unwanted activities, the necessity for producing them in accelerators with high-intensity beams, and the need to build special radiochemistry laboratory and detection facilities nearby. In addition, it is often necessary to prepare and use highly radioactive and rare targets, e.g. ^{248}Cm, ^{249}Bk, ^{249}Cf. Techniques have been developed for detection of a single atom at a time, usually by measuring its radioactive decay. Often the longest-lived known isotope of the element that is used for chemical studies is not the isotope first

discovered. Knowledge of the nuclear decay properties and a measurement technique that positively shows that the detected decay arises from the element in question are required. The technique of α–α correlation to known daughter or granddaughter activities can provide such positive identification and has been widely used because many of the transactinide isotopes decay by alpha emission to known alpha-decaying daughter isotopes. Measurement of characteristic X-rays associated with the decay can also provide positive identification of atomic number, but the technique is difficult to apply when only a few atoms can be detected.

14.3.2 Production methods and facilities required

Chemical studies require use of an isotope with a half-life long enough to permit chemical separation and a reasonable production and detection rate, which for the transactinide elements may range from a few atoms per minute for Rf to only an atom per week in the case of Hs. In addition, the isotope must have unique decay characteristics so that it can be positively identified even on an atom-at-a-time basis in order to prove that it belongs to the element whose chemistry is being studied. The isotopes of elements Rf through Hs that were used in the first definitive chemical studies for each element, their production modes, approximate cross sections, and approximate detection rates for the initial experiments that had different overall efficiencies and transport times are listed in Table 14.3, together with those for Lr, the last of the actinides.

14.3.3 Chemical procedures

The chemical procedures used in atom-at-a-time studies must be fast enough to be accomplished in times comparable to the half-lives of the isotopes used in those studies and must give the same results for a few atoms as for macro

Table 14.3 *Isotopes used in first definitive chemical studies of Lr through Hs.*

amounts. Chemical methods in which a single atom rapidly participates in many identical chemical interactions in two-phase systems with fast kinetics that reach equilibrium quickly have proven to be valid. Adloff and Guillaumont (1993) have given a thorough discussion of the validity of conclusions about chemical behavior obtained from very small numbers of atoms. An equilibrium constant was defined for such reactions in terms of the probabilities of finding the species in one phase or the other. Adloff and Guillaumont concluded that it is valid to combine the results of many separate one-atom-at-a-time experiments in order to get statistically significant results. Thus the results obtained from many identical experiments, each performed with only a single atom, can be added together to obtain statistically significant information about chemical behavior (Guillaumont *et al*., 1989, 1991).

In early studies, activities recoiling from the target were deposited on a thin 'catcher' foil placed directly behind the target in the production chamber of the accelerator. The foil was then removed manually or remotely shuttled to a detection system without disturbing the accelerator vacuum, and its alpha and SF activity measured with appropriate radiation detectors. Alternatively, the collector foil was removed and chemically processed. In either case, the valuable target is not destroyed, and considerable decontamination from all of the activity remaining in the target itself is achieved. Later, gas transport systems using a variety of gases and aerosols were developed to rapidly and efficiently transport reaction products to collection sites outside the radiation field where chemistry can be carried out within a few seconds, either manually or with computer-controlled automated systems that have been developed for both aqueous- and gas-phase chemistry. Although the automated systems are not necessarily faster, they usually give more reproducible results and are more appropriate for carrying out the many repetitive, around the clock experiments lasting weeks at a time that are required to get statistically significant information. Several detailed reviews (Gäggeler, 1990; Hoffman, 1994; Wierczinski and Hoffman, 1996; Hoffman and Lee, 1999; Kratz, 1999a) of these methods have been given.

(a) Gas-phase chemistry

Both thermochromatographic and isothermal methods have been used to study gas-phase properties of the heaviest elements. These methods are particularly useful for short-lived isotopes because the lengthy process of evaporating liquid samples that is required in most aqueous chemistry experiments is avoided. Gas-phase chromatographic methods permit determination of the adsorption enthalpy, ΔH_{ads}, by using correlations between measured properties such as temperature of adsorption and ΔH_{ads}. The latter were shown to be linearly related to the sublimation enthalpy, ΔH_{sub} (Zvara *et al*., 1970), which is used to compare the volatilities with lighter homologs.

Pioneering studies of the volatilities of the halides of elements 104 and 105 were carried out in the late 1960s and 1970s by Zvara *et al*. (1974, 1976) using thermochromatographic separations. In this method, a longitudinal, negative temperature gradient is established along a chromatographic column through which a gas stream is conducted. It contains the volatile species of interest that deposit on the surface of the column according to their volatilities. Later, the deposition zones are determined from fission tracks registered in detectors positioned along the column. These fissions are associated with specific deposition temperatures, which are then correlated with ΔH_{ads}. The advantage of this method is that production and separation of the detected species takes place very rapidly and species with half-lives as short as a few seconds can be measured. It also has some disadvantages. Positions of the deposition zones are determined only after the experiments are finished. This makes the interpretation of the results very difficult because it is necessary to correct for the half-lives of the various species involved before their volatilities can be compared. Furthermore, real-time observation of the nuclear decay and the determination of the half-lives of the detected species are not possible. Another difficulty is that if only SF activity is measured in the experiments, it is difficult to prove what the atomic number of the detected species actually was because only the fission fragments are detected (see discussion in Section 14.1).

Improved gas thermochromatographic systems have now been developed in which volatile species are transported through a thermochromatographic column (TC) where they are deposited directly on the surface of the pairs of opposing (Si) photodiode detectors that form the column. Both the radiations from the radioactive species and their deposition positions as a function of temperature along the column can be determined simultaneously and recorded. In this way, the isotope (and element) being studied can be positively identified and its deposition temperature at various positions along the TC (Si) (subjected to an appropriate negative temperature gradient) can be determined. Such a cryogenic on-line TC system was used (Düllmann *et al*., 2002b) to perform the first successful chemical studies of element 108 (Hs) using the alpha-emitting isotopes ^{269,270}Hs and compare the behavior of Hs with Os, its lighter group 8 homolog. These investigations are described in detail in Section 14.6.4b.

Recent studies of gas-phase chemistry have utilized isothermal chromatographic systems such as the On-Line Gas Analyzer (OLGA) developed by Gäggeler (1994) and the Heavy Element Volatility Instrument (HEVI) developed by Kadkhodayan *et al*. (1996) and the alpha-emitting isotopes shown in Table 14.3 to compare the behavior of the halides and oxyhalides of elements 104 through 107 with those of their lighter homologs in groups 4 through 7 of the periodic table. In such systems the entire chromatographic column (usually quartz) is kept at a constant temperature. Volatile species pass through the column and undergo numerous sorption/desorption steps. Chromatographic experiments are carried out at a series of temperatures and the chemical yield of

the volatile, short-lived species is studied as a function of temperature. Retention time is indicative of the volatility at each isothermal temperature and can be deduced from the observed changes in the yield from low to high values. The half-life of the nuclide under investigation serves as an 'internal' clock for the process. Just half of the atoms introduced into the isothermal gas chromatographic column will exit from the other end when the time it takes for an atom to pass through the column (the retention time) corresponds to its half-life. That is, the retention time in the chromatographic column at the temperature where the yield is 50% ($T_{50\%}$) of this maximum value is equal to the half-life of the short-lived nuclide (Gäggeler, 1997) and can be used as a relative measure of volatility. If the retention time is very short compared to the known half-life, the yield through the column will approach 100%. A Monte Carlo program taking account of all the experimental conditions is used to deduce the ΔH_{ads} for the measured species. Examples of these studies are discussed in Section 14.6.

(b) Solution chemistry

The Automated Rapid Chemistry Apparatus (ARCA) and the microcentrifuge system SISAK (Special Isotopes Studied by the AKUFE, Swedish acronym for the centrifuge liquid–liquid extraction technique) are examples of automated, computer-controlled systems that have been used in studies of solution chemistry of the heaviest elements.

(*i*) *ARCA*

ARCA can be used to perform rapid, repeated, high-pressure liquid chromatography column experiments on a timescale of seconds. The separations usually are carried out using microscale ion-exchange resin columns. After sorption on the column, the absorbed species are eluted and distribution coefficients are determined from the retention times of the species on the column. The collected liquid samples must then be dried before measurement of alpha emission and/or SF decay with high-resolution solid-state detectors, thus limiting detection to nuclides with half-lives longer than ~30 s. However, longer-lived daughter products can be detected in subsequent steps and used to infer properties of the parent element. The ARCA system has been used successfully for separations of elements 104 through 106, as described in detail in several reviews (Hoffman, 1994; Schädel, 1995; Hoffman and Lee, 1999; Kratz, 1999a,b).

(*ii*) *SISAK*

SISAK is a well-established on-line technique that has been used for studies of gamma-emitting nuclides with half-lives as short as 0.8 s, e.g., ^{109,110}Tc (Alzitzoglou *et al.*, 1990) and was later adapted for use with alpha emitters (Alstad *et al.*, 1995). The SISAK system can be used to perform liquid–liquid

extractions on the timescale of a few seconds and has been coupled to a flowing liquid scintillation system to provide continuous separation and measurement of α–α correlations and SFs for nuclides as short as a few seconds (Omtvedt *et al.*, 1998). This permits chemical studies of shorter-lived nuclides, but the detection energy resolution is not as good. However, a recent experiment by Omtvedt *et al.* (2002) showed that rapid pre-separation by the Berkeley Gas-filled Separator (BGS) furnished sufficient decontamination from the extremely high background of unwanted activities so that the SISAK system could be used to obtain more detailed information about the chemical properties of Rf using 4.7-s ^{257}Rf produced in the ^{208}Pb(^{50}Ti,n) reaction. The same technique can be extended to studies of 4.4-s ^{258}Db produced via ^{208}Pb(^{51}V,n) or ^{209}Bi(^{50}Ti,n) reactions as well as to still heavier elements although the production rates are steadily decreasing as Z increases. Additional developments to increase production rates will be required. Another limitation will be the requirement to choose extraction systems with fast enough kinetics to achieve equilibrium.

14.4 RELATIVISTIC EFFECTS ON CHEMICAL PROPERTIES

14.4.1 Relativistic effects on atomic electronic shells

The relativistic mass increase can be expressed as $m = m_0\sqrt{1-(v/c)^2}$ where m_0 is the rest mass and v is the velocity of an electron. As the Z of the heavy elements increases, the stronger attraction to the core causes the electrons to move faster, and the resultant mass increase leads to a decrease in the Bohr radius of the hydrogen-like s and $p_{1/2}$ electrons: $a_B = \hbar^2/mc^2 = a_B^0\sqrt{1-(v/c)^2}$. The contraction and stabilization of these orbitals is the direct relativistic effect; it was shown to originate from the region of the inner K- and L-shells (Schwarz *et al.*, 1989; Baerends *et al.*, 1990). This effect was originally thought to be large only for the 'fast' electrons in inner core shells of heavy atoms. Later, it was also found to be large for the outer s and $p_{1/2}$ valence electrons. For example, the relativistic contraction for the 7s orbital in Db is $\Delta_R\langle r\rangle_{ns} = (\langle r\rangle^{nr} - \langle r\rangle^{rel}/\langle r\rangle^{nr}) = 25\%$, as shown in Fig. 14.3. As a consequence, the relativistic stabilization of this 7s orbital is 2.6 eV, as shown in Fig. 14.4.

The effect of the *n*s orbital contraction reaches its maximum in the 6th period with Au (17.3%) and in the 7th period with element 112 (31%); the phenomenon has been called the relativistic effect gold maximum and group 12 maximum, respectively (Pyykkö, 1988; Schwerdtfeger and Seth, 1998). The same maximum is, consequently, observed with the relativistic stabilization of the 6s and 7s orbitals (Fig. 14.5). The shift of the maximum to element 112 in the 7th period in contrast to gold in the 6th period is due to the fact that in both elements 111 and 112 the ground state electronic configuration is d^qs^2, while the electronic configuration changes from Au ($d^{10}s^1$) to Hg ($d^{10}s^2$). (See the discussion of relativistic effects in relation to electronic configurations by Autschbach *et al.* (2002).)

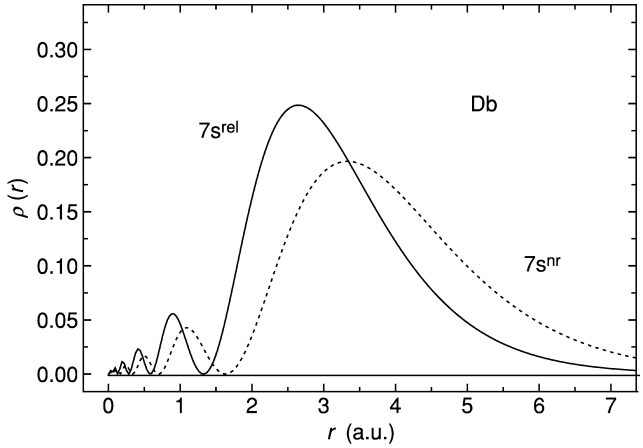

Fig. 14.3 *Relativistic* (*solid line*) *and nonrelativistic* (*dashed line*) *radial distribution of the* 7*s valence electrons in Element* 105, *Db.*

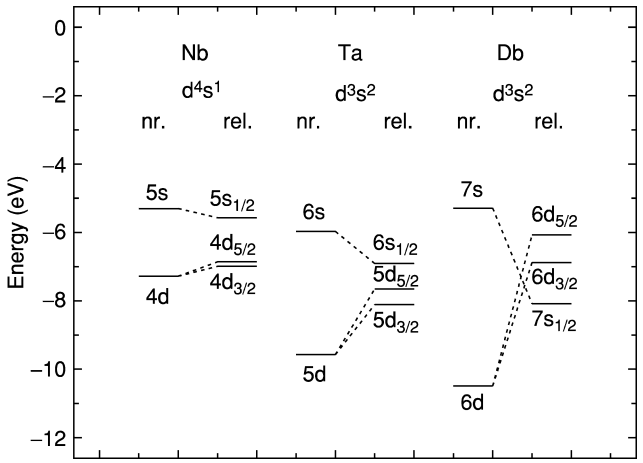

Fig. 14.4 *Relativistic stabilization of the* n*s orbitals, the destabilization of the* (n − 1)*d orbitals and their SO splitting for the group* 5 *elements. Dirac–Fock values are from Desclaux* (1973).

The contraction of the outer s and $p_{1/2}$ orbitals was recently explained as due to the admixture of higher bound and (partially) continuum orbitals due to relativistic perturbations (Schwarz *et al.*, 1989; Baerends *et al.*, 1990).

The relativistic contraction of the s and $p_{1/2}$ shells results in a more efficient screening of the nuclear charge so that orbitals of the outer d- and f-electrons, which never come close to the core, become more expanded and energetically destabilized. This is called the second or indirect relativistic effect. It was

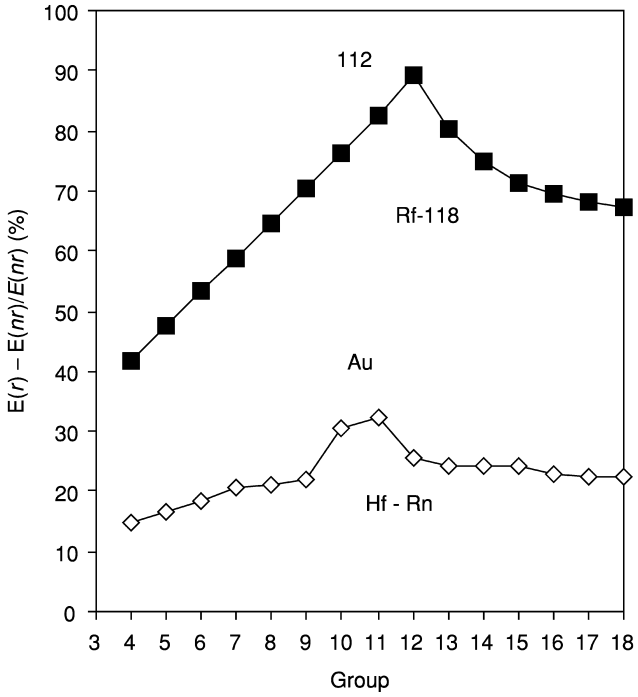

Fig. 14.5 *Relativistic stabilization of the* 6*s and* 7*s orbitals in the* 6*th and* 7*th periods of the periodic table. Redrawn from the data of Schwerdtfeger and Seth* (1998). *Relativistic Dirac–Fock data are from Desclaux* (1973). E(r) *is the relativistic orbital energy and* E(nr) *is the nonrelativistic orbital energy.* (*Figure from Pershina,* 2003).

realized that though contracted s and $p_{1/2}$ core (innermost) orbitals cause indirect destabilization of the outer orbitals, relativistically expanded d- and f-orbitals cause the indirect stabilization of the outer valence s- and p-orbitals. That partially explains the very large relativistic stabilization of the 6s and 7s orbitals in Au and in element 112, respectively (Fig. 14.5). Since both d-shells and f-shells become fully populated at the end of the d- and f-series, respectively, a maximum of indirect stabilization of the valence s- and p-orbitals will occur (Schwarz *et al.*, 1989) there. An example of the relativistic destabilization of the $(n - 1)$d orbitals is shown in Fig. 14.4 for the group 5 elements. This figure shows that trends in the relativistic and nonrelativistic energies of the valence electrons are opposite in going from the 5d to the 6d elements. Their spatial distributions show a similar effect (Fig. 14.3). Thus, only the relativistic description of the wave function can give the appropriate predictions of trends in properties within the chemical groups.

The third relativistic effect is the well-known spin–orbit (SO) splitting of levels with $l > 0$ (p-, d-, f-electrons, etc.) into $j = l \pm 1/2$. It also originates in

the vicinity of the nucleus. The SO splitting decreases with increasing l quantum number: $\mathrm{SO}(n\mathrm{p}_{1/2} - n\mathrm{p}_{3/2}) > \mathrm{SO}(n\mathrm{d}_{3/2} - n\mathrm{d}_{5/2}) > \mathrm{SO}(n\mathrm{f}_{5/2} - n\mathrm{f}_{7/2})$. All three of these effects are of the same order of magnitude and increase roughly as Z^2. The effects can be seen from the energies of one-electron levels of the 7th series of the elements shown in Fig. 14.6.

Breit effects (accounting for magnetostatic interactions) on energies of the valence orbitals and on ionization potentials (IPs) are usually small, e.g. 0.02 eV for element 121 (Eliav *et al.*, 1998a). They can, however, reach a few percent for the fine structure level splitting, e.g. 3.6% of the total amount of the Tl ^{2}P splitting. Quantum electrodynamic (QED) effects are known to be very important for the inner shells, e.g. in accurate calculations of x-ray spectra. The effects were shown to be small, but not negligible for the valence electron shells, and are of the order of 1–2% of the kinetic relativistic effects. That means that existing studies of relativistic effects have uncertainties of no more than 2% (Pyykkö *et al.*, 1998). Recent monographs are recommended for a discussion of relativistic effects on chemical properties (Schwarz, 1990; Wilson *et al.*, 1991).

14.4.2 Current relativistic quantum-chemical methods

Early predictions of chemical properties of the heaviest elements were made in the 1970s on the basis of relativistic atomic electronic structure calculations and extrapolations of properties from the lighter elements (Keller *et al.*, 1970, 1973; Fricke and Waber, 1971; Fricke, 1975; Penneman and Mann, 1976). Influenced by the success of chemical experiments on the heaviest elements and due to the further development of the quantum-mechanical theory, a new wave of predictions of chemical properties based on relativistic molecular calculations

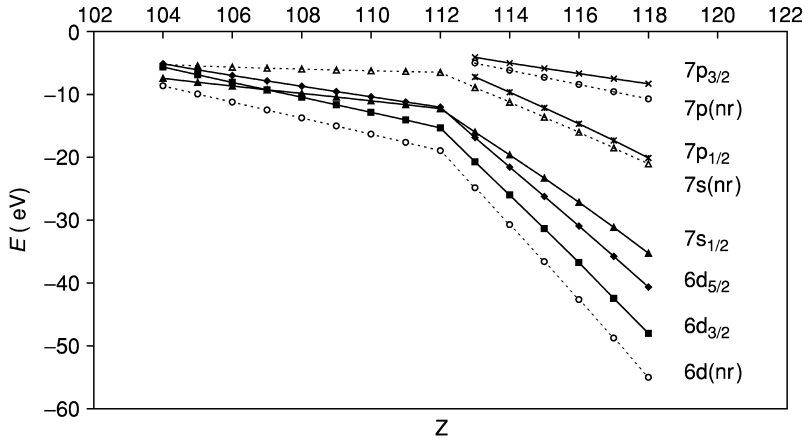

Fig. 14.6 *Relativistic* (*Dirac–Fock, solid lines*) *and nonrelativistic* (*Hartree–Fock, dashed lines*) *orbital energies for elements* 104 *through* 118. *The Dirac–Fock data are from Desclaux* (1973)*; Hartree–Fock data are from Schwerdtfeger and Seth* (1998).

appeared, beginning in the 1990s. These calculations were performed using the most advanced quantum-chemical methods at the time. Overviews of their application to transition elements are given by Pyykkö (1988), to actinides by Pepper and Bursten (1991), and to transactinides by Pershina (1996, 2003), Pershina and Hoffman (2003), and Schwerdtfeger and Seth (1998). All-electron *ab initio* methods based on the Dirac–Coulomb–Breit (DCB) Hamiltonian with some possible corrections such as the radiative correction, the extension of the finite nuclei, and coupling with nuclear spin offer fully relativistic treatment of any atomic system. Since the Dirac equation is written for one electron, the real problem of *ab initio* methods is the treatment of the instantaneous electron–electron interaction, called electron correlation. Correlation effects are taken into account by the configuration interaction (CI) technique, the many-body perturbation theory (MBPT) and currently, most accurately by the Fock-space coupled cluster (CC) procedure, called single double CC excitations (CCSDs) (Ishikawa and Kaldor, 1996; Kaldor and Eliav, 1998, 2000). However, the CCSD method is presently limited to treating electronic configurations with no more than two electrons or holes beyond the closed shell. The DCB CCSD calculations have been performed for elements as heavy as 103, 104, 111–115, 118–122 (Kaldor and Eliav, 2000; Eliav *et al*., 2002).

Atomic calculations using approximations of the DCB equations and some numerical techniques were very successful in the past. Calculations of the electronic structures of the heaviest elements up to very high Z were performed by Desclaux (1973), Mann and Waber (1970), Fricke and Waber (1971), and Fricke *et al*. (1971) using the one-configuration Dirac–Fock (DF) or the Dirac–Slater (DS) methods. (The DS method contains the Slater potential for the exchange-correlation term.) Later, a correlated method, the multi-configuration Dirac–Fock (MCDF) in some slightly different modifications (Desclaux, 1975; Grant, 1986; Parpia *et al*., 1996), was applied in calculations of the electronic structures of many of the heaviest elements up to $Z = 118$ (Desclaux and Fricke, 1980; Pyper and Grant, 1981; Glebov *et al*., 1989; Johnson *et al*., 1990, 1999, 2002; Fricke *et al*., 1993).

Molecular fully relativistic DF linear combination of atomic orbitals (DF-LCAO) codes including correlation effects are still under development (Grant, 1994; Grant and Quiney, 2000). Calculations are restricted to molecules with very few atoms, such as $(113)_2$ (Wood and Pyper, 1981), 111H, 117H, (113), (117), and $114H_4$ (Saue *et al*., 1996; Seth *et al*., 1996; Faegri and Saue, 2001). Algebraic solution of the molecular Dirac equation encounters difficulties due to the fact that the Dirac operator is unbound. Some special techniques like the projection operator technique are used to avoid the variational collapse connected with it. In contrast to nonrelativistic calculations, large basis sets are needed to describe accurately the inner-shell region where relativistic perturbation operators are dominant. The condition of kinetic balance relating the large and small components of the four-component wave function (Grant, 1986) must be observed. Kinetically balanced Gaussian type wave functions

with a Gaussian distribution for the nuclear potential are presently the best suited for these purposes. These methods place heavy demands on computer memory and computational time.

Some pseudopotentials (PPs) (Schwerdtfeger *et al.*, 1989; Schwerdtfeger and Seth, 1998) or relativistic effective core potentials (RECPs) (Ermler *et al.*, 1988; Nash *et al.*, 1997; Han and Lee, 1999) are used to solve the many-electron problem in an efficient way. According to these approximations, frozen inner shells are omitted and replaced in the Hamiltonian by an additional PP term. As a result, the number of basis functions is drastically reduced, and, hence the number of two-electron integrals is reduced. Then, the one-electron integrals are solved for the valence basis functions and this additional term by applying *ab initio* schemes at the self-consistent-field (SCF) level or with electron correlation (CI, MBPT, or CCSD) included. The RECP and the PP have been generated for the transactinides (Nash *et al.*, 1997; Schwerdtfeger and Seth, 1998) and quite a number of calculations have been performed for gas-phase compounds of the heaviest elements.

The next group of methods that can successfully be applied to the calculations of the ground state properties of large, chemically interesting systems are methods based on the density functional theory (DFT). This is a theory of the electronic ground state structure couched in terms of the electronic density distribution $\rho(r)$ (Kohn *et al.*, 1996; Rosen, 1997). It has become increasingly useful in calculations of the ground state density and energy of molecules, clusters, and solids, as well as of solvation and adsorption processes. It is an alternative and complementary approach to the traditional methods of quantum chemistry expressed in terms of the many-electron wave function $\psi(r_1, \ldots, r_N)$. The modern DFT is exact and the methods are accurate upon the introduction of the non-local effects via accurate exchange-correlation potentials, like the relativistic general gradient approximation (RGGA). The electronic structures of a number of the heaviest element compounds have been calculated (Bastug *et al.*, 1993; Varga *et al.*, 1999; Pershina and Bastug, 2000; Pershina *et al.*, 2001, 2002a,b) using the fully relativistic four-component RGGA DFT method. A slightly different Beijing DFT code (Liu *et al.*, 1997; Liu and van Wüllen, 1999) was used for some calculations on the simple heaviest systems. The DS discrete-variational (DS-DV) method, a predecessor of the RGGA DFT method which is intrinsically approximate, was extensively used previously by Pershina *et al.* Reviews of the systems for the heaviest elements are given in Pershina (1996), Pershina and Fricke (1999), Pershina and Hoffman (2003), and Pershina (2003).

There are many other theoretical methods appropriate for calculations of the electronic structures of the heaviest element systems, with some limitations. Their descriptions can be found elsewhere (Pepper and Bursten, 1991; Pershina, 1996; Schwerdtfeger and Seth, 1998). Presently, the combination of the PP (RECP) and DFT methods is the best way to study the electronic structures of the heaviest systems.

14.5 PREDICTIONS OF CHEMICAL PROPERTIES FOR ELEMENTS 104 THROUGH 112

14.5.1 Atomic properties

(a) Electronic configurations

Table 14.4 shows the current best calculations of the electronic configurations of the 6d element atoms and ions in comparison with their 5d homologs. The filling of the 6d shell takes place in the first nine of the transactinide elements, $Z = 104$ through 112. Relativistic changes in the energies of the 7s and 6d electrons (Fig. 14.6) result in the stabilization of the $7s^2$ electronic pair in the ground and first ionized states over the entire 7th period of the periodic table, which is different from the ground states of Pt($5d^9 6s$) and Au($5d^{10} 6s$) or from some of the 1+ and 2+ ionized states, as shown in Table 14.4. For example, the nonrelativistic configuration of element 111 is $6d^{10}7s$ according to Eliav *et al.* (1994). It was thought earlier that the relativistic stabilization of the $7p_{1/2}$ electrons of Rf (the $7s^2 7p6d$ ground state) indicated by MCDF calculations (Glebov *et al.*, 1989; Johnson *et al.*, 1990) would influence the properties of its compounds, but the $7s^2 7p6d$ electronic configuration was not confirmed by the more accurate CCSD calculations of Eliav *et al.* (1995a). Inclusion of dynamic correlation was required to obtain the correct $6d^2 7s^2$ ground state for Rf. However, the CCSD calculations of Eliav *et al.* (1995b) did confirm the $7s^2 7p_{1/2}$ ground state of Lr obtained earlier from the MCDF calculations of

Desclaux and Fricke (1980). The relativistic stabilization of the $7p_{1/2}$ electrons manifests itself in some excited states of the transactinides that are different from those of their lighter homologs. For example, the first excited state of Rf is $6d7s^27p(^3D_2)$, only 0.3 eV above its $6d^27s^2(^3F_2)$ ground state (Eliav *et al.*, 1995a), in contrast to Hf, whose first excited state is $5d^26s^2(^3F_3)$, although its ground state is $5d^26s^2(^3F_2)$. Ionized states of elements 104 through 112 show no 7p character, so properties of their compounds in the most typical oxidation states also should not be influenced by this orbital.

(b) Stabilities of oxidation states and ionization potentials

The most accurate IPs calculated for the 6d elements are given in Table 14.5. IPs for elements of the 7th period are shown in Fig. 14.8 in comparison with those of elements of the 6th period. Earlier predictions of stable oxidation states were made on the basis of atomic DF calculations as given in the review of Fricke (1975). They indicated the 4+, 5+, and 6+ states as the most stable for gaseous compounds of Rf, Db, and Sg, respectively, although in solutions the 4+ state was suggested as the most stable for Sg, though not confirmed by later calculations (Pershina *et al.*, 1999). The close proximity of the energy levels of the 7s and 6d electrons (Fig. 14.6) is the reason for the increased stability of the maximum oxidation states of the 6d elements. Indeed, recent MCDF calculations for elements 104 through 108 (Johnson *et al.*, 1990, 1999, 2002; Fricke *et al.*, 1993) have shown a decrease in the multiple IP ($0 \rightarrow Z^+_{max}$) within the transition element groups 4 through 8, as illustrated in Fig. 14.7. This is also the reason that lower oxidation states are not stable at the beginning of the 6d series: the 7s and 6d levels are spatially so close to each other that the stepwise ionization process, for example, for Db or Sg, results in the $6d^2$ and not in the $7s^2$ configuration of Db^{3+} or Sg^{4+} (Pershina *et al.*, 1999). Since the 6d orbitals of the 6d elements are more destabilized than the 4d and 5d orbitals of the 4d and

5d elements, respectively, Db^{3+} and Sg^{4+} will be even less stable than Ta^{3+} and W^{4+}. Redox potentials estimated on the basis of these MCDF calculations, as discussed in Section 14.5.3a, indicate that the 6+ state of Sg will also be the most stable in solutions (Pershina *et al.*, 1999).

Predicted stable oxidation states of elements 107 through 110 vary widely. They were discussed in an early paper of Penneman and Mann (1976) that used relativistic Hartree–Fock calculations of the gaseous ion and the hydration parameters of Jorgensen to predict that the most stable oxidation states of elements 107 through 110 in aqueous solutions would be 3+, 2+, 1+, and 0. Earlier, Cunningham (1969) predicted 7+, 8+, 6+, 6+, respectively, for oxidation states of these elements, based on extrapolation by group in the periodic table. Since the Jorgensen hydration parameters did not consider the stabilizing effects of oxyanion formation as observed experimentally for W(VI) and for Re and Os, the higher oxidation states suggested by Cunningham are probably more realistic for solutions where oxyanions can be formed. No predictions based on modern relativistic calculations have been reported for elements 107 through 110.

A most stable oxidation state of 3+ was suggested for element 111, predicted to be a noble metal. It was considered to be as reactive as Au^{3+}, but with more extensive complex formation. Oxidation state 1− was also thought to be possible by analogy to Au^-, while 1+ was predicted to be less stable than for Au. The destabilization of the 6d orbitals at the end of the transactinide series is a reason for the 6d electrons to be chemically active. As a consequence, an enhanced

stability of higher oxidation states can be expected, for example, of the 5+ states of element 111, and of the 4+ state of element 112 (Fricke, 1975; Schwerdtfeger and Seth, 1998).

It was suggested that the 2+ oxidation state of element 112 would be less stable than that of Hg as its IP_2 of 22.49 eV is larger than that for Hg of 18.75 eV (see Table 14.5). The 1+ state of element 112 also will be less stable than that of Hg (see Fig. 14.8) and probably will not be realized in element 112 at all, since compounds of Hg(I) exhibit the diatomic species $(Hg–Hg)^{2+}$. Higher oxidation states such as 4+ will surely be important in aqueous solutions and in compounds. The neutral state of element 112 is also likely to be very stable due to the inertness of the $7s^2$ electrons.

(c) Ionic radii and polarizability

The ionic radii (IR) of elements are defined by the maximum of the radial charge density, r_{max}, or the expectation values $\langle r_{nj} \rangle$ of an outer valence orbital of an ion. The DF $\langle r_{nj} \rangle$ values for elements up to $Z = 120$ were tabulated by Desclaux (1973). The MCDF r_{max} for elements 104 through 108 in various oxidation states were calculated by Johnson *et al.* (1990, 1999, 2002) and by Fricke *et al.* (1993). Using these r_{max}, IR of elements 104 through 108 were estimated by these workers using a linear correlation between r_{max} and the experimentally known IR for the lighter group 4 to 8 elements (Shannon, 1976). The predictions

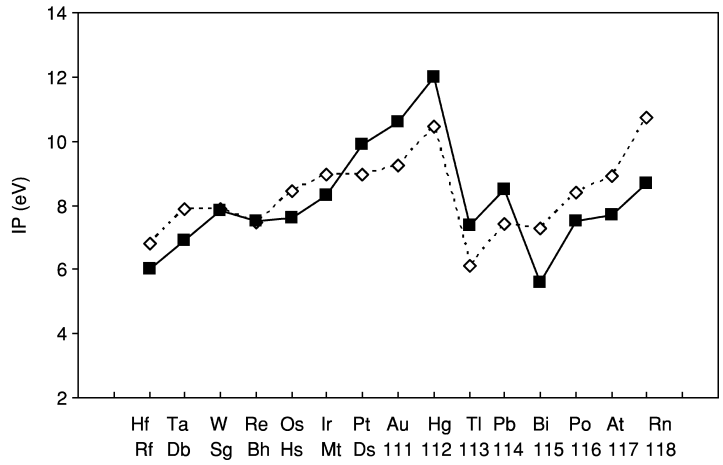

Fig. 14.8 *First ionization potentials for the* 7*th period* (*calculated, solid line*) *and the* 6*th period elements* (*experimental, dashed line*). *CCSD calculations for Rf and elements* 111 *through* 115 (*Eliav* et al., 1994, 1995*b*, 1996*a*, 1998*a*,*b*; *Landau* et al., 2001); *MCDF for elements* 105 *through* 108 (*Fricke* et al., 1993; *Johnson* et al., 1999, 2002; *Pyper and Grant*, 1981).

for the IR of Rf through Hs in their highest oxidation states are summarized in Table 14.6 and Fig. 14.7 together with experimental values for the lighter elements.

The indicated IR of the 4d and 5d elements are almost equal due to the lanthanide contraction, which is 86% a nonrelativistic effect, while the IR of the transactinides are about 0.05 Å larger than the IR of the 5d elements due to an orbital expansion of the $6p_{3/2}$ orbitals, the outer orbitals for the maximum oxidation state. Nevertheless, they are still smaller than the IR of the actinides due to actinide contraction (of 0.030 Å), which is mostly a relativistic effect. Relativistic effects on polarizability (α) change roughly as Z^2 and α should be the smallest in group 12 and in the 7th period for element 112. Its α is relativistically decreased from 74.66 to 25.82 a.u., as shown by PP CCSD(T) calculations (Seth *et al.*, 1997). As a consequence, element 112 is expected to have the weakest van der Waals bond and be extremely volatile.

14.5.2 Gas-phase compounds

(a) Electronic structures of Rf through element 112 and role of relativity

(*i*) *Rf through Hs*

A large series of calculations were performed for halides, oxides, and oxyhalides of Rf through Hs using the DFT and RECP methods: MCl_4 (M = Zr, Hf, and Rf), MCl_5 and MBr_5, $MOCl_3$, and $MOBr_3$ (M = V, Nb, Ta, and Db), MF_6 and MCl_6, $MOCl_4$, MO_2Cl_2, and MO_4^{2-} (M = Mo, W, and Sg) (Pershina, 1996, Pershina and Fricke, 1999), MO (M = Nb, Ta, and Db) (Dolg *et al.*, 1993), $M(CO)_6$ (M = Mo, W, and Sg) (Nash and Bursten, 1995; Nash and Bursten, 1999b), MO_3Cl (M = Tc, Re, and Bh) (Pershina and Bastug, 2000), and MO_4 (M = Ru, Os, and Hs) (Pershina *et al.*, 2001). Various electronic structure

[a] For CN = 4.
[b] More realistic values obtained from the geometry optimization of molecular compounds are IR = 0.76 Å for Rf^{4+} (Varga *et al.*, 2000) and 0.69 Å for Db^{5+} (Han *et al.*, 1999a).

properties such as IP, electron affinity (EA), electron transition energies, charge density distribution and bonding, as well as their trends in the groups, have been predicted.

Bonding in the compounds of Rf through Hs was shown to be typical of d-element compounds. The bonding is dominated by the large participation of both $6d_{3/2}$ and $6d_{5/2}$ orbitals. The 7s orbital, as well as both $6p_{1/2}$ and $6p_{3/2}$ orbitals, each contribute about 15% to the bonding, and this contribution is increased relative to that of the lighter homologs. The contribution of the $7p_{1/2}$ orbital of 9.4% in $DbCl_5$ is, for example, 50% larger than the contribution of the $5p_{1/2}$ orbital of Nb in $NbCl_5$ (Pershina *et al.*, 1992a). The contribution of the 6d orbitals with respect to that of the 7s and $7p_{1/2}$ orbitals is thus decreased, although it does not change the d-character of the chemical properties.

Molecular orbital (MO) levels for the highest chlorides of Rf, Db, and Sg are shown in Fig. 14.9. They are similar to those of d-element compounds. The group of binding (occupied) levels (with the upper MOs of predominantly 3p character of Cl) is separated from the group of the unoccupied levels of d-character by the energy gap ΔE. A decrease in ΔE from $RfCl_4$ to $SgCl_6$ is indicative of a decrease in the metal–ligand overlap of the atomic wave functions.

The most common feature found in the calculations for all these compounds is an increase in covalence, i.e. a decrease in the effective charge, Q_M, and an increase in the overlap population (OP), as shown in Figs. 14.10 and 14.11. The OP is the amount of the electronic density localized on the bond between atoms in a molecule and is a direct counterpart of the covalent contribution to the

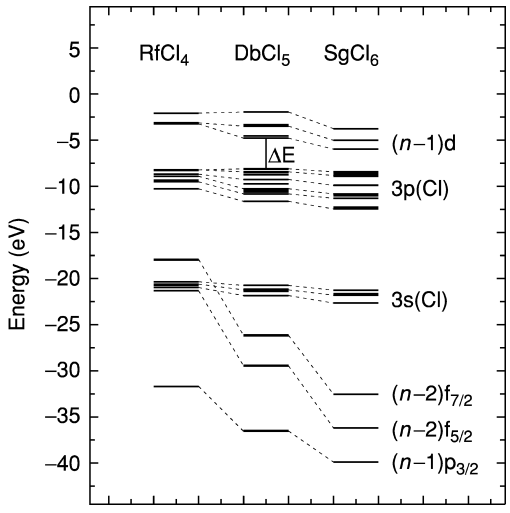

Fig. 14.9 *MO levels for $RfCl_4$, $DbCl_5$, and $SgCl_6$* (*Pershina and Fricke*, 1994).

binding energy (Mulliken, 1955). Comparison of the relativistic with nonrelativistic calculations (Fig. 14.10) shows this increase to be a purely relativistic effect due to the increasing contribution of the relativistically stabilized and contracted 7s and $7p_{1/2}$ atomic orbitals (AOs), as well as of the expanded 6d AOs in bonding (Pershina and Fricke, 1993).

Calculated molecular properties of gas-phase chlorides, oxychlorides, and oxides of groups 4 through 8 elements and of their homologs studied experimentally are summarized in Table 14.7. Results of molecular calculations (Pershina and Fricke, 1993; Pershina, 1996) have shown that relativistic effects increase IP, decrease EA, and increase the stability of the maximum oxidation state in each compound of the *n*d transition elements, with these effects increasing with increasing Z within the chemical groups. As a consequence, IP, ΔE, and the stabilities of the maximum oxidation states increase from the 4d to the 6d compounds, while the EAs decrease. Nonrelativistically, trends in all these properties would just be reversed from the 5d to the 6d compounds, similarly to the Q_M and OP shown in Fig. 14.10.

Trends in binding energies, D_e, and equilibrium bond distances, R_e, for various types of compounds are depicted in Fig. 14.12. There is a decrease in D_e for almost all of the 6d relative to the 5d element compounds except for MO_4 (M = Ru, Os, and Hs) and MCl_6 (M = Mo, W, and Sg). Within all the groups, relativistic effects enhance bonding of the compounds with increasing Z, though increasing SO splitting of the d-orbitals partially diminishes the binding energy, reaching a decrease of about 1.5 eV for 6d element compounds like SgO_2Cl_2, as shown by RECP calculations (Han *et al.*, 1999a). This is one of the reasons that most of the transactinide compounds have atomization energies lower than those of the homologous 5d elements. The other reason is a decrease in the ionic contribution to bonding, which is also a relativistic effect. The calculated R_e (Fig. 14.12) reflect the experimentally known similarities of bond lengths for the 4d and 5d compounds (due to the lanthanide contraction) and they show an increase in R_e of about 0.05 Å in the transactinide compounds compared to the 5d compounds.

Another important trend is the decrease in the metal–ligand single bond strength in going from the group 4 to the group 6 halides, as well as a decrease in the relative stability of the maximum oxidation state. As a consequence, volatile species such as $SgCl_6$ and $SgOCl_4$ are expected to decompose (a weak Sg–Cl bond) into compounds of Sg(v) at high temperatures by analogy with $MoCl_6$ and $MoOCl_4$. SgO_2Cl_2 was found to be the most stable of all the halides or oxyhalides and was, therefore, recommended (Pershina, 1996) for gas-phase chromatography experiments (Schädel *et al.*, 1997a). An increase in dipole moment, μ, of the low-symmetry molecules within the transition element groups was predicted for all the group 4 to 7 compounds (Table 14.7). The μ and α, as well as the molecular sizes, are decreased by relativistic effects. The PP calculations performed for the gas-phase MO (M = Nb, Ta, and Db) (Dolg *et al.*, 1993) have shown that relativistic effects stabilize the $^2\Delta$ ground state by 2.74 eV

(*ii*) *Mt through element* 112

Elements 109 (Mt) and 110 (Ds) have received little attention in recent years. The position of these elements in the periodic table indicates that they should be noble metals. Volatile hexafluorides and octafluorides might be produced and used for chemical separations. The relativistic DS-DV molecular calculations of Rosen *et al.* (1979) and of Waber and Averill (1974) performed for DsF_6 have shown that its electronic structure is very similar to that of PtF_6, with similar values of IP.

Earlier detailed predictions of chemical properties of element 111 based on atomic calculations were made by Keller *et al.* (1973). Due to the fact that the maximum of relativistic effects in the *n*s shell in group 11 occurs at element 111, there has been widespread interest in the electronic structure of its compounds. The effect of the 7s orbital contraction was investigated for the simplest molecule, 111H, whose electronic structure was calculated by a variety of methods including the fully relativistic DCB *ab initio* method (Seth *et al.*, 1996; Liu and

van Wüllen, 1999). The bonding was shown to be considerably increased by relativistic effects, which doubled the dissociation energy, though the SO splitting diminished it by 0.7 eV. Calculations (Liu and van Wüllen, 1999) were also performed for other dimers, AuX and 111X where X = F, Cl, Br, O, Au, and 111.

The stability of higher oxidation states of element 111 was examined in calculations of energies of the decomposition reactions $MF_6^- \rightarrow MF_4^- + F_2$ and $MF_4^- \rightarrow MF_2^- + F_2$ using the relativistic PP method (Seth *et al.*, 1998a,b). The results support the earlier predictions that the 3+ and 5+ oxidation states will be more stable for this element than they are for Au (due to a larger participation of the 6d orbitals in bonding) and that the 1+ oxidation state of element 111 may be difficult to prepare. The SO coupling was shown to stabilize the molecules in the following order: $MF_6^- > MF_4^- > MF_2$. This order is consistent with the relative involvement of the $(n-1)$d electrons in bonding for each type of molecule.

The most interesting among the heaviest elements from the chemical point of view is element 112, where the maximum of relativistic effects on the 7s shell in the entire 7th period and within group 12 occurs (see Fig. 14.5). Due to the strong relativistic contraction and stabilization of the 7s orbitals (and accordingly its highest IP in group 12) and its closed-shell configuration, it is expected to be rather inert and may be a distinctly noble metal. It was suggested that the interatomic interaction in the metallic state will be small, possibly even leading to high volatility as in the noble gases. Pitzer (1975a) estimated that the very high excitation energy of about 8.6 eV for the $6d^{10}7s^2 \rightarrow 6d^{10}7s7p$ transition into the configuration of the metallic state will not be compensated by the energy gain of the metal–metal bond formation. An extrapolation of the sublimation enthalpy from its homologs, Zn, Cd, and Hg, also suggests that element 112 should be quite volatile (Eichler, 1974). Recently, a similar conclusion was obtained by using a more sophisticated empirical model (Ionova *et al.*, 1996).

Estimates of adsorption enthalpies of element 112 on various metal surfaces using some adsorption models suggest, nevertheless, that element 112 can be deposited on some metals, like Ag, Au, Pd, or Pt (Eichler and Rossbach, 1983). The ability of element 112 to form a metal–metal bond was also predicted by recent relativistic MO calculations for 112M, where M = Cu, Pd, Pt, Ag, and Au (Pershina *et al.*, 2002a). Element 112 was calculated to form a rather strong bond with the above-mentioned transition elements, only about 15–20 kJ mol^{-1} weaker than that of HgM, with the D_e of 112Pd being the largest.

Molecular relativistic PP calculations (Seth *et al.*, 1997) have predicted that the 2+ oxidation state of element 112 will be less stable than that of Hg. They have calculated that $112F_2$ is, indeed, less stable than HgF_2 and that it will decompose readily into 112 and F_2. Seth *et al.* (1997) also came to the conclusion that element 112 should exhibit a typical transition element character in higher oxidation states, because its 6d orbitals are relativistically destabilized and, therefore, should participate more in coordination bonding. Thus, for

example, the 4+ oxidation state of element 112 as in $112F_4$ may be accessible while the 2+ state may not. In combination with an appropriate polar solvent, the species $112F_5^-$ and/or $112F_3^-$ should be formed rather than $112F_4$ or $112F_2$, although these compounds will probably undergo strong hydrolysis in aqueous solutions, and perhaps bromides or even iodides will be more stable and would be better for experimental investigations.

(b) Predictions of volatilities

A more extensive series of the DFT calculations (Pershina, 1996; Pershina and Bastug, 2000; Pershina *et al.*, 2001) permitted establishment of some relationships between molecular properties such as covalence or dipole moment and volatility. Because covalent compounds are typically more volatile than ionic compounds, the higher covalence of high-symmetry halides or oxides of the transactinides is expected to result in their higher volatilities compared with those of their 4d and 5d homologs. For example, $RfCl_4$ is expected to be more volatile than $HfCl_4$ since it is more covalent and is expected to have the T_d symmetry shown by $HfCl_4$ in the vapor phase. Low-symmetry compounds, e.g. oxyhalides of C_n symmetry, have dipole moments and, therefore, are attracted more strongly to the surface of a chromatographic column due to an additional electrostatic (dipole moment–surface charge) interaction than are high-symmetry compounds of the same element such as pure halides. Therefore, one expects that $DbCl_5$ (D_{3h} symmetry) will be more volatile than $DbOCl_3$ (C_{3v} symmetry). For low-symmetry compounds, a trend in volatility in a chemical group will be opposite to the trend in μ, since larger dipole moments cause stronger electrostatic interactions with the surface of a chromatography column. Accordingly, the following decreasing trends in volatility were predicted: $MoO_2Cl_2 > WO_2Cl_2 > SgO_2Cl_2$ and $TcO_3Cl > ReO_3Cl > BhO_3Cl$. These trends are opposite to the increasing dipole moments. Indeed, these trends were confirmed experimentally by the observations (Kadkhodayan, 1993; Kadkhodayan *et al.*,1996; Türler *et al.*, 1998b; Sylwester *et al.*, 2000) that $RfCl_4$ is more volatile than $HfCl_4$, while $DbOCl_3$ (Türler *et al.*, 1996), SgO_2Cl_2 (Schädel *et al.*, 1997a; Türler *et al.*, 1999), and BhO_3Cl (Eichler *et al.*, 2000) are less volatile than the corresponding compounds of their lighter homologs in the respective chemical groups.

In addition, enthalpies of adsorption, $\Delta H_{ads}(BhO_3Cl) = -78.5$ kJ mol^{-1} compared to $\Delta H_{ads}(TcO_3Cl) = -48.2$ kJ mol^{-1} and ΔH_{ads} $(ReO_3Cl) = -61$ kJ mol^{-1}, on the quartz surface of the chromatography column were predicted by Pershina and Bastug (2000) using a model of physisorption and by performing calculations of the electronic structures of those molecules. The obtained adsorption enthalpies indicate that volatility decreases as $TcO_3Cl > ReO_3Cl > BhO_3Cl$, in excellent agreement with the experimental value $\Delta H_{ads}(BhO_3Cl) = -77.8$ kJ mol^{-1} (Eichler *et al.*, 2000). In a similar way, $\Delta H_{ads} = -(36.7 \pm 1.5)$ kJ mol^{-1} on a quartz surface was predicted by Pershina *et al.* (2001) for HsO_4

as compared to $\Delta H_{ads}(RuO_4) = -(40.4 \pm 1.5)$ kJ mol^{-1} and ΔH_{ads} $(OsO_4) = -(38.0 \pm 1.5)$ kJ mol^{-1}. Thus, the volatility of group 8 tetroxides in the specific experiments is expected to change as $RuO_4 < OsO_4 \leq HsO_4$. Such a sequence is also expected from an extrapolation of this property within the group (Düllmann *et al.*, 2002b). This trend is in accord with the idea of increasing volatility with increasing covalence of compounds.

14.5.3 Solution chemistry

(a) Redox potentials

Some earlier estimates of oxidation states of the transactinides made on the basis of empirical modifications of the Born–Haber cycle were reviewed by Fricke (1975). They were mostly related to simple M^{z+} ions, and the results were rather inconsistent. Recently, redox potentials (E°) for complex species of Rf, Db, and Sg in aqueous solutions were estimated (Ionova *et al.*, 1992; Pershina and Fricke, 1994; Pershina *et al.*, 1999) using correlations between the MCDF-calculated IPs (Johnson *et al.*, 1990; 1999; Fricke *et al.*, 1993) and the tabulated redox potentials for group 4, 5, and 6 elements (Bratsch, 1989). Two correlation plots for groups 5 and 6 are shown in Fig. 14.13.

These estimates indicate that the stability of the maximum oxidation state increases with Z within groups 5 and 6, while that of lower oxidation states decreases. Thus, the 5+ and 6+ states of Db and Sg will be more stable than their 3+ and 4+ states, respectively. The 3+ state of Db will be less stable than the 3+ states of Nb or Ta, and the 4+ state of Sg will be less stable than the 4+ states of Mo and W.

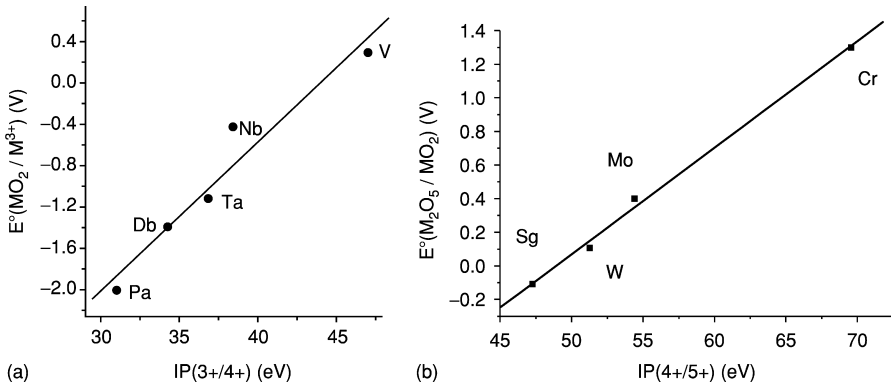

Fig. 14.13 (*a*) *Correlation between IP*(3+/4+) *and the standard potentials* $E^o(MO_2/M^{3+})$ *where M = V, Nb, Ta, Db, Pa. The standard potential for Db is from Ionova* et al. (1992). *The standard potentials for Nb, Ta, and Pa are from Bratsch* (1989). (*b*) *Correlation between IP*(4+/5+) *and the standard potentials* $E^o(M_2O_5/MO_2)$ *where M=Cr, Mo, W, and Sg* (*Pershina* et al., 1999).

The increasing stability of the maximum oxidation state and the decreasing stability of lower oxidation states at the beginning of the 6d series is a relativistic effect caused by destabilization of the 6d orbitals, as discussed earlier. Along the 6d series, the stability of the maximum oxidation state decreases in the order: $Lr^{3+} > Rf^{4+} > Db^{5+} > Sg^{6+}$. For comparison, the results are summarized in Table 14.8, together with those for Lr, the last of the actinides.

(b) Hydrolysis

Aqueous ions of transition elements undergo strong hydrolysis, as do their heaviest homologs. In acidic solutions, hydrolysis involves either the cation $M(H_2O)_n^{Z+} \Leftrightarrow MOH(H_2O)_{n-1}^{(Z-1)+} + H^+$ or the anion, or both. The hydrolysis of cations of a given oxidation state is known to decrease within groups 4, 5, and 6 as one proceeds down the periodic table and it increases from group 4 to group 6 (Baes and Mesmer, 1976). Hydrolysis/protonation of group 4, 5, and 6 cations and of their compounds was considered theoretically on the basis of relativistic DFT calculations (Pershina, 1998a,b; Pershina and Kratz, 2001; Pershina *et al*., 2002b).

For group 4 elements, about 50% of each type of the species indicated in the following equilibrium exists in aqueous solutions at pH = 0: $M(H_2O)_8^{4+} \Leftrightarrow MOH(H_2O)_7^{3+}$. For this reaction, the following trend in hydrolysis of the group 4 elements was predicted from the calculated Gibbs energy changes: Zr > Hf > Rf (Pershina *et al*., 2002b). The first hydrolysis constant

[g] Pershina *et al*. (1994).

$\log K_{11}(\mathrm{Rf}) \approx -4$ was then calculated and compared to $\log K_{11}(\mathrm{Zr}) = 0.3$ and $\log K_{11}(\mathrm{Hf}) = -0.25$. This hydrolysis sequence is in agreement with the order of extraction of group 4 elements into thenoyltrifluoroacetone (TTA) obtained in the experiments described in Section 14.6.1c(iv).

For group 5 elements and Pa, hydrolysis proceeds very rapidly, with the ultimate formation of products such as $M(OH)_5(aq)$. Hydrolysis of group 5 cations was studied theoretically for the following reaction: $M(H_2O)_6^{5+} \Leftrightarrow M(OH)_6^- + 6H^+$ where M = Nb, Ta, Db, and Pa. Calculations (Pershina, 1998a) of the Gibbs energy changes of this reaction showed that the trend toward decreasing hydrolysis is continued with Db, giving the sequence Nb > Ta > Db >> Pa.

Hydrolysis of group 6 elements proceeds even further than that of the group 5 elements, with the formation of MO_4^{2-} at higher pH according to the following scheme: $M(H_2O)_6^{6+}$ (this species is not observed) $\Leftrightarrow \ldots \Leftrightarrow [M(OH)_4(H_2O)]^{2+}$ $\Leftrightarrow [MO(OH)_3(H_2O)_2]^+ \Leftrightarrow MO_2(OH)_2(H_2O)_2 \Leftrightarrow [MO_3(OH)]^- \Leftrightarrow MO_4^{2-}$. The protonation process, the reverse of the reaction shown above, was considered theoretically (Pershina and Kratz, 2001). The resulting relative values of Gibbs energy changes suggest that for the first two protonation steps (see Table 14.12) the trend in group 6 should be W > Sg ≥ Mo rather than Sg > W > Mo. For the third and subsequent protonation processes, the trend should be Sg > W > Mo. The values of log *K* were defined for Sg, as shown in Table 14.9. The predicted trends in log *K* are in agreement with experiments on Mo and W at various pH values (Baes and Mesmer, 1976) and with Sg for the protonation/hydrolysis of the positively charged complexes (Schädel *et al.*, 1998).

(c) Complexation

If one molecular complex ML_i, among many others, is extracted into an organic phase, the distribution coefficient, K_d (expressed in terms of the complex formation constant β_i), is a good measure of its stability and the sequence in the K_d values for a given series should reflect the sequence in the stability of the complexes (Ahrland *et al.*, 1973). Thus, by predicting $\log\beta_i = \Delta G^r/2.3RT$ one

Table 14.9 *Values of log* K *for the stepwise protonation of* MO_4^{2-} (*M = Mo, W, and Sg*) (*Pershina and Kratz*, 2001).

	log K_n		
Reaction	*Mo*	*W*	*Sg*
$MO_4^{2-} + H^+ \Leftrightarrow MO_3(OH)^-$	3.7	3.8	3.74
$MO_3(OH)^- + H^+ + 2H_2O \Leftrightarrow MO_2(OH)_2(H_2O)_2$	3.8	4.3	4.1 ± 0.2
$MO_4^{2-} + 2H^+ + 2H_2O \Leftrightarrow MO_2(OH)_2(H_2O)_2$	7.50	8.1	8.9 ± 0.1
$MO_2(OH)_2(H_2O)_2 + H^+ \Leftrightarrow MO(OH)_3(H_2O)_2^+$	0.93	0.98	1.02

can predict sequences in the extraction of complexes into an organic phase or their sorption by cation- or anion-exchange resins.

Complex formation is known to increase within the transition element groups with increasing Z. However, in aqueous solutions it competes with hydrolysis as described by the following equilibrium: $x\mathrm{M(H_2O)}_{w^\circ}^{z+} + y\mathrm{OH}^- + i\mathrm{L}^- \Leftrightarrow \mathrm{M}_x\mathrm{O}_u\mathrm{(OH)}_{z-2u}\mathrm{(H_2O)}_w\mathrm{L}_a^{(xz-y-i)} + (xw^\circ + u - w)\mathrm{H_2O}$. This may change trends in the stabilities of the complexes and, consequently, their extraction into an organic phase.

(*i*) *Rf through Sg*

Complexation of group 4 elements in HF solutions is described by the following equilibria:

$$\mathrm{M(H_2O)}_8^{4+} \Leftrightarrow \mathrm{MF(H_2O)}_7^{3+} \Leftrightarrow \mathrm{MF_3(H_2O)}_5^- \Leftrightarrow \tag{14.1}$$

$$\mathrm{MF_4(H_2O)_4} \Leftrightarrow \mathrm{MF_5(H_2O)}^- \Leftrightarrow \mathrm{MF}_6^{2-}. \tag{14.2}$$

Results of DFT calculations of the relative Gibbs energy changes of these equilibria (Pershina *et al.*, 2002b) suggest that the trend in the formation of the positively charged complexes according to equation (14.1) should be Zr $\geq$ Hf $>$ Rf. This means that the K_d values for sorption by a cation resin of the positively charged complexes formed at HF concentrations below $<$0.01 M will have the following trend in group 4: Rf $>$ Hf $\geq$ Zr. (In the case of the formation of positively charged complexes of a lower charge from complexes with a higher charge (equation (14.1)), the sequence in the K_d values is opposite to the sequence in the complex formation, since complexes with a lower positive charge are more poorly sorbed on cation exchange resin than those with a higher charge.) For the formation of anionic complexes (equation (14.2)) sorbed by an anion-exchange resin, the trend becomes more complicated depending on the pH, i.e. depending on whether the fluorination process starts from the hydrated or the hydrolyzed species. Thus, for experiments conducted at HF concentrations above 0.001 M where some hydrolyzed or partially fluorinated species are present, the trend for the formation of MF_6^{2-} (equation (14.2)) and hence of K_d should be reversed in group 4: Rf $\geq$ Zr $>$ Hf.

The predicted sequences are in agreement with experiments on cation- and anion-exchange resin separations of Zr, Hf, and Rf from mixed HF/HCl solutions, where fluorinated complexes were sorbed on the resin and Cl^- ions served as counter-ions competing for its active centers (Trubert *et al.*, 1999). At high HCl concentrations, where no hydrolysis takes place, the complexation reaction is $\mathrm{M(H_2O)}_8^{4+} + 6\mathrm{HCl} \Leftrightarrow \mathrm{MCl}_6^{2-}$. Results of the DFT calculations of Gibbs energy changes for this reaction (Pershina *et al.*, 2002b) suggest that the trend in complex formation and in the K_d values should definitely be continued with Rf to give the sequence Zr $>$ Hf $>$ Rf.

Group 5 elements form a large variety of complexes, such as $M(OH)_2Cl_4^-$, $MOCl_4^-$, $MOCl_5^{2-}$, and MCl_6^- (M = Nb, Ta, Db, and Pa), in HCl solutions with different degrees of hydrolysis. Their formation is described in a general form by the following equilibrium reactions: $M(OH)_6^- + iL^- \Leftrightarrow MO_u(OH)_{z-2u}L_i^{(6-i)-}$. The DFT calculations of Gibbs energy changes for these reactions (Pershina, 1998b) showed the following trend in the complex formation and extraction of group 5 elements: Pa >> Nb $\geq$ Db > Ta. Thus, a reversal of the trend from Ta to Db was predicted for group 5 elements. The following sequence in the formation of various types of complexes as a function of increasing acid concentration was predicted (Pershina and Bastug, 1999): $M(OH)_2Cl_4^- > MOCl_4^- > MCl_6^-$. For the acids of interest, the sequence was predicted as: $MF_6^- > MCl_6^- > MBr_6^-$.

Complex formation of the group 6 elements, Mo, W, and Sg, in HF solutions is described as: MO_4^{2-} (or $MO_3(OH)^-$) + HF $\Leftrightarrow$ $MO_3F^- \Leftrightarrow MO_2F_2(H_2O)_2 \Leftrightarrow MO_2F_3(H_2O)^- \Leftrightarrow MOF_5^-$. The calculated Gibbs energy changes of these reactions show a very complicated dependence of trends in the complex formation on HF concentration and pH. Thus, at low [HF] $< \sim$0.1 M, a reversal of the trend from W to Sg should occur, while at high [HF] > 0.1 M, the trend is continued with Sg: Sg > W > Mo. It should be noted that such complicated trends could not be obtained by any extrapolation of properties within the group, but are the result of considering complex formation in equilibrium with hydrolysis and by calculating relativistically the electronic structure of the complexes.

(*ii*) *Bh through element* 112

The aqueous chemistry of these elements promises to be very interesting and should provide extensive information about complexing ability as well as information about the potential reduction reactions. Some general considerations on the basis of atomic calculations are presented by Fricke and Waber (1971); Fricke (1975). Some aspects of the complex formation of elements 107 through 112 in aqueous solution were discussed by Keller and Seaborg (1977) and Seaborg and Keller (1986). It is expected that element 112 will have extensive complex-ion chemistry, as do other elements of the second half of the 6d transition series. From early relativistic atomic calculations, Pitzer (1975a) postulated some very interesting properties for element 112 caused by relativistic effects on the $7s^2$ shell. He suggested that element 112, eka-Hg, would be more noble than Hg, and even though the oxide, the chloride, and the bromide would be unstable, $112Cl_4^{2-}$ and $112Br_4^{2-}$ would exist in solution, and $112F_2$ would be stable.

Recently, Seth *et al.* (1997) have considered the possibility of formation of $112F_5^-$ and $112F_3^-$, by analogy with Hg where the addition of F^- to HgF_2 or HgF_4 was found to be energetically favorable. However, in aqueous solutions these complexes probably undergo strong hydrolysis. Thus, experiments might only be possible with $112Br_5^-$ or $112I_5^-$.

14.6 MEASURED CHEMICAL PROPERTIES FOR ELEMENTS 104 THROUGH 112

The experimental results for Rf, Db, and Sg, the results of the first experimental investigations for Bh and Hs, and a preliminary report of experiments designed to study element 112 are briefly reviewed. Several more detailed reviews of the experimental techniques, measured chemical properties of Rf, Db (Ha), and Sg, and prospects for studies of still heavier elements are available and should be consulted for additional information (Schädel, 1995, 2002; Gregorich, 1997a; Hoffman and Lee, 1999; Kratz, 1999b).

A summary of some predicted chemical properties of elements 104 through 112 is given in Table 14.10. First experimental investigations of the chemical properties of the transactinides focused on the most fundamental and simplest properties. For example, the determination that the most stable oxidation states of elements 104 and 105 in aqueous solutions were 4+ and 5+, respectively, allowed their placement at the bottom of groups 4 and 5 in the periodic table as members of the 6d transition series. In later experiments, attempts were made to perform more complex studies of transactinide properties for comparison with their lighter homologs in the periodic table. Such studies present even greater challenges because of the need to investigate the transactinides and their lighter homologs under exactly the same chemical conditions – the ideal situation being to measure them all in the same on-line experiments conducted at the accelerators where they are produced.

14.6.1 Chemistry of rutherfordium (104)

(a) Historical

In early gas-phase studies at Dubna, Zvara *et al.* (1969, 1970) reported that the chloride of a 0.3-s SF activity produced in the ^{242}Pu(^{22}Ne,4n) reaction and initially assigned to ^{260}Rf formed a chloride, presumably $RfCl_4$, that was less volatile than $HfCl_4$. However, the existence of such an isotope has never been confirmed (see Fig. 14.2) and these claims were apparently incorrect as discussed in detail by Kratz (1999b). Zvara *et al.* (1972) later proposed that they were actually measuring the SF branch of the known alpha-emitting 3-s ^{259}104, which was produced in the same experiments via the ^{242}Pu(^{22}Ne,5n) reaction. They then reported that the volatility of the Rf tetrachloride was similar to that of $HfCl_4$ and much more volatile than the chlorides of the actinides and Sc. They concluded from their results that Rf properly belonged to group 4 of the periodic table. However, only SF events were measured and there is still some doubt about the magnitude of the SF branch of ^{259}104, which decays predominantly by alpha emission. The results could not be considered definitive because positive identification of the element being studied was not possible since only SF decay was detected.

Studies of the solution chemistry of element 104 were conducted in 1970 by Silva *et al.* (1970b) using 75-s ^{261}Rf (see Table 14.3). Positive identification of ^{261}Rf was made by measuring its known half-life and characteristic alpha-decay sequence. Elutions with α-hydroxyisobutyrate solutions from cation-exchange resin columns were used to compare the behavior of ^{261}Rf with No^{2+}, trivalent actinides, Hf^{4+}, and Zr^{4+}. In several hundred repetitive experiments in which 100 atoms were produced for study, the behavior of element 104 was shown to be similar to that of the group 4 elements Zr and Hf, which did not sorb on the column. Its behavior was entirely different from that of No^{2+} and the trivalent actinides that did sorb on the column at pH 4.0.

Some time later, Hulet *et al.* (1980) used ^{261}Rf to perform further experiments to compare the anionic chloride complexes of Rf with those of Hf, Cm, and Fm. Extraction chromatography with a column containing trioctylmethylammonium chloride on an inert fluorocarbon powder was used rather than an ion-exchange resin column because of the faster kinetics. The products recoiling from the nuclear reaction were transported to a fast computer-controlled apparatus that performed the many repetitive experiments necessary to get statistically significant information. The results showed that in 12 M HCl solutions the anionic chloride complexes of Rf and the Hf tracer were strongly extracted by the quaternary amine while the trivalent actinides were not and ran through the column. The chloride complexation of Rf was clearly similar to Hf and much stronger than that of the trivalent actinides, again confirming its position in group 4 of the periodic table. This experiment is especially noteworthy in that it was the first sophisticated, computer-controlled automated system to be used to perform very rapid solution chemistry experiments on an atom-at-a-time basis.

Following these pioneering studies of Rf, a rather long period of time elapsed before additional experiments were conducted in the late 1980s. MCDF calculations (Desclaux and Fricke, 1980; Glebov *et al.*, 1989) indicated that relativistic effects might cause replacement of the expected 6d orbital in Lr by $7p_{1/2}$ orbitals. Spurred by Keller's (1984) extrapolation that Rf might have the configuration $7s^27p^2$ rather than $6d^27s^2$ as expected by analogy to the $5d^26s^2$ configuration of Hf, experimental investigations of relativistic effects in Rf were undertaken. In 1989, Zhuikov *et al.* (1989) examined the volatility of 3-s ^{259}Rf relative to Au, Tl, and Pb tracers in on-line measurements in a quartz column at 1170°C. Under reducing conditions using Ar/H_2 carrier gas, they found that Hf and Rf did not pass through the column while the other elements did. They deduced a lower limit of 370 kJ mol^{-1} for the sublimation enthalpy of metallic 104, much higher than for Pb and other heavy 'p-elements'. Later MCDF relativistic calculations (Glebov *et al.*, 1989; Johnson *et al.*, 1990) indicated that the ground state of Rf is 80% [$6d7s^27p$] while the $7s^27p^2$ state is 2.9 eV above the ground state. Zhuikov *et al.* (1990) and Ryzhkov *et al.* (1992) further concluded that there was no basis for expecting any distinct 'p-character' in the chemical properties of Rf and evaluated various experimental approaches for investigating relativistic effects, including volatilities in the elemental state,

thermochromatography of tetrahalides, and the stability of lower oxidation states. Zhuikov *et al*. warned that gas chromatography experiments that depend on Rf or Hf in the atomic state are not useful for investigating relativistic effects because of the difficulty in stabilizing the atomic states at the temperatures above 1500°C that are needed for chromatography columns. However, they suggested that thermochromatography of the tetrahalides appeared promising.

(b) Gas-phase chemistry

In the late 1980s an international team of scientists from Switzerland, Germany, and the USA studied the gas-phase properties of the tetrahalides of Rf using the automated isothermal systems OLGA (Türler *et al*., 1996) and HEVI (Kadkhodayan *et al*., 1992). The alpha-emitting isotope 75-s ^{261}Rf (see Table 14.3), produced at the LBNL 88-Inch Cyclotron, was used in the experiments and was positively identified by using surface barrier detectors to measure α–α correlations from its known decay scheme. The Zr and Hf activities were identified via gamma spectroscopy. A schematic diagram of HEVI and the arrangement used in some of the gas-phase studies of element 104 tetrachlorides and tetrabromides at LBNL is shown in Fig. 14.14.

The adsorption enthalpies on the SiO_2 surface of the column were calculated from Monte Carlo fits to the measurements of the relative yields as a function of the isothermal temperature between about 100 and 600°C. The Monte Carlo model was introduced by Zvara (1985) and adapted for use with isothermal gas chromatography by Türler (1996). The calculation takes account of the flow rate, half-life of the isotope, temperature, and other variables to generate yield curves as a function of temperature. A rather complete description of this model has been given by Gäggeler (1997). The adsorption enthalpies resulting from the most recent experiments on the tetrabromides (Sylwester *et al*., 2000) are shown, together with those for the tetrachlorides (Kadkhodayan *et al*., 1996), in Fig. 14.15.

Under these conditions, Rf produced volatile $RfCl_4$ at about the same temperature as $ZrCl_4$, indicating their similar volatilities. $HfCl_4$ was unexpectedly less volatile. The analysis of the data using the Monte Carlo model gave the following ΔH_{ads} for group 4 chlorides on SiO_2: –(74 ± 5) kJ mol^{-1} for Zr, –(96 ± 5) kJ mol^{-1} for Hf, and –(77 ± 6) kJ mol^{-1} for Rf (Fig. 14.14). $RfCl_4$ showed about the same volatility as $ZrCl_4$ within the error bars as expected from relativistic calculations (Pershina and Fricke, 1994). 'Nonrelativistic' extrapolations gave lower volatility for $RfCl_4$ (Türler *et al*., 1996). The observation of the relatively high volatily of $RfCl_4$ was a confirmation of the influence of relativistic effects. Experiments with the bromides showed that they are generally less volatile than the chlorides and that $RfBr_4$ is more volatile than $HfBr_4$ (Fig. 14.14), in agreement with theoretical predictions (Pershina and Fricke, 1999). No attempts to measure the volatilities of the fluorides have yet been reported.

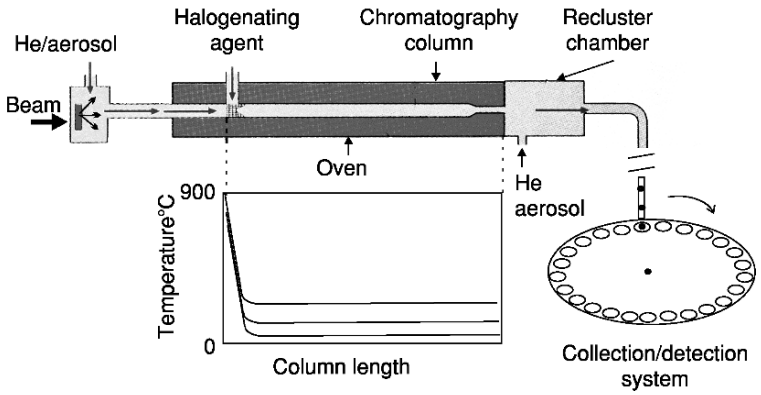

Fig. 14.14 *Schematic diagram of a system used for gas-phase studies is shown. The recoiling products from the reaction are attached to either KCl, KBr, or* MoO_3 *aerosols and transported in He gas to the entrance to HEVI where they were deposited on a quartz wool plug and halogenated at* 900°C. *Volatile products are transported through the quartz column in flowing He gas and are again attached to aerosols and transported in a gas-jet system and deposited on thin polypropylene films placed on the periphery of a horizontal wheel that is rotated so as to position the foils successively between pairs of surface barrier detectors for* alpha *and SF spectroscopy.*

(c) Solution chemistry

Additional experimental investigations of the solution chemistry of Rf were initiated in the late 1980s. Manual studies to compare the extraction from aqueous solutions into triisooctylamine (TIOA), tri-*n*-butylphosphate (TBP), and TTA of 75-s ^{261}Rf, its lighter homologs Zr and Hf, and the pseudohomologs Th(IV) and Pu(IV) were reported by the Berkeley group (Czerwinski, 1992b; Czerwinski *et al*., 1994a,b; Bilewicz *et al*., 1996; Kacher *et al*., 1996a,b; Hoffman and Lee, 1999). A comprehensive review and summary, as of 1997, of the results from experiments on the extraction behavior of Rf was given by Gregorich (1997a). Later studies used ARCA for repeated chromatographic studies and SISAK for very rapid automated liquid–liquid extractions (Alstad *et al*., 1995; Omtvedt *et al*., 2002).

(*i*) *Extraction of anionic species*

Batch extractions

In repeated manual extractions taking about a min each and using only microliters of each phase, the effect of chloride concentration and pH on extractions into TIOA were investigated. In general, these extractions (Czerwinski *et al*., 1994a,b; Kacher *et al*., 1996a,b) confirmed the earlier results (Hulet *et al*., 1980), showing that Rf generally behaves as a group 4 element, and unlike the trivalent actinides, forms negatively charged complexes in concentrated HCl that are extracted efficiently. Rf is nearly 100% extracted into TIOA from 12 M HCl, as are Zr and Nb, while Th and trivalent actinides and lanthanides are poorly extracted.

Extractions into TIOA/xylene from HF solutions were also performed (Kacher *et al*., 1996b). Although there were some experimental difficulties with the experiments, they clearly showed that Rf was extracted from 0.5 M HF but not from 4 M HF. This was attributed to the extraction of F^- at the higher fluoride concentrations, which complexes all of the TIOA, thus limiting the extraction of the anionic metal fluoride complexes. The extractability of the group 4 elements was found to decrease in the order: Ti > Zr ~ Hf > Rf. This behavior was cited as evidence that the equilibria for the group 4 elements are the same and that Rf is extracted in the chemical form RfF_6^{2-} similarly to Ti, Zr, and Hf, which are extracted as MF_6^{2-} complexes.

Column separations

Pfrepper *et al*. (1998) produced ^{261}Rf and $^{165–169}$Hf isotopes (few-minute half-lives) simultaneously at the Dubna U-400 cyclotron and devised a multi-column technique for continuous on-line processing and detection of ^{253}Es, the long-lived descendant of ^{261}Rf. Using an anion-exchange column with 0.27 M HF/0.1–0.2 M HNO_3 as the eluant, Es was eluted and measured to obtain the K_d values for Rf, which were nearly the same as those for Hf. The ionic charge of

the Rf complex was obtained from measurements of K_d vs. [HNO_3]. The ionic charge was calculated to be –(1.9 ± 0.2), similar to that of Hf, indicating formation of RfF_6^{2-}. This again indicates that Rf is similar to Hf and to other members of group 4. The technique, though extremely complex, ensures that equilibrium has been attained and has the virtue of measuring both Rf and Hf in the same experiment. However, it does not give any additional information about specific differences in the chemical behavior of Rf and of its lighter homologs and pseudohomologs.

Other researchers (Haba *et al.*, 2002) used batch extractions with an anion-exchange resin (CA08Y) to determine K_d values for the Rf homologs Zr and Hf, and the pseudohomologs Th(IV) and Pu(IV) as a function of HCl and HNO_3 concentrations in order to determine appropriate conditions for on-line studies with ^{261}Rf and ^{169}Hf at the same time. They then performed on-line measurements of ^{261}Rf and ^{169}Hf produced in ^{18}O-induced reactions with a ^{248}Cm target containing natural Gd, to study their sorption behavior on this anion-exchange resin in solutions of 1.0–11.5 M HCl and in 8 M HNO_3 using an automated ion-exchange separation apparatus coupled to an alpha-spectroscopy detection system. They found that the adsorption of Rf increased steeply with increasing HCl concentration between 7.0 and 11.5 M, as did the adsorption of Zr and Hf, indicating that like Zr and Hf, anionic complexes such as $Rf(OH)Cl_5^{2-}$ or $RfCl_6^{2-}$ are formed. Their results are consistent with previous experiments with Aliquat 336 (Hulet *et al.*, 1980) and TIOA (Czerwinski *et al.*, 1994a). The adsorption order in the region of 9 M HCl was Rf > Zr > Hf. This behavior is quite different from that of Th(IV), whose distribution coefficients are less than 1 and further decrease in this region. In 8 M HNO_3, more than 80% of Rf, Hf, and Zr were eluted while 99% of the pseudohomolog Th(IV) was retained, indicating that Rf, like Hf and Zr, formed cationic or neutral species, unlike Th(IV) or Pu(IV).

(*ii*) *Extraction of neutral complexes with TBP*

It is well known that TBP extracts neutral complexes by forming adducts with neutral metal salts that are extractable into the TBP organic phase. The adduct is presumed to have the form $ML_4 \cdot xTBP_{(org)}$ where x can be determined by measuring the slope of log K_d as a function of log [TBP]. If the TBP concentration is too high, aggregation of the TBP molecules may give erroneous results. Furthermore, there are very large statistical uncertainties in determination of K_d values when the small number of atoms produced is measured only in the organic phase. The calculation of K_d = (extraction yield)/(1−extraction yield) is probably only accurate for relatively small K_d values because if the K_d values are high the denominator becomes a very small difference between two very similar numbers with large errors. Extractions from HCl into TBP are also unusually dependent on both [H^+] and [A^-], indicating that hydrolysis plays an important role.

Batch extractions

Extractions of ^{261}Rf, Hf, Zr, Th, and Pu into TBP were first studied by Czerwinski *et al*. (1994b) using manual extractions from aqueous solutions of 8, 10, and 12 M HCl, with $[H^+]$ held constant at 8, 10, and 12 M and $[Cl^-]$ adjusted with LiCl to 8, 10, and 12 M. The Zr, Th, and Pu(IV) results were obtained from off-line tracer experiments. In pure HCl solutions, the extraction of Pu, Th, and Zr was nearly 100% at all three molarities, consistent with previously reported (Peppard *et al*., 1956) data for Zr and Th, while extraction of Rf and Hf was low at 8 M and increased to higher values at 10 and 12 M HCl. Extraction of Hf remained lower than that of Rf at all molarities. With $[H^+]$ held at 8 M, an increase in $[Cl^-]$ to 10 and 12 M resulted in significant decreases of both Rf and Pu extraction into TBP/benzene while extraction of Zr, Hf, and Th remained high. This was interpreted as indicating that chloride complexation is stronger for Rf than for Zr, Hf, and Th, and that Rf, similarly to Pu(IV), forms anionic species of the type MCl_6^{2-}, which does not extract into TBP. The trends in extraction yields vs. $[H^+] = 8$, 10, and 12 M for $[Cl^-]$, which are constant at 12 M, show that the Hf yields are independent of $[H^+]$ and remain nearly constant between 75 and 80% while the extraction yields for Rf sharply increase, indicating different extraction mechanisms for Rf and Hf. At the highest $[Cl^-]$ concentrations, the extraction yield for Hf follows that of Th, which does not form anionic chloride complexes, while the trend for Rf follows Pu(IV), which does. Problems with losses of Rf and Hf on Teflon collector foils used in some of the on-line studies resulted in absolute values that were probably too low for the higher K_d values. Nevertheless, much useful information can be obtained from an examination of relative extraction yields.

The extractability decreases in the order Zr > Pu > Rf > Hf > Th for 8 M HCl, in the order Zr > Pu > Rf ~ Th > Hf for 10 M HCl, and in the order Zr ~ Rf ~ Pu > Th > Hf for 12 M HCl. A striking observation that needs to be investigated further is that with $[H^+]$ held constant at 8 M the extraction of Rf increases to ~80% when $[Cl^-]$ is increased to 10 M and then decreases sharply to ~25% when $[Cl^-]$ is increased to 12 M, similar to the extraction of Pu(IV), which decreases to less than 20% while that of Zr remains at ~100% and Hf and Th increase to 80–90%. This would indicate formation of an anionic species of Rf similar to $PuCl_6^{2-}$ and unlike all the other group 4 elements and Th. Extraction as a function of $[H^+]$ between 8 and 12 M with $[Cl^-]$ constant at 12 M indicated little effect on the extraction of Zr and Hf, but the extraction of Rf increased from 25 to ~100%. The extracted complex might be of the type $RfCl_4 \cdot x HCl \cdot y TBP$, where x is 1 or 2, values that have been observed in extraction of other elements into TBP.

Kacher *et al*. (1996a) conducted studies to compare extractions of these elements from HBr solutions into TBP with the results of the previous HCl/TBP experiments. They expected the stability of the bromide complexes to differ from that of the HCl complexes because bromide is a larger and more polarizable anion than chloride. They found that the most likely extracted form of Zr

was $ZrBr_4 \cdot \sim 1TBP$ for the HBr/TBP system and $\sim 2TBP$ for the HCl/TBP system. In general, the extraction of these elements from HBr is much lower than from HCl, and 0.35 M TBP was used to obtain increased extraction. At 9 M HBr, essentially no Rf was extracted but increasing $[Br^-]$ with LiBr to 10, 12, and 13 M resulted in more than 88% extraction of Zr and Rf and ~80% extraction of Th throughout this range while extraction of Pu(IV) increased from about 25 to 70%. In these experiments, Pt collection foils were used to avoid losses of the on-line cyclotron-measured isotopes Rf and Hf. (The Pu tracer was fumed with $NaNO_2$ to make sure it was in the tetravalent state.) Extraction as a function of [HBr] from 7.75 to 9 M HBr solutions was investigated, but without addition of LiBr neither Th nor Rf was extracted. Zr begins to extract at a somewhat lower concentration than Hf, indicating a somewhat stronger tendency to form neutral complexes; Ti extracted only above 9 M HBr. Thus the order of extractability is Zr > Hf >> Ti ~ Rf, a reversal in the trend Zr > Rf > Hf seen in the HCl/TBP extractions. Experiments to examine the extraction at concentrations up to 12 M HBr are necessary to confirm this trend.

Column experiments

In order to check and resolve some of the differences in the previously reported results for the TBP/HCl system, Brüchle *et al*. (1998) and Günther *et al*. (1998) measured K_d values for the TBP/HCl system for the carrier-free radionuclides ^{98}Zr (from fission), and ^{169}Hf and ^{261}Rf produced on-line at the Paul Scherrer Institute (PSI) cyclotron. The recoiling products were transferred via He(KCl) jet to ARCA II whose 40 microchromatographic columns (1.6-mm diameter × 8-mm long) were filled with the inert support Voltalef™ (Lehmann & Voss, Hamburg, Germany) coated with undiluted TBP. The use of undiluted TBP is expected to shift the complete extraction of both Zr and Hf to higher HCl concentrations, as shown earlier (Czerwinski *et al*., 1994b), and prior batch experiments from >10 M HCl confirmed this. From 8 M HCl, 80% Zr and only 20% Hf extraction was found. Chromatographic separations of Zr and Hf were then conducted with ARCA. The radioactive ions were sorbed from 12 M HCl. Most (75%) of the Hf and no Zr were eluted with 8 M HCl and then the remaining Hf and Zr were stripped with 2 M HCl. The K_d for Hf was calculated to be 53 from the relationship, $K_d = [(100)(\%aq)^{-1}–1][vol_{aq}/vol_{org}]$, consistent with batch measurements. Subsequent experiments to determine the K_d for Rf in 8 M HCl were conducted at the PSI cyclotron in the same way. After 90 s collection times, the reaction products were sorbed on the columns in 12 M HCl. Hf and Zr fractions were eluted with 8 and 2 M HCl, respectively, and analyzed for alpha decays from ^{261}Rf and its daughter ^{257}No. Two α–α mother–daughter correlations were observed in the Hf fraction and three in the Zr fraction, indicating that Rf extraction is somewhere between that of Hf and Zr in 8 M HCl. After lengthy and complex considerations of contributions from random and background effects, they (Günther *et al*., 1998) concluded that the K_d for Rf is 150 compared to the K_d of 1180 for Zr and of 60 for Hf obtained

from the batch experiments with 8 M HCl, giving the order of decreasing extraction Zr > Rf > Hf. The percentage extraction in their work, 52% for Rf and 25% for Hf from 8 M HCl, appears to be consistent with that of ~60% for Rf and ~25% for Hf obtained by Czerwinski *et al.* (1994b). In a detailed discussion of corrections for the differences in volumes used in the two studies and the dependence of the equilibrium constant on the differences in the TBP concentrations in the organic phase, they finally concluded that Czerwinski's K_d values for Hf and probably for Rf are significantly too low (probably due to sorption on the Teflon collection foils), but that their K_d values were also lower than expected for undiluted TBP because of aggregation effects.

Thus it appears that measurements of relative extractability can be obtained for experiments carried out under exactly the same conditions, but that determination of absolute K_d values is subject to numerous difficulties. The inconsistencies in the K_d results reported by various researchers are probably due in large part to differences in the exact details of the experimental conditions and can greatly affect the measurements, as pointed out above. In addition, results of on-line experiments for the transactinides often are compared with results of off-line tracer studies of their homologs. Furthermore, in the very rapid separations with ion-exchange resin columns required in the study of short-lived isotopes it is necessary to make sure that equilibrium is attained in order to obtain valid results. Some evidence of non-equilibrium effects was reported by Paulus *et al.* (1999) for most amines other than Aliquat 336 and will require further study. Care must be taken in batch experiments to remove any fluoride ion that may have been present in stored tracer solutions. Kacher *et al.* (1996b) found that fluoride ion concentrations as low as 0.02 M reduced the K_d values for extraction into TBP from HBr by about 2 for Hf and 10 for Zr.

(*iii*) *Extraction of fluoride complexes*

Cationic complexes

The fluoride complexation of Zr, Hf, ^{261}Rf, and Th in mixed HNO_3/HF solutions was investigated (Strub *et al.*, 2000) by studying K_d values for both anion- and cation-exchange resins using ARCA. A detailed study of the complexation as a function of fluoride- and nitrate-ion concentrations was performed. They found all four elements to be strongly sorbed on the cation-exchange resin Aminex A6 at HF concentrations below 0.001 M. The K_d values for Zr and Hf decreased between 0.001 and 0.01 M HF, presumably due to the formation of fluoride complexes. Those for Rf and Th decreased at an order of magnitude higher HF concentrations, and the K_d for Rf remained very high even in 0.01 M HF. The K_d for Rf was found to be >148 in 0.1 M HNO_3/5×10^{-4} M HF while under these conditions ^{265}Sg had been found to elute (Türler *et al.*, 1998a). As discussed in Section 14.5.3c (Eqs. 14.1 and 14.2) at [HF] < 0.01 M, positively charged complexes of higher charge will be formed, which will sorb on the cation resin. The observed order of sorption Rf > Hf ≥ Zr

corresponds to the opposite trend in the complex formation, as discussed in Section 14.5.3c, in agreement with theoretical predictions.

Anionic complexes

Trubert *et al.* (1999) determined distribution coefficients for Zr, Hf, and Rf on the macroporous anion exchanger Bio-Rad (Bio-Rad Laboratory, Hercules, CA, USA) AG® MP-1 from HF/HCl media with concentrations between 0.02 M and concentrated HF and [HCl] $\leq$ 0.8 M. They used batch experiments with Zr and Hf tracers and examined the K_d values as a function of free H^+, Cl^-, and F^- species in solution. They performed on-line column experiments using their automated system at the tandem accelerator at Orsay where ^{261}Rf and ^{167}Hf were produced.

A rather complicated two-column technique (Pfrepper *et al.*, 1998) was used in which the Rf or Hf parents were partially sorbed on a first anion-exchange resin column and the remainder plus the trivalent decay products Fm and Lu are sorbed on a subsequent cation-exchange resin column. One-hour irradiation times were used and the longer-lived ^{253}Fm–^{253}Es granddaughters of ^{261}Rf were finally measured to deduce the K_d for Rf. The one K_d value for Rf obtained for 0.02 M HF/0.4 M HCl was slightly higher than those for Zr and Hf, respectively, in agreement with the theoretically predicted trend Rf $>$ Hf $\geq$ Zr (Section 14.5.3c), but more data are needed before any conclusions can be drawn.

An increase in K_d values for Zr and Hf was observed by Strub *et al.* (2000) with the anion-exchange resin (similar to Bio-Rad AG®1-X8) and solutions between 0.001 and 0.01 M HF, consistent with the observation of decreasing values in the HF range for the cation-exchange resin. Surprisingly, the results of the experiments showed that again Rf and Th behaved differently from Zr and Hf and did not show the high K_d values expected for anionic fluoride complexes even at HF concentrations as high as 1 M. Rf seemed to resemble Th rather than Zr and Hf, which was different from the theoretical predictions (Pershina *et al.*, 2002b). There were indications that the action of the counter-ion was responsible for the unexpected behavior, and by varying the NO_3^- concentration Strub *et al.* (2000) were able to show that Rf did form anionic species, but apparently NO_3^- competed more effectively than F^- for the binding sites on the anion resin. Additional experiments are needed to investigate the effect of varying [NO_3^-] at constant [F^-] and varying [F^-] at much lower [NO_3^-].

(*iv*) *Extraction of cationic complexes*

TTA batch extractions

The chelating agent TTA extracts cationic species from aqueous solutions. Its electron donor groups are oxygen atoms and the tendency for different metals to be extracted is a measure of their affinity for oxygen atoms. This affinity should have a strong correlation with the log of the first hydrolysis constants of the metal ions. Thus TTA can be used to obtain information about hydrolysis of the group 4 ions.

The Berkeley group (Czerwinski, 1992b) performed some preliminary measurements of the extraction of the group 4 elements, Th, and Pu from 0.1 and 0.4 M HCl into 0.5 M TTA/benzene. The initial measurements gave K_d values, decreasing in the order Zr > Hf ~ Pu > Rf > Th, similar to the decreasing values of the logs of the first hydrolysis constants that have been measured for Zr, Hf, Th, and Pu (Baes and Mesmer, 1976). These extraction results are discussed by Gregorich (1997b), who states that on this basis the tendency for Rf to hydrolyze should be between that for Th and Pu and less than that for Zr and Hf. This prediction is in agreement with the theoretical calculation for the hydrolysis of group 4 elements (Pershina *et al.*, 2002b). However, more tracer measurements of the effect on extraction as a function of [HCl] and [TTA] are needed to determine if the equilibria involved in the extraction of Pu and Th are the same as for the group 4 elements. The kinetics of TTA extractions are relatively slow so they may not be the best choice for rapid separations of short-lived species.

HDBP extractions with SISAK

The SISAK microcentrifuge liquid–liquid extraction system described in Section 14.3.3b was used to study extraction of 4.7-s ^{257}Rf [1] from 6 M HNO_3 and 0.25 M dibutylphosphoric acid (HDBP) in toluene. ^{257}Rf was produced at the LBNL 88-Inch Cyclotron in the ^{208}Pb(^{50}Ti,n) reaction, with a cross section of ~10 nb.[1] In preliminary test experiments, ^{257}Rf was pre-separated in the BGS, which reduced unwanted background activities by more than three orders of magnitude, and then transferred to the specially designed Recoil Transfer Chamber (RTC) attached at the BGS focal plane (Kirbach *et al.*, 2002). The Rf ions passed from the BGS detector chamber (held at a pressure of only 1.3 mbar) through a thin Mylar window into the RTC containing He gas whose pressure could be varied from 480 to 2000 mbar, as appropriate, to stop the separated ions. The positive identification of Rf atoms entering the RTC was accomplished by measuring their α decay with an array of Si-strip detectors and six to seven ^{257}Rf–^{253}No α–α correlations per hour were found in these experiments. They were then sorbed on aerosols in a He/KCl gas-jet system and transported without chemical separation directly to the SISAK liquid scintillation detection cells. The transport time was measured with $^{170-x}$Hf isotopes (half-lives > 1 min) produced at the same time in ^{120}Sn(^{50}Ti,xn) reactions. An alpha event in the appropriate preset energy range caused the cell to close and to switch to daughter mode. The cell remained closed for more than five ^{253}No ($t_{1/2}$ = 1.6 min) daughter half-lives. In this way an α–α correlation matrix was successfully obtained and clearly showed that the SISAK liquid scintillation system could detect nuclides at a rate of less than one atom per hour. A number

[1] ^{257}Rf has been reported (Hessberger *et al.*, 1997) to have a metastable state with a half-life of ~4.0 s from which ~60% of the α-decay is estimated to originate and a ground state that α-decays with a half-life of ~3.5 s, but this has not yet been confirmed. Both decay primarily by α-emission so for the purposes of this experiment it makes very little difference.

of other important improvements including pulse-shape discrimination to reduce the beta-background, real-time scintillation yield monitoring by continuous measurement of the Compton edge of ^{137}Cs γ-rays, and improvements in the detection cell efficiencies were also made. Experimental details of the system have been published (Omtvedt *et al.*, 2002). The pre-separation thus permits designing studies of the chemical properties of Rf without the necessity for adding time-consuming and yield-loss steps to remove radioactive isotopes that would interfere with its detection and measurement.

After this successful demonstration, liquid–liquid extraction experiments were performed to compare the extraction behavior of Rf from 6 M HNO_3 into 0.25 M HDBP/toluene with that of its lighter homologs Zr and Hf. A schematic diagram of the setup is shown in Fig. 14.16. The activity-containing aerosols in the He jet are dissolved in the 'de-gasser' centrifuge containing 6 M HNO_3 and the He gas is removed. The main extraction is performed in the next centrifuge. An important step is to wash any dissolved HNO_3 from the organic phase before adding the scintillator ingredients because the acid will cause degradation of the energy resolution, as will any O_2. It is removed by sparging with He, which is removed in the last centrifuge. Flow rates of the order of 0.4–0.8 ml s^{-1} were used and the centrifuges typically operate at 25000–40000 rpm. This was the first time a transactinide, Rf, was extracted and unequivocally identified by the SISAK liquid scintillation system and demonstrates that this method can be used to investigate the chemical properties of the transactinides. The results indicate that Rf behaves similarly to Zr and Hf, as expected. In this demonstration, the conditions were chosen to maximize extraction of Rf and the other group 4 elements rather than to investigate possible differences among them. The next step will be to use the pre-separation technique to conduct experiments with chemical systems designed to distinguish differences in the behavior of individual elements within a periodic table group.

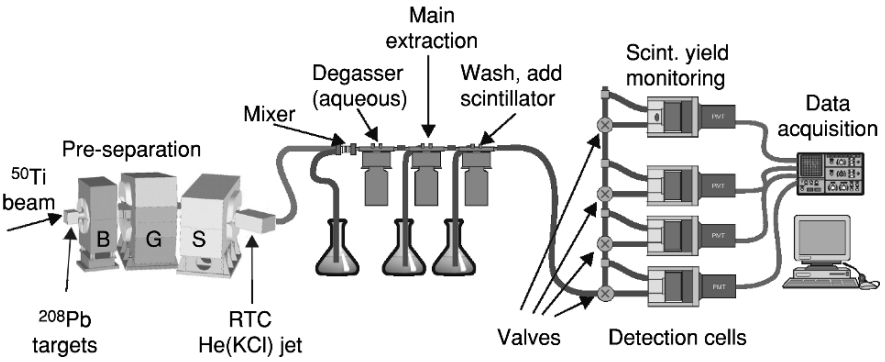

Fig. 14.16 *Schematic diagram of a typical SISAK liquid–liquid extraction configuration with BGS as a pre-separator.*

14.6.2 Chemistry of dubnium/(hahnium) (105)

As discussed in Section 14.5 and shown in Tables 14.4–14.6, the ground state configuration for element 105 is predicted to be $6d^37s^2$ although the relativistic destabilization of the 6d electrons and the close proximity of the 7s and 6d levels should stabilize the higher oxidation states of the 6d elements relative to their 5d homologs. Thus, the most stable oxidation state of Db is expected to be 5+ and the 3+ and 4+ states are even less stable than in its lighter homolog Ta.

(a) Historical

In the only published studies of the early chemistry of element 105, Zvara *et al.* (1974, 1976) reported investigations of the volatilities of the chlorides and bromides of element 105 with 1.8-s ^{261}Db compared to those of Nb and Hf. They used a thermochromatographic system similar to that used in the studies of Rf. Again, they detected SF events from the SF branch in mica track detectors placed along the chromatography column. After corrections for the much shorter half-life of ^{261}Db, the distribution of the fission tracks was compared with the adsorption zones of the tracers (3.3-min ^{169}Hf and 14.6-h ^{90}Nb). From these experiments, Zvara *et al.* concluded that the volatility of Db bromide was less than that of Nb bromide and about the same as that of Hf bromide. Again, only SF events were detected and because the SF branch ($\leq$18%?) is still not well known, it is not certain that the detected fissions belonged to element 105. A complete discussion of these early results was given by Hyde *et al.* (1987), who interpreted these results as indicating that Db behaved more like the group 4 element Hf than like Nb and Ta.

(b) Solution chemistry

No further studies of element 105 chemistry were reported until 1988 when Gregorich *et al.* (1988) reported the very first study of its behavior in aqueous solutions. These experiments were undertaken simply to show whether its most stable oxidation state in aqueous solution was 5+. At that time it had been postulated (Keller, 1984) that Ha might have a $7s^26d7p^2$ rather than a $6d^37s^2$ valence configuration expected by analogy with Ta, whose most stable state in aqueous solution is 5+. The α-emitting, 35-s ^{262}Db (then called Ha), produced in the reaction of ^{18}O with the radioactive target, 320-d ^{249}Bk (see Table 14.3) at the LBL 88-Inch Cyclotron, was used. The recoiling reaction products attached to KCl aerosols were transferred from the target system and outside the cyclotron shielding via a He gas-jet system to a 4-position collection site in a fume hood located outside the radiation area. Here very simple 'manual' chemistry was performed using only a few microliters of solution. The sorption of Ha on glass cover slips after fuming twice with concentrated nitric acid and washing

with 1.5 M HNO_3 was compared with that of tracers of the group 5 elements Nb and Ta and with the group 4 elements Zr and Hf produced on-line under similar conditions. These group 5 elements are known to sorb on glass surfaces while the group 4 elements do not. Measurements of the energy and time distribution of the alpha decay and of time-correlated pairs of alphas from ^{262}Db and its 4-s daughter ^{258}Lr were recorded and analyzed to provide positive identification that element 105 was detected. Some 800 manual extractions taking about 50-s each were performed and a total of 26 alpha and 26 SF events were recorded. Element 105, like its group 5 homologs Nb(V) and Ta(V), was found to sorb on the glass surfaces while Zr and Hf and the trivalent actinides did not. This confirmed the group 5 character of Ha and demonstrated that it properly belonged in the periodic table as the heaviest member of group 5. Its extraction behavior into methylisobuytlketone from mixed HNO_3/HF solutions under conditions in which Ta was extracted but Nb was not was also investigated (Gregorich *et al.*, 1988). Surprisingly, it was found that element 105 did not extract and that its behavior was more like Nb than Ta, indicating that details of complexing behavior cannot be predicted based only on simple extrapolations of trends within a group in the periodic table. This behavior was explained much later (Pershina, 1998b), as discussed in detail in Sections 14.5.3b and 14.5.3c.

This surprising result provided the impetus for further exploration of the complex behavior of element 105. Chromatographic experiments using ARCA II to carry out the thousands of required repetitive experiments were performed jointly by the GSI/Mainz, PSI/Bern, and LBL/Berkeley groups in 1988, 1990, and 1993 at LBL, and in 1992 at GSI. In the first extraction chromatography column separations with the anion exchanger TIOA on inert supports, all the group 5 elements and Pa(V) were extracted from concentrations of HCl > 10 M. At lower concentrations of HCl, small amounts of added HF gave selective back extraction, showing different chemical behavior for these elements (Kratz *et al.*, 1989; Zimmermann *et al.*, 1993). Element 105 showed a marked non-Ta-like behavior at concentrations below 12 M HCl and follows the behavior of Nb and the pseudohomolog Pa(V). Because of this similarity to Nb and Pa, it was concluded that the complex was $DbOX_4^-$ or $[Db(OH)_2X_4]^-$. ARCA was also used to investigate the extraction of Db from HBr into diisobutyl carbinol (DIBC), a specific extractant for Pa, with subsequent elutions with mixed HCl/HF and HCl. The extraction sequence Pa > Nb > Db was obtained and attributed to the increasing tendency to form non-extractable polynegative complexes (Gober *et al.*, 1992). Due to the difficulties encountered in the theoretical interpretation of the results of these experiments because of the small amounts of HF added to the various halide solutions (long recommended for reducing hydrolysis of group 5 elements to prevent them from unwanted sorption on containers, etc.), it was recommended that future experiments be carried out in pure rather than mixed halide solutions (Pershina, 1998b).

Experiments conducted with ARCA also showed that Ha was eluted promptly from cation-exchange columns with α-hydroxyisobutyrate (Kratz *et al.*, 1992;

Schädel *et al.*, 1992) together with Nb, Ta, and Pa, whereas trivalent and tetravalent ions were retained, again confirming that Ha is most stable in aqueous solution as a pentavalent species. The new isotope 27-s ^{263}105 was also identified in these experiments.

Subsequently, Pershina (1998b) and Pershina and Bastug (1999) predicted the sequence Pa >> Nb ≥ Db > Ta for extraction into the anion exchanger TIOA from halide solutions. Paulus *et al.* (1999) remeasured K_d values for Nb, Ta, and Pa in new batch extraction experiments with the quaternary ammonium salt Aliquat-336 and pure HCl, HBr, and HF solutions. New chromatographic column separations with ARCA II were then conducted to study chloride and fluoride complexation separately. The Aliquat-336/HCl experiments confirmed the extraction sequence Pa >> Nb ≥ Db > Ta, as theoretically predicted. In the Aliquat 336/HF system the K_d value for element 105 in 4 M HF was >570, close to those for Nb and Ta of >1000 and different from that of ~10 for Pa.

In his review of transactinide chemistry, Kratz (1999b) discussed all the results for the ARCA experiments on element 105 in detail and concluded that the amine extraction behavior of dubnium halide complexes is always close to Nb, consistent with the predicted inversion of the trend in properties between the 5d and the 6d elements. In pure HF solution, Db differs most from Pa, and in pure HCl solution, it differs from both Pa and Ta. In mixed HCl/HF solutions, it differs markedly from Ta. The experimental results are in agreement with the calculated Gibbs energy changes (see Section 14.5.3c) of 12, 20, and 22 eV for the reactions for complex formation (Pershina *et al.*, 2002b) of the fluorides, chlorides, and bromides, respectively. For example, the equilibrium between hydrolysis and halogenation always favors formation of an extractable fluoride complex rather than the hydrolyzed species even at very low HF concentrations, whereas [HCl] > 3 M is required for formation of extractable chloride complexes, and [HBr] > 6 M is required for the formation of extractable bromide complexes.

(c) Gas-phase chemistry

The first on-line isothermal gas chromatography experiments were performed by an international group (Gäggeler *et al.*, 1992; Türler *et al.*, 1992) using OLGA II with 35-s ^{262}Db. The volatile species were deposited on a moving tape that was subsequently stepped in front of six large-area-passivated implanted planar Si detectors to measure alpha particles and SF events to identify element 105. From the yields as a function of isothermal temperature measured for the bromides of Nb, Ta, and Db, adsorption enthalpies of –88, –94, and –155 kJ mol^{-1}, respectively, were obtained from least-squares fits of Monte Carlo simulations to the isothermal yield curves. Within the error limits, the adsorption enthalpies (volatilities) are nearly the same for Nb and Ta, but Db appears to be significantly less volatile. It was postulated that traces of oxygen in the system might have led to formation of the oxytribromide of Db,

which was predicted to be less volatile than the pentabromide (Pershina *et al*., 1992b), and Db was also predicted to have a much stronger tendency to form oxyhalides than Nb or Ta, as discussed in Section 14.5.2b.

Investigations (Kadkhodayan *et al*., 1996; Türler, 1996) of the volatility of the chlorides of the group 5 elements showed that they were more volatile than their respective bromides, with element 105 being similar to Nb, but for Ta, only a species with much lower volatility, presumably $TaOCl_3$, was observed. In more recent experiments conducted by Türler *et al*. (1996) the volatilities of Db and Nb chlorides were studied as a function of controlled partial pressures of O_2. It was shown that the concentrations of O_2 and oxygen-containing compounds were extremely important in determining whether or not the oxychlorides were formed and in determining the resultant volatilities of the Nb and Db compounds. The results showed that for pO_2 between 1 ppm (vol.) and 80 ppm (vol.) both a volatile species and a less volatile species, presumably MCl_5 and $MOCl_3$, were formed in about equal amounts. The more volatile species, $NbCl_5$, was shown to be the major component at $pO_2 \leq 1$ ppm (vol.). Subsequent experiments with Db were conducted under similar conditions and a two-step yield curve was obtained indicating that both $DbCl_5$ and $DbOCl_3$ were present. Adsorption enthalpies of –80 and –99 kJ mol^{-1} for the Nb species and –98 and –117 kJ mol^{-1} for the Db species were deduced, indicating that the Db species are less volatile than those of Nb. As predicted, the oxychlorides are less volatile than the chlorides, but the experiments need to be extended to lower temperatures for Db with pO_2 kept as low as possible to see if $DbCl_5$ can be measured as a single component, and the measurements need to be extended to Ta.

14.6.3 Chemistry of seaborgium (106)

(a) Historical

Early attempts were made to study the chemistry of Sg using 0.9-s ^{263}Sg produced in the $^{249}Cf(^{18}O,4n)$ reaction at the U-400 cyclotron at Dubna (Timokhin *et al*., 1996; Yakushev *et al*., 1996). Recoiling reaction products were thermalized and carried in Ar gas from the target chamber into a fast on-line TC consisting of a 3.5 mm i.d. by 120 cm long tube of fused SiO_2 where air saturated with $SOCl_2$ was used as a chlorinating agent. The inner surface of the silica column served as a solid-state detector for SF events. In two experiments, Timokhin *et al*. (1996) found a total of 29 fission tracks in zones in the temperature region of 150–250°C, close to the deposition temperature of 16-s ^{166}W. No tracks were found in the start zone or outside the indicated region while alpha activities from actinide products were seen mostly in the start zone. They claimed that this was the first chemical identification of element 106 as SgO_2Cl_2 and that it formed an oxychloride similar to that of W. However, the assignment of the fissions to element 106 based on detection of a small

fission branch of ^{263}Sg is uncertain because it was not shown that the observed fissions did not belong to elements 104 or 105. Kratz (1999b) gave a detailed critique of the Timokhin reports and concluded that their conclusions were not justified.

The discovery by a Dubna–Lawrence Livermore National Laboratory (LLNL) collaboration (Lazarev *et al*., 1994; Lougheed *et al*., 1994) of the longer-lived isotopes ^{266}Sg and ^{265}Sg in ^{248}Cm(^{22}Ne,4n,5n) reactions with cross sections of ~80 and 260 pb for 116 and 121 MeV ^{22}Ne projectiles, respectively, made chemical studies of element 106 much more feasible. These new isotopes were separated and identified using the gas-filled recoil separator at the Dubna U-400 cyclotron. The partial alpha half-lives of 2–30 s for ^{265}Sg and 10–30 s for ^{266}Sg had to be estimated from the measured alpha-decay energies because the time intervals between the Sg isotopes and their Rf daughters were not measured as the signals from the implanted Sg isotopes were below the threshold of their detector system. On-line procedures for studying the chemistry of element 106 with both OLGA and ARCA were developed using W and Mo, the presumed lighter group 6 homologs of element 106.

(b) Gas-phase chemistry

Theoretical predictions (Pershina and Fricke, 1996) based on relativistic MO calculations indicated that SgO_2Cl_2 was the most stable of the Sg oxychlorides. Based on this prediction, the gas-phase chromatography experiments discussed in Section 14.5.2b were conducted under conditions designed to study and identify SgO_2Cl_2. The trend in volatilities of these oxychlorides within group 6, which was predicted using relationships between molecular properties such as covalence or dipole moment and volatility, was $MoO_2Cl_2 > WO_2Cl_2 > SgO_2Cl_2$. Eichler *et al*. (1999) estimated the thermochemical quantities for chlorides, oxychlorides, and oxides of Sg by extrapolation. By the use of empirical correlations, they also found SgO_2Cl_2 to be the most suitable compound for the gas-phase chemistry experiments and expected its standard sublimation enthalpy to be between 125 and 144 kJ mol^{-1}, resulting in an adsorption enthalpy between –97 and –108 kJ mol^{-1} and less volatile than its W homolog.

OLGA III was used in experiments to study the behavior of fission-product Mo isotopes and short-lived W isotopes produced at the PSI Philips cyclotron in preparation for studies of element 106 (Gärtner *et al*., 1997). The reactive gas mixture O_2, Cl_2, and $SOCl_2$ at 900°C was used; adsorption enthalpies of −90 and −100 kJ mol^{-1} were measured for MoO_2Cl_2 and WO_2Cl_2, respectively, in agreement with predictions. The isothermal yield curve was measured for 58-min ^{229}U produced in the ^{232}Th(α,7n) reaction and the resulting adsorption enthalpy of −91 kJ mol^{-1} was interpreted as indicating formation of UCl_6.

The first chemical experiments on Sg were conducted in 1995 and in 1996 at the Universal Linear Accelerator (UNILAC) at GSI using the ^{248}Cm

(^{22}Ne,4n,5n) reactions to produce ^{266,265}Sg. The reaction products recoiling out of the target were thermalized in helium gas containing carbon aerosols ($\sim 0.1 - 1$ μm diameter, generated using a spark discharge generator). In about 3 s, the flowing helium gas continuously transported the reaction products attached to the carbon aerosols through a capillary to a quartz wool plug in the reaction chamber (900–1000°C) at the inlet of OLGA III. There the reactive chlorinating gas consisting of O_2, Cl_2, and $SOCl_2$ was added to form volatile compounds, which were transported through the 1.5-mm i.d. × 1.8 m long isothermal quartz chromatography column to a recluster chamber where the chemically separated volatile Sg compounds were again attached to aerosol particles. They were transported within about 6 s to a rotating wheel system and collected on thin polypropylene foils placed in the 64-collection positions located around the periphery of a wheel that was stepped every 10 s to move the collected activity consecutively between pairs of Passivated Ion-implanted Planar Silicon (PIPS) detectors for measurement of alpha and SF activities. The times, energies, and positions of all events were recorded in list mode by a computer. A mother–daughter stepping mode was used to avoid interference from 45-s ^{212}Po^{m} contamination in the alpha energy region of interest (8.8 MeV). In this mode every other position on the 64-position wheel was left empty. When an alpha particle with the decay energy of ^{265,266}Sg was detected in a bottom detector, the daughter Rf nucleus was assumed to have recoiled out of this aerosol deposit onto the top detector. This initiated the daughter mode, causing a single step that positioned the empty collection sites between the detector pairs. The system waited for 2 min to permit the Rf daughter on the detector to decay in an environment clean of contamination. In the first experiment, two decays of ^{265}Sg were identified in daughter mode, one triple correlation was observed in parent mode, and one $\alpha-\alpha$ correlation from ^{266}Sg–^{262}Rf was recorded (Schädel *et al.*, 1997a).

The isothermal temperature was varied in the second experiment conducted in 1996 (Türler *et al.*, 1999) to obtain the adsorption enthalpy for Sg. The experimental conditions were similar except that a 200 s wait in the daughter mode was used. The yield of short-lived W isotopes produced from ^{22}Ne reactions with ^{152}Gd incorporated in the ^{248}Cm target was measured with a high-purity Ge detector and used to monitor the yield of the chemical separation. An adsorption enthalpy of $-(96 \pm 1)$ kJ mol^{-1} was obtained for $^{168}WO_2Cl_2$, in agreement with the previous measurement. The isothermal yield curves obtained for SgO_2Cl_2 along with those for the Mo and W compounds are shown in Fig. 14.17. Based on detection of 11 events attributable to Sg, an adsorption enthalpy of $-(100 \pm 4)$ kJ mol^{-1} was derived. Adsorption enthalpies of $-(90 \pm 3)$ kJ mol^{-1} and $-(96 \pm 1)$ kJ mol^{-1} were obtained for Mo and W oxychlorides, respectively. Thus the volatility sequence is $MoO_2Cl_2 > WO_2Cl_2 > SgO_2Cl_2$, as theoretically predicted. Türler *et al.* (1998a) analyzed the decay properties of the 13 correlated chains of ^{265}Sg and ^{266}Sg observed in these experiments and recommended the following half-lives and cross sections for

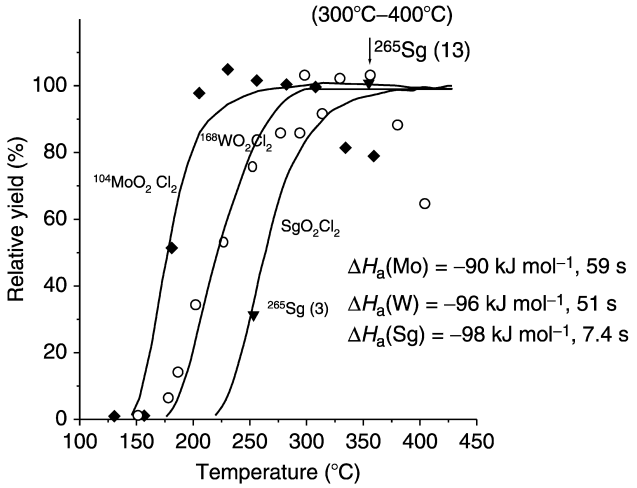

Fig. 14.17 *Relative yields vs. isothermal temperatures for* MoO_2Cl_2 (*solid diamonds*), WO_2Cl_2 (*open circles*), *and* SgO_2Cl_2 (*solid triangles*). (*Data from Türler* et al., 1999).

^{22}Ne energies between 120 and 124 MeV: ^{265}Sg, $t_{1/2} = 7.4^{+3.3}_{-2.7}$ s, cross section ~240 pb; ^{266}Sg, $t_{1/2} = 21^{+20}_{-12}$ s, cross section ~25 pb.

Hübener *et al.* (2001) reported that Sg forms volatile oxide-hydroxides similar to those of U and the group 6 elements Mo and W. They used high-temperature on-line isothermal gas chromatography with quartz columns to study Sg and W in the O_2–H_2O(g)/SiO_2 system. ^{266}Sg, produced as above, was transported in a He/MoO_3 gas-jet system into the chromatography system. Group 6 elements formed oxide-hydroxides that were volatile at a temperature of 1325 K upon addition of O_2. ^{266}Sg was unambiguously identified by measuring its decay chain. They postulated a dissociative adsorption and associative desorption process to explain their results.

(c) Solution chemistry

The first successful studies of the chemical properties of Sg in aqueous solution were reported by Schädel *et al.* (1997a,b) using ^{265,266}Sg produced in the reaction of 121 MeV ^{22}Ne projectiles with ^{248}Cm targets of 0.15 mg cm^{-2} in the first experiment and 0.95 mg cm^{-2} in the second experiment at the UNILAC at GSI. The emphasis in these experiments was on rapid preparation of samples for alpha spectroscopy with decontamination from the high-energy Bi and Po alpha activities and of trivalent actinides, and efficient separation of the Rf and No daughter activities from Sg. If these conditions are met, Rf and No isotopes observed later in the chemically separated Sg fraction can be presumed to be daughters of Sg precursor nuclei. A system with anionic or possibly neutral oxy- and oxyfluoride compounds was chosen because the formation of neutral and

anionic complexes with F^- ions is a characteristic property of group 4, 5, and 6 elements, with distinct differences between the behaviors of the three groups. Based on previous on-line tracer experiments, a solution of 0.1 M HNO_3/5 × 10^{-4} M HF was used to elute the activity from the columns of the cation-exchange resin Bio-Rad AG Aminex A6. The recoiling activities attached to KCl aerosols were swept from the recoil chamber with He gas into a capillary and transported in flowing He some 18 m to ARCA II where they were collected, dissolved, and fed into the 1.8-mm i.d. × 8-mm chromatographic columns filled with the cation-exchange resin Aminex A6. The transport and collection efficiency of about 45% was monitored frequently by checking the production rate of $^{252-255}$Fm isotopes of known cross section. Although the mean separation time of Sg from Rf and No took only 5 s, the evaporation of the eluted samples took about 20 s and on the average, α-particle and SF measurements using a system of eight PIPS detectors were not begun until 38 s after the end of the collection. The energies, times, and detector positions were recorded in list mode on a magnetic disk and tape for later data analysis and identification of the Sg isotopes. Collections times of 45 s were used for most of the 3900 collection and elution cycles. Observation of three correlated α−α events identified as the ^{261}Rf(78 s)→^{257}No(26 s)→decay sequence indicated the decay of ^{265}Sg in the chemically separated Sg fractions. From this observation, it was concluded that Sg behaved as a typical hexavalent group-6 element as did W studied previously in similar on-line experiments. This indicated the formation of SgO_2F_2 by analogy to its Mo and W homologs and showed behavior different from the pseudohomolog U(VI), which remained on the column, presumably as UO_2^{2+}.

An investigation of the fluoride complexation of Zr, Hf, Rf, and Th in mixed HNO_3/HF solutions was undertaken (Strub *et al.*, 2000) to verify experimentally that under the conditions of the first experiments on the solution chemistry of Sg using ARCA, ^{261}Rf would not be eluted from the cation-exchange resin. These detailed studies of sorption on both cation- and anion-exchange resins using ARCA confirmed the validity of the assumption in the Sg experiments that Rf would remain on the Aminex A6 cation-exchange resin column. Therefore, it was concluded that Rf could only have been in the Sg fraction as a result of the alpha decay of 7-s ^{265}Sg.

A new series of 4575 experiments was conducted (Schädel *et al.*, 1998) with ARCA using the same Aminex A6 cation-exchange resin to determine if Sg would form SgO_4^{2-} under the same conditions as before if fluoride ions were not present. The activity was dissolved in 0.1 M HNO_3 without any HF; subsequent analysis of the effluent showed that Sg still remained on the column while W was eluted with 0.1 M HNO_3. This non-tungsten-like behavior of Sg was tentatively attributed to its weaker tendency to hydrolyze in dilute HNO_3 so that its hydrolysis stopped at $M(OH)_4(H_2O)_2^{2+}$ or $MO(OH)_3(H_2O)_2^+$ while hydrolysis of Mo and W proceeded to the neutral species $MO_2(OH)_2$. Thus, in the previous experiments in the presence of fluoride ions, Sg might have been eluted from the

cation-exchange column as neutral or anionic fluoride complexes of the type SgO_2F_2 or $SgO_2F_3^-$ rather than as SgO_4^{2-}.

This hypothesis has been examined theoretically by considering hydrolysis of group 6 elements, as described in Sections 14.5.3b and 14.5.3c. The calculations (Pershina and Kratz, 2001) show that between a pH of 0 and 1, Sg forms complexes with charges of 1+ or 2+ while W forms neutral complexes. Hydrolysis of group-6 elements proceeds even faster at higher pH and a reversal of the trend in group-6 should be observed at pH > 4 (see Section 14.5.3b). Theoretical considerations of complex formation in HF solutions (Pershina *et al.*, 2002b) indicate that it competes with hydrolysis in aqueous solutions, that the dependence on pH and HF concentrations is very complicated, and that reversals of the trends occur. Further experiments can be planned based on the theoretical predictions that cover a wide range of pH values. These reversals of trends among the group 6 elements and U(IV) should be investigated experimentally.

14.6.4 Chemistry of bohrium (107) and hassium (108)

(a) Bohrium

The isotope, 17-s ^{267}Bh (Wilk *et al.*, 2000), produced in the ^{249}Bk(^{22}Ne,4n) reaction, was used in studies to compare the volatility of the oxychloride of Bh with those of its group 7 homologs Re and Tc in on-line isothermal gas chromatographic experiments using the OLGA system (Eichler *et al.*, 2000) conducted at the PSI cyclotron. The recoiling reaction products were sorbed on carbon particles suspended in He gas and continuously transported over a distance of a few meters to the OLGA where they were treated with HCl and oxygen to produce the volatile oxychlorides. These were conducted into the quartz chromatographic column, where their retention time is primarily dependent on the sorption interaction with the chlorinated column surface at a given isothermal temperature and the carrier gas velocity. The molecules passing through the column were attached to aerosols and then deposited stepwise on foils placed in positions on the circumference of a rotating wheel where their decay by alpha emission and SF was measured to identify them positively as ^{267}Bh based on their decay sequences to known daughter activities as reported in Wilk *et al.* (2000). Six such decay chains were observed over nearly 1 month of irradiation time. The relative yields for the trioxychlorides of ^{267}Bh as well as for those for Re and Tc obtained in similar experiments as a function of the isothermal temperatures are shown in Fig. 14.18.

A Monte Carlo program based on a microscopic model of the adsorption process was used to deduce ΔH_{ads} of –75 kJ mol^{-1} with a 68% confidence interval of –66 to –81 kJ mol^{-1} for BhO_3Cl, the most probable oxychloride under these conditions. The ΔH_{ads} values for the Tc and Re oxychlorides studied under the same conditions are –51 and –61 kJ mol^{-1}, respectively. Thus Bh oxychloride shows a stronger adsorption interaction with the chlorinated quartz

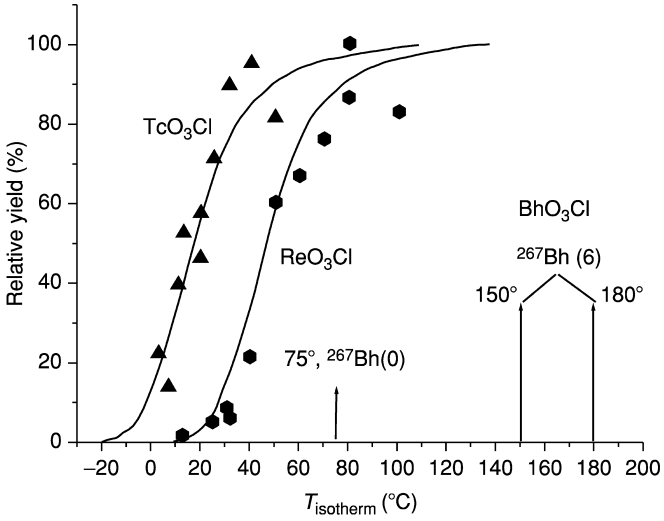

Fig. 14.18 *Relative yields vs. isothermal temperatures for TcO_3Cl (solid triangles) and ReO_3Cl (solid hexagons). A total of six events attributed to ^{267}Bh were detected at the isothermal temperatures of* 150 *and* 180°*C* (*Eichler* et al., 2000). *No events were detected at* 75°*C.*

surface than either Tc or Re compounds and it is less volatile than Re and Tc. This is in very good agreement with the calculations (Pershina and Bastug, 2000) where ΔH_{ads} of –48.2 kJ mol^{-1} for Tc and –78.5 kJ mol^{-1} for Bh were predicted, giving a volatility sequence of $TcO_3Cl > ReO_3Cl > BhO_3Cl$ (see discussion in Section 14.5.2).

(b) Hassium

Systems were developed for separating and detecting Hs as a volatile oxide based on the expectation that it would form a highly volatile tetroxide, as do its group 8-homologs osmium and ruthenium. Fully relativistic density functional calculations have been performed for MO_4 (M = Ru, Os, and Hs), as discussed in Section 14.5.2b. The volatility sequence for the tetroxides was predicted to be $HsO_4 \geq OsO_4 > RuO_4$ based on the calculated adsorption enthalpies of –(36.7 ± 1.5), –(38.0 ± 1.5), and –(40.4 ± 1.5) kJ mol^{-1}, respectively (Pershina *et al.*, 2001).

In preparation for experiments with Hs, Kirbach *et al.* (2002) developed the Cryo-Thermochromatographic Separator (CTS) to perform on-line investigations of the oxides of the α-emitters ^{171,172}Os (8 s,19 s) produced in ^{118,120}Sn (^{56}Fe,3–5*n*) reactions at the LBNL 88-Inch Cyclotron. The CTS consists of a channel formed by two facing rows of 32 PIN (Positive Implanted N-type silicon) diode α-particle detectors upon which a negative temperature gradient

from 247 K at the entrance to 176 K at the exit was maintained. The volatile species deposit on the detector surfaces at a characteristic temperature and are identified from their measured α-decay energies.

After pre-separation with the BGS to remove unwanted transfer reaction products and scattered beam particles, the separated Os ions were stopped in the RTC (described earlier) in a mixture of He gas containing 10 vol% O_2 at 100 kPa. The Os activities were transferred in a continuously flowing He/O_2 mixture through a Teflon capillary to a quartz tube heated to 1200 K where OsO_4 was formed and then transported through another capillary to the CTS. The detector pair in which the activity was deposited and the alpha spectra at each position were recorded to identify these activities. The temperature was determined from thermocouple measurements and also from the measured resistances of the PIN diodes. Monte Carlo fits to the adsorption distributions were obtained by adjusting the model to more closely approximate the slit-like CTS cross section and resulted in an adsorption enthalpy of $-(40.2 \pm 1.5)$ kJ mol^{-1} for quartz surfaces.

Düllmann *et al.* (2002a) devised the *In-situ* Volatilization and On-line detection apparatus (IVO) in which products recoiling from a nuclear reaction are thermalized and stopped in a recoil chamber containing He gas while the high-energy beam particles travel directly through the chamber to a beam stop, thus removing them from the system. The thermalized recoil products are then converted *in situ* to the volatile species to be studied and are swept by the carrier gas to a chromatography column. Volatile species pass through the column to a recluster chamber where they are sorbed on aerosols and transported via gas jet either to an additional quartz column to measure the retention times of the volatile species or directly to an on-line detection system. Short-lived Os isotopes were used to test IVO for future chemical studies with Hs. From the Monte Carlo simulations an adsorption enthalpy of $-(38.0 \pm 1.5)$ kJ mol^{-1} was obtained for $^{173}OsO_4$ on quartz surfaces, in agreement within the uncertainty limits with the value of $-(40.2 \pm 1.5)$ kJ mol^{-1} obtained by Kirbach *et al.* (2002). Subsequent to these prototype experiments, an international team of scientists (Düllmann *et al.*, 2002b) conducted the first studies of the chemistry of hassium, the heaviest element to date whose chemistry has been successfully investigated. The $^{248}Cm(^{26}Mg,5n,4n)$ reactions with estimated production cross sections of only a few picobarns were used to produce $\sim$10 s ^{269}Hs reported previously (Hofmann *et al.*, 1996, 2002) and possibly ^{270}Hs ($\sim$4 s) (Türler *et al.*, 2003) at the UNILAC at GSI. Three ^{248}Cm targets were positioned on a rotating wheel to increase the production rate. The IVO device was used to transport recoiling products to a quartz wool plug where Os and Hs were oxidized to the tetroxides by treatment with oxygen at 600°C. They were transported in helium through a Teflon capillary to the entrance to the Cryo On-Line Detector (COLD) TC formed by 12 pairs of opposing Si PIN-photodiode detectors with an outermost layer of Si_3N_4 positioned so that the gas flow was confined to the active detector surfaces. A schematic diagram of the system is shown in Fig. 14.19.

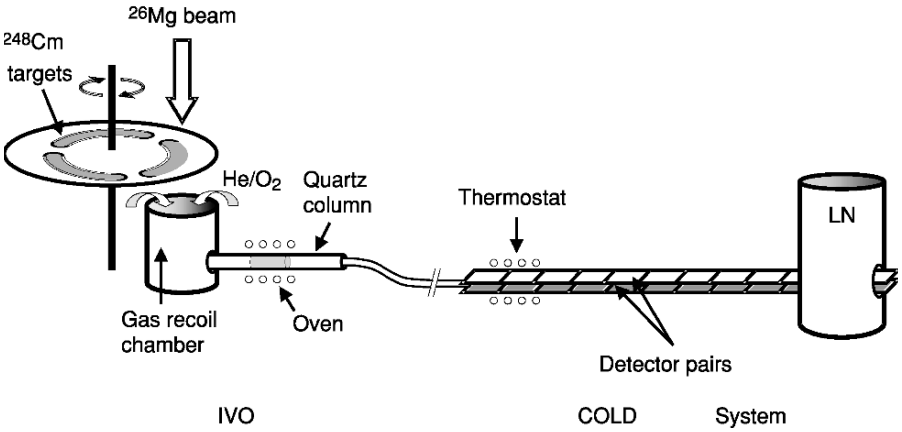

Fig. 14.19 *Schematic of IVO-COLD system for study of gas-phase properties of HsO_4 and lighter homologs* (*adapted from Düllmann* et al., 2002*b*).

Spectra of the alpha particles and SFs of the species deposited within each of the detectors of the array were measured and recorded to provide identification of the ^{269,270}Hs isotopes. The detection efficiency was about 77% for detection of a single alpha particle. A negative temperature gradient from –20 to –170°C was established along the TC formed by the detector array and measured at five positions. The system was checked at the beginning and at the end of the experiment by on-line measurements of the short-lived Os isotopes. In the 64 h experiment performed to produce Hs, three $\alpha-\alpha$-correlated decay chains were detected and assigned to the decay of ^{269}Hs. Two others, possibly due to the new nuclide ^{270}Hs or an isomer of ^{269}Hs, were detected, but a definite assignment could not be made. Based on detection of the three decay chains attributable to ^{269}Hs and two to a new nuclide ^{270}Hs (Türler *et al.*, 2003), HsO_4 was found to condense at a higher temperature than OsO_4 under similar conditions, indicating that the Hs oxide is less volatile than that of Os. The data for Hs and Os are shown in Fig. 14.20.

The Monte Carlo simulations that best fit these data give an adsorption enthalpy of $-(39 \pm 1)$ kJ mol^{-1} for OsO_4 on the silicon nitride surface, in good agreement with the previously measured values for SiO_2. An adsorption enthalpy of $-(46 \pm 2)$ kJ mol^{-1} was deduced for HsO_4 using only the three events assigned to ^{269}Hs and a $t_{1/2}$ value of 11 s in the analysis. This value is considerably more negative than the predicted value of $-(36.7 \pm 1.5)$ kJ mol^{-1} and suggests that HsO_4 is less volatile than OsO_4, in disagreement with calculations (Pershina, 1998a) that indicated that they should be nearly the same. More data and a better half-life measurement for ^{269}Hs are needed to investigate this discrepancy further. The possibility of different behaviors of HsO_4 on the Si_3N_4 detector surface compared to the SiO_2-coated detector surfaces should

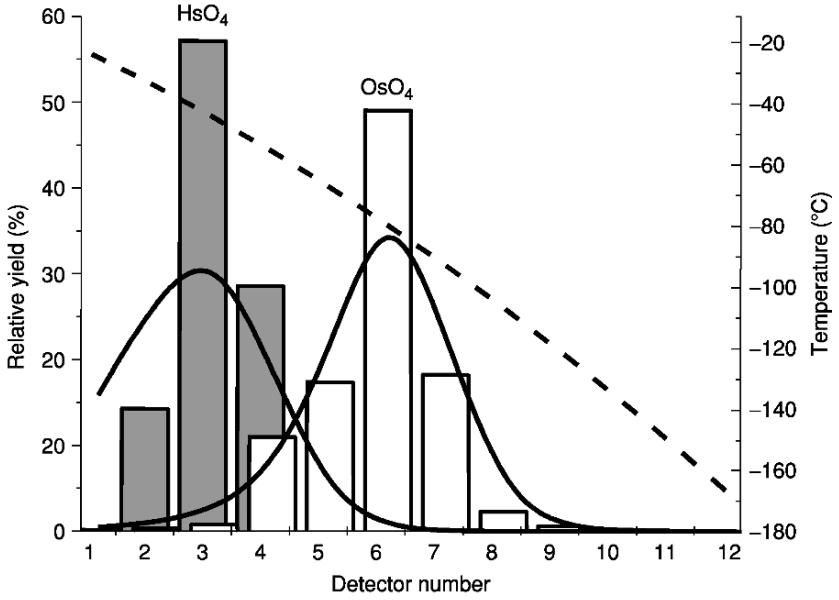

Fig. 14.20 *Combined thermochromatograms for Hs and Os oxides based on deposition positions (temperatures) for each of the* 12 *detector pairs. Dashed line indicates the temperature profile. The bars represent measured values and the curves result from Monte Carlo simulations of the migration process along the column.*

be considered and experiments with the tetroxide of Ru, predicted to be more volatile than those of either Os or Hs, should be conducted on both surfaces to investigate possible differences and the possibility that other oxides may be formed.

14.6.5 Summary of measured compared to predicted chemical properties

(a) Gas-phase studies

Observed trends in the volatility of the compounds of groups 4 through 8 compared to the theoretical predictions are summarized in Table 14.11. It can be seen that the measured and predicted trends in volatilities of the halide and oxyhalide compounds are in excellent agreement. However, in the case of the presumed tetroxides of Os and Hs there appears to be a discrepancy. This discrepancy emphasizes the need for additional investigations because few Hs disintegrations events were measured and their nuclear characteristics have not been unequivocally established.

Table 14.11 *Comparison of measured and predicted trends in volatilities of the compounds of Rf, Db, Sg, Bh, and Hs and their lighter homologs in periodic table groups* 4 *through* 8.

(b) Aqueous-phase studies

The measured trends in hydrolysis, complex formation, and extraction of complexes of Rf, Db, and Sg and their lighter homologs in groups 4 through 6 of the periodic table under a variety of experimental conditions compared to theoretical predictions for the same systems are summarized in Table 14.12. Care must be taken to ensure that the conditions for the experimental studies are the same as for the theoretical predictions since small differences in pH, purity of halide solutions, etc. can affect the equilibria that determine whether hydrolysis or complex formation dominates and whether the resultant complexes are neutral or charged. The order of extraction into organic solvents and sorption in cation- and anion-exchange chromatography differs greatly, depending on the charge on the complex. In general, agreement of the experimental results with the predictions is excellent when these factors are carefully controlled, as discussed in Section 14.5.3c.

There are some prospects for studies of the aqueous chemistry of elements heavier than 106 as well as for more detailed studies of elements 104, 105, and 106 using shorter-lived isotopes that may have higher production rates. The RTC (Kirbach *et al.*, 2002) coupled with the BGS could be used so that the separated isotopes can be transported to different rapid chemical separation systems such as SISAK-III described earlier (Omtvedt *et al.*, 2002) for few-second liquid–liquid extractions or other automated systems such as ARCA. This might permit detailed studies of complex formation of elements Bh and Hs that would be of special interest in acid solutions.

14.6.6 Prospects for experimental studies of chemistry of Mt through element 112

(a) Predictions of half-lives and production modes

Prospects for chemical studies of Mt depend on the confirmation of longer-lived isotopes than ^{268}Mt, currently the longest-lived known isotope of Mt. This isotope decays primarily by alpha emission, with a half-life reported to be about 40 ms; it was detected as the alpha-decay product of ^{272}111 produced with a cross section of 2.5 pb in the ^{209}Bi(^{64}Ni,n) reaction (Hofmann *et al.*, 2002). The half-lives of the ^{264}Bh daughter and the ^{260}Db granddaughter of ^{268}Mt are only about 1 s, so even techniques involving chemical separation of the daughters to infer the parent chemical properties do not appear feasible. Longer-lived isotopes of Mt are expected around the deformed nuclear shell at 162 neutrons and might be produced using the ^{238}U(^{37}Cl,4n) or the ^{249}Bk (^{26}Mg,4n) reaction to make ^{271}Mt. The half-life of this odd-proton, odd-neutron isotope was estimated from interpolation of Smolańczuk's (1997) calculations

for even proton–even neutron nuclides to be a few seconds and decay primarily by alpha emission. The cross section for the first reaction is expected to be similar to that of 2.5 pb, measured for the ^{238}U(^{34}S, 5n)$\rightarrow$^{267}Hs reaction (Lazarev *et al.*, 1995) as the enhancement of the cross section due to the extra two neutrons in ^{37}Cl compared to ^{34}S is expected to balance the decrease due to the higher Z of Mt. Based on this cross section, detection of two or three chains a week might be expected using multiple ^{238}U targets in the BGS. The BGS is capable of positively separating and identifying such a new nuclide based on measurement of the known alpha-decay chain of its daughters even if the ^{271}Mt half-life is as short as a few tenths of a second. The overall yield for the reaction with the highly radioactive target ^{249}Bk will be much lower because the cross section is expected to be only a few tenths of 1 pb and it is much more difficult to use multiple targets.

The production of longer-lived isotopes of elements 110, 111, and 112 with half-lives in the range of seconds to minutes have now been reported using 'warm/hot' fusion reactions or as decay products of elements 114 and 115. (See Table 14.2 and Fig. 14.2(b) and discussion in Section 14.1.) It may be possible to produce ^{277}110 directly in the 'warm' fusion reaction ^{232}Th(^{48}Ca,3n), but the cross section may be low and the systematics of these reactions need to be investigated further. The isotope ^{280}110 with a half-life of 7.6 s has been reported as the granddaughter of ^{288}114 produced in a four neutron out reaction in the bombardment of ^{244}Pu targets with ^{48}Ca (Oganessian *et al.*, 2000a; Oganessian, 2001), but this indirect production method is not favorable for chemical studies. Currently, there appear to be no suitable reactions for direct production of the very neutron-rich isotopes of Ds.

Some isotopes of the odd-proton element 111 should have half-lives of seconds or more and hindrances toward fission and alpha decay should exist. An isotope with mass number 280 and with a half-life of 3.6 s has been reported in the alpha-decay chain of ^{288}115 produced in the bombardment of ^{243}Am with ^{48}Ca projectiles (Oganessian *et al.*, 2004a).

SF activity attributed to ^{283}112 produced in the ^{238}U(^{48}Ca,3n) reaction and from the alpha decay of ^{287}112 produced via the ^{242}Pu(^{48}Ca,3n) reaction has been reported by Oganessian *et al.* (1999a,c, 2004b) who obtained a half-life of $\sim$5 min by averaging these results. However, as discussed in Section 14.1, it is difficult to positively identify a new nuclide that decays only by SF and even if this assignment is verified, its positive identification in chemical studies would be equally difficult and likely to be inconclusive. The production of 112 isotopes in ^{238}U(^{48}Ca,xn) reactions should be investigated further to determine the cross sections and if there is an alpha branch in ^{283}112 or ^{284}112. Then more definitive chemical studies could be undertaken. Such experiments would also help to assess the usefulness of 'warm' fusion reactions for production of a broad range of heavy element reactions for chemical studies.

(b) Chemical methods

Even though it appears that isotopes of the elements from Mt through element 112 can exist with half-lives long enough for chemical studies, the most difficult problem will be to increase the production rates and to perform on-line experiments with continuous separation and detection capabilities that can be operated for times long enough to obtain statistically significant results. These times will be of the order of weeks or months and will certainly require computer-controlled automated systems to carry out both gas-phase and solution chemistry. As the production cross sections for the elements of interest become ever smaller, the use of some pre-separation technique – either physical such as BGS or chemical such as IVO – will become mandatory in order to separate out the multitude of unwanted products before use of the more selective systems mentioned below.

The stable oxidation states of these elements both in the gas phase and in solution are predicted to vary widely, as shown in Table 14.10. From element 107 on, the maximum oxidation state is expected to be relatively unstable in aqueous solutions. Experimental studies designed simply to try to determine the most stable oxidation states in aqueous solution should be devised. Thus, for example, the stability of Bh(IV) relative to Bh(VII), or Hs(IV) relative to Hs(VIII) could be investigated by performing anion-exchange separations from HCl solutions in which the 4+ states might form negatively charged complexes that would be retained on the anion column. The relative positions of the peaks of the elution curves associated with reduction would give information about relative stabilities of lower oxidation states. Complex formation can also be studied for elements 109 and heavier. The imaginative gas-separation techniques developed for study of Bh and Hs can be applied to Mt and Ds, which are predicted to form volatile hexafluorides and octafluorides, as discussed in Section 14.5.2b.

Some preliminary chemical experiments on element 112 have been reported by Yakushev *et al.* (2001) and by Yakushev (2002) using the spontaneously fissioning nuclide $^{283}112$ ($\sim$5 min) reported by Oganessian *et al.* (1999a, 2004b) to be formed in the $^{238}U(^{48}Ca,3n)$ reaction with a cross section of 5 pb. The experiment was designed to determine whether element 112 behaved similarly to its periodic table homolog Hg, which had been shown to deposit on Au- or Pd-coated silicon surface barrier detectors (Yakushev *et al.*, 2001), or whether it behaved as a noble gas like Rn and remained in the gas phase. An unambiguous answer about the physical or chemical properties of element 112 was not obtained. The system was improved by introducing a special ionization chamber after the silicon detectors to measure alpha decays and SF events of nuclei remaining in the gas. More than 95% of the simultaneously produced Hg isotopes were deposited on the first Au-coated detector. Again, no events attributable to element 112 were detected on either the Au- or the Pd-coated

silicon detectors, but eight SF events were registered in the ionization chamber (Yakushev, 2002). These SF events were attributed to element 112, which indicates that it is more chemically inert than Hg and remained in the gas phase. The ΔH_{ads} of element 112 was deduced to be more positive than –55 kJ mol^{-1}. Further experiments with a temperature gradient in the chromatography column are now planned to better define ΔH_{ads}. It is also important to confirm that the observed SF events actually belong to element 112. If an alpha-decaying isotope of element 112 with a suitable half-life and production rate can be identified it would be much more suitable for chemical studies because it could be positively identified from its half-life and characteristic alpha-decay chain.

Experiments on element 112, similar to those conducted in Dubna, are planned by researchers at PSI (Soverna *et al.*, 2001) using a chromatographic column with a negative temperature gradient from 35 to –190°C. Silicon detectors coated with Au and Pd will be placed along the chromatographic column to detect element 112 and its deposition temperature will be determined relative to those of Hg at 115°C and Rn at –115°C in order to deduce ΔH_{ads}.

Eichler and Schädel (2002) investigated the adsorption of Rn on polycrystalline surfaces of transition metals and found the strength of adsorption to decrease in the order: Ni > Pd ≈ Cu > Au > Ag. They suggest that low-temperature vacuum thermochromatographic techniques could be used to rapidly separate element 112 from 114 and Rn and to determine whether its behavior is more like its lighter homolog Hg or an inert noble gas.

Isotopes of Hg have been studied by carrying them on Pd aerosols to serve as a model system for possible studies of elements 112 or 114 (Düllmann *et al.*, 2002a). Recoiling Hg isotopes produced in ^{168}Yb(^{22}Ne,xn)$^{190-x}$Hg reactions in the IVO setup at the PSI Philips cyclotron were thermalized in He, swept through an isothermal quartz column at 800°C to the re-cluster chamber, and transported on Pd aerosols to a suitable detection device for measurement of alpha spectra. The short-lived nuclides $^{183-185}$Hg were identified, indicating that volatile metals such as Hg can be transported in gas-flow systems without the presence of aerosol particles and then quickly adsorbed on metal aerosols if the enthalpy of adsorption is sufficiently large. The aerosols can then be transported to a detection system for measurements at low pressure and room temperature. Such a technique may also be applicable to measurements of transactinides with $Z = 112$ to 117.

Plans to separate elements with $Z > 108$ as noble metals by electrochemical deposition from aqueous solutions have been described (Kratz, 1999a). The choice of an appropriate electrode material is very important and estimates of suitable electrodes have been made for lighter homologs of the heaviest elements (Eichler and Kratz, 2000). Pd and Pt were found to be suitable electrode metals for the deposition of Hg, Tl, Pb, Bi, and Po, the homologs of elements 112 through 116.

14.7 FUTURE: ELEMENTS BEYOND 112 (INCLUDING SHEs)

14.7.1 Predictions of electronic structures and chemical properties

(a) Introduction

The ground state configurations of the free neutral atoms of elements 113 through 184 obtained from relativistic DF calculations are summarized in Table 14.13.

[a] Fricke (1975).

Chemical properties for elements 113 through 121, as predicted by various researchers, are summarized in Table 14.14. A rather complete discussion and summary of the chemical properties predicted for these elements as of 1986 was given by Seaborg and Keller (1986).

(b) Elements 113 through 115

In elements 113 through 118, the filling of the 7p shell is expected to takes place. Chemistry of these elements will be strongly influenced by relativistic effects: the large relativistic stabilization of the $7s^2$ electron pair (a large 7s–7p gap hindering the hybridization) and a very large SO splitting of the 7p levels into $7p_{1/2}$ and $7p_{3/2}$, reaching 11.8 eV for element 118 (Fig. 14.21). Since the electrons occupying the $7p_{1/2}$ orbital will then form a closed subshell, an enhanced stability of lower oxidation states of these elements is expected. However, destabilization of the 6d levels would contribute to a more transition element character for the earlier 7p elements (Han *et al*., 1999b; Seth *et al*., 1999).

(*i*) *Element* 113

Element 113 has one electron in the $7p_{1/2}$ valence shell. Due to relativistic stabilization of the $7p_{1/2}$ electrons, its first IP of 7.306 eV, as shown in Table 14.15, is the largest in group 13 (Eliav *et al*., 1996a). The 1+ state is thus predicted to be the most stable.

The CCSD calculations (Eliav *et al*., 1996a) revealed a dramatic reduction in the excitation energy of an electron from the d^{10} shell: the $d^{10}s \rightarrow d^9s^2$ energy of 113^{2+} is 0.1 eV as compared to 8 eV for Tl^{2+}. It is, therefore, predicted that divalent or trivalent compounds of element 113 with an open $6d^9$ shell could exist. The calculated EA of Tl and element 113 are 0.4 and 0.68 eV, respectively.

The very large SO splitting of the 7p orbital will influence the chemistry of element 113 compounds by destabilizing the binding energy by almost 1 eV in the monohydride 113H. In this molecule, the 6d and 7s orbitals were shown to participate little in bonding (Han *et al*., 1999a,b, 2000; Seth *et al*., 1999) and all the effects are defined by the large participation of the $7p_{1/2}$ shell. Element 113 was calculated to be more electronegative than Ga, In, Tl, and even Al among all the monohydrides. Involvement of the 6d electrons in bonding in element 113 was confirmed by PP calculations (Han *et al*., 1999b; Seth *et al*., 1999) for $113H_3$, $113F_3$, and $113Cl_3$. As a consequence, a T-shape geometric configuration rather than a trigonal planar was predicted for these molecules. The stability of a high-coordination compound MF_6^- with the metal in the 5+ oxidation state is foreseen. $113F_5$ will probably be unstable since the energy of the reaction $113F_5 \rightarrow 113F_3 + F_2$ is only –53.4 kJ mol^{-1} (Seth *et al*., 1999). The calculated energies of the decomposition reaction $MX_3 \rightarrow MX + X_2$ (M = B, Al, Ga, In, Tl and element 113) confirmed a decrease in the stability of the 3+ oxidation state in group 13.

The standard electrode potential $E^{\circ}(113^{+}/113)$ was predicted to be +0.6 eV and 113^{+} is expected to be more easily complexed than Tl^{+} and to be similar to Ag^{+} (Keller *et al.*, 1970). For example, the solubility of TlCl in water is not increased much by adding excess HCl (Alekseeva *et al.*, 1972) or NH_3, whereas AgCl dissolves when NH_3 is added. Element 113 is expected to be more like silver in this respect. The smallest sublimation enthalpy in the group was predicted for element 113 by extrapolation (Keller *et al.*, 1970) and can be explained by the relativistic stabilization of the $7p_{1/2}$ orbital.

(*ii*) *Element* 114

The most interesting among the 7p elements is element 114 where a very large SO splitting of the 7p orbital and the relativistically stabilized 7s and $7p_{1/2}$ electrons result in a closed-shell ground state $7s^2 7p_{1/2}{}^2$, suggesting that the element should be rather inert. This is also reflected by the largest IP in group 14 (Table 14.15). One of the most striking features seen in Table 14.14 is the great decrease in boiling point in going from element 113 to element 114. This decrease was predicted by Keller *et al.* (1970) on the basis of extrapolations of the heats of sublimation of the group 13 and 14 elements versus periods of the periodic system. The boiling points were then calculated using Trouton's rule. This effect is a result of adding a second $7p_{1/2}$ electron in element 114 to form a

closed-shell $7p_{1/2}{}^2$ configuration, similar to the s^2 one, making this configuration responsible for much weaker bonding in a metallic state.

The group 14 elements show increasing stability of the 2+ oxidation state relative to the 4+ state as one goes to higher atomic numbers. Lead is known to be most stable of the group 14 elements in the 2+ oxidation state. Due to the very large 7s orbital stabilization, the sp^3 hybridization energy needed for the 4+ valence is very large in element 114, so that the 4+ oxidation state of element 114 is expected to be unstable, while the 2+ state should be the most stable in the group. Recent calculations (Liu *et al*., 2001) have, indeed, shown $114O_2$ to be thermodynamically unstable in contrast to PbO_2. Energies of the decomposition reactions $MX_4 \rightarrow MX_2 + X_2$ and $MX_2 \rightarrow M + X_2$ (M=Ge, Sn, and Pb; X = H, F, and Cl) were calculated at the PP level (Seth *et al*., 1998b; Nash and Bursten, 1999a). The results confirm a trend of decreasing stability of the 4+ oxidation state in the group. The neutral (monatomic) state was calculated to be more stable for element 114 than for Pb. Element 114 should also have a greater tendency to form complexes in solutions than Pb. Because the stability of the 2+ state increases within group 14, element 114 would probably form MX^+, MX_2, MX_3^-, or MX_4^{2-} (X = Cl, Br, and I) by analogy with Pb. $114F_6^{2-}$, suggested by Seth *et al*. (1998b), will probably be unstable in the aqueous phase due to strong hydrolysis of the fluorides in aqueous solutions. Thus, aqueous complexes of element 114 such as $114Br_3^-$ or $114I_3^-$ should be preferentially formed. Pitzer (1975a) predicted stable $(114)X_2$ (X = F, Cl, and Br). The standard electrode potential $E^\circ(114^{2+}/114)$ was estimated as +0.9 V by Keller *et al*. (1970). We thus see that relativistic effects on the $7p_{1/2}$ electrons cause a diagonal relationship to be introduced into the periodic table near element 114, causing 114^{2+} to be somewhere between Hg^{2+} or Cd^{2+} and Pb^{2+} in its chemistry and causing 113^+ to act more like Ag^+ than Tl^+.

(*iii*) *Element* 115

In element 115, one electron is located in the relativistically destabilized $7p_{3/2}$ orbital and, therefore, is loosely bound,while $7p_{1/2}{}^2$ serves as an inert pair. Thus, the 1+ oxidation state of element 115, like that of Tl^+, should be preferred. This is also supported by a drastic decrease in the first IP between 114 and 115 (Fig. 14.8). Furthermore, calculations show that element 115 has the smallest IP in group 15 and in the 7th period, as shown in Table 14.15 and Fig. 14.8. Keller *et al*. (1974) made some detailed predictions of the chemical properties of element 115 based on extrapolations of the properties of group 15 elements and relativistic atomic DS and DF calculations. Their results indicate that the chemical properties of element 115 should be analogous through a diagonal relationship to those of Tl (group 13) as well as to those of Bi. They predicted a standard electrode potential $E^\circ(115^+/115) = -1.5$ V, indicating that element 115 metal should be quite reactive. They also suggested that 115(III) should be relatively stable and have some chemical properties somewhat similar

to Tl(III), but that its chemical properties will be closer to those of Bi(III). The 5+ state seems unlikely. Melting and boiling points of the metal should be close to those of element 113.

(c) Elements 116 through 118

The chemistry of elements 116 through 118 will be defined mostly by the participation of the $7p_{3/2}$ orbital in bonding. Certain predicted volatility characteristics of elements 116, 117, and 118 or their compounds may offer advantages for chemical identification. This will be especially true for element 118. The chemical properties of element 116 can be deduced by extrapolations from Po, though the 2+ state should be more stable than the 4+ state because the $7p_{1/2}^2$ electrons are expected to be rather inert. Estimates of formation enthalpies of MX_2 and MX_4 (X = F, Cl, Br, I, SO_4^{2-}, CO_3^{2-}, NO_3^-, and PO_4^{3-}) for Po and element 116 (Grant and Pyper, 1977) on the basis of the MCDF atomic calculations are consistent with the expected instability of 116^{4+}. The chemistry of element 116 is expected to be mainly cationic, i.e. the relative ease of formation of the divalent compounds should approach that of Be or Mg, and tetravalent compounds such as $116F_4$ should be formed only with the most electronegative atoms.

In element 117, the 1– oxidation state becomes less important than that of the lighter group 17 halide ions due to the destabilization of the $7p_{3/2}$ orbital. The EA of element 117 is the smallest in the group (2.6 eV as predicted by Cunningham, 1969 and 1.8 eV as given by Waber *et al.*, 1969). Therefore, the 3+ state should be at least as important as the 1– state, so that element 117 might resemble Au^{3+} in its ion-exchange behavior in halide media. The trend to decreasing participation of the $np_{1/2}$ orbital bonding in group 17 was found to be continued further with element 117 (Hoffman, 1996; Saue *et al.*, 1996; Nash and Bursten, 1999c; Han *et al.*, 2000). In the group HI, HAt, and H117, an increasing trend in R_e and a decreasing trend in D_e are continued with H117. Analogous to its lighter homologs, Element 117 should form dimers X_2. The DCB CCSD(T) calculations for X_2 (X = F through At) (Visscher *et al.*, 1996) found a considerable antibonding σ-character in the HOMO of At_2 due to the SO coupling while without the SO coupling it is an antibonding π-orbital. The bonding in $(117)_2$ is predicted to continue this trend and have a strong π-character.

The elements in the noble gas group become less inert with increasing Z. Earlier predictions of properties of element 118 were made by extrapolation from lighter homologs within the group (Grosse, 1965; Pitzer, 1975a,b). Early calculations of Penneman and Mann (1976) indicated that ionization energies of element 118 should be less than the experimental values for xenon, and that chemical compounds should be expected for 118. The first IP of element 118 is 8.7 eV (see Table 14.15), about the same as the IP(114) = 8.54 eV and smaller than IP(Rn) = 10.74 eV and IP(112) = 11.97 eV. The outer 8s orbital of element 118 is relativistically stabilized to give the atom a positive EA of 0.056 eV, as

shown by recent CCSD calculations (Eliav *et al.*, 1996b). The polarizability of 118 is expected to be the largest in group 18. Its largest polarizability, together with its smallest IP, implies that it will have the highest reactivity in the group. It should be stable in the 4+ oxidation state, and should form stable tetrafluorides and tetrachlorides as well. Recent RECP calculations (Han and Lee, 1999) of free energies of the reactions $M + F_2 \rightarrow MF_2$ and $MF_2 + F_2 \rightarrow MF_4$, where M = Xe, Rn, and element 118, confirmed an increase in the stabilities of the 2+ and 4+ oxidation states in group 18. The SO effects were shown to stabilize $118F_4$ by a significant amount, about 2 eV, though they elongate R_e by 0.05 Å. The influence of the SO interaction on the geometry of MF_4 was investigated by RECP calculations (Han and Lee, 1999; Nash and Bursten, 1999a,b). It was found that the D_{4h} geometrical configuration for XeF_4 and RnF_4 becomes slightly unstable for $118F_4$. A T_d configuration was shown to be more stable than D_{4h} by about 0.20 eV. The reason was the availability of only stereochemically active $7p_{3/2}$ electrons for bonding. An important observation was made that the fluorides of element 118 will most probably be ionic rather than covalent as is the case of Xe. Therefore, they are predicted to be non-volatile.

(d) Elements 119 through 121

In elements 119 and 120, the filling of the 8s shell will take place, so that these elements should be homologs of the alkali and alkaline earth elements in groups 1 and 2 and will be stable in the 1+ and 2+ oxidation states, respectively. Their first IPs (Fricke, 1975) should be about 0.5 eV higher than those of Fr and Ra, respectively, due to the relativistic stabilization of the 8s electrons, and closer to the values of Rb and Sr. Thus, an upturn in the IPs from Cs to element 119 and from Ba to element 120 (see Fig. 14.22) was predicted (Penneman and Mann, 1976). Recent DK CCSD calculations (Lim *et al.*, 1999) showed the first IP of element 119 to be relativistically increased from 3.31 to 4.53 eV, while polarizability is decreased from 693.94 to 184.83 a.u. Due to the relativistic stabilization of the 8s orbital, the EA for element 119, of 662 meV, is 20 meV higher (being the highest in the group) than that for Fr, according to recent DCB CCSD calculations (Landau *et al.*, 2001).

The atomic radii of elements 119 and 120 are expected to be 2.4 and 2.0 Å, respectively, very similar to the values of Rb and Sr, as shown in Fig. 14.23. They show the same reversal of the trend (a downturn from Cs/Ba to 119/120) as do the IPs in groups 1 and 2 (Fricke, 1975). Thus, the chemical properties of elements 119 and 120 should be close to those of Rb and Sr, respectively, rather than to Fr and Ra in the 1+ and 2+ oxidation states. On the other hand, the ions will have larger radii than Rb^+ and Sr^{2+} because of the larger extension of the filled 7p shell compared to the lower p-shells. Another important point is that due to the relatively small ionization energy of the outer $7p_{3/2}$ electrons and their spatial extension, higher oxidation states like 3+ or 4+, respectively, could be reached in elements 119 and 120.

The value for Element* 119 *is from DF CCSD calculations* (*Landau* et al., 2001). *The values for elements* 120, 165 *and* 166 *are from DF calculations* (*Fricke,* 1975).

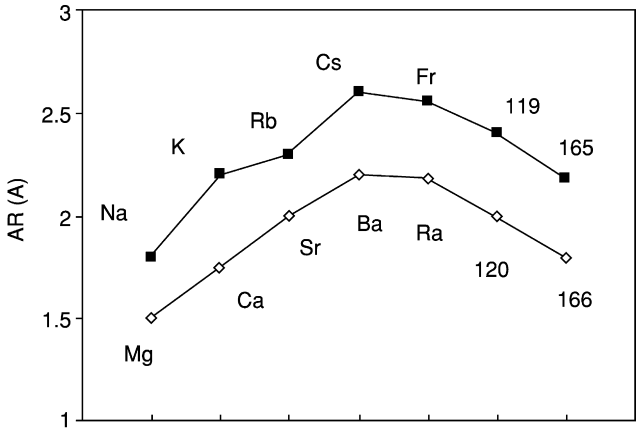

Fig. 14.23 *Atomic radii* (*AR*) *of alkali and alkaline earth elements. The data for Na through Cs and Mg through Ra are experimental. The other data are from DS calculations.* (*Redrawn from Fricke,* 1975).

The next element, 121, will have a relativistically stabilized 8p electron in its ground state electronic configuration $8s^2 8p_{1/2}$ (see Table 14.13) in contrast to that of $8s^2 7d$ predicted by a simple extrapolation within the group. As early as 1969, Griffin *et al.* (1969) showed that the large SO splitting brings an 8p

electron into the stable atomic ground state. Recent CCSD calculations for element 121 (Eliav *et al.*, 1998a) gave $IP_1 = 4.45$ eV and EA = 0.75 eV, the highest EA in group 3. Griffin *et al.* also showed that large changes occur in the spatial distribution of the valence orbitals in going from element 120 to 121. For example, the effective radius of the 5g electrons changes from 25 Bohr units for element 120 in the excited configuration $8s^15g^1$ to 0.8 Bohr units for element 121 in the configuration $8s^17d^15g^1$. This phenomenon, called 'radial collapse', occurs as late as element 125 as a consequence of indirect relativistic effects. Due to the proximity of the valence levels, higher oxidation states are possible.

(e) Superactinide elements and beyond

Element 122 belongs to a very long, unprecedented transition series that is characterized by the filling of not only 6f but also 5g orbitals with partially filled $8p_{1/2}$ orbitals, which is a direct relativistic effect. These elements were dubbed 'superactinides' by Seaborg (1968) as early as 1968. Quite a number of theoretical calculations of the ground state electronic configurations (Griffin *et al.*, 1969; Mann, 1969; Mann and Waber, 1970; Fricke *et al.*, 1971) were performed for this region and the results have been summarized by Fricke (1975). The calculated ground state configurations of the free neutral atoms of elements 113 through 184 are listed in Table 14.13. Here, at the beginning of the superactinides, not only two but four electron shells, namely $8p_{1/2}$, $7d_{3/2}$, $6f_{5/2}$, and $5g_{7/2}$, are expected to compete simultaneously. These open shells, together with the 8s electrons, determine the chemistry.

As shown in Table 14.13, a 7d electron is added to the ground state in element 122 and the 8p electron is relativistically stabilized so that the configuration is $8s^27d8p$, in contrast to the $7s^26d^2$ state of Th. This is the last element where accurate CCSD calculations (Eliav *et al.*, 2002) exist. The first four calculated IPs of element are 5.6, 11.3, 20.4, and 27.14 eV as compared to the first and the fourth IPs, 6.54 and 28.75 eV, of Th. A decrease in the first IP from Th to element 122 is due to the ionized $8p_{1/2}$ electron.

Elements 122 through 152 might have chemical properties somewhat similar to those of the actinides but there will be some differences. The very small binding energies of all the valence electrons will cause the higher oxidation states to be reached in these elements. This will be a continuation of the trend from the lanthanides (where 3+ states are highest) to the superactinides.

For ionic compounds it is important to establish which external orbitals are left after all outer s-, p-, and d-electrons are removed. Will there be some g- and f-electrons left or will they be easily excited to an outer electron shell, so that they can be removed as well? Some investigations showed that for element 126 in the divalent state, one g-electron will move to an f-electronic state, and the 8s electrons will not be the first to be removed. Thus, the divalent ions are expected

to act as soft Lewis acids and possibly form covalent complex ions readily. From some calculations of excited states, it is assumed that very high oxidation states may be possible around element 128 in complex compounds, but that normally these elements will have 4+ as their main oxidation state in ionic compounds. The maximum valence will be reduced to 6+ at element 132 and in the region of 140, it will be 3+ to 4+. At the end of the superactinide series, the normal oxidation states are expected to be only 2+ because the 6f shell will be buried deep inside the electron core and the 8s and $8p_{1/2}$ orbitals will be strongly bound. At element 156, only two 7d relativistically destabilized electrons will be available for bonding. This behavior should be similar to that of the low oxidation states of elements at the end of the actinides. Thus, at the end of the superactinide series, the elements will be more noble.

A contraction of bond lengths, analogous to the actinide contraction, is expected for the superactinide series. The total effect will be very large because of the 32 electrons, with the expected contraction of 0.02 Å per element. The predictions of chemical properties by extrapolation will be very difficult und unreliable in this area, since most of the elements have no homologs. From atomic calculations, one can already say that the behavior will be very different due to the stronger relativistic effects.

The fifth series of transition elements is expected to begin beyond the superactinides. Several early DF calculations in this region were performed. In elements 155 to 164, the filling of the 7d shell will take place so that they will be the d transition elements of the 8th period. The 8s and $8p_{1/2}$ electrons will be bound so strongly in these elements that they will not participate in the chemical bonding in contrast to the 7s electrons of the 7th period. Nevertheless, the 9s and $9p_{1/2}$ states will be easily available in 164 for hybridization so that the chemical behavior is expected to be similar to that of other d-elements. From DF calculations of excited states of element 164, Penneman and Mann (1976) suggested that the 7d orbitals will be chemically very active. Thus, in aqueous solutions, strong ligands can form tetra- and hexavalent bonds in addition to the predominant bivalent bonds. Consequently, tetrahedral $164(CO)_4$, $164(PF_3)_4$, and linear $164(CN)_2^{2-}$ might be prepared, which would be a striking contrast to lead (Fricke, 1975). The softness of element 164 should be similar to that of Hg, so that its location in the same group in the periodic table is justified. The metallic state of element 164 should have a larger cohesive energy than almost any other element because of covalent bonding, so that the melting point should be high (Fricke and Waber, 1971). The same authors indicated that the properties of elements 118 and 164 might also be analogous.

In elements 165 and 166, the 9s shell will be filled, suggesting that they should be homologs of group 1 and 2 elements and that their IPs and IR (Fricke, 1975) will be similar to those of the group 1 and 2 elements, respectively. Nevertheless, because of the underlying 7d shell, elements 165 and 166 might exhibit

properties similar to those of the group 13 and 14 elements. Therefore, higher oxidation states than 1+ and 2+, respectively, might occur.

In elements 167 through 172 the $9p_{1/2}$ shell will fill before the $8p_{3/2}$ shell. The energies of these orbitals are so close to each other that this situation is analogous to the nonrelativistic p-shell in the 3d period. Thus, the common oxidation states of elements 167 to 179 will be 3+ to 6+. Element 171 is expected to have many states from 1– to 7+, as do halogens. H(171) would form due to its high electron affinity of 3.0 eV (Fricke *et al.*, 1971). Compounds with F and O are also expected. Element 172 might be a noble gas similar to Xe due to the similar values of their IPs. The major difference is that element 172 is predicted to be a liquid or a solid at normal temperatures because of its large atomic weight.

Mann reported that his program was unable to go beyond $Z = 176$. Model calculations of Fricke and Waber (1972) took into account a phenomenological formulation of quantum electrodynamic effects and made it possible to extend the DF calculations to even higher elements. They calculated the DF ground state for element 184, as shown in Table 14.13. The 10s and $10p_{1/2}$ electrons do not appear in the ground state configuration and only $8d^3$ and $7f^4$ electrons might be available for chemical bonding. The chemical behavior will be then even simpler than that of the early superactinides. With increasing ionization of the 184 ion, a redistribution of electrons occurs between the 6g and 7f shells so that the number of electrons in the 6g shell increases. Since the 6g electrons are very deep inside the ion, only 7f electrons will be available for bonding. By analogy to U, the 5+ and 6+ states may be easily reached, but in aqueous solution the 4+ oxidation state will be the most stable. Higher oxidation states are not likely because the binding energy of the electrons in the deeply buried 6g shell will increase rapidly with higher ionization. Thus, in the very long SHE transition series, where many outer electron shells are being filled simultaneously in the neutral atom, a large increase in ionization energies will occur so that extremely high or unusual oxidation states are not expected.

In summary, in the area of the SHEs, the relativistic effects are so strong that any classification based on the knowledge of their electronic configurations or extrapolations of properties from the known elements is inappropriate. It is interesting to note that even without relativistic effects, the chemistry of the heaviest SHEs would be different from that of their lighter homologs due to very large shell-structure effects. The nonrelativistic expansion and destabilization of the *n*s valence orbitals and contraction and stabilization of the *n*d, *n*f, and orbitals of higher angular quantum number *l* with very large *n* also would have drastically changed the properties of the SHEs. However, due to the opposite actions of relativistic and shell-structure effects, the relativistic and nonrelativistic changes are predicted to go in opposite directions. A more detailed periodic table up to element 172 was given by Fricke (1975). Some discussions of the chemistry of SHEs can be found in Penneman *et al.* (1971),

Fricke (1975), and Jorgensen (1968), and more recently in a review of the evolution of the periodic table by Seaborg (1996).

14.7.2 Prospects for experimental studies of chemistry of elements beyond element 112, including SHEs

The prerequisites for successful studies of the chemistry of elements beyond 112 will be similar to those discussed previously for Mt through 112. These include the existence of isotopes with long enough half-lives for chemical studies, knowledge of their nuclear decay properties so that they can be positively identified as belonging to the element being studied, synthesis reactions with the highest possible cross sections, techniques for increasing the production rates such as cooled, multiple targets, the highest possible beam currents at accelerators with facilities for conducting these studies, and, ideally, dedicated beamlines for optimal utilization of facilities by international groups of scientists. After the chemistry of a given element is known, the atomic number of new isotopes can be positively assigned based on their established chemical properties and detailed studies of nuclear properties such as SF can be conducted on chemically separated samples.

(a) Chemical methods

A useful technique that should prove invaluable in the study of very low-yield, short-lived elements is pre-separation of the nuclides of interest from the host of unwanted activities using a dedicated on-line separator such as the BGS at the appropriate accelerator. At the focal plane the separated isotopes can be stopped in an RTC containing an appropriate gas and can even be treated chemically to adjust oxidation states and volatility. The resultant volatile species can then be rapidly and continuously transported to a cryo-thermochromatographic separator or any other desired chemical separation/detection system.

The ingenious isothermal gas-phase techniques that have already been applied in the studies of volatile Hs oxides can be used to study other volatile species that can be similarly swept in carrier gas directly to an on-line detection system or to a cryogenic TC composed of the particle detectors. In this way, simultaneous on-line measurements can be performed of the decay properties of the radioactive nuclides in the volatile species and their deposition temperature on the surface of the detectors that form the chromatography column. Vacuum cryo-thermochromatographic techniques in which the relative reactivity of elements 114 through 118 are determined based on their sorption on a variety of transition metal surfaces might be used to assess whether their behavior is more like their lighter homologs or the inert noble gases.

The continuous, computer-controlled automated procedures discussed in the previous sections can be used and other procedures designed specifically to exploit the chemistry predicted for each of these elements. Continuously

operating, rapid systems for liquid–liquid extractions followed by detection in flowing liquid-scintillation detectors such as the SISAK-III/liquid scintillation system (Omtvedt *et al.*, 1998, 2002) can be used for on-line studies of isotopes with half-lives as short as a few seconds provided chemical systems that rapidly come to equilibrium can be devised. Alternatively, they could be used to continuously purify longer-lived SHEs. A variety of computer-controlled, continuous multi-ion-exchange column techniques that include automated transport of samples to the detection equipment have been developed (Haba *et al.*, 2002; Nagame *et al.*, 2002) for performing rapid separations of isotopes with half-lives as short as a few seconds and then inferring their presence based on detection of their longer-lived daughters in subsequent chemical separations. Such continuous systems might also be adapted for processing longer-lived SHEs for subsequent off-line detection.

New methods for studying gas-phase ion chemistry in a Penning trap have been reported by Rieth *et al.* (2002) and it has been shown by the ISOLTRAP group at the Centre Européen pour la Recherche Nucléaire (CERN) (Kugler *et al.*, 1992; Bollen *et al.*, 1996) that nuclides as short as a few tenths of a second can be used with Penning trap mass spectrometers. These techniques have potential application to gas-phase studies of elements beyond 112. Kinetic data on ion–molecule interactions can be obtained with single-ion detection, and mass spectrometry can be used to unambiguously determine the stoichiometry of the reaction products. However, the reaction rates must be increased in order to make the technique viable for the low production rates of less than one atom per week expected for the heaviest elements.

(b) Predicted and reported half-lives and nuclear properties of SHEs

One of the most significant nuclear properties of elements 107 through 112 is that they decay predominantly by alpha emission rather than SF, contrary to earlier predictions. This experimental discovery sparked a renewal of interest in searching for elements beyond 112 and revived hope that the long-predicted island of SHEs might finally be reached. Armbruster and Münzenberg (1989) proposed that even though the neutron-deficient isotopes of elements 107 through 112 are probably not spherical, they should qualify as SHEs because without the stabilization of nuclear shells they would not exist. These elements have not been generally recognized as SHEs.

The discovery of longer-lived isotopes in this region, ^{265,266}Sg, ^{267}Bh, and ^{269,270}Hs, substantiated the theoretical model and calculations (Sobiczewski *et al.*, 1994; Smolańczuk *et al.*, 1995) predicting a doubly magic deformed region of extra stability in the vicinity of proton number 108 and neutron number 162 in addition to the island of spherical stability originally predicted to be around $Z = 114$ and $N = 184$, as shown in Fig. 14.24.

Evidence for three isotopes of element 114, ^{287,288,289}114, has been reported (Oganessian *et al.*, 1999a) although only one event of 21-s ^{289}114 was detected

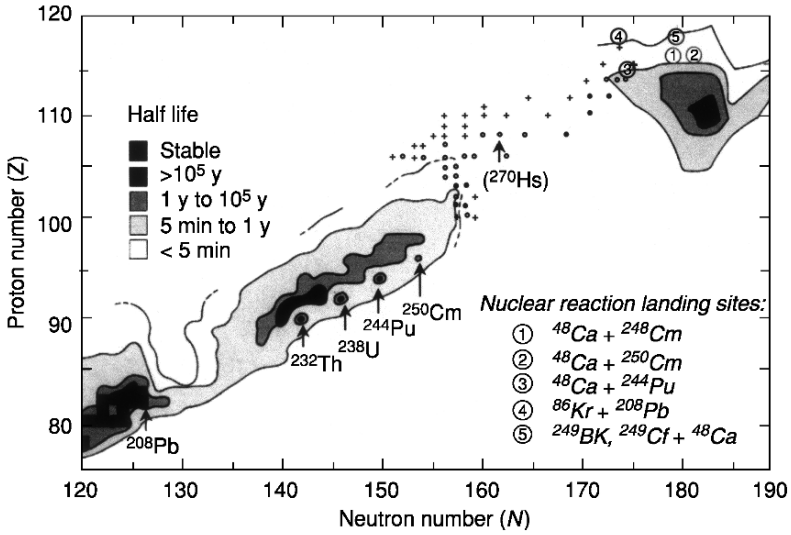

Fig. 14.24 *Updated plot of heavy element topology from* 1978 *showing some landing points for proposed reactions. Heavy element isotopes reported since* 1978 *up to mid-*2002 *are indicated with symbols denoting the following half-life ranges:* 0.1 ms to 0.1 s (+); 0.1 s to 5 min (○); > 5 min (●).

and it was not confirmed in subsequent experiments (Lougheed *et al.*, 2000). The discovery of isotopes of element 116, $^{292}116$, has been discussed by Oganessian (2002) and Oganessian *et al.* (2002, 2004c). Calculations (Smolańczuk, 1997) indicate that these isotopes are nearly spherical with deformation energies ranging from only about 0.1 MeV for $^{292}116$ to 0.3–0.2 MeV for the 114 isotopes, compared to zero deformation energy for the spherical doubly magic $^{298}114$ and 7.8 MeV for the doubly deformed magic nucleus, $^{270}108$. Thus, element 114 and 116 isotopes qualify as spherical SHEs even though they do not have the full complement of 184 neutrons. However, their existence still awaits confirmation by other groups.

Recent theoretical predictions (Chasman and Ahmad, 1997; Smolańczuk, 2001a,b) indicate that isotopes with half-lives of microseconds or longer will exist all along the way to the predicted islands of stability. However, the half-lives predicted for nuclei in the region of the spherical island of stability have decreased dramatically since the 1970s when half-lives of billions of years were predicted. For example, Smolańczuk (2001a,b) predicted that the spherical doubly magic superheavy nucleus $^{298}114$ will decay predominantly by alpha emission with a half-life of only 12 min, but that ^{292}Ds may alpha decay with a half-life of about 50 years.

Some other recent calculations (Kruppa *et al.*, 2000) predict that the strongest spherical shell effects might be at $Z = 124$ or 126 and $N = 184$ while still others

propose the maximum effect might be at $Z = 120$ and $N = 172$. Doughnut-like, toroidal nuclear shapes with lower densities or a hole in the middle to alleviate the effects of Coulomb repulsion have even been postulated. How many more elements can exist is still unclear and it is even more unclear how many of these we can actually produce.

(c) Production reactions

So-called 'cold' fusion reactions in which the compound nucleus is produced with small excitation energy and emits only a single neutron were used to discover the elements from Bh through 112 (Hofmann, 1998). After the discovery of element 112 in 1996 (Hofmann *et al*., 1996), researchers at GSI unsuccessfully attempted to produce element 113 using the cold fusion reaction ^{209}Bi (^{70}Zn,n) ^{278}113 (Hofmann and Münzenberg, 2000). From two experiments lasting about 3 weeks each, they set a limit of 0.6 pb on the cross section at a mean excitation energy of 10.5 MeV. They concluded that the cross section for production of element 116 would be only 1 femtobarn and that their experimental setup would have to be greatly improved in order to investigate this region further. Contrary to these expectations that the production cross sections for the 1n evaporation channel in cold fusion reactions to produce elements above 112 would continue to decrease exponentially with the proton number of the projectile, Smolańczuk (1999a) suggested that the cold fusion reaction ^{208}Pb(^{86}Kr,n) reaction to produce the hypothetical spherical SHE nuclide ^{293}118 with an excitation energy of only 13 MeV would have an unusually large cross section of a few hundred picobarns. The predicted increase in formation cross section was attributed to the fact that ^{86}Kr contains the magic number of 50 neutrons, which leads to a larger Q value with a subsequent increase in the transmission probability through the Coulomb barrier. He also predicted that ^{293}118 would decay by a unique decay sequence of six high-energy alpha particles. However, the results of Gregorich *et al*. (2002) setting upper limits of less than 1 pb for the formation cross section for this reaction based on detection of the predicted high-energy alpha-decay chain make the use of cold fusion reactions appear less attractive for production of SHEs. Estimates of the predicted cross section were later lowered to about 6 pb (Smolańczuk, 2001b), and it was pointed out that the excitation functions are quite narrow and have a rather sharp threshold (Smolańczuk, 1999c) so use of too low a bombarding energy might result in a negative result and the idea should not be totally abandoned.

Similar cold fusion reactions with ^{208}Pb or ^{209}Bi targets with ^{87}Rb or ^{86}Kr projectiles could be used to produce ^{294}119 (Smolańczuk, 1999a,b), whose half-life is estimated to be only microseconds. However, ^{294}119 is predicted to decay to isotopes of the new longer-lived, odd-Z elements 117, 115, and 113 via a succession of alpha emissions, ending with the known isotope 3.6-h ^{262}Lr. Production of ^{295}120 ($\sim$2 μs) via the ^{208}Pb(^{88}Sr,1n) reaction and detection of its high-energy alpha-decay chain have also been proposed (Smolańczuk, 2001a).

The reported elements 114 and 116 were synthesized using reactions of ^{244}Pu and ^{248}Cm with ^{48}Ca projectiles to form the compound nuclei ^{292}114 and ^{296}116, which then emitted four neutrons to produce 2.6-s ^{288}114 and 53-ms ^{292}116 (Oganessian *et al*., 2000a,b; Oganessian, 2001, 2002). They were calculated to have excitation energies of only 33 and 31 MeV, respectively, due to the stability of the doubly magic projectile, compared to >45 MeV for 'hot' fusion reactions. The detection limit of these experiments was about 0.5 pb, several orders of magnitude more sensitive than in the unsuccessful attempt reported in 1984 by an international group of nuclear scientists, both chemists and physicists (Armbruster *et al*., 1985), who conducted an exhaustive 'final' investigation of the reaction of ^{248}Cm with ^{48}Ca projectiles to produce SHEs. Oganessian also proposed that the reaction of ^{48}Ca with ^{249}Cf targets be used to produce element ^{294}118 via the '3n out' reaction. However, the viability of the '3n out' reactions in this region has yet to be confirmed. Loveland *et al*. (2002) set a limit of <2 pb for SF and alpha events for the ^{238}U(^{48}Ca,3n)^{283}Ds reaction. Hot fusion reactions between ^{48}Ca projectiles and ^{249}Bk and ^{249}Cf targets to produce elements ^{293,294}117 and ^{293,294}118, respectively, are under investigation by the Dubna/LLNL group.

The ^{237}Np and ^{249}Bk targets with ^{48}Ca projectiles can probably be used to make the odd-proton element 113 and more neutron-rich isotopes of element 117, respectively. Other highly radioactive targets such as ^{249}Cf or even ^{254}Es with appropriate projectiles might be used to make more neutron-rich isotopes of elements as heavy as 118, but considerable development work will be required.

Reactions that can produce a higher ratio of neutrons to protons will certainly be most advantageous and need to be investigated. Myers and Swiatecki (2000) have suggested that so-called 'unshielded' reactions in which the Coulomb barrier has sunk below the bombarding energy may result in enhanced production yields for some of the higher Z elements. Their hypothesis that the cross section for ^{277}112 produced in the symmetric reaction ^{142}Ce(^{136}Xe,n) might be much larger than that for the 112 discovery reaction ^{208}Pb(^{70}Zn, n)^{277}112 should be tested experimentally. If so, the unshielded reaction ^{170}Er (^{136}Xe,n) reaction to make ^{305}122, which has 183 neutrons, might be a method for getting closer to these regions. It should decay by successive alpha emission to the isotope ^{289}114, reported by the Dubna/LLNL group. Whether additional SHEs can be produced depends very much upon whether the cross sections for the 'cold' fusion reactions in which only a single neutron is emitted and the 'warm'/'hot' fusion reactions with three or four neutrons emitted are large enough to permit detection.

It now appears likely that many more relatively long-lived nuclides can exist than are presently known, but a major research effort to explore new types of production reactions, imaginative techniques for optimizing overall yields by using multiple targets and higher beam currents, innovative chemical separations, and a dedicated on-line installation for chemical studies at an appropriate

accelerator with access to a pre-separator will be required in order to fully explore their chemical properties. If, on the other hand, relatively long-lived new elements are discovered, then methods for 'stockpiling' them for off-line studies or producing them as by-products of other experiments must be devised to facilitate studies of their chemistry. The prospect lies ahead of a whole new landscape for the exploration of the chemical properties of the heaviest elements and their compounds, determining the influence of relativistic effects, assigning their positions in the periodic table, and extending and further defining the architecture of the periodic table.

CHAPTER FIFTEEN

SUMMARY AND COMPARISON OF PROPERTIES OF THE ACTINIDE AND TRANSACTINIDE ELEMENTS

Norman M. Edelstein, Jean Fuger,
Joseph J. Katz, and Lester R. Morss

15.1 INTRODUCTION

15.1.1 Scope

This chapter is intended to provide a unified view of selected aspects of the physical, chemical, and biological properties of the actinide elements, their typical compounds, and their ions in aqueous solutions. The f-block elements have many unique features, and a comparison of similar species of the lanthanide and actinide transition series provides valuable insights into the properties of both. Comparative data are presented on the electronic configurations, oxidation states, oxidation–reduction (redox) potentials, thermochemical data, crystal structures, and ionic radii of the actinide elements, together with

important topics related to their environmental properties and toxicology. Many of the topics in this chapter, and some that are not discussed here, are the subjects of subsequent chapters of this work, which should be consulted for more comprehensive treatments. This chapter provides an opportunity to discuss the biological and environmental aspects of the actinide elements, subjects that were barely mentioned in the first edition of this work and discussed only briefly in the second edition, but have assumed great importance in recent years. This chapter also provides a summary of the chemical properties of the transactinide elements that have been characterized.

15.1.2 The actinide concept

The actinide concept has achieved nearly universal acceptance as a way of integrating the transuranium elements into the periodic table. This concept was first expounded by G. T. Seaborg in 1944 (Seaborg *et al.*, 1949, pp. 1492–524, especially pp. 1517–20) and first enunciated in public on November 16, 1945 (C&E News, 1945). The chemical and electronic evidence that established the actinides as an inner transition series has been recently reviewed (Gruen, 1992). A succinct summary of this important principle will therefore be sufficient here.

The actinide concept considers the elements with atomic numbers 89–103 to be members of a transition series, the first member of which is actinium (atomic number 89). The elements with atomic numbers 89–103 are thus analogs of the lanthanide transition series that starts with lanthanum (atomic number 57) and includes the rare earth elements cerium through lutetium (atomic number 71). It is important, in comparing the lanthanide and actinide transition series, to keep in mind that the electronic configuration of any given element may be significantly different in the gaseous atoms, in ions in solids or solutions, and in the metallic state. In the lanthanide 3+ ions, 14 4f electrons are added in sequence beginning with cerium, atomic number 58 (Table 15.3). In the actinide series, 5f electrons are added successively beginning formally with thorium (atomic number 90) and ending with lawrencium (atomic number 103). Note the qualification 'formally.' No compelling evidence exists to show that thorium metal, or thorium ions in solution or in any of its well-defined compounds, contain 5f electrons. There is convincing evidence that protactinium metal displays 5f electron character, as is expected for the third member of an actinide series (Zachariasen, 1973; Fournier, 1976; Haire *et al.*, 2003).

The subsequent trivalent ions of the actinide series contain their appropriate complements of 5f electrons. Although there are important differences between the actinide and lanthanide elements, there are also striking similarities. The metallic elements and 3+ ions with half-filled f-electron shells, for example, are of special interest because of the enhanced stability of this particular electron configuration. Curium (atomic number 96), with seven 5f electrons in the metal and 3+ species, has magnetic, optical, and chemical properties that are remarkably similar to those of gadolinium (atomic number 64), with seven

4f electrons, as would be expected from the actinide concept. The principal differences between the two transition series arise largely from the lower binding energies and less effective shielding by outer electrons of 5f as compared to 4f electrons. Both the similarities and the differences between the actinide and lanthanide series have had great heuristic value in actinide element research. Further discussion of the electronic structure of the actinide elements is given in Section 15.4. Much more detailed expositions of the actinides as a 5f transition series are given in subsequent chapters.

15.2 SOURCES OF ACTINIDE AND TRANSACTINIDE ELEMENTS

15.2.1 Natural sources

The elements actinium through plutonium occur in nature. Only the elements thorium, protactinium, and uranium are present in amounts sufficient to warrant extraction from natural sources. Thorium and uranium are widely disseminated in the Earth's crust ($\sim$10000 and $\sim$3000 μg kg^{-1} respectively), and, in the case of uranium, in significant concentrations in the oceans (3.3 μg L^{-1}). More importantly, thorium and uranium are found highly enriched in certain mineral formations, and are obtained by conventional mining operations. The richest deposits of uranium are found in northern Saskatchewan, Canada. The annual world production of uranium from uranium ore in the period 1995–2000 was about 35000 metric tons of uranium oxide. Proven uranium reserves were about 3.2 million metric tons, with the richest deposits in Canada, Kazakhstan, USA, and Australia (World Energy Council, 1988). Thorium reserves were estimated at 1.2 million metric tons in 2004 (U.S. Geological Survey, 2002), but this estimate would be much higher if thorium extraction were economically viable; the largest deposits are in India, Australia, and the U.S. Extraction of thorium and uranium from their ores had been practiced for many years before the discovery of the transuranium elements, and an extensive technology exists for the extraction of thorium and uranium from many different types of ores.

Hundreds of thousands of tons of uranium have been processed for isotopic separation. Five grades of isotopically separated uranium are commonly recognized: depleted uranium (less than 0.71% ^{235}U), natural uranium (0.71% ^{235}U), low-enriched uranium (LEU) (0.71–20% ^{235}U), highly enriched uranium (HEU) (20–90% ^{235}U), and weapon-grade uranium (greater than 90% ^{235}U). Of these grades, HEU and weapon-grade uranium are the most important. HEU is produced (almost in equal amounts by gaseous diffusion or centrifuge enrichment) from natural uranium for use in nuclear weapons and for use in commercial nuclear reactors. Worldwide, at the end of 1994, 450 metric tons of HEU (calculated as weapon-grade equivalent) was inside nuclear weapons and 1300 metric tons had been removed from weapons. An additional 20 metric tons exist

in civil inventories. This total (1770 metric tons) is slowly decreased (20 metric tons per year in 1996) by blending down of Russian HEU (Albright *et al.*, 1996).

Neptunium (^{237}Np and ^{239}Np) and plutonium (^{239}Pu) are present in extremely minute amounts in nature as a result of natural nuclear reactions with neutrons in uranium ores. The longer-lived ^{244}Pu has been found in the rare earth mineral bastnasite to the extent of 1 part in 10^{18}, and may possibly be a primordial endowment (see Section 15.8.1).

15.2.2 Neutron irradiation

Actinium and protactinium are decay products of the naturally occurring uranium isotope ^{235}U and are present in uranium minerals in such low concentration that recovery from natural sources is a very difficult task. By comparison, it is relatively straightforward to obtain actinium, protactinium, and most of the remaining transuranium elements by neutron irradiation of elements of lower atomic number in nuclear reactors (Seaborg, 1963, 1978; Hyde *et al.*, 1964). Thus, actinium has been produced in multigram quantities by the transmutation of radium with neutrons produced in a high-flux nuclear reactor:

$$^{226}\mathrm{Ra} + \mathrm{n} \rightarrow {}^{227}\mathrm{Ra} + \gamma$$

$$^{227}\mathrm{Ra} \rightarrow {}^{227}\mathrm{Ac} + \beta^{-}$$

The product actinium can be separated from the precursor radium by solvent extraction or ion exchange, and gram amounts of actinium have been obtained by these procedures. This is not at all an easy task, considering the highly radioactive substances involved and the hazards of radon emission that accompanies these nuclear reactions, but it is preferable by far to extraction from natural sources. Protactinium can be produced by the nuclear reactions:

$$^{230}\mathrm{Th} + \mathrm{n} \rightarrow {}^{231}\mathrm{Th} + \gamma$$

$$^{231}\mathrm{Th} \rightarrow {}^{231}\mathrm{Pa} + \beta^{-}$$

The amount of ^{231}Pa produced in this way, however, is much less than the amounts (more than 100 g) of protactinium obtained from residues accumulated from the very large-scale extraction of uranium from ores. Because of the extreme tendency of protactinium(v) to form colloidal polymers that are easily adsorbed on solid surfaces, and cannot be removed from aqueous media by solvent extraction, the recovery of protactinium from uranium ore processing residues can only be described as a heroic enterprise.

Neptunium-237 is a long-lived isotope of element 93 that is produced in kilogram amounts. It is formed as a by-product in nuclear reactors when neutrons produced in the fission of uranium-235 react with uranium-238:

$$^{238}\mathrm{U} + \mathrm{n} \rightarrow {}^{237}\mathrm{U} + 2\mathrm{n}$$

$$^{237}\mathrm{U} \rightarrow {}^{237}\mathrm{Np} + \beta^{-}$$

Neptunium-237 is also formed by neutron capture in uranium-235:

$$^{235}\mathrm{U} + \mathrm{n} \rightarrow {}^{236}\mathrm{U} + \gamma$$

$$^{236}\mathrm{U} + \mathrm{n} \rightarrow {}^{237}\mathrm{U} + \gamma$$

$$^{237}\mathrm{U} \rightarrow {}^{237}\mathrm{Np} + \beta^{-}$$

The waste solutions from the processing of irradiated uranium fuel usually contain the neptunium, which can be isolated and purified by a combination of solvent extraction, ion exchange, and precipitation techniques.

The strategically important isotope ^{239}Pu is produced by the ton in nuclear reactors. Excess neutrons from the fission of uranium-235 are captured by uranium-238 to yield plutonium-239:

$$^{238}\mathrm{U} + \mathrm{n} \rightarrow {}^{239}\mathrm{U} \rightarrow {}^{239}\mathrm{Np} \rightarrow {}^{239}\mathrm{Pu}$$

Neutrons also cause the uranium nuclei to fission:

$$^{235}\mathrm{U} + \mathrm{n} \rightarrow \text{fission products} + 2.5n + 200\ \mathrm{MeV}$$

After removal from the reactor, the irradiated fuel can be chemically separated to extract the plutonium and also to separate the highly radioactive fission products.

Plutonium produced in nuclear reactors in which the fuel is irradiated for long periods of time contains plutonium isotopes with mass numbers up to 244, formed from ^{239}Pu by successive neutron capture. Industrial-scale processes for the separation and purification of plutonium are described in detail in Chapter 7. Three grades of plutonium are commonly recognized: weapon-grade plutonium (less than 7% ^{240}Pu), fuel-grade plutonium (7–18% ^{240}Pu), and reactor-grade plutonium (more than 18% ^{240}Pu).

Plutonium is an element that was until recently produced in 'production' reactors, i.e. reactors that were dedicated to produce nuclear materials for military purposes. More than 260 metric tons of military plutonium have been produced and separated worldwide (Albright *et al.*, 1996). Plutonium is also formed as a by-product of electricity production in all commercial (civilian) nuclear power reactors. As of 2000 the total 'discharge' of plutonium (plutonium in and separated from civilian spent fuel) from commercial nuclear power reactors was estimated to be 1380 metric tons, and this amount is predicted to increase by 741 metric tons in the decade 2001–10 (Albright *et al.*, 1996).

Although HEU and weapon-grade plutonium are primarily for military purposes and the lower grades are used in commercial nuclear reactors, enriched

uranium and plutonium of all grades are commonly discussed together because ^{235}U and ^{239}Pu are the two primary fissile isotopes and because they have the greatest security risk of potential diversion from peaceful to military or terrorist uses. Therefore, the total inventory must include both military and civilian stocks.

Plutonium has been separated from civilian reactor fuel principally at the B205 reprocessing plant in UK, at three reprocessing plants (UP1, UP2, UP3) in France, at Wiederaufarbeitungsanlage Karlsruhe (WAK) in Germany, and at Tokaimura in Japan. As of 1995, 132 metric tons of civilian plutonium had been removed at these plants. When plutonium separated by other countries is added, the total at the end of 1993 was 145 metric tons, of which 21 metric tons was in use in fast reactors and 17 metric tons in thermal reactors. The world annual separation of civilian plutonium continues at the rate of ca. 16 metric tons per year. By 2010, it is predicted that 437 metric tons will have been separated (Albright *et al.*, 1996).

Worldwide, at the end of 1994, 70 metric tons of plutonium were contained in nuclear weapons and 160 metric tons had been removed from weapons. The world inventory of all types of plutonium was 1160 metric tons at the end of 1994. The majority of this plutonium, 755 metric tons, was unseparated plutonium remaining in spent reactor fuel. This increases at the rate of approximately 70 metric tons per year.

The isotope ^{238}Pu is an important heat source for terrestrial and extraterrestrial applications (Section 15.11.2). The heat is generated by its nuclear alpha-particle decay. This isotope is available in kilogram quantities from the neutron irradiation of neptunium-237:

$$^{237}Np + n \rightarrow {}^{238}Np \rightarrow {}^{238}Pu$$

followed by chemical separation. Its 87.7 year half-life makes it the best isotope for this purpose. High-level waste from the isolation of plutonium-239 contains much larger quantities of plutonium-238, as well as heavier plutonium isotopes, formed by various nuclear reactions in reactor fuel elements, but the isotopic separation would be difficult and prohibitively expensive. The plutonium in a typical pressurized water reactor (PWR) fuel is approximately 1.3% ^{238}Pu after 33000 MWd ton^{-1} burnup (Albright *et al.*, 1996). As of 2000 approximately 10 metric tons of plutonium-238 exists in stored spent fuel elements and process residues accumulated in the U.S. and by the European Community, mixed with heavier plutonium isotopes (Albright *et al.*, 1996).

The elements americium and curium are obtained as by-products of the large-scale production of plutonium-239, or by the irradiation of plutonium-239 or isotopes of transplutonium elements in special high-neutron-flux reactors. The plutonium in a typical PWR fuel is approximately 14% ^{241}Pu after 33000 MWd ton^{-1} burnup (Albright *et al.*, 1996), producing ^{241}Am by beta decay with a half-life of 13.2 years. Kilogram quantities of americium-241 can be separated from

irradiated fuel by a combination of precipitation, ion exchange, and solvent extraction.

Isotopes of curium are also found in waste streams from plutonium-239 production, but in amounts smaller than those of americium. Curium (as ^{242}Cm and ^{244}Cm) is produced in nuclear reactors primarily by the beta decay of ^{242}Am and ^{244}Am, isotopes that were formed by neutron capture in ^{241}Am and ^{243}Am, respectively. The amount of ^{244}Cm accumulated in process wastes and in unprocessed irradiated fuel elements as of 2000 is estimated to be more than 1 metric ton (NEA, 2002). The high specific radioactivity (18.1-year half-life) of ^{244}Cm means that it has to be considered in separation schemes for reprocessing and transmutation, but it decays to low enough levels in a few hundred years that long-term storage is not a concern. Separation and purification of curium and americium is best carried out by the solvent extraction procedures described below because both are present as 3+ ions, which have similar chemical properties (see Section 15.3.6).

The sequence of neutron captures and beta decays that forms transuranium elements by slow neutron capture starting with plutonium-239 is shown in Fig. 15.1. A high neutron flux is essential to expedite the production of transplutonium elements. Fig. 15.2 shows that, even with a neutron flux in excess of 10^{14} cm^{-1} s^{-1}, years of irradiation may be required to attain useful conversions. Starting with 1 kg of ^{239}Pu, about 1 mg of ^{252}Cf would be present after 5–10 years of continuous irradiation at a neutron flux of 3×10^{14} cm$^{-1} \cdot$ s^{-1}. To increase the production rate, large quantities of ^{239}Pu can first be irradiated in production reactors, followed by continued irradiation in higher-neutron-flux reactors. The High Flux Isotope Reactor (HFIR) at Oak Ridge National

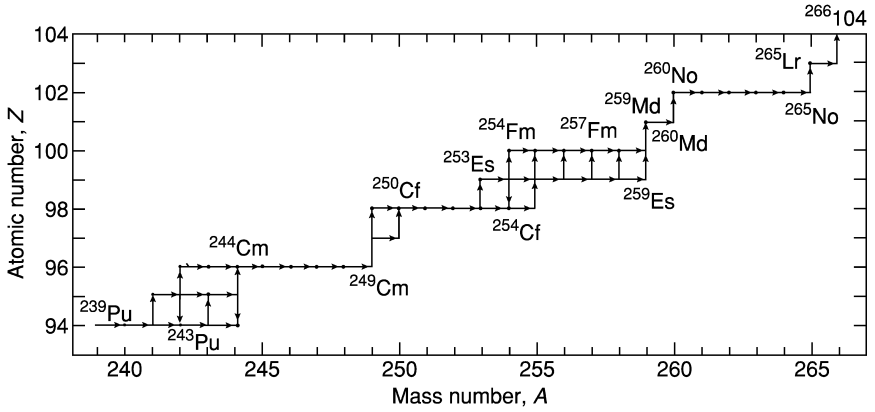

Fig. 15.1 *Nuclear reaction sequence for production of transplutonium elements by intensive slow-neutron irradiation. The principal path is shown by heavy arrows (horizontal, neutron capture; vertical, beta decay). The sequence above ^{258}Fm is a prediction.*

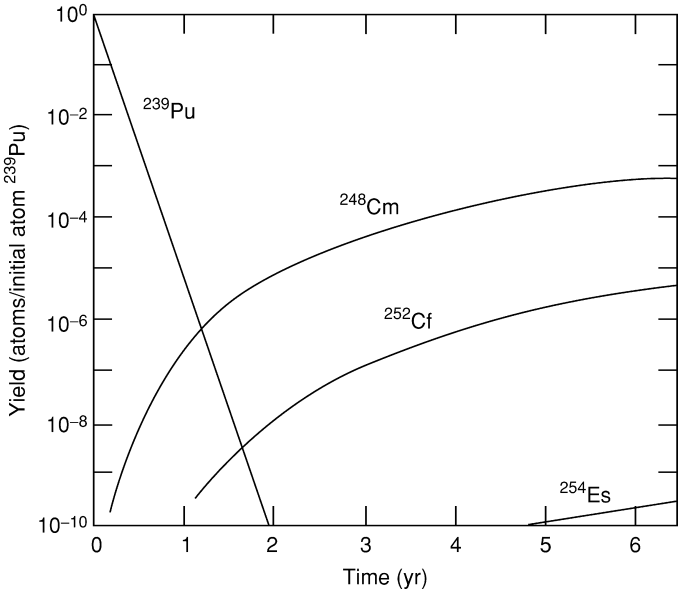

Fig. 15.2 *Production of some transplutonium nuclides by irradiation of* ^{239}*Pu at a neutron flux of* 3×10^{14} cm^{-2} s^{-1}.

Laboratory in Tennessee can provide neutron fluxes of about 2×10^{15} $cm^{-2} \cdot s^{-1}$. This reactor and tritium-production reactors that were in operation from 1953 to 1993 at the Savannah River Site in South Carolina, have made major contributions to the production of transcurium elements. A special facility, presently called the Radioisotope Engineering Development Center (REDC), was established at Oak Ridge in 1966 to fabricate plutonium targets, to extract transplutonium elements from the highly irradiated targets, and to provide pure samples of transplutonium isotopes as heavy as ^{257}Fm for research and industry. Neutron irradiation cannot be used to prepare the elements beyond fermium (^{257}Fm) because some of the intermediate nuclides have such short half-lives that the low equilibrium concentrations present effectively prevent the formation of significant amounts of the desired isotopes. Thus, only milligram amounts of einsteinium and picogram amounts of fermium can be obtained by protracted neutron irradiation even under the most favorable circumstances. Table 15.1 lists the past production rates of isotopes of elements from curium-248 to fermium-257 in the Oak Ridge HFIR/REDC operation (National Research Council, 1983; Keller *et al.*, 1984; Alexander, 2005). The SM-2 loop reactor in Russia has similar power and flux levels, giving it the potential for producing similar quantities of these transcurium isotopes. Isotopes that are sufficiently long-lived for work in weighable amounts are obtainable at least in

Table 15.1 *Production of transcurium isotopes in the U.S.*[a]

Isotope	*Half-life*	*Amount/year* (1983)	*Amount/campaign* (2004)
^{248}Cm	3.48×10^5 yr	150 mg[b]	100 mg[b]
^{249}Bk	330 d	50 mg	45 mg
^{249}Cf	351 yr	50 mg[c]	<45 mg[c]
^{252}Cf	2.645 yr	500 mg	400 mg
^{253}Es	20.47 d	2 mg[d]	1–2 mg[d]
^{254}Es	275.7 d	3 μg	4 μg
^{257}Fm	100.5 d	1 pg	1 pg

[a] One or two separation campaigns per year until about 1995; one campaign every 18–24 months from about 1995 to 2003.
[b] From alpha decay of ^{252}Cf.
[c] From beta decay of ^{249}Bk.
[d] Mixed with 0.06–0.3% ^{254}Es; chemical separation of ^{253}Cf followed by its beta decay can yield ~200 μg of isotopically pure ^{253}Es.

principle for all of the actinide elements through einsteinium. The elements above einsteinium appear likely to remain amenable to chemical study only by tracer techniques because (except for ^{257}Fm) only isotopes with short half-lives are known, and because it is unlikely that isotopes of the elements beyond einsteinium can be formed in weighable quantities by neutron irradiation or any other process.

Very heavy elements have been detected under circumstances where very intense neutron fluxes were produced. Such is the case for a few microseconds after a thermonuclear explosion. Isotopes of einsteinium and fermium were first discovered in the debris of the first thermonuclear explosion detonated at Eniwetok Atoll in November 1952 (Hyde *et al.*, 1964; Choppin *et al.*, 2002, p. 423). The route whereby elements of high atomic number are formed in the detonation of a thermonuclear device is again multiple neutron capture in ^{238}U, which is a component of the thermonuclear device. Thus, the synthesis of ^{255}Fm in the explosion occurred by way of ^{255}U (formed by the capture of 17 neutrons in ^{238}U) followed by a long sequence of short-lived beta decays that take place after the neutron capture reactions are complete:

$$^{238}\mathrm{U} + 17\mathrm{n} \rightarrow {}^{255}\mathrm{U} \xrightarrow{\beta^-} {}^{255}\mathrm{Np} \xrightarrow{\beta^-} {}^{255}\mathrm{Pu} \xrightarrow{\beta^-} {}^{255}\mathrm{Fm}$$

15.2.3 Heavy-ion bombardment

In lieu of the extraordinarily intense neutron fluxes associated with a thermonuclear explosion, synthesis of the transfermium elements in amounts sufficient to study their chemical properties has depended on nuclear reactions of charged particles (i.e. ^{4}He, ^{10}B, ^{12}C, and ^{16}O accelerated to appropriate energies in

heavy-ion accelerators) with targets of an actinide element of a lower atomic number. Such syntheses are made very difficult by the limited availability of target materials of high atomic number, by the low reaction yields, and by the difficulties inherent in the separation, isolation, and characterization of very short-lived radioactive isotopes. A distinctive feature of these procedures is that the product nuclide is produced and collected one atom at a time, necessitating isolation and identification procedures that are highly innovative. However, the obstacles have been successfully surmounted, and numerous isotopes of the heaviest actinide elements mendelevium, nobelium, and lawrencium have been produced, their nuclear properties measured, and salient features of their chemical properties established (Ghiorso, 1982 and Chapter 13, this work).

The currently known transactinide elements 104 through 111 were discovered at Berkeley, Dubna, and Darmstadt (see Table 1.1 and Chapter 14) using physical and nuclear techniques for synthesis, separation, and identification. The longest known confirmed half-lives for these elements range from 75 s for Rf to only ~40 ms for Mt. Discoveries of isotopes of Rf and Db with half-lives of seconds to minutes permitted investigations of their chemical properties after 1970. However, the first isotope discovered for element 106, Sg, had a half-life of just under a second, and the first-discovered isotopes of elements 107 through 111 had half-lives of only milliseconds. Nuclear theorists predicted that half-lives of isotopes of these elements near the deformed nuclear shells they calculated to be at $Z = 108$ and $N = 162$ would be stabilized by orders of magnitude. These predictions motivated experimentalists to design suitable production reactions, and in 1994 isotopes of Sg with alpha decay half-lives estimated to be tens of seconds were produced in reactions of the actinide target ^{248}Cm with ^{22}Ne beams and detected by physical means by a Dubna/Lawrence Livermore National Laboratory (LLNL) collaboration. These results helped to substantiate the theoretical predictions and innovative techniques to perform chemical investigations of Sg, Bh, and Hs were undertaken during the period 1997–2003. Isotopes of these elements with half-lives as long as 15–20 s were successfully identified in these studies by observation of their alpha decay to known daughter isotopes. These studies furnished valuable information about the chemical properties of Sg in both gas and aqueous phases, and of Bh and Hs in the gas phase.

Comparison of the observed chemical properties with the proposed lighter homologs in the periodic table confirms their placement in the periodic table as members of a 6d transition series; nevertheless there is some evidence for deviations that may be attributable to the influence of relativistic effects, expected to be strongest in the heaviest elements. To date, no chemical studies have been conducted beyond Hs because longer-lived isotopes of Mt have not yet been identified. A surprising amount of information has been obtained about the oxidation states of the transfermium and transactinide ions in solution even though in many cases only a few atoms or even a single atom at

a time was available for study. Discoveries of isotopes of elements 110, 111, and 112 were reported in 1995; for element 110 the reports have been confirmed and the name darmstadtium, symbol Ds, was approved by IUPAC in 2003. The name roentgenium, symbol Rg, for element 111 was approved by IUPAC late in 2004. A consortium of scientists from Dubna and LLNL has reported elements 113 through 116 (Table 1.1), but these have not yet been confirmed at another laboratory. The chemistry of transactinide elements and their predicted chemical and nuclear properties is discussed in Chapter 14.

An exciting frontier is the additional exploration of the chemical properties of the heavier transactinides, especially those beyond element 108 where relativistic effects become ever more important. Effects on chemical bonding have not been investigated satisfactorily even for the beginning of the transactinides. The synthesis of longer-lived isotopes of the elements beyond ^{108}Hs will be required to investigate even their rudimentary chemical properties, e.g. whether element 112 is a noble metal or a rare gas.

Some recent theoretical calculations indicate that in addition to the experimentally confirmed island of deformed stability near $Z = 108$, $N = 162$ and the island of spherical stability originally predicted to be around atomic number $Z = 114$ and neutron number $N = 184$, there may be islands of spherical stability around $Z = 120$ and $N = 172$, and $Z = 124$ or 126 and $N = 184$. If the reports by the Dubna/LLNL collaboration of the production in relatively high yield of neutron-rich, long-lived isotopes of elements 112 through 116 in irradiations of ^{244}Pu and other actinide targets with ^{48}Ca projectiles are confirmed, then many isotopes will become available for chemical studies. This would constitute a whole new region of nuclear stability with neutron numbers from $\sim$163 to $\sim$173, which could truly be called a region of 'superheavy elements.' The chemical properties of elements beyond 122 are currently impossible to predict and classify on the basis of the periodic table because the energy spacing for the 7d, 6f, and 5g levels, and later, for the 9s, $9p_{1/2}$, and $8p_{3/2}$ levels become so close and overlapping that clear structures on the basis of pure p, d, f, and g blocks are no longer distinguishable. An international collaborative effort will be required to initiate and implement such a frontier research program.

15.2.4 Atomic weights

The question of atomic weights deserves a brief comment. Many of the radionuclides listed in Table 15.2 can be obtained in high isotopic purity. Compounds of curium, for example, will have different formula weights depending on the particular curium isotope that is present in the compound. Atomic and molecular weights must be calculated from the relative abundances of isotopes present in a given sample.

Table 15.2 *Long-lived actinide nuclides suitable for physical and chemical investigation.*

Element	*Isotope*	*Half-life*
actinium	^{227}Ac	21.772 yr
thorium	^{232}Th	1.405×10^{10} yr
protactinium	^{231}Pa	3.276×10^{4} yr
uranium	^{233}U	1.592×10^{5} yr
	^{238}U[a]	4.468×10^{9} yr
neptunium	^{236}Np	1.54×10^{5} yr
	^{237}Np	2.144×10^{6} yr
plutonium	^{238}Pu	87.7 yr
	^{239}Pu	2.411×10^{4} yr
	^{240}Pu	6564 yr
	^{242}Pu	3.733×10^{5} yr
	^{244}Pu	8.08×10^{7} yr
americium	^{241}Am	432.2 yr
	^{243}Am	7370 yr
curium	^{244}Cm	18.10 yr
	^{245}Cm	8500 yr
	^{246}Cm	4760 yr
	^{247}Cm	1.56×10^{7} yr
	^{248}Cm	3.48×10^{5} yr
	^{250}Cm	$\sim$8300 yr[b]
berkelium	^{247}Bk[c]	1380 yr
	^{249}Bk	330 d
californium	^{249}Cf	351 yr
	^{252}Cf	2.645 yr
einsteinium	^{253}Es	20.47 d
	^{254}Es	275.7 d
	^{255}Es	39.8 d
fermium	^{257}Fm	100.5 d

[a] Natural isotopic composition is 99.275% ^{238}U, 0.720% ^{235}U, and 0.005% ^{234}U. Half-life given is for the major constituent ^{238}U.
[b] Produced only in very small amounts from neutron irradiations in thermonuclear explosions.
[c] Produced so far only in tracer quantities from charged particle irradiations.

15.3 EXPERIMENTAL TECHNIQUES

15.3.1 Hazards

All of the actinide elements, with the exception of uranium and thorium, are radioactive to such a degree that handling requires special equipment and shielded facilities (Gmelin, 1973; Choppin *et al.*, 2002, pp. 498–513; this work, Figs. 1.2–1.4) when samples above the tracer level are handled. The special containment and manipulation techniques for work with the actinide

elements are necessitated by the potential health hazards to the investigator and other occupants of the laboratory. Containment in the form of hoods and gloved boxes is now standard, and these are available through normal commercial channels. Shielded facilities are more specialized, and, for the most part, are found in laboratories devoted to the study or processing of the actinide elements.

The toxicity of the actinide elements, which requires an absolute barrier between the experiment and the experimenter, is dictated to only a small extent by external radiation hazards. Plutonium-239 is intensely radioactive, emitting 1.4×10^8 alpha particles per milligram per minute. However, the alpha radiation from plutonium-239 can easily be shielded by even a thin sheet of paper. It is the consequences of inhalation and ingestion that make plutonium-239 and most isotopes of the other actinide elements such toxic substances. Plutonium-239, inhaled into the lungs as fine particulate matter, is deposited in the lungs or translocated to the bone, and, over a period of time, may give rise to lung or bone neoplasms (see Section 15.10). The biological properties of the actinide elements are discussed in more detail in Sections 15.9 and 15.10 and in Chapter 31.

15.3.2 Long-lived actinide nuclides

Isotopes sufficiently long-lived for work with weighable amounts are in principle available for all the actinide elements through einsteinium (element 99). Long-lived actinide isotopes particularly suitable for physical and chemical investigations by more or less ordinary laboratory procedures are listed in Table 15.2. Not all of these are available in high isotopic purity. The elements above fermium, it appears, will always require tracer techniques for their investigation. This is not as restrictive a prospect as it may seem, for an astonishing amount of chemical information has been acquired from the few atoms of the heaviest actinide and transactinide elements that have already been prepared.

Most of the chemical studies with plutonium have been carried out with ^{239}Pu, but the isotopes ^{242}Pu and ^{244}Pu are more suitable (but available in very limited quantities) because of their longer half-lives and therefore lower specific activities. The solution chemistry of shorter-lived actinide ions in concentrated aqueous solution is complicated by radiolysis products such as hydrogen peroxide rapidly formed by the high-energy alpha particles produced by radioactive decay. In solid compounds, the high-energy heavy recoil particles can seriously damage or even destroy the crystal lattice. Americium chemistry, often studied with ^{241}Am, which emits about 8×10^9 alpha particles per milligram per minute, has fewer ambiguities when the studies are performed with ^{243}Am, which has a specific alpha activity about 20 times less than ^{241}Am. Much of the early research with curium used the isotopes ^{242}Cm and ^{244}Cm. The heavier curium isotopes, especially ^{248}Cm, obtained in relatively

high isotopic purity as the alpha-particle decay daughter of ^{252}Cf, make life much simpler for the investigator, although ^{248}Cm decays in small part by spontaneous fission, which creates a significant neutron hazard. The isotope ^{249}Bk and Cf as a mixture of the isotopes ^{249}Cf, ^{250}Cf, ^{251}Cf, and ^{252}Cf are available from the intense neutron irradiation of lighter elements. The most useful isotope for the study of californium is ^{249}Cf, which can be isolated in pure form from the beta decay of its parent ^{249}Bk. The isotope ^{253}Es (half-life 20.47 days), another product of intense neutron irradiation, is used to study the chemical properties of einsteinium, but the longer-lived ^{254}Es (half-life 275.7 days) would be more useful for work with macroscopic quantities. However, it is not produced initially free of ^{253}Es. There are severe problems in working with weighable amounts of berkelium, californium, and einsteinium because of their intense radioactivity. Spontaneous fission is an important mode of decay for ^{252}Cf (half-life 2.645 years): 1 μg of this isotope emits approximately 1.4×10^8 neutrons min^{-1}. Californium produced in the highest-flux reactors contains sufficient ^{252}Cf to cause very severe handling and shielding problems because of the spontaneous-fission neutron flux. Remote control manipulation is essential when more than a few micrograms of ^{252}Cf are used. While spontaneous fission makes for problems in chemical studies, ^{252}Cf provides very convenient neutron and fission fragment sources, which have important scientific, medical, and industrial uses (see Sections 15.11.3 and 15.11.4).

15.3.3 Tracer techniques

Investigations may be carried out on the tracer level, where solutions are handled in ordinary-sized laboratory equipment, but where the substance studied is present in extremely low concentrations. Concentrations of the radioactive species of the order of 10^{-12} M or much less are not unusual in tracer work with radioactive nuclides. A much larger amount of a suitably chosen nonradioactive host or carrier is subjected to chemical manipulation, and the behavior of the radioactive species (as monitored by its radioactivity) is determined relative to the behavior of the carrier. Thus the solubility of an actinide compound can be judged by whether the radioactive ion is carried by a precipitate formed by the nonradioactive carrier. Interpretation of such studies is made difficult by the adsorption of radioactive ions on vessel walls or colloidal particles in solution. Tracer studies provide information on the oxidation states of ions and complex-ion formation, and are used in the development of liquid–liquid solvent extraction and chromatographic separation procedures. Tracer techniques are not applicable to solid state or to most spectroscopic studies. Despite the difficulties inherent in tracer experiments, these methods continue to be used with the heaviest actinide and transactinide elements, where only a few to a few score atoms may be available (Benes and Majer, 1980).

15.3.4 Ultramicrochemical manipulations

Chemistry under the microscope often provides an alternative to tracer techniques. It is possible to work with microgram or even smaller amounts of material in very small volumes of solution not visible to the naked eye at ordinary concentrations, say 10^{-1} M to 10^{-3} M. Ultramicrochemical investigations yield results of normal validity, but skill, experience, a good microscope, and much patience are necessary to carry out such experiments. X-ray diffraction methods can be applied to microgram or even smaller samples of solid compounds. Many actinide element compounds have been identified and their molecular formulas established on samples of a few micrograms synthesized directly in the capillary that is subsequently used to record the X-ray diffraction pattern. With milligram amounts, operations can be readily carried out in a conventional manner. Most of the chemical results described in this book were obtained on about the milligram scale by semi-micro procedures. With highly radioactive isotopes (e.g. ^{253}Es), the microgram scale may still be preferred even when larger amounts of material are available. In the past, usable X-ray diffraction patterns were difficult to obtain from highly radioactive crystals because of radiation damage. Such problems are considerably ameliorated when smaller samples and modern methods of obtaining X-ray diffraction patterns are used.

15.3.5 Ion-exchange chromatography

Separations based on ion exchange have contributed to the science and technology of actinides in a variety of ways. In particular, the development of ion-exchange materials based on functionalized polymers (with well-characterized and reproducible properties) have enabled important procedures for both analysis and purification of actinides. Both cation-exchange resins containing (in particular) sulfonic and carboxylic acid groups, and anion-exchange resins with quaternary ammonium or methylpyridinium groups have been employed to separate actinides or to separate actinides from fission product lanthanides. Inorganic ion-exchange materials also have been used in actinide separations, particularly for waste management purposes. In this chromatographic technique (see Chapter 24), actinides, either as cations or anionic coordination complexes, are partitioned between a mobile aqueous phase and the solid resin phase. Actinide ions in the III, IV, V, and VI oxidation states are sorbed to different degrees and in different orders on cation and anion-exchange resins. The selectivity of separations is often determined by the complexants present in the mobile phase.

Ion-exchange separations can be rapid and selective and offer the inherent enhanced separation efficiency of being operable in a chromatographic mode. Because the elution order and approximate peak positions can be predicted with considerable confidence, ion exchange has been the key to the discovery of the transcurium elements. The power of the method can be judged from Fig. 15.3,

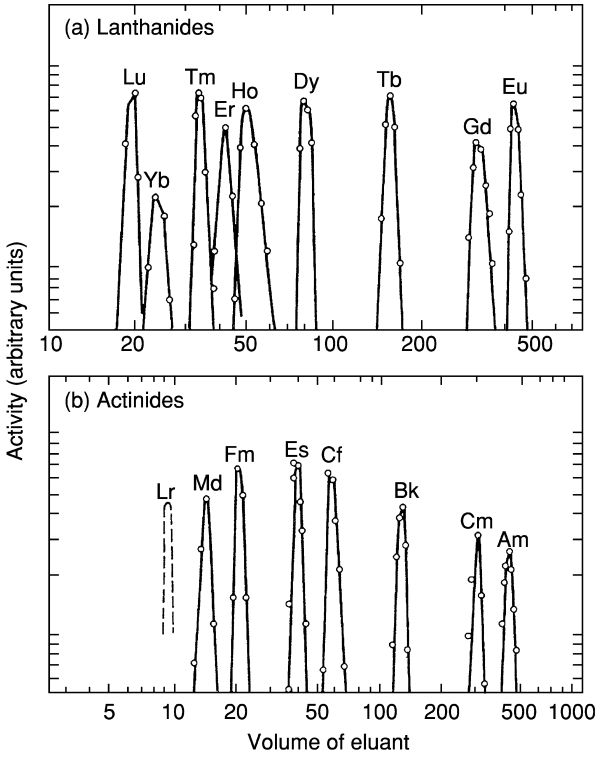

Fig. 15.3 *Elution of tripositive lanthanide and actinide ions on Dowex* 50 *cation-exchange resin and ammonium* α*-hydroxyisobutyrate eluant.* Lr^{3+} *band* (*dashed line*) *was predicted.*

which compares the order of elution of the trivalent lanthanide and actinide ions from the cation-exchange resin Dowex 50 (a copolymer of styrene and divinylbenzene containing sulfonic acid groups). The eluting agent is an aqueous solution of ammonium α-hydroxyisobutyrate. In this system elution occurs in the inverse order of atomic number for both lanthanide and actinide elements. The order of elution is determined by the relative stability of the aqueous complexes formed in the mobile phase. As a result, the differences between these adjacent metal ions are correlated with the variation of ionic radius with atomic number. There are many similarities between the 4f and 5f series of elements, but few parallels are more striking than those observed for the trivalent ions in ion exchange.

15.3.6 Liquid–liquid extraction

Liquid–liquid (or solvent) extraction is a separation technique that depends on the partition of ions between two immiscible liquid phases, one of which is usually an acidic aqueous solution (see Chapter 24). Under most circumstances,

the organic phase contains a strongly lipophilic extracting agent that interacts with a metal cation to form an electroneutral lipophilic complex. Among the most important actinide extractants are tri(*n*-butyl)phosphate (TBP) (basis of the PUREX process), bis(2-ethylhexyl)phosphoric acid, octyl(phenyl)-*N*,*N*-diisobutyl-carbamoylmethylphosphine oxide (basis of the TRUEX process), and *N*,*N*-dimethyl-*N*′,*N*′-dibutyl-2-hexoxyethylmalonamide (basis of the DIAMEX process). Tertiary (e.g. tricaprylamine or trilaurylamine) or quaternary amines (e.g. tricaprylammonium chloride) can also accomplish effective and selective separations of actinide ions through the formation of lipophilic ion pairs of actinide ions associated with enough normally hydrophilic anions (like Cl^- or NO_3^-) to create an anionic coordination complex. As is the case for ion exchange, the most effective separations in solvent extraction are those relying on the differences in actinide oxidation states. Some classes of solvent extraction reagents are capable of the separation of the individual trivalent actinide cations, as in the ion exchange example above. In recent years, solvent extraction reagents capable of efficiently separating trivalent actinides from fission product lanthanides have emerged. Separations are achieved because the partition coefficients of individual actinide ions in a mixture are significantly different. For production purposes, solvent extraction enables rapid and efficient separations when applied in a countercurrent multistage process. Solvent extraction is widely used for actinide element separations both in laboratory investigations and on a large industrial scale.

15.3.7 Column partition chromatography

A technique closely related to liquid–liquid extraction, also discussed in Chapter 24, is column partition chromatography, sometimes referred to as extraction chromatography. Partition chromatography is essentially a solvent extraction system in which one of the liquid phases is made stationary by adsorption on a solid support. The other liquid phase is mobile. Extraction chromatographic materials are usually (but not always) employed for analytical separations using column chromatography, which significantly increases separation efficiency. Either the aqueous or the organic phase can be immobilized. The aqueous phase can be made stationary by adsorption on silica gel, diatomaceous earth, or 5–10 μm diameter microspheres of silica. The same extracting agents that are used in ordinary solvent extraction can be used in partition chromatography. The organic phase can be adsorbed on beads (50–200 μm in diameter) of poly(vinylchloride), poly(tetrafluoroethylene), poly(monochlorotrifluoroethylene), or other solid support. When the stationary phase is organic, the technique is referred to as reversed-phase partition chromatography. This technique is widely used in radioanalytical chemistry, though its application to large-scale separation of actinides from dissolved spent fuel has been considered.

15.4 ELECTRONIC CONFIGURATION

15.4.1 General considerations

Establishing the electronic configuration of the elements and their ions has historically been a primary objective in physical and chemical research. This stems from the conviction that it ought to be possible to deduce *a priori* many of the properties of an element and its compounds from a detailed knowledge of its electronic configuration, a goal that is still approaching full realization. There are other reasons why such information is of particular interest in actinide chemistry. The f-block elements have unusual electronic configurations, and the comparative aspects of lanthanide and actinide electronic structures, as manifested in the chemical and physical properties of homologous elements, is a matter of keen interest. The striking similarities and differences between corresponding elements of the two series provide important insights into the contributions that the valence-electron quantum numbers make to the physical and chemical properties of the f-block elements.

Information relevant to the electronic configuration can be obtained from X-ray absorption spectroscopy, atomic emission spectroscopy (AES), X-ray photoelectron spectroscopy, paramagnetic susceptibility measurements, electron paramagnetic resonance, electronic transition spectroscopy, transmission electron microscopy, X-ray and neutron crystallography, and atomic-beam experiments. Discussions of the theoretical and experimental aspects of atomic spectroscopy, magnetic properties, crystal structures of solids, and electronic absorption spectroscopy are found in the later chapters of this work.

15.4.2 Spectroscopic studies

In AES and inductively coupled plasma mass spectrometry (ICP-MS) the wavelengths of light emitted from a vaporized atom in an excited electronic state are used as a 'signature' of the atomic number of the atom. These techniques are now used routinely for elemental analyses of research, industrial, and environmental materials, but AES was essentially the technique used originally to characterize the electronic properties of actinides. In an electrical discharge most of the species produced are electrically neutral atoms, but among them are small numbers of ionized species that have lost one, two, or three of their valence electrons. Because the spectra result from changes in the quantum numbers of the valence electrons present in the atom or ion, it is possible in principle to make deductions about the electronic energy levels of the emitting species. In practice, however, there are very severe problems in the interpretation of the emission spectra of the actinide elements. In the free atoms in the gas phase, the valence electrons interact strongly with the 5f electrons and also with each other. Each 5f level is split by these interactions to give many energy levels that are more widely split than the 5f levels themselves. The result is an

enormous number of lines in the emission spectra of actinide elements. In the uranium spectrum, 100000 lines have been measured, and between 5000 and 20000 lines have been measured for each of the elements from plutonium to berkelium. The number of assigned lines varies considerably but is much smaller, from about 2500 for uranium to about 100 for curium. The ground electronic configurations of neutral actinium, thorium, uranium, americium, berkelium, californium, and einsteinium were determined by atomic spectroscopy. The ground electronic structures of protactinium, neptunium, plutonium, curium, and fermium were deduced from atomic-beam experiments (Gmelin, 1973; see Chapter 16).

The dominant features of the electronic transition spectra of actinide ions in solution or in solid crystals arise for the most part from transitions within the $5f^N$ subshell. However, in the gas phase the predominant population consists of neutral atoms, which possess all of their valence electrons and therefore experience more interactions between the 5f electrons and the d- and s-shell valence electrons. The 5f electrons in actinide ions, either in crystals or in solution, are perturbed to a lesser extent because valence electrons in the 6d and 7s subshells are missing, and the 5f electrons are shielded from the electric fields of other ions by the remaining 6s and 6p electrons. The electronic transition spectra of actinide ions in solution therefore provide more information about the structure of the 5f levels, but the free-atom spectra provide more information about the interactions between the 5f and the valence electrons.

15.4.3 Electronic structure

Table 15.3 shows the assignments of the configuration (beyond the radon structure) of the ground-state gas-phase neutral atom of each of the elements from actinium to lawrencium, as well as the configurations of the singly charged, doubly charged, and triply charged gaseous atoms. Included for comparison are the ground-state neutral-atom and triply charged electronic configurations (beyond the xenon structure) of the 4f lanthanide elements and the configurations of the 3+ ions of both series. The similarities between the lanthanide and actinide elements were recognized from very early work on the actinides. It can be seen from Table 15.3 that the incorporation of the 14 5f electrons into the elements of the actinide series is not as regular as in the 4f series, especially in the actinide elements preceding curium.

The atomic spectra indicate quite clearly that the 6d levels of thorium in the gas-phase neutral atom are lower in energy than the 5f levels. As in other transition series, the relative energy levels of the electron shell being filled become lower as successive electrons are added, and, in the elements following thorium, the 5f shell appears clearly to be of lower energy than the 6d shell. Triply ionized Th^{3+} has one 5f electron in the gas phase as the ground configuration with the 6d configuration ~1.25 eV higher. But in the very few molecular Th^{3+} compounds synthesized to date, the 6d configuration is stabilized by the

[a] Configurations from Chapters 14 and 16. Predicted configurations are given in parentheses.

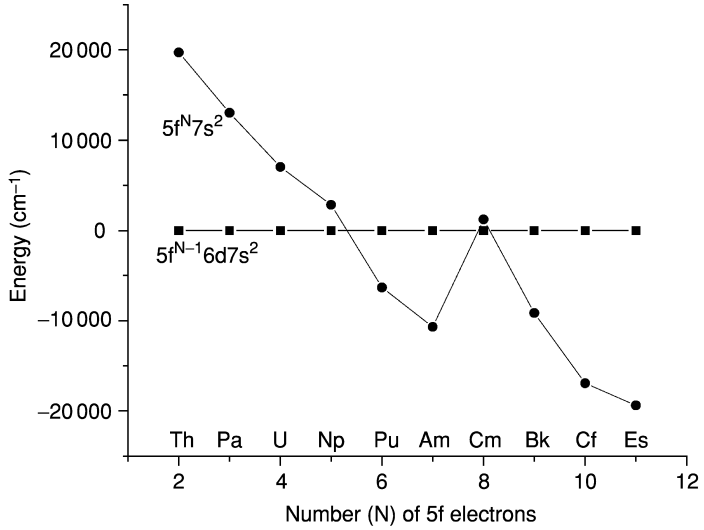

Fig. 15.4 *Relative energies of the $5f^N7s^2$ and $5f^{N-1}6d7s^2$ electron configurations in the gaseous actinide atoms showing the stabilization of the $5f^N7s^2$ as the atomic number Z ($Z = 88 + N$) increases.*

ligand field relative to the 5f configuration, and is found to be the ground configuration. For the elements beyond neptunium, the electronic configurations of the 4f and 5f elements strongly resemble each other. That the relative energy levels of the outer d- and s-shell electrons relative to the 5f electrons are not identical to those observed in the 4f block elements is not unexpected. Fig. 15.4 represents the relative energies of electron configurations that interchange 5f and 6d electrons for most of the actinide elements; as the curves intersect, inversion of behavior is inevitable.

15.4.4 Position in the periodic table

Before 1944, the elements thorium, protactinium, and uranium were assigned positions in the periodic table immediately below the elements hafnium, tantalum, and tungsten. It became evident that to accommodate the transuranium elements in the periodic table would require a radically new arrangement. The arguments for positioning them as a new 'actinide' transition series, similar to the rare earths, became strong by 1944 but experimental data to support this view were still scanty. With the passage of time the evidence in favor of a new transition series has become very convincing. Fig. 15.5 shows a modern periodic table, which not only includes the actinide elements as a transition series, but also indicates the location of the transactinides and a new superactinide transition series that may never be discovered.

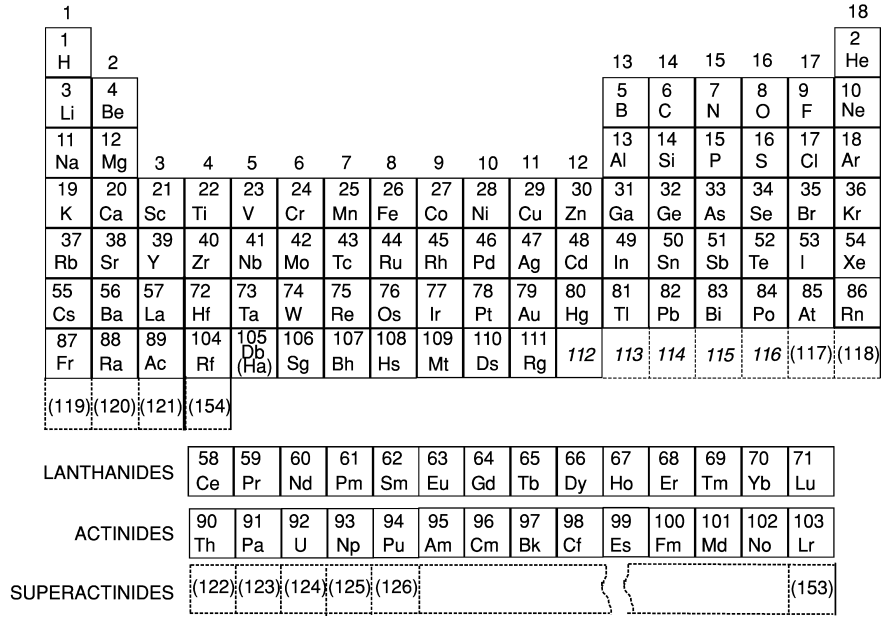

Fig. 15.5 *Modern periodic table showing predicted locations of many undiscovered transuranium elements (atomic numbers in parentheses). For element* 105 *two symbols are shown. The official IUPAC name is dubnium (Db), adopted in* 1997. *Hahnium (Ha) is also shown; this name also was used for a number of years after the discovery of this element.*

15.5 OXIDATION STATES

15.5.1 Ions in aqueous solution

Tables 15.4 and 15.6 list the oxidation states of the actinide elements and the color of the actinide ions, respectively. It is clear that the actinide oxidation states are far more variable than those of the lanthanides. The close proximity of the energy levels of the 7s, 6d, and 5f electrons almost guarantees multiple oxidation states for the actinide ions, at least in the first half of the actinide series. The multiplicity of oxidation states, coupled with the hydrolytic behavior of the ions, make the chemical behavior of the elements from protactinium to americium among the most complex of the elements in the periodic table.

In Table 15.4, the most stable states are shown in bold type and the more unstable states are indicated by parentheses. Oxidation states that have been claimed to exist, but not independently substantiated, are indicated with question marks. The most unstable oxidation states have only been observed in solid compounds, or produced as transient species in solution by pulse radiolysis (Sullivan *et al.*, 1976a,b, 1982; Gordon *et al.*, 1978). In this very interesting technique, a beam of energetic electrons is injected into an aqueous

solution of the ion (for actinides, mainly the 3+ ions) under investigation. When N_2O is present in the reaction mixture, the hydrated electrons formed by the injection of the electrons into water are converted into OH radicals, which are strong oxidants. If *t*-butanol is present in place of nitrous oxide, the OH radicals are scavenged, and only the hydrated electron, e^-(aq), a powerful reducing agent, is formed. The reactions of these reagents with actinide ions are followed spectrophotometrically. Reaction of the 3+ ions in 0.1 M perchloric acid with e^-(aq) forms Am(II), Cm(II), and Cf(II). When OH radicals react, Am(IV) and Cm(IV), but no Cf(IV), are produced. All of the 2+ and 4+ species are transient. The 2+ species disappear with rate constants of about 10^5 s^{-1} by what appears to be a first-order process. Am(II), Cm(II), and Cf(II) have half-lives of the order of 5–20 μs. Am(IV) appears to be

appreciably more stable and has a half-life of about 1 ms. Pulse radiolysis has been shown to be a widely applicable method for producing ionic species in oxidation states that are difficult or impossible to access by conventional chemical procedures.

With the exception of thorium and protactinium, all of the actinide elements show a 3+ state in aqueous solution, although the 3+ state does not become the preferred or stable oxidation state under ordinary conditions until americium is reached. Stable organometallic compounds of Th(III) have been characterized and have a $6d^1$ configuration as the ground state (Blake *et al.*, 2001). A stable 4+ state is observed in the elements thorium through plutonium and in berkelium. Am(IV) can be stabilized in aqueous media by very strong complexing agents such as carbonate, tungstophosphate and tungstosilicate heteropolyanions. The 5+ oxidation state is well established for the elements protactinium through americium, and the 6+ state in the elements uranium through americium. The 4+ state in curium is confined to a few solid compounds, particularly CmO_2 and CmF_4, and appears to be present in a stable complex ion that exists in concentrated cesium fluoride solution. The Cf(IV) state is limited to the solid compounds CfO_2, CfF_4, a complex oxide $BaCfO_3$, and in tungstophosphate solutions; the oxidation of Cf(III) to Cf(IV) in strong carbonate solutions is a disputed topic.

The 2+ oxidation state first appears at americium in a few solid compounds and then at californium in the second half of the series. The II oxidation state becomes increasingly more stable in proceeding to nobelium. Md(II) and No(II) have been observed in aqueous solution and this appears to be the most stable oxidation state for nobelium. Am(II) has not only been encountered in solid compounds, but also in electrochemical and pulse radiolysis experiments in acetonitrile solution. The formation of Bk(IV) is associated with enhanced stability of the half-filled 5f configuration ($5f^7$), and the No(II) state reflects the stability of the full 5f shell ($5f^{14}$). The increase in the stability of the lower oxidation states of the heavier actinide elements relative to the lanthanides may be the result of stronger binding of the 5f (and 6d) electrons in the elements near the heavy end of the actinide series. Claims have been advanced that all the elements from plutonium to nobelium can be prepared in the 2+ state, and that this is a stable oxidation state for the elements fermium to nobelium (Mikheev, 1984). There has been no confirmation of these claims. The findings from pulse radiolysis show that even the 2+ state of the actinides preceding einsteinium are transient species, and have very short lifetimes (Gordon *et al.*, 1978; Sullivan *et al.*, 1982). Mendelevium has been reported to possess a stable 1+ oxidation state (Mikheev, 1984), but the evidence for monovalent ions of the actinide elements is doubtful. (See chapter 13.)

The transactinide elements rutherfordium through hassium have been studied by innovative chemical techniques, in particular thermochromatography (by which the relative volatilities of halides of elements 104–108 have been determined). The resulting oxidation states are shown in Table 15.5.

15.5.2 Ion types

Actinide ions in the same oxidation state have essentially the same coordination environments. In aqueous solutions at a pH < 3, four structural types of actinide cations exist. Formulas and colors of these ions are listed in Table 15.6. Only simple (uncomplexed) ions are listed. The ions of the type M^{3+} or M^{4+}, as is the case for cations with a high charge, show a strong inclination to solvation, hydrolysis, and polymerization (see Section 15.5.3). For the actinide elements in higher oxidation states (U through Am), the effective charge on the simple ion is decreased by the formation of oxygenated species of the general type MO_2^+ and MO_2^{2+}. The actinyl ions MO_2^+ and MO_2^{2+} are remarkably stable, having strong covalently bonded O=M=O ions, and persisting as a unit through a great variety of chemical transformations. Infrared spectroscopy shows conclusively that the ion MO_2^{2+} exists as a symmetrical, linear or very nearly linear, group. Crystallographic studies have shown that in solids UO_2^{2+} have four, five, or six ligands, typically in an equatorial plane perpendicular to the O=U=O axis; X-ray scattering in dilute perchloric acid solution shows UO_2^{2+} coordinated to five water molecules (Neuefeind *et al.*, 2004). The stability and linearity of the MO_2^{2+} ions are understood from theoretical bonding arguments (Zhang and Pitzer, 1999; Hay *et al.*, 2000). The corresponding 5+ state actinyl ions, AnO_2^+ (An = U, Np, Pu, Am), have the same symmetrical linear structure but with weaker metal–oxygen bonds. There is a regular decrease in the strength of the metal–oxygen bond with increasing atomic number in the actinyl ions from uranium to americium. The 7+ oxidation state, found in some

Table 15.6 *Ion types and colors for actinide ions in aqueous solution.*

compounds of neptunium and plutonium in alkaline aqueous solution, contains in some cases tetroxo species $MO_4(OH)_2^{3-}$ (Williams *et al.*, 2001). The existence of Am(VII), even in alkaline media, is still a matter of debate (see Chapter 8). In acid solution, actinide ions in the 7+ oxidation state oxidize water rapidly.

Reduction potentials for the actinide elements are shown in Fig. 15.6. These show standard potentials in volts in aqueous acidic solution relative to the standard hydrogen electrode. The measured potentials were determined by electrochemical cells at or near equilibrium, and enthalpy of reaction measurements coupled with entropy measurements or estimates. Species not found in aqueous solution, but whose thermodynamic properties have been estimated, are indicated in parentheses.

The M^{4+}/M^{3+} and the MO_2^{2+}/MO_2^{+} couples are reversible, and, as expected, rapid reactions occur with one-electron oxidizing and reducing agents when no bond breaking or making takes place. The MO_2^{+}/M^{3+}, MO_2^{+}/M^{4+}, and MO_2^{2+}/M^{4+} couples are not reversible, presumably because of the barrier introduced by formation and rupture of covalent 'yl' bonds and the subsequent reorganization of the solvent shell, and also because some of these are two-electron reductions.

A summary of qualitative information about the oxidation–reduction characteristics of the actinide ions is presented in Table 15.7. The disproportionation and redox reactions of UO_2^{+}, Pu^{4+}, PuO_2^{+}, and AmO_2^{+} are especially complex, and, despite extensive study, many aspects of these reactions still remain to be explored. In the case of plutonium, the situation is especially complicated, because ions in all four oxidation states 3+, 4+, 5+, and 6+ can exist simultaneously in aqueous solution in comparable concentrations. The kinetics of the redox reactions of the actinide elements were reviewed by Newton (1975) and are presented in Chapter 23. Mechanisms of redox reactions involving uranium species are discussed in Chapter 5.

15.5.3 Hydrolysis and polymerization

All metal cations in aqueous solution interact extensively with the solvent water, and to a lesser or greater extent exist as hydrated cations (Baes and Mesmer, 1976; Burgess, 1978). The more highly charged the naked cation, the greater the extent of interaction with the solvent. Aquo cations, especially those of 4+, 3+, and small 2+ ions, act as acids in solution:

$$M(OH_2)_x^{n+} \rightarrow M(OH_2)_{x-1}(OH)^{(n-1)+} + H^+$$

This reaction illustrates the increase in acidity caused by hydrolysis of water as a protic ligand coordinated to metal cations. Because the acidity of water coordinated to 3+ and 4+ species is the more strongly enhanced the higher the charge on the metal cation, actinide elements in their most frequently encountered oxidation states undergo extensive hydrolytic reactions. Th^{4+}(aq) begins to hydrolyze to $Th(OH)^{3+}$ below pH 2. At higher pH, more hydrolyzed and

Table 15.7 *Stability of actinide ions in aqueous solution* (*usually acidic*).

Ion	*Stability*
Md^{2+}	stable to water, but readily oxidized
No^{2+}	stable
Ac^{3+}	stable
U^{3+}	oxidizes to U^{4+} and reduces water; aqueous solutions evolve H_2 on standing
Np^{3+}	stable to water, but easily oxidized by air to
Pu^{3+}	stable to water and air, but easily oxidized to Pu^{4+}
Am^{3+}	stable; can be oxidized with difficulty
Cm^{3+}	stable
Bk^{3+}	stable; can be oxidized to Bk^{4+}
Cf^{3+}	stable
Es^{3+}	stable
Fm^{3+}	stable
Md^{3+}	stable, but rather easily reduced to Md^{2+}
No^{3+}	easily reduced to No^{2+}
Lr^{3+}	stable
Th^{4+}	stable
Pa^{4+}	stable to water, but readily oxidized
U^{4+}	stable to water, but slowly oxidized by air to UO_2^{2+}
Np^{4+}	stable to water, but slowly oxidized by air to NpO_2^+
Pu^{4+}	stable in concentrated acid, e.g. 6 M HNO_3, but disproportionates to Pu^{3+} and PuO_2^{2+} at lower acidities
Am^{4+}	known in solution only in presence of strong complexants
Cm^{4+}	known in solution only in presence of strong complexants
Bk^{4+}	marginally stable; easily reduced to Bk^{3+}
Pa^{5+}	stable, hydrolyses readily
UO_2^+	disproportionates to U^{4+} and UO_2^{2+}; most nearly stable at pH 2–4
NpO_2^+	stable; disproportionates only at high acidities
PuO_2^+	tends to disproportionate to Pu^{4+} and PuO_2^{2+} (ultimate products); most nearly stable at very low acidities
AmO_2^+	disproportionates in strong acid to Am^{3+} and AmO_2^{2+}; reduces fairly rapidly under the action of its own a radiation at lower acidities (as ^{241}Am isotope)
UO_2^{2+}	stable; difficult to reduce
NpO_2^{2+}	stable; easy to reduce
PuO_2^{2+}	stable; easy to reduce; reduces slowly under the action of its own alpha radiation (as ^{239}Pu isotope)
AmO_2^{2+}	easy to reduce; reduces fairly rapidly under the action of its own alpha radiation (as ^{241}Am isotope)
$NpO_4(OH)_2^{3-}$	observed only in alkaline solution
$PuO_4(OH)_2^{3-}$	observed only in alkaline solution; oxidizes water

polymerized Th(IV) species begin to predominate. The mononuclear Pa(IV) species $PaO^{2+}(aq)$ or $Pa(OH)_2^{2+}(aq)$ have been claimed to exist at low concentrations; however, polymers are already evident at protactinium concentrations well below micromolar and in tracer experiments. U(IV) begins to undergo

hydrolysis in aqueous solution above pH 2.9, and, at somewhat higher pH, is largely present as hydrolyzed and polymerized species. $U(OH)^{3+}$ has been identified as the predominant U(IV) species in solution at low uranium concentrations and moderate acidities. Pu(IV) requires strongly acid conditions to exist as a simple Pu^{4+}(aq) ion. Even in moderately acid solutions, Pu(IV) hydrolyzes extensively, and may form polymers of high molecular weight. The actinyl ions typical of the 5+ and 6+ states presumably are formed with great speed whenever oxidation to the 5+ and 6+ states occurs in water. Once the uranyl, neptunyl, plutonyl, and americyl ions are formed, the only practical way to remove the coordinated oxygen atoms is by reduction to the 4+ or 3+ state. Although uranyl nitrate can be obtained as an anhydrous compound, in this form it is coordinatively unsaturated, and it is usually encountered as the hexahydrate or coordinated to equivalent ligands.

It is well known that aquo cations of heavy elements in the 3+ oxidation state or higher readily lose protons to form hydroxo complexes. Subsequent condensation reactions between the hydroxo complexes can then form polynuclear species in which the metal ions are linked through hydroxo (M–OH–M) or oxo (M–O–M) bridges. For the formation of polynuclear species, the pH range is critical; at too low a pH the ion will exist as the simple aquo cation, and at too high a pH the hydrous oxide or hydroxide precipitates. The actinide ions with oxidation number 4+ are particularly prone to hydrolysis and polymerization, but the MO_2^{2+} oxo cations also have considerable tendencies toward polynuclear ion formation. Among the 4+ cations, Th(IV), U(IV), and especially Pu(IV) form polymeric species. Th(IV) has a very complicated solution chemistry and, except in strong acid solutions, polynuclear species are easily generated in which Th(IV) ions are cross-linked by hydroxo bridges. Similarly, U(IV) forms polynuclear aggregates that may contain both hydroxo and oxo bridges. The $U(OH)^{3+}$ ion, which predominates in acidic solutions and low uranium concentrations, rapidly undergoes polymerization in solutions of moderate or low acidity. The formation of very large polymers occurs with U(IV) at much lower ligand numbers than is the case for Th(IV). The hydrolytic behavior of the Np(IV) ion is similar to that of Pu(IV), although Np^{4+} is an appreciably weaker acid.

The hydrated Pu(IV) ion is a stronger acid than the U(IV) ion, and it is exceptionally prone to polymer formation. As hydrolysis proceeds and before actual precipitation occurs, positively charged polymers of colloidal dimensions with molecular weights as high as 10^{10} have been observed. Although all of the polynuclear species of the actinide ions are of scientific interest, the polymers of Pu(IV) have attracted the most attention because of practical considerations. The effect of concentration, acidity, temperature, and ionic strength on polymer formation are ill-defined, and, as the Pu(IV) polymers are very stable and depolymerization is not at all easily affected, unpredictable behavior of Pu(IV) solutions can pose major problems and create potentially serious hazards, such as criticality, in nuclear fuel processing.

The actinyl ions MO_2^+ and MO_2^{2+} are considerably less acidic than are the 4+ state monomeric ions, and therefore have a smaller tendency to undergo hydrolysis. Hydrolysis decreases in the order $M^{4+} > MO_2^{2+} > M^{3+} > MO_2^+$. This trend follows the expected decreasing ratio of charge to ion size as the determining factor in hydrolysis.

The order of acidity for the 4+ species is $Pu^{4+} \approx Np^{4+} > U^{4+} \gg Th^{4+}$ (Neck and Kim, 2001). The similar hydrolytic behavior of Np^{4+} and Pu^{4+} cannot be understood simply in terms of charge-to-size considerations. On the basis of increasing charge and decreasing ionic size, it is expected that the degree of hydrolysis for a series of ions of any charge in the actinide series would increase with atomic number. This hydrolytic behavior of Np(IV) implies that additional, and as yet unidentified, factors make important contributions to the interaction of the actinide ions with water.

The actinyl(V) ions, which carry the low charge of 1+, are weak acids, with the singular exception of Pa(V). The protactinyl(V) ion is a much stronger acid than its successors in the actinide series and, in fact, the least hydrolyzed species of Pa(V) appears to be $PaO(OH)^{2+}$. In both its 4+ and 5+ oxidation states, protactinium shows a very unusual tendency to hydrolyze. Experience with protactinium chemistry in extremely dilute acidic solutions indicates that Pa(V) is already extensively hydrolyzed. The chemical investigation of protactinium at any level is rendered extremely difficult by the formation of intractable polymers. The use of strong complexing agents such as fluoride circumvents some of these difficulties.

The actinyl(VI) ions all undergo hydrolysis to an appreciable extent. Hydrolysis of UO_2^{2+} even in dilute solution results in almost total conversion to polynuclear species. These are small polymers, containing fewer than five uranium atoms. The tendency to form polymers of colloidal dimensions thus appears to be much diminished in the actinyl(VI) ions relative to the actinide(IV) ions. Precipitation occurs gradually or rapidly, depending on the kinetics of colloidal aggregation. The strong inclination to form insoluble precipitates after only a small amount of hydrolysis makes characterization of the water-soluble polymers of the actinyl ions a difficult challenge.

15.5.4 Complex-ion formation

The tendency to form complex ions in solution is to a considerable extent an expression of the same forces that lead to hydrolysis. The high positive charge on a bare 3+ or 4+ ion provides a strong driving force for interaction with nucleophiles. Water is only one example of such a nucleophilic ligand. Other nucleophiles that may be present in a solution can compete for coordination to the electrophilic cation to form complex ions. In most cases of complex formation, water molecules directly bound to the metal cation are displaced by the entering ligand to form an inner-sphere complex that may or may not contain water still bound to the metal ion. Alternatively, ligands may form hydrogen

bonds to water molecules of the outer hydrate shell to form outer-sphere complexes. Strong complexes are for the most part of the inner-sphere type. For inorganic anions, the complexing power of the actinide cations is in the order fluoride > nitrate > chloride > perchlorate for the singly charged anions, and carbonate > oxalate > sulfate for doubly charged anions. The stability of the complexes for a given ligand follows the order $M^{4+} > MO_2^{2+} \approx M^{3+} > MO_2^{+}$. For ions of the same charge, the stability of the complex increases with decreasing ionic radius in the first half of the actinide series. Many irregularities are encountered in the series of ions of uranium through americium, just as in the hydrolytic behavior of the tetravalent actinides. Overall, however, the stability of the actinide complexes increases as the ratio of effective charge to ionic radius increases. As a general rule, the actinide ions form somewhat more stable complexes than do the homologous lanthanide ions.

The phosphate anion PO_4^{3-} and organic phosphates are powerful complexing agents for actinide ions. The phosphate anion acts as a bridge between metal ions to form aggregates that are insoluble in water. The M^{4+} and MO_2^{2+} ions form complexes with many organic phosphates, either neutral or anionic, that are preferentially soluble in nonpolar aliphatic hydrocarbons. Typical of such ligands are TBP and dibutyl phosphate (DBP). Phosphine oxides are also potent coordinating ligands. Oxygen-containing donor compounds such as the ketones, diisopropyl ketone or methyl isobutyl ketone, and the ethers, diethyl ether, ethyleneglycol diethyl ether, or diethyleneglycol dibutyl ether, act likewise and are good complexing agents for actinide ions. All of these ligands have oxygen atoms with lone electron pairs not otherwise engaged in chemical bonding that can act as electron donors in coordination interactions. Complexes with such reagents have been used on a very large scale in the extraction and separation of the actinide elements by liquid–liquid extraction. In recent years, extractants containing soft donor atoms (nitrogen, sulfur) have received much attention, especially as they offer great potential for the separation of trivalent actinides from the chemically similar lanthanides. Among other compounds, polyaza and dithiophosphinic acid derivatives are investigated extensively. The reader is referred to Chapter 24 for a discussion of the comparative merits of various extractant systems.

Chelating ligands form strong complexes with actinide ions. Examples of such are the β-diketones, the tropolones, 8-hydroxyquinoline and its derivatives, and ethylenediaminetetraacetic acid (EDTA), among many others. In its enol form, acetylacetone, a typical diketone, forms very strong complexes with M^{4+} ions. Even though these complexes have significant water solubility, they are easily and completely extracted by benzene, carbon tetrachloride, or similar nonpolar solvents. The acetylacetone complexes of the MO_2^{2+} actinyl ions form weaker complexes that show little preference for a nonpolar organic phase. The structure of the diketone can be modified to enhance the preferential solubility of the metal complex for the organic phase. The most important of such modified diketone chelating agents is 2-thenoyltrifluoroacetone ($C_4H_3COCH_2COCF_3$),

which has been widely used to extract plutonium from aqueous solutions into nonpolar solvents. Tropolone ($C_7H_6O_2$, 2-hydroxy-2,4,6-cycloheptatrien-1-one) is a seven-membered cyclic carbon compound containing a keto carbonyl function and a weakly acid hydroxyl group, both of which are able to form strong complexes with highly charged metal cations. EDTA is an effective sequestering agent for the actinide ions in aqueous solutions. The strongest EDTA complexes are formed by M^{4+}. The strength of the EDTA complexes with M^{3+} ions increases steadily from Pu^{3+} to Cf^{3+}. Possibly for steric reasons, EDTA interacts in a different way with actinyl(VI) ions; in these systems EDTA is a bridging ligand, and gives rise to linear polynuclear complexes.

There is a great deal more to be said about the actinide ions in solution, about hydrolytic phenomena, and about complex-ion formation. For a comprehensive and authoritative treatment of these important subjects, the reader is referred to Chapters 23 and 24.

15.6 THE METALLIC STATE

The actinide metals pose some of the most interesting problems in actinide research and, in fact, in all of materials science. Many actinide compounds behave in a perfectly conventional way (except for radioactivity), and have properties that can be safely inferred from lanthanide chemistry or the chemistry of similar compounds of well-studied elements. For no category of materials is this less true than for the actinide metals and intermetallics. Many of the actinides in their elemental state and in intermetallic compounds are unique. They have metallurgical properties that are unprecedented in conventional metals, and their properties cannot be described by conventional theories of the metallic state. The theoretical framework of the metallic state has been broadened to accommodate this group of unusual metals, and this led to a better understanding of complex phenomena not only in the actinide series but also in such complex materials as high-temperature superconductors (Santini *et al.*, 1999; Sarrao *et al.*, 2002).

15.6.1 Preparation

The actinide metals are highly electropositive and may react, especially on surfaces and in finely divided form, with water vapor, oxygen, nitrogen, and hydrogen. The chemical reactivity and radioactivity of most of the actinides makes confinement in atmosphere-controlled gloved boxes compulsorily. For some of the heavier actinide metals, shielding is required because of gamma rays or because of neutrons released by spontaneous fission. The actinide elements form very stable oxides and fluorides, so that vigorous reducing agents and high temperatures are necessary for their reduction to the metals. The earliest preparations of the actinide metals were carried out by reduction of the anhydrous

actinide tri- or tetrafluoride with the appropriate alkali or alkaline earth metal at high temperature. For submilligram amounts this is still the method of choice, especially with lithium or barium as reductants. Alternatively, especially at the industrial scale, the actinide oxide is reduced at high temperature with lanthanum or thorium metal. All of the starting materials must be as pure as possible to yield a pure product. Reduction of the oxide is the preferred route to milligram-to-gram amounts of Ac, Am, Cm, Bk, Cf, and submilligram amounts of Es (Heathman and Haire, 1998). Uranium, thorium, and plutonium metals are obtained from appropriate industrial-scale operations.

Much modern research on the metallic state requires very pure metals. Depending on the nature of the impurities, the actinide metals can be purified by volatilization of the impurities in a very high vacuum, by volatilization of the metal itself to form films of very pure metal, or by electrodeposition from molten salt baths. Very pure protactinium and thorium metals can be obtained by the van Arkel process, which consists of converting the crude metal to the volatile iodide by reaction with elemental iodine at an elevated temperature, and decomposing the gaseous metal iodide on a hot filament (Müller and Spirlet, 1985). This process produces exceptionally pure metals, which have been used for such demanding purposes as superconductivity measurements that require metals of the highest purity.

15.6.2 Crystal structures

The crystal structures, phase transformations, and metallic radii of the actinide metals are listed in Table 15.8, together with melting points, densities, and enthalpies of sublimation. The crystal structures of metallic protactinium, uranium, neptunium, and plutonium are complex, have no counterparts among the lanthanide metals, and resemble the 3d transition metals more closely than the lanthanides. The lanthanide metals show a generally uniform hexagonal close-packed (hcp) or face-centered cubic (fcc) crystal structure pattern at low temperatures, and body-centered cubic (bcc) at high temperatures. The lighter actinide elements have a bcc structure at the melting point, which changes to fcc in the elements after plutonium. For the actinide elements americium through einsteinium, the characteristic crystal structures at all temperatures below the melting point are the fcc and double hexagonal close-packed (dhcp) structures. In uranium, neptunium, and plutonium, complex crystal structures are observed at low temperatures.

The differences between the actinide and lanthanide metals can be rationalized by a consideration of the differences between the 4f and 5f electron shells (Santini *et al*., 1999). In the 4f series, all the 4f electrons (added after cerium) are buried in the interior of the electron cloud. The 4f electrons thus experience relatively little interaction with valence electrons in the outer shells. The maxima in the 4f radial charge density occur well inside the usual interatomic distances in solids, and consequently the 4f electron properties of the free atoms are

[d] Zachariasen, W. H. (1973) *J. Inorg. Nucl. Chem.* 35, 3487–97. Zachariasen adjusted high-temperature radii to room temperature. For Ac, Cf, and Es see Chapter 2, 11, 12 respectively.

retained in the metallic as well as ionic lanthanide solids. Cerium is the only 4f metal that does not conform to this generalization, presumably because its 4f electron shell is not yet fully stabilized. The actinide 5f electrons behave quite differently. For the early members of the actinide series, the 5f electrons have a greater radial distribution than do their 4f homologs. The first few 5f electrons are not confined to the core of the atom, and they can therefore interact or mix with the other valence electrons to affect interatomic interactions in the solid state. Beyond plutonium, all the 5f electrons are localized within the atomic core, and the resemblance between the f-block elements becomes closer. Americium is the first actinide metal whose crystal structure resembles that of the lanthanide metals. In the transcurium metals, the resemblance to the lanthanide metals becomes increasingly strong. The room temperature crystal structure for the elements for Am to Cf is dhcp, just as it is in the light lanthanides (see Table 15.8).

A natural consequence of the increase in nuclear charge along the actinide series for a given oxidation state is an increasing tendency for the 6d and 7s electrons to experience less shielding from the nuclear charge. This leads to a contraction of the atomic radius. Shielding of the valence electrons from the nucleus is also diminished by delocalization of the 5f electrons in the early part of the actinide series. In metals, the atomic radius expands significantly when the 5f electrons are localized in the core, which occurs at americium and curium. The transition from delocalized to localized f-electron behavior at americium is clearly reflected in the complex chemical and physical properties of uranium, neptunium, and especially plutonium metals in the crossover region of the actinide series. Recent experiments have shown that americium metal exhibits delocalized 5f electron behavior and a structure similar to alpha uranium under high pressure (Lindbaum *et al*., 2003).

15.6.3 Polymorphic transformations

Protactinium, uranium, neptunium, and plutonium metal have complex structures unlike anything encountered in the lanthanide metals (see Table 15.8). For example, plutonium metal is unique among metals, having no fewer than six allotropic modifications between room temperature and its melting point at 913.0 K. A remarkable phenomenon occurs as plutonium metal is heated. Plutonium metal undergoes a 26% volume increase going from room temperature through the α, β, γ, and δ phases with increasing temperature. However as the temperature continues to increase the δ and δ' phases undergo a contraction with a concomitant increase in density. An immense effort has been expended to map the phase transformations in uranium and plutonium metals and their alloys because of their great importance in nuclear technology. Details of the electronic properties of the actinide metals can be found in Chapter 21 and in Lam *et al*. (1974) and Spirlet (1982). The metallurgy of Pu and its phase transitions are discussed in Chapter 7.

15.6.4 Electronic structures

We have noted in Section 15.6.2 the effects of localized and delocalized 5f electrons on the crystal structures and phase transformations of the actinide metals. These effects are observed in many materials, but perhaps most clearly in the actinide metals. The basis for the differences observed for localized and delocalized 5f electrons has been discussed briefly in Section 15.4, but because of their importance in the metallic state some additional discussion of the electronic state in the actinide metals is appropriate. The classical d-electron or d-block transition series and the f-block elements have as a principal feature of their electronic architecture the filling of the 3d, 4d, and 5d electron shells for the d-block series, and the 4f and 5f energy levels in the lanthanide and actinide series. The f electrons occupy energy levels or orbitals closer to the nucleus of the atom than do the outer s and p valence electrons. In the lanthanide elements beyond cerium, the 4f levels are highly localized and, because overlap between the levels is minimal, these energy levels are not broadened to any appreciable extent by 4f–4f interactions. Nor do the 4f electrons mix significantly with the d, s, or p valence electrons. In the d-block metals, the d-electron levels have significant overlap with other d-electrons; the d-electrons also mix or hybridize with s and p levels. The extensive mixing of the d, s, and p orbitals in d-block elements generates broad energy bands whose existence is reflected in the magnetic and electrical properties of the d-block transition metals.

The electronic properties of the 5f elements are intermediate between those of the d-block elements and the 4f elements. At the beginning of the actinide series, the 5f electrons interact strongly with each other, and the band character of the delocalized (itinerant) 5f electrons inhibits the development of magnetism. As the 5f shell is filled, the 5f electrons become increasingly localized and the energy levels fall so that they are well below the Fermi band level. The transition from delocalized to localized 5f electrons takes place in the vicinity of plutonium, as shown in schematic fashion in Fig. 15.7. In the crossover region, which extends from uranium to americium, the electronic behavior is especially complicated because the energy differences between localized and delocalized 5f electrons is small. Comparatively small perturbations can convert the localized 5f electrons into mobile electrons with a band structure, or the reverse. This delicate balance near the middle of the actinide series gives rise to unusual crystal structures, unusual thermodynamic and mechanical properties, multiple valence states, and collective phenomena such as magnetism, superconductivity, and valence fluctuations. So complex are the phenomena near the middle of the actinide series that modern theories of the metallic state have serious difficulties in dealing with them, a situation that is under active study and may well turn out to be not the least valuable contribution that the study of the actinide elements will have made to the understanding of the solid state (Albers, 2001).

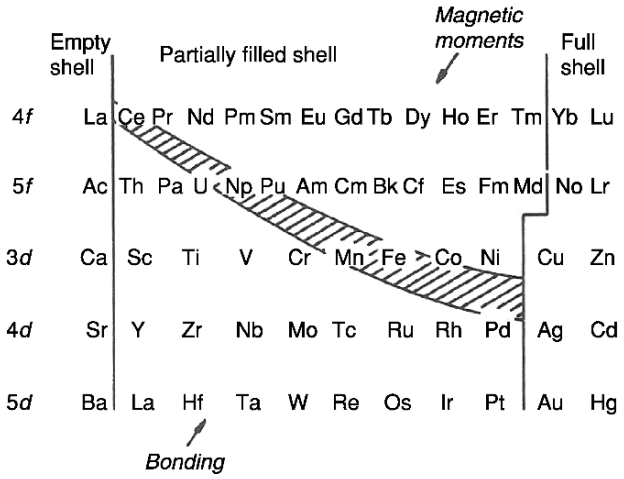

Fig. 15.7 *Transition metals* (*f- and d-series*) *showing the crossover from delocalized* (*bonding*) *to localized* (*magnetic moments*) *f- and d-electron behavior. From Smith and Kmetko* (1983), *with permission.*

One of the most powerful techniques for the elucidation of the electronic states of the actinide elements is the application of high pressure (Benedict, 1984; Haire *et al.*, 2004). The early actinides at 1 atm exhibit complex phase structures due to the behavior of the itinerant (nonlocalized) 5f electrons. The transplutonium elements do not have 5f itineracy contributing to the bonding and show complex phase behavior under high pressures. For americium metal, these 5f electrons become delocalized at high pressures, and the same crystal structures found for the light actinides are obtained (Lindbaum *et al.*, 2003). Pressure also affects the superconducting transition temperature and the magnetic properties of the actinide metals. Similarly, large pressure effects have been observed in actinide alloys and compounds (Heathman and Haire, 1998; Haire *et al.*, 2004).

15.6.5 Superconductivity

Superconductivity in the actinide metals is closely related to the degree of delocalization of the 5f electrons. Highly localized 5f electrons, which are characteristic of the latter portion of the actinide series, are associated with temperature-dependent paramagnetism and the absence of superconductivity. Delocalized 5f electrons participate in chemical bonding, show small temperature-independent magnetic moments, and are conducive to superconductivity. Protactinium metal becomes superconducting at 1.4 K, thorium metal at 1.368 K, and uranium metal at 0.68 K. These three elements have delocalized (itinerant) 5f electrons. Neptunium and plutonium, especially the latter, are

anomalous. The 5f electrons in americium are localized, but americium metal is superconducting at 0.625 K, because its spin and orbital angular momenta cancel one another and its magnetic moment at low temperature is almost zero. The transamericium actinide metals all contain strongly localized 5f electrons, are not superconductors, and have large magnetic moments at low temperatures. Plutonium is not superconducting, but the intermetallic compound $PuCoGa_5$ shows a superconducting transition at $T_c = 18.5$ K. This surprising result is attributed to the presence of a local magnetic moment in the normal state. The superconductivity in this compound is of an unconventional type and could be due to magnetically mediated superconductivity. Thus the transuranics appear to represent a promising area of superconductor research, intermediate between known heavy fermion materials and the high-temperature superconductors derived from copper oxides (Sarrao *et al*., 2002).

15.7 SOLID COMPOUNDS

15.7.1 Introductory remarks

Thousands of compounds of the actinide elements have been prepared (Gmelin, 1972; Müller and Blank, 1975; Müller and Lindner, 1975; Shannon, 1976). Compounds that have special scientific or technological importance are described in the preceding chapters on the chemistry of the individual actinide elements, and in a systematic way in Chapter 22. In the past few years there have been important additions to the roster of actinide compounds and new chemical phenomena that are particularly characteristic of, although perhaps not entirely confined to, the chemical behavior of the actinide compounds, and these are commented on here.

15.7.2 Binary compounds

Table 15.9 lists the binary hydrides, oxides, and halides of the actinide elements along with their melting points, color, and crystallographic parameters. The properties of the hydrides and oxides in Table 15.9 are for compounds that are stoichiometric or come close to the indicated stoichiometric composition. The methods of preparation of the compounds in Table 15.9 are essentially classical procedures adapted to a micro- or semi-microscale and to the radioactivity of the actinide elements (Müller, 1983). There are claims in the literature for the synthesis of actinide halides in which the actinide element is in an unusually high or low oxidation state. Reports of the synthesis of the higher-valent actinide fluorides PuF_5, EsF_4, AmF_6, and CmF_6 have not been confirmed. Following the discovery of the lanthanide dihalides $NdCl_2$ and $TmCl_2$, the dichlorides, dibromides, and diiodides of americium and californium have been prepared. These studies were reviewed by Morss and Edelstein (1984).

15.7.3 Other compounds

The actinide M^{3+} ions in aqueous solution resemble the tripositive lanthanide ions in their precipitation reactions, allowing for differences in the redox properties of early members of the actinide series. The chloride, bromide, nitrate, bromate, and perchlorate anions form water-soluble salts, which can be isolated as hydrated solids by evaporation. The acetates, iodates, and iodides are somewhat less soluble in water. The sulfates are sparingly soluble in hot solutions, and somewhat more soluble in the cold. Insoluble precipitates are formed with hydroxide, fluoride, carbonate, oxalate, and phosphate anions. Precipitates formed from aqueous solution are usually hydrated, and the preparation of anhydrous salts from the hydrates without formation of hydrolyzed species can only be accomplished with difficulty. The actinide(IV) ions resemble Ce(IV) in forming fluorides and oxalates that are insoluble even in acid solution. The nitrates, sulfates, perchlorates, and sulfides are all water-soluble. The 4+ state actinide ions form insoluble iodates and arsenates even in rather strong acid solution. The actinyl(V) ions can be precipitated as the insoluble potassium salts from concentrated carbonate solutions. Actinyl(VI) ions in solutions containing high concentrations of acetate ions form an insoluble crystalline double salt, $NaAnO_2(O_2CCH_3)_3$ (An = actinide). The hydroxides or hydrous oxides of any of the actinide ions in all oxidation states are insoluble in water. Some complex oxides such as $M^{I}_2U_2O_7$ or $M^{II}U_2O_7$(with $M^{I} = Na, NH_4 \ldots$; $M^{II} = Mg \ldots$) can be precipitated from moderately alkaline solutions. The actinyl(VII) ions NpO_5^{3-} and PuO_5^{3-} exist as $MO_4(OH)_2^{3-}$ in alkaline solution, from which they can be precipitated by several di- and tripositive cations.

Actinide(IV) ions form insoluble peroxy compounds with hydrogen peroxide in moderately acid solution. The solid peroxy compounds incorporate inorganic anions such as sulfate, nitrate, or chloride that may be present in the solution. Phosphates, arsenates, cyanides, cyanates, thiocyanates, selenocyanates, sulfites, selenates, selenites, tellurates, and tellurites of some actinides have all been prepared, but our knowledge of these compounds is far from thorough.

15.7.4 Oxides and nonstoichiometric systems

There are many inorganic compounds whose composition is not necessarily expressible as the ratio of small whole numbers. Instead, they exist over a range of compositions. Compounds of variable composition often have electrical, magnetic, and thermal properties that are exceedingly sensitive to the exact composition. Nonstoichiometry is purely a solid-state phenomenon, which is associated with vacancies and/or interstitial ions in or near cation or anion sites in a crystal lattice (Anderson, 1970). Electrical neutrality in the crystal must of course be maintained, and deviations from exact stoichiometry can only exist if compensated by a change in the oxidation state of another constituent of the

crystal. Nonstoichiometry is therefore encountered in binary and ternary compounds of transition elements with hydrogen, oxygen, chalcogens, pnictogens, carbon, silicon, and boron. The presence of a metallic ion in more than one oxidation state in a crystal endows nonstoichiometric compounds with a variety of interesting properties: they may be highly colored; they may show metallic electrical conductivity, or they may be semiconductors; they frequently show marked catalytic activity; and they may differ significantly in chemical reactivity from the stoichiometric compounds of the same elements. Nonstoichiometric compounds are important as transistors, thermistors, rectifiers, ionic electrical conductors, thermoelectric generators, photodetectors, and other electronic and optical devices. The actinide elements, because of the multiplicity of oxidation states that they can assume, are particularly prone to the formation of nonstoichiometric systems. This is especially true for the elements uranium through curium. The oxide systems illustrate many of the salient features of nonstoichiometry in actinide element chemistry.

The first actinide element to form nonstoichiometric oxides is protactinium. It is also the first of the actinide elements to have two readily accessible oxidation states. The black dioxide PaO_2 is obtained by reduction of Pa_2O_5 with hydrogen or carbon. Intermediate phases with the composition $PaO_{2.18–2.20}$, $PaO_{2.33}$, $PaO_{2.40–2.42}$, and $PaO_{2.42–2.44}$ have been identified by X-ray crystallography. Pa_2O_5 itself occurs in several crystal modifications determined by the method and temperature of preparation. The black color of PaO_2 indicates that it is probably nonstoichiometric and the white color of Pa_2O_5 indicates that it is stoichiometric.

The complexity of the uranium–oxygen system is awesome. In the composition range UO_2 to UO_3 there are close to a dozen phases, many of which exist in several crystal modifications. UO_3 itself occurs in six polymorphs. The complex phase relationships result from the easy change in oxidation state of the uranium as additional oxygen is introduced into the UO_2 lattice. The additional oxygen incorporated in hyperstoichiometric UO_{2+x} is distributed at random into vacant lattice sites. The original fluorite structure is distorted, but remains recognizably the same phase over a range of compositions. The stoichiometric range of a phase is a measure, at a particular temperature and oxygen pressure, of its ability to accommodate randomly distributed oxygen without change in the long-range order of a crystal. When random incorporation is no longer possible, additional oxygen is ordered in a superlattice structure, and a new phase appears, possibly because of variable composition. In the uranium–oxygen system such an abrupt transformation occurs at the composition $UO_{2.4}$. Six more phases occur between $UO_{2.4}$ and UO_3.

Only two neptunium oxide phases, with compositions of NpO_2 to $NpO_{2.5}$, are known. The composition of the latter oxide is consistent with the well-known stability of the Np(v) state. Plutonium has two oxides corresponding to the oxidation states 3+ and 4+, and an oxide of intermediate composition, $PuO_{1.61}$. Despite the existence of stable 6+ states for both neptunium and plutonium, no

binary oxide corresponding to the 6+ oxidation state is known for neptunium but hyperstoichiometric PuO_{2+x} does appear to exist (Haschke *et al.*, 2000). Recent spectroscopic evidence indicates that it contains Pu(v) rather than Pu(vi) (Conradson *et al.*, 2004).

For the transplutonium elements through fermium, the 3+ oxidation state is the stable one, and the actinide elements following plutonium have (or should have, for Fm–Lr) oxides of the composition An_2O_3. All of the transplutonium elements to californium also form oxides in which the actinide elements have the formal oxidation state 4+, which is consistent with the known ability of these elements to assume oxidation states higher than 3+. The relative ease of formation of the transplutonium dioxides from $MO_{1.5}$ is in the order $BkO_2 > AmO_2 > CmO_2 > CfO_2$. Curium and californium are also reported to form intermediate oxides of the composition $CmO_{1.714}$ and $CfO_{1.714}$. In the case of $CfO_{1.714}$, this is the highest oxide that can be prepared in air or in oxygen at 1 atm pressure. The oxide systems of the transcalifornium elements still remain to be explored. By comparison, the nonstoichiometric compounds of the actinides elements with the chalcogenides and pnictides have only received a modest amount of study.

15.7.5 Crystal structures and ionic radii

The vast accumulation of crystallographic structural data, especially structures of ionic compounds solved by single-crystal diffractometry, has provided the basis for the determination of the ionic radii of monatomic ions in several coordination numbers. Actinide ionic radii for coordination number 6 are presented in Table 15.10. Ionic radii for the lanthanide series are listed for comparison. For both the 3+ and 4+ ions of the actinide series, the ionic radii decrease with increasing atomic number, a phenomenon that is caused by decreased shielding by f-electrons of the outer valence electrons from the increasing nuclear charge. This behavior, termed 'actinide contraction,' is very similar to the corresponding 'lanthanide contraction.' As a consequence of the ionic character of most actinide compounds, and the similarity of the ionic radii for a given oxidation state, analogous compounds of lanthanide and actinide ions with similar ionic radii are generally isostructural. In the series UBr_3, $NpBr_3$, $PuBr_3$, and $AmBr_3$, for example, the structural type changes with increasing atomic number, which is consistent with the contraction in ionic radius and with lanthanide tribromides that have similar Ln^{3+} ionic radii (Brown, 1968; Eick, 1994). The extraordinary stability of the fluorite-type MO_2 structure is responsible for the existence of such compounds as PaO_2, AmO_2, CmO_2, and CfO_2, despite the relative instability of the 4+ oxidation state of these elements in solution and in many solids. The actinide contraction and the isostructural relationships among the compounds of 4f and 5f elements are particularly convincing examples of evidence for the actinide elements as a 5f transition series.

Table 15.10 *Ionic radii of lanthanides and actinides* (*coordination number* 6) (*Shannon*, 1976, *except as noted*).

No. of 4f or 5f electrons	*Lanthanide series*						*Actinide series*

15.7.6 Organoactinide compounds

When the first edition of this book was in preparation (1956), the prospects of an organoactinide chemistry, i.e. compounds containing an actinide–carbon bond, were judged to be very dim. At this time of writing, the situation is very different. A rich organometallic chemistry of the actinide elements has come into existence in the last four decades, so luxuriant in fact that presenting a concise summary that does justice to the subject is not possible. This field of inquiry is one of the most active and important in current actinide element research (see Chapters 25 and 26). Not only are new organoactinide compounds with remarkable properties appearing, but studies of their structure and physical properties by the use of nuclear magnetic resonance (NMR), optical and vibrational spectroscopy, photoelectron spectroscopy, crystallography, and many other physical and chemical techniques are contributing valuable information on the electronic structure and the nature of chemical bonding in the 5f elements, subjects that are of great importance in every aspect of actinide element chemistry.

The large size and the generally ionic bonding for the 5f ions result in different reactivities and coordination with the same ligands as compared to the d-transition series. In addition, the early actinides, uranium, neptunium, and plutonium in particular, have stable oxidation states ranging from trivalent to hexavalent, which introduces a range of possible organometallic compounds with varying formal charge on the metal ion. Due to the relatively easy availability of thorium and uranium starting materials and the low specific activity of the naturally occurring isotopes of these elements, most of the work to date has been done with thorium and uranium. Only a few organometallic compounds of the transuranium elements have been characterized.

The best known covalent organometallic compound of a transition metal, $Fe(C_5H_5)_2$ (ferrocene), was synthesized in 1951 (Keally and Pauson, 1951). The main group elements were well known to form compounds in which covalent metal–carbon bonds were formed, but transition metals were widely regarded as incapable of forming stable bonds of this kind. The first stable transition-metal organometallic compounds were derivatives of cyclopentadiene, C_5H_6. Its anion, cyclopentadienide ion (Cp^-), is aromatic and possesses 6 π electrons capable of coordination to vacant d-orbitals on a transition metal. In 1956, uranium, newly recognized as a member of a 5f transition element series, became the first of the actinide elements to yield a stable cyclopentadienyl (Cp) compound, tris(cyclopentadienyl)uranium chloride, Cp_3UCl (Reynolds and Wilkinson, 1956). A decade was to pass before the first transuranium organometallic derivative, tris(cyclopentadienyl)neptunium chloride, was prepared (Baumgartner *et al.*, 1965). Since then, hundreds of organometallic derivatives of the actinide metals have been prepared. Among these are compounds containing other π-donor ligands, such as indenyl and cyclooctatetraenyl groups. The introduction of bulky alkyl- and silyl-substituted derivatives of

these π-donor ligands has extended the scope of these reactions and allowed the isolation of discrete molecular entities because the large ionic radii of the actinide ions require sterically demanding ligands so that only one or a few coordinatively unsaturated sites are available for reaction. These compounds provide an excellent environment for the study of chemical bonding in the f-block elements.

Cyclopentadienyl organoactinide compounds can be prepared by a variety of reactions (Marks and Fischer, 1979). One method for actinides in the 3+ and 4+ oxidation states is by reaction of potassium or sodium cyclopentadienide with the anhydrous actinide halide (AnX_n) in an organic solvent such as tetrahydrofuran (THF), toluene, or diethyl ether:

$$AnX_4 + 4KCp \rightarrow AnCp_4 + 4KX$$

$$AnX_4 + 3KCp \rightarrow Cp_3AnX + 3KX$$

$$AnX_3 + 3KCp \rightarrow AnCp_3 + 3KX$$

The actinide compounds are recovered from the reaction mixture by extraction with an appropriate organic solvent, and can be further purified by sublimation in a good vacuum when the volatility of the compound permits. The actinide cyclopentadienylides can also be prepared by metathesis in the molten phase by heating the actinide halide with beryllium or magnesium cyclopentadienides. The tris(cyclopentadienyl) compounds are strong Lewis acids and form adducts with many Lewis bases. They are ionic substances, although the bonding has more covalent character than in the corresponding lanthanide compounds. All of the actinide(III) compounds, with the exception of the uranium compound, are soluble in organic solvents, are reasonably stable, and are appreciably volatile, but all are sensitive to air. The tetrakiscyclopentadienyl complexes are soluble in organic solvents and moderately stable to air; they are not, however, appreciably volatile.

Compounds of the type Cp_3AnX, where the actinide element is in the 4+ oxidation state and X is an anion, have been prepared in large numbers and with a great variety of anions. Evidence has been adduced that the uranium tris (cyclopentadienyl) chloride ionizes in oxygen-free water to form the UCp_3^+ and Cl^- ions. The halide ion (X^-) in compounds of the type Cp_3AnX can be exchanged in solution by reaction with KX'. Anions (X'^-) that can be introduced include not only other halides, but also sulfate, perchlorate, nitrate, thiocyanate, etc., and also more exotic anions such as BH_4^-, BPh_3CN^-, $Co_3(CO)_{10}^-$, and OR^- (where R is an alkyl or other organic entity). These compounds have been subjected to structural analysis as well as examination by modern spectroscopic techniques. NMR spectroscopy has shown that the hydrogen atoms in the borohydride derivatives are all equivalent. The crystal structure indicates that in the BH_4^- anion there are two structurally distinct hydrogen atoms, bridging and terminal atoms. The equivalence of the hydrogen

atoms on the NMR timescale demonstrates the existence of a rapid internal dynamic exchange process. The NMR studies have not only revealed unusual features of the structure of the organometallic compounds but have also contributed to the theory of NMR paramagnetic chemical shifts by virtue of the magnetic properties of the 5f electrons in the compounds.

The discovery in 1968 by Streitwieser and coworkers (Streitwieser and Muller-Westerhof, 1968; Seyferth, 2004) that the dianion of cyclooctatetraene (COT), $C_8H_8^{2-}$, can act as a ligand to the actinide elements signaled an important new development in organoactinide chemistry. The first compound of this class was uranocene, prepared by reaction of UCl_4 with potassium salt of COT:

$$UCl_4 + 2K_2(COT) \rightarrow U(COT)_2 + 4KCl$$

Subsequently, the corresponding compounds of Th, Pa, Np, and Pu have been prepared. All have a sandwich structure in which two planar COT dianion rings enclose a metal atom. Uranocene is the most intensively studied of these compounds. It is exceedingly reactive toward oxygen, but it reacts only slowly with water or acetic acid. Unlike the cyclopentadienyl compounds of the actinides, all reactions with strong electrophiles completely decompose uranocene. The nature of the bonding in the actinide bis-cyclooctatetraene compounds has naturally attracted much interest. From crystal structure data, ionic bonding seems plausible, but photoelectron, NMR, and Mössbauer spectroscopy all suggest substantial covalency. This conclusion is reinforced by *ab initio* calculations on this series of molecules. NMR has been especially useful in studying ligand-exchange reactions, in mapping the electron spin distribution, and in exploring the dynamic processes in these compounds.

Attempts to prepare organometallic compounds that contain a direct metal–carbon bond were made in the very early days of the Manhattan Project, with the objective of producing compounds sufficiently volatile to be useful in isotope separation by diffusion or electromagnetic separation methods. All products prepared by the reactions then available for the synthesis of σ metal–carbon bonds gave products that were unstable at room temperature. The first cyclopentadienyl compound containing a true σ metal–carbon bond was obtained by alkylation of tris(cyclopentadienyl) uranium(IV) chloride (Brandi *et al.*, 1973; Gebala and Tsutsui, 1973; Marks *et al.*, 1973):

$$UCp_3Cl + RLi \rightarrow UCp_3R + LiCl$$

where R = methyl, and many other straight- and branched-chain alkyl groups, unsaturated alkenes such as allyl and vinyl, aromatic radicals such as phenyl, tolyl, or benzyl, or many other functional groups. Analogous compounds of thorium, but not of the other actinide elements, have also been reported. The structure of the UCp_3R compounds is basically a distorted tetrahedron with the three cyclopentadienyl rings at three of the corners, and the sigma bonded alkyl

group at the fourth corner on the three-fold axis of rotation of the molecule. The NMR spectra are very informative about the structure, the spin delocalization of U(IV), and the structural dynamics of the molecule. At room temperature the three cyclopentadienyl rings are magnetically equivalent, but at low temperature the equivalence vanishes because of restricted rotation about the uranium–carbon σ bond.

The chemistry of the actinide–carbon σ bond has been studied intensively. The Cp_3AnR (and alkyl- or silyl-substituted Cp) compounds are extremely sensitive to air, have high thermal stability, and completely lack any tendency for β-hydride elimination by the alkyl moiety. Hydrogen elimination is a common process in d-block organometallic compounds, and its complete suppression in the actinide hydrocarbyl derivatives is noteworthy. Uranium(IV) and thorium(IV) bis(pentamethylcyclopentadienyl) dichlorides can be readily alkylated with lithium reagents in diethyl ether solutions to yield the air-sensitive but thermally stable bis(pentamethylcyclopentadienyl) actinide dialkyls. These actinide hydrocarbyls are highly reactive. Hydrogenolysis yields organoactinide hydrides; this constituted the first preparation of a member of this class of compounds. The dialkyls also show remarkable reactivity with carbon monoxide at low temperatures to form metal–oxygen and carbon–carbon double bonds, reactions that are of interest in catalysis.

A complete review of the present state of organometallic chemistry of the actinides (including the details and references to the work described here) is presented in Chapter 25 and the use of organoactinide compounds in catalysis is given in Chapter 26. Chapter 17 covers the bonding in organometallic compounds of the actinides as described by *ab initio* calculations.

15.8 ENVIRONMENTAL ASPECTS OF THE ACTINIDE ELEMENTS

The development of a large-scale nuclear power industry and the detonation of nuclear weapons in the atmosphere have created worldwide anxiety about the long-term consequences arising from the introduction of transuranium elements into the atmosphere, the hydrosphere, and the biosphere. The radioactive nature of the transuranium elements, and the relatively long half-lives of many of these radionuclides, provide ample reasons for concern. In this section, a summary of the distribution and migration of the actinide elements in the environment is presented. In the preparation of this section we have made extensive use of a number of reviews (Walters *et al.*, 1983; Allard *et al.*, 1984; Bidoglio *et al.*, 1984; Scoppa, 1984; Silva and Nitsche, 1995; Runde, 2000; Choppin *et al.*, 2002, 2003; this work, Chapter 22). A summary of the environmental research on the transuranium elements conducted under the auspices of the U.S. Department of Energy to 1980 provides a comprehensive and authoritative guide to the voluminous literature on the subject (Hanson, 1980).

15.8.1 Actinide elements of natural origin

Several of the actinide elements are natural constituents of the Earth's crust. Of these, thorium and uranium are relatively common and, in the aggregate, occur in enormous quantities in the lithosphere. Uranium and thorium, in fact, are present in the Earth's crust to a larger extent than such familiar elements as mercury, bismuth, tin, cadmium, and silver, and in about the same concentration as lead. The uranium concentration is estimated at 1–10 $\mu g\ g^{-1}$ (1–10 ppm) in the igneous rocks of the Earth's crust; some sedimentary rocks contain much more, as also do some granites. The concentration of thorium in igneous rock is somewhat higher than that of uranium, in the range 5–20 $\mu g\ g^{-1}$ (Hedrick, 1999). The uranium content of seawater is 3.3 $\mu g\ L^{-1}$; thorium concentrations in water are much lower (6×10^{-4} $\mu g\ L^{-1}$) (Allard *et al.*, 1984). Estimates of about 10^{14} tons for the uranium content of the Earth's crust (to a depth of 20 km) have been made, and about 10^{10} tons of uranium may be contained in the Earth's oceans. Other naturally occurring radioactive elements, which are all decay progeny of long-lived thorium or uranium isotopes, are present in the lithosphere and oceans to much smaller extents: protactinium and radium have an abundance of about 10^{-12} mass percent, and the remaining radioactive isotopes as little as several orders of magnitude less. The concentration of radioactive nuclides in secular equilibrium with the progenitors of the natural uranium and thorium decay series is determined by the half-lives of the daughter radionuclides, and, unless concentrated by some geochemical process, they will be present in very small concentrations. Radioactivity is a primeval endowment of the world we inhabit.

Neptunium and plutonium are found in nature in minute amounts, formed by nuclear reactions with fission neutrons in uranium. The ratio of $^{239}Pu/^{238}U$ is on the order of 10^{-12} (see Chapter 7, Table 7.3). Longer-lived ^{244}Pu, which may be primordial in origin, is present in the rare earth mineral bastnasite to the extent of 1 part in 10^{18} (Hoffman *et al.*, 1971). The amount of the naturally occurring plutonium isotopes are so small that for all practical purposes any of the transuranium elements encountered in the environment must be taken as man-made.

There is convincing evidence that some uranium ores have in past geological epochs sustained natural chain reactions. Some samples of pitchblende, U_3O_8, from the Oklo Mine in Gabon, Africa, have a ^{235}U content distinctly lower than the natural average of 0.72%. Some samples contained less than 0.5% ^{235}U, and other elements in these samples had isotopic compositions that varied considerably from the norm. For example, some of the pitchblende from the Oklo Mine had an unusually high content of ^{143}Nd, and an equally unusually low content of ^{142}Nd. Fission-product neodymium contains a high percentage of ^{143}Nd, whereas ^{142}Nd is not formed in the fission of ^{235}U. A high ^{143}Nd content is found in ore that has a low ^{235}U content. These observations strongly suggest that in some remote bygone age, ^{235}U had undergone fission, a conclusion

supported by the unusual isotopic compositions of elements in the ore, indicating they were produced by fission. It is not likely that similar natural 'reactors' are in operation today. Fissile ^{235}U has a much shorter half-life than ^{238}U. In the early days of the Earth, the ^{235}U content of uranium minerals relative to ^{238}U was therefore higher. The age of the Oklo deposit has been established at 1.74×10^9 years. Calculation indicates that the ^{235}U content of the Oklo pitchblende 1.74×10^9 years ago was about 3%. At this concentration of fissile material, water suffusing the ore deposit could have brought regions of the deposit to criticality, and a slow or intermittent chain reaction could have ensued. It is believed that other concentrated uranium ore deposits could have achieved supercriticality in the presence of water as a neutron moderator $(2–3) \times 10^9$ years ago. Such chain reactions conceivably played an important part in early geological events. It is interesting to note that the fission products produced at Oklo over an estimated period of 10^6 years are still retained in the rock in which they were formed more than a billion years ago (Maurette, 1976; Casas *et al.*, 2004).

15.8.2 Man-made actinides

In terms of amount, by far the most significant of the synthetic actinide elements is plutonium. Commercial nuclear power reactors produce approximately 70 metric tons per year worldwide of a mixture of plutonium isotopes as a by-product. About 1380 metric tons of plutonium was estimated to be in the world plutonium inventory in 2000, mostly still in unprocessed spent fuel assemblies from nuclear reactors (Albright *et al.*, 1996). Plutonium produced for nuclear weapons is mainly ^{239}Pu, but plutonium produced as a by-product of energy production contains substantial amounts of ^{240}Pu, ^{241}Pu, and ^{242}Pu and small amounts of ^{238}Pu (Albright *et al.*, 1996, p. 20).

The plutonium in the terrestrial environment (at or near the Earth's surface and in ocean sediment) is due, in decreasing order of importance, to the testing of nuclear weapons in the atmosphere, the reentry into the atmosphere and disintegration of satellites equipped with ^{238}Pu power sources, and the processing of irradiated nuclear reactor fuel.

(a) Nuclear weapons testing

A total of approximately 7700 kg of plutonium has been released in atmospheric and underground nuclear explosions. During the period 1950–63, when testing nuclear weapons in the atmosphere was regarded as acceptable practice by the USSR and the U.S., 4400 kg of plutonium, primarily ^{239}Pu and ^{240}Pu, were injected into the atmosphere in 543 acknowledged atmospheric detonations, mostly as plutonium oxide (Kim, 1986; Hobart, 1990). More than 99% of this has by now been redeposited on Earth; 10.87 PBq of ^{239,240}Pu has been deposited on the ocean (UNSCEAR, 2000); the concentration varies greatly as a

function of latitude, longitude, and depth (Nakano and Povinec, 2003). The highest Pu concentrations in the ocean near the end of the 20th century were $\sim$0.1 Bq m^{-3} in the vicinity of Eniwetok and Bikini atolls at a depth of about 800 m. Of the original 12.8 PBq (1.28×10^{16} Bq, 3.5×10^{5} Ci) of plutonium originally present in the atmosphere of the Northern Hemisphere, about 37 TBq (1000 Ci) remain, a decrease by a factor of 1000 or more (Olivier *et al.*, 2004). Another 1.4 metric tons of plutonium have been deposited in the ground in the course of surface and subsurface testing of nuclear devices (Allard *et al.*, 1984). When more recent weapons tests are included, approximately 6 metric tons of plutonium have been deposited in the Earth's environment from weapons tests that peaked in 1963 (Allard *et al.*, 1984; Olivier *et al.*, 2004).

(b) Disintegration of satellites

Plutonium that is highly enriched in ^{238}Pu has been released into the atmosphere, largely the result of the disintegration over the Indian Ocean in 1964 of a Transit satellite (Table 15.12) carrying a nuclear power source (Nenot and Metivier, 1984).

(c) Nuclear fuel processing and storage

The amount of plutonium in the environment resulting from nuclear reactors and fuel reprocessing operations is small. Measurements in the waters of the Seine Bay (taken near the La Hague fuel reprocessing plant) indicated a plutonium concentration of about 10000 times less than the concentration of natural uranium (Nenot and Metivier, 1984). Since that time the amounts of plutonium released from all these sources has been much smaller. However, there is a potential for future release from stored spent nuclear fuel: Examination of accelerated commercial spent fuel corrosion products by electron microscopy showed that U–Pu enriched layers exist in the corroded fuel and that some of the plutonium may be present as soluble and mobile Pu(v) (Buck *et al.*, 2004).

What complicates the environmental situation is that plutonium is not the only transuranium element produced in nuclear reactors. Americium and curium are also formed by multiple neutron capture (see Fig. 15.1). The amounts of long-lived actinides in spent fuel as a function of time after removal from a reactor are shown in Table 15.11. The elements americium and curium formed in the reactor undergo radioactive decay to produce radioactive daughter species (Allard *et al.*, 1984):

$$^{245}\mathrm{Cm} \rightarrow {}^{241}\mathrm{Pu} \rightarrow {}^{241}\mathrm{Am} \rightarrow {}^{237}\mathrm{Np} \rightarrow {}^{233}\mathrm{U} \rightarrow {}^{229}\mathrm{Th}$$

$$^{242}\mathrm{Am} \rightarrow {}^{242}\mathrm{Cm} \rightarrow {}^{238}\mathrm{Pu} \rightarrow {}^{234}\mathrm{U} \rightarrow {}^{230}\mathrm{Th} \rightarrow {}^{226}\mathrm{Ra}$$

$$^{243}\mathrm{Am} \rightarrow {}^{239}\mathrm{Pu} \rightarrow {}^{235}\mathrm{U} \rightarrow {}^{231}\mathrm{Pa} \rightarrow {}^{227}\mathrm{Ac}$$

[b] Appendix II, this work.

The effect of radioactive decay of the americium and curium is an increase in the intensity of radioactivity with time after removal from the reactor. For a period from 10 to 10^3–10^4 years after discharge from the reactor, the environmental hazards will be preponderantly due to ^{241}Am; from 10^4 to 10^5 years the nuclides ^{239}Pu and ^{240}Pu will be the principal actinides present; and for the period after 10^6 years, ^{237}Np will be the principal actinide present. The chemical properties of uranium, neptunium, plutonium, and americium thus determine the mode and extent of dispersion of alpha-emitting radionuclides introduced into the environment from nuclear operations. Table 15.12 indicates the amounts of transuranium elements released into the atmosphere as of 1980. The disposal of low-level waste streams from nuclear fuel reprocessing in the sea is estimated to add considerably less than 0.1 kg (0.3 TBq) per year of plutonium to the environmental inventory (Allard *et al.*, 1984).

15.8.3 Actinides in the hydrosphere

From the discussion of ions in solution and their redox and hydrolytic properties in Section 15.5, it can be inferred that the transuranium elements in a marine (ocean) environment will tend to form insoluble compounds. Under the redox conditions that obtain in the ocean, the stable oxidation states of plutonium,

americium, and curium are expected to be Pu(IV), Pu(V), Am(III), and Cm(III). Under reducing conditions, neptunium is expected to be in the Np(IV) state and to behave much as does Pu(IV). Under oxidizing conditions, however, the neptunyl(V) ion, NpO_2^+, will be the stable species, and the similar Pu(V) ion PuO_2^+ predominates; these ionic species have smaller tendency to undergo hydrolysis or to form strong complexes than do the 4+ state ions or other actinyl ions in the 6+ oxidation state (Orlandini *et al.*, 1986). Plutonium and the other transplutonium elements in the 3+ and 4+ oxidation states readily undergo hydrolysis at the normal pH of marine waters to form hydroxides and oxides that are essentially insoluble in water. However, these ions form strong complexes with oxygen-containing ligands, which may change their redox potentials significantly, and this may render them oxidizable. The overall effect of the formation of higher oxidation states and complex ions is to produce actinide ions that are more soluble in water. The carbonate ion in particular is important because it is present in natural waters; it forms soluble complexes that stabilize the higher oxidation states of neptunium and plutonium. Allard *et al.* (1984) made a detailed analysis of the interaction of the transuranium elements with natural complexing agents as a function of concentration and pH, and calculated solubilities in water that may be expected for these elements under various conditions. Because natural conditions vary a great deal, it is difficult to make precise generalizations, but general trends can be discerned without too much difficulty. The transuranium actinides under most conditions form insoluble species that result in actinide enrichment in bottom sediments. The tendency to form strong complexes with water-insoluble oxygen-containing ligands (e.g. the exoskeletons of marine organisms) is another route for the removal of the transuranium actinides from the water column to the bottom sediments. The nature of the chemical forms in which the actinide elements occur in marine sediments, and the chemical processes that occur between

seawater and sediments, are topics of active research (Morse and Choppin, 1986; McCubbin *et al*., 2002).

The availability of ocean transuranium elements to marine organisms has received attention. Plutonium is accumulated quite efficiently by benthic (sea-bottom) algae and invertebrates and by plankton. While it is a fairly straightforward matter to determine the plutonium content of harvested organisms, it is not so simple to decide the route by which the plutonium entered or just where in the organism the plutonium is retained. Transfer of plutonium in the water to starfish can take place via ingested food, but it can also occur by adsorption on the surface of the organism. The high concentration of plutonium in starfish appears to be due largely to the strong affinity of polymeric plutonium hydrosols or simple plutonium ions for the mucus sheath that coats the organism. Neptunium, as the NpO_2^+ ion, is rapidly accumulated and excreted by marine zooplankton, but appears, on the basis of limited observations, to be less available than either plutonium or americium.

The transfer rate of americium from sediments containing it in insoluble form is low, and it appears for the most part to be adsorbed on the exterior of bivalve molluscs, *Polychaeta* (marine worms), and isopods (crustaceans). In the presence of higher concentrations of carbonate (Atlantic sediments containing 83% carbonate as compared to Pacific sediments containing only 8% carbonate), the transfer of americium to living organisms increased several fold (Scoppa, 1984). Experiments in which the marine environment was simulated show that the accumulation of ^{241}Am by tiny crustaceans (krill) occurred mainly by adsorption on the exoskeleton, and that only a small amount of americium was retained by the krill after molting. Americium sorbed on diatoms ingested by krill was not assimilated and was excreted in a short time.

Based on a limited amount of data acquired in the Irish Sea near the reprocessing plant at Sellafield, UK, invertebrates and algae accumulate higher concentrations of curium than do the edible parts of fish. The behavior of californium has been studied in a preliminary way in seawater, sediments, and plankton (Scoppa, 1984). Cf(III) is rapidly adsorbed by particulate matter and sediments with distribution coefficients of 10^4 to 10^5. It is also taken up rapidly by marine zooplankton. The relative order of uptake by krill is Cf(III) > Am(III) > Pu(V+VI) > Np(V). Assimilation and incorporation of Cf(III) by the zooplankton in the internal tissues is extremely low in these organisms, and take-up is most likely due to adsorption on the surface of the organisms.

Actinide elements have been released into freshwater (rivers and lakes) as a result of subsurface plumes from leaking waste tanks or other storage of nuclear wastes at former military reactor processing sites. At the Hanford site (Washington state, USA) several tons of uranium, accompanied by other radionuclides, has contaminated the vadose zone. Synchrotron X-ray spectroscopy and diffraction studies of borehole samples showed uranium to be present in the U(VI) solids that are known forms. These solids make it unlikely that uranium is

migrating in the vadose zone but will make it difficult to remove the uranium as a remediation option (Catalano *et al.*, 2004).

15.8.4 Actinide sorption and mobility

Polymeric actinide ions carry a positive charge, and are easily scavenged by negatively charged surfaces. As depolymerization is a very slow process even in strong acid solution, the Pu(IV) polymer is an attractive candidate for an explanation of the ease with which it is removed and the tenacity with which it is retained by clays or soils. Many minerals, especially clays with zeolitic channels and cages, have ion-exchange properties. Ion-exchange sites firmly bind the simple actinide ions in the III and IV oxidation states, and binding of the actinyl ions in the 5+ and 6+ states is considerably weaker. Plutonium is strongly sorbed on many minerals in the pH range normally encountered in the environment under both oxidizing and reducing conditions.

The overall effect of ion exchange and other sorption processes by solid phases is to remove actinides at tracer concentrations from an aqueous phase. The uptake on solids is in the same sequence as the order of hydrolysis: Pu(IV) > U(VI) > Am(III) > Np(V).

Assimilation in plants commonly declines in the order: Np(V) > U(VI) > Am (III) > Pu(IV), Np(IV). Both phenomena are evidently contingent on the species formed by hydrolysis: the easily immobilized species are also assimilated with difficulty by plants. The uptake of actinides by living organisms from solid phase is minor, and this is also the case for actinide elements immobilized on food. Of the 4400–7700 kg of plutonium that came to Earth after atmospheric testing of nuclear weapons, the total amount fixed in the world population is estimated to be less than 1 g (Allard *et al.*, 1984). Allard *et al.* (1984) conclude from the available evidence that plutonium in the environment is not concentrated in the food chain. Surface-adsorbed actinides appear to be the major mechanism for the introduction of transuranium elements into the terrestrial food chain even though the actinides are not actually incorporated into the internal tissues of the organisms (Teale and Brown, 2003). The enrichment of actinides in the food chain to humans is minimized by discrimination against the absorption of actinides by organisms at higher levels in the food chain. Thus, it is unlikely that the concentration of plutonium in a human being will significantly exceed the concentration in natural waters, regardless of the mode of ingestion.

Organic and inorganic particles or colloids to which actinide elements are attached constitute a major mode of dissemination of the actinide elements in the environment. Natural waters contain particulate silt and organic matter, which may or may not be living. Transport of actinide elements adsorbed on particulate matter will then depend on particle size, water flow, and factors other than the chemical properties of the actinide species themselves.

Living organisms can also act as carriers even if the actinide elements are not actually incorporated into the tissues of the organism.

15.8.5 Nuclear waste disposal

The fate of actinide elements introduced into the environment is not merely a scientific issue. The disposal of the by-products of the nuclear power industry has become a matter of industrial and public concern. For each 1000 kg of uranium fuel irradiated in a typical nuclear reactor for a 3 year period, about 50 kg of uranium are consumed. In addition to a large amount of energy evolved as heat, 35 kg of radioactive fission products and 15 kg of plutonium and transplutonium elements are produced. Many of the fission-product nuclides are stable or are short-lived radionuclides that decay to stable isotopes, but others are highly radioactive for decades or longer. All of the fission products are isotopes of elements whose chemical properties are well understood. The transuranium elements produced in the reactor by neutron capture, however, have unique chemical properties, which are reasonably well understood but are not easily inferred by extrapolation from the chemistry of the classical elements. Plutonium is fissile and can be recycled as a nuclear fuel in conventional or breeder reactors, but the transplutonium elements are not fissile to the extent of supporting a nuclear chain reaction, and in any event they are produced in amounts too small to be of interest for large-scale uses. The transplutonium elements must therefore be secured and stored.

The exact form in which fission products and heavy elements are extracted from spent fuel elements is determined by the chemical process used to treat the spent fuel. In the past, most fuel reprocessing has been by solvent extraction, and it is probable that solvent extraction will continue to be the most widely used processing procedure, at least until new reactor types are introduced. Solvent extraction is efficient in separating uranium, fission products, and transuranium elements, but large volumes of liquid waste streams with rather low but not negligible levels of radioactivity are generated in the process. The plutonium is generally separated from the transplutonium elements, leaving a complex mixture of fission products and americium, curium, and transcurium elements, which as they decay form isotopes of neptunium, uranium, and natural radioactive elements. These must be immobilized and stored in a way and in places where no geological or man-made catastrophe will release the radioactive material into the environment, even over an enormously long timespan.

Many schemes have been considered for disposal of both fission products and actinide elements. These proposals has been discussed by Choppin *et al*., 2002, pp. 599–640), National Academy of Sciences (1995), and Van Tuyle *et al*. (2002) among others. Nuclear 'incineration,' the transmutation of excess plutonium and the 'minor actinides' neptunium, americium, and curium (which are the predominant source of radioactivity from spent fuel after about 600 years)

in nuclear reactors after their separation from other components of spent fuel, is a realistic option pursued in several countries. Prolonged neutron irradiation in a conventional fission nuclear reactor, or possibly in a fast breeder reactor, will transmute long-lived actinide isotopes, especially excess weapons plutonium, to short-lived radioactive or stable isotopes faster than they will be formed from the uranium or uranium–plutonium mixed oxide (MOX) fuel in the reactor, especially if the nuclear fuel is an 'inert matrix' ceramic oxide that has no uranium. The actinide elements subjected to nuclear incineration in a reactor must be free of lanthanide fission products, as some of these have very large cross sections for neutron capture and thus could adversely affect the neutron economy of a nuclear reactor. A drawback of reactor incineration is that some plutonium is bred; this drawback can be mitigated by the use of uranium-free 'inert matrix fuels' that are ceramic oxides such as yttria stabilized zirconia or zirconates. These fuels are inert in the sense that the fuel cannot breed plutonium (Degueldre and Yamashita, 2003).

Another transmutation scheme is accelerator transmutation of long-lived nuclear wastes. An accelerator generates high neutron fluxes by spallation. These neutrons drive a subcritical reactor to fission the long-lived actinide isotopes without breeding additional plutonium. This technology can transmute fissile ^{235}U and ^{239}Pu, as well as the isotopes ^{237}Np, ^{241}Pu, and ^{241}Am that dominate both the long-term heat load and radiotoxicity of the waste.

Immobilization and disposal in appropriate geological formations has received the most attention. The first step in immobilization is to convert the liquid waste streams from fuel processing into dry solids by evaporation or some other drying process. The dry residue is calcined to convert the radioactive mix to metal oxides. In this form the calcined oxides are leachable and can easily become airborne. Their thermal conductivity is low, and good heat conductivity is essential to dissipate the heat liberated by radioactive decay. A great variety of glassy and crystalline matrices have been explored. Prime requirements are stability to radiation and to chemical attack by or to solubility in water, since exposure to groundwater is a possibility that must be guarded against in any subterranean repository. Borosilicate glasses are preferred matrices in most countries, and in fact France (La Hague) and the U.S. (Savannah River plant) have glass melters that have been in operation for one or more decades (CEA, 2002). Additional encapsulation of the solidified waste is generally considered mandatory, and for this purpose corrosion-resistant metals such as copper or C-22 alloy (UNS 06022, a nickel–chromium–molybdenum–tungsten alloy) have been selected for waste canisters.

The requirements for a geological repository are quite stringent. The repository must be sited in a region of high geological stability, free of earthquakes and volcanic activity. The chosen stratum must be free of vents to the surface, and it must have little or no groundwater circulation. It is important that the geological formation have good heat conduction properties to enable heat evolved by radioactive decay, which is very substantial, to be conducted away

rapidly enough to prevent destruction of the containment by high temperature. Rock salt, granite, and clay all have their proponents. Disposal in the Arctic ice caps and burial in deep seabeds also have been considered. Rock salt formations, at least in the U.S., appear to be the geological stratum of choice for transuranic wastes. Unaltered rock salt formations of great age and of unquestionable seismic stability are known. Rock salt has exceptionally good heat transfer properties. Extremely dry salt domes that have existed for more than 100 million years without appreciable alteration exist in many places. Salt is plastic, and holes and fractures in the salt bed will self-seal. As long as the surface layers are not breached by drilling, and that provision is made in repository design for the corrosive properties of brine, rock salt domes appear to have most of the features required for a secure repository.

Clays likewise have desirable properties. The migration rate of fission products and actinides through clay is very slow and, once adsorbed in such a matrix, the transuranium elements are effectively immobilized. However, clay deposits frequently are percolated by water, and it is difficult to guarantee that even a bed dry for geological epochs will remain that way. Still, even radionuclides that enter underground water are readily removed and immobilized by ion exchange on clays and other minerals. A very good example of efficient and extraordinarily effective immobilization of radioactive fission products by natural processes is found in the Oklo mineral formation, where the products of a natural chain reaction have remained in close proximity to their point of origin although the rock formation has been suffused repeatedly by water in the past billion years (see Section 15.8.1). Although there are unanswered questions about nuclear repositories, there are many reasons to expect that the technical problems in nuclear waste disposal can be solved satisfactorily. Indeed, most of the necessary technology has been in existence for some time, and a high level of technical sophistication has been available for many years (Topp, 1982). It seems likely that interim or monitored retrieval storage will be the method of choice for the storage of nuclear waste. Storage of this kind is easier to prove safe and could be useful for a century or more.

15.9 BIOLOGICAL BEHAVIOR OF THE ACTINIDE ELEMENTS

15.9.1 General considerations

In this section we have made extensive use of several authoritative reviews (Bulman, 1980; Raymond and Smith, 1981; Nenot and Metivier, 1984; Banaszak *et al.*, 1999; Gorden *et al.*, 2003) that emphasize aspects of importance in the biological behavior of the actinide elements, both in the ecosphere and in humans. None of the elements heavier than iodine (atomic number 53) is, so far as is known, essential to life, and an intrusion by any of them into living organisms is generally regarded as a noxious event best avoided. Studies on

the heavier elements tend to be sparse or fragmentary except where special circumstances apply, e.g. mercury or lead. Were it not for the long-lived radioactivity of the actinide elements, it is likely that they too would attract little interest. Uranium, neptunium, plutonium, and americium are regarded as the major health hazards among the actinide elements, and thus have been the focus of research activity (Thompson, 1982). Recently, interest in the oxidation–reduction and coordination of neptunium with microorganisms and their organic by-products (e.g. humic and fulvic acids) has reawakened and is now a theme in bioremediation research because Np(V) appears to be the most mobile of the actinide ionic species (Songkasiri *et al.*, 2002). This, coupled with the realization that long-lived ^{237}Np formed by the radioactive decay of ^{241}Pu (via the decay sequence

$$^{241}\mathrm{Pu} \xrightarrow{\beta^-} {}^{241}\mathrm{Am} \xrightarrow{\alpha} {}^{237}\mathrm{Np}$$

in nuclear waste) makes ^{237}Np the major contributor to the radioactivity of nuclear waste at times greater than 10^5 years, has stimulated new interest in the biological properties of neptunium. A comprehensive treatment of the behavior of actinides in animals and man is found in chapter 31.

15.9.2 State of actinide elements in body fluids

The forms in which plutonium, americium, and curium occur in blood and urine are continuing topics of major concern, for they are intimately involved in transport in the body after ingestion and in subsequent excretion. Boocock and Popplewell (1965) found that plutonium injected intravenously into the rat was bound in the blood serum to transferrin, a protein produced in the liver that transports iron between tissues and bone marrow. Pu(IV) in the blood is rapidly and firmly bound to transferrin. By far the greater part of the plutonium is captured by transferrin, but small amounts are believed to be complexed by citrate ion or low-molecular-weight carbohydrates or peptides. This may reflect a complex equilibrium situation, or may be an indication that more than one ionic species of plutonium in more than one oxidation state is present. The binding of plutonium to transferrin is strong, but Fe(III) can displace it, and plutonium is not bound by iron-saturated transferrin. Bicarbonate ion is required to bind iron to transferrin, and this is also the case for plutonium. The half-life for the removal of transferrin-bound iron and plutonium from the circulation is the same. The exact nature of the binding sites remains unknown, and whether the same site is used for binding iron and plutonium is unsettled. Transferrin contains a sialic acid component (an oligo- or polysaccharide containing an acidic sugar, *N*-acetylneuraminic acid), which is an excellent complexing agent for metal ions. However, destruction of the polysaccharide moiety inhibits the binding of Pu(IV) but not of Fe(III), suggesting a more complicated binding site situation than at first anticipated. Pu(IV) shows

remarkable similarity to Fe(III) in its coordination behavior, attributed by Raymond *et al.* (1984) to similar ratios of charge to ionic radius for Pu(IV) ($4.6e$ Å^{-1}) and Fe(III) ($4.2e$ Å^{-1}). The 3+ ions of americium, curium, and the transcurium elements bind very weakly, if at all, to transferrin. Instead, the actinide(III) ions present in biological fluids are weakly associated with various plasma proteins. Uranium, present as the uranyl ion UO_2^{2+}, which has a much diminished tendency to form complex ions as compared to uranium in lower oxidation states, is found in the blood in roughly equal amounts associated with protein and as uranyl carbonate complex ions. U(IV), however, binds strongly to protein and is excreted very slowly.

Such studies as are available indicate that plutonium, americium, and curium are cleared through the kidneys and excreted in the urine as citrate complexes, whereas uranyl ion is excreted as a bicarbonate complex. Although there is by now a considerable body of information on the rate of excretion of plutonium in the urine as influenced by a variety of additives and presumptive therapeutic agents, much remains to be learned about the chemistry of the elimination of the actinide elements through the kidney.

Plutonium, americium, and curium are cleared from the liver through bile, which is the principal source of these elements in feces. The clearance of the actinide elements through the feces, however, constitutes only a very small fraction of the radioactivity transported in mammals. Transport of the actinide elements also appears to take place in lymph fluid. This is presumed to be the mode of transport of plutonium introduced in a wound. Plutonium as a simple ion in the lymphatic system moves with the fluid flow, but plutonium as a colloid or as particulate matter is transported in lymphocytes whose function is to scavenge ingested particulate matter. Plutonium in the fluid phase of the lymph migrates as a transferrin complex (Bulman, 1980). The behavior of plutonium and the transplutonium elements in the lymphatic system may well have an important bearing on the decorporation of ingested actinide elements, but too little information is available to make any definitive declarations on this point.

15.9.3 Uptake of actinide elements in the liver

Actinide elements are rapidly cleared from the body fluids. As is usual in the removal of xenobiotics, the first repository is the liver. According to Bulman (1980), the mechanism by which plutonium, americium, and curium are removed from the blood and trapped in the liver is not well understood. The actinide elements bound by transferrin are transferred in the liver to ferritin, an iron storage protein, but nothing is known about the transfer process. It might be expected that actinide element colloids would be taken up by endocytosis, the process of cellular uptake or internalization by which particles, macromolecules, and fluid droplets are removed from the bloodstream and incorporated

into living cells. However, the literature does not support this view. Endocytosis (or pinocytosis as the process is also known) is not considered to play an important part in the incorporation of actinide elements into liver cells (Taylor, 1972). What seems well established is the critical role of phospholipids in the uptake of the actinide elements by the liver. Actinide(III) and (IV) ions are complexed strongly by phosphates in simple aqueous systems. Th(IV) likewise interacts strongly with phospholipids (Boocock and Popplewell, 1965; Barton, 1968). Such behavior for other actinides ions in the 3+ and 4+ oxidation states would not be unexpected. Phospholipids could thus act as ionophores in the concentration of the actinide elements in the liver. The evidence in support of this hypothesis is mostly indirect. Based on the behavior of Fe(III) and the uptake of plutonium in animals treated so as to have a much higher than normal concentration of phospholipids in the liver, there is reason to suppose that phospholipids cause concentration of plutonium by the liver. Thioacetamide characteristically increases the accumulation of acidic phospholipids in the liver, and this compound is found to cause a 2.5-fold increase in the uptake of Pu(IV) by the liver. The effect of various phospholipids on the liquid–liquid partition of Pu(IV), Am(III), and Cm(III) between water and water-immiscible organic solvents provides additional evidence of the ionophore capabilities of phospholipids. Nevertheless, the exact nature of the receptors involved in actinide uptake (if indeed there are specific receptors) remains to be established.

Several research groups have provided evidence that plutonium, americium, and curium are taken up by lysosomes in the liver. Lysosomes are specialized parts of cells or organelles in which an important part of the cellular metabolism is carried out. The lysosome is surrounded by a single membrane and contains a complex mixture of hydrolytic enzymes; together these enzymes are able to dismantle proteins, nucleic acids, polysaccharides, and lipids to their component parts. The actinide elements not translocated from the liver remain associated with the lysosomes, possibly bound to the iron storage proteins ferritin and hemosiderin. Lysosomes are associated with endocytosis and at least a fraction of the lysosomes are formed by endocytosis. If the main part of the actinide uptake is really associated with liver lysosomes, then it may be premature to exclude endocytosis as a primary event in liver uptake of actinide ions. A substantial association of the cellular actinide content with mitochondria is also probable.

A body of evidence indicates that, within 3 days of administration, considerable amounts of plutonium are bound to lysosomal ferritin, and similar findings have been reported for americium and curium administered as monomeric citrates (Boocock *et al.*, 1976). Americium has been reported to associate with lysosomal ferritin and lipofuscin, a yellow-brown pigment that accumulates in aging cells. Lipofuscin contains phospholipids and is known to bind metal ions.

15.9.4 Uptake of actinides by bone

The ultimate fate of plutonium that is not excreted promptly after administration or ingestion is deposition in the bone and other mineralized tissues. Whether the mineralization is phosphate- or carbonate-based appears to be immaterial. In cartilaginous fish, plutonium is concentrated in the skeleton to a significant extent, and in fish with a bony skeleton, the plutonium concentration in the soft tissues may be less than 1% of that in the skeleton. The uptake of actinide elements from the body fluids by bone is a slow process, because of the strong binding of plutonium by transferrin. Autoradiography of bone shows quite different patterns of deposition for plutonium and americium compared to the deposition of radioactive calcium. Calcium deposition is uniform, whereas actinide deposition is irregular. The lack of uniformity in the distribution of the actinides deposited in bone may be related to variations in the pH of the bone surface, or to different concentrations of citrate ion at different locations on the bone surface.

Glycoprotein has been suggested as the important agent in the fixation of plutonium, but glycoprotein is less important for americium or curium (Mahlum, 1967). Glycoproteins that have a high acidic amino acid content bind plutonium *in vitro*. Calcium ion is required for plutonium fixation, which suggests that calcium nucleation sites are necessary for plutonium uptake. Phospholipids have also been implicated in the process, and a lysosome–inositol triphosphatide complex that plays an important part in a model of bone calcification is known to complex Pu(IV), Am(III), and Cm(III) from citrate solutions or plasma (Bulman and Griffin, 1980). Eventually the plutonium in bone accumulates in immobilized deposits of hemosiderin, which, unlike the iron storage protein ferritin, is insoluble in aqueous media. Hemosiderin contains a large core of iron hydroxides and phosphates, and is the repository of the iron content of heme liberated by the catabolism of hemoglobin. Hemosiderin deposits are located close to the surfaces of the bone in the reticuloendothelial cells of the bone marrow (Durbin, 1975). Once plutonium is incorporated into bone, it is not totally immobilized, but the rate at which it leaves the bone is slow and the process by which it is released is unknown. The half-time for the spontaneous removal of plutonium from bone has been estimated as 65–130 years (Bulman, 1980). Release of plutonium from hemosiderin should not be taken to imply that the mobile plutonium will be excreted through the kidney. More probably, it will be bound to transferrin and recycled into the liver and bone.

15.9.5 Bioremediation of actinides from the environment

Biological treatments of organic, agricultural, and domestic wastes have been in use for centuries and are used very widely. Bioremediation of such wastes is usually ecologically and economically preferable to chemical treatment. These

wastes can be converted to harmless and sometimes beneficial products. Although the biotreatment of metals, especially radioactive metals, cannot decrease the elemental composition of the metal or the specific activity of radionuclides in waste, it can increase the concentration of metallic species to facilitate their removal from the environment or cause the metal to precipitate to prevent its migration. Therefore the bioremediation of actinides requires microbial interactions that changes the actinide's complexation behavior or oxidation state.

Thomas and McCaskie (1996) demonstrated that microorganisms (especially *Pseudomonas*) can hydrolyze the widely used extractant TBP into phosphate and also precipitate U(VI) as a uranyl phosphate, thereby breaking down an organophosphorus pollutant and immobilizing a dissolved actinide. Microbes can serve as reducing agents to convert mobile actinides, e.g. U(VI), Np(V), and Pu(VI) to readily precipitated tetravalent ions. Banaszak *et al.* (1999) presented the redox couples of many important electron transport coenzymes and showed how these coenzymes can catalyze the reduction of actinide ions via sulfate reduction, Fe(III)/Fe(II) reduction, or other electron transfer processes at pH 7. Reductants that can reduce Fe(III) to Fe(II), or are more reducing, can reduce U(VI) to U(IV), Np(V) to Np(IV), and Pu(V) to Pu(IV) or Pu(III). The more reduced actinide ions can be precipitated, a process referred to as biomineralization. Bioremediation research utilizes the disciplines of microbiology, enzymology, actinide chemistry, and environmental science (NABIR, 2003).

15.10 TOXICOLOGY OF THE ACTINIDE ELEMENTS

Although plutonium has been known since 1940 and has been manufactured and handled on a large scale, there have been few cases of injury to workers and the average intakes by most workers have been consistently low. In recent years, information has become available from Russia where there have been instances of high-level exposure to plutonium with a reported increase in lung cancer deaths compared to other workers whose exposure was within occupational limits (see Section 15.10.3). Most of the information about the toxicity of plutonium has been learned from animal experimentation. The application of information acquired in this way to human toxicology can only be estimated by extrapolation (Clarke *et al.*, 1996). The information available about the other actinide elements is much less abundant, and some generalizations must be accepted with reservations.

15.10.1 Ingestion and inhalation

Any of the actinide elements in the environment can enter the human body by ingestion, by inhalation of particulate matter, by passage through the skin, or by accidents accompanied by forcible introduction of the actinide into the body. Absorption through the intestinal tract appears to be one of the least important

routes for the incorporation of plutonium and the transplutonium elements. Plutonium has not been found to concentrate in the food chain (see Section 15.8.4); however, solubilizing ligands have been found to increase the uptake of plutonium and americium into plants, presenting a possible means of their introduction into the food chain (Francis, 1973; Bulman, 1978; Vyas and Mistry, 1983). Plutonium itself is not very bioavailable as it does not readily pass through the intestinal wall when ingested. Unbroken skin presents an essentially impermeable barrier to the passage of actinide ions. Likewise, the fate of plutonium deposited in an open wound is largely dependent on the chemical state of the plutonium. If the plutonium is in a soluble form such as a citrate complex, it will rapidly reach the circulatory system and form a transferrin complex. If it is deposited in a wound as an insoluble compound, translocation is slower (Clarke *et al.*, 1996). The toxic effects and ability of Pu (IV) to form strong complexes with bone and tissue is similar to the behavior of Fe(III). The currently available treatments for chelation therapy to extract actinides that have been introduced into the body are most effective if administered within hours of exposure. After this point, the actinides can be incorporated into bone and tissues, rendering them fixed (Durbin *et al.*, 1998).

By far the most likely (and serious) mode of entry for plutonium into the body is inhalation of insoluble particulate matter into the lungs. Factors that influence the translocation of plutonium oxides from the lung to other parts of the body include particle size, chemical composition, lung burden, calcination temperature, and isotopic composition (Lataillade *et al.*, 1995). Extremely small particles (1 nm in diameter) of PuO_2 are quickly absorbed from the lung and enter the circulation as low-molecular-weight complexes. Large particles (0.025–0.22 μm) clear very slowly. AmO_2 made by calcination of americium oxalate at 650°C was observed to be removed so rapidly from the lung as to raise questions whether the compound should continue to be considered insoluble. It is possible that the americium dioxide preparation was actually americium hydroxide polymer, and it may be that small deviations from stoichiometry could have a considerable effect on the rate of dissolution and removal from the lung. Variations in stoichiometry are expected to be much more prominent in plutonium than in americium, which may be responsible for the surprising differences in the behavior of the oxides of these actinide elements. Curium dioxide behaves quite similarly to americium dioxide, but there is at least one important and puzzling difference between the two. While americium dioxide does not bind to protein, curium dioxide does (Bulman, 1980). In the absence of information about the stoichiometry of the actinide oxide, or the preparations used in the experiments, it is difficult to ascertain whether it is particle size or deviations from stoichiometry that are responsible for the biological behavior of the actinide oxides. Many questions about the behavior of actinide particulates in the lung remain, and the answers could have implications for other lung pathologies. It has been found that $^{238}PuO_2$ clears the lung much faster than does $^{239}PuO_2$ (NCRP, 2001). The magnitude of the difference is clearly beyond

the range of ordinary isotope effects, and must be attributed to the increased radiation damage incurred by the oxide particles from the more energetic alpha particles emitted by the shorter-lived radionuclide ^{238}Pu (Bulman, 1980).

15.10.2 Acute toxicity of plutonium

There is general agreement that the chemical toxicity of plutonium is inconsequential compared to the radiotoxicity, or the effects caused by its alpha radiation (Bulman, 1980; Nenot and Metivier, 1984; Clarke *et al*., 1996; Voelz, 2000; Guilmette, 2001). By far, the greatest risk from plutonium is the long-term possibility to develop cancer. One way to compare risks between two materials is by a comparison of relative limits on concentration in air of the two substances. These limits are extrapolated from experimental observations with animals. The limit in air for plutonium is referred to as the derived air concentration (C_{DAC}). This is the concentration in air which, if breathed alone for one work year, would irradiate 'reference man' to the limits for occupational exposure, and is 0.006 μCi cm^{-3} for ^{239}Pu (4×10^{-4} μg m^{-3}). Comparing plutonium-239 to most materials handled on the small industrial scale shows plutonium-239 to be a very toxic material. Its toxicity per unit mass is similar to that of long-lived fission products such as strontium-90 and cesium-137 but less than that of short-lived fission products such as iodine-121 (Clarke *et al*., 1996).

All data on the chemical toxicity of plutonium are derived from animal experiments. On the assumption that ions of similar size and charge will have similar toxicological properties, which is reasonable in this situation, to produce a similar change in an adult human liver would require the intravenous injection of about 200 mg of plutonium (Bulman, 1980). Further evidence supports this conclusion. The amount of material that causes death in 50% of animals after n days is known as the $LD_{50}(n)$ value. The $LD_{50}(30)$ value obtained from studies on dogs after intravenous injection of plutonium is about 0.32 mg per kg of tissue. When extrapolated to a human of 70 kg, the $LD_{50}(30)$ value is about 22 mg (Voelz, 2000). Neptunium-237 injected into rats intravenously at 3 mg kg^{-1} induces short-term subacute changes in the liver, but is nowhere near as toxic as strychnine. There is substantial evidence that the chemical toxicity of plutonium is comparable to that of neptunium, and that plutonium is not an extraordinarily virulent chemical poison. The toxic manifestations of plutonium are due to long-term effects of radiation damage from its radioactive decay.

The acute toxicity of uranium in the form of the uranyl ion varies considerably with the experimental animal; the acute dose in the rabbit and guinea-pig is in the range 0.1–0.3 mg kg^{-1}, and in mice it may be as much as 20–25 mg kg^{-1} (Bulman, 1980). Differences in toxicity in different species have been attributed to differences in diet that result in the excretion of urine of widely differing pH. Herbivores excrete very acidic urine, which interferes with the formation of carbonate and citrate complexes of uranyl ion. These are the forms in which

uranium is cleared through the kidneys. Under conditions that lower the carbonate and citrate concentrations, uranium clears the organism more slowly, and a given dose of uranium in a herbivore appears to have a higher toxicity than in an organism that can eliminate uranium more rapidly. Acute toxic symptoms produced in yeast by uranyl salts appear to be a result of the suppression of glucose metabolism by interaction of the uranyl ion with the cell surface. Reagents such as phosphate that complex uranyl ion strongly reverse the inhibition of respiratory activity (Bulman, 1980). The small amount of data gathered from human studies indicates that the renal injury is consistent to what is seen in animal models (Diamond, 1989).

15.10.3 Long-term effects of ingested plutonium

The maximum allowed dose of ^{239}Pu in humans was referred to as maximum permissible body burden and was set at 0.65 μg for radiation workers from 1953 to 1977. The International Commission on Radiation Protection published a series of reports between 1977 and 1988 that effectively decreased the lifetime body burden of ^{239}Pu to 0.5 μg (0.05 Sv) for U.S. radiation workers; these values are approximate because dose calculations must be made for internal deposition of each isotope to specific organs (Voelz, 2000). A population of 26 white male workers at Los Alamos National Laboratory who acquired plutonium body burdens between 260 and 8510 Bq (0.1–3.7 μg if pure ^{239}Pu) during World War II was followed for 50 years. As of 1994, seven persons were dead compared with the expected 16 deaths based on mortality rates for white males in the U.S. in the general population and age group. Comparing the mortality rate of the exposed workers with that of 876 unexposed Los Alamos workers of the same period, the mortality rate of the exposed workers is not elevated. As of 1995, the 16 living white males had diseases and physical changes expected of a male population with a median age of 72 years. Out of 26 white male workers, eight had been diagnosed as having one or more cancers, within the expected range for a similar, unexposed population. The cause of death in three of the seven deceased men was cancer of the prostate, lung, and bone; however mortality from all cancers was not statistically elevated (Voelz *et al*., 1997).

Long-term chromosomal analyses of British plutonium workers who had more than 20% of the maximum permissible body burden of ^{239}Pu (doses greater than 0.25 Sv) showed no evidence for induction of persistent transmissible genomic instability (Whitehouse and Tawn, 2001). However, some Russian workers have been exposed to much higher levels of plutonium at the Mayak nuclear facility (among 2283 plutonium workers from 1948 to 1958, the mean accumulated dose was 8 Sv for males and 14 Sv for females). An increased risk of lung, liver, and bone cancers was associated with these higher exposures (Tokarskaya *et al*., 1997; Koshurnikova *et al*., 1998; Gilbert *et al*., 2000; Voelz, 2000; Grogan *et al*., 2001). In many cases, the ingrowth of ^{241}Am from decay of ^{241}Pu that is present in most plutonium samples is actually the largest

contributor to the dose from inhaled or ingested plutonium (Hisamatsu and Takizawa, 2003).

Most of the available information on the effects of plutonium in mammals has come from animal experiments. Low doses of radiation in the lungs of rats produce three types of cancer: sarcomas (10%), bronchoalveolar cancers (40%), and bronchogenic cancers (50%). The lowest dose at which a significant increase in lung cancers occurs is 37 Bq g^{-1} of lung tissue for inhaled insoluble plutonium compounds. The mode of distribution of plutonium in the lung has a large effect, and whether the plutonium was acquired in a single exposure or by multiple exposures is also a factor that is important in subsequent pathology. In the dose range 0.06–37 kBq kg^{-1} of bone, an osteosarcoma incidence from 31% to 100% has been observed in dogs. Organisms experiencing rapid bone growth are more sensitive to osteosarcomas from plutonium than are adults. Liver appears to be less sensitive to alpha radiation than either lung or bone. The effects of ingested plutonium on the blood are largely due to irradiation of the hematopoietic tissues where blood cells are formed. No leukemia has ever been detected in dogs. In humans exposed to plutonium, stable chromosomal aberrations in the blood have been seen. Finally, no hereditary diseases have been observed in the progeny of animals whose bodies contained plutonium (Nenot and Metivier, 1984; ICRP, 1986).

15.10.4 Removal of actinide elements from the body

Once plutonium has gained access to the bloodstream, there is no normal physiological process that will eliminate it rapidly from the body. Foreign chemicals or organic poisons that are introduced into the body are converted in the liver by oxidation and conjugation into compounds that can be excreted. Heavy metals are either deposited in insoluble form or else they become complexed to body constituents, and no such metabolic elimination pathway exists. Plutonium retention is not absolute, but the excretion rate is so slow that in a normal lifespan only a fraction of the deposited actinide will be removed from the body. Early attempts to increase the rate of plutonium excretion were based on competitive displacement by innocuous metal ions of a size and charge that would enable them to compete successfully with Pu(IV) for binding sites or crystal lattice sites. Zirconyl(IV) citrate was found to accelerate considerably the excretion of injected plutonium, but only if the zirconium was administered within a very short time after the plutonium. Zirconyl citrate appears to be reasonably effective in displacing Pu(IV) from the bloodstream but not from body tissues. Other hydrous metal oxides such as those of thorium or aluminum minimize deposition of plutonium in bone, but increase the amount of plutonium deposited in the liver. Therapeutic approaches along these lines have therefore fallen into disuse.

The only practical strategy for increasing the excretion of plutonium is based on the use of chelating agents to form water-soluble complexes of plutonium

(ICRP, 1990). Citrate and ascorbate are effective complexing agents to a degree, but are metabolized too rapidly to be of practical utility. Useful therapeutic agents have been sought among the numerous chelating agents that have been synthesized for ion sequestration purposes, particularly derivatives and analogs of EDTA. EDTA itself is quite effective in accelerating the excretion of plutonium, provided it is administered within a short time after plutonium ingestion, but it is much less effective when the interval between ingestion and therapy is of the order of weeks (Schubert, 1955; Durbin, 1973; Vaughn *et al*., 1973). Of the considerable number of derivatives and analogs of EDTA that have received attention, the most successful is diethylenetriaminepentaacetic acid (DTPA). This compound has one carboxyl group more available for chelation than EDTA, making it an octadentate ligand system capable of fully complexing Pu(IV) in its preferred coordination geometry, thus significantly enhancing the stability of the complex. DTPA administered promptly in a single dose after plutonium ingestion causes the excretion of about 90% of the plutonium in the following 6 days as compared to less than 5% excretion in controls; when pigs were used as the experimental animal (Taylor, 1978). To achieve such good results, DTPA must be administered within 30 min after plutonium injection in beagles. A delay in the administration of DTPA for as little as 2 h results in only 15% of the injected plutonium being excreted during the first day. Delayed treatment with multiple doses of DTPA is effective in removing moderate amounts of plutonium from the pig. In these experiments, it was observed that the principal source of the excreted plutonium was the soft tissues, and that removal of plutonium from the bone did not proceed to the point where the number of bone tumors formed was significantly reduced (James and Taylor, 1971). DTPA is also limited in that it must be administered as the calcium or zinc salt to prevent toxicity from the depletion of these essential divalent metals. Additional details on the use of DTPA can be found elsewhere (Rosenthal and Lindenbaum, 1967; Smith, 1972; Durbin, 1973; Vaughn *et al*., 1973; Bruenger *et al*., 1991; Durbin *et al*., 1998). Many other chelating agents related in structure to EDTA and DTPA (for example, citrate and nitrilotriacetic acid, NTA) have been studied, but none of these are significantly better performers. Increasing the number of carboxyl groups does not improve decorporation, and the replacement of oxygen functions by sulfur or phosphorus analogs degrades their performance.

The *in vivo* situation of chelating agents is much more complicated than sequestration of alkaline earth ions in a detergent solution, or in laboratory systems arranged for the measurements of complexation constants. It has been recognized for some time (Schubert, 1955) that, because the calcium-ion concentration in serum is much greater than that of other metal ions, unless a chelating agent has a much lower affinity for calcium ion than for another metal ion, the chelating agent will exist predominantly as the calcium complex in the circulatory system. The apparent efficacy of a chelating agent is thus increased by a low affinity for calcium ion as well as by an enhanced affinity

for plutonium. A foreign metal ion will be partitioned between natural chelators engaged in the transport or metabolic activities of metal ions and any chelating agents that may be introduced for therapeutic purposes. The naturally occurring iron sequestering agent desferrioxamine (DFO) is a very much weaker complexing agent for calcium ion than is DTPA, and even though it does not bind much more strongly to Fe(III) than does DTPA, it is much more effective in removing iron from the body, presumably because of its lower affinity for calcium ion. Whereas DFO is more efficient in plutonium removal than DTPA, provided it is administered within an hour after injection of plutonium, its efficacy decreases more rapidly than that of DTPA as the time interval between plutonium incorporation and therapy increases. Combined use of DTPA and DFO appears to remove the greatest amount of plutonium. The presumption is that plutonium ion liberated from the Pu(IV)–DFO complex is recomplexed and excreted as the DTPA complex before irreversible deposition of the plutonium can occur. Once plutonium has been deposited in insoluble form or incorporated into bone, no known therapeutic approach is efficacious. Inhalation of insoluble plutonium can only be countered by repeated pulmonary lavage with isotonic saline solution (Nenot and Metivier, 1984).

While conventional chelating agents have received by far the most attention in search for effective decorporation of plutonium, other work has aimed at the development of new more selective ligand systems. Raymond *et al.* (1982) have undertaken a search for new chelating agents that would bind strongly to and be specific for actinide ions. They have adopted a biomimetic approach in which compounds are modeled after the powerful and highly specific siderophores, natural iron sequestering agents used by microorganisms to acquire Fe(III) from the environment. Ligands have been generated which incorporate hydroxamic acid, hydroxypyridonate (HOPO), catecholamide (CAM), and terephthalamide (TAM) chelating subunits analogous to those found in the siderophores into a variety of backbones (Gorden *et al.*, 2003). The rationale behind their design method was that by introducing several coordinating functional groups, enough binding sites on the ligand are provided to occupy all of the coordination sites on the metal ion. Enterobactin, a hexadentate siderophore containing three CAM subunits, has the largest formation constant and complexation ability for Fe(III). An octadentate system should be more selective for the larger Pu(IV) ion. The metal ion is then encapsulated, so to speak, by the chelating agent, preventing deposition, increasing solubility and hence, excretion. Siderophore-like systems have also been explored by other researchers to see if they have the potential to introduce Pu or the actinides into the food chain (Ruggiero *et al.*, 2002).

The Raymond–Durbin collaboration has developed a large number of new ligands. Many of these have been tested in mice as actinide decorporation agents. Of these, the best chelating systems for Pu(IV) were, as expected, octadentate ligand systems, e.g. the Pu(IV)–HOPO molecule in Fig. 15.8 , but many

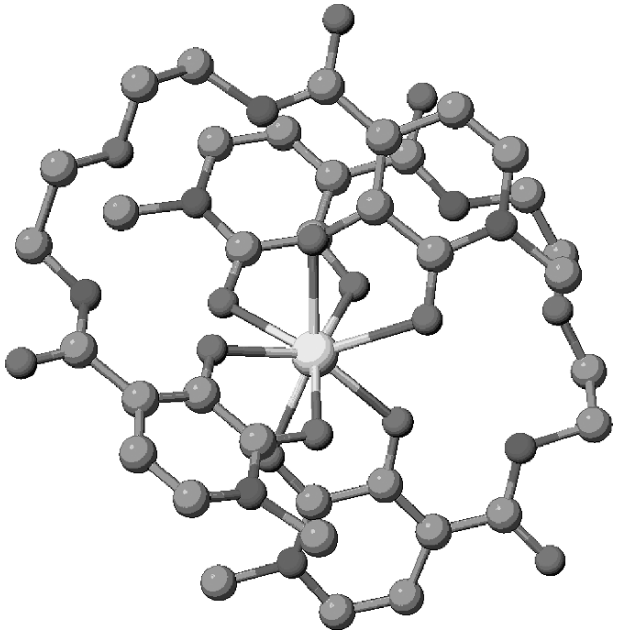

Fig. 15.8 *Molecular structure of Pu(IV)-(5-LIO-Me-3,2-HOPO)$_2$ generated from crystallographic data showing octadentate coordination about the Pu(IV) ion. The geometric arrangement of the ligands about the Pu ion is best described as a distorted bicapped trigonal prism* (*Gorden* et al., 2005).

questions remain about the importance of denticity, binding group acidity, backbone flexibility, and solubility in the development of a highly effective, orally bioavailable chelator of low toxicity. Octadentate HOPO systems have been shown to be as much as 40% more effective in mice than an equimolar amount of $CaNa_3$–DTPA, the current clinical drug of choice, as well as to be orally active. Other systems have also been demonstrated to be effective for the chelation of Am(III) as well as U(VI), Th(IV), and Np(IV/V), for which DTPA is not effective (Gorden *et al*., 2003). Preliminary *in vitro* studies suggest that these complexes are also capable of redissolving Pu(IV) or Am(III) after it has deposited in bone mineral (Guilmette *et al*., 2003).

15.11 PRACTICAL APPLICATIONS OF THE ACTINIDE ELEMENTS

The principal application of the actinide elements is in the production of nuclear energy. Although this is by far the most important use for any of the actinide elements, a surprising number of other uses have been found. These include the

use of short-lived (tens of years) actinide isotopes as portable power supplies for satellites; in ionization smoke detectors; in the therapy of cancer; in neutron radiography; in mineral prospecting and oil-well logging; as neutron sources in nuclear reactor start-up; and as neutron sources in a variety of analytical procedures, the most important of which are neutron activation analysis and heavy-ion desorption mass spectroscopy.

15.11.1 Nuclear power

The practical importance of the actinide elements derives from the discovery of nuclear fission by Hahn and Strassmann in 1939. Atoms of one naturally occurring isotope (0.72% abundance) of uranium, ^{235}U, split into two approximately equal fragments by the capture of a neutron, an event that releases an enormous amount of energy. Approximately 2.5 neutrons are released per fission event, making it possible to initiate an explosive chain reaction in the pure fissile isotope; alternatively, controlled fission in a nuclear reactor can be used to provide heat to generate electricity. The plutonium isotope ^{239}Pu is produced in chain-reacting nuclear reactors by capture of excess neutrons in nonfissionable ^{238}U. Plutonium-239 itself is also fissionable with slow (essentially zero-energy) neutrons. The naturally occurring thorium isotope ^{232}Th, which does not undergo fission, can be converted by neutron capture to ^{233}U, which is a fissionable nuclide. The complete utilization of nonfissionable ^{238}U (through conversion to fissionable ^{239}Pu) and nonfissionable ^{232}Th (through conversion to fissionable ^{233}U) can be accomplished by breeder reactors. The fissile isotopes ^{233}U, ^{235}U, and ^{239}Pu constitute an enormous, effectively inexhaustible, energy resource. The future of nuclear power, however, is clouded by technological and social problems. The technical problems relate to the safety of nuclear reactors, to the ability to prevent access of radioactive substances to the environment, and to the prevention of the diversion of plutonium for the clandestine manufacture of nuclear weapons. We adhere to the school of thought that believes the technological problems of safe nuclear energy and environmental contamination are soluble problems. Indeed, many of these problems have already been solved, and those that remain do not require the discovery of new or unheard of scientific principles for their solution. The social, economic, and political problems are another matter. The fully justified fear of nuclear war is projected onto nuclear power, as if nuclear power and nuclear war were synonymous, and as if the fear of nuclear war could be exorcised by abolishing nuclear power. Prevention of nuclear war and the proliferation of nuclear weapons can only be accomplished by international statesmanship, not by a refusal to make use of the limitless energy that can be supplied by fission.

Some countries (France and Japan are notable examples) have embraced nuclear power, with the probable result that they will have a future economic advantage in world trade from the cheaper electric power that nuclear energy can provide. Nuclear power promises a more prosperous future, but whether the

promise becomes a reality in many additional countries will depend on the solution of the social, economic, and international problems that enmesh the issue of nuclear energy.

15.11.2 Portable power sources

Radioactive decay is accompanied by the evolution of heat, and radioactive nuclides can therefore be used as portable heat sources. One gram of ^{238}Pu produces about 0.56 W of thermal power, primarily from its 87.7 year alpha decay, and this isotope of plutonium has found use in space vehicles to drive thermoelectric power units. Several satellites with ^{238}Pu generators that produce 25 W have been deployed in space. Several of the Apollo spacecrafts carried a ^{238}Pu generator that produced 73 W of electrical power, fueled with 2.6 kg of ^{238}Pu in the form of PuO_2, to run the scientific experiments of some Apollo lunar expeditions. The satellite that sent the amazing photographs of Jupiter and the outer planets back to Earth used a 50 W ^{238}Pu power supply for this purpose. Space Nuclear Auxiliary Power (SNAP) thermoelectric power units containing 54 kg of plutonium-238 provide the nuclear-powered energy in the Cassini–Huygens 1966–2005 mission to Saturn and its moon Titan (see Chapter 7, section 7.2, of this book). This space probe is expected to accompany Saturn for 4 years. Much smaller ^{238}Pu generators were implanted as human cardiac pacemakers beginning in 1970; although chemical battery and electronics technologies have rendered nuclear pacemakers obsolete, several nuclear pacemakers have been in operation for over 30 years (see Chapter 7, section 7.2, of this book and section 15.11.4).

15.11.3 Neutron sources

The radionuclide americium-241 emits alpha particles, which produce neutrons by an (α,n) nuclear reaction with light elements. A mixture of americium-241 with beryllium produces 1.0×10^7 neutrons per second per gram of ^{241}Am. A large number of ^{241}Am–Be sources are in daily use worldwide in oil-well logging operations to measure the amount of oil produced in a given period of time. These sources have also been used to measure the water content of soils, and to monitor process streams in industrial plants. ^{241}Am itself has extensive uses in dissipating static electrical charges and in smoke detectors, where it functions to ionize air.

The radioactive decay of the nuclide californium-252 is largely by alpha emission, but part of the decay is by spontaneous fission. ^{252}Cf thus provides an intense neutron source: 1 g emits 2.4×10^{12} neutrons per second. ^{252}Cf is the only commercially available nuclide that can be fabricated into small neutron sources that produce an intense neutron flux over a useful period of time. The physical size of these sources is considerably smaller than alpha neutron sources, and less space must be provided in the ^{252}Cf sources to accommodate gaseous products. Since ^{252}Cf neutron sources became available in 1975, a

surprising variety of industrial and scientific uses have been developed for them (Martin *et al.*, 2000).

One of the largest uses of these sources is in reactor start-up operations. Before achieving criticality, a neutron source is inserted into the reactor to allow instrument calibration and observation of the approach to criticality. ^{252}Cf sources are used in reactor start-up all over the world because of the high neutron flux that can be obtained and their small size (<1 cm^3), which is very advantageous in the start-up procedure. ^{252}Cf neutron sources are used in the nuclear power industry as fuel-rod scanners, a procedure in which the amount and uniformity of the fissile material in the fuel rod is measured. This is the second largest industrial application of californium neutron sources.

Applications to neutron activation analysis constitute another important use of ^{252}Cf neutron sources. Neutron capture in many elements forms radioactive species that then decay with highly characteristic γ-ray emissions. This analytical procedure is very sensitive and specific, and is widely used for the analysis of trace elements. Neutron activation finds use in uranium borehole logging to make accurate determinations of the uranium concentrations in boreholes, and as little as 100 ppm of U_3O_8 can be detected by this procedure. Other industrial uses for ^{252}Cf sources are in the continuous monitoring of the sulfur and ash content of coal on a moving conveyor belt at the rate of 50 metric tons h^{-1}. Batch analysis of the vanadium content of crude oil is still another application of neutron activation analysis.

15.11.4 Medical and other applications

Americium-241 has found use in the diagnosis of thyroid disorders, because the 59.6 keV γ-rays allow determination of iodine in the thyroid by X-ray fluorescence (Reiners *et al.*, 1998). Americium-241 is used worldwide in ionization smoke detectors because it emits alpha particles, has a relatively long half-life, and decays to ^{237}Np, which has a much longer half-life. Household smoke detectors contain a small quantity (<35 kBq, approximately 200 μg) of ^{241}Am as AmO_2. Ionization smoke detectors in public or commercial buildings contain up to 2 MBq of ^{241}Am. The nearly monoenergetic alpha particles and 59.6 keV γ-rays of ^{241}Am have made it useful in thickness gauges and radiography (see Chapter 8, section 8.3, of this book).

Miniature power generators using ^{238}Pu have been developed for use in heart pacemakers. The pacemaker itself is a device planted in the chest and connected to the heart muscles; a programmed electrical pulse is periodically administered, which assures regularity in the heartbeat. A typical nuclear-powered heart pacemaker contains about 160 mg of ^{238}Pu encased in a tantalum–iridium–platinum alloy. Several thousand such devices were in use worldwide by 1980 and some remain in use in 2005, having been functioning for over 30 years (see Section 7.2). Heart pacemakers that operate from chemical batteries have a limited life, and must be replaced periodically by a surgical procedure, but they

have replaced nuclear pacemakers since about 1980 because of their efficiency and safety (Parsonnet, 2005).

Actinium-225 is used in alpha-particle generators for tumor radiotherapy (see Chapter 2, section 2.9.3, of this book). Californium-252 attracted early attention as a possible therapeutic agent in cancer treatment. The general impression formed from early work was that neutron therapy was inferior to X-ray therapy. More recent studies, however, indicate that neutron irradiation may have advantages over X-rays or γ-rays in certain situations. In the period 1976–82, several hundred cancer cases were treated by neutron irradiation supplied by ^{252}Cf (Murayama, 1991). Although not a cure, ^{252}Cf neutron therapy appears to have promise in the treatment of pelvic cancer and in brachytherapy (short exposure therapy). Sources containing ≤ 30 μg of ^{252}Cf as a Cf_2O_3 wire in a Pd matrix have been prepared by the Radiochemical Engineering Development Center of Oak Ridge National Laboratory (Martin *et al.*, 1997). Neutron sources have also been prepared by the Research Institute of Atomic Reactors (RIAR), Dimitrovgrad, Russia (Karelin *et al.*, 1997). Neutrons appear to have particular utility in tumors whose oxygen supply is impaired, and which, as a consequence, are relatively insensitive to X-rays or γ-rays. While the applications of neutrons in the treatment of cancer are still experimental, there is a possibility that further clinical studies may well find a use for the neutron-emitting californium isotopes in therapy.

ABBREVIATIONS

AES	atomic emission spectroscopy
Bq	SI derived unit of radioactivity, 1 disintegration per second
CAM	catecholamide
Ci	Curie $= 3.7 \times 10^{10}$ disintegrations per second $= 3.7 \times 10^{10}$ Bq.
Cp	cyclopentadienyl, C_5H_5
CEA	Commission de l'Energie Atomique
COT	cyclooctatetrene, C_8H_8
DFO	desferrioxamine
DIAMEX	DIAMide EXtraction process used to separate the lanthanides and the "minor actinides" Np, Am, Cm from fission products
DTPA	diethylenetriaminepentaacetic acid
EDTA	ethylenediaminetetraacetic acid
HEU	highly enriched uranium (20–90% ^{235}U)
HFIR	High Flux Isotope Reactor
HOPO	hydroxypyridonate
ICP-MS	inductively-coupled plasma mass spectroscopy
IUPAC	International Union of Pure and Applied Chemistry
LEU	low enriched uranium (0.7–20% ^{235}U)

LLNL	Lawrence Livermore National Laboratory
MOX	Mixed oxide fuel (usually UO_2-PuO_2 solid solution)
MWd	Megawatt-days
NMR	nuclear magnetic resonance
NTA	nitrilotriacetic acid
PBq	petabequerel (1×10^{15} Bq)
PUREX	Plutonium uranium reduction extraction
PWR	pressurized water reactor
RIAR	Research Institute of Atomic Reactors
REDC	Radioisotope Engineering Development Center
SNAP	Space Nuclear Auxiliary Power
Sv	Sievert (derived SI unit of equivalent dose used for radiation protection purposes); 1 Sv = 1 J kg^{-1} = 100 rem
TAM	terephthalamide
TBP	tri(*n*-butyl)phosphate
TBq	terabecquerel (1×10^{12} Bq)
THF	tetrahydrofuran

ACKNOWLEDGMENT

Part of the work reported herein was performed under the auspices of the Office of Basic Energy Sciences, U.S. Department of Energy under Contract W-31–109-ENG-38.

CHAPTER SIXTEEN

SPECTRA AND ELECTRONIC STRUCTURES OF FREE ACTINIDE ATOMS AND IONS

Earl F. Worden, Jean Blaise, Mark Fred*,
Norbert Trautmann, and Jean-François Wyart

Dedicated to Mark Fred (1912–1994), John G. Conway (1922–1995), and Frank Tomkins (1915–1999).

* Deceased.

16.1 INTRODUCTION

This chapter reviews the spectra and the deduced electronic properties of isolated actinide atoms and ions observed in the vapor phase at low density. The free atoms or ions have all or most of the valence electrons present, and the observed spectra can be assigned to transitions due essentially to changes in the quantum numbers of the valence electrons. This is in contrast to the spectra of actinides in crystals or in solution (dealt with in depth in Chapter 18), where the observed spectra are largely due to transitions within the 5f shell. In crystals, the actinide ions are exposed to the electric field of the surrounding ions, which produces a Stark effect on the levels. The magnitude of the effect is relatively small because the 5f electrons are shielded from the crystal field by the 6s and 6p electrons. The result is a small perturbation in which each 5f level is split into a number of close components. In free atoms, the valence electrons interact strongly with the 5f electrons and also with each other. Hence each 5f level gives rise to many daughter levels that are more widely split than the parent separations and have large angular momentum contributions from the parent. The result in this case is a great number of levels whose structure is not simply related to the structure of the 5f levels or to the structure of the valence-electron levels by themselves. It is evident that the 5f level structure can be obtained more directly from crystal spectra but the properties of the valence electrons (in particular, implications for the chemical properties) must be deduced from the free-atom spectra.

Historically, the correlation between actinide chemistry and spectroscopy was anticipated before much experimental information was available in either field. Therefore interest in actinide spectroscopy was as an aid to predicting actinide chemistry, in the expectation that smaller quantities of these elements would be required. In practice, the chemistry developed first as soon as sufficient amounts of material were produced, while the spectroscopy encountered difficulties because the complexities were underestimated. The difficulty was not so much as the enormous total number of levels, which could be counted readily, but the extent to which the levels interacted so as to preclude simplification.

The interaction implies that each level is a mixture of various pure states labeled by quantum numbers for the 5f shell and also by quantum numbers for each valence-electron shell. Different levels have different mixtures, and the composition of each level cannot be deduced by inspection because of the large number of quantum numbers, with a different energy dependence for each. Thus the compositions must be derived by comparison with theoretical calculations. The calculations are difficult to perform even with a large computer, and because of the mixing, the results do not give a simple picture of the way in which the energy of an actinide atom depends on the valence-electron configuration. This complexity is inherent in atoms with 5f electrons, and the chemistry is correspondingly more difficult to predict. Nevertheless, it is clearly desirable to attempt it.

We begin with a discussion of some experimental techniques, then present an introduction to the theory, and finally relate the electronic structure obtained from the spectroscopic data to the chemistry of the actinide elements. Laser spectroscopic techniques are discussed, which have improved the quality of isotope shift (IS) and hyperfine structure (hfs) data. These methods have increased the accuracy of the ionization potentials (IPs) of the actinide elements where sufficient (and in some cases only very small) quantities of atoms can be produced. A few new energy levels have been found for Fm and Es by the resonance ionization mass spectroscopy (RIMS) technique, but no new information has been obtained to date on the electronic structure of the heavier actinides (beyond Fm). A discussion of the spectroscopy of deformed isomers of Am is included.

16.2 EXPERIMENTAL SPECTROSCOPY OF FREE ACTINIDE ATOMS AND IONS

The main interest in actinide spectra, besides finding lines useful for chemical analyses of the elements, is in energy level analysis. This methodology determines the relative energies of various electron configurations for each actinide and the way the interactions between different kinds of electrons vary along the actinide series. The first step in this process is to obtain the complete (as possible) spectra for each element. For conventional actinide spectroscopy, the limit is Es, the element with atomic number 99. Thus four elements, Fm to Lw, have little experimental spectroscopic results. Limited beam and laser spectroscopy, plus extrapolation and theory, are all that is available for determining the optical spectra and electronic structure of these four elements.

In each actinide spectrum, tens of thousands of spectral lines are observed and many more are possible but weak. No order is apparent. The determination of the energy levels from the lines is based chiefly on the search for recurrent differences (or sums) between the energies (wavenumbers) of various pairs of lines, indicating pairs of transitions to a given pair of levels from levels of opposite parity. The level structure can be derived in principle by establishing a number of such level pairs. For actinide spectra, a purely numerical approach is not possible for the following reasons:

(1) The large line density usually yields many more fortuitous recurrences than real ones, but improvement in the accuracy of the line list can significantly reduce the number.
(2) The real recurrences due to transitions involving a given pair of levels are limited by selection rules.
(3) The strong lines can often be paired with weak lines that may be too weak to be observed and thus be missed.

Hence one needs to observe the energies of as many lines as possible, measured with the highest accuracy and resolution, as contrasted with spectrochemical analysis, where only a relatively small number of strong lines are required. Corroborative information, such as Zeeman data, ISs, hfs, vapor absorption or self-absorption in an electrodeless discharge lamp (EDL), spectral assignment, is essential.

Experimental techniques have been adequate for the production of neutral (atomic, An I where An represents any actinide element) and first-ion spectra (singly ionized, An II), in spite of the limitations of available sample size and the associated radioactivity for all the actinides up to and including Es. The usual light source is an EDL made from quartz tubing with about 2–3 mm i.d., 5–6 mm o.d., and about 22–25 mm long, into which the sample ($\sim$0.1 mg as anhydrous An iodides) is sublimed. The lamp is then sealed off under vacuum, as described in Tomkins and Fred (1957) and in Worden *et al.* (1963). A microwave discharge supplies the heat to volatilize the sample, and the electron energy to dissociate the molecules and excite the atomic spectrum. This source is sensitive, confines the radioactivity, gives sharp lines, and can be run in a magnetic field. It can also be used to differentiate lines of the neutral spectrum from those of the first ion by observation of the spectrum at high and low microwave powers (or high and low atom density). At very high power or high atom density, self-reversal of lines from the low-lying levels of the neutral atoms, and in some cases the first ion of the element, were observed. The lamps allow complete recovery of the element after use. This is a very important consideration for rare isotopes where the cost of production is high and only limited quantities are available. Unfortunately a comparable source for the higher ions (much higher electron temperature required) is not yet available. A few lines of the third spectrum of some actinides have been observed in special hollow cathode lamps but not from EDLs.

The design and construction of EDLs of Es, when amounts of $\sim$100 mg or more became available, had to be changed because of the poor yields ($<$15%) obtained with no carrier element present (Worden *et al.*, 1968, 1970 and especially Worden *et al.*, 1974). These changes are described in detail in Appendix 16.1.

Initial analyses of all actinide spectra are based on measurements of photographic plates taken on the Argonne National Laboratory (ANL) 9.15 m Paschen-Runge and 3.4 m Ebert spectrographs with high-angle gratings (now decommissioned). These instruments covered a large wavelength range at high resolving power with a single exposure (providing wavenumber (energy) accuracy of 0.02 cm^{-1} or higher (Tomkins and Fred, 1963; Worden and Conway, 1970; Worden *et al.*, 1970, 1974, 1987). Because photographic plates were used, several exposures were required. The plates were measured using semiautomatic comparators with 1 μm accuracy (Tomkins and Fred, 1951). The thorium spectrum was used in order to provide standards to establish the unknown

wavelengths. In the case of the highly radioactive elements, it was essential to remove the lines of the decay products as well as other impurity lines from the line list before beginning the analyses of the spectra. The near-infrared and infrared spectra of the actinide elements were observed with Fourier transform spectrometers (FTSs) (see for example Conway *et al*., 1976). The assembly of an accurate line list and other supporting data suitable for level analysis required 3–6 years. The hfs and IS can be obtained with FTSs, but calibration of the IS data is needed when using separated isotopes in EDLs where there are no internal standard lines for production of a calibrated energy scale (Pulliam *et al*., 2003).

An FTS with comparable resolving power but better energy accuracy (0.005 cm^{-1} or higher) than the ANL spectrograph has been operational at the Laboratoire Aimé Cotton (LAC), Orsay, France, since 1970. Built initially for the infrared region, it covers the region 4000–400 nm (Connes *et al.*, 1970). A second FTS covered the visible and ultraviolet regions down to 345 nm. By 1976, another high-resolution FTS had been built at the National Solar Observatory, Kitt Peak, Arizona (Brault, 1976). All the actinide spectra from Th to Cf have now been recorded with one or more of these instruments. Observation of the infrared spectrum with high resolution and accuracy is especially important for the term analyses of the lanthanide and actinide spectra because of the large number of low-lying energy levels that give transitions in this spectral region. The spectra of a number of actinides have been recorded over the full range ($\sim$1800 to 50 000 cm^{-1}, or because of quartz lamp limitations, 3500–45 000 cm^{-1}) on the 1 m FTS at Kitt Peak.

The advent of atomic vapor laser isotope separation (AVLIS) in the early 1970s stimulated considerable interest in the laser spectroscopy of actinides, primarily on U and other light actinide elements that continues to the present. These efforts involve many countries besides the USA, including Canada, France, England, Germany, Italy, Japan, India, and China. More conventional actinide spectroscopy, in addition to laser spectroscopy, has continued in France and Germany. Blaise and Wyart at LAC are compiling actinide energy levels and extending current analyses and theory for some heavier actinides. German work is based on the low-level detection of actinides, and has resulted in the very accurate determination of actinide IPs, the study of isomer shifts, and recently the finding of a limited number of levels in Es (Peterson *et al*., 1998) and Fm (Sewtz *et al*., 2003) by laser techniques. Complete line lists with level assignments of some of the actinides are now available from the National Institute of Standards and Technology (NIST). Atlases that include scans, line frequencies, and level assignments for FTS observations are available from Los Alamos National Laboratory (LANL) on Th (Palmer and Engleman, 1983) and U (Palmer *et al*., 1980).

The present status of the term analyses of actinide spectra varies from essentially complete for the elements with even atomic number (Th, U, Pu, Cm, and Cf) to partial analyses for some of the odd isotopes. In the first category, nearly

all the strong and moderate-intensity lines have been classified and only weak lines remain to be assigned. However, these are a considerable fraction of the total number. Conventional publication of so much data is impracticable; thus this information is in some cases available only in the laboratory doing the work. Nevertheless, wavelengths of the strongest emission lines of all the actinides from Ac through Cf have been tabulated according to the stage of ionization (Reader and Corliss, 1980). Blaise and Wyart (1992) have published all known energy levels of the actinides analyzed up to that time and list ionization stage, energies, intensities, *J*-values, and level assignments of selected lines of all actinides through Es. The contents of this volume are being transferred and updated on a database at LACs website www.lac.u-psud.fr. Table 16.1 summarizes the lowest determined level for each known configuration of the actinide elements. In some cases, the references in Table 16.1 include extensive line lists of the classified lines and known energy levels.

After a major campaign in 1975–76 to observe the ^{253}Es and ^{250}Cf atomic spectra, the number of workers doing energy-level analyses has steadily decreased worldwide. At the present time only a very few laboratories are pursuing studies of this type.

16.3 EMPIRICAL ANALYSIS OF ACTINIDE SPECTRA

A neutral actinide has typically less than a 1000 known experimental levels, the first ion somewhat fewer, primarily due to the low excitation energy of the EDL source. The levels are organized by half-dozen into terms, some dozens of terms form a configuration, and there are often ten or more configurations identified for a given stage of ionization. The order in this hierarchy, however, is not evident. There is considerable overlapping of different terms and of different configurations. The terms are not pure in any coupling scheme but must be described as mixtures to account for their properties, and there is more often than not mixing of configurations. The only way most levels can be identified with a given configuration is by the use of the observed IS, the intensities of its transitions to levels of known configurations, and by comparison with theoretical calculations with appropriate parameters.

There are several fortunate circumstances that make it possible to identify the lowest level of each configuration and thereby the relative energies of the configurations (for interpretation of the structure). In *SL* coupling the lowest level of a configuration is usually found to be fairly pure and follows Hund's rules, i.e. this term has maximum multiplicity and maximum orbital angular momentum. Fig. 16.1 shows, as an example of Hund's rules, the lowest term of a number of configurations in neutral plutonium. Although Hund's rules apply only in configurations of equivalent electrons, they are followed, with few exceptions, in configurations with several open subshells.

Table 16.1 *Lowest levels found for identified configurations, with parity, terms, IS values, and hfs widths* (*Widths are negative for inverted hfs splitting*). *Under configuration all have the radon core as part of the configuration. Under references, the first initial of all authors plus the date gives the reference. A question mark means the data are missing or in question.*

[a] Complete energy levels etc. of all the atoms and ions in this table are given in BW92.

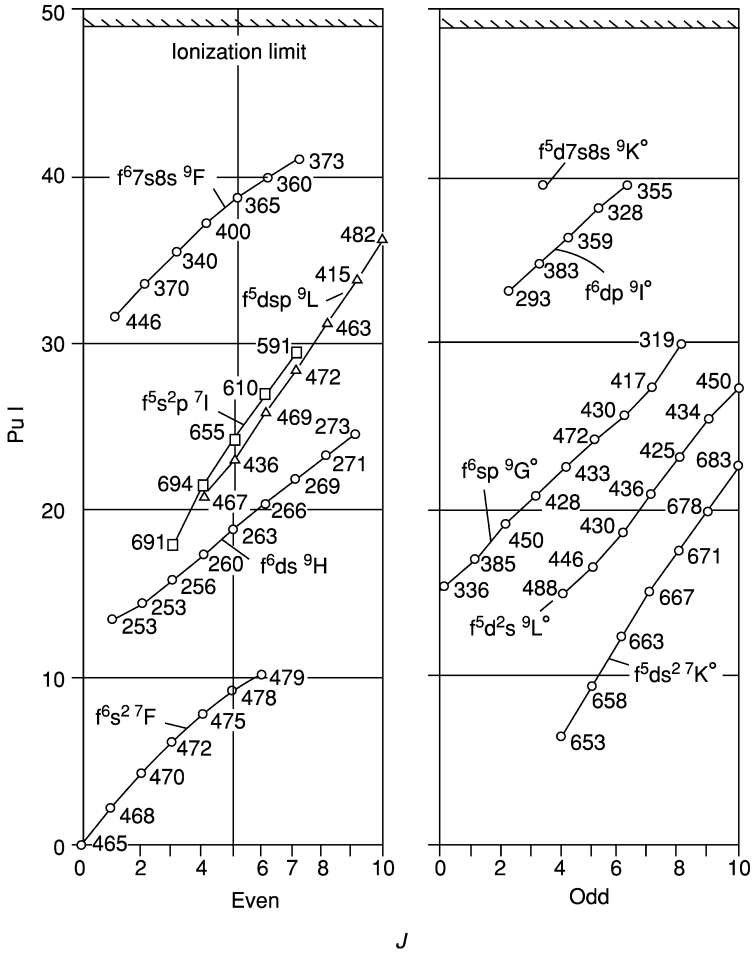

Fig. 16.1 *Hund's rule multiplet of various electron configurations of neutral plutonium,* Pu(*I*). *The number opposite each fine-structure level is the observed isotope shifts* (^{240}Pu–^{239}Pu) *in* 10^{-3} cm^{-1}.

One of the most useful types of experimental corroboration can be obtained from IS values. In the heavy elements the difference in energy of an atomic level from one isotope to another is due to the difference in nuclear volume between the isotopes. For an electron very near the center of the atom, the Coulomb attraction is decreased from that for a point nucleus. The effect is greater for heavier (larger) isotopes. The IS is also greater for electron configurations with more s-electrons since s-electrons have (nonrelativistically) a finite electron

density at the nucleus. The IS is therefore larger for the $5f^n7s^2$ configuration than for the $5f^n7s7p$ configuration. The size of the shift is not directly proportional to the number of 7s electrons because the total s-electron density at the nucleus is modified by the mutual shielding among the electrons. If two 7s electrons are present, the inner electron density of one to some extent shields the outer density of the other from the nuclear attraction, and consequently the $7s^2$ central density is less than twice that for $7s^1$. The presence of an inner electron (5f or, somewhat less so, 6d) also shields a 7s electron. So converting a 5f to a 6d electron reduces the shielding of the 7s electron and increases the IS. Nonrelativistic Hartree–Fock (HF) calculations (Wilson, 1968) gave the result that in converting from one type of valence electron to another, the 5s and 6s electron densities also changed appreciably and had to be considered since it is the total density of all the s-electrons that is responsible for the IS. Relativistic HF calculations (Rajnak and Fred, 1977), on the other hand, ascribe the shift to changes in the shielding of just the 7s electron. Fig. 16.2 shows the experimental shifts and calculated densities at the nucleus for a number of Pu I configurations, illustrating the linear relationship. The experimental shifts are also given for the fine-structure levels of the terms plotted in Fig. 16.1, showing that there is a sensibly constant shift within each set of levels. They are, in fact, fairly constant not only within the lowest term, but also for all the levels of a configuration. The fluctuation is evidently due to varying amounts of configuration interaction (CI), which mixes different configurations and hence mixes the shifts in proportion. The IS values thus make it possible to assign many experimental levels to a definite configuration, which is a very valuable property even though it says nothing about the assignment of term quantum numbers to individual levels within a configuration.

16.4 ELECTRONIC CONFIGURATIONS OF ACTINIDES, SYSTEMATICS OF ACTINIDE CONFIGURATIONS, AND RELATION TO CHEMISTRY

Electron configurations, analogous to the Pu configurations shown in Fig. 16.1, occur in the other actinide elements, i.e. configurations with the same combination of valence electrons but with the number of 5f electrons increasing as Z, the atomic number, increases. These can be generalized into various series, such as $5f^n7s^2$, $5f^{n-1}6d7s^2$, etc., where for the neutral atom $n = Z-88$. Within a series, the S and L of the Hund's rules term change from series member to member because of the changing contribution from the 5f shell. There are also corresponding series for the ions, e.g. $5f^n7s$, $5f^{n-1}6d7s$.

The usefulness of the series concept comes from the regularity in energy of the lowest term. The relative energies of different series change with Z but the change is systematic. This is illustrated in Fig. 16.3(a) and (b) for the neutral

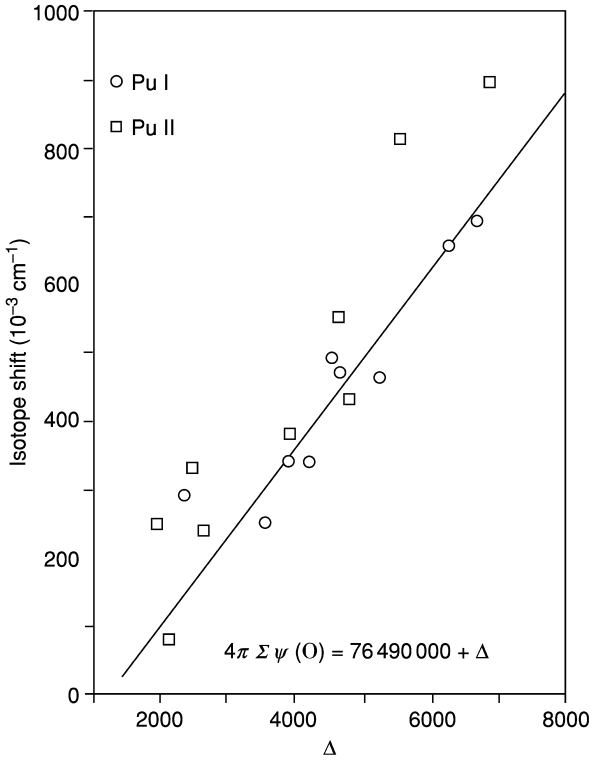

Fig. 16.2 *Isotope shifts of configurations of Pu I and Pu II as a function of electron density at the nucleus.*

atoms; the data are given in Tables 16.1 and 16.2. The absolute binding energies increase with Z (become more negative), but the quantity of interest is usually the relative energy between series. In Fig. 16.3(a) the zero energy for each element has been taken arbitrarily as the configuration $5f^{n-1}6d7s^2$ (the lowest with three valence electrons, trivalent) and in Fig. 16.3(b) the lowest configuration is taken as $5f^n7s^2$ (divalent). The regularity provides independent evidence of the correct assignment of levels to the various series for the individual actinide elements, except for the irregular behavior near the middle of the 5f shell.

This irregularity is due mainly to the fact that the overall spread in energy of the f^n configurations is greatest for the half-filled shell, $n = 7$. (Each f^n configuration consists of a number of SL terms due to the 5f–5f repulsion, and these terms have quite different energies.) Fig. 16.4 shows the approximate position of the lowest term of each f^n configuration with respect to the weighted average of the configuration, and also with respect to the lowest term of f^{n-1}. When f^n is

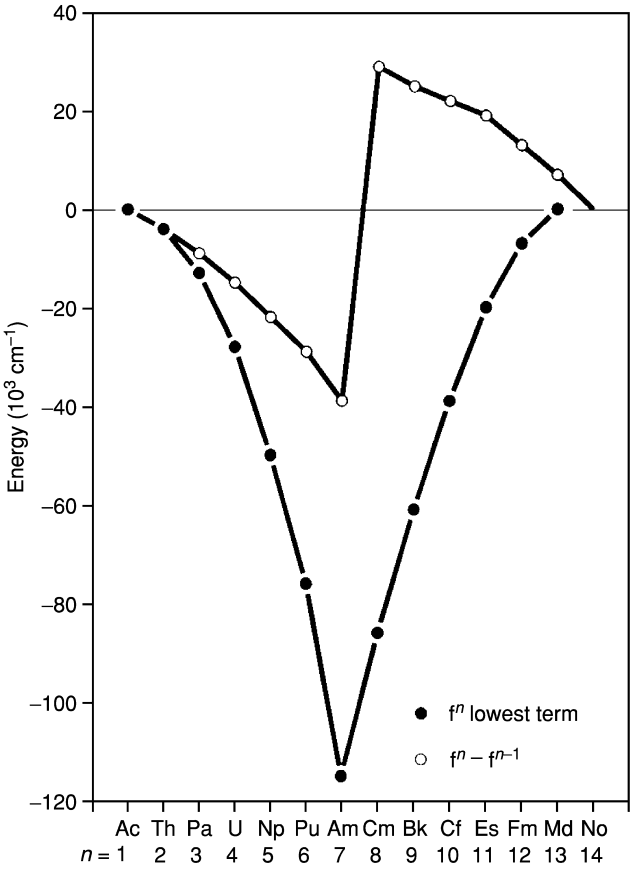

Fig. 16.4. *Approximate energy of the lowest term of f^n relative to the weighted average of f^n and of f^{n-1}.*

compared with $f^{n-1}d$ (the $7s^2$ electrons do not contribute to the structure), the irregularity is reduced because the f–d electrostatic interaction changes sign at $n = 8$, and also slope.

Inspection of Fig. 16.3(a) shows three families of series based on f^n, f^{n-1}, and f^{n-2} having respectively negative, zero, and positive slope. The relative positions of different series characterized by various configurations of outer electrons tend to repeat for each family, and consequently the existence of families is clearly due to the properties of the 5f electrons. For simplicity, Fig. 16.4 presents the lowest series of each family, those configurations with $7s^2$. Now HF calculations show that most of the energy in actinide configurations comes from the electrostatic attraction between the individual 5f electrons and the nucleus. This

attraction increases with Z (the actinide contraction) and the total of the 5f attraction energy is proportional to the number of 5f electrons. The $7s^2$ energy is nearly constant with Z and so does not affect the trend of the series. The 6d energy is also nearly constant but gives an additional (almost constant) contribution to $5f^{n-1}6d7s^2$ and twice as much to $5f^{n-2}6d^27s^2$; it affects the absolute positions of the three series but not the slopes (see Fig. 16.3a). The three series have roughly equal energies for atomic numbers around that of uranium ($Z = 92$). For smaller Z, the 6d binding energy is more important than the 5f binding energy, but for larger Z the 5f becomes increasingly more stable due to an increase with both Z and n.

The electron–nucleus attraction energy is related by the virial theorem to the mean value of r (the electron–nucleus separation) for the different kinds of electrons. Fig. 16.5 shows (nonrelativistic) HF solutions for the radial distribution $P(r)$ for plutonium as a typical actinide. The abscissa is chosen as $r^{1/2}$ (in atomic units) in order to show more detail at small r and less at large r. The figure also shows the total electron density due to the first 86 electrons in the radon core, plotted to a reduced ordinate scale. At the bottom of the figure is Z^*, the effective Z, which describes how the nuclear charge seen by an electron at separation r is reduced by the shielding due to the electron density between zero and r. The 5f electrons clearly see a larger Z^* than do 6d or 7p. The 5f Coulomb energy $-Z^*e^2/\langle r\rangle$ is more negative ($\langle r\rangle$ is the expectation value of r,

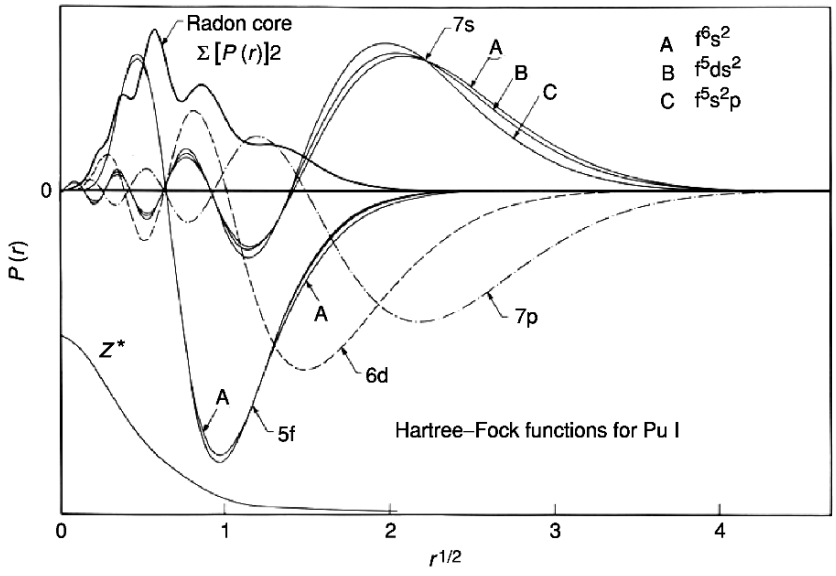

Fig. 16.5 *Radial distribution functions of valence electrons in neutral plutonium.*

i.e. r averaged over the radial density distribution). The total energy also includes a centrifugal term $+l(l+1)/r^2$ (l is the azimuthal quantum number), which tends to equalize the 5f, 6d, and 7p Coulomb energies, and the details vary along the actinide series as first shown by Goeppert Mayer (1941). It can be seen that the 7s radial function has its main contribution well outside the radon core, the 6d not quite so much, while the 5f electron is completely inside the core. The 5f electron is an inner electron and not much affected by the environment outside the core.

The determination of the electronic structure of the actinide elements through spectroscopy was expected to lend considerable knowledge to the chemistry of the elements. In fact the opposite is true because of complications in the observation and the analyses of the spectra, the chemistry was well known before elucidation of the spectra was possible. There are clear implications for actinide chemistry in the relative energies and radial distributions of the last ($Z-86$) electrons of a neutral actinide atom (see Fig. 16.5). For a typical actinide, the 6d and $7s^2$ electrons extend beyond the radon core and are available for forming chemical bonds, i.e. a typical actinide should be trivalent. At the beginning of the series, however, the 5f electron is not so firmly bound and has a larger $\langle r \rangle$, which reduces the amount of shielding of the nuclear charge as seen by the 6d electron. Hence for thorium, 6d is favored over 5f because of its larger Z^* and smaller centrifugal loss, and the ground state is $6d^27s^2$, resulting in a neutral atom with four external electrons (quadrivalent).

The tendency of the actinides to be multivalent in the first part of the actinide series because of the presence of 7s, 7p and 6d and 5f electrons of about equivalent energy is well known. The tendency to become more lanthanide-like in behavior toward the middle of the series and then have more divalent character near and beyond Es is related to the known electronic structure of these actinides. The increased stability of the 5f electrons as the atomic number is increased can be determined from the systematics of the electronic structure. At the heavy end of the actinide series, the 5f electrons become increasingly bound compared with 6d and it is more favorable to convert an added electron to another 5f, producing $5f^n7s^2$ as the ground state (divalent). This change in valence along the series is reduced in the lanthanides, as is shown in Fig. 16.6, where the relative energy of configurations $4f^n6s^2$, $4f^{n-1}5d6s^2$, and $4f^{n-1}5d6s6p$ are compared with the corresponding actinide configurations. The increased stability of 5f vs 4f in the second half of the series is evident and explains the tendency toward divalent character in the actinides beyond Es. The first actinide to show a stable divalent ion in solution was Md (Hulet *et al.*, 1967).

Brewer (1971a,b, 1984) developed methods based on the thermodynamic data of actinide metals and the regularities of the lowest energy levels of known actinide configurations (described above) to estimate the lowest energy levels of missing configurations of free atoms and ions in the 4f and 5f series.

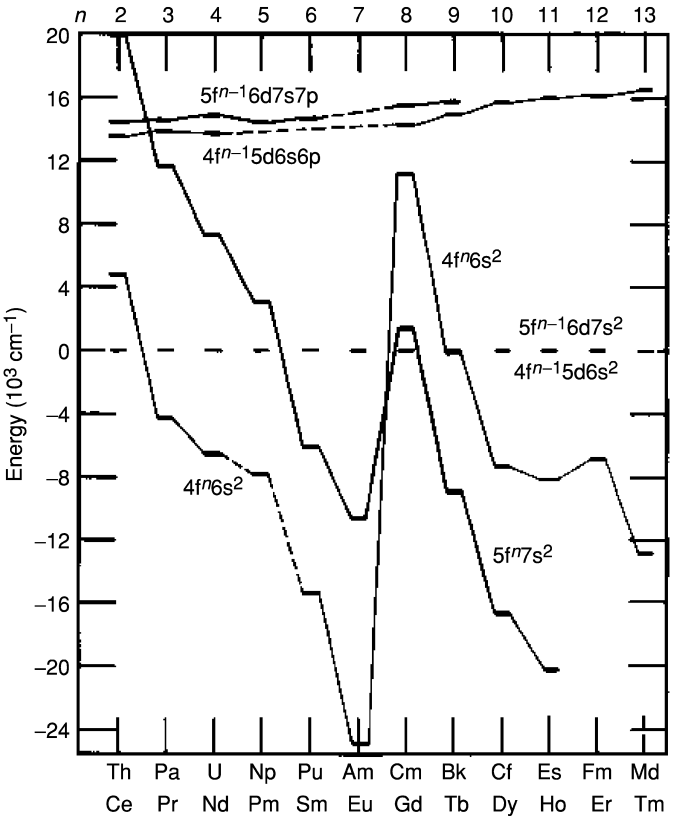

Fig. 16.6 *The energies of the lowest levels of the configurations, $f^n s^2$, $f^{n-1}ds^2$, and $f^{n-1}dsp$ for the actinides (5f) and lanthanides (4f) plotted vs n with the lowest level of the $f^{n-1}ds^2$ configuration at zero. Level energies with dashed level and connector lines are predicted values from Brewer* (1971a). *The lower energy for $5f^n7s^2$ for Cm and beyond is evident as the actinide series is ascended. This explains the tendency for the actinides to be more lanthanide-like at the center then become more divalent in character for the heavier actinides of Es and beyond.*

His estimates have proven to be very useful in assigning unknown configurations during spectral analyses.

These qualitative considerations are compared with some solution chemistry results in Fig. 16.7(a) and (b). The standard oxidation–reduction potentials $E^{\circ}(M^{(n+1)+}/M^{n+})$, converted from volts to cm^{-1}, are plotted for comparison with the energies of f–d transitions in free atoms. The full symbols are experimental values, the open symbols the calculated ones (Nugent, 1975). The similarity in shape of the two sets of curves is evident. There are approximate shifts of about 30000 cm^{-1} for the (III)/(II) potentials (Fig. 16.7(a)) and

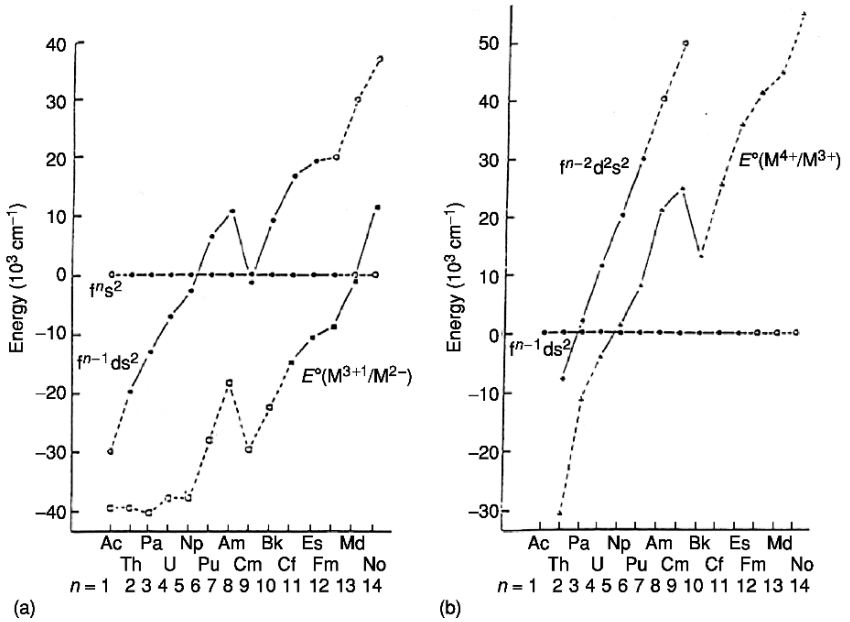

Fig. 16.7 *Comparison of actinide standard oxidation–reduction potentials and the relative energies of the series on converting a 5f electron to a 6d electron across the series.*

about 20000 cm^{-1} for (IV)/(III) (Fig. 16.7(b)) in the same direction, i.e. less energy is required for f→d conversion in solution than in the free neutral atom.

16.5 THEORETICAL TERM STRUCTURE OF THE FREE ACTINIDES

The energy of an atomic level results from various interactions and is an eigenvalue of the Hamiltonian operator describing the N-electron atom. If relativistic effects are first neglected, the Schrödinger equation $H\Psi = E\Psi$ is to be solved with

$$H = \sum_{i=1}^{N} \left(\frac{p_i^2}{2m} - \frac{Ze^2}{r_i} \right) + \sum_{i>j=1}^{N} \left(\frac{e^2}{r_{ij}} \right)$$

where $p_i^2/2m$ represents the kinetic energy and r_i the distance to the nucleus for electron i of mass m and electron charge e. The last term in H (named Q hereafter) accounts for the repulsions between all pairs of electrons separated by the distance r_{ij} and is too large to be treated as a perturbation. The central field approximation of Slater (1929), i.e. electrons being assumed to move in

a spherically symmetric potential $-U(r_i)/e$, gives the following equation H' considered as zeroth-order perturbation theory

$$H' = \sum_i \left(\frac{p_i^2}{2m} + U(r_i) \right).$$

The difference, H–H', is the perturbation potential,

$$H - H' = \sum_{i=1}^{N} \left(-U(r_i) - \frac{Ze^2}{r_i} \right) + \sum_{i)j=1}^{N} \left(\frac{e^2}{r_{ij}} \right)$$

The eigenvalues of H' depend on the n and l quantum numbers only, defining the configurations $\ldots n_a l_a^p n_b l_b^q \ldots$ and the first summation in the $H-H'$ equation contributes as a global shift for each configuration. The *active* two-electron part Q splits the highly degenerate states of the configurations into terms of definite total spin S and total orbital angular momenta L. Spin-dependent interactions have a leading term that couples the spin angular momentum s_i and the orbital angular momentum l_i of each of the electrons e_i. The spin–orbit operator

$$\Lambda = \sum_i \xi(r_i) s_i l_i$$

is then added to $H-H'$. The matrix elements of Λ have radial parts, the spin–orbit radial integrals ζ_{nl}, which increase rapidly with atomic number. Consequently, Λ can be considered a perturbation on SL terms for low Z elements only, where all levels with total angular momentum J ($\mathbf{J} = \mathbf{L} + \mathbf{S}$) allowed in a term ($| L - S | \leq J \leq L + S$) are close in energy. In actinides, the spin–orbit splitting (fine structure) of the terms is larger than their separations. LS coupling selection rules for transitions are violated and prevent total spin and orbital momenta S and L, respectively, from being quantum numbers of interest. The complexity of the actinide spectra is correlated with the relative magnitude of various parts in Q and in Λ. All the individual s and l angular momenta sum as $\mathbf{J} = \Sigma_i(\mathbf{s}_i + \mathbf{l}_i)$ with intermediate steps and the angular momenta associated with these steps define a coupling scheme. It is chosen so that the off-diagonal elements of the matrix of the $Q + \Lambda$ operator are as small as possible. In odd-Z elements, due to the nuclear magnetic moment $\mathbf{I}$ and its coupling with $\mathbf{J}$, the total angular momentum $\mathbf{J}$ should be replaced by $\mathbf{F} = \mathbf{I} + \mathbf{J}$. Then the hyperfine Hamiltonian $\mathbf{A} \cdot \mathbf{I} \cdot \mathbf{J}$ has to be added to $Q + \Lambda$. Actinides display the largest hfs patterns of all spectra; however, the hyperfine splitting is small compared with level separations and may be interpreted as a perturbation of the fine-structure levels with wave functions $|\alpha J M_J>$, α being a symbol for all couplings ending on J.

The angular and radial parts in the monoelectronic eigenfunctions and in the Hamiltonian operators lead to separate radial and angular integrals. All radial integrals needed in any configuration (electrostatic Slater integrals and spin–orbit integrals), and how they can be determined from experimental energy

levels in two-electron configurations, are fully described (Condon and Shortley, 1935). The application of this parametric approach to larger atomic systems needed Racah methods to be achieved. Racah derived the symmetry properties in configurations of l^N and the double tensor $\mathbf{w}^{(\kappa k)}$ properties of the operators involved in the Hamiltonian and showed how their ranks κ and k in the spin and orbital spaces explain selection rules and some singularities in matrix elements (Racah, 1942, 1943, 1949; Judd, 1963).

Although globally satisfactory, the first-order parametric theory faces certain problems. The electrostatic operator Q has matrix elements between configurations of the same parity $p = (-1)^{\Sigma l}$ and this would lead to the calculation of the H_1 operator with a basis set of many configurations. This was done with success by Racah (1950) for the two-electron configurations of Th III, but even with present-day computers the size of matrices that can be diagonalized is limited. Perturbation theory allows CI to be calculated as second-order effects, as long as they are distant (Rajnak and Wybourne, 1964). In case of f^n, two-particle operators lead to the correction terms $\alpha L(L+1) + \beta G(G2) + \gamma G(R7)$, where α, β and γ are effective parameters and $G(G2)$ and $G(R7)$ are Casimir operators of symmetry groups needed to classify f^n states. Three-particle operators involved in f^n to $f^{n\pm1}n'l'^{\mu l}$ excitations also lead to six additional parameters (Judd, 1966). In the case of several open shells, two-electron electrostatic operators lead to Slater-type effective parameters (Feneuille and Pelletier-Allard, 1968; Crosswhite, 1971). Although λ is an effective operator valid in a given configuration, second-order operators acting on spin and orbital spaces (cross products $Q \times \Lambda$) have been investigated (Goldschmidt, 1983). Further details are not given here as they can be found in several textbooks (Slater, 1960; Wybourne, 1965; Cowan, 1981; Rudzikas, 1997).

Judd (1985) has made a survey of atomic structure theory for complex spectra. He included a new way of parameterization. Radial integrals and the usual effective parameters are correlated in the sense that the introduction of a neglected parameter changes the values of those already used in the analysis. This can be overcome by replacing the usual operators by linear combinations associated with 'orthogonal' parameters. An application to Pr III $4f^3$ was made (Judd and Crosswhite, 1984) and the angular coefficients of relevant operators were further studied (Hansen *et al.*, 1996; Judd and Lo, 1996) but the actinides have not yet been investigated in this way.

16.6 DETERMINATION OF RADIAL PARAMETERS

A description of the level structure of an actinide configuration as given by the eigenvalues and eigenvectors of the energy matrix H has been outlined above. To obtain quantitative information, it is necessary to provide numerical values for the matrix elements and then to diagonalize the matrix. The problem thus divides naturally into several stages: evaluating the angular coefficients f_k, g_k of

the electrostatic integrals $R^k(n^a l^a\, n^b l^b, n^c l^c\, n^d l^d)$ with ($a = c$, $b = d$) for the direct Slater integrals, F^k, and ($a = d$, $b = c$) for the Slater exchange integrals, G^k. The same procedure may be applied for the spin–orbit integrals, for the electrostatic CI integrals R^k, and for effective CI parameters. Then initial values are provided for the radial integrals and the effective parameters, followed by diagonalization and optimization of the effective parameters by comparison of the calculated energy levels with the assigned experimental levels.

The angular coefficients are calculated exactly by application of the Wigner–Eckart theorem and by means of Racah algebra techniques as described by Judd (1963). They are products of phase factors, n–j symbols, and contain sums over the states of the parent configuration f^{n-1} as the decoupling of one (or more) f electrons out of f^n is needed. For that purpose, fractional parentage coefficients can be found in Nielson and Koster (1964). The analytic expression of angular coefficients was used as input in the first computer programs to determine numerical values of the angular coefficients (Racah, 1951; Bordarier, 1970). As an intricate function of all spin and orbital momenta involved in the selected coupling scheme, it was subject to errors although an implicit check of the Racah algebra consistency was provided by the integer form $a(b)^{1/2}/c$ of the whole numerical process. A nearly automatic code was developed at LANL (Cowan, 1968, 1981), requiring only the number of electrons in each open shell, input of the fractional parentage coefficients, and a list of terms for each shell. This code is widely distributed and was adapted at other sites, such as ANL (Crosswhite, 1975) and for PC users (Kramida, 1997). It runs faster than the earlier codes as all calculations are performed in the decimal form.

After an initial set of radial integrals is chosen, the Slater–Condon method of treating them as adjustable parameters may be applied. Upon diagonalization, the eigenfunctions lead to coefficients of the parameters in intermediate coupling and to a linear expansion for the energy of each level. In the subsequent least-squares minimization of $\Delta_i = E_i(\text{exp})$–$E_i(\text{th})$ (where $E_i(\text{exp})$ and $E_i(\text{th})$ are the experimental and calculated levels), and the mean error $\sigma = (\Sigma \Delta_i^2/(N_{\text{lev}}$–$N_{\text{par}}))^{1/2}$ measures the quality of the fit and is critically dependant on the number of known levels N_{lev} relative to the number N_{par} of unknown parameters. Some iterations of the diagonalization/least-squares fits lead after convergence to a set of fitted parameters with standard errors. In the complex first and second spectra, inappropriate initial parameters may lead to term inversions in the comparisons of $E_i(\text{exp})$ vs $E_i(\text{th})$ and it sometimes happens that iterations diverge when processed in an automatic way.

Besides obtaining a low mean error on energies, validity checks of the parametric study may be obtained by using the eigenfunctions for the calculations of hfs constants. This was done for U I (Avril *et al.*, 1994). In addition, theoretical studies of the IS may be used, e.g. in Th(I,II) (Blaise *et al.*, 1988a). For even-Z elements, all investigated with the support of Zeeman effect, first checks are provided by comparisons between large sets of Landé factors $g_i(\text{exp})$ and easily derived $g_i(\text{calc})$ values.

16.7 ACTINIDE PARAMETERS

16.7.1 Least-squares fitted values

Actinide parameter values cannot be derived in a straightforward way because of the difficulties discussed above. In almost no case can the parameters be determined precisely; the values obtained depend on the assumptions made in defining the energy matrix and these vary from case to case and cannot be compared reliably. The early actinides (Th to Np) are more completely known but have more close configurations, and so the parameter values derived are sensitive to how much CI is included. The middle actinides (Pu to Cf) have larger configuration separations but more terms in each, leaving the choice between complete configurations with CI neglected or truncated subconfigurations with CI considered. The late actinides (Es and beyond), which get some simplicity being closer to $5f^{14}$, may provide values that are still unavailable from lower-Z elements. A rare example taken from einsteinium (Worden *et al.*, 1974; Blaise *et al.*, 2003) is shown in Fig. 16.8. In the first excited configuration of Es I $5f^{11}7s7p$, the lowest level $^4I_{15/2}$ of the core $5f^{11}$ is relatively well isolated from others and the relationships $Q(7s,7p) > \Lambda(7p) > Q(5f,7s)$, $Q(5f,7p)$ lead to a case

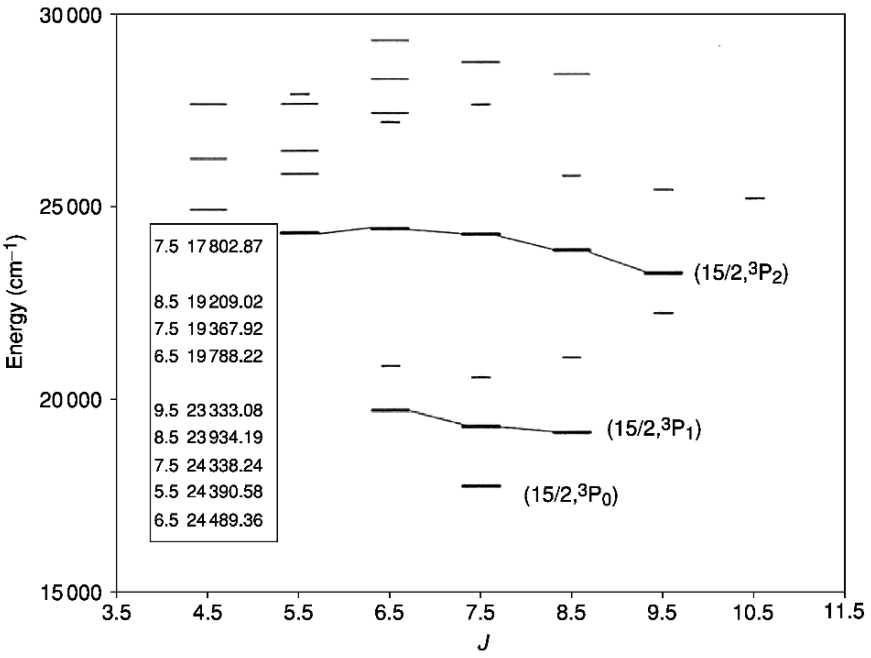

Fig. 16.8 *The low-lying levels for various configurations of Es I. The experimental values for the $5f^{11}7s7p$ of Es (heavy bars) are grouped in J_c–J_2 multiplets. Some predicted levels of $5f^{10}6d7s^2$ (light short bars) and of $5f^{11}7s7p$ (light long bars) are also given.*

of ($5f^{11}$ J_c–($7s7p)^3P$ J_2) J coupling with a clear separation of (15/2, $^3P_0$) and multiplets (15/2, $^3P_1$) and (15/2,$^3P_2$). As the theoretical splitting of any sp^3P term is approximately equal to $1.5\zeta_p$, an approximate value of 4100 cm^{-1} is readily derived for the ζ_{7p} spin–orbit parameter. Conversely, a case of complexity characterizing most of the lanthanides is found in the study of $5f^36d7s^2$ + $5f^36d^27s$ configurations of U I (Petit, 1999) using an extended version of RCG/RCE codes (Cowan, 1981). The complete basis sets of both configurations lead to 3642 theoretical levels, of which 155 are identified and 29 parameters are fitted with an excellent mean error. The eigenfunctions of the lower levels describe Landé g-values properly. On the other hand, the lack of experimental evidence for the expected perturbing configuration $5f^36d^3$ and the large number of levels without g-values or IS set the limit for additional theoretical assignments.

The small value of the ratio $N_{known}/N_{predict}$ mentioned for U I is usual in the I (free atom) and II (singly ionized ion) spectra of f-elements. Not all parameters involved in the description of a configuration can be derived reliably from the least-squares fitting on its very low energy part. If SL coupling is obeyed, all levels of a term have the same dependence on Slater integrals and the determination of the F^k(ff) ($k = 0,2,4,6$) parameters would require at least four terms of f^n to be known, which is not fulfilled in many free atoms and ions of actinides. The lowest terms of highest multiplicity have separations that are a function of only one parameter, the Racah parameter $E^3 = (1/135)F^2 + (2/1089)F^4 - (175/42471)F^6$. Owing to the strength of the 5f spin–orbit interaction, its off-diagonal matrix elements lead to term mixings and those intermediate coupling conditions lead to the differentiation of the coefficients of the electrostatic parameters for all the levels. Hence the least-squares fit does yield values of all the F^k(ff) but with rather large statistical errors.

In order to reduce those statistical errors and to improve the predictive character of the parametric calculations, the techniques of generalized least-squares (GLS) first used by Racah and coworkers in 3d-elements have been applied to actinides (Blaise *et al.*, 1980). It is known that for long periodic trends, the parameters determined as described above have a slow empirical dependence on Z. The simple expansions of the parameters as $P = A(P) + (n–7)B(P) + (n–7)^2C(P)$ lead to the determination from all the known levels of $5f^n7s^2$ and $5f^n7s$, of the A, B, and C GLS-constants for the parameters F^k(ff), α, β and γ. In the singly ionized free ion spectra, 112 levels of seven elements from U II $5f^47s$ through Es II $5f^{11}7s$ were interpreted by this GLS method with 22 free parameters and a small error of $\sigma = 84$ cm^{-1}.

16.7.2. Comparisons with *ab initio* radial integrals

Various *ab initio* studies of atomic systems have confirmed Racah's empirical statement that in $3d^n$ atoms and ions the radial integrals are smoothly Z-dependent. The same trends are found in the 4d, 4f, 5d, and 5f elements. Consider the theoretical values from relativistic HF (HFR) calculations

(Crosswhite, 1975). Fig. 16.9(a) shows various cases with certain regularities. The integrals F^k(ff) all increase with atomic number, the increase approaching linearity for the second half of the series. The ratios of the limiting slopes of F^2:F^4:F^6 are 1:0.643:0.464. The numerical values of the integrals for $5f^n7s^2$ are for Th I 49704:31366:22660 = 1.0:0.631:0.456 and for Fm I 90499:58914:43210 = 1:0.651:0.477. For hydrogenic-shaped 5f radial functions, the ratios are 1:0.688:0.527. The similarity to hydrogen can be taken to mean that over the range in r which includes most of the HF 5f radial function, the potential does not change greatly from that for a fairly constant effective nuclear charge Z^*. The increase of the F^k integrals with Z corresponds to the actinide contraction.

Fig 16.9(a) shows that the HF values of F^k(ff) are only mildly affected by changes in the outer electrons and for each k, converge toward the same limit with increasing Z, independent also of ionic charge. The change in the integral for constant Z but varying number of 5f electrons is much greater and amounts to a constant shift. All these effects are in the direction expected for changes in the shielding of the 5f electrons. The HFR overlap integrals F^k(5f6d) and G^k(5f6d) in Fig. 16.9(b) and (c) show the opposite effect: they decrease with Z because the 5f functions contract while the 6d functions remain constant, and they are more sensitive to the number of 7s electrons, that affects their relative shielding. The one-electron integrals ζ_f, which are proportional to $<1/r^3>$, increase with Z and their dependence on outer electrons is consistent with shielding effects. The effect of increasing Z on ζ_d and ζ_f is shown in Fig. 16.9(d).

Now consider the experimental parameters and how they compare with theory. Table 16.3 presents some experimental values of F^k(ff) parameters, the corresponding HFR integrals and several ways of comparing them. The experimental parameters P_{exp} are all smaller than the calculated integrals P_{HFR}, which is an almost universal characteristic throughout the periodic table. The ratio (P_{exp}/P_{HFR}) is roughly 2/3 with irregular variations. Another ratio is F^k/F^2 that can be formed independently for P_{exp} and P_{HFR}. A third possibility is the difference (P_{exp}–P_{HFR}) that was found to be nearly constant for each F^k for tripositive lanthanide ions (Carnall *et al.*, 1978). It should be stressed that parameter comparisons are meaningful only if they have been derived with similar approximations, i.e. the same terms in the Hamiltonian operator were calculated on similar sets of configurations, only the number n of core electrons being varied. Parametric studies still continue to make general trends better known.

16.8 SUMMARY OF ACTINIDE CONFIGURATIONS

Table 16.1 lists the lowest level of all known actinide configurations of the species studied and Table 16.2 shows the lowest level of some common configurations of the neutral actinide spectra. Thousands of higher levels are known, but for this survey we are more interested in generalities than in details. The

trend of analogous configurations as a function of atomic number in the neutral atoms has been shown in Figs. 16.3(a), (b), and 16.6. The relative configuration energies as a function of ionization stage are given in Table 16.4 for Th I–IV 5f, 6d, 7s, and 7p, showing that the 5f configuration becomes increasingly more stable as outer electrons are removed (5f gains 17000 cm^{-1} over 6d in going from Th I to Th IV). The change in 5f energy with increase in atomic number corresponds to the actinide contraction, which increases the effective nuclear charge Z^*. Increasing ionization also increases Z^* by reducing the shielding of 5f electrons from the nucleus as outer electrons are removed. The effect on the 5f energy is thus in the same direction as with increasing Z. The outer electrons 7s and 7p are more nearly hydrogenic and have energies that become more negative as approximately the square of the ionic charge (about the same for all Z). Hence the 7s–7p difference increases with ionic charge.

Racah (1950) treated the term structure of Th III in a classic paper on least-squares parameter fitting in intermediate coupling with CI. With these off-diagonal matrix elements included, the calculated energies were in much better agreement with observation, and in addition, the calculated g-values were also in better agreement than the pure SL Landé g-factors. This has been the general experience in fitting spectra with more than two electrons: the better the energy fit, the better the g-value fit; it also applies to other properties such as IS, hfs, and relative intensities of transitions, and thus lends confidence to the calculation. Attempts to make the g-value fit more exact by trying to fit the energies and g-values simultaneously have not been successful because these are not independent quantities. If the calculated g-values are not more or less in agreement with observation, it is an indication that some interactions are missing from the energy matrix. Since parameter fits in the general case are not exact and are in a state of flux, no attempt has been made in Table 16.1 or 16.2 to try to include calculated g-values or other calculated properties. Comparison of g (exp) with calculated SL g-values serves as an indication of how much intermediate coupling and CI are present and not that the assignment is in doubt. Tables 16.1 and 16.2 show that, in moving toward the middle of the actinide series, the multiplicity increases in accord with Hund's rules.

Thus in Pa I (the first true actinide with a 5f electron in the ground state), there are quartets and sextets (and also doublets in the higher states), whereas in Am I there are octets and decets (and also sextets, quartets, and doublets). This has a profound effect on the intensity distribution of the observed spectral lines. In pure SL coupling, there is a selection rule $\Delta S = 0$ (octet terms have transitions only to octets, etc.). In intermediate coupling, as obtains in the actinides, there are off-diagonal spin–orbit matrix elements between terms of adjacent multiplicity ($\Delta S = 0, \pm 1$), which means that octet terms, for example, will also have some decet and sextet eigenvector components, and therefore have transitions to decet and sextet terms. There will be, however, no transitions to quartet and doublet terms. The strong lines (those involving the low terms) will therefore consist of transitions between terms of high multiplicity that are

comparatively few in number. There will also be transitions among the terms of low multiplicity but these will be very numerous and weak. The observed Am I spectrum thus consists of a relatively small number of strong lines superimposed on a weak complex background. The strong lines are easy to classify into a transition array; the weak lines are not. The determination of the G^k parameters requires knowledge of terms of all multiplicities, not obtainable from just the strong lines. At the beginning of the actinide series, by contrast, the multiplicities are all low and the ΔS selection rule is not so restrictive, hence the range in intensity is not so great. In fact Pa I appears at first sight to have the most complex spectrum of all the actinides because of the comparatively uniform intensities, despite fewer expected terms. The Pa spectrum is further complicated by the presence of hfs. Many transitions have four hfs components that have a large degradation in intensity because of the low nuclear spin (^{231}Pa, $I = 3/2$) and low J values, so they often cannot be distinguished from neighboring weak lines. In Am (for the relatively long half-life isotopes ^{241}Am and ^{243}Am, $I = 5/2$), each level has six hfs components when $J \geq 5/2$, in Bk and Es (for ^{249}Bk and ^{253}Es, $I = 7/2$) each level has eight hfs components when $J \geq 7/2$, with less degradation so they usually stand out from the background. Hence the analysis and interpretation of a spectrum like Pa is no easier than for later elements with larger multiplicities.

Another characteristic of the actinide series is the fact that the L values for f^n go through a maximum not at the half-filled shell, as in the case of the S values, but at the one-fourth and three-fourths-filled shells. Thus the ground state of Np I f^4ds^2 is $^6L_{11/2-21/2}$ and for Np(I) f^4d^2s it is $^8M_{11/2-25/2}$. These high J values are poorly excited by electron collision in the light source, so transitions to the highest J levels are weak and hard to find, in contrast to multiplets at the beginning of the actinides. For the three-fourths-filled f^n shell, the multiplets are inverted and not so much of a problem. The high L values for Np have a considerable effect on the hfs because the large orbital angular momentum produces a high magnetic field at the nucleus that increases the orbital contribution. The Np I ground level has a total width of 0.776 cm^{-1} in spite of having no unpaired s-electron, the usual source of large hfs (Fred *et al.*, 1977). Bk I and Es I have even larger widths, 1.150 and 1.532 cm^{-1}, due to larger nuclear spin, larger J value, and larger Z (Worden *et al.*, 1974, 1987). The ability to measure the intervals of the hfs patterns to better than 1 part in 1000 is a great help in the empirical analysis of these spectra. Moreover, the quantum numbers of the various levels can be obtained by comparing the relative widths with those calculated by standard hfs theory.

To summarize, the spectroscopic properties of all the actinide elements that can be studied by conventional emission spectroscopy, Ac to Es, have now been investigated experimentally and theoretically. The present status is satisfactory in that most of the electronic structure information of interest for actinide chemistry is available. The experimental completion of the determination of the electronic structure of the last four elements in the actinide series will

take considerable effort and new techniques due to the limited availability of the elements and their short half-lives. Theoretical estimates together with extrapolations (e.g. Vander Sluis and Nugent, 1972; Brewer, 1984) from the known structure of the lower actinide elements are needed. In addition, further efforts are required to provide the complete details for some of the lighter actinide elements.

16.9 NEW PROPERTIES OF ACTINIDES DETERMINED BY CONVENTIONAL SPECTROSCOPY AND MATERIAL LEFT FOR DATA REDUCTION

The signs of the nuclear magnetic moments in both ^{249}Cf and ^{251}Cf have been determined to be negative (Conway *et al.*, 1995). From the examination of the direction of degradation of the hfs of the ground and first excited levels in the second spectrum of ^{249}Cf, the $^{6}I_{17/2}$ and the $^{4}I_{15/2}$ of $5f^{10}7s$ were found to be inverted and regular, respectively. Since the hfs of both isotopes degraded in the same direction, it was concluded from this data that the sign of the nuclear magnetic dipole moment of both isotopes is negative. The nuclear spins of both isotopes were confirmed as 9/2 for ^{249}Cf and 1/2 for ^{251}Cf. A large number of ^{251}Cf lines with two components were observed indicating the nuclear spin of this isotope is 1/2. With the high J values involved in most Cf transitions, the off-diagonal components for ^{251}Cf are very weak (3% or less of the total intensity when $J > 3$) (White, 1934) and so they were not observed in the spectra resulting in many lines with two components.

There is considerable actinide spectroscopic data awaiting analyses. One complete set of photographic plates for Bk taken on the ANL spectrograph is in storage at LLNL. The Bk structure was determined from measurements of photographic plates taken on a 3.4 m Ebert spectrometer with a special high-angle grating and order sorter (the resolution and dispersion were about equal to that of the ANL spectrograph). Worden, using a Grant comparator at LLNL, measured the plates and then the data were analyzed (Worden *et al.*, 1987). Some of the Zeeman spectra taken on the ANL spectrograph were measured (again by Worden) to determine Landé g-values used in the level analyses. A complete set of plates was taken in 1976 on the ANL spectrograph using EDLs with the major isotope ^{250}Cf and known ^{249}Cf, ^{251}Cf, and ^{252}Cf content, including some with an additional spike of ^{252}Cf. The IS values for ^{250}Cf vs ^{249}Cf, ^{251}Cf, and ^{252}Cf should result from measurements of these plates as well as a better set of wavelengths (there are no hfs and subsequent broadening with ^{250}Cf as there is with the current ^{249}Cf-line list). Improved analyses of the neutral and especially the first ion spectra (where the hfs is larger) should be possible.

The complete Es spectrum was measured on the ANL spectrograph in 1975. Earlier measurements were done at LLNL (Worden *et al.*, 1974). The ANL

photographic plates should produce a much more complete list and many more levels should be obtained. Blaise and Wyart are currently working on these data to improve the analyses of the Es I and II spectra (Blaise *et al.*, 2003; Wyart *et al.*, 2005).

16.10 LASER SPECTROSCOPY OF ACTINIDES

A large number of hfs A and B factors for ^{235}U have been determined by laser spectroscopy. The data list included 35 odd (28 low-lying odd levels of the configuration $5f^36d7s^2$) and 34 even levels from 15500 to 31000 cm^{-1}, many with very high precision (Childs *et al.*, 1979a,b; Hackel *et al.*, 1979; Greenland *et al.*, 1981; Avril *et al.*, 1986, 1994; Demers *et al.*, 1986). A very large number of high-lying upper levels of both parities have been found by multi-step laser spectroscopy of U by researchers in the USA, France, England, India, Japan, and China. However, these level determinations are inaccurate (uncertainties ranging from 0.5 to 2 cm^{-1}) as compared with typical emission spectra levels derived from grating spectrographs or FTS instruments (with 0.02 to 0.001 cm^{-1} uncertainty) so no references are given.

The signs of the ground state A and B factors of neutral ^{241}Am (Le Garrec and Petit, 1986) and ^{243}Am (Meisel *et al.*, 1987) have been determined by high-resolution laser spectroscopy of the Am isotopes to be $A < 0$ and $B > 0$. The ^{242m}Am isotope has the same sign because the hfs has the same degradation. Considerable laser spectroscopy of Pu has been accomplished, but little except the IP has been published in the open literature (Worden *et al.*, 1993). The same is true of Np where the energy separation of 24.27 cm^{-1} between the two lowest levels of Np II (Fred and Blaise, 1978) was used to help confirm the observation of Rydberg series in Np I (Worden and Conway, 1979). A review of multi-step laser excitation of lanthanides and actinides has been published (Worden and Conway, 1980) with a discussion of properties that can be determined by the use of laser spectroscopy.

16.11 IONIZATION POTENTIALS OF ACTINIDES BY LASER SPECTROSCOPY

The precise determination of the first IP of the actinide elements is important for the identification of systematic trends in binding energies of the elements. It is also important for drawing conclusions about the electronic structure of the atoms, since the first IP is directly connected to the atomic spectra. Information about the electronic structure of the actinides is required to predict deviations from the regularities of the periodic table (Pyykkö and Desclaux, 1979) caused by relativistic effects which are expected in this region as a result of the relativistic mass increase of the inner electrons (Pyykkö, 1988). The IPs are useful

quantities in the Born–Haber cycle (Morss, 1971) and also allow comparison with predictions of multi-configuration Dirac–Fock calculations (Fricke *et al.*, 1993), a successful theoretical treatment for heavy multi-electron atoms.

Ionization energies of the neutral atoms were derived by Sugar using interpolation of the series properties of the $5f^n7s8s$ configurations. They are given in Table 16.5 (Sugar, 1974). The first accurate experimental value of an IP of an actinide element was by multi-step laser spectroscopic observation of reasonably long high-energy Rydberg series in uranium by Solarz *et al.* (1976) who obtained the value 49958.1(4.0) cm^{-1}. In the Solarz technique, delayed ionization by use of a CO_2 laser was employed to separate the short-lived valence levels from the long-lived Rydberg levels enabling their detection in the very complex spectrum. The photoionization limit was often determined first to limit the scan range needed for measuring Rydberg levels to less than 50 to 100 cm^{-1}. Such a limit is usually easy to detect by the sharp rise in ions as the photoionization laser is scanned in a multi-step excitation scheme. These were normally determined with the apparatus used in the configuration without delayed field ionization (Worden *et al.*, 1978). In an experiment similar to that of Solarz *et al.*, Coste *et al.* (1982) used delayed field ionization to measure an

Table 16.5 *First IPs (IP_{exp}) of the actinide elements determined by RIMS. Tabulated are also IPs (IP) from laser spectroscopy measurements. RA, Rydberg autoionization; RC, Rydberg convergence of relative long series.

IP of 49958.4(5) cm^{-1} for the U atom. The IP of neutral Np was measured at 50 536(4) cm^{-1} using similar laser techniques (Worden and Conway, 1979). These values are, respectively, 2 and 1% larger than Sugar's estimates (see Table 16.5). Rydberg levels have been measured by delayed field ionization and were created by a number of different processes (Worden *et al.*, 1978; Worden and Conway, 1980) including collisional ioniziation converging to the ground state and auto-ionization levels converging to excited levels in the ion. The IP of ^{239}Pu was measured using a number of laser methods by Worden *et al.* (1993) to obtain the value 48 604(1) cm^{-1}. The experiments included the observation and measurement of hfs of ^{239}Pu and the IS of ^{240}Pu–^{239}Pu in auto-ionization levels, the first such measurement for an actinide.

16.12 FIRST IONIZATION POTENTIALS OF THE ACTINIDES BY RESONANCE IONIZATION MASS SPECTROMETRY

The first IPs of the common lighter actinide elements Th, U, Np, and Pu have been determined by laser spectroscopy (Solarz *et al.*, 1976; Worden and Conway, 1979; Coste *et al.*, 1982, Johnson *et al.*, 1992; Worden *et al.*, 1993). The most precise measurements were performed by the study of long-lived Rydberg series converging to one or more limits in the ion. For these elements, gram amounts of the metal were readily available for use in experiments. About 1 g of material was used to determine the IP of Np by these techniques (Worden and Conway, 1979). As much as 2 g of ^{239}Pu was used for the determination of the IP of ^{239}Pu by the observation of the threshold of ionization and of a large number of Rydberg series that converged to five separate limits in the ion (Worden *et al.*, 1993). A large amount of other types of spectroscopy was done with these samples that was not part of the IP determination and has not been published.

RIMS, first developed for ultra-trace analysis of actinide nuclides (Ruster *et al.*, 1989), has been introduced as a method that allows the accurate determination of the first IP of the actinides with samples of only 10^{12} atoms ($\sim$400 pg) or less. This makes possible the measurement of IPs of the heavier actinides and some light actinides that can be conveniently handled only in small quantities because of the strong radioactivity or that may be available only in very limited amounts.

The method is based on the determination of the photoionization thresholds in the presence of an external electric field and is explained in detail in a number of papers (Riegel *et al.*, 1993; Trautmann, 1994; Köhler *et al.*, 1997; Erdmann *et al.*, 1998). There it is shown that the observed ionization threshold is proportional to the square root of the electric field strength E. For the determination of the first IP, the wavelength of the laser for the ionizing step in a multi-step process is scanned across the threshold in the presence of E. The ionization threshold $W_{th}(E)$, the total energy of the exciting lasers, is indicated by a sudden increase of the ion count rate. This procedure is repeated for various electric

field strengths and the extrapolation of $W_{th}(E)$ to zero field strength leads to the energy of the first IP.

The experimental set-up (Ruster *et al.*, 1989) for resonance ionization mass spectrometry generally consists of three tunable dye lasers pumped by two pulsed copper vapor lasers (6.5 kHz pulse repetition rate, with 30 and 50 W average output power, 30 ns pulse duration) and a time-of-flight (TOF) mass spectrometer. The dye laser beams are focused into the TOF region where they interact perpendicularly with the atomic beam of the element under investigation. Ionization by two- or three-step resonant laser excitation takes places in the presence of an electric field. The importance of 6.5 kHz excitation is for efficient excitation of the atoms in the atomic beam of this set-up. Special care is taken to make the electric field homogenous and to keep it free of stray electric fields by use of corrective electrodes.

For the determination of the first IP of actinium (Waldek *et al.*, 2001), a frequency doubled titanium–sapphire laser pumped by a NdYAG laser (Grüning *et al.*, 2004) was used for one-step resonant excitation and a dye laser for the ionization step. In all experiments, the wavelengths of the laser beams were measured by pulsed wavemeters with a precision of $\Delta\lambda/\lambda = 10^{-6}$.

One crucial part for the application of resonance ionization mass spectrometry to determine the first IP is the creation of an atomic actinide beam. This is achieved by resistive heating of a sandwich filament consisting of a thin tantalum foil on which the element under investigation is electrochemically deposited in the form of the hydroxide (3 mm spot) and covered with a thin layer ($\sim$1 μm) of titanium or zirconium produced by sputtering. By heating such a sandwich filament, the hydroxide is converted to the oxide, which is reduced to the metallic state during diffusion through the covering layer. For the elements of uranium up to fermium, a titanium layer was used whereas for actinium the reduction by titanium was not efficient and therefore zirconium was used. Efficient release from these filaments occurs at temperatures between 800 and 1200°C, depending on the element. For protactinium, it was not possible to produce an atomic beam in this way, not even with thorium as reducing agent. As a result, an experimental value of the first IP of protactinium with RIMS is still missing.

For all the measurements of the photoionization thresholds either two-step (Ac, Np) or three-step (Th, U, Pu, Am, Cm Bk, Cf, Es) excitation schemes were used, each starting from the atomic ground state (Table 16.6). The wavelengths for the excitation steps were selected by use of energy levels published by Blaise and Wyart (1992) or by finding levels with scans of the appropriate laser. The photo-ionization thresholds were determined with various electric field strengths of 1.6–340 V cm^{-1}. The precision of the photo-ionization threshold method was checked by the re-determination of the first IP of Th, U, Np, and Pu. There is excellent agreement as can be seen from Table 16.5. With quantities of only $\sim 10^{12}$ atoms each, the first IPs of Ac, Am, Cm, Bk, Cf, and Es were determined for the first time by RIMS. Plots of the obtained ionization

Table 16.6 *Excitation schemes of the actinide elements used for the determination of the first IP by RIMS. The last step laser wavelength is approximate because the laser is scanned in the presence of an electric field of various voltages.*

thresholds of these elements versus the square root of the applied electric field strength E are shown in Fig. 16.10. The values fit perfectly the linear extrapolation to zero field strength by least-squares fits. The first IP of all the actinide elements from Ac to Es with the exception of Pa have been determined with RIMS (Riegel *et al*., 1993; Trautmann, 1994; Deissenberger *et al*., 1995; Köhler *et al*., 1996, 1997; Erdmann *et al*., 1998; Peterson *et al*., 1998; Waldek *et al*., 2001). The results are summarized in Table 16.5 together with experimental data obtained by other methods and published in the literature (Solarz *et al*., 1976; Worden and Conway, 1979; Johnson *et al*., 1992; Worden *et al*., 1993) as well as with predictions from extrapolation of spectroscopic data (Sugar, 1974). The uncertainties of the RIMS values are statistical errors given as two standard deviations (2σ) derived from the least-squares fits including weighted errors for each data point.

An attempt to determine the first IP of Fm with 2 to 5×10^{10} atoms of ^{255}Fm ($t_{1/2} = 20.1$ h) with RIMS failed due to the short half-life of ^{255}Fm and the fact that no spectroscopic data for Fm were available. However, with a sandwich filament, where 2.7×10^{10} atoms of ^{257}Fm were electrodeposited on a Ta backing and covered with ~1 μm Ti, an atomic beam of Fm was produced at ~1000°C. The atoms were stored for ~40 ms in argon gas buffer-optical cell. They were resonantly excited and ionized with two beams of an excimer-dye consisting of a 200 Hz excimer pump laser that runs on XeF at wavelengths of 351/353 nm, and a one-step tunable dye laser. The resulting ions were identified after extraction from the optical cell with a quadrupole mass filter and a channeltron detector. Two atomic resonances of Fm were observed for the first time in this experiment at wavenumbers of 25099.80(4) cm^{-1} and 25111.80(4) cm^{-1}, and their lifetimes were estimated (Sewtz *et al*., 2003).

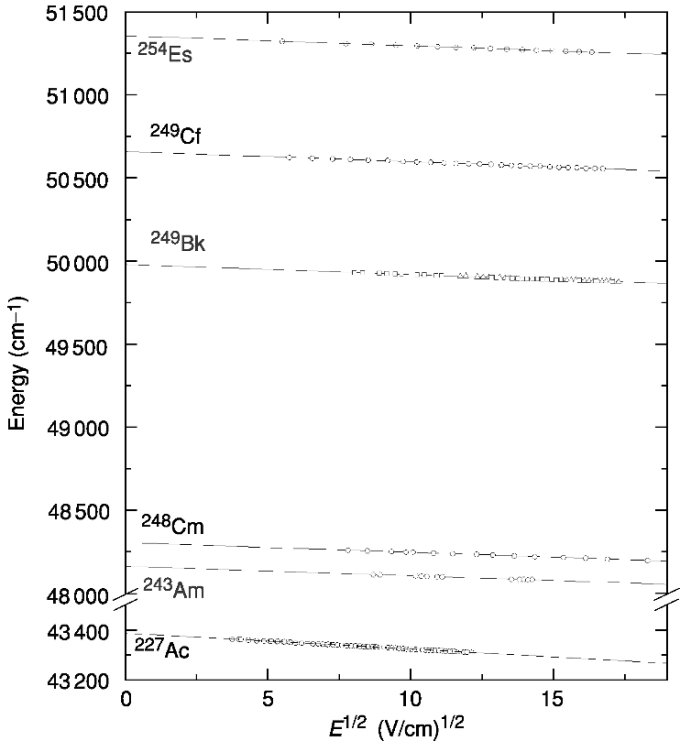

Fig. 16.10 *Plot of the measured ionization thresholds vs the square root of the electric field strength* E *for Ac, Am, Cm, Bk, Cf, and Es. Extrapolation to zero field strength yields the first IP. With this method, the first IPs of the six actinide elements shown here were determined experimentally for the first time.*

The ionization energies of the process $f^n s^2 \rightarrow f^n s$ were calculated by means of semiempirical Slater–Condon and *ab initio* HF calculations (Rajnak and Shore, 1978). For the lanthanides as well as for the actinides, the removal of an s-electron from the lowest $f^n s^2$ level producing an ion in the lowest $f^n s$ level is the most frequent mode of ionization in the f-series, and these ionization energies are called 'normalized IP–IP_n'. In all cases where the ground states differ from the configurations $f^n s^2$ and $f^n s$, corrections must be made by use of the known level energies of the lowest levels of the $f^n s^2$ and $f^n s$ configurations in the neutral and singly ionized atoms. In the lanthanide series (Worden *et al.*, 1978), it was observed that in a plot of IP_n versus n, the plot forms two straight lines connected at the half-filled shell ($n = 7$). The change in slope is interpreted as an effective exchange integral. A similar behavior is expected for the first IPs of the actinide elements.

In order to compare the experimental results with theoretical predictions (Sugar, 1974; Rajnak and Shore, 1978), the first IPs, normalized to

$5f^n7s^2 \rightarrow 5f^n7s$, are plotted versus the number of 5f electrons in Fig. 16.11. The experimental values of the heavier actinide elements are a little bit lower than the extrapolated data (Sugar, 1974) and slightly above the HF calculations (Rajnak and Shore, 1978). For the lighter actinides, the experimental IPs show strong deviations from the linear dependence, which might be connected to the fact that the ground states differ from f^ns^2 and most likely are due to CI. As pointed out (Rajnak and Shore, 1978), the actinide IPs should follow the trend for binding energies of the s-electrons by forming two straight lines, with a change of slope at Am, the half-filled f-shell. While the early actinides show considerable scatter, the higher actinides do follow the predicted behavior very well.

The high precision of RIMS in measuring the first IP of the actinides may also enable a determination of the isotope dependence of the IP, especially for elements which differ significantly in their neutron number, like ^{232}U and ^{238}U or ^{236}Pu and ^{244}Pu. The extension of the method to elements beyond Fm is difficult due to the limited amounts of material available and the short half-lives of the transfermium isotopes. For such investigations with online produced isotopes, an apparatus for RIMS in a buffer gas cell has been developed and might be suitable (Backe *et al.*, 1997). This method is based on resonance ionization in an argon buffer gas cell followed by ion-guide extraction and mass-selective direct detection of the resonantly ionized atoms.

16.13 LASER SPECTROSCOPY OF SUPER-DEFORMED FISSION ISOMERS OF AMERICIUM

Fission isomers are interpreted as shape isomers (Bjornholm and Lynn, 1980; Metag *et al.*, 1980) corresponding to a second minimum in the potential energy surface (Strutinsky, 1967, 1968). The structure of the fission barrier with a double hump results from the superposition of shell corrections to the nuclear binding energy onto the rather flat maximum of the macroscopic part of the deformation energy as described by the liquid drop model. The double-humped fission barrier explains the basic features of fission isomers; e.g. their excitation energy of 2–3 MeV, their stability against γ-decay due to the inner barrier, and their short half-lives for spontaneous fission determined by the penetration of the outer barrier that is much smaller than the barrier for the spontaneous fission decay from the ground state. The fission isomers are mainly located in the actinide region and their half-lives are in the ps- to ms-range and thus 24–30 orders of magnitude shorter than those for spontaneous fission from the respective nuclear ground states.

The deformation parameter, the magnetic moment, and the nuclear spin can best be obtained by optical IS and hfs spectroscopy (Otten, 1989). These are valuable data for testing nuclear matter in the state of extreme deformation as is the case for fission isomers. A measurement of the IS allows the determination of the nuclear deformation parameter β_2. If the IS can be measured in chains of fission isomers, information on the stability of nuclear deformation as a function of the neutron number can be obtained. Furthermore, by resolved optical hyperfine spectroscopy, the intrinsic quadrupole moment, the nuclear spin, and the g-factor can be deduced. However, such experiments are not easy to perform due to the low production rate of fission isomers, on the order of a few per second and their very short half-lives ($t_{1/2} \leq 14$ ms).

Bemis and coworkers (Bemis *et al.*, 1979) provided the first direct experimental proof for the large deformation in ^{240f}Am ($t_{1/2} = 0.9$ ms) by laser spectroscopy. With the laser-induced nuclear polarization (LINUP) technique, they determined the relative IS ratio $IS^{240f/241}/IS^{243/241} = 26.8\ (20)$ by measuring the 640.5 nm optical transition ($^{10}P_{7/2} \rightarrow {}^{8}S_{7/2}$) for the isotopes ^{240f}Am, ^{241}Am, and ^{243}Am.

In order to extend the optical measurements on fission isomers, an ultrasensitive technique, radioactive-detected resonance ionization spectroscopy (RADRIS) in a buffer gas cell, has been developed (Backe *et al.*, 1992b, 1998) to perform hyperfine spectroscopy of fission isomers produced in heavy-ion-induced reactions. The method is based on resonance ionization in a buffer gas cell combined with radioactive decay detection and its feasibility was demonstrated with the β-active isotope ^{208}Tl (Lauth *et al.*, 1992). The first experiment on ^{242f}Am with the RADRIS technique was done at the Max-Planck-Institut für Kernphysik in Heidelberg (Backe *et al.*, 1992b). The experimental set-up is shown in Fig. 16.12. The ^{242f}Am fission isomers were produced via the reaction

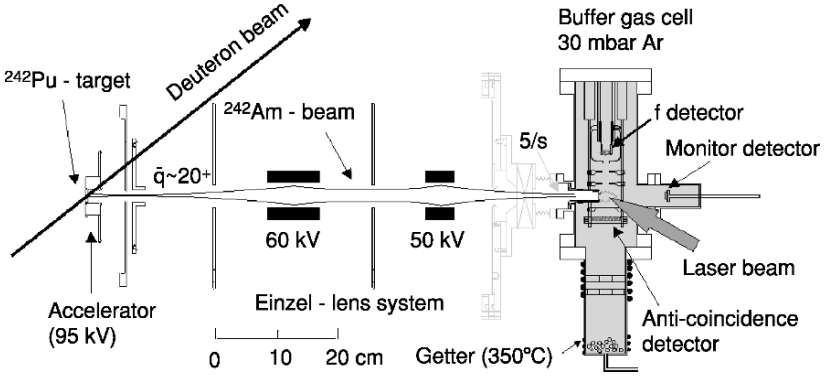

Fig. 16.12 *Experimental set-up for fission-detected resonance ionization spectroscopy in a buffer gas cell* (*Backe* et al., 1998). *For the production of* ^{242f}*Am a deuteron beam hits a* ^{242}*Pu-target and the fission isomers recoiling out of the target are accelerated and focused with an Einzel-lens system onto the entrance window of the optical buffer gas cell. The anti-coincidence fission detector is a PIN PD chip and the fission detector a windowless PIN photodiode. A dye laser and an excimer laser are used for resonance excitation and ionization. Getter techniques are applied to purify the gases.*

^{242}Pu (d,2n) ^{242f}Am by using a pulsed (5 ms on, 5 ms off) 12 MeV deuteron beam on a 50 μg/cm^2 $^{242}PuF_3$-target with a thin carbon backing. The fission isomers leaving the target have a recoil energy <100 keV and non-equilibrium ionic charge states between 10^+ and 35^+ (Metag *et al.*, 1980) as a result of conversion electron transitions followed by Auger cascades. After post-acceleration at a potential of 95 kV, the energy of the fission isomers was high enough to penetrate a 50 μg/cm^2 thick entrance window of the optical cell. On their way to the buffer gas cell, the fission isomers were focused with an Einzel-lens system. The ^{242f}Am beam at the entrance of the cell amounted typically to 5/s at a deuteron beam current of 5 μA. The optical cell, filled with 30 mbar argon and as quenching gas 0.3 mbar nitrogen, was loaded with the fission isomers during the beam-on periods. A fraction of ~15% of the recoiling ions was neutralized in the gas (Backe *et al.*, 1992a). The ions, not neutralized in the collision with the buffer gas, were fixed onto a thin electrode foil (250 μg/cm^2) in front of the anti-coincidence fission detector by applying an electric field. The gas acted as a storage medium for the neutral fission isomers. The diffusion time to the cell walls has been estimated to be ~30 ms. Resonance ionization was performed in the beam-off periods by two-color excitation/ionization. For this, an excimer laser (EMG 104 MSC, Lambda Physik) lasing with XeF at 351 and 353 nm for the second step and a dye laser (FL 2001, Lambda Physik) for the first excitation step were used. The resonantly ionized fission isomers were transported within 1.40(8) ms in an electric field of the ion electrode system to the fission detector. Fission events originating from isomers sticking on the foil

in front of the anti-coincidence detector or from neutrals in the gas phase were completely rejected by the signal, which the simultaneously emitted second fission fragment generated in the anti-coincidence detection. The bandwidth of the dye laser could be improved from 6 to 1.5 GHz by means of an intercavity etalon. Wavelength calibrations and the optimization of the laser system were performed in an off-line buffer gas cell with the long-lived α-active isotopes ^{243}Am and ^{241}Am (Backe *et al.*, 1993). During the online experiments, the wavelength of the dye laser was continuously monitored with absorption in Te_2 vapor (Cariou and Luc, 1980).

In addition to the fission isomer ^{242f}Am, the ^{240f}Am and ^{244f}Am fission isomers were produced. The reaction ^{242}Pu(p,3n) ^{240f}Am (σ = 10 μb) with a pulsed (2 ms on, 2 ms off) proton beam of 23 MeV energy (Backe *et al.*, 1998) produced the ^{240f}Am fission isomer. A 14 MeV deuteron beam on a ^{244}Pu target of 30 μg/cm^2 thickness (2 ms on, 2 ms off) was used to create the ^{244f}Am fission isomer with $t_{1/2}$ = 1.0 ms via the reaction ^{244}Pu (d,2n) ^{244f}Am (Backe *et al.*, 2000). The target consisted of $^{244}PuO_2$ (97.88% ^{244}Pu) on a thin carbon backing (34 μg/cm^2).

Most of the measurements were done with ^{242f}Am. The IS of ^{242f}Am has been measured for three optical transitions for which the IS values IS$^{243/241}$ between the ^{243}Am and ^{241}Am isotopes are known (Worden, 1991–1993; Blaise and Wyart, 1992). The initial IS measurement was performed at λ_1 = 468.17 nm (Backe *et al.*, 1992b, 1993). An IS$^{242f/241}$ (468 nm) = –1.18(9) cm^{-1} was determined, corresponding to an IS ratio IS$^{242f/241}$/IS$^{243/241}$ = 24.6(24) using IS$^{243/241}$ = 0.048(3) cm^{-1} for this wavelength. A second measurement (Backe *et al.*, 1998) with λ_1 = 499.08 nm yielded an IS$^{242f/241}$ (499 nm) = +2.83(9) cm^{-1} and an isotope ratio IS$^{242f/241}$/IS$^{243/241}$ = 44.9(26) with IS$^{243/241}$ (499 nm) = 0.063(3) cm^{-1}. The disagreement of the two isotope ratio values originates from an anomaly in the 468.17 nm transition caused by configuration mixing. The same explanation can be given for the disagreement with the ~41 value and the value of 26.8 obtained by Bemis *et al.* at the 640.5 nm transition. The configuration mixing is between the 15608 cm^{-1} level and a level at 15273 cm^{-1} of the same parity and J with a large IS of opposite sign. A third measurement (Backe *et al.*, 1996, 1998) at λ_1 = 500.02 nm resulted in an IS$^{242f/241}$ (500 nm) = +10.358(14) cm^{-1}. The isotope ratio of IS$^{242f/241}$/IS$^{243/241}$ = 41.4(8) was obtained with IS$^{243/241}$ = 0.250(5) cm^{-1} in good agreement with the value at λ_1 = 499.08 um.

The IS measurements of ^{240f}Am at the 500 nm transition (Backe *et al.*, 1998) delivered a resonance signal just 0.56 cm^{-1} away from the one of ^{242f}Am. The IS$^{240f/241}$ = 9.80(3) cm^{-1} corresponds to an IS ratio IS$^{240f/241}$/IS$^{243/241}$ = 39.2(8). The IS of ^{244f}Am relative to ^{241}Am at a wavelength of 500 nm was determined to be IS$^{244f/241}$ = 10.49(4) cm^{-1}, with a signal very close to ^{240f}Am and ^{242f}Am, which gives an IS ratio IS$^{244f/241}$/IS$^{241/243}$ = 42.0(9) (Backe *et al.*, 2000, 2001). Fig. 16.13 summarizes the resonance ionization signals at the 500.02 nm transition of the fission isomers ^{244f}Am, ^{242f}Am and ^{240f}Am relative to ^{241}Am.

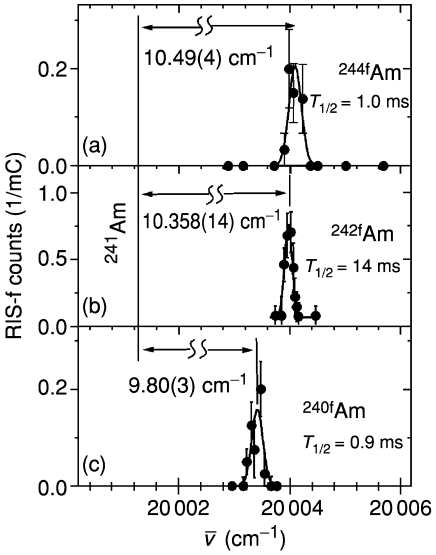

Fig. 16.13 *Resonance ionization signals of the fission isomers* ^{244f}*Am* (*a*), ^{242f}*Am* (*b*), *and* ^{240f}*Am* (*c*) *at the* 500.02 nm *transition* (*Backe* et al., 2001). *The IS values to the reference isotope* ^{241}*Am are indicated.*

Table 16.7 *Isotope shifts* $IS^{24xf/241}$, *IS ratios* $IS^{24xf/241}/IS^{243/241}$, *and nuclear parameters* $\lambda^{24xf/241}$ *for the fission isomers* ^{240f}*Am,* ^{242f}Am, and ^{244f}*Am. The measurements were performed at the* 500 nm *transition. The deformation parameters* β_2 *and the quadrupole moments* Q_{20} *have been calculated with the deformed droplet model* (*Backe* et al., 2001).

Isomer	$IS^{24xf/241}$ (cm^{-1})	$IS^{24xf/241}/IS^{243/241}$	$\lambda^{24xf/241}$ (fm^2)	β_2	Q_{20} (eb)
^{240f}Am	9.80(3)	39.2(8)	5.06(30)	0.690	33.9
^{242f}Am	10.358(14)	41.4(8)	5.34(28)	0.699	34.5
^{244f}Am	10.49(4)	42.0(9)	5.41(31)	0.694	34.4

In the determination of the deformation of the fission isomeric states, the mass shift contributions were neglected because the normal mass shift is only 0.004% of the measured IS of the fission isomers. The deformation parameters β_2 and the intrinsic quadrupole moments Q_{20} of the fission isomeric states have been evaluated (Backe *et al.*, 1998) on the basis of the droplet model (Meyers and Schmidt, 1983) and from the nuclear parameters employing a charge distribution of the deformed Fermi model (Brack *et al.*, 1974) with the assumption that the IS between ^{243}Am and ^{241}Am comes from a pure nuclear volume change. The results obtained with the deformed droplet model are presented in Table 16.7 for the three fission isomers of Am. In the analysis, a hexadecapole parameter $\beta_4^{II} = 0.08$ has been assumed, which is a theoretical prediction value

(Howard and Möller, 1980). The small differences of the nuclear charge parameters of the three fission isomers (e.g. $\Lambda^{244f/242f} = 0.069(21)$ fm^2) result in small changes of the deformation parameters β_2 and the quadrupole moments Q_{20}, as can be seen from Table 16.7.

Precise IS measurements are now available for the fission isomers ^{240f}Am, ^{242f}Am, and ^{244f}Am obtained with the fission RADRIS method in a buffer gas cell at very low production rates of ~5/s. The results demonstrate the stability of the deformation in the second potential minimum if neutron pairs are added in accordance with earlier calculations (Howard and Möller, 1980). The experimentally determined deformation parameters are a little bit larger than the theoretically calculated value $\beta_2 = 0.61$ (Howard and Möller, 1980). The laser spectroscopic method corroborates independently the charge plunger measurements (Metag *et al.*, 1980) and confirms the extreme deformation of fission isomers. To illustrate this, Fig. 16.14 shows the quadrupole moments of fission isomers and nuclear ground states for the lighter actinides. First hyperfine spectroscopic measurements, required for the determination of the nuclear spin and the *g*-factor, have been performed at the 466.28 nm transition of ^{242f}Am (Backe *et al.*, 1996). From the obtained data, a negative *g*-factor and a spin of $I = 2$–3 were derived (Lauth *et al.*, 1998). However, more detailed deformed shell-model calculations are required for the interpretation of the measured *g*-factor of ^{242f}Am. In addition to the results obtained with resonance ionization spectroscopy in a buffer gas cell, this method should also be applicable for studies of the atomic and nuclear properties of transeinsteinium elements (Backe *et al.*, 1997; Sewtz *et al.*, 2003).

APPENDIX 16.1 THE CONSTRUCTION OF Es ELECTODELESS LAMPS

The design and construction of the EDL was modified when amounts of ~100 μg or more of Es became available because of the poor yields (<15%) obtained with no carrier element present (Worden *et al.*, 1968, 1970, and especially Worden *et al.*, 1974). The vacuum system used to prepare the pure Es lamps is shown in Fig. A16.1. A 6 mm outer diameter (o.d.) quartz frit was used to collect and wash ~100 μg of Es oxalate precipitated from a recently purified Es solution taken from a resin column. The high specific activity (5.6×10^{10} alpha activity per min per microgram) of ~100 μg of Es prevented collecting and washing of the precipitate in the usual 6 mm o.d. cone (because the intense alpha activity stirred up the solid) as done in normal lamp preparation. The quartz frit was inserted into reaction tube (at this point not sealed to the vacuum system as shown in Fig. A16.1) and the Es oxalate converted to Es_2O_3 by heating with a torch to red heat in the quartz frit with air present. The constriction at B was then made with a torch while holding the reaction tube vertical. The reaction tube was then turned horizontal and sealed to the Pyrex system at A in Fig. A16.1.

The assembly was pumped down to high vacuum ($<10^{-3}$ Pa) and the entire quartz part of the assembly was out-gassed with a tube furnace at ~1000°C. The thin capillary containing the AlI_3 was moved so that the iron slugs could break the tip using external magnets. Then the capillary assembly was moved so that the tip of the capillary was inside the reaction tube at constriction B. The AlI_3 was then sublimed into the reaction tube with a torch. The Es material and sublimed AlI_3 reactant and the final lamp were sealed off together at point B under high vacuum. The reaction at 560°C was carried out in a tube furnace with the reaction tube and lamp blank contained in a stainless steel tube with a

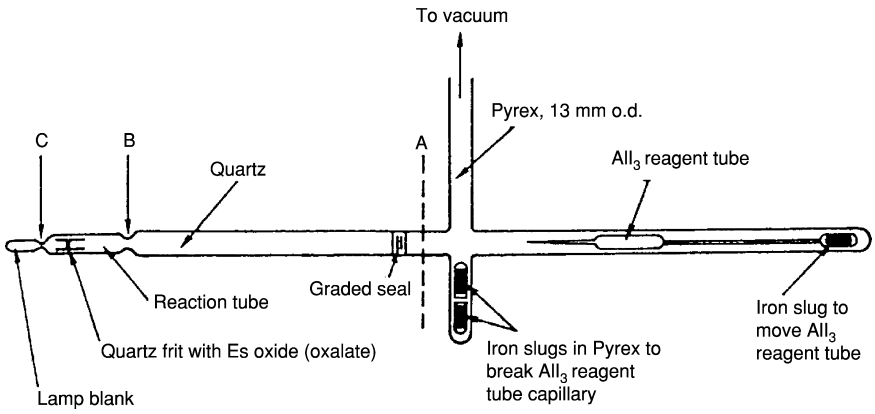

Fig. A16.1 *Vacuum apparatus for the preparation of einsteinium electrodeless lamps.*

sealed screw top for about 3 h. The stainless steel tube was cooled and the reaction tube and lamp blank removed. The product EsI_3 plus the excess AlI_3 was sublimed at ~750–800°C into the lamp blank cooled with wet asbestos cloth on the end of the lamp. The oven temperature was then reduced to ~500°C and the AlI_3 and other high vapor pressure impurities were sublimed into the reaction tube cooled with wet asbestos cloth. The lamp was then separated from the reaction tube at point C using a torch with wet asbestos cloth covering the lamp and reaction tube. This produced a lamp with up to 90% of the Es in the lamp, but also many impurities. The lamp life was about the same as lamps of other actinides prepared by the standard technique.

These procedures for the pure Es lamps were carried out at ANL so the time from purification of the 20.5 day half-life ^{253}Es to observation of the spectrum on the ANL spectrograph was reduced. The minimum time for the process was reduced to about 12 h vs the previous times of 2–3 days.

ACKNOWLEDGMENTS

This work was performed in part under the auspices of the U.S. Department of Energy by University of California, Lawrence Livermore National Laboratory under Contract W-7405-Eng-48. CHAPTER SEVENTEEN

THEORETICAL STUDIES OF THE ELECTRONIC STRUCTURE OF COMPOUNDS OF THE ACTINIDE ELEMENTS

Nikolas Kaltsoyannis, P. Jeffrey Hay, Jun Li,
Jean-Philippe Blaudeau, and Bruce E. Bursten

17.1 INTRODUCTION

In this chapter, we will present an overview of the theoretical and computational developments that have increased our understanding of the electronic structure of actinide-containing molecules and ions. The application of modern electronic structure methodologies to actinide systems remains one of the great challenges in quantum chemistry; indeed, as will be discussed below, there is no other portion of the periodic table that leads to the confluence of complexity with respect to the calculation of ground- and excited-state energies, bonding descriptions, and molecular properties. But there is also no place in the periodic table in which effective computational modeling of electronic structure can be more useful. The difficulties in creating, isolating, and handling many of the

actinide elements provide an opportunity for computational chemistry to be an unusually important partner in developing the chemistry of these elements.

The importance of actinide electronic structure begins with the earliest studies of uranium chemistry and predates the discovery of quantum mechanics. The fluorescence of uranyl compounds was observed as early as 1833 (Jørgensen and Reisfeld, 1983), a presage of the development of actinometry as a tool for measuring photochemical quantum yields. Interest in nuclear fuels has stimulated tremendous interest in understanding the properties, including electronic properties, of small actinide-containing molecules and ions, especially the oxides and halides of uranium and plutonium. The synthesis of uranocene in 1968 (Streitwieser and Müller-Westerhoff, 1968) led to the flurry of activity in the organometallic chemistry of the actinides that continues today. Actinide organometallics (or organoactinides) are nearly always molecular systems and are often volatile, which makes them amenable to an arsenal of experimental probes of molecular and electronic structure (Marks and Fischer, 1979). Theoretical and computational studies of the electronic structure of actinide systems have developed in concert with the experimental studies, and have been greatly facilitated by the extraordinary recent advances in high-performance computational technology.

We will focus on computational studies of the electronic structure of discrete (molecular or ionic) actinide-containing systems. We begin by discussing some of the general tenets of bonding that are relevant to the actinide elements and some of the challenges that are unique to this field. We then present the results of computational electronic structure studies on a variety of molecular actinide systems. The literature of molecular electronic structure of actinide systems has been compiled by Pyykkö (1986, 1993, 2000b), as well as being available as a database on the web (http://www.csc.fi/rtam). Pepper and Bursten (1991) reviewed the methodology and applications in the field in 1991. The reader is referred to those reviews for some of the details on earlier studies in this field. We restrict our discussion in this chapter to molecular actinide systems and do not discuss the extensive body of research in the use of theoretical electronic structure methods to model solid-state actinide chemistry. The reader is referred to Chapter 21 and some recent review articles (Lander *et al.*, 1994; Soderlind, 1998; Wills and Eriksson, 2000) for discussions of theoretical electronic structure methods applied to the metallic actinide elements and solid-state actinide compounds. We will also have minimal discussion of compounds of the transactinide elements in this chapter. The electronic structure of compounds of the transactinides is discussed in Chapter 14 and in the excellent review by Pershina (1996).

17.1.1 Electronic structure of actinide atoms

The challenge in undertaking theoretical studies of actinide complexes begins, of course, with the complex electronic structure of the actinide atoms. The lanthanide and actinide elements are distinct from the p- and d-block elements

in having f-orbitals as part of the active valence orbitals of the atom. The methodologies that can be successful in describing the electronic structure of such systems must obviously be able to accommodate valence f-orbitals. The historical development of methods that could handle f-electrons has been discussed by Pepper and Bursten (1991) and will be briefly recounted later in this chapter.

The most common representation of the angular functions of the seven real f-orbitals is presented in Table 17.1 and Fig. 17.1. Real orbitals are constructed by forming linear combinations of the spherical harmonics $Y_{l,m_l}(\theta,\phi)$ with common $|m_l|$ values, such as $Y_{3,1} \pm Y_{3,-1}$. The resulting real orbitals can be described with Cartesian labels in the same way we do for p- and d-orbitals. They are characterized by a distinct $|m_l|$ value, giving axially quantized orbitals of σ ($m_l = 0$), π ($|m_l| = 1$), δ ($|m_l| = 2$), and ϕ ($|m_l| = 3$) symmetry with respect to the z-axis. In addition, a set of f-orbitals convenient for systems with cubic symmetry can be formed via linear combinations of these real f-orbitals (see, for example, Cotton, 1990).

Both the lanthanide and actinide elements have valence f-orbitals, but they have distinct differences that originate in electronic structure. The 5f orbitals of the actinide elements are in close energetic proximity to other valence orbitals, which leads to complex and fluctuating electron distributions for the early actinide elements. Table 17.2 compares the ground electron configurations of isovalent lanthanide and actinide atoms. It is evident that, when comparing the early members of each series, the 6d orbitals of the actinide elements are more energetically accessible than are the 5d orbitals of the lanthanide elements. The radial functions for the outer orbitals of actinide atoms also indicate that the characterization of these elements as ones for which the chemistry is dominated by the behavior of the 5f electrons might be considered somewhat of a misnomer. Fig. 17.2 shows the radial functions obtained for the Pu atom from recent relativistic Cowan–Griffin *ab initio* atomic calculations of Seijo *et al.* (2001). As expected, the 7s and 6d radial functions are significantly more diffuse than the 5f radial function. Somewhat more surprising, the 6s and 6p orbitals, which are typically considered to be core orbitals, have radial functions of comparable or greater extension than the 5f radial function. These results underscore the fact that the electronic structure of actinide atoms can involve complex electron occupancies that span several different n and l values, even in the absence of spin–orbit effects.

The fact that there are so many atomic orbitals (AOs) in spatial and energetic proximity near the highest valence level of the actinide atoms leads to another complicating factor in describing the electronic structure of actinide systems, namely the presence of a large number of electronic states close to the ground state. Particularly for the early actinides and their simple ions, the presence of multiple $5f^n6d^m7s^k$ configurations of comparable energy, and the energetically close multiplets that can arise from each of these configurations, leads to the enormously complex state energetics and optical spectra observed for these

systems (Wybourne, 1965; Dieke, 1968; Carnall and Crosswhite, 1986). With the exception of $5f^1$ complexes (Kaltsoyannis and Bursten, 1995; Seijo and Barandiarán, 2001), the various multiplets of actinide systems in general cannot be described within a single-configuration framework, which has greatly hindered the use of first-principles calculations of the electronic state energies. As a result, until recently most efforts to understand the optical spectra of actinide ions involved crystal-field models that incorporated empirically obtained parameters (Crosswhite and Crosswhite, 1984; Carnall, 1992). In

[a] There have been discussions about whether the lanthanide and actinide series should begin with La and Ac, respectively, as has been done here, or with Ce and Th, respectively. See Jensen (1982).

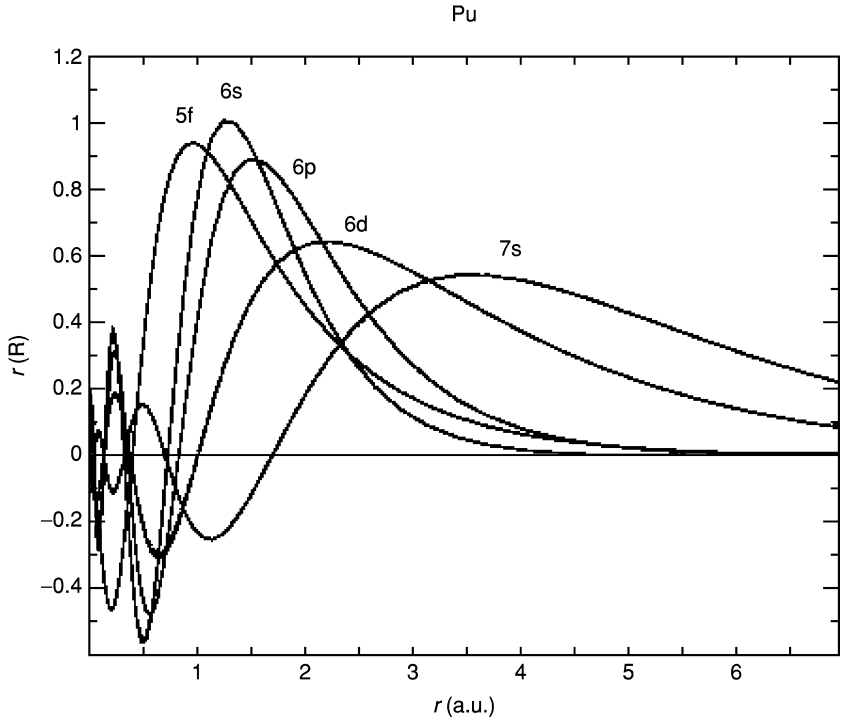

Fig. 17.2 *Radial functions for the outer orbitals of a Pu atom from relativistic atomic calculations* (*reproduced from Seijo* et al., 2001).

recent years, correlated electronic structure methods with spin–orbit operators have been used to address optical excitations in f^n ($n > 1$) actinide-containing systems (Matsika and Pitzer, 2000; Gagliardi *et al.*, 2001b; Matsika *et al.*, 2001; Mochizuki and Tatewaki, 2002), but this still remains as one of the biggest challenges in computational actinide chemistry.

17.1.2 Relativistic effects

Another challenge in describing the electronic structure of the actinide and transactinide elements is the necessity to include the effects of relativity on the behavior of the electrons. Although Dirac (1929) merged special relativity and quantum mechanics in 1929, and Breit (1932) extended Dirac's ideas to many-electron systems shortly thereafter, the importance of relativistic corrections in molecular quantum chemistry was not fully appreciated until the 1970s. Dirac himself was not convinced of the importance of relativistic effects, which he said would be "of no importance in the consideration of atomic and molecular structure and ordinary chemical reactions" (1929). Dirac clearly understated the chemical consequences of his discovery! Beginning with the third-row transition metal atoms, and even more so for the actinide and transactinide atoms, the high kinetic energy of the core electrons, which correspond to classical speeds close to the speed of light, leads to large relativistic effects. Powell (1968) presented an early and readily understood introduction to the derivation of Dirac's relativistic quantum mechanics and its impact on chemistry, and a number of more detailed reviews (Pyykkö, 1978, 1988; Pitzer, 1979; Pyykkö and Desclaux, 1979; Christiansen *et al.*, 1985; Balasubramanian and Pitzer, 1987; Ermler *et al.*, 1988; Balasubramanian, 1989; Schwarz, 1990; Kaltsoyannis, 1997; Bond, 2000) and monographs (Malli, 1983; Balasubramanian, 1989, 1994, 1997; Dolg and Stoll, 1996; Schwerdtfeger, 2002, 2004; Hess, 2003; Hirao and Ishikawa, 2004) over the last 25 years discuss the chemical consequences of relativistic effects in greater detail. We provide a brief recap here of the major relativistic effects that influence the electronic structure of actinide complexes.

Because most of the chemical distinctiveness of the actinide elements results from the presence of valence f-electrons, much of our focus will be on the effects of relativity on the 5f orbitals. The magnitude of many of the relativistic effects increases as Z^n (Z = atomic number; $n > 1$). Hence, relativistic effects are more pronounced for the actinide elements than for the lanthanide elements. This trend is apparent in Fig. 17.3, in which the nonrelativistic and Dirac–Fock relativistic atomic orbital energies obtained by Desclaux (1973) for lanthanide and corresponding actinide atoms are compared. This figure illustrates the two general classes of relativistic effects on the electronic structure, both of which are greater for the actinides than for the lanthanides. The first effect is the increase in the energies of the nf and $(n + 1)$d orbitals relative to the $(n + 1)$p and $(n + 2)$s orbitals ($n = 4$ and 5). These overall changes in the orbital energies are primarily due to 'classical' relativistic effects, such as the relativistic mass correction for core electrons, that lead to greater shielding of the higher l-value orbitals. The 5f orbitals in actinides are more destabilized by relativistic effects than are the 4f orbitals of the lanthanides. As a result, the valence 5f electrons in the actinide elements are more weakly bound, and hence more chemically active, than the 4f electrons in the lanthanide elements.

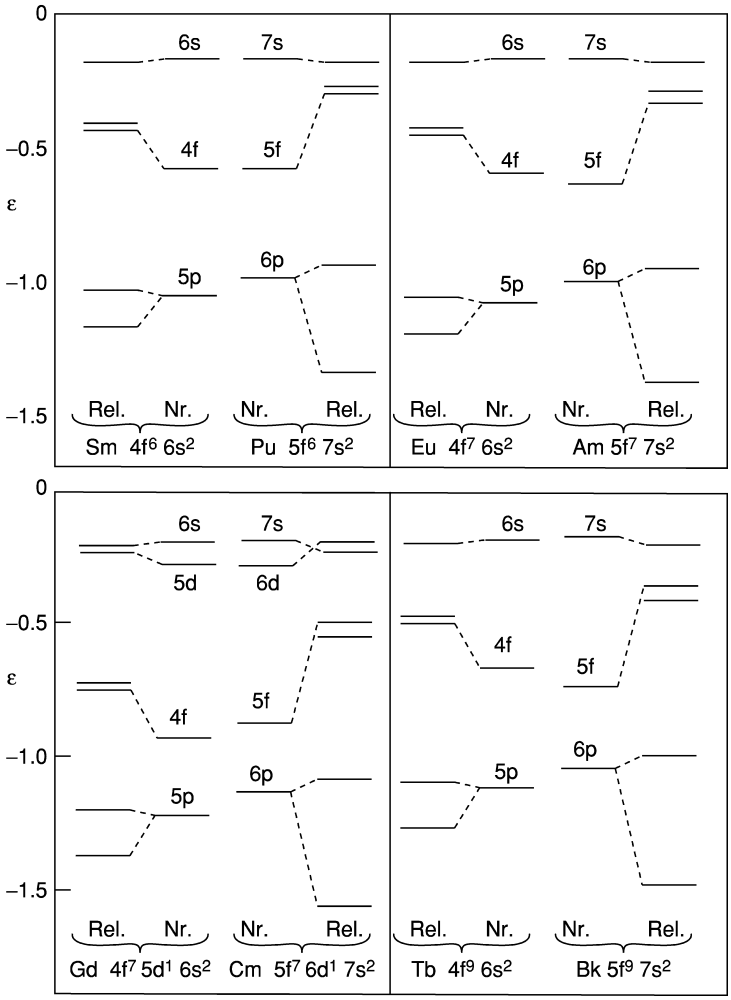

Fig. 17.3 *The Dirac–Fock average of configuration orbital energies* (a.u.) *obtained by Desclaux* (1973) *for the lanthanides Sm, Eu, Gd, and Tb and for the corresponding actinides Pu, Am, Cm, and Bk. The inner columns for each lanthanide–actinide pair denote nonrelativistic orbital energies. The shifts in energy due to the relativistic effects are evident in the relativistic orbital energies, displayed in the outer columns for each lanthanide–actinide pair* (*adapted from Pyykkö,* 1978).

The second relativistic effect is the splitting of subshells with $l \geq 1$ because of spin–orbit coupling, which can be considered a 'quantum' relativistic effect. The spin–orbit splitting generally decreases with the increase of l and with increasing orbital energy. In Fig. 17.3, for example, the $(n + 1)$p orbitals are split more

than the *n*f orbitals. These two classes of relativistic effects are lucidly discussed in a review by Pitzer (1979) and spin–orbit effects in molecules have recently been reviewed by Marian (2001).

The various methods for the inclusion of relativistic effects in electronic structure calculations have been discussed briefly by Pepper and Bursten (1991) and in greater detail by Balasubramanian (1997). They will also be developed more fully in Section 17.2. In general, the methods can be separated into two broad classes depending on how the relativistic effects are incorporated into the molecular Hamiltonian. In the so-called *scalar* relativistic methods, the relativistic mass–velocity and Darwin terms are incorporated into the Hamiltonian in such a way that preserves the separation of the spatial and spin components of the resultant wavefunction. Scalar relativistic methods thus generate wavefunctions that are bases for the representations of the familiar single point groups used in nonrelativistic calculations. Spin–orbit effects are not explicitly included in scalar-relativistic calculations, although they can be included via perturbative methods.

In the second general approach to relativistic molecular electronic structure calculations, the full Dirac equation is solved using a variety of simplifying formalisms, such as the Dirac–Fock approach that is the relativistic analog to nonrelativistic Hartree–Fock (HF) methods. Spin–orbit coupling is explicitly included in these methods, which yield four-component wavefunctions. The two small components, which are usually needed only for calculations involving electromagnetic field interactions, are often omitted from the molecular wavefunction. Because the spatial and spin components of the electronic wavefunction are coupled in these approaches, the calculated orbitals are bases for the less-familiar double point groups, which sometimes complicates the interpretation of the results.

As this chapter develops, we will see that scalar-relativistic methods, which use *LS* labels for the molecular states, are generally adequate for the calculation of many of the ground state properties of actinide systems, including molecular geometries and vibrational frequencies, although the reader is referred to the discussion concerning the plutonyl (PuO_2^{2+}) ion below. The calculation of excited state properties, especially optical excitation energies, almost always demands an approach that includes spin–orbit effects explicitly. When these effects are included, double-group labels are required. For example, for linear molecules, the states are labeled based on Ω values rather than on Λ values.

17.1.3 Actinide–ligand bonding: General considerations

In this chapter, we will address a number of different molecular and ionic systems that contain a variety of ancillary atoms and ligands bonded to an actinide center. Although these systems might appear at first glance to be very different, there are some general observations that can be made about the nature of the ligand-to-actinide bonding.

The actinide elements are classified as hard Lewis acids, especially in their more positive oxidation states (Katz *et al.*, 1986; Kaltsoyannis and Scott, 1999). The interactions of ligands with an actinide center are conventional Lewis acid–base interactions in which the ligand serves as an electron donor to a vacant acceptor orbital on the metal. In this sense, the formation of actinide–ligand complexes is entirely analogous to the formation of metal–ligand bonds in transition-metal coordination chemistry. There are several general factors that distinguish actinide coordination chemistry from that of the transition metals and the lanthanide elements:

(1) As hard Lewis acids, both the actinide and lanthanide ions generally prefer to coordinate hard Lewis bases such as F^-, O^{2-}, and other O-containing ligands, including OH^- and H_2O. Indeed, the chemistry of the actinides tends to be dominated by aqua complexes, fluorides, oxides, and oxyfluorides, although much of our subsequent discussion will involve different types of ligands, such as hydrocarbyls.
(2) The 4f orbitals of the lanthanides are too contracted in their radial distributions to be involved to any significant extent in covalent interactions with ligands, particularly in the +3 oxidation state that dominates lanthanide chemistry. The 5f orbitals of the early actinide elements are less contracted and can therefore have significant overlap with ligand orbitals. The 5f orbitals contract as one moves across the actinide series, which is consistent with the observation that the chemistry of the later actinides is similar to that of the lanthanides. As a consequence, the bonding in the lanthanides and the later actinides tends to be largely ionic, whereas significant covalent character can be found in the early actinides (Burns and Bursten, 1989).
(3) For most of the actinide (An) systems, we will see that the An 6d orbitals serve as more effective acceptor orbitals than the An 5f orbitals because the former are more diffuse than the latter. Thus, if a choice is allowed by symmetry, the ligands tend to interact more strongly with the 6d orbitals than the 5f orbitals. In centrosymmetric systems, such as the actinyl ions(AnO_2^{q+}), the actinide hexafluorides (AnF_6) and the actinocenes (An (η^8-$C_8H_8)_2$), interactions of the ligands with the An 6d and 5f orbitals will be partitioned based on the inversion symmetry of the ligand group orbitals.
(4) In most cases, any metal-based electrons will reside primarily in the 5f orbitals of the An center. For example, in U(IV) complexes the two electrons formally remaining on the U atom will be localized within the U 5f orbitals.

As noted earlier, the large number of An atomic orbitals generally leads to a large number of electronic states close to the ground state. Strong interactions of the An center with ligands serve to destabilize some of the An orbitals and greatly increase the energy of configurations that involve those orbitals. Thus, the distribution of states near the ground state can be somewhat simpler than that for free ions or atoms of the elements.

17.2 RELATIVISTIC APPROACHES FOR ELECTRONIC STRUCTURE OF ACTINIDES

A variety of methods are used in electronic structure calculations on actinide molecules. Some of these methods and their historical development were outlined in the 1991 review by Pepper and Bursten (1991). In this section, we will touch upon some of the salient features covered in that review as well as address recent developments and applications over the past decade. In discussing these theoretical approaches, it is useful to categorize them according to three aspects: (a) whether the electronic structure calculation is based on wavefunction-based *ab initio* approaches, such as Hartree–Fock and CI, or by density functional theory (DFT) approaches, such as local density and generalized-gradient methods; (b) the manner in which relativistic effects are included; and (c) whether the approach explicitly involves all-electron or only valence-electron character.

17.2.1 Hartree–Fock and density functional approaches

While electronic structure approaches for molecules differ in their methodologies, they share many common features. The starting point is the molecular energy expressed in terms of the total wavefunction for the molecule and a Hamiltonian describing the interactions. The total wavefunction, in turn, is comprised of an antisymmetrized product of one-electron molecular orbitals (ϕ_i). By applying the variational principle to the expression for the molecular energy, one obtains a set of self-consistent field (SCF) equations that are solved iteratively to obtain the molecular orbitals (MOs). The MOs are typically represented as linear combinations of atomic orbitals (LCAO), which may be expanded in terms of Gaussian- or Slater-type functions. From the molecular orbitals, one can then calculate the energy of the molecule, the total charge density, and other molecular properties.

In Hartree–Fock calculations, the exchange interaction is treated explicitly in the expression for the molecular energy:

$$E_{\mathrm{HF}} = E_{\mathrm{kin}} + E_{\mathrm{coul}} + E_{\mathrm{exch}}$$

where E_{HF}, E_{kin}, E_{coul}, and E_{exch} are the Hartree–Fock total energy, the electron kinetic energy, the Coulomb repulsion energy, and the exchange energy, respectively. The nonlocal Hartree–Fock exchange operator is associated with interchanging electrons of the same spin. Electron correlation effects are treated by including excitations from occupied to virtual levels by perturbation theory (e.g. second-order Møller–Plesset perturbation theory (MP2) to fourth-order Møller–Plesset perturbation theory (MP4)) (Møller and Plesset, 1934; Pople *et al.*, 1977), coupled-cluster theory (Bartlett, 1981, 1989), including coupled cluster with single and double excitations (CCSD; Purvis and Bartlett, 1982) and coupled cluster singles, doubles and perturbative triples (CCSD(T); Raghavachari *et al.*, 1989; Watts *et al.*, 1993), and configuration interaction

(CI, e.g. configuration interaction with single and double excitations [CISD]) (Shavitt, 1977; Szabo and Ostlund, 1989; Jensen, 1999).

DFT is based on the famous Hohenberg–Kohn theorem (Hohenberg and Kohn, 1964), which states that the electronic ground state of a molecule can be obtained uniquely from knowledge of the electron density $\rho(r)$ at all points in the molecule. Exchange and correlation effects are treated by the use of exchange and correlation functionals, which depend on the density, and lead to an expression for the energy similar to that for Hartree–Fock except for the 'exchange-correlation' energy, E_{xc}:

$$E_{DFT} = E_{kin} + E_{coul} + E_{xc}(\rho)$$

By expanding the electron density via a set of Kohn–Sham (KS) orbitals, one can derive the one-electron KS equation, similar to the Hartree–Fock equation (Kohn and Sham, 1965; Koch and Holthausen, 2001).

At the time of the 1991 review by Pepper and Bursten, DFT methods were very much in their infancy. At that time the majority of DFT methods used the local density approximation (LDA), in which the functional depends only on the density. Among the early LDA approaches that were widely applied to inorganic systems including actinides were the Xα-scattered wave (Xα-SW) and Dirac–Slater (DS) discrete variational (DV) methods, including early versions of the quasi-relativistic Hartree–Fock–Slater (HFS) approach (see relativistic methods in next section). At that time, the Xα variant of the LDA methods had questionable reliability with respect to the calculation of total energy and could not be used generally to determine geometries and vibrational properties. Pepper and Bursten (1991) made the following statement about DFT in the conclusion of their review:

> "Recent developments in density functional theory, including improved functionals and methods for the accurate calculation of binding energies, also bode well for computational actinide chemistry. These methods have the advantage of providing easily interpreted information about bonding interactions in actinide systems, and have proved useful for many years in organotransition metal and organoactinide chemistry. Again, the improved approaches are just beginning to be applied to actinide systems, with promising results."

Indeed, as will be evident in this chapter, DFT methods have become a major contributor to our understanding of actinide electronic structure. We will briefly discuss some of the major developments in DFT since the 1991 review, including the improved accuracies of molecular energies and other quantities using DFT methods as well as the development of improved functionals for DFT calculations.

Among numerous efforts in developing 'good' exchange-correlation functionals beyond the LDA, Becke (1988) developed a gradient-corrected exchange functional in 1988. This exchange functional depends both on the density, ρ, and on its gradient, $\nabla\rho$, at any point in space. In the past decade, developments by many individuals, including Lee *et al.* (1988), Perdew and Wang (1992),

Perdew *et al*. (1992), Becke (1993a), and others have led to new functionals [often known as generalized-gradient approximations (GGA)] for both exchange and correlation that have received wide usage by the community because of the improvements in orbital energies, bond energies, structures, and other properties.

In 1993 Becke launched another revolution in the density functional world by developing a 'hybrid' functional (Becke, 1993b). The hybrid approach differs in the treatment of exchange by adding a certain amount of the nonlocal exact exchange calculated in Hartree–Fock formalism to the local and gradient-corrected terms of the exchange functional of traditional DFT. Overall the form of the functional had three linear parameters that determined the amount of exact exchange as well as the relative amounts of local and gradient-corrected terms in the exchange and correlation functionals. The parameters were determined for a set of small organic molecules by the best fit to a set of experimental energies. When combining with appropriate correlation functionals (e.g. LYP and PW91), these functionals, denoted as B3LYP and B3PW91, have achieved great success in the computational chemistry of organic and inorganic molecules. The performance of these hybrid functionals in the prediction of thermochemical properties and molecular structures has led numerous investigators to apply these functionals to actinide chemistry as well.

Finally, another crucial development in the past decade for both Hartree–Fock and DFT methods has been the implementation of techniques for calculating the gradient and second derivative of the molecular energy as a function of nuclear coordinates. The information on the gradient gives directly the forces on the nuclei for a particular molecular configuration and this, in turn, enables the optimization of molecular geometries to be carried out routinely for various functionals, Hartree–Fock methods, and the hybrid approaches. Similarly the second derivatives provide the vibrational frequencies at the equilibrium structure and the Hessian matrix to characterize stationary points (e.g. minima and saddle points) and to move along molecular potential energy surfaces.

17.2.2 Relativistic effects

Relativistic effects are incorporated into electronic structure calculations by a variety of techniques that are partially summarized in Table 17.3. They are categorized on the basis of whether they are Hartree–Fock- or DFT-based, on how many components of the wavefunction are treated (see below), and on other characteristics.

The formal starting point for most relativistic methods is the Dirac equation (Dirac, 1929). In the previous section, each molecular orbital ϕ_i was a scalar function associated with either up or down spin. In relativistic theory ϕ_i is represented as a four-component spinor comprised of 'large' (or *electronic*) and 'small' (or *positronic*) components with each component having spin up (α) and spin down (β). For a one-electron system the Dirac equation is

Table 17.3 *Summary of theoretical methods for treating molecules including heavy atoms divided according to wave-function-based (Hartree-Fock) or density-functional-based approaches.*

Wave-function-based approaches	*Density functional approaches*
nonrelativistic

two-component relativistic	
SO multi-configuration SCF	SO DFT
SO-CASPT2, SO-MRCI	two-component ZORA
	two-component DKH
four-component relativistic	
Dirac–Hartree–Fock	Dirac–Kohn–Sham

$$H\Psi = \left[\vec{\alpha} \cdot \vec{p} + (\beta - 1)mc^2 + V\right]\Psi = \mathrm{i}\hbar\frac{\partial\Psi}{\partial t}$$

The $\vec{\alpha}$ and β are the Dirac matrices and are 4 $\times$ 4 dimensional (the $\vec{\sigma}$ are the familiar 2 $\times$ 2 Pauli matrices and I is the 2 $\times$ 2 identity matrix):

$$\vec{\alpha} = \begin{pmatrix} 0 & \vec{\sigma} \\ \vec{\sigma} & 0 \end{pmatrix} \qquad \beta = \begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix}$$

For many-electron systems, in analogy to the nonrelativistic many-electron Schrödinger equation, the relativistic equation is termed the Dirac–Coulomb equation (here h_{D} is the one-electron Dirac equation):

$$H_{\mathrm{Dirac}} = \sum_i h_{\mathrm{D}}(i) + \sum_{i>j}\frac{1}{r_{ij}}$$

Analogous to the nonrelativistic Hartree–Fock (for wavefunction methods) and Kohn–Sham (for DFT methods) equations, these equations are the bases for the Dirac–HF and Dirac–Kohn–Sham methods, respectively. Dirac-based codes are thus four-component methods that are computationally extremely demanding and, for this reason, such methods have been applied to relatively few actinide molecules. There are several well-known codes [e.g. MOLFDIR (MOLFDIR), DIRAC (DIRAC; Saue *et al*., 1997)], Beijing density functional code (BDF; Liu *et al*., 2004), BERTHA (BERTHA; Grant and Quiney, 2000), and PORPHET4R (Matsuoka and Watanabe, 2004) that have been developed for these methods (Hirao and Ishikawa, 2004).

Several techniques exist to separate the large and small components, thus enabling a formal treatment of only the electronic (i.e. large) components and resulting in two-component methods (one for spin up and one for spin down). One such method is the Foldy–Wouthuysen transformation (Foldy and Wouthuysen, 1950; Foldy, 1956), which results in a two-component Hamiltonian (to order α^2, where α is the fine structure constant) called the Pauli Hamiltonian:

$$H = H_{\mathrm{NR}} + H_{\mathrm{mv}} + H_{\mathrm{D}} + H_{\mathrm{so}}$$

In the Pauli Hamiltonian, H_{NR}, H_{mv}, H_{D}, and H_{so} are the nonrelativistic Hamiltonian, the mass–velocity term, the Darwin term, and the spin–orbit coupling term, respectively:

$$H_{\mathrm{mv}} = \frac{-p^4}{8m^3c^2}$$

$$H_{\mathrm{D}} = \frac{1}{8m^2c^2}\left(p^2 V_{\mathrm{ext}}\right)$$

$$H_{\mathrm{so}} = \frac{1}{4c^2}\left(\nabla(V_{\mathrm{N}} + V_{\mathrm{el}}) \times \vec{p}\right) \bullet \vec{s}$$

Baerends and coworkers have developed a zeroth-order regular approximation (ZORA) that overcomes some of the problems of the Pauli formalism (*vide infra*). Rösch and coworkers (Knappe and Rösch, 1990; Rösch *et al*., 1996) have developed a linear combination of Gaussians DFT method in the PARAGAUSS program (PARAGAUSS) that implements the all-electron second-order Douglas–Kroll–Hess (DKH) scheme (Douglas and Kroll, 1974; Jansen and Hess, 1989) for transforming the Dirac equation. The DKH method has also been implemented by de Jong and coworkers and Hirata *et al.* (de Jong *et al*., 2001a; Hirata *et al*., 2004) in the software package NWChem (NWChem) in scalar form and by Peralta and Scuseria (2004) in Gaussian in both scalar and spin–orbit forms. Dyall (1997, 2001) proposed an alternative series of transformations via so-called normalized elimination of the small components (NESC) from the four-component wavefunctions. Nakajima and Hirao (1999) suggested a formalism named relativistic scheme by eliminating small components (RESC).

As noted in Section 17.1.2, when spin–orbit coupling effects are ignored or averaged out, the relativistic methods reduce to scalar relativistic (one-component) methods. The vast majority of electronic structure calculations on actinide species use these simpler 'scalar relativistic' methods in which the wavefunction has the same form as in nonrelativistic quantum chemistry and each orbital has either α or β spin. In these scalar relativistic methods, only the mass–velocity and Darwin terms are included in addition to the usual nonrelativistic Hamiltonian. Scalar relativistic methods include calculations

with effective core potentials (ECPs; see next section), where the relativistic terms are implicitly incorporated into the potential.

Among density functional approaches the quasi-relativistic (QR) and ZORA are popular relativistic methods that are included in the Amsterdam Density Functional (ADF) software. The quasi-relativistic method of Ziegler *et al.* (1989) is based on the Pauli formalism, where only the first-order terms are retained. These methods treat the relativistic terms self-consistently and are typically employed with frozen relativistic core orbitals to reduce variational instabilities. The ZORA method (van Lenthe *et al.*, 1993, 1994), which is equivalent to the earlier CPD (Chang, Pelissier, and Durand) method (Chang *et al.*, 1986), includes higher order effects in a slightly different manner. ZORA is also implemented by van Wullen (1999), by the Li group in BDF (Wang *et al.*, 2000; Hong *et al.*, 2001), and Gagliardi *et al.* (1998, 2001c) in three other DFT codes. These QR, ZORA, and DKH approaches can utilize either the LDA or GGA DFT functionals. Such approaches are beginning to be applied to the chemistry of heavy atoms, including the two-component ZORA method, implemented in ADF (ADF) and MAGIC (MAGIC), and spin–orbit DFT, which is now part of NWChem (NWChem).

17.2.3 Relativistic effective core potentials

An alternative approach to including relativistic effects is to replace the inner core electrons using relativistic effective core potentials (RECPs) derived from all-electron relativistic atomic calculations. RECPs have been recently reviewed by Dolg (2002). With these methods, the quantum chemical calculations are carried out in nonrelativistic fashion without any explicit relativistic terms in the calculation. In addition to including the effects of the core electrons, the RECPs implicitly treat the relativistic effects on the valence orbitals, since relativistic orbitals were used to construct the RECPs. A major question, especially for actinides, concerns which electrons should be included in the core. For an atom such as U, the 'large core' would treat the outer $6s^2 6p^6 7s^2 5f^3 6d^1$ electrons as valence electrons and treat the remaining 78 electrons as core electrons. Note that the 'large core' approach actually includes a smaller number of electrons than are in the noble gas configuration of [Xe], which includes the so-called semi-core 6s and 6p electrons. As noted elsewhere, the 6s and 6p electrons are energetically and spatially in the same region as the other valence electrons and play an important role in the valence electronic structure. The other common choices for core size are a 68-electron core (with the 5d shell in the valence space) and a 60-electron core (with the 5s and 5p shells in the valence).

RECPs have been developed starting with numerical Dirac–Fock orbitals by Pitzer, Christiansen, Ermler and colleagues (Lee *et al.*, 1977; Christiansen *et al.*, 1979). After transforming to a two-component 'spinor' equation, they obtain two spin–orbit-coupled RECPs for each orbital (such as $6p_{1/2}$ and $6p_{3/2}$), except for the case of s orbitals. The two RECPs can be combined in a weighted

average to obtain an average RECP (AREP) to facilitate calculations in scalar relativistic mode. The other combination of RECPs yields a rigorous spin–orbit potential that can be used in two-component SCF or spin–orbit CI calculations. Atomic RECPs for the entire periodic chart have been derived according to this procedure. Of interest for 5f elements are potentials for Fr–Pu by Ermler *et al.* (1991) and for Am through element 118 by Nash *et al.* (1997, 1999).

Starting from a scalar relativistic Cowan–Griffin numerical atomic wavefunction (Cowan and Griffin, 1976), Hay, Wadt, Kahn and coworkers developed the first RECPs for uranium and applied it to UF_6 (Hay *et al.*, 1979). They have subsequently developed RECPs for much of the periodic table (Hay and Wadt, 1985). In their approach, an 'average' RECP is directly obtained because there is only one radial function for, for example, the 6p shell of U atom. Spin–orbit effects have been treated by an approximate operator. The most recent versions of these potentials have been reported for U, Np, and Pu (Hay and Martin, 1998).

Alternative approaches developed by Preuss, Stoll, Dolg and coworkers fit the RECP parameters to calculated levels from all-electron relativistic methods (Küchle *et al.*, 1994). The atomic results can be obtained either from Dirac-based methods or an alternative scalar-relativistic method developed by Wood and Boring (1978), which is analogous to the Cowan–Griffin method. In addition to 'large core' actinide RECPs, 'small-core' RECPs have been developed in which the 5s, 5p, and 5d shells are also treated as valence electrons, because they are in the same principal quantum shell as the 5f electrons, even though these electrons are 'deep' in terms of energy. Among the codes that have capabilities for relativistic ECPs are GAUSSIAN (GAUSSIAN), GAMESS (GAMESS), TURBOMOLE (TURBOMOLE), NWChem (NWChem), and COLUMBUS (Pitzer and Winter, 1988; Shepard *et al.*, 1988).

An alternative to RECPs are those based on the Huzinaga–Cantu equation (Huzinaga and Cantu, 1971) and are known as model potentials. For these potentials, the valence-space orbitals, unlike those previously discussed, preserve the nodal (radial) structure of the all-electron orbitals. The most commonly used form is the so-called *ab initio* model potentials (AIMP) of Seijo, Barandiarán, and coworkers (Huzinaga *et al.*, 1987; Seijo and Barandiarán, 1999), who have recently published a set of AIMPs, with appropriate basis sets, for lanthanides and actinides (Seijo *et al.*, 2001). These potentials are based on a spin-dependent relativistic Wood–Boring AIMP Hamiltonian, which can be divided into a Cowan–Griffin spin-free relativistic Hamiltonian and a pure spin–orbit Hamiltonian.

The model potentials are formed by replacement of the core operators in two ways: for local, long-range operators, such as the Coulomb operator, a simple local operator is used. For local, short-range, or non-local operators, such as the exchange or the mass–velocity and Darwin Cowan–Griffin operators, a spectral representation is used (Seijo *et al.*, 2003). Recently, alternate formulations of incorporating relativistic effects, namely the aforementioned relativistic

elimination of small components (RESC) (Motegi *et al.*, 2001) and the DKH approaches (Paulovic *et al.*, 2002, 2003) have been incorporated into AIMP methods.

In the latter of these studies, spin–orbit relativistic (i.e. two-component) calculations are performed in a two-step procedure: a large scalar relativistic (one-component) calculation is used to incorporate electron correlation followed by a smaller spin–orbit (two-component) calculation. There are some important assumptions made in this approach. Its underlying principle is that the correlation calculation converges more slowly than the spin–orbit one, and that the two results are additive. The CIPSO code of Teichteil and coworkers (Teichteil and Spiegelmann, 1983; Teichteil *et al.*, 1983) is a well-known example of this method and has been applied to actinides in several studies (Maron *et al.*, 1999; Vallet *et al.*, 1999a,b). Recently, this method has been extended to the EPCISO code, which accounts for spin–orbit polarization effects (Vallet *et al.*, 2000). Another implementation of the two-step method has been developed by the Roos group; the first step being a complete active space plus second-order perturbation theory (CASPT2) correlation calculation (Andersson *et al.*, 1992), followed by a restricted active space self-consistent field (RASSCF) state interaction (RASSI) method to perform the spin–orbit calculation (Malmqvist *et al.*, 2002).

The COLUMBUS codes of Pitzer *et al.* (Pitzer and Winter, 1988; Shepard *et al.*, 1988) have incorporated RECPs within a two-component approach. Initially their methodology was developed by using the observation that when the calculations are carried out under C_{2v}^*, D_2^*, or D_{2h}^* double-group symmetry (see Section 17.2.5), the spin–orbit integrals are either pure real or pure imaginary, thus allowing the program to use real arithmetic. Recently, Yabushita *et al.* (1999) developed a spin–orbit formalism for the COLUMBUS graphical-unitary group approach (GUGA) CI program. Their method uses configuration state functions (CSFs) based on spatial orbitals (e.g. from a one-component SCF or multi-configuration self-consistent field [MCSCF] calculation) in a CI expansion that uses a spin–orbit Hamiltonian. Thus, the correlation and the spin–orbit effects are treated simultaneously and variationally via the spin–orbit CI approach. This method has been used with CI expansions of the order of a million CSFs on actinide systems, including several of the actinyl ions (Zhang and Pitzer, 1999; Matsika and Pitzer, 2000; Matsika *et al.*, 2001).

17.2.4 Excited electronic states

The preceding discussion has focused primarily on methodologies for calculating properties of the electronic ground state of actinide molecules. There has been considerably less activity involving excited states, in part because of the unique challenges actinides present with respect to the importance of spin–orbit and other relativistic effects, and in part because of the inherent challenge of

many electronic states involving unpaired 5f electrons in multiple electron configurations (Section 17.1.1). For Hartree–Fock-based methods, CI techniques have been the most popular approach to determining excited-state energies. For a ground state with no unpaired electrons, single excitations from occupied MOs to virtual MOs provide a zero-order description of the electronic states. Inclusion of higher order excitations explicitly treats the electron correlation effects needed for more quantitative results. Spin–orbit CI calculations (Pitzer and Winter, 1988; Yabushita *et al.*, 1999) have evolved to the point where fairly accurate calculations can be carried out on complexes of modest size. Illustrations of spin–orbit configuration interaction (SOCI) results will be presented in the section on the spectroscopy of actinyl species. There is also a recent review on the development and application of the multi-configuration-based relativistic quantum chemistry in exploring excited states of heavy elements, including actinides (Roos and Malmqvist, 2004).

While DFT is based on the ground electronic state of a system (or the lowest state of a given spin and symmetry), there have been various developments for treating excited electronic states within a DFT approach. Among the earliest LDA approaches was the transition state theory of Slater (1974), in which the prescription of exciting one-half electron from occupied to virtual level corresponded to the proper excitation energy in DFT. Within the QR and ZORA techniques in the ADF program and others, one can solve self-consistently for the excited states by progressively removing an electron from various occupied orbitals and promoting it into the virtual levels.

More recently, time-dependent DFT (TD-DFT) techniques have been developed (van Gisbergen *et al.*, 1995; Jamorski *et al.*, 1996; Petersilka *et al.*, 1996; Casida *et al.*, 1998) in terms of 'response functions' to provide an alternative description of the excited states in molecules. In TD-DFT, an excited state is made up of all possible particle–hole excitations (as well as counter-intuitive hole–particle 'de-excitations') between occupied and virtual MOs. This approach is applicable to closed-shell ground states to compute excited singlet and triplet excited states, and to open-shell ground states as well. Numerous TD-DFT results with a variety of functionals (LDA, GGA, and hybrid) have been reported for organic molecules and transition metal complexes. To date, very little work has been done on actinide species, mainly because the calculated excitation energies would hardly be useful without including spin–orbit coupling effects. Notably, recent developments by Liu and coworkers that allow calculations of TD-DFT excitation energies with spin–orbit coupling is a highly promising approach for tackling excited states of actinides (Gao *et al.*, 2004).

17.2.5 Double groups

As previously mentioned, the incorporation of a spin–orbit operator in the Hamiltonian requires the use of two-component wavefunctions and double groups, because the operator allows the mixing of functions with different

spins. Thus, one needs to incorporate a framework where spin functions are allowed to transform under symmetry operations of a point group. Originally suggested by Bethe (1929), double groups incorporate such transformations (Wigner, 1959; Herzberg, 1991). Before describing double groups, it is instructive to review some of the tenets of angular momentum coupling and term symbols in atoms and molecules. The following discussion is based on the development in Levine's textbook on quantum chemistry (Levine, 2000); readers are also referred to the classic series of texts by Herzberg (1944, 1989, 1991).

For atoms, the two most common methods for coupling spin and angular momenta are the *LS* and the *j–j* coupling schemes. *LS*, or Russell–Saunders, coupling is used when the electronic repulsion splitting is greater than the spin–orbit splitting, whereas *j–j* coupling is used if the latter is greater than the former. When coupling two angular momenta $\overrightarrow{j_1}$ (characterized by quantum number j_1) and $\overrightarrow{j_2}$ (characterized by j_2), one uses vector sums to obtain the possible quantum numbers characterizing the total angular momentum, which are defined by the following relation:

$$j = j_1 + j_2, j_1 + j_2 - 1, j_1 + j_2 - 2, ..., |j_1 - j_2|$$

To couple any number of angular momenta, one first couples two angular momenta according to the formula above, then couples the resulting values with the third angular momentum, and repeats the procedure as needed.

In *LS* coupling, there is a defined total electronic orbital angular momentum, labeled by $\overrightarrow{L}$, characterized by the quantum number L, formed by the vector sum of the individual electron orbital angular momenta, $\overrightarrow{l}_i$. Analogously, there is a defined total spin angular momentum, labeled by $\overrightarrow{S}$, characterized by S, formed by the vector sum of the individual electron spin angular momenta, $\overrightarrow{s_i}$. The total electronic angular momentum, $\overrightarrow{J}$, characterized by J, is the vector sum of $\overrightarrow{L}$ and $\overrightarrow{S}$. The possible J values for a given L and S are:

$$J = L + S, L + S - 1, ..., |L - S|$$

In *j–j* coupling, the orbital angular momentum, $\overrightarrow{l_i}$, characterized by l_i and the spin angular momentum, $\overrightarrow{s_i}$, characterized by s_i, for each electron is coupled to form the total angular momentum for the particular electron, $\overrightarrow{j_i}$, characterized by j_i. The total angular momentum is the vector sum of these individual angular momenta, the J values are obtained using:

$$\overrightarrow{J} = \sum_i \overrightarrow{j_i}$$

For a non-spin–orbit Hamiltonian, the total orbital and total spin angular momentum operators, which correspond to the quantum numbers L and S, commute with the Hamiltonian, and are good quantum numbers – enabling their use in the labeling of wavefunctions (i.e. the electronic states). The labels for atomic states, called term symbols, use the multiplicity, defined as

the quantity $2S + 1$, as a left superscript and using a capital letter to represent the total orbital angular momentum: S for $L = 0$, P for 1, D for 2, F for 3, G for 4, and then alphabetically (omitting J). Thus one obtains ${}^{2S+1}L$ for the term symbol, and ^{1}P, ^{2}D, and ^{3}S as examples. When one includes the J values, which are subscripts, one would obtain ${}^{2S+1}L_J$ and for the previous examples: ${}^1\mathrm{P}_1$; ${}^2\mathrm{D}_{3/2}$, ${}^2\mathrm{D}_{5/2}$; and ${}^3\mathrm{S}_1$.

For linear molecules, including diatomics, the total angular momenta are no longer good quantum numbers, but their z-components are. Thus, when coupling angular momenta for linear molecules, algebraic sums are used rather than vector sums. Greek letters are used for the z-component of orbital angular momenta, the total z-component angular momentum is now characterized by the quantum number Λ, and the analogous coupling to LS coupling is referred to as ΛS coupling. To couple two individual electron z-components, one obtains (note that each λ quantum number corresponds to a z-component of $\pm M_\lambda$ where $\lambda = M_\lambda$):

$$\lambda = \lambda_1 + \lambda_2 \quad \text{and} \quad \lambda = \lambda_1 - \lambda_2$$

Again, to couple more than two angular momenta z-components, one uses the above relation repeatedly. The total orbital momentum is now labeled Σ for $\Lambda = 0$, Π for 1, Δ for 2, Φ for 3, Γ for 4, and so on. Since (for a non-spin–orbit Hamiltonian) the total spin is still a good quantum number, the molecular term symbols are ${}^{2S+1}\Lambda$. For Σ ($\Lambda = 0$) states, there is an additional label, corresponding to reflection symmetry in a mirror plane containing the internuclear axis. Σ states, symmetric with respect to this symmetry operation, have a plus sign as a right superscript and Σ states antisymmetric with respect to this operation have a minus sign. The total component angular momentum is labeled Ω and is obtained by coupling Λ with the z-component of spin (called Σ). The values of $\Lambda + \Sigma$ are thus, note that this value may be negative:

$$\Lambda + S, \Lambda + S - 1, ..., \Lambda - S$$

The possible values of Ω, the total z-component angular momentum are:

$$\Omega = \Lambda + S, \Lambda + S - 1, ..., |\Lambda - S|$$

The molecular term symbol is ${}^{2S+1}\Lambda_{\Lambda+\Sigma}$, thus a ${}^4\Pi$ state will split into ${}^4\Pi_{5/2}$, ${}^4\Pi_{3/2}$, ${}^4\Pi_{1/2}$, and ${}^4\Pi_{-1/2}$ states.

The coupling for linear molecules analogous to j–j coupling for atoms is called ω–ω coupling. The z-component angular momentum for each electron is coupled to the spin z-component to form the individual electron total z-component angular momenta, ω_i. The individual ω_i are then coupled to form the Ω values.

For nonlinear polyatomics, electronic states are labeled by the irreducible representations of the point group of the molecule and the multiplicity of the state, referred to as ΓS coupling. The term symbols are ${}^{2S+1}\Gamma$. In analogy to j–j and ω–ω coupling, one can incorporate spin into a total symmetry label, but

that involves determining how spin functions transform, invoking double groups.

When spin functions are allowed to transform under symmetry operations, the fact that they are antisymmetric with respect to a rotation of 2π leads to the necessary modification of the identity operator, which now corresponds to a rotation of 4π. The operator corresponding to a rotation of 2π is labeled R, and the number of symmetry operators is now doubled (hence the name *double* group). An alternative perspective for atoms, more mathematical, is use of the nomenclature of Lie groups, for which a 2-to-1 homomorphism can be shown to exist between the two-dimensional special unitary group, SU(2), and the full special three-dimensional rotation group, SO(3) or O_3^+ (Arfken, 1985; Hamermesh, 1989). The resulting double point groups have double the number of operators than the simple groups, although the number of classes is not necessarily doubled. Character tables for these double groups are available in various references (Koster *et al.*, 1963; Pyykkö and Toivonen, 1983; Herzberg, 1991). Due to the additional classes, there are additional irreducible representations in these groups, referred to as double-valued representations, corresponding to states that change sign upon rotation by 2π. It can be shown that odd-electron functions necessarily transform as one of these double-valued representations, while even-electron functions transform as one of the irreducible representations of the simple group, now referred to as single-valued representations. Of particular importance for Hartree–Fock or DFT calculations that include a spin–orbit operator is that, because orbitals are one-electron functions, they now carry labels from the double-valued irreducible representations. Calculations that include only the spin–orbit operator in the subsequent correlation step and perform the Hartree–Fock calculations with a spin-free Hamiltonian retain the single-valued irreducible representation labels for the orbitals.

Of importance for chemical purposes is how functions transform. For example, for two electrons, the singlet spin function transforms as the totally symmetric irreducible representation and the triplet functions transforms in the same fashion as the angular momentum vector operators – e.g. functions with a z-axis projection of zero, such as S_z, transform under the same irreducible representation as L_z does. To obtain the double-group label of a function, the direct product of the irreducible representation for the spatial function and the irreducible representations for the spin function are determined. For atoms, this procedure is analogous to obtaining J values. S^2 and L^2 no longer commute with the Hamiltonian and their magnitudes are no longer good quantum numbers, but the magnitude of the total angular momentum, J, is still good. For example, for a ^{3}P function, one obtains J values of 2, 1, and 0 and the states are labeled $^3P_2$, $^3P_1$, and $^3P_0$. The spin–orbit operator allows mixing of the $^3P_1$ with a $^1P_1$ function. Where the spin–orbit interaction is much larger than electron–electron repulsion, the states are more properly labeled by J values alone, which leads to the progression from Russell–Saunders (or LS) coupling

to *j–j* coupling. For linear molecules, the double-group irreducible representations correspond to Ω values, where Ω is the *z*-component of the total angular momentum. The *z*-component of the orbital angular momentum, Λ, is no longer a good quantum number, Ω is still a valid quantum number. For a $^3\Pi$ state, one obtains Ω values of 2, 1, 0^+, and 0^- and the states are labeled $^3\Pi_2$, $^3\Pi_1$, $^3\Pi_{0+}$, and $^3\Pi_{0-}$. The $^3\Pi_1$ can mix with $^1\Pi_1$. For linear molecules, the analog to *j–j* coupling is *ω–ω* coupling. For nonlinear polyatomics, the double-group label is obtained by first determining the representation of the spin functions. For example, in C_{2v}^*, the triplet functions transform as $A_2 + B_1 + B_2$, while the singlet function transforms as the A_1 irreducible representation. Thus, a $^3B_1$ function in *ΓS* coupling transforms, after the direct product is taken, as the B_2, A_1, and A_2 irreducible representations of the double group. A $^1A_2$ function would transform as the A_2 irreducible representation of the double group and would be able to mix with the A_2 portion of the triplet function. Note that the double-group label does not have an explicit spin label as a superscript; the spin symmetry is incorporated in the label itself.

A final point is that different authors use different labels for the additional irreducible representations of the double group. For example, for the O_h^* group, Herzberg (1991) uses two sets of labels $E_{1/2g}$, $E_{5/2g}$, $G_{3/2g}$, $E_{1/2u}$, $E_{5/2u}$, and $G_{3/2u}$, while other authors use the labels Γ_{6g}, Γ_{7g}, Γ_{8g}, Γ_{6u}, Γ_{7u}, and Γ_{8u}.

17.3 THEORETICAL STUDIES OF THE ACTINYL IONS AND ACTINIDE OXO COMPLEXES

Because the actinide elements, and especially the most studied early actinides, tend to be very electropositive, much of their chemistry is dominated by high positive oxidation states. The electropositive nature of the actinides leads to high oxophilicity, as exemplified by the high-valent (typically +5 and +6 oxidation states) actinide elements in actinyl ions, AnO_2^{q+}. The U(VI) uranyl ion, UO_2^{2+}, is by far the most studied of the actinyl ions, and the electronic structure of this isolated species has been the subject of numerous theoretical studies. In the next section, the bonding in UO_2^{2+} is discussed briefly, followed by discussion of actinyl complexes of the general form $[AnO_2(L)_n]^q$. This is followed by sections on the spectroscopy of 'bare' actinyl species and actinyls in ionic solids. The section ends with discussion of other high-valent actinide oxo compounds and of actinide oxyfluorides.

17.3.1 The uranyl ion and related species

The most common oxidation state for uranium is +6, which corresponds to an f^0 center with a radon-like electron configuration. In the presence of oxygen, the most common discrete ionic and molecular uranium species formed contain the

uranyl ion, UO_2^{2+}, which nearly always has a linear O–U–O linkage. Similarly, neptunium and plutonium commonly form NpO_2^{q+} and PuO_2^{q+} species in which the actinide center is in the +5 or +6 oxidation state. The 'bare' uranyl species has not been isolated in the gaseous state, and can only be approached in matrix isolation studies or in ionic lattices, as will be discussed in later sections.

Electronic structure calculations on UO_2^{2+} have served as benchmarks for theoretical methods as well as a means for understanding the bonding in this relatively simple system and in the complexes it forms with other ligands. As has been detailed by Pepper and Bursten (1991), the electronic structure of UO_2^{2+} has been surprisingly controversial, especially given the apparent simplicity of this symmetric, linear, triatomic system. Among the significant questions addressed by these calculations are the following: (a) how important are relativistic effects on the electronic structure of the uranyl and related ions? (b) how covalent are the U–O bonds? (c) what are the relative contributions of the U 5f and 6d orbitals in the U–O interactions? and (d) what are the bonding principles that cause UO_2^{2+} to favor a linear geometry? Many of these questions are general ones that serve as proxies for the challenges in all electronic structure calculations on molecular actinide systems. Inasmuch as the uranyl ion is the smallest commonly found molecular actinide ion, it is not surprising that it has received intense scrutiny by theoretical methods. To provide an historical framework, the contributions of electronic structure theory in addressing the above questions about the uranyl ion will be briefly discussed here, followed by discussion of some of the recent advances in applications of theoretical methods to the chemistry of the actinyl ions.

The high symmetry and small size of the UO_2^{2+} ion has made it an attractive early candidate for electronic structure calculations of actinide complexes. McGlynn and Smith (1961) presented a nonrelativistic semiempirical MO description of the electronic structure of the uranyl ion in 1961. The importance of relativistic effects in the bonding of the uranyl ion was recognized as early as 1965, and all of the theoretical methods used to study UO_2^{2+} over the last 40 years have included explicit or implicit relativistic corrections. Many of the early and more recent studies of the bonding in uranyl have addressed the debate over 5f contributions to the U–O bonds, a seemingly straightforward question that has led to lively debates among theoretical and experimental actinide chemists.

The question of 5f covalency in actinide systems is not a new one. Chemical evidence for f-orbital covalency in actinyl nitrates was provided in 1950 by Glueckauf and McKay (1950), but was disputed shortly thereafter by Katzin (Glueckauf and McKay, 1950; Katzin, 1950). In 1952, Connick and Hugus used experimental data for UO_2^{2+} to propose U 5f orbital participation in the U–O bonds (Connick and Hugus, 1952). In 1953, Elliott used a model involving 5f interactions to explain the temperature dependence of paramagnetism in NpO_2^{2+} and PuO_2^{2+} (Elliott, 1953). Eisenstein proposed group theoretical arguments in favor of 5f and 6d covalency in uranyl and other actinide compounds (Eisenstein and Pryce, 1955; Eisenstein, 1956). Coulson and Lester (1956) soon

after proposed that f-orbital interactions must contribute to the bonding in hexavalent actinyl complexes, but that ionic interactions are probably dominant. They surprisingly proposed that the 6f orbitals of the actinides would dominate any f-orbital interactions because of the contracted nature of the 5f orbitals. At roughly the same time, Seaborg and coworkers attributed the difference in the ion-exchange behavior of analogous lanthanide and actinide complexes to significant 5f orbital contributions in the actinide systems (Diamond *et al*., 1954).

Although relativistic quantum chemical methodology continued to grow in sophistication from the 1960s through the 1980s, there was still surprisingly little agreement among quantum chemists concerning the 5f contributions to and the energetic ordering of the highest occupied orbitals in UO_2^{2+}. Because it is an f^0 ion, the highest-energy orbitals of UO_2^{2+} are predominantly O 2p in character. For the linear ion, the formally filled O 2pσ orbitals lead to group orbitals of σ_g and σ_u symmetry. Likewise, the formally filled doubly-degenerate O 2pπ orbitals generate filled doubly-degenerate π_g and π_u orbitals of UO_2^{2+}. Because of the centrosymmetric symmetry of the linear ion, the allowed interactions of the U 6d and 5f orbitals are mutually exclusive; the gerade 6dσ and 6dπ orbitals can interact with the O 2p σ_g and π_g combinations, whereas the ungerade 5fσ and 5fπ orbitals can interact with the σ_u and π_u ligand group orbitals. A qualitative MO diagram for UO_2^{2+} is presented in Fig. 17.4. All of the orbital methods agree that the four highest occupied MOs are the O 2p-based σ_g, σ_u, π_g, and π_u MOs, followed by low-lying U 5f virtual orbitals. There has been marked disagreement over the actual ordering of the highest filled orbitals, however. The disagreements about the orbital orderings in UO_2^{2+} were especially marked in the late 1970s and early 1980s when a number of relativistic methods were applied to the ion, including the relativistic extended Hückel (REX) calculations of Pyykkö and Lohr (1981), the quasi-relativistic multiple-scattering (QR-MS) Xα calculations of Wood and Boring (Boring *et al*., 1975; Boring and Wood, 1979; Wood *et al*., 1981), the Dirac–Slater multiple-scattering (DS-MS) Xα calculations of Yang *et al*. (1978), the Dirac–Slater discrete-variational (DS-DV) Xα calculations of Ellis *et al.* (1975), the Hartree–Fock calculations with RECPs by Wadt (1981), and the relativistic HFS calculations of DeKock *et al.* (1984). Jørgensen and Reisfeld (1983) compared the lack of quantitative agreement among these various methods for the orbital ordering in UO_2^{2+} to the 'effect of throwing dice'. Most of these early calculations predict a σ_u highest occupied molecular orbital (HOMO), as shown in Fig. 17.4. A detailed discussion of the lively debate over the ordering of the O 2p-based orbitals in linear UO_2^{2+} is given in the review by Pepper and Bursten (1991). As an illustrative example of a very recent calculation, the following ordering was obtained in a hybrid DFT calculation (Sonnenberg *et al*., 2005) for the highest occupied orbitals for the bare uranyl ion: π_g (–24.91 eV) < π_u (–24.56) < σ_g (–24.27) < σ_u (–23.63). The 5f-based virtual orbitals had the ordering ϕ_u (–18.38) < δ_u (–17.95) < π_u (–15.49).

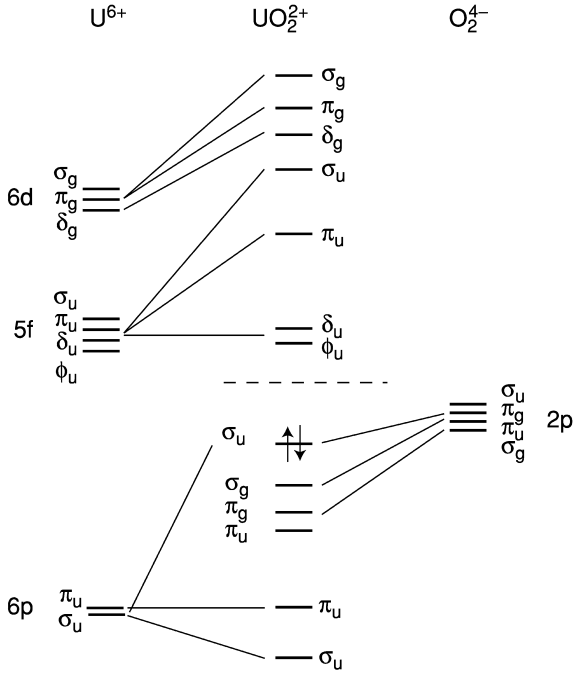

Fig. 17.4 *Schematic diagram of the MO interactions in* UO_2^{2+}, *showing the interaction of the U* 6*d and* 5*f atomic orbitals with the oxygen* 2*s and* 2*p orbitals* (*adapted from Pepper and Bursten*, 1991).

It is now clear that accurate accounting of both electron correlation and relativistic effects are essential for the prediction of the ordering of these frontier orbitals.

The electronic structural origins of the nearly invariably linear geometry of the UO_2^{2+} ion have been the focus of many theoretical studies, especially given that isoelectronic ThO_2 and the analogous transition metal ion MoO_2^{2+} typically exhibit bent geometries. The issue was first addressed on the basis of extended Hückel calculations by Tatsumi and Hoffmann (1980) and later using REX by Pyykkö *et al.* (1989) The factors include the relative admixture of 5f(σ_u) vs 6d as the ion bends, the role of the filled 'outer core' U 6p shell, and the relative contributions of covalent and ionic bonding. RECP calculations at the Hartree–Fock level by Wadt correctly predicted bent ThO_2 and linear UO_2^{2+} but disagreed in the interpretation of the role of U 6p orbitals (Wadt, 1981).

Dyall (1999) has carried out Dirac–Hartree–Fock calculations on ThO_2, PaO_2^+, and UO_2^{2+} and has analyzed in detail the role of the actinide 6p, 6d, and 5f orbitals across the series on the basis of the more sophisticated results.

He observes that the energy of the U 6d orbitals remain roughly unchanged across this region of the actinide series whereas the 5f orbitals drop in energy and becoming more radially contracted. For Th, the 5f orbitals lie above the 6d and it is favorable to bend and use f–d hybrids in the bonding, while for U the lower energy of the 5f orbitals favors linearity. In Fig. 17.5, the energy of the orbitals (actually spinors from the Dirac–Hartree–Fock [DHF] results) as a function of bending is shown. The highest-energy spinor, which corresponds to the σ_u orbital, increases in energy with bending for UO_2^{2+} but decreases for ThO_2.

A summary of the results of recent theoretical calculations on UO_2^{2+} using a variety of methods (Wahlgren *et al.*, 1998; Dyall, 1999; Ismail *et al.*, 1999; Vallet *et al.*, 1999b; Han and Hirao, 2000; Zhou *et al.*, 2000; de Jong *et al.*, 2001b; Garcia-Hernandez *et al.*, 2002), is given in Table 17.4. The methods are grouped into Hartree–Fock-based and density functional theory categories. Both of these include all-electron (AE) calculations along with calculations employing RECPs. The latter include two types denoted 'large core' with 78 electrons replaced by the RECP (Ermler *et al.*, 1991; Hay and Martin, 1998) and 'small core' with 60 electrons replaced (Küchle *et al.*, 1994). Among all-electron calculations, the U=O bond length is calculated to be about 1.65 Å from the various Hartree–Fock-based methods (DHF and DK-HF). With the small-core

relativistic effective core potentials (RECPs), Hartree–Fock calculations lead to similar bond lengths to those found using the all-electron DHF method, while there are slightly greater differences noted with the large-core RECPs. When correlation effects are explicitly included, as in CCSD(T) approaches, the bond length increases to 1.71 Å. The density functional results (for the LDA and B3LYP functionals summarized in the table) that incorporate correlation effects through the exchange-correlation functional reasonably reflect this with predicted U=O bond lengths ranging from 1.69 to 1.71 Å. Again larger discrepancies arise with the large core RECP.

The calculated vibrational stretching frequencies generally follow the trend that higher frequencies are associated with shorter U=O bond lengths. DHF calculations, with shorter bond lengths, predict symmetric and asymmetric stretching frequencies of 1240 and 1300 cm^{-1}, while the correlated methods and DFT approaches give 1020–1050 and 1110–1140 cm^{-1} for the same values. Comparison with experiment is problematic in the absence of isolated gas-phase spectroscopic studies, but comparisons with observed frequencies will be given below for uranyl complexes.

Garcia-Hernandez *et al.* (2002) examined the Np(VI) analog $[NpO_2]^{2+}$ with a $5f^1$ configuration using all-electron Douglas–Kroll–Hess approaches. For the Np–O bond length they obtained 1.698, 1.716, and 1.718 Å using the VWN, BP, and PBEN functionals, respectively. Results with spin–orbit DKH showed practically no change in the computed bond lengths. For symmetric stretch frequencies, the same calculations predicted 1009 cm^{-1} (VWN), 972 cm^{-1} (BP), and 969 cm^{-1} (PBEN).

17.3.2 Actinyl complexes

In solution and the solid state, additional ligands bind to the actinyl ions in the equatorial plane of the O=An=O unit. Among the most common characterized species are the aqua complexes $[UO_2(H_2O)_5]^{2+}$ found at low pH, the hydroxo

complexes $[UO_2(OH)_4]^{2-}$, $[UO_2(OH)_5]^{3-}$, and $[UO_2(OH)_4(H_2O)]^{2-}$ found at high pH, and the halide species $[UO_2X_4]^{2-}$ found in crystals (Fig. 17.6). In this class of $[UO_2L_n]$ complexes, the equatorial ligands are weak σ-donors. In this case, the U atom can use acceptor orbitals oriented in the equatorial plane that are not utilized in the bonds with the actinyl oxo atoms. The orbitals that in principle can act as acceptors in the equatorial plane include the 6d(x^2–y^2), 6d(xy), 5f(x^3–$3xy^2$) and 5f(y^3–$3x^2y$), and, to a lesser extent, the 7s and 7p orbitals. In the case of hydroxo complexes, the OH^- ligands can be π-donors and can compete with the metal orbitals involved in the U=O π_u and π_g bonds.

Clavaguéra-Sarrio *et al.* (2003b) have recently reported a DFT study of the binding energies and geometries of $UO_2L_2^{q+}(q = 0, 2)$ complexes with 33 different ligands L with the goal of predicting preferred coordination geometries. They determined that ligand polarization and charge transfer to the uranyl ion are likely to be necessary in any force-field model for uranyl–ligand bonding.

(a) Aqua complexes

Aqua complexes of actinyls have been studied in solution and the solid state using extended X-ray absorption fine structure (EXAFS) spectroscopy (Allen *et al.*, 1997), X-ray crystallography (Alcock and Esperas, 1977; Aaberg *et al.*, 1983), and X-ray scattering (Neuefeind *et al.*, 2004). The experimental studies show a preferred coordination number of five water molecules. The $[UO_2(H_2O)_5]^{2+}$ ion is the commonly observed U(VI) species in aqueous solution at low pH (Fig. 17.6) and consequently this complex has been the subject of several recent theoretical studies (Gropen, 1999; Spencer *et al.*, 1999; Tsushima and Suzuki, 1999; Wahlgren *et al.*, 1999; Hay *et al.*, 2000; Fuchs *et al.*, 2002; Clavaguéra-Sarrio *et al.*, 2003a) including DFT-based approaches and model potentials with Douglas–Kroll corrections. The oxygen atoms of the five water molecules are coordinated in nearly perfect five-fold symmetry about the uranyl ion, with the water molecules nearly perpendicular to the equatorial plane. Subtle differences in the structure of this complex are obtained among the calculations (Table 17.5). The AIMP-DK and DFT calculations with LDA and B3LYP functionals all predict U=O bond lengths in the range 1.75–1.78 Å. These theoretical results are in good agreement with the EXAFS solution bond length of 1.76 Å, which is slightly longer than the solid state value of 1.71 Å. The U-OH_2 bond lengths are predicted to be 2.42–2.52 Å in the DFT calculations, which compare favorably with the experimental bond lengths of 2.41–2.45 Å (Hay *et al.*, 2000). In the DKH studies (Fuchs *et al.*, 2002), the effects of solvation were included where the U=O bond length decreased from 1.771 to 1.662 Å while the U–OH_2 bond length increased from 2.530 to 2.639 Å.

Several studies have addressed the issue of why five is the preferred coordination number for H_2O with UO_2^{2+} (Spencer *et al.*, 1999; Tsushima and Suzuki, 1999; Hay *et al.*, 2000). In particular, several groups have explored the relative

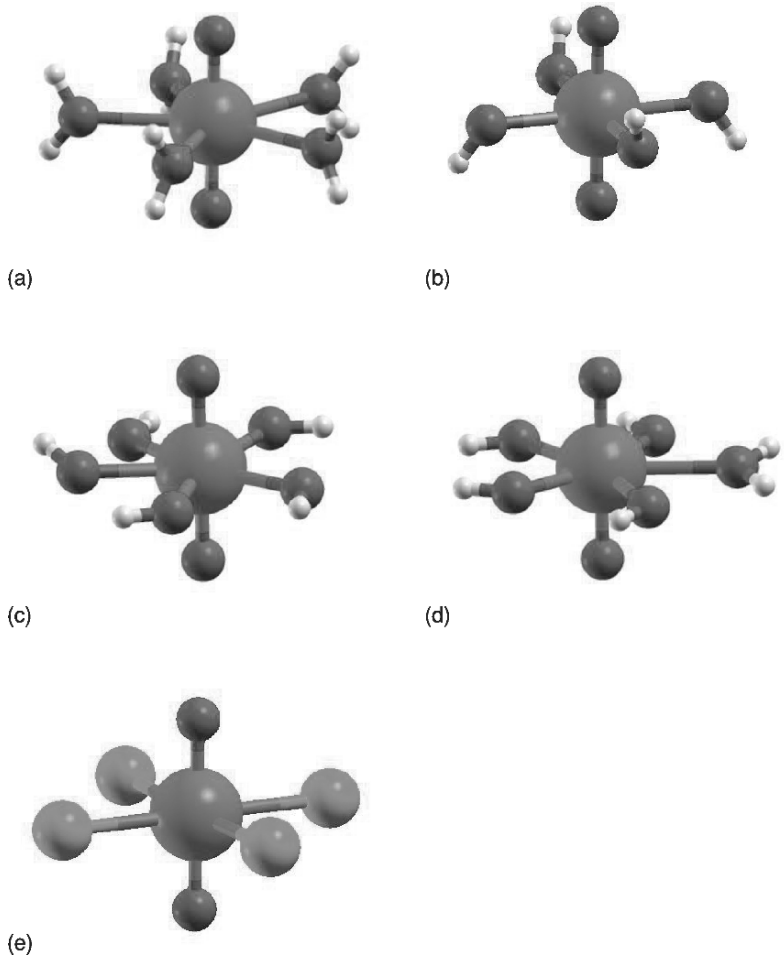

Fig. 17.6 *Structures of* (*a*) $[UO_2(H_2O)_5]^{2+}$, (*b*) $[UO_2(OH)_4]^{2-}$, (*c*) $[UO_2(OH)_5]^{3-}$, (*d*) $[UO_2(OH)_4(H_2O)]^{2-}$, *and* (*e*) $[UO_2Cl_4]^{2-}$ *as determined by DFT calculations* (*rendered from results reported in Schreckenbach* et al.*,* 1998, 1999*; Wahlgren* et al.*,* 1999*; Clavaguéra-Sarrio* et al., 2003*a; Sonnenberg* et al.*,* 2005).

energetics of binding four, five, or six water molecules to various actinyl ions. These approaches used a combination of energies from density functional calculations, thermodynamic quantities derived from calculated vibrational frequencies, and solvation energies from dielectric continuum models. Spencer *et al.* (1999) used DFT (Becke–Lee–Yang–Parr functional [BLYP]) calculations to obtain the relative ordering 5 < 4 (+7.2 kcal mol^{-1}) < 6 (+18.5) for $[UO_2(H_2O)_n]^{2+}$ species. They obtained a similar ordering pattern for $[PuO_2(H_2O)_n]^{2+}$ ions. Calculations using DFT (B3LYP) and different solvent

models gave a slightly different ordering of $5 < 6 < 4$ water molecules in the first coordination shell (Tsushima and Suzuki, 1999; Hay *et al.*, 2000). Additional structures are found with at least one water molecule displaced from the first shell into the second shell, where the molecule is hydrogen bonded to the uranyl oxygen atoms rather than directly coordinated to the uranium center.

As one proceeds across the actinide series, there is only a slight change in the experimental An–O bond length as measured in solution by EXAFS: 1.76 Å in $[UO_2(H_2O)_5]^{2+}$ (Allen *et al.*, 1997), 1.75 Å in $[NpO_2(H_2O)_5]^{2+}$ (Reich *et al.*, 2000; Den Auwer *et al.*, 2003), and 1.74 Å in $[PuO_2(H_2O)_5]^{2+}$ (Conradson, 1998). DFT (B3LYP) calculations using LC-RECPs predict a slight shortening of bond length of 1.756–1.742 Å across U(VI) to Pu(VI) (Hay *et al.*, 2000) (Fig. 17.7). In addition the calculations reasonably well describe the decrease in symmetric and antisymmetric O=An=O stretch frequencies across the series (Jones and Penneman, 1953; Basile *et al.*, 1974). It is somewhat curious that as the bond lengths are getting slightly shorter, the frequencies are actually decreasing – the reverse of the usual correlation. This trend is attributed to the decrease in An(5f)–O(2p) overlap going across the series as the 5f orbitals become more radially contracted.

The mechanisms for exchange of water (H_2O^*) with the aqua complex $[UO_2(H_2O)_5]^{2+}$ were investigated by Vallet *et al.* (2001). The possibilities of associative (via a six-coordinate intermediate), dissociative (via four-coordinate intermediate), and interchange (via a concerted symmetric transition state) pathways were probed using a combination of Hartree–Fock, MP2, and CPCM (conductor-like polarizable comtinuum model) solvent model (Fig. 17.8). The calculated activation energies were 74, 19, and 21 kJ mol^{-1}, respectively, for the D-, A- and I-mechanisms in the solvent. Comparison with the experimental value of 26 ± 1 kJ mol^{-1} eliminates the D mechanism, leaving it difficult to distinguish between the A- and I-mechanisms. A later study extended

these studies to exchange in aqua complexes of UO_2^+, NpO_2^{2+}, and AmO_2^{2+} with similar findings (Vallet *et al.*, 2004). This same group has modeled electron exchange between UO_2^+ and UO_2^{2+} in solution, examining potential intermediates in both outer-sphere and inner-sphere electron-exchange mechanisms (Privalov *et al.*, 2004). Other than this contribution, relatively little work has been done on dimeric and polymeric species that can be the dominant species in solution depending on the conditions. Schlosser *et al.* (2003) compared all-electron DFT results on one of the few dimeric complexes for which there is a crystal structure, $[(UO_2)_2(\mu^2\text{-}OH)_2Cl_2(H_2O)_4]$. In addition, the role of hydrogen bonding in the crystal was studied by adding a layer of water molecules.

(b) Hydroxide complexes

At higher pH, one finds uranyl species with hydroxide ligands displacing water molecules coordinated to the metal. The first hydrolysis product formed is $[UO_2(H_2O)_4(OH)]^+$, which can also exist in dimeric form (Clark *et al.*, 1995). At much higher pH, the $[UO_2(OH)_4]^{2-}$ species has been observed and characterized in the solid state (Clark *et al.*, 1999). The structures of the tetrahydroxide species have been investigated using DFT techniques with RECPs (Schreckenbach *et al.*, 1998) and with model potentials with Douglas–Kroll corrections (AIMP-DK) (Wahlgren *et al.*, 1999). As shown in Table 17.6, the calculated U=O distances agree rather well with experiment while the U–OH bond lengths are overestimated somewhat by ~0.1 Å compared to the crystal structure.

The U=O bonds in the hydroxide complexes are longer than those in the aqua complexes. This observation indicates weaker U=O interactions because of the competition with the equatorial OH^- ligands, which are acting as strong π-donors. The lone pair orbitals on the OH^- ligands have the proper symmetry to interact with the π_u and π_g U–O bonding orbitals of the UO_2^{2+} moiety (Schreckenbach *et al.*, 1998).

Solution EXAFS studies of uranyl hydroxide complexes in two different alkaline environments found relatively similar U–OH bond lengths (2.22–2.24 Å) that differ only slightly from the X-ray structure of $[UO_2(OH)_4]^{2-}$ (Clark *et al.*, 1999; Wahlgren *et al.*, 1999). The number of oxygen atoms in the equatorial plane was found to be 5 ± 0.5. Clark *et al.* interpret this result in terms of a $[UO_2(OH)_5]^{3-}$ structure. Calculations on the pentahydroxide structure by Wahlgren *et al.* gave U–OH bond lengths 0.3 Å longer, and hence they ruled out this form in favor of the tetrahydroxide. They also examined a third species with one water and four hydroxide ligands bound to the uranyl. More recently, Sonnenberg *et al.* (2005) found a stable pentahydroxide species with C_{5v} symmetry with no imaginary frequencies having U–OH bond lengths of 2.45 Å without incorporating solvent effects, which would be 0.2 Å longer than the derived value from the EXAFS analysis.

Schreckenbach *et al.* (1998) investigated the possible isomerization of the tetrahydroxide in which protons are transferred from the equatorial hydroxides to the uranyl oxygen atoms to reconstitute the tetrahydroxide. Such a mechanism was suggested to account for the scrambling of ^{18}O in the complex in basic solution (Fig. 17.9). They found an unusual *cis*-oxo form with a bent O=U=O bond angle of 128° (Table 17.6) to be a local minimum with a calculated energy 18 kcal mol^{-1} above the more stable 'usual' *trans*-oxo form. The barrier between the two forms was calculated to be 38 kcal mol^{-1}, too high to account for rapid isomerization via a unimolecular mechanism.

(c) Complexes with bidentate ligands

Actinyl species can be found complexed to other inorganic ligands in a variety of conditions. Because waste treatments of actinides in solution use nitrates, actinyl complexes with coordinated nitrate ligands are common (Castellato *et al.*, 1981; Allen *et al.*, 1996). Actinyl complexes with carbonate ligands are also common and are especially relevant to studies of actinides in the environment with naturally occurring minerals, carbonate species are another important actinide complex (Clark *et al.*, 1995). Craw *et al.* examined prototypical nitrate complexes $UO_2(NO_3)_2(H_2O)_2$ at the Hartree–Fock level (Table 17.7) as well as a sulfate complex and their Pu(VI) analogs (Craw *et al.*, 1995). As shown

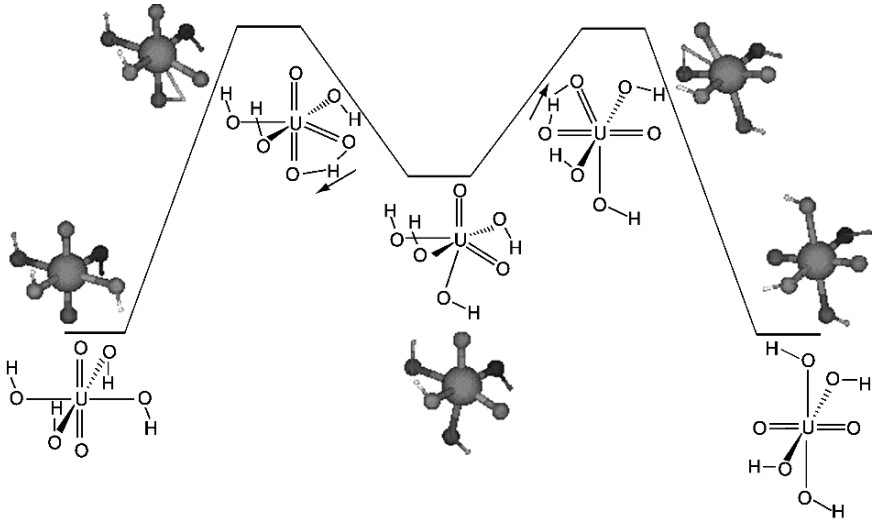

Fig. 17.9 *Isomers of* $[UO_2(OH)_4]^{2-}$ *involving conventional trans and unusual cis-O=U=O linkages* (*reproduced from Schreckenbach* et al., 1998).

in Fig. 17.10, the nitrato complexes are coordinated in a bidentate mode. An analysis of the bonding in these complexes showed primarily ionic bonding dominated by electrostatic forces.

Gagliardi and Roos (Gagliardi *et al.*, 2001a; Gagliardi and Roos, 2002) have used complete active space self-consistent field (CASSCF)/CASPT2 calculations to examine carbonato complexes of the uranyl and neptunyl ions that have been the focus of several experimental studies (Clark *et al.*, 1995, 1996; Docrat *et al.*, 1999). Solid-state structures with both $[UO_2(CO_3)_3]^{4-}$ and $[UO_2(CO_3)_3]^{5-}$ are known. In both cases, three carbonates bind in the equatorial plane in a bidentate mode. Experimentally the U=O bond length increases from 1.80 to 1.90 Å when the extra electron is added in going from the U(VI) to the U(V) complex. The calculations also give an increase in the U=O bond length of 1.845 to 1.929 Å between the U(VI) and U(V) complexes. Similar increases in the $U–O_{eq}$ bond length are also noted. For the Np(V) species $[NpO_2(CO_3)_2(H_2O)_2]^{3-}$, the calculated Np=O bond length, 1.854 Å, is between the U(VI)=O and U(V)=O values and is in excellent agreement with the experimental value of 1.85 Å.

Vázquez *et al.* (2003) studied tris-carbonato, tris-acetato, and related uranyl complexes using gradient-corrected DFT using the ADF code also employing a solvent continuum model. They also explored dimeric complexes with bridging hydroxide groups and examined the role of Ca^{2+} counter-ions and explicit water molecules. Coupez and Wipff (2003) reported Hartree–Fock and DFT calculations with diamide ligands (malonamide and succinamide) comparing the

relative stabilities of six- and seven-membered chelate rings in their bidentate coordination to the uranyl.

17.3.3 'Bare' actinyl species and actinyl ions in solids

While uranyl is the prototypical actinyl ion, with an oxidation state of +6, high-valent dioxo species are also well known for Np, Pu, and Am. For these actinides, the -yl name has also been applied to the +5 and +6 oxidation states (Katz *et al.*, 1986). In an overview of the electronic structure and spectra of these ions, Matsika *et al.* (2001) were able to characterize the strengths of different interactions found in actinyls. The strongest interaction is the antibonding one between the $5f\sigma_u$ and the $5f\pi_u$ and the ligand orbitals, resulting in high orbital energies for the molecular orbitals mostly derived from these 5f orbitals. Comparisons between the actinide electron repulsion parameters and the actinide spin–orbit parameter (ζ_{5f}) indicate that the electron repulsion is more

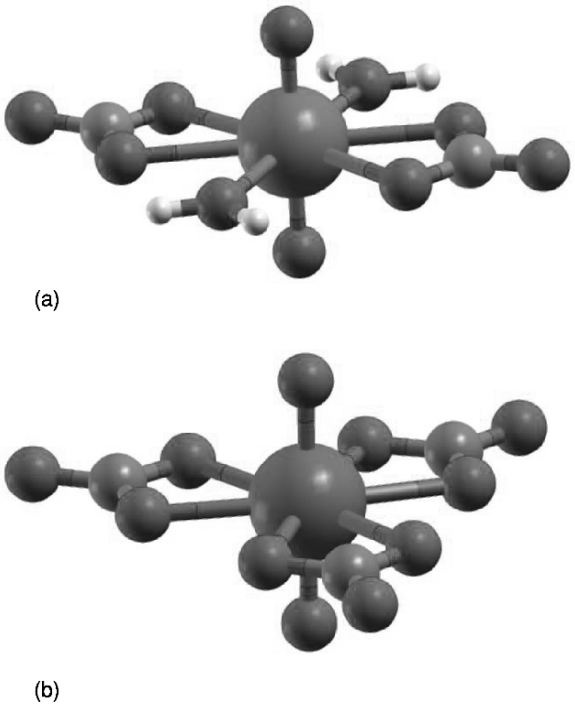

Fig. 17.10 *Calculated structures of bidentate complexes with* (*a*) *nitrate and* (*b*) *carbonate ligands* (*see Craw* et al.*,* 1995*; Gagliardi and Roos,* 2002).

significant, but that the spin–orbit splitting needs to be included. Lastly, the $5f\delta_u$ and the $5f\phi_u$ orbitals display weak-field coupling, i.e. the two-electron open-shell state is $\delta_u^1\phi_u^1$ rather than δ_u^2 or ϕ_u^2. The electron configurations for these ions can thus be characterized as $\sigma_u^2(\delta_u\phi_u)^n$,$\sigma_u^2(\delta_u\phi_u)^{n-1}\pi_u^1$,$\sigma_u^1(\delta_u\phi_u)^{n+1}$, with n ranging from zero to four, the ground states for these configurations for the various actinyl species are listed in Table 17.8. For example, for f^2 systems, the two actinyl ions studied were NpO_2^+ and PuO_2^{2+}. The lowest state for a given electron configuration is listed – for example, for the $\sigma_u{}^1(\delta_u\phi_u)$ ^3H configuration, that state would be $^5\Phi_{1g}$ for each of the two actinyl ions. Note that the occupation number for the δ_u and the ϕ_u orbitals are given together due to the strength of the electronic interactions listed above.

As mentioned previously, the COLUMBUS codes have recently enabled two-component multi-reference configuration interaction singles and doubles (SO-MRCISD) using CSF expansions on the order of millions. The great advantage of these calculations for linear molecules is that since the spin–orbit effects are incorporated in the variational calculation, the resultant states are eigenfunctions of the total z-component angular momentum, Ω. A survey of the computational uranyl literature referred to above reveals little information concerning

Table 17.8 *Lowest energy electronic states for various f^n actinyl electron configurations* (*see Matsika* et al., 2001).

[a] Note that the σ_u orbital refers to the highest ligand-based occupied orbital.

excited states. Experimentally, much of the spectroscopic work is based on actinyl ions in crystalline environments or in solutions. Computational modeling of the latter is discussed elsewhere in this review; as for the former, there are two well-known approaches: embedded potentials using AIMP, developed by Seijo and Barandiarán (1999), recently applied to Pa^{4+} and U^{4+} defects in chloride hosts (Barandiarn *et al.*, 2003) and to a study of Pa^{4+} defects in Cs_2ZrCl_6 (Seijo and Barandiarán, 2001), and a layered-cluster computational model developed by Winter and Pitzer (1985) and applied to actinyl systems by Matsika and Pitzer (2001). These authors have also examined the spectral intensities of actinyl ions (Matsika *et al.*, 2000).

The low-lying transitions of non-f^0 actinyl species are known to be f→f transitions, which are formally electric-dipole forbidden if the molecule has a center of symmetry based on group theory (Matsika *et al.*, 2001). By adding equatorial ligands to the actinyl complexes, the center of inversion can be removed. A study of intensities for $NpO_2^+ + nCl^-$ complexes reveals that, for the odd n cases (odd being required to remove the inversion point), the $n = 5$ case reproduces the experimental spectrum (Matsika *et al.*, 2000). Analysis of the crystal field shows that five-coordination allows for mixing between the 5fϕ and 6dδ orbitals, resulting in calculated oscillator strengths that can reproduce the experimental spectrum.

The excited states of the uranyl ion have been calculated for both gas-phase and crystalline environments by SO-MRCISD (Zhang and Pitzer, 1999; Matsika and Pitzer, 2001) and by CASPT2 [using Douglas–Kroll for scalar relativistic effects and RASSI (restricted active space state interaction) with atomic mean field integrals for spin–orbit effects] (Pierloot, 2003) methods. Both methods agree with the experimental results (Denning, 1992) as to the progression of the Ω values of the low-lying excited states: 1_g, 2_g, 3_g, 2_g, 3_g, and 4_g. The first three spin–orbit states are derived from the ΛS term $^3\Delta_g$ and the next three from $^3\Phi_g$–note that there is mixing between the two ΛS states in the $\Omega = 2_g$ and $\Omega = 3_g$ states. The latter method appears to have better quantitative agreement for transition energies (T_e) for the fluorescent transition, which is the $1_g \rightarrow 0_g^+$ transition: 20 363 cm^{-1} (for $Cs_2UO_2Cl_4^{2-}$) using

SO-MRCISD, 20 028 cm^{-1} (for the isolated $UO_2Cl_4^{2-}$ complex) using CASPT2, and 20096 cm^{-1} from experiment.

There are far fewer experimental and computational studies for the neptunyl ions as compared to uranyl. For the NpO_2^{2+} ion, which is an f^1 system, the SO-MRCISD method gives a bond length of 1.66 Å and a symmetric stretching frequency of 1059 cm^{-1} for the gas phase (Matsika and Pitzer, 2000). All-electron scalar-relativistic DFT studies give values from 1.701 to 1.721 Å for the former and 1011 to 970 cm^{-1} for the latter, depending on the functional used (Garcia-Hernandez *et al*., 2002). The experimental values (in solution and in the solid state) range from 1.75 (Clark, 1999; Tait, 1999) to 1.80 Å (Volkoy and Kapshuhof, 1976) and from 863 to 914 cm^{-1} (Basile *et al*., 1974; Budantseva *et al*., 2000). Matsika and Pitzer (2001) calculated a bond length of 1.70 Å and 950 cm^{-1} for NpO_2^{2+} doped into $Cs_2UO_2Cl_4$, values that are much closer to experiment and which emphasizes the need for comparing theory and experiment for the same phase of matter. The excited states show an interesting pattern: the ground state is an $\Omega = 5/2u$ state that is 86% $^2\Phi_{5/2u}$ and 14% $^2\Delta_{5/2u}$, the first excited state is an $\Omega = 3/2u$ that is predominantly $^2\Delta_{3/2u}$, followed by a 5/2u state (86% $^2\Delta_{5/2u}$ and 14% $^2\phi_{5/2u}$) and a 7/2u state ($^2\Phi_{7/2u}$). Although the 5fδ orbital is lower in energy than the 5fϕ orbital, the latter participates more in the ground state due to the greater spin–orbit splitting of the fϕ orbital. For NpO_2^{2+} doped into $Cs_2NpO_2Cl_4$, the calculated T_e values for the analogs of these states are 0, 1663, 5775, and 8463 cm^{-1} compared to the experimental 0, 1000, 6880, and 7990 cm^{-1} (Denning *et al*., 1982a,b), which is good agreement for this level of theory (Matsika and Pitzer, 2001). Calculations on the energy of the first charge transfer state, a $^4H_{7/2u}$ state from a $\sigma_u^1\delta_u^1\phi_u^1$ configuration, are very dependent on the level of correlation. The experimental value is 13264.9 cm^{-1} above the ground state, and the calculated values differ between 12622 cm^{-1} (for 15 electrons correlated, in the isolated ion) and 18236 cm^{-1} (for seven electrons correlated, in the crystal).

The Pu(VI) plutonyl ion, PuO_2^{2+}, is an f^2 system for which there are very little experimental data. The ground state has been determined by electron spin resonance (Bleaney, 1955) and spectroscopic methods (Denning, 1992) to be $^3H_{4g}$. Initial calculations on PuO_2^{2+} led to the proposal of a $^3\Sigma_g^-$ ground state derived from a δ_u^2 configuration (Craw *et al*., 1995). However, as mentioned above, the δ_u and ϕ_u orbitals are weak-field-coupled and the ground state is proposed by several authors to be a ^3H_g state from a $\delta_u^1\phi_u^1$ configuration (Ismail *et al*., 1999; Maron *et al*., 1999; Hay *et al*., 2000). The bond lengths for this ground state vary from 1.6770 Å using averaged quadratic coupled cluster (AQCC; Maron *et al*., 1999) to 1.6883 Å using B3LYP (Ismail *et al*., 1999). Examination of vertical excitations show the importance of spin–orbit splitting, as the ground state is more properly labeled as an $\Omega = 4_g$ state. The progression of states shows the interposition of states derived from different ΛS states, the total spin–orbit splitting between the $\Omega = 4_g$ and $\Omega = 6_g$ states is 7849 cm^{-1} from two-step quasi-degenerate perturbation theory calculations by Maron *et al.* (1999)

and 9613 cm^{-1} from a SO-MRCISD calculation (Blaudeau *et al.*, unpublished). Hay *et al.* (2000) also performed spin–orbit studies on plutonyl, as well as on the aqua complexes. Recently, an EPCISO calculation has been performed by Clavaguéra-Sarrio *et al.* (2004), which predicts the splitting between the $\Omega = 4_g$ and $\Omega = 6_g$ states to be 14329 cm^{-1} (see Table 17.9 for the splittings of the ^3H_g and $^3\Sigma_g^-$ states; note that there are other states in the spectra that are not listed in the table). Their explanation of the discrepancy between this calculation and the previous ones are due to the inclusion of spin–orbit polarization effects in the EPCISO method. All of the calculations show the interspersing of the Ω states derived from different ΛS states, and thus the importance of incorporating spin–orbit methods in the calculations. A charge-transfer state, $^5\Phi_{1g}$ state from a $\sigma_u^1\delta_u^2\phi_u^1$ configuration, is found in the latter set of calculations at an adiabatic T_e of 20279 cm^{-1}; the experimental value is 19000 cm^{-1} (Jørgensen, 1970). Comparing the calculated excited states for the isoelectronic species NpO_2^+ and PuO_2^{2+}, the transition energies are lower for the monocation, e.g. the first excited state, with $\Omega = 0_g^+$, lies at 3366 cm^{-1}, compared to 3951 cm^{-1} for the plutonium species (Matsika and Pitzer, 2000; Blaudeau *et al.*, unpublished).

What is most significant for these results is that they illustrate the absolute need to include spin–orbit effects for open-shell actinide systems. Interestingly, the study by Clavaguéra-Sarrio *et al.* (2004) show that the geometries and frequencies of these states are very similar due to the atomic nature of the 5fδ and the 5fϕ orbitals. Thus, single-reference methods, such as DFT, can still predict the structural properties of these molecules, although wavefunction techniques that include spin–orbit effects are required to predict the electronic spectra.

17.3.4 Other high oxidation state oxygen species

There has been much recent experimental and theoretical interest in actinide oxide species with formal metal oxidation states greater than +6. Domanov *et al.* report the formation of a volatile species they tentatively identify as a Pu(VIII) oxide, PuO_4 (Domanov *et al.*, 2002). They refer to previous work by

Pershina and coworkers that had concluded that such a species in solution would be thermodynamically unstable (Ionova *et al.*, 1981; Pershina *et al.*, 1982). Pyykkö *et al.* speculated on the existence of neutral UO_6, with a formal oxidation state of +12 for the uranium atom (Pyykkö *et al.*, 2000). The octahedral structure of this hexaoxide is a minimum for several computational methods, including DFT and MRCI. However, it is found to have an imaginary frequency at the Dirac–Fock level. Some earlier studies included calculations on anionic U(VI) oxides, including UO_4^{2-} and UO_4^{6-}, with good agreement to experimental geometries (Ellis *et al.*, 1982; Pyykkö and Zhao, 1991).

Np(VII) species in solution have been studied by two groups. Williams *et al.* (2001) found a NpO_4^- complex, which, in agreement with DFT calculations, has D_{2d} symmetry. The deviation from planar geometry is slight (the *trans*-O–Np–O angle is 169.8°) but significant, as the planar form has an imaginary frequency. On the other hand, Bolvin *et al.* undertook calculations on the isoelectronic ions NpO_4^- and UO_4^{2-} and found the former to be square planar and the latter to be tetrahedral (Bolvin *et al.*, 2001a,b). Both studies agree that the increased contribution of the 5f orbitals destabilize the tetrahedral forms, and the different geometries for the Np and the U complexes are due to the lower energy of the 5f orbitals for Np(VII) compared to U(VI).

17.4 ACTINIDE HALIDE COMPLEXES

The actinide halides, particularly UF_6, have occupied a central role in actinide chemistry since the Manhattan Project. The high vapor pressure of UF_6 at room temperature made it the compound of choice to use in the gaseous diffusion cascade process for the separation of uranium isotopes. In addition, UF_6 is the most promising candidate for laser-induced isotope enrichment, in which the isotopic shifts of optical excitations are used to achieve isotope separation. The irradiation of UF_6 also generates the unsaturated photoproducts UF_5 and UF_4, which formally are f^1 U(V) and f^2 U(IV) complexes, respectively. Because of the dominant role these compounds play in actinide technology, the electronic structure of the ground and excited states of these highly symmetric (in the gas phase) uranium fluorides and related actinide halides has intrigued experimental and theoretical actinide chemists. In this section, some of the more recent theoretical calculations on the electronic structure of molecular actinide halides will be presented.

17.4.1 UF_6 and related complexes

The properties of actinide halides have been extensively studied both experimentally and theoretically. Much as the uranyl ion has been for oxo chemistry, the hexafluoride UF_6 has been the benchmark for theoretical studies of actinide halides over the past 25 years. Early electronic structure studies of UF_6 have

been extensively reviewed by Pepper and Bursten (1991) and included REX, nonrelativistic and relativistic MS-Xα calculations, and relativistic ECP calculations. The principal focus of these studies was on the energies of the occupied orbitals, the participation of the 5f orbitals in the bonding, and the nature of the excited states. The highest occupied valence orbitals, shown schematically in Fig. 17.11, arise naturally from the symmetry-adapted combination of six sets of fluorine 2p orbitals with admixture of 6d and 5f character on U. The two lowest

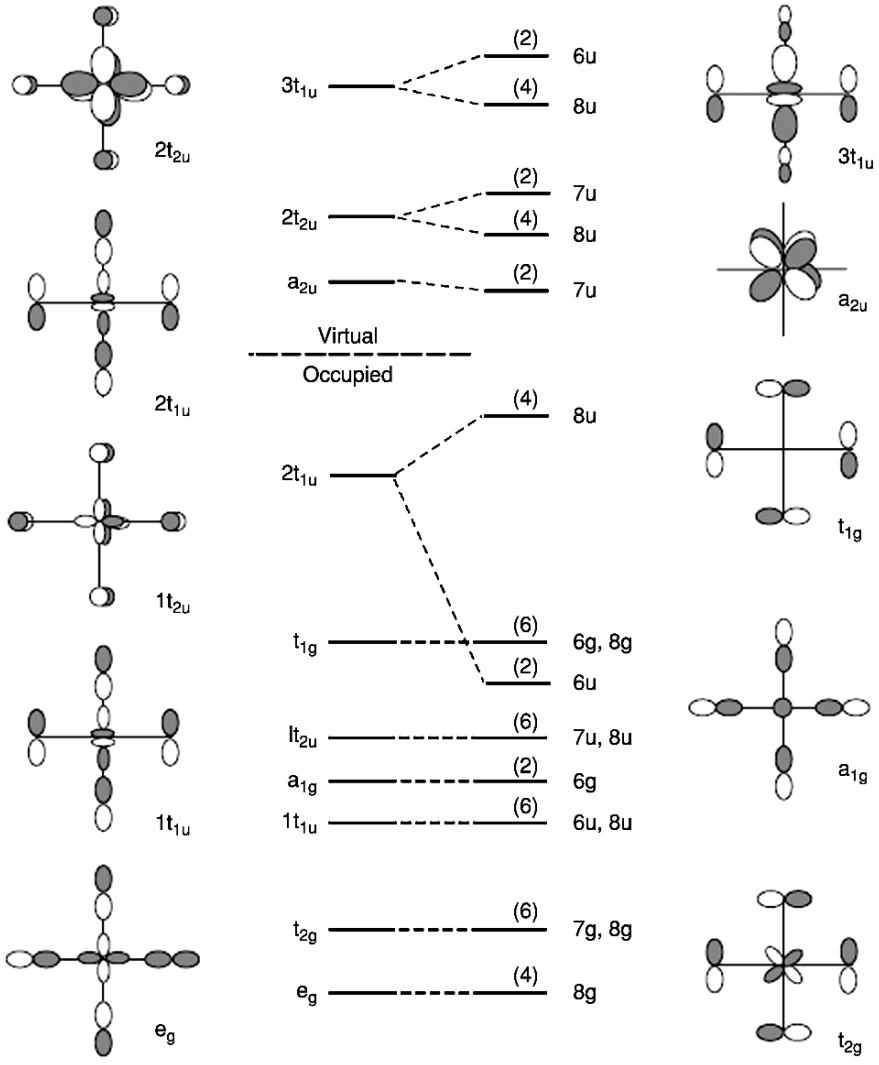

Fig. 17.11 *Schematic energy-level diagram for* UF_6 *without* (*left*) *and with* (*right*) *spin–orbit coupling* (*adapted from Hay*, 1983).

orbitals in this set, of e_g and t_{2g} symmetry, are of the proper symmetry for 6d mixing from the U, while the higher energy occupied orbitals of t_{1u} and t_{2u} symmetry can have 5f admixture. The lowest virtual orbitals having a_{2u}, t_{2u}, and t_{1u} symmetry essentially comprise the 5f set of orbitals. As one goes down the actinide series from UF_6, a formally $5f^0$ system, to NpF_6 ($5f^1$) and PuF_6 ($5f^2$), the additional electrons populate this manifold of orbitals that are unoccupied in UF_6. When spin–orbit effects are included, only modest splittings are observed with the exception of the highest occupied orbital ($2t_{1u}$), which, in addition to some 5f character, also has significant mixing with the occupied 6p orbital of U. This mixing leads to a large splitting ($\sim$1.2 eV) between the two spinor components γ_{8u} and γ_{6u}, where γ_{8u} and γ_{6u} are the double-group symmetries arising from the $2t_{1u}$ level when spin–orbit effects are included.

Several studies in recent years of UF_6 have been carried out using the modern approaches described in the earlier section. Hartree–Fock-based approaches include all-electron Hartree–Fock and Dirac HF calculations by de Jong and Nieuwpoort (1996) and RECP studies (Hay and Martin, 1998). Density functional approaches include DS-DV by Onoe *et al.* (1993), all-electron Douglas–Kroll local density (SVWN), and valence-electron SVWN by Garcia-Hernandez *et al.* (2002), and quasi-relativistic BLYP using ADF by Schreckenbach (2000). In Table 17.10, the energies of the occupied orbitals are shown from selected theoretical Hartree–Fock and DFT approaches. In general, we note that the predicted ionization potentials from Hartree–Fock-based methods using the orbital energies according Koopmans' theorem begin around 17 eV, which is considerably higher than the first observed peak at 14.1 eV in the photoelectron spectra. DFT methods give somewhat correspondingly lower predicted IPs ranging from 8 eV for a scalar (DV-DS), 11 eV for gradient-corrected (QR-PW91), and 12 eV for hybrid (B3LYP). Analysis of the bonding for the DHF wavefunctions showed a charge of +2.22 on U and populations 5f (1.82), 6d (1.31), 7s (0.06), while the DV-DS results showed a charge of 1.39 on U and populations 5f (2.51), 6d (1.83).

As mentioned in the earlier section on methods, one of the major developments over the past decade has been the capability to calculate geometries and frequencies using analytic derivative techniques. The geometries and frequencies of the AnF_6 hexafluorides have been determined using these capabilities, quasi-relativistic DFT by Schreckenbach *et al.* with ADF, and all-electron Douglas–Kroll DFT by Garcia-Hernandez *et al.* (Hay and Martin, 1998; Schreckenbach *et al.*, 1999; Garcia-Hernandez *et al.*, 2002) and with RECPs using Hartree–Fock and DFT approaches. The results are summarized in Table 17.11 and compared with experiment (Seip, 1965; Kimura *et al.*, 1968; McDowell *et al.*, 1974). Generally the experiences from these investigations have shown that methods that predict bond lengths accurately also typically calculate vibrational frequencies in good agreement with experiment. In this regard the LDA approaches (SWVN) either with RECPs or in all-electron DKH calculations are a good compromise in computational effort and

accuracy. Hartree–Fock approaches underestimate U–F bond lengths (and overestimate vibrational frequencies) whereas the opposite is true for gradient-corrected DFT methods. Hybrid approaches give predictions of bond lengths and frequencies similar to local density approaches.

The calculation of bond energies is a more difficult challenge for theoretical methods. Coupled with this is the relatively sparse database of thermochemical properties for actinide-containing molecules. For the uranium fluorides and chlorides, however, there is thermochemical data for most of these species, and the bond energy in UF_6 to form $UF_5 + F$ is especially well known: 70 ± 2 kcal mol^{-1}, as measured by Hildenbrand and Lau (1991). Recently Batista *et al.* (2004b) carried out a systematic study of DFT approaches in their predictions of this bond energy. In addition the results of all-electron Douglas–Kroll–Hess results were compared using the same functionals. These results are summarized in Table 17.12. Among the main conclusions is that the SC-RECP (60-electron) potential of Küchle *et al.* is required to give agreement with the all-electron DKH results with a given functional. By contrast the results with the 78-electron LCRECP (not shown in the table) overestimates the bond energy for a particular method by 40–50 kcal mol^{-1} compared to the SC-RECP and DKH result. When corrected for zero-point and spin–orbit effects, the agreement between the hybrid DFT (B3LYP, PBE0), all-electron DKH and experiment is within the experimental uncertainties. These authors also presented an analysis of the effects on vibrational frequencies with variation of functionals and types of core potentials.

[a] Hildenbrand and Lau (1991).

The spectroscopy of the excited electronic states of UF_6 shows broad relatively unstructured bands in the ultraviolet region with the first strong peak occurring at 5.4–5.8 eV (C-band) and weaker peaks at lower energies 3.2–3.4 eV (A-band) and 3.8–4.6 eV (B-band) (Hay, 1983). Excited states were probed using earlier QR-MS (Boring and Wood, 1979), DS-DV (Koelling *et al.*, 1976), and RECP-SO (Hay, 1983) methods; there have been surprisingly few recent studies using newer techniques. Qualitatively the methods assign the weaker bands to 'u-to-u' dipole-forbidden excitations such as t_{1u} (8u) to the virtual 5f manifold while the strong C band is variously assigned to allowed 'g-to-u' excitations such as t_{1g}–t_{1u}, a_{1g}–t_{1u}, and t_{1g}–t_{2u}.

The structures and vibrational properties of UF_6, NpF_6, and PuF_6 were studied using DFT approaches with LC-RECPs (Hay and Martin, 1998) where the best agreement with available experimental data was obtained at the local density (SVWN) and hybrid (B3LYP) functionals. All-electron DKH calculations on NpF_6 had similar conclusions (Garcia-Hernandez *et al.*, 2002). The predicted Np–F bond lengths were 1.978 Å (VWN), 2.008 Å (BP), and 2.019 Å (PBEN) of which the local density VWN value agrees most closely with experiment (1.981 Å). By comparison the LC-RECP calculations with B3LYP hybrid functional and VWN functionals predicted a bond length of 2.013 and 1.998 Å, respectively.

Schreckenbach (2000) compared QR-PW91 and ECP-B3LYP calculations on the chlorine-substituted fluoride series $UF_{6-n}Cl_n$ and the related methoxide series $UF_{6-n}(OCH3)_n$. Batista *et al.* (2004a) computed the equilibrium structures of the UF_n and UCl_n series of halide species for $n = 1$–6 using ECP-B3LYP calculations. They found structures and corresponding symmetries as follows: UF_5 (C_{4v}), UF_4 (T_d), UF_3 (C_{3v}), and UF_2 (C_{2v}), as shown in Fig. 17.12, and similarly for the chloride analogs. Gagliardi *et al.* (2002) optimized the equilibrium geometries of ThX_4 (X = F, Cl, Br, and I) and computed the vibrational frequencies, of which only ν_3 and ν_4 had been measured for gas-phase ThF_4 and only ν_3 had been measured for gas-phase $ThCl_4$. Mochizuki and Tatewaki (2003)

have reported DHF studies on CmF_n ($n = 1$–4). The bonding was found to be largely ionic in character, with some donation from the F 2p to the Cm 6d orbitals.

The electronic structure of the $5f^1$ actinide hexahalide complexes PaX_6^{2-} (X = F, Cl, Br, I), UX_6^- (X = F, Cl, Br), and NpF_6 were studied using relativistic DV-Xα approach (Kaltsoyannis and Bursten, 1995). Increased 5f participation was found in going from Pa to U to Np while the metal character remained relatively unchanged as one proceeds from F down to I. Electronic transition energies were calculated using the Slater's transition state method (Slater, 1974).

17.4.2 Actinide oxyhalides

Complexes containing halides and the actinyl AnO_2^{2+} unit represent another interesting class of species. The properties of uranyl halide species $[UO_2X_4]^{2-}$ are known in solid state structures for the chlorides but there are no known structures for the fluorides. While $[UO_2F_n]^{2-n}$ species exist in solution for $n = 0$–5, the solid state fluoride structures include dimers, neutral UO_2F_2 with six equatorial fluorine ligands around each U, and uranyl complexes with five or six equatorial F or H_2O ligands. In Table 17.13, the results of calculations on $[UO_2F_4]^{2-}$ and $[UO_2Cl_4]^{2-}$ are shown along with experimental values for various crystal structures of the chloride complexes. The bonding is analogous to the tetrahydroxide species discussed above except that the halides are much poorer π-donors than hydroxide ligands. The computational studies to date have focused primarily on the structures, vibrational frequencies, and to some extent on the thermodynamics with regard to overall stability with less emphasis on the nature of the bonding.

Recently, Straka *et al.* (2001) have examined all possible $[UO_2F_n]^{q+}$ species with f^0 configuration using DFT approaches. These include the known UO_2F_2 species and other reactive forms, some of which have been detected in mass spectra and matrix isolation studies. Some of these predictions are also given in Table 17.13. In addition, they examined other actinides from Pa through Am with f^0 configurations where the trends in bond lengths as a function of the actinide and the coordination number were examined (Fig. 17.13). Most recently, Straka (2005) has used DHF calculations to explore the bonding in later actinide AnO_2F_4 (An = Pu, Cm, Cf, Fm) complexes. These calculations suggest that the Pu and Cm species have D_{4h} symmetry and are stable with respect to decomposition to the elements. Infante and Visscher (2004a) investigated solvated forms of $[UO_2F_4]^{2-}$ complexes and especially on the relative stability of one vs two aqua equatorial groups in the first coordination shell in a study that combined quantum and classical (QM/MM) methods. In a related study, Wang and Pitzer (2001) studied the various structures arising from $UO_2F_2(H_2O)_n$, for $n = 2$–4 and the results for $n = 2$ are shown in Table 17.13. The possibilities of bonding in the series UF_4X_2 for a variety of pseudohalide ligands

X (H,Cl, CN, etc.) were probed by Straka *et al.* (2003) by computing the structures, frequencies, and thermochemistry with SC RECP calculations with the B3LYP functional. By examining substitution energies of 2X for 2F in UF_6, they were able to gauge relative stabilities. While none of the complexes was more stable than UF_6, they found relative stabilities NCO < Cl < NC < NCS < CN < OCN < SCN and related these trends to the poorer π-accepting ability of CN, for example, relative to NC and other ligands.

Kovács *et al.* (2004) used the ZORA approach to determine the structures, vibrational analyses, and bonding of UX_6 and UO_2X_2 (X = F, Cl, Br, I) molecules. The UX_6 complexes maintained O_h symmetry, while the UO_2X_2 complexes, which have C_{2v} symmetry, showed structural variations with the heavier halides, with the O=U=O and X–U–X bond angles decreasing as the

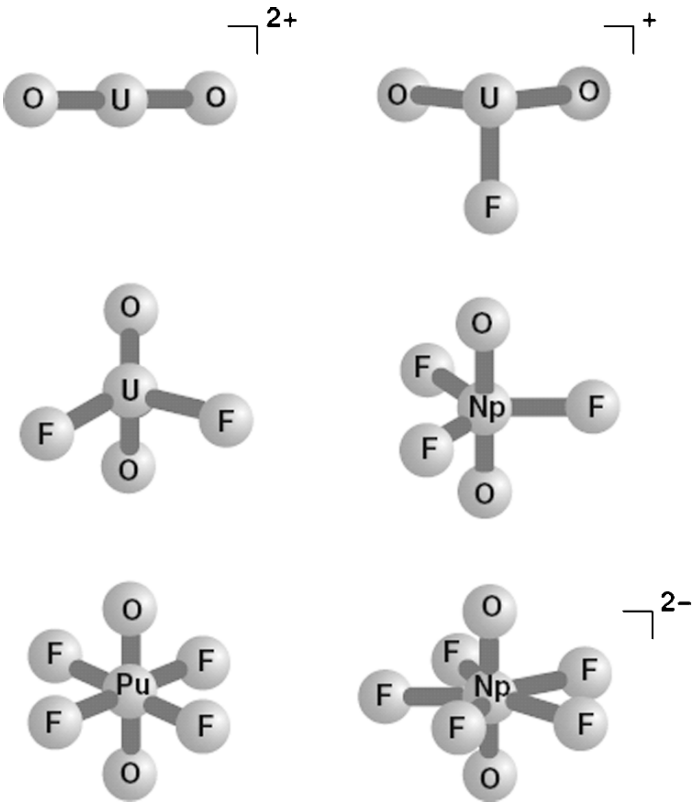

Fig. 17.13 *Calculated structures of* AnO_2F_n ($n = 1$–5) *species* (*adapted from Straka* et al., 2001).

halide ligands get heavier. For example, the X–U–X angle decreases from 110.6° for UO_2F_2 to 97.5° for UO_2I_2. They report the uranium 5f plays a predominant role in the orbital interactions, with increased contribution from the 6d in the heavier halide complexes.

17.5 ACTINIDE ORGANOMETALLICS

The growth in actinide chemistry following the Manhattan Project coincided with the birth of modern organometallic chemistry that followed the discovery of ferrocene in the early 1950s. It is therefore not surprising that actinide organometallic chemistry has developed into a thriving field. The growth in the chemistry and spectroscopy of actinide organometallics has been nicely reviewed in a series of articles by Marks (1976, 1979, 1982) and in Chapters 25 and 26. The study of organoactinide compounds benefits from some of the typical advantages of organometallic chemistry, including the use

of weakly coordinating nonaqueous solvents, the intrinsically molecular nature of organometallic compounds, and the well-developed arsenal of spectroscopic probes developed for organometallic systems. In this section, we will discuss theoretical aspects of the electronic structure of the major classes of organoactinide complexes, with an emphasis on systems in which an actinide atom is bonded to two or more cyclic hydrocarbyl ligands.

17.5.1 Actinocenes

The history of the actinocenes, $An(COT)_2$ ($COT = \eta^8\text{-}C_8H_8$), dates back to 1963, when R.D. Fischer first predicted that uranocene would be a stable compound, i.e. the actinide analog of the prototypical d-element sandwich molecule ferrocene (Fischer, 1963). Five years later, Streitwieser and Müller-Westerhoff (1968) reported the synthesis and characterization of $U(COT)_2$, thereby opening up a whole new area of organometallic chemistry. Subsequently several other actinocenes and actinocene anions were reported (Streitwieser, 1984; Streitwieser and Kinsley, 1985; Parry *et al.*, 1999), with An = Th, Pa, Np, Pu, and Am. Much of the chemistry of actinocenes has been the subject of recent reviews (see, for example, Roesky, 2001; Seyferth, 2004) and is detailed in Chapter 25.

The actinocenes have proved an irresistible challenge for many theoretical groups, due partly to the high molecular symmetry (which allows the relative roles of the 6d and 5f orbitals of the metal to be differentiated) and to the fact that $M(COT)_2$ compounds occur only in the f-block. These researchers have employed many different computational techniques, ranging from relativistic EHMO theory (Pyykkö and Lohr, 1981), to intermediate neglect of differential overlap (INDO; Cory *et al.*, 1994), to more sophisticated *ab initio* methods (Chang and Pitzer, 1989; Chang *et al.*, 1994; Dolg *et al.*, 1995; Liu *et al.*, 1997), as well as density functional approaches (Rösch and Streitweiser, 1983; Boerrigter *et al.*, 1988; Kaltsoyannis and Bursten, 1997; Li and Bursten, 1998). In this section, we shall review the issues that have been addressed by these studies, and summarize the key conclusions.

(a) Geometric structures of the actinocenes

The crystal structures of $Th(COT)_2$ and $U(COT)_2$ were reported in 1972 by Avdeef *et al.* (1972). Both molecules were found to have planar and parallel carbocyclic rings, sandwiching the metal center in an eclipsed (D_{8h}) orientation. It has been common practice for theoretical studies to assume the crystallographic geometry (e.g. Pyykkö and Lohr, 1981; Chang and Pitzer, 1989; Kaltsoyannis and Bursten, 1997), and there have been very few attempts to calculate the geometry of actinocenes. Most of these have focussed on optimizing the metal–ring distance while retaining both D_{8h} symmetry and planar rings. The results are summarized in Table 17.14, from which it can be seen that the metal–ring distance is generally overestimated.

Table 17.14 *Optimized metal–ring centroid distances* (Å) *in* $An(COT)_2$ ($M = Th$ *to* Pu).

[c] Liu *et al*. (1997).
[d] Li and Bursten (1998).
[e] Avdeef *et al*. (1972).

In 1998, Li and Bursten reported fully optimized geometries for $Pa(COT)_2$ using relativistic DFT with a variety of different functionals (Li and Bursten, 1998). They found that the D_{8h} and D_{8d} (staggered) structures were essentially isoenergetic (providing some late-in-the-day computational justification of the ubiquitous assumption of D_{8h} symmetry in previous theoretical studies), and that the PW91 functional best reproduced the average of the experimental metal–ring distances in $Th(COT)_2$ and $U(COT)_2$. They also found that the hydrogen atoms are tilted toward the metal atom by as much 9°, suggesting that the previous universal assumption of ring planarity in $Pa(COT)_2$ in particular and actinocenes in general may be a source of error and a possible reason for discrepancies between theoretical and experimental data. A ball-and-stick representation of the optimized PW91 geometry of $Pa(COT)_2$ under the constraint of D_{8h} symmetry is shown in Fig. 17.14.

(b) Orbital interactions in the actinocenes

In 1998, Dolg and Fulde wrote: "any discussion of atomic or molecular electronic structure in terms of orbitals and single configurations....is a simplification, which works in many but not in all cases" (Dolg and Fulde, 1998). They were writing with reference to the lanthanocenes and actinocenes, and in particular to their finding that the ground state of the 4f systems are not well represented by a single configuration, a result which they predicted to also hold for the later actinocenes. Notwithstanding these observations, we will set out the basic electronic structure of the actinocenes within the usual orbital approach. This brings with it the conceptual advantages of the independent-particle description, and serves as a good starting point for discussion of the effects of relativity, the calculation of excited-state properties, and the introduction of multi-configurational character to the molecular wavefunctions.

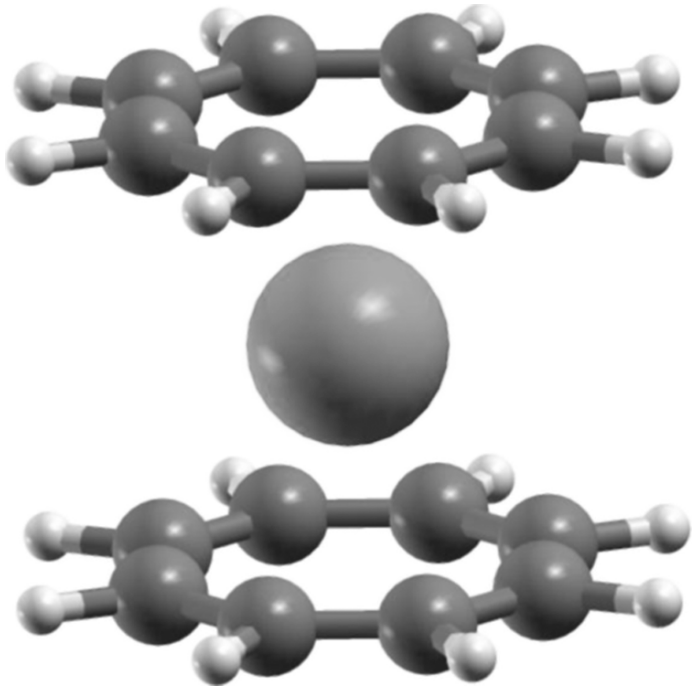

Fig. 17.14 *Representation of the optimized structure of protactinocene, Pa(η^8-C_8H_8)$_2$, from scalar-relativistic DFT (PW91) calculations (apdated from Li and Bursten, 1998).*

The generally accepted orbital interaction diagram for the actinocenes is given in Fig. 17.15. The eight-carbon 2pπ atomic orbitals of a D_{8h} C_8H_8 ring give rise to eight molecular orbitals (MOs) transforming as a_{2u}, e_{1g}, e_{2u}, e_{3g}, and b_{1u} in order of increasing energy. These orbitals are commonly denoted π_n ($n = 0$–4), where n is the number of vertical nodes (i.e. nodes perpendicular to the plane of the ring). In a ligand field of two COT rings, these π MOs give rise to the combinations shown in the second column from the right in Fig. 17.15. The valence atomic orbitals (AOs) of the actinide elements that interact with the $(COT)_2$ ligands are primarily the 5f and the 6d. It is common practice to take advantage of the pseudoaxial nature of the D_{8h} $(COT)_2$ ligand-field and label the metal orbitals as σ, π, δ, and ϕ, corresponding to $m_l = 0$, ±1, ±2, or ±3 respectively. In the absence of spin–orbit coupling, the 5f orbitals split in the $(COT)_2$ ligand field as e_{3u} (fϕ) $\approx$ a_{2u} (fσ) $<$ e_{1u} (fπ) $\ll$ e_{2u} (fδ), the strong destabilization of the latter resulting from their significant interaction with the highest occupied e_{2u} ring pπ levels. The 6d orbitals split as a_{1g} (dσ) $\ll$ e_{2g} (dδ) $<$ e_{1g} (dπ), and the total d-orbital splitting is larger than for the 5f on account of their greater radial extension and hence greater interaction with the ligand field.

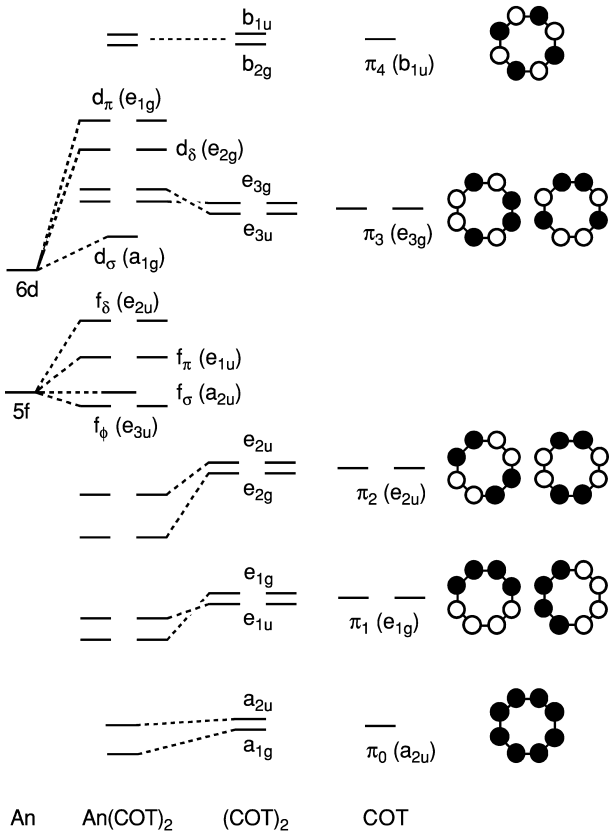

Fig. 17.15 *Principal interactions between the orbitals of two COT rings and the valence orbitals of an actinide atom in forming the frontier MOs of the actinocenes under D_{8h} single-group symmetry* (*reproduced from Li and Bursten*, 1998).

(c) Electronic configurations, ground states, and oxidation states in the actinocenes

In their 1994 INDO study, Cory *et al.* found that the highest occupied MO (HOMO) of $Th(COT)_2$ was the ring e_{2u} orbital, and that the metal-based levels were empty (Cory *et al.*, 1994). Moving across the actinides increased the number of metal electrons from 1 for $Pa(COT)_2$ to 4 for plutonocene, and it was found that all of these electrons occupy the e_{3u} ($f\phi$) orbitals. These findings are consistent with the experimental observations that $Th(COT)_2$ and $Pu(COT)_2$ are diamagnetic (although the magnetic moment of $Pu(COT)_2$ exhibits unusual temperature dependence), that $Pa(COT)_2$ and $Np(COT)_2$ have doublet ground states, and that uranocene has a triplet ground state (Karraker *et al.*, 1970; Hayes and Edelstein, 1972; Karraker, 1973). Chang *et al.* (1994) also

concluded that $An(COT)_2$ (An = Pa to Pu) have the $5f^n$ ($n = 1$–4) ground state configuration.

Earlier *ab initio* (SOCI) work by Chang and Pitzer (1989) on $U(COT)_2$ also concluded that it has an f^2 ground state configuration. These authors reported that the best simple description of the ground state was weak-field L–S $^3H_4$, with $|M_j| = 3$, where M_j is the magnetic quantum number. In the notation of the D_{8h}^* double point group, the spin–orbit-coupled ground state is E_{3g} (see below for more on spin–orbit coupling). Several configurations were found to contribute to this state, the leading one being $\pi(e_{2u})^4 e_{3u}^1 e_{1u}^1$, i.e. $f\phi^1 f\pi^1$. Several years later, Liu *et al.* (1997) also found that the ground configuration of uranocene is $5f^2$, although they calculated that the leading configuration to the ground state is $f\phi^1 f\sigma^1$.

In 1995 Dolg *et al.* used the MRCI and averaged coupled-pair functional (ACPF) *ab initio* methods to study $Th(COT)_2$ and its lanthanide analog $Ce(COT)_2$. They concluded that the ground state of $Th(COT)_2$ is $^1A_{1g}$, and that the dominant configuration to this state is $\pi(e_{2u})^4 f^0 d^0$, i.e. that there are no metal-based valence electrons (Dolg *et al.*, 1995). $Ce(COT)_2$ was also found to have a $^1A_{1g}$ ground state, but the $\pi(e_{2u})^4$ configuration was in this case found to contribute only $\approx 20\%$ to the ground state. The dominant contribution ($\approx 80\%$) comes from the $\pi(e_{2u})^3 f\delta^1$ configuration, in which the electrons are antiferromagnetically coupled in two MOs, and the direct product of their spatial symmetries is A_{1g}. Thus $Ce(COT)_2$ is best described as having a single metal-localized valence f-electron, i.e. as a Ce(III) compound containing two formally $COT^{1.5-}$ rings. This view, which was soon verified experimentally by Edelstein *et al.* (1996), is by contrast to that held historically, which saw both $Ce(COT)_2$ and $Th(COT)_2$ as M(IV) species.

Dolg and Fulde (1998) subsequently concluded that all of the lanthanocenes are Ln(III) compounds, and predicted that the later actinocenes should also be viewed in this way. By contrast, the early actinocenes are best described in the traditional manner, i.e. as An(IV) compounds with two COT^{2-} rings and a single dominant $\pi(e_{2u})^4 f^n$ configuration. It is perhaps rather fortunate then that the only actinocenes to have been studied by single-reference density functional methods are $Th(COT)_2$–$Pu(COT)_2$, precisely those that *ab initio* calculations suggest should be amenable to study by single-reference techniques.

Of those density functional studies, the most comprehensive remains the 1988 contribution from Boerrigter *et al.* (1988), which surveyed the first five actinocenes from $Th(COT)_2$ to $Pu(COT)_2$ using both nonrelativistic and relativistic HFS techniques. Their nonrelativistic calculations concluded that $Th(COT)_2$–$Pu(COT)_2$ have between 0 and 4 5f electrons, respectively, and that these electrons occupy the $f\phi$, $f\sigma$, and $f\pi$ levels equally. The relativistic spin–orbit-coupled calculations also find 0–4 5f electrons, occupying closely spaced $e_{5/2u}$ and $e_{1/2u}$ levels (D_{8h}^*). They concluded that both of these spin–orbit-coupled levels are composed primarily of atomic $5f_{5/2}$ character, and may be traced mainly to the $f\phi$ nonrelativistic molecular orbital. Two subsequent DFT studies of $Pa(COT)_2$

(Kaltsoyannis and Bursten, 1997; Li and Bursten, 1998) concur with the findings of Boerrigter *et al.*

(d) Metal–ring covalency

One of the most appealing features of actinocene electronic structure is the way in which the D_{8h} point group separates the metal's d- and f-orbitals into irreducible representations of g and u parity, thus preventing them from mixing with the same $(COT)_2^{4-}$ levels. There have been many estimates of covalency in the actinocenes, and in particular much has been made of its separation into d and f contributions. The metal content of the ring-based e_{2g} and e_{2u} levels has been a popular method for estimating the extent of covalency, and Table 17.15 collects the data from a range of studies. Uranocene is clearly the molecule for which most data are available, and it is notable that, while the exact numbers differ from study to study, all of the calculations show significant metal character to the e_{2g} and e_{2u} levels (or their spin–orbit-coupled equivalents). Boerrigter *et al.* (1988) find that the relative roles of the 6d and 5f orbitals alter from Th $(COT)_2$ to Pu$(COT)_2$, with the extent of 5f covalency significantly increasing with increasing actinide atomic number.

Other estimates of covalency have been made that do not explicitly involve the e_{2u}/e_{2g} composition. Chang and Pitzer (1989) calculated a metal charge of +0.98 in U$(COT)_2$, much reduced from the formal value of +4. They concluded

Table 17.15 *Metal 5f* (e_{2u}) *and 6d* (e_{2g}) *content (%) of the* $(COT)_2$*-based* e_{2u} *and* e_{2g} *molecular orbitals of An*$(COT)_2$ (*M = Th to Pu*).

that there is extensive metal–ring covalency, and that this is mainly through the uranium 6d AOs as the total $(COT)_2^{4-} \rightarrow U^{4+}$6d donation is 1.98 electrons, significantly larger than the 0.5 electrons donated into the metal 5f orbitals. Dolg *et al.* (1995) found that the bonding in thoracene is also significantly covalent and is mainly 6d-based, using analysis methods similar to those employed by Chang and Pitzer. Cory *et al.* (1994) used the metal fδ and dδ populations to also conclude that 6d covalency is larger than 5f, although the fδ population increases from $Th(COT)_2$ to $Pu(COT)_2$ while the dδ remains approximately constant.

The consensus from all of these studies is that there is significant mixing of the metal AOs with the highest occupied pπ MOs of the COT rings and that, for the early actinocenes at least, 6d covalency is larger than that involving the 5f orbitals. Experimental estimates of covalency are not easy to obtain, and hence it can be difficult to assess the reliability of the computational results. However, a very important experimental contribution in this area came in 1989 from Brennan *et al.* (1989), who studied $U(COT)_2$ by variable photon energy photoelectron spectroscopy. They concluded that (a) the second and third ionization bands are due unequivocally to the ring e_{2u}^{-1} and e_{2g}^{-1} ionizations, respectively (providing good evidence for the MO ordering shown in Fig. 17.15), (b) there is direct evidence for significant U 5f orbital character to the ring e_{2u}-based MOs, and (c) that the position of the e_{2g} ionization band at higher energy than the e_{2u} band is strong indirect evidence for an even larger U 6d contribution to these MOs.

(e) Electronic transitions in the actinocenes

Thus far we have not considered in detail the effects of relativity on actinocene electronic structure. However, almost all of the data discussed to this point are taken from calculations in which some or all of the so-called scalar-relativistic corrections – e.g. the Darwin and mass–velocity terms – have been incorporated in one way or another. Such an approach is in many cases adequate, but is not really satisfactory when attempting to understand the electronic transitions of actinocenes, especially where comparisons with experiment are sought. This type of investigation requires that spin–orbit coupling effects are also taken into account. Indeed, non-spin–orbit-coupled calculations typically give poor agreement with experiment when excited states are involved.

(*i*) *Pa*(*COT*)$_2$

Barring f^0 thoracene, $Pa(COT)_2$, is in principle the simplest actinocene in terms of its electronic transitions, as it has only one metal-localized valence f-electron. It has proved a fertile testing ground for both *ab initio* (Chang *et al.*, 1994) and density functional studies (Kaltsoyannis and Bursten, 1997; Li and Bursten, 1998). The effect of spin–orbit coupling on a free f^1 atom or ion is to split the

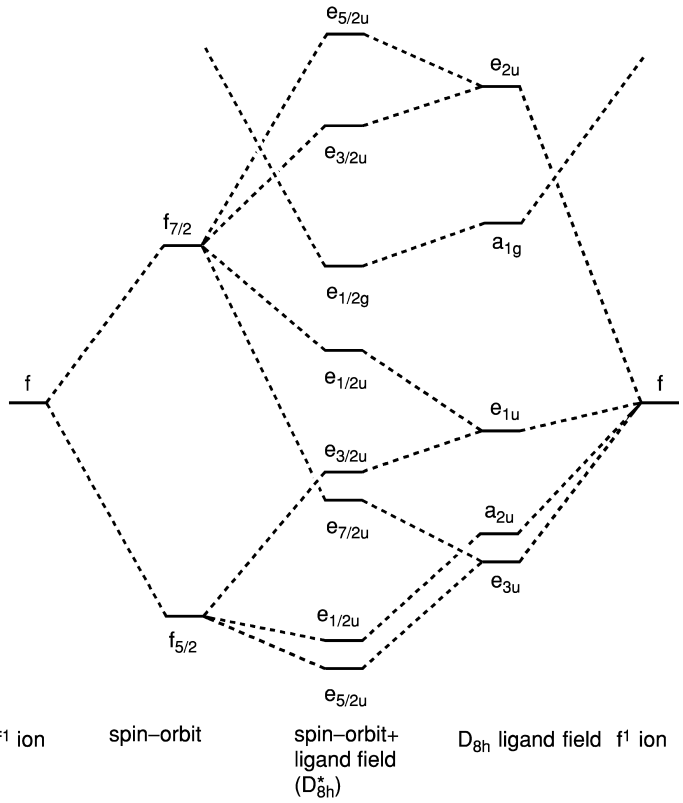

Fig. 17.16 *Correlation of the orbitals of an f1 Pa^{4+} ion split by spin–orbit coupling with the spin–orbit-coupled orbitals of $Pa(COT)_2$ under the D^*_{8h} double group (adapted from Li and Bursten*, 1998).

f-orbitals into a lower energy $f_{5/2}$ level and a higher energy $f_{7/2}$ level, which are respectively six- and eight-fold spin–orbit degenerate. This splitting is indicated on the left-hand side of Fig. 17.16, which is a correlation diagram showing the effects of spin–orbit coupling and the D_{8h} ligand field on an f^1 ion in a $(COT)_2^{4-}$ environment. In the absence of spin–orbit coupling but in the D_{8h} field, the f-orbitals are split as shown on the right-hand side of the figure. This f-orbital ordering is as presented in Fig. 17.15.

One of the main reasons for the complexity of actinide molecular electronic spectra is that both the effects of the ligand field and spin–orbit coupling must be taken into account. This is in contrast to the situation in the d-block, where ligand-field effects dominate, and to the lanthanides where spin–orbit coupling is the principal perturbation. The central column of Fig. 17.16 shows the combined effects of spin–orbit coupling and the D_{8h} ligand field on the f^1 ion.

All of the spin–orbitals now carry one of the labels of the D^*_{8h} double group, reflecting the fact that they are now properly characterized by non-integral total angular momentum, (i.e. spin + orbital). These arguments have been developed in greater detail (Kaltsoyannis and Bursten, 1997; Li and Bursten, 1998).

In Fig. 17.15, the metal d-based MOs are shown as being less stable than those arising from the 5f orbitals. While this is certainly the case for uranium/neptunium onwards, for the very early actinides the 6dσ level is comparable in energy with the 5f manifold. Indeed, the DFT calculations of Boerrigter *et al.* (1988) predict the lowest unoccupied molecular orbital (LUMO) of $Th(COT)_2$ to be the 6dσ orbital, while for $Pa(COT)_2$ this level lies in amongst the f-manifold. This result has been confirmed by other studies (Chang *et al.*, 1994; Kaltsoyannis and Bursten, 1997; Li and Bursten, 1998) and is taken into account on Fig. 17.16 by the presence of the $e_{1/2g}$ (a_{1g}) orbital. It might be expected that the presence of a low-lying d-based orbital would have a significant effect on calculations of the electronic transitions of $Pa(COT)_2$, and this has indeed been found to be the case.

Although the optical spectrum of $Pa(COT)_2$ has not been reported, limited data are available for the octamethyl derivative $Pa(TMCOT)_2$ (Solar *et al.*, 1980). The latter has an absorption maximum at 380 nm, with a low-energy shoulder at 490 nm. Based on comparison with the bathochromic shifts induced by the replacement of COT by TMCOT in other actinocenes, Solar *et al.* estimated that the absorption maximum in $Pa(COT)_2$ would occur at ca. 365 nm. There have been three attempts to calculate the electronic transitions of $Pa(COT)_2$, and three different assignments of the proposed 365 nm band. All of the f → f and many of the f → d transitions are formally forbidden, and Chang *et al.* (1994) concluded that the 365 nm peak arises from a ligand-to-metal charge transfer (LMCT) transition from the highest occupied ring π_2 levels into the $e_{1/2g}$ (dσ) orbital, calculated at 341 nm. Later, Kaltsoyannis and Bursten (1997) suggested that the band arises from both f → π_3 metal-to-ligand charge transfer (MLCT) and π_2 → f LMCT transitions at 351 and 360 nm, respectively. Most recently, Li and Bursten (1998) concluded that the band is due to a 368 nm ligand-field transition from the (predominantly fϕ) $e_{5/2u}$ HOMO to one of the spin–orbit-coupled components of the dδ levels. This latter study, which is the most complete and convincing, also concluded that the experimental low-energy shoulder is due to the π_2 → dσ transition.

(*ii*) *Th*(*COT*)$_2$ *and U*(*COT*)$_2$

As noted above, $Th(COT)_2$ has no metal-localized valence electrons. Experimentally it has a strong absorption at ca. 450 nm (Streitwieser, 1979), which Rösch and Streitwieser assigned to an LMCT π_2 → fϕ transition (Rösch and Streitweiser, 1983). Subsequent calculations by Dolg *et al.* (1995) placed this transition at 230 nm, and assigned the experimental peak to an LMCT π_2 → dσ transition. This ties in well with the DFT calculations of Boerrigter *et al.* (1988)

which, as we saw previously, predict the LUMO of $Th(COT)_2$ to be the $6d\sigma$ level.

The actinocene for which the most extensive experimental transition energy data are available is $U(COT)_2$ (Dallinger *et al.*, 1978; Amberger, 1983). These electronic transitions have been studied computationally by two groups using SOCI *ab initio* techniques (Chang and Pitzer, 1989; Chang *et al.*, 1994; Liu *et al.*, 1997). The experimental and theoretical (allowed transitions only) data are collected in Table 17.16, from which it may be seen that the two studies concur as to the assignment of the lowest energy transition, but differ over the nature of the experimental transition at 0.290 eV. It should be noted that $U(COT)_2$ is computationally significantly more difficult to handle than either $Th(COT)_2$ or $Pa(COT)_2$, owing to the presence of two 5f-based electrons and their significant mutual repulsion. Such difficulties manifest themselves in the discrepancies between experimental and theoretical data.

17.5.2 Actinide–cyclopentadienyl complexes

It is now 50 years since the discovery of the first organometallic sandwich molecule, ferrocene $[FeCp_2]$ ($Cp = \eta^5\text{-}C_5H_5$) (Wilkinson *et al.*, 1952; Wilkinson, 1975), and in the intervening period, the cyclopentadienyl ligand has become almost synonymous with organometallic chemistry. Indeed, the first organoactinide compound to be reported was the Cp derivative $[UCp_3Cl]$ (Reynolds and Wilkinson, 1956), and there have been hundreds more subsequently. As with the actinocenes, Cp–actinide systems have been a target of many theoretical studies, and those up to 1990 have been reviewed by Bursten and Strittmatter (1991). In this section, we will summarize these efforts and set out their key conclusions.

Several structural motifs are commonly observed for Cp–actinide complexes. $[AnCp_4]$ systems feature four η^5-bonded Cp rings, and are without parallel in transition metal chemistry. 'Base-free' tris-Cp complexes and their pseudotetrahedral derivatives $[AnCp_3X]$ (X = wide variety of ligands) are common and

have been widely studied, as have the bis-Cp systems [$AnCp_2$] and [$AnCp_2X_2$]. The present review makes the somewhat arbitrary division of Cp–actinide chemistry into these three motifs, i.e. we group the compounds according to the number of carbocyclic rings bonded to the metal. The motifs are collected in Fig. 17.17.

(a) [$AnCp_4$] complexes

These compounds are known for Th, Pa, U, and Np, and the crystal structure of [UCp_4] shows it to contain four η^5-Cp ligands in a pseudotetrahedral arrangement (Burns, 1973). These systems were the subject of semiempirical and early DFT studies in the 1970s and 1980s, though they have not been subsequently probed by more modern methods. Quasi-relativistic Xα-SW (QR-Xα-SW) calculations on [$ThCp_4$] and [UCp_4] showed that, with the exception of a small An 7s contribution, the metal does not interact with the π_0 MOs of the Cp rings (i.e. those C 2pπ orbitals with no vertical nodes) (Bursten *et al.*, 1985). By contrast, the Cp π_1 levels interact significantly with the An, with donation into the 6d and, to a lesser extent, 5f orbitals. The 6d–Cp interaction was found to be more stabilizing than donation to the 5f levels (Bursten and Fang, 1985). The two metal-based electrons in the formally U(IV) [UCp_4] were found to

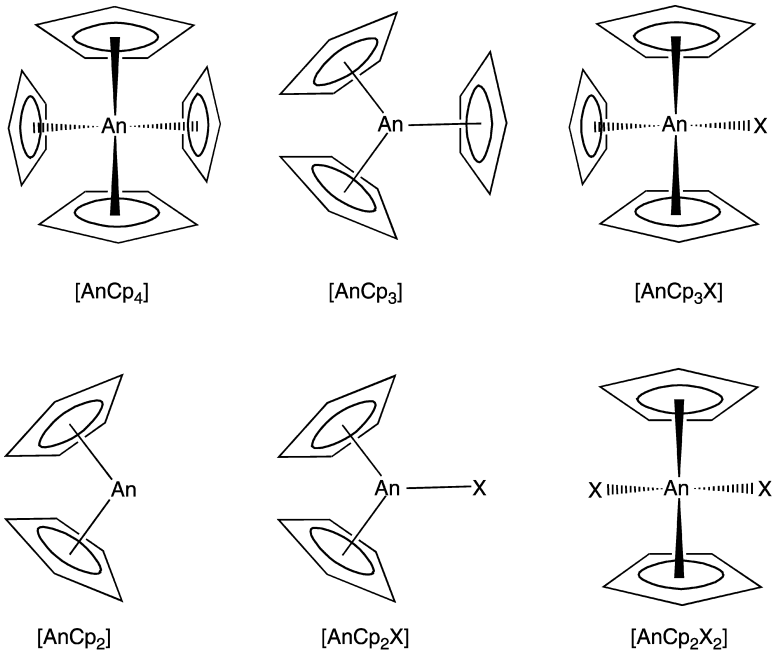

Fig. 17.17 *Structural motifs exhibited in complexes with actinide atoms and pentahapto-cyclopentadienyl ligands.*

occupy an essentially pure U 5f orbital of t_2 symmetry (T_d single-point group notation) with parallel spins.

Extended Hückel calculations on $[U(\eta^5\text{-}Cp)_4]$ and $[U(\eta^5\text{-}Cp)_3(\eta^1\text{-}Cp)]$ probed the actinide preference for η^5 coordination (Tatsumi and Nakamura, 1984). The conclusion from these studies was that the all-η^5 system is indeed more stable than the $(\eta^5)_3/\eta^1$ arrangement, in agreement with experiment.

(b) 'Base-free' $[AnCp_3]$ complexes

The $[AnCp_3]$ complexes without an additional axial ligand are perhaps the most widely studied Cp–actinide system. The metal and the Cp centroids are coplanar, giving rise to a virtually D_{3h} molecular symmetry. The interactions of a Cp_3 ligand field with a central metal are now well established, based on the results of extended Hückel, QR-Xα-SW, and DV-Xα studies (Lauher and Hoffmann, 1976; Bursten *et al.*, 1989a; Strittmatter and Bursten, 1991; Kaltsoyannis and Bursten, 1997), and we now set out the key features. The principal metal–ring bonding occurs between the valence AOs of the central atom and the highest occupied π_1 MOs of the Cp rings (e_1'' in the D_{5h} symmetry of a Cp ring), with a lesser interaction between the metal AOs and the Cp $\pi_0(a_2'')$ level (as was found for the $[AnCp_4]$ systems). In a C_{3v} ligand field, the Cp π_0 orbitals give rise to $a_1 + e$ symmetry combinations, while the π_1 orbitals result in $a_1 + a_2 + 2e$ levels. Ligand–ligand interactions result in the a_2 π_1 combination being destabilized above the others. This a_2 combination is important in that its interaction (or lack thereof) with the central metal elegantly rationalizes the paucity of the $[MCp_3]$ unit when M is a transition metal and the abundance of this unit for the actinides. There is no d AO that transforms as a_2 symmetry in C_{3v}. By contrast, the $f_{y(3x^2-y^2)}$ orbital can stabilize the ligand a_2 combination and provide significant metal–ligand bonding in the process.

A qualitative energy level diagram for the interaction of an actinide atom with the Cp π_1 MOs in a C_{3v} $[AnCp_3]$ complex is shown in Fig. 17.18. The 5f/π_1 a_2 interaction is shown as being the most important involving the 5f orbitals; the other six 5f-based levels span a very narrow energy range, reflecting their largely actinide nature. The relative position of the 5f manifold and the $6d_{z^2}$ level has been extensively studied, due in part to the experimental observation that $[ThCp_3''](Cp_3'' = \eta^5 - C_5H_3(SiMe_3)_2)$ possesses a $6d^1$ ground configuration (Kot *et al.*, 1988). The evidence from both Xα-SW (Bursten *et al.*, 1989a) and DV-Xα (Kaltsoyannis and Bursten, 1997) calculations is that at the start of the actinide series, the $6d_{z^2}$ orbital lies below the 5f manifold in $[AnCp_3]$ complexes. Furthermore, the d-below-f ordering is found to be a relativistic effect, as nonrelativistic DV-Xα calculations predict a $5f^1$ ground configuration for $[ThCp_3]$ (Kaltsoyannis and Bursten, 1997). Xα-SW studies predict that as the actinide series is crossed the 5f manifold is stabilized with respect to the $6d_{z^2}$ level, and hence that the later $[AnCp_3]$ compounds have a $5f^n >$ ground state configuration (Bursten *et al.*, 1989a).

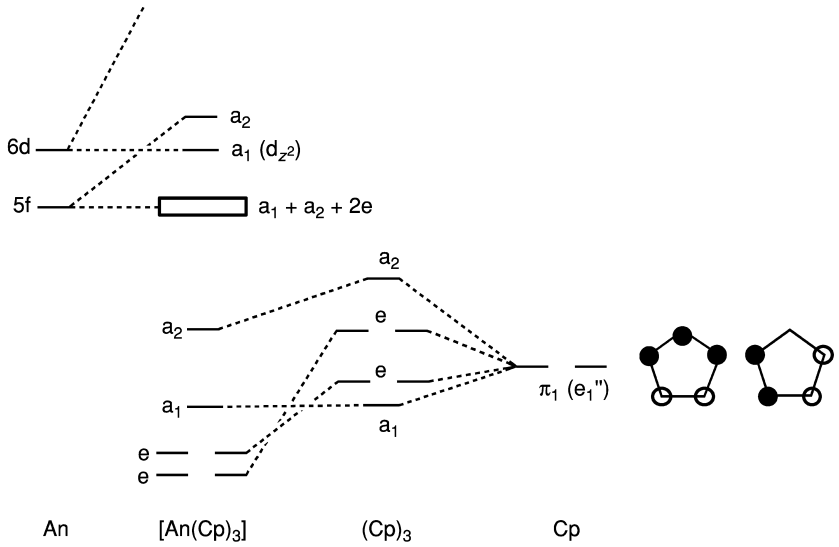

Fig. 17.18 *Qualitative energy-level diagram for the interaction of an actinide atom with the Cp π_1 MOs in a C_{3v} [$AnCp_3$] complex.*

The discrepancy between the nonrelativistic and relativistic results for the ground state configuration of [$ThCp_3$] is an excellent example of the need to incorporate relativity when calculating actinide electronic structure. More specifically, the calculated electronic absorption spectrum of $6d^1$ [$ThCp_3$] is very different from that from a $5f^1$ ground state configuration, with intense d $\rightarrow$ f transitions as opposed to weak Laporte-forbidden f $\rightarrow$ f transitions. The experimental spectrum of [$ThCp_3''$] indeed displays intense peaks, consistent with the $6d^1$ ground state configuration (Kot *et al.*, 1988).

As ever, the nature and extent of metal–ligand covalency has been the subject of extensive research and discussion (Burns and Bursten, 1989; Jensen and Bond, 2002). In particular, the relative contributions of the An 6d and 5f AOs to the two Cp π_1-based e symmetry MOs has come under scrutiny, as these are the two π_1-based MOs to which both An 6d and 5f AOs can contribute (the a_2 level can only have metal 5f character by symmetry, and the a_1 orbital is found to contain almost no metal contribution). Xα-SW calculations find that the 6dδ and 6dπ contributions to these orbitals are much larger than those of the 5f for the early An, with increasing 5f character to one of the levels (6dπ) with increasing An atomic number (Strittmatter and Bursten, 1991). The total metal involvement is in the 15–25% range, depending upon the orbital and compound in question. These results were later corroborated for [$ThCp_3$] by DV-Xα calculations (Kaltsoyannis and Bursten, 1997). The An 5f content of the a_2 level was found by Xα-SW to increase very significantly across the actinides,

to as high as 55% in [$CfCp_3$]. By contrast, the DV-Xα studies of [$ThCp_3$] find only 10% metal 5f content in this level.

(c) [$AnCp_3X$] complexes

When a fourth ligand X binds to a [$AnCp_3$] fragment, the Cp ligands pyramidalize to open up a coordination site for the X moiety. Several groups have investigated the nature of the An–X interaction, with much attention being paid to the An orbitals involved in the An–X bond. Early extended Hückel work on $[UCp_3]^+$ indicated that pyramidalization causes a stabilization and hybridization of the metal $6d_{z^2}$ and $7p_z$ AOs, resulting in a low-lying σ orbital that can accept charge from the X ligand (Tatsumi and Nakamura, 1984). A similar conclusion was drawn from Xα-SW calculations on [UCp_3] and [$ThCp_3$] (Bursten *et al.*, 1989a), although these studies suggested that the vacant hybrid is approximately isoenergetic with the 5f levels, in contrast to the extended Hückel calculations, which place the σ acceptor level well above the 5f manifold.

Xα-SW studies of the U–H bonding in [UCp_3H] support the results of the pyramidal base-free calculations in concluding that the U–H bond is indeed dominated by the U $6d_{z^2}$ AO (Bursten *et al.*, 1989b). Subsequent nonrelativistic DV-Xα calculations on [UCp_3X] (X = Me, NH_2, BH_4, NCS) suggest that the situation may be more complex, however, in that the U AO involved in the U–X σ bond depends upon the energies of the X orbitals (Gulino *et al.*, 1992). Thus, when X = NH_2 or NCS, the σ-bond is dominated by U $6d_{z^2}$, while for X = Me the U $5f_{z^3}$ plays a much larger role in σ-bonding. By contrast, RECP *ab initio* studies by the same workers on [$AnCp_3Me$] (An = Th, U) concluded that the An–Me σ bond is dominated by the metal $6d_{z^2}$ AO (Di Bella *et al.*, 1993).

The bonding of X to the An center is not necessarily restricted to purely σ interactions; π-donor and even π-acceptor ligands can also bind to the [$AnCp_3$] moiety as well. Quasi-relativistic Xα-SW calculations on [UCp_3CO], a model for the experimentally characterized $[UC_3^{\dagger}CO]$($Cp^{\dagger} = \eta^5$-$C_5H_4SiMe_3$) (Brennan *et al.*, 1986), found a U–C σ-bond similar in nature to those discussed above (i.e. a CO $5\sigma \rightarrow$ U $6d_{z^2}$ donation) (Bursten and Strittmatter, 1987). However, in addition, there is significant π-backbonding from the U 5fπ AOs into the vacant CO π^* orbitals. Thus, the overall U–CO interaction is an excellent example of the classic Dewar–Chatt–Duncanson model of synergic bonding, more usually associated with transition metal carbonyl complexes. Furthermore, the computational evidence for U $\rightarrow$ CO π-backbonding provides solid rationalization of the experimental observation that the CO stretching vibration in $[UCp_3^{\dagger}CO]$ is about 170 cm^{-1} lower than in free CO. Since that initial synthesis, a number of other UCp_3CO complexes with different substituents on the Cp rings have been synthesized and characterized (Parry *et al.*, 1995; Del Mar Conejo *et al.*, 1999; Evans *et al.*, 2003). The observed C–O stretching frequencies of these complexes show some surprising trends that will stimulate further theoretical studies (Kaltsoyannis, 2003). Recent experimental and theoretical studies

by Andersen, Eisenstein and coworkers have addressed the bonding of CO to organolanthanide complexes of the type Cp^*_2Ln, and propose significant differences between the binding of CO to 4f metals relative to 5f metals (Maron *et al.*, 2002).

Compounds in which there is π donation from ligand to metal have also been investigated computationally. Cramer *et al.* (1988) conducted extended Hückel calculations on N-based π-donor [UCp_3X] complexes where X = NH_2, NPH_3, $NHCHCHPH_3$, and NPh. They concluded that, for the latter three complexes, there is significant N 2pπ → U π donation, mainly into the U 6dπ levels. Subsequent DV-Xα calculations on similar complexes where X = NH_2 and NCS also found π character to the U–N bond, although they indicated that the donation is from N 2pπ → U 5fπ (Gulino *et al.*, 1992). Interestingly, this study found that alterations in X produced almost no change in the metal's charge (+1.8 ± 0.06) or configuration ($5f^{3.4}6d^{0.7}$). The conclusion was that this electronic 'buffering' of the U is facilitated by changes in the U–Cp bonding; as the donation from X, and hence U–X covalency, increases, the U–Cp bonding becomes more ionic.

In addition to N-donor ligands, complexes containing alkoxide groups have also been studied, using extended Hückel (Gulino *et al.*, 1992), Xα-SW (Bursten *et al.*, 1989b), DV-Xα and fully relativistic local density Dirac–Slater (Gulino *et al.*, 1993) approaches. The conclusions from all studies are broadly similar; the An–O bond has both σ and π character, with significant O 2pπ → An 6d and (lesser) 5f π donation. A comparison of [$ThCp_3OMe$] with the U analog found that 1.895 e^- are transferred to the Th center (along the Me→O→$AnCp_3$ direction), increasing to 2.185 e^- in [UCp_3OMe], i.e. the U compound was found to be more covalent (Gulino *et al.*, 1993). These workers noted, as have others (Bursten and Strittmatter, 1991), that the partial π character of the An–O bond may account for the prevalence of linear (or nearly linear) An–O–R vectors in actinide alkoxide systems.

(d) [$AnCp_2X_2$], [$AnCp_2X$], and [$AnCp_2$] complexes

The metallocene structures MCp_2X_2 are common structures for the transition metal, lanthanide, and actinide elements, and thus provide an opportunity to compare and contrast the electronic structure of d- and f-block metals. Many of the f-element complexes of formulation MCp_2X_2 contain the sterically bulky and electron-rich pentamethylcyclopentadienyl (η^5-C_5Me_5, denoted Cp^*) ligand; the steric bulk of the Cp^* ligand is often needed to avoid the coordination of more than two Cp ligands about the large f-element centers (Janiak and Schumann, 1991).

The 1980s saw a number of extended Hückel calculations on compounds of the general formula [$AnCp_2X_2$], in which unsubstituted Cp rings were used to model the much bulkier Cp^* groups used in synthetic investigations (Tatsumi *et al.*, 1985; Smith *et al.*, 1986; Tatsumi and Nakamura, 1987). These extended

Hückel calculations are well summarized in the 1991 review by Bursten and Strittmatter (1991), and space does not allow us to go into detail here. Topics covered include (a) rationalization of the existence of both 'O inside' and 'O outside' structures in $[UCp_2Cl(\eta^2\text{-COR})]$, by contrast to the transition metal preference for O inside (Tatsumi *et al.*, 1985), (b) rationalization of the preference for the butadiene *s-cis* geometry in $[AnCp_2(C_4H_6)]$ (An = Th, U) (Smith *et al.*, 1986), (c) determination that the actinacyclopentadiene complex is ca. 250 kJ mol^{-1} more stable than the corresponding cyclobutadiene structure in $[UCp_2(C_4H_4)]$ (Tatsumi and Nakamura, 1987), and (d) studies of CO insertion pathways in $[UCp_2Me_2]^{2+}$ (Tatsumi *et al.*, 1985). Slightly earlier, quasi-relativistic Xα-SW calculations on $[UCp_2X_2]$ (X = Cl, Me) were used to show that Me^- is a stronger σ donor than Cl^- to the actinide center, and concluded that there no significant $Cl^- \rightarrow U$ π donation (Bursten and Fang, 1983). Hay has recently reported DFT calculations on models of the formally U(VI) bis-imido complexes $Cp^*_2U(=NR)_2$ and related N-ligand systems (Hay, 2003). These systems demonstrate some of the complex chemical transformations that can occur at a uranium center (Arney *et al.*, 1992; Warner *et al.*, 1998; Kiplinger *et al.*, 2002), and an understanding of their behavior challenges the ability of calculations to determine reaction pathways for large actinide-containing systems.

In 1996, Di Bella *et al.* used configuration interaction *ab initio* methods to study the formally U(III) $[UCp_2CH(SiH_3)_2]$ (Di Bella *et al.*, 1996). The U center was found to have a $5f^3$ ground state configuration, and it was argued that the stability of this configuration vs $5f^26d^1$ correlates well with the inherent chemical stability of U(III) organometallics in comparison with $6d^1$ Th(III) analogs. In agreement with previous studies, the U–Cp bonding was found to be primarily U 6d/Cp π_1, with the metal 5f electrons being only marginally involved in bonding. The U–$CH(SiH_3)_2$ bond is σ only.

More recently, Kaltsoyannis and Russo (2002) have used ZORA relativistic gradient-corrected DFT to show that the equilibrium geometry of $[NoCp^*_2]$ is bent by 26° (i.e. the angle subtended by the centroids of the Cp^* rings and the No atom is 154°), this structure being ca. 9 kJ mol^{-1} more stable than the linear arrangement. This study also examined the lanthanide analog, $[YbCp^*_2]$, and also found it to be bent, in excellent agreement with gas-phase electron diffraction data (Andersen *et al.*, 1986). The bent structure of $[NoCp^*_2]$ was traced to a combination of valence orbital and electrostatic factors. The involvement of the No 5f AOs in bonding to the Cp^* rings is minimal, although ca. 10% metal d content is found in the Cp^* ring pπ e_{1g} levels.

(e) Bis(cyclopentadienyl) actinide complexes with metal–metal bonds

Despite extensive efforts, no organometallic (or nonorganometallic!) compound has been synthesized containing a direct An–An bond. Nevertheless, organometallic systems do exist that contain a bond between an actinide metal and a

transition metal (both direct and bridged), and some have been investigated computationally. Xα-SW calculations have been performed on [MCp_2(I)–$RuCp(CO)_2$] (M = Zr, Th) (Bursten and Novo-Gradac, 1987), a model for the first ever compound with a direct actinide–transition metal bond (Sternal *et al.*, 1985). The M–Ru bonding was found to be very similar in the transition metal and actinide systems, consisting of donation from the filled $4d_{z^2}$ orbital of Ru to the empty d_{z^2} valence function of Zr or Th. The bond is highly polarized toward the Ru, and is best described as a dative donor–acceptor bond from [$RuCp(CO)_2$]$^-$ to the d^0 Zr(IV) or d^0f^0 Th(IV) center.

Extended Hückel (Ortiz, 1986), Xα-SW (Makhyoun *et al.*, 1987), and *ab initio* (HF + generalized valence bond [GVB]) calculations (Hay *et al.*, 1986) have been performed on bis-Cp systems containing bridged bonds between Th and a late transition metal (Ni or Pt). The latter study took [$Th(Cl)_2(\mu\text{-}PH_2)_2Pt(PH_3)$] as a model for the experimental Cp^*_2 system (the replacement of Cp by Cl is a computational simplification often made in early calculations on large systems, justified on the grounds that both ligands possess one filled σ and two filled π orbitals with respect to the ligand–metal axis), and concluded that there is direct M–M bonding between the $5d_{x^2-y^2}$ orbital of Pt and the $6d_{x^2-y^2}$ orbital of Th, with the larger fraction of the electron density on the Pt. The bond is best described as dative, from the formally filled $5d^{10}$ shell of the Pt into the formally empty 6d shell of Th.

17.5.3 Sandwich complexes with six- and seven-membered rings: $An(\eta^6\text{-}C_6H_6)_2$ and $An(\eta^7\text{-}C_7H_7)_2$

In 1999, Hong *et al.* published the results of an in-depth *ab initio* study of the energetics and bonding in [MBz_2] (M = Th, U, variety of lanthanide elements; Bz = η^6-C_6H_6) (Hong *et al.*, 1999). These calculations employed extensive electron correlation techniques (e.g. state-averaged CASSCF, MRCI, and CCSD(T)) in conjunction with large pseudopotential basis sets, and assumed D_{6h} molecular symmetry (i.e. the Bz rings were fixed to be parallel to one another). It was found that both [$ThBz_2$] and [UBz_2] are stable with respect to dissociation into two benzene rings plus the metal, but that the An–ring bonding is weaker than in analogous bis-COT systems due to the lack of ionic contributions to the bonding (Bz is, of course, formally neutral and closed shell).

In a conclusion reminiscent of their earlier work on the lanthanocenes and actinocenes (Dolg *et al.*, 1995; Dolg and Fulde, 1998), these workers found that the ground state of both [$ThBz_2$] and [UBz_2] is not completely described by a single configuration. Thus, while the leading configuration to the ground state of the Th and U compounds is $e^4_{2g}5f^0$ and $e^4_{2g}5f^2$, respectively (the e_{2g} level being a mixture of An $6d_{\pm2}$ and ring π_2), the ground state wavefunctions have a contribution from the $e^2_{2g}a^2_{1g}5f^0$ (Th) and $e^2_{2g}a^2_{1g}5f^2$ (U) configurations (the a_{1g} orbital is a mixture of An 7s and $6d_0$). The principal source of metal–ring

covalency is a backbonding interaction from the An $6d_{\pm 2}$ levels to the ring π_2 orbitals, although there is some evidence for weak $5f_{\pm 2}$ involvement in this process.

Hong *et al.*'s assumption of D_{6h} symmetry for $[MBz_2]$ was called into question by the work of Li and Bursten (1999), published in the same year. These workers used gradient-corrected DFT to probe the geometric structures of $[AnBz_2]$ (An = Th to Am) and $[An(\eta^6\text{-}C_6H_3R_3)_2]$ (An = Th, U, Pu; R = Me, ^{t}Bu). They found that the equilibrium geometry of $[AnBz_2]$ is significantly bent, with the angle subtended by vectors connecting the ring centroids and the metal ranging from 135 to 142°, depending on the metal. This bending is electronically driven, with greater covalency in the bent geometry arising from greater Bz → An 6d and 5f donation. Fig. 17.19 shows the calculated energy curves for the $TiBz_2$ and $ThBz_2$ as a function of the centroid–metal–centroid angle, showing that the former is 'linear' whereas the latter is predicted to prefer a 'bent' geometry.

Replacement of three H atoms on each ring by Me groups also results in bent equilibrium geometries. However, when the Me groups are replaced by the much bulkier ^{t}Bu units the equilibrium geometry reverts to linear, i.e. for very bulky R substituents, the steric repulsion between the rings overcomes the electronic preference for bending. These conclusions are summarized in Fig. 17.20, which shows the calculated structures of $U(\eta^6\text{-}C_6H_3Me_3)_2$ and $U(\eta^6\text{-}C_6H_3{}^tBu_3)_2$. The former is found to have a bent geometry with a centroid–U–centroid angle of 139.8° whereas the latter is found to be linear. It is notable that the experimental crystal structure of $Gd(\eta^6\text{-}C_6H_3{}^tBu_3)_2$ is indeed linear (Brennan *et al.*, 1987).

Shortly after Li and Bursten's work was published, Hong *et al.* (2000) revisited $[ThBz_2]$ and $[UBz_2]$ using both *ab initio* and ZORA DFT methods. They found that neither molecule is bent at the *ab initio* SCF level. Inclusion of electron correlation, however, using MP2 and CCSD(T) methods, results in significantly bent structures (ca. 140–145°), although the energy differences between the linear and bent geometries is so small that the equilibrium geometry cannot be unequivocally established using these *ab initio* techniques, probably because of the use of an unrelaxed structure for the rings. Hong *et al.* then went on to conduct ZORA DFT studies which also indicated that the bent structures are the most stable, and hence they concluded that "qualitatively...we confirm their [Li and Bursten] result that the bis benzene complexes of Th and U have bent structures", and that bending enhances the metal–ring bonding. Dolg (2001) has also reported additional calculations on these systems at the scalar-relativistic level using a combination of energy-consistent *ab initio* pseudopotentials and gradient-corrected density functionals.

A number of recent investigations have focused on actinide sandwich molecules involving the cycloheptatrienyl ligand (Cht = η^7-C_7H_7). In 1995, Ephritikhine and coworkers isolated a salt of the $[U(Cht)_2]^-$ anion, which is the first and, to date, only experimental example of a sandwich complex involving two Cht ligands (Arliguie *et al.*, 1995). The $[U(Cht)_2]^-$ anion was characterized

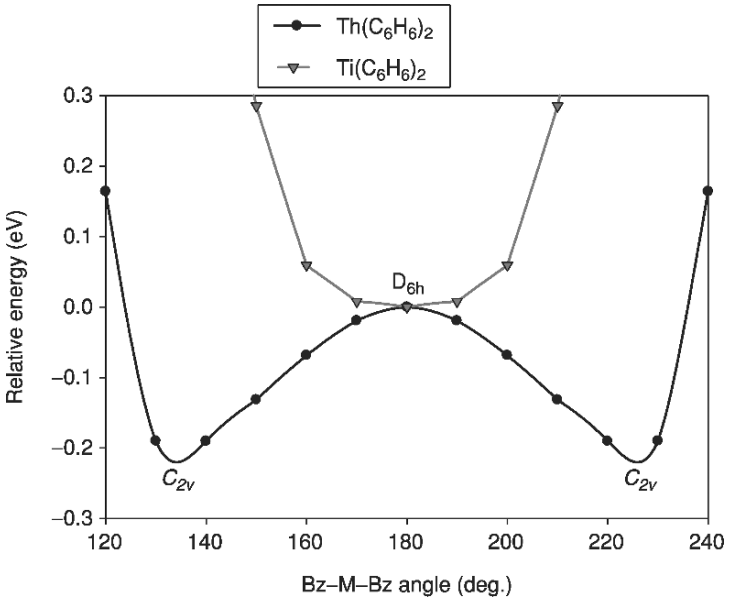

Fig. 17.19 *DFT-calculated potential energy curves for* $Ti(\eta^6\text{-}C_6H_6)_2$ *and* $Th(\eta^6\text{-}C_6H_6)_2$ *as a function of centroid–metal–centroid angle* (*reproduced from Li and Bursten*, 1999).

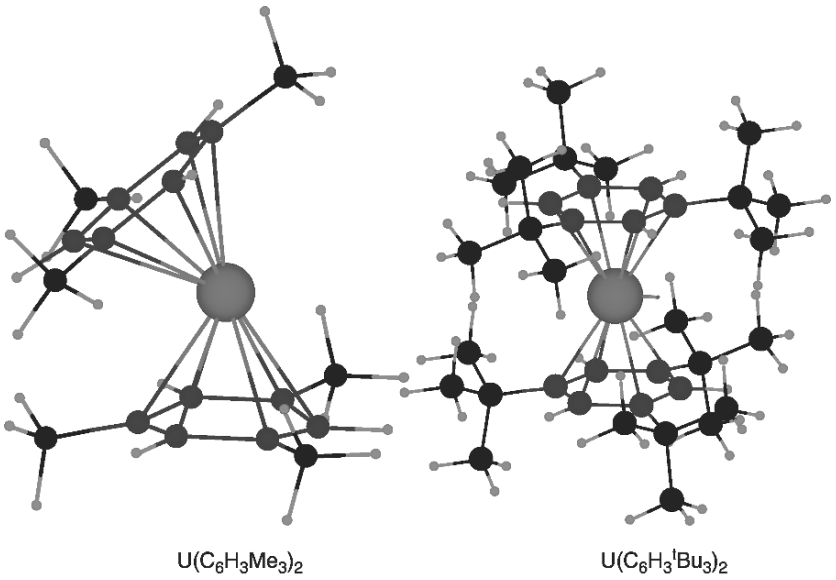

Fig. 17.20 *DFT-calculated structures of* $U(\eta^6\text{-}C_6H_3Me_3)_2$ *and* $U(\eta^6\text{-}C_6H_3{}^tBu_3)_2$ *as a function of centroid–metal–centroid angle* (*reproduced from Li and Bursten*, 1999).

crystallographically and was found to be a 'parallel' sandwich complex, i.e. the two Cht ligands are parallel to one another with a centroid–U–centroid angle of 180°.

Li and Bursten (1997) reported relativistic DFT calculations at both the LDA and Becke–Perdew86 (BP86) levels on $[An(Cht)_2]^q$ (An = Th to Am; $q = 2-$, $1-$, 0, $1+$) complexes. The geometries were optimized in both D_{7h} and D_{7d} symmetries, with the latter (staggered rings) arrangement being found to be 2–4 kJ mol^{-1} more stable. The H atoms were found to be canted in toward the metal atom (e.g. by 4° in $[UCht_2]^-$), reminiscent of the results of similar calculations by the same researchers on protactinocene (Section 17.5.1) (Li and Bursten, 1998).

The metal–ring bonding was found to involve both the An 5fδ and 6dδ levels. The former interact with the e_2'' π_2 levels of the Cht ligands, and are as important as the 6dδ in stabilizing the frontier pπ orbitals of the rings. As the actinide atomic number increases, the An 5f and ring frontier pπ orbitals come into closer energetic proximity, resulting in an increase in the 5f contribution to the ring e_2'' levels and a decrease in the 6d content.

One of the most interesting aspects of this study concerns the formal oxidation states of the Cht rings and hence the metal centers. Formal charges of $1+$ and $3-$ for a Cht ring satisfy the Hückel $4n+2$ rule for aromaticity. When reporting the experimental characterization of $[U(Cht)_2]^-$, Ephritikhine *et al.* suggested that the complex is a U(v) f^1 system with two $3-$ rings (Arliguie *et al.*, 1995). Li and Bursten, however, suggest that this is not the best description on the grounds that the $3e_2''$ level of $[U(Cht)_2]$ (HOMO) and $[U(Cht)_2]^-$ (HOMO–1) is an approximately equal mixture of U 5f and Cht π_2. They argued that two of the four electrons in this level should be associated with the metal and two with the rings, resulting in an f^2 U(IV)/2 × Cht^{2-} description for $[U(Cht)_2]$, with $[U(Cht)_2]^-$ being a U(III) f^3 system. That the formal description of the oxidation state of the Cht ligand is intermediate between the +1 and –3 limits is in agreement with previous experimental and theoretical studies of mixed ring transition metal Cht/Cp complexes (Green *et al.*, 1992, 1994; Kaltsoyannis, 1995). Gourier *et al.* (1998) performed an EPR and angle-selected ENDOR study of the $[U(Cht)_2]^-$ anion to determine the ordering of the electronic energy levels and the metal–ligand interaction. They indeed find that the single electron is localized in the U 5f-orbital, a spin–orbit-coupled mixture of fσ and fπ orbitals, and there exists strong participation of the fδ orbitals in the covalent bonding.

17.5.4 π-Backbonding in U(III) complexes containing N-based ligands

In our discussion of $[AnCp_3X]$ complexes, we came across Xα-SW calculations on $[UCp_3CO]$ (Bursten and Strittmatter, 1987), which found a significant π-backbonding interaction between the 5f AOs of the U(III) center and the CO π^* levels. Slightly over a decade after these calculations were published, Roussel and Scott (1998) reported the synthesis and

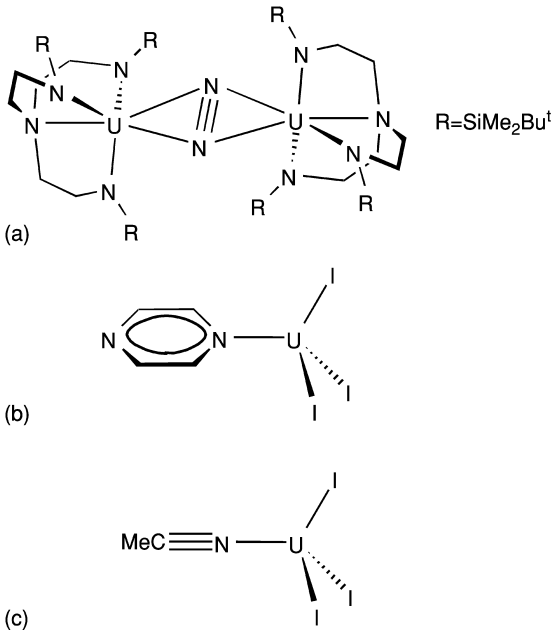

Fig. 17.21 *Molecular structures of three uranium compounds featuring metal→ligand π-backbonding* (*see Roussel and Scott*, 1998; *Mazzanti* et al., 2002).

characterization of the first dinitrogen compound of an actinide element, $[\{(NN_3)U\}_2(\mu^2 + \eta^2 : \eta^2 + N_2)]$ $[NN_3 = N(CH_2CH_2NSiBu^tMe_2)_3]$ (Fig. 17.21a). The fact that the N–N distance in this compound is essentially the same as in free dinitrogen prompted these workers to conclude that the interaction between the N_2 and U centers is σ-donation from ligand to metal. Subsequent quasi-relativistic gradient-corrected DFT calculations on the model complex $[\{(NH_2)_3(NH_3)U\}_2(\mu^2\text{-}\eta^2\text{:}\eta^2\text{-}N_2)]$ (Kaltsoyannis and Scott, 1998), however, found that the only significant metal–N_2 interaction is π-backbonding from the 5f AOs of the formally U(III) centers into the N_2 π_g N–N antibonding MOs, very reminiscent of the earlier Xα-SW calculations on $[UCp_3CO]$. A three-dimensional representation of one of the two such π-backbonding MOs is shown in Fig. 17.22.

One of the more curious aspects of the work on $[\{(NH_2)_3(NH_3)U\}_2(\mu^2\text{-}\eta^2\text{:}\eta^2\text{-}N_2)]$ is the N–N bond length. Significant population of the N_2 π_g level should result in an increase in the N–N distance, and geometry optimizations of $[\{(NH_2)_3(NH_3)U\}_2(\mu^2\text{-}\eta^2\text{:}\eta^2\text{-}N_2)]$ indeed lead to a shortening of the U–N (N_2) distance and a lengthening of the N–N distance in comparison with experiment. These conclusions were reinforced by analogous DFT studies of UN_2 (Brown and Kaltsoyannis, 1999) and U_2N_2 (Roussel *et al.*, 2001).

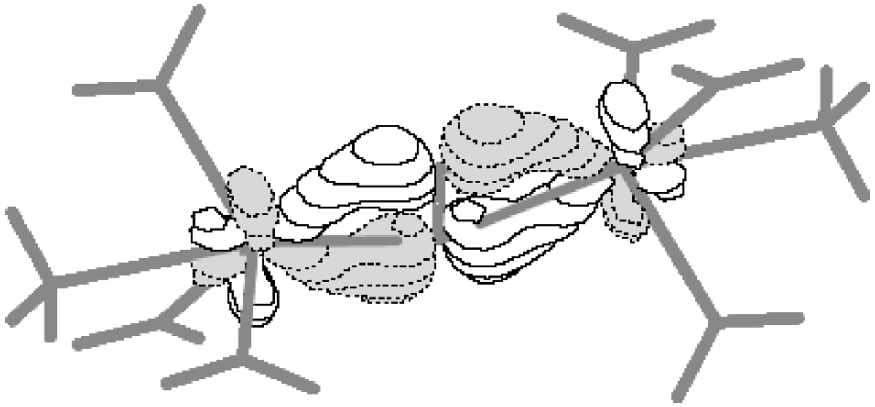

Fig. 17.22 *Three-dimensional representation of one of the two* $U_2 \rightarrow N_2$ *π-backbonding MOs in* $[\{(NH_2)_3(NH_3)U\}_2(\mu^2\text{-}\mu^2\text{:}\eta^2\text{-}N_2)]$, *a computational model for* $[\{(NH_2)_3(NH_3)U\}_2(\mu^2\text{-}\eta^2\text{:}\eta^2\text{-}N_2)]$ (*see Fig.* 17.21(*a*) *and Kaltsoyannis and Scott*, 1998).

A possible explanation for the discrepancy between theory and experiment is that the NN_3 ligands are so bulky that they prevent the two ends of the molecule from coming any closer together, as would accompany a reduction in the U–N (N_2) distance. The conclusion was therefore that there is an electronic driving force toward U–N(N_2) shortening and N–N lengthening, but that this is opposed (and overcome) by the highly sterically demanding NN_3 ligands.

Recent experimental work by Cloke and Hitchcock (2002) has, however, called this conclusion into question. These workers have synthesized and characterized a bimetallic dinitrogen uranium complex with $CpCp^*$ and pentalene ancillary ligands, $[(U(\eta^5\text{-}C_5Me_5)(\eta^8\text{-}C_8H_4\{Si^iPr_3\text{-}1,4\}_2))_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)]$. By contrast to triamidoamine system of Roussel and Scott, the N–N distance in the Cloke complex is significantly longer than in free N_2, consistent with the presence of an N=N double bond. Intriguingly, however, the U–N distances are essentially the same as in $[\{(NN_3)U\}_2\ (\mu^2\eta^2\text{:}\eta^2\text{-}N_2)]$, and Cloke has suggested that the difference between $[\{(NN_3)U\}_2\ (\mu^2\text{-}\eta^2\text{:}\eta^2\text{-}N_2)]$ and $[(U(\eta^5\text{-}C_5Me_5)(\eta^8\text{-}C_8H_4\{Si^iPr_3\text{-}1,4\}_2))_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)]$ may be a consequence of different frontier orbital geometries in the two ligand environments.

A model for the Cloke pentalene system has been studied computationally by Cloke *et al*. (2004). These relativistic, gradient-corrected DFT studies reinforce the conclusions from the previous work on $[\{(NH_2)_3(NH_3)U\}_2(\mu^2\text{-}\eta^2\text{:}\eta^2\text{-}N_2)]$, i.e. both complexes contain two $5f^2$ U(IV) centers, with substantial covalent interaction between the U 5f atomic orbitals and one component of the N_2 π_g orbitals. The interaction may be characterized as reduction of the N_2 to N_2^{2-}, and geometry optimizations of the Cloke model concur with experiment in finding an N–N distance appreciably longer than in free N_2. However, this agreement between theory and experiment is only achieved at the expense of a

non-Aufbau electronic occupation. The origin of the short N–N distance in $[(N_3N']U)_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)]$ is therefore still not unambiguously resolved.

Mazzanti *et al.* (2002) have recently reinforced previous conclusions that U(III) can function as a π basic center. These workers have conducted quasi-relativistic gradient-corrected DFT calculations on [M(pyrazine)I_3] (Fig. 17.21b), [M(acetonitrile)I_3] (Fig. 17.21c), and [M(pyrazine)$_3I_3$] (M = La, Nd, U), models for experimentally characterized tris[(2-pyrazinyl)methyl]amine systems. Geometry optimizations of these compounds reproduce experimental trends, i.e. there is a reduction in M–N from La to U even though the ionic radii of La^{3+} and U^{3+} are very similar. The calculations reveal that there is essentially no orbital interaction between Ln^{3+} and the N-donor ligands, in contrast to the actinide system in which there is π-backdonation from the 5f AOs of U^{3+} into the π^* levels of both acetonitrile and pyrazine. This interaction leads to a larger total bonding energy for the U(III) species compared with the Ln systems (even though the shorter U–N distances produce larger Pauli repulsion energies).

Meyer *et al.* have also encountered π effects in uranium–nitrogen chemistry (Castro-Rodrigues *et al.*, 2003b). These researchers have conducted DFT calculations on uranium tris-aryloxide derivatives supported by triazacyclononane, in which the metal center is also bonded to $NCCH_3$, $NSi(CH_3)_3$, or N_3. In the $NCCH_3$ and $NSi(CH_3)_3$ systems, the acetonitrile– and imido–uranium bonds display strong covalent π interactions; interestingly, the azide derivative features an essentially electrostatic U–N_3 interaction. The uranium tris-aryloxide moiety has also been employed by the same researchers in the synthesis of an alkane-coordinated system (Castro-Rodrigues *et al.*, 2003a). Preliminary DFT calculations of this complex indicate a weak σ-type orbital interaction between the (η^2-H,C)-coordinated alkane and U-based fragments.

17.5.5 Miscellaneous organometallic systems

In 1989, Van der Sluys *et al.* reported the synthesis and structure of U[CH$(SiMe_3)_2]_3$, a U(III) complex that was the first homoleptic alkyl complex of an actinide element (Van der Sluys *et al.*, 1989). The molecule exhibits a somewhat nonintuitive pyramidal structure that could have been motivated for electronic or steric reasons. Ortiz *et al.* (1992) used *ab initio* CASSCF methods to study the electronic and geometric structures of [$AnMe_3$] (An = U, Np, Pu) as models of the isolated complex. They found that the pyramidal structure was more stable than the planar for the ground state of each molecule. The driving force toward pyramidalization is increased An 6d orbital participation in the An–C bonding orbitals. For example, the U $6d_{xz}$ and $6d_{yz}$ atomic populations increase from 0.04 to 0.34 electrons as [UMe_3] pyramidalizes from 0 to 23° out of plane. Further evidence for the key role of the 6d AOs come from the observation that if these functions are removed from the basis set, the planar geometry is the most stable for each molecule. Later scalar-relativistic DFT calculations by

Joubert and Maldivi (2001) lead to similar conclusions. Schneider *et al.* (1991) used Dirac–Fock–Slater calculations based on the discrete-variational Xα method to investigate the effects of spin–orbit and ligand-field effects on UH_3 and $U(NH_2)_3$. They found that the metal–ligand σ-bonding predominantly involves the U 6d orbitals and that the trigonal ligand field effectively quenches the spin–orbit coupling in the 6d manifold.

Nash and Bursten (1995) used relativistic DV-Xα calculations to study the electronic structure of octahedral $[M(CO)_6]$ (M = Cr, W, U, Sg). Population analyses and electron density plots indicate that there is more extensive π-backbonding in the actinide system than in the transition metal molecules. However, while $[Cr(CO)_6]$ and $[W(CO)_6]$ are stable species, $[U(CO)_6]$ cannot be isolated outside of a cold matrix, perhaps at odds with the electronic structure results. The rationalization of theory and experiment is that for the U species only there is a high density of 5f-based dissociative states close in energy to the ground state. Indeed, the calculations on $[U(CO)_6]$ required a thermal spreading factor (a Boltzmann weighting of orbital populations around the HOMO) to achieve SCF convergence. The authors conclude that "the 'clean' MO description of the transition metal systems is lost in $[U(CO)_6]$ owing to the energetic closeness of the U 5f and 6d AOs". The same authors also performed higher-level (MP2, CCSD(T)) calculations on $Sg(CO)_6$ (Nash and Bursten, 1999). These calculations affirm that $Sg(CO)_6$ is predicted to be a d^6 transition-metal carbonyl complex analogous to $Mo(CO)_6$ and $W(CO)_6$.

Recently, Korobkov *et al.* (2001) reported the results of hybrid DFT (B3LYP) studies on a model binuclear tetrapyrrole system $[(TP)U_2I_4]^{2-}$, in which the bridging $C(CH_2)_5$ units of the experimentally characterized molecule are replaced by CH_2 groups. Both high- and low-spin calculations were performed, essentially corresponding to ferromagnetic and antiferromagnetic coupling of the two U(III) $5f^3$ centers. The results, in agreement with experimental magnetic measurements, indicate that the ground state is low spin, but only by a very small energy (ca. 1 kJ mol^{-1}). The unpaired electrons are found in all spin cases to be nearly pure U 5f in character.

As we have seen, there has been a great deal of interest in organoactinide sandwich molecules and, more recently, in bimetallic uranium complexes involving π-backbonding from the U centers. Cummins *et al.* have synthesized and studied computationally inverted sandwich molecules of the form $[\{L_nU\}_2(\mu\text{-}R)]$, where L is a nitrogen-based ligand and R is toluene, naphthalene, or COT (Diaconescu *et al.*, 2000; Diaconescu and Cummins, 2002). The ORTEP of $[\{(N[Ad]Ar)_2U\}_2(\mu\text{-}C_7H_8)]$ is shown in Fig. 17.23, and it can clearly be seen how the carbocyclic toluene ligand bridges the two U centers. DFT calculations reveal that the primary bonding interaction between the metals and the bridging ligand in $[\{(NH_2)_2U\}_2(\mu\text{-}C_6H_6)]$, a model for $[\{(N[Ad]Ar)_2U\}_2(\mu\text{-}C_7H_8)]$, is δ-backbonding from the U 5f atomic orbitals into the free arene LUMO. Fig. 17.24 presents three-dimensional representations of the two near-degenerate δ-backbonding levels. It is noticeable that the computed arene ring

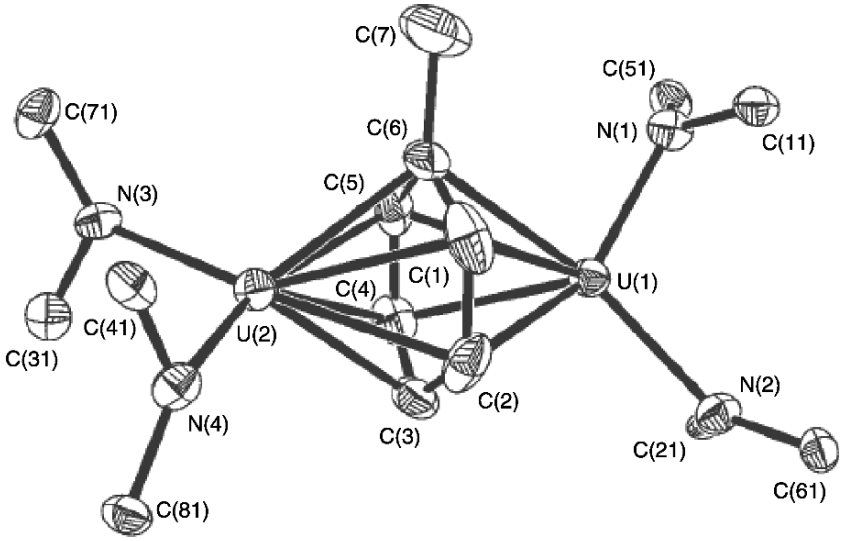

Fig. 17.23 *Structural drawing of* [{(N[*Ad*]*Ar*)$_2$*U*}$_2$(μ-C_7H_8)] (*reproduced from Diaconescu* et al., 2000).

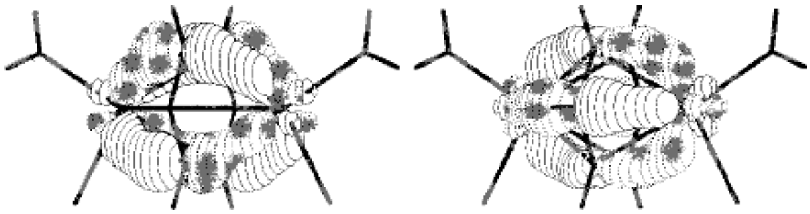

Fig. 17.24 *Two near-degenerate δsymmetry U→Bz backbonding orbitals in* [{(NH_2)$_2$*U*}$_2$ (μ-C_6H_6)], *a model for* [{(N[*Ad*]*Ar*)$_2$*U*}$_2$(μ-C_7H_8)] (*reproduced from Diaconescu* et al., 2000).

C–C distance is 1.461 Å, significantly longer than in free benzene (1.39 Å), as expected for partial population of the e_2 symmetry-free benzene LUMO. Similar conclusions concerning the nature of the bonding between the U centers and the arene bridge in $[(C_5Me_5)_2U]_2(\eta\text{-}\mu^6\text{:}\mu^6\text{-}C_6H_6)$ were drawn by Evans *et al.* (2004).

17.6 MATRIX-ISOLATED ACTINIDE MOLECULES

In previous sections of this chapter, we have examined the electronic structure of some very small and some very large actinide-containing molecules and ions. Part of the appeal of the actinyl ions discussed in Section 17.3 is their small size

and their high symmetry, both of which facilitate high-level electronic structural studies. In contrast, the large organometallic complexes discussed in Section 17.5 present a much larger challenge to computational methods. One difficulty in comparing calculated electronic structural properties of the AnO_2^{q+} actinyl ions with experimental data is the fact that actinyl ions are generally found experimentally with equatorial ligands. Indeed, the experimental properties of isolated AnO_2^{q+} ions are largely unknown.

In this section, we will discuss another class of small actinide-containing species, namely those that can be isolated and detected in low-temperature matrices. Matrix isolation has been proven to be an effective way to stabilize reactive or transient species so that spectroscopic characterizations can be performed on otherwise thermodynamically unstable molecules (Bondybey *et al.*, 1996; Himmel *et al.*, 2002). Inert gas (e.g. noble-gas, N_2, H_2) matrices are frequently used because they usually protect (or prevent) the newly formed gas-phase products from undertaking further reactions. For several decades, matrix isolation techniques have helped scientists to identify and characterize thousands of new compounds, including many species that are unexpected from the traditional point of view of chemistry (Jacox, 2003). The first studies of matrix-isolated transient actinide molecules occurred in the early 1970s. These early studies reported the first data on matrix-isolated UO, UO_2, and UO_3 (Abramowitz *et al.*, 1971; Leary *et al.*, 1971; Abramowitz and Acquista, 1972; Carstens *et al.*, 1972), as well as the first uranium carbonyl complexes (Slater *et al.*, 1971), and the generation of UF_5 in matrices (Paine *et al.*, 1976; Jones and Ekberg, 1977). Reedy and coworkers performed a series of matrix-isolation experiments in the 1970s that led to a number of new species that will be discussed below. In the last decade, Andrews and coworkers have extensively explored the chemistry of Th and U in noble-gas (Ng) matrices, and these more recent studies will be much of the focus of the remainder of this section.

The generation of isolated small actinide transients is a very fertile area for electronic structure calculations, especially given some of the potential difficulties in characterizing transient molecules using only experimental methods (Beattie, 1999). Many of the new actinide molecules that have been detected in solid matrices are formed from the reaction of electronically excited actinide atoms, typically generated via laser ablation, with small substrate molecules, such as O_2, CO, NO, N_2, H_2O, and CO_2. Vibrational spectroscopy has been the most common and sensitive experimental probe of the products trapped within the low-temperature matrices. In addition, the use of isotopomers of the substrate molecules has allowed the vibrational studies to determine the stoichiometries of the reactions as well as the isotope shifts in the vibrational frequencies. Thus, the experimental studies typically can determine the reaction stoichiometries between the actinide atoms and the substrate molecules, and provide the vibrational frequencies of multiple isotopomers of the actinide-containing products. Theoretical studies of the matrix-isolated species can provide predictions of the geometric structures, relative isomer energies, and

electronic structures of the proposed products. In recent years, the ability to determine vibrational frequencies and normal modes directly from the electronic structure calculations has provided an important benchmark for the quality of the theoretical methods. Indeed, the understanding of matrix-isolated actinide molecules has greatly benefited from the synergy between experimental and theoretical studies, and the combination of experiments and theory has led to much more progress than either would in isolation.

Here we will provide a brief summary of recent developments in this fruitful field of actinide chemistry, with particular focus on the actinide oxides, nitrides, nitride–oxides, and carbide–oxides. The analogous transition-metal species characterized using the same technique have been reviewed recently (Zhou *et al.*, 2001; Andrews and Citra, 2002). The geometries, electronic structures, and vibrational frequencies of UO_2^{2+}, UO_2, UN_2, PuO_2^{2+}, and PuN_2 were recently investigated (Clavaguéra-Sarrio *et al.*, 2004). We will proceed by discussing the molecular and electronic structures of the actinide molecules formed upon the reactions of laser-ablated actinide atoms with various small molecules. Typically, the reaction of laser-ablated actinide atoms with small molecules leads to the formation of many products because of the excess energy of the laser-ablated atoms and the existence of multiple reaction channels. We will focus on some selected matrix-isolated actinide molecules that have been definitively characterized via experiment and are of fundamental importance in actinide chemistry. Also, we will limit our discussion primarily to molecules with three atoms or more that result from the addition of actinide atoms to diatomic or larger substrate molecules.

Many of the species that we will discuss in this section are triatomic molecules of the type XAnY involving a variety of actinide atoms in different oxidation states. This chemistry becomes closely linked to that of the actinyl ions, AnO_2^{q+}, that were discussed in Section 17.3. Not surprisingly, the majority of actinide matrix-isolation experiments have involved uranium because of the availability of the element and the relative ease with which it can be handled. Thus, many of the matrix-isolated species will be closely related to the uranyl ion, UO_2^{2+}, which, as we have pointed out, is probably the most prevalent species in uranium chemistry. In order to give a sense of the electronic structural diversity even among formally U(VI) species isoelectronic to UO_2^{2+}, we will present first a comparison of the energy-level diagrams for the isoelectronic series UO_2^{2+}, NUO^+, and CUO. The electronic structure of this series was first considered by Pyykkö *et al.* (1994) via Hartree–Fock calculations with quasi-relativistic pseudopotentials. The relative MO energies of UO_2^{2+}, NUO^+, and CUO from recent scalar-relativistic DFT calculations (Bursten *et al.*, 2003) are presented in Fig. 17.25. The electronic structures of these U(VI) f^0 species are qualitatively similar inasmuch as the highest occupied MOs form the familiar $(\sigma)^2(\pi)^4(\pi)^4(\sigma)^2$ manifold that is derived from the formally filled 2p orbitals of the $(O\cdots O)^{4-}$, $(N\cdots O)^{5-}$, and $(C\cdots O)^{6-}$ ligand sets. Quantitatively, however, the relative positions of the MOs vary substantially across the series because of

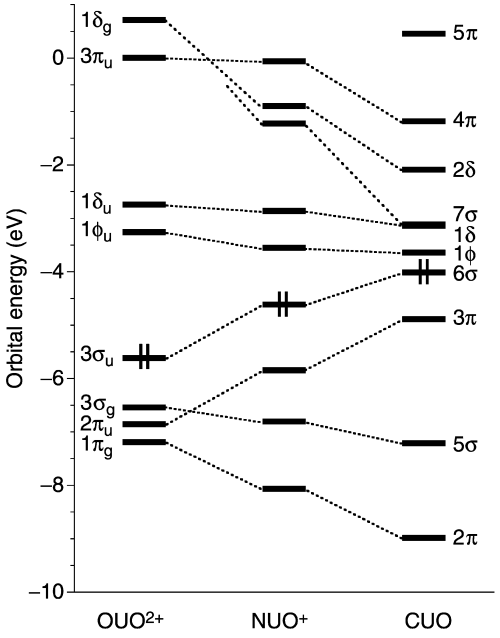

Fig. 17.25 *MO energies of the isoelectronic series* UO_2^{2+}, *NUO*$^+$, *and CUO from scalar-relativistic DFT calculations. The orbitals are labeled under* $D_{\infty h}$ *symmetry for* UO_2^{2+} *and* $C_{\infty v}$ *symmetry for NUO*$^+$ *and CUO* (*reproduced from Bursten* et al., 2003).

the changes in the relative energies of the 2p orbitals for O, N, and C atoms. In particular, the rise of the HOMO across the series places it closer to the LUMO, which is a U-localized 5fφ orbital in each case. We will find the energetic ordering of the MOs in this figure and the trends in orbital energies to be useful in this section.

17.6.1 Matrix-isolated actinide dioxides

The oxides occupy a central place in the natural, environmental, and technological aspects of actinide chemistry (Matthews, 1987). A variety of actinide oxides exist as solids or aqueous solutions in nature and in human-made reservoirs, such as nuclear fuel rods, nuclear waste repositories, and actinide storage tanks. We will focus our discussion here on the electronic structure of molecular actinide oxides, and particularly some of the actinide dioxides, that have been isolated in low-temperature matrices. As noted above, the largest body of research in this area has involved uranium chemistry. In addition to the ubiquitous chemistry of the uranyl ion, gas-phase reactions of uranium and other actinide atoms with atmospheric components are of great interest because

actinide metals experience oxidation when exposed to the atmosphere. Reactions of actinide atoms with oxygen, and the products thereof, thus represent one of the most important aspects of actinide chemistry.

Matrix-isolated uranium oxides were first explored in the early 1970s and the infrared (IR) spectra of UO, UO_2, and UO_3 were observed and assigned in several laboratories (Abramowitz *et al.*, 1971; Leary *et al.*, 1971; Abramowitz and Acquista, 1972; Carstens *et al.*, 1972). The IR spectra and assignments reported by Reedy and coworkers for UO, UO_2, and UO_3 (Gabelnick *et al.*, 1973a,b,c) and for ThO and ThO_2 (Green *et al.*, 1980) are generally accepted and has led to the interesting observation that UO_2 is linear (like UO_2^{2+}) whereas molecular ThO_2 has a bent structure (Pepper and Bursten, 1991). Green and Reedy (1978a) also reported the IR spectra of PuO and PuO_2 in Ar and Kr matrices. Because of the difficulty in handling the radioactive Pu systems, there are comparatively few experimental data available for them, although Green (1980) has also reported the gas-phase enthalpies of formation of PuO and PuO_2, and Capone *et al.* (1999) have reported an ionization energy for gaseous PuO_2.

In 1993, Andrews and coworkers generated UO_n species in an argon matrix via the reaction of laser-ablated U atoms with O_2 molecules in an argon carrier followed by condensation of a solid matrix at low temperature, and were able to obtain more accurate IR frequencies for UO, UO_2, and UO_3 (Hunt and Andrews, 1993). These species are also formed upon the reaction of laser-ablated U atoms with other substrates that can provide O atoms (e.g. NO, CO, CO_2) as will be discussed later. Interestingly, despite its stability and ubiquitous presence in solution and coordination chemistry, the UO_2^{2+} dication has not yet been observed in noble-gas matrices. The 'bare' UO_2^{2+} ion was first observed in the gas phase in 1996 (Cornehl *et al.*, 1996), although the vibrational properties of the bare ion are still unknown experimentally. Because the uranyl ion is highly charged, it is expected to have strong electrostatic or even covalent interactions with the matrix atoms or other residue counter-anions in the reactions. To date, the best known matrix-isolated species containing the UO_2^{2+} ion are those with various counter-ions, such as $UO_2^{2+}(NO^-)$, $UO_2^{2+}(NO_2^-)$, and $UO_2^{2+}(O_2^-)$ (Green *et al.*, 1976; Hunt and Andrews, 1993).

As shown in Section 17.3, there have been a great number of theoretical calculations on the free uranyl dication and other actinyl cations, and those results will not be repeated here. In order to relate the neutral uranium oxides detected via matrix isolation to the UO_2^{2+} ion, however, it is relevant to discuss briefly here the electronic structures of the UO_2^q $(q = +2,\ +1,\ 0,\ -1)$ series. With reference to Fig. 17.25, the UO_2^{2+} ion has a closed-shell $^1\Sigma_g^+$ ground state with a $(3\sigma_u)^2(f\phi_u)^0(f\delta_u)^0$ electron configuration, consistent with the notion that uranyl is a U(VI) complex with an f^0 configuration. The UO_2^+ cation, which has one more electron than UO_2^{2+}, has a $^2\Phi_u$ ground state corresponding to the $(3\sigma_u)^2(f\phi_u)^1(f\delta_u)^0$ configuration. Although the $^2\Delta_u$ state, from the $(3\sigma_u)^2(f\phi_u)^0(f\delta_u)^1$ configuration, is only slightly higher in energy, the first-order

spin–orbit splitting of $^2\Phi_u$ is much larger than that of $^2\Delta_u$, which renders the $^2\Phi_u$ as the ground state. Upon adding two electrons to UO_2^{2+} to form neutral UO_2, we see the effect that changing the oxidation state of U has upon the relevant atomic orbital energies and, hence, the ground state of the molecule. At first glance one might expect that UO_2 would have a ^3H_g state derived from the $(3\sigma_u)^2(f\phi_u)^1(f\delta_u)^1$ configuration, which is the case for the isoelectronic PuO_2^{2+} ion. However, because of the increase in the U–O bond lengths and the decrease in the formal oxidation state to U(IV), the U 7s orbital is energetically very close to the $(f\phi_u f\delta_u)$ manifold in UO_2. As we will discuss in detail below, the free UO_2 molecule has a 'nonintuitive' $^3\Phi_u$ state derived from the $(3\sigma_u)^2(f\phi_u)^1(f\delta_u)^0(7s)^1$ configuration. Similarly, the UO_2^- anion has a $^2\Phi_u$ ground state from the $(3\sigma_u)^2(f\phi_u)^1(f\delta_u)^0(7s)^2$ configuration.

The nonintuitive ground state of UO_2 is a problem of great current interest and serves as a paradigm of the challenges in determining the electronic structures of even small actinide molecules. Part of the current interest in the electronic structure of matrix-isolated UO_2 is due to some current experimental anomalies that, at the time of this writing, are not resolved. UO_2 has very different IR-active U–O stretching frequencies in solid argon than in solid neon. In 1993, Hunt and Andrews reported that UO_2 in solid argon has an antisymmetric stretching mode at 776.0 cm^{-1} (Hunt and Andrews, 1993), a value that is in close agreement with earlier Knudsen effusion studies (Gabelnick *et al.*, 1973a). In 2000, Zhou *et al.* reported that UO_2 in solid neon exhibits a stretch at 914.8 cm^{-1}, ca. 139 cm^{-1} higher than in solid argon (Zhou *et al.*, 2000). The large shift in frequency from an argon to a neon matrix is unlikely to be due to typical polarizability-based matrix effects, which tend to cause shifts on the order of 5–20 cm^{-1} in vibrational frequencies (Jacox, 1994). As will be discussed in detail below, similar large frequency shifts were seen for matrix-isolated CUO and were ultimately shown to be the result of a noble-gas induced change in the electronic state of that molecule due to direct U–Ng bonds.

Calculations on the isolated UO_2 molecule have been carried out at several different levels of theory over the past few years, starting with some early Hartree–Fock–Slater work by Baerends *et al.* (Allen *et al.*, 1988; van Wezenbeek *et al.*, 1991). Zhou *et al.* (2000) reported DFT calculations on UO, UO_2^q ($q = 1+, 0, 1-$), and UO_3, including the calculation of vibrational frequencies and were the first to propose that neutral UO_2 has a $^3\Phi_u$ ground state arising from a $5f^17s^1$ configuration for the U(IV) center. Their calculated antisymmetric stretching frequency for UO_2 was 931 cm^{-1}, which is in good agreement with the experimental value observed in solid neon. Gagliardi and Roos with coworkers carried out CASSCF/CASPT2 and CASPT2/SO calculations on the geometries, electronic states, and vibrational frequencies of UO_2^{2+}, UO_2^+, and UO_2 (Gagliardi and Roos, 2000; Gagliardi *et al.*, 2001b). They also concluded that UO_2 has a $^3\Phi_u$ ($\Omega = 2$) ground state and found that the lowest state

derived from the $5f^2$ configuration was the ^3H_g ($\Omega = 4$) state, which was 0.52 eV above the ground state. Chang and Pitzer performed SOCI calculations on neutral UO_2 (Chang, 2002). They also found a $^3\Phi_u$ ($\Omega = 2$) ground state, with the ^3H_g ($\Omega = 4$) state only 0.20 eV above the ground state. Majumdar *et al.* (2002) also calculated the geometries and frequencies of the UO_2^q ($q = 2+,\ 1+,\ 0,\ 1-$) series using CASSCF and MRCI methods. A summary of the calculated geometric parameters and vibrational frequencies of the various uranium oxide species is presented in Table 17.17.

The theoretical results on isolated UO_2 could not be used to reconcile the difference in the experimentally observed IR stretching frequencies of UO_2 in argon and neon. Li *et al.* (2004) have performed scalar-relativistic DFT and CCSD(T) calculations on a series of UO_2 and $UO_2(Ar)_n$ complexes to explore the possibility that the electronic state of UO_2 is different in Ar than in Ne. Their calculated geometries and vibrational frequencies for UO_2, $UO_2(Ar)$, and $UO_2(Ar)_5$ are listed in Table 17.18, and Fig. 17.26 shows their linear transit potential energy curves for the interaction between five Ar atoms and UO_2 in two different electronic states of the model complex $UO_2(Ar)_5$. On the basis of these calculations, Li *et al.* proposed that UO_2 forms direct U–Ar bonds in the argon matrix, and that these bonds lead to stabilization of the $5f^2$-derived ^3H_g state below the $5f^17s^1$-derived $^3\Phi_u$ state that is the apparent ground state for UO_2 in solid neon. The significantly lower U–O antisymmetric stretching frequency for the ^3H_g state of UO_2 relative to the $^3\Phi_u$ state was proposed to explain the different IR frequencies of UO_2 in argon and neon matrices.

Recent experiments by Heaven *et al.* suggest that UO_2 is in the same electronic state in the gas phase and in an argon matrix (Han *et al.*, 2003). By using resonance-enhanced multiphoton ionization (REMPI) spectroscopy, they obtained a new value of 6.13 eV for the first ionization energy of UO_2, which was in good agreement with the calculated values of Zhou *et al.* (2000) and Gagliardi *et al.* (2001b). Their results were consistent with a $^3\Phi_u$ ground state for UO_2. They have also obtained dispersed fluorescence spectra for molecular UO_2 in solid argon, which suggest that UO_2 has the same ground state in the matrix as in the gas phase (Lue *et al.*, 2004), although these results cannot reconcile the different stretching frequencies of UO_2 in solid neon relative to solid argon. There are clearly still some unanswered questions with regard to the electronic state of UO_2 in noble-gas matrices. The recent calculation of the electronic spectra of isolated UO_2 by Gagliardi *et al.* (2005) represents one of such efforts. Nevertheless, the mystery of the different results from the two experiments will likely persist until it is possible to perform accurate theoretical calculations on the electronic spectra of UO_2 with the Ar matrix environment included.

The proposal of direct U–Ar bonds when UO_2 is in an argon matrix followed shortly after the proposal of the first uranium-to-noble-gas bonds, which involved the CUO molecule that will be discussed in the next section. Other recent discoveries in the interactions of noble-gas atoms with metal

centers, notably the remarkable stability of the $[AuXe_4]^{2+}$ complex (Seidel and Seppelt, 2000), suggest that the interaction of Ng atoms will be stronger with cationic centers because of electrostatic stabilization. Consistent with this notion, recent experimental and theoretical results suggest U–Ng interactions in a series of $UO_2^+(Ng)_n(Ng = Ne, Ar, Kr, Xe)$ complexes in low-temperature matrices that are stronger than those for neutral UO_2 (Wang *et al.*, 2004).

A recent combined experimental and computational study also provides evidence for the formation of Ar atom binding to the simplest neutral uranyl complex, i.e. $H_2UO_2(Ar)_n$ (Liang *et al.*, 2005).

There have been other neutral actinide oxide molecules that have been studied by matrix-isolation techniques. As noted earlier, the bent structure of ThO_2 was indicated by the IR spectra of the matrix-isolated molecule. The interesting observation that ThO_2 is bent whereas the isoelectronic UO_2^{2+} ion is linear has stimulated a number of theoretical investigations. Much of the early work in this area was covered in detail by Pepper and Bursten (1991). Since that review was written, there have been applications of higher-level methods by Dyall (1999) and by Straka *et al.* (2001). The bent structure of ThO_2 is attributed to the favorable mixing of the Th 5f and 6d orbitals that can occur upon bending. Liang and Andrews (2002) recently generated ThS and ThS_2 in an argon matrix and investigated these molecules using scalar-relativistic DFT calculations. The IR spectrum of matrix-isolated ThS_2 indicates that it is also a bent molecule, and the DFT calculations predict a S–Th–S bond angle of 112°.

As noted earlier, Green and Reedy (1978a) reported the matrix isolation of PuO_2 in 1978, formed from the sputtering of a plutonium cathode with Ar/O or Kr/O mixtures. Isotopic labeling of the O atoms allowed them to conclude that PuO_2 was a linear molecule. PuO_2 is formally a Pu(IV) complex with four metal-based electrons, and based on our discussion this far it is anticipated to have a complex electronic structure. To date, the only detailed electronic structure calculations on PuO_2 have been carried out by Archibong and Ray (2000), who used coupled-cluster and CAS calculations with RECPs. They found that the two lowest-energy states of PuO_2 are nearly degenerate, namely a $^5\Sigma_g^+$ state derived from the $(f\delta_u)^2(f\phi_u)^2$ electron configuration and a $^5\Phi_u$ state from the $(f\delta_u)^2(f\phi_u)^1(7s\sigma)^1$ configuration. Because these states are derived from different configurations (f^4 vs f^3s^1), they have significantly different calculated properties, as has been proposed for UO_2 and CUO. The calculated Pu–O bond lengths in the $^5\Sigma_g^+$ state range from 1.85 to 1.88 Å, depending on the method, and from 1.78 to 1.80 Å in the $^5\Phi_u$ state. The shorter An–O bonds in the states derived from the $f^{n-1}s^1$ configuration relative to those from the f^n configuration is consistent with what was observed for UO_2 (Table 17.18). Based on a comparison of the calculated antisymmetric stretching frequencies and $^{16}O/^{18}O$ isotopic ratios, Archibong and Ray propose that the $^5\Sigma_g^+$ state is the likely ground state of PuO_2.

17.6.2 Matrix-isolated actinide carbide oxides

One of the most interesting aspects of the chemistry of matrix-isolated actinide atoms has involved their reactions with CO and CO_2 as matrix substrates. The activation and sequestration of these two important molecules are and will continue to be fundamental areas of research. As we will see in this section,

actinide atoms, and particularly laser-ablated actinide atoms, have a remarkable ability to react with CO and CO_2. We will also see that some atypical species have been formed as well as some unusual types of bonds, providing many challenges to electronic structure calculations. To date, the experimental studies have been limited to reactions of Th and U with CO and CO_2, and we will limit our discussion here to some of the carbide–oxide products that form from these reactions. A discussion of some of the carbonyl species formed in these reactions will be presented later in this section.

The reaction of laser-ablated U atoms with CO produces a number of interesting products corresponding to the addition of one or more CO molecules to a U atom (Tague *et al.*, 1993; Zhou *et al.*, 1999a; Andrews *et al.*, 2000b). The 1:1 stoichiometry products are UCO and CUO, and the 2:1 products are $U(CO)_2$, OUCCO, and $(\eta^2\text{-}C_2)UO_2$. Evidence has also been found for the higher binary carbonyl complexes $U(CO)_n$ (n = 3–6). Table 17.19 presents the calculated scalar-relativistic DFT relative energies, geometric parameters, and some of the calculated vibrational frequencies of the 1:1 and 2:1 adducts of CO to U (Zhou *et al.*, 1999a). In both the isomers of UCO and $U(CO)_2$, the calculated lowest energy isomer is the one that involves the maximum number of U–O bonds, consistent with the high oxophilicity of uranium.

Table 17.19 *Relative energies, geometric parameters, and vibrational frequencies for the isomers of UCO and $U(CO)_2$ from scalar-relativistic DFT calculations, along with the experimental frequencies of the matrix-isolated species in solid neon* (*see Zhou* et al., 1999*a*).

[a] This value is uncertain.

Of the species formed in these reactions, the CUO molecule is especially interesting from an electronic structural viewpoint for several reasons. CUO is isoelectronic with UO_2^{2+} and can be considered as an f^0 U(VI) complex like the uranyl ion. Fig. 17.27 shows a qualitative interaction diagram that compares the valence MOs of CUO to those of UO_2^{2+}. This diagram is constructed by allowing the MOs of the f^0 fragment UO^{4+} to interact with the AOs of either O^{2-} or C^{4-}. As expected for isoelectronic systems, there is a one-to-one correspondence of the filled MOs of UO_2^{2+} (labeled under $D_{\infty h}$ symmetry) and CUO ($C_{\infty v}$ symmetry). The energies of the MOs in CUO differ from those of UO_2^{2+} because of the higher energy of the C 2s and 2p orbitals relative to the O 2s and 2p orbitals. In particular, the C 2p-based 4σ HOMO of CUO is much closer in energy to the empty 5f-based MOs than is the corresponding $2\sigma_u$ HOMO of UO_2^{2+}. As shown, the CUO molecule has a closed-shell $^1\Sigma^+$ ground state analogous to the $^1\Sigma_g^+$ ground state of UO_2^{2+}.

The CUO molecule was first isolated in 1993 by Andrews and coworkers (Tague *et al.*, 1993) in solid argon, where it exhibits stretching modes at 804.4 and 852.6 cm^{-1}. Later studies of CUO in solid neon led to very different frequencies, 1047.3 and 872.2 cm^{-1}, which isotopic substitution showed predominantly U–C and U–O stretching modes, respectively (Zhou *et al.*, 1999a). These large frequency shifts upon changing the matrix are greater than would be expected for normal polarizability-based matrix effects. As shown in Fig. 17.27, CUO is expected to have a $^1\Sigma^+$ ground state with a $(4\sigma)^2(5f\phi)^0$ configuration. However, the U–C-based 4σ orbital is so close in energy to the U $5f\phi$ orbital that the open-shell $^3\Phi$ excited state corresponding to the $(4\sigma)^1(5f\phi)^1$ configuration is very close in energy to the $^1\Sigma^+$ ground state. Initial scalar-relativistic DFT calculations predicted that the $^3\Phi$ excited state is only about 1 kcal mol^{-1} higher in energy than the singlet 'ground state' of free CUO and that the two states would have very different vibrational frequencies because they arise from different electronic configurations. The experimentally observed large vibrational frequency shifts were thus preliminarily explained in terms of a matrix-induced ground state reversal (Andrews *et al.*, 2000a).

To understand the ground-state reversal of CUO in the Ne and Ar matrices, further detailed theoretical calculations were performed to model the interaction between CUO and the noble-gas matrix. It was discovered that the CUO molecule tends to form direct albeit weak bonds to the Ar atoms in the matrix, leading to the proposal of a $CUO(Ar)_n$ complex that has a U–Ar bond (Li *et al.*, 2002). The formation of the U–Ar bond stabilizes the $^3\Phi$ ($^3A''$ under C_s symmetry) state of the molecule to such an extent that it drops below the $^1\Sigma^+$ ($^1A'$ under C_s) ground state of the isolated CUO molecule, as shown by the DFT energy curves shown in Fig. 17.28. This proposal of the first U–Ar bonding was affirmed by matrix experiments that showed that the U–Ar interactions occur even in a matrix of 1% Ar in neon (Fig. 17.29). The discovery of direct actinide-to-noble-gas bonding adds to the recent renaissance in noble-gas chemistry (Pyykkö, 2000a; Christe, 2001).

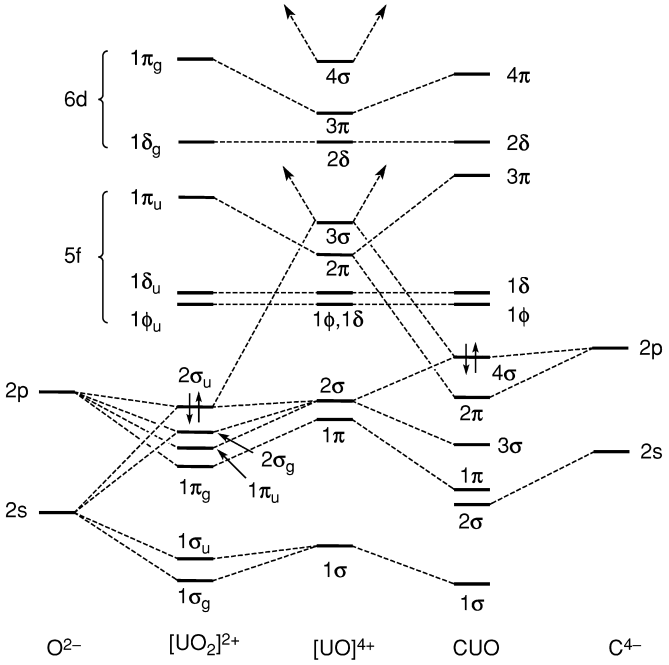

Fig. 17.27 *Qualitative interaction diagram showing the formation of the molecular orbitals of* UO_2^{2+} *and CUO by the interaction of* O^{2-} *and* C^{4-} *with* UO^{4+}. *Only the 5f and 6d orbitals of U are shown, although the U 7s and 7p AOs contribute non-negligibly to the bonding* (*reproduced from Zhou* et al., 1999*a*).

As noted above, the very small energetic separation (1 kcal mol^{-1}) between the $^1\Sigma^+$ ground state and the $^3\Phi$ excited state of CUO was first found using scalar-relativistic DFT calculations. The validity of this small gap was questioned because of concerns about the ability of DFT to calculate excited-state energies reliably and the lack of inclusion of spin–orbit effects, which are expected to affect the two states to a different extent. Recent CCSD(T) calculations with geometry optimizations on CUO and CUO(Ng) (Ng = Ne, Ar, Kr, Xe) confirm that the previous DFT triplet–singlet energy difference is underestimated and that the coordination of one (or more) heavier Ng atom indeed stabilizes the $^3\Phi$ excited state more than the $^1\Sigma^+$ ground state of CUO (Bursten *et al.*, 2003). This energy difference is found to be around 16 kcal mol^{-1} from CCSD(T) calculations without including spin–orbit effects. Roos *et al.* (2003) performed CASPT2/SO calculations with spin–orbit effects included and found that the $^3\Phi$ state is stabilized by spin–orbit coupling by about 8–10 kcal mol^{-1} relative to the $^1\Sigma^+$ state. The additional differential stabilization of the $^3\Phi$ state upon multiple coordination of heavier Ng atoms would therefore seem to make the proposed ground-state reversal of CUO quite feasible. A recent study by

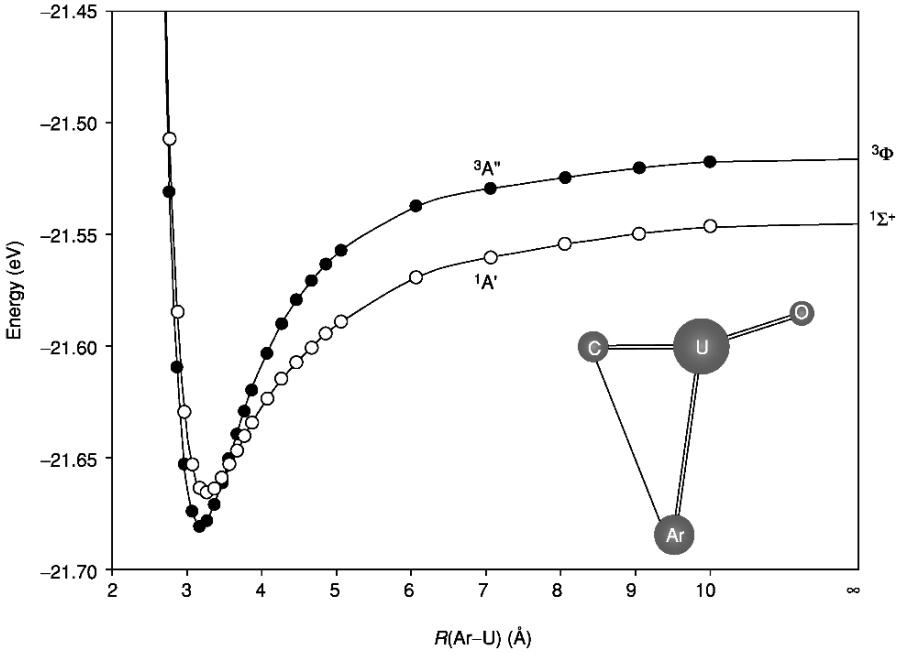

Fig. 17.28 *Potential energy curves for the* $^1A'$ *and* $^3A''$ *states of CUO(Ar) as a function of the U–Ar distance. The U–Ar bond length in this complex is* 3.16 Å (*reproduced from Li* et al., 2002).

Infante and Visscher (2004b) at the fully relativistic CCSD(T) level has confirmed that with inclusion of the high-level electron correlation and spin–orbit effects the $^3\Phi$ triplet state lies ~14 kcal mol^{-1} above the $^1\Sigma^+$ ground state for isolated CUO. They concluded that "our result gives further justification to the interpretation of the measured frequency shifts of this species (CUO) in various noble gas matrices as being caused by significant interaction between the uranium and the heavier noble gas atoms."

Binding energy calculations on $CUO(Ng)_n$ (Ng = Ar, Kr, Xe; n = 1–6) predicted that CUO prefers five-coordination for Ar and Kr, and four-coordination for Xe. Experimental efforts indeed uncovered the coordination of CUO by multiple noble-gas atoms (Liang *et al.*, 2002; Andrews *et al.*, 2003). Recent experiments further confirm that the multiple coordination of CUO is necessary for the ground state reversal, with the experimentally determined singlet-to-triplet crossover points as $CUO(Ar)_3$, $CUO(Kr)_3$, and $CUO(Xe)_4$ (Liang *et al.*, 2003, 2004; Andrews *et al.*, 2004).

The only other CAnO species that has been detected thus far experimentally is the CThO molecule, which is formed upon the reaction of laser-ablated Th atoms with CO in excess neon (Zhou *et al.*, 1999b; Li *et al.*, 2001). The properties of the CThO molecule differ markedly from those of CUO because of the

difference in the number of valence electrons for Th and U. As discussed earlier, the $^1\Sigma^+$ state of CUO is isoelectronic with UO_2^{2+} and is best considered as a U(VI) complex. Because Th has only four valence electrons, the maximum oxidation state of Th is +4. The most obvious Lewis structure of CThO is the carbene :C=Th=Ö:, which is the actinide analog of the organic carbene ketenylidene, (:C=C=Ö:). Ketenylidene, which has been detected in interstellar space (Ohishi *et al.*, 1991), is a linear radical with a triplet ground state (Devillers and Ramsay, 1971). It was not apparent *a priori* whether CThO is linear or bent, and whether its ground state is a singlet or a triplet. Fig. 17.30 shows linear-transit potential energy curves from scalar-relativistic DFT calculations for the lowest singlet and triplet states of CThO (Li *et al.*, 2001). These studies predict that CThO prefers a highly bent structure ($\angle$CThO = 108.9°) with a triplet ground state. The bending of CThO is caused by factors similar to those used to explain the bent structure of ThO_2. From the CUO energy level in Fig. 17.25, linear CThO is expected to be a closed-shell molecule with a $(3\pi)^4(6\sigma)^0$ configuration. Because the 6dσ orbital participates strongly in the 6σ orbital, the unoccupied 6σ and occupied 3π MOs are very close in energy in linear structure; thus, a bending distortion via a second-order Jahn–Teller

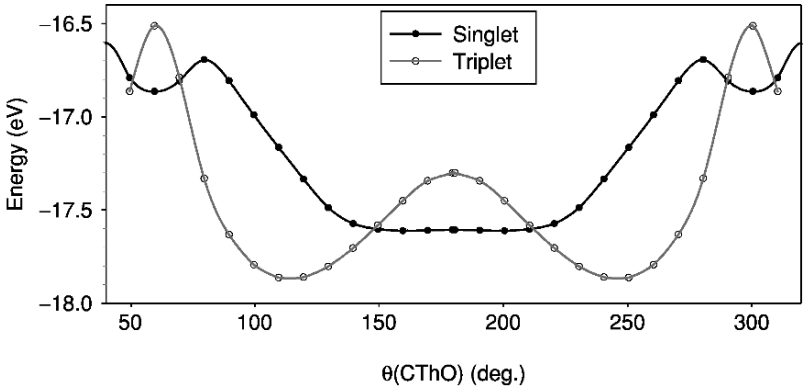

Fig. 17.30 *Linear-transit energy curves for the lowest singlet and triplet states of CThO* (*reproduced from Li* et al., 2001).

interaction is energetically favorable. The degenerate 3π orbital splits into $a' + a''$ upon bending, and the ground state of bent CThO corresponds to an $(a'')^2(a')^1(a')^1$ configuration that correlates with the $(3\pi)^3(6\sigma)^1$ configuration of the linear molecule.

The difference in the valence electronic structures of CUO and CThO has a remarkable effect on the observed stretching frequencies of the molecules. CThO in solid neon exhibits stretches at 617.7 and 812.2 cm^{-1}, and isotopic substitution demonstrates that these are predominantly Th–C and Th–O modes, respectively. The scalar-relativistic DFT calculations on isolated CThO model these vibrations extremely well, with calculated frequencies of 621 and 811 cm^{-1} and excellent calculated values for the isotopic ratios. Some of the properties of $^1\Sigma^+$ CUO and $^3A'$ CThO are compared in Table 17.20. Particularly notable are the changes in the calculated An–C bond lengths and the calculated and experimental An–C stretching frequencies. The Th–C bond length in CThO is more than 0.35 Å longer than the U–C bond length in CUO, and the predominantly Th–C stretching frequency is more than 400 cm^{-1} lower than the predominantly U–C stretching frequency. Both of these changes are consistent with a significantly lower bond order for the Th–C bond in CThO relative to the U–C bond in CUO, which is consistent with the simple Lewis structures of the molecules. The Th–O bond in CThO is slightly longer and weaker than the U–O bond in CUO, although the difference of the An–O bonding is not nearly as great as for the An–C bonds.

We will briefly discuss here the electronic structural aspects of some of the other products of the reactions of laser-ablated U and Th atoms with CO (Zhou *et al.*, 1999a; Li *et al.*, 2001). The most stable product from the addition of two CO molecules to a U atom is the unusual molecule $(\eta^2\text{-}C_2)UO_2$. This molecule results from the insertion of a U atom into two CO molecules, and its stability

[a] The vibrations are labeled 'An–C' and 'An–O' based on the predominant component of the normal mode.

relative to the other isomers [$U(CO)_2$ and OUCCO] is a consequence of the high oxophilicity of uranium and its preference for the +6 oxidation state. (η^2-C_2)UO_2 can be viewed as a closed-shell organometallic complex of the uranyl ion with a C_2^{2-} ligand that is obtained by deprotonating acetylene. Experimentally, (η^2-C_2)UO_2 shows two vibrational frequencies in the U–O stretching region at 843.2 and 922.1 cm^{-1}. Scalar-relativistic DFT calculations found a minimum structure with calculated symmetric and antisymmetric U–O stretching frequencies at 849 and 910 cm^{-1}, respectively, in good agreement with the experimental values. The calculated structure of (η^2-C_2)UO_2 is unusual in two respects. First, the UO_2 moiety is bent (∠O–U–O = 155.8°), which is highly unusual for uranyl complexes. Second, the dihedral angle between the C–U–C and O–U–O planes is 55°, nearly halfway between a pseudotetrahedral (C_{2v}) structure with a dihedral angle of 90° and a completely planar structure. It is proposed that the 'twisted' C_2 structure allows for the maximum donation from the filled π orbitals of the C_2^{2-} ligand to the f^0d^0 UO_2^{2+} fragment (Zhou *et al.*, 1999a). There is no experimental evidence for the formation of the analogous (η^2-C_2)ThO_2 molecule. Because Th cannot achieve a +6 oxidation state, this isomer is calculated to be considerably higher in energy than OTh(η^3-CCO), which is a lower oxidation state complex of Th (Li *et al.*, 2001). The OUCCO and OTh (η^3-CCO) molecules are highly unusual inasmuch as they are the first examples of mononuclear ketenylidene complexes (Geoffrey and Bassner, 1988).

The major products of the reaction of laser-ablated Th or U atoms with CO_2 are the OThCO and OUCO molecules (Tague *et al.*, 1993; Andrews *et al.*, 2000b). These oxocarbonyl complexes were the first reported complexes of Th(II) and U(II). They provide an interesting contrast in structure and bonding because of the presence of a π-basic oxo ligand, which typically favors high oxidation states, and a π-acidic CO ligand, which generally favors lower oxidation states. Scalar-relativistic DFT calculations on these products lead to the prediction that they are high-spin complexes with linear CO ligands and

severely bent O–U–C linkages. The calculated electronic states, geometries, and vibrational frequencies, along with the experimental frequencies in solid neon, are presented in Table 17.21.

The OUCO molecule is predicted to be a planar, bent molecule with four unpaired electrons that correspond to a $(7s)^1(5f)^3$ configuration at the U(II) center. The bending of the molecule is a consequence of a Renner–Teller distortion that splits the 5fϕ orbitals, which are degenerate in the linear geometry. The bent geometry allows the U atom to serve as an efficient conduit of electron density from the strongly donating oxo ligand to the CO ligand, thus helping to explain the ca. 300 cm^{-1} reduction of the C–O stretching frequency in OUCO relative to free CO.

The bonding in OThCO differs substantially from that in OUCO because Th(II) has only two metal-localized valence electrons. Further, because the 6d orbitals of Th are lower in energy than the 5f orbitals, the two metal-based electrons are predicted to adopt a $(7s)^1(6d)^1$ electron configuration. Linear OThCO is predicted to have a Renner–Teller-active $^3\Pi$ state. Distortion causes OThCO to bend even more severely than OUCO, and it has a quite remarkable 90° O–Th–C angle. The greater radial extension of the 6d orbitals relative to the 5f orbitals allows the former to interact more strongly with the 2π orbitals of the CO ligand. As a result, the calculated and observed C–O stretching frequencies in OThCO are lower than those for OUCO even though the Th–C bond is predicted to be longer than the U–C bond.

17.6.3 Matrix-isolated actinide binary carbonyls

Binary zero-valent carbonyl complexes of the actinides have been a long-sought goal of actinide chemists because of their potential attractiveness in isotope-separation processes. In 1971, Slater *et al.* reported the isolation of

[a] Not observed.

$U(CO)_n$ ($n = 1$–6) in solid argon (Slater *et al.*, 1971). Since then there have been some reports of isolable carbonyl complexes of uranium, most notably the U(III) cyclopentadienyl carbonyl complexes discussed in Section 17.5.2. To date, however, the only reports of binary actinide carbonyls have involved matrix-isolated species. In this section, we will discuss the electronic structures of some actinide mono- and dicarbonyls. The higher carbonyls tend to be harder to characterize experimentally and there has been only one theoretical study of one of these species (Nash and Bursten, 1995).

The binary uranium carbonyls $U(CO)_n$ ($n = 1$–6) were reinvestigated by Zhou *et al.* (1999a) in a neon matrix. The monocarbonyl UCO was difficult to identify experimentally and a vibrational band at 1917.8 cm^{-1} was tentatively assigned to this species. The dicarbonyl $U(CO)_2$ exhibited absorptions at 1840.2 and 1790.8 cm^{-1}, which were assigned to the symmetric and antisymmetric C–O stretching modes, respectively, of a bent (C_{2v}) molecule. It is to be noted that the stretches assigned to $U(CO)_2$ are both at significantly lower frequencies than that for UCO, which is counter-intuitive. ThCO and $Th(CO)_2$ have both been identified in a neon matrix, along with the first report of the higher binary carbonyls of Th (Li *et al.*, 2001). The C–O stretch for ThCO is observed at 1817.5 cm^{-1} and the symmetric and antisymmetric stretches of $Th(CO)_2$ are assigned at 1827.7 and 1775.6 cm^{-1}, respectively. The reduction of the C–O stretching frequencies in these complexes by more than 300 cm^{-1} below that of free CO is quite striking given that Th is considered an early metal with only four electrons for potential backbonding.

Theoretical studies of even these simple mono- and dicarbonyl complexes are extremely challenging because of the presence of four (Th) or six (U) metal-based valence electrons at the An(0) center. The coordinative unsaturation of these complexes combined with the energetic closeness of the An 7s, 5f, and 6d orbitals leads to a large number of low-lying states that will almost certainly demand multiconfigurational approaches to discern. To date, the only computational studies of these molecules have used scalar-relativistic DFT, which is intrinsically a single-configuration approach. Nevertheless, the results reported do provide useful information about the bonding in these complexes and we will discuss them briefly here. We will focus on ThCO and $Th(CO)_2$, which are somewhat cleaner systems than the uranium complexes because of the smaller number of metal-based electrons.

Scalar-relativistic DFT calculations on ThCO predict that it is a linear molecule with Th–C = 2.261 Å and C–O = 1.181 Å, and a $^3\Sigma^-$ ground state that corresponds to a $(7s)^2(6d\pi)^2$ electron configuration at Th. Two other states, namely a $^5\Delta$ $[(7s)^1(6d\pi)^2(5f\delta)^1]$ and a $^3\Pi$ $[(7s)^1(6d\pi)^3]$ are found at 3.2 and 11.1 kcal mol^{-1} above the ground state, respectively. The calculated C–O stretching frequency of ThCO is 1790 cm^{-1}, in good agreement with the experimental neon-matrix value, and the calculated $^{12}C/^{13}C$ and $^{16}O/^{18}O$ isotopic vibrational ratios are also in excellent agreement with the experimental values.

An energy level diagram for ThCO is presented in Fig. 17.31 (Li *et al*., 2001). This diagram illustrates some of the important features of the bonding within actinide carbonyl complexes. The relativistic destabilization of the Th 5f orbitals and stabilization of the Th 7s orbital are shown in the first two columns, which compare atomic results on Th at the nonrelativistic and scalar-relativistic levels. The dominant interactions involve the Th 6d orbitals. The Th 6dσ orbital is strongly destabilized by interaction with the filled 5σ orbital of CO whereas the 6dπ orbitals are stabilized by a backbonding interaction with the CO 2π orbitals. In contrast, the Th 7s and 5f orbitals are minimally affected by the CO ligand. The $^3\Sigma^-$ ground state of ThCO corresponds to the $(3\pi)^2(6\sigma)^2$ MO configuration in which only two of the four Th-based electrons are involved in Th-to-CO π-backbonding. The large reduction in the C–O stretching frequency with only two π-electrons involved is attributed to the highly electropositive nature of Th, which leads to very effective charge transfer from Th to CO. The authors also reported a calculation on the hypothetical $^1\Sigma^+$ excited state that arises from the $(3\pi)^4(6\sigma)^0$ configuration in which all four of the Th-based electrons are involved in π-backbonding. This excited state is found ca. 36 kcal mol^{-1} above the $^3\Sigma^-$ ground state, and leads to a predicted C–O stretching frequency of 1630 cm^{-1}, a value considerably lower than the lowest known CO-stretching frequency of any terminal metal carbonyl.

Scalar-relativistic DFT calculations on $Th(CO)_2$ also led to some interesting and unusual results. Three relatively low-lying states were found, each with different spin multiplicities. The ground state is predicted to be a closed-shell $^1A_1$ state in which two MOs that each involve strong Th 6d → CO 2π-backbonding are doubly occupied. The two occupied MOs are sketched in Fig. 17.32. By doubly occupying these MOs, all four of the metal-based electrons are involved in metal-to-ligand backbonding. The calculated geometry of ground state $Th(CO)_2$ is highly unusual inasmuch as it has two terminal CO ligands with ∠C–Th–C = 49.6°. This very acute angle is a consequence of the strong desire of electropositive Th to transfer its electrons to the ligands. At this small angle, the CO ligands are brought into close enough proximity (1.89 Å) to produce a significant C–C bonding interaction, which lowers the energies of the 2π orbitals and facilitates even better Th-to-CO donation. In essence, the strong Th 6d → CO 2π-backbonding has led to partial reductive coupling of the two carbon atoms. The low-lying triplet and quintet excited states depopulate the MOs in Fig. 17.32, leading to longer C–C interactions and correspondingly larger C–Th–C angles.

The calculated symmetric and antisymmetric C–O stretching frequencies for $^1A_1$ $Th(CO)_2$ are 1766 and 1734 cm^{-1}, respectively, which are slightly lower than the neon-matrix experimental values. Both the experimental and calculated mean C–O stretching frequencies of $Th(CO)_2$ are lower than the corresponding values for ThCO, which seems consistent with (i) the fact that two electrons are involved in backbonding in ThCO whereas four electrons are involved in $Th(CO)_2$ and (ii) the acute C–Th–C angle in $Th(CO)_2$ allows for

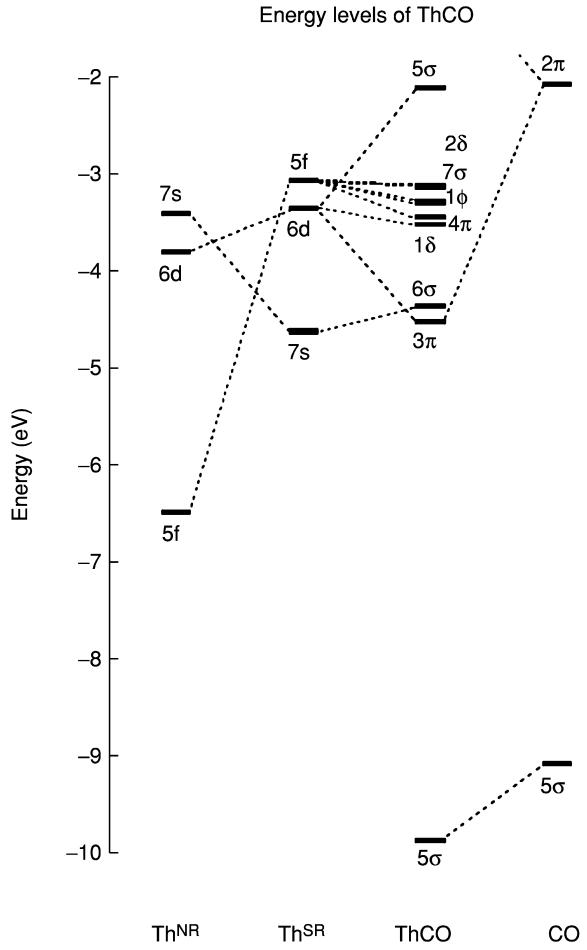

Fig. 17.31 *Energy-level diagram showing the interaction of a CO ligand with a Th atom to form ThCO. The atomic energy levels of Th^{NR} and Th^{SR} are for nonrelativistic and scalar-relativistic calculations on Th, respectively* (*reproduced from Li* et al., 2001).

better backbonding than can occur for a single CO ligand. The extreme ability of Th(0) to transfer electron density to CO is remarkable and is unprecedented among the transition metals.

17.6.4 Matrix-isolated actinide nitrides

The dinitrogen molecule is one of the most stable molecules with the N≡N bond energy of 225 kcal mol^{-1} (9.76 eV) (Gingerich, 1967). As a result, significant activation energy is needed to activate the N_2 molecule, as is the case for

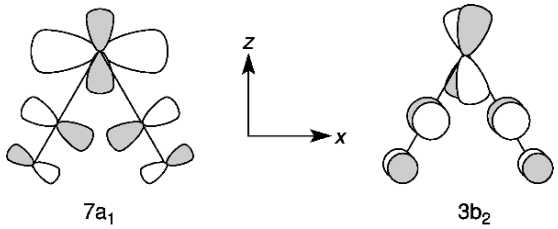

Fig. 17.32 *Sketches of the two highest occupied MOs of the calculated ground state of* $Th(CO)_2$. *Both MOs are doubly occupied in the ground state* (*reproduced from Li* et al., 2001).

activating the CO molecule. In the preceding sections we have seen that laser-ablated actinide atoms have sufficient activity to insert into the CO molecule, and the dinitrogen molecule can analogously be activated by energetic actinide atoms. Green and Reedy first generated the mono- and dinitrides of Th, U, and Pu via reactions of cathode-sputtered actinides with N_2 in a solid argon matrix (Green and Reedy, 1976, 1978b, 1979). By reacting laser-ablated Th and U atoms with N_2, N_2/O_2 mixtures, NO, NO_2, and N_2O, the Andrews group isolated the actinide mononitrides (AnN), dinitrides (NAnN), and some dinuclear actinide species in noble-gas matrices (Hunt *et al.*, 1993; Kushto *et al.*, 1997, 1998). Sankaran *et al.* (2001) also reported the matrix IR spectra of the UN and NUN molecules.

DFT calculations have been carried out on the matrix-isolated AnN and NAnN molecules using the ADF program with the PW91 and BP86 functional (Kushto *et al.*, 1997, 1998). It is predicted that without spin–orbit coupling the ThN, UN, and PuN are in $^2\Sigma$, $^4\Sigma$, and $^6\Pi$ electronic states, respectively, and the optimized bond lengths are consistent with triple bonds for these diatomic actinide molecules. All the NAnN (An = Th, U, Pu) molecules are predicted to be linear, consistent with the experimental IR spectra. Because the NUN molecule is isoelectronic to the uranyl ion, the electronic structures of these NAnN molecules can be qualitatively deduced from Fig. 17.27. Specifically, NUN is expected to have a $^1\Sigma_g^+$ ground state corresponding to the $(3\sigma_u)^2(f\phi_u)^0(f\delta_u)^0$ configuration, and NThN and NPuN should have the $(3\sigma_u)^0(f\phi_u)^0(f\delta_u)^0$ and $(3\sigma_u)^2(f\phi_u)^1(f\delta_u)^1$ configuration, respectively. The DFT calculations on the Th, U, and Pu dinitrides confirm these expectations: the Th and U dinitrides are found to have singlet states, while the NPuN molecule is in triplet state. Note instead of the $^3\Pi_g$ state assigned originally, the ground state of NPuN should be a ^3H_g state with a $(5f\phi)^1(5f\delta)^1$ configuration, as is confirmed in later calculations (Clavaguéra-Sarrio *et al.*, 2004).

The DFT-optimized An–N bond lengths and calculated vibrational frequencies of AnN and NAnN complexes are listed in Table 17.22, together with the experimentally measured data in Ar and N_2 matrixes. In agreement with the predicted linear structure of the NAnN molecules, only one IR absorption,

Table 17.22 *Predicted bond lengths* (Å) *and vibrational frequencies* (cm^{-1}) *of the AnN and NAnN molecules from scalar-relativistic DFT calculations, along with the experimental frequencies of the matrix-isolated species in solid argon and dinitrogen matrices* (*see Kushto* et al., 1997, 1998).

			ν_{sym} (*An–N*)	$\nu_{antisym}$(*An–N*)	
	An–N	ν_{bend}	*Calculated*	*Calculated*	*Experimental*
ThN	1.795			999	934.3 (Ar), 835.6 (N_2)
UN	1.746			1045	1000.9 (Ar), 890.5 (N_2)
PuN	1.756			863	855.73 (Ar)
NThN	1.864	64 × 2	828	830	756.6 (Ar), 716.4 (N_2)
NUN	1.717	53 × 2	1087	1123	1050.8 (Ar), 1010.3 (N_2)
NpuN	1.703	143 × 2	1012	1091	1029.74 (Ar)

corresponding to the antisymmetric stretching mode, was observed for each NAnN species in the matrices. By using the Ar matrix frequencies for different isotopomers, the NUN symmetric stretching frequency is estimated to be 1008.3 cm^{-1} via an F–G matrix approach (Hunt *et al.*, 1993). The large differences of the calculated 'gas-phase' antisymmetric frequencies and those measured in the Ar and N_2 matrices imply that, like the CUO and UO_2 molecules, these highly unsaturated species have significant chemical and physical interactions with the micro-solvating atoms in the Ar matrix, and even stronger interactions with those in the N_2 matrix. A recent CCSD(T) calculation on the $(f\phi_u)^1(f\delta_u)^1$ electron configuration of NPuN by Archibong and Ray (2000) leads to an optimized Pu–N bond length of 1.719 Å and the antisymmetric stretching frequency at 1117 cm^{-1}, in good agreement with the predictions from the DFT calculations. Gagliardi *et al.* (2003) also performed a CASPT2/SO calculation to explore the reaction energetics of U inserting to N_2 molecule.

The NThN molecule offers some interesting questions with respect to bonding. Terminal nitride ligands are generally formulated as N^{3-} and thus NUN and NPuN are considered complexes of U(VI) and Pu(VI) that have An≡N triple bonds. Because the maximum oxidation state of Th is +4, the bonds in NThN must be considered double bonds and the nitride ligands in this complex are formally N^{2-}. The calculated bond length for NThN is considerably longer than that in NUN and NPuN, consistent with these expected differences in the bonding.

17.6.5 Matrix-isolated actinide nitride–oxides

The NO^+ ion is another member of the isoelectronic series that includes N_2 and CO. Andrews and coworkers have examined the reactions of laser-ablated U and Th atoms with N_2/O_2 mixtures or NO. They have determined the

vibrational spectra and molecular structures of a series of actinide molecules of formula NAnO and $NAnO^+$ (An = Th, U) and have also performed DFT calculations on some of these species (Kushto *et al*., 1997; Kushto and Andrews, 1999; Zhou and Andrews, 1999). The NUO^+ ion was also observed by Heinemann and Schwarz (1995) in gas-phase ion–molecule reactions. Inasmuch as the NUO^+ molecule is isoelectronic with UO_2^{2+} and CUO, and the NUO molecule is isoelectronic with the UO_2^+ ion, it is not unexpected that both NUO and NUO^+ are predicted to be linear. In contrast, the NThO molecule is bent, with an optimized N–Th–O angle of 127.5°, similar to the OThO and CThO molecules. From Fig. 17.27, the NUO^+ ion is expected to have an electron configuration of $(6\sigma)^2(f\phi)^0(f\delta)^0$. However, because the N 2p orbitals are lower in energy than the C 2p orbitals, the HOMO–LUMO gap of NUO^+ is larger than that of CUO. As a result, a ground-state reversal such as that observed for CUO is unlikely to occur. The NUO molecule has a $^2\Phi$ ground state with the $(6\sigma)^2(f\phi)^1(f\delta)^0$ configuration. The geometric parameters and vibrational frequencies of the actinide nitride–oxides from the DFT calculations reported by Zhou and Andrews (1999) are summarized in Table 17.23. Gagliardi and Roos (2000) also have reported CASPT2 calculations on the geometric structures and vibrational frequencies of NUO and the NUO^+ ion.

In this section, we have summarized the geometric structures, electronic structures, and vibrational frequencies of some of the small molecules and ions that have been detected experimentally via matrix isolation. The combined efforts of low-temperature matrix-isolation experiments with state-of-the-art computational chemistry methods have greatly helped to rationalize and understand the chemistry of these unique actinide species. Further experimental and theoretical studies on these and other actinide species will greatly advance our

understanding of the structure and bonding of actinide complexes. In particular, the presumably innocent noble-gas matrices have been shown to play sometimes significant roles in the geometries, electronic structures, and spectroscopy of actinide compounds. The existence of the noble-gas actinide bonding indicates that the long overlooked role of noble gas atoms will have to be considered in future matrix-isolation experiments and in reinterpreting previous experimental results.

17.7 SPECIATED ACTINIDE IONS

In contrast to the high-valent actinyl series, An(III) and An(IV) ions exist in solution as bare ions (surrounded, of course, with solvent molecules and counter-ions). As with the actinyl ions, the characterization of their behavior in aqueous solution, i.e. their speciation, is of great interest in order to obtain a better understanding of their structures, stabilities, reactivities, and solution chemistry and of their environmental implications.

Recently, a hydration (electrostatic) model to describe monoatomic ions has been developed by David and Vokhmin (2001). They predict experimental An–O distances of 2.56, 2.52, 2.51, 2.51, and 2.44 Å for U^{3+}, Np^{3+}, Pu^{3+}, Am^{3+}, and Cf^{3+}, respectively. Their coordination numbers for the first solvation shell are between 9 and 10 for the first four ions and 8.5 for Cf^{3+}. Blaudeau and coworkers performed DFT (PW91) calculations on the hydrated Pu^{3+} ion and predicted a coordination number of eight or nine in the complex (Blaudeau *et al.*, 1999). Their calculated bond lengths were 2.508 Å for the eight-coordinate complex in which the water molecules form a nearly cubic cage around the plutonium ion with a total symmetry of D_{2d}, and 2.585 Å (axial) and 2.491 Å (equatorial) for a D_{3h} nine-coordinate tricapped trigonal prismatic complex. These values were in good agreement with a subsequent crystal structure determination of $[Pu(H_2O)_9][CF_3SO_3]_3$ (Fig. 17.33), which contains an isolated $Pu(H_2O)_9^{3+}$ ion with Pu–O distances of 2.574 Å (axial) and 2.476 Å (equatorial) (Matonic *et al.*, 2001). Earlier solution EXAFS studies, which are not as definitive concerning coordination number as the X-ray crystallography, had concluded that Pu–O = 2.51 Å and the coordination number was 9 or 10 for Pu^{3+} (Ankudinov *et al.*, 1998; Gropen, 1999).

Yang *et al.* (2001) performed quantum mechanical and molecular dynamics (MD) calculations on the Th^{4+} ion using DFT (B3LYP) methodology and AMBER force fields. In the aqueous phase, calculated using a polarized continuum model (PCM), they found a C_{4v} nine-water capped-square-antiprism complex to be the most stable. Their calculated Th–O bond distance was 2.54 Å. These results compare reasonably well with experimental EXAFS measurements, for which a coordination number of 9–11 and a bond length of 2.45 Å were found (Moll *et al.*, 1999). The MD simulations lead to a well-defined

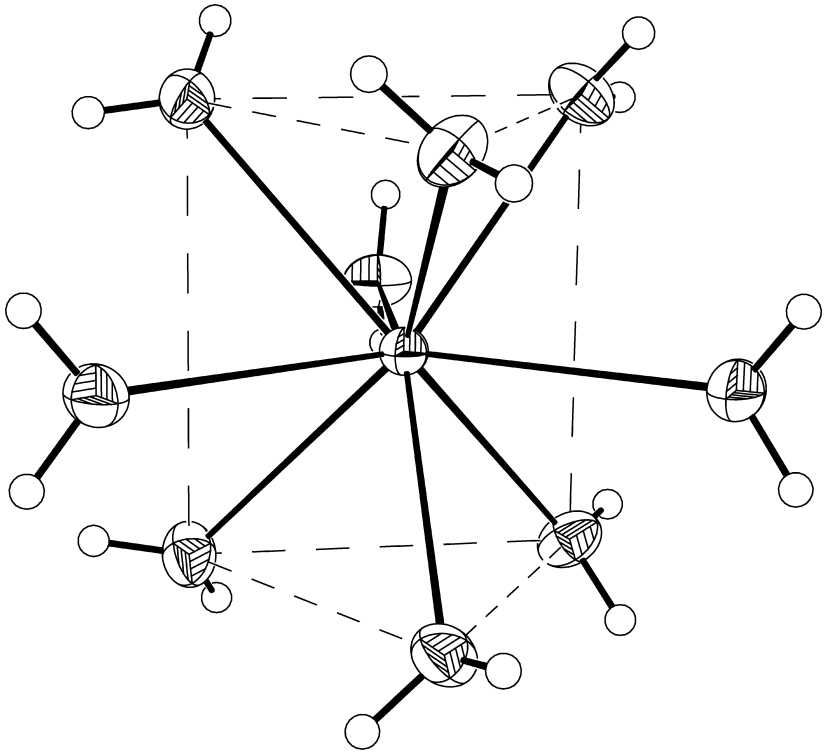

Fig. 17.33 *The structure of the* $[Pu(H_2O)_9]^{3+}$ *ion from the X-ray crystal structure of* $[Pu(H_2O)_9][CF_3SO_3]_3$ (*reproduced from Matonic* et al., 2001).

second shell consisting of 18.9 water molecules at a distance of 4.75 Å from the metal ion. In a further study, Tsushima *et al.* (2003) concluded that incorporation of the second shell in the geometry optimizations improves the Th–O bond distance to 2.50 Å. Mochizuki and Tsushima (2003) performed RECP-based B3LYP calculations with a conductive PCM and found a reduction in the calculated bond length to 2.47 and 2.48 Å. They also performed DIRAC four-component all-electron calculations of the $Ac(H_2O)_n^{3+}$ ($n = 1$, 2, 4, and 6) complexes and the analogous Th^{4+} complexes. They found that the thorium complexes have a shorter metal–oxygen distance, larger stabilization energies, and larger amounts of ligand-to-metal electron donation. Mochizuki and Tatewaki (2002) performed similar calculations on the analogous Cm^{3+} complexes. They found the curium–oxygen bond distance to increase with the number of water molecules in the complex and the stabilization energy per water molecule was reduced. These studies provide important information about the solvation properties of actinides ions. Further theoretical calculations are needed to address the important chemical properties (e.g. charge-transfer or redox chemistry) of actinide ions in solutions.

17.8 UNSUPPORTED METAL–METAL BONDS CONTAINING ACTINIDE ATOMS

The rich manifold of s, p, d, and f orbitals on actinide atoms has led to numerous theoretical explorations on the possibility of forming discrete complexes that contain direct metal–metal bonds involving one or more actinide atoms. As noted earlier, one bonding motif that contains an unsupported (and therefore unambiguous) metal–metal bond involving an actinide atom is the $Cp^*_2(X)Th - RuCp(CO)_2(X = Cl, I)$ system reported by Marks and coworkers in 1985 (Sternal *et al.*, 1985). This system was studied theoretically using quasi-relativistic Xα-SW calculations (Bursten and Novo-Gradac, 1987), which indicated that the $CpRu(CO)_2$ fragment in the molecule is best considered as an 'organometallic pseudohalide' that leads to a very polarized Ru–Th bond characteristic of 'early–late' heterodimetallic complexes (Gade, 2000). The conclusions of this theoretical study were applied in the synthesis of other organometallic complexes that contain unsupported actinide–transition metal bonds, such as the $Cp_3An–MCp(CO)_2$ (An = Th, U; M = Fe, Ru) complexes (Sternal and Marks, 1987). Mass spectrometric evidence has been presented for the formation of cationic complexes that contain direct An–M bonds from the reaction of Th^+ and U^+ with $Fe(CO)_5$ (da Conceicao Vieira *et al.*, 2001). The proposed complexes, $[AnFe(CO)_n]^+$ (An = Th, U) have the potential to lead to more covalent An–Fe bonding because of the lower oxidation state of the actinide centers, but theoretical studies are yet to be done for this structurally uncharacterized system.

Gagliardi (2003) recently exploited the pseudohalide characteristics of Au atoms as ligands to explore the structure and bonding in UAu_4 at the DFT and CASPT2 levels of theory. It is predicted that UAu_4 has a geometry slightly distorted from tetrahedral with U–Au bond lengths of 2.72 Å. The molecule is predicted to have a triplet ground state, analogous to the uranium tetrahalides. The U–Au bond is predicted to be ionic, although a comparison of the atomic populations of UAu_4 with those of other MAu_4 (M = Ti, Zr, Hf, Th) complexes indicates that the U–Au bond should have greater covalency than the other systems. Gagliardi and Pyykkö (2004) extended the analogy between An–main group and An–transition metal bonding to explore the possibility of strong U–M bonding in species such as NUIr, which is electronically similar to NUN. NUIr is predicted to be a closed-shell molecule with a very short U–Ir bond of 2.15 Å at the CASPT2 level with an extended basis. The bond is predicted to be polar, with a partial positive charge on U and partial negative charges on N and Ir, although less so than the other systems mentioned in this section. Similar results were obtained for the neutral isoelectronic molecules FURe, OUOs, and CUPt.

Truly covalent metal–metal bonds involving actinide atoms could be made in principle via direct actinide–actinide bonding in a symmetric discrete complex. To date, there are no well-characterized complexes that contain direct

actinide–actinide bonds; indeed, such systems remain as an experimental 'holy grail' in actinide chemistry. Most of the attention to the bonding and electronic structure of actinide–actinide bonded systems has focused on homonuclear diatomic molecules. March *et al.* have used simple models to predict that homonuclear diatomics of the heavy elements are unlikely to exist (Mucci and March, 1985; Pucci and March, 1986). Contrary to this prediction, the diatomic molecule U_2 has been detected in the gas phase via mass spectrometry (Gorokhov *et al.*, 1974; Gingerich, 1980), and was proposed to have a dissociation enthalpy of 52 ± 5 kcal mol^{-1}. This molecule has been the subject of several theoretical studies. Bursten and Ozin (1984) first examined the electronic structure of U_2 and Np_2 at an assumed bond distance of 2.2 Å using the quasi-relativistic Xα-SW method. They proposed that these molecules could form ϕ bonds via the 'face-to-face' interaction of the An 5fϕ AOs. Pepper and Bursten (1990) later used CASSCF and single-reference CI calculations to explore the bonding in U_2. They found a complex electronic structure for this molecule, including a relatively low-spin short-bond-length (SBL) state, and completely spin-uncoupled long-bond-length (LBL) state. Interestingly, they found the LBL minimum (at ca. 3.0 Å) to be lower in energy than the SBL minimum (at ca. 2.2 Å), although they expressed concerns about the lack of inclusion of spin–orbit effects in their calculations. Archibong and Ray (1999) have used DFT, CISD, and CCSD(T) calculations with RECPs to explore the possible existence of the Pu_2 diatomic molecule. They find that the molecule is bound, but that the Pu 5f electrons are localized, which leads to a rather weak interaction. The predicted Pu–Pu bond length, 4.4–4.5 Å depending on the method, is quite long and the predicted ground state is $^{13}\Sigma_g$ in the absence of spin–orbit effects.

Most recently, Gagliardi and Roos (2005) have reexamined the bonding in the U_2 molecule using CASSCF/CASPT2 methodology that includes spin–orbit effects. They find that the molecule has a very complex electronic structure: six of the 12 valence electrons fully occupy 7sσ and 6dπ bonding orbitals, one electron each occupy the 6dσ and 6dδ orbitals, one electron each occupy the weakly bonding 5fπ and 5fδ orbitals, and the last two electrons are essentially localized in the 5fϕ atomic orbitals on the two U atoms. They therefore describe the bonding in the molecule as having "three strong 'normal' electron-pair bonds, two fully developed one-electron bonds, two weak one-electron bonds, and two localized electrons," leading to the prediction of a net quintuple bond in the molecule. Fig. 17.34 depicts the active MOs of U_2 used to construct this unusual bond, and the occupation number of each from the CASPT2 calculations. With the inclusion of spin–orbit coupling, they predict a U–U bond length of 2.43 Å and a bond dissociation energy of 30.5 kcal mol^{-1}. It is highly unusual that a molecule with a quintuple bond possesses a dissociation energy lower than that of most systems with single bonds, which emphasize the weakness and complexity of the actinide–actinide bonds.

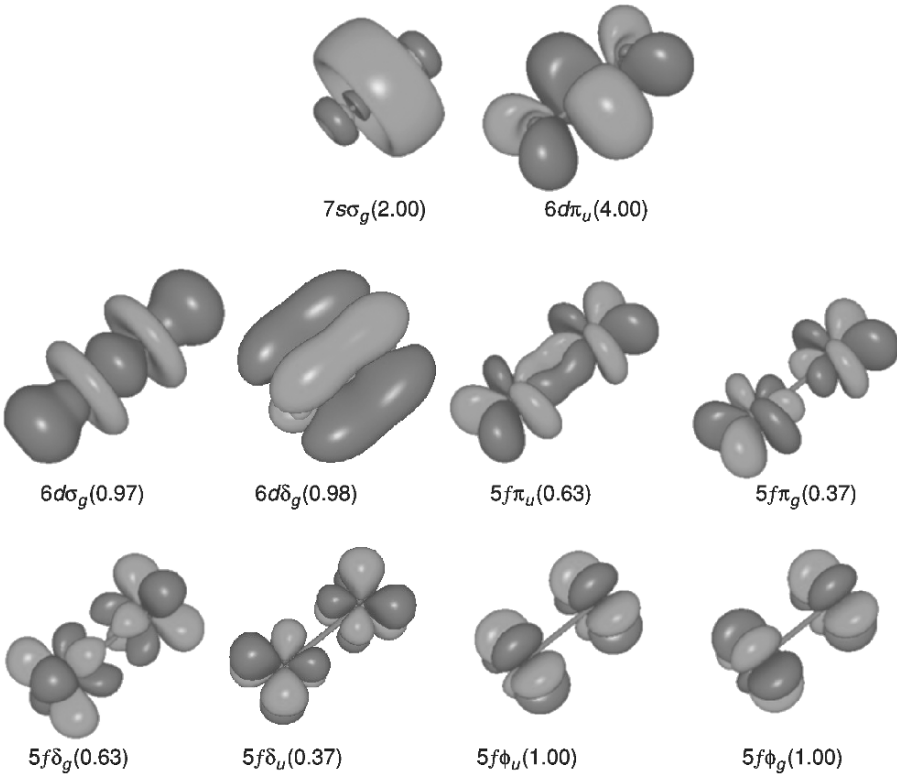

Fig. 17.34 *The active MOs that form the bond in U_2 from CASPT2 calculations. The number in parentheses is the electron occupation of the orbital in the ground state* (*reproduced from Gagliardi and Roos*, 2005).

17.9 CONCLUDING COMMENTS

We hope that this chapter has given the reader a sense of the challenges and complexity of obtaining and describing the electronic structure of discrete actinide-containing systems. As was stated at the outset, the large number of active atomic orbitals on actinide atoms and ions, the necessarily large number of electrons, the need to include relativistic effects, and the generally large coordination numbers all serve to make the electronic structure of molecular actinide complexes appreciably more complicated than that of transition-metal systems (and, perforce, purely organic systems). We have attempted to show the reader how recent advances in computational resources coupled with new theoretical methodologies have led to great progress in the quantitative description of actinide electronic structure. In particular, the growth of density functional methods and new electron correlation techniques during the last

10–15 years has greatly facilitated advances in this field, particularly with respect to the calculation of geometries, vibrational frequencies, and ground state metal–ligand interactions.

In spite of the progress that has been made, there are areas of actinide electronic structure that still require a great deal of development so as to allow computational actinide chemistry to be an even stronger partner to the experimental studies of actinide science. Very recent developments have led to better descriptions of the electronic structure of excited states of actinide systems, to improved treatment of dynamic correlation effects with the inclusion of scalar and spin–orbit relativistic effects, and to more effective combining of quantum mechanics and molecular mechanics methods (QM/MM methods) for the theoretical analysis of very large actinide molecular systems, such as those that are relevant to the interaction of actinide atoms and ions with biomolecules. These new capabilities portend an even greater role that theoretical studies will play in the understanding of experimental observations and the prediction of new properties of actinide systems.

Improved methods and enhanced computational capabilities will enable higher quality calculations of the types of actinide systems discussed in this chapter. They will also allow computational actinide chemists to address the 'next generation' of actinide electronic structure problems, including the interaction of actinide-containing molecules with realistically modeled solvents and surfaces and the complex equilibria exhibited in actinide chemistry (particularly aqueous actinide chemistry). We anticipate that the next decade will be one of continued growth in the scope and utility of theoretical actinide chemistry. Continuing efforts to improve relativistic electronic structural methodologies within DFT and electron correlation techniques, coupled with ever-increasing computational capabilities, will provide new, more powerful electronic structure codes for addressing actinide electronic structure. We expect that more reliable methods will be developed for exploring excited states of actinide systems, including the complex multiplets that are characteristic of the optical spectroscopy of actinide complexes. Improved methods for the calculation of the molecular energetics of actinide complexes could lead to predictive capabilities with thermodynamic accuracy. We are also hopeful that relativistic molecular electronic structure approaches will be improved to the point of allowing for the facile calculation of potential energy surfaces for actinide-containing molecules, including reaction transition states. It will be an exciting time for our field.

LIST OF ABBREVIATIONS

ADF	Amsterdam density functional code
AIMP	*ab initio* model potential
An	Actinide

AO	atomic orbital
ACPF	averaged coupled-pair functional
AQCC	averaged quadratic coupled cluster
B3LYP	Becke's three parameter exchange functional plus the correlation functional of Lee, Yang and Parr
BDF	Beijing density functional code
BLYP	Becke–Lee–Yang–Parr functional
BP86	Becke–Perdew 86 functional
Bz	Benzene
CASPT2	complete active space plus second-order perturbation theory
CASSCF	complete active space self-consistent field
CCSD	coupled cluster with single and double excitations
CCSD(T)	coupled cluster singles, doubles and perturbative triples
Cht	cycloheptatrienyl
CISD	configuration interaction with single and double excitations
COT	cyclooctatetraene
Cp	cyclopentadienyl
Cp*	pentamethylcyclopentadienyl
DFT	density functional theory
DHF	Dirac–Hartree–Fock method
DKH	Douglas–Kroll–Hess hamiltonian
DV-Xα	discrete variational Xα method
ECP	effective core potential
EHMO	extended Hückel molecular orbital
Gaussian	Gaussian computational chemistry code
GGA	generalized gradient approximation
GVB	generalized valence bond
HF	Hartree–Fock
HFS	Hartree–Fock–Slater
HOMO	highest occupied molecular orbital
INDO	intermediate neglect of differential overlap
IR	infrared
LCAO	linear combination of atomic orbitals
LDA	local density approximation
LMCT	ligand-to-metal charge transfer
LUMO	lowest unoccupied molecular orbital
MCSCF	multi-configuration self-consistent field
MLCT	metal-to-ligand charge transfer
MO	molecular orbital
MP2	second-order Møller–Plesset perturbation theory
MRCI	multi-reference configuration interaction
MRCISD	multi-reference configuration interaction with single and double excitations
NESC	normalized elimination of the small components

Ng	noble gas
NWChem	Northwest computational chemistry code
PCM	polarized continuum model
PW91	Perdew–Wang 1991 functional
QR-SW-Xα	quasi-relativistic scattered wave Xα
RASSCF	restrictive active space self-consistent field
RESC	relativistic scheme by eliminating small components
RECP	relativistic effective core potential
REX	relativistic extended Hückel
SCF	self-consistent field
SO	spin–orbit
SOCI	spin–orbit configuration interaction
SO-MRCISD	spin-orbit multi-reference configuration interaction singles and doubles
SW-Xα	scattered-wave Xα method
TD-DFT	time-dependent density functional theory
TMCOT	tetramethylcyclooctatetraene
Tp	tetrapyrrole
ZORA	zeroth-order regular approximation (to the Dirac equation)

ACKNOWLDEGMENTS

NK acknowledges the EPSRC for support of actinide chemistry in the UK. PJH and BEB acknowledge support by the Division of Chemical Sciences, Geosciences, and Biosciences, Office of Basic Energy Sciences, U.S. Department of Energy. PJH also acknowledges support for actinide research by Laboratory Directed Research and Development at Los Alamos National Laboratory under the auspices of the U.S. DOE, and BEB also acknowledges computational support from the Ohio Supercomputer Center. JL acknowledges the computational resources from the Molecular Science Computing Facility and the support from EMSL, a national scientific user facility sponsored by the U.S. DOE, OBER and located at PNNL. The authors thank Dr. Constance Brett for assistance in preparing the manuscript.

CHAPTER EIGHTEEN

OPTICAL SPECTRA AND ELECTRONIC STRUCTURE

Guokui Liu and James V. Beitz

18.1 INTRODUCTION

Much of our knowledge of the electronic properties of actinides in solutions and solids is obtained from optical spectroscopy. One of the features that sets actinide spectra apart from those of other elements in the periodic table, aside from the lanthanide series, is that their f-orbitals can be considered both as containing optically active electrons and as belonging to the core of inner shells. As a result of this dominant characteristic, the spectra of these elements, particularly of the lower valence states, are moderately insensitive to changes in the ionic environment. Although ion–ligand interactions shift and split the energy levels of the f-orbitals, the scale of this crystal-field splitting is generally smaller than the intra-ionic Coulomb interaction and spin–orbit coupling. The relative insensitivity of these f-electrons to external forces also means that for these elements there is a close connection between energy levels in compounds and those in gaseous free atoms and ions. Table 18.1 lists the scales of various mechanisms of electronic interactions that will be discussed in this chapter through analysis and modeling of the optical spectra of the various valence states of actinide ions in solutions and compounds.

Table 18.1 *Energy level scales of actinide ions in crystals.*

Interaction mechanism	*Energy* (cm^{-1})[a]	*Optical probe*
configuration splitting ($5f^N$–$5f^{N-1}6d$)	10^5	visible and UV spectroscopy
splitting within a $5f^N$ configuration		
noncentral electrostatic field	10^4	absorption, fluorescence, and laser excitation spectroscopy
spin–orbit interaction	10^3	
crystal-field interaction	10–10^2	
hyperfine splitting	10^{-3}–10^{-1}	selective and nonlinear laser spectroscopy

[a] 1 eV = 8065.7 cm^{-1}.

For the actinide valence states of most interest to chemists, 1+ through 7+, very few gaseous free-ion spectra have been sufficiently analyzed to provide a basis for guiding theoretical interpretations. From an experimental point of view, optical spectroscopy usually probes energy levels with photon sources in the infrared, visible, and ultraviolet (UV) region with energies below 45 000 cm^{-1}. This situation is responsible for the fact that most of our structural information for the f^N states comes from observation of forced electric dipole absorption and luminescence transitions in optically clear crystals. The latter analysis is much simplified by the fact that only transitions between nominal f^N levels are involved. Electric dipole transitions normally are forbidden by the parity selection rule, but in crystals such as $LaCl_3$ that have no center of symmetry, enough of the character of opposite-parity configurations can be mixed in to induce such transitions. At the same time, the admixture (of the order 0.1%) is small enough for the actinide ions in low-lying states of a $5f^N$ configuration that the f-character of the levels is preserved and level calculations can be made on the assumption of a pure $5f^N$ configuration.

The stability of f-orbitals against changes in the ionic environment results in energy levels of various compounds being closely correlated among themselves as well as with those of the free ion, where known. In consequence, *ab initio* free-ion calculations have proven to be very useful for interpreting spectra of the same ion in a solid, and a parametric model based on these calculations has been developed for systematic analyses of the $4f^N$ (lanthanides) (Crosswhite, 1977; Carnall *et al.*, 1989) and $5f^N$ (actinides) (Carnall, 1992; Liu *et al.*, 1994b) optical spectra. This model can be applied in a consistent way to ions of both the actinide and lanthanide series (Crosswhite and Crosswhite, 1984; Görller-Walrand and Binnemans, 1996; Liu, 2000). The free-ion energy levels for trivalent actinide ions in $5f^N$ ($N = 2$ through 13) configurations may be calculated using the parametric model as shown in Fig. 18.1 by the horizontal lines.

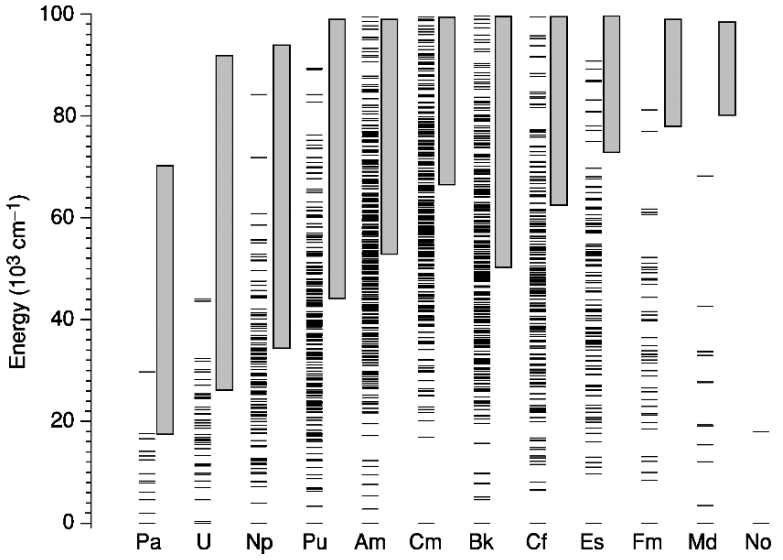

Fig. 18.1 *Calculated free-ion energy levels* (*horizontal lines*) *for the trivalent ions in the* $5f^N$*configurations and the energy range* (*shaded vertical bars*) *for the excited configurations.*

The method of parametric modeling is discussed here to help systematize the overall view of actinide spectra. This chapter is based primarily on Chapter 16 by Carnall and Crosswhite in the second edition of this series. In this review advances in actinide spectroscopy are updated, and in particular, recent progress in the optical spectroscopy of trivalent and tetravalent actinide ions in crystals are included. Our emphasis is on the fundamental understanding of actinide spectra that are interpreted by a parametric model in terms of free-ion and crystal-field interactions (Wybourne, 1965a; Hüfner, 1978; Judd, 1988).

With the experimental techniques used, highly excited states belonging to many different configurations may be produced simultaneously, making interpretation difficult. The estimated energy ranges of the $5f^{N-1}6d$, $5f^{N-1}7s$, and $5f^{N-1}7p$ configurations are plotted in Fig. 18.1 as gray bars for comparison with the calculated energy levels of the free-ion states of the $5f^N$ configurations of trivalent actinide ions (Brewer, 1971a). It is obvious that large portions of the upper states of $5f^N$ configurations overlap with the low-lying states of $5f^{N-1}6d$, $5f^{N-1}7s$, and $5f^{N-1}7p$ configurations. Therefore, a major complicating factor in the theoretical interpretation of $5f^N$ spectra is the extensive inter-configurational mixing, often termed as configurational interaction (Wybourne, 1965a; Dieke, 1968; Goldschmidt, 1978; Hüfner, 1978; Crosswhite and Crosswhite, 1984).

These effects of mixing other configurations into the $5f^N$ states involve not only competing configurations with large overlaps but also cumulative interactions with infinitely many distant electronic configurations. That this is a serious problem is demonstrated by analysis of isotope shifts and hyperfine structure in actinide free-ion spectra (Fred, 1967). The parameters that describe the energy level structure for a configuration would show less variation if the independent-particle model provided a fully accurate description of actinide free-ion spectra. In the parametric model for f-element spectral analysis, the effects of configuration interaction are partially compensated by the use of effective operators in the atomic Hamiltonian for f^N shells (Wybourne, 1965a; Judd, 1966, 1968a,b; Crosswhite *et al.*, 1968; Goldschmidt, 1978; Poon and Newman, 1983; Judd and Crosswhite, 1984; Judd and Suskin, 1984).

Qualitatively, the spectroscopic properties of lanthanides and actinides are very similar because both f-shell electron densities are primarily within already filled s- and p-shells of one higher principal quantum number, which partially shield the f-shells from external influences. A comparison of the Nd^{3+} and U^{3+} analogs is shown in Fig. 18.2, where the squares of the f-electron radial functions are multiplied by an arbitrary factor for emphasis. The same theoretical framework has been used successfully in modeling solid-state spectra of trivalent (Edelstein *et al.*, 1967; Carnall, 1989) and tetravalent actinides (Edelstein, 1987; Krupa, 1987; Liu *et al.*, 1994b; Liu, 2000), as well as for the lanthanide series (Crosswhite, 1977; Carnall *et al.*, 1989; Görller-Walrand and Binnemans, 1996).

Notice that in Fig. 18.2 for U^{3+} (relative to Nd^{3+} $4f^3$) the $5f^3$ peak is considerably displaced toward greater r values with respect to the shielding of s- and p-shells, and the relative magnitude of the 5f electron tail at large r with respect to the rest of the core function is larger and more exposed. Because of the greater extension of the 5f orbitals with respect to those of the shielding 6s and 6p shells, they are more sensitive to changes in the valence electron situation than is the case for the corresponding lanthanide ions. As a result, actinides in solution and in solids, particularly in the first half of the $5f^N$ series, appear in different valence states from 3+ to 6+, making 5f spectroscopy extremely rich and complicated.

18.2 RELATIVE ENERGIES OF ACTINIDE ELECTRONIC CONFIGURATIONS

In order to emphasize the systematic correlations found in the energy level structure of actinide ions both as a function of atomic number Z and for configurations with the same number of f-electrons but different charge states, we begin by considering the types of interactions that have been used successfully to account for observed energy level structures. In the discussion of atomic spectra, attention is focused on identification of the ground (lowest-energy) and

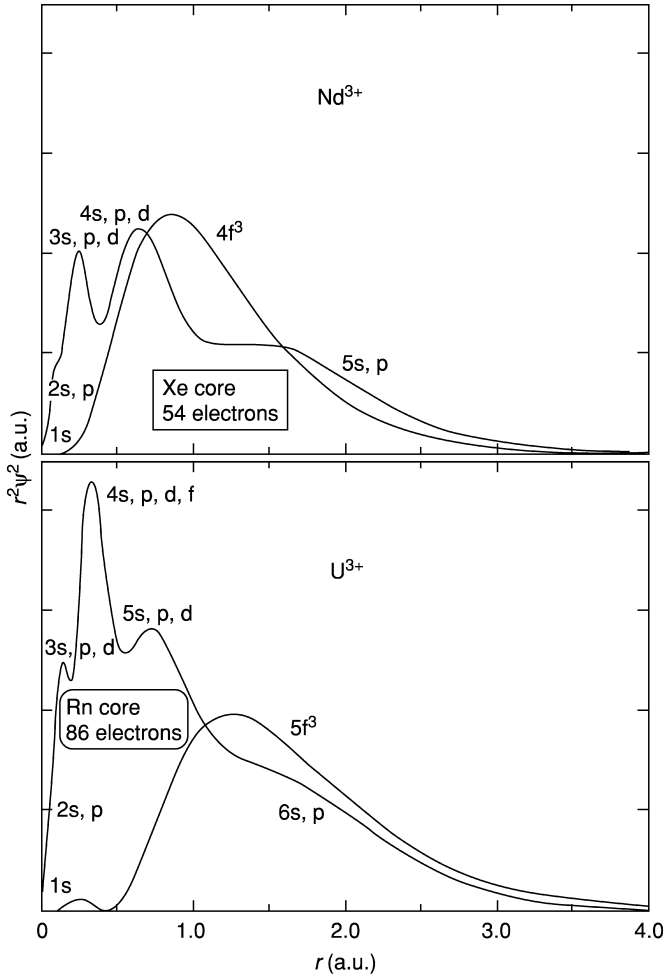

Fig. 18.2 *Comparison of the overlap of* $4f^3$–$5s,p$ *configurations and those of* $5f^3$–$6s,p$ *configurations for* Nd^{3+} *and* U^{3+}, *respectively.*

excited electronic configurations of neutral as well as ionized species. The relative energies of the various electronic configurations thus established provide the basis for extending the interpretation of spectra (and thus electronic structure) to condensed media. In gaseous atomic or ionic species, the energy level structure is attributed primarily to the interactions between electrons in unfilled shells. In condensed media, the additional effect of the ligand field is superimposed. Several summaries of the atomic spectra of the actinides have been published (Kanellakopulos and Fischer, 1973; Peterson, 1976;

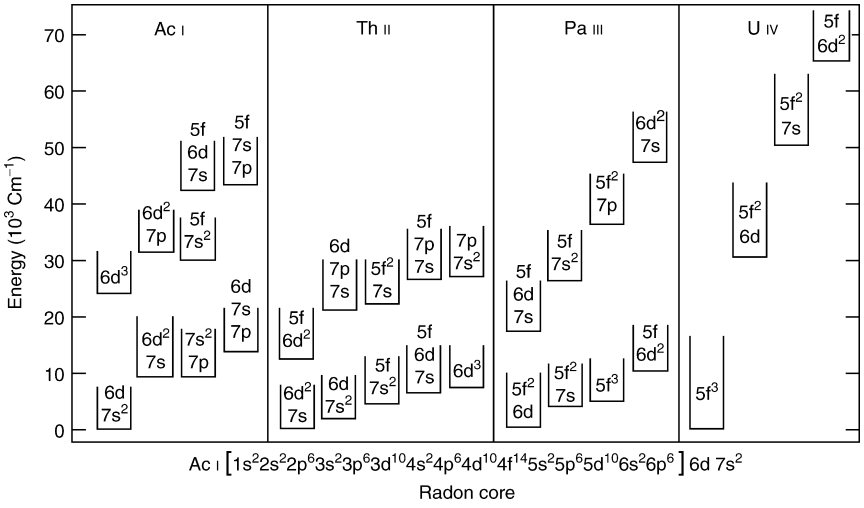

Fig. 18.3 *Three-electron configurations beyond the radon core.*

Crosswhite, 1982; Blaise *et al.*, 1983; Crosswhite and Crosswhite, 1984; Worden *et al.*, 2005).

The progenitor of the actinide (5f) series is actinium. The electronic structure of zero-valent actinium Ac I[1] is represented as three electrons ($6d7s^2$) outside the radon core. This can be written [Rn] ($6d7s^2$), but in the subsequent discussion the core symbol [Rn] will be omitted from the notation. All of the actinide atomic and ionic species are built on the radon core, but the properties of the electronic structure beyond the core depend on the energy with respect to the ground state, atomic number Z, and the state of ionization (Brewer, 1971a,b, 1983). Thus, within the energy range indicated in Fig. 18.3, in addition to configurations involving 6d and 7s electrons, there are those containing 7p and 5f electrons.

Fig. 18.3 is to be interpreted in the following manner. In Ac I the lowest-energy electron states result from the coupling of two 7s electrons and one 6d electron. Further, an energy equivalent to about 9000 cm^{-1} is sufficient to promote a ground-state 7s electron to the 6d shell, thus forming the lowest level of the excited configuration ($6d^27s$). Essentially the same energy is required to promote a ground-state 6d electron to the 7p shell, giving the excited configuration ($7s^27p$). Only the lowest-energy state (relative to the ground state) for each configuration is indicated in the figure. In most cases large numbers of excited states exist within each of the configurations, so that the density of levels from overlapping configurations increases appreciably with

[1] In atomic spectroscopy, Roman letters I, II, III, IV,...refer to ionic oxidation states 0, 1+, 2+, 3+,... respectively, while in some chemistry literature, notations such as An(I) refers to An^+.

excitation energy. However, since the coupling of two 7s electrons result in a filled subshell, the ground configuration in Ac I ($6d7s^2$) is simple in structure, involving only the states of a single 6d electron, $^2D_{3/2}$ and $^2D_{5/2}$. Such states, written in terms of the quantum numbers S, L, and J, are subsequently referred to as free-ion states.

In Th II, the ground state belongs to $6d^27s$, but as Fig. 18.3 indicates, the spectrum at lower energies is very complex due to a number of electronic configurations with nearly the same energy relative to the ground state. In Pa III, the three electrons beyond the Rn core in the ground state belong to the $5f^26d$ configuration. In U IV, further stabilization of the 5f orbital has taken place and excited configurations occur at much higher energies relative to the ground state than was the case in Pa III, Th II, and Ac I. Thus in U IV, the only electronic transitions observed in absorption in the range up to ~30 000 cm^{-1} are those *within* the $5f^3$ configuration.

Experimentally, free-ion spectra (for both neutral and ionic species) usually have been observed in emission, and the underlying energy level structures are deduced from coincidences of energy differences of pairs of spectral lines, subject to verification by isotope shift, hyperfine structure, and magnetic g-factor tests. In condensed phases, spectra are more commonly measured in absorption. Since the application of tunable lasers, laser-induced fluorescence spectra and excitation spectra also have been used in condensed phases to probe energy levels of actinide ions that possess a metastable emitting state. Relative intensities associated with 'parity-allowed' and 'forbidden' transitions are reflected in the nature of two processes: transitions in which the initial and final states belong to electronic configurations of different parity (parity-allowed transitions, e.g. $5f^3 \rightarrow 5f^26d$) and those in which both states belong to the same configuration (parity-forbidden transitions, e.g. $5f^3 \rightarrow 5f^3$). The latter are weak and sharp. The former are much more intense and are associated with broader absorption bands.

The primary purpose of this chapter is to elucidate the electronic energy level structure of the $5f^N$ configurations of actinide ions in condensed phases. The energy levels of trivalent and tetravalent actinide ions in $5f^N$ configurations spread up to ~100 000 cm^{-1} for $4 \leq N \geq 10$, and even extend higher than 150 000 cm^{-1} for $N = 6, 7, 8$. However, as shown in Fig. 18.3, the energy levels of the excited state configurations, specifically, $5f^{N-1}6d$, $5f^{N-1}7s$, and $5f^{N-1}7p$ are present below 100 000 cm^{-1} and thus overlap the energy levels of the $5f^N$ states. This overlap induces complexity in modeling the energy level structures, since the commonly used theory treats the inter-configurational coupling as a perturbation, an approximation that is valid only when the respective configurations are well separated. In this section, a systematic comparison of the energies between the ground states of $5f^N$ configurations and the higher-lying energy configurations that are accessible via optical excitation is given. The energy required to promote an electron from a 5f to a 6d orbital varies rapidly in an irregular manner as the nuclear charge is increased, but a large portion of the

variation and most of the irregularity can be attributed to the pairing energy within the $5f^N$ configuration (Jørgensen, 1975, 1980). A method of using thermodynamic and spectroscopic data for calculating energies of various electronic configurations of lanthanide and actinide ions was developed by Brewer (1971a,b).

For the case of electrons in a 6d orbital, ion–lattice coupling is much stronger than for a 5f orbital. As a result, the energy levels of the $5f^{N-1}6d$ configuration exhibits much stronger host dependence than that of the $5f^N$ configurations. Systematic variation of the $5f^{N-1}6d$ energy level structures for trivalent lanthanide ions in CaF_2 was measured in ultraviolet absorption spectra (Loh, 1966). (van Peterson *et al.*, 2002) conducted further experimental measurements and theoretical modeling of the inter-configuration $4f^N$ to $4f^{N-1}5d$ transitions of rare earth (RE) ions in $LiYF_4$ and YPO_4. For actinide ions, extensive studies of $5f^N$ to $5f^{N-1}6d$ transitions are limited to the $5f^1$ and $5f^2$ configurations. The 6d states of Pa^{4+} in several crystalline hosts were measured based on observed 5f−6d electronic transitions (Piehler *et al.*, 1991; Edelstein *et al.*, 1992). The lowest-energy level of the 6d state is only $\sim$20 000 cm^{-1} above the ground state of Pa^{4+}. In the series of $5f^1$ ions, the differences between the lowest 6d energy level and the ground $5f^1$ level for U^{5+} and Np^{6+} increase as do the total splittings of the 5f energy levels with atomic number (Carnall and Crosswhite, 1985).

18.3 MODELING OF FREE-ION INTERACTIONS

The well-developed theoretical framework for modeling the electronic interactions and analyzing the optical spectra of lanthanide ions has been adopted to modeling the actinides because of the similarities in the electronic properties of actinides in the $5f^N$ configurations and the lanthanides in the $4f^N$ configurations (Crosswhite, 1977; Edelstein, 1979, 1995; Carnall and Crosswhite, 1985; Carnall *et al.*, 1991; Liu *et al.*, 1994b; Liu, 2000). In this section a brief review of the free-ion part of the model theory and its applications to actinide spectroscopy is given.

18.3.1 Central field approximation

Interpretation of optical spectra of actinides in condensed phases follows the general approach in atomic spectroscopy that utilizes the central field approximation and Hartree–Fock method (Hartree, 1957; Slater, 1960; Weissbluth, 1978). In the central field approximation, each electron is assumed to move independently in the field of the nucleus and a central field made up of the spherically averaged potential fields of each of the other electrons. The non-spherical part of the electronic interactions is treated as a perturbation to a spherically symmetric potential, so that the basis of the hydrogen atom wave functions can be used to construct the eigenstates of an N-electron atom (ion). The same method has been used to classify electronic states and evaluate energy levels of lanthanide and actinide ions (Judd, 1963b; Wybourne, 1965a).

The primary terms of the Hamiltonian for an N-electron ion in the absence of external fields are commonly expressed as

$$\mathscr{H} = \mathscr{H}_0 + \mathscr{H}_{\mathrm{C}} + \mathscr{H}_{\mathrm{S-O}}, \tag{18.1}$$

where

$$\mathscr{H}_0 = -\sum_{i=1}^{N} \frac{\hbar^2}{2m} \boldsymbol{\nabla}_i^2 - \sum_{i=1}^{N} \frac{Ze^2}{r_i}, \tag{18.2}$$

$$\mathscr{H}_{\mathrm{C}} = \sum_{i<j}^{N} \frac{e^2}{r_{ij}}, \tag{18.3}$$

$$\mathscr{H}_{\mathrm{S-O}} = \sum_{i}^{N} \xi(r_i) \boldsymbol{l}_i \cdot \boldsymbol{s}_i. \tag{18.4}$$

In equation (18.2), the first term is the kinetic energy and the second term is the potential energy of the electrons in the field of the nucleus. All levels that belong to a particular configuration are shifted equally by this term, which is purely radial, without affecting the energy level structure of the configuration. The term $\mathscr{H}_{\mathrm{C}}$ in equation (18.3) represents the inter-electron Coulombic repulsion between a pair of electrons at a distance of r_{ij}, which varies for different states of the same configuration. The term $\mathscr{H}_{\mathrm{S-O}}$ describes the spin–orbit interactions, which can be understood as magnetic dipole–dipole interactions between the spin and angular momenta of the electrons. In equation (18.4), the spin–orbit coupling constant $\xi(r_i)$ is defined as solely a function of r_i.

Exact solutions of Schrödinger's equation are not possible for systems with more than one electron. In the framework of the central field approximation, one assumes that it is possible to construct a potential energy function $U(r_i)$, which is a spherically symmetric, one-electron operator, and is a good approximation to the actual potential energy of the electron i in the field of the nucleus and the other $N-1$ electrons. Therefore, $\mathscr{H}_0$ can be replaced by (Weissbluth, 1978)

$$\mathscr{H}_0' = \sum_{i=1}^{N} \left[-\frac{\hbar^2}{2m} f \boldsymbol{\nabla}_i^2 + U(r_i) \right], \tag{18.5}$$

with

$$\sum_{i=1}^{N} U(r_i) = -\sum_{i=1}^{N} \frac{Ze^2}{r_i} + \left\langle \sum_{i<j}^{N} \frac{e^2}{r_{ij}} \right\rangle. \tag{18.6}$$

The second term in equation (18.6) is an average over a sphere of the electron repulsion. This term is therefore independent of the angular coordinates. Since $\mathscr{H}_0'$ contains the kinetic energy, the potential energy of N-electrons, and most of the inter-electron repulsion, it is called the Hamiltonian of the central

field. Since most of the inter-electron repulsion is included in the central field Hamiltonian equation (18.5), the second term in equation (18.1) can be rewritten as

$$\mathscr{H}'_{\mathrm{c}} = \sum_{i<j}^{N} \frac{e^2}{r_{ij}} - \left\langle \sum_{i<j}^{N} \frac{e^2}{r_{ij}} \right\rangle, \tag{18.7}$$

which is small enough to be treated, along with the spin–orbit Hamiltonian (equation (18.4)), as a perturbation to the central field potential.

The eigenfunctions of $\mathscr{H}'_0$ for a N-electron ion are obtained as a linear combination of one-electron wave functions that satisfy the Pauli exclusion principle and are subject to the orthonormality condition. This method, known as the Hartree–Fock approach, is generally used for seeking an approximate solution to the N-electron Schrödinger equation (Hartree, 1957; Weissbluth, 1978). All effects of noncentral field interactions including spin–orbit coupling and many-body collective electronic interactions are considered by introducing additional effective operators and diagonalizing the Hamiltonian with parameters determined in comparison with experiments.

In the Hartree–Fock method, the wave function of each electron is expressed as a product of radial functions and angular functions of the spherical harmonics multiplied by a spin function

$$\Psi_{nlm_{\mathrm{l}}m_{\mathrm{s}}}(\mathbf{r}, m_s) = \frac{1}{r} R_{n\mathrm{l}}(r)\, Y_{lm_{\mathrm{l}}}(\theta, \varphi)\sigma(m_{\mathrm{s}}), \tag{18.8}$$

where the radial function $R_{nl}(r)$ depends on the central field potential, which determines the radial charge distribution functions such as that plotted in Fig. 18.2 for U^{3+}. The spherical harmonic function $Y_{lm_{\mathrm{l}}}(\theta, \varphi)$ in equation (18.8) is characterized by the four conventional quantum numbers n, l, m_{l}, and m_{s}, which define a unique state of an electron in an atom. For electrons in a $5f^N$ configuration,

$$\begin{aligned} &n = 5, \\ &l = 3, m_{\mathrm{l}} = -l, -l, +1, ..., l, \\ &m_{\mathrm{s}} = \frac{1}{2} \end{aligned} \tag{18.9}$$

The central field wave function for N-electrons thus may be written in the form of a determinant as

$$\Psi(\lambda_1, \lambda_2, ..., \lambda_N) = \frac{1}{\sqrt{N!}} \begin{vmatrix} \Psi_1(\lambda_1) & \Psi_2(\lambda_1) & \cdots & \Psi_N(\lambda_1) \\ \Psi_1(\lambda_2) & \Psi_2(\lambda_2) & \cdots & \Psi_N(\lambda_2) \\ \vdots & & & \\ \Psi_1(\lambda_N) & \Psi_2(\lambda_N) & \cdots & \Psi_N(\lambda_N) \end{vmatrix}, \tag{18.10}$$

in which $\Psi_i(\lambda_j)$ are spin orbital wave functions in the form of equation (18.8). The subscript i identifies a particular choice of the four quantum numbers n, l,

m_l, and m_s, where λ_j represents the space and spin coordinates of the jth electron. The primary purpose of the central field approximation is to use the N-electron wave functions defined by equation (18.10) as the basis functions for the perturbation terms of a Hamiltonian that includes inter-electron Coulomb (18.3) and spin–orbit interactions (18.4).

18.3.2 *LS* coupling and intermediate coupling

To construct wave functions for a multielectron atom on the basis of the central field approximation, one needs to choose a coupling scheme for angular momentum summation to determine the wave functions of the N-independent electrons defined by equation (18.10). There are two coupling schemes that are commonly used for two extreme cases in atomic spectroscopy (Judd, 1963b; Cowan, 1981). In lighter atoms, where spin–orbit interactions (equation (18.4)) tend to be small compared with the electrostatic interactions between electrons (equation (18.3)), the so-called Russell–Saunders coupling scheme, or LS coupling scheme is a good choice, since L and S are approximately good quantum numbers. With increasing Z, electrostatic interactions decrease and spin–orbit interactions become more important, and in the heavier atoms, spin–orbit interactions become much stronger than the Coulomb interactions. Thus, one should consider the j–j coupling scheme. For f-elements, the Coulomb electrostatic interactions and spin–orbit interactions have the same order of magnitude. Therefore, neither coupling scheme is really appropriate. Calculations of energy levels of actinide ions involve a mathematically more complicated scheme that is called intermediate coupling, which is usually developed from the LS scheme.

In the LS coupling scheme, orbital momentum (l) and spin momentum (s) of individual electrons are summed separately (Weissbluth, 1978; Cowan, 1981). Thus

$$\boldsymbol{L} = \sum_{i=1}^{N} \boldsymbol{l}_i, \quad \boldsymbol{S} = \sum_{i=1}^{N} \boldsymbol{s}_i, \tag{18.11}$$

where $\boldsymbol{L}$ and $\boldsymbol{S}$ are the total orbital and total spin momentum operators, respectively. $\boldsymbol{J}$ defined as

$$\boldsymbol{J} = \boldsymbol{L} + \boldsymbol{S}, \tag{18.12}$$

is the total angular momentum operator which has $2J+1$ eigenstates represented by the magnetic quantum number $M = -J, -J+1, \ldots, J$.

In the LS coupling scheme, the electronic states of an actinide ion may be specified completely by writing the basis states as

$$\Psi = |nl\tau LSJM\rangle, \tag{18.13}$$

where nl, which is 5f or 6d for actinide ions, represents the radial part of the basis states. Usually, the symbol ${}^{2S+1}L_J$ is used to label a free-ion state that is

called a multiplet. Whereas S and J are specified with numbers $(0, \frac{1}{2}, 1, ...)$, L is traditionally specified with letters S, P, D, F, G, H, ... respectively, for $L = 0$, 1, 2, 3, 4, 5, ... Table 18.2 lists the electronic configurations and ground states identified by $^{2S+1}L_J$ for divalent, trivalent, and tetravalent ions in the actinide series. All tetravalent ions (An^{4+}) have the lowest spectroscopic energies in $5f^N$ configurations, however, this is not true for the lighter divalent ions. For Th^{3+}, the ground state in known compounds is $6d^1$, $^2D_{3/2}$ instead of the calculated $5f^1$, $^2F_{5/2}$ (Brewer, 1971a,b).

An additional quantum number τ, the seniority number, is needed for distinguishing the states that have the same L and S quantum numbers. In fact, two more quantum numbers are needed to completely define the states of an f^N configuration. One such classification number is $W = (w_1w_2w_3)$, with three integers for characterizing the irreducible representations of the seven-dimensional rotational group R_7. The other classification number is $U = (u_1u_2)$ for characterizing the irreducible representations of the group G_2. Details as to classification of the f^N states are given by Judd (1963b) and Wybourne (1965a). Table 18.3 lists the classification of the states for the f^N configurations with $N \leq 7$. Columns 5 and 11 list the LS terms with the same S, and columns 6 and 12 list the number of $^{2S+1}L_J$ multiplets in the classification. The LS terms of the $5f^{14-N}$ configuration are identical for those of the $5f^N$ configuration ($N \leq 7$), although the seniority of the states is different.

Inclusion of spin–orbit coupling breaks the symmetry of the LS coupling scheme. In this case,

$$\begin{aligned} \left[\mathscr{H}_{\text{S–O}}, \boldsymbol{L}\right] \neq 0, \left[\mathscr{H}_{\text{S–O}}, \boldsymbol{S}\right] \neq 0, \\ \left[\mathscr{H}_{\text{S–O}}, J^2\right] = \left[\mathscr{H}_{\text{S–O}}, J_Z\right] = 0, \end{aligned} \tag{18.14}$$

Table 18.3 *Classification of the free-ion states of the f^N configurations* (*Wybourne,* 1965a).

namely, J^2 and M still commute, but $\boldsymbol{L}$ and $\boldsymbol{S}$ do not. Thus L and S are no longer good quantum numbers, but J and M are still good; therefore, the wave functions $|nl\tau LSJM\rangle$ are not eigenfunctions of the Hamiltonian shown in equation (18.1). One may obtain a new set of eigenfunctions by diagonalizing the primary terms of the Hamiltonian defined by equations (18.4) and (18.7) with the basis set in terms of $|nl\tau LSJM\rangle$ based on perturbation theory and the concept of the central field approximation. As a result, the new eigenfunctions are linear combinations of the LS basis sets, and are known as the free-ion wave functions in the intermediate coupling scheme. If we do not include inter-configurational coupling, the eigenfunctions in the intermediate coupling scheme are expressed as

$$\Psi(nlJ) = \sum_{\tau LS} a_{\tau LSJ} |nl\tau LSJ\rangle, \tag{18.15}$$

where the coefficients $a_{\tau LSJ}$ are determined by the matrix elements

$$a_{\tau LSJ} = \sum_{\tau' L' S'} \langle nl\tau LSJ| \mathscr{H}_{\mathrm{C}} + \mathscr{H}_{\mathrm{S-O}} |nl\tau' L' S' J'\rangle \delta_{JJ'}. \tag{18.16}$$

The energy levels of the free-ion states are independent of M, so they are $(2J+1)$-fold degenerate. The new basis set (equation (18.15)) in the intermediate coupling scheme describes the energy states of a Hamiltonian that includes Coulomb and spin–orbit interactions and is obtained from the mixing of all LS terms with the same J in a given $5f^N$ configuration. The transformation coefficients of $a_{\tau SLJ}$ are the components of the eigenvector pertaining to the basis state in the LS coupling (Judd, 1963b).

18.3.3 Effective-operator Hamiltonian

In spectroscopy, a powerful method for evaluating atomic energy level structure is to define and diagonalize an effective-operator Hamiltonian with the wave functions of the central field Hamiltonian. Racah (1949) used this method for

calculating the matrix elements of tensor operators of the electronic angular momentum (Racah, 1949). Since then, many developments have been made, particularly for applications of the effective-operator method to rare earth spectroscopy (Judd, 1963b; Wybourne, 1965a). An essential part of the effective-operator method is to determine the matrix elements of irreducible tensor operators using the Wigner–Eckart theorem. According to the Wigner–Eckart theorem, for a tensor operator $\mathbf{T}^{(k)}$ of rank k with $2k+1$ components $T_q^{(k)}(q = -k, -k+1, \ldots, k)$ that acts on a set of basis functions $|\tau LSJM\rangle$, each of which is an eigenfunction of the operators J^2 and J_z, the matrix elements of $T_q^{(k)}$ can be reduced as

$$\left\langle \tau LSJM \middle| T_q^{(k)} \middle| \tau' L' S' J' M' \right\rangle = (-1)^{J-M} \begin{bmatrix} J & k & J' \\ -M & q & M' \end{bmatrix} \left\langle \tau LSJ \middle\| \mathbf{T}^{(k)} \middle\| \tau' L' S' J' \right\rangle, \tag{18.17}$$

where the $3-j$ symbols involve only geometrical properties of the tensor operator (Rotenberg *et al.*, 1959). The physical nature of the operator is contained entirely in the reduced matrix elements $\left\langle \tau LSJ \middle\| T^{(k)} \middle\| \tau' L' S' J' \right\rangle$. Information on the use of tensor operators in atomic spectroscopy is provided in several textbooks (Judd, 1963b, 1975; Weissbluth, 1978).

In central field approximation, the orbital electronic wave functions of an actinide ion are represented by products of radial and angular parts as shown in equation (18.8). The effective operator for Coulomb electrostatic intra-ion interaction may be expressed by expanding $1/r_{ij}$ into scalar products of tensor operators of spherical harmonics. Therefore, for N-equivalent electrons in orbital nl, the matrix elements of the effective-operator Hamiltonian for the Coulomb electrostatic interaction may be expressed as:

$$\left\langle l^N \tau LS \middle| \sum_{i>j}^{N} \frac{e^2}{r_{ij}} \middle| l^N \tau' \; L' S' \right\rangle = \sum_k f_k(l,l) F^{(k)}(nl, nl), \tag{18.18}$$

where $F^k(nl, nl)$, with $k = 0, 2, 4, 6$, are the Slater radial integrals for the radial part of the electrostatic interaction, which is defined as:

$$F^k(nl, nl) = e^2 \int_0^\infty \int_0^\infty \frac{r_<^k}{r_>^{k+1}} [R_{nl}(r_i)]^2 \left[R_{nl}\left(r_j\right)\right]^2 \mathrm{d}r_i \mathrm{d}r_j \tag{18.19}$$

The value of F^k may be calculated using the Hartree–Fock method, but in analyses of actinide-ion spectra, F^k is considered as an experimentally determined parameter.

The angular part of the matrix element in equation (18.18) is defined as

$$f_k(l,l) = \left\langle l^N \tau LS \middle| \sum_{i>j} \mathbf{C}^{(k)}(i) \cdot \mathbf{C}^{(k)}(j) \middle| l^N \tau' L' S' \right\rangle. \tag{18.20}$$

Using the Wigner–Eckart theorem, the matrix elements in equation (18.20) are best handled by introducing the tensor operator $\mathbf{U}^{(k)}$. In combination with the symmetry properties of angular momentum, f_k can be expressed in terms of the reduced matrix elements of $\mathbf{U}^{(k)}$ as:

$$f_k(l,l) = \frac{1}{2}(2l+1)^2 \begin{pmatrix} l & k & l \\ 0 & 0 & 0 \end{pmatrix}^2 \left\{ \frac{1}{2L+1} \sum_{\tau' L'} \left| \left\langle l^N \tau L S \middle\| \mathbf{U}^{(k)} \middle\| l^N \tau' L' S \right\rangle \right|^2 - \frac{N}{2l+1} \right\}. \tag{18.21}$$

In the particular case of $k = 0$, it is easy to find that

$$f_0(l,l) = N(N-1)/2. \tag{18.22}$$

For the d^N and f^N configurations, the values for the reduced matrix elements of tensor operator $\mathbf{U}^{(k)}$ have been tabulated (Nielson and Koster, 1963). Because of the symmetry properties of the $3-j$ symbol, $f_k(l,l)$ has nonzero values only if $l+l \geq k \geq |l-l|$; and k is even. For f-electrons, $l = 3$, thus f_k vanishes except for $k = 0, 2, 4, 6$.

As defined in equation (18.4), the Hamiltonian for spin–orbit coupling for N-electrons in an actinide ion is a linear summation of the independent spin–orbit interaction for a single electron. In LS coupling, the N-equivalent electronic matrix element of the spin–orbit interaction is expressible in terms of the tensor operator $\mathbf{V}^{(11)}$. Hence the matrix element of spin–orbit interaction for N-equivalent electrons can be expressed as

$$\left\langle nl^N \tau L S J \middle| \sum_{i=1}^{N} \xi(r_i) \boldsymbol{l}_i \cdot \boldsymbol{s}_i \middle| nl^N \tau' L' S' J' \right\rangle = \zeta_{nl} A_{nl}(ls), \tag{18.23}$$

where ζ_{nl} is the spin–orbit interaction parameter defined as a radial integral

$$\zeta_{nl} = \int_0^\infty [R_{nl}(r)]^2 \xi(r) \mathrm{d}r. \tag{18.24}$$

where $R_{nl}(r)$ is the radial wave function.

The spin–orbit parameter can be evaluated numerically using the Hartree–Fock central field potential, but it is usually adjusted to obtain the experimentally observed energies. The matrix element in equation (18.23) can be expressed as (Sobelman, 1972)

$$A_{nl}(ls) = (-1)^{L+S'+J} \sqrt{(2l+1)(l+1)l} \delta_{JJ'} \delta_{MM'} \begin{Bmatrix} L & S & J \\ S' & L' & 1 \end{Bmatrix} \left\langle \tau L S \middle\| \mathbf{V}^{(11)} \middle\| \tau' L' S' \right\rangle, \tag{18.25}$$

where $\{\ldots\}$ is a $6-j$ symbol, and the values for the reduced matrix elements of the tensor operators $\mathbf{V}^{(11)}$ have been tabulated by Slater (1960), Sobelman (1972), and Nielson and Koster (1963).

The electrostatic and spin–orbit interactions usually give the right order for the energy level splitting of the f^N configurations. However, these primary terms of the free-ion Hamiltonian do not accurately reproduce the experimentally measured energy level structures. The reason is the parameters F^k and ζ_{nf}, which are associated with interactions within a f^N configuration, cannot absorb all the effects of additional mechanisms such as relativistic effects and configuration interactions. Introduction of new terms in the effective-operator Hamiltonian is required to better interpret the experimental data. It was demonstrated (Judd and Crosswhite, 1984) that, in fitting the experimental free-ion energy levels of Pr^{3+} (f^2 configuration), the standard deviation between observed and calculated f-state energies could be reduced from 733 to 24 cm^{-1} by adding nine more parameterized effective operators into the Hamiltonian.

Among several corrective terms included in the effective-operator Hamiltonian, a significant contribution to the f^N energy level structure is from configuration interactions between configurations of the same parity. This contribution can be taken into account by a set of three two-electron operators (Wybourne, 1965a):

$$\mathscr{H}_{c1} = \alpha L(L+1) + \beta G(G_2) + \gamma G(R_7) \tag{18.26}$$

where α, β, and γ are the parameters associated with the continuous groups $G(G_2)$ and $G(R_7)$ (Rajnak and Wybourne, 1963, 1964) the latter being eigenvalues of Casimir operators for the groups G_2 and R_7 (Judd, 1963a).

For f^N configurations of $N \geq 3$, three-body interaction terms were introduced by Judd (1966) and Crosswhite *et al.* (1968) as

$$\mathscr{H}_{c2} = \sum_{i=2,3,4,6,7,8} T^i t_i \tag{18.27}$$

where T^i are parameters associated with three-particle operators t^i. This set of effective operators scaled with respect to the total spin $\boldsymbol{S}$ and total orbital angular momentum $\boldsymbol{L}$ are needed in the Hamiltonian to represent the coupling of the f^N states to those in the higher energy configurations (d, p, s) via inter-electron Coulombic interactions. It is common to include six three-electron operators $t^i (i = 2, 3, 4, 6, 7, 8)$. When perturbation theory is carried beyond the second order, an additional eight three-electron operators t^i ($11 \leq i \leq 19$, with $i = 13$ excluded) are required (Judd and Lo, 1996). A complete table of matrix elements of the 14 three-electron operators for the f-shell have been published (Hansen *et al.*, 1996).

In addition to the magnetic spin–orbit interaction parameterized by ζ_{nf}, relativistic effects including spin–spin and spin–other–orbit, both being

parameterized by the Marvin integrals M^0, M^2, and M^4 (Marvin, 1947), are included as the third corrective term of the effective-operator Hamiltonian (Judd *et al.*, 1968).

$$\mathscr{H}_{c3} = \sum_{i=0,2,4} M^i m_i, \tag{18.28}$$

where m_i is the effective operator and M^i is the radial parameter associated with m_i.

As demonstrated (Judd *et al.*, 1968; Carnall *et al.*, 1983), for improving the parametric fitting of the f-element spectra, two-body effective operators can be introduced to account for configuration interaction through electrostatically correlated magnetic interactions. This effect can be characterized by introducing three more effective operators as

$$\mathscr{H}_{c4} = \sum_{i=2,4,6} P^i p_i, \tag{18.29}$$

where p_i is the operator and P^i is the radial parameter.

In summary, 20 effective operators are utilized for fitting spectra, including those for two- and three-electron interactions. The total effective-operator Hamiltonian for free-ion interactions is

$$\begin{aligned}\mathscr{H}_{FI} = &\sum_{k=0,2,4,6} F^k f_k + \zeta_{nl} A_{nl} + \alpha L(L+1) + \beta G(G_2) + \gamma G(R_7) \\ &+ \sum_{i=2,3,4,6,7,8} T^i t_i + \sum_{i=0,2,4} M^i m_i + \sum_{i=2,4,6} p_i P^i.\end{aligned} \tag{18.30}$$

This effective-operator Hamiltonian has been used as the most comprehensive free-ion Hamiltonian in previous spectroscopic analyses of f-element ions in solids (Crosswhite, 1977; Crosswhite and Crosswhite, 1984; Carnall *et al.*, 1989; Liu, 2000). The 20 parameters associated with the free-ion operators are adjusted in the fitting of experimental energy levels.

18.3.4 Reduced matrices and free-ion state representation

In equation (18.30), all effective operators for the free-ion interactions have well-defined group-theoretical properties (Judd, 1963b; Wybourne, 1965a). Within the intermediate coupling scheme, all matrix elements can be reduced, using the Wigner–Eckart theorem, to new forms that are independent of J, viz.

$$\langle \tau SLJ | \mathscr{H}_i | \tau' S' L' J' \rangle = P_i \delta_{JJ'} c(SLS'L'J) \langle \tau SL \| O_i \| \tau' S' L' \rangle, \tag{18.31}$$

where P_i is the parameter, $c(SLS'L'J)$ is a numerical coefficient, and $\langle \tau SL \| O_i \| \tau' S' L' \rangle$ is the reduced matrix element of the effective-operator O_i. Once the reduced matrix elements are calculated, it is not difficult to diagonalize the entire free-ion Hamiltonian with the wave functions in the LS basis set. The free-ion eigenfunctions are thus obtained in the form of the intermediate

coupling representation. All matrix elements of the effective-operator Hamiltonian are evaluated in terms of the parameters of the effective operators.

Because the reduced matrix elements are independent of J, the matrix of the free-ion Hamiltonian thus can be reduced into a maximum of 13 independent submatrices for $J = 0, 1, 2, \ldots, 12$ for even N and $J = \frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \ldots, \frac{25}{2}$ *for odd N* in an f^N configuration. The number of submatrices and their size can be determined from the values of N_J (the number of J levels for a given SL multiplet) given in Table 18.3. Separation of the free-ion matrix into submatrices greatly facilitates the evaluation of free-ion energy levels. However, evaluation of matrix elements is still a considerable effort, particularly with inclusion of the corrective terms in the Hamiltonian. For an f^N configuration with $3 < N < 11$, there are more than 10^4 free-ion matrix elements and each of them may have as many as 20 terms to be evaluated on the basis of angular momentum operations. Fortunately, several groups have calculated the matrix elements that are available on web sites (http://chemistry.anl.gov) from which one may download a MS-Windows based computer program named SPECTRA to calculate the eigenvalues and eigenfunctions of the free-ion Hamiltonian defined in equation (18.30). As discussed in the following sections, SPECTRA can also be used for nonlinear least-squares fitting of observed levels to determine values of the Hamiltonian parameters.

Due to the SL–$S'L'$ mixing in the intermediate coupling scheme, labeling a multiplet as $^{2S+1}L_J$ is incomplete. In most cases, the nominal labeling of a free-ion state as $^{2S+1}L_J$ only indicates that this multiplet has a leading component from the pure LS basis $|LSJ\rangle$. Diagonalization of each of the submatrices produces free-ion eigenfunctions in the form of equation (18.15). As an example, the leading LS terms for the free-ion wave functions of the nominal $^4I_{9/2}$ ground state of the $4f^3$ ion Nd^{3+} and the $5f^3$ ion $U^{3+}$are:

$$\Psi(4f^3, {}^4I_{9/2}) = 0.984\,{}^4I - 0.174\,{}^2H - 0.017\,{}^2G + \text{etc.}$$

$$\Psi(5f^3, {}^2I_{9/2}) = 0.912\,{}^4I - 0.391\,{}^2H - 0.081\,{}^2G + 0.048\,{}^4G + 0.032\,{}^4F + \text{etc.}$$

In general, SL–$S'L'$ mixing becomes more significant in the excited multiplets.

18.3.5 Parameterization of the free-ion Hamiltonian

In an empirical approach to interpretation of the experimentally observed energy level structure of an f-element ion in solids, establishing accurate parameters for the model Hamiltonian essentially relies on systematic analyses that encompass theoretical calculations for incorporating trends of parameter variation across the f-element series. In the previous work that led to the establishment of the free-ion parameters for the trivalent actinide ions (Carnall, 1992) and the tetravalent actinide ions (Carnall *et al.*, 1991; Liu *et al.*, 1994b), the results of analyses of simpler spectra were carried over to more complex ones through consideration of their systematic trends and symmetry properties.

Table 18.4 lists values of the free-ion interaction parameters obtained from analyses of the spectra of An^{3+}:$LaCl_3$.

In early attempts to develop a systematic interpretation of trivalent actinide and lanthanide spectra, initial sets of F^k and ζ_{nf} for some members of the series had to be estimated. This was done by a linear extrapolation based on the fitted parameters that were available from the analyses of other individual spectra. As more extensive data and improved modeling yielded better determined and more consistent F^k and ζ_{nf} values for the 3+ actinides (and lanthanides), it became apparent that the variation in the parameters was nonlinear, as indicated for F^2(5f,5f) in Fig. 18.4. This nonlinearity could also be observed in the values of parameters of the *ab initio* calculations. The difference between the *ab initio* and fitted values of parameters (ΔF) appears to exhibit a much more linear variation with Z than do the parameter values. Consequently, ΔF has been adopted as the basis for a useful predictive model.

For the trivalent actinides, the values of ΔF are not constant over the series, but use of a single average value over a group of four or five elements is not an unreasonable approximation. Thus, in developing a predictive model for the F^k and ζ_{nf} parameters, an attempt is made to establish average values of ΔF for a particular valence state and type of crystal-field interaction. The energy level structure computation based on the predicted parameters can be compared to that observed, and then appropriate modifications sought by a fitting procedure where necessary.

Detailed results of Hartree–Fock calculations on f-electrons were previously analyzed (Carnall *et al.*, 1983; Crosswhite and Crosswhite, 1984). The most important trends are those of the electrostatic-interaction parameters F^k and spin–orbit parameters ζ_{nf} which increase with the number of f-electrons, N. The experimentally determined values of F^k and ζ_{nf} for trivalent actinides in $LaCl_3$ are shown as a function of N in Figs. 18.4 and 18.5, respectively. These values were obtained from the systematic analyses of experimental spectra (Carnall, 1992). Fig. 18.5 also shows the systematic trends for ζ_{nf} for the trivalent actinide ions that were obtained from Hartree–Fock calculations. Although the Hartree–Fock calculations predict the same trends across the series, the Hartree–Fock values for F^k and ζ_{nf} are always larger than the empirical parameters obtained by allowing them to vary in fitting experimental data. The relativistic Hartree–Fock (HFR) values of ζ_{nf} agree remarkably well with empirical values, whereas the F^k values remain considerably larger than the empirical values. Presumably, this is because, in addition to relativistic effects, f-electron coupling with orbitals of higher-lying energies reduces the radial integrals assumed in the HFR approximation. Moreover, the experimental results are obtained for ions in condensed phases, not in a gaseous phase, which leads on average to an ~5% change (Crosswhite, 1977). Because of the absence of mechanisms that absorb these effects in the HFR model, HFR values of F^ks cannot be used directly as initial parameters for the least-squares fitting process. Scaling of HFR values to the experimentally determined ones is

necessary to establish a systematic trend for a specific parameter. With this procedure, linear extrapolations of model parameters from one ion to another lead to values consistent with those obtained in the actual fitting process.

In addition to HFR calculations of F^ks and ζ_{nf}, estimated values for $M^k (k = 0, 2, 4)$ can also be computed using the HFR method (Judd *et al.*, 1968). These parameters do not vary dramatically across the f-series. In practice, experience has shown that they can be taken as given or varied as a single parameter while maintaining the HFR ratios $M^2/M^0 = 0.56$ and $M^4/M^0 = 0.31$ (Carnall, 1989). For actinide ions, the ratio M^4/M^0 may be maintained at 0.38−0.4 (see Table 18.4).

For the rest of the free-ion effective operators introduced above, no direct Hartree–Fock calculated values can be derived. Only a term-by-term HFR calculation is possible to give additional guidance for parameter estimates. For example, the HFR values of P^ks for Pr^{2+} and Pr^{3+} have been determined by Copland *et al.* (1971). In establishing systematic trends of parameters for An^{3+}:$LaCl_3$, Carnall (1989) constrained the P^k parameters by the ratios $P^4 = 0.5P^2$ and $P^6 = 0.1P^2$ whereas P^2 was varied freely along with other parameters. These ratios are consistent with the HFR estimation. The variation of these parameters across the series is not significant, and no obvious systematic trends have been established.

Once the systematic trends of free-ion parameters are established, constraints can be imposed on other parameters that are relatively insensitive to the available experimental data. Some parameters such as T^i, M^k, and P^k do not vary significantly across the series and as a good approximation can be fixed at the same values for neighboring ions in the same series. In fact, most of the free-ion parameters are not host sensitive. Typically, there are changes of ~1% in the values of the free-ion parameters between different lattice environments. The free-ion parameters given in Table 18.4 can be used as initial inputs for least-squares fitting of the energy level structure of a trivalent f-element ion in any crystalline lattice. If there is a limited number of experimentally determined levels, one may allow only the F^k and ζ_{nf} parameters to vary freely along with the crystal field parameters and keep the other free-ion parameters fixed. For further improvement of the fits, α, β, and γ can be released. For a final refinement, M^0 and P^2 may be varied freely with $M^{2,4}$ and $P^{4,6}$ varied following M^0 and P^2, respectively, at fixed ratios.

Multiconfiguration calculations have shown that similar values of these effective-operator parameters are to be expected at both ends of the lanthanide sequence (Morrison, 1972), and empirical evaluations are in agreement with this for both the lanthanides and actinides. For three (or 11) electrons, similar arguments show the need for additional (three-body) operators to parameterize the electrostatic interactions completely. If consideration is limited to the interactions arising from second-order perturbation theory, only six new operators are needed (Judd *et al.*, 1968; Judd and Suskin, 1984), and their experimental

evaluation is consistent with results expected from first-principles calculations (Poon and Newman, 1983).

Similar arguments hold for corrections to the spin–orbit interaction, as well as additional terms of relativistic origin such as the spin–other–orbit and spin–spin interactions. Hartree–Fock calculations give good estimates of the Marvin radial integrals $M^k(k = 0, 2, 4)$ associated with spin–other-orbit and spin–spin interactions (Judd *et al.*, 1968). Experimental investigations are needed for evaluation of the magnetic corrections associated with configuration interactions, but experience has shown that a single set of parameters $P^k\left(k = 2, 4, 6 \text{ with } P^4 = 0.75P^2 \text{ and } P^6 = 0.50P^2\right)$ accounts for a large part of this class of corrections (Judd *et al.*, 1968). Use of sets of all of the foregoing parameters has been explored in detail for all of the trivalent ions from U^{3+} through Es^{3+}, and values are shown in Table 18.4 for An^{3+}: $LaCl_3$.

18.4 MODELING OF CRYSTAL-FIELD INTERACTION

When an actinide or lanthanide ion occurs in a condensed-phase medium, the spherical symmetry of its electronic structure is destroyed, and ionic energy levels shift and split under the influence of the electric field produced by the crystalline environment. The energy level shifts and splittings depend on the nature and strength of the interaction with the environment. Some of this interaction can be absorbed by the nominal 'free-ion' parameters themselves and a measure of this contribution would give clues as to the nature of the interactions. Unfortunately, mainly because of the different methods by which the free-ion and condensed-phase levels are determined, there are very few cases in which both sets of parameters are known well enough for meaningful comparisons to be drawn.

In addition to modifications of the atomic parameters, there are medium-related effects that must be taken into account explicitly. The broken spherical symmetry that normally results when an isolated free gaseous ion is placed in a ligand field gives rise to a splitting of the free-ion level into a maximum of $(2J+1)$ components. A single-particle crystal field model has had remarkable success for lanthanide ions and a somewhat qualified, but nevertheless satisfactory, success for the trivalent actinide ions in providing an interpretation of experimental data (Dieke, 1968; Hüfner, 1978; Carnall, 1992; Liu, 2000). The degree to which the $2J+1$ fold degeneracy of a free-ion state is removed depends only on the point symmetry about the ion. The magnitude of crystal-field splittings is determined primarily by the crystal field strength that is expressed in terms of the crystal field parameters of the effective-operator Hamiltonian. The 5f electrons of actinide ions, which participate primarily in ionic bonding with surrounding ligands, have localized states that are conventionally described in the framework of crystal field theory (Stevens, 1952; Wybourne, 1965a). Using effective-operator techniques and the parameterization method,

the framework of crystal field theory has been developed with the same basis set of eigenfunctions of the effective-operator Hamiltonian for the free-ion interactions discussed in Section 18.3.5.

Because electronic interactions in solids are complex, various interaction mechanisms that influence the electronic states of an actinide ion in a solid environment may not be accurately calculated in the framework of current crystal field theory. Evaluation of the crystal field parameters, however, is theoretically much more difficult than predicting the number of energy levels for each free-ion state. To date, an empirical approach has been the most effective method for evaluation of the crystal field parameters of f-states of actinide ions (Krupa, 1987; Carnall, 1992; Liu *et al*., 1994b). Phenomenological modeling and *ab initio* calculations of ion–ligand interactions are able to provide theoretical guidance for the analysis of crystal field spectra. From theoretical approaches, analytical expressions of crystal field parameters using phenomenological models are available for calculating the crystal field parameters of actinide and lanthanide ions in a specific crystalline lattice. The exchange charge model (Malkin *et al*., 1970; Malkin, 1987) and the superposition model (Newman, 1971; Newman and Ng, 1989a) are two crystal field models that have achieved significant success and are useful for guiding spectral analyses. In addition, *ab initio* calculations of the solid-state electronic energy level structure have advanced significantly along with the rapid development of computer technology and are likely to be increasingly important in future studies (Matsika *et al*., 2001; Seijo and Barandiaran, 2001).

18.4.1 Correlation of free-ion and condensed-phase energy level structures

It was pointed out earlier that, because of the different techniques used in studying condensed-phase and free-ion spectra, the configurations available for direct comparison in the two cases have very little overlap. When crystals or solutions are cooled to near 4 K so that only the lowest (ground) electronic state is populated, the resultant absorption spectrum is directly interpretable in terms of energy levels, and, except for complications of superimposed vibronic bands and the added perturbations of crystal field effects themselves, the analysis can proceed to energy level assignments and parametric fitting. In free-ion emission studies, on the other hand, many overlapping transition arrays between the multiple configurations displayed in Fig. 18.1 are obtained simultaneously, and one must first analyze this complex structure. This can only be done with the aid of additional tags on the energy levels such as isotope shift, hyperfine structure, or Landé *g*-factor information, which requires that multiple experiments be performed. Of the many configurations that finally result, most are too heavily involved with s-, p-, and d-orbitals for easy comparison with the f-shell cases discussed here. See Chapter 16 for a detailed discussion of free-atom and free-ion spectra. Nevertheless, with some assistance from theory,

cases are available from which to begin constructing a useful interpretative and predictive model.

Considering the analogous lanthanide situation, nearly all the $4f^2$ atomic levels are known for Pr^{3+} as a free-ion (Pr IV; Crosswhite *et al.*, 1965) and as an ion in $LaCl_3$ (Crosswhite *et al.*, 1965; Rana *et al.*, 1984) and LaF_3 (Carnall *et al.*, 1969, 1989) hosts. The corresponding parametric results are given in Table 18.5. This is the only example now available in either the lanthanide or actinide series for which this direct comparison can be made. For this reason, this case will be examined more closely. Columns 2 (free-ion) and 3 ($LaCl_3$ crystal) in the upper part of Table 18.5 give the results found for the parametric model. Comparing the two cases line-by-line, significant differences can be seen for the major parameters F^k and ζ_{4f}, and lesser ones for α and β. Any possible differences in the M^k and P^k values are masked by the statistical uncertainties. The parameter shifts attributed to the Pr^{3+} environment are given in column 4 and the relative change of the crystal values, compared to those of the free ion, in column 5. Note that the most important change, nearly 5%, occurs for F^2, and about half of this for F^4, F^6, and ζ_{4f}. Also α is in the same range, but with a large uncertainty. The most striking change seems to be for β, which shows an increase in magnitude of some 10–15%.

The $5f^2$ free-ion configurations are completely known for both Th III (deBruin *et al.*, 1941) and U V (Wyart *et al.*, 1980; Van Deurzen *et al.*, 1984), but the Th^{2+} condensed-phase analog is not known, and analyzed data for U^{4+} are limited in scope. The $4f^3$ Pr III configuration is nearly completely known (Suger, 1963), but

Table 18.5 *Medium shift of free-ion parameters for selected f-element ions.*

there is no corresponding divalent crystal case for comparison. On the other hand, both the Nd^{3+}:$LaCl_3$ (Crosswhite *et al.*, 1976) and U^{3+}:$LaCl_3$ (Crosswhite *et al.*, 1980) spectra are very well documented, but experimental work for both Nd IV and U IV are incomplete. In fact, except for thorium, no doubly or triply ionized actinide free-ion analyses are known.

Although the parametric analyses are incomplete, enough free-ion data are available in a few cases to permit a determination of one or both of the major parameters F^k and ζ_{nf}. For the actinides, these are all neutral atomic and singly ionized cases, for which, again, no condensed-phase analogs are available. These are U I $5f^47s^2$, U II $5f^37s^2$, Pu I $5f^67s^2$, Pu II $5f^57s^2$, and Cf I $5f^{10}7s^2$, all of which contain the closed shell $7s^2$. Using Hartree–Fock (Cowan and Griffin, 1976) results to make corrections for the removal of the $7s^2$ shells, parametric values for the divalent U III, Pu III, and Cf III, and trivalent U IV and Pu IV cases can be inferred. The best example is for Pu IV. A comparison of estimated free-ion parameters with the Pu^{3+}:$LaCl_3$ results is given in Table 18.5. Although the statistical uncertainties are large, the relative changes are consistent with those for Pr^{3+} in the same host.

Because the shifts due to the crystalline environment and those due to the addition of the $7s^2$ shell are nearly the same, it has turned out that, for initial identification, the crystal absorption lines can be related directly to the free-ion spectral lines, at least in those cases for which the crystal field can be treated in the weak-field approximation.

18.4.2 Crystal-field Hamiltonian and matrix element evaluation

Based on the concept that the crystal-field interaction can be treated approximately as a point-charge perturbation on the free-ion energy states, which have their eigenfunctions constructed with the basis of spherical harmonic functions, the effective operators of crystal-field interaction may be defined with the tensor operators of the spherical harmonics $\mathbf{C}^{(k)}$. Following Wybourne's formalism (Wybourne, 1965a,b), the crystal field potential may be defined by:

$$\mathscr{H}_{\mathrm{CF}} = \sum_{k,q,i} B_q^k C_q^{(k)}(i), \tag{18.32}$$

where the summation involving i is over all the equivalent electrons of the open shell of the ion of interest; where the B_q^k are crystal field parameters and the $C_q^{(k)}$ are components of the tensor operators $\mathbf{C}^{(k)}$ that transform like spherical harmonics.

In addition to Wybourne's formalism for crystal field parameters, the Stevens' notation of crystal field parameters $A_k^q\langle r^k\rangle$ are often found in the literature. The crystal-field interaction is often characterized by quantitative comparison of the crystal field strength defined as (Wybourne, 1965a; Auzel and Malta, 1983):

$$N_v = \left[\frac{1}{4\pi}\sum_{q,k}\frac{\left(B_q^k\right)^2}{2k+1}\right]^{1/2}, \tag{18.33}$$

With tensor operators, evaluation of the crystal field matrix elements can be performed with the same methods used for the free-ion matrix elements. Upon application of the Wigner–Eckart theorem, the matrix elements of the crystal-field interaction can be expressed with the reduced matrix elements of a unit tensor $\mathbf{U}^{(k)}$ (Wybourne, 1965a; Weissbluth, 1978):

$$\left\langle l\tau SLJM\left|\sum_i C_q^k(i)\right|l\tau' L'J'M'\right\rangle = (-1)^{J-M}\begin{pmatrix} J & k & J' \\ -M & q & M'\end{pmatrix} \left\langle l\tau SLJ\|\boldsymbol{U}^{(k)}\|l'\tau' S'L'J'\right\rangle\left\langle l\left\|\boldsymbol{C}^{(k)}\right\|l\right\rangle. \tag{18.34}$$

In *LS* coupling, the matrix elements of the unit tensor can be further reduced to

$$\left\langle l\tau LSJ\|\mathbf{U}^{(k)}\|l\tau' L'S'J'\right\rangle = (-1)^{S+L'+J+k}[(2J+1)(2J'+1)]^{1/2} \begin{Bmatrix} J & J' & k \\ L' & L & S\end{Bmatrix}\left\langle l\tau LS\|\boldsymbol{U}^{(k)}\|l\tau' L'S'\right\rangle \tag{18.35}$$

With equations (18.34) and (18.35), the reduced matrix elements of the crystal-field Hamiltonian can be written as:

$$\langle l\tau SLJM\,|\,\mathscr{H}_{\mathrm{CF}}|l\tau' S'L'J'M'\rangle = \sum_{k,q} B_q^k(-1)^{J-M}\begin{pmatrix} J & k & J' \\ -M & q & M'\end{pmatrix} D_J^k, \tag{18.36}$$

where

$$D_J^k = (-1)^{S+L'+J+k}[(2J+1)(2J'+1)]^{1/2}\begin{Bmatrix} J & J' & k \\ L' & L & S\end{Bmatrix} \left\langle l\tau SL\|\mathbf{U}^{(k)}\|l\tau' S'L'\right\rangle(-1)^l(2l+1)\begin{pmatrix} l & k & l \\ 0 & 0 & 0\end{pmatrix} \tag{18.37}$$

where $l = 3$ for f^N configurations. Since all the coefficients, including the values of the $3{-}j$ and $6{-}j$ symbols and the doubly reduced matrix elements of the unit tensor, are known for a given free-ion multiplet, it is obvious that evaluation of crystal-field splittings can be performed by fitting the crystal field parameters B_q^k.

The doubly reduced matrix elements of $\mathbf{U}^{(k)}$ may be obtained directly from Nielson and Koster (1963) or from the SPECTRA program. The values of the $3{-}j$ ( ) and $6{-}j$ { } symbols can be obtained from the compilation of Rotenberg *et al*. (1959) or by direct computer evaluation. The values of k and q for which the matrix elements are nonzero are determined by the symmetry of the crystal

field and the f-electron angular momentum. For f^N configurations ($l = 3$), the $3-j$ symbols in equation (18.37) require that $k = 0, 2, 4, 6$, and $|q| \leq k$. The values of q are also restricted by the point group of the f-ion site, because the crystal-field Hamiltonian has to be invariant under all symmetry operations of the point group. Restrictions due to point group symmetry properties on the nonzero matrix elements of the crystal-field Hamiltonian are discussed later in this section.

For the matrix element of $k = q = 0$, the zero-order of crystal-field interaction is spherically symmetric and does not split the free-ion energy levels, but induces a shift to all energy levels in the same f^N configuration. In general, B_0^0 is not included in evaluation of the crystal-field splitting. Therefore, its contribution to energy level shift is combined with the spherically symmetric component of the free-ion electrostatic interactions. One parameter, namely F^0, absorbs contributions from spherically symmetric components of free-ion and crystal-field interactions.

Once the matrix elements in equation (18.36) are evaluated, the Hamiltonian of the crystal-field interaction may be diagonalized together with the free-ion Hamiltonian to obtain the crystal-field splittings as a function of crystal field parameters. For spectral analysis, the free-ion parameters may also be considered as variables for fitting an experimental spectrum. As a result of the crystal-field interactions, each of the $^{2S+1}L_J$ multiplets splits into crystal field levels. Because the off-diagonal matrix elements of the crystal field between different J-multiplets may not be zero, crystal field operators induce J-mixing. In consequence, for actinide ions in crystals, both J and M are no longer good quantum numbers.

As a result of J-mixing, the eigenfunction of a crystal field level is expressed as

$$|\mu\rangle = \sum_{J,M} a_{JM} |JM\rangle, \tag{18.38}$$

where, in principle, the summation is over all JM terms of a given f^N configuration. However, inclusion of all J-multiplets results in extremely large matrices, particularly, for the configurations with $4 \leq N \leq 10$. Diagonalization of the effective-operator Hamiltonian on the entire $LSJM$ basis could be very time-consuming in an analysis of an experimental spectrum from optical spectroscopy. Such spectra usually cover energy levels that are less than 40 000 cm^{-1} above the ground state (Carnall, 1992; Liu *et al.*, 1994b). Off-diagonal matrix elements between free-ion states separated by a large energy gap are small. As an approximation, crystal field calculations without including J-mixing is appropriate only for the isolated multiplets, such as the first $^5D_1$ excited state of Am^{3+} or the $^8S_{7/2}$ ground state of Cm^{3+}. In practice, the crystal field energy level structure of a $5f^N$ configuration is usually calculated over the restricted energy region in which experimental data are available. Free-ion multiplets with energy

levels far from this region usually are not be included in the calculation. Namely, the free-ion eigenfunction basis may be truncated before diagonalizing the matrix of crystal-field Hamiltonian. Theoretically, this truncation of free-ion states is justified because crystal-field coupling diminishes between two free-ion multiplets as their energy gap increases. From the perturbation point of view, the leading contribution of J-mixing to the energy level splitting of the J-multiplets is proportional to $1/\Delta E_{JJ'}$. Given that the crystal-field splitting of a free-ion multiplet is about 100−1000 cm^{-1}, multiplets that are separated by 10^4 cm^{-1} should have no significant influence on each other.

In computational analyses of experimental spectra, one may truncate the free-ion states whose energy levels are far from the region of interest. This is readily accomplished after diagonalization of the free-ion matrix to produce a calculated free-ion energy level structure. These levels are considered to be the centers of gravity for the crystal-field splitting (Carnall *et al.*, 1983; Carnall, 1992). One chooses the numbers of J-multiplets to be included in the crystal-field matrices for each J-value. Therefore, the chosen J-multiplets are still complete sets of free-ion eigenfunctions that contain all SL components of the given J. This way of free-ion state truncation ensures that no contribution from the free-ion interactions is lost when constructing the free-ion wave functions for each J-multiplet.

One example is the $^8S_{7/2}$ ground state of ions in a $5f^7$ configuration for Am^{2+}, Cm^{3+}, or Bk^{4+} in which both diagonal and off-diagonal matrix elements of the crystal field operators vanish (Wybourne, 1966; Newman, 1970; Liu *et al.*, 1993; Newman and Ng, 2000). The observed crystal-field splittings must be attributed to the contributions of the mixture of other LS terms in the ground state free-ion wave function and nonzero off-diagonal matrix elements between different J values (Liu *et al.*, 1993, 1998; Murdoch *et al.*, 1996, 1998). Because of large energy gaps from the ground state to the excited multiplets ($\sim$16 000 cm^{-1}), J-mixing is negligible in this case. It has been shown that for the $^8S_{7/2}$ ground state splitting, the leading contributions are from the fourth and higher orders of the coupled matrix elements between the spin–orbit ($\mathbf{V}^{(11)}$) and crystal field ($\mathbf{U}^{(k)}$) operators (Liu *et al.*, 1993; Brito and Liu, 2000). Without inclusion of J-mixing, the leading contributions to the crystal-field splitting of the $^8S_{7/2}$ multiplet of an f_7 configuration are from the mixed matrix elements such as

$$\begin{aligned}&\left\langle {}^8S\middle|\mathbf{V}^{(11)}\middle|{}^6P\right\rangle\left\langle {}^6P\middle|\mathbf{U}^{(2)}\middle|{}^6D\right\rangle\left\langle {}^6D\middle|\mathbf{U}^{(2)}\middle|{}^6P\right\rangle\left\langle {}^6P\middle|\mathbf{V}^{(11)}\middle|{}^8S\right\rangle\\&\left\langle {}^8S\middle|\mathbf{V}^{(11)}\middle|{}^6P\right\rangle\left\langle {}^6P\middle|\mathbf{U}^{(11)}\middle|{}^6I\right\rangle\left\langle {}^6I\middle|\mathbf{U}^{(6)}\middle|{}^6P\right\rangle\left\langle {}^6P\middle|\mathbf{V}^{(11)}\middle|{}^8S\right\rangle.\end{aligned} \tag{18.39}$$

It is obvious that truncation of LS terms in the $J = 7/2$ multiplets should affect the scale of the coupled matrix elements, and thus affect the calculated crystal-field splitting. The same situation occurs for the off-diagonal matrix elements between different J-levels, but is less important because of the large energy gap between the ground state and the first excited state.

18.4.3 Symmetry rules

The geometric properties of the crystal field operators will now be discussed in more detail. In addition to the angular momentum of the f-ions that restricts k and q for a set of nonvanishing crystal field operators, the site symmetry in a crystalline lattice also imposes limits on crystal field operators. The tensor operators for the crystal-field interaction must be invariant under the point group symmetry operations imposed by the site symmetry of the ion in question. Here the interest is to identify the nonvanishing components of crystal field operators and their matrix elements. First, for states of the same parity, namely $l = l'$, k must be even. It is also required that B_q^k must be real in any symmetry group that contains a rotation operation about the y-axis by π or a reflection through the $x-z$ plane; otherwise B_q^k ($q \neq 0$) is complex. In the latter case, one of the B_q^k can be made real by a rotation of the coordinate system about the z-axis. The B_q^k for $q < 0$ are related to those of $q > 0$ by

$$B_{-q}^k = (-1)^q B_q^{k*}. \tag{18.40}$$

Also under the invariant conditions of the point group theory, the crystallographic axis of the lowest symmetry determines the values of q for the nonvanishing crystal field operators. For example, at a site of C_{3v} symmetry, there is a three-fold axis of rotational symmetry with a reflection plane that contains the C_3 axis (Tinkham, 1964; Hüfner, 1978). The ligand field must exhibit this symmetry. Hence, if a $2\pi/3$ rotation is performed on the crystal field potential followed by a reflection with regard to the plane, the potential is invariant only if $q = 0$, ± 3, and ± 6. Thus, within an f^N configuration, the crystal-field Hamiltonian may be written as

$$\begin{aligned}\mathscr{H}(C_{3v}) = \sum_i [&B_0^2 C_0^{(2)}(i) + B_0^4 C_0^{(4)}(i) + B_3^4 (C_{-3}^{(4)}(i) - C_3^{(4)}(i)) \\ &+ B_0^6 C_0^{(6)}(i) + B_3^6 (C_{-3}^{(6)}(i) - C_3^{(6)}(i)) + B_6^6 (C_{-6}^{(6)}(i) + C_6^{(6)}(i))].\end{aligned} \tag{18.41}$$

If the reflection plane is perpendicular to the C_3 axis, the site symmetry becomes C_{3h}, which occurs for doped f^N impurity ions in lanthanum ethylsulfate, $LaCl_3$, and $LaBr_3$ (Morosin, 1968). This potential invariant property requires $q = 0$, ± 6 only, but, since there is no rotation symmetry about the y-axis by π or a reflection through the x–z plane for the C_{3h} site, there is an imaginary noncylindrical term in the Hamiltonian:

$$\begin{aligned}\mathscr{H}(C_{3h}) = \sum_j [&B_0^2 C_0^{(2)}(j) + B_0^4 C_0^{(4)}(j) + B_0^6 C_0^{(6)}(j) + B_6^6 (C_{-6}^{(6)}(j) \\ &+ C_6^{(6)}(j)) + iB_6'^6 (C_6^{(6)}(j) - C_{-6}^{(6)}(j))].\end{aligned} \tag{18.42}$$

D_{3h} is a symmetry group that includes all rotation and reflection operations of C_{3h} (Tinkham, 1964; Hüfner, 1978). The crystal field operators for ions at a

D_{3h} site are the real terms for C_{3h} without the imaginary term $iB_6'^6(C_6^{(6)} - C_{-6}^{(6)})$. The nonvanishing terms of crystal field operators for various lattice sites of f-ions in crystals are listed in Table 18.6.

The free-ion degeneracy in M may be partially or completely removed by the crystal-field interaction. In the crystal-field energy matrix using the JM basis set, the terms for which $M-M' = q$ for the operator $C_q^{(k)}$ are nonzero. Otherwise the crystal-field matrix elements are zero. Based on this property, the crystal-field matrix may be reduced into several independent submatrices, each of which is characterized by a crystal quantum number μ (or γ). Each μ represents a group of M, such that $M-M' = q(0, 2, 3, 4, 6)$ belongs to the same submatrix (Hüfner, 1978). All matrix elements between the submatrices are zero. The crystal field quantum number may be used to classify the crystal field energy levels even when J and M are not good quantum numbers. Considering C_{3h} (and D_{3h}) as an example, the JM and $J'M'$ (J may be equal to J') with $M-M' = 6$ belong to the same crystal field submatrix. For an even number of f-electrons, there are four independent submatrices, and for an odd number of f-electrons, there are three independent submatrices. The parameters of nonvanishing crystal field terms for symmetries of common crystal hosts of f-element ions are given in Table 18.6 along with the numbers of reduced crystal-field matrices.

Without a magnetic field, the electrostatic crystal field alone does not completely remove the free-ion degeneracy for the odd-numbered electronic configurations. Known as Kramers' degeneracy (Kramers, 1930; Hüfner, 1978), all crystal field levels are at least doubly degenerate. The crystal quantum number and JM classification schemes are given for D_{3h} symmetry in Table 18.7. In calculation of energy level structure for degenerate doublets, one may cut off half of the submatrix elements. In many cases, calculations of crystal field energy levels have been carried out usefully by assuming a higher site symmetry than the real one so that fewer parameters are required. In some cases, this approach was used because actinide ions in many solids occupy a low-symmetry site and the limited number of observed energy levels could not accurately determine a large number of crystal field parameters (Carnall *et al.*, 1991). In other cases, a crystal lattice that does not have mirror symmetries in its coordinates requires complex crystal field parameters for the $q \neq 0$ terms (Table 18.6). If one uses as an approximation only the real part of the crystal field operators, energy level calculation becomes much easier. Because the use of high symmetry as an approximation is equivalent to upgrading a lower-symmetry site to a higher one within the same crystal symmetry group, this approach has been called the descent-of-symmetry method (Görller-Walrand and Binnemans, 1996). This method may be applied to the groups of monoclinic, trigonal, and tetragonal structures listed in Table 18.6. For example, the C_{3h} symmetry of $LaCl_3$ was replaced by D_{3h} (Morrison and Leavitt, 1982); the S_4 site symmetry of trivalent lanthanide ions in $LiYF_4$ is often treated as D_{2d} (Esterowitz *et al.*, 1979; Görller-Walrand *et al.*, 1985; Liu *et al.*, 1994a). Similarly, the actual C_2 symmetry of LaF_3 was replaced by C_{2v} (Carnall *et al.*, 1989).

In general, use of the descent-of-symmetry method may have more complicated consequences than that of the above examples. For a specific symmetry modification, one may estimate the changes in crystal field parameters based on the rotational symmetry of point charges in polar coordinates (θ,ϕ) and assuming that the ligand ions in each coordination shell are at the same distance from the f-element ion. For an arbitrary rotation, the B_0^k parameters should only depend on the θ-coordinates, whereas the B_q^k parameters ($q \neq 0$) depend on both θ- and ϕ-coordinates. Changes in the ϕ-coordinates have no influence on B_0^k and $|B_q^k| = [(\mathrm{Re}B_q^k)^2 + (\mathrm{Im}B_q^k)^2]^{1/2}$. Descent-of-symmetry operations that have this property are $C_{n\mathrm{h}} \rightarrow D_{n\mathrm{h}}$, $S_4 \rightarrow D_{2\mathrm{d}}$, and $C_n \rightarrow C_{n\mathrm{v}}$. The symmetry changes that incorporate a change in θ-coordinates will change all parameters, such as $D_{n\mathrm{h}} \rightarrow C_{n\mathrm{v}}$ and $D_{n\mathrm{h}} \rightarrow C_n$. If the symmetry of the f-element site is lowered, not only are additional parameters required, but there are also changes in the crystal field parameters found in the higher symmetry. In consequence, there is far less rationale for using D_n has an approximation for C_n and $C_{n\mathrm{v}}$.

Site distortion is a common phenomenon when f-element ions are doped into crystals. A dopant ion may have site symmetry lower than that of the host ion it replaces. This is especially true if the charge on the dopant ion and/or its ionic radius is different from that of the host ion. Accordingly, both the sign and magnitude of crystal field parameters are subject to change. As discussed above, different crystal structures may undergo different types of distortion that reflect the properties of the specific coordination polyhedron in a given crystal. Görller-Walrand and Binnemans (1996) give a detailed description of the effects of structural distortion in terms of changes in the θ- and ϕ-coordinates. However, changes in radial distances may occur as well. For ions at a distorted site that further reduces the degeneracy of electronic states, analyses of crystal field spectra must be conducted using a lower symmetry.

18.4.4 Empirical evaluation of crystal field parameters

Extensive mixing of *SL*-basis states, brought about by the spin–orbit and crystal-field interactions for each *J*-multiplet, can result in the least-squares method for empirical evaluation of crystal field parameters converging to a false solution. A false solution can be recognized if there is sufficient characterization of the states from supplementary data, such as Zeeman splitting factors or polarized spectra. However, this in itself may not produce the true solution. The latter can only be found if sufficiently accurate initial parameters are available for the least-squares fitting process to be effective. Therefore, establishing accurate parameters for the model Hamiltonian essentially relies on systematic analyses that encompass theoretical calculations for incorporating trends of parameter variation across the f-element series (Carnall, 1989; Liu *et al.*, 1994b; Liu, 2000). The results of analyses of simpler spectra are carried over to more complex ones through consideration of their symmetry properties.

For f-element ions in crystals of well-defined site symmetry, crystal field theory is widely used along with group theory for predicting the number of energy levels and determining selection rules for electronic transitions between crystal field levels. Whereas the number of nonvanishing crystal field parameters can be determined by the symmetry arguments, their values are usually determined by analyzing the experimentally observed crystal-field splittings. Experimental data that carry supplementary spectroscopic information, such as polarized transitions allowed by electric or magnetic dipolar selection rules, ensure the accuracy of the experimentally fitted crystal field parameters (Liu *et al.*, 1992, 1994a, 1998). In addition, the temperature dependence of observed crystal-field splittings may be analyzed to distinguish pure electronic lines from vibronic features. Properties such as magnetic susceptibility as a function of temperature may be calculated from the empirical wave functions as a further check on the accuracy of the crystal field parameters. If multiple sites exist, site-resolved spectra are required to distinguish energy levels of ions at different sites (Tissue and Wright, 1987; Liu *et al.*, 1994b; Murdoch *et al.*, 1996). Accordingly, as a procedure of

parametric modeling, correct assignment of observed energy levels is crucial to avoid a false solution. For spectra that lack sufficient experimental information to achieve unambiguous assignment, this procedure may involve several iterations of trial calculations and analyses that require a firm understanding of the basics of crystal-field splitting of free-ion states (Carnall, 1989, 1992).

For setting initial parameters of the crystal-field Hamiltonian to be fit by observed energy levels, one may simply use the previously established parameters for different f-element ions in the same or similar host materials. For the series of trivalent actinide ions in $LaCl_3$, one of the most extensively studied host crystals, the parameters of free-ion and crystal-field interactions are listed in Table 18.4. Comprehensive summaries of previously studied lanthanide systems are given (Morrison and Leavitt, 1982; Görller-Walrand and Binnemans, 1996). Alternatively, the signs and magnitudes of crystal field parameters can be predicted according to the coordination of the f-element ion using the point charge model of the electrostatic crystal field potential. For this purpose, only the nearest ligand (NL) atoms need to be considered. As a function of the radial and angular coordinates, the expressions for the B_q^k parameters are given in the following section. The signs of the crystal field parameters are determined by the angular part of the electrostatic potential and may be obtained by symmetry analysis. The predicted signs are important for checking the signs of the parameters obtained by the fitting procedure. Some sign combinations may correspond to a coordination that is physically impossible. Generally, determination of the magnitudes requires more quantitative calculations of the overlap integrals between the f-electrons and the electrons of the ligands. The electrostatic interactions beyond the nearest ligands may bring about significant contributions to the parameters with $k = 2$. For these parameters, the total contribution from the long-range interactions may exceed that of the NL so that a change in the sign of B_q^2 determined by the NL atoms is possible (Zhorin and Liu, 1998). Moreover, the electrostatic point charge model is not realistic in describing the short-range interactions between the f-element ion and its nearest ligands. Charge exchange interactions including covalency may dominate the crystal field parameters with $k = 4$ and 6. For these reasons, an empirical approach with theoretical guidance is necessary to ensure that the parameterization is within the limitations of physical interactions.

In a nonlinear least-squares fitting process, the magnitudes and signs of crystal field parameters are varied to best reproduce the observed energy level structure. This is actually a process of optimizing crystalline structure within a given restriction through variation of the crystal field parameters. The parameters that have higher weight are better determined than the parameters that have less influence on the observed energy levels. Adding an imaginary parameter may only change the real part of the term that has the same q and k but does not have much influence on other parameters. If the values of the crystal field parameters for a system of higher symmetry are used as initial values of the parameters for a different system of lower symmetry, the fitting may either

fall into a false solution or leave the added parameters less accurately determined. In this case, one should assign the unambiguously observed energy levels, most likely the isolated multiplets, and only allow the most significant crystal field parameters to vary freely. Once these weighted parameters converge, further fitting should be performed on the entire set of crystal field parameters, along with the variation of the free-ion parameters.

18.4.5 Theoretical evaluation of crystal field parameters

Quantum mechanical calculations of crystal field energies and corresponding crystal field parameters for f-element ions in compounds with different chemical characteristics were carried out by several groups in the framework of the cluster approximation. For an f-ion and its nearest ligands (chlorine, fluorine, or oxygen ions), the fully antisymmetric and orthonormalized wave functions of zero-order are constructed as linear combinations of products of individual ion wave functions, and the energy matrix is built with the complete Hamiltonian that contains one- and two-electron operators including the interaction with the electrostatic field created by the rest of the crystal. The first-order contributions to the energy matrix include integrals over one-electron wave functions of the occupied states of the cluster. Higher-order contributions correspond to configuration mixing. The procedure and details of calculations have been described in several original and review papers (Newman, 1971; Eremin, 1989; Garcia and Faucher, 1995; Shen and Bray, 1998; Zhorin and Liu, 1998; Newman and Ng, 2000). Here we present only a brief description of the results of *ab initio* simulations that are important for modeling of the main physical mechanisms responsible for crystal-field splittings.

The first-order terms in the energy matrix include Coulombic, exchange, and overlap integrals over 5f orbitals of the actinide ion and outer orbitals of ligand ions. From these terms, the 5f-electron energy in the electrostatic field of the ligand point multipole moments and the charge penetration contribution may be singled out. The second-order terms may be classified according to intermediate (virtual) excited states of the cluster. In this regard, the following electronic excitations should be considered:

(1) Intra-ion excitations from the filled electronic shell of the actinide ion to the empty excited shell (in particular, $6p^6 \rightarrow 6p^5 6d^1$). These processes shield the inner valence $5f^N$ shell and may be accounted for, at least partly, by introducing shielding (or antishielding) factors into the multipole moments of the valence electron $\left(\langle 5f|r^k|5f\rangle \rightarrow (1-\sigma_k)\langle 5f|r^k|5f\rangle\right)$ (Rajnak and Wybourne, 1964).
(2) Intra-ion excitations from the valence shell into empty shells and from the filled shells into the valence shell (in particular, $5f^N \rightarrow 5f^{N-1}6d^1$ or $6p^6 \rightarrow 6p^5 5f^{N+1}$). These processes contribute to the linear shielding and cause additional corrections to parameters of the effective Hamiltonian bilinear in parameters of the electrostatic field.

(3) Inter-ion excitations, mainly into the charge-transfer states of the actinide ion with the extra electron in the valence shell promoted from the outer-filled shell of the ligand. Actually, mixing of the ground configuration with the charge-transfer states corresponds to a partially covalent character in the chemical bonding between an actinide ion and its ligands.

It should be noted that the effective-operator Hamiltonian (equation (18.32)) with a single set of crystal field parameters, operating within the total space of wave functions of $5f^N$ configuration, can be introduced if all excited configurations of the cluster under consideration are separated from the ground configuration by an energy gap that is much larger than the width of the energy spectrum of the ground configuration. Otherwise the crystal field parameters become term (*LSJ*) dependent. In particular, a crystal field analysis carried out on an extended basis containing the ground $4f^2$ and excited 4f5d, 4f6p configurations of Pr^{3+} in YPO_4 (Moune *et al*., 2002) greatly improved the agreement between the experimental data and the calculated energy levels. For the $5f^N$ configurations, the inter-configuration coupling is anticipated to be much stronger because of smaller gaps between the ground and excited state configurations, particularly, for the lighter actinides in the first half of the $5f^N$ series.

A general conclusion about the dominant role of overlap and covalent contributions to the crystal field parameters B_q^4 and B_q^6 follows from all *ab initio* calculations carried out up to the present time. When Hartree–Fock one-electron wave functions of free ions are used in simulations, relative differences between the theoretical and experimental values of these parameters do not exceed 50%. However, for the quadrupole component of the crystal field parameters B_q^2, contributions from the long-range interactions of valence electrons with point charges, dipole, and quadrupole moments of ions in the crystal lattice are comparable to contributions from the interactions with the nearest ligand ions, and the theoretical estimations differ substantially from the experimental data.

Whereas the free-ion parameters vary smoothly across the 5f series, trends in crystal field parameters, particularly B_q^4 and B_q^6, usually break at the f^7 configuration. Experimental evidence for this effect is evident in the systematic analysis of the spectra of trivalent actinides doped into single-crystal $LaCl_3$ (Carnall, 1992) and trivalent lanthanides in LaF_3 (Carnall *et al*., 1989). An abrupt change in the magnitude of parameters with $k = 4$ and 6 occurs at the center of the series. Judd (1979) has interpreted this effect as a problem of the one-electron operators of the crystal-field Hamiltonian. One-electron operators, $\mathbf{U}^k$, change sign at the center of the series. Inclusion of two-electron operators in the crystal-field Hamiltonian would likely remove this discontinuity.

Although extensive Hartree–Fock calculations have been utilized for establishing systematic trends of free-ion interactions that lead to the determination of the parameters of the effective-operator Hamiltonian, most analyses of crystal-field interactions are carried out with the crystal field parameters determined by the fitting of experimental data. Attempts to calculate the crystal field

parameters from first principles may not be realistic. Given the complexity of electronic interactions in solids, *ab initio* calculations of electronic structure of heavy element ions in solids currently are not capable of achieving accuracy that is comparable to experimental results. Therefore, theoretical models, more or less phenomenological on the basis of the point-charge approximation, are essential in providing a clear theoretical understanding of electronic interactions of the f-element ions in solids. Model calculations do not only generate the phenomenological crystal field parameters that provide guidance to parametric modeling of the crystal field spectra of f-element ions in solids, but also reveal more fundamental aspects of the ion–ligand interactions that are poorly characterized by the point-charge approximation itself. Among the crystal field models introduced in the literature, the angular overlap model (Jørgensen *et al.*, 1963), the exchange charge model (Malkin *et al.*, 1970; Malkin, 1987), and the superposition model (Newman, 1971; Newman and Ng, 1989b, 2000) have been used for calculations of crystal field parameters for both 4f elements and 5f elements in various crystals.

Detailed discussions of the superposition model of the crystal field and its application to analysis of experimental spectra were provided by Newman and Ng (1989b, 2000). The superposition model neglects the ligand–ligand overlap effects and reflects the total crystal-field interaction as a linear 'superposition' of local ion–ligand pair-wise electrostatic interactions. The crystal field parameters are expressed as a sum of individual contributions from ions in the host crystal lattice,

$$B_q^k = \sum_L \bar{B}_k(R_L) g_{k,q}(\theta_L, \varphi_L), \tag{18.43}$$

where $g_{k,q}$ are normalized spherical harmonic functions, and R_L, θ_L, φ_L locate the position of ligand L in the lattice coordination environment. The distance-dependent parameters $\bar{B}_k(R_L)$ are referred to as intrinsic crystal field parameters, which by definition are dependent only on the radial distance between the f-ion and the ligand L. Based on the assumption of the point charge model that the ion–ligand electrostatic interaction has a specific power law dependence, the intrinsic parameters can be defined as

$$\bar{B}_k(R) = \bar{B}_k(R_0)(R_0/R)^{t_k}, \tag{18.44}$$

where R_0 is the distance between the f-ion and a reference ligand located on the z-axis of the crystalline lattice, and τ_k are power law exponents that reflect the distance dependence of the ion–ligand interaction (Newman and Ng, 2000). $\bar{B}_k(R_0)$and τ_k can be empirically determined as phenomenological parameters. It should be noted that the parameters τ_k are not generally in agreement with the electrostatic power law components $\tau_2 = 3$, $\tau_4 = 5$, $\tau_6 = 7$. For chloride ligands, in particular, $\tau_4 = 12 - 16$, $\tau_6 = 5 - 7$ for different RE ions (Reid and Richardson, 1985). Values of the rank 4 and 6 parameters quickly decrease with R, and the corresponding sums (equation (18.43)) are limited to the nearest neighbors of the f-ion. Because of their long-range effect, values of the rank 2

parameters are often difficult to determine. One may break the rank 2 operator into two terms, labeled as p and s (Levin and Cherpanov, 1983):

$$\bar{B}_2(R_L) = \bar{B}_2^p(R_0)(R_0/R_L)^3 + \bar{B}_2^s(R_0)(R_0/R_L)^{10} \tag{18.45}$$

to represent, respectively, the ligand point charge contribution and the short-range contribution.

Apparently, model calculations of crystal field parameters result in less discrepancies for some systems than for others. This is mainly due to uncertainties in structure information to which crystal field calculations, particularly of the rank 4 and 6 parameters, are extremely sensitive. Crystal lattice constants determined from X-ray diffraction or neutron scattering may be of very high resolution only for intrinsic sites. For impurity f-element ions doped into host materials, an unknown structural distortion is induced in most cases. The doping-induced site distortion depends in part on the ionic radius difference between the host ion and the doped f-element ion. If a model calculation is conducted based on the structure of the host, the calculated crystal field parameters are expected to be more or less different from those determined by fitting experimental data for the system.

The exchange charge model (ECM) (Malkin *et al.*, 1970; Larionov and Malkin, 1975; Malkin, 1987) is an extension of the angular overlap model (Jørgensen, 1962). It considers both long-range and short-range interactions between the actinide or lanthanide ion and lattice ions. The effective crystal-field Hamiltonian is assumed to be a sum

$$\mathscr{H}_{\mathrm{CF}} = \mathscr{H}^{\mathrm{pm}} + \mathscr{H}^{\mathrm{ec}} \tag{18.46}$$

where the first term corresponds to the electrostatic interaction of valence electrons localized on the f-element ion with point multipole moments of the lattice ions. The second term approximates all contributions due to the spatial distribution of electron density. Both terms have the form of equation (18.44) with parameters $B_q^{(\mathrm{pm})k}$ and $B_q^{(\mathrm{ec})k}$. Matrix elements of the effective-operator Hamiltonian $\mathscr{H}^{\mathrm{ec}}$ in the basis of one-electron wave functions of the metal ion interacting with spherical ligand ions may be calculated (Malkin *et al.*, 1970; Malkin, 1987).

To gain a greater insight into the energy level calculations, it is instructive to compare contributions to the electrostatic crystal field parameters with those from overlap and covalency effects. The ECM introduces the renormalization of the parameters of the electrostatic crystal field only and does not change the structure of the Hamiltonian $\mathscr{H}^{\mathrm{pm}}$. This renormalization may be considered to be a result of the 'nonlocal' interaction of the valence electron with the exchange charges localized at the bonds connecting the metal ion with its nearest neighbor ions. The concept of exchange charge, for which the crystal field model under consideration was named, and was first introduced by Dick and Overhauser (1958) in the theory of dielectric properties of solids. Values of exchange charges are proportional to the linear combinations of the overlap integrals and depend on the rank k of the corresponding tensor $\boldsymbol{B}^{(k)}$ of crystal field parameters. It is

Table 18.8 *Crystal field parameters from ECM calculation and experimental fit* (cm^{-1}).[a]

important that the ECM allows for consideration of both even and odd components of the crystal field. In particular, integral intensities of spectral lines in the intra-configurational $5f^N-5f^N$ spectra and their frequencies may be fitted in the framework of a single model.

As an example of ECM calculation, Table 18.8 lists the values of crystal field parameters calculated by using the ECM in comparison with the experimentally determined ones. It is evident that the dominant contributions to B_q^2 are from electrostatic interactions, whereas those to B_q^4 and B_q^6 are from short-range interactions. It is generally realized that the second-order parameters B_q^k with $k = 2$ are less accurately determined by the model calculation, particularly for a disordered lattice. This is because the second-order parameters characterize the long-range electrostatic interactions that are difficult to calculate accurately. It should be noted that the contradiction between the calculated and experimental values of the B_0^2 parameter in Nd^{3+}:$LaCl_3$ (in particular, different signs) may be removed when taking into account large contributions due to point dipole and quadrupole moments of chlorine ions (Eremin, 1989).

18.4.6 Corrections to the crystal-field Hamiltonian

As described in earlier sections, the parameterization approach is able to reproduce the crystal field energy level structures of actinide or lanthanide ions in satisfactory agreement with high-resolution absorption and luminescence spectra. The standard deviation in a nonlinear least-squares fit to experimental spectra in the low-lying energy levels (40 000 cm^{-1}) can be less than 10 cm^{-1} for lanthanide ions (Liu *et al.*, 1994a). However, crystal field modeling of energy levels for some particular states in the 4f configurations is invariably poor as, for instance, in the cases of the $^2H_{11/2}$ multiplet of Nd^{3+} and $^3K_8$ of Ho^{3+}. The discrepancies are much larger for the actinides in $5f^N$ configurations

(Edelstein, 1979; Carnall, 1992; Liu *et al*., 1994b; Murdoch *et al*., 1997; Liu, 2000). Faucher *et al*. (1996) reported in energy level analysis of U^{4+} in the octahedral sites of Cs_2UBr_6 and Cs_2ZrBr_6 evidence of strong interaction between the $5f^2$ and $5f^17p^1$ configurations. Adjustment of the parameters in the free-ion Hamiltonian does not result in much improvement. This problem is primarily due to the exclusion of the electron correlation effect in the one-electron crystal field model. The effects of electron–electron interaction cannot be completely absorbed into the effective-operator Hamiltonian of the one-electron crystal field model. Reid and coworkers (Reid, 2000) have reviewed progress in the modification of the one-electron crystal field theory with inclusion of correlation crystal field operators in the Hamiltonian.

There are various physical mechanisms that contribute to multiplet-dependent crystal-field splittings that can be described generally as correlation effects. The two obvious mechanisms, namely, the spin-correlated crystal field potential (Newman, 1971; Judd, 1977b) and the anisotropic ligand polarization effect, also known as nephelauxetic effect (Jørgensen, 1962; Gerloch and Slade, 1973), have been identified as large contributors, although, it is not clear what physical mechanisms produce the dominant contribution to shift the f-electron energy levels. To correct the discrepancy that appears in analyses of optical spectra with the one-electron crystal field model, it becomes necessary to introduce a full parameterization of the anisotropic two-electron interaction. To facilitate calculations of the matrix elements with the same basis for the one-electron operator Hamiltonian, Judd's $\mathbf{g}_{iq}^{(k)}$ operators (Judd, 1977a), which are orthogonal over the complete f^N basis sets, are used to define the correlation crystal field (CCF) Hamiltonian (Reid, 1987):

$$\mathscr{H}_{\mathrm{CCF}} = \sum_{ikq} G_{iq}^{k} \mathbf{g}_{iq}^{(k)}, \tag{18.47}$$

where G_{iq}^{k} are parameters of CCF. The index k runs through the even integers from 0 to 12 ($4l$, for f^N configurations). The parameter q is restricted by symmetry, and the number of operators varies with k. The operators $\mathbf{g}_{i}^{(k)}$with $k = 0$ correspond to Coulomb interactions and those with $i = 1$ to one-electron operators, in fact $\mathbf{g}_{1}^{(k)} \equiv \mathbf{U}^{(k)}$.

The main problem in the application of the CCF Hamiltonian is the very large number of parameters that are necessary to account for electron–electron correlation. However, the successful parameterization of f-ion crystal field energy level structure is largely dependent on the accuracy and the number of observed and properly assigned energy levels. In general, nonlinear least-square fitting requires that the number of assigned energy levels should be much larger than the total number of freely varied parameters. Expansion of the effective-operator Hamiltonian by including the operators for the correlation crystal-field interaction is effective only if there are sufficient experimental data and correctly determined parameters for the free-ion and one-electron crystal-field Hamiltonian for initial input. Otherwise, fits may fall into false minima and

produce inconsistent parameters. To correct the one-electron crystal field discrepancy by adding more terms to the crystal-field interaction, one should always consider restrictions on operators and introduce constraints based on physical relationships to reduce the number of freely varied parameters.

As discussed in Section 18.3, the effective-operator Hamiltonian for the free-ion interaction includes a corrective term (equation (18.26)) due to configuration interaction. In crystal field theory, the effect of configuration interaction was also considered (Rajnak and Wybourne, 1964). For a configuration of equivalent electrons l^N, most mechanisms of configuration interaction lead to a simple scaling of the crystal field parameters B_q^k. However, a one-electron excitation, either from the l^N shell to unfilled orbitals or from closed shells into the l^N shell, also results in effects that cannot be accommodated by a scaling of the B_q^k parameters alone. As a result, the crystal field parameters are expected to vary from one multiplet to another.

For the weak crystal-field interaction of the f-element ions in crystals, the usual method of a second-order perturbation theory can be used to characterize the configuration interaction (Judd, 1963a; Rajnak and Wybourne, 1963, 1964). The single particle operator $C_q^{(k)}$ in equation (18.32) can only couple configurations that differ by the excitation of a single electron. Thus, for an nl^N-type configuration, only three types of configurations are coupled:

(1) $nl^N n'l'^{4l'+1}$ with $nl^N n'l'^{4l'+1}n'l''$;
(2) nl^N with $nl^{N-1}n'l'$;
(3) $nl^N n'l'^{4l'+2}$ with $nl^{N+1}n'l'^{4l'+2}$.

As a result of the interaction between these configurations, each matrix element of equation (18.32) must be replaced by

$$(1+\Delta)\left\langle l^N\tau SLJM\left|B_q^k C_q^{(k)}\right|l^N\tau' S'L'J,M'\right\rangle \tag{18.48}$$

where Δ is known as the configuration interaction correction factor. This factor is the sum of two terms Δ_1 and Δ_2, where

$$\Delta_1 = \frac{-1}{E}\sum_m \frac{\langle nl^N\psi|\mathscr{H}_{\mathrm{CF}}|m\rangle\langle m|\mathscr{H}_{\mathrm{CF}}|nl^N\psi'\rangle}{\langle nl^N\psi|\mathscr{H}_{\mathrm{CF}}|nl^N\psi'\rangle}, \tag{18.49}$$

and

$$\Delta_2 = \frac{-2}{E}\sum_m \frac{\langle nl^N\psi|\mathscr{H}_{\mathrm{CF}}|m\rangle\langle m|\mathscr{H}_{C}|nl^N\psi'\rangle}{\langle nl^N\psi|\mathscr{H}_{\mathrm{CF}}|nl^N\psi'\rangle} \tag{18.50}$$

and E is the mean excitation energy of the excited electron, m is a state of the perturbing configuration, $\mathscr{H}_{\mathrm{CF}}$ is the crystal-field Hamiltonian, and $\mathscr{H}_{\mathrm{C}}$ is the Coulomb interaction in the free-ion Hamiltonian.

The first correction factor Δ_1 corresponds to configuration mixing purely by the crystal field, whereas the second factor Δ_2 represents an electrostatically correlated crystal-field interaction between the configurations. Methods for

evaluating the matrix elements have been discussed in detail in previous work (Judd, 1963a; Rajnak and Wybourne, 1964). It has been shown that the primary effect of configuration interaction is simply to scale the crystal field parameters B_q^k. The individual parameters are shielded (or antishielded) by different amounts depending on the perturbing configuration. This overall scaling effect is absorbed into the crystal field parameters determined from the experimental data. However, it has been shown that the second factor Δ_2 may be different for different *SL* states. This means that the crystal field parameters are no longer independent of free-ion states. If this mechanism is important, the crystal field parameters determined in fitting observed states in the narrow energy range of the low-lying multiplets give an inadequate description of the crystal-field splittings of the multiplets at higher energies.

18.5 INTERPRETATION OF THE OBSERVED SPECTRA OF TRIVALENT ACTINIDE IONS

Most of the actinide elements may be easily stabilized as trivalent ions in solids. Accordingly, a majority of the spectroscopic studies of actinides has been performed on the trivalent ions in $5f^N$ configurations. Whereas higher oxidation states can be stabilized for the lighter members in the first half of the actinide series, the 3+ oxidation state is most stable for the spectroscopically studied heavier actinides in condensed phases. Spectroscopic analyses and empirical modeling of the free-ion and crystal-field Hamiltonian were successfully conducted first on the trivalent ions using the model Hamiltonian reviewed in Section 18.4.6. Similarities are found between the series of trivalent actinide and lanthanide ions in terms of free-ion interactions and crystal-field splittings of the energy levels of the f-electrons.

When the results of a Hartree–Fock calculation are compared to those of a parametric analysis of experimentally identified levels for a given element, the magnitude of the computed energies, particularly those for F^k, are generally found to be too high. For a more realistic Hamiltonian, using parametric approach, one can apply subtractive corrections to the estimates derived from *ab initio* calculations. These corrections turn out to be essentially constant over the series and almost identical for both $4f^N$ and $5f^N$ shells (Crosswhite, 1977; Liu, 2000). The significance of this is that mixing with high configurations can be taken as essentially a fixed contribution to a global parametric model (Crosswhite and Crosswhite, 1984; Carnall, 1992; Liu *et al*., 1994b).

Many of the early spectroscopic studies of actinides in solids were conducted on actinide chlorides or trivalent actinide ions doped into crystals of $LaCl_3$ (Carnall, 1992), which can incorporate the actinide series from U^{3+} through Es^{3+} as impurities that substitute at the La^{3+} lattice site (C_{3h} symmetry). These studies, supplemented by Zeeman-effect studies of the influence of applied magnetic fields on the energy levels, provided the basis for experimental

characterization of the observed transitions in terms of the free-ion *SLJ* and crystal field quantum numbers. The available data for the $5f^N$ energy levels of trivalent actinide ions in $LaCl_3$ and actinide chlorides have enabled a systematic analysis and modeling of the $5f^N$ energy level structure (Carnall, 1992). The significance of such a systematic analysis and theoretical modeling, like that for the lanthanide series in $LaCl_3$ and LaF_3, is to provide a fundamental understanding of the electronic properties of actinides in solids along with values of free-ion interaction parameters that can be used for analyzing the spectra of the actinide ions in other compounds and solutions.

The relative energies of some of the low-lying states in U^{3+}:$LaCl_3$ are shown in Fig. 18.6 (Crosswhite *et al.*, 1980). As indicated, each free-ion state is split by the crystal field. When measured at the temperature of liquid He (~4 K), only transitions from the lowest state (taken as the zero of energy and having a

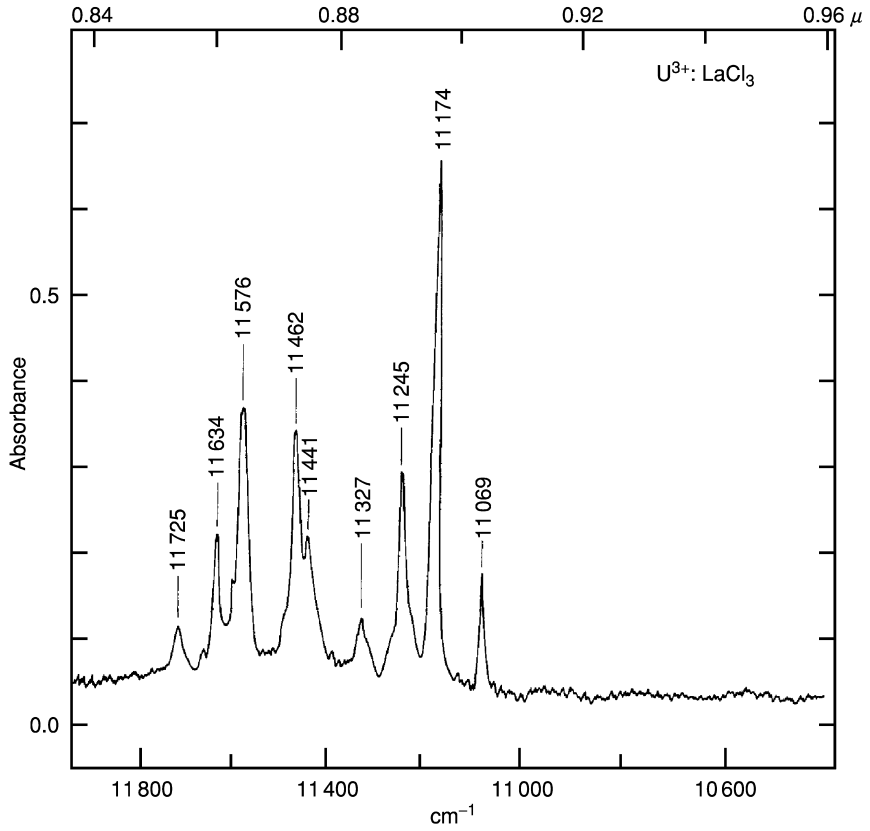

Fig. 18.6 *Absorption spectrum of the crystal-field splittings of* U^{3+}*:*$LaCl_3$ *in the range* 11 000–11 800 cm^{-1} *at* 4 K. (*Reprinted with permission from Crosswhite* et al., 1980. *Copyright* 1980, *American Institute of Physics.*)

crystal field quantum number $\mu = 5/2$ in this case) are observed. Most of the experimental results that have been reported were photographed using high-resolution grating spectrographs. Transitions to only three levels $^4I_{11/2}$ were readily observed in absorption; that to a $\mu = 1/2$ state (found by other techniques near 4580 cm^{-1}) were too weak to be apparent. Fig. 18.6 shows the absorption spectrum of U^{3+}:$LaCl_3$ in the range of 11 000 cm^{-1}. Lines in this spectrum are attributed the multiplets of $^4G_{5/2}$, $^4I_{15/2}$, $^4S_{3/2}$, and $^4F_{7/2}$ (Carnall, 1992). Electric dipole selection rules between the ground (μ=5/2) and excited (μ=5/2) states show that absorption transitions are forbidden, so the levels that would have corresponded to absorption transitions at 4556 and 4608 cm^{-1} had to be established by fluorescence methods. Assigning energies corresponding to the centers of these components, thus defining the 'free-ion' levels for the ion in a particular medium yields the energy level scheme indicated at the left in Fig. 18.7. Although the levels are shifted to somewhat lower energies than those of the true gaseous free-ion states, the basic structure appears to be preserved and is usually only moderately changed from medium to medium for trivalent lanthanides and actinides. For example, the center of gravity of the $^4I_{11/2}$ state in U^{3+}:$LaCl_3$ in Fig. 18.7 is 4544 cm^{-1}.

As the energies of the components of various groups are established experimentally, the model free-ion and crystal field parameters that reproduce the splittings can be computed by a suitable (nonlinear least-squares) fitting procedure. The computed values are then used to predict the splitting patterns in other groups where not all of the allowed components can be observed. Thus in the analysis of such spectral data there is a continual interplay between theory and experiment. When large numbers of levels have been experimentally confirmed, most (in some cases, all) of the parameters of the model can be varied simultaneously to establish the final values (Table 18.4). Fig. 18.8 shows the calculated energy levels that result from crystal-field splitting for An^{3+} in $LaCl_3$ (Carnall, 1992).

In typical analyses of actinide and lanthanide spectra in condensed phases, the range of observation may extend well into the near-ultraviolet region. The number of assignments made to different multiplets and states is usually sufficient to determine most of the energy level parameters. However, in Fig. 18.8 some of the observations on which this diagram is based were limited to less than 50% of the total extent of the f^N configurations. The accuracy of predicted energy level in the ultraviolet range clearly remains to be thoroughly tested. The Slater parameters in An^{3+} are typically only two-thirds as large as those for the Ln^{3+}, but ζ_{5f} is a factor of 2 larger than ζ_{4f}; so while the total energy range of the $5f^N$ configuration is reduced, the states are significantly more mixed in character because of the increased spin–orbit interaction.

The lanthanide orthophosphates, such as $LuPO_4$ and YPO_4, are good hosts for the incorporation of dilute f^N impurities. A wide variety of lanthanide and actinide ions, diluted in these materials, have been produced to carry out fundamental spectroscopic investigations (Morrison and Leavitt, 1982; Görller-Walrand and Binnemans, 1996). For the actinide series, Cm^{3+} doped

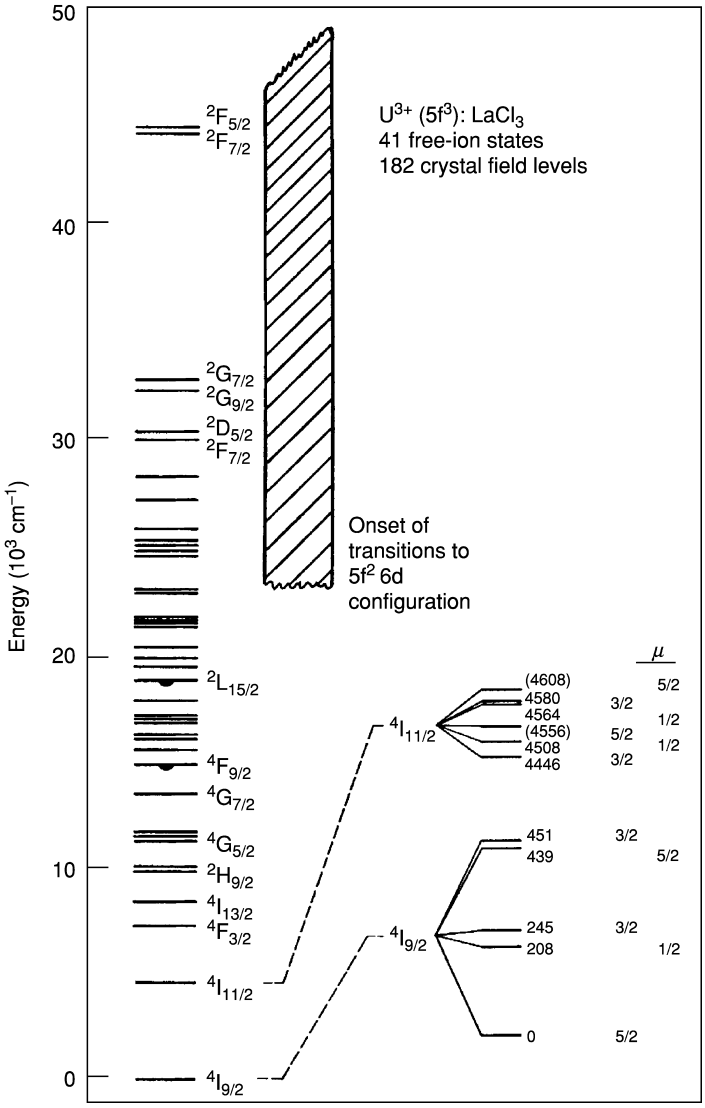

Fig. 18.7 *Energy level structure for* U^{3+}*:*$LaCl_3$.

into $LuPO_4$ and YPO_4, has been the most extensively studied system (Murdoch *et al.*, 1996, 1997; Liu *et al.*, 1998). The greater spatial extent of the 5f electron shell results in a smaller electrostatic interaction between equivalent electrons in the 5f shell than in the 4f shell. Thus for Cm^{3+}, the energy level of the first excited multiplet ($J = 7/2$) is at $\sim$16 000 cm^{-1}. Utilizing this metastable emitting state, excited state absorption studies allowed the collection of data to

40 000 cm^{-1} using two visible lasers (Murdoch *et al.*, 1997). The ground term multiplet splitting is small, because the largest component of the ground multiplet has zero angular momentum. Early detailed studies of the Cm^{3+} optical spectra were performed with the ^{244}Cm isotope. During the past decade or so, multimilligram quantities of ^{248}Cm have become available. Several single crystals were doped with the ^{248}Cm isotope and optical studies of these samples

were performed using laser-selective excitation and fluorescence techniques. Edelstein (2002) has recently published a review of the spectroscopic studies of Cm^{3+} in various hosts.

The free-ion model based on studies of the 3+ actinide ions in $LaCl_3$ has been used in analysis of the optical spectra of Cm^{3+} in $LuPO_4$. For the crystal-field splitting, because the metal ion site is D_{2d} in the phosphates instead of C_{3h} in $LaCl_3$, a different set of crystal field parameters must be established. Fig. 18.9 shows the excitation spectra of Cm^{3+} in $LuPO_4$ (Fig. 18.9a) and YPO_4

(Fig. 18.9b) in which the crystal field energy levels for the first excited multiplet (nominal $^6D_{7/2}$) were observed to extend from 16 560 to 17 200 cm^{-1}. In addition to the zero-phonon lines (ZPL) indicated by the vertical arrows, vibronic sidebands have intensities comparable to those of the upper ZPLs. The insert in Fig. 18.9b shows the crystal-field splitting in the ground state which also is a $J = 7/2$ (nominal $^8S_{7/2}$). Whereas the excited state crystal-field splitting is more than 800 cm^{-1}, the ground state splitting is only 12 cm^{-1}. As pointed out in Section 18.4.2, the crystal-field interaction vanishes in the ground state of an f^7 configuration unless a fourth-order coupling to the excited states is considered (Liu *et al.*, 1993). Although the excited $^6D_{7/2}$ also has no first-order crystal-field splitting, the more significant mixture of *LS* terms in its wave functions results in much larger crystal-field splitting. Many experimental results of the ground state splitting of actinide ions in the $5f^7$ configuration, which include Am^{2+}, Cm^{3+}, and Bk^{4+} in different crystalline hosts, have been reported (Edelstein and Easley, 1968; Liu *et al.*, 1996; Murdoch *et al.*, 1996; Brito and Liu, 2000).

In different hosts, the values for the An^{3+} free-ion parameters listed in Table 18.4 may vary 1% or less. In fitting the Cm^{3+}:$LuPO_4$ (or YPO_4) data, the parameters of three-body coupling operators, T^k, were kept fixed at the values for Cm^{3+} in $LaCl_3$ (Murdoch *et al.*, 1996, 1997). The energy levels of Cm^{3+} in $LuPO_4$ up to 35 000 cm^{-1} were probed by high-resolution techniques using two-step excited state absorption and one color two-phonon absorption methods (Murdoch *et al.*, 1997). The modeling of the Cm^{3+}:$LuPO_4$ energy level structure with the experimental data up to 35 000 cm^{-1} did not result in significant changes in the free-ion parameters determined in the systematic analysis of the $5f^N$ ions in $LaCl_3$. This consistency leads to two important conclusions as regards the applications of the free-ion and crystal field model: (a) the free-ion interaction parameters are relatively insensitive to host lattice; and (b) the parameters determined by analysis of the low-lying energy states can reproduce energy levels of high-lying states with satisfactory accuracy.

In appropriate hosts, the $^5D_1$ state of Am^{3+} ($5f^6$ configuration) is a metastable emitting state as is the $^6D_{7/2}$ state of Cm^{3+} ($5f^7$ configuration) (Carnall, 1992). In such cases, both ions emit visible luminescence so they are very suitable for laser-induced fluorescence excitation studies. In addition to $LaCl_3$ and $LuPO_4$, these two ions in other crystalline hosts such as Cs_2NaYCl_6 (Murdoch *et al.*, 1998), ThO_2 (Hubert *et al.*, 1993; Thouvenot *et al.*, 1993a, 1994), and $CaWO_4$ (Liu *et al.*, 1997a,b) have been investigated using laser spectroscopic methods. These studies showed that Am^{3+} and Cm^{3+} exhibit spectroscopic properties that are similar to those found in studies in $LaCl_3$, although the strength of the crystal-field interaction may be significantly different. Table 18.9 provides a comparison between the free-ion and crystal-field interactions of Eu^{3+} and Am^{3+} both of which have the f^6 configuration.

The ratios of free-ion interactions and crystal field strength for the 4f and 5f ions listed in Table 18.9 indicate that the electrostatic interaction is reduced approximately to 60% and the spin–orbit coupling is increased by 190%

(Edelstein and Easley, 1968) for the values of the lanthanide analogs in the same f^N configuration. These changes are attributed to the more extended 5f orbitals of Am^{3+} in comparison with the 4f orbitals of Eu^{3+}. In addition, the strength of the crystal-field interaction is doubled for the actinide ion. This trend of

variations is shown systematically in Fig. 18.10 for the two series of ions in the $LaCl_3$ crystal lattice (Liu, 2000).

Edelstein and Easley (1968) observed the trivalent state for ^{243}Am and ^{244}Cm doped into CaF_2 when the crystals were initially grown. However, due to the high level of radioactivity caused mainly by the alpha decay of ^{244}Cm ($t_{1/2}$ = 18.1 years) part of the Am^{3+} was reduced to Am^{2+} and part of the Cm^{3+} was oxidized to Cm^{4+}. It was observed that the ratio of Am^{2+} to Am^{3+} in the cubic sites of CaF_2 was approximately 10:1. The energy level structures of Am^{2+} and Cm^{3+} in CaF_2 were probed and analyzed based on the crystal field model for $5f^7$ configuration (Edelstein *et al.*, 1966; Edelstein and Easley, 1968). A recent study (Beitz *et al.*, 1998) reported that Es^{3+} ($5f^{10}$) can be stabilized in LaF_3 and its spectroscopic properties in terms of free-ion interactions are very similar to Es^{3+} in $LaCl_3$, although a crystal field strength approximately twice of that for Ho^{3+} ($4f^{10}$) in LaF_3 is expected. Although the spectra of several organometallic 3+ actinides, such as plutonium tricyclopentadienide, have been measured, the analysis of data is still quite incomplete (Carnall, 1979b). Nevertheless, it seems apparent that now the energy level parameters for such systems can be approximated by those characteristics of the trivalent actinide in the $LaCl_3$ host.

There have been several recent laser spectroscopic studies on U^{3+} ions in various ternary chloride and bromide crystalline systems. Because of relatively low-phonon energies of lattice vibration, strong luminescence from U^{3+} can be observed in these crystals. Using effective-operator Hamiltonian and parameterization method, Karbowiak and colleagues have analyzed the absorption and emission spectra of U^{3+} in Ba_2YCl_7, $CsCdBr_3$, and Cs_2NaYBr_6, respectively. Both U^{3+} and U^{4+} were observed in the Ba_2YCl_7 system, which possesses monoclinic symmetry. For uranium ions at a C_1 site, a total of 27 crystal field parameters are required to calculate the energy levels (Karbowiak *et al.*, 1997, 2003). Using time-resolved and site-selected laser excitation methods, this group has investigated the spectroscopic and excited state dynamics of U^{3+} in RbY_2Cl_7. The strength of the free-ion and crystal-field interaction in these systems is generally consistent with that for the U^{3+}:$LaCl_3$ systems. A general correlation between the magnitudes of crystal field parameters and the U^{3+} luminescence decay rate has been realized in the analyses of the site-selected spectra and luminescence dynamics.

18.6 INTERPRETATION OF THE OBSERVED SPECTRA OF TETRAVALENT ACTINIDE IONS

It is well known that a major difference between the lanthanide and actinide series is the greater stability of 4+ and higher valance states of the actinides, particularly in the first half of the respective series. There have been numerous analyses of the spectra of tetravalent uranium compounds, whereas the number

of published spectroscopic analyses rapidly decreases as heavier members of the actinide series in the 4+ valence states are considered. The reasons are, first of all, differences in stability of the tetravalent state for actinide compounds are such that reducing and then oxidizing conditions become necessary as the actinide atomic number increases. Secondly, the low specific radioactivity of uranium of natural isotopic abundance makes the doped crystalline materials easy to handle and limits radiolytic degradation. Moreover, the f^2 configuration of U^{4+} provides experimental features that are suitable for theoretical analyses and constitute a useful basis for extending the interpretation of spectra of other An^{4+} ions in condensed media. There is a series of crystalline hosts, notably ThX_4 and Cs_2MX_6 (M = Zr, Th; X = Cl, Br), $ThSiO_4$, and $ZrSiO_4$, in which $Pa^{4+}(5f)$ and $U^{4+}(5f^2)$ can be doped for spectroscopic studies (Krupa, 1987). In addition, Np^{4+}, Pu^{4+}, and Am^{4+} have been successfully doped into $ThSiO_4$ (Krupa *et al.*, 1983; Krupa and Carnall, 1993). However, in contrast to most other binary compounds, the tetravalent actinides as fluorides are sufficiently stable and PaF_4 through CfF_4 can be prepared and are isostructural to UF_4 and CeF_4 (Brown, 1968; Morss, 2005).

Since 1986, significant progress in analyses of the crystal field spectra of tetravalent actinide ions in solids has been reported. The structural characteristic of f→f transitions has been observed and analyzed using the theoretical model of free-ion and crystal-field interactions that was discussed in Sections 18.3 and 18.4. The observations are consistent with trends indicated in Fig. 18.1, which suggest that transitions to the $f^{N-1}d$ configurations in An v will lie even higher in energy relative to the lowest-energy f^N state than in the corresponding transitions for An iv. The lowest f→d transition in the atomic spectrum of U v was assigned at 59 183 cm^{-1} (Van Deurzen *et al.*, 1984). Consequently, broad and intense band structure in the spectra of An^{4+} compounds beginning near 40 000–45 000 cm^{-1} would be consistent with the onset of f→d transitions. The energy level structure of the free-ion U^{4+} ($5f^2$) configuration has provided a valuable basis for comparison in developing the analysis of An^{4+} spectra in solids.

Krupa (1987) reviewed spectroscopic properties of $Pa^{4+}(5f^1)$, $U^{4+}(5f^2)$, and $Np^{4+}(5f^3)$ in crystalline host $ThBr_4$, $ThCl_4$, and $ThSiO_4$. For Pa^{4+} in Cs_2ZrCl_6, electron paramagnetic resonance and near-infrared absorption spectra were measured and the data analyzed by Axe *et al.* (1961) in terms of the crystal-field and spin–orbit interactions for a $5f^1$ electron. Additional optical studies have been reported for pure Pa^{4+} hexahalo compounds and Pa^{4+} diluted into Cs_2ZrCl_6 (Brown *et al.*, 1974, 1976; Edelstein *et al.*, 1974, 1992; Piehler *et al.*, 1991). For this one-electron system, there are no electrostatic terms for the free-ion interactions, thus the splitting of the free-ion energy states, which consist of the $^2F_{5/2}$ ground state and the $^2F_{7/2}$ excited state, is solely due to spin–orbit coupling. Crystal-field splittings in the tetravalent ions are much larger than those of the trivalent ions. Table 18.10 lists the spectroscopic parameters of Pa^{4+} in $ThCl_4$ and $ThBr_4$ in D_{2d} symmetry (Malek and Krupa, 1986; Krupa,

1987). The data for Pa^{4+} in Cs_2ZrCl_6 are considerably better than for the ThX_4 systems. Also some data are given for the excited 6d system.

Analysis of the spectra of U^{4+} in both high-symmetry (O_h) and relatively low-symmetry (D_{2d} and D_2) sites have been published. Somewhat in contrast to observations made with trivalent ions, the magnitude of the crystal-field splitting in the two cases differs significantly. An example of the high-symmetry case is that of U^{4+} in Cs_2UCl_6 (Johnston *et al.*, 1966a,b). The low-symmetry (D_{2d}) case is illustrated in the analysis of U^{4+}:$ThBr_4$ (Delamoye *et al.*, 1983). Recently, spectroscopic analyses were reported by Karbowiak *et al.* (2003) for U^{4+} in Ba_2YCl_7. In this work, values of the 27 crystal field parameters of the Hamiltonian were determined in fitting a total of 60 observed crystal field energy levels to the model Hamiltonian. The crystal-field splitting in the Cs_2UCl_6 is over twice as large as that in U^{4+}:$ThBr_4$. As a result, much more complex structure caused by the mixing of states of different J in close proximity occurs within a given energy range in Cs_2UCl_6 compared to the U^{4+}:$ThBr_4$ case. In the analyses of the crystal field spectrum of U^{4+} on the octahedral sites of Cs_2UBr_6 and Cs_2ZrBr_6, Faucher *et al.* (1996) reported that there is a strong coupling between the $5f^2$ and $5f^17p^1$ configurations. Therefore, additional effective operators for the configuration interaction are necessary to better interpret the observed energy level structure.

The extensive analysis of the data for U^{4+}:$ThBr_4$ and the similar crystal field parameters deduced for Pa^{4+}:$ThCl_4$ (Krupa *et al.*, 1983) have provided a new

basis for examining other An^{4+} spectra. As Auzel and coworkers have shown (Auzel *et al.*, 1982), band intensities in the spectrum of aquated U^{4+} can be assigned in terms of crystal-field split *SLJ* levels similar to those deduced for U^{4+}:$ThBr_4$. Using the method of extrapolation discussed in Sections 18.3 and 18.4, energy level parameters that are consistent with those for Pa^{4+}:$ThCl_4$ and U^{4+}:$ThBr_4$ can be extrapolated to obtain a set for Np^{4+}, and a good correlation is found between this energy level structure and the band structure observed for aquated Np^{4+}. That the apparent correlation between band structure observed for the iso-f-electron configurations of aquated An^{4+} and aquated An^{3+} ions continues along the series is evident when comparing the spectra of aquated Pu^{4+} and aquated Np^{3+}. Jørgensen called attention to this apparent correlation in the band structure observed for the iso-f-electron configurations An^{3+} and An^{4+} spectra at a time when little was known about the extent of the ligand fields involved (Jørgensen, 1959). Concern that the data for aquated An^{4+} should be interpreted in terms of large ligand-field splitting characteristic of Cs_2UCl_6, instead of a weaker-field case may have been partially responsible for the slow pace in exploration of Jørgensen's insight. Of course, development of this An^{3+}/An^{4+} spectral correlation also required an understanding of the energy level structures in An^{3+}, which was not well understood in 1959. Adopting the electrostatic and spin–orbit parameters for U^{4+}:$ThBr_4$ as a basis for estimating parameters for the An^{4+} ions, the general character of the spectra of the An^{4+} ions can be interpreted (Conway, 1964).

In solid compounds such as Cs_2UCl_6, where the 4+ ions occupy sites of inversion symmetry, the observed structure is almost exclusively vibronic in character, as contrasted with the electronic transitions characteristic of 3+ compounds. The electronic origins were deduced from progressions in the vibronic structure, because the electronic transitions themselves were symmetry-forbidden. An analysis of the intensities of vibronic bands has been reported (Satten *et al.*, 1983; Reid and Richardson, 1984). Other extensive analyses of the spectra of U^{4+} in crystalline hosts include those for U^{4+}:$ZrSiO_4$ (Richman *et al.*, 1967; Mackey *et al.*, 1975).

Because of much stronger ion–lattice coupling for the 6d orbitals, in contrast to the 5f−5f transitions in which vibronic coupling is relatively weak, the spectra of 5f↔6d transitions, however, are often dominated by the vibronic bands associated with the f−d electronic transitions in both absorption and emission spectra even when there is no inversion symmetry. The assignment and analyses of the crystal field spectra become difficult, because the pure electronic transitions (ZPL) may be obscured by the broad and intense vibronic sidebands. Fig. 18.11 shows the emission spectrum of the $6d^2D_{3/2}$ (Γ_{8g}) $\rightarrow 5f^2F_{5/2}$ (Γ_{8u}) electronic transition of Pa^{4+}:Cs_2ZrCl_6, with the zero-phonon line at 17 847 cm^{-1} accompanied by various vibronic sidebands (Piehler *et al.*, 1991). From the optical spectra, the vibrational frequencies of different modes can be measured and assigned to the local and lattice modes that couple to the electronic transitions. In the 5f−6d spectra (see Fig. 18.11), and also in charge-transfer spectra

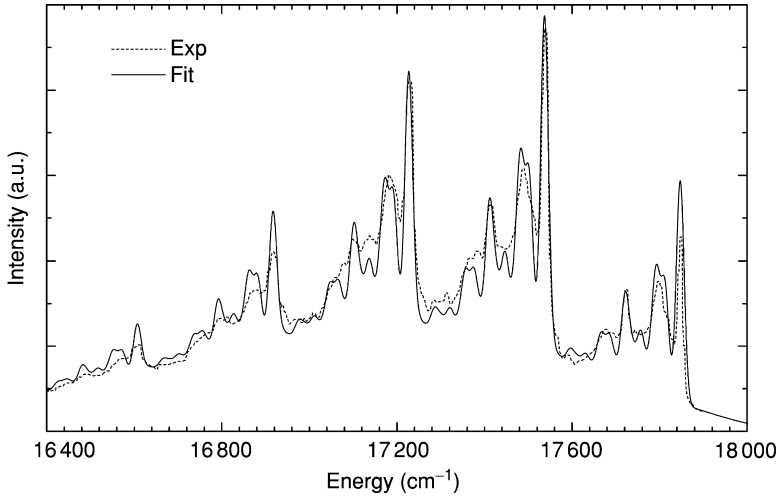

Fig. 18.11 *The emission spectrum of the* $6d^2D_{3/2}(\Gamma_{8g}) \rightarrow 5f^2F_{5/2}(\Gamma_{8u})$*electronic vibronic transitions for* Pa^{4+} *in* Cs_2ZrCl_6 *at* 4.2 K (*experimental data from Piehler* et al., 1991). *The energy of the zero-phonon line of the electronic transition is* 17 847 cm^{-1}. *The vibrational frequencies obtained from fitting the spectrum are* $\nu_1(A_{1g}) = 310$ cm^{-1}, ν_5 $(T_{2g}) = 123$ cm^{-1}, ν_{L1} $(T_{1g}) = 35$ cm^{-1}, *and* ν_{L2} $(T_{2g}) = 55$ cm^{-1}.

(discussed later), certain vibrational progression frequencies have harmonics up to fifth order, whereas others appears only to first order. Liu *et al*. (2002) demonstrated recently that the progressions of multiple vibrational frequencies can be simulated using a modified model of the Huang–Rhys theory of electron–phonon interaction (Huang and Rhys, 1950). The dashed line in Fig. 18.11 is a model fit to the experimental spectrum.

A systematic analysis of crystal field spectra has been reported for tetravalent actinide ions from U^{4+} through Bk^{4+} in AnF_4 and An^{4+}:CeF_4 (Carnall *et al*., 1991; Liu *et al*., 1994b). The tetravalent fluorides were chosen because An^{4+} (An = U to Cf) can be stabilized and they all, including CeF_4, which has no f-electron in the lowest-energy configuration, are isostructural. The absorption spectrum of UF_4 is plotted in Fig. 18.12 in comparison with that of U^{4+} ion in aqueous solution, and the liquid helium temperature absorption spectra of NpF_4 and PuF_4 are shown in Fig. 18.13 (Carnall *et al*., 1991). Crystal structure data for UF_4 established that there are two different low-symmetry sites, C_1 and C_2, for the An^{4+} ion. Both sites have eight nearest neighbor fluorine ions arranged in a slightly distorted antiprismatic configuration; however, there are twice as many C_1 as C_2 sites in the unit cell which aids in identifying sites in the site-resolved spectra. The site-selective excitation spectra of the $^7F_0 - ^5L_6$ transitions are shown in Fig. 18.14 for a 0.1% Cm^{4+}:CeF_4 sample at 4.3 K. Crystal field modeling was conducted based on an approximate C_2 site symmetry. The spectra have similar characteristics as those of An^{3+} ions in crystals

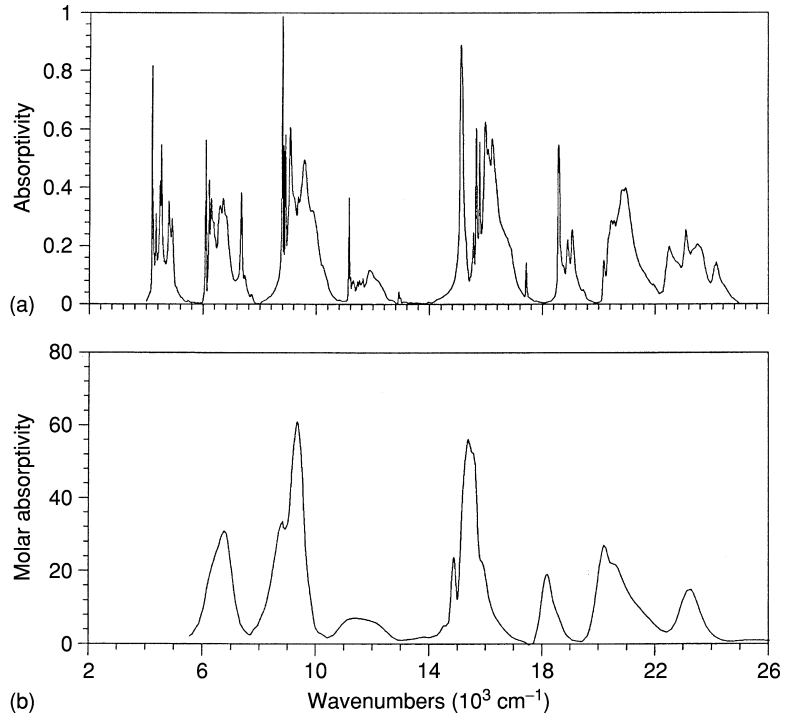

Fig. 18.12 *Absorption spectra of* (*a*) UF_4 *in a KBr pellet at* ~4 K*;* (*b*) *aquated* U^{4+} *at* 298 K *both in the near-infrared to visible range.* (*Reprinted with permission from Carnall* et al., 1991. *Copyright* 1991*, American Institute of Physics.*)

(see Fig. 18.9 for Cm^{3+}:$LuPO_4$). Sharp ZPL are resolved in the low-energy region and broad vibronic transitions that span ~800 cm^{-1} with the strongest features ~400 cm^{-1} above the first ZPL are also found. The vibronic lines in the An^{4+} spectra are relatively stronger than those in An^{3+} spectra. This suggests a stronger ion–ligand coupling for tetravalent ions, which is consistent with the larger crystal-field splittings in the An^{4+} systems.

Optical spectroscopic data, including low-temperature absorption (see Figs. 18.12 and 18.13) and laser excitation and luminescence spectra of tetravalent actinides in fluoride compounds, have provided adequate experimental information for a systematic analysis and parameterization of the free-ion and crystal-field interactions. The Hamiltonian of the free-ion and crystal-field interactions has been established through the same parameterization method used for the trivalent ions that was discussed in Section 18.5. The Hamiltonian parameters for An^{4+} in CeF_4 are listed in Table 18.11. The parameterization method ensures a consistent set of free-ion and crystal field parameters from one ion to the next. Given the limited number of energy levels that could be assigned

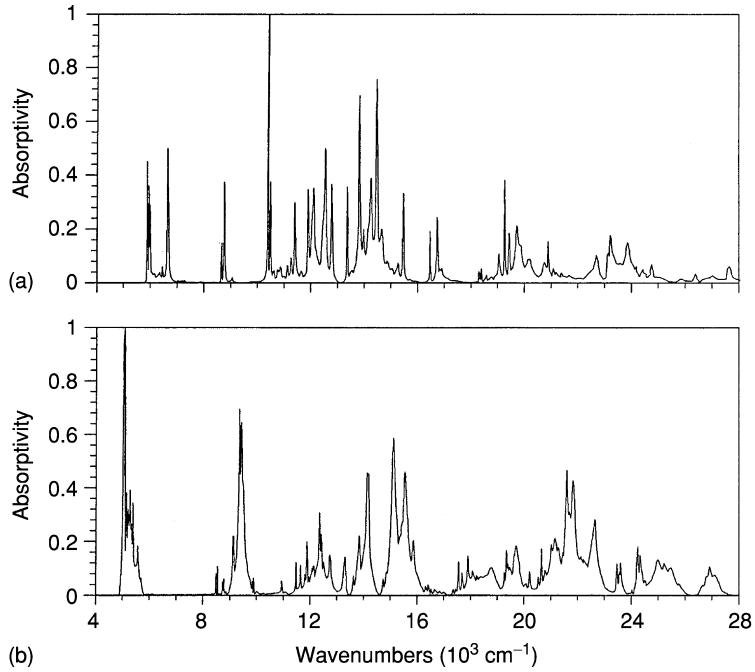

Fig. 18.13 *Absorption spectra of* (*a*) NpF_4 *in a KBr pellet at* ~4 K*;* (*b*) PuF_4 *in KBr pellet at* ~4 K *in the range* 4000–30 000 cm^{-1}. (*Reprinted with permission from Carnall* et al., 1991. *Copyright* 1991, *American Institute of Physics.*)

without ambiguity, the observed spectra of AnF_4 were modeled based on the standard model crystal field with constrained parameters. For instance, the three-body parameters T^i were fixed at average values determined in the analysis of An^{3+}:$LaCl_3$ spectra (Carnall, 1992). The M^h values were assigned in each case based on *ab initio* calculations and were not varied. Although P^2 was varied, in all cases P^4 and P^6 were constrained by the ratios $P^4 = 0.5P^2$ and $P^6 = 0.1P^2$. In fitting experimental data, the modeling, therefore, relied on the systematic variations of F^k and ζ_{5f}. In UF_4, it was pointed out that the magnitude of the crystal-field interaction was relatively large, and *J*-mixing was very significant in higher energy states, the ground crystal field state remained more than 95% pure in terms of *J*-character. Although the excited states above 50 000 cm^{-1} were truncated in the construction of the free-ion wave functions for Pu^{4+}, Am^{4+}, Cm^{4+}, and Bk^{4+}, the ground state eigenfunctions had relatively pure *J*-character, fully consistent with the results for U^{4+} and Np^{4+}. The nominal $^6H_{5/2}$ ground state in Am^{4+} is more than 96% $J = 5/2$, whereas the $^7F_0$ ground state in Cm^{4+} is more than 98% $J = 0$ character. Thus the experimental problem of interpreting magnetic susceptibility measurements in CmF_4 where temperature-dependent results are not consistent with a $J = 0$ ground state (Nave

et al., 1983) seems unlikely to be rationalized by assuming appreciable *J*-mixing. For Bk^{4+}, the $J = 0$ character is more than 99.5%, but the contribution from the pure $^8S_{7/2}$ is reduced to 75.5% (Brito and Liu, 2000).

Systematic analysis of the free-ion and crystal-field interactions in AnF_4 (An = U–Bk) provides a useful comparison of the trends in free-ion parameter values between those that would have been expected based on parameters computed using *ab initio* methods and those obtained from fitting the experimental data. As shown in Fig. 18.15, when plotted as a function of atomic number, the model free-ion parameters for An^{4+} exhibit similar increasing trends as those predicted by Hartree–Fock calculations. However, the normalized Hartree–Fock-based values of F^k were typically found to show a steeper slope than those obtained in fitting the experimental data.

It has been shown that a significant change in the ratios of F^4/F^2 and F^6/F^2 from U^{4+} to Np^{4+} is required to fit the experimental data (Carnall *et al.*, 1991; Liu *et al.*, 1994b). However, in the analysis of the transneptunium ions, the ratios of F^4/F^2 and F^6/F^2 could be held constant. In this context, values of F^2

All values are normalized to those for NpF_4.* (*Reprinted with permission from Liu* et al., 1994a,b. *Copyright* 1994, *American Institute of Physics.*)

for all the ions studied exhibited a functional (but not linear) increase with atomic number. It is important to note that the values of F^2 for all transneptunium members of the AnF_4 series would be poorly estimated based solely on linear projections from U^{4+} or Np^{4+}. Similar to the An^{3+} series, a regular behavior appears to be characteristic of the transneptunium actinide tetrafluorides. The computed values of ζ_{5f} from fitting the experimental data are generally quite consistent with *ab initio* values normalized to agree with the empirical value for NpF_4. In comparison to the An^{3+} series, the slope found for the variation of F^k for An^{4+} as a function of atomic number is reduced. This is particularly evident for F^2 in Fig. 18.15 and provides the rationale for increasingly similar energies found in the lower energy free-ion states of iso-f-electron An^{3+} and An^{4+} spectra as a function of increasing atomic number.

The parametric free-ion electrostatic interaction parameters F^k for UF_4 and NpF_4 are a few percent larger than those that have been determined by fitting spectroscopic data for the tetravalent chlorides and bromides listed in Table 18.10, and those for UF_4 are smaller than the gaseous free-ion values for UV

(Van Deurzen *et al.*, 1984), as expected. Indeed all the free-ion parameter values used in the analysis of AnF_4 spectra are fully consistent with those available from other analysis of An^{4+} spectra in a variety of crystal environments (Krupa, 1987).

For tetravalent actinide ions, it is useful to emphasize that the crystal field is no longer a small interaction relative to that of the free ion, but is capable of radically transforming the energy level scheme without any change in magnitude in the free-ion interaction parameters. This is readily evident in comparing the parameters and energy level schemes for UCl_4 and Cs_2UCl_6. One of the consequences of this change in the hierarchy of interactions that comprise the theoretical model is that there is a decreased sensitivity in energy level structure calculations to the values of the F^k integrals in the analysis of An^{4+} compared to An^{3+} and Ln^{3+} spectra. This is a direct result of the stronger crystal-field and spin–orbit interactions. Recognition of this fact is important because it explains the relatively uncertain F^k values obtained from fitting experimental data. In most cases, very few free-ion states are actually included in the calculation. Indeed, those states that are included tend to be the lowest-energy states in the configuration and to exhibit the smallest J-mixing that would aid in defining the parameters.

Most of the experimental data from absorption spectra include contributions from An^{4+} ions on two crystallographic sites. One of the basic aspects of modeling the AnF_4 crystal field spectra is the reliance, not only on the results of a model calculation of the crystal field parameters in the actual C_2 symmetry, but also the assumption that for purposes of interpreting the observed energy level structure, it is possible to use an approximate C_{2v} symmetry. It was shown that the predictions that were made as a result of this approximation could be directly related to the observed structure and were consistent with the few available measurements that had been obtained independently. In fact, as shown in Table 18.11, very little change in crystal field parameter values over the series was required. This again confirms the arguments in Section 18.4.3 on using the descent-of-symmetry method to simplify the analysis of crystal field spectra of lanthanide and actinide ions in crystals of low symmetry.

In the history of f-element spectroscopy, theoretical interpretations of the crystal-field splitting of the $^8S_{7/2}$ ground state in a half-filled shell of the f^7 configuration have been contradictory. The lanthanides in such a configuration are Eu^{2+}, Gd^{3+}, and Tb^{4+}; and the actinide ions include Am^{2+}, Cm^{3+}, and Bk^{4+}. Early arguments were focused on the Gd^{3+} ion because the ground state crystal-field splitting observed in EPR experiments was less than 0.5 cm^{-1} (Hubert *et al.*, 1985) and could not be interpreted by the crystal field theory. A series of mechanisms were considered but failed to provide a consistent interpretation (Wybourne, 1966; Newman, 1970, 1975). However, the $^8S_{7/2}$ ground-state splittings in the actinide ions is much larger than that of the Gd^{3+}. For Am^{2+} and Cm^{3+}, the observed splitting varies from 2 to 20 cm^{-1}

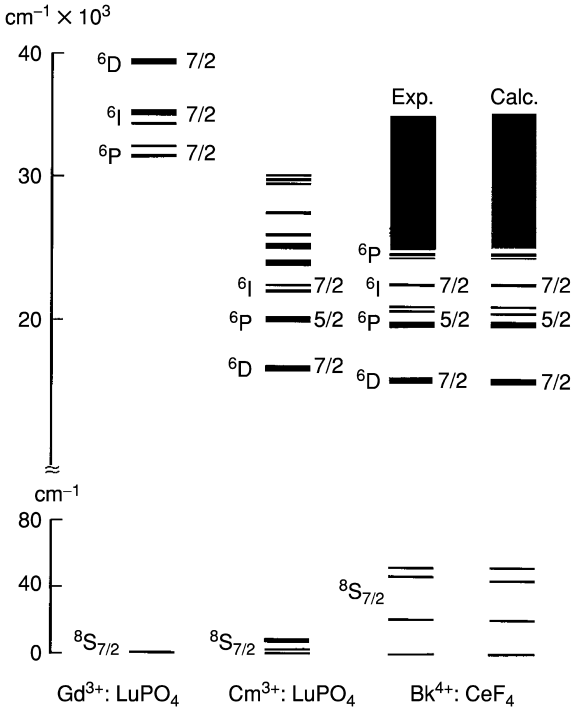

Fig. 18.16 *Partial energy level diagrams of Gd^{3+}, Cm^{3+}, and Bk^{4+} based on computed and experimental crystal field energies.* (*Reprinted with permission from Brito and Liu,* 2000. *Copyright* 2000, *American Institute of Physics.*)

(Edelstein and Easley, 1968; Liu *et al.*, 1993; Murdoch *et al.*, 1996; Edelstein, 2002), while for Bk^{4+} it is on the order of 60 cm^{-1} (Liu *et al.*, 1994b; Brito and Liu, 2000).

As a summary of previous work on the $5f^7$ ion, a comparison of the crystal-field splittings of Gd^{3+}, Cm^{3+}, and Bk^{4+} ions including the ground-state splitting is shown in Fig. 18.16. For the $5f^7$ systems, no additional mechanisms other than the crystal-field interaction are needed to provide a satisfactory interpretation to the observed splitting in the $^8S_{7/2}$ ground state of actinide ions (Liu *et al.*, 1993; Brito and Liu, 2000). As indicated in Section 18.4.2, the observed crystal-field splittings must be attributed to the contributions of the mixture of other *LS* terms into the ground state free-ion wave function (see equation (18.39)) and nonzero off-diagonal matrix elements between different *J*-multiplets. Because of the large energy gaps from the ground state to the excited multiplets of Gd^{3+}, the excited state *LS* components in the ground state is small, and *J*-mixing is also negligible in this case. However, for the actinide ions in $5f^N$ configurations, as discussed in Section 18.3, the ground-state wave

functions contains considerable *LS* components of the excited states, and thus lead to much larger splittings that should not occur for a pure *S*-state.

18.7 SPECTRA AND ELECTRONIC STRUCTURE OF DIVALENT ACTINIDE IONS AND ACTINIDES IN VALENCE STATES HIGHER THAN 4+

Although spectra of actinide compounds and solutions exhibiting other than the 3+ and 4+ valence states are well known, systematic analyses of the electronic structure in other valence states are very tentative now. Extensive analysis is limited to a few isolated cases. However, tabulations of electrostatic (Varga *et al.*, 1970) and spin–orbit integrals (Lewis *et al.*, 1970), computed using *ab initio* methods, have been published, and the relative energies of electronic configurations occurring within the usual spectral range of interest to chemists have been estimated from free-ion spectra (Brewer, 1971a,b).

The electrostatic and spin–orbit interactions in any given valence state are expected to vary systematically across the series. However, in the trivalent and tetravalent series it was necessary to introduce effective operators to explicitly screen the effects of configuration interaction to obtain good correlation with the experiment. In the absence of these correction terms, the values of the Slater integrals obtained in fitting the data exhibited a much more erratic behavior when plotted as a function of Z. In the discussion of 2+ and high valent actinides, it should be noted that the role of second-order correction terms has not been studied in detail for these oxidation states. What is clear is that the importance of both spin–orbit coupling and crystal-field interactions relative to the electrostatic interaction increases with increasing valence.

One of the reasons for introducing the theoretical interpretation of trivalent and tetravalent spectra in some detail was to provide the basis for discussing models appropriate to other valence states. Although detailed models have yet to be constructed, and may lead to revision of some of the values given here, it is advantageous to introduce a generalizing element into the discussion and relate available spectra to this central theme rather than approach each different actinide ion as a unique entity.

It has been realized for An^{2+} that the interactions appear to be of the same relative magnitude as for An^{3+}; however for An^{4+} and An^{5+} the crystal-field interaction becomes, relatively, much more important, and extraction of well-defined parameters for the free-ion and crystal-field interactions becomes more difficult. In An^{3+} spectra, the correction terms H_{corr} act mainly on the electrostatic part of the free-ion Hamiltonian, although some provision for second-order magnetic effects are included. In this discussion it is assumed that it is not necessary to modify the magnitudes of the terms associated with H_{corr} in treating other valence states. Since the crystal-field splitting is computed using a single-particle model, corrections to E_{cf} may be required as the relative magnitude of the crystal field increases.

In early attempts to develop a systematic interpretation of trivalent actinide and lanthanide spectra, initial sets of F^k and ζ_{nf} for some members of the series had to be estimated. This was done by linear extrapolation based on the fitted parameters that were available from the analyses of other individual spectra. As more extensive data and improved modeling yielded better determined and more consistent F^k and ζ_{nf} values for the 3+ actinides (and lanthanides), it became apparent that the variation in the parameters was nonlinear, as indicated for F^2 (5f,5f) in Fig. 18.4. This nonlinearity could also be observed in the values of parameters obtained from the *ab initio* calculations. The difference between the *ab initio* and fitted values of parameters (ΔP) appears to exhibit a much more linear variation with Z than do the parameter values. Consequently, ΔP has been adopted as the basis for a useful predictive model (Carnall *et al.*, 1966; Crosswhite, 1977; Crosswhite and Crosswhite, 1984).

For the trivalent actinides the values of ΔP are not constant over the series, but use of a single average value over a group of four or five elements is not an unreasonable approximation. Thus, in developing a predictive model for the F^k and ζ_{nf} parameters, an attempt is made to establish average values of ΔP for a particular valence state and type of crystal-field interaction. The energy level structure computation based on the predicted parameters can be compared to that observed, and then appropriate modifications sought by a fitting procedure where necessary.

18.7.1 Divalent actinide-ion spectra

Efforts to prepare divalent actinide compounds and analyze their spectra have been less successful than was the case for lanthanides, where the divalent ion for each member of the series could be stabilized in CaF_2 (McClure and Kiss, 1963). In both Am^{2+}:CaF_2 and Es^{2+}:CaF_2 (Edelstein *et al.*, 1966, 1967, 1970; Baybarz *et al.*, 1972), intense absorption bands were observed. These bands could be attributed to either f→d or charge-transfer transitions. The presence of divalent actinide ions in these cases was established by measurements of the electron paramagnetic resonance spectra, not on the basis of the observed optical spectra. In contrast to the more intense absorption bands reported for Es^{2+}:CaF_2, weak absorption bands consistent with the intensities expected for f→f transitions were identified in the 10 000–20 000 cm^{-1} region in both $EsCl_2$ and Es^{2+}:$LaCl_3$ (Fellows *et al.*, 1978). The relatively narrow band structure exhibited by the Es^{2+} halides was also found to be characteristic of the Cf^{2+} halides (Peterson *et al.*, 1977; Wild *et al.*, 1978).

Although it was not possible to stabilize Cm^{2+} in CaF_2 under the same conditions that yielded for Am^{2+}:CaF_2, evidence for the formation of both Am^{2+} and Cm^{2+} has been obtained in solution in pulse radiolysis studies; however, as in the spectrum of Am^{2+}:CaF_2, the absorption bands were broad and intense. The nature of the absorption process is therefore not clear. A charge-transfer process cannot be excluded (Sullivan *et al.*, 1976).

Because the available spectroscopic results for divalent actinides are fragmentary, a consistent interpretation that accounts for all observations and predicts the energies of other bands that might be accessible to observation will be adopted. The basic aspects of this tentative model can be deduced in part from available data for divalent lanthanide spectra.

The free-ion spectra of Ce III and Pr IV are known. Initial estimates of F^k and ζ_{4f} values appropriate to Ln^{2+} in condensed phases can be made by assuming that the change observed in these parameters for iso-f-electron couples such as Ce III/Pr IV (both $4f^2$) will also be characteristic of the couple Ce^{2+}/Pr^{3+} in condensed phases. This suggests a reduction of 20–30% in comparing values of F^k and ζ_{4f} for divalent compared to isoelectronic trivalent-ion cases. Comparing the results for Eu^{2+}:CaF_2 (Downer *et al.*, 1983) with those for Gd^{3+}:LaF_3 (Carnall *et al.*, 1971), the parameters for Eu^{2+} ($4f^7$) are 82–86% of those for Gd^{3+} ($4f^7$). The little information available on divalent lanthanide ion crystal-field splitting (Dieke, 1968) suggests that the crystal-field interaction is even smaller than for the trivalent case. This also was suggested in an analysis of Eu^{2+} in strontium fluoride (Downer *et al.*, 1983).

Based on the small crystal-field splitting indicated for the divalent lanthanides, it is reasonable to assume as a first-order approximation that the corresponding actinide crystal-field splitting will be small. Although fragmentary, available spectroscopic data for An^{2+} appear to be consistent with this estimate. The initial model can consequently be limited to free-ion considerations. The initial F^k and ζ_{5f} parameters for An^{2+} may be estimated to be 85–90% of those for the iso-f-electronic An^{3+}:$LaCl_3$ ion. The effects of configuration interaction for An^{2+} can be taken to approximate those for An^{3+}. The resulting model energy level schemes for An^{2+} are plotted in Fig. 18.17 where the overlap of the $5f^{N-1}6d$ and $5f^N$ configurations is also indicated (Brewer, 1971a,b).

Examining the range of energies in which f→f transitions might be observed, it is seen from the figure that the largest 'optical windows' are expected in Am^{2+}, Cf^{2+}, and Es^{2+}. In Np^{2+}, Pu^{2+}, Cm^{2+}, and Bk^{2+}, it is probable that f→f transitions will only be observed in the infrared range. This of course assumes that the $5f^N$ is consistently the ground state configuration. Transitions resulting from the promotion of f→d would be expected to result in intense (allowed) absorption bands such as those observed in Ln^{2+} spectra (McClure and Kiss, 1963). The much weaker f→f transitions occurring in the same energy range as the allowed transitions would be masked, so the optical window corresponding to the pure f→f energy spectrum will be somewhat smaller than that for the gaseous free-ion f→d transition energies indicated in Fig. 18.17 (Brewer, 1971a,b). The computed level structure for Cf^{2+} and Es^{2+} agree with the experimental results, but indicate the existence of bands not yet reported.

Systematic energy level calculations are of considerable importance in predicting the energies at which luminescence might be observed. In general, the longest-lived luminescence will originate from the state with the largest energy gap between it and the next lower-energy state. Based on the computed large

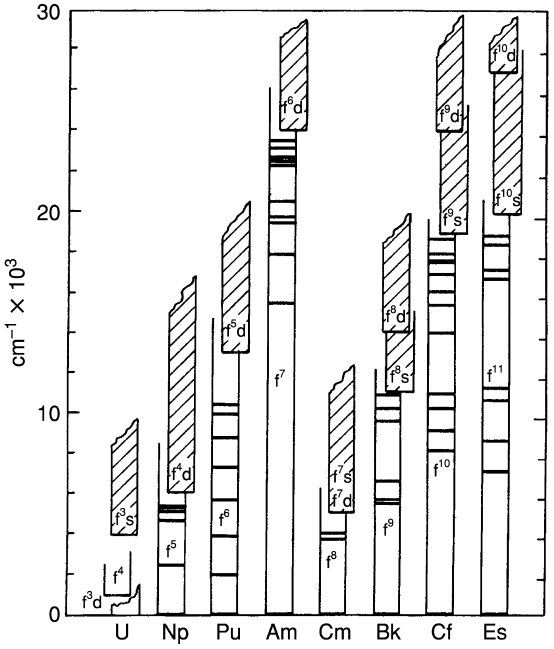

Fig. 18.17 *Estimated ranges of energies in which 5f–5f transitions in An^{2+} may be experimentally observed.*

energy gap between the ground ($^8S_{7/2}$) and first excited ($^6P_{7/2}$) states in Am^{2+} ($5f^7$), isolated Am^{2+} sites would be expected to exhibit luminescence near 14 000 cm^{-1} (Edelstein *et al.*, 1966; Edelstein and Easley, 1968; Edelstein, 1991).

18.7.2 Spectra of actinide ions in the pentavalent and hexavalent states

The actinide ions with well-defined valence states greater than VI are confined to the light half of the 5f series. A large number of stable compounds are known, and spectra have been recorded in solution, in solids, and in gas phase. However, there have been relatively few attempts to develop detailed energy level analyses. Although Hartree–Fock type calculations of F^k and ζ_{nf} can be carried out for any arbitrary state of ionization of an actinide ion, the relative importance of the ligand (or crystal) field must also be established to develop a correlation for experimentally observed transition energies. *Ab initio* models of the ligand field are characteristically very crude. The spectra of penta- and higher-valent actinides are strong crystal field cases and the development of correction terms for first-order crystal field model may well be essential to any detailed analysis.

Two types of ionic structure are normally encountered in the higher-valent species: the actinyl ions AnO_2^+ and AnO_2^{2+} (Denning, 1992; Matsika and Pitzer,

2001; Denning *et al.*, 2002), and halides such as UCl_5, $CsUF_6$, and PuF_6. Mixed oxohalide complexes are also known. In the actinyl ions (An = U, Np, Pu, Am) the axial field imposed by the two nearest-neighbor (−y1) oxygen atoms plays a dominant role in determining the observed energy level structure (Eisenstein and Pryce, 1966; Bell, 1969). The analysis of spectra of higher-valent actinide halides is also based on a strong ligand-field interaction, but the symmetry is frequently found to be octahedral or distorted octahedral (Goodman and Fred, 1959; Eisenstein and Pryce, 1960; Kugel *et al.*, 1976; Eichberger and Lux, 1980). Typical iso-f-electronic penta- and higher-valent actinide species are shown in Table 18.12, where X is a halide ion.

Aqueous solution spectra characteristic of the NpO_2^+ and PuO_2^{2+} ions, both having the $5f^2$ electronic structure, are shown in Fig. 18.18. Some qualitative similarities in band patterns for these iso-f-electronic ions appear to exist, but detailed analysis of the observed structure in terms of a predictive model is tentative. Charge-transfer bands for NpO_2^{2+} (20 800 cm^{-1}), PuO_2^{2+} (19 000 cm^{-1}), and AmO_2^{2+} (∼18 000 cm^{-1}) have been identified (Jørgensen, 1970). Spectra of the actinyl ions and the molar absorptivities of the more intense bands in aqueous solution have been tabulated (Carnall, 1973, 1982). The charge-transfer transitions in crystalline $CsNpO_2Cl_4$ and $CsNpO_2(NO_3)$ as reported by Denning *et al.* (1982) are apparently much lower than that predicted for NpO_2^{2+} (20 800 cm^{-1}). In their analysis, Denning *et al.* (1982) assigned five charge-transfer bands of $CsNpO_2Cl_4$ and $CsNpO_2(NO_3)$ between 13 000 and 20 000 cm^{-1}.

Attempts to interpret the spectra of the penta- and hexahalides of the actinides have used the effective-operator Hamiltonian discussed in Sections 18.3 and 18.4. However, the results are limited primarily to U^{5+} and Np^{6+}, both having the $5f^1$ configuration and Np^{5+} and Pu^{6+} with the $5f^2$ configuration. The magnitude of the spin–orbit interaction is known for U v. Its free-ion spectrum has been interpreted in terms of a coupling constant, $\zeta_{5f} = 2173.9$ cm^{-1}, based on a $^2F_{5/2} \rightarrow {}^2F_{7/2}$ energy difference of 7608.6 cm^{-1} (Kaufman and Radziemski, 1976). The optical properties of Np and Pu ions and compounds were analyzed by Edelstein (1992). The spectra of several complex pentavalent uranium halide

compounds appear in the literature and, based on representative crystallographic determinations, the site symmetry usually is close to octahedral. The combined effect of the spin–orbit and octahedral ligand-field interactions is to split the parent ^2F state into five components whose irreducible double group labels are indicated in Fig. 18.19.

The energy level structures of several actinide 4+, 5+, and 6+ compounds with the $5f^1$ ion at a site of octahedral (or approximated as octahedral) symmetry are compared in Table 18.13. As indicated in Table 18.13, there has been considerable variation in the ligand field parameters deduced by different investigators from absorption spectra in which the energies of observed features are surprisingly consistent. The case of UCl_5, which has a dimeric structure that gives rise to approximately octahedral U^{5+} sites, is particularly interesting because the spectra of solutions (UCl_5 in $SOCl_2$) (Karraker, 1964), of a single crystal (Leung and Poon, 1977), and of the vapor phase, $(UCl_5)_2$ or $UCl_5 \cdot AlCl_3$ (Gruen and McBeth, 1969), all give absorption features that are similar to both the relative intensities of the transitions and their energies. The importance of the nearest-neighbor coordination sphere in determining the spectra, essential

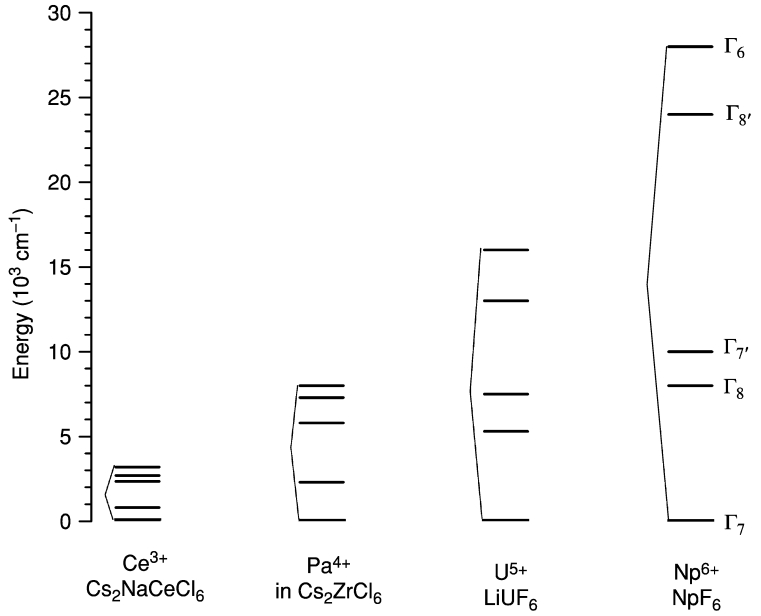

Fig. 18.19 *Comparison of crystal-field splittings of the $5f^1$ states of actinide ions in various hosts.*

to the exclusion of the effects of long-range order, is consistent with the behavior expected for strong octahedral bonding. However, more evidence is needed to justify the assignments and to establish uniquely the limits over which the ligand field parameters may vary.

The spectra of $CsUF_6$ (Reisfeld and Crosby, 1965) and $CsNpF_6$ (Hecht *et al.*, 1979) have been reported and analyzed, and that of $CsPuF_6$ has been measured (Morss *et al.*, 1983). However, the treatment of $CsUF_6$, which has been considered to be a model for other cases of distorted octahedral symmetry, has been questioned both experimentally (Ryan, 1971) and on theoretical grounds. Both Leung (1977) and Soulie (1978) have pointed out that there is actually a very significant distortion of the O_h symmetry originally assumed for $CsUF_6$ (Reisfeld and Crosby, 1965), with D_{3d} symmetry providing the basis for a much improved interpretation. If electrostatic interaction parameters of the same order of magnitude as those suggested by Poon and Newman (1982) are utilized for $CsNpF_6$, together with the D_{3d} ligand field parameters for $CsUF_6$, and further extrapolation of these results is carried out to provide values for the $CsPuF_6$ case, the resulting energy level structure is that indicated in Fig. 18.20. The general aspects of this predicted structure appear to be consistent with available experimental data. Aside from the structure of the ground state, a relatively isolated $^3F_2$ state in $CsNpF_6$ should be observed. However, with the

exception of this $^3F_2$ state, neither the spectrum of $CsNpF_6$ nor that of $CsPuF_6$ is expected to exhibit any extensive, easily recognizable band structure. A relatively high density of excited states is predicted and detailed analysis will be difficult.

The actinide hexafluorides, UF_6, NpF_6, and PuF_6, form a unique group of volatile actinide molecular species. They are not regarded as strongly bonded since the metal–fluorine distances tend to be rather large (~1.98 Å) (Claassen, 1959). The combination of well-characterized spectroscopic and magnetic (Goodman and Fred, 1959; Hutchison and Weinstock, 1960; Edelstein, 1992) results for NpF_6 and PuF_6 has served to establish a reasonable basis for the energy level analysis in octahedral symmetry summarized in Table 18.13. A consistent set of F^k and ζ_{5f} parameters can be combined with the crystal field for NpF_6 to yield an estimate of the parameters set for PuF_6 and AmF_6. However, in terms of the free-ion interaction parameters, no consistent results have been

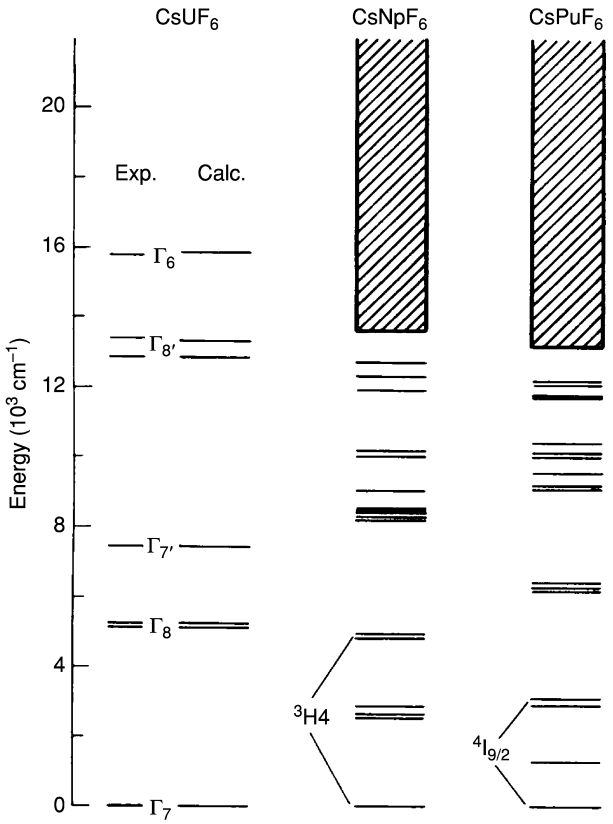

Fig. 18.20 *Computed energy levels schemes for $CsUF_6$, $CsNpF_6$, and $CsPuF_6$. The cross-hatched areas indicate that a relative dense energy structure is predicted.*

achieved when the parameters are varied in fitting of the observed energy levels of PuF_6 (Edelstein, 1992). As listed in Table 18.13, the value of F^2 for PuF_6 is reduced by greater than 50% from its Hartree–Fock value and F^4 is greater than the calculated Hartree–Fock value (Wadt, 1987). In comparison with Hartree–Fock values and the parameters for NpF_6, the empirical values for F^6 and ζ seem to be of reasonable magnitude. The energies of some of the lower-lying states in NpF_6 and PuF_6 are shown in Fig. 18.21. The two upper levels of NpF_6 at 23 500 and 28 000 cm^{-1} were not well resolved in absorption spectra (Steindler and Gerding, 1966) and the uncertainty in assigning these two levels could result in uncertainties in the spin–orbit and crystal field parameters. The indicated structure is consistent with the principal features in the absorption spectrum of PuF_6 (Kugel *et al.*, 1976) as shown in Fig. 18.22. Detection of luminescence in the selective excitation of NpF_6 and PuF_6 and at energies in

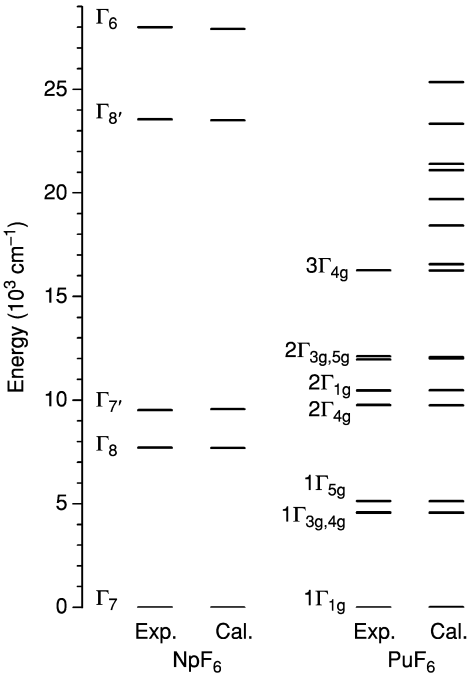

Fig. 18.21 *Comparison of observed and computed energy level schemes for NpF_6 (data from Goodman and Fred,* 1959) *and PuF_6 (data from Edelstein,* 1992). *Analysis of near-infrared spectra of matrix-isolated NpF_6 was also reported* (*Mulford* et al., 1991)

agreement with the energy gaps between the predicted ground and first excited states in both spectra has been reported (Beitz *et al.*, 1982).

18.7.3 Charge-transfer transitions and structure of actinyl ions

In addition to electronic transitions from $5f^N$ to excited configurations, an electron may be excited from a ligand to a 5f orbital, creating a charge-transfer state, with a configuration consisting of $5f^{N+1}$ plus a ligand 'hole'. The spectra of UO_2^{2+}, UF_6, and Np^{7+} shows typical charge-transfer transitions for the actinide series since, in contrast to the transitions between states within the $5f^N$ configuration which characterize most of the actinide spectra discussed in previous sections; the above species contain no f-electrons in open shells. The energies of these states are highly ligand-dependent and, especially in organic systems, they can be at a lower energy than the $5f^{N-1}6d$ states. For lighter actinide ions in oxygen environments, actinyl ions are formed through charge-transfer bonding (Jørgensen, 1957). The most extensive studies of ion-to-ligand charge transfer have been conducted on uranyl (UO_2^{2+}) ion in various solutions and compounds (Denning *et al.*, 1982, 2002; Denning, 1992). Fig. 18.23 shows

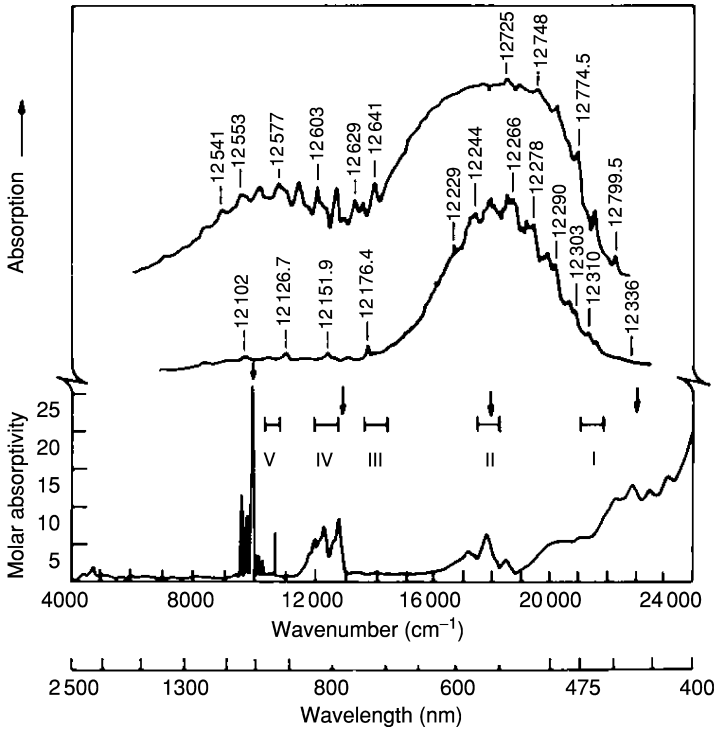

Fig. 18.22 *The absorption spectrum of PuF_6. Arrows indicate regions reported to show vibrational structure. Bars indicate regions examined by intra-cavity laser absorption:* I, 455–470; II, 550–574; III, 697–729; IV, 786–845; V, 918–971 nm. *At the top is a densitometer trace of the high-resolution absorption spectrum of PuF_6 in the* 781–830 nm *region obtained in multipass experiments. Data from Kugel* et al. (1976).

the energy level structure of UO_2^{2+} charge-transfer states in comparison with that of the U^{6+} and O^{2-} ions. The lowest-energy level of the excited charge-transfer states starts at (20 000 cm^{-1} for uranyl ion and at (14 000 cm^{-1} for neptunyl ion (NpO_2^{2+}), which is below the energy levels of several 5f states of the Np^{6+} core (Denning *et al.*, 1982, 2002). In the neptunyl case, energy levels of different origins, namely $5f^N$, $5f^{N-1}6d$, and ion–ligand charge transfer, may overlap in the same energy region, and thus make spectrum analysis difficult. Emission from charge-transfer states of actinide ions in condensed phase is relatively rare except for the case of uranyl (UO_2^{2+}) ions, which often exhibit a strong luminescence in solution. This is because of the large energy gap between its ground and excited charge-transfer states that suppresses quenching due to nonradiative phonon relaxation (Riseberg and Moos, 1968).

The spectra of UO_2^{2+} compounds with a characteristic structure in the visible–ultraviolet range below 400 nm are commonly observed charge-transfer

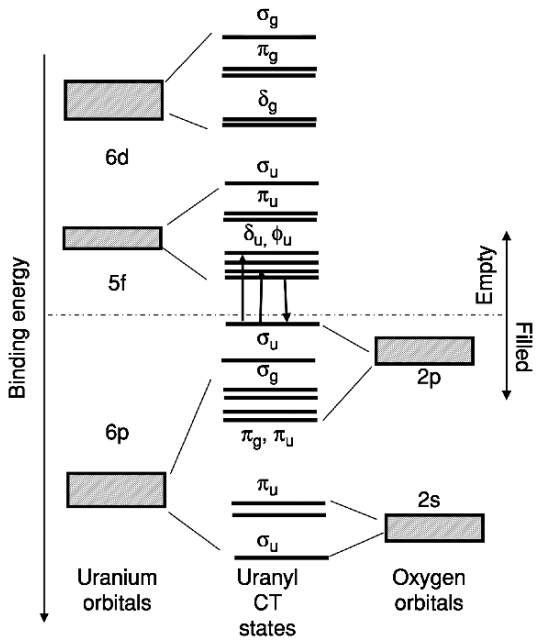

Fig. 18.23 *Illustration of electronic energy level scheme of uranyl ion* UO_2^{2+}.

transitions in the actinide series. Analyses of crystal spectra such as that for $Cs_2UO_2Cl_4$ are now available (Denning *et al.*, 1980, 1982; Denning, 1992). Because of the energy gap between the emitting and ground states as shown in Fig. 18.23 is much larger than the vibration energies, in many cases including uranyl species in solutions, fluorescence emission is often the dominant channel of relaxation from the lowest level of the excited charge-transfer states. Fig. 18.24(a) shows the fluorescence spectrum of $UO_2Cl_4^{2-}$:Cs_2ZrCl_6 single crystal at 20 K (Metcalf *et al.*, 1995). The ZPL is accompanied by a progression of vibronic lines due to the O–U–O stretching and bending modes, which characterize the uranyl structure and are relatively insensitive to the environment of the uranyl ion in the equatorial plane. Usually, the linear dioxo cation O–U–O is coordinated by an additional four to six ligand ions in its equatorial plane. The vibrational frequencies of different modes of the complexed ion can be determined directly from the spectrum. They are typically 820, 900, and 240 cm^{-1} for the symmetric, asymmetric, and bending modes of the UO_2^{2+} ion, respectively. As to the nature of the uranyl bonding, variation of the vibrational frequencies is correlated with the energy levels of the charge-transfer states (Denning, 1992). The spectrum of the uranyl ion in single crystals of $UO_2Cl_4^{2-}$:Cs_2ZrCl_6 exhibits extremely sharp line widths, indicating that the uranyl ions in the crystal have highly identical local structure so that

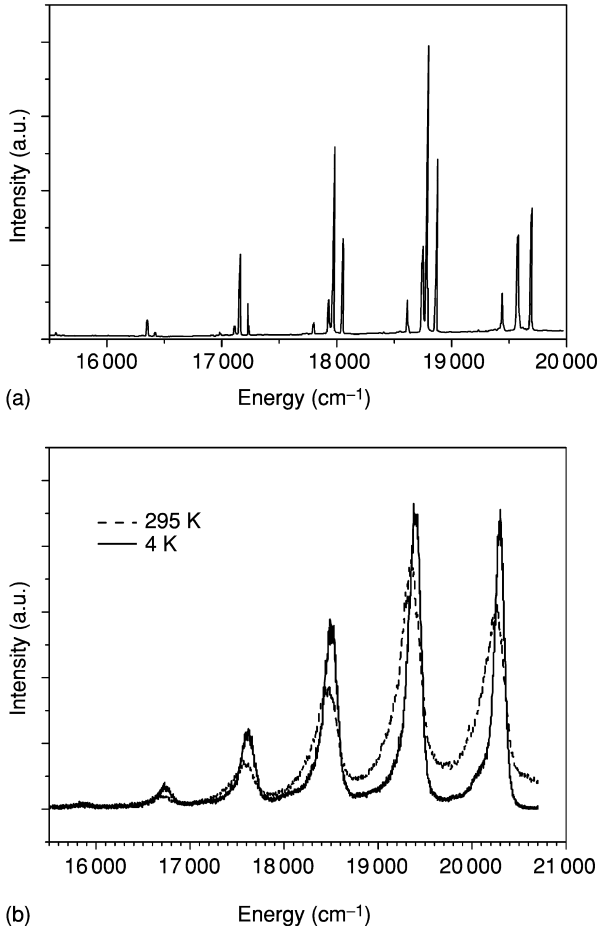

Fig. 18.24 *Spectra of uranyl charge-transfer vibronic transitions:* (*a*) *fluorescence spectrum of* UO_2^{2+} in Cs_2ZrCl_6 *at* 20 K (*data from Metcalf* et al., 1995) *and* (*b*) *fluorescence spectra of* UO_2^{2+} *in* B_2O_3 *glass at* 4 *and* 295 K.

inhomogeneous line broadening induced by structure defects is not significant. If structure variation and impurity phases exist, inhomogeneous line broadening would obscure the features due to different vibrational modes. Fig. 18.24(b) shows the emission spectra of uranyl in B_2O_3 glass matrix at 4 and 295 K. In comparison with Fig. 18.24(a), the lines become much broader, whereas the changes in the overall spectral profile and line locations are insignificant. Given the nature of charge-transfer states, it is apparent that the energy levels of charge-transfer states are more sensitive to local structure disordering than that of the 5f−5f transitions. Therefore, in structurally disordered environments such as glasses and solutions, inhomogeneous line broadening obscures

observation of separated lines of the asymmetric and bending modes. Only the progression of the symmetric mode, up to five quanta of phonon sidebands, is often observed. Based on the theory of ion–phonon interaction (Huang and Rhys, 1950), the spectra of charge-transfer vibronic transitions of uranyl species may be theoretically simulated using a model proposed by Liu *et al*. (2002). The Huang–Rhys parameter of the uranyl vibronic coupling is typically in the range of 1.0–1.5.

For the closely related case of NpO_2^{2+} ion doped into single-crystal $Cs_2UO_2Cl_4$, detailed spectroscopic studies have identified a single electronic transition belonging to the $5f^1$ configuration, but the other structure observed is similar in origin to that reported for UO_2^{2+}, i.e. transitions to molecular-orbital states (Stafsudd *et al*., 1969; Jørgensen, 1982; DeKock *et al*., 1985). Extensive analyses of the absorption and fluorescence spectra of UF_6 have been published, and are covered in a review (Carnall, 1982). In the visible to near-ultraviolet range, the character of the spectrum is similar to that of UO_2^{2+}.

18.8 RADIATIVE AND NONRADIATIVE ELECTRONIC TRANSITIONS

18.8.1 Intensity of 5f–5f transitions

A systematic understanding of the energy level structure for An^{3+} serves as a foundation upon which to base the interpretation of other physical measurements. Considerable success has now been achieved in developing a parameterized model of f → f transition intensities.

The intensity of an absorption band can be defined in terms of the area under the band envelope normalized for the concentration of the absorbing ion and the path length of light in the absorbing medium. A proportional quantity, the oscillator strength P, has been tabulated for trivalent actinide-ion absorption bands in aqueous solution. The experimentally determined oscillator strengths of transitions can in turn be related to the mechanisms by which light is absorbed (Condon and Shortley, 1963; Reid, 2000):

$$P = \frac{8\pi^2 mc\sigma}{3he^2(2J+1)}\left(\chi\overline{F}^2 + n\overline{M}^2\right) \tag{18.51}$$

where $\overline{F}$and $\overline{M}$ are, respectively, the matrix elements of the electric dipole and magnetic dipole operators joining the initial state J to a final state J', $\chi = (n^2+2)^2/9n$ and n is the refractive index of the medium, σ is the energy of the transition (cm^{-1}), and the other symbols have their usual meanings.

Only a few transitions observed for the 3+ actinide ions have any significant magnetic dipole character; however, the matrix elements of $\bar{M}^2$ can be evaluated directly from the knowledge of the eigenvectors of the initial (ΨJ) and final ($\Psi' J'$) states. Following the results of Condon and Shortley (1963), the magnetic dipole operator is given as

$$M = -\frac{e}{2mc}\sum_i (l_i + 2s_i). \tag{18.52}$$

The matrix elements of the operator in equation (18.51) can then be written as

$$\overline{M}^2 = \frac{e^2}{4m^2c^2}\langle \Psi J \| L + 2S \| \Psi' J' \rangle^2. \tag{18.53}$$

The nonzero matrix elements, which should be calculated in the intermediate coupling scheme, will be those diagonal in the quantum numbers τ, S, and L. The selection rule on J is $\Delta J = 0, \pm 1$.

The Judd–Ofelt theory (Judd, 1962; Ofelt, 1962) has successfully addressed the problem of computing the matrix elements of $\overline{F}^2$, and can be written in the form:

$$\overline{F}^2 = e^2 \sum_{k=2,4,6} \Omega_k \left\langle \Psi J \left\| \mathbf{U}^{(k)} \right\| \Psi' J' \right\rangle^2 \tag{18.54}$$

where Ω_k are three parameters which in practice are evaluated from measured band intensities. These parameters involve the radial parts of the f^N wave functions, the wave functions of perturbing configurations such as $5f^{N-1}6d$, and the interaction between the central ion and the immediate environment. Since the Ω_k parameters contain many contributions, model calculations are not possible. Nevertheless, the relative simplicity of the intensity calculations using equation (18.51) have resulted in extremely useful analyses of experimental data. The matrix elements in equation (18.54) may be calculated using the SPECTRA program. For the trivalent actinide ions, the matrix elements of $\mathbf{U}^{(k)}$ have been tabulated (Carnall, 1989) for states of $5f^3$ to $5f^{12}$ configurations with energies up to 40 000 cm^{-1}. It should be noted that the intensity theory presented here is applied only to the free-ion multiplets, and the empirical values for the intensities of these multiplets are obtained by integrating over the band intensities in solution.

Judd (1962) showed that the theory could successfully reproduce the observed intensities of bands of Nd^{3+} and Er^{3+} in aqueous solution ($RE(H_2O)_x$ where x is 8 or 9) throughout the optical range, and that the intensity parameters Ω_k computed from first principles were consistent with those derived from fitting experimental data. Later systematic treatments of the intensities observed in the spectra of all aquated Ln^{3+} ions have confirmed and extended the original correlation (Carnall *et al.*, 1968; Carnall, 1979a) and, more recently, it was found that a similar systematic treatment of band intensities for aquated An^{3+}-ion spectra could be successfully carried out with only Ω_4 and Ω_6 treated as variables (Carnall *et al.*, 1984). The emphasis on aquated f^N-ion spectra comes from the ability to identify many relatively isolated bands with single or very limited numbers of *SLJ* states, the corresponding unambiguous quantitative nature of the oscillator-strength calculation, and the wide range of data

available, i.e. most members of the 4f and 5f series can be readily obtained as trivalent aquated ions in dilute acid solution. Intensity correlations for Ln^{3+} ion in many different host crystals, as well as in vapor complexes, have been developed (Beitz, 1994b; Reid, 2000). For the actinides, systematic and quantitative examination of transition intensities is presently restricted to aquated An^{3+}.

Examination of Fig. 18.8 shows that, particularly for U^{3+}, Np^{3+}, and Pu^{3+}, the density of states is high and few of the observed bands can be uniquely identified. Both the relative intensities of observed transitions and the density of states decrease in magnitude with increasing atomic number. Starting with aquated Cm^{3+}, the heavy-actinide aquated-ion spectra are all amenable to intensity analyses with excellent correlation found between observed oscillator strengths and intensities computed using the Judd parameterization (Carnall *et al.*, 1983). The oscillator strengths of aquated An^{3+} bands tend to be a factor of 10−100 greater than those observed for the lanthanides, Starting with aquated Bk^{3+}, there is an apparent transition to a heavy-lanthanide-like character in the spectra, with no bands being disproportionately intense. Analysis reveals that the trends in the intensity parameter values over the series can be correlated with the extent to which higher-lying opposite-parity configurations like $f^{N-1}d$ are mixed into the f^N configuration. There is much less mixing of $f^{N-1}d$ states into $5f^8(Bk^{3+})$ than in $5f^3(U^{3+})$ which it is consistent with the energy level structures of the $f^{N-1}d$ and f^N configurations of the two ions. An example of the type of correlation obtained between experiment and theory for aquated An^{3+} was previously discussed for aquated Cm^{3+} (Carnall and Rajnak, 1975). Figs. 18.25 and 18.26 compare the observed absorption spectra of U^{3+} and Cf^{3+} in dilute perchloric acid, respectively. These spectra are from the work of Carnall (1992) and have been published, along with those of other An^{3+} ions, with split abscissa scales to highlight weakly absorbing transitions (Beitz, 1994b). Also shown in Figs. 18.25 and 18.26 as vertical bars are the centers of gravity expected for the actinide ion's 5f electron states based on the free-ion parameters established for trivalent actinide ions in single crystals of lanthanum trichloride. It is evident in Fig. 18.26 that the free-ion states provide an excellent basis for interpretation and assignment of the parity-forbidden f–f absorption bands of Cf^{3+}. The very strong absorption bands that occur in the blue and ultraviolet spectral ranges of the U^{3+} spectrum can be assigned as arising from parity-allowed transitions. In addition, it is evident that the f–f absorption bands of U^{3+} at longer wavelengths are significantly more intense than those of the comparatively heavy actinide ion Cf^{3+}. Qualitatively, the high intensity of U^{3+} f–f transitions can be attributed to interaction with the low-lying opposite-parity states of U^{3+}. Put another way, the f-electron states of light actinide ions contain a larger contribution from opposite-parity states than is the case for heavier actinide ions.

Band intensities of spectra such as those shown in Figs. 18.25 and 18.26 have been analyzed systematically (Carnall and Crosswhite, 1985; Carnall *et al.*, 1985;

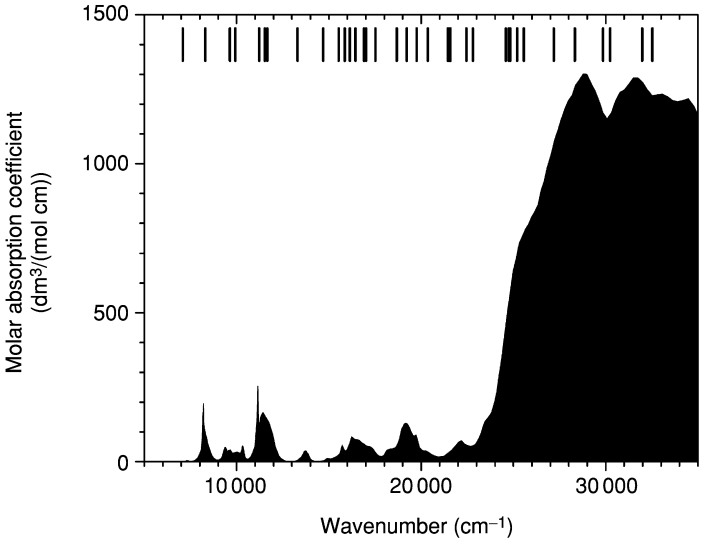

Fig. 18.25 *Optical absorption spectrum of* U^{3+} *in dilute acid solution* (*shaded curve*) *compared to the* 5*f electron free-ion state energies from studies on* U^{3+} *in* $LaCl_3$ (*vertical bars*). *Data from Carnall* (1992).

Beitz, 1994b) from the f–f transition intensities using the Judd–Ofelt formalism (see equation (18.54)). The results of these analyses for aquated U^{3+} through aquated Es^{3+}, based on a fixed value of the Judd–Ofelt parameter Ω_2 at 1×10^{-20} cm^2, are shown in Fig. 18.27. The difficulty in uniquely determining band areas for the strongly overlapping bands of light actinide ions results in large error estimates for these ions. The Judd–Ofelt parameters for aquated trivalent lanthanide ions become nearly constant in value beginning at neodymium and continuing across the series of lanthanide elements (Carnall, 1979a). A similar trend is evident in Fig, 18.27 beginning at Bk^{3+} for aquated trivalent actinide ions. Few opportunities exist for experimentally establishing Ω_2 values for trivalent actinide ions. One such case is found in the branching ratios for emission from the $^5D_1$ state of aquated Am^{3+}. Partial measurement of those ratios led Beitz (1994a) to conclude that an Ω_2 value of 7×10^{-20} cm^2 was consistent with the Ω_4 and Ω_6 values shown in Fig. 18.27 (Beitz, 1994a). Görller-Walrand and Binnemans (1998) have reviewed the application of Judd–Ofelt theory to lanthanide and actinide f–f transitions.

18.8.2 Florescence lifetimes

One reason of interest for determining absorption intensity correlations is that, once the parameters of the Judd–Ofelt theory are evaluated, they can be used to compute the radiative lifetime of any excited state of interest via the Einstein expression

$$A(\Psi J, \Psi' J') = \frac{64\pi^2\sigma^3}{3h(2J+1)}\left(\chi'\overline{F}^2 + n^3\overline{M}^2\right) \tag{18.55}$$

where $|\Psi J\rangle$ and $|\Psi' J'\rangle$ are the initial and final states, A is the rate of relaxation of ΨJ by radiative processes, and $\overline{F}^2$ and $\overline{M}^2$ are the terms defined in equations (18.52) and (18.54). The observed fluorescent lifetime of a particular excited state, τ_T, is determined by the sum of the inverse of the radiative and nonradiative lifetimes. Usually the nonradiative relaxation mechanisms are dominant. Thus

$$(\tau_T)^{-1} = A_T(\Psi J) + W(\Psi J) \tag{18.56}$$

where A_T (ΨJ) is the total radiative relaxation rate from state $|\Psi J\rangle$, that is, the sum of the rates of radiative decay to all states with energy less than that of $|\Psi J\rangle$. If τ_R (calc) is the (computed) total radiative lifetime of $|\Psi J\rangle$, then τ_R (calc) $= [A\ (\Psi J)]^{-1}$. Similarly, $W_T(\Psi J)$ is a total rate summed over all nonradiative relaxation processes. The magnitude of the energy gap between a fluorescing state and the next lower-energy state appears to play a major role in determining the nonradiative lifetime of that state; shorter empirical fluorescent lifetimes are correlated with narrower gaps for the same fluorescing level in different systems.

On the basis of the existence of relatively large energy gaps in the spectra of some of the heavier actinides (Fig. 18.8), experiments were initiated and luminescence lifetimes were successfully measured in solution for some of the excited states of aquated Bk^{3+} and Es^{3+} (Beitz *et al.*, 1981), as well as aquated Cm^{3+} (Beitz and Hessler, 1980) and aquated Am^{3+} (Beitz *et al.*, 1987). As indicated in Fig. 18.28, which shows the lower energy level structure for the heavier aquated

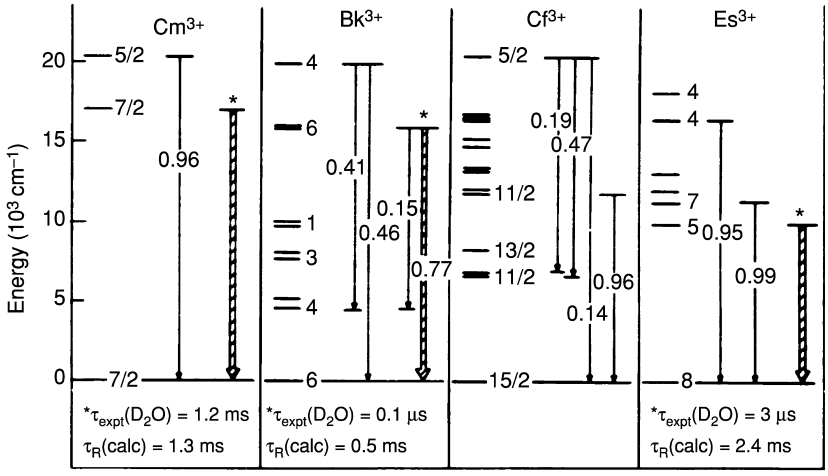

Fig. 18.28 *Energy level schemes and selected branching ratios for radiative relaxation for Cm^{3+} through Es^{3+}.*

An^{3+} ions, only in aquated Cm^{3+} does the observed lifetime of 1.2 ms in D_2O (Kimura *et al.*, 2001) compare well with the computed radiative lifetime, $\tau_R = 1.3$ ms. With smaller energy gaps, the nonradiative relaxation rate clearly becomes rate-determining. Inability to observe a luminescing state for aquated Cf^{3+} in preliminary experiments suggests that lifetimes may be in the nanosecond time range (Beitz *et al.*, 1981; Carnall *et al.*, 1983).

In addition to computing radiative lifetimes, it is instructive to establish the most probable pathway for fluorescence from a given state. Thus the branching ration, β_R, from a given relaxing state to a particular final state is

$$\beta_R(\Psi J, \Psi' J') = \frac{A(\Psi J, \Psi' J')}{A_T(\Psi J)}. \tag{18.57}$$

As indicated in Fig. 18.28 for Cf^{3+}, $\beta_R = 0.47$ for emission from an excited ($J = 5/2$) state to a lower-lying ($J = 11/2$) state, whereas $\beta_R = 0.14$ for emission to the ground state. In the case of $J = 5/2$ state, it would be appropriate to monitor for luminescence near 13 000 cm^{-1} as well as near 20 000 cm^{-1}.

18.8.3 Nonradiative phonon relaxation

The identification of the mechanisms of nonradiative relaxation of actinide ions in solution as well as in solids remains an important area for research (Hessler *et al.*, 1980; Liu and Beitz, 1990a,b). The nonradiative relaxation rate between crystal field energy levels belonging to different multiplets is predominantly determined by temperature, the energy gap, and the lattice phonon modes of the particular host crystal (Riseberg and Moos, 1968; Miyakawa and Dexter, 1970). With the assumption that the phonons involved are of equal energy, a commonly used expression for the temperature-dependent multiphonon relaxation rate is (Riseberg and Moos, 1968)

$$W(T) = W(0)\left[\frac{\exp(\hbar\omega_m/kT)}{\exp(\hbar\omega_m/kT) - 1}\right]^{\Delta E/\hbar\omega_m}, \tag{18.58}$$

where $\hbar\omega_m$ is the maximum phonon energy the lattice vibrations that couples to the electronic transition of the metal ion, ΔE is the energy gap between the populated state and the next low-lying state, and $W(0)$ is the spontaneous transition rate at $T = 0$ when the phonon modes are all initially in their ground state. At low temperatures where $\hbar\omega_m \gg kT$, nonradiative relaxation rate is dominated by $W(0)$, which can be expressed as a simple exponential function depending on the energy gap, ΔE

$$W(0) = C\exp(-\alpha\Delta E/\hbar\omega_m), \tag{18.59}$$

where C and α are empirical parameters which are characteristic of the particular crystal. Known as the energy gap law, this exponential dependence of the transition rate on the energy gap has been used to describe quite generally the

energy gap dependence of multiphonon transitions rates for the 4f and 5f states (Riseberg and Moos, 1967, 1968).

Extensive experimental results for lanthanide systems are available for comparison with those obtained for actinide ions. It should be possible to explore bonding differences between selected actinides and lanthanides by examining their excited state relaxation behavior. Because of smaller electrostatic interaction and larger spin–orbit coupling and crystal-field splittings, the energy gaps between different *J*-multiplets of actinide ions are much smaller than that of the isoelectronic lanthanide ions. Therefore, phonon-induced nonradiative relaxation in actinide systems is more efficient than in the lanthanide systems. Except for a few cases, such as the $^6D_{7/2}$ state of Cm^{3+} and Bk^{4+}, that have a large energy gap to the low-lying states, the lifetime of most 5f–5f electronic transitions of actinide ions in solids and solutions are predominantly determined by nonradiative relaxation. A direct comparison of the use of the energy gap law for Cm^{3+} in $LaCl_3$ and the trivalent rare earth ions in $LaCl_3$ has been reported (Illemassene *et al.*, 1997). A comparison of the emitting state lifetimes of Cm^{3+} in various crystals is given in Fig. 18.16. A summary of spectroscopic studies of Cm^{3+} in crystals $LaCl_3$, $LuPO_4$, ThO_2, Cs_2NaYCl_6, and $CsCdBr_3$ was given in a review paper (Edelstein, 2002). The lifetimes of the actinide ions with the $5f^7$ configuration (Cm^{3+}, Bk^{4+}) are roughly consistent with the energy gap law in that for the hosts $LuPO_4$, ThO_2, and in CeF_4, only one or at most two levels luminesce. For the heavier halide hosts, the vibrational spread is small and the crystal field strength is relatively small so many more levels luminesce.

Early studies on multiphonon relaxation of 5f states of aquated trivalent actinide ions have been reviewed (Yusov, 1993; Beitz, 1994a) and compared to similar work on 4f states of aquated trivalent lanthanide ions (Beitz, 1994b). Aquated ions are those whose inner coordination sphere consists only of water molecules. Systematic studies of the 5f state luminescence lifetimes of aquated trivalent actinide ions began in 1980 with the work of Beitz and Hessler (1980) who reported the luminescence emission spectra of $^{248}Cm^{3+}$ in dilute perchloric or hydrochloric acid as well as luminescence lifetimes in H_2O and D_2O solutions. They assigned the emission as arising from the electronically excited $^6D_{7/2}$ state of Cm^{3+} based on a study of the solution absorption spectrum of Cm^{3+} in perchloric acid (Carnall and Rajnak, 1975). A subsequent study by Beitz and coworkers on the luminescence of $^{244}Cm^{3+}$ in dilute acid solution showed that speciation studies on ultratrace levels of Cm^{3+} could be carried out using elementary laser-induced fluorescence techniques (Beitz *et al.*, 1988). Laser-induced luminescence studies also have been reported on Am^{3+} (Beitz *et al.*, 1987; Yusov, 1990; Thouvenot *et al.*, 1993b; Kimura and Kato, 1998), Bk^{3+} (Carnall *et al.*, 1984) and Es^{3+} (Beitz *et al.*, 1983) in dilute acid solutions and as well as additional studies on aquated Cm^{3+} (Yusov, 1987; Kimura and Choppin, 1994; Kimura *et al.*, 1996, 1997). In all cases, the observed luminescence bands were assigned as arising from a 5f state lying at or below the energy

of the exciting photons and that, among all such states, in addition possessed the largest ΔE value. The reported 5f state emission spectra of aquated trivalent actinide ions are in good agreement with the calculated free-ion states of trivalent actinide ions doped into lanthanum trichloride (Carnall, 1992).

Aquated actinide ions are prototypical species for the investigation of coordination complexes that form as ligands other than water become associated with an actinide ion. It should be appreciated that the coordination sphere of trivalent actinide ions is dynamic unless there is an exceptionally strong ligand bonding. For example, using nanosecond laser excitation, there are no reports of emission from aquated actinide ions that differ as to the number of coordinated water molecules, which suggests that the coordination environment of aquated actinide ions reaches equilibrium on the submicrosecond timescale. In the case of aquated actinide ions, interest naturally exists as to the number of inner-sphere coordinated water molecules, and luminescence studies have been reported that provide a measure of that number.

Kimura and Choppin (1994) doped Cm^{3+} into a series of solid-hydrated lanthanum compounds and determined the influence of the number of inner-sphere coordinated water molecules on the observed Cm^{3+} luminescence lifetimes. Their data are plotted in Fig. 18.29 where the solid line expresses the resulting correlation as

$$n_{H_2O} = 0.65k_{obs} - 0.88 \tag{18.60}$$

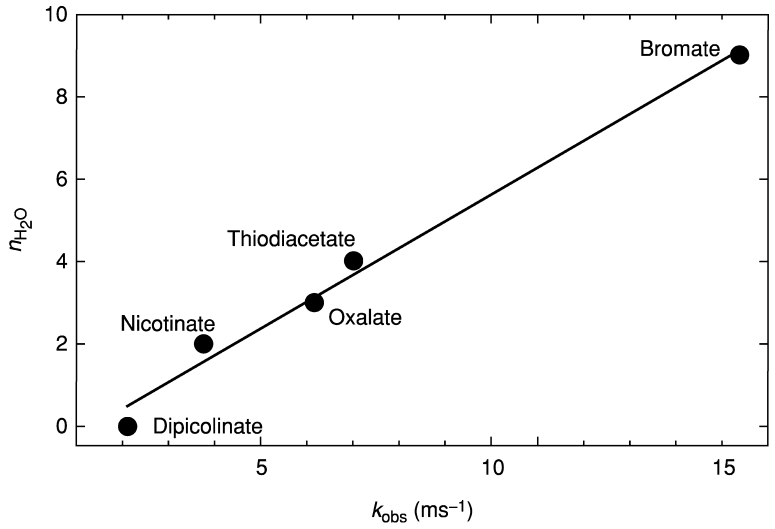

Fig. 18.29 *Observed $^{248}Cm^{3+}$ luminescence decay rate, $k_{obs,}$ from Cm^{3+} doped into a series of solid-hydrated lanthanum compounds at Cm:La = 1:6.9 × 10^3 as a function of the number of inner-sphere coordinated water molecules, n_{H_2O}. Data from Kimura and Choppin* (1994).

where n_{H_2O} is the number of inner-sphere coordinated water molecules and k_{obs} is the measured luminescence lifetime in units of ms^{-1}. Analysis of the data in Fig. 18.29 using equation (18.60) results in a calculated 95% confidence limit of $\pm$ 0.74 for n_{H_2O} values, if one assumes that there is no error as to the number of inner-sphere coordinated water molecules in a given compound. The correlation embodied in equation (18.60) should be valid as long as there is no contribution from ligands other than H_2O or HDO to de-excitation of the emitting state and the purely radiative decay rate of the emitting state remains essentially unchanged across the series of compounds. The value of n_{H_2O} for aquated Cm^{3+} reported by Kimura and Choppin was 9.2 $\pm$ 0.5 water molecules.

Subsequently, Kimura and Kato (1998) studied aquated and complexed $^{241}Am^{3+}$ luminescence via its $^5D_1 \rightarrow {}^7F_1$ transition. They reported $k_{obs} = 24.6 \pm 0.6$ ns for aquated Am^{3+} in H_2O and 162 $\pm$ 4 ns for Am^{3+} in 99.9% D_2O. They adopted a different analysis procedure based on the assumption that the number of inner-sphere water molecules is 9 for aquated Am^{3+} and aquated Cm^{3+}. With that assumption and from the linear correlation they observed between the observed luminescence decay rate, k_{obs}, and the deuterium mole fraction in H_2O–D_2O mixtures, they determined

$$n_{H_2O} = 2.56 \times 10^{-4} k_{obs} - 1.43 \tag{18.61}$$

for the case of aquated Am^{3+} and

$$n_{H_2O} = 0.612\, k_{obs} - 0.48 \tag{18.62}$$

for the case of aquated Cm^{3+}. Subsequently, Kimura and coworkers studied the luminescence lifetimes of Am^{3+} and Cm^{3+} of unstated actinide isotopic composition at 25°C (Kimura *et al.*, 2001). They reported lifetime values for aquated Am^{3+} in H_2O of 25 $\pm$ 0.75 and 160 $\pm$ 5 ns for aquated Am^{3+} in 99.95% D_2O along with the values of 65 $\pm$ 2 μs for aquated Cm^{3+} in H_2O and 1200 $\pm$ 36 μs for aquated Cm^{3+} in 99.95% D_2O. These values together with equations (18.61) and (18.62) give $n_{H_2O} = 8.9$ for aquated Cm^{3+} and $n_{H_2O} = 8.8$ for aquated Am^{3+}. On the basis of preferential solvation in the nonaqueous solutions, an estimate of the Gibbs free energy of transfer of Am^{3+} and Cm^{3+} ions from aqueous to nonaqueous solutions also was obtained using the observed luminescence lifetimes in mixtures of water and organic solvents.

Due to its spectroscopy and photophysics, Cm^{3+} is the trivalent actinide ion most commonly studied in solution using luminescence techniques. As noted earlier, luminescence from three other aquated trivalent actinide ions has been reported. Selected lifetime values from these studies are shown in Table 18.14. In nearly all cases where the stated measurement errors were 5% or less of the observed value and the lifetime was at least a factor of 10 longer than the excitation pulse width, the reported lifetime values are concordant at the 95% confidence level. The seeming exception occurs for Cm^{3+} in D_2O solution. Beitz and Hessler (1980) reported that the luminescence lifetime of Cm^{3+} in 1 M $DClO_4$ solution was 940 $\pm$ 40 μs, whereas Kimura and coworkers reported

Table 18.14 *Selected 5f state luminescence lifetimes, τ, for actinide ions in dilute acid solution at ambient temperature.*[a]

Actinide ion	*Emitting state*[b]	*τ in H_2O*	*τ in D_2O*
U^{4+}	$^1S_0$	<20 ns	
Am^{3+}	$^5D_1$	22 ± 3 ns	160 ± 5 ns
Cm^{3+}	$^6D_{7/2}$	65 ± 3 μs	1200 ± 36 μs
Bk^{3+}	$^7F_6$		100 ± 20 ns
Es^{3+}	$^5F_5$	1.05 ± 0.05 μs	2.87 ± 0.09 μs

[a] See text for selection basis and literature references.
[b] Term symbols for emitting states from the work of Carnall and coworkers (Carnall *et al.*, 1991; Carnall, 1992).

that the lifetime of aquated Cm^{3+} in 0.01 M $DClO_4$ was 1200 ± 36 μs (Kimura *et al.*, 2001). Both studies reported that the lifetime of Cm^{3+} in H_2O was 65 μs. Beitz and Hessler used triply distilled D_2O that was 99% D_2O by near-infrared absorption spectroscopy to make up their solutions whereas Kimura and coworkers used as-received 99.95% D_2O. The work of Kimura and coworkers provides evidence that the observed luminescence lifetime of Cm^{3+} in a mixture of H_2O and D_2O is given by the expression

$$k_{obs} = (1 - \chi)\, k_{H_2O} + \chi\, k_{D_2O} + C, \tag{18.63}$$

where k_{obs} is the observed Cm^{3+} luminescence lifetime in a mixture of H_2O and D_2O in which χ is the deuterium mole fraction of the solution, C is a constant, and k_{H_2O} and k_{D_2O} are the luminescence decay rates of Cm^{3+} in 100% H_2O and 100% D_2O solutions, respectively. Taking into account the stated errors in the measured luminescence lifetimes and equation (18.63), the reported 940 ± 40 and 1200 ± 36 μs Cm^{3+} lifetime values in heavy water solutions agree with each other at the 95% confidence level given the differing degree of solvent deuteration in the two studies.

Reported lifetimes for the $^5D_1$ state of aquated Am^{3+} in H_2O are more discordant which can be attributed primarily to the use of excitation pulses whose width was not insignificant compared to the luminescence decay time of aquated Am^{3+}. The value reported by Beitz (1994a) is selected for inclusion in Table 18.14 because a deconvolution procedure was used to correct for the finite excitation pulse width. The lifetimes reported by Kimura and coworkers for Cm^{3+} and Am^{3+} (Kimura *et al.*, 2001) in D_2O were selected for inclusion in Table 18.14 because of the higher level of solution deuteration in their studies in comparison with earlier studies by others.

A limit for the luminescence lifetime of the $^1S_0$ state of U^{4+} in 1 M perchloric acid has been reported (Kiarshima *et al.*, 2003) and is included in Table 18.14. Based on their excitation and emission spectra, the energy gap between the U^{4+} emitting state and its next lower 5f state is comparable to the Cm^{3+} energy gap. In consequence, one might have expected that nonradiative decay would

only moderately diminish the observed lifetime of the $^1S_0$ state. However, Kiarshima and coworkers report that the luminescence lifetime of the $^1S_0$ state of aquated U^{4+} is <20 ns. Evidently the $^1S_0$ state is primarily quenched by processes other than those that are responsible for the nonradiative decay of the observed 5f emitting states of aquated trivalent actinide ions. Candidate processes for U^{4+} include intersystem crossing to a lower-lying opposite-parity state of U^{4+} and electron transfer to or from neighboring ligands.

Insight into the factors influencing the nonradiative decay of emitting 5f states of aquated trivalent actinide ions can be obtained by plotting the data of Table 18.14 for such ions semilogarithmically as shown in Fig. 18.30. The solid and dashed lines are fits of the data for ions in H_2O and D_2O, respectively, to equation (18.59). Use of this equation is justified ($\hbar\omega_m \gg kT$) if energy is transferred to a stretching or bending vibrational modes of water at ambient temperature. The resulting fit values for $(\alpha/\hbar\omega_m)$ are 6.23×10^{-4} cm for H_2O solutions and 7.52×10^{-4} cm for D_2O solutions. Based on equation (18.59), nonradiative decay occurs primarily to stretching vibrational modes of water for Es^{3+} and Cm^{3+}. However, the currently available data for aquated trivalent actinide ions in H_2O are too less to determine if energy transfer to bending vibrational modes of water makes a significant contribution to the overall nonradiative decay rate at low values of ΔE as might be expected from recent studies on multiphonon-induced nonradiative decay in single crystals (Ermeneux *et al.*, 2000).

18.8.4 Ion–ion interaction and energy transfer

The success of the single-particle model for interpretation of the solid-state actinide spectra is largely due to the localized nature of the 5f electrons. In the modeling of $5f^N$ electronic energy level structure, the coupling between neighboring f-element ions is neglected even for actinides in stoichiometric compounds, although ion–ion interaction induced band structure and cooperative pair transitions have been observed in lanthanide compounds (Cone and Meltzer, 1987) and are expected to be more significant in the actinide compounds because of more extended 5f orbitals (Fig. 18.3). However, the effects of ion–ion interactions on the excited state dynamics such as luminescence decay are very significant even in dilute crystals with actinide doping level below 1% (Liu and Beitz, 1990a). As a result of ion–ion interactions, luminescence emission from a $5f^N$ state is usually observed only in dilute crystals. The excited state lifetime and the luminescence decay dynamics are strongly dependent on the actinide ion concentration as well as on sample temperature. Fig. 18.31 shows the $^5D_1$ luminescence decay of 0.1 at% Cm^{4+} (a) and 5 at% Cm^{4+} (b) in crystalline CeF_4 at 4 K. There is an obvious deviation from a single exponential decay for the 0.1 at% Cm^{4+}:CeF_4 sample and the decay rate in the long time range is approximately $5 \times 10^3\ s^{-1}$. In the 5 at% Cm^{4+}:CeF_4 sample, most Cm^{4+} ions relaxed from the excited state within 15 μs. At long times, behavior similar

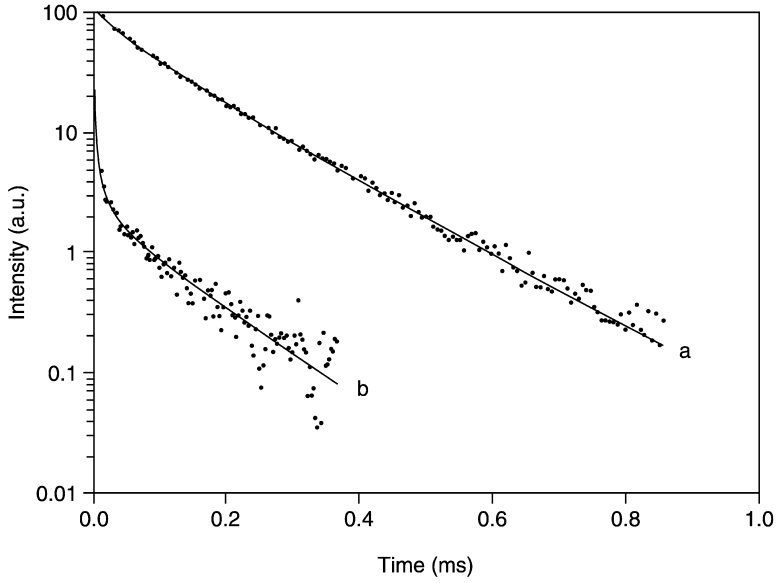

Fig. 18.31 *Nonexponential fluorescence decays of Cm^{3+} ions in CeF_4 induced by interionic excitation energy transfer.* (*a*) *the $^5D_1$ fluorescence decay of* 0.1% (*atom*) *Cm^{4+}:CeF_4 at* 4 K*; and* (*b*) *the $^5D_1$ fluorescence decay of* 5% (*atom*) *Cm^{4+}:CeF_4 at* 4 K. to that of the 0.1 at% Cm^{4+}:CeF_4 sample is due to the contribution from Cm^{4+} ions at isolated sites where energy transfer is improbable.

The theory of energy transfer of luminescent ions in solids has been developed for interpretation of sensitized luminescence (Förster, 1948; Dexter, 1953). This theory is based on the assumption that the rate of excitation energy transfer (W_{da}) from a donor, d, to an acceptor, a, depends on the distance between d and a, R_{da}, as

$$W_{da} = \alpha\left(\frac{R_0}{R_{da}}\right)^s, \tag{18.64}$$

where the parameter α contains the matrix elements of the interaction between d and a, and R_0 is the distance between the nearest neighbors. These matrix elements depend on the transition probabilities as well as the energy mismatches if d and a do not have identical excitation energy levels. In equation (18.64), s takes an integer value of 6, 8, or 10 for electric dipole–dipole, dipole–quadrupole, or quadrupole–quadrupole interactions, respectively. For the simple case where energy-transfer processes are irreversible, the luminescence decay rate may be evaluated using

$$\frac{dP_d}{dt} = -\kappa P_d - \sum_a W_{da} P_d, \tag{18.65}$$

where P_d is the probability of excitation of the donor, κ is for the intrinsic decay rate, and the summation is over all possible acceptors. In f-element ions in dielectric crystals, the donors and acceptors are the same. It is often difficult, especially for the doped crystals or structurally disordered solids, to perform the lattice summation over the occupied acceptor sites in equation (18.65). Inokuti and Hirayama (1965) first obtained a general approximate solution for ion concentration $c \ll 1$:

$$\ln\frac{P(0)}{P(t)} = \kappa t + c\Gamma(1 - 3/s)(\alpha t)^{3/s}, \tag{18.66}$$

where $\Gamma(1 - 3/s)$ is the gamma function and other quantities are the same as defined in equations (18.64) and (18.65). The solid line in Fig. 18.31 are fitted results using the Inokuti and Hirayama model.

Although nonexponential luminescence decay is the direct consequence of ion–ion interactions that are easy to measure by experiment, there are different microscopic mechanisms that may not be revealed in detail in the analysis of the decay dynamics alone. Analysis of energy level structure is often critical in understanding the energy-transfer processes. For actinide and lanthanide ions in insulating crystals, resonant migration excitation of excitation among the identical ions is common, and if there is inhomogeneous line broadening, phonon-assisted (phonon absorption from or emission to the lattice) energy-transfer results in temperature-dependent spectral diffusion as well as nonexponential luminescence decay (Yen, 1987). In many cases, energy transfer occurs in such a way that the donor gives the acceptor a part of its excitation energy and

nonradiatively relaxes to an intermediate state, whereas with this amount of energy the acceptor is excited into the same or a different intermediate state. This type of energy transfer is called cross-relaxation. As shown in Fig. 18.31, the nonexponential decay of Cm^{4+} in the $^5D_1$ level is dependent on the Cm^{4+} doping level. The mechanism for the nonexponential decay is mainly due to the cross-relaxation into the low-lying excited states of $^7F_{3,4}$ states (Liu and Beitz, 1990a). A special type of cross-relaxation is up-conversion energy transfer. In this process, the donor and acceptor are both in metastable states while the donor relaxes into a low-lying state and the acceptor is further excited into a high-lying state. This energy-transfer process enables emission of a photon with energy higher than the initial excitation energy. Instead of emission of a higher energy photon, this type of energy transfer may end up with energy lost to the lattice or lead to ionization, a process called annihilation.

Extensive studies of the microscopic mechanisms of ion–ion interactions and various consequences of energy-transfer processes have been done for lanthanide ions and detailed reviews of the previous work have been published (Cone and Meltzer, 1987; Yen, 1987). Much less work has been conducted on actinide systems. Many experimental results from the actinide systems may be interpreted using the same framework developed from modeling the lanthanide systems, such as those of Cm^{4+}:CeF_4 (Liu and Beitz, 1990a,b). The excited state dynamics of both U^{3+} and U^{4+} ion in a host crystal of Ba_2YCl_7 was recently reported. It is shown that energy transfer induced up-conversion of U^{4+} excitation leads to strong luminescence from the $^1I_6$ state at 19 600 cm^{-1} (Karbowiak *et al.*, 2003). Consistent with the observations in analyses of crystal-field splittings and ion–phonon coupling, ion–ion interactions in the actinide systems with the same level of ion concentration are much stronger than that in the lanthanide systems. This explains in general the more significant nonexponential decay and quenching of actinide luminescence emission.

ACKNOWLEDGMENTS

We dedicate this chapter to the memory of William T. Carnall who was our actinide spectroscopy mentor, colleague, and friend. We also thank him for permission to base our present work on the chapter that he coauthored in the second edition of this work. This work was performed under the auspices of the Office of Basic Energy Sciences, Office of Science, U.S. Department of Energy under contract W-31-109-ENG-38.

CHAPTER NINETEEN

THERMODYNAMIC PROPERTIES OF ACTINIDES AND ACTINIDE COMPOUNDS

Rudy J. M. Konings, Lester R. Morss, and Jean Fuger

19.1 INTRODUCTION

The necessity of obtaining accurate thermodynamic quantities for the actinide elements and their compounds was recognized at the outset of the Manhattan Project, when a dedicated team of scientists and engineers initiated the program to exploit nuclear energy for military purposes. Since the end of World War II, both fundamental and applied objectives have motivated a great deal of further study of actinide thermodynamics. This chapter brings together many research papers and critical reviews on this subject. It also seeks to assess, to systematize, and to predict important properties of the actinide elements, ions, and compounds, especially for species in which there is significant interest and for which there is an experimental basis for the prediction.

Many experimental and theoretical studies of thermochemical and thermophysical properties of thorium, uranium, and plutonium species were undertaken by Manhattan Project investigators. Some of these reports appeared in

the National Nuclear Energy Series (Seaborg *et al*., 1949). These papers, and others in the literature through 1956, formed the basis for Table 11.11 *Summary of thermodynamic data for the actinide elements* of the first edition of this work. This table, compiled by J. D. Axe and E. F. Westrum Jr., listed 126 species, of which the properties of 40 were estimates. A fair measure of the progress in actinide thermodynamics is the number of subsequent research papers and reviews.

Two other monumental works, which appeared in 1952, must be mentioned here: the U.S. National Bureau of Standards Circular no. 500 (Rossini *et al*., 1952) included all known data through uranium, and Latimer's oxidation potentials (Latimer, 1952) included oxidation–reduction data on all actinides through americium. Following the publication of the first edition of this work, with its thermodynamic summary in Table 11.11, the only major reviews of actinide thermodynamics during the decade 1960–69 were the monograph of Rand and Kubaschewski (1963) on uranium, the IAEA panel reports on oxides (IAEA, 1965, 1967) and carbides (Rand, 1968), and long reviews by Rand (1966) and Oetting (1967). However, until the 1970s, the reviews of actinide thermodynamics lagged behind the reports of these measurements themselves.

Critical efforts to compile and to assess actinide thermodynamic properties improved during the 1970s and 1980s. Krestov (1972) prepared an extensive compilation of rare earth and actinide thermochemical properties. Rand (1975) comprehensively and critically reviewed thorium thermodynamics, and the thermodynamics group of the U.S. National Bureau of Standards (Wagman *et al*., 1981) published the final volume of the Technical Note 270 series, which included the elements actinium through uranium. At nearly the same time the parallel compendium of Glushko *et al*. (1978) was published in the USSR. The most contemporary and thoroughly annotated compilation is the 14-part series issued under the auspices of the International Atomic Energy Agency, *The Chemical Thermodynamics of Actinide Elements and Compounds*, of which ten volumes have been published (Fuger and Oetting, 1976; Oetting *et al*., 1976; Cordfunke and O'Hare, 1978; Chiotti *et al*., 1981; Fuger *et al*., 1983; Flotow *et al*., 1984; Grønvold *et al*., 1984; Holley *et al*., 1984; Hildenbrand *et al*., 1985; Fuger *et al*., 1992). The nine volumes of this compilation published before 1986 formed the basis for most of the data in the second edition of this work.

After this 'golden age' of thermodynamics of the actinides a significant decrease in the number of experimental studies occurred during the last two decades, when the programs in many laboratories in the U.S. and Europe faced significant budget reductions. Also the review activities at the IAEA stopped before the series was completed. Fortunately many new review activities in this field started in the 1990s. The Nuclear Energy Agency (NEA) of the OECD initiated a project, the Thermodynamic Database Project (NEA-TDB), with the goal to assess and publish the thermochemical data of those actinides that are highly relevant to waste disposal studies: uranium, neptunium, plutonium, and americium (Grenthe *et al*., 1992; Silva *et al*., 1995; Lemire *et al*., 2001;

Guillaumont *et al.*, 2003). The volumes for these elements, which strongly rely upon the work done in the frame of the IAEA activities, have all been published and a supplement with extensions and corrections has been issued recently (Guillaumont *et al.*, 2003). At the Institute for Transuranium Elements (ITU), a systematic review of lanthanide and actinide elements and compounds was undertaken, with the goal of establishing a web-based information center (Konings, 2004b) focused on high-temperature properties. The results of these two projects form, together with the IAEA series, the basis for the present chapter. The thermodynamic studies on the transactinide elements are restricted to a few experimentally determined adsorption enthalpies of halides of elements 104, 105, and 106 on metal surfaces and quantum chemical calculations. For that reason these elements will not be dealt with in this chapter. The reader is referred to Chapter 14.

19.2 ELEMENTS

19.2.1 Actinides in the condensed phase

A systematic and critical review of the available thermodynamic quantities for the actinide elements was made by Ward *et al.* (1986), which is much more complete than the earlier reviews by Hultgren *et al.* (1973) and Oetting *et al.* (1976). Since then the thermodynamic quantities of some actinide elements were reviewed individually in other compilations. Thorium and uranium were carefully reviewed by the CODATA Workgroup for Key Values for Thermodynamics (Cox *et al.*, 1989) and recommended values for the standard entropy, heat capacity, and enthalpy of sublimation at room temperature were given. Reviews for plutonium and americium were reported by Cordfunke and Konings (1990), for uranium, neptunium, plutonium, and americium by the NEA-TDB Project teams (Grenthe *et al.*, 1992; Silva *et al.*, 1995; Lemire *et al.*, 2001; Guillaumont *et al.*, 2003), and for americium and curium by Konings (2001b, 2002). These reviews are essentially based on the same information as the work of Ward *et al.* Because few new measurements have been reported since 1986, the differences in values between these reviews mainly arise from the estimation methods, as explained below.

(a) Entropy

The low-temperature heat capacities have been measured for the actinides Th through Am. The experimental measurements were reviewed by Ward *et al.* (1986). The values given by Ward *et al.* (1986) for the heat capacity and entropy of Pa are based on the estimates of Oetting *et al.* (1976), but thereafter heat capacity measurements were reported by Hall *et al.* (1990) from 10 to 300 K.

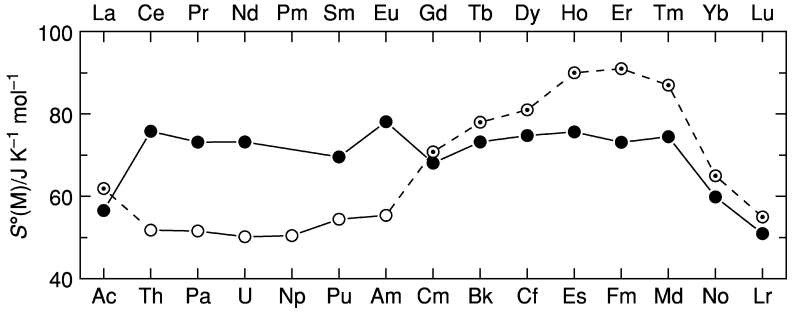

Fig. 19.1 *The standard entropies of lanthanide* (•) *and actinide* (○) *metals at* $T = 298.15$ K; *estimated values are indicated by* (⊙).

These authors reported preliminary results on several occasions but because the numbers given vary somewhat, the results cited here are from their final report.

The variation of the standard entropies along the actinide metal series is shown in Fig. 19.1. The entropies of the elements Th to Am are below the lattice entropies of the corresponding lanthanides, showing the absence of magnetic contributions. At Cm a distinct increase of the entropy occurs, showing the magnetic character of this element. Konings (2001b) suggested that the entropy of this element can be estimated by adding the excess entropy of Gd to that of Am. Ward and his colleagues (Kleinschmidt *et al.*, 1983; Ward *et al.*, 1986) suggested a more general formula to estimate the entropies of the metals heavier than americium from those of lanthanide and lighter actinide metals by correlation with metallic radius (r), atomic weight (M), and magnetic entropy (S_μ):

$$S_u(298.15\ \text{K}) = S_k(298.15\ \text{K})(r_u/r_k) + \frac{3}{2}R\ \ln(M_u/M_k) + S_\mu \qquad (19.1)$$

where u refers to the unknown element and k to the known element. S_μ is taken equal to $S_{\text{spin}} = (2J + 1)$, where J is the total angular momentum quantum number. The selected values for the entropies of the actinide elements are listed in Table 19.1.

(b) High-temperature properties

High-temperature heat capacity data have only been measured for Th, U, and Pu and the results allow an adequate description of the thermal functions of these elements into the liquid phase. Measurements for Np have only been made up to 480 K (Evans and Mardon, 1959). Oetting *et al.* (1976) and Ward *et al.* (1986) presented estimates for most other actinide metals based on a simple empirical correlation with the lanthanide metals, often adjusted to fit the second- and third-law analysis of the vapor pressure studies. Very similar data for Np and Am were presented in the OECD-NEA project. A semi-empirical

approach was used by Konings (2003) who presented the heat capacity of α- and β-Am as the sum of the harmonic, anharmonic, dilatation, electronic, and magnetic contributions:

$$C_p = C_{har} + C_{anh} + C_{dil} + C_{ele} + C_{mag} \quad (19.2)$$

This approach gives a good agreement with the low-temperature values; at elevated temperatures the results are somewhat higher than the earlier estimated heat capacity data. Larger differences were found for γ-Am and liquid Am, for which simplified versions of equation (19.2) were used.

Table 19.2 summarizes the transition temperatures and enthalpies for which, again, the data from the above-mentioned reviews have been adopted in most cases. The melting points are plotted in Fig. 19.2 together with those of the lanthanide metals. The melting points in the lanthanide series increase regularly, indicating an increasing cohesive energy in the condensed phase. Eu and Yb form exceptions to this trend as they have a divalent state, whereas the other lanthanides have a predominantly trivalent state. In the actinide series, tetravalent (Th–Pu), trivalent (Ac, Am–Cf, Lr), and divalent (Es–No) states are present, explaining why the melting points of the actinide metals are significantly different from those of the lanthanides. In this context, it is interesting to examine the variation in the sum of the transition entropies of the actinides, shown in Fig. 19.3. Clearly the elements U–Am have a considerably higher value of $\Sigma(\Delta_{trs}S)$ compared to the other actinide metals, for which the values are almost identical to the lanthanide elements. The value for Am is to be discussed in somewhat greater detail (Konings, 2003). The selected values for this element in the NEA-TDB review are based on the work of Wade and Wolf (1967) that was made on massive samples of Am. These values disagree seriously with those of the recent work of Gibson and Haire (1992). However, the values of $\Sigma(\Delta_{trs}S)$ derived from both these studies do not fit the trend suggested by Fig. 19.3. The results of Seleznev *et al.* (1977, 1978) are intermediate between these two studies and $\Sigma(\Delta_{trs}S)$ of Am derived from this work (8.7 J K^{-1} mol^{-1}) fits well in the trend for the trivalent lanthanide metals. Therefore Seleznev's values have been recommended (Konings, 2003). Clearly more work is required for this element.

The trend of the heat capacity of the actinides in the liquid phase is shown in Fig. 19.4 together with that for the liquid lanthanides. The actinides Th–Pu, for which experimental data are available, are tetravalent in the liquid, which explains why the two patterns are different. Am and Cm have a trivalent state, like the lanthanides (except Eu and Yb which are divalent).

The recommended heat capacity functions are summarized in Table 19.2.

19.2.2 Actinides in the gas phase

Heat capacity and entropy of the gaseous actinide elements have been calculated from atomic parameters and electronic energy levels. As discussed by Brewer (1984) the levels for the actinides are complete (through experiments and

estimations) to about 15000 cm^{-1}, which permits the calculation of the values up to about 2000 K with reasonable accuracy. The room temperature values are shown in Table 19.1. The gaseous ions, for which thermodynamic data are also available, are dealt with extensively in Chapter 16 and are excluded from this chapter.

With these data and the thermal functions for the solid, sublimation enthalpies can be derived from the vapor pressure measurements for the actinide elements. Such measurements have been performed for all actinide metals except Md, No, and Lr, though the measurements for Ac (Foster, 1953) are of a very approximate nature. The work performed at Los Alamos and Oak Ridge National Laboratories is noteworthy because these researchers extended the measurements of the transplutonium elements to Cf and finally measured the vapor pressure of Es (Kleinschmidt *et al.*, 1984) and Fm (Haire and Gibson, 1989) using samples containing 10^{-5} to 10^{-7} at% of the actinides in rare earth alloys by applying Henry's law for dilute solutions. The enthalpies of sublimation derived from these studies are listed in Table 19.1. They are plotted in Fig. 19.5 together with the sublimation enthalpies of the lanthanide metals. The trend in the latter series shows a typical pattern, with La, Gd, and Lu forming an approximate linear baseline from which the others systematically deviate. This trend can be understood from the electronic states of the condensed and gaseous atoms, as discussed by Nugent *et al.* (1973), who showed that the difference between the value linearly interpolated in the La–Gd–Lu series and the experimental value corresponds to the energy difference between the lowest electronic energy level of the $f^n s^2 d^1$ configuration and the lowest level of the $f^{n+1} s^2$ configuration. An exception is Eu, which is divalent in the condensed state.

The trend in the actinide series decreases more as a function of Z compared to that for the lanthanides. The explanation for this is found in the complexity of the valence states, as discussed in Section 19.2.2. Several predictions of $\Delta_{sub}H$ for Ac, Md, No, and Lr were made. Nugent *et al.* (1973) correlated energetics of divalent and trivalent lanthanides and actinides. Fournier (1976) correlated

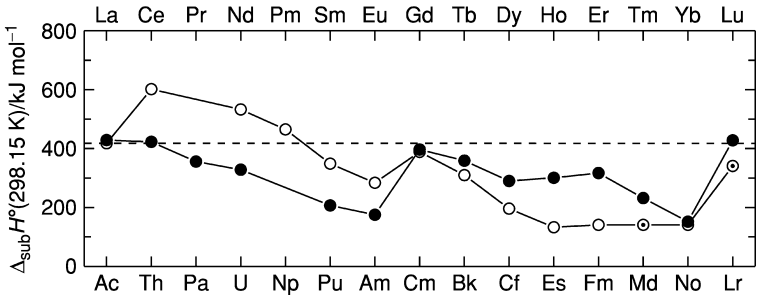

Fig. 19.5 *Enthalpies of sublimation of lanthanide* (•) *and actinide* (○) *metals at* $T =$ 298.15 K*; estimated values are indicated by* (⊙).

electronic configuration with metallic radius, melting temperature, and enthalpy of sublimation. A more reliable series of sublimation properties was generated by David *et al.* (1978) and David (1986), who included experimental radioelectrochemical measurements in the correlation. An independent method of estimation of sublimation properties is that of thermochromatography, which has been utilized effectively for the actinides (Hubener and Zvara, 1982). There is general agreement that the enthalpy of sublimation of Lr is in the range 320–350 kJ mol^{-1}, and we select the value estimated by David (1986). His values for Md and No must, however, be considered to be somewhat too high as the estimate for Fm is 32 kJ mol^{-1} higher than the experimental value by Kleinschmidt *et al.* (1984). Fournier estimated the sublimation enthalpies of Fm–No to be approximately the same, as was approximately the case for the results of David. We therefore suggest the same enthalpy of sublimation for Md and No as for Fm. The results are summarized in Table 19.1.

19.3 IONS IN AQUEOUS SOLUTIONS

19.3.1 Enthalpy of formation

For most of the transuranium elements, the enthalpy of formation of aqueous ions were the first thermochemical property to be determined. One reason was that the measurement of the 'heat of solution' of metals or, later, of enthalpies of redox reactions between actinide ions was an appropriate step in the determination of enthalpies of formation of compounds. A more fundamental reason is that the enthalpy of formation of an aqueous ion establishes a fundamental property of that ion and is a reference for all stability studies of compounds of that ion. Because solution microcalorimetry is more readily done than combustion microcalorimetry, milligram-scale enthalpy-of-formation studies of aqueous ions have been possible whereas such studies of oxides and halides by combustion calorimetry have not. In fact, microcalorimetry studies of transuranium elements have been carried out for more than 50 years, with barely an order of magnitude improvement in sensitivity in all that time!

The existing values of actinide aqueous-ion enthalpies of formation of actinium through berkelium were assessed by Fuger and Oetting (1976) in the frame of a series of publications under the auspices of the IAEA (Vienna). More recently, reassessments of the values for the ions of U, Np, Pu, and Am were presented in the NEA-TDB reviews, and for Cm ions by Konings (2001a). For these ions, the new values are preferred to those of Fuger and Oetting. Only in a few instances the differences are significant. For the quadrivalent (and pentavalent) Pa aqueous species, the values accepted here are very marginally different from those recommended by Fuger and Oetting, because of the later measurements with metal samples in the standard body-centered tetragonal form (Fuger *et al.*, 1978) instead of a quenched face-centered cubic form. For berkelium and californium,

newer measurements (Fuger *et al.*, 1981, 1984) have provided the tabulated enthalpies of formation. All An^{3+} values are plotted in Fig. 19.6, together with the Ln^{3+} values. The latter vary smoothly within a small band, with exception of Eu^{3+} and Yb^{3+}. These two metals are divalent in the crystal state, whereas the other lanthanide metals are trivalent. In the actinide series the electronic structure is more complex, as discussed in the previous sections, leading to a much more irregular pattern.

An important correlation between trivalent f-block ions and their 'trivalent' atoms ($f^n ds^2$) is the promotion energy function $P(M)$ proposed by Nugent *et al.* (1973), who utilized it for predicting enthalpies of formation of aqueous ions systematically (Fig. 19.7). David (1986) used the heavy actinide thermodynamic properties to establish a $P(M)$ function relating all of the actinide metals and their 3+ aqueous ions. Morss and Sonnenberger (1985) used newer data to

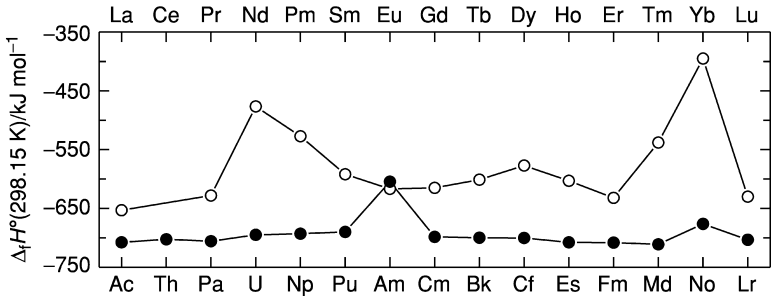

Fig. 19.6 *The enthalpy of formation of the lanthanide* (•) *and actinide* (○) *trivalent aqueous ions at* $T = 298.15$ K.

refine this $P(M)$ function and to develop similar $P(M)$ plots relating f-block metals and their sesquioxides and trichlorides (Fig. 19.8). David's predictions for $\Delta_f H^\circ(Bk^{3+})$ and $\Delta_f H^\circ(Cf^{3+})$ have been borne out by experiments and consequently, their estimates for the heaviest trivalent actinides are used here. Some enthalpies of formation of tetravalent and higher ions have been calculated from Gibbs energies (electromotive force (EMF) measurements) and entropies (estimates) (Fuger and Oetting, 1976).

Enthalpies of formation of the tetravalent ions Am^{4+} and Cm^{4+} have been estimated from enthalpies of formation and solution of the dioxides (Morss and Fuger, 1981; Morss, 1983, 1985). The enthalpy of formation of Cf^{4+} was obtained from that of Cf^{3+}, the semiempirically deduced standard potential for the Cf^{4+}/Cf^{3+} couple, 3.2 V (see below), and the assumption that the difference in entropies between the Cf^{4+} and the Cf^{3+} ions is the same as for the corresponding Bk system.

19.3.2 Entropies

Entropies of aqueous ions can be determined directly by measuring the enthalpy and Gibbs energy of solution of a salt that contains the ions, and also by measuring the heat capacity of the solid salt and calculating its entropy.

$$\Delta_f S^\circ = (\Delta_f H^\circ - \Delta_f G^\circ)/T \tag{19.3}$$

The absolute entropy of the ion is then calculated from the equation representing $\Delta_f S^\circ$:

$$MX_n(cr) = M^{n+}(aq) + nX^-(aq) \tag{19.4}$$

Standard-state entropies of aqueous ions are by convention referenced to $S^\circ(H^+(aq)) = 0$. Four actinide aqueous-ion entropies (Th^{4+}, Pu^{3+}, UO_2^{2+}, and NpO_2^{2+}) have been determined by the former method.

The temperature coefficient of the EMF of an equilibrium reaction involving the ion can be used to calculate the entropy of the reaction, from which, using auxiliary data, the entropy of formation of the ion can be calculated. This is, for instance, the case of the entropy of the $Pu^{4+}(aq)$ ion. When, for a given reaction, the standard enthalpies of formation of the intervening ions, as well as the standard potential, are known, then the entropy change for this reaction is, of course, fixed. Alternatively, the experimental knowledge of the standard potential and of the entropy change fixes the standard enthalpy of formation.

Fuger and Oetting (1976) summarized all experimental data and selected or estimated entropies of the aqueous ions of Th through Bk. We have adopted their values for the ions of Th, Pa, and Cm. For Bk, we have used the temperature dependence of the Bk^{4+}/Bk^{3+} potential by Simakin *et al.* (1977). For the ions of U, Np, Pu, and Am, the values recommended by the NEA-TDB assessment (Grenthe *et al.*, 1992; Silva *et al.*, 1995; Lemire *et al.*, 2001; Guillaumont *et al.*, 2003) have been taken. For the aqueous ions beyond Bk, only estimated entropies are available. These estimates are fairly trustworthy because they depend only upon the ionic charges, the ionic radii, and the magnetic degeneracy of the ground states.

Several semiempirical equations have been proposed to fit entropies of aqueous ions to the above parameters, for example (Morss, 1976; Morss and McCue, 1976):

$$S(M^{z+}) = \frac{3}{2}R\ \ln(\text{at.wt.}) + R\ \ln(2J+1) + 256.8 - 32.84(|z|+3)^2/(r+c) \tag{19.5}$$

where $R = 8.314\ \text{J K}^{-1}\ \text{mol}^{-1}$, J is the total angular momentum quantum number of the ion, z is the ionic charge, r is the ionic radius (in nm) for coordination number 6 taken from Shannon (1976) (except that coordination number 8 is used for $z = 4$), and c is a term added to the radius to represent the inner-sphere hydration: $c = 0.120$ nm for cations and $c = 0.040$ nm for anions. David (1986) has proposed the following equation:

$$S(M^{z+}) = \frac{3}{2}R\ \ln(\text{at. wt.}) + R\ \ln(2J+1) + S_c(r) \tag{19.6}$$

where $S_c(r)$ is a structural entropy term, dependent for a given z only on the hydrated-ion structure. Equation (19.6) was devised by David to take into account the change in inner-sphere hydration number from 9 to 8 between Sm and Tb in the Ln^{3+} ions and between Cm and Es in the An^{3+} ions. Very recently, David and coworkers (David and Vokhmin, 2001, 2002; David *et al.*, 2001) developed a hydration and entropy model for covalent and ionic ions, leading to estimates very close to those obtained earlier. We thus accept David's estimates

of the heavy An^{3+} ion entropies. Equation (19.5) has been used for divalent and tetravalent ions (Table 19.3). The necessary ionic radii for equation (19.5) were estimated by comparison of isoelectronic 4f and 5f ions as well as by Shannon-type plots of unit-cell volumes of dihalides and dioxides against r^3. Other predictive equations give fairly consistent entropy estimates (Lebedev, 1981; David, 1986) even though ionic radii as small as 100 pm for No^{2+} have been estimated (Silva *et al.*, 1974; David, 1986).

For the An^{4+} ions the situation is less clear. Entropy values have been derived for Th^{4+}, U^{4+}, Np^{4+}, and Pu^{4+} from experiments. However, the trend in the values for these compounds, even when corrected for the $R\ln(2J+1)$ contribution, is not smooth as one could expect from equation (19.6), as shown by Konings (2001a), who suggested that the Np^{4+} value may be in error. He suggested $S°(Np^{4+}, aq, 298.15\ K) = -414\ J\ K^{-1}\ mol^{-1}$, which is the lower limit of the experimental value, $-(426.4 \pm 12.4)\ J\ K^{-1}\ mol^{-1}$ as given by NEA (Lemire *et al.*, 2001). Also his estimate for Am^{4+} ($-422\ J\ K^{-1}\ mol^{-1}$) is different from the NEA value $-(406 \pm 21)\ J\ K^{-1}\ mol^{-1}$ (Silva *et al.*, 1995). Clearly further experiments are needed to resolve these discrepancies.

19.3.3 Electrode potentials

Fuger and Oetting (1976) assessed the reversible cell EMF and polarographic data that allowed them to calculate Gibbs energy differences between many aqueous-ion pairs. By this way they were able to connect all aqueous ions and to tabulate Gibbs energies of formation of all actinide aqueous ions in acid solution. Comprehensive summaries of reduction potential literature values have been assembled by Martinot (1978) and Martinot and Fuger (1985). The latter authors have presented reduction potentials in acid solution for all of these elements including estimates of the reduction potentials for the Bk^{3+}/Bk and Cf^{3+}/Cf couples, based on calorimetric measurements on $Bk^{3+}(aq)$ and $Cf^{3+}(aq)$ (Fuger *et al.*, 1981, 1984). The reduction potentials of the U, Np, Pu, and Am ions were discussed extensively and assessed in the NEA-TDB series (Grenthe *et al.*, 1992; Silva *et al.*, 1995; Lemire *et al.*, 2001; Guillaumont *et al.*, 2003).

No selection was made by Fuger and Oetting (1976) and by Lemire *et al.* (2001) for the heptavalent/hexavalent neptunium and plutonium couples, although the literature values were discussed. We adopt here, for the formal potentials in 1 mol dm^{-3} NaOH the values (0.59 ± 0.05) V and (0.85 ± 0.05) V for the Np(VII/VI) and Pu(VII/VI) couples, respectively, from the review of Perethrukhin *et al.* (1995). Conventionally, we write the heptavalent species as MO_3^+, noting that, in neptunium, strong arguments have been brought recently in support of the existence of the tetroxo species $NpO_4(OH)_2^{3-}$ in 1 mol dm^{-3} NaOH (Williams *et al.*, 2001). Reduction of Np(VII) to NpO_2^{2+} in acid media occurs rapidly: we will take for the 1 mol dm^{-3} $HClO_4$ medium,

the value (2.04 ± 0.05) V from the determination of Musikas *et al.* (1974). For the corresponding Pu and Am couples in the same medium, Perethrukhin suggested the values (2.3 ± 0.1) V and (2.5 ± 0.1) V, respectively. The uncertainties have been increased, compared to those given in the references cited. No value exists for the corresponding Pu couple in acid media, which is even more oxidizing. The question of the existence of any Am(VII), even in basic media, has been briefly discussed by Silva *et al.* (1995), and no selection was made.

The heavier actinide ions present especially challenging problems. These elements have short-lived isotopes with available amounts ranging between micrograms and single atoms. They also have accessible divalent states. To achieve meaningful experimental measurements on these ions, Maly (1967) and Maly and coworkers (Maly and Cunningham, 1967; Maly *et al.*, 1968), as well as Samhoun and David (1976) and David (1986) developed radioelectrochemical tracer methods, and Mikheev (1983) and his coworkers developed co-crystallization systematics. Judicious application of radiopolarography, radiocoulometry, amalgamation energies, and co-crystallization has yielded E° for An^{3+}/An^{2+}, An^{2+}/An, and An^{3+}/An couples (David, 1986) and has provided Gibbs energies of formation for Es^{3+}, Md^{3+}, and No^{3+}. The best Gibbs energies of formation of Fm^{3+} and Lr^{3+} have actually been calculated from estimates of enthalpies of sublimation, promotion energies $P(M)$, and entropies (David, 1986). Fig. 19.9 summarizes standard reduction potentials that are consistent with the Gibbs energies of formation calculated from enthalpies of formation and standard entropies. Because of the necessity of making EMF measurements in strongly acidic solution, and the impossibility of making measurements approaching standard state (nearly neutral solution), both the Gibbs energies of formation and reduction potentials refer to formal potentials rather than standard potentials (unit concentration rather than unit activity of hydrogen ion). When no thermochemical data were available, notably for the divalent ions, the potentials have been estimated.

The reduction potentials in Fig. 19.9 are 'Latimer' diagrams showing the potentials of half-reactions in which the left-hand species is reduced to the right-hand species with the appropriate number of electrons, H^+, and H_2O to balance the half-reaction. (Species not found in aqueous solution, but whose thermodynamic properties have been estimated, are indicated in parentheses.)

The potentials are summarized in Fig. 19.10 as nE°, a property proportional to $\Delta_f G^\circ$, versus n, the oxidation state, so that the lowest-lying species for each element is the one most stable in equilibrium with the H^+/H_2 couple.

A substantial number of studies have dealt with the electrochemical behavior of complexed actinides in aqueous solution. Complexation of f-block ions by ligands such as carbonate and polyphosphotungstate has allowed otherwise unstable species such as Am(IV) and U(V) to be studied electrochemically (Kosyakov *et al.*, 1977; Volkov *et al.*, 1981; Hobart *et al.*, 1982, 1983). Carbonate and bicarbonate stabilize acidic cations at relatively high pH (typical

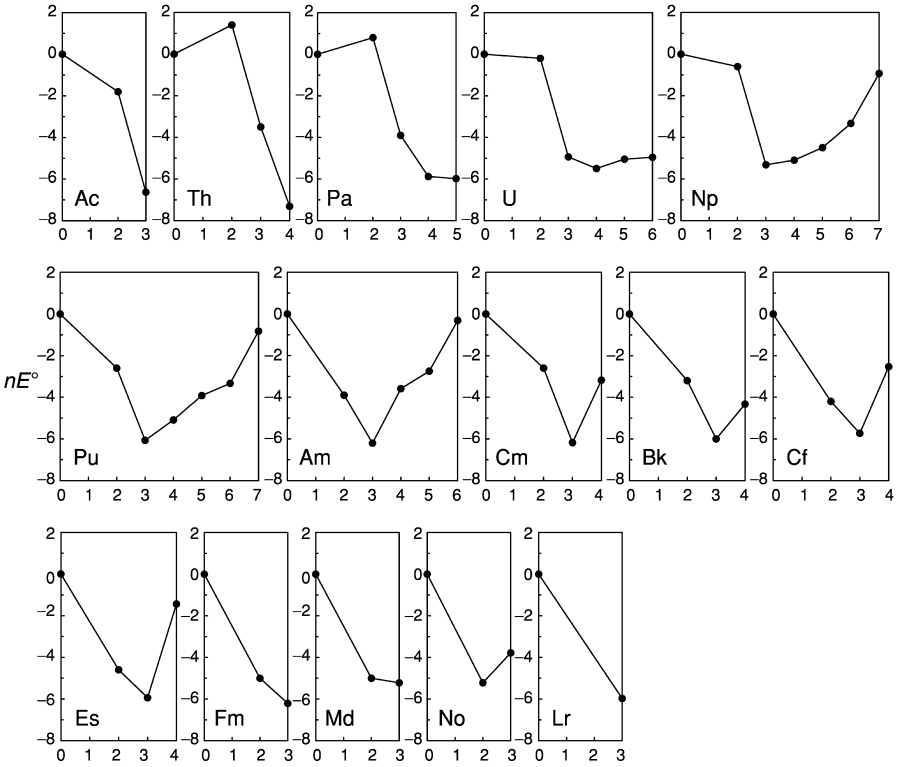

Fig. 19.10 *Comparative stability of actinide aqueous ions* (*relative to the* $H^+(aq)/H_2(g)$ *couple*).

of environmental and biological systems), and many actinide–carbonate studies have been reviewed (Cleveland, 1979; Newton and Sullivan, 1985).

Ions that are stabilized as complexes can be utilized to determine standard redox potentials. The $E°(Am^{4+}/Am^{3+})$ measured by cyclic voltammetry in 2 M $Na_2CO_3/NaHCO_3$ at pH 9.7, namely (0.92 ± 0.01) V, could be corrected for the preferred complexation of Am(IV) in this medium by 1.7 V to yield $E°(Am^{4+}/Am^{3+}) = (2.6 \pm 0.1)$ V (Hobart *et al.*, 1982), in good agreement with the accepted (Fig. 19.2) thermochemical value of (2.62 ± 0.09) V.

Polyphosphotungstate appears to be able to complex Cm(IV) and Cf(IV) sufficiently well to stabilize these ions in aqueous solution (Kosyakov *et al.*, 1977). Because the An^{4+}/An^{3+} potential shift of 1.7 V in carbonate is more favorable for stabilization of An^{4+} than is the shift of 1.0 V in polyphosphotungstate (Volkov *et al.*, 1981), it was expected that Cm(IV) and Cf(IV) would be readily produced in carbonate. Such was not found to be the case, however (Hobart *et al.*, 1983).

19.3.4 Heat capacities

Heat capacities, as well as entropies, of aqueous ions are the fundamental thermodynamic properties that reflect their structure and hydration. Heat capacities are also necessary for the calculation of other thermodynamic properties at temperatures other than 298.15 K. For the actinides, high-temperature properties (at least to 473 K) are essential for calculation of redox, complexation, and heterogeneous equilibria, which are useful in separation and waste management technologies.

The most thorough treatment of uranium and plutonium aqueous-ion equilibria over extended temperatures is that of Lemire and Tremaine (1980). This paper uses the systematic relationships developed by Criss and Cobble (1964), which relate aqueous-ion entropies, heat capacities, and their high-temperature behavior. Lemire and Tremaine had to rely on estimated heat capacities for almost all of their calculations, and most of their equilibrium constants are uncertain by two or more orders of magnitude. Lemire (1984) has also written a report on neptunium aqueous-ion equilibria over extended temperatures. However, in more recent years, the limitations of the Criss–Cobble relationships, when applied to tri- and quadrivalent aqueous species became more apparent. For instance, Shock *et al*. (1997), using the revised Helgerson–Kirkham–Flowers equation of state for aqueous ions, estimated $C^{o}_{p,m}(U^{3+}, aq, 298.15\ K) = -125.3\ J\ K^{-1}\ mol^{-1}$, distinctly more negative than the value $-(64 \pm 22)\ J\ K^{-1}\ mol^{-1}$ (mean value over the temperature range 298–473 K) accepted by Grenthe *et al*. (1992) from the estimate reported by Lemire and Tremaine. For another trivalent ion, Al^{3+}, Hovey and Tremaine (1986) have determined $C^{o}_{p,m}(Al^{3+}, aq, 298.15\ K) = -119\ J\ K^{-1}\ mol^{-1}$, whereas the Criss–Cobble relationship leads to $16\ J\ K^{-1}\ mol^{-1}$.

For quadrivalent actinide ions, the Criss–Cobble relation leads to −28, −48, and $-63\ J\ K^{-1}\ mol^{-1}$ for Th^{4+} (Morss and McCue, 1976), U^{4+}, and Pu^{4+} (Lemire and Tremaine, 1980), respectively. However, Hovey (1997) has determined recently $C^{o}_{p,m}(Th^{4+}, aq, 298.15\ K) = -(224 \pm 5)\ J\ K^{-1}\ mol^{-1}$. The flow microcalorimetric technique used by this author, under conditions minimizing hydrolysis and complexation, is far superior to measurements of integral heats of dilution or solution used in two previous studies (Apelblatt and Sahar, 1975; Morss and McCue, 1976). From the above, it appears that the Criss–Cobble relationships underestimate the heat capacities of tri- and quadrivalent ions by 100–160 $J\ K^{-1}\ mol^{-1}$. The values adopted recently by the NEA-TDB assessment (Guillaumont *et al*., 2003) $C^{o}_{p,m}(U^{3+}, aq, 298.15\ K) = -(150 \pm 50)\ J\ K^{-1}\ mol^{-1}$ and $C^{0}_{p,m}(U^{4+}, aq, 298.15K) = -(220 \pm 50) J\ K^{-1}\ mol^{-1}$ are in line with $C^{o}_{p,m}(Th^{4+}, aq, 298.15\ K) = -(224 \pm 5)\ J\ K^{-1}\ mol^{-1}$ (Hovey, 1997).

The value $C^{o}_{p,m}(UO_2^{2+}, aq, 298.15\,K) = (42.4 \pm 3.0)\ J\ K^{-1} mol^{-1}$, and the function $C^{o}_{p,m}(UO_2^{2+}, aq, T) = \{350.5 - 0.8722(T/K) - 5308((T/K) - 190)^{-1})\}$

$J\,K^{-1}mol^{-1}$, for the temperature range 283–328 K, adopted in the NEA assessment (Grenthe *et al.*, 1992) is also based on sound experiments (Hovey *et al.*, 1989).

For actinide ions, with 1+ charge, the only experimental results $C^{o}_{p,m}(NpO_2^+, aq, 298.15\ K) = -(4 \pm 25)\,J\,K^{-1}\,mol^{-1}$, and $C^{o}_{p,m}(NpO_2ClO_4, aq, T) = \{3.56779 \times 10^3 - 4.95931(T/K) - 6.32244 \times 10^5 (T/K)^{-1}\}\,J\,K^{-1}\,mol^{-1}$ in the temperature range 291–373 K, adopted in the NEA assessment (Lemire *et al.*, 2001) depend on measurements by Lemire and coworkers (Lemire *et al.*, 1993; Lemire and Campbell, 1996a) on NpO_2ClO_4 solutions. Use of $C^{o}_{p,m}(HClO_4, aq, T) = \{3.25118 \times 10^3 - 4.86333(T/K) - 5.45295 \times 10^5 (T/K)^{-1}\}\,J\,K^{-1}\,mol^{-1}$, in the same temperature range, from Lemire and Campbell (1996b) leads to $C^{o}_{p,m}(NpO_2^+, aq, T) = \{0.31661 \times 10^3 - 0.09598(T/K) - 0.87049 \times 10^5 (T/K)^{-1}\}\,J\,K^{-1}\,mol^{-1}$, with $C^{o}_{p,m}(H^+, aq, T) = 0\,J\,K^{-1}\,mol^{-1}$ in the reported temperature range.

Obviously, in recent years, progress has been made in our knowledge of the behavior of the electrolytes at high temperature. Nevertheless, more heat capacity data are needed for the multicharged ions.

19.4 IONS IN MOLTEN SALTS

Electrochemistry of actinides in molten salts has been pursued by many authors. The main incentives have been the molten salt reactor development and the pyrochemical reprocessing of spent fuel. The early work (up to 1980) has been summarized through reviews (Gruen, 1976; Plambeck, 1976; Martinot, 1978, 1982). In some cases, such as hydroxide and carbonate melts, high oxidation states of the actinides are stabilized, whereas in halide melts the use of strong Lewis acid molten salts stabilizes lower oxidation states (4+, 3+, and 2+). Coprecipitation of lanthanide tri- and dichlorides and oxychlorides with trace amounts of some actinides has yielded some An^{3+}/An^{2+} E° values and has produced evidence (unconfirmed by other methods) of divalent Pu, Cm, and Bk (Mikheev, 1983).

We will briefly summarize the data for the fluoride ($LiF–BeF_2$) and chloride (LiCl–KCl) systems as these are of interest to the renewed studies of the molten salt reactor and the pyrochemical reprocessing of spent fuel, in the framework of the partitioning and transmutation (P&T) and advanced nuclear reactor development programs worldwide. The apparent standard potentials are summarized in Tables 19.4 and 19.5.

The data for the actinide fluorides in $LiF–BeF_2$ (0.67:0.33 molar ratio) are taken from the review of Martinot (1982) who selected the data assessed by Baes (1966, 1969) for the Molten Salt Reactor Experiment (MSRE). These data are not based on electrochemical measurements but are derived from chemical

equilibria in LiF–BeF_2 (0.67:0.33). For example, the uranium potentials were derived from the equilibria:

$$UO_2(s) = U^{4+}(sln) + 2\,O^{2-}(sln) \tag{19.7}$$

$$\frac{1}{2}\,H_2(g) + UF_4(sln) = UF_3(sln) + HF(g) \tag{19.8}$$

via the Gibbs energies of formation, scaling the results to the HF/F^- and the Be^{2+}/Be^0 couples.

Martinot (1982) summarized the data for the actinides in molten chloride salts, primarily based on his own electrochemical measurements. But recently many new studies have been reported on plutonium and americium in LiCl–KCl (Roy *et al*., 1996; Fusselman *et al*., 1999; Lambertin *et al*., 2000; Serp *et al*., 2004). Here a contradictory observation is made: the results of Martinot indicate an increase of the apparent potential of the An^{3+}/An^0 couple from U to Cm, whereas the more recent results indicate the opposite trend (Fig. 19.11), which is in agreement with the trend in potentials of the aqueous ions. Baes (1966) indeed noted that the potentials in molten salts correlate very well with those in solutions, and for that reason we reject the results of Martinot. Recently, data on Am^{2+}/Am^0 couple have been obtained (Fusselman *et al*., 1999). Yamana and Moriyama (2002) measured the Ln^{2+}/Ln^{3+} couples of Nd, Eu, Dy, and Yb and showed an excellent correlation with the aqueous Ln^{2+}/Ln^{3+} potentials.

19.5 OXIDES AND COMPLEX OXIDES

19.5.1 Binary oxides with O/An > 2.00

Many binary uranium oxides with O/U > 2.00 are known, and the thermodynamic properties of most of them are well established (see Table 19.6). The room temperature values for γ-UO_3 and U_3O_8 are CODATA Key Values (Cox *et al*., 1989); those of the other binary uranium compounds have been reviewed

[c] Morss and Fuger (1981).

by Grenthe *et al*. (1992). Pa_2O_5 and Np_2O_5 are the only other well-known binary oxide with O/An > 2.00. None of the thermodynamic properties of Pa_2O_5 have been measured. Those of Np_2O_5 are fairly well established through enthalpy of formation measurements (Belyaev *et al*., 1979; Merli and Fuger, 1994) and high-temperature enthalpy increment measurements (Belyaev *et al*., 1979) that have been reviewed by Lemire *et al*. (2001). Because of the better stoichiometry and better thermochemical cycle used by Merli and Fuger, the $\Delta_f H°(Np_2O_5,cr)$ derived from that work has been accepted. No lanthanide comparison for these compounds can be made because there are no lanthanide oxides with O/Ln > 2.00. Recently the existence of PuO_{2+x} with x up to 0.5 has been claimed (Haschke *et al*., 2001) and its thermodynamic properties have been estimated (Haschke and Allen, 2002).

19.5.2 Dioxides

(a) Enthalpy of formation

The dioxides from ThO_2 through CfO_2 are all known, but many of these have not been studied thermodynamically (see Table 19.7). Because the enthalpy of formation values of ThO_2, UO_2 (CODATA Key Values, see Cox *et al*., 1989) and NpO_2 to CmO_2 are based on a sound experimental basis, the values for the other actinide dioxides can be estimated with reasonable accuracy.

Table 19.7 *Thermodynamic properties of the crystalline actinide dioxides at* 298.15 K*; estimated values are in italics.*

	S_{exs} (J K^{-1} mol^{-1})	$S°$(298.15 K) (J K^{-1} mol^{-1})	$\Delta_f H°$(298.15 K) (kJ mol^{-1})	*References*

[a] Cox *et al.* (1989).
[b] Estimated in the present work.
[c] NEA-TDB (Silva *et al.*, 1995; Lemire *et al.*, 2001; Guillaumont *et al.*, 2003).
[d] Konings (2001b).

Morss and Fuger (1981) established that the reaction enthalpy of the idealized dissolution reaction

$$AnO_2(c) + 4H^+(aq) \rightarrow An^{4+}(aq) + 2H_2O(l) \qquad (19.9)$$

varies regularly in the actinide series. The enthalpy of this reaction represents in part the difference between the lattice enthalpy of the crystalline dioxide and the enthalpy of hydration of its ionic components. Both these properties are difficult to calculate and change substantially as a function of ionic properties, whereas their difference (the enthalpy of solution) should change slowly and smoothly as a function of ionic size. Because the enthalpies of formation of $H^+(aq)$ and $H_2O(l)$ are constant in this equation, the quantity $\{\Delta_f H°(MO_2, cr) - \Delta_f H°(M^{4+}, aq)\}$ can be used for establishing relationships. Fig. 19.12 shows the relation with the molar volume of the unit cell. Ionic radii could have been used, because these are tabulated as a function of coordination number, but often they are reliable to only two significant figures. The values for PaO_2, BkO_2, and CfO_2 can be derived by interpolation or extrapolation of the linear relationship. These values are included in Table 19.7.

(b) Entropy

The low-temperature heat capacities have been measured for the solid dioxides from ThO_2 to PuO_2 and standard entropies for these compounds are known (see Table 19.7). The values for ThO_2 and UO_2 are CODATA Key Values (Cox *et al.*, 1989), those for NpO_2 and PuO_2 have been evaluated by the NEA-TDB (Lemire *et al.*, 2001). Konings (2001a) estimated the entropies of AmO_2 and CmO_2, proposing that the $S°$(298.15 K) of these compounds can be adequately

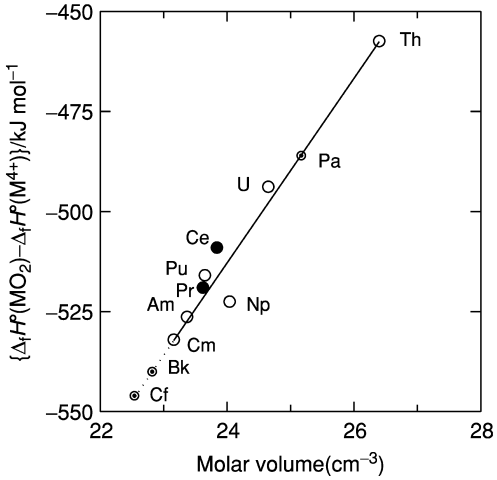

Fig. 19.12 *The difference between the enthalpies of formation of f-element dioxides and the corresponding* M^{4+} *aqueous ions; lanthanides* (•), *actinides* (○), *and estimated values* (⊙).

described as the sum of a lattice component and an excess component arising from f-electron excitation:

$$S = S_{\text{lat}} + S_{\text{exs}} \tag{19.10}$$

S_{lat} was assumed to be the value for ThO_2 and S_{exs} was calculated from the crystal field energies of these compounds (Krupa and Gajek, 1991; Krupa, 2001). Good agreement with the experimental values for UO_2, NpO_2, and PuO_2 was found and the description explains the significantly lower entropy value of PuO_2 among these compounds. This estimation procedure was adopted in the recent evaluation of the entropies of Am compounds by the NEA-TDB project (Guillaumont *et al.*, 2003). In a subsequent study, Konings (2004a) argued that the experimental data give evidence that S_{exs} is composed of two terms, the f-electron excitation and a residual term:

$$S_{\text{exs}} = S_{\text{f}} + S_{\text{res}} \tag{19.11}$$

We have used a similar method to estimate the entropies of PaO_2, BkO_2, CfO_2, and EsO_2, where in absence of crystal field data, the excess contribution was calculated from the degeneracy of the unsplit ground state, which probably overestimates the entropy somewhat.

(c) High-temperature properties

The high-temperature properties of the major actinide dioxides (UO_2, ThO_2, PuO_2) have been reviewed by many authors. The data are mostly restricted to the solid phase, except for UO_2, which has been studied in detail in the crystal,

liquid, and gas phases (up to 8000 K) for obvious reasons. Fink (2000) reviewed the thermophysical properties of UO_2 recently and presented recommended values for a large number of thermodynamic and thermophysical properties. Numerous equations of state for UO_2 have been published, the most recent and complete one by Ronchi *et al.* (2002). Also the high-temperature properties of thorium oxide in the crystal phase are reasonably well established (Bakker *et al.*, 1997). The melting points of the actinide dioxides are shown in Fig. 19.13 along with those for the lanthanide and actinide sesquioxides.

The high-temperature heat capacities of ThO_2, UO_2, and PuO_2 are shown in Fig. 19.14. The heat capacity approaches the Dulong–Petit value ($9R = 74.8$ J K^{-1} mol^{-1}) between 500 and 1500 K. In this temperature range the lattice contributions dominate the heat capacity with a minor but significant

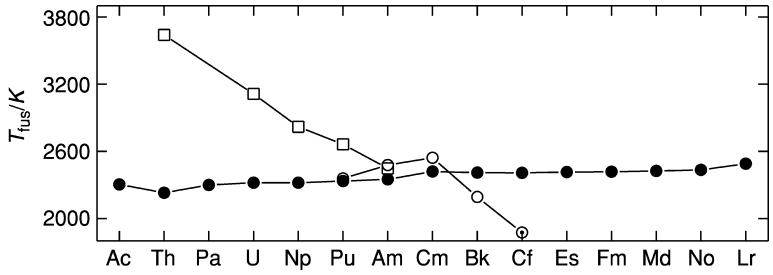

Fig. 19.13 *The melting points of the lanthanide sesquioxides* (•), *the actinide sesquioxides* (○) *and actinide dioxides* (□)*; estimated values are indicated by* (⊙).

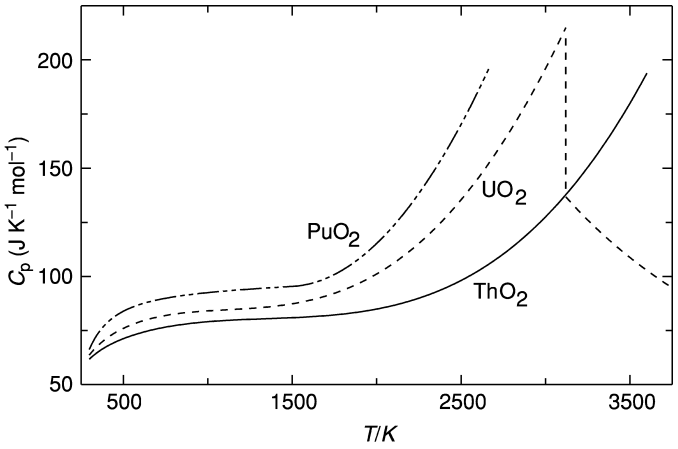

Fig. 19.14 *The high-temperature heat capacity of the actinide dioxides* (*see Table* 19.9).

contribution of 5f electron excitations. Peng and Grimvall (1994) showed that for ThO_2 and UO_2 the harmonic lattice contributions dominate up to about 500 K; above that temperature, the anharmonic contributions should be included.

As discussed in Section 19.5.2(b), the difference between the heat capacity of ThO_2 and the other actinide dioxides in the temperature range up to 1500 K is mainly due to the excess contribution arising from the population of excited f-electron levels of the An^{4+} ions:

$$C_p = C_{lat} + C_{exs} \tag{19.12}$$

Thus the heat capacity of the other actinide dioxides can be approximated by adding C_{exs}, which can be calculated from electronic energy levels.

Above 1500 K, the heat capacity strongly increases towards the melting point. In this temperature range, λ-type phase transitions have been observed for UO_2 (Hiernaut *et al.*, 1993) as well as ThO_2 (Ronchi and Hiernaut, 1996) at about $0.85T_{fus}$, which are related to order–disorder anion displacements in the oxygen sublattice. Below the phase transition, the formation of Frenkel lattice defects is the main cause of the rapid increase of the heat capacity; above the phase transition, Schottky defects become more important. The experimental data for PuO_2 by Ogard (1970) suggest a similar effect above 2400 K, but it has been attributed to partial melting of PuO_2 through interaction with the tungsten container (Fink, 1982; Oetting and Bixby, 1982). Because no clear evidence exists for this interaction, it has been included in the recommended equations given in this work (unlike in Cordfunke and Konings, 1990; Lemire *et al.*, 2001).

The experimental heat capacity data for NpO_2 (Arkhipov *et al.*, 1974) are in poor agreement with the low-temperature data and with the values estimated by Yamashita *et al.* (1997) and Serizawa *et al.* (2001). These authors calculated the lattice heat capacity from the phonon and dilatation contributions using Debye temperature, thermal expansion, and Grüneisen constants, and the electronic contributions from crystal field energies. No experimental data are known for PaO_2 and AmO_2. CmO_2 is unstable above 653 K.

As shown in Fig. 19.13 the melting points of the dioxides steadily decrease from ThO_2 to PuO_2, the change being more than 1200 K. This strong variation is accompanied by a strong increase in the oxygen pressure as the dioxides start to lose oxygen according to the reaction

$$MO_2(c) = MO_{2-x}(s) + \frac{x}{2}O_2(g) \tag{19.13}$$

which for PuO_2 and AmO_2 is already significant below the melting point, which means that the melting points are only defined in an oxygen atmosphere. The decrease of stability is related to the strong changes in stability of the 4+ oxidation states. Only the melting enthalpy of UO_2 is known with some accuracy. The values for the other dioxides have been estimated assuming that the entropy of melting is constant along the AnO_2 series.

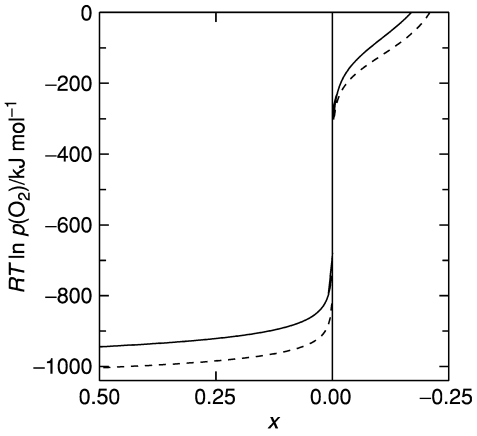

Fig. 19.15 *The oxygen potential of* UO_{2-x} *at* 1500 K (*solid line*) *and* 1250 K (*broken line*) *as a function of x calculated from the Lindemer and Besmann* (1985) *model; note that the hyperstoichiometric range is given with negative values.*

Recommended equations for the high-temperature heat capacity are given in Table 19.8.

(d) Nonstoichiometry

The actinide dioxides are well known for their wide ranges of nonstoichiometry. Hypostoichiometry has been reported for all actinide dioxides. Hyperstoichiometry is only known for UO_2 although recent studies have presented evidence that it could also occur in PuO_2 (Haschke *et al.*, 2001).

Lindemer and Besmann (1985) presented a thermochemical model to represent the oxygen potential–temperature–composition data for $AnO_{2\pm x}$ assuming a solution of two fluorite structures with different O/An ratios. The reaction can be represented by

$$\left(\frac{2a}{b-2a}\right)\mathrm{AnO_2} + \mathrm{O_2} = \left(\frac{2}{b-2a}\right)\mathrm{An}_a\mathrm{O}_b \tag{19.14a}$$

for the hyperstoichiometric range and

$$\left(\frac{2}{2a-b}\right)\mathrm{An}_a\mathrm{O}_b + \mathrm{O_2} = \left(\frac{2a}{2a-b}\right)\mathrm{AnO_2} \tag{19.14b}$$

for the hypostoichiometric range. In these equations, An_aO_b is a hypothetical end-member of the fluorite solid solution $AnO_{2\pm x}$. The oxygen potential can then be represented by:

$$RT\ln(p\mathrm{O_2}) = \Delta_r H - T\Delta_r S + RTf(x) + Ef'(x) \tag{19.15}$$

Table 19.8 *High-temperature heat capacity of the binary actinide oxides;* $C_p/(\mathrm{J\ K^{-1}\ mol^{-1}}) = a(\mathrm{T/K})^{-2} + b + c(\mathrm{T/K}) + d(T/K)^2 + e(\mathrm{T/K})^3 + f(\mathrm{T/K})^4$ (*estimated values are in italics*); *temperature T indicates the transition or melting temperatures except marked with m, when it indicates the maximum valid temperature of the polynomial equation.*

where $f(x)$ and $f'(x)$ are functions of x that follow from the mass balance, and E is a temperature-dependent interaction energy term that was used in modeling the experimental data:

$$E = \Delta H_e - T\Delta S_e \tag{19.16}$$

Lindemer and Besmann (1985) analyzed the vast amount of experimental data and showed that hyperstoichiometric UO_{2+x} can be represented as a mixture of UO_2 and U_3O_7 for oxygen potentials above $RT\ln(p) = -26\,6700 + 16.5(T/K)$, or $U_2O_{4.5}$ below this limit; hypostoichiometric UO_{2-x} as a mixture of UO_2 and the hypothetical end-member compound $U_{1/3}$. Besmann and Lindemer (1985, 1986) showed that PuO_{2-x} can be represented as a mixture of PuO_2 and $Pu_{4/3}O_2$.

Also for the Np–O, Am–O, Cm–O, Bk–O, and Cf–O systems, the $T-p(O_2)-x$ relations have been measured. The Np–O system was studied by Bartscher and Sari (1986) using the gas equilibrium technique, the other systems by Eyring and coworkers (Chikalla and Eyring, 1967; Turcotte *et al.*, 1971, 1973, 1980; Haire and Eyring, 1994) using oxygen decomposition measurements, and the Am–O system by Casalta (1996) using a galvanic cell. The data of most of these systems, however, do not allow a detailed description of the $T-p(O_2)-x$ relations due to insufficient knowledge of the composition of the solid phase. An exception is the Am–O system and Thiriet and Konings (2003) applied the Lindemer–Besmann approach to the results of Chikalla and Eyring (1967), showing that AmO_{2-x} can be represented as a mixture of $Am_{5/4}O_2$ and AmO_2.

19.5.3 Sesquioxides

(a) Enthalpy of formation

Unlike the 4f elements, for which sesquioxides are ubiquitous, only the sesquioxides of Ac and Pu through Es have been prepared (Haire and Eyring, 1994). Experimental data from solution calorimetry are available for Am_2O_3, Cm_2O_3, and Cf_2O_3 and the enthalpies of formation of these three compounds are well established (although by only one set of measurements). Their values, the former taken from the most recent assessments (Silva *et al.*, 1995; Konings, 2001b) and Cf_2O_3 from the original paper (Morss *et al.*, 1987), are given in Table 19.9.

As discussed for the dioxides, a systematic approach to the prediction of the enthalpies of formation of other sesquioxides can be made on the basis of the reaction enthalpy of the idealized dissolution reaction

$$An_2O_3(cr) + 6H^+(aq) \rightarrow 2An^{3+}(aq) + 3H_2O(l) \tag{19.17}$$

The enthalpy of this reaction can be used for establishing a relationship with molar volume, which was chosen as a parameter because there are three different sesquioxide structures with different coordination numbers and numbers of molecules per unit cell, as shown in Fig. 19.16. It is evident that, for all the three structure types, the enthalpies of solution of actinide sesquioxides are

Table 19.9 *Standard entropies and enthalpies of formation of the crystalline actinide and lanthanide sesquioxides; estimated values are in italics.*

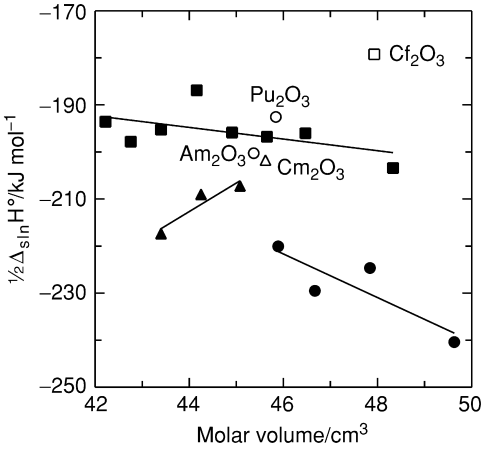

Fig. 19.16 *The enthalpy of solution* (*reaction* 19.17) *of the f-element sesquioxides; closed symbols, lanthanides; open symbols, actinides;* (●, ○), *hexagonal,* (▲, △), *monoclinic,* (■, □), *cubic.*

significantly less exothermic than for structurally similar lanthanide sesquioxides. With the exception of the enthalpy of formation of Pu_2O_3 (see below), the enthalpies of formation of the other sesquioxides were estimated from Fig. 19.16, taking in account their known or expected structural type.

Using the calculated enthalpies of formation of the sesquioxides of U and Np, it can be shown that these sesquioxides are thermodynamically unstable with respect to disproportionation to the metals and the much more stable dioxides, e.g. using enthalpies of formation and estimated entropies:

$$2Np_2O_3(c) = 3NpO_2(c) + Np(c), \quad \Delta G^\circ = -162 \text{ kJ mol}^{-1} \qquad (19.18)$$

The corresponding U reaction has $\Delta G = -322$ kJ mol^{-1}. The case of Pu_2O_3 deserves special mention. Its enthalpy of formation has been estimated as $-(1710 \pm 13)$ kJ mol^{-1} (IAEA, 1967) from high-temperature EMF measurements, as $-(1685 \pm 21)$ kJ mol^{-1} (Chereau *et al.*, 1977) from high-temperature calorimetry, and as -1656 kJ mol^{-1} (Besmann and Lindemer, 1983) from earlier measurements and more recent heat capacity values. The last value is adopted in Lemire *et al.* (2001). Because there is an experimentally derived standard entropy of Pu_2O_3, we can calculate its Gibbs energy of reaction (19.17), -289 kJ mol^{-1}, for comparison with that of the structurally similar Nd_2O_3, -332 kJ mol^{-1}. Actinide sesquioxides appear to be more stable than structurally similar lanthanide sesquioxides in comparison with the corresponding aqueous solutions, so that nuclear waste oxide matrices that accept lanthanide ions should bind corresponding trivalent actinides (Pu^{3+}, Am^{3+}) even more strongly. The reason for this behavior is not clear; a rationalization is that the 5f covalence is stronger to oxygen in solid oxides than in hydrated ions.

Recommended values for the standard enthalpies of formation and entropies of the actinide and lanthanide sesquioxides are assembled in Table 19.9.

(b) Entropy

Low-temperature heat capacity measurements have been reported for Pu_2O_3 only (Flotow and Tetenbaum, 1981). This value was used to derive the entropies of Am_2O_3 and Cm_2O_3 (Konings, 2001a; Konings *et al.*, 2005) using equation (19.10), calculating the excess entropy from known crystal field energies. Because information on the lattice component in the actinide sesquioxide series is missing, and the lattice component was obtained by scaling the values derived from the isostructural lanthanide series (Fig. 19.17). In this series the lattice entropy can be described by a simple linear relation between La_2O_3 and Gd_2O_3, for which the lattice values are well known due to the f^0 and f^7 configurations.

(c) High-temperature properties

High-temperature properties of the actinide sesquioxides have hardly been studied. The phase transitions in the sesquioxides have been determined and it has been shown that the sesquioxides exhibit a polymorphism: bcc → monoclinic → hexagonal. The cubic to monoclinic transition is, however, irreversible, and the monoclinic form is thought to be the thermodynamically stable phase. The measured melting points of Pu_2O_3, Am_2O_3, Cm_2O_3, and Bk_2O_3 are plotted in Fig. 19.13 and show a maximum at Cm_2O_3.

The only measurements of high-temperature properties are for Pu_2O_3, Am_2O_3, Cm_2O_3, and Bk_2O_3. The most extensive are the studies made for $^{244}Cm_2O_3$,

which was considered as an isotopic heat source in the 1970s. Vapor pressure studies (see Section 19.5.5) and thermal conductivity and thermal diffusivity measurements were reported. To convert the latter measurements to thermal conductivity, Gibby *et al.* (1970) estimated the heat capacity of Cm_2O_3. As discussed by Konings (2001a), these values are very high when compared to the lanthanide sesquioxide data. Since reliable high-temperature heat capacity data for the lanthanide sesquioxides are available, the functions of the actinide sesquioxides can be estimated from those by simple correlation (equation (19.13)).

19.5.4 Monoxides

Solid monoxides of Th and of U through Am have been reported as surface layers on the metals, as the reduction product of PuO_2 with Pu or C, or as the product of reaction of Am with HgO. However, these solid 'monoxides' may be oxycarbides (Larson and Haschke, 1981). Usami *et al.* (2002) claim the formation of AmO by lithium reduction of AmO_2. The product was, however, not characterized but its formation was deduced from a mass balance. The authors estimated its Gibbs energy of formation as -481.1 kJ mol^{-1} at 923 K.

Among the reported lanthanide monoxides, only EuO is well characterized, impure YbO can be prepared with difficulty, and 'metallic' (trivalent) monoxides of La, Ce, Pr, Nd, and Sm can be synthesized at high temperature and pressure. Earlier reports of lanthanide monoxides as surface phases are believed to be oxynitrides, oxycarbides, or hydrides (Morss, 1983). Thermodynamic calculations have shown how marginally stable the few lanthanide monoxides are, even under the exotic conditions of their preparation, and that classical (divalent) CfO should be unstable with respect to disproportionation (Morss, 1983). Thus the only hope of synthesis of actinide monoxides would appear to be the high-pressure route for AmO and CfO, an extremely demanding synthetic procedure.

19.5.5 Oxides in the gas phase

Gaseous actinide oxide molecules of the types AnO, AnO_2, and AnO_3 have all been identified in Knudsen cell effusion or matrix isolation experiments of vapors above the solid oxides. The experimental work is restricted to the oxides of Th to Cm.

Thorium dioxide principally vaporizes to give ThO_2 molecules. Numerous vapor pressure studies have been performed for the solid–gas equilibrium, none of them, however, with techniques to confirm the vapor composition. Ackermann and Rauh (1973a) as well as Belov and Semenov (1980) reported the existence of the monoxide ThO in the vapor phase using mass spectrometry. Ackermann and Rauh (1973b) derived enthalpies of formation of the two molecules from the existing studies by correcting the vapor pressure studies for the ThO contribution. The thermal functions of the gaseous molecules have

been calculated from molecular parameters (Rand, 1975). The properties of the ThO molecule are based on experimental results as summarized by Rand (1975) and have been confirmed by quantum chemical calculations (Küchle *et al*., 1994). ThO_2 is a bent molecule, as was derived from matrix-isolation and molecular beam deflection studies (Linevsky, 1963; Kaufman *et al*., 1967; Gabelnick *et al*., 1974).

In the Pa–O system the monoxide and dioxide species have been identified in the vapor above PaO_{2-x} (Kleinschmidt and Ward, 1986) and above Pa metal in the presence of small amounts of oxygen (Bradbury, 1981).

The situation for uranium is more complex. The binary molecules UO, UO_2, and UO_3 coexist above solid and liquid UO_2, and at very high temperatures even dimeric molecules of these species and ionic species contribute to the vapor pressure. The UO_2 molecule does not have a bent structure, like ThO_2, but is linear; UO_3 is planar with a T-shaped geometry (Green, 1980). The relative fractions of these species are highly dependent on the temperature and O/U ratio of the condensed phase. Ronchi *et al*. (2002) have presented a detailed analysis of these complex equilibria, for which a large number of studies has been made up to very high temperatures, and their recommended values for the enthalpies of formation and entropies are listed in Table 19.10.

Ackermann *et al*. (1966a) measured the vapor pressure of NpO_2 by the Knudsen effusion technique. Mass spectrometric measurements confirmed that NpO_2 is the dominant vapor species but that NpO(g) also has a significant contribution to the vapor. Ackermann and Rauh (1975) studied the isomolecular

exchange reactions with La and Y by mass spectrometry. In addition, Ackermann and Rauh (1975) studied the NpO vapor pressure over the univariant system (NpO_2(cr)+Np(l)+vapor) by Knudsen effusion technique. This approach yields results that are within the limits of uncertainty of the analysis of the isomolecular exchange reactions. The selected enthalpies of formation are derived from these studies.

In the Pu–O system, it has been thought for a long time that only PuO_2 and PuO exist as binary molecular species, but recently the existence of the PuO_3 molecule has been reported (Ronchi *et al.*, 2000). Matrix-isolation spectroscopy (Green and Reedy, 1978a,b) has established the linear molecular structure of PuO_2 and yielded values for the vibrational stretching frequencies. Archibong and Ray (2000) calculated the molecular properties of PuO_2 using quantum chemical techniques. They found that the $^5\Sigma_g^+$ and the $^5\Phi_u$ states are both candidates for the ground state, being almost equal in energy, the former preferred because of somewhat better agreement with the experiments for the two stretching frequencies. However, the data for the internuclear distance and the bending frequency for the $^5\Sigma_g^+$ state differ considerably from the estimates by Green (1980) on basis of the UO_2 data, whereas the data for the $^5\Phi_u$ state agree reasonably. The enthalpies of formation of PuO and PuO_2 are taken from Glushko *et al.* (1978).

The vapor pressure of americium oxides has been deduced from measurements of plutonium oxides containing small amounts of ^{241}Am as decay product using Raoult's law (Ackermann *et al.* 1966b; Ohse, 1968). Although no direct measurement of the vapor species was made in either study, it was assumed that the AmO and AmO_2 molecules are present. These data do not, however, allow the derivation of formation properties.

For the Cm–O system, Knudsen cell effusion measurements have been performed (Smith and Peterson, 1970) from which it was concluded that Cm_2O_3 vaporizes according to the reaction:

$$Cm_2O_3(cr,l) = 2\,CmO(g) + O(g) \tag{19.19}$$

which is analogous to the lanthanide sesquioxides. Hiernaut and Ronchi (2004) recently measured the vapor pressure of $(Cm,Pu)_2O_3$ by Knudsen effusion mass spectrometry, confirming the results and conclusions of Smith and Peterson (1970).

The dissociation energy of the actinide monoxides are plotted in Fig. 19.18 together with those of the lanthanide monoxides (Pedley and Marshall, 1983). The pattern that emerges for the actinide monoxides is parallel to that of the lanthanide monoxides and the dissociation energies of AmO can be estimated. Haire (1994) discussed this pattern in more detail, and extended the estimates to the heaviest actinides. He described the dissociation energy by a base energy $D_{0,\mathrm{base}}$ and a ΔE value (as proposed by Murad and Hildenbrand (1980)):

$$D_0 = D_{0,\mathrm{base}} + \Delta E \tag{19.20}$$

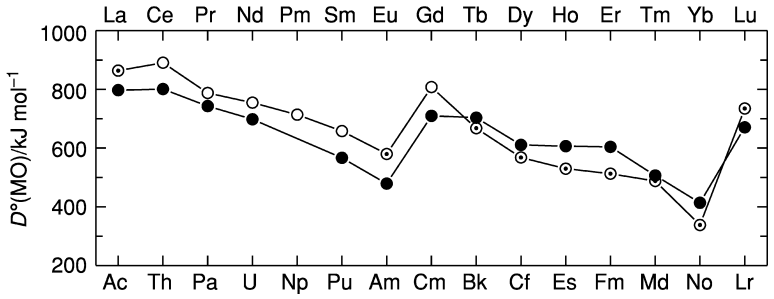

Fig. 19.18 *Dissociation energy of lanthanide* (•) *and actinide* (○) *monoxides; estimated values* (*see text*) *are indicated by* (⊙).

A ds-state was assumed for these molecules, which means that a promotion energy of a f-electron to a d-state is required. This is the origin of the ΔE value, which can be derived from theoretical calculation (Brooks *et al.*, 1984). The $D_{0\ \mathrm{base}}$ value was represented by interpolation of the LaO–GdO–LuO line, i.e. those lanthanides that already have one d-electron. In transposing this relationship to the actinides, Haire assumed that the base relation is the same in the 4f and 5f series but the value for CmO adopted here (the actinide analog of GdO) suggests that there is a systematic difference of about 70 kJ mol^{-1} (Fig. 19.18). We have corrected Haire's values for this difference and the data for the monoxides beyond CmO thus obtained are shown in Fig. 19.18.

Recently Santos *et al.* (2002a,b) suggested that the excited 'bonding' state is obtained by promotion of an s-electron to a d-level to create the double bond. The lowest-lying excited states to be considered are $4f^{n-3}5d^26s$ and $4f^{n-2}5d6s$. Gibson (2003) showed how the energy required to promote gaseous lanthanide atoms to the excited 'bonding' state is responsible for the trends in the LnO dissociation energies. He defined the intrinsic Ln=O bond energy as "the bonding interaction between an oxygen atom and a lanthanide atom, Ln*, that has an electron configuration suitable for formation of the covalent formally double bond in the Ln=O molecule." He identified the $4f^{n-3}5d^26s$ configuration as the appropriate one for bonding and the two 5d electrons as the electrons that provide bonding with the oxygen. Thus the trend was explained as:

$$D^0(\mathrm{LnO}) = D^{0*}(\mathrm{LnO}) = \Delta E\ [\mathrm{ground} \rightarrow \mathrm{bonding\ configuration}] \qquad (19.21)$$

19.5.6 Complex oxides

(a) Ternary and quaternary oxides with alkali metal ions

An extensive number of thermodynamic studies of the alkali uranates have been reported and the existing thermochemical data have been assessed by Cordfunke and O'Hare (1978) and Grenthe *et al.* (1992), the latter study

updated by Guillaumont *et al.* (2003). These thermochemical data are, however, much fewer than the large number of phases existing in the A_2O–UO_3–UO_2 phase diagrams (Lindemer *et al.*, 1981). And no thermodynamic studies exist for ternary compounds with the alkali ions containing tetravalent actinide ions. Thermochemical measurements have also been reported for a few ternary oxides of alkali metals and Np(VI). No thermochemical measurements have been reported for compounds of the alkali metal with other actinide oxides, surprisingly not even for the sodium plutonates.

(*i*) *Enthalpy of formation*

The enthalpies of formation of the alkali uranates are generally derived from enthalpy of solution measurements in hydrochloric or nitric acid, often involving very complex reaction cycles to compensate the oxidation of uranium. The measurements have been made for mixed compounds of the general formulas $nA_2O \cdot mUO_3$ (hexavalent U) and $nA_2O \cdot mUO_{2.5}$ (pentavalent U). All existing literature have been reviewed by Grenthe *et al.* (1992) and Guillaumont *et al.* (2003) using currently accepted auxiliary data. Johnson (1975) as well as Lindemer *et al.* (1981) discussed correlations and methods to estimate unknown enthalpies of formation for the complex alkali uranates up to high n/m ratios (e.g. $Cs_2O \cdot 15UO_3$), but their procedures are quite arbitrary.

For the alkali metal neptunates(VI) with the general formulas A_2NpO_4, $A_2Np_2O_7$, and A_4NpO_5, the enthalpies of formation were derived from the enthalpies of solution of the compounds in hydrochloric acid. These results were recently assessed by Lemire *et al.* (2001). The values of the enthalpies of formation of all these compounds are given in Table 19.11.

(*ii*) *Entropy*

Only a few low-temperature heat capacity measurements have been made for the alkali uranates, and they are restricted to sodium and cesium compounds (see Table 19.11). Lindemer *et al.* (1981) estimated the entropy values for the other alkali uranates assuming that $\Delta_r S$ for the formation reaction from the oxides is zero. The experimental results show that this is not the case and that the values for $\Delta_r S$ strongly depend on the crystallographic modification and tend to be slightly positive. For these reasons, the values by Lindemer *et al.* (1981) have not been included in the present tabulations.

(*iii*) *High-temperature properties*

High-temperature enthalpy increment measurements have been made for a few alkali uranates. These are essentially the same compounds for which low-temperature measurements have been performed. Most of the early data have been reviewed by Cordfunke and O'Hare (1978) and Cordfunke and Konings (1990) and they are summarized in Table 19.13. In the 1990s, the

[b] Alpha form.

Indian group led by Venugopal and coworkers measured the enthalpy increments of a number uranates of potassium, rubidium, and cesium. They were reviewed by Guillaumont *et al.* (2003), and some of their recommendations have been included in Table 19.13.

(b) Ternary and quaternary oxides with alkaline-earth ions

(*i*) *Enthalpy of formation*

The following perovskites with alkaline-earth ions containing tetravalent actinide ions have been studied thermodynamically: $BaUO_3$ (Williams *et al.*, 1984; Cordfunke *et al.*, 1997), $BaPuO_3$ (Morss and Eller, 1989), $BaAmO_3$ and $SrAmO_3$ (Goudiakas *et al.*, 1990), $BaCmO_3$, and $BaCfO_3$ (Fuger *et al.*, 1993). Efforts to obtain the strontium analog of $BaUO_3$, $SrUO_3$, resulted in a perovskite phase with the empirical formula $Sr_2UO_{4.5}$ (crystallographic formula $Sr_2(Sr_{2/3}U_{1/3})UO_6$) (Cordfunke and IJdo, 1994). Also $BaUO_3$ cannot be prepared with a Ba/U ratio of exactly 1, as was found independently by Barrett *et al.* (1982), Williams *et al.* (1984), and Cordfunke *et al.* (1997). The latter two groups determined the enthalpy of the ideal composition by extrapolating the data for different Ba/U ratios and found excellent agreement [$-(1690 \pm 10)$ kJ mol^{-1} and $-(1680 \pm 10)$ kJ mol^{-1}]. However, there are several reports of studies on materials claimed to be $SrUO_3$ and $BaUO_3$. Huang *et al.* (1997a) derived the enthalpy of formation of $SrUO_{3.1}$ from Knudsen effusion mass spectrometric measurements. Ali *et al.* (2001) used a comparable method (but a complex reaction) for $SrThO_3$.

Using the Goldschmidt tolerance factor t, expressed as $t = (R_{Ba} + R_O)/(2^{1/2})(R_{An} + R_O)$, where R_{Ba}, R_O, and R_{An} represent the ionic radii of Ba^{2+}, O^{2-}, and the actinide 4+ ion, respectively, Morss and Eller (1989) showed that the enthalpy of formation of the complex oxides from BaO and AnO_2 becomes less favorable as t decreases. This correlation was extended by Fuger *et al.* (1993) to a large number of complex oxides of the general formula $MM'O_3$ (M = Ba, and M′ = Ti, Hf, Zr, Ce, Tb, U, Pu, Am, Cm, and M = Sr, and M′ = Ti, Mo, Zr, Ce, Tb, Am) and allowed the prediction of the enthalpy of formation of yet unprepared actinide(IV) complex oxides with BaO and SrO. This correlation was in accordance with the inability to obtain stoichiometric $BaUO_3$.

Cordfunke *et al.* (1997) suggested that a continuous series exists between $BaUO_3$–$Ba_{1+y}UO_{3+x}$–Ba_3UO_6. The oxidation of U^{4+} ions is accompanied by the formation of metal vacancies on the Ba and U sites, and Ba substitution on the U-vacancies, finally resulting in $Ba_2(Ba,U)O_6$. $Ba_2U_2O_7$ does not belong to this series, which is explained by the fact that $Ba_2U_2O_7$ is a complex oxide containing pentavalent uranium. For the system Sr–U–O it was shown by Cordfunke *et al.* (1999) that the enthalpies of formation of the U(VI) compounds linearly depend on the Sr/U ratio (Fig. 19.19). The data fall into two groups, the

pseudo-hexagonal types ($Sr_3U_{11}O_{36}$, $Sr_2U_3O_{11}$, $SrUO_4$, and UO_3) and the perovskite types ($Sr_5U_3O_{14}$, Sr_2UO_5, Sr_3UO_6). Takahashi *et al.* (1993) studied the enthalpies of formation of $SrUO_{4-y}$ ($0 \leq y \leq 0.5$) also finding an almost linear relationship.

Complex oxides of the formula $nAO \cdot mAnO_3$ with alkaline-earth ions containing hexavalent actinides are well known. AUO_4 compounds have been identified and thermochemically characterized for magnesium, calcium, strontium, and barium. Also the enthalpies of formation of many A_3AnO_6 (An = U, Np, Pu) and quaternary $Ba_2A'AnO_6$ (A′ = Mg, Ca, Sr and An = U, Np, Pu) compounds have been determined (see Table 19.12). All the values listed have been taken from the NEA assessments (Grenthe *et al.*, 1992; Silva *et al.*, 1995; Lemire *et al.*, 2001; Guillaumont *et al.*, 2003) except for those on curium and californium compounds (Fuger *et al.*, 1993).

The enthalpy of formation from the binary oxides, here called the enthalpy of complexation $\Delta_{cplx}H$, is an excellent measure for the stability of these compounds. It can be calculated easily for the uranates, but not for complex Np(VI) oxides or for complex Pu(VI) oxides, because NpO_3(c) and PuO_3(c) are unknown. For the construction of Fig. 19.20, we have therefore utilized the value estimated in Section 19.5.1. The exothermic enthalpy effect of the reactions indicated in Fig. 19.20 implies that the compounds are thermodynamically stable at room temperature, assuming a negligible entropy change upon the formation of the complex oxides from the binary oxides. Extrapolation of the trends indicated that the beryllium compounds are not stable under these conditions.

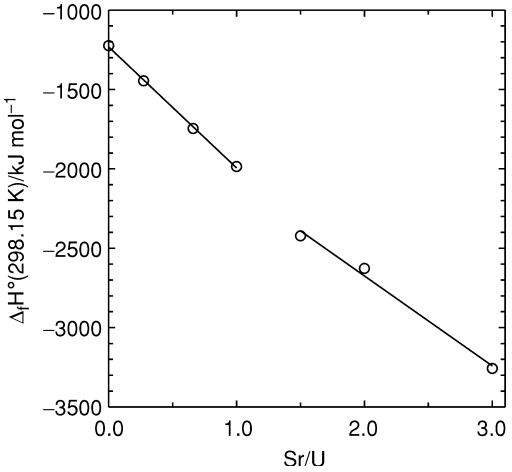

Fig. 19.19 *The enthalpy of formation in the strontium uranates in the Sr–U*^{VI}*–O system* (*after Cordfunke* et al., 1999).

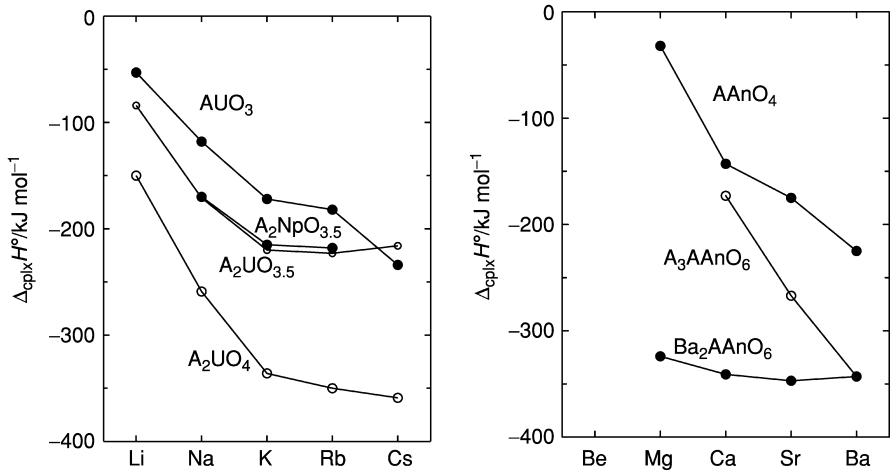

Fig. 19.20 *Enthalpies of complexation of complex actinide(VI) oxides where A represents a alkali or alkaline earth and An an actinide ion.*

There are, as of the time of writing, no thermochemical data on complex oxides containing trivalent actinides (e.g. $AmAlO_3$ or $SrAm_2O_4$). Indeed, such measurements are still lacking for the lanthanides.

(*ii*) *Entropy*

Low-temperature heat capacity measurements have been reported for a few alkaline-earth uranates. The data for the AUO_4 monouranates of the series A = Mg to Ba (Table 19.12) need some further discussion. The two measurements for $BaUO_4$ are discordant, though made by well-known research groups. The results of Westrum *et al.* (1980) give $S°(298.15\ K) = 177.84\ J\ K^{-1}\ mol^{-1}$ whereas the results of O'Hare *et al.* (1980) gave $153.97\ J\ K^{-1}\ mol^{-1}$. In most assessments the latter value is selected because the sample was better characterized. However, the values for the other alkaline-earth monouranates are from the same set of measurements by Westrum *et al.* (1980) and the reported data indicate a regular trend with molar volume for the orthorhombic compounds (A = Mg, Sr, Ba). The value of O'Hare *et al.* (1980) does not fit in the series, which would imply that the values for the other compounds measured by Westrum *et al.* (1980) are in error, which is not considered in the NEA-TDB selections (Grenthe *et al.*, 1992). Another way of looking at this problem is to consider the entropy of complexation from the oxides. The values for the orthorhombic monouranates derived from the measurements of Westrum *et al.* (1980) all suggest that the quantity $\Delta_{cplx}S°(298.15\ K)$ is positive which is

the case for most orthorhombic complex oxides. The result for $BaUO_4$ from O'Hare *et al.* (1980) in contrast, suggests a negative value. Clearly further measurements are required to solve this problem.

(*iii*) *High-temperature properties*

High-temperature heat capacity data have been measured for the AUO_4 compounds of the series A = Mg to Ba and have been evaluated by Cordfunke and O'Hare (1978); the resulting recommended equations are summarized in Table 19.13. They agree with the less exhaustive selections of the NEA assessment (Grenthe *et al.*, 1992). Melting points of these compounds are not known. The high-temperature properties of the other alkaline-earth compounds are poorly known. Recently, Japanese researchers have extensively studied materials claimed to be stoichiometric $BaUO_3$ and $SrUO_3$. The heat capacity (Matsuda *et al.*, 2001), thermal expansion, thermal conductivity and melting point (Yamanaka *et al.*, 2001), and the vaporization behavior (Huang *et al.*, 1997a) were measured. Vaporization measurements have also been made for $SrUO_3$ (Huang *et al.*, 1997b) and $BaPuO_3$ (Nakajima *et al.*, 1999b). Dash *et al.* (2000) reported enthalpy increments of $Sr_3U_{11}O_{36}$ and $Sr_3U_2O_9$. The relevant thermodynamic data extracted from these studies are listed in Table 19.12.

(c) Other ternary and quaternary oxides/oxysalts

Enthalpies of formation data for uranium carbonates, nitrates, phosphates, arsenates, and silicates have been measured and the available data were reviewed and summarized in the NEA-TDB assessments (Grenthe *et al.*, 1992; Guillaumont *et al.*, 2003). Heat capacity and entropy data have hardly been measured for these compounds and only estimates are available. The data are summarized in Table 19.14. Also included are the enthalpies of formation of several actinide (Th,U) bearing mineral phases reported by Helean *et al.* (2002, 2003) and by Mazeina *et al.* (2005) using high temperature solution calorimetry. Data for complex oxides or oxyacids of other actinides are not known with sufficient accuracy for inclusion in this chapter.

19.6 HALIDES

Because of the fundamental and applied interest in the many actinide halides, their thermodynamic properties have received much attention. The authoritative assessment by Fuger *et al.* (1983), which formed the basis for the data in the second edition of this work, is still the major source of information though parts of it have been updated in the NEA-TDB series on *Chemical Thermodynamics* (U through Am).

Table 19.13 *High-temperature heat capacity of selected crystalline complex actinide oxides;* $C_p/(\mathrm{J\ K^{-1}\ mol^{-1}}) = a(\mathrm{T/K})^{-2} + b + c(\mathrm{T/K}) + d(\mathrm{T/K})^2$ (*estimated values are in italics, maximum temperatures in brackets*).

19.6.1 Hexahalides

(a) Solid hexahalides

The enthalpy of formation of UF_6 is a key value for the U–F thermochemistry. This value is well established by fluorine combustion calorimetry (Johnson, 1979). The heat capacity of UF_6 has been measured accurately up to the melting point and beyond (Brickwedde *et al.*, 1948), from which the entropy can be

[b] Fuger *et al*. (1983) taking in account the enthalpy of dissolution of the standard state of the metal (Fuger *et al*., 1978) and more recent auxiliary values.

derived. The resulting values are summarized in Table 19.15. Unfortunately the situation is different for NpF_6 and PuF_6. Low-temperature heat capacity measurements have been made for NpF_6, also into the liquid range, but a determination of its enthalpy of formation is lacking. Lemire *et al*. (2001) derived this quantity from the estimated difference $\{\Delta_f H°(MF_6, cr) - \Delta_f H°(MO_2^{2+}, aq)\}$ obtained by interpolation in the AnF_6 series. For PuF_6, no thermodynamic measurements of the solid phase have been made except for the vapor pressure. But since the properties of the gas phase are well established (see below), the enthalpy of formation and the standard entropy can be derived with reasonable accuracy.

UCl_6 is the only known solid actinide hexachloride. Its thermochemical properties were intensely studied in the World War II period. Thereafter Gross *et al*. (1971) and Cordfunke *et al*. (1982) performed enthalpy-of-solution studies on this compound and derived the enthalpy of formation. As discussed by Grenthe *et al*. (1992) the values for UCl_6 from these two studies disagree (unlike similar work for UCl_5) and the results of Cordfunke *et al*. (1982) were selected. The heat capacity and entropy for UCl_6 at low temperature were measured by Ferguson and Rand in the early 1940s, as reported in Katz and Rabinowitch (1951); the high-temperature heat capacity of UCl_6 is an estimate by Barin and Knacke (1973).

The high-temperature heat capacity equations plus the melting data of the hexahalides are summarized in Table 19.16.

(b) Gaseous hexahalides

The gaseous hexafluorides of U, Np, and Pu were studied extensively in the 1950s and 1960s. Gas-phase electron diffraction, Raman, and infrared studies

have established the octahedral structure (O_h symmetry) and the molecular and vibrational parameters. From these data the entropies can be calculated accurately; the major uncertainty coming from neglect of excited electronic states for incompletely filled f-shells. The enthalpies of formation of these species can then be obtained from analyses of the vapor pressure measurements that have been performed and such data have been derived in the NEA-TDB series (Grenthe *et al.*, 1992; Lemire *et al.*, 2001; Guillaumont *et al.*, 2003). The molecular properties of AmF_6, and thus the entropy, can be extrapolated from those of the other actinide hexahalides (Kim and Mulford, 1990). Its enthalpy of formation is derived from the extrapolation of the mean bond enthalpy of the other actinide hexahalides, which linearly varies along the actinide series.

Except for UCl_6, no other gaseous hexachlorides are known. The molecular properties of UCl_6 have not been determined experimentally. Estimates (Hildenbrand *et al.*, 1985) have been used in the NEA assessments (Grenthe *et al.*, 1992; Guillaumont *et al.*, 2003) but more recently reliable results from quantum chemical calculations have become available (Han, 2001). An approximate value for the enthalpy of formation of UCl_6 is derived from vapor pressure measurements performed in the 1940s (see Grenthe *et al.* (1992)).

19.6.2 Pentahalides

(a) Solid pentahalides

Fuger *et al.* (1983) accepted the enthalpies of formation of $PaCl_5$, $PaBr_5$, and α-UF_5 and β-UF_5 (as well as some intermediate uranium fluorides) to be well established based upon single reliable thermochemical studies by Fuger and Brown (1975) for the Pa compounds, and by O'Hare *et al.* (1982) for the UF_5 modifications. For UCl_5, Fuger *et al.* (1983) discussed the results of three different studies, but these gave an unclear picture. The discrepancy seems to be resolved by the measurements of Cordfunke *et al.* (1982). Properties of UBr_5 are based on high-temperature heterogeneous equilibria and have large uncertainties when extrapolated to 298.15 K. The other pentahalides (PaF_5, NpF_5) have not been studied thermochemically. The properties of PaF_5 cannot yet be estimated because of insufficient experimental data. Those of NpF_5 have been approximated by Lemire *et al.* (2001) on the basis of the experimental observation that NpF_5 does not disproportionate to NpF_6(g) and NpF_4(cr) below 591 K (Malm *et al.*, 1993).

The experimental basis for the entropies of the actinide pentahalides is very poor. Low-temperature heat capacity measurements have only been reported for UF_5 (Brickwedde *et al.*, 1951), but the sample contained 17% UF_4 and UO_2F_2. Fuger *et al.* (1983) adjusted the result for S°(298.15 K) by $+11.3\ J\ K^{-1}\ mol^{-1}$, to be consistent with dissociation pressure measurements in the U–F system. Fuger *et al.* also gave (rough) estimates of the entropies of $PaCl_5$, $PaBr_5$, and UCl_5, based on a systematic difference between MX_4 and MX_5 compounds.

Table 19.16 *High-temperature heat capacity of the actinide halides;* $C_p/(\mathrm{J\ K^{-1}\ mol^{-1}}) = a(\mathrm{T/K})^{-2} + b + c(\mathrm{T/K}) + c(\mathrm{T/K})^2$ (*estimated values in italics*); $T_{min} = 298.15$ K*;* T_{trs} *and* $\Delta_{trs}H$ *refer to transition or fusion, as can be deduced from the phase indicators.*

[a] NEA-TBD (Grenthe *et al.*, 1992; Lemire *et al.*, 2001; Guillaumont *et al.*, 2003).
[b] Fuger *et al.* (1983).
[c] Rand (1975).
[d] Burnett (1966).
[e] Weigel and Kohl (1985).
[f] Peterson and Burns (1973).

Their value for $PaCl_5$ is, however, significantly lower than that derived by Kovács *et al.* (2003) by combining the entropy of sublimation from the work of Weigel *et al.* (1969) with the entropy of the gas obtained from quantum chemical data. A comparison to other MCl_5 compounds showed that this value for solid $PaCl_5$ is unexpectedly high compared to UCl_5 and the transition metal pentahalides, which Kovács *et al.* attributed to the distinctly different crystal structure of $PaCl_5$ (pentagonal bipyramidal). However, no calorimetric measurements have been performed for any of the pentachloride compounds, and all entropies have been derived from (other complex) solid–gas equilibria.

The selected solid pentahalide data are listed in Table 19.15.

(b) Gaseous pentahalides

$PaCl_5$, $PaBr_5$, UF_5, UCl_5, UBr_5, and PuF_5 are the only gaseous pentahalides that have been studied experimentally. Vapor pressure measurements for the protactinium pentahalides were reported by Weigel *et al.* (1969, 1974) from which the enthalpy of formation of $PaCl_5$ has been derived (see Table 19.17). The interpretation of the UF_5 vapor pressure measurements is complicated due to the existence of dimeric molecules and dissociation reactions. The enthalpy of formation of UF_5 can also be derived from molecular equilibrium measurements by mass spectrometry. At least six such studies have been performed. They were reviewed in the NEA-TDB (Grenthe *et al.*, 1992; Guillaumont *et al.*, 2003) and the recommended values from that work are included in Table 19.17. Also for UCl_5(g) and UBr_5(g), molecular equilibrium studies have been performed. The derived enthalpies of formation are included in Table 19.17. An approximate value for the enthalpy of formation of PuF_5 was calculated indirectly from ionization potential measurements by Kleinschmidt (1988), but since this value is rather uncertain, it is not included.

[b] Kovács *et al.* (2003).

Little experimental information exists on the molecular properties of the actinide pentahalides. Spectroscopic experiments of matrix-isolated UF_5 molecules (Kunze *et al.*, 1976; Paine *et al.*, 1976; Jones and Ekberg, 1977) indicate a tetragonal pyramidal structure (C_{4v}). Quantum chemical calculations (Wadt and Hay, 1979; Onoe *et al.*, 1997) showed that energy barrier between the C_{4v} and the trigonal bipyramidal structure (D_{3h}) is small (<4 kJ mol^{-1}) and it was suggested that the structure of UF_5 may be fluxional between C_{4v} and D_{3h} at high temperatures. Quantum chemical calculations of PaF_5 and $PaCl_5$ gave similar results (Kovács *et al.*, 2003). The derived entropy values are included in Table 19.17. It is likely that the Pa compounds follow the trend in the d-transition metal halides and have a D_{3h} equilibrium structure, whereas the U pentahalides have a C_{4v} equilibrium structure as a result of stronger participation of the 5f electrons in the An–F bonding.

19.6.3 Tetrahalides

(a) Solid tetrahalides

(*i*) *Enthalpy of formation*

Knowledge of actinide tetrafluoride enthalpies of formation is relatively poor. UF_4 has been studied extensively but the review by Grenthe *et al.* (1992) lists 14 experimental studies that show considerable scatter. Their selected value is based on reliable thermochemical cycles with UF_6(cr) using fluorine combustion calorimetry (Johnson, 1985) and UO_3(cr) using solution calorimetry (Cordfunke and Ouweltjes, 1981), which yielded values that differ by 10.7 kJ mol^{-1}. For ThF_4 the values derived from combustion calorimetry and high-temperature equilibria are discordant, as was discussed in detail by Wagman *et al.* (1977). We adopt here the value recommended by these authors, with increased uncertainty limits. For PuF_4, there are only estimates from the high-temperature equilibria, as discussed in detail by Lemire *et al.* (2001). Estimates of the enthalpies of formation of AmF_4 and CmF_4 can be derived from decomposition measurements by Gibson and Haire (1988a,b). We have accepted the assessed values for UF_4, NpF_4, and PuF_4 of the NEA-TDB (Grenthe *et al.*, 1992; Silva *et al.*, 1995; Lemire *et al.*, 2001) and made estimates of tetrafluoride thermochemistry with those of other tetravalent compounds.

The situation for the other tetrahalides is globally better. The most reliable values for UCl_4 of the ten studies performed cluster around −1019 kJ mol^{-1} (Grenthe *et al.*, 1992). Also the enthalpies of formation of thorium, protactinium, uranium, and neptunium tetrahalides appear to be well established. For the thorium and protactinium compounds, we have accepted the recommended values by Fuger *et al.* (1983) for the uranium, neptunium, plutonium, and americium compounds as the recommended values of NEA-TDB (Grenthe *et al.*, 1992; Lemire *et al.*, 2001; Guillaumont *et al.*, 2003). [a] Beta modification.
[b] Believed to be unstable.

lists and Fig. 19.21 plots the enthalpies of formation of all known tetravalent actinide compounds and the aqueous ions as a function of Z. The enthalpy scale has been compressed to facilitate comparison. Interpolations can be made, using the best-fit curves shown, because each set of tetravalent compounds is isostructural, and other enthalpies of formation have thereby been estimated. The differences between the values thus calculated and those predicted by Fuger *et al.* (1983) are relatively small.

An interesting but unstable compound is $PuCl_4$. It has been detected in the gas phase by Gruen and DeKock (1967). Abraham *et al.* (1949) observed an increased volatility of $PuCl_3$ in a stream of chlorine gas. This was explained by the formation of gaseous $PuCl_4$, which decomposed to form solid $PuCl_3$ and Cl_2 upon condensation. Nevertheless, by comparison with other tetrahalides and complex chlorides, the enthalpy of formation of $PuCl_4$(s) is predictable within narrow error limits and has been included in Table 19.18 and Fig. 19.21.

(*ii*) *Heat capacity and entropy*

The low-temperature heat capacities of ThF_4, UF_4, PuF_4, and UCl_4 have been measured experimentally. The results for the fluorides are reliable. The measurements for UF_4 have been made down to 1.3 K and include careful analysis of the excess entropy contribution arising from the Schottky anomaly that corresponds to a crystal field level of 10.7 cm^{-1} for the U^{4+} ions at the C_2 symmetry site (one-third of the ions). The heat capacity measurements for UCl_4 (15–355 K) date from the World War II period and have only been reported in summary in the *Chemistry of Uranium* by Katz and Rabinowitch (1951). The recommended entropies of these actinide tetrahalides are listed in Table 19.18. We have estimated the entropies of the other tetrafluorides and tetrachlorides from these values using equations (19.10) and (19.11), and the procedure described for the dioxides.

The values for the tetrabromides and tetraiodides are estimates based on extrapolation of the trend F to I. It is known from transition metal and lanthanide halides that the entropies regularly increase as a function of the logarithm of the halide mass. Fig. 19.22 shows the relationship between the entropy divided by the number of halide ligands (n) for the uranium and europium halides. We have extrapolated the almost parallel relations as indicated, and used the estimated values for the UBr_4 and UI_4 as a basis for the estimation.

(*iii*) *High-temperature properties*

High-temperature data for the actinide tetrahalides are even more problematic. Experimental enthalpy increment data have been measured for UF_4 and ThF_4 crystal, but the results of ThF_4 are unpublished (see Fuger *et al.* (1983) and references therein). No high-temperature data for the tetrabromides have been

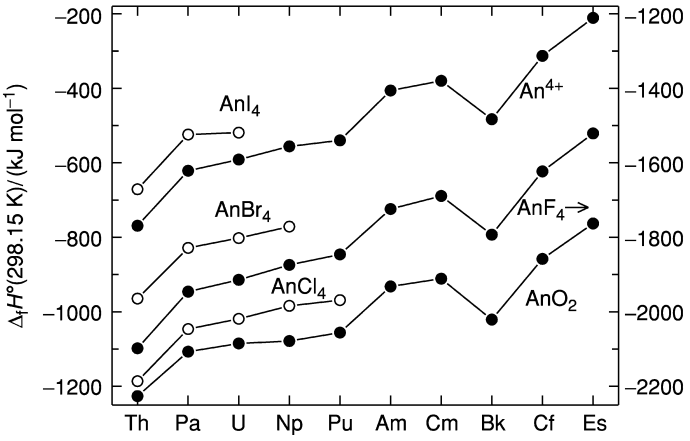

Fig. 19.21 *Comparison of enthalpies of formation of actinide(IV) species.*

reported, but a heat capacity study of UI_4 was made by Popov *et al.* (1959). This study indicated a phase transition close to the melting point. From these data the heat capacity of the other actinide tetrahalides were estimated with reasonable accuracy by Fuger *et al.* (1983) and later by the NEA-TDB (Grenthe *et al.*, 1992; Lemire *et al.*, 2001; Guillaumont *et al.*, 2003). The values thus obtained are listed in Table 19.16.

(b) Gaseous tetrahalides

The gaseous tetrahalides of uranium have been the subject of studies for many years. Early electron diffraction studies were interpreted as a tetrahedral (T_d) structure whereas later measurements on UX_4 molecules seem to indicate a distorted tetrahedron. The latter seemed to be confirmed by analyses of vapor pressure data (Hildenbrand, 1988), which gave good second/third law agreement in case a C_{2v} molecular structure was assumed. Only in the 1990s it was established with certainty by a combination of gas-phase electron diffraction, high-temperature gas-phase infrared spectroscopy, and quantum chemical calculations that UF_4 and UCl_4 have a tetrahedral structure (Haaland *et al.*, 1995; Konings *et al.*, 1996). The entropies of UF_4 and UCl_4 calculated from the molecular and vibrational parameters derived from these studies are consistent with the entropies obtained from vapor pressure measurements, which have been reported for most of these compounds. Konings and Hildenbrand (1998) discussed in detail that this is essentially true for all known gaseous actinide tetrahalides, for which they estimated the molecular and vibrational parameters in a systematic manner. Since then further electron diffraction results and also results from quantum chemical calculations have become available, which have led to further refinement of the recommended values.

The calculated entropies and the enthalpies of formation derived from vapor pressure measurements for these species are listed in Table 19.19. The numbers principally come from the NEA-TDB reviews, in which the most recent refinements have not been included and a simplified approach to the estimation of the vibrational frequencies was used. However, since this will have a moderate effect, we have accepted these numbers.

19.6.4 Trihalides

(a) Solid trihalides

(*i*) *Enthalpy of formation*

Trigonal trifluorides are known for all the actinides Ac and U–Cf. Surprisingly, thermodynamic measurements have been performed only for UF_3 and PuF_3; even more surprising is the unsatisfactory situation regarding even these two trifluorides. Fuger *et al.* (1983) and later Grenthe *et al.* (1992) have evaluated all of the experimental results and listed their unresolved questions. For UF_3 several independent thermochemical pathways have been used, yielding unresolvable inconsistencies with a variety of uranium species; sample impurities plagued the fluorine combustion measurements and complex thermochemical cycles, involving many species, obfuscate the solution calorimetry measurements. For PuF_3 the one measurement (Westrum and Eyring, 1949) is uncertain primarily because it was a reaction to an unanalyzed trifluoride precipitate assumed to be anhydrous but probably $PuF_3 \cdot 0.4H_2O$. Nevertheless,

these two data points must be used to compare and to predict the properties of all f-element trifluorides.

Fortunately, there are enthalpy-of-formation data on almost all lanthanide trifluorides, though not all of them are reliable (Konings and Kovács, 2003). Table 19.20 and Fig. 19.23 present these data along with structural data that permit a correlation of the quantity $\{\Delta_f H°(MF_3,cr) - \Delta_f H°(M^{3+},aq)\}$ with the ionic radii. It can be seen that the most reliable data for the lanthanide trifluorides fall into two groups of different crystal structures (trigonal/hexagonal and orthorhombic), and that the two actinide trifluorides (trigonal) do not clearly fit to this trend. Clearly, the correlation is less evident than for the lanthanide chlorides, bromides, and iodides so that the correlation will have limited value until better lanthanide and actinide trifluoride enthalpy measurements are made.

Trichlorides, tribromides, and triiodides of all elements from uranium through einsteinium are known. Solution calorimetry enthalpies of formation

are known for these trihalides of uranium through plutonium, although that of $NpCl_3$ requires an estimate of its heat of solution (Fuger *et al.*, 1983). In addition, the enthalpies of formation of $AmCl_3$ and $CfBr_3$ are known from solution calorimetry; that of other actinide trihalides as well as heavier trihalides must be estimated. This can be done by a correlation of the quantity $\{\Delta_f H°(MX_3,cr) - \Delta_f H°(M^{3+},aq)\}$ with ionic radius for isostructural compounds (Fig. 19.23). It can be seen that the trend in the actinide chloride and bromides series is parallel to that in the lanthanide series and thus permits extrapolation beyond Pu. In the actinide iodides, the trend is opposite. Such data sets are shown in Tables 19.21–19.23. The resultant enthalpies of formation are consistent with the data reported in the NEA-TDB project.

(*ii*) *Heat capacity and entropy*

Low-temperature heat capacities of UF_3 and PuF_3 have been measured, and high-temperature data are only available for UF_3. Recently, an inconsistency between the low-temperature data for these compounds was pointed out by Konings (2001a). The entropy value of PuF_3, derived from measurements by Osborne *et al*. (1974), yields a lattice entropy that is significantly higher than that of UF_3 derived from data by Cordfunke and Westrum, which are only published as a summary (Cordfunke *et al*., 1989). This lattice entropy is not consistent with those of the lanthanide trifluorides and it was suggested that the extrapolation to 0 K of the UF_3 value did not include the magnetic contribution, which is equal to R ln(2) and completely removes the inconsistency. From the results for PuF_3 and those for the lanthanide trifluorides, Konings (2001a) estimated the lattice entropies of NpF_3, AmF_3, and CmF_3 which were combined with an excess entropy calculated from crystal field levels to give the standard entropy. These values are given in Table 19.20.

Heat capacity and thus entropy data for the other actinide trihalides have only been reported for UCl_3 and UBr_3. As discussed above the entropy values for UCl_3 and UBr_3 derived from the results of Cordfunke *et al*. (1989) must be R ln(2) higher to account for the magnetic contribution at low temperatures (Konings, 2001a). Estimates for the standard entropies of the transuranium trichlorides up to $CmCl_3$ were presented by Konings (2001a) and are included in Table 19.21. Estimates for the standard entropy for the uranium triiodide and the bromides and iodides of neptunium, plutonium, and americium were presented in the NEA-TDB project, but the method used is less accurate than that proposed by Konings (2001a). In the case of the americium compounds, where the differences between the two sets of data largely exceeds the uncertainty limits, the values proposed by Konings (2001a) have been adopted by the NEA-TDB project (Guillaumont *et al*., 2003). The value for $PuCl_3 \cdot 6H_2O$ is included in Table 19.21 as it is a key value for the estimation of the entropies of the aqueous ion of this element.

(*iii*) *High-temperature properties*

The high-temperature heat capacity of solid UF_3, UCl_3, and UBr_3 has been derived from enthalpy increment measurements (Cordfunke *et al*., 1989). Measurements for other actinide trihalides have not been made. As discussed by Konings and Kovács (2003) the heat capacity of the lanthanide trihalides can be described very well as the sum of the lattice and excess components, the latter arising from the electronic states of the lanthanide ions. A similar approach can be used for the estimation of the heat capacity of the actinide trihalides. The recommended functions are listed in Table 19.16.

The melting point and melting enthalpy of many trihalides have been reported. They are summarized in Table 19.16. The data for the trichlorides

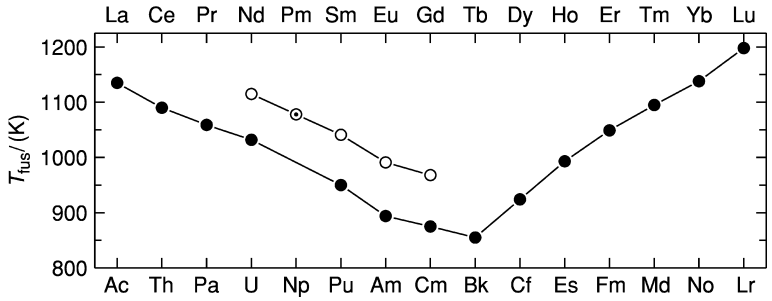

Fig. 19.24 *Melting temperature of the lanthanide* (•) *and actinide* (○) *trichlorides; estimated values are indicated by* (⊙).

are the most extensive; they are known from UCl_3 to $CmCl_3$. These values are of the same order as those of the lanthanide trichlorides and the trend in the actinide trichlorides series is parallel, as shown in Fig. 19.24.

(b) Gaseous trihalides

The situation for the gaseous actinide trihalides is complicated: the measured condensed gas-phase equilibria are not always clearly defined, the condensed phase data are often uncertain (see above) and the molecular geometry of these species has not been measured except for UCl_3 and UI_3. For these two compounds, gas-phase electron diffraction (ED) measurements have been reported (Bazhanov *et al.*, 1990a,b), which indicated a pyramidal structure with a X–M–X bond angle close to 90°. Quantum chemical calculations for the uranium(III) halides also indicate a pyramidal structure (Joubert and Maldivi, 2001) but with a bond angle much closer to the planar 120°. Fortunately, the molecular properties of the lanthanide trihalides are much better known and can be used for comparison. Experimental and theoretical studies have indicated a gradual increase of the X–Ln–X bond angle to the planar 120° from F to I and La to Lu (Molnar and Hargittai, 1995; Konings and Kovács, 2003), which is consistent with simple steric considerations. The lanthanide trifluorides are most probably pyramidal, the trichlorides, tribromides, and triiodides are quasi-planar (light lanthanides) or planar (heavy lanthanides). Quantum chemical calculations for UCl_3 and UI_3 agree with this trend but the experimental bond angles for UCl_3 $(95 \pm 3)°$ and UI_3 $(89 \pm 3)°$ disagree. The situation for the vibrational frequencies is equally complicated. The asymmetric stretching frequency of UCl_3 was determined experimentally by high-temperature infrared spectroscopic measurements (Kovács *et al.*, 1996), but the value (275 cm^{-1}) is considerably lower than those estimated from the electron diffraction data (310 ± 30 cm^{-1}) and derived from the quantum chemical calculations (300 cm^{-1} to 341 cm^{-1}, depending on the theoretical level). Clearly further research is needed to establish the molecular and thus the thermodynamic properties

of the gaseous actinide trihalides more precisely. For the present chapter we accept the estimated values given in the NEA-TDB reviews, but increased the uncertainties assigned in that work. The values are given in Table 19.19.

Enthalpies of formation of gaseous UF_3, UCl_3, and UBr_3 have been evaluated from experimental studies by Grenthe *et al.* (1990) and the enthalpies of formation derived in this work are listed in Table 19.19. For UF_3, vapor pressure and molecular equilibria studies were used, and are in fair agreement. For UCl_3 and UBr_3, only the molecular equilibria studies were used. Such data are also available for the lower thorium fluorides, chlorides, and bromides. Vapor pressure measurements have been reported also for the trifluorides AmF_3, PuF_3, and CfF_3 and the trichlorides $PuCl_3$ and $AmCl_3$, and the tribromide $PuBr_3$.

Fig. 19.25 shows the mean bond enthalpy of the actinide trifluorides as well as of the lanthanide trifluorides. The figure shows approximately the same trend for the two groups, the actinide series being somewhat shifted compared to the lanthanide series. From this trend, the enthalpies of formation of the other gaseous trihalides can be estimated with confidence.

19.6.5 Di- and monohalides

(a) Solid dihalides

The existence of the dichlorides, dibromides, and diiodides of Am and Cf has been reported. However, no experimental thermochemical data are available. Because these dihalides parallel lanthanide dihalides of similar M^{2+} ionic radii, it is possible to estimate their enthalpies of formation by a method similar to that used by Morss and Fahey (1976), based on the difference $\{\Delta_f H^\circ(MX_2,cr) - \Delta_f H^\circ(M^{2+},aq)\}$. Konings (2002a) estimated the standard entropy of $AmCl_2$ as $S^\circ(298.15\ K) = (148.1 \pm 5.0)\ J\ K^{-1}\ mol^{-1}$. This value is the sum of a lattice contribution estimated from the experimental data for some lanthanide

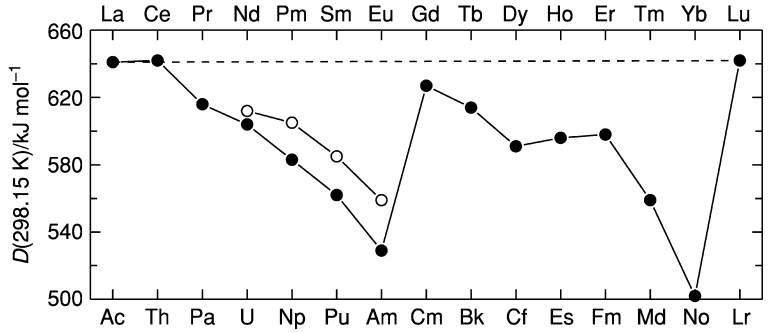

Fig. 19.25 *The mean bond enthalpy at* 298.15 K *of the gaseous lanthanide* (•) *and actinide trifluorides* (○).

dichlorides and the excess contribution $R \ln(8)$. Using a similar approach, we estimate the entropies of some other actinide dichlorides.

The data for these estimations, and the resulting predicted enthalpies of formation, are shown in Table 19.24. The Gibbs energies of these reactions are given in the following equations:

$$\mathrm{Am(cr)} + 2\mathrm{AmCl_3(cr)} = 3\mathrm{AmCl_2(cr)}, \quad \Delta_r G = -35 \text{ kJ mol}^{-1} \tag{19.22}$$

and

$$\mathrm{Cf(cr)} + 2\mathrm{CfCl_3(cr)} = 3\mathrm{CfCl_2(cr)}, \quad \Delta_r G = -91 \text{ kJ mol}^{-1} \tag{19.23}$$

illustrate the relative difficulty and ease of preparing the dihalides of americium compared to californium.

(b) Gaseous di- and monohalides

The di- and monohalides of thorium and uranium have been identified in mass spectrometric measurements by different authors. Lau and coworkers (Lau and Hildenbrand, 1982; Lau *et al*., 1989) studied the exchange reactions of the lower thorium and uranium fluorides with BaF; Gorokhov *et al*. (1984) and Hildenbrand and Lau (1991) studied the molecular equilibria between the uranium fluorides among themselves. The results for the uranium compounds have been analyzed in detail by Grenthe *et al*. (1990) and updated by Guillaumont *et al*. (2003), who demonstrated that the results are in reasonable agreement, considering the large number of approximations made in the analysis. Similar studies have been made for the lower chlorides and bromides (Lau and Hildenbrand, 1984, 1987, 1990; Hildenbrand and Lau, 1990). Almost no experimental data on the molecular properties of these species are available and thus all thermal functions are based on rather qualitative estimates (using alkaline-earth dihalide data), introducing large uncertainties. For this reason, the recommended values for the lower uranium halide species given in Table 19.25 should be used with caution, especially when used well outside the temperature range of the experimental studies.

As discussed by Lau and Hildenbrand (1982), the mean bond energy decreases gradually in the uranium halide series (Fig. 19.26). This trend can be used to approximate the enthalpies of formation of the lower halides of other actinides, when needed.

19.7 COMPLEX HALIDES, OXYHALIDES, AND NITROHALIDES

19.7.1 Solid complex halides

Many complex halides of thorium and uranium have been prepared for crystallographic, magnetic, and spectroscopic studies. Preparative conditions suggested that these compounds are more stable than the parent (binary)

halides. For example, UF_5 is difficult to prepare but complex halides such as $CsUF_6$ are relatively stable. Among the transuranium elements, fewer high-valent binary halides are known, but complex halides (e.g. Cs_2PuCl_6 and $CsPuF_6$) are known whereas the binary actinide halides ($PuCl_4$ and PuF_5) have been sought without success. Some of these complex halides have been exploited in separation schemes for the actinides. As discussed by Fuger *et al.* (1983), their thermodynamic properties have been of interest since the beginning of the 20th century.

Fuger *et al.* (1983) also assessed all of their thermodynamic properties. More recently the compounds of Np, Pu, and Am were also reviewed by the NEA-TDB teams (Silva *et al.*, 1995; Lemire *et al.*, 2001; Guillaumont *et al.*, 2003). In Table 19.26 the values selected by the NEA teams are given for compounds of Np, Pu, and Am and the values selected by Fuger *et al.* (1983) for compounds of Th, Pa, and U. All these data have been recalculated using the latest NEA-selected values. In the framework of a general study on several $Cs_2NaAnCl_6$ compounds, Schoebrechts *et al.* (1989) also reported the enthalpy of formation of $Cs_2NaCfCl_6$ and estimates for the corresponding compounds of Cm and Bk. These values are also given in Table 19.26.

Fig. 19.27 displays the enthalpies of complexation, e.g.

$$2CsCl(cr) + UCl_4(cr) = Cs_2UCl_6(cr), \quad \Delta H = \Delta_{cplx}H \tag{19.24}$$

of some of these compounds. Interpolation and extrapolation of $\Delta_{cplx}H$ along with enthalpies of formation of the binary compounds provide the values necessary to predict the enthalpies of formation of several of these complex halides. Note that $\Delta_{cplx}H$ becomes more favorable (exothermic) as the alkali-metal ion A^+ becomes larger and, to a lesser extent, as the actinide ion An^{4+} becomes smaller. As with complex oxides, these are both structural-packing (ionic) and acid–base (covalent) effects.

19.7.2 Solid oxyhalides and nitrohalides

There are many oxyhalides of actinide oxidation states +3 through +6. In general these are more stable than a mixture of oxide and halide, e.g.

$$UF_6(cr) + 2UO_3(c,\gamma) = 3UO_2F_2(cr), \quad \Delta_rG^\circ = -318 \text{ kJ mol}^{-1} \tag{19.25}$$

reflecting the acid–base nature of the reactions. In some cases, however, e.g.

$$UCl_4(cr) + UO_2(cr) = 2UOCl_2(cr), \quad \Delta_rG^\circ = +12 \text{ kJ mol}^{-1} \tag{19.26}$$

$$NpCl_4(cr) + NpO_2(cr) = 2NpOCl_2(cr), \quad \Delta_rG^\circ = +59 \text{ kJ mol}^{-1} \tag{19.27}$$

the Gibbs energy of the reactions is positive, reflecting the limited stability of such oxyhalides with respect to the stoichiometric mixture of the oxide and chloride in the same oxidation state.

We have accepted the assessed enthalpies of formation from calorimetric and vapor–solid hydrolysis equilibria by Fuger *et al.* (1983) for Th, Pa, and Cm compounds, and the more recently assessed values by the NEA teams for compounds of U to Am (Table 19.27). Also included are the recent results of Burns *et al.* (1998) for CfOCl and BkOCl, the former based on experiments, the latter based on an interpolation in the AnOCl series (An = U, Pu, Am, Cm, and Cf).

Heat capacity data have been reported for uranium oxyhalides UO_2F_2, UO_2Cl_2, $UOCl_2$, and $UOBr_2$. The entropy values derived in these studies have been accepted in the NEA-TDB review (Grenthe *et al.*, 1992). High-temperature

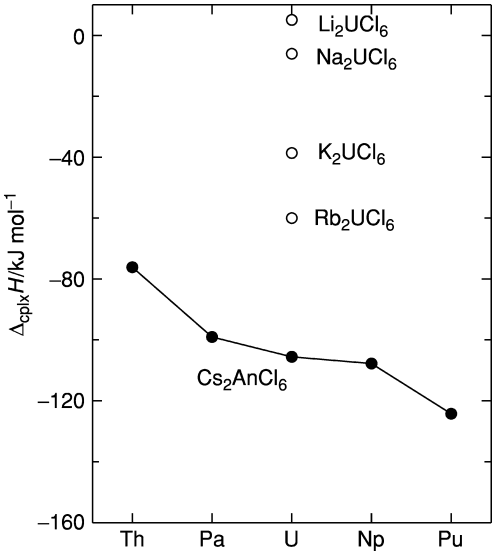

Fig. 19.27 *Enthalpies of complexation of complex actinide(IV) halides.*

enthalpy increments of UO_2X_2 (for X = F, Cl, and Br) have been measured by Cordfunke *et al.* (1979). Their data are in reasonable to good agreement with the low-temperature data. Cordfunke and Kubaschewski (1984) also cite unpublished experimental data for $UOCl_2$ and $U_2O_2Cl_5$ by Cordfunke, and estimated the heat capacity functions of other oxyhalides. They are listed in Table 19.28.

In contrast, data for mixed nitride halides are scarce. Recently Akabori *et al.* (2002) and Huntelaar *et al.* (2002) have presented data for the enthalpy of formation, the entropy, and high-temperature heat capacity of UNCl, which are included in Tables 19.27 and 19.28.

19.7.3 Gaseous oxyhalides

Several oxyhalides are stable in the gaseous phase and experimental vapor pressure data have been reported for UO_2F_2, UOF_4, and UO_2Cl_2 from which the enthalpies of formation of the gaseous molecules can be derived. In the NEA-TDB review, these studies were analyzed by third-law method using estimated molecular parameters from Glushko *et al.* (1978). The estimates for structure parameters and vibrational frequencies of UO_2F_2 differ considerably from those obtained by Privalov *et al.* (2002) using quantum chemical calculations at different theoretical levels (SCF, B3LYP). Souter and Andrews (1997) identified the molecules UO_2F_2, UOF_4, and UO_2F by infrared matrix-isolation spectroscopy. The asymmetric O–U–O stretching frequency found is in reasonable

19.8 HYDRIDES

19.8.1 Enthalpy of formation

The enthalpies of formation of the actinide hydrides have been principally derived from hydrogen pressure measurements in which the pressure–temperature–composition relation was studied. The equilibrium reaction in these metal–hydrogen systems can be described as:

$$\left(\frac{2}{2-s-x}\right)\mathrm{AnH}_s + \mathrm{H}_2 = \left(\frac{2}{2-s-x}\right)\mathrm{AnH}_{2-x} \qquad (19.28)$$

where s and $(2-x)$ both generally have the values 1.3, 2, 3, and 3.75. The AnH_2 compounds occur in all systems from Th to Cm, except U. In the U–H system, only the trihydride occurs, which is also found in the systems with Np, Pu, and

Am, though almost no data exist for the latter. The composition H/An = 1.3 is typical for the Pa–H system, and H/An = 3.75 for the Th–H system.

Flotow *et al.* (1984) systematically analyzed the equilibrium data for Th, Pa, U, Np, Pu, and Am, and their recommended enthalpies of formation for the hydrides of Th, Pa, U, and Pu are summarized in Table 19.30. Ward *et al.* (1987) measured the hydrogen dissociation pressure in the Np–H and derived thermodynamic data for NpH_2, $NpH_{2.6}$, and NpH_3. Gibson and Haire (1990) measured the hydrogen dissociation pressures of milligram-sized samples of the americium and curium hydrides, and made comparison to the lanthanide hydrides (Dy, Ho). Their results for AmH_2 are in good agreement with the recommended values by Flotow *et al.* (1984), who selected the average results of two discordant studies; their results for CmH_2 are the first ones to be reported. They have been included in Table 19.30. The variation of the enthalpy of formation of the actinide dihydrides is shown in Fig. 19.28, together with the data for the lanthanide dihydrides (Libowitz and Maeland, 1979). As observed for the elements and many compounds, the trend in light actinides dihydrides is significantly different from that of the lanthanides and the two curves approach each other near Am and Cm.

19.8.2 Entropy

Low-temperature heat capacity measurements (up to 300 K) have been reported for ThH_2, $ThH_{3.75}$, UH_3, and $PuH_{1.9}$ and the entropy values at 298.15 K recommended by Flotow *et al.* (1984) are listed in Table 19.30. The entropies of the other compounds have been derived by Flotow *et al.* (1984) from the high-temperature hydrogen equilibrium measurements, using estimated heat capacity data. Flotow *et al.* (1984) also estimated the entropy of CmH_2 by linear extrapolation of the data of the dihydrides of Np, Pu, and Am, but it is doubtful whether this is correct in view of the trend shown for the enthalpies of formation, which indicates that CmH_2 resembles more the lanthanide dihydrides than the light actinide dihydrides.

19.8.3 High-temperature properties

High-temperature heat capacity data have been reported only for PuH_2 (Oetting *et al.*, 1984). The high-temperature heat capacity of ThH_2, $ThH_{3.75}$, and UH_3 were calculated by Flotow *et al.* (1984). They described the total heat capacity as the sum of the electronic, optical mode, and residual contributions:

$$C_p = C_{ele} + C_{\mu H} + C_{residual} \tag{19.29}$$

where the electronic heat capacity coefficient and the residual term were obtained from the low-temperature measurements, which extent to 350 K, and

19.9 HYDROXIDES AND OXYHYDRATES

19.9.1 Trihydroxides

(a) Enthalpy of formation

The only experimental determinations of the enthalpy of formation of a trivalent actinide hydroxide are two solution-calorimetry studies for $Am(OH)_3$, but the two results differ considerably (Morss and Williams, 1994; Merli *et al.*, 1997) due to a difference of enthalpies of solution of the trihydroxide of (23 ± 8) kJ mol^{-1}. The value selected in Table 19.32 is that calculated by Guillaumont *et al.* (2003), based primarily on the measured solubility product of $Am(OH)_3$ measured by Silva (1982) corrected for hydrolysis and ionic strength, and an estimated entropy of $Am(OH)_3$ (Guillaumont *et al.*, 2003). The selected value

[b] Merli *et al.* (1997).
[c] Morss and Hall (1994); Diakonov *et al.* (1998b) recommend –(1414 ± 10) kJ mol^{-1}.
[d] Diakonov *et al.* (1998a,b).
[e] Following the procedure of Guillaumont *et al.* (2003), p. 350, for $S°(Am(OH)_3,cr) = S_{lat} + S_{exc}$ using data from Konings (2001a) and estimating S_{exc} from that of sesquioxides Pu_2O_3 and Cm_2O_3.
[f] Guillaumont *et al.*(2003).

is nearly consistent with the experimental value of Merli *et al.* (1997), $\Delta_f H°(M(OH)_3,cr) = -(1343.6 \pm 1.8)$ kJ mol^{-1}. Their sample was well characterized and their calorimetric results are supported by similar measurements that they carried out for lanthanide hydroxides, which are consistent with solubility data.

(b) Entropy

The entropies of the solid trihydroxides $An(OH)_3$ have been estimated using the approach outlined earlier (equation (19.10)) (Konings, 2001a). The lattice component was estimated from the lanthanide trihydroxides, assuming the displacement of the trend to be the same as for the sesquioxides. The excess entropy was calculated from the degeneracy of the ground state. The values thus obtained are listed in Table 19.32 together with data for the lanthanide trihydroxides.

(c) Solubility products

Solubility products, often denoted 'solubility constants,' refer to equilibria such as:

$$M(OH)_3(cr) = M^{3+}(aq) + 3\,OH^-(aq), \quad K = K^0_{s,0} \tag{19.30}$$

Because americium has important long-lived isotopes and because it exists in solution as Am(III), its hydrolysis and solubility in aqueous solutions have been

the most carefully studied of the An(III) ions. The NEA review (Guillaumont *et al.*, 2003) selected the value of (15.6 ± 0.6) for the equilibrium

$$Am(OH)_3(cr) + 3\ H^+(aq) = Am^{3+}(aq) + 3\,H_2O(l), \quad K = {}^*K^0_{s,0} \qquad (19.31)$$

from the study of Silva (1982) because the solid phase in equilibrium with the solution was crystalline $Am(OH)_3$. The asterisk (*) in this notation refers to the protonation that is part of the equilibrium. For this equilibrium at 298.15 K, $\log_{10} K^0_{s,0} = \log_{10} {}^*K^0_{s,0} - 3\log_{10} K_w = 15.6 - 3 \times 14 = -26.4$. Guillaumont *et al.* (2003) also selected the value $\log_{10} {}^*K^0_{s,0} = (16.9 \pm 0.8)$ for the equilibrium (equation (19.31)) with $Am(OH)_3$(am), where 'am' refers to the precipitate that was amorphous to X-rays after aging for 4 months.

Latimer (1952) estimated the solubility products of actinide(III) hydroxides, $An(OH)_3$, from corresponding values for freshly precipitated hydroxides of the lanthanides. It is well known that, as these gelatinous precipitates age, their crystallinity increases and their solubility product decreases, so that the aged precipitates more nearly reflect equilibrium conditions. Baes and Mesmer (1976) exhaustively surveyed the literature and evaluated heterogeneous equilibria for lanthanide and actinide hydroxides and hydrated oxides. Additional thermochemical and extensive solubility data are available for the lanthanide trihydroxides. Diakonov *et al.* (1998a,b) carried out an extensive critical review of the thermochemical and solubility literature on rare earth hydroxides. These authors showed that there is a systematic trend of $\log_{10} K^0_{s,0}$ data for all rare earth hydroxides as a function of M^{3+} ionic radii. Specifically, the values of solubility product $\log_{10} K^0_{s,0}$ and $\log_{10} {}^*K_{s,0}$ become more positive as Z increases, because the ionic radii decrease and the Ln^{3+} ions become more acidic.

This trend could be extended to estimate solubility products for actinide trihydroxides. After the review of Diakonov *et al.* was published, Cordfunke and Konings (2001c) critically reviewed all the literature on enthalpy of formation of rare earth aqueous ions and recommended a set of values that are more comprehensive than the enthalpies of formation of rare earth aqueous ions used by Diakonov *et al.* One could use the recommended values of Diakonov *et al.*, with corrections for Cordfunke and Konings enthalpies of formation of rare earth aqueous ions, to extrapolate the relation between $\{\Delta_f H^\circ(M(OH)_3,cr) - \Delta_f H^\circ(M^{3+}, aq)\}$ and the M^{3+} ionic radii to derive estimates of $\log_{10} {}^*K_{s,0}$ for $An(OH)_3$. However, the one 'anchor,' $Am(OH)_3$, has such a significant uncertainty that such an extrapolation is considered too speculative for this chapter. Because the calorimetric data of Merli *et al.* for $Am(OH)_3$ are not quite in agreement with solubility data, enthalpy and entropy estimates for other actinide trihydroxides were not used to estimate solubility product measurements for other actinide trihydroxides in this chapter. We do cite the value of $\log_{10} {}^*K_{s,0} = (15.8 \pm 1.5)$ calculated for $Pu(OH)_3$ (Felmy *et al.*, 1989). This value is slightly smaller than the estimate for $Am(OH)_3$ cited above, consistent with the systematic trend for rare earth hydroxides as a function of ionic radius.

19.9.2 Oxides, hydrated oxides, and oxyhydroxides of An(IV), An(V), and An(VI)

The thermodynamics of crystalline anhydrous oxides was discussed in Section 19.5. Therefore, for these compounds, only solubility product values of interest are mentioned here for comparison with those of the amorphous corresponding compounds.

Under basic conditions, all actinide ions precipitate as hydroxides or hydrated oxides. Very few of these precipitates have been thoroughly characterized; interpolations, extrapolations, and approximations are usually necessary. Lemire *et al.* (2001) and Guillaumont *et al.* (2003) evaluated the literature results on the solubilities of some amorphous and crystalline actinide oxides, hydrated oxides, and oxyhydroxides. Their recommended values are given in Table 19.33. In this table the solubility product refers to the equilibrium constant for reactions such as

$$MO_2(\text{am or cr}) + 2\ H_2O\,(l) = M^{4+}(aq) + 4\ OH^-(aq), \quad K = K^0_{s,0} \quad (19.30a)$$

$$NpO_2OH(am) + H^+(aq) = NpO_2^+(aq) + H_2O(1), \quad K = {}^*K^0_{s,0} \quad (19.31a)$$

As mentioned in equation (19.31), the asterisk (*) in this notation refers to the protonation that is part of the equilibrium.

Selections were also made (Grenthe *et al.*, 1992; Guillaumont *et al.*, 2003) for other hydrates of UO_3. We cite here two properties of $UO_3 \cdot 2H_2O$(cr) ('schoepite'): $S°(298.15) = (188.54 \pm 0.38)$ J K^{-1} mol^{-1} and $\Delta_f H°(298.15) = -(1826.1 \pm 1.7)$ kJ mol^{-1}, as given by NEA-TDB (Grenthe *et al.*, 1992) based on measurements by Tasker *et al.* (1988). The solubility product of this compound is given in Table 19.33. We note that $UO_3 \cdot 2H_2O$(cr), which is often called schoepite, should be referred to as metaschoepite (Finch *et al.*, 1998).

The enthalpy of formation of the uranium(VI) peroxide studtite, $(UO_2)O_2(H_2O)$(cr), has been determined to be $-(2344.7 \pm 4.0)$ kJ mol^{-1} (Hughes-Kubatko *et al.*, 2003). The authors calculated the solubility at 298.15 K,

$$UO_2^{2+}(aq) + H_2O_2(aq) + 4\,H_2O(l) = (UO_2)O_2(H_2O)(cr) + 2\,H^+(aq) \quad (19.33)$$

and concluded that this peroxide is stable under the conditions where aqueous peroxide is formed from radiolysis of water by alpha particles.

The enthalpy of formation of NpO_2OH(am) was selected as $-(1222.9 \pm 5.5)$ kJ mol^{-1} by Lemire *et al.* (2001) from enthalpy of solution measurements by two different groups (Campbell and Lemire, 1994; Merli and Fuger, 1994) who used material containing different amounts of water.

The enthalpy of formation of $UO_3 \cdot H_2O(\beta)$ was selected as $-(1533.8 \pm 1.3)$ kJ mol^{-1} by Grenthe *et al.* (1992) from the difference in the enthalpy of solution of this compound (Cordfunke, 1964) and that of γ-UO_3. The enthalpy of formation of $NpO_3 \cdot H_2O$(cr) (= $NpO_2(OH)_2$(cr)) was selected as $-(1377 \pm 5)$ kJ mol^{-1}

Table 19.33 *Solubility products of the actinide crystalline and amorphous oxides at* 298.15 K, *from NEA-TDB* (*Grenthe* et al., 1992; *Silva* et al., 1995; *Lemire* et al., 2001; *Guillaumont* et al., 2003).

by Lemire *et al.* (2001), primarily from the enthalpy of solution measurements by Fuger *et al.* (1969).

No other hydroxides of tetravalent or higher-valent actinides have been adequately characterized for thermodynamic property determinations and calculations of solubility at equilibrium conditions.

19.9.3 Gaseous oxyhydroxides

It has been shown by several authors that the volatility of the uranium oxides is significantly enhanced in the presence of water vapor, as a result of the formation of the gaseous species $UO_2(OH)_2$ (Dharwadkar *et al.*, 1975; Krikorian *et al.*, 1993a). The equilibrium data of these studies were analyzed in the NEA-TDB review (Guillaumont *et al.*, 2003) using second- and third-law methods to derive the enthalpy of formation. The agreement between the studies is very poor. Moreover, the thermal functions for the third-law analysis, obtained from two sets of estimated molecular parameters (Ebbinghaus, 1995; Gorokhov and Sidorova, 1998), result in appreciably different entropy values. For that reason no selected values were presented by NEA-TDB. Recently, Privalov *et al.* (2002) calculated the geometry and vibrational frequencies of $UO_2(OH)_2$ using quantum chemical techniques. The thermodynamic functions calculated from their results are close to those of Gorokhov and Sidorova (1998). Also an increased volatility was reported in the presence of steam for the oxides of Pu and Am (Krikorian *et al.*, 1993b).

19.10 CARBIDES

The thermodynamic properties of the binary actinide carbides in the Th–C, U–C, Np–C, Pu–C, and Am–C systems were reviewed by Holley *et al.* (1984) as part of the IAEA series on the chemical thermodynamics of the actinide elements and compounds. In the NEA-TDB series that covers the compounds from U to Am (Grenthe *et al.*, 1992; Lemire *et al.*, 2001), most of the data by Holley *et al.* (1984) were accepted unchanged. Solid dicarbides, sesquicarbides, and monocarbides of the actinides have all been reported to exist, all generally showing wide ranges of nonstoichiometry, which makes the comparison of the different experimental results difficult. For the Pu–C system also, the compound Pu_3C_2 has been found.

19.10.1 Solid carbides

(a) Enthalpy of formation

The dicarbide exists in the Th–C and U–C systems with certainty, and in the Pu–C system only at high temperatures. The situation for the Pa–C and Np–C

systems is not yet fully clear, but claims for the synthesis of the dicarbides have been made. The measurements for thorium and uranium dicarbide have all been made on samples that are slightly substoichiometric ($C/M \approx 1.90$–1.97), and contain variable amount of oxygen impurities. Holley *et al.* (1984) gave recommended values for the composition $C/M = 1.94$ for both Th and U, probably the most stable composition, based on an analysis of the high-temperature equilibria and combustion calorimetry, which are given in Table 19.34.

The sesquicarbide is known for the U–C, Np–C, Pu–C, and Am–C systems, and measurements of the enthalpies of formation are only known for the first three compounds. Of these compounds, U_2C_3 is probably not thermodynamically stable at room temperature (its lower stability limit is estimated to be 1200 K) but samples have been cooled down without difficulty. High-temperature equilibria and combustion calorimetry have been reported, data which were analyzed by Holley *et al.* (1984). The value for Np_2C_3 is based on a preliminary measurement by combustion calorimetry; for U_2C_3 and Pu_2C_3 the combustion values at 298.15 K were slightly adjusted by Holley *et al.* (1984) to get a reasonable agreement with the high-temperature Gibbs energy values. From these values, Holley *et al.* (1984) estimated the enthalpy of formation of Am_2C_3 as $\Delta_f H^\circ(298.15\ \text{K}) = -(151 \pm 42)\ \text{kJ mol}^{-1}$.

The monocarbides are best described by the formula MC_{1-x}; they are known for all actinide–carbon systems from Th to Pu. The boundary compositions are $ThC_{0.98}$, UC, $NpC_{0.94}$, and $PuC_{0.84}$ and the enthalpies of formation of compositions, close to those recommended by Holley *et al.* (1984), are included in Table 19.34.

The enthalpy of formation of Pu_3C_2 was calculated by Holley *et al.* (1984) from phase considerations: (i) Pu_3C_2 is stable with respect to Pu and $PuC_{0.88}$ from 300 to 800 K and (ii) Pu_3C_2 decomposes to Pu and $PuC_{0.78}$ at 848 K.

(b) Entropy

A relatively large number of low-temperature heat capacity measurements have been made for the actinide carbides. For the Pu–C system measurements for 16 compositions have been reported, with reasonable though not complete consistency (see Holley *et al.*, 1984). Thus most of the entropy values listed in Table 19.34 are based on experimental studies; exceptions are Np_2C_3 and Pu_3C_2. Most of the experimental values have been corrected for the randomization entropy:

$$S_{\text{ran}} = x\ \ln\ x - (1-x)\ln(1-x) \tag{19.32}$$

which arises from the random ordering of the carbon and vacancies in the monocarbide, and of C and C_2 groups in the dicarbides.

(c) High-temperature properties

Enthalpy increment measurements have been reported for the three uranium carbides as well as PuC and Pu_2C_3. All data show a steep rise in the derived heat capacity above 1200 K, as is also observed in the oxides and nitrides and which have been attributed to the contribution of lattice vacancies. Fig. 19.29 shows the heat capacity of the three uranium carbides indicating rather similar behavior. Holley *et al*. (1984) estimated the heat capacity of ThC and ThC_2 from these data assuming a similar shape of the C_p curve. The heat capacity equations are summarized in Table 19.35.

19.10.2 Gaseous carbides

Gupta and Gingerich (1979, 1980) have detected gaseous AnC_n molecules with $n = 1$ to 6 in the Th–C and U–C systems by mass spectrometry. In the Th–C system, the molecules ThC_2 and ThC_4 contribute significantly to the vapor pressure, and in the ThC_2–C region the contribution of the former is about equal to that of Th(g). In the U–C system, only UC_2 has significant contribution for thermodynamic measurements. Holley *et al*. (1984) give estimated molecular properties for the thorium compounds ThC_2 and ThC_4 from which the thermal functions have been calculated. They assume a linear Th–C–C structure for ThC_2 and a linear C_2–Th–C_2 structure for ThC_4. With these functions they derived the enthalpies of formation of these molecules using third-law analysis. The resulting values are given in Table 19.36. Such treatment was not followed for UC_2 because of insufficient and inconsistent information.

19.11 PNICTIDES

The planned volume on the actinide pnictides in the IAEA series on the chemical thermodynamics of the actinide elements and compounds has not been completed and as a result a systematic review of the actinide nitride series is not available. However, in the NEA-TDB series, the data for the nitride compounds of uranium, neptunium, and plutonium have been reviewed, but with emphasis on the room temperature data.

19.11.1 Solid nitrides

(a) Enthalpy of formation

The enthalpies of formation of the mononitrides for ThN, UN, and PuN are based on calorimetric studies, as are those of the sesquinitrides $UN_{1.5+x}$ (α-U_2N_3) and $UN_{1.466}$ (β-U_2N_3) and Th_3N_4. The selected data for the compounds of U and Pu, which are summarized in Table 19.34, are from the NEA-TDB reports (Grenthe *et al.*, 1992; Lemire, *et al.*, 2001; Guillaumont *et al.*, 2003), the value of ThN and Th_3N_4 are taken from the assessment by Rand (1975).

The measurements for the uranium nitrides have not been made for the stoichiometric compositions as these are often difficult to prepare or do not exist: in α-U_2N_3, the N/U ratio varies from 1.54 to 1.75, in β-U_2N_3 from 1.45 to 1.49. The enthalpies of formation of the various uranium nitrides vary linearly as a function of the N/U ratio, as shown in Fig. 19.30. Thus the enthalpy of formation of α-U_2N_3 is represented by the following equation:

$$\Delta_f H°(UN_{1.5+x},\ \text{cr},\ 298.15\ \text{K})/\text{kJ mol}^{-1} = -366.7 - 138.2x$$

which is a simple linear representation of the two compositions with N/U 1.606 and 1.674 for which experimental measurements have been made (see Grenthe *et al.*, 1992).

The enthalpy of formation of ThN is significantly more negative than that of UN and PuN. This can be explained by the fact that the chemical bonding in ThN is less ionic and more covalent than in UN and PuN. Kuznietz (1968)

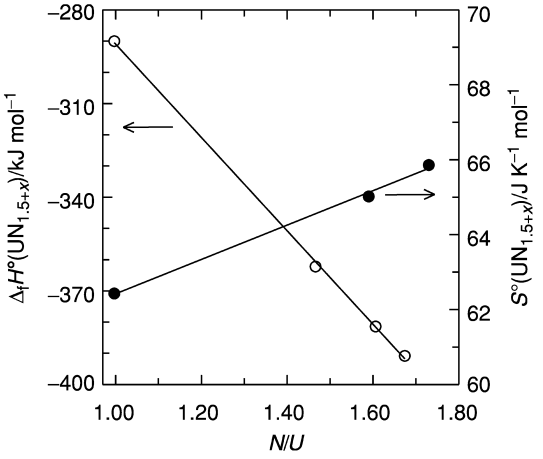

Fig. 19.30 *The enthalpy of formation* (○) *and the standard entropy* (●) *of the uranium nitrides as a function of the N/U ratio.*

proposed that the ThN lattice consists of Th^{4+} and N^{3-} ions with one conduction electron for each Th atom. Recently some indirect information on the enthalpies of formation of the mononitrides NpN and AmN was obtained from high-temperature Knudsen cell studies. Nakajima *et al.* (1997, 1999a) studied the vaporization of NpN and (Np,Pu)N. From their results, they found that the Gibbs energy of formation of NpN is between the values for UN and PuN. This is a justification for the approach of Lemire *et al.* (2002) who estimated the enthalpy of NpN by interpolation of the values for UN and PuN. Ogawa *et al.* (1995) studied the vaporization of PuN containing small amount of ^{241}Am as decay product. From these results, they estimated the enthalpy of formation of AmN as -294 kJ mol^{-1} at 1600 K.

(b) Entropy

Low-temperature heat capacity measurements of three mononitrides have been reported: ThN, UN, and PuN. As is the case for the enthalpies of formation, the value for ThN is distinctly different (lower) from that of UN and PuN. Lemire *et al.* (2001) assumed the entropy of NpN to be between the values for UN and PuN. Low-temperature heat capacity measurements have also been reported for Th_3N_4 and α-U_2N_3 (two compositions with N/U 1.59 and 1.73). The recommended values are summarized in Table 19.34. Like the enthalpy of formation, the standard entropy varies linearly with the N/U ratio, as shown in Fig. 19.30, and the value for $UN_{1.466}$ is obtained by interpolation. Based on

this observation, the standard entropy of α-U_2N_3 is represented by the following equation:

$$S^\circ(UN_{1.5+x},\ \text{cr},\ 298.15\ \text{K})/\text{J K}^{-1}\ \text{mol}^{-1} = 64.48 + 6.00x$$

(c) High-temperature properties

The high-temperature properties of UN and PuN were reviewed by Matsui and Ohse (1987), those of UN by Hayes *et al.* (1990), and more recently by Chevalier *et al.* (2000). These are the only two mononitrides for which calorimetric enthalpy increment measurements are available. Below 1700 K, the UN data recommended by Matsui and Ohse (1987) and Hayes *et al.* (1990) are in good agreement, as they are based on the same set of experimental data. But Hayes *et al.* (1990) indicate that UN shows a nonlinear increase in the heat capacity at high temperatures, likely due to the contribution of lattice defects, based on measurements by Conway and Flagella (1969), which were not considered by Matsui and Ohse (1987). This effect has not been observed in PuN, but the experimental data for this compound are limited to 1560 K. This situation is similar to the dioxides. Kurosaki *et al.* (2000) performed molecular dynamics calculations of the heat capacity of UN, and obtained a good agreement with the experimental results up to 1500 K, where the effects of lattice defects are marginal. Experimental high-temperature heat capacity data for the higher nitrides are scarce. The heat capacity of NpN has been measured by Nakajima and Arai (2003) by differential scanning calorimetry. The recommended high-temperature heat capacity functions are given in Table 19.35.

The actinide mononitrides vaporize to give An(g) and N_2(g) molecules, as has been demonstrated experimentally for ThN, UN, PuN, and NpN. The detailed mass spectrometric studies for UN have demonstrated also that the UN molecule occurs in the vapor phase, though its pressure is about three orders of magnitude lower than that of U(g). The decomposition temperatures under 1 bar nitrogen are 3053 K for UN, 2948 K for NpN, and 2843 K for PuN. Under nitrogen pressure, the mononitrides melt congruently: 3080 K at 2–3 bar N_2 for ThN (Rand, 1975), 3123 K at 2.5 bar N_2 for UN (Matsui and Ohse, 1987), 3103 K at 9.9 bar N_2 for NpN, and 3103 K at 5 bar N_2 for PuN (Lemire *et al.*, 2001). Th_3N_4 decomposes to ThN before melting.

19.11.2 Gaseous nitrides

The actinide mononitrides principally vaporize to give the gaseous elements, but molecular UN has been identified in the vapor as a minor species by mass spectrometry (Gingerich, 1969; Venugopal *et al.*, 1992). Molecular ThN, UN, and PuN species were also identified by infrared absorption spectroscopy in

low-temperature inert-gas matrices (Ar) as reported by Green and Reedy (1976, 1978b, 1979). From these measurements the harmonic frequency ω_e and the first anharmonic correction coefficient were derived. Unlike the actinide monoxides, the experimental data for mononitrides do not show a regular decrease from ThN to PuN. The value for UN ($\omega_e = 1007.7$ cm^{-1}) is significantly higher than the values for ThN ($\omega_e = 941.9$ cm^{-1}) and PuN ($\omega_e = 861.8$ cm^{-1}). The reason for this is not clear. Overall the experimental data are insufficient to derive reliable thermodynamic properties.

19.11.3 Phosphides, arsenides, and antimonides

The thermodynamic data on phosphides, arsenides, and antimonides are restricted to the uranium compounds, some plutonium compounds and a single neptunium compound. They are summarized in Table 19.37, and have been

Table 19.37 *Thermodynamic properties of selected crystalline actinide chalcogenides; estimated values are given in italics.*

19.12 CHALCOGENIDES

19.12.1 Sulfides

The experimental thermodynamic data on the actinide sulfides are restricted to the compounds of thorium and uranium. Data for the other actinides, essentially neptunium and plutonium, are based on estimates. A thorough review of the thermodynamic properties of the actinide sulfides (and the selenides and tellurides) was made by Grønvold *et al.* (1984), after which little new information has become available. For these systems, compounds with a wide variety of S/An ratios have been reported: the solids AnS, An_3S_4, An_2S_3, An_7S_{12}, AnS_2, An_2S_5, and AnS_3, and the gases AnX and AnX_2. The thermodynamic data for the solid compounds are summarized in Table 19.37, which is essentially based on the analyses by Grønvold *et al.* (1984). The values in the NEA-TDB report on uranium are essentially revisions of this work and are adopted here. The entropies of the uranium sulfides are a linear function of the S/U ratio, as shown in Fig. 19.31, confirming the estimates for U_3S_5 and U_2S_5.

19.12.2 Selenides and tellurides

Very few data also exist for the selenides and tellurides, again mainly for uranium compounds. However, for this compound group some plutonium compounds have been reported. Low-temperature heat capacities of PuSe and

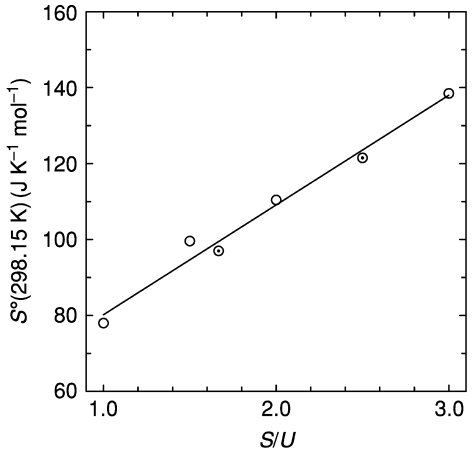

Fig. 19.31 *The entropies of the uranium sulfides* (*per mole of U*) *as a function of the S/U ratio; estimated values are indicated by* (⊙).

PuTe were measured by Hall *et al.* (1990, 1992) (see Table 19.37). No experimental determinations of the enthalpies of formation of these compounds exist.

19.13 OTHER BINARY COMPOUNDS

19.13.1 Compounds with group IIA elements

Thermodynamic data for binary compounds with group IIA elements are restricted to the actinide–beryllium systems. The compounds $ThBe_{13}$, UBe_{13}, and $PuBe_{13}$ have been characterized. A relatively complete data set is only available for UBe_{13} (see Tables 19.38 and 19.39) and have been assessed by the NEA team (Grenthe *et al.*, 1992). They include low-temperature heat capacity, enthalpy of formation and high-temperature heat capacity, and enthalpy increment measurements, the latter, however, in a limited temperature range (273–379 K). Unfortunately the high-temperature data are not consistent, and for this reason they give no recommendation. The value for the enthalpy of formation of $PuBe_{13}$ is taken from the assessment by Chiotti *et al.* (1981), and is based on an assessment of enthalpy of solution measurements.

19.13.2 Compounds with group IIIA elements

The systems of the actinides with group IIIA elements have significant technological relevance: the U–Al system for (materials testing) reactor fuel and the Pu–Ga for nuclear weapons. Also uranium borides have been considered for nuclear fuel materials. It is not surprising that these systems have been studied in more detail. Thermodynamic data for UB_2 are well established, and the high-temperature enthalpy increment measurement extend up to 2300 K. An anomalous increase of the heat capacity is observed (Fig. 19.32), as for many uranium compounds. The data have been assessed by Chiotti *et al.* (1981) and their selected values are included in Tables 19.38 and 19.39. For the U–Al compounds, only enthalpy of solution and EMF measurements have been made. However, Chiotti *et al.* (1981) do not give recommended values for the enthalpies of formation of the U–Al compounds. In Table 19.38 we have listed the values derived by Chiotti and Kately (1969), which are in good agreement with the other measurements. For the U–Ga system, Chiotti *et al.* (1981) cite only EMF and vapor pressure measurements and do not give thermodynamic values at 298.15 K. However, Palenzona and Cirafici (1975) measured the enthalpy of formation of UGa_3 and Prabhahara *et al.* (1998) measured the enthalpy of formation of UGa_3 and UGa_2 by solution calorimetry. Their results for UGa_3 are in poor agreement, but the results of Prabhahara *et al.* (1998) agree nicely with the EMF and vapor pressure studies. Their values are given in Table 19.38. In contrast, enthalpy of solution measurements are known for a number

compounds of these systems, except the U–Ge system. This is because there is often a distinct difference between the results from calorimetric (solution) measurements and EMF or vapor pressure measurement. However, measurement of the enthalpy of formation has been made that can be considered reliable. Robbins and Jenkins (1955) measured the enthalpy of formation of $ThSi_2$, Gross *et al.* (1962) measured the enthalpy of formation of USi_3, USi_2, USi, and U_3Si_2. For the U–Ge system, Chiotti *et al.* (1981) selected the values derived by Rand and Kubaschewski (1963) from vapor pressure measurements. These data are included Table 19.38.

19.13.4 Compounds with the transition elements (IB–VIIIB)

Chiotti *et al.* (1981) and Colinet and Pasturel (1994) discussed the thermodynamic data of the actinide intermetallic compounds with the transition metals in detail, Ward *et al.* (1986) the actinide–noble metal intermetallic compounds. The experimental basis for these compounds is limited and most of the work is done for the compounds of Th, U, and Pu.

(a) Enthalpies of formation

Extensive data exist for the systems An–Cd, An–Zn, and An–Bi that are of relevance to pyrochemical reprocessing, although the thermodynamic characterization of the compounds in these systems is limited. In most cases, only ΔG

functions at elevated temperatures have been reported, derived from EMF or vapor pressure measurements (see Chiotti *et al.*, 1981).

A large number of thermodynamic studies have been performed on the intermetallic compounds of uranium and the noble metals Ru, Rh, and Pd. The data were reviewed by Cordfunke and Konings (1990) and the recommended values are included in Table 19.38. The experimental EMF data on URu_3 and URh_3 reasonably agree, but a big discrepancy exists for UPd_3 for which a fluorine combustion study gave a much more negative value (-524 kJ mol^{-1}) than the value derived from vapor pressure measurements (-260 kJ mol^{-1}). Jung and Kleppa (1991) performed direct reaction calorimetry on these three compounds, and their result for UPd_3 $-(286 \pm 22)$ kJ mol^{-1} suggests that the fluorine combustion values are found to be in error. On the other hand, Prasad *et al.* (2000) reported a value close to the combustion value, derived from gas-equilibrium measurements. This example shows the difficulties determining accurate thermochemical data for these compounds.

Two semiempirical models are generally used to explain the trends and to estimate the unknown thermodynamic quantities of the actinide intermetallic compounds: the Engel–Brewer model and the Miedema model, as discussed extensively by Chiotti *et al.* (1981) and Ward *et al.* (1986). The Engel–Brewer model correlates thermodynamic properties with electronic structure. Brewer postulated that the s- and p-electrons involved in the bonding determine the crystal structure, whereas the d-electrons affect the chemical bonding and thermodynamic properties. The Engel–Brewer model is based on the promotion of atoms to valence states involving unpaired electrons suitable for bond formation with covalent character. The promotional energy to unpair the electrons was found to be 67 kJ mol^{-1} for the d^3s state in Th, 75 kJ mol^{-1} for the f^3d^2s state in U, and 180 kJ mol^{-1} for the f^5d^2s state in Pu (Brewer, 1970).

The Miedema model (de Boer *et al.*, 1988) correlates the enthalpy of formation of an intermetallic compound with the electronegativity and the electron density at the atomic cell boundary:

$$\Delta H = f(c)\left[-P(\Delta\phi^*)^2 + Q_0\left(\Delta n_{\mathrm{ws}}^{1/3}\right)^2\right] \tag{19.33}$$

where $f(c)$ is a function of the concentration of the metals, ϕ^* and Δn_{ws} the electronic work function of a pure metal and the electronic potential at the cell boundary, and P and Q_0 are constants. Fig. 19.33 shows the enthalpies of formation of actinide AnM_2 compounds with the 3d, 4d, and 5d transition elements predicted by this model (Ward *et al.*, 1986), indicating the limited stability of actinide compounds with the early d-transition elements (IVB, VB, and VIB) and a high stability of the compound with late d-transition elements. The Miedema model predicts $\Delta_f H^\circ(298.15\ \mathrm{K}) = -244$ kJ mol^{-1} for UPd_3 (de Boer *et al.*, 1988), which is close to the experimental values obtained by reaction calorimetry and vapor pressure measurements (see above). As concluded by Chiotti *et al.* (1981) after a systematic analysis of the thermodynamic

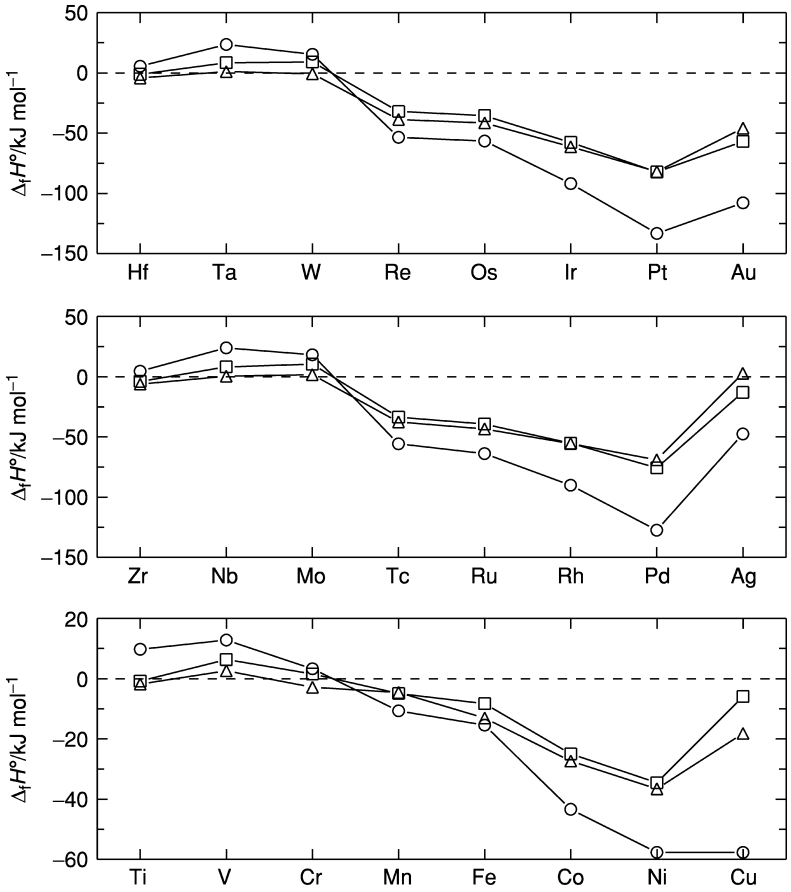

Fig. 19.33 *The enthalpies of formation predicted for actinide intermetallic phases* AnM_2 *from the Miedema correlation, as a function of the transition metal component,* (○) *Th,* (□) *U and* (Δ) *Pu* (*after Ward* et al., 1986).

data for intermetallic actinide compounds, estimates with Miedema's model are seldom in error by more than 20%, though it does not take into account the role of 5f electrons.

(b) Heat capacity and entropy

Accurate low-temperature (up to 300 K) heat capacity measurements have only been made for a limited number of uranium intermetallic compounds (URu_3, URh_3, and UPd_3). The derived entropy values at 298.15 K are given in Table 19.38. Also heat capacity measurements for some plutonium intermetallic compounds (Pu_6Fe) have been made, but of significantly less accuracy due to the small sample masses used. It should be noted, however, that low-temperature

heat capacity measurements below 50 K have been made for many actinide intermetallic compounds, due to their interesting magnetic and superconducting properties. It can be noted here that the heat capacity data for UPd_3 confirm that the f-electrons in this compound are localized, leading to discrete energy levels, in contrast to URu_3 and URh_3, in which the f-electrons are itinerant.

Moriyama *et al.* (1990) proposed a correlation to estimate the entropies of intermetallic compounds based on the assumption that the (vibrational) entropy is proportional to the logarithm of the bond energy. The entropies of the MA_n compound and the elements M and A are described by:

$$S(MA_n) = a \ln[\{E(M) + nE(A) - \Delta_f H^\circ\}/(1+n)] + b_1 \tag{19.34}$$

$$S(M) = a \ln E(M) + b_2$$

$$S(A) = a \ln E(A) + b_3$$

where E is the bond energy of the metal, which was approximated by the sublimation enthalpy. The entropy of formation of the MA_n compound was then calculated from the equation:

$$\Delta_f S(MA_n) - a \ln H' + b' \tag{19.35}$$

with $H' = [\{E(M) + nE(A) - \Delta_f H^\circ(MA_n)\}/(1+n)]^{(1+n)} E(M)^{-1} E(A)^{-n}$. Indeed a linear relation was found for the actinide intermetallics considered. The coefficient a was determined empirically to be –61.9 J K^{-1} mol^{-1} and b was found to be zero, using known entropy values for actinide intermetallics.

(c) High-temperature properties

High-temperature heat capacities of only a limited number of intermetallic actinide compounds have been measured. Systematic studies have been made on the intermetallic compounds of uranium with the noble metals Rh, Ru, and Pd. Cordfunke *et al.* (1985) and Burriel *et al.* (1988) have reported enthalpy increment measurements for URh_3, URu_3, and UPd_3 and found excellent agreement with the low-temperature data. Arita *et al.* (1997) measured the heat capacity of UPd_3 but their results poorly agree with the enthalpy data of Burriel *et al.* (1988). However, their results indicate a rapid increase above 900 K (Fig. 19.32) that was attributed to lattice defect formation. The recommended heat capacity functions are summarized in Table 19.39. No data are known for the liquid phase of any of these compounds.

19.14 CONCLUDING REMARKS

The present chapter shows that a steady progress has been made in the determination and understanding of the thermodynamic properties of the actinide elements and compounds since the first edition of this work. Not only

the number of compounds has been extended considerably, but also the quality of the data and the quality of the methods for estimation has improved considerably. In general it can be concluded that the systematics in the thermodynamic properties reflect the well-known change from itinerant f-electrons at the beginning of the actinide series to localized f-electrons from Am and beyond.

However, the overall quality of the thermodynamic data differs considerably between the various groups of compounds:

- The thermodynamic properties of the main actinide elements are fairly well established. Improvement is still needed for Ac, Pa, and the elements from Am onwards, but due to the high radioactivity of these elements and their limited availability, many additional measurements are not to be expected in the coming decades. But since the trends in the thermodynamic properties are reasonably well understood, the estimates presented here must be considered reliable.
- The thermodynamic data for actinide ions in aqueous solutions are still not satisfactory, even for the main actinides. Especially the values for the standard entropies of the aqueous species are based on few experiments and need improvement. The thermodynamic data of ions in molten salts have improved considerably for the LiCl–KCl (eutectic) but are still of poor quality for LiF–BeF_2. Other molten salt solvents have hardly been studied.
- The solid oxides (binary, ternary, quaternary) have been studied extensively and many systematics have been established. For this group there is a considerable mismatch between the large number of enthalpy of formation data and the limited number of entropy data. Also the high-temperature heat capacity data are limited. This is very apparent for the complex solid oxides. The data for the gaseous binary oxides are incomplete and require further studies: experimental studies to identify the molecular species and quantum chemical studies to estimate their properties.
- The actinide halides show the largest number of different oxidation states in both solid and gaseous state. Except for some technologically important halides (UF_6) the thermodynamic properties of this group are still surprisingly poorly characterized in spite of many studies, and for the solid dihalides, for example, no measurements exist at all. Trends and systematics in the AnX_n series and comparison to the LnX_3 and LnX_2 series, however, allow reasonable estimates, but there is still a need for experimental studies, especially heat capacity data at low and high temperatures.
- Relatively many studies of the dissociation pressures of the An–H_2 systems have been performed. However, the thermodynamic properties of only limited number of compounds can be derived from these data.
- The properties of the actinide hydroxides have hardly been studied, and the few experimental results (e.g. $Am(OH)_3$) are not consistent.

- The thermodynamic data for the carbides, pnictides, and chalcogenides are restricted to compounds of Th, U, and Pu. Because of their potential technological interest as nuclear fuels, the data are quite complete generally and extend up to high temperatures, though the available data on the gaseous molecules is scanty. The carbides, pnictides, and chalcogenides of other actinide have hardly been studied.
- Although the binary phase diagrams of actinides and other elements are generally well established, the basic thermodynamic data for alloys and intermetallic compounds are poorly known, even for technologically relevant systems. Predictive models have been developed, but the lack of reliable data makes it difficult to judge them. Moreover, the chemical bonding in actinide compounds is much more complex than in lanthanide or transition metal compounds, and possibly beyond the applicability of these models.

The need for further thermodynamic studies is thus as relevant as in the past decades. This is especially true because the trends in nuclear technology are moving in the direction of advanced nuclear systems for energy production with fuel cycles that include the proper treatment of plutonium and the minor actinides: fast reactors with innovative fuels, molten salt reactors, and advanced reprocessing (hydrochemical or pyrochemical). The development of these technologies demands better data for many actinide compounds, not only the pure substances but also their multicomponent mixtures, which have not been addressed in this chapter. To assure that such data will become available, the expertise in the field of actinide thermodynamics (both experimental and theoretical) must thus be maintained at a level that is needed for engineering, safety, and environmental applications, which is not evident now.

The data presented in this chapter are included in the f-MPD web-based material property information center of the Institute for Transuranium Elements (www.f-elements.net), from which complete thermodynamic tables can be retrieved. Corrections and updates will also be available from this site.

CHAPTER TWENTY

MAGNETIC PROPERTIES

Norman M. Edelstein and Gerard H. Lander

20.1 INTRODUCTION

20.1.1 Magnetic measurements

The magnetic properties of actinide ions and compounds arise from the spin and orbital angular momenta of the unpaired electrons. The theoretical basis for understanding these properties was provided by Van Vleck in 1932 in his classic work *The Theory of Electric and Magnetic Susceptibilities* (Van Vleck, 1932). The Van Vleck equation is expressed as follows:

$$\chi_M = \frac{N \sum_i [(E_i^{(1)})^2/kT - 2E_i^{(2)}] \exp(-E_i^0/kT)}{\sum_i \exp(-E_i^0/kT)} \tag{20.1}$$

where χ_M is the molar susceptibility and E_i the energy of the ith energy level, which can be expanded as a power series in the magnetic field H:

$$E_i = E_i^0 + E_i^{(1)}H + E_i^{(2)}H^2 + \cdots \tag{20.2}$$

The material can possess no residual moment in the absence of a magnetic field, so that:

$$\sum_i E_i^{(1)} \exp(-E_i^0/kT) = 0 \tag{20.3}$$

The term in equation (20.1) involving $E^{(1)}$ is the first-order Zeeman interaction and the term involving $E^{(2)}$ is the second-order Zeeman interaction. If the ground crystal field (CF) state is a singlet and the next state is greater than kT away in a particular temperature range, the first-order term will be zero and only the second-order term will contribute to the paramagnetic susceptibility, which will be independent of temperature (temperature-independent paramagnetism, TIP).

If enough information is available about an ion or molecule (i.e. from optical spectroscopy) such that the properties of the energy levels in a magnetic field can be calculated, magnetic susceptibility measurements provide a good test for the eigenfunctions. Conversely, magnetic data can be used to determine information about energy levels and their eigenfunctions. Magnetic measurements usually are performed in the temperature range 2–300 K (energy range $\sim$1.5–200 cm^{-1}). From optical data, the crystal or ligand-field splittings of the ground state of some $5f^1$ hexahalo compounds are shown in the second column of Table 20.1 and vary from 1730 cm^{-1} in Pa^{4+} to about 7500 cm^{-1} for Np^{6+}. For $5f^2$ U^{4+} compounds, the total crystal-field splitting of the ground $^3H_4$ term is about 2240 cm^{-1} in Cs_2UCl_6 (Johnston *et al.*, 1966), about 2000 cm^{-1} in Cs_2UBr_6 (Johnston *et al.*, 1966), about 2400 cm^{-1} in $U(C_5H_5)_4$ (Amberger, 1976b), and about 1800 cm^{-1} for $U(BH_4)_4$ diluted in $Zr(BH_4)_4$ (Bernstein and Keiderling, 1973). For the $5f^3$ and $5f^4$ ions, U^{3+} and Np^{3+} diluted in $LaCl_3$, the total crystal-field splitting of the ground terms are 451 and 465 cm^{-1}, respectively (Carnall, 1992). From the above data, it is clear that temperature-dependent magnetic susceptibility measurements provide information only about the ground crystal field state and possibly a few lower-lying states. Most susceptibility measurements are performed on polycrystalline samples that give only the average susceptibility. Magnetic susceptibility values can also be performed on liquid solutions of pure compounds by use of the Evans nuclear magnetic resonance (NMR) method (Evans, 1959).

Electron paramagnetic resonance (EPR) measurements for actinide ions are usually made at liquid-helium temperatures in order to lengthen the spin–lattice relaxation time (T_1) so that the resonance can be observed (Abragam and Bleaney, 1970; Boatner and Abraham, 1978). Consequently information is obtained only about the ground crystal field state and possibly the first excited state. The spectra are interpreted in terms of an effective spin Hamiltonian:

$$H = \mu_B(g_x H_x S_x + g_y H_y S_y + g_z H_z S_z) \tag{20.4}$$

where μ_B is the Bohr magneton, and g_i, H_i, and S_i ($i = x, y, z$) are the components of the g-tensor, the magnetic field, and the spin operator along the principal axes of the crystal field. For a crystal or molecule with the highest-symmetry rotation axis (the z-axis by definition) of three-fold symmetry or greater, $g_x = g_y = g_\perp$ and $g_z = g_{||}$. For T_d or O_h symmetry, the g-value is isotropic (except when a Γ_8 state is lowest). For this review, hyperfine and quadrupole effects usually are not considered.

Table 20.1 *Optical transitions, g-values, and the best-fit parameters to the Eisenstein–Pryce theory for some* $5f^1$ *hexahalo compounds* (*Eichberger and Lux,* 1980).

	Electronic transitions and ground state g-value					*Best-fit parameters*

[a] See Piehler *et al.* (1991) for more accurate optical data on Pa^{4+} diluted in Cs_2ZrCl_6.

An electron configuration with an odd number of electrons ($f^1, f^3, \ldots$., etc.) has a Kramers degeneracy that can be lifted by a magnetic field but not by a crystal field. However, it is possible that the pair of states that lies lowest will not have an EPR signal because the selection rule $\Delta J_z = \pm 1$ will be violated. For example, consider a $J = 5/2$ term in a purely axial crystal field. This term will be split into three doublets: $J_z = \pm 1/2$, $\pm 3/2$, and $\pm 5/2$. If the crystal field is such that the $J_z = \pm 3/2$ or $J_z = \pm 5/2$ state is lowest, there will be no EPR transitions allowed.

An ion with an electron configuration with an even number of electrons($f^2, f^4, \ldots$., etc.) is called a non-Kramers ion. If the highest-symmetry axis is a C_2 axis, the crystal field will split an integer J term into $2J + 1$ singlets, and EPR will not be observed. If the highest-symmetry axis is C_3 or higher, a doubly or triply degenerate crystal field state could be lowest, and EPR might be observed. However, EPR has been reported only for the non-Kramers ions U^{4+} and PuO_2^{2+}, both $5f^2$, in the actinide series. Non-Kramers ions are discussed in detail by Abragam and Bleaney (1970).

For an f^n configuration, where n is the number of equivalent electrons, the electrostatic interaction between two f electrons results in a series of terms that can be classified by the total orbital and spin angular momenta, L and S, defined as:

$$L = \sum_i^n l_i \qquad S = \sum_i^n s_i \tag{20.5}$$

where l_i and s_i are the orbital and spin angular momenta of the ith electron. The eigenstates are then labeled by the quantum numbers (or symbols) ^{2S+1}L. This classification is called Russell–Saunders coupling. Inclusion of the spin–orbit interaction will cause mixing of the spin and orbital angular momenta and requires the use of J, the total angular momentum, defined as:

$$\boldsymbol{J} = \boldsymbol{L} + \boldsymbol{S} \tag{20.6}$$

The ^{2S+1}L multiplet is split into levels labeled by their J eigenvalues, $J = L + S, L + S - 1, \ldots., L - S + 1, L - S$, where each J level has a $2J + 1$ degeneracy. It is this J degeneracy which is split by the crystal field (Judd, 1963; Wybourne, 1965). Usually, the lowest J level is relatively isolated, the ligand-field splittings are approximately 100–1000 cm^{-1}, and only the lowest few crystal field states as indicated above provide the main contribution to the measured magnetic susceptibility. The effects of the various interactions are shown in Fig. 20.1 for the f^2 configuration.

A large number of magnetic susceptibility and EPR measurements have been made on actinide ions in crystal fields of O_h or T_d symmetry. In these symmetries, the ordering of the energy levels of a J-term depends only on the ratio of two crystal field parameters, the fourth-order term and the sixth-order term. From magnetic data, the ground crystal field state may be determined, which in

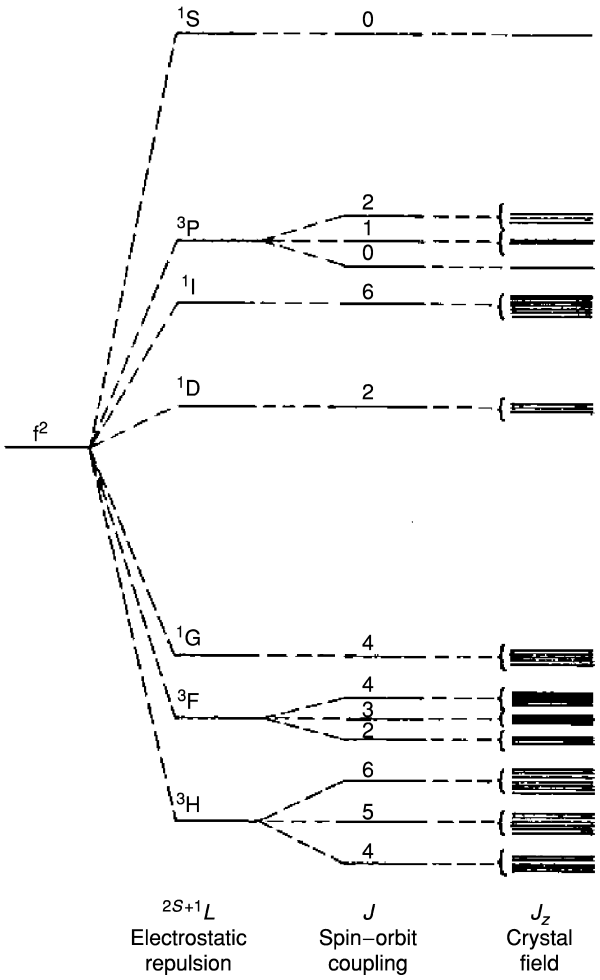

Fig. 20.1 *Schematic of the effects of the electrostatic, spin–orbit, and crystal field interactions on the f^2 configuration.*

turn can set a limit on the ratio of the fourth- to the sixth-order term. Lea *et al.* (1962) tabulated the results in reduced coordinates for all J levels of interest and their nomenclature is widely used. An illustration of the application of the Lea, Leask, and Wolf method (plus the effects of mixing other J states by the crystal field) is given in the study of Hendricks *et al.* (1974) on the temperature dependence of the magnetic susceptibility of the isostructural series, Cs_2NaMCl_6, M = U^{3+}, Np^{3+}, Pu^{3+}, Am^{3+}, Cm^{3+}, and Bk^{3+}. The data are shown in Table 20.2. From a consideration of these data, limits were placed on the possible values of the fourth- and sixth-order crystal field parameters B_0^4

and B_0^6 (defined as described by Wybourne (1965)). However, recent optical results on U^{3+} ion diluted into the elpasolite host Cs_2NaYCl_6 yielded much different crystal field parameters than those obtained by Hendricks *et al.* (Karbowiak *et al.*, 1998).

Magnetic susceptibility data are usually represented by a plot of $1/\chi_M$ vs T. This plot is linear over a particular range of temperatures, and the data are fitted to the Curie–Weiss law:

$$\chi_M = C/(T - \theta) \tag{20.7}$$

where χ_M is the molar magnetic susceptibility (expressed in cgs units in cm^3 mol^{-1} or emu mol^{-1}), T and θ (the Weiss constant) are expressed in K (kelvin), and C is the Curie constant. Note that equation (20.7) uses (T–θ) in the denominator. Some authors use (T+θ) and this is a point of great confusion. All data quoted in this chapter using the Curie–Weiss law will use the form in equation (20.7).

Sometimes, in order to analyze magnetic susceptibility data that shows temperature-dependent behavior, a modified Curie law of the form

$$\chi = \chi_0 + C/T \tag{20.8}$$

has been utilized where χ_0 is the temperature-independent susceptibility and μ_{eff} may be obtained from the value of C, the Curie constant.

Another common way of representing data is to use the effective moment, μ_{eff} (in units of the Bohr magneton μ_B):

$$\mu_{\text{eff}} = 2.828\ C^{1/2} = 2.828\,[\chi_{\text{M}}(T-\theta)]^{1/2} \tag{20.9}$$

or

$$\mu_{\text{eff}}^2 = 8.0\,\chi_{\text{M}}(T-\theta) \tag{20.10}$$

If the data do not follow the Curie–Weiss law, μ_{eff} is commonly defined as:

$$\mu_{\text{eff}} = 2.828\,(\chi_{\text{M}}T)^{1/2} \tag{20.11}$$

Considering the temperature range where only the ground crystal field state is populated and there is no second-order Zeeman effect, the molar susceptibility in the z-direction may be written as:

$$\chi_z = N\mu_{\text{B}}^2 g_z^2/4kT \tag{20.12}$$

with similar equations for the x- and y-directions. In eq. 20.12 N is Avogadro's number and k is the Boltzmann factor. Because $\chi_{\text{ave}} = 1/3(\chi_x + \chi_y + \chi_z)$, therefore:

$$\chi_{\text{ave}} = \frac{N\mu_{\text{B}}^2(g_x^2 + g_y^2 + g_z^2)}{12kT} \tag{20.13}$$

The g_x, g_y, and g_z in equation (20.13) are the same g-values obtained from EPR measurements on the ground crystal field state. Magnetic susceptibility measurements and units are discussed in detail by Myers (1973) and Boudreaux and Mulay (1976). All data quoted in this chapter will be in cgs units (see equation (20.7)).

For the lanthanide series, it is common to assume the ground term crystal-field splitting is much less than kT where k is the Boltzmann constant and $T \sim$300 K (at 300 K, $kT = 208.34\ \text{cm}^{-1} = 25.85$ meV). In this case

$$\mu_{\text{eff}} = g_J[J(J+1)]^{1/2} \tag{20.14}$$

where g_J is the free-ion g-value of the particular ground J multiplet. This equation is usually *not* valid for actinide compounds at room temperature as in most cases (see above) the crystal-field splittings of the ground term are larger than kT. Exceptions are found in the case of the $5f^7$ ions, Am^{2+}, Cm^{3+}, and Bk^{4+}. For the Am^{2+} and Cm^{3+} ions, the total crystal-field splitting of the ground terms are much less than 100 cm^{-1}. Thus for Cm^{3+} compounds, $\mu_{\text{eff}} = 7.62\mu_{\text{B}}$ with $g_J = 1.925$ (Edelstein and Easley, 1968).

20.1.2 Introduction to neutron and synchrotron X-ray scattering

The techniques discussed so far, magnetic susceptibility and EPR, are useful in the sense that they can determine many details about the magnetic state of an actinide ion. On the other hand, what they cannot determine is the interaction *between* actinide ions. For example, at low temperature the actinide ions,

especially those with a Kramers ground state, frequently order magnetically. The *exchange interaction* between the actinide ions energetically prefers a certain configuration of neighboring dipoles. Naturally, it is important to know the exact form of this magnetic structure. In certain cases EPR and Mössbauer spectroscopies (which are both single-site sensitive) are able to determine the magnetic structure. For example, if all the moments are aligned along the unique axis in a uniaxial crystal structure, then this symmetry will be reflected in the spectra. In general, however, one needs a technique that is sensitive to the long-range ordering of the moments and one naturally turns to methods involving the scattering of radiation.

The technique of choice for studies of this type is the scattering of thermal neutrons. Pioneered for magnetic structures in the period 1949–60 at Oak Ridge National Laboratory by Shull and his collaborators, this technique is in very wide use and there are a number of good books introducing the technique (Bacon, 1962; Squires, 1978; Kostorz, 1979; Skold and Price, 1987). In very early work (Shull and Wilkinson, 1955; Wilkinson *et al*., 1955) the famous ferromagnet UH_3 was examined (although to reduce the incoherent scattering from H they made a sample of isostructural UD_3). The key to magnetic structure determination is that for most antiferromagnetic (AF) structures, the repeat distances of the magnetic structure is more complex than the chemical structure. The result is new neutron diffraction peaks when the magnetic moments order. From the position and intensity of these diffraction peaks, the periodicity and the arrangements of the ordered moments, as well as their magnitude, may be deduced. Neutrons can, of course, be used also for chemical structure determinations, and the fact that the scattering from an actinide atom and an oxygen atom are roughly comparable means that the contrast is completely different from that of studies using X-rays. Much work in this respect is done on oxides and nitrides, and a summary of some of this work has been given (Lander, 1993) with particular reference to actinides. A good example of a study of this sort will be described later in connection with UO_2 at low temperature.

The *magnetic* scattering of neutrons is by the magnetic dipole moments in the material. For the actinides this arises from the 5f electrons around the nucleus. If the magnetic structure is well known, then the intensities may be measured as a function of momentum transfer Q ($= 4\pi \sin\theta/\lambda$, where θ is the Bragg angle and λ is the wavelength of the incident radiation) to give a so-called magnetic form factor $f(Q)$. By analogy with the scattering factor in X-ray studies, $f(Q)$ is proportional to the Fourier transform of the distribution of the outer 5f electrons. Again this is discussed (Lander, 1993), and there have been many studies of this type in actinides, including some Pu compounds.

Finally, thermal neutrons at 300 K have an energy corresponding to kT ($= 25.85$ meV, $= 208.34$ cm^{-1}) so that it is possible for them to lose energy to (or gain from) the sample and this energy change may be measured by inelastic neutron scattering. As with EPR and optical spectroscopies, the crystal field levels may be determined. Most importantly, and unlike spectroscopic methods

based on photons, the neutrons (which are electrically neutral) can penetrate deep into the solid so this technique is good also for opaque materials. This means that complex experimental environments can readily be used, for example, at low temperatures down to 100 mK, high temperatures up to 2500°C, and high magnetic fields. Furthermore, if single crystals are available, then the neutrons can map out the dispersion curves of both the phonons and the magnons. UO_2 is a famous example of this, where both types of excitations were published more than 30 years ago (Cowley and Dolling, 1968).

Unfortunately, there are two major disadvantages for neutron studies. The first one is caused by the presence of resonant terms in the neutron-nuclear cross sections for actinides (Lander, 1993). This interaction is a complex one, not easy to calculate from first principles. However, generally speaking, the heavier nuclides are less stable than the lighter ones, and part of this trend toward instability results in resonant terms in the cross section. Thus, when a neutron impinges upon the nucleus there are probabilities for scattering and absorption. The latter results in the formation of a compound nucleus, which usually rapidly decays and gives rise to other types of radiation. If a neutron is captured then it is no longer available for scattering; the beam penetration is restricted. Materials like Cd and Gd have enormous absorption cross sections for thermal neutrons, and are frequently used to stop neutron beams. In the actinides there is an appreciable absorption cross section for ^{237}Np, but, of course, the most famous absorption cross sections are those due to the fission process in both ^{235}U and ^{239}Pu. In the case of ^{235}U, the fission cross section is actually for low-energy neutrons, which can penetrate the nuclear barrier, forming an unstable compound nucleus that then breaks up with the emission of fast neutrons and γ-rays. This, of course, was the famous discovery of Hahn and Strassman in 1938. Fortunately, ^{235}U is only a small fraction of normal uranium. However, the most common isotope of Pu is ^{239}Pu with a very large cross section, so for most neutron experiments using Pu, the heavier isotope ^{242}Pu should be used.

The second disadvantage for neutrons is the available intensities. Neutron sources are weak, much weaker (in terms of flux per $cm^2\ s^{-1}$) than synchrotron or laser sources, mainly because they are impossible to focus. Large samples are therefore needed. For neutron powder diffraction, samples of up to several grams are frequently used, although studies of much smaller samples are possible. Examples are the work on CmO_2 (Morss *et al.*, 1989) and Cm_2CuO_4 (Soderholm *et al.*, 1999), discussed below, in which amounts of $\sim$50 mg were studied. For single-crystal studies, the samples can be at the few milligram level, but this still contrasts with samples of $\sim$50 μg that can be examined by conventional laboratory X-ray sources. For inelastic neutron scattering and the study of phonons, samples sizes of grams are again required. This is a serious handicap for neutron diffraction on *any* element in the periodic table. For many studies, this is not a problem, but the acquisition of large single crystals for phonon or magnon measurements can be a serious limitation. For example,

despite the huge effort on high T_c superconducting materials after their discovery in 1986, it took approximately 5 years until the first details of the phonon and magnetic excitation spectra were published. This did not represent a lack of interest on the part of neutron specialists, but rather an absence of suitable crystals. Moreover, this technique can, of course, only be done at a central user facility, either a spallation source or reactor. The difficulty for actinides as compared to most other elements is that their quantity in user facilities is frequently restricted. The large quantities required in neutron scattering studies are not a problem with uranium, but have severely limited the possible range of experiments on transuranium materials. The restrictions continue to become more severe in 'open' facilities, and experiments that were readily performed (for example at Argonne in the 1970s) are no longer possible at most facilities.

Synchrotron radiation (another activity performed at large user facilities) is making a sizeable impact in actinide science, especially in the field of environmental studies using methods based on absorption spectroscopy. Can such beams be of any use in magnetic studies, the subject of this chapter? Initially, when the synchrotrons were built, their impact on magnetism was predicted to be small. It was known, for example, that photons do indeed have a 'magnetic' cross section, but it was very small. For example, for iron the magnetic photon cross section is some six orders of magnitude smaller than the Thompson (charge) cross section (Blume, 1985; Blume and Gibbs, 1988; Lovesey and Collins, 1996). Indeed, this cross section has been of only limited use, although as the synchrotron fluxes continually increase in intensity, this may change. One example is the work on UAs (Langridge *et al*., 1997) in which the spin and orbital contributions to the magnetism were separated. The weak intensities resulted in large uncertainties, but this technique may well become more popular as synchrotron fluxes increase.

Synchrotron radiation is, of course, tunable in the sense that any wavelength (energy) may be chosen, unlike laboratory-based sources. This naturally led to the idea that the energy should be tuned to a resonant absorption edge – something incidentally also useful in protein crystallography as the cross section for charge scattering also changes appreciably near an absorption edge (James, 1962). The result in magnetic studies was the discovery of large *enhancements* in the (weak) non-resonant magnetic scattering. Although there had been some attempts to see these previously, the first really large effects were observed in holmium metal by Gibbs and his collaborators (Gibbs *et al*., 1988) and were immediately interpreted in terms of atomic resonance theory (Hannon *et al*., 1988). This general technique is called resonant X-ray scattering (RXS).

Turning to the actinides, enhancements at the M_4 and M_5 edges are shown in Fig. 20.2 taken from McWhan *et al*. (1990) on the antiferromagnetic material UAs. M-edges correspond to the initial states having a principal quantum number n of 3. The M_4 and M_5 edges have the azimuthal quantum number $l = 2$ and correspond to transitions from $3d_{3/2}$ and $3d_{5/2}$ core states, respectively.

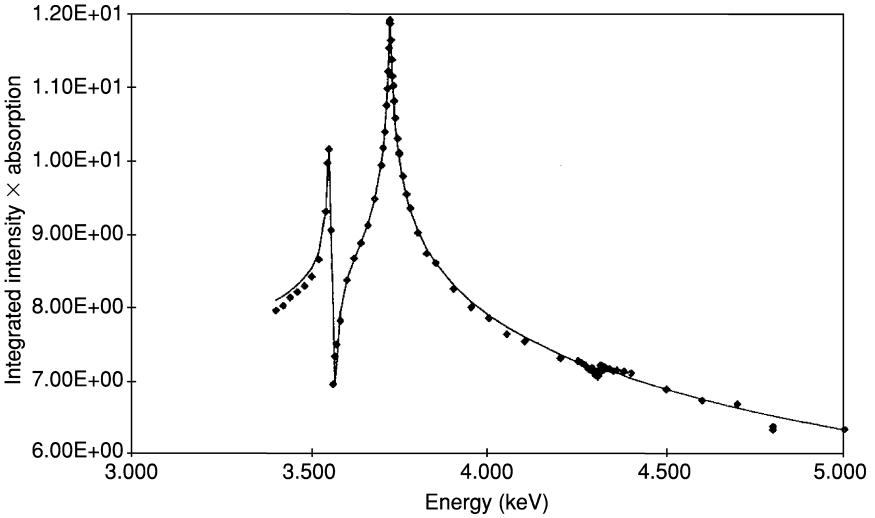

Fig. 20.2 *Intensity of the* (003/2) *reflection from a single crystal of UAs at* $T = 10$ K *as a function of photon energy. UAs* (*simple fcc NaCl crystal structure*) *has a magnetic structure that repeats in two unit cells. This results in magnetic reflections occurring at half integer Miller indexes. Notice that the intensity is plotted on a log scale so that the enhancement approaches* 10^6 *as compared to the intensity off resonance. The positions of the M resonances are* $M_5 = 3.550$, $M_4 = 3.726$, *and* $M_3 = 4.304$ keV. *The solid line is the result of a calculation involving three dipole oscillators, and fits the data very well. Reprinted from McWhan* (1998), *Copyright* 1998 *with permission from Elsevier.*

Electric dipole (E1) transitions change the azimuthal quantum number by ± 1 so that the final states involve the $5f_{5/2}$ and $5f_{7/2}$ states, the valence band states. However, in the actinides, there may be already electrons in the 5f states. In UAs, for example, one would expect most of the three 5f electrons to be in the lower energy $5f_{5/2}$ orbitals. At low temperature, these states become polarized, leading to a magnetic moment on the atom. The promotion of an electron into the valence band 5f states causes a resonance between the states already there, resulting in a reemission of radiation when the excited state decays to annihilate the core hole. In the case of the valence states being polarized, as when UAs becomes antiferromagnetically ordered below T_N, the emitted radiation is also polarized, and it is this that leads to the large enhancement of magnetic scattering at the resonant energy. One can see immediately from this that for the light actinides the signal at the M_4 edge should be greater than that at the M_5, because the 5f polarized states are mostly in $5f_{5/2}$ levels corresponding to the M_4 transition. (Transitions at the M_5 edge involve mainly $5f_{7/2}$ states but also $5f_{5/2}$ with smaller matrix elements, hence the intensities are smaller. For a half-filled shell the intensities at the two edges should be similar.)

The process involving resonance effects also occurs in absorption spectroscopy. The development of the two techniques, so-called X-ray magnetic circular dichroism (XMCD) has been remarkably parallel (Thole *et al.*, 1985; Schütz *et al.*, 1987). The amplitude of the effects in either technique depends on a number of factors, in particular the overlap of the wavefunctions of the core and valence states and matrix elements summed over all possible excited states. The advantage of XMCD is that (provided a model of the magnetism is available) the signal may be related directly to the orbital moment of the valence states, and it is also possible with reasonable assumptions to deduce the spin moment. These so-called 'sum rules' (Carra and Altarelli, 1990) can be derived primarily because absorption involves only the imaginary part of the cross section. In the case of scattering one must deduce *both* the real and imaginary parts, and that has proved intractable so far for resonance scattering experiments. XMCD also has the advantage (see below) that any edge can be accessed without the necessity to fulfill Bragg's law as is necessary for scattering. However, XMCD has the major *disadvantage* that it cannot give any information about the spatial extent of the scattering centers as it is restricted to $Q = 0$, where Q is the momentum transfer. Moreover, it cannot examine antiferromagnets since (by definition) they have no net magnetization so no magnetic signal at $Q = 0$. (X-ray linear dichroism is a possible technique to overcome this, but the matrix elements are very small.) From this discussion, it is clear that RMS and XMCD are indeed complementary. There have been a number of experiments reported on U compounds (none yet on transuranium compounds), especially on UFe_2 (Finazzi *et al.*, 1997) and on the heavy-fermion intermetallic materials (Dalmas de Rotier *et al.*, 1999; Bombardi *et al.*, 2001).

Scattering experiments have played an important role in studies of one of the oxides, NpO_2. Before discussing particular experiments, a general overview (Fig. 20.3) of the energies of the resonances will be given. The boxes in Fig. 20.3 give the ranges of the electron binding energies across a series that are of interest for magnetism. For example in the 3d series the K-edges correspond to transitions from the 1s to the 4p states. Since the 4p states are not expected to be polarized strongly, the matrix elements are small. On the other hand, transitions at $L_{2,3}$ edges are to the strongly polarized 3d states, so it is these edges that need to be used to observe an appreciable signal. Similarly (as explained above) it is the $M_{4,5}$ edges that will be useful for f magnetism as found in the rare earths and actinides. No modification of these electron-binding energies is possible except perhaps at enormous pressures. For scattering processes Bragg's law, $2d \sin \theta/\lambda$, is utilized where d is the interplanar spacing, θ is Bragg's angle, and λ is the wavelength of the radiation. Using the relationship for photons that $E = 12.4/\lambda$, where E is in keV, and λ in Å, Bragg's law demands d spacings *larger* than 3.1 Å for radiation less than 2 keV in energy. Now 3.1 Å has been chosen as it represents a large d-spacing from a simple solid. Larger d-spacings require either more complex solids or the examinations of d-spacings in multilayers or domains. The latter can reach up to $\sim$1000 Å and represent science on the

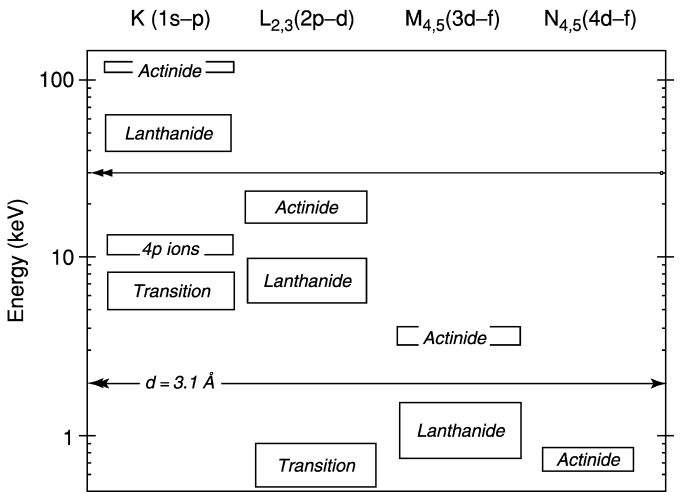

Fig. 20.3 *Each box shows the energy spread of the electron binding energies across the series for the transitions marked at the top of the figure. The upper horizontal line gives the approximate maximum energy* (∼30 keV) *of most magnetic scattering beamlines. The lower horizontal line gives the d-space corresponding to the maximum that will fulfill Bragg's law for an incident photon energy of* 2 keV. *For lower energies, such as the transition metal* $L_{2,3}$ *edges, greater d-spaces are required. For a normal crystal structure with a small unit cell this implies these edges are beyond the Bragg cut-off and no scattering can be observed. For dichroism there are no such restrictions, and, in principle, all edges are accessible. Reprinted from Lander* (2002). *Copyright* 2002 *with permission from Elsevier.*

nanoscale. Now it can be understand why this technique has not been enormously useful for Å-level magnetism in the transition-element series, the important edge is simply too low in energy (Lander, 2002). Similarly, even in the rare earths most of the work is done at the L-edges, which represent transitions to the (sparsely polarized) 5d states. It is only recently with the building of dedicated magnetic scattering beamlines in vacuum that work on the rare-earth M-edges is being reported (Schüssler-Langeheine *et al.*, 2001). The M-edges of the actinides are then unique, magnetism on the atomic scale with the largest resonance effects can be examined. Accordingly a large amount of work, starting with the first study of UAs as shown in Fig. 20.2, has been done with U, Np, and even Pu compounds (Langridge *et al.*, 1994a,b; Lander, 2002; Normile *et al.*, 2002).

Compared to neutrons RXS can use minute amounts of material. Samples of about 1 mg are regularly used, and intensity corresponding to a doping of ∼40 μg of Np was seen in one crystal. On the other hand, no method (yet) is available to relate the observed signal to the magnetic moment. In addition, it has not proved possible to observe signals from polycrystalline samples (except with

very poor *q*-space resolution (Collins *et al*., 1995)). In principle, this could be remedied by building a special apparatus to collect more of the solid angle from the Debye–Scherrer cone, but the strong absorption means that the beam only would penetrate a few micrometers at most (and only ~0.2 μm at the U M-edges) so the sampling through the powder would always be poor. Since neutrons are so good at sampling a large volume of material, very little effort has been made at synchrotron sources with RXS, but it might be justified for actinides because of the small sample quantities that could be used.

As is so often the case, the techniques are really complementary and scientists in this field should choose the technique for the problem, and not vice versa!

20.1.3 Scope, other reviews, and units

Although in this chapter the coverage has been primarily restricted to *ionic* actinide compounds, in actinide condensed matter physics a major interest is actually in studies of intermetallic and semiconductor compounds. Chapter 21 reviews the physical properties of actinide metals and alloys, including their magnetic properties. The two volumes edited by Freeman and Darby (1974) contain information about the magnetic properties of many actinide materials, including a review by Lam and coworkers (Lam and Chan, 1974; Lam and Aldred, 1974) on actinide salts, carbides, chalcogenides, pnictides (group V), and various intermetallic compounds, plus another review by Nellis and Brodsky (1974) on the pure metals and alloys. A later review article by Brodsky (1978) covered the magnetic properties of the actinide elements and their magnetic compounds. An earlier review covers the $5f^0$, $5f^1$, and some selected data for $5f^2$ and higher configurations (Sidall, 1976). Some magnetic data are given in the review by Keller (1972) on lanthanide and actinide mixed oxides and by Dell and Bridger (1972) in their review of actinide chalcogenides and pnictides. The review article by Boatner and Abraham (1978) summarizes all the EPR data on actinide ions published through 1976. Kanellakopulos (1979) reviewed the magnetic properties of cyclopentadienyl compounds of the trivalent and tetravalent actinides. Fournier (1985) reviewed the magnetic properties of actinide solid compounds and Huray and Nave (1987) have surveyed magnetic measurements on transplutonium actinides. A comprehensive survey of actinide metals and their compounds is given in Landolt-Börnstein (Troc *et al*., 1991; Troc and Suski, 1993). Santini *et al*. (1999) reviewed the magnetism of actinide compounds that can be categorized as actinide intermetallics and strongly correlated systems.

The discovery of heavy-fermion materials in the early 1980s and the accompanying interplay between magnetism and superconductivity has been of great interest both in the neutron and synchrotron communities, as well as in the larger solid state physics community. Much of the corresponding neutron work has been reviewed (Lander and Aeppli, 1991; Lander, 1993; Holland-Moritz

and Lander, 1994). The general neutron trends were illustrated in the following papers (Bernhoeft *et al.*, 1998; Metoki *et al.*, 1998). For the high-intensity X-ray case, a good background and useful references are given in the reviews by McWhan (1998) and Lander (2002). Further excitement in the condensed matter physics community has been caused by the discovery of the *ferromagnetic* superconductor UGe_2 with $T_c \sim 0.5$ K (Saxena *et al.*, 2000), and the recent discovery of a Pu-based compound ($PuCoGa_5$) that becomes a superconductor at the astonishingly high temperature of 18 K (Sarrao *et al.*, 2002).

The remainder of this chapter is divided into two major sections. In the first section, the actinide ions are classified according to their electron configuration, and magnetic measurements are reviewed for each electron configuration. The actinide dioxides (AnO_2) are not included in this section but are reviewed separately in the second major section. The actinide dioxides are isostructural with a face-centered cubic (fcc) fluorite structure. Thus the crystal field parameters (which determine the ground state electronic and magnetic properties) for each of the dioxides should be correlated. Therefore, in principle, the results of the analyses for one of the dioxides should be relevant to the series. In fact the actinide dioxide story is complicated and considerable efforts, both experimental and theoretical, have been expended to try to understand their properties. For these reasons this subject is best treated separately.

Two different energy units are used in this review depending on the discussion. The units are meV and cm^{-1}. The conversions between these units are as follows: (1 eV = 8065.479 cm^{-1}); (1 meV = 0.001 eV = 8.065 cm^{-1}); (1 cm^{-1} = 1.2399×10^{-4} eV or 0.12399 meV). It is useful to note that kT (where k is the Boltzmann constant) at 300 K = 25.85 meV = 208.34 cm^{-1}.

20.2 $5f^0\ ^1S_0$; Th^{4+}, Pa^{5+}, U^{6+}, UO_2^{2+}

For a closed-shell configuration, compounds formed with these ions should be diamagnetic. This is found to be true for Th^{4+} and Pa^{5+}, but uranyl compounds and UF_6 exhibit TIP. The weak paramagnetism for UF_6 was attributed by Eisenstein and Pryce (1960) to the coupling of higher-energy states into the ground configuration by the magnetic field. From an analysis of the observed susceptibility they concluded that the bonding in the actinide hexafluorides is at least partially covalent. A similar model was proposed earlier by Eisenstein and Pryce (1955) and later by McGlynn and Smith (1962) to explain the weak paramagnetism of uranyl salts. Studies by Denning and coworkers (Denning, 1992) on the high-resolution spectral characteristics, including Zeeman effect measurements of the uranyl ion in tetragonal and trigonal equatorial fields (perpendicular to O–U–O bond axis), has resulted in the determination of paramagnetic magnetic moments for some excited states and a consistent description of the bonding within the uranyl group. The magnetism of a number of ternary U(VI) oxides have been measured and their TIP were

attributed to a nonnegligible degree of covalency in the An–O bonds (Bickel and Kanellakopulos, 1993). These data are listed in Table 20.3.

20.3 $5f^1\ {}^2F_{5/2}$; Th^{3+} ($6d^1$), Pa^{4+}, U^{5+}, Np^{6+}, NpO_2^{2+}, Pu^{7+}

The $5f^1$ ions are good examples for the interpretation of magnetic data because electron repulsion is absent and at most six transitions are allowed in the optical spectrum.

An interesting change in the ground configuration occurs for the known Th^{3+} compounds. Initially a purple trivalent thorium complex, formulated as $Th(C_5H_5)_3$, was reported by Kanellakopulos *et al.* (1974), with a room-temperature magnetic moment of $0.331\mu_B$. A second compound, also formulated as $Th(C_5H_5)_3$ but green in color, was prepared by Kalina *et al.* (1977), who reported a magnetic moment of $0.404\mu_B$. Trisindenylthorium(III) has been prepared by Goffart and also has a very low magnetic moment (Kanellakopulos, 1979). Blake *et al.* (1986) prepared the first crystallographically characterized Th^{3+} compound, $[Th\{\eta^5\text{-}C_5H_3(SiMe_3)_2\}_3]$. Kot *et al.* (1988) showed that this compound has a room-temperature EPR spectrum that is consistent only with a $6d^1$ ground state. Subsequently two other Th^{3+} compounds (Parry *et al.*, 1999; Blake *et al.*, 2001) have been synthesized and shown to have EPR spectra consistent with the $6d^1$ ground configuration rather than a $5f^1$ configuration. Because the relative energies of these two configurations are so close in energy (for the Th^{3+} free ion, the ground configuration is $5f^1$ with the start of the $6d^1$

configuration at 9192.84 cm^{-1}, see Chapter 16, Table 16.1) it is possible that other new Th^{3+} compounds may indeed have a $5f^1$ ground configuration.

The magnetic susceptibility of protactinium tetrachloride was measured between 3.2 and 296 K (Hendricks *et al.*, 1971), follows the Curie–Weiss law from 182 to 210 K with $\mu_{\text{eff}} = 1.04(6)\mu_B$ and $\theta = +158$ K, and exhibits a ferromagnetic transition at 182 ± 2 K. A high degree of covalency has been suggested to explain this relatively high transition temperature. The magnetic susceptibility of protactinium tetraformate (Schenk *et al.*, 1975) was measured from 80 to 300 K and follows the Curie–Weiss law with $\mu_{\text{eff}} = 1.23\mu_B$ and $\theta = -3$ K. The crystal structure of this compound and its Np analog were reported to have the M^{4+} ion at the center of a nearly undistorted cube of eight oxygen atoms. However, the U analog was stated to have lower symmetry, which appears inconsistent (Hauck, 1976). By assuming that the $J = 5/2$, Γ_7 state was lowest and is the only one that contributes to the measured susceptibility, a value of $\mu_{\text{eff}} = 1.24\mu_B$ (with $g_J = 6/7$) was calculated from the wave functions given by Lea *et al.* (1962), in good agreement with the experimental value.

The susceptibility of tetrakis(cyclopentadienyl)protactinium was measured between 4.2 and 300 K (Kanellakopulos, 1979). Above 90 K, the magnetic susceptibility followed the Curie–Weiss law with θ = –8.6 K, and the magnetic moment at room temperature is $0.725\mu_B$. A $J = 5/2$ state will split into at most three Kramers doublet levels, and in this compound it is reported that the first two levels are separated by approximately 15–30 cm^{-1} and that the third level is at about 600 cm^{-1}. J mixing cannot explain the low magnitude of the magnetic moment.

A large number of magnetic measurements have been reported for $5f^1$ ions in compounds with octahedral or pseudo-octahedral nearest neighbor coordination. These studies include EPR measurements of the $5f^1$ ion (Pa^{4+}, U^{5+}, Np^{6+}, and in one case Pu^{7+}) diluted in nonmagnetic hosts or magnetic susceptibility measurements of the $5f^1$ compounds, either pure or again diluted in a host matrix. For a $5f^1$ ion only the crystal (or ligand) field and the spin–orbit coupling are the important interactions. The necessary theory to interpret the magnetic and optical measurements may be easily formulated starting from the one-electron f-orbitals in a crystal field as the basis set (S, S_z representation) or from the spin–orbit coupled (J, J_z representation) basis set (Axe, 1960; Eisenstein and Pryce, 1960; Hutchison and Weinstock, 1960; Axe *et al.*, 1961; Judd, 1963; Reisfeld and Crosby, 1965; Hecht *et al.*, 1971). For O_h symmetry, the energy levels and magnetic properties are dependent upon two crystal field parameters and the spin–orbit parameter as shown schematically in Fig. 20.4.

For one $5f^1$ electron in a free ion (no crystal field), the ^2F Russell–Saunders state splits into two J states, $J = 5/2$ and $J = 7/2$, when the effect of spin–orbit interaction ζ is included with an energy splitting between the two states of $7\zeta/2$ (far right side of Fig. 20.4). Now assuming an octahedral array of ligands about the metal ion, the $J = 5/2$ state breaks up into a doubly degenerate

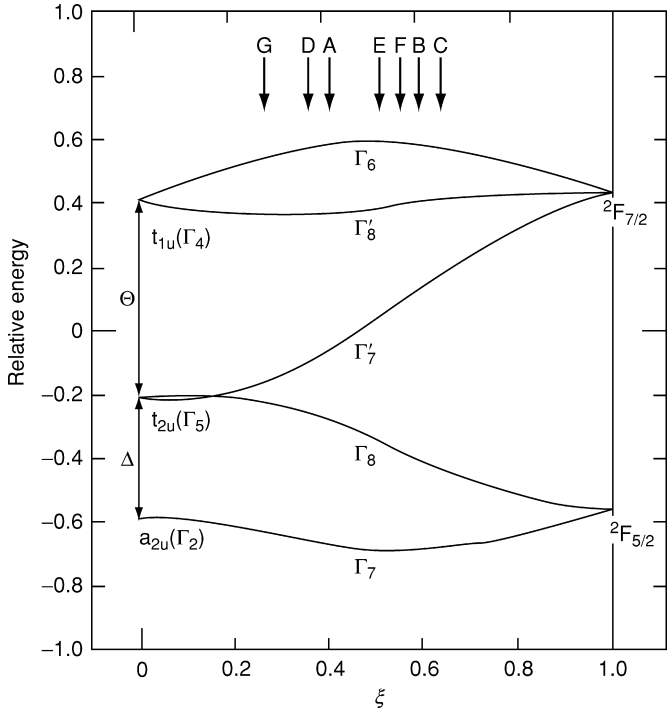

Fig. 20.4 *Relative energy splittings of an f^1 ion (O_h symmetry) as a function of the relative magnitudes of the crystal field and spin–orbit coupling interactions. The ordinate is defined as relative energy* $= E/[(\Delta + \Theta)^2 + (7\zeta/2)^2]^{1/2}$ *and the abscissa* ξ *can be determined from the equation* $\xi = [(7\zeta/2)/(\Delta + \Theta)]/[1+(7\zeta/2)/(\Delta + \Theta)]$. *The figure is drawn for the ratio* $\Theta/\Delta = 13/8$. *The arrows at the top represent the approximate parameter values for A,* $(NEt_4)_2PaF_6$*; B,* $(NEt_4)_2PaCl_6$*; C,* $(NEt_4)_2PaBr_6$*; D,* $(NEt_4)UF_6$*; E,* $(NEt_4)UCl_6$*; F,* $(NEt_4)UBr_6$*; G,* NpF_6. *The data are from Brown* et al. (1976).

Γ_7 state and a four-fold degenerate Γ_8 state. The higher-lying $J = 7/2$ state breaks up into two doubly degenerate states, Γ_6 and Γ'_7, and one four-fold degenerate Γ'_8 state. The ground state in this symmetry is the $J = 5/2$, Γ_7 state. The parameters Θ and Δ represent the splittings of the f-orbitals for O_h symmetry when the spin–orbit interaction is zero. This is represented at the far left side of Fig. 20.4. As the relative strengths of the crystal field and spin–orbit interactions become comparable, the relative energy splittings change as shown in the center of Fig. 20.4. The ground Γ_7 state g-value depends only on the spin–orbit coupling constant and the difference in energy between the two lowest f-orbitals (Δ) in the limit of zero spin–orbit coupling.

If the ground Γ_7 state were a pure $J = 5/2$ state, the measured g-value could easily be calculated. However, the crystal field interaction is not small as compared to the spin–orbit coupling interaction so the excited $J = 7/2$,

Γ_7' state is mixed into the ground $J = 5/2$, Γ_7 state via this interaction. The resulting expression for the ground state g-value in $5f^1$ octahedrally coordinated complexes is given by Axe (1960):

$$g = -2\left(\frac{5}{7}\cos^2\phi - \frac{4\sqrt{3}}{21}\sin 2\phi - \frac{12}{7}\sin^2\phi\right)$$

where

$$\Gamma_7^{(1)} = |^2F_{5/2}\Gamma_7 > \cos\phi - |^2F_{7/2}\Gamma_7' > \sin\phi$$

and ϕ is determined by the relative magnitudes of the crystal field parameters. There are four electronic transitions (O_h symmetry) that should be observed in these systems. Three optical and/or near-infrared transitions between the $J = 5/2$ and $J = 7/2$ states have been reported for most of these octahedral complexes. In some cases the $\Gamma_7 \rightarrow \Gamma_8$ transition of the $J = 5/2$ state that occurs in the infrared or near-infrared region has also been observed. These electronic absorption data plus the EPR data on the ground state allow the parameters (including orbital reduction factors) of the Eisenstein–Pryce model (Eisenstein and Pryce, 1960; Hecht *et al.*, 1971; Edelstein, 1977; Eichberger and Lux, 1980) for an octahedral f^1 system to be evaluated as shown in Table 20.1. Note the much different ground state g-values for various compounds.

A careful study of the magnetic susceptibility of NpF_6 and NpF_6 diluted in UF_6 (very slightly distorted O_h symmetry) in the temperature range 4.2–336.9 K has been reported by Hutchison *et al.* (1962). The g-value extrapolated to infinite dilution was found to be 0.605 ± 0.004. The g-value was found to vary as a function of the mole fraction of NpF_6 (six different samples of varying mole fractions were measured), with a maximum value of 0.694 ± 0.011 at a mole fraction of 0.34. No explanation has been given for these observations. The magnetic measurements agree with EPR measurements of NpF_6 diluted in UF_6 (Hutchison and Weinstock, 1960) and with the calculations of Eisenstein and Pryce (1960). Analysis of the fluorine superhyperfine structure measured by electron-nuclear double resonance (ENDOR) in single crystals of NpF_6 diluted in UF_6 (Butler and Hutchison, 1981) indicates that 5f orbital covalency effects are approximately an order of magnitude larger in NpF_6 than in 4f complexes. This is consistent with the larger radial extension of 5f orbitals as compared to 4f orbitals. Similarly, a series of papers on the EPR of U^{5+} in complexes of the type MUF_6 (M = Li, Na, Cs, NO) measured at 77 K have been reported (Rigny and Plurien, 1967; Drifford *et al.*, 1968; Rigny *et al.*, 1971a). These octahedral complexes showed a small g-value anisotropy due to axial distortions. The data have been analyzed on this basis. Other, similar complexes with M = K, NH_4, Rb, Ag, and Tl showed no EPR spectra at 77 K, which has been attributed to larger distortions of theUF_6^- octahedra. Selbin and coworkers (Selbin *et al.*, 1972; Selbin and Sherrill, 1974) have measured and analyzed the room-temperature EPR spectra of a number of polycrystalline salts of the type

UX_6^- and UOX_5^{2-} (X = F^-, Cl^-, Br^-, no signal observed for UF_6^-). Their analysis was based on an extension of the standard octahedral theory to include a tetragonal distortion. Although observations of the room temperature signals for the UOX_5^{2-} species have been questioned (Lewis *et al.*, 1973), the magnitude of the *g*-value obtained is consistent with that of other $5f^1$ hexahalide or distorted hexahalide complexes. Some EPR and optical measurements have been reported or reanalyzed for NpF_6, UX_6^- (X = F, Cl, Br) (Eichberger and Lux, 1980), and PaX_6^{2-} (X = F, Cl, Br, I) (Brown *et al.*, 1976) (see Table 20.1).

Early studies on the optical and magnetic properties have been reported for $5f^1$ ions in uranates, neptunates, and one plutonate (Keller, 1972; Miyake *et al.*, 1977a, 1979, 1982, 1984; Kanellakopulos *et al.*, 1980a). For these compounds, the magnetic ions (U^{5+}, Np^{6+}, Pu^{7+}) are surrounded by an octahedral or distorted octahedral array of oxygen atoms. Hinatsu, in a series of recent papers, has reanalyzed earlier data and provided new measurements on some compounds plus other distorted actinide perovskites. He has given a consistent analysis of this body of data (Hinatsu and Edelstein, 1991; Hinatsu *et al.*, 1992a,b; Hinatsu, 1994a,b). Hinatsu's results are consistent with the *g*-values of about 0.7 reported by Lewis *et al.* (1973) from EPR measurements for U^{5+} diluted in $LiNbO_3$, $LiTaO_3$, and $BiNbO_4$. The latter study could not find any verifiable EPR spectra due to U^{5+} in a number of magnetically concentrated crystals including $NaUO_3$ and $LiUO_3$.

In an interesting paper, Bickel and Kanellakopulos (1993) compiled magnetic data on a number of $5f^1$ ternary actinide oxides that they analyzed in terms of a temperature-dependent term and a temperature-independent term (see equation 20.8). Table 20.4 lists the results of the magnetic measurements and some crystallographic data for a number of compounds. The compounds studied have the $5f^1$ ion at the center of a more or less distorted AnO_6 anionic array. For U^{5+} and Np^{6+} compounds in this symmetry, the first excited level is more than $\sim$4000 cm^{-1} higher in energy. Therefore the room-temperature moment should reflect the value of $1.24\mu_B$ obtained from a Γ_7 ground state. Table 20.4 shows the experimental values, all of which are lower than the theoretical value. Bickel and Kanellakopulos (1993) argue that this can be interpreted, along with the observed TIP for these compounds, as due to the degree of covalency. They also point out that the observation of low-temperature magnetic transitions in these compounds, due to exchange interactions, depends on the shortest An–An distance. This behavior is reminiscent of that found in actinide metals and alloys. In that case, when the actinide ion–actinide ion distance is less than a certain critical distance (the Hill parameter), approximately 3.5 Å, the material exhibits itinerant behavior (TIP). At a distance greater than the critical distance, localized magnetism is found. For the ionic compounds discussed by Bickel and Kanellakopulos, the equivalent behavior is exchange interactions at shorter distances vs no magnetic ordering at larger distances. See Chapter 21 for further discussion.

* Ordering temperature.
[a] No ordering observed above 4.2 K.

A recent report of a newly synthesized U^{5+} hexakisamido complex (Meyer *et al.*, 2000) reported $g = 1.12$ as measured by EPR at 20 K with a $\mu_{\text{eff}} = 1.16$ BM from 5 to 35 K. This complex has six N atoms arranged in octahedral coordination around the U^{5+} ion from each of six dbabh groups (dbabh = 2,3:5,6-dibenzo-7-azabicyclo[2.2.1]hepta-2,5-diene) and its g-value is in accord with those measured for hexahalogenated U^{5+} complexes.

The magnetic susceptibility of UCl_5 (a dimeric compound with a pseudo-octahedral array of chlorine atoms, two of which are bridging) as a function of temperature was first reported by Handler and Hutchison (1956) and later by Fuji *et al.* (1979). The latter authors have also reported the g-value as measured by EPR (Miyake *et al.*, 1977b). They have combined the magnetic data with optical measurements by Leung and Poon (1977) and fitted all the data with a crystal field model based on a weak C_{2v} distortion of the predominantly octahedral (O_h) crystal field. However, they calculated an isotropic g-value on the basis of octahedral symmetry when in fact their model predicts an anisotropic g-tensor. Soulie and Edelstein (1980) have adopted a different point of view by noting the large difference in distances between the two bridging chlorines (U–Cl ~2.68 Å) and the four nonbridging chlorines (U–Cl ~2.43 Å) in the crystal structure. They used the Newman superposition model (Newman, 1971) and fitted the optical and magnetic data. Their best fit gave $g_x = 0.226$ and $g_y \approx g_z \approx 1.186$, as observed. This g_x-value could not be experimentally observed because

of the large magnetic field necessary to do so. However the derived spin–orbit coupling constant of 1196 cm^{-1} is much smaller than that observed in any U^{5+} compound and the calculated $\mu_{eff} \sim 0.85\mu_B$ is lower than the measured value of $1.08\mu_B$.

In the eight-fold cubic coordination of Na_3UF_8, Lewis *et al.* (1973) measured a *g*-value of 1.2 at 7 K. The magnetic susceptibilities of M_3UF_8 (M = Na, Cs, Rb, and NH_4) have been measured from 8 to 300 K (Rigny *et al.*, 1971b). The experimental data were fitted very satisfactorily with a model that assumed a trigonal (D_{3d}) distortion to the eight-fold cubic coordination of the fluorine atoms.

An interesting EPR study of six organouranium(v) complexes (five organouranium amides and one organouranium alkoxide) in dilute frozen solutions at 15 K has been published (Gourier *et al.*, 1997). From an interpretation of the anisotropic *g*-values obtained from the EPR spectra, a picture of the bonding was established for these compounds. The major assumption made was that all ligands, with the exception of the alkoxide ligands, were bound only weakly with the 5f orbitals of the U(v) ion so that only the ground $J = 5/2$ crystal field state has to be considered. With this assumption the experimental *g*-values of the organouranium(v) amide complexes could be quantitatively fit. This model did not work with the organouranium(v) alkoxide compound. This was attributed to a strong U(v) 5f-OR (where R is the alkyl group on the alkoxide) interaction so that the above weak field approximation is not valid.

The magnetic uranium bis-cycloheptatrienyl sandwich compound $[K(C_{12}H_{24}O_6)][U(\eta^7\text{-}C_7H_7)_2]$ has been synthesized (Arliguie *et al.*, 1995). The ionic configuration of the U ion should be $5f^3$ since the formal charge on each of the cycloheptatrienyl rings is -3. However, theoretical calculations by Li and Bursten (1997) have shown that the U ion has a localized $5f^1$ configuration. Thus this molecule can be considered as the $5f^1$ analog of uranocene because the molecular orbitals of the C_7H_7 rings have the same group theoretical symmetries as the cyclooctatetraenyl rings of uranocene. The EPR spectrum of a frozen solution of this compound in methyl-tetrahydrofuran (THF) was measured below 15 K and the ENDOR spectrum was measured at selected fields at 4 K (Gourier *et al.*, 1998). From an analysis of the measured *g*-tensor they concluded that the strong participation of the $5f_\delta$ orbitals in bonding and spin–orbit effects were responsible for the f-orbital composition of the singly occupied molecular orbital. The proton ENDOR measurements allowed a lower limit of $\rho_\pi \geq 4 \times 10^{-2}$ to be set for the positive spin density on the $2p\pi$ carbon orbitals of the cycloheptatrienyl ligands in this compound.

Two bimetallic, pentavalent uranium derivatives $[(MeC_5H_4)_3U]_2[\mu\text{-}1,4\text{-}N_2C_6H_4]$ and $[(MeC_5H_4)_3U]_2[\mu\text{-}1,3\text{-}N_2C_6H_4]$ have been synthesized and magnetic measurements have been performed from room temperature to 5 K (Rosen *et al.*, 1990). In each of these dimers, the two U atoms are coupled to the imido N atoms on the substituted benzene rings. The U-dimer coupled by the $[\mu\text{-}1,4\text{-}N_2C_6H_4]$ moiety can form a conjugated ring while the other U-compound

Table 20.5 *Magnetic data for some U(v) compounds. The values given below are for the range of temperatures where the Curie–Weiss formula approximately holds. The references should be checked for details.*

[a] All magnetic data are given per U atom. To obtain the value per formula unit for dimeric compounds multiply by the sqrt(2).

cannot. From room temperature down to ~40 K the magnetic susceptibility measurements of these two compounds were similar. Below ~40 K an antiferromagnetic coupling was observed for the $[2\mu\text{-}1,4\text{-}N_2C_6H_4]$ coupled dimer but no such coupling was observed from the $[\mu\text{-}1,3\text{-}N_2C_6H_4]$ coupled dimer. A value of the exchange constant J, of ~–19 cm^{-1}, was obtained for the magnitude of the exchange interaction by a fit of the observed magnetism to that calculated for an isolated one-dimensional dimer as a model for the $[\mu\text{-}1,4\text{-}N_2C_6H_4]$ coupled dimer. Table 20.5 lists the magnetic properties of some U(v) imide compounds.

20.4 $5f^2\ ^3H_4$; U^{4+}, Np^{5+}, Pu^{6+}

U(IV) compounds have been widely studied. The total crystal-field splitting for the $^3H_4$ ground term of the $5f^2$ configuration is usually of the same order as or greater than 200 cm^{-1} (kT at room temperature). Thus only the ground crystal field state or perhaps the two or three lowest-lying states will provide first-order contributions to the observed magnetic susceptibility. Measurements over

as wide a temperature range as possible are clearly desirable. For most U^{4+} compounds, few optical data are available so magnetic data are usually interpreted by considering only the ground $^3H_4$ term, determining the crystal-field splittings for a particular point symmetry group (usually from crystallographic data), choosing a ground state either empirically or by calculation (e.g. point-charge or angular-overlap model), and then calculating the susceptibility. A $J = 4$ state in a point group symmetry lower than tetragonal will split into nine singlet states. In higher symmetries, there will be some singlet states and some doubly and/or triply degenerate states. If a singlet state lies lowest there will be a range of temperatures for which the compound will exhibit only TIP. Some examples from the voluminous literature follow.

One of the few cases for which anisotropic magnetic susceptibility measurements of a single crystal have been reported is UCl_4 (Gamp *et al.*, 1983). In this compound, the anisotropy of the susceptibility is very large ($\chi_\perp > \chi_\parallel$) which makes powder measurements difficult because the crystallites tend to reorient in a static homogeneous magnetic field with the axis of greatest susceptibility parallel to the field. This effect is stronger at low temperatures and depends on the magnitude of the applied field. Gamp *et al.* (1983) found it impossible to obtain reliable powder susceptibility data for UCl_4 at temperatures below 20 K, even with a field as small as 0.05 T. The powder reoriented slowly and the measured susceptibility data increased with time until it reached the value of $\chi_\perp$ measured in the single crystal. This is illustrated in Fig. 20.5. Using the available optical data, Gamp *et al.* (1983) obtained a reasonable fit between the calculated single crystal susceptibilities and the experimental values. The fit could easily have been improved with only minor changes in the crystal field parameter set or the introduction of orbital reduction factors.

The UCl_4 crystal field scheme was examined directly by neutron inelastic scattering by Delamoye *et al.* (1986). The first excited state ($\Gamma_4 \rightarrow \Gamma_5$) was found at 92(1) cm^{-1}, which is in disagreement with the 109 cm^{-1} deduced from susceptibility (Gamp *et al.*, 1983). The neutron study also observed the next higher level (Γ_5') at 1125(3) cm^{-1}. This last level is in good agreement with the predictions of the susceptibility. Here is an example where the susceptibility predicts a value of the crystal field energy splitting too large compared to that measured by neutrons. As in PuO_2 (see below), one could invoke the exchange interaction (Colarieti-Tosti *et al.*, 2002), but there appears a more direct explanation in terms of coupling between the magnetic and lattice modes (phonons). This is illustrated by the most unusual behavior of the temperature dependence of the $\Gamma_4 \rightarrow \Gamma_5$ excitation as shown in Fig. 20.6. From simple Boltzmann statistics, the peak should decrease by only 20% of its strength between 10 and 50 K. Instead it has lost 70% of its intensity, broadened considerably, and shifted to lower energy. At 160 K (where the peak should still be ~40% of its 10 K value), it has lost about 90% of its intensity and shifted to ~75 cm^{-1}, a decrease in frequency of almost 20%. The only explanation for these effects is that there is strong coupling to the lattice vibrations (phonons). It is not

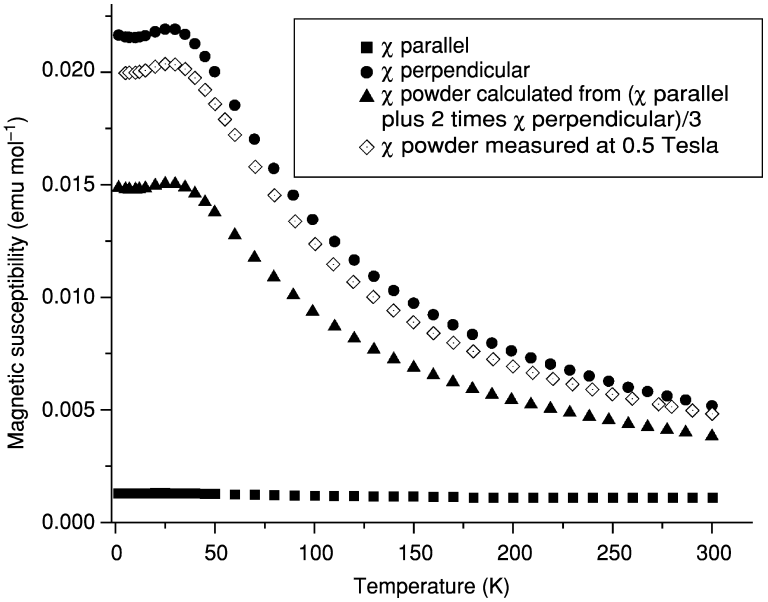

Fig. 20.5 *The values of $\chi_{\|}$ and $\chi_{\perp}$ obtained from measurements on a single crystal of UCl_4 and the calculated average magnetic susceptibility of polycrystalline UCl_4 derived from these measurements. The calculated average susceptibility is compared with susceptibility measurements on a polycrystalline sample of UCl_4 at* 0.5 T. *For the polycrystalline sample in a magnetic field, a strong force is applied along the strong magnetic axis of the crystallites and tends to reorient the crystallites. Thus the measured value of a powdered sample has a susceptibility greater than that calculated from the values of $\chi_{\|}$ and $\chi_{\perp}$ obtained from the single crystal measurements. See Gamp* et al. (1983) *for details.*

surprising, therefore, that simple predictions of the crystal-field splittings from the susceptibility should not agree with the neutron measurements, as interactions with the phonons are not considered. Efforts to include configuration interaction to explain the discrepancy between simple models and the experiments may also have to be taken into account (Zolnierek *et al.*, 1984), but before these large interactions with the lattice modes are understood, such an effort would appear premature.

Another interesting experiment was performed on UCl_4 to look for covalency effects between the U and Cl atoms (Lander *et al.*, 1985). In these experiments a single crystal is placed in a high magnetic field (4.6 T in this case) and then from the scattering of polarized neutrons the magnetization in the unit cell is deduced. If, for example, there would be strong mixing of the U 5f and Cl p-states then one might expect to observe a reduced spin density at the Cl site. Naively, it would be expected that covalency is small in compounds such as UCl_4, and such mixing of the 5f states unlikely. This indeed was the case, and no spin density was found at the Cl site. However, a small spin density midway between the

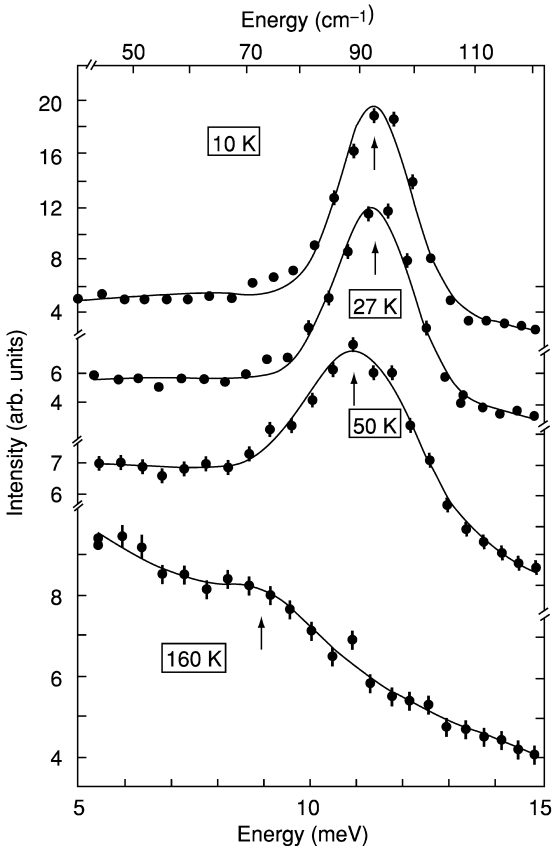

Fig. 20.6 *The temperature dependence of the intensities of the neutron inelastic scattering of the* $\Gamma_4 \rightarrow \Gamma_5$ *excitation in* UCl_4. *The shift in energy and the loss of intensity provide evidence for strong electronic–phonon coupling. Reprinted from Delamoye* et al. (1986). *Copyright* 1986 *with permission from Elsevier.*

U and Cl ions was modeled as an electron transfer from the 5f to the 6d antibonding orbital, and then a covalent bond formed between the U 6d and Cl p-states. Given the interesting possibilities for covalency in 5f compounds, it is perhaps surprising that experiments such as these have not been more common in the actinides. The difficulty is that single crystals are required (and they must be at least 10 mm^3) and their low-temperature properties must be well-known. For example, an experiment was reported on UCp_3Cl, where the covalency effects would be expected to be much larger than in the tetrachloride. Unfortunately, although good crystals were available, on cooling to low temperature many phase transitions occurred (Raison *et al.*, 1994a,b). Such complexities made it impossible to examine the spin densities and learn the details of the covalency. New efforts along these lines would seem worthwhile, especially

as neutron intensities have increased (which means that smaller crystals can be used), available magnetic fields have increased (now up to 10 T and in special cases to 15 T), and local-spin-density-approximation methods can be used to calculate the expected covalency effects.

Blaise *et al.* (1986) have measured the temperature-dependent magnetic susceptibility of a single crystal of tetrakis(1,1,1-trifluoro-4-phenylbutane-2,4-dionato) U(IV). The data were fit with a crystal field model based on distorted cubic symmetry. Optical and magnetic studies on $U(NCS)_8(NEt_4)_4$ ($Et = C_2H_5$) have been published by several groups (Folcher *et al.*, 1976; Soulie and Goodman, 1976, 1979; Carnall *et al.*, 1980; Kanellakopulos *et al.*, 1980c). In this compound the uranium ion is at a site of cubic symmetry (in cubic symmetry no magnetic anisotropy is possible) in the first coordination sphere surrounded by eight nitrogen atoms from the thiocyanate groups. By fitting the measured magnetic susceptibility in the temperature range 4.2–290 K, Soulie and Goodman (1976, 1979) evaluated the appropriate free-ion and crystal field parameters. They found good agreement above 30 K with the measured susceptibility but with significant deviations below this temperature. These deviations were attributed to a slight D_{4h} distortion of the cubic symmetry (confirmed by Raman spectra), which was not taken into account in their calculations. Subsequently Kanellakopulos and coworkers (Carnall *et al.*, 1980; Kanellakopulos *et al.*, 1980c) determined another set of empirical parameters using cubic crystal field parameters obtained from the assignment of the optical spectrum. They then took into account the lower symmetry by using perturbation theory to split the ground triplet state in cubic symmetry into a singlet state and a higher-lying doublet state. The use of this model and the introduction of an orbital reduction factor resulted in satisfactory agreement between the calculated and experimental susceptibility data.

The optical spectra of $U(BD_4)_4$ diluted in $Zr(BD_4)_4$ were measured by Bernstein and Keiderling (1973) and reinterpreted by Rajnak *et al.* (1984b). The U^{4+} ion in the $U(BD_4)_4$ molecule in this host crystal has tetrahedral symmetry (T_d) but the pure compound is polymeric with a lower site symmetry at the metal ion. Shinomoto *et al.* (1983) synthesized the $U(BH_3CH_3)_4$ compound which is monomeric and has the same (T_d) symmetry found for $U(BD_4)_4$ diluted in $Zr(BD_4)_4$. The magnetic susceptibility of $U(BH_3CH_3)_4$ has been measured from 2 to 330 K. Using the eigenvectors obtained from the reanalysis of the Keiderling data, the magnetic data could be fit. However in order to get the best fit, Rajnak *et al.* (1984b) empirically adjusted the energy splitting between the ground E-state and the first excited T_1 state (T_d) and included an orbital reduction factor of $k = 0.85$. In addition to the magnetic susceptibility, the temperature dependence of the solution shifts of the ^1H, ^{11}B, and ^{13}C NMR have been obtained for the $M(BH_3CH_3)_4$ (M = Pa, Th, U, Np) (Gamp *et al.*, 1987; Kot and Edelstein, 1995). Because of the high symmetry at the paramagnetic actinide metal ion, there is no contribution due to the metal ion dipolar term. Thus the measured NMR shifts should arise from the unpaired spin

density transferred from the metal ion to the ligand orbitals. The traditional equation used to determine the unpaired spin density is:

$$\frac{\Delta H}{H_0} = \frac{\beta}{3kT}\langle S_z\rangle \frac{A}{\gamma(h/2\pi)} \tag{20.15}$$

where $\Delta H/H_0$ is the NMR shift, β is the Bohr magneton, k is the Boltzmann constant, A is the hyperfine constant in energy units, γ is the nuclear gyromagnetic ratio, and h is Planck's constant. $\langle S_z\rangle$ is the thermal average of the spin operator and can be calculated from the eigenvectors obtained from the optical analyses. The usual assumptions made in these types of analyses is that the above equation is valid for all crystal field states using the same value of A, and that each of the f-orbitals is equally effective in transferring spin into ligand orbitals. Difficulties were encountered in analyzing the NMR shifts in the actinide methylborohydrides. McGarvey (1998) has shown that the data can be explained if it is assumed that each of the f-orbitals contributes a different amount of spin into the ligand orbitals.

The temperature dependence of the magnetic susceptibility of three U^{4+} sulfates, $U(SO_4)_2 \cdot 4H_2O$, $U_6O_4(OH)_4(SO_4)_6$, and $U(OH)_2SO_4$, in the temperature range 4.2–300 K has been reported by Mulak (1978). These three compounds have a similar antiprismatic coordination about the U^{4+} ion by oxygen anions with almost the same U–O distances. Using a simplified model of the U^{4+} ion with a $^3H_4$ ground term, $J = 4$ as a good quantum number in a D_{4d} crystal field, and only the energy splittings between the two lowest crystal field states as empirical parameters, the temperature dependence of the magnetic susceptibility was fitted. A further low-symmetry distortion has to be introduced (which split the energy levels that were doubly degenerate in D_{4d} symmetry) in order to obtain satisfactory agreement. Despite the very similar coordination environment about the U^{4+} ion in the three compounds, there are significant differences in the low-temperature magnetic behavior. In particular, the magnetic susceptibility for $U(OH)_2SO_4$ from 4.2 to 21 K is approximately constant while above 21 K the susceptibility decreases with a temperature dependence typical of a paramagnetic compound with a degenerate ground state. This low-temperature behavior was attributed to a crystallographic transition induced by the cooperative Jahn–Teller effect. Hinatsu *et al.* (1981) reported the temperature dependence from 1.8 to 300 K of a crystalline uranium(IV) sulfate that showed a broad maximum in the susceptibility at 21.5 K. They assumed a one-dimensional chain structure with U atoms linked by hydroxyl groups (or possibly oxygen atoms) and fitted their data to an exchange interaction between uranium atoms along this one-dimensional chain.

The synthesis of the organometallic 'sandwich' compound uranocene, $U(C_8H_8)_2$, by Müller-Westerhoff and Streitwieser (1968) led to a renaissance in the organometallic chemistry of the actinide series (Seyferth, 2004). Magnetic susceptibility measurements have played an important role in the discussions

of the electronic structure of these types of compounds. Karraker *et al.* (1970) initially reported the temperature-dependent susceptibility of $U(C_8H_8)_2$ and interpreted the data on the basis of a crystal field of C_{8h} symmetry acting on the $^3H_4$ ground term. The data were fitted with a $J_z = \pm 4$ ground state and the inclusion of an orbital reduction factor to account for covalency. This model also fitted the experimental results for $Np(C_8H_8)_2$ and $Pu(C_8H_8)_2$. Hayes and Edelstein (1972) then proceeded to calculate the necessary crystal field parameters using molecular orbital theory and the Wolfsberg–Helmholz approximation. From the calculated crystal field parameters and published free-ion parameters they found the ground crystal field state to be the $J_z = \pm 3$ level. More careful measurements by Karraker (1973) have shown that the susceptibility of $U(C_8H_8)_2$ at low temperature became temperature independent and was attributed by Hayes and Edelstein as being due to a possible low-temperature crystal structure phase transition causing the U^{4+} ion to be at a symmetry site lower than C_{8h}. This model was disputed by Amberger *et al.* (1975). They recalculated the crystal field parameters for uranocene in three ways: using the purely electrostatic approach, the angular overlap model, and a molecular orbital model. Assuming rigorous D_{8h} symmetry, they found that a crystal-field splitting with a singlet ground state ($J_z = 0$) and an excited doublet state at 17 cm^{-1} ($J_z = \pm 1$) gave the best agreement with their molecular orbital calculation and the experimental data. Subsequently, Edelstein *et al.* (1976) showed that some uranocene-type molecules with alkyl or phenyl groups attached to the cyclooctatetraene rings showed the temperature-dependent behavior expected for a degenerate ground state down to 4.2 K. This behavior is inconsistent with the Amberger *et al.* model. Warren (1977) has discussed the magnetic properties of uranocene-type compounds in his extensive review on ligand field theory of f-orbital sandwich complexes. Later experimental and theoretical papers have utilized the magnetic data as tests of the validity of their data and/or calculations (Dallinger *et al.*, 1978; Boerrigter *et al.*, 1988; Chang and Pitzer, 1989).

Another class of organometallic U(IV) compounds that have been thoroughly studied is tetrakis(cyclopentadienyl)uranium(IV), UCp_4, and its tris(cyclopentadienyl) derivatives, Cp_3UR, where R = BH_4, BF_4, OR, F, Cl, Br, I, etc (Kanellakopulos, 1979). These compounds have been divided into two categories: those showing a small dipole moment and a small range of temperature-independent susceptibilities; and a second category exhibiting larger dipole moments and a more extended range of temperature-independent susceptibilities. These differences have been attributed to an increasing trigonal distortion in the second category of compounds. Amberger *et al.* (1976) have used three different semiempirical calculations to estimate the two crystal field parameters needed for the assumed T_d symmetry of UCp_4. The temperature-dependent magnetic susceptibility of UCp_4 was then fitted assuming a weak crystal field of lower symmetry that split the tetrahedral energy levels. The tetrahedral wave functions were used for the calculations and the energy differences of four levels

plus one scaling parameter were varied. Satisfactory agreement with the experimental data was obtained. Amberger (1976a,b) also analyzed optical spectra of UCp_4 and Cp_3UCl assuming T_d symmetry. He further analyzed the fine structure of the spectrum and determined the crystal-field splitting of the ground $^3H_4$ term. Using tetrahedral wave functions and the crystal-field splitting of the ground term he was able to satisfactorily fit the observed susceptibility using only one scaling parameter. Magnetic data for a number of Cp_3UR compounds have been given by Aderhold *et al.* (1978).

A number of other structurally characterized U(IV) compounds were synthesized and magnetic measurements are reported. Some results are listed in Table 20.6. Most of these compounds are monomeric, but a number of dimers and even some higher oligomers have been found. Compounds with amido, amidoamine, alkoxide, and other ligands were characterized and are given in Table 20.6.

In general for U(IV) compounds Curie–Weiss behavior is found at higher temperatures with the susceptibility tending toward temperature-independent behavior at the lowest temperatures. The U^{4+} ion is a non-Kramers' ion with two 5f electrons and will usually have an orbital singlet ground state at low temperatures (this depends on the point symmetry at the U^{4+} ion and will generally be true for lower-symmetry groups) which is the reason for the temperature-independent behavior. For dimeric U^{4+} compounds and higher oligomers, if the U–U distances are short (less than 3.6 Å) or if the bridging ligand(s) facilitate electron exchange, deviations from this type of behavior suggest magnetic interactions between the two U centers.

Le Borgne *et al.* (2002) reported the syntheses, crystal structures, and magnetic properties of heteronuclear trimetallic compounds of the type $[\{ML(py)\}_2U]$ (M = Co, Ni, Zn) and $[\{CuL(py)\}M'\{CuL\}]$ (M′ = U, Th, Zr) where L = *N*,*N*′-bis(3-hydroxysalicylidene)-2,2-dimethyl-1,3-propanediamine and py is pyridine. The crystal structures show that the two ML fragments are orthogonal and linked to the central U ion by two pairs of oxygen atoms from each of the Schiff base ligands. In each of the compounds the three metal ions are linear and the eight oxygen atoms exhibit similar dodecahedral geometry around the U ion. The magnetic susceptibilities of the Co_2U, Ni_2U, and Cu_2U compounds were measured and compared with that of the appropriate Zn_2U derivative, where the paramagnetic 3d ion was replaced by the diamagnetic Zn^{2+} ion. By subtracting the magnetic data of the U–3d diamagnetic ion complexes from similar data for the U–paramagnetic 3d ion complexes (in the temperature range from 300 to 2 K), a weak antiferromagnetic coupling was observed between the Ni^{2+} and the U^{4+} ions, and a ferromagnetic interaction was found between the Cu^{2+} and U^{4+} ions. In a later paper (Salmon *et al.*, 2003), this same group synthesized and magnetically and structurally characterized $[ML^2(py)U(acac)_2]$ and $[(ML^2)_2U]$, where M = Cu and Zn and L^2 = *N*, *N*′-bis(3-hydroxysalicylidene)-2-dimethyl-1,3-propanediamine, and acac is acetylacetonate ($C_5H_7O_2$). Again the Cu, U compounds and the Cu, Zn analogs

Table 20.6 *Magnetic data for some U(IV) and neptunyl(V) compounds. The values given below are for the range of temperatures where the Curie–Weiss formula approximately holds. At lower temperatures more complex magnetic behavior is observed. The references should be checked for details.*

* All magnetic data are given per U atom. To obtain the value per formula unit for dimeric compounds multiply by the sqrt(2).

[a] Spirlet *et al.* (1996). $Cp = C_5H_5$.

were shown to be very similar structurally so that the magnetism of the appropriate Zn, U compound could be subtracted from the magnetism of the Cu, U compound to obtain the influence of the Cu^{2+} ion on the exchange interactions between the Cu and U ions. For the dimeric compound the difference in χT vs T was approximately constant from 300 to 100 K with a value of 040 ± 0.05 cm^3 mol^{-1} K, similar to that of an isolated Cu^{2+} ion. Below 100 K the difference in magnetic behavior is indicative of antiferromagnetic exchange between the U^{4+} – Cu^{2+} ions. Similar experiments were performed with the trimetallic $[(ML^2)_2U]$ complexes and it was found that the low-temperature magnetic behavior of the $[(CuL^2)_2U]$ compound was also antiferromagnetic. The low-temperature magnetism in the latter compound is different from ferromagnetic interaction found in the somewhat structurally similar [{CuL(py)}U{CuL}] described earlier.

A similar type of experiment has been reported for an oxalate-bridged U(IV)–Mn(II) compound, $K_2MnU(C_2O_4)_4 \cdot 9H_2O$ (Mortl *et al.*, 2000). In this compound the U(IV) ion is linked to four Mn(II) ions by each of the oxalate ligands and each of the Mn(II) ions are also linked by the oxalate ligands to four U(IV) ions. The magnetic susceptibility of this compound has been measured from 2 to 300 K. For this compound, the experimental magnetic measurements have been interpreted as the sum of the individual U(IV) and Mn(II) contributions. No indication of magnetic coupling has been found between the U(IV) ion and the Mn(II) ion down to 2 K.

A number of complex U^{4+} fluoride compounds have been synthesized and structurally characterized. As part of the determination of their physical properties, the temperature-dependent magnetic susceptibilities have been measured and analyzed (over the appropriate temperature range using the Curie–Weiss equation). Table 20.6 lists magnetic data for some structurally diverse U(IV) complex fluoride compounds.

There have been a few measurements performed on NpO_2^+ compounds. The compounds that are formulated as having dimeric neptunyl $(NpO_2^+)_2$ units exhibit complex magnetic behavior at low temperatures. Metamagnetism, that is the field-induced transformation of a compound from an antiferromagnetic state to a ferromagnetic state, was originally reported by Jones and Stone (1972) for the neptunyl(v) oxalate complex, $(NpO_2)_2C_2O_4 \cdot 4H_2O$. This compound exhibited Curie–Weiss behavior above 15 K (see Table 20.6). The susceptibility displayed a peak characteristic of an antiferromagnetic transition with $T_N = 11.6 \pm 0.1$ K. However the susceptibility maximum shifted to lower temperatures as the external magnetic field was increased, and above 0.075 T the susceptibility peak disappeared and ferromagnetic saturation was observed. From these observations, it was concluded that this compound was metamagnetic. Recent magnetic studies have been reported for neptunyl(v) formate and phthalate compounds $[NpO_2(O_2CH)(H_2O)]$ and $(NpO_2)_2(O_2C)_2C_6H_4 \cdot 6H_2O$ (Nakamoto *et al.*, 1999, 2001). The formate complex, which forms infinite two-dimensional sheets linked by NpO_2^+ bonding, follows the Curie–Weiss law from 50 K to room temperature (see Table 20.6). Below 50 K, this neptunyl compound exhibits complex magnetic behavior that is attributed to ferromagnetic ordering with $T_c = 12$ K. The authors note the situation in the neptunyl(v) formate complex is similar to that found earlier in the neptunyl(v) oxalate complex and attributed in the earlier work to metamagnetism. The neptunyl phthalate magnetic data can be fit in two regions with the Curie–Weiss law as shown in Table 20.6. Below 4.5 K, complex magnetic ordering is found that is attributed to the existence of two kinds of Np sublattices, one is ferromagnetic and the other is antiferromagnetic.

20.5 $5f^3\ ^4I_{9/2}$; U^{3+}, Np^{4+}, Pu^{5+}

UH_3 has a ferromagnetic transition at approximately 172 K and a saturation magnetic moment in the temperature range 63–196 K of approximately $1\mu_B$ (Gruen, 1955). The magnetic susceptibilities of the uranium(III) halides are listed in Table 20.7 (Berger and Sienko, 1967; Jones *et al.*, 1974). UF_3 followed the Curie–Weiss law down to about 125 K, below which temperature the susceptibility increased more rapidly than expected from the higher-temperature data (Berger and Sienko, 1967). Jones *et al.* (1974) reported the magnetic susceptibilities of U trihalides (Cl, Br, and I). For the most part, the properties could be understood on the basis of crystal field calculations. Of special interest was the report of antiferromagnetic magnetic ordering (as judged by a maximum in the susceptibility) at 22.0, 15.0, and 3.4 K in the U-trihalides Cl, Br, and I. Extensive neutron studies have also been performed on these compounds (Murasik and Furrer, 1980; Murasik *et al.*, 1981, 1985, 1986; Schmid *et al.*, 1990). Neutron diffraction confirmed the hexagonal crystal structure for UCl_3 and UBr_3, but then surprisingly found that the assumed T_N values of Jones *et al.* were not

[e] Low-temperature phase is ferromagnetic.

correct. The actual ordering temperatures in UCl_3 and UBr_3 are 6.5 and 5.4 K, respectively. The ordered moments are $\sim 2\mu_B$ for both systems. However, at lower temperatures there is a second transition (3.8 K for UCl_3 and 3.0 K for UBr_3) to a more complex magnetic structure. On cooling, the moments are initially parallel to the crystallographic *c*-axis, but then rotate to perpendicular to *c*-axis at low temperature, and with a magnetic moment of only about $0.8\mu_B$. These lower-temperature transitions were not apparently observed by Jones *et al.* (1974). The neutron work also determined the crystal field transitions that range from about 20 to 400 cm^{-1}. From the crystal field level scheme they showed that many of the properties could be understood on the basis of the extreme magnetic anisotropy. There is antiferromagnetic exchange *only* along the chains of U atoms along the *c*-axis. The peak in the susceptibility in this case is actually *not* an indication of the antiferromagnetic order, but rather the competition between the exchange and anisotropic contributions to the susceptibility. All these measurements, both the original magnetic and more recent neutron studies, were performed on polycrystalline samples, which makes the amount of information extracted in the neutron study quite remarkable.

Furthermore, a relatively sharp mode was observed at 32 cm^{-1} in both UCl_3 and UBr_3 at low temperature and was assigned to one-dimensional spin–wave excitations along the *c*-axis.

These studies would be most interesting to continue with single crystals. The whole question of one-dimensional magnetism is now much in fashion; the exchange interactions in actinides are usually stronger than in the lanthanides, thus making the examples more interesting. It is furthermore a salutary lesson in making a simple interpretation of the susceptibility curves.

EPR measurements have been reported for surprisingly few U^{3+} compounds and the data up to 1977 were discussed by Boatner and Abraham (1978). Crosswhite *et al.* (1980), from their analysis of the optical spectrum of U^{3+} diluted in $LaCl_3$, have calculated $g_{\|} = -4.17$, which agrees well with the magnetic resonance value of $|g_{\|}| = 4.153$ (Hutchison *et al.*, 1956). Magnetic susceptibility data for Cs_2NaUCl_6 (Hendricks *et al.*, 1974) (Table 20.2) as a function of temperature have been given. A recent optical study of U^{3+} diluted in Cs_2NaYCl_6 has given the energy levels for this system and shown that a Γ_8 (O_h) state is lowest in energy (Karbowiak *et al.*, 1998) consistent with the magnetic data.

The temperature-dependent magnetic susceptibility of a number of substituted tris-cyclopentadienyl U and Nd compounds and their Lewis base adducts has been measured and are listed in Table 20.8. The EPR spectra of these compounds also have been measured as powders or frozen glasses and compared with the corresponding Nd^{3+} compounds ($4f^3$ configuration) (Lukens, 1995).

[a] All magnetic data are given per U atom. To obtain the value per formula unit for dimeric compounds multiply by the sqrt(2).

Magnetic susceptibility results for some other U(III) compounds are given in Table 20.9.

Two interesting dimeric molecules were reported by Korobkov *et al.* (2001). One of these two dimeric molecules, $[Li(THF)_4]_2\{U_2[(-CH_2-)_5]_4$-calix[4]tetrapyrrole$\}[\mu\text{-}I]_4$ had two U(III) ions held together by the $[(-CH_2-)_5]_4$-calix[4]tetrapyrrole ligand with a short U–U distance of 3.4560(8) Å. The second compound $[Li(THF)_2]_2(\mu\text{-}Cl)_2\{U_2[(\text{-}CH_2\text{-})_5]_4$-calix[4]tetrapyrrole$\}Cl_2 \cdot THF$, formally a mixed valence U(III)–U(IV) dimer with a similar geometry as the first dimer, also had a short U–U distance of 3.365(6) Å. The magnetic moment of the U(III)–U(III) dimer was $1.99\mu_B$ (per U) at 300 K falling to $0.55\mu_B$ (per U) at 2 K. For the U(III)–U(IV) dimer the magnetic moment at 300 K was $3.04\mu_B$ (per mole) and $1.03\mu_B$ (per mole) at 2 K. The authors suggest that the low moment for the U(III)–U(III) dimer could be due to antiferromagnetic behavior at low temperatures while the U(III)–U(IV) dimer could be explained by the sum of the magnetic moments of two isolated U(III) and U(IV) compounds (no magnetic exchange). Clearly much further work has to be done to determine whether magnetic exchange takes place in these dimers.

$NpCl_4$ (Table 20.7) was reported to have a ferromagnetic transition at 6.7 K (Stone and Jones, 1971). Kanellakopulos *et al.* (1980c) reported the temperature dependence of the magnetic susceptibility data for $NpCl_4$ and $((C_2H_5)_2N)_4Np(NCS)_8$ and presented an analysis of these data. This group (Stollenwerk *et al.*, 1979; Dornberger *et al.*, 1980; Stollenwerk, 1980) also measured and discussed

the optical spectra and magnetic susceptibilities of Cp_4Np ($Cp = C_5H_5$) and Cp_3NpX where X = Cl, Br, and I. Low-temperature magnetic susceptibility data for $NpBr_4$ are given in Table 20.7.

From magnetic susceptibility measurements (Karraker and Stone, 1980) and EPR measurements (Bernstein and Dennis, 1979; Edelstein *et al.*, 1980) of hexachloro complexes of Np^{4+}, the ground state of the $^4I_{9/2}$ term was shown to be Γ_8 (O_h). Limits on the ratios of the fourth- to the sixth-order crystal field parameters have been determined, and these limits are consistent in the isostructural series MCl_6^{2-}, $M = Pa^{4+}, U^{4+}, Np^{4+}$. Depending on the cation involved, the Γ_8 state may be split by 5–10 cm^{-1} due to small deviations from O_h symmetry. The free-ion *g*-value ($\sim$0.6) for Np^{4+} deduced from the data are much reduced from the value of 0.77 obtained from optical data. Warren (1983) has suggested that the rather large value of the orbital reduction factor needed to fit the EPR data could be due to the occurrence of the Ham effect (which would change the value of the ratios of the crystal field parameters needed to fit the data). However EPR data obtained at liquid-helium temperatures for Np $(BH_4)_4$ and $Np(BD_4)_4$ diluted in the corresponding $Zr(BH_4)_4$ and $Zr(BD_4)_4$ hosts show that the doublet Γ_6 state (T_d) of the $^4I_{9/2}$ term is lowest (Rajnak *et al.*, 1984a). Again the free-ion *g*-value (0.515) is much lower than expected. Richardson and Gruber (1972) claimed that they observed the EPR spectrum of Np^{4+} diluted in ThO_2. EPR and optical spectra of Np^{4+} diluted in $ZrSiO_4$ at 4.2 K were obtained by Poirot *et al.* (1988) with measured ground Γ_6 state (D_{2d} symmetry) *g*-values of $|g_{\|}| = 0.8$ (6) and $|g_{\perp}| = 2.59$ (2), consistent with the optical analysis.

$SrNpO_3$ and $BaNpO_3$ show magnetic transitions at 31 and 48 K, respectively (Kanellakopulos *et al.*, 1980b; Bickel and Kanellakopulos, 1993). A sharp increase in magnetization was observed below the transition temperature, which suggests a complicated magnetic structure.

20.6 $5f^4\ ^5I_4$; Np^{3+}, Pu^{4+}

The magnetic susceptibility and magnetization of NpH_x ($x = 2.04$, 2.67, and 3) have been measured in the temperature range 4–700 K (Aldred *et al.*, 1979). The dihydride data could be fitted with a crystal field model based on cubic symmetry (O_h) for the Np^{3+}, $5f^4$ configuration, with a nominal $^5I_4$ ground state split into a ground Γ_3 doublet and a Γ_4 and a Γ_5 triplet at 512 and 549 cm^{-1}, respectively. The Γ_1 singlet is calculated to be at 1851 cm^{-1} above the Γ_5 state. Magnetic data for $Cs_2NaNpCl_6$ (Hendricks *et al.*, 1974) are shown in Table 20.2 and were assigned as due to the magnetic properties of the Γ_5 (O_h) ground state. The magnetic properties of NpX_3 (X = Cl, Br, and I) are given in Table 20.7 (Jones *et al.*, 1974).

Magnetic susceptibilities from 2.5 to 50 K for Pu^{4+} in three hexachloro complexes were reported by Karraker (1971). Surprisingly, one of the compounds,

Cs_2PuCl_6, had a temperature-dependent paramagnetism at low temperatures, which means a non-Kramers doublet is the lowest state. The other two $PuCl_6^{2-}$ complexes had temperature-independent susceptibilities at the lowest temperatures, which arises from a singlet state being the ground state. These data have been interpreted on the basis of a model based on the distorted O_h symmetry of the $PuCl_6^{2-}$ octahedron.

Magnetic susceptibility measurements have been reported for $Pu(C_8H_8)_2$ and $Pu(C_8H_7R)_2$, where R is an alkyl group (Karraker *et al.*, 1970; Karraker, 1973). These compounds were reported to be diamagnetic. However, the susceptibility is expected to exhibit TIP for the $^5I_4$ state in C_{8h} symmetry if the $J_z = 0$ state is lowest.

20.7 $5f^5\ ^6H_{5/2}$; Pu^{3+}, Am^{4+}

The magnetic properties of PuH_x ($2.0 \leq x \leq 3$) have been measured between 4 and 700 K (Aldred *et al.*, 1979). The cubic PuH_2 appears to order antiferromagnetically at 30 K. Cubic Pu compounds with higher hydrogen concentrations order ferromagnetically with higher transition temperatures as x increases. A maximum is reached at $T = 66$ K and $x = 2.7$. Hexagonal PuH_3 becomes ferromagnetic at 101 K. The temperature dependence of the magnetic susceptibility indicates that the ground state configuration is Pu^{3+}, $5f^5$. The magnetic properties of PuX_3 (X = Cl, Br, and I) (Jones *et al.*, 1974) are given in Table 20.7. $PuCl_3$ shows an antiferromagnetic transition at 4.5 K while PuI_3 has a ferromagnetic transition at 4.75 K. For $PuCl_3$, magnetic susceptibility calculations using wave functions obtained from optical data on Pu^{3+} diluted in $LaCl_3$ reproduce the observed susceptibility. Magnetic data for the octahedral complex $Cs_2NaPuCl_6$ (Hendricks *et al.*, 1974) are given in Table 20.2.

EPR measurements of $|g_{\|}| = 0.585$ (2) and $|g_{\perp}| = 0.875$ (1) were reported for $^{239}Pu^{3+}$ diluted in $LaCl_3$ at 4.2 K by Lämmermann and Stapleton (1961). These values agreed well with the results obtained from a subsequent optical analysis of this system (Lämmermann and Conway, 1963). Kot *et al.* (1993b) measured the EPR spectra of Pu^{3+} in $LuPO_4$ at 4.2 K and found $|g_{\|}| = 0.772(2)$ and $|g_{\perp}| = 0.658(2)$. Pu_2O_3 becomes antiferromagnetic at $T_N = 19$ K, as judged by the specific heat (Flotow and Tetenbaum, 1981). Magnetic susceptibility and neutron diffraction measurements ($T = 4$–300 K) also indicate that hexagonal β-Pu_2O_3 becomes antiferromagnetic at $T \sim 19$ K (McCart *et al.*, 1981) with a second transition at 4 K. Neutron diffraction was not initially able to determine the magnetic configurations, but in subsequent neutron work by Wulff and Lander (1988) the configuration with a moment of $0.60\mu_B$/Pu and the moments aligned parallel to the unique c-axis of the hexagonal structure were determined. The ground state moment is consistent with that from the Kramers doublet $|J = 5/2, J_z = \pm 3/2\rangle$ and the valence state is (as expected) trivalent Pu.

Table 20.10 *Measured g-values for $5f^5$ ions at cubic sites in crystals with the fluorite structure. For each type of host or ion, the matrices are listed in order of increasing lattice constant, or decreasing CF. Data taken at ~5 K (Kolbe* et al., 1974).

Matrix	*Ion*	$\|g\|$
CeO_2	Pu^{3+}	1.333 (1)
ThO_2	Pu^{3+}	1.3124 (5)
CaF_2	Pu^{3+}	1.297 (2)
SrF_2	Pu^{3+}	1.250 (2)
BaF_2	Pu^{3+}	1.187 (4)
$SrCl_2$	Pu^{3+}	1.1208 (5)
CeO_2	Am^{4+}	1.3120 (5)
ThO_2	Am^{4+}	1.2862 (5)

EPR measurements on Pu^{3+} and Am^{4+} at liquid-helium temperatures in various cubic hosts have been summarized by Boatner and Abraham (1978). For both Pu^{3+} and Am^{4+} with a nominally $^6H_{5/2}$ ground state, strong intermediate-coupling effects cause the Γ_7 state (O_h) to be the ground crystal field state, rather than the Γ_7 (O_h) state as expected for pure Russell–Saunders coupling (Edelstein *et al.*, 1969). Crystal field mixing between the ground state and the excited *J*-states makes the measured *g*-value a very sensitive indicator of the magnitude of the crystal field (Lam and Chan, 1974). Table 20.10 illustrates the effect of the decreasing crystal field strength on the measured ground state *g*-values. For each type of crystal or ion, the crystal field decreases (the lattice constant of the host matrix increases) as one scans down Table 20.10, and the magnitude of *g* decreases also. In the limit of zero crystal field mixing of excited multiplets, the ground state *g*-value should be $|g| = 0.700$. ENDOR measurements on Pu^{3+} in CaF_2 have shown the interaction with the nearest neighbor fluorine ions is much stronger than found for the 4f series (Kolbe and Edelstein, 1971). The magnetic data for Am^{4+} given above have been utilized in conjunction with optical data for Am^{3+} in ThO_2 to estimate the crystal field parameters for AnO_2 series (Hubert *et al.*, 1993).

The magnetic susceptibility of the high-T_c superconductor-related compound $Pb_2Sr_2AmCu_3O_8$ has been measured from ~4 to 300 K. The data can be fit with an effective moment for the Am^{4+} ion of $0.94\mu_B$ after subtracting off the contribution from the Cu sublattice. This compound shows no superconductivity (Soderholm *et al.*, 1996).

20.8 $5f^6\ ^7F_0$; Am^{3+}, Cm^{4+}

A $^7F_0$ ground term has a singlet ground state that is expected to show TIP. The magnitude of the TIP depends on the energy differences to the excited states. Measurements on some Am^{3+} and Cm^{4+} compounds sometimes show a

Table 20.11 *Magnetic susceptibility of Am metal, and some Am^{3+} and Cm^{4+} compounds. If more than one set of data are given, the results are from different samples.*

temperature dependence that is not understood. In order to analyze these data, a modified Curie law has been utilized and is given in equation (20.8).

The few available data for these ions are given in Table 20.11. Karraker *et al.* measured the magnetic susceptibility of $Cs_2NaAmCl_6$ (Hendricks *et al.*, 1974) and found the susceptibility was temperature independent, as expected for a $J = 0$ ground state, but the magnitude found was much larger than that calculated considering only the second-order Zeeman effect to the optically determined $J = 1$ state at 2720 cm^{-1}. Subsequent measurements on $Cs_2NaAmCl_6$ and Am_2O_3 agreed much better with the calculated value (Soderholm *et al.*, 1986). Am metal was found to exhibit TIP, suggesting a localized $5f^6$ configuration plus conduction electrons (Cunningham, 1962; Nellis and Brodsky, 1974; Kanellakopulos *et al.*, 1975). The susceptibility of $^{248}CmO_2$ should also be temperature-independent but exhibits Curie–Weiss behavior (Nave *et al.*, 1983; Morss *et al.*, 1989). Nave *et al.* (1983) also have measured two other $^{248}Cm^{4+}$ compounds and have found complex magnetic behavior that they have analyzed using equation (20.8). Their measurements were performed on samples of mass ~50–1000 μg and it should be noted that measurements of different samples of nominally the same material were not very reproducible. A recent

calculation of the Cm magnetic moment in CmO_2 gave $3.39\mu_B$/atom. The authors suggested that an itinerant magnetism model based on delocalized electrons might be more appropriate for this system rather than the usual crystal field theory (Milman *et al.*, 2003). See Section 20.14.5 for a more detailed discussion of CmO_2.

20.9 $5f^7\ ^8S_{7/2}$; Am^{2+}, Cm^{3+}, Bk^{4+}

In the limit of pure Russell–Saunders coupling an f^7-configuration has an $^8S_{7/2}$ ground term. A crystal field interaction will not split the orbitally non-degenerate S state. For the $4f^7$ ion, Gd^{3+}, it is indeed found that crystal-field splittings of the ground $J = 7/2$ term are of the order of about 0.2 cm^{-1}. However, the ground term for Cm^{3+} is only 87% $^8S_{7/2}$ because spin–orbit coupling mixes in substantial amounts of the $^6P_{7/2}$, $^6D_{7/2}$, and higher terms that result in crystal-field splittings of about 5–100 cm^{-1}. Early EPR studies have been reviewed by Boatner and Abraham (1978). The first authentic identification of the EPR spectra of the Cm^{3+} ion was by Abraham *et al.* (1963) in single crystals of lanthanum ethylsulfate and lanthanum trichloride. The strongest observed EPR resonance for Cm^{3+} in $LaCl_3$ was assigned as the ground state with $J_z = \pm 1/2$. Later calculations based on optical data conflicted with this assignment (Carnall, 1992). High-resolution laser spectroscopy measurements (Liu *et al.*, 1993) have shown the total ground term $J = 7/2$ splitting is $\sim$2 cm^{-1} and that the $J_z = \pm 1/2$ level is not the ground state but the first excited state, in agreement with the Carnall's assignments. Am^{2+} ions have approximately the same magnetic properties as Cm^{3+}, and it was this fact that was used for the first identification of Am^{2+} as a chemically stable oxidation state (Edelstein *et al.*, 1966). A considerable amount of EPR studies have been performed on the Cm^{3+} and Am^{2+} ions at cubic symmetry sites in single crystals with the fluorite structure MX_2 (M = Ca, Sr, Ba; X = F), $SrCl_2$, ThO_2, and CeO_2. For a $5f^7$ ion in this symmetry, the ground state is an isotropic Γ_6 state and the first excited state is a Γ_8 state. If the splitting between these two states is of the order of magnitude of the magnetic splittings, these states can be mixed by the magnetic field in the EPR experiment and will result in the ground Γ_6 state showing anisotropy as the crystal orientation is changed with respect to the magnetic field. From the magnitude of the anisotropy, the Γ_6–Γ_8 splitting can be deduced. Later optical measurements on Cm^{3+} in ThO_2 confirmed the Γ_6–Γ_8 splitting of 15.5 (3) cm^{-1} found for this system (Thouvenot *et al.*, 1994). The measured ground state *g*-values and splittings are shown in Table 20.12. Detailed EPR measurements have been reported for Cm^{3+} in YPO_4 and $LuPO_4$ (Abraham *et al.*, 1987; Kot *et al.*, 1993a). Interestingly, for the Cm^{3+} diluted into $LuPO_4$ system, EPR measurements at $\sim$300 K were observed for the Cm^{3+} ion. Subsequent high-resolution optical measurements showed the zero-field splittings deduced from the EPR spectra were not accurately determined

Table 20.12 *EPR g-values and zero-field splittings for Cm^{3+} and Am^{2+} ions in cubic sites in fluorite-type crystals. Under O_h symmetry, a $J = 7/2$ state will split into a ground Γ_6 state, a Γ_8 state, and the highest energy Γ_7 state.*

(Murdoch *et al.*, 1996). In the Cm^{3+}:$LuPO_4$ system, the energy levels occur in pairs with two lowest levels separated by 3.49 cm^{-1} and the two highest levels separated by 1.39 cm^{-1}. The splitting between these pairs of levels is 4.64 cm^{-1}. This splitting was not determined accurately in the EPR measurements because the data were not sensitive to small perturbations of the first-order Zeeman splitting of each of the Kramers' doublets that occurs between Kramers' doublets separated by such a large energy gap.

There has been one early study of the magnetic properties of AmI_2, a divalent Am compound. The results are given in Table 20.13 along with values for Cm metal and some trivalent Cm compounds.

As discussed earlier, Cm^{3+} compounds are expected to have ground term crystal-field splittings of less than 50 cm^{-1}. Thus at temperatures where all the ground term levels are populated, μ_{eff} should equal the free-ion value of $7.64\mu_B$. Early work on the preparation of Cm compounds and the metal were performed with ^{244}Cm, $\tau_{1/2} = 18.1$ years. Later studies have been conducted with ^{248}Cm, $\tau_{1/2} = 340000$ years. Studies with ^{248}Cm should, in principle, be more reliable as problems from radiation damage and the growth of daughter isotopes are minimized. Magnetic susceptibility measurements of Cm^{3+} diluted in $Cs_2NaLuCl_6$ (Table 20.2) suggested a crystal-field splitting of 5–10 cm^{-1}. Recent optical studies on the related system, Cm^{3+} diluted in Cs_2NaYCl_6, have

[k] Soderholm *et al.* (1989) and Soderholm (1992). Includes a contribution from the Cu^{2+} ions to μ_{eff}.
[l] Soderholm *et al.* (1999). No value of Θ is given, low-temperature neutron diffraction indicates the spins order ferromagnetically within the *a–b* plane and are antiferromagnetically ordered along the *c*-axis.
[m] Skanthakumar *et al.* (2001). The large value of μ_{eff} above 100 K is attributed to a local paramagnetic moment on Cu^{2+} plus that of the Cm^{3+} ion. It is suggested that Cu^{2+} moment ordering occurs below 100 K resulting in the expected Cm^{3+} free-ion moment.

reported a 4.8 cm^{-1} splitting between the ground state and the first excited state. Because the ionic radius of the Lu^{3+} ion is less than that of the Y^{3+} ion, the crystal-field splitting in the Lu system should be larger, in accord with the susceptibility measurement. Above 7.5 K, there is reasonably good agreement

with the calculated free-ion moment. The temperature-dependent magnetic susceptibility of BkO_2 diluted in ThO_2 showed the ground state to be a Γ_6 (O_h) and the excited Γ_8 (O_h) state to be at about 80 cm^{-1} (Karraker, 1975b). The *g*-value of the ground state was 5.04, about 10% higher than the more accurate value of 4.488 ± 0.004 measured by EPR (Boatner *et al.*, 1972). The total overall splitting of the ground $J = 7/2$ state was estimated to be about 300 cm^{-1}. A possible antiferromagnetic transition at 3 K has been suggested to account for the anomalous magnetic behavior of these samples below 10 K. This transition would require segregation of the BkO_2 in the host ThO_2 matrix. Nave *et al.* (1983) measured the magnetic susceptibility of a 56.6 μg sample of BkO_2 (containing a 3% Cf impurity at the time of the measurement) and find Curie–Weiss behavior from 4.2 to 300 K with $\mu_{eff} = 7.92\mu_B$ and $\theta = -250$ K. Their value agrees with the calculated value for an $^8S_{7/2}$ state. However, it does conflict with the EPR results and Karraker's results which indicate a considerable splitting of the ground $J = 7/2$ term.

Interactions involving Cm^{3+} may be judged from a very complete work on Cm_2CuO_4 by Soderholm *et al.* (1999), where $\mu_{eff} = 7.89\ (5)\mu_B$, $T_N = 25$ K, and the ordered moment is $4.8\ (2)\mu_B$ at 15 K. This is a lower moment than expected, which might be due to measurements being made at an elevated temperature compared to T_N, but also may be caused also by covalency effects. The sample used for the neutron experiments was 42 mg (^{248}Cm), and the magnetic structure is the same as found for Gd_2CuO_4, which orders at 6.4 K. As far as known this is the only observation of magnetism in a Cm compound with neutrons. Cm_2CuO_4 is isostructural with the famous high-T_c-related La_2CuO_4 and it would be interesting to know what is the value of the moment on the Cu atom in the Cm compound. Unfortunately, this was below their experimental cut-off.

Another similar study (but without neutrons) was done by Skanthakumar *et al.* (2001) on the compound $Pb_2Sr_2Cm_{1-x}Ca_xCu_3O_8$ with $x = 0$ and 0.5. Again, these materials are related to high-T_c analogs with rare earths, although none of the Cm-doped compounds becomes superconducting.

A number of magnetic susceptibility measurements have been reported for Cm metal (Table 20.13), but reports by various investigators disagree (Marei and Cunningham, 1972; Kanellakopulos *et al.*, 1975; Fournier *et al.*, 1977; Huray *et al.*, 1980). The Soderholm group has been using the Cm^{3+} ion as a probe to study the influence of magnetic electrons on the superconductivity of some high-T_c-related oxides (Soderholm, 1992). In the course of this work, some new Cm compounds have been synthesized and their susceptibilities determined as shown in Table 20.13.

20.10 $5f^8$ $^7F_6$; Bk^{3+}, Cf^{4+}

The magnetic data for $^{249}Bk^{3+}$ diluted in $Cs_2NaLuCl_6$ are given in Table 20.2 (Hendricks *et al.*, 1974). The magnetic susceptibility is temperature independent, which shows that a singlet state is the ground state. From the systematics

of the crystal field parameters for the host crystal, the ground state is assigned as a Γ_1 (O_h) state, and from the magnitude of the susceptibility, the first excited state is calculated to be a triplet Γ_4 (O_h) state at about 85 cm^{-1}. Magnetic measurements for other ^{249}Bk compounds and the metal are listed in Table 20.14. The theoretical value for the $5f^8$ ground term free-ion g-value in intermediate coupling is 1.446 (1.50 for the pure $^7F_6$ ground term). From the magnetic susceptibility of Bk^{3+} adsorbed on ion-exchange beads, Fujita (1969) measured from 9.3 to 298 K (Table 20.14) a $\mu_{eff} = 9.40(6)\mu_B$, which corresponds to a free ion $g = 1.452$ (8) in excellent agreement with the expected value. The magnetic susceptibility of $^{249}BkF_3$ has also been reported and is in agreement with the free-ion value. The results of measurements of the magnetic susceptibility of Bk metal (Fujita, 1969; Nave *et al.*, 1980) are also given in Table 20.14. These measurements were performed on very small amounts (μg) of ^{249}Bk metal. Since $\tau_{1/2}$ of ^{249}Bk is only 320 days, there were varying amounts of ^{249}Cf metal (although corrections were applied for the amount of Cf) in the samples. Thus it is not surprising that different ^{249}Bk samples showed different magnetic behavior, especially at lower temperatures. Clearly these very difficult measurements need to be repeated. Measurements have been reported for $^{249}CfO_2$ and for $^{249}Cf_7O_{12}$. The latter compound can be thought of as comprising 40% Cf^{3+} and 60% Cf^{4+} and, assuming that susceptibilities can be simply added, the free-ion moment should be $9.7\mu_B$. As can be seen from Table 20.14, the measured higher temperature values are slightly lower than the expected free-ion values.

20.11 $5f^9\ ^6H_{15/2};\ Cf^{3+}$

The EPR spectrum of $^{249}Cf^{3+}$ in $Cs_2NaLuCl_6$ powder has been observed at 4.2 K (Edelstein and Karraker, 1975). From the measured isotropic g-value of 6.273 (10), the ground crystal field was identified as the Γ_6 (O_h) state and a free-ion g-value of 1.255 was deduced as compared with a calculated intermediate-coupling g-value of 1.279 for the nominally $^6H_{15/2}$ term. For the $4f^9$ analog, Dy^{3+}, the free-ion g-value is 1.333. The magnetic susceptibility of $^{249}Cf^{3+}$ (~2.4 mg) diluted into octahedral Cs_2NaYCl_6 (Table 20.2) was reported in the temperature range from 2.2 to 100 K (Karraker and Dunlap, 1976). From an analysis of the data, the Γ_6 state was determined to be the ground state, in agreement with EPR measurements, with a Γ_8^1 level as the first excited level at about 50 cm^{-1}. The total crystal-field splitting was calculated to be about 860 cm^{-1}. Limits were set for the ratio of B_0^4/B_0^6, which were consistent with those determined previously for the trivalent actinide compounds Cs_2NaMCl_6 $(M = U^{3+}, \ldots, Bk^{3+})$. EPR measurements of $|g_\parallel| = 3.56(2)$ and $|g_\perp| = 7.79(3)$ were reported for Cf^{3+} diluted in $LuPO_4$ at 4.2 K by Kot *et al.* (1993b).

Table 20.14 also lists magnetic susceptibility data for $^{249}Cf^{3+}$ compounds and for ^{249}Cf metal. From the magnetic susceptibility of Cf^{3+} adsorbed on ion-exchange beads (Fujita, 1969) measured from 77 to 297 K (Table 20.14),

[r] Morss *et al.* (1987) bcc, two samples of 3.097 and 1.23 μg, the numbers given in the table are the recommended average of measurements on the two samples, no indication of magnetic ordering was observed down to ~2 K.
[s] Chang *et al.* (1990) one hexagonal and three orthorhombic samples, masses ranging from 30 to 90 μg, high temperature results did not depend on the age of the samples.

a $\mu_{eff} = 9.14(6)\mu_B$ was obtained. This value is significantly lower than the expected free-ion value of $10.21\mu_B$ for the $^6H_{15/2}$ ground term. The magnetic susceptibilities of a number of compounds of Cf^{3+} have been measured. For the most part, the high-temperature data that could be fit by the Curie–Weiss law gave effective moments that were close to the free-ion value. However, as found before for small samples of highly radioactive isotopes, the low-temperature data were quite complex and sample dependent. Magnetic susceptibility measurements of ^{249}Cf metal samples were reported by two groups and are listed in Table 20.14. The high-temperature results are in fair agreement although one group reported complex low-temperature data for the metal.

20.12 $5f^{10}$; $^5I_8$; Es^{3+}

Very few measurements have been reported for trivalent Es compounds because of the difficulties associated with measurements on materials with short-lived isotopes. The most abundant isotope of Es is ^{253}Es with $\tau_{1/2} = 20.4$ days. A magnetic susceptibility measurement was reported for Es_2O_3 in the temperature range 4.2–180 K on an amorphous sample. The data fit the Curie–Weiss law with $\mu_{eff} = -10.5\mu_B$ and $\Theta = -53$ K. Correcting for the growth of ^{249}Bk (the sample was 4 days old and contained 13% Bk) gave a value of $10.5\mu_B$, consistent with the free-ion value. Measurements were reported for a 3.25 μg sample of EsF_3 in the temperature range 4.2–200 K 10 days after separation and preparation, which meant there was 31% ^{249}Bk in the sample. The data were fit with the Curie–Weiss law with $\mu_{eff} = -10.9\mu_B$ and $\Theta = -37$ K. After correction for the Bk content, the effective moment was $11.4\mu_B$. These measurements on Es samples should be treated conservatively as the true sample temperatures, the container corrections, and ^{249}Bk corrections lead to large uncertainties (Huray and Nave, 1987).

Elements beyond Es have half-lives that are too short to permit magnetic measurements of metals or compounds by conventional methods discussed here.

20.13 $5f^{11}$; $^4I_{15/2}$; Es^{2+}

The only reported Es metal (a divalent metal) magnetic measurement was made on a 0.25 μg sample. The purity of this sample is questionable since the preparative method may have resulted in an Au–Es alloy. Data were taken for

[t] Nave *et al.* (1987) and Moore *et al.* (1988) orthorhombic form obtained after melting the hexagonal samples, two polycrystalline samples of mass of 12.3 and 19.3 μg, exhibits metamagnetic behavior at low temperatures.

[u] Nave *et al.* (1987) and Moore *et al.* (1988) hexagonal, two microcrystalline samples of mass of 12.3 and 19.3 μg, exhibits metamagnetic behavior at low temperatures.

[v] Karraker and Dunlap (1976) 2.37 mg of $^{249}Cf^{3+}$ diluted in ~0.2 g of polycrystalline Cs_2NaYCl_6.

this sample with apparent temperature readings from 4.2 to 90 K. In this interval, a local moment of $11.3\mu_B$ was obtained, higher than the $10.2\mu_B$ free-ion value. The authors note the small sample size, large corrections for the sample holder, and uncertainty in the sample temperature due to self-heating as well as corrections for ^{249}Bk growth lead to a large uncertainty in the measured value (Huray and Nave, 1987).

The EPR spectrum at 4.2 K of $^{253}Es^{2+}$ diluted in CaF_2 was reported by Edelstein and coworkers (Edelstein *et al.*, 1970; Edelstein, 1971) and used to identify the stabilization of this oxidation state by the CaF_2 host. The measured *g*-value of 5.809 ± 0.005 identified the ground state as a Γ_6 (O_h) state. Subsequently, Boatner *et al.* (1976) found that the ground state of $^{253}Es^{2+}$ diluted in $SrCl_2$ had a *g*-value of 6.658 ± 0.003, which was assigned to the Γ_7 (O_h) state. Boatner *et al.* (1976) also reported the EPR spectrum of $^{253}Es^{2+}$ diluted in BaF_2, which was similar to that of Es^{2+} in CaF_2. Thus, the ratio of the crystal field parameters changed on going from CaF_2 or BaF_2 to $SrCl_2$, causing the ground state to switch. Analogous behavior had been found for the $4f^{11}$ ion, Ho^{2+}, in the same host crystals. The magnitude of the measured *g*-values is smaller than expected, and has been attributed primarily to covalency effects (Edelstein, 1971; Boatner *et al.*, 1976).

20.14 THE ACTINIDE DIOXIDES

Starting with the actinide oxides, AnO_2, one would intuitively expect that the situation might be relatively simple. If one takes oxygen as divalent, then an ionic compound can be made with An^{4+} and $2O^{2-}$. Indeed, from many considerations this appears a good approximation. All compounds have the well-known fcc CaF_2 fluorite structure. (See Chapter 15, Table 15.9, for a list of lattice constants.) This apparently simple cubic structure belies the complications that occur for the different oxides. As in so many cases, the devil is in the details. Despite half a century of effort, there remain many puzzles in the actinide dioxides, and they will be discussed at some length in this article. The magnetic properties should reflect this ionic nature, i.e. for UO_2 a $5f^2$ configuration is anticipated with a crystal-field splitting that gives a well-defined ground state.

20.14.1 Uranium dioxide

Early work on the magnetic susceptibilities of solid solutions of UO_2 in ThO_2 (cubic symmetry) was interpreted as showing 'spin only' behavior for the d^2 configuration on extrapolation to infinite dilution. Subsequently Hutchison and Candela (1957) showed that a model based on the $5f^2$ configuration with a strong spin–orbit interaction and the ratio of the crystal field parameters such that the Γ_5 (O_h) triplet state is lowest would also fit the observed magnetism. Ordered magnetism of UO_2 was first suggested by Jones *et al.* (1952) from their

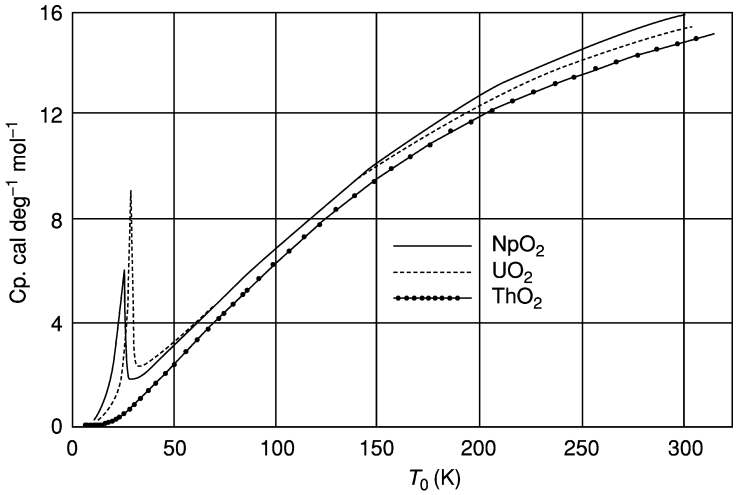

Fig. 20.7 *Heat capacities of ThO_2, UO_2, and NpO_2. Figure reprinted with permission from Osborne and Westrum* (1953). *Copyright* 1953 *by the American Institute of Physics.*

heat capacity measurements. Within a year, the heat capacities of ThO_2, UO_2, and NpO_2 were measured (Osborne and Westrum, 1953) and are reproduced in Fig. 20.7. These showed important anomalies for UO_2 and NpO_2, at 30 and 25 K, respectively. The assumption, of course, was that both materials exhibited a phase transition to a magnetically ordered state. Although magnetic susceptibility measurements were made on UO_2 in 1950, the best data were presented by Arrott and Goldman (1957). They showed that the magnetic phase transition disappeared when additional oxygen entered the lattice to the level of $UO_{2.07}$. Almost a decade then passed before the microscopic proof of antiferromagnetism was given by neutron diffraction. Two papers were published essentially simultaneously, Willis and Taylor (1965) and Frazer *et al.* (1965). Both reported work on single crystals and showed that UO_2 has a first-order transition to an antiferromagnetic state at 30.8 K. The uranium moments (of $1.75\mu_B$ at 5 K) are aligned in alternating ferromagnetic (100) sheets in a sequence $+ - + -$. The magnetic repeat may be characterized by a wave vector of $\mathbf{k} = 1$, i.e. the magnetic and chemical unit cells are the same. The magnetic moments are perpendicular to the propagation direction, i.e. $\boldsymbol{\mu} \perp \mathbf{k}$, in what may be described as a transverse structure (Fig. 20.8). These experiments, the availability of single crystals, and the increasing interest in f-electron magnetism ushered in the 'golden era' of experiments on UO_2, essentially the period from 1965 to 1980. Blume (1966), assuming a model where the electronic structure of U^{4+} consisted of a nonmagnetic singlet ground state with a low-lying magnetic triplet state and including bilinear isotropic exchange interactions, was able to account semiquantitatively for the first-order magnetic phase transition (see also

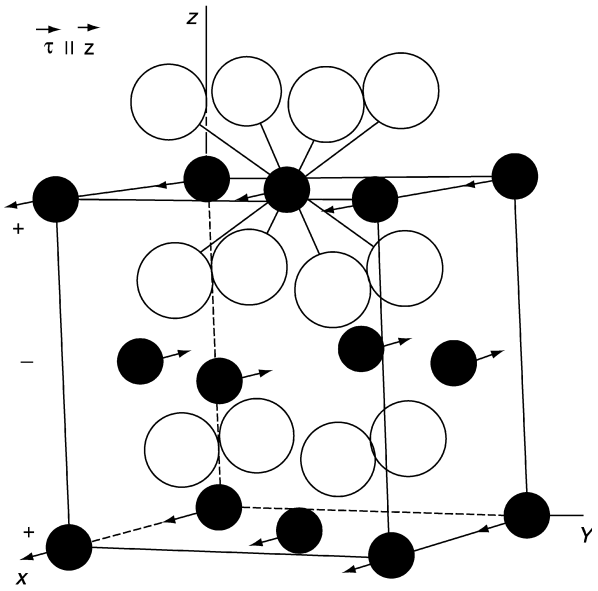

Fig. 20.8 *Magnetic structure of UO_2. The open circles are oxygen and the closed circles are uranium. In the arrangement shown the propagation direction* $\mathbf{k} = [001]$, (**k** *and* $\boldsymbol{\tau}$ *are equivalent*) *and the moments are transverse to this direction. Alessandrini *et al.*, 1976). Rahman and Runciman (1966) showed that this was unlikely, their full manifold calculation showed that the crystal field ground state was most probably the triplet Γ_5. This could also explain the moment (which should be $2.0\mu_B$ for a pure $^3H_4$ ground state) as the mixing of higher L and S components would tend to reduce the ordered moment. They obtained crystal field parameters $V_4 = -409$ meV and $V_6/V_4 \sim -0.06$. They could not easily explain the first-order phase transition, but did predict a splitting of $\sim$171 meV between the ground state and the doublet Γ_4 and $\sim$630 meV to the next excited crystal field state. Neutron inelastic scattering was incapable of verifying these energy splittings in the 1960s and the opaque character of UO_2 make the optical technique of limited value. However, on a lower energy scale, neutrons had already been used to measure the complete phonon dispersion spectra at room temperature (Dolling *et al.*, 1965). At lower temperature, the neutron inelastic experiments by Cowley and Dolling (1968) showed a possible strong interaction between the magnons and the lattice, and this was reinforced by the elastic constant measurements as measured by Brandt and Walker (1967, 1968). Interestingly, they showed that the c_{44} elastic mode actually started to soften just below room temperature, and showed a strong minimum at the phase

transition. Within a year, in two remarkable papers, Allen (1968a,b) proposed a theory for the spin–lattice interaction in UO_2 that was based on a Jahn–Teller (JT) interaction and first introduced the idea of *quadrupole* interactions in the actinides. Allen proposed that the quadrupoles ordered and would thus give rise to an internal strain that would lead to a change in the position of the oxygen atoms without giving rise to an external change in the symmetry of UO_2. No measurements had found evidence for a large *external* (i.e. a lowering of the overall cubic symmetry) crystallographic distortion at the phase transition. Pirie and Smith (1970), using X-rays, searched for possible shifts of the U-atoms, but in such a measurement any oxygen shift would have been impossible to observe.

Following the work of Allen, an important paper was published by Sasaki and Obata (1970) giving new insights into the Jahn–Teller effects that might occur in the oxides. Their essential contribution was to realize that there could also be a *dynamic* JT effect that could occur at temperatures above the phase transition, and by coupling to the lattice this would explain the anomalies found in both the elastic constant work of Brandt and Walker (1967, 1968), and the susceptibility measurements of Arrott and Goldman (1957).

There is no evidence that the neutron experts understood the theory of Allen, which was advanced for its time, or Sasaki and Obata's work. It was not until 1975 that the internal distortion of the oxygen cage was discovered with neutron diffraction in the course of precise measurement of the intensities from a single crystal (Faber *et al.*, 1975; Faber and Lander, 1976). The experiment was designed to study something completely different, the magnetic form factor of U^{4+} at high values of Q, and the observation of the oxygen internal distortion was accidental! The full theory of this distortion was published by Siemann and Cooper (1979). The exact internal modes proposed by Allen are incorrect, but other modes are found. This does not distract from the originality of Allen's ideas. The coupling of magnetism and internal modes is illustrated in Fig. 20.9. The oxygen displacement from the equilibrium position is 0.014 Å. That such a small movement of the oxygen atoms could be measured is an example of how the neutrons are sensitive to light atoms in the presence of heavy ones.

The next step in the UO_2 saga came with the experiments on many actinide compounds at the Commissariat à l'Energie Atomique (CEA) in Grenoble, France during the period 1977–87 under the leadership of J. Rossat-Mignod. This group determined that many of the NaCl-type actinide compounds had a more complicated form of magnetic structure than originally proposed (Rossat-Mignod *et al.*, 1984). Instead of having a single **k** propagation vector in a certain volume of the crystal, a number of symmetry equivalent **k** vectors coexist in the same volume of the crystal. UO_2 was determined to have a triple **k** magnetic structure both by cooling the material in a magnetic field, as well as by applying uniaxial stress to the sample. This does not change the understanding of the magnetic structure or internal distortion, as long as one realizes that only one component of the moment and distortion are shown in Figs. 20.8 and 20.9. It did, however, lead to a reinterpretation of the magnon dispersion curves of

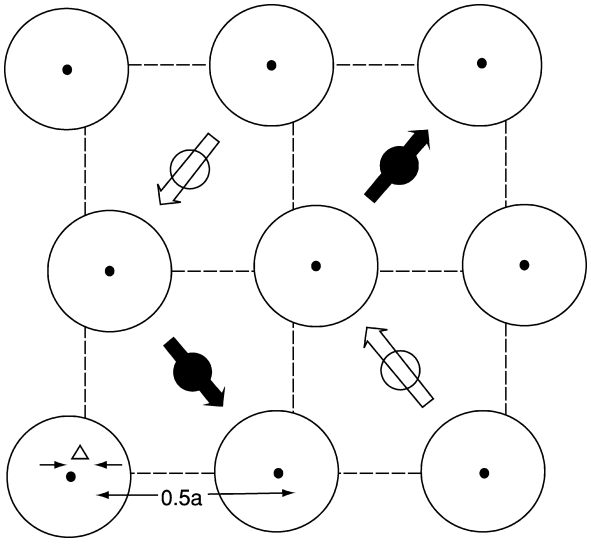

Fig. 20.9 *The* (001) *projection of the fluorite structure. The large circles represent oxygen atoms at* $z = 1/4$ *and* 3/4 *displaced from the ideal fluorite structure* (*indicated by the dashed lines*). *The shift of the oxygen atoms is not drawn to scale,* $\Delta = 0.014$ Å. *The smaller closed and open circles represent the uranium atoms at* $z = 0$ *and* 1/2, *respectively. Cowley and Dolling (1968) and Giannozzi and Erdos (1987). However, efforts to reproduce the dispersion of the magnons (discussed later), despite the 3**k**-structures were not successful. Apparently some element was still missing in the understanding of these curves.

During this period many other experiments were, of course, conducted on UO_2. It is a semiconductor with a band gap of $\sim$2 eV, and much of the electronic structure aspects were reviewed by Schoenes (1980) and by Brooks *et al.* (1984). There is little doubt from photoemission that the 5f states are considerably removed from the Fermi level E_F in UO_2. They are measured at 1.4 eV below E_F, a strong indication of the localization of the $5f^2$ state. Kelly and Brooks (1987) have shown that the local density approximation can account for the lattice parameter and estimate the width of the valence band. However, these electronic structure calculations show also that the simple concept of an ionic solid is not a good approximation in any of the light actinide oxides. There is appreciable mixing of the actinide 6p states with the 2p states of oxygen resulting in a measure of covalency for all actinide oxides.

In examining the optical properties (Schoenes, 1980) the localized nature of the 5f electrons in UO_2 also became apparent, and many features of the

electronic structure were observed as interband transitions. One extraordinary effect, shown in Fig. 20.10a was the presence below T_N of intense and sharp peaks at 151 and 154 meV. Schoenes identified these as two-phonon excitations as they are at exactly double the highest energy longitudinal optic (LO) modes involving principally oxygen atoms as measured by Dolling *et al.* (1965). The question is why they should be so strong and temperature dependent

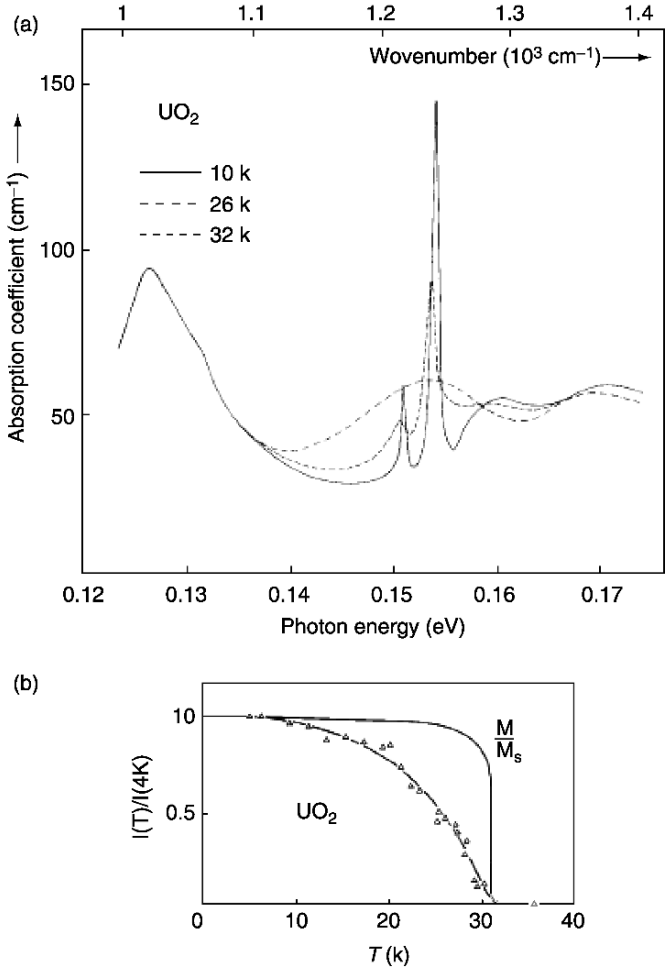

Fig. 20.10 (*a*) *The absorption coefficient of* UO_2 *measured in optical spectroscopy for various temperatures above and below* $T_N = 30.8$ K. *The sharp peaks at* 151 *and* 154 meV *are thought to be multiphonon excitations.* (*b*) *The temperature dependence of the area of the* 154 meV *peak compared to the normalized sublattice magnetization as measured by neutrons. (see Fig. 20.10b)? As found from the experiments that will be described for NpO_2 (see below), it now appears that these excitations are a consequence of the LO phonon coupling to the quadrupolar distortion induced by the 5f quadrupole moment around the uranium nucleus. The fact that the T-dependence is continuous rather than discontinuous, as seen in the sublattice magnetization, suggests that the quadrupole coupling is a higher-order effect, and the dipole ordering is the primary-order parameter. It would seem worthwhile to measure this LO phonon as a function of temperature with neutron inelastic scattering.

Rahman and Runciman (1966) utilized the crystal field model to predict that there was a large splitting of the $^3H_4$ ground state manifold, with the first excited state being at least 150 meV above the ground state. With the advent of spallation neutron sources in the early 1980s, these types of crystal field energies became accessible, and the first indication for crystal field excitations in UO_2 was published in 1985 (Kern *et al.*, 1985). *Two* excitations were observed at 155 and 172 meV, whereas only *one* was expected according to the Rahman and Runciman calculation. These authors suggested that the R&R calculations might still be correct but that the V_6/V_4 ratio might be rather different from the –0.06 suggested by Rahman and Runciman. Three years later, using the more powerful spallation source ISIS near Oxford in UK, Osborn *et al.* (1988) showed that the crystal field spectra of UO_2 consisted of *four* excitations spread over the range 152–183 meV; these are shown for various temperatures in Fig. 20.11. They also searched up to energy transfers of 800 meV, but found no evidence of further transitions. The first point to note is that in the crystal field model for the $^3H_4$ multiplet there should be only two transitions in the ground state multiplet. (Transitions from Γ_5 to Γ_3 and Γ_4 are allowed, but not to Γ_1.) Since the overall multiplet is now within 180 meV, rather than the $\sim$700 meV proposed by Rahman and Runciman, the crystal field interaction is much weaker than in the Rahman and Runciman model. In a detailed paper, Amoretti *et al.* (1989) showed that $V_4 \sim -123$ meV, less than 1/3 that was proposed by Rahman and Runciman, and $V_6/V_4 = -0.21$. The extra lines (above the two expected) arise from the lowering of the symmetry due to the internal distortion of the oxygen cage (Fig. 20.9). Amoretti *et al.* (1989) were able to show that the spectra are better explained with a 3**k** magnetic structure (physical displacements along $\langle 111 \rangle$) rather than a 2**k** model (physical displacements along $\langle 110 \rangle$). Interestingly, one can see that the four lines are still present *above* T_N, whereas there is no longer a static distortion of the oxygen cage. However, dynamic effects are still present, as pointed out by Sasaki and Obata (1970), and these will give rise to a splitting of the crystal field levels, although it is noticeable that the transitions are starting to broaden in width by 35 K.

Following this direct measurement of the crystal-field splitting, the theorists returned to the fray and showed that the smaller value of V_4 (as compared to the original calculations of Rahman and Runciman) could be understood (Gajek *et al.*, 1988; Rahman, 1998). The latter paper shows that the ground state is $\sim$90% $^3H_4$, justifying the approximations made in interpreting the neutron

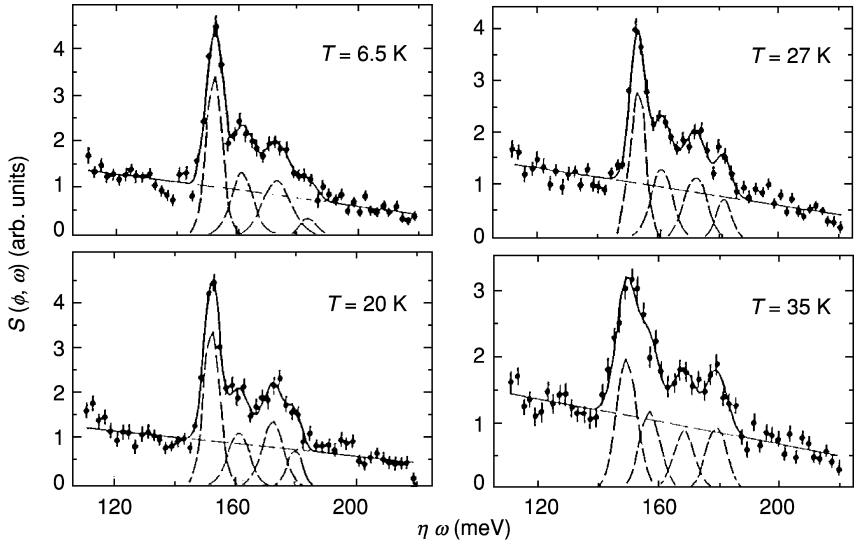

Fig. 20.11 *Neutron spectra measured with an incident energy of* 290 meV *for different temperatures between* 6.5 *and* 35 K, *where* $T_N = 30.8$ K. *The smooth line is the fit to four Gaussian line shapes and a sloping background. spectra. The moment calculated is $1.94\mu_B$, only a small reduction from the $2.00\mu_B$ in the simple Russell–Saunders coupling for the Γ_5 ground state. The reduction from 1.94 to $1.75\mu_B$ is thus due to the JT effect, as discussed above. All of this established beyond doubt that the ground state was the triplet Γ_5.

For the ground states of the heavier actinides, more mixing of excited states into the ground state is expected, but this work on UO_2 shows that although taking into account intermediate coupling (mixing of excited L and S values) is necessary, J-mixing is probably not so important for *any* ground state properties of the actinides. This result suggests many of the earlier calculations, e.g. Chan and Lam (1974) were not relevant. Furthermore, this has important implications for studies of intermetallics compounds, which are not covered in this review (but see Chapter 21 and Vol. 17, 19, and 32 of *Handbook of Physics and Chemistry of the Rare-Earths*). Because the conduction-electron states in intermetallic compounds are known to shield the crystal field interactions, the crystal field parameters are expected to be *lower* than in the actinide oxides. Thus it is expected that crystal-field splittings in intermetallics should be in the range 20–50 meV, as compared to 150 meV in UO_2. The range for intermetallics is thus excellently matched to neutron spectroscopy, and in practice this has been found (Holland-Moritz and Lander, 1994). However, when the crystal field transitions in intermetallics are *not* observed with neutron spectroscopy, it

cannot be argued that the crystal field transitions are outside the range of neutron spectroscopy. More subtle interactions, due to the hybridization of the 5f electrons with the conduction-electron states, are involved.

An elegant NMR study has been performed at low temperature on both the ^{235}U and ^{17}O NMR nuclei in UO_2 (Ikushima *et al.*, 2001). The results lend support to the idea of a 3**k** magnetic structure in UO_2 below T_N. Furthermore, Ikushima *et al.* (2001) give strong evidence for a local distortion driven by the U quadrupoles, and an excitation spectrum that shows the presence of magnon–phonon coupling.

The understanding of UO_2 is almost complete, but there are still the magnon dispersion curves, first measured in 1968, that still defy a complete theoretical interpretation, despite the realization of the 3**k** state. Again, new neutron technology has come into play, in this case in the ability to have enough neutron intensity to analyze the polarization of the scattered neutrons. Briefly, when a neutron is scattered from a magnetic moment the spin state of the neutron is *changed*; on the other hand, when the neutron is scattered from a nucleus, the spin state is *unchanged*. With a sufficiently large single crystal of UO_2, it proved possible to examine the magnon dispersion curves with polarization analysis, and the results are shown in Fig. 20.12 (Caciuffo *et al.*, 1999). The hope in these

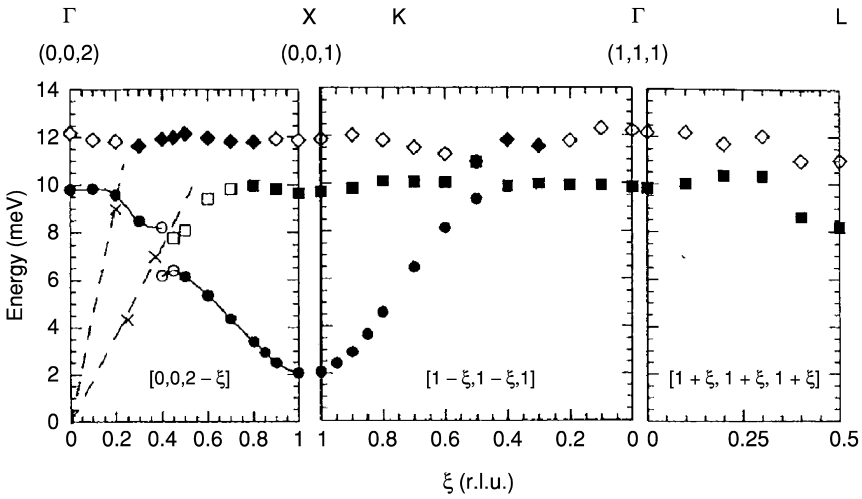

Fig. 20.12 *Magnon dispersion curves of UO_2 measured at* 16.5 K *along the principal crystallographic directions. The broken lines and crosses correspond to acoustic phonon branches measured at* 270 K. *Open symbols indicate a qualitatively smaller magnon intensity than the filled points. In all measurements the neutron spin state was spin flip, i.e. changed, and the nonspin-flip cross section was found negligible. Figure reprinted with permission from Caciuffo* et al. experiments was that a 'mixed' mode would be found to identify the famous magnon–phonon coupling first proposed by Cowley and Dolling (1968). No sign of this interaction was found. However, if it occurs in the region $\xi \sim 0.5$ in the $[00\bar{2}\xi]$ zone, then it is difficult to observe as the intensity drops to almost zero, for reasons that are not immediately clear. Theory is still unable to reproduce the magnon dispersion curves. This is certainly the most important question to resolve before a complete understanding of the magnetism of UO_2 is achieved.

In this long story of the magnetism of UO_2 not a word has been said about the new technique of RXS. In a sense this technique came too late! One discovery still needing confirmation in UO_2 is the presence of the quadrupole moments. Rather than treat this here, it is more appropriate to raise it after the discussion of NpO_2 (below). However, one interesting story using synchrotrons is worth recounting. The signal from uranium in resonant magnetic scattering is so strong (see Fig. 20.2 and discussion) that it opens the possibility for doing different kinds of experiments. One of these is the possibility of observing the scattering from *surface magnetism* in UO_2. Experiments of this sort to study the surface *charge* arrangements are common with synchrotrons, but are extremely rare for *magnetism* because they require scattering from a very small magnetic volume near the surface of the material. After many efforts involving surface preparation and different experiments, *surface magnetic scattering* was observed from UO_2 (Watson *et al.*, 1996). Strictly speaking, the parameters investigated have little specific to UO_2; they concern what happens near the surface of an antiferromagnet that undergoes a discontinuous phase transition in which the magnetism melts. One of the more interesting aspects is that as emphasis is put more and more on the surface layers it is found that the phase transition is in fact continuous. The crucial data are shown in Fig. 20.13. Although it is not strictly correct to interpret the different values of the L index in Fig. 20.13 as representing different depths into the antiferromagnet, as a first approximation it is acceptable. The bulk magnetism signal (similar to that observed with neutrons) is shown at (001). The model of magnetism near the surface in UO_2 is that near the phase transition, the top few surface layers lose their magnetism, and below them is an interfacial layer of reduced moments that grows in spatial extent as the temperature approaches T_N. These results are in agreement with some of the theories, based on symmetry arguments, but in disagreement with a simple melting transition, which is observed for ferromagnets. That there is a difference is perhaps not surprising as a ferromagnet has a net magnetization, which couples to the lattice, whereas such an interaction is absent in an antiferromagnet. More recent experiments have gone on to study the roughening of the magnetic order just before the phase transition. Interestingly, such studies are relevant to a current problem in magnetic multilayers, viz. the interplay of charge and magnetic roughness in defining the interfacial structure of the multilayers.

20.14.2 Neptunium dioxide

Progress in understanding was slow and steady over the last 50 years in the study of UO_2. Not so with NpO_2. The problem turned out to be considerably more complicated. The story starts with the same paper on the heat capacity from Osborne and Westrum (1953) (Fig. 20.7). Since NpO_2 has a $5f^3$:Np^{4+} configuration, the ground state is $^4I_{9/2}$, a Kramers' ion in which the lowest ground state must be a magnetic doublet. This means given even the smallest amount of magnetic exchange the compound should order magnetically as no crystal field interaction can induce a singlet (nonmagnetic) state. The transition at $T_o = 25$ K in the heat capacity was thus assumed to be due to magnetic ordering. Note that the entropy at the transition (area under the curve) is very similar for both UO_2 and NpO_2, reinforcing the supposition of

ordered magnetism in both. Magnetic susceptibility measurements by Ross and Lam (1967) showed a strong peak at T_o, again suggesting antiferromagnetic order, as in UO_2. The first surprise came when neutron diffraction (on polycrystalline samples) by Cox and Frazer (1967) and Heaton *et al.* (1967) failed to find any change in the diffraction pattern on cooling below 25 K. They put an upper limit of $\sim 0.4\mu_B$ on any possible moment, much less than expected from the $5f^3$ ground state quartet. This limit was drastically reduced by the Mössbauer experiments of Dunlap *et al.* (1968) that showed that there was a very small amount of line broadening developing below T_o. When interpreted in terms of magnetic dipole ordering, this line broadening suggested a moment of $\sim 0.01\mu_B$. At that time, in the 1960s, a moment so small was unheard of, so the problem remained unsolved. The discovery of the internal distortions in UO_2 in the mid-1970s led those involved, especially theorists, to return to the unsolved mystery of NpO_2. Erdos and coworkers published a number of papers trying to explain the low-temperature magnetic properties of NpO_2 (Erdos *et al.*, 1980; Solt and Erdos, 1980). The essential point was to introduce a *quadrupole* interaction and allow this to cause an internal distortion. The magnetism was then 'removed' by postulating an unusual ground state or other assumptions about the presence of Np^{3+} ions. Since the UO_2 studies had shown that small extra diffraction peaks were present at low temperature as a consequence of the rearrangement of the oxygen atoms, an effort was made to see whether similar peaks could be found from NpO_2. Boeuf *et al.* (1983) reported a null effect, but the crystals of NpO_2 were small (no crystals larger than ~ 2 mm^3 have ever been produced), so these experiments could not be as sensitive as in the case of UO_2. Given the sensitivity of the Mössbauer signal from the ^{237}Np ion, it was not surprising that Friedt *et al.* (1985) returned to this technique and made a series of precise measurements down to 1.5 K, including applying a magnetic field. They suggested that there was *no* dipole magnetism at all, and that all the effects could be explained by a JT distortion of the oxygen cage. However, since this had not been observed in the experiments of Boeuf *et al.* (1983), they suggested that the distortion should be dynamic in nature. If it were, then this should give rise to a change in the phonon spectra, which might be reflected in the thermal parameters at low temperatures. Caciuffo *et al.* (1987) searched for any such changes, but without success.

By this time experimentalists were unenthusiastic about working on NpO_2, but it seemed at least important to establish the crystal field parameters, as there had been the suggestion that NpO_2 was not even Np^{4+} (Zolnierek *et al.*, 1981). The first attempts by Kern *et al.* (1988) showed that any crystal field peaks were broad, much broader than the experimental resolution. The problem needed the higher intensity of the ISIS (UK) source and this experiment was performed by Amoretti *et al.* (1992). The data and fits are shown in Fig. 20.14. Clearly these are less convincing than those found for UO_2 (Fig. 20.11). Any crystal field scheme with Np^{4+} predicts the highest Γ_6 state at well over 200 meV and the matrix element is small. The transition(s) observed, therefore, must be between

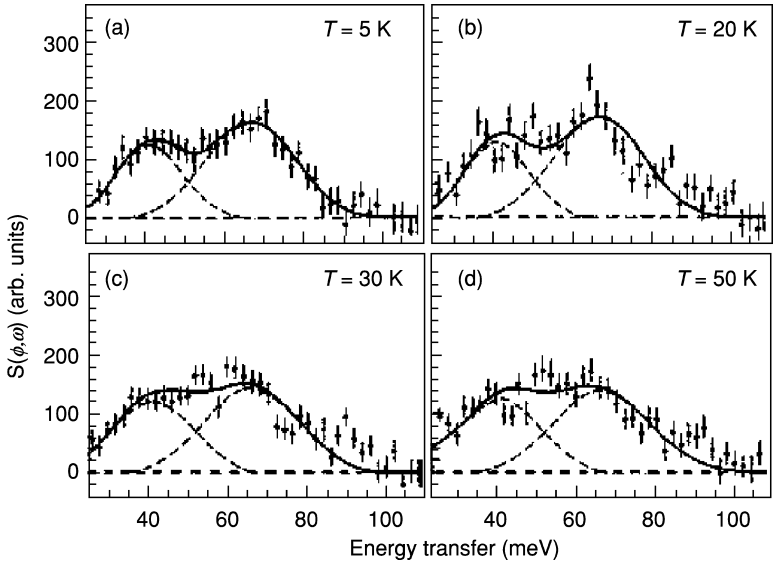

Fig. 20.14 *Neutron inelastic magnetic scattering cross section for NpO_2 as a function of temperature. the two Γ_8 states. The extent of this splitting, around 55 meV, with evidence for a splitting of the peak as observed in UO_2, is completely consistent with the V_4 parameter deduced for UO_2, after taking into account the change in the cation. Amoretti *et al.* (1992) also made measurements at lower energy and saw an interesting effect as the temperature was lowered through T_o, which is shown in Fig. 20.15. The transition must correspond to the splitting of the ground state Γ_8 quartet below T_o. It thus appeared after these measurements that the crystal field parameters were as expected (based on UO_2) for NpO_2 and one really had a Np^{4+} ion (as the chemists and the Mössbauer spectroscopists insisted all the time!) and there was a need for a new idea.

Muon spectroscopy (Kalvius *et al.*, 2001) is also sensitive to the presence of dipole moments. The difficulty with this method is that there is always some uncertainty about at which point the muon annihilates, giving rise to the measured signal. However, Kopmann *et al.* (1998) showed that the signal from magnetic ordering was readily observed in UO_2 and went on to observe a small effect in NpO_2. Again, as with the neutron signal shown in Fig. 20.15, there is an 'effect' at T_o, but if it was dipole moment ordering, then the Mössbauer spectroscopy would have observed it.

Given the huge sensitivity to magnetism in 5f shells that was discussed in connection with RXS (see Fig. 20.2), one of the first samples to try with this

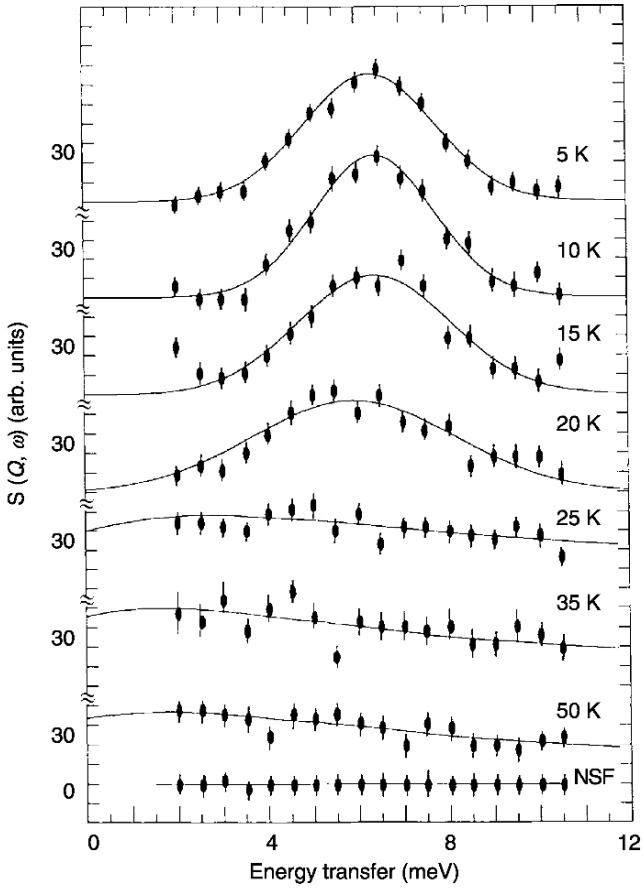

Fig. 20.15 *Evolution of the spin-flip scattering* (*i.e. the neutron spin state is changed on scattering indicating a magnetic cross section*) *as the temperature is lowered through the* 25 K *transition in* NpO_2. *The momentum transfer is* $Q = 1.3$ Å^{-1} *and the sample is polycrystalline. technique was NpO_2, once the problem of looking at transuranium samples at the ESRF in Grenoble was solved. A large signal was indeed observed below T_o by Mannix *et al.* (1999). Because Mannix *et al.* (1999) did not have all the necessary tools to analyze the polarization of the scattered photons, they were cautious in ascribing this signal to dipole ordering, and, of course, the RXS technique cannot relate the intensity of the scattering to the magnitude of the dipole moment. They did, however, measure the dependence of the scattered intensity on the photon energy, and this is shown for UO_2 and NpO_2 in

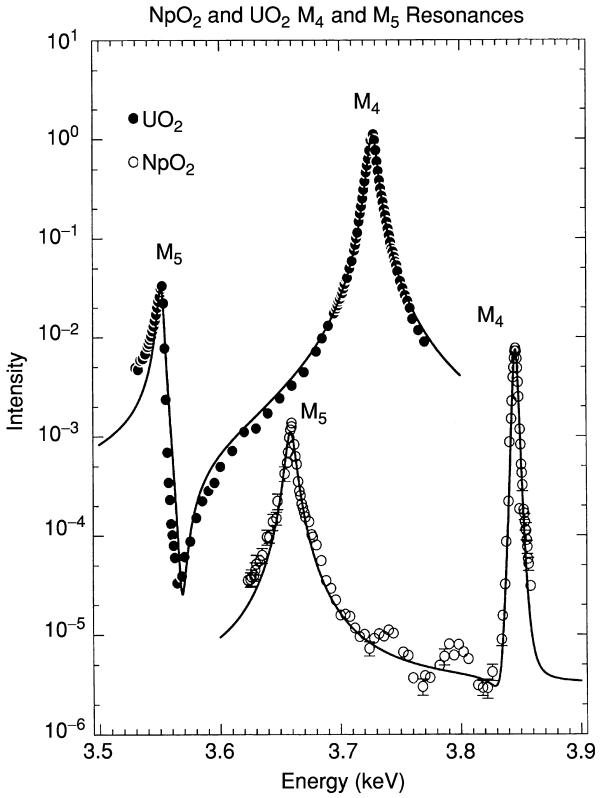

Fig. 20.16 *The energy dependence of the integrated intensity from UO_2 and NpO_2 as a function of incident photon energy. Note that the signal for UO_2 is fit to simple Lorentzian curves, as was the case for UAs, shown in Fig.* 20.2. *On the other hand, the NpO_2 spectra, especially that at the strong M_4 cannot be fit to a Lorentzian and requires a Lorentzian-squared function to fit the observed variation. Notice also the different energies for the $M_{4,5}$ edges for U and Np. This allows the RXS technique to be element selective, and one can look at mixed $(U,Np)O_2$ oxides and probe independently the magnetism on the two types of cations. For a study like this see Normile* et al. (2002). *Reprinted from Lander* (2002). *Copyright* 2002 *with permission from Elsevier.*

Fig. 20.16. The energy dependence, which was not published by Mannix *et al.* (1999), as it was not understood, suggested that perhaps the scattering was not simple dipole.

At the same time that these experiments were in progress, Santini and Amoretti (2000) proposed that the ordering in NpO_2 was not dipole $\langle M \rangle$ but rather of an octupole $\langle M^3 \rangle$ nature. These can be best understood in terms of the shapes of the resulting charge distributions. For dipole ordering the magnetic moment is a vector quantity but it does not require a distortion of the charge density, which can then remain spherical around the atom. For *quadrupole*

ordering $\langle M^2 \rangle$ there is *no* net magnetic moment as the (even) operator does not destroy time reversal symmetry, however, it does change the shape of the charge density of the electrons around the nucleus. Shapes such as prolate or oblate are typical symmetries of quadrupoles. For octupole moments $\langle M3 \rangle$ time reversal symmetry is broken as the operator is odd; in addition, the charge distributions become even more aspherical. Santini and Amoretti (2000, 2002) proposed this model for NpO_2 to explain the essentially 'zero' of Mössbauer spectroscopy, and yet to have a magnetic operator that would break time-reversal symmetry to explain the results of the muon experiments.

As the capabilities increased at the ESRF synchrotron, it became important to return to these experiments on NpO_2. The new capabilities allowed the polarization of the scattered photons to be analyzed and, at the same time, the crystal to be rotated about the scattering vector while the intensity was monitored. This proved crucial. The scattering at the (001) and (003) reflections, first reported by Mannix *et al.* (1999), were found to originate totally from *quadrupole* charge distributions. This can be understood by both the azimuthal and polarization dependence, see Paixão *et al.* (2002). Furthermore, the absence of either internal or external lattice distortions in NpO_2 implies that the configuration involves 3**k** quadrupole ordering. A schematic picture of this is shown in Fig. 20.17. It is important to realize that the scattering observed here is *not* magnetic in origin. It arises from the aspherical nature of the charge distribution

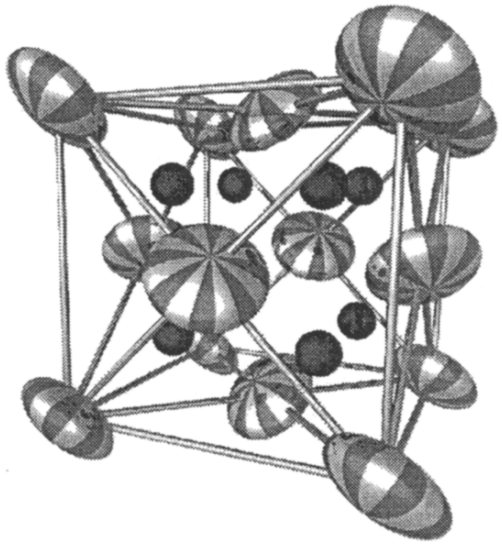

Fig. 20.17 *Crystal structure of NpO_2 in the antiferromagnetic-quadrupole state. The ellipsoids represent the orientation of the local symmetry axis at the Np position, not the actual charge distributions. The oxygen atoms are shown as spheres. of the 5f states. The local symmetry around the Np atoms is broken by the quadrupole distribution of the 5f states, and this gives rise to new reflections that are not allowed by the original space group. RXS is a particularly powerful tool as it tells us the nature of the electrons that make up the quadrupole distribution. In this case the strong energy dependence (Fig. 20.16) is related to the particular matrix elements that give rise to the scattering. This particular feature of RXS is becoming more important, and has also been used in the 3d series, see for example, Zimmerman *et al.* (2001). In general this is called Templeton scattering, after the pioneering crystallography of Templeton and Templeton (1985) even before tunable synchrotron beams were available.

This section on NpO_2 will finish by returning to UO_2 and asking whether it would not also be possible to demonstrate directly the presence of the quadrupoles. Indeed, it would be, but in the case of UO_2 there is also strong *dipole* scattering. If both of these occur at the same place in the reciprocal lattice then distinguishing the much weaker quadrupole effects becomes difficult. As far as known, NpO_2 is the only material that exhibits quadrupolar ordering without an ordering of dipoles at the same or a lower temperature. On the other hand, the observation of a temperature-independent susceptibility (Erdos *et al.*, 1980) and the asymmetry in the muon experiments suggests that there exists an operator that lifts time reversal. (This cannot be done by the quadrupole operator as it is even in M.) The only possibility is that there is simultaneous ordering of an octupole moment, but a symmetry analysis has shown that it must be a different type from that proposed by Santini and Amoretti (2000). Observing this is almost impossible with the RXS technique and 5f electrons because the matrix elements will be small. Thus, the saga of NpO_2 is not over completely, but at least the field now is illuminated, as opposed to the darkness surrounding research on NpO_2 for almost 50 years!

20.14.3 Plutonium dioxide

The electronic state of Pu^{4+} is $5f^4$:$^5I_4$ and relatively simple considerations lead to the suggestion that the crystal field ground state might be a singlet Γ_1. (In a simple picture, the crystal field states for Pu^{4+} are simply the inverse of those for U^{4+}.) This idea was strongly reinforced by the first reported measurement of the susceptibility of stoichiometric PuO_2 by Raphael and Lallement (1968). Remarkably they showed that the susceptibility was completely independent of temperature up to 1000 K, with a value 0.54×10^{-3} emu mol^{-1} (after correcting for the small diamagnetism of the radon core). In order to calculate the above value of the TIP from the simple crystal field model, the necessary crystal-field splitting between the ground state (singlet) Γ_1 and first excited (triplet) Γ_4 was found to be $\sim$280 meV. (If χ is temperature independent up to 1000 K, then the magnetically active triplet state must be at least $\sim$2000–3000 K away in energy). The resulting V_4 is approximately –320 meV, and this is not far from the value first proposed for UO_2 (Rahman and Runciman, 1966) of $V_4 \sim$ –400 meV.

Yet, as discussed above, this value was found to be much smaller from experiments on UO_2.

Performing crystal field measurements on PuO_2 with neutrons proved *much* harder than on UO_2. For these measurements, samples of 30–80 g of materials are needed; moreover, it is quite impossible to use the ^{239}Pu isotope for inelastic scattering, so one has to use samples with the rare isotope ^{242}Pu. Still, these measurements were clearly of great importance, and finally a suitable sample (79 g, triply encapsulated) was transported to Intense Pulsed Neutron Source (IPNS) at Argonne and the experiment performed. At least *two* peaks were seen, spread over ~85–125 meV. In the crystal field scheme only *one* transition is expected as the matrix elements for transitions from the Γ_1 singlet state are zero except for the one transition $\Gamma_1 \rightarrow \Gamma_4$. However, by examining the Q-dependence of the scattering it became clear that most of the observed peaks increased in intensity with Q, whereas electronic transitions should decrease with Q. In fact only the transition at ~120 meV appeared electronic and the others were assigned to H-modes from an impurity, probably from water in the PuO_2 (Kern *et al.*, 1990). (Neutron scattering is extremely sensitive to hydrogen and, although these impurities were later detected by infrared spectroscopy, neutrons are still a wonderful analytical tool – if rather expensive – for free or bound H.) This was rather an unfortunate situation, and it took almost a decade to get the sample purified at Los Alamos, and then actually run on the Los Alamos spallation source. However, the result (Kern *et al.*, 1999) merited the wait. A single peak at 123 (4) meV was observed, but with a width significantly greater than the experimental resolution (Fig. 20.18). By calibrating the spectrometer with the known scattering from vanadium, Kern *et al.* (1999) were able to put the scattering on an absolute scale. They then took the crystal field parameters (V_4 and V_6) from UO_2 and extrapolated them to PuO_2 where they predicted a single transition at 115 meV. Moreover, the absolute calculated intensity of the transition also agreed perfectly with the experiment, so this gives considerable confidence to the crystal field parameters.

However, there is now a *major* discrepancy between χ as determined by Raphael and Lallement (1968) and χ calculated from the crystal field scheme. Using the observed V_4 and V_6 parameters, the calculated $\chi = 0.90 \times 10^{-3}$ emu mol^{-1}, a value almost twice as great as measured! Many thought that the 1968 measurement must be wrong, but any impurities in the Pu would normally lead to a *larger* value, and the amount of diamagnetic impurities (e.g. ThO_2) to make the difference exceeded 10% and appeared unreasonable. Recently, this value of the experimental χ has been remeasured (Kolberg *et al.*, 2002) and found to be correct.

Earlier attempts by Goodman (Kern *et al.*, 1990) to question the crystal field scheme and develop a so-called strong coupling approach are still a possibility to explain these results (and those for CmO_2 as discussed below), but they have not yet been fully developed. More recently, Colarieti-Tosti *et al.* (2002) have reported on a first principles calculation of the crystal field scheme, and they

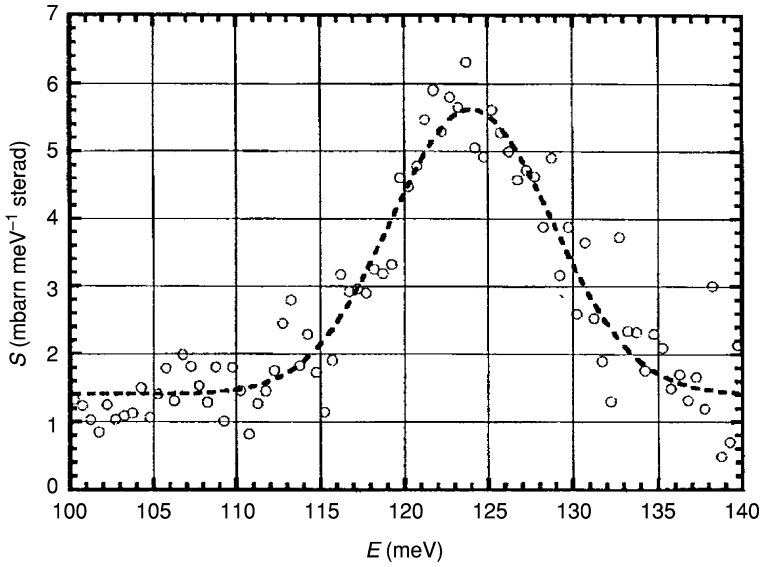

Fig. 20.18 *Neutron inelastic spectra from PHAROS of* 29 g *of* $^{242}PuO_2$ *at* $T = 30$ K. *The incident neutron energy was* 184 meV. *The resolution of the instrument is* ~4 meV *at these energy transfers, but the Gaussian fit gives a width of* 11 meV. *No other electronic signal was found between* 10 *and* 100 meV. *Figure reprinted with permission from Kern* et al. (1999). *Copyright* 1999 *by the American Physical Society.*

arrive at an energy separation $\Gamma_1 \rightarrow \Gamma_4 \sim 99$ meV, which is relatively close to the observed value of 123 meV. These authors went on to consider the discrepancy between the measured and calculated susceptibility, and they introduced the idea that there is an *antiferromagnetic* exchange interaction between the Pu^{4+} ions, mediated by the admixture of the actinide 6d states into valence band. Knowing that UO_2 orders antiferromagnetically, a rough value of the exchange parameter may be deduced, and then scaled to the case of Pu. The resulting calculations (demonstrated with other data in Fig. 20.19) are in good agreement with experiment, except that they show some curvature for $T > \sim 400$ K. It is still difficult to understand what appeared to be the amazingly uninteresting susceptibility of PuO_2 first measured in 1968.

Recently Kolberg *et al.* (2002) have suggested that the dynamical JT effect may play a role also in $(U,Pu)O_2$ materials, as discussed earlier for pure UO_2. Indeed, with this additional interaction agreement between theory and experiment might be possible. All this work shows that the complications in PuO_2 have, like those in the other oxides, now stretched over almost half a century. The broadening of the crystal field transition remains so far unexplained. However, a slight broadening of the excited Γ_4 state could either come from antiferromagnetic exchange or the dynamic JT effect.

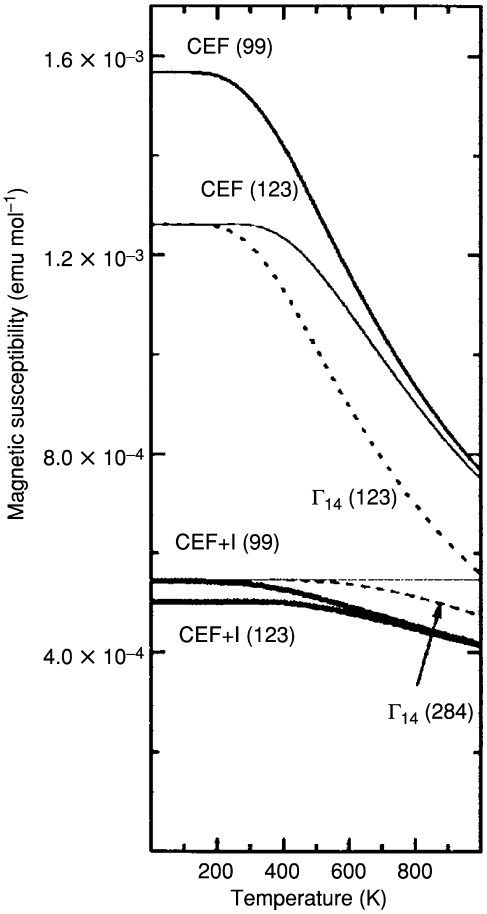

Fig. 20.19 *The magnetic susceptibility of PuO_2. The measurements are the T-independent straight dotted line. The calculated bare susceptibility with a single $\Gamma_1 \rightarrow \Gamma_4$ excitation energy of* 284 meV *fits the data at $T = 0$ and is shown as the dashed line labeled Γ_{14}* (284). *The corresponding bare susceptibility with $\Gamma_1 \rightarrow \Gamma_4 =$* 123 meV, *which fits the neutron experiment, is the dotted line labeled Γ_{14}* (123). *Adding additional CF transitions to the* 123 meV *model produces the improvement shown by the solid line labeled CEF* (123). *Similarly the CEF* (99) *line uses all the CF transitions with $\Gamma_1 \rightarrow \Gamma_4 =$* 99 meV. *The effect of using the antiferromagnetic molecular field deduced from that of UO_2 to enhance the bare susceptibility is given by the curves labeled CEF+I. Figure reprinted with permission from Colarieti-Tosti* et al. (2002). *Copyright* 2002 *by the American Physical Society.*

20.14.4 Americium dioxide

For the heavier elements starting with Am, experiments become really sparse. Am^{4+} in AmO_2 should have a ground $5f^5$:$^6H_{5/2}$ state, i.e. a Kramers' ion so that the degeneracy cannot be lifted by a crystal field interaction (the same as Np in

NpO_2). EPR studies of Am^{4+} doped into ThO_2 and CeO_2 establish the Γ_7 doublet as the ground state (Abraham *et al.*, 1971; Kolbe *et al.*, 1974) with a $g_{\text{eff}} = 1.27$. Karraker (1975a) has made susceptibility measurements (on a sample with 224 mg of ^{243}Am and a radiation field of $\sim$150 roentgen h^{-1} at the sample!) and found an effective moment of $1.31\mu_B$ at low temperature. Since $S = 5/2$, this gives $g = 0.44$ which is in excellent accord with the value for a $5f^5$ state when intermediate coupling is taken into account (Lander, 1993). With an effective spin of $S_{\text{eff}} = 1/2$, corresponding to the Γ_7 doublet, one obtains $g_{\text{eff}} = 1.51$, in reasonable agreement with the EPR work.

Karraker (1975a) also found clear evidence for a phase transition at $T_o = 8.5$ K. The susceptibility shows a peak and then decreases as the temperature decreases. This was puzzling at the time, as a Mössbauer experiment (Kalvius *et al.*, 1969) had found *no* evidence for any phase transition. Later, Boeuf *et al.* (1979) prepared another sample of $^{243}AmO_2$ and performed neutron scattering experiments at the Institute Laue Langevin in Grenoble. They observed no magnetic diffraction peaks below T_o in agreement with the Mössbauer results. No further experiments have been reported on the low-temperature properties of AmO_2 since 1979.

Of course, given what happens in the case of NpO_2 (the ordering of the quadrupoles) in a Kramers ion with an odd number of 5f electrons (Paixão *et al.*, 2002), it is easy to suggest that the same thing happens in AmO_2. This would make a really beautiful experiment with RXS, but one would need a single crystal, even if only of $\sim$20 μg.

20.14.5 Curium dioxide

With Cm^{4+} the ground state should be a $5f^6\ ^7F_0$ state. Since $L = |S| = 3$, there should be *no* sign whatsoever of magnetism, particularly in the susceptibility. The splitting to the first excited state is at $\sim$400 meV, so the susceptibility should be temperature-independent and small. The difficulty is that Cm^{3+} is more stable thermodynamically than Cm^{4+} so it is not difficult to imagine small amounts of Cm^{3+} in the CmO_2 matrix. Cm^{3+} has the $5f^7\ ^8S_{7/2}$ configuration and so it could contribute $\sim 7\mu_B$ of magnetism. Many early efforts on CmO_2 reported a sloping susceptibility, but in all cases it was expected that was a consequence of contamination with Cm^{3+}.

In 1986 Morss at Argonne set out to make stoichiometric CmO_2 from the rare isotope ^{248}Cm. This had the advantage that the radiation from ^{248}Cm is relatively small compared to the more abundant ^{244}Cm so that radiation damage and production of defects, which could convert Cm^{4+} into Cm^{3+}, were reduced. The sample ($\sim$55 mg) was then studied with neutron diffraction at the IPNS spallation source at Argonne. The small sample and the relatively modest flux at IPNS meant that the strongest powder diffraction peak in CmO_2 gave $\sim$1 ct min^{-1}, with a peak/background ratio of 0.6. (Part of the background came from the neutrons emitted from the ^{248}Cm sample itself.) Despite these difficulties,

Rietveld analysis was successful and gave a Cm:O stoichiometry of 1.97 (3), which is statistically insignificant from the stoichiometric composition (Morss *et al.*, 1989). The X-ray pattern from CmO_2 is, of course, totally dominated by the scattering from the Cm, so this is a good illustration of the power of neutrons, where the scattering from curium and oxygen have almost equal scattering lengths. In agreement with X-rays, no evidence of additional phases was found.

Susceptibility measurements were then made and showed, once again, a slope, which corresponded to $\mu_{\text{eff}} = 3.36\ (6)\mu_{\text{B}}$. More than 10 years have gone by since this work and no suggestion has been made to resolve the difficulty between simple crystal field theory (with a $^7F_0$ ground state) and the finite effective moment. However, taking the theory, developed for another *even* 5f electron material (Pu with four 5f electrons), can be utilized by assuming that the susceptibility is affected by the exchange and possibly also JT interactions as found in another even-f system, UO_2. Although $J = 0$, there is an S quantum number of 3 (6f electrons) and the spin state of Cm will give rise to antiferromagnetic exchange via coupling to the excited (magnetic) $J = 1$ state. Detailed calculations for this have not been made, but should be. Furthermore, this effect is not expected to give a constant μ_{eff} for all Cm^{4+} ions. The antiferromagnetic exchange passes through the actinide 6d states and their mixing with the oxygen p-states. This will change depending on the anions involved, for example it will be different for CmO_2 than CmF_4. More experiments on these materials would be interesting and should further increase our understanding of the interactions in the ionic actinide systems. As discussed in Section 20.8, Milman *et al.* (2003) performed density functional theory (DFT) calculations for Cm compounds and suggested that an itinerant magnetism model might be appropriate for CmO_2.

20.14.6 Summary of the magnetic properties of the actinide dioxides

Many physicists have been kept busy for the last half a century studying the properties of the actinide dioxides. Initially it was expected that the data would be relatively straightforward to analyze because of the very simple fcc structure. As happens frequently in actinide research, the trail has been tortuous, and in all cases there are still experiments to be done, although a general understanding of the ground state magnetic properties now appears reasonably sound. Neutron inelastic scattering has played an important role in establishing the crystal field interactions and showing that the earlier theoretical models were incorrect. The crystal field ground states are then perturbed by higher-order interactions, notably the quadrupolar ones, and this is a consequence of the aspherical nature of the 5f electron states. The effect is particularly apparent in NpO_2 ($5f^3$), in which the quadrupoles order at 25 K, presumably because of their interactions with the lattice, and there is *no* accompanying dipole ordering (at least down to 1.5 K). For the moment NpO_2 appears unique in this respect, but no doubt

other materials will be found; AmO_2 appears a good candidate. The interactions with the lattice are very strong for all the oxides, and give rise to a number of effects. Most notably, the Jahn–Teller interactions cause an internal *static* distortion in UO_2, but can be dynamic in nature as well (Sasaki and Obata, 1970). If the susceptibility of PuO_2 ($5f^4$) is reasonably well explained by the indirect exchange through the oxygen p-states (thus implying a measure of covalency in these materials), the situation in CmO_2 ($5f^6$) is more complicated. Perhaps some of the same arguments can be used, together with the JT effect, but it is still not possible to exclude the presence of Cm^{3+} ions in the compound, and these would give a large susceptibility term, as they are $5f^7$. The detailed exchange interactions (measured by neutron inelastic scattering on single crystals, Caciuffo *et al.*, 1999) in UO_2 still are not understood from first principles, illustrating the complexity of the interactions that occur in these oxides.

ABBREVIATIONS

AF	antiferromagnetic
bcc	body-centered cubic
BM (β)	Bohr magneton
^{t}Bu	^{t}butyl – tertiary butyl – $(CH_3)_3C$
CEA	Commissariat à l'Energie Atomique
CF	crystal field
cm^{-1}	wave numbers
Cp	cyclopentadienyl – C_5H_5
dhcp	double hexagonal close-packed
DFT	density functional theory
ENDOR	electron-nuclear double resonance
EPR or epr	electron paramagnetic resonance
Et	ethyl – C_2H_5 – CH_3CH_2
fcc	face-centered cubic
IPNS	Intense Pulsed Neutron Source
JT	Jahn–Teller
LO	longitudinal optic
Me	methyl – CH_3
meV	millielectron volts
mK	milli-Kelvin
NMR or nmr	nuclear magnetic resonance
RXS	resonant X-ray scattering
T_c	temperature below which superconductivity occurs
TIP	temperature-independent paramagnetism
T_N	Neel temperature

T_o	Temperature at and below which a magnetically ordered phase appears
XMCD	X-ray magnetic circular dichroism

UNITS

Two different energy units are used in this review depending on the discussion. The units are meV and cm^{-1}. The conversion between these units is as follows: (1 eV = 8065.479 cm^{-1}); (1 meV = 0.001 eV = 8.065 cm^{-1}); (1 cm^{-1} = 1.2399 × 10^{-4} eV or 0.12399 meV). It is useful to note that kT (where k is the Boltzmann constant) at 300 K = 25.85 meV = 208.34 cm^{-1}.

CHAPTER TWENTY ONE

5f-ELECTRON PHENOMENA IN THE METALLIC STATE

A. J. Arko, John J. Joyce, and Ladia Havela

21.1 INTRODUCTION

In this chapter, the properties of actinides in the metallic state will be reviewed with an emphasis on those properties which are unique or predominantly found in the metallic solid state. Such properties include magnetism, superconductivity, enhanced mass, spin and charge-density waves, as well as quantum critical points. An introduction to fundamental condensed matter principles is included to focus the discussion on the properties in the metallic state. Systematics of the actinide 5f electronic structure will be presented for elements, alloys, metallic, and semi-metallic compounds so as to elucidate the unique characteristics that arise from the properties of actinides and 5f electrons in a periodic potential.

There are two defining characteristics to materials in the metallic state: first, the material exhibits a periodic potential which controls much of the electronic structure, and second, there is a finite density of electronic states at the chemical potential which influences, among other properties, the thermodynamic and

transport characteristics. For the early actinide metals, these two characteristics are often manifested as narrow bands containing a substantial 5f electron component. Complexity in material properties often arises when competing or overlapping energy scales are available. In the metallic state, with a continuum of electron energy levels available, there is the possibility for interaction of charge with spin and lattice degrees of freedom. Because the actinides have an open 5f electron shell which, in the metallic state, often straddles the boundary between localized and itinerant character, the interplay between spin, charge, and lattice degrees of freedom leads to varied and interesting properties. In order to better understand the controlling role of the 5f electrons in the metallic state, one should look beyond the elements and beyond standard temperature and pressure. To elucidate the fundamental properties of 5f electrons in the metallic state, we consider the actinide elements at low temperature and high pressure. An additional dimension to the understanding of the 5f metals can be attained by considering the actinide elements in a metallic host matrix, e.g. alloys and compounds.

Atoms in a closely spaced periodic environment (crystalline condensed matter) experience an overlapping of outer electron shells with neighboring atoms. If the outer shells are open, then these electrons are shared between neighboring atoms and can travel from atom to atom through the periodic array. This sharing of electrons, a form of bonding, becomes the glue that holds the atoms together. In the crudest sense, this is the metallic state. Here attention is given to those atoms (materials) whose outer shell comprises an unfilled 5f shell, namely, actinide materials. A thorough treatment of the subject covers volumes (Kittel, 1963, 1971; Ziman, 1972; Ashcroft and Mermin, 1976; Harrison, 1980, 1999), so the overview presented here is cursory. The intent is primarily to cover those aspects of the metallic state that differentiate 5f electron systems from simpler metals containing only s, p, or d electrons, since many properties of 5f systems appear anomalous by comparison.

In the atomic and molecular configurations of f-electron materials, the highly directional nature of the f-orbitals plays a central role in the unique properties of the lanthanides and actinides. In the metallic state, however, it is widely accepted that it is the very limited radial extent of the 5f wave functions relative to the s, p, or d wave functions of the valence band that is at the heart of the exotic phenomena (consequently the 5f electrons are nearly localized), though the understanding of the actinides and their compounds is still incomplete. These metals and their compounds are among the most complex in the periodic table, displaying some of the most unusual behaviors relative to non-f systems, such as very low melting temperatures, large anisotropic thermal expansion coefficients, very low-symmetry crystal structures, many solid-to-solid phase transitions, exotic magnetic states, incommensurate charge-density waves, etc. Some insights can be gained by using the 4f series as a guide, but the comparison is limited since the radial extent of the 4f electrons is even smaller than that of the 5f electrons.

A comprehensive picture of actinides in the metallic state is slowly emerging. Many of the very unusual properties appear to be a direct consequence of the formation of extremely narrow 5f bands in which the electrons are not completely free. Rather, their motion is affected by the presence of neighboring 5f electrons. This differs from the lanthanide metals whose 4f electrons tend to be localized in atomic states except perhaps for Ce and Yb (Gschneidner and Eyring, 1993).

In recent years, there have been many advances in the theoretical capability to calculate the electronic structure of materials that form narrow bands. In particular, extensions to density functional theory (DFT) now allow the inclusion of some of the electron–electron interactions that previously were the exclusive domain of many-body physics. Yet even this approach often proves insufficient.

The problem of narrow bands or localization of electrons in an unfilled shell is strongly related to magnetic properties as well. However, there is a fundamental difference between band magnetism and localized magnetism. Although the electronic and magnetic properties of a material are related, the pervasiveness and sheer volume of unusual magnetic behavior observed in the 5f series suggest that they be treated separately.

21.2. OVERVIEW OF ACTINIDE METALS

The anomalous nature of the electronic properties of the 5f series of metals is apparent when considering the electrical resistivity, atomic volume (or equivalently the Wigner–Seitz radius), and a composite crystallographic phase diagram of the actinide metals through Cm. These physical properties are shown in Figs. 21.1–21.3. While these data have been presented on numerous occasions, they remain most illuminating, clearly showing a transition from itinerant (participating in bonding) behavior of the 5f electrons in the light actinides to localized (limited to an atomic site) behavior beyond Pu. It is the transition region that is least understood and where much of the anomalous behavior is centered.

Fig. 21.1 shows the electrical resistivity, ρ, as a function of temperature for the actinides through Cm (the last element obtained in sufficient bulk to allow such measurements). One immediately sees that the overall resistivity increases dramatically up to α-Pu (the low-temperature stable phase of Pu) and then begins to drop for Am. The α-Pu value of 150 $\mu\Omega$ cm ($\mu\Omega$ cm) is much higher than that of Cu (as a material with conventional metallic properties) where the room temperature value is of the order of 1 $\mu\Omega$ cm. The resistivity is intimately tied to the electronic structure of the material and several models ranging in complexity detail the relationship between resistivity and electronic structure. Within the free-electron model, ρ is related to the relaxation time τ of electrons

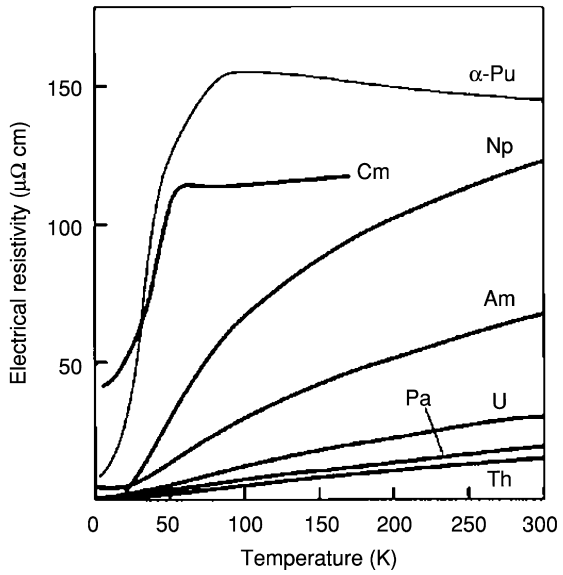

Fig. 21.1 *Electrical resistivity as a function of temperature between* 0 *and* 300 K *for the actinides metals Th through Cm* (*after Hecker,* 2001).

and mean free path defined as $\lambda = v_F\tau$, where v_F is the velocity of electrons at the Fermi surface, called Fermi velocity, by the relationship

$$\rho = m^*/Ne^2\tau \tag{21.1}$$

where m^* is the effective mass of electrons of charge e whose density is N. Clearly the mean free path of conduction electrons in 5f metals is very short and τ is the time between two scattering events compared to normal metals. It is shortest for α-Pu and begins to increase again with Am. Indeed, for α-Pu the mean free path of the conduction electrons is no more than the interatomic spacing. One can hardly call these free electrons.

Additionally, the α-Pu resistivity increases with decreasing temperature, an effect contrary to normal metals like Cu, while it appears relatively normal for Th through U. Such a negative temperature dependence is often associated with magnetic scattering of electrons (thus decreasing their mean free path) although experimental evidence indicates a lack of magnetism in Pu metal.

The Wigner–Seitz radius (Wigner and Seitz, 1933), or the equilibrium atomic volume of an atom in a metallic lattice, is likewise instructive, especially when compared to the volumes occupied by atoms in metals with an open 5d or 4f shell. Fig. 21.2 compares the Wigner–Seitz radius of the lanthanides and actinides with those of the 5d transition metals. It was shown by Friedel (1969) that the atomic volume should display a parabolic dependence with increasing atomic number Z as one fills an open shell of electrons involved in bonding

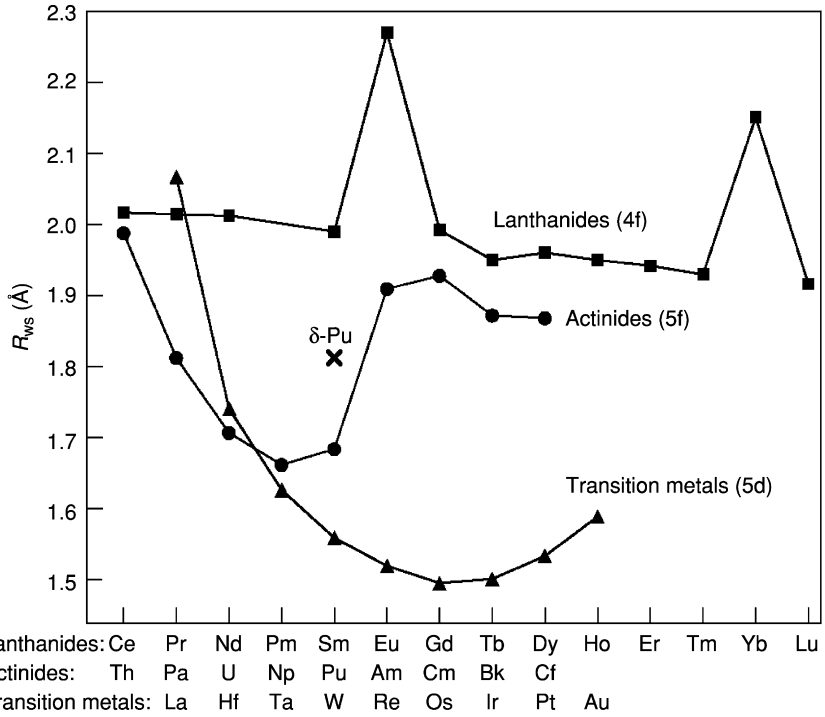

Fig. 21.2 *The Wigner–Seitz radius* (R_{WS}) *for the lanthanides, actinides and the* 5*d transition metal series. The transition metals show a parabolic dependence with bonding d-orbitals in accordance with the predictions of Friedel. The lanthanides display a nominally constant volume with non-bonding 4f states. The actinides show mixed character with Th through* α*-Pu on the bonding Friedel curve while Am–Cf look lanthanide-like with a non-bonding f-character* (*courtesy of Los Alamos Science*).

and conduction (i.e. the 5d electrons in Fig. 21.2). This is attributed to an increasing nuclear charge with its increasing Coulomb attraction, which is not completely screened by outer electrons shared by their neighbors, thus resulting in a volume contraction. But then, as the shell fills, the screening is again effective and the atom relaxes.

If, on the other hand, the outer electrons are instead localized as is the case of the 4f electrons in lanthanides, then the nuclear charge for each value of Z is effectively screened by the localized electrons, and the atomic volume remains unaffected as Z increases. This is clearly evident for the lanthanides in Fig. 21.2, except for Eu and Yb, exhibiting valency irregularities (the metals are divalent, not trivalent as the other lanthanides). The atomic volumes of early actinides appear to follow a parabolic curve up to the metal Np, suggesting 5f participation in bonding, but then begin to strongly deviate, behaving more like the

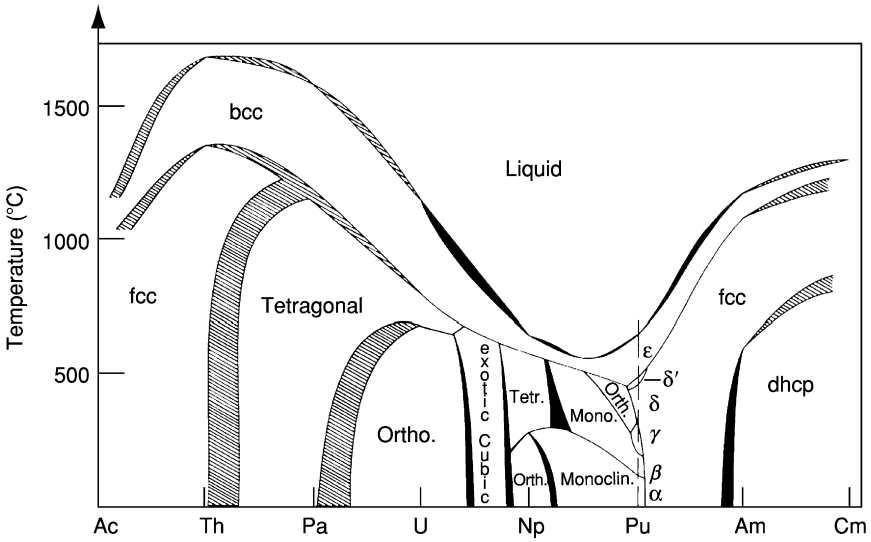

Fig. 21.3 *The binary phase diagram for the actinides Am through Cm showing the reduction in melting point and increase in complexity of the crystal structure and phases as the series moves from bonding (Ac–U) through localized (Am, Cm) with Pu having the lowest symmetry α-phase as well as the lowest melting point and six solid state allotropes (after Smith and Kmetko,* 1983).

localized 4f electrons beyond Pu (i.e. the atomic volumes remain relatively constant with increasing Z). It is as if there were two distinct 5f series: the first ending with Np and the second beginning with Am. In the intermediate region, the various phases of Pu are found, and also much of the correlated electron behavior of interest in this chapter.

The abrupt ending of the parabolic dependence of the equilibrium volumes of the actinides between plutonium and americium differentiates them from the lanthanides and the transition metals. But in addition, the transition metals and actinides also differ in their low-temperature crystal structures. The transition metals form close-packed, high-symmetry structures, such as hexagonal close-packed (hcp), face-centered cubic (fcc), and body-centered cubic (bcc), whereas the light actinides form at low temperatures low-symmetry, open-packed structures. For instance, protactinium forms a body-centered tetragonal (bct) structure, and uranium and neptunium form orthorhombic structures with two and eight atoms per cell, respectively. These data suggest that anomalous behavior already starts in the light actinides where many compounds of the light actinides display strongly correlated electron behavior (Ott and Fisk, 1987; Stewart, 2001).

The crystal structures, along with alloying information, are summed up in the composite phase diagram of Fig. 21.3 (Smith and Kmetko, 1983).

This phase diagram is composed of a series of binary phase diagrams of adjacent actinide metals from Ac to Cm plotted side by side (the x-axis between any two adjacent metals varies from 0 to 100% of the content of the heavier metal). The shaded areas having no crystal structure label represent areas of uncertainty.

In the early part of the series (between Ac and Th) structures are obtained somewhat similar to transition metals while beyond Am, typical structures of the rare earth metals are found. Indeed, it appears that beyond Am the anticipated 'second rare earth series' is obtained. In the region of Np and Pu, however, striking deviations from normal behavior are observed. The most obvious is the large drop in the melting temperature, reaching a value as low as 600°C near Np and Pu. Equally anomalous in this region, however, are the large number of allotropes, or solid-state crystalline phases. In fact, the actinides have the largest number of allotropes of any series in the periodic table. Also in this region one obtains the highest number of bonding f-electrons.

Many of these relevant parameters to actinide metals are captured in Table 21.1. Note the appearance of magnetism in the second rare earth series above Am, as well as the absence of many-body ordering phenomena in Pu and Np and the superconductivity in the light actinides (Am would nominally be magnetic if not for a fortuitous $J = 0$ ground state allowing for superconductivity). The occurrence of interesting electronic properties increases enormously as one changes from the pure actinide elements to actinide alloys and compounds.

Figs. 21.1–21.3 are entirely consistent with each other. The metallic radii are smallest at the crossover to localization, and as shown in Fig. 21.2, the low-temperature phases of the heavier actinides (beginning with americium) form dhcp structures. As in most metals, it is the bcc phase that forms prior to melting. However, the temperature range over which this phase is formed in the actinides is very small compared to transition metals and appears to be another signature of narrow bands, as described below (Wills and Eriksson, 2000).

A detailed description of the properties for Pu metal is presented in Chapter 7. Here the emphasis is on overall 5f electronic properties and their differences from simpler metals. To recognize these differences, a short discussion of free electron and condensed-matter behavior is presented. The papers by Boring and Smith (2000), and Wills and Eriksson (2000) serve as more detailed references and the main sources for this material.

21.3 BASIC PROPERTIES OF METALS (FREE-ELECTRON MODEL)

21.3.1 Formation of energy bands in simple metals

In general, most materials (metal or non-metal), when condensed in the solid state, form a crystalline array of repeating unit cells. Indeed, it is this repetition in space that allows for the mathematical determination of the electron wave

functions to within a phase factor. These cyclic wave functions are called Bloch states after Felix Bloch, who first introduced them (Bloch, 1928). The simplest elements, with a single outer electron, such as lithium or sodium, typically form cubic crystal structures at room temperature. The outer electrons from their atomic valence shells become conduction electrons traveling almost freely through the lattice. That is, these valence electrons occupy one-electron Bloch states, and they are therefore responsible for bonding in the solid.

A logical progression can be followed for band formation starting from the isolated atom, to molecules and finally, band formation and the formation of Bloch states in a metal. In the isolated atom, the electrons exist in a potential well with well-defined energy levels or states. The levels representing the outermost, or valence states, are responsible for bonding. Considering first the case of only two isolated atoms (i.e. molecular case), when two atoms are brought together, their outer electron wave functions (orbitals) overlap, and the valence electrons feel a strong electrostatic pull from both nuclei (typically depicted as a double-well electrostatic potential). The atomic orbitals combine to form molecular orbitals that may bind the two atoms into a diatomic molecule. The single atomic energy level splits into two allowed states: one lower in energy, or bonding, and the other higher in energy, or antibonding. The energy difference between these two levels is proportional to the amount of overlap of the two-electron atomic orbitals, and the molecular orbitals (wave functions) corresponding to the bonding and antibonding energy levels are the sum and difference, respectively, of the atomic orbitals.

If one generalizes to the case of N atoms brought close together to form a perfect crystal, the single valence electron now sees the periodic electrostatic potential due to all N atoms (where N is a number of order 10^{23}). The wave function (Bloch state) is now a combination of overlapping wave functions from all the atoms and extends over the entire volume occupied by those atoms. As in the molecular case, that wave function can be a bonding state or an antibonding state. The original atomic valence levels generalize to a band of very closely spaced energy levels, half of them bonding and half of them antibonding, and the width of the energy band is approximately equal to the energy splitting between the bonding and antibonding energy levels in the diatomic molecule. This broad band forms whether the crystal is an insulator, a metal, or a semiconductor, the metal being the case where the uppermost band is not completely occupied by the available electrons.

Because in a macroscopic sample the number of energy levels in the energy band is large (approximately 10^{23}, corresponding to the number of valence electrons in the crystal) and the spacing between these energy levels is small, the electron energies may be considered to be a continuous variable. The number of electron energy levels per unit energy is then described in terms of a density of states (DOS) that varies with energy. Because each electron must have a slightly different energy (the Pauli exclusion principle), electrons fill up

the energy levels one by one, in the order of increasing energy (in accordance with the Fermi–Dirac statistics). This concept will be detailed below.

21.3.2 Brillouin zones

A Bloch state, or the three-dimensional extended wave function of a valence electron in a solid, may be represented in one dimension by the valence electron wave function appearing at every atomic site along a line of atoms, but its amplitude is modulated by the plane wave $e^{i\boldsymbol{k}\cdot\boldsymbol{r}}$ where $\boldsymbol{k}$ is the momentum of the allowed state and $\boldsymbol{r}$ is the position vector. As mentioned before, this general form for a Bloch state in a solid emerges from the requirement of translational invariance. That is, the electron wave function in a given unit cell must obey the Bloch condition

$$u_k(r + \boldsymbol{T}_n) = u_k(r), \tag{21.2}$$

where $\boldsymbol{T}_n$ is a set of vectors connecting equivalent points of the repeating unit cells of the solid and u_k is the one-electron potential. The wave function must therefore be of the form

$$\Psi_k(r) = e^{i\boldsymbol{k}\cdot\boldsymbol{r}} u_k(r), \tag{21.3}$$

where a plane wave with wave vector $\boldsymbol{k}$ modulates the atomic wave function in a solid. The wave vector $\boldsymbol{k}$, or the corresponding crystal momentum $\boldsymbol{p} = h\boldsymbol{k}$, is the quantum number characterizing that Bloch state, and the allowed magnitudes and directions of $\boldsymbol{k}$ reflect the periodic structure of the lattice. Indeed, the momentum vectors $\boldsymbol{k}$ are related to the vectors of the unit cell in an inverse fashion. For example, if $\boldsymbol{T}_n$ is the vector in a unit cell in real space (e.g. along the [100] direction) which connects equivalent points, then the corresponding crystal momentum vector is $2\pi/\boldsymbol{T}_n$ which connects equivalent points in momentum space (i.e. a reciprocal lattice vector). The most basic periodic crystal unit is not necessarily the unit cell. Often a unit cell can be further reduced to a primitive cell, or a Bravais lattice, which defines the most basic repetitive unit. One can then derive a set of real space vectors that define a Bravais lattice. The inverse of these vectors defines the most basic repetitive unit in momentum space – the Brillouin zone. Energy bands are defined within this three-dimensional reciprocal, or momentum space having axes of k_x, k_y, and k_z. For a simple cubic unit cell, both the primitive cell in real space and its associated Brillouin zone are likewise simple cubic. Allowed energy band states, of course, can have a continuously varying set of momentum states, with the reciprocal lattice vectors being only a special set of crystal momenta defining the Brillouin zone boundaries along various high-symmetry directions. Within a solid, the periodic, crystalline symmetries replace the more common localized potentials of atoms and molecules. Also, the crystal momentum quantum numbers replace the usual orbital angular-momentum components. Within this framework, the metallic,

condensed matter properties of magnetism, superconductivity, enhanced mass, spin, and charge-density waves are quantified.

21.3.3 Complex and hybridized bands

The electronic structure gets more complicated in metals containing more than one type of valence electrons. A typical band structure for uranium metal (Wills and Eriksson, 2000) is shown in Fig. 21.4. Here the multiple overlapping bands are created when the conduction electrons in a solid originate from various s, p, d, and f valence orbitals of an atom. In general, the width of each band increases as the interatomic distance decreases and the overlap of the wave functions increases. Also, the s and p bands are always wider (span a wider energy range) than the d band, which in turn is always wider than the f band, reflecting the larger radial extent of the non-f wave functions. The overlapping bands in Fig. 21.4 portray a case where at a given value of $\boldsymbol{k}$ (a position vector in momentum space) one has wave functions of more than one orbital symmetry (angular momentum) but having nearly the same energy. This implies that the Bloch functions with a given quantum number (wave vector) $\boldsymbol{k}$ could be represented as a linear combinations of states originating from the s, p, d, and f atomic orbitals. In other words, the Bloch states could be 'hybridized' states containing many angular-momentum components, in contrast to atomic

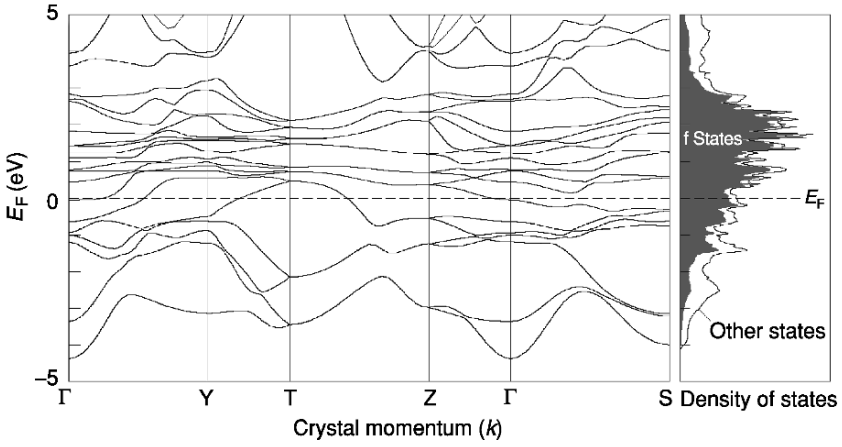

Fig. 21.4 *An electronic structure calculation for α-U metal including energy bands and the density of states. The DFT predictions for the energy bands* E(**k**) *are plotted along several different directions in the unit cell of the reciprocal lattice. The labels on the* **k***-axis denote different high-symmetry points in reciprocal space:* $\Gamma = (000)$, $Y = (100)$, $T = (111)$. *The narrow bands close to the Fermi level are dominated by the 5f levels. Some of the bands cross the Fermi level making α-uranium a metal. The shaded area for the density of states curve represents the 5f orbital contribution* (*courtesy of Los Alamos Science*).

orbitals that contain only one angular-momentum component. The angular-momentum mixture for a given band can vary from point to point in momentum space. Near $\boldsymbol{k}$-values where several bands are nearly degenerate one obtains a strong admixture, while for regions in $\boldsymbol{k}$-space where bands do not cross each other, the orbital symmetry of a band may contain only a single component. The dashed line in Fig. 21.4 is the Fermi energy (E_F) and separates the occupied from unoccupied energy levels.

The 5f states dominate the bonding primarily because there are three 5f electrons per atom and only one d-electron per atom occupying the Bloch states and participating in bonding. The narrow 5f band is referred to as the dominant band. Because narrow bands correspond to small overlaps of wave functions, these 5f band electrons may be easily pushed toward localization by various effects, in which case they do not contribute to bonding. Compared with the band widths of non-f metals, the actinide 5f bands are narrow and reflect the limited wave function overlap between f-orbitals on adjacent sites. The narrowness of the 5f bands and the proximity to the Fermi energy make the 5f bands central to understanding the actinide metallic state.

21.3.4 Density of states

A very useful concept to consider is the concept of the density of allowed energy states per unit energy interval. Recall that the allowed states in a band are not actually continuous, but are very closely spaced. Since each band of allowed states may contain two electrons from each atom (spin up and spin down), one can see that bands that disperse rapidly with energy will have fewer allowed states per unit energy interval than slowly dispersing or 'flat' bands. The right frame of Fig. 21.4 shows the DOSs resulting from the multiband structure on the left panel of Fig. 21.4. Note that the 5f states outnumber all the others at the Fermi energy E_F (see below for description). If an energy sub-band is filled (two electrons of opposite spin occupy all its energy levels), there will be no electron density at E_F and the solid is an insulator. If a band is only partially filled, the solid is a metal.

21.3.5 The Fermi energy and effective mass

Electrons, being spin-½ particles, obey Fermi statistics with the occupation of states occurring in order of increasing energy. The mathematical expression for Fermi–Dirac statistics is

$$f = 1/[\exp\{(E - E_F)/k_B T\} + 1]. \tag{21.4}$$

where k_B is the Boltzmann factor. The probability, f, for occupation of states at $T = 0$ is unity up to the Fermi energy, E_F, and zero above this energy. E_F is defined as the highest occupied energy state in a metal after all the electrons in a crystal (or in a box in the case of true free electrons) have been accounted for at

$T = 0$. As the atomic levels are filled up and the band states (i.e. the valence states involved in bonding) become occupied, the energy or momentum of a band electron from a particular atom is not precisely known. One only knows that it occupies one of the near continuum of allowed energies in a band and that the lowest states in a band must be occupied first.

In many elements (e.g. the alkali metals), the atom has only one electron to contribute to the uppermost or valence band. In that case, the uppermost band is unfilled (half filled for the alkali metals). More importantly, in the case of complex systems as shown in Fig. 21.4, the complexities introduced by the crystal structure and the subsequent hybridization result in an overlapping of valence bands, such that some states from a higher band actually lie below a lower one. This is clearly shown in Fig. 21.4 where the s–d bands cross the f-bands. In this case, the upper band begins to be filled before the lower one is fully occupied, so that, when all the electrons are exhausted, neither band is filled, and empty states exist just above E_F. The highest occupied energy (at $T = 0$ K) is E_F and the material is a metal because the electrons occupying the highest energy state have many empty allowed states in their vicinity into which they can scatter in order to travel throughout the crystal. By contrast, in the case of insulators where the uppermost band is fully occupied and there is an energy gap before the next band that is unoccupied, the Pauli exclusion principle prevents the occupation of states that already contain two electrons. Thus the electrons are not free to change states and move throughout the crystal unless they obtain sufficient energy to access an empty state beyond the energy gap between filled and empty states.

At finite temperature T, some electrons within k_BT below E_F can occupy empty states within k_BT above E_F. This is shown in Fig. 21.5 where the Fermi–Dirac distribution function has been convoluted with a model DOS. The probability of occupation of states below E_F is unity except within a few k_BT of E_F where some electrons can scatter into empty states within a few k_BT above E_F. Fig. 21.5 shows that electrons with binding energies higher than $(E_F - k_BT)$ contribute to the bonding, and only the narrow stripe just above E_F is responsible for the metallic behavior. Most of the properties of a metal (excluding magnetism) are determined by the band states within a few k_BT of E_F. The sudden drop in occupation is referred to as the Fermi edge. One immediately begins to see that densities of states whose width is of the order of k_BT will be dramatically affected by temperature. Of course, in complex systems electrons from more than one band and angular momentum are allowed to scatter into empty states. The substantive effects of the Fermi function are generally considered to occur within $\pm 2.2k_BT$ of the Fermi level. These values represent the 90% (below E_F) and 10% (above E_F) occupancy values for electron states at a finite temperature T.

Within the free-electron model (i.e. free-electron gas in a box) the energy is measured from the bottom of the free-electron band parabola. The electron energy dispersion is

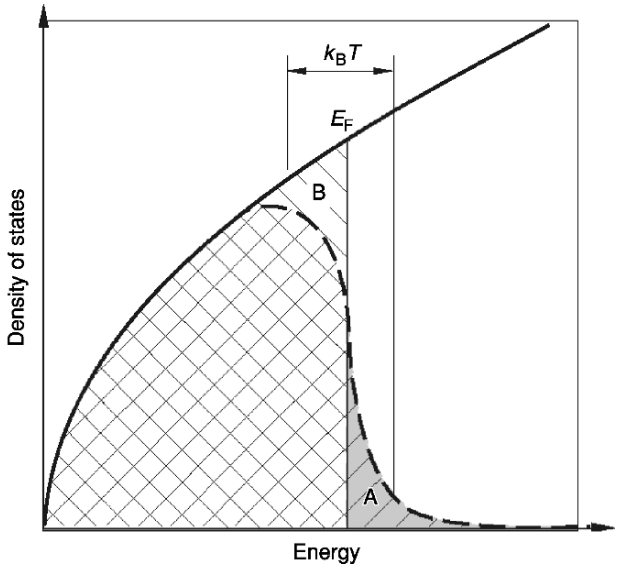

Fig. 21.5 *The solid line is the density of states for a free-electron gas plotted as a function of one-electron energy. At* T = 0, *electrons occupy all the states up to the Fermi energy* E_F. *The dashed curve shows the density of filled states at a finite temperature* T. *Only electrons within* k_BT *of the Fermi level can be thermally excited from states below the Fermi energy* (*region B*) *to states above that level* (*region A*) (*courtesy of Los Alamos Science*).

$$E = (\boldsymbol{p})^2/2m^*, \tag{21.5}$$

where $\boldsymbol{p}$ is the momentum and m^* is effective mass of the electron. The uppermost filled level is at the Fermi energy and is given by $E_F = (\boldsymbol{p}_F)^2/2m^*$, where $\boldsymbol{p}_F$ is the momentum of this uppermost level. Here E_F essentially corresponds to the bandwidth of the occupied states. If one then takes a repetitive box (i.e. a crystal lattice) one fulfills the requirement of periodicity, so that a free-electron parabola exists in each box – or Brillouin zone. The parabola from each Brillouin zone may extend through many other adjacent zones so that the resulting band (reduced or folded back into the first zone by virtue of periodicity) can be very complex. Nonetheless, in the case of alkali metals and other simple metals the bandwidth definition of the Fermi energy is still often used. The crystal momentum is zero at the center of the reciprocal lattice where $k = 0$. In a complex band system such as shown in Fig. 21.4, this definition loses some of its meaning. Nonetheless, if one adheres to this definition, one may define the Fermi temperature, $T_F = E_F/k_B$, as well as the Fermi velocity, $v_F = [2E_F/m^*]^{1/2}$. The use of m^* rather than m_o is appropriate in the formula because even the periodic crystal potential has some effect on the effective mass. Indeed many of

the properties of the free-electron model can be transferred to real material systems by substituting m^* for m_o.

The effective mass is essentially a measure of the interactions (correlations) that slow down (sometimes even speed up) the electron motion. Because of electron–electron interactions $\boldsymbol{v}_F$ can be smaller for a given $\boldsymbol{p}$, sometimes much smaller, than predicted by free-electron theory. It is as if the electron were much heavier than a free electron. Formally,

$$m^* = \hbar/(\mathrm{d}^2E(k)/\mathrm{d}k^2), \tag{21.6}$$

where $E(k)$ is a band that crosses the Fermi level and the derivative is evaluated at the Fermi level. It is easy to see that a very slowly dispersing or nearly flat band (this is obviously no longer a free-electron parabola) will have a much larger m^* than a rapidly varying band such as is found for s- and p-electrons where the wave function overlap is large. Correlations can be viewed as effectively resulting in a flattening of the bands at the Fermi edge.

21.3.6 Fermi surface

If one draws the energy band states in three dimensions defined by the crystal momentum $\hbar\boldsymbol{k}$ (in Fig. 21.4 they are shown in one dimension along a major symmetry axis) and connects all the points where each band crosses E_F, then these points trace out a surface in momentum space (or $\boldsymbol{k}$-space) known as the Fermi surface. In the free-electron model, each state on the Fermi surface corresponds to an electron having a constant absolute value of Fermi momentum $|\boldsymbol{p}_F|$ with kinetic energy given by the free particle formula above. In the case of a free-electron parabolic band, the Fermi surface is essentially a sphere, provided that the Fermi momentum $\boldsymbol{p}_F$ exists within the first Brillouin zone. If it extends into the next zone, one may still simply reconstruct the Fermi surface from a lattice of overlapping spheres. Again, in complex systems where several bands of differing angular momentum and bandwidth cross the Fermi energy, the topology of the Fermi surface can become extremely complex, one cannot use the simple bandwith definition of the Fermi energy, and $\boldsymbol{p}_F$ must be defined for each band.

The topology of the Fermi surface can be experimentally determined by means of de Haas–van Alphen (dHvA) oscillations. While a complete description of this effect is far beyond the scope of this chapter, qualitatively this is a measurement of the oscillatory diamagnetic susceptibility. For metal single crystals at low temperatures in the presence of a changing magnetic field, B, the diamagnetic susceptibility is influenced by B because the presence of B imposes an additional quantum condition on the free-electron orbits. The energy states of the electrons in the allowed orbits are called Landau levels, and these change with changing B. Without going into detail, the changing Landau levels (as B is varied) induce oscillations in the susceptibility, the frequency of

which (proportional to $1/B$) is directly related to the cross-sectional area of the Fermi surface in momentum space. By measuring the oscillations for differing directions of B, one can reconstruct the topology of the Fermi surface. Furthermore, by measuring the amplitude of the oscillations as a function of temperature, it is possible to determine the m^* of the orbiting electrons.

21.3.7 Electronic heat capacity

For a gas of free particles heated from absolute zero to a temperature T, classical statistical mechanics would predict that, on the average, the kinetic energy of each particle would increase by an amount $k_B T$. But because of the Pauli exclusion principle, the electrons obey Fermi–Dirac statistics and only those conduction electrons occupying states within $k_B T$ of the Fermi level E_F can be heated (by phonon scattering) because only they can access states not occupied by other electrons (see Fig. 21.5). The number of electrons that participate in properties such as electrical conduction and electronic heat capacity decreases to a fraction T/T_F of the total number of conduction electrons in the metal. At room temperature, T/T_F is about 1/200 in most metals. Thus, replacing the classical Maxwell–Boltzmann statistics with the Fermi–Dirac quantum statistics implied by the exclusion principle has a profound impact on the electronic properties of metals.

The factor T/T_F shows up explicitly in the low-temperature specific heat of a metal. In general, the specific heat is the sum of a lattice-vibration term (proportional to T^3) and an electronic term γT, which is due to the thermal excitation of the electrons. The classical coefficient of the electronic term is $\gamma = Nk_B$ (where N is the number of conduction electrons) but because of the exclusion principle, it becomes

$$\gamma = 2Nk_B T/T_F, \tag{21.7}$$

and only electrons near the Fermi energy can be excited. Thus, in simple metals obeying the free-electron model, γ is inversely proportional to T_F, or equivalently, E_F, and therefore proportional to m^* (see above), or to the density of electronic states at the Fermi level, $N(E_F)$. The prefactor 2 represents two possible spin directions.

A common unit of γ is (mJ mol^{-1} K^{-2}) and the value is about 1 for a typical free-electron metal like Cu. In strongly correlated actinide materials, values as large as 1000 have been observed. Here electrons behave more like strongly interacting particles of a liquid, e.g. more like a Fermi liquid. Because of interactions, m^* increases and shows an increase in the value of γ over that predicted by the free-electron model. Thus, low-temperature specific heat measurements reveal the strength of the electron–electron correlations in a metal and therefore provide a major tool for identifying unusual metals.

21.3.8 Electrical resistivity

For free electrons the resistivity ρ is given by equation (21.1). In a perfect crystal, electrical resistance would be zero near the classical $T = 0$ limit because the non-interacting conduction electrons, acting as waves, would move through the perfect lattice unimpeded. Above $T = 0$, the thermal excitations of lattice vibrations (phonons) affect the lattice periodicity and thus scatter the Bloch waves which depend on periodicity. Near $T = 0$, in the absence of strong electron–electron (e–e) interactions and impurities, $\rho(T)$ increases as T^5, while at higher temperatures $\rho(T) = AT$, where A is a constant. In general, anything that destroys the perfect translational invariance of the crystal lattice will scatter electrons. This is reflected in the mean free path of electrons, λ, the distance traveled by electrons between scattering events (see equation (21.1)). Foreign atoms, lattice vacancies, more complicated defects such as stacking faults, and finally, magnetic moments in an array without the full symmetry of the lattice can scatter electrons since they destroy the periodicity. Many of these imperfections are temperature-independent and lead to a finite limiting resistance as $T = 0$ is approached, called the residual resistance or ρ_0. Hence, this limit is used as a measure of the quality of metal samples, for which the lowest ρ_0 signifies the most perfect sample. It has been shown that correlated electron materials (and actinide metals in particular, see Fig. 21.1) often have anomalously high $\rho(T)$ and ρ_0 despite very small or zero magnetic moments at low temperatures. For systems with a high $N(E_F)$, strong electron–electron scattering gives rise to a term aT^2, where the prefactor a reflects the e–e correlations so that a/γ^2 is approximately constant for various materials.

21.3.9 One-electron band model

It has been shown that even a free-electron model for a periodic system yields a relatively complex band structure. The periodic potential actually introduces gaps at the Brillouin zone boundaries, and, depending on $\boldsymbol{p}_F$ relative to the zone boundaries, the Fermi surface can be very complicated. To obtain the band structure in materials with several valence electrons having more than one type of angular momentum requires substantial calculations. However, the problem of dealing with 10^{23} electrons can be reduced to a one-electron problem by assuming that an electron sees only an averaged potential between the ions and the remaining electrons, and that this periodic electrostatic potential can be modeled in a self-consistent fashion.

Slater first proposed calculating the electronic states, the energy bands in Fig. 21.4, of solids by the same self-consistent method that had been applied so successfully to describe the electronic states of atoms and molecules (Slater, 1937). In this method, one treats electrons as independent particles and calculates the average Coulomb forces on a single electron. The equation for the one-electron states is essentially the time-independent Schrödinger equation,

$$(T + V_{\text{eff}})\psi_{\text{i}}(\boldsymbol{r}) = E_i\psi_i(\boldsymbol{r}) \tag{21.8}$$

where T is a kinetic energy operator (e.g. $-\hbar^2\nabla^2/2m$ in a non-relativistic approximation and ∇ is the derivative with respect to position, V_{eff} is the average effective potential, and E_i are the eigenstates. The other electrons and all the ions in the solid are the source of these Coulomb forces on one electron and give rise to the V_{eff}. This calculation, repeated for all the electrons in the unit cell, leads to a charge distribution

$$n(r) = \Sigma|\psi_i(\boldsymbol{r})|^2 \tag{21.9}$$

from which a new electrostatic potential seen by the electrons can be obtained as a solution of the Poisson equation. Using the new electrostatic potential, one then repeats the calculations for each electron until the charge density (distribution of electrons) and the crystal potential (forces on the electrons) have converged to self-consistent values. Slater's approach led to all the modern electronic band structure calculations commonly labeled one-electron methods. These one-electron band-structure methods are adaptations of the familiar Hartree–Fock methods that work so well for atoms and molecules. They were put on a more rigorous footing through Kohn's development of DFT. Unlike the genuine Hartree–Fock method, the non-local part of electron–electron interaction is treated less formally, but it includes the long-range screening, unimportant for simple molecules but prominent in the electron gas.

Once a metal is formed, its conduction electrons (approximately 10^{23} per cubic centimeter) can act collectively, in a correlated manner, giving rise to what is called quasiparticle behavior (not determined by averaged electrostatic forces) and to collective phenomena such as superconductivity and magnetism. These phenomena are outside the scope of the independent electron model, which cannot accommodate all the electron–electron interactions found in the actinide series. Many-body interactions do not readily lend themselves to reduction to an average potential. Nevertheless, great strides have been made toward including correlations into the one-electron picture. In particular, DFT described below can incorporate the concept of exchange as well as Coulomb correlation. These electron correlations are described in the next section.

21.3.10 Electron–electron correlations

Electrons in a crystal are simultaneously attracted to the ions and repelled from each other via Coulomb repulsion. To minimize the total energy of the system, the electrons must minimize the electron–electron repulsion while maximizing the electron–ion attraction, and the way to minimize the Coulomb repulsion is for them to stay as far from each other as possible. In calculations on the helium atom it was found that: first, the two He electrons are indistinguishable – that is, electron 1 can be in orbital A or B, and so can electron 2; second, the electrons have to obey the Pauli exclusion principle, which means

that the total wave function for the two electrons has to be antisymmetric, and that antisymmetry implies that the Hamiltonian must contain an exchange term. This exchange term determines the probability that two electrons of the same spin can exist near each other. It is what separates the Hartree–Fock calculations of many-electron atoms from the original Hartree calculations of those atoms.

When the exchange term was included in the calculation of an electron gas, it was found that around each electron, there is a 'hole', or depression in the probability of finding another electron close by. Indeed, this probability was found to be one-half the value it would have without the exchange term. This exchange hole demonstrates that the electron motion of the two electrons is correlated with each other, in the sense that electrons with the same spin cannot get close to each other.

In the 1930's, Wigner performed similar calculations for electrons of opposite spins, which led to a 'correlation' hole (very similar to the exchange hole) for the probability of finding an electron of opposite spin near a given electron (Wigner, 1934). The picture of an exchange hole and a correlation hole around each electron is a great visual image of electron correlations in solids. Modern one-electron calculations include these correlations in an average way because these terms can be calculated from the average electron density around a given electron. The cost in energy of putting two electrons on the same site is referred to as the Coulomb correlation energy.

Several theories will be considered in this chapter that include interactions beyond the one-electron method, these approaches are termed correlated-electron theory. Likewise, any solid (metal, insulator, and so on) that exhibits behavior not explained by either the free-electron model or the one-electron band model is considered a correlated-electron system. If the properties of a solid deviate strongly from the predictions of free-electron or band models (e.g. heavy fermions), that solid is called a strongly correlated system. While many actinide metals and compounds fall within this group, still many others can be described as weakly correlated systems that are quite tractable within the one-electron approach.

21.3.11 Density functional theory

This section concludes with a brief description of DFT, a one-electron band structure approach which includes both exchange and correlation, and which has been very successful in describing weakly correlated systems. Two common variants are used: the local density approximation (LDA), which expresses the exchange and correlation potential, $E_{xc}(n(\boldsymbol{r}))$, as a function of local electron density, while the generalized gradient approximation (GGA) includes, in addition to these terms, the gradient of $n(\boldsymbol{r})$ as well. Formally, as in the Slater approach, the starting point for DFT calculations is the time-independent Schrödinger equation (similar to equation (21.8) above).

One would, in principle, calculate the ground-state (lowest-energy configuration) total electronic energy from

$$H\psi(\boldsymbol{r}_1, \boldsymbol{r}_2, \ldots \boldsymbol{r}_n) = E\psi(\boldsymbol{r}_1, \boldsymbol{r}_2, \ldots \boldsymbol{r}_n)\,, \tag{21.10}$$

where H is the Hamiltonian containing the kinetic energy and all the interactions of the system (i.e. electron–electron correlation and exchange and electron–nuclei interactions) and $\boldsymbol{r}_1$,$\boldsymbol{r}_2$,... $\boldsymbol{r}_n$ are the n position vectors. However, in the most generalized form $\psi(\boldsymbol{r}_1$,$\boldsymbol{r}_2$,... $\boldsymbol{r}_n)$ is now a many-electron wave function of the n-electron system, and E is the total electron energy of the entire system in the ground state. The input parameters in equation (21.10) are the atomic numbers of the atoms and the geometry of the crystal (the lattice constant, the crystal structure, and the atomic positions). From the solution of this equation, one should, in principle, be able to calculate the equilibrium crystal structure, the cohesive energy, as well as the band structure. Unfortunately, there is no practical way to solve equation (21.10) for a solid.

To get around this problem, Hohenberg and Kohn (1964), Kohn and Sham (1965), and Dreitzler and Gross (1990) pointed out that the total energy of a solid (or atom) may be expressed uniquely as a functional of the electron density (equation (21.9) (i.e. $E = E[n(\boldsymbol{r})]$ just as E_{xc} above). This function can be minimized in order to determine the ground-state energy. Therefore, instead of working with a many-electron wave function, $\psi(\boldsymbol{r}_1$,$\boldsymbol{r}_2$,... $\boldsymbol{r}_n)$, one can express the ground-state energy in terms of the electron density at a single point (as in equation (21.9)), where that density is due to all the electrons in the solid.

In addition, Hohenberg and Kohn (1964), Kohn and Sham (1965), and Dreitzler and Gross (1990) demonstrated that, instead of calculating the electron density from the many-electron wave function, one may work with the solutions to an effective one-electron problem (equation (21.8)). The method uses the form of the total-energy functional to identify an effective potential $V_{\mathrm{eff}}(r)$ as described above for one-electron states, and then to solve for the one-electron states to produce a density equal to the many-electron density. To account for the relativistic effects in actinides, it is necessary to replace the non-relativistic Schrödinger-like one-electron equation (equation (21.8)) by the relativistic Dirac equation. By finding the correct form for the effective potential, the electron density in equation (21.9) will be the same as that required by DFT.

The one-electron problem defined by equation (21.8) has the same form as the equations solved by band theorists before DFT was invented, and the eigenvalues of those equations as a function of crystal momentum are precisely the energy bands. The contribution of DFT is to provide a rigorous prescription for determining the new effective potential and for calculating the total ground-state energy, $E[n(\boldsymbol{r})]$.

The total energy functional within DFT is given by

$$E[n(\boldsymbol{r})] = T[n(\boldsymbol{r})] + E_{\mathrm{H}}[n(\boldsymbol{r})] + E_{\mathrm{xc}}[n(\boldsymbol{r})] + E_{\mathrm{eN}}[n(\boldsymbol{r})] + E_{\mathrm{NN}}, \tag{21.11}$$

where T is the effective kinetic energy of the one-electron states obtained from equation (21.9), E_{H} is the usual classical Hartree interaction between an electron and a charge cloud, E_{eN} is the interaction between an electron and nuclei, and E_{NN} is the inter-nuclear Coulomb interaction. The important term is E_{xc}, which is the one part of equation (21.11) that goes beyond the classical Hartree term obtained from the expression

$$E_{\mathrm{xc}}[n(\boldsymbol{r})] = \int n(\boldsymbol{r})\varepsilon_{\mathrm{xc}}(n(\boldsymbol{r}))\mathrm{d}\boldsymbol{r}. \tag{21.12}$$

This term represents the difference between the true energy of the eigenstates and the one-electron eigenstates. The operator of exchange-correlation $\varepsilon_{\mathrm{xc}}[n(\boldsymbol{r})]$ represents the sum of the exchange term $\varepsilon_{\mathrm{x}}(\boldsymbol{r})$ plus the correlation term $\varepsilon_{\mathrm{c}}(\boldsymbol{r})$.

The new (and presumably more correct) effective potential can now be obtained from the relationship

$$V_{\mathrm{eff}}(\boldsymbol{r}) = \delta/\delta n(\boldsymbol{r})[E_{\mathrm{H}}(n(\boldsymbol{r})) + E_{\mathrm{xc}}(n(\boldsymbol{r})) + E_{\mathrm{eN}}(n(\boldsymbol{r}))]. \tag{21.13}$$

With this new potential, the problem again reduces to a one-electron problem by substituting this potential into equation (21.8). From these definitions, it is clear that the effective potential in which the electron moves has contributions from the electron's interaction with the nuclei and the other electrons in the solid both by the classical Hartree term and by the quantum mechanical exchange and correlation terms.

Because all electron–electron interactions that go beyond the classical Hartree term are found in $E_{\mathrm{xc}}[n(\boldsymbol{r})]$, it is crucial to have a good approximation for this term. Unfortunately, there is no exact form of this term for a real solid. However, if one assumes the functional to be local, a numerical form may be obtained from many-body calculations (quantum Monte Carlo or perturbation series expansion), and very good values may be obtained for the ground-state energy for different values of the electron density. If the electron density of a real system varies smoothly in space, one expects that a form of E_{xc} taken from a uniform electron gas should be applicable to the real system as well. This approximation is none other than the LDA. The good agreement, for many solids, on cohesive energy, equilibrium volume, and structural properties between this approximate theoretical approach and experimental values suggests that the LDA form of E_{xc} works even if the electron density varies rapidly in space.

Thus, the total ground-state energy can be obtained by solving an effective one-electron equation. This tremendous simplification of replacing interacting electrons with effective one-electron states will work only if one can find the correct, effective one-electron potential. Good approximations can be obtained for $\varepsilon_{\mathrm{x}}(\boldsymbol{r})$ and $\varepsilon_{\mathrm{c}}(\boldsymbol{r})$ as determined by comparisons between the thus calculated band structures and experimental band structures measured by optical properties and photoelectron spectroscopy (PES).

21.4 GENERAL OBSERVATIONS OF 5f BANDS IN ACTINIDES

21.4.1 Narrow 5f bands

It is correct to say that the short radial extent of the 5f wave function yields only a small overlap between electrons from neighboring atoms and that this in turn results in very narrow 5f bands. Nevertheless, if the atomic spacing were sufficiently small, the overlap would be significant, as it is for 5f metals up to α-Pu. Why then does one not get a continuation of the actinide contraction (see Fig. 21.2) if the 5f electrons are involved in bonding?

Boring and Smith (2000) in their review argue that it is the presence of non-f bands at E_F (i.e. the 6p, 7s and to some extent the 6d bands), which contributes a repulsive force to the interatomic bonding forces (i.e. the s, p, d electrons with their larger radial extent, begin to repel each other at much larger distances). This is shown in Fig. 21.6 where the atomic-sphere approximation is used to calculate the contributions to bonding from individual bands for Pu (for

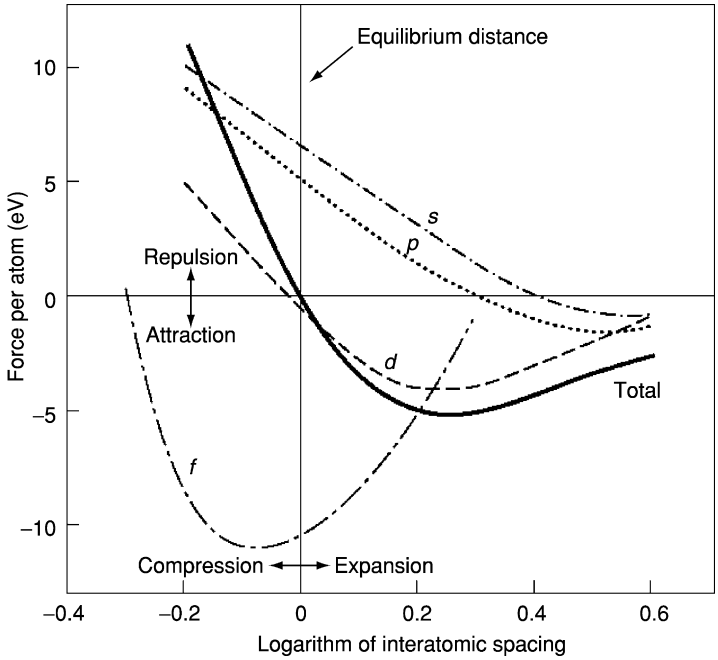

Fig. 21.6 *The force per atom as a function of interatomic spacing. DFT predictions for the bonding curves of δ-Pu in the fcc structure are plotted vs the interatomic spacing* $x = \ln(a/a_0)$. *Included are the curve for the total cohesive energy per atom, and the individual contributions from the s, p, d, and f states. The f band is narrow at this larger volume* (*courtesy of Los Alamos Science*).

simplicity, in the fcc phase) as a function of interatomic spacing. For any single band, the calculated equilibrium spacing is that at which the interatomic forces on the atom are zero – i.e. where the calculated curve crosses the horizontal zero line.

From Fig. 21.6, one can see that if plutonium had only an f-band contribution, its equilibrium lattice constant would be smaller than that found. The f-band would be wider, and Pu would stabilize in a high-symmetry crystal structure. In reality, the contribution from the s–p band (a repulsive term at true equilibrium) helps to stabilize plutonium at a larger volume; the f-band is narrow at that larger volume, and the narrowness leads to the low-symmetry crystal structure. This argument is universal for multiband metals. In the transition metals, the s–p band is repulsive at equilibrium and leads to slightly larger volumes than would be the case if these metals had only d bands. For metals above Pu the repulsive force of the s–p bands is sufficient to prevent additional lattice contraction. The additional f-electron is no longer involved in bonding and it becomes energetically favorable for the entire f-subshell to localize. Another factor to the total energy balance is the correlation energy of electrons localized in atomic 5f states. The system gains the 5f bonding energy by the 5f delocalization, but as the electrons in atomic states can be better correlated than in band states, part of the correlation energy is lost.

In actinide compounds the whole range of narrow band behavior is observed, from transition-metal-like to localized. The existence of non-actinide atoms in compounds immediately yields a larger An–An separation so that a greater tendency toward localization is expected even in uranium compounds. This is in fact the case.

21.4.2 Low-symmetry structures from 5f bands

Fig. 21.3 shows a large number of low-symmetry crystal structures among the actinide metals. Actinide compounds, especially the more strongly correlated materials, show the same tendencies. It has long been assumed (at least for the pure metals) that it is the directional nature of the 5f bonds which leads to the low-symmetry structures. In recent years, the charge density for several actinides using the full-potential DFT method has been calculated. For elemental actinides up to Pu, no dominant directional 5f bonds have been found and, most importantly, no charge buildup between atoms (Söderlind *et al.*, 1995). What, then, is the driving force for the numerous transitions and low-symmetry allotropic phases? A general reason can be seen in the narrow 5f bands themselves. There exists a high density of 5f states at or near E_F so that a lowering of the electronic energy can occur through a Peierls-like distortion (Merrifield, 1966). The original Peierls distortion model was demonstrated in a one-dimensional lattice. It was shown that a row of perfectly spaced atoms can lower the total energy by forming pairs (or dimers). The lower symmetry causes the otherwise degenerate electronic energy levels to split, some becoming lower

Table 21.2 *Typical energies of the various interactions characterizing the localized picture of magnetism for ions with 3d, 5f or 4f unfilled shells.*

Interaction	3*d* (meV)	5*f* (meV)	4*f* (meV)
coulomb (U)	1000–10000	1000–10000	1000–10000
spin–orbit (Δ_{S-O})	10–100	300	100
crystal field (CF)	1000	100	10
exchange	100	10	1
bandwidth (W)	4000–10000	700–5000	<500–2000

and others becoming higher in energy. The lowered levels are occupied by electrons, and therefore the distortion increases the bonding and lowers the total energy of the system. In the one-dimensional system, the distortion opens an energy gap at the Fermi level and makes the system an insulator. However, in the higher dimensional systems, the material can remain a metal in spite of the distortion because there are Bloch states from other bands that fill this gap.

In real three-dimensional lattices, the energy levels are degenerate along high-symmetry directions. If those levels lie close to E_F, a Peierls-like distortion of the crystal (i.e. a lowering of the symmetry) would increase the one-electron contribution to bonding, just as in the one-dimensional case described above. The Peierls mechanism is particularly effective if there are many degenerate levels near E_F, that is, if the energy bands are narrow, the DOS is large, and a large energy gain results from the distortion and filling of the lowered bands. Materials with broad bands (wider than 4 eV), gain less energy from level splitting because there are fewer levels near E_F. Indeed, symmetry-lowering distortions are rare in these materials. This is the dominant mechanism in cases where the energy is not lowered by other mechanisms removing part of the high-density states from the vicinity of E_F (magnetic ordering, superconductivity). In Table 21.2, a list of interaction energy ranges is given which highlights the types of interactions that are relevant in the actinides as well as the lanthanides and transition metals. The table shows Coulomb, spin–orbit, crystal field, exchange and bandwidth parameters. In the actinides, the large values and overlapping energy ranges for the interactions make the electronic structure calculations (and understanding) challenging.

21.4.3 The Hill plot

A very informative look at the effect of An–An spacing, and hence the effect of bandwidth, is provided in Fig. 21.7. This figure shows the transition temperatures for various uranium compounds, both magnetic and superconducting, plotted as a function of An–An spacing. Superconducting or magnetic-transition temperatures are plotted vertically, and the spacing between the f-electron elements is plotted horizontally. Hill first presented these results in the early

1970s (Hill, 1970) and found similar results for many different actinides and lanthanides. However, the presentation of data for uranium compounds yields much of the necessary information. Although some of this discussion pertains to magnetism, it is nevertheless presented here owing to its association with narrow 5f bands.

Fig. 21.7 shows that the crossover from itinerant to localized electrons can clearly be achieved if the actinide atoms are spread out. The most important aspect of Fig. 21.7 is the observation that a very limited number of magnetic uranium compounds are found with actinide spacing (in this case U–U) of less than about 3.4 Å. Inasmuch as magnetism is generally associated with more localized electrons, one may surmise that the 5f bandwidths for An–An separations smaller than 3.4 Å become too broad to support magnetism. Indeed, at these separations one may obtain direct f–f overlap. In Hill's initial plot, the known behaviors fell into only two of the four quadrants – large spacing correlated with magnetism and short spacing with superconductivity. Hill originally conjectured that the f-electrons could hybridize only with f-electrons at

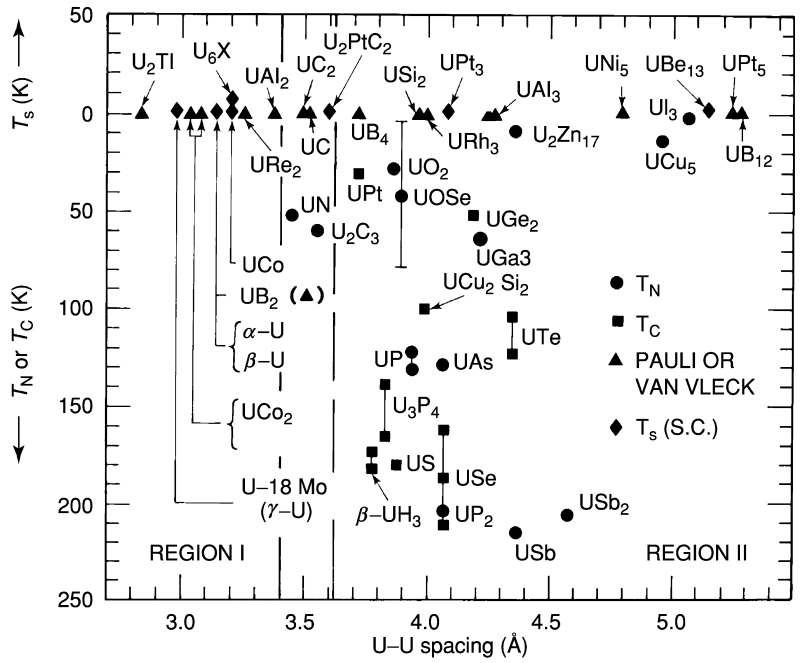

Fig. 21.7 *The 'Hill' plot for uranium compounds shows the interactinide spacing against a transition temperature* (*magnetic or superconducting*). *It is a general observation that magnetism is favored with the U–U spacing greater than 3.4Å while non-magnetic ground states are common below the separation. For uranium compounds, this distance roughly defines the localized/itinerant boundary for 5f states* (*after Hill*, 1970).

other sites and that the intervening non-f-electron atoms were just spacers to change the degree of overlap between the f-electron wave functions. Hill's plot became a major step toward understanding the light actinides, but it is now clear that the situation is more complex.

Fig. 21.7 depicts many more materials than were plotted in Hill's initial version. A large number of materials with large separations are now known to be non-magnetic. The existence of superconducting compounds is also found which, based on the relatively large distance between two f-electron atoms, should be magnetic. Two such compounds, namely, UPt_3 and UBe_{13}, are plotted in Fig. 21.7. They belong to a class of materials known as heavy-fermion superconductors first discovered in $CeCu_2Si_2$ (Steglich *et al.*, 1979) and later discovered in UBe_{13} (Ott *et al.*, 1983) and UPt_3 (Stewart *et al.*, 1984) setting off a period of intense research in heavy fermion and unconventional superconductivity research.

To understand the existence of non-magnetic compounds despite the large An–An separation, the concept of hybridization described in Section 21.3.3 above is utilized. It is not necessary to have direct f–f overlap of wave functions to produce relatively broad f-bands. Hybridization produces relatively wide f-bands that are broadened by the admixture of other symmetry components (the spd bands). It was shown by Koelling *et al.* (1985) that the lobes of the f-wave function allow the $AuCu_3$ simple cubic structure to be particularly amenable to hybridization with p- or d-bands along certain high-symmetry directions. Most materials having this structure are non-magnetic. Another observation is that for compounds in which the ligand atom contributes a high d-density at E_F, one generally obtains a strong f–d hybridization and a suppression of magnetism.

However, it is not true that the 5f-electrons are necessarily localized in compounds that are magnetic. Only one binary intermetallic compound (UPd_3) has been shown to exhibit true localized behavior of the 5f electrons. In nearly all other compounds, the hybridization with ligand sp bands is weak and leads to narrow band magnetism. In the case of extremely weak hybridization, one obtains the heavy-fermion compounds, among which those that have a superconducting transition (e.g. UPt_3 and UBe_{13} in Fig. 21.7) are very likely unconventional superconductors (Ott and Fisk, 1987).

21.5 STRONGLY HYBRIDIZED 5f BANDS

From the above Hill plot (Fig. 21.7), it is evident that many uranium compounds (and other actinide compounds also, particularly with Th and Pa, that are not shown in Fig. 21.7) have the characteristics of simple transition metals. This is true for the pure metals Th, Pa, and U as well (Np and α-Pu are questionable owing to a dearth of microscopic measurements). This class of materials is considered first. Because the pure metals are difficult to obtain in

single-crystal form, the compound UIr_3 will be considered as representative for this class of materials.

21.5.1 Fermi surface measurements in UIr_3

The $AuCu_3$-type compounds were perhaps the most extensively studied within the actinide group in the early years. They form readily (the phase often forms congruently from the melt and thus allows for very pure single crystals) which is just one more indication of strong bonding. UIr_3, like many of its isostructural materials, displays a large but temperature-independent paramagnetic susceptibility (of the order of 10^{-8} m^3/mol), thus indicating no localized magnetic moments. Its resistivity (linear with T at high temperatures) is of the order 20 $\mu\Omega$ cm at 300 K, which is again large but not when compared to Pu. It does, however, indicate that even in these relatively simple metals, one obtains some correlated electron behavior, not explained by the free-electron model.

In the 1970s, Koelling and coworkers calculated the electronic structure of UIr_3 as well as other U compounds using DFT, and found excellent agreement with experiment (see Arko *et al.*, 1985). Fig. 21.8 shows the measured de Haas–van Alphen frequencies (proportional to the extremal cross-sectional areas of the various pockets of the Fermi surface) for various directions of the magnetic field along symmetry lines. These are superimposed on dHvA frequencies calculated from the DFT band structure (solid lines) along the same symmetry directions. The agreement is phenomenal, especially when one considers that many of the refinements of DFT were not yet available in the early 1970s. Both the calculated Fermi surface volume and the topology are experimentally reproduced (Arko *et al.*, 1985).

It has been assumed that the Fermi surface remains unaltered in the presence of electron–electron correlations from what it would be in the absence of such interactions (Luttinger theorem; Luttinger, 1960). Thus, under this supposition, calculating the Fermi surface correctly is no proof of the validity of DFT. However, the Luttinger theorem states that only the Fermi surface volume is preserved, since the number of quasiparticle (defined below) states corresponds to the number of free-electron states. The topology, on the other hand, might be allowed to change if bands at the Fermi energy are altered by the interactions. Calculating the correct topology from DFT would suggest that the correlations are relatively weak and their effects have been included. In the case of UIr_3, this appears to be the case. This conclusion is reinforced by the observation that the measured m^* values do not exceed five times m_0. Recall that m^* is a rough measure of the electron–electron correlation strength.

21.5.2 Background on photoemission measurements

Since the dHvA effect only probes the states near E_F it is useful to consider other measurements that probe the electronic structure at higher binding energies. Perhaps the most direct such measurement is PES. In its simplest form this

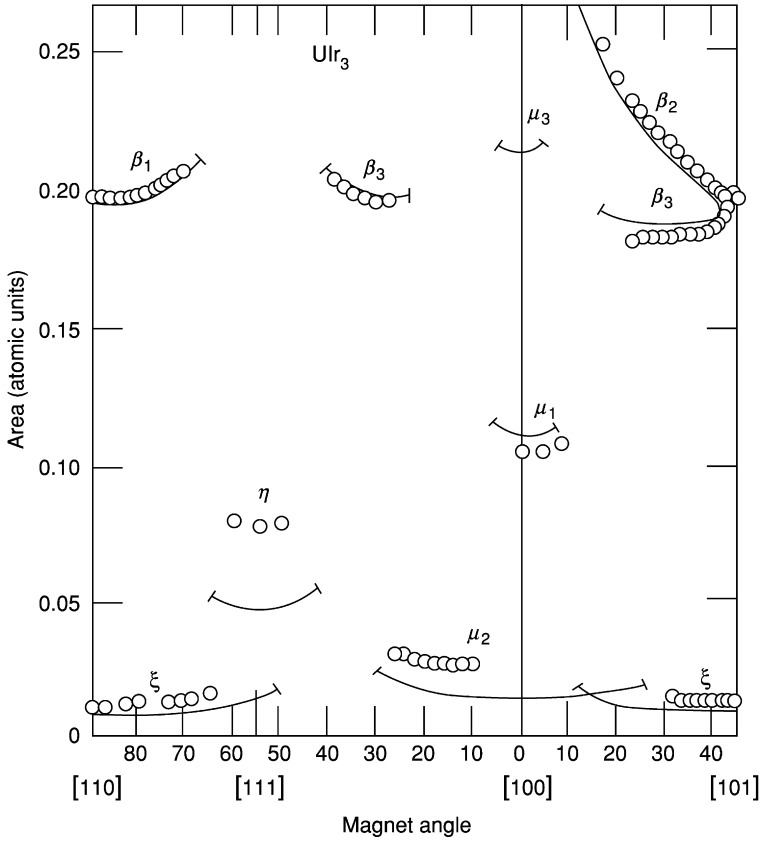

Fig. 21.8 *de Haas–van Alphen results indicating extremal areas for the Fermi surface of* UIr_3. *The open circles are the experimental data and the solid line is the DFT calculation. The agreement between experiment and theory is quite good over a large portion of the crystal structure* (*after Arko* et al., 1985).

measurement assumes that when an electron in quantum state $\boldsymbol{k}$ and energy eigenvalue E_k absorbs a photon and is ejected from the solid, the measured binding energy, E_B, is

$$E_B = E_{B,k} = -E_k \tag{21.14}$$

and the spectral function is a delta function at $E = -E_{kv}$ (i.e. absorption occurs at E_B and not elsewhere). This is referred to as Koopmans' theorem or the sudden approximation. For a non-interacting free-electron gas, this approximation seems reasonable. Even in the presence of small interactions, the above rule holds to a good approximation. However, in an interacting system, there occurs

a relaxation in the (N–1) electron solid and the relationship no longer holds. It becomes necessary to renormalize E_k by adding a correcting self-energy term $\Sigma(k,E)$ (Louie, 1992).

Assuming small corrections by measuring both the kinetic energy in vacuum, E_{Kin}, and angle θ of the outgoing electron (θ is measured relative to the surface normal), it is possible to determine both the energy and the momentum of the electron prior to the absorption of the photon; i.e. its energy state in the metal. The relationship is given by $E_{\mathrm{Kin}} = h\nu - E_{\mathrm{B}} - \phi$, where E_{Kin} is as above, $h\nu$ is the photon energy, E_{B} is the binding energy (or E_k) of the electron, and ϕ is the work function, or the energy lost in exiting the surface of the sample. The momentum components parallel and perpendicular to the sample surface are given by:

$$k_{||} = (\sqrt{2mE_{\mathrm{Kin}}})\sin(\theta), \quad \text{and} \quad k_{\perp} = (\sqrt{2mE_{\mathrm{Kin}}})\cos(\theta). \tag{21.15}$$

Since a photon does not change the direction of electron motion, the momentum information is preserved on photon absorption (so-called direct transitions). Indeed, as the electron exits through the sample surface, $k_{||}$ is preserved. An excellent reference for photoemission is the volume edited by Kevan (1992).

It is possible to determine electron momentum, $\boldsymbol{k}$, and map out the $E(\boldsymbol{k})$ vs $\boldsymbol{k}$ dispersion – i.e. the band structure by selectively sampling only electrons emitted in a narrow range of angles θ and measuring their energy. This is the so-called angle-resolved photoemission spectroscopy (ARPES). On the other hand, if the measurement accepts all electrons with a wide range of θ into the spectrometer, this will integrate over all momenta and yield, to a first approximation, the DOS. This is referred to as angle-integrated photoemission, or PES.

An important variation of PES is the so-called resonant photoemission. In simplified form, the data are taken at two photon energies: at the Fano resonance and at the Fano anti-resonance (Fano, 1961). The resonant energy roughly corresponds to a core level binding energy (in the case of U, $h\nu = 98$ eV, which is nearly the binding energy of the $5d_{5/2}$ core level). At this photon energy, the 5f photoemission cross section is greatly enhanced, while at the anti-resonance ($h\nu = 92$ eV for U), the 5f emission is strongly suppressed. By subtracting a PES spectrum taken at $h\nu = 92$ eV from one taken at $h\nu = 98$ eV one obtains the PES emission due to 5f electrons only. To a first approximation, this allows the measurement of the 5f DOS. Clearly this is a powerful tool. A fine reference for actinide photoemission is the chapter by Naegele *et al.*, (1985).

21.5.3 Photoemission in UIr_3

The ARPES measurements on UIr_3 is shown in Fig. 21.9 (Arko *et al.*, 1983). Most of the experimental data points ($E_{\mathrm{B},k}$) fall on top of the calculated bands, the notable exception being the experimental band labeled 'e' (see below). Since this data was obtained on a first generation synchrotron at 300 K with

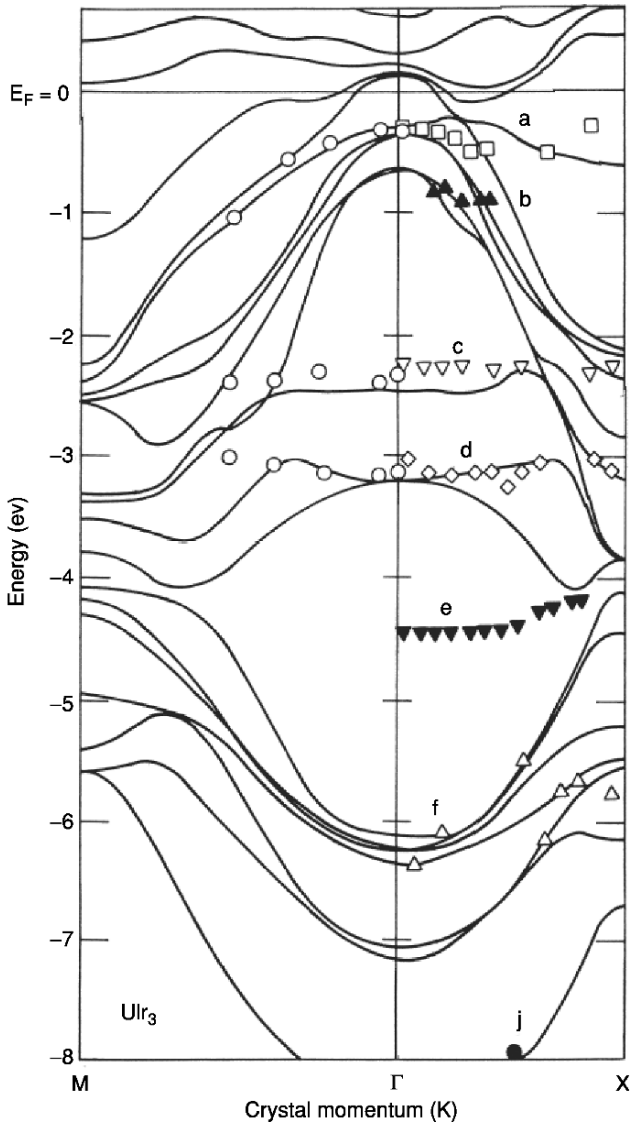

Fig. 21.9 *ARPES measurements and comparison to DFT calculations for* Uir_3. *The experimental data are the symbols and the calculation is represented by the solid lines. The agreement between experiment and theory is again quite good. The synergy between ARPES and DFT calculations is obvious in this comparison between the experimental and computational* E(**k**) *diagrams* (*after Arko* et al., 1983).

resolution no better than 200 meV, the agreement between experiment and theory is quite good. High-resolution low-temperature data would clear up the details at E_F, but from the data above the calculated bands at E_F are correct.

The 5f DOS is obtained by the resonance photoemission measurement described above (Arko *et al.*, 1983). Fig. 21.10 shows the calculated 5f DOS in UIr_3 as well as the measured result labeled 5f PES (dashed line). Although there appears to be a problem with intensity, it is necessary to consider that the 5f photoemission cross section varies with binding energy. If the 5f photoemission cross section is convoluted with the calculated 5f DOS, nearly perfect agreement with experiment is obtained. Thus UIr_3 (and the analogous compound URh_3) are simple band-like materials.

A vexing problem is band 'e' in Fig. 21.9, which has all the characteristics of a satellite. It is situated in a large gap in the calculated bands so that it is unlikely to be reproduced by DFT even with today's refinements. It was initially

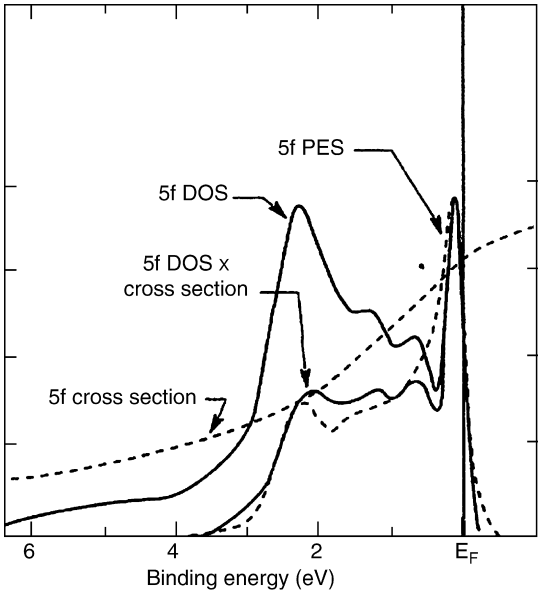

Fig. 21.10 *The calculated density of electronic states for UIr_3 compared against resonance photoemission. The resonance PES strongly enhances the 5f character in the spectrum. By separating the 5f component of the density of states in the DFT calculation, a direct comparison is made between experiment and theory. When the theoretical 5f DOS is modulated by the 5f cross section as a function of binding energy before comparison to the resonance photoemission, the results again show very good agreement between experiment and theory.*

attributed to Umklapp processes (translations by a reciprocal lattice vector, Arko *et al*., 1985). While this may yet prove to be the case there is a possibility that it is due to correlations that are not contained within the DFT calculation. Band 'e' suggests that despite the general agreement with DFT, there is more to the story. It suggests electron correlation effects that are not strong enough to result in a renormalization of the band structure. While satellites are common in core level and atomic spectra, DFT is unable to account for such essentially final-state effects. By contrast, Fermi liquid theory, because of its different approach to weak correlations, yields a satellite as a natural consequence of the incoherent part of quasiparticle (see below) spectral weight (Kevan, 1992). Although band 'e' is not assigned to the incoherent part of the 5f spectral weight (it appears to be at a very high binding energy), this point is considered because of its applicability to more strongly correlated systems considered later.

21.6 WEAK CORRELATIONS – LANDAU FERMI LIQUID

Prior to the development of DFT, Landau (1957) argued that electrons in the conduction band act as if they were nearly free even though the individual electrons are subject to strong Coulomb forces. Landau's idea was based on the effect of the electrons' correlated motions from mutual interactions in the solid. The electrons tend to 'clothe' themselves, so as to screen their charge (the details are complex and involve the entire system). These 'clothed' electrons were called 'quasiparticles'. Based on properties of strongly interacting electrons at the Fermi level, Landau showed that the system of strongly interacting electrons can be remapped onto a system of weakly interacting quasiparticles, which preserve some characteristics of electrons such as spin, momentum, and charge, while other quantities like the mass are renormalized. The consequence is that expressions known from weakly interacting electrons and describing temperature dependences of magnetic susceptibility, electrical resistivity, and specific heat preserve the same analytical form, while only prefactors are renormalized by the interactions. In mathematical terms, E_k is renormalized, as above, so that $E_k^1 = E_k^0 + \Sigma(k, E)$, where E_k^0 is the free particle eigenvalue, and $\Sigma(k,E)$ is the self-energy term with real and imaginary components. For the weakly interacting Fermi liquid, $\Sigma(k,E)$ can be parameterized in the form

$$\Sigma(k, E) = \alpha E + \mathrm{i}\beta E^2 \tag{21.16}$$

The general effect of $\Sigma(k,E)$ on photoemission (see Kevan, 1992 for a complete derivation) is to yield a spectral function (for E_k^1) consisting of a coherent part called the quasiparticle peak, and an incoherent part which can, in a loose fashion, be associated with a satellite resulting from a relaxation of the (N–1) particle system. A schematic of such a spectral function is shown in

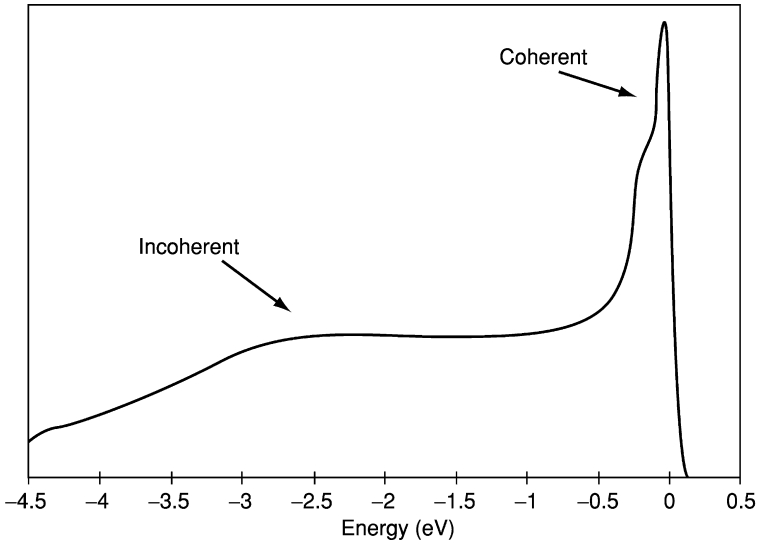

Fig. 21.11 *A schematic representation of a photoemission spectrum within a correlated electron description of the system. The coherent portion of the spectrum would represent the well-defined quasiparticle character described by Landau's Fermi liquid theory, and the incoherent portion would represent emission not consistent with such well-defined quasiparticles. The self-energy which contains all of the interactions beyond the one-electron picture may represent both a shift in energy and a broadening from the one-electron states.*

Fig. 21.11. In atomic spectra such satellites are referred to a shake-up satellites. The strength of the incoherent peak increases with increasing interaction strength. For the weakly interacting Fermi liquid it can be shown that the coherent part of E_{k}^{1} (the position of the quasiparticle peak) is given by

$$E_k^1 = E_k^0(1-\alpha)^{-1}. \tag{21.17}$$

The resolution at E_{F} in Fig. 21.9 is insufficient to draw conclusions regarding E_{k}^{1}, but it is possible that the very weak band "e" can be associated with the incoherent part of E_{k}^{1}.

It is useful to look at the signature that a Fermi liquid has on electrical resistivity. The net effect of the correlations is to contribute a quadratic temperature term to the resistivity at low temperatures; i.e., $\rho(T) = aT^2$ where a is a constant. If the interaction is sufficiently strong, this term, due to electron–electron interactions, will dominate over the weak T^5 term at very low temperatures. At higher temperatures, of course, the usual linear term may be expected. Fig. 21.12 shows plots of resistivity vs temperature for several actinide

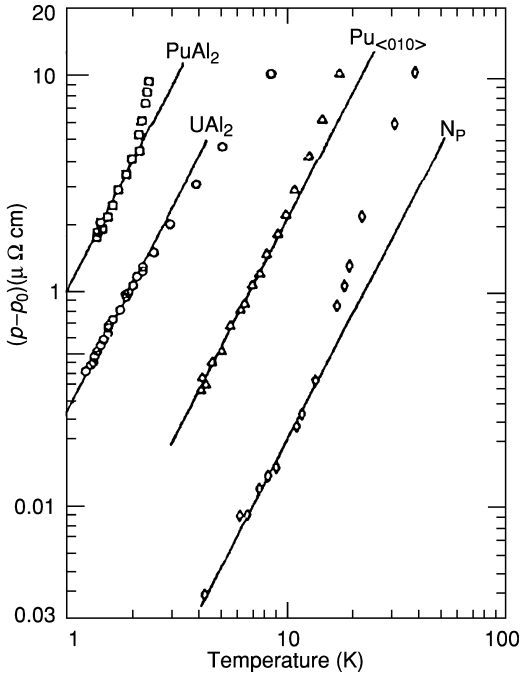

Fig. 21.12 *Resistivity for Np, Pu, $PuAl_2$, and UAl_2 as a function of temperature. The T^2 dependence of the resistivity clearly places these materials in the Fermi liquid category of metals. At higher temperatures, additional effects beyond the electronic contributions begin to have a substantial role in the resistivity* (*after Arko* et al., 1972).

systems where clearly the T^2 term is dominant. The T^2 term persists in strongly correlated systems so that all compounds are considered Fermi liquids if they display a T^2 rise in resistivity at low temperatures.

21.7 STRONG CORRELATIONS

21.7.1 Heavy fermions

Perhaps the most interesting compounds in the actinide series are the so-called heavy-fermion compounds. In general, these are very narrow band materials on the verge of localization whose conduction 5f electrons behave as if they had an extremely heavy effective mass. Indeed they blur the distinction between itinerant and localized states, making it seem as if there was a continuous transition. Fully localized electrons, with their definite energy levels, can be thought of as belonging to an infinitely narrow band and having an infinite effective mass

since they are unable to travel beyond the bounds of their atomic site. The effective masses of heavy-fermion materials, by contrast, range from tens to hundreds of times the mass of a typical itinerant electron in normal metals, indicating a very low but finite velocity through the crystal.

The unusual collective ground states of heavy fermions arise from very strong electron correlations involving the electrons in their narrow bands, and their low-energy excitations are associated with the spin and charge fluctuations in that narrow band. Of the light-actinide metals, only δ-Pu might be associated with heavy-fermion behavior, and even here there is room for debate. It is the large An–An separation in compounds that results in the narrow bands, particularly when hybridization is weak. Recent experiments on the phonon dispersions by inelastic X-ray scattering for delta phase Pu (Wong *et al.*, 2003) demonstrate the unique nature of Pu and the complex interactions involving electron-phonon coupling in this material.

Heavy-fermion behavior was first discovered in Ce compounds having one 4f electron; in particular, $CeCu_2Si_2$. Despite their magnetic susceptibility that at high temperatures suggested magnetic behavior, the susceptibility became temperature-independent at the low-T end and the material exhibited a superconducting transition with an extremely large specific heat anomaly. Subsequently similar behavior was observed in materials having 5f electrons, initially UPt_3 and UBe_{13}. This was most unusual since it was assumed that nearly localized electrons cannot even conduct electricity, much less support superconductivity. It slowly became clear that a new ground state of matter existed, one in which electron interactions were so highly correlated that only an extreme quasiparticle picture could cause that behavior. More specialized information on heavy fermion (both actinide and anomalous lanthanide) systems can be found in reviews of Grewe and Steglich (1991) and Nieuwenhuys (1995).

The unusual bulk properties of UBe_{13} are displayed in Fig. 21.13. The behavior of specific heat C_P at low temperatures, particularly the extremely large C_P/T ratio (in normal metals it is of the order 1 mJ mol^{-1} K^{-2}) points to an m^* perhaps on the order of 1000 and is also reflected in the large superconducting anomaly. Note that the low-temperature state of heavy fermions can be superconducting, antiferromagnetic, or simply paramagnetic. In all cases, however, as shown for UBe_{13} in Fig. 21.13, the magnetic susceptibility (plotted as $1/\chi$ in Fig. 21.13) exhibits Curie–Weiss behavior at high temperatures, but then levels off or even decreases at low temperatures. The upper critical field is extremely high, reaching a value of 6 T at 0.4 K. A most unusual property is the electrical resistivity, ρ, which has a negative temperature dependence down to about 10 K, and then drops precipitously.

Although there remains disagreement as to the nature of this ground state, the most widely accepted model is the so-called single impurity model (SIM). The origins of the SIM stem from the theory used for transition metal impurities in a noble metal matrix, a true impurity scenario. The model was extended to f-electron systems and later to situations where the 'impurity' nature of the

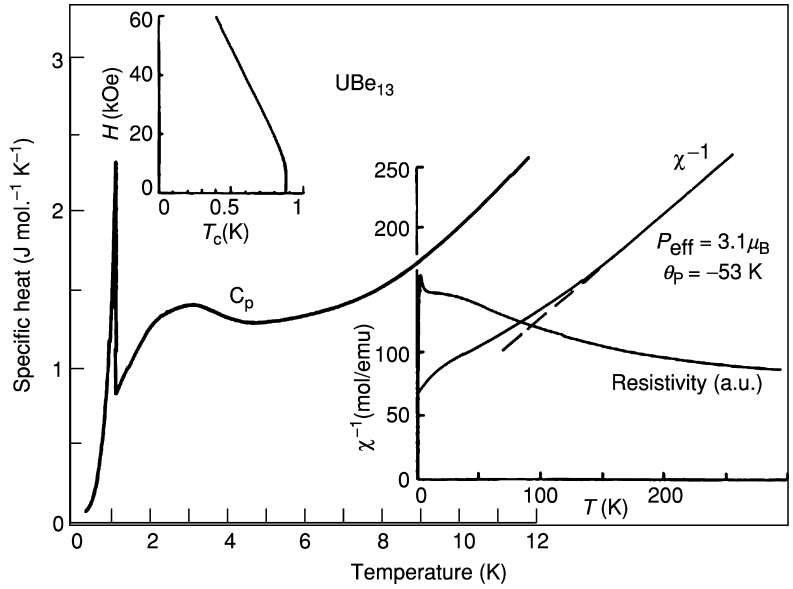

Fig. 21.13 *The thermodynamic properties (magnetic susceptibility, specific heat, and magnetic field dependence of* T_C*) of the heavy-fermion–superconductor* UBe_{13} *are plotted against temperature. The superconducting transition just below* 1 K *is clear from the specific heat while the anomalous resistivity and susceptibility for a metal are plotted on a much larger temperature scale showing the heavy-fermion nature of* UBe_{13} *(after Fisk* et al.*,* 1985).

problem was far exceeded. This model presumably strictly applies to Ce compounds having only one f-electron, but the similarities of properties in all heavy fermions suggest that one model might qualitatively apply to all. Attempts to compensate for the SIM shortcomings in the area of periodicity have given rise to extensions of the original idea in a periodic array with the Kondo lattice and Anderson lattice being two such models. A more detailed description of these models and predictions may be found in Arko *et al.* (1999). The description given here is for completeness and due to the lack of a more comprehensive model.

Within the SIM picture, the 4f or 5f electrons behave at high temperatures as if they were localized magnetic impurities at binding energy ε_f (sometimes called the bare f-level), having no interaction with each other or non-f electrons. As the temperature is lowered, however, they do hybridize slightly with the remaining non-f conduction electrons via a Kondo-like interaction whereby the conduction electrons align antiparallel to the f spin in order to screen the magnetic moment. The hybridization strength Δ is generally small. When the moment is fully screened, the susceptibility becomes independent of T. At still lower temperatures, this cloud of conduction electrons, which through hybridization has acquired a small amount of f-character, forms a coherent

ordered array (Kondo and Anderson lattice models) and a very narrow f-band at the Fermi energy. The amount of f-character at the Fermi energy is $(1-n_f)$ where n_f is nearly unity and represents the f-character remaining in the localized f-state at ε_f – the bare f-level. Essentially, $\Delta(1-n_f)$ is the probability that a conduction electron will occupy an already occupied f-level. A very loosely defined characteristic temperature, the Kondo temperature or $T_K = \Delta(1-n_f)/k_B$, approximates the onset of coherence. Indeed, most properties of heavy fermions in principle scale with T_K.

The SIM more or less successfully explains the bulk properties shown in Fig. 21.13. The heavy mass arises from the screening cloud and associated spin fluctuations, the negative $\rho(T)$ from the scattering from localized impurity moments, and the precipitous drop in ρ is due to coherence. However, there are numerous unresolved problems even for Ce compounds, among which is the fact that the approximations of SIM are only valid for n_f near unity (Arko *et al.*, 1999), whereas n_f values as low as 0.5 have been erroneously ascribed to heavy fermions.

Since the bare 5f-level, essential to SIM, has never been clearly observed in actinide compounds, Fig. 21.14 portrays instead photoelectron spectra of $CeBe_{13}$, having a T_K of 400 K in order to elucidate some of the problems. The near-E_F peak in the figure has been associated with the f-density acquired by the conduction electrons (the Kondo resonance), while the feature near -2.5 eV has been associated with the bare f peak. Despite its crucial importance to the validity of SIM, an unconventional temperature dependence has never been established for the near-E_F peak. The problem remains unresolved in large part due to the difficulty of the measurement and is outside the scope of this chapter. Instead the focus is on only one of the many discrepancies with SIM, namely the $\boldsymbol{k}$-dependence of the bare f-peak evident in the figure between the (100) and the (110) directions. This is totally inconsistent with the concept of a localized state.

While the SIM appears to capture some of the physics associated with bulk properties, its failure to incorporate periodicity causes it to fail the test of microscopic measurements. Newer models such as the periodic Anderson model (PAM) or the dynamical mean-field theory (DMFT) (Savrasov *et al.*, 2001) do incorporate the f-electron periodicity and show some promise, though the calculations are extremely difficult. It is useful to also point out that in the mid-1990s, Bedell and his coworkers developed very simplified one- and two-band Fermi liquid models of heavy-fermion compounds such as UPt_3 (Sanchez-Castro and Bedell, 1993). The surprise was that these simplified models yielded quantitative results in agreement with the low-energy and low-temperature physics of these materials. This is presented here because the dispersing bare-f level of Fig. 21.14, while totally inconsistent with SIM, is consistent with Landau's incoherent state. It would appear that Landau's principle of one-to-one correspondence between electron and quasiparticle states continues to have validity and yields profound insights into systems of strongly interacting particles.

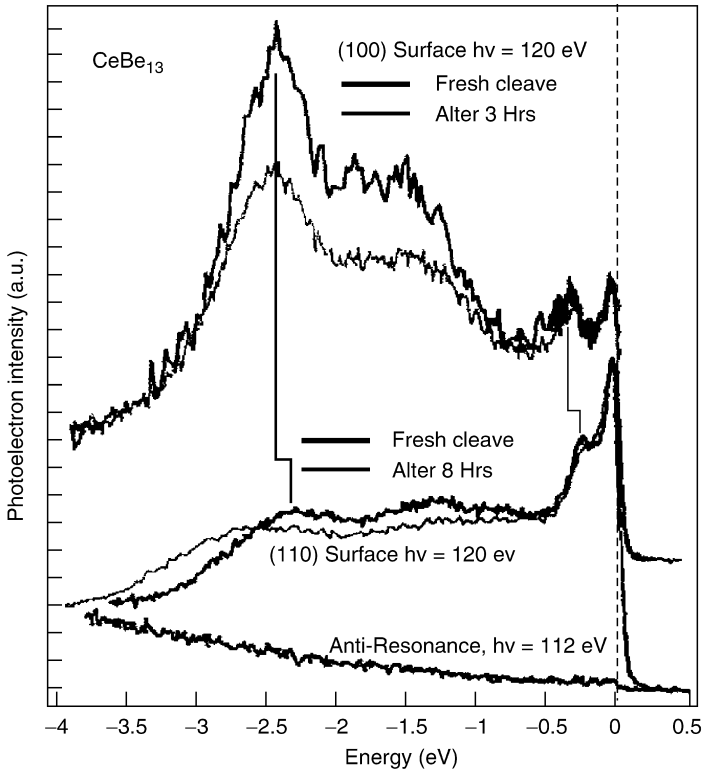

Fig. 21.14 *Resonance photoemission data for the enhanced mass compound $CeBe_{13}$ with a characteristic temperature of 400* K. *The PES data show two crystallographic orientations which demonstrate major variations in the electronic structure of the material, particularly the 5f levels, as a function of position in reciprocal space. The dotted vertical line at the zero of binding energy is the Fermi level. The peaks centered between* 2 *and* 2.5 eV *below the Fermi energy are attributed to the 'bare' f^0 peak in Kondo-type description of the system. The data are presented for freshly cleaned samples and three hour old samples in order to assess the role of surface features in the electronic structure* (*after Arko* et al., 1999).

21.7.2 Special case of plutonium systems

Plutonium and its compounds appear to present ground states different from heavy fermions or predictions from DFT-derived band structure calculations. Even α-Pu, which has been considered a relatively ordinary transition-metal-like system based on the ability to correctly calculate its atomic volume, does not yield PES results consistent with DFT calculations. All phases in the ordered state, however, conform to the requirements of a Fermi liquid as shown in Fig. 21.12. While the resistivities of both α-Pu and δ-Pu closely resemble resistivities of heavy fermions (see Fig. 21.15), the magnetic susceptibilities are

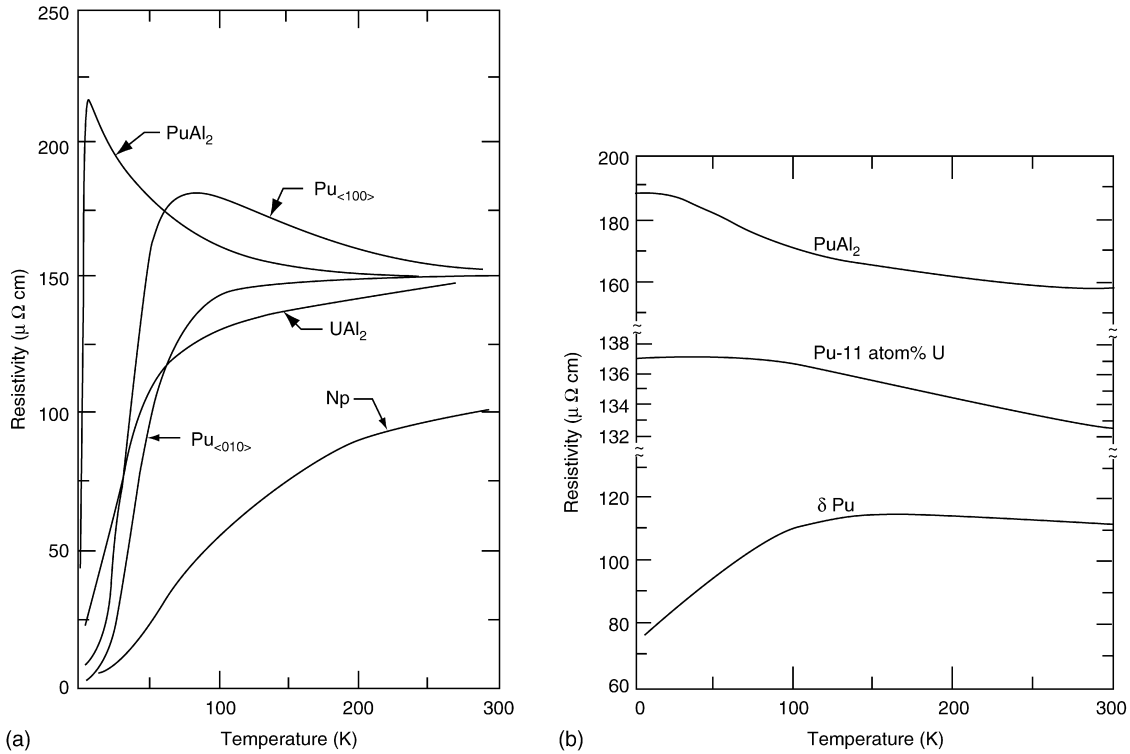

Fig. 21.15 *Electrical resistivity as a function of temperature for $PuAl_2$ and other actinides. The role of disorder and radiation are manifest in the resistivity. The difference in the low-temperature resistivity for $PuAl_2$ in* (*a*) *and* (*b*) *is a result of radiation damage. A similar effect may be generated by alloying where the impurities disrupt the integrity of the lattice as seen in* (*b*). *Separating intrinsic many-body phenomena such as quantum criticality from radiation and impurity effects is an ongoing challenge in actinide metals, alloys, and compounds* (*after Arko* et al., 1972).

temperature-independent, albeit large (of the order of 10^{-9} m^3 mol^{-1}). The specific heat γ-values are 17 and $\approx$ 64 mJ/mol. K^2 for α- and δ-Pu, respectively, which places them near the bottom of the range for heavy fermions (Lashley *et al.*, 2003). Eriksson *et al.* (1999) took a novel approach to the Pu problem and explored the localization of an integral fraction of the 5f electrons in δ-Pu in their DFT calculation (actually, the generalized gradient approximation or GGA, which extends LDA), while allowing other 5f electrons to be itinerant and involved in bonding. This is the mixed-level model (Eriksson *et al.*, 1999; Wills *et al.*, 2004). Using this technique, they were able to correctly calculate the atomic volume of δ-Pu, as well as obtain agreement with PES spectra (Joyce *et al.*, 2004). Indeed, the same approach appears to work for several other Pu compounds as well (Joyce *et al.*, 2003). This computational scheme provides an understanding of the 5f electronic structure as consisting of 5f electrons both in a localized as well as in an itinerant configuration for Pu, which is the cross-over point in the actinide series between localized and itinerant f-electron characteristics. The concept of the 5f electrons having a dual nature is not unique to Pu metal or its intermetallic compounds. This approach of separating the 5f character into localized and itinerant can also be found in insulating Pu oxides and other actinide systems (Petit *et al.*, 2003), the magnetically mediated, heavy-fermion superconductor UPd_2Al_3 (Sato *et al.*, 2001) and for the original actinide heavy-fermion superconductor UPt_3 (Zwicknagl and Fulde, 2003). For the δ-phase of Pu metal, the dual nature of the 5f electrons was initially proposed by Joyce *et al.* (1998). In Fig. 21.16 the energies are calculated for localized and itinerant 5f electrons for U, Pu, and Am. Clearly, an itinerant 5f framework is appropriate for U and just as clearly, a localized model is the choice for Am. In the boundary region of Pu, the energy level for localized and itinerant 5f character are nearly degenerate, and thus this mixed level character in Pu and Pu-based compounds would not be surprising.

An alternative interpretation for Pu PES results was considered (Gouder *et al.*, 2000; Havela *et al.*, 2002, 2003). The fact that a number of Pu-based systems show similar characteristic narrow features in the range 0–1 eV below E_F led to a conjecture that details of particular band structure are not dominant in this energy range. Instead final-state effects, either a fingerprint of atomic-state multiplet (whose high-energy lying states can be seen due to the excitation at the photoemission process) in analogy to 4f systems, or a general structure originating from many-electron process, are responsible for the observed structures (Fig. 21.17). It is interesting that the 5f states tend to localize in ultra-thin layers, as the reduced mean number of nearest neighbors leads to a preference for nonbonding 5f states. Calculations based on a DMFT may yield better agreement in the future, but these calculations at this point are in the early stages (see Savrasov *et al.*, 2001).

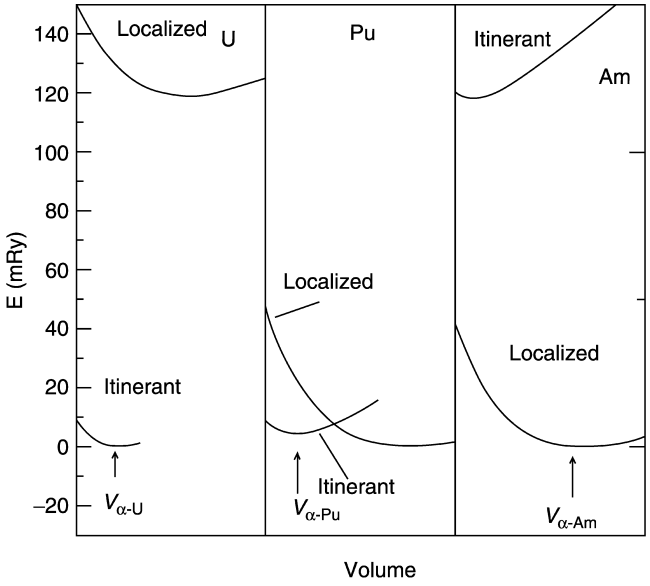

Fig. 21.16 *Total energy vs metallic radius (volume) for uranium, plutonium, and americium treating the 5f electrons as either localized or itinerant. For uranium, the calculation strongly favors an itinerant character to the 5f levels while for americium the localized 5f character is favored. Plutonium sits at the boundary between localized and itinerant. The boundary position of Pu supports the mixed-level approach to treating Pu 5f electrons (after Wills and Eriksson,* 2000).

21.7.3 Non-Fermi liquid effects and the quantum critical point

Actinide metals and most of their associated compounds typically follow the Fermi liquid scaling of electrical resistivity and electronic specific heat. Their respective coefficients reach the strongly renormalized (enhanced) values for narrow 5f-band systems. This contrasts with the systems with broad 5f-bands on one side and magnetic materials with sizeable moments on the other side, where the respective coefficients reach smaller values. The latter case deals with correlations of non-f electrons only. But some compounds persistently fail to meet the Fermi liquid rules at all. While the Fermi liquid concept requires resistivity to increase from zero temperature with a T^2 dependence, in such anomalous cases the value of the exponent can be lower. Instead of the normal constant value for C/T, logarithmically increasing C/T values with decreasing T are found. Such behavior can be encountered in the vicinity of the onset of magnetic ordering, in particular, if the parameters of the system are tuned so that its critical temperature for magnetic ordering reaches the $T = 0$ K limit. In such a situation, thermal fluctuations are suppressed and quantum fluctuations start to dominate.

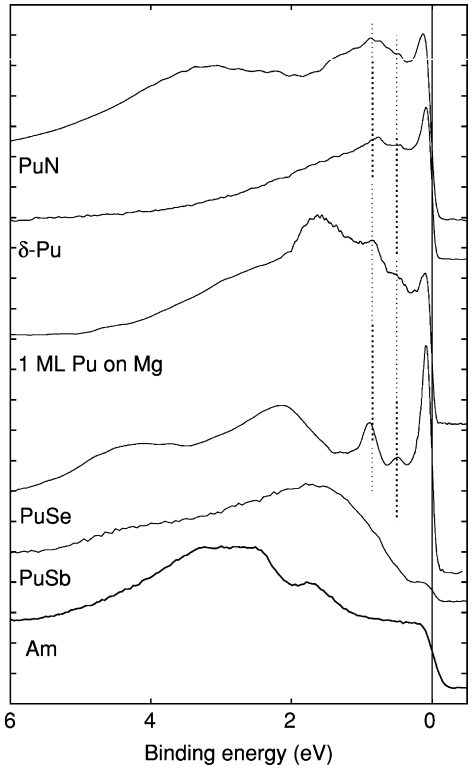

Fig. 21.17 *Examples of UPS valence-band spectra* ($h\nu = 40.8$ eV) *of selected Pu systems and Am demonstrate the effect of the* 5*f localization* (*in Am and PuSb*), *which reduces the spectral intensity at the Fermi level* (E = 0). *More itinerant Pu systems* (*PuN, δ-Pu, PuSe*) *exhibit a high spectral intensity at* E_F, *while a variable fraction of the localized* 5*f states is observed* 1–3 eV *below* E_F. *The latter dominates also for one monolayer of Pu on Mg. The dotted lines indicate positions of rather generally occurring features, which do not belong to particular DFT electronic states.* (*Reprinted with permission from Havela* et al., 2003.)

Unfortunately, efforts to bring a system to this so-called quantum critical point by the proper doping of impurities into the system also results in a randomness in the structure due to the statistical occupation of atomic positions. In most instances of non-Fermi liquid (NFL) behavior, the explanation has been one of disorder. Fig. 21.15a shows the resistivities of $PuAl_2$ and other materials whose low-temperature resistivity has been shown to vary as T^2 in Fig. 21.12. Upon disorder (via self-damage by α-particles), the resistivity of $PuAl_2$ in Fig. 21.15b no longer drops at low temperatures, but rather seems to level off. Only about 1% of the sample is estimated to sustain disorder caused by damage from α-particle bombardment during 1 month of shelf time, assuming that no room temperature annealing occurred. This shows how little disorder it takes

to destroy coherence in very narrow bands. The resistivity of Fig. 21.15a can be entirely reproduced by annealing the specimen at 1000°C for 12 h (Arko *et al.*, 1973).

One of the microscopic models accounting for the NFL behavior in such inhomogeneous systems is based on a distribution of Kondo temperatures T_K due to the atomic disorder. Numerous such systems include $(U,Y)Pd_3$, $U(Cu,Pd)_5$, or $(U,Th)Ru_2Si_2$. A summary of NFL features in actinides and lanthanides can be found in Stewart (2001). Sometimes NFL scaling is observed even in undoped systems. Undoubtedly in such a case the sample has the real characteristics of strongly correlated systems. Approximate theories indicate several fundamental classes of NFL behavior (instead of one class of FL scaling) which depend on the character of magnetic interactions (ferro- or antiferromagnetic) and on dimensionality (for example f-sites may form weakly interacting sheets or chains, thus reducing the effective dimensionality). These parameters determine the degrees of freedom of the quantum fluctuations, which affect the type of analytical behavior describing basic quantities. For example, in the proximity of three-dimensional ferromagnetism, the characteristics $\rho \sim T^n$, $n = 5/3$ and $C/T \sim -\ln(T/T_0)$ are expected. For antiferromagnetic coupling, the n value is reduced to 3/2 and further reduction takes place for lower dimensionality. In the two-dimensional case, $n = 4/3$ and 1 for the ferromagnetic and antiferromagnetic coupling, respectively. Although the majority of undoped NFL systems are found among Ce or Yb intermetallics, there are also a few U-based intermetallics. For example, at ambient pressure, NFL features are observed in UCoAl, U_2Co_2Sn, or U_2Pt_2In. The review article by Stewart (2001) describes these and other examples.

21.8 CONVENTIONAL AND UNCONVENTIONAL SUPERCONDUCTIVITY

Superconductivity, with its basic characteristic of the complete disappearance of electrical resistivity at low temperatures, has been traditionally considered as a contradiction to magnetic ordering. The reason is related to the Cooper pairs, consisting of two electrons with opposite momentum and spin, which are the basic ingredient of the superconducting state (Bardeen *et al.*, 1957). Indeed, a very small admixture of magnetic ions into a normal superconductor rapidly suppresses the superconductivity, and this phenomenon has to be attributed to the breaking of such electron pairs by exchange interactions, which prefer a parallel orientation of electron spins.

This conventional superconductivity is commonly found in actinides that are only weakly magnetic, although the critical temperatures T_c are very low. For example, $T_c = 1.37$ K for Th (Gordon *et al.*, 1966), 1.4 K for Pa (Fowler *et al.*, 1965), and 0.68 K for α-U (Hein *et al.*, 1957). For heavier actinides, superconductivity was found for Am ($T_c = 0.79$ K) (Smith and Haire, 1978). Similarly, intermetallic compounds with high actinide content also tend toward

superconductivity. The highest T_c values are found in compounds of the form U_6T, where T = Mn, Fe, Co, Ni, reaching the highest $T_c = 3.7$ K for U_6Fe, and U_3Ir ($T_c = 1.24$). Several others, U_3Si, U_3Os, U_2Ti, all have T_c below 1 K (see Sechovsky and Havela, 1988 and references therein). The same is true for amorphous U-rich systems (metallic glasses) (Poon *et al.*, 1985), while similar Th-based systems (e.g. $Th_{80}Co_{20}$) reach T_c at nearly 4 K. For lower U content, a tendency to magnetic ordering appears and superconductivity ceases. But this is not universally the case. A strange island of superconductivity was discovered for some compounds with a high inter-uranium spacing, which have characteristics close to a normal magnetic ordering (UBe_{13}, UPt_3, see above). (Ott and Fisk, 1987). Some variations of these compounds even order antiferromagnetically and the magnetic order and superconductivity coexist. In this case of so-called unconventional superconductivity, the pairing mechanism of the Cooper pairs is related to magnetic interactions instead of the electron–phonon coupling of normal Cooper pairs (Bardeen *et al.*, 1957) in the BCS mechanism. Here the superconducting state may be based on electrons with parallel spins (as opposed to antiparallel) with the total wave function therefore having a different symmetry. This phenomenon is called d-wave or p-wave symmetry in contrast to the s-wave symmetry in conventional BCS superconductivity. Such superconductors can be strongly anisotropic, including the anisotropy of the superconducting gap, and the superconducting state also can be much more resistant against a magnetic field (Ott and Fisk, 1987). The intimate connection of the superconductivity and the heavy-fermion character of the electronic structure is manifest in the huge jump of the specific heat C, scaling with γT_c. This scaling strongly suggests that the heavy-fermion character and the superconductivity are related to the same set of 5f electrons.

The most prominent materials among unconventional superconductors were already mentioned in the Heavy Fermion section. In the first of these, UBe_{13}, T_c can reach 0.85–0.90 K, and is very dependent on the actual purity of the sample (Ott and Fisk, 1987). This compound is of particular interest by virtue of its enormous γ ($\gamma = 1100$ mJ mol^{-1}K^{-2} and it is one of the U compounds with the most 'heavy' electrons) and its strongly anomalous resistivity in the normal state, increasing with decreasing T towards a sharp maximum at $T = 2.5$ K. It was first assumed to be non-magnetic, but very small static magnetic moments of $0.001\mu_B$ were deduced from muon spin-relaxation studies (Heffner *et al.*, 1990). The very high upper critical field $B_{c2} = 9$ T (considering the low T_c value) is consistent with the unconventional nature of the superconductivity.

UPt_3 with $\gamma = 420$ mJ mol^{-1} K^{-2} can be also classified as a heavy-fermion superconductor. The superconducting transition temperature again depends strongly on the sample quality. A T_c of 0.53 K can be obtained in well-annealed samples (Franse *et al.*, 1984). Unlike UBe_{13}, UPt_3 displays well-documented antiferromagnetic correlations, shown by neutron scattering experiments. An unusual static magnetic order with very low magnetic moments develops below about 5 K (Aeppli *et al.*, 1988).

Superconductivity ($T_c = 0.8$ K) and antiferromagnetism ($T_N = 17.5$ K) coexist also in URu_2Si_2, which has only a moderate γ value (75 mJ mol^{-1} K^{-2}) (Maple *et al.*, 1986). Although ordered magnetic moments do not exceed $0.04\mu_B$/U where μ_B is the Bohr magneton, the specific heat anomaly at T_N and the total entropy related to magnetic ordering is so large that there appeared numerous speculations about other type of ordering (e.g. quadrupolar), invisible to the neutron diffraction, which could induce a secondary weak magnetic ordering. The search for this so-called hidden order is still in progress (see for example Chandra *et al.*, 2002). An alternative approach, based on dynamic long-range correlations carrying a large magnetic entropy, has been proposed (Bernhoeft *et al.*, 2003).

Even larger ordered moments and higher superconducting transition temperatures are found in the superconducting antiferromagnets UPd_2Al_3 and UNi_2Al_3. UPd_2Al_3 has a higher ordered moment $(0.85 \pm 0.03)\mu_B$/U and ordering temperature of 14.4 K (Krimmel *et al.*, 1993). Unlike the Néel temperature, the superconducting critical temperature is strongly sample dependent, varying with a slight off-stoichiometry and/or heat treatment of single crystalline samples between 1.5 and 2.0 K. An interplay of superconductivity and magnetic fluctuations revealed by inelastic neutron scattering (Bernhoeft *et al.*, 1998) indicates importance of magnetic interactions in the unconventional superconductivity mechanism. UNi_2Al_3 orders antiferromagnetically below $T_N = 4.5$ K and the magnetic order coexists with superconductivity below $T_c \approx 1$ K (Geibel *et al.*, 1991), γ reaches 140 and 120 mJ mol^{-1} K^{-2} for the Pd and Ni compounds, respectively.

All these compounds are very exotic, but even more surprising was the recent discovery of the ferromagnetic superconductors UGe_2 and URhGe. The superconductivity in UGe_2 appears only in a state induced by high pressure. Although high pressure finally led to the suppression of magnetism, at pressures around 12 GPa, where the superconducting temperature reaches its maximum (about 0.7 K), the magnetization still corresponded to about $0.8\mu_B$/U with the Curie temperature at about 30 K. The superconductivity disappeared in fields of several tesla, where a high-magnetization state was induced in a first-order magnetic phase transition. An overview of the data on this compound as well as on URhGe is given in Flouquet *et al.* (2003). On the other hand, URhGe is already superconducting at ambient pressure. Its critical temperature reaches only 0.3 K ($T_c = 9.5$ K), with U moments around $0.4\mu_B$/U.

The most recent breakthrough in the superconductivity of actinides was the discovery of Pu-based nearly magnetic systems with superconductivity in the temperature range exceeding 18 K (Sarrao *et al.*, 2002). The fact is surprising because $PuCoGa_5$ is the first known Pu superconductor. The Ce-based isostructural compounds $CeCoIn_5$, and $CeIrIn_5$ are superconducting also, but only in the 1 K range, and for $CeRhIn_5$ only under pressure. The high γ value of $PuCoGa_5$, 77 mJ mol^{-1} K^{-2} points to strong electron–electron correlations. This value, and the high estimated upper critical field 74 T, is indicative of

an unconventional superconductivity. The T_c of $PuCoGa_5$ can be further enhanced to about 22 K by applying pressure (Griveau *et al.*, 2004). $PuRhGa_5$ is superconducting, as well, with $T_c = 8.6$ K (Bauer *et al.*, 2004).

21.9 MAGNETISM IN ACTINIDES

The peculiar character of the electronic structure of actinides, with the 5f states ranging between localized and itinerant, implies an extreme variability of magnetic features of elemental actinides as well as actinide-based alloys and intermetallic compounds. The gradual filling of the 5f shell in the sequence of actinide elements does not dominate the development of the magnetic properties of the pure elements in the way expected on the basis of parallel lanthanide series. This is especially true for the early actinides, in which a 5f band is formed, as described in Sections 21.3 and 21.4. Therefore more similarity is found with the d transition metals, exhibiting broad s and p bands and narrow d bands. As a consequence, the density of electronic states at the Fermi level, $N(E_F)$, is a more important parameter than the filling of the 5f band itself. The interactinide spacing has a crucial role. For pure elements, it is too small, and substantial 5f–5f overlap leads to a rather broad 5f band and weak magnetic behavior.

For heavier actinides (from Am onwards) the 5f localization was documented for the pure elements, and atomic correlations in analogy to rare earths leads to the formation of local moments and their ordering. At closer inspection, specific features of band magnetism appear in systems based on elements up to Pu. The main characteristics of the 5f band magnetism comprise strong spin–orbit interaction, leading to large orbital moments formed even in the case of band-like states, exchange interactions mediated or assisted by the hybridization of the 5f states with the ligand states, and enormous magnetic anisotropy arising from the anisotropy of the hybridization (bonding anisotropy). Another characteristic is a high sensitivity of magnetic properties to external variables, like pressure, magnetic field, and to fine details of composition. More detailed information can be found in review chapters (Sechovský and Havela, 1988, 1998). Electronic structure calculations based on the density functional approach are discussed by Johansson and Brooks (1993) and by Norman and Koelling (1993). The impact of magnetism on transport properties for actinides and lanthanides are compared by Fournier and Gratz (1993).

21.9.1 General features of magnetism of light-actinide systems

The fundamental difference between the character of the 4f electron states in lanthanides and the 5f states in light actinides can be attributed to a much larger spatial extent of the 5f wave functions, and thus a much stronger interaction with their metallic environment, compared to the 4f case. The 5f electrons are, as

a rule, delocalized due to their participation in bonding, which leads to a considerable hybridization of the 5f states with the valence states of neighboring atoms (5f-ligand hybridization). The delocalization of the 5f electrons has serious consequences, such as the formation of a more or less narrow 5f band intersected by the Fermi energy E_F (the bandwidth W_{5f} is of the order of several eV) rather than discrete energy levels. Consequently, the magnetic moments due to the itinerant 5f electrons are much smaller than expected for a free ion (irrespective whether the L–S or j–j coupling schemes are used – ground state magnetic moments are similar), and magnetic moments can disappear in a broadband limit leading to weak temperature-independent (Pauli) paramagnetism. This situation resembles to a certain extent the 3d transition metals. The strength of magnetic coupling in cases of existing 5f moments is typically much larger than for the 4f moments interacting via the Ruderman–Kittel–Kasuya–Yosida (RKKY) interaction, which is reflected by higher ordering temperatures compared to isostructural rare earth systems. The impact on magnetic excitations is even more dramatic, no crystal-field excitations can be observed by inelastic neutron scattering in the vast majority of systems studied so far, but a rather broad quasielastic response reflecting the 5f-moments instability in analogy to, for example, cerium mixed valence materials is observed (Holland-Moritz and Lander, 1994).

21.9.2 Magnetism in pure An elements

A small separation between the ions of the pure elements leads to large overlap of the 5f wave functions of nearest neighbors, amounting to the formation of a broad 5f band and weakly paramagnetic behavior. With increasing 5f occupation, the value of the Pauli-type susceptibility increases due to the increase of $N(E_F)$, the DOSs at the Fermi level, which is corroborated by a similar increase in the low-temperature electronic specific heat coefficient γ (see Table 21.1). This tendency is interrupted between Pu and Am, where the 5f states localize, and do not contribute to bonding for heavier actinides. The reason for the localization (and loss of the 5f bonding energy) can be found qualitatively in the gain of electron correlation energy for atomic-like 5f states (which is partly lost in the 5f band case). For details, see Johansson and Brooks (1993).

Quantitatively, the lack of magnetic ordering can be deduced from the Stoner criterion, which specifies conditions for magnetic ordering in band systems. If the Stoner product $U^*N(E_F)$, which contains besides the DOS at the Fermi level the intra-atomic Coulomb interaction parameter U, is larger than 1, the spin-up and spin-down sub-bands are not occupied equally and net magnetization arises. For light-actinide metals, this criterion is not fulfilled and the sub-bands are not split. Light-actinide metals can lower their electron energies by forming different open crystal structures, sometimes of a very low symmetry (in analogy to Jahn–Teller effect). The best example of this phenomenon is Pu having six allotropes, with the ground-state allotrope, α-Pu, showing a

complicated monoclinic structure. A similar situation is found in α-U, the structure of which is orthorhombic, but an incommensurate charge-density wave is formed below $T = 43$ K (Lander *et al.*, 1994). Due to the weakly magnetic character, superconductivity can appear at the beginning of the actinide series, as mentioned earlier.

Plutonium, the element on the verge of localization, exhibits the most complex behavior. Its room temperature phase, α-Pu, is monoclinic with 16 atoms per unit cell. At $T = 388$ K, it undergoes a phase transition to an even more complicated monoclinic β-phase with 34 atoms per unit cell. For remaining phases, most of data exists on the fcc δ-phase with four atoms per unit cell, which has atomic volume expanded by 26% compared to the α-phase, and which can be stabilized by several percent doping with Al, Ce, Ga, or other trivalent elements. Comparing the fcc δ-phase to the data for α-Pu given in Table 21.1, γ is strongly enhanced to (64 ± 3) mJ mol^{-1} K^{-2} (Lashley *et al.*, 2003). It is an interesting fact that all the Pu phases have only a small difference in magnetic susceptibility (see Table 21.1). The highest value was recorded for the β-phase, which also exhibits a noticeable temperature dependence in the narrow temperature range of its existence (Olsen *et al.*, 1992). The most surprising is the lack of magnetic order in the δ-phase with the largest atomic volume. LDA or GGA calculations invariably lead to a magnetic state, with spin and orbital moments only partially canceling each other (Söderlind and Sadigh, 2004). Méot-Reymond and Fournier (1996) discussed the properties of δ-Pu in terms of a Kondo effect (i.e. many-electron effect based on dynamical screening of a local atomic spin by spins of conduction electrons) with the characteristic Kondo temperature T_K higher than room temperature. Also Savrasov *et al.* (2001) suspect dynamic phenomena, described by a DMFT, to wash out magnetism. Another conjecture trying to solve the δ-Pu puzzle is the idea that there are magnetic moments in δ-Pu, but they are disordered, not leading to a long-range order (Niklasson *et al.*, 2003). But as the low δ-Pu susceptibility is quite robust with respect to various dopings or even lattice expansion (Hecker *et al.*, 2004 and references therein), it seems that it is fundamentally non-magnetic. Such non-magnetic character ($S = 0$, $L = 0$) could be obtained using an LDA+U method, where U denotes an explicit involvement of intra-atomic coulomb correlations going beyond LDA (Shick *et al.*, 2005) but this approach needs to be reconciled with the photoemission and the enhanced mass results. Such calculations suggest that the 5f count in δ-Pu is about 5.5, and is not only much higher than typically 5.0 in α-Pu, but relatively close to the non-magnetic $5f^6$ configuration.

The elements beyond Pu behave rather similarly to the lanthanide series. The analogy starts with the crystal structures. Am, Cm, Bk, and Cf all have dhcp structures, but the structures change and the 5f states delocalize under external pressure, yielding low-symmetry structures of the light-actinides type (Lindbaum *et al.*, 2003). The non-magnetic ground state of Am (exhibiting a low value of γ and quite high Van Vleck susceptibility) can be understood in the

framework of either L–S or j–j coupling for the $5f^6$ configuration. Most of information on curium (Cm) was obtained on the ^{244}Cm isotope (half-life 18 years), which is available in large amounts (milligrams) but displays high self-heating and radiation damage. A maximum in the magnetic susceptibility indicating antiferromagnetic (AF) ordering was observed at $T = 52$ K for this isotope, and a simple antiferromagnetic order was indeed confirmed by neutron diffraction. For ^{248}Cm, which has a longer half-life of 340,000 years, but is available only in small amounts, the antiferromagnetic ordering occurred at $T = 64$ K. Values of effective moment are compatible with $\mu_{\text{eff}} = 7.55\mu_{\text{B}}$ expected for the intermediate coupling model. Besides the ground-state dhcp crystal structure, a high-temperature fcc phase can occur in a low-temperature metastable state. Its magnetic ordering temperature is enhanced to $T = 205$ K. Berkelium (Bk) and californium (Cf) can be studied only in sub-milligram quantities. For Bk, antiferromagnetic ordering was deduced below $T = 34$ K. Cf is probably ferromagnetic below approximately 51 K. Both materials display μ_{eff} values compatible with free-ion theoretical values in the paramagnetic state. Einsteinium, which can be studied in sub-microgram quantities only, yields a moment of $11.3\mu_{\text{B}}$, which is even somewhat higher than the theoretical value. For more detailed information on magnetism of transplutonium actinides, see the review of Huray and Nave (1987) and references therein.

21.9.3 Magnetic properties of actinide intermetallic compounds

Similar to pure actinide elements, the magnetic properties of intermetallic compounds reflect the gradual filling of the incomplete 5f-shell. In Th compounds, the very small filling of the 5f states cannot give rise to the 5f magnetic moments, and compounds are typically Pauli paramagnets with susceptibility χ_0 of the order of 10^{-9} to 10^{-8} m^3 mol^{-1} for intermetallic compounds, indicating a low DOS at E_{F}. The ground state is frequently superconducting (Sechovsky and Havela, 1988). Exceptions are compounds such as Th_2Fe_{17} ($T_{\text{C}} = 295$ K) and Th_2Co_{17} ($T_{\text{C}} = 1035$ K), in which the magnetism is dominated by transition-metal components (Buschow, 1971).

In the compounds of U, Np, and Pu magnetic ordering can appear when the actinide–actinide spacing is enhanced to such an extent that the 5f-band narrowing and consequent increase of the DOS at E_{F} leads to the fulfillment of the Stoner criterion. The proximity of these elements to the boundary between the localized and itinerant character of the 5f-electronic states makes them very sensitive to variations of the environment. In the first approximation, the width of the 5f band can be taken as a function of the overlap of the 5f atomic wave functions centered on nearest neighbors, and the increase of the overlap can be taken as the principal delocalizing mechanism of the 5f electrons. The prominence of the Hill limit, introduced earlier (see Fig. 21.7), is evident. The situation is best documented for U compounds, where the Hill distance $d_{\text{U–U}} = 3.4$–3.6 Å is an approximate boundary value of the spacing, corresponding to the critical

5f–5f overlap. For smaller spacing values, most of the compounds are non-magnetic (often superconducting), for d_{U-U} larger than the Hill limit, the compounds usually show a magnetically ordered ground state. The value of the Hill limit should be taken as very approximative, the width of the 5f band is naturally affected also by the coordination number.

For compounds with d_{U-U} larger than the Hill limit, the principal control parameter is not the U–U spacing, but the hybridization of the 5f states with electronic states of other components. In particular, in compounds with transition metals, it is mainly the overlap of the 5f states with the d-states of the transition metal that affects the strength of the hybridization. The 5f states remain pinned at the Fermi level in most cases, whereas the late transition metals (as well as noble metals) being much more electronegative have their particular d states shifted towards higher binding energies thus leaving the 5f–d overlap small on the energy scale. The reduced 5f–d hybridization leads to the onset of the 5f magnetism, whereas the d-states are occupied more than in the pure d-element. Even if the d-element itself is magnetically ordered (Co, Ni, Fe), in the compound with U, it behaves as essentially non-magnetic (a similar effect appears in Th compounds). Exceptions are compounds with very high content of the transition metal component, in which case the d-magnetism can prevail. In compounds with the earlier d-metals like Fe or Ru, the d-states appear closer to the Fermi energy and the 5f–d overlap increases, leading typically to a non-magnetic ground state (as in UFeAl). But in some cases, magnetic moments appear both on the U and transition-metal ions. Prominent examples are Laves phases with Fe, all ordering ferromagnetically. Relatively high T_C values (UFe_2, 162 K; $NpFe_2$, 492 K; $PuFe_2$, 564 K;, $AmFe_2$, 613 K) point to the dominance of Fe–sublattice exchange interactions, but actinide magnetic moments are non-negligible, reaching $1.1\mu_B$/Np or $0.45\mu_B$/Pu. The tiny total moment in the case of U is caused by the orbital ($0.23\mu_B$) and spin ($0.22\mu_B$) components nearly canceling each other (Sechovsky and Havela, 1988 and references therein).

In compounds with non-transition metals, it is mainly the size of ligand atoms that affects the hybridization. Compounds with larger ligands are typically magnetic (e.g. UIn_3), whereas those with smaller ligands and greater hybridization form broad bands with low $N(E_F)$ and are weakly paramagnetic (USi_3). Several characteristic groups of U compounds can be thus distinguished.

(a) Compounds with very high U content

The stoichiometry leads to a small U spacing, d_{U-U}. The consequence is a broad 5f band similar to U metal. These compounds are weakly paramagnetic and superconducting. The examples, U_6Fe, U_6Co, U_6Ni, U_3Ir, U_3Si, U_3Os, and U_2Ti were mentioned in the section on superconductivity. The lower U concentration compound, which can be classified as a regular superconductor with moderate $d_{U-U} = 3.2$ Å, UCo has $T_C = 1.22$ K (Chen *et al.*, 1985).

(b) Lower U content, small $d_{U—U}$ much below the Hill limit

This stoichiometry leads to a weakly paramagnetic behavior, possibly with an influence of spin fluctuations, and the ground state is not superconducting. As examples, one may give U_3Si_2, UAl_2, or UCo_2. The last two compounds belong to an extended group of so-called Laves phases, which combine atoms of two different sizes into a very closely packed cubic or hexagonal structure. Therefore although the U content is relatively low, the packing leads to $d_{U–U}$ much below the Hill limit. Some of these compounds do not undergo magnetic ordering, also partly due to the strong hybridization of the 5f states with the d-state of transition metal constituents (UMn_2, UCo_2, URe_2). But the Laves phases with Fe and Ni are ferromagnets, and belong therefore to the next group (Sechovsky and Havela, 1988 and references therein).

(c) Itinerant ferromagnets with $d_{U—U}$ around or below the Hill limit, 3.4 Å

When proceeding from the most U-rich compounds and decreasing the U concentration, one observes magnetic order (ferromagnetism) at the 1:1 stoichiometry. Typical examples have very small ordered moments and relatively high ordering temperatures (UIr: $T_C = 46$ K, spontaneous magnetic moment $\mu_s = 0.45\mu_B$). For UNi_2, the very small spontaneous moment $0.08\mu_B$/U led to the conjecture that the magnetism was due to a small fraction of Ni atoms occupying wrong crystallographic positions (Franse *et al.*, 1981). But neutron diffraction proved finally that magnetism was not carried by Ni, but by U, and what is observed in the magnetization is a small difference between the orbital and spin moments with antiparallel orientation (Fournier *et al.*, 1986). UFe_2, the first U compound for which magnetic ordering was reported (Gordon, 1949), is a somewhat different case. Fe atoms carry magnetic moments (although much reduced by the hybridization compared to Fe metal) and lead to a high Curie temperature $T_C = 162$ K. The nearly complete mutual cancellation of spin and orbital moments reduces the contribution of U to the total magnetization to practically zero, but polarized neutron diffraction can accurately detect both components (for details, see Sechovsky and Havela, 1988).

Focusing thus on the sequence of the U-3d Laves phases, an interesting non-monotonic development of magnetism is observed. UMn_2 is non-magnetic and strongly hybridized, as the 5f and 3d bands have a strong energy overlap, and this situation does not allow the formation of Mn or U moments. In UFe_2, the 3d states shift towards somewhat higher binding energies, but the hybridization with the 5f states, given by the energy overlap, remains strong. The Fe sublattice orders ferromagnetically, allowing for the formation of the U moments. In UCo_2, the 3d band shifts even deeper and is close to filling. The Fermi level is in a minimum between the 3d and 5f states, therefore magnetism is lost again. For UNi_2, the 3d band is filled, the Fermi level is on the ascending

edge of the 5f band, and the Stoner criterion leads to magnetism of purely 5f origin (Eriksson *et al.*, 1989).

(d) Low U concentration, large $d_{U—U}$, ferromagnetic ground state

Ferromagnetism appears typically for uranium compounds with a moderate U–U spacing. For higher spacing, ferromagnetism changes to antiferromagnetism due to a more indirect exchange interaction. The ferromagnet with the highest $d_{U–U}$ (among known binaries) is UGa_2 (shortest $d_{U–U}$ in UGa_2 is 4.01 Å). It exhibits a sizeable spontaneous moment of $2.7\mu_B$/U and a rather high $T_C = 126$ K (Andreev *et al.*, 1979). As γ is only about 5 mJ mol^{-1} K^{-2} (Ballou, 1983), it was often assumed to form 5f localized states, but both the decreasing magnetization under pressure and microscopic (PES) data point to the itinerant character (Reihl *et al.*, 1985; Gouder *et al.*, 2001). Another prominent representative of this group is UGe_2 ($T_C = 52$ K, $\mu_s = 1.43\mu_B$/U), mentioned in the context of unconventional superconductivity, which was observed under pressure (Saxena *et al.*, 2000).

(e) Compounds with a very low U concentration

Within this group, the U—U spacing is significantly over the Hill limit, and consequently the direct 5f–5f overlap becomes insignificant. The strength of the 5f–ligand hybridization determines whether the ground state is magnetic or non-magnetic. This can be well demonstrated for the series UT_3 where T is a transition metal and UX_3 with X a p-metal, all sharing the $AuCu_3$ cubic structure type. For UX_3, the relation of the hybridization and the radius of the p metal can be found. For large X-radii, the falloff of the wave functions of the X-ligand at the U atom is generally small, and the hybridization is weak. For small X ligands, the spatial variations of their wave functions are larger and the hybridization is stronger (Koelling *et al.*, 1985). The crossover from weak Pauli paramagnetism to magnetic ordering occurs as X gets heavier, where X represents elements from the columns of the periodic table with p^1 and p^2 states. Thus USi_3, UGe_3, and UAl_3 are weak paramagnets, USn_3 still shows non-magnetic spin fluctuations, whereas UGa_3, UPb_3, UIn_3 and UTl_3 are antiferromagnets. The highest ordering temperature $T_N = 95$ K was found in UIn_3. In the group of UT_3 compounds, magnetic ordering depends mainly on the strength of the 5f–d hybridization, modulated by the overlap of the two types of states determined by the energy scale (Koelling *et al.*, 1985). It is generally reduced for T at the end of transition-metal series, as the d band shifts below the Fermi level, whereas the 5f states stay pinned at E_F. The development is similar to that in the Laves phases, but no d-originating magnetism is found in this group. UCo_3, URu_3, URh_3, and UIr_3 are weak paramagnets, nearly magnetic UPt_3 (heavy-fermion superconductor) and UPd_3 with localized $5f^2$ states and a quadrupolar ordering have a different structure type. UPd_3 is thus an interesting reference case; no

other binary compound exhibits the f-states shifted from the Fermi level (shown by PES; see Baer, 1984). Also neutron scattering experiments reveal well-defined crystal-field (CF) excitations (Buyers and Holden, 1985; McEwen *et al.*, 1993), normally absent in the spectra of uranium intermetallics, and γ reaches only 5 mJ mol^{-1} K^{-2} (Andres *et al.*, 1978). Compounds with high concentrations of a transition element can exhibit also high-temperature magnetic ordering. For example, ferromagnetic order with a high Curie temperature (360 K) in $UCo_{5.3}$, studied by Deryagin and Andreev (1978), is undoubtedly related to Co.

(f) Heavy-fermion materials

The last group comprises those having a substantially enhanced γ-coefficient of the specific heat and show a coexistence of magnetic ordering and superconductivity of an unconventional type. If these materials undergo a magnetic ordering, the critical temperatures are very low. Typical examples are UCu_5 ($T_N = 15$ K), U_2Zn_{17} ($T_N = 9.7$ K), UCd_{11} ($T_N = 5$ K), and the heavy-fermion superconductor UBe_{13}. For details, see Ott and Fisk (1987) and references therein.

(g) Other compounds

Besides binary compounds, there exist large groups of ternary compounds, often including a transition metal T and a non-transition metal X (UTX, U_2T_2X, UT_2X_2), which follow the tendencies of the 5f-ligand hybridization mentioned above. The advantage of studies of the *5*f magnetism in such compounds is that both the transition and non-transition metal components can be varied, while the structure type, i.e. the symmetry of environment of actinide atoms, is preserved. Thus the crossover from a non-magnetic to a magnetic ground state can be studied in more detail.

Materials, which are in the boundary region (i.e. nearly or weakly magnetic), show a variety of so-called spin-fluctuation features. Those with a non-magnetic ground state exhibit Curie–Weiss behavior of the magnetic susceptibility at high temperatures, but at low temperatures, a broad maximum in $\chi(T)$ appears (e.g. URuAl, UCoAl), other types of spin fluctuations are characterized by a plateau in $\chi(T)$ below a characteristic temperature, and then a low-temperature upturn as found in URuGa (Sechovsky and Havela, 1998). High ordering temperatures can be achieved with ternary compounds, for example, in compounds of the $UT_{10}Si_2$-type ($ThMn_{12}$ structure type), in which both the U and transition metal T (Fe, Co) carry magnetic moments. The highest $T_C = 750$ K was recorded for $U(Fe_{0.5}Co_{0.5})_{10}Si_2$ (Berlureau *et al.*, 1991).

The occurrence of magnetic ordering in Np-based compounds is dominated by mechanisms analogous to their U-counterparts. Important information is obtained using the ^{237}Np Mössbauer spectroscopy, which can determine microscopic parameters of the Np magnetism such as the magnetic hyperfine field B_{hf} on the Np nucleus. Values were found approximately proportional to the local

Np magnetic moment μ_{Np} (Dunlap and Kalvius, 1985; Potzel *et al.*, 1993): $B_{hf}/\mu_{Np} = 215$ (T/μ_B). The boundary between the magnetic and non-magnetic behavior for different Np materials is not much different than for their U-isotypes and demonstrates that for Np compounds, the mechanisms of the 5f-delocalization play a comparable role. Thus the non-magnetic behavior of Np in $NpGe_3$ and $NpRh_3$ has to be attributed to the 5f–p and 5f–d hybridization in analogy to UGe_3 and URh_3 (Sechovsky and Havela, 1988 and references therein). On the other hand, differences also exist. For example, $NpSn_3$ is an itinerant antiferromagnet, whereas USn_3 shows spin-fluctuations not undergoing magnetic ordering. Such a difference can be generally attributed to a higher 5f count or weaker 5f delocalization. On the other hand, Np_2Rh_2Sn is a non-magnetic spin fluctuator, whereas U_2Rh_2Sn undergoes antiferromagnetic order ($T_N = 24$ K) (Sechovsky and Havela, 1998). Moreover, ^{237}Np Mössbauer spectroscopy under high pressure has been a convenient tool to distinguish different types of magnetically ordered compounds. For those with more stable 5f moments, the Np moment does not decrease with pressure in the GPa range while the ordering temperature increases (e.g. $NpCo_2Si_2$), whereas a pronounced decrease of both parameters points to a stronger 5f-moment instability, e.g. as in Np Laves phases $NpOs_2$ or $NpAl_2$ (Potzel *et al.*, 1993 and references therein).

For intermetallic compounds of Pu, two tendencies cross each other. One is a stronger tendency to 5f localization due to the proximity of the Pu–Am borderline. On the other hand, the tendency to magnetism is diminished by small free-ion magnetic moments of the $5f^5$ state in both *L–S* and *j–j* coupling schemes. For $5f^6$, the moment is zero. For example, $PuMn_2$ is a weak paramagnet (although $NpMn_2$ is a ferromagnet), and a similar situation is found for the couples $NpCo_2$–$PuCo_2$ and $NpNi_2$–$PuNi_2$, and $NpRe_2$–$PuRe_2$. The Pu compounds that order magnetically include $PuRh_2$ ($T_N = 10$ K), $PuFe_2$ ($T_C = 564$ K, due to the ferromagnetism of the iron sublattice), $PuPt_3$ ($T_N = 40$ K), $PuPd_3$ ($T_N = 24$ K), $PuRh_3$ ($T_N = 6.6$ K). The knowledge of magnetism of Am intermetallics is fragmentary. The ferromagnetism of $AmFe_2$ ($T_C = 613$ K) is explained by the properties of the Fe sublattice. $AmRh_2$ is a paramagnet. For details, see Sechovsky and Havela (1988).

21.9.4 Magnetic properties of other actinide compounds

A large majority of actinide compounds even with non-metallic elements have metallic character. The magnetic behavior is dominated by the f–p hybridization, which has a dual role. It leads both to a delocalization of the 5f states and mediates the exchange interaction. The metallic character appears in most of the rocksalt-type of compounds, monopnictides AnX (An = U, Np, Pu, X = P, As, Sb, Bi) and monochalcogenides AnY (An = U, Np, Y = S, Se, Te), which are magnetically ordered and reach appreciable temperatures for the magnetic phase transition, as, for example, $T_N = 213$ K in USb or 285 K in UBi. On the other hand, Pu monochalcogenides are semimetallic and

non-magnetic (for details, see Vogt and Mattenberger, 1993). Carbides, which are of slightly under-stoichiometric ratios (AnC_{1-x}) are weakly magnetic for An = Th, Pa, U. NpC_{1-x} is ferromagnetic below $T = 225$ K, whereas antiferromagnetic ordering is found up to about 300 K, depending on the x values. PuC_{1-x} undergoes antiferromagnetic ordering with T_N ranging between 100 and 30 K, depending on the stoichiometry (Fournier and Troc, 1985). A large data set exists for nitrides AnN. Whereas ThN and AmN are weakly magnetic, magnetic ordering appears for UN ($T_N = 53$ K), NpN ($T_C \approx 90$ K), presumably also in PuN ($T_N = 13$ K), in CmN ($T_C = 109$ K), and data exist even for BkN ($T_C = 88$ K). For other compounds, high-temperature magnetic ordering can be found, for example, in U_3As_4 ($T_C = 196$ K), U_3Sb_4 ($T_C = 146$ K), or even 400 K for antiferromagnetic ordering in U_2N_2As. USb_2 and UAs_2 are antiferromagnets with $T_N = 205$ and 273 K, respectively (Fournier and Troc, 1985). The magnetism of actinide dioxides is covered in Chapter 18.

U forms a trihydride with hydrogen known to be a ferromagnet ($T_C = 180$ K). antiferromagnetic order was found in PuH_2 ($T_N = 30$ K), whereas PuH_3 is ferromagnetic ($T_C = 101$ K) (Aldred *et al.*, 1979) Np hydrides are weakly paramagnetic, which can be understood as due to crystal field effects for the $5f^4$ ionic state (Aldred *et al.*, 1979). For a review covering hydrides, see Wiesinger and Hilscher (1991). Hydrogen can be absorbed also by a number of binary and ternary intermetallic compounds. Similar to elemental light actinides, it strongly supports the tendency to form local 5f magnetic moments and order magnetically, which can be at least be partly attributed to the 5f-band narrowing due to enhanced inter-actinide spacing. Actinide compounds with non-metallic components are, together with discussions of general aspects of actinide compounds, covered in the review of Fournier and Troc (1985). Properties of systems containing boron are covered by Rogl (1991).

21.9.5 Orbital moments in light actinides

Although the majority of light actinides and their intermetallic compounds are characterized by itinerant 5f-states, an important difference with 3d magnetics is in the energy of the spin–orbit coupling Δ_{S-O} and the width of the 3d (5f) band W_{3d} (W_{5f}). Whereas $\Delta_{S-O} << W_{3d}$, their respective values in light actinides become comparable because Δ_{S-O}(5f) is of the order of eV. The relevant energy scales are indicated in Table 21.2. Due to the strong spin–orbit interaction, typically a large orbital magnetic moment μ_L is induced. It is antiparallel to the spin moment for U, in analogy with light lanthanides and the third Hund's rule stating that the total angular momentum is given by $J = L–S$ for the first half of the series. The existence of such orbital moments for the 5f-band systems was revealed first from band structure calculations involving a spin–orbit interaction term coupling the spin and orbital moment densities. Experimentally it was confirmed by the studies of the neutron form-factor, which adopts a very specific shape with a maximum, especially if the spin and orbital moments are

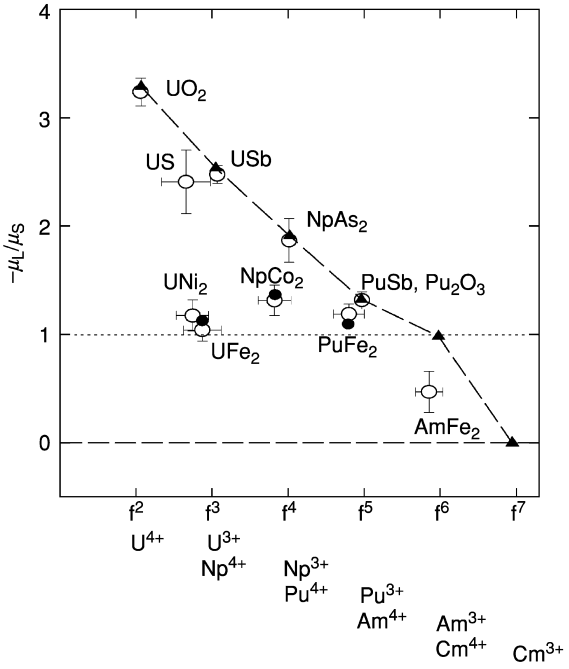

Fig. 21.18 *Ratio of the orbital μ_L and spin μ_S moments in a number of magnetically ordered materials plotted as a function of the number of the 5f-electrons. The triangles, which are connected by a dashed line, are the values derived from single-ion theory including intermediate coupling. Experimental results are shown by open circles. Results of band structure calculations are shown by solid circles.* (*Reprinted from Sechovsky and Havela,* 1998, *with permission from Elsevier.*)

of the same size. Such a case, where the total moment is close to zero, but the spatial extent of spin and orbital moment densities is different, was observed for example in UNi_2 or UFe_2. In the latter case, the U-moment consists of the orbital part $\mu_L = 0.23\mu_B$ and $\mu_S = -0.22\mu_B$. Recently, orbital moments became accessible also in X-ray scattering studies using synchrotron radiation. The strong spin–orbit interaction leads to a characteristic shape for the 5f band consisting of two features, the lower states classified as $j = 5/2$ (containing six states per atom), and the upper states classified as $j = 7/2$ (with eight states per atom). The magnitude of the splitting (up to 3 eV) leads to the formation of a minimum between these features. The weaker tendency to magnetic ordering in Pu systems comparing to Np can be understood as due to the lower sub-band being nearly filled.

A different sensitivity of the spin or orbital moments to external variables led to the assumption that the ratio of orbital and spin moments should reflect the degree of the 5f-delocalization. Indeed, as seen from Fig. 21.18, the compounds showing the least delocalized nature of the 5f states (UO_2, USb, $NpAs_2$, PuSb)

are located on the line representing values of $-\mu_L/\mu_S$ of a free $5f^n$ ion. On the other hand, magnetically ordered materials with presumably the most itinerant 5f states (UFe_2, UNi_2, $NpCo_2$, $PuFe_2$) have this ratio close to 1 (Lander *et al.*, 1991).

Relatively large orbital moments induced by the magnetic field exist probably even in weakly paramagnetic materials like U metal. Surprisingly, in an external magnetic field, the spin and orbital magnetic moments orient parallel to each other, as shown by a simple balance of the Zeeman and spin–orbit energy in the case of weak susceptibility (Hjelm *et al.*, 1993).

21.9.6 Exchange interactions and magnetic anisotropy
